For any hope of inferring the true weights w^*, we must ensure that the comparison hyper-graph is "connected", i.e., for every pair of items $i,j\in[d]$, there must exist a path connecting item i and item j in the comparison hyper-graph. We assume this condition is satisfied. We also continue to assume that $w^*\in\mathcal{W}_B := \{w\in\mathbb{R}^d \mid \|w\|_\infty\le B,\ \langle w,1\rangle=0\}$.

The popular Plackett-Luce model falls in this class, as illustrated below.

Example 1 (Plackett-Luce model (Plackett, 1975; Luce, 1959)) *The Plackett-Luce model concerns the process of choosing an item from a given set. Specifically, given m items with quality scores $w_1^*,\ldots,w_m^*$ respectively, the likelihood of choosing item $\ell\in[m]$ under this model is given by*

$$\frac{e^{w_\ell^*}}{\sum_{j=1}^m e^{w_j^*}} =: F([w_\ell^*,w_1^*,\ldots,w_{\ell-1}^*,w_{\ell+1}^*,\ldots,w_m^*]).$$

Every choice is made independent of all other choices.

It is easy to verify that the Plackett-Luce model satisfies shift invariance. Furthermore, the function F does not depend on the ordering of the last $(m-1)$ coordinates in its argument. We now show that it also satisfies strong log-concavity. A little algebra gives

$$\nabla^2(-\log F(x)) = \frac{\langle e^x,1\rangle\mathrm{diag}(e^x)-e^x(e^x)^T}{(\langle e^x,1\rangle)^2},$$

where $e^x := [e^{x_1}\cdots e^{x_m}]^T$. We now derive a lower bound for the expression above. An application of the Cauchy-Schwarz inequality yields that for any vector $v\in\mathbb{R}^m$,

$$v^T(e^x(e^x)^T)v \le v^T\mathrm{diag}(e^x)\langle e^x,1\rangle v,$$

with equality if and only if $v\in\mathrm{span}(1)$. It follows that $\lambda_2(\nabla^2(-\log F(x)))>0$ for all $x\in[-B,B]^m$. Defining the scalar $\beta := \min_{x\in[-B,B]^m}\lambda_2(\frac{\langle e^x,1\rangle\mathrm{diag}(e^x)-e^x(e^x)^T}{(\langle e^x,1\rangle)^2})$, one can see that setting $H=\beta(I-11^T)$ satisfies the strong log-concavity conditions.

Our goal is to capture the scaling of the minimax error with respect to the number of observations n, the dimension d of the problem, and the choice of the subsets compared $\{E_i\}_{i\in[n]}$. It is well understood (Miller, 1956; Kiger, 1984; Shiffrin and Nosofsky, 1994; Saaty and Ozdemir, 2003) that humans have a limited information storage and processing capacity, which makes it difficult to compare more than a small number of items. For instance, Saaty and Ozdemir (2003) recommend eliciting preferences over *no more than seven options*. Thus in this work we restrict our attention to $m=\mathcal{O}(1)$. Moreover, the amount of noise in the selection process also depends on the number of items m presented at a time: the higher the number, the greater the noise. We thus do not use a "noise parameter σ"in this setting, and assume the noise to be incorporated in the function F, which itself is a function of m.

Our results involve the Laplacian of the comparison graph, defined for the m-wise comparison setting as follows. Let L be an $(d \times d)$ matrix that depends on the choice of the comparison topology as

$$L := \frac{1}{n}\sum_{i=1}^{n} E_i(mI - 11^T)E_i^T. \tag{10}$$

We call L the Laplacian of the comparison hyper-graph. One can verify that when applied to the special case of $m = 2$, the matrix L defined in (10) reduces to the Laplacian of the pairwise-comparison graph defined earlier in (4).

The following theorem presents our main results for the m-wise comparison setting.

Theorem 4 *For the m-*wise *model, the minimax risk is sandwiched as*

$$c_{3\ell}\frac{\inf_z F(z)}{m^2\lambda_m(H)\sup_z \|\nabla F(z)\|_{H^\dagger}^2}\frac{d}{n} \le \inf_{\widehat{w}}\sup_{w^*\in\mathcal{W}_B}\mathbb{E}\left[\|\widehat{w}-w^*\|_L^2\right] \le c_{3u}\frac{m^2\sup_z\|\nabla\log F(z)\|_2^2}{\lambda_2(H)^2}\frac{d}{n},$$

in the squared L semi-norm and as

$$c_{4\ell}\frac{\inf_z F(z)}{m^2\lambda_m(H)\sup_z \|\nabla F(z)\|_{H^\dagger}^2}\frac{d^2}{n} \le \inf_{\widehat{w}}\sup_{w^*\in\mathcal{W}_B}\mathbb{E}\left[\|\widehat{w}-w^*\|_2^2\right] \le c_{4u}\frac{m^2\sup_z\|\nabla\log F(z)\|_2^2}{\lambda_2(H)^2}\frac{d}{\lambda_2(L)n},$$

in the squared ℓ_2 norm. Here we assume $n \ge c_5\frac{\mathrm{tr}(L^\dagger)\inf_z F(z)}{B^2\lambda_m(H)\sup_z\|\nabla F(z)\|_{H^\dagger}^2}$ for both the lower bounds, and where the suprema and infima with respect to the parameter z are taken over the set $[-B,B]^m$.

The proof of Theorem 4 is provided in Appendix D. Our results establish that the dependence of the squared L semi-norm and squared Euclidean minimax error on m occurs only as multiplicative pre-factors, and the error exponent is independent of m. Thus, if one follows the standard recommendation in the psychology literature Miller (1956); Kiger (1984); Shiffrin and Nosofsky (1994); Saaty and Ozdemir (2003)—namely to choose $m = \mathcal{O}(1)$—then the best possible scaling of the squared L semi-norm minimax risk with respect to d and n is always $\frac{d}{n}$, that of the squared Euclidean minimax risk is always $\frac{d^2}{n}$, and evenly spreading the samples across all possible choices of m items is optimal. Nevertheless, a more refined modeling and analysis is required to understand the precise tradeoffs governing the choice of the number m of items presented to the user.

Finally, when specialized to the case of $m = 2$, the upper bounds of Theorem 4 are identical (up to constant factors) to those of Theorem 1 and Theorem 2. The lower bound for the L semi-norm is identical to that of Theorem 1. The additional generality results in a lower bound for the ℓ_2 norm that is weaker in general as compared to Theorem 2, but is tight when the underlying hypergraph forms a complete graph.

4. Role of graph topology

We now return to the setting of pairwise comparisons. In certain applications, one may have the liberty to decide which pairs are compared. The results of the previous section

demonstrated the role played by the Laplacian of the comparison graph in the estimation error. We now employ these results to derive guidelines towards designing the comparison graph. Let us focus on the estimation error in the squared ℓ_2 norm in the ordinal setting. As discussed earlier, we assume that the graph induced by the comparisons is connected. An application of Theorem 2 lets us identify good topologies for pairwise comparisons in the fixed-design setup.

A popular class of comparison topologies is that of evenly distributed samples on an unweighted graph (e.g., Negahban et al. (2012)). Consider any fixed, unweighted graph $G = (V, E)$. We assume that the samples are distributed evenly along the edges E of G, and that the sample size n is sufficiently large. Using standard matrix concentration inequalities, it is straightforward to extend our analysis to the setting of random chosen comparisons from a fixed graph (see, for instance, Oliveira (2009)). Let L' denote the Laplacian of G. We define the *scaled Laplacian* of G as

$$L := \frac{1}{|E|}L'.$$

One can verify that the matrix L defined here is identical to what was defined in (4) in a more general context. In order to differentiate from L, we refer to L' as the *regular Laplacian* of the graph G. For a given budget n on the number of samples, we say that a comparison graph is *optimal* if the error under this graph is the smallest (up to constants) among all graphs.

4.1 Analytical results

Consider the Ordinal model and the squared ℓ_2-norm as the metric of interest. We claim that in order to determine whether a given comparison graph achieves minimax risk (up to a constant pre-factor), it suffices to examine the eigen-spectrum of the scaled Laplacian matrix. In particular, we claim that:

- If the scaled Laplacian has a second smallest eigenvalue that scales as $\frac{1}{\lambda_2(L)} = \Theta(d)$, then the comparison graph is optimal, and leads to the smallest possible minimax risk, in particular one that scales as $\frac{d^2}{n}$.
- Conversely, if the scaled Laplacian matrix has an eigen-spectrum satisfying

$$d^2 = o\left(\max_{d'\in\{2,\ldots,d\}}\sum_{i=\lfloor 0.99d'\rfloor}^{d'}\frac{1}{\lambda_i(L)}\right), \tag{11}$$

  then the associated estimation error is strictly larger than the minimax risk. In particular, this sub-optimality holds whenever $d^2 = o(\frac{1}{\lambda_2(L)})$.

In order to verify these claims, we note that by definition (4) of the Laplacian matrix, we have

$$\mathrm{tr}(L) = \frac{1}{n}\sum_{i=1}^{n}\mathrm{tr}(x_i x_i^T) = 2.$$

It follows that $\lambda_2(L) \le \frac{2}{d-1}$, i.e., that $\frac{1}{\lambda_2(L)} = \Omega(d)$. As we will see shortly, several classes of graphs satisfy $\frac{1}{\lambda_2(L)} = \Theta(d)$. Comparing the lower bound of $\Omega(\frac{d^2}{n})$ on the minimax risk (8a) with the upper bound (8c) gives the sufficient condition of $\frac{1}{\lambda_2(L)} = \Theta(d)$ for optimality, and the smallest minimax risk as $\Theta(\frac{d^2}{n})$. The lower bound (8a) now also gives the claimed condition for strict sub-optimality.

In order to illustrate these claims, let us consider a few canonical classes of graphs, and study how the estimation error under the squared Euclidean norm scales in the Ordinal model. The spectra of the regular Laplacian matrices of these graphs can be found in various standard texts on spectral graph theory (e.g., Brouwer and Haemers (2011)).

- **Complete graph.** A complete graph has one edge between every pair of nodes. The spectrum of the regular Laplacian of the complete graph is $0, d, \ldots, d$, and hence the spectrum of the scaled Laplacian L is $0, \frac{2}{d-1}, \ldots, \frac{2}{d-1}$. Substituting $\lambda_2(L) = \frac{2}{d-1}$ in Theorem 2b gives an upper bound of $\Theta(\frac{d^2}{n})$ on the minimax risk, and Theorem 2 gives a matching lower bound. The sufficiency condition discussed above proves optimality.

- **Constant-degree expander.** The spectrum of the regular Laplacian of a constant-degree expander graph is $0, \Theta(d), \Omega(d), \ldots, \Omega(d)$. Since the number of edges is $\Theta(d)$, the spectrum of the scaled Laplacian equals $0, \Theta(\frac{1}{d}), \Omega(\frac{1}{d}), \ldots, \Omega(\frac{1}{d})$. The evaluation of this class of graphs with respect to the minimax risk is identical to that of complete graphs, giving a lower and upper bound of $\Theta(\frac{d^2}{n})$ on the minimax risk, and guaranteeing optimality.

- **Complete bipartite.** The d nodes are partitioned into two sets comprising, say, m_1 and m_2 nodes. There is an edge between every pair of nodes in different sets, and there are no edges between any two nodes in the same set. The eigenvalues of the regular Laplacian of this graph are $0, \underbrace{m_2, \ldots, m_2}_{m_1-1}, \underbrace{m_1, \ldots, m_1}_{m_2-1}, m_1 + m_2$. Since the total number of edges is $m_1 m_2$, the scaled Laplacian L has a spectrum $0, \underbrace{\frac{1}{m_1}, \ldots, \frac{1}{m_1}}_{m_1-1}, \underbrace{\frac{1}{m_2}, \ldots, \frac{1}{m_2}}_{m_2-1}, \frac{1}{m_1} + \frac{1}{m_2}$. Suppose without loss of generality that $m_1 \ge m_2$. Also suppose that $m_2 > 1$ (the case of $m_2 = 1$ is the star graph discussed below). Then we have $\frac{1}{m_1} \le \frac{1}{m_2} \le \frac{1}{m_1} + \frac{1}{m_2}$ and that $d > m_1 \ge \frac{d}{2}$. Furthermore since $m_2 > 1$, the multiplicity of $\frac{1}{m_1}$ in the spectrum of the scaled Laplacian is at least 1. Thus we have $\lambda_2(L) = \Theta(\frac{1}{d})$. Theorem 2 then gives lower and upper bounds on the minimax risk as $\Theta(\frac{d^2}{n})$ and the sufficiency condition discussed above guarantees its optimality.

- **Star.** A star graph has one central node with edges to every other node. It is a special case of the complete bipartite graph with $m_1 = d-1$ and $m_2 = 1$. The spectrum of the regular Laplacian is $0, 1, \ldots, 1, d$. Since there are $(d-1)$ edges, the spectrum of the scaled Laplacian is $0, \frac{1}{d-1}, \ldots, \frac{1}{d-1}, \frac{d}{d-1}$. Theorem 2 and the sufficiency condition discussed above imply that this class of graphs is optimal and is associated to a minimax risk of $\Theta(\frac{d^2}{n})$.

- **Path.** A path graph is associated to an arbitrary ordering of the d nodes with edges between pairs j and $(j+1)$ for every $j \in \{1, \ldots, d-1\}$. The spectrum of the regular Laplacian is given by $2\big(1 - \cos\big(\frac{\pi i}{d}\big)\big)$, $i \in \{0, \ldots, d-1\}$, and that of the scaled Laplacian is thus $\frac{2}{d-1}\big(1 - \cos\big(\frac{\pi i}{d}\big)\big)$, $i \in \{0, \ldots, d-1\}$. The relation $(1 - \cos x) = \sin^2 \frac{x}{2}$ and the approximation $\sin x \approx x$ for values of x close to zero gives $\lambda_2(L) = \Theta(\frac{1}{d^3})$. The minimax risk is thus upper bounded as $\mathcal{O}(\frac{d^4}{n})$ and lower bounded as $\Omega(\frac{d^3}{n})$. This class of graphs is thus strictly suboptimal.

- **Cycle.** A cycle is identical to a path except for an additional edge between node d and node 1. The spectrum of the regular Laplacian is given by $2\big(1 - \cos\big(\frac{2\pi i}{d}\big)\big)$, $i \in \{0, \ldots, d-1\}$, and that of the scaled Laplacian is thus $\frac{2}{d}\big(1 - \cos\big(\frac{2\pi i}{d}\big)\big)$, $i \in \{0, \ldots, d-1\}$. The relation $(1 - \cos x) = \sin^2 \frac{x}{2}$ and the approximation $\sin x \approx x$ for values of x close to zero gives $\lambda_2(L) = \Theta(\frac{1}{d^3})$. The minimax risk is thus upper bounded as $O(\frac{d^4}{n})$ and lower bounded as $\Omega(\frac{d^3}{n})$. This class of graphs is thus strictly suboptimal.

- **Barbell.** The nodes are partitioned into two sets of $\frac{d}{2}$ nodes each, and there is an edge between every pair of nodes within each set. In addition, there is exactly one edge across the sets. The spectrum of the regular Laplacian can be computed as $0, \Theta(\frac{1}{d}), \Theta(d), \ldots, \Theta(d)$. Since there are $\Theta(d^2)$ edges, the spectrum of the scaled Laplacian turns out to become $0, \Theta(\frac{1}{d^3}), \Theta(\frac{1}{d}), \ldots, \Theta(\frac{1}{d}), \Omega(\frac{1}{d})$. Applying the results derived earlier in the paper, we get that a lower bound of $\Omega(\frac{d^3}{n})$ and an upper bound of $O(\frac{d^4}{n})$ on the minimax risk, thereby also establishing the sub-optimality of this class of graphs.

- **2D Lattice.** An $(m_1 \times m_2)$ lattice has $d = m_1 m_2$ vertices arranged as a $(m_1 \times m_2)$ grid. Assume $m_1 = \Theta(d)$ and $m_2 = \Theta(d)$. This class of graphs can be written as a Cartesian product of a path graph of length m_1 and a second path graph of length m_2. As a result, the spectrum of the scaled Laplacian is $\frac{2}{d}\big(2 - \cos\big(\frac{\pi i}{m_1}\big) - \cos\big(\frac{\pi j}{m_2}\big)\big)$, $i \in \{0, \ldots, m_1 - 1\}, j \in \{0, \ldots, m_2 - 1\}$. Again, using the small angle approximation of the sinusoid, one can compute an upper bound on the minimax risk as $\mathcal{O}(\frac{d^3}{n})$ and a lower bound of $\Omega(\frac{d^2}{n})$. We do not know at this point whether the 2D lattice minimizes the minimax risk.

- **Hypercube.** Assume $d = 2^m$ for some integer m. Representing each node as a distinct m-length binary vector, an edge exists between the nodes corresponding to any pair of vectors within a Hamming distance of one. The hypercube is an m-fold Cartesian product of a path with two nodes, and hence the regular Laplacian has an eigenvalue of $2i$ with multiplicity $\binom{m}{i}$, for $i \in \{0, \ldots, m\}$. The scaled Laplacian has an eigenvalue of $\frac{2i}{d \log d}$ with multiplicity $\binom{m}{i}$, for $i \in \{0, \ldots, m\}$. A lower bound on the minimax risk is $\Omega(\frac{d^2}{n})$ and an upper bound is $O(\frac{d^2 \log d}{n})$. We do not know if the hypercube is optimal, our bounds do tell us that any sub-optimality is bounded by at most a logarithmic factor.

Observe that the degree-k expander requires $n \ge kd$ samples while the complete graph requires $n \ge \binom{d}{2}$ samples, so in practical applications at least for small sample sizes we should prefer a low-degree expander.

Finally, if the conjecture discussed at the end of Section 3.2 were true, namely that the ℓ_2 minimax risk scales as $\sigma^2 \mathrm{tr}(L^\dagger)/n$, then the condition $\mathrm{tr}(L^\dagger) = \Theta(d^2)$ would be necessary and sufficient for optimality of a comparison graph with the scaled Laplacian L. Observe that the graphs designated as 'optimal' in the discussion above indeed satisfy this condition. On the other hand, the graphs established as strictly suboptimal have $\mathrm{tr}(L^\dagger) = \Omega(d^3)$.

4.2 Experiments and simulations

This section evaluates the dependence of the squared ℓ_2-error on the topology of the comparison graph. We consider the following five topologies: path, barbell, complete, expander and 2D-lattice. In order to form an expander graph, we used the construction due to Gabber and Galil (1981). For any chosen graph topology, the n difference vectors are selected as one edge each chosen uniformly at random (with replacement) from the comparison graph. Recall that our theory predicts that the complete and expander graphs yield the best performance, and that the line and dumbbell graphs fare the worst. Also recall that our theory predicts the error scales as $\|w^* - \widehat{w}\|_2^2$ scales with n as $1/n$ in the complete and expander topologies.

4.2.1 Experiments on synthetic data

This section describes simulations using data generated synthetically from the Thurstone model. In the simulations, we first generate a quality score vector $w^* \in \mathcal{W}_B$ using one of the procedures described below. Once w^* is chosen, the n pairwise comparisons for any given topology are generated as follows. An edge is selected uniformly (with replacement) at random from the underlying graph, and the chosen edge determines the pair of items compared. The outcome of the comparison is generated as per the Thurstone model with the chosen w^* as the underlying quality score. Finally, the maximum likelihood estimator for the Thurstone model is employed to estimate w^*. Every point in the plots is an average across 40 trials.

The following six procedures are employed to generated the true quality score vector w^* in the six respective subfigures of Figure 3.

(a) Gaussian: w^* is drawn from the standard normal distribution $\mathcal{N}(0, I)$.

(b) Uniform: w^* is drawn uniformly at random from the set $[-1, 1]^d$.

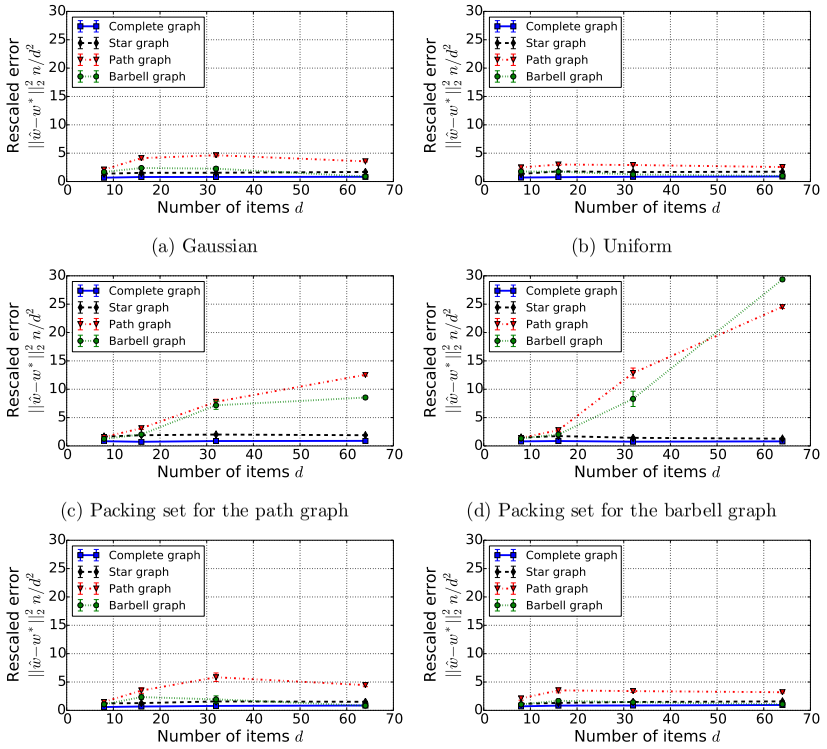
(c) Packing set for the path graph: We first choose a vector z as by setting a value of 0 in the first coordinate, a value -1 in $\frac{d}{2}$ of the other coordinates chosen uniformly at random, and a value 1 in the remaining coordinates. Letting $L = U^T \Lambda U$ denote the eigen-decomposition of the Laplacian matrix of the path graph, w^* is set as $U^T \Lambda^\dagger z$, where $\Lambda^\dagger$ is the Moore-Penrose pseudoinverse of Λ. This generation process mimics a construction used to prove the lower bound in Theorem 2, and tailors the construction for the path graph.

(d) Packing set for the barbell graph: The procedure is identical to that in (c), except that the Laplacian matrix used is that of the barbell graph.

(e) Packing set for the complete graph: The procedure is identical to that in (c), except that the Laplacian matrix used is that of the complete graph.

(f) Packing set for the star graph: The procedure is identical to that in (c), except that the Laplacian matrix used is that of the star graph.

The vector w^* generated in this procedure is then scaled and shifted to ensure $w^* \in \mathcal{W}_B$. The values of B and σ are set as 1.



(a) Gaussian (b) Uniform

(c) Packing set for the path graph (d) Packing set for the barbell graph

(e) Packing set for the complete graph (f) Packing set for the star graph

Figure 3: Estimation error under different topologies for different generative processes in the synthetic simulations.

Figure 3 plots the estimation error under various topologies of the comparison graph. Observe in the figure that the error is the lowest under the complete and the star graphs, and the highest under the barbell and the path graphs. In particular, the error consistently varies as $\Theta(d^2/n)$ for the complete and star graphs – this phenomenon holds even in plots (e) and (f) where the procedure to choose w^* forms the worst case for the complete and star graphs respectively according to the proof of Theorem 2. On the other hand, the minimax error varies as $\Omega(d^3/n)$ in the worst case for the path and the barbell graphs. Finally, observe that in the simulations, the (constant) multiplicative factors to the term $\frac{d^2}{n}$ in the error turn out to be rather small, in the range of 0 to 9.

Although not the primary focus of this paper, we note that our implementation for computing the maximum likelihood estimate under the Thurstone model requires several tens of minutes for modest problem dimensions. Computing the MLE is a convex optimization problem. Our implementation, which is not optimized for speed, employs the sequential least squares programming subroutine of the Scipy package in the Python programming language.

4.2.2 Experiments on MTurk

In this section, we describe the results of experiments conducted on the popular Amazon Mechanical Turk (`https://www.mturk.com/`; henceforth referred to as "MTurk") commercial crowdsourcing platform, evaluating the effects of the choice of the topology. MTurk is an online platform where individuals or businesses can put up a task, and any individual can log in and complete the tasks in exchange for a payment that is specified along with the task. In our experiments, each worker was offered 20 cents per completed task. A worker was allowed to do no more than one task in an experiment. Workers were required to answer all the questions in a task. Only those workers who had 100 or more prior approved works and an approval rate of 95% or higher were allowed. Workers from any country were allowed to participate, except for the task of estimating distances between cities (for which only USA-based workers were permitted since all questions involved American cities).

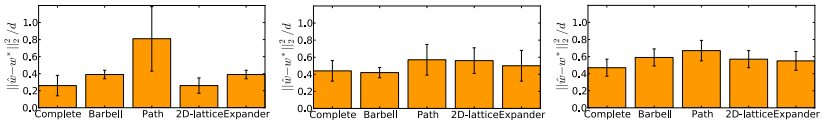
We conducted three experiments that required the workers to make ordinal choices.

(a) *Estimating areas of circles:* In each question, the worker was shown a circle in a bounding box (Figure 5a), and the worker was required to identify the fraction of the box's area that the circle occupied.

(b) *Estimating age of people from photographs:* The worker was shown photographs of people (Figure 5b) and was asked to estimate their ages.

(c) *Estimating distances between pairs of cities:* Pairs of cities were listed (Figure 5c) and for each pair, the worker had to estimate the distance between them.

For each experiment, we recruited 140 workers on MTurk, and assigned them to one of the five topologies uniformly at random. In this experiment and others involving aggregation of ordinal data from MTurk, the aggregation procedure follows maximum likelihood estimation under the Thurstone model, and the estimator is supplied the best-fitting value of σ obtained via 3-fold cross-validation. Each run of the estimation procedure employs the data provided by five randomly chosen workers from the pool of workers who performed



(a) Area of circle (b) Age from photograph (c) City distances

Figure 4: Estimation error under different topologies in the experiments conducted on MTurk. Also shown is the standard deviation across the estimates (The error bars are smaller by a factor of $\sqrt{\text{number of samples}}$).

that task. (The number five is inspired by practical systems as in Wang et al. (2011); Piech et al. (2013).) The complete dataset pertaining to these experiments is available on the first author's website.

Figure 4 plots the squared ℓ_2 estimation error for the three experiments under the five topologies considered, and the associated standard deviation. We see that the relative errors are generally consistent with our theory, with the complete graph exhibiting the best performance and the path graph faring the worst. On real datasets, model misspecification can in some cases cause the outcomes to differ from our theoretical predictions. Understanding the effect of model misspecification, especially on topology considerations, is an important question we hope to address in future work.

5. Cardinal versus ordinal measurements

In this section, we compare two approaches towards eliciting data: a score-based "cardinal" approach and a comparison-based "ordinal" approach. In a cardinal approach, evaluators directly enter numeric scores as their answers (Figure 1b), while an ordinal approach involves comparing (pairs of) items (Figure 1a).

There are obvious advantages and disadvantages associated with either approach. On one hand, the cardinal approach allows for very fine measurements. For instance, the cardinal measurements in Figure 1 can take any value between 0 and 100, whereas an ordinal measurement is binary. One might be tempted to go even further and argue that ordinal measurements necessarily give less information, for one can always convert a set of cardinal measurements into ordinal, simply by ordering the measurements by value. If this conversion were valid, the data processing inequality (Cover and Thomas, 2012), would then guarantee that estimators based on ordinal data can never outperform estimators based on cardinal data. However, this conversion assumes that cardinal and ordinal measurements suffer from the same type of statistical fluctuation. The following set of experiments show this assumption is false.

5.1 Raw data from MTurk

We conducted seven different experiments on MTurk to investigate the possibility of a "data-processing inequality" between the elicited cardinal and ordinal responses: Are responses elicited in ordinal form equivalent to data obtained by first eliciting cardinal responses and then subtracting pairs of items? Our experiments lead us to conclude that this is generally

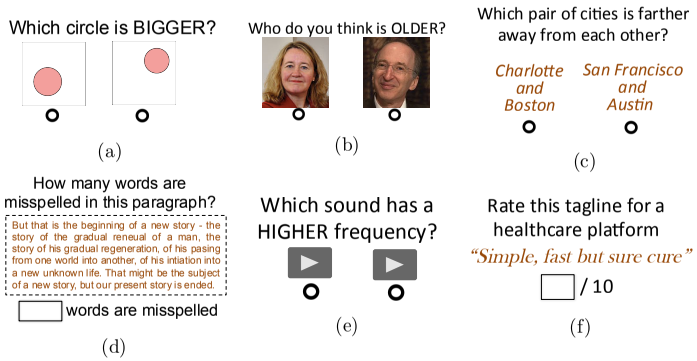


Figure 5: Screenshots of the tasks presented to the subjects. For each task, only one version (cardinal or ordinal) is shown here.

not the case: converting cardinally collected data into ordinal (by subtracting pairs of responses) often leads to a higher amount of noise as compared to that in data that is elicited directly in ordinal form.

The tasks were selected to have a broad coverage of several important subjective judgment paradigms such as preference elicitation, knowledge elicitation, audio and visual perception and skill utilization.

In addition to the three experiments described in Section 4.2.2, we conducted the following four experiments.

(d) *Finding spelling mistakes in text:* The worker had to identify the number of words that were misspelled in each paragraph shown (Figure 5d).

(e) *Identifying sounds:* The worker was presented with audio clips, each of which was the sound of a single key on a piano (which corresponds to a single frequency). The worker had to estimate the frequency of the sound in each audio clip (Figure 5e).

(f) *Rating tag-lines for a product:* A product was described and tag-lines for this product were shown (Figure 5f). The worker had to rate each of these tag-lines in terms of its originality, clarity and relevance to this product.

(g) *Rating relevance of the results of a search query:* Results for the query 'Internet' for an image search were shown (Figure 1) and the worker had to rate the relevance of these results with respect to the given query.

Note that the data collected for experiments (a)–(c) here was different and independent of the data collected for these tasks in Section 4.2.2.

The number of items d in the experiments ranged from 10 to 25. For each of the seven experiments, we recruited 100 workers, and assigned each worker to either the ordinal or the cardinal version of the task at random. Upon obtaining the data, we first reduced the

Task	Circle	Age	Distance	Spelling	Audio	Tagline	Relevance
Error in Ordinal	**6%**	**13%**	**17%**	**40%**	**20%**	44%	**31%**

Table 1: Comparison of the average amount of error when ordinal data is collected directly versus when cardinal data is collected and converted to ordinal. Also tabulated is the median time (in seconds) taken to complete a task by a subject in either type of task.

cardinal data obtained from the experiments into ordinal form by comparing answers given by the subjects to consecutive questions. For five of the experiments ((a) through (e)), we had access to the "ground truth" solutions, using which we computed the fraction of answers that were incorrect in the ordinal and the cardinal-converted-to-ordinal data (any tie in the latter case was counted as half an error). For the two remaining experiments ((f) and (g)) for which there is no ground truth, we computed the 'error' as the fraction of (ordinal or cardinal-converted-to-ordinal) answers provided by the subjects that disagreed with each other. It is important to note that in the experiments in this section, we did *not* run any estimation procedure on the data: we only measured the noise in the *raw responses*. The entire data pertaining to these experiments, including the interface seen by the workers and the data obtained from their work, is available on the first author's website.

The results are summarized in Table 1. If the cardinal measurements could always be converted to ordinal ones with the same noise level as directly eliciting ordinal responses, then it would be unlikely for the amount of error in the ordinal setting to be smaller than that in the cardinal setting. Table 1 shows that converting cardinal data to an ordinal form very often results in a higher (and sometimes significantly higher) per-sample error in the (raw) responses than direct elicitation of ordinal evaluations. Such an outcome may be explained by the argument that the inherent evaluation process in humans is not the same in the cardinal and ordinal cases: humans do *not* perform an ordinal evaluation by first performing cardinal evaluations and then comparing them (Barnett, 2003; Stewart et al., 2005). One can also see from Table 1 that the amount of time required for cardinal evaluations was typically (much) higher than for ordinal evaluations. One can thus assume that we typically have the per-observation error in the ordinal case lower than that in the cardinal case. In particular, considering the Thurstone and the Cardinal models (introduced in Section 2.1) with σ and σ_c denoting the standard deviations of the noise in the Thurstone and the Cardinal models respectively, the above empirical results imply that $\sigma < \sqrt{2}\sigma_c$.

5.2 Analytical comparison of Cardinal versus Ordinal

As discussed earlier, while cardinal measurements allow more flexibility in the range of responses, ordinal measurements contain a lower per-sample error. Ordinal measurements have additional benefits in that they avoid calibration issues that are frequently encountered in cardinal measurements (Tsukida and Gupta, 2011), such as the evaluators' inherent (and possibly time-varying) biases, or tendencies to give inflated or conservative evaluations. Ordinal measurements are also recognized to be easier or faster for humans to make (Barnett, 2003; Stewart et al., 2005), allowing for more evaluations with the same amount of time, effort and cost.

The lack of clarity regarding when to use a cardinal versus an ordinal approach forms the motivation of this section. Can we make as reliable estimates from paired comparisons as from numeric scores? How much lower does the noise have to be for comparative measurements to be preferred over cardinal measurements? The answers to these questions help to determine how responses should be elicited.

In order to compare the cardinal and ordinal methods of data elicitation, we focus on a setting with evenly budgeted measurements. In accordance with the fixed-design setup assumed throughout the paper, we choose the vectors x_i a priori. Suppose that n is large enough, and that in the ordinal case we compare each pair $n/\binom{d}{2}$ times. In the cardinal case suppose that we evaluate the quality of each item n/d times. We consider the Gaussian-noise models Thurstone and Cardinal introduced earlier in Section 2.1. In order to capture the fact that the amount of noise is different in the cardinal and ordinal settings, we denote the standard deviation of the noise in the cardinal setting as σ_c, and retain our notation of σ for the noise in the ordinal setting. In order to bring the two models on the same footing, we measure the error in terms of the squared ℓ_2-norm.

Let γ_G and ζ_G denote the parameters γ and ζ (defined in (1) and (6) respectively) specialized to the Gaussian distribution. Define $b_\ell(\sigma, B) := \frac{c_{2\ell}}{\zeta_G(B,\sigma)}$, $b_u(\sigma, B) := \frac{c_{2u}\zeta_G(B,\sigma)}{\gamma_G(B,\sigma)}$ and $b(\sigma, B) := \left\lceil \frac{c_2\sigma^2}{\zeta_G B^2} \right\rceil$. Observe that b_ℓ, b_u and b are independent of the parameters n and d.

With these preliminaries in place, we now compare the minimax error in the estimation under the cardinal and ordinal settings.

Proposition 5 *Given a sample size n that is a multiple of $d(d-1)b(\sigma, B)$, suppose that we observe each coordinate n/d times under the* Cardinal *model. Then the minimax risk is given by*

$$\inf_{\widehat{w}} \sup_{w^* \in \mathcal{W}_B} \mathbb{E}\Big[\|\widehat{w} - w^*\|_2^2\Big] = \sigma_c^2 \frac{d}{n}. \tag{12a}$$

Similarly, if we observe each pair $n/\binom{d}{2}$ times in the Thurstone *model, then the minimax risk is sandwiched as*

$$\sigma^2 b_\ell(\sigma, B)\frac{d}{n} \le \inf_{\widehat{w}} \sup_{w^* \in \mathcal{W}_B} \mathbb{E}\Big[\|\widehat{w} - w^*\|_2^2\Big] \le \sigma^2 b_u(\sigma, B)\frac{d}{n}. \tag{12b}$$

In the cardinal case, when each coordinate is measured the same number of times, the Cardinal model reduces to the well-studied normal location model, for which the MLE

is known to be the minimax estimator and its risk is straightforward to characterize (see Lehmann and Casella (1998) for instance). In the ordinal case, the result follows from the general treatment in Section 3.

Let us now return to the question deciding between the cardinal and the ordinal methods of data elicitation. Suppose that we believe the Gaussian-noise models to be reasonably correct, and the per-observation errors σ and σ_c under the two settings are known or can be separately measured. Proposition 5 shows that the scaling of the minimax error in the cardinal and ordinal settings is identical in terms of the problem parameters n and d. As an important consequence, our result thus allows for the choice to be made based *only* on the parameters (σ, σ_c, B), and independent of n and d: the ordinal approach incurs a lower minimax error when $b_u(\sigma, B)\sigma^2 < \sigma_c^2$ while the cardinal approach is better off in terms of minimax error whenever $b_\ell(\sigma, B)\sigma^2 > \sigma_c^2$. Establishing the exact decision boundary would require tightening the constants in the bounds, a task we leave for future work.

5.3 Aggregate estimation error in experiments on MTurk

For the sake of completeness, we also computed the estimation error in the cardinal and ordinal settings. We consider data from the three experiments (c), (d) and (e).[2] We normalize the true vector to have $\|w^*\|_\infty = 1$ and set $B = 1$. For each of the three experiments, we execute 100 iterations of the following procedure. Select five workers from the cardinal and five from the ordinal pool of workers uniformly at random. (The number five is inspired by practical systems as in Wang et al. (2011); Piech et al. (2013).) We run the maximum-likelihood estimator of the Cardinal model on the data from the five workers selected from the cardinal pool, and the maximum-likelihood estimator of the Thurstone model on the data from the five workers of the ordinal pool. Note that unlike Section 5.1, the cardinal data here is *not* converted to ordinal.

Task	Spelling	Distance	Audio
$\frac{\|w^* - \widehat{w}\|_2^2}{d}$ in Ordinal	0.358 ± 0.035	**0.168 ± 0.026**	**0.444 ± 0.055**
$\frac{\|w^* - \widehat{w}\|_2^2}{d}$ in Cardinal	**0.350 ± 0.045**	0.330 ± 0.028	0.508 ± 0.053
Kendall's tau coefficient in Ordinal	**0.277 ± 0.049**	**0.547 ± 0.034**	**0.513 ± 0.047**
Kendall's tau coefficient in Cardinal	0.129 ± 0.046	0.085 ± 0.038	0.304 ± 0.049

Table 2: Evaluation of the inferred solution from the data received from multiple workers (mean and standard deviation shown).

The results are tabulated in Table 2. To put the results in perspective of the rest of the paper, let us also recall the per-sample errors in these experiments from Table 1. Observe that among these three experiments, the per-sample noise in the cardinal data was closest to that in the ordinal data in the experiment on identifying the number of spelling mistakes. The gap was larger in the two remaining experiments. This fact is reflected in

2. We restrict attention to these three experiments for the following reasons. There is no ground truth for experiments (f) and (g). In experiment (a), the size of each circle in each question is chosen independently from a continuous distribution, making all questions different and preventing aggregation. Experiment (b) employs a disconnected topology.

the results of Table 2 where the estimator on the cardinal data incurs a lower ℓ_2-error than the estimator on the ordinal data in the experiment on identifying the number of spelling mistakes, whereas the outcome goes the other way in the two remaining experiments. Our theory needs to tighten the constants in order to address this regime. With respect to the Kendall's tau correlation coefficient—a particular type of ordinal metric—the estimator on the ordinal data consistently gives a higher accuracy as compared to the cardinal case.

6. Conclusions

In this paper, we presented topology-aware minimax error bounds under a broad class of preference-elicitation models. We demonstrated the utility of these results in guiding the selection of comparisons and in guiding the choice of the elicitation paradigm (cardinal versus ordinal) when these options are available. A direction for future work would be to characterize the precise thresholds for making the choice between the cardinal and ordinal approaches. Secondly, the Thurstone and BTL models are parametric idealizations that have proved useful in a wide variety of applications. In future work we would like to investigate more flexible semi-parametric and non-parametric pairwise comparison models (see, for instance, Chatterjee (2014); Braverman and Mossel (2008)).

Appendix A. Proof of Theorem 1

The following two sections prove the lower and upper bounds (respectively) on the minimax risk of Ordinal model under the squared L semi-norm.

A.1 Lower bound

Our lower bounds are based on the Fano argument, which is a standard method in minimax analysis (see for instance Tsybakov (2008)). Suppose that our goal is to bound the minimax risk of estimating a parameter w over an indexed class of distributions $\mathcal{P} = \{\mathbb{P}_w \mid w \in \mathcal{W}\}$ in the square of a pseudo-metric ρ. Consider a collection of vectors $\{w^1, \ldots, w^M\}$ contained within $\mathcal{W}$ such that

$$\min_{\substack{j,k\in[M]\\ j\neq k}} \rho\big(w^j, w^k\big) \geq \delta \quad \text{and} \quad \frac{1}{\binom{M}{2}} \sum_{\substack{j,k\in[M]\\ j\neq k}} D_{\mathrm{KL}}(\mathbb{P}_{w^j} \| \mathbb{P}_{w^k}) \leq \beta.$$

We refer to any such subset as an (δ, β)-packing set.

Lemma 6 (Pairwise Fano minimax lower bound) *Suppose that we can construct a (δ, β)-packing with cardinality M. Then the minimax risk is lower bounded as*

$$\inf_{\widehat{w}} \sup_{w^* \in \mathcal{W}} \mathbb{E}\Big[\rho(\widehat{w}, w^*)^2\Big] \geq \frac{\delta^2}{2}\Big(1 - \frac{\beta + \log 2}{\log M}\Big). \tag{13}$$

The main difficulty in deriving the lower bound is the construction of a suitable packing set for application in Lemma 6. To this end, given a scalar $\alpha \in (0, \frac{1}{4})$ whose value will be specified later, define the integer

$$M(\alpha) := \left\lfloor \exp\Big\{\frac{d}{2}\big(\log 2 + 2\alpha \log 2\alpha + (1-2\alpha)\log(1-2\alpha)\big)\Big\}\right\rfloor. \tag{14}$$

The following two lemmas aid in our construction of a packing set. The first lemma is a straightforward consequence of the Gilbert-Varshamov bound (Gilbert, 1952; Varshamov, 1957).

Lemma 7 *For any $\alpha \in (0, \frac{1}{4})$, there exists a set of $M(\alpha)$ binary vectors $\{z^1, \ldots, z^{M(\alpha)}\} \subset \{0,1\}^d$ such that*

$$\alpha d \leq \|z^j - z^k\|_2^2 \leq d \qquad \text{for all } j \neq k \in [M(\alpha)], \text{ and} \tag{15a}$$

$$\langle e_1, z^j \rangle = 0 \qquad \text{for all } j \in [M(\alpha)], \tag{15b}$$

where e_1 denotes the first canonical basis vector.

The next lemma derives an upper bound on the Kullback-Leibler divergence between the probability distributions induced by any pair of quality score vectors.

Lemma 8 *For any pair of quality score vectors w^j and w^k, and for*

$$\zeta := \frac{\max\limits_{x\in[0,2B/\sigma]} F'(x)}{F(2B/\sigma)(1 - F(2B/\sigma))},$$

we have

$$D_{\mathrm{KL}}(\mathbb{P}_{w^j} \| \mathbb{P}_{w^k}) \leq \frac{n\zeta}{\sigma^2}(w^j - w^k)^T L (w^j - w^k). \tag{16}$$

We prove these two lemmas at the end of this section.

Taking these two lemmas as given for the moment, consider the set $\{z^1, \ldots, z^{M(\alpha)}\}$ of d-dimensional binary vectors given by Lemma 7. The Laplacian L of the comparison graph is symmetric and positive-semidefinite, and so has a diagonalization of the form $L = U^T \Lambda U$ where $U \in \mathbb{R}^{d\times d}$ is an orthonormal matrix, and Λ is a diagonal matrix of nonnegative eigenvalues.

Letting matrix $\Lambda^\dagger$ denote the Moore-Penrose pseudo-inverse of Λ, consider the collection $\{w^1, \ldots, w^{M(\alpha)}\}$ of vectors given by $w^j := \frac{\delta}{\sqrt{d}} U^T \sqrt{\Lambda^\dagger} z^j$ for each $j \in [M(\alpha)]$. Since $1 \in$

nullspace(L), we are guaranteed that $\langle 1,\, w^j\rangle = \frac{\delta}{\sqrt{d}} 1^T U^T \sqrt{\Lambda^\dagger} z^j \;= 0$. On the other hand,

$$\begin{aligned}(w^j - w^k)^T L (w^j - w^k) &\le \frac{\delta^2}{d}(z^j - z^k)^T \sqrt{\Lambda^\dagger} U L U^T \sqrt{\Lambda^\dagger}(z^j - z^k)\\ &= \frac{\delta^2}{d}(z^j - z^k)\sqrt{\Lambda^\dagger}\Lambda\sqrt{\Lambda^\dagger}(z^j - z^k)\\ &= \frac{\delta^2}{d}\|z^j - z^k\|_2^2,\end{aligned}$$

Here the last step makes use of the fact that the first coordinate of each vector z^j and z^k is zero. It follows that $\alpha\delta^2 \le \|w^j - w^k\|_L^2 \le \delta^2$.

Setting $\delta^2 := 0.01\frac{\sigma^2 d}{n\zeta}$, we find that

$$\|w^j\|_\infty \;\le\; \frac{\delta}{\sqrt{d}}\|\sqrt{\Lambda^\dagger} z^j\|_2 \;\overset{(i)}{\le}\; \frac{\delta}{\sqrt{d}}\sqrt{\mathrm{tr}(\Lambda^\dagger)} \;\overset{(ii)}{=}\; \frac{\delta}{\sqrt{d}}\sqrt{\mathrm{tr}(L^\dagger)} \;\overset{(iii)}{\le}\; B,$$

where inequality (i) follows from the fact that z^j has entries in $\{0, 1\}$; equation (ii) follows since $L^\dagger = U^T\Lambda^\dagger U$ by definition; and inequality (iii) follows from our choice of δ and our assumption $n \ge \frac{c\sigma^2 \mathrm{tr}(L^\dagger)}{\zeta B^2}$ on the sample size with $c = 0.01$. We have thus verified that each vector w^j also satisfies the boundedness constraint $\|w^j\|_\infty \le B$ required for membership in $\mathcal{W}_B$. Finally, observe that

$$\max_{j\neq k} D_{\mathrm{KL}}(\mathbb{P}_{w^j}\|\mathbb{P}_{w^k}) \le \frac{n\zeta\delta^2}{\sigma^2}, \quad \text{and} \quad \min_{j\neq k}\|w^j - w^k\|_L^2 \ge \alpha\delta^2.$$

We have thus constructed a suitable packing set for applying Lemma 6, which yields the lower bound

$$\mathbb{E}[\|\widehat{w} - w^*\|_L^2] \ge \frac{\alpha}{2}\delta^2\Big\{1 - \frac{\frac{\delta^2\zeta n}{\sigma^2} + \log 2}{\log M(\alpha)}\Big\}.$$

Substituting our choice of δ and setting $\alpha = 0.01$ proves the claim for $d > 9$.

In order to handle the case $d \le 9$, we consider the set of the three d-length vectors given by $z^1 = [0 \;\; \cdots \;\; 0 \;\; -1]$, $z^2 = [0 \;\; \cdots \;\; 0 \;\; 1]$ and $z^3 = [0 \;\; \cdots \;\; 0 \;\; 0]$. Construct the packing set $\{w^1, w^2, w^3\}$ from these three vectors $\{z^1, z^2, z^3\}$ as done above for the case of $d > 9$. From the calculations made for the general case above, we have for all pairs $\min_{j\neq k}\|w^j - w^k\|_L^2 \ge \frac{\delta^2}{9}$ and $\max_{j,k}\|w^j - w^k\|_L^2 \le 4\delta^2$, and as a result $\max_{j,k} D_{\mathrm{KL}}(\mathbb{P}_{w^j}\|\mathbb{P}_{w^k}) \le \frac{4n\zeta\delta^2}{\sigma^2}$. Choosing $\delta^2 = \frac{\sigma^2\log 2}{8n\zeta}$ and applying Lemma 6 proves the theorem.

The only remaining detail is to prove and Lemma 7 and Lemma 8.

Proof of Lemma 7: The Gilbert-Varshamov bound Gilbert (1952); Varshamov (1957) guarantees the existence of a binary code $\{\widetilde{z}^1, \ldots, \widetilde{z}^N\}$ in dimension $(d-1)$, minimum Hamming distance $\lceil \alpha d\rceil$, and the number of code words N at least

$$N \ge \frac{2^{d-1}}{\sum_{\ell=0}^{\lceil\alpha d\rceil - 1}\binom{d-1}{\ell}}.$$

Since $d \ge 2$ and $\alpha \in (0, \frac{1}{4})$, we have

$$\frac{\lceil \alpha d\rceil - 1}{d-1} \le 2\alpha \le \frac{1}{2}.$$

Applying standard bounds on the tail of the binomial distribution gives

$$\begin{aligned}\frac{1}{2^{d-1}}\sum_{\ell=0}^{\lceil\alpha d\rceil - 1}\binom{d-1}{\ell} &\le \exp\Big(-(d-1)D_{\mathrm{KL}}(\tfrac{\lceil\alpha d\rceil - 1}{d-1}\|\tfrac{1}{2})\Big)\\ &\le \exp\Big(-(d-1)D_{\mathrm{KL}}(2\alpha\|\tfrac{1}{2})\Big),\end{aligned}$$

and hence $N \ge M(\alpha)$.

We now define the set of vectors $\{z^1, \ldots, z^{M(\alpha)}\}$ as $(z^i)^T = [0 \;\; (\widetilde{z}^i)^T]$ for every $i \in [M(\alpha)]$. Given this condition, it is easy to see that $\langle e_1,\, z^j\rangle = 0$ for every vector z^j in this set. Finally, the minimum distance condition gives the desired constraints on the difference between any pair of vectors in this set under the squared ℓ_2 metric.

Proof of Lemma 8: For any pair of quality score vectors w^j and w^k, the KL divergence between the distributions $\mathbb{P}_{w^j}$ and $\mathbb{P}_{w^k}$ is given by

$$D_{\mathrm{KL}}(\mathbb{P}_{w^j}\|\mathbb{P}_{w^k}) = \sum_{i=1}^n F(\langle w^j,\, x_i\rangle/\sigma)\log\frac{F(\langle w^j,\, x_i\rangle/\sigma)}{F(\langle w^k,\, x_i\rangle/\sigma)} + (1 - F(\langle w^j,\, x_i\rangle/\sigma))\log\frac{1 - F(\langle w^j,\, x_i\rangle/\sigma)}{1 - F(\langle w^k,\, x_i\rangle/\sigma)}.$$

For any $a, b \in (0, 1)$, we have the elementary inequality $a\log\frac{a}{b} \le (a-b)\frac{a}{b}$. Applying this inequality to our expression above gives

$$\begin{aligned}D_{\mathrm{KL}}(\mathbb{P}_{w^j}\|\mathbb{P}_{w^k}) &\le \sum_{i=1}^n (F(\langle w^j,\, x_i\rangle/\sigma) - F(\langle w^k,\, x_i\rangle/\sigma))\frac{F(\langle w^j,\, x_i\rangle/\sigma)}{F(\langle w^k,\, x_i\rangle/\sigma)}\\ &\qquad - \Big\{F(\langle w^j,\, x_i\rangle/\sigma)) - F(\langle w^k,\, x_i\rangle/\sigma)\Big\}\frac{1 - F(\langle w^j,\, x_i\rangle/\sigma)}{1 - F(\langle w^k,\, x_i\rangle/\sigma)}\\ &\le \sum_{i=1}^n \frac{(F(\langle w^j,\, x_i\rangle/\sigma) - F(\langle w^k,\, x_i\rangle/\sigma))^2}{F(\langle w^k,\, x_i\rangle/\sigma)(1 - F(\langle w^k,\, x_i\rangle/\sigma))}.\end{aligned}$$

Since $\max\{\|w^j\|_\infty, \|w^k\|_\infty\} \le B$, and since F is a non-decreasing function, we have

$$D_{\mathrm{KL}}(\mathbb{P}_{w^j}\|\mathbb{P}_{w^k}) \le \sum_{i=1}^n \frac{(F(\langle w^j,\, x_i\rangle/\sigma) - F(\langle w^k,\, x_i\rangle/\sigma))^2}{F(2B/\sigma)(1 - F(2B/\sigma))}.$$

Finally, applying the mean value theorem and recalling the definition of ζ (from (6)) yields

$$D_{\mathrm{KL}}(\mathbb{P}_{w^j}\|\mathbb{P}_{w^k}) \le \sum_{i=1}^n \zeta(\langle w^j,\, x_i\rangle/\sigma - \langle w^k,\, x_i\rangle/\sigma)^2 \;=\; \frac{n\zeta}{\sigma^2}(w^j - w^k)^T L (w^j - w^k),$$

as claimed.

A.2 Upper bound

For the Ordinal model, the MLE is given by $\widehat{w} \in \arg\min_{w \in \mathcal{W}_B} \ell(w)$, where

$$\ell(w) = -\frac{1}{n}\sum_{i=1}^{n}\Big\{\mathbf{1}[y_i = 1]\log F\big(\frac{\langle x_i,\, w\rangle}{\sigma}\big) + \mathbf{1}[y_i = -1]\log\Big(1 - F\big(\frac{\langle x_i,\, w\rangle}{\sigma}\big)\Big)\Big\}, \qquad \text{and} \tag{17a}$$

$$\mathcal{W}_B := \big\{w \in \mathbb{R}^d \mid \langle 1,\, w\rangle = 0, \quad \text{and} \quad \|w\|_\infty \le B\big\}. \tag{17b}$$

Our goal is to bound the estimation error of the MLE in the squared semi-norm $\|v\|_L^2 = v^T L v$.

For the purposes of this proof (as well as subsequent ones), let us state and prove an auxiliary lemma that applies more generally to M-estimators that are based on minimizing an arbitrary convex and differentiable function over some subset $\mathcal{W}$ of the set $\mathcal{W}_\infty := \{w \in \mathbb{R}^d \mid \langle 1,\, w\rangle = 0\}$. The MLE under consideration here is a special case. This lemma requires that ℓ is differentiable and strongly convex at w^* with respect to the semi-norm $\|\cdot\|_L$, meaning that there is some constant $\kappa > 0$ such that

$$\ell(w^* + \Delta) - \ell(w^*) - \langle \nabla\ell(w^*),\, \Delta\rangle \ge \kappa\|\Delta\|_L^2 \tag{18}$$

for all perturbations $\Delta \in \mathbb{R}^d$ such that $(w^* + \Delta) \in \mathcal{W}$. Finally, it is also convenient to introduce the semi-norm $\|u\|_{L^\dagger} = \sqrt{u^T L^\dagger u}$, where $L^\dagger$ is the Moore-Penrose pseudo-inverse of L.

Lemma 9 (Upper bound for M-estimators) *Consider the M-estimator*

$$\widehat{w} \in \arg\min_{w \in \mathcal{W}} \ell(w), \qquad \textit{where } \mathcal{W} \textit{ is any subset of } \mathcal{W}_\infty, \tag{19}$$

and ℓ is a differentiable cost function satisfying the κ-strong convexity condition (18) *at some $w^* \in \mathcal{W}$. Then*

$$\|\widehat{w} - w^*\|_L \le \frac{1}{\kappa}\|\nabla\ell(w^*)\|_{L^\dagger}. \tag{20}$$

Proof Since $\widehat{w}$ and w^* are optimal and feasible, respectively, for the original optimization problem, we have $\ell(\widehat{w}) \le \ell(w^*)$. Defining the error vector $\Delta = \widehat{w} - w^*$, adding and subtracting the quantity $\langle \nabla\ell(w^*),\, \Delta\rangle$ yields the bound

$$\ell(w^* + \Delta) - \ell(w^*) - \langle \nabla\ell(w^*),\, \Delta\rangle \le -\langle \nabla\ell(w^*),\, \Delta\rangle.$$

By the κ-convexity condition, the left-hand side is lower bounded by $\kappa\|\Delta\|_L^2$. As for the right-hand side, note that Δ satisfies the constraint $\langle 1,\, \Delta\rangle = 0$, and thus is orthogonal to the nullspace of the Laplacian matrix L. Therefore, by Lemma 16 (in Appendix F), we have $|\langle \nabla\ell(w^*),\, \Delta\rangle| \le \|\nabla\ell(w^*)\|_{L^\dagger}\,\|\Delta\|_L$. Combining the pieces yields the claimed inequality (20). ■

In order to apply Lemma 9 to the MLE for the Ordinal model, we need to verify that the negative log likelihood (17a) satisfies the strong convexity condition, and we need to bound the random variable $\|\nabla\ell(w^*)\|_{L^\dagger}$ defined in the dual norm $\|\cdot\|_{L^\dagger}$.

Verifying strong convexity: By chain rule, the Hessian of ℓ is given by

$$\nabla^2\ell(w) = \frac{1}{n\sigma^2}\sum_{i=1}^{n}\Big\{\mathbf{1}[y_i = 1]T_{i1} + \mathbf{1}[y_i = -1]T_{i2}\Big\}\, x_i x_i^T,$$

where

$$T_{i1} := \frac{F'(\frac{\langle w, x_i\rangle}{\sigma})^2 - F(\frac{\langle w, x_i\rangle}{\sigma})F''(\frac{\langle w, x_i\rangle}{\sigma})}{F(\frac{\langle w, x_i\rangle}{\sigma})^2}, \quad \text{and} \quad T_{i2} := \frac{F'(\frac{\langle w, x_i\rangle}{\sigma})^2 + (1 - F(\frac{\langle w, x_i\rangle}{\sigma}))F''(\frac{\langle w, x_i\rangle}{\sigma})}{(1 - F(\frac{\langle w, x_i\rangle}{\sigma}))^2}.$$

Observe that the term T_{i1} is simply the second derivative of $\log F$ evaluated at $\frac{\langle w, x_i\rangle}{\sigma}$, and hence the strong log-concavity of F implies $T_{i1} \ge \gamma$. On the other hand, the term T_{i2} is the second derivative of $\log(1 - F)$. Since $F(-x) = 1 - F(x)$ for all x, it follows that the function $x \mapsto 1 - F(x)$ is also strongly log-concave with parameter γ and hence $T_{i2} \ge \gamma$. Putting together the pieces, we conclude that

$$v^T\nabla^2\ell(w)v \ge \frac{\gamma}{n\sigma^2}\|Xv\|_2^2 \qquad \text{for all } v, w \in \mathcal{W}_B,$$

where $X \in \mathbb{R}^{n\times d}$ has the differencing vector $x_i \in \mathbb{R}^d$ as its i^{th} row.

Thus, if we introduce the error vector $\Delta := \widehat{w} - w^*$, then we may conclude that

$$\ell(w^* + \Delta) - \ell(w^*) - \langle \nabla\ell(w^*),\, \Delta\rangle \ge \frac{\gamma}{n\sigma^2}\|X\Delta\|_2^2 \;=\; \frac{\gamma}{\sigma^2}\|\Delta\|_L^2,$$

showing that ℓ is strongly convex around w^* with parameter $\kappa = \frac{\gamma}{\sigma^2}$. An application of Lemma 9 then gives $\|\Delta\|_L^2 \le \frac{\sigma^4}{\gamma^2}\|\nabla\ell(w^*)\|_{L^\dagger}^2$.

Bounding the dual norm: In order to obtain a concrete bound, it remains to control the quantity $\nabla\ell(w^*)^T L^\dagger \nabla\ell(w^*)$. Observe that the gradient takes the form

$$\nabla\ell(w^*) = \frac{-1}{n\sigma}\sum_{i=1}^{n}\big[\mathbf{1}[y_i = 1]\frac{F'(\langle w^*,\, x_i\rangle/\sigma)}{F(\langle w^*,\, x_i\rangle/\sigma)} - \mathbf{1}[y_i = -1]\frac{F'(\langle w^*,\, x_i\rangle/\sigma)}{1 - F(\langle w^*,\, x_i\rangle/\sigma)}\big]x_i.$$

Define a random vector $V \in \mathbb{R}^n$ with independent components as

$$V_i = \begin{cases} \frac{F'(\langle w^*, x_i\rangle/\sigma)}{F(\langle w^*, x_i\rangle/\sigma)} & \text{w.p.} \quad F(\langle w^*,\, x_i\rangle/\sigma) \\ \frac{-F'(\langle w^*, x_i\rangle/\sigma)}{1-F(\langle w^*, x_i\rangle/\sigma)} & \text{w.p.} \quad 1 - F(\langle w^*,\, x_i\rangle/\sigma). \end{cases}$$

With this notation, we have $\nabla\ell(w^*) = -\frac{1}{n\sigma}X^T V$. One can verify that $\mathbb{E}[V] = 0$ and

$$|V_i| \le \sup_{z\in[-2B/\sigma, 2B/\sigma]} \max\Big\{\frac{F'(z)}{F(z)}, \frac{F'(z)}{1 - F(z)}\Big\} \le \sup_{z\in[-2B/\sigma, 2B/\sigma]} \frac{F'(z)}{F(z)(1 - F(z))} \le \zeta, \tag{21}$$

where ζ is as defined in (6). Defining the n-dimensional square matrix $M := \frac{\sigma^2}{\gamma^2 n^2}XL^\dagger X^T$, our definitions and previous bounds imply that $\|\Delta\|_L^2 \le V^T M V$.

Consequently, our problem has been reduced to controlling the fluctuations of the quadratic form $V^T M V$; in order to do so, we apply the Hanson-Wright inequality (see Lemma 13 in Appendix E). A straightforward calculation yields

$$\|M\|_{\text{fro}}^2 = (d-1)\frac{\sigma^4}{\gamma^4 n^2} \quad \text{and} \quad \|M\|_{\text{op}} = \frac{\sigma^2}{\gamma^2 n},$$

where we have used the fact that $L = \frac{1}{n} X^T X$. Moreover, since the components of V are independent and of zero mean, a straightforward calculation yields that $\mathbb{E}[V^T M V] \leq \mathbb{E}[\|V\|_\infty^2 \text{tr}(M)] \leq \frac{\zeta^2 \sigma^2 d}{\gamma^2 n}$.

Since $|V_i| \leq \zeta$, the variables are ζ-sub-Gaussian, and hence the Hanson-Wright inequality implies that

$$\mathbb{P}\Big[V^T M V - \frac{\zeta^2 \sigma^2 d}{\gamma^2 n} > t\Big] \leq 2\exp\big(-c \min\{\frac{t^2 \gamma^4 n^2}{\zeta^4 (d-1)\sigma^4}, \frac{t\gamma^2 n}{\zeta^2 \sigma^2}\}\big) \quad \text{for all } t > 0.$$

Consequently, after some simple algebra, we conclude that

$$\mathbb{P}\Big(\|\Delta\|_L^2 > t \frac{c\zeta^2\sigma^2}{\gamma^2}\frac{d}{n}\Big) \leq e^{-t} \quad \text{for all } t \geq 1,$$

for some universal constant c. Integrating this tail bound yields the bound on the expectation.

Appendix B. Proof of Theorem 2

The following two sections prove the upper and lower bounds (respectively) on the minimax risk in the squared Euclidean norm for Ordinal model. We prove the lower bound in two parts corresponding to the two components of the "max" in the statement of the theorem.

B.1 Upper bound

The proof of the upper bound under the Euclidean norm follows directly from the upper bound under the L semi-norm proved in Theorem 1. From the setting described in Section 2, we have that the nullspace of the matrix L is given by the span of the all ones vector. Furthermore, we have $\langle w^* - \widehat{w}, 1\rangle = 0$, and $\|w^* - \widehat{w}\|_L^2 \geq \lambda_2(L)\|w^* - \widehat{w}\|_2^2$. Substituting this inequality into the upper bound (7b) gives the desired result.

B.2 Lower bound: Part I

Since the Laplacian L of the comparison graph is symmetric and positive-semidefinite. By diagonalization, we can write $L = U^T \Lambda U$ where $U \in \mathbb{R}^{d\times d}$ is an orthonormal matrix, and Λ is a diagonal matrix of nonnegative eigenvalues with $\Lambda_{jj} = \lambda_j(L)$.

We first use the Fano method (Lemma 6) to prove that the minimax risk is lower bounded as $c\sigma^2 \frac{d^2}{n}$. For scalars $\alpha \in (0, \frac{1}{4})$ and $\delta > 0$ whose values will be specified later, recall the set $\{z^1, \ldots, z^{M(\alpha)}\}$ of vectors in the Boolean hypercube $\{0,1\}^d$ given by Lemma 7. We then define a second set $\{w^j, j \in [M(\alpha)]\}$ via $w^j := \frac{\delta}{\sqrt{d}} U^T P z^j$, where P is a permutation matrix to be specified momentarily. At this point, the only constraint imposed on P is

that it keeps the first coordinate constant. By construction, for each $j \neq k$, we have $\|w^j - w^k\|_2^2 = \frac{\delta^2}{d}\|z^j - z^k\|_2^2 \geq \alpha\delta^2$, where the final inequality follows from the fact that the set $\{z^1, \ldots, z^{M(\alpha)}\}$ comprises binary vectors with a minimum Hamming distance at least αd.

Consider any distinct $j, k \in [M(\alpha)]$. Then, for some $\{i_1, \ldots, i_r\} \subseteq \{2, \ldots, d\}$ with $\alpha d \leq r \leq d$, it must be that

$$\|w^j - w^k\|_L^2 = \frac{\delta^2}{d}\|U^T P z^j - U^T P z^k\|_L^2 = \frac{\delta^2}{d}\|z^j - z^k\|_\Lambda^2 = \frac{\delta^2}{d}\sum_{m=1}^{r} \lambda_{i_m}(L).$$

It follows that for some non-negative numbers $a_2, \ldots, a_d$ such that $\alpha d \leq \sum_{i=2}^d a_i \leq d$,

$$\frac{1}{\binom{M(\alpha)}{2}}\sum_{j\neq k}\|w^j - w^k\|_L^2 = \frac{\delta^2}{d}\sum_{i=2}^{d} a_i \lambda_i(L).$$

We choose the permutation matrix P such that the last $(d-1)$ coordinates are permuted to have $a_2 \geq \cdots \geq a_d$ and the d^{th} coordinate remains fixed. With this choice, we get

$$\frac{1}{\binom{M(\alpha)}{2}}\sum_{j\neq k}\|w^j - w^k\|_L^2 \leq \frac{\delta^2}{d}\frac{d}{d-1}\text{tr}(L) \leq \frac{2\delta^2}{d}\text{tr}(L).$$

Lemma (14) (Appendix F) gives the trace constraint $\text{tr}(L) = 2$, which in turn guarantees that $\frac{1}{\binom{M(\alpha)}{2}}\sum_{j\neq k}\|w^j - w^k\|_L^2 \leq \frac{4\delta^2}{d}$. For the choice of P specified above, we have for every $j \in [M(\alpha)]$,

$$\langle 1, w^j\rangle = \frac{\delta}{\sqrt{d}} e_1^T P z^j = e_1^T z^j = 0,$$

where the final equation employed the property (15b).

Setting $\delta^2 = 0.01\frac{\sigma^2 d^2}{4n\zeta}$, we have $\|w^j\|_\infty \leq \frac{\delta}{\sqrt{d}}\|z^j\|_2 \overset{(i)}{\leq} \delta \overset{(ii)}{\leq} B$, where inequality (i) follows from the fact that z^j has entries in $\{0,1\}$; inequality (ii) follows from our choice of δ and our assumption $n \geq \frac{c\sigma^2 \text{tr}(L^\dagger)}{\zeta B^2}$ on the sample size with $c = 0.002$, where Lemma 14 guarantees $n \geq \frac{c\sigma^2 d^2}{4\zeta B^2}$. We have thus verified that each vector w^j also satisfies the boundedness constraint $\|w^j\|_\infty \leq B$ required for membership in $\mathcal{W}_B$.

From the proof of Theorem 1, we have that for any distinct $D_{\text{KL}}(\mathbb{P}_{w^j}\|\mathbb{P}_{w^k}) \leq \frac{n\zeta}{\sigma^2}\|w^j - w^k\|_L^2$, and hence

$$\frac{1}{\binom{M(\alpha)}{2}}\sum_{j\neq k} D_{\text{KL}}(\mathbb{P}_{w^j}\|\mathbb{P}_{w^k}) \leq \frac{n\zeta}{\sigma^2}\frac{4\delta^2}{d} = 0.01\, d,$$

where we have substituted our previous choice of δ.

Applying Lemma 6 with the packing set $\{w^1, \ldots, w^{M(\alpha)}\}$ gives that any estimator $\widetilde{w}$ must incur an error lower bounded as

$$\sup_{w^* \in \mathcal{W}_B} \mathbb{E}\big[\|\widetilde{w} - w^*\|_2^2\big] \geq \frac{\alpha\delta^2}{2}\big(1 - \frac{0.01d + \log 2}{\log M(\alpha)}\big).$$

Substituting our choice of δ and setting $\alpha = 0.01$ proves the claim for $d > 9$.

For the case of $d \le 9$, consider the set of the three d-length vectors $z^1 = [0 \ \cdots \ 0 \ -1]$, $z^2 = [0 \ \cdots \ 0 \ 1]$ and $z^3 = [0 \ \cdots \ 0 \ 0]$. Construct the packing set $\{w^1, w^2, w^3\}$ from these three vectors $\{z^1, z^2, z^3\}$ as done above for the case of $d > 9$. From the calculations made for the general case above, we have for all pairs $\min_{j\neq k} \|w^j - w^k\|_2^2 \ge \frac{\delta^2}{9}$ and $\max_{j,k} \|w^j - w^k\|_L^2 \le 4\delta^2$, and as a result $\max_{j,k} D_{\mathrm{KL}}(\mathbb{P}_{w^j} \| \mathbb{P}_{w^k}) \le \frac{4n\zeta\delta^2}{\sigma^2}$. Choosing $\delta^2 = \frac{\sigma^2 \log 2}{8n\zeta}$ and applying Lemma 6 yields the claim.

B.3 Lower bound: Part II

Given an integer $d' \in \{2, \ldots, d\}$, and scalars $\alpha \in (0, \frac{1}{4})$ and $\delta > 0$, define the integer

$$M'(\alpha) := \left\lfloor \exp\left\{ \frac{d'}{2}\big(\log 2 + 2\alpha \log 2\alpha + (1-2\alpha)\log(1-2\alpha) \big) \right\} \right\rfloor. \tag{22}$$

Applying Lemma 7 with d' as the dimension yields a subset $\{z^1, \ldots, z^{M'(\alpha)}\}$ of the Boolean hypercube $\{0,1\}^{d'}$ with the stated properties. We then define a set of d-length vectors $\{\widetilde{w}^1, \ldots, \widetilde{w}^{M'(\alpha)}\}$ via

$$\widetilde{w}^j = [0 \ (z^j)^T \ 0 \ \cdots \ 0]^T \quad \text{for each } j \in [M(\alpha)].$$

For each $j \in [M(\alpha)]$, let us define $w^j := \frac{\delta}{\sqrt{d'}} U^T \sqrt{\Lambda^\dagger}\widetilde{w}^j$. Now, letting $e_1 \in \mathbb{R}^d$ denote the first standard basis vector, we have $\langle 1, w^j \rangle = \frac{\delta}{\sqrt{d'}} 1^T U^T \sqrt{\Lambda^\dagger}\widetilde{w}^j \ = 0$. where we have used the fact that $1 \in \mathrm{nullspace}(L)$. Furthermore, for any $j \neq k$, we have

$$\|w^j - w^k\|_2^2 = \frac{\delta^2}{d'}(\widetilde{w}^j - \widetilde{w}^k)^T \Lambda^\dagger (\widetilde{w}^j - \widetilde{w}^k) \ge \frac{\delta^2}{d'} \sum_{i=\lceil (1-\alpha)d' \rceil}^{d'} \frac{1}{\lambda_i}.$$

Thus, setting $\delta^2 = 0.01 \frac{\sigma^2 d'}{n\zeta}$ yields

$$\|w^j\|_\infty \ \le \ \frac{\delta}{\sqrt{d'}} \|\sqrt{\Lambda^\dagger}\widetilde{w}^j\|_2 \ \overset{(i)}{\le} \ \frac{\delta}{\sqrt{d'}} \sqrt{\mathrm{tr}(\Lambda^\dagger)} \ \overset{(ii)}{=} \ \frac{\delta}{\sqrt{d'}} \sqrt{\mathrm{tr}(L^\dagger)} \ \overset{(iii)}{\le} \ B,$$

where inequality (i) follows from the fact that z^j has entries in $\{0,1\}$; step (ii) follows because the matrices $\sqrt{\Lambda^\dagger}$ and $\sqrt{L^\dagger}$ have the same eigenvalues; and inequality (iii) follows from our choice of δ and our assumption $n \ge \frac{c\sigma^2 \mathrm{tr}(L^\dagger)}{\zeta B^2}$ on the sample size with $c = 0.01$. We have thus verified that each vector w^j also satisfies the boundedness constraint $\|w^j\|_\infty \le B$ required for membership in $\mathcal{W}_B$. Furthermore, for any pair of distinct vectors in this set, we have

$$\|w^j - w^k\|_L^2 = \frac{\delta^2}{d'} \|z^j - z^k\|_2^2 \le \delta^2.$$

From the proof of Theorem 1, we $D_{\mathrm{KL}}(\mathbb{P}_{w^j} \| \mathbb{P}_{w^k}) \le \frac{n\zeta}{\sigma^2} \|w^j - w^k\|_L^2 \le 0.01 d'$. Applying Lemma 6 with the packing set $\{w^1, \ldots, w^{M'(\alpha)}\}$ gives that any estimator $\widetilde{w}$ must incur an error lower bounded as

$$\sup_{w^* \in \mathcal{W}_B} \mathbb{E}\big[\|\widetilde{w} - w^*\|_2^2\big] \ge \frac{\frac{\delta^2}{d'} \sum_{i=\lceil (1-\alpha)d' \rceil}^{d'} \frac{1}{\lambda_i}}{2} \big(1 - \frac{0.01 d' + \log 2}{\log M'(\alpha)}\big).$$

Substituting our choice of δ and setting $\alpha = 0.01$ proves the claim for $d' > 9$.

For the case of $d' \le 9$, we now prove a lower bound of $\frac{c\sigma^2}{n} \frac{9}{\lambda_2(L)}$ for a universal constant $c > 0$. This quantity is at least as large as the claimed lower bound. Consider the packing set of three d-length vectors $w^1 = \delta U \sqrt{\Lambda^\dagger}[0 \ 1 \ 0 \ \cdots \ 0]^T$, $w^2 = -w^1$ and $w^3 = [0 \ \cdots \ 0]^T$ for some $\delta > 0$. Then for every $j \neq k$, one can verify that $\|w^j - w^k\|_L^2 \le 4\delta^2$, $\|w^j - w^k\|_2^2 \ge \frac{\delta^2}{\lambda_2(L)}$. Choosing $\delta^2 = \frac{\sigma^2 \log 2}{8n\zeta}$ and applying Lemma 6 proves the claim for $d' \le 9$.

Finally, taking the maximum over all values of $d' \in \{2, \ldots, d\}$ gives the claimed lower bound.

Appendix C. Proof of Theorem 3

We now turn to the proof of Theorem 3 on the minimax rate for the Paired Cardinal model. Recall that this observation model takes the standard linear model, $y = Xw^* + \epsilon$, where $y \in \mathbb{R}^n, w \in \mathbb{R}^d$ and $\epsilon \sim N(0, \sigma^2 I)$.

C.1 Upper bound under the squared L semi-norm

The maximum likelihood estimate in the Paired Cardinal model is a special case of the general M-estimator (19) with $\ell(w) := \frac{1}{2n} \sum_{i=1}^n \big(y_i - \langle x_i, w \rangle\big)^2$. For this quadratic objective function, it is easy to verify that the γ-convexity condition holds with $\gamma = 1$. (In particular, note that the Hessian of ℓ is given by $L = X^T X/n$.)

Given the result of Lemma 9, it remains to upper bound $\|\nabla \ell(w^*)\|_{L^\dagger}$. A straightforward computation yields $\|\nabla \ell(w^*)\|_{L^\dagger}^2 = \frac{\varepsilon}{\sigma}^T Q \frac{\varepsilon}{\sigma}$ where $Q := \frac{\sigma^2}{n^2} X L^\dagger X^T$. Consequently, the random variable $\|\nabla \ell(w^*)\|_{L^\dagger}^2$ is quadratic form in the standard Gaussian random vector $\frac{\varepsilon}{\sigma}$. An application of Lemma 15 (Appendix F) gives $\mathrm{tr}(Q) = \frac{\sigma^2}{n}\big(d-1\big)$ and $|||Q|||_{\mathrm{op}} = \frac{\sigma^2}{n}$, and then applying a known tail bound on Gaussian quadratic forms (see Lemma 12 in Appendix E) yields

$$\mathbb{P}\left[\frac{\|\nabla \ell(w^*)\|_{L^\dagger}^2}{\sigma^2} \ge \Big(\sqrt{\frac{d}{n}} + \frac{\delta}{\sqrt{n}} \Big)^2 \right] \le e^{-\frac{\delta^2}{2}} \qquad \text{for all } \delta \ge 0.$$

Since $d \ge 2$, we have $\big(\sigma\sqrt{\frac{d}{n}} + \frac{\sigma}{\sqrt{n}}\delta\big)^2 \le \frac{2\sigma^2 d\delta^2}{n}$ for all $\delta \ge 4$, which yields

$$\mathbb{P}\Big[\|\nabla \ell(w^*)\|_{L^\dagger}^2 \ge t \, \frac{4\sigma^2 d}{n} \Big] \le e^{-t} \qquad \text{for all } t \ge 8.$$

Integrating this tail bound yields that $\mathbb{E}\Big[\|\nabla \ell(w^*)\|_{L^\dagger}^2\Big] \le c\sigma^2 \frac{d}{n}$, from which the claim follows.

C.2 Lower bound under the squared L semi-norm

Based on the pairwise Fano lower bound previously stated in Lemma 6, we need to construct a suitable (δ, β)-packing, where the semi-norm $\rho(w^j, w^k) = \|w^j - w^k\|_L$ is defined by the Laplacian. Given the additive Gaussian noise observation model, we also have

$$D_{\mathrm{KL}}(\mathbb{P}_{w^j} \| \mathbb{P}_{w^k}) = \frac{n}{2\sigma^2} \|w^j - w^k\|_L^2, \tag{23}$$

The construction of the packing and the remainder of the proof proceeds in a manner identical to the proof of the lower bound in Theorem 1, except for the absence of the requirement of $\|w^j\|_\infty \le B$ on the elements $\{w^j\}$ of the packing set.

C.3 Upper bound under the squared Euclidean norm

The upper bound follows by direct analysis of the (unconstrained) least-squares estimate, which has the explicit form $\widehat{w} = \frac{1}{n} L^\dagger X^T y$, and thus

$$\mathbb{E}\|\widehat{w} - w^*\|_2^2 = \mathbb{E}\|\frac{1}{n} L^\dagger X^T \epsilon\|_2^2 \;=\; \sigma^2 \mathrm{tr}(\frac{1}{n^2} L^\dagger X^T X L^\dagger)$$

where we have used the fact that $\epsilon \sim N(0, \sigma^2 I_n)$. Since $L = X^T X/n$ by definition, we conclude that $\mathbb{E}\|\widehat{w} - w^*\|_2^2 = \frac{\sigma^2 \mathrm{tr}(L^\dagger)}{n}$ as claimed.

C.4 Lower bound under the squared Euclidean norm

We obtain the lower bound by computing the Bayes risk with respect to a suitably defined (proper) prior distribution over the weight vector w^*. In particular, if we impose the prior $w^* \sim N(0, \frac{\sigma^2}{n} L^\dagger)$, Bayes' rule then leads to the posterior distribution

$$\mathbb{P}\big(w \mid y; X\big) \propto \exp\left(\frac{-1}{2\sigma^2}\|y - Xw\|_2^2\right) \exp\left(\frac{-n}{2\sigma^2} w^T L w\right) \mathbf{1}\{\langle w, 1\rangle = 0\}.$$

Thus conditioned on y, w is distributed as $N\left((X^T X + nL)^{-1} X^T y, \frac{\sigma^2}{2} L^\dagger\right)$. By applying iterated expectations, the Bayes risk is given by $\mathbb{E}\|w - \frac{1}{2} L^\dagger X^T y\|_2^2 = \frac{\sigma^2}{2}\mathrm{tr}(L^\dagger)$, which completes the proof.

Appendix D. Proof of Theorem 4

This section presents the proof of Theorem 4 for the setting of m-wise comparisons. We first state some simple properties of the model introduced in Section 3.3, which we use subsequently in the proofs of the results.

Lemma 10 *The Laplacian of the underlying pairwise-comparison graph satisfies the trace constraints* $\mathrm{nullspace}(L) = 1$, $\lambda_2(L) > 0$ *and* $\mathrm{tr}(L) = m(m-1)$.

Lemma 11 *For any $j \in [m]$, $i \in [n]$ and any vector $v \in \mathbb{R}^m$, we have*

$$\frac{\lambda_2(H)}{m} v^T(mI - 11^T)v \le v^T R_j H R_j^T v \le \frac{\lambda_{\max}(H)}{m} v^T(mI - 11^T)v.$$

See Section D.2 for the proof of these auxiliary lemmas.

D.1 Upper bound under the squared L semi-norm

We prove this upper bound by applying Lemma 9. In this case, the rescaled negative log likelihood takes the form

$$\ell(w) = -\frac{1}{n}\sum_{i=1}^n \sum_{j=1}^m \mathbf{1}[y_i = j] \log F\big(w^T E_i R_j\big),$$

and the MLE is obtained by constrained minimization over the set $\mathcal{W}_B := \big\{w \in \mathbb{R}^d \mid \langle 1, w\rangle = 0, \quad \text{and} \quad \|w\|_\infty \le B\big\}$. As in our proof of the upper bound in Theorem 1, we need to verify the κ-strong convexity condition, and to control the dual norm $\|\nabla \ell(w^*)\|_{L^\dagger}$.

Verifying strong convexity: The gradient of the negative log likelihood is

$$\nabla \ell(w) = -\frac{1}{n}\sum_{i=1}^n \sum_{j=1}^m \mathbf{1}[y_i = j] E_i R_j \nabla \log F(v)\big|_{v = w^T E_i R_j}.$$

The Hessian of the negative log likelihood can be written as

$$\nabla^2 \ell(w) = \frac{1}{n}\sum_{i=1}^n \sum_{j=1}^m \mathbf{1}[y_i = j] E_i R_j \nabla^2 \log F(v)\big|_{v = w^T E_i R_j} R_j^T E_i^T.$$

Using our strongly log-concave assumption on F, we have that for any vector $z \in \mathbb{R}^d$,

$$\begin{aligned} z^T \nabla^2 \ell(w) z &= -\frac{1}{n}\sum_{i=1}^n \sum_{j=1}^m \mathbf{1}[y_i = j] z^T E_i R_j \nabla^2 \log F(v)\big|_{v = w^T E_i R_j} R_j^T E_i^T z \\ &\ge \frac{1}{n}\sum_{i=1}^n \sum_{j=1}^m \mathbf{1}[y_i = j] z^T E_i R_j H R_j^T E_i^T z \\ &\ge \frac{\lambda_2(H)}{m}\frac{1}{n}\sum_{i=1}^n \sum_{j=1}^m \mathbf{1}[y_i = j] z^T E_i (mI - 11^T) E_i^T z, \end{aligned}$$

where the last step follows from Lemma 11. The definition (10) of L implies that

$$z^T \nabla^2 \ell(w) z \ge \frac{\lambda_2(H)}{m} z^T L z = \frac{\lambda_2(H)}{m}\|z\|_L^2.$$

Consequently, the κ-convexity condition holds around w^* with $\kappa = \frac{\lambda_2(H)}{m}$. An application of Lemma 9 then yields

$$\|\widehat{w}_{\mathrm{ML}} - w^*\|_L^2 \le \frac{m^2}{\lambda_2(H)^2}\|\nabla \ell(w^*)\|_{L^\dagger}^2 \;=\; \frac{m^2}{\lambda_2(H)^2} \nabla \ell(w^*)^T L^\dagger \nabla \ell(w^*). \tag{24}$$

Controlling the dual norm: The gradient of the negative log likelihood can then be rewritten as $\nabla \ell(w^*) = -\frac{1}{n}\sum_{i=1}^n E_i V_i$, where each index $i \in [n]$, the random vector vector $V_i \in \mathbb{R}^m$ is given by $V_i := \sum_{j=1}^m \mathbf{1}[y_i = j]\; R_j \nabla \log F(\langle w^*, E_i\rangle R_j)$. Now observe that the matrix $M := I - \frac{1}{m} 11^T$ is symmetric and positive semi-definite with rank $(m-1)$, eigenvalues $\{1, \ldots, 1, 0\}$, its nullspace equals the span of the all-ones vector, and that $M^\dagger = M$. Using this matrix, we define the transformed vector $\widetilde{V}_i := (M^\dagger)^{\frac{1}{2}} V_i$ for each $i \in [n]$.

Consider a vector x and its shifted version $x + t1$, where $t \in \mathbb{R}$ and 1 denotes the vector of all ones. By the shift invariance property, the function $g(t) = F(x + t1) - F(x)$ is constant, and hence

$$g'(0) = \langle \nabla F(x), 1\rangle = 0, \quad \text{and} \quad g''(0) = \langle 1, \big(\nabla^2 F(x)\big)1\rangle = 0, \tag{25}$$

which implies that $1 \in \text{nullspace}(\nabla^2 F(x))$. Continuing on, we also have that $\langle \nabla \log F(x),\, 1\rangle = \frac{1}{F(x)}\langle \nabla F(x),\, 1\rangle = 0$. Consequently, $\langle V_i,\, 1\rangle = 0 = \langle V_i,\, \text{nullspace}(M)\rangle$. This allows us to write

$$\nabla \ell(w^*) = -\frac{1}{n}\sum_{i=1}^{n} E_i M^{\frac{1}{2}} \widetilde{V}_i, \quad \text{and} \quad \nabla \ell(w^*)^T L^\dagger \nabla \ell(w^*) = \frac{1}{n^2}\sum_{i=1}^{n}\sum_{\ell=1}^{n} \widetilde{V}_i^T M^{\frac{1}{2}} E_i^T L^\dagger E_\ell M^{\frac{1}{2}} \widetilde{V}_\ell.$$

By definition, for every pair $i \neq \ell \in [n]$, $\widetilde{V}_i$ is independent of $\widetilde{V}_\ell$. Moreover, for every $i \in [n]$,

$$\begin{aligned}
\mathbb{E}[\widetilde{V}_i] &= \mathbb{E}[(M^\dagger)^{\frac{1}{2}} \sum_{j=1}^{m} \mathbf{1}[y_i = j] R_j \nabla \log F(v)\big|_{v=(w^*)^T E_i R_j}] \\
&= (M^\dagger)^{\frac{1}{2}} \sum_{j=1}^{m} F((w^*)^T E_i R_j) R_j \nabla \log F(v)\big|_{v=(w^*)^T E_i R_j} \\
&= (M^\dagger)^{\frac{1}{2}} \sum_{j=1}^{m} R_j \nabla F(v)\big|_{v=(w^*)^T E_i R_j}.
\end{aligned}$$

In order to further evaluate this expression, define a function $g : \mathbb{R}^m \to \mathbb{R}$ as $g(z) = \sum_{j=1}^m F(z^T R_j)$. Then by definition we have $g(z) = 1$. Taking derivatives, we get $0 = \nabla g(z) = \sum_{j=1}^m R_j \nabla F(z^T R_j)$. It follows that $\mathbb{E}[\widetilde{V}_i] = 0$, and hence that

$$\begin{aligned}
\mathbb{E}[\nabla \ell(w^*)^T L^\dagger \nabla \ell(w^*)] &= \frac{1}{n^2}\mathbb{E}[\sum_{i=1}^{n}\sum_{\ell=1}^{n} \widetilde{V}_i^T M^{\frac{1}{2}} E_i^T L^\dagger E_\ell M^{\frac{1}{2}} \widetilde{V}_\ell] \\
&= \frac{1}{n^2}\mathbb{E}[\sum_{i=1}^{n} \widetilde{V}_i^T M^{\frac{1}{2}} E_i^T L^\dagger E_i M^{\frac{1}{2}} \widetilde{V}_i] \\
&\leq \frac{1}{n}\mathbb{E}[\sup_{\ell \in [n]} \|\widetilde{V}_\ell\|_2^2] \text{tr}(\frac{1}{n}\sum_{i=1}^{n} M^{\frac{1}{2}} E_i^T L^\dagger E_i M^{\frac{1}{2}}).
\end{aligned}$$

Since $L = \frac{m}{n}\sum_{i=1}^n E_i M E_i^T$, we have $\text{tr}(\frac{1}{n}\sum_{i=1}^n M^{\frac{1}{2}} E_i^T L^\dagger E_i M^{\frac{1}{2}}) = \frac{d-1}{m}$, as well as

$$\|\widetilde{V}_\ell\|_2^2 = \sum_{j=1}^{m} \mathbf{1}[y_i = j] (\nabla \log F(v)\big|_{v=(w^*)^T E_i R_j})^T R_j^T M R_j \nabla \log F(v)\big|_{v=(w^*)^T E_i R_j}.$$

Recalling the previously defined matrix M, observe that since R_j is simply a permutation matrix, we have $R_j^T M R_j = M$ for every $j \in [m]$. By chain rule, we have $\langle \nabla \log F(v),\, 1\rangle = \frac{1}{F(v)}\langle \nabla F(v),\, 1\rangle = 0$, where the last step follows from our previous calculation. It follows that

$$\mathbb{E}\big[\langle \nabla \ell(w^*),\, L^\dagger \nabla \ell(w^*)\rangle\big] \leq \frac{d}{n} \sup_{v \in [-B,B]^m} \|\nabla \log F(v)\|_2^2.$$

Substituting this bound into equation (24) yields the claim.

D.1.1 Lower bound under the squared L semi-norm

For any pair of quality score vectors w^j and w^k, the KL divergence between the distributions $\mathbb{P}_{w^j}$ and $\mathbb{P}_{w^k}$ is given by

$$D_{\text{KL}}(\mathbb{P}_{w^j} \| \mathbb{P}_{w^k}) = \sum_{i=1}^{n}\sum_{l=1}^{m} F(w^{jT} E_i R_l) \log \frac{F(w^{jT} E_i R_l)}{F(w^{kT} E_i R_l)}.$$

Applying the inequality $\log x \leq x - 1$, valid for $x > 0$, we find that

$$D_{\text{KL}}(\mathbb{P}_{w^j} \| \mathbb{P}_{w^k}) \leq \sum_{i=1}^{n}\sum_{l=1}^{m} F(w^{jT} E_i R_l)\Big(\frac{F(w^{jT} E_i R_l)}{F(w^{kT} E_i R_l)} - 1\Big).$$

Now employing the fact that $\sum_{l=1}^m F(w^{jT} E_i R_l) = \sum_{l=1}^m F(w^{kT} E_i R_l) = 1$ gives

$$\begin{aligned}
D_{\text{KL}}(\mathbb{P}_{w^j} \| \mathbb{P}_{w^k}) &\leq \sum_{i=1}^{n}\sum_{l=1}^{m} \Big(\frac{F(w^{jT} E_i R_l)^2}{F(w^{kT} E_i R_l)} - 2F(w^{jT} E_i R_l) + F(w^{kT} E_i R_l)\Big). \\
&= \sum_{i=1}^{n}\sum_{l=1}^{m} \frac{(F(w^{jT} E_i R_l) - F(w^{kT} E_i R_l))^2}{F(w^{kT} E_i R_l)} \\
&\leq \frac{1}{F(-B, B, \ldots, B)} \sum_{i=1}^{n}\sum_{l=1}^{m} (F(w^{jT} E_i R_l) - F(w^{kT} E_i R_l))^2 \\
&\leq \frac{1}{F(-B, B, \ldots, B)} \sum_{i=1}^{n}\sum_{l=1}^{m} (\langle \nabla F(z_{il}),\, w^{jT} E_i R_l - w^{kT} E_i R_l\rangle)^2,
\end{aligned}$$

for some $z_{il} \in [-B, B]^m$. Letting $\zeta = \frac{\sup_{z \in [-B,B]^m} \|\nabla F(z)\|_{H^\dagger}^2}{F(-B,B,\ldots,B)}$ and applying Lemma 16 (noting that $\langle w^{jT} E_i R_l,\, \text{nullspace}(H)\rangle = 0$ for all i, j, l) gives

$$\begin{aligned}
D_{\text{KL}}(\mathbb{P}_{w^j} \| \mathbb{P}_{w^k}) &\leq \sum_{i=1}^{n}\sum_{l=1}^{m} \zeta \|w^{jT} E_i R_l - w^{kT} E_i R_l\|_H^2 \\
&\leq \zeta (w^j - w^k)^T \Big(\sum_{i=1}^{n}\sum_{l=1}^{m} E_i R_l H R_l^T E_i^T\Big)(w^j - w^k) \\
&\leq \zeta \lambda_m(H) n \|w^j - w^k\|_L^2, \qquad (26)
\end{aligned}$$

where the final step is a result of Lemma 11.

Consider the pair of scalars $\alpha \in (0, \frac{1}{4})$ and $\delta > 0$ whose values will be specified later. Let $M(\alpha)$ be as defined in (14). Consider the packing set $\{w^1, \ldots, w^{M(\alpha)}\}$ constructed in Appendix A.1. Each of these vectors is of length d, satisfies $\langle w^j,\, 1\rangle = 0$, and furthermore, each pair from this set satisfies $\alpha\delta^2 \leq \|w^j - w^k\|_L^2 \leq \delta^2$. Setting $\delta^2 = 0.01\frac{d}{n\zeta\lambda_m(H)}$ yields

$$D_{\text{KL}}(\mathbb{P}_{w^j} \| \mathbb{P}_{w^k}) \leq 0.01d.$$

Every element from the packing set also satisfies $\|w^j\|_\infty \leq B$ when $n \geq \frac{0.01\sigma^2 \text{tr}(L^\dagger)}{\zeta B^2 \lambda_m(H)}$, and thus belongs to the class $\mathcal{W}_B$.

Applying Lemma 6 yields the lower bound

$$\|\widehat{w} - w^*\|_L^2 \geq \frac{\alpha}{2} 0.01 \frac{d}{n\zeta\lambda_m(H)} \Big\{ 1 - \frac{0.01d + \log 2}{\log M(\alpha)} \Big\}.$$

Setting $\alpha = 0.01$ proves the claim for $d > 9$.

For the case of $d \leq 9$, consider the set of the three d-length vectors $z^1 = [0 \ \cdots \ 0 \ -1]$, $z^2 = [0 \ \cdots \ 0 \ 1]$ and $z^3 = [0 \ \cdots \ 0 \ 0]$. Construct the packing set $\{w^1, w^2, w^3\}$ from these three vectors $\{z^1, z^2, z^3\}$ as done above for the case of $d > 9$. From the calculations made for the general case above, we have for all pairs $\min_{j \neq k} \|w^j - w^k\|_L^2 \geq \frac{\delta^2}{9}$ and $\max_{j,k} \|w^j - w^k\|_L^2 \leq 4\delta^2$, and as a result $\max_{j,k} D_{\mathrm{KL}}(\mathbb{P}_{w^j} \| \mathbb{P}_{w^k}) \leq 4n\zeta\lambda_m(H)\delta^2$. Choosing $\delta^2 = \frac{\log 2}{8n\zeta\lambda_m(H)}$ and applying Lemma 6 proves the claim.

D.1.2 Upper bound under the squared Euclidean norm

The upper bound under the squared ℓ_2-norm follows directly from the upper bound under the squared L semi-norm in Theorem 4: noting that $(w^* - \widehat{w}) \perp \text{nullspace}(L)$, we get that

$$(w^* - \widehat{w})^T L (w^* - \widehat{w}) \geq \lambda_2(L) \|w^* - \widehat{w}\|_2^2.$$

Substituting this inequality in the upper bound on the minimax risk under the squared L semi-norm in Theorem 4 gives the desired result.

D.1.3 Lower bound under the squared Euclidean norm

Define $\zeta = \frac{\sup_{z \in [-B,B]^m} \|\nabla F(z)\|_{H^\dagger}^2}{F(-B,B,\ldots,B)}$. Equation (26) in Appendix D.1.1 shows that for any vectors $w^j, w^k \in \mathcal{W}_B$,

$$D_{\mathrm{KL}}(\mathbb{P}_{w^j} \| \mathbb{P}_{w^k}) \leq \zeta\lambda_m(H) n \|w^j - w^k\|_L^2,$$

Consider the pair of scalars $\alpha \in (0, \frac{1}{4})$ and $\delta > 0$ whose values will be specified later. Let $M(\alpha)$ be as defined in (14). In Appendix B.2 we constructed a set $\{w^1, \ldots, w^{M(\alpha)}\}$ of vectors of length d that satisfy $\langle w^j, 1\rangle = 0$ for every $j \in [M(\alpha)]$, and for every pair of vectors in this set, $\|w^j - w^k\|_2^2 \geq \alpha\delta^2$ and $\frac{1}{\binom{M(\alpha)}{2}} \sum_{j \neq k} \|\widetilde{w}^j - \widetilde{w}^k\|_L^2 \leq \frac{2\delta^2}{d} \mathrm{tr}(L)$. Applying Lemma 10 gives

$$\frac{1}{\binom{M(\alpha)}{2}} \sum_{j \neq k} \|\widetilde{w}^j - \widetilde{w}^k\|_L^2 \leq \frac{2\delta^2}{d} m(m-1).$$

Setting $\delta^2 = 0.005 \frac{d^2}{n\zeta\lambda_m(H)m(m-1)}$ yields

$$D_{\mathrm{KL}}(\mathbb{P}_{w^j} \| \mathbb{P}_{w^k}) \leq 0.01d.$$

In a manner similar to Lemma 14 in the pairwise comparison case, one can show that in the general setting of this section, $\mathrm{tr}(L^\dagger) \geq \frac{d^2}{4m(m-1)}$. Then, every element from the packing set also satisfies $\|w^j\|_\infty \leq B$ when $\delta \leq B$, which holds true under our assumption

of $n \geq \frac{c\sigma^2 \mathrm{tr}(L^\dagger)}{\zeta B^2 \lambda_m(H)} \geq \frac{c\sigma^2 d^2}{4m(m-1)\zeta B^2 \lambda_m(H)}$ with $c = 0.01$. Each element of our packing set thus belongs to the class $\mathcal{W}_B$. Applying Lemma 6 yields the lower bound

$$\|\widehat{w} - w^*\|_L^2 \geq \frac{\alpha}{2} 0.01 \frac{d^2}{n\zeta\lambda_m(H)m(m-1)} \Big\{ 1 - \frac{0.01d + \log 2}{\log M(\alpha)} \Big\}.$$

Setting $\alpha = 0.01$ proves the claim for $d > 9$.

For the case of $d \leq 9$, consider the set of the three d-length vectors $z^1 = [0 \ \cdots \ 0 \ -1]$, $z^2 = [0 \ \cdots \ 0 \ 1]$ and $z^3 = [0 \ \cdots \ 0 \ 0]$. Construct the packing set $\{w^1, w^2, w^3\}$ from these three vectors $\{z^1, z^2, z^3\}$ as done above for the case of $d > 9$. From the calculations made for the general case above, we have for all pairs $\min_{j \neq k} \|w^j - w^k\|_2^2 \geq \frac{\delta^2}{9}$ and $\max_{j,k} \|w^j - w^k\|_L^2 \leq 4\delta^2$, and as a result $\max_{j,k} D_{\mathrm{KL}}(\mathbb{P}_{w^j} \| \mathbb{P}_{w^k}) \leq 4n\zeta\lambda_m(H)\delta^2$. Choosing $\delta^2 = \frac{\log 2}{8n\zeta\lambda_m(H)}$ and applying Lemma 6 proves the claim.

D.2 Some implied properties of the model

In this section, we prove the two auxiliary lemmas stated at the start of this appendix.

D.2.1 Proof of Lemma 10

From the definition (10) of L, have

$$L1 = \frac{1}{n} \sum_{i=1}^n E_i (mI - 11^T) E_i^T 1 \ = \ \frac{1}{n} \sum_{i=1}^n E_i (mI - 11^T) 1 \ = 0,$$

showing that $1 \in \text{nullspace}(L)$.

Now consider any non-zero vector $v := [v_1, \ldots, v_d]^T \in \mathbb{R}^d$ such that $v \notin \text{span}(1)$. Then there must exist some $i, j \in [d]$ such that $v_i \neq v_j$. We know that there exists some path from item i to j in the comparison hyper-graph. Thus there must exist some hyper-edge in this path with two items, say i', j', such that $v_{i'} \neq v_{j'}$. Suppose that hyper-edge corresponds to sample $\ell \in [n]$. Let $v' := E_\ell^T v$. Then $v' \notin \text{span}(1)$. The Cauchy-Schwarz inequality $\langle v', v'\rangle\langle 1, 1\rangle > (\langle v', 1\rangle)^2$ thus implies

$$v^T E_\ell (mI - 11^T) E_\ell^T v > 0.$$

Furthermore, for any $v'' \in \mathbb{R}^m$, the Cauchy-Schwarz inequality $\langle v'', v''\rangle\langle 1, 1\rangle > (\langle v'', 1\rangle)^2$ implies that for any $i \in [n]$, we have $v^T E_i (mI - 11^T) E_i^T v \geq 0$. Overall we conclude that have $v^T L v > 0$ for every $v \notin \text{span}(1)$, and hence, $\text{nullspace}(L) = 1$ and $\lambda_2(L) > 0$.

Finally, we have

$$\mathrm{tr}(L) = \frac{1}{n} \sum_{i=1}^n \mathrm{tr}(E_i (mI - 11^T) E_i^T) \ = \ \frac{1}{n} \sum_{i=1}^n \Big(m\mathrm{tr}(E_i E_i^T) - \mathrm{tr}(E_i 11^T E_i^T) \Big). \tag{27}$$

By the definition of the matrices $\{E_i\}_{i \in [n]}$, $\mathrm{tr}(E_i E_i^T) = m$ and $\mathrm{tr}(E_i 11^T E_i^T) = m$. Substituting these values in (27) gives the desired result $\mathrm{tr}(L) = m(m-1)$. ■

D.2.2 Proof of Lemma 11

Let $h_1, \ldots, h_m$ denote the m eigenvectors of H, with $h_1 = \frac{1}{\sqrt{m}}1$. Then for any vector $v' \in \mathbb{R}^m$,

$$v'^T H v' = \sum_{i=2}^m \lambda_i(H)\langle v',\, h_i\rangle^2 \geq \lambda_2(H)\sum_{i=2}^m \langle v',\, h_i\rangle^2 = \lambda_2(H)\Big(\sum_{i=1}^m \langle v',\, h_i\rangle^2 - \frac{1}{m}\langle v',\, 1\rangle^2\Big)$$
$$= \lambda_2(H) v'^T (I - \frac{1}{m}11^T)v',$$

where the final step employed the property $\sum_{i=1}^m h_i h_i^T = I$ of the eigenvectors $h_1, \ldots, h_m$ of H. A similar argument gives

$$v'^T H v' = \sum_{i=2}^m \lambda_i(H)\langle v',\, h_i\rangle^2 \leq \lambda_{\max}(H)\sum_{i=2}^m \langle v',\, h_i\rangle^2 = \lambda_{\max}(H)\Big(\sum_{i=1}^m \langle v',\, h_i\rangle^2 - \frac{1}{m}\langle v',\, 1\rangle^2\Big)$$
$$= \lambda_{\max}(H) v'^T (I - \frac{1}{m}11^T)v'.$$

Setting $v' = R_j^T v$ gives

$$\lambda_2(H) v^T R_j (I - \frac{1}{m}11^T) R_j^T v \leq v^T R_j H R_j^T v \leq \lambda_{\max}(H) v^T R_j (I - \frac{1}{m}11^T) R_j^T v.$$

Observe that the matrix $I - \frac{1}{m}11^T$ is invariant to permutation of the coordinates, and hence $R_j(I - \frac{1}{m}11^T)R_j^T = I - \frac{1}{m}11^T$. This gives

$$\frac{\lambda_2(H)}{m} v^T (mI - 11^T) v \leq v^T R_j H R_j^T v \leq \frac{\lambda_{\max}(H)}{m} v^T (mI - 11^T) v.$$

■

Appendix E. Some useful tail bounds

In this appendix, we collect a few useful tail bounds for quadratic forms in Gaussian and sub-Gaussian random variables.

Lemma 12 (Tail bound for Gaussian quadratic form) *For any positive semidefinite matrix Q and standard Gaussian vector $g \sim N(0, I_d)$, we have*

$$\mathbb{P}\big[g^T Q g \geq \big(\sqrt{\mathrm{tr}(Q)} + \sqrt{|||Q|||_{op}}\,\delta\big)^2\big] \leq e^{-\delta/2}. \tag{28}$$

valid for all $\delta \geq 0$.

Proof Note that the function $g \mapsto \|\sqrt{Q}g\|_2$ is Lipschitz with constant $\|\sqrt{Q}\|_{\mathrm{op}}$. Consequently, by concentration for Lipschitz functions of Gaussian vectors (Ledoux, 2001), the random variable $Z = \|\sqrt{Q}g\|_2$ satisfies the upper bound

$$\mathbb{P}\big[Z \geq \mathbb{E}[Z] + t\big] \leq \exp\big(-\frac{t^2}{2\|\sqrt{Q}\|_{\mathrm{op}}^2}\big) = \exp\big(-\frac{t^2}{2\|Q\|_{\mathrm{op}}}\big).$$

By Jensen's inequality, we have $\mathbb{E}[Z] = \mathbb{E}[\|\sqrt{Q}g\|_2] \leq \sqrt{\mathbb{E}[g^T Q g]} = \sqrt{\mathrm{tr}(Q)}$. Setting $t = \sqrt{|||Q|||_{\mathrm{op}}}\,\delta$ completes the proof. ■

Lemma 13 ((Hanson and Wright, 1971; Rudelson and Vershynin, 2013)) *Let $V \in \mathbb{R}^d$ be a random vector with independent zero-mean components that are sub-Gaussian with parameter K, and let $M \in \mathbb{R}^{d\times d}$ be an arbitrary matrix. Then there is a universal constant $c > 0$ such that*

$$\mathbb{P}\left[\left|V^T M V - \mathbb{E}[V^T M V]\right| > t\right) \leq 2\exp\left(-c\min\left\{\frac{t^2}{K^4|||M|||_{fro}^2}, \frac{t}{K^2|||M|||_{op}}\right\}\right) \qquad \text{for all } t > 0. \tag{29}$$

Appendix F. Properties of Laplacian matrices

By construction, the Laplacian L of the comparison graph is symmetric and positive-semidefinite. By the singular value decomposition, we can write $L = U^T \Lambda U$ where $U \in \mathbb{R}^{d\times d}$ is an orthonormal matrix, and Λ is a diagonal matrix of nonnegative eigenvalues with $\Lambda_{jj} = \lambda_j(L)$ for every $j \in [d]$. Given our assumption of $\lambda_1(L) \leq \cdots \leq \lambda_d(L)$, we also have $\Lambda_{11} \leq \cdots \leq \Lambda_{dd}$. Also recall that $L^\dagger$ denotes the Moore-Penrose pseudo-inverse of L. In terms of the notation introduced, the Moore-Penrose pseudo-inverse is then given by $L^\dagger = U^T \Lambda^\dagger U$, where $\Lambda^\dagger$ is a diagonal matrix with entries

$$\Lambda^\dagger_{jj} = \begin{cases} (\Lambda_{jj}^{-1}) & \text{if } \Lambda_{jj} > 0 \\ 0 & \text{otherwise.} \end{cases}$$

The following pair of lemmas establish some useful properties about L.

Lemma 14 *The Laplacian matrix (4) satisfies the trace constraints*

$$\mathrm{tr}(L) = 2, \quad \textit{and} \quad \mathrm{tr}(L^\dagger) \geq \frac{d^2}{4}.$$

Proof From the definition (4) of the matrix L, we have $\mathrm{tr}(L) = \frac{1}{n}\sum_{i=1}^n \mathrm{tr}(x_i x_i^T) = 2$. We also know that $\lambda_1(L) = 0$, and hence $\sum_{j=2}^d \lambda_j(L) = 2$. Given the latter constraint, the sum $\sum_{j=2}^d \frac{1}{\lambda_j(L)}$ is minimized when $\lambda_2(L) = \cdots = \lambda_d(L)$. Some simple algebra now gives the claimed result. ■

Lemma 15 *For the matrix L defined in (4), and for a $(n \times d)$ matrix X with x_i^T as its i^{th} row,*

$$\mathrm{tr}(\frac{1}{n}x^T L^\dagger x) = d - 1, \quad |||\frac{1}{n}x^T L^\dagger x|||_{fro} = d - 1, \quad \textit{and} \quad |||\frac{1}{n}x^T L^\dagger x|||_{op} = 1.$$

Proof Let $Q = \frac{1}{n} x^T L^\dagger x$. Since $L = \frac{1}{n} X^T X = U^T \Lambda U$, the diagonal entries of Λ are the squared singular values of $X/\sqrt{n}$. Consequently, there must exist an orthonormal matrix V such that $X/\sqrt{n} = V\sqrt{\Lambda}U^T$, and thus we can write $Q = V\sqrt{\Lambda}\,\Lambda^\dagger\,\sqrt{\Lambda}\,V^T$. By definition of the Moore-Penrose pseudo-inverse, the matrix $\sqrt{\Lambda}\,\Lambda^\dagger\,\sqrt{\Lambda}$ is a diagonal matrix; since the Laplacian graph is connected, its diagonal contains $(d-1)$ ones and a single zero. Noting that V is an orthonormal matrix gives the claimed result. ■

For future reference, we state and prove a lemma showing that these two semi-norms satisfy a restricted form of the Cauchy-Schwarz inequality:

Lemma 16 *For any two vectors u and v such that $u \perp \text{nullspace}(L)$ or/and $v \perp \text{nullspace}(L)$, we have*

$$|\langle u, v\rangle| \leq \|u\|_{L^\dagger}\, \|v\|_L. \tag{30}$$

Proof Since $L = U^T \Lambda U$ and $L^\dagger = U^T \Lambda^\dagger U$, we have

$$\sqrt{v^T L v}\sqrt{u^T L^\dagger u} = \sqrt{v^T U^T \Lambda U v}\,\sqrt{u^T U^T \Lambda^\dagger U u} = \|\widetilde{v}\|_2 \|\widetilde{u}\|_2 \geq |\langle \widetilde{v}, \widetilde{u}\rangle|,$$

where we have defined $\widetilde{v} := \sqrt{\Lambda} U v$ and $\widetilde{u} := \sqrt{\Lambda^\dagger} U u$. Continuing on,

$$\langle \widetilde{v}, \widetilde{u}\rangle = v^T U^T \sqrt{\Lambda}\sqrt{\Lambda^\dagger} U u \;=\; v^T U U^T u,$$

where we have used the fact that u or/and v are orthogonal to the null space of L. Since U is orthonormal, we conclude that $\langle \widetilde{v}, \widetilde{u}\rangle = \langle v, u\rangle$, which completes the proof. ■

Appendix G. Minimax risk without assumptions on quality scores

The setting considered throughout the paper imposes two restrictions (2) on the quality score vector w^*. The first condition is that of shift invariance, that is, $\langle w^*, 1\rangle = 0$. The necessity of this condition for identifiability under the Ordinal model is easy to verify. The second condition is that the quality score vectors are B-bounded, that is, $\|w^*\|_\infty \leq B$ for some finite B. In this section, for the sake of completeness, we show that the minimax risk is infinite in the absence of this condition.

Proposition 17 *Any estimator $\widetilde{w}$ based on n samples from the* Ordinal *model (with unbounded quality score vectors) has error lower bounded as*

$$\sup_{w^* \in \mathcal{W}_\infty} \mathbb{E}\Big[\|\widetilde{w} - w^*\|_2^2\Big] = \sup_{w^* \in \mathcal{W}_\infty} \mathbb{E}\Big[\|\widetilde{w} - w^*\|_L^2\Big] = \infty.$$

The remainder of this section is devoted to the formal proof of Proposition 17. Consider the event where for every comparison, the item with the higher quality score in w^* wins. For any $w^* \in \mathcal{W}_\infty \backslash \{0\}$, this event occurs with a probability at least $\frac{1}{2^n}$. Under this event, the true w^* is indistinguishable from the quality score vector $cw^* \in \mathcal{W}_\infty$ for every $c \geq 0$, and the error is also unbounded. Since the probability of this event is strictly bounded away from zero, the expected error is also unbounded.

Abstract

We introduce a new representation learning approach for domain adaptation, in which data at training and test time come from similar but different distributions. Our approach is directly inspired by the theory on domain adaptation suggesting that, for effective domain transfer to be achieved, predictions must be made based on features that cannot discriminate between the training (source) and test (target) domains.

The approach implements this idea in the context of neural network architectures that are trained on labeled data from the source domain and unlabeled data from the target domain (no labeled target-domain data is necessary). As the training progresses, the approach promotes the emergence of features that are (i) discriminative for the main learning task on the source domain and (ii) indiscriminate with respect to the shift between the domains. We show that this adaptation behaviour can be achieved in almost any feed-forward model by augmenting it with few standard layers and a new *gradient reversal* layer. The resulting augmented architecture can be trained using standard backpropagation and stochastic gradient descent, and can thus be implemented with little effort using any of the deep learning packages.

We demonstrate the success of our approach for two distinct classification problems (document sentiment analysis and image classification), where state-of-the-art domain adaptation performance on standard benchmarks is achieved. We also validate the approach for descriptor learning task in the context of person re-identification application.

Keywords: domain adaptation, neural network, representation learning, deep learning, synthetic data, image classification, sentiment analysis, person re-identification

1. Introduction

The cost of generating labeled data for a new machine learning task is often an obstacle for applying machine learning methods. In particular, this is a limiting factor for the further progress of deep neural network architectures, that have already brought impressive advances to the state-of-the-art across a wide variety of machine-learning tasks and applications. For problems lacking labeled data, it may be still possible to obtain training sets that are big enough for training large-scale deep models, but that suffer from the *shift* in data distribution from the actual data encountered at "test time". One important example is training an image classifier on synthetic or semi-synthetic images, which may come in abundance and be fully labeled, but which inevitably have a distribution that is different from real images (Liebelt and Schmid, 2010; Stark et al., 2010; Vázquez et al., 2014; Sun and Saenko, 2014). Another example is in the context of sentiment analysis in written reviews, where one might have labeled data for reviews of one type of product (*e.g.*, movies), while having the need to classify reviews of other products (*e.g.*, books).

Learning a discriminative classifier or other predictor in the presence of a *shift* between training and test distributions is known as *domain adaptation* (DA). The proposed approaches build mappings between the *source* (training-time) and the *target* (test-time) domains, so that the classifier learned for the source domain can also be applied to the target domain, when composed with the learned mapping between domains. The appeal of the domain adaptation approaches is the ability to learn a mapping between domains in the situation when the target domain data are either fully unlabeled (*unsupervised domain annotation*) or have few labeled samples (*semi-supervised domain adaptation*). Below, we focus on the harder unsupervised case, although the proposed approach (*domain-adversarial learning*) can be generalized to the semi-supervised case rather straightforwardly.

Unlike many previous papers on domain adaptation that worked with fixed feature representations, we focus on combining domain adaptation and deep feature learning within one training process. Our goal is to embed domain adaptation into the process of learning representation, so that the final classification decisions are made based on features that are both discriminative and invariant to the change of domains, *i.e.*, have the same or very similar distributions in the source and the target domains. In this way, the obtained feed-forward network can be applicable to the target domain without being hindered by the shift between the two domains. Our approach is motivated by the theory on domain adaptation (Ben-David et al., 2006, 2010), that suggests that a good representation for cross-domain transfer is one for which an algorithm cannot learn to identify the domain of origin of the input observation.

We thus focus on learning features that combine (i) discriminativeness and (ii) domain-invariance. This is achieved by jointly optimizing the underlying features as well as two discriminative classifiers operating on these features: (i) the *label predictor* that predicts class labels and is used both during training and at test time and (ii) the *domain classifier* that discriminates between the source and the target domains during training. While the parameters of the classifiers are optimized in order to minimize their error on the training set, the parameters of the underlying deep feature mapping are optimized in order to *minimize* the loss of the label classifier and to *maximize* the loss of the domain classifier. The latter

update thus works *adversarially* to the domain classifier, and it encourages domain-invariant features to emerge in the course of the optimization.

Crucially, we show that all three training processes can be embedded into an appropriately composed deep feed-forward network, called *domain-adversarial neural network* (DANN) (illustrated by Figure 1, page 12) that uses standard layers and loss functions, and can be trained using standard backpropagation algorithms based on stochastic gradient descent or its modifications (*e.g.*, SGD with momentum). The approach is generic as a DANN version can be created for almost any existing feed-forward architecture that is trainable by backpropagation. In practice, the only non-standard component of the proposed architecture is a rather trivial *gradient reversal* layer that leaves the input unchanged during forward propagation and reverses the gradient by multiplying it by a negative scalar during the backpropagation.

We provide an experimental evaluation of the proposed domain-adversarial learning idea over a range of deep architectures and applications. We first consider the simplest DANN architecture where the three parts (label predictor, domain classifier and feature extractor) are linear, and demonstrate the success of domain-adversarial learning for such architecture. The evaluation is performed for synthetic data as well as for the sentiment analysis problem in natural language processing, where DANN improves the state-of-the-art *marginalized Stacked Autoencoders* (mSDA) of Chen et al. (2012) on the common Amazon reviews benchmark.

We further evaluate the approach extensively for an image classification task, and present results on traditional deep learning image data sets—such as MNIST (LeCun et al., 1998) and SVHN (Netzer et al., 2011)—as well as on Office benchmarks (Saenko et al., 2010), where domain-adversarial learning allows obtaining a deep architecture that considerably improves over previous state-of-the-art accuracy.

Finally, we evaluate domain-adversarial *descriptor* learning in the context of person re-identification application (Gong et al., 2014), where the task is to obtain good pedestrian image descriptors that are suitable for retrieval and verification. We apply domain-adversarial learning, as we consider a *descriptor predictor* trained with a Siamese-like loss instead of the label predictor trained with a classification loss. In a series of experiments, we demonstrate that domain-adversarial learning can improve cross-data-set re-identification considerably.

2. Related work

The general approach of achieving domain adaptation explored under many facets. Over the years, a large part of the literature has focused mainly on linear hypothesis (see for instance Blitzer et al., 2006; Bruzzone and Marconcini, 2010; Germain et al., 2013; Baktashmotlagh et al., 2013; Cortes and Mohri, 2014). More recently, non-linear representations have become increasingly studied, including neural network representations (Glorot et al., 2011; Li et al., 2014) and most notably the state-of-the-art mSDA (Chen et al., 2012). That literature has mostly focused on exploiting the principle of robust representations, based on the denoising autoencoder paradigm (Vincent et al., 2008).

Concurrently, multiple methods of matching the feature distributions in the source and the target domains have been proposed for unsupervised domain adaptation. Some approaches perform this by reweighing or selecting samples from the source domain (Borgwardt et al., 2006; Huang et al., 2006; Gong et al., 2013), while others seek an explicit feature space transformation that would map source distribution into the target one (Pan et al., 2011; Gopalan et al., 2011; Baktashmotlagh et al., 2013). An important aspect of the distribution matching approach is the way the (dis)similarity between distributions is measured. Here, one popular choice is matching the distribution means in the kernel-reproducing Hilbert space (Borgwardt et al., 2006; Huang et al., 2006), whereas Gong et al. (2012) and Fernando et al. (2013) map the principal axes associated with each of the distributions.

Our approach also attempts to match feature space distributions, however this is accomplished by modifying the feature representation itself rather than by reweighing or geometric transformation. Also, our method uses a rather different way to measure the disparity between distributions based on their separability by a deep discriminatively-trained classifier. Note also that several approaches perform transition from the source to the target domain (Gopalan et al., 2011; Gong et al., 2012) by changing gradually the training distribution. Among these methods, Chopra et al. (2013) does this in a "deep" way by the layerwise training of a sequence of deep autoencoders, while gradually replacing source-domain samples with target-domain samples. This improves over a similar approach of Glorot et al. (2011) that simply trains a single deep autoencoder for both domains. In both approaches, the actual classifier/predictor is learned in a separate step using the feature representation learned by autoencoder(s). In contrast to Glorot et al. (2011); Chopra et al. (2013), our approach performs feature learning, domain adaptation and classifier learning jointly, in a unified architecture, and using a single learning algorithm (backpropagation). We therefore argue that our approach is simpler (both conceptually and in terms of its implementation). Our method also achieves considerably better results on the popular Office benchmark.

While the above approaches perform unsupervised domain adaptation, there are approaches that perform *supervised* domain adaptation by exploiting labeled data from the target domain. In the context of deep feed-forward architectures, such data can be used to "fine-tune" the network trained on the source domain (Zeiler and Fergus, 2013; Oquab et al., 2014; Babenko et al., 2014). Our approach does not require labeled target-domain data. At the same time, it can easily incorporate such data when they are available.

An idea related to ours is described in Goodfellow et al. (2014). While their goal is quite different (building generative deep networks that can synthesize samples), the way they measure and minimize the discrepancy between the distribution of the training data and the distribution of the synthesized data is very similar to the way our architecture measures and minimizes the discrepancy between feature distributions for the two domains. Moreover, the authors mention the problem of saturating sigmoids which may arise at the early stages of training due to the significant dissimilarity of the domains. The technique they use to circumvent this issue (the "adversarial" part of the gradient is replaced by a gradient computed with respect to a suitable cost) is directly applicable to our method.

Also, recent and concurrent reports by Tzeng et al. (2014); Long and Wang (2015) focus on domain adaptation in feed-forward networks. Their set of techniques measures and minimizes the distance between the data distribution means across domains (potentially, after embedding distributions into RKHS). Their approach is thus different from our idea of matching distributions by making them indistinguishable for a discriminative classifier.

Below, we compare our approach to Tzeng et al. (2014); Long and Wang (2015) on the Office benchmark. Another approach to deep domain adaptation, which is arguably more different from ours, has been developed in parallel by Chen et al. (2015).

From a theoretical standpoint, our approach is directly derived from the seminal theoretical works of Ben-David et al. (2006, 2010). Indeed, DANN directly optimizes the notion of $\mathcal{H}$-divergence. We do note the work of Huang and Yates (2012), in which HMM representations are learned for word tagging using a posterior regularizer that is also inspired by Ben-David et al.'s work. In addition to the tasks being different—Huang and Yates (2012) focus on word tagging problems—, we would argue that DANN learning objective more closely optimizes the $\mathcal{H}$-divergence, with Huang and Yates (2012) relying on cruder approximations for efficiency reasons.

A part of this paper has been published as a conference paper (Ganin and Lempitsky, 2015). This version extends Ganin and Lempitsky (2015) very considerably by incorporating the report Ajakan et al. (2014) (presented as part of the *Second Workshop on Transfer and Multi-Task Learning*), which brings in new terminology, in-depth theoretical analysis and justification of the approach, extensive experiments with the shallow DANN case on synthetic data as well as on a natural language processing task (sentiment analysis). Furthermore, in this version we go beyond classification and evaluate domain-adversarial learning for descriptor learning setting within the person re-identification application.

3. Domain Adaptation

We consider classification tasks where X is the input space and $Y = \{0, 1, \ldots, L-1\}$ is the set of L possible labels. Moreover, we have two different distributions over $X \times Y$, called the *source domain* $\mathcal{D}_\mathrm{S}$ and the *target domain* $\mathcal{D}_\mathrm{T}$. An *unsupervised domain adaptation* learning algorithm is then provided with a *labeled source sample* S drawn *i.i.d.* from $\mathcal{D}_\mathrm{S}$, and an *unlabeled target sample* T drawn *i.i.d.* from $\mathcal{D}_\mathrm{T}^X$, where $\mathcal{D}_\mathrm{T}^X$ is the marginal distribution of $\mathcal{D}_\mathrm{T}$ over X.

$$S = \{(\mathbf{x}_i, y_i)\}_{i=1}^n \sim (\mathcal{D}_\mathrm{S})^n\,; \quad T = \{\mathbf{x}_i\}_{i=n+1}^N \sim (\mathcal{D}_\mathrm{T}^X)^{n'},$$

with $N = n + n'$ being the total number of samples. The goal of the learning algorithm is to build a classifier $\eta : X \to Y$ with a low *target risk*

$$R_{\mathcal{D}_\mathrm{T}}(\eta) \;=\; \Pr_{(\mathbf{x},y)\sim\mathcal{D}_\mathrm{T}} \Big(\eta(\mathbf{x}) \neq y\Big)\,,$$

while having no information about the labels of $\mathcal{D}_\mathrm{T}$.

3.1 Domain Divergence

To tackle the challenging domain adaptation task, many approaches bound the target error by the sum of the source error and a notion of distance between the source and the target distributions. These methods are intuitively justified by a simple assumption: the source risk is expected to be a good indicator of the target risk when both distributions are similar. Several notions of distance have been proposed for domain adaptation (Ben-David et al., 2006, 2010; Mansour et al., 2009a,b; Germain et al., 2013). In this paper, we focus on the $\mathcal{H}$-divergence used by Ben-David et al. (2006, 2010), and based on the earlier work of Kifer et al. (2004). Note that we assume in definition 1 below that the hypothesis class $\mathcal{H}$ is a (discrete or continuous) set of binary classifiers $\eta : X \to \{0, 1\}$.[1]

Definition 1 (Ben-David et al., 2006, 2010; Kifer et al., 2004) *Given two domain distributions $\mathcal{D}_\mathrm{S}^X$ and $\mathcal{D}_\mathrm{T}^X$ over X, and a hypothesis class $\mathcal{H}$, the* $\mathcal{H}$-divergence *between $\mathcal{D}_\mathrm{S}^X$ and $\mathcal{D}_\mathrm{T}^X$ is*

$$d_{\mathcal{H}}(\mathcal{D}_\mathrm{S}^X, \mathcal{D}_\mathrm{T}^X) \;=\; 2 \sup_{\eta\in\mathcal{H}} \left| \Pr_{\mathbf{x}\sim\mathcal{D}_\mathrm{S}^X} \big[\eta(\mathbf{x}) = 1\big] - \Pr_{\mathbf{x}\sim\mathcal{D}_\mathrm{T}^X} \big[\eta(\mathbf{x}) = 1\big] \right|.$$

That is, the $\mathcal{H}$-divergence relies on the capacity of the hypothesis class $\mathcal{H}$ to distinguish between examples generated by $\mathcal{D}_\mathrm{S}^X$ from examples generated by $\mathcal{D}_\mathrm{T}^X$. Ben-David et al. (2006, 2010) proved that, for a symmetric hypothesis class $\mathcal{H}$, one can compute the *empirical* $\mathcal{H}$*-divergence* between two samples $S \sim (\mathcal{D}_\mathrm{S}^X)^n$ and $T \sim (\mathcal{D}_\mathrm{T}^X)^{n'}$ by computing

$$\hat{d}_{\mathcal{H}}(S, T) \;=\; 2\left(1 - \min_{\eta\in\mathcal{H}} \left[\frac{1}{n}\sum_{i=1}^{n} I[\eta(\mathbf{x}_i)=0] + \frac{1}{n'}\sum_{i=n+1}^{N} I[\eta(\mathbf{x}_i)=1]\right]\right), \tag{1}$$

where $I[a]$ is the indicator function which is 1 if predicate a is true, and 0 otherwise.

3.2 Proxy Distance

Ben-David et al. (2006) suggested that, even if it is generally hard to compute $\hat{d}_{\mathcal{H}}(S, T)$ exactly (*e.g.*, when $\mathcal{H}$ is the space of linear classifiers on X), we can easily approximate it by running a learning algorithm on the problem of discriminating between source and target examples. To do so, we construct a new data set

$$U \;=\; \{(\mathbf{x}_i, 0)\}_{i=1}^n \cup \{(\mathbf{x}_i, 1)\}_{i=n+1}^N\,, \tag{2}$$

where the examples of the source sample are labeled 0 and the examples of the target sample are labeled 1. Then, the risk of the classifier trained on the new data set U approximates the "min" part of Equation (1). Given a generalization error ϵ on the problem of discriminating between source and target examples, the $\mathcal{H}$-divergence is then approximated by

$$\hat{d}_{\mathcal{A}} \;=\; 2\,(1 - 2\epsilon)\,. \tag{3}$$

In Ben-David et al. (2006), the value $\hat{d}_{\mathcal{A}}$ is called the *Proxy* $\mathcal{A}$*-distance* (PAD). The $\mathcal{A}$*-distance* being defined as $d_{\mathcal{A}}(\mathcal{D}_\mathrm{S}^X, \mathcal{D}_\mathrm{T}^X) = 2 \sup_{A\in\mathcal{A}} \left| \Pr_{\mathcal{D}_\mathrm{S}^X}(A) - \Pr_{\mathcal{D}_\mathrm{T}^X}(A) \right|$, where $\mathcal{A}$ is a subset of X. Note that, by choosing $\mathcal{A} = \{A_\eta | \eta \in \mathcal{H}\}$, with A_η the set represented by the characteristic function η, the $\mathcal{A}$-distance and the $\mathcal{H}$-divergence of Definition 1 are identical.

In the experiments section of this paper, we compute the PAD value following the approach of Glorot et al. (2011); Chen et al. (2012), *i.e.*, we train either a linear SVM or a deeper MLP classifier on a subset of U (Equation 2), and we use the obtained classifier error on the other subset as the value of ϵ in Equation (3). More details and illustrations of the linear SVM case are provided in Section 5.1.5.

1. As mentioned by Ben-David et al. (2006), the same analysis holds for multiclass setting. However, to obtain the same results when $|Y| > 2$, one should assume that $\mathcal{H}$ is a symmetrical hypothesis class. That is, for all $h \in \mathcal{H}$ and any permutation of labels $c : Y \to Y$, we have $c(h) \in \mathcal{H}$. Note that this is the case for most commonly used neural network architectures.

3.3 Generalization Bound on the Target Risk

The work of Ben-David et al. (2006, 2010) also showed that the $\mathcal{H}$-divergence $d_{\mathcal{H}}(\mathcal{D}_{\mathrm{S}}^X, \mathcal{D}_{\mathrm{T}}^X)$ is upper bounded by its empirical estimate $\hat{d}_{\mathcal{H}}(S,T)$ plus a constant complexity term that depends on the *VC dimension* of $\mathcal{H}$ and the size of samples S and T. By combining this result with a similar bound on the source risk, the following theorem is obtained.

Theorem 2 (Ben-David et al., 2006) *Let $\mathcal{H}$ be a hypothesis class of VC dimension d. With probability $1-\delta$ over the choice of samples $S \sim (\mathcal{D}_{\mathrm{S}})^n$ and $T \sim (\mathcal{D}_{\mathrm{T}}^X)^n$, for every $\eta \in \mathcal{H}$:*

$$R_{\mathcal{D}_{\mathrm{T}}}(\eta) \;\leq\; R_S(\eta) + \sqrt{\frac{4}{n}\left(d\log\tfrac{2en}{d} + \log\tfrac{4}{\delta}\right)} + \hat{d}_{\mathcal{H}}(S,T) + 4\sqrt{\frac{1}{n}\left(d\log\tfrac{2n}{d} + \log\tfrac{4}{\delta}\right)} + \beta\,,$$

with $\beta \geq \inf_{\eta^* \in \mathcal{H}} \left[R_{\mathcal{D}_{\mathrm{S}}}(\eta^*) + R_{\mathcal{D}_{\mathrm{T}}}(\eta^*)\right]$, and

$$R_S(\eta) \;=\; \frac{1}{n}\sum_{i=1}^{m} I\left[\eta(\mathbf{x}_i) \neq y_i\right]$$

is the empirical source risk.

The previous result tells us that $R_{\mathcal{D}_{\mathrm{T}}}(\eta)$ can be low only when the β term is low, *i.e.*, only when there exists a classifier that can achieve a low risk on both distributions. It also tells us that, to find a classifier with a small $R_{\mathcal{D}_{\mathrm{T}}}(\eta)$ in a given class of fixed VC dimension, the learning algorithm should minimize (in that class) a trade-off between the source risk $R_S(\eta)$ and the empirical $\mathcal{H}$-divergence $\hat{d}_{\mathcal{H}}(S,T)$. As pointed-out by Ben-David et al. (2006), a strategy to control the $\mathcal{H}$-divergence is to find a representation of the examples where both the source and the target domain are as indistinguishable as possible. Under such a representation, a hypothesis with a low source risk will, according to Theorem 2, perform well on the target data. In this paper, we present an algorithm that directly exploits this idea.

4. Domain-Adversarial Neural Networks (DANN)

An original aspect of our approach is to explicitly implement the idea exhibited by Theorem 2 into a neural network classifier. That is, to learn a model that can generalize well from one domain to another, we ensure that the internal representation of the neural network contains no discriminative information about the origin of the input (source or target), while preserving a low risk on the source (labeled) examples.

In this section, we detail the proposed approach for incorporating a "domain adaptation component" to neural networks. In Subsection 4.1, we start by developing the idea for the simplest possible case, *i.e.*, a single hidden layer, fully connected neural network. We then describe how to generalize the approach to arbitrary (deep) network architectures.

4.1 Example Case with a Shallow Neural Network

Let us first consider a standard neural network (NN) architecture with a single hidden layer. For simplicity, we suppose that the input space is formed by m-dimensional real

vectors. Thus, $X = \mathbb{R}^m$. The hidden layer G_f learns a function $G_f : X \to \mathbb{R}^D$ that maps an example into a new D-dimensional representation[2], and is parameterized by a matrix-vector pair $(\mathbf{W}, \mathbf{b}) \in \mathbb{R}^{D\times m} \times \mathbb{R}^D$:

$$G_f(\mathbf{x}; \mathbf{W}, \mathbf{b}) \;=\; \mathrm{sigm}\big(\mathbf{W}\mathbf{x} + \mathbf{b}\big)\,, \tag{4}$$

with $\mathrm{sigm}(\mathbf{a}) = \left[\frac{1}{1+\exp(-a_i)}\right]_{i=1}^{|\mathbf{a}|}$.

Similarly, the prediction layer G_y learns a function $G_y : \mathbb{R}^D \to [0,1]^L$ that is parameterized by a pair $(\mathbf{V}, \mathbf{c}) \in \mathbb{R}^{L\times D} \times \mathbb{R}^L$:

$$G_y(G_f(\mathbf{x}); \mathbf{V}, \mathbf{c}) \;=\; \mathrm{softmax}\big(\mathbf{V}G_f(\mathbf{x}) + \mathbf{c}\big)\,,$$

with $\mathrm{softmax}(\mathbf{a}) = \left[\frac{\exp(a_i)}{\sum_{j=1}^{|\mathbf{a}|}\exp(a_j)}\right]_{i=1}^{|\mathbf{a}|}$.

Here we have $L = |Y|$. By using the softmax function, each component of vector $G_y(G_f(\mathbf{x}))$ denotes the conditional probability that the neural network assigns $\mathbf{x}$ to the class in Y represented by that component. Given a source example $(\mathbf{x}_i, y_i)$, the natural classification loss to use is the negative log-probability of the correct label:

$$\mathcal{L}_y\big(G_y(G_f(\mathbf{x}_i)), y_i\big) \;=\; \log\frac{1}{G_y(G_f(\mathbf{x}))_{y_i}}\,.$$

Training the neural network then leads to the following optimization problem on the source domain:

$$\min_{\mathbf{W},\mathbf{b},\mathbf{V},\mathbf{c}} \left[\frac{1}{n}\sum_{i=1}^{n} \mathcal{L}_y^i(\mathbf{W},\mathbf{b},\mathbf{V},\mathbf{c}) + \lambda\cdot R(\mathbf{W},\mathbf{b})\right], \tag{5}$$

where $\mathcal{L}_y^i(\mathbf{W},\mathbf{b},\mathbf{V},\mathbf{c}) = \mathcal{L}_y\big(G_y(G_f(\mathbf{x}_i;\mathbf{W},\mathbf{b});\mathbf{V},\mathbf{c}), y_i\big)$ is a shorthand notation for the prediction loss on the i-th example, and $R(\mathbf{W},\mathbf{b})$ is an optional regularizer that is weighted by hyper-parameter λ.

The heart of our approach is to design a *domain regularizer* directly derived from the $\mathcal{H}$-divergence of Definition 1. To this end, we view the output of the hidden layer $G_f(\cdot)$ (Equation 4) as the internal representation of the neural network. Thus, we denote the source sample representations as

$$S(G_f) \;=\; \big\{G_f(\mathbf{x}) \,\big|\, \mathbf{x} \in S\big\}\,.$$

Similarly, given an unlabeled sample from the target domain we denote the corresponding representations

$$T(G_f) \;=\; \big\{G_f(\mathbf{x}) \,\big|\, \mathbf{x} \in T\big\}\,.$$

Based on Equation (1), the empirical $\mathcal{H}$-divergence of a symmetric hypothesis class $\mathcal{H}$ between samples $S(G_f)$ and $T(G_f)$ is given by

$$\hat{d}_{\mathcal{H}}\big(S(G_f), T(G_f)\big) \;=\; 2\left(1 - \min_{\eta\in\mathcal{H}}\left[\frac{1}{n}\sum_{i=1}^{n} I\big[\eta(G_f(\mathbf{x}_i))=0\big] + \frac{1}{n'}\sum_{i=n+1}^{N} I\big[\eta(G_f(\mathbf{x}_i))=1\big]\right]\right). \tag{6}$$

2. For brevity of notation, we will sometimes drop the dependence of G_f on its parameters $(\mathbf{W},\mathbf{b})$ and shorten $G_f(\mathbf{x};\mathbf{W},\mathbf{b})$ to $G_f(\mathbf{x})$.

Let us consider $\mathcal{H}$ as the class of hyperplanes in the representation space. Inspired by the Proxy $\mathcal{A}$-distance (see Section 3.2), we suggest estimating the "min" part of Equation (6) by a *domain classification layer* G_d that learns a logistic regressor $G_d : \mathbb{R}^D \to [0,1]$, parameterized by a vector-scalar pair $(\mathbf{u}, z) \in \mathbb{R}^D \times \mathbb{R}$, that models the probability that a given input is from the source domain $\mathcal{D}_{\mathrm{S}}^X$ or the target domain $\mathcal{D}_{\mathrm{T}}^X$. Thus,

$$G_d(G_f(\mathbf{x}); \mathbf{u}, z) \;=\; \mathrm{sigm}\big(\mathbf{u}^\top G_f(\mathbf{x}) + z\big)\,. \tag{7}$$

Hence, the function $G_d(\cdot)$ is a *domain regressor*. We define its loss by

$$\mathcal{L}_d\big(G_d(G_f(\mathbf{x}_i)), d_i\big) \;=\; d_i \log \frac{1}{G_d(G_f(\mathbf{x}_i))} + (1-d_i) \log \frac{1}{1-G_d(G_f(\mathbf{x}_i))}\,,$$

where d_i denotes the binary variable (*domain label*) for the i-th example, which indicates whether $\mathbf{x}_i$ come from the source distribution ($\mathbf{x}_i \sim \mathcal{D}_{\mathrm{S}}^X$ if $d_i{=}0$) or from the target distribution ($\mathbf{x}_i \sim \mathcal{D}_{\mathrm{T}}^X$ if $d_i{=}1$).

Recall that for the examples from the source distribution ($d_i{=}0$), the corresponding labels $y_i \in Y$ are known at training time. For the examples from the target domains, we do not know the labels at training time, and we want to predict such labels at test time. This enables us to add a domain adaptation term to the objective of Equation (5), giving the following regularizer:

$$R(\mathbf{W}, \mathbf{b}) \;=\; \max_{\mathbf{u}, z} \left[-\frac{1}{n} \sum_{i=1}^{n} \mathcal{L}_d^i(\mathbf{W}, \mathbf{b}, \mathbf{u}, z) - \frac{1}{n'} \sum_{i=n+1}^{N} \mathcal{L}_d^i(\mathbf{W}, \mathbf{b}, \mathbf{u}, z) \right], \tag{8}$$

where $\mathcal{L}_d^i(\mathbf{W}, \mathbf{b}, \mathbf{u}, z) {=} \mathcal{L}_d\big(G_d(G_f(\mathbf{x}_i; \mathbf{W}, \mathbf{b}); \mathbf{u}, z), d_i\big)$. This regularizer seeks to approximate the $\mathcal{H}$-divergence of Equation (6), as $2(1{-}R(\mathbf{W}, \mathbf{b}))$ is a surrogate for $\hat{d}_{\mathcal{H}}\big(S(G_f), T(G_f)\big)$. In line with Theorem 2, the optimization problem given by Equations (5) and (8) implements a trade-off between the minimization of the source risk $R_S(\cdot)$ and the divergence $\hat{d}_{\mathcal{H}}(\cdot, \cdot)$. The hyper-parameter λ is then used to tune the trade-off between these two quantities during the learning process.

For learning, we first note that we can rewrite the complete optimization objective of Equation (5) as follows:

$$\begin{aligned} &E(\mathbf{W}, \mathbf{V}, \mathbf{b}, \mathbf{c}, \mathbf{u}, z) \qquad\qquad (9)\\ &\quad= \frac{1}{n} \sum_{i=1}^{n} \mathcal{L}_y^i(\mathbf{W}, \mathbf{b}, \mathbf{V}, \mathbf{c}) - \lambda \left(\frac{1}{n} \sum_{i=1}^{n} \mathcal{L}_d^i(\mathbf{W}, \mathbf{b}, \mathbf{u}, z) + \frac{1}{n'} \sum_{i=n+1}^{N} \mathcal{L}_d^i(\mathbf{W}, \mathbf{b}, \mathbf{u}, z) \right), \end{aligned}$$

where we are seeking the parameters $\hat{\mathbf{W}}, \hat{\mathbf{V}}, \hat{\mathbf{b}}, \hat{\mathbf{c}}, \hat{\mathbf{u}}, \hat{z}$ that deliver a saddle point given by

$$\begin{aligned} (\hat{\mathbf{W}}, \hat{\mathbf{V}}, \hat{\mathbf{b}}, \hat{\mathbf{c}}) &= \operatorname*{argmin}_{\mathbf{W}, \mathbf{V}, \mathbf{b}, \mathbf{c}} E(\mathbf{W}, \mathbf{V}, \mathbf{b}, \mathbf{c}, \hat{\mathbf{u}}, \hat{z})\,,\\ (\hat{\mathbf{u}}, \hat{z}) &= \operatorname*{argmax}_{\mathbf{u}, z} E(\hat{\mathbf{W}}, \hat{\mathbf{V}}, \hat{\mathbf{b}}, \hat{\mathbf{c}}, \mathbf{u}, z)\,. \end{aligned}$$

Thus, the optimization problem involves a minimization with respect to some parameters, as well as a maximization with respect to the others.

Algorithm 1 Shallow DANN – Stochastic training update

Input:
— samples $S = \{(\mathbf{x}_i, y_i)\}_{i=1}^{n}$ and $T = \{\mathbf{x}_i\}_{i=1}^{n'}$,
— hidden layer size D,
— adaptation parameter λ,
— learning rate μ,
Output: neural network $\{\mathbf{W}, \mathbf{V}, \mathbf{b}, \mathbf{c}\}$

$\mathbf{W}, \mathbf{V} \leftarrow$ random_init(D)
$\mathbf{b}, \mathbf{c}, \mathbf{u}, d \leftarrow 0$

  end for
end while

Note: In this pseudo-code, $\mathbf{e}(y)$ refers to a "one-hot" vector, consisting of all 0s except for a 1 at position y, and $\odot$ is the element-wise product.

We propose to tackle this problem with a simple stochastic gradient procedure, in which updates are made in the opposite direction of the gradient of Equation (9) for the minimizing parameters, and in the direction of the gradient for the maximizing parameters. Stochastic estimates of the gradient are made, using a subset of the training samples to compute the averages. Algorithm 1 provides the complete pseudo-code of this learning procedure.[3] In words, during training, the neural network (parameterized by $\mathbf{W}, \mathbf{b}, \mathbf{V}, \mathbf{c}$) and the domain regressor (parameterized by $\mathbf{u}, z$) are competing against each other, in an adversarial way, over the objective of Equation (9). For this reason, we refer to networks trained according to this objective as Domain-Adversarial Neural Networks (DANN). DANN will effectively attempt to learn a hidden layer $G_f(\cdot)$ that maps an example (either source or target) into a representation allowing the output layer $G_y(\cdot)$ to accurately classify source samples, but crippling the ability of the domain regressor $G_d(\cdot)$ to detect whether each example belongs to the source or target domains.

3. We provide an implementation of *Shallow DANN* algorithm at `http://graal.ift.ulaval.ca/dann/`

4.2 Generalization to Arbitrary Architectures

For illustration purposes, we've so far focused on the case of a single hidden layer DANN. However, it is straightforward to generalize to other sophisticated architectures, which might be more appropriate for the data at hand. For example, deep convolutional neural networks are well known for being state-of-the-art models for learning discriminative features of images (Krizhevsky et al., 2012).

Let us now use a more general notation for the different components of DANN. Namely, let $G_f(\cdot;\theta_f)$ be the D-dimensional neural network feature extractor, with parameters θ_f. Also, let $G_y(\cdot;\theta_y)$ be the part of DANN that computes the network's label prediction output layer, with parameters θ_y, while $G_d(\cdot;\theta_d)$ now corresponds to the computation of the domain prediction output of the network, with parameters θ_d. Note that for preserving the theoretical guarantees of Theorem 2, the hypothesis class $\mathcal{H}_d$ generated by the domain prediction component G_d should include the hypothesis class $\mathcal{H}_y$ generated by the label prediction component G_y. Thus, $\mathcal{H}_y \subseteq \mathcal{H}_d$.

We will note the prediction loss and the domain loss respectively by

$$\begin{aligned} \mathcal{L}_y^i(\theta_f,\theta_y) &= \mathcal{L}_y\big(G_y(G_f(\mathbf{x}_i;\theta_f);\theta_y), y_i\big)\,, \\ \mathcal{L}_d^i(\theta_f,\theta_d) &= \mathcal{L}_d\big(G_d(G_f(\mathbf{x}_i;\theta_f);\theta_d), d_i\big)\,. \end{aligned}$$

Training DANN then parallels the single layer case and consists in optimizing

$$E(\theta_f,\theta_y,\theta_d) = \frac{1}{n}\sum_{i=1}^{n}\mathcal{L}_y^i(\theta_f,\theta_y) - \lambda\left(\frac{1}{n}\sum_{i=1}^{n}\mathcal{L}_d^i(\theta_f,\theta_d) + \frac{1}{n'}\sum_{i=n+1}^{N}\mathcal{L}_d^i(\theta_f,\theta_d)\right), \tag{10}$$

by finding the saddle point $\hat{\theta}_f,\hat{\theta}_y,\hat{\theta}_d$ such that

$$(\hat{\theta}_f,\hat{\theta}_y) = \operatorname*{argmin}_{\theta_f,\theta_y} E(\theta_f,\theta_y,\hat{\theta}_d)\,, \tag{11}$$

$$\hat{\theta}_d = \operatorname*{argmax}_{\theta_d} E(\hat{\theta}_f,\hat{\theta}_y,\theta_d)\,. \tag{12}$$

As suggested previously, a saddle point defined by Equations (11-12) can be found as a stationary point of the following gradient updates:

$$\theta_f \longleftarrow \theta_f - \mu\left(\frac{\partial\mathcal{L}_y^i}{\partial\theta_f} - \lambda\frac{\partial\mathcal{L}_d^i}{\partial\theta_f}\right), \tag{13}$$

$$\theta_y \longleftarrow \theta_y - \mu\frac{\partial\mathcal{L}_y^i}{\partial\theta_y}, \tag{14}$$

$$\theta_d \longleftarrow \theta_d - \mu\lambda\frac{\partial\mathcal{L}_d^i}{\partial\theta_d}, \tag{15}$$

where μ is the learning rate. We use stochastic estimates of these gradients, by sampling examples from the data set.

The updates of Equations (13-15) are very similar to stochastic gradient descent (SGD) updates for a feed-forward deep model that comprises feature extractor fed into the label

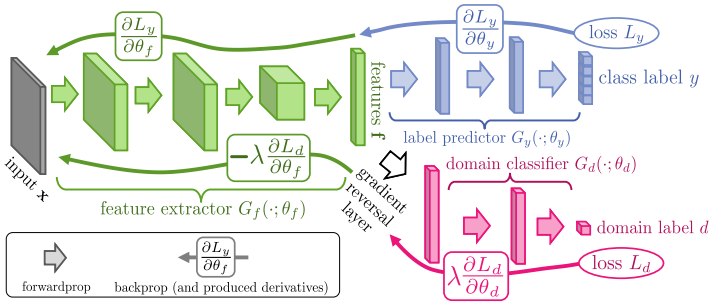

Figure 1: The **proposed architecture** includes a deep *feature extractor* (green) and a deep *label predictor* (blue), which together form a standard feed-forward architecture. Unsupervised domain adaptation is achieved by adding a *domain classifier* (red) connected to the feature extractor via a *gradient reversal layer* that multiplies the gradient by a certain negative constant during the backpropagation-based training. Otherwise, the training proceeds standardly and minimizes the label prediction loss (for source examples) and the domain classification loss (for all samples). Gradient reversal ensures that the feature distributions over the two domains are made similar (as indistinguishable as possible for the domain classifier), thus resulting in the domain-invariant features.

predictor and into the domain classifier (with loss weighted by λ). The only difference is that in (13), the gradients from the class and domain predictors are subtracted, instead of being summed (the difference is important, as otherwise SGD would try to make features dissimilar across domains in order to minimize the domain classification loss). Since SGD—and its many variants, such as ADAGRAD (Duchi et al., 2010) or ADADELTA (Zeiler, 2012)—is the main learning algorithm implemented in most libraries for deep learning, it would be convenient to frame an implementation of our stochastic saddle point procedure as SGD.

Fortunately, such a reduction can be accomplished by introducing a special *gradient reversal layer* (GRL), defined as follows. The gradient reversal layer has no parameters associated with it. During the forward propagation, the GRL acts as an identity transformation. During the backpropagation however, the GRL takes the gradient from the subsequent level and changes its sign, *i.e.*, multiplies it by -1, before passing it to the preceding layer. Implementing such a layer using existing object-oriented packages for deep learning is simple, requiring only to define procedures for the forward propagation (identity transformation), and backpropagation (multiplying by -1). The layer requires no parameter update.

The GRL as defined above is inserted between the feature extractor G_f and the domain classifier G_d, resulting in the architecture depicted in Figure 1. As the backpropagation process passes through the GRL, the partial derivatives of the loss that is downstream

the GRL (*i.e.*, $\mathcal{L}_d$) w.r.t. the layer parameters that are upstream the GRL (*i.e.*, θ_f) get multiplied by -1, *i.e.*, $\frac{\partial \mathcal{L}_d}{\partial \theta_f}$ is effectively replaced with $-\frac{\partial \mathcal{L}_d}{\partial \theta_f}$. Therefore, running SGD in the resulting model implements the updates of Equations (13-15) and converges to a saddle point of Equation (10).

Mathematically, we can formally treat the gradient reversal layer as a "pseudo-function" $\mathcal{R}(\mathbf{x})$ defined by two (incompatible) equations describing its forward and backpropagation behaviour:

$$\mathcal{R}(\mathbf{x}) = \mathbf{x}\,, \tag{16}$$

$$\frac{d\mathcal{R}}{d\mathbf{x}} = -\mathbf{I}\,, \tag{17}$$

where $\mathbf{I}$ is an identity matrix. We can then define the objective "pseudo-function" of $(\theta_f, \theta_y, \theta_d)$ that is being optimized by the stochastic gradient descent within our method:

$$\tilde{E}(\theta_f, \theta_y, \theta_d) = \frac{1}{n}\sum_{i=1}^{n} \mathcal{L}_y\left(G_y(G_f(\mathbf{x}_i;\theta_f);\theta_y), y_i\right) \tag{18}$$

$$-\,\lambda\left(\frac{1}{n}\sum_{i=1}^{n} \mathcal{L}_d\left(G_d(\mathcal{R}(G_f(\mathbf{x}_i;\theta_f));\theta_d), d_i\right) + \frac{1}{n'}\sum_{i=n+1}^{N} \mathcal{L}_d\left(G_d(\mathcal{R}(G_f(\mathbf{x}_i;\theta_f));\theta_d), d_i\right)\right).$$

Running updates (13-15) can then be implemented as doing SGD for (18) and leads to the emergence of features that are domain-invariant and discriminative at the same time. After the learning, the label predictor $G_y(G_f(\mathbf{x};\theta_f);\theta_y)$ can be used to predict labels for samples from the target domain (as well as from the source domain). Note that we release the source code for the Gradient Reversal layer along with the usage examples as an extension to `Caffe` (Jia et al., 2014).[4]

5. Experiments

In this section, we present a variety of empirical results for both *shallow* domain adversarial neural networks (Subsection 5.1) and *deep* ones (Subsections 5.2 and 5.3).

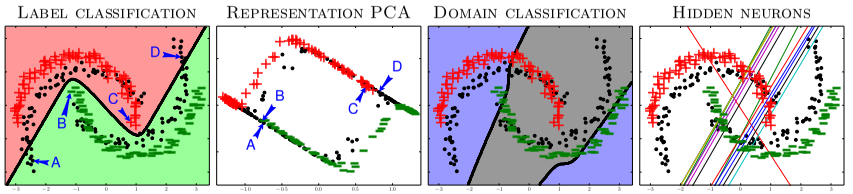
5.1 Experiments with Shallow Neural Networks

In this first experiment section, we evaluate the behavior of the simple version of DANN described by Subsection 4.1. Note that the results reported in the present subsection are obtained using Algorithm 1. Thus, the stochastic gradient descent approach here consists of sampling a pair of source and target examples and performing a gradient step update of all parameters of DANN. Crucially, while the update of the regular parameters follows as usual the opposite direction of the gradient, for the adversarial parameters the step must follow the gradient's direction (since we maximize with respect to them, instead of minimizing).

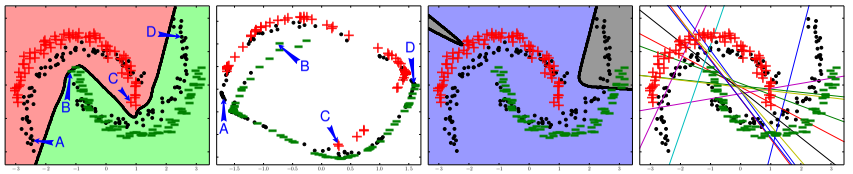
5.1.1 Experiments on a Toy Problem

As a first experiment, we study the behavior of the proposed algorithm on a variant of the *inter-twinning moons* 2D problem, where the target distribution is a rotation of the source

4. `http://sites.skoltech.ru/compvision/projects/grl/`



(a) Standard NN. For the "domain classification", we use a *non adversarial* domain regressor on the hidden neurons learned by the Standard NN. (This is equivalent to run Algorithm 1, without Lines 22 and 31)



(b) DANN (Algorithm 1)

Figure 2: The *inter-twinning moons* toy problem. Examples from the source sample are represented as a "+"(label 1) and a "−"(label 0), while examples from the unlabeled target sample are represented as black dots. See text for the figure discussion.

one. As the source sample S, we generate a lower moon and an upper moon labeled 0 and 1 respectively, each of which containing 150 examples. The target sample T is obtained by the following procedure: (1) we generate a sample S' the same way S has been generated; (2) we rotate each example by 35°; and (3) we remove all the labels. Thus, T contains 300 unlabeled examples. We have represented those examples in Figure 2.

We study the adaptation capability of DANN by comparing it to the standard neural network (NN). In these toy experiments, both algorithms share the same network architecture, with a hidden layer size of 15 neurons. We train the NN using the same procedure as the DANN. That is, we keep updating the domain regressor component using target sample T (with a hyper-parameter $\lambda = 6$; the same value is used for DANN), but we disable the *adversarial* back-propagation into the hidden layer. To do so, we execute Algorithm 1 by omitting the lines numbered 22 and 31. This allows recovering the NN learning algorithm—based on the source risk minimization of Equation (5) without any regularizer—and simultaneously train the domain regressor of Equation (7) to discriminate between source and target domains. With this toy experience, we will first illustrate how DANN adapts its decision boundary when compared to NN. Moreover, we will also illustrate how the representation given by the hidden layer is less adapted to the source domain task with DANN than with NN (this is why we need a domain regressor in the NN experiment). We recall that this is the founding idea behind our proposed algorithm. The analysis of the experiment appears in Figure 2, where upper graphs relate to standard NN, and lower graphs relate to DANN. By looking at the lower and upper graphs pairwise, we compare NN and DANN from four different perspectives, described in details below.

The column "Label Classification" of Figure 2 shows the decision boundaries of DANN and NN on the problem of predicting the labels of both source and the target examples. As expected, NN accurately classifies the two classes of the source sample S, but is *not fully adapted* to the target sample T. On the contrary, the decision boundary of DANN perfectly classifies examples from both source and target samples. In the studied task, DANN clearly adapts to the target distribution.

The column "Representation PCA" studies how the domain adaptation regularizer affects the representation $G_f(\cdot)$ provided by the network hidden layer. The graphs are obtained by applying a Principal component analysis (PCA) on the set of all representation of source and target data points, *i.e.*, $S(G_f) \cup T(G_f)$. Thus, given the trained network (NN or DANN), every point from S and T is mapped into a 15-dimensional feature space through the hidden layer, and projected back into a two-dimensional plane by the PCA transformation. In the DANN-PCA representation, we observe that target points are homogeneously spread out among source points; In the NN-PCA representation, a number of target points belong to clusters containing no source points. Hence, labeling the target points seems an easier task given the DANN-PCA representation.
To push the analysis further, the PCA graphs tag four crucial data points by the letters A, B, C and D, that correspond to the moon extremities in the original space (note that the original point locations are tagged in the first column graphs). We observe that points A and B are very close to each other in the NN-PCA representation, while they clearly belong to different classes. The same happens to points C and D. Conversely, these four points are at the opposite four corners in the DANN-PCA representation. Note also that the target point A (resp. D)—that is difficult to classify in the original space—is located in the "+"cluster (resp. "−"cluster) in the DANN-PCA representation. Therefore, the representation promoted by DANN is better suited to the adaptation problem.

The column "Domain Classification" shows the decision boundary on the domain classification problem, which is given by the domain regressor G_d of Equation (7). More precisely, an example $\mathbf{x}$ is classified as a source example when $G_d(G_f(\mathbf{x})) \geq 0.5$, and is classified as a domain example otherwise. Remember that, during the learning process of DANN, the G_d regressor struggles to discriminate between source and target domains, while the hidden representation $G_f(\cdot)$ is *adversarially* updated to prevent it to succeed. As explained above, we trained a domain regressor during the learning process of NN, but without allowing it to influence the learned representation $G_f(\cdot)$.
On one hand, the DANN domain regressor clearly fails to generalize source and target distribution topologies. On the other hand, the NN domain regressor shows a better (although imperfect) generalization capability. Inter alia, it seems to roughly capture the rotation angle of the target distribution. This again corroborates that the DANN representation does not allow discriminating between domains.

The column "Hidden Neurons" shows the configuration of hidden layer neurons (by Equation 4, we have that each neuron is indeed a linear regressor). In other words, each of the fifteen plot line corresponds to the coordinates $\mathbf{x} \in \mathbb{R}^2$ for which the i-th component of $G_f(\mathbf{x})$ equals $\frac{1}{2}$, for $i \in \{1, \ldots, 15\}$. We observe that the standard NN neurons are grouped in three clusters, each one allowing to generate a straight line of the *zigzag* decision boundary for the label classification problem. However, most of these neurons are also able

to (roughly) capture the rotation angle of the domain classification problem. Hence, we observe that the adaptation regularizer of DANN prevents these kinds of neurons to be produced. It is indeed striking to see that the two predominant patterns in the NN neurons (*i.e.*, the two parallel lines crossing the plane from lower left to upper right) are vanishing in the DANN neurons.

5.1.2 Unsupervised Hyper-Parameter Selection

To perform unsupervised domain adaption, one should provide ways to set hyper-parameters (such as the domain regularization parameter λ, the learning rate, the network architecture for our method) in an unsupervised way, *i.e.*, without referring to labeled data in the target domain. In the following experiments of Sections 5.1.3 and 5.1.4, we select the hyper-parameters of each algorithm by using a variant of *reverse cross-validation* approach proposed by Zhong et al. (2010), that we call *reverse validation*.

To evaluate the *reverse validation risk* associated to a tuple of hyper-parameters, we proceed as follows. Given the labeled source sample S and the unlabeled target sample T, we split each set into training sets (S' and T' respectively, containing 90% of the original examples) and the validation sets (S_V and T_V respectively). We use the labeled set S' and the unlabeled target set T' to learn a classifier η. Then, using the same algorithm, we learn a *reverse* classifier η_r using the *self-labeled* set $\{(\mathbf{x}, \eta(\mathbf{x}))\}_{\mathbf{x} \in T'}$ and the unlabeled part of S' as target sample. Finally, the reverse classifier η_r is evaluated on the validation set S_V of source sample. We then say that the classifier η has a *reverse validation risk* of $R_{S_V}(\eta_r)$. The process is repeated with multiple values of hyper-parameters and the selected parameters are those corresponding to the classifier with the lowest reverse validation risk.

Note that when we train neural network architectures, the validation set S_V is also used as an early stopping criterion during the learning of η, and *self-labeled* validation set $\{(\mathbf{x}, \eta(\mathbf{x}))\}_{\mathbf{x} \in T_V}$ is used as an early stopping criterion during the learning of η_r. We also observed better accuracies when we initialized the learning of the reverse classifier η_r with the configuration learned by the network η.

5.1.3 Experiments on Sentiment Analysis Data Sets

We now compare the performance of our proposed DANN algorithm to a standard neural network with one hidden layer (NN) described by Equation (5), and a Support Vector Machine (SVM) with a linear kernel. We compare the algorithms on the *Amazon reviews* data set, as pre-processed by Chen et al. (2012). This data set includes four domains, each one composed of reviews of a specific kind of product (books, dvd disks, electronics, and kitchen appliances). Reviews are encoded in 5 000 dimensional feature vectors of unigrams and bigrams, and labels are binary: "0" if the product is ranked up to 3 stars, and "1" if the product is ranked 4 or 5 stars.

We perform twelve domain adaptation tasks. All learning algorithms are given 2 000 labeled source examples and 2 000 unlabeled target examples. Then, we evaluate them on separate target test sets (between 3 000 and 6 000 examples). Note that NN and SVM do not use the unlabeled target sample for learning.

Here are more details about the procedure used for each learning algorithms leading to the empirical results of Table 1.

		Original data			mSDA representation		
Source	Target	DANN	NN	SVM	DANN	NN	SVM

(b) Pairwise Poisson binomial test

Table 1: Classification accuracy on the Amazon reviews data set, and Pairwise Poisson binomial test.

- For the DANN algorithm, the adaptation parameter λ is chosen among 9 values between 10^{-2} and 1 on a logarithmic scale. The hidden layer size l is either 50 or 100. Finally, the learning rate μ is fixed at 10^{-3}.
- For the NN algorithm, we use exactly the same hyper-parameters grid and training procedure as DANN above, except that we do not need an adaptation parameter. Note that one can train NN by using the DANN implementation (Algorithm 1) with $\lambda = 0$.
- For the SVM algorithm, the hyper-parameter C is chosen among 10 values between 10^{-5} and 1 on a logarithmic scale. This range of values is the same as used by Chen et al. (2012) in their experiments.

As presented at Section 5.1.2, we used *reverse cross validation* selecting the hyper-parameters for all three learning algorithms, with *early stopping* as the stopping criterion for DANN and NN.

The "Original data" part of Table 1a shows the target test accuracy of all algorithms, and Table 1b reports the probability that one algorithm is significantly better than the others according to the Poisson binomial test (Lacoste et al., 2012). We note that DANN has a significantly better performance than NN and SVM, with respective probabilities **0.87** and **0.83**. As the only difference between DANN and NN is the domain adaptation regularizer, we conclude that our approach successfully helps to find a representation suitable for the target domain.

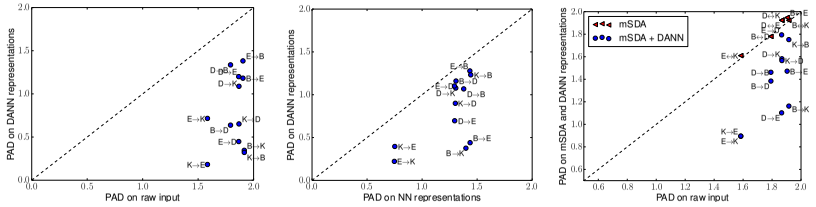
5.1.4 Combining DANN with Denoising Autoencoders

We now investigate on whether the DANN algorithm can improve on the representation learned by the state-of-the-art *Marginalized Stacked Denoising Autoencoders* (mSDA) proposed by Chen et al. (2012). In brief, mSDA is an unsupervised algorithm that learns a new robust feature representation of the training samples. It takes the unlabeled parts of both source and target samples to learn a feature map from input space X to a new representation space. As a *denoising autoencoders* algorithm, it finds a feature representation from which one can (approximately) reconstruct the original features of an example from its noisy counterpart. Chen et al. (2012) showed that using mSDA with a linear SVM classifier reaches state-of-the-art performance on the *Amazon reviews* data sets. As an alternative to the SVM, we propose to apply our Shallow DANN algorithm on the same representations generated by mSDA (using representations of both source and target samples). Note that, even if mSDA and DANN are two representation learning approaches, they optimize different objectives, which can be complementary.

We perform this experiment on the same *Amazon reviews* data set described in the previous subsection. For each source-target domain pair, we generate the mSDA representations using a corruption probability of 50% and a number of layers of 5. We then execute the three learning algorithms (DANN, NN, and SVM) on these representations. More precisely, following the experimental procedure of Chen et al. (2012), we use the concatenation of the output of the 5 layers and the original input as the new representation. Thus, each example is now encoded in a vector of 30 000 dimensions. Note that we use the same grid search as in the previous Subsection 5.1.3, but use a learning rate μ of 10^{-4} for both DANN and the NN. The results of "mSDA representation" columns in Table 1a confirm that combining mSDA and DANN is a sound approach. Indeed, the Poisson binomial test shows that DANN has a better performance than the NN and the SVM, with probabilities **0.92** and **0.88** respectively, as reported in Table 1b. We note however that the standard NN and the SVM find the best solution on respectively the second and the fourth tasks. This suggests that DANN and mSDA adaptation strategies are not fully complementary.

5.1.5 Proxy Distance

The theoretical foundation of the DANN algorithm is the domain adaptation theory of Ben-David et al. (2006, 2010). We claimed that DANN finds a representation in which the source and the target example are hardly distinguishable. Our toy experiment of Section 5.1.1 already points out some evidence for that and here we provide analysis on real data. To do so, we compare the Proxy $\mathcal{A}$-distance (PAD) on various representations of the *Amazon Reviews* data set; these representations are obtained by running either NN, DANN, mSDA,



(a) DANN on *Original data*. (b) DANN & NN with 100 hidden neurons. (c) DANN on *mSDA representations*.

Figure 3: Proxy $\mathcal{A}$-distances (PAD). Note that the PAD values of mSDA representations are symmetric when swapping source and target samples.

or mSDA and DANN combined. Recall that PAD, as described in Section 3.2, is a metric estimating the similarity of the source and the target representations. More precisely, to obtain a PAD value, we use the following procedure: (1) we construct the data set U of Equation (2) using both source and target representations of the training samples; (2) we randomly split U in two subsets of equal size; (3) we train linear SVMs on the first subset of U using a large range of C values; (4) we compute the error of all obtained classifiers on the second subset of U; and (5) we use the lowest error to compute the PAD value of Equation (3).

Firstly, Figure 3a compares the PAD of DANN representations obtained in the experiments of Section 5.1.3 (using the hyper-parameters values leading to the results of Table 1) to the PAD computed on raw data. As expected, the PAD values are driven down by the DANN representations.

Secondly, Figure 3b compares the PAD of DANN representations to the PAD of standard NN representations. As the PAD is influenced by the hidden layer size (the discriminating power tends to increase with the representation length), we fix here the size to 100 neurons for both algorithms. We also fix the adaptation parameter of DANN to $\lambda \simeq 0.31$; it was the value that has been selected most of the time during our preceding experiments on the *Amazon Reviews* data set. Again, DANN is clearly leading to the lowest PAD values.

Lastly, Figure 3c presents two sets of results related to Section 5.1.4 experiments. On one hand, we reproduce the results of Chen et al. (2012), which noticed that the mSDA representations have greater PAD values than original (raw) data. Although the mSDA approach clearly helps to adapt to the target task, it seems to contradict the theory of Ben-David et al.. On the other hand, we observe that, when running DANN on top of mSDA (using the hyper-parameters values leading to the results of Table 1), the obtained representations have much lower PAD values. These observations might explain the improvements provided by DANN when combined with the mSDA procedure.

5.2 Experiments with Deep Networks on Image Classification

We now perform extensive evaluation of a deep version of DANN (see Subsection 4.2) on a number of popular image data sets and their modifications. These include large-scale data sets of small images popular with deep learning methods, and the Office data sets (Saenko et al., 2010), which are a *de facto* standard for domain adaptation in computer vision, but have much fewer images.

5.2.1 Baselines

The following baselines are evaluated in the experiments of this subsection. The *source-only* model is trained without consideration for target-domain data (no domain classifier branch included into the network). The *train-on-target* model is trained on the target domain with class labels revealed. This model serves as an upper bound on DA methods, assuming that target data are abundant and the shift between the domains is considerable.

In addition, we compare our approach against the recently proposed unsupervised DA method based on *subspace alignment (SA)* (Fernando et al., 2013), which is simple to setup and test on new data sets, but has also been shown to perform very well in experimental comparisons with other "shallow" DA methods. To boost the performance of this baseline, we pick its most important free parameter (the number of principal components) from the range $\{2, \ldots, 60\}$, so that the test performance on the target domain is maximized. To apply SA in our setting, we train a source-only model and then consider the activations of the last hidden layer in the label predictor (before the final linear classifier) as descriptors/features, and learn the mapping between the source and the target domains (Fernando et al., 2013).

Since the SA baseline requires training a new classifier after adapting the features, and in order to put all the compared settings on an equal footing, we retrain the last layer of the label predictor using a standard linear SVM (Fan et al., 2008) for all four considered methods (including ours; the performance on the target domain remains approximately the same after the retraining).

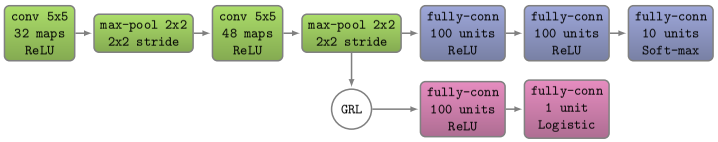
For the Office data set (Saenko et al., 2010), we directly compare the performance of our full network (feature extractor and label predictor) against recent DA approaches using previously published results.

5.2.2 CNN architectures and Training Procedure

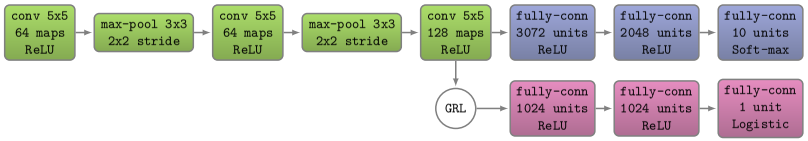
In general, we compose feature extractor from two or three convolutional layers, picking their exact configurations from previous works. More precisely, four different architectures were used in our experiments. The first three are shown in Figure 4. For the Office domains, we use pre-trained `AlexNet` from the `Caffe`-package (Jia et al., 2014). The adaptation architecture is identical to Tzeng et al. (2014).[5]

For the domain adaption component, we use three ($x \to 1024 \to 1024 \to 2$) fully connected layers, except for MNIST where we used a simpler ($x \to 100 \to 2$) architecture to speed up the experiments. Admittedly these choices for domain classifier are arbitrary, and better adaptation performance might be attained if this part of the architecture is tuned.

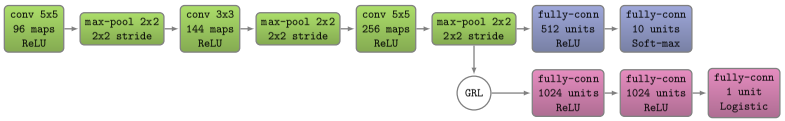
5. A 2-layer domain classifier ($x \to 1024 \to 1024 \to 2$) is attached to the 256-dimensional bottleneck of `fc7`.



(a) MNIST architecture; inspired by the classical LeNet-5 (LeCun et al., 1998).



(b) SVHN architecture; adopted from Srivastava et al. (2014).



(c) GTSRB architecture; we used the single-CNN baseline from Cireşan et al. (2012) as our starting point.

Figure 4: CNN architectures used in the experiments. Boxes correspond to transformations applied to the data. Color-coding is the same as in Figure 1.

For the loss functions, we set $\mathcal{L}_y$ and $\mathcal{L}_d$ to be the logistic regression loss and the binomial cross-entropy respectively. Following Srivastava et al. (2014) we also use dropout and ℓ_2-norm restriction when we train the SVHN architecture.

The other hyper-parameters are not selected through a grid search as in the small scale experiments of Section 5.1, which would be computationally costly. Instead, the learning rate is adjusted during the stochastic gradient descent using the following formula:

$$\mu_p = \frac{\mu_0}{(1+\alpha\cdot p)^\beta}\,,$$

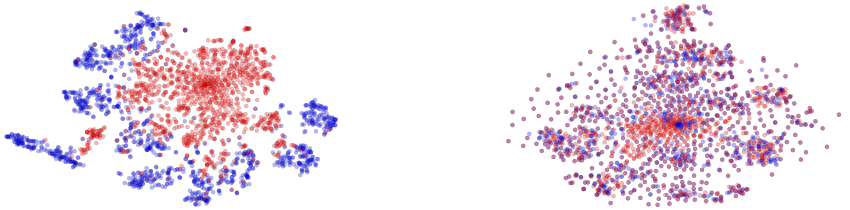
where p is the training progress linearly changing from 0 to 1, $\mu_0 = 0.01$, $\alpha = 10$ and $\beta = 0.75$ (the schedule was optimized to promote convergence and low error on the *source* domain). A momentum term of 0.9 is also used.

The domain adaptation parameter λ is initiated at 0 and is gradually changed to 1 using the following schedule:

$$\lambda_p = \frac{2}{1+\exp(-\gamma\cdot p)} - 1\,,$$

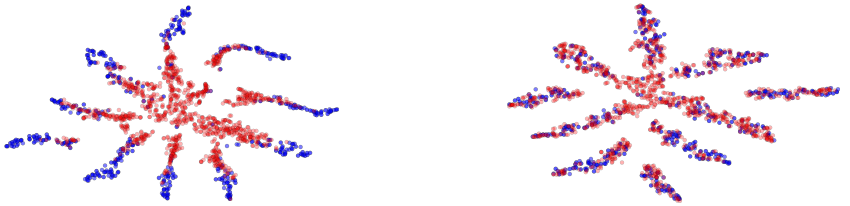
where γ was set to 10 in all experiments (the schedule was not optimized/tweaked). This strategy allows the domain classifier to be less sensitive to noisy signal at the early stages of the training procedure. Note however that these λ_p were used only for updating the *feature*

MNIST → MNIST-M: top feature extractor layer



(a) Non-adapted (b) Adapted

Syn Numbers → SVHN: last hidden layer of the label predictor



(a) Non-adapted (b) Adapted

Figure 5: The effect of adaptation on the distribution of the extracted features (best viewed in color). The figure shows t-SNE (van der Maaten, 2013) visualizations of the CNN's activations **(a)** in case when no adaptation was performed and **(b)** in case when our adaptation procedure was incorporated into training. *Blue* points correspond to the source domain examples, while *red* ones correspond to the target domain. In all cases, the adaptation in our method makes the two distributions of features much closer.

extractor component G_f. For updating the *domain classification* component, we used a fixed $\lambda = 1$, to ensure that the latter trains as fast as the *label predictor* G_y.[6]

Finally, note that the model is trained on 128-sized batches (images are preprocessed by the mean subtraction). A half of each batch is populated by the samples from the source domain (with known labels), the rest constitutes the target domain (with labels not revealed to the algorithms except for the train-on-target baseline).

5.2.3 Visualizations

We use t-SNE (van der Maaten, 2013) projection to visualize feature distributions at different points of the network, while color-coding the domains (Figure 5). As we already observed with the shallow version of DANN (see Figure 2), there is a strong correspondence

6. Equivalently, one can use the same λ_p for both feature extractor and domain classification components, but use a learning rate of μ/λ_p for the latter.

between the success of the adaptation in terms of the classification accuracy for the target domain, and the overlap between the domain distributions in such visualizations.

5.2.4 Results On Image Data Sets

We now discuss the experimental settings and the results. In each case, we train on the source data set and test on a different target domain data set, with considerable shifts between domains (see Figure 6). The results are summarized in Table 2 and Table 3.

MNIST → MNIST-M. Our first experiment deals with the MNIST data set (LeCun et al., 1998) (source). In order to obtain the target domain (MNIST-M) we blend digits from the original set over patches randomly extracted from color photos from BSDS500 (Arbelaez et al., 2011). This operation is formally defined for two images I^1, I^2 as $I^{out}_{ijk} = |I^1_{ijk} - I^2_{ijk}|$, where i, j are the coordinates of a pixel and k is a channel index. In other words, an output sample is produced by taking a patch from a photo and inverting its pixels at positions corresponding to the pixels of a digit. For a human the classification task becomes only slightly harder compared to the original data set (the digits are still clearly distinguishable) whereas for a CNN trained on MNIST this domain is quite distinct, as the background and the strokes are no longer constant. Consequently, the source-only model performs poorly. Our approach succeeded at aligning feature distributions (Figure 5), which led to successful adaptation results (considering that the adaptation is unsupervised). At the same time, the improvement over source-only model achieved by subspace alignment (SA) (Fernando et al., 2013) is quite modest, thus highlighting the difficulty of the adaptation task.

Synthetic numbers → SVHN. To address a common scenario of training on synthetic data and testing on real data, we use Street-View House Number data set SVHN (Netzer et al., 2011) as the target domain and synthetic digits as the source. The latter (Syn Numbers) consists of ≈ 500,000 images generated by ourselves from Windows™ fonts by varying the text (that includes different one-, two-, and three-digit numbers), positioning, orientation, background and stroke colors, and the amount of blur. The degrees of variation were chosen manually to simulate SVHN, however the two data sets are still rather distinct, the biggest difference being the structured clutter in the background of SVHN images.

The proposed backpropagation-based technique works well covering almost 80% of the gap between training with source data only and training on target domain data with known target labels. In contrast, SA (Fernando et al., 2013) results in a slight classification accuracy drop (probably due to the information loss during the dimensionality reduction), indicating that the adaptation task is even more challenging than in the case of the MNIST experiment.

MNIST ↔ SVHN. In this experiment, we further increase the gap between distributions, and test on MNIST and SVHN, which are significantly different in appearance. Training on SVHN even without adaptation is challenging — classification error stays high during the first 150 epochs. In order to avoid ending up in a poor local minimum we, therefore, do not use learning rate annealing here. Obviously, the two directions (MNIST → SVHN and SVHN → MNIST) are not equally difficult. As SVHN is more diverse, a model trained on SVHN is expected to be more generic and to perform reasonably on the MNIST data set. This, indeed, turns out to be the case and is supported by the appearance of the

Figure 6: Examples of domain pairs used in the experiments. See Section 5.2.4 for details.

Method / Source / Target	MNIST / MNIST-M	Syn Numbers / SVHN	SVHN / MNIST	Syn Signs / GTSRB
Source only	.5225	.8674	.5490	.7900
SA (Fernando et al., 2013)	.5690 (4.1%)	.8644 (−5.5%)	.5932 (9.9%)	.8165 (12.7%)
DANN	**.7666** (52.9%)	**.9109** (79.7%)	**.7385** (42.6%)	**.8865** (46.4%)
Train on target	.9596	.9220	.9942	.9980

Table 2: Classification accuracies for digit image classifications for different source and target domains. MNIST-M corresponds to difference-blended digits over non-uniform background. The first row corresponds to the lower performance bound (*i.e.*, if no adaptation is performed). The last row corresponds to training on the target domain data with known class labels (upper bound on the DA performance). For each of the two DA methods (ours and Fernando et al., 2013) we show how much of the gap between the lower and the upper bounds was covered (in brackets). For all five cases, our approach outperforms Fernando et al. (2013) considerably, and covers a big portion of the gap.

Method / Source / Target	Amazon / Webcam	DSLR / Webcam	Webcam / DSLR
GFK(PLS, PCA) (Gong et al., 2012)	.197	.497	.6631
SA* (Fernando et al., 2013)	.450	.648	.699
DLID (Chopra et al., 2013)	.519	.782	.899
DDC (Tzeng et al., 2014)	.618	.950	.985
DAN (Long and Wang, 2015)	.685	.960	.990
Source only	.642	.961	.978
DANN	**.730**	**.964**	**.992**

Table 3: Accuracy evaluation of different DA approaches on the standard Office (Saenko et al., 2010) data set. All methods (except SA) are evaluated in the "fully-transductive" protocol (some results are reproduced from Long and Wang, 2015). Our method (last row) outperforms competitors setting the new state-of-the-art.

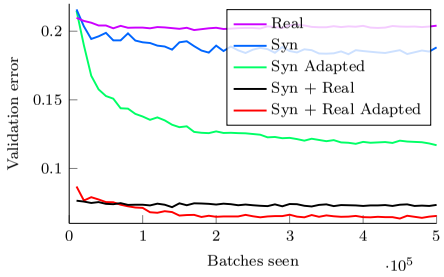


Figure 7: Results for the traffic signs classification in the semi-supervised setting. *Syn* and *Real* denote available labeled data (100,000 synthetic and 430 real images respectively); *Adapted* means that $\approx$ 31,000 unlabeled target domain images were used for adaptation. The best performance is achieved by employing both the labeled samples and the large unlabeled corpus in the target domain.

feature distributions. We observe a quite strong separation between the domains when we feed them into the CNN trained solely on MNIST, whereas for the SVHN-trained network the features are much more intermixed. This difference probably explains why our method succeeded in improving the performance by adaptation in the SVHN $\rightarrow$ MNIST scenario (see Table 2) but not in the opposite direction (SA is not able to perform adaptation in this case either). Unsupervised adaptation from MNIST to SVHN gives a failure example for our approach: it doesn't manage to improve upon the performance of the non-adapted model which achieves $\approx$ 0.25 accuracy (we are unaware of any unsupervised DA methods capable of performing such adaptation).

Synthetic Signs $\rightarrow$ *GTSRB.* Overall, this setting is similar to the Syn Numbers $\rightarrow$ SVHN experiment, except the distribution of the features is more complex due to the significantly larger number of classes (43 instead of 10). For the source domain we obtained 100,000 synthetic images (which we call Syn Signs) simulating various imaging conditions. In the target domain, we use 31,367 random training samples for unsupervised adaptation and the rest for evaluation. Once again, our method achieves a sensible increase in performance proving its suitability for the synthetic-to-real data adaptation.

As an additional experiment, we also evaluate the proposed algorithm for semi-supervised domain adaptation, *i.e.*, when one is additionally provided with a small amount of labeled target data. Here, we reveal 430 labeled examples (10 samples per class) and add them to the training set for the label predictor. Figure 7 shows the change of the validation error throughout the training. While the graph clearly suggests that our method can be beneficial in the semi-supervised setting, thorough verification of semi-supervised setting is left for future work.

Office data set. We finally evaluate our method on Office data set, which is a collection of three distinct domains: Amazon, DSLR, and Webcam. Unlike previously discussed data

sets, Office is rather small-scale with only 2817 labeled images spread across 31 different categories in the largest domain. The amount of available data is crucial for a successful training of a deep model, hence we opted for the fine-tuning of the CNN pre-trained on the ImageNet (`AlexNet` from the `Caffe` package, see Jia et al., 2014) as it is done in some recent DA works (Donahue et al., 2014; Tzeng et al., 2014; Hoffman et al., 2013; Long and Wang, 2015). We make our approach more comparable with Tzeng et al. (2014) by using exactly the same network architecture replacing domain mean-based regularization with the domain classifier.

Following previous works, we assess the performance of our method across three transfer tasks most commonly used for evaluation. Our training protocol is adopted from Gong et al. (2013); Chopra et al. (2013); Long and Wang (2015) as during adaptation we use all available labeled source examples and unlabeled target examples (the premise of our method is the abundance of unlabeled data in the target domain). Also, all source domain data are used for training. Under this "fully-transductive" setting, our method is able to improve previously-reported state-of-the-art accuracy for unsupervised adaptation very considerably (Table 3), especially in the most challenging Amazon $\rightarrow$ Webcam scenario (the two domains with the largest domain shift).

Interestingly, in all three experiments we observe a slight over-fitting (performance on the target domain degrades while accuracy on the source continues to improve) as training progresses, however, it doesn't ruin the validation accuracy. Moreover, switching off the domain classifier branch makes this effect far more apparent, from which we conclude that our technique serves as a regularizer.

5.3 Experiments with Deep Image Descriptors for Re-Identification

In this section we discuss the application of the described adaptation method to person re-identification *(re-id)* problem. The task of person re-identification is to associate people seen from different camera views. More formally, it can be defined as follows: given two sets of images from different cameras (*probe* and *gallery*) such that each person depicted in the probe set has an image in the gallery set, for each image of a person from the probe set find an image of the same person in the gallery set. Disjoint camera views, different illumination conditions, various poses and low quality of data make this problem difficult even for humans (*e.g.*, Liu et al., 2013, reports human performance at Rank1=71.08%).

Unlike classification problems that are discussed above, re-identification problem implies that each image is mapped to a vector descriptor. The distance between descriptors is then used to match images from the probe set and the gallery set. To evaluate results of re-id methods the *Cumulative Match Characteristic* (CMC) curve is commonly used. It is a plot of the identification rate (recall) at rank-k, that is the probability of the matching gallery image to be within the closest k images (in terms of descriptor distance) to the probe image.

Most existing works train descriptor mappings and evaluate them within the same data set containing images from a certain camera network with similar imaging conditions. Several papers, however, observed that the performance of the resulting re-identification systems drops very considerably when descriptors trained on one data set and tested on another. It is therefore natural to handle such cross-domain evaluation as a domain-adaptation problem, where each camera network (data set) constitutes a domain.

Figure 8: Matching and non-matching pairs of probe-gallery images from different person re-identification data sets. The three data sets are treated as different domains in our experiments.

Recently, several papers with significantly improved re-identification performance (Zhang and Saligrama, 2014; Zhao et al., 2014; Paisitkriangkrai et al., 2015) have been presented, with Ma et al. (2015) reporting good results in cross-data-set evaluation scenario. At the moment, deep learning methods (Yi et al., 2014) do not achieve state-of-the-art results probably because of the limited size of the training sets. Domain adaptation thus represents a viable direction for improving deep re-identification descriptors.

5.3.1 Data Sets and Protocols

Following Ma et al. (2015), we use PRID (Hirzer et al., 2011), VIPeR (Gray et al., 2007), CUHK (Li and Wang, 2013) as target data sets for our experiments. The *PRID* data set exists in two versions, and as in Ma et al. (2015) we use a single-shot variant. It contains images of 385 persons viewed from camera A and images of 749 persons viewed from camera B, 200 persons appear in both cameras. The *VIPeR* data set also contains images taken with two cameras, and in total 632 persons are captured, for every person there is one image for each of the two camera views. The *CUHK* data set consists of images from five pairs of cameras, two images for each person from each of the two cameras. We refer to the subset of this data set that includes the first pair of cameras only as *CUHK/p1* (as most papers use this subset). See Figure 8 for samples of these data sets.

We perform extensive experiments for various pairs of data sets, where one data set serves as a source domain, *i.e.*, it is used to train a descriptor mapping in a supervised way with known correspondences between probe and gallery images. The second data set is used as a target domain, so that images from that data set are used without probe-gallery correspondence.

In more detail, CUHK/p1 is used for experiments when CUHK serves as a target domain and two settings ("whole CUHK" and CUHK/p1) are used for experiments when CUHK serves as a source domain. Given PRID as a target data set, we randomly choose 100 persons appearing in both camera views as training set. The images of the other 100 persons from camera A are used as probe, all images from camera B excluding those used in training (649 in total) are used as gallery at test time. For VIPeR, we use random 316 persons for training and all others for testing. For CUHK, 971 persons are split into 485 for training and 486 for testing. Unlike Ma et al. (2015), we use all images in the first pair of cameras of CUHK instead of choosing one image of a person from each camera view. We also performed two

experiments with all images of the whole CUHK data set as source domain and VIPeR and PRID data sets as target domains as in the original paper (Yi et al., 2014).

Following Yi et al. (2014), we augmented our data with mirror images, and during test time we calculate similarity score between two images as the mean of the four scores corresponding to different flips of the two compared images. In case of CUHK, where there are 4 images (including mirror images) for each of the two camera views for each person, all 16 combinations' scores are averaged.

5.3.2 CNN architectures and Training Procedure

In our experiments, we use siamese architecture described in Yi et al. (2014) (*Deep Metric Learning* or *DML*) for learning deep image descriptors on the source data set. This architecture incorporates two convolution layers (with 7×7 and 5×5 filter banks), followed by ReLU and max pooling, and one fully-connected layer, which gives 500-dimensional descriptors as an output. There are three parallel flows within the CNN for processing three part of an image: the upper, the middle, and the lower one. The first convolution layer shares parameters between three parts, and the outputs of the second convolution layers are concatenated. During training, we follow Yi et al. (2014) and calculate pairwise cosine similarities between 500-dimensional features within each batch and backpropagate the loss for all pairs within batch.

To perform domain-adversarial training, we construct a DANN architecture. The feature extractor includes the two convolutional layers (followed by max-pooling and ReLU) discussed above. The label predictor in this case is replaced with *descriptor predictor* that includes one fully-connected layer. The domain classifier includes two fully-connected layers with 500 units in the intermediate representation ($x \to 500 \to 1$).

For the verification loss function in the descriptor predictor we used Binomial Deviance loss, defined in Yi et al. (2014) with similar parameters: $\alpha = 2$, $\beta = 0.5$, $c = 2$ (the asymmetric cost parameter for negative pairs). The domain classifier is trained with logistic loss as in subsection 5.2.2.

We used learning rate fixed to 0.001 and momentum of 0.9. The schedule of adaptation similar to the one described in subsection 5.2.2 was used. We also inserted dropout layer with rate 0.5 after the concatenation of outputs of the second max-pooling layer. 128-sized batches were used for source data and 128-sized batches for target data.

5.3.3 Results on Re-identification data sets

Figure 9 shows results in the form of CMC-curves for eight pairs of data sets. Depending on the hardness of the annotation problem we trained either for 50,000 iterations (CUHK/p1 $\to$ VIPeR, VIPeR $\to$ CUHK/p1, PRID $\to$ VIPeR) or for 20,000 iterations (the other five pairs).

After the sufficient number of iterations, domain-adversarial training consistently improves the performance of re-identification. For the pairs that involve PRID data set, which is more dissimilar to the other two data sets, the improvement is considerable. Overall, this demonstrates the applicability of the domain-adversarial learning beyond classification problems.

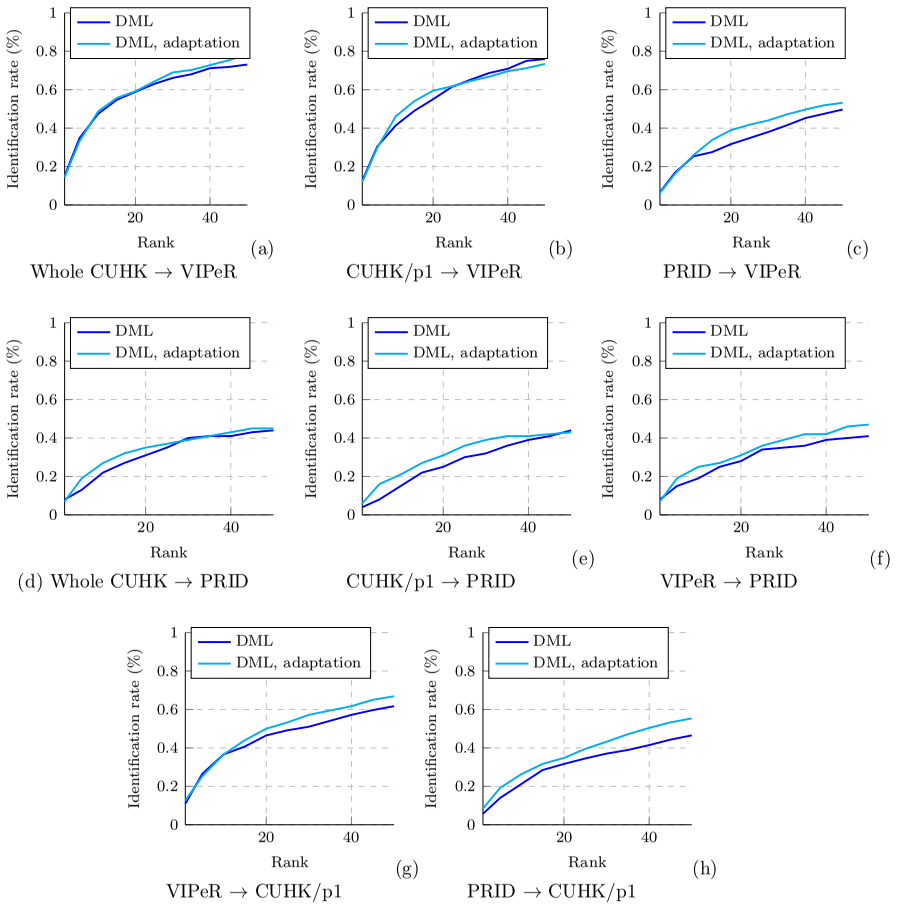

Figure 9: Results on VIPeR, PRID and CUHK/p1 with and without domain-adversarial learning. Across the eight domain pairs domain-adversarial learning improves re-identification accuracy. For some domain pairs the improvement is considerable.

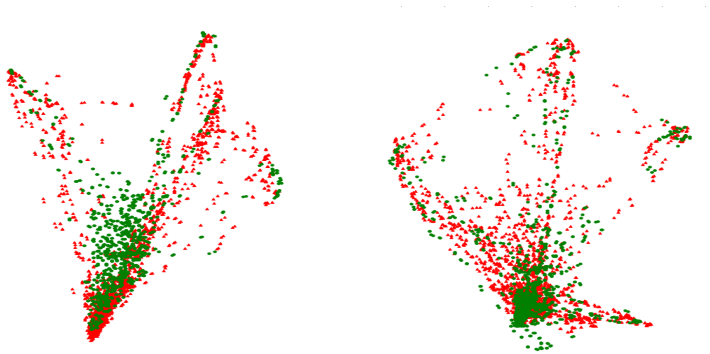

(a) DML (b) DML, adaptation

Figure 10: The effect of adaptation shown by t-SNE visualizations of source and target domains descriptors in a VIPeR → CUHK/p1 experiment pair. VIPeR is depicted with *green* and CUHK/p1 - with *red*. As in the image classification case, domain-adversarial learning ensures a closer match between the source and the target distributions.

Figure 10 further demonstrates the effect of adaptation on the distributions of the learned descriptors in the source and in target sets in VIPeR → CUHK/p1 experiments, where domain adversarial learning once again achieves better intermixing of the two domains.

6. Conclusion

The paper proposes a new approach to domain adaptation of feed-forward neural networks, which allows large-scale training based on large amount of annotated data in the source domain and large amount of unannotated data in the target domain. Similarly to many previous shallow and deep DA techniques, the adaptation is achieved through aligning the distributions of features across the two domains. However, unlike previous approaches, the alignment is accomplished through standard backpropagation training.

The approach is motivated and supported by the domain adaptation theory of Ben-David et al. (2006, 2010). The main idea behind DANN is to enjoin the network hidden layer to learn a representation which is predictive of the source example labels, but uninformative about the domain of the input (source or target). We implement this new approach within both shallow and deep feed-forward architectures. The latter allows simple implementation within virtually any deep learning package through the introduction of a simple gradient reversal layer. We have shown that our approach is flexible and achieves state-of-the-art

results on a variety of benchmark in domain adaptation, namely for sentiment analysis and image classification tasks.

A convenient aspect of our approach is that the domain adaptation component can be added to almost any neural network architecture that is trainable with backpropagation. Towards this end, We have demonstrated experimentally that the approach is not confined to classification tasks but can be used in other feed-forward architectures, *e.g.*, for descriptor learning for person re-identification.

Acknowledgments

This work has been supported by National Science and Engineering Research Council (NSERC) Discovery grants 262067 and 0122405 as well as the Russian Ministry of Science and Education grant RFMEFI57914X0071. Computations were performed on the Colosse supercomputer grid at Université Laval, under the auspices of Calcul Québec and Compute Canada. The operations of Colosse are funded by the NSERC, the Canada Foundation for Innovation (CFI), NanoQuébec, and the Fonds de recherche du Québec – Nature et technologies (FRQNT). We also thank the Graphics & Media Lab, Faculty of Computational Mathematics and Cybernetics, Lomonosov Moscow State University for providing the synthetic road signs data set.

Probabilistic Low-Rank Matrix Completion from Quantized Measurements

Sonia A. Bhaskar SBHASKAR@STANFORD.EDU

Stanford University
Stanford, CA 94305, USA

Editor: Benjamin Recht

Abstract

We consider the recovery of a low rank real-valued matrix M given a subset of noisy discrete (or quantized) measurements. Such problems arise in several applications such as collaborative filtering, learning and content analytics, and sensor network localization. We consider constrained maximum likelihood estimation of M, under a constraint on the entry-wise infinity-norm of M and an exact rank constraint. We provide upper bounds on the Frobenius norm of matrix estimation error under this model. Previous theoretical investigations have focused on binary (1-bit) quantizers, and been based on convex relaxation of the rank. Compared to the existing binary results, our performance upper bound has faster convergence rate with matrix dimensions when the fraction of revealed observations is fixed. We also propose a globally convergent optimization algorithm based on low rank factorization of M and validate the method on synthetic and real data, with improved performance over previous methods.

Keywords: constrained maximum likelihood, quantization, matrix completion, collaborative filtering, convex optimization

1. Introduction

Recovery of a low-rank matrix from a subset of its entries is known as the matrix completion problem. This problem arises in many applications, including collaborative filtering (Rennie and Srebro, 2005; Koren et al., 2009), sensor network localization (Shang et al., 2004; Karbasi and Oh, 2013), learning and content analytics (Lan et al., 2014c,b), rank aggregation (Gleich and Lim, 2011), and manifold learning (Tenenbaum et al., 2000; Saul and Roweis, 2003). In many of these applications, the entries of the matrix are not real-valued, but discrete or quantized, e.g., binary-valued or multiple-valued. For example, in the Netflix problem where a subset of the users' ratings is observed, the ratings take integer values between 1 and 5. Classical matrix completion has treated these values as real-valued with good results, however, performance improvement can be achieved when the observations are treated as discrete (Davenport et al., 2014; Lan et al., 2014a).

We consider the problem of completing a matrix from a subset of its entries, but instead of assuming the observed entries are real-valued, we observe subset of quantized measurements. These observations are related to the underlying matrix M via a probabilistic model, as follows. Given $M \in \mathbb{R}^{m\times n}$, a subset of indices $\Omega \subseteq [m] \times [n]$, and a twice differentiable function $f_\ell : \mathbb{R} \to [0,1]$, with $\ell \in [K]$, $K \geq 2$, we observe

$$Y_{ij} = \ell \text{ with probability } f_\ell(M_{ij}) \text{ for } (i,j) \in \Omega, \tag{1}$$

where $\sum_{\ell=1}^{K} f_\ell(M_{ij}) = 1$. One important application of this model is the K-level quantization of noisy $M_{ij} + Z_{ij}$, where Y_{ij} is given by (Lan et al., 2014a)

$$Y_{ij} = \mathcal{Q}(M_{ij} + Z_{ij}), \quad (i,j) \in \Omega, \tag{2}$$

where the noise matrix Z has i.i.d. entries with cumulative distribution function (CDF) $\Phi(z)$, and the function $\mathcal{Q} : \mathbb{R} \to [K]$ corresponds to a scalar quantizer that maps a real number to one of the K ordered labels according to

$$\mathcal{Q}(x) = \ell \text{ if } \omega_{\ell-1} < x \leq \omega_\ell, \ \ell \in [K], \tag{3}$$

where $\omega_0 < \omega_1 < \cdots < \omega_K$ are the quantization bin boundaries. We will take $\omega_0 = -\infty$ and $\omega_K = \infty$. This quantization model was first considered in McCullagh (1980) for regression applications.

It then follows that

$$\begin{aligned} f_\ell(M_{ij}) &= P(Y_{ij} = \ell | M_{ij}) \\ &= \Phi(\omega_\ell - M_{ij}) - \Phi(\omega_{\ell-1} - M_{ij}). \end{aligned} \tag{4}$$

This observation model arises in many applications. In connectivity-based sensor network localization (Shang et al., 2004; Karbasi and Oh, 2013), M is a matrix of distances between sensors, and Y_{ij} takes binary values based on whether sensor i and sensor j are within a specified radius of each other. In learning and content analytics (Lan et al., 2014c,b), M governs the learners' responses to questions, and in recommender systems (Rennie and Srebro, 2005; Koren et al., 2009), M can represent the true underlying preferences of users. The matrix Y is then the matrix of ratings $\ell \in [K]$, which may represent quantization of some underlying real-valued user preference. Hence, the model (1)-(3) accounts for finer ordering of users' true preferences which then are quantized to discrete values dictated by the rating system. It is known that Netflix uses such real-valued predictions to order movie recommendations when generating recommendations for a user.

The probabilistic model described in (1)-(3) was first introduced by Davenport et al. (2014) for the case of binary ($K = 2$), or 1-bit, observations and has been studied in depth in the literature. This case corresponds to (2) with $\omega_1 = 0$ when the quantization model is considered. Under the assumption that M is low-rank, Davenport et al. (2014) and Lafond et al. (2014) proposed a convex program using maximum likelihood estimation and a nuclear (or trace) norm to promote a low-rank solution. Both works present theoretical recovery guarantees for the estimate, with the latter improving the convergence rate of the upper bound on the error. In Cai and Zhou (2013), a constrained maximum likelihood estimator was also considered but with the max-norm in place of the nuclear norm. Upper and lower bounds on the error norm of the solution to the resulting convex program were also given of the same order as Davenport et al. (2014). The binary model is also investigated in Soni et al. (2014) for sparse factor models using maximum likelihood estimation with an exact low-rank constraint; their results apply to non-sparse models also.

The theoretical recovery guarantee for the estimate given in Soni et al. (2014) is in the form of an upper bound on the expectation of the error norm, in contrast to Davenport et al. (2014), Lafond et al. (2014) and Cai and Zhou (2013), where the (high probability) upper bounds on the error norm itself are given. The bounds presented in this paper are also on the error norm, not on its expectation.

The extension to multi-level observations ($K \geq 2$) was introduced in Lan et al. (2014a), with a focus on the quantized observation model given in (2). A constrained maximum likelihood estimator, similar to that of Davenport et al. (2014), was proposed and validated through numerical experiments, but no theoretical results were given. An extension to multi-level observations was also proposed in Lafond et al. (2014). In contrast to the quantization observation model of Lan et al. (2014a), which involves just one M, the observation model of Lafond et al. (2014) related the matrix Y of K level observations to a vector of $K-1$ underlying matrices $(M^j)_{j=1}^{K-1}$. An upper bound on the error norm was given for a penalized maximum likelihood estimate of this vector of matrices, of the same order as established for the binary case. Recently Cao and Xie (2015) also investigated matrix completion for categorical data and extended the results of Davenport et al. (2014) to multi-level observations. The error bounds of Cao and Xie (2015) are of the same order as that of Davenport et al. (2014) for the binary case. The multi-level observation model of Cao and Xie (2015) does not include the quantized observation model given in (2).

Generalized performance bounds for a generic regularized convex program with arbitrary regularizer were given in Gunasekar et al. (2014) and Lafond (2015), which can be applied to the observation model (1) for $K \geq 2$ when the the link function f comes from the exponential family. Hence, this theoretical guarantee does not apply when considering a quantization observation model, given in (2) when $K > 2$. In this paper, we will allow for an arbitrary log-concave link function in our observation model and theoretical results, which will allow for applications such as noisy K-level quantization.

Another line of work in the context of collaborative filtering has been concerned with probabilistic matrix factorization (PMF) models (Salakhutdinov and Mnih, 2008; Gopalan et al., 2014), some of which can handle integer-valued observations. In an item ratings context, for an $m \times n$ ratings matrix M, one writes $M = UV^\top$ where the factors $U \in \mathbb{R}^{m\times d}$, $V \in \mathbb{R}^{n\times d}$ represent latent users and item feature matrices. A Gaussian model for the observations, parametrized by these factors, is used in Salakhutdinov and Mnih (2008), and a Poisson model is used in Gopalan et al. (2014) allowing for integer-valued observations. The item and user feature vectors are assigned priors, and hyperparameters and feature vectors are estimated by maximizing the log-posterior in Salakhutdinov and Mnih (2008) and minimizing the Kullback-Leibler divergence in Gopalan et al. (2014). To our knowledge, there are no theoretical recovery guarantees regarding the performance of these PMF models. Also in the context of collaborative filtering, Koren and Sill (2011, 2013) proposed an ordinal model for predicting missing rating distributions from revealed multi-level numerical ratings. The model of Koren and Sill (2011, 2013) is a quantized observation model similar to that in Lan et al. (2014a), and as in Lan et al. (2014a), no theoretical results were given. Modeling of ordinal data with Gaussian restricted Boltzmann machines for both vector-variates and matrix-variates has been investigated in Tran et al. (2012), where a quantized observation model is also considered. No theoretical results were given Tran et al. (2012).

Aside from the PMF models, all prior works have considered convex programs which use a convex relaxation of matrix rank as a surrogate for promoting low rank. While this may be advantageous in cases where the matrix is approximately low rank and also because it results in a convex problem, often in applications the rank is known (as in sensor network localization), or can be reliably estimated. One question is, if we consider an exact rank constraint, can performance guarantees be proved and performance improvement be achieved, and can we find an algorithm to lead us to a global solution?

In this paper, we extend the theory of 1-bit matrix completion to that of multi-level discrete measurements, with an emphasis on the application to quantization. We consider maximum likelihood (ML) estimation of M from multi-level quantized observations, and establish upper bounds on the estimation error norm for this problem, which has a faster rate of convergence than previously established upper bounds for the binary case. In contrast to Gunasekar et al. (2014) and Lafond (2015), we do not restrict the likelihood (i.e., the link function f) to come from an exponential family distribution. We allow the likelihood to come from any strictly log-concave distribution, which includes distributions of bounded discrete random variables from the exponential family. We furthermore focus on the application to a quantization observation model similar to that of Lan et al. (2014a), where the likelihood is not from the exponential family when the number of levels is greater than two (that is, when $K > 2$). Rather than using a convex relaxation to promote a low-rank solution as in previous works, we use an exact rank constraint. We present several algorithms based on matrix factorization for solving our optimization problem, one of which is globally convergent. Our method outperforms some of the existing low-rank matrix completion methods on both synthetic and real world data.

In a preliminary short version of this paper (Bhaskar, 2015), we presented Algorithms 1 and 2 (for known bin boundaries) and stated a preliminary version of our performance upper bound without any proof. The present paper provides a more comprehensive upper bound of the Frobenius norm of the error with the complete proof, an additional algorithm, Algorithm 3, and more extensive numerical experiments which include validation on the MovieLens 1M dataset.

The paper is organized as follows. In Section 2 we discuss the assumptions on the target matrix to make it identifiable and also discuss our sampling model on which we follow Bhojanapalli and Jain (2014). In Section 3, we state our main results regarding theoretical guarantees on matrix recovery. We first describe the proposed constrained ML estimation of the target matrix M from multi-level quantized observations. We then establish upper bounds on the estimation error norm for this problem, which yield a faster rate of convergence than previously established upper bounds for the binary case. In Section 4 we present several algorithms based on matrix factorization for solving our optimization problem, one of which is globally convergent. We corroborate our results with numerical examples in Section 5 where we test our methods on synthetic and real data, and also compare our methods with that of Keshavan et al. (2009, 2010) (OptSpace), Cai et al. (2010) (SVT), Cai and Zhou (2013) and Davenport et al. (2014). Proofs of technical claims are given in the two appendices.

Notation: We use capital letters, such as M, to denote a matrix, and M_{ij} for its (i,j)th entry. We let $\|M\|_2$, $\|M\|_F$, $\|M\|_*$ and $\|M\|_\infty$ denote the operator, Frobenius, nuclear (or trace) and entry-wise infinity norm, respectively, of M. The notation $M^\top$ denotes the

transpose of M, $|\mathcal{S}|$ denotes the cardinality of the set $\mathcal{S}$, $[n]$ denotes the set of integers $\{1, \ldots, n\}$, $\mathbf{1}_n \in \mathbb{R}^n$ is the vector of all ones, $\tilde{\mathbf{1}}_n = \mathbf{1}_n/\sqrt{n}$, and $\mathbf{1}_{[A]}$ denotes the indicator function, i.e. $\mathbf{1}_{[A]} = 1$ when A is true, and $\mathbf{1}_{[A]} = 0$ otherwise. We use $\langle A, B \rangle$ to denote $\mathrm{tr}(A^\top B) = \sum_{ij} A_{ij} B_{ij}$. The abbreviations w.h.p. and w.p.1 stand for with high probability and with probability one, respectively.

2. Preliminaries and Model Assumptions

In this section, we discuss the assumptions on the target matrix M to make it identifiable. We also discuss our sampling model on which we follow Bhojanapalli and Jain (2014).

2.1 Low-rank Matrices

The problem of completing a matrix from a subset of its entries is ill-posed without imposing structural assumptions on the matrix. Hence, some relationship between the entries must be assumed to reconstruct M from a subset of its entries. The majority of the literature on matrix completion assumes that the matrix M to be recovered is low rank, i.e., that it spans a low-dimensional subspace. This assumption is reasonable in many applications.

We assume that M is a low-rank matrix with rank bounded by r. We note that in many applications, such as sensor network localization, where M is known to exist in 2 or 3-dimensional grid, or DNA haplotype assembly, the rank r is known. In examples such as collaborative filtering, where M is a matrix in which rows may represent users and columns may represent their preferences for an item, M is low rank since the users' preferences are believed to be a function of just a few factors. In applications where the rank r is not explicitly known, as in the former example, it can be reliably estimated (Keshavan et al., 2010).

We furthermore assume that the true matrix M satisfies $\|M\|_\infty \leq \alpha$, which helps make the recovery of M well-posed by preventing excessive "spikiness" of the matrix. In classical matrix completion (Cai et al., 2010), the incoherence assumption is used to ensure that the left and right singular vectors are not aligned with the standard basis vectors, and to facilitate establishment of recovery guarantees. This assumption was made less stringent in Negahban and Wainright (2012) by instead restricting the "spikiness" ratio of the matrix. The assumption $\|M\|_\infty \leq \alpha$ follows from this condition (Gunasekar et al., 2014). We refer the reader to Davenport et al. (2014), Cai and Zhou (2013), Klopp (2014) and Negahban and Wainright (2012) for further details.

2.2 Sampling Model

We now discuss our assumptions on the set Ω, on which we follow Bhojanapalli and Jain (2014), where the classical matrix completion problem is considered. Consider a bipartite graph $G = ([m], [n], E)$, where the edge set $E \subseteq [m] \times [n]$ is related to the index set of revealed entries Ω as $(i, j) \in E$ iff $(i, j) \in \Omega$. Abusing the notation, we use G for both the graph and its bi-adjacency matrix where $G_{ij} = 1$ if $(i, j) \in E$, $G_{ij} = 0$ if $(i, j) \notin E$.

We denote the association of G to Ω by $G \backslash \Omega$. Without loss of generality we take $m \geq n$. We assume that each row of G has d nonzero entries (thus $|\Omega| = md$) with the following properties on its singular value decomposition (SVD):

(A1) The left and right top singular vectors of G are $\mathbf{1}_m/\sqrt{m}$ and $\mathbf{1}_n/\sqrt{n}$, respectively.

(A2) We have $\sigma_1(G) \geq d$ and $\sigma_2(G) \leq C\sqrt{d}$, where $C > 0$ is some universal constant. Here $\sigma_1(G)$ and $\sigma_2(G)$ respectively denote the largest and the second largest singular values of G.

Thus we require G to have a large enough spectral gap.

Examples. We now discuss a few examples of graphs families which satisfy assumptions (A1) and (A2).

(1) Ramanujan graphs, a class of regular expander graphs (Hoory et al., 2006).

(2) Erdös-Renyi random graphs with average degree $d \geq c \log(m)$. These graphs satisfy this spectral gap property with high probability (Feige and Ofek, 2005). More explicitly, if G is an Erdös-Renyi bipartite random graph with probability p of an edge being placed, then the ensemble average of the bi-adjacency matrix $\mathbb{E}[G] = p\mathbf{1}_m\mathbf{1}_n^\top = \sqrt{nmp^2}\tilde{\mathbf{1}}_m\tilde{\mathbf{1}}_n^\top$ and $\tilde{G} = G - \mathbb{E}[G]$ is a random matrix with zero-mean i.i.d. entries of variance $p(1-p)$ with the largest singular value having $\mathcal{O}(\sqrt{m+n})$ with high probability (and also with probability 1) (Bolla et al., 2010). Thus, $\sigma_1(G) = \sqrt{nmp^2}$ is the dominant singular value of G, and (A1) and (A2) hold with high probability (and also with probability 1) (Bolla et al., 2010). Note that the uniform sampling assumption used in Davenport et al. (2014), Gunasekar et al. (2014), and Lan et al. (2014c), generates an Erdös-Renyi random graph.

(3) Stochastic block models for certain choices of inter- and intra-cluster edge connection probabilities. Consider the case of two clusters of the left and right vertices, with $m/2$ left vertices and $n/2$ right vertices of graph G belonging to the first cluster and the remaining left and right vertices to second cluster. Suppose that each intra-cluster edge is placed with probability p and an inter-cluster edge is placed with probability q. Then the ensemble average of the bi-adjacency matrix $\mathbb{E}[G]$ consists of elements equal to p for edges with both vertices in the same cluster and q for edges with vertices in different clusters. This can be expressed as (see also Nadakuditi and Newman, 2012)

$$\mathbb{E}[G] = \frac{\sqrt{mn}(p+q)}{2}\tilde{\mathbf{1}}_m\tilde{\mathbf{1}}_n^\top + \frac{\sqrt{mn}|p-q|}{2}\tilde{\mathbf{u}}_m\tilde{\mathbf{u}}_n^\top \tag{5}$$

where $\tilde{\mathbf{u}}_m = \mathbf{u}_m/\sqrt{m}$, the elements of $\mathbf{u}_m \in \mathbb{R}^m$ are ± 1, $+1$ if the left vertex is in the first cluster, -1 otherwise; similarly for $\mathbf{u}_n$ and $\tilde{\mathbf{u}}_n$. For even m and n (clusters of equal size), (5) is an SVD of $\mathbb{E}[G]$ since $\{\tilde{\mathbf{1}}_m, \tilde{\mathbf{u}}_m\}$ and $\{\tilde{\mathbf{1}}_n, \tilde{\mathbf{u}}_n\}$ are sets of orthonormal vectors representing the left and right singular vectors of non-zero singular values of $\mathbb{E}[G]$, which is of rank 2. The matrix $\tilde{G} = G - \mathbb{E}[G]$ is a random matrix with bounded and independent entries, with the largest singular value having $\mathcal{O}(\sqrt{m+n})$ (Bolla et al., 2010). Thus, the two largest singular values of G are $\frac{\sqrt{mn}(p+q)}{2}$ and $\frac{\sqrt{mn}|p-q|}{2}$ (perturbed by random $\tilde{G}$). When $p = q$, we have an Erdös-Renyi random graph with the largest spectral gap. As q becomes smaller, the spectral gap decreases. By (5), (A1) is true, but for (A2) to be true, one should have $|p - q| = \mathcal{O}(1/\sqrt{m})$. For fixed p and q,

$\sigma_2(G) = \frac{\sqrt{mn}|p-q|}{2}$ does not satisfy (A2) although the spectral gap can be made smaller by making $|p-q|$ smaller. As shown in Bhojanapalli and Jain (2014), the stochastic block model is a useful device to study the effect of the spectral gap on the performance of matrix recovery approaches. Such stochastic block models also apply to practical settings such as modeling connectivity subnetworks in the brain (Ghanbari et al., 2013).

3. Main Results

In this section, we describe the rank-constrained ML estimation of the target matrix M from multi-level quantized observations. We then establish upper bounds on the estimation error norm for this problem, which yield a faster rate of convergence than previously established upper bounds for the binary case.

3.1 Rank-Constrained Maximum Likelihood Estimation

We wish to estimate unknown M from the observed entries of Y using a constrained ML approach. We assume Y is related to M via the probabilistic model given in (1)-(4). We use $X \in \mathbb{R}^{m\times n}$ to denote the optimization variable. The negative log-likelihood function is given by

$$F_{\Omega,Y}(X) = -\sum_{(i,j)\in\Omega}\left[\sum_{\ell=1}^{K}\log(f_\ell(X_{ij}))\mathbf{1}_{[Y_{ij}=\ell]}\right] \tag{6}$$

which is a convex function in X when the function f_ℓ is log-concave in X_{ij}, and can be an implicit function of $\boldsymbol{\omega}$, where

$$\boldsymbol{\omega} = [\omega_1\ \omega_2\ \cdots\ \omega_{K-1}]^\top \in \mathbb{R}^{K-1} \tag{7}$$

is the vector of bin boundaries.

Two common choices for which the function f_ℓ, and its associated CDFs and pdfs, are log-concave, are:

(i) Logistic model with logistic CDF $\Phi(x) = \Phi_{log}(x/\sigma) = \frac{1}{1+e^{-x/\sigma}}$, $\sigma > 0$.

(ii) Probit model with $\Phi(x) = \Phi_{norm}(x/\sigma)$ where $\sigma > 0$ and $\Phi_{norm}(x)$ is the CDF of the standard normal distribution $\mathcal{N}(0,1)$.

We consider two classes of problems. In the first, $\boldsymbol{\omega}$ is known, and thus the distribution in (4) is completely specified. We will assume that the bin boundaries ω_ℓ, $\ell \in [K]$, are known for our theoretical results. In the other, $\boldsymbol{\omega}$ is unknown and will be determined as part of the optimization problem. By allowing the bin boundaries to be determined by the optimization, we allow the distribution in (4) to be tuned to real data. For our numerical results, we allow the ω_ℓs to be unknown and estimate them (along with M), as in Lan et al. (2014a).

When $\boldsymbol{\omega}$ is known, we seek the solution to the optimization problem (P1): (s.t. stands for subject to)

$$\begin{aligned}(\text{P1}):\quad &\widehat{M} = \arg\min_{X} F_{\Omega,Y}(X)\\ &\text{s.t.}\quad \|X\|_\infty \le \alpha,\ \text{rank}(X) \le r.\end{aligned} \tag{8}$$

As a result of the rank constraint, (P1) is a nonconvex optimization problem. In Section 4, we will discuss factorization methods for solving this problem which come with guarantees of global convergence. In Section 3.2, we present performance upper bounds for problem (P1).

When $\boldsymbol{\omega}$ is unknown, the constrained ML estimate we wish to obtain is given by the solution to the optimization problem (P2):

$$\begin{aligned}(\text{P2}):\quad &\left(\widehat{M},\widehat{\boldsymbol{\omega}}\right) = \arg\min_{X,\boldsymbol{\omega}} F_{\Omega,Y}(X)\ \text{s.t.}\ \ \|X\|_\infty \le \alpha,\\ &\text{rank}(X) \le r \text{ and } \omega_1 < \omega_2 < \cdots < \omega_{K-1}.\end{aligned} \tag{9}$$

The negative log-likelihood $F_{\Omega,Y}(X)$ is not jointly convex in X and $\boldsymbol{\omega}$. However, we show in Lemma 3 in Appendix A that f_ℓ is log-concave in ω_k for fixed X and ω_is ($i \ne k$), and in Section 3.3, that it is strictly log-concave in X for fixed $\boldsymbol{\omega}$ whenever $\Phi(x)$ is log-concave. Thus, $F_{\Omega,Y}(X)$ is convex in ω_k for fixed X and ω_is ($i \ne k$), and convex in X for fixed $\boldsymbol{\omega}$. Consequently, as seen later in Section 4, it will require an alternating minimization procedure (block-coordinate descent).

3.2 Performance Upper Bounds

We now present performance upper bounds for $\widehat{M}$ in (8), i.e., problem (P1) where $\boldsymbol{\omega}$, the vector of true bin boundaries, is assumed to be known. We first define some constants which appear in the bound, involving functions of $f_\ell(x)$ and its first two derivatives. With $\dot{f}(x) := (\mathrm{d}f(x)/\mathrm{d}x)$, define

$$\gamma_\alpha \le \min_{\ell\in[K]}\inf_{|x|\le\alpha}\left\{\frac{\dot{f}_\ell^2(x)}{f_\ell^2(x)} - \frac{\ddot{f}_\ell(x)}{f_\ell(x)}\right\}, \tag{10}$$

$$L_\alpha \ge \max_{\ell\in[K]}\sup_{|x|\le\alpha}\left\{\left|\dot{f}_\ell(x)\right|/f_\ell(x)\right\}, \tag{11}$$

where α is the bound on the entry-wise infinity-norm of $\widehat{M}$ (see Equation 8). For further reference, define the constraint set

$$\mathcal{C} := \left\{X \in \mathbb{R}^{m\times n}\ :\ \|X\|_\infty \le \alpha,\ \text{rank}(X) \le r\right\}. \tag{12}$$

Theorem 1 *Suppose that $M \in \mathcal{C}$, and $G\backslash\Omega$ satisfies assumptions (A1) and (A2). Without loss of generality, assume $m \ge n$. Further, suppose Y is generated according to (1) where $f_\ell(x)$ is log-concave in x $\forall \ell \in [K]$. Then, provided $\gamma_\alpha > 0$, with probability at least $1 - 2(9\alpha\sqrt{mn})^{-r(m+n+1)} - C_1\exp(-C_2 m)$, any global minimizer $\widehat{M}$ of (8) satisfies*

$$\frac{1}{\sqrt{mn}}\|\widehat{M} - M\|_F \le \min\left(2\alpha,\ U_1,\ U_2\right) \tag{13}$$

where

$$U_1 = \max\left(\frac{C_{1\alpha} r\sigma_2(G)}{\sigma_1(G)}, \frac{C_{2\alpha} m\sqrt{r^3 n}}{\sigma_1^2(G)}\right) \le \max\left(\frac{C_{1\alpha} Cr\sqrt{m}}{\sqrt{|\Omega|}}, \frac{C_{2\alpha} m^3\sqrt{r^3 n}}{|\Omega|^2}\right), \tag{14}$$

$$U_2 = \max\left(\frac{C_{1\alpha} r\sigma_2(G)}{\sigma_1(G)},\ \frac{C_{3\alpha} r^{0.75}\left(|\Omega|(m+n+1)\log(9\alpha\sqrt{mn})\right)^{0.25}}{\sigma_1(G)}\right) \tag{15}$$

$$\leq \max\left(\frac{C_{1\alpha} C r\sqrt{m}}{\sqrt{|\Omega|}},\ C_{3\alpha}\left(\frac{r}{|\Omega|}\right)^{0.75} m\left((m+n+1)\log(9\alpha\sqrt{mn})\right)^{0.25}\right). \tag{16}$$

Here, $C_{1\alpha} = 4\sqrt{2}\alpha$, $C_{2\alpha} = 32.16\sqrt{2}L_\alpha/\gamma_\alpha$, $C_{3\alpha} = 8\sqrt{\frac{(1+\alpha)L_\alpha}{\gamma_\alpha}}$, $C_1, C_2, C > 0$ are universal constants, and γ_α and L_α are given by (10), (11).

A proof of Theorem 1 is given in Appendix B. In the binary case ($K = 2$) the link function f in (4) belongs to the exponential family for a large class of CDFs $\Phi(x)$ (e.g., logistic or Gaussian), but not for $K > 3$. The bounding approaches in Gunasekar et al. (2014), Lafond (2015) and Cao and Xie (2015) for $K > 3$ require f to come from the exponential family whereas our approach based on a Taylor series approximation and some concentration inequalities applies to the quantization model (4). One of the novelties in our proof compared to existing works is how we bound the gradient of the cost function in two different ways (see Lemmas 5 and 6 in Appendix B).

Of some interest is the case where the fraction of revealed entries $p = \frac{|\Omega|}{mn}$ is fixed and we let m and n become large, with $m/n \equiv \delta \geq 1$ fixed. In this case we have the following Corollary.

Corollary 2 *Assume the conditions of Theorem 1. Let $p = \frac{|\Omega|}{mn}$ be fixed independent of m and n. Then*

$$U_1 \leq \mathcal{O}\left(\frac{\delta}{p^2}\sqrt{\frac{r^3}{n}}\right), \quad U_2 \leq \mathcal{O}\left(\left(\frac{r^3\delta^2\log(n)}{p^3 n}\right)^{1/4}\right).$$

Then with probability at least $1 - C_1\exp(-C_2 m) - 2/(9\alpha n\sqrt{\delta})^{2rn}$, any global minimum $\widehat{M}$ to (8) satisfies

$$\frac{1}{\sqrt{mn}}\|\widehat{M} - M\|_F \leq \min\left(\mathcal{O}\left(\frac{\delta}{p^2}\sqrt{\frac{r^3}{n}}\right), \mathcal{O}\left(\left(\frac{r^3\delta^2\log(n)}{p^3 n}\right)^{1/4}\right)\right). \tag{17}$$

Corollary 2 suggests that for "larger" fixed values of p, U_1 dominates, signifying a convergence rate of at least $1/\sqrt{n}$ for $\frac{1}{\sqrt{mn}}\|\widehat{M} - M\|_F$ whereas for "small" values of p, U_2 is likely to dominate signifying convergence rate of at least $(\log(n)/n)^{1/4}$. In our simulation results shown later in Figure 5 for $m = n = 100, 200$, or 400, and $p = 0.2, 0.4$, or 0.6, we find that $\frac{1}{mn}\|\widehat{M} - M\|_F^2$ decays approximately as $\mathcal{O}(1/n)$.

3.3 Constants γ_α and L_α for the logistic and probit models

It is known that $f_\ell(x)$ is log-concave iff $\ddot{f}_\ell(x)f_\ell(x) \leq (\dot{f}_\ell(x))^2$ (Boyd and Vandenberghe, 2004). Thus $\gamma_\alpha \geq 0$ for log-concave $f_\ell(x)$ and $\gamma_\alpha > 0$ for strictly log-concave $f_\ell(x)$. For the

logistic model, i.e., when $\Phi(x) = \Phi_{log}(x/\sigma)$, some tedious calculations show that

$$\frac{\dot{f}_\ell^2(x)}{f_\ell^2(x)} - \frac{\ddot{f}_\ell(x)}{f_\ell(x)} = \frac{1}{\sigma^2}\Big[\Phi_{log}\left(\frac{\omega_\ell - x}{\sigma}\right)\left(1 - \Phi_{log}\left(\frac{\omega_\ell - x}{\sigma}\right)\right) + \Phi_{log}\left(\frac{\omega_{\ell-1} - x}{\sigma}\right)\left(1 - \Phi_{log}\left(\frac{\omega_{\ell-1} - x}{\sigma}\right)\right)\Big]$$
$$> 0 \ \ \forall x \in \mathbb{R},\ \forall \ell \in [K]. \tag{18}$$

Therefore, by (10), $\gamma_\alpha > 0$ for the logistic model. Similarly one can verify numerically that $\gamma_\alpha > 0$ for the probit model when $\Phi(x) = \Phi_{norm}(x/\sigma)$. For the logistic model, it turns out that $L_\alpha = 1/(2\sigma\beta_{\alpha\sigma})$ where

$$\beta_{\alpha\sigma} := \min_{\ell\in[K]} \inf_{|x|\leq\alpha} \left\{\Phi_{log}(\frac{\omega_\ell - x}{\sigma}) - \Phi_{log}(\frac{\omega_{\ell-1} - x}{\sigma})\right\} > 0. \tag{19}$$

For the probit model, we have $L_\alpha = \sqrt{2}/(\sqrt{\pi}\sigma\beta_{n\alpha\sigma})$ where

$$\beta_{n\alpha\sigma} := \min_{\ell\in[K]} \inf_{|x|\leq\alpha} \left\{\Phi_{norm}(\frac{\omega_\ell - x}{\sigma}) - \Phi_{norm}(\frac{\omega_{\ell-1} - x}{\sigma})\right\} > 0. \tag{20}$$

3.4 Comparison of Convergence Rates

We first provide a comparison of our bounds with those of Davenport et al. (2014) and Cai and Zhou (2013), who have established bounds for only the binary ($K = 2$) level case. Consider $M \in \mathbb{R}^{n\times n}$, with p fraction of its entries sampled. Then $m = n$, and $|\Omega| = pn^2$. The bounds proposed in Davenport et al. (2014) and Cai and Zhou (2013) yield (for $|\Omega| \geq 4n\log(n)$)

$$\frac{1}{n^2}\|\widehat{M} - M\|_F^2 \leq \mathcal{O}\left(\sqrt{\frac{r}{pn}}\right). \tag{21}$$

Our bound (Corollary 2) yields

$$\frac{1}{n^2}\|\widehat{M} - M\|_F^2 \leq \min\left(\mathcal{O}\left(\frac{r^3}{p^4 n}\right), \mathcal{O}\left(\sqrt{\frac{r^3\log(n)}{p^3 n}}\right)\right). \tag{22}$$

For $K = 2$, the results of Lafond et al. (2014), Gunasekar et al. (2014) and Lafond (2015) apply to our model but not for $K > 2$. The bound of Lafond et al. (2014) and Lafond (2015) yields

$$\frac{1}{n^2}\|\widehat{M} - M\|_F^2 \leq \mathcal{O}\left(\frac{r\log(n)}{pn}\right) \tag{23}$$

and the bound of (Gunasekar et al., 2014, Corollary 1) yields

$$\frac{1}{n^2}\|\widehat{M} - M\|_F^2 \leq \mathcal{O}\left(\alpha^{*2}\frac{r\log(n)}{pn}\right) = \mathcal{O}\left(\frac{rm\log(n)}{p}\right) \tag{24}$$

since in Gunasekar et al. (2014), $\alpha^* \geq \sqrt{mn}\|M\|_\infty$. The bound in Soni et al. (2014) as applied to non-sparse models and $K = 2$, yields

$$\frac{1}{n^2}\mathbb{E}\left[\|\widehat{M} - M\|_F^2\right] \leq \mathcal{O}\left(\frac{r\log(n)}{pn}\right) \tag{25}$$

where the expectation is over the noise (Z_{ij} in Equation 2) and sampling distributions of the revealed matrix entries. Thus, (25) is similar to (23) but is averaged over the noise and sampling distributions. The multi-level observation model of Cao and Xie (2015) does not include the quantized observation model given in (2) but applies to a multinomial logistic model. The bound in Cao and Xie (2015) yields

$$\frac{1}{n^2}\|\widehat{M} - M\|_F^2 \leq \mathcal{O}\left(\sqrt{\frac{r}{pn}}\right). \tag{26}$$

In (21)-(26) the omitted constants do not depend on r, p or n.

Comparing (21)-(26) for the case $K = 2$, we see our method has faster convergence rate in n for fixed rank r and fraction of revealed entries p, compared to Davenport et al. (2014), Cai and Zhou (2013), Lafond et al. (2014), Gunasekar et al. (2014), Lafond (2015) and Soni et al. (2014); the same comment applies for $K > 2$ when comparing with Cao and Xie (2015). On the other hand, for fixed n, our bound is inferior to these other bounds in p or r. One may notice if the revealed entries scale with n according to $p \sim \mathcal{O}(\log(n)/n)$ then Davenport et al. (2014) and Cao and Xie (2015) yield bounded error while our bound grows with n; in our case we need $p \geq \mathcal{O}(1/n^{1/3})$. We believe this to be an artifact of our proof, as our numerical results in Figure 1 show our method outperforms Cai and Zhou (2013) and Davenport et al. (2014), especially for low values of p and higher values of rank r.

4. Optimization

In this section, we describe the algorithms used to solve problems (P1) and (P2). We use the matrix factorization technique (Bach et al., 2008; Burer and Monteiro, 2003; Lee et al., 2010) where instead of optimizing with respect to X, it is factorized into two matrices $U \in \mathbb{R}^{m\times k}$ and $V \in \mathbb{R}^{n\times k}$ such that $X = UV^\top$. One then optimizes with respect to the factors U, V. This method is non-convex, however, it is known (Bach et al., 2008; Burer and Monteiro, 2003; Lee et al., 2010) that if k is chosen to be large enough, it is guaranteed that the local minimum of the problem is also the global minimum of the non-factorized problem.

4.1 Known Bin Boundaries

We have the following approximate projected gradient method for solving problem (P1) following the algorithm of Cai and Zhou (2013), where the case of $K = 2$ was considered.

4.1.1 Algorithm 1: Approximate Projected Gradient Method

Given initial estimates U^0, V^0, one updates

$$\begin{bmatrix} U^{t+1} \\ V^{t+1} \end{bmatrix} = \mathcal{P}_\alpha\left(\begin{bmatrix} U^t - \frac{\tau}{\sqrt{t}}\nabla_X F_{\Omega,Y}(U^tV^{t\top})V^t \\ V^t - \frac{\tau}{\sqrt{t}}\nabla_X F_{\Omega,Y}(U^tV^{t\top})^\top U^t \end{bmatrix}\right) \tag{27}$$

where U^t, V^t are the estimates at iteration t, and

$$\mathcal{P}_\alpha\left([U^\top\ V^\top]^\top\right) = \begin{cases} \sqrt{\alpha/\|UV^\top\|_\infty}[U^\top\ V^\top]^\top & \text{if} \quad \|UV^\top\|_\infty > \alpha \\ [U^\top\ V^\top]^\top & \text{if} \quad \|UV^\top\|_\infty \leq \alpha. \end{cases} \tag{28}$$

In (27) the stepsize τ is selected via a backtracking line search using Armijo's rule, to minimize the cost $F_{\Omega,Y}(U^{t+1}V^{t+1\top})$.

In addition to the approximate projection $\mathcal{P}_\alpha$ in (28), Cai and Zhou (2013) (for $K = 2$) also uses another projection to enforce a max-norm constraint. In Cai and Zhou (2013), for $K = 2$, the negative log-likelihood cost is minimized w.r.t. X subject to the constraints $\|X\|_\infty \leq \alpha$ and $\|X\|_{\max} \leq R$ for some $\alpha > 0$ and $R > 0$. The operator $\mathcal{P}_\alpha$ enforces the constraint $\|X\|_\infty \leq \alpha$. The factored form definition of the max norm (Lee et al., 2010) is given by $\|X\|_{\max} = \inf\left\{\max(\|\bar{U}\|_{2,\infty}^2, \|\bar{V}\|_{2,\infty}^2) : X = \bar{U}\bar{V}^\top\right\}$ where $\|\bar{U}\|_{2,\infty} = \max_i \sqrt{\sum_j \bar{U}_{ij}^2}$, $\bar{U} \in \mathbb{R}^{m\times k}$, $\bar{V} \in \mathbb{R}^{n\times k}$, $k = 1, 2, \ldots, \min(m, n) = n$. For fixed k and $X = UV^\top$, Cai and Zhou (2013) enforce the constraint set $\|X\|_{\max} \leq R$ by requiring $\max(\|U\|_{2,\infty}^2, \|V\|_{2,\infty}^2) \leq R$. As stated in Cai and Zhou (2013), the global minimum of the cost over the constraints $\|X\|_\infty \leq \alpha$ and $\|X\|_{\max} \leq R$ is the same as that over the constraints $\|X\|_\infty \leq \alpha$, $\|U\|_{2,\infty}^2 \leq R$ and $\|V\|_{2,\infty}^2 \leq R$ if $\text{rank}(X) \leq k$. If a matrix A has rank r and $\|A\|_\infty \leq \alpha$, then $\|A\|_{\max} \leq \sqrt{r}\alpha$ (Cai and Zhou, 2013). Therefore, in our case the max-norm constraint is unnecessary as it is automatically satisfied for any $R \geq \sqrt{r}\alpha$. In this sense, our Algorithm 1 is the same as the approach of Cai and Zhou (2013) when $K = 2$ and one picks $R \geq \sqrt{r}\alpha$.

Remark 1 *The hard rank constraint results in a nonconvex constraint set. Thus,* (8) *is a nonconvex optimization problem; similarly for Algorithm 1 for which the rank constraint is implicit in the factorization of X. However, the following result is shown in (Bach et al., 2008, Proposition 4), based on Burer and Monteiro (2003), for nonconvex problems of this form. If (U^*, V^*) is a local minimum of the reformulated (i.e., factored) problem, then $X^* = U^*V^{*\top}$ is the global minimum of problem* (8)*, so long as U^* and V^* are rank-deficient. (Rank deficiency of (U^*, V^*) is a sufficient condition, not necessary.) This result is invoked in Recht and Re (2013), Lee et al. (2010) and Cai and Zhou (2013) for problems of this form. Thus one would expect to achieve global convergence for the problem of* (8) *provided iterations (27)-(28) converge to a local minimum. These iterations represent a projected gradient method which converges to a stationary point if one has orthogonal projection onto a convex constraint set (Bertsekas, 1999, Prop. 2.3.1). However, the "projection" $\mathcal{P}_\alpha$ in (28) is not an orthogonal projection and the set $\{\|UV^\top\|_\infty \leq \alpha\}$ is not convex in U, V (although $\{\|X\|_\infty \leq \alpha\}$ is convex in X), therefore, convergence to even a local minimum is not ensured. However, numerically, this method has still provided good results (similarly reported in Cai and Zhou (2013)). In Cai and Zhou (2013), for the $K = 2$ case, there are two additional constraints $\|U\|_{2,\infty}^2 \leq R$ and $\|V\|_{2,\infty}^2 \leq R$ which are convex sets in U and V, and the corresponding projections are orthogonal projections. However, the projection corresponding to our $\mathcal{P}_\alpha$ in Cai and Zhou (2013) is not orthogonal.*

Thus, for problems of this form, one can choose $k = r + 1$ to achieve global convergence if an upper bound r on the rank of M is known.

The convergence deficiency discussed in Remark 1 motivates the following log-barrier penalty function approach.

4.1.2 Algorithm 2: Logarithmic Barrier Gradient Method

The constraint $\max_{i,j}|X_{ij}| \leq \alpha$ translates to $X_{ij} - \alpha \leq 0$ and $-X_{ij} - \alpha \leq 0\ \forall (i,j)$, which motivates the log-barrier penalty function $-\log\left(1-(X_{ij}/\alpha)^2\right)$, which is finite for $|X_{ij}| < \alpha$, and is infinite otherwise. This leads to the objective function

$$\tilde{F}_{\Omega,Y}(X) = F_{\Omega,Y}(X) - \lambda \sum_{(i,j)} \log\left(1-(X_{ij}/\alpha)^2\right) \tag{29}$$

and the optimization problem

$$\widehat{M} = \arg\min_{X} \tilde{F}_{\Omega,Y}(X) \text{ s.t. } \text{rank}(X) \leq r. \tag{30}$$

The parameter $\lambda > 0$ in (29) sets the accuracy of approximation of $\max_{i,j}|X_{ij}| \leq \alpha$ via the log-barrier function (which is twice-differentiable and convex in X, hence so is $\tilde{F}_{\Omega,Y}(X)$). Now, however, the factorization approach $X = UV^\top$ is well-justified, per Remark 1, and convergence is guaranteed.

The log-barrier method is ill-conditioned and solving the problem for a fixed value of λ generally only works well for small problems or good choices of initialization (Boyd and Vandenberghe, 2004). The above problem is typically solved via a sequence of central path following solutions (Boyd and Vandenberghe, 2004) where one gradually reduces λ toward 0. In our approach we initialize it with the solution to Algorithm 1, providing a good initialization, and then either use a single "small" value of λ, or select λ via 5-fold cross-validation. One may therefore view augmentation with the log-barrier cost as regularization of $F_{\Omega,Y}(X)$.

We solve the factored version $X = UV^\top$ of problem (30) for a fixed λ using a gradient method as follows. Given initial estimates U^0, V^0, one updates

$$\begin{bmatrix} U^{t+1} \\ V^{t+1} \end{bmatrix} = \begin{bmatrix} U^t - \frac{\tau}{\sqrt{t}} \nabla_X \tilde{F}_{\Omega,Y}(U^t V^{t\top}) V^t \\ V^t - \frac{\tau}{\sqrt{t}} \nabla_X \tilde{F}_{\Omega,Y}(U^t V^{t\top})^\top U^t \end{bmatrix} \tag{31}$$

where U^t, V^t are the estimates at iteration t and $\nabla_X \tilde{F}_{\Omega,Y}(U^t V^{t\top}) = \nabla_X \tilde{F}_{\Omega,Y}(X)\big|_{X=U^tV^{t\top}}$. In (31) the stepsize τ is selected via a backtracking line search using Armijo's rule, to minimize the cost $\tilde{F}_{\Omega,Y}(U^{t+1}V^{t+1\top})$.

Define $Z = [U^\top\ V^\top]^\top \in \mathbb{R}^{(m+n)\times k}$ and let $\bar{F}_{\Omega,Y}(Z^t) = \tilde{F}_{\Omega,Y}(U^t V^{t\top})$. Then (31) can be rewritten as

$$Z^{t+1} = Z^t - \frac{\tau}{\sqrt{t}} \nabla_Z \bar{F}_{\Omega,Y}(Z^t), \quad \nabla_Z \bar{F}_{\Omega,Y}(Z^t) = \begin{bmatrix} \nabla_X \tilde{F}_{\Omega,Y}(U^t V^{t\top}) V^t \\ \nabla_X \tilde{F}_{\Omega,Y}(U^t V^{t\top})^\top U^t \end{bmatrix}. \tag{32}$$

Thus, (31) is a gradient descent method using Armijo's rule for stepsize selection, for unconstrained minimization of the continuously differentiable cost $\tilde{F}_{\Omega,Y}(UV^\top) = \bar{F}_{\Omega,Y}(Z)$ w.r.t. Z. By (Bertsekas, 1999, Prop. 1.2.1), the iterations given in (31) converge to a stationary point of $\tilde{F}_{\Omega,Y}(UV^\top)$. Since the cost is non-increasing at every iteration, the stationary point is either a local minimum or a saddle point. In theory, convergence to saddle points can not be excluded for gradient descent algorithms for continuously differentiable functions. However, we assume that we escape saddle points in practice as saddle points are generally unstable from a numerical point of view, i.e., a perturbation always exists at the saddle point which will decrease the cost function.

4.2 Unknown Bin Boundaries

As noted earlier $F_{\Omega,Y}(X)$ is convex in ω_k for fixed X and ω_is ($i \neq k$), and convex in X for fixed $\boldsymbol{\omega}$, however, $F_{\Omega,Y}(X)$ is not jointly convex in X and $\boldsymbol{\omega}$. Thus the problem (P2) specified in (9) is multi-convex in X and $\omega_1, \omega_2, \cdots, \omega_{K-1}$, and one approach to solve it is via block-coordinate descent (Xu and Yin, 2013), for which there are no convergence guarantees, in general. In order to detail this approach, with an abuse of notation, we now explicitly denote the dependence of $F_{\Omega,Y}(X)$ on the ω_is as $F_{\Omega,Y}(X, \omega_1, \cdots, \omega_{K-1})$, and that of $\tilde{F}_{\Omega,Y}(X)$ as $\tilde{F}_{\Omega,Y}(X, \omega_1, \cdots, \omega_{K-1})$. Following Xu and Yin (2013) and our Algorithms 1 and 2, our optimization algorithm for the case of unknown bin boundaries is given in Algorithm 3 where, in Step 5, δ_0 makes the constraint set for ω_i convex.

Algorithm 3 Block-Coordinate Descent Method for Solving (9)

Input: Set of observed entries Y_{ij} for $(i,j) \in \Omega$, initialization $U^0 \in \mathbb{R}^{m\times k}$, $V^0 \in \mathbb{R}^{m\times k}$, $\omega_1^0, \omega_2^0, \cdots, \omega_{K-1}^0 \in \mathbb{R}$, $\omega_1^0 < \omega_2^0 < \cdots < \omega_{K-1}^0$, parameters α, λ

Output: Solution $X^* = U^* V^{*\top}$, $\boldsymbol{\omega}^*$

1: **for** $\ell = 1, 2, \cdots$, until convergence, **do**
2: $\left(L^\ell, R^\ell\right) \leftarrow \arg\min_{U,V} F_{\Omega,Y}(UV^\top, \omega_1^{\ell-1}, \cdots, \omega_{K-1}^{\ell-1})$ subject to $\|UV^\top\|_\infty \leq \alpha$. Solve using approximate projected gradient method (27) initialized with $U^{\ell-1}, V^{\ell-1}$.
3: $\left(U^\ell, V^\ell\right) \leftarrow \arg\min_{U,V} \tilde{F}_{\Omega,Y}(UV^\top, \omega_1^{\ell-1}, \cdots, \omega_{K-1}^{\ell-1})$. Solve using log-barrier gradient method (31) initialized with L^ℓ, R^ℓ.
4: **for** $i = 1, 2, \cdots, K-1$, **do**
5: $\omega_i^\ell \leftarrow \arg\min_{\omega_i} F_{\Omega,Y}(U^\ell V^{\ell\top}, \omega_1^\ell, \cdots, \omega_{i-1}^\ell, \omega_i, \omega_{i+1}^{\ell-1}, \cdots, \omega_{K-1}^{\ell-1})$ subject to $\omega_{i-1}^\ell + \delta_0 \leq \omega_i \leq \omega_{i+1}^{\ell-1} - \delta_0$ for some "small" $\delta_0 > 0$. Solve using a gradient descent method initialized with $\omega_i = \omega_i^{\ell-1}$.
6: **end for**
7: **end for**
8: **return** $X^* = U^* V^{*\top}$, $\boldsymbol{\omega}^*$

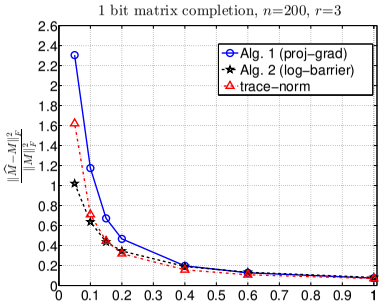
In Step 2 of Algorithm 3, we have used the solution of the approximate projected gradient method (27), to provide a good initialization to the log-barrier algorithm in Step 3, since we are not using central path following, for the reasons aforementioned in Section 4.1.2.

5. Numerical Experiments

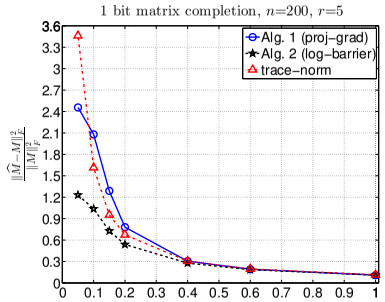
In this section, we test our methods on synthetic and real data, and also compare our methods with that of Keshavan et al. (2009, 2010) (OptSpace), Cai et al. (2010) (SVT), Cai and Zhou (2013) and Davenport et al. (2014).

5.1 Synthetic Data

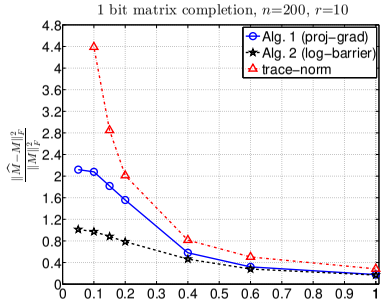
In this section, we report the results of evaluating our method on synthetic data. We set $m = n$ and construct $M \in \mathbb{R}^{n\times n}$ as $M = M_1 M_2^\top$ where M_1 and M_2 are $n \times r$ matrices with



(a) $r = 3$



(b) $r = 5$



(c) $r = 10$

Figure 1: Relative MSE $\|\widehat{M} - M\|_F^2/\|M\|_F^2$ for varied values of $p = q$, $n = 200$, $\alpha = 1$, Gaussian noise with $\sigma = 0.18$, K=2: binary case, $w_1 = 0$, known bin boundaries, "trace-norm" refers to Davenport et al. (2014), the proposed Alg. 1 (proj-grad) coincides with the algorithm of Cai and Zhou (2013) when $K = 2$ and one picks $R \geq \sqrt{r}\alpha$ in Cai and Zhou (2013).

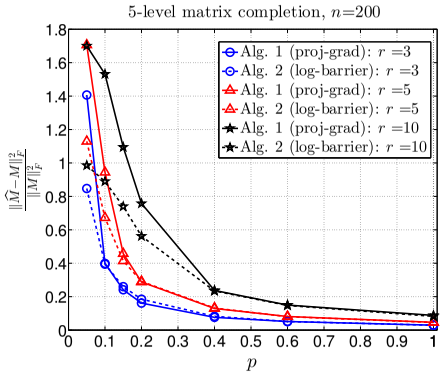


Figure 2: Relative MSE $\|\widehat{M} - M\|_F^2/\|M\|_F^2$ for varied values of $p = q$, $n = 200$, $\alpha = 1$, Gaussian noise with $\sigma = 0.18$, K=5: $w_1 = -0.4$, $w_2 = -0.15$, $w_3 = 0.15$, $w_4 = 0.4$, known bin boundaries.

i.i.d. entries drawn from a uniform distribution on $[-0.5, 0.5]$. Then we scaled M to achieve $\|M\|_\infty = 1 = \alpha$. We pick $r = 3$, 5 or 10, and vary matrix sizes $n = 100, 200$, or 400. We used the model (2) with Z_{ij} as a zero-mean Gaussian with standard deviation $\sigma = 0.18$. These choices follow the numerical experiments of Cai and Zhou (2013) and Davenport et al. (2014), which dealt with the case of binary observations (i.e., in which $K = 2$). We generate the set Ω of revealed indices via a stochastic block model as in Bhojanapalli and Jain (2014). In the basic stochastic block model, we divide the set of nodes $[n]$ into two clusters, where each intra-cluster edge is sampled uniformly with probability p and an inter-cluster edge is sampled with probability q. For our simulations, initially we chose $p = q$ which corresponds to the Bernoulli sampling model of Davenport et al. (2014). Then we change the fraction of revealed 1-bit entries as $p = 0.05, 0.1, 0.15, 0.2, 0.4, 0.6$ or 1. Algorithm 1 was implemented with random initialization and its result was used to initialize Algorithm 2 where we either picked λ via 5-fold cross-validation (how well the label values of revealed Y_{ij} in the test set are matched), or simply used a small fixed λ. We assumed the bin boundaries to be known. The resulting relative mean-square error (MSE) $\|\widehat{M} - M\|_F^2/\|M\|_F^2$, averaged over 20 Monte Carlo runs, is shown for $n = 200$ in Figure 1 for $K = 2$, and Figure 2 for $K = 5$. As expected, the performance improves with increasing n and increasing p. For comparison, Figure 1 also shows the MSE for Davenport et al. (2014) and Cai and Zhou (2013), and it is seen that Algorithm 2 (log-barrier) significantly outperforms Davenport et al. (2014) and Cai and Zhou (2013) for low values of p and high values of r (e.g., $r = 10$ and $p < 0.4$), and the performances are comparable for higher values of p and lower values of r (e.g., $r = 3$ and $p > 0.1$). Note that as aforementioned, Algorithm 1 (proj-grad) coincides with the algorithm of Cai and Zhou (2013) when $K = 2$ and one picks $R \geq \sqrt{r}\alpha$ in Cai and Zhou (2013).

In Figure 3 we show the results for the case of $r = 5$ and $m = n = 200$ for both known and estimated bin boundaries. As before, the results were averaged over 20 Monte Carlo runs, and the missing entries were set via the stochastic block model with $p = q$. For the case of unknown bin boundaries, we used Algorithm 3 with initialization $\omega_1^0 = -0.3$, $\omega_2^0 = -0.1$, $\omega_3^0 = 0.1$ and $\omega_4^0 = 0.3$, and $\alpha = 1$, $\lambda = 0.5$. Also shown are the results of the algorithm OptSpace of Keshavan et al. (2010) which is a matrix completion algorithm that assumes a real-valued low-rank matrix. The results using OptSpace were obtained for two cases: the case labeled "quantized noisy M" refers to the case where OptSpace is provided with revealed Y_{ij}'s, and the case labeled "unquantized noisy M" refers to the case where OptSpace works on revealed noisy M_{ij}s (i.e., $M_{ij} + Z_{ij}$s). For OptSpace, we scaled the estimate $\widehat{M}$ to have the same Frobenius norm as the true M before computing the MSE. It is seen that for $p \geq 0.2$, there is no loss in performance when bin boundaries are estimated, using the proposed approach. The algorithm OptSpace performs poorly for quantized data.

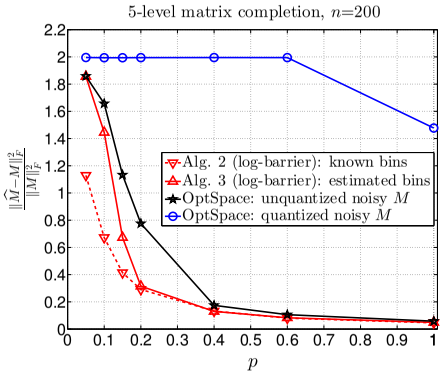

Figure 3: Relative MSE $\|\widehat{M} - M\|_F^2/\|M\|_F^2$ for varied values of $p = q$, $n = 200$, $\alpha = 1$, Gaussian noise with $\sigma = 0.18$, K=5: true bin boundaries $w_1 = -0.4$, $w_2 = -0.15$, $w_3 = 0.15$, $w_4 = 0.4$, known and estimated bin boundaries. OptSpace is the method of Keshavan et al. (2010).

In Figure 4, we show the results for varying number of quantization levels K, with $r = 3, 5, 10$, $p = 0.2$, $m = n = 200$ and known bin boundaries. The matrix M is constructed as for Figure 1. The results were over 20 Monte Carlo runs, and the missing entries were set via the stochastic block model with $p = q$. With $\alpha = 1$, the bin boundaries were picked as $w_1 = 0$ for $K = 2$, $w_1 = -0.2$, $w_2 = 0.2$ for $K = 3$, $w_1 = -0.25$, $w_2 = 0$, $w_3 = 0.25$ for $K = 4$, $w_1 = -0.4$, $w_2 = -0.15$, $w_3 = 0.15$, $w_4 = 0.4$ for $K = 5$ and $w_1 = -0.4$, $w_2 = -0.2$, $w_3 = -0.05$, $w_4 = 0.05$, $w_5 = 0.2$, $w_6 = 0.4$ for $K = 7$. These choices yield a comparable number of entries in each bin. It is seen from Figure 4 that performance improves with increasing K. This is not surprising since with increasing K, bin intervals

shrink and the quantization error becomes smaller. For the considered model there are two sources of error/noise: additive noise and quantization error.

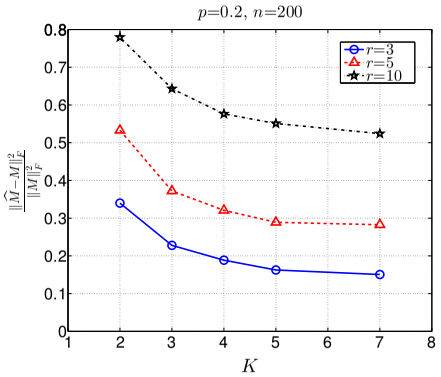

Figure 4: Relative MSE $\|\widehat{M} - M\|_F^2/\|M\|_F^2$ for varied values of K, $p = 0.2$, $n = 200$, $\alpha = 1$, Gaussian noise with $\sigma = 0.18$.

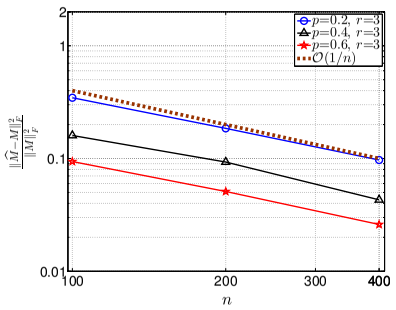
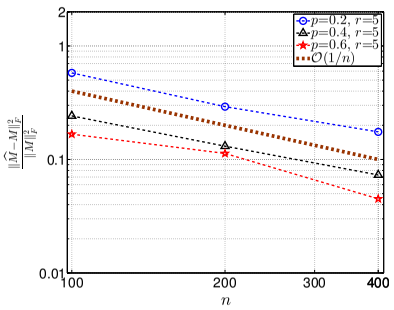
In Figure 5 we show the relative MSE for $r = 3$, 5 and 10, respectively, and $n = 100, 200, 400$, $p = q = 0.2, 0.4, 0.6$. In Section 3.2 (see Equation 22), the upper bound on MSE was established as $\min\left(\mathcal{O}\left(\frac{r^3}{p^4 n}\right), \mathcal{O}\left(\sqrt{\frac{r^3 \log(n)}{p^3 n}}\right)\right)$. Therefore, for fixed r and p, the bound is $\mathcal{O}\left(\frac{1}{n}\right)$, whereas for fixed n and p, the bound is $\mathcal{O}\left(r^{1.5}\right)$, and for fixed n and r, the bound is $\mathcal{O}\left(p^{-1.5}\right)$. We also plot the lines $1/n$ in Figure 5 to show the scale of the upper bound $\mathcal{O}(1/n)$ for fixed r and p. As we can see, the empirical estimation errors follow approximately the same scaling, suggesting that our analysis is tight with respect to n, up to some constant. In Figures 6 and 7 we show the relative MSE as a function of r and p, respectively, for $p = q = 0.2$ and $n = 100, 200, 400$. We also plot the lines $r^{1.5}$ and $1/p^{1.5}$ in Figures 6 and 7, respectively, to show the scale of the upper bound $\mathcal{O}\left(r^{1.5}\right)$ for fixed n and p, and the upper bound $\mathcal{O}\left(1/p^{1.5}\right)$ for fixed n and r. Now we see that these bounds are not tight. The empirical MSE results are approximately $\mathcal{O}(r)$ for fixed n and p and $\mathcal{O}(1/p)$ for fixed n and r.

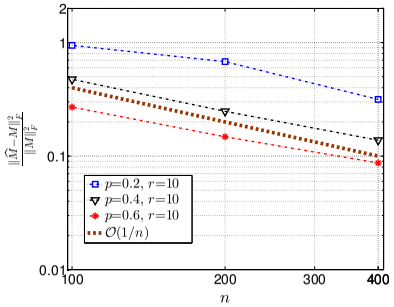
In Figure 8 we additionally plot the relative MSE for $n = 200$ and rank $r = 5$, via the same method described above, but with varying p and keeping $p+q = 0.7$, under the probit model. This enables us to study the performance of the model under nonuniform sampling. Note that when $p = q = 0.35$, then the spectral gap is largest (Bhojanapalli and Jain, 2014) and the MSE is the smallest, and as p gets larger, the spectral gap decreases, leading to larger MSE.



(a) $r = 3$



(b) $r = 5$



(c) $r = 10$

Figure 5: Relative MSE: $K = 5$, $p = q$, $r = 3$, 5 or 10, $n = 100$, 200, 400, known bin boundaries, $\alpha = 1$, Gaussian noise $\sigma = 0.18$.

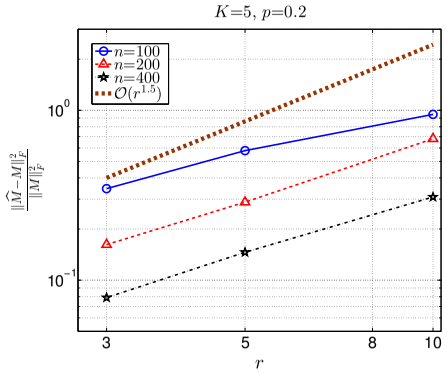


Figure 6: Relative MSE $\|\widehat{M} - M\|_F^2 / \|M\|_F^2$ for varied values of r, $p = 0.2$, $K = 5$, $\alpha = 1$, Gaussian noise with $\sigma = 0.18$.

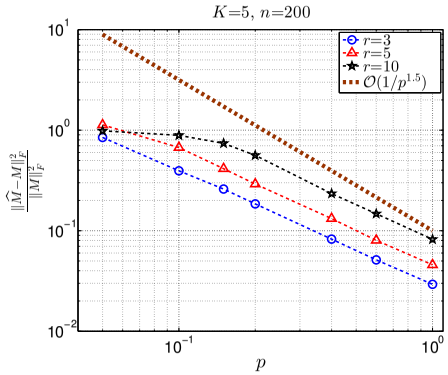

Figure 7: Relative MSE $\|\widehat{M} - M\|_F^2 / \|M\|_F^2$ for varied values of p, $n = 200$, $K = 5$, $\alpha = 1$, Gaussian noise with $\sigma = 0.18$.

5.2 MovieLens Dataset

Now we consider the MovieLens 1M dataset (available from http://www.grouplens.org) consisting of 1,000,000 movie ratings on a scale from 1 to 5, from 6040 users on 3952 movies (95.8% missing entries). A given set of ratings has a matrix representation with rows representing the users and columns representing the movies, and the (i, j)th entry of the matrix is non-zero if user i has given a rating for movie j. Thus estimating the remaining ratings in the matrix corresponds to a matrix completion problem. We consider

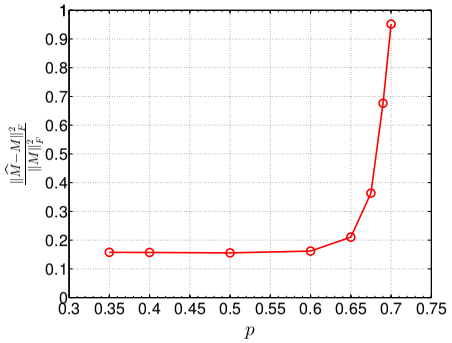

Figure 8: Relative MSE versus p, known bin boundaries, fixed $p+q=0.7$, $K=5$, $n=200$, Gaussian noise $\sigma=0.18$.

20 independent realizations of 80%/20% training/test splits of the 1 million revealed entries. For each data split, we train the proposed Algorithms 1 and 3, and the approaches OptSpace (Keshavan et al., 2009, 2010) and SVT (Cai et al., 2010), on the training set and compare their performance on the corresponding test set in predicting the revealed matrix entries in the test set. For implementation of OptSpace and SVT, we used the code made available by the authors online. Let Ω_T denote the test set, Y_{ij} the original rating in the data set and $\widehat{Y}_{ij}$ the predicted rating of user i for movie j. For performance assessment, we use the normalized mean absolute error (NMAE) and the root mean-square error (RMSE) in prediction on test set, defined as

$$RMSE = \sqrt{\frac{1}{|\Omega_T|}\sum_{(i,j)\in\Omega_T}\left(Y_{ij}-\widehat{Y}_{ij}\right)^2},$$

$$NMAE = \frac{1}{|\Omega_T|(Y_{max}-Y_{min})}\sum_{(i,j)\in\Omega_T}|Y_{ij}-\widehat{Y}_{ij}|,$$

where Y_{max} and Y_{min} are the upper and lower bounds, respectively, on the ratings (5 and 1, respectively). Both metrics are widely used for evaluation of prediction accuracy (Gunawardana and Shani, 2009); for instance, RMSE has been used in Salakhutdinov and Mnih (2008) and NMAE in Keshavan et al. (2009).

Remark 2 *Estimation of missing entries of Y. In many applications such as this one, one may wish to estimate missing discrete Y_{ij}s instead of (or in addition to) the continuous-valued M. We will use the model (1). If one wishes to pick the estimate $\widehat{Y}_{ij}$ of Y_{ij} given M_{ij}, to minimize the MSE $\mathbb{E}\{[\widehat{Y}_{ij}-Y_{ij}]^2\}$, then $\widehat{Y}_{ij}=\mathbb{E}\{Y_{ij}\,|\,M_{ij}\}=\sum_{\ell=1}^{K}\ell\, f_\ell(M_{ij})$. If, on the other hand, the optimality criterion is the MAE $\mathbb{E}\{|\widehat{Y}_{ij}-Y_{ij}|\}$, then given M_{ij}, $\widehat{Y}_{ij}$ is a*

MovieLens 1M		
Approach	RMSE	NMAE

Alg. 3 (log-barrier + unknown bins): probit	0.8580 ± 0.0027	0.1561 ± 0.0005
OptSpace	0.8947 ± 0.0033	0.1767 ± 0.0006
SVT	0.9023 ± 0.0014	0.1754 ± 0.0003

Table 1: Test data RMSE and NMAE (± one standard deviation) averaged over 20 realizations of 80%/20% training/test splits drawn from MovieLens 1M data

median of conditional distribution $f_\ell(M_{ij})$. For the model (1)-(4), if $\Phi(0)=0.5$ (true for the logistic and probit models considered in this paper), then a median of $f_\ell(M_{ij})$ is given by $\mathcal{Q}(M_{ij})$. These estimators are used with M_{ij} replaced with the estimated $\widehat{M}_{ij}$.

For Algorithm 1 we used $\alpha=1$, $\text{rank}(M)=7$, the logistic model with $\sigma=1/16$, and considered fixed bin boundaries $\omega_1^0=-0.6$, $\omega_2^0=-0.2$, $\omega_3^0=0.2$ and $\omega_4^0=0.6$ spaced (arbitrarily) uniformly over $[-\alpha,\alpha]$ to get equal width bins. An alternative initialization would be to pick the bin boundaries to match the distribution of the revealed entries. Let p_ℓ denote the fraction of revealed entries with $Y_{ij}=\ell$. Then a reasonable choice is to satisfy $\Phi(\omega_\ell)-\Phi(\omega_{\ell-1})=p_\ell$, leading to $\omega_0^0=-\infty$, $\omega_L^0=\infty$, and $\omega_\ell^0=\Phi^{-1}(\sum_{i=1}^{\ell}p_i)$ for $\ell=1,\cdots,L-1$. For a given choice of α, this requires a proper choice of σ to ensure that ω_ℓ, $\ell=1,\cdots,L-1$, are within $[-\alpha,\alpha]$. Note that scaling the variables, M, α, σ, and the bin boundaries by the same factor will lead to the same likelihood for observed data. Since we fixed (arbitrarily) $\alpha=1$, different values of σ, the bin boundaries, and X will lead to a different likelihood for the observed data.

For Algorithm 3, based on additional optimization w.r.t. $\boldsymbol{\omega}$, we used $\alpha=1$, $\text{rank}(M)=7$, initialization $\omega_1^0=-0.6$, $\omega_2^0=-0.2$, $\omega_3^0=0.2$ and $\omega_4^0=0.6$, and either the logistic model with $\sigma=1/16$, or the probit model with $\sigma=1/13$. The results (RMSE and NMAE) averaged over 20 runs are shown in Table 1. It is seen that our methods outperform OptSpace and SVT under both performance measures, and fixed bin boundaries also yield useful and improved predictions. Tran et al. (2012) reported the results shown in Table 2 for their Matrix Cumulative RBM (restricted Boltzmann machines) based method and the OrdRec method of Koren and Sill (2011, 2013) when tested on the MovieLens 1M dataset; both these approaches are based on a quantization observation model. Comparing Tables 1 and 2 we see that our methods outperform OrdRec and Matrix Cumulative RBM under both performance measures.

Acknowledgments

I would like to thank Andrea Montanari and Adel Javanmard for helpful discussions.

Appendix A. Proof of a Technical Lemma

Here we provide a proof of the assertion made in Section 3.1 (after Equation 9) that $f_\ell(X_{ij})$ is log-concave in ω_k for fixed X and ω_is ($i \neq k$) for log-concave $\Phi(x)$.

Lemma 3 *The probability $f_\ell(X_{ij})$ defined in (4) is log-concave in ω_k for fixed X and ω_is ($i \neq k$) for log-concave $\Phi(x)$.*

Proof We have $f_\ell(x) = \Phi(\omega_\ell - x) - \Phi(\omega_{\ell-1} - x)$. Therefore, it is obviously log-concave in ω_i, $i \in [K-1]$, $i \neq \ell$ or $\ell - 1$. By p. 121, Problem 3.48, of Boyd and Vandenberghe (2004) $\Phi(\omega_\ell - x) - \Phi(\omega_{\ell-1} - x)$ is log-concave in ω_ℓ for fixed x and $\omega_{\ell-1}$. To show that $\Phi(\omega_\ell - x) - \Phi(\omega_{\ell-1} - x)$ is log-concave in $\omega_{\ell-1}$ for fixed x and ω_ℓ, we will modify a proof given in Prop. 1 of An (1995) to prove log-concavity of $1 - \Phi(x)$ in x. Let $\phi(x) = \frac{d\Phi(x)}{dx} \geq 0$. Then with $y_0 = \omega_\ell - x$ and $y = \omega_{\ell-1} - x$, we have $y_0 > y$ for every x,

$$s(y) := \Phi(\omega_\ell - x) - \Phi(\omega_{\ell-1} - x) = \int_y^{y_0} \phi(u)\, du \geq 0$$

and

$$h(y) := -\frac{d \log s(y)}{dy} = \frac{\phi(y)}{s(y)}.$$

By Prop. 1 of An (1995), $s(y)$ is log-concave iff $h(y)$ is non-decreasing is y. For $y_1 < y_2$, we have

$$\begin{aligned}
& h(y_2) - h(y_1) \geq 0 \\
\iff & \phi(y_2)s(y_1) - \phi(y_1)s(y_2) \\
& = \phi(y_2) \int_{y_1}^{y_0} \phi(u)\, du - \phi(y_1) \int_{y_2}^{y_0} \phi(u)\, du \\
& = \int_0^{y_0 - y_2} [\phi(y_2)\phi(y_1 + v) - \phi(y_1)\phi(y_2 + v)]\, dv + \int_{y_0 - y_2}^{y_0 - y_1} \phi(y_2)\phi(y_1 + v) dv \\
& \geq 0
\end{aligned}$$

where we have used the fact that $\int_{y_0 - y_2}^{y_0 - y_1} \phi(y_2)\phi(y_1 + v) dv \geq 0$ since the integrand is non-negative and $y_1 < y_2$, and since $\phi(x)$ is log-concave, by Lemma 1 of An (1995)

$$\int_0^{y_0 - y_2} [\phi(y_2)\phi(y_1 + v) - \phi(y_1)\phi(y_2 + v)]\, dv \geq 0.$$

Thus, for fixed x and ω_ℓ, $s(y)$ is log-concave in y, hence, in $\omega_{\ell-1}$. ■

Appendix B. Proof of Theorem 1

Our proof is based on a second-order Taylor series expansion and a matrix concentration inequality. Let $\theta = \text{vec}(X) \in \mathbb{R}^{mn}$ and $\tilde{F}_{\Omega,Y}(\theta) = F_{\Omega,Y}(X)$. The objective function $F_{\Omega,Y}(X)$ is continuous in X and the set $\mathcal{C}$ is compact, therefore, $F_{\Omega,Y}(X)$ achieves a minimum in $\mathcal{C}$. If $\hat{\theta} = \text{vec}(\widehat{M})$ minimizes $\tilde{F}_{\Omega,Y}(\theta)$ subject to the constraints, then $\tilde{F}_{\Omega,Y}(\hat{\theta}) \leq \tilde{F}_{\Omega,Y}(\theta^*)$ where $\theta^* = \text{vec}(M)$. By the second-order Taylor's theorem, expanding around θ^* we have

$$\tilde{F}_{\Omega,Y}(\theta) = \tilde{F}_{\Omega,Y}(\theta^*) + \langle \nabla_\theta \tilde{F}_{\Omega,Y}(\theta^*), \theta - \theta^* \rangle + \frac{1}{2} \langle \theta - \theta^*, \left(\nabla^2_{\theta\theta} \tilde{F}_{\Omega,Y}(\tilde{\theta}) \right) (\theta - \theta^*) \rangle \qquad (33)$$

where $\tilde{\theta} = \theta^* + \gamma(\theta - \theta^*)$ for some $\gamma \in [0, 1]$, with corresponding matrices $\tilde{X} = M + \gamma(X - M)$. We need several auxiliary results before we can prove Theorem 1.

We need the following result from Chatterjee (2013) concerning spectral norms of random matrices for Lemma 5.

Lemma 4 *(Theorem 8.4 of Chatterjee (2013)) Take any two numbers m and n such that $1 \leq n \leq m$. Suppose that $A = [a_{ij}]_{1 \leq i \leq m, 1 \leq j \leq n}$ is a matrix whose entries are independent random variables that satisfy, for some $\sigma^2 \in [0, 1]$,*

$$\mathbb{E}[a_{ij}] = 0,\ \mathbb{E}[a_{ij}^2] \leq \sigma^2,\ \text{and } |a_{ij}| \leq 1\ a.s.$$

Suppose that $\sigma^2 \geq m^{-1+\varepsilon}$ for some $\varepsilon > 0$. Then

$$P\left(\|A\|_2 \geq 2.01\sigma\sqrt{m} \right) \leq C_1(\varepsilon) e^{-C_2 \sigma^2 m},$$

where $C_1(\varepsilon)$ is a constant that depends only on ε and C_2 is a positive universal constant. The same result is true when $m = n$ and A is symmetric or skew-symmetric, with independent entries on and above the diagonal, all other assumptions remaining the same. Lastly, all results remain true if the assumption $\sigma^2 \geq m^{-1+\varepsilon}$ is changed to $\sigma^2 \geq m^{-1}(\log(m))^{6+\varepsilon}$.

Using (6), it follows that

$$\frac{\partial F_{\Omega,Y}(X)}{\partial X_{ij}} = -\left(\sum_{\ell=1}^{K} \frac{\dot{f}_\ell(X_{ij})}{f_\ell(X_{ij})} \mathbf{1}_{[Y_{ij} = \ell]} \right) \mathbf{1}_{[(i,j) \in \Omega]}, \qquad (34)$$

$$\frac{\partial^2 F_{\Omega,Y}(X)}{\partial X_{ij}^2} = \sum_{\ell=1}^{K} \left(\frac{\dot{f}_\ell^2(X_{ij})}{f_\ell^2(X_{ij})} - \frac{\ddot{f}_\ell(X_{ij})}{f_\ell(X_{ij})} \right) \mathbf{1}_{[Y_{ij} = \ell]} \mathbf{1}_{[(i,j) \in \Omega]} \qquad (35)$$

and

$$\frac{\partial^2 F_{\Omega,Y}(X)}{\partial X_{i_1 j_1} \partial X_{i_2 j_2}} = 0 \text{ if } (i_1, j_1) \neq (i_2, j_2). \tag{36}$$

Let $w = \mathrm{vec}(X^{(1)} - M) = \theta^{(1)} - \theta^*$; for later use, we would like $\theta^{(1)}$ in w to be not necessarily equal to θ in the gradient or the Hessian of the objective function. Using (34) and the notation

$$\nabla_\theta \tilde{F}_{\Omega,Y}(\theta^*) = \mathrm{vec}\left(\left[\frac{\partial F_{\Omega,Y}(X)}{\partial X_{ij}} \right] \Big|_{X=M} \right) = \mathrm{vec}\left(\left[\frac{\partial F_{\Omega,Y}(M)}{\partial X_{ij}} \right] \right),$$

we have

$$\langle \nabla_\theta \tilde{F}_{\Omega,Y}(\theta^*), w \rangle = \langle \nabla_X F_{\Omega,Y}(M), X^{(1)} - M \rangle \tag{37}$$

where $\langle A, B \rangle := \mathrm{tr}(A^\top B)$, $|\langle A, B \rangle| \leq \|A\|_2 \|B\|_*$, $\|B\|_*$ is the nuclear (or Schatten) norm of B, and

$$[\nabla_X F_{\Omega,Y}(M)]_{ij} =: z_{ij} = -\left(\sum_{\ell=1}^{K} \frac{\dot{f}_\ell(M_{ij})}{f_\ell(M_{ij})} \mathbf{1}_{[Y_{ij}=\ell]} \right) \mathbf{1}_{[(i,j)\in\Omega]}. \tag{38}$$

Using (1), (11), and the fact that $\sum_{\ell=1}^{K} f_\ell(X_{ij}) = 1$, we have

$$\mathbb{E}[z_{ij}] = -\left(\sum_{\ell=1}^{K} \dot{f}_\ell(M_{ij}) \right) \mathbf{1}_{[(i,j)\in\Omega]} = 0, \tag{39}$$

and

$$|z_{ij}| \leq L_\alpha \implies \mathbb{E}[z_{ij}^2] \leq L_\alpha^2. \tag{40}$$

Lemma 5 *Let $w = \mathrm{vec}(X^{(1)} - M) = \theta^{(1)} - \theta^*$ and $X^{(1)}, M \in \mathcal{C}$. Then with probability at least $1 - C_1(\varepsilon)\exp(-C_2 m)$, we have*

$$\left| \langle \nabla_\theta \tilde{F}_{\Omega,Y}(\theta^*), w \rangle \right| \leq 2.01 L_\alpha \sqrt{2rm} \|X^{(1)} - M\|_F,$$

where $\varepsilon \in (0,1)$, $C_1(\varepsilon)$ is a constant that depends only on ε and C_2 is a positive universal constant.

Proof Using (37), we have

$$\begin{aligned} |\langle \nabla_\theta \tilde{F}_{\Omega,Y}(\theta^*), w \rangle| &= |\langle \nabla_X F_{\Omega,Y}(M), X^{(1)} - M \rangle| \\ &\leq \|\nabla_X F_{\Omega,Y}(M)\|_2 \|X^{(1)} - M\|_*. \end{aligned} \tag{41}$$

Consider $\tilde{z}_{ij} := \left[L_\alpha^{-1} \nabla_X F_{\Omega,Y}(M) \right]_{ij}$. Then we have $\mathbb{E}[\tilde{z}_{ij}] = 0$, $|\tilde{z}_{ij}| \leq 1$ and $\mathbb{E}[\tilde{z}_{ij}^2] \leq 1$. We will apply Lemma 4 to $L_\alpha^{-1} \nabla_X F_{\Omega,Y}(M)$, for which we have to ensure that $\mathbb{E}[\tilde{z}_{ij}^2] \leq \sigma^2$ and $m^{-1+\varepsilon} \leq \sigma^2$ for some $\varepsilon > 0$. Therefore, we pick $\sigma^2 = 1 = \max\left(1, \frac{1}{m^{1-\varepsilon}}\right)$. Hence, by Lemma 4, $\|L_\alpha^{-1} \nabla_X F_{\Omega,Y}(M)\|_2 \leq 2.01\sqrt{m}$ with probability at least $1 - C_1(\varepsilon)\exp(-C_2 m)$ for some positive constants $C_1(\varepsilon)$ and C_2. Since for any rank r matrix A, $\|A\|_* \leq \sqrt{r}\|A\|_F$, we have $\|X^{(1)} - M\|_* \leq \sqrt{2r}\|X^{(1)} - M\|_F$, yielding the desired result. ■

Lemma 6 *Let $w = \mathrm{vec}(X - M) = \theta - \theta^*$ and $X, M \in \mathcal{C}$. Then with probability at least $1 - 2(9\alpha\sqrt{mn})^{-r(m+n+1)} - C_1\exp(-C_2 m)$, we have*

$$\left| \langle \nabla_\theta \tilde{F}_{\Omega,Y}(\theta^*), w \rangle \right| \leq 4(1+\alpha) L_\alpha \sqrt{|\Omega| r (m+n+1) \log(9\alpha\sqrt{mn})}.$$

Proof Define the set $S_{rK} = \{X \in \mathbb{R}^{m\times n} : \mathrm{rank}(X) \leq r,\ \|X\|_F \leq K\}$ for some $K > 0$. By Lemma A.2 in the supplementary material of Wang and Xu (2012) (which is based on Lemma 3.1 in Candes and Plan (2011)), there exists a 1-net for the Frobenius norm, $\overline{S}_{rK}(1) = \{Q \in \mathbb{R}^{m\times n} : \mathrm{rank}(Q) \leq r,\ \|X - Q\|_F \leq 1\} \subset S_{rK}$ with its cardinality $|\overline{S}_{rK}(1)| \leq (9K)^{(m+n+1)r}$. That is, given any $X \in S_{rK}$, there exists $Q \in \overline{S}_{rK}(1) \subset S_{rK}$ such that $\|X - Q\|_F \leq 1$. Suppose that $X \in S_{rK}$ is such that $\|X\|_\infty \leq \alpha$. Then for $Q \in \overline{S}_{rK}(1)$, we have

$$\|Q\|_\infty \leq \|Q - X\|_\infty + \|X\|_\infty \leq \|Q - X\|_F + \|X\|_\infty \leq 1 + \alpha. \tag{42}$$

Also, $\|X\|_F \leq \sqrt{mn}\|X\|_\infty \leq \alpha\sqrt{mn}$. For $X, M \in S_{rK}$ and $Q \in \overline{S}_{rK}(1)$, consider

$$\begin{aligned} u_X &:= \langle \nabla_\theta \tilde{F}_{\Omega,Y}(\theta^*), w \rangle = \langle \nabla_X F_{\Omega,Y}(M), X - M \rangle \\ &= \langle \nabla_X F_{\Omega,Y}(M), Q - M \rangle + \langle \nabla_X F_{\Omega,Y}(M), X - Q \rangle = u_Q + \langle \nabla_X F_{\Omega,Y}(M), X - Q \rangle. \end{aligned} \tag{43}$$

Therefore, for any $X \in S_{rK}$ and corresponding $Q \in \overline{S}_{rK}(1)$, we have

$$\begin{aligned} |u_X| &\leq |u_Q| + |\langle \nabla_X F_{\Omega,Y}(M), X - Q \rangle| \\ &\leq |u_Q| + \|\nabla_X F_{\Omega,Y}(M)\|_2 \|X - Q\|_* \\ &\leq |u_Q| + 2.01 L_\alpha \sqrt{2rm} \ \text{ with probability } \geq 1 - C_1\exp(-C_2 m) \end{aligned} \tag{44}$$

where in the last inequality we have used Lemma 5 with $C_1 = C_1(1/2)$, and the fact that $\|X - Q\|_F \leq 1$ and both X and Q are of rank r. Now consider u_Q and rewrite it as

$$u_Q = \sum_{(i,j)\in\Omega} h_{ij} \ \text{ where } \ h_{ij} = \frac{\partial F_{\Omega,Y}(M)}{\partial X_{ij}} (Q_{ij} - M_{ij}).$$

We have $\mathbb{E}[h_{ij}] = 0$ (see Equations 38 and 39), and

$$\begin{aligned} |h_{ij}| &\leq \left| \frac{\partial F_{\Omega,Y}(M)}{\partial X_{ij}} \right| \times |Q_{ij} - M_{ij}| \\ &\leq L_\alpha(|Q_{ij}| + |M_{ij}|) \leq L_\alpha(1 + 2\alpha) =: \beta_\alpha. \end{aligned} \tag{45}$$

Apply the Hoeffding inequality to u_Q to obtain

$$\mathbb{P}\left(|u_Q| > t \right) \leq 2\exp\left(-2\frac{t^2}{|\Omega|\beta_\alpha^2} \right).$$

Set $K = \alpha\sqrt{mn}$ (since $\|X\|_F \leq \alpha\sqrt{mn}$) and apply the union bound over all $Q \in \overline{S}_{rK}(1)$ to obtain

$$\begin{aligned} \mathbb{P}\left(\cup_{Q\in\overline{S}_{rK}(1)} \{|u_Q| > t\} \right) &\leq 2\left(9\alpha\sqrt{mn}\right)^{(m+n+1)r} \exp\left(-2\frac{t^2}{|\Omega|\beta_\alpha^2} \right) \\ &\leq 2\exp\left(-\frac{2t^2}{|\Omega|\beta_\alpha^2} + (m+n+1)r\log\left(9\alpha\sqrt{mn}\right) \right). \end{aligned}$$

We pick

$$t = \beta_\alpha \sqrt{|\Omega|(m+n+1)r\log\left(9\alpha\sqrt{mn}\right)} \tag{46}$$

to achieve

$$\begin{aligned}\mathbb{P}\left(\cup_{Q\in\overline{S}_{rK}(1)}\{|u_Q|>t\}\right) &\le 2\exp\left(-(m+n+1)r\log\left(9\alpha\sqrt{mn}\right)\right)\\ &= \frac{2}{(9\alpha\sqrt{mn})^{r(m+n+1)}}.\end{aligned} \tag{47}$$

Now using (44)-(47), the union bound and the fact that the chosen $t > 2.01L_\alpha\sqrt{2rm}$, we have the desired result. ■

Lemma 7 *Let $w = \mathrm{vec}(X^{(1)} - M) = \theta^{(1)} - \theta^*$ and $X^{(1)}, X, M \in \mathcal{C}$. Then for any $\tilde{\theta} = \theta^* + \gamma(\theta - \theta^*)$ and any $\gamma \in [0,1]$, we have*

$$\langle w, \left[\nabla^2_{\theta\theta}\tilde{F}_{\Omega,Y}(\tilde{\theta})\right] w\rangle \ge \gamma_\alpha \left\|\left(X^{(1)} - M\right)_\Omega\right\|_F^2$$

where $X_\Omega = X_{ij}$ if $(i,j)\in\Omega$, and $= 0$ otherwise.

Proof Using (10), (35) and (36), we have

$$\begin{aligned}\langle w, \left[\nabla^2_{\theta\theta}\tilde{F}_{\Omega,Y}(\tilde{\theta})\right] w\rangle &= \sum_{(i,j)\in\Omega}\left(\frac{\partial^2 F_{\Omega,Y}(\tilde{X})}{\partial X_{ij}^2}\right)(X^{(1)}_{ij} - M_{ij})^2\\ &\ge \gamma_\alpha \sum_{(i,j)\in\Omega}(X^{(1)}_{ij} - M_{ij})^2 = \gamma_\alpha\left\|\left(X^{(1)} - M\right)_\Omega\right\|_F^2.\end{aligned} \tag{48}$$

■

We need a result similar to Theorem 4.1 of Bhojanapalli and Jain (2014) regarding closeness of a fixed matrix to its sampled version, which is proved therein for square matrices M under an incoherence assumption on M. In Lemma 8 we prove a similar result for rectangular Z with bounded $\|Z\|_\infty$. Take $Z \in \mathbb{R}^{m\times n}$, $m \ge n$, and as in Lemma 7, define the operator $\mathcal{R}_\Omega$ as $Z_\Omega := \mathcal{R}_\Omega(Z) = Z_{ij}$ if $(i,j)\in\Omega$, and $= 0$ otherwise.

Lemma 8 *Let $G\backslash\Omega$ satisfy assumptions (A1) and (A2) in Section 2. Let $Z \in \mathbb{R}^{m\times n}$ have rank $\le r$. Then we have*

$$\left\|\left(\frac{\sqrt{mn}}{\sigma_1(G)}R_\Omega - I\right)(Z)\right\|_2 \le \frac{\sqrt{mn}\sigma_2(G)}{\sigma_1(G)}\|Z\|_{\max} \tag{49}$$

$$\le \frac{\sqrt{rmn}\sigma_2(G)}{\sigma_1(G)}\|Z\|_\infty \le Cm\sqrt{\frac{nr}{|\Omega|}}\|Z\|_\infty. \tag{50}$$

Proof Normalize $\mathbf{1}_m$ to unit norm as $\tilde{\mathbf{1}}_m = \mathbf{1}_m/\sqrt{m}$, and similarly for $\tilde{\mathbf{1}}_n$. It then follows from the properties (A1)-(A2) that

$$G = \sigma_1(G)\tilde{\mathbf{1}}_m\tilde{\mathbf{1}}_n^\top + \sum_{i=2}^n \sigma_i(G)U_iV_i^\top \tag{51}$$

where the SVD of G is $G = U\Sigma_G V^\top$ and U_i is the i-th column of U. First some preliminaries. If $\mathrm{rank}(Z) \le r$, then we have $\|Z\|_{\max} \le \sqrt{r}\|Z\|_\infty$. By the factored form definition of the max norm (Lee et al., 2010), we have $\|Z\|_{\max} = \inf\left\{\max(\|\bar{U}\|^2_{2,\infty}, \|\bar{V}\|^2_{2,\infty}) : Z = \bar{U}\bar{V}^\intercal\right\}$ where $\|\bar{U}\|_{2,\infty} = \max_i\sqrt{\sum_j \bar{U}_{ij}^2}$, $\bar{U}\in\mathbb{R}^{m\times k}$, $\bar{V}\in\mathbb{R}^{n\times k}$, $k = 1, 2, \cdots, \min(m,n) = n$. Hence, there exist $U_Z \in \mathbb{R}^{m\times k}$ and $V_Z \in \mathbb{R}^{n\times k}$ for some $1 \le k \le \min(m,n)$ such that $Z = U_Z V_Z^\top$, $\|U_Z\|^2_{2,\infty} \le \|Z\|_{\max}$ and $\|V_Z\|^2_{2,\infty} \le \|Z\|_{\max}$. For Z of rank $\le r$, one should have $k \le r$, but this fact is not needed in our proof. We now follow the proof of Theorem 4.1 of Bhojanapalli and Jain (2014) with $Z = \sum_{i=1}^k U_{Zi}V_{Zi}^\top$. Note that

$$\|\frac{\sqrt{mn}}{\sigma_1(G)}R_\Omega(Z) - Z\|_2 = \max_{x,y:\,\|x\|_2=1=\|y\|_2} y^\top\left(\frac{\sqrt{mn}}{\sigma_1(G)}R_\Omega(Z) - Z\right)x.$$

As in the proof of Theorem 4.1 of Bhojanapalli and Jain (2014), noting that $R_\Omega(Z) = Z\circ G$ where $\circ$ denotes the Hadamard (elementwise) product, we have

$$y^\top\left(\frac{\sqrt{mn}}{\sigma_1(G)}\mathcal{R}_\Omega(Z) - Z\right)x = \sum_{i=1}^k\left(\frac{\sqrt{mn}}{\sigma_1(G)}(y\circ U_{Zi})^\top G(x\circ V_{Zi}) - (y^\top U_{Zi})(x^\top V_{Zi})\right). \tag{52}$$

Let $y\circ U_{Zi} = \alpha_i\tilde{\mathbf{1}}_m + \beta_i\tilde{\mathbf{1}}^i_{m\perp}$ where $\tilde{\mathbf{1}}^i_{m\perp}$ is a unit norm vector orthogonal to $\tilde{\mathbf{1}}_m$. Then $\alpha_i = \tilde{\mathbf{1}}_m^\top(y\circ U_{Zi}) = y^\top U_{Zi}/\sqrt{m}$. Using the fact that $\tilde{\mathbf{1}}_m^\top G = \sigma_1(G)\tilde{\mathbf{1}}_n^\top$, we have

$$\begin{aligned}&y^\top\left(\frac{\sqrt{mn}}{\sigma_1(G)}\mathcal{R}_\Omega(Z) - Z\right)x\\ &= \sum_{i=1}^k\left(\frac{\sqrt{mn}}{\sigma_1(G)}\left[(1/\sqrt{m})y^\top U_{Zi}\tilde{\mathbf{1}}_m^\top G(x\circ V_{Zi}) + \beta_i\tilde{\mathbf{1}}^{i\top}_{m\perp}G(x\circ V_{Zi})\right] - (y^\top U_{Zi})(x^\top V_{Zi})\right)\\ &= \sum_{i=1}^k\left(\frac{\sqrt{mn}}{\sigma_1(G)}\beta_i\tilde{\mathbf{1}}^{i\top}_{m\perp}G(x\circ V_{Zi})\right)\end{aligned} \tag{53}$$

where we have also used $\tilde{\mathbf{1}}_n^\top(x\circ V_{Zi}) = x^\top V_{Zi}/\sqrt{n}$. Using the SVD (51) of G, we have

$$\tilde{\mathbf{1}}^{i\top}_{m\perp}G = \sum_{\ell=2}^n \sigma_\ell(G)(\tilde{\mathbf{1}}^{i\top}_{m\perp}U_\ell)V_\ell^\top$$

$$\implies |\tilde{\mathbf{1}}^{i\top}_{m\perp}Gz| \le \sigma_2(G)\|z\|_2 \text{ for any } z\in\mathbb{R}^n.$$

Using the above inequality in (53) we obtain

$$y^\top \left(\frac{\sqrt{mn}}{\sigma_1(G)} R_\Omega(Z) - Z \right) x \leq \frac{\sqrt{mn}}{\sigma_1(G)} \sigma_2(G) \sum_{i=1}^{k} |\beta_i| \|x \circ V_{Zi}\|_2$$
$$\leq \frac{\sqrt{mn}}{\sigma_1(G)} \sigma_2(G) \sqrt{\sum_{i=1}^{k} \beta_i^2} \sqrt{\sum_{i=1}^{k} \|x \circ V_{Zi}\|_2^2} \,. \tag{54}$$

We have $\beta_i = \tilde{\mathbf{1}}_{m\perp}^{i\top}(y \circ U_{Zi})$, hence, $|\beta_i| \leq \|(y \circ U_{Zi})\|_2$. Therefore,

$$\sum_{i=1}^{k} \beta_i^2 \leq \sum_{i=1}^{k} \|(y \circ U_{Zi})\|_2^2 = \sum_{j=1}^{m} \sum_{i=1}^{k} y_j^2 U_{Zji}^2$$
$$\leq \sum_{j=1}^{m} y_j^2 \|U_Z^j\|_2^2 \leq \|U_Z\|_{2,\infty}^2 \sum_{j=1}^{m} y_j^2 \leq \|Z\|_{\max} \tag{55}$$

where U_Z^j denotes the jth row of U_Z and $\sum_{j=1}^m y_j^2 = 1$. Similarly, we have

$$\sum_{i=1}^{k} \|x \circ V_{Zi}\|_2^2 = \sum_{j=1}^{n} \sum_{i=1}^{k} x_j^2 V_{Zji}^2 \leq \sum_{j=1}^{n} x_j^2 \|\tilde{V}_Z^j\|_2^2$$
$$\leq \|\tilde{V}_Z\|_{2,\infty}^2 \sum_{j=1}^{n} x_j^2 \leq \|Z\|_{\max} \,. \tag{56}$$

It then follows from (54)-(56) that

$$y^\top \left(\frac{\sqrt{mn}}{\sigma_1(G)} R_\Omega(Z) - Z \right) x \leq \frac{\sqrt{mn}\sigma_2(G)}{\sigma_1(G)} \|Z\|_{\max}$$
$$\implies \|\frac{\sqrt{mn}}{\sigma_1(G)} R_\Omega(Z) - Z\|_2 \leq \frac{\sqrt{mn}\sigma_2(G)}{\sigma_1(G)} \|Z\|_{\max}. \tag{57}$$

This establishes (49). Now use the facts $\|Z\|_{\max} \leq \sqrt{r}\|Z\|_\infty$ and $|\Omega| = md$ to establish (50). ■

Lemma 9 *Let $X, M \in \mathcal{C}$. Then we have*

$$\|(X - M)_\Omega\|_F \geq \frac{\sigma_1(G)}{\sqrt{2rmn}} \|X - M\|_F - 2\alpha\sqrt{r}\sigma_2(G).$$

Proof Let $Z = X - M$, $a = \sqrt{mn}/\sigma_1(G)$, and $b = (\sigma_2(G)/\sigma_1(G))\sqrt{rmn}$. Then by Lemma 8 and the fact that $\text{rank}(Z) \leq \text{rank}(X) + \text{rank}(M) \leq 2r$, we have

$$|a\|Z_\Omega\|_2 - \|Z\|_2| \leq \|aZ_\Omega - Z\|_2 \leq b\|Z\|_\infty. \tag{58}$$

Using $\|Z\|_\infty = \|X - M\|_\infty \leq \|X\|_\infty + \|M\|_\infty \leq 2\alpha$, (58) can be expressed as $\|Z\|_2 \leq a\|Z_\Omega\|_2 + 2\alpha b$. Since $\|A\|_2 \leq \|A\|_F \; \forall A$, we then have $\|Z\|_2 \leq a\|Z_\Omega\|_F + 2\alpha b$. Since $\|A\|_F \leq \sqrt{\text{rank}(A)}\|A\|_2 \; \forall A$, we have $\|Z\|_F \leq \sqrt{2r}\|Z\|_2 \leq (\sqrt{2r}a)\|Z_\Omega\|_F + \sqrt{2r}2\alpha b$, leading to the desired result. ■

We now turn to the proof of Theorem 1.

Proof of Theorem 1 The bound 2α follows from the fact that $\widehat{M}, M \in \mathcal{C}$. To establish bound U_1, we will use Lemma 5 and to establish U_2, we will use Lemma 6. We first prove U_1. Consider $\tilde{F}_{\Omega,Y}(\theta) = F_{\Omega,Y}(X)$. The objective function $F_{\Omega,Y}(X)$ is continuous in X and the set $\mathcal{C}$ is compact, therefore, $F_{\Omega,Y}(X)$ achieves a minimum in $\mathcal{C}$. Now suppose that $\widehat{M} \in \mathcal{C}$ minimizes $F_{\Omega,Y}(X)$. Then $F_{\Omega,Y}(\widehat{M}) \leq F_{\Omega,Y}(X) \; \forall X \in \mathcal{C}$, including $X = M$. Define

$$c_g = 2.01 L_\alpha \sqrt{2rm}, \quad c_h = \frac{\sigma_1^2(G)\gamma_\alpha}{4rmn}, \quad \bar{c}_h = \frac{\gamma_\alpha}{2}. \tag{59}$$

Using (33) and Lemmas 5 and 7, we have w.h.p. (specified in Lemma 5)

$$F_{\Omega,Y}(\widehat{M}) \geq F_{\Omega,Y}(M) - c_g\|\widehat{M} - M\|_F + \bar{c}_h \left\| \left(\widehat{M} - M \right)_\Omega \right\|_F^2 \,. \tag{60}$$

Since $\widehat{M}$ minimizes $F_{\Omega,Y}(X)$, we have

$$0 \geq F_{\Omega,Y}(\widehat{M}) - F_{\Omega,Y}(M)$$
$$\geq -c_g\|\widehat{M} - M\|_F + \bar{c}_h \left\| \left(\widehat{M} - M \right)_\Omega \right\|_F^2 \,. \tag{61}$$

Set

$$\eta = 2\alpha r(\sigma_2(G)/\sigma_1(G))\sqrt{2mn} \quad \text{and} \quad a_0 = \sigma_1(G)/\sqrt{2rmn} \,.$$

Then Lemma 9 implies $\|(X - M)_\Omega\|_F \geq a_0 [\|X - M\|_F - \eta]$. Now consider two cases: (i) $\|\widehat{M} - M\|_F < 2\eta$, (ii) $\|\widehat{M} - M\|_F \geq 2\eta$. In case (i), we clearly have an obvious upper bound on $\|\widehat{M} - M\|_F$. Turning to case (ii), we have

$$\|\widehat{M} - M\|_F - \eta \geq \|\widehat{M} - M\|_F - \frac{1}{2}\|\widehat{M} - M\|_F$$
$$= \frac{1}{2}\|\widehat{M} - M\|_F. \tag{62}$$

Using (61), (62) and Lemma 9 with $X = \widehat{M}$, we have

$$0 \geq F_{\Omega,Y}(\widehat{M}) - F_{\Omega,Y}(M)$$
$$\geq -c_g\|\widehat{M} - M\|_F + \frac{c_h}{4}\|\widehat{M} - M\|_F^2$$
$$= \|\widehat{M} - M\|_F \left[-c_g + \frac{c_h}{4}\|\widehat{M} - M\|_F \right]. \tag{63}$$

In order for (63) to be true, we must have $\|\widehat{M} - M\|_F \leq 4c_g/c_h$ otherwise the right-side of (63) is positive violating (63). Combining the two cases, we obtain

$$\begin{aligned}\|\widehat{M} - M\|_F &\leq \max\left(2\eta, \frac{4c_g}{c_h}\right) \\ &= \max\left(4\alpha r\sqrt{2mn}\frac{\sigma_2(G)}{\sigma_1(G)}, \frac{32.16\sqrt{2}L_\alpha(rm)^{1.5}n}{\gamma_\alpha\sigma_1^2(G)}\right). \end{aligned} \tag{64}$$

This is the bound U_1 stated in (13)-14) of the theorem after division by $\sqrt{mn}$. The high probability stated in the theorem follows from Lemma 5 after setting $\varepsilon = 0.5$. Finally, we use $(\sigma_2(G)/\sigma_1(G)) \leq (C/\sqrt{d}) = C\sqrt{m}/\sqrt{|\Omega|}$ and $(1/\sigma_1^2(G)) \leq (1/d^2) = m^2/|\Omega|^2$ to derive (14).

Finally we turn to proving U_2. Define

$$\bar{c}_g = 4(1+\alpha)L_\alpha\sqrt{|\Omega|r(m+n+1)\log(9\alpha\sqrt{mn})}. \tag{65}$$

Using (33) and Lemmas 6 and 7, we have w.h.p. (specified in Lemma 6)

$$F_{\Omega,Y}(\widehat{M}) \geq F_{\Omega,Y}(M) - \bar{c}_g + \bar{c}_h\left\|\left(\widehat{M} - M\right)_\Omega\right\|_F^2. \tag{66}$$

Arguing as earlier, we then have

$$\left\|\left(\widehat{M} - M\right)_\Omega\right\|_F \leq \sqrt{\frac{2\bar{c}_g}{\gamma_\alpha}}. \tag{67}$$

As before, we have either $\|\widehat{M} - M\|_F < 2\eta$ or $\|\widehat{M} - M\|_F \geq 2\eta$; the former yields an obvious upper bound while the latter case yields

$$\left\|\widehat{M} - M\right\|_F \leq \frac{2}{a_0}\left\|\left(\widehat{M} - M\right)_\Omega\right\|_F \leq \frac{2}{a_0}\sqrt{\frac{2\bar{c}_g}{\gamma_\alpha}}. \tag{68}$$

The stated bound U_2 in (15)-16) then follows just as U_1. This completes the proof. ■

Abstract

This paper considers optimization problems where nodes of a network have access to summands of a global objective. Each of these local objectives is further assumed to be an average of a finite set of functions. The motivation for this setup is to solve large scale machine learning problems where elements of the training set are distributed to multiple computational elements. The decentralized double stochastic averaging gradient (DSA) algorithm is proposed as a solution alternative that relies on: (i) The use of local stochastic averaging gradients. (ii) Determination of descent steps as differences of consecutive stochastic averaging gradients. Strong convexity of local functions and Lipschitz continuity of local gradients is shown to guarantee linear convergence of the sequence generated by DSA in expectation. Local iterates are further shown to approach the optimal argument for almost all realizations. The expected linear convergence of DSA is in contrast to the sublinear rate characteristic of existing methods for decentralized stochastic optimization. Numerical experiments on a logistic regression problem illustrate reductions in convergence time and number of feature vectors processed until convergence relative to these other alternatives.

Keywords: decentralized optimization, stochastic optimization, stochastic averaging gradient, linear convergence, large-scale optimization, logistic regression

1. Introduction

We consider machine learning problems with large training sets that are distributed into a network of computing agents so that each of the nodes maintains a moderate number of samples. This leads to decentralized consensus optimization problems where summands of the global objective function are available at different nodes of the network. In this class of problems agents (nodes) try to optimize the global cost function by operating on their local functions and communicating with their neighbors only. Specifically, consider a variable $\mathbf{x} \in \mathbb{R}^p$ and a connected network of size N where each node n has access to a local objective function $f_n : \mathbb{R}^p \to \mathbb{R}$. The local objective function $f_n(\mathbf{x})$ is defined as the average of q_n local instantaneous functions $f_{n,i}(\mathbf{x})$ that can be individually evaluated at node n. Agents cooperate to solve the global optimization problem

$$\tilde{\mathbf{x}}^* := \operatorname*{argmin}_{\mathbf{x}} \sum_{n=1}^{N} f_n(\mathbf{x}) = \operatorname*{argmin}_{\mathbf{x}} \sum_{n=1}^{N} \frac{1}{q_n} \sum_{i=1}^{q_n} f_{n,i}(\mathbf{x}). \tag{1}$$

The formulation in (1) models a training set with a total of $\sum_{n=1}^{N} q_n$ training samples that are distributed among the N agents for parallel processing conducive to the determination of the optimal classifier $\tilde{\mathbf{x}}^*$ (Bekkerman et al. (2011); Tsianos et al. (2012a); Cevher et al. (2014)). Although we make no formal assumption, in cases of practical importance the total number of training samples $\sum_{n=1}^{N} q_n$ is very large, but the number of elements q_n available at a specific node is moderate.

Analogous formulations are also of interest in decentralized control systems (Bullo et al. (2009); Cao et al. (2013); Lopes and Sayed (2008)), wireless systems (Ribeiro (2010, 2012)), and sensor networks (Schizas et al. (2008); Khan et al. (2010); Rabbat and Nowak (2004)). Our interest here is in solving (1) with a method that has the following three properties

- Decentralized; nodes operate on their local functions and communicate with neighbors only.
- Stochastic; nodes determine a descent direction by evaluating only one out of the q_n functions $f_{n,i}$ at each iteration.
- Linear convergence rate; the expected distance to the optimum is scaled by a subunit factor at each iteration.

Decentralized optimization is relatively mature and various methods are known with complementary advantages. These methods include decentralized gradient descent (DGD) (Nedić and Ozdaglar (2009); Jakovetic et al. (2014); Yuan et al. (2013)), network Newton (Mokhtari et al. (2015a,b)), decentralized dual averaging (Duchi et al. (2012); Tsianos et al. (2012b)), the exact first order algorithm (EXTRA) (Shi et al. (2015)), as well as the alternating direction method of multipliers (ADMM) (Boyd et al. (2011); Schizas et al. (2008); Shi et al. (2014); Iutzeler et al. (2013)) and its linearized variants (Ling and Ribeiro (2014); Ling et al. (2015); Mokhtari et al. (2015c)). The ADMM, its variants, and EXTRA converge linearly to the optimal argument but DGD, network Newton, and decentralized dual averaging have sublinear convergence rates. Of particular importance to this paper, is the fact that DGD has (inexact) linear convergence to a neighborhood of the optimal argument when it uses constant stepsizes. It can achieve exact convergence by using diminishing stepsizes, but the convergence rate degrades to sublinear. This lack of linear convergence is solved by EXTRA through the use of iterations that rely on information of two consecutive steps (Shi et al. (2015)).

All of the algorithms mentioned above require the computationally costly evaluation of the local gradients $\nabla f_n(\mathbf{x}) = (1/q_n) \sum_{i=1}^{q_n} \nabla f_{n,i}(\mathbf{x})$. This cost can be avoided by stochastic decentralized algorithms that reduce computational cost of iterations by substituting all local gradients with their stochastic approximations. This reduces the computational cost per iteration but results in sublinear convergence rates of order $O(1/t)$ even if the corresponding deterministic algorithm exhibits linear convergence. This is a drawback that also exists in centralized stochastic optimization where linear convergence rates in expectation are established by decreasing the variance of the stochastic gradient approximation (Roux et al. (2012); Schmidt et al. (2013); Shalev-Shwartz and Zhang (2013); Johnson and Zhang (2013); Konečnỳ and Richtárik (2013); Defazio et al. (2014)). In this paper we build on the ideas of the stochastic averaging gradient (SAG) algorithm (Schmidt et al. (2013)) and its unbiased version SAGA (Defazio et al. (2014)). Both of these algorithms use the idea of stochastic incremental averaging gradients. At each iteration only one of the stochastic gradients is updated and the average of all of the most recent stochastic gradients is used for estimating the gradient.

The contribution of this paper is to develop the decentralized double stochastic averaging gradient (DSA) method, a novel decentralized stochastic algorithm for solving (1). The method exploits a new interpretation of EXTRA as a saddle point method and uses stochastic averaging gradients in lieu of gradients. DSA is *decentralized* because it is implementable in a network setting where nodes can communicate only with their neighbors. It is *double* because iterations utilize the information of two consecutive iterates. It is *stochastic* because the gradient of only one randomly selected function is evaluated at each iteration and it is an *averaging* method because it uses an average of stochastic gradients to approximate the local gradients. DSA is proven to converge linearly to the optimal argument $\tilde{\mathbf{x}}^*$ in expectation when the local instantaneous functions $f_{n,i}$ are strongly convex, with Lipschitz continuous gradients. This is in contrast to all other decentralized stochastic methods to solve (1) that converge at sublinear rates.

We begin the paper with a discussion of DGD, EXTRA and stochastic averaging gradient. With these definitions in place we define the DSA algorithm by replacing the gradients used in EXTRA

by stochastic averaging gradients (Section 2). We follow with a digression on the limit points of DGD and EXTRA iterations to explain the reason why DGD does not achieve exact convergence but EXTRA is expected to do so (Section 2.1). A reinterpretation of EXTRA as a saddle point method that solves for the critical points of the augmented Lagrangian of a constrained optimization problem equivalent to (1) is then introduced. It follows from this reinterpretation that DSA is a stochastic saddle point method (Section 2.2). The fact that DSA is a stochastic saddle point method is the critical enabler of the subsequent convergence analysis (Section 3). In particular, it is possible to guarantee that strong convexity and gradient Lipschitz continuity of the local instantaneous functions $f_{n,i}$ imply that a Lyapunov function associated with the sequence of iterates generated by DSA converges linearly to its optimal value in expectation (Theorem 7). Linear convergence in expectation of the local iterates to the optimal argument $\tilde{\mathbf{x}}^*$ of (1) follows as a trivial consequence (Corollary 8). We complement this result by showing convergence of all the local variables to the optimal argument $\tilde{\mathbf{x}}^*$ with probability 1 (Theorem 9).

The advantages of DSA relative to a group of stochastic and deterministic alternatives in solving a logistic regression problem are then studied in numerical experiments (Section 4). These results demonstrate that DSA is the only decentralized stochastic algorithm that reaches the optimal solution with a linear convergence rate. We further show that DSA outperforms deterministic algorithms when the metric is the number of times that elements of the training set are evaluated. The behavior of DSA for different network topologies is also evaluated. We close the paper with pertinent remarks (Section 5).

Notation Lowercase boldface $\mathbf{v}$ denotes a vector and uppercase boldface $\mathbf{A}$ a matrix. For column vectors $\mathbf{x}_1, \ldots, \mathbf{x}_N$ we use the notation $\mathbf{x} = [\mathbf{x}_1; \ldots; \mathbf{x}_N]$ to represent the stack column vector $\mathbf{x}$. We use $\|\mathbf{v}\|$ to denote the Euclidean norm of vector $\mathbf{v}$ and $\|\mathbf{A}\|$ to denote the Euclidean norm of matrix $\mathbf{A}$. For a vector $\mathbf{v}$ and a positive definite matrix $\mathbf{A}$, the $\mathbf{A}$-weighted norm is defined as $\|\mathbf{v}\|_{\mathbf{A}} := \sqrt{\mathbf{v}^T\mathbf{A}\mathbf{v}}$. The null space of matrix $\mathbf{A}$ is denoted by null($\mathbf{A}$) and the span of a vector by span($\mathbf{x}$). The operator $\mathbb{E}_{\mathbf{x}}[\cdot]$ stands for expectation over random variable $\mathbf{x}$ and $\mathbb{E}[\cdot]$ for expectation with respect to the distribution of a stochastic process.

2. Decentralized Double Stochastic Averaging Gradient

Consider a connected network that contains N nodes such that each node n can only communicate with peers in its neighborhood $\mathcal{N}_n$. Define $\mathbf{x}_n \in \mathbb{R}^p$ as a local copy of the variable $\mathbf{x}$ that is kept at node n. In decentralized optimization, agents try to minimize their local functions $f_n(\mathbf{x}_n)$ while ensuring that their local variables $\mathbf{x}_n$ coincide with the variables $\mathbf{x}_m$ of all neighbors $m \in \mathcal{N}_n$ – which, given that the network is connected, ensures that the variables $\mathbf{x}_n$ of all nodes are the same and renders the problem equivalent to (1). DGD is a well known method for decentralized optimization that relies on the introduction of nonnegative weights $w_{ij} \geq 0$ that are not null if and only if $m = n$ or if $m \in \mathcal{N}_n$. Letting $t \in \mathbb{N}$ be a discrete time index and α a given stepsize, DGD is defined by the recursion

$$\mathbf{x}_n^{t+1} = \sum_{m=1}^{N} w_{nm}\mathbf{x}_m^t - \alpha\nabla f_n(\mathbf{x}_n^t), \qquad n = 1, \ldots, N. \tag{2}$$

Since $w_{nm} = 0$ when $m \neq n$ and $m \notin \mathcal{N}_n$, it follows from (2) that node n updates $\mathbf{x}_n$ by performing an average over the variables $\mathbf{x}_m^t$ of its neighbors $m \in \mathcal{N}_n$ and its own $\mathbf{x}_n^t$, followed by descent through the negative local gradient $-\nabla f_n(\mathbf{x}_n^t)$. If a constant stepsize is used, DGD iterates $\mathbf{x}_n^t$ approach a neighborhood of the optimal argument $\tilde{\mathbf{x}}^*$ of (1) but don't converge exactly. To achieve exact convergence diminishing stepsizes are used but the resulting convergence rate is sublinear (Nedić and Ozdaglar (2009)).

EXTRA is a method that resolves either of these issues by mixing two consecutive DGD iterations with different weight matrices and opposite signs. To be precise, introduce a second set of weights

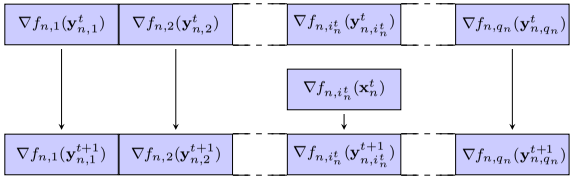

Figure 1: Stochastic averaging gradient table at node n. At each iteration t a random local instantaneous gradient $\nabla f_{n,i_n^t}(\mathbf{y}_{n,i_n^t}^t)$ is updated by $\nabla f_{n,i_n^t}(\mathbf{x}_n^t)$. The rest of the local instantaneous gradients remain unchanged, i.e., $\nabla f_{n,i}(\mathbf{y}_{n,i}^{t+1}) = \nabla f_{n,i}(\mathbf{y}_{n,i}^t)$ for $i \neq i_n^t$. This list is used to compute the stochastic averaging gradient in (7).

$\tilde{w}_{nm}$ with the same properties as the weights w_{nm} and define EXTRA through the recursion

$$\mathbf{x}_n^{t+1} = \mathbf{x}_n^t + \sum_{m=1}^{N} w_{nm}\mathbf{x}_m^t - \sum_{m=1}^{N} \tilde{w}_{nm}\mathbf{x}_m^{t-1} - \alpha\left[\nabla f_n(\mathbf{x}_n^t) - \nabla f_n(\mathbf{x}_n^{t-1})\right], \quad n = 1, \ldots, N. \tag{3}$$

Observe that (3) is well defined for $t > 0$. For $t = 0$ we utilize the regular DGD iteration in (2). In the nomenclature of this paper we say that EXTRA performs a decentralized double gradient descent step because it operates in a decentralized manner while utilizing a difference of two gradients as descent direction. Minor modification as it is, the use of this gradient difference in lieu of simple gradients, endows EXTRA with exact linear convergence to the optimal argument $\tilde{\mathbf{x}}^*$ under mild assumptions (Shi et al. (2015)).

If we recall the definitions of the local functions $f_n(\mathbf{x}_n)$ and the instantaneous local functions $f_{n,i}(\mathbf{x}_n)$ available at node n, the implementation of EXTRA requires that each node n computes the full gradient of its local objective function f_n at $\mathbf{x}_n^t$ as

$$\nabla f_n(\mathbf{x}_n^t) = \frac{1}{q_n}\sum_{i=1}^{q_n} \nabla f_{n,i}(\mathbf{x}_n^t). \tag{4}$$

This is computationally expensive when the number of instantaneous functions q_n is large. To resolve this issue, local stochastic gradients can be substituted for the local objective functions gradients in (3). These stochastic gradients approximate the gradient $\nabla f_n(\mathbf{x}_n)$ of node n by randomly choosing one of the instantaneous functions gradients $\nabla f_{n,i}(\mathbf{x}_n)$. If we let $i_n^t \in \{1, \ldots q_n\}$ denote a function index that we choose at time t at node n uniformly at random and independently of the history of the process, then the stochastic gradient is defined as

$$\hat{\mathbf{s}}_n(\mathbf{x}_n^t) := \nabla f_{n,i_n^t}(\mathbf{x}_n^t). \tag{5}$$

We can then write a stochastic version of EXTRA by replacing $\nabla f_n(\mathbf{x}_n^t)$ by $\hat{\mathbf{s}}_n(\mathbf{x}_n^t)$ and $\nabla f_n(\mathbf{x}_n^{t-1})$ by $\hat{\mathbf{s}}_n(\mathbf{x}_n^{t-1})$. Such an algorithm would have a small computational cost per iteration. On the negative side, it either has a linear convergence to a neighborhood of the optimal solution $\mathbf{x}^*$ with constant stepsize α, or it would converge sublinearly to the optimal argument when the stepsize diminishes as time passes. Here however, we want to design an algorithm with low computational complexity that converges linearly to the exact solution $\mathbf{x}^*$.

To reduce this noise we propose the use of stochastic averaging gradients instead (Defazio et al. (2014)). The idea is to maintain a list of gradients of all instantaneous functions in which one randomly chosen element is replaced at each iteration and to use an average of the elements of this

list for gradient approximation; see Figure 1. Formally, define the variable $\mathbf{y}_{n,i} \in \mathbb{R}^p$ to represent the iterate value the last time that the instantaneous gradient of function $f_{n,i}$ was evaluated. If we let $i_n^t \in \{1,\dots,q_n\}$ denote the function index chosen at time t at node n, as we did in (5), the variables $\mathbf{y}_{n,i}$ are updated recursively as

$$\mathbf{y}_{n,i}^{t+1} = \mathbf{x}_n^t, \quad \text{if } i = i_n^t, \qquad \mathbf{y}_{n,i}^{t+1} = \mathbf{y}_{n,i}^t, \quad \text{if } i \neq i_n^t. \tag{6}$$

With these definitions in hand we can define the stochastic averaging gradient at node n as

$$\hat{\mathbf{g}}_n^t := \nabla f_{n,i_n^t}(\mathbf{x}_n^t) - \nabla f_{n,i_n^t}(\mathbf{y}_{n,i_n^t}^t) + \frac{1}{q_n}\sum_{i=1}^{q_n} \nabla f_{n,i}(\mathbf{y}_{n,i}^t). \tag{7}$$

Observe that to implement (7) the gradients $\nabla f_{n,i}(\mathbf{y}_{n,i}^t)$ are stored in the local gradient table shown in Figure 1.

The DSA algorithm is a variation of EXTRA that substitutes the local gradients $\nabla f_n(\mathbf{x}_n^t)$ in (3) for the local stochastic average gradients $\hat{\mathbf{g}}_n^t$ in (7),

$$\mathbf{x}_n^{t+1} = \mathbf{x}_n^t + \sum_{m=1}^N w_{nm}\mathbf{x}_m^t - \sum_{m=1}^N \tilde{w}_{nm}\mathbf{x}_m^{t-1} - \alpha\left[\hat{\mathbf{g}}_n^t - \hat{\mathbf{g}}_n^{t-1}\right]. \tag{8}$$

The DSA initial update is given by applying the same substitution for the update of DGD in (2) as

$$\mathbf{x}_n^1 = \sum_{m=1}^N w_{nm}\mathbf{x}_m^0 - \alpha\,\hat{\mathbf{g}}_n^0. \tag{9}$$

DSA is summarized in Algorithm 1 for $t \geq 0$. The DSA update in (8) is implemented in Step 9. This step requires access to the local iterates $\mathbf{x}_m^t$ of neighboring nodes $m \in \mathcal{N}_n$ which are collected in Step 2. Furthermore, implementation of the DSA update also requires access to the stochastic averaging gradients $\hat{\mathbf{g}}_n^{t-1}$ and $\hat{\mathbf{g}}_n^t$. The latter is computed in Step 4 and the former is computed and stored at the same step in the previous iteration. The computation of the stochastic averaging gradients requires the selection of the index i_n^t. This index is chosen uniformly at random in Step 3. Determination of stochastic averaging gradients also necessitates access and maintenance of the gradients table in Figure 1. The i_n^t element of this table is updated in Step 5 by replacing $\nabla f_{n,i_n^t}(\mathbf{y}_{n,i_n^t}^t)$ with $\nabla f_{n,i_n^t}(\mathbf{x}_n^t)$, while the other vectors remain unchanged. To implement the first DSA iteration at time $t = 0$ we have to perform the update in (9) instead of the update in (8) as in Step 7. Further observe that the auxiliary variables $\mathbf{y}_{n,i}^0$ are initialized to the initial iterate $\mathbf{x}_n^0$. This implies that the initial values of the stored gradients are $\nabla f_{n,i}(\mathbf{y}_{n,i}^0) = \nabla f_{n,i}(\mathbf{x}_n^0)$.

We point out that the weights w_{nm} and $\tilde{w}_{nm}$ can't be arbitrary. If we define weight matrices $\mathbf{W}$ and $\tilde{\mathbf{W}}$ with elements w_{nm} and $\tilde{w}_{nm}$, respectively, they have to satisfy conditions that we state as an assumption for future reference.

Assumption 1 *The weight matrices $\mathbf{W}$ and $\tilde{\mathbf{W}}$ must satisfy the following properties*

(a) Both are symmetric, $\mathbf{W} = \mathbf{W}^T$ and $\tilde{\mathbf{W}} = \tilde{\mathbf{W}}^T$.

(b) The null space of $\mathbf{I} - \tilde{\mathbf{W}}$ includes the span of $\mathbf{1}$, i.e., null$(\mathbf{I} - \tilde{\mathbf{W}}) \supseteq$ span$(\mathbf{1})$, the null space of $\mathbf{I} - \mathbf{W}$ is the span of $\mathbf{1}$, i.e., null$(\mathbf{I} - \mathbf{W}) =$ span$(\mathbf{1})$, and the null space of the difference $\tilde{\mathbf{W}} - \mathbf{W}$ is the span of $\mathbf{1}$, i.e., null$(\tilde{\mathbf{W}} - \mathbf{W}) =$ span$(\mathbf{1})$.

(c) They satisfy the spectral ordering $\mathbf{W} \preceq \tilde{\mathbf{W}} \preceq (\mathbf{I} + \mathbf{W})/2$ and $\mathbf{0} \prec \tilde{\mathbf{W}}$.

Algorithm 1 DSA algorithm at node n

Require: Vectors $\mathbf{x}_n^0$. Gradient table initialized with instantaneous gradients $\nabla f_{n,i}(\mathbf{y}_{n,i}^0)$ with $\mathbf{y}_{n,i}^0 = \mathbf{x}_n^0$.

1: **for** $t = 0, 1, 2, \dots$ **do**
2: Exchange variable $\mathbf{x}_n^t$ with neighboring nodes $m \in \mathcal{N}_n$;
3: Choose i_n^t uniformly at random from the set $\{1,\dots,q_n\}$;
4: Compute and store stochastic averaging gradient as per (7):
$\hat{\mathbf{g}}_n^t = \nabla f_{n,i_n^t}(\mathbf{x}_n^t) - \nabla f_{n,i_n^t}(\mathbf{y}_{n,i_n^t}^t) + \frac{1}{q_n}\sum_{i=1}^{q_n}\nabla f_{n,i}(\mathbf{y}_{n,i}^t)$;
5: Take $\mathbf{y}_{n,i_n^t}^{t+1} = \mathbf{x}_n^t$ and store $\nabla f_{n,i_n^t}(\mathbf{y}_{n,i_n^t}^{t+1}) = \nabla f_{n,i_n^t}(\mathbf{x}_n^t)$ in i_n^t gradient table position. All other entries in the table remain unchanged. The vector $\mathbf{y}_{n,i_n^t}^{t+1}$ is not explicitly stored;
6: **if** $t = 0$ **then**
7: Update variable $\mathbf{x}_n^t$ as per (9): $\mathbf{x}_n^{t+1} = \sum_{m=1}^N w_{nm}\mathbf{x}_n^t - \alpha\hat{\mathbf{g}}_n^t$;
8: **else**
9: Update variable $\mathbf{x}_n^t$ as per (8): $\mathbf{x}_n^{t+1} = \mathbf{x}_n^t + \sum_{m=1}^N w_{nm}\mathbf{x}_n^t - \sum_{m=1}^N \tilde{w}_{nm}\mathbf{x}_n^{t-1} - \alpha\left[\hat{\mathbf{g}}_n^t - \hat{\mathbf{g}}_n^{t-1}\right]$;
10: **end if**
11: **end for**

Requiring the matrix $\mathbf{W}$ to be symmetric and with specific null space properties is necessary to let all agents converge to the same optimal variable. Analogous properties are necessary in DGD and are not difficult to satisfy. The condition on spectral ordering is specific to EXTRA but is not difficult to satisfy either. E.g., if we have a matrix $\mathbf{W}$ that satisfies all the conditions in Assumption 1, the weight matrix $\tilde{\mathbf{W}} = (\mathbf{I} + \mathbf{W})/2$ makes Assumption 1 valid.

We also point that, as written in (7), computation of local stochastic averaging gradients $\hat{\mathbf{g}}_n^t$ is costly because it requires evaluation of the sum $\sum_{i=1}^{q_n}\nabla f_{n,i}(\mathbf{y}_{n,i}^t)$ at each iteration. To be more precise, if we implement the update in (7) naively, at each iteration we should compute the sum $\sum_{i=1}^{q_n}\nabla f_{n,i}(\mathbf{y}_{n,i}^t)$ which has a computational cost of the order $O(q_n)$. This cost can be avoided by updating the sum at each iteration with the recursive formula

$$\sum_{i=1}^{q_n}\nabla f_{n,i}(\mathbf{y}_{n,i}^t) \;=\; \sum_{i=1}^{q_n}\nabla f_{n,i}(\mathbf{y}_{n,i}^{t-1}) + \nabla f_{n,i_n^{t-1}}(\mathbf{x}_n^{t-1}) - \nabla f_{n,i_n^{t-1}}(\mathbf{y}_{n,i_n^{t-1}}^{t-1}). \tag{10}$$

Using the update in (10), we can update the sum $\sum_{i=1}^{q_n}\nabla f_{n,i}(\mathbf{y}_{n,i}^t)$ required for (7) in a computationally efficient manner. Important properties and interpretations of EXTRA and DSA are presented in the following sections after pertinent remarks.

Remark 1 The local stochastic averaging gradients in (7) are unbiased estimates of the local gradients $\nabla f_n(\mathbf{x}_n^t)$. Indeed, if we let $\mathcal{F}_t$ measure the history of the system up until time t we have that the sum in (7) is deterministic given this sigma-algebra. This observation implies that the conditional expectation $\mathbb{E}\left[(1/q_n)\sum_{i=1}^{q_n}\nabla f_{n,i}(\mathbf{y}_{n,i}^t)\,|\,\mathcal{F}^t\right]$ can be simplified as $(1/q_n)\sum_{i=1}^{q_n}\nabla f_{n,i}(\mathbf{y}_{n,i}^t)$. Thus, the conditional expectation of the stochastic averaging gradient is,

$$\mathbb{E}\left[\hat{\mathbf{g}}_n^t\,\middle|\,\mathcal{F}^t\right] = \mathbb{E}\Big[\nabla f_{n,i_n^t}(\mathbf{x}_n^t)\,\Big|\,\mathcal{F}^t\Big] - \mathbb{E}\Big[\nabla f_{n,i_n^t}(\mathbf{y}_{n,i_n^t}^t)\,\Big|\,\mathcal{F}^t\Big] + \frac{1}{q_n}\sum_{i=1}^{q_n}\nabla f_{n,i}(\mathbf{y}_{n,i}^t). \tag{11}$$

With the index i_n^t chosen equiprobably from the set $\{1,\dots,q_n\}$, the expectation of the second term in (11) is the same as the sum in the last term – each of the indexes is chosen with probability $1/q_n$. In other words, we can write $\mathbb{E}\Big[\nabla f_{n,i_n^t}(\mathbf{y}_{n,i_n^t}^t)\,\Big|\,\mathcal{F}^t\Big] = (1/q_n)\sum_{i=1}^{q_n}\nabla f_{n,i}(\mathbf{y}_{n,i}^t)$. Therefore,

these two terms cancel out each other and, since the expectation of the first term in (11) is simply $\mathbb{E}\big[\nabla f_{n,i_n^t}(\mathbf{x}_n^t)\,\big|\,\mathcal{F}^t\big] = (1/q_n)\sum_{i=1}^{q_n}\nabla f_{n,i}(\mathbf{x}_n^t) = \nabla f_n(\mathbf{x}_n^t)$, we can simplify (11) to

$$\mathbb{E}\left[\hat{\mathbf{g}}_n^t\,\big|\,\mathcal{F}^t\right] = \nabla f_n(\mathbf{x}_n^t). \tag{12}$$

The expression in (12) means, by definition, that $\hat{\mathbf{g}}_n^t$ is an unbiased estimate of $\nabla f_n(\mathbf{x}_n^t)$ when the history $\mathcal{F}^t$ is given.

Remark 2 The local stochastic averaging gradient $\hat{\mathbf{g}}_n^t$ at node n contains three terms. The first two terms $\nabla f_{n,i_n^t}(\mathbf{x}_n^t)$ and $\nabla f_{n,i_n^t}(\mathbf{y}_{n,i_n^t}^t)$ are the new and old gradients of the chosen objective function f_{n,i_n^t} at node n, respectively. The last term $(1/q_n)\sum_{i=1}^{q_n}\nabla f_{n,i}(\mathbf{y}_{n,i}^t)$ is the average of the average of all the instantaneous gradients available at node n. This update can be considered as a localized version of the stochastic averaging gradient update in the SAGA algorithm (Defazio et al. (2014)). Notice that instead of the difference $\nabla f_{n,i_n^t}(\mathbf{x}_n^t) - \nabla f_{n,i_n^t}(\mathbf{y}_{n,i_n^t}^t)$ in (7) we could use the difference $(\nabla f_{n,i_n^t}(\mathbf{x}_n^t) - \nabla f_{n,i_n^t}(\mathbf{y}_{n,i_n^t}^t))/q_n$ which would lead to stochastic averaging gradient suggested in the SAG algorithm (Schmidt et al. (2013)). As studied in (Defazio et al. (2014)), both of these approximations lead to a variance reduction method. The one suggested by SAGA is an unbiased estimator of the exact gradient $(1/q_n)\sum_{i=1}^{q_n}\nabla f_{n,i}(\mathbf{x}_n^t)$, while the one suggested by SAG is a biased estimator of the gradient with smaller variance. Since the analysis of the estimator suggested by SAGA is simpler, we use its idea to define the local stochastic averaging gradient $\hat{\mathbf{g}}_n^t$ in (7).

2.1 Limit Points of DGD and EXTRA

The derivation of EXTRA hinges on the observation that the optimal argument of (1) is not a fixed point of the DGD iteration in (2) but is a fixed point of the iteration in (3). To explain this point define $\mathbf{x} := [\mathbf{x}_1;\ldots;\mathbf{x}_N] \in \mathbb{R}^{Np}$ as a vector that concatenates the local iterates $\mathbf{x}_n$ and the aggregate function $f:\mathbb{R}^{Np}\to\mathbb{R}$ as the one that takes values $f(\mathbf{x}) = f(\mathbf{x}_1,\ldots,\mathbf{x}_N) := \sum_{n=1}^N f_n(\mathbf{x}_n)$. Decentralized optimization entails the minimization of $f(\mathbf{x})$ subject to the constraint that all local variables are equal,

$$\begin{aligned}\mathbf{x}^* := \operatorname{argmin}\ & f(\mathbf{x}) = f(\mathbf{x}_1,\ldots,\mathbf{x}_N) = \sum_{n=1}^N f_n(\mathbf{x}_n),\\ \text{s.t.}\quad & \mathbf{x}_n = \mathbf{x}_m, \quad \text{for all } n,m.\end{aligned} \tag{13}$$

The problems in (1) and (13) are equivalent in the sense that the vector $\mathbf{x}^*\in\mathbb{R}^{Np}$ is a solution of (13) if it satisfies $\mathbf{x}_n^* = \tilde{\mathbf{x}}^*$ for all n, or, equivalently, if we can write $\mathbf{x}^* = [\tilde{\mathbf{x}}^*;\ldots;\tilde{\mathbf{x}}^*]$. Regardless of interpretation, the Karush, Kuhn, Tucker (KKT) conditions of (13) dictate that that optimal argument $\mathbf{x}^*$ must sastisfy

$$\mathbf{x}^* \subset \operatorname{span}(\mathbf{1}_N\otimes\mathbf{I}_p), \qquad (\mathbf{1}_N\otimes\mathbf{I}_p)^T\nabla f(\mathbf{x}^*) = \mathbf{0}. \tag{14}$$

The first condition in (14) requires that all the local variables $\mathbf{x}_n^*$ be equal, while the second condition requires the sum of local gradients to vanish at the optimal point. This latter condition is not the same as $\nabla f(\mathbf{x}) = \mathbf{0}$. If we observe that the gradient $\nabla f(\mathbf{x}^t)$ of the aggregate function can be written as $\nabla f(\mathbf{x}) = [\nabla f_1(\mathbf{x}_1);\ldots;\nabla f_N(\mathbf{x}_N)]\in\mathbb{R}^{Np}$, the condition $\nabla f(\mathbf{x}) = \mathbf{0}$ implies that all the local gradients are null, i.e., that $\nabla f_n(\mathbf{x}_n) = \mathbf{0}$ for all n. This is stronger than having their sum being null as required by (14).

Define now the extended weight matrices as the Kronecker products $\mathbf{Z} := \mathbf{W}\otimes\mathbf{I}\in\mathbb{R}^{Np\times Np}$ and $\tilde{\mathbf{Z}} := \tilde{\mathbf{W}}\otimes\mathbf{I}\in\mathbb{R}^{Np\times Np}$. Note that the required conditions for the weight matrices $\mathbf{W}$ and $\tilde{\mathbf{W}}$ in Assumption 1 enforce some conditions on the extended weight matrices $\mathbf{Z}$ and $\tilde{\mathbf{Z}}$. Based on Assumption 1(a), the matrices $\mathbf{Z}$ and $\tilde{\mathbf{Z}}$ are also symmetric, i.e., $\mathbf{Z} = \mathbf{Z}^T$ and $\tilde{\mathbf{Z}} = \tilde{\mathbf{Z}}^T$. Conditions in

Assumption 1(b) imply that $\operatorname{null}\{\tilde{\mathbf{Z}}-\mathbf{Z}\} = \operatorname{span}\{\mathbf{1}\otimes\mathbf{I}\}$, $\operatorname{null}\{\mathbf{I}-\mathbf{Z}\} = \operatorname{span}\{\mathbf{1}\otimes\mathbf{I}\}$, and $\operatorname{null}\{\mathbf{I}-\tilde{\mathbf{Z}}\}\supseteq \operatorname{span}\{\mathbf{1}\otimes\mathbf{I}\}$. Lastly, the spectral properties of matrices $\mathbf{W}$ and $\tilde{\mathbf{W}}$ in Assumption 1(c) yield that matrix $\tilde{\mathbf{Z}}$ is positive definite and the expression $\mathbf{Z}\preceq\tilde{\mathbf{Z}}\preceq(\mathbf{I}+\mathbf{Z})/2$ holds.

According to the definition of the extended weight matrix $\mathbf{Z}$, the DGD iteration in (2) is equivalent to

$$\mathbf{x}^{t+1} = \mathbf{Z}\mathbf{x}^t - \alpha\nabla f(\mathbf{x}^t), \tag{15}$$

where, according to (13), the gradient $\nabla f(\mathbf{x}^t)$ of the aggregate function can be written as $\nabla f(\mathbf{x}^t) = [\nabla f_1(\mathbf{x}_1^t);\ldots;\nabla f_N(\mathbf{x}_N^t)]\in\mathbb{R}^{Np}$. Likewise, the EXTRA iteration in (3) can be written as

$$\mathbf{x}^{t+1} = (\mathbf{I}+\mathbf{Z})\mathbf{x}^t - \tilde{\mathbf{Z}}\mathbf{x}^{t-1} - \alpha\left[\nabla f(\mathbf{x}^t) - \nabla f(\mathbf{x}^{t-1})\right]. \tag{16}$$

The fundamental difference between DGD and EXTRA is that a fixed point of (15) does not necessarily satisfy (14), whereas the fixed points of (16) are guaranteed to do so. Indeed, taking limits in (15) we see that the fixed points $\mathbf{x}^\infty$ of DGD must satisfy

$$(\mathbf{I}-\mathbf{Z})\mathbf{x}^\infty + \alpha\nabla f(\mathbf{x}^\infty) = \mathbf{0}, \tag{17}$$

which is incompatible with (14) except in peculiar circumstances – such as, e.g., when all local functions have the same minimum. The limit points of EXTRA, however, satisfy the relationship

$$\mathbf{x}^\infty - \mathbf{x}^\infty = (\mathbf{Z}-\tilde{\mathbf{Z}})\mathbf{x}^\infty - \alpha[\nabla f(\mathbf{x}^\infty) - \nabla f(\mathbf{x}^\infty)]. \tag{18}$$

Canceling out the variables on the left hand side and the gradients in the right hand side it follows that $(\mathbf{Z}-\tilde{\mathbf{Z}})\mathbf{x}^\infty = \mathbf{0}$. Since the null space of of $\mathbf{Z}-\tilde{\mathbf{Z}}$ is $\operatorname{null}(\mathbf{Z}-\tilde{\mathbf{Z}}) = \mathbf{1}_N\otimes\mathbf{I}_p$ by assumption, we must have $\mathbf{x}^\infty\subset\operatorname{span}(\mathbf{1}_N\otimes\mathbf{I}_p)$. This is the first condition in (14). For the second condition in (14) sum the updates in (16) recursively and use the telescopic nature of the sum to write

$$\mathbf{x}^{t+1} = \tilde{\mathbf{Z}}\mathbf{x}^t - \alpha\nabla f(\mathbf{x}^t) - \sum_{s=0}^t(\tilde{\mathbf{Z}}-\mathbf{Z})\mathbf{x}^s. \tag{19}$$

Substituting the limit point in (19) and reordering terms, we see that $\mathbf{x}^\infty$ must satisfy

$$\alpha\nabla f(\mathbf{x}^\infty) = (\mathbf{I}-\tilde{\mathbf{Z}})\mathbf{x}^\infty - \sum_{s=0}^\infty(\tilde{\mathbf{Z}}-\mathbf{Z})\mathbf{x}^s. \tag{20}$$

In (20) we have that $(\mathbf{I}-\tilde{\mathbf{Z}})\mathbf{x}^\infty = \mathbf{0}$ because the null space of $(\mathbf{I}-\tilde{\mathbf{Z}})$ is $\operatorname{null}(\mathbf{Z}-\tilde{\mathbf{Z}}) = \mathbf{1}_N\otimes\mathbf{I}_p$ by assumption and $\mathbf{x}^\infty\subset\operatorname{span}(\mathbf{1}_N\otimes\mathbf{I}_p)$ as already shown. Implementing this simplification and considering the multiplication of the resulting equality by $(\mathbf{1}_N\otimes\mathbf{I}_p)^T$ we obtain

$$(\mathbf{1}_N\otimes\mathbf{I}_p)^T\alpha\nabla f(\mathbf{x}^\infty) = -\sum_{s=0}^\infty(\mathbf{1}_N\otimes\mathbf{I}_p)^T(\mathbf{Z}-\tilde{\mathbf{Z}})\mathbf{x}^s. \tag{21}$$

In (21), the terms $(\mathbf{1}_N\otimes\mathbf{I}_p)^T(\mathbf{Z}-\tilde{\mathbf{Z}}) = \mathbf{0}$ because the matrices $\mathbf{Z}$ and $\tilde{\mathbf{Z}}$ are symmetric and $(\mathbf{1}_N\otimes\mathbf{I}_p)$ is in the null space of the difference $\mathbf{Z}-\tilde{\mathbf{Z}}$. This implies that $(\mathbf{1}_N\otimes\mathbf{I}_p)^T\alpha\nabla f(\mathbf{x}^\infty) = \mathbf{0}$, which is the second condition in (14). Therefore, given the assumption that the sequence of EXTRA iterates $\mathbf{x}^t$ has a limit point $\mathbf{x}^\infty$ it follows that this limit point satisfies both conditions in (14) and for this reason exact convergence with constant stepsize is achievable for EXTRA.

2.2 Stochastic Saddle Point Method Interpretation of DSA

The convergence proofs of DSA build on a reinterpretation of EXTRA as a saddle point method. To introduce this primal-dual interpretation consider the update in (19) and define the sequence of

vectors $\mathbf{v}^t = \sum_{s=0}^{t}(\tilde{\mathbf{Z}}-\mathbf{Z})^{1/2}\mathbf{x}^s$. The vector $\mathbf{v}^t$ represents the accumulation of variable dissimilarities in different nodes over time. Considering this definition of $\mathbf{v}^t$ we can rewrite (19) as

$$\mathbf{x}^{t+1} = \mathbf{x}^t - \alpha\left[\nabla f(\mathbf{x}^t) + \frac{1}{\alpha}(\mathbf{I}-\tilde{\mathbf{Z}})\mathbf{x}^t + \frac{1}{\alpha}(\tilde{\mathbf{Z}}-\mathbf{Z})^{1/2}\mathbf{v}^t\right]. \tag{22}$$

Furthermore, based on the definition of the sequence $\mathbf{v}^t = \sum_{s=0}^{t}(\tilde{\mathbf{Z}}-\mathbf{Z})^{1/2}\mathbf{x}^s$ we can write the recursive expression

$$\mathbf{v}^{t+1} = \mathbf{v}^t + \alpha\left[\frac{1}{\alpha}(\tilde{\mathbf{Z}}-\mathbf{Z})^{1/2}\mathbf{x}^{t+1}\right]. \tag{23}$$

Consider $\mathbf{x}$ as a primal variable and $\mathbf{v}$ as a dual variable. Then, the updates in (22) and (23) are equivalent to the updates of a saddle point method with stepsize α that solves for the critical points of the augmented Lagrangian

$$\mathcal{L}(\mathbf{x},\mathbf{v}) = f(\mathbf{x}) + \frac{1}{\alpha}\mathbf{v}^T(\tilde{\mathbf{Z}}-\mathbf{Z})^{1/2}\mathbf{x} + \frac{1}{2\alpha}\mathbf{x}^T(\mathbf{I}-\tilde{\mathbf{Z}})\mathbf{x}. \tag{24}$$

In the Lagrangian in (24) the factor $(1/\alpha)\mathbf{v}^T(\tilde{\mathbf{Z}}-\mathbf{Z})^{1/2}\mathbf{x}$ stems from the linear constraint $(\tilde{\mathbf{Z}}-\mathbf{Z})^{1/2}\mathbf{x}=\mathbf{0}$ and the quadratic term $(1/2\alpha)\mathbf{x}^T(\mathbf{I}-\tilde{\mathbf{Z}})\mathbf{x}$ is the augmented term added to the Lagrangian. Therefore, the optimization problem whose augmented Lagrangian is the one given in (24) is

$$\mathbf{x}^* = \operatorname*{argmin}_{\mathbf{x}} \; f(\mathbf{x}) \qquad \text{s.t. } \frac{1}{\alpha}(\tilde{\mathbf{Z}}-\mathbf{Z})^{1/2}\mathbf{x} = \mathbf{0}. \tag{25}$$

Observing that the null space of $(\tilde{\mathbf{Z}}-\mathbf{Z})^{1/2}$ is $\text{null}((\tilde{\mathbf{Z}}-\mathbf{Z})^{1/2}) = \text{null}(\tilde{\mathbf{Z}}-\mathbf{Z}) = \text{span}\{\mathbf{1}_N \otimes \mathbf{I}_p\}$, the constraint in (25) is equivalent to the consensus constraint $\mathbf{x}_n = \mathbf{x}_m$ for all n,m that appears in (13). This means that (25) is equivalent to (13), which, as already argued, is equivalent to the original problem in (1). Hence, EXTRA is a saddle point method that solves (25) which, because of their equivalence, is tantamount to solving (1). Considering that saddle point methods converge linearly, it follows that the same is true of EXTRA.

That EXTRA is a saddle point method provides a simple explanation of its convergence properties. For the purposes of this paper, however, the important fact is that if EXTRA is a saddle point method, DSA is a stochastic saddle point method. To write DSA in this form define $\hat{\mathbf{g}}^t := [\hat{\mathbf{g}}_1^t;\ldots;\hat{\mathbf{g}}_N^t] \in \mathbb{R}^{Np}$ as the vector that concatenates all the local stochastic averaging gradients at step t. Then, the DSA update in (8) can be written as

$$\mathbf{x}^{t+1} = (\mathbf{I}+\mathbf{Z})\mathbf{x}^t - \tilde{\mathbf{Z}}\mathbf{x}^{t-1} - \alpha\left[\hat{\mathbf{g}}^t - \hat{\mathbf{g}}^{t-1}\right]. \tag{26}$$

Comparing (16) and (26) we see that they differ in the latter using stochastic averaging gradients $\hat{\mathbf{g}}^t$ in lieu of the full gradients $\nabla f(\mathbf{x}^t)$. Therefore, DSA is a stochastic saddle point method in which the primal variables are updated as

$$\mathbf{x}^{t+1} = \mathbf{x}^t - \alpha\hat{\mathbf{g}}^t - (\mathbf{I}-\tilde{\mathbf{Z}})\mathbf{x}^t - (\tilde{\mathbf{Z}}-\mathbf{Z})^{1/2}\mathbf{v}^t, \tag{27}$$

and the dual variables $\mathbf{v}^t$ are updated as

$$\mathbf{v}^{t+1} = \mathbf{v}^t + (\tilde{\mathbf{Z}}-\mathbf{Z})^{1/2}\mathbf{x}^{t+1}. \tag{28}$$

Notice that the initial primal variable $\mathbf{x}^0$ is an arbitrary vector in $\mathbb{R}^{Np}$, while according to the definition $\mathbf{v}^t = \sum_{s=0}^{t}(\tilde{\mathbf{Z}}-\mathbf{Z})^{1/2}\mathbf{x}^s$. We then need to set the initial multiplier to $\mathbf{v}^0 = (\tilde{\mathbf{Z}}-\mathbf{Z})^{1/2}\mathbf{x}^0$. This is not a problem in practice because (27) and (28) are not used for implementation. In our converge analysis we utilize the (equivalent) stochastic saddle point expressions for DSA shown in (27) and (28). The expression in (8) is used for implementation because it avoids exchanging dual variables – as well as the initialization problem. The convergence analysis is presented in the following section.

3. Convergence Analysis

Our goal here is to show that as time progresses the sequence of iterates $\mathbf{x}^t$ approaches the optimal argument $\mathbf{x}^*$. To do so, in addition to the conditions on the weight matrices $\mathbf{W}$ and $\tilde{\mathbf{W}}$ in Assumption 1, we assume the instantaneous local functions $f_{n,i}$ have specific properties that we state next.

Assumption 2 The instantaneous local functions $f_{n,i}(\mathbf{x}_n)$ are differentiable and strongly convex with parameter μ.

Assumption 3 The gradient of instantaneous local functions $\nabla f_{n,i}$ are Lipschitz continuous with parameter L, i.e., for all $n \in \{1,\ldots,N\}$ and $i \in \{1,\ldots,q_n\}$ we can write

$$\|\nabla f_{n,i}(\mathbf{a}) - \nabla f_{n,i}(\mathbf{b})\| \leq L\,\|\mathbf{a}-\mathbf{b}\| \quad \mathbf{a},\mathbf{b} \in \mathbb{R}^p. \tag{29}$$

The condition imposed by Assumption 2 implies that the local functions $f_n(\mathbf{x}_n)$ and the global cost function $f(\mathbf{x}) = \sum_{n=1}^{N} f_n(\mathbf{x}_n)$ are also strongly convex with parameter μ. Likewise, Lipschitz continuity of the local instantaneous gradients considered in Assumption 3 enforces Lipschitz continuity of the local functions gradient $\nabla f_n(\mathbf{x}_n)$ and the aggregate function gradient $\nabla f(\mathbf{x})$ – see, e.g., (Lemma 1 of Mokhtari et al. (2015a)).

3.1 Preliminaries

In this section we study some basic properties of the sequences of primal and dual variables generated by the DSA algorithm. In the following lemma, we study the relation of the iterates $\mathbf{x}^t$ and $\mathbf{v}^t$ with the optimal primal $\mathbf{x}^*$ and dual $\mathbf{v}^*$ arguments.

Lemma 3 *Consider the DSA algorithm as defined in* (6)-(9) *and recall the updates of the primal* $\mathbf{x}^t$ *and dual* $\mathbf{v}^t$ *variables in* (27) *and* (28)*, respectively. Further, define the positive semidefinite matrix* $\mathbf{U} := (\tilde{\mathbf{Z}}-\mathbf{Z})^{1/2}$*. If Assumption 1 holds true, then the sequence of primal* $\mathbf{x}^t$ *and dual* $\mathbf{v}^t$ *variables satisfy*

$$\alpha\left[\hat{\mathbf{g}}^t - \nabla f(\mathbf{x}^*)\right] = (\mathbf{I}+\mathbf{Z}-2\tilde{\mathbf{Z}})(\mathbf{x}^* - \mathbf{x}^{t+1}) + \tilde{\mathbf{Z}}(\mathbf{x}^t - \mathbf{x}^{t+1}) - \mathbf{U}(\mathbf{v}^{t+1} - \mathbf{v}^*). \tag{30}$$

Proof Considering the update rule for the dual variable in (28) and the definition $\mathbf{U} = (\tilde{\mathbf{Z}}-\mathbf{Z})^{1/2}$, we can substitute $\mathbf{U}\mathbf{v}^t$ in (27) by $\mathbf{U}\mathbf{v}^{t+1} - \mathbf{U}^2\mathbf{x}^{t+1}$. Applying this substitution into the DSA primal update in (27) yields

$$\alpha\hat{\mathbf{g}}^t = -(\mathbf{I}+\mathbf{Z}-\tilde{\mathbf{Z}})\mathbf{x}^{t+1} + \tilde{\mathbf{Z}}\mathbf{x}^t - \mathbf{U}\mathbf{v}^{t+1}. \tag{31}$$

By adding and subtracting $\tilde{\mathbf{Z}}\mathbf{x}^{t+1}$ to the right hand side of (31) and considering the fact that $(\mathbf{I}+\mathbf{Z}-2\tilde{\mathbf{Z}})\mathbf{x}^* = \mathbf{0}$ we obtain

$$\alpha\hat{\mathbf{g}}^t = (\mathbf{I}+\mathbf{Z}-2\tilde{\mathbf{Z}})(\mathbf{x}^* - \mathbf{x}^{t+1}) + \tilde{\mathbf{Z}}(\mathbf{x}^t - \mathbf{x}^{t+1}) - \mathbf{U}\mathbf{v}^{t+1}. \tag{32}$$

One of the KKT conditions of problem (25) implies that the optimal variables $\mathbf{x}^*$ and $\mathbf{v}^*$ satisfy $\alpha\nabla f(\mathbf{x}^*) + \mathbf{U}\mathbf{v}^* = \mathbf{0}$ or equivalently $-\alpha\nabla f(\mathbf{x}^*) = \mathbf{U}\mathbf{v}^*$. Adding this equality to both sides of (32) follows the claim in (30). ■

In the subsequent analyses of convergence of DSA, we need an upper bound for the expected value of squared difference between the stochastic averaging gradient $\hat{\mathbf{g}}^t$ and the optimal argument gradient $\nabla f(\mathbf{x}^*)$ given the observations until step t, i.e. $\mathbb{E}\left[\|\hat{\mathbf{g}}^t - \nabla f(\mathbf{x}^*)\|^2 \mid \mathcal{F}^t\right]$. To establish this upper bound first we define the sequence $p^t \in \mathbb{R}$ as

$$p^t := \sum_{n=1}^{N}\left[\frac{1}{q_n}\sum_{i=1}^{q_n}\left(f_{n,i}(\mathbf{y}_{n,i}^t) - f_{n,i}(\tilde{\mathbf{x}}^*) - \nabla f_{n,i}(\tilde{\mathbf{x}}^*)^T(\mathbf{y}_{n,i}^t - \tilde{\mathbf{x}}^*)\right)\right]. \tag{33}$$

Notice that based on the strong convexity of the local instantaneous functions $f_{n,i}$, each term $f_{n,i}(\mathbf{y}_{n,i}^t) - f_{n,i}(\tilde{\mathbf{x}}^*) - \nabla f_{n,i}(\tilde{\mathbf{x}}^*)^T(\mathbf{y}_{n,i}^t - \tilde{\mathbf{x}}^*)$ is positive and as a result the sequence p^t defined in (33) is always positive. In the following lemma, we use the result in Lemma 3 to guarantee an upper bound for the expectation $\mathbb{E}\left[\|\hat{\mathbf{g}}^t - \nabla f(\mathbf{x}^*)\|^2 \mid \mathcal{F}^t\right]$ in terms of p^t and the optimality gap $f(\mathbf{x}^t) - f(\mathbf{x}^*) - \nabla f(\mathbf{x}^*)^T(\mathbf{x}^t - \mathbf{x}^*)$.

Lemma 4 *Consider the DSA algorithm in* (6)-(9) *and the definition of the sequence* p^t *in* (33)*. If Assumptions 1-3 hold true, then the squared norm of the difference between the stochastic averaging gradient* $\hat{\mathbf{g}}^t$ *and the optimal gradient* $\nabla f(\mathbf{x}^*)$ *in expectation is bounded above by*

$$\mathbb{E}\left[\left\|\hat{\mathbf{g}}^t - \nabla f(\mathbf{x}^*)\right\|^2 | \mathcal{F}^t\right] \leq 4Lp^t + 2\left(2L - \mu\right)\left(f(\mathbf{x}^t) - f(\mathbf{x}^*) - \nabla f(\mathbf{x}^*)^T(\mathbf{x}^t - \mathbf{x}^*)\right). \tag{34}$$

Proof See Appendix A. ■

Observe that as the sequence of iterates $\mathbf{x}^t$ approaches the optimal argument $\mathbf{x}^*$, all the local auxiliary variables $\mathbf{y}_{n,i}^t$ converge to $\tilde{\mathbf{x}}^*$ which follows convergence of p^t to null. This observation in association with the result in (34) implies that the expected value of the difference between the stochastic averaging gradient $\hat{\mathbf{g}}^t$ and the optimal gradient $\nabla f(\mathbf{x}^*)$ vanishes as the sequence of iterates $\mathbf{x}^t$ approaches the optimal argument $\mathbf{x}^*$.

3.2 Convergence

In this section we establish linear convergence of the sequence of iterates $\mathbf{x}^t$ generated by DSA to the optimal argument $\mathbf{x}^*$. To do so, define $0 < \gamma$ and $\Gamma < \infty$ as the smallest and largest eigenvalues of the positive definite matrix $\tilde{\mathbf{Z}}$, respectively. Likewise, define γ' as the smallest non-zero eigenvalue of the matrix $\tilde{\mathbf{Z}} - \mathbf{Z}$ and Γ' as the largest eigenvalue of the matrix $\tilde{\mathbf{Z}} - \mathbf{Z}$. Further, define the vectors $\mathbf{u}^t, \mathbf{u}^* \in \mathbb{R}^{2Np}$ and matrix $\mathbf{G} \in \mathbb{R}^{2Np \times 2Np}$ as

$$\mathbf{u}^* := \begin{bmatrix} \mathbf{x}^* \\ \mathbf{v}^* \end{bmatrix}, \quad \mathbf{u}^t := \begin{bmatrix} \mathbf{x}^t \\ \mathbf{v}^t \end{bmatrix}, \quad \mathbf{G} = \begin{bmatrix} \tilde{\mathbf{Z}} & \mathbf{0} \\ \mathbf{0} & \mathbf{I} \end{bmatrix}. \tag{35}$$

Observe that the vector $\mathbf{u}^* \in \mathbb{R}^{2Np}$ concatenates the optimal primal and dual variables and the vector $\mathbf{u}^t \in \mathbb{R}^{2Np}$ contains primal and dual iterates at step t. Further, $\mathbf{G} \in \mathbb{R}^{2Np \times 2Np}$ is a block diagonal positive definite matrix that we introduce since instead of tracking the value of ℓ_2 norm $\|\mathbf{u}^t - \mathbf{u}^*\|_2^2$ we study the convergence properties of $\mathbf{G}$ weighted norm $\|\mathbf{u}^t - \mathbf{u}^*\|_{\mathbf{G}}^2$. Notice that the weighted norm $\|\mathbf{u}^t - \mathbf{u}^*\|_{\mathbf{G}}^2$ is equivalent to $(\mathbf{u}^t - \mathbf{u}^*)^T\mathbf{G}(\mathbf{u}^t - \mathbf{u}^*)$. Our goal is to show that the sequence $\|\mathbf{u}^t - \mathbf{u}^*\|_{\mathbf{G}}^2$ converges linearly to null. To do this we show linear convergence of a Lyapunov function of the sequence $\|\mathbf{u}^t - \mathbf{u}^*\|_{\mathbf{G}}^2$. The Lyapunov function is defined as $\|\mathbf{u}^t - \mathbf{u}^*\|_{\mathbf{G}}^2 + cp^t$ where $c > 0$ is a positive constant.

To prove linear convergence of the sequence $\|\mathbf{u}^t - \mathbf{u}^*\|_{\mathbf{G}}^2 + cp^t$ we first show an upper bound for the expected error $\mathbb{E}\left[\|\mathbf{u}^{t+1} - \mathbf{u}^*\|_{\mathbf{G}}^2 \mid \mathcal{F}^t\right]$ in terms of $\|\mathbf{u}^t - \mathbf{u}^*\|_{\mathbf{G}}^2$ and some parameters that capture optimality gap.

Lemma 5 *Consider the DSA algorithm as defined in* (6)-(9)*. Further recall the definitions of* p^t *in* (33) *and* $\mathbf{u}^t$, $\mathbf{u}^*$, *and* $\mathbf{G}$ *in* (35)*. If Assumptions 1-3 hold true, then for any positive constant* $\eta > 0$ *we can write*

$$\begin{aligned}\mathbb{E}\left[\|\mathbf{u}^{t+1} - \mathbf{u}^*\|_{\mathbf{G}}^2 \mid \mathcal{F}^t\right] \leq \|\mathbf{u}^t - \mathbf{u}^*\|_{\mathbf{G}}^2 - 2\mathbb{E}\left[\|\mathbf{x}^{t+1} - \mathbf{x}^*\|_{\mathbf{I}+\mathbf{Z}-2\tilde{\mathbf{Z}}}^2 \mid \mathcal{F}^t\right] + \frac{\alpha 4L}{\eta}p^t \\ - \mathbb{E}\left[\|\mathbf{x}^{t+1} - \mathbf{x}^t\|_{\tilde{\mathbf{Z}}-2\alpha\eta\mathbf{I}}^2 \mid \mathcal{F}^t\right] - \mathbb{E}\left[\|\mathbf{v}^{t+1} - \mathbf{v}^t\|^2 \mid \mathcal{F}^t\right] \\ - \left(\frac{4\alpha\mu}{L} - \frac{2\alpha(2L-\mu)}{\eta}\right)\left(f(\mathbf{x}^t) - f(\mathbf{x}^*) - \nabla f(\mathbf{x}^*)^T(\mathbf{x}^t - \mathbf{x}^*)\right).\end{aligned} \tag{36}$$

Proof See Appendix B. ■

Lemma 5 shows an upper bound for the squared norm $\|\mathbf{u}^{t+1} - \mathbf{u}^*\|_{\mathbf{G}}^2$ which is the first part of the Lyapunov function $\|\mathbf{u}^t - \mathbf{u}^*\|_{\mathbf{G}}^2 + cp^t$ at step $t+1$. Likewise, we provide an upper bound for the second term of the Lyapunov function at time $t+1$ which is p^{t+1} in terms of p^t and some parameters that capture optimality gap. This bound is studied in the following lemma.

Lemma 6 *Consider the DSA algorithm as defined in* (6)-(9) *and the definition of* p^t *in* (33)*. Further, define* $q_{\min}$ *and* $q_{\max}$ *as the smallest and largest values for the number of instantaneous functions at a node, respectively. If Assumptions 1-3 hold true, then for all* $t > 0$ *the sequence* p^t *satisfies*

$$\mathbb{E}\left[p^{t+1} \mid \mathcal{F}^t\right] \leq \left[1 - \frac{1}{q_{\max}}\right]p^t + \frac{1}{q_{\min}}\left[f(\mathbf{x}^t) - f(\mathbf{x}^*) - \nabla f(\mathbf{x}^*)^T(\mathbf{x}^t - \mathbf{x}^*)\right]. \tag{37}$$

Proof See Appendix C. ■

Lemma 6 provides an upper bound for p^{t+1} in terms of its previous value p^t and the optimality error $f(\mathbf{x}^t) - f(\mathbf{x}^*) - \nabla f(\mathbf{x}^*)^T(\mathbf{x}^t - \mathbf{x}^*)$. Combining the results in Lemmata 5 and 6 we can show that in expectation the Lyapunov function $\|\mathbf{u}^{t+1} - \mathbf{u}^*\|_{\mathbf{G}}^2 + c\,p^{t+1}$ at step $t+1$ is strictly smaller than its previous value $\|\mathbf{u}^t - \mathbf{u}^*\|_{\mathbf{G}}^2 + c\,p^t$ at step t.

Theorem 7 *Consider the DSA algorithm as defined in* (6)-(9)*. Further recall the definition of the sequence* p^t *in* (33)*. Define* η *as an arbitrary positive constant chosen from the interval*

$$\eta \in \left(\frac{L^2 q_{\max}}{\mu q_{\min}} + \frac{L^2}{\mu} - \frac{L}{2}\ ,\ \infty\right). \tag{38}$$

If Assumptions 1-3 hold true and the stepsize α *is chosen from the interval* $\alpha \in (0, \gamma/2\eta)$*, then for arbitrary* c *chosen from the interval*

$$c \in \left(\frac{4\alpha L q_{\max}}{\eta}\ ,\ \frac{4\alpha\mu q_{\min}}{L} - \frac{2\alpha q_{\min}(2L-\mu)}{\eta}\right), \tag{39}$$

there exits a positive constant $0 < \delta < 1$ *such that*

$$\mathbb{E}\left[\|\mathbf{u}^{t+1} - \mathbf{u}^*\|_{\mathbf{G}}^2 + c\,p^{t+1} \mid \mathcal{F}^t\right] \leq (1-\delta)\left(\|\mathbf{u}^t - \mathbf{u}^*\|_{\mathbf{G}}^2 + c\,p^t\right). \tag{40}$$

Proof See Appendix D. ■

We point out that the linear convergence constant δ in (40) is explicitly available – see (100) in Appendix D. It is a function of the strong convexity parameter μ, the Lipschitz continuity constant L, lower and upper bounds on the eigenvalues of the matrices $\tilde{\mathbf{Z}}$, $\tilde{\mathbf{Z}} - \mathbf{Z}$, and $\mathbf{I} + \mathbf{Z} - 2\tilde{\mathbf{Z}}$, the smallest $q_{\min}$ and largest $q_{\max}$ values for the number of instantaneous functions available at a node, and the stepsize α. Insight on the dependence of δ with problem parameters is offered in Section 3.3.

The inequality in (40) shows that the expected value of the sequence $\|\mathbf{u}^t - \mathbf{u}^*\|_{\mathbf{G}}^2 + c\,p^t$ at time $t+1$ given the observation until step t is strictly smaller than the previous iterate at step t. Note that, it is not hard to verify that if the positive constant η is chosen from the interval in (38), the interval in (39) is non-empty. Computing the expected value with respect to the initial sigma field $\mathbb{E}\left[.\mid \mathcal{F}^0\right] = \mathbb{E}\left[.\right]$ implies that in expectation the sequence $\|\mathbf{u}^t - \mathbf{u}^*\|_{\mathbf{G}}^2 + c\,p^t$ converges linearly to null, i.e.,

$$\mathbb{E}\left[\|\mathbf{u}^t - \mathbf{u}^*\|_{\mathbf{G}}^2 + c\,p^t\right] \leq (1-\delta)^t\left(\|\mathbf{u}^0 - \mathbf{u}^*\|_{\mathbf{G}}^2 + c\,p^0\right). \tag{41}$$

We use the result in (41) to establish linear convergence of the sequence of squared norm error $\|\mathbf{x}^t - \mathbf{x}^*\|^2$ in expectation.

Corollary 8 *Consider the DSA algorithm as defined in* (6)-(9) *and recall* γ *is the minimum eigenvalue of the positive definite matrix* $\tilde{\mathbf{Z}}$*. Suppose the conditions of Theorem 7 hold, then there exits a positive constant* $0 < \delta < 1$ *such that*

$$\mathbb{E}\left[\|\mathbf{x}^t - \mathbf{x}^*\|^2\right] \leq (1-\delta)^t \frac{\left(\|\mathbf{u}^0 - \mathbf{u}^*\|^2_{\mathbf{G}} + c\,p^0\right).}{\gamma} \tag{42}$$

Proof First note that according to the definitions of $\mathbf{u}$ and $\mathbf{G}$ in (35) and the definition of p^t in (33) , we can write $\|\mathbf{x}^t - \mathbf{x}^*\|^2_{\tilde{\mathbf{Z}}} \leq \|\mathbf{u}^t - \mathbf{u}^*\|^2_{\mathbf{G}} + c\,p^t$. Further, note that the weighted norm $\|\mathbf{x}^t - \mathbf{x}^*\|^2_{\tilde{\mathbf{Z}}}$ is lower bounded by $\gamma\|\mathbf{x}^t - \mathbf{x}^*\|^2$, since γ is a lower bound for the eigenvalues of $\tilde{\mathbf{Z}}$. Combine these two observations to obtain $\gamma\|\mathbf{x}^t - \mathbf{x}^*\|^2 \leq \|\mathbf{u}^t - \mathbf{u}^*\|^2_{\mathbf{G}} + c\,p^t$. This inequality in conjunction with the expression in (41) follows the claim in (42). ■

Corollary 8 states that the sequence $\mathbb{E}\left[\|\mathbf{x}^t - \mathbf{x}^*\|^2\right]$ linearly converges to null. Note that the sequence $\mathbb{E}\left[\|\mathbf{x}^t - \mathbf{x}^*\|^2\right]$ is not necessarily monotonically decreasing as the sequence $\mathbb{E}\left[\|\mathbf{u}^t - \mathbf{u}^*\|^2_{\mathbf{G}} + c\,p^t\right]$ is. The result in (42) shows linear convergence of the sequence of variables generated by DSA in expectation. In the following Theorem we show that the local variables $\mathbf{x}_n^t$ generated by DSA almost surely converge to the optimal argument of (1).

Theorem 9 *Consider the DSA algorithm as defined in* (6)-(9) *and suppose the conditions of Theorem 7 hold. Then, the sequences of the local variables* $\mathbf{x}_n^t$ *for all* $n = 1, \ldots, N$ *converge almost surely to the optimal argument* $\tilde{\mathbf{x}}^*$*, i.e.,*

$$\lim_{t\to\infty} \mathbf{x}_n^t \;=\; \tilde{\mathbf{x}}^* \quad a.s. \qquad \text{for all } n = 1, \ldots, N. \tag{43}$$

Proof See Appendix E. ■

Theorem 9 provides almost sure convergence of $\mathbf{x}^t$ to the optimal solution $\mathbf{x}^*$ which is stronger result than convergence in expectation as in Corollary 8.

3.3 Convergence Constant

The constant δ that controls the speed of convergence can be simplified by selecting specific values for η, α, and c. This uncovers connections to the properties of the local objective functions and the network topology. To make this clearer recall the definitions of γ and Γ as the smallest and largest eigenvalues of the positive definite matrix $\tilde{\mathbf{Z}}$, respectively, and γ' and Γ' as the smallest and largest *positive* eigenvalues of the positive semi-definite matrix $\tilde{\mathbf{Z}} - \mathbf{Z}$, respectively. Further, recall that the local objective functions are strongly convex with constant μ and their gradients are Lipschitz continuous with constant L. Then, define the condition numbers of the objective function and the graph as

$$\kappa_f = \frac{L}{\mu}, \qquad \kappa_g = \frac{\max\{\Gamma, \Gamma'\}}{\min\{\gamma, \gamma'\}}, \tag{44}$$

respectively. The condition number of the function is a measure of how difficult it is to minimize the local functions using gradient descent directions. The condition number of the graph is a measure of how slow the graph is in propagating a diffusion process. Both are known to control the speed of convergence of distributed optimization methods. The following corollary illustrates that these condition numbers also determine the convergence speed of DSA.

Corollary 10 *Consider the DSA algorithm as defined in* (6)-(9) *and suppose the conditions of Theorem 7 hold. Choose the weight matrices* $\mathbf{W}$ *and* $\tilde{\mathbf{W}}$ *as* $\tilde{\mathbf{W}} = (\mathbf{I}+\mathbf{W})/2$*, assign the same number*

of instantaneous local functions $f_{n,i}$ *to each node, i.e.,* $q_{\min} = q_{\max} = q$*, and set the constants* η*,* α *and* c *as*

$$\eta = \frac{2L^2}{\mu}, \quad \alpha = \frac{\gamma\mu}{8L^2}, \quad c = \frac{q\gamma\mu^2}{4L^3}\left(1 + \frac{\mu}{4L}\right). \tag{45}$$

The linear convergence constant $0 < \delta < 1$ *in* (40) *reduces to*

$$\delta = \min\left[\frac{1}{16\kappa_g^2},\; \frac{1}{q[1 + 4\kappa_f(1+\gamma/\gamma')]},\; \frac{1}{4(\gamma/\gamma')\kappa_f + 32\kappa_g\kappa_f^4}\right]. \tag{46}$$

Proof The given values for η, α, and c satisfy the conditions in Theorem 7. Substitute then these values into the expression for δ in (100). Simplify terms and utilize the condition number definitions in (44). The second term in the minimization in (100) becomes redundant because it is dominated by the first. ■

Observe that while the choices of η, α, and c in (45) satisfy all the required conditions of Theorem 7, they are not necessarily optimal for maximizing the linear convergence constant δ. Nevertheless, the expression in (46) shows that the convergence speed of DSA decreases with increases in the graph condition number κ_g, the local functions condition number κ_f, and the number of functions assigned to each node q. For a cleaner expression observe that both, γ and γ' are the minimum eigenvalues of the weight matrix $\mathbf{W}$ and the weight matrix difference $\tilde{\mathbf{W}} - \mathbf{W}$. They can therefore be chosen to be of similar order. For reference, say that we choose $\gamma = \gamma'$ so that the ratio $\gamma/\gamma' = 1$. In that case, the constant δ in (46) reduces to

$$\delta = \min\left[\frac{1}{16\kappa_g^2},\; \frac{1}{q(1 + 8\kappa_f)},\; \frac{1}{4(\kappa_f + 8\kappa_f^4\kappa_g)}\right]. \tag{47}$$

The three terms in (47) establish separate regimes, problems where the graph condition number is large, problems where the number of functions at each node is large, and problems where the condition number of the local functions are large. In the first regime the first term in (47) dominates and establishes a dependence in terms of the square of the graph's condition number. In the second regime the middle term dominates and results in an inverse dependence with the number of functions available at each node. In the third regime, the third term dominates. The dependence in this case is inversely proportional to κ_f^4.

4. Numerical Experiments

We numerically study the performance of DSA in solving a logistic regression problem. In this problem we are given $Q = \sum_{n=1}^N q_n$ training samples that we distribute across N distinct nodes. Denote q_n as the number of samples that are assigned to node n. We assume that the samples are distributed equally over the nodes, i.e., $q_n = q_{max} = q_{min} = q = Q/N$ for $n = 1, \ldots, N$. The training points at node n are denoted by $\mathbf{s}_{n,i} \in \mathbb{R}^p$ for $i = 1, \ldots, q_n$ with associated labels $l_{n,i} \in \{-1, 1\}$. The goal is to predict the probability $\mathrm{P}\left(l = 1 \mid \mathbf{s}\right)$ of having label $l = 1$ for sample point $\mathbf{s}$. The logistic regression model assumes that this probability can be computed as $\mathrm{P}\left(l = 1 \mid \mathbf{s}\right) = 1/(1+\exp(-\mathbf{s}^T\mathbf{x}))$ given a linear classifier $\mathbf{x}$ that is computed based on the training samples. It follows from this model that the regularized maximum log likelihood estimate of the classifier $\mathbf{x}$ given the training samples $(\mathbf{s}_{n,i}, l_{n,i})$ for $i = 1, \ldots, q_n$ and $n = 1, \ldots, N$ is the solution of the optimization problem

$$\tilde{\mathbf{x}}^* := \operatorname*{argmin}_{\mathbf{x}\in\mathbb{R}^p} \frac{\lambda}{2}\|\mathbf{x}\|^2 + \sum_{n=1}^N \sum_{i=1}^{q_n} \log\left(1 + \exp(-l_{n,i}\mathbf{s}_{n,i}^T\mathbf{x})\right), \tag{48}$$

where the regularization term $(\lambda/2)\|\mathbf{x}\|^2$ is added to reduce overfitting to the training set. The optimization problem in (48) can be written in the form of (1) by defining the local objective functions f_n as

$$f_n(\mathbf{x}) = \frac{\lambda}{2N}\|\mathbf{x}\|^2 + \sum_{i=1}^{q_n} \log\Big(1+\exp(-l_{n,i}\mathbf{s}_{n,i}^T\mathbf{x})\Big). \tag{49}$$

Observe that the local functions f_n in (49) can be written as the average of a set of instantaneous functions $f_{n,i}$ defined as

$$f_{n,i}(\mathbf{x}) = \frac{\lambda}{2N}\|\mathbf{x}\|^2 + q_n \log\Big(1+\exp\big(-l_{n,i}\mathbf{s}_{n,i}^T\mathbf{x}\big)\Big), \tag{50}$$

for all $i = 1, \ldots, q_n$. Considering the definitions of the instantaneous local functions $f_{n,i}$ in (50) and the local functions f_n in (49), problem (48) can be solved using the DSA algorithm.

In our experiments in Sections 4.1-4.4, we use a synthetic dataset where the components of the feature vectors $\mathbf{s}_{n,i}$ with label $l_{n,i} = 1$ are generated from a normal distribution with mean μ and standard deviation σ_+, while sample points with label $l_{n,i} = -1$ are generated from a normal distribution with mean $-\mu$ and standard deviation σ_-. In Section 4.5, we consider a large-scale real dataset for training the classifier.

We consider a network of size N where the edges between nodes are generated randomly with probability p_c. The weight matrix $\mathbf{W}$ is generated using the Laplacian matrix $\mathbf{L}$ of network as

$$\mathbf{W} = \mathbf{I} - \mathbf{L}/\tau, \tag{51}$$

where τ should satisfy $\tau > (1/2)\lambda_{\max}(\mathbf{L})$. In our experiments we set this parameter as $\tau = (2/3)\lambda_{\max}(\mathbf{L})$. We capture the error of each algorithm by the sum of squared differences of the local iterates $\mathbf{x}_n^t$ from the optimal solution $\tilde{\mathbf{x}}^*$ as

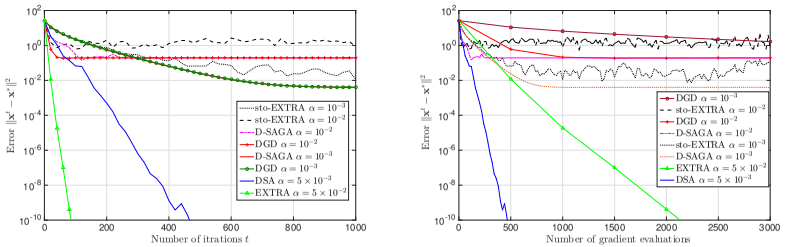
$$e^t = \|\mathbf{x}^t - \mathbf{x}^*\|^2 = \sum_{n=1}^{N} \|\mathbf{x}_n^t - \tilde{\mathbf{x}}^*\|^2. \tag{52}$$

We use a centralized algorithm for computing the optimal argument $\tilde{\mathbf{x}}^*$ in all of our experiments.

4.1 Comparison with Decentralized Methods

We provide a comparison of DSA with respect to DGD, EXTRA, stochastic EXTRA, and decentralized SAGA. The stochastic EXTRA (sto-EXTRA) is defined by using the stochastic gradient in (5) instead of using full gradient as in EXTRA or stochastic averaging gradient as in DSA. The decentralized SAGA (D-SAGA) is a stochastic version of the DGD algorithm that uses stochastic averaging gradient instead of exact gradient which is the naive approach for developing a decentralized version of the SAGA algorithm. In our experiments, the weight matrix $\tilde{\mathbf{W}}$ in EXTRA, stochastic EXTRA, and DSA is chosen as $\tilde{\mathbf{W}} = (\mathbf{I}+\mathbf{W})/2$. We use the total number of sample points $Q = 500$, feature vectors dimension $p = 2$, regularization parameter $\lambda = 10^{-4}$, probability of existence of an edge $p_c = 0.35$. To make the dataset *not* linearly separable we set the mean as $\mu = 2$ and the standard deviations to $\sigma_+ = \sigma_- = 2$. Moreover, the maximum eigenvalue of the Laplacian matrix is $\lambda_{\max}(\mathbf{L}) = 8.017$ which implies that the choice of τ in (51) is $\tau = (2/3)\lambda_{\max}(\mathbf{L}) = 5.345$. We set the total number of nodes $N = 20$ which implies that each node has access to $q = Q/N = 25$ samples.

Fig. 2 illustrates the convergence paths of DSA, EXTRA, DGD, Stochastic EXTRA, and Decentralized SAGA with constant stepsizes for $N = 20$ nodes. For EXTRA and DSA different stepsizes are chosen and the best performance for EXTRA and DSA are achieved by $\alpha = 5 \times 10^{-2}$ and $\alpha = 5 \times 10^{-3}$, respectively. It is worth mentioning that the choice of stepsize α for DSA in practice is larger than the theoretical result in Theorem 6 and Corollary 9 which suggest stepsize of the



(a) (b)

Figure 2: Convergence paths of DSA, EXTRA, DGD, Stochastic EXTRA, and Decentralized SAGA for a logistic regression problem with $Q = 500$ samples and $N = 20$ nodes. Distance to optimality $e^t = \|\mathbf{x}^t - \mathbf{x}^*\|^2$ is shown with respect to number of iterations t and number of gradient evaluations in Fig 2(a) and Fig. 2(b), respectively. DSA and EXTRA converge linearly to the optimal argument $\mathbf{x}^*$, while DGD, Stochastic EXTRA, and Decentralized SAGA with constant step sizes converge to a neighborhood of the optimal solution. Smaller choice of stepsize for DGD, Stochastic EXTRA, and Decentralized SAGA leads to a more accurate convergence, while the speed of convergence becomes slower. DSA outperforms EXTRA in terms of number of gradient evaluations to achieve a target accuracy.

order $O(\mu/L^2)$. As shown in Fig. 2, DSA is the only stochastic algorithm that converges linearly. Decentralized SAGA after a few iterations achieves the performance of DGD and they both cannot converge to the optimal argument. By choosing a smaller stepsize as $\alpha = 10^{-3}$, they reach a more accurate convergence relative to the case that the stepsize is $\alpha = 10^{-2}$; however, the speed of convergence is slower for the smaller stepsize. Stochastic EXTRA also suffers from inexact convergence, but for a different reason. DGD and decentralized SAGA have inexact convergence since they solve a penalty version of the original problem, while stochastic EXTRA can not reach the optimal solution since the noise of stochastic gradient is not vanishing. DSA resolves both issues by combining the idea of stochastic averaging from SAGA to control the noise of stochastic gradient estimation and the double descent idea of EXTRA to solve the correct optimization problem.

Fig. 2(a) illustrates convergence paths of the considered methods in terms of number of iterations t. Notice that the number of iterations t indicates the number of local iterations processed at each node. Convergence rate of EXTRA is faster than DSA in terms of number of iterations or equivalently number of communications as shown in Fig. 2(a); however, the complexity of each iteration for EXTRA is higher than DSA. Therefore, it is reasonable to compare the performances of these algorithms in terms of number of processed feature vectors or equivalently number of gradient evaluations. For instance, DSA requires $t = 380$ iterations or equivalently 380 gradient evaluations to achieve the error $e^t = 10^{-8}$, while to achieve the same accuracy EXTRA requires $t = 69$ iterations which is equivalent to $t \times q_n = 69 \times 25 = 1725$ processed feature vectors or gradient evaluations.

To illustrate this difference better, we compare the convergence paths of DSA, EXTRA, DGD, Stochastic EXTRA, and Decentralized SAGA in terms of number of gradient evaluations in Fig. 2(b). Note that the total number of gradient evaluations at each node for the stochastic methods such as DSA, sto-EXTRA, and D-SAGA is equal to the the number of iterations t, while for EXTRA and DGD – which are deterministic methods – the number of gradient evaluations is equal to the product $t \times q$. This is true since each node in the stochastic methods only evaluates 1 gradient

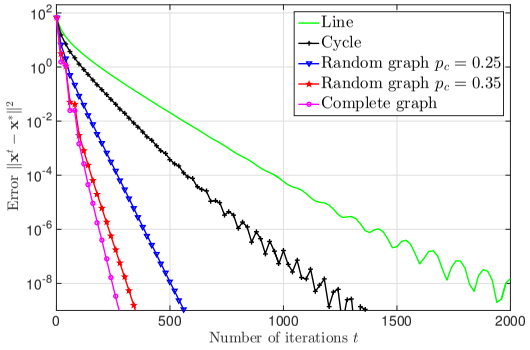


Figure 3: Convergence of DSA for different network topologies when the total number of samples is $Q = 500$ and the size of network is $N = 50$. Distance to optimality $e^t = \|\mathbf{x}_t - \mathbf{x}^*\|^2$ is shown with respect to number of iterations t. As the graph condition number κ_g becomes larger the linear convergence of DSA becomes slower. The best performance belongs to the complete graph which has the smallest condition number and the slowest convergence path belongs to the line graph which has the largest graph condition number.

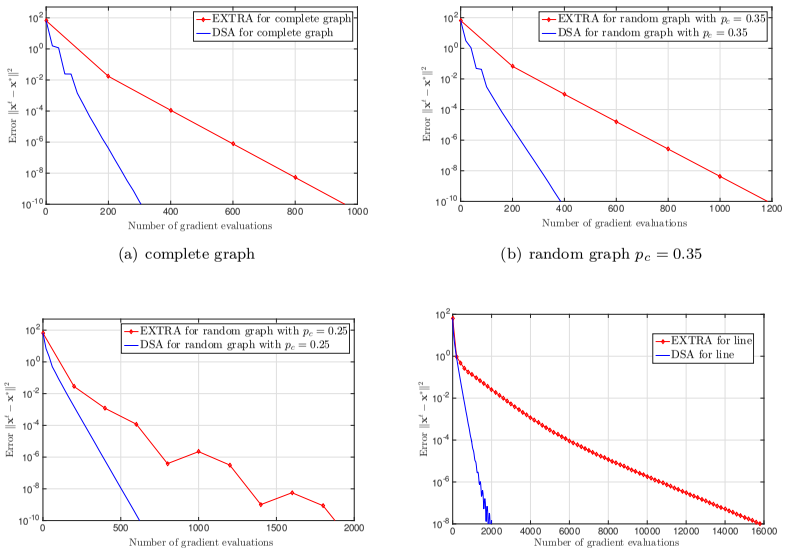
per iteration, while in the deterministic methods each node requires q gradient evaluations per iteration. The convergence paths in Fig. 2(b) showcase the advantage of DSA relative to EXTRA in requiring less processed feature vectors (or equivalently gradient evaluations) for achieving a specific accuracy. It is important to mention that the initial gradient evaluations for the DSA method is not considered in Fig. 2(b) since the initial decision variable is $\mathbf{x}^0 = \mathbf{0}$ in all experiments and evaluation of the initial gradients $\nabla f_{n,i}(\mathbf{x}^0) = -(1/2)ql_{n,i}\mathbf{s}_{n,i}$ is not computationally expensive relative to the general gradient computation which is given by $\nabla f_{n,i}(\mathbf{x}) = (\lambda\mathbf{x}/N) - (ql_{n,i}\mathbf{s}_{n,i})/(1 + \exp(l_{n,i}\mathbf{x}^T\mathbf{s}_{n,i}))$. However, if we consider this initial processing the plot for DSA in Fig. 2(b) will be shifted by $q = 25$ gradient evaluations which doesn't change the conclusion that DSA outperforms EXTRA in terms of gradient evaluations

4.2 Effect of Graph Condition Number κ_g

In this section we study the effect of the graph condition number κ_g as defined in (44) on the performance of DSA. We keep the parameters in Fig. 2 except for the network size N which we set as $N = 50$. Thus, each node has access to $q = 500/50 = 10$ sample points. The convergence paths of the DSA algorithm for random networks with $p_c = 0.25$ and $p_c = 0.35$, complete graph, cycle, and line are shown in Fig. 3. Notice that the graph condition number of the line graph, cycle graph, random graph with $p_c = 0.25$, random graph with $p_c = 0.35$, and complete graph are $\kappa_g = 1.01 \times 10^3$, $\kappa_g = 2.53 \times 10^2$, $\kappa_g = 17.05$, $\kappa_g = 4.87$, and $\kappa_g = 4$, respectively. For each network topology, we have hand-optimized the stepsize α and the best choice of stepsize for the complete graph, random graph with $p_c = 0.35$, random graph with $p_c = 0.25$, cycle, and line are $\alpha = 2 \times 10^{-2}$, $\alpha = 1.5 \times 10^{-2}$, $\alpha = 10^{-2}$, $\alpha = 5 \times 10^{-3}$, and $\alpha = 3 \times 10^{-3}$, respectively.

As we expect for the topologies that the graph has more edges and the graph condition number κ_g is smaller we observe a faster linear convergence for DSA. The best performance belongs to the



(a) complete graph (b) random graph $p_c = 0.35$

(c) random graph $p_c = 0.25$ (d) line

Figure 4: Convergence paths of DSA and EXTRA for different network topologies when the total number of samples is $Q = 500$ and the size of network is $N = 50$. Distance to optimality $e^t = \|\mathbf{x}^t - \mathbf{x}^*\|^2$ is shown with respect to number of gradient evaluations. DSA converges faster relative to EXTRA in all of the considered networks. The difference between the convergence paths of DSA and EXTRA is more substantial when the graph has a large condition number κ_g. The stepsize α for DSA and EXTRA in all the considered cases is hand-optimized and the results for the best choice of α are reported.

complete graph which requires $t = 247$ iterations to achieve the relative error $e^t = 10^{-8}$. In the random graphs with connectivity probabilities $p_c = 0.35$ and $p_c = 0.25$, DSA achieves the relative error $e^t = 10^{-8}$ after $t = 310$ and $t = 504$ iterations, respectively. For the cycle and line graphs the numbers of required iterations for reaching the relative error $e^t = 10^{-8}$ are $t = 1133$ and $t = 1819$, respectively. These observations match the theoretical result in (47) that DSA converges faster when the graph condition number κ_g is smaller.

We also compare the performances of DSA and EXTRA over different topologies to verify the claim that DSA is more efficient than EXTRA in terms of number of gradient evaluations over different network topologies. The parameters are as in Fig. 3 and the stepsize α for EXTRA in different topologies are optimized separately. In particular, the best stepsize for the complete graph, random graph with $p_c = 0.35$, random graph with $p_c = 0.25$, and line are $\alpha = 6 \times 10^{-2}$, $\alpha = 5 \times 10^{-2}$, $\alpha = 3 \times 10^{-2}$, and $\alpha = 5 \times 10^{-2}$, respectively. Fig. 4 shows the convergence paths of DSA and EXTRA versus number of gradient evaluations for four different network topologies. We observe

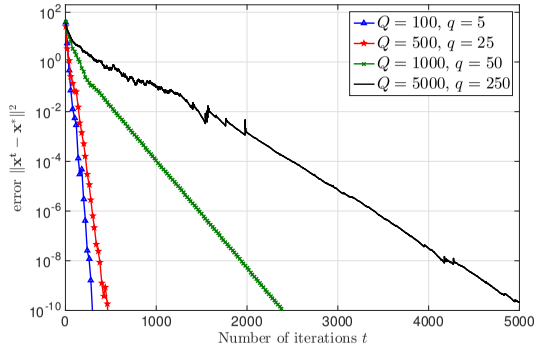


Figure 5: Comparison of convergence paths of DSA for different number of samples Q when the network size is $N = 20$ and the graph is randomly generated with the connectivity ratio $p_c = 0.35$. Convergence time for DSA increases by increasing the total number of sample points Q which is equivalent to increasing the number of samples at each node $q = Q/N$.

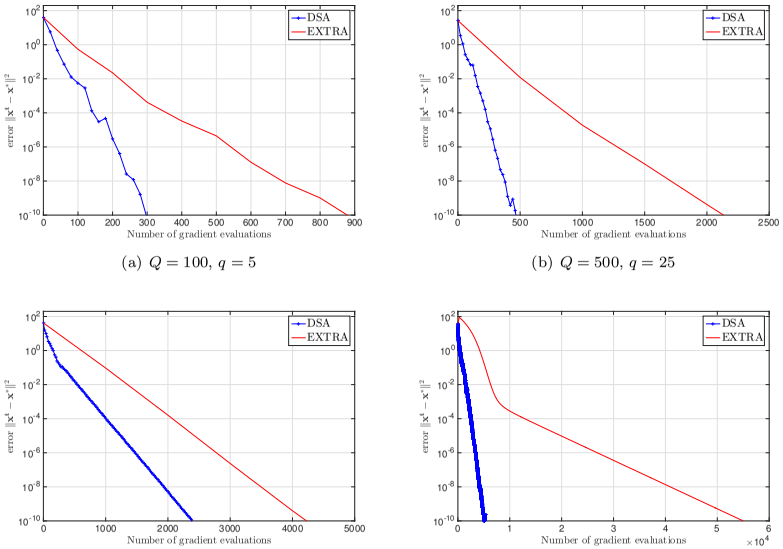
that in the considered graphs, DSA achieves a target accuracy $\|\mathbf{x}^t - \mathbf{x}^*\|^2$ faster than EXTRA. In other words, to achieve a specific accuracy $\|\mathbf{x}^t - \mathbf{x}^*\|^2$ DSA requires less number of local gradient evaluations relative to EXTRA. In addition, the gap between the performance of DSA and EXTRA is more substantial when the graph condition number κ_g is larger. In particular, in the case that we have a complete graph, which has a small graph condition number, the difference between the convergence paths of DSA and EXTRA is less significant comparing to the line graph which has a large graph condition number.

4.3 Effect of Number of Functions (Samples) at Each Node q

To evaluate performance for different number of functions (sample points) available at each node which is indicated by q, we use the same setting as in Fig. 2; however, we consider scenarios with different number of samples Q which leads to different number of samples at each node q. To be more precise, we fix the total number of nodes in the network as $N = 20$ and we consider the cases that the total number of samples are $Q = 100$, $Q = 500$, $Q = 1000$, and $Q = 5000$ where the corresponding number of samples at each node are $q = 5$, $q = 25$, $q = 50$, and $q = 250$, respectively. Similar to the experiment in Fig. 2, the graph is generated randomly with connectivity ratio $p_c = 0.35$.

For each of these scenarios the DSA stepsize α is hand-optimized and the best choice is used for comparison with others. The results are reported for $\alpha = 10^{-4}$, $\alpha = 10^{-3}$, $\alpha = 5 \times 10^{-3}$, and $\alpha = 10^{-1}$ when the total number of samples are $Q = 5000$, $Q = 1000$, $Q = 500$, $Q = 100$, respectively. The resulting convergence paths are shown in Fig. 5.

The convergence paths in Fig. 5 show that as we increase the total number of samples Q and consequently the number of assigned samples to each node q, we observe that DSA converges slower to the optimal argument. This conclusion is expected from the theoretical result in (47) which shows that the linear convergence rate of DSA becomes slower by increasing q. In particular, to achieve the target accuracy of $\|\mathbf{x}^t - \mathbf{x}^*\|^2 = 10^{-8}$ DSA requires $t = 260$, $t = 380$, $t = 1960$, and $t = 4218$



(a) $Q = 100,\ q = 5$ (b) $Q = 500,\ q = 25$

(c) $Q = 1000,\ q = 50$ (d) $Q = 5000,\ q = 250$

Figure 6: Convergence paths of DSA and EXTRA for the cases that $(Q = 100, q = 5)$, $(Q = 500, q = 25)$, $(Q = 1000, q = 50)$, and $(Q = 5000, q = 250)$ are presented. Distance to optimality $e^t = \|\mathbf{x}^t - \mathbf{x}^*\|^2$ is shown with respect to number of gradient evaluations. The total number of nodes in the network is fixed and equal to $N = 20$ and the graph is randomly generated with the connectivity ratio $p_c = 0.35$. DSA converges faster relative to EXTRA and they both converge slower when the total number of samples Q increases.

iterations (or equivalently gradient evaluations) for the cases that $q = 5$, $q = 25$, $q = 50$, $q = 250$, respectively.

To have a more comprehensive comparison of DSA and EXTRA, we also compare their performances under the four different settings considered in Fig. 5. The convergence paths of these methods in terms of number of gradient evaluations for $(Q = 100, q = 5)$, $(Q = 500, q = 25)$, $(Q = 1000, q = 50)$, and $(Q = 5000, q = 250)$ are presented in Fig 6. The optimal stepsizes for EXTRA in the considered settings are $\alpha = 4 \times 10^{-1}$, $\alpha = 5 \times 10^{-2}$, $\alpha = 3 \times 10^{-2}$, and $\alpha = \times 10^{-2}$, respectively. An interesting observation is the effect of q on the convergence rate of EXTRA. We observe that EXTRA converges slower as the number of samples at each node q increases which is identical to the observation for DSA in Fig. 5. Moreover, for all of the settings considered in Fig. 6, DSA outperforms EXTRA in terms of number of required gradient evaluations until convergence. Moreover, by increasing the total number of samples Q and subsequently the number of assigned samples to each node q the advantage of DSA with respect to EXTRA in terms of computational complexity becomes more significant. This observation justifies the use of DSA for large-scale optimization problems as we consider in Section 4.5.

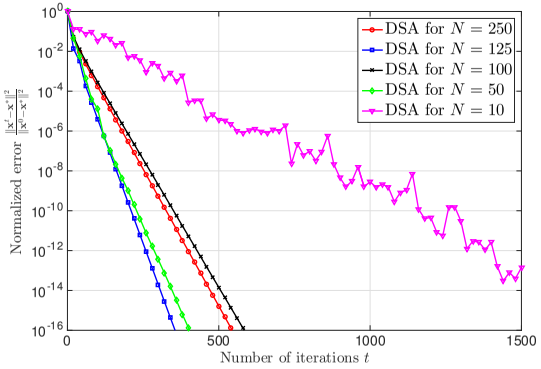


Figure 7: Normalized error $\|\mathbf{x}^t-\mathbf{x}^*\|^2/\|\mathbf{x}^0-\mathbf{x}^*\|^2$ of DSA versus number of iterations t for networks with different number of nodes N when the total number of samples is fixed $Q = 500$. The graphs are randomly generated with the connectivity ratio $p_c = 0.35$. Picking a very small or large value for N which leads to a very large or small value for q, respectively, is not preferable. The best performance belongs to the case that $N = 125$ and $q = 4$.

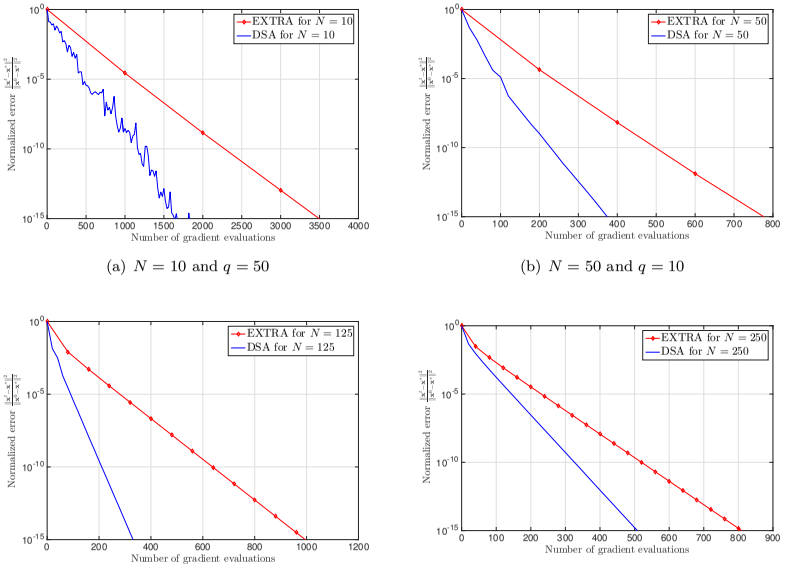
4.4 Effect of Number of Nodes N

In some settings, we can choose the number of nodes (processors) N for training the dataset. In this section, we study the effect of network size N on the convergence path of DSA when a fixed number of samples Q is given to train the classifier $\mathbf{x}$. Notice that when Q is fixed, by changing the number of nodes N, the number of assigned samples to each node $q = Q/N$ changes proportionally. Then, we may want to pick the number of nodes N or equivalently the number of assigned samples to each node q which leads to the best performance of DSA for training Q samples. Hence, we fix the total number of sample points as $Q = 500$ and assign the same amount of sample points q to each node. We consider 5 different settings with $N = 10$, $N = 50$, $N = 100$, $N = 125$, and $N = 250$ which their corresponding number of assigned samples to each node are $q = 50$, $q = 10$, $q = 5$, $q = 4$, and $q = 2$, respectively. The DSA stepsize for each of the considered settings is hand-optimized. The stepsizes $\alpha = 5 \times 10^{-3}$, $\alpha = 2 \times 10^{-2}$, $\alpha = 6 \times 10^{-2}$, and $\alpha = 8 \times 10^{-2}$ are considered for the cases that the number of assigned samples to each node are $q = 50$, $q = 10$, $q = 5$, $q = 4$, and $q = 2$, respectively.

Fig. 7 shows the convergence paths of DSA for networks with different number of nodes. Notice that the normalized error $\tilde{e}^t = \|\mathbf{x}^t-\mathbf{x}^*\|^2/\|\mathbf{x}^0-\mathbf{x}^*\|^2$ is reported, since the dimension of the vector $\mathbf{x}$ is different for different choices of N. Comparison of the convergence paths in Fig. 7 shows that the best performance belongs to the case that $N = 125$ and each node has access to $q = 4$ sample points. The performance of DSA becomes worse for the case that there are $N = 5$ nodes in the network and each node has $q = 100$ sample points. This observation implies that the DSA algorithm is also preferable to SAGA which corresponds to the case that $N = 1$. Moreover, we observe that when the number of nodes is large as $N = 250$ and each node has access to $q = 2$ samples, DSA doesn't perform well. Thus, increasing the size of network N doesn't always lead to a better performance for DSA. The best performance is observed when a moderate subset of the samples is assigned to each node.



(a) $N = 10$ and $q = 50$

(b) $N = 50$ and $q = 10$

(c) $N = 125$ and $q = 4$

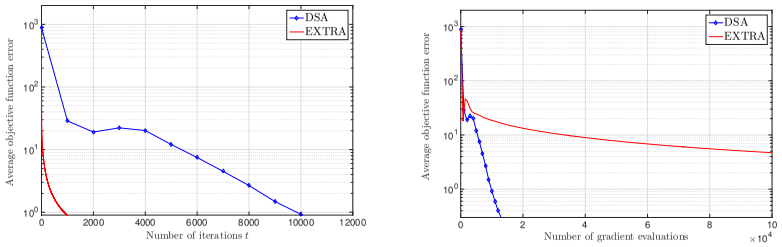
(d) $N = 250$ and $q = 2$

Figure 8: Convergence paths of DSA and EXTRA for different different number of nodes N when the total number of sample points is fixed as $Q = 500$. The graphs are randomly generated with the connectivity ratio $p_c = 0.35$. Normalized distance to optimality $\tilde{e}^t = \|\mathbf{x}^t - \mathbf{x}^*\|^2/\|\mathbf{x}^0 - \mathbf{x}^*\|^2$ is shown with respect to number of gradient evaluations. DSA converges faster relative to EXTRA in all of the considered settings.

We also study the convergence rates of DSA and EXTRA in terms of number of gradient evaluations for networks with different number of nodes N. Fig. 8 demonstrates the convergence paths of DSA and EXTRA for the cases that $N = 10$, $N = 50$, $N = 125$, and $N = 250$. Similar to DSA, we report the best performance of EXTRA for each setting which is achieved by the stepsizes $\alpha = 5 \times 10^{-2}$, $\alpha = 8 \times 10^{-2}$, $\alpha = 8 \times 10^{-2}$, and $\alpha = 10^{-1}$ for $N = 10$, $N = 50$, $N = 125$, and $N = 250$, respectively. Observe that in all settings DSA is more efficient relative to EXTRA and it requires less number of gradient evaluations for convergence.

4.5 Large-scale Classification Application

In this section we solve the logistic regression problem in (48) for the protein homology dataset provided in KDD Cup 2004. The dataset contains $Q = 1.45 \times 10^5$ sample points and each sample point has $p = 74$ features. We consider the case that the sample points are distributed over $N = 200$ nodes which implies that each node has access to $q = 725$ samples. We set the connectivity ratio $p_c = 0.35$ and hand optimize the stepsize α for DSA and EXTRA separately. The best performance of DSA is observed for $\alpha = 2 \times 10^{-7}$ and the best choice of stepize for EXTRA is $\alpha = 6 \times 10^{-7}$. We capture the error in terms of the average objective function error e^t_{avg} of the network which is



(a) (b)

Figure 9: Convergence paths of DSA and EXTRA for the protein homology classification problem with $Q = 1.45 \times 10^5$ samples. The graph has $N = 200$ nodes and it is randomly generated with the connectivity ratio $p_c = 0.35$. The average objective function error is shown with respect to number of iterations t and number of gradient evaluations, respectively.

defined as

$$e_{avg}^t := \frac{1}{N} \sum_{m=1}^{N} \left[\sum_{n=1}^{N} f_n(\mathbf{x}_m^t) - \sum_{n=1}^{N} f_n(\mathbf{x}^*) \right]. \tag{53}$$

Note that the difference $\sum_{n=1}^N f_n(\mathbf{x}_m^t) - \sum_{n=1}^N f_n(\mathbf{x}^*)$ shows the objective function error associated with the decision variable of node m at time t. Thus, the expression in (53) indicates the average objective function error of the network at step t.

The average objective function error for DSA and EXTRA in terms of number of iterations t and number of gradient evaluations are presented in Fig. 9(a) and Fig. 9(b), respectively. As we observe, the results in Fig. 9 for the large-scale classification problem match the observations in Fig. 2 for the classification problem with a synthetic dataset. In particular, both algorithms converge linearly, while EXTRA converges faster than DSA in terms of number of iterations or equivalently in terms of communication cost. On the other hand, DSA outperforms EXTRA in terms of computational complexity or number of required gradients to reach a target accuracy. Moreover, notice that the difference between the performances of DSA and EXTRA in terms of number of gradient evaluations is more significant in Fig. 9(b) relative to the one in Fig. 2(b). Thus, by increasing the problem dimension we obtain more computational complexity benefit by using DSA instead of EXTRA.

5. Conclusions

Decentralized double stochastic averaging gradient (DSA) is proposed as an algorithm for solving decentralized optimization problems where the local functions can be written as an average of a set of local instantaneous functions. DSA exploits stochastic averaging gradients in lieu of gradients and mixes information of two consecutive iterates to determine the descent direction. By assuming strongly convex local instantaneous functions with Lipschitz continuous gradients, the DSA algorithm converges linearly to the optimal arguments in expectation. In addition, the sequence of local iterates $\mathbf{x}_n^t$ for each node in the network almost surely converges to the optimal argument $\tilde{\mathbf{x}}^*$. A comparison between the DSA algorithm and a group of stochastic and deterministic alternatives are provided for solving a logistic regression problem. The numerical results show DSA is the only stochastic decentralized algorithm to reach linear convergence. DSA outperforms decentralized stochastic alternatives in terms of number of required iteration for convergence, and exhibits faster

convergence relative to deterministic alternatives in terms of number feature vectors processed until convergence.

DSA utilizes the idea of stochastic averaging gradient suggested in SAGA to reduce the computational cost of EXTRA. Although, this modification is successful in reducing the computational complexity of EXTRA and remaining the convergence rate linear, it requires stronger assumptions to prove the linear convergence. In DSA, the local instantaneous functions are required to be strongly convex which is a stricter assumption relative to the required condition for EXTRA that the global objective function should be strongly convex. This assumption for the linear convergence of DSA is inherited from the SAGA algorithm and it can be relaxed by using SVRG (Johnson and Zhang (2013)) instead of SAGA for estimating the gradients of the local functions. This modification in the update of DSA is an obvious extension of the current work and can be considered as a future research direction.

Appendix A. Proof of Lemma 4

According to the definition of $\hat{\mathbf{g}}^t$ which is the concatenation of the local stochastic averaging gradients $\hat{\mathbf{g}}_n^t$ and the fact that the expected value of sum is equal to the sum of expected values, we can write the expected value $\mathbb{E}\left[\|\hat{\mathbf{g}}^t - \nabla f(\mathbf{x}^*)\|^2 \mid \mathcal{F}^t\right]$ as

$$\mathbb{E}\left[\left\|\hat{\mathbf{g}}^t - \nabla f(\mathbf{x}^*)\right\|^2 \mid \mathcal{F}^t\right] = \sum_{n=1}^{N} \mathbb{E}\left[\left\|\hat{\mathbf{g}}_n^t - \nabla f_n(\tilde{\mathbf{x}}^*)\right\|^2 \mid \mathcal{F}^t\right]. \tag{54}$$

We proceed by finding upper bounds for the summands of (54). Observe that using the standard variance decomposition for any random variable vector $\mathbf{a}$ we can write $\mathbb{E}\left[\|\mathbf{a}\|^2\right] = \|\mathbb{E}[\mathbf{a}]\|^2 + \mathbb{E}\left[\|\mathbf{a} - \mathbb{E}[\mathbf{a}]\|^2\right]$. Notice that the same relation holds true when the expectations are computed with respect to a specific field $\mathcal{F}$. By setting $\mathbf{a} = \hat{\mathbf{g}}_n^t - \nabla f_n(\tilde{\mathbf{x}}^*)$ and considering that $\mathbb{E}[\mathbf{a} \mid \mathcal{F}^t] = \nabla f_n(\mathbf{x}_n^t) - \nabla f_n(\tilde{\mathbf{x}}^*)$, the variance decomposition implies

$$\begin{aligned}\mathbb{E}\left[\left\|\hat{\mathbf{g}}_n^t - \nabla f_n(\tilde{\mathbf{x}}^*)\right\|^2 \mid \mathcal{F}^t\right] &= \left\|\nabla f_n(\mathbf{x}_n^t) - \nabla f_n(\tilde{\mathbf{x}}^*)\right\|^2 \\ &\quad + \mathbb{E}\left[\left\|\hat{\mathbf{g}}_n^t - \nabla f_n(\tilde{\mathbf{x}}^*) - \nabla f_n(\mathbf{x}_n^t) + \nabla f_n(\tilde{\mathbf{x}}^*)\right\|^2 \mid \mathcal{F}^t\right]. \end{aligned} \tag{55}$$

The next step is to find an upper bound for the last term in (55). Adding and subtracting $\nabla f_{n,i_n^t}(\tilde{\mathbf{x}}^*)$ and using the inequality $\|\mathbf{a}+\mathbf{b}\|^2 \leq 2\|\mathbf{a}\|^2 + 2\|\mathbf{b}\|^2$ for $\mathbf{a} = \nabla f_{n,i_n^t}(\mathbf{x}_n^t) - \nabla f_{n,i_n^t}(\tilde{\mathbf{x}}^*) - \nabla f_n(\mathbf{x}_n^t) + \nabla f_n(\tilde{\mathbf{x}}^*)$ and $\mathbf{b} = -(\nabla f_{n,i_n^t}(\mathbf{y}_{n,i_n^t}^t) - \nabla f_{n,i_n^t}(\tilde{\mathbf{x}}^*) - (1/q_n)\sum_{i=1}^{q_n} \nabla f_{n,i}(\mathbf{y}_{n,i}^t) + \nabla f_n(\tilde{\mathbf{x}}^*))$ lead to

$$\begin{aligned}&\mathbb{E}\left[\left\|\hat{\mathbf{g}}_n^t - \nabla f_n(\tilde{\mathbf{x}}^*) - \nabla f_n(\mathbf{x}_n^t) + \nabla f_n(\tilde{\mathbf{x}}^*)\right\|^2 \mid \mathcal{F}^t\right] \\ &\leq 2\mathbb{E}\left[\left\|\nabla f_{n,i_n^t}(\mathbf{x}_n^t) - \nabla f_{n,i_n^t}(\tilde{\mathbf{x}}^*) - \nabla f_n(\mathbf{x}_n^t) + \nabla f_n(\tilde{\mathbf{x}}^*)\right\|^2 \mid \mathcal{F}^t\right] \\ &\quad + 2\mathbb{E}\left[\left\|\nabla f_{n,i_n^t}(\mathbf{y}_{n,i_n^t}^t) - \nabla f_{n,i_n^t}(\tilde{\mathbf{x}}^*) - \frac{1}{q_n}\sum_{i=1}^{q_n} \nabla f_{n,i}(\mathbf{y}_{n,i}^t) + \nabla f_n(\tilde{\mathbf{x}}^*)\right\|^2 \mid \mathcal{F}^t\right]. \end{aligned} \tag{56}$$

In this step we use the standard variance decomposition twice to simplify the two expectations in the right hand side of (56). Based on the standard variance decomposition $\mathbb{E}\left[\|\mathbf{a} - \mathbb{E}[\mathbf{a}]\|^2\right] =$

$\mathbb{E}\left[\|\mathbf{a}\|^2\right]-\|\mathbb{E}\left[\mathbf{a}\right]\|^2$ we obtain $\mathbb{E}\left[\|\mathbf{a}-\mathbb{E}\left[\mathbf{a}\right]\|^2\right]\leq\mathbb{E}\left[\|\mathbf{a}\|^2\right]$. Therefore, by setting $\mathbf{y}=\nabla f_{n,i_n^t}(\mathbf{y}_{n,i_n^t}^t)-\nabla f_{n,i_n^t}(\tilde{\mathbf{x}}^*)$ and observing that the expected value $\mathbb{E}\left[\nabla f_{n,i_n^t}(\mathbf{y}_{n,i_n^t}^t)-\nabla f_{n,i_n^t}(\tilde{\mathbf{x}}^*)\mid\mathcal{F}^t\right]$ is equal to $(1/q_n)\sum_{i=1}^{q_n}\nabla f_{n,i}(\mathbf{y}_{n,i}^t)-\nabla f_n(\tilde{\mathbf{x}}^*)$ we obtain that

$$\mathbb{E}\left[\left\|\nabla f_{n,i_n^t}(\mathbf{y}_{n,i_n^t}^t)-\nabla f_{n,i_n^t}(\tilde{\mathbf{x}}^*)-\frac{1}{q_n}\sum_{i=1}^{q_n}\nabla f_{n,i}(\mathbf{y}_{n,i}^t)+\nabla f_n(\tilde{\mathbf{x}}^*)\right\|^2\mid\mathcal{F}^t\right]$$
$$\leq\mathbb{E}\left[\left\|\nabla f_{n,i_n^t}(\mathbf{y}_{n,i_n^t}^t)-\nabla f_{n,i_n^t}(\tilde{\mathbf{x}}^*)\right\|^2\mid\mathcal{F}^t\right].\tag{57}$$

Moreover, by choosing $\mathbf{a}=\nabla f_{n,i_n^t}(\mathbf{x}_n^t)-\nabla f_{n,i_n^t}(\tilde{\mathbf{x}}^*)$ and noticing the relation for the expected value which is $\mathbb{E}\left[\nabla f_{n,i_n^t}(\mathbf{x}_n^t)-\nabla f_{n,i_n^t}(\tilde{\mathbf{x}}^*)\mid\mathcal{F}^t\right]=\nabla f_n(\mathbf{x}_n^t)-\nabla f_n(\tilde{\mathbf{x}}^*)$, the equality $\mathbb{E}\left[\|\mathbf{a}-\mathbb{E}\left[\mathbf{a}\right]\|^2\right]=\mathbb{E}\left[\|\mathbf{a}\|^2\right]-\|\mathbb{E}\left[\mathbf{a}\right]\|^2$ yields

$$\mathbb{E}\left[\left\|\nabla f_{n,i_n^t}(\mathbf{x}_n^t)-\nabla f_{n,i_n^t}(\tilde{\mathbf{x}}^*)-\nabla f_n(\mathbf{x}_n^t)+\nabla f_n(\tilde{\mathbf{x}}^*)\right\|^2\mid\mathcal{F}^t\right]$$
$$=\mathbb{E}\left[\left\|\nabla f_{n,i_n^t}(\mathbf{x}_n^t)-\nabla f_{n,i_n^t}(\tilde{\mathbf{x}}^*)\right\|^2\mid\mathcal{F}^t\right]-\left\|\nabla f_n(\mathbf{x}_n^t)-\nabla f_n(\tilde{\mathbf{x}}^*)\right\|^2.\tag{58}$$

By substituting the upper bound in (57) and the simplification in (58) into (56), and considering the expression in (55) we obtain that

$$\mathbb{E}\left[\left\|\hat{\mathbf{g}}^t-\nabla f(\mathbf{x}^*)\right\|^2\mid\mathcal{F}^t\right]\leq 2\sum_{n=1}^{N}\mathbb{E}\left[\left\|\nabla f_{n,i_n^t}(\mathbf{y}_{n,i_n^t}^t)-\nabla f_{n,i_n^t}(\tilde{\mathbf{x}}^*)\right\|^2\mid\mathcal{F}^t\right]-\sum_{n=1}^{N}\left\|\nabla f_n(\mathbf{x}_n^t)-\nabla f_n(\tilde{\mathbf{x}}^*)\right\|^2$$
$$+2\sum_{n=1}^{N}\mathbb{E}\left[\left\|\nabla f_{n,i_n^t}(\mathbf{x}_n^t)-\nabla f_{n,i_n^t}(\tilde{\mathbf{x}}^*)\right\|^2\mid\mathcal{F}^t\right].\tag{59}$$

We proceed by finding an upper bound for the first sum in the right hand side of (59). Notice that if the gradients of the function g are Lipschitz continuous with parameter L, then for any two vectors $\mathbf{a}_1$ and $\mathbf{a}_2$ we can write $g(\mathbf{a}_1)\geq g(\mathbf{a}_2)+\nabla g(\mathbf{a}_2)^T(\mathbf{a}_1-\mathbf{a}_2)+(1/2L)\|\nabla g(\mathbf{a}_1)-\nabla g(\mathbf{a}_2)\|^2$. According to the Lipschitz continuity of the instantaneous local functions gradient $\nabla f_{n,i}(\mathbf{x}_n)$, we can write the inequality for $g=f_{n,i}$, $\mathbf{a}_1=\mathbf{y}_{n,i}^t$ and $\mathbf{a}_2=\tilde{\mathbf{x}}^*$ which is equivalent to

$$\frac{1}{2L}\left\|\nabla f_{n,i}(\mathbf{y}_{n,i}^t)-\nabla f_{n,i}(\tilde{\mathbf{x}}^*)\right\|^2\leq f_{n,i}(\mathbf{y}_{n,i}^t)-f_{n,i}(\tilde{\mathbf{x}}^*)-\nabla f_{n,i}(\tilde{\mathbf{x}}^*)^T(\mathbf{y}_{n,i}^t-\tilde{\mathbf{x}}^*).\tag{60}$$

Summing up both sides of (60) for all $i=1,\ldots,q_n$ and dividing both sides of the implied inequality by q_n yield

$$\frac{1}{q_n}\sum_{i=1}^{q_n}\left\|\nabla f_{n,i}(\mathbf{y}_{n,i}^t)-\nabla f_{n,i}(\tilde{\mathbf{x}}^*)\right\|^2\leq 2L\left[\frac{1}{q_n}\sum_{i=1}^{q_n}f_{n,i}(\mathbf{y}_{n,i}^t)-f_{n,i}(\tilde{\mathbf{x}}^*)-\nabla f_{n,i}(\tilde{\mathbf{x}}^*)^T(\mathbf{y}_{n,i}^t-\tilde{\mathbf{x}}^*)\right].\tag{61}$$

Since the random functions f_{n,i_n^t} has a uniform distribution over the set $\{f_{n,1},\ldots,f_{n,q_n}\}$, we can substitute the left hand side of (61) by $\mathbb{E}\left[\left\|\nabla f_{n,i_n^t}(\mathbf{y}_{n,i_n^t}^t)-\nabla f_{n,i_n^t}(\tilde{\mathbf{x}}^*)\right\|^2\mid\mathcal{F}^t\right]$. Apply this substitution and sum up both sides of (61) for $n=1,\ldots,N$. According to the definition of sequence p^t in (33), if we sum up the right hand side of (61) over n it can be simplified as $2Lp^t$. Applying these simplifications we obtain

$$\sum_{n=1}^{N}\mathbb{E}\left[\left\|\nabla f_{n,\boldsymbol{\theta}_n^t}(\mathbf{y}_n^t)-\nabla f_{n,\boldsymbol{\theta}_n^t}(\tilde{\mathbf{x}}^*)\right\|^2\mid\mathcal{F}^t\right]\leq 2Lp^t.\tag{62}$$

Substituting the upper bound in (62) into (59) and simplifying the sum $\sum_{n=1}^{N}\|\nabla f_n(\mathbf{x}_n^t)-\nabla f_n(\tilde{\mathbf{x}}^*)\|^2$ as $\|\nabla f(\mathbf{x}^t)-\nabla f(\mathbf{x}^*)\|^2$ yield

$$\mathbb{E}\left[\left\|\hat{\mathbf{g}}^t-\nabla f(\mathbf{x}^*)\right\|^2\mid\mathcal{F}^t\right]\leq 2\sum_{n=1}^{N}\mathbb{E}\left[\left\|\nabla f_{n,i_n^t}(\mathbf{x}_n^t)-\nabla f_{n,i_n^t}(\tilde{\mathbf{x}}^*)\right\|^2\mid\mathcal{F}^t\right]-\left\|\nabla f(\mathbf{x}^t)-\nabla f(\mathbf{x}^*)\right\|^2$$
$$+4Lp^t.\tag{63}$$

To show that the sum in the right hand side of (63) is bounded above we use the Lipschitz continuity of the instantaneous functions gradients $\nabla f_{n,i}$. Using the same argument from (60) to (62) we can write

$$\sum_{n=1}^{N}\mathbb{E}\left[\left\|\nabla f_{n,i_n^t}(\mathbf{x}_n^t)-\nabla f_{n,i_n^t}(\tilde{\mathbf{x}}^*)\right\|^2\mid\mathcal{F}^t\right]\tag{64}$$
$$\leq 2L\sum_{n=1}^{N}\frac{1}{q_n}\left[\sum_{i=1}^{q_n}f_{n,i}(\mathbf{x}_n^t)-f_{n,i}(\tilde{\mathbf{x}}^*)-\nabla f_{n,i}(\tilde{\mathbf{x}}^*)^T(\mathbf{x}_n^t-\tilde{\mathbf{x}}^*)\right].$$

Considering the definition of the local objective functions $f_n(\mathbf{x}_n)=(1/q_n)\sum_{i=1}^{q_n}f_{n,i}(\mathbf{x}_n)$ and the aggregate function $f(\mathbf{x}):=\sum_{n=1}^{N}f_n(\mathbf{x}_n)$, the right hand side of (64) can be simplified as

$$\sum_{n=1}^{N}\mathbb{E}\left[\left\|\nabla f_{n,i_n^t}(\mathbf{x}_n^t)-\nabla f_{n,i_n^t}(\tilde{\mathbf{x}}^*)\right\|^2\mid\mathcal{F}^t\right]\leq 2L\left(f(\mathbf{x}^t)-f(\mathbf{x}^*)-\nabla f(\mathbf{x}^*)^T(\mathbf{x}^t-\mathbf{x}^*)\right).\tag{65}$$

Replacing the sum in (63) by the upper bound in (65) implies

$$\mathbb{E}\left[\left\|\hat{\mathbf{g}}^t-\nabla f(\mathbf{x}^*)\right\|^2\mid\mathcal{F}^t\right]\leq 4Lp^t-\left\|\nabla f(\mathbf{x}^t)-\nabla f(\mathbf{x}^*)\right\|^2+4L\left(f(\mathbf{x}^t)-f(\mathbf{x}^*)-\nabla f(\mathbf{x}^*)^T(\mathbf{x}^t-\mathbf{x}^*)\right).\tag{66}$$

Considering the strong convexity of the global objective function f with constant μ we can write

$$\left\|\nabla f(\mathbf{x}^t)-\nabla f(\mathbf{x}^*)\right\|^2\geq 2\mu\left(f(\mathbf{x}^t)-f(\mathbf{x}^*)-\nabla f(\mathbf{x}^*)^T(\mathbf{x}^t-\mathbf{x}^*)\right).\tag{67}$$

Therefore, we can substitute $\|\nabla f(\mathbf{x}^t)-\nabla f(\mathbf{x}^*)\|^2$ in (65) by the lower bound in (67) and the claim in (34) follows.

Appendix B. Proof of Lemma 5

According to the Lipschitz continuity of the aggregate function gradients $\nabla f(\mathbf{x})$, we can write $(1/L)\|\nabla f(\mathbf{x}^t)-\nabla f(\mathbf{x}^*)\|^2\leq(\mathbf{x}^t-\mathbf{x}^*)^T(\nabla f(\mathbf{x}^t)-\nabla f(\mathbf{x}^*))$. By adding and subtracting $\mathbf{x}^{t+1}$ to the term $\mathbf{x}^t-\mathbf{x}^*$ and multiplying both sides of the inequality by 2α we obtain

$$\frac{2\alpha}{L}\left\|\nabla f(\mathbf{x}^t)-\nabla f(\mathbf{x}^*)\right\|^2\leq 2\alpha(\mathbf{x}^{t+1}-\mathbf{x}^*)^T(\nabla f(\mathbf{x}^t)-\nabla f(\mathbf{x}^*))+2\alpha(\mathbf{x}^t-\mathbf{x}^{t+1})^T(\nabla f(\mathbf{x}^t)-\nabla f(\mathbf{x}^*)).\tag{68}$$

Expanding the difference $\nabla f(\mathbf{x}^t)-\nabla f(\mathbf{x}^*)$ as $\hat{\mathbf{g}}^t-\nabla f(\mathbf{x}^*)+\nabla f(\mathbf{x}^t)-\hat{\mathbf{g}}^t$ for the first inner product in the right hand side of (68) implies

$$\frac{2\alpha}{L}\left\|\nabla f(\mathbf{x}^t)-\nabla f(\mathbf{x}^*)\right\|^2\leq 2\alpha(\mathbf{x}^t-\mathbf{x}^{t+1})^T(\nabla f(\mathbf{x}^t)-\nabla f(\mathbf{x}^*))+2\alpha(\mathbf{x}^{t+1}-\mathbf{x}^*)^T(\hat{\mathbf{g}}^t-\nabla f(\mathbf{x}^*))$$
$$+2\alpha(\mathbf{x}^{t+1}-\mathbf{x}^*)^T(\nabla f(\mathbf{x}^t)-\hat{\mathbf{g}}^t).\tag{69}$$

We proceed to simplify the inner product $2\alpha(\mathbf{x}^{t+1}-\mathbf{x}^*)^T(\hat{\mathbf{g}}^t-\nabla f(\mathbf{x}^*))$ in the right hand side of (69) by substituting $\alpha(\hat{\mathbf{g}}^t-\nabla f(\mathbf{x}^*))$ with its equivalent as introduced in (30). By applying this substitution the inner product $2\alpha(\mathbf{x}^{t+1}-\mathbf{x}^*)^T(\hat{\mathbf{g}}^t-\nabla f(\mathbf{x}^*))$ can be simplified as

$$2\alpha(\mathbf{x}^{t+1}-\mathbf{x}^*)^T(\hat{\mathbf{g}}^t-\nabla f(\mathbf{x}^*)) = -2\|\mathbf{x}^{t+1}-\mathbf{x}^*\|^2_{\mathbf{I}+\mathbf{Z}-2\tilde{\mathbf{Z}}}+2(\mathbf{x}^{t+1}-\mathbf{x}^*)^T\tilde{\mathbf{Z}}(\mathbf{x}^t-\mathbf{x}^{t+1}) - 2(\mathbf{x}^{t+1}-\mathbf{x}^*)^T\mathbf{U}(\mathbf{v}^{t+1}-\mathbf{v}^*). \tag{70}$$

Based on the KKT condition of problem (25), the optimal primal variable satisfies $(\tilde{\mathbf{Z}}-\mathbf{Z})^{1/2}\mathbf{x}^*=\mathbf{0}$ which by considering the definition of the matrix $\mathbf{U}=(\tilde{\mathbf{Z}}-\mathbf{Z})^{1/2}$ we obtain that $\mathbf{U}\mathbf{x}^*=\mathbf{0}$. This observation in conjunction with the update rule of the dual variable $\mathbf{v}^t$ in (28) implies that we can substitute $\mathbf{U}(\mathbf{x}^{t+1}-\mathbf{x}^*)$ by $\mathbf{v}^{t+1}-\mathbf{v}^t$. Making this substitution into the last summand of the right hand side of (70) and considering the symmetry of the matrix $\mathbf{U}$ yield

$$2\alpha(\mathbf{x}^{t+1}-\mathbf{x}^*)^T(\hat{\mathbf{g}}^t-\nabla f(\mathbf{x}^*)) = -2\|\mathbf{x}^{t+1}-\mathbf{x}^*\|^2_{\mathbf{I}+\mathbf{Z}-2\tilde{\mathbf{Z}}}+2(\mathbf{x}^{t+1}-\mathbf{x}^*)^T\tilde{\mathbf{Z}}(\mathbf{x}^t-\mathbf{x}^{t+1}) - 2(\mathbf{v}^{t+1}-\mathbf{v}^t)^T(\mathbf{v}^{t+1}-\mathbf{v}^*). \tag{71}$$

According to the definition of the vector $\mathbf{u}$ and matrix $\mathbf{G}$ in (35), the last two summands of (71) can be simplified as $2(\mathbf{u}^{t+1}-\mathbf{u}^t)^T\mathbf{G}(\mathbf{u}^*-\mathbf{u}^{t+1})$. Moreover, observe that the inner product $2(\mathbf{u}^{t+1}-\mathbf{u}^t)^T\mathbf{G}(\mathbf{u}^*-\mathbf{u}^{t+1})$ can be simplified as $\|\mathbf{u}^t-\mathbf{u}^*\|^2_{\mathbf{G}}-\|\mathbf{u}^{t+1}-\mathbf{u}^*\|^2_{\mathbf{G}}-\|\mathbf{u}^{t+1}-\mathbf{u}^t\|^2_{\mathbf{G}}$. Applying this simplification into (71) implies

$$2\alpha(\mathbf{x}^{t+1}-\mathbf{x}^*)^T(\hat{\mathbf{g}}^t-\nabla f(\mathbf{x}^*)) = -2\|\mathbf{x}^{t+1}-\mathbf{x}^*\|^2_{\mathbf{I}+\mathbf{Z}-2\tilde{\mathbf{Z}}}+\|\mathbf{u}^t-\mathbf{u}^*\|^2_{\mathbf{G}}-\|\mathbf{u}^{t+1}-\mathbf{u}^*\|^2_{\mathbf{G}} - \|\mathbf{u}^{t+1}-\mathbf{u}^t\|^2_{\mathbf{G}}. \tag{72}$$

The next step is to find an upper bound for the inner product $2\alpha(\mathbf{x}^t-\mathbf{x}^{t+1})^T(\nabla f(\mathbf{x}^t)-\nabla f(\mathbf{x}^*))$. Note that for any two vectors $\mathbf{a}$ and $\mathbf{b}$, and any positive scalar η the inequality $2\mathbf{a}^T\mathbf{b}\leq\eta\|\mathbf{a}\|^2+\eta^{-1}\|\mathbf{b}\|^2$ holds. Thus, by setting $\mathbf{a}=\mathbf{x}^t-\mathbf{x}^{t+1}$ and $\mathbf{b}=\nabla f(\mathbf{x}^t)-\nabla f(\mathbf{x}^*)$ we obtain that

$$2\alpha(\mathbf{x}^t-\mathbf{x}^{t+1})^T(\nabla f(\mathbf{x}^t)-\nabla f(\mathbf{x}^*))\leq\frac{\alpha}{\eta}\|\nabla f(\mathbf{x}^t)-\nabla f(\mathbf{x}^*)\|^2+\alpha\eta\|\mathbf{x}^t-\mathbf{x}^{t+1}\|^2. \tag{73}$$

Now we substitute the terms in the right hand side of (69) by their simplifications or upper bounds. Replacing the inner product $2\alpha(\mathbf{x}^{t+1}-\mathbf{x}^*)^T(\hat{\mathbf{g}}^t-\nabla f(\mathbf{x}^*))$ by the simplification in (72), substituting expression $2\alpha(\mathbf{x}^t-\mathbf{x}^{t+1})^T(\nabla f(\mathbf{x}^t)-\nabla f(\mathbf{x}^*))$ by the upper bound in (73), and substituting inner product $2\alpha(\mathbf{x}^{t+1}-\mathbf{x}^*)^T(\nabla f(\mathbf{x}^t)-\hat{\mathbf{g}}^t)$ by the sum $2\alpha(\mathbf{x}^t-\mathbf{x}^*)^T(\nabla f(\mathbf{x}^t)-\hat{\mathbf{g}}^t)+2\alpha(\mathbf{x}^{t+1}-\mathbf{x}^t)^T(\nabla f(\mathbf{x}^t)-\hat{\mathbf{g}}^t)$ imply

$$\frac{2\alpha}{L}\left\|\nabla f(\mathbf{x}^t)-\nabla f(\mathbf{x}^*)\right\|^2\leq -2\|\mathbf{x}^{t+1}-\mathbf{x}^*\|^2_{\mathbf{I}+\mathbf{Z}-2\tilde{\mathbf{Z}}}+\|\mathbf{u}^t-\mathbf{u}^*\|^2_{\mathbf{G}}-\|\mathbf{u}^{t+1}-\mathbf{u}^*\|^2_{\mathbf{G}} - \|\mathbf{u}^{t+1}-\mathbf{u}^t\|^2_{\mathbf{G}}+\alpha\eta\|\mathbf{x}^t-\mathbf{x}^{t+1}\|^2+\frac{\alpha}{\eta}\|\nabla f(\mathbf{x}^t)-\nabla f(\mathbf{x}^*)\|^2 + 2\alpha(\mathbf{x}^t-\mathbf{x}^*)^T(\nabla f(\mathbf{x}^t)-\hat{\mathbf{g}}^t)+2\alpha(\mathbf{x}^{t+1}-\mathbf{x}^t)^T(\nabla f(\mathbf{x}^t)-\hat{\mathbf{g}}^t). \tag{74}$$

Considering that $\mathbf{x}^t-\mathbf{x}^*$ is deterministic given observations until step t and observing the relation $\mathbb{E}\left[\hat{\mathbf{g}}^t\mid\mathcal{F}^t\right]=\nabla f(\mathbf{x}^t)$, we obtain that $\mathbb{E}\left[(\mathbf{x}^t-\mathbf{x}^*)^T(\nabla f(\mathbf{x}^t)-\hat{\mathbf{g}}^t)\mid\mathcal{F}^t\right]=0$. Therefore, by computing the expected value of both sides of (74) given the observations until step t and regrouping the terms we obtain

$$\|\mathbf{u}^t-\mathbf{u}^*\|^2_{\mathbf{G}}-\mathbb{E}\left[\|\mathbf{u}^{t+1}-\mathbf{u}^*\|^2_{\mathbf{G}}\mid\mathcal{F}^t\right]\geq\alpha\left(\frac{2}{L}-\frac{1}{\eta}\right)\left\|\nabla f(\mathbf{x}^t)-\nabla f(\mathbf{x}^*)\right\|^2+\mathbb{E}\left[\|\mathbf{u}^{t+1}-\mathbf{u}^t\|^2_{\mathbf{G}}\mid\mathcal{F}^t\right] + 2\mathbb{E}\left[\|\mathbf{x}^{t+1}-\mathbf{x}^*\|^2_{\mathbf{I}+\mathbf{Z}-2\tilde{\mathbf{Z}}}\mid\mathcal{F}^t\right]-\alpha\eta\mathbb{E}\left[\|\mathbf{x}^t-\mathbf{x}^{t+1}\|^2\mid\mathcal{F}^t\right] - \mathbb{E}\left[2\alpha(\mathbf{x}^{t+1}-\mathbf{x}^t)^T(\nabla f(\mathbf{x}^t)-\hat{\mathbf{g}}^t)\mid\mathcal{F}^t\right]. \tag{75}$$

By applying inequality $2\mathbf{a}^T\mathbf{b}\leq\eta\|\mathbf{a}\|^2+\eta^{-1}\|\mathbf{b}\|^2$ for the vectors $\mathbf{a}=\mathbf{x}^{t+1}-\mathbf{x}^t$ and $\mathbf{b}=\nabla f(\mathbf{x}^t)-\hat{\mathbf{g}}^t$, we obtain that the inner product $2(\mathbf{x}^{t+1}-\mathbf{x}^t)^T(\nabla f(\mathbf{x}^t)-\hat{\mathbf{g}}^t)$ is bounded above by $\eta\|\mathbf{x}^{t+1}-\mathbf{x}^t\|^2+(1/\eta)\|\nabla f(\mathbf{x}^t)-\hat{\mathbf{g}}^t\|^2$. Replacing $2(\mathbf{x}^{t+1}-\mathbf{x}^t)^T(\nabla f(\mathbf{x}^t)-\hat{\mathbf{g}}^t)$ in (75) by its upper bound $\eta\|\mathbf{x}^{t+1}-\mathbf{x}^t\|^2+(1/\eta)\|\nabla f(\mathbf{x}^t)-\hat{\mathbf{g}}^t\|^2$ yields

$$\|\mathbf{u}^t-\mathbf{u}^*\|^2_{\mathbf{G}}-\mathbb{E}\left[\|\mathbf{u}^{t+1}-\mathbf{u}^*\|^2_{\mathbf{G}}\mid\mathcal{F}^t\right]\geq\alpha\left(\frac{2}{L}-\frac{1}{\eta}\right)\left\|\nabla f(\mathbf{x}^t)-\nabla f(\mathbf{x}^*)\right\|^2+\mathbb{E}\left[\|\mathbf{u}^{t+1}-\mathbf{u}^t\|^2_{\mathbf{G}}\mid\mathcal{F}^t\right] + 2\mathbb{E}\left[\|\mathbf{x}^{t+1}-\mathbf{x}^*\|^2_{\mathbf{I}+\mathbf{Z}-2\tilde{\mathbf{Z}}}\mid\mathcal{F}^t\right]-2\alpha\eta\mathbb{E}\left[\|\mathbf{x}^t-\mathbf{x}^{t+1}\|^2\mid\mathcal{F}^t\right] - \frac{\alpha}{\eta}\mathbb{E}\left[\|\nabla f(\mathbf{x}^t)-\hat{\mathbf{g}}^t\|^2\mid\mathcal{F}^t\right]. \tag{76}$$

Observe that the squared norm $\|\mathbf{u}^{t+1}-\mathbf{u}^t\|^2_{\mathbf{G}}$ can be expanded as $\|\mathbf{x}^{t+1}-\mathbf{x}^t\|^2_{\tilde{\mathbf{Z}}}+\|\mathbf{v}^{t+1}-\mathbf{v}^t\|^2$. Using this simplification for $\|\mathbf{u}^{t+1}-\mathbf{u}^t\|^2_{\mathbf{G}}$ and regrouping the terms in (76) lead to

$$\|\mathbf{u}^t-\mathbf{u}^*\|^2_{\mathbf{G}}-\mathbb{E}\left[\|\mathbf{u}^{t+1}-\mathbf{u}^*\|^2_{\mathbf{G}}\mid\mathcal{F}^t\right]\geq\alpha\left(\frac{2}{L}-\frac{1}{\eta}\right)\left\|\nabla f(\mathbf{x}^t)-\nabla f(\mathbf{x}^*)\right\|^2 + \mathbb{E}\left[\|\mathbf{x}^{t+1}-\mathbf{x}^t\|^2_{\mathbf{Z}-2\alpha\eta\mathbf{I}}\mid\mathcal{F}^t\right]+\mathbb{E}\left[\|\mathbf{v}^{t+1}-\mathbf{v}^t\|^2\mid\mathcal{F}^t\right] + 2\mathbb{E}\left[\|\mathbf{x}^{t+1}-\mathbf{x}^*\|^2_{\mathbf{I}+\mathbf{Z}-2\tilde{\mathbf{Z}}}\big|\mathcal{F}^t\right]-\frac{\alpha}{\eta}\mathbb{E}\left[\|\nabla f(\mathbf{x}^t)-\hat{\mathbf{g}}^t\|^2\big|\mathcal{F}^t\right]. \tag{77}$$

We proceed by simplifying the expectation $\mathbb{E}\left[\|\nabla f(\mathbf{x}^t)-\hat{\mathbf{g}}^t\|^2\big|\mathcal{F}^t\right]$ in (77). Note that by adding and subtracting $\nabla f(\mathbf{x}^*)$, the expectation can be written as $\mathbb{E}\left[\|\nabla f(\mathbf{x}^t)-\nabla f(\mathbf{x}^*)+\nabla f(\mathbf{x}^*)-\hat{\mathbf{g}}^t\|^2\mid\mathcal{F}^t\right]$ and by expanding the squared norm and simplifying the terms we obtain

$$\mathbb{E}\left[\left\|\nabla f(\mathbf{x}^t)-\hat{\mathbf{g}}^t\right\|^2\mid\mathcal{F}^t\right]=\mathbb{E}\left[\left\|\hat{\mathbf{g}}^t-\nabla f(\mathbf{x}^*)\right\|^2\mid\mathcal{F}^t\right]-\mathbb{E}\left[\left\|\nabla f(\mathbf{x}^t)-\nabla f(\mathbf{x}^*)\right\|^2\mid\mathcal{F}^t\right]. \tag{78}$$

Substituting the simplification in (78) into (77) yields

$$\|\mathbf{u}^t-\mathbf{u}^*\|^2_{\mathbf{G}}-\mathbb{E}\left[\|\mathbf{u}^{t+1}-\mathbf{u}^*\|^2_{\mathbf{G}}\mid\mathcal{F}^t\right]\geq\frac{2\alpha}{L}\left\|\nabla f(\mathbf{x}^t)-\nabla f(\mathbf{x}^*)\right\|^2 + \mathbb{E}\left[\|\mathbf{x}^{t+1}-\mathbf{x}^t\|^2_{\mathbf{Z}-2\alpha\eta\mathbf{I}}\mid\mathcal{F}^t\right]+\mathbb{E}\left[\|\mathbf{v}^{t+1}-\mathbf{v}^t\|^2\mid\mathcal{F}^t\right] + 2\mathbb{E}\left[\|\mathbf{x}^{t+1}-\mathbf{x}^*\|^2_{\mathbf{I}+\mathbf{Z}-2\tilde{\mathbf{Z}}}\big|\mathcal{F}^t\right]-\frac{\alpha}{\eta}\mathbb{E}\left[\|\hat{\mathbf{g}}^t-\nabla f(\mathbf{x}^*)\|^2\mid\mathcal{F}^t\right]. \tag{79}$$

Considering the strong convexity of the global objective function f with constant μ we can write $\|\nabla f(\mathbf{x}^t)-\nabla f(\mathbf{x}^*)\|^2\geq 2\mu\left(f(\mathbf{x}^t)-f(\mathbf{x}^*)-\nabla f(\mathbf{x}^*)^T(\mathbf{x}^t-\mathbf{x}^*)\right)$. Substituting the squared norm $\|\nabla f(\mathbf{x}^t)-\nabla f(\mathbf{x}^*)\|^2$ by this lower bound in (79) follows

$$\|\mathbf{u}^t-\mathbf{u}^*\|^2_{\mathbf{G}}-\mathbb{E}\left[\|\mathbf{u}^{t+1}-\mathbf{u}^*\|^2_{\mathbf{G}}\mid\mathcal{F}^t\right]\geq\frac{4\alpha\mu}{L}\left(f(\mathbf{x}^t)-f(\mathbf{x}^*)-\nabla f(\mathbf{x}^*)^T(\mathbf{x}^t-\mathbf{x}^*)\right) + \mathbb{E}\left[\|\mathbf{x}^{t+1}-\mathbf{x}^t\|^2_{\mathbf{Z}-2\alpha\eta\mathbf{I}}\mid\mathcal{F}^t\right]+\mathbb{E}\left[\|\mathbf{v}^{t+1}-\mathbf{v}^t\|^2\mid\mathcal{F}^t\right] + 2\mathbb{E}\left[\|\mathbf{x}^{t+1}-\mathbf{x}^*\|^2_{\mathbf{I}+\mathbf{Z}-2\tilde{\mathbf{Z}}}\big|\mathcal{F}^t\right]-\frac{\alpha}{\eta}\mathbb{E}\left[\|\hat{\mathbf{g}}^t-\nabla f(\mathbf{x}^*)\|^2\mid\mathcal{F}^t\right]. \tag{80}$$

Substituting the upper bound for the expectation $\mathbb{E}\left[\|\hat{\mathbf{g}}^t-\nabla f(\mathbf{x}^*)\|^2\mid\mathcal{F}^t\right]$ in (34) into (80) and regrouping the terms show the validity of the claim in (36).

Appendix C. Proof of Lemma 6

Given the information until time t, each auxiliary vector $\mathbf{y}^{t+1}_{n,i}$ is a random variable that takes values $\mathbf{y}^t_{n,i}$ and $\mathbf{x}^t_n$ with associated probabilities $1-1/q_n$ and $1/q_n$, respectively. This observation holds

since with probability $1/q_n$ node n may choose index i to update at time $t+1$ and with probability $1-(1/q_n)$ choose other indices. Therefore, we can write

$$\mathbb{E}\left[\frac{1}{q_n}\sum_{i=1}^{q_n}\left(\nabla f_{n,i}(\tilde{\mathbf{x}}^*)^T(\mathbf{y}_{n,i}^{t+1}-\tilde{\mathbf{x}}^*)\right)\mid\mathcal{F}^t\right]=\left[1-\frac{1}{q_n}\right]\frac{1}{q_n}\sum_{i=1}^{q_n}\nabla f_{n,i}(\tilde{\mathbf{x}}^*)^T(\mathbf{y}_{n,i}^t-\tilde{\mathbf{x}}^*)+\frac{1}{q_n}\nabla f_n(\tilde{\mathbf{x}}^*)^T(\mathbf{x}_n^t-\tilde{\mathbf{x}}^*). \tag{81}$$

Likewise, the distribution of random function $f_{n,i}(\mathbf{y}_{n,i}^{t+1})$ given observation until time t has two possibilities $f_{n,i}(\mathbf{y}_{n,i}^t)$ and $f_{n,i}(\mathbf{x}_n^t)$ with associated probabilities $1-1/q_n$ and $1/q_n$, respectively. Hence, we can write $\mathbb{E}\left[f_{n,i}(\mathbf{y}_{n,i}^{t+1})\mid\mathcal{F}^t\right]=(1-1/q_n)f_{n,i}(\mathbf{y}_{n,i}^t)+(1/q_n)f_{n,i}(\mathbf{x}_n^t)$. By summing this relation for all $i\in 1,\ldots,q_n$ and divining both sides of the resulted expression by q_n we obtain

$$\mathbb{E}\left[\frac{1}{q_n}\sum_{i=1}^{q_n}f_{n,i}(\mathbf{y}_{n,i}^{t+1})\mid\mathcal{F}^t\right]=\left[1-\frac{1}{q_n}\right]\frac{1}{q_n}\sum_{i=1}^{q_n}f_{n,i}(\mathbf{y}_{n,i}^t)+\frac{1}{q_n}f_n(\mathbf{x}_n^t). \tag{82}$$

To simplicity equations let us define the sequence p_n^t as

$$p_n^t:=\frac{1}{q_n}\sum_{i=1}^{q_n}f_{n,i}(\mathbf{y}_{n,i}^t)-f_n(\tilde{\mathbf{x}}^*)-\frac{1}{q_n}\sum_{i=1}^{q_n}\nabla f_{n,i}(\tilde{\mathbf{x}}^*)^T(\mathbf{y}_{n,i}^t-\tilde{\mathbf{x}}^*). \tag{83}$$

Subtracting (81) from (82) and adding $-f_n(\tilde{\mathbf{x}}^*)$ to the both sides of equality in association with the definition of the sequence p_n^t in (83) yield

$$\mathbb{E}\left[p_n^{t+1}\mid\mathcal{F}^t\right]=\left[1-\frac{1}{q_n}\right]p_n^t+\frac{1}{q_n}\left[f_n(\mathbf{x}_n^t)-f_n(\tilde{\mathbf{x}}^*)-\nabla f_n(\tilde{\mathbf{x}}^*)^T(\mathbf{x}_n^t-\tilde{\mathbf{x}}^*)\right]. \tag{84}$$

We proceed to find and upper bound for the terms in the right hand side of (84). First note that according to the strong convexity of the local instantaneous functions $f_{n,i}$ and local functions f_n both terms in the right hand side of (84) are non-negative. Observing that the number of instantaneous functions at each node q_n satisfies the condition $q_{\min}\leq q_n\leq q_{\max}$, we obtain

$$1-\frac{1}{q_n}\leq 1-\frac{1}{q_{\max}}\ ,\qquad \frac{1}{q_n}\leq\frac{1}{q_{\min}}. \tag{85}$$

Substituting the upper bounds in (85) into (84), summing both sides of the implied inequality over $n\in\{1,\ldots,N\}$, and considering the definitions of the optimal argument $\mathbf{x}^*=[\tilde{\mathbf{x}}^*;\ldots;\tilde{\mathbf{x}}^*]$ and the aggregate function $f(\mathbf{x})=\sum_{n=1}^N f_n(\mathbf{x}_n)$ lead to

$$\sum_{n=1}^N\mathbb{E}\left[p_n^{t+1}\mid\mathcal{F}^t\right]\leq\left[1-\frac{1}{q_{\max}}\right]\sum_{n=1}^N p_n^t+\frac{1}{q_{\min}}\left[f(\mathbf{x}^t)-f(\mathbf{x}^*)-\nabla f(\mathbf{x}^*)^T(\mathbf{x}^t-\mathbf{x}^*)\right]. \tag{86}$$

Now observe that according to the definitions of the sequences p^t and p_n^t in (33) and (83), respectively, p^t is the sum of p_n^t for all n, i.e. $p^t=\sum_{n=1}^N p_n^t$. Hence, we can rewrite (86) as

$$\mathbb{E}\left[p^{t+1}\mid\mathcal{F}^t\right]\leq\left[1-\frac{1}{q_{\max}}\right]p^t+\frac{1}{q_{\min}}\left[f(\mathbf{x}^t)-f(\mathbf{x}^*)-\nabla f(\mathbf{x}^*)^T(\mathbf{x}^t-\mathbf{x}^*)\right]. \tag{87}$$

Therefore, the claim in (37) is valid.

Appendix D. Proof of Theorem 7

To prove the result in Theorem 7 first we prove the following Lemma to establish an upper bound for the squared error norm $\|\mathbf{v}^t-\mathbf{v}^*\|^2$.

Lemma 11 *Consider the DSA algorithm as defined in* (6)-(9). *Further, recall γ' as the smallest non-zero eigenvalue and Γ' as the largest eigenvalue of the matrix $\tilde{\mathbf{Z}}-\mathbf{Z}$. If Assumptions 1-3 hold, then the squared norm of the difference $\|\mathbf{v}^t-\mathbf{v}^*\|^2$ is bounded above as*

$$\|\mathbf{v}^t-\mathbf{v}^*\|^2\leq\frac{8}{\gamma'}\mathbb{E}\left[\left\|\mathbf{x}^{t+1}-\mathbf{x}^*\right\|^2_{(\mathbf{I}+\mathbf{Z}-2\tilde{\mathbf{Z}})^2}\mid\mathcal{F}^t\right]+\frac{8}{\gamma'}\mathbb{E}\left[\left\|\mathbf{x}^t-\mathbf{x}^{t+1}\right\|^2_{\tilde{\mathbf{Z}}^2}\mid\mathcal{F}^t\right]+\frac{16\alpha^2L}{\gamma'}\ p^t+\frac{2\Gamma'}{\gamma'}\mathbb{E}\left[\|\mathbf{v}^t-\mathbf{v}^{t+1}\|^2\mid\mathcal{F}^t\right]+\frac{8\alpha^2\left(2L-\mu\right)}{\gamma'}\left[f(\mathbf{x}^t)-f(\mathbf{x}^*)-\nabla f(\mathbf{x}^*)^T(\mathbf{x}^t-\mathbf{x}^*)\right]. \tag{88}$$

Proof Consider the inequality $\|\mathbf{a}+\mathbf{b}\|^2\leq 2\|\mathbf{a}\|^2+2\|\mathbf{b}\|^2$ for the case that $\mathbf{a}=\mathbf{U}(\mathbf{v}^{t+1}-\mathbf{v}^*)$, $\mathbf{b}=\mathbf{U}(\mathbf{v}^t-\mathbf{v}^{t+1})$ which can be written as

$$\|\mathbf{U}(\mathbf{v}^t-\mathbf{v}^*)\|^2\leq 2\|\mathbf{U}(\mathbf{v}^{t+1}-\mathbf{v}^*)\|^2+2\|\mathbf{U}(\mathbf{v}^t-\mathbf{v}^{t+1})\|^2. \tag{89}$$

We proceed by finding an upper bound for $2\|\mathbf{U}(\mathbf{v}^{t+1}-\mathbf{v}^*)\|^2$. Based on the result of Lemma 3 in (30), the term $\mathbf{U}(\mathbf{v}^{t+1}-\mathbf{v}^*)$ is equal to the sum of vectors $\mathbf{a}+\mathbf{b}$ where $\mathbf{a}=(\mathbf{I}+\mathbf{Z}-2\tilde{\mathbf{Z}})(\mathbf{x}^{t+1}-\mathbf{x}^*)-\tilde{\mathbf{Z}}(\mathbf{x}^t-\mathbf{x}^{t+1})$ and $\mathbf{b}=-\alpha\hat{\mathbf{g}}^t-\nabla f(\mathbf{x}^*)$. Therefore, using the inequality $\|\mathbf{a}+\mathbf{b}\|^2\leq 2\|\mathbf{a}\|^2+2\|\mathbf{b}\|^2$ we can write

$$\left\|\mathbf{U}(\mathbf{v}^{t+1}-\mathbf{v}^*)\right\|^2\leq 2\left\|(\mathbf{I}+\mathbf{Z}-2\tilde{\mathbf{Z}})(\mathbf{x}^{t+1}-\mathbf{x}^*)-\tilde{\mathbf{Z}}(\mathbf{x}^t-\mathbf{x}^{t+1})\right\|^2+2\alpha^2\left\|\hat{\mathbf{g}}^t-\nabla f(\mathbf{x}^*)\right\|^2. \tag{90}$$

By using the inequality $\|\mathbf{a}+\mathbf{b}\|^2\leq 2\|\mathbf{a}\|^2+2\|\mathbf{b}\|^2$ one more time for vectors $\mathbf{a}=(\mathbf{I}+\mathbf{Z}-2\tilde{\mathbf{Z}})(\mathbf{x}^{t+1}-\mathbf{x}^*)$ and $\mathbf{b}=-\tilde{\mathbf{Z}}(\mathbf{x}^t-\mathbf{x}^{t+1})$, we obtain an upper bound for the term $\|(\mathbf{I}+\mathbf{Z}-2\tilde{\mathbf{Z}})(\mathbf{x}^{t+1}-\mathbf{x}^*)-\tilde{\mathbf{Z}}(\mathbf{x}^t-\mathbf{x}^{t+1})\|^2$. Substituting this upper bound into (90) yields

$$\left\|\mathbf{U}(\mathbf{v}^{t+1}-\mathbf{v}^*)\right\|^2\leq 4\left\|\mathbf{x}^{t+1}-\mathbf{x}^*\right\|^2_{(\mathbf{I}+\mathbf{Z}-2\tilde{\mathbf{Z}})^2}+4\left\|\mathbf{x}^t-\mathbf{x}^{t+1}\right\|^2_{\tilde{\mathbf{Z}}^2}+2\alpha^2\left\|\hat{\mathbf{g}}^t-\nabla f(\mathbf{x}^*)\right\|^2. \tag{91}$$

Inequality (91) shows an upper bound for $2\|\mathbf{U}(\mathbf{v}^{t+1}-\mathbf{v}^*)\|^2$ in (89). Moreover, we know that the second term $\|\mathbf{U}(\mathbf{v}^t-\mathbf{v}^{t+1})\|^2$ is also bounded above by $\Gamma'\|\mathbf{v}^t-\mathbf{v}^{t+1}\|^2$ where Γ' is the largest eigenvalue of matrix $\tilde{\mathbf{Z}}-\mathbf{Z}=\mathbf{U}^2$. Substituting these upper bounds into (89) and computing the expected value of both sides given the information until step t yield

$$\|\mathbf{U}(\mathbf{v}^t-\mathbf{v}^*)\|^2\leq\ 8\mathbb{E}\left[\left\|\mathbf{x}^{t+1}-\mathbf{x}^*\right\|^2_{(\mathbf{I}+\mathbf{Z}-2\tilde{\mathbf{Z}})^2}\mid\mathcal{F}^t\right]+8\mathbb{E}\left[\left\|\mathbf{x}^t-\mathbf{x}^{t+1}\right\|^2_{\tilde{\mathbf{Z}}^2}\mid\mathcal{F}^t\right]+4\alpha^2\mathbb{E}\left[\left\|\hat{\mathbf{g}}^t-\nabla f(\mathbf{x}^*)\right\|^2\mid\mathcal{F}^t\right]+2\Gamma'\mathbb{E}\left[\|\mathbf{v}^t-\mathbf{v}^{t+1}\|^2\mid\mathcal{F}^t\right]. \tag{92}$$

Note the vectors $\mathbf{v}^t$ and $\mathbf{v}^*$ lie in the column space of the matrix $\mathbf{U}$. Thus, we obtain that $\|\mathbf{U}(\mathbf{v}^t-\mathbf{v}^*)\|^2\geq\gamma'\|\mathbf{v}^t-\mathbf{v}^*\|^2$. Substituting this lower bound for $\|\mathbf{U}(\mathbf{v}^t-\mathbf{v}^*)\|^2$ in (92) and deviding both sides of the imposed inequality by γ' yield

$$\|\mathbf{v}^t-\mathbf{v}^*\|^2\leq\frac{8}{\gamma'}\mathbb{E}\left[\left\|\mathbf{x}^{t+1}-\mathbf{x}^*\right\|^2_{(\mathbf{I}+\mathbf{Z}-2\tilde{\mathbf{Z}})^2}\mid\mathcal{F}^t\right]+\frac{8}{\gamma'}\mathbb{E}\left[\left\|\mathbf{x}^t-\mathbf{x}^{t+1}\right\|^2_{\tilde{\mathbf{Z}}^2}\mid\mathcal{F}^t\right]+\frac{4\alpha^2}{\gamma'}\mathbb{E}\left[\left\|\hat{\mathbf{g}}^t-\nabla f(\mathbf{x}^*)\right\|^2\mid\mathcal{F}^t\right]+\frac{2\Gamma'}{\gamma'}\mathbb{E}\left[\|\mathbf{v}^t-\mathbf{v}^{t+1}\|^2\mid\mathcal{F}^t\right]. \tag{93}$$

By substituting the expectation $\mathbb{E}\left[\|\hat{\mathbf{g}}^t-\nabla f(\mathbf{x}^*)\|^2\mid\mathcal{F}^t\right]$ in the right hand side of (93) with its upper bound in (34), the claim in (88) follows. ■

Using the result in Lemma 11 we show that the sequence $\|\mathbf{u}^t-\mathbf{u}^*\|_{\mathbf{G}}^2+c\,p^t$ converges linearly to zero.

Proof of Theorem 7: Proving the linear convergence claim in (40) is equivalent to showing that

$$\delta\|\mathbf{u}^t-\mathbf{u}^*\|_{\mathbf{G}}^2+\delta c\,p^t\leq\|\mathbf{u}^t-\mathbf{u}^*\|_{\mathbf{G}}^2-\mathbb{E}\left[\|\mathbf{u}^{t+1}-\mathbf{u}^*\|_{\mathbf{G}}^2\mid\mathcal{F}^t\right]+c\,(p^t-\mathbb{E}\left[p^{t+1}\mid\mathcal{F}^t\right]). \tag{94}$$

Substituting the terms $\mathbb{E}\left[\|\mathbf{u}^{t+1}-\mathbf{u}^*\|_{\mathbf{G}}^2\mid\mathcal{F}^t\right]$ and $\mathbb{E}\left[p^{t+1}\mid\mathcal{F}^t\right]$ by their upper bounds as introduced in Lemma 5 and Lemma 6, respectively, yields a sufficient condition for the claim in (94) as

$$\begin{aligned}\delta\|\mathbf{u}^t-\mathbf{u}^*\|_{\mathbf{G}}^2+\delta c\,p^t\leq{}&\mathbb{E}\left[\|\mathbf{x}^{t+1}-\mathbf{x}^t\|^2_{\tilde{\mathbf{Z}}-2\alpha\eta\mathbf{I}}\mid\mathcal{F}^t\right]+\mathbb{E}\left[\|\mathbf{v}^{t+1}-\mathbf{v}^t\|^2\mid\mathcal{F}^t\right]\\&+2\mathbb{E}\left[\|\mathbf{x}^{t+1}-\mathbf{x}^*\|^2_{\mathbf{I}+\mathbf{Z}-2\tilde{\mathbf{Z}}}\mid\mathcal{F}^t\right]+\left(\frac{c}{q_{\max}}-\frac{4\alpha L}{\eta}\right)p^t\\&+\left[\frac{4\alpha\mu}{L}-\frac{2\alpha(2L-\mu)}{\eta}-\frac{c}{q_{\min}}\right]\left[f(\mathbf{x}^t)-f(\mathbf{x}^*)-\nabla f(\mathbf{x}^*)^T(\mathbf{x}^t-\mathbf{x}^*)\right].\end{aligned} \tag{95}$$

We emphasize that if the inequality in (95) holds, then the inequalities in (94) and (40) are valid. Note that the weighted norm $\|\mathbf{u}^t-\mathbf{u}^*\|_{\mathbf{G}}^2$ in the left hand side of (95) can be simplified as $\|\mathbf{x}^t-\mathbf{x}^*\|_{\tilde{\mathbf{Z}}}^2+\|\mathbf{v}^t-\mathbf{v}^*\|^2$. Considering the definition of Γ as the maximum eigenvalue of the matrix $\tilde{\mathbf{Z}}$, we can conclude that $\|\mathbf{x}^t-\mathbf{x}^*\|_{\tilde{\mathbf{Z}}}^2$ is bounded above by $\Gamma\|\mathbf{x}^t-\mathbf{x}^*\|^2$. Considering this relation and observing the upper bound for $\|\mathbf{v}^t-\mathbf{v}^*\|^2$ in (88), we obtain that $\|\mathbf{u}^t-\mathbf{u}^*\|_{\mathbf{G}}^2=\|\mathbf{x}^t-\mathbf{x}^*\|_{\tilde{\mathbf{Z}}}^2+\|\mathbf{v}^t-\mathbf{v}^*\|^2$ is bounded above by

$$\begin{aligned}\|\mathbf{u}^t-\mathbf{u}^*\|_{\mathbf{G}}^2\;\leq\;&\frac{8}{\gamma'}\mathbb{E}\left[\left\|\mathbf{x}^{t+1}-\mathbf{x}^*\right\|^2_{(\mathbf{I}+\mathbf{Z}-2\tilde{\mathbf{Z}})^2}\mid\mathcal{F}^t\right]+\frac{8}{\gamma'}\mathbb{E}\left[\left\|\mathbf{x}^t-\mathbf{x}^{t+1}\right\|^2_{\tilde{\mathbf{Z}}^2}\mid\mathcal{F}^t\right]+\frac{16\alpha^2L}{\gamma'}\,p^t\\&+\frac{2\Gamma'}{\gamma'}\mathbb{E}\left[\|\mathbf{v}^t-\mathbf{v}^{t+1}\|^2\mid\mathcal{F}^t\right]+\Gamma\|\mathbf{x}^t-\mathbf{x}^*\|^2\\&+\frac{8\alpha^2\,(2L-\mu)}{\gamma'}\left[f(\mathbf{x}^t)-f(\mathbf{x}^*)-\nabla f(\mathbf{x}^*)^T(\mathbf{x}^t-\mathbf{x}^*)\right].\end{aligned} \tag{96}$$

Further, the strong convexity of the global objective function f implies that the squared norm $\|\mathbf{x}^t-\mathbf{x}^*\|^2$ is upper bound by $(2/\mu)(f(\mathbf{x}^t)-f(\mathbf{x}^*)-\nabla f(\mathbf{x}^*)^T(\mathbf{x}^t-\mathbf{x}^*))$. Replacing the the squared norm $\|\mathbf{x}^t-\mathbf{x}^*\|^2$ in (96) by its upper bound leads to

$$\begin{aligned}\|\mathbf{u}^t-\mathbf{u}^*\|_{\mathbf{G}}^2\leq{}&\frac{8}{\gamma'}\mathbb{E}\left[\left\|\mathbf{x}^{t+1}-\mathbf{x}^*\right\|^2_{(\mathbf{I}+\mathbf{Z}-2\tilde{\mathbf{Z}})^2}\mid\mathcal{F}^t\right]+\frac{8}{\gamma'}\mathbb{E}\left[\left\|\mathbf{x}^t-\mathbf{x}^{t+1}\right\|^2_{\tilde{\mathbf{Z}}^2}\mid\mathcal{F}^t\right]+\frac{16\alpha^2L}{\gamma'}\,p^t\\&+\frac{2\Gamma'}{\gamma'}\mathbb{E}\left[\|\mathbf{v}^t-\mathbf{v}^{t+1}\|^2\mid\mathcal{F}^t\right]\\&+\left(\frac{8\alpha^2\,(2L-\mu)}{\gamma'}+\frac{2\Gamma}{\mu}\right)\left[f(\mathbf{x}^t)-f(\mathbf{x}^*)-\nabla f(\mathbf{x}^*)^T(\mathbf{x}^t-\mathbf{x}^*)\right].\end{aligned} \tag{97}$$

Replacing $\|\mathbf{u}^t-\mathbf{u}^*\|_{\mathbf{G}}^2$ in (95) by the upper bound in (97) and regrouping the terms lead to

$$\begin{aligned}0\leq{}&\mathbb{E}\left[\|\mathbf{x}^{t+1}-\mathbf{x}^t\|^2_{\tilde{\mathbf{Z}}-\alpha(\eta+\eta)\mathbf{I}-\frac{8\delta}{\gamma'}\tilde{\mathbf{Z}}^2}\mid\mathcal{F}^t\right]+\mathbb{E}\left[\|\mathbf{x}^{t+1}-\mathbf{x}^*\|^2_{(\mathbf{I}+\mathbf{Z}-2\tilde{\mathbf{Z}})^{\frac{1}{2}}\left[2\mathbf{I}-\frac{8\delta}{\gamma'}(\mathbf{I}+\mathbf{Z}-2\tilde{\mathbf{Z}})\right](\mathbf{I}+\mathbf{Z}-2\tilde{\mathbf{Z}})^{\frac{1}{2}}}\mid\mathcal{F}^t\right]\\&+\mathbb{E}\left[\|\mathbf{v}^{t+1}-\mathbf{v}^t\|^2_{(1-\frac{2\delta\Gamma'}{\gamma'})\mathbf{I}}\mid\mathcal{F}^t\right]+\left[\frac{c}{q_{\max}}-\frac{4\alpha L}{\eta}-\delta c-\frac{16\delta\alpha^2L}{\gamma'}\right]p^t\\&+\left[\frac{4\alpha\mu}{L}-\frac{2\alpha(2L-\mu)}{\eta}-\frac{c}{q_{\min}}-\frac{8\delta\alpha^2\,(2L-\mu)}{\gamma'}-\frac{2\delta\Gamma}{\mu}\right](f(\mathbf{x}^t)-f(\mathbf{x}^*)-\nabla f(\mathbf{x}^*)^T(\mathbf{x}^t-\mathbf{x}^*)).\end{aligned} \tag{98}$$

Notice that if the inequality in (98) holds true, then the relation in (95) is valid and as we mentioned before the claim in (94) holds. To verify the sum in the right hand side of (98) is always positive and the inequality is valid, we enforce each summands in the right hand side of (98) to be non-negative. Therefore, the following conditions should be satisfied

$$\begin{aligned}&\gamma-\alpha(\eta+\eta)-\frac{8\delta}{\gamma'}\Gamma^2\geq0,\quad 2-\frac{8\delta}{\gamma'}\lambda_{max}(\mathbf{I}+\mathbf{Z}-2\tilde{\mathbf{Z}})\geq0,\quad 1-\frac{2\delta\Gamma'}{\gamma'}\geq0,\\&\frac{c}{q_{\max}}-\frac{4\alpha L}{\eta}-\delta c-\frac{16\delta\alpha^2L}{\gamma'}\geq0,\quad \frac{4\alpha\mu}{L}-\frac{2\alpha(2L-\mu)}{\eta}-\frac{c}{q_{\min}}-\frac{8\delta\alpha^2\,(2L-\mu)}{\gamma'}-\frac{2\delta\Gamma}{\mu}\geq0.\end{aligned} \tag{99}$$

Recall that γ is the smallest eigenvalue of the positive definite matrix $\mathbf{Z}$. All the inequalities in (99) are satisfied, if δ is chosen as

$$\begin{aligned}\delta=\min\Bigg\{&\frac{(\gamma-2\alpha\eta)\gamma'}{8\Gamma^2},\frac{\gamma'}{4\lambda_{max}(\mathbf{I}+\mathbf{Z}-2\tilde{\mathbf{Z}})},\frac{\gamma'}{2\Gamma'},\frac{\gamma'(c\eta-4\alpha Lq_{\max})}{\eta q_{\max}(c\gamma'+16\alpha^2L)},\\&\left[\frac{4\alpha\mu}{L}-\frac{2\alpha(2L-\mu)}{\eta}-\frac{c}{q_{\min}}\right]\left[\frac{8\alpha^2\,(2L-\mu)}{\gamma'}+\frac{2\Gamma}{\mu}\right]^{-1}\Bigg\}.\end{aligned} \tag{100}$$

where η, c and α are selected from the intervals

$$\eta\in\left(\frac{L^2q_{\max}}{\mu q_{\min}}+\frac{L^2}{\mu}-\frac{L}{2}\;,\;\infty\right),\;\alpha\in\left(0\;,\;\frac{\gamma}{2\eta}\right),\;c\in\left(\frac{4\alpha Lq_{\max}}{\eta}\;,\;\frac{4\alpha\mu q_{\min}}{L}-\frac{2\alpha q_{\min}(2L-\mu)}{\eta}\right). \tag{101}$$

Notice that considering the conditions for the variables η, α and c in (101), the constant δ in (100) is strictly positive $\delta>0$. Moreover, according to the definition in (100) the constant δ is smaller than $\gamma'/2\Gamma'$ which leads to the conclusion that $\delta\leq1/2<1$. Therefore, we obtain that $0<\delta<1$ and the claim in (40) is valid.

Appendix E. Proof of Theorem 9

The proof uses the relationship in the statement (40) of Theorem 7 to build a supermartingale sequence. To do this define the stochastic processes ζ^t and β^t as

$$\zeta^t:=\|\mathbf{u}^t-\mathbf{u}^*\|_{\mathbf{G}}^2+c\,p^t,\quad \beta^t:=\delta\left(\|\mathbf{u}^t-\mathbf{u}^*\|_{\mathbf{G}}^2+c\,p^t\right). \tag{102}$$

The stochastic processes ζ^t and β^t are alway non-negative. Let now $\mathcal{F}_t$ be a sigma-algebra measuring ζ^t, β^t, and $\mathbf{u}^t$. Considering the definitions of ζ^t and β^t and the relation in (40) we can write

$$\mathbb{E}\left[\zeta^{t+1}\mid\mathcal{F}^t\right]\leq\zeta^t-\beta^t. \tag{103}$$

Since the sequences α^t and β^t are nonnegative it follows from (103) that they satisfy the conditions of the supermartingale convergence theorem – see e.g. theorem E7.4 Solo and Kong (1995) . Therefore, we obtain that: (i) The sequence ζ^t converges almost surely. (ii) The sum $\sum_{t=0}^{\infty}\beta^t<\infty$ is almost surely finite. The definition of β^t in (102) implies that

$$\sum_{t=0}^{\infty}\delta\left(\|\mathbf{u}^t-\mathbf{u}^*\|_{\mathbf{G}}^2+c\,p^t\right)<\infty,\qquad\text{a.s.} \tag{104}$$

Since $\|\mathbf{x}^t-\mathbf{x}^*\|_{\tilde{\mathbf{Z}}}^2\leq\|\mathbf{u}^t-\mathbf{u}^*\|_{\mathbf{G}}^2+c\,p^t$ and the eigenvalues of $\tilde{\mathbf{Z}}$ are lower bounded by γ we can write $\gamma\|\mathbf{x}^t-\mathbf{x}^*\|^2\leq\|\mathbf{u}^t-\mathbf{u}^*\|_{\mathbf{G}}^2+c\,p^t$. This inequality in association with the fact that the sum in (104) is finite leads to

$$\sum_{t=0}^{\infty}\delta\,\gamma\,\|\mathbf{x}^t-\mathbf{x}^*\|^2<\infty,\qquad\text{a.s.} \tag{105}$$

Observing the fact that δ and γ are positive constants, we can conclude from (105) that the sequence $\|\mathbf{x}^t - \mathbf{x}^*\|^2$ is almost surely summable and it converges with probability 1 to 0.

Abstract

The statistical analysis of massive and complex data sets will require the development of algorithms that depend on distributed computing and collaborative inference. Inspired by this, we propose a collaborative framework that aims to estimate the unknown mean θ of a random variable X. In the model we present, a certain number of calculation units, distributed across a communication network represented by a graph, participate in the estimation of θ by sequentially receiving independent data from X while exchanging messages via a stochastic matrix A defined over the graph. We give precise conditions on the matrix A under which the statistical precision of the individual units is comparable to that of a (gold standard) virtual centralized estimate, even though each unit does not have access to all of the data. We show in particular the fundamental role played by both the non-trivial eigenvalues of A and the Ramanujan class of expander graphs, which provide remarkable performance for moderate algorithmic cost.

Keywords: distributed computing, collaborative estimation, stochastic matrix, graph theory, complexity, Ramanujan graph

1. Introduction

A promising way to overcome computational problems associated with inference and prediction in large-scale settings is to take advantage of distributed and collaborative algorithms, whereby several processors perform computations and exchange messages with the end-goal of minimizing a certain cost function. For instance, in modern data analysis one is frequently faced with problems where the sample size is too large for a single computer or standard computing resources. Distributed processing of such large data sets is often regarded as a possible solution to data overload, although designing and analyzing algorithms in this setting is challenging. Indeed, good distributed and collaborative architectures should maintain the desired statistical accuracy of their centralized counterpart, while retaining sufficient flexibility and avoiding communication bottlenecks which may excessively slow down computations. The literature is too vast to permit anything like a fair summary within the confines of a short introduction—the papers by Duchi et al. (2012), Jordan (2013), Zhang et al. (2013), and references therein contain a sample of relevant work.

Similarly, the advent of sensor, wireless, and peer-to-peer networks in science and technology necessitates the design of distributed and information-exchange algorithms (Boyd et al., 2006; Predd et al., 2009). Such networks are designed to perform inference and prediction tasks for the environments they are sensing. Nonetheless, they are typically characterized by constraints on energy, bandwidth, and/or privacy, which limit the sensors' ability to share data with each other or with a hub for centralized processing. For example, in a hospital network, the aim is to make safer decisions by sharing information between therapeutic services. However, a simple exchange of database entries containing patient details can pose information privacy risks. At the same time, a large percentage of medical data may require exchanging high-resolution images, the centralized processing of which may be computationally prohibitive. Overall, such constraints call for the design of communication-constrained distributed procedures, where each node exchanges information with only a few of its neighbors at each time instance. The goal in this setting is to distribute the learning task in a computationally efficient way, and make sure that the statistical performance of the network matches that of the centralized version.

The foregoing observations have motivated the development and analysis of many local message-passing algorithms for distributed and collaborative inference, optimization, and learning. Roughly speaking, message-passing procedures are those that use only local communication to approximately achieve the same end as global (i.e., centralized) algorithms, which require sending raw data to a central processing facility. Message-passing algorithms are thought to be efficient by virtue of their exploitation of local communication. They have been successfully involved in kernel linear least-squares regression estimation (Predd et al., 2009), support vector machines (Forero et al., 2010), sparse L_1 regression (Mateos et al., 2010), gradient-type optimization (Tsitsiklis et al., 1986; Bertsekas and Tsitsiklis, 1997), and various online inference and learning tasks (Bianchi et al., 2011a,b, 2013). An important research effort has also been devoted to so-called averaging and consensus problems, where a set of autonomous agents—which may be sensors or nodes of a computer network—compute the average of their opinions in the presence of restricted communication capabilities and try to agree on a collective decision (e.g., Blondel et al., 2005; Olshevsky and Tsitsiklis, 2011).

However, despite their rising success and impact in machine learning, little is known regarding the statistical properties of message-passing algorithms. The statistical performance of collaborative computing has so far been studied in terms of consensus (i.e., whether all nodes give the same result), with perhaps mean convergence rates (e.g., Olshevsky and Tsitsiklis, 2011; Duchi et al., 2012; Zhang et al., 2013). While it is therefore proved that using a network, even sparse (i.e., with few connections), does not degrade the rate of convergence, the problem of whether it is optimal to do this remains unanswered, including for the most basic statistics. For example, which network properties guarantee collaborative calculation performances equal to those of a hypothetical centralized system? The goal

of this article is to give a more precise answer to this fundamental question. In order to present in the clearest way possible the properties such a network must have, we undertake this study for the most simple statistic possible: the mean.

In the model we consider, there are a number of computing agents (also known as nodes or processors) that sequentially estimate the mean of a random variable by regularly updating an estimate stored in their memory. Meanwhile, they exchange messages, thus informing each other about the results of their latest computations. Agents that receive messages use them to directly update the value in their memory by forming a convex combination. We focus primarily on the properties that the communication process must satisfy to ensure that the statistical precision of a single processor—that only sees part of the data—is similar to that of an inaccessible centralized intelligence that could tackle the whole data set at once. The literature is surprisingly quiet on this question, which we believe is of fundamental importance if we want to provide concrete tradeoffs between communication constraints and statistical accuracy.

This paper makes several important contributions. First, in Section 2 we introduce communication network models and define a performance ratio allowing us to quantify the statistical quality of a network. In Section 3 we analyze the asymptotic behavior of this performance ratio as the number of data items t received online sequentially per node becomes large, and give precise conditions on communication matrices A so that this ratio is asymptotically optimal. Section 4 goes one step further, connecting the rate of convergence of the ratio with the behavior of the eigenvalues of A. In Section 5 we present the remarkable Ramanujan expander graphs and analyze the tradeoff between statistical efficiency and communication complexity for these graphs with a series of simulation studies. Lastly, Section 6 provides several elements for analysis of more complicated asynchronous models with delays. A short discussion follows in Section 7. For clarity, proofs are gathered in Section 8.

2. The model

Let X be a square-integrable real-valued random variable, with $\mathbb{E}X = \theta$ and $\mathrm{Var}(X) = \sigma^2$. We consider a set $\{1, \dots, N\}$ of computing entities ($N \geq 2$) that collectively participate in the estimation of θ. In this distributed model, agent i sequentially receives an i.i.d. sequence $X_1^{(i)}, \dots, X_t^{(i)}, \dots$, distributed as the prototype X, and forms, at each time t, an estimate of θ. It is assumed throughout that the $X_t^{(i)}$ are independent when both $t \geq 1$ and $i \in \{1, \dots, N\}$ vary.

In the absence of communication between agents, the natural estimate held by agent i at time t is the empirical mean

$$\bar{X}_t^{(i)} = \frac{1}{t} \sum_{k=1}^{t} X_k^{(i)}.$$

Equivalently, processor i is initialized with $X_1^{(i)}$ and performs its estimation via the iteration

$$\bar{X}_{t+1}^{(i)} = \frac{t\bar{X}_t^{(i)} + X_{t+1}^{(i)}}{t+1}, \quad t \geq 1.$$

Let $\top$ denote transposition and assume that vectors are in column format. Letting $\mathbf{X}_t = (X_t^{(1)}, \dots, X_t^{(N)})^\top$ and $\bar{\mathbf{X}}_t = (\bar{X}_t^{(1)}, \dots, \bar{X}_t^{(N)})^\top$, we see that

$$\bar{\mathbf{X}}_{t+1} = \frac{t\bar{\mathbf{X}}_t + \mathbf{X}_{t+1}}{t+1}, \quad t \geq 1. \tag{1}$$

In a more complicated collaborative setting, besides its own measurements and computations, each agent may also receive messages from other processors and combine this information with its own conclusions. At its core, this message-passing process can be modeled by a *directed* graph $\mathscr{G} = (\mathscr{V}, \mathscr{E})$ with vertex set $\mathscr{V} = \{1, \dots, N\}$ and edge set $\mathscr{E}$. This graph represents the way agents communicate, with an edge from j to i (in that order) if j sends information to i. Furthermore, we have an $N \times N$ stochastic matrix $A = (a_{ij})_{1 \leq i,j \leq N}$ (i.e., $a_{ij} \geq 0$ and for each i, $\sum_{j=1}^N a_{ij} = 1$) with associated graph $\mathscr{G}$, i.e., $a_{ij} > 0$ if and only if $(j, i) \in \mathscr{E}$. The matrix A accounts for the way agents incorporate information during the collaborative process. Denoting by $\hat{\boldsymbol{\theta}}_t = (\hat{\theta}_t^{(1)}, \dots, \hat{\theta}_t^{(N)})^\top$ the collection of estimates held by the N agents over time, the computation/combining mechanism is assumed to be as follows:

$$\hat{\boldsymbol{\theta}}_{t+1} = \frac{t}{t+1} A\hat{\boldsymbol{\theta}}_t + \frac{1}{t+1}\mathbf{X}_{t+1}, \quad t \geq 1,$$

with $\hat{\boldsymbol{\theta}}_1 = (X_1^{(1)}, \dots, X_1^{(N)})^\top$. Thus, each individual estimate $\hat{\theta}_{t+1}^{(i)}$ is a convex combination of the estimates $\hat{\theta}_t^{(j)}$ held by the agents over the network at time t, augmented by the new observation $X_{t+1}^{(i)}$.

The matrix A models the way processors exchange messages and collaborate, ranging from $A = I_N$ (the $N \times N$ identity matrix, i.e., no communication) to $A = \mathbf{1}\mathbf{1}^\top/N$ (where $\mathbf{1} = (1, \dots, 1)^\top$, i.e., full communication). We note in particular that the choice $A = I_N$ gives back iteration (1) with $\hat{\boldsymbol{\theta}}_t = \bar{\mathbf{X}}_t$. We also note that, given a graph $\mathscr{G}$, various choices are possible for A. Thus, aside from a convenient way to represent a communication channel over which agents can retrieve information from each other, the matrix A can be seen as a "tuning parameter" on $\mathscr{G}$ to improve the statistical performance of $\hat{\boldsymbol{\theta}}_t$, as we shall see later. Important examples for A include the choices

$$A_1 = \frac{1}{2}\begin{pmatrix} 1 & 1 & & & & & & & & \\ 1 & 0 & 1 & & & & & & & \\ & 1 & 0 & 1 & & & & & & \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ & & & & 1 & 0 & 1 & & & \\ & & & & & 1 & 0 & 1 & & \\ & & & & & & 1 & 1 & & \end{pmatrix} \tag{2}$$

and

$$A_2 = \frac{1}{3}\begin{pmatrix} 2 & 1 & & & & & & & & \\ 1 & 1 & 1 & & & & & & & \\ & 1 & 1 & 1 & & & & & & \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ & & & & 1 & 1 & 1 & & & \\ & & & & & 1 & 1 & 1 & & \\ & & & & & & 1 & 2 & & \end{pmatrix} \tag{3}$$

(unmarked entries are zero).

It is easy to verify that for all $t \geq 1$,

$$\hat{\boldsymbol{\theta}}_t = \frac{1}{t}\sum_{k=0}^{t-1} A^k \mathbf{X}_{t-k}. \tag{4}$$

Thus, denoting by $\|\cdot\|$ the Euclidean norm (for vector or matrices), we may write, for all $t \geq 1$,

$$\begin{aligned}\mathbb{E}\|\hat{\boldsymbol{\theta}}_t - \theta\mathbf{1}\|^2 &= \frac{1}{t^2}\mathbb{E}\left\|\sum_{k=0}^{t-1} A^k(\mathbf{X}_{t-k} - \theta\mathbf{1})\right\|^2 \\ &\qquad \text{(since } A^k \text{ is a stochastic matrix)} \\ &= \frac{1}{t^2}\sum_{k=1}^{t}\mathbb{E}\left\|A^{t-k}(\mathbf{X}_k - \theta\mathbf{1})\right\|^2,\end{aligned}$$

by independence of $\mathbf{X}_1, \ldots, \mathbf{X}_t$. It follows that

$$\begin{aligned}\mathbb{E}\|\hat{\boldsymbol{\theta}}_t - \theta\mathbf{1}\|^2 &\leq \mathbb{E}\|\mathbf{X}_1 - \theta\mathbf{1}\|^2 \times \frac{1}{t^2}\sum_{k=0}^{t-1}\|A^k\|^2 \\ &\leq \mathbb{E}\|\mathbf{X}_1 - \theta\mathbf{1}\|^2 \times \frac{N}{t}.\end{aligned}$$

In the last inequality, we used the fact that A^k is a stochastic matrix and thus $\|A^k\|^2 \leq N$ for all $k \geq 0$. We can merely conclude that $\mathbb{E}\|\hat{\boldsymbol{\theta}}_t - \theta\mathbf{1}\|^2 \to 0$ as $t \to \infty$ (mean-squared error consistency), and so $\hat{\theta}_t^{(i)} \to \theta$ in probability for each $i \in \{1, \ldots, N\}$. Put differently, the agents asymptotically agree on the (true) value of the parameter, independently of the choice of the (stochastic) matrix A—this property is often called consensus in the distributed optimization literature (see, e.g., Bertsekas and Tsitsiklis, 1997). We insist on the fact that in our framework, consensus is obvious, and is not the question we are looking at here.

The consensus property, although interesting, does not say anything about the positive (or negative) impact of the graph on the comparative performances of estimates with respect to a centralized version. To clarify this remark, assume that there exists a centralized intelligence that could tackle all data $X_1^{(1)}, \ldots, X_t^{(1)}, \ldots, X_1^{(N)}, \ldots, X_t^{(N)}$ at time t, and take advantage of these sample points to assess the value of the parameter θ. In this ideal framework, the natural estimate of θ is the global empirical mean

$$\bar{\mathbb{X}}_{Nt} = \frac{1}{Nt}\sum_{i=1}^{N}\sum_{k=1}^{t} X_k^{(i)},$$

which is clearly the best we can hope for with the data at hand. However, this estimate is to be considered as an unattainable "gold standard" (or oracle), insofar as it uses the whole $(N \times t)$-sample. In other words, its evaluation requires sending all examples to a centralized processing facility, which is precisely what we want to avoid.

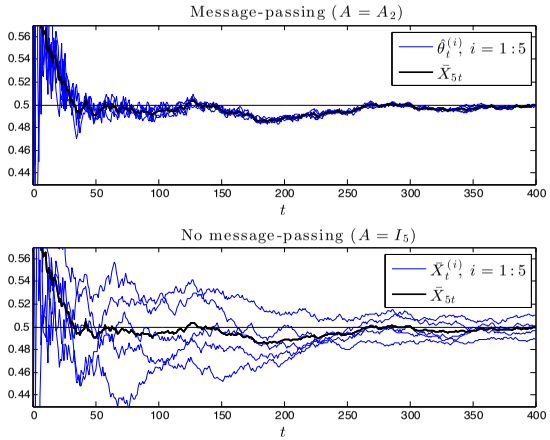

Figure 1: Convergence of individual nodes' estimates with and without message-passing.

Thus, a natural question arises: can the message-passing process be tapped to ensure that the individual estimates $\hat{\theta}_t^{(i)}$ achieve statistical accuracy "close" to that of the gold standard $\bar{\mathbb{X}}_{Nt}$? Figure 1 illustrates this pertinent question.

In the trials shown, i.i.d. uniform random variables on $[0, 1]$ are delivered online to $N = 5$ nodes, one to each at each time t. With message-passing (here, $A = A_2$), each node aggregates the new data point with data it has seen previously and messages received from its nearest neighbors in the network. We see that all of the five nodes' updates seem to converge with a performance comparable to that of the (unseen) global estimate $\bar{\mathbb{X}}_{Nt}$ to the mean 0.5. In contrast, in the absence of message-passing ($A = I_5$), individual nodes' estimates do still converge to 0.5, but at a slower rate.

To deal with this question of statistical accuracy satisfactorily, we first need a criterion to compare the performance of $\hat{\boldsymbol{\theta}}_t$ with that of $\bar{\mathbb{X}}_{Nt}$. Perhaps the most natural one is the following ratio, which depends upon the matrix A:

$$\tau_t(A) = \frac{\mathbb{E}\left\|(\bar{\mathbb{X}}_{Nt} - \theta)\mathbf{1}\right\|^2}{\mathbb{E}\|\hat{\boldsymbol{\theta}}_t - \theta\mathbf{1}\|^2}, \quad t \geq 1.$$

The more this ratio is close to 1, the more the collaborative algorithm is statistically efficient, in the sense that its performance compares favorably to that of the centralized gold standard. In the remainder of the paper, we call $\tau_t(A)$ the *performance ratio* at time t.

Of particular interest in our approach is the stochastic matrix A, which plays a crucial role in the analysis. Roughly, a good choice for A is one for which $\tau_t(A)$ is not too far from 1, while ensuring that communication over the network is not prohibitively expensive. Although there are several ways to measure "complexity" of the message-passing process, we have in mind a setting where the communication load is well-balanced between agents,

in the sense that no node should play a dominant role. To formalize this idea, we define the communication-complexity index $\mathscr{C}(A)$ as the maximal indegree of the edges of the graph $\mathscr{G}$ associated with A, i.e., the maximal number of edges pointing to a node in $\mathscr{G}$ (by convention, self-loops are counted twice when $\mathscr{G}$ is undirected). Essentially, A is communication-efficient when $\mathscr{C}(A)$ is small with respect to N or, more generally, when $\mathscr{C}(A) = \mathrm{O}(1)$ as N becomes large.

To provide some context, $\mathscr{C}(A)$ measures in a certain sense the "local" aspect of message exchanges induced by A. We have in mind node connection set-ups where $\mathscr{C}(A)$ is small, perhaps due to energy or bandwidth constraints in the system's architecture, or when for privacy reasons data must not be sent to a central node. Indeed, a large $\mathscr{C}(A)$ roughly means that one or several nodes play centralized roles—precisely what we are trying to avoid. Furthermore, the decentralized networks we are interested in can be seen as being more autonomous than high-$\mathscr{C}(A)$ ones, in the sense that having few network connections means less things that can potentially break, as well as improved robustness due to the fact that the loss of one node does not lead to destruction of the whole system. As examples, the matrices A_1 and A_2 defined earlier have $\mathscr{C}(A_1) = 3$ and $\mathscr{C}(A_2) = 4$, respectively, while the stochastic matrix A_3 below has $\mathscr{C}(A_3) = N + 1$:

$$A_3 = \frac{1}{N}\begin{pmatrix} 1 & 1 & 1 & \cdots & 1 & 1 & 1 \\ 1 & N-1 & & & & & \\ 1 & & N-1 & & & & \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ 1 & & & & & & N-1 \end{pmatrix}. \tag{5}$$

Thus, from a network complexity point of view, A_1 and A_2 are preferable to A_3 where node 1 has the flavor of a central command center.

Now, having defined $\tau_t(A)$ and $\mathscr{C}(A)$, it is natural to suspect that there will be some kind of tradeoff between implementing a low-complexity message-passing algorithm (i.e., $\mathscr{C}(A)$ small) and achieving good asymptotic performance (i.e., $\tau_t(A) \approx 1$ for large t). Our main goal in the next few sections is to probe this intuition by analyzing the asymptotic behavior of $\tau_t(A)$ as $t \to \infty$ under various assumptions on A. We start by proving that $\tau_t(A) \leq 1$ for all $t \geq 1$, and give precise conditions on the matrix A under which $\tau_t(A) \to 1$. Thus, thanks to the benefit of inter-agent communication, the statistical accuracy of individual estimates may be asymptotically comparable to that of the gold standard, despite the fact that none of the agents in the network have access to all of the data. Indeed, as we shall see, this stunning result is possible even for low-$\mathscr{C}(A)$ matrices. The take-home message here is that the communication process, once cleverly designed, may "boost" the individual estimates, even in the presence of severe communication constraints. We also provide an asymptotic development of $\tau_t(A)$, which offers valuable information on the optimal way to design the communication network in terms of the eigenvalues of A.

3. Convergence of the performance ratio

Recall that a stochastic square matrix $A = (a_{ij})_{1 \leq i,j \leq N}$ is irreducible if for every pair of indices i and j, there exists a nonnegative integer k such that $(A^k)_{ij}$ is not equal to 0. The matrix is said to be reducible if it is not irreducible.

Proposition 1 *We have $\frac{1}{N} \leq \tau_t(A) \leq 1$ for all $t \geq 1$. In addition, if A is reducible, then*

$$\tau_t(A) \leq 1 - \frac{1}{N+1}, \quad t \geq 1.$$

It is apparent from the proof of the proposition (all proofs are found in Section 8) that the lower bound $1/N$ for $\tau_t(A)$ is achieved by taking $A = I_N$, which is clearly the worst choice in terms of communication. This proposition also shows that the irreducibility of A is a necessary condition for the collaborative algorithm to be statistically efficient, for otherwise there exists $\varepsilon \in (0,1)$ such that $\tau_t(A) \leq 1 - \varepsilon$ for all $t \geq 1$.

We recall from the theory of Markov chains (e.g., Grimmett and Stirzaker, 2001) that for a fixed agent $i \in \{1, \ldots, N\}$, the period of i is the greatest common divisor of all positive integers k such that $(A^k)_{ii} > 0$. When A is irreducible, the period of every state is the same and is called the period of A. The following lemma describes the asymptotic behavior of $\tau_t(A)$ as t tends to infinity.

Lemma 2 *Assume that A is irreducible, and let d be its period. Then there exist projectors $Q_1, \ldots, Q_d$ such that*

$$\tau_t(A) \to \frac{1}{\sum_{\ell=1}^{d} \|Q_\ell\|^2} \quad \text{as } t \to \infty.$$

The projectors $Q_1, \ldots, Q_d$ in Lemma 2 originate from the decomposition

$$A^k = \sum_{\ell=1}^{d} \lambda_\ell^k Q_\ell + \sum_{\gamma \in \Gamma} \gamma^k Q_\gamma(k),$$

where $\lambda_1 = 1, \ldots, \lambda_d$ are the eigenvalues of A (distinct) of unit modulus, Γ the set of eigenvalues of A of modulus strictly smaller than 1, and $Q_\gamma(k)$ certain $N \times N$ matrices (see Theorem 8 in the proofs section). In particular, we see that $\tau_t(A) \to 1$ as $t \to \infty$ if and only if $\sum_{\ell=1}^{d} \|Q_\ell\|^2 = 1$. It turns out that this condition is satisfied if and only if A is irreducible, aperiodic (i.e., $d = 1$), and bistochastic, i.e., $\sum_{i=1}^{N} a_{ij} = \sum_{j=1}^{N} a_{ij} = 1$ for all $(i,j) \in \{1, \ldots, N\}^2$. This important result is encapsulated in the next theorem.

Theorem 3 *We have $\tau_t(A) \to 1$ as $t \to \infty$ if and only if A is irreducible, aperiodic, and bistochastic.*

Theorem 3 offers necessary and sufficient conditions for the communication matrix A to be asymptotically statistically efficient. Put differently, under the conditions of the theorem, the message-passing process conveys sufficient information to local computations to make individual estimates as accurate as the gold standard for large t. We again stress that this theorem is new and different from results obtained in the consensus literature. The theorem shows that one machine, on its own, if it is well-informed, does as good a job as a virtual central machine that has access to all the data.

In the context of multi-agent coordination, an example of such a communication network is the so-called (time-invariant) equal neighbor model (Tsitsiklis et al., 1986; Olshevsky and Tsitsiklis, 2011), in which

$$a_{ij} = \begin{cases} 1/|N^{(i)}| & \text{if } j \in N^{(i)} \\ 0 & \text{otherwise,} \end{cases}$$

where

$$N^{(i)} = \big\{ j \in \{1, \dots, N\} : a_{ij} > 0 \big\}$$

is the set of agents whose value is taken into account by i, and $|N^{(i)}|$ its cardinality. Clearly, the communication matrix A is stochastic, and also bistochastic as soon as A is symmetric (bidirectional model). Assuming in addition that the directed graph $\mathscr{G}$ associated with A is connected means that A is irreducible. Moreover, if $a_{ii} > 0$ for some $i \in \{1, \dots, N\}$, then A is also aperiodic, so the conditions of Theorem 3 are fulfilled.

Another way to choose an irreducible, aperiodic, and bistochastic matrix on an undirected graph is by letting $a_{ij} = 1/\max(1 + d(i), 1 + d(j))$, where $d(i)$ is the degree of node i; following this, a_{ii} is set to that which is needed to make each row sum to 1.

It is also interesting to note that there exist low-$\mathscr{C}(A)$ matrices that meet the requirements of Theorem 3. This is for instance the case of matrices A_1 and A_2 in (2) and (3), which are irreducible, aperiodic, and bistochastic, and satisfy $\mathscr{C}(A) \leq 4$. Also note that the matrix A_3 in (5), though irreducible, aperiodic, and bistochastic, should be avoided because $\mathscr{C}(A_3) = N + 1$.

We stress that the irreducibility and aperiodicity conditions are inherent properties of the graph $\mathscr{G}$, not A, insofar as these conditions do not depend upon the actual values of the nonzero entries of A. This is different for the bistochasticity condition, which requires knowledge of the coefficients of A. In fact, as observed by Sinkhorn and Knopp (1967), it is not always possible to associate such a bistochastic matrix with a given directed graph $\mathscr{G}$. To be more precise, consider $G = (g_{ij})_{1 \leq i,j \leq N}$, the transpose of the adjacency matrix of the graph $\mathscr{G}$—that is, $g_{ij} \in \{0, 1\}$ and $g_{ij} = 1 \Leftrightarrow (j, i) \in \mathscr{E}$. Then G is said to have total support if, for every positive element g_{ij}, there exists a permutation σ of $\{1, \dots, N\}$ such that $j = \sigma(i)$ and $\prod_{k=1}^{N} g_{k\sigma(k)} > 0$. The main theorem of Sinkhorn and Knopp (1967) asserts that there exists a bistochastic matrix A of the form $A = D_1 G D_2$, where D_1 and D_2 are $N \times N$ diagonal matrices with positive diagonals, if and only if G has total support. The algorithm to induce A from G is called the Sinkhorn-Knopp algorithm. It does this by generating a sequence of matrices whose rows and columns are normalized alternately. It is known that the convergence of the algorithm is linear, and upper bounds have been given for its rate of convergence (e.g., Knight, 2008).

Nevertheless, if for some reason we face a situation where it is impossible to associate a bistochastic matrix with the graph $\mathscr{G}$, Proposition 4 below shows that it is still possible to obtain information about the performance ratio, provided A is irreducible and aperiodic.

Proposition 4 *Assume that A is irreducible and aperiodic. Then*

$$\tau_t(A) \to \frac{1}{N\|\boldsymbol{\mu}\|^2} \quad \text{as } t \to \infty,$$

where $\boldsymbol{\mu}$ is the stationary distribution of A.

To illustrate this result, take $N = 2$ and consider the graph $\mathscr{G}$ with (symmetric) adjacency matrix $\mathbf{1}\mathbf{1}^\top$ (i.e., full communication). Various stochastic matrices may be associated with $\mathscr{G}$, each with a certain statistical performance. For $\alpha > 1$ a given parameter, we may choose for example

$$H_\alpha = \frac{1}{\alpha} \begin{pmatrix} 1 & \alpha - 1 \\ 1 & \alpha - 1 \end{pmatrix}.$$

When $\alpha = 2$, we have $\tau_t(H_2) \to 1$ by Theorem 3. More generally, using Proposition 4, it is an easy exercise to prove that, as $t \to \infty$,

$$\tau_t(H_\alpha) \to \frac{\alpha^2}{2 + 2(\alpha - 1)^2}.$$

We see that the statistical performance of the local estimates deteriorates as α becomes large, for in this case $\tau_t(H_\alpha)$ gets closer and closer to $1/2$. This toy model exemplifies the role the stochastic matrix is playing as a "tuning parameter" to improve the performance of the distributed estimate.

4. Convergence rates

Theorem 3 gives precise conditions ensuring $\tau_t(A) = 1 + o(1)$, but does not say anything about the rate (i.e., the behavior of the second-order term) at which this convergence occurs. It turns out that a much more informative limit may be obtained at the price of the mild additional assumption that the stochastic matrix A is symmetric (and hence bistochastic).

Theorem 5 *Assume that A is irreducible, aperiodic, and symmetric. Let $1 > \gamma_2 \geq \cdots \geq \gamma_N > -1$ be the eigenvalues of A different from 1. Then*

$$\tau_t(A) = \frac{1}{1 + \frac{1}{t} \sum_{\ell=2}^{N} \frac{1 - \gamma_\ell^{2t}}{1 - \gamma_\ell^2}}.$$

In addition, setting

$$\mathscr{S}(A) = \sum_{\ell=2}^{N} \frac{1}{1 - \gamma_\ell^2} \quad \text{and} \quad \Gamma(A) = \max_{2 \leq \ell \leq N} |\gamma_\ell|,$$

we have, for all $t \geq 1$,

$$1 - \frac{\mathscr{S}(A)}{t} \leq \tau_t(A) \leq 1 - \frac{\mathscr{S}(A)}{t} + \Gamma^{2t}(A) \frac{\mathscr{S}(A)}{t} + \Big(\frac{\mathscr{S}(A)}{t} \Big)^2.$$

Clearly, we thus have

$$t\big(1 - \tau_t(A)\big) \to \mathscr{S}(A) \quad \text{as } t \to \infty.$$

The take-home message is that the smaller the coefficient $\mathscr{S}(A)$, the better the matrix A performs from a statistical point of view. In this respect, we note that $\mathscr{S}(A) \geq N - 1$ (uniformly over the set of stochastic, irreducible, aperiodic, and symmetric matrices). Consider the full-communication matrix

$$A_0 = \frac{1}{N} \mathbf{1}\mathbf{1}^\top, \tag{6}$$

which models a saturated communication network in which each agent shares its information with all others. The associated communication topology, which has $\mathscr{C}(A_0) = N + 1$, is

roughly equivalent to a centralized algorithm and, as such, is considered inefficient from a computational point of view. On the other hand, intuitively, the amount of statistical information propagating through the network is large so $\mathscr{S}(A_0)$ should be small. Indeed, it is easy to see that in this case, $\gamma_\ell = 0$ for all $\ell \in \{2, \dots, N\}$ and $\mathscr{S}(A_0) = N-1$. Therefore, although complex in terms of communication, A_0 is statistically optimal.

Remark 6 *Interestingly, as pointed out by a referee, $\mathscr{S}(A)$ has a graph theoretic interpretation as the Kemeny constant of the Markov chain A^2, and may be written in terms of hitting times. Consequently, for a number of graphs it is easy to compute—see Jadbabaie and Olshevsky (2015) for example.*

For a comparative study of statistical performance and communication complexity of matrices, let us consider the sparser graph associated with the tridiagonal matrix A_1 defined in (2). With this choice, $\gamma_\ell = \cos\frac{(\ell-1)\pi}{N}$ (Fiedler, 1972), so that

$$\mathscr{S}(A_1) = \sum_{\ell=1}^{N-1} \frac{1}{1-\cos^2\frac{\ell\pi}{N}} = \frac{N^2}{6} + \mathrm{O}(N) \quad \text{as } N \to \infty. \tag{7}$$

Thus, we lose a power of N but now have lower communication complexity $\mathscr{C}(A_1) = 3$.

Let us now consider the tridiagonal matrix A_2 defined in (3). Noticing that $3A_2 = 2A_1 + I_N$, we deduce that for the matrix A_2, $\gamma_\ell = \frac{1}{3} + \frac{2}{3}\cos\frac{(\ell-1)\pi}{N}$, $2 \le \ell \le N$. Thus, as $N \to \infty$,

$$\mathscr{S}(A_2) = \frac{N^2}{9} + \mathrm{O}(N). \tag{8}$$

By comparing (7) and (8), we can conclude that the matrices A_1 and A_2, which are both low-$\mathscr{C}(A)$, are also nearly equivalent from a statistical efficiency point of view. A_2 is nevertheless preferable to A_1, which has a larger constant in front of the N^2. This slight difference may be due to the fact that most of the diagonal elements of A_1 are zero, so that agents $i \in \{2, \dots, N-1\}$ do not integrate their current value in the next iteration, as happens for A_2. Furthermore, for large N, the performance of A_1 and A_2 are expected to dramatically deteriorate in comparison with those of A_0, since $\mathscr{S}(A_1)$ and $\mathscr{S}(A_2)$ are proportional to N^2, while $\mathscr{S}(A_0)$ is proportional to N.

Figure 2 shows the evolution of $\tau_t(A)$ for N fixed and t increasing for the matrices $A = A_0$, A_1, A_2 as well as the identity I_N. As expected, we see convergence of $\tau_t(A_i)$ to 1, with degraded performance as the number of agents N increases. Also, we see that the lack of message-passing for I_N means it is statistically inefficient, with constant $\tau_t(I_N) = 1/N$ for all t.

The discussion and plots above highlight the crucial influence of $\mathscr{S}(A)$ on the performance of the communication network. Indeed, Theorem 5 shows that the optimal order for $\mathscr{S}(A)$ is N, and that this scaling is achieved by the computationally-inefficient choice A_0—see (6). Thus, a natural question to ask is whether there exist communication networks that have $\mathscr{S}(A)$ proportional to N and, simultaneously, $\mathscr{C}(A)$ constant or small with respect to N. These two conditions, which are in a sense contradictory, impose that the absolute values of the non-trivial eigenvalues γ_ℓ stay far from 1, while the maximal indegree of the graph $\mathscr{G}$ remains moderate. It turns out that these requirements are satisfied by so-called Ramanujan graphs, which are presented in the next section.

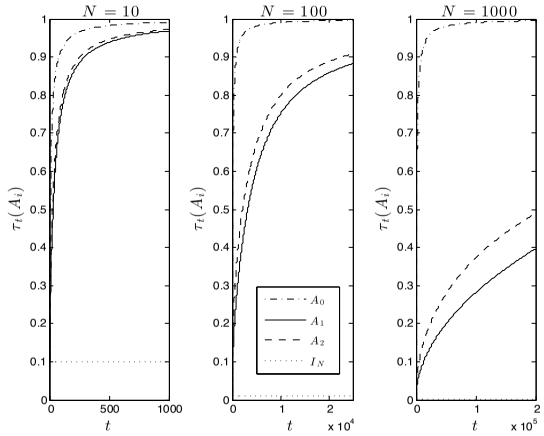

Figure 2: Evolution of $\tau_t(A_i)$ with t for different values of N, for $A = A_0$, A_1, A_2, and I_N.

5. Ramanujan graphs

In this section, we consider *undirected* graphs $\mathscr{G} = (\mathscr{V}, \mathscr{E})$ that are also d-regular, in the sense that all vertices have the same degree d; that is each vertex is incident to exactly d edges. Recall that in this definition, self-loops are counted twice and multiple edges are allowed. However, in what follows, we restrict ourselves to graphs without self-loops and multiple edges. In this setting, the natural (bistochastic) communication matrix A associated with $\mathscr{G}$ is $A = \frac{1}{d}G$, where $G = (g_{ij})_{1 \le i,j \le N}$ is the adjacency matrix of $\mathscr{G}$ ($g_{ij} \in \{0,1\}$ and $g_{ij} = 1 \Leftrightarrow (i,j) \in \mathscr{E}$). Note that $\mathscr{C}(A) = d$.

The matrix G is symmetric and we let $d = \mu_1 \ge \mu_2 \ge \cdots \ge \mu_N \ge -d$ be its (real) eigenvalues. Similarly, we let $1 = \gamma_1 \ge \gamma_2 \ge \cdots \ge \gamma_N \ge -1$ be the eigenvalues of A, with the straightforward correspondence $\gamma_i = \mu_i/d$. We note that A is irreducible (or, equivalently, that $\mathscr{G}$ is connected) if and only if $d > \mu_2$ (see, e.g., Shlomo et al., 2006, Section 2.3). In addition, A is aperiodic as soon as $\mu_N > -d$. According to the Alon-Boppana theorem (Nilli, 1991) one has, for every d-regular graph,

$$\mu_2 \ge 2\sqrt{d-1} - \mathrm{o}_N(1),$$

where the $\mathrm{o}_N(1)$ term is a quantity that tends to zero for every fixed d as $N \to \infty$. Moreover, a d-regular graph $\mathscr{G}$ is called Ramanujan if

$$\max\big(|\mu_\ell| : \mu_\ell < d\big) \le 2\sqrt{d-1}.$$

In view of the above, a Ramanujan graph is optimal, at least as far as the spectral gap measure of expansion is concerned. Ramanujan graphs fall in the category of so-called

expander graphs, which have the apparently contradictory features of being both highly connected and at the same time sparse (for a review, see Shlomo et al., 2006).

Although the existence of Ramanujan graphs for any degree larger than or equal to 3 has been recently established by Marcus et al. (2015), their explicit construction remains difficult to use in practice. However, a conjecture by Alon (1986), proved by Friedman (2008) (see also Bordenave, 2015) asserts that most d-regular graphs are Ramanujan, in the sense that for every $\varepsilon > 0$,

$$\mathbb{P}\Big(\max\big(|\mu_2|, |\mu_N|\big) \geq 2\sqrt{d-1} + \varepsilon \Big) \to 0 \quad \text{as } N \to \infty,$$

or equivalently, in terms of the eigenvalues of A,

$$\mathbb{P}\Big(\max\big(|\gamma_2|, |\gamma_N|\big) \geq \frac{2\sqrt{d-1}}{d} + \varepsilon \Big) \to 0 \quad \text{as } N \to \infty.$$

In both results, the limit is along any sequence going to infinity with Nd even, and the probability is with respect to random graphs uniformly sampled in the family of d-regular graphs with vertex set $\mathscr{V} = \{1, \ldots, N\}$.

In order to generate a random irreducible, aperiodic d-regular Ramanujan graph, we can first generate a random d-regular graph using an improved version of the standard *pairing* algorithm, proposed by Steger and Wormald (1999). We retain it if it passes the tests of being irreducible, aperiodic, and Ramanujan as described above. Otherwise, we continue to generate a d-regular graph until all these conditions are satisfied. Figure 3 gives an example of a 3-regular Ramanujan graph with $N = 16$ vertices, generated in this way.

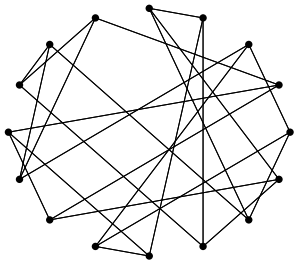

Figure 3: Randomly-generated 3-regular Ramanujan graph with $N = 16$ vertices.

Now, given an irreducible and aperiodic communication matrix A associated with a d-regular Ramanujan graph $\mathscr{G}$, we have, whenever $d \geq 3$,

$$\mathscr{S}(A) \leq \frac{N-1}{1 - \frac{4(d-1)}{d^2}}.$$

Thus, recalling that $\mathscr{S}(A) \geq N - 1$, we see that $\mathscr{S}(A)$ scales optimally as N while having $\mathscr{C}(A) = d$ (fixed). This remarkable super-efficiency property can be compared with the

full-communication matrix A_0, which has $\mathscr{S}(A_0) = N - 1$ but inadmissible complexity $\mathscr{C}(A_0) = N + 1$.

The statistical efficiency of these graphs is further highlighted in Figure 4. It shows results for 3- and 5-regular Ramanujan-type matrices (A_3 and A_5) as well as the previous results for non-Ramanujan-type matrices A_0, A_1, and A_2 (see Figure 2).

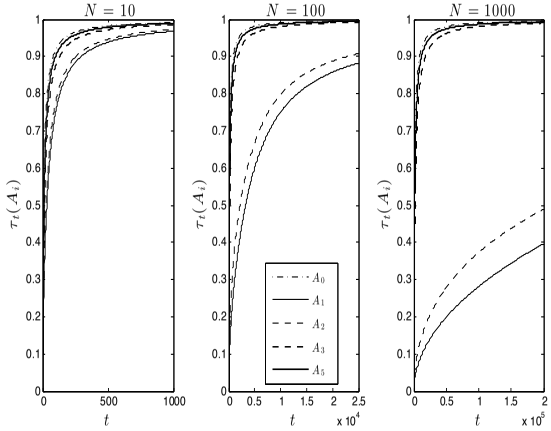

Figure 4: Evolution of $\tau_t(A_i)$ with t for different values of N, for $A = A_0$, A_1, A_2 as before with the addition of 3- and 5-regular Ramanujan-type matrices A_3 and A_5.

We see that A_3 is already close to the statistical performance of A_0, the saturated network, and for all intents and purposes A_5 is essentially as good as A_0, even when there are $N = 1000$ nodes; i.e., the statistical performance of the 5-regular Ramanujan graph is barely distinguishable from that of the totally connected graph! Nevertheless, we must not forget that the possibility of building such efficient networks in real-world situations will ultimately depend on the specific application, and may not always be possible.

Next, assuming that the Ramanujan-type matrix A is irreducible and aperiodic, it is apparent that there is a compromise to be made between the communication complexity of the algorithm (as measured by the degree index $\mathscr{C}(A) = d$) and its statistical performance (as measured by the coefficient $\mathscr{S}(A)$). Clearly, the two are in conflict. Upon this a question arises: is it possible to reach a compromise in the range of statistical performances $\mathscr{S}(A)$ while varying the communication complexity between $d = 3$ and $d = N$? The answer is affirmative, as shown in the following simulation exercise.

We fix $N = 200$ and then for each $d = 3, \ldots, N$:

(i) Generate a matrix A_d associated with a d-regular Ramanujan graph as before.

(*ii*) Compute the (non-unitary) eigenvalues $\gamma_2^{(d)}, \ldots, \gamma_N^{(d)}$ of the matrix A_d and evaluate the sum

$$\mathscr{S}(A_d) = \sum_{\ell=2}^{N} \frac{1}{1 - \left(\gamma_\ell^{(d)}\right)^2}.$$

(*iii*) Plot $\mathscr{S}(A_d)$ and $\beta\mathscr{C}(A_d) = \beta d$ as well as penalized sums $\mathscr{S}(A_d) + \beta\mathscr{C}(A_d)$ for $\beta \in \{1/2, 1, 2, 4\}$, where β represents an explicit cost incurred when increasing the number of connections between nodes.

Results are shown in Figure 5, where $d^\star$ refers to the d for which the penalized sum $\mathscr{S}(A_d) + \beta\mathscr{C}(A_d)$ is minimized.

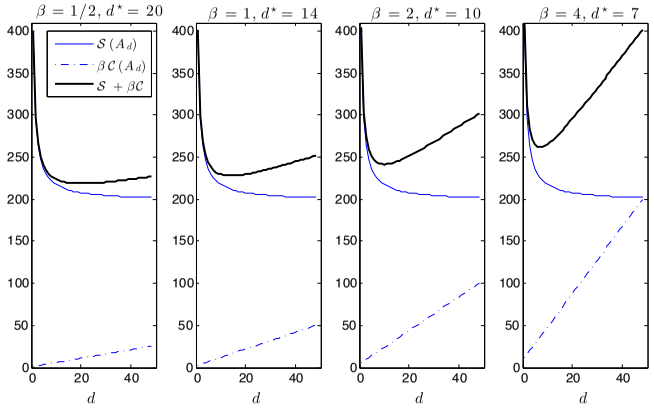

Figure 5: Statistical efficiency vs communication complexity tradeoff for four different node communication penalties β. $d^\star$ is the d which minimizes $\mathscr{S}(A_d) + \beta\mathscr{C}(A_d)$.

We observe that $\mathscr{S}(A_d)$ is decreasing whereas $\mathscr{C}(A_d)$ increases linearly. The tradeoff between statistical efficiency and communication complexity can be seen as minimizing their penalized sum, where β for example represents a monetary cost incurred by adding new network connections between nodes. We see that the optimal $d^\star$ and thus the number of node connections decreases as the cost of adding new ones increases.

Next, let us investigate the tradeoffs involved in the case where we have a large but fixed total number T of data to be streamed to N nodes, each receiving one new data value from time $t = 1$ to time $t = T/N$. In this context, the natural question to ask is how many nodes should we choose, and how much communication should we allow between them in order to get "very good" results for a "low" cost? Here a low cost comes from both limiting the number of nodes as well as the number of connections between them.

In the same set-up for A_d defined above, one way to look at this is to ask, for each N, what is the smallest $d \in \{3, \ldots, N\}$ and therefore the smallest communication cost

$\mathscr{C}(A_d) = d$ for which the performance ratio $\tau_t(A_d)$ is at least 0.99 after receiving all the data, i.e., when $t = T/N$? Then, as there is also a cost associated with increasing N, minimizing $\mathscr{C}(A_{d^\star})/N$ (where $d^\star$ is this smallest d chosen) should help us choose the number of nodes N and the amount of connection $\mathscr{C}(A_{d^\star})$ between them. The result of this is shown in Figure 6 for $T = 100$ million data points.

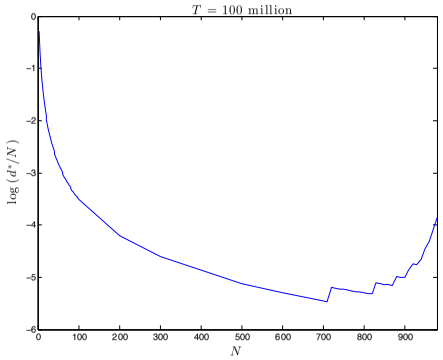

Figure 6: Optimizing the number of nodes N and the level of communication d required between nodes to obtain a performance ratio $\tau_t(A_d) \geq 0.99$ given a large fixed quantity of data T.

The minimum is found at $(N, d^\star) = (710, 3)$, suggesting that with 100 million data points, one can get excellent performance results ($\tau_t(A_{d^\star}) \geq 0.99$) for a low cost with around 700 nodes, each connected only to three other nodes! Increasing N further raises the cost necessary to obtain the same performance, both due to the price of adding more nodes, as well as requiring more connections between them: $d^\star$ must increase to 4, 5, and so on.

6. Asynchronous models

The models considered so far assume that messages from one agent to another are immediately delivered. However, a distributed environment may be subject to communication delays, for instance when some processors compute faster than others or when latency and finite bandwidth issues perturb message transmission. In the presence of such communication delays, it is conceivable that an agent will end up averaging its own value with an outdated value from another processor. Situations of this type fall within the framework of distributed asynchronous computation (Tsitsiklis et al., 1986; Bertsekas and Tsitsiklis, 1997). In the present section, we have in mind a model where agents do not have to wait at predetermined moments for predetermined messages to become available. We thus allow

some agents to compute faster and execute more iterations than others and allow communication delays to be substantial.

Communication delays are incorporated into our model as follows. For B a nonnegative integer, we assume that the last instant before t where agent j sent a message to agent i is $t - B_{ij}$, where $B_{ij} \in \{0, \dots, B\}$. Put differently, recalling that $\hat{\theta}_t^{(i)}$ is the estimate held by agent i at time t, we have

$$\hat{\theta}_{t+1}^{(i)} = \frac{1}{t+1} \sum_{j=1}^{N} a_{ij}(t - B_{ij}) \hat{\theta}_{t-B_{ij}}^{(j)} + \frac{1}{t+1} X_{t+1}^{(i)}, \quad t \geq 1. \tag{9}$$

Thus, at time t, when agent i uses the value of another agent j, this value is not necessarily the most recent one $\hat{\theta}_t^{(j)}$, but rather an outdated one $\hat{\theta}_{t-B_{ij}}^{(j)}$, where B_{ij} represents the communication delay. The time instants $t - B_{ij}$ are deterministic and, in any case, $0 \leq B_{ij} \leq B$, i.e., we assume that delays are bounded. Notice that some of the values $t - B_{ij}$ in (9) may be negative—in this case, by convention we set $\hat{\theta}_{t-B_{ij}}^{(j)} = 0$. Our goal is to establish a counterpart to Theorem 3 in the presence of communication delays. As usual, we set $\hat{\boldsymbol{\theta}}_t = (\hat{\theta}_t^{(1)}, \dots, \hat{\theta}_t^{(N)})^\top$.

Let $\kappa(t)$ be the smallest ℓ such that for all $(k_0, \dots, k_\ell) \in \{1, \dots, N\}^{\ell+1}$ satisfying $\prod_{j=1}^{\ell} a_{k_{j-1}k_j} > 0$, we have

$$t - \ell - \sum_{j=1}^{\ell} B_{k_{j-1}k_j} \leq B.$$

Observe that $t - \ell - \sum_{j=1}^{\ell} B_{k_{j-1}k_j}$ is the last time before t when a message was sent from agent k_0 to agent k_ℓ via $k_1, \dots, k_{\ell-1}$. Accordingly, $\kappa(t)$ is nothing but the smallest number of transitions needed to return at a time instant earlier than B, whatever the path. We note that $\kappa(t)$ is roughly of order t, since

$$\frac{1}{B+1} \leq \liminf_{t\to\infty} \frac{\kappa(t)}{t} \leq \limsup_{t\to\infty} \frac{\kappa(t)}{t} \leq 1.$$

From now on, it is assumed that $A = A_1$, i.e., the irreducible, aperiodic, and symmetric matrix defined in (2). Besides its simplicity, this choice is motivated by the fact that A_1 is communication-efficient while its associated performance obeys

$$\tau_t(A) \approx 1 - \frac{N^2}{6t}$$

for large t and N. The main result of the section now follows.

Theorem 7 *Assume that X is bounded and let $A = A_1$ be defined as in (2). Then, as $t \to \infty$,*

$$\mathbb{E}\left\| \frac{t}{\kappa(t)} \hat{\boldsymbol{\theta}}_t - \theta \mathbf{1} \right\|^2 = \mathrm{O}\left(\frac{1}{t}\right).$$

The advantages one hopes to gain from asynchronism are twofold. First, a reduction of the synchronization penalty and a potential speed advantage over synchronous algorithms,

perhaps at the expense of higher communication complexity. Second, a greater implementation flexibility and tolerance to system failure and uncertainty. On the other hand, the powerful result of Theorem 7 comes at the price of assumptions on the transmission network, which essentially demand that communication delays B_{ij} are time-independent. In fact, we find that the introduction of delays considerably complicates the consistency analysis of $\tau_t(A)$ even for the simple case of the empirical mean. This unexpected mathematical burden is due to the fact that the introduction of delays makes the analysis of the variance of the estimates quite complicated.

7. Conclusions and future work

This article has introduced new ideas which show how units collaborating among themselves can "boost" the statistical properties of the individual estimates by appropriately sharing information. Clearly, calculating the mean is a "simple" task with respect to current applications—our main motivation was to open a new front in this research direction. The obvious next step is to deal with more realistic problems in maximum likelihood, prediction, and learning.

As kindly pointed out by a referee, casting the problem using a single irreducible and aperiodic matrix A is a much more constrained approach than simply asking what are "good" communication schemes on a given graph and letting A be random and depend on t, i.e., A_t. In this more general case, we could have many more zeros than the graph's adjacency matrix, the case of random pairwise gossip being an example. There may be interesting choices of A_t that lead to good convergence properties. This is a promising direction for future research.

8. Proofs

We start this section by recalling the following important theorem, whose proof can be found for example in Foata and Fuchs (2004, Theorems 6.8.3 and 6.8.4). Here and elsewhere, A stands for the stochastic communication matrix.

Theorem 8 *Let $\lambda_1, \dots, \lambda_d$ be the eigenvalues of A of unit modulus (with $\lambda_1 = 1$) and Γ be the set of eigenvalues of A of modulus strictly smaller than 1.*

(*i*) *There exist projectors $Q_1, \dots, Q_d$ such that, for all $k \geq N$,*

$$A^k = \sum_{\ell=1}^{d} \lambda_\ell^k Q_\ell + \sum_{\gamma\in\Gamma} \gamma^k Q_\gamma(k),$$

where the matrices $\{Q_\gamma(k) : k \geq N, \gamma \in \Gamma\}$ satisfy $Q_\gamma(k)Q_{\gamma'}(k') = Q_\gamma(k+k')$ if $\gamma = \gamma'$, and 0 otherwise. In addition, for all $\gamma \in \Gamma$, $\lim_{k\to\infty} \gamma^k Q_\gamma(k) = 0$.

(*ii*) *The sequence $(A^k)_{k\geq 0}$ converges in the Cesàro sense to Q_1, i.e.,*

$$\frac{1}{t} \sum_{k=0}^{t} A^k \to Q_1 \quad \text{as } t \to \infty.$$

8.1 Proof of Proposition 1

According to (4), since A^k is a stochastic matrix, we have

$$\hat{\boldsymbol{\theta}}_t - \theta\mathbf{1} = \frac{1}{t}\sum_{k=0}^{t-1} A^k(\mathbf{X}_{t-k} - \theta\mathbf{1}).$$

Therefore, it may be assumed, without loss of generality, that $\theta = 0$. Thus,

$$\tau_t(A) = \frac{\mathbb{E}\left\|\bar{\mathbb{X}}_{Nt}\mathbf{1}\right\|^2}{\mathbb{E}\|\hat{\boldsymbol{\theta}}_t\|^2}.$$

Next, let $A^k = (a_{ij}^{(k)})_{1\le i,j\le N}$. Then, for each $i \in \{1,\dots,N\}$,

$$\hat{\theta}_t^{(i)} = \frac{1}{t}\sum_{k=0}^{t-1}\sum_{j=1}^{N} a_{ij}^{(k)} X_{t-k}^{(j)}, \quad t \ge 1.$$

By independence of the samples,

$$\mathbb{E}\big(\hat{\theta}_t^{(i)}\big)^2 = \frac{\sigma^2}{t^2}\sum_{k=0}^{t-1}\sum_{j=1}^{N}\big(a_{ij}^{(k)}\big)^2.$$

Upon noting that $\mathbb{E}(\bar{\mathbb{X}}_{Nt})^2 = \frac{\sigma^2}{Nt}$, we get

$$\begin{aligned}\tau_t(A) &= \frac{N\mathbb{E}\big(\bar{\mathbb{X}}_{Nt}\big)^2}{\mathbb{E}\big(\hat{\theta}_t^{(1)}\big)^2 + \cdots + \mathbb{E}\big(\hat{\theta}_t^{(N)}\big)^2}\\ &= \frac{t}{\sum_{k=0}^{t-1}\|A^k\|^2}.\end{aligned}$$

Since each A^k is a stochastic matrix, $\|A^k\|^2 \le N$ and, by the Cauchy-Schwarz inequality, $\|A^k\| \ge 1$. Thus, $\frac{1}{N} \le \tau_t(A) \le 1$, the lower bound being achieved when A is the identity matrix.

Let us now assume that A is reducible, and let $C \subsetneq \{1,\dots,N\}$ be a recurrence class. Arguing as above, we obtain that for all $i \in C$,

$$\mathbb{E}\big(\hat{\theta}_t^{(i)}\big)^2 = \frac{\sigma^2}{t^2}\sum_{k=0}^{t-1}\sum_{j=1}^{N}\big(a_{ij}^{(k)}\big)^2 \ge \frac{\sigma^2}{t^2}\sum_{k=0}^{t-1}\sum_{j\in C}\big(a_{ij}^{(k)}\big)^2.$$

Since C is a recurrence class, the restriction of A to entries in C is a stochastic matrix as well. Thus, setting $N_1 = |C|$, by the Cauchy-Schwarz inequality,

$$\mathbb{E}\big(\hat{\theta}_t^{(i)}\big)^2 \ge \begin{cases} \frac{\sigma^2}{tN_1} & \text{if } i \in C\\ \frac{\sigma^2}{tN} & \text{otherwise.}\end{cases}$$

To conclude,

$$\begin{aligned}\tau_t(A) &= \frac{\sigma^2/t}{\sum_{i\in C}\mathbb{E}\big(\hat{\theta}_t^{(i)}\big)^2 + \sum_{i\notin C}\mathbb{E}\big(\hat{\theta}_t^{(i)}\big)^2}\\ &\le \frac{1}{1+(N-N_1)/N}\\ &\le \frac{N}{N+1},\end{aligned}$$

since $N - N_1 \ge 1$.

8.2 Proof of Lemma 2

As in the previous proof, we assume that $\theta = 0$. Recall that

$$\hat{\boldsymbol{\theta}}_t = \frac{1}{t}\sum_{k=0}^{t-1} A^k\mathbf{X}_{t-k}, \quad t \ge 1.$$

Thus, for all $t \ge 1$,

$$\begin{aligned}\mathbb{E}\|\hat{\boldsymbol{\theta}}_t\|^2 &= \frac{1}{t^2}\mathbb{E}\left\|\sum_{k=0}^{t-1} A^k\mathbf{X}_{t-k}\right\|^2\\ &= \frac{1}{t^2}\sum_{k=0}^{t-1}\mathbb{E}\|A^k\mathbf{X}_{t-k}\|^2\\ &\qquad \text{(by independence of } \mathbf{X}_1,\dots,\mathbf{X}_t)\\ &= \frac{1}{t^2}\mathbb{E}\mathbf{X}_1^\top\Big(\sum_{k=0}^{t-1}(A^k)^\top A^k\Big)\mathbf{X}_1.\end{aligned}$$

Denote by $\lambda_1 = 1,\dots,\lambda_d$ the eigenvalues of A of modulus 1, and let Γ be the set of eigenvalues γ of A of modulus strictly smaller than 1. According to Theorem 8, there exist projectors $Q_1,\dots,Q_d$ and matrices $Q_\gamma(k)$ such that for all $k \ge N$,

$$A^k = \sum_{\ell=1}^{d}\lambda_\ell^k Q_\ell + \sum_{\gamma\in\Gamma}\gamma^k Q_\gamma(k).$$

Therefore,

$$\begin{aligned}\sum_{k=0}^{t-1}(A^k)^\top A^k &= \sum_{k=0}^{t-1}(\bar{A}^k)^\top A^k\\ &= \sum_{k=0}^{t-1}\left(\sum_{\ell=1}^{d}\bar{\lambda}_\ell^k\bar{Q}_\ell + \sum_{\gamma\in\Gamma}\bar{\gamma}^k\bar{Q}_\gamma(k)\right)^\top\left(\sum_{j=1}^{d}\lambda_j^k Q_j + \sum_{\gamma\in\Gamma}\gamma^k Q_\gamma(k)\right)\\ &= \sum_{k=0}^{t-1}\sum_{\ell,j=1}^{d}\bar{\lambda}_\ell^k\lambda_j^k\bar{Q}_\ell^\top Q_j + \mathrm{o}(t).\end{aligned}$$

Here, we have used Cesàro's lemma combined with the fact that, by Theorem 8, for any $\gamma \in \Gamma$, $\lim_{k\to\infty} \gamma^k Q_\gamma(k) = 0$.

Since A is irreducible, according to the Perron-Frobenius theorem (e.g., Grimmett and Stirzaker, 2001, page 240), we have that $\lambda_\ell = e^{\frac{2\pi i(\ell-1)}{d}}$, $1 \le \ell \le d$. Accordingly,

$$\bar{\lambda}_\ell \lambda_j = e^{\frac{2\pi i(j-\ell)}{d}} = 1 \Leftrightarrow j = \ell.$$

Thus,

$$\sum_{k=0}^{t-1} (A^k)^\top A^k = t \sum_{\ell=1}^{d} \bar{Q}_\ell^\top Q_\ell + \mathrm{O}(1) + \mathrm{o}(t).$$

Letting $Q = \sum_{\ell=1}^d \bar{Q}_\ell^\top Q_\ell$, we obtain

$$\begin{aligned} t\mathbb{E}\|\hat{\boldsymbol{\theta}}_t\|^2 &= \mathbb{E}\mathbf{X}_1^\top Q \mathbf{X}_1 + \mathbb{E}\mathbf{X}_1^\top \left(\frac{1}{t} \sum_{k=0}^{t-1} (A^k)^\top A^k - Q \right) \mathbf{X}_1 \qquad (10) \\ &= \mathbb{E}\mathbf{X}_1^\top Q \mathbf{X}_1 + \mathrm{o}(1) \\ &= \sum_{\ell=1}^{d} \mathbb{E}\|Q_\ell \mathbf{X}_1\|^2 + \mathrm{o}(1). \end{aligned}$$

Denoting by $Q_{\ell,ij}$ the (i,j)-entry of Q_ℓ, we conclude

$$\begin{aligned} t\mathbb{E}\|\hat{\boldsymbol{\theta}}_t\|^2 &= \sum_{\ell=1}^{d} \mathbb{E} \sum_{i=1}^{N} \left(\sum_{j=1}^{N} Q_{\ell,ij} X_1^{(j)} \right)^2 + \mathrm{o}(1) \\ &= \sigma^2 \sum_{\ell=1}^{d} \sum_{i,j=1}^{N} Q_{\ell,ij}^2 + \mathrm{o}(1) \\ &\quad \text{(by independence of } X_1^{(1)}, \ldots, X_1^{(N)}) \\ &= \sigma^2 \sum_{\ell=1}^{d} \|Q_\ell\|^2 + \mathrm{o}(1). \end{aligned}$$

Lastly, recalling that $\mathbb{E}\|\bar{\mathbb{X}}_{Nt}\mathbf{1}\|^2 = \frac{\sigma^2}{t}$, we obtain

$$\tau_t(A) = \frac{1}{\sum_{\ell=1}^d \|Q_\ell\|^2 + \mathrm{o}(1)} = \frac{1}{\sum_{\ell=1}^d \|Q_\ell\|^2} + \mathrm{o}(1).$$

8.3 Proof of Theorem 3

Sufficiency. Assume that A is irreducible, aperiodic, and bistochastic. The first two conditions imply that 1 is the unique eigenvalue of A of unit modulus. Therefore, according to Lemma 2, we only need to prove that the projector Q_1 satisfies $\|Q_1\| = 1$.

Since A is bistochastic, its stationary distribution is the uniform distribution on the set $\{1, \ldots, N\}$. Moreover, since A is irreducible and aperiodic, we have, as $k \to \infty$,

$$A^k \to \frac{1}{N} \begin{pmatrix} 1 & 1 & \ldots & 1 \\ \vdots & \vdots & \vdots & \vdots \\ 1 & 1 & \ldots & 1 \end{pmatrix}.$$

By comparing this limit with that of the second statement of Theorem 8, we conclude by Cesàro's lemma that

$$Q_1 = \frac{1}{N} \begin{pmatrix} 1 & 1 & \ldots & 1 \\ \vdots & \vdots & \vdots & \vdots \\ 1 & 1 & \ldots & 1 \end{pmatrix}.$$

This implies in particular that $\|Q_1\| = 1$.

Necessity. Assume that $\tau_t(A)$ tends to 1 as $t \to \infty$. According to Proposition 1, A is irreducible. Thus, by Lemma 2, we have $\sum_{\ell=1}^d \|Q_\ell\|^2 = 1$. Observe, since each Q_ℓ is a projector, that $\|Q_\ell\| \ge 1$. Therefore, the identity $\sum_{\ell=1}^d \|Q_\ell\|^2 = 1$ implies $d = 1$ and $\|Q_1\| = 1$. We conclude that A is aperiodic.

Then, since A is irreducible and aperiodic, we have, as $k \to \infty$,

$$A^k \to \begin{pmatrix} \boldsymbol{\mu} \\ \vdots \\ \boldsymbol{\mu} \end{pmatrix},$$

where $\boldsymbol{\mu}$ is the stationary distribution of A, represented as a row vector. Comparing once again this limit with the second statement of Theorem 8, we see that

$$Q_1 = \begin{pmatrix} \boldsymbol{\mu} \\ \vdots \\ \boldsymbol{\mu} \end{pmatrix}.$$

Thus, $\|Q_1\|^2 = N\|\boldsymbol{\mu}\|^2 = 1$. In particular, letting $\boldsymbol{\mu} = (\mu_1, \ldots, \mu_N)$, we have

$$N \sum_{i=1}^{N} \mu_i^2 = \sum_{i=1}^{N} \mu_i.$$

This is an equality case in the Cauchy-Schwarz inequality, from which we deduce that $\boldsymbol{\mu}$ is the uniform distribution on $\{1, \ldots, N\}$. Since $\boldsymbol{\mu}$ is the stationary distribution of A, this implies that A is bistochastic.

8.4 Proof of Proposition 4

If A is irreducible and aperiodic, then by Lemma 2, $\tau_t(A) \to \frac{1}{\|Q_1\|^2}$ as $t \to \infty$. But, as $k \to \infty$,

$$A^k \to \begin{pmatrix} \boldsymbol{\mu} \\ \vdots \\ \boldsymbol{\mu} \end{pmatrix},$$

where the stationary distribution $\boldsymbol{\mu}$ of A is represented as a row vector. By the second statement of Theorem 8, we conclude that $\|Q_1\|^2 = N\|\boldsymbol{\mu}\|^2$.

8.5 Proof of Theorem 5

Without loss of generality, assume that $\theta = 0$. Since A is irreducible and aperiodic, the matrix Q in the proof of Lemma 2 is $Q = Q_1^\top Q_1$. Moreover, since A is also bistochastic, we have already seen that as $k \to \infty$,

$$A^k \to \frac{1}{N}\begin{pmatrix} 1 & 1 & \dots & 1 \\ \vdots & \vdots & \vdots & \vdots \\ 1 & 1 & \dots & 1 \end{pmatrix}. \tag{11}$$

However, by the second statement of Theorem 8, the above matrix is equal to Q_1. Thus, the projector Q_1 is symmetric, which implies $Q = Q_1$.

Next, we deduce from (10) that

$$\begin{aligned} \tau_t(A) &= \frac{\sigma^2}{\mathbb{E}\mathbf{X}_1^\top Q \mathbf{X}_1 + \mathbb{E}\mathbf{X}_1^\top \big(\frac{1}{t}\sum_{k=0}^{t-1}(A^k)^\top A^k - Q\big)\mathbf{X}_1} \\ &= \frac{\sigma^2}{\sigma^2 + \mathbb{E}\mathbf{X}_1^\top \big(\frac{1}{t}\sum_{k=0}^{t-1} A^{2k} - Q\big)\mathbf{X}_1}, \end{aligned} \tag{12}$$

by symmetry of A and the fact that $\mathbb{E}\mathbf{X}_1^\top Q \mathbf{X}_1 = \sigma^2$. The symmetric matrix A can be put into the form

$$A = UDU^\top,$$

where U is a unitary matrix with real entries (so, $U^\top = U^{-1}$) and $D = \mathrm{diag}(1, \gamma_2, \dots, \gamma_N)$, with $1 > \gamma_2 \geq \cdots \geq \gamma_N > -1$. Therefore, as $k \to \infty$,

$$\frac{1}{t}\sum_{k=0}^{t-1} A^{2k} = U\Big(\frac{1}{t}\sum_{k=0}^{t-1} D^{2k}\Big)U^\top \to U\begin{pmatrix} 1 & 0 & \dots & 0 \\ 0 & 0 & \dots & 0 \\ \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & \dots & 0 \end{pmatrix}U^\top.$$

However, by (11) and Cesàro's lemma,

$$\frac{1}{t}\sum_{k=0}^{t-1} A^{2k} \to Q \quad \text{as } k \to \infty.$$

It follows that $Q = UMU^\top$, where

$$M = \begin{pmatrix} 1 & 0 & \dots & 0 \\ 0 & 0 & \dots & 0 \\ \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & \dots & 0 \end{pmatrix}.$$

Thus,

$$\begin{aligned} \frac{1}{t}\sum_{k=0}^{t-1} A^{2k} - Q &= U\Big(\frac{1}{t}\sum_{k=0}^{t-1} D^{2k} - M\Big)U^\top \\ &= U\Big(\frac{1}{t}\sum_{k=0}^{t-1} \mathrm{diag}\big(0, \gamma_2^{2k}, \dots, \gamma_N^{2k}\big)\Big)U^\top \\ &= U\mathrm{diag}\Big(0, \frac{1}{t}\frac{1-\gamma_2^{2t}}{1-\gamma_2^2}, \dots, \frac{1}{t}\frac{1-\gamma_N^{2k}}{1-\gamma_N^2}\Big)U^\top. \end{aligned}$$

Next, set

$$\alpha_\ell = \frac{1}{t}\frac{1-\gamma_\ell^{2t}}{1-\gamma_\ell^2}, \quad 2 \leq \ell \leq N,$$

and let $U = (u_{ij})_{1 \leq i,j \leq N}$. With this notation, the (i,j)-entry of the matrix $\frac{1}{t}\sum_{k=0}^{t-1} A^{2k} - Q$ is

$$\sum_{\ell=2}^{N} u_{i\ell}\alpha_\ell u_{j\ell}.$$

Hence,

$$\mathbf{X}_1^\top\Big(\frac{1}{t}\sum_{k=0}^{t-1} A^{2k} - Q\Big)\mathbf{X}_1 = \sum_{i=1}^{N} X_1^{(i)} \sum_{j=1}^{N}\Big(\sum_{\ell=2}^{N} u_{i\ell}\alpha_\ell u_{j\ell}\Big)X_1^{(j)}.$$

Thus,

$$\begin{aligned} \mathbb{E}\mathbf{X}_1^\top\Big(\frac{1}{t}\sum_{k=0}^{t-1} A^{2k} - Q\Big)\mathbf{X}_1 &= \sigma^2 \sum_{i=1}^{N}\sum_{\ell=2}^{N} u_{i\ell}\alpha_\ell u_{i\ell} \\ &= \sigma^2 \sum_{i=1}^{N}\sum_{\ell=2}^{N} \alpha_\ell u_{i\ell}^2 \\ &= \sigma^2 \sum_{\ell=2}^{N} \alpha_\ell \\ &= \frac{\sigma^2}{t}\sum_{\ell=2}^{N} \frac{1-\gamma_\ell^{2t}}{1-\gamma_\ell^2}. \end{aligned}$$

We conclude from (12) that

$$\tau_t(A) = \frac{1}{1 + \frac{1}{t}\sum_{\ell=2}^{N}\frac{1-\gamma_\ell^{2t}}{1-\gamma_\ell^2}}.$$

This shows the first statement of the theorem. Using the inequality $\frac{1}{1+x} \geq 1 - x$, valid for all $x \geq 0$, we have

$$\begin{aligned} \tau_t(A) &\geq 1 - \frac{1}{t}\sum_{\ell=2}^{N}\frac{1-\gamma_\ell^{2t}}{1-\gamma_\ell^2} \\ &\geq 1 - \frac{\mathscr{S}(A)}{t}. \end{aligned}$$

Finally, evoking the inequality $\frac{1}{1+x} \leq 1 - x + x^2$, valid for all $x \geq 0$, we conclude

$$\begin{aligned}\tau_t(A) &\leq 1 - \frac{1}{t}\sum_{\ell=2}^{N} \frac{1-\gamma_\ell^{2t}}{1-\gamma_\ell^2} + \Big(\frac{1}{t}\sum_{\ell=2}^{N} \frac{1-\gamma_\ell^{2t}}{1-\gamma_\ell^2}\Big)^2 \\ &\leq 1 - \frac{\mathscr{S}(A)}{t} + \Gamma^{2t}(A)\frac{\mathscr{S}(A)}{t} + \Big(\frac{\mathscr{S}(A)}{t}\Big)^2.\end{aligned}$$

8.6 Proof of Theorem 7

From now on, we fix $k_0 \in \{1,\dots,N\}$ and let $Z_t^{(i)} = t\hat{\theta}_t^{(i)}$ for any $i \in \{1,\dots,N\}$. Thus, for all $t \geq 1$,

$$Z_t^{(k_0)} = \sum_{k=1}^{N} a_{k_0 k} Z_{t-B_{k_0 k}-1}^{(k)} + X_t^{(k_0)},$$

and

$$Z_t^{(k_0)} = \sum_{k_1,k_2=1}^{N} a_{k_0 k_1} a_{k_1 k_2} Z_{t-B_{k_0 k_1}-B_{k_1 k_2}-2}^{(k_2)} + \sum_{k_1=1}^{N} a_{k_0 k_1} X_{t-B_{k_0 k_1}-1}^{(k_1)} + X_t^{(k_0)}. \tag{13}$$

Our first task is to iterate this formula. To do so, we need additional notation. For ℓ a positive integer and $k \in \{1,\dots,N\}$, let $\underline{K}^\ell(k)$ be the set of vectors in $\{1,\dots,N\}^{\ell+1}$ of the form $(k_0, k_1, \dots, k_{\ell-1}, k)$ such that $w(\underline{K}^\ell(k)) > 0$, where

$$w\big(\underline{K}^\ell(k)\big) = a_{k_0 k_1} a_{k_1 k_2} \dots a_{k_{\ell-2} k_{\ell-1}} a_{k_{\ell-1} k}.$$

In particular, by our choice of A, we have $w(\underline{K}^\ell(k)) = 2^{-\ell}$ for any k. Next, we set

$$\Delta\big(\underline{K}^\ell(k)\big) = \ell + B_{k_0 k_1} + B_{k_1 k_2} + \dots + B_{k_{\ell-2} k_{\ell-1}} + B_{k_{\ell-1} k}.$$

When $\ell = 0$, then by convention $\underline{K}^0(k) = (k_0)$, $w(\underline{K}^0(k)) = 1$ if $k = k_0$ and 0 otherwise, and $\Delta(\underline{K}^0(k)) = 0$.

We are now ready to iterate (13). To do so, observe that

$$\begin{aligned}Z_t^{(k_0)} &= \sum_{k=1}^{N} \sum_{\underline{K}^{\kappa(t)}(k)} w\big(\underline{K}^{\kappa(t)}(k)\big) Z_{t-\Delta(\underline{K}^{\kappa(t)}(k))}^{(k)} \\ &\quad + \sum_{\ell=0}^{\kappa(t)-1} \sum_{k=1}^{N} \sum_{\underline{K}^\ell(k)} w\big(\underline{K}^\ell(k)\big) X_{t-\Delta(\underline{K}^\ell(k))}^{(k)} \\ &\stackrel{\text{def}}{=} R_t^1 + R_t^2.\end{aligned} \tag{14}$$

By the definition of $\kappa(t)$, for all $k \in \{1,\dots,N\}$, $t - \Delta(\underline{K}^{\kappa(t)}(k)) \leq B$. Since X is bounded, we deduce that there exists $C > 0$ such that

$$|R_t^1| \leq C \sum_{k=1}^{N} \sum_{\underline{K}^{\kappa(t)}(k)} w\big(\underline{K}^{\kappa(t)}(k)\big).$$

This implies that $|R_t^1| \leq C$. To see this, note that $A^{\kappa(t)}$ is a stochastic matrix and that for all $k \in \{1,\dots,N\}$,

$$\sum_{\underline{K}^{\kappa(t)}(k)} w\big(\underline{K}^{\kappa(t)}(k)\big) = (A^{\kappa(t)})_{k_0 k}.$$

The analysis of the term R_t^2 is more delicate. The difficulty arises from the fact that this term is *not* a sum of independent random variables, and therefore its components must be grouped. Since each B_{ij} is smaller than B and $\Delta(\underline{K}^\ell(k)) = x$ implies $x \geq \ell$, we obtain

$$\begin{aligned}R_t^2 &= \sum_{\ell=0}^{\kappa(t)-1} \sum_{k=1}^{N} \sum_{x=0}^{(B+1)\ell} \sum_{\underline{K}^\ell(k):\Delta(\underline{K}^\ell(k))=x} w\big(\underline{K}^\ell(k)\big)\, X_{t-x}^{(k)} \\ &= \sum_{x=0}^{(B+1)(\kappa(t)-1)} \sum_{k=1}^{N} \sum_{\ell=\lfloor x/(B+1)\rfloor+1}^{x} \sum_{\underline{K}^\ell(k):\Delta(\underline{K}^\ell(k))=x} w\big(\underline{K}^\ell(k)\big)\, X_{t-x}^{(k)}\end{aligned}$$

($\lfloor\cdot\rfloor$ is the floor function). By independence of the $X_j^{(i)}$, we get

$$\mathrm{Var}(R_t^2) = \sigma^2 \sum_{x=0}^{(B+1)(\kappa(t)-1)} \sum_{k=1}^{N} \Bigg(\sum_{\ell=\lfloor x/(B+1)\rfloor+1}^{x} \sum_{\underline{K}^\ell(k):\Delta(\underline{K}^\ell(k))=x} w\big(\underline{K}^\ell(k)\big) \Bigg)^2.$$

Recalling that $w(\underline{K}^\ell(k)) = 2^{-\ell}$, we obtain

$$\mathrm{Var}(R_t^2) = \sigma^2 \sum_{x=0}^{(B+1)(\kappa(t)-1)} \sum_{k=1}^{N} \Bigg(\sum_{\ell=\lfloor x/(B+1)\rfloor+1}^{x} \frac{1}{2^\ell} \Big|\underline{K}^\ell(k) : \Delta\big(\underline{K}^\ell(k)\big) = x\Big| \Bigg)^2.$$

Next, consider the Markov chain $(Y_n)_{n\geq 0}$ with transition matrix A such that $Y_0 = k_0$. Observe that

$$\mathbb{P}\Big(Y_\ell = k, \sum_{j=1}^{\ell} B_{Y_{j-1}Y_j} = x - \ell\Big) = \frac{1}{2^\ell} \Big|\underline{K}^\ell(k) : \Delta\big(\underline{K}^\ell(k)\big) = x\Big|.$$

Moreover, for fixed x, the events

$$\Big\{ \sum_{j=1}^{\ell} B_{Y_{j-1}Y_j} = x - \ell \Big\}, \quad \Big\lfloor \frac{x}{B+1} \Big\rfloor + 1 \leq \ell \leq x,$$

are disjoint since the B_{ij} are nonnegative. Thus,

$$\sum_{\ell=\lfloor x/(B+1)\rfloor+1}^{x} \frac{1}{2^\ell} \Big|\underline{K}^\ell(k) : \Delta\big(\underline{K}^\ell(k)\big) = x\Big| \leq 1,$$

and so,

$$\mathrm{Var}(R_t^2) \leq \sigma^2 \sum_{x=0}^{(B+1)(\kappa(t)-1)} \sum_{k=1}^{N} 1 = \sigma^2 N\big((B+1)\kappa(t) - B\big). \tag{15}$$

The expectation of R_t^2 is easier to compute. Indeed, since each A^ℓ is a stochastic matrix,

$$\mathbb{E}R_t^2 = \theta \sum_{\ell=0}^{\kappa(t)-1} \sum_{k=1}^{N} \sum_{\underline{K}^\ell(k)} w\big(\underline{K}^\ell(k)\big) = \theta \sum_{\ell=0}^{\kappa(t)-1} \sum_{k=1}^{N} (A^\ell)_{k_0 k} = \theta\kappa(t).$$

Combining (14), (15), and the fact that $|R_t^1| \leq C$, we obtain

$$\begin{aligned}\mathbb{E}\bigg(\frac{t}{\kappa(t)}\hat{\theta}_t^{(k_0)} - \theta\bigg)^2 &= \mathbb{E}\bigg(\frac{R_t^1}{\kappa(t)} + \frac{R_t^2}{\kappa(t)} - \theta\bigg)^2 \\ &= \mathbb{E}\bigg(\frac{R_t^2 - \mathbb{E}R_t^2}{\kappa(t)} + \frac{R_t^1}{\kappa(t)}\bigg)^2 \\ &= \mathrm{O}\bigg(\frac{1}{\kappa(t)}\bigg).\end{aligned}$$

The result follows from the identity $1/\kappa(t) = \mathrm{O}(1/t)$.

Abstract

We derive two convergence results for a sequential alternating maximization procedure to approximate the maximizer of random functionals such as the realized log likelihood in MLE estimation. We manage to show that the sequence attains the same deviation properties as shown for the profile M-estimator by Andresen and Spokoiny (2013), that means a finite sample Wilks and Fisher theorem. Further under slightly stronger smoothness constraints on the random functional we can show nearly linear convergence to the global maximizer if the starting point for the procedure is well chosen.

Keywords: alternating maximization, alternating minimization, profile maximum likelihood, EM-algorithm, M-estimation, local linear approximation, local concentration, semiparametric

Contents

1. Introduction

This paper presents two convergence results for an alternating maximization procedure to approximate M-estimators. Let $\mathbb{Y} \in \mathcal{Y}$ denote some observed random data, and $\mathbb{P}$ denote the data distribution. In the semiparametric profile M-estimation framework the target of analysis is

$$\boldsymbol{\theta}^* = \Pi_{\boldsymbol{\theta}} \boldsymbol{\upsilon}^* = \Pi_{\boldsymbol{\theta}} \operatorname*{argmax}_{\boldsymbol{\upsilon}} \mathbb{E}_{\mathbb{P}} \mathcal{L}(\boldsymbol{\upsilon}, \mathbb{Y}), \tag{1}$$

where $\mathcal{L} : \Upsilon \times \mathcal{Y} \to \mathbb{R}$ is an appropriate functional, $\Pi_{\boldsymbol{\theta}} : \Upsilon \to \mathbb{R}^p$ is a projection and where Υ is some high dimensional or even infinite dimensional parameter space. A prominent way of estimating $\boldsymbol{\theta}^*$ is the profile M-estimator (pME)

$$\widetilde{\boldsymbol{\theta}} \overset{\text{def}}{=} \Pi_{\boldsymbol{\theta}} \widetilde{\boldsymbol{\upsilon}} \overset{\text{def}}{=} \Pi_{\boldsymbol{\theta}} \operatorname*{argmax}_{(\boldsymbol{\theta},\boldsymbol{\eta})} \mathcal{L}(\boldsymbol{\theta}, \boldsymbol{\eta}) = \operatorname*{argmax}_{\boldsymbol{\theta}} \max_{\boldsymbol{\eta}} \mathcal{L}(\boldsymbol{\theta}, \boldsymbol{\eta}). \tag{2}$$

This paper focuses on finite dimensional parameter spaces $\Upsilon \subseteq \mathbb{R}^{p^*}$ with $p^* = p + m \in \mathbb{N}$ being the full dimension, as infinite dimensional maximization problems are computationally not feasible. This is motivated by the sieve M-estimation technique, which projects the estimation problem to a finite dimensional submodel - see Section 1.2 for details.

The alternating maximization procedure is used in situations where a direct computation of the full maximum estimator (ME) $\widetilde{\boldsymbol{\upsilon}} \in \mathbb{R}^{p^*}$ is not feasible or simply very difficult to implement. Consider for example the task to calculate the pME where with scalar random observations $\mathbb{Y} = (y_i)_{i=1}^n \subset \mathbb{R}$, parameter $\boldsymbol{\upsilon} = (\boldsymbol{\theta}, \boldsymbol{\eta}) \in \mathbb{R}^p \times \mathbb{R}^m$ and a function basis $(\boldsymbol{e}_k) \subset L^2(\mathbb{R})$

$$\mathcal{L}(\boldsymbol{\theta}, \boldsymbol{\eta}) = -\frac{1}{2} \sum_{i=1}^{n} \Big| y_i - \sum_{k=0}^{m} \boldsymbol{\eta}_k \boldsymbol{e}_k(\boldsymbol{X}_i^\top \boldsymbol{\theta}) \Big|^2.$$

In this case the maximization problem is high dimensional and non-convex (see Section 3 for more details). But for fixed $\boldsymbol{\theta} \in S_1 \subset \mathbb{R}^p$ maximization with respect to $\boldsymbol{\eta} \in \mathbb{R}^m$ is rather simple while for fixed $\boldsymbol{\eta} \in \mathbb{R}^m$ the maximization with respect to $\boldsymbol{\theta} \in \mathbb{R}^p$ can be feasible for low $p \in \mathbb{N}$. This motivates the following iterative procedure. Given some (data dependent) functional $\mathcal{L} : \mathbb{R}^p \times \mathbb{R}^m \to \mathbb{R}$ and an initial guess $\widetilde{\boldsymbol{\upsilon}}_0 \in \mathbb{R}^{p+m}$ set for $k \in \mathbb{N}$

$$\begin{aligned} \widetilde{\boldsymbol{\upsilon}}_{k,k+1} &\overset{\text{def}}{=} (\widetilde{\boldsymbol{\theta}}_k, \widetilde{\boldsymbol{\eta}}_{k+1}) = \left(\widetilde{\boldsymbol{\theta}}_k, \operatorname*{argmax}_{\boldsymbol{\eta} \in \mathbb{R}^m} \mathcal{L}(\widetilde{\boldsymbol{\theta}}_k, \boldsymbol{\eta}) \right), \\ \widetilde{\boldsymbol{\upsilon}}_{k,k} &\overset{\text{def}}{=} (\widetilde{\boldsymbol{\theta}}_k, \widetilde{\boldsymbol{\eta}}_k) = \left(\operatorname*{argmax}_{\boldsymbol{\theta} \in \mathbb{R}^p} \mathcal{L}(\boldsymbol{\theta}, \widetilde{\boldsymbol{\eta}}_k), \widetilde{\boldsymbol{\eta}}_k \right). \end{aligned} \tag{3}$$

The so called "alternating maximization procedure" (or minimization) is a widely applied algorithm in many parameter estimation tasks (see Jain, Netrapalli, and Sanghavi, 2013; Netrapalli, Jain, and Sanghavi, 2013; Keshavan, Montanari, and Oh, 2010; Yi, Caramanis, and Sanghavi, 2013). Some natural questions arise: Does the sequence $(\widetilde{\boldsymbol{\theta}}_k)$ converge to

a limit that satisfies the same statistical properties as the profile estimator? And if the answer is yes, after how many steps does the sequence acquire these properties? Under what circumstances does the sequence actually converge to the global maximizer $\widetilde{\boldsymbol{\upsilon}}$? This problem is hard because the behavior of each step of the sequence is determined by the actual finite sample realization of the functional $\mathcal{L}(\cdot, \mathbb{Y})$. To the authors' knowledge no general "convergence" result is available that answers the questions from above except for the treatment of specific models again (see Jain, Netrapalli, and Sanghavi, 2013; Netrapalli, Jain, and Sanghavi, 2013; Keshavan, Montanari, and Oh, 2010; Yi, Caramanis, and Sanghavi, 2013) or variants of the procedure (Cheng, 2013).

We address this difficulty via employing new finite sample techniques (Andresen and Spokoiny, 2014; Spokoiny, 2012), which allow to answer the above questions: with growing iteration number $k \in \mathbb{N}$ the estimators $\widetilde{\boldsymbol{\theta}}_k$ attain the same statistical properties as the profile M-estimator and Theorem 7 provides a choice of the necessary number of steps $K \in \mathbb{N}$. Under slightly stronger conditions on the structure of the model we can give a convergence result to the global maximizier that does not rely on unimodality. Further we can address the important question under which ratio of full dimension $p^* = p + m \in \mathbb{N}$ to sample size $n \in \mathbb{N}$ the sequence behaves as desired. For instance for smooth $\mathcal{L}$ our results become sharp if $p^*/\sqrt{n}$ is small and convergence to the full maximizer already occurs if p^*/n is small.

The alternating maximization procedure can be understood as a special case of the Expectation Maximization algorithm (EM algorithm) as we illustrate in Section 1.1. The EM algorithm itself was derived in a work of Dempster, Laird, and Rubin (1977) where particular versions of this approach are generalized. This paper (Dempster, Laird, and Rubin, 1977) also contains a variety of problems where an application of the EM algorithm can be fruitful; for a brief history of the EM algorithm (see McLachlan and Krishnan, 1997, Section 1.8). We briefly explain the EM algorithm in Section 1.1.

Since the EM algorithm is very popular in applications a lot of research on its behavior has been done. We are only dealing with a special case of this procedure so we restrict our selves to citing the well-known convergence result by Wu Wu (1983), which is still state of the art in most settings. Unfortunately Wu's result - as most convergence results on these iterative procedures - only ensures convergence to some set of local maximizers or fixpoints of the procedure. Only in very special cases like unimodality can actual convergence to the maximizer be ensured.

In a recent work (Balakrishnan, Wainwright, and Yu, 2014) a new way is presented of addressing the properties of the EM sequence in a very general i.i.d. setting, based on concavity of $\mathcal{L}$. They assume that the functional $\mathcal{L}$ is concave and smooth enough (First order stability) and that for a sample $(\boldsymbol{Y}_i)_{i=1,\dots,n}$ with high probability an uniform bound is satisfied of the kind

$$\max_{\boldsymbol{\theta}^\circ \in B_r(\boldsymbol{\theta}^*)} \left| \operatorname*{argmax}_{\boldsymbol{\theta}} \mathcal{L}(\boldsymbol{\theta}, \widetilde{\boldsymbol{\eta}}_{\boldsymbol{\theta}^\circ}) - \operatorname*{argmax}_{\boldsymbol{\theta}} \mathbb{E}\mathcal{L}(\boldsymbol{\theta}, \widetilde{\boldsymbol{\eta}}_{\boldsymbol{\theta}^\circ}) \right| \leq \epsilon_n. \tag{4}$$

Under these assumptions, with high probability and some $\nu < 1$ they show

$$\|\widetilde{\boldsymbol{\theta}}_k - \boldsymbol{\theta}^*\| \leq \nu^k \|\boldsymbol{\theta}_0 - \boldsymbol{\theta}^*\| + \mathsf{C}\epsilon_n. \tag{5}$$

Unfortunately this does not answer our two questions to full satisfaction. First the bound (4) is rather high level and has to be checked for each model, while we seek (and find) properties of the functional - such as smoothness and bounds on the moments of its gradient - that lead to comparably desirable behavior. Further with (5) it remains unclear whether for large $k \in \mathbb{N}$ the alternating sequence satisfies a Fisher expansion or whether a Wilks type phenomenon occurs. In particular it remains open which ratio of dimension to sample size ensures good performance of the procedure. Also the actual convergence of $\widetilde{\boldsymbol{\theta}}_k \to \widetilde{\boldsymbol{\theta}}$ is not addressed.

These results apply to our problem if the involved regularity criteria are met. But as noted these results do not tell us if the limit of the sequence $(\widetilde{\boldsymbol{\theta}}_k)$ actually is the profile and the statistical properties of limit points are not clear without too restrictive assumptions on $\mathcal{L}$ and the data.

Another new work (Cheng, 2013) contains the analysis of a slightly altered algorithm in a very general semiparametric asymptotic framework. Instead of alternatingly maximizing the functional $\mathcal{L}$ a kind of gradient decent procedure for the profile likelihood $pl(\boldsymbol{\theta}) \stackrel{\text{def}}{=} \max_{\boldsymbol{\eta}} \mathcal{L}(\boldsymbol{\theta}, \boldsymbol{\eta})$ is analyzed, i.e. they define

$$\boldsymbol{\theta}_k \stackrel{\text{def}}{=} \boldsymbol{\theta}_{k-1} + \widehat{\mathrm{D}}(\boldsymbol{\theta}_{k-1})^{-2} \ell(\boldsymbol{\theta}_{k-1}), \tag{6}$$

where $\widehat{\boldsymbol{\eta}}(\cdot)$ is an estimator of $\operatorname{argmax}_{\boldsymbol{\eta}} \mathbb{E}\mathcal{L}(\cdot, \boldsymbol{\eta})$, $\widehat{\mathrm{D}}(\cdot)$ is an estimator of $\nabla^2 \mathbb{E} \max_{\boldsymbol{\eta}} \mathcal{L}(\cdot, \boldsymbol{\eta})$ and $\ell(\cdot)$ is an estimator of $\nabla \max_{\boldsymbol{\eta}} \mathcal{L}(\cdot, \boldsymbol{\eta})$. Under common regularity conditions it is shown, that $\|\boldsymbol{\theta}_k - \widetilde{\boldsymbol{\theta}}\| = o_{\mathbb{P}}(1/\sqrt{n})$ if $k(n) \in \mathbb{N}$ is chosen such that the rate of the initial guess $\boldsymbol{\theta}_0$ - obtained via a stochastic grid search - and the rate of the estimator of the nuisance parameter are addressed. These results resemble very much what is aimed for in this work but it is important to note a series of differences between the results of that work and the present paper. First and most importantly, the treated algorithm in that paper (Cheng, 2013) is similar in virtue to the alternating procedure, but in fact is a different procedure. It is a gradient descend scheme and involves a very careful data driven choice of step sizes when carrying out the estimations necessary in (6) and in that sense differs substantially from the simple and direct alternating maximization. Also the estimating step of the nuisance component is not object of the analysis but assumed to be sufficiently good for the arguments to go through. Finally the results of (Cheng, 2013) are purely asymptotic.

In this work we carry out a finite sample analysis for the alternating maxmimization procedure in (3). Instead of a general semiparametric framework we address sieve profile estimators also called *finite dimensional linear series estimation* (see Chen, 2007; Andresen and Spokoiny, 2014), see Section 1.2 for more details. In this setting the bias of estimation - induced by projection the full model to a finite dimensional sub model - can be treated separately and the model becomes finite dimensional as far as the algorithm is concerned. This allows a very careful and explicit analysis of the behavior of the procedure. In particular the speed of convergence can be linked to characteristics of the information matrix $-\nabla^2 \mathbb{E}\mathcal{L}(\boldsymbol{\upsilon}^*)$ - namely to the constant $\nu < 1$ in (20) - and to the the full dimension of the projected parameter space. The resulting number of iterations necessary for efficient estimation can be given in a rather simple and closed form. Finally our results are nonasymptotic which in this context is crucial as a clear comparison of the computational and the estimation error for finite samples is needed for reasonable inference.

Our main result can be summarized as follows: Under a set of regularity conditions on the data and the functional $\mathcal{L}$ points of the sequence $(\widetilde{\boldsymbol{\theta}}_k)$ behave for large iteration number $k \in \mathbb{N}$ like the pME. To be more precise we show in Theorem 7 that if the initial guess $\widetilde{\boldsymbol{\upsilon}}_0 \in \Upsilon$ is good enough the step estimator sequence $(\widetilde{\boldsymbol{\theta}}_k)$ satisfies with high probability

$$\left\| \check{\mathrm{D}}\big(\widetilde{\boldsymbol{\theta}}_k - \boldsymbol{\theta}^*\big) - \check{\boldsymbol{\xi}} \right\|^2 \leq \epsilon(p^* + \nu^k \mathrm{R}_0), \tag{7}$$

$$\left| \max_{\boldsymbol{\eta}} \mathcal{L}(\widetilde{\boldsymbol{\theta}}_k, \boldsymbol{\eta}) - \max_{\boldsymbol{\eta}} \mathcal{L}(\boldsymbol{\theta}^*, \boldsymbol{\eta}) - \|\check{\boldsymbol{\xi}}\|^2/2 \right| \leq (p + \mathtt{x})^{1/2} \epsilon (p^* + \nu^k \mathrm{R}_0), \tag{8}$$

where $\nu < 1$ is introduced in (20) and $\epsilon > 0$ is some small number, for example $\epsilon = \mathtt{C}/\sqrt{n}$ in the smooth i.i.d setting. Further $\mathrm{R}_0 > 0$ is a bound related to the quality of the initial guess. Generally it is proportional to the full dimension and in this way the rate with which the full nuisance can be estimated affects the speed of the convergence of the procedure. The random variable $\check{\boldsymbol{\xi}} \in \mathbb{R}^p$ and the matrix $\check{\mathrm{D}} \in \mathbb{R}^{p \times p}$ are related to the efficient influence function in semiparametric models and its covariance. These are up to $\nu^k \mathrm{R}_0$ the same properties as those proven for the pME by Andresen and Spokoiny (2014) under nearly the same set of conditions. Up to the finite sample bounds on the right hand sides this means that the estimating points of the procedure admit a Fisher expansion - in other words are asymptotical normal - and a Wilks expansion. Consequently the usual inference procedures based on confidence and concentration sets can be applied to these estimators. Further in our second main result we manage to show under slightly stronger smoothness conditions that $(\widetilde{\boldsymbol{\theta}}_k, \widetilde{\boldsymbol{\eta}}_k)$ approaches the ME $(\widetilde{\boldsymbol{\theta}}, \widetilde{\boldsymbol{\eta}}) = \operatorname{argmax} \mathcal{L}(\boldsymbol{\theta}, \boldsymbol{\eta}^*)$ with nearly linear convergence speed, i.e. $\|\mathcal{D}((\boldsymbol{\theta}_k, \boldsymbol{\eta}_k) - \widetilde{\boldsymbol{\upsilon}})\| \leq \tau^{k/\log(k)}$ with some $0 < \tau < 1$ and $\mathcal{D}^2 = -\mathbb{E}\nabla^2 \mathcal{L}(\boldsymbol{\upsilon}^*)$ (see Theorem 14).

To clarify we want to mention that the term convergence refers to the behavior of the sequence $(\widetilde{\boldsymbol{\theta}}_k, \widetilde{\boldsymbol{\eta}}_k)$ when the number of iterations $k \in \mathbb{N}$ tends to infinity. We show $(\widetilde{\boldsymbol{\theta}}_k, \widetilde{\boldsymbol{\eta}}_k) \to (\widetilde{\boldsymbol{\theta}}, \widetilde{\boldsymbol{\eta}})$. This has to be distinguished from the usual stochastic convergence results of the M-estimator $(\widetilde{\boldsymbol{\theta}}, \widetilde{\boldsymbol{\eta}})$ towards the target $(\boldsymbol{\theta}^*, \boldsymbol{\eta}^*)$ or the weak convergence to a normal distribution as the sample size increases. Our setup is assuming finite sample size such that even with $k \to \infty$ there remains a gap between $(\widetilde{\boldsymbol{\theta}}_k, \widetilde{\boldsymbol{\eta}}_k)$ and $(\boldsymbol{\theta}^*, \boldsymbol{\eta}^*)$ and between $\widetilde{\boldsymbol{\theta}}_k$ and $\boldsymbol{\theta}^*$ that is related to the parametric and semiparametric Cramer-Rao lower bounds respectively. This is why we can in the finite sample setting only hope to obtain convergence of the alternating procedure to $(\widetilde{\boldsymbol{\theta}}, \widetilde{\boldsymbol{\eta}})$ but not to $(\boldsymbol{\theta}^*, \boldsymbol{\eta}^*)$. But for a growing sample size (7) implies the weak convergence results also for the estimator $\widetilde{\boldsymbol{\theta}}_k$ when $k(n) \in \mathbb{N}$ is large enough and ϵp^* vanishes (see Section 1.3).

In the following we write $\widetilde{\boldsymbol{\upsilon}}_{k,k(+1)}$ in statements that are true for both $\widetilde{\boldsymbol{\upsilon}}_{k,k+1}$ and $\widetilde{\boldsymbol{\upsilon}}_{k,k}$. Also we do not specify whether the elements of the resulting sequence are sets or single points. All statements made about properties of $\widetilde{\boldsymbol{\upsilon}}_{k,k(+1)}$ are to be understood in the sense that they hold for "every point of $\widetilde{\boldsymbol{\upsilon}}_{k,k(+1)}$".

1.1 Relation to the EM Algorithm

In the introduction we claimed that the alternating procedure analyzed in this work is related to the EM algorithm. In this section we want to elaborate on that.

First we explain the EM algortihm. Consider data $(\mathbb{X}) \sim \mathbb{P}_{\boldsymbol{\theta}}$ for some parametric family $(\mathbb{P}_{\boldsymbol{\theta}}, \boldsymbol{\theta} \in \Theta)$. Assume that a parameter $\boldsymbol{\theta} \in \Theta$ is to be estimated as maximizer of the functional $\mathcal{L}_c(\boldsymbol{\theta}, \mathbb{X}) \in \mathbb{R}$, but that only $\mathbb{Y} \in \mathcal{Y}$ is observed, where $\mathbb{Y} = f_Y(\mathbb{X})$ is the image of the complete data set $\mathbb{X} \in \mathcal{X}$ under some map $f_Y : \mathcal{X} \to \mathcal{Y}$. Prominent examples for the map f_Y are projections onto subspaces of $\mathcal{X}$ if both $\mathcal{Y}, \mathcal{X}$ are vector spaces. The information lost under the map can be regarded as missing data or latent variables. As a direct maximization of the functional is impossible without knowledge of $\mathbb{X}$ the EM algorithm serves as a workaround. It consists of the iteration of two steps: starting with some initial guess $\widetilde{\boldsymbol{\theta}}_0$ the kth "Expectation step" derives the functional Q via

$$Q(\boldsymbol{\theta}, \boldsymbol{\theta}_k) = \mathbb{E}_{\boldsymbol{\theta}_k}[\mathcal{L}_c(\boldsymbol{\theta}, \mathbb{X})|\mathbb{Y}],$$

which means that on the right hand side the conditional expectation is calculated under the distribution $\mathbb{P}_{\boldsymbol{\theta}_k}$. The kth "Maximation step" then simply locates the maximizer $\boldsymbol{\theta}_{k+1}$ of Q.

Now we can present the convergence result of Wu (1983) in more detail. Wu presents regularity conditions that ensure that $\mathcal{L}(\boldsymbol{\theta}_{k+1}|\mathbb{Y}) \geq \mathcal{L}(\boldsymbol{\theta}_k|\mathbb{Y})$ where

$$\mathcal{L}(\boldsymbol{\theta}|\mathbb{Y}) \stackrel{\text{def}}{=} \mathbb{E}\left[\mathcal{L}_c(\boldsymbol{\theta}, \mathbb{X})|\mathbb{Y} = f_Y(\mathbb{X})\right],$$

such that $\mathcal{L}(\boldsymbol{\theta}_k|\mathbb{Y}) \to \mathcal{L}^*$ for some limit value $\mathcal{L}^*(\mathbb{Y}) > 0$, that may depend on the starting point $\boldsymbol{\theta}_0$. Additionally Wu gives conditions that guarantee that the sequence $\boldsymbol{\theta}_k$ (possibly a sequence of sets) converges to $C(\mathcal{L}^*) \stackrel{\text{def}}{=} \{\boldsymbol{\theta}|\, \mathcal{L}(\boldsymbol{\theta}|\mathbb{Y}) = \mathcal{L}^*(\mathbb{Y})\}$. Dempster, Laird, and Rubin (1977) show that the speed of convergence is linear in the case of point valued $\boldsymbol{\theta}_k$ and of some differentiability criterion being met. A limitation of these results is that it is not clear whether $\mathcal{L}^*(\mathbb{Y}) = \sup \mathcal{L}(\boldsymbol{\theta}|\mathbb{Y})$ and thus it is not guaranteed that $C(\mathcal{L}^*)$ is the desired MLE and not just some local maximum. Of course this problem disappears if $\mathcal{L}(\cdot|\mathbb{Y})$ is unimodal and the regularity conditions are met but this assumption may be too restrictive.

To see that the procedure (3) is a special case of the EM algorithm we have to find the right triplet $(\mathbb{X}, f_Y, \mathcal{L}_c)$. For this we take $\mathbb{X} = (\boldsymbol{Z}, \mathbb{Y})$ with $\boldsymbol{Z} \sim \operatorname{argmax}_{\boldsymbol{\eta}} \mathcal{L}\{(\boldsymbol{\theta}, \boldsymbol{\eta}), \mathbb{Y}\}$ under $\mathbb{P}_{\boldsymbol{\theta}}$. Further we set $f_Y(\mathbb{X}) = \mathbb{Y}$ and $\mathcal{L}_c(\boldsymbol{\theta}, \boldsymbol{X}) \stackrel{\text{def}}{=} \mathcal{L}(\boldsymbol{\theta}, \boldsymbol{\eta}, \mathbb{Y})$, where $\boldsymbol{X} = (\boldsymbol{\eta}, \mathbb{Y})$. Then we find

$$\begin{aligned}
Q(\boldsymbol{\theta}, \widetilde{\boldsymbol{\theta}}^{(k-1)}) &= \mathbb{E}_{\widetilde{\boldsymbol{\theta}}^{(k-1)}}[\mathcal{L}_c(\boldsymbol{\theta}, \mathbb{X})|\mathbb{Y}] \\
&= \mathbb{E}_{\widetilde{\boldsymbol{\theta}}^{(k-1)}}\Big[\mathcal{L}_c\Big(\boldsymbol{\theta}, \operatorname*{argmax}_{\boldsymbol{\eta}} \mathcal{L}\{(\boldsymbol{\theta}^{(k-1)}, \boldsymbol{\eta}), \mathbb{Y}\}, \mathbb{Y}\Big)\Big|\mathbb{Y}\Big] \\
&= \mathcal{L}_c\Big(\boldsymbol{\theta}, \operatorname*{argmax}_{\boldsymbol{\eta}} \mathcal{L}\{(\widetilde{\boldsymbol{\theta}}^{(k-1)}, \boldsymbol{\eta}), \mathbb{Y}\}, \mathbb{Y}\Big) \\
&= \mathcal{L}(\boldsymbol{\theta}, \widetilde{\boldsymbol{\eta}}^{(k)}, \mathbb{Y}),
\end{aligned}$$

and thus the resulting sequence is the same as in (3).

1.2 Linear Series Estimators

In semiparametric models the profile M estimator $\widetilde{\boldsymbol{\theta}} \in \mathbb{R}^p$ from Equation (2) cannot be calculated in practice if the full model is infinite dimensional. There are various ways to circumvent this problem. Next to non parametric estimation and plugin of the nuisance $\boldsymbol{\eta} \in \mathcal{X}$ a prominent approach is the so called sieve technique that motivates the setting in this work.

The sieve approach was systematically introduced by Grenander (see Grenander, 1981, Chapter 8) and consists in choosing a suitable sequence of subsets $(\Upsilon_m)_{m=1}^{\infty} \subset \Upsilon$ such that for each $\boldsymbol{\upsilon} \in \Upsilon$ there exists a sequence $\Pi_m(\boldsymbol{\upsilon}) \subset \Upsilon_m$ with $\|\boldsymbol{\upsilon} - \Pi_m(\boldsymbol{\upsilon})\| \to 0$. Furthermore the sets $\Upsilon_m \subset \Upsilon$ have to be such that $\sup_{\boldsymbol{\upsilon} \in \Upsilon_m} \mathcal{L}(\boldsymbol{\upsilon})$ can be calculated in practice. In the setting of semiparametric M-Estimation we assume $\Upsilon = \Upsilon_{\boldsymbol{\theta}} \times \Upsilon_{\boldsymbol{\eta}} \subseteq \mathbb{R}^p \times \mathcal{X}$ with some infinite dimensional separable Hilbert space $\mathcal{X}$ and countable basis $\{\boldsymbol{e}_1, \boldsymbol{e}_2, \ldots\} \subset \mathcal{X}$. We set $\Upsilon_m = \Upsilon_{\boldsymbol{\theta}} \times \Pi_m \Upsilon_{\boldsymbol{\eta}}$, where $\Pi_m : \mathcal{X} \to \mathcal{X}_m$ denotes the orthogonal projection onto $\mathcal{X}_m \stackrel{\text{def}}{=} \operatorname{span}(\boldsymbol{e}_1, \ldots, \boldsymbol{e}_m\}$. For each $m \in \mathbb{N}$ the sieve profile M-estimator is defined as

$$\widetilde{\boldsymbol{\theta}}_m \stackrel{\text{def}}{=} \Pi_{\boldsymbol{\theta}} \widetilde{\boldsymbol{\upsilon}}_m \stackrel{\text{def}}{=} \Pi_{\boldsymbol{\theta}} \operatorname*{argmax}_{\substack{\boldsymbol{\theta} \in \mathbb{R}^p \\ \boldsymbol{\eta} \in \mathbb{R}^m}} \mathcal{L}\left(\boldsymbol{\theta}, \sum_{k=1}^{m} \eta_k \boldsymbol{e}_k\right).$$

This means that for the calculation of the estimator $\widetilde{\boldsymbol{\theta}}_m$ only a finite dimensional setting has to be considered. In our analysis we will focus on the behavior of the alternating maximization procedure in that case.

But of course the projection onto a finite dimensional submodel induces an approximation bias " $\boldsymbol{\upsilon}^* - \boldsymbol{\upsilon}_m^*$ " where

$$(\boldsymbol{\theta}_m^*, \boldsymbol{\eta}_m^*) \stackrel{\text{def}}{=} \boldsymbol{\upsilon}_m^* \stackrel{\text{def}}{=} \operatorname*{argmax}_{\substack{\boldsymbol{\theta} \in \mathbb{R}^p \\ \boldsymbol{\eta} \in \mathbb{R}^m}} \mathbb{E}\mathcal{L}\left(\boldsymbol{\theta}, \sum_{k=1}^{m} \eta_k \boldsymbol{e}_k\right).$$

In (Andresen and Spokoiny, 2014) it is explained in detail how this bias can be treated. Once the bias is controlled this leads for each $m \in \mathbb{N}$ to bounds of the kind

$$\begin{aligned}
\left\|\breve{\mathrm{D}}(\widetilde{\boldsymbol{\theta}}_m - \boldsymbol{\theta}^*) - \breve{\boldsymbol{\xi}}_m\right\| &\leq \breve{\Diamond}(\mathtt{x}) + \alpha(m), \\
\left|\max_{\boldsymbol{\eta} \in \Pi_m \Upsilon_{\boldsymbol{\eta}}} \mathcal{L}(\widetilde{\boldsymbol{\theta}}_m, \boldsymbol{\eta}) - \max_{\boldsymbol{\eta} \in \Pi_m \Upsilon_{\boldsymbol{\eta}}} \mathcal{L}(\boldsymbol{\theta}^*, \boldsymbol{\eta}) - \|\breve{\boldsymbol{\xi}}_m\|^2\right| &\leq p\breve{\Diamond}(\mathtt{x}) + \alpha(m),
\end{aligned}$$

where $\alpha(m) \geq 0$ quantifies the impact of the bias " $\boldsymbol{\upsilon}^* - \boldsymbol{\upsilon}_m^*$ ". The choice of $m \in \mathbb{N}$ then has to balance the two terms $\breve{\Diamond}(\mathtt{x})$ and $\alpha(m)$, which leads to common optimal choices for the dimension based on the "smoothness" of the nuisance component $\boldsymbol{\eta}^* \in \mathcal{X}$. To ease notation we drop the $\cdot_m$ in the following, as the treatment of the bias can be done separately, (see Andresen and Spokoiny, 2014).

1.3 Finite sample Wilks and Fisher Theorems

Before we present our main results we want to explain what type of results we aim at and how they can be interpreted. Hopefully this will ease the understanding and will make some of the apparently cumbersome notation more intelligible.

Usually in asymptotic treatments of semiparametric M-estimators like $\widetilde{\boldsymbol{\theta}}$ in (2) the aim is to derive statements of the kind

$$\sqrt{n}(\widetilde{\boldsymbol{\theta}} - \boldsymbol{\theta}^*) - \breve{d}^{-1}\breve{\boldsymbol{\xi}} = o_{\mathbb{P}}(1), \tag{9}$$

$$\max_{\boldsymbol{\eta}} \mathcal{L}(\widetilde{\boldsymbol{\theta}}, \boldsymbol{\eta}) - \max_{\boldsymbol{\eta}} \mathcal{L}(\boldsymbol{\theta}^*, \boldsymbol{\eta}) - \|\breve{\boldsymbol{\xi}}\|^2/2 = o_{\mathbb{P}}(1), \tag{10}$$

$$\breve{\boldsymbol{\xi}} \xrightarrow{w} \mathcal{N}(0, \breve{d}^{-1}\breve{v}^2\breve{d}^{-1}),$$

where $n \in \mathbb{N}$ denotes the sample size. The random variable $\breve{\boldsymbol{\xi}} \in \mathbb{R}^p$ is called semiparametric score. Below we will briefly explain its derivation along with the explanation of the matrices $\breve{v}^2, \breve{d}^2 \in \mathbb{R}^{p\times p}$. But before, we sketch how (9) and (10) can be used for the construction of asymptotic confidence sets that yield statistical tests. Given the matrices $\breve{v}^2, \breve{d}^2$ the construction works as follows. Let $q_\alpha^2 > 0$ be an $\alpha-$ level quantile of a $\chi^2_p(\breve{d}^{-2}\breve{v}^2\breve{d}^{-2})$-distribution. Set

$$\mathcal{E}(q_\alpha) = \left\{\boldsymbol{\theta} : \sqrt{n}\|(\widetilde{\boldsymbol{\theta}} - \boldsymbol{\theta})\| \le q_\alpha\right\}; \tag{11}$$

then one can use (9) to show

$$\mathbb{P}\left\{\boldsymbol{\theta}^* \notin \mathcal{E}\left(q_\alpha\right)\right\} = \mathbb{P}\left\{\sqrt{n}\|(\widetilde{\boldsymbol{\theta}} - \boldsymbol{\theta}^*)\| \ge q_\alpha\right\} \to 1 - \alpha.$$

Similarly one can exploit (10).

Now we explain the definition of $\breve{v}^2$ and $\breve{d}^2$. Introduce

$$n\breve{v}^{-2}(\boldsymbol{\upsilon}) \stackrel{\text{def}}{=} \Pi_{\boldsymbol{\theta}} \operatorname{Cov}(\nabla\mathcal{L}(\boldsymbol{\upsilon}))^{-1}\Pi_{\boldsymbol{\theta}}^\top,$$
$$n\breve{d}^{-2}(\boldsymbol{\upsilon}) \stackrel{\text{def}}{=} -\Pi_{\boldsymbol{\theta}} \left(\nabla^2\mathbb{E}\mathcal{L}(\boldsymbol{\upsilon})\right)^{-1}\Pi_{\boldsymbol{\theta}}^\top,$$

where $\Pi_{\boldsymbol{\theta}}$ is the orthogonal projection onto the $\boldsymbol{\theta}$-commponent in $\mathbb{R}^p$ and $\Pi_{\boldsymbol{\theta}}^\top$ is its dual operator. Then $\breve{v}^2 = \breve{v}^2(\boldsymbol{\upsilon}^*)$ and $\breve{d}^2 = \breve{d}^2(\boldsymbol{\upsilon}^*)$.

Remark 1 *Note that these two matrices coincide if the functional $\mathcal{L}$ was the complete loglikelihood of the observations and that then $\breve{d}^2$ would equal the covariance of the efficient influence function (see Kosorok, 2005, for more details).*

For the definition of the semiparametric score $\breve{\boldsymbol{\xi}} \in \mathbb{R}^p$ consider

$$nd^2(\boldsymbol{\upsilon}) = \begin{pmatrix} d^2(\boldsymbol{\upsilon}) & a(\boldsymbol{\upsilon}) \\ a^\top(\boldsymbol{\upsilon}) & h^2(\boldsymbol{\upsilon}) \end{pmatrix} \stackrel{\text{def}}{=} -\nabla^2\mathbb{E}\mathcal{L}(\boldsymbol{\upsilon}) \in \mathbb{R}^{p^*\times p^*}.$$

Then

$$\begin{aligned}\breve{\boldsymbol{\xi}} &\stackrel{\text{def}}{=} \frac{1}{\sqrt{n}}\breve{d}(\boldsymbol{\upsilon}^*)(1 - \mathbb{E}_\epsilon)\Pi_{\boldsymbol{\theta}} d^{-2}(\boldsymbol{\upsilon}^*)\nabla\mathcal{L}(\boldsymbol{\upsilon}^*) \\ &= \frac{1}{\sqrt{n}}(1 - \mathbb{E}_\epsilon)\breve{d}^{-1}(\boldsymbol{\upsilon}^*)\left\{\nabla_{\boldsymbol{\theta}}\mathcal{L}(\boldsymbol{\upsilon}^*) - ah^{-2}(\boldsymbol{\upsilon}^*)\nabla_{\boldsymbol{\eta}}\mathcal{L}(\boldsymbol{\upsilon}^*)\right\},\end{aligned}$$

This random variable is related to the efficient influence function in semiparametric estimation and it plays the role that the usual score $\nabla\mathcal{L}(\boldsymbol{\upsilon}^*)$ plays in the setting of parametric M-estimation.

In this work we derive (9) and (10) for $\widetilde{\boldsymbol{\theta}}_k$ instead of $\widetilde{\boldsymbol{\theta}}$ but with finite sample bounds for the terms on the right-hand sides of (9) and (10). To be more precise we derive statements of the following kind. With probability greater than $1 - \mathtt{C}\mathrm{e}^{-\mathtt{x}}$

$$\left\|\sqrt{n}(\widetilde{\boldsymbol{\theta}}_k - \boldsymbol{\theta}^*) - \breve{d}^{-1}\breve{\boldsymbol{\xi}}\right\| \le \epsilon(p^* + \nu^k\mathrm{R}_0), \tag{12}$$

$$\left|\max_{\boldsymbol{\eta}} \mathcal{L}(\widetilde{\boldsymbol{\theta}}_k, \boldsymbol{\eta}) - \max_{\boldsymbol{\eta}} \mathcal{L}(\boldsymbol{\theta}^*, \boldsymbol{\eta}) - \|\breve{\boldsymbol{\xi}}\|^2/2\right| = (p + \mathtt{x})^{1/2}\epsilon(p^* + \nu^k\mathrm{R}_0), \tag{13}$$

with some small value $\epsilon > 0$ as in (7) and (8). Note that for vanishing right hand sides these equations imply (9) and (10) when n tends to infty. Using the scheme in (11) the bounds (12) and (13) allow the construction of (conservative) finite sample "confidence sets". Assume that (approximate) quantiles q_α for $\|\breve{\boldsymbol{\xi}}\|$ are available, i.e. that with some small $\epsilon > 0$ and any $\alpha \in [0, 1]$

$$\mathbb{P}(\|\breve{\boldsymbol{\xi}}\| \le q_\alpha) \in (\alpha - \delta, \alpha + \delta),$$

then with some generic constant $\mathtt{C} > 0$ (see Andresen and Spokoiny, 2014, Remark 2.13)

$$\alpha + \delta + \mathtt{C}\mathrm{e}^{-\mathtt{x}} \le \mathbb{P}\left\{\boldsymbol{\theta}^* \in \mathcal{E}(q_\alpha + \epsilon(p^* + \nu^k\mathrm{R}_0)\right\},$$
$$\mathbb{P}\left\{\boldsymbol{\theta}^* \in \mathcal{E}(q_\alpha - \epsilon(p^* + \nu^k\mathrm{R}_0)\right\} \le \alpha - \delta - \mathtt{C}\mathrm{e}^{-\mathtt{x}}.$$

The important achievement is that one can make approximate confidence statements for the estimators of the alternating procedure and this even in the finite sample case, without ignoring "hopefully small enough" terms. As remarked above such approximate quantiles could be attained via an plug-in-estimation of $\breve{d}^{-2}\breve{v}^2\breve{d}^{-2}$ combined with a Gaussian approximation or a bootstrap.

2. Main Results

This Section contains the thorough presentation of our main convergence results. It involves the introduction of various technicalities and may appear a bit cumbersome on first read. We recommend to carefully read Section 1.3 first to ease understanding.

2.1 Conditions

This section collects the conditions imposed on the model. We use the same set of assumptions as Andresen and Spokoiny (2014) and this section closely follows Section 2.1 of that paper.

Let the full dimension of the paramter space be finite, i.e. $p^* < \infty$. Our conditions involve the symmetric positive definite *information matrix* $\mathcal{D}_0^2 \in \mathbb{R}^{p^* \times p^*}$ and a central point $\boldsymbol{\upsilon}^* \in \mathbb{R}^{p^*}$. To ease presentation in this paper we identify $\boldsymbol{\upsilon}^*$ with the "true point" from (1) and define

$$\mathcal{D}_0^2 \stackrel{\text{def}}{=} -\nabla^2 \mathbb{E}\mathcal{L}(\boldsymbol{\upsilon}^*),$$

where we assume, that the second derivative exists. In the context of semiparametric estimation, it is convenient to represent the *information matrix* in block form:

$$\mathcal{D}_0^2 = \begin{pmatrix} \mathrm{D}_0^2 & \mathrm{A}_0 \\ \mathrm{A}_0^\top & \mathrm{H}_0^2 \end{pmatrix}.$$

First we state an *identifiability condition*, which basically imposes that $\mathcal{D}^2$ is positive definite. Note that in this work $\|\cdot\|$ allways denotes the spectral norm when its argument is a matrix.

$(\boldsymbol{\mathcal{I}})$ It holds for some $\nu < 1$

$$\|\mathrm{H}_0^{-1}\mathrm{A}_0^\top \mathrm{D}_0^{-1}\| \leq \sqrt{\nu}. \tag{14}$$

The condition $(\mathcal{I})$ allows to introduce the important $p \times p$ efficient information matrix $\breve{\mathrm{D}}_0^2$ which is defined as the inverse of the $\boldsymbol{\theta}$-block of the inverse of the full dimensional matrix $\mathcal{D}_0^2$. The exact formula is given by

$$\breve{\mathrm{D}}_0^2 \stackrel{\text{def}}{=} \mathrm{D}_0^2 - \mathrm{A}_0 \mathrm{H}^{-2} \mathrm{A}_0^\top,$$

and $(\mathcal{I})$ ensures that the matrix $\breve{\mathrm{D}}_0^2$ is positive definite such that $\breve{\mathrm{D}}$ is well defined. At the same time $\nu < 1$ ensures that the alternating sequence actually converges. As can be seen in Theorem 7 the speed of convergence is linear in ν.

Using the matrix $\mathcal{D}_0^2$ and the central point $\boldsymbol{\upsilon}^* \in \mathbb{R}^{p^*}$, we define the local set $\Upsilon_\circ(\mathtt{r}) \subset \Upsilon \subseteq \mathbb{R}^{p^*}$ with some $\mathtt{r} \geq 0$:

$$\Upsilon_\circ(\mathtt{r}) \stackrel{\text{def}}{=} \bigl\{\boldsymbol{\upsilon} = (\boldsymbol{\theta}, \boldsymbol{\eta}) \in \Upsilon \colon \|\mathcal{D}_0(\boldsymbol{\upsilon} - \boldsymbol{\upsilon}^*)\| \leq \mathtt{r}\bigr\}. \tag{15}$$

2.1.1 Smoothness

Usually in the context of regular M-estimation one assumes local quadraticity, i.e. that

$$pl(\boldsymbol{\theta}) = \nabla pl(\boldsymbol{\theta}^*)(\boldsymbol{\theta} - \boldsymbol{\theta}^*) + \frac{1}{2}(\boldsymbol{\theta}^* - \boldsymbol{\theta}^*)^\perp \nabla^2 pl(\boldsymbol{\theta}^*)(\boldsymbol{\theta}^* - \boldsymbol{\theta}^*) + o_{\mathbb{P}}(1),$$

for $\boldsymbol{\theta} \in \mathbb{R}^p$ close enough to $\boldsymbol{\theta}^*$. The functional $pl(\cdot)$ in this context denotes the profile-functional and is defined as

$$pl(\boldsymbol{\theta}) \stackrel{\text{def}}{=} \max_{\boldsymbol{\eta}} \mathcal{L}(\boldsymbol{\theta}, \boldsymbol{\eta}),$$

see for instance (Cheng, 2013).

In our setting we need a precise bound for the accuracy of a quadratic approximation of the expected profile functional $\mathbb{E}pl$. We want to bound the error of a local linear approximation of the projected gradient $\breve{\nabla}_{\boldsymbol{\theta}} \mathbb{E}\mathcal{L}(\boldsymbol{\upsilon})$ which is defined as

$$\breve{\nabla}_{\boldsymbol{\theta}} = \nabla_{\boldsymbol{\theta}} - \mathrm{A}_0 \mathrm{H}_0^{-2} \nabla_{\boldsymbol{\eta}}.$$

Instead of local quadraticity of the profile functional we impose that for $(\boldsymbol{\theta}, \boldsymbol{\eta}) = \boldsymbol{\upsilon} \in \Upsilon_\circ(\mathtt{r})$ - with the local set $\Upsilon_\circ(\mathtt{r})$ defined in (15) - with some small $\breve{\epsilon} > 0$

$$\Bigl\| \breve{\mathrm{D}}^{-1} \Bigl(\breve{\nabla} \mathbb{E}\mathcal{L}(\boldsymbol{\upsilon}) - \breve{\nabla} \mathbb{E}\mathcal{L}(\boldsymbol{\upsilon}^*) \Bigr) - \breve{\mathrm{D}}(\boldsymbol{\theta} - \boldsymbol{\theta}^*) \Bigr\| \leq \breve{\epsilon} \mathtt{r}^2.$$

The following condition serves a less high level way of checking that such an approximation holds (see Andresen and Spokoiny, 2014, Lemma B.1)

$(\boldsymbol{\breve{\mathcal{L}}_0})$ For each $\mathtt{r} \leq \mathtt{r}_0$, there is a constant $\breve{\epsilon} > 0$ such that it holds on the set $\Upsilon_\circ(\mathtt{r})$:

$$\|\mathrm{D}^{-1}\mathrm{D}^2(\boldsymbol{\upsilon})\mathrm{D}^{-1} - I_p\| \leq \breve{\epsilon}\mathtt{r}, \quad \|\mathrm{D}^{-1}(\mathrm{A}(\boldsymbol{\upsilon}) - \mathrm{A})\mathrm{H}^{-1}\| \leq \breve{\epsilon}\mathtt{r},$$
$$\bigl\|\mathrm{D}^{-1}\mathrm{A}\mathrm{H}^{-1}\bigl(I_m - \mathrm{H}^{-1}\mathrm{H}^2(\boldsymbol{\upsilon})\mathrm{H}^{-1}\bigr)\bigr\| \leq \breve{\epsilon}\mathtt{r}.$$

If $\mathbb{E}\mathcal{L}$ is three times continuously differentiable one obtains $\breve{\epsilon} \leq \mathtt{C}\|\mathcal{D}^{-1}\|$. In i.i.d. models one usually has $\|\mathcal{D}^{-1}\| = O(1/\sqrt{n})$.

Remark 2 *Here and in what follows we implicitly assume that the function $\mathcal{L}(\boldsymbol{\upsilon}) \colon \mathbb{R}^{p^*} \to \mathbb{R}$ is sufficiently smooth in $\boldsymbol{\upsilon} \in \mathbb{R}^{p^*}$, $\nabla\mathcal{L}(\boldsymbol{\upsilon}) \in \mathbb{R}^{p^*}$ stands for the gradient and $\nabla^2\mathbb{E}\mathcal{L}(\boldsymbol{\upsilon}) \in \mathbb{R}^{p^* \times p^*}$ for the Hessian of the expectation $\mathbb{E}\mathcal{L} : \mathbb{R}^{p^*} \to \mathbb{R}$ at $\boldsymbol{\upsilon} \in \mathbb{R}^{p^*}$. By smooth enough we mean that we can interchange $\nabla\mathbb{E}\mathcal{L} = \mathbb{E}\nabla\mathcal{L}$ on $\Upsilon_\circ(R_0)$, where $\Upsilon_\circ(\mathtt{r})$ is defined in (15) and $R_0 > 0$ in (19). It is worth mentioning that $\mathcal{D}_0^2 = \mathcal{V}_0^2 \stackrel{\text{def}}{=} \mathrm{Cov}(\nabla\mathcal{L}(\boldsymbol{\upsilon}^*))$ if the model $\boldsymbol{Y} \sim \mathbb{P}_{\boldsymbol{\upsilon}^*} \in (\mathbb{P}_{\boldsymbol{\upsilon}})$ is correctly specified and sufficiently regular; see e.g. (Ibragimov and Khas'minskij, 1981).*

2.1.2 Complexity

The usual approach to gain asymptotic control on profile M-estimators would be to assume that the class

$$\{\breve{\nabla}\mathcal{L}(\boldsymbol{\upsilon}), \boldsymbol{\upsilon} \in \Upsilon_\circ(\mathtt{r})\},$$

is $\mathbb{P}$-Donsker (see Cheng, 2013).

To pin down the estimator sequence $(\widetilde{\boldsymbol{\theta}}_k, \widetilde{\boldsymbol{\eta}}_k)_{k \in \mathbb{N}}$ and to obtain finite sample results we use a more specific approach, which is based on a new finite sample approach (Spokoiny,

2012; Andresen and Spokoiny, 2014). First note that we assume that - as far as the alternating procedure is concerned - the model is finite dimensional, which means that $\Upsilon_\circ(\mathtt{r}) \subset \Upsilon \subset \mathbb{R}^{p^*}$ in (15) is automatically compact for finite radius $\mathtt{r} > 0$. If we can ensure the right smoothness and moment conditions on $\check{\nabla}\mathcal{L}(\boldsymbol{\upsilon})$, we automatically obtain that the above class is $\mathbb{P}$-Donsker. But using the new techniques (Spokoiny, 2012; Andresen and Spokoiny, 2014) we manage to obtain slightly stronger bounds that are useful in a finite sample setting.

To understand the next condition consider first the definition of a subgaussian random vector. A random vector $\boldsymbol{X} \in \mathbb{R}^p$ is called subgaussian, if for any $\mu \in \mathbb{R}$ and some $\boldsymbol{\nu} > 0$

$$\sup_{\|\gamma\|\le 1} \log \mathbb{E} \exp\Big\{\mu \gamma^\top \boldsymbol{X}\Big\} \le \boldsymbol{\nu}^2 \mu^2/2. \tag{16}$$

Obviously this is a strong condition. As it turns out in many situations it is sufficient to assume subexponentiality, which simply relaxes subgaussianity to demanding that (16) is met for any $|\mu| \le \mathtt{g}$ with some $\mathtt{g} > 0$. In this way many distributions that would be excluded by assuming subgaussianity can still be treated.

Our next condition combines subexponentiality with a smoothness constraint on the stochastic component of $\check{\nabla}\mathcal{L}(\boldsymbol{\upsilon})$. It assumes that - with some $\check{\epsilon} > 0$ - the random vector

$$\frac{1}{\check{\epsilon}\|\mathcal{D}(\boldsymbol{\upsilon} - \boldsymbol{\upsilon}')\|} \check{\mathrm{D}}^{-1}\big\{\check{\nabla}_{\boldsymbol{\theta}}\boldsymbol{\zeta}(\boldsymbol{\upsilon}) - \check{\nabla}_{\boldsymbol{\theta}}\boldsymbol{\zeta}(\boldsymbol{\upsilon}')\big\} \in \mathbb{R}^p,$$

is uniformly subexponential for $\boldsymbol{\upsilon}, \boldsymbol{\upsilon}' \in \Upsilon_\circ(\mathtt{r})$, with the stochastic component defined as $\zeta(\boldsymbol{\upsilon}) \stackrel{\text{def}}{=} \mathcal{L}(\boldsymbol{\upsilon}) - \mathbb{E}\mathcal{L}(\boldsymbol{\upsilon})$. It reads:

$(\check{\mathcal{E}}\mathcal{D}_1)$ For all $0 < \mathtt{r} < \mathtt{r}_0$, there exists a constant $\check{\epsilon} \le 1/2$ such that for all $|\mu| \le \check{\mathtt{g}}$ and $\boldsymbol{\upsilon}, \boldsymbol{\upsilon}' \in \Upsilon_\circ(\mathtt{r})$

$$\sup_{\boldsymbol{\upsilon},\boldsymbol{\upsilon}' \in \Upsilon_\circ(\mathtt{r})} \sup_{\|\gamma\|\le 1} \log \mathbb{E} \exp\left\{\mu \frac{\gamma^\top \check{\mathrm{D}}^{-1}\big\{\check{\nabla}_{\boldsymbol{\theta}}\boldsymbol{\zeta}(\boldsymbol{\upsilon}) - \check{\nabla}_{\boldsymbol{\theta}}\boldsymbol{\zeta}(\boldsymbol{\upsilon}')\big\}}{\check{\epsilon}\|\mathcal{D}(\boldsymbol{\upsilon} - \boldsymbol{\upsilon}')\|}\right\} \le \frac{\check{\nu}_1^2 \mu^2}{2}.$$

To convey more intuition consider for some pair $\boldsymbol{\upsilon}, \boldsymbol{\upsilon}' \in \Upsilon_\circ(\mathtt{r})$ the function

$$\psi_\gamma(t) \stackrel{\text{def}}{=} \gamma^\top \check{\mathrm{D}}^{-1}\big\{\check{\nabla}_{\boldsymbol{\theta}}\boldsymbol{\zeta}(\boldsymbol{\upsilon}) - \check{\nabla}_{\boldsymbol{\theta}}\boldsymbol{\zeta}(\boldsymbol{\upsilon} + t(\boldsymbol{\upsilon}' - \boldsymbol{\upsilon}))\big\}.$$

Then $(\check{\mathcal{E}}\mathcal{D}_1)$ is met with $\check{\epsilon} \le \|\mathcal{D}^{-1}\|$, if - uniformly in γ - for any pair $\boldsymbol{\upsilon}, \boldsymbol{\upsilon}' \in \Upsilon_\circ(\mathtt{r})$ the corresponding function $\psi_\gamma : [0,1] \to \mathbb{R}$ is Lipshitz continuous and the Lipshitz constant a subexponential random variable.

2.1.3 Moments

We need another condition that allows to control the deviation behavior of $\|\check{\mathrm{D}}^{-1}\check{\nabla}\boldsymbol{\zeta}(\boldsymbol{\upsilon}^*)\|$. To present this condition define the covariance matrix $\mathcal{V}_0^2 \in \mathbb{R}^{p^* \times p^*}$ and $\check{V}^2 \in \mathbb{R}^{p \times p}$

$$\mathcal{V}_0^2 \stackrel{\text{def}}{=} \mathrm{Cov}\big\{\nabla\mathcal{L}(\boldsymbol{\upsilon}^*)\big\}, \quad \check{V}^2 = \mathrm{Cov}(\check{\nabla}_{\boldsymbol{\theta}}\zeta(\boldsymbol{\upsilon}^*)).$$

We impose subexponential moments on $\check{V}^{-1}\check{\nabla}_{\boldsymbol{\theta}}\zeta(\boldsymbol{\upsilon}^*)$:

$(\check{\mathcal{E}}\mathcal{D})$ There exist constants $\nu_0 > 0$ and $\check{\mathtt{g}} > 0$ such that for all $|\mu| \le \check{\mathtt{g}}$

$$\sup_{\|\gamma\|\le 1} \log \mathbb{E} \exp\Big\{\mu \gamma^\top \check{V}^{-1}\check{\nabla}_{\boldsymbol{\theta}}\zeta(\boldsymbol{\upsilon}^*)\Big\} \le \frac{\check{\nu}_0^2 \mu^2}{2}.$$

2.1.4 Conditions for the Full Model

So far we only presented conditions that allow to treat the properties of $\widetilde{\boldsymbol{\theta}}_k$ on local sets $\Upsilon_\circ(\mathtt{r}_k)$, for some sequence $(\mathtt{r}_k)_{k\in\mathbb{N}}$. To show that that the sequence of estimators $(\boldsymbol{\upsilon}_k)_{k\in\mathbb{N}}$ satisfies $\boldsymbol{\upsilon}_k \in \Upsilon_\circ(\mathtt{r}_k)$ for an appropriately decreasing sequence $(\mathtt{r}_k)_{k\in\mathbb{N}}$ the following, stronger conditions are employed, which can be interpreted just as the previous ones.

$(\boldsymbol{\mathcal{L}_0})$ For each $\mathtt{r} \le \mathtt{r}_0$, there is a constant $\epsilon > 0$ such that it holds on the set $\Upsilon_\circ(\mathtt{r})$:

$$\big\|\mathcal{D}_0^{-1}\big\{\nabla^2\mathbb{E}\mathcal{L}(\boldsymbol{\upsilon})\big\}\mathcal{D}_0^{-1} - I_{p^*}\big\| \le \epsilon\mathtt{r}.$$

$(\mathcal{E}\mathcal{D}_1)$ There exists a constant $\epsilon \le 1/2$, such that for all $|\mu| \le \mathtt{g}$ and all $0 < \mathtt{r} < \mathtt{r}_0$

$$\sup_{\boldsymbol{\upsilon},\boldsymbol{\upsilon}' \in \Upsilon_\circ(\mathtt{r})} \sup_{\|\gamma\|=1} \log \mathbb{E} \exp\left\{\frac{\mu\, \gamma^\top \mathcal{D}_0^{-1}\big\{\nabla\boldsymbol{\zeta}(\boldsymbol{\upsilon}) - \nabla\boldsymbol{\zeta}(\boldsymbol{\upsilon}')\big\}}{\epsilon\, \|\mathcal{D}_0(\boldsymbol{\upsilon} - \boldsymbol{\upsilon}')\|}\right\} \le \frac{\nu_1^2 \mu^2}{2}.$$

$(\mathcal{E}\mathcal{D})$ There exist constants $\nu_0 > 0$ and $\mathtt{g} > 0$ such that for all $|\mu| \le \mathtt{g}$

$$\sup_{\|\gamma\|\le 1} \log \mathbb{E} \exp\Big\{\mu \gamma^\top \mathcal{V}_0^{-1}\nabla\zeta(\boldsymbol{\upsilon}^*)\Big\} \le \frac{\nu_0^2 \mu^2}{2}.$$

It is important to note, that the constants $\check{\epsilon}, \check{\nu}$ and ϵ, ν in the respective weak and strong version can differ substantially and may depend on the full dimension $p^* \in \mathbb{N}$ in less or more severe ways ($\mathcal{A}\mathrm{H}^{-2}\nabla_{\boldsymbol{\eta}}\mathcal{L}$ might be quite smooth while $\nabla_{\boldsymbol{\eta}}\mathcal{L}$ could be less regular).

For the convergence statement in Theorem 14 we additionally need the following condition, that controls the moments and the smoothness of the process $\nabla^2(\mathcal{L} - \mathbb{E}\mathcal{L})$:

$(\mathcal{E}\mathcal{D}_2)$ There exists a constant $\epsilon_2 \le 1/2$, such that for all $|\mu| \le \mathtt{g}$ and all $0 < \mathtt{r} < \mathtt{r}_0$

$$\sup_{\boldsymbol{\upsilon},\boldsymbol{\upsilon}' \in \Upsilon_\circ(\mathtt{r})} \sup_{\|\gamma_1\|=1} \sup_{\|\gamma_2\|=1} \log \mathbb{E} \exp\left\{\frac{\mu\, \gamma_1^\top \mathcal{D}^{-1}\big\{\nabla^2\boldsymbol{\zeta}(\boldsymbol{\upsilon}) - \nabla^2\boldsymbol{\zeta}(\boldsymbol{\upsilon}')\big\}\gamma_2}{\epsilon_2\, \|\mathcal{D}(\boldsymbol{\upsilon} - \boldsymbol{\upsilon}')\|}\right\} \le \frac{\nu_2^2 \mu^2}{2}.$$

2.1.5 Quadratic Drift Beats Linear Fluctuation

Finally we present two conditions that allow to ensure that with a high probability the sequence $(\boldsymbol{\upsilon}_{k,k(+1)})$ stays close to $\boldsymbol{\upsilon}^*$ if the initial guess $\widetilde{\boldsymbol{\upsilon}}_0$ lands close to $\boldsymbol{\upsilon}^*$. These conditions have to be satisfied on the whole set $\Upsilon \subseteq \mathbb{R}^{p^*}$.

The first condition imposes that $\mathbb{E}\mathcal{L}(\boldsymbol{\upsilon})$ decreases nearly quadratically as the distance of $\boldsymbol{\upsilon}$ to $\boldsymbol{\upsilon}^*$ grows.

$(\mathcal{L}\mathtt{r})$ For any $\mathtt{r} > \mathtt{r}_0$ there exists a value $\mathtt{b} > 0$, such that

$$\mathbb{E}\left[\mathcal{L}(\boldsymbol{\upsilon}) - \mathcal{L}(\boldsymbol{\upsilon}^*)\right] \leq \mathtt{b}\|\mathcal{D}_0(\boldsymbol{\upsilon} - \boldsymbol{\upsilon}^*)\|^2.$$

The next condition bounds moments of the full gradient $\nabla\mathcal{L}(\boldsymbol{\upsilon})$ - again via subexponentiality.

$(\mathcal{E}\mathtt{r})$ For any $\mathtt{r} \geq \mathtt{r}_0$ there exists a constant $\mathtt{g}(\mathtt{r}) > 0$ such that

$$\sup_{\boldsymbol{\upsilon}\in\Upsilon_\circ(\mathtt{r})} \sup_{\mu\leq\mathtt{g}(\mathtt{r})} \sup_{\|\boldsymbol{\gamma}\|\leq 1} \log\mathbb{E}\exp\left\{\mu\boldsymbol{\gamma}^\top\mathcal{D}^{-1}\nabla\zeta(\boldsymbol{\upsilon})\right\} \leq \frac{\nu_{\mathtt{r}}^2\mu^2}{2}.$$

We impose one further merely technical condition:

$(\mathbf{B}_1)$ We assume for all $\mathtt{r} \geq \frac{6\nu_{\mathtt{r}}}{\mathtt{b}}\sqrt{\mathtt{x}+4p^*}$

$$1 + \sqrt{\mathtt{x}+4p^*} \leq \frac{3\nu_{\mathtt{r}}^2}{\mathtt{b}}\mathtt{g}(\mathtt{r}).$$

Remark 3 *Without this the calculation of $R_0(\mathtt{x})$ in Section 4.3 would become technically more involved, without that further insight would be gained.*

Remark 4 *The condition $(\mathcal{E}\mathtt{r})$ can be substantially relaxed to $\mathtt{b} = \mathtt{b}(\mathtt{r}) > 0$ that decreases to 0 as $\mathtt{r} \to \infty$. We avoid the resulting technicalities and refer the reader to the original publication for the non constant case (see Spokoiny, 2012, Theorem 4.1).*

2.2 Dependence on Initial Guess

Our main theorem is only valid under the conditions from Section 2.1 and under some constraints on the quality of the initial guess $\widetilde{\boldsymbol{\upsilon}}_0 \in \mathbb{R}^{p^*}$ which we denote by (A_1), (A_2) and (A_3):

$(\mathbf{A}_1)$ With probability greater $1-\beta$ the initial guess satisfies $\mathcal{L}(\widetilde{\boldsymbol{\upsilon}}_0) - \mathcal{L}(\boldsymbol{\upsilon}^*) \geq -\mathrm{K}_0$ for some $\mathrm{K}_0 \geq 0$.

$(\mathbf{A}_2)$ The conditions $(\breve{\mathcal{E}}\mathcal{D}_1)$, $(\breve{\mathcal{L}}_0)$, $(\mathcal{E}\mathcal{D}_1)$ and $(\mathcal{L}_0)$ from Section 2.1 hold for all $\mathtt{r} \leq \mathrm{R}_0(\mathtt{x})$ where $\mathrm{R}_0(\mathtt{x})$ can be bounded with (see (19))

$$\mathrm{R}_0(\mathtt{x}) \leq \mathtt{C}\sqrt{\mathtt{x}+p^*+\mathrm{K}_0}.$$

$(\mathbf{A}_3)$ $\mathrm{K}_0 \in \mathbb{R}$ and $\epsilon > 0$ are small enough to ensure

$$\epsilon\mathtt{C}(\nu)\mathrm{R}_0 < 1, \tag{17}$$

with

$$\mathtt{C}(\nu) \stackrel{\text{def}}{=} \frac{16\sqrt{2}(1+\sqrt{\nu})}{(1-\nu)(1-\sqrt{\nu})}, \tag{18}$$

where $\nu > 0$ is defined in (14).

Condition (A_1) allows to concentrate the analysis on a local set $\{\|\mathcal{D}(\boldsymbol{\upsilon} - \boldsymbol{\upsilon}^*)\| \leq \mathrm{R}_0(\mathtt{x})\} \subset \Upsilon$ with dominating probability (see Theorem 28). Conditions (A_2) and (A_3) ensure that this neighborhood is small enough to imply convergence of the procedure. They impose a bound on $\mathrm{R}_0(\mathtt{x})$ and thus on K_0 from (A_1). These conditions boil down to $\epsilon\sqrt{\mathrm{K}_0}$ being significantly smaller than 1, which is a quantification of the quality of the first guess. There are numerous ways to initiate the procedure. In Section 3 we use a grid search and show that for a sufficiently fine grid these conditions can be met in the treated model.

Remark 5 *One way of obtaining condition (A_1) is to show that $\|\mathcal{D}(\widetilde{\boldsymbol{\upsilon}} - \boldsymbol{\upsilon}^*)\| \leq R$ with probability greater $1-\beta$ for some finite $R \in \mathbb{R}$ and $0 \leq \beta(R) < 1$. Then one can use - with some constant $\mathtt{C} > 0$ -*

$$K_0 \leq (1/2 + \epsilon(1+12\nu_0))(R + \mathtt{C}\sqrt{\mathtt{x}+p^*})^2,$$

as we show in Lemma 31.

Remark 6 *The precise definition of $R_0(\mathtt{x}) > 0$ reads*

$$R_0(\mathtt{x}) \stackrel{\text{def}}{=} \mathfrak{z}(\mathtt{x}) \vee \frac{6\nu_{\mathtt{r}}}{\mathtt{b}(1-\nu)}\sqrt{\mathtt{x} + 2.4p^* + \frac{\mathtt{b}^2}{9\nu_{\mathtt{r}}^2}K_0}, \tag{19}$$

with the term

$$\mathfrak{z}(\mathtt{x}) \approx \mathtt{C}\sqrt{p^*+\mathtt{x}},$$

which is defined in (30).

2.3 Introduction of Important Objects

In this section we collect the most important objects and bounds that are relevant for Theorem 7. Remember the $p^* \times p^*$ *information matrix* $\mathcal{D}^2$ from Section 2.1, which is defined similarly to the Fisher information matrix:

$$\mathcal{D}^2 \stackrel{\text{def}}{=} -\nabla^2\mathbb{E}\mathcal{L}(\boldsymbol{\upsilon}^*) = \begin{pmatrix} \mathrm{D}^2 & \mathcal{A} \\ \mathcal{A}^\top & \mathrm{H}^2 \end{pmatrix}.$$

A crucial object is the constant $0 \leq \nu$ defined by

$$\|\mathrm{D}^{-1}\mathcal{A}\mathrm{H}^{-1}\|^2 \stackrel{\text{def}}{=} \nu, \tag{20}$$

which we assume with condition $(\mathcal{I})$ to be smaller 1. It determines the speed of convergence of the alternating procedure (see Theorem 7).

Further introduce the $p \times p$ matrix $\breve{\mathrm{D}}$ and the p-vectors $\breve{\nabla}_{\boldsymbol{\theta}}$ and $\breve{\boldsymbol{\xi}}$ as

$$\breve{\mathrm{D}}^2 = \mathrm{D}^2 - \mathcal{A}\mathrm{H}^{-2}\mathcal{A}^\top,$$
$$\breve{\boldsymbol{\xi}} = \breve{\mathrm{D}}^{-1}\breve{\nabla}_{\boldsymbol{\theta}}\mathcal{L}(\boldsymbol{\upsilon}^*), \quad \breve{\nabla}_{\boldsymbol{\theta}}\mathcal{L} = \nabla_{\boldsymbol{\theta}}\mathcal{L} - \mathcal{A}\mathrm{H}^{-2}\nabla_{\boldsymbol{\eta}}\mathcal{L}.$$

The random variable $\breve{\boldsymbol{\xi}} \in \mathbb{R}^p$ is related to the efficient influence function in semiparametric models. If the model is regular and correctly specified $\breve{\mathtt{D}}^2$ is the covariance of the efficient influence function and its inverse the semiparametric Cramer-Rao lower bound for regular estimators.

We define the *semiparametric uniform spread*

$$\breve{\diamondsuit}_Q(\mathtt{r},\mathtt{x}) \stackrel{\text{def}}{=} \breve{\epsilon}\left\{\frac{16}{(1-\nu^2)^2}\mathtt{r}^2 + \mathfrak{z}_Q(\mathtt{x}, 2p^*+2p)^2\right\}(1+6\breve{\nu}_1^2). \tag{21}$$

This object is central for our analysis as it describes the accuracy of our main results. It is small if $\breve{\epsilon}(\mathtt{r}^2+\mathtt{x}+p^*)$ is small, since $\mathfrak{z}_Q(\mathtt{x},p^*) \approx \sqrt{p^*+\mathtt{x}}$ (see its definition in Equation (42)).

2.4 Statistical Properties of the Alternating Sequence

In this Section we present our main theorem in full rigor, i.e. that the limit of the alternating sequence satisfies a finite sample Wilks Theorem and Fisher expansion.

Theorem 7 *Assume that the conditions* $(\mathcal{L}_\mathtt{r})$, $(\mathcal{E}\mathtt{r})$ *and* (B_1) *of Section 2.1 are met. Further assume* (A_1), (A_2) *and* (A_3) *of Section 2.2. Then it holds with probability greater* $1-8\mathrm{e}^{-\mathtt{x}}-\beta$ *for all* $k \in \mathbb{N}$

$$\left\|\breve{D}(\widetilde{\boldsymbol{\theta}}_k - \boldsymbol{\theta}^*) - \breve{\boldsymbol{\xi}}\right\| \le \breve{\diamondsuit}_Q(\mathtt{r}_k,\mathtt{x}), \tag{22}$$

$$\left|\max_{\boldsymbol{\eta}} \mathcal{L}(\widetilde{\boldsymbol{\theta}}_k,\boldsymbol{\eta}) - \max_{\boldsymbol{\eta}} \mathcal{L}(\boldsymbol{\theta}^*,\boldsymbol{\eta}) - \|\breve{\boldsymbol{\xi}}\|^2/2\right| \le 5\left(\|\breve{\boldsymbol{\xi}}\| + \breve{\diamondsuit}_Q(\mathtt{r}_k,\mathtt{x})\right)\breve{\diamondsuit}_Q(\mathtt{r}_k,\mathtt{x}), \tag{23}$$

where

$$\mathtt{r}_k \le \mathtt{C}\left(\sqrt{p^*+\mathtt{x}} + \nu^k R_0\right),$$

with a constant $\mathtt{C}$ *that depends on* $\nu<1$ *and* $1-\mathtt{C}(\nu)\epsilon R_0 > 0$. *In particular this means that if*

$$k \ge \frac{\log(p^*+\mathtt{x}) - \log\{R_0\}}{\log(\nu)},$$

we have

$$\breve{\diamondsuit}_Q(\mathtt{r}_k,\mathtt{x}) \approx \breve{\diamondsuit}_Q\left(\mathtt{C}\sqrt{p^*+\mathtt{x}},\mathtt{x}\right).$$

Remark 8 *Note that with linear convergence speed this leads to statements about* $\widetilde{\boldsymbol{\theta}}_k$ *that are very similar to those in (Andresen and Spokoiny, 2014) for the profile M estimator* $\widetilde{\boldsymbol{\theta}}$.

Remark 9 *Concerning the properties of* $\breve{\boldsymbol{\xi}} \in \mathbb{R}^p$ *we repeat remark 2.1 of (Andresen and Spokoiny, 2014). In case of correct model specification the deviation properties of the quadratic form* $\|\breve{\boldsymbol{\xi}}\|^2 = \|\breve{D}^{-1}\breve{\nabla}_{\boldsymbol{\theta}}\|^2$ *are essentially the same as those of a chi-square random variable with* p *degrees of freedom; see Theorem 39 in the appendix. In the case of a possible*

model misspecification the behavior of the quadratic form $\|\breve{\boldsymbol{\xi}}\|^2$ *will depend on the characteristics of the matrix* $\breve{\mathbb{B}} \stackrel{\text{def}}{=} \mathrm{Cov}(\breve{\boldsymbol{\xi}})$; *see again Theorem 39. Moreover, in the asymptotic setup the vector* $\breve{\boldsymbol{\xi}}$ *is asymptotically standard normal; see Section 2.2. of (Andresen and Spokoiny, 2014) for the i.i.d. case.*

Remark 10 *These results allow to derive some important corollaries like concentration and confidence sets (see Section 1.3).*

Remark 11 *In general an exact numerical computation of*

$$\theta(\boldsymbol{\eta}) \stackrel{\text{def}}{=} \operatorname*{argmax}_{\boldsymbol{\theta}\in\mathbb{R}^p} \mathcal{L}(\boldsymbol{\theta},\boldsymbol{\eta}), \quad \text{or} \quad \eta(\boldsymbol{\theta}) \stackrel{\text{def}}{=} \operatorname*{argmax}_{\boldsymbol{\eta}\in\mathbb{R}^m} \mathcal{L}(\boldsymbol{\theta},\boldsymbol{\eta}),$$

is not possible. Define $\widehat{\theta}(\boldsymbol{\eta})$ *and* $\widehat{\eta}(\boldsymbol{\theta})$ *as the numerical approximations to* $\theta(\boldsymbol{\eta})$ *and* $\eta(\boldsymbol{\theta})$ *and assume that - with the local set* $\Upsilon_\circ(\mathtt{r})$ *defined in* (15) *-*

$$\|D(\widehat{\theta}(\boldsymbol{\eta}) - \theta(\boldsymbol{\eta}))\| \le \tau, \ \text{ for all } \ \boldsymbol{\eta} \in \Upsilon_{\circ,\boldsymbol{\eta}}(R_0) \stackrel{\text{def}}{=} \{\boldsymbol{\upsilon} \in \Upsilon_\circ(R_0),\, \Pi_{\boldsymbol{\eta}}\boldsymbol{\upsilon} = \boldsymbol{\eta}\},$$

$$\|H(\widehat{\eta}(\boldsymbol{\theta}) - \eta(\boldsymbol{\theta}))\| \le \tau, \ \text{ for all } \ \boldsymbol{\theta} \in \Upsilon_{\circ,\boldsymbol{\theta}}(R_0) \stackrel{\text{def}}{=} \{\boldsymbol{\upsilon} \in \Upsilon_\circ(R_0),\, \Pi_{\boldsymbol{\theta}}\boldsymbol{\upsilon} = \boldsymbol{\theta}\}.$$

Then we can easily modify the proof of Theorem 7 via adding $\mathtt{C}(\nu)\tau$ *to the error terms and the radii* $\mathtt{r}_k$, *where* $\mathtt{C}(\nu)$ *is some rational function of* ν.

2.5 Convergence to the ME

Even though Theorem 7 tells us that the statistical properties of the alternating sequence resemble those of its target - the profile ME $\widetilde{\boldsymbol{\theta}}$ - it is an interesting question if the underlying approach allows to qualify conditions under which the sequence actually attains the maximizer $\widetilde{\boldsymbol{\upsilon}}$.

Define the radius $\mathtt{r}_0(\mathtt{x}) > 0$ to be the smallest radius $\mathtt{r} > 0$ such that $\mathbb{P}(\widetilde{\boldsymbol{\upsilon}}, \widetilde{\boldsymbol{\upsilon}}_{\boldsymbol{\theta}^*} \in \Upsilon_\circ(\mathtt{r}_0)) \ge 1-\mathrm{e}^{-\mathtt{x}}$, where

$$\widetilde{\boldsymbol{\upsilon}}_{\boldsymbol{\theta}^*} \stackrel{\text{def}}{=} \operatorname*{argmax}_{\substack{\boldsymbol{\upsilon}\in\Upsilon \\ \Pi_{\boldsymbol{\theta}}\boldsymbol{\upsilon}=\boldsymbol{\theta}^*}} \mathcal{L}(\boldsymbol{\upsilon}).$$

Remark 12 *This radius can be determined using conditions* $(\mathcal{L}_\mathtt{r})$ *and* $(\mathcal{E}\mathtt{r})$ *of Section 2.1 and Theorem 28 which would yield* $\mathtt{r}_0(\mathtt{x}) = O(\sqrt{\mathtt{x}+p^*})$.

Without further assumptions Theorem 7 yields the following Corollary:

Corollary 13 *Under the assumptions of Theorem 7 it holds with probability greater* $1-8\mathrm{e}^{-\mathtt{x}}-\beta$

$$\|\breve{D}(\widetilde{\boldsymbol{\theta}} - \widetilde{\boldsymbol{\theta}}_k)\| \le \breve{\diamondsuit}_Q(\mathtt{r}_k,\mathtt{x}) + \breve{\diamondsuit}_Q(\mathtt{r}_0,\mathtt{x}).$$

Corollary 13 is a first step in the direction of an actual convergence result but the gap $\breve{\diamondsuit}_Q(\mathtt{r}_k,\mathtt{x}) + \breve{\diamondsuit}_Q(\mathtt{r}_0,\mathtt{x})$ is not a zero sequence in $k \in \mathbb{N}$. It turns out that it is possible to

prove convergence to the ME at the cost of assuming more smoothness of the functional $\mathcal{L}$ and using the right bound for the maximal eigenvalue of the Hessian $\nabla^2\mathcal{L}(\upsilon^*)$.

Define $\mathfrak{z}_2(\mathtt{x}, \nabla^2\mathcal{L}(\upsilon^*))$ via

$$\mathbb{P}\Big(\|\mathcal{D}^{-1}\nabla^2\mathcal{L}(\upsilon^*)\| \geq \mathfrak{z}_2\left(\mathtt{x}, \nabla^2\mathcal{L}(\upsilon^*)\right) \Big) \leq \mathrm{e}^{-\mathtt{x}},$$

and $\kappa(\mathtt{x}, \mathrm{R}_0)$ as

$$\kappa(\mathtt{x}, \mathrm{R}_0) \stackrel{\mathrm{def}}{=} \frac{2\sqrt{2}(1+\sqrt{\nu})}{\sqrt{1-\nu}} \left\{ \epsilon \mathrm{R}_0 + 9\epsilon_2\nu_2 \|\mathcal{D}^{-1}\| \mathfrak{z}_1(\mathtt{x}, 6p^*)\mathrm{R}_0 + \|\mathcal{D}^{-1}\| \mathfrak{z}_2\left(\mathtt{x}, \nabla^2\mathcal{L}(\upsilon^*)\right) \right\},$$

where $\mathfrak{z}_1(\mathtt{x}, \cdot) \approx \sqrt{\mathtt{x} + p^*}$, see (46). With these definitions we can prove the following Theorem:

Theorem 14 *Let the conditions $(\mathcal{L}_\mathtt{r})$, $(\mathcal{E}\mathtt{r})$ and (B_1) be met. Further suppose (A_1) and (A_2), with $(\mathcal{E}\mathcal{D}_2)$ instead of $(\mathcal{E}\mathcal{D}_1)$. Assume that $\kappa(\mathtt{x}, R_0) < (1-\nu)$. Then*

$$\mathbb{P}\left(\bigcap_{k \in \mathbb{N}} \left\{ \|\mathcal{D}(\upsilon_{k,k(+1)} - \widetilde{\upsilon})\| \leq \mathtt{r}_k^* \right\} \right) \geq 1 - 3\mathrm{e}^{-\mathtt{x}} - \beta,$$

where

$$\mathtt{r}_k^* \leq \begin{cases} \nu^k \frac{4\sqrt{2}}{1-\kappa(\mathtt{x},R_0)k} R_0, & \kappa(\mathtt{x}, R_0)k \leq 1, \\ \nu^{\frac{k}{\log(k)}\log\left(\frac{1-\nu}{\kappa(\mathtt{x},R_0)}\right)} c_k R_0, & \textit{otherwise}, \end{cases} \tag{24}$$

with some sequence $(c_k) \in \mathbb{N}$, where $0 < c_k \to 2$.

Remark 15 *This means that we obtain nearly linear convergence to the global maximizer $\widetilde{\upsilon}$.*

Remark 16 *As in Remark 11 if no exact numerical computation of the stepwise maximizers is possible we can easily modify the proof of Theorem 14 via adding $\mathtt{C}(\nu)\tau$ to $\kappa(\mathtt{x}, R_0)$ to address that case.*

Remark 17 *For the case that $\mathcal{L}(\upsilon) = \sum_{i=1}^n \ell_i(\upsilon)$ with a sum of independent marginal functionals $\ell_i : \Upsilon \to \mathbb{R}$ we can use Corollary 3.7 of (Tropp, 2012) to obtain*

$$\mathfrak{z}_2\left(\mathtt{x}, \nabla^2\mathcal{L}(\upsilon^*)\right) = \sqrt{2\tau}\nu\sqrt{\mathtt{x} + \log(p^*)},$$

if for some sequence of matrices $(\boldsymbol{A}_i) \subset \mathbb{R}^{p^* \times p^*}$

$$\log \mathbb{E} \exp \lambda \nabla^2 \ell_i(\upsilon^*) \preceq \nu^2\lambda^2/2\boldsymbol{A}_i, \quad \|\sum_{i=1}^n \boldsymbol{A}_i\| \leq \tau.$$

In the case of smooth i.i.d models this means that

$$\kappa(\mathtt{x}, R_0) \leq \frac{\mathtt{C}}{\sqrt{n}}(\mathtt{x} + R_0 + \log(p^*)),$$

if $p^* + \mathtt{x} = o(n)$.

Remark 18 *It may happen that $\kappa(\mathtt{x}, R_0)/(1-\nu)$ is very close to or even larger than 1. But a close look at the proof of Theorem 14 reveals that this can be improved using Lemma 33. For this purpose bound $\mathtt{r}_k^* \leq \mathtt{C}^*(\mathfrak{z}(\mathtt{x}) + \nu^k R_0)$ with $\mathtt{r}_k^*$ defined in (33) and with some constant $\mathtt{C}^* > 0$. Then the result of Theorem 14 is true with $\kappa(\mathtt{x}, \mathtt{C}^*\sqrt{p^* + \mathtt{x}})$ instead of $\kappa(\mathtt{x}, R_0)$ and with probability greater $1 - 10\mathrm{e}^{-\mathtt{x}}$. See Remark 38 for more details.*

2.6 Critical Dimension

We want to address the issue of *critical parameter dimensions* when the full dimension p^* grows with the sample size n. We write $p^* = p_n$. The results of Theorem 7 are accurate if the spread function $\breve{\Diamond}_Q(\mathtt{r}_k, \mathtt{x})$ from (21) is small. The critical size of p_n then depends on the exact bounds on $\epsilon, \check{\epsilon}$. In the i.i.d setting we have $\epsilon \asymp \check{\epsilon} \asymp 1/\sqrt{n}$ such that $\breve{\Diamond}(\mathtt{r}_k, \mathtt{x}) \asymp p_n/\sqrt{n}$ for large $k \in \mathbb{N}$. In other words, one needs that "${p_n}^2/n$ is small" to obtain an accurate non-asymptotic version of the Wilks phenomenon and the Fisher Theorem for the limit of the alternating sequence. This is not surprising because good performance of the ME itself can only be guaranteed if "${p_n}^2/n$ is small", as is shown by Andresen and Spokoiny (2014). There are examples where the pME only satisfies a Wilks- or Fisher result if "${p_n}^2/n$ is small", such that in any of those settings the alternating sequence started in the global maximizer does not admit an accurate Wilks- or Fisher expansion.

Interesting enough the constrain $\kappa(\mathtt{x}, \mathrm{R}_0) < (1-\nu)$ of Theorem 14 for the convergence of the sequence to the global maximizer means that one needs $p_n/n \ll 1$ in the smooth i.i.d. setting if $\mathrm{R}_0 \leq \mathtt{C}_{\mathrm{R}_0}\sqrt{p_n + \mathtt{x}}$. Further Theorem 14 states a lower bound for the speed of convergence that in the smooth i.i.d. setting decreases if p_n/n grows. Unfortunately we were unable to find an example that meets the conditions of Section 2.1 and where no convergence occurs if p_n/n tends to infinity. So whether this dimension effect on the convergence is an artifact of our proofs or indeed a property of the alternating procedure remains an open question.

3. Application to Single Index Model

We illustrate how the results of Theorem 7 and Theorem 14 can be applied in Single Index modeling. This section is based on (Andresen, 2015). See that paper for a more detailed presentation.

Consider the following model

$$y_i = f(\boldsymbol{X}_i^\top \boldsymbol{\theta}^*) + \varepsilon_i, \qquad i = 1, ..., n,$$

for some $f : \mathbb{R} \to \mathbb{R}$ and $\boldsymbol{\theta}^* \in S_1^{p,+} \subset \mathbb{R}^p$ and with i.i.d errors $\varepsilon_i \in \mathbb{R}$, $\mathrm{Var}(\varepsilon_i) = \sigma^2$ and i.i.d random variables $\boldsymbol{X}_i \in \mathbb{R}^p$ with distribution denoted by $\mathbb{P}^{\boldsymbol{X}}$. The single-index model is widely applied in statistics. For example in econometric studies it serves as a compromise between too restrictive parametric models and flexible but hardly estimable purely non-parametric models. Usually the statistical inference focuses on estimating the index vector $\boldsymbol{\theta}^*$. A lot of research has already been done in this field. For instance, (Delecroix. et al., 1997) show the asymptotic efficiency of the general semiparametric maximum-functional estimator for particular examples and in (Haerdle et al., 1993) the right choice of band-

width for the nonparametric estimation of the link function is analyzed. We want to use this model to illustrate our theoretical results.

To ensure identifiability of $\boldsymbol{\theta}^* \in \mathbb{R}^p$ we assume that it lies in the half sphere $S_1^{p,+} \stackrel{\text{def}}{=} \{\boldsymbol{\theta} \in \mathbb{R}^p : \|\boldsymbol{\theta}\| = 1,\, \theta_1 > 0\} \subset \mathbb{R}^p$. For simplicity we assume that the support of the $\boldsymbol{X}_i \in \mathbb{R}^p$ is contained in the ball of radius $s > 0$. This allows to approximate $f \in \{f : [-s, s] \mapsto \mathbb{R}\}$ by an orthonormal C^3-Daubechies-wavelet basis $(\boldsymbol{e}_k)_{k\in\mathbb{N}}$ on the interval.

A candidate to estimate $\boldsymbol{\theta}^*$ is the sieve profile ME

$$\widetilde{\boldsymbol{\theta}}_m \stackrel{\text{def}}{=} \Pi_{\boldsymbol{\theta}} \operatorname*{argmax}_{(\boldsymbol{\theta},\boldsymbol{\eta})\in\Upsilon_m} \mathcal{L}_m(\boldsymbol{\theta}, \boldsymbol{\eta}),$$

where

$$\mathcal{L}_m(\boldsymbol{\theta}, \boldsymbol{\eta}) = -\frac{1}{2}\sum_{i=1}^{n}\Big|y_i - \sum_{k=0}^{m} \boldsymbol{\eta}_k \boldsymbol{e}_k(\boldsymbol{X}_i^\top \boldsymbol{\theta})\Big|^2,$$

and where $\Upsilon_m = S_1^{p,+} \times \mathbb{R}^m$. Again we will suppress the sub index $\cdot_m$ in the following.

In this setting a direct computation of $\widetilde{\boldsymbol{\upsilon}}$ becomes involved, as the maximization problem is high dimensional and not convex. But as noted in the introduction the maximization with respect to $\boldsymbol{\eta}$ for given $\boldsymbol{\theta}$ is high dimensional but convex and consequently feasible. Further for moderate $p \in \mathbb{N}$ the maximization with respect to $\boldsymbol{\theta}$ for fixed $\boldsymbol{\eta}$ is computationally realistic. So an alternating maximization procedure is applicable. To show that it behaves in a desired way we apply the technique presented above.

For the initial guess $\widetilde{\boldsymbol{\upsilon}}_0 \in \Upsilon$ one can use a simple grid search. For this take a uniform grid $G_N \stackrel{\text{def}}{=} (\boldsymbol{\theta}_1, \ldots, \boldsymbol{\theta}_N) \subset S_1^+$ and define

$$\widetilde{\boldsymbol{\upsilon}}_0 \stackrel{\text{def}}{=} \operatorname*{argmax}_{\substack{(\boldsymbol{\theta},\boldsymbol{\eta})\in\Upsilon \\ \boldsymbol{\theta}\in G_N}} \mathcal{L}(\boldsymbol{\upsilon}). \tag{25}$$

Note that given the grid the above maximizer is easily obtained. Simply calculate

$$\widetilde{\boldsymbol{\eta}}_{0,k} \stackrel{\text{def}}{=} \operatorname{argmax} \mathcal{L}(\boldsymbol{\theta}_k, \boldsymbol{\eta}) = \left(\frac{1}{n}\sum_{i=1}^{n} \boldsymbol{e}\boldsymbol{e}^\top(\boldsymbol{X}_i^\top \boldsymbol{\theta}_k)\right)^{-1} \frac{1}{n}\sum_{i=1}^{n} y_i \boldsymbol{e}^\top(\boldsymbol{X}_i^\top \boldsymbol{\theta}_k) \in \mathbb{R}^m, \tag{26}$$

where by abuse of notation $\boldsymbol{e} = (\boldsymbol{e}_1, \ldots, \boldsymbol{e}_m) \in \mathbb{R}^m$. Now observe that

$$\widetilde{\boldsymbol{\upsilon}}_0 = \operatorname*{argmax}_{k=1,\ldots,N} \mathcal{L}(\boldsymbol{\theta}_k, \widetilde{\boldsymbol{\eta}}_{0,k}).$$

Define the mesh size of the grid $\tau \stackrel{\text{def}}{=} \sup_{\boldsymbol{\theta},\boldsymbol{\theta}^\circ\in G_N} \|\boldsymbol{\theta} - \boldsymbol{\theta}^\circ\|$.

To apply the result presented in Theorem 7 and Theorem 14 we need a list of assumptions denoted by $(\mathcal{A})$.

($\mathbf{Cond}_{\boldsymbol{X}}$) The random variables $(\boldsymbol{X}_i)_{i=1,\ldots,n} \subset \mathbb{R}^p$ are i.i.d and bounded with distribution denoted by $\mathbb{P}^{\boldsymbol{X}}$ and independent of $(\varepsilon_i)_{i=1,\ldots,n} \subset \mathbb{R}$.

The measure $\mathbb{P}^{\boldsymbol{X}}$ is absolutely continuous with respect to the Lebesgue measure. The

Lebesgue density $p_{\boldsymbol{X}}$ of $\mathbb{P}^{\boldsymbol{X}}$ is Lipschitz continuous and positive on $B_s(0) \subset \mathbb{R}^p$. For any pair $\boldsymbol{\theta} \in S_1^{+,p}$ with $\boldsymbol{\theta} \perp \boldsymbol{\theta}^*$ we have almost surely

$$\operatorname{Var}\left(\boldsymbol{X}^\top\boldsymbol{\theta}\middle|\boldsymbol{X}^\top\boldsymbol{\theta}^*\right) > 0.$$

($\mathbf{Cond}_f$) For some $\boldsymbol{\eta}^* \in B_{\mathtt{r}^\circ}(0) \subset l^2 \stackrel{\text{def}}{=} \{(u_k)_{k\in\mathbb{N}} : \sum_{k=1}^{\infty} u_k^2 < \infty\}$

$$f = \sum_{k=1}^{\infty} \eta_k^* \boldsymbol{e}_k,$$

where $\|f'\|_\infty < \infty$ and $\|f''\|_\infty < \infty$ and where with some $\alpha > 2$

$$\sum_{k=0}^{\infty} k^{2\alpha} \eta_k^{*2} < \infty.$$

On some interval $[t_0 - h, t_0 + h] \subseteq [-s + s]$ with $h > 0$ it holds true that

$$|f'(t)| > 0.$$

($\mathbf{Cond}_\varepsilon$) The errors $(\varepsilon_i) \in \mathbb{R}$ are i.i.d. with $\mathbb{E}[\varepsilon_i] = 0$, $\operatorname{Cov}(\varepsilon_i) = \sigma^2$ and satisfy for all $|\mu| \le \widetilde{g}$ for some $\widetilde{g} > 0$ and some $\widetilde{\nu} > 0$

$$\log \mathbb{E}[\exp\{\mu\varepsilon_1\}] \le \widetilde{\nu}^2\mu^2/2.$$

Remark 19 *Note that our assumptions in terms of moments and smoothness are quite common in this model. For instance (Haerdle et al., 1993) assume that the density $p_{\boldsymbol{X}}$ of the regressors $(\boldsymbol{X}_i)$ is twice continuously differentiable, that f has two bounded derivatives and that the errors (ε_i) are centered with bounded polynomial moments of arbitrary degree.*

Remark 20 $\operatorname{Var}\left(\boldsymbol{X}^\top\boldsymbol{\theta}^\circ\middle|\boldsymbol{X}^\top\boldsymbol{\theta}^*\right) = 0$ *would mean that* $\boldsymbol{X}^\top\boldsymbol{\theta}^\circ = a(\boldsymbol{X}^\top\boldsymbol{\theta}^*)$ *for some measurable function* $a : \mathbb{R} \to \mathbb{R}$. *But then we would have for any* $(\alpha, \beta) \in \mathbb{R}^2$ *with* $\alpha^2 + \beta^2 = 1$ *that*

$$f(\boldsymbol{X}^\top(\alpha\boldsymbol{\theta}^* + \beta\boldsymbol{\theta}^\circ)) = f(\alpha\boldsymbol{X}^\top\boldsymbol{\theta}^* + \beta a(\boldsymbol{X}^\top\boldsymbol{\theta}^*)) \stackrel{\text{def}}{=} f^\circ_{\alpha,\beta}(\boldsymbol{X}^\top\boldsymbol{\theta}^*),$$

such that the problem would no longer be identifiable. Also $|f'(t)| > 0$ *on some interval is necessary for identifyability of* $\boldsymbol{\theta}^*$.

Proposition 21 *Let* $\tau = o(p^{*-3/2})$ *and* $p^{*5}/n \to 0$. *With initial guess given by Equation* (25) *and for not too large* $\mathtt{x} > 0$ *the alternating sequence satisfies* (22) *and* (23) *with probability greater* $1 - 9\exp\{-\mathtt{x}\}$ *and where with some constant* $\mathtt{C} \in \mathbb{R}$

$$\overset{\circ}{\diamondsuit}_Q(\mathtt{r}, \mathtt{x}) \le \frac{\mathtt{C}(p^* + \mathtt{x})^{3/2}}{\sqrt{n}}(\mathtt{r}^2 + p^* + \mathtt{x}).$$

Proposition 22 *Take the initial guess given by Equation* (25). *Assume* $(\mathcal{A})$. *Further assume that* $p^{*4}/n \to 0$ *and* $\tau = o(p^{*-3/2})$. *Then we get the claim of Theorem 14 with* $\beta = \mathrm{e}^{-\mathtt{x}}$ *and*

$$\kappa(\mathtt{x}, R_0) = O(\tau p^{*3/2} + \sqrt{\tau \mathtt{x}} p^{*3/2}/n^{1/4}) + O(p^{*2}/\sqrt{n}) \to 0,$$

for moderate choice of $\mathtt{x} > 0$.

Remark 23 *The constraint* $\tau = o(p^{*-3/2})$ *implies that for the calculation of the initial guess the vector* $\widetilde{\boldsymbol{\eta}}_{0,l}$ *of* (26) *and the functional* $\mathcal{L}(\cdot)$ *have to be evaluated* $N = p^{*3(p-1)/2}$ *times.*

For details and proofs see (Andresen, 2015).

4. Proof of Theorem 7

In this section we present the proof of Theorem 7. As the proof is quite technical and complex we want to first explain the basic ideas of the proof. In a second section we will outline more clearly the steps of the proof. Finally we carry out each of these steps which combine to yield the proof.

4.1 Idea of the Proof

To ease the understanding of what follows in the subsequent sections we want to illustrate the central ideas with a simple model. Consider for some positive definite matrix $\mathcal{D} \in \mathbb{R}^{p^* \times p^*}$ and some vector $\boldsymbol{\upsilon}^* = (\boldsymbol{\theta}^*, \boldsymbol{\eta}^*) \in \mathbb{R}^{p+m} = \mathbb{R}^{p^*}$ the model

$$\mathbb{Y} = \boldsymbol{\upsilon}^* + \boldsymbol{\varepsilon} \in \mathbb{R}^{p^*}, \text{ where } \boldsymbol{\varepsilon} \sim \mathcal{N}(0, \mathcal{D}^{-2}), \quad \mathcal{D}^2 = \begin{pmatrix} \mathrm{D}^2 & A \\ A^\top & \mathrm{H}^2 \end{pmatrix} \in \mathbb{R}^{p^* \times p^*}.$$

Set $\mathcal{L}$ to be the true log likelihood of the observations, i.e.

$$\mathcal{L}(\boldsymbol{\upsilon}, \mathbb{Y}) = -\|\mathcal{D}(\boldsymbol{\upsilon} - \mathbb{Y})\|^2/2.$$

With any starting initial guess $\widetilde{\boldsymbol{\upsilon}}_0 \in \mathbb{R}^{p+m}$ we obtain from (3) for $k \in \mathbb{N}$ and the usual first order criterion of maximality the following two equations

$$\begin{aligned} \mathrm{D}(\widetilde{\boldsymbol{\theta}}_k - \boldsymbol{\theta}^*) &= \mathrm{D}\boldsymbol{\varepsilon}_{\boldsymbol{\theta}} + \mathrm{D}^{-1} A (\widetilde{\boldsymbol{\eta}}_k - \boldsymbol{\eta}^*), \\ \mathrm{H}(\widetilde{\boldsymbol{\eta}}_{k+1} - \boldsymbol{\eta}^*) &= \mathrm{H}\boldsymbol{\varepsilon}_{\boldsymbol{\eta}} + \mathrm{H}^{-1} A^\top (\widetilde{\boldsymbol{\theta}}_k - \boldsymbol{\theta}^*). \end{aligned}$$

Combining these two equations we derive, assuming $\|\mathrm{D}^{-1} A \mathrm{H}^{-2} A^\top \mathrm{D}^{-1}\| \stackrel{\text{def}}{=} \|\boldsymbol{M}_0\| = \nu < 1$

$$\begin{aligned} \mathrm{D}(\widetilde{\boldsymbol{\theta}}_k - \boldsymbol{\theta}^*) &= \mathrm{D}^{-1}(\mathrm{D}^2 \boldsymbol{\varepsilon}_{\boldsymbol{\theta}} - A \boldsymbol{\varepsilon}_{\boldsymbol{\eta}}) + \mathrm{D}^{-1} A \mathrm{H}^{-1} A^\top \mathrm{D}^{-1} \mathrm{D}(\widetilde{\boldsymbol{\theta}}_{k-1} - \boldsymbol{\theta}^*) \\ &= \sum_{l=1}^{k} \boldsymbol{M}_0^{k-l} \mathrm{D}^{-1}(\mathrm{D}^2 \boldsymbol{\varepsilon}_{\boldsymbol{\theta}} - A \boldsymbol{\varepsilon}_{\boldsymbol{\eta}}) + \boldsymbol{M}_0^k \mathrm{D}(\widetilde{\boldsymbol{\theta}}_0 - \boldsymbol{\theta}^*) \\ &\to \mathbf{X} \stackrel{\text{def}}{=} \mathrm{D}(\widehat{\boldsymbol{\theta}} - \boldsymbol{\theta}^*). \end{aligned}$$

Because the limit $\widehat{\boldsymbol{\theta}}$ is independent of the initial point $\widetilde{\boldsymbol{\upsilon}}_0$ and because the profile $\widetilde{\boldsymbol{\theta}}$ is a fix-point of the procedure the unique limit satisfies $\widehat{\boldsymbol{\theta}} = \widetilde{\boldsymbol{\theta}}$. This argument is based on the fact that in this setting the functional is quadratic such that the gradient satisfies

$$\nabla \mathcal{L}(\boldsymbol{\upsilon}) = \mathcal{D}^2_{\boldsymbol{\upsilon}^*}(\boldsymbol{\upsilon} - \boldsymbol{\upsilon}^*) + \mathcal{D}^2_{\boldsymbol{\upsilon}^*} \boldsymbol{\varepsilon}.$$

Any smooth function is quadratic around its maximizer which motivates a local linear approximation of the gradient of the functional $\mathcal{L}$ to derive our results with similar arguments. This is done in the proof of Theorem 7 .

First it is ensured that the whole sequence $(\widetilde{\boldsymbol{\upsilon}}_{k,k(+1)})_{k \in \mathbb{N}_0}$ satisfies for some $\mathrm{R}_0(\mathtt{x}) > 0$ and with probability greater that $1 - \mathrm{e}^{-\mathtt{x}}$

$$\{\widetilde{\boldsymbol{\upsilon}}_{k,k(+1)},\, k \in \mathbb{N}_0\} \subset \{\|\mathcal{D}(\boldsymbol{\upsilon} - \boldsymbol{\upsilon}^*)\| \le \mathrm{R}_0(\mathtt{x})\}, \tag{27}$$

where $\mathcal{D}^2 \stackrel{\text{def}}{=} -\nabla^2 \mathbb{E}\mathcal{L}(\boldsymbol{\upsilon}^*)$ (see Theorem 28). In the second step we approximate with $\zeta = \mathcal{L} - \mathbb{E}\mathcal{L}$

$$\mathcal{L}(\boldsymbol{\upsilon}) - \mathcal{L}(\boldsymbol{\upsilon}^*) = \nabla \zeta(\boldsymbol{\upsilon}^*)(\boldsymbol{\upsilon} - \boldsymbol{\upsilon}^*) - \|\mathcal{D}(\boldsymbol{\upsilon} - \boldsymbol{\upsilon}^*)\|^2/2 + \alpha(\boldsymbol{\upsilon}, \boldsymbol{\upsilon}^*), \tag{28}$$

where $\alpha(\boldsymbol{\upsilon}, \boldsymbol{\upsilon}^*)$ is defined by (28). Similar to the toy case above this allows using the first order criterion of maximality and (27) to obtain a bound of the kind

$$\begin{aligned} \|\mathcal{D}(\boldsymbol{\upsilon}_{k,k} - \boldsymbol{\upsilon}^*)\| &\le \mathtt{C} \sum_{l=0}^{k} \nu^l \left(\|\mathcal{D}^{-1} \nabla \zeta(\boldsymbol{\upsilon}^*)\| + |\alpha(\boldsymbol{\upsilon}_{l,l}, \boldsymbol{\upsilon}^*)| \right) \\ &\le \mathtt{C}_1 \left(\|\mathcal{D}^{-1} \nabla \zeta(\boldsymbol{\upsilon}^*)\| + \epsilon(\mathrm{R}_0) \right) + \nu^k \mathrm{R}_0 \stackrel{\text{def}}{=} \mathtt{r}_k. \end{aligned}$$

This is done in Lemma 32 using results from (Andresen and Spokoiny, 2014) to show that $\epsilon(\mathrm{R}_0)$ is small. Finally the same arguments as in (Andresen and Spokoiny, 2014) allow to obtain our main result using that with high probability for all $k \in \mathbb{N}_0$ $\widetilde{\boldsymbol{\upsilon}}_{k,k} \in \{\|\mathcal{D}(\boldsymbol{\upsilon} - \boldsymbol{\upsilon}^*)\| \le \mathtt{r}_k\}$. For the convergence result similar arguments are used. The only difference is that instead of (28) we use the approximation

$$\mathcal{L}(\boldsymbol{\upsilon}) - \mathcal{L}(\widetilde{\boldsymbol{\upsilon}}) = -\|\mathcal{D}(\boldsymbol{\upsilon} - \widetilde{\boldsymbol{\upsilon}})\|^2/2 + \alpha'(\boldsymbol{\upsilon}, \widetilde{\boldsymbol{\upsilon}}),$$

exploiting that $\nabla \mathcal{L}(\widetilde{\boldsymbol{\upsilon}}) \equiv 0$, which allows to obtain actual convergence to the ME.

4.2 A Desirable Set

In this section we will explain the agenda of the proof. The first step of the proof is to find a desirable set $\Omega(\mathtt{x}) \subset \Omega$ of high probability, on which a linear approximation of the gradient of the functional $\mathcal{L}(\boldsymbol{\upsilon})$ can be carried out with sufficient accuracy. Once this set is found all subsequent analysis concerns events in $\Omega(\mathtt{x}) \subset \Omega$.

For this purpose define - with the local set $\Upsilon_\circ(\mathtt{r})$ defined in (15) - for some $K \in \mathbb{N}$ the set

$$\Omega(\mathtt{x}) = \bigcap_{k=0}^{K} (C_{k,k} \cap C_{k,k+1}) \cap C(\nabla) \cap \{\mathcal{L}(\widetilde{\boldsymbol{\upsilon}}_0) - \mathcal{L}(\boldsymbol{\upsilon}^*) \geq -\mathrm{K}_0\}, \text{ where} \tag{29}$$

$$C_{k,k(+1)} = \Big\{ \|\mathcal{D}(\widetilde{\boldsymbol{\upsilon}}_{k,k(+1)} - \boldsymbol{\upsilon}^*)\| \leq \mathrm{R}_0(\mathtt{x}),\ \|\mathrm{D}(\widetilde{\boldsymbol{\theta}}_k - \boldsymbol{\theta}^*)\| \leq \mathrm{R}_0(\mathtt{x}),$$
$$\|\mathrm{H}(\widetilde{\boldsymbol{\eta}}_{k(+1)} - \boldsymbol{\eta}^*)\| \leq \mathrm{R}_0(\mathtt{x}) \Big\},$$

$$C(\nabla) = \bigcap_{\mathtt{r} \leq \mathrm{R}_0(\mathtt{x})} \left\{ \sup_{\boldsymbol{\upsilon} \in \Upsilon_\circ(\mathtt{r})} \left\{ \frac{1}{6\epsilon\nu_1} \|\mathcal{Y}(\boldsymbol{\upsilon})\| - 2\mathtt{r}^2 \right\} \leq \mathfrak{z}_Q(\mathtt{x}, 4p^*)^2 \right\}$$
$$\bigcap_{\mathtt{r} \leq 4\mathrm{R}_0(\mathtt{x})} \left\{ \sup_{\boldsymbol{\upsilon} \in \Upsilon_\circ(\mathtt{r})} \left\{ \frac{1}{6\check{\epsilon}\check{\nu}_1} \|\check{\mathcal{Y}}(\boldsymbol{\upsilon})\| - 2\mathtt{r}^2 \right\} \leq \mathfrak{z}_Q(\mathtt{x}, 2p^* + 2p)^2 \right\}$$
$$\cap \Big\{ \max\{\|\mathcal{D}^{-1}\nabla\mathcal{L}\|, \|\mathrm{D}^{-1}\nabla_{\boldsymbol{\theta}}\mathcal{L}\|, \|\mathrm{H}^{-1}\nabla_{\boldsymbol{\eta}}\mathcal{L}\|\} \leq \mathfrak{z}(\mathtt{x}) \Big\}$$
$$\cap \{\widetilde{\boldsymbol{\upsilon}}, \widetilde{\boldsymbol{\upsilon}}_{\boldsymbol{\theta}^*} \in \Upsilon_\circ(\mathtt{r}_0(\mathtt{x}))\}.$$

For $\boldsymbol{\zeta}(\boldsymbol{\upsilon}) = \mathcal{L}(\boldsymbol{\upsilon}) - \mathbb{E}\mathcal{L}(\boldsymbol{\upsilon})$ the semiparametric normalized stochastic gradient gap is defined as

$$\check{\mathcal{Y}}(\boldsymbol{\upsilon}) = \check{\mathrm{D}}^{-1}\Big(\check{\nabla}_{\boldsymbol{\theta}}\boldsymbol{\zeta}(\boldsymbol{\upsilon}) - \check{\nabla}_{\boldsymbol{\theta}}\boldsymbol{\zeta}(\boldsymbol{\upsilon}^*)\Big).$$

the parametric normalized stochastic gradient gap $\mathcal{Y}(\boldsymbol{\upsilon})$ is defined as

$$\mathcal{Y}(\boldsymbol{\upsilon}) = \mathcal{D}^{-1}\Big(\nabla\zeta(\boldsymbol{\upsilon}) - \nabla\zeta(\boldsymbol{\upsilon}^*)\Big),$$

and $\mathtt{r}_0(\mathtt{x}) > 0$ is chosen such that $\mathbb{P}(\widetilde{\boldsymbol{\upsilon}}, \widetilde{\boldsymbol{\upsilon}}_{\boldsymbol{\theta}^*} \in \Upsilon_\circ(\mathtt{r}_0)) \geq 1 - \mathrm{e}^{-\mathtt{x}}$, where

$$\widetilde{\boldsymbol{\upsilon}}_{\boldsymbol{\theta}^*} \stackrel{\text{def}}{=} \operatorname*{argmax}_{\substack{\boldsymbol{\upsilon} \in \Upsilon \\ \Pi_{\boldsymbol{\theta}}\boldsymbol{\upsilon} = \boldsymbol{\theta}^*}} \mathcal{L}(\boldsymbol{\upsilon}).$$

The constant $\mathfrak{z}(\mathtt{x})$ in the definition of $C(\nabla)$ is only introduced for ease of notation. This makes some bounds less sharp but allows to address all terms that are of order $\sqrt{p^* + \mathtt{x}}$ with one symbol. It is defined as

$$\mathfrak{z}(\mathtt{x}) \stackrel{\text{def}}{=} \mathfrak{z}(\mathtt{x}, \mathcal{D}^{-1}\mathcal{V}^2\mathcal{D}^{-1}) \vee \mathfrak{z}_Q(\mathtt{x}, 4p^*) \approx \sqrt{p^* + \mathtt{x}}, \tag{30}$$

where $\mathcal{V}^2 \in \mathbb{R}^{p^* \times p^*}$ denotes the *covariance matrix* from Section 2.1

$$\mathcal{V}^2 \stackrel{\text{def}}{=} \mathrm{Cov}(\nabla\mathcal{L}(\boldsymbol{\upsilon}^*)).$$

Remark 24 *$\mathfrak{z}(\mathtt{x}, \cdot)$ is explained in more detail in Section A and $\mathfrak{z}_Q(\mathtt{x}, \cdot)$ is defined in Equation (42). The constant $\mathfrak{z}(\mathtt{x}, I\!B)$ is comparable to the "$1 - \mathrm{e}^{-\mathtt{x}}$"-quantile of the norm of $\boldsymbol{X}$, where $\boldsymbol{X} \sim \mathcal{N}(0, I\!B)$, i.e. it is of order of the trace of $I\!B$. The constant $\mathfrak{z}_Q(\mathtt{x}, \mathbb{Q})$ arises as an exponential deviation bound for the supremum of a smooth process over a set with complexity described by $\mathbb{Q}$.*

Remark 25 *We intersect the set with the event $\{\widetilde{\boldsymbol{\upsilon}}, \widetilde{\boldsymbol{\upsilon}}_{\boldsymbol{\theta}^*} \in \Upsilon_\circ(\mathtt{r}_0)\}$ where we a priory demand $\mathtt{r}_0(\mathtt{x}) > 0$ to be chosen such that $\mathbb{P}(\widetilde{\boldsymbol{\upsilon}}, \widetilde{\boldsymbol{\upsilon}}_{\boldsymbol{\theta}^*} \in \Upsilon_\circ(\mathtt{r}_0)) \geq 1 - \mathrm{e}^{-\mathtt{x}}$. Note that condition $(\mathcal{E}\mathtt{r})$ together with $(\mathcal{L}\mathtt{r})$ allow to set $\sqrt{p^* + \mathtt{x}} \approx \mathtt{r}_0 \leq R_0$ (see Theorem 28).*

In Section 4.3 we show that this set is of probability greater $1 - 8\mathrm{e}^{-\mathtt{x}} - \beta_{(\boldsymbol{A})}$. We want to explain the purpose of this set along the architecture of the proof of our main theorem.

$\{\mathcal{L}(\widetilde{\boldsymbol{\upsilon}}_0, \boldsymbol{\upsilon}^*) \geq -\mathbf{K}_0\}$: This set ensures, that the first guess satisfies $\mathcal{L}(\widetilde{\boldsymbol{\upsilon}}_0, \boldsymbol{\upsilon}^*) \geq -\mathrm{K}_0$, which means that it is close enough to the target $\boldsymbol{\upsilon}^* \in \mathbb{R}^{p^*}$. This fact allows us to obtain an a priori bound for the deviation of the sequence $(\widetilde{\boldsymbol{\upsilon}}_{k,k(+1)}) \subset \Upsilon$ from $\boldsymbol{\upsilon}^* \in \Upsilon$ with Theorem 28.

$\{\mathcal{D}(\widetilde{\boldsymbol{\upsilon}}_{k,k(+1)} - \boldsymbol{\upsilon}^*) \leq \mathbf{R}_0(\mathtt{x})\}$: As just mentioned this event is of high probability due to $\mathcal{L}(\widetilde{\boldsymbol{\upsilon}}_0, \boldsymbol{\upsilon}^*) \geq -\mathrm{K}_0$ and Theorem 28. This allows to concentrate the analysis on the set $\Upsilon_\circ(\mathrm{R}_0)$ on which Taylor expansions of the functional $\mathcal{L} : \mathbb{R}^{p^*} \to \mathbb{R}$ become accurate.

$C(\nabla)$: This set ensures that on $\Omega(\mathtt{x}) \subset \Omega$ all occurring random quadratic forms and stochastic errors are controlled by $\mathfrak{z}(\mathtt{x}) \in \mathbb{R}$. Consequently we can derive in the proof of Lemma 32 an a priori bound of the form $\|\mathcal{D}(\widetilde{\boldsymbol{\upsilon}}_{k,k(+1)} - \boldsymbol{\upsilon}^*)\| \leq \mathtt{r}_k$ for a decreasing sequence of radii $(\mathtt{r}_k) \subset \mathbb{R}_+$ satisfying $\limsup_{k\to\infty} \mathtt{r}_k = \mathtt{C}\mathfrak{z}(\mathtt{x})$. Further this set allows to obtain in Lemma 34 the bounds for all $k \in \mathbb{N}$.

On $\Omega(\mathtt{x}) \subset \Omega$ we find $\widetilde{\boldsymbol{\upsilon}}_{k,k(+1)} \in \Upsilon_\circ(\mathtt{r}_k)$ such that we can follow the arguments of Theorem 2.2 of (Andresen and Spokoiny, 2014) to obtain the desired result with accuracy measured by $\check{\Diamond}_Q(\mathtt{r}_k, \mathtt{x})$.

The sketch in figure 4.2 illustrates the behavior of the first steps of the procedure. The axes correspond to the $\boldsymbol{\theta}$- or $\boldsymbol{\eta}$-subspaces respectively. The two ellipsoids with center $\boldsymbol{\upsilon}^*$ and solid frame represent the local sets $\Upsilon_\circ(R_K) \subset \Upsilon_\circ(\mathrm{R}_0)$, with $R_K > 0$ from Remark 5. We see that the initial guess $\widetilde{\boldsymbol{\upsilon}}_0$ lies in $\Upsilon_\circ(R)$. The elements $(\boldsymbol{\upsilon}_{k,k(+1)})$ of the alternating sequence all land inside of the respective $\Upsilon_\circ(\mathtt{r}_k)$, which are represented by shrinking ellipsoids centered in $\boldsymbol{\upsilon}^*$ with doted frames. Note that not the set $\Upsilon_\circ(R_K)$ but $\Upsilon_\circ(\mathrm{R}_0)$ contains all points of the sequence.

4.3 Probability of Desirable Set

Here we show that the set $\Omega(\mathtt{x})$ actually is of probability greater $1 - 8\mathrm{e}^{-\mathtt{x}} - \beta$. We prove the following two Lemmas, which together yield the claim.

Lemma 26 *The set $C(\nabla)$ satisfies*

$$\mathbb{P}(C(\nabla)) \geq 1 - 7\mathrm{e}^{-\mathtt{x}}.$$

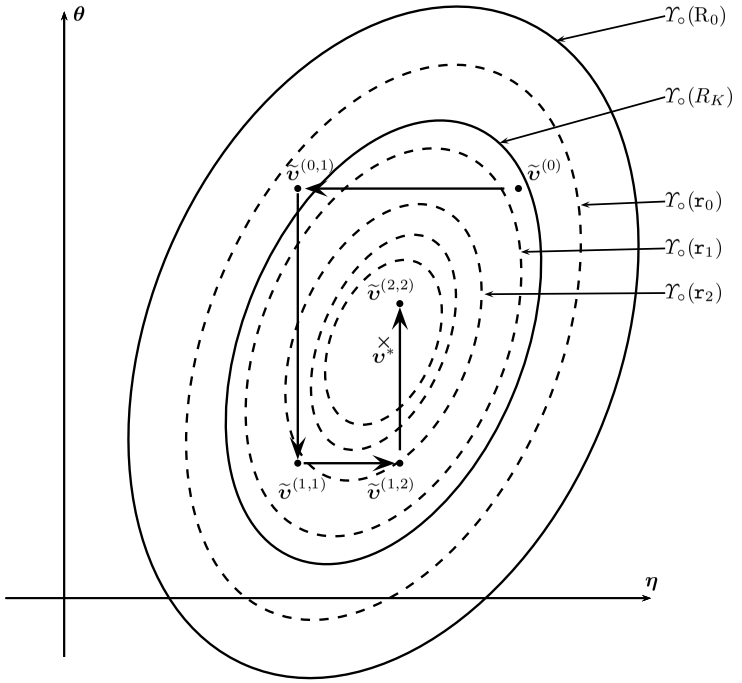

Figure 1: The behavior of the procedure for the first 4 steps of the alternating algorithm.

Proof The proof is similar to the proof of Theorem 3.1 in (Spokoiny, 2012). Denote

$$\mathcal{A} \stackrel{\text{def}}{=} \bigcap_{\mathtt{r}\le \mathrm{R}_0(\mathtt{x})} \left\{ \sup_{\upsilon\in\Upsilon_\circ(\mathtt{r})} \left\{ \frac{1}{6\epsilon\nu_1}\|\mathcal{Y}(\upsilon)\| - 2\mathtt{r}^2 \right\} \le \mathfrak{z}_Q(\mathtt{x}, 4p^*)^2 \right\}$$

$$\mathcal{B} \stackrel{\text{def}}{=} \bigcap_{\mathtt{r}\le 4\mathrm{R}_0(\mathtt{x})} \left\{ \sup_{\upsilon\in\Upsilon_\circ(\mathtt{r})} \left\{ \frac{1}{6\check{\epsilon}\check{\nu}_1}\|\check{\mathcal{Y}}(\upsilon)\| - 2\mathtt{r}^2 \right\} \le \mathfrak{z}_Q(\mathtt{x}, 2p^*+2p)^2 \right\}$$

$$\mathcal{C} \stackrel{\text{def}}{=} \Big\{ \max\{\|\mathcal{D}^{-1}\nabla\mathcal{L}\|, \|\mathrm{D}^{-1}\nabla_{\boldsymbol{\theta}}\mathcal{L}\|, \|\mathrm{H}^{-1}\nabla_{\boldsymbol{\eta}}\mathcal{L}\|\} \le \mathfrak{z}(\mathtt{x}) \Big\}.$$

We estimate

$$\begin{aligned}\mathbb{P}(C(\nabla)) \ge 1 &- \mathbb{P}\left(\mathcal{A}^c\right) - \mathbb{P}\left(\mathcal{B}^c\right) - \mathbb{P}\left(\mathcal{C}^c\right) \\ &- \mathbb{P}\left(\widetilde{\upsilon}, \widetilde{\upsilon}_{\boldsymbol{\theta}^*} \notin \Upsilon_\circ(\mathtt{r}_0)\right) - \mathbb{P}\left(\|\check{\boldsymbol{\xi}}\| > \mathfrak{z}(\mathtt{x}, \mathrm{Cov}(\check{\boldsymbol{\xi}}))\right).\end{aligned}$$

We bound using for both terms Theorem 42 which is applicable due to $(\mathcal{ED}_1)$ and $(\check{\mathcal{E}}\mathcal{D}_1)$:

$$\mathbb{P}(\mathcal{A}^c) \le \mathrm{e}^{-\mathtt{x}}, \;\; \mathbb{P}\left(\mathcal{B}^c\right) \le \mathrm{e}^{-\mathtt{x}}.$$

For the set $\mathcal{C} \subset \Omega$ observe that we can use $(\boldsymbol{\mathcal{I}})$ and Lemma 27 to find

$$\|\mathrm{H}^{-1}\nabla_{\boldsymbol{\eta}}\| \vee \|\mathrm{D}^{-1}\nabla_{\boldsymbol{\theta}}\| \le \|\mathcal{D}^{-1}\nabla\|.$$

This implies that

$$\begin{aligned}&\{\|\mathcal{D}^{-1}\nabla\| \le \mathfrak{z}(\mathtt{x}, I\!\!B)\} \\ &\quad\subseteq \{\|\mathrm{D}^{-1}\nabla_{\boldsymbol{\theta}}\| \vee \|\mathrm{H}^{-1}\nabla_{\boldsymbol{\eta}}\| \le \mathfrak{z}(\mathtt{x}, I\!\!B)\}.\end{aligned}$$

Using the deviation properties of quadratic forms as sketched in Section A we find

$$\mathbb{P}\left(\|\mathcal{D}^{-1}\nabla\| > \mathfrak{z}(\mathtt{x}, I\!\!B)\right) \le 2\mathrm{e}^{-\mathtt{x}}, \;\; \mathbb{P}\big(\|\check{\mathrm{D}}^{-1}\check{\nabla}\| > \mathfrak{z}(\mathtt{x}, \mathrm{Cov}(\check{\boldsymbol{\xi}}))\big) \le 2\mathrm{e}^{-\mathtt{x}}.$$

By the choice of $\mathfrak{z}(\mathtt{x}) > 0$ and $\mathtt{r}_0 > 0$ this gives the claim. ■

We cite Lemma B.2 of (Andresen and Spokoiny, 2014):

Lemma 27 *Let*

$$\mathcal{D}^2 = \begin{pmatrix} D^2 & A \\ A^\top & H^2 \end{pmatrix} \in \mathbb{R}^{(p+p)\times(p+p)}, \quad D \in \mathbb{R}^{p\times p},\ H \in \mathbb{R}^{m\times m} \text{ invertible},$$

$$\|D^{-1}AH^{-1}\| < 1.$$

Then for any $\boldsymbol{\upsilon} = (\boldsymbol{\theta}, \boldsymbol{\eta}) \in \mathbb{R}^{p+m}$ *we have* $\|H^{-1}\boldsymbol{\eta}\| \vee \|D^{-1}\boldsymbol{\theta}\| \le \|\mathcal{D}^{-1}\boldsymbol{\upsilon}\|$.

The next step is to show that the set $\bigcap_{k=1}^{K}(C_{k,k}\cap C_{k,k+1})$ has high probability, that is independent of the number of necessary steps. A close look at the proof of Theorem 4.1 of (Spokoiny, 2012) shows that it actually yields the following modified version:

Theorem 28 ((Spokoiny, 2012), Theorem 4.1) *Suppose* $(\mathcal{E}\mathtt{r})$ *and* $(\mathcal{L}\mathtt{r})$ *with* $\mathtt{b}(\mathtt{r})\equiv\mathtt{b}$. *Further define the following random set*

$$\Upsilon(K)\stackrel{\text{def}}{=}\{\boldsymbol{\upsilon}\in\Upsilon:\mathcal{L}(\boldsymbol{\upsilon},\boldsymbol{\upsilon}^*)\geq -K\}.$$

If for a fixed $\mathtt{r}_0$ *and any* $\mathtt{r}\geq\mathtt{r}_0$, *the following conditions are fulfilled:*

$$1+\sqrt{\mathtt{x}+2p^*}\leq 3\nu_{\mathtt{r}}^2\mathtt{g}(\mathtt{r})/\mathtt{b},$$
$$6\nu_{\mathtt{r}}\sqrt{\mathtt{x}+2p^*+\frac{\mathtt{b}}{9\nu_{\mathtt{r}}^2}K}\leq\mathtt{r}\mathtt{b},$$

then

$$\mathbb{P}(\Upsilon(K)\subseteq\Upsilon_\circ(\mathtt{r}_0))\geq 1-\mathrm{e}^{-\mathtt{x}}.$$

Note that with $(\mathcal{I})$

$$\|\mathrm{D}(\widetilde{\boldsymbol{\theta}}_k-\boldsymbol{\theta}^*)\|\vee\|\mathrm{H}(\widetilde{\boldsymbol{\eta}}_{k(+1)}-\boldsymbol{\eta}^*)\|\leq\frac{1}{1-\nu}\|\mathcal{D}(\widetilde{\boldsymbol{\upsilon}}_{k,k(+1)}-\boldsymbol{\upsilon}^*)\|.$$

With assumption (B_1) and

$$\mathrm{R}_0(\mathtt{x})=\frac{6\nu_{\mathtt{r}}}{\mathtt{b}(1-\nu)}\sqrt{\mathtt{x}+\mathbb{Q}+\frac{\mathtt{b}}{9\nu_{\mathtt{r}}^2}\mathrm{K}_0},$$

this implies the desired result as $\mathcal{L}(\boldsymbol{\upsilon}_{k,k(+1)},\boldsymbol{\upsilon}^*)\geq\mathcal{L}(\widetilde{\boldsymbol{\upsilon}}_0,\boldsymbol{\upsilon}^*)$ such that with Theorem 28

$$\begin{aligned}\mathbb{P}\left(\bigcap_{k=0}^{K}(C_{k,k}\cap C_{k,k+1})\right)&\geq\mathbb{P}\left(\bigcap_{k=0}^{K}(C_{k,k}\cap C_{k,k+1})\cap\{\mathcal{L}(\widetilde{\boldsymbol{\upsilon}}_0,\boldsymbol{\upsilon}^*)\geq-\mathrm{K}_0\}\right)\\&\quad-\mathbb{P}(\mathcal{L}(\widetilde{\boldsymbol{\upsilon}}_0,\boldsymbol{\upsilon}^*)\leq-\mathrm{K}_0)\\&\geq\mathbb{P}\left\{\Upsilon(\mathrm{K}_0)\subset\Upsilon_\circ\Big((1-\nu)\mathrm{R}_0(\mathtt{x})\Big)\right\}-\beta_{(\boldsymbol{A})}\\&\geq 1-\mathrm{e}^{-\mathtt{x}}-\beta_{(\boldsymbol{A})}.\end{aligned}$$

Remark 29 *This also shows that the sets of maximizers* $(\widetilde{\boldsymbol{\upsilon}}_{k,k(+1)})$ *are nonempty and well defined since the maximization always takes place on compact sets of the form* $\{\boldsymbol{\theta}\in\mathbb{R}^p,(\boldsymbol{\theta},\boldsymbol{\eta})\in\Upsilon_\circ(R_0)\}$ *or* $\{\boldsymbol{\eta}\in\mathbb{R}^m,(\boldsymbol{\theta},\boldsymbol{\eta})\in\Upsilon_\circ(R_0)\}$.

Remark 30 *To address the claim of Remark 5 we present the following lemma:*

Lemma 31 *On the set* $C(\nabla)\cap\{\widetilde{\boldsymbol{\upsilon}}_0\in\Upsilon_\circ(R_K)\}$ *it holds*

$$\mathcal{L}(\boldsymbol{\upsilon}_0,\boldsymbol{\upsilon}^*)\geq-(1/2+\epsilon(1+12\nu_0))(R+\mathfrak{z}(\mathtt{x}))^2.$$

Proof *With similar arguments as in the proof of Lemma 32 we have on* $C(\nabla)\subset\Omega$ *that*

$$\begin{aligned}&\mathcal{L}(\boldsymbol{\upsilon}_0)-\mathcal{L}(\boldsymbol{\upsilon}^*)\\&\quad\geq\mathbb{E}[\mathcal{L}(\boldsymbol{\upsilon}_0)-\mathcal{L}(\boldsymbol{\upsilon}^*)]-\|\mathcal{D}^{-1}\nabla\boldsymbol{\zeta}(\boldsymbol{\upsilon}^*)\|R-|\{\nabla\boldsymbol{\zeta}(\widehat{\boldsymbol{\upsilon}})-\nabla\boldsymbol{\zeta}(\boldsymbol{\upsilon}^*)\}(\boldsymbol{\upsilon}_0-\boldsymbol{\upsilon}^*)|\\&\quad\geq-\|\mathcal{D}(\boldsymbol{\upsilon}_0-\boldsymbol{\upsilon}^*)\|^2/2-\|\mathcal{D}^{-1}\nabla\boldsymbol{\zeta}(\boldsymbol{\upsilon}^*)\|R\\&\qquad-\|\mathcal{D}^{-1}\big\{\nabla\mathcal{L}(\widehat{\boldsymbol{\upsilon}})-\nabla\mathcal{L}(\boldsymbol{\upsilon}^*)\big\}\|R-\epsilon R_K^2\\&\quad\geq-R^2/2-\mathfrak{z}(\mathtt{x})R-\epsilon(1+12\nu_0)\left(R^2+\mathfrak{z}(\mathtt{x})^2\right).\end{aligned}$$

■

4.4 Proof Convergence

We derive the a priori bound $\widetilde{\boldsymbol{\upsilon}}_{k,k(+1)}\in\Upsilon_\circ(\mathtt{r}_k)$ with an adequately decreasing sequence $(\mathtt{r}_k)\subset\mathbb{R}_+$ using the argument of Section 4.1, where $\limsup\mathtt{r}_k\approx\mathfrak{z}(\mathtt{x})$. For this purpose we define the *parametric uniform spread*

$$\diamondsuit_Q(\mathtt{r},\mathtt{x})\stackrel{\text{def}}{=}\epsilon\left\{2\mathtt{r}^2+\mathfrak{z}_Q(\mathtt{x},4p^*)^2\right\}(1+6\nu_1^2).\tag{31}$$

Lemma 32 *Assume that for some sequence* $(\mathtt{r}_k^{(l)})_{k\in\mathbb{N}}$

$$\Omega(\mathtt{x})\subseteq\bigcap_{k\in\mathbb{N}}\left\{\boldsymbol{\upsilon}_{k,k(+1)}\in\Upsilon_\circ\left(\mathtt{r}_k^{(l)}\right)\right\}.$$

Then under the assumptions of Theorem 7 we get on $\Omega(\mathtt{x})$ *for all* $k\in\mathbb{N}_0$

$$\begin{aligned}\left\|\mathcal{D}(\widetilde{\boldsymbol{\upsilon}}_{k,k(+1)}-\boldsymbol{\upsilon}^*)\right\|&\leq 2\sqrt{2}(1-\sqrt{\nu})^{-1}\left(\mathfrak{z}(\mathtt{x})+(1+\sqrt{\nu})\nu^k R_0(\mathtt{x})\right)\\&\quad+2\sqrt{2}(1+\sqrt{\nu})\sum_{r=0}^{k-1}\nu^r\diamondsuit_Q\left(\mathtt{r}_r^{(l)}\right)\\&=:\mathtt{r}_k^{(l+1)}.\end{aligned}$$

Proof

1. We first show that on $\Omega(\mathtt{x})$

$$\mathrm{D}(\widetilde{\boldsymbol{\theta}}_k-\boldsymbol{\theta}^*)=\mathrm{D}^{-1}\nabla_{\boldsymbol{\theta}}\mathcal{L}(\boldsymbol{\upsilon}^*)-\mathrm{D}^{-1}\mathcal{A}(\widetilde{\boldsymbol{\eta}}_k-\boldsymbol{\eta}^*)+\boldsymbol{\tau}\big(\mathtt{r}_k^{(l)}\big),\tag{32}$$
$$\mathrm{H}(\widetilde{\boldsymbol{\eta}}_k-\boldsymbol{\eta}^*)=\mathrm{H}^{-1}\nabla_{\boldsymbol{\eta}}\mathcal{L}(\boldsymbol{\upsilon}^*)-\mathrm{H}^{-1}\mathcal{A}^\top(\widetilde{\boldsymbol{\theta}}_{k-1}-\boldsymbol{\theta}^*)+\boldsymbol{\tau}\big(\mathtt{r}_k^{(l)}\big),$$

where - with $\diamondsuit_Q(\mathtt{r},\mathtt{x})$ defined in (31) -

$$\|\boldsymbol{\tau}(\mathtt{r})\| \leq \diamondsuit_Q(\mathtt{r},\mathtt{x}).$$

The proof is the same in each step for both statements such that we only prove the first one. The arguments presented here are similar to those of Theorem D.1 in (Andresen and Spokoiny, 2014). By assumption on $\Omega(\mathtt{x})$ we have $\widetilde{\boldsymbol{\upsilon}}_{k,k(+1)} \in \Upsilon_\circ\big(\mathtt{r}_k^{(l)}\big)$. Define with $\zeta = \mathcal{L} - \mathbb{E}\mathcal{L}$

$$\alpha(\boldsymbol{\upsilon},\boldsymbol{\upsilon}^*) := \mathcal{L}(\boldsymbol{\upsilon}) - \mathcal{L}(\boldsymbol{\upsilon}^*) - \big(\nabla\zeta(\boldsymbol{\upsilon}^*)(\boldsymbol{\upsilon}-\boldsymbol{\upsilon}^*) - \|\mathcal{D}(\boldsymbol{\upsilon}-\boldsymbol{\upsilon}^*)\|^2/2\big).$$

Note that

$$\begin{aligned}\mathcal{L}(\boldsymbol{\upsilon}) - \mathcal{L}(\boldsymbol{\upsilon}^*) &= \nabla\zeta(\boldsymbol{\upsilon}^*)(\boldsymbol{\upsilon}-\boldsymbol{\upsilon}^*) - \|\mathcal{D}(\boldsymbol{\upsilon}-\boldsymbol{\upsilon}^*)\|^2/2 + \alpha(\boldsymbol{\upsilon},\boldsymbol{\upsilon}^*)\\ &= \nabla_{\boldsymbol{\theta}}\zeta(\boldsymbol{\upsilon}^*)(\boldsymbol{\theta}-\boldsymbol{\theta}^*) - \|\mathrm{D}(\boldsymbol{\theta}-\boldsymbol{\theta}^*)\|^2/2 + (\boldsymbol{\theta}-\boldsymbol{\theta}^*)^\top\mathcal{A}(\boldsymbol{\eta}-\boldsymbol{\eta}^*)\\ &\quad +\nabla_{\boldsymbol{\eta}}\zeta(\boldsymbol{\upsilon}^*)(\boldsymbol{\eta}-\boldsymbol{\eta}^*) - \|\mathrm{H}(\boldsymbol{\eta}-\boldsymbol{\eta}^*)\|^2/2 + \alpha(\boldsymbol{\upsilon},\boldsymbol{\upsilon}^*).\end{aligned}$$

Setting $\nabla_{\boldsymbol{\theta}}\mathcal{L}(\widetilde{\boldsymbol{\theta}}_k,\widetilde{\boldsymbol{\eta}}_k) = 0$ we find

$$\mathrm{D}(\widetilde{\boldsymbol{\theta}}_k - \boldsymbol{\theta}^*) - \mathcal{D}^{-1}\big(\nabla_{\boldsymbol{\theta}}\zeta(\boldsymbol{\upsilon}^*) - \mathcal{A}(\widetilde{\boldsymbol{\eta}}_k - \boldsymbol{\eta}^*)\big) = \mathcal{D}^{-1}\nabla_{\boldsymbol{\theta}}\alpha(\widetilde{\boldsymbol{\upsilon}}_{k,k},\boldsymbol{\upsilon}^*).$$

As we assume that $\widetilde{\boldsymbol{\upsilon}}_{k,k} \in \Upsilon_\circ(\mathrm{R}_0)$ it suffices to show that with dominating probability

$$\sup_{(\boldsymbol{\theta},\widetilde{\boldsymbol{\eta}}_k)\in\Upsilon_\circ(\mathrm{R}_0)} \|\mathcal{U}_{\boldsymbol{\theta}}(\boldsymbol{\theta},\widetilde{\boldsymbol{\eta}}_k)\| \leq \diamondsuit(\mathtt{r}_k^{(l)}),$$

where

$$\mathcal{U}_{\boldsymbol{\theta}}(\boldsymbol{\theta},\widetilde{\boldsymbol{\eta}}_k) \stackrel{\mathrm{def}}{=} \mathrm{D}^{-1}\big\{\nabla_{\boldsymbol{\theta}}\mathcal{L}(\widetilde{\boldsymbol{\upsilon}}_{k,k}) - \nabla_{\boldsymbol{\theta}}\mathcal{L}(\boldsymbol{\upsilon}^*) - \mathrm{D}^2(\boldsymbol{\theta}-\boldsymbol{\theta}^*) - \mathcal{A}(\widetilde{\boldsymbol{\eta}}_k - \boldsymbol{\eta}^*)\big\}.$$

To see this note first that with Lemma 27 $\|\mathrm{D}^{-1}\Pi_{\boldsymbol{\theta}}\mathcal{D}\boldsymbol{\upsilon}\| \leq \|\mathcal{D}^{-1}\mathcal{D}\boldsymbol{\upsilon}\|$. This gives by condition $(\boldsymbol{\mathcal{L}_0})$, Lemma 27 and Taylor expansion

$$\begin{aligned}\sup_{(\boldsymbol{\theta},\widetilde{\boldsymbol{\eta}}_k)\in\Upsilon_\circ(\mathtt{r})} \|\mathbb{E}\mathcal{U}(\boldsymbol{\theta},\widetilde{\boldsymbol{\eta}}_k)\| &\leq \sup_{\boldsymbol{\upsilon}\in\Upsilon_\circ(\mathtt{r})} \|\mathrm{D}^{-1}\Pi_{\boldsymbol{\theta}}\Big(\nabla\mathbb{E}\mathcal{L}(\boldsymbol{\upsilon}) - \nabla\mathbb{E}\mathcal{L}(\boldsymbol{\upsilon}^*) - \mathcal{D}(\boldsymbol{\upsilon}-\boldsymbol{\upsilon}^*)\Big)\|\\ &\leq \sup_{\boldsymbol{\upsilon}\in\Upsilon_\circ(\mathtt{r})} \|\mathrm{D}^{-1}\Pi_{\boldsymbol{\theta}}\mathcal{D}\|\|\mathcal{D}^{-1}\nabla^2\mathbb{E}\mathcal{L}(\boldsymbol{\upsilon})^2\mathcal{D}^{-1} - I_{p^*}\|^{1/2}\mathtt{r}\\ &\leq \epsilon\mathtt{r}^2.\end{aligned}$$

For the remainder note that again with Lemma 27

$$\|\mathrm{D}^{-1}\Big(\nabla_{\boldsymbol{\theta}}\zeta(\boldsymbol{\upsilon}) - \nabla_{\boldsymbol{\theta}}\zeta(\boldsymbol{\upsilon}^*)\Big)\| \leq \|\mathcal{D}^{-1}\Big(\nabla\zeta(\boldsymbol{\upsilon}) - \nabla\zeta(\boldsymbol{\upsilon}^*)\Big)\|.$$

This yields that on $\Omega(\mathtt{x})$

$$\begin{aligned}\sup_{(\boldsymbol{\theta},\widetilde{\boldsymbol{\eta}}_k)\in\Upsilon_\circ(\mathtt{r})} \Big\|\mathcal{U}_{\boldsymbol{\theta}}(\boldsymbol{\theta},\widetilde{\boldsymbol{\eta}}_k) - \mathbb{E}\mathcal{U}_{\boldsymbol{\theta}}(\boldsymbol{\theta},\widetilde{\boldsymbol{\eta}}_k)\Big\| &\leq \sup_{\boldsymbol{\upsilon}\in\Upsilon_\circ(\mathtt{r})} \Big\|\mathrm{D}^{-1}\Big(\nabla_{\boldsymbol{\theta}}\zeta(\boldsymbol{\upsilon}) - \nabla_{\boldsymbol{\theta}}\zeta(\boldsymbol{\upsilon}^*)\Big)\Big\|\\ &\leq \sup_{\boldsymbol{\upsilon}\in\Upsilon_\circ(\mathtt{r})} \Big\{\frac{1}{6\nu_1\epsilon}\|\mathcal{Y}(\boldsymbol{\upsilon})\|\Big\} 6\nu_1\epsilon \leq 6\nu_1\epsilon\big\{\mathfrak{z}_Q(\mathtt{x},4p^*) + 2\mathtt{r}^2\big\}.\end{aligned}$$

Using the same argument for $\widetilde{\boldsymbol{\eta}}_k$ gives the claim.

2. We prove the apriori bound for the distance of the k. estimator to the oracle

$$\big\|\mathcal{D}(\widetilde{\boldsymbol{\upsilon}}_{k,k(+1)} - \boldsymbol{\upsilon}^*)\big\| \leq \mathtt{r}_k^{(l+1)}.$$

To see this we first use the inequality

$$\|\mathcal{D}(\widetilde{\boldsymbol{\upsilon}}_{k,k(+1)} - \boldsymbol{\upsilon}^*)\| \leq \sqrt{2}\|\mathrm{D}(\widetilde{\boldsymbol{\theta}}_k - \boldsymbol{\theta}^*)\| + \sqrt{2}\|\mathrm{H}(\widetilde{\boldsymbol{\eta}}_{k(+1)} - \boldsymbol{\eta}^*)\|.$$

Now we find with (32)

$$\begin{aligned}\|\mathrm{D}(\widetilde{\boldsymbol{\theta}}_k - \boldsymbol{\theta}^*)\| &\leq \|\mathrm{D}^{-1}\nabla_{\boldsymbol{\theta}}\mathcal{L}(\boldsymbol{\upsilon}^*)\| + \|\mathrm{D}^{-1}\mathcal{A}(\widetilde{\boldsymbol{\eta}}_k - \boldsymbol{\eta}^*)\| + \|\boldsymbol{\tau}\big(\mathtt{r}_k^{(l)}\big)\|\\ &\leq \|\mathrm{D}^{-1}\nabla_{\boldsymbol{\theta}}\mathcal{L}(\boldsymbol{\upsilon}^*)\| + \|\mathrm{D}^{-1}\mathcal{A}\mathrm{H}^{-1}\|\|\mathrm{H}(\widetilde{\boldsymbol{\eta}}_k - \boldsymbol{\eta}^*)\| + \|\boldsymbol{\tau}\big(\mathtt{r}_k^{(l)}\big)\|.\end{aligned}$$

Next we use that on $\Omega(\mathtt{x})$

$$\|\mathrm{D}^{-1}\mathcal{A}\mathrm{H}^{-1}\| \leq \sqrt{\nu},\ \|\mathrm{D}^{-1}\nabla_{\boldsymbol{\theta}}\mathcal{L}(\boldsymbol{\upsilon}^*)\| \leq \mathfrak{z}(\mathtt{x}),\ \|\mathrm{H}^{-1}\nabla_{\boldsymbol{\eta}}\mathcal{L}(\boldsymbol{\upsilon}^*)\| \leq \mathfrak{z}(\mathtt{x}),$$

and

$$\|\mathrm{H}(\widetilde{\boldsymbol{\eta}}_k - \boldsymbol{\eta}^*)\| \leq \|\mathrm{H}^{-1}\nabla_{\boldsymbol{\eta}}\mathcal{L}(\boldsymbol{\upsilon}^*)\| + \|\mathrm{H}^{-1}\mathcal{A}^\top(\widetilde{\boldsymbol{\theta}}_{k-1} - \boldsymbol{\theta}^*)\| + \|\boldsymbol{\tau}\big(\mathtt{r}_k^{(l)}\big)\|,$$

to derive the recursive formula

$$\|\mathrm{D}(\widetilde{\boldsymbol{\theta}}_k - \boldsymbol{\theta}^*)\| \leq (1+\sqrt{\nu})\Big(\mathfrak{z}(\mathtt{x}) + \|\boldsymbol{\tau}\big(\mathtt{r}_k^{(l)}\big)\|\Big) + \nu\|\mathrm{D}(\widetilde{\boldsymbol{\theta}}_{k-1} - \boldsymbol{\theta}^*)\|.$$

Deriving the analogous formula for $\|\mathrm{H}(\widetilde{\boldsymbol{\eta}}_k - \boldsymbol{\eta}^*)\|$ and solving the recursion gives the claim. ■

Lemma 33 *Assume the same as in Theorem 7. Further assume that* (17) *is met with* $\mathtt{C}(\nu)$ *defined in* (18)*. Then*

$$\Omega(\mathtt{x}) \subseteq \bigcap_{k\in\mathbb{N}} \big\{\boldsymbol{\upsilon}_{k,k(+1)} \in \Upsilon_\circ(\mathtt{r}_k^*)\big\},$$

where - with $\mathtt{C}(\nu) \geq 0$ *defined in* (18) -

$$\begin{aligned}\mathtt{r}_k^* \leq & \left(\mathtt{C}(\nu) + \frac{4\epsilon\mathtt{C}(\nu)^4\mathfrak{z}(\mathtt{x})}{1-\epsilon\mathtt{C}(\nu)\mathfrak{z}(\mathtt{x})}\right)2\mathfrak{z}(\mathtt{x}) \\ & +\nu^k\left(\mathtt{C}(\nu) + \frac{4\epsilon\mathtt{C}(\nu)^4 R_0}{1-\epsilon\mathtt{C}(\nu)R_0}\right)R_0.\end{aligned} \tag{33}$$

Proof We proof this claim via induction. On $\Omega(\mathtt{x})$ we have

$$\boldsymbol{v}_{k,k(+1)} \in \Upsilon_\circ(\mathrm{R}_0), \quad \text{set } \mathtt{r}_k^{(0)} \stackrel{\text{def}}{=} \mathrm{R}_0.$$

Now with Lemma 32 we find that if

$$\Omega(\mathtt{x}) \subseteq \bigcap_{k\in\mathbb{N}}\left\{\boldsymbol{v}_{k,k(+1)} \in \Upsilon_\circ(\mathtt{r}_k^{(l)})\right\},$$

that then

$$\Omega(\mathtt{x}) \subseteq \bigcap_{k\in\mathbb{N}}\left\{\boldsymbol{v}_{k,k(+1)} \in \Upsilon_\circ(\mathtt{r}_k^{(l+1)})\right\},$$

where

$$\begin{aligned}\mathtt{r}_k^{(l)} \leq & \, 2\sqrt{2}(1-\sqrt{\nu})^{-1}\left(\mathfrak{z}(\mathtt{x}) + (1+\sqrt{\nu})\nu^k\mathrm{R}_0(\mathtt{x})\right) \\ & +2\sqrt{2}(1+\sqrt{\nu})\sum_{r=0}^{k-1}\nu^r \diamondsuit_Q\left(\mathtt{r}_{k-r}^{(l-1)}, \mathtt{x}\right).\end{aligned}$$

Setting $l = 1$ this gives

$$\mathtt{r}_k^{(1)} \leq 2\sqrt{2}(1-\sqrt{\nu})^{-1}\left\{(\mathfrak{z}(\mathtt{x}) + \diamondsuit_Q(\mathrm{R}_0, \mathtt{x})) + (1+\sqrt{\nu})\nu^k\mathrm{R}_0(\mathtt{x})\right\}.$$

We show that

$$\Omega(\mathtt{x}) \subseteq \bigcap_{k\in\mathbb{N}}\left\{\boldsymbol{v}_{k,k(+1)} \in \Upsilon_\circ\left(\limsup_{l\to\infty}\mathtt{r}_k^{(l)}\right)\right\} \subseteq \bigcap_{k\in\mathbb{N}}\left\{\boldsymbol{v}_{k,k(+1)} \in \Upsilon_\circ(\mathtt{r}_k^*)\right\}.$$

So we have to show that $\limsup_{l\to\infty}\mathtt{r}_k^{(l)} \leq \mathtt{r}_k^*$ in (33). For this we estimate further

$$\begin{aligned}\mathtt{r}_k^{(l)} \leq & \, 2\sqrt{2}(1-\sqrt{\nu})^{-1}\left(\mathfrak{z}(\mathtt{x}) + (1+\sqrt{\nu})\nu^k\mathrm{R}_0(\mathtt{x})\right) \\ & +2\sqrt{2}(1+\sqrt{\nu})\epsilon\sum_{r=0}^{k-1}\nu^r\left(\left(\mathtt{r}_{k-r}^{(l-1)}\right)^2 + \mathfrak{z}(\mathtt{x})^2\right) \\ \leq & \, 2\sqrt{2}(1-\sqrt{\nu})^{-1}\left(\mathfrak{z}(\mathtt{x}) + \epsilon\mathfrak{z}(\mathtt{x})^2 + (1+\sqrt{\nu})\nu^k\mathrm{R}_0(\mathtt{x})\right) \\ & +2\sqrt{2}(1+\sqrt{\nu})\epsilon\sum_{r=0}^{k-1}\nu^r\left(\mathtt{r}_{k-r}^{(l-1)}\right)^2 \\ \leq & \, \mathtt{C}(\nu)\left\{\left(\mathfrak{z}(\mathtt{x}) + \epsilon\mathfrak{z}(\mathtt{x})^2\right) + \nu^k\mathrm{R}_0 + \epsilon\sum_{r=0}^{k-1}\nu^r\left(\mathtt{r}_{k-r}^{(l-1)}\right)^2\right\},\end{aligned}$$

where $\mathtt{C}(\nu) > 0$ is defined in (18). We set

$$A_{s,k}^{(l)} \stackrel{\text{def}}{=} \sum_{r_1=0}^{k-1}\nu^{r_1}\left(\sum_{r_2=0}^{k-r_1-1}\nu^{r_2}\left(\dots\sum_{r_s=0}^{k-r_1-\dots-r_{s-1}-1}\nu^{r_s}\left(\mathtt{r}_{k-r_1-\dots-r_s}^{(l-1)}\right)^2\dots\right)^2\right)^2.$$

Claim

$$\begin{aligned}A_{s,k}^{(l)} \leq & \, 4^{\sum_{t=0}^{s-1}2^t}\mathtt{C}(\nu)^{2^s}\left\{\left(\frac{1}{1-\nu}\right)^{\sum_{t=0}^{s-1}2^t}\left(\mathfrak{z}(\mathtt{x}) + \epsilon\mathfrak{z}(\mathtt{x})^2\right)^{2^s}\right. \\ & \left.+\nu^k\left(\frac{1}{\nu^{-1}-1}\right)^{\sum_{t=0}^{s-1}2^t}\mathrm{R}_0^{2^s}\right\} \\ & +4^{\sum_{t=0}^{s-1}2^t}(\mathtt{C}(\nu)\epsilon)^{2^s}A_{s+1,k}^{(l-1)}.\end{aligned} \tag{34}$$

We proof this claim via induction. Clearly

$$\begin{aligned}A_{1,k}^{(l)} = & \sum_{r_1=0}^{k-1}\nu^{r_1}\left(\mathtt{r}_{k-r_1}^{(l-1)}\right)^2 \leq 4\mathtt{C}(\nu)^2\sum_{r_1=0}^{k-1}\nu^{r_1}\left\{\left(\mathfrak{z}(\mathtt{x}) + \epsilon\mathfrak{z}(\mathtt{x})^2\right)^2 + \nu^{2(k-r_1)}\mathrm{R}_0^2\right\} \\ & +4\mathtt{C}(\nu)^2\epsilon^2\sum_{r_1=0}^{k-1}\nu^{r_1}\left(\sum_{r_2=0}^{k-r_1-r_2-1}\nu^{r_2}\left(\mathtt{r}_{k-r_1-r_2}^{(l-2)}\right)^2\right)^2 \\ \leq & \, 4\mathtt{C}(\nu)^2\left\{\frac{1}{1-\nu}\left(\mathfrak{z}(\mathtt{x}) + \epsilon\mathfrak{z}(\mathtt{x})^2\right)^2 + \frac{\nu^k}{\nu^{-1}-1}\mathrm{R}_0^2\right\} \\ & +4\mathtt{C}(\nu)^2\epsilon^2A_{2,k}^{(l-1)}.\end{aligned}$$

Furthermore

$$A_{s,k}^{(l)} \stackrel{\text{def}}{=} \sum_{r_1=0}^{k-1} \nu^{r_1} \left(\sum_{r_2=0}^{k-r_1-1} \nu^{r_2} \left(\dots \sum_{r_s=0}^{k-r_1-\dots-r_{s-1}-1} \nu^{r_s} \left(\mathtt{r}_{k-r_1-\dots-r_s}^{(l-1)} \right)^2 \dots \right)^2 \right)^2$$
$$= \sum_{r_1=0}^{k-1} \nu^{r_1} \left(A_{s-1,k-r_1}^{(l)} \right)^2. \tag{35}$$

Plugging in (34) we get for $s \geq 2$

$$A_{s,k}^{(l)} \leq \sum_{r_1=0}^{k-1} \nu^{r_1} \left(4^{\sum_{t=0}^{s-2} 2^t} \mathtt{C}(\nu)^{2^{s-1}} \left\{ \left(\frac{1}{1-\nu} \right)^{\sum_{t=0}^{s-2} 2^t} \left(\mathfrak{z}(\mathtt{x}) + \epsilon \mathfrak{z}(\mathtt{x})^2 \right)^{2^{s-1}} \right.\right.$$
$$\left.\left. + \nu^k \left(\frac{1}{\nu^{-1}-1} \right)^{\sum_{t=0}^{s-2} 2^t} \mathrm{R}_0^{2^{s-1}} \right\} \right.$$
$$\left. + 4^{\sum_{t=0}^{s-2} 2^t} (\mathtt{C}(\nu)\epsilon)^{2^{s-1}} A_{s,k-r_1}^{(l-1)} \right)^2.$$

Shifting the index this gives

$$A_{s,k}^{(l)} \leq 4 \sum_{r_1=0}^{k-1} \nu^{r_1} \left(4^{\sum_{t=1}^{s-1} 2^t} \mathtt{C}(\nu)^{2^s} \left\{ \left(\frac{1}{1-\nu} \right)^{\sum_{t=1}^{s-1} 2^{t-1}} \left(\mathfrak{z}(\mathtt{x}) + \epsilon \mathfrak{z}(\mathtt{x})^2 \right)^{2^s} \right.\right.$$
$$\left.\left. + \nu^k \left(\frac{1}{\nu^{-1}-1} \right)^{\sum_{t=1}^{s-1} 2^t} \mathrm{R}_0^{2^s} \right\} \right.$$
$$\left. + 4^{\sum_{t=1}^{s-1} 2^t} (\mathtt{C}(\nu)\epsilon)^{2^s} (A_{s,k-r_1}^{(l-1)})^2 \right).$$

Direct calculation then leads to

$$A_{s,k}^{(l)} \leq 4^{\sum_{t=0}^{s-1} 2^t} \mathtt{C}(\nu)^{2^s} \left\{ \left(\frac{1}{1-\nu} \right)^{\sum_{t=0}^{s-1} 2^t} \left(\mathfrak{z}(\mathtt{x}) + \epsilon \mathfrak{z}(\mathtt{x})^2 \right)^{2^s} \right.$$
$$\left. + \nu^k \left(\frac{1}{\nu^{-1}-1} \right)^{\sum_{t=0}^{s-1} 2^t} \mathrm{R}_0^{2^s} \right\}$$
$$+ 4^{\sum_{t=0}^{s-1} 2^t} (\mathtt{C}(\nu)\epsilon)^{2^s} \sum_{r_1=0}^{k-1} \nu^{r_1} (A_{s,k-r_1}^{(l-1)})^2,$$

which gives (34) with (35). Similarly we can prove

$$A_{s,k}^{(1)} = \left(\frac{1}{1-\nu} \right)^{2^s-1} \mathrm{R}_0^{2^s}.$$

Abbreviate

$$\lambda_s \stackrel{\text{def}}{=} 4^{2^s-1} \mathtt{C}(\nu)^{2^s}, \quad \beta_s \stackrel{\text{def}}{=} 4^{2^s-1} (\mathtt{C}(\nu)\epsilon)^{2^s},$$
$$\mathfrak{z}_s(\mathtt{x}) \stackrel{\text{def}}{=} \left(\frac{1}{1-\nu} \right)^{2^s-1} \left(\mathfrak{z}(\mathtt{x}) + \epsilon \mathfrak{z}(\mathtt{x})^2 \right)^{2^s}, \quad \mathrm{R}_s \stackrel{\text{def}}{=} \left(\frac{1}{\nu^{-1}-1} \right)^{2^s-1} \mathrm{R}_0^{2^s}.$$

Then

$$\mathtt{r}_k^{(l)} \leq \mathtt{C}(\nu) \left\{ \left(\mathfrak{z}(\mathtt{x}) + \epsilon \mathfrak{z}(\mathtt{x})^2 \right) + \nu^k \mathrm{R}_0 + \epsilon A_{1,k}^{(l)} \right\}$$
$$\leq \sum_{s=0}^{l-1} \lambda_s \prod_{r=0}^{s-1} \beta_r \mathfrak{z}_s(\mathtt{x}) + \nu^k \sum_{s=0}^{l-1} \lambda_s \prod_{r=0}^{s-1} \beta_r \mathrm{R}_s + \prod_{r=0}^{l-1} \beta_r \mathrm{R}_l. \tag{36}$$

We estimate further

$$\sum_{s=0}^{l-1} \lambda_s \prod_{r=0}^{s-1} \beta_r \mathfrak{z}_s(\mathtt{x}) - \mathtt{C}(\nu) \left(\mathfrak{z}(\mathtt{x}) + \epsilon \mathfrak{z}(\mathtt{x})^2 \right) = \sum_{s=1}^{l-1} \lambda_s \prod_{r=0}^{s-1} \beta_r \mathfrak{z}_s(\mathtt{x})$$
$$\leq \sum_{s=1}^{l-1} 4^{2^s} \mathtt{C}(\nu)^{2^{s+1}} \epsilon^{2^s-1} \left(\frac{1}{1-\nu} \right)^{2^s-1} \left(\mathfrak{z}(\mathtt{x}) + \epsilon \mathfrak{z}(\mathtt{x})^2 \right)^{2^s}$$
$$= \epsilon 4^2 \mathtt{C}(\nu)^4 \left(\frac{1}{1-\nu} \right) \left(\mathfrak{z}(\mathtt{x}) + \epsilon \mathfrak{z}(\mathtt{x})^2 \right)^2$$
$$\sum_{s=1}^{l-1} \left(\epsilon 4 \mathtt{C}(\nu) \frac{1}{1-\nu} \left(\mathfrak{z}(\mathtt{x}) + \epsilon \mathfrak{z}(\mathtt{x})^2 \right) \right)^{2^s-1}.$$

Assuming (17) and the definition of $\mathrm{R}_0 > \mathfrak{z}(\mathtt{x})$ this gives

$$\sum_{s=0}^{l-1} \lambda_s \prod_{r=0}^{s-1} \beta_r \mathfrak{z}_s(\mathtt{x}) \leq \left(\mathtt{C}(\nu) + \frac{4\epsilon \mathtt{C}(\nu)^4 \mathfrak{z}(\mathtt{x})}{1 - \epsilon \mathtt{C}(\nu) \mathfrak{z}(\mathtt{x})} \right) 2\mathfrak{z}(\mathtt{x}).$$

With the same argument we find under (17) that

$$\nu^k \sum_{s=0}^{l-1} \lambda_s \prod_{r=0}^{s-1} \beta_r \mathrm{R}_s \leq \nu^k \left(\mathtt{C}(\nu) + \frac{4\epsilon \mathtt{C}(\nu)^4 \mathrm{R}_0}{1 - \epsilon \mathtt{C}(\nu) \mathrm{R}_0} \right) \mathrm{R}_0.$$

Additionally (17) implies

$$\prod_{r=0}^{l-1} \beta_r \mathrm{R}_r \leq \left(\epsilon 4 \mathtt{C}(\nu) \frac{1}{\nu^{-1}-1} \right)^{2^{l-1}} \mathrm{R}_0^{2^l} \to 0.$$

Plugging these bounds into (36) and letting $l \to \infty$ gives the claim. ■

4.5 Result after Convergence

In the previous section we showed that

$$\Omega(\mathtt{x}) \subset \bigcap_{\mathtt{r}\leq 4\mathrm{R}_0(\mathtt{x})} \left\{ \sup_{\boldsymbol{\upsilon}\in\Upsilon_\circ(\mathtt{r})} \left\{ \frac{1}{6\breve{\epsilon}\breve{\nu}_1}\|\breve{\mathcal{Y}}(\boldsymbol{\upsilon})\| - 2\mathtt{r}^2 \right\} \leq \mathfrak{z}_Q(\mathtt{x}, 2p^* + 2p)^2 \right\}$$
$$\cap \bigcap_{k\in\mathbb{N}} \{\boldsymbol{\upsilon}_{k,k} \in \Upsilon_\circ(\mathtt{r}_k^*),\, \boldsymbol{\upsilon}_{k,k+1} \in \Upsilon_\circ(\mathtt{r}_k^*)\} \cap \{\widetilde{\boldsymbol{\upsilon}}, \widetilde{\boldsymbol{\upsilon}}_{\boldsymbol{\theta}^*} \in \Upsilon_\circ(\mathtt{r}_0)\},$$

where $\mathtt{r}_k^*$ is defined in (33). The claim of Theorem 7 follows with the following lemma:

Lemma 34 *Assume* $(\breve{\mathcal{E}}\mathcal{D}_1)$, $(\breve{\mathcal{L}}_0)$, *and* $(\mathcal{I})$. *Then it holds on* $\Omega(\mathtt{x}) \subseteq \epsilon$ *that for all* $k \in \mathbb{N}$

$$\left\|\breve{D}\big(\widetilde{\boldsymbol{\theta}}_k - \boldsymbol{\theta}^*\big) - \breve{\boldsymbol{\xi}}\right\| \leq \breve{\Diamond}_Q(\mathtt{r}_k, \mathtt{x}), \tag{37}$$
$$\left|2\breve{L}(\widetilde{\boldsymbol{\theta}}_k, \boldsymbol{\theta}^*) - \|\breve{\boldsymbol{\xi}}\|^2\right| \leq 5\left(\|\breve{D}^{-1}\breve{\nabla}\| + \breve{\Diamond}_Q(\mathtt{r}_k, \mathtt{x})\right)\breve{\Diamond}_Q(\mathtt{r}_k, \mathtt{x}), \tag{38}$$

where the spread $\breve{\Diamond}(\mathtt{r}, \mathtt{x})$ *is defined in* (21) *and where*

$$\mathtt{r}_k \stackrel{\mathrm{def}}{=} \mathtt{r}_k^* \vee \mathtt{r}_0.$$

Proof The proof is nearly the same as that of Theorem 2.2 of (Andresen and Spokoiny, 2014) which is inspired by the proof of Theorem 1 of (Murphy and van der Vaart, 2000). So we only sketch it and refer the reader to (Andresen and Spokoiny, 2014) for the skipped arguments. We define

$$l : \mathbb{R}^p \times \Upsilon \to \mathbb{R}, \;\; (\boldsymbol{\theta}_1, \boldsymbol{\theta}_2, \boldsymbol{\eta}) \mapsto \mathcal{L}(\boldsymbol{\theta}_1, \boldsymbol{\eta} + \mathrm{H}^{-2}\mathcal{A}^\top(\boldsymbol{\theta}_2 - \boldsymbol{\theta}_1)).$$

Note that

$$\nabla_{\boldsymbol{\theta}_1} l(\boldsymbol{\theta}_1, \boldsymbol{\theta}_2, \boldsymbol{\eta}) = \breve{\nabla}_{\boldsymbol{\theta}}\mathcal{L}(\boldsymbol{\theta}_1, \boldsymbol{\eta} + \mathrm{H}^{-2}\mathcal{A}^\top(\boldsymbol{\theta}_2 - \boldsymbol{\theta}_1)), \;\; \widetilde{\boldsymbol{\theta}}_k = \operatorname*{argmax}_{\boldsymbol{\theta}} l(\boldsymbol{\theta}, \widetilde{\boldsymbol{\theta}}_k, \widetilde{\boldsymbol{\eta}}_k),$$

such that $\breve{\nabla}_{\boldsymbol{\theta}}\mathcal{L}(\widetilde{\boldsymbol{\theta}}_k, \widetilde{\boldsymbol{\eta}}_k) = 0$. This gives

$$\left\|\breve{\mathrm{D}}\big(\widetilde{\boldsymbol{\theta}}_k - \boldsymbol{\theta}^*\big) - \breve{\boldsymbol{\xi}}\right\| = \left\|\breve{\mathrm{D}}^{-1}\breve{\nabla}\mathcal{L}(\widetilde{\boldsymbol{\theta}}_k, \widetilde{\boldsymbol{\eta}}_k) - \breve{\mathrm{D}}^{-1}\breve{\nabla}\mathcal{L}(\boldsymbol{\upsilon}^*) + \breve{\mathrm{D}}\big(\widetilde{\boldsymbol{\theta}}_k - \boldsymbol{\theta}^*\big)\right\|.$$

Now the right hand side can be bounded just as in the proof of Theorem 2.2 of (Andresen and Spokoiny, 2014). This gives (37).

For (38) we can represent:

$$\breve{L}(\widetilde{\boldsymbol{\theta}}_k) - \breve{L}(\boldsymbol{\theta}^*) = l(\widetilde{\boldsymbol{\theta}}_k, \widetilde{\boldsymbol{\theta}}_k, \widetilde{\boldsymbol{\eta}}_{k+1}) - l(\boldsymbol{\theta}^*, \boldsymbol{\theta}^*, \widetilde{\boldsymbol{\eta}}_{\boldsymbol{\theta}^*}),$$

where

$$\widetilde{\boldsymbol{\eta}}_{\boldsymbol{\theta}^*} \stackrel{\mathrm{def}}{=} \Pi_{\boldsymbol{\eta}} \operatorname*{argmax}_{\substack{\boldsymbol{\upsilon}\in\Upsilon,\\ \Pi_{\boldsymbol{\theta}}\boldsymbol{\upsilon}=\boldsymbol{\theta}^*}} \mathcal{L}(\boldsymbol{\upsilon}).$$

Due to the definition of $\widetilde{\boldsymbol{\theta}}_k$ and $\widetilde{\boldsymbol{\eta}}_{k+1}$

$$l(\widetilde{\boldsymbol{\theta}}_k, \boldsymbol{\theta}^*, \widetilde{\boldsymbol{\eta}}_{\boldsymbol{\theta}^*}) - l(\boldsymbol{\theta}^*, \boldsymbol{\theta}^*, \widetilde{\boldsymbol{\eta}}_{\boldsymbol{\theta}^*}) \leq \breve{L}(\widetilde{\boldsymbol{\theta}}_k) - \breve{L}(\boldsymbol{\theta}^*) \leq l(\widetilde{\boldsymbol{\theta}}_k, \widetilde{\boldsymbol{\theta}}_k, \widetilde{\boldsymbol{\eta}}_{k+1}) - l(\boldsymbol{\theta}^*, \widetilde{\boldsymbol{\theta}}_k, \widetilde{\boldsymbol{\eta}}_{k+1}).$$

Again the remaining steps are exactly the same as in the proof of Theorem 2.2 of (Andresen and Spokoiny, 2014).

■

5. Proof of Corollary 13

Proof Note that with the argument of Section 4.3 $\mathbb{P}(\epsilon'(\mathtt{x})) \geq 1 - 8\mathrm{e}^{-\mathtt{x}} - \beta$ where with $\Omega(\mathtt{x})$ from (29)

$$\epsilon'(\mathtt{x}) = \Omega(\mathtt{x}) \cap \{\widetilde{\boldsymbol{\upsilon}} \in \Upsilon_\circ(\mathtt{r}_0)\}.$$

On $\epsilon'(\mathtt{x})$ it holds due to Theorem 7 and due to Theorem 2.1 of (Andresen and Spokoiny, 2014)

$$\|\breve{\mathrm{D}}(\widetilde{\boldsymbol{\theta}}_k - \boldsymbol{\theta}^*) - \breve{\boldsymbol{\xi}}\| \leq \breve{\Diamond}_Q(\mathtt{r}_k, \mathtt{x}), \;\; \|\breve{\mathrm{D}}(\widetilde{\boldsymbol{\theta}} - \boldsymbol{\theta}^*) - \breve{\boldsymbol{\xi}}\| \leq \breve{\Diamond}(\mathtt{r}_0, \mathtt{x}).$$

Now the claim follows with the triangular inequality and noting that $\breve{\Diamond}(\mathtt{r}_0, \mathtt{x}) \leq \breve{\Diamond}_Q(\mathtt{r}_0, \mathtt{x})$.
■

6. Proof of Theorem 14

We prove this Theorem in a similar manner to the convergence result in Lemma 32. Redefine the set $\Omega(\mathtt{x})$

$$\Omega(\mathtt{x}) \stackrel{\mathrm{def}}{=} \bigcap_{k=0}^{K} (C_{k,k} \cap C_{k,k+1}) \cap C(\nabla) \cap \{\mathcal{L}(\widetilde{\boldsymbol{\upsilon}}_0) - \mathcal{L}(\boldsymbol{\upsilon}^*) \geq -\mathrm{K}_0\}, \text{ where} \tag{39}$$
$$C_{k,k(+1)} = \Big\{\|\mathcal{D}(\widetilde{\boldsymbol{\upsilon}}_{k,k(+1)} - \boldsymbol{\upsilon}^*)\| \leq \mathrm{R}_0(\mathtt{x}),\, \|\mathrm{D}(\widetilde{\boldsymbol{\theta}}_k - \boldsymbol{\theta}^*)\| \leq \mathrm{R}_0(\mathtt{x}),$$
$$\|\mathrm{H}(\widetilde{\boldsymbol{\eta}}_{k(+1)} - \boldsymbol{\eta}^*)\| \leq \mathrm{R}_0(\mathtt{x})\Big\},$$
$$C(\nabla) = \left\{ \sup_{\boldsymbol{\upsilon}\in\Upsilon_\circ(\mathrm{R}_0(\mathtt{x}))} \|\mathcal{Y}(\nabla^2)(\boldsymbol{\upsilon})\| \leq 9\nu_2\epsilon_2\mathfrak{z}_1(\mathtt{x}, 6p^*)\mathrm{R}_0(\mathtt{x}) \right\}$$
$$\cap\{\|\mathcal{D}^{-1}\nabla^2\boldsymbol{\zeta}(\boldsymbol{\upsilon}^*)\| \leq \mathfrak{z}(\mathtt{x}, \nabla^2\boldsymbol{\zeta}(\boldsymbol{\upsilon}^*))\}.$$

where

$$\mathcal{Y}(\nabla^2)(\boldsymbol{\upsilon}) \stackrel{\text{def}}{=} \mathcal{D}^{-1}\left(\nabla^2\boldsymbol{\zeta}(\boldsymbol{\upsilon}) - \nabla^2\boldsymbol{\zeta}(\boldsymbol{\upsilon}^*)\right) \in \mathbb{R}^{p^{*2}}.$$

We see that on $\Omega(\mathtt{x})$

$$\boldsymbol{\upsilon}_{k,k(+1)} \in \widetilde{\Upsilon}_\circ(\mathrm{R}_0) \stackrel{\text{def}}{=} \{\|\mathcal{D}(\boldsymbol{\upsilon}-\widetilde{\boldsymbol{\upsilon}})\| \le \mathrm{R}_0 + \mathtt{r}_0\} \cap \Upsilon_\circ(\mathrm{R}_0).$$

Lemma 35 *Under the conditions of Theorem 14*

$$\mathbb{P}(\Omega(\mathtt{x})) \ge 1 - 3\mathrm{e}^{-\mathtt{x}} - \beta.$$

Proof The proof is very similar to the one presented in Section 4.3, so we only give a sketch. By assumption

$$\mathbb{P}\left(\|\mathcal{D}^{-1}\nabla^2\boldsymbol{\zeta}(\boldsymbol{\upsilon}^*)\| \le \mathfrak{z}(\mathtt{x}, \nabla^2\boldsymbol{\zeta}(\boldsymbol{\upsilon}^*))\right) \ge 1 - \mathrm{e}^{-\mathtt{x}},$$

and due to $(\mathcal{ED}_2)$ with Theorem 47

$$\mathbb{P}\left(\sup_{\boldsymbol{\upsilon}\in\Upsilon_\circ(\mathrm{R}_0(\mathtt{x}))} \|\mathcal{Y}(\nabla^2)(\boldsymbol{\upsilon})\| \le 9\nu_2\epsilon_2\mathfrak{z}_1(\mathtt{x}, 6p^*)\mathrm{R}_0(\mathtt{x})\right) \ge 1 - \mathrm{e}^{-\mathtt{x}}.$$

■

Lemma 36 *Assume for some sequence* $(\mathtt{r}_k^{(l)})$ *that*

$$\bigcap_{k\in\mathbb{N}} \left\{\left\|\mathcal{D}(\widetilde{\boldsymbol{\upsilon}}_{k,k(+1)} - \widetilde{\boldsymbol{\upsilon}})\right\| \le \mathtt{r}_k^{(l)}\right\} \subseteq \Omega(\mathtt{x}).$$

Then we get on $\Omega(\mathtt{x})$

$$\begin{aligned}\left\|\mathcal{D}(\widetilde{\boldsymbol{\upsilon}}_{k,k(+1)} - \widetilde{\boldsymbol{\upsilon}})\right\| &\le 2\sqrt{2}(1+\sqrt{\nu})\sum_{r=0}^{k-1}\nu^r\|\boldsymbol{\tau}(\mathtt{r}_{k-r}^{(l)})\| + 2\sqrt{2}\nu^k(R_0 + \mathtt{r}_0),\\ &=: \mathtt{r}_k^{(l+1)}. \end{aligned} \tag{40}$$

where

$$\|\boldsymbol{\tau}(\mathtt{r})\| \le \left[\epsilon R_0 + 9\nu_2\epsilon_2\|\mathcal{D}^{-1}\|\mathfrak{z}_1(\mathtt{x}, 6p^*)R_0 + \|\mathcal{D}^{-1}\|\mathfrak{z}(\mathtt{x}, \nabla^2\boldsymbol{\zeta}(\boldsymbol{\upsilon}^*))\right]\mathtt{r}.$$

Proof

1. We first show that on $\Omega(\mathtt{x})$

$$\begin{aligned}\mathrm{D}(\widetilde{\boldsymbol{\theta}}_k - \widetilde{\boldsymbol{\theta}}) &= -\mathrm{D}^{-1}\mathcal{A}(\widetilde{\boldsymbol{\eta}}_k - \widetilde{\boldsymbol{\eta}}) + \boldsymbol{\tau}(\mathtt{r}_k^{(l)}),\\ \mathrm{H}(\widetilde{\boldsymbol{\eta}}_k - \boldsymbol{\eta}^*) &= -\mathrm{H}^{-1}\mathcal{A}^\top(\widetilde{\boldsymbol{\theta}}_{k-1} - \widetilde{\boldsymbol{\theta}}) + \boldsymbol{\tau}(\mathtt{r}_k^{(l)}).\end{aligned}$$

The proof is very similar to that of Lemma 32. Define

$$\alpha(\boldsymbol{\upsilon}, \widetilde{\boldsymbol{\upsilon}}) := \mathcal{L}(\boldsymbol{\upsilon}) - \mathcal{L}(\widetilde{\boldsymbol{\upsilon}}) + \|\mathcal{D}(\boldsymbol{\upsilon}-\widetilde{\boldsymbol{\upsilon}})\|^2/2.$$

Note that

$$\begin{aligned}\mathcal{L}(\boldsymbol{\upsilon}) - \mathcal{L}(\widetilde{\boldsymbol{\upsilon}}) &= \nabla\mathcal{L}(\boldsymbol{\upsilon}) - \|\mathcal{D}(\boldsymbol{\upsilon}-\widetilde{\boldsymbol{\upsilon}})\|^2/2 + \alpha(\boldsymbol{\upsilon}, \boldsymbol{\upsilon}^*)\\ &= -\|\mathrm{D}(\boldsymbol{\theta}-\widetilde{\boldsymbol{\theta}})\|^2/2 + (\boldsymbol{\theta}-\boldsymbol{\theta}^*)^\top\mathcal{A}(\boldsymbol{\eta}-\widetilde{\boldsymbol{\eta}})\\ &\quad -\|\mathrm{H}(\boldsymbol{\eta}-\widetilde{\boldsymbol{\eta}})\|^2/2 + \alpha(\boldsymbol{\upsilon}, \widetilde{\boldsymbol{\upsilon}}).\end{aligned}$$

Setting $\nabla_{\boldsymbol{\theta}}\mathcal{L}(\widetilde{\boldsymbol{\theta}}_k, \widetilde{\boldsymbol{\eta}}_k) = 0$ we find

$$\mathrm{D}(\widetilde{\boldsymbol{\theta}}_k - \widetilde{\boldsymbol{\theta}}) = \mathrm{D}^{-1}\mathcal{A}(\widetilde{\boldsymbol{\eta}}_k - \widetilde{\boldsymbol{\eta}}) + \mathrm{D}^{-1}\nabla_{\boldsymbol{\theta}}\alpha(\widetilde{\boldsymbol{\upsilon}}_{k,k}, \widetilde{\boldsymbol{\upsilon}}).$$

We want to show

$$\sup_{(\boldsymbol{\theta},\widetilde{\boldsymbol{\eta}}_k)\in\widetilde{\Upsilon}_\circ\left(\mathtt{r}_k^{(l)}\right)\cap\Upsilon_\circ(\mathrm{R}_0)} \mathrm{D}^{-1}\nabla_{\boldsymbol{\theta}}\alpha((\boldsymbol{\theta}, \widetilde{\boldsymbol{\eta}}_k), \widetilde{\boldsymbol{\upsilon}}) \le \|\boldsymbol{\tau}\left(\mathtt{r}_k^{(l)}\right)\|,$$

where

$$\mathrm{D}^{-1}\nabla_{\boldsymbol{\theta}}\alpha(\boldsymbol{\upsilon}, \widetilde{\boldsymbol{\upsilon}}) \stackrel{\text{def}}{=} \mathrm{D}^{-1}\left\{\nabla_{\boldsymbol{\theta}}\mathcal{L}(\boldsymbol{\upsilon}) - \mathrm{D}^2\left(\boldsymbol{\theta}-\widetilde{\boldsymbol{\theta}}\right) - \mathcal{A}(\widetilde{\boldsymbol{\eta}}_k - \widetilde{\boldsymbol{\eta}})\right\}.$$

To see this note that by assumption we have $\Omega(\mathtt{x}) \subseteq \{\widetilde{\boldsymbol{\upsilon}} \in \Upsilon_\circ(\mathtt{r}_0)\} \subseteq \{\widetilde{\boldsymbol{\upsilon}} \in \Upsilon_\circ(\mathrm{R}_0)\}$. By condition $(\boldsymbol{\mathcal{L}_0})$, Lemma 27 and Taylor expansion we have

$$\begin{aligned}&\sup_{(\boldsymbol{\theta},\widetilde{\boldsymbol{\eta}}_k)\in\widetilde{\Upsilon}_\circ(\mathtt{r}_k^{(l)})\cap\Upsilon_\circ(\mathrm{R}_0)} \|\mathbb{E}\mathcal{U}(\boldsymbol{\theta}, \widetilde{\boldsymbol{\eta}}_k)\|\\ &\le \sup_{\boldsymbol{\upsilon}\in\widetilde{\Upsilon}_\circ(\mathtt{r}_k^{(l)})\cap\Upsilon_\circ(\mathrm{R}_0)} \|\mathrm{D}^{-1}\Pi_{\boldsymbol{\theta}}\Big(\nabla\mathbb{E}\mathcal{L}(\boldsymbol{\upsilon}) - \nabla\mathbb{E}\mathcal{L}(\widetilde{\boldsymbol{\upsilon}}) - \mathcal{D}\left(\boldsymbol{\upsilon}-\boldsymbol{\upsilon}^*\right)\Big)\|\\ &\le \sup_{\boldsymbol{\upsilon}\in\Upsilon_\circ(\mathrm{R}_0)} \|\mathrm{D}^{-1}\Pi_{\boldsymbol{\theta}}\mathcal{D}\|\|\mathcal{D}^{-1}\nabla^2\mathbb{E}\mathcal{L}(\boldsymbol{\upsilon})\mathcal{D}^{-1} - I_{p^*}\|\mathtt{r}_k^{(l)}\\ &\le \epsilon\mathtt{r}_k^{(l)2}.\end{aligned}$$

For the remainder note that with $\zeta = \mathcal{L} - \mathbb{E}\mathcal{L}$ on $\Omega(\mathtt{x})$ using Lemma 27 we can bound

$$\begin{aligned}
&\sup_{(\boldsymbol{\theta},\widetilde{\boldsymbol{\eta}}_k)\in\widetilde{\Upsilon}_\circ(\mathtt{r}_k^{(l)})\cap\Upsilon_\circ(\mathrm{R}_0)} \left\|\mathcal{U}_{\boldsymbol{\theta}}(\boldsymbol{\theta},\widetilde{\boldsymbol{\eta}}_k) - \mathbb{E}\mathcal{U}_{\boldsymbol{\theta}}(\boldsymbol{\theta},\widetilde{\boldsymbol{\eta}}_k)\right\| \\
&\quad\le \sup_{\boldsymbol{\upsilon}\in\widetilde{\Upsilon}_\circ(\mathtt{r}_k^{(l)})\cap\Upsilon_\circ(\mathrm{R}_0)} \left\|\mathrm{D}^{-1}\Big(\nabla_{\boldsymbol{\theta}}\boldsymbol{\zeta}(\boldsymbol{\upsilon}) - \nabla_{\boldsymbol{\theta}}\boldsymbol{\zeta}(\widetilde{\boldsymbol{\upsilon}})\Big)\right\| \\
&\quad\le \sup_{\boldsymbol{\upsilon}\in\Upsilon_\circ(\mathtt{r})} \left\|\mathcal{D}^{-1}\nabla^2\boldsymbol{\zeta}(\boldsymbol{\upsilon})\mathcal{D}^{-1}\right\| \mathtt{r}_k^{(l)} \\
&\quad\le \sup_{\boldsymbol{\upsilon}\in\Upsilon_\circ(\mathrm{R}_0)} \left\{\frac{1}{9\nu_2\epsilon_2}\|\mathcal{D}^{-1}\left(\nabla^2\boldsymbol{\zeta}(\boldsymbol{\upsilon}) - \nabla^2\boldsymbol{\zeta}(\boldsymbol{\upsilon}^*)\right)\mathcal{D}^{-1}\|\right\} 6\nu_1\epsilon\mathtt{r}_k^{(l)} \\
&\qquad + \left\{\|\mathcal{D}^{-1}\nabla^2\boldsymbol{\zeta}(\boldsymbol{\upsilon}^*)\mathcal{D}^{-1}\|\right\}\mathtt{r}_k^{(l)} \\
&\quad\le \left[9\nu_2\epsilon_2\|\mathcal{D}^{-1}\|_{\mathfrak{z}1}(\mathtt{x},6p^*)\mathrm{R}_0 + \|\mathcal{D}^{-1}\|_{\mathfrak{z}}(\mathtt{x},\nabla^2\boldsymbol{\zeta}(\boldsymbol{\upsilon}^*))\right]\mathtt{r}_k^{(l)}.
\end{aligned}$$

Using the same argument for $\widetilde{\boldsymbol{\eta}}_k$ gives the claim.

Now the claim follows as in the proof of Lemma 32. ∎

Lemma 37 *Assume that* $\kappa(\mathtt{x},R_0) < 1-\nu$ *where*

$$\kappa(\mathtt{x},R_0) \stackrel{\mathrm{def}}{=} \frac{2\sqrt{2}(1+\sqrt{\nu})}{\sqrt{1-\nu}}\Big(\epsilon R_0 + 9\epsilon_2\nu_2\|\mathcal{D}^{-1}\|_{\mathfrak{z}1}(\mathtt{x},6p^*)R_0 + \|\mathcal{D}^{-1}\|_{\mathfrak{z}2}\left(\mathtt{x},\nabla^2\mathcal{L}(\boldsymbol{\upsilon}^*)\right)\Big).$$

Then

$$\Omega(\mathtt{x}) \subseteq \bigcap_{k\in\mathbb{N}}\left\{\boldsymbol{\upsilon}_{k,k(+1)} \in \widetilde{\Upsilon}_\circ(\mathtt{r}_k)\right\},$$

where $(\mathtt{r}_k)_{k\in\mathbb{N}}$ *satisfy the bound* (24).

Proof Define for all $k\in\mathbb{N}_0$ the sequence $\mathtt{r}_k^{(0)} = \mathrm{R}_0$. We estimate

$$\|\boldsymbol{\tau}(\mathtt{r}_k^{(l)})\| \le \frac{1}{\sqrt{1-\nu}}\left(\epsilon\mathrm{R}_0 + 6\nu_1\epsilon_2\|\mathcal{D}^{-1}\|_{\mathfrak{z}1}(\mathtt{x},6p^*)\mathrm{R}_0 + \|\mathcal{D}^{-1}\|_{\mathfrak{z}}(\mathtt{x},\mathit{I\!B}(\nabla^2))\right)\mathtt{r}_k^{(l)},$$

such that by definition

$$2\sqrt{2}(1+\sqrt{\nu})\sum_{r=0}^{k-1}\nu^r\|\boldsymbol{\tau}(\mathtt{r}_{k-r}^{(l)})\| \le \kappa(\mathtt{x},\mathrm{R}_0)\sum_{r=0}^{k-1}\nu^r\mathtt{r}_{k-r}^{(l)}.$$

Plugging in the recursive formula for $\mathtt{r}_k^{(l)}$ from (40) and denoting $\widetilde{\mathrm{R}}_0 \stackrel{\mathrm{def}}{=} \mathrm{R}_0 + \mathtt{r}_0$ we find

$$\begin{aligned}
\mathtt{r}_k^{(l)} &\le \kappa(\mathtt{x},\mathrm{R}_0)\sum_{r=0}^{k-1}\nu^r\mathtt{r}_{k-r}^{(l-1)} + 2\sqrt{2}\nu^k\widetilde{\mathrm{R}}_0 \\
&\le \kappa(\mathtt{x},\mathrm{R}_0)\sum_{r=0}^{k-1}\nu^r\left(\kappa(\mathtt{x},\mathrm{R}_0)\sum_{s=0}^{k-r-1}\nu^s\mathtt{r}_{k-r-s}^{(l-2)} + 2\nu^{k-r}\widetilde{\mathrm{R}}_0\right) + 2\sqrt{2}\widetilde{\mathrm{R}}_0\nu^k \\
&\le \kappa(\mathtt{x},\mathrm{R}_0)^2\sum_{r=0}^{k-1}\nu^r\sum_{s=0}^{k-r-1}\nu^s\mathtt{r}_{k-r-s}^{(l-2)} + 2\sqrt{2}\nu^k\widetilde{\mathrm{R}}_0\left(\kappa(\mathtt{x},\mathrm{R}_0)k+1\right) \\
&\le \kappa(\mathtt{x},\mathrm{R}_0)^2\sum_{r=0}^{k-1}\nu^r\sum_{s=0}^{k-r-1}\nu^s\left(\kappa(\mathtt{x},\mathrm{R}_0)\sum_{t=0}^{k-r-s-1}\nu^t\mathtt{r}_{k-r-s-t}^{(l-3)} + 2\nu^{k-r-s}\widetilde{\mathrm{R}}_0\right) \\
&\quad + 2\sqrt{2}\nu^k\widetilde{\mathrm{R}}_0\left(\kappa(\mathtt{x},\mathrm{R}_0)k+1\right) \\
&\le \kappa(\mathtt{x},\mathrm{R}_0)^3\sum_{r=0}^{k-1}\nu^r\sum_{s=0}^{k-r-1}\nu^s\mathtt{r}_{k-r-s}^{(l-3)} + 2\sqrt{2}\nu^k\widetilde{\mathrm{R}}_0\left(\kappa(\mathtt{x},\mathrm{R}_0)^2k^2 + \kappa(\mathtt{x},\mathrm{R}_0)k+1\right).
\end{aligned}$$

By induction this gives for $l\in\mathbb{N}$

$$\begin{aligned}
\mathtt{r}_k^{(l)} &\le \kappa(\mathtt{x},\mathrm{R}_0)^l\sum_{r_1=0}^{k-1}\nu^{r_1}\sum_{r_2=0}^{k-r_1-1}\nu^{r_2}\ldots\sum_{r_l=0}^{k-\sum_{s=1}^{l-1}r_s-1}\nu^{r_l}\widetilde{\mathrm{R}}_0 \\
&\quad + 2\sqrt{2}\nu^k\widetilde{\mathrm{R}}_0\sum_{s=0}^{l-1}\kappa(\mathtt{x},\mathrm{R}_0)^s k^s \\
&\le \left(\left(\frac{\kappa(\mathtt{x},\mathrm{R}_0)}{1-\nu}\right)^l + 2\sqrt{2}\nu^k\sum_{s=0}^{l-1}\left(\kappa(\mathtt{x},\mathrm{R}_0)k\right)^s\right)\widetilde{\mathrm{R}}_0 \\
&\le \begin{cases}\left(\left(\frac{\kappa(\mathtt{x},\mathrm{R}_0)}{1-\nu}\right)^l + 2\sqrt{2}\nu^k\frac{1}{1-\kappa(\mathtt{x},\mathrm{R}_0)k}\right)\widetilde{\mathrm{R}}_0, & \kappa(\mathtt{x},\mathrm{R}_0)k\le 1,\\ \kappa(\mathtt{x},\mathrm{R}_0)^l\left(\left(\frac{1}{1-\nu}\right)^l + 2\sqrt{2}\nu^k\frac{k^l}{\kappa(\mathtt{x},\mathrm{R}_0)k-1}\right)\widetilde{\mathrm{R}}_0, & \text{otherwise.}\end{cases}
\end{aligned}$$

By Lemma 36

$$\Omega(\mathtt{x}) \subset \bigcap_{k\in\mathbb{N}_0}\bigcap_{l\in\mathbb{N}}\left\{\widetilde{\boldsymbol{\upsilon}}_{k,k(+1)} \in \widetilde{\Upsilon}_\circ\big(\mathtt{r}_k^{(l)}\big)\right\}.$$

Set if $\kappa(\mathtt{x},\mathrm{R}_0)/(1-\nu) < 1$

$$l(k) \stackrel{\mathrm{def}}{=} \begin{cases}\infty, & \kappa(\mathtt{x},\mathrm{R}_0)k\le 1,\\ \frac{k\log(\nu)+\log(2\sqrt{2})-\log(\kappa(\mathtt{x},\mathrm{R}_0)k-1)}{-\log(1-\nu)-\log(k)}, & \text{otherwise.}\end{cases}$$

Then with $\mathtt{r}_k^* \stackrel{\text{def}}{=} \mathtt{r}_k^{(\lfloor l(k) \rfloor)}$ we get

$$\Omega(\mathtt{x}) \subset \bigcap_{k\in\mathbb{N}_0} \left\{ \widetilde{\boldsymbol{\upsilon}}_{k,k(+1)} \in \widetilde{\Upsilon}_\circ\big(\mathtt{r}_k^*\big) \right\},$$

$$\mathtt{r}_k^* \leq \begin{cases} \frac{\nu^k 2\sqrt{2}}{1-\kappa(\mathtt{x},\mathrm{R}_0)k} \widetilde{\mathrm{R}}_0, & \kappa(\mathtt{x},\mathrm{R}_0)k \leq 1, \\ 2\left(\frac{\kappa(\mathtt{x},\mathrm{R}_0)}{1-\nu}\right)^{\frac{k}{\log(k)}L(k)-1} \widetilde{\mathrm{R}}_0, & \text{otherwise.} \end{cases}$$

The sequence $L(k) > 0$ is defined as

$$L(k) \stackrel{\text{def}}{=} \left\lfloor \frac{\log(1/\nu) - \frac{1}{k}\left(\log(2\sqrt{2}) - \log(\kappa(\mathtt{x},\mathrm{R}_0)k-1)\right)}{1 + \frac{1}{\log(k)}\log(1-\nu)} \right\rfloor \in \mathbb{N},$$

where $\lfloor x \rfloor \in \mathbb{N}_0$ denotes the largest natural number smaller than $x > 0$. To ensure that $L(k) > 0$ we assume that $k\log(1/\nu) - \log(2\sqrt{2}) > k$. Further as $\kappa(\mathtt{x},\mathrm{R}_0) < (1-\nu)$ and $L(k)$ is only relevant once $\kappa(\mathtt{x},\mathrm{R}_0)k > 1$ it follows that

$$0 < 1 + \frac{1}{\log(k)}\log(1-\nu) < 1.$$

Then

$$L(k) \geq \log(1/\nu) - \frac{1}{k}\Big(\log(2\sqrt{2}) - \log(\kappa(\mathtt{x},\mathrm{R}_0)k-1)\Big) > 1.$$

Consequently

$$\begin{aligned} \left(\frac{\kappa(\mathtt{x},\mathrm{R}_0)}{1-\nu}\right)^{\frac{k}{\log(k)}L(k)} &\leq \nu^{\frac{k}{\log(k)}\log\left(\frac{1-\nu}{\kappa(\mathtt{x},\mathrm{R}_0)}\right)} \left(\frac{\kappa(\mathtt{x},\mathrm{R}_0)}{1-\nu}\right)^{-\frac{1}{\log(k)}\left(\log(2\sqrt{2})-\log(\kappa(\mathtt{x},\mathrm{R}_0)k-1)\right)} \\ &\stackrel{\text{def}}{=} \nu^{\frac{k}{\log(k)}\log\left(\frac{1-\nu}{\kappa(\mathtt{x},\mathrm{R}_0)}\right)} c_k, \end{aligned}$$

where $c_k \to \frac{\kappa(\mathtt{x},\mathrm{R}_0)}{1-\nu}$. Finally note that $\widetilde{\mathrm{R}}_0 \leq 2\mathrm{R}_0$ and the proof is complete. ■

Remark 38 *As pointed out in Remark 18 the above result can be improved. Redefine* $\Omega(\mathtt{x})$ *as the intersection of the two sets in* (29) *and* (39). *Then* $\mathbb{P}(\Omega(\mathtt{x})) \geq 1 - 10\mathrm{e}^{-\mathtt{x}}$. *Also redefine*

$$\kappa(\mathtt{x},\mathtt{r}) \stackrel{\text{def}}{=} \frac{2\sqrt{2}(1+\sqrt{\nu})}{\sqrt{1-\nu}} \Big(\epsilon\mathtt{r} + 3\epsilon_2 \|\mathcal{D}^{-1}\|_{\mathfrak{z}1}(\mathtt{x}, 6p^*)\mathtt{r} + \|\mathcal{D}^{-1}\|_{\mathfrak{z}2}\left(\mathtt{x}, \nabla^2\mathcal{L}(\boldsymbol{\upsilon}^*)\right) \Big).$$

By the arguments of the proof of Theorem 7 we find with $\mathtt{r}_k^*$ *defined in* (33)

$$\Omega(\mathtt{x}) \subset \bigcap_{k\in\mathbb{N}} \{\boldsymbol{\upsilon}_{k,k(+1)} \in \Upsilon_\circ(\mathtt{r}_k^*)\}.$$

Using this in Lemma 36 instead of $\cap_{k\in\mathbb{N}}\{\boldsymbol{\upsilon}_{k,k(+1)} \in \Upsilon_\circ(R_0)\}$ *we can bound*

$$\begin{aligned} \|\boldsymbol{\tau}(\mathtt{r}_k^{(l)})\| &\leq \frac{1}{\sqrt{1-\nu}} \Big(\epsilon\mathtt{r}_k^* + 6\nu_1\epsilon_2 \|\mathcal{D}^{-1}\|_{\mathfrak{z}1}(\mathtt{x}, 6p^*)\mathtt{r}_k^* \\ &\quad + \|\mathcal{D}^{-1}\|_{\mathfrak{z}}(\mathtt{x}, I\!B(\nabla^2)) \Big) \mathtt{r}_k^{(l)}. \end{aligned}$$

Consequently, representing $\mathtt{r}_k^* = \mathtt{C}\left(\mathfrak{z}(\mathtt{x}) + \nu^k R_0\right)$ *we find*

$$\begin{aligned} \mathtt{r}_k^{(l)} &\leq \kappa(\mathtt{x}, \mathtt{C}_\mathfrak{z}(\mathtt{x})) \sum_{r=0}^{k-1} \nu^r \mathtt{r}_{k-r}^{(l-1)} + 2\sqrt{2}\nu^k(R_0 + \mathtt{r}_0) \\ &\quad + \mathtt{C}\epsilon(1 + \|\mathcal{D}^{-1}\|_{\mathfrak{z}1}(\mathtt{x}, 6p^*)) \sum_{r=0}^{k-1} \nu^k R_0 \mathtt{r}_{k-r}^{(l-1)} \\ &\leq \kappa(\mathtt{x}, \mathtt{C}_\mathfrak{z}(\mathtt{x})) \sum_{r=0}^{k-1} \nu^r \mathtt{r}_{k-r}^{(l-1)} + \mathtt{C}_1\epsilon R_0 k\nu^k(R_0 + \mathtt{r}_0), \end{aligned}$$

where $\mathtt{C}_1 \leq 2\sqrt{2} + \mathtt{C}(1 + \|\mathcal{D}^{-1}\|_{\mathfrak{z}1}(\mathtt{x}, 6p^*))$. *With the same arguments as in the proof of Lemma 37 we infer*

$$\begin{aligned} &\mathtt{r}_k^{(l)}/(R_0 + \mathtt{r}_0) \\ &\leq \begin{cases} \left(\left(\frac{\kappa(\mathtt{x},\mathtt{C}_\mathfrak{z}(\mathtt{x}))}{1-\nu}\right)^l + k\nu^k \frac{\mathtt{C}_1\epsilon R_0}{1-\kappa(\mathtt{x},\mathtt{C}_\mathfrak{z}(\mathtt{x}))k} \right), & \kappa(\mathtt{x},\mathtt{C}_\mathfrak{z}(\mathtt{x}))k \leq 1, \\ \kappa(\mathtt{x},\mathtt{C}_\mathfrak{z}(\mathtt{x}))^l \left(\left(\frac{1}{1-\nu}\right)^l + \nu^k \frac{k^{l+1}\mathtt{C}_1\epsilon R_0}{\kappa(\mathtt{x},\mathtt{C}_\mathfrak{z}(\mathtt{x}))k-1} \right), & \textit{otherwise.} \end{cases} \end{aligned}$$

Set

$$l(k) \stackrel{\text{def}}{=} \begin{cases} \infty, & \kappa(\mathtt{x},\mathtt{C}_\mathfrak{z}(\mathtt{x}))k \leq 1, \\ \frac{k\log(\nu) + \log(\mathtt{C}_1\epsilon R_0) - \log(\kappa(\mathtt{x},\mathtt{C}_\mathfrak{z}(\mathtt{x}))k-1) - \log(k)}{-\log(1-\nu) - \log(k)}, & \textit{otherwise.} \end{cases}$$

Then with $\mathtt{r}_k^* \stackrel{\text{def}}{=} \mathtt{r}_k^{(\lfloor l(k) \rfloor)}$ *we get with a slight adaptation of* $L(k)$

$$\Omega(\mathtt{x}) \subset \bigcap_{k\in\mathbb{N}_0} \left\{ \widetilde{\boldsymbol{\upsilon}}_{k,k(+1)} \in \widetilde{\Upsilon}_\circ\big(\mathtt{r}_k^*\big) \right\},$$

$$\mathtt{r}_k^* \leq \begin{cases} \frac{\nu^k 2\sqrt{2}}{1-\kappa(\mathtt{x}\mathtt{C}_\mathfrak{z}(\mathtt{x}))k}(R_0 + \mathtt{r}_0), & \kappa(\mathtt{x},\mathtt{C}_\mathfrak{z}(\mathtt{x}))k \leq 1, \\ 2\left(\frac{\kappa(\mathtt{x},\mathtt{C}_\mathfrak{z}(\mathtt{x}))}{1-\nu}\right)^{\frac{k}{\log(k)}L(k)-1}(R_0 + \mathtt{r}_0), & \textit{otherwise.} \end{cases}$$

This gives the claim.

Appendix A. Deviation Bounds for Quadratic Forms

This section is the same as Section A of Andresen and Spokoiny (2014). The following general result from Spokoiny (2012) helps to control the deviation for quadratic forms of type $\|I\!B\boldsymbol{\xi}\|^2$ for a given positive matrix $I\!B$ and a random vector $\boldsymbol{\xi}$. It will be used several times in our proofs. Suppose that

$$\log \mathbb{E} \exp\bigl(\boldsymbol{\gamma}^\top \boldsymbol{\xi}\bigr) \le \|\boldsymbol{\gamma}\|^2/2, \qquad \boldsymbol{\gamma} \in \mathbb{R}^p, \|\boldsymbol{\gamma}\| \le \mathtt{g}.$$

For a symmetric matrix $I\!B$, define

$$\mathtt{p} = \operatorname{tr}(I\!B^2), \qquad \mathtt{v}^2 = 2\operatorname{tr}(I\!B^4), \qquad \lambda^* \stackrel{\text{def}}{=} \|I\!B^2\|_\infty \stackrel{\text{def}}{=} \lambda_{\max}(I\!B^2).$$

For ease of presentation, suppose that $\mathtt{g}^2 \ge 2\mathtt{p}_{I\!B}$. The other case only changes the constants in the inequalities. Note that $\|\boldsymbol{\xi}\|^2 = \boldsymbol{\eta}^\top I\!B\,\boldsymbol{\eta}$. Define $\mu_c = 2/3$ and

$$\begin{aligned} \mathtt{g}_c &\stackrel{\text{def}}{=} \sqrt{\mathtt{g}^2 - \mu_c \mathtt{p}_{I\!B}}, \\ 2(\mathtt{x}_c + 2) &\stackrel{\text{def}}{=} (\mathtt{g}^2/\mu_c - \mathtt{p}_{I\!B})/\lambda^* + \log\det\bigl(I_p - \mu_c I\!B/\lambda^*\bigr). \end{aligned}$$

Proposition 39 *Let (ED_0) hold with $\nu_0 = 1$ and $\mathtt{g}^2 \ge 2\mathtt{p}_{I\!B}$. Then for each $\mathtt{x} > 0$*

$$\mathbb{P}\bigl(\|I\!B\boldsymbol{\xi}\| \ge \mathfrak{z}(\mathtt{x}, I\!B)\bigr) \le 2\mathrm{e}^{-\mathtt{x}},$$

where $\mathfrak{z}(\mathtt{x}, I\!B)$ is defined by

$$\mathfrak{z}^2(I\!B, \mathtt{x}) \stackrel{\text{def}}{=} \begin{cases} \mathtt{p}_{I\!B} + 2\mathtt{v}_{I\!B}(\mathtt{x}+1)^{1/2}, & \mathtt{x}+1 \le \mathtt{v}_{I\!B}/(18\lambda^*), \\ \mathtt{p}_{I\!B} + 6\lambda^*(\mathtt{x}+1), & \mathtt{v}_{I\!B}/(18\lambda^*) < \mathtt{x}+1 \le \mathtt{x}_c + 2, \\ \bigl|\mathtt{y}_c + 2\lambda^*(\mathtt{x} - \mathtt{x}_c + 1)/\mathtt{g}_c\bigr|^2, & \mathtt{x} > \mathtt{x}_c + 1, \end{cases}$$

with $\mathtt{y}_c^2 \le \mathtt{p}_{I\!B} + 6\lambda^*(\mathtt{x}_c + 2)$.

Appendix B. A Uniform Bound for the Norm of a Random Process

We want to derive for a random process $\breve{\mathtt{y}}(\boldsymbol{\upsilon}) \in \mathbb{R}^p$ a bound of the kind

$$\mathbb{P}\left(\sup_{\mathtt{r} \le \mathtt{r}^*} \sup_{\boldsymbol{\upsilon} \in \Upsilon_\circ(\mathtt{r})} \left\{\frac{1}{\epsilon}\|\breve{\mathtt{y}}(\boldsymbol{\upsilon})\| - 2\mathtt{r}^2\right\} \ge \mathtt{C}\mathfrak{z}_Q(\mathtt{x}, p^*)\right) \le \mathrm{e}^{-\mathtt{x}}.$$

This is a slightly stronger result than the one derived in Section D of (Andresen and Spokoiny, 2014) but the ideas employed here are very similar.

We want to apply Corollary 2.5 of the supplement of Spokoiny (2012) which we cite here as a Theorem. Note that we slightly generalized the formulation of the theorem, to make it applicable in out setting. The proof remains the same.

Theorem 40 *Let $(U(\mathtt{r}))_{0 \le \mathtt{r} \le \mathtt{r}^*} \subset \mathbb{R}^p$ be a sequence of balls around $\boldsymbol{\upsilon}^*$ induced by the metric $d(\cdot,\cdot)$. Let a random real valued process $\mathcal{U}(\mathtt{r}, \boldsymbol{\upsilon})$ fulfill for any $0 \le \mathtt{r} \le \mathtt{r}^*$ that $\mathcal{U}(\mathtt{r}, \boldsymbol{\upsilon}^*) = 0$ and*

($\mathcal{E}d$) *For any* $\upsilon, \upsilon^\circ \in U(\mathtt{r})$

$$\log \mathbb{E} \exp\Big\{ \lambda \frac{\mathcal{U}(\mathtt{r},\upsilon) - \mathcal{U}(\mathtt{r},\upsilon^\circ)}{d(\upsilon,\upsilon^\circ)} \Big\} \le \frac{\nu_0^2 \lambda^2}{2}, \qquad |\lambda| \le \mathtt{g}. \tag{41}$$

Finally assume that $\sup_{\upsilon \in U(\mathtt{r})} (\mathcal{U}(\mathtt{r},\upsilon))$ *increases in* $\mathtt{r}$. *Then with probability greater* $1 - \mathrm{e}^{-\mathtt{x}}$

$$\sup_{\upsilon \in U(\mathtt{r})} \Big\{ \frac{1}{3\nu_1} \mathcal{U}(\mathtt{r},\upsilon) - d(\upsilon,\upsilon^*)^2 \Big\} \le \mathfrak{z}_Q(\mathtt{x}, p^*)^2,$$

where $\mathfrak{z}_Q(\mathtt{x}, p^*) \stackrel{\mathrm{def}}{=} \mathbb{Q}(U(\mathtt{r}^*))$ *denotes the entropy of the set* $U(\mathtt{r}^*) \subset \mathbb{R}^p$ *and where with* $\mathtt{g}_0 = \nu_0 \mathtt{g}$ *and for some* $\mathbb{Q} > 0$

$$\mathfrak{z}_Q(\mathtt{x}, \mathbb{Q})^2 \stackrel{\mathrm{def}}{=} \begin{cases} (1 + \sqrt{\mathtt{x} + \mathbb{Q}})^2 & \text{if } 1 + \sqrt{\mathtt{x} + \mathbb{Q}} \le \mathtt{g}_0, \\ 1 + \{2\mathtt{g}_0^{-1}(\mathtt{x} + \mathbb{Q}) + \mathtt{g}_0\}^2 & \text{otherwise.} \end{cases} \tag{42}$$

To use this result let $\breve{\mathtt{y}}(\upsilon)$ be a smooth centered random vector process with values in $\mathbb{R}^p$ and let $\mathcal{D} : \mathbb{R}^{p^*} \to \mathbb{R}^{p^*}$ be some linear operator. We aim at bounding the maximum of the norm $\|\breve{\mathtt{y}}(\upsilon)\|$ over a vicinity $\Upsilon_\circ(\mathtt{r}) \stackrel{\mathrm{def}}{=} \{\|\mathcal{D}(\upsilon - \upsilon^*)\| \le \mathtt{r}\}$ of υ^*. Suppose that $\breve{\mathtt{y}}(\upsilon)$ satisfies for each $0 < \mathtt{r} < \mathtt{r}^*$ and for all pairs $\upsilon, \upsilon^\circ \in \Upsilon_\circ(\mathtt{r}) = \big\{\upsilon \in \Upsilon \colon \|\mathcal{D}(\upsilon - \upsilon^*)\| \le \mathtt{r}\big\} \subset \mathbb{R}^{p^*}$

$$\sup_{\|\boldsymbol{u}\| \le 1} \log \mathbb{E} \exp\Big\{ \lambda \frac{\boldsymbol{u}^\top \big(\breve{\mathtt{y}}(\upsilon) - \breve{\mathtt{y}}(\upsilon^\circ)\big)}{\epsilon \|\mathcal{D}(\upsilon - \upsilon^\circ)\|} \Big\} \le \frac{\nu_0^2 \lambda^2}{2}. \tag{43}$$

Remark 41 *In the setting of Theorem 7 we have*

$$\breve{\mathtt{y}}(\upsilon) = \breve{D}^{-1} \Big(\breve{\nabla} \boldsymbol{\zeta}(\upsilon) - \breve{\nabla} \boldsymbol{\zeta}(\upsilon^*) \Big),$$

and condition (43) *becomes* $(\mathcal{E}\mathcal{D}_1)$ *from 2.1.*

Theorem 42 *Let a random* p*-vector process* $\breve{\mathtt{y}}(\upsilon)$ *fulfill* $\breve{\mathtt{y}}(\upsilon^*) = 0$ *and let condition* (43) *be satisfied. Then for each* $0 \le \mathtt{r} \le \mathtt{r}^*$, *on a set of probability greater* $1 - \mathrm{e}^{-\mathtt{x}}$

$$\sup_{\mathtt{r} \le \mathtt{r}^*} \sup_{\upsilon \in \Upsilon_\circ(\mathtt{r})} \Big\{ \frac{1}{6\epsilon\nu_1} \|\breve{\mathtt{y}}(\upsilon)\| - 2\mathtt{r}^2 \Big\} \le \mathfrak{z}_Q(\mathtt{x}, 2p^* + 2p)^2,$$

with $\mathtt{g}_0 = \nu_0 \mathtt{g}$.

Remark 43 *Note that the entropy of the original set* $\Upsilon_\circ(\mathtt{r}) \subset \mathbb{R}^{p^*}$ *is equal to* $2p^*$. *So in order to control the norm* $\|\breve{\mathtt{y}}(\upsilon)\|$ *one only pays with the additional sumand* $2p$.

Proof In what follows, we use the representation

$$\|\breve{\mathtt{y}}(\upsilon)\| = \epsilon \sup_{\|\boldsymbol{u}\| \le \|\mathcal{D}(\upsilon - \upsilon^*)\|} \frac{1}{\epsilon \|\mathcal{D}(\upsilon - \upsilon^*)\|} \boldsymbol{u}^\top \breve{\mathtt{y}}(\upsilon).$$

This implies

$$\sup_{\upsilon \in \Upsilon_\circ(\mathtt{r})} \|\breve{\mathtt{y}}(\upsilon)\| = \epsilon \sup_{\upsilon \in \Upsilon_\circ(\mathtt{r})} \sup_{\|\boldsymbol{u}\| \le \|\mathcal{D}(\upsilon - \upsilon^*)\|} \frac{1}{\epsilon \|\mathcal{D}(\upsilon - \upsilon^*)\|} \boldsymbol{u}^\top \breve{\mathtt{y}}(\upsilon).$$

Due to Lemma 44 the process $\mathcal{U}(\mathtt{r},\upsilon,\boldsymbol{u}) \stackrel{\mathrm{def}}{=} \frac{1}{\epsilon \|\mathcal{D}(\upsilon - \upsilon^*)\|} \boldsymbol{u}^\top \breve{\mathtt{y}}(\upsilon)$ satisfies condition $(\mathcal{E}d)$ (see (41)) as process on $U(\mathtt{r}^*)$ where

$$U(\mathtt{r}) \stackrel{\mathrm{def}}{=} \Upsilon_\circ(\mathtt{r}) \times B_{\mathtt{r}}(0). \tag{44}$$

Further $\sup_{(\upsilon,\boldsymbol{u}) \in U(\mathtt{r})} \mathcal{U}(\mathtt{r},\upsilon,\boldsymbol{u})$ is increasing in $\mathtt{r}$. This allows to apply Theorem 42 to obtain the desired result. Set $d((\upsilon,\boldsymbol{u}),(\upsilon^\circ,\boldsymbol{u}^\circ))^2 = \|\mathcal{D}(\upsilon - \upsilon^*)\|^2 + \|\boldsymbol{u} - \boldsymbol{u}^\circ\|^2$. We get on a set of probability greater $1 - \mathrm{e}^{-\mathtt{x}}$

$$\sup_{(\upsilon,\boldsymbol{u}) \in U(\mathtt{r}^*)} \Big\{ \frac{1}{6\epsilon\nu_1 \|\mathcal{D}(\upsilon - \upsilon^*)\|} \boldsymbol{u}^\top \breve{\mathtt{y}}(\upsilon) - \|\mathcal{D}(\upsilon - \upsilon^*)\|^2 - \|\boldsymbol{u}\|^2 \Big\} \le \mathfrak{z}_Q\Big(\mathtt{x}, \mathbb{Q}\big(U(\mathtt{r}^*)\big)\Big).$$

The constant $\mathbb{Q}\big(U(\mathtt{r}^*)\big) > 0$ quantifies the complexity of the set $U(\mathtt{r}^*) \subset \mathbb{R}^{p^*} \times \mathbb{R}^p$. We point out that for compact $M \subset \mathbb{R}^{p^*}$ we have $\mathbb{Q}(M) = 2p^*$ (see Supplement of Spokoiny (2012), Lemma 2.10). This gives $\mathbb{Q}\big(U\big) = 2p^* + 2p$. Finally observe that

$$\begin{aligned} &\sup_{\mathtt{r} \le \mathtt{r}^*} \sup_{\upsilon \in \Upsilon_\circ(\mathtt{r})} \Big\{ \frac{1}{6\epsilon\nu_1} \|\breve{\mathtt{y}}(\upsilon)\| - 2\mathtt{r}^2 \Big\} \\ &\quad \le \sup_{\mathtt{r} \le \mathtt{r}^*} \sup_{(\upsilon,\boldsymbol{u}) \in U(\mathtt{r})} \Big\{ \frac{1}{6\epsilon\nu_1 \|\mathcal{D}(\upsilon - \upsilon^*)\|} \boldsymbol{u}^\top \breve{\mathtt{y}}(\upsilon) - \|\mathcal{D}(\upsilon - \upsilon^*)\|^2 - \|\boldsymbol{u}\|^2 \Big\} \\ &\quad = \sup_{(\upsilon,\boldsymbol{u}) \in U(\mathtt{r}^*)} \Big\{ \frac{1}{6\epsilon\nu_1 \|\mathcal{D}(\upsilon - \upsilon^*)\|} \boldsymbol{u}^\top \breve{\mathtt{y}}(\upsilon) - \|\mathcal{D}(\upsilon - \upsilon^*)\|^2 - \|\boldsymbol{u}\|^2 \Big\}. \end{aligned}$$

■

Lemma 44 *Suppose that* $\breve{\mathtt{y}}(\upsilon)$ *satisfies for each* $\|\boldsymbol{u}\| \le 1$ *and* $|\lambda| \le \mathtt{g}$ *the inequality* (43). *Then the process* $\mathcal{U}(\upsilon,\boldsymbol{u}) = \frac{1}{2\epsilon \|\mathcal{D}(\upsilon - \upsilon^*)\|} \breve{\mathtt{y}}(\upsilon)^\top \boldsymbol{u}_1$ *satisfies* **($\mathcal{E}d$)** *from* (41) *with* $|\lambda| \le \mathtt{g}/2$, $d((\upsilon,\boldsymbol{u}),(\upsilon^\circ,\boldsymbol{u}^\circ))^2 = \|\mathcal{D}(\upsilon - \upsilon^*)\|^2 + \|\boldsymbol{u} - \boldsymbol{u}^\circ\|^2$, $\nu = 2\nu_0$ *and* $U \subset \mathbb{R}^{p^* + p}$ *defined in* (44), *i.e. for any* $(\upsilon,\boldsymbol{u}_1),(\upsilon^\circ,\boldsymbol{u}_2) \in U$

$$\log \mathbb{E} \exp\Big\{ \lambda \frac{\mathcal{U}(\upsilon,\boldsymbol{u}_1) - \mathcal{U}(\upsilon^\circ,\boldsymbol{u}_2)}{d((\upsilon,\boldsymbol{u}_1),(\upsilon^\circ,\boldsymbol{u}_2))} \Big\} \le \frac{\nu_0^2 \lambda^2}{2}, \qquad |\lambda| \le \mathtt{g}/2.$$

Proof Let $(\boldsymbol{\upsilon},\boldsymbol{u}_1),(\boldsymbol{\upsilon}^\circ,\boldsymbol{u}_2)\in U$ and w.l.o.g. $\boldsymbol{u}_1\le\|\mathcal{D}(\boldsymbol{\upsilon}-\boldsymbol{\upsilon}^*)\|\le\|\mathcal{D}(\boldsymbol{\upsilon}^\circ-\boldsymbol{\upsilon}^*)\|$. By the Hölder inequality and (43), we find

$$\begin{aligned}
&\log\mathbb{E}\exp\biggl\{\lambda\frac{\mathcal{U}(\boldsymbol{\upsilon},\boldsymbol{u}_1)-\mathcal{U}(\boldsymbol{\upsilon},\boldsymbol{u}_2)}{d((\boldsymbol{\upsilon},\boldsymbol{u}_1),(\boldsymbol{\upsilon}^\circ,\boldsymbol{u}_2))}\biggr\}\\
&\quad=\log\mathbb{E}\exp\biggl\{\lambda\frac{\mathcal{U}(\boldsymbol{\upsilon},\boldsymbol{u}_1)-\mathcal{U}(\boldsymbol{\upsilon}^\circ,\boldsymbol{u}_1)+\mathcal{U}(\boldsymbol{\upsilon}^\circ,\boldsymbol{u}_1)-\mathcal{U}(\boldsymbol{\upsilon}^\circ,\boldsymbol{u}_2)}{d((\boldsymbol{\upsilon},\boldsymbol{u}_1),(\boldsymbol{\upsilon}^\circ,\boldsymbol{u}_2))}\biggr\}\\
&\quad\le\frac{1}{2}\log\mathbb{E}\exp\biggl\{2\lambda\frac{\boldsymbol{u}_1^\top\bigl(\frac{1}{\|\mathcal{D}(\boldsymbol{\upsilon}-\boldsymbol{\upsilon}^*)\|}\breve{\mathcal{Y}}(\boldsymbol{\upsilon})-\frac{1}{\|\mathcal{D}(\boldsymbol{\upsilon}^\circ-\boldsymbol{\upsilon}^*)\|}\breve{\mathcal{Y}}(\boldsymbol{\upsilon}^\circ)\bigr)}{\epsilon\|\mathcal{D}(\boldsymbol{\upsilon}-\boldsymbol{\upsilon}^\circ)\|}\biggr\}\\
&\qquad+\frac{1}{2}\log\mathbb{E}\exp\biggl\{2\lambda\frac{(\boldsymbol{u}_1^\top-\boldsymbol{u}_2^\top)\breve{\mathcal{Y}}(\boldsymbol{\upsilon}^\circ)}{\epsilon\|\boldsymbol{u}_1-\boldsymbol{u}_2\|\|\mathcal{D}(\boldsymbol{\upsilon}-\boldsymbol{\upsilon}^*)\|}\biggr\}\\
&\quad\le\sup_{\|\boldsymbol{u}\|\le1}\frac{1}{2}\log\mathbb{E}\exp\biggl\{2\lambda\frac{\boldsymbol{u}^\top\bigl(\breve{\mathcal{Y}}(\boldsymbol{\upsilon})-\breve{\mathcal{Y}}(\boldsymbol{\upsilon}^\circ)\bigr)}{\epsilon\|\mathcal{D}(\boldsymbol{\upsilon}-\boldsymbol{\upsilon}^\circ)\|}\biggr\}\\
&\qquad+\sup_{\|\boldsymbol{u}\|\le1}\frac{1}{2}\log\mathbb{E}\exp\biggl\{2\lambda\frac{\boldsymbol{u}^\top\bigl(\breve{\mathcal{Y}}(\boldsymbol{\upsilon}^\circ)-\breve{\mathcal{Y}}(\boldsymbol{\upsilon}^*)\bigr)}{\epsilon\|\mathcal{D}(\boldsymbol{\upsilon}-\boldsymbol{\upsilon}^*)\|}\biggr\}\\
&\quad\le\frac{4\nu_0^2\lambda^2}{2},\qquad\lambda\le\mathtt{g}/2.
\end{aligned}$$

■

Appendix C. A Bound for the Spectral Norm of a Random Matrix Process

We want to derive for a random process $\breve{\mathcal{Y}}(\boldsymbol{\upsilon})\in\mathbb{R}^{p^*\times p^*}$ a bound of the kind

$$\mathbb{P}\biggl(\sup_{\boldsymbol{\upsilon}\in\Upsilon_\circ(\mathtt{r})}\Bigl\{\|\breve{\mathcal{Y}}(\boldsymbol{\upsilon})\|\Bigr\}\ge\mathtt{C}\epsilon_2\mathfrak{z}_1(\mathtt{x},p^*)\mathtt{r}\biggr)\le\mathrm{e}^{-\mathtt{x}}.$$

We derive such a bound in a very similar manner to Theorem E.1 of Andresen and Spokoiny (2014).

We want to apply Corollary 2.2 of the supplement of Spokoiny (2012). Again we slightly generalized the formulation but the proof remains the same.

Corollary 45 *Let $(U(\mathtt{r}))_{0\le\mathtt{r}\le\mathtt{r}^*}\subset\mathbb{R}^p$ be a sequence of balls around $\boldsymbol{\upsilon}^*$ induced by the metric $d(\cdot,\cdot)$. Let a random real valued process $\mathcal{U}(\boldsymbol{\upsilon})$ fulfill that $\mathcal{U}(\boldsymbol{\upsilon}^*)=0$ and*

($\mathcal{E}d$) *For any $\boldsymbol{\upsilon},\boldsymbol{\upsilon}^\circ\in U(\mathtt{r})$*

$$\log\mathbb{E}\exp\biggl\{\lambda\frac{\mathcal{U}(\boldsymbol{\upsilon})-\mathcal{U}(\boldsymbol{\upsilon}^\circ)}{d(\boldsymbol{\upsilon},\boldsymbol{\upsilon}^\circ)}\biggr\}\le\frac{\nu_0^2\lambda^2}{2},\qquad|\lambda|\le\mathtt{g}.\tag{45}$$

Then for each $0\le\mathtt{r}\le\mathtt{r}^*$, on a set of probability greater $1-\mathrm{e}^{-\mathtt{x}}$

$$\sup_{\boldsymbol{\upsilon}\in U(\mathtt{r})}\mathcal{U}(\boldsymbol{\upsilon})\le3\nu_1\mathfrak{z}_1(\mathtt{x},p^*)^2d(\boldsymbol{\upsilon},\boldsymbol{\upsilon}^*),$$

where $\mathfrak{z}_1(\mathtt{x},p^*)\stackrel{\mathrm{def}}{=}\mathbb{Q}(U(\mathtt{r}^*))$ denotes the entropy of the set $U(\mathtt{r}^*)\subset\mathbb{R}^p$ and where with $\mathtt{g}_0=\nu_0\mathtt{g}$ and for some $\mathbb{Q}>0$

$$\mathfrak{z}_1(\mathtt{x},\mathbb{Q})\stackrel{\mathrm{def}}{=}\begin{cases}\sqrt{2(\mathtt{x}+\mathbb{Q})} & \text{if }\sqrt{2(\mathtt{x}+\mathbb{Q})}\le\mathtt{g}_0,\\ \mathtt{g}_0^{-1}(\mathtt{x}+\mathbb{Q})+\mathtt{g}_0/2 & \text{otherwise.}\end{cases}\tag{46}$$

To use this result let $\mathcal{Y}(\boldsymbol{\upsilon})$ be a smooth centered random process with values in $\mathbb{R}^{p^*\times p^*}$ and let $\mathcal{D}:\mathbb{R}^{p^*}\to\mathbb{R}^{p^*}$ be some linear operator. We aim at bounding the maximum of the spectral norm $\|\mathcal{Y}(\boldsymbol{\upsilon})\|$ over a vicinity $\Upsilon_\circ(\mathtt{r})\stackrel{\mathrm{def}}{=}\{\|\boldsymbol{\upsilon}-\boldsymbol{\upsilon}^*\|_{\mathcal{Y}}\le\mathtt{r}\}$ of $\boldsymbol{\upsilon}^*$. Suppose that $\mathcal{Y}(\boldsymbol{\upsilon})$ satisfies $\mathcal{Y}(\boldsymbol{\upsilon}^*)=0$ and for each $0<\mathtt{r}<\mathtt{r}^*$ and for all pairs $\boldsymbol{\upsilon},\boldsymbol{\upsilon}^\circ\in\Upsilon_\circ(\mathtt{r})=\bigl\{\boldsymbol{\upsilon}\in\Upsilon\colon\|\boldsymbol{\upsilon}-\boldsymbol{\upsilon}^*\|_{\mathcal{Y}}\le\mathtt{r}\bigr\}\subset\mathbb{R}^{p^*}$

$$\sup_{\|\boldsymbol{u}_1\|\le1}\sup_{\|\boldsymbol{u}_2\|\le1}\log\mathbb{E}\exp\biggl\{\lambda\frac{\boldsymbol{u}_1^\top\bigl(\mathcal{Y}(\boldsymbol{\upsilon})-\mathcal{Y}(\boldsymbol{\upsilon}^\circ)\bigr)\boldsymbol{u}_2}{\epsilon_2\|\mathcal{D}(\boldsymbol{\upsilon}-\boldsymbol{\upsilon}^\circ)\|}\biggr\}\le\frac{\nu_2^2\lambda^2}{2}.\tag{47}$$

Remark 46 *In the setting of Theorem 14 we have $\|\boldsymbol{\upsilon}-\boldsymbol{\upsilon}^\circ\|_{\mathcal{Y}}=\|\mathcal{D}(\boldsymbol{\upsilon}-\boldsymbol{\upsilon}^\circ)\|$ and*

$$\mathcal{Y}(\boldsymbol{\upsilon})=\mathcal{D}^{-1}\nabla^2\boldsymbol{\zeta}(\boldsymbol{\upsilon})-\mathcal{D}^{-1}\nabla^2\boldsymbol{\zeta}(\boldsymbol{\upsilon}^*),$$

and condition (47) *becomes* ($\mathcal{E}\mathcal{D}_2$) *from 2.1.*

Theorem 47 *Let a random process $\mathcal{Y}(\boldsymbol{\upsilon})\in\mathbb{R}^{p^*\times p^*}$ fulfill $\mathcal{Y}(\boldsymbol{\upsilon}^*)=0$ and let condition* (47) *be satisfied. Then for each $0\le\mathtt{r}\le\mathtt{r}^*$, on a set of probability greater than $1-\mathrm{e}^{-\mathtt{x}}$*

$$\sup_{\boldsymbol{\upsilon}\in\Upsilon_\circ(\mathtt{r})}\|\mathcal{Y}(\boldsymbol{\upsilon})\|\le9\epsilon_2\nu_2\mathfrak{z}_1(\mathtt{x},6p^*)\mathtt{r},$$

with $\mathtt{g}_0=\nu_0\mathtt{g}$.

Remark 48 *Note that the entropy of the original set $\Upsilon_\circ(\mathtt{r})\subset\mathbb{R}^{p^*}$ is multiplied by 3. So in order to control the spectral norm $\|\mathcal{Y}(\boldsymbol{\upsilon})\|$ one only pays with this factor.*

Proof In what follows, we use the representation

$$\|\mathcal{Y}(\boldsymbol{\upsilon})\|=\epsilon_2\sup_{\|\boldsymbol{u}_1\|\le\mathtt{r}}\sup_{\|\boldsymbol{u}_2\|\le\mathtt{r}}\frac{1}{\epsilon_2\mathtt{r}^2}\boldsymbol{u}_1^\top\breve{\mathcal{Y}}(\boldsymbol{\upsilon})\boldsymbol{u}_2.$$

This implies

$$\sup_{\boldsymbol{\upsilon}\in\Upsilon_\circ(\mathtt{r})}\|\mathcal{Y}(\boldsymbol{\upsilon})\|=\epsilon\sup_{\boldsymbol{\upsilon}\in\Upsilon_\circ(\mathtt{r})}\sup_{\|\boldsymbol{u}_2\|\le\mathtt{r}}\sup_{\|\boldsymbol{u}_2\|\le\mathtt{r}}\frac{1}{\epsilon\mathtt{r}^2}\boldsymbol{u}_1^\top\breve{\mathcal{Y}}(\boldsymbol{\upsilon})\boldsymbol{u}_2.$$

Due to Lemma 49 the process $\mathcal{U}(\upsilon) \stackrel{\mathrm{def}}{=} \frac{1}{\epsilon \mathtt{r}^2} \boldsymbol{u}_1^\top \mathcal{Y}(\upsilon) \boldsymbol{u}_2$ satisfies condition $(\mathcal{E}d)$ (see (45)) as process on

$$U(\mathtt{r}) \stackrel{\mathrm{def}}{=} \Upsilon_\circ(\mathtt{r}) \times B_{\mathtt{r}}(0) \times B_{\mathtt{r}}(0) \subset \mathbb{R}^{3p^*}. \tag{48}$$

This allows to apply Corollary 45 to obtain the desired result. We get on a set of probability greater $1 - \mathrm{e}^{-\mathtt{x}}$

$$\sup_{\upsilon \in \Upsilon_\circ(\mathtt{r})} \|\mathcal{Y}(\upsilon)\| \le \sup_{(\upsilon, \boldsymbol{u}_1, \boldsymbol{u}_2) \in U(\mathtt{r})} \left\{ \frac{1}{\mathtt{r}^2} \boldsymbol{u}_1^\top \mathcal{Y}(\upsilon) \boldsymbol{u}_2 \right\} \le 9 \epsilon_2 \nu_2 \mathfrak{z}_1 \Bigl(\mathtt{x}, \mathbb{Q}\bigl(U(\mathtt{r}^*)\bigr) \Bigr) \mathtt{r}.$$

The constant $\mathbb{Q}\bigl(U(\mathtt{r})\bigr) > 0$ quantifies the complexity of the set $U(\mathtt{r}) \subset \mathbb{R}^{3p^*}$. We point out that for compact $M \subset \mathbb{R}^{3p^*}$ we have $\mathbb{Q}(M) = 6p^*$ (see Supplement of Spokoiny (2012), Lemma 2.10). This gives the claim. ∎

Lemma 49 *Suppose that* $\mathcal{Y}(\upsilon) \in \mathbb{R}^{p^* \times p^*}$ *satisfies* $\mathcal{Y}(\upsilon^*) = 0$ *and for each* $\|\boldsymbol{u}_1\| \le 1$, $\|\boldsymbol{u}_2\| \le 1$ *and* $|\lambda| \le \mathtt{g}$ *the inequality* (47). *Then the process*

$$\mathcal{U}(\upsilon, \boldsymbol{u}_1, \boldsymbol{u}_2) = \frac{1}{2\epsilon_2 \mathtt{r}^2} \boldsymbol{u}_1^\top \mathcal{Y}(\upsilon)^\top \boldsymbol{u}_2$$

satisfies $(\boldsymbol{\mathcal{E}d})$ *from* (45) *with* $U \subset \mathbb{R}^{3p^*}$ *defined in* (48), *with* $|\lambda| \le \mathtt{g}/3$ *and with*

$$d((\upsilon, \boldsymbol{u}_1, \boldsymbol{u}_2), (\upsilon^\circ, \boldsymbol{u}_1^\circ, \boldsymbol{u}_2^\circ))^2 = \|\mathcal{D}(\upsilon - \upsilon^*)\|^2 + \|\boldsymbol{u}_1 - \boldsymbol{u}_1^\circ\|^2 + \|\boldsymbol{u}_2 - \boldsymbol{u}_2^\circ\|^2,$$

i.e. for any $(\upsilon, \boldsymbol{u}_1, \boldsymbol{u}_2), (\upsilon^\circ, \boldsymbol{u}_1^\circ, \boldsymbol{u}_2^\circ) \in U$

$$\log \mathbb{E} \exp\left\{ \lambda \frac{\mathcal{U}(\upsilon, \boldsymbol{u}_1, \boldsymbol{u}_2) - \mathcal{U}(\upsilon^\circ, \boldsymbol{u}_1^\circ, \boldsymbol{u}_2^\circ)}{d((\upsilon, \boldsymbol{u}_1, \boldsymbol{u}_2), (\upsilon^\circ, \boldsymbol{u}_1^\circ, \boldsymbol{u}_2^\circ))} \right\} \le \frac{9\nu_2^2 \lambda^2}{2}, \qquad |\lambda| \le \mathtt{g}/3.$$

Proof Let $(\upsilon, \boldsymbol{u}_1, \boldsymbol{u}_2), (\upsilon^\circ, \boldsymbol{u}_1^\circ, \boldsymbol{u}_2^\circ) \in U$. By the Hölder inequality and (47), we find

$$\begin{aligned}
&\log \mathbb{E} \exp\left\{ \lambda \frac{\mathcal{U}(\upsilon, \boldsymbol{u}_1, \boldsymbol{u}_2) - \mathcal{U}(\upsilon^\circ, \boldsymbol{u}_1^\circ, \boldsymbol{u}_2^\circ)}{d((\upsilon, \boldsymbol{u}_1, \boldsymbol{u}_2), (\upsilon^\circ, \boldsymbol{u}_1^\circ, \boldsymbol{u}_2^\circ))} \right\} \\
&\quad = \log \mathbb{E} \exp\left\{ \lambda \left(\frac{\mathcal{U}(\upsilon, \boldsymbol{u}_1, \boldsymbol{u}_2) - \mathcal{U}(\upsilon^\circ, \boldsymbol{u}_1, \boldsymbol{u}_2)}{d((\upsilon, \boldsymbol{u}_1, \boldsymbol{u}_2), (\upsilon^\circ, \boldsymbol{u}_1^\circ, \boldsymbol{u}_2^\circ))} + \frac{\mathcal{U}(\upsilon^\circ, \boldsymbol{u}_1, \boldsymbol{u}_2) - \mathcal{U}(\upsilon^\circ, \boldsymbol{u}_1^\circ, \boldsymbol{u}_2)}{d((\upsilon, \boldsymbol{u}_1, \boldsymbol{u}_2), (\upsilon^\circ, \boldsymbol{u}_1^\circ, \boldsymbol{u}_2^\circ))} \right. \right. \\
&\qquad \left. \left. + \frac{\mathcal{U}(\upsilon^\circ, \boldsymbol{u}_1^\circ, \boldsymbol{u}_2) - \mathcal{U}(\upsilon^\circ, \boldsymbol{u}_1^\circ, \boldsymbol{u}_2^\circ)}{d((\upsilon, \boldsymbol{u}_1, \boldsymbol{u}_2), (\upsilon^\circ, \boldsymbol{u}_1^\circ, \boldsymbol{u}_2^\circ))} \right) \right\} \\
&\quad \le \frac{1}{3} \log \mathbb{E} \exp\left\{ 3\lambda \frac{\boldsymbol{u}_1^\top \bigl(\frac{1}{\mathtt{r}^2} \breve{\mathcal{Y}}(\upsilon) - \frac{1}{\mathtt{r}^2} \breve{\mathcal{Y}}(\upsilon^\circ) \bigr) \boldsymbol{u}_2}{\epsilon_2 \|\mathcal{D}(\upsilon - \upsilon^\circ)\|} \right\} \\
&\qquad + \frac{1}{3} \log \mathbb{E} \exp\left\{ 3\lambda \frac{(\boldsymbol{u}_1 - \boldsymbol{u}_1^\circ)^\top) \mathcal{Y}(\upsilon^\circ) \boldsymbol{u}_2}{\epsilon_2 \|\boldsymbol{u}_1 - \boldsymbol{u}_2\| \mathtt{r}^2} \right\} \\
&\qquad + \frac{1}{3} \log \mathbb{E} \exp\left\{ 3\lambda \frac{(\boldsymbol{u}_1^\circ)^\top) \mathcal{Y}(\upsilon^\circ) (\boldsymbol{u}_2 - \boldsymbol{u}_2^\circ)}{\epsilon_2 \|\boldsymbol{u}_1 - \boldsymbol{u}_2\| \mathtt{r}^2} \right\} \\
&\quad \le \frac{1}{3} \sup_{\|\boldsymbol{u}_1\| \le 1} \sup_{\|\boldsymbol{u}_2\| \le 1} \log \mathbb{E} \exp\left\{ 3\lambda \frac{\boldsymbol{u}_1^\top \bigl(\mathcal{Y}(\upsilon) - \mathcal{Y}(\upsilon^\circ) \bigr) \boldsymbol{u}_2}{\epsilon_2 \|\mathcal{D}(\upsilon - \upsilon^\circ)\|} \right\} \\
&\qquad + \frac{2}{3} \sup_{\|\boldsymbol{u}_1\| \le 1} \sup_{\|\boldsymbol{u}_2\| \le 1} \log \mathbb{E} \exp\left\{ 3\lambda \frac{\boldsymbol{u}_1^\top \bigl(\mathcal{Y}(\upsilon^\circ) - \mathcal{Y}(\upsilon^*) \bigr) \boldsymbol{u}_2}{\epsilon_2 \|\mathcal{D}(\upsilon - \upsilon^*)\|} \right\} \\
&\quad \le \frac{9\nu_2^2 \lambda^2}{2}, \qquad \lambda \le \mathtt{g}/3.
\end{aligned}$$

Abstract

Structured tasks are distinctive: each task has its own measure of performance, such as the word error rate in speech recognition, the BLEU score in machine translation, the NDCG score in information retrieval, or the intersection-over-union score in visual object segmentation. This paper presents StructED, a software package for learning structured prediction models with training methods that aimed at optimizing the task measure of performance. The package was written in Java and released under the MIT license. It can be downloaded from `http://adiyoss.github.io/StructED/`.

Keywords: structured prediction, structural SVM, CRF, direct loss minimization

1. Introduction

Ultimately the objective of discriminative training is to learn the model parameters so as to optimize a desired measure of performance. In binary classification, the objective is to find a prediction function that assigns a binary label to a single object, and minimizes the error rate (0-1 loss) on unseen data. In structured prediction, however, the goal is to predict a structured label (e.g., a graph, a sequence of words, a human pose, etc.), which often cannot be evaluated using the binary error rate, but rather with a task-specific measure of performance, generally called here *task loss*. There is a voluminous amount of work on training procedures for maximizing the BLEU score in machine translation, minimizing word/phone error rate in speech recognition or maximizing NDCG in information retrieval.

The most common approaches to learning parameters for structured prediction, namely structured perceptron, structural support vector machine (SSVM) and conditional random fields (CRF) do not directly minimize the task loss. The structured perceptron (Collins, 2002) solves a feasibility problem, which is independent of the task loss. The surrogate loss of SSVM (Joachims et al., 2005) is the structured hinge loss, a convex upper bound to the task loss, which is based on a generalization of the binary SVM hinge loss. However, while the binary SVM is strongly consistent, namely, converges to the error rate of the optimal linear predictor in the limit of infinite training data, the structured hinge loss is not consistent and does not converge to the expected task loss, i.e., the risk, of the optimal linear predictor even when the task loss is the 0-1 loss (McAllester, 2006). The objective of CRF is the log loss function, which is independent of the task loss (Lafferty et al., 2001).

Several structured prediction libraries already exist, such as CRF++ (Kudo, 2005), CRFsuite (Okazaki, 2007), Dlib (King, 2009), PyStruct (Müller and Behnke, 2014), and SVM-Struct (Joachims et al., 2009). All provide a general framework for training a model with either structured perceptron, CRF, or SSVM using several optimization techniques. Nevertheless, CRF++ and CRFsuite were not designed to support discriminative training with a task-specific evaluation metric, but rather use the binary error rate as their task loss function; whereas SVM-Struct, PyStruct, and Dlib support the training of structural SVM with a user-defined task loss function, but do not include, in their current phase, other training methods that are directly aimed at minimizing the task loss.

In this work we present StructED, a software package that is focused on training methods for structured prediction models that are aimed at minimizing a given task loss. The package provides several interfaces to define and implement a structured task, and allows the user to estimate the model parameters with several different training methods. The goal is not to provide several optimization alternatives to the structured hinge loss or the log loss as was already done in the previous packages, but rather to propose an implementation of a variety of surrogate loss functions that were designed to minimize the task loss and were theoretically motivated (McAllester and Keshet, 2011).

Note that most training methods require the task loss function to be decomposable in the size of the output label. Decomposable task loss functions are required in order to solve the loss-augmented inference that is used within the training procedure (Ranjbar et al., 2013), and evaluation metrics like intersection-over-union or word error rate which are not decomposable need to be approximated when utilized in SSVM, for example. Our package provides an implementation of methods (structured probit and orbit loss) that do not expect the task loss to be decomposable and can handle it directly without being approximated.

2. Structured Prediction and Risk Minimization

Consider a supervised learning setting with input instances $\boldsymbol{x} \in \mathcal{X}$ and target labels $\boldsymbol{y} \in \mathcal{Y}$, which refers to a set of objects with an internal structure. We assume a fixed mapping $\boldsymbol{\phi} : \mathcal{X} \times \mathcal{Y} \to \mathbb{R}^d$ from the set of input objects and target labels to a real vector of length d, where we call the elements of this mapping *feature functions*. Also, consider a linear decoder with parameters $\boldsymbol{w} \in \mathbb{R}^d$, such that $\hat{\boldsymbol{y}}_{\boldsymbol{w}}$ is a good approximation to the true label of $\boldsymbol{x}$, as follows:

$$\hat{\boldsymbol{y}}_{\boldsymbol{w}}(\boldsymbol{x}) = \operatorname*{argmax}_{\boldsymbol{y} \in \mathcal{Y}} \ \boldsymbol{w}^\top \boldsymbol{\phi}(\boldsymbol{x}, \boldsymbol{y}) \tag{1}$$

Ideally, the learning algorithm finds $\boldsymbol{w}$ such that the prediction rule optimizes the expected desired *measure of preference* or *evaluation metric* on unseen data. We define the task loss function, $\ell(\boldsymbol{y}, \hat{\boldsymbol{y}}_{\boldsymbol{w}})$, to be a non-negative measure of error when predicting $\hat{\boldsymbol{y}}_{\boldsymbol{w}}$ instead of $\boldsymbol{y}$ as the label of $\boldsymbol{x}$. Our goal is to find the parameter vector $\boldsymbol{w}$ that minimizes this function. When the desired evaluation metric is a utility function that needs to be maximized (like BLEU or NDCG), we define the task loss to be 1 minus the evaluation metric.

Our goal is to set $\boldsymbol{w}$ so as to minimize the expected task loss (i.e., risk) for predicting $\hat{\boldsymbol{y}}_{\boldsymbol{w}}$,

$$\boldsymbol{w}^* = \operatorname*{argmin}_{\boldsymbol{w}} \ \mathbb{E}_{(\boldsymbol{x},\boldsymbol{y}) \sim \rho}[\ell(\boldsymbol{y}, \hat{\boldsymbol{y}}_{\boldsymbol{w}}(\boldsymbol{x}))], \tag{2}$$

where the expectation is taken over pairs $(\boldsymbol{x}, \boldsymbol{y})$ drawn from an unknown probability distribution ρ. This objective function is hard to minimize directly. A common practice is to replace the task loss with a surrogate loss function, denoted $\bar{\ell}(\boldsymbol{w}, \boldsymbol{x}, \boldsymbol{y})$, which is easier to minimize; and to replace the expectation with a regularized average with respect to a set of training examples $\mathcal{S} = \{(\boldsymbol{x}_i, \boldsymbol{y}_i)\}_{i=1}^m$, where each pair $(\boldsymbol{x}_i, \boldsymbol{y}_i)$ is drawn i.i.d from ρ:

$$\boldsymbol{w}^* = \operatorname*{argmin}_{\boldsymbol{w}} \frac{1}{m} \sum_{i=1}^{m} \bar{\ell}(\boldsymbol{w}, \boldsymbol{x}_i, \boldsymbol{y}_i) + \frac{\lambda}{2} \|\boldsymbol{w}\|^2, \tag{3}$$

where λ is a trade-off parameter between the loss term and the regularization. Different training algorithms are defined by different surrogate loss functions, e.g., the surrogate loss of max-margin Markov model (Taskar et al., 2003) is the structured hinge loss with the Hamming distance, whereas the one for CRF is the log loss function. These loss functions are convex in the model parameters, $\boldsymbol{w}$.

Recently, several works proposed different surrogate loss functions which are closer to the task loss in some sense: structured ramp-loss (McAllester and Keshet, 2011), structured probit loss (Keshet et al., 2011), and orbit loss (Karmon and Keshet, 2015). Direct loss minimization (McAllester et al., 2010) is a perceptron-like method of performing direct gradient descent on the risk (2) in the case where $\mathcal{Y}$ is discrete but $\mathcal{X}$ is continuous. All of the training objectives that were proposed in these works are non-convex functions in the model parameters, are strongly consistent and perform well in general.

3. Implementation

Implementation of a structured prediction task involves defining a set of feature functions. Given a trained model, the prediction is performed by finding the output label that maximizes the weighted sum of those feature functions according to (1). Such maximization involves the enumeration over all possible output labels, which is often intractable and handled by dynamic programming or by approximated inference techniques. As a result, and in contrast to packages for binary classification, here the user has to write code that implements the feature functions, the decoder and the evaluation metric.

Currently the implemented training methods are structured perceptron (SP), SSVM, CRF, structured passive-aggressive (SPA; Crammer et al., 2006), direct loss minimization (DLM), structured ramp loss (SRL), structured probit loss (SPL), and orbit loss (Karmon and Keshet, 2015).

The package exposes interfaces for task loss functions, feature extractors, decoding algorithms and training algorithms. In order to train a new model the user has to consider four interfaces, which correspond to: (i) a set of feature functions, $\boldsymbol{\phi}(\boldsymbol{x}, \boldsymbol{y})$; (ii) a task loss function[1], $\ell(\boldsymbol{y}, \hat{\boldsymbol{y}})$; (iii) a decoder to perform the inference in (1), as well as the loss-augmented inference (needed by SPA, SRL, DLM, SSVM); and (iv) a training algorithm. The user can either implement those interfaces or use any of the already implemented interfaces.

The objective in (3) is optimized using stochastic gradient descent (SGD) for both the convex (SSVM and CRF) and non-convex (SRL, SPL, orbit) surrogate losses. DLM cannot be expressed as a surrogate loss function in objective (3), and is optimized using SGD as

1. BLUE and NDCG are currently not implemented.

well. SP and SPA are online algorithms and are implemented as batch algorithms with averaging of the weight vectors as an online-to-batch conversion (Cesa-Bianchi et al., 2004).

4. Experiments

While the library focuses on different training methods for minimizing a given task loss, it is important to verify that the implemented algorithms run in an acceptable amount of time. We compared our implementation of SSVM optimized by SGD to the corresponding implementation in PyStruct on the MNIST data set of handwritten digits. We got similar accuracy and training times (StructED : 92.6%, 149 sec; PyStruct: 90.2%, 145 sec).

We conclude the paper by demonstrating the advantage of the package with a simple structured prediction task of automatic vowel duration measurement. In this task the input is a speech segment of arbitrary duration that contains a vowel between two consonants (e.g., *bat*, *taught*, etc.), and the goal is to accurately predict the duration of the vowel. This task is a required measurement in linguistic studies and is often done manually. The training data includes speech segments that are labeled with the vowel onset and offset times, denoted y_b and y_e, respectively. The task loss is defined as $\ell(\boldsymbol{y}, \hat{\boldsymbol{y}}) = \max\{0, |y_b - \hat{y}_b| - \tau_b\} + \max\{0, |y_e - \hat{y}_e| - \tau_e\}$, where $\hat{y}_b$ and $\hat{y}_e$ are predicted vowel onset and offset times, respectively, and τ_b and τ_e are parameters (τ_b=10 msec and τ_e=15 msec). We had a training set of 90 examples, a validation set of 20 examples and a test set of 20 examples. We extracted 21 unique acoustic features every 5 msec, including the confidence of a frame-based phoneme classifier, the first and the second formants and other acoustic features. We trained all algorithms on this task and present their performance in terms of task loss (the lower the better) and training times in Table 1 (training parameters for each of the training methods can be found in the package's Examples folder).

Algorithm	Task loss [msec]	Time [sec]
SP	72.5	13
SSVM	72.0	13
CRF	70.5	31
SPA	69.0	12
SRL	64.5	25
SPL	64.5	617
DLM	63.5	24
Orbit loss	58.5	13

Table 1: Error rate and training times on vowel duration measurement task.

Results suggest that training methods, which are designed to minimize the task loss, lead to improved performance compared to SP, SSVM, CRF or SPA. It is also evident that these methods, except orbit loss, take at least twice as much time to train: DLM and SRL need two inference operations per training iteration and SPL needs hundreds to thousands of inferences per training iteration.

The implementation of the above example is straightforward and is given in the Examples section of the package website `http://adiyoss.github.io/StructED/` along with several other usage examples and further details.

Abstract

We present a method for extracting depth information from a rectified image pair. Our approach focuses on the first stage of many stereo algorithms: the matching cost computation. We approach the problem by learning a similarity measure on small image patches using a convolutional neural network. Training is carried out in a supervised manner by constructing a binary classification data set with examples of similar and dissimilar pairs of patches. We examine two network architectures for this task: one tuned for speed, the other for accuracy. The output of the convolutional neural network is used to initialize the stereo matching cost. A series of post-processing steps follow: cross-based cost aggregation, semiglobal matching, a left-right consistency check, subpixel enhancement, a median filter, and a bilateral filter. We evaluate our method on the KITTI 2012, KITTI 2015, and Middlebury stereo data sets and show that it outperforms other approaches on all three data sets.

Keywords: stereo, matching cost, similarity learning, supervised learning, convolutional neural networks

1. Introduction

Consider the following problem: given two images taken by cameras at different horizontal positions, we wish to compute the disparity d for each pixel in the left image. Disparity refers to the difference in horizontal location of an object in the left and right image—an object at position (x, y) in the left image appears at position $(x-d, y)$ in the right image. If we know the disparity of an object we can compute its depth z using the following relation:

$$z = \frac{fB}{d},$$

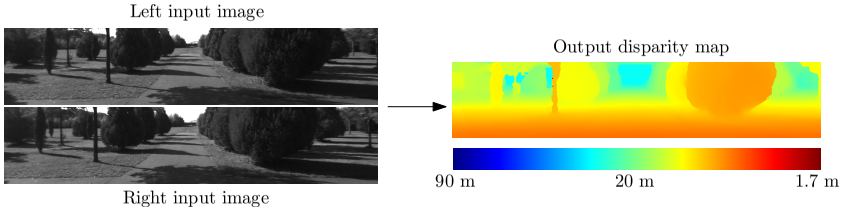

Figure 1: The input is a pair of images from the left and right camera. The two input images differ mostly in horizontal locations of objects (other differences are caused by reflections, occlusions, and perspective distortions). Note that objects closer to the camera have larger disparities than objects farther away. The output is a dense disparity map shown on the right, with warmer colors representing larger values of disparity (and smaller values of depth).

where f is the focal length of the camera and B is the distance between the camera centers. Figure 1 depicts the input to and the output from our method.

The described problem of stereo matching is important in many fields such as autonomous driving, robotics, intermediate view generation, and 3D scene reconstruction. According to the taxonomy of Scharstein and Szeliski (2002), a typical stereo algorithm consists of four steps: matching cost computation, cost aggregation, optimization, and disparity refinement. Following Hirschmüller and Scharstein (2009) we refer to the first two steps as computing the matching cost and the last two steps as the stereo method. The focus of this work is on computing a good matching cost.

We propose training a convolutional neural network (LeCun et al., 1998) on pairs of small image patches where the true disparity is known (for example, obtained by LIDAR or structured light). The output of the network is used to initialize the matching cost. We proceed with a number of post-processing steps that are not novel, but are necessary to achieve good results. Matching costs are combined between neighboring pixels with similar image intensities using cross-based cost aggregation. Smoothness constraints are enforced by semiglobal matching and a left-right consistency check is used to detect and eliminate errors in occluded regions. We perform subpixel enhancement and apply a median filter and a bilateral filter to obtain the final disparity map.

The contributions of this paper are

- a description of two architectures based on convolutional neural networks for computing the stereo matching cost;
- a method, accompanied by its source code, with the lowest error rate on the KITTI 2012, KITTI 2015, and Middlebury stereo data sets; and
- experiments analyzing the importance of data set size, the error rate compared with other methods, and the trade-off between accuracy and runtime for different settings of the hyperparameters.

This paper extends our previous work (Žbontar and LeCun, 2015) by including a description of a new architecture, results on two new data sets, lower error rates, and more thorough experiments.

2. Related Work

Before the introduction of large stereo data sets like KITTI and Middlebury, relatively few stereo algorithms used ground truth information to learn parameters of their models; in this section, we review the ones that did. For a general overview of stereo algorithms see Scharstein and Szeliski (2002).

Kong and Tao (2004) used the sum of squared distances to compute an initial matching cost. They then trained a model to predict the probability distribution over three classes: the initial disparity is correct, the initial disparity is incorrect due to fattening of a foreground object, and the initial disparity is incorrect due to other reasons. The predicted probabilities were used to adjust the initial matching cost. Kong and Tao (2006) later extend their work by combining predictions obtained by computing normalized cross-correlation over different window sizes and centers. Peris et al. (2012) initialized the matching cost with AD-Census (Mei et al., 2011), and used multiclass linear discriminant analysis to learn a mapping from the computed matching cost to the final disparity.

Ground-truth data was also used to learn parameters of probabilistic graphical models. Zhang and Seitz (2007) used an alternative optimization algorithm to estimate optimal values of Markov random field hyperparameters. Scharstein and Pal (2007) constructed a new data set of 30 stereo pairs and used it to learn parameters of a conditional random field. Li and Huttenlocher (2008) presented a conditional random field model with a non-parametric cost function and used a structured support vector machine to learn the model parameters.

Recent work (Haeusler et al., 2013; Spyropoulos et al., 2014) focused on estimating the confidence of the computed matching cost. Haeusler et al. (2013) used a random forest classifier to combine several confidence measures. Similarly, Spyropoulos et al. (2014) trained a random forest classifier to predict the confidence of the matching cost and used the predictions as soft constraints in a Markov random field to decrease the error of the stereo method.

A related problem to computing the matching cost is learning local image descriptors (Brown et al., 2011; Trzcinski et al., 2012; Simonyan et al., 2014; Revaud et al., 2015; Paulin et al., 2015; Han et al., 2015; Zagoruyko and Komodakis, 2015). The two problems share a common subtask: to measure the similarity between image patches. Brown et al. (2011) introduced a general framework for learning image descriptors and used Powell's method to select good hyperparameters. Several methods have been suggested for solving the problem of learning local image descriptors, such as boosting (Trzcinski et al., 2012), convex optimization (Simonyan et al., 2014), hierarchical moving-quadrant similarity (Revaud et al., 2015), convolutional kernel networks (Paulin et al., 2015), and convolutional neural networks (Zagoruyko and Komodakis, 2015; Han et al., 2015). Works of Zagoruyko and Komodakis (2015) and Han et al. (2015), in particular, are very similar to our own, differing mostly in the architecture of the network; concretely, the inclusion of pooling and subsampling to account for larger patch sizes and larger variation in viewpoint.

3. Matching Cost

A typical stereo algorithm begins by computing a matching cost at each position $\mathbf{p}$ for all disparities d under consideration. A simple method for computing the matching cost is the sum of absolute differences:

$$C_{\text{SAD}}(\mathbf{p}, d) = \sum_{\mathbf{q} \in \mathcal{N}_{\mathbf{p}}} |I^L(\mathbf{q}) - I^R(\mathbf{q} - \mathbf{d})|, \tag{1}$$

where $I^L(\mathbf{p})$ and $I^R(\mathbf{p})$ are image intensities at position $\mathbf{p}$ in the left and right image and $\mathcal{N}_{\mathbf{p}}$ is the set of locations within a fixed rectangular window centered at $\mathbf{p}$.

We use bold lowercase letters $\mathbf{p}$ and $\mathbf{q}$ to denote image locations. A bold lowercase $\mathbf{d}$ denotes the disparity d cast to a vector, that is, $\mathbf{d} = (d, 0)$. We use `typewriter` font for the names of hyperparameters. For example, we would use `patch_size` to denote the size of the neighbourhood area $\mathcal{N}_{\mathbf{p}}$.

Equation (1) can be interpreted as measuring the cost associated with matching a patch from the left image, centered at position $\mathbf{p}$, with a patch from the right image, centered at position $\mathbf{p} - \mathbf{d}$. We want the cost to be low when the two patches are centered around the image of the same 3D point, and high when they are not.

Since examples of good and bad matches can be constructed from publicly available data sets (for example, the KITTI and Middlebury stereo data sets), we can attempt to solve the matching problem by a supervised learning approach. Inspired by the successful application of convolutional neural networks to vision problems, we used them to assess how well two small image patches match.

3.1 Constructing the Data Set

We use ground truth disparity maps from either the KITTI or Middlebury stereo data sets to construct a binary classification data set. At each image position where the true disparity is known we extract one negative and one positive training example. This ensures that the data set contains an equal number of positive and negative examples. A positive example is a pair of patches, one from the left and one from the right image, whose center pixels are the images of the same 3D point, while a negative example is a pair of patches where this is not the case. The following section describes the data set construction step in detail.

Let $< \mathcal{P}^L_{n\times n}(\mathbf{p}), \mathcal{P}^R_{n\times n}(\mathbf{q}) >$ denote a pair of patches, where $\mathcal{P}^L_{n\times n}(\mathbf{p})$ is an $n \times n$ patch from the left image centered at position $\mathbf{p} = (x, y)$, $\mathcal{P}^R_{n\times n}(\mathbf{q})$ is an $n \times n$ patch from the right image centered at position $\mathbf{q}$, and d denotes the correct disparity at position $\mathbf{p}$. A negative example is obtained by setting the center of the right patch to

$$\mathbf{q} = (x - d + o_{\text{neg}}, y),$$

where o_{neg} is chosen from either the interval $[\texttt{dataset\_neg\_low}, \texttt{dataset\_neg\_high}]$ or, its origin reflected counterpart, $[-\texttt{dataset\_neg\_high}, -\texttt{dataset\_neg\_low}]$. The random offset o_{neg} ensures that the resulting image patches are not centered around the same 3D point.

A positive example is derived by setting

$$\mathbf{q} = (x - d + o_{\text{pos}}, y),$$

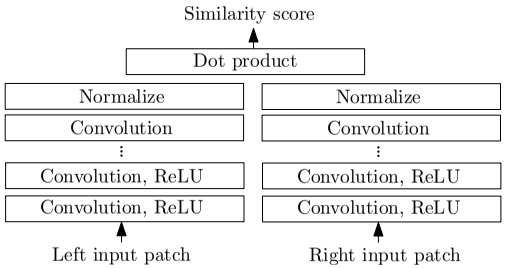

Figure 2: The fast architecture is a siamese network. The two sub-networks consist of a number of convolutional layers followed by rectified linear units (abbreviated "ReLU"). The similarity score is obtained by extracting a vector from each of the two input patches and computing the cosine similarity between them. In this diagram, as well as in our implementation, the cosine similarity computation is split in two steps: normalization and dot product. This reduces the running time because the normalization needs to be performed only once per position (see Section 3.3).

where o_{pos} is chosen randomly from the interval $[-\texttt{dataset\_pos}, \texttt{dataset\_pos}]$. The reason for including o_{pos}, instead of setting it to zero, has to do with the stereo method used later on. In particular, we found that cross-based cost aggregation performs better when the network assigns low matching costs to good matches as well as near matches. In our experiments, the hyperparameter `dataset_pos` was never larger than one pixel.

3.2 Network Architectures

We describe two network architectures for learning a similarity measure on image patches. The first architecture is faster than the second, but produces disparity maps that are slightly less accurate. In both cases, the input to the network is a pair of small image patches and the output is a measure of similarity between them. Both architectures contain a trainable feature extractor that represents each image patch with a feature vector. The similarity between patches is measured on the feature vectors instead of the raw image intensity values. The fast architecture uses a fixed similarity measure to compare the two feature vectors, while the accurate architecture attempts to learn a good similarity measure on feature vectors.

3.2.1 Fast Architecture

The first architecture is a siamese network, that is, two shared-weight sub-networks joined at the head (Bromley et al., 1993). The sub-networks are composed of a number of convolutional layers with rectified linear units following all but the last layer. Both sub-networks output a vector capturing the properties of the input patch. The resulting two vectors are

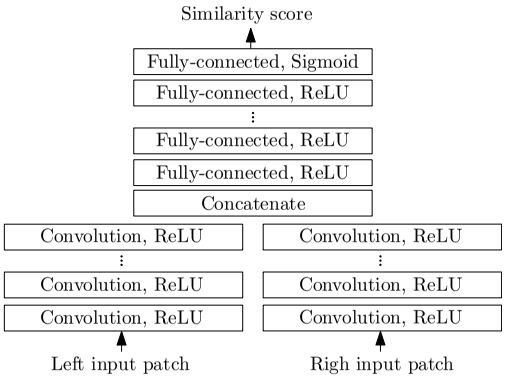

Figure 3: The accurate architecture begins with two convolutional feature extractors. The extracted feature vectors are concatenated and compared by a number of fully-connected layers. The inputs are two image patches and the output is a single real number between 0 and 1, which we interpret as a measure of similarity between the input images.

compared using the cosine similarity measure to produce the final output of the network. Figure 2 provides an overview of the architecture.

The network is trained by minimizing a hinge loss. The loss is computed by considering pairs of examples centered around the same image position where one example belongs to the positive and one to the negative class. Let s_+ be the output of the network for the positive example, s_- be the output of the network for the negative example, and let m, the margin, be a positive real number. The hinge loss for that pair of examples is defined as $\max(0, m + s_- - s_+)$. The loss is zero when the similarity of the positive example is greater than the similarity of the negative example by at least the margin m. We set the margin to 0.2 in our experiments.

The hyperparameters of this architecture are the number of convolutional layers in each sub-network (`num_conv_layers`), the size of the convolution kernels (`conv_kernel_size`), the number of feature maps in each layer (`num_conv_feature_maps`), and the size of the input patch (`input_patch_size`).

3.2.2 Accurate Architecture

The second architecture is derived from the first by replacing the cosine similarity measure with a number of fully-connected layers (see Figure 3). This architectural change increased the running time, but decreased the error rate. The two sub-networks comprise a number of convolutional layers, with a rectified linear unit following each layer. The resulting two vectors are concatenated and forward-propagated through a number of fully-connected

layers followed by rectified linear units. The last fully-connected layer produces a single number which, after being transformed with the sigmoid nonlinearity, is interpreted as the similarity score between the input patches.

We use the binary cross-entropy loss for training. Let s denote the output of the network for one training example and t denote the class of that training example; $t = 1$ if the example belongs to the positive class and $t = 0$ if the example belongs to the negative class. The binary cross-entropy loss for that example is defined as $t \log(s) + (1 - t) \log(1 - s)$.

The decision to use two different loss functions, one for each architecture, was based on empirical evidence. While we would have preferred to use the same loss function for both architectures, experiments showed that the binary cross-entropy loss performed better than the hinge loss on the accurate architecture. On the other hand, since the last step of the fast architecture is the cosine similarity computation, a cross-entropy loss was not directly applicable.

The hyperparameters of the accurate architecture are the number of convolutional layers in each sub-network (`num_conv_layers`), the number of feature maps in each layer (`num_conv_feature_maps`), the size of the convolution kernels (`conv_kernel_size`), the size of the input patch (`input_patch_size`), the number of units in each fully-connected layer (`num_fc_units`), and the number of fully-connected layers (`num_fc_layers`).

3.3 Computing the Matching Cost

The output of the network is used to initialize the matching cost:

$$C_{\text{CNN}}(\mathbf{p}, d) = -s(< \mathcal{P}^L(\mathbf{p}), \mathcal{P}^R(\mathbf{p} - \mathbf{d}) >),$$

where $s(< \mathcal{P}^L(\mathbf{p}), \mathcal{P}^R(\mathbf{p} - \mathbf{d}) >)$ is the output of the network when run on input patches $\mathcal{P}^L(\mathbf{p})$ and $\mathcal{P}^R(\mathbf{p} - \mathbf{d})$. The minus sign converts the similarity score to a matching cost.

To compute the entire matching cost tensor $C_{\text{CNN}}(\mathbf{p}, d)$ we would, naively, have to perform the forward pass for each image location and each disparity under consideration. The following three implementation details kept the running time manageable:

- The outputs of the two sub-networks need to be computed only once per location, and do not need to be recomputed for every disparity under consideration.

- The output of the two sub-networks can be computed for all pixels in a single forward pass by propagating full-resolution images, instead of small image patches. Performing a single forward pass on the entire $w \times h$ image is faster than performing $w \cdot h$ forward passes on small patches because many intermediate results can be reused.

- The output of the fully-connected layers in the accurate architecture can also be computed in a single forward pass. This is done by replacing each fully-connected layer with a convolutional layer with 1×1 kernels. We still need to perform the forward pass for each disparity under consideration; the maximum disparity d is 228 for the KITTI data set and 400 for the Middlebury data set. As a result, the fully-connected part of the network needs to be run d times, and is a bottleneck of the accurate architecture.

To compute the matching cost of a pair of images, we run the sub-networks once on each image and run the fully-connected layers d times, where d is the maximum disparity under consideration. This insight was important in designing the architecture of the network. We could have chosen an architecture where the two images are concatenated before being presented to the network, but that would imply a large cost at runtime because the whole network would need to be run d times. This insight also led to the development of the fast architecture, where the only layer that is run d times is the dot product of the feature vectors.

4. Stereo Method

The raw outputs of the convolutional neural network are not enough to produce accurate disparity maps, with errors particularly apparent in low-texture regions and occluded areas. The quality of the disparity maps can be improved by applying a series of post-processing steps referred to as the stereo method. The stereo method we used was influenced by Mei et al. (2011) and comprises cross-based cost aggregation, semiglobal matching, a left-right consistency check, subpixel enhancement, a median, and a bilateral filter.

4.1 Cross-based Cost Aggregation

Information from neighboring pixels can be combined by averaging the matching cost over a fixed window. This approach fails near depth discontinuities, where the assumption of constant depth within a window is violated. We might prefer a method that adaptively selects the neighborhood for each pixel, so that support is collected only from pixels of the same physical object. In cross-based cost aggregation (Zhang et al., 2009) we build a local neighborhood around each location comprising pixels with similar image intensity values with the hope that these pixels belong to the same object.

The method begins by constructing an upright cross at each position; this cross is used to define the local support region. The left arm $\mathbf{p}_l$ at position $\mathbf{p}$ extends left as long as the following two conditions hold:

- $|I(\mathbf{p}) - I(\mathbf{p}_l)| <$ `cbca_intensity`; the image intensities at positions $\mathbf{p}$ and $\mathbf{p}_l$ should be similar, their difference should be less than `cbca_intensity`.

- $\|\mathbf{p} - \mathbf{p}_l\| <$ `cbca_distance`; the horizontal distance (or vertical distance in case of top and bottom arms) between positions $\mathbf{p}$ and $\mathbf{p}_l$ is less than `cbca_distance` pixels.

The right, bottom, and top arms are constructed analogously. Once the four arms are known, we can compute the support region $U(\mathbf{p})$ as the union of horizontal arms of all positions $\mathbf{q}$ laying on $\mathbf{p}$'s vertical arm (see Figure 4).

Zhang et al. (2009) suggest that aggregation should consider the support regions of both images in a stereo pair. Let U^L and U^R denote the support regions in the left and right image. We define the combined support region U_d as

$$U_d(\mathbf{p}) = \{\mathbf{q} | \mathbf{q} \in U^L(\mathbf{p}), \mathbf{q} - \mathbf{d} \in U^R(\mathbf{p} - \mathbf{d})\}.$$

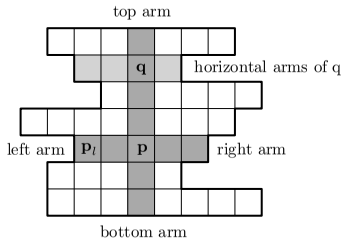

Figure 4: The support region for position $\mathbf{p}$ is the union of horizontal arms of all positions $\mathbf{q}$ on $\mathbf{p}$'s vertical arm.

The matching cost is averaged over the combined support region:

$$C^0_{\text{CBCA}}(\mathbf{p}, d) = C_{\text{CNN}}(\mathbf{p}, d),$$
$$C^i_{\text{CBCA}}(\mathbf{p}, d) = \frac{1}{|U_d(\mathbf{p})|} \sum_{\mathbf{q} \in U_d(\mathbf{p})} C^{i-1}_{\text{CBCA}}(\mathbf{q}, d),$$

where i is the iteration number. We repeat the averaging a number of times. Since the support regions are overlapping, the results can change at each iteration. We skip cross-based cost aggregation in the fast architecture because it is not crucial for achieving a low error rate and because it is relatively expensive to compute.

4.2 Semiglobal Matching

We refine the matching cost by enforcing smoothness constraints on the disparity image. Following Hirschmüller (2008), we define an energy function $E(D)$ that depends on the disparity image D:

$$E(D) = \sum_{\mathbf{p}} \Bigg(C^4_{\text{CBCA}}(\mathbf{p}, D(\mathbf{p})) + \sum_{\mathbf{q} \in \mathcal{N}_\mathbf{p}} P_1 \cdot 1\{|D(\mathbf{p}) - D(\mathbf{q})| = 1\} + \sum_{\mathbf{q} \in \mathcal{N}_\mathbf{p}} P_2 \cdot 1\{|D(\mathbf{p}) - D(\mathbf{q})| > 1\} \Bigg),$$

where $1\{\cdot\}$ denotes the indicator function. The first term penalizes disparities with high matching costs. The second term adds a penalty P_1 when the disparity of neighboring pixels differ by one. The third term adds a larger penalty P_2 when the neighboring disparities differ by more than one.

Rather than minimizing $E(D)$ in all directions simultaneously, we could perform the minimization in a single direction with dynamic programming. This solution would introduce unwanted streaking effects, since there would be no incentive to make the disparity image smooth in the directions we are not optimizing over. In semiglobal matching we

minimize the energy in a single direction, repeat for several directions, and average to obtain the final result. Although Hirschmüller (2008) suggested choosing sixteen direction, we only optimized along the two horizontal and the two vertical directions; adding the diagonal directions did not improve the accuracy of our system. To minimize $E(D)$ in direction $\mathbf{r}$, we define a matching cost $C_\mathbf{r}(\mathbf{p}, d)$ with the following recurrence relation:

$$C_\mathbf{r}(\mathbf{p}, d) = C^4_{\text{CBCA}}(\mathbf{p}, d) - \min_k C_r(\mathbf{p} - \mathbf{r}, k) + \min \Big\{ C_r(\mathbf{p} - \mathbf{r}, d), C_r(\mathbf{p} - \mathbf{r}, d-1) + P_1, C_r(\mathbf{p} - \mathbf{r}, d+1) + P_1, \min_k C_\mathbf{r}(\mathbf{p} - \mathbf{r}, k) + P_2 \Big\}.$$

The second term is subtracted to prevent values of $C_\mathbf{r}(\mathbf{p}, d)$ from growing too large and does not affect the optimal disparity map.

The penalty parameters P_1 and P_2 are set according to the image gradient so that jumps in disparity coincide with edges in the image. Let $D_1 = |I^L(\mathbf{p}) - I^L(\mathbf{p} - \mathbf{r})|$ and $D_2 = |I^R(\mathbf{p} - \mathbf{d}) - I^R(\mathbf{p} - \mathbf{d} - \mathbf{r})|$ be the difference in image intensity between two neighboring positions in the direction we are optimizing over. We set P_1 and P_2 according to the following rules:

$P_1 = $ `sgm_P1`,	$P_2 = $ `sgm_P2`	if $D_1 <$ `sgm_D`, $D_2 <$ `sgm_D`;
$P_1 = $ `sgm_P1/sgm_Q2`,	$P_2 = $ `sgm_P2/sgm_Q2`	if $D_1 \geq$ `sgm_D`, $D_2 \geq$ `sgm_D`;
$P_1 = $ `sgm_P1/sgm_Q1`,	$P_2 = $ `sgm_P2/sgm_Q1`	otherwise.

The hyperparameters `sgm_P1` and `sgm_P2` set a base penalty for discontinuities in the disparity map. The base penalty is reduced by a factor of `sgm_Q1` if one of D_1 or D_2 indicate a strong image gradient or by a larger factor of `sgm_Q2` if both D_1 and D_2 indicate a strong image gradient. The value of P_1 is further reduced by a factor of `sgm_V` when considering the two vertical directions; in the ground truth, small changes in disparity are much more frequent in the vertical directions than in the horizontal directions and should be penalised less.

The final cost $C_{\text{SGM}}(\mathbf{p}, d)$ is computed by taking the average across all four directions:

$$C_{\text{SGM}}(\mathbf{p}, d) = \frac{1}{4} \sum_\mathbf{r} C_\mathbf{r}(\mathbf{p}, d).$$

After semiglobal matching we repeat cross-based cost aggregation, as described in the previous section. Hyperparameters `cbca_num_iterations_1` and `cbca_num_iterations_2` determine the number of cross-based cost aggregation iterations before and after semiglobal matching.

4.3 Computing the Disparity Image

The disparity image $D(\mathbf{p})$ is computed by the winner-takes-all strategy, that is, by finding the disparity d that minimizes $C(\mathbf{p}, d)$,

$$D(\mathbf{p}) = \operatorname*{argmin}_d C(\mathbf{p}, d).$$

4.3.1 Interpolation

The interpolation steps attempt to resolve conflicts between the disparity map predicted for the left image and the disparity map predicted for the right image. Let D^L denote the disparity map obtained by treating the left image as the reference image—this was the case so far, that is, $D^L(\mathbf{p}) = D(\mathbf{p})$—and let D^R denote the disparity map obtained by treating the right image as the reference image. D^L and D^R sometimes disagree on what the correct disparity at a particular position should be. We detect these conflicts by performing a left-right consistency check. We label each position $\mathbf{p}$ by applying the following rules in turn:

$$\begin{array}{ll} \textit{correct} & \text{if } |d - D^R(\mathbf{p} - \mathbf{d})| \leq 1 \text{ for } d = D^L(\mathbf{p}), \\ \textit{mismatch} & \text{if } |d - D^R(\mathbf{p} - \mathbf{d})| \leq 1 \text{ for any other } d, \\ \textit{occlusion} & \text{otherwise.} \end{array}$$

For positions marked as *occlusion*, we want the new disparity value to come from the background. We interpolate by moving left until we find a position labeled *correct* and use its value. For positions marked as *mismatch*, we find the nearest *correct* pixels in 16 different directions and use the median of their disparities for interpolation. We refer to the interpolated disparity map as D_{INT}.

4.3.2 Subpixel Enhancement

Subpixel enhancement provides an easy way to increase the resolution of a stereo algorithm. We fit a quadratic curve through the neighboring costs to obtain a new disparity image:

$$D_{\text{SE}}(\mathbf{p}) = d - \frac{C_+ - C_-}{2(C_+ - 2C + C_-)},$$

where $d = D_{\text{INT}}(\mathbf{p})$, $C_- = C_{\text{SGM}}(\mathbf{p}, d-1)$, $C = C_{\text{SGM}}(\mathbf{p}, d)$, and $C_+ = C_{\text{SGM}}(\mathbf{p}, d+1)$.

4.3.3 Refinement

The final steps of the stereo method consist of a 5×5 median filter and the following bilateral filter:

$$D_{\text{BF}}(\mathbf{p}) = \frac{1}{W(\mathbf{p})} \sum_{\mathbf{q} \in \mathcal{N}_\mathbf{p}} D_{\text{SE}}(\mathbf{q}) \cdot g(\|\mathbf{p} - \mathbf{q}\|) \cdot 1\{|I^L(\mathbf{p}) - I^L(\mathbf{q})| < \texttt{blur\_threshold}\},$$

where $g(x)$ is the probability density function of a zero mean normal distribution with standard deviation `blur_sigma` and $W(\mathbf{p})$ is the normalizing constant,

$$W(\mathbf{p}) = \sum_{\mathbf{q} \in \mathcal{N}_\mathbf{p}} g(\|\mathbf{p} - \mathbf{q}\|) \cdot 1\{|I^L(\mathbf{p}) - I^L(\mathbf{q})| < \texttt{blur\_threshold}\}.$$

The role of the bilateral filter is to smooth the disparity map without blurring the edges. D_{BF} is the final output of our stereo method.

5. Experiments

We used three stereo data sets in our experiments: KITTI 2012, KITTI 2015, and Middlebury. The test set error rates reported in Tables 1, 2, and 4 were obtained by submitting

Rank	Method		Setting	Error	Runtime
1	**MC-CNN-acrt**	**Accurate architecture**		2.43	67
2	Displets	Güney and Geiger (2015)		2.47	265
3	MC-CNN	Žbontar and LeCun (2015)		2.61	100

Table 1: The highest ranking methods on the KITTI 2012 data set as of October 2015. The "Setting" column provides insight into how the disparity map is computed: "F" indicates the use of optical flow, "MV" indicates more than two temporally adjacent images, and "MS" indicates the use of epipolar geometry for computing the optical flow. The "Error" column reports the percentage of misclassified pixels and the "Runtime" column measures the time, in seconds, required to process one pair of images.

the generated disparity maps to the online evaluation servers. All other error rates were computed by splitting the data set in two, using one part for training and the other for validation.

5.1 KITTI Stereo Data Set

The KITTI stereo data set (Geiger et al., 2013; Menze and Geiger, 2015) is a collection of rectified image pairs taken from two video cameras mounted on the roof of a car, roughly 54 centimeters apart. The images were recorded while driving in and around the city of Karlsruhe, in sunny and cloudy weather, at daytime. The images were taken at a resolution of 1240×376. A rotating laser scanner mounted behind the left camera recorded ground truth depth, labeling around 30 % of the image pixels.

The ground truth disparities for the test set are withheld and an online leaderboard is provided where researchers can evaluate their method on the test set. Submissions are allowed once every three days. Error is measured as the percentage of pixels where the true disparity and the predicted disparity differ by more than three pixels. Translated into distance, this means that, for example, the error tolerance is 3 centimeters for objects 2 meters from the camera and 80 centimeters for objects 10 meters from the camera.

Rank	Method		Setting	Error	Runtime

Table 2: The leading submission on the KITTI 2015 leaderboard as of October 2015. The "Setting", "Error", and "Runtime" columns have the same meaning as in Table 1.

Two KITTI stereo data sets exist: KITTI 2012[1] and, the newer, KITTI 2015[2]. For the task of computing stereo they are nearly identical, with the newer data set improving some aspects of the optical flow task. The 2012 data set contains 194 training and 195 testing images, while the 2015 data set contains 200 training and 200 testing images. There is a subtle but important difference introduced in the newer data set: vehicles in motion are densely labeled and car glass is included in the evaluation. This emphasizes the method's performance on reflective surfaces.

The best performing methods on the KITTI 2012 data set are listed in Table 1. Our accurate architecture ranks first with an error rate of 2.43 %. Third place on the leaderboard is held by our previous work (Žbontar and LeCun, 2015) with an error rate of 2.61 %. The two changes that reduced the error from 2.61 % to 2.43 % were augmenting the data set (see Section 5.4) and doubling the number of convolution layers while reducing the kernel size from 5×5 to 3×3. The method in second place (Güney and Geiger, 2015) uses the matching cost computed by our previous work (Žbontar and LeCun, 2015). The test error rate of the fast architecture is 2.82 %, which would be enough for fifth place had the method been allowed to appear in the public leaderboard. The running time for processing a single image pair is 67 seconds for the accurate architecture and 0.8 seconds for the fast architecture. Figure 5 contains a pair of examples from the KITTI 2012 data set, together with the predictions of our method.

Table 2 presents the frontrunners on the KITTI 2015 data sets. The error rates of our methods are 3.89 % for the accurate architecture and 4.46 % for the fast architecture, occupying first and second place on the leaderboard. Since one submission per paper is

1. The KITTI 2012 scoreboard: `http://www.cvlibs.net/datasets/kitti/eval_stereo_flow.php?benchmark=stereo`
2. The KITTI 2015 scoreboard: `http://www.cvlibs.net/datasets/kitti/eval_scene_flow.php?benchmark=stereo`

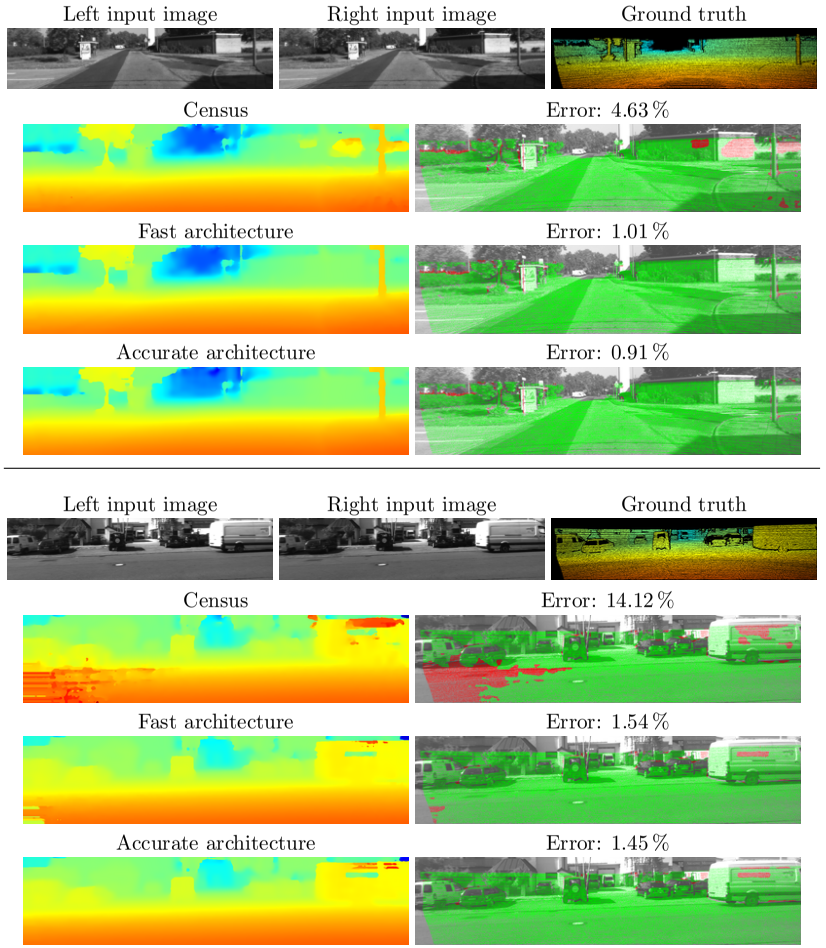

Figure 5: Examples of predicted disparity maps on the KITTI 2012 data set. Note how some regions of the image (the white wall in the top example, and the asphalt in the bottom example) cause problems for the census transform. The fast and the accurate architecture perform better, with the accurate architecture making fewer mistakes on average.

Year	Number of Image Pairs	Resolution	Maximum Disparity
2001	8	380×430	30
2003	2	1800×1500	220
2005	6	1400×1100	230
2006	21	1400×1100	230
2014	23	3000×2000	800

Table 3: A summary of the five Middlebury stereo data sets. The column "Number of Image Pairs" counts only the image pairs for which ground truth is available. The 2005 and 2014 data sets additionally contain a number of image pairs with ground truth disparities withheld; these image pairs constitute the test set.

allowed, only the result of the accurate architecture appears on the public leaderboard. See Figure 6 for the disparity maps produced by our method on the KITTI 2015 data set.

5.2 Middlebury Stereo Data Set

The image pairs of the Middlebury stereo data set are indoor scenes taken under controlled lighting conditions. Structured light was used to measure the true disparities with higher density and precision than in the KITTI data set. The data sets were published in five separate works in the years 2001, 2003, 2005, 2006, and 2014 (Scharstein and Szeliski, 2002, 2003; Scharstein and Pal, 2007; Hirschmüller and Scharstein, 2007; Scharstein et al., 2014). In this paper, we refer to the Middlebury data set as the concatenation of all five data sets; a summary of each is presented in Table 3.

Each scene in the 2005, 2006, and 2014 data sets was taken under a number of lighting conditions and shutter exposures, with a typical image pair taken under four lighting conditions and seven exposure settings for a total of 28 images of the same scene.

An online leaderboard[3], similar to the one provided by KITTI, displays a ranked list of all submitted methods. Participants have only one opportunity to submit their results on the test set to the public leaderboard. This rule is stricter than the one on the KITTI data set, where submissions are allowed every three days. The test set contains 15 images borrowed from the 2005 and 2014 data sets.

The data set is provided in full, half, and quarter resolution. The error is computed at full resolution; if the method outputs half or quarter resolution disparity maps, they are upsampled before the error is computed. We chose to run our method on half resolution images because of the limited size of the graphic card's memory available.

Rectifying a pair of images using standard calibration procedures, like the ones present in the OpenCV library, results in vertical disparity errors of up to nine pixels on the Middlebury data set (Scharstein et al., 2014). Each stereo pair in the 2014 data set is rectified twice: once using a standard, imperfect approach, and once using precise 2D correspondences for perfect rectification (Scharstein et al., 2014). We train the network on imperfectly rectified

3. The Middlebury scoreboard: `http://vision.middlebury.edu/stereo/eval3/`

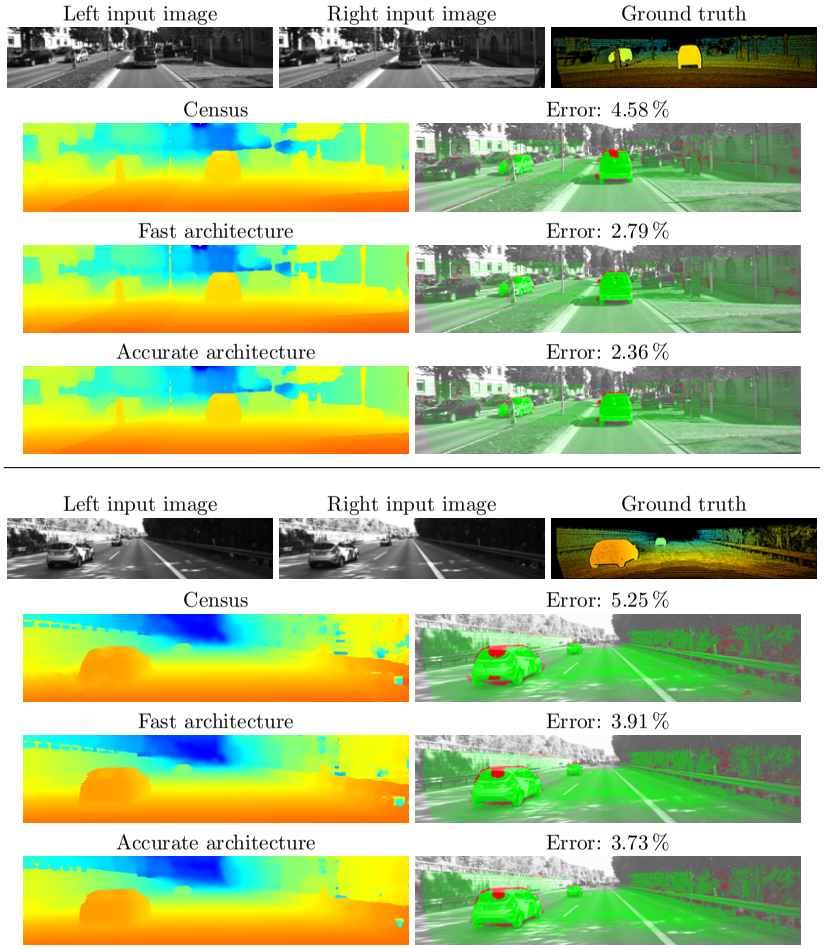

Figure 6: Examples of predictions on the KITTI 2015 data set. Observe that vehicles in motion are labeled densely in the KITTI 2015 data set.

Rank	Method		Resolution	Error	Runtime

10	SNCC	Einecke and Eggert (2010)	Half	22.2	1.38

Table 4: The top ten methods on the Middlebury stereo data set as of October 2015. The "Error" column is the weighted average error after upsampling to full resolution and "Runtime" is the time, in seconds, required to process one pair of images.

image pairs, since only two of the fifteen test images (*Australia* and *Crusade*) are rectified perfectly.

The error is measured as the percentage of pixels where the true disparity and the predicted disparity differ by more than two pixels; this corresponds to an error tolerance of one pixel at half resolution. The error on the evaluation server is, by default, computed only on non-occluded pixels. The final error reported online is the weighted average over the fifteen test images, with weights set by the authors of the data set.

Table 4 contains a snapshot of the third, and newest, version of the Middlebury leaderboard. Our method ranks first with an error rate of 8.29 % and a substantial lead over the second placed MeshStereo method, whose error rate is 13.4 %. See Figure 7 for disparity maps produced by our method on one image pair from the Middlebury data set.

5.3 Details of Learning

We construct a binary classification data set from all available image pairs in the training set. The data set contains 25 million examples on the KITTI 2012, 17 million examples on the KITTI 2015, and 38 million examples on the Middlebury data set.

At training time, the input to the network was a batch of 128 pairs of image patches. At test time, the input was the entire left and right image. We could have used entire images during training as well, as it would allow us to implement the speed optimizations described in Section 3.3. There were several reasons why we preferred to train on image patches: it was easier to control the batch size, the examples could be shuffled so that one batch contained patches from several different images, and it was easier to maintain the same number of positive and negative examples within a batch.

We minimized the loss using mini-batch gradient descent with the momentum term set to 0.9. We trained for 14 epochs with the learning rate initially set to 0.003 for the accurate architecture and 0.002 for the fast architecture. The learning rate was decreased

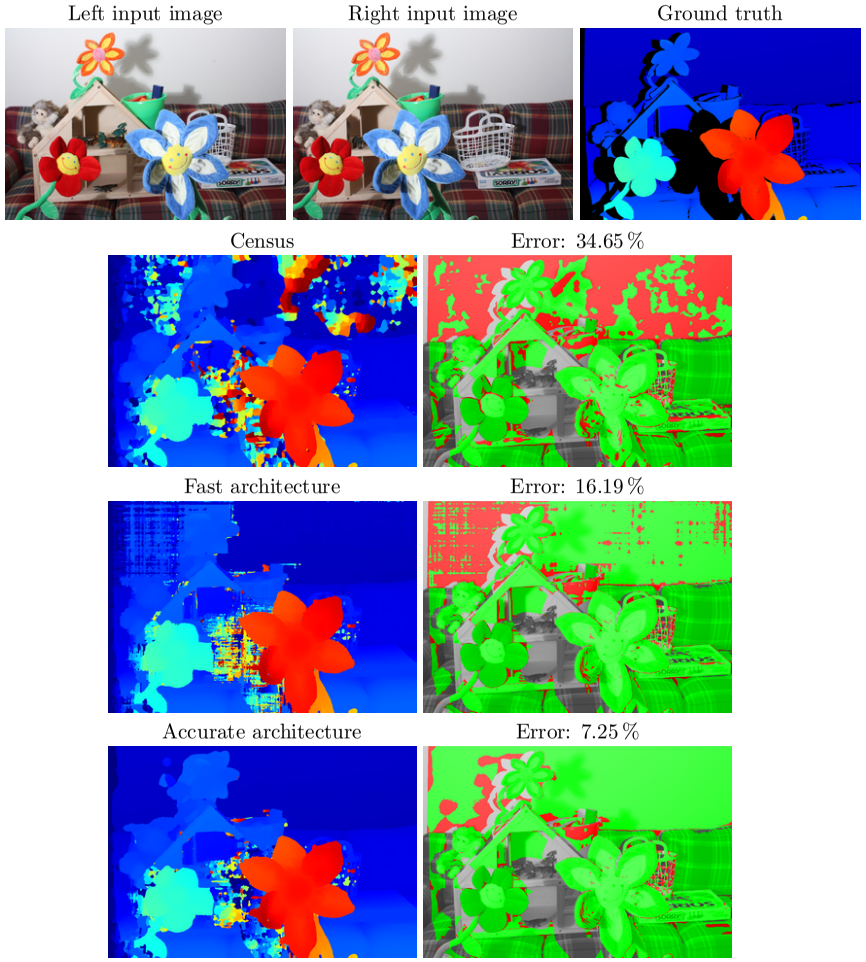

Figure 7: An example of a particularly difficult image pair from the Middlebury data set; the white wall in the background is practically textureless. The accurate architecture is able to classify most of it correctly. The fast architecture doesn't do as well but still performs better than census.

Table 5: The hyperparameter values we used for the fast and accurate architectures (abbreviated "fst" and "acrt"). Note that hyperparameters concerning image intensity values (`cbca_intensity` and `sgm_D`) apply to the preprocessed images and not to raw images with intensity values in the range from 0 to 255.

by a factor of 10 on the 11^{th} epoch. The number of epochs, the initial learning rate, and the learning rate decrease schedule where treated as hyperparameters and were optimized with cross-validation. Each image was preprocessed by subtracting the mean and dividing by the standard deviation of its pixel intensity values. The left and right image of a stereo pair were preprocessed separately. Our initial experiments suggested that using color information does not improve the quality of the disparity maps; therefore, we converted all color images to grayscale.

The post-processing steps of the stereo method were implemented in CUDA (Nickolls et al., 2008), the network training was done with the Torch environment (Collobert et al., 2011) using the convolution routines from the cuDNN library (Chetlur et al., 2014). The OpenCV library (Bradski, 2000) was used for the affine transformation in the data augmentation step.

The hyperparameters where optimized with manual search and simple scripts that helped automate the process. The hyperparameters we selected are shown in Table 5.

5.4 Data Set Augmentation

Augmenting the data set by repeatedly transforming the training examples is a commonly employed technique to reduce the network's generalization error. The transformations are applied at training time and do not affect the runtime performance. We randomly rotate, scale and shear the training patches; we also change their brightness and contrast. Since the transformations are applied to patches after they have been extracted from the images, the data augmentation step does not alter the ground truth disparity map or ruin the rectification.

The parameters of the transformation are chosen randomly for each pair of patches, and after one epoch of training, when the same example is being presented to the network for the second time, new random parameters are selected. We choose slightly different transformation parameters for the left and right image; for example, we would rotate the left patch by 10 degrees and the right by 14. Different data sets benefited from different types of transformations and, in some cases, using the wrong transformations increased the error.

On the Middlebury data set we took advantage of the fact that the images were taken under different lighting conditions and different shutter exposures by training on all available images. The same data set augmentation parameters were used for the KITTI 2012 and KITTI 2015 data sets.

The Middlebury test data sets contains two images worth mentioning: *Classroom*, where the right image is underexposed and, therefore, darker than the left; and *Djembe*, where the left and right images were taken under different light conditions. To handle these two cases we train, 20 % of the time, on images where either the shutter exposure or the arrangements of lights are different for the left and right image.

We combat imperfect rectification on the Middlebury data set by including a small vertical disparity between the left and right image patches.

Before describing the steps of data augmentation, let us introduce some notation: in the following, a word in `typewriter` is used to denote the name of a hyperparameter defining a set, while the same word in *italic* is used to denote a number drawn randomly from that set. For example, `rotate` is a hyperparameter defining the set of possible rotations and *rotate* is a number drawn randomly from that set. The steps of data augmentation are presented in the following list:

- Rotate the left patch by *rotate* degrees and the right patch by *rotate* + *rotate_diff* degrees.
- Scale the left patch by *scale* and the right patch by *scale* · *scale_diff*.
- Scale the left patch in the horizontal direction by *horizontal_scale* and the right patch by *horizontal_scale* · *horizontal_scale_diff*.
- Shear the left patch in the horizontal direction by *horizontal_shear* and the right patch by *horizontal_shear* + *horizontal_shear_diff*.

	KITTI 2012		Middlebury	
Hyperparameter	Range	Error	Range	Error
`rotate`	$[-7, 7]$	2.65	$[-28, 28]$	7.99
`scale`			$[0.8, 1]$	8.17
`horizontal_scale`	$[0.9, 1]$	2.62	$[0.8, 1]$	8.08
`horizontal_shear`	$[0, 0.1]$	2.61	$[0, 0.1]$	7.91
`brightness`	$[0, 0.7]$	2.61	$[0, 1.3]$	8.16
`contrast`	$[1, 1.3]$	2.63	$[1, 1.1]$	7.95
`vertical_disparity`			$[0, 1]$	8.05
`rotate_diff`			$[-3, 3]$	8.00
`horizontal_scale_diff`			$[0.9, 1]$	7.97
`horizontal_shear_diff`			$[0, 0.3]$	8.05
`brightness_diff`	$[0, 0.3]$	2.63	$[0, 0.7]$	7.92
`contrast_diff`			$[1, 1.1]$	8.01
No data set augmentation		2.73		8.75
Full data set augmentation		2.61		7.91

Table 6: The hyperparameters governing data augmentation and how they affect the validation error. The "Error" column reports the validation error when a particular data augmentation step is not used. The last two rows report validation errors with and without data augmentation. For example, the validation error on the KITTI 2012 is 2.73 % if no data augmentation is used, 2.65 % if all steps except rotation are used, and 2.61 % if all data augmentation steps are used.

- Translate the right patch in the vertical direction by *vertical_disparity*.
- Adjust the brightness and contrast by setting the left and right image patches to:

$$\mathcal{P}^L \leftarrow \mathcal{P}^L \cdot \mathit{contrast} + \mathit{brightness} \text{ and}$$
$$\mathcal{P}^R \leftarrow \mathcal{P}^R \cdot (\mathit{contrast} \cdot \mathit{contrast\_diff}) + (\mathit{brightness} + \mathit{brightness\_diff}),$$

  with addition and multiplication carried out element-wise where appropriate.

Table 6 contains the hyperparameters used and measures how each data augmentation step affected the validation error.

Data augmentation reduced the validation error from 2.73 % to 2.61 % on the KITTI 2012 data set and from 8.75 % to 7.91 % on the Middlebury data set.

5.5 Runtime

We measure the runtime of our implementation on a computer with a NVIDIA Titan X graphics processor unit. Table 7 contains the runtime measurements across a range of hyperparameter settings for three data sets: KITTI, Middlebury half resolution, and a

new, fictitious data set, called Tiny, which we use to demonstrate the performance of our method on the kind of images typically used for autonomous driving or robotics. The sizes of images we measured the runtime on were: 1242 × 350 with 228 disparity levels for the KITTI data set, 1500 × 1000 with 200 disparity levels for the Middlebury data set, and 320 × 240 with 32 disparity levels for the Tiny data set.

Table 7 reveals that the fast architecture is up to 90 times faster than the accurate architecture. Furthermore, the running times of the fast architecture are 0.78 seconds on KITTI, 2.03 seconds on Middlebury, and 0.06 seconds on the Tiny data set. We can also see that the fully-connected layers are responsible for most of the runtime in the accurate architecture, as the hyperparameters controlling the number of convolutional layer and the number of feature maps have only a small effect on the runtime.

Training times depended on the size of the data set and the architecture, but never exceeded two days.

5.6 Matching Cost

We argue that the low error rate of our method is due to the convolutional neural network and not a superior stereo method. We verify this claim by replacing the convolutional neural network with three standard approaches for computing the matching cost:

- *The sum of absolute differences* computes the matching cost according to Equation (1), that is, the matching cost between two image patches is computed by summing the absolute differences in image intensities between corresponding locations. We used 9 × 9 patches.
- *The census transform* (Zabih and Woodfill, 1994) represents each image position as a bit vector. The size of this vector is a hyperparameter whose value, after examining several, we set to 81. The vector is computed by cropping a 9×9 image patch centered around the position of interest and comparing the intensity values of each pixel in the patch to the intensity value of the pixel in the center. When the center pixel is brighter the corresponding bit is set. The matching cost is computed as the hamming distance between two census transformed vectors.
- *Normalized cross-correlation* is a window-based method defined with the following equation:

$$C_{NCC}(\mathbf{p}, d) = \frac{\sum_{\mathbf{q} \in \mathcal{N}_\mathbf{p}} I^L(\mathbf{q}) I^R(\mathbf{q} - \mathbf{d})}{\sqrt{\sum_{\mathbf{q} \in \mathcal{N}_\mathbf{p}} I^L(\mathbf{q})^2 \sum_{\mathbf{q} \in \mathcal{N}_\mathbf{p}} I^R(\mathbf{q} - \mathbf{d})^2}}.$$

  The normalized cross-correlation matching cost computes the cosine similarity between the left and right image patch, when the left and right image patches are viewed as vectors instead of matrices. This is the same function that is computed in the last two layers of the fast architecture (normalization and dot product). The neighbourhood $\mathcal{N}_\mathbf{p}$ was set to a square 11×11 window around $\mathbf{p}$.

The "sad", "cens", and "ncc" columns of Table 8 contain the results of the sum of absolute differences, the census transform, and normalized cross-correlation on the KITTI 2012, KITTI 2015, and Middlebury data sets. The validation errors in the last rows of Table 8

Hyperparameter		KITTI fst	KITTI acrt	Middlebury fst	Middlebury acrt	Tiny fst	Tiny acrt

Full stereo method		0.78	67.1	2.03	84.8	0.06	1.9

Table 7: The time, in seconds, required to compute the matching cost, that is, the time spent in the convolutional neural network without any post-processing steps. The time does include computing the matching cost twice: once when the left image is taken to be the reference image and once when the right image is taken to be the reference image. We measure the runtime as a function of four hyperparameters controlling the network architecture; for example, the first six rows contain the runtime as the number of convolutional layers in the network increases from one to six. The last row of the table contains the running time for the entire method, including the post-processing steps. As before, we abbreviate the fast and accurate architectures as "fst" and "acrt".

should be used to compare the five methods. On all three data sets the accurate architecture performs best, followed by the fast architecture, which in turn is followed by the census transform. These are the three best performing methods on all three data sets. Their error rates are 2.61 %, 3.02 %, and 4.90 % on KITTI 2012; 3.25 %, 3.99 %, and 5.03 % on KITTI 2015; and 7.91 %, 9.87 %, and 16.72 % on Middlebury. The sum of absolute differences and the normalized cross-correlation matching costs produce disparity maps with larger errors. For a visual comparison of our method and the census transform see Figures 5, 6, and 7.

5.7 Stereo Method

The stereo method includes a number of post-processing steps: cross-based cost aggregation, semiglobal matching, interpolation, subpixel enhancement, a median, and a bilateral filter. We ran a set of experiments in which we excluded each of the aforementioned steps and recorded the validation error (see Table 8).

The last two rows of Table 8 allude to the importance of the post-processing steps of the stereo method. We see that, if all post-processing steps are removed, the validation error of the accurate architecture increases from 2.61 % to 13.49 % on KITTI 2012, from 3.25 % to 13.38 % on KITTI 2015, and from 7.91 % to 28.33 % on Middlebury.

Out of all post-processing steps of the stereo method, semiglobal matching affects the validation error the strongest. If we remove it, the validation error increases from 2.61 % to 4.26 % on KITTI 2012, from 3.25 % to 4.51 % on KITTI 2015, and from 7.91 % to 11.99 % on Middlebury.

We did not use the left-right consistency check to eliminate errors in occluded regions on the Middlebury data set. The error rate increased from 7.91 % to 8.22 % using the left-right consistency check on the accurate architecture, which is why we decided to remove it.

5.8 Data Set Size

We used a supervised learning approach to measure the similarity between image patches. It is, therefore, natural to ask how does the size of the data set affect the quality of the disparity maps. To answer this question, we retrain our networks on smaller training sets obtained by selecting a random set of examples (see Table 9).

We observe that the validation error decreases as we increase the number of training examples. These experiments suggest a simple strategy for improving the results of our stereo method: collect a larger data set.

5.9 Transfer Learning

Up to this point the training and validation sets were created from the same stereo data set, either KITTI 2012, KITTI 2015, or Middlebury. To evaluate the performance of our method in the transfer learning setting, we run experiments where the validation error is computed on a different data set than the one used for training. For example, we would use the Middlebury data set to train the matching cost neural network and evaluate its performance on the KITTI 2012 data set. These experiments give us some idea of the expected performance in a real-world application, where it isn't possible to train a specialized

Table 8: The numbers measure validation error when a particular post-processing step is excluded from the stereo method. The last two rows of the tables should be interpreted differently: they contain the validation error of the raw convolutional neural network and the validation error after the complete stereo method. For example, if we exclude semiglobal matching, the fast architecture achieves an error rate of 8.78 % on the KITTI 2012 data set and an error rate of 3.02 % after applying the full stereo method. We abbreviate the method names as "fst" for the fast architecture, "acrt" for the accurate architecture, "sad" for the sum of absolute differences, "cens" for the census transform, and "ncc" for the normalized cross-correlation matching cost.

	KITTI 2012		KITTI 2015		Middlebury

	Middlebury	3.16	3.07	4.48	4.49	9.87	7.91

Table 10: The validation error when the training and test sets differ. For example, the validation error is 3.16 % when the Middlebury data set is used for training the fast architecture and the trained network is tested on the KITTI 2012 data set.

network because no ground truth is available. The results of these experiments are shown in Table 10.

Some results in Table 10 were unexpected. For example, the validation error on KITTI 2012 is lower when using the Middlebury training set compared to the KITTI 2015 training set, even though the KITTI 2012 data set is obviously more similar to KITTI 2015 than Middlebury. Furthermore, the validation error on KITTI 2012 is lower when using the fast architecture instead of the accurate architecture when training on KITTI 2015.

The matching cost neural network trained on the Middlebury data set transfers well to the KITTI data sets. Its validation error is similar to the validation errors obtained by networks trained on the KITTI data sets.

5.10 Hyperparameters

Searching for a good set of hyperparameters is a daunting task—with the search space growing exponentially with the number of hyperparameters and no gradient to guide us. To better understand the effect of each hyperparameter on the validation error, we conduct a series of experiments where we vary the value of one hyperparameter while keeping the others fixed to their default values. The results are shown in Table 11 and can be summarized by observing that increasing the size of the network improves the generalization

Hyperparameter		KITTI 2012 fst	KITTI 2012 acrt	KITTI 2015 fst	KITTI 2015 acrt	Middlebury fst	Middlebury acrt

Table 11: Validation errors computed across a range of hyperparameter settings.

performance, but only up to a point, when presumably, because of the size of the data set, the generalization performance starts do decrease.

Note that the `num_conv_layers` hyperparameter implicitly controls the size of the image patches. For example, a network with one convolutional layer with 3×3 kernels compares image patches of size 3×3, while a network with five convolutional layers compares patches of size 11×11.

6. Conclusion

We presented two convolutional neural network architectures for learning a similarity measure on image patches and applied them to the problem of stereo matching.

The source code of our implementation is available at `https://github.com/jzbontar/mc-cnn`. The online repository contains procedures for computing the disparity map, training the network, as well as the post-processing steps of the stereo method.

The accurate architecture produces disparity maps with lower error rates than any previously published method on the KITTI 2012, KITTI 2015, and Middlebury data sets. The fast architecture computes the disparity maps up to 90 times faster than the accurate architecture with only a small increase in error. These results suggest that convolutional neural networks are well suited for computing the stereo matching cost even for applications that require real-time performance.

The fact that a relatively simple convolutional neural network outperformed all previous methods on the well-studied problem of stereo is a rather important demonstration of the power of modern machine learning approaches.

Abstract

Policy gradient methods are reinforcement learning algorithms that adapt a parameterized policy by following a performance gradient estimate. Many conventional policy gradient methods use Monte-Carlo techniques to estimate this gradient. The policy is improved by adjusting the parameters in the direction of the gradient estimate. Since Monte-Carlo methods tend to have high variance, a large number of samples is required to attain accurate estimates, resulting in slow convergence. In this paper, we first propose a Bayesian framework for policy gradient, based on modeling the policy gradient as a Gaussian process. This reduces the number of samples needed to obtain accurate gradient estimates. Moreover, estimates of the natural gradient as well as a measure of the uncertainty in the gradient estimates, namely, the gradient covariance, are provided at little extra cost. Since the proposed Bayesian framework considers system trajectories as its basic observable unit, it does not require the dynamics within trajectories to be of any particular form, and thus, can be easily extended to partially observable problems. On the downside, it cannot take advantage of the Markov property when the system is Markovian.

To address this issue, we proceed to supplement our Bayesian policy gradient framework with a new actor-critic learning model in which a Bayesian class of non-parametric critics, based on Gaussian process temporal difference learning, is used. Such critics model the action-value function as a Gaussian process, allowing Bayes' rule to be used in computing the posterior distribution over action-value functions, conditioned on the observed data. Appropriate choices of the policy parameterization and of the prior covariance (kernel) between action-values allow us to obtain closed-form expressions for the posterior distribution of the gradient of the expected return with respect to the policy parameters. We perform detailed experimental comparisons of the proposed Bayesian policy gradient and actor-critic algorithms with classic Monte-Carlo based policy gradient methods, as well as with each other, on a number of reinforcement learning problems.

Keywords: reinforcement learning, policy gradient methods, actor-critic algorithms, Bayesian inference, Gaussian processes

1. Introduction

Policy gradient (PG) methods[1] are reinforcement learning (RL) algorithms that maintain a parameterized action-selection policy and update the policy parameters by moving them in the direction of an estimate of the gradient of a performance measure. Early examples of PG algorithms are the class of REINFORCE algorithms (Williams, 1992),[2] which are suitable for solving problems in which the goal is to optimize the average reward. Subsequent work (e.g., Kimura et al., 1995, Marbach, 1998, Baxter and Bartlett, 2001) extended these algorithms to the cases of infinite-horizon Markov decision processes (MDPs) and partially observable MDPs (POMDPs), while also providing much needed theoretical analysis.[3] However, both the theoretical results and empirical evaluations have highlighted a major shortcoming of these algorithms, namely, the high variance of the gradient estimates. This problem may be traced to the fact that in most interesting cases, the time-average of the observed rewards is a high-variance (although unbiased) estimator of the true average reward, resulting in the sample-inefficiency of these algorithms.

One solution proposed for this problem was to use an artificial *discount factor* in these algorithms (Marbach, 1998, Baxter and Bartlett, 2001), however, this creates another problem by introducing bias into the gradient estimates. Another solution, which does not involve biasing the gradient estimate, is to subtract a *reinforcement baseline* from the average reward estimate in the updates of PG algorithms (e.g., Williams, 1992, Marbach, 1998, Sutton et al., 2000). In Williams (1992) an average reward baseline was used, and in Sutton et al. (2000) it was conjectured that an approximate value function would be a good choice for a state-dependent baseline. However, it was shown in Weaver and Tao (2001) and Greensmith et al. (2004), perhaps surprisingly, that the mean reward is in general *not* the optimal constant baseline, and that the true value function is generally *not* the optimal state-dependent baseline.

A different approach for speeding-up PG algorithms was proposed by Kakade (2002) and refined and extended by Bagnell and Schneider (2003) and Peters et al. (2003). The idea is to replace the policy gradient estimate with an estimate of the so-called *natural* policy gradient. This is motivated by the requirement that the policy updates should be invariant to bijective transformations of the parametrization. Put more simply, a change in the way the policy is parametrized should not influence the result of the policy update. In terms of the policy update rule, the move to natural-gradient amounts to linearly transforming the gradient using the inverse Fisher information matrix of the policy. In empirical evaluations, natural PG has been shown to significantly outperform conventional PG (e.g., Kakade 2002, Bagnell and Schneider 2003, Peters et al. 2003, Peters and Schaal 2008).

1. The term has been coined in Sutton et al. (2000), but here we use it more liberally to refer to a whole class of reinforcement learning algorithms.
2. Note that policy gradient methods have been studied in the control community (see e.g., Dyer and McReynolds 1970, Jacobson and Mayne 1970, Hasdorff 1976) before REINFORCE. However, unlike REINFORCE that is model-free, they were all based on the exact model of the system (model-based).
3. It is important to note that the pioneering work of Gullapali and colleagues in the early 1990s (Gullapalli, 1990, 1992, Gullapalli et al., 1994) in applying policy gradient methods to robot learning problems had an important role in popularizing this class of algorithms. In fact policy gradient methods have been continuously proven to be one of the most effective class of algorithms in learning in robots.

Another approach for reducing the variance of policy gradient estimates, and as a result making the search in the policy-space more efficient and reliable, is to use an explicit representation for the value function of the policy. This class of PG algorithms are called actor-critic algorithms. Actor-critic (AC) algorithms comprise a family of RL methods that maintain two distinct algorithmic components: An *actor*, whose role is to maintain and update an action-selection policy; and a *critic*, whose role is to estimate the value function associated with the actor's policy. Thus, the critic addresses the problem of *prediction*, whereas the actor is concerned with *control*. Actor-critic methods were among the earliest to be investigated in RL (Barto et al., 1983, Sutton, 1984). They were largely supplanted in the 1990's by methods, such as SARSA (Rummery and Niranjan, 1994), that estimate action-value functions and use them directly to select actions without maintaining an explicit representation of the policy. This approach was appealing because of its simplicity, but when combined with function approximation was found to be unreliable, often failing to converge. These problems led to renewed interest in PG methods.

Actor-critic algorithms (e.g., Sutton et al. 2000, Konda and Tsitsiklis 2000, Peters et al. 2005, Bhatnagar et al. 2007) borrow elements from these two families of RL algorithms. Like value-function based methods, a critic maintains a value function estimate, while an actor maintains a separately parameterized stochastic action-selection policy, as in policy based methods. While the role of the actor is to select actions, the role of the critic is to evaluate the performance of the actor. This evaluation is used to provide the actor with a feedback signal that allows it to improve its performance. The actor typically updates its policy along an estimate of the gradient (or natural gradient) of some measure of performance with respect to the policy parameters. When the representations used for the actor and the critic are *compatible*, in the sense explained in Sutton et al. (2000) and Konda and Tsitsiklis (2000), the resulting AC algorithm is simple, elegant, and provably convergent (under appropriate conditions) to a local maximum of the performance measure used by the critic, plus a measure of the temporal difference (TD) error inherent in the function approximation scheme (Konda and Tsitsiklis, 2000, Bhatnagar et al., 2009).

Existing AC algorithms are based on parametric critics that are updated to optimize frequentist fitness criteria. By "frequentist" we mean algorithms that return a point estimate of the value function, rather than a complete posterior distribution computed using Bayes' rule. A Bayesian class of critics based on Gaussian processes (GPs) has been proposed by Engel et al. (2003, 2005), called Gaussian process temporal difference (GPTD). By their Bayesian nature, these algorithms return a full posterior distribution over value functions. Moreover, while these algorithms may be used to learn a parametric representation for the posterior, they are generally capable of searching for value functions in an infinite-dimensional Hilbert space of functions, resulting in a non-parametric posterior.

Both conventional and natural policy gradient and actor-critic methods rely on Monte-Carlo (MC) techniques in estimating the gradient of the performance measure. MC estimation is a frequentist procedure, and as such violates the *likelihood principle* (Berger and Wolpert, 1984).[4] Moreover, although MC estimates are unbiased, they tend to suffer from high variance, or alternatively, require excessive sample sizes (see O'Hagan, 1987 for a discussion). In the case of policy gradient estimation this is exacerbated by the fact that consistent policy improvement requires multiple gradient estimation steps.

4. The likelihood principle states that in a parametric statistical model, all the information about a data sample that is required for inferring the model parameters is contained in the likelihood function of that sample.

In O'Hagan (1991) a Bayesian alternative to MC estimation is proposed.[5] The idea is to model integrals of the form $\int f(x)g(x)dx$ as GPs. This is done by treating the first term f in the integrand as a *random function*, the randomness of which reflects our subjective uncertainty concerning its true identity. This allows us to incorporate our prior knowledge of f into its prior distribution. Observing (possibly noisy) samples of f at a set of points $\{x_1, \ldots, x_M\}$ allows us to employ Bayes' rule to compute a posterior distribution of f conditioned on these samples. This, in turn, induces a posterior distribution over the value of the integral.

In this paper, we first propose a Bayesian framework for policy gradient estimation by modeling the gradient as a GP. Our Bayesian policy gradient (BPG) algorithms use GPs to define a prior distribution over the gradient of the expected return, and compute its posterior conditioned on the observed data. This reduces the number of samples needed to obtain accurate gradient estimates. Moreover, estimates of the natural gradient as well as a measure of the uncertainty in the gradient estimates, namely the gradient covariance, are provided at little extra cost. Additional gains may be attained by learning a transition model of the environment, allowing knowledge transfer between policies. Since our BPG models and algorithms consider complete system trajectories as their basic observable unit, they do not require the dynamics within each trajectory to be of any special form. In particular, it is not necessary for the dynamics to have the Markov property, allowing the resulting algorithms to handle partially observable MDPs, Markov games, and other non-Markovian systems. On the downside, BPG algorithms cannot take advantage of the Markov property when this property is satisfied. To address this issue, we supplement our BPG framework with actor-critic methods and propose an AC algorithm that incorporates GPTD as its critic. However, rather than merely plugging-in our critic into an existing AC algorithm, we show how the posterior moments returned by the GPTD critic allow us to obtain closed-form expressions for the posterior moments of the policy gradient. This is made possible by utilizing the Fisher kernel (Shawe-Taylor and Cristianini, 2004) as our prior covariance kernel for the GPTD state-action *advantage* values. Unlike the BPG methods, the Bayesian actor-critic (BAC) algorithm takes advantage of the Markov property of the system trajectories and uses individual state-action-reward transitions as its basic observable unit. This helps reduce variance in the gradient estimates, resulting in steeper learning curves when compared to BPG and the classic MC approach.

It is important to note that a short version of the two main parts of this paper, *Bayesian policy gradient* and *Bayesian actor-critic*, appeared in Ghavamzadeh and Engel (2006) and Ghavamzadeh and Engel (2007), respectively. This paper extends these conference papers in the following ways:

- We have included a discussion on using Bayesian Quadrature (BQ) for estimating vector-valued integrals to the paper. This is totally relevant to this work because the gradient of a policy (the quantity that we are interested in estimating using BQ) is a vector-valued integral when the size of the policy parameter vector is more than 1, which is usually the case. This also helps to better see the difference between

5. O'Hagan (1991) mentions that this approach may be traced even as far back as Poincaré (1896).

the two models we propose for BPG. In Model 1, we place a vector-valued Gaussian process (GP) over a component of the gradient integrant, while in Model 2, we put a scalar-valued GP over a different component of the gradient integrant.

- We describe the BPG and BAC algorithms in more details and show the details of using online sparsification in these algorithms. Moreover, we show how BPG can be extended to partially observable Markov decision processes (POMDPs) along the same lines that the standard PG algorithms can be used in such problems.

- In comparison to Ghavamzadeh and Engel (2006), we report more details of the experiments and more experimental results, especially in using the posterior variance (covariance) of the gradient to select the step size for updating the policy parameters.

- We include all the proofs in this paper (almost none was reported in the two conference papers), in particular, the proofs of Propositions 3, 4, 5, and 6. These proofs are important and the proof techniques are novel and definitely useful for the community. The importance of these proofs come from the fact that they show how with the right choice of GP prior (the one that uses the family of Fisher information kernels), we are able to use BQ and have a Bayesian estimate of the gradient integral, while initially everything indicates that BQ cannot be used for the estimation of this integral.

- We apply the BAC algorithm to two new domains: "Mountain Car", a 2-dimensional continuous state and 1-dimensional discrete action problem, and "Ship Steering", a 4-dimensional continuous state and 1-dimensional continuous action problem.

2. Reinforcement Learning, Policy Gradient, and Actor-Critic Methods

Reinforcement learning (RL) (Bertsekas and Tsitsiklis, 1996, Sutton and Barto, 1998) is term describing a class of learning problems in which an agent (or controller) interacts with a dynamic, stochastic, and incompletely known environment (or plant), with the goal of finding an action-selection strategy, or *policy*, to optimize some measure of its long-term performance. This interaction is conventionally modeled as a Markov decision process (MDP) (Puterman, 1994), or if the environmental state is not completely observable, as a partially observable MDP (POMDP) (Astrom, 1965, Smallwood and Sondik, 1973, Kaelbling et al., 1998). In this work we restrict our attention to the discrete-time MDP setting.

Let $\mathcal{P}(\mathcal{X})$, $\mathcal{P}(\mathcal{A})$, and $\mathcal{P}(\mathbb{R})$ denote the set of probability distributions on (Borel) subsets of the sets $\mathcal{X}$, $\mathcal{A}$, and $\mathbb{R}$, respectively. A MDP is a tuple $(\mathcal{X}, \mathcal{A}, q, P, P_0)$ where $\mathcal{X}$ and $\mathcal{A}$ are the state and action spaces; $q(\cdot|x,a) \in \mathcal{P}(\mathbb{R})$ and $P(\cdot|x,a) \in \mathcal{P}(\mathcal{X})$ are the probability distributions over rewards and next states when action a is taken at state x (we assume that q and P are stationary); and $P_0(\cdot) \in \mathcal{P}(\mathcal{X})$ is the probability distribution according to which the initial state is selected. We denote the random variable distributed according to $q(\cdot|x,a)$ as $r(x,a)$ and its mean as $\bar{r}(x,a)$.

In addition, we need to specify the rule according to which the agent selects an action at each possible state. We assume that this rule is *stationary*, i.e., does not depend explicitly on time. A stationary policy $\mu(\cdot|x) \in \mathcal{P}(\mathcal{A})$ is a probability distribution over actions, conditioned on the current state. A MDP controlled by a policy μ induces a

Markov chain over state-action pairs $\boldsymbol{z}_t = (x_t, a_t) \in \mathcal{Z} = \mathcal{X} \times \mathcal{A}$, with a transition probability density $P^\mu(\boldsymbol{z}_t|\boldsymbol{z}_{t-1}) = P(x_t|x_{t-1}, a_{t-1})\mu(a_t|x_t)$, and an initial state density $P_0^\mu(\boldsymbol{z}_0) = P_0(x_0)\mu(a_0|x_0)$. We generically denote by $\xi = (\boldsymbol{z}_0, \boldsymbol{z}_1, \ldots, \boldsymbol{z}_T) \in \Xi$, $T \in \{0, 1, \ldots, \infty\}$ a path generated by this Markov chain. Note that Ξ is the set of all possible trajectories that can be generated by the Markov chain induced by the current policy μ. The probability (density) of such a path is given by

$$\Pr(\xi;\mu) = P_0^\mu(\boldsymbol{z}_0)\prod_{t=1}^{T} P^\mu(\boldsymbol{z}_t|\boldsymbol{z}_{t-1}) = P_0(x_0)\prod_{t=0}^{T-1}\mu(a_t|x_t)P(x_{t+1}|x_t,a_t). \tag{1}$$

We denote by $R(\xi) = \sum_{t=0}^{T-1}\gamma^t r(x_t,a_t)$ the (possibly discounted, $\gamma \in [0,1]$) *cumulative return* of the path ξ. $R(\xi)$ is a random variable both because the path ξ itself is a random variable, and because, even for a given path, each of the rewards sampled in it may be stochastic. The expected value of $R(\xi)$ for a given path ξ is denoted by $\bar{R}(\xi)$. Finally, we define the *expected return* of policy μ as

$$\eta(\mu) = \mathbf{E}\big[R(\xi)\big] = \int_\Xi \bar{R}(\xi)\Pr(\xi;\mu)d\xi. \tag{2}$$

The t-step state-action occupancy density of policy μ is given by

$$P_t^\mu(\boldsymbol{z}_t) = \int_{\mathcal{Z}^t} d\boldsymbol{z}_0 \ldots d\boldsymbol{z}_{t-1} P_0^\mu(\boldsymbol{z}_0)\prod_{i=1}^{t} P^\mu(\boldsymbol{z}_i|\boldsymbol{z}_{i-1}).$$

It can be shown that under certain regularity conditions (Sutton et al., 2000), the expected return of policy μ may be written in terms of state-action pairs (rather than in terms of trajectories as in Equation 2) as

$$\eta(\mu) = \int_{\mathcal{Z}} d\boldsymbol{z}\pi^\mu(\boldsymbol{z})\bar{r}(\boldsymbol{z}), \tag{3}$$

where $\pi^\mu(\boldsymbol{z}) = \sum_{t=0}^{\infty}\gamma^t P_t^\mu(\boldsymbol{z})$ is a discounted weighting of state-action pairs encountered while following policy μ. Integrating a out of $\pi^\mu(\boldsymbol{z}) = \pi^\mu(x,a)$ results in the corresponding discounted weighting of states encountered by following policy μ: $\nu^\mu(x) = \int_{\mathcal{A}} da\pi^\mu(x,a)$. Unlike ν^μ and π^μ, $(1-\gamma)\nu^\mu$ and $(1-\gamma)\pi^\mu$ are distributions. They are analogous to the stationary distributions over states and state-action pairs of policy μ in the undiscounted setting, respectively, since as $\gamma \to 1$, they tend to these distributions, if they exist.

Our aim is to find a policy μ^* that maximizes the expected return, i.e., $\mu^* = \arg\max_\mu \eta(\mu)$. A policy μ is assessed according to the expected cumulative rewards associated with states x or state-action pairs $\boldsymbol{z}$. For all states $x \in \mathcal{X}$ and actions $a \in \mathcal{A}$, the action-value function and the value function of policy μ are defined as

$$Q^\mu(\boldsymbol{z}) = \mathbf{E}\left[\sum_{t=0}^{\infty}\gamma^t r(\boldsymbol{z}_t)|\boldsymbol{z}_0 = \boldsymbol{z}\right] \qquad \text{and} \qquad V^\mu(x) = \int_{\mathcal{A}} da\mu(a|x)Q^\mu(x,a).$$

In policy gradient (PG) methods, we define a class of smoothly parameterized stochastic policies $\{\mu(\cdot|x;\boldsymbol{\theta}), x \in \mathcal{X}, \boldsymbol{\theta} \in \Theta\}$. We estimate the gradient of the expected return, defined

by Equation 2 (or Equation 3), with respect to the policy parameters $\boldsymbol{\theta}$, from the observed system trajectories. We then improve the policy by adjusting the parameters in the direction of the gradient (e.g., Williams 1992, Marbach 1998, Baxter and Bartlett 2001). Since in this setting a policy μ is represented by its parameters $\boldsymbol{\theta}$, policy dependent functions such as $\eta(\mu)$, $\Pr(\xi;\mu)$, $\pi^\mu(\boldsymbol{z})$, $\nu^\mu(x)$, $V^\mu(x)$, and $Q^\mu(\boldsymbol{z})$ may be written as $\eta(\boldsymbol{\theta})$, $\Pr(\xi;\boldsymbol{\theta})$, $\pi(\boldsymbol{z};\boldsymbol{\theta})$, $\nu(x;\boldsymbol{\theta})$, $V(x;\boldsymbol{\theta})$, and $Q(\boldsymbol{z};\boldsymbol{\theta})$, respectively. We assume

Assumption 1 (Differentiability) *For any state-action pair (x,a) and any policy parameter $\boldsymbol{\theta}\in\Theta$, the policy $\mu(a|x;\boldsymbol{\theta})$ is continuously differentiable in the parameters $\boldsymbol{\theta}$.*

The *score function* or *likelihood ratio* method has become the most prominent technique for gradient estimation from simulation. It has been first proposed in the 1960's (Aleksandrov et al., 1968, Rubinstein, 1969) for computing performance gradients in i.i.d. (independently and identically distributed) processes, and was then extended to *regenerative* processes including MDPs by Glynn (1986, 1990), Reiman and Weiss (1986, 1989), Glynn and L'Ecuyer (1995), and to episodic MDPs by Williams (1992). This method estimates the gradient of the expected return with respect to the policy parameters $\boldsymbol{\theta}$, defined by Equation 2, using the following equation:[6]

$$\nabla\eta(\boldsymbol{\theta}) = \int \bar{R}(\xi)\frac{\nabla\Pr(\xi;\boldsymbol{\theta})}{\Pr(\xi;\boldsymbol{\theta})}\Pr(\xi;\boldsymbol{\theta})d\xi. \tag{4}$$

In Equation 4, the quantity $\frac{\nabla\Pr(\xi;\boldsymbol{\theta})}{\Pr(\xi;\boldsymbol{\theta})} = \nabla\log\Pr(\xi;\boldsymbol{\theta})$ is called the (Fisher) score function or likelihood ratio. Since the initial-state distribution P_0 and the state-transition distribution P are independent of the policy parameters $\boldsymbol{\theta}$, we may write the score function for a path ξ using Equation 1 as[7]

$$\boldsymbol{u}(\xi;\boldsymbol{\theta}) = \nabla\log\Pr(\xi;\boldsymbol{\theta}) = \frac{\nabla\Pr(\xi;\boldsymbol{\theta})}{\Pr(\xi;\boldsymbol{\theta})} = \sum_{t=0}^{T-1}\frac{\nabla\mu(a_t|x_t;\boldsymbol{\theta})}{\mu(a_t|x_t;\boldsymbol{\theta})} = \sum_{t=0}^{T-1}\nabla\log\mu(a_t|x_t;\boldsymbol{\theta}). \tag{5}$$

Previous work on policy gradient used classical MC to estimate the gradient in Equation 4. These methods generate i.i.d. sample paths $\xi_1,\ldots,\xi_M$ according to $\Pr(\xi;\boldsymbol{\theta})$, and estimate the gradient $\nabla\eta(\boldsymbol{\theta})$ using the MC estimator

$$\widehat{\nabla\eta}(\boldsymbol{\theta}) = \frac{1}{M}\sum_{i=1}^{M}R(\xi_i)\nabla\log\Pr(\xi_i;\boldsymbol{\theta}) = \frac{1}{M}\sum_{i=1}^{M}R(\xi_i)\sum_{t=0}^{T_i-1}\nabla\log\mu(a_{t,i}|x_{t,i};\boldsymbol{\theta}). \tag{6}$$

This is an unbiased estimate, and therefore, by the law of large numbers, $\widehat{\nabla\eta}(\boldsymbol{\theta})\to\nabla\eta(\boldsymbol{\theta})$ as M goes to infinity, with probability one.

The policy gradient theorem (Marbach, 1998, Proposition 1; Sutton et al., 2000, Theorem 1; Konda and Tsitsiklis, 2000, Theorem 1) states that the gradient of the expected return, defined by Equation 3, for parameterized policies satisfying Assumption 1 is given by

$$\nabla\eta(\boldsymbol{\theta}) = \int dxda\;\nu(x;\boldsymbol{\theta})\nabla\mu(a|x;\boldsymbol{\theta})Q(x,a;\boldsymbol{\theta}). \tag{7}$$

6. Throughout the paper, we use the notation ∇ to denote $\nabla_{\boldsymbol{\theta}}$ – the gradient w.r.t. the policy parameters.
7. To simplify notation, we omit $\boldsymbol{u}$'s dependence on the policy parameters $\boldsymbol{\theta}$, and denote $\boldsymbol{u}(\xi;\boldsymbol{\theta})$ as $\boldsymbol{u}(\xi)$ in the sequel.

Observe that if $b:\mathcal{X}\to\mathbb{R}$ is an arbitrary function of x (also called a *baseline*), then

$$\int_{\mathcal{Z}} dxda\;\nu(x;\boldsymbol{\theta})\nabla\mu(a|x;\boldsymbol{\theta})b(x) = \int_{\mathcal{X}} dx\;\nu(x;\boldsymbol{\theta})b(x)\nabla\Big(\int_{\mathcal{A}} da\mu(a|x;\boldsymbol{\theta})\Big) = \int_{\mathcal{X}} dx\;\nu(x;\boldsymbol{\theta})b(x)\nabla(1) = 0,$$

and thus, for any baseline $b(x)$, the gradient of the expected return can be written as

$$\nabla\eta(\boldsymbol{\theta}) = \int dxda\;\nu(x;\boldsymbol{\theta})\nabla\mu(a|x;\boldsymbol{\theta})\big(Q(x,a;\boldsymbol{\theta})+b(x)\big) = \int_{\mathcal{Z}} d\boldsymbol{z}\pi(\boldsymbol{z};\boldsymbol{\theta})\nabla\log\mu(a|x;\boldsymbol{\theta})\big(Q(\boldsymbol{z};\boldsymbol{\theta})+b(x)\big). \tag{8}$$

The baseline may be chosen in such a way so as to minimize the variance of the gradient estimates (Greensmith et al., 2004).

Now consider the actor-critic (AC) framework in which the action-value function for a fixed policy μ, Q^μ, is approximated by a learned function approximator. If the approximation is sufficiently good, we may hope to use it in place of Q^μ in Equations 7 and 8, and still point roughly in the direction of the true gradient. Sutton et al. (2000) and Konda and Tsitsiklis (2000) showed that if the approximation $\hat{Q}^\mu(\cdot;\boldsymbol{w})$ with parameter $\boldsymbol{w}$ is *compatible*, i.e., $\nabla_{\boldsymbol{w}}\hat{Q}^\mu(x,a;\boldsymbol{w}) = \nabla\log\mu(a|x;\boldsymbol{\theta})$, and if it minimizes the mean squared error

$$\mathcal{E}^\mu(\boldsymbol{w}) = \int_{\mathcal{Z}} d\boldsymbol{z}\pi^\mu(\boldsymbol{z})\big[Q^\mu(\boldsymbol{z}) - \hat{Q}^\mu(\boldsymbol{z};\boldsymbol{w})\big]^2 \tag{9}$$

for parameter value $\boldsymbol{w}^*$, then we may replace Q^μ with $\hat{Q}^\mu(\cdot;\boldsymbol{w}^*)$ in Equations 7 and 8. The second condition means that $\hat{Q}^\mu(\cdot;\boldsymbol{w}^*)$ is the projection of Q^μ onto the space $\{\hat{Q}^\mu(\cdot;\boldsymbol{w})|\boldsymbol{w}\in\mathbb{R}^n\}$, with respect to a ℓ_2-norm weighted by π^μ.

An approximation for the action-value function, in terms of a linear combination of basis functions, may be written as $\hat{Q}^\mu(\boldsymbol{z};\boldsymbol{w}) = \boldsymbol{w}^\top\boldsymbol{\psi}(\boldsymbol{z})$. This approximation is compatible if the $\boldsymbol{\psi}$'s are compatible with the policy, i.e., $\boldsymbol{\psi}(\boldsymbol{z};\boldsymbol{\theta}) = \nabla\log\mu(a|x;\boldsymbol{\theta})$. Note that compatibility is well defined under Assumption 1. Let $\mathcal{E}^\mu(\boldsymbol{w})$ denote the mean squared error

$$\mathcal{E}^\mu(\boldsymbol{w}) = \int_{\mathcal{Z}} d\boldsymbol{z}\pi^\mu(\boldsymbol{z})\big[Q^\mu(\boldsymbol{z}) - \boldsymbol{w}^\top\boldsymbol{\psi}(\boldsymbol{z}) - b(x)\big]^2 \tag{10}$$

of our compatible linear approximation $\boldsymbol{w}^\top\boldsymbol{\psi}(\boldsymbol{z})$ and an arbitrary baseline $b(x)$. Let $\boldsymbol{w}^* = \arg\min_{\boldsymbol{w}}\mathcal{E}^\mu(\boldsymbol{w})$ denote the optimal parameter. It can be shown that the value of $\boldsymbol{w}^*$ does not depend on the baseline $b(x)$. As a result, the mean squared-error problems of Equations 9 and 10 have the same solutions (see e.g., Bhatnagar et al. 2007, 2009). It can also be shown that if the parameter $\boldsymbol{w}$ is set to be equal to $\boldsymbol{w}^*$, then the resulting mean squared error $\mathcal{E}^\mu(\boldsymbol{w}^*)$, now treated as a function of the baseline $b(x)$, is further minimized by setting $b(x) = V^\mu(x)$ (Bhatnagar et al., 2007, 2009). In other words, the variance in the action-value function estimator is minimized if the baseline is chosen to be the value function itself.

A convenient and rather flexible choice for a space of policies that ensures compatibility between the policy and the action-value representation is a parametric exponential family

$$\mu(a|x;\boldsymbol{\theta}) = \frac{1}{Z_{\boldsymbol{\theta}}(x)}\exp\Big(\boldsymbol{\theta}^\top\boldsymbol{\phi}(x,a)\Big),$$

where $Z_{\boldsymbol{\theta}}(x) = \int_{\mathcal{A}} da \exp\big(\boldsymbol{\theta}^\top \boldsymbol{\phi}(x,a)\big)$ is a normalizing factor, referred to as the *partition function*. It is easy to show that $\boldsymbol{\psi}(\boldsymbol{z}) = \boldsymbol{\phi}(\boldsymbol{z}) - \mathbf{E}_{a|x}[\boldsymbol{\phi}(\boldsymbol{z})]$, where $\mathbf{E}_{a|x}[\cdot] = \int_{\mathcal{A}} da \mu(a|x;\boldsymbol{\theta})[\cdot]$, and as a result, $\hat{Q}^\mu(\boldsymbol{z};\boldsymbol{w}^*) = \boldsymbol{w}^{*\top}\big(\boldsymbol{\phi}(\boldsymbol{z}) - \mathbf{E}_{a|x}[\boldsymbol{\phi}(\boldsymbol{z})]\big) + b(x)$ is a compatible action-value function for this family of policies. Note that $\mathbf{E}_{a|x}[\hat{Q}(\boldsymbol{z};\boldsymbol{w}^*)] = b(x)$, since $\mathbf{E}_{a|x}\big[\boldsymbol{\phi}(\boldsymbol{z}) - \mathbf{E}_{a|x}[\boldsymbol{\phi}(\boldsymbol{z})]\big] = 0$. This means that if $\hat{Q}^\mu(\boldsymbol{z};\boldsymbol{w}^*)$ approximates $Q^\mu(\boldsymbol{z})$, then $b(x)$ must approximate the value function $V^\mu(x)$. The term $\hat{A}^\mu(\boldsymbol{z};\boldsymbol{w}^*) = \hat{Q}^\mu(\boldsymbol{z};\boldsymbol{w}^*) - b(x) = \boldsymbol{w}^{*\top}\big(\boldsymbol{\phi}(\boldsymbol{z}) - \mathbf{E}_{a|x}[\boldsymbol{\phi}(\boldsymbol{z})]\big)$ approximates the *advantage function* $A^\mu(\boldsymbol{z}) = Q^\mu(\boldsymbol{z}) - V^\mu(x)$ (Baird, 1993).

3. Bayesian Quadrature

Bayesian quadrature (BQ) (O'Hagan, 1991) is, as its name suggests, a Bayesian method for evaluating an integral using samples of its integrand. We consider the problem of evaluating the integral

$$\rho = \int f(x) g(x) dx. \tag{11}$$

If $g(x)$ is a probability density function, i.e., $g(x) = p(x)$, this becomes the problem of evaluating the expected value of $f(x)$. A well known frequentist approach to evaluating such expectations is the Monte-Carlo (MC) method. For MC estimation of such expectations, it is typically required that samples $x_1, x_2, \ldots, x_M$ are drawn from $p(x)$.[8] The integral in Equation 11 is then estimated as

$$\hat{\rho}_{MC} = \frac{1}{M} \sum_{i=1}^{M} f(x_i). \tag{12}$$

It is easy to show that $\hat{\rho}_{MC}$ is an unbiased estimate of ρ, with variance that diminishes to zero as $M \to \infty$. However, as O'Hagan (1987) points out, MC estimation is fundamentally unsound, as it violates the likelihood principle, and moreover, does not make full use of the data at hand. The alternative proposed in O'Hagan (1991) is based on the following reasoning: In the Bayesian approach, $f(\cdot)$ is random simply because it is unknown. We are therefore uncertain about the value of $f(x)$ until we actually evaluate it. In fact, even then, our uncertainty is not always completely removed, since measured samples of $f(x)$ may be corrupted by noise. Modeling f as a Gaussian process (GP) means that our uncertainty is completely accounted for by specifying a Normal prior distribution over functions. This prior distribution is specified by its mean and covariance, and is denoted by $f(\cdot) \sim \mathcal{N}\big(\bar{f}(\cdot), k(\cdot,\cdot)\big)$. This is shorthand for the statement that f is a GP with prior mean and covariance

$$\mathbf{E}\big[f(x)\big] = \bar{f}(x) \quad \text{and} \quad \mathbf{Cov}\big[f(x), f(x')\big] = k(x,x'), \quad \forall x, x' \in \mathcal{X}, \tag{13}$$

respectively. The choice of kernel function k allows us to incorporate prior knowledge on the smoothness properties of the integrand into the estimation procedure. When we are provided with a set of samples $\mathcal{D}_M = \big\{\big(x_i, y(x_i)\big)\big\}_{i=1}^M$, where $y(x_i)$ is a (possibly noisy) sample of $f(x_i)$, we apply Bayes' rule to condition the prior on these sampled values. If the measurement noise is normally distributed, the result is a Normal posterior distribution of

8. If samples are drawn from some other distribution, importance sampling variants of MC may be used.

$f|\mathcal{D}_M$. The expressions for the posterior mean and covariance are standard:

$$\begin{aligned} \mathbf{E}\big[f(x)|\mathcal{D}_M\big] &= \bar{f}(x) + \boldsymbol{k}(x)^\top \boldsymbol{C}(\boldsymbol{y} - \bar{\boldsymbol{f}}), \\ \mathbf{Cov}\big[f(x), f(x')|\mathcal{D}_M\big] &= k(x,x') - \boldsymbol{k}(x)^\top \boldsymbol{C} \boldsymbol{k}(x'). \end{aligned} \tag{14}$$

Here and in the sequel, we make use of the definitions:

$$\begin{aligned} &\bar{\boldsymbol{f}} = \big(\bar{f}(x_1), \ldots, \bar{f}(x_M)\big)^\top, && && \boldsymbol{k}(x) = \big(k(x_1,x), \ldots, k(x_M,x)\big)^\top, \\ &\boldsymbol{y} = \big(y(x_1), \ldots, y(x_M)\big)^\top, && [\boldsymbol{K}]_{i,j} = k(x_i,x_j), && \boldsymbol{C} = (\boldsymbol{K} + \boldsymbol{\Sigma})^{-1}, \end{aligned}$$

where $\boldsymbol{K}$ is the kernel (or Gram) matrix, and $[\boldsymbol{\Sigma}]_{i,j}$ is the measurement noise covariance between the ith and jth samples. It is typically assumed that the measurement noise is i.i.d., in which case $\boldsymbol{\Sigma} = \sigma^2 \boldsymbol{I}$, where σ^2 is the noise variance and $\boldsymbol{I}$ is the (appropriately sized - here $M \times M$) identity matrix.

Since integration is a linear operation, the posterior distribution of the integral in Equation 11 is also Gaussian, and the posterior moments are given by (O'Hagan, 1991)

$$\begin{aligned} \mathbf{E}[\rho|\mathcal{D}_M] &= \int \mathbf{E}\big[f(x)|\mathcal{D}_M\big] g(x) dx, \\ \mathbf{Var}[\rho|\mathcal{D}_M] &= \iint \mathbf{Cov}\big[f(x), f(x')|\mathcal{D}_M\big] g(x) g(x') dx dx'. \end{aligned} \tag{15}$$

Substituting Equation 14 into Equation 15, we obtain

$$\mathbf{E}[\rho|\mathcal{D}_M] = \rho_0 + \boldsymbol{b}^\top \boldsymbol{C}(\boldsymbol{y} - \bar{\boldsymbol{f}}) \quad \text{and} \quad \mathbf{Var}[\rho|\mathcal{D}_M] = b_0 - \boldsymbol{b}^\top \boldsymbol{C} \boldsymbol{b},$$

where we made use of the definitions:

$$\rho_0 = \int \bar{f}(x) g(x) dx\,, \qquad \boldsymbol{b} = \int \boldsymbol{k}(x) g(x) dx\,, \qquad b_0 = \iint k(x,x') g(x) g(x') dx dx'. \tag{16}$$

Note that ρ_0 and b_0 are the prior mean and variance of ρ, respectively.

Rasmussen and Ghahramani (2003) experimentally demonstrated how this approach, when applied to the evaluation of an expectation, can outperform MC estimation by orders of magnitude in terms of the mean-squared error.

In order to prevent the problem from "degenerating into infinite regress", as phrased by O'Hagan (1991),[9] we should choose the functions g, k, and $\bar{f}$ so as to allow us to solve the integrals in Equation 16 analytically. For example, O'Hagan provides the analysis required for the case where the integrands in Equation 16 are products of multivariate Gaussians and polynomials, referred to as Bayes-Hermite quadrature. One of the contributions of our work is in providing analogous analysis for kernel functions that are based on the *Fisher kernel* (Jaakkola and Haussler, 1999, Shawe-Taylor and Cristianini, 2004).

It is important to note that in MC estimation, samples must be drawn from the distribution $p(x) = g(x)$, whereas in the Bayesian approach, samples may be drawn from arbitrary distributions. This affords us with flexibility in the choice of sample points, allowing us, for instance, to actively design the samples $x_1, \ldots, x_M$ so as to maximize information gain.

9. What O'Hagan means by "degenerating into infinite regress" is simply that if we cannot compute the posterior integrals of Equation 16 analytically, then we have started with estimating one integral (Equation 11) and ended up with three (Equation 16), and if we repeat this process, this can go forever and leave us with infinite integrals to evaluate. Therefore, for Bayesian MC to work, it is crucial to be able to analytically calculate the posterior integrals, and this can be achieved through the way we divide the integrant into two parts and the way we select the kernel function.

3.1 Vector-Valued Integrals

O'Hagan (1991) treated the case where the integral to be estimated is a scalar-valued integral. However, in the context of our PG method, it is useful to consider vector-valued integrals, such as the gradient of the expected return with respect to the policy parameters, which we shall study in Section 4. In the BQ framework, an integral of the form in Equation 11 may be vector-valued for one of two possible reasons: either f is a vector-valued GP and g is a scalar-valued function, or f is a scalar-valued GP and g is a vector-valued function. These two possibilities correspond to two very different data-generation models. In the first of these, an n-valued function $f(\cdot) = \big(f_1(\cdot), \ldots, f_n(\cdot)\big)^\top$ is sampled from the GP distribution of f. This distribution may include correlations between different components of f. Hence, in general, to specify the GP prior distribution, one needs to specify not only the covariance kernel of each component j of f, $k_{j,j}(x,x') = \mathbf{Cov}\big[f_j(x), f_j(x')\big]$, but also cross-covariance kernels for pairs of different components, $k_{j,\ell}(x,x') = \mathbf{Cov}\big[f_j(x), f_\ell(x')\big]$. Thus, instead of a single kernel function, we now need to specify a matrix of kernel functions.[10] Similarly, we also need to specify a vector of prior means, consisting of a function for each component: $\bar{f}_j(x) = \mathbf{E}\big[f_j(x)\big]$. The distribution of the measurement noise added to $f(x)$ to produce $y(x)$ may also include correlations, requiring us to specify an array of noise covariance matrices $\mathbf{\Sigma}_{j,\ell}$. As we show below, the GP posterior distribution is also specified in similar terms.

In the second model, a scalar-valued function is sampled from the GP prior distribution, which is specified by a single prior mean function and a single prior covariance-kernel function. Gaussian noise may be added, and the result is then multiplied by each of the components of the n-valued function g to produce the integrand. This model is significantly simpler, both conceptually and in terms of the number of parameters required to specify it. To see how a model of the first kind may arise, consider the following example.

Example 1 *Let $\rho(\boldsymbol{\theta}) = \int f(x;\boldsymbol{\theta})g(x)dx$, where f is a scalar GP, parameterized by a vector of parameters $\boldsymbol{\theta}$. Its prior mean and covariance functions must therefore depend on $\boldsymbol{\theta}$. We denote these dependencies by writing:*

$$\mathbf{E}\big[f(x;\boldsymbol{\theta})\big] = \bar{f}(x;\boldsymbol{\theta}), \quad \mathbf{Cov}\big[f(x;\boldsymbol{\theta}), f(x';\boldsymbol{\theta})\big] = k(x,x';\boldsymbol{\theta}), \quad \forall x, x' \in \mathcal{X}.$$

We choose $\bar{f}(x;\boldsymbol{\theta})$ and $k(x,x';\boldsymbol{\theta})$ so as to be once and twice differentiable in $\boldsymbol{\theta}$, respectively. Suppose now that we are not interested in estimating $\rho(\boldsymbol{\theta})$, but rather in its gradient with respect to the parameters $\boldsymbol{\theta}$: $\nabla_{\boldsymbol{\theta}}\rho(\boldsymbol{\theta}) = \int \nabla_{\boldsymbol{\theta}} f(x;\boldsymbol{\theta})g(x)dx$. It may be easily verified that the mean functions and covariance kernels of the vector-valued GP $\nabla_{\boldsymbol{\theta}} f(x;\boldsymbol{\theta})$ are given by

$$\mathbf{E}\big[\nabla_{\boldsymbol{\theta}} f(x;\boldsymbol{\theta})\big] = \nabla_{\boldsymbol{\theta}}\bar{f}(x;\boldsymbol{\theta}) \quad \text{and} \quad \mathbf{Cov}\big[\partial_{\theta_j} f(x;\boldsymbol{\theta}), \partial_{\theta_\ell} f(x';\boldsymbol{\theta})\big] = \partial_{\theta_j}\partial_{\theta_\ell} k(x,x';\boldsymbol{\theta}),$$

where ∂_{θ_j} denotes the jth component of $\nabla_{\boldsymbol{\theta}}$. □

Propositions 1 and 2 specify the form taken by the mean and covariance functions of the integral GP under the two models discussed above.

10. Note that to satisfy the symmetry property of the covariance operator, we require that $k_{j,\ell}(x,x') = k_{\ell,j}(x',x) = k_{\ell,j}(x,x')$, for all $x, x' \in \mathcal{X}$ and $j, \ell \in \{1,\ldots,n\}$.

Proposition 1 (Vector-valued GP) *Let f be an n-valued GP with mean functions $\bar{f}_j(x) = \mathbf{E}\big[f_j(x)\big]$ and covariance functions $k_{j,\ell}(x,x') = \mathbf{Cov}\big[f_j(x), f_\ell(x')\big]$, $\forall j,\ell \in \{1,\ldots,n\}$, and let g be a scalar-valued function. Then, the mean and covariance of ρ defined by Equation 11 are of the following form:*

$$\mathbf{E}\big[\rho_j\big] = \int \bar{f}_j(x)g(x)dx, \quad \mathbf{Cov}\big[\rho_j, \rho_\ell\big] = \iint k_{j,\ell}(x,x')g(x)g(x')dxdx', \quad \forall j,\ell \in \{1,\ldots,n\}.$$

Proposition 2 (Scalar-valued GP) *Let f be a scalar-valued GP with mean function $\bar{f}(x) = \mathbf{E}\big[f(x)\big]$ and covariance function $k(x,x') = \mathbf{Cov}\big[f(x), f(x')\big]$, and let g be an n-valued function. Then, the mean and covariance of ρ defined by Equation 11 are of the following form:*

$$\mathbf{E}\big[\rho_j\big] = \int \bar{f}(x)g_j(x)dx, \quad \mathbf{Cov}\big[\rho_j, \rho_\ell\big] = \iint k(x,x')g_j(x)g_\ell(x')dxdx', \quad \forall j,\ell \in \{1,\ldots,n\}.$$

The proofs of these two propositions follow straightforwardly from the definition of the covariance operator in terms of expectations, and the order-exchangeability of GP expectations and integration with respect to x.

To wrap things up, we need to describe the form taken by the posterior moments of f in the vector-valued GP case. Using the standard Gaussian conditioning formulas, it is straightforward to show that

$$\begin{aligned}
\mathbf{E}\big[f_j(x)|\mathcal{D}_M\big] &= \bar{f}_j(x) + \sum_{m,m'} \boldsymbol{k}_{j,m}(x)^\top \boldsymbol{C}_{m,m'}(\boldsymbol{y}_{m'} - \bar{\boldsymbol{f}}_{m'}),\\
\mathbf{Cov}\big[f_j(x), f_\ell(x')|\mathcal{D}_M\big] &= k_{j,\ell}(x,x') - \sum_{m,m'} \boldsymbol{k}_{j,m}(x)^\top \boldsymbol{C}_{m,m'}\boldsymbol{k}_{m',\ell}(x'),
\end{aligned} \tag{17}$$

where

$$\begin{aligned}
&\bar{\boldsymbol{f}}_j = \big(\bar{f}_j(x_1), \ldots, \bar{f}_j(x_M)\big)^\top, && \boldsymbol{k}_{j,\ell}(x) = \big(k_{j,\ell}(x_1,x), \ldots, k_{j,\ell}(x_M,x)\big)^\top,\\
&\boldsymbol{y}_\ell = \big(y_\ell(x_1), \ldots, y_\ell(x_M)\big)^\top, && [\boldsymbol{K}_{j,\ell}]_{i,i'} = k_{j,\ell}(x_i, x_{i'}),
\end{aligned}$$

$$\boldsymbol{K} = \begin{bmatrix} \boldsymbol{K}_{1,1} & \ldots & \boldsymbol{K}_{1,n} \\ \vdots & & \vdots \\ \boldsymbol{K}_{n,1} & \ldots & \boldsymbol{K}_{n,n} \end{bmatrix}, \quad \boldsymbol{\Sigma} = \begin{bmatrix} \boldsymbol{\Sigma}_{1,1} & \ldots & \boldsymbol{\Sigma}_{1,n} \\ \vdots & & \vdots \\ \boldsymbol{\Sigma}_{n,1} & \ldots & \boldsymbol{\Sigma}_{n,n} \end{bmatrix}, \quad \boldsymbol{C} = (\boldsymbol{K} + \boldsymbol{\Sigma})^{-1},$$

and $\boldsymbol{C}_{j,\ell}$ is the (j,ℓ)th $M \times M$ block of $\boldsymbol{C}$. The posterior moments of f, given in Equation 17, may now be substituted into the expressions for the moments of the integral ρ, given in Proposition 1, to produce the posterior moments of ρ in the vector-valued GP case.

Clearly, models of the first type (vector-valued GP) are potentially richer and more complex than models of the second type (scalar-valued GP), as the latter only requires us to define a single prior mean function, a single prior covariance kernel function, and a single noise covariance matrix; while the former requires us to define n prior mean functions, and $n(n+1)/2$ prior covariance kernel functions and noise covariance matrices. One way to simplify the first type of models is to define a single prior mean function $\bar{f}$, a single prior covariance kernel function k, and to postulate that $\bar{f}_j(x) = \bar{f}(x)$, $k_{j,\ell}(x,x') = \delta_{j,\ell}\, k(x,x')$, and

$\boldsymbol{\Sigma}_{j,\ell} = \delta_{j,\ell}\boldsymbol{\Sigma}$, $\forall j, \ell \in \{1,\dots,n\}$, where δ denotes the Kronecker delta function. Applying these simplifying assumptions to the expressions for the posterior moments (Equation 17) results in a complete decoupling between the posterior moments for the different components of f, and consequently a decoupling between the components of the integral ρ as well, since Equation 17 becomes

$$\begin{aligned}\mathbf{E}\big[f_j(x)|\mathcal{D}_M\big] &= \bar{f}_j(x) + \boldsymbol{k}_{j,j}(x)^\top \boldsymbol{C}_{j,j}(\boldsymbol{y}_j - \bar{\boldsymbol{f}}_j),\\ \mathbf{Cov}\big[f_j(x), f_\ell(x')|\mathcal{D}_M\big] &= \delta_{j,\ell}\left(k_{j,j}(x,x') - \boldsymbol{k}_{j,j}(x)^\top \boldsymbol{C}_{j,\ell}\boldsymbol{k}_{\ell,\ell}(x')\right),\end{aligned} \tag{18}$$

where $\boldsymbol{C}_{j,\ell} = \delta_{j,\ell}\left(\boldsymbol{K}_{j,\ell} + \boldsymbol{\Sigma}_{j,\ell}\right)^{-1}$. Note that all the terms in Equation 18, except $\boldsymbol{y}_j$, do not depend on the indices j and ℓ. In other words, these simplifying assumptions amount to assuming that ρ is a vector of n independent integrals, each of which may be estimated individually as

$$\begin{aligned}\mathbf{E}\big[f_j(x)|\mathcal{D}_M\big] &= \bar{f}(x) + \boldsymbol{k}(x)^\top \boldsymbol{C}(\boldsymbol{y}_j - \bar{\boldsymbol{f}}),\\ \mathbf{Cov}\big[f_j(x), f_\ell(x')|\mathcal{D}_M\big] &= \delta_{j,\ell}\left(k(x,x') - \boldsymbol{k}(x)^\top \boldsymbol{C}\boldsymbol{k}(x')\right),\end{aligned}$$

where $\boldsymbol{C} = (\boldsymbol{K} + \boldsymbol{\Sigma})^{-1}$. It should, however, be kept in mind that ignoring correlations between the components of f, when such correlations exist, may result in suboptimal use of the available data (see Rasmussen and Williams, 2006, Chapter 9 for references on GP regression with multiple outputs).

4. Bayesian Policy Gradient

In this section, we use vector-valued Bayesian quadrature to estimate the gradient of the expected return with respect to the policy parameters, allowing us to propose new *Bayesian policy gradient* (BPG) algorithms. In the frequentist approach to policy gradient, the performance measure used is $\eta(\boldsymbol{\theta}) = \int \bar{R}(\xi)\Pr(\xi;\boldsymbol{\theta})d\xi$ (Equation 2). In order to serve as a useful performance measure, it has to be a deterministic function of the policy parameters $\boldsymbol{\theta}$. This is achieved by averaging the cumulative return $R(\xi)$ over all possible paths ξ and all possible returns accumulated in each path. In the Bayesian approach we have an additional source of randomness, namely, our subjective Bayesian uncertainty concerning the process generating the cumulative return. Let us denote

$$\eta_B(\boldsymbol{\theta}) = \int \bar{R}(\xi)\Pr(\xi;\boldsymbol{\theta})d\xi, \tag{19}$$

where $\eta_B(\boldsymbol{\theta})$ is a random variable because of the Bayesian uncertainty. Under the quadratic loss, the optimal Bayesian performance measure is the posterior expected value of $\eta_B(\boldsymbol{\theta})$, $\mathbf{E}\big[\eta_B(\boldsymbol{\theta})|\mathcal{D}_M\big]$. However, since we are interested in optimizing the performance rather than evaluating it,[11] we would rather evaluate the posterior distribution of the *gradient* of $\eta_B(\boldsymbol{\theta})$ with respect to the policy parameters $\boldsymbol{\theta}$. The posterior mean of the gradient is [12]

$$\nabla\mathbf{E}\big[\eta_B(\boldsymbol{\theta})|\mathcal{D}_M\big] = \mathbf{E}\big[\nabla\eta_B(\boldsymbol{\theta})|\mathcal{D}_M\big] = \mathbf{E}\left[\int R(\xi)\frac{\nabla\Pr(\xi;\boldsymbol{\theta})}{\Pr(\xi;\boldsymbol{\theta})}\Pr(\xi;\boldsymbol{\theta})d\xi\Big|\mathcal{D}_M\right]. \tag{20}$$

11. Although evaluating the posterior distribution of performance is an interesting question in its own right.
12. We may interchange the order of the gradient and the expectation operators for the mean, $\nabla\mathbf{E}\big[\eta_B(\boldsymbol{\theta})\big] = \mathbf{E}\big[\nabla\eta_B(\boldsymbol{\theta})\big]$, but the same is not true for the variance, namely, $\nabla\mathbf{Var}\big[\eta_B(\boldsymbol{\theta})\big] \neq \mathbf{Cov}\big[\nabla\eta_B(\boldsymbol{\theta})\big]$.

Consequently, in BPG we cast the problem of estimating the gradient of the expected return (Equation 20) in the form of Equation 11. As described in Section 3, we need to partition the integrand into two parts, $f(\xi;\boldsymbol{\theta})$ and $g(\xi;\boldsymbol{\theta})$. We will model f as a GP and assume that g is a function known to us. We will then proceed by calculating the posterior moments of the gradient $\nabla\eta_B(\boldsymbol{\theta})$ conditioned on the observed data. Because in general, $R(\xi)$ cannot be known exactly, even for a given ξ (due to the stochasticity of the rewards), $R(\xi)$ should always belong to the GP part of the model, i.e., $f(\xi;\boldsymbol{\theta})$. Interestingly, in certain cases it is sufficient to know the Fisher information matrix corresponding to $\Pr(\xi;\boldsymbol{\theta})$, rather than having exact knowledge of $\Pr(\xi;\boldsymbol{\theta})$ itself. We make use of this fact in the sequel. In the next two sections, we investigate two different ways of partitioning the integrand in Equation 20, resulting in two distinct Bayesian policy gradient models.

4.1 Model 1 – Vector-Valued GP

In our first model, we define g and f as follows:

$$g(\xi;\boldsymbol{\theta}) = \Pr(\xi;\boldsymbol{\theta}) \quad , \quad f(\xi;\boldsymbol{\theta}) = \bar{R}(\xi)\frac{\nabla\Pr(\xi;\boldsymbol{\theta})}{\Pr(\xi;\boldsymbol{\theta})} = \bar{R}(\xi)\nabla\log\Pr(\xi;\boldsymbol{\theta}).$$

We place a vector-valued GP prior over $f(\xi;\boldsymbol{\theta})$ which induces a GP prior over the corresponding noisy measurement $y(\xi;\boldsymbol{\theta}) = R(\xi)\nabla\log\Pr(\xi;\boldsymbol{\theta})$. We adopt the simplifying assumptions discussed at the end of Section 3.1: We assume that each component of $f(\xi;\boldsymbol{\theta})$ may be evaluated independently of all other components, and use the same kernel function and noise covariance for all components of $f(\xi;\boldsymbol{\theta})$. We therefore omit the component index j from $\boldsymbol{K}_{j,j}$, $\boldsymbol{\Sigma}_{j,j}$ and $\boldsymbol{C}_{j,j}$, denoting them simply as $\boldsymbol{K}$, $\boldsymbol{\Sigma}$ and $\boldsymbol{C}$, respectively. Hence, for the jth component of f and y we have, a priori

$$\begin{aligned}\boldsymbol{f}_j &= \big(f_j(\xi_1;\boldsymbol{\theta}),\dots,f_j(\xi_M;\boldsymbol{\theta})\big)^\top \sim \mathcal{N}(\boldsymbol{0},\boldsymbol{K}),\\ \boldsymbol{y}_j &= \big(y_j(\xi_1;\boldsymbol{\theta}),\dots,y_j(\xi_M;\boldsymbol{\theta})\big)^\top \sim \mathcal{N}(\boldsymbol{0},\boldsymbol{K}+\boldsymbol{\Sigma}).\end{aligned}$$

In this vector-valued GP model, the posterior mean and covariance of $\nabla\eta_B(\boldsymbol{\theta})$ are

$$\mathbf{E}\big[\nabla\eta_B(\boldsymbol{\theta})|\mathcal{D}_M\big] = \boldsymbol{Y}\boldsymbol{C}\boldsymbol{b} \qquad \text{and} \qquad \mathbf{Cov}\big[\nabla\eta_B(\boldsymbol{\theta})|\mathcal{D}_M\big] = \Big(b_0 - \boldsymbol{b}^\top\boldsymbol{C}\boldsymbol{b}\Big)\boldsymbol{I}, \tag{21}$$

respectively, where

$$\boldsymbol{Y} = \begin{bmatrix}\boldsymbol{y}_1^\top\\ \vdots\\ \boldsymbol{y}_n^\top\end{bmatrix}, \quad \boldsymbol{b} = \int \boldsymbol{k}(\xi)\Pr(\xi;\boldsymbol{\theta})d\xi\,, \quad \text{and} \quad b_0 = \iint k(\xi,\xi')\Pr(\xi;\boldsymbol{\theta})\Pr(\xi';\boldsymbol{\theta})d\xi d\xi'. \tag{22}$$

Our choice of kernel, which allows us to derive closed-form expressions for $\boldsymbol{b}$ and b_0, and as a result for the posterior moments of the gradient, is the quadratic Fisher kernel (Jaakkola and Haussler, 1999, Shawe-Taylor and Cristianini, 2004)

$$k(\xi_i,\xi_j) = \Big(1 + \boldsymbol{u}(\xi_i)^\top\boldsymbol{G}(\boldsymbol{\theta})^{-1}\boldsymbol{u}(\xi_j)\Big)^2, \tag{23}$$

where $\boldsymbol{u}(\xi) = \nabla \log \Pr(\xi;\boldsymbol{\theta})$ is the Fisher score function of the path ξ defined by Equation 5, and $\boldsymbol{G}(\boldsymbol{\theta})$ is the corresponding Fisher information matrix defined as[13]

$$\boldsymbol{G}(\boldsymbol{\theta}) = \mathbf{E}\big[\boldsymbol{u}(\xi)\boldsymbol{u}(\xi)^\top\big] = \int \boldsymbol{u}(\xi)\boldsymbol{u}(\xi)^\top \Pr(\xi;\boldsymbol{\theta}) d\xi. \tag{24}$$

Proposition 3 *Using the quadratic Fisher kernel from Equation 23, the integrals $\boldsymbol{b}$ and b_0 in Equation 22 have the following closed form expressions*

$$(\boldsymbol{b})_i = 1 + \boldsymbol{u}(\xi_i)^\top \boldsymbol{G}^{-1}\boldsymbol{u}(\xi_i) \qquad \textit{and} \qquad b_0 = 1 + n.$$

Proof See Appendix A. ■

4.2 Model 2 – Scalar-Valued GP

In our second model, we define g and f as follows:

$$g(\xi;\boldsymbol{\theta}) = \nabla \Pr(\xi;\boldsymbol{\theta}) \quad , \quad f(\xi) = \bar{R}(\xi).$$

Now g is a vector-valued function, while f is a scalar valued GP representing the expected return of the path given as its argument. The noisy measurement corresponding to $f(\xi_i)$ is $y(\xi_i) = R(\xi_i)$, namely, the *actual* return accrued while following the path ξ_i. In this model, the posterior mean and covariance of the gradient $\nabla\eta_B(\boldsymbol{\theta})$ are

$$\mathbf{E}\big[\nabla\eta_B(\boldsymbol{\theta})|\mathcal{D}_M\big] = \boldsymbol{BCy} \qquad \text{and} \qquad \mathbf{Cov}\big[\nabla\eta_B(\boldsymbol{\theta})|\mathcal{D}_M\big] = \boldsymbol{B}_0 - \boldsymbol{BCB}^\top, \tag{25}$$

respectively, where

$$\boldsymbol{y} = \big(R(\xi_1),\ldots,R(\xi_M)\big)^\top, \qquad \boldsymbol{B} = \int \nabla \Pr(\xi;\boldsymbol{\theta})\boldsymbol{k}(\xi)^\top d\xi\,,$$
$$\boldsymbol{B}_0 = \iint k(\xi,\xi')\nabla \Pr(\xi;\boldsymbol{\theta})\nabla \Pr(\xi';\boldsymbol{\theta})^\top d\xi d\xi'. \tag{26}$$

Here, our choice of kernel function, which again allows us to derive closed-form expressions for $\boldsymbol{B}$ and $\boldsymbol{B}_0$, is the Fisher kernel (Jaakkola and Haussler, 1999, Shawe-Taylor and Cristianini, 2004)

$$k(\xi,\xi') = \boldsymbol{u}(\xi)^\top \boldsymbol{G}^{-1}\boldsymbol{u}(\xi'). \tag{27}$$

Proposition 4 *Using the Fisher kernel from Equation 27, the integrals $\boldsymbol{B}$ and $\boldsymbol{B}_0$ in Equation 26 have the following closed-form expressions*

$$\boldsymbol{B} = \boldsymbol{U} \qquad \textit{and} \qquad \boldsymbol{B}_0 = \boldsymbol{G},$$

where $\boldsymbol{U} = \big[\boldsymbol{u}(\xi_1),\ldots,\boldsymbol{u}(\xi_M)\big]$.

13. To simplify notation, we omit $\boldsymbol{G}$'s dependence on the policy parameters $\boldsymbol{\theta}$, and denote $\boldsymbol{G}(\boldsymbol{\theta})$ as $\boldsymbol{G}$ in the sequel.

	Model 1	**Model 2**
Deter. factor (g)	$g(\xi;\boldsymbol{\theta}) = \Pr(\xi;\boldsymbol{\theta})$	$g(\xi;\boldsymbol{\theta}) = \nabla \Pr(\xi;\boldsymbol{\theta})$
GP factor (f)	$f(\xi;\boldsymbol{\theta}) = \bar{R}(\xi)\nabla \log \Pr(\xi;\boldsymbol{\theta})$	$f(\xi) = \bar{R}(\xi)$
Measurement (y)	$y(\xi;\boldsymbol{\theta}) = R(\xi)\nabla \log \Pr(\xi;\boldsymbol{\theta})$	$y(\xi) = R(\xi)$
Prior mean of f	$\mathbf{E}\big[f_j(\xi;\boldsymbol{\theta})\big] = 0$	$\mathbf{E}\big[f(\xi)\big] = 0$
Prior Cov. of f	$\mathbf{Cov}\big[f_j(\xi;\boldsymbol{\theta}), f_\ell(\xi';\boldsymbol{\theta})\big] = \delta_{j,\ell}\, k(\xi,\xi')$	$\mathbf{Cov}\big[f(\xi), f(\xi')\big] = k(\xi,\xi')$
Kernel function	$k(\xi,\xi') = \big(1 + \boldsymbol{u}(\xi)^\top \boldsymbol{G}^{-1}\boldsymbol{u}(\xi')\big)^2$	$k(\xi,\xi') = \boldsymbol{u}(\xi)^\top \boldsymbol{G}^{-1}\boldsymbol{u}(\xi')$
$\mathbf{E}\big[\nabla\eta_B(\boldsymbol{\theta})\|\mathcal{D}_M\big] =$	$\boldsymbol{YCb}$	$\boldsymbol{BCy}$
$\mathbf{Cov}\big[\nabla\eta_B(\boldsymbol{\theta})\|\mathcal{D}_M\big] =$	$(b_0 - \boldsymbol{b}^\top\boldsymbol{Cb})\boldsymbol{I}$	$\boldsymbol{B}_0 - \boldsymbol{BCB}^\top$
$\boldsymbol{b}$ or $\boldsymbol{B}$	$(\boldsymbol{b})_i = 1 + \boldsymbol{u}(\xi_i)^\top \boldsymbol{G}^{-1}\boldsymbol{u}(\xi_i)$	$\boldsymbol{B} = \boldsymbol{U}$
b_0 or $\boldsymbol{B}_0$	$b_0 = 1 + n$	$\boldsymbol{B}_0 = \boldsymbol{G}$

Table 1: Summary of the Bayesian policy gradient Models 1 and 2.

Proof See Appendix B. ■

Table 1 summarizes the two BPG models presented in Sections 4.1 and 4.2. Our choice of Fisher-type kernels was motivated by the notion that a good representation should depend on the process generating the data (see Jaakkola and Haussler, 1999, Shawe-Taylor and Cristianini, 2004, for a thorough discussion). Our particular selection of linear and quadratic Fisher kernels were guided by the desideratum that the posterior moments of the gradient be analytically tractable as discussed in Section 3.

As described above, in either model, we are restricted in the choice of kernel (quadratic Fisher kernel in Model 1 and Fisher kernel in Model 2) in order to be able to derive closed-form expressions for the posterior mean and covariance of the gradient integral. The loss due to this restriction depends on the problem at hand and is hard to quantify. This loss is exactly the loss of selecting an inappropriate prior in any Bayesian algorithm or, more generally, of choosing a wrong representation (function space) in a machine learning algorithm (referred to as *approximation error* in approximation theory). However, the experimental results of Section 6 indicate that this restriction did not cause a significant error (especially for Model 1) in our gradient estimates, as those estimated by BPG were more accurate than the ones estimated by the MC-based method, given the same number of samples.

4.3 A Bayesian Policy Gradient Evaluation Algorithm

We can now use our two BPG models to define corresponding algorithms for evaluating the gradient of the expected return with respect to the policy parameters. Pseudo-code for these algorithms is shown in Algorithm 1. The generic algorithm (for either model) takes a set of policy parameters $\boldsymbol{\theta}$ and a sample size M as input, and returns an estimate of the posterior moments of the gradient of the expected return with respect to the policy parameters. This algorithm generates M sample paths to evaluate the gradient. For each path ξ_i, the algorithm first computes its score function $\boldsymbol{u}(\xi_i)$ (Line 6). The score function is needed for computing the kernel function k, the measurement $\boldsymbol{y}$ in Model 1, and $\boldsymbol{b}$ or

$\boldsymbol{B}$. The algorithm then computes the return R and the measurement $y(\xi_i)$ for the observed path ξ_i (Lines 7 and 9), and updates the kernel matrix $\boldsymbol{K}$ (Line 8) using

$$\boldsymbol{K} := \begin{bmatrix} \boldsymbol{K} & \boldsymbol{k}(\xi_i) \\ \boldsymbol{k}^\top(\xi_i) & k(\xi_i,\xi_i) \end{bmatrix}. \tag{28}$$

Finally, the algorithm adds the measurement error $\boldsymbol{\Sigma}$ to the covariance matrix $\boldsymbol{K}$ (Line 12) and computes the posterior moments of the policy gradient (Line 14). $\boldsymbol{B}(:,i)$ on Line 10 denotes the ith column of the matrix $\boldsymbol{B}$.

Algorithm 1 A Bayesian Policy Gradient Evaluation Algorithm

1: **BPG_Eval**$(\boldsymbol{\theta}, M)$
   - sample size $M > 0$
   - a vector of policy parameters $\boldsymbol{\theta} \in \mathbb{R}^n$

2: Set $\boldsymbol{G} = \boldsymbol{G}(\boldsymbol{\theta})$, $\mathcal{D} = \emptyset$
3: **for** $i = 1$ to M **do**
4: Sample a path ξ_i using the policy $\mu(\boldsymbol{\theta})$
5: $\mathcal{D} := \mathcal{D} \bigcup \{\xi_i\}$
6: $\boldsymbol{u}(\xi_i) = \sum_{t=0}^{T_i-1} \nabla \log \mu(a_{t,i}|x_{t,i};\boldsymbol{\theta})$
7: $R(\xi_i) = \sum_{t=0}^{T_i-1} r(x_{t,i}, a_{t,i})$
8: Update $\boldsymbol{K}$ using Equation 28
9: $y(\xi_i) = R(\xi_i)\boldsymbol{u}(\xi_i)$ (Model 1) or $y(\xi_i) = R(\xi_i)$ (Model 2)
10: $(\boldsymbol{b})_i = 1 + \boldsymbol{u}(\xi_i)^\top \boldsymbol{G}^{-1}\boldsymbol{u}(\xi_i)$ (Model 1) or $\boldsymbol{B}(:,i) = \boldsymbol{u}(\xi_i)$ (Model 2)
11: **end for**
12: $\boldsymbol{C} = (\boldsymbol{K} + \boldsymbol{\Sigma})^{-1}$
13: $b_0 = 1 + n$ (Model 1) or $\boldsymbol{B}_0 = \boldsymbol{G}$ (Model 2)
14: Compute the posterior mean and covariance of the policy gradient
$\mathbf{E}\big(\nabla\eta_B(\boldsymbol{\theta})|\mathcal{D}\big) = \boldsymbol{YCb}$, $\mathbf{Cov}\big(\nabla\eta_B(\boldsymbol{\theta})|\mathcal{D}\big) = (b_0 - \boldsymbol{b}^\top\boldsymbol{Cb})\boldsymbol{I}$ (Model 1)
or
$\mathbf{E}\big(\nabla\eta_B(\boldsymbol{\theta})|\mathcal{D}\big) = \boldsymbol{BCy}$, $\mathbf{Cov}\big(\nabla\eta_B(\boldsymbol{\theta})|\mathcal{D}\big) = \boldsymbol{B}_0 - \boldsymbol{BCB}^\top$ (Model 2)
15: **return** $\mathbf{E}\big(\nabla\eta_B(\boldsymbol{\theta})|\mathcal{D}\big)$ and $\mathbf{Cov}\big(\nabla\eta_B(\boldsymbol{\theta})|\mathcal{D}\big)$

The kernel functions used in Models 1 and 2 (Equations 23 and 27) are both based on the Fisher kernel. Computing the Fisher kernel requires calculating the Fisher information matrix $\boldsymbol{G}(\boldsymbol{\theta})$ (Equation 24). Consequently, every time we update the policy parameters, we need to recompute $\boldsymbol{G}$. In Algorithm 1 we assume that the Fisher information matrix is known. However, in most practical situations this will not be the case, and consequently the Fisher information matrix must be estimated. Let us briefly outline two possible approaches for estimating the Fisher information matrix in an online manner.

1) Monte-Carlo Estimation: The BPG algorithm generates a number of sample paths using the current policy parameterized by $\boldsymbol{\theta}$ in order to estimate the gradient $\nabla\eta_B(\boldsymbol{\theta})$. We can use these generated sample paths to estimate the Fisher information matrix $\boldsymbol{G}(\boldsymbol{\theta})$ in an online manner, by replacing the expectation in $\boldsymbol{G}$ with empirical averaging as $\hat{\boldsymbol{G}}_M(\boldsymbol{\theta}) = \frac{1}{M}\sum_{i=1}^{M} \boldsymbol{u}(\xi_i)\boldsymbol{u}(\xi_i)^\top$. It can be shown that $\hat{\boldsymbol{G}}_M$ is an unbiased estimator of $\boldsymbol{G}$. One may obtain this estimate recursively $\hat{\boldsymbol{G}}_{i+1} = (1-\frac{1}{i})\hat{\boldsymbol{G}}_i + \frac{1}{i}\boldsymbol{u}(\xi_i)\boldsymbol{u}(\xi_i)^\top$, or more generally $\hat{\boldsymbol{G}}_{i+1} = (1-\zeta_i)\hat{\boldsymbol{G}}_i + \zeta_i\boldsymbol{u}(\xi_i)\boldsymbol{u}(\xi_i)^\top$, where ζ_i is a step-size with $\sum_i \zeta_i = \infty$ and $\sum_i \zeta_i^2 < \infty$. Using the Sherman-Morrison matrix inversion lemma, it is possible to directly estimate the inverse of the Fisher information matrix as

$$\hat{\boldsymbol{G}}_{i+1}^{-1} = \frac{1}{1-\zeta_i}\left[\hat{\boldsymbol{G}}_i^{-1} - \zeta_i \frac{\hat{\boldsymbol{G}}_i^{-1}\boldsymbol{u}(\xi_i)\big(\hat{\boldsymbol{G}}_i^{-1}\boldsymbol{u}(\xi_i)\big)^\top}{1-\zeta_i + \zeta_i\boldsymbol{u}(\xi_i)^\top\hat{\boldsymbol{G}}_i^{-1}\boldsymbol{u}(\xi_i)}\right].$$

2) Maximum Likelihood Estimation: The Fisher information matrix defined by Equation 24 depends on the probability distribution over paths. This distribution is a product of two factors, one corresponding to the current policy and the other corresponding to the MDP's state-transition probability P (see Equation 1). Thus if P is known, the Fisher information matrix may be evaluated offline. We can model P using a parameterized model and then estimate the maximum likelihood (ML) model parameters. This approach may lead to a model-based treatment of policy gradients, which could allow us to transfer information between different policies. Current policy gradient algorithms, including the algorithms described in this paper, are extremely wasteful of training data, since they do not have any *disciplined* way to use data collected for previous policy updates in computing the update of the current policy. Model-based policy gradient may help solve this problem.

4.4 BPG Online Sparsification

Algorithm 1 can be made more efficient, both in time and memory, by sparsifying the solution. Such sparsification may be performed incrementally and helps to numerically stabilize the algorithm when the kernel matrix is singular, or nearly so. Sparsification may, in some cases, reduce the accuracy of the solution (the posterior moments of the policy gradient), but it often makes the algorithms significantly faster, especially for large sample sizes. Here we use an online sparsification method proposed by Engel et al. (2002) (see also Csató and Opper, 2002) to selectively add a new observed path to a set of *dictionary* paths $\tilde{\mathcal{D}}$ used as a basis for representing or approximating the full solution. We only add a new path ξ_i to $\tilde{\mathcal{D}}$, if $k(\xi_i,\xi_i) - \tilde{\boldsymbol{k}}(\xi_i)^\top\tilde{\boldsymbol{K}}^{-1}\tilde{\boldsymbol{k}}(\xi_i) > \tau$, where $\tilde{\boldsymbol{k}}$ and $\tilde{\boldsymbol{K}}$ are the dictionary kernel vector and kernel matrix before observing ξ_i, respectively, and τ is a positive threshold parameter that determines the level of accuracy in the approximation as well as the level of sparsity attained. If the new path is added to $\tilde{\mathcal{D}}$ the dictionary kernel matrix $\tilde{\boldsymbol{K}}$ is expanded as shown in Equation 28.

Proposition 5 *Let $\tilde{\boldsymbol{K}}$ be the $m \times m$ sparse kernel matrix, where $m \leq M$ is the cardinality of $\tilde{\mathcal{D}}_M$. Let $\boldsymbol{A}$ be the $M \times m$ matrix, whose ith row is $[\boldsymbol{A}]_{i,|\tilde{\mathcal{D}}_i|} = 1$ and $[\boldsymbol{A}]_{i,j} = 0$; $\forall j \neq |\tilde{\mathcal{D}}_i|$, if we add the sample path ξ_i to the set of sample paths, and be $\tilde{\boldsymbol{k}}(\xi_i)^\top\tilde{\boldsymbol{K}}^{-1}$ followed by zeros, otherwise. Finally, let $(\tilde{\boldsymbol{b}})_i = 1 + \boldsymbol{u}(\xi_i)^\top\boldsymbol{G}^{-1}\boldsymbol{u}(\xi_i)$ and $\tilde{\boldsymbol{B}} = [\boldsymbol{u}(\xi_1), \ldots, \boldsymbol{u}(\xi_m)]$ with $\xi_i \in \tilde{\mathcal{D}}$. Then, using the sparsification method described above, the posterior moments of the gradient*

are given by

$$\mathbf{E}\big[\nabla\eta_B(\boldsymbol{\theta})|\mathcal{D}_M\big] = \boldsymbol{Y}\boldsymbol{\Sigma}^{-1}\boldsymbol{A}\big(\tilde{\boldsymbol{K}}\boldsymbol{A}^\top\boldsymbol{\Sigma}^{-1}\boldsymbol{A}+\boldsymbol{I}\big)^{-1}\tilde{\boldsymbol{b}}$$

for Model 1

$$\mathbf{Cov}\big[\nabla\eta_B(\boldsymbol{\theta})|\mathcal{D}_M\big] = \Big[(1+n)-\tilde{\boldsymbol{b}}^\top\boldsymbol{A}^\top\boldsymbol{\Sigma}^{-1}\boldsymbol{A}\big(\tilde{\boldsymbol{K}}\boldsymbol{A}^\top\boldsymbol{\Sigma}^{-1}\boldsymbol{A}+\boldsymbol{I}\big)^{-1}\tilde{\boldsymbol{b}}\Big]\boldsymbol{I}$$

and

$$\mathbf{E}\big[\nabla\eta_B(\boldsymbol{\theta})|\mathcal{D}_M\big] = \tilde{\boldsymbol{B}}\big(\boldsymbol{A}^\top\boldsymbol{\Sigma}^{-1}\boldsymbol{A}\tilde{\boldsymbol{K}}+\boldsymbol{I}\big)^{-1}\boldsymbol{A}^\top\boldsymbol{\Sigma}^{-1}\boldsymbol{y}$$

for Model 2

$$\mathbf{Cov}\big[\nabla\eta_B(\boldsymbol{\theta})|\mathcal{D}_M\big] = \boldsymbol{G}-\tilde{\boldsymbol{B}}\big(\boldsymbol{A}^\top\boldsymbol{\Sigma}^{-1}\boldsymbol{A}\tilde{\boldsymbol{K}}+\boldsymbol{I}\big)^{-1}\boldsymbol{A}^\top\boldsymbol{\Sigma}^{-1}\boldsymbol{A}\tilde{\boldsymbol{B}}^\top\,.$$

Proof See Appendix C. ■

4.5 A Bayesian Policy Gradient Algorithm

So far we were concerned with estimating the gradient of the expected return with respect to the policy parameters. In this section, we present a Bayesian policy gradient (BPG) algorithm that employs the Bayesian gradient estimation methods proposed in Section 4.3 to update the policy parameters. The pseudo-code of this algorithm is shown in Algorithm 2. The algorithm starts with an initial vector of policy parameters $\boldsymbol{\theta}_0$, and updates the parameters in the direction of the posterior mean of the gradient of the expected return estimated by Algorithm 1. This is repeated N times, or alternatively, until the gradient estimate is sufficiently close to zero.

Algorithm 2 A Bayesian Policy Gradient Algorithm

BPG$(\boldsymbol{\theta}_0, \boldsymbol{\beta}, N, M)$
- initial policy parameters $\boldsymbol{\theta}_0 \in \mathbb{R}^n$
- learning rates β_j , $j = 0, \ldots, N-1$
- number of policy updates $N > 0$
- sample size $M > 0$ for the gradient evaluation algorithm (**BPG_Eval**)

for $j = 0$ to $N-1$ **do**
  $\Delta\boldsymbol{\theta}_j = \mathbf{E}\big(\nabla\eta_B(\boldsymbol{\theta}_j)|\mathcal{D}_M\big)$ from **BPG_Eval**$(\boldsymbol{\theta}_j, M)$
  $\boldsymbol{\theta}_{j+1} = \boldsymbol{\theta}_j + \beta_j\Delta\boldsymbol{\theta}_j$ (Conventional Gradient)
  or
  $\boldsymbol{\theta}_{j+1} = \boldsymbol{\theta}_j + \beta_j\boldsymbol{G}(\boldsymbol{\theta}_j)^{-1}\Delta\boldsymbol{\theta}_j$ (Natural Gradient)
end for
return $\boldsymbol{\theta}_N$

5. Extension to Partially Observable Markov Decision Processes

The Bayesian policy gradient models and algorithms of Section 4 can be extended to partially observable Markov decision processes (POMDPs) along the same lines as in Section 6

of Baxter and Bartlett (2001). In the partially observable case, the stochastic parameterized policy $\mu(\cdot|\cdot;\boldsymbol{\theta})$ controls a POMDP, i.e., the policy has access to an observation process that depends on the state, but it may not observe the state itself directly.

Specifically, for each state $x \in \mathcal{X}$, an observation $o \in \mathcal{O}$ is generated independently according to a probability distribution P_o over observations in $\mathcal{O}$. We denote the probability of observation o at state x by $P_o(o|x)$. A stationary stochastic parameterized policy $\mu(\cdot|\cdot;\boldsymbol{\theta})$ is a function mapping observations $o \in \mathcal{O}$ into probability distributions over the actions $\mu(\cdot|o;\boldsymbol{\theta}) \in \mathcal{P}(\mathcal{A})$. In this case, the probability of a path $\xi = (x_0, a_0, x_1, a_1, \ldots, x_{T-1}, a_{T-1}, x_T)$, $T \in \{0, 1, \ldots, \infty\}$ generated by the Markov chain induced by policy $\mu(\cdot|\cdot;\boldsymbol{\theta})$ is given by

$$\Pr(\xi;\mu) = \Pr(\xi;\boldsymbol{\theta}) = P_0(x_0)\int\prod_{t=0}^{T-1}P_o(o_t|x_t)\mu(a_t|o_t;\boldsymbol{\theta})P(x_{t+1}|x_t,a_t)do_0da_0\ldots do_{T-1}da_{T-1}.$$

The Fisher score of this path may be written as

$$\boldsymbol{u}(\xi;\boldsymbol{\theta}) = \nabla\log\Pr(\xi;\boldsymbol{\theta}) = \frac{\nabla\Pr(\xi;\boldsymbol{\theta})}{\Pr(\xi;\boldsymbol{\theta})} = \int\left(\sum_{t=0}^{T-1}\nabla\log\mu(a_t|o_t;\boldsymbol{\theta})\right)do_0da_0\ldots do_{T-1}da_{T-1},$$

which is the same as in the observable case (Equation 5), except here the policy is defined over observations instead of states. As a result, the models and algorithms of Section 4 may be used in the partially observable case with no change, substituting observations for states.

Moreover, similarly to the gradient estimated by the GPOMDP algorithm in Baxter and Bartlett (2001), the gradient estimated by Algorithm 1, $\nabla\eta_B(\boldsymbol{\theta})$, may be employed with the conjugate-gradients and line-search methods of Baxter et al. (2001) for making better use of gradient information. This allows us to exploit the information contained in the gradient estimate more aggressively than by simply adjusting the parameters by a small amount in the direction of $\nabla\eta_B(\boldsymbol{\theta})$. Conjugate-gradients and line-search are two widely used techniques in non-stochastic optimization that allow us to find better gradient directions than the pure gradient direction, and to obtain better step sizes, respectively.

Note that in this section, we followed Baxter and Bartlett (2001) (the GPOMDP algorithm) and considered stochastic policies that map observations to actions. However, as mentioned by Baxter and Bartlett (2001), it is immediate that the same algorithm works for any finite history of observations. Moreover, along the same way that Aberdeen and Baxter (2001) showed that GPOMDP can be extended to apply to policies with internal state, our BPG POMDP algorithm can also be extended to handle such policies.

6. BPG Experimental Results

In this section, we compare the Bayesian quadrature (BQ) and the plain MC gradient estimates on a simple bandit problem as well as on a continuous state and action linear quadratic regulator (LQR). We also evaluate the performance of the Bayesian policy gradient (BPG) algorithm described in Algorithm 2 on the LQR, and compare it with a Monte-Carlo based policy gradient (MCPG) algorithm.

	Exact	MC (10)	BQ (10)	MC (100)	BQ (100)
$r(a) = a$	$\begin{pmatrix}1\\0\end{pmatrix}$	$\begin{pmatrix}0.995 \pm 0.438\\-0.001 \pm 0.977\end{pmatrix}$	$\begin{pmatrix}0.986 \pm 0.050\\0.001 \pm 0.060\end{pmatrix}$	$\begin{pmatrix}1.000 \pm 0.140\\0.004 \pm 0.317\end{pmatrix}$	$\begin{pmatrix}1.000 \pm 0.000001\\0.000 \pm 0.000004\end{pmatrix}$
$r(a) = a^2$	$\begin{pmatrix}0\\2\end{pmatrix}$	$\begin{pmatrix}0.014 \pm 1.246\\2.034 \pm 2.831\end{pmatrix}$	$\begin{pmatrix}0.001 \pm 0.082\\1.925 \pm 0.226\end{pmatrix}$	$\begin{pmatrix}0.005 \pm 0.390\\1.987 \pm 0.857\end{pmatrix}$	$\begin{pmatrix}0.000 \pm 0.000003\\2.000 \pm 0.000011\end{pmatrix}$

Table 2: The true gradient of the expected return and its MC and BQ estimates for two instances of the bandit problem corresponding to two different reward functions.

System:
Initial State: $x_0 \sim \mathcal{N}(0.3, 0.001)$
Reward: $r_t = x_t^2 + 0.1a_t^2$
Transition: $x_{t+1} = x_t + a_t + n_x \; ; \; n_x \sim \mathcal{N}(0, 0.01)$

Policy:
Actions: $a_t \sim \mu(\cdot|x_t; \boldsymbol{\theta}) = \mathcal{N}(\lambda x_t, \sigma^2)$
Parameters: $\boldsymbol{\theta} = (\lambda \; , \; \sigma)^\top$

6.1 A Simple Bandit Problem

The goal of this example is to compare the BQ and MC estimates of the gradient (for some fixed set of policy parameters) using the same sample. Our bandit problem has a single state and a continuous action space $\mathcal{A} = \mathbb{R}$, thus, each path ξ_i consists of a single action a_i. The policy, and therefore also the distribution over the paths is given by $a \sim \mathcal{N}(\theta_1 = 0, \theta_2^2 = 1)$. The parameters θ_1 and θ_2 are the mean and the standard deviation of this distribution. The score function of the path $\xi = a$ and the Fisher information matrix for the policy are $\boldsymbol{u}(\xi) = [a, a^2 - 1]^\top$ and $\boldsymbol{G} = \text{diag}(1, 2)$, respectively.

Table 2 shows the exact gradient of the expected return and its MC and BQ estimates using 10 and 100 samples for two instances of the bandit problem corresponding to two different deterministic reward functions $r(a) = a$ and $r(a) = a^2$. The average over 10^4 runs of the MC and BQ estimates and their standard deviations are reported in Table 2. The true gradient is analytically tractable and is reported as "Exact" in Table 2 for reference.

As shown in Table 2, the variance of the BQ estimates are lower than the variance of the MC estimates by an order of magnitude for the small sample size ($M = 10$), and by 6 orders of magnitude for the large sample size ($M = 100$). The BQ estimate is also more accurate than the MC estimate for the large sample size, and is roughly the same for the small sample size.

6.2 Linear Quadratic Regulator

In this section, we consider the following linear system in which the goal is to minimize the expected return over 20 steps.[14] Thus, it is an episodic problem with paths of length 20.

We run two sets of experiments on this system. We first fix the set of policy parameters and compare the BQ and MC estimates of the gradient of the expected return using the same sample. We then proceed to solving the complete policy gradient problem and compare the performance of the BPG algorithm (with both conventional and natural gradients) with a Monte-Carlo based policy gradient (MCPG) algorithm.

14. What we mean by reward and return in this section is in fact cost and loss, and this is why we are dealing with a minimization, and not a maximization, problem here. The reason for this is to maintain consistency in notations and definitions throughout the paper.

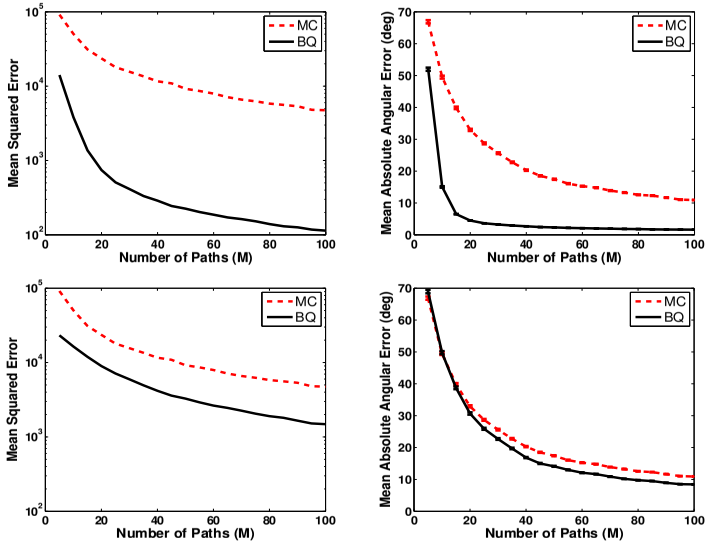

Figure 1: Results for the LQR problem using Model 1 (top row) and Model 2 (bottom row) with sparsification. Shown are the MSE (left column) and the mean absolute angular error (right column) of the MC and BQ estimates as a function of the number of sample paths M. All results are averaged over 10^4 runs.

6.2.1 Gradient Estimation

In this section, we compare the BQ and MC estimates of the gradient of the expected return for the policy induced by parameters $\lambda = -0.2$ and $\sigma = 1$. We use several different sample sizes (number of paths used for gradient estimation) $M = 5j \; , \; j = 1, \ldots, 20$ for the BQ and MC estimates. For each sample size, we compute the MC and BQ estimators using the same sample, repeat this process 10^4 times, and then compute the average. The true gradient is analytically tractable and is used for comparison purposes.

Figure 1 shows the mean squared error (MSE) (left column) and the mean absolute angular error (right column) of the MC and BQ estimates of the gradient for several different sample sizes. The absolute angular error is the absolute value of the angle between the true and estimated gradients. In this figure, the BQ gradient estimates were calculated using Model 1 (top row) and Model 2 (bottom row) with sparsification. The error bars in the figures on the right column are the standard errors of the mean absolute angular errors.

We ran another set of experiments in which we added i.i.d. Gaussian noise to the rewards: $r_t = x_t^2 + 0.1a_t^2 + n_r \; ; \; n_r \sim \mathcal{N}(0, \sigma_r^2)$. Note that in Models 1 and 2, $y(\xi)$, the noisy sample

of $f(\xi)$, is of the form $R(\xi)\nabla \log \Pr(\xi;\boldsymbol{\theta})$ and $R(\xi)$, respectively (see Sections 4.1 and 4.2). Moreover, since each reward r_t is a Gaussian random variable with variance σ_r^2, the return $R(\xi) = \sum_{t=0}^{T-1} r_t$ is also a Gaussian random variable with variance $T\sigma_r^2$. Therefore in this case, the measurement noise covariance matrices for Models 1 and 2 may be written as $\boldsymbol{\Sigma} = T\sigma_r^2 \operatorname{diag}\left(\left(\frac{\partial}{\partial\theta_i}\log p(\xi_1;\boldsymbol{\theta})\right)^2,\ldots,\left(\frac{\partial}{\partial\theta_i}\log p(\xi_M;\boldsymbol{\theta})\right)^2\right)$ and $\boldsymbol{\Sigma} = T\sigma_r^2\boldsymbol{I}$, respectively, where $T = 20$ is the path length.[15] We tried two different Gaussian reward noise standard deviations: $\sigma_r = 0.1$ and 1 in our experiments. Adding noise to the rewards slightly increased the error of the BQ and MC estimates of the gradient. However, the graphs comparing these estimates remained quite similar to those shown in Figure 1. Hence in Figure 2, we compare the MSE (left column) and the mean absolute angular error (right column) of the BQ estimates with and without noise in the rewards as a function of the number of sample paths M. In this figure, the noise in the rewards has variance $\sigma_r^2 = 1$, and the BQ gradient estimates were calculated using Model 1 (top row) and Model 2 (bottom row) with sparsification.

6.2.2 Policy Optimization

In this section, we use Bayesian policy gradient (BPG) to optimize the policy parameters in the LQR problem. Figure 3 shows the performance of the BPG algorithm with the conventional (BPG) and natural (BPNG) gradient estimates, versus a MC-based policy gradient (MCPG) algorithm, for sample sizes (number of sample paths used to estimate the gradient of each policy) $M = 5$, 10, 20, and 40. We use Algorithm 2 with the number of updates set to $N = 100$, and Model 1 with sparsification for the BPG and BPNG methods. Since Algorithm 2 computes the Fisher information matrix for each set of policy parameters, the estimate of the natural gradient is provided at little extra cost at each step. The returns obtained by these methods are averaged over 10^4 runs. The policy parameters are initialized randomly at each run. In order to ensure that the learned parameters do not exceed an acceptable range, the policy parameters are defined as $\lambda = -1.999 + 1.998/(1+e^{\kappa_1})$ and $\sigma = 0.001 + 1/(1+e^{\kappa_2})$. The optimal solution is $\lambda^* \approx -0.92$, $\sigma^* = 0.001$, $\eta_B(\lambda^*,\sigma^*) = 0.3067$, corresponding to $\kappa_1^* \approx -0.16$ and $\kappa_2^* \to \infty$.

Figure 3 shows that the MCPG algorithm performs better than BPG and BPNG only for the smallest sample size ($M = 5$), whereas for larger samples BPG and BPNG dominate MCPG. The better performance of MCPG for very small sample size is due to the fact that in this case, the Bayesian estimators, BPG and BPNG, like any other Bayesian estimator or posterior in such case, rely more on the prior, and thus, are not accurate if the prior is not very informative. A similar phenomenon was also reported by Rasmussen and Ghahramani (2003). We used two different learning rates for the two components of the gradient. For a fixed sample size, BPG and MCPG methods start with an initial learning rate and decrease it according to the schedule $\beta_j = \beta_0\big(20/(20+j)\big)$. The BPNG algorithm uses a fixed learning rate multiplied by the determinant of the Fisher information matrix. We tried many values for the initial learning rates used by these algorithms and those in Table 3 yielded the best performance of those we tried.

So far we have assumed that the Fisher information matrix is known. In the next experiment, we estimate it using both MC and a model-based maximum likelihood (ML)

15. In Model 1, $\boldsymbol{\Sigma}$ is the measurement noise covariance matrix for the ith component of the gradient $\frac{\partial}{\partial\theta_i}\eta_B(\boldsymbol{\theta})$. Note that $\frac{\partial}{\partial\theta_i}\log p(\xi_j;\boldsymbol{\theta})$ depends only on the policy and can be calculated using Equation 5.

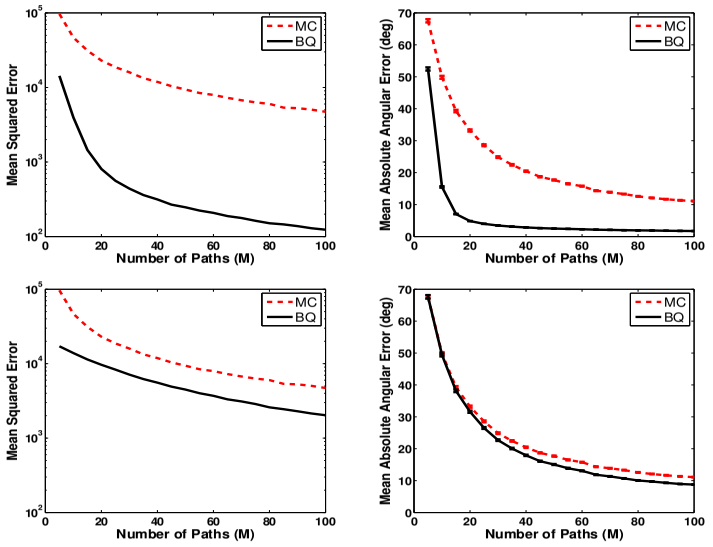

Figure 2: Results for the LQR problem in which the rewards are corrupted by i.i.d. Gaussian noise with $\sigma_r^2 = 1$. Shown are the MSE (left column) and the mean absolute angular error (right column) of the BQ estimates with and without noise in the rewards as a function of the number of sample paths M. The BQ gradient estimates were calculated using Model 1 (top row) and Model 2 (bottom row) with sparsification. All results are averaged over 10^4 runs.

β_0	$M=5$	$M=10$	$M=20$	$M=40$
MCPG	0.01, 0.05	0.05, 0.05	0.05, 0.10	0.05, 0.10
BPG	0.01, 0.05	0.07, 0.10	0.15, 0.15	0.10, 0.30
BPNG	0.010, 0.005	0.010, 0.005	0.015, 0.005	0.015, 0.005
BPG-var	0.05, 0.05	0.10, 0.10	0.10, 0.15	0.15, 0.30

method, as discussed in Section 4.3. In the ML approach, we model the transition probability function as $P(x_{t+1}|x_t,a_t) = \mathcal{N}(c_1x_t + c_2a_t + c_3, c_4^2)$, and then estimate its parameters (c_1,c_2,c_3,c_4) using observing state transitions. Figure 4 shows that the BPG algorithm, when the Fisher information matrix is estimated using ML and MC, still performs bet-

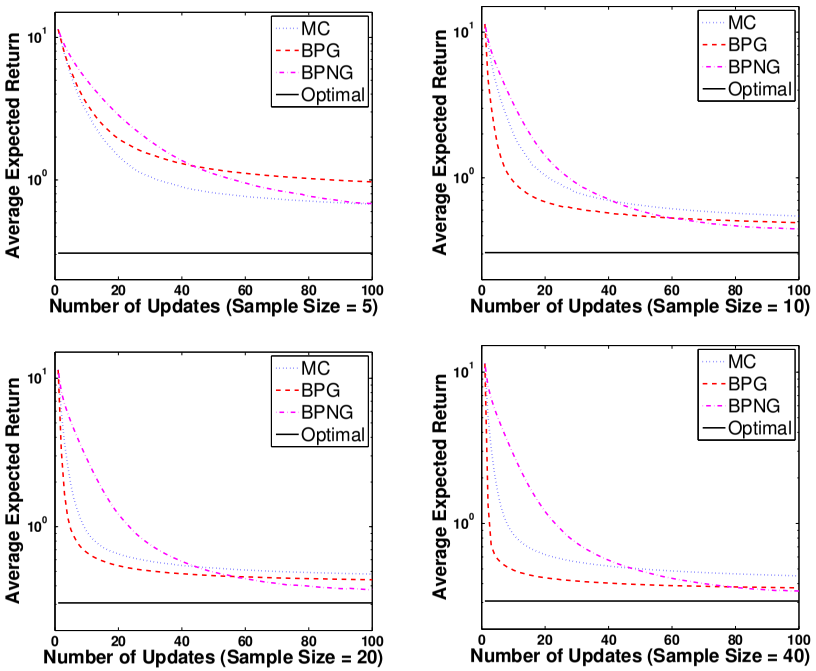

Figure 3: A comparison of the average expected returns of the Bayesian policy gradient algorithm using conventional (BPG) and natural (BPNG) gradient estimates, with the average expected return of a MC-based policy gradient algorithm (MCPG) for sample sizes $M = 5$, 10, 20, and 40. All results are averaged over 10^4 runs.

ter than MCPG. Top and bottom rows contain the results for the BPG algorithm with conventional (BPG-ML and BPG-MC) and natural (BPNG-ML and BPNG-MC) gradient estimates, respectively. Although the BPG-ML (BPNG-ML) outperforms BPG-MC (BPNG-MC) for small sample sizes, the difference in their performance disappears as we increase the sample size. One reason for the good performance of BPG-ML is that the form of the state transition function $P(x_{t+1}|x_t, a_t)$ has been selected correctly. Here we used the same initial learning rates and learning rate schedules as in the experiments of Figure 3 (see Table 3).

Although the proposed Bayesian policy gradient algorithm (Algorithm 2) uses only the posterior mean of the gradient in its updates, it can be extended to make judicious use of the

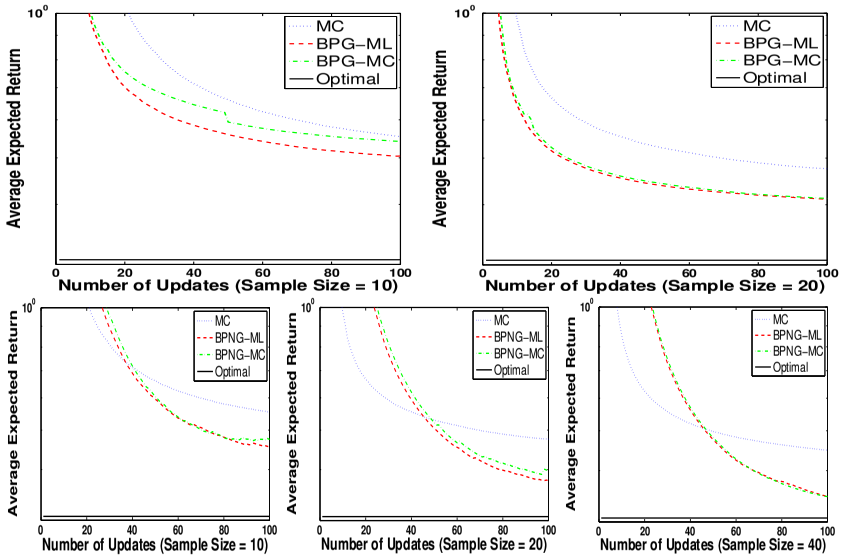

Figure 4: A comparison of the average expected returns of the BPG algorithm, when the Fisher information matrix is estimated using ML and MC, with the average expected return of a MC-based policy gradient algorithm (MCPG). The top and bottom rows contain the results for the BPG algorithm with conventional (BPG-ML and BPG-MC) and natural (BPNG-ML and BPNG-MC) gradient estimates, respectively. All results are averaged over 10^4 runs.

second moment information provided by the Bayesian policy gradient estimation algorithm (Algorithm 1). In the last experiment of this section, we use the posterior covariance of the gradient, provided by Algorithm 1, to select the learning rate and the direction of the updates in Algorithm 2. The idea is to use a small learning rate when the variance of the gradient estimate is large, and to have a large update when it is small. We refer to the resulting algorithm by the name BPG-var. This algorithm uses a fixed learning rate parameter (see Table 3) multiplied by $\Big[(1+n)\boldsymbol{I} - \mathbf{Cov}\big(\nabla\eta_B(\boldsymbol{\theta})|\mathcal{D}_M\big)\Big]/(1+n)$ in its updates. Note that $n+1$ is b_0 in the calculation of the posterior covariance of the gradient in Model 1 (see Proposition 3), and is used here as an upper bound for the posterior covariance of the gradient. Figure 5 compares the average expected return of BPG-var with BPG and MCPG for sample sizes $M = 5$, 10, 20, and 40. The figure shows that BPG-var performs better than BPG and MCPG for all the sample sizes. It even has a better performance than MCPG for the smallest sample size ($M = 5$). Comparing Figures 3 and 5 shows that

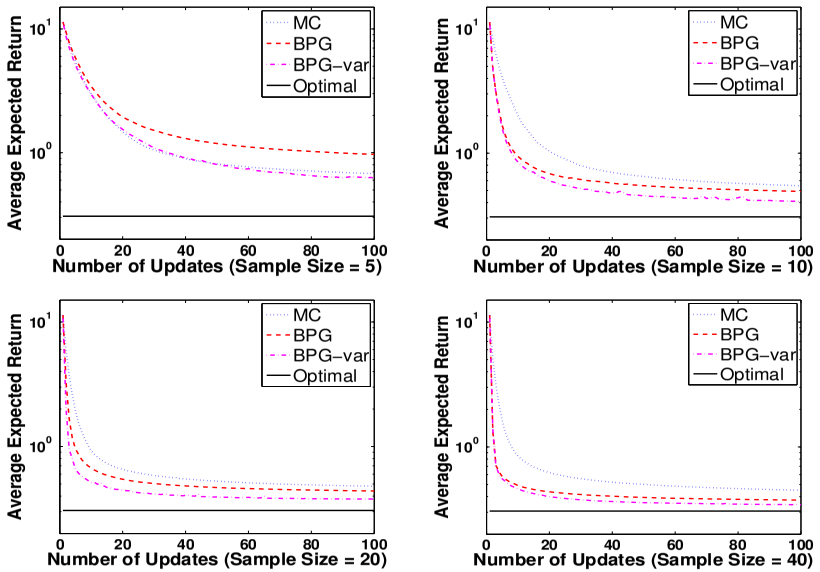

Figure 5: A comparison of the average expected returns of the BPG algorithm that uses the posterior covariance in its updates (BPG-var), with the average expected return of the BPG and a MC-based policy gradient algorithm (MCPG) for sample sizes $M = 5$, 10, 20, and 40. All results are averaged over 10^4 runs.

BPG-var converges faster than BPNG and has similar final performance. As we expected, BPG-var and BPG perform more and more alike as we increase the sample size. This is because by increasing the sample size the estimated gradient (the posterior mean of the gradient), and as a result, the update direction used by BPG becomes more reliable.

In an approach similar to the one used in the experiments of Figure 5, Vien et al. (2011) used BQ to estimate the Hessian matrix distribution, and then used its mean as learning rate schedule to improve the performance of BPG. They empirically showed that their method performs better than BPG and BPNG in terms of convergence speed.

7. Bayesian Actor-Critic

The models and algorithms of Section 4 consider complete trajectories as the basic observable unit, and thus, do not require the dynamics within each trajectory to be of any special form. In particular, it is not necessary for the dynamics to have the Markov property,

allowing the resulting algorithms to handle partially observable MDPs, Markov games, and other non-Markovian systems. On the down side, these algorithms cannot take advantage of the Markov property when operating in Markovian systems. Moreover, since the unit of observation of these algorithms is the entire trajectory, their gradient estimates have larger variance than the algorithms that will be discussed in this section, whose unit of observation is *(current state, action, next state)*, since they take advantage of the Markov property, especially when the size of the trajectories is large.

In this section, we apply the Bayesian quadrature idea to the policy gradient expression given by Equation 7, i.e.,

$$\nabla\eta(\boldsymbol{\theta}) = \int dxda\ \nu(x;\boldsymbol{\theta})\nabla\mu(a|x;\boldsymbol{\theta})Q(x,a;\boldsymbol{\theta}),$$

and derive a family of Bayesian actor-critic (BAC) algorithms. In this approach, we place a Gaussian process (GP) prior over action-value functions using a prior covariance kernel defined on state-action pairs: $k(\boldsymbol{z},\boldsymbol{z}') = \mathbf{Cov}\big[Q(\boldsymbol{z}),Q(\boldsymbol{z}')\big]$. We then compute the GP posterior conditioned on the sequence of individual observed transitions. In the same vein as Section 4, by an appropriate choice of a prior on action-value functions, we are able to derive closed-form expressions for the posterior moments of $\nabla\eta(\boldsymbol{\theta})$. The main questions here are: **1)** how to compute the GP posterior of the action-value function given a sequence of observed transitions? and **2)** how to choose a prior for the action-value function that allows us to derive closed-form expressions for the posterior moments of $\nabla\eta(\boldsymbol{\theta})$? Fortunately, well developed machinery for computing the posterior moments of $Q(\boldsymbol{z})$ is provided in a series of papers by Engel et al. (2003, 2005) (for a thorough treatment see Engel, 2005). In the next two sections, we will first briefly review some of the main results pertaining to the Gaussian process temporal difference (GPTD) model proposed in Engel et al. (2005), and then will show how they may be combined with the Bayesian quadrature idea in developing a family of Bayesian actor-critic algorithms.

7.1 Gaussian Process Temporal Difference Learning

The Gaussian process temporal difference (GPTD) learning (Engel et al., 2003, 2005) model is based on a statistical generative model relating the observed reward signal r to the unobserved action-value function Q

$$r(\boldsymbol{z}_i) = Q(\boldsymbol{z}_i) - \gamma Q(\boldsymbol{z}_{i+1}) + N(\boldsymbol{z}_i,\boldsymbol{z}_{i+1}), \tag{29}$$

where $N(\boldsymbol{z}_i,\boldsymbol{z}_{i+1})$ is a zero-mean noise signal that accounts for the discrepancy between $r(\boldsymbol{z}_i)$ and $Q(\boldsymbol{z}_i) - \gamma Q(\boldsymbol{z}_{i+1})$. Let us define the finite-dimensional processes $\boldsymbol{r}_t$, Q_t, N_t, and the $t \times (t+1)$ matrix $\boldsymbol{H}_t$ as follows:

$$\begin{aligned} &\boldsymbol{r}_t = \big(r(\boldsymbol{z}_0),\ldots,r(\boldsymbol{z}_t)\big)^\top, && Q_t = \big(Q(\boldsymbol{z}_0),\ldots,Q(\boldsymbol{z}_t)\big)^\top, \\ &N_t = \big(N(\boldsymbol{z}_0,\boldsymbol{z}_1),\ldots,N(\boldsymbol{z}_{t-1},\boldsymbol{z}_t)\big)^\top, \end{aligned} \tag{30}$$

$$\boldsymbol{H}_t = \begin{bmatrix} 1 & -\gamma & 0 & \ldots & 0 \\ 0 & 1 & -\gamma & \ldots & 0 \\ \vdots & & & & \vdots \\ 0 & 0 & \ldots & 1 & -\gamma \end{bmatrix}. \tag{31}$$

The set of Equations 29 for $i = 0, \ldots, t-1$ may be written as $\boldsymbol{r}_{t-1} = \boldsymbol{H}_t Q_t + N_t$. Under certain assumptions on the distribution of the discounted return random process (Engel et al., 2005), the covariance of the noise vector N_t is given by

$$\boldsymbol{\Sigma}_t = \sigma^2 \boldsymbol{H}_t \boldsymbol{H}_t^\top = \sigma^2 \begin{bmatrix} 1+\gamma^2 & -\gamma & 0 & \ldots & 0 \\ -\gamma & 1+\gamma^2 & -\gamma & \ldots & 0 \\ \vdots & \vdots & & & \vdots \\ 0 & 0 & \ldots & -\gamma & 1+\gamma^2 \end{bmatrix}. \tag{32}$$

In episodic tasks, if $\boldsymbol{z}_{t-1}$ is the last state-action pair in the episode (i.e., $\boldsymbol{x}_t$ is a zero-reward absorbing terminal state), $\boldsymbol{H}_t$ becomes a square $t \times t$ invertible matrix of the form shown in Equation 31 with its last column removed. The effect on the noise covariance matrix $\boldsymbol{\Sigma}_t$ is that the bottom-right element becomes 1 instead of $1+\gamma^2$.

Placing a GP prior on Q and assuming that N_t is also normally distributed, we may use Bayes' rule to obtain the posterior moments of Q:

$$\begin{aligned} \hat{Q}_t(\boldsymbol{z}) &= \mathbf{E}\left[Q(\boldsymbol{z})|\mathcal{D}_t\right] = \boldsymbol{k}_t(\boldsymbol{z})^\top \boldsymbol{\alpha}_t, \\ \hat{S}_t(\boldsymbol{z}, \boldsymbol{z}') &= \mathbf{Cov}\left[Q(\boldsymbol{z}), Q(\boldsymbol{z}')|\mathcal{D}_t\right] = k(\boldsymbol{z}, \boldsymbol{z}') - \boldsymbol{k}_t(\boldsymbol{z})^\top \boldsymbol{C}_t \boldsymbol{k}_t(\boldsymbol{z}'), \end{aligned} \tag{33}$$

where $\mathcal{D}_t$ denotes the observed data up to and including time step t. We used here the following definitions:

$$\begin{aligned} \boldsymbol{k}_t(\boldsymbol{z}) &= \left(k(\boldsymbol{z}_0, \boldsymbol{z}), \ldots, k(\boldsymbol{z}_t, \boldsymbol{z})\right)^\top, & \boldsymbol{K}_t &= \left[\boldsymbol{k}_t(\boldsymbol{z}_0), \boldsymbol{k}_t(\boldsymbol{z}_1), \ldots, \boldsymbol{k}_t(\boldsymbol{z}_t)\right], \\ \boldsymbol{\alpha}_t &= \boldsymbol{H}_t^\top \left(\boldsymbol{H}_t \boldsymbol{K}_t \boldsymbol{H}_t^\top + \boldsymbol{\Sigma}_t\right)^{-1} \boldsymbol{r}_{t-1}\,, & \boldsymbol{C}_t &= \boldsymbol{H}_t^\top \left(\boldsymbol{H}_t \boldsymbol{K}_t \boldsymbol{H}_t^\top + \boldsymbol{\Sigma}_t\right)^{-1} \boldsymbol{H}_t\,. \end{aligned} \tag{34}$$

Note that $\hat{Q}_t(\boldsymbol{z})$ and $\hat{S}_t(\boldsymbol{z}, \boldsymbol{z}')$ are the posterior mean and covariance functions of the posterior GP, respectively. As more samples are observed, the posterior covariance decreases, reflecting a growing confidence in the Q-function estimate $\hat{Q}_t$.

7.2 A Family of Bayesian Actor-Critic Algorithms

We are now in a position to describe the main idea behind our BAC approach. Making use of the linearity of Equation 7 in Q and denoting $\boldsymbol{g}(\boldsymbol{z}; \boldsymbol{\theta}) = \pi^\mu(\boldsymbol{z}) \nabla \log \mu(\boldsymbol{a}|\boldsymbol{x}; \boldsymbol{\theta})$, we obtain the following expressions for the posterior moments of the policy gradient (O'Hagan, 1991):

$$\begin{aligned} \mathbf{E}[\nabla \eta(\boldsymbol{\theta})|\mathcal{D}_t] &= \int_{\mathcal{Z}} d\boldsymbol{z} \boldsymbol{g}(\boldsymbol{z}; \boldsymbol{\theta}) \hat{Q}_t(\boldsymbol{z}; \boldsymbol{\theta}), \\ \mathbf{Cov}\left[\nabla \eta(\boldsymbol{\theta})|\mathcal{D}_t\right] &= \int_{\mathcal{Z}^2} d\boldsymbol{z} d\boldsymbol{z}' \boldsymbol{g}(\boldsymbol{z}; \boldsymbol{\theta}) \hat{S}_t(\boldsymbol{z}, \boldsymbol{z}') \boldsymbol{g}(\boldsymbol{z}'; \boldsymbol{\theta})^\top. \end{aligned} \tag{35}$$

Substituting the expressions for the posterior moments of Q from Equation 33 into Equation 35, we obtain

$$\begin{aligned} \mathbf{E}[\nabla \eta(\boldsymbol{\theta})|\mathcal{D}_t] &= \int_{\mathcal{Z}} d\boldsymbol{z} \boldsymbol{g}(\boldsymbol{z}; \boldsymbol{\theta}) \boldsymbol{k}_t(\boldsymbol{z})^\top \boldsymbol{\alpha}_t, \\ \mathbf{Cov}\left[\nabla \eta(\boldsymbol{\theta})|\mathcal{D}_t\right] &= \int_{\mathcal{Z}^2} d\boldsymbol{z} d\boldsymbol{z}' \boldsymbol{g}(\boldsymbol{z}; \boldsymbol{\theta}) \left(k(\boldsymbol{z}, \boldsymbol{z}') - \boldsymbol{k}_t(\boldsymbol{z})^\top \boldsymbol{C}_t \boldsymbol{k}_t(\boldsymbol{z}')\right) \boldsymbol{g}(\boldsymbol{z}'; \boldsymbol{\theta})^\top. \end{aligned}$$

These equations provide us with the general form of the posterior policy gradient moments. We are now left with a computational issue, namely, how to compute the integrals appearing in these expressions? We need to be able to evaluate the following integrals:

$$\boldsymbol{B}_t = \int_{\mathcal{Z}} d\boldsymbol{z} \boldsymbol{g}(\boldsymbol{z}; \boldsymbol{\theta}) \boldsymbol{k}_t(\boldsymbol{z})^\top, \qquad \boldsymbol{B}_0 = \int_{\mathcal{Z}^2} d\boldsymbol{z} d\boldsymbol{z}' \boldsymbol{g}(\boldsymbol{z}; \boldsymbol{\theta}) k(\boldsymbol{z}, \boldsymbol{z}') \boldsymbol{g}(\boldsymbol{z}'; \boldsymbol{\theta})^\top. \tag{36}$$

Using these definitions, we may write the gradient posterior moments compactly as

$$\mathbf{E}[\nabla \eta(\boldsymbol{\theta})|\mathcal{D}_t] = \boldsymbol{B}_t \boldsymbol{\alpha}_t\,, \qquad \mathbf{Cov}\left[\nabla \eta(\boldsymbol{\theta})|\mathcal{D}_t\right] = \boldsymbol{B}_0 - \boldsymbol{B}_t \boldsymbol{C}_t \boldsymbol{B}_t^\top. \tag{37}$$

In order to render these integrals analytically tractable, we choose our prior covariance kernel to be the sum of an arbitrary state-kernel k_x and the (invariant) Fisher kernel k_F between state-action pairs (see e.g., Shawe-Taylor and Cristianini, 2004, Chapter 12). The (policy dependent) Fisher information kernel and our overall state-action kernel are then given by

$$k_F(\boldsymbol{z}, \boldsymbol{z}') = \boldsymbol{u}(\boldsymbol{z}; \boldsymbol{\theta})^\top \boldsymbol{G}(\boldsymbol{\theta})^{-1} \boldsymbol{u}(\boldsymbol{z}')\,, \qquad k(\boldsymbol{z}, \boldsymbol{z}') = k_x(\boldsymbol{x}, \boldsymbol{x}') + k_F(\boldsymbol{z}, \boldsymbol{z}')\,, \tag{38}$$

where $\boldsymbol{u}(\boldsymbol{z}; \boldsymbol{\theta})$ and $\boldsymbol{G}(\boldsymbol{\theta})$ are the score function and Fisher information matrix defined as[16]

$$\boldsymbol{u}(\boldsymbol{z}; \boldsymbol{\theta}) = \nabla \log \mu(a|x; \boldsymbol{\theta}), \tag{39}$$

$$\boldsymbol{G}(\boldsymbol{\theta}) = \mathbf{E}_{x \sim \nu^\mu, a \sim \mu}\left[\nabla \log \mu(a|x; \boldsymbol{\theta}) \nabla \log \mu(a|x; \boldsymbol{\theta})^\top\right] = \mathbf{E}_{\boldsymbol{z} \sim \pi^\mu}\left[\boldsymbol{u}(\boldsymbol{z}; \boldsymbol{\theta}) \boldsymbol{u}(\boldsymbol{z}; \boldsymbol{\theta})^\top\right]. \tag{40}$$

Although here we have total flexibility in selecting the state kernel, we are restricted to the Fisher kernel for state-action pairs. This restriction may cause an error in approximating some action-value functions Q. This error depends on the problem at hand and is hard to quantify. This is exactly the same as selecting an inaccurate prior in any Bayesian algorithm or choosing a wrong representation (function space) in any machine learning algorithm (referred to as *approximation error* in the approximation theory). However, this restriction did not cause a significant error in our experiments (see Section 8), as in almost all of them, the gradients estimated by BAC were more accurate than those estimated by the MC-based method, given the same number of samples.

Note that in Sections 4 to 6 we used a formulation in which the observable unit is a system trajectory, and thus, the expected return and its gradient are defined by Equations 2 and 4. In this formulation, the score function and Fisher information matrix are defined by Equations 5 and 24. However, in the formulation used in this section and in the rest of the paper, where the observable unit is an individual state-action-reward transition, the expected return and its gradient are defined by Equations 3 and 7. In this formulation, the score function and Fisher information matrix are defined by Equations 39 and 40, respectively.

A nice property of the Fisher kernel is that while $k_F(\boldsymbol{z}, \boldsymbol{z}')$ depends on the policy, it is invariant to policy reparameterization. In other words, it only depends on the actual probability mass assigned to each action and not on its explicit dependence on the policy parameters. As mentioned above, another attractive property of this particular choice of kernel is that it renders the integrals in Equation 36 analytically tractable, as made explicit in the following proposition

16. Similar to $\boldsymbol{u}(\xi)$ and $\boldsymbol{G}$ defined by Equations 5 and 24, to simplify the notation, we omit the dependence of $\boldsymbol{u}$ and $\boldsymbol{G}$ to the policy parameters $\boldsymbol{\theta}$, and replace $\boldsymbol{u}(\boldsymbol{z}; \boldsymbol{\theta})$ and $\boldsymbol{G}(\boldsymbol{\theta})$ with $\boldsymbol{u}(\boldsymbol{z})$ and $\boldsymbol{G}$ in the sequel.

Proposition 6 *Let $k(\boldsymbol{z}, \boldsymbol{z}') = k_x(x, x') + k_F(\boldsymbol{z}, \boldsymbol{z}')$ for all $(\boldsymbol{z}, \boldsymbol{z}') \in \mathcal{Z}^2$, where $k_x : \mathcal{X}^2 \to \mathbb{R}$ is an arbitrary positive definite state-kernel and $k_F : \mathcal{Z}^2 \to \mathbb{R}$ is the Fisher information kernel. Then $\boldsymbol{B}_t$ and $\boldsymbol{B}_0$ from Equation 36 satisfy*

$$\boldsymbol{B}_t = \boldsymbol{U}_t \,, \qquad\qquad \boldsymbol{B}_0 = \boldsymbol{G}, \tag{41}$$

where $\boldsymbol{U}_t = \big[\boldsymbol{u}(\boldsymbol{z}_0), \boldsymbol{u}(\boldsymbol{z}_1), \ldots, \boldsymbol{u}(\boldsymbol{z}_t)\big]$.

Proof See Appendix D. ■

An immediate consequence of Proposition 6 is that, in order to compute the posterior moments of the policy gradient, we only need to be able to evaluate (or estimate) the score vectors $\boldsymbol{u}(\boldsymbol{z}_i)$, $i = 0, \ldots, t$ and the Fisher information matrix $\boldsymbol{G}$ of our policy. Evaluating the Fisher information matrix $\boldsymbol{G}$ is somewhat more challenging, since on top of taking the expectation with respect to the policy $\mu(a|x;\boldsymbol{\theta})$, computing $\boldsymbol{G}$ involves an additional expectation over the state-occupancy density $\nu^\mu(x)$, which is not generally known. In most practical situations we therefore have to resort to estimating $\boldsymbol{G}$ from data. When ν^μ in the definition of the Fisher information matrix (Equation 40) is the stationary distribution over states under policy μ, one straightforward method to estimate $\boldsymbol{G}$ from a trajectory $\boldsymbol{z}_0, \boldsymbol{z}_1, \ldots, \boldsymbol{z}_t$ is to use the (unbiased) estimator (see Proposition 6 for the definition of $\boldsymbol{U}_t$):

$$\hat{\boldsymbol{G}}_t = \frac{1}{t+1} \sum_{i=0}^{t} \boldsymbol{u}(\boldsymbol{z}_i)\boldsymbol{u}(\boldsymbol{z}_i)^\top = \frac{1}{t+1} \boldsymbol{U}_t \boldsymbol{U}_t^\top. \tag{42}$$

In case ν^μ in Equation 40 is a discounted weighting of states encountered by following policy μ (as it is considered in this paper), a method for estimating $\boldsymbol{G}$ from a number of trajectories is shown in Algorithm 3. Note that $(1-\gamma)\nu^\mu$ corresponds to the distribution of a Markov chain that starts from a state sampled according to P_0 and at each step either follows the policy μ with probability γ or restarts from a new initial state drawn from P_0 with probability $1-\gamma$. It is easy to show that the average number of steps between two successive restarts of this distribution is $1/(1-\gamma)$.

Algorithm 4 is a pseudocode sketch of the Bayesian actor-critic algorithm, using either the conventional gradient or the natural gradient in the policy update, and with $\boldsymbol{G}$ estimated using either $\hat{\boldsymbol{G}}_t$ in Equation 42 or $\hat{\boldsymbol{G}}(\boldsymbol{\theta})$ in Algorithm 3.

7.3 BAC Online Sparsification

As was done for the BPG algorithms in Section 4.4, Algorithm 4 may be made more efficient, both in time and memory, by sparsifying the solution. Engel et al. (2005) presented a sparse approximation of the GPTD algorithm by using an online sparsification method from Engel et al. (2002). This sparsification method incrementally constructs a dictionary $\tilde{\mathcal{D}}$ of representative state-action pairs. Upon observing a new state-action pair $\boldsymbol{z}_i$, the distance between the feature-space image of $\boldsymbol{z}_i$ and the span of the images of current dictionary members is computed. If the squared distance $\delta_i = k(\boldsymbol{z}_i, \boldsymbol{z}_i) - \tilde{\boldsymbol{k}}_{i-1}^\top(\boldsymbol{z}_i)\tilde{\boldsymbol{K}}_{i-1}^{-1}\tilde{\boldsymbol{k}}_{i-1}(\boldsymbol{z}_i)$ exceeds some positive threshold τ, $\boldsymbol{z}_i$ is added to the dictionary, otherwise, it is left out. In

end while
return $\boldsymbol{\theta}$

calculating δ_i, $\tilde{\boldsymbol{k}}_{i-1}$ and $\tilde{\boldsymbol{K}}_{i-1}$ are the dictionary kernel vector and kernel matrix before observing $\boldsymbol{z}_i$, respectively. Engel et al. (2005) showed that using this sparsification procedure, the posteriors moments of Q may be compactly approximated as $\hat{Q}_t(\boldsymbol{z}) = \tilde{\boldsymbol{k}}_t^\top(\boldsymbol{z})\tilde{\boldsymbol{\alpha}}_t$ and $\hat{S}_t(\boldsymbol{z},\boldsymbol{z}') = k(\boldsymbol{z},\boldsymbol{z}') - \tilde{\boldsymbol{k}}_t^\top(\boldsymbol{z})\tilde{\boldsymbol{C}}_t\tilde{\boldsymbol{k}}_t(\boldsymbol{z}')$, where

$$\tilde{\boldsymbol{\alpha}}_t = \tilde{\boldsymbol{H}}_t^\top\left(\tilde{\boldsymbol{H}}_t\tilde{\boldsymbol{K}}_t\tilde{\boldsymbol{H}}_t^\top + \boldsymbol{\Sigma}_t\right)^{-1}\boldsymbol{r}_{t-1}\,, \qquad \tilde{\boldsymbol{C}}_t = \tilde{\boldsymbol{H}}_t^\top\left(\tilde{\boldsymbol{H}}_t\tilde{\boldsymbol{K}}_t\tilde{\boldsymbol{H}}_t^\top + \boldsymbol{\Sigma}_t\right)^{-1}\tilde{\boldsymbol{H}}_t\,. \quad (43)$$

In Equation 43, $\tilde{\boldsymbol{H}}_t = \boldsymbol{H}_t\boldsymbol{A}_t$, where $\boldsymbol{A}_t$ is a $|\mathcal{D}_t| \times |\tilde{\mathcal{D}}_t|$ matrix whose i'th row is $[\boldsymbol{A}]_{i,|\tilde{\mathcal{D}}_i|} = 1$ and $[\boldsymbol{A}]_{i,j} = 0\ ;\ \forall j \neq |\tilde{\mathcal{D}}_i|$, if we add the state-action pair $\boldsymbol{z}_i$ to the dictionary, and is $\tilde{\boldsymbol{k}}_{i-1}^\top(\boldsymbol{z}_i)\tilde{\boldsymbol{K}}_{i-1}^{-1}$ followed by zeros otherwise.

Proposition 7 *Using the sparsification method described above, the posterior moments of the gradient are approximated as*

$$\mathbf{E}\big[\nabla\eta(\boldsymbol{\theta})|\mathcal{D}_t\big] = \tilde{\boldsymbol{U}}_t\tilde{\boldsymbol{\alpha}}_t\,, \qquad \mathbf{Cov}\big[\nabla\eta(\boldsymbol{\theta})|\mathcal{D}_t\big] = \boldsymbol{G} - \tilde{\boldsymbol{U}}_t\tilde{\boldsymbol{C}}_t\tilde{\boldsymbol{U}}_t^\top\,,$$

where $\tilde{\boldsymbol{\alpha}}_t$ and $\tilde{\boldsymbol{C}}_t$ are given by Equation 43 and $\tilde{\boldsymbol{U}}_t = \big[\boldsymbol{u}(\boldsymbol{z}_1),\ldots,\boldsymbol{u}(\boldsymbol{z}_{|\tilde{\mathcal{D}}_t|})\big]$ with $\boldsymbol{z}_i \in \tilde{\mathcal{D}}_t$.

Proof The proof is straightforward by plugging the sparsified posterior mean and covariance of Q with $\tilde{\boldsymbol{\alpha}}_t$ and $\tilde{\boldsymbol{C}}_t$ from Equation 43 in Equation 35 and following the steps until the end of Proposition 6. ■

8. BAC Experimental Results

In this section, we empirically[17] evaluate the performance of the Bayesian actor-critic method presented in this paper in a 10-state random walk problem as well as in the widely used continuous-state-space mountain car problem (Sutton and Barto, 1998) and ship steering problem (Miller et al., 1990). In Section 8.1, we first compare BAC, Bayesian quadrature (BQ), and Monte Carlo (MC) gradient estimates in the 10-state random walk problem. We then evaluate the performance of the BAC algorithm on the same problem, and compare it with a Bayesian policy gradient (BPG) algorithm and a MC-based policy gradient (MCPG) algorithm. In Section 8.2, we compare the performance of the BAC algorithm with a MCPG algorithm on the mountain car problem. The BPG, BAC, and MCPG algorithms used in our experiments are Algorithms 2 and 4 presented in this paper, and Algorithm 1 in Baxter and Bartlett (2001), respectively. In Section 8.3, we compare the performance of the BAC algorithm with a MCPG algorithm on a problem in the ship steering domain. Similar to Section 8.2, the BAC, and MCPG algorithms used in our experiments are Algorithm 4 presented in this paper and Algorithm 1 in Baxter and Bartlett (2001), respectively.

17. The code for all the experiments of this section is available at `https://sequel.lille.inria.fr/Software/BAC`.

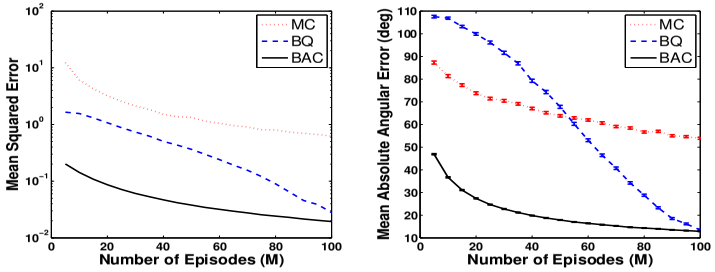

Figure 6: The mean squared error and the mean absolute angular error of MC, BQ, and BAC gradient estimations as a function of the number of sample episodes M. All results are averaged over 10^3 runs.

8.1 A Random Walk Problem

In this section, we consider a 10-state random walk problem, $\mathcal{X} = \{1,2,\ldots,10\}$, with states arranged linearly from state 1 on the left to state 10 on the right. The agent has two actions to choose from: $\mathcal{A} = \{left, right\}$. The left wall is a retaining barrier, meaning that if the $left$ action is taken at state 1, in the next time-step the state will be 1 again. State 10 is a zero reward absorbing state. The only stochasticity in the transitions is induced by the policy, which is defined as $\mu(right|x) = 1/1+\exp(-\theta_x)$ and $\mu(left|x) = 1-\mu(right|x)$, for all $x \in \mathcal{X}$. Note that each state x has an independent parameter θ_x. Each episode begins at state 1 and ends when the agent reaches state 10. The mean reward is 1 for states 1–9 and is 0 for state 10. The observed rewards for states 1–9 are obtained by corrupting the mean rewards with a 0.1 standard deviation i.i.d. Gaussian noise. The discount factor is $\gamma = 0.99$. In the BAC experiments, we use the Gaussian state kernel $k_x(x,x') = \exp(-||x-x'||^2/(2\sigma_k^2))$ with $\sigma_k = 3$ and the state-action kernel $0.01k_F(\boldsymbol{z},\boldsymbol{z}')$.

We first compare the MC, BQ, and BAC estimates of $\nabla\eta(\boldsymbol{\theta})$ for the policy induced by the parameters $\theta_x = \log(41/9)$ for all $x \in \mathcal{X}$, which is equivalent to $\mu(right|x) = 0.82$. We use several different sample sizes: $M = 5j,\ j = 1,\ldots,20$. Here, by sample size we mean the number of episodes used to estimate the gradient. For each value of M, we compute the gradient estimates 10^3 times. The true gradient is calculated analytically for reference. Figure 6 shows the mean squared error and the mean absolute angular error of MC, BQ, and BAC estimates of the gradient for different sample sizes M. The error bars in the right figure are the standard errors of the mean absolute angular errors. The results depicted in Figure 6 indicate that the BAC gradient estimates are more accurate and have lower variance than their MC and BQ counterparts.

Next, we use BAC to optimize the policy parameters and compare its performance with a BPG algorithm and a MCPG algorithm for $M = 1$, 25, 50, and 75. The BPG algorithm uses Model 1 of Section 4.1. We use Algorithm 4 with the number of policy updates set to

β	$M=1$	$M=25$	$M=50$	$M=75$
MCPG	0.005	0.075	0.1	0.75
BPG	0.0035	0.015	0.09	0.5
BAC	5	5	5	5

Table 4: Learning rates used by the algorithms in the experiments of Figure 7.

500 and the same kernels as in the previous experiment. The Fisher information matrix is estimated using Algorithm 3. The returns obtained by these methods are averaged over 10^3 runs. For a fixed sample size M, we tried many values of the learning rate, β, for MCPG, BPG, and BAC, and those in Table 4 yielded the best performance. Note that the learning rate used for each algorithm in each experiment is fixed and does not converge to zero. BAC showed a very robust performance when we changed the learning rate. By robust we mean that it never generated a policy for which an episode does not end after 10^6 steps. This seems to be due to the fact that BAC gradient estimates are more accurate and have less variance than their MC and BPG counterparts. The performance of BPG improves as we increase the sample size M. It performs worse than MCPG for $M=1$ and 25, but achieves a performance similar to BAC for $M=100$.

Figure 7 depicts the results of these experiments. From left to right and top to bottom the sub-figures correspond to the experiment in which all the algorithms used $M=1,\ 25,\ 50$, and 75 trajectories per policy update, respectively. Each curve depicts the difference between the exact average discounted return for the 500 policies that follow each policy update and η^* – the optimal average discounted return. All curves are averaged over 10^3 repetitions of the experiment. The BAC algorithm clearly learns significantly faster than the other algorithms (note that the vertical scale is logarithmic).

Remark: Since BQ (and as a result BPG) is based on defining a kernel over system trajectories (quadratic Fisher kernel in Model 1 and Fisher kernel in Model 2), its performance degrades when the system generates trajectories of different size. This effect can be observed by most kernels that have been used in the literature for the trajectories generated by dynamical systems. This can be also observed in our experiments: BQ performs much better than MC in the "Linear Quadratic Regulator" problem (Section 6.2), in which all the system trajectories are of size 20, while its superiority over MC is less apparent in the "Random Walk" problem (Section 8.1). This is why we are not going to use BQ and BPG in the "Mountain Car" (Section 8.2) and "Ship Steering" (Section 8.3) problems, in which the system trajectories have different lengths.

8.2 Mountain Car

In this section, we consider the mountain car problem as formulated in Sutton and Barto (1998), and report the results of applying the BAC and MCPG algorithms to optimize the policy parameters in this task. The state $\boldsymbol{x}$ consists of the position x and the velocity $\dot{x}$ of the car: $\boldsymbol{x}=(x,\dot{x})$. The reward is -1 on all time steps until the car reaches its goal at the top of the hill, which ends the episode. There are three possible actions: *forward*, *reverse*, and *zero*. The car moves according to the following simplified dynamics:

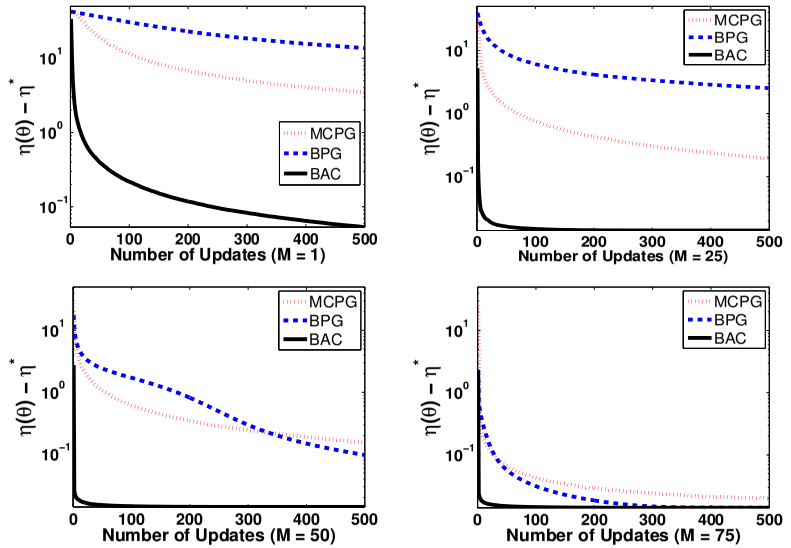

Figure 7: Results for the policy learning experiment. The graphs depict the performance of the policies learned by each algorithm during 500 policy updates. From left to right and top to bottom the number of episodes used to estimate the gradient is $M=1,\ 25,\ 50$ and 75. All results are averaged over 10^3 independent runs.

$$-1.2 \le x_{t+1} \le 0.5 \quad , \quad -0.07 \le \dot{x}_{t+1} \le 0.07 \ ,$$
$$x_{t+1} = \text{bound}[x_t + \dot{x}_{t+1}] \quad , \quad \dot{x}_{t+1} = \text{bound}\left[\dot{x}_t + 0.001 a_t - 0.0025\cos(3x_t)\right] .$$

When x_{t+1} reaches the left boundary, $\dot{x}_{t+1}$ is set to zero and when it reaches the right boundary, the goal is reached and the episode ends. Each episode starts from a random position and velocity uniformly sampled from their domains. We use the discount factor $\gamma=0.99$.

In order to define the policy, we first map the states $\boldsymbol{x}=(x,\dot{x})$ to the unit square $[0,1]\times[0,1]$. The policy used in our experiments has the following form:

$$\mu(a_i|\boldsymbol{x}) = \frac{\exp\left(\phi(\boldsymbol{x},a_i)^\top \boldsymbol{\theta}\right)}{\sum_{j=1}^3 \exp\left(\phi(\boldsymbol{x},a_j)^\top \boldsymbol{\theta}\right)} \ , \qquad i=1,2,3.$$

The policy feature vector is defined as $\phi(\boldsymbol{x},a_i) = \left(\phi(\boldsymbol{x})^\top \delta_{a_1 a_i}, \phi(\boldsymbol{x})^\top \delta_{a_2 a_i}, \phi(\boldsymbol{x})^\top \delta_{a_3 a_i}\right)^\top$, where $\delta_{a_j a_i}$ is 1 if $a_j = a_i$, and is 0 otherwise. The state feature vector $\phi(\boldsymbol{x})$ is composed of

Table 5: Learning rates used by the algorithms in the experiments of Figure 8.

16 Gaussian functions arranged in a 4×4 grid over the unit square as follows:

$$\phi(\boldsymbol{x}) = \Big(\exp\big(-||\boldsymbol{x} - \bar{\boldsymbol{x}}_1||^2/(2\kappa^2)\big), \ldots, \exp\big(-||\boldsymbol{x} - \bar{\boldsymbol{x}}_{16}||^2/(2\kappa^2)\big) \Big)^\top,$$

where the $\bar{\boldsymbol{x}}_i$'s are the 16 points of the grid $\{0, 0.25, 0.5, 1\} \times \{0, 0.25, 0.5, 1\}$ and $\kappa = 1.3 \times 0.25$.

In Figure 8, we compare the performance of BAC with a MCPG algorithm for $M = 5,\ 10,\ 20$, and 40 episodes used to estimate each gradient. For BAC, we use Algorithm 4 with the number of policy updates set to 500, a Gaussian state kernel $k_x(\boldsymbol{x}, \boldsymbol{x}') = \exp\big(-||\boldsymbol{x} - \boldsymbol{x}'||^2/(2\sigma_k^2)\big)$, with $\sigma_k = 1.3 \times 0.25$, and the state-action kernel $k_F(\boldsymbol{z}, \boldsymbol{z}')$. The Fisher information matrix is estimated using Algorithm 3. After every 50 policy updates the learned policy is evaluated for 10^3 episodes to estimate accurately the average number of steps to goal. Each evaluation episode starts from a random position and velocity uniformly chosen from their ranges, and continues until the car either reaches the goal or a limit of 200 time-steps is exceeded. The experiment is repeated 100 times for the entire horizontal axis to obtain average results and confidence intervals. The error bars in this figure are the standard errors of the performance of the algorithms.

For a fixed sample size M, each method starts with an initial learning rate and decreases it according to the schedule $\beta_t = \beta_0 \beta_c/(\beta_c + t)$. We tried many values of the learning rate parameters (β_0, β_c) for MCPG and BAC, and those in Table 5 yielded the best performance. Note that $\beta_c = \infty$ means that we used a fixed learning rate β_0 for that experiment. The graphs indicate that BAC performs better and has lower variance than MCPG. It is able to find a good policy with only $M = 5$ sample size and its performance does not change much as the sample size is increased. On the other hand, the performance of MCPG improves and its variance is reduced as we increase the sample size. Note that for $M = 40$, MCPG finally achieves a similar performance (still with slower rate) as BAC.

8.3 Ship Steering

In this section, we perform comparative experiments between BAC and MCPG on a more challenging problem in the continuous state continuous action *ship steering* domain (Miller et al., 1990).

Domain Description In this domain, a ship is located in a 150×150 meter square water surface. At any point in time t, the state of the ship is described by four continuous variables that are defined below along with their range of values

$$\mathbf{x}_t = (x_t, y_t, \theta_t, \dot{\theta}_t) \in [0\text{m}, 150\text{m}] \times [0\text{m}, 150\text{m}] \times [-180^\circ, 180^\circ] \times [-15^\circ/\text{s}, 15^\circ/\text{s}],$$

where x_t and y_t represent the position of the ship, θ_t the angle between the vertical axis and the ship orientation, and $\dot{\theta}_t$ the actual turning rate (see the upper-left panel in Figure 9).

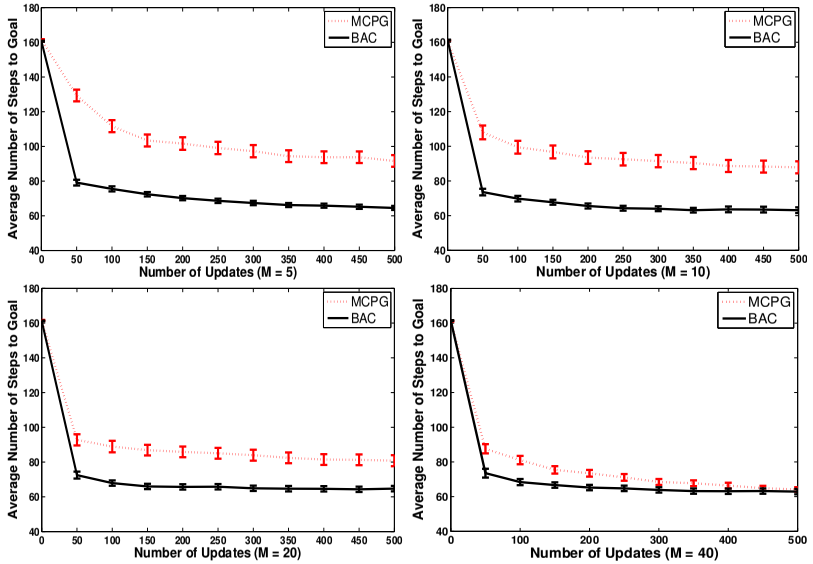

Figure 8: The graphs depict the performance of the policies learned by BAC and a MCPG algorithm during 500 policy updates in the mountain car problem. From left to right and top to bottom the number of episodes used to estimate the gradient is $M = 5,\ 10,\ 20$, and 40. All results are averaged over 100 independent runs.

At the beginning of each episode, the ship starts at $(x_1, y_1) = (40\text{m}, 40\text{m})$, with θ_1 and $\dot{\theta}_1$ sampled uniformly at random from their ranges. The only available action variable is $a_t \in [-15^\circ, 15^\circ]$, which is the *desired* turning rate. To model the ship inertia and water resistance, there is a $T = 5$ time steps lag for the desired turning rate to become the actual turning rate. Moreover, the ship moves with the constant speed of $V = 3\text{m/s}$ and $\Delta = 0.2\text{s}$ is the sampling interval. The following set of equations summarizes the ship's dynamics:

$$x_{t+1} = x_t + \Delta\, V \sin\theta_t \qquad y_{t+1} = y_t + \Delta\, V \cos\theta_t$$
$$\theta_{t+1} = \theta_t + \Delta\, \dot{\theta}_t \qquad \dot{\theta}_{t+1} = \dot{\theta}_t + \frac{\Delta}{T}(a_t - \dot{\theta}_t)$$

The goal of the ship is to navigate to $(x_*, y_*) = (100\text{m}, 100\text{m})$ within 500 times steps. If this does not happen or the ship moves out of the boundary, the episode terminates as a failure. The goal of the policy is to maximize the probability of the ship successfully reaching (x_*, y_*). Thus, we set the discount factor to $\gamma = 1$ in this problem.

β	$M = 5$	$M = 10$	$M = 20$
MCPG	0.01	0.01	0.01
BAC	0.5	0.4	0.5

Table 6: Learning rates used by the algorithms in the experiments of Figure 9.

Learning For both MCPG and BAC, we used a CMAC function approximator with 9 four dimensional tilings, each of them discretizing the state space into $5 \times 5 \times 36 \times 5 = 4500$ tiles. Therefore, each policy parameter $\boldsymbol{w}$ is of size $N = 9 \times 4500 = 40500$. Each state $\mathbf{x}$ is represented by a binary vector $\phi(\mathbf{x})$, where $\phi_i(\mathbf{x}) = 1$ if and only if the state $\mathbf{x}$ falls in the ith tile, and thus, $\sum_{i=1}^{N} \phi_i(\mathbf{x}) \leq 9$. To define a precise mapping from states to actions, $\boldsymbol{w}_t : \mathbf{x_t} = (x_t, y_t, \theta_t, \dot{\theta}_t) \rightarrow a_t$, we first sample $\tilde{a}_t$ from the Gaussian

$$\tilde{a}_t \sim \mathcal{N}\left(\frac{\sum_{i=1}^{N} \boldsymbol{w}_t^{(i)} \phi_i(\mathbf{x}_t)}{\sum_{i=1}^{N} \phi_i(\mathbf{x}_t)}, 1\right),$$

and then map it to the allowed range $[-15°, 15°]$ using the sigmoid transformation

$$a_t = 15° \cdot \frac{2}{\pi} \cdot \arctan\left(\frac{\pi}{2} \cdot \tilde{a}_t\right).$$

For the BAC experiments, we used the Gaussian state kernel $k_x(\mathbf{x}, \mathbf{x}') = \exp(-||\mathbf{x} - \mathbf{x}'||^2/(2\sigma_k^2))$, with $\sigma_k = 1$ and the state-action kernel $k_F(\boldsymbol{z}, \boldsymbol{z}')$, i.e., the Fisher kernel.

Setup In order to improve the computational efficiency, we use several numerical approximations. First, to calculate the score function for a trajectory (Equation 5) in both MCPG and BAC, we approximate the gradient of the action distribution in a_t with the one in $\tilde{a}_t$, i.e.,

$$\nabla \log \mu(a_t|\mathbf{x}_t; \boldsymbol{w}_t) \approx \nabla \log \mu(\tilde{a}_t|\mathbf{x}_t; \boldsymbol{w}_t).$$

Second, we calculate the gradient using the online sparsification procedure described in Section 4.4. Finaly, we never explicitly calculate the inverse of the Fisher information matrix $\hat{\boldsymbol{G}}$ and instead calculate the product of $\hat{\boldsymbol{G}}^{-1}$ with the score. For the numerical stability we also add 10^{-6} to the diagonal of $\hat{\boldsymbol{G}}$.

Similar to the other experiments in the paper, we varied the number of trajectories used to estimate the gradient of a policy as $M = 5$, 10, and 20. Table 6 shows the best values of the learning rate β for both MCPG and BAC for different values of M. To evaluate each method, we ran 100 independent learning trials. At each trial, we evaluate the performance of the policy every 100 iterations by executing it 100 (independent) times with θ_1 and $\dot{\theta}_1$ randomly sampled. For each of these execution, we observe if the ship reached (x_*, y_*) within 500 steps and estimate the policy success ratio. We set the total number of gradient updates to $T = 3000$ for $M = 5$ and 10 and to $T = 1000$ for $M = 20$.

Results The results for all the experiments are presented in Figure 9 along with their standard deviations. Naturally, using more trajectories for the gradient update improves both methods. However, this improvement is bigger for the BAC method. In the case of $M = 5$, MCPG produces slightly better policies at the beginning of learning, but is

soon outperformed by BAC. For $M = 10$ and 20, BAC produces better policies from the beginning, especially for $M = 20$. This is consistent with the results of the other experimental domains reported in the paper. For all values of M, BAC converges to a policy with a better success ratio than MCPG. Finally, as expected, BAC has usually less variance in its performance than MCPG.

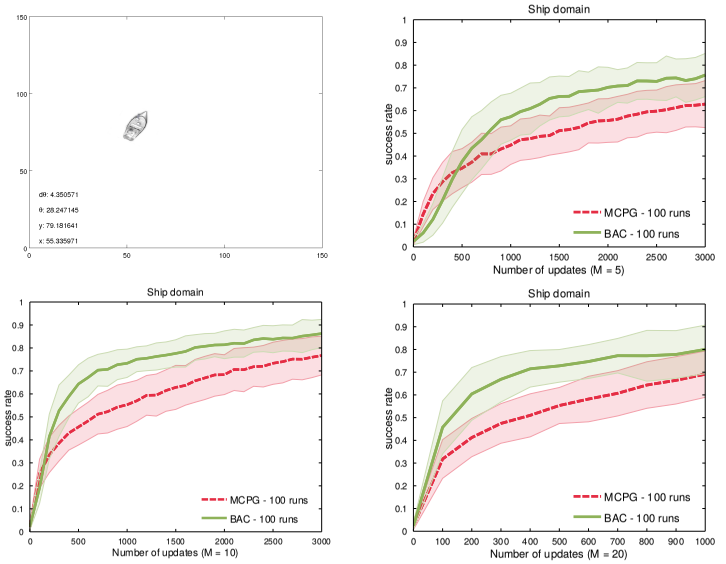

Figure 9: Success rate of the policies learned by BAC and MCPG in the ship steering problem.

9. Other Advancements in Bayesian Reinforcement Learning

The algorithms presented in this paper belong to the class of *Bayesian model-free RL*, as they do not assume that the system's dynamic is known and do not explicitly construct a model of the system. In recent years, Bayesian methodology has been used to develop algorithms in several other areas of RL. In this section, we provide a brief overview of these results (for more details, see the survey by Ghavamzadeh et al. 2015).

Another widely-used class of RL algorithms are those that build an explicit model of the system and use it to find a good (or optimal) policy, thus, are known as *model-based RL* algorithms. Recent years have witnessed many applications of the Bayesian methodology to this class of RL algorithms. The main idea of model-based Bayesian RL is to explicitly

maintain a posterior over the model parameters and to use it to select actions in order to appropriately balance exploration and exploitation. The class of model-based Bayesian RL algorithms include those that work with MDPs and those that work with POMDPs (e.g., Ross et al. 2008, Doshi et al. 2008). The MDP-based algorithms can be further divided to those that are offline (e.g., Duff 2001, Poupart et al. 2006), those that are online (e.g., Dearden et al. 1999, Strens 2000, Wang et al. 2005, Ross et al. 2008), and those that have probably approximately correct (PAC)-guarantees (e.g., Kolter and Ng 2009, Asmuth et al. 2009, Sorg et al. 2010).

The use of Bayesian methodology has also been explored to solve the *inverse RL* (IRL) problem, i.e., learning the underlying model of the decision-making agent (expert) from its observed behavior and the dynamics of the system (Russell, 1998). The main idea of Bayesian IRL (BIRL) is to use a prior to encode the reward preference and to formulate the compatibility with the expert's policy as a likelihood in order to derive a probability distribution over the space of reward functions, from which the expert's reward function is somehow extracted. The most notable works in the area of BIRL include those by Ramachandran and Amir (2007), Choi and Kim (2011, 2012), Michini and How (2012a,b).

Bayesian techniques have also been used to derive algorithms for the *collaborative multi-agent RL* problem. When dealing with multi-agent systems, the complexity of the decision problem is increased in the following way: while single-agent BRL requires maintaining a posterior over the MDP parameters (in the case of model-based methods) or over the value/policy (in the case of model-free methods), in multi-agent BRL, it is also necessary to keep a posterior over the policies of the other agents. Chalkiadakis and Boutilier (2013) showed that this belief can be maintained in a tractable manner subject to certain structural assumptions on the domain, for example that the strategies of the agents are independent of each other.

Multi-task RL (MTRL) is another area that has witnessed the application of Bayesian methodology. All approaches to MTRL assume that the tasks share similarity in some components of the problem such as dynamics, reward structure, or value function. The Bayesian MTRL methods assume that the shared components are drawn from a common generative model (Wilson et al., 2007, Mehta et al., 2008, Lazaric and Ghavamzadeh, 2010). In Mehta et al. (2008), tasks share the same dynamics and reward features, and only differ in the weights of the reward function. The proposed method initializes the value function for a new task using the previously learned value functions as a prior. Wilson et al. (2007) and Lazaric and Ghavamzadeh (2010) both assume that the distribution over some components of the tasks is drawn from a hierarchical Bayesian model.

Bayesian learning methods have also been used for regret minimization in multi-armed bandits. This area that goes back to the seminal work of Gittins (1979), has become very active with the Bayesian version of the upper confidence bound (UCB) algorithm (Kaufmann et al., 2012a) and the recent advancements in the analysis of Thompson Sampling (Agrawal and Goyal, 2012, Kaufmann et al., 2012b, Agrawal and Goyal, 2013a,b, Russo and Van Roy, 2014, Gopalan et al., 2014, Guha and Munagala, 2014, Liu and Li, 2015) and its state-of-the-art empirical performance (Scott, 2010, Chapelle and Li, 2011), which has also led to its use in several industrial applications (Graepel et al., 2010, Tang et al., 2013).

10. Discussion

In this paper, we first proposed an alternative approach to the conventional frequentist (Monte-Carlo based) policy gradient estimation procedure. Our approach is based on *Bayesian quadrature* (O'Hagan, 1991), a Bayesian method for integral evaluation. The idea is to model the gradient of the expected return with respect to the policy parameters, which is of the form of an integral, as Gaussian processes (GPs). This is done by dividing the integrand into two parts, treating one as a random function (or random field), whose random nature reflects our subjective uncertainty concerning its true identity. This allows us to incorporate our prior knowledge of this term (part) into its prior distribution. Observing (possibly noisy) samples of this term allows us to employ Bayes' rule to compute a posterior distribution of it conditioned on these samples. This in turn induces a posterior distribution over the value of the integral, which is the gradient of the expected return. By properly partitioning the integrand and by appropriately selecting a prior distribution, a closed-form expression for the posterior moments of the gradient of the expected return is obtained. We proposed two different ways of partitioning the integrand resulting in two distinct Bayesian models. For each model, we showed how the posterior moments of the gradient conditioned on the observed data are calculated. In line with previous work on Bayesian quadrature, our Bayesian approach tends to significantly reduce the number of samples needed to obtain accurate gradient estimates. Moreover, estimates of the natural gradient and the gradient covariance are provided at little extra cost. We performed detailed experimental comparisons of the Bayesian policy gradient (BPG) algorithms presented in the paper with classic Monte-Carlo based algorithms on a bandit problem as well as on a linear quadratic regulator problem. The experimental results are encouraging, but we conjecture that even better gains may be attained using this approach. This calls for additional theoretical and empirical work. It is important to note that the gradient estimated by Algorithm 1 may be employed in conjunction with conjugate-gradients and line-search methods for making better use of the gradient information. We also showed that the models and algorithms presented in this paper can be extended to partially observable problems without any change along the same lines as Baxter and Bartlett (2001). This is due to the fact that our BPG framework considers complete system trajectories as its basic observable unit, and thus, does not require the dynamic within each trajectory to be of any special form. This generality has the downside that our proposed framework cannot take advantage of the Markov property when the system is Markovian.

To address this issue, we then extended our BPG framework to actor-critic algorithms and presented a new Bayesian take on the actor-critic architecture. By using GPs and choosing their prior distributions to make them compatible with a parametric family of policies, we were able to derive closed-form expressions for the posterior distribution of the policy gradient updates. The posterior mean is used to update the policy and the posterior covariance to gauge the reliability of this update. Our Bayesian actor-critic (BAC) framework uses individual state-action-reward transitions as its basic observable unit, and thus, is able to take advantage of the Markov property of the system trajectories (when the system is indeed Markovian). This improvement seems to be borne out in our experiments, where BAC provides more accurate estimates of the policy gradient than either of the two BPG models for the same amount of data. Similar to BPG, another feature of BAC

is that its natural-gradient variant is obtained at little extra cost. For both BPG and BAC, we derived the sparse form of the algorithms, which would make them significantly more time and memory efficient. Finally, we performed an experimental evaluation of the BAC algorithm, comparing it with classic Monte-Carlo based policy gradient algorithms, as well as our BPG algorithms, on a random walk problem, the widely used mountain car problem (Sutton and Barto, 1998), and the continuous state and continuous action ship steering domain (Miller et al., 1990).

Additional experimental work is required to investigate the behavior of BPG and BAC algorithms in larger and more realistic domains, involving continuous and high-dimensional state and action spaces. The BPG and BAC algorithms proposed in the paper use only the posterior mean of the gradient in their updates. We conjecture that the second-order statistics obtained from BPG and BAC (both in the actor and critic) may be used to devise more efficient algorithms. In one of the experiments in Section 6, we employed the covariance information provided by Algorithm 1 for risk-aware selection of the step size in the gradient updates, which showed promising performance. Other interesting directions for future work include **1)** investigating other possible partitions of the integrand in the expression for $\nabla\eta_B(\boldsymbol{\theta})$ into a GP term and a deterministic term, **2)** using other types of kernel functions such as sequence kernels, **3)** combining our approach with MDP model estimation to allow transfer of learning between different policies (model-based Bayesian policy gradient), and **4)** investigating more efficient methods for estimating the Fisher information matrix. Another direction is to derive a fully non-parametric actor-critic algorithm. In BAC, the critic is based on Gaussian process temporal difference learning, which is a non-parametric method, while the actor uses a family of parameterized policies. The idea here would be to replace the actor in the BAC algorithm with a non-parametric actor that performs gradient search in a function space (e.g., a reproducing kernel Hilbert space) of policies.

Acknowledgments

Part of the computational experiments was conducted using the Grid'5000 experimental testbed (https://www.grid5000.fr). Yaakov Engel was supported by an Alberta Ingenuity fellowship.

Appendix A. Proof of Proposition 3

We start the proof with the $M \times 1$ vector $\boldsymbol{b}$, whose ith element can be written as

$$
\begin{aligned}
(\boldsymbol{b})_i &= \int k(\xi,\xi_i)\Pr(\xi;\boldsymbol{\theta})d\xi \\
&\overset{(a)}{=} \int \left(1+\boldsymbol{u}(\xi)^\top \boldsymbol{G}^{-1}\boldsymbol{u}(\xi_i)\right)^2 \Pr(\xi;\boldsymbol{\theta})d\xi \\
&\overset{(b)}{=} \int \Pr(\xi;\boldsymbol{\theta})d\xi + 2\left(\int \boldsymbol{u}(\xi)\Pr(\xi;\boldsymbol{\theta})d\xi\right)^\top \boldsymbol{G}^{-1}\boldsymbol{u}(\xi_i) + \int \boldsymbol{u}(\xi_i)^\top \boldsymbol{G}^{-1}\boldsymbol{u}(\xi)\boldsymbol{u}(\xi)^\top \boldsymbol{G}^{-1}\boldsymbol{u}(\xi_i)\Pr(\xi;\boldsymbol{\theta})d\xi \\
&\overset{(c)}{=} 1 + \left(\boldsymbol{u}(\xi_i)^\top \boldsymbol{G}^{-1}\right)\left(\int \boldsymbol{u}(\xi)\boldsymbol{u}(\xi)^\top \Pr(\xi;\boldsymbol{\theta})d\xi\right)\left(\boldsymbol{G}^{-1}\boldsymbol{u}(\xi_i)\right) \\
&\overset{(d)}{=} 1 + \left(\boldsymbol{u}(\xi_i)^\top \boldsymbol{G}^{-1}\right)\boldsymbol{G}\left(\boldsymbol{G}^{-1}\boldsymbol{u}(\xi_i)\right) \overset{(e)}{=} 1 + \boldsymbol{u}(\xi_i)^\top \boldsymbol{G}^{-1}\boldsymbol{u}(\xi_i)
\end{aligned}
$$

(a) substitutes $k(\xi,\xi_i)$ with the quadratic Fisher kernel from Equation 23, **(b)** is algebra, **(c)** follows from **(i)** $\int \Pr(\xi;\boldsymbol{\theta})d\xi = 1$, and **(ii)** $\int \boldsymbol{u}(\xi)\Pr(\xi;\boldsymbol{\theta})d\xi = \int \nabla \log \Pr(\xi;\boldsymbol{\theta})\Pr(\xi;\boldsymbol{\theta})d\xi$ $= \int \nabla \Pr(\xi;\boldsymbol{\theta})d\xi = \nabla \int \Pr(\xi;\boldsymbol{\theta})d\xi = \nabla(1) = 0$, **(d)** is the result of replacing the integral with the Fisher information matrix $\boldsymbol{G}$, **(e)** is algebra, and thus, the claim follows.

Now the proof for the scalar b_0

$$
\begin{aligned}
b_0 &= \iint k(\xi,\xi')\Pr(\xi;\boldsymbol{\theta})\Pr(\xi';\boldsymbol{\theta})d\xi d\xi' \\
&\overset{(a)}{=} \iint \left(1+\boldsymbol{u}(\xi)^\top \boldsymbol{G}^{-1}\boldsymbol{u}(\xi')\right)^2 \Pr(\xi;\boldsymbol{\theta})\Pr(\xi';\boldsymbol{\theta})d\xi d\xi' \\
&\overset{(b)}{=} \iint \Pr(\xi;\boldsymbol{\theta})\Pr(\xi';\boldsymbol{\theta})d\xi d\xi' + 2\iint \boldsymbol{u}(\xi)^\top \boldsymbol{G}^{-1}\boldsymbol{u}(\xi')\Pr(\xi;\boldsymbol{\theta})\Pr(\xi';\boldsymbol{\theta})d\xi d\xi' \\
&+ \iint \boldsymbol{u}(\xi)^\top \boldsymbol{G}^{-1}\boldsymbol{u}(\xi')\boldsymbol{u}(\xi')^\top \boldsymbol{G}^{-1}\boldsymbol{u}(\xi)\Pr(\xi;\boldsymbol{\theta})\Pr(\xi';\boldsymbol{\theta})d\xi d\xi' \\
&\overset{(c)}{=} 1 + 2\left(\int \boldsymbol{u}(\xi)\Pr(\xi;\boldsymbol{\theta})d\xi\right)^\top \boldsymbol{G}^{-1}\left(\int \boldsymbol{u}(\xi')\Pr(\xi';\boldsymbol{\theta})d\xi'\right) \\
&+ \int \boldsymbol{u}(\xi)^\top \boldsymbol{G}^{-1}\left(\int \boldsymbol{u}(\xi')\boldsymbol{u}(\xi')^\top \Pr(\xi';\boldsymbol{\theta})d\xi'\right)\boldsymbol{G}^{-1}\boldsymbol{u}(\xi)\Pr(\xi;\boldsymbol{\theta})d\xi \\
&\overset{(d)}{=} 1 + \int \boldsymbol{u}(\xi)^\top \boldsymbol{G}^{-1}\boldsymbol{u}(\xi)\Pr(\xi;\boldsymbol{\theta})d\xi
\end{aligned} \tag{44}
$$

(a) substitutes $k(\xi,\xi')$ with the quadratic Fisher kernel from Equation 23, **(b)** is algebra, **(c)** follows from **(i)** $\iint \Pr(\xi;\boldsymbol{\theta})\Pr(\xi';\boldsymbol{\theta})d\xi d\xi' = 1$, and **(ii)** $\int \boldsymbol{u}(\xi)\Pr(\xi;\boldsymbol{\theta})d\xi = 0$, and finally **(d)** is the result of replacing the integral within the parentheses with the Fisher information matrix $\boldsymbol{G}$.

The Fisher information matrix $\boldsymbol{G}$ is positive definite and symmetric. Thus, it can be written as $\boldsymbol{G} = \boldsymbol{V}\boldsymbol{\Lambda}\boldsymbol{V}^\top$, where $\boldsymbol{V} = [\boldsymbol{v}_1,\ldots,\boldsymbol{v}_n]$ and $\boldsymbol{\Lambda} = \mathrm{diag}[\lambda_1,\ldots,\lambda_n]$ are the matrix of orthonormal eigenvectors and the diagonal matrix of eigenvalues of matrix $\boldsymbol{G}$, respectively.

By replacing $\boldsymbol{G}^{-1}$ with $\boldsymbol{V}\boldsymbol{\Lambda}^{-1}\boldsymbol{V}^\top$ in Equation 44 we obtain

$$
\begin{aligned}
b_0 &= 1 + \int \boldsymbol{u}^\top(\xi)\boldsymbol{V}\boldsymbol{\Lambda}^{-1}\boldsymbol{V}^\top\boldsymbol{u}(\xi)\Pr(\xi;\boldsymbol{\theta})d\xi \\
&\overset{\text{(a)}}{=} 1 + \int \left(\boldsymbol{V}^\top\boldsymbol{u}(\xi)\right)^\top \boldsymbol{\Lambda}^{-1}\left(\boldsymbol{V}^\top\boldsymbol{u}(\xi)\right)\Pr(\xi;\boldsymbol{\theta})d\xi \overset{\text{(b)}}{=} 1 + \int \left(\sum_{i=1}^n \lambda_i^{-1}\left(\boldsymbol{V}^\top\boldsymbol{u}(\xi)\right)_i^2\right)\Pr(\xi;\boldsymbol{\theta})d\xi \\
&\overset{\text{(c)}}{=} 1 + \sum_{i=1}^n \lambda_i^{-1}\left(\int \left(\boldsymbol{v}_i^\top\boldsymbol{u}(\xi)\right)^2\Pr(\xi;\boldsymbol{\theta})d\xi\right) \overset{\text{(d)}}{=} 1 + \sum_{i=1}^n \lambda_i^{-1}\left(\int \boldsymbol{v}_i^\top\boldsymbol{u}(\xi)\boldsymbol{v}_i^\top\boldsymbol{u}(\xi)\Pr(\xi;\boldsymbol{\theta})d\xi\right) \\
&\overset{\text{(e)}}{=} 1 + \sum_{i=1}^n \lambda_i^{-1}\left(\int \boldsymbol{v}_i^\top\boldsymbol{u}(\xi)\boldsymbol{u}(\xi)^\top\boldsymbol{v}_i\Pr(\xi;\boldsymbol{\theta})d\xi\right) \overset{\text{(f)}}{=} 1 + \sum_{i=1}^n \lambda_i^{-1}\boldsymbol{v}_i^\top\left(\int \boldsymbol{u}(\xi)\boldsymbol{u}(\xi)^\top\Pr(\xi;\boldsymbol{\theta})d\xi\right)\boldsymbol{v}_i \\
&\overset{\text{(g)}}{=} 1 + \sum_{i=1}^n \lambda_i^{-1}\boldsymbol{v}_i^\top\boldsymbol{G}\boldsymbol{v}_i \overset{\text{(h)}}{=} 1 + \sum_{i=1}^n \lambda_i^{-1}\boldsymbol{v}_i^\top\lambda_i\boldsymbol{v}_i = 1 + \sum_{i=1}^n \boldsymbol{v}_i^\top\boldsymbol{v}_i = 1 + \sum_{i=1}^n ||\boldsymbol{v}_i||^2 \overset{\text{(i)}}{=} 1 + n
\end{aligned}
$$

(a) and **(b)** are algebra, **(c)** is the result of switching the sum and the integral, **(d)** is algebra, **(e)** follows from the fact that $\boldsymbol{v}_i^\top\boldsymbol{u}(\xi)$ is a scalar, and thus, can be replaced by its transpose, **(f)** is algebra, **(g)** substitutes the integral within the parentheses with the Fisher information matrix $\boldsymbol{G}$, **(h)** replaces $\boldsymbol{G}\boldsymbol{v}_i$ with $\lambda_i\boldsymbol{v}_i$, **(i)** follows from the orthonormality of $\boldsymbol{v}_i$'s, and thus, the claim follows.

Appendix B. Proof of Proposition 4

We start with the proof of $\boldsymbol{B}$. This $n \times M$ matrix may be written as

$$
\begin{aligned}
\boldsymbol{B} &= \int \nabla\Pr(\xi;\boldsymbol{\theta})\boldsymbol{k}(\xi)^\top d\xi = \int \nabla\Pr(\xi;\boldsymbol{\theta})\left[k(\xi,\xi_1),\ldots,k(\xi,\xi_M)\right]d\xi \\
&\overset{\text{(a)}}{=} \int \nabla\Pr(\xi;\boldsymbol{\theta})\left[\boldsymbol{u}(\xi)^\top\boldsymbol{G}^{-1}\boldsymbol{u}(\xi_1),\ldots,\boldsymbol{u}(\xi)^\top\boldsymbol{G}^{-1}\boldsymbol{u}(\xi_M)\right]d\xi \\
&\overset{\text{(b)}}{=} \left(\int \nabla\Pr(\xi;\boldsymbol{\theta})\boldsymbol{u}(\xi)^\top d\xi\right)\boldsymbol{G}^{-1}\left[\boldsymbol{u}(\xi_1),\ldots,\boldsymbol{u}(\xi_M)\right] \\
&\overset{\text{(c)}}{=} \left(\int \boldsymbol{u}(\xi)\boldsymbol{u}(\xi)^\top\Pr(\xi;\boldsymbol{\theta})d\xi\right)\boldsymbol{G}^{-1}\left[\boldsymbol{u}(\xi_1),\ldots,\boldsymbol{u}(\xi_M)\right] \\
&\overset{\text{(d)}}{=} \boldsymbol{G}\boldsymbol{G}^{-1}\left[\boldsymbol{u}(\xi_1),\ldots,\boldsymbol{u}(\xi_M)\right] \overset{\text{(e)}}{=} \left[\boldsymbol{u}(\xi_1),\ldots,\boldsymbol{u}(\xi_M)\right] = \boldsymbol{U}
\end{aligned}
$$

(a) substitutes $k(\xi,\xi_i)$ with the Fisher kernel from Equation 27, **(b)** is algebra, **(c)** follows from $\nabla\Pr(\xi;\boldsymbol{\theta}) = \boldsymbol{u}(\xi)\Pr(\xi;\boldsymbol{\theta})$, **(d)** substitutes the integral within the parentheses with the Fisher information matrix $\boldsymbol{G}$, **(e)** is algebra, and thus, the claim follows.

Now the proof for the $n \times n$ matrix $\boldsymbol{B}_0$

$$
\begin{aligned}
\boldsymbol{B}_0 &= \iint k(\xi,\xi')\nabla\Pr(\xi;\boldsymbol{\theta})\nabla\Pr(\xi';\boldsymbol{\theta})^\top d\xi d\xi' \\
&\overset{\text{(a)}}{=} \iint \nabla\Pr(\xi;\boldsymbol{\theta})k(\xi,\xi')\nabla\Pr(\xi';\boldsymbol{\theta})^\top d\xi d\xi' \\
&\overset{\text{(b)}}{=} \iint \left(\boldsymbol{u}(\xi)\Pr(\xi;\boldsymbol{\theta})\right)\boldsymbol{u}(\xi)^\top\boldsymbol{G}^{-1}\boldsymbol{u}(\xi')\left(\boldsymbol{u}(\xi')\Pr(\xi';\boldsymbol{\theta})\right)^\top d\xi d\xi' \\
&\overset{\text{(c)}}{=} \left(\int \boldsymbol{u}(\xi)\boldsymbol{u}(\xi)^\top\Pr(\xi;\boldsymbol{\theta})d\xi\right)\boldsymbol{G}^{-1}\left(\int \boldsymbol{u}(\xi')\boldsymbol{u}(\xi')^\top\Pr(\xi';\boldsymbol{\theta})d\xi'\right) \overset{\text{(d)}}{=} \boldsymbol{G}\boldsymbol{G}^{-1}\boldsymbol{G} = \boldsymbol{G}
\end{aligned}
$$

(a) follows from the fact that $k(\xi,\xi')$ is scalar, **(b)** substitutes $k(\xi,\xi')$ with the Fisher information kernel from Equation 27 and $\nabla\Pr(\xi;\boldsymbol{\theta})$ with $\boldsymbol{u}(\xi)\Pr(\xi;\boldsymbol{\theta})$, **(c)** is algebra, **(d)** is the result of substituting the integrals within the parentheses with the Fisher information matrix $\boldsymbol{G}$, and thus, the claim follows.

Appendix C. Proof of Proposition 5

Here we only show the proof for Model 1, the proof for Model 2 is straightforward following the same arguments. The sparse approximations of the kernel matrix $\boldsymbol{K}$ and kernel vector $\boldsymbol{k}(\cdot)$ may be written as $\boldsymbol{K} \approx \boldsymbol{A}\tilde{\boldsymbol{K}}\boldsymbol{A}^\top$ and $\boldsymbol{k}(\cdot) \approx \boldsymbol{A}\tilde{\boldsymbol{k}}(\cdot)$, respectively (Equations. 2.2.8 and 2.2.9 in Engel, 2005). If we replace $\boldsymbol{K}$ and $\boldsymbol{k}(\cdot)$ in Equation 21 with their sparse approximations, we obtain

$$
\begin{aligned}
\mathbf{E}\left[\nabla\eta_B(\boldsymbol{\theta})|\mathcal{D}_M\right] &= \boldsymbol{Y}\left(\boldsymbol{A}\tilde{\boldsymbol{K}}\boldsymbol{A}^\top + \boldsymbol{\Sigma}\right)^{-1}\boldsymbol{b}, \\
\mathbf{Cov}\left[\nabla\eta_B(\boldsymbol{\theta})|\mathcal{D}_M\right] &= \left[b_0 - \boldsymbol{b}^\top\left(\boldsymbol{A}\tilde{\boldsymbol{K}}\boldsymbol{A}^\top + \boldsymbol{\Sigma}\right)^{-1}\boldsymbol{b}\right]\boldsymbol{I}.
\end{aligned} \tag{45}
$$

Sparsification does not change b_0 and it remains equal to $n+1$ (see Proposition 3), however it modifies $\boldsymbol{b}$ to

$$
\boldsymbol{b} = \int \boldsymbol{k}(\xi)\Pr(\xi;\boldsymbol{\theta})d\xi = \int \boldsymbol{A}\tilde{\boldsymbol{k}}(\xi)\Pr(\xi;\boldsymbol{\theta})d\xi = \boldsymbol{A}\int \tilde{\boldsymbol{k}}(\xi)\Pr(\xi;\boldsymbol{\theta})d\xi = \boldsymbol{A}\tilde{\boldsymbol{b}},
$$

where $\tilde{\boldsymbol{b}} = \int \tilde{\boldsymbol{k}}(\xi)\Pr(\xi;\boldsymbol{\theta})d\xi$ is exactly $\boldsymbol{b}$, only the kernel vector $\boldsymbol{k}(\cdot)$ has been replaced by the sparse kernel vector $\tilde{\boldsymbol{k}}(\cdot)$. Thus using Proposition 3, we have $(\tilde{\boldsymbol{b}})_i = 1 + \boldsymbol{u}(\xi_i)^\top\boldsymbol{G}^{-1}\boldsymbol{u}(\xi_i)$, with $\xi_i \in \tilde{\mathcal{D}}$. By replacing $\boldsymbol{b}$ with $\boldsymbol{A}\tilde{\boldsymbol{b}}$ in Equation 45, we obtain

$$
\begin{aligned}
\mathbf{E}\left[\nabla\eta_B(\boldsymbol{\theta})|\mathcal{D}_M\right] &= \boldsymbol{Y}\left(\boldsymbol{A}\tilde{\boldsymbol{K}}\boldsymbol{A}^\top + \boldsymbol{\Sigma}\right)^{-1}\boldsymbol{A}\tilde{\boldsymbol{b}} = \boldsymbol{Y}\boldsymbol{\Sigma}^{-1}\left(\boldsymbol{A}\tilde{\boldsymbol{K}}\boldsymbol{A}^\top\boldsymbol{\Sigma}^{-1} + \boldsymbol{I}\right)^{-1}\boldsymbol{A}\tilde{\boldsymbol{b}}, \\
\mathbf{Cov}\left[\nabla\eta_B(\boldsymbol{\theta})|\mathcal{D}_M\right] &= \left(b_0 - \tilde{\boldsymbol{b}}^\top\boldsymbol{A}^\top\left(\boldsymbol{A}\tilde{\boldsymbol{K}}\boldsymbol{A}^\top + \boldsymbol{\Sigma}\right)^{-1}\boldsymbol{A}\tilde{\boldsymbol{b}}\right)\boldsymbol{I} = \left(b_0 - \tilde{\boldsymbol{b}}^\top\boldsymbol{A}^\top\boldsymbol{\Sigma}^{-1}\left(\boldsymbol{A}\tilde{\boldsymbol{K}}\boldsymbol{A}^\top\boldsymbol{\Sigma}^{-1} + \boldsymbol{I}\right)^{-1}\boldsymbol{A}\tilde{\boldsymbol{b}}\right)\boldsymbol{I}.
\end{aligned}
$$

The claim follows using Lemma 1.3.2 in Engel (2005).

Appendix D. Proof of Proposition 6

We start the proof with the $n \times (t+1)$ matrix $\boldsymbol{B}_t$, whose ith column may be written as

$$
\begin{aligned}
(\boldsymbol{B}_t)_i &= \int_{\mathcal{Z}} d\boldsymbol{z}\boldsymbol{g}(\boldsymbol{z};\boldsymbol{\theta})k(\boldsymbol{z},\boldsymbol{z}_i) = \int_{\mathcal{Z}} d\boldsymbol{z}\pi^\mu(\boldsymbol{z})\nabla\log\mu(a|x;\boldsymbol{\theta})\Big(k_x(x,x_i) + k_F(\boldsymbol{z},\boldsymbol{z}_i)\Big) \\
&= \int_{\mathcal{Z}} d\boldsymbol{z}\pi^\mu(\boldsymbol{z})\nabla\log\mu(a|x;\boldsymbol{\theta})k_x(x,x_i) + \int_{\mathcal{Z}} d\boldsymbol{z}\pi^\mu(\boldsymbol{z})\nabla\log\mu(a|x;\boldsymbol{\theta})k_F(\boldsymbol{z},\boldsymbol{z}_i) \\
&= \int_{\mathcal{X}} dx\nu^\mu(x)k_x(x,x_i)\int_{\mathcal{A}} da\mu(a|x;\boldsymbol{\theta})\nabla\log\mu(a|x;\boldsymbol{\theta}) + \int_{\mathcal{Z}} d\boldsymbol{z}\pi^\mu(\boldsymbol{z})\boldsymbol{u}(\boldsymbol{z})\boldsymbol{u}(\boldsymbol{z})^\top\boldsymbol{G}^{-1}\boldsymbol{u}(\boldsymbol{z}_i) \\
&= \int_{\mathcal{X}} dx\nu^\mu(x)k_x(x,x_i)\int_{\mathcal{A}} da\nabla\mu(a|x;\boldsymbol{\theta}) + \left(\int_{\mathcal{Z}} d\boldsymbol{z}\pi^\mu(\boldsymbol{z})\boldsymbol{u}(\boldsymbol{z})\boldsymbol{u}(\boldsymbol{z})^\top\right)\boldsymbol{G}^{-1}\boldsymbol{u}(\boldsymbol{z}_i) \\
&= \int_{\mathcal{X}} dx\nu^\mu(x)k_x(x,x_i)\nabla\left(\int_{\mathcal{A}} da\mu(a|x;\boldsymbol{\theta})\right) + \boldsymbol{G}\boldsymbol{G}^{-1}\boldsymbol{u}(\boldsymbol{z}_i) \\
&= \int_{\mathcal{X}} dx\nu^\mu(x)k_x(x,x_i)\nabla(1) + \boldsymbol{u}(\boldsymbol{z}_i) = \boldsymbol{u}(\boldsymbol{z}_i)
\end{aligned}
$$

The 1st line follows from the definition of matrix $\boldsymbol{B}_t$, function $\boldsymbol{g}$, and kernel k, the 2nd line is algebra, the 3rd line follows from the definition of π^μ and the Fisher kernel k_F, the 4th line is algebra, the 5th line is the result of replacing the integral in the parentheses with the Fisher information matrix $\boldsymbol{G}$, finally the 6th line is algebra, and the claim follows.

Now the proof for the $n \times n$ matrix $\boldsymbol{B}_0$

$$
\begin{aligned}
\boldsymbol{B}_0 &= \int_{\mathcal{Z}^2} d\boldsymbol{z} d\boldsymbol{z}' \boldsymbol{g}(\boldsymbol{z};\boldsymbol{\theta}) k(\boldsymbol{z},\boldsymbol{z}') \boldsymbol{g}(\boldsymbol{z}';\boldsymbol{\theta})^\top \\
&\overset{\text{(a)}}{=} \int_{\mathcal{Z}^2} d\boldsymbol{z} d\boldsymbol{z}' \pi^\mu(\boldsymbol{z}) \nabla \log \mu(a|x;\boldsymbol{\theta}) \Big(k_x(x,x') + k_F(\boldsymbol{z},\boldsymbol{z}') \Big) \nabla \log \mu(a'|x';\boldsymbol{\theta})^\top \pi^\mu(\boldsymbol{z}') \\
&\overset{\text{(b)}}{=} \int_{\mathcal{Z}^2} d\boldsymbol{z} d\boldsymbol{z}' \pi^\mu(\boldsymbol{z}) \nabla \log \mu(a|x;\boldsymbol{\theta}) k_x(x,x') \nabla \log \mu(a'|x';\boldsymbol{\theta})^\top \pi^\mu(\boldsymbol{z}') \\
&+ \int_{\mathcal{Z}^2} d\boldsymbol{z} d\boldsymbol{z}' \pi^\mu(\boldsymbol{z}) \nabla \log \mu(a|x;\boldsymbol{\theta}) k_F(\boldsymbol{z},\boldsymbol{z}') \nabla \log \mu(a'|x';\boldsymbol{\theta})^\top \pi^\mu(\boldsymbol{z}') \\
&\overset{\text{(c)}}{=} \int_{\mathcal{X}^2} dx dx' \nu^\mu(x) \nu^\mu(x') k_x(x,x') \int_{\mathcal{A}^2} da da' \mu(a|x;\boldsymbol{\theta}) \nabla \log \mu(a|x;\boldsymbol{\theta}) \nabla \log \mu(a'|x';\boldsymbol{\theta})^\top \mu(a'|x';\boldsymbol{\theta}) \\
&+ \int_{\mathcal{Z}^2} d\boldsymbol{z} d\boldsymbol{z}' \pi^\mu(\boldsymbol{z}) \boldsymbol{u}(\boldsymbol{z}) \boldsymbol{u}(\boldsymbol{z})^\top \boldsymbol{G}^{-1} \boldsymbol{u}(\boldsymbol{z}') \boldsymbol{u}(\boldsymbol{z}')^\top \pi^\mu(\boldsymbol{z}') \\
&\overset{\text{(d)}}{=} \int_{\mathcal{X}^2} dx dx' \nu^\mu(x) \nu^\mu(x') k_x(x,x') \int_{\mathcal{A}} da \nabla \mu(a|x;\boldsymbol{\theta}) \int_{\mathcal{A}} da' \nabla \mu(a'|x';\boldsymbol{\theta})^\top \\
&+ \left(\int_{\mathcal{Z}} d\boldsymbol{z} \pi^\mu(\boldsymbol{z}) \boldsymbol{u}(\boldsymbol{z}) \boldsymbol{u}(\boldsymbol{z})^\top \right) \boldsymbol{G}^{-1} \left(\int_{\mathcal{Z}} d\boldsymbol{z}' \pi^\mu(\boldsymbol{z}') \boldsymbol{u}(\boldsymbol{z}') \boldsymbol{u}(\boldsymbol{z}')^\top \right) = \boldsymbol{G} \boldsymbol{G}^{-1} \boldsymbol{G} = \boldsymbol{G}
\end{aligned}
$$

(a) follows from the definition of function $\boldsymbol{g}$ and kernel k, **(b)** is algebra, **(c)** follows from the definition of π^μ and the Fisher kernel k_F, **(c)** is algebra, finally **(d)** follows from $\int_{\mathcal{A}} da \nabla \mu(a|x;\boldsymbol{\theta}) = 0$ and $\boldsymbol{G} = \int_{\mathcal{Z}} d\boldsymbol{z} \pi^\mu(\boldsymbol{z}) \boldsymbol{u}(\boldsymbol{z}) \boldsymbol{u}(\boldsymbol{z})^\top$, and the claim follows.

Abstract

Kernel-based reinforcement learning (KBRL) stands out among approximate reinforcement learning algorithms for its strong theoretical guarantees. By casting the learning problem as a local kernel approximation, KBRL provides a way of computing a decision policy which converges to a unique solution and is statistically consistent. Unfortunately, the model constructed by KBRL grows with the number of sample transitions, resulting in a computational cost that precludes its application to large-scale or on-line domains. In this paper we introduce an algorithm that turns KBRL into a practical reinforcement learning tool. *Kernel-based stochastic factorization* (KBSF) builds on a simple idea: when a transition probability matrix is represented as the product of two stochastic matrices, one can swap the factors of the multiplication to obtain another transition matrix, potentially much smaller than the original, which retains some fundamental properties of its precursor. KBSF exploits such an insight to compress the information contained in KBRL's model into an approximator of fixed size. This makes it possible to build an approximation considering both the difficulty of the problem and the associated computational cost. KBSF's computational complexity is linear in the number of sample transitions, which is the best one can do without discarding data. Moreover, the algorithm's simple mechanics allow for a fully incremental implementation that makes the amount of memory used independent of the number of sample transitions. The result is a kernel-based reinforcement learning algorithm that can be applied to large-scale problems in both off-line and on-line regimes. We derive upper bounds for the distance between the value functions computed by KBRL and KBSF using the same data. We also prove that it is possible to control the magnitude of the variables appearing in our bounds, which means that, given enough computational resources, we can make KBSF's value function as close as desired to the value function that would be computed by KBRL using the same set of sample transitions. The potential of our algorithm is demonstrated in an extensive empirical study in which KBSF is applied to difficult tasks based on real-world data. Not only does KBSF solve problems that had never been solved before, but it also significantly outperforms other state-of-the-art reinforcement learning algorithms on the tasks studied.

Keywords: reinforcement learning, dynamic programming, Markov decision processes, kernel-based approximation, stochastic factorization

1. Introduction

Reinforcement learning provides a conceptual framework with the potential to materialize a long-sought goal in artificial intelligence: the construction of situated agents that learn how to behave from direct interaction with the environment (Sutton and Barto, 1998). But such an endeavor does not come without its challenges; among them, extrapolating the field's basic machinery to large-scale domains has been a particularly persistent obstacle.

It has long been recognized that virtually any real-world application of reinforcement learning must involve some form of approximation. Given the mature stage of the supervised-learning theory, and considering the multitude of approximation techniques available today, this realization may not come across as a particularly worrisome issue at first glance. However, it is well known that the sequential nature of the reinforcement learning problem renders the incorporation of function approximators non-trivial (Bertsekas and Tsitsiklis, 1996).

Despite the difficulties, in the last two decades the collective effort of the reinforcement learning community has given rise to many reliable approximate algorithms (Szepesvári, 2010). Among them, Ormoneit and Sen's (2002) kernel-based reinforcement learning (KBRL) stands out for two reasons. First, unlike other approximation schemes, KBRL always converges to a unique solution. Second, KBRL is consistent in the statistical sense, meaning that adding more data improves the quality of the resulting policy and eventually leads to optimal performance.

Unfortunately, the good theoretical properties of KBRL come at a price: since the model constructed by this algorithm grows with the number of sample transitions, the cost of computing a decision policy quickly becomes prohibitive as more data become available. Such a computational burden severely limits the applicability of KBRL. This may help explain why, in spite of its nice theoretical guarantees, kernel-based learning has not been widely adopted as a practical reinforcement learning tool.

This paper presents an algorithm that can potentially change this situation. *Kernel-based stochastic factorization* (KBSF) builds on a simple idea: when a transition probability matrix is represented as the product of two stochastic matrices, one can swap the factors of the multiplication to obtain another transition matrix, potentially much smaller than the original, which retains some fundamental properties of its precursor (Barreto and Fragoso, 2011). KBSF exploits this insight to compress the information contained in KBRL's model into an approximator of fixed size. Specifically, KBSF builds a model, whose size is independent of the number of sample transitions, which serves as an approximation of the model that would be constructed by KBRL. Since the size of the model becomes a parameter of the algorithm, KBSF essentially detaches the structure of KBRL's approximator from its configuration. This extra flexibility makes it possible to build an approximation that takes into account *both* the difficulty of the problem *and* the computational cost of finding a policy using the constructed model.

KBSF's computational complexity is linear in the number of sample transitions, which is the best one can do without throwing data away. Moreover, we show in the paper that the amount of memory used by our algorithm is independent of the number of sample transitions. Put together, these two properties make it possible to apply KBSF to large-scale problems in both off-line and on-line regimes. To illustrate this possibility in practice,

we present an extensive empirical study in which KBSF is applied to difficult control tasks based on real-world data, some of which had never been solved before. KBSF outperforms least-squares policy iteration and fitted Q-iteration on several off-line problems and SARSA on a difficult on-line task.

We also show that KBSF is a sound algorithm from a theoretical point of view. Specifically, we derive results bounding the distance between the value function computed by our algorithm and the one computed by KBRL using the same data. We also prove that it is possible to control the magnitude of the variables appearing in our bounds, which means that we can make the difference between KBSF's and KBRL's solutions arbitrarily small.

We start the paper presenting some background material in Section 2. Then, in Section 3, we introduce the stochastic-factorization trick, the insight underlying the development of our algorithm. KBSF itself is presented in Section 4. This section is divided in two parts, one theoretical and one practical. In Section 4.1 we present theoretical results showing that not only is the difference between KBSF's and KBRL's value functions bounded, but it can also be controlled. Section 4.2 brings experiments with KBSF on four reinforcement-learning problems: single and double pole-balancing, HIV drug schedule domain, and epilepsy suppression task. In Section 5 we introduce the incremental version of our algorithm, which can be applied to on-line problems. This section follows the same structure of Section 4, with theoretical results followed by experiments. Specifically, in Section 5.1 we extend the results of Section 4.1 to the on-line scenario, and in Section 5.2 we present experiments on the triple pole-balancing and helicopter tasks. In Section 6 we take a closer look at the approximation computed by KBSF and present a practical guide on how to configure our algorithm to solve a reinforcement learning problem. In Section 7 we summarize related works and situate KBSF in the context of kernel-based learning. Finally, in Section 8 we present the main conclusions regarding the current research and discuss some possibilities of future work.

The paper has three appendices. Appendix A has the proofs of our theoretical results. The details of the experiments that were omitted in the main body of the text are described in Appendix B. In Appendix C we provide a table with the main symbols used in the paper that can be used as a reference to facilitate reading.

Parts of the material presented in this article have appeared before in two papers published in the *Neural Information Processing Systems* conference (NIPS, Barreto et al., 2011, 2012). The current manuscript is a substantial extension of the aforementioned works.

2. Background

We consider the standard framework of reinforcement learning, in which an *agent* interacts with an *environment* and tries to maximize the amount of *reward* collected in the long run (Sutton and Barto, 1998). The interaction between agent and environment happens at discrete time steps: at each instant t the agent occupies a state $s_{(t)} \in S$ and must choose an action a from a finite set A. The sets S and A are called the *state* and *action spaces*, respectively. The execution of action a in state $s_{(t)}$ moves the agent to a new state $s_{(t+1)}$, where a new action must be selected, and so on. Each transition has a certain probability of occurrence and is associated with a reward $r \in \mathbb{R}$. The goal of the agent is to find a *policy* $\pi : S \mapsto A$, that is, a mapping from states to actions, that maximizes the expected

return. Here we define the *return* from time t as:

$$R_{(t)} = r_{(t+1)} + \gamma r_{(t+2)} + \gamma^2 r_{(t+3)} + ... = \sum_{i=1}^{T} \gamma^{i-1} r_{(t+i)}, \quad (1)$$

where $r_{(t+1)}$ is the reward received at the transition from state $s_{(t)}$ to state $s_{(t+1)}$. The interaction of the agent with the environment may last forever ($T = \infty$) or until the agent reaches a terminal state ($T < \infty$); each sequence of interactions is usually referred to as an *episode*. The parameter $\gamma \in [0, 1)$ is the *discount factor*, which determines the relative importance of individual rewards depending on how far in the future they are received.

2.1 Markov Decision Processes

As usual, we assume that the interaction between agent and environment can be modeled as a *Markov decision process* (MDP, Puterman, 1994). An MDP is a tuple $M \equiv (S, A, P^a, R^a, \gamma)$, where P^a and R^a describe the dynamics of the task at hand. For each action $a \in A$, $P^a(\cdot|s)$ defines the next-state distribution upon taking action a in state s. The reward received at transition $s \xrightarrow{a} s'$ is given by $R^a(s, s')$, with $|R^a(s, s')| \leq R_{\max} < \infty$. Usually, one is interested in the expected reward resulting from the execution of action a in state s, that is, $r^a(s) = E_{s' \sim P^a(\cdot|s)}\{R^a(s, s')\}$.

Once the interaction between agent and environment has been modeled as an MDP, a natural way of searching for an optimal policy is to resort to *dynamic programming* (Bellman, 1957). Central to the theory of dynamic-programming is the concept of a *value function*. The value of state s under a policy π, denoted by $V^\pi(s)$, is the expected return the agent will receive from s when following π, that is, $V^\pi(s) = E_\pi\{R_{(t)}|s_{(t)} = s\}$ (here the expectation is over all possible sequences of rewards in (1) when the agent follows π). Similarly, the value of the state-action pair (s, a) under policy π is defined as $Q^\pi(s, a) = E_{s' \sim P^a(\cdot|s)}\{R^a(s, s') + \gamma V^\pi(s')\} = r^a(s) + \gamma E_{s' \sim P^a(\cdot|s)}\{V^\pi(s')\}$.

The notion of value function makes it possible to impose a partial ordering over decision policies. In particular, a policy π' is considered to be at least as good as another policy π if $V^{\pi'}(s) \geq V^\pi(s)$ for all $s \in S$. The goal of dynamic programming is to find an optimal policy π^* that performs no worse than any other. It is well known that there always exists at least one such policy for a given MDP (Puterman, 1994). When there is more than one optimal policy, they all share the same value function V^*.

When both the state and action spaces are finite, an MDP can be represented in matrix form: each function P^a becomes a matrix $\mathbf{P}^a \in \mathbb{R}^{|S| \times |S|}$, with $p^a_{ij} = P^a(s_j|s_i)$, and each function r^a becomes a vector $\mathbf{r}^a \in \mathbb{R}^{|S|}$, where $r^a_i = r^a(s_i)$. Similarly, V^π can be represented as a vector $\mathbf{v}^\pi \in \mathbb{R}^{|S|}$ and Q^π can be seen as a matrix $\mathbf{Q}^\pi \in \mathbb{R}^{|S| \times |A|}$. [1]

When the MDP is finite, dynamic programming can be used to find an optimal decision-policy $\pi^* \in A^{|S|}$ in time polynomial in the number of states $|S|$ and actions $|A|$ (Ye, 2011).

1. Throughout the paper we will use the conventional and matrix notations interchangeably, depending on the context. When using the latter, vectors will be denoted by small boldface letters and matrices will be denoted by capital boldface letters. We will also use the same notation for all MDPs and associated components, distinguishing between them through the use of math accents. So, for example, if $\bar{M}$ is an MDP, its transition functions and matrices will be referred to as $\bar{P}^a$ and $\bar{\mathbf{P}}^a$, its expect-reward functions and vectors will be denoted by $\bar{r}^a$ and $\bar{\mathbf{r}}^a$, its optimal decision policy will be $\bar{\pi}^*$, and so on (see Table 2).

Let $\mathbf{v} \in \mathbb{R}^{|S|}$ and let $\mathbf{Q} \in \mathbb{R}^{|S|\times|A|}$. Define the operator $\Gamma : \mathbb{R}^{|S|\times|A|} \mapsto \mathbb{R}^{|S|}$ such that $\Gamma\mathbf{Q} = \mathbf{v}$ if and only if $v_i = \max_j q_{ij}$ for all i. Also, given an MDP M, define $\Delta : \mathbb{R}^{|S|} \mapsto \mathbb{R}^{|S|\times|A|}$ such that $\Delta\mathbf{v} = \mathbf{Q}$ if and only if $q_{ia} = r_i^a + \gamma \sum_{j=1}^{|S|} p_{ij}^a v_j$ for all i and all a. The *Bellman operator* of the MDP M is given by $T \equiv \Gamma\Delta$. A fundamental result in dynamic programming states that, starting from $\mathbf{v}^{(0)} = \mathbf{0}$, the expression $\mathbf{v}^{(t)} = T\mathbf{v}^{(t-1)} = \Gamma\mathbf{Q}^{(t)}$ gives the optimal t-step value function, and as $t \to \infty$ the vector $\mathbf{v}^{(t)}$ approaches $\mathbf{v}^*$. At any point, the optimal t-step policy can be obtained by selecting $\pi_i^{(t)} \in \text{argmax}_j\, q_{ij}^{(t)}$ (Puterman, 1994).

In contrast with dynamic programming, in reinforcement learning it is assumed that the MDP is unknown, and the agent must learn a policy based on transitions sampled from the environment. If the process of learning a decision policy is based on a fixed set of sample transitions, we call it *batch* reinforcement learning. On the other hand, in *on-line* reinforcement learning the computation of a decision policy takes place concomitantly with the collection of data (Sutton and Barto, 1998).

2.2 Kernel-Based Reinforcement Learning

Kernel-based reinforcement learning (KBRL) is a batch algorithm that uses a finite model approximation to solve a continuous MDP $M \equiv (\mathbb{S}, A, P^a, R^a, \gamma)$, where $\mathbb{S} \subseteq [0,1]^{d_\mathbb{S}}$ and $d_\mathbb{S} \in \mathbb{N}_*^+$ is the dimension of the state space (Ormoneit and Sen, 2002). Let $S^a \equiv \{(s_k^a, r_k^a, \hat{s}_k^a) | k = 1, 2, ..., n_a\}$ be sample transitions associated with action $a \in A$, where $s_k^a, \hat{s}_k^a \in \mathbb{S}$ and $r_k^a \in \mathbb{R}$. Let $\phi : \mathbb{R}^+ \mapsto \mathbb{R}^+$ be a Lipschitz continuous function satisfying $\int_0^1 \phi(x)dx = 1$. Let $\mathrm{k}_\tau(s, s')$ be a kernel function defined as

$$\mathrm{k}_\tau(s, s') = \phi\left(\frac{\|s - s'\|}{\tau}\right), \tag{2}$$

where $\tau \in \mathbb{R}$ and $\|\cdot\|$ is a norm in $\mathbb{R}^{d_\mathbb{S}}$ (for concreteness, the reader may think of $\mathrm{k}_\tau(s, s')$ as the Gaussian kernel, although the definition also encompasses other functions). Finally, define the normalized kernel function associated with action a as

$$\kappa_\tau^a(s, s_i^a) = \frac{\mathrm{k}_\tau(s, s_i^a)}{\sum_{j=1}^{n_a} \mathrm{k}_\tau(s, s_j^a)}. \tag{3}$$

KBRL uses (3) to build a finite MDP whose state space $\hat{S}$ is composed solely of the $n = \sum_a n_a$ states $\hat{s}_i^a$. We assume without loss of generality that the action space A is ordered and the sampled states are ordered lexicographically as $\hat{s}_i^a < \hat{s}_j^b \iff a < b$ or $(a = b$ and $i < j)$; if a given state $s \in \mathbb{S}$ occurs more than once in the set of sample transitions, each occurrence will be treated as a distinct state in the finite MDP. The transition functions of KBRL's model, $\hat{P}^a : \hat{S} \times \hat{S} \mapsto [0, 1]$, are given by:

$$\hat{P}^a\left(\hat{s}_i^b | s\right) = \begin{cases} \kappa_\tau^a(s, s_i^b), & \text{if } a = b, \\ 0, & \text{otherwise,} \end{cases} \tag{4}$$

where $a, b \in A$. Similarly, the reward functions of the MDP constructed by KBRL, $\hat{R}^a : \hat{S} \times \hat{S} \mapsto \mathbb{R}$, are

$$\hat{R}^a(s, \hat{s}_i^b) = \begin{cases} r_i^a, & \text{if } a = b, \\ 0, & \text{otherwise.} \end{cases} \tag{5}$$

Based on (4) and (5) we can define the transition matrices and expected-reward vectors of KBRL's MDP. The matrices $\hat{\mathbf{P}}^a$ are derived directly from the definition of $\hat{P}^a(\hat{s}_i^b|s)$, replacing s with the sampled states $\hat{s}_i^a$ (see Figure 2a). The vectors $\hat{\mathbf{r}}^a$ are computed as follows. Let $\mathbf{r} \equiv [(\mathbf{r}^1)^\intercal, (\mathbf{r}^2)^\intercal, ..., (\mathbf{r}^{|A|})^\intercal]^\intercal \in \mathbb{R}^n$, where $\mathbf{r}^a \in \mathbb{R}^{n_a}$ are the vectors composed of the sample rewards, that is, the i^{th} element of $\mathbf{r}^a$ is $r_i^a \in S^a$. Since $R^a(s, \hat{s}_i^b)$ does not depend on the start state s, we can write

$$\hat{\mathbf{r}}^a = \hat{\mathbf{P}}^a\mathbf{r}. \tag{6}$$

KBRL's MDP is thus given by $\hat{M} \equiv (\hat{S}, A, \hat{\mathbf{P}}^a, \hat{\mathbf{r}}^a, \gamma)$.

Once $\hat{M}$ has been defined, one can use dynamic programming to compute its optimal value function $\hat{V}^*$. Then, the value of any state-action pair of the continuous MDP can be determined as:

$$\hat{Q}(s, a) = \sum_{i=1}^{n_a} \kappa_\tau^a(s, s_i^a)\left[r_i^a + \gamma\hat{V}^*(\hat{s}_i^a)\right], \tag{7}$$

where $s \in \mathbb{S}$ and $a \in A$. Ormoneit and Sen (2002) have shown that, if $n_a \to \infty$ for all $a \in A$ and the kernel's width τ shrink at an "admissible" rate, the probability of choosing a suboptimal action based on $\hat{Q}(s, a)$ converges to zero (see their Theorem 4).

As discussed, using dynamic programming one can compute the optimal value function of $\hat{M}$ in time polynomial in the number of sample transitions n (which is also the number of states in $\hat{M}$). However, since each application of the Bellman operator $\hat{T}$ is $O(n^2|A|)$, the computational cost of such a procedure can easily become prohibitive in practice. Thus, the use of KBRL leads to a dilemma: on the one hand one wants as much data as possible to describe the dynamics of the task, but on the other hand the number of transitions should be small enough to allow for the numerical solution of the resulting model. In the following sections we describe a practical approach to weigh the relative importance of these two conflicting objectives.

3. Stochastic Factorization

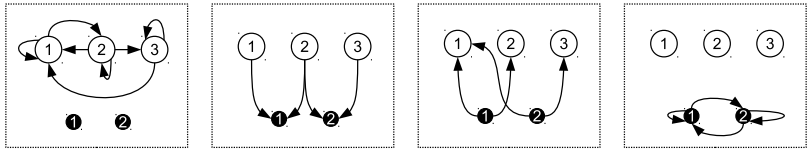
A *stochastic matrix* has only nonnegative elements and each of its rows sums to 1. That said, we can introduce the concept that will serve as a cornerstone for the rest of the paper:

Definition 1 *Given a stochastic matrix $\mathbf{P} \in \mathbb{R}^{n\times p}$, the relation $\mathbf{P} = \mathbf{DK}$ is called a* stochastic factorization *of $\mathbf{P}$ if $\mathbf{D} \in \mathbb{R}^{n\times m}$ and $\mathbf{K} \in \mathbb{R}^{m\times p}$ are also stochastic matrices. The integer $m > 0$ is the* order *of the factorization.*

This mathematical construct has been explored before. For example, Cohen and Rothblum (1991) briefly discuss it as a special case of nonnegative matrix factorization, while Cutler and Breiman (1994) study slightly modified versions of stochastic factorization for statistical data analysis. However, in this paper we will focus on a useful property of this type of factorization that has only recently been noted (Barreto and Fragoso, 2011).

3.1 Stochastic-Factorization Trick

Let $\mathbf{P} \in \mathbb{R}^{n\times n}$ be a transition matrix, that is, a square stochastic matrix, and let $\mathbf{P} = \mathbf{DK}$ be an order m stochastic factorization. In this case, one can see the elements of



$$\mathbf{P} = \begin{bmatrix} \times & \times & 0 \\ \times & \times & \times \\ \times & 0 & \times \end{bmatrix} \quad \mathbf{D} = \begin{bmatrix} \times & 0 \\ \times & \times \\ 0 & \times \end{bmatrix} \quad \mathbf{K} = \begin{bmatrix} \times & \times & 0 \\ \times & 0 & \times \end{bmatrix} \quad \bar{\mathbf{P}} = \begin{bmatrix} \times & \times \\ \times & \times \end{bmatrix}$$

Figure 1: Reducing the dimension of a transition model from $n = 3$ states to $m = 2$ artificial states. Original states s_i are represented as big white circles; small black circles depict artificial states $\bar{s}_h$. The symbol '$\times$' is used to represent nonzero elements. These figures have appeared before in the article by Barreto and Fragoso (2011).

$\mathbf{D}$ and $\mathbf{K}$ as probabilities of transitions between the states s_i and a set of m artificial states $\bar{s}_h$. Specifically, the elements in each row of $\mathbf{D}$ can be interpreted as probabilities of transitions from the original states to the artificial states, while the rows of $\mathbf{K}$ can be seen as probabilities of transitions in the opposite direction. Under this interpretation, each element $p_{ij} = \sum_{h=1}^{m} d_{ih}k_{hj}$ is the sum of the probabilities associated with m two-step transitions: from state s_i to each artificial state $\bar{s}_h$ and from these back to state s_j. In other words, p_{ij} is the accumulated probability of all possible paths from s_i to s_j with a stopover in one of the artificial states $\bar{s}_h$. Following similar reasoning, it is not difficult to see that by *swapping* the factors of a stochastic factorization, that is, by switching from $\mathbf{DK}$ to $\mathbf{KD}$, one obtains the transition probabilities between the artificial states $\bar{s}_h$, $\bar{\mathbf{P}} = \mathbf{KD}$. If $m < n$, $\bar{\mathbf{P}} \in \mathbb{R}^{m \times m}$ will be a compact version of $\mathbf{P}$. Figure 1 illustrates this idea for the case in which $n = 3$ and $m = 2$.

The stochasticity of $\bar{\mathbf{P}}$ follows immediately from the same property of $\mathbf{D}$ and $\mathbf{K}$. What is perhaps more surprising is the fact that this matrix shares some fundamental characteristics with the original matrix $\mathbf{P}$. Specifically, it is possible to show that: (*i*) for each recurrent class in $\mathbf{P}$ there is a corresponding class in $\bar{\mathbf{P}}$ with the same period and, given some simple assumptions about the factorization, (*ii*) $\mathbf{P}$ is irreducible if and only if $\bar{\mathbf{P}}$ is irreducible and (*iii*) $\mathbf{P}$ is regular if and only if $\bar{\mathbf{P}}$ is regular (for details, see the article by Barreto and Fragoso, 2011). We will refer to this insight as the "*stochastic-factorization trick*":

Given a stochastic factorization of a transition matrix, $\mathbf{P} = \mathbf{DK}$, swapping *the factors of the factorization yields another transition matrix* $\bar{\mathbf{P}} = \mathbf{KD}$, *potentially much smaller than the original, which retains the basic topology and properties of* $\mathbf{P}$.

Given the strong connection between $\mathbf{P} \in \mathbb{R}^{n \times n}$ and $\bar{\mathbf{P}} \in \mathbb{R}^{m \times m}$, the idea of replacing the former by the latter comes almost inevitably. The motivation for this would be, of course, to save computational resources when $m < n$. For example, Barreto and Fragoso

(2011) have shown that it is possible to recover the stationary distribution of $\mathbf{P}$ through a linear transformation of the corresponding distribution of $\bar{\mathbf{P}}$. In this paper we will use the stochastic-factorization trick to reduce the computational cost of KBRL. The strategy will be to summarize the information contained in KBRL's MDP in a model of fixed size.

3.2 Reducing a Markov Decision Process

The idea of using stochastic factorization to reduce dynamic programming's computational requirements is straightforward: given factorizations of the transition matrices $\mathbf{P}^a$, we can apply our trick to obtain a reduced MDP that will be solved in place of the original one. In the most general scenario, we would have one independent factorization $\mathbf{P}^a = \mathbf{D}^a\mathbf{K}^a$ for each action $a \in A$ and then use $\bar{\mathbf{P}}^a = \mathbf{K}^a\mathbf{D}^a$ instead of $\mathbf{P}^a$. However, in the current work we will focus on the particular case in which there is a single matrix $\mathbf{D}$, which will prove to be convenient both mathematically and computationally.

Obviously, in order to apply the stochastic-factorization trick to an MDP, we have to first *compute* the matrices involved in the factorization. Unfortunately, such a procedure can be computationally demanding, exceeding the number of operations necessary to calculate $\mathbf{v}^*$ (Vavasis, 2009; Barreto et al., 2014). Thus, in practice we may have to replace the exact factorizations $\mathbf{P}^a = \mathbf{DK}^a$ with approximations $\mathbf{P}^a \approx \mathbf{DK}^a$. The following proposition bounds the error in the value-function approximation resulting from the application of our trick to approximate stochastic factorizations:

Proposition 2 *Let* $M \equiv (S, A, \mathbf{P}^a, \mathbf{r}^a, \gamma)$ *be a finite MDP with* $|S| = n$ *and* $0 \leq \gamma < 1$. *Let* $\mathbf{D} \in \mathbb{R}^{n \times m}$ *be a stochastic matrix and, for each* $a \in A$, *let* $\mathbf{K}^a \in \mathbb{R}^{m \times n}$ *be stochastic and let* $\bar{\mathbf{r}}^a$ *be a vector in* $\mathbb{R}^m$. *Define the MDP* $\bar{M} \equiv (\bar{S}, A, \bar{\mathbf{P}}^a, \bar{\mathbf{r}}^a, \gamma)$, *with* $|\bar{S}| = m$ *and* $\bar{\mathbf{P}}^a = \mathbf{K}^a\mathbf{D}$. *Then,*

$$\left\|\mathbf{v}^* - \Gamma\mathbf{D}\bar{\mathbf{Q}}^*\right\|_\infty \leq \xi_v \equiv \frac{1}{1-\gamma}\max_a \|\mathbf{r}^a - \mathbf{D}\bar{\mathbf{r}}^a\|_\infty + \frac{\bar{R}_{\text{dif}}}{(1-\gamma)^2}\left(\frac{\gamma}{2}\max_a \|\mathbf{P}^a - \mathbf{DK}^a\|_\infty + \sigma(\mathbf{D})\right), \quad (8)$$

where

$$\sigma(\mathbf{D}) = \max_i (1 - \max_j d_{ij}), \quad (9)$$

$\|\cdot\|_\infty$ *is the maximum norm, and* $\bar{R}_{\text{dif}} = \max_{a,i} \bar{r}_i^a - \min_{a,i} \bar{r}_i^a$.[2]

The proofs of most of our theoretical results are in Appendix A.1. We note that Proposition 2 is only valid for the maximum norm; in Appendix A.2 we derive another bound for the distance between $\mathbf{v}^*$ and $\Gamma\mathbf{D}\bar{\mathbf{Q}}^*$ which is valid for any norm.

Our bound depends on two factors: the quality of the MDP's factorization, given by $\max_a \|\mathbf{P}^a - \mathbf{DK}^a\|_\infty$ and $\max_a \|\mathbf{r}^a - \mathbf{D}\bar{\mathbf{r}}^a\|_\infty$, and the "level of stochasticity" of $\mathbf{D}$, measured by $\sigma(\mathbf{D})$. When the MDP factorization is exact, we recover a computable version of Sorg and Singh's (2009) bound for soft homomorphisms (see (32)). On the other hand, when $\mathbf{D}$ is deterministic—that is, when all its nonzero elements are 1—expression (8) reduces to Whitt's (1978) classical result regarding state aggregation in dynamic programming. Finally, if we have exact deterministic factorizations, the right-hand side of (8) reduces to

2. We recall that $\|\cdot\|_\infty$ induces the following norm over the space of matrices: $\|\mathbf{A}\|_\infty = \max_i \sum_j |a_{ij}|$.

zero. This also makes sense, since in this case the stochastic-factorization trick gives rise to an exact homomorphism (Ravindran, 2004).

Proposition 2 elucidates the basic mechanism through which one can use the stochastic-factorization trick to reduce the number of states in an MDP (and hence the computational cost of finding a policy using dynamic programming). One possible way to exploit this result is to see the computation of $\mathbf{D}$, $\mathbf{K}^a$, and $\bar{\mathbf{r}}^a$ as an optimization problem in which the objective is to minimize some function of $\max_a \|\mathbf{P}^a - \mathbf{D}\mathbf{K}^a\|_\infty$, $\max_a \|\mathbf{r}^a - \mathbf{D}\bar{\mathbf{r}}^a\|_\infty$, and possibly also $\sigma(\mathbf{D})$ (Barreto et al., 2014). Note though that addressing the factorization problem as an optimization may be computationally infeasible when the dimension of the matrices $\mathbf{P}^a$ is large—which is exactly the case we are interested in here. To illustrate this point, we will draw a connection between the stochastic factorization and a popular problem known in the literature as *nonnegative matrix factorization* (Paatero and Tapper, 1994; Lee and Seung, 1999).

In a nonnegative matrix factorization the elements of $\mathbf{D}$ and $\mathbf{K}^a$ are greater or equal to zero, but in general no stochasticity constraint is imposed. Cohen and Rothblum (1991) have shown that it is always possible to derive a stochastic factorization from a nonnegative factorization of a stochastic matrix, which formally characterizes the former as a particular case of the latter. Unfortunately, nonnegative factorization is hard: Vavasis (2009) has shown that a particular version of the problem is in fact NP-hard.

Instead of solving the problem exactly, one can resort instead to an approximate nonnegative matrix factorization. However, since the number of states n in an MDP determines both the number of rows and the number of columns of the matrices $\mathbf{P}^a$, even the fast "linear" approximate methods run in $O(n^2)$ time, which is infeasible for large n (Barreto et al., 2014). One can circumvent this computational obstacle by exploiting structure in the optimization problem or by resorting to heuristics. In another article on the subject we explore both these alternatives at length (Barreto et al., 2014). However, in this paper we adopt a different approach. Since the model $\hat{M}$ built by KBRL is itself an approximation, instead of insisting in finding a near-optimal factorization for $\hat{M}$ we apply our trick to *avoid* the construction of $\mathbf{P}^a$ and $\mathbf{r}^a$. As will be seen, this is done by applying KBRL's own approximation scheme to $\hat{M}$.

4. Kernel-Based Stochastic Factorization

In Section 2 we presented KBRL, an approximation framework for reinforcement learning whose main drawback is its high computational complexity. In Section 3 we discussed how the stochastic-factorization trick can in principle be useful to reduce an MDP, as long as one circumvents the computational burden imposed by the calculation of the matrices involved in the process. We now show that by combining these two approaches we get an algorithm that overcomes the computational limitations of its components. We call it *kernel-based stochastic factorization*, or KBSF for short.

KBSF emerges from the application of the stochastic-factorization trick to KBRL's MDP $\hat{M}$ (Barreto et al., 2011). Similarly to Ormoneit and Sen (2002), we start by defining a "mother kernel" $\bar{\phi}(x) : \mathbb{R}^+ \mapsto \mathbb{R}^+$. In Section 4.1 we list our assumptions regarding $\bar{\phi}$. Here, it suffices to note that, since our assumptions and Ormoneit and Sen's (2002) are not mutually exclusive, we can have $\phi \equiv \bar{\phi}$ (by using the Gaussian function in both

cases, for example). Let $\bar{S} \equiv \{\bar{s}_1, \bar{s}_2, ..., \bar{s}_m\}$ be a set of *representative states*. Analogously to (2) and (3), we define the kernel $\bar{\mathrm{k}}_{\bar{\tau}}(s, s') = \bar{\phi}(\|s - s'\|/\bar{\tau})$ and its normalized version $\bar{\kappa}_{\bar{\tau}}(s, \bar{s}_i) = \bar{\mathrm{k}}_{\bar{\tau}}(s, \bar{s}_i)/\sum_{j=1}^{m} \bar{\mathrm{k}}_{\bar{\tau}}(s, \bar{s}_j)$. We will use κ_τ^a to build matrices $\mathbf{K}^a$ and $\bar{\kappa}_{\bar{\tau}}$ to build matrix $\mathbf{D}$.

As shown in Figure 2a, KBRL's matrices $\hat{\mathbf{P}}^a$ have a very specific structure, since only transitions ending in states $\hat{s}_i^a \in S^a$ have a nonzero probability of occurrence. Suppose that we want to apply the stochastic-factorization trick to KBRL's MDP. Assuming that the matrices $\mathbf{K}^a$ have the same structure as $\hat{\mathbf{P}}^a$, when computing $\bar{\mathbf{P}}^a = \mathbf{K}^a\mathbf{D}$ we only have to look at the sub-matrices of $\mathbf{K}^a$ and $\mathbf{D}$ corresponding to the n_a nonzero columns of $\mathbf{K}^a$. We call these matrices $\dot{\mathbf{K}}^a \in \mathbb{R}^{m \times n_a}$ and $\dot{\mathbf{D}}^a \in \mathbb{R}^{n_a \times m}$. The strategy of KBSF is to fill out matrices $\dot{\mathbf{K}}^a$ and $\dot{\mathbf{D}}^a$ with elements

$$\dot{k}_{ij}^a = \kappa_\tau^a(\bar{s}_i, s_j^a) \quad \text{and} \quad \dot{d}_{ij}^a = \bar{\kappa}_{\bar{\tau}}(\hat{s}_i^a, \bar{s}_j). \tag{10}$$

Note that, based on $\dot{\mathbf{D}}^a$, one can easily recover $\mathbf{D}$ as $\mathbf{D}^\intercal \equiv [(\dot{\mathbf{D}}^1)^\intercal, (\dot{\mathbf{D}}^2)^\intercal, ...(\dot{\mathbf{D}}^{|A|})^\intercal] \in \mathbb{R}^{n \times m}$. Similarly, if we let $\mathbf{K} \equiv [\dot{\mathbf{K}}^1, \dot{\mathbf{K}}^2, ...\dot{\mathbf{K}}^{|A|}] \in \mathbb{R}^{m \times n}$, then $\mathbf{K}^a \in \mathbb{R}^{m \times n}$ is matrix $\mathbf{K}$ with all elements replaced by zeros except for those corresponding to matrix $\dot{\mathbf{K}}^a$(see Figures 2b and 2c for an illustration). It should be thus obvious that $\bar{\mathbf{P}}^a = \mathbf{K}^a\mathbf{D} = \dot{\mathbf{K}}^a\dot{\mathbf{D}}^a$.

In order to conclude the construction of KBSF's MDP, we have to define the vectors of expected rewards $\bar{\mathbf{r}}^a$. As shown in expression (5), the reward functions of KBRL's MDP, $\hat{R}^a(s, s')$, only depend on the ending state s'. Recalling the interpretation of the rows of $\mathbf{K}^a$ as transition probabilities from the representative states to the original ones, illustrated in Figure 1, it is clear that

$$\bar{\mathbf{r}}^a = \dot{\mathbf{K}}^a\mathbf{r}^a = \mathbf{K}^a\mathbf{r}. \tag{11}$$

Therefore, the formal specification of KBSF's MDP is given by $\bar{M} \equiv (\bar{S}, A, \dot{\mathbf{K}}^a\dot{\mathbf{D}}^a, \dot{\mathbf{K}}^a\mathbf{r}^a, \gamma) = (\bar{S}, A, \mathbf{K}^a\mathbf{D}^a, \mathbf{K}^a\mathbf{r}, \gamma) = (\bar{S}, A, \bar{\mathbf{P}}^a, \bar{\mathbf{r}}^a, \gamma)$.

As discussed in Section 2.2, KBRL's approximation scheme can be interpreted as the derivation of a finite MDP. In this case, the sample transitions define both the finite state space $\hat{S}$ and the model's transition and reward functions. This means that the state space and the dynamics of KBRL's model are inexorably linked: except maybe for degenerate cases, changing one also changes the other. By defining a set of representative states, KBSF decouples the MDP's structure from its particular instantiation. To see why this is so, note that, if we fix the representative states, different sets of sample transitions will give rise to different models. Conversely, the same set of transitions can generate different MDPs, depending on how the representative states are defined.

A step by step description of KBSF is given in Algorithm 1. As one can see, KBSF is very simple to understand and to implement. It works as follows: first, the MDP $\bar{M}$ is built as described above. Then, its action-value function $\bar{\mathbf{Q}}^*$ is determined through any dynamic programming algorithm. Finally, KBSF returns an approximation of $\hat{\mathbf{v}}^*$—the optimal value function of KBRL's MDP—computed as $\tilde{\mathbf{v}} = \Gamma\mathbf{D}\bar{\mathbf{Q}}^*$. Based on $\tilde{\mathbf{v}}$, one can compute an approximation of KBRL's action-value function $\hat{Q}(s, a)$ by simply replacing $\tilde{V}$ for $\hat{V}^*$ in (7), that is,

$$\tilde{Q}(s, a) = \sum_{i=1}^{n_a} \kappa_\tau^a(s, s_i^a) \left[r_i^a + \gamma \tilde{V}(\hat{s}_i^a) \right], \tag{12}$$

$$\hat{\mathbf{P}}^a = \begin{array}{c} \\ \hat{s}_1^a \\ \hat{s}_2^a \\ \hat{s}_3^a \\ \hat{s}_1^b \\ \hat{s}_2^b \end{array} \begin{array}{c} \begin{array}{cccc} \hat{s}_1^a & \hat{s}_2^a & \hat{s}_3^a & \hat{s}_1^b \quad \hat{s}_2^b \end{array} \\ \begin{bmatrix} \kappa_\tau^a(\hat{s}_1^a, s_1^a) & \kappa_\tau^a(\hat{s}_1^a, s_2^a) & \kappa_\tau^a(\hat{s}_1^a, s_3^a) & 0 \quad 0 \\ \kappa_\tau^a(\hat{s}_2^a, s_1^a) & \kappa_\tau^a(\hat{s}_2^a, s_2^a) & \kappa_\tau^a(\hat{s}_2^a, s_3^a) & 0 \quad 0 \\ \kappa_\tau^a(\hat{s}_3^a, s_1^a) & \kappa_\tau^a(\hat{s}_3^a, s_2^a) & \kappa_\tau^a(\hat{s}_3^a, s_3^a) & 0 \quad 0 \\ \kappa_\tau^a(\hat{s}_1^b, s_1^a) & \kappa_\tau^a(\hat{s}_1^b, s_2^a) & \kappa_\tau^a(\hat{s}_1^b, s_3^a) & 0 \quad 0 \\ \kappa_\tau^a(\hat{s}_2^b, s_1^a) & \kappa_\tau^a(\hat{s}_2^b, s_2^a) & \kappa_\tau^a(\hat{s}_2^b, s_3^a) & 0 \quad 0 \end{bmatrix} \end{array},$$

$$\hat{\mathbf{P}}^b = \begin{array}{c} \\ \hat{s}_1^a \\ \hat{s}_2^a \\ \hat{s}_3^a \\ \hat{s}_1^b \\ \hat{s}_2^b \end{array} \begin{array}{c} \begin{array}{ccccc} \hat{s}_1^a & \hat{s}_2^a & \hat{s}_3^a & \hat{s}_1^b & \hat{s}_2^b \end{array} \\ \begin{bmatrix} 0 & 0 & 0 & \kappa_\tau^a(\hat{s}_1^a, s_1^b) & \kappa_\tau^a(\hat{s}_1^a, s_2^b) \\ 0 & 0 & 0 & \kappa_\tau^a(\hat{s}_2^a, s_1^b) & \kappa_\tau^a(\hat{s}_2^a, s_2^b) \\ 0 & 0 & 0 & \kappa_\tau^a(\hat{s}_3^a, s_1^b) & \kappa_\tau^a(\hat{s}_3^a, s_2^b) \\ 0 & 0 & 0 & \kappa_\tau^a(\hat{s}_1^b, s_1^b) & \kappa_\tau^a(\hat{s}_1^b, s_2^b) \\ 0 & 0 & 0 & \kappa_\tau^a(\hat{s}_2^b, s_1^b) & \kappa_\tau^a(\hat{s}_2^b, s_2^b) \end{bmatrix} \end{array}$$

(a) KBRL's matrices

$$\mathbf{D} = \begin{array}{c} \\ \hat{s}_1^a \\ \hat{s}_2^a \\ \hat{s}_3^a \\ \hat{s}_1^b \\ \hat{s}_2^b \end{array} \begin{array}{c} \begin{array}{cc} \bar{s}_1 & \bar{s}_2 \end{array} \\ \begin{bmatrix} \bar{\kappa}_{\bar{\tau}}(\hat{s}_1^a, \bar{s}_1) & \bar{\kappa}_{\bar{\tau}}(\hat{s}_1^a, \bar{s}_2) \\ \bar{\kappa}_{\bar{\tau}}(\hat{s}_2^a, \bar{s}_1) & \bar{\kappa}_{\bar{\tau}}(\hat{s}_2^a, \bar{s}_2) \\ \bar{\kappa}_{\bar{\tau}}(\hat{s}_3^a, \bar{s}_1) & \bar{\kappa}_{\bar{\tau}}(\hat{s}_3^a, \bar{s}_2) \\ \bar{\kappa}_{\bar{\tau}}(\hat{s}_1^b, \bar{s}_1) & \bar{\kappa}_{\bar{\tau}}(\hat{s}_1^b, \bar{s}_2) \\ \bar{\kappa}_{\bar{\tau}}(\hat{s}_2^b, \bar{s}_1) & \bar{\kappa}_{\bar{\tau}}(\hat{s}_2^b, \bar{s}_2) \end{bmatrix} \end{array},$$

$$\mathbf{K}^a = \begin{array}{c} \\ \bar{s}_1 \\ \bar{s}_2 \end{array} \begin{array}{c} \begin{array}{ccccc} \hat{s}_1^a & \hat{s}_2^a & \hat{s}_3^a & \hat{s}_1^b & \hat{s}_2^b \end{array} \\ \begin{bmatrix} \kappa_\tau^a(\bar{s}_1, s_1^a) & \kappa_\tau^a(\bar{s}_1, s_2^a) & \kappa_\tau^a(\bar{s}_1, s_3^a) & 0 & 0 \\ \kappa_\tau^a(\bar{s}_2, s_1^a) & \kappa_\tau^a(\bar{s}_2, s_2^a) & \kappa_\tau^a(\bar{s}_2, s_3^a) & 0 & 0 \end{bmatrix} \end{array},$$

$$\mathbf{K}^b = \begin{array}{c} \\ \bar{s}_1 \\ \bar{s}_2 \end{array} \begin{array}{c} \begin{array}{ccccc} \hat{s}_1^a & \hat{s}_2^a & \hat{s}_3^a & \hat{s}_1^b & \hat{s}_2^b \end{array} \\ \begin{bmatrix} 0 & 0 & 0 & \kappa_\tau^a(\bar{s}_1, s_1^b) & \kappa_\tau^a(\bar{s}_1, s_2^b) \\ 0 & 0 & 0 & \kappa_\tau^a(\bar{s}_2, s_1^b) & \kappa_\tau^a(\bar{s}_2, s_2^b) \end{bmatrix} \end{array}.$$

(b) KBSF's sparse matrices

$$\dot{\mathbf{D}}^a = \begin{array}{c} \\ \hat{s}_1^a \\ \hat{s}_2^a \\ \hat{s}_3^a \end{array} \begin{array}{c} \begin{array}{cc} \bar{s}_1 & \bar{s}_2 \end{array} \\ \begin{bmatrix} \bar{\kappa}_{\bar{\tau}}(\hat{s}_1^a, \bar{s}_1) & \bar{\kappa}_{\bar{\tau}}(\hat{s}_1^a, \bar{s}_2) \\ \bar{\kappa}_{\bar{\tau}}(\hat{s}_2^a, \bar{s}_1) & \bar{\kappa}_{\bar{\tau}}(\hat{s}_2^a, \bar{s}_2) \\ \bar{\kappa}_{\bar{\tau}}(\hat{s}_3^a, \bar{s}_1) & \bar{\kappa}_{\bar{\tau}}(\hat{s}_3^a, \bar{s}_2) \end{bmatrix} \end{array},$$

$$\dot{\mathbf{K}}^a = \begin{array}{c} \\ \bar{s}_1 \\ \bar{s}_2 \end{array} \begin{array}{c} \begin{array}{ccc} \hat{s}_1^a & \hat{s}_2^a & \hat{s}_3^a \end{array} \\ \begin{bmatrix} \kappa_\tau^a(\bar{s}_1, s_1^a) & \kappa_\tau^a(\bar{s}_1, s_2^a) & \kappa_\tau^a(\bar{s}_1, s_3^a) \\ \kappa_\tau^a(\bar{s}_2, s_1^a) & \kappa_\tau^a(\bar{s}_2, s_2^a) & \kappa_\tau^a(\bar{s}_2, s_3^a) \end{bmatrix} \end{array},$$

$$\dot{\mathbf{D}}^b = \begin{array}{c} \\ \hat{s}_1^b \\ \hat{s}_2^b \end{array} \begin{array}{c} \begin{array}{cc} \bar{s}_1 & \bar{s}_2 \end{array} \\ \begin{bmatrix} \bar{\kappa}_{\bar{\tau}}(\hat{s}_1^b, \bar{s}_1) & \bar{\kappa}_{\bar{\tau}}(\hat{s}_1^b, \bar{s}_2) \\ \bar{\kappa}_{\bar{\tau}}(\hat{s}_2^b, \bar{s}_1) & \bar{\kappa}_{\bar{\tau}}(\hat{s}_2^b, \bar{s}_2) \end{bmatrix} \end{array},$$

$$\dot{\mathbf{K}}^b = \begin{array}{c} \\ \bar{s}_1 \\ \bar{s}_2 \end{array} \begin{array}{c} \begin{array}{cc} \hat{s}_1^b & \hat{s}_2^b \end{array} \\ \begin{bmatrix} \kappa_\tau^a(\bar{s}_1, s_1^b) & \kappa_\tau^a(\bar{s}_1, s_2^b) \\ \kappa_\tau^a(\bar{s}_2, s_1^b) & \kappa_\tau^a(\bar{s}_2, s_2^b) \end{bmatrix} \end{array}.$$

(c) KBSF's dense matrices

Figure 2: Matrices built by KBRL and KBSF for the case in which the original MDP has two actions, a and b, and $n_a = 3$, $n_b = 2$, and $m = 2$.

where $s \in \mathbb{S}$ and $a \in A$. Note that $\tilde{V}(\hat{s}_i^a)$ corresponds to one specific entry of vector $\tilde{\mathbf{v}}$, whose index is given by $\sum_{b=0}^{a-1} n_b + i$, where we assume that $n_0 = 0$.

Algorithm 1 Batch KBSF

Input: $S^a = \{(s_k^a, r_k^a, \hat{s}_k^a) | k = 1, 2, ..., n_a\}$ for all $a \in A$ ▷ Sample transitions
$\bar{S} = \{\bar{s}_1, \bar{s}_2, ..., \bar{s}_m\}$ ▷ Set of representative states
Output: $\tilde{\mathbf{v}} \approx \hat{\mathbf{v}}^*$
for each $a \in A$ **do**
  Compute matrix $\dot{\mathbf{D}}^a$: $\dot{d}_{ij}^a = \bar{\kappa}_{\bar{\tau}}(\hat{s}_i^a, \bar{s}_j)$
  Compute matrix $\dot{\mathbf{K}}^a$: $\dot{k}_{ij}^a = \kappa_\tau^a(\bar{s}_i, s_j^a)$
  Compute vector $\bar{\mathbf{r}}^a$: $\bar{r}_i^a = \sum_j \dot{k}_{ij}^a r_j^a$
  Compute matrix $\bar{\mathbf{P}}^a = \dot{\mathbf{K}}^a \dot{\mathbf{D}}^a$
Solve $\bar{M} \equiv (\bar{S}, A, \bar{\mathbf{P}}^a, \bar{\mathbf{r}}^a, \gamma)$ ▷ *i.e.*, compute $\bar{\mathbf{Q}}^*$
Return $\tilde{\mathbf{v}} = \Gamma \mathbf{D} \bar{\mathbf{Q}}^*$, where $\mathbf{D}^\intercal = \left[(\dot{\mathbf{D}}^1)^\intercal, (\dot{\mathbf{D}}^2)^\intercal, ...(\dot{\mathbf{D}}^{|A|})^\intercal\right]$

As shown in Algorithm 1, the key point of KBSF's mechanics is the fact that the matrices $\check{\mathbf{P}}^a = \mathbf{D}\mathbf{K}^a$ are never actually computed, but instead we directly solve the MDP $\bar{M}$ containing m states only. This results in an efficient algorithm that requires only $O(nm|A|d_{\mathbb{S}} + \hat{n}m^2|A|)$ operations and $O(\hat{n}m)$ bits to build a reduced version of KBRL's MDP, where $\hat{n} = \max_a n_a$. After the reduced model $\bar{M}$ has been constructed, KBSF's computational cost becomes a function of m only. In particular, the cost of solving $\bar{M}$ through dynamic programming becomes polynomial in m instead of n: while one application of $\hat{T}$, the Bellman operator of $\hat{M}$, is $O(n\hat{n}|A|)$, the computation of $\bar{T}$ is $O(m^2|A|)$. Therefore, KBSF's time and memory complexities are only linear in n.

We note that, in practice, KBSF's computational requirements can be reduced even further if one enforces the kernels κ_τ^a and $\bar{\kappa}_{\bar{\tau}}$ to be sparse. In particular, given a fixed $\bar{s}_i$, instead of computing $\bar{\mathrm{k}}_{\bar{\tau}}(\bar{s}_i, s_j^a)$ for $j = 1, 2, ..., n_a$, one can evaluate the kernel on a prespecified neighborhood of $\bar{s}_i$ only. Assuming that $\bar{\mathrm{k}}_{\bar{\tau}}(\bar{s}_i, s_j^a)$ is zero for all s_j^a outside this region, one can avoid not only computing the kernel but also storing the resulting values (the same reasoning applies to the computation of $\mathrm{k}_\tau(\hat{s}_i^a, \bar{s}_j)$ for a fixed $\hat{s}_i^a$).

4.1 Theoretical results

Since KBSF comes down to the solution of a finite MDP, it always converges to the same approximation $\tilde{\mathbf{v}}$, whose distance to KBRL's optimal value function $\hat{\mathbf{v}}^*$ is bounded by Proposition 2. Once $\tilde{\mathbf{v}}$ is available, the value of any state-action pair can be determined through (12). The following result generalizes Proposition 2 to the entire continuous state space $\mathbb{S}$:

Proposition 3 *Let $\hat{Q}$ be the value function computed by KBRL through (7) and let $\tilde{Q}$ be the value function computed by KBSF through (12). Then, for any $s \in \mathbb{S}$ and any $a \in A$, $|\hat{Q}(s,a) - \tilde{Q}(s,a)| \leq \gamma \xi_v$, with ξ_v defined in (8).*

Proof

$$|\hat{Q}(s,a) - \tilde{Q}(s,a)| = \left| \sum_{i=1}^{n_a} \kappa_\tau^a(s, s_i^a) \left[r_i^a + \gamma \hat{V}^*(\hat{s}_i^a) \right] - \sum_{i=1}^{n_a} \kappa_\tau^a(s, s_i^a) \left[r_i^a + \gamma \tilde{V}(\hat{s}_i^a) \right] \right|$$
$$\leq \gamma \sum_{i=1}^{n_a} \kappa_\tau^a(s, s_i^a) \left| \hat{V}^*(\hat{s}_i^a) - \tilde{V}(\hat{s}_i^a) \right| \leq \gamma \sum_{i=1}^{n_a} \kappa_\tau^a(s, s_i^a) \xi_v \leq \gamma \xi_v,$$

where the second inequality results from the application of Proposition 2 and the third inequality is a consequence of the fact that $\sum_{i=1}^{n_a} \kappa_\tau^a(s, s_i^a)$ defines a convex combination. ■

Proposition 3 makes it clear that the approximation computed by KBSF depends crucially on ξ_v. In the remainder of this section we will show that, if the distances between sampled states and the respective nearest representative states are small enough, then we can make ξ_v as small as desired by setting $\bar{\tau}$ to a sufficiently small value.

4.1.1 General results

We assume that KBSF's kernel $\bar{\phi}(x) : \mathbb{R}^+ \mapsto \mathbb{R}^+$ has the following properties:

(i) $\bar{\phi}(x) \geq \bar{\phi}(y)$ if $x < y$,

(ii) $\exists\, A_{\bar{\phi}} > 0, \lambda_{\bar{\phi}} \geq 1, B_{\bar{\phi}} \geq 0$ such that $A_{\bar{\phi}} \exp(-x) \leq \bar{\phi}(x) \leq \lambda_{\bar{\phi}} A_{\bar{\phi}} \exp(-x)$ if $x \geq B_{\bar{\phi}}$.

Assumption (ii) implies that the function $\bar{\phi}$ is positive and will eventually decay exponentially. Note that we assume that $\bar{\phi}$ is greater than zero everywhere in order to guarantee that $\bar{\kappa}_{\bar{\tau}}$ is well defined for any value of $\bar{\tau}$. It should be straightforward to generalize our results for the case in which $\bar{\phi}$ has finite support by ensuring that, given sets of sample transitions S^a and a set of representative states $\bar{S}$, $\bar{\tau}$ is such that, for any $\hat{s}_i^a \in S^a$, with $a \in A$, there is a $\bar{s}_j \in \bar{S}$ for which $\bar{\mathrm{k}}_{\bar{\tau}}(\hat{s}_i^a, \bar{s}_j) > 0$ (note that this assumption is naturally satisfied by the "sparse kernels" used in some of the experiments—see Appendix B).

Let $rs : \mathbb{S} \times \{1, 2, ..., m\} \mapsto \bar{S}$ be a function that orders the representative states according to their distance to a given state s, that is,

$$rs(s,i) = \bar{s}_k \iff \bar{s}_k \text{ is the } i^{\text{th}} \text{ nearest representative state to } s. \tag{13}$$

Define

$$dist : \mathbb{S} \times \{1, 2, ..., m\} \mapsto \mathbb{R}$$
$$dist(s,i) = \|s - rs(s,i)\|. \tag{14}$$

We will show that, for any $\epsilon > 0$ and any $w \in \{1, 2, ..., m\}$, there is a $\delta > 0$ such that, if $\max_{a,i} dist(\hat{s}_i^a, w) < \delta$, then we can set $\bar{\tau}$ in order to guarantee that $\xi_v < \epsilon$. To show that, we will need the following two lemmas:

Lemma 4 *For any $s_i^a \in S^a$ and any $\epsilon > 0$, there is a $\delta > 0$ such that $|\kappa_\tau^a(s, s_i^a) - \kappa_\tau^a(s', s_i^a)| < \epsilon$ if $\|s - s'\| < \delta$.*

Lemma 5 *Let $s \in \mathbb{S}$, let $m > 1$, and assume there is a $w \in \{1, 2, ..., m-1\}$ such that $dist(s,w) < dist(s,w+1)$. Define*

$$W^w(s) \equiv \{k \mid \|s - \bar{s}_k\| \leq dist(s,w)\} \text{ and } \bar{W}^w(s) \equiv \{1, 2, ..., m\} - W^w(s). \tag{15}$$

Then, for any $\alpha > 0$, $\sum_{k \in W^w(s)} \bar{\kappa}_{\bar{\tau}}(s, \bar{s}_k) < \alpha \sum_{k \in \bar{W}^w(s)} \bar{\kappa}_{\bar{\tau}}(s, \bar{s}_k)$ for $\bar{\tau}$ sufficiently small.

Lemma 4 is basically a continuity argument: it shows that, for any fixed s_i^a, $|\kappa_\tau^a(s, s_i^a) - \kappa_\tau^a(s', s_i^a)| \to 0$ as $\|s - s'\| \to 0$. Lemma 5 states that, if we order the representative states according to their distance to a fixed state s, and then partition them in two subsets, we can control the relative magnitude of the corresponding kernels's sums by adjusting the parameter $\bar{\tau}$ (we redirect the reader to Appendix A.1 for details on how to set $\bar{\tau}$). Based on these two lemmas, we present the main result of this section:

Proposition 6 *Let $w \in \{1, 2, ..., m\}$. For any $\epsilon > 0$, there is a $\delta > 0$ such that, if $\max_{a,i} dist(\hat{s}_i^a, w) < \delta$, then we can guarantee that $\xi_v < \epsilon$ by making $\bar{\tau}$ sufficiently small.*

Proposition 6 tells us that, regardless of the specific reinforcement learning problem at hand, if the distances between sampled states $\hat{s}_i^a$ and the respective w nearest representative states are small enough, then we can make KBSF's approximation of KBRL's value function as accurate as desired by setting $\bar{\tau}$ to a sufficiently small value (one can see how exactly to set $\bar{\tau}$ in the proof of the proposition). How small the maximum distance $\max_{a,i} dist(\hat{s}_i^a, w)$ should be depends on the particular choice of kernel k_τ and on the sets of sample transitions S^a.

Note that a fixed number of representative states m imposes a minimum possible value for $\max_{a,i} dist(\hat{s}_i^a, w)$, and if this value is not small enough decreasing $\bar{\tau}$ may actually hurt the approximation (this is easier to see if we consider that $w = 1$). The optimal value for $\bar{\tau}$ in this case is again context-dependent. As a positive flip side of this statement, we note that, even if $\max_{a,i} dist(\hat{s}_i^a, w) > \delta$, it might be possible to make $\xi_v < \epsilon$ by setting $\bar{\tau}$ appropriately. Therefore, rather than as a practical guide on how to configure KBSF, Proposition 6 should be seen as a theoretical argument showing that KBSF is a sound algorithm, in the sense that in the limit it recovers KBRL's solution.

4.1.2 Error rate

In the previous section we deliberately refrained from making assumptions on the kernel $\bar{\kappa}_{\bar{\tau}}$ used by KBSF in order to make Proposition 6 as general as possible. In what follows we show that, by restricting the class of kernels used by our algorithm, we can derive stronger results regarding its behavior. In particular, we derive an upper bound for ξ_v that shows how this approximation error depends on the variables of a given reinforcement learning problem. Our strategy will be to define an "admissible kernel" whose width is determined based on data.

We will need the following assumption:

(iii) $|\phi(x) - \phi(y)| \leq C_\phi |x - y|$, with $C_\phi \geq 0$.

Assumption (iii) simply states that the function ϕ used to construct the kernel κ_τ^a is Lipschitz continuous with constant C_ϕ. This is actually part of Ormoneit and Sen's (2002) Assumption 4, and is explicitly listed here for convenience only.

We will now define an auxiliary function which will be used in the definition of our admissible kernel. To simplify the notation, let

$$\varsigma_k^{a,i,j} \equiv |\kappa_\tau^a(\hat{s}_i^a, s_j^a) - \kappa_\tau^a(\bar{s}_k, s_j^a)|. \tag{16}$$

Based on (15) and (16), we define the following function:

$$\mathcal{F}(\bar{\tau}, w | S^a, \bar{S}, \kappa_\tau^a, \bar{\mathrm{k}}_{\bar{\tau}}) = \frac{R_{\max}}{(1-\gamma)^2}\left[\max_{a,i} \sum_{k \in \bar{W}^w(\hat{s}_i^a)} \bar{\kappa}_{\bar{\tau}}(\hat{s}_i^a, \bar{s}_k) \sum_{j=1}^{n_a} \varsigma_k^{a,i,j} + \frac{1}{2}\max_{a,i}(1 - \bar{\kappa}_{\bar{\tau}}(\hat{s}_i^a, rs(\hat{s}_i^a, 1)))\right], \tag{17}$$

where $\bar{\tau} > 0$, $w \in \{1, 2, ..., m\}$, $R_{\max} = \max_{a,i} |r_i^a|$, and rs and $\bar{W}^w$ are defined in (13) and (15), respectively. Note that the definition of $\mathcal{F}$ makes it clear its dependency on the representative states, sets of sample transitions, and kernels adopted.

Lemma 5 implies that, as $\bar{\tau} \to 0$, $\bar{\kappa}_{\bar{\tau}}(\hat{s}_i^a, rs(\hat{s}_i^a, 1)) \to 1$ and $\sum_{k \in \bar{W}^w(\hat{s}_i^a)} \bar{\kappa}_{\bar{\tau}}(\hat{s}_i^a, \bar{s}_k) \to 0$ for all a, i, and w (see equation (35) in Appendix A.1 for a clear picture). Thus, for any w, $\mathcal{F}(\bar{\tau}, w) \to 0$ as $\bar{\tau} \to 0$. This leads to the following definition:

Definition 7 *Given $\epsilon > 0$ and $w \in \{1, 2, ..., m\}$, an* admissible kernel $\bar{\kappa}_{\bar{\tau}}^{\epsilon,w}$ *is any kernel whose parameter $\bar{\tau}$ is such that $\mathcal{F}(\bar{\tau}, w) < \epsilon$.*

The definition above allows us to enunciate the following proposition:

Proposition 8 *Let $\mathrm{k}_{\min} = \phi\left(\sqrt{d_{\mathbb{S}}}/\tau\right)$, where τ is the parameter used by KBRL's kernel κ_τ^a. Given $\epsilon > 0$ and $w \in \{1, 2, ..., m\}$, suppose that KBSF is adopted with an admissible kernel $\bar{\kappa}_{\bar{\tau}}^{\epsilon,w}$. Then,*

$$\xi_v \leq \frac{2wC_\phi R_{\max}}{\tau \mathrm{k}_{\min}(1-\gamma)^2} \max_{a,i} dist(\hat{s}_i^a, w) + \epsilon, \tag{18}$$

where C_ϕ is the Lipschitz constant of function ϕ appearing in Assumption (iii), $R_{\max} = \max_{a,i} |r_i^a|$, and $\gamma \in [0, 1)$ is the discount factor of the underlying MDP.

Proposition 8 shows that ξ_v is bounded by the maximum distance between a sampled state and the w^{th} closest representative state scaled by constants characterizing the MDP and the kernels used by KBSF.

Assuming that ϵ and w are fixed, among the quantities appearing in (18) we only have control over τ and $\max_{a,i} dist(\hat{s}_i^a, w)$—the latter through the definition of the representative states. Regarding $\max_{a,i} dist(\hat{s}_i^a, w)$, the same observation made above applies here: given sample transitions S^a, a fixed value for $m < n$ imposes a lower bound on this term, and thus on the right-hand side of (18). As $m \to n$, this lower bound approaches some value ϵ', with $0 \leq \epsilon' < \epsilon$. The fact that (18) is generally greater than zero even when $m = n$ reflects the fact that ξ_v depends on $\sigma(\mathbf{D})$, the level of stochasticity of $\mathbf{D}$ (see (8) and (9)). Since Assumption (ii) implies that $\bar{\mathrm{k}}_{\bar{\tau}}(s, s') > 0$ for all $s, s' \in \mathbb{S}$, matrix $\mathbf{D}$ will never become deterministic, no matter how small $\bar{\tau}$ is (see Figure 2b). If we replace $\bar{\mathrm{k}}_{\bar{\tau}}$ by a kernel with finite support, then we can set $\epsilon = 0$ in Definition 7, and therefore in the right-hand side of (18). Needless to say, this does not mean that using a kernel with finite support will lead to better performance in practice.

As for the definition of τ, we see that the right-hand side of (18) decreases as $\tau \to \infty$. This means that we can make the value function computed by KBSF arbitrarily close to the one computed by KBRL. Note though that increasing τ also changes the model constructed by KBRL, and an excessively large value for this parameter makes the resulting approximation meaningless (see (4) and (5)). Similarly, we might be tempted to always set w to 1 in order to minimize the right-hand side of (18). Note however that a kernel $\bar{\kappa}_{\bar{\tau}}^{\epsilon,w}$ that is admissible for $w > 1$ may not be so for $w = 1$, and in this case the bound would no longer be valid.

4.2 Empirical results

We now present a series of computational experiments designed to illustrate the behavior of KBSF in a variety of challenging domains. We start with a simple problem, the "puddle world", to show that KBSF is indeed capable of compressing the information contained in KBRL's model. We then move to more difficult tasks, and compare KBSF with other state-of-the-art reinforcement-learning algorithms. We start with two classical control tasks, single and double pole-balancing. Next we study two medically-related problems based on real data: HIV drug schedule and epilepsy-suppression domains.

All problems considered in this paper have a continuous state space and a finite number of actions, and were modeled as discounted tasks. The algorithms's results correspond to the performance of the greedy decision policy derived from the final value function computed. In all cases, the decision policies were evaluated on challenging test states from which the tasks cannot be easily solved. The details of the experiments are given in Appendix B.

4.2.1 Puddle world (proof of concept)

In order to show that KBSF is indeed capable of summarizing the information contained in KBRL's model, we use the puddle world task (Sutton, 1996). The puddle world is a simple two-dimensional problem in which the objective is to reach a goal region avoiding two "puddles" along the way. We implemented the task exactly as described by Sutton (1996), except that we used a discount factor of $\gamma = 0.99$ and evaluated the decision policies on a set of pre-defined test states surrounding the puddles (see Appendix B).

The experiment was carried out as follows: first, we collected a set of n sample transitions $(s_k^a, r_k^a, \hat{s}_k^a)$ using a random exploration policy (that is, a policy that selects actions uniformly at random). In the case of KBRL, this set of sample transitions defined the model used to approximate the value function. In order to define KBSF's model, the states $\hat{s}_k^a$ were grouped by the k-means algorithm into m clusters and a representative state $\bar{s}_j$ was placed at the center of each resulting cluster (Kaufman and Rousseeuw, 1990). As for the kernels's widths, we varied both τ and $\bar{\tau}$ in the set $\{0.01, 0.1, 1\}$ (see Table 1). The results reported represent the best performance of the algorithms over 50 runs; that is, for each n and each m we picked the combination of parameters that generated the maximum average return. We use the following convention to refer to specific instances of each method: the first number enclosed in parentheses after an algorithm's name is n, the number of sample transitions used in the approximation, and the second one is m, the size of the model used to approximate the value function. Note that for KBRL n and m coincide.

In Figure 3a and 3b we observe the effect of fixing the number of transitions n and varying the number of representative states m. As expected, KBSF's results improve as $m \to n$. More surprising is the fact that KBSF has essentially the same performance as KBRL using models one order of magnitude smaller. This indicates that KBSF is summarizing well the information contained in the data. Depending on the values of n and m, such a compression may represent a significant reduction on the consumption of computational resources. For example, by replacing KBRL(8000) with KBSF(8000, 100), we obtain a decrease of approximately 99.58% on the number of operations performed to find a policy, as shown in Figure 3b (the cost of constructing KBSF's MDP is included in all reported run times).

In Figures 3c and 3d we fix m and vary n. Observe in Figure 3c how KBRL and KBSF have similar performances, and both improve as n increases. However, since KBSF is using a model of fixed size, its computational cost depends only linearly on n, whereas KBRL's cost grows with $n^2\hat{n}$, roughly. This explains the huge difference in the algorithms's run times shown in Figure 3d.

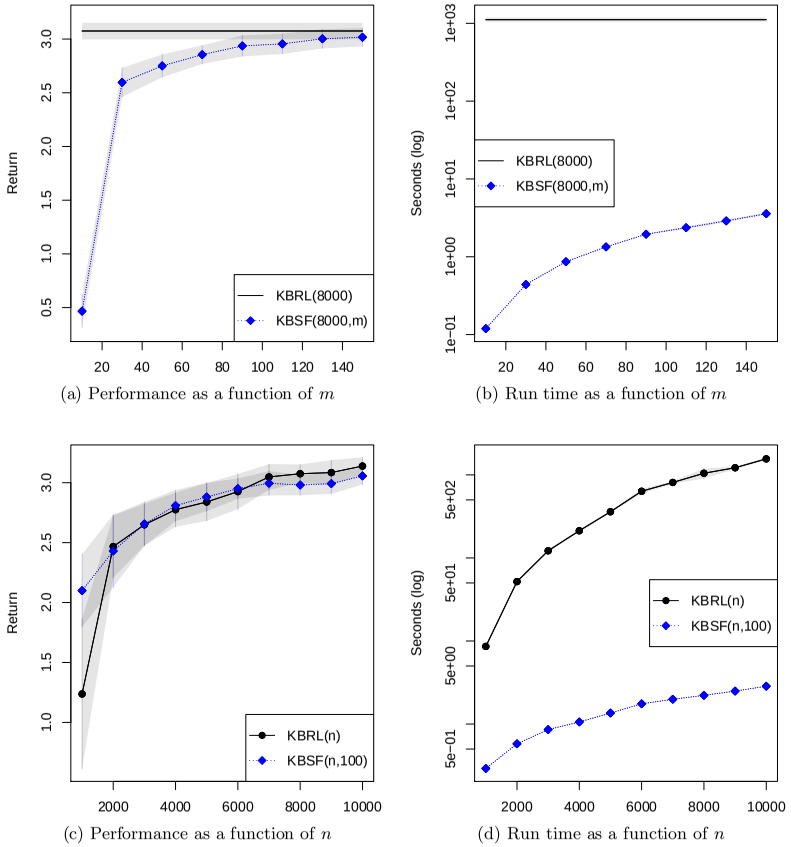
4.2.2 Single and double pole-balancing (comparison with LSPI)

We now evaluate how KBSF compares to other modern reinforcement learning algorithms on more difficult tasks. We first contrast our method with Lagoudakis and Parr's (2003) least-squares policy iteration algorithm (LSPI). Besides its popularity, LSPI is a natural candidate for such a comparison for three reasons: it also builds an approximator of fixed size out of a batch of sample transitions, it has good theoretical guarantees, and it has been successfully applied to several reinforcement learning tasks.

We compare the performance of LSPI and KBSF on the pole balancing task. Pole balancing has a long history as a benchmark problem because it represents a rich class of unstable systems (Michie and Chambers, 1968; Anderson, 1986; Barto et al., 1983). The objective in this problem is to apply forces to a wheeled cart moving along a limited track in order to keep one or more poles hinged to the cart from falling over. There are several variations of the task with different levels of difficulty; among them, balancing two poles side by side is particularly hard (Wieland, 1991). In this paper we compare LSPI and KBSF on both the single- and two-poles versions of the problem. We implemented the tasks using a realistic simulator described by Gomez (2003). We refer the reader to Appendix B for details on the problems's configuration.

The experiments were carried out as described in the previous section, with sample transitions collected by a random policy and then clustered by the k-means algorithm. In both versions of the pole-balancing task LSPI used the same data and approximation architectures as KBSF. To make the comparison with LSPI as fair as possible, we fixed the width of KBSF's kernel κ_τ^a at $\tau = 1$ and varied $\bar{\tau}$ in $\{0.01, 0.1, 1\}$ for both algorithms. Also, policy iteration was used to find a decision policy for the MDPs constructed by KBSF, and this algorithm was run for a maximum of 30 iterations, the same limit used for LSPI.

Figure 4 shows the results of LSPI and KBSF on the single and double pole-balancing tasks. We call attention to the fact that the version of the problems used here is significantly harder than the more commonly-used variants in which the decision policies are evaluated on a single state close to the origin. This is probably the reason why LSPI achieves a



(a) Performance as a function of m

(b) Run time as a function of m

(c) Performance as a function of n

(d) Run time as a function of n

Figure 3: Results on the puddle-world task averaged over 50 runs. The algorithms were evaluated on a set of test states distributed over a region of the state space surrounding the "puddles" (details in Appendix B). The shadowed regions represent 99% confidence intervals.

success rate of no more than 60% on the single pole-balancing task, as shown in Figure 4a. In contrast, KBSF's decision policies are able to balance the pole in 90% of the attempts, on average, using as few as $m = 30$ representative states.

The results of KBSF on the double pole-balancing task are still more impressive. As Wieland (1991) rightly points out, this version of the problem is considerably more difficult than its single pole variant, and previous attempts to apply reinforcement-learning techniques to this domain resulted in disappointing performance (Gomez et al., 2006). As shown in Figure 4c, KBSF(10^6, 200) is able to achieve a success rate of more than 80%. To put this number in perspective, recall that some of the test states are quite challenging, with the two poles inclined and falling in opposite directions.

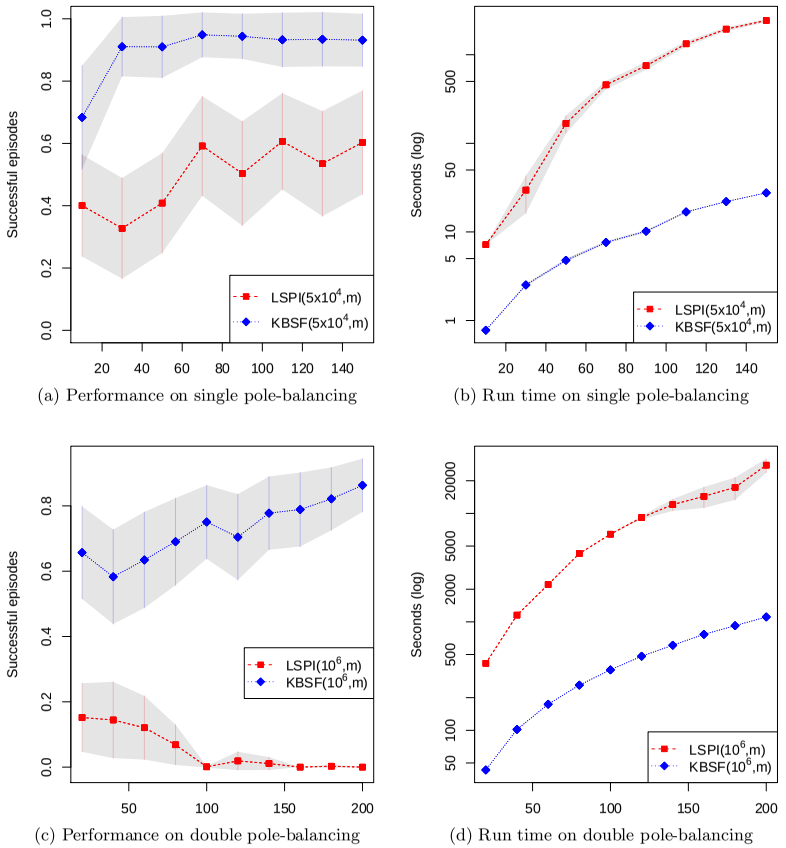
The good performance of KBSF comes at a relatively low computational cost. A conservative estimate reveals that, were KBRL(10^6) run on the same computer used for these experiments, we would have to wait for more than 6 *months* to see the results. KBSF(10^6, 200) delivers a decision policy in less than 7 minutes. KBSF's computational cost also compares well with that of LSPI, as shown in Figures 4b and 4d. LSPI's policy evaluation step involves the update and solution of a linear system of equations, which take $O(nm^2)$ and $O(m^3|A|^3)$, respectively. In addition, the policy-update stage requires the definition of $\pi(\hat{s}_k^a)$ for all n states in the set of sample transitions. In contrast, at each iteration KBSF only performs $O(m^3)$ operations to evaluate a decision policy and $O(m^2|A|)$ operations to update it.

4.2.3 HIV drug schedule domain (comparison with fitted Q-iteration)

We now compare KBSF with the fitted Q-iteration algorithm (Ernst et al., 2005; Antos et al., 2007; Munos and Szepesvári, 2008). Fitted Q-iteration is a conceptually simple method that also builds its approximation based solely on sample transitions. Here we adopt this algorithm with an ensemble of trees generated by Geurts et al.'s (2006) extra-trees algorithm. This combination, which we call FQIT, generated the best results on the extensive empirical evaluation performed by Ernst et al. (2005).

We chose FQIT for our comparisons because it has shown excellent performance on both benchmark and real-world reinforcement-learning tasks (Ernst et al., 2005, 2006). In all experiments reported in this paper we used FQIT with ensembles of 30 trees. As detailed in Appendix B, besides the number of trees, FQIT has three main parameters. Among them, the minimum number of elements required to split a node in the construction of the trees, denoted here by $\eta_{\min}$, has a particularly strong effect on both the algorithm's performance and computational cost. Thus, in our experiments we fixed FQIT's parameters at reasonable values—selected based on preliminary experiments—and only varied $\eta_{\min}$. The respective instances of the tree-based approach are referred to as FQIT($\eta_{\min}$).

We compare FQIT and KBSF on an important medical problem which we will refer to as the HIV drug schedule domain (Adams et al., 2004; Ernst et al., 2006). Typical HIV treatments use drug cocktails containing two types of medication: reverse transcriptase inhibitors (RTI) and protease inhibitors (PI). Despite the success of drug cocktails in maintaining low viral loads, there are several complications associated with their long-term use. This has attracted the interest of the scientific community to the problem of optimizing drug-scheduling strategies. One strategy that has been receiving a lot of attention recently



(a) Performance on single pole-balancing
(b) Run time on single pole-balancing
(c) Performance on double pole-balancing
(d) Run time on double pole-balancing

Figure 4: Results on the pole-balancing tasks, as a function of the number of representative states m, averaged over 50 runs. The values correspond to the fraction of episodes initiated from the test states in which the pole(s) could be balanced for 3000 steps (one minute of simulated time). The test sets were regular grids defined over the hypercube centered at the origin and covering 50% of the state-space axes in each dimension (see Appendix B). Shadowed regions represent 99% confidence intervals.

is structured treatment interruption (STI), in which patients undergo alternate cycles with and without the drugs. Although many successful STI treatments have been reported in the literature, as of now there is no consensus regarding the exact protocol that should be followed (Bajaria et al., 2004).

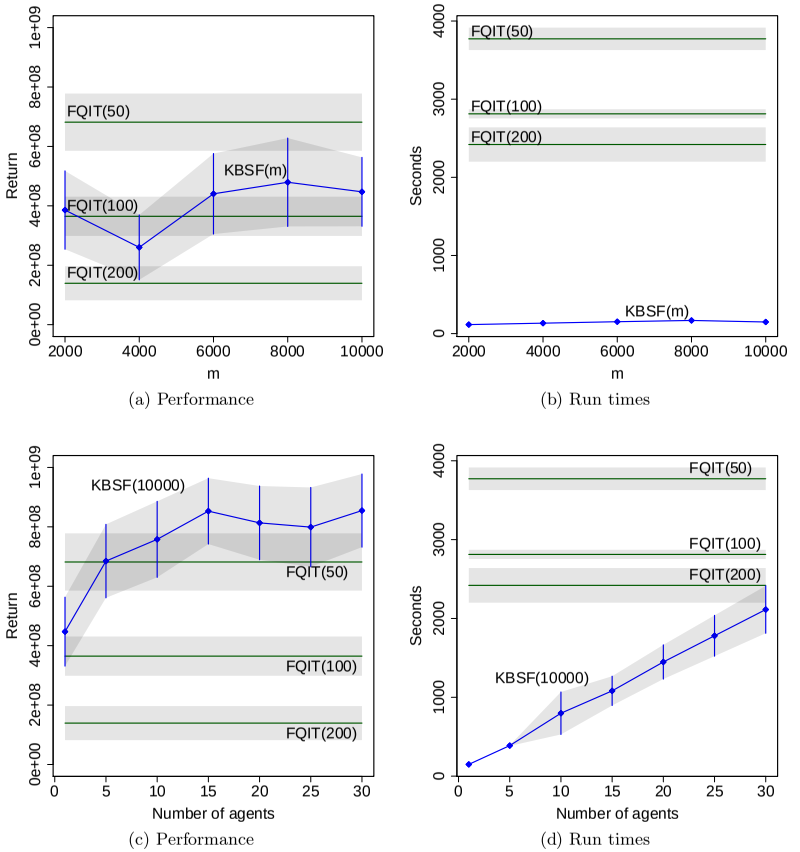
The scheduling of STI treatments can be seen as a sequential decision problem in which the actions correspond to the types of cocktail that should be administered to a patient (Ernst et al., 2006). To simplify the problem's formulation, it is assumed that RTI and PI drugs are administered at fixed amounts, reducing the actions to the four possible combinations of drugs: none, RTI only, PI only, or both. The goal is to minimize the viral load using as little drugs as possible. Following Ernst et al. (2006), we performed our experiments using a model that describes the interaction of the immune system with HIV. This model was developed by Adams et al. (2004) and has been identified and validated based on real clinical data. The resulting reinforcement learning task has a 6-dimensional continuous state space whose variables describe the overall patient's condition.

We formulated the problem exactly as proposed by Ernst et al. (2006, see Appendix B for details). The strategy used to generate the data also followed the protocol proposed by these authors, which we now briefly explain. Starting from a batch of 6000 sample transitions generated by a random policy, each algorithm first computed an initial approximation of the problem's optimal value function. Based on this approximation, a 0.15-greedy policy was used to collect a second batch of 6000 transitions, which was merged with the first.[3] This process was repeated for 10 rounds, resulting in a total of 60000 sample transitions.

We varied FQIT's parameter $\eta_{\min}$ in the set $\{50, 100, 200\}$. For the experiments with KBSF, we fixed $\tau = \bar{\tau} = 1$ and varied m in $\{2000, 4000, ..., 10000\}$ (in the rounds in which $m \geq n$ we simply used all states $\hat{s}_i^a$ as representative states). As discussed in the beginning of this section, it is possible to reduce KBSF's computational cost with the use of sparse kernels. In our experiments with the HIV drug schedule task, we only computed the $\mu = 2$ largest values of $\mathrm{k}_\tau(\bar{s}_i, \cdot)$ and the $\bar{\mu} = 3$ largest values of $\bar{\mathrm{k}}_{\bar{\tau}}(\hat{s}_i^a, \cdot)$ (see Appendix B.2). The representative states $\bar{s}_i$ were selected at random from the set of sampled states $\hat{s}_i^a$ (the reason for this will become clear shortly). Since in the current experiments the number of sample transitions n was fixed, we will refer to the particular instances of our algorithm simply as KBSF(m).

Before discussing the results, we point out that FQIT's performance on the HIV drug schedule task is very good, comparable to that of Adams et al.'s (2004) approach, which uses a model of the task. FQIT's results, along with KBSF's, are shown in Figure 5. As shown in Figure 5a, the performance of FQTI improves when $\eta_{\min}$ is decreased, as expected. In contrast, increasing the number of representative states m does not have a strong impact on the quality of KBSF's solutions (in fact, in some cases the average return obtained by the resulting policies decreases slightly when m grows). Overall, the performance of KBSF on the HIV drug schedule task is not nearly as impressive as on the previous problems. For example, even when using $m = 10000$ representative states, which corresponds to one sixth of the sampled states, KBSF is unable to reproduce the performance of FQIT with $\eta_{\min} = 50$.

3. As explained by Sutton and Barto (1998), an ϵ-greedy policy selects the action with maximum value with probability $1 - \epsilon$, and with probability ϵ it picks an action uniformly at random.



(a) Performance (b) Run times

(c) Performance (d) Run times

Figure 5: Results on the HIV drug schedule task averaged over 50 runs. The STI policies were evaluated for 5000 days starting from a state representing a patient's unhealthy state (see Appendix B). The shadowed regions represent 99% confidence intervals.

On the other hand, when we look at Figure 5b, it is clear that the difference on the algorithms's performance is counterbalanced by a substantial difference on the associated computational costs. As an illustration, note that KBSF(10000) is 15 times faster than FQTI(100) and 20 times faster than FQTI(50). This difference on the algorithms's run times is expected, since each iteration of FQIT involves the construction (or update) of an ensemble of trees, each one requiring at least $O(n \log(n/\eta_{\min}))$ operations, and the improvement of the current decision policy, which is $O(n|A|)$ (Geurts et al., 2006). As discussed before, KBSF's efficiency comes from the fact that its computational cost per iteration is independent of the number of sample transitions n.

Note that the fact that FQIT uses an ensemble of trees is both a blessing and a curse. If on the one hand this reduces the variance of the approximation, on the other hand it also increases the algorithm's computational cost (Geurts et al., 2006). Given the big gap between FQIT's and KBSF's time complexities, one may wonder if the latter can also benefit from averaging over several models. In order to verify this hypothesis, we implemented a very simple model-averaging strategy with KBSF: we trained several agents independently, using Algorithm 1 on the same set of sample transitions, and then put them together on a single "committee". In order to increase the variability within the committee of agents, instead of using k-means to determine the representative states $\bar{s}_j$ we simply selected them uniformly at random from the set of sampled states $\hat{s}_i^a$ (note that this has the extra benefit of reducing the method's overall computational cost). The actions selected by the committee of agents were determined through "voting"—that is, we simply picked the action chosen by the majority of agents, with ties broken randomly.

We do not claim that the approach described above is the best model-averaging strategy to be used with KBSF. However, it seems to be sufficient to boost the algorithm's performance considerably, as shown in Figure 5c. Note how KBSF already performs comparably to FQTI(50) when using only 5 agents in the committee. When this number is increased to 15, the expected return of KBSF's agents is considerably larger than that of the best FQIT's agent, with only a small overlap between the 99% confidence intervals associated with the algorithms's results. The good performance of KBSF is still more impressive when we look at Figure 5d, which shows that even when using a committee of 30 agents this algorithm is faster than FQIT(200).

4.2.4 Epilepsy-suppression domain (comparison with LSPI and fitted Q-iteration)

We conclude our empirical evaluation of KBSF by using it to learn a neuro-stimulation policy for the treatment of epilepsy. It has been shown that the electrical stimulation of specific structures in the neural system at fixed frequencies can effectively suppress the occurrence of seizures (Durand and Bikson, 2001). Unfortunately, *in vitro* neuro-stimulation experiments suggest that fixed-frequency pulses are not equally effective across epileptic systems. Moreover, the long term use of this treatment may potentially damage the patients's neural tissues. Therefore, it is desirable to develop neuro-stimulation policies that replace the fixed-stimulation regime with an adaptive scheme.

The search for efficient neuro-stimulation strategies can be seen as a reinforcement learning problem. Here we study this problem using a generative model developed by Bush et al.

(2009) based on real data collected from epileptic rat hippocampus slices. Bush et al.'s model was shown to reproduce the seizure pattern of the original dynamical system and was later validated through the deployment of a learned treatment policy on a real brain slice (Bush and Pineau, 2009). The associated decision problem has a five-dimensional continuous state space and highly non-linear dynamics. At each time step the agent must choose whether or not to apply an electrical pulse. The goal is to suppress seizures as much as possible while minimizing the total amount of stimulation needed to do so.

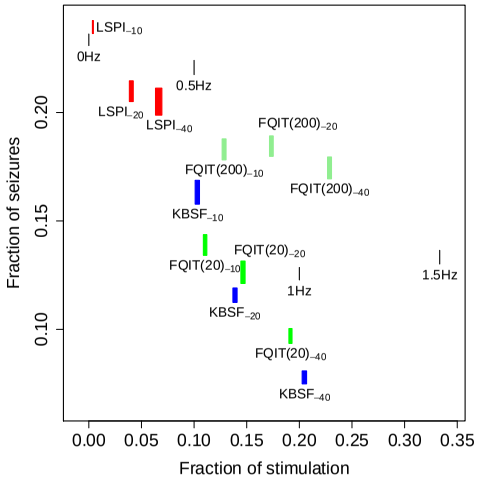
The experiments were performed as described in Section 4.2.1, with a single batch of sample transitions collected by a policy that selects actions uniformly at random. Specifically, the random policy was used to collect 50 trajectories of length 10000, resulting in a total of 500000 sample transitions. We use as a baseline for our comparisons the already mentioned fixed-frequency stimulation policies usually adopted in *in vitro* clinical studies (Bush and Pineau, 2009). In particular, we considered policies that apply electrical pulses at frequencies of 0 Hz, 0.5 Hz, 1 Hz, and 1.5 Hz.

We compare KBSF with LSPI and FQIT. For this task we ran both LSPI and KBSF with sparse kernels, that is, we only computed the kernels at the 6-nearest neighbors of a given state ($\mu = \bar{\mu} = 6$; see Appendix B.2 for details). This modification made it possible to use $m = 50000$ representative states with KBSF. Since for LSPI the reduction on the computational cost was not very significant, we fixed $m = 50$ to keep its run time within reasonable bounds. Again, KBSF and LSPI used the same approximation architectures, with representative states defined by the k-means algorithm. We fixed $\tau = 1$ and varied $\bar{\tau}$ in $\{0.01, 0.1, 1\}$. FQIT was configured as described in the previous section, with the parameter $\eta_{\min}$ varying in $\{20, 30, ..., 200\}$. In general, we observed that the performance of the tree-based method improved with smaller values for $\eta_{\min}$, with an expected increase in the computational cost. Thus, in order to give an overall characterization of FQIT's performance, we only report the results obtained with the extreme values of $\eta_{\min}$.

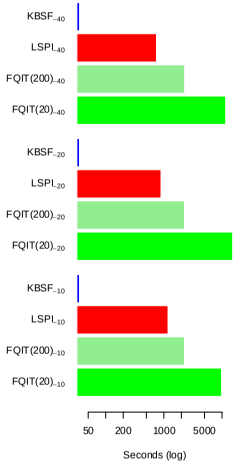
Figure 6 shows the results on the epilepsy-suppression task. In order to obtain different compromises between the problem's two conflicting objectives, we varied the relative magnitude of the penalties associated with the occurrence of seizures and with the application of an electrical pulse (Bush et al., 2009; Bush and Pineau, 2009). Specifically, we fixed the latter at -1 and varied the former with values in $\{-10, -20, -40\}$. This appears in the plots as subscripts next to the algorithms's names. As shown in Figure 6a, LSPI's policies seem to prioritize reduction of stimulation at the expense of higher seizure occurrence, which is clearly sub-optimal from a clinical point of view. FQIT(200) also performs poorly, with solutions representing no advance over the fixed-frequency stimulation strategies. In contrast, FQTI(20) and KBSF are both able to generate decision policies that are superior to the 1 Hz policy, which is the most efficient stimulation regime known to date in the clinical literature (Jerger and Schiff, 1995). However, as shown in Figure 6b, KBSF is able to do it at least 100 times faster than the tree-based method.

5. Incremental KBSF

As clear in the previous section, one characteristic of KBSF that sets it apart from other methods is its low demand in terms of computational resources. Specifically, both time and memory complexities of our algorithm are linear in the number of sample transitions n. In



(a) Performance. The length of the rectangles's edges represent 99% confidence intervals.



(b) Run times (confidence intervals do not show up in logarithmic scale)

Figure 6: Results on the epilepsy-suppression problem averaged over 50 runs. The decision policies were evaluated on episodes of 10^5 transitions starting from a fixed set of 10 test states drawn uniformly at random.

terms of the number of operations performed by the algorithm, this is the best one can do without discarding transitions. However, in terms of memory usage, it is possible to do even better. In this section we show how to build KBSF's approximation incrementally, without ever having access to the entire set of sample transitions at once. Besides reducing the memory complexity of the algorithm, this modification has the additional advantage of making KBSF suitable for on-line reinforcement learning.

In the batch version of KBSF, described in Section 4, the matrices $\bar{\mathbf{P}}^a$ and vectors $\bar{\mathbf{r}}^a$ are determined using all the transitions in the corresponding sets S^a. This has two undesirable consequences. First, the construction of the MDP $\bar{M}$ requires an amount of memory of $O(\hat{n}m)$, where $\hat{n} = \max_a n_a$. Although this is a significant improvement over KBRL's memory usage, which is lower bounded by $(\min_a n_a)^2|A|$, in more challenging domains even a linear dependence on $\hat{n}$ may be impractical. Second, in the batch version of KBSF the only way to incorporate new data into the model $\bar{M}$ is to recompute the multiplication $\bar{\mathbf{P}}^a = \dot{\mathbf{K}}^a\dot{\mathbf{D}}^a$ for all actions a for which there are new sample transitions available. Even if we ignore the issue with memory usage, this is clearly inefficient in terms of computation. In what follows we present an incremental version of KBSF that circumvents these important limitations (Barreto et al., 2012).

We assume the same scenario considered in Section 4: there is a set of sample transitions $S^a = \{(s^a_k, r^a_k, \hat{s}^a_k)|k = 1, 2, ..., n_a\}$ associated with each action $a \in A$, where $s^a_k, \hat{s}^a_k \in \mathbb{S}$ and $r^a_k \in \mathbb{R}$, and a set of representative states $\bar{S} = \{\bar{s}_1, \bar{s}_2, ..., \bar{s}_m\}$, with $\bar{s}_i \in \mathbb{S}$. Suppose now that we split the set of sample transitions S^a in two subsets S_1 and S_2 such that $S_1 \cap S_2 = \emptyset$ and $S_1 \cup S_2 = S^a$ (we drop the "a" superscript in the sets S_1 and S_2 to improve clarity). Without loss of generality, suppose that the sample transitions are indexed so that $S_1 \equiv \{(s^a_k, r^a_k, \hat{s}^a_k)|k = 1, 2, ..., n_1\}$ and $S_2 \equiv \{(s^a_k, r^a_k, \hat{s}^a_k)|k = n_1 + 1, n_1 + 2, ..., n_1 + n_2 = n_a\}$. Let $\bar{\mathbf{P}}^{S_1}$ and $\bar{\mathbf{r}}^{S_1}$ be matrix $\bar{\mathbf{P}}^a$ and vector $\bar{\mathbf{r}}^a$ computed by KBSF using only the n_1 transitions in S_1 (if $n_1 = 0$, we define $\bar{\mathbf{P}}^{S_1} = \mathbf{0} \in \mathbb{R}^{m\times m}$ and $\bar{\mathbf{r}}^{S_1} = \mathbf{0} \in \mathbb{R}^m$ for all $a \in A$). We want to compute $\bar{\mathbf{P}}^{S_1\cup S_2}$ and $\bar{\mathbf{r}}^{S_1\cup S_2}$ from $\bar{\mathbf{P}}^{S_1}$, $\bar{\mathbf{r}}^{S_1}$, and S_2, without using the set of sample transitions S_1.

We start with the transition matrices $\bar{\mathbf{P}}^a$. We know that

$$\begin{aligned}\bar{p}^{S_1}_{ij} &= \textstyle\sum_{t=1}^{n_1} \dot{k}^a_{it}\dot{d}^a_{tj} = \sum_{t=1}^{n_1} \frac{\mathrm{k}_\tau(\bar{s}_i, s^a_t)}{\sum_{l=1}^{n_1}\mathrm{k}_\tau(\bar{s}_i, s^a_l)} \frac{\bar{\mathrm{k}}_{\bar{\tau}}(\hat{s}^a_t, \bar{s}_j)}{\sum_{l=1}^{m}\bar{\mathrm{k}}_{\bar{\tau}}(\hat{s}^a_t, \bar{s}_l)} \\ &= \frac{1}{\sum_{l=1}^{n_1}\mathrm{k}_\tau(\bar{s}_i, s^a_l)} \sum_{t=1}^{n_1} \frac{\mathrm{k}_\tau(\bar{s}_i, s^a_t)\bar{\mathrm{k}}_{\bar{\tau}}(\hat{s}^a_t, \bar{s}_j)}{\sum_{l=1}^{m}\bar{\mathrm{k}}_{\bar{\tau}}(\hat{s}^a_t, \bar{s}_l)}.\end{aligned}$$

To simplify the notation, define

$$z^{S_1}_i = \sum_{l=1}^{n_1}\mathrm{k}_\tau(\bar{s}_i, s^a_l),\ z^{S_2}_i = \sum_{l=n_1+1}^{n_1+n_2}\mathrm{k}_\tau(\bar{s}_i, s^a_l),\ \text{and}\ b^t_{ij} = \frac{\mathrm{k}_\tau(\bar{s}_i, s^a_t)\bar{\mathrm{k}}_{\bar{\tau}}(\hat{s}^a_t, \bar{s}_j)}{\sum_{l=1}^{m}\bar{\mathrm{k}}_{\bar{\tau}}(\hat{s}^a_t, \bar{s}_l)},$$

with $t \in \{1, 2, ..., n_1 + n_2\}$. Then, we can write

$$\bar{p}^{S_1\cup S_2}_{ij} = \frac{1}{z^{S_1}_i + z^{S_2}_i}\left(\textstyle\sum_{t=1}^{n_1} b^t_{ij} + \sum_{t=n_1+1}^{n_1+n_2} b^t_{ij}\right) = \frac{1}{z^{S_1}_i + z^{S_2}_i}\left(\bar{p}^{S_1}_{ij} z^{S_1}_i + \textstyle\sum_{t=n_1+1}^{n_1+n_2} b^t_{ij}\right).$$

Now, defining $b_{ij}^{S_2} = \sum_{t=n_1+1}^{n_1+n_2} b_{ij}^t$, we have the simple update rule:

$$\boxed{\bar{p}_{ij}^{S_1 \cup S_2} = \frac{1}{z_i^{S_1} + z_i^{S_2}} \left(b_{ij}^{S_2} + \bar{p}_{ij}^{S_1} z_i^{S_1} \right)}. \tag{19}$$

We can apply similar reasoning to derive an update rule for the rewards $\bar{r}_i^a$. We know that

$$\bar{r}_i^{S_1} = \frac{1}{\sum_{l=1}^{n_1} \mathrm{k}_\tau(\bar{s}_i, s_l^a)} \sum_{t=1}^{n_1} \mathrm{k}_\tau(\bar{s}_i, s_t^a) r_t^a = \frac{1}{z_i^{S_1}} \sum_{t=1}^{n_1} \mathrm{k}_\tau(\bar{s}_i, s_t^a) r_t^a.$$

Let $e_i^t = \mathrm{k}_\tau(\bar{s}_i, s_t^a) r_t^a$, with $t \in \{1, 2, ..., n_1 + n_2\}$. Then,

$$\bar{r}_i^{S_1 \cup S_2} = \frac{1}{z_i^{S_1} + z_i^{S_2}} \left(\sum_{t=1}^{n_1} e_i^t + \sum_{t=n_1+1}^{n_1+n_2} e_i^t \right) = \frac{1}{z_i^{S_1} + z_i^{S_2}} \left(z_i^{S_1} \bar{r}_i^{S_1} + \sum_{t=n_1+1}^{n_1+n_2} e_i^t \right).$$

Defining $e_i^{S_2} = \sum_{t=n_1+1}^{n_1+n_2} e_i^t$, we have the following update rule:

$$\boxed{\bar{r}_i^{S_1 \cup S_2} = \frac{1}{z_i^{S_1} + z_i^{S_2}} \left(e_i^{S_2} + \bar{r}_i^{S_1} z_i^{S_1} \right)}. \tag{20}$$

Since $b_{ij}^{S_2}$, $e_i^{S_2}$, and $z_i^{S_2}$ can be computed based on S_2 only, we can discard the sample transitions in S_1 after computing $\bar{\mathbf{P}}^{S_1}$ and $\bar{\mathbf{r}}^{S_1}$. In order to do that, we only have to keep the variables $z_i^{S_1}$. These variables can be stored in $|A|$ vectors $\mathbf{z}^a \in \mathbb{R}^m$, resulting in a modest memory overhead. Note that we can apply the ideas above recursively, further splitting the sets S_1 and S_2 in subsets of smaller size. Thus, we have a fully incremental way of computing KBSF's MDP which requires almost no extra memory.

Algorithm 2 shows a step-by-step description of how to update $\bar{M}$ based on a set of sample transitions. Using this method to update its model, KBSF's space complexity drops from $O(\hat{n}m)$ to $O(m^2)$. Since the amount of memory used by KBSF is now independent of n, it can process an arbitrary number of sample transitions (or, more precisely, the limit on the amount of data it can process is dictated by time only, not space).

Instead of assuming that S_1 and S_2 are a partition of a fixed data set S^a, we can consider that S_2 was generated based on the policy learned by KBSF using the transitions in S_1. Thus, Algorithm 2 provides a flexible framework for integrating learning and planning within KBSF. Specifically, our algorithm can cycle between learning a model of the problem based on sample transitions, using such a model to derive a policy, and resorting to this policy to collect more data. Algorithm 3 shows a possible implementation of this framework. In order to distinguish it from its batch counterpart, we will call the incremental version of our algorithm *i*KBSF. *i*KBSF updates the model $\bar{M}$ and the value function $\bar{\mathbf{Q}}$ at fixed intervals t_m and t_v, respectively. When $t_m = t_v = n$, we recover the batch version of KBSF; when $t_m = t_v = 1$, we have a fully on-line method which stores no sample transitions.

Algorithm 3 allows for the inclusion of new representative states to the model $\bar{M}$. Using Algorithm 2 this is easy to do: given a new representative state $\bar{s}_{m+1}$, it suffices to set $z_{m+1}^a = 0$, $\bar{r}_{m+1}^a = 0$, and $\bar{p}_{m+1,j} = \bar{p}_{j,m+1} = 0$ for $j = 1, 2, ..., m+1$ and all $a \in A$. Then, in the following applications of update rules (19) and (20), the dynamics of $\bar{M}$ will naturally reflect the existence of state $\bar{s}_{m+1}$. Note that the inclusion of new representative states

Algorithm 2 Update KBSF's MDP

Input: $\bar{\mathbf{P}}^a$, $\bar{\mathbf{r}}^a$, $\mathbf{z}^a$ for all $a \in A$ ▷ Current model
$S^a = \{(s_k^a, r_k^a, \hat{s}_k^a) | k = 1, 2, ..., n_a\}$ for all $a \in A$ ▷ Sample transitions
Output: Updated $\bar{M}$ and $\mathbf{z}^a$

for $a \in A$ **do**
  for $t = 1, ..., n_a$ **do** $\bar{z}_t \leftarrow \sum_{l=1}^m \bar{\mathrm{k}}_{\bar{\tau}}(\hat{s}_t^a, \bar{s}_l)$
  $n_a \leftarrow |S^a|$
  for $i = 1, 2, ..., m$ **do**
    $z' \leftarrow \sum_{t=1}^{n_a} \mathrm{k}_\tau(\bar{s}_i, s_t^a)$
    for $j = 1, 2, ..., m$ **do**
      $b \leftarrow \sum_{t=1}^{n_a} \mathrm{k}_\tau(\bar{s}_i, s_t^a) \bar{\mathrm{k}}_{\bar{\tau}}(\hat{s}_t^a, \bar{s}_j) / \bar{z}_t$
      $\bar{p}_{ij} \leftarrow \frac{1}{z_i^a + z'} (b + \bar{p}_{ij} z_i^a)$ ▷ Update transition probabilities
    $e \leftarrow \sum_{t=1}^{n_a} \mathrm{k}_\tau(\bar{s}_i, s_t^a) r_t^a$
    $\bar{r}_i \leftarrow \frac{1}{z_i^a + z'} (e + \bar{r}_i z_i^a)$ ▷ Update rewards
    $z_i^a \leftarrow z_i^a + z'$ ▷ Update normalization factor

Algorithm 3 Incremental KBSF (*i*KBSF)

$\bar{S} = \{\bar{s}_1, \bar{s}_2, ..., \bar{s}_m\}$ ▷ Set of representative states
Input: t_m ▷ Interval to update model
t_v ▷ Interval to update value function
Output: Approximate value function $\tilde{Q}(s, a)$

$\bar{\mathbf{P}}^a \leftarrow \mathbf{0} \in \mathbb{R}^{m \times m}$, $\bar{\mathbf{r}}^a \leftarrow \mathbf{0} \in \mathbb{R}^m$, $\mathbf{z}^a \leftarrow \mathbf{0} \in \mathbb{R}^m$, for all $a \in A$
$\bar{\mathbf{Q}} \leftarrow$ arbitrary matrix in $\mathbb{R}^{m \times |A|}$
$s \leftarrow$ initial state
$a \leftarrow$ random action
for $t \leftarrow 1, 2, ...$ **do**
  Execute a in s and observe r and $\hat{s}$
  $S^a \leftarrow S^a \bigcup \{(s, r, \hat{s})\}$
  if $(t \mod t_m = 0)$ **then** ▷ Update model
    Add new representative states to $\bar{M}$ using S^a ▷ This step is optional
    Update $\bar{M}$ and $\mathbf{z}^a$ using Algorithm 2 and S^a
    $S^a \leftarrow \emptyset$ for all $a \in A$ ▷ Discard transitions
  if $(t \mod t_v = 0)$ update $\bar{\mathbf{Q}}$ ▷ Update value function
  $s \leftarrow \hat{s}$
  Select a based on $\tilde{Q}(s, a) = \sum_{i=1}^m \bar{\kappa}_{\bar{\tau}}(s, \bar{s}_i) \bar{q}_{ia}$

does not destroy the information already in the model. This allows *i*KBSF to refine its approximation on the fly, as needed. One can think of several ways of detecting the need for new representative states. A simple strategy, based on Proposition 6, is to impose a maximum distance allowed between a sampled state $\hat{s}_i^a$ and the nearest representative state, $dist(\hat{s}_i^a, 1)$. So, anytime the agent encounters a new state $\hat{s}_i^a$ for which $dist(\hat{s}_i^a, 1)$ is above a given threshold, $\hat{s}_i^a$ is added to the model as $\bar{s}_{m+1}$. In Section 5.2 we report experiments with *i*KBSF using this approach. Before that, though, we discuss the theoretical properties of the incremental version of our algorithm.

5.1 Theoretical results

As discussed, *i*KBSF does not need to store sample transitions to build its approximation. However, the computation of $\tilde{Q}(s,a)$ through (12) requires all the tuples $(s_i^a, r_i^a, \hat{s}_i^a)$ to be available. In some situations, it may be feasible to keep the transitions in order to compute $\tilde{Q}(s,a)$. However, if we want to use *i*KBSF to its full extend, we need a way of computing $\tilde{Q}(s,a)$ without using the sample transitions. This is why upon reaching state s at time step t *i*KBSF selects the action to be performed based on

$$\tilde{Q}_t(s,a) = \sum_{i=1}^{m} \bar{\kappa}_{\bar{\tau}}(s, \bar{s}_i) \bar{Q}_t(\bar{s}_i, a), \tag{21}$$

where $\bar{Q}_t(\bar{s}_i, a)$ is the action-value function available to *i*KBSF at the t^{th} iteration (see Algorithm 3). Note that we do not assume that *i*KBSF has computed the optimal value function of its current model $\bar{M}_t$—that is, it may be the case that $\bar{Q}_t(\bar{s}_i, a) \neq \bar{Q}_t^*(\bar{s}_i, a)$.

Unfortunately, when we replace (12) with (21) Proposition 3 no longer applies. In this section we address this issue by deriving an upper bound for the difference between $\tilde{Q}_t(s,a)$ and $\hat{Q}_t(s,a)$, the action-value function that would be computed by KBRL using all the transitions processed by *i*KBSF up to time step t. In order to derive our bound, we assume that *i*KBSF uses a fixed set $\bar{S}$—meaning that no representative states are added to the model $\bar{M}$—and that it never stops refining its model, doing so at every iteration t (*i.e.*, $t_m = 1$ in Algorithm 3). We start by showing the following lemma:

Lemma 9 *Let $M \equiv (S, A, \mathbf{P}^a, \mathbf{r}^a, \gamma)$ and $\tilde{M} \equiv (S, A, \tilde{\mathbf{P}}^a, \tilde{\mathbf{r}}^a, \gamma)$ be two finite MDPs. Then, for any $s \in S$ and any $a \in A$,*

$$|Q^*(s,a) - \tilde{Q}^*(s,a)| \leq \frac{1}{1-\gamma} \max_a \|\mathbf{r}^a - \tilde{\mathbf{r}}^a\|_\infty + \frac{\gamma}{2(1-\gamma)^2} R_{\text{dif}} \max_a \|\mathbf{P}^a - \tilde{\mathbf{P}}^a\|_\infty,$$

where $R_{\text{dif}} = \max_{a,i} r_i^a - \min_{a,i} r_i^a$.

Lemma 9 provides an upper bound for the difference in the action-value functions of any two MDPs having the same state space S, action space A, and discount factor γ.[4] Our strategy will be to use this result to bound the error introduced by the application of the stochastic-factorization trick in the context of *i*KBSF.

4. Strehl and Littman's (2008) Lemma 1 is similar to our result. Their bound is more general than ours, as it applies to any Q^π, but it is also slightly looser.

When $t_m = 1$, at any time step t *i*KBSF has a model $\bar{M}_t$ built based on the t transitions observed thus far. As shown in the beginning of this section, $\bar{M}_t$ exactly matches the model that would be computed by batch KBSF using the same data and the same set of representative states. Thus, we can think of matrices $\bar{\mathbf{P}}_t^a$ and vectors $\bar{\mathbf{r}}_t^a$ available at the t^{th} iteration of *i*KBSF as the result of the stochastic-factorization trick applied with matrices $\mathbf{D}_t$ and $\mathbf{K}_t^a$. Although *i*KBSF does not explicitly compute such matrices, they serve as a theoretical foundation to build our result on.

Proposition 10 *Suppose iKBSF is executed with a fixed set of representative states $\bar{S}$ using $t_m = 1$. Let $\mathbf{D}_t$, $\mathbf{K}_t^a$ and $\bar{\mathbf{r}}_t^a$ be the matrices and the vector (implicitly) computed by this algorithm at iteration t. Then, if s is the state encountered by iKBSF at time step t,*

$$|\hat{Q}_t(s,a) - \tilde{Q}_t(s,a)| \leq \frac{1}{1-\gamma} \max_a \|\hat{\mathbf{r}}_t^a - \mathbf{D}_t \bar{\mathbf{r}}_t^a\|_\infty + \frac{\bar{R}_{\text{dif},t}}{(1-\gamma)^2} \left(\frac{\gamma}{2} \max_a \|\hat{\mathbf{P}}_t^a - \mathbf{D}_t \mathbf{K}_t^a\|_\infty + \sigma(\mathbf{D}_t) \right) + \epsilon_{\bar{Q}_t}, \tag{22}$$

for any $a \in A$, where $\tilde{Q}_t$ is the value function computed by iKBSF at time step t through (21), $\hat{Q}_t$ is the value function computed by KBRL through (7) based on the same data, $\bar{R}_{\text{dif},t} = \max_{a,i} \bar{r}_{i,t}^a - \min_{a,i} \bar{r}_{i,t}^a$, $\sigma(\mathbf{D}_t) = \max_i (1 - \max_j d_{ij,t})$, and $\epsilon_{\bar{Q}_t} = \max_{i,a} |\bar{Q}_t^*(\bar{s}_i, a) - \bar{Q}_t(\bar{s}_i, a)|$.

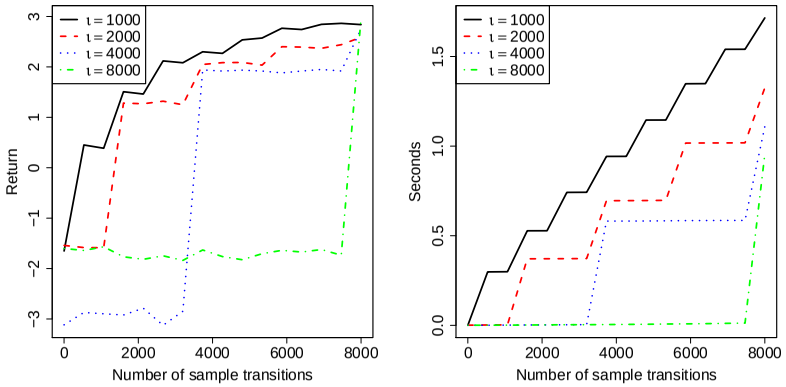
Proposition 10 shows that, at any time step t, the error in the action-value function computed by *i*KBSF is bounded above by the quality and the level of stochasticity of the stochastic factorization implicitly computed by the algorithm. The term $\epsilon_{\bar{Q}_t}$ accounts for the possibility that *i*KBSF has not computed the optimal value function of its model at step t, either because $t_m \neq t_v$ or because the update of $\bar{\mathbf{Q}}$ in Algorithm 3 is not done to completion (for example, one can apply the Bellman operator $\bar{T}$ a fixed number of times, stopping short of convergence). The restriction $t_m = 1$ is not strictly necessary if we are willing to compare $\tilde{Q}_t(s,a)$ with $\hat{Q}_{t'}(s,a)$, where $t' = \lfloor (t + t_m)/t \rfloor$ (the next time step scheduled for a model update). However, such a result would be somewhat circular, since the sample transitions used to build $\hat{Q}_{t'}(s,a)$ may depend on $\tilde{Q}_t(s,a)$. Finally, we note that, given the similarity between the right-hand sides of (8) and (22), it should be trivial to derive results analogous to Propositions 6 and 8 that also apply to *i*KBSF.

5.2 Empirical results

We now look at the empirical performance of the incremental version of KBSF. Following the structure of Section 4.2, we start with the puddle world task to show that *i*KBSF is indeed able to match the performance of batch KBSF without storing all sample transitions. Next we exploit the scalability of *i*KBSF to solve two difficult control tasks, triple pole-balancing and helicopter hovering. We also compare *i*KBSF's performance with that of other reinforcement learning algorithms.

5.2.1 Puddle world (proof of concept)

We use the puddle world problem as a proof of concept (Sutton, 1996). In this first experiment we show that *i*KBSF is able to recover the model that would be computed by its batch counterpart. In order to do so, we applied Algorithm 3 to the puddle-world task using a random policy to select actions.



(a) Performance (b) Run times

Figure 7: Results on the puddle-world task averaged over 50 runs. KBSF used 100 representative states evenly distributed over the state space and $t_m = t_v = \iota$ (see legends). Sample transitions were collected by a random policy. The agents were tested on two sets of states surrounding the "puddles" (see Appendix B).

Figure 7 shows the result of the experiment when we vary the parameters t_m and t_v. Note that the case in which $t_m = t_v = 8000$ corresponds to the batch version of KBSF, whose results on the puddle world are shown in Figure 3. As expected, the performance of KBSF policies improves gradually as the algorithm goes through more sample transitions, and in general the intensity of the improvement is proportional to the amount of data processed. More important, the performance of the decision policies after all sample transitions have been processed is essentially the same for all values of t_m and t_v, which confirms that *i*KBSF can be used as an instrument to circumvent KBSF's memory demand. Thus, if one has a batch of sample transitions that does not fit in the available memory, it is possible to split the data in chunks of smaller sizes and still get the same value-function approximation that would be computed if the entire data set were processed at once. As shown in Figure 7b, there is only a small computational overhead associated with such a strategy (this results from unnormalizing and normalizing the elements of $\bar{\mathbf{P}}^a$ and $\bar{\mathbf{r}}^a$ multiple times through update rules (19) and (20)).

5.2.2 Triple pole-balancing (comparison with fitted Q-iteration)

As discussed in Section 4.2.2, the pole balancing task has been addressed in several different versions, and among them simultaneously balancing two poles is particularly challenging (Wieland, 1991). Figures 4c and 4d show that the batch version of KBSF was able to satisfactorily solve the double pole-balancing task. In order to show the scalability of the incremental version of our algorithm, in this section we raise the bar, adding a third pole

to the problem. We perform our simulations using the parameters usually adopted with the two-pole problem, with the extra pole having the same length and mass as the longer pole (Gomez, 2003, see Appendix B). This results in a difficult control problem with an 8-dimensional state space $\mathbb{S}$.

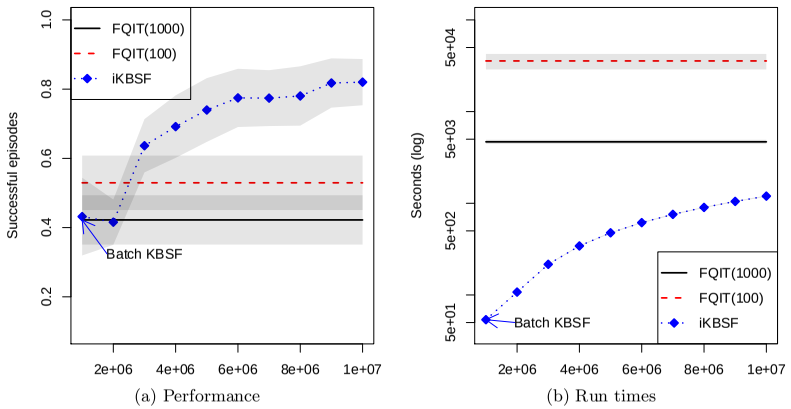
In our experiments with KBSF on the two-pole task we used 200 representative states and 10^6 sample transitions collected by a random policy. Here we start our experiment with triple pole-balancing using exactly the same configuration, and then we let *i*KBSF refine its model $\bar{M}$ by incorporating more sample transitions through update rules (19) and (20). We also let *i*KBSF grow its model if necessary. Specifically, a new representative state is added to $\bar{M}$ on-line every time the agent encounters a sample state $\hat{s}_i^a$ for which $\bar{\mathrm{k}}_{\bar{\tau}}(\hat{s}_i^a, \bar{s}_j) < 0.01$ for all $j \in 1, 2, ..., m$. This corresponds to setting a maximum allowed distance from a sampled state to the closest representative state, $\max_{a,i} dist(\hat{s}_i^a, 1)$.

Given the poor performance of LSPI on the double pole-balancing task, shown in Figures 4c and 4d, on the three-pole version of the problem we only compare KBSF with FQIT. We used FQIT with the same configuration adopted in Sections 4.2.3 and 4.2.4, with the parameter $\eta_{\min}$ varying in the set $\{10000, 1000, 100\}$. As for KBSF, the widths of the kernels were fixed at $\tau = 100$ and $\bar{\tau} = 1$ and sparse kernels were used ($\mu = 50$ and $\bar{\mu} = 10$).

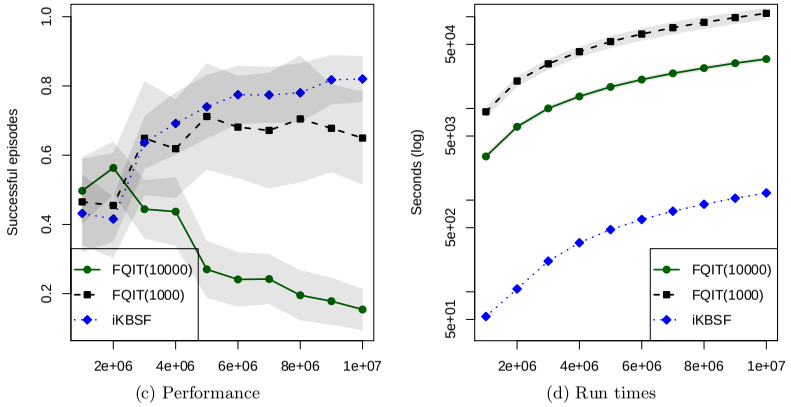
In order to show the benefits provided by the incremental version of our algorithm, we assumed that both KBSF and FQIT could store at most 10^6 sample transitions in memory. In the case of *i*KBSF, this is not a problem, since we can always split the data in subsets of smaller size and process them incrementally. Here, we used Algorithm 3 with a 0.3-greedy policy, $t_m = t_v = 10^6$, and $n = 10^7$. In the case of FQIT, we have two options to circumvent the limited amount of memory available. The first one is to use a single batch of 10^6 sample transitions. The other option is to use the initial batch of transitions to compute an approximation of the problem's value function, then use an 0.3-greedy policy induced by this approximation to collect a second batch, and so on. Here we show the performance of FQIT using both strategies.

We first compare the performance of *i*KBSF with that of FQIT using a single batch of sample transitions. This is shown in Figure 8a and 8b. For reference, we also show the results of batch KBSF—that is, we show the performance of the policy that would be computed by our algorithm if we did not have a way of computing its approximation incrementally. As shown in Figure 8a, both FQIT and batch KBSF perform poorly in the triple pole-balancing task, with average success rates below 55%. These results suggest that the amount of data used by these algorithms is insufficient to describe the dynamics of the control task. Of course, we could give more sample transitions to FQIT and batch KBSF. Note however that, since they are batch learning methods, there is an inherent limit on the amount of data that these algorithms can use to construct their approximation. In contrast, the amount of memory required by *i*KBSF is independent of the number of sample transitions n. This fact together with the fact that KBSF's computational complexity is only linear in n allow our algorithm to process a large amount of data in reasonable time. This can be clearly observed in Figure 8b, which shows that *i*KBSF can build an approximation using 10^7 sample transitions in under 20 minutes. As a reference for comparison, FQIT(1000) took an average of 1 hour and 18 minutes to process 10 times less data.

As shown in Figure 8a, *i*KBSF's ability to process a large number of sample transitions allows our algorithm to achieve a success rate of approximately 80%. This is similar to the



(a) Performance (b) Run times



(c) Performance (d) Run times

Figure 8: Results on the triple pole-balancing task, as a function of the number of sample transitions n, averaged over 50 runs. Figures 8a and 8b show results of FQIT when using a single batch of 10^6 transitions; in Figures 8c and 8d ten sets of 10^6 transitions were used in sequence by the algorithm (see text for details). The values correspond to the fraction of episodes initiated from the test states in which the 3 poles could be balanced for 3000 steps (one minute of simulated time). The test sets were regular grids of 256 cells defined over the hypercube centered at the origin and covering 50% of the state-space axes in each dimension (see Appendix B for details). Shadowed regions represent 99% confidence intervals.

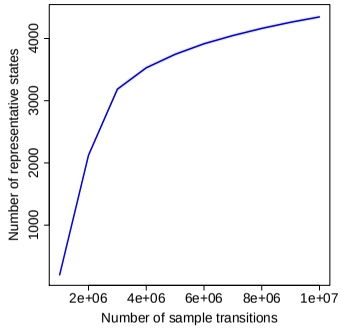


Figure 9: Number of representative states used by iKBSF on the triple pole-balancing task. Results were averaged over 50 runs (99% confidence intervals are almost imperceptible in the figure).

performance of batch KBSF on the two-pole version of the problem (*cf.* Figure 4). The good performance of iKBSF on the triple pole-balancing task is especially impressive when we recall that the decision policies were evaluated on a set of test states representing all possible directions of inclination of the three poles. In order to achieve the same level of performance with KBSF, approximately 2 Gb of memory would be necessary, even using sparse kernels, whereas iKBSF used less than 0.03 Gb of memory.

One may argue that the above comparison between FQIT and KBSF is not fair, since the latter used ten times the amount of data used by the former. Thus, in Figures 8c and 8d we show the results of FQIT using 10 batches of 10^6 transitions—exactly the same number of transitions processed by iKBSF. Here we cannot compare iKBSF with FQIT(100) because the computational cost of the tree-based approach is prohibitively large (it would take over 4 days only to train a single agent, not counting the test phase). When we look at the other instances of the algorithm, we see two opposite trends. Surprisingly, the extra sample transitions actually made the performance of FQIT(10000) *worse*. On the other hand, FQIT(1000) performs significantly better using more data, though still not as well as iKBSF (both in terms of performance and computing time).

To conclude, observe in Figure 9 how the number of representative states m grows as a function of the number of sample transitions processed by KBSF. As expected, in the beginning of the learning process m grows fast, reflecting the fact that some relevant regions of the state space have not been visited yet. As more and more data come in, the number of representative states starts to stabilize.

5.2.3 Helicopter hovering task (comparison with SARSA)

In the previous two sections we showed how iKBSF can be used to circumvent the inherent memory limitations of batch learning. We now show how our algorithm performs in a fully

on-line regime. For that, we focus on a challenging reinforcement learning task in which the goal is to control an autonomous helicopter.

Helicopters have unique control capabilities, such as low speed flight and in-place hovering, that make them indispensable instruments in many contexts. Such flexibility comes at a price, though: it is widely recognized that a helicopter is significantly harder to control than a fixed-wing aircraft (Ng et al., 2003; Abbeel et al., 2007). Part of this difficulty is due to the complex dynamics of the helicopter, which is not only non-linear, noisy, and asymmetric, but also counterintuitive in some aspects (Ng et al., 2003).

An additional complication of controlling an autonomous helicopter is the fact that a wrong action can easily lead to a crash, which is both dangerous and expensive. Thus, the usual practice is to first develop a model of the helicopter's dynamics and then use the model to design a controller (Ng et al., 2003). Here we use the model constructed by Abbeel et al. (2005) based on data collected on actual flights of an XCell Tempest helicopter (see Appendix B). The resulting reinforcement learning problem has a 12-dimensional state space whose variables represent the aircraft's position, orientation, and the corresponding velocities and angular velocities along each axis.

In the version of the task considered here the goal is to keep the helicopter hovering as close as possible to a fixed position. All episodes start at the target location, and at each time step the agent receives a negative reward proportional to the distance from the current state to the desired position. Because the tail rotor's thrust exerts a sideways force on the helicopter, the aircraft cannot be held stationary in the zero-cost state even in the absence of wind. The episode ends when the helicopter leaves the hover regime, that is, when any of the state's variables exceeds pre-specified thresholds.

The helicopter is controlled via a 4-dimensional continuous vector whose variables represent the longitudinal cyclic pitch, the latitudinal cyclic pitch, the tail rotor collective pitch, and the main rotor collective pitch. By adjusting the value of these variables the pilot can rotate the helicopter around its axes and control the thrust generated by the main rotor. Since KBSF was designed to deal with a finite number of actions, we discretized the set A using 4 values per dimension, resulting in 256 possible actions. The details of the discretization process are given below.

Here we compare iKBSF with the SARSA(λ) algorithm using tile coding for value function approximation (Rummery and Niranjan, 1994, Sutton, 1996—see Appendix B). We applied SARSA with $\lambda = 0.05$, a learning rate of 0.001, and 24 tilings containing 4^{12} tiles each. Except for λ, all the parameters were adjusted in a set of preliminary experiments in order to improve the performance of the SARSA agent. We also defined the action-space discretization based on SARSA's performance. In particular, instead of partitioning each dimension in equally-sized intervals, we spread the break points unevenly along each axis in order to maximize the return obtained by the SARSA agent. The result of this process is described in Appendix B. The interaction of the SARSA agent with the helicopter hovering task was dictated by an ϵ-greedy policy. Initially we set $\epsilon = 1$, and at every 50000 transitions the value of ϵ was decreased in 30%.

The iKBSF agent collected sample transitions using the same exploration regime. Based on the first batch of 50000 transitions, $m = 500$ representative states were determined by the k-means algorithm. No representative states were added to iKBSF's model after that.

Both the value function and the model were updated at fixed intervals of $t_v = t_m = 50000$ transitions. We fixed $\tau = \bar{\tau} = 1$ and $\mu = \bar{\mu} = 4$.

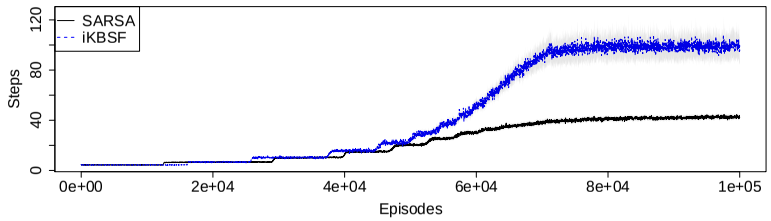
Figure 10 shows the results obtained by SARSA and KBSF on the helicopter hovering task. Note in Figure 10a how the average episode length increases abruptly at the points in which the value of ϵ is decreased. This is true for both SARSA and KBSF. Also, since the number of steps executed per episode increases over time, the interval in between such abrupt changes decreases in length, as expected. Finally, observe how the performance of both agents stabilizes after around 70000 episodes, probably because at this point there is almost no exploration taking place anymore.

When we compare KBSF and SARSA, it is clear that the former significantly outperforms the latter. Specifically, after the cut-point of 70000 episodes, the KBSF agent executes approximately 2.25 times the number of steps performed by the SARSA agent before crashing. Looking at Figures 10a and 10b, one may argue at first that there is nothing surprising here: being a model-based algorithm, KBSF is more sample efficient than SARSA, but it is also considerably slower (Atkeson and Santamaria, 1997). Notice though that the difference between the run times of SARSA and KBSF shown in Figure 10b is in part a consequence of the good performance of the latter: since KBSF is able to control the helicopter for a larger number of steps, the corresponding episodes will obviously take longer. A better measure of the algorithms's computational cost can be seen in Figure 10c, which shows the average time taken by each method to perform one transition. Observe how KBSF's computing time peaks at the points in which the model and the value function are updated. In the beginning KBSF's MDP changes considerably, and as a result the value function updates take longer. As more data come in, the model starts to stabilize, accelerating the computation of $\bar{\mathbf{Q}}^*$ (we "warm start" policy iteration with the value function computed in the previous round). At this point, KBSF's computational cost per step is only slightly higher than SARSA's, even though the former computes a model of the environment while the latter directly updates the value function approximation.

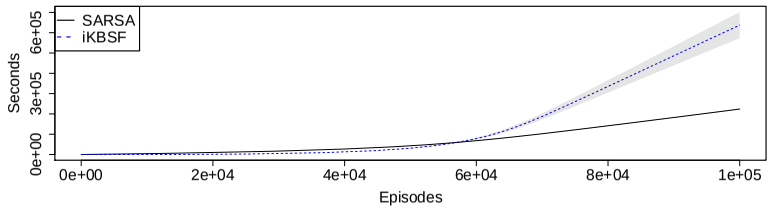
To conclude, we note that our objective in this section was exclusively to show that KBSF can outperform a well-known on-line algorithm with compatible computational cost. Therefore, we focused on the comparison of the algorithms rather than on obtaining the best possible performance on the task. Also, it is important to mention that more difficult versions of the helicopter task have been addressed in the literature, usually using domain knowledge in the configuration of the algorithms or to guide the collection of data (Ng et al., 2003; Abbeel et al., 2007). Since our focus here was on evaluating the on-line performance of KBSF, we addressed the problem in its purest form, without using any prior information to help the algorithms solve the task (see Asbah et al.'s paper for experiments on the helicopter hovering task with a more specialized version of KBSF, 2013).

6. Discussion

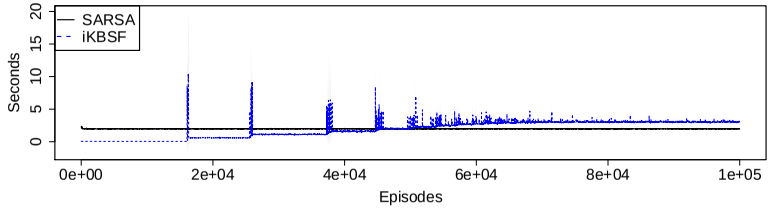
In this section we deepen our discussion about KBSF. We start with an analysis of the approximation computed by our algorithm, in which we draw interesting connections with KBRL, and then we proceed to discuss some issues that come up when one uses KBSF in practice.



(a) Performance



(b) Run time



(c) Average time per step (time of an episode divided by the number of steps)

Figure 10: Results on the helicopter hovering task averaged over 50 runs. The learned controllers were tested from a fixed state (see text for details). The shadowed regions represent 99% confidence intervals.

6.1 A closer look at KBSF's approximation

As outlined in Section 2, KBRL defines the probability of a transition from state $\hat{s}_i^b$ to state $\hat{s}_k^a$ as being $\kappa_\tau^a(\hat{s}_i^b, s_k^a)$, where $a, b \in A$ (see Figure 2a). Note that the kernel κ_τ^a is computed with the initial state s_k^a, and not $\hat{s}_k^a$ itself. The intuition behind this is simple: since we know the transition $s_k^a \xrightarrow{a} \hat{s}_k^a$ has occurred before, the more "similar" $\hat{s}_i^b$ is to s_k^a, the more likely the transition $\hat{s}_i^b \xrightarrow{a} \hat{s}_k^a$ becomes (Ormoneit and Sen, 2002).

From (10), it is clear that the computation of matrices $\mathbf{K}^a$ performed by KBSF follows the same reasoning underlying the computation of KBRL's matrices $\hat{\mathbf{P}}^a$; in particular, $\kappa_\tau^a(\bar{s}_j, s_k^a)$ gives the probability of a transition from $\bar{s}_j$ to $\hat{s}_k^a$. However, when we look at matrix $\mathbf{D}$ things are slightly different: here, the probability of a "transition" from $\hat{s}_i^b$ to representative state $\bar{s}_j$ is given by $\bar{\kappa}_{\bar{\tau}}(\hat{s}_i^b, \bar{s}_j)$—a computation that involves $\bar{s}_j$ itself. If we were to strictly adhere to KBRL's logic when computing the transition probabilities to the representative states $\bar{s}_j$, the probability of transitioning from $\hat{s}_i^b$ to $\bar{s}_j$ upon executing action a should be a function of $\hat{s}_i^b$ and a state s' from which we knew a transition $s' \xrightarrow{a} \bar{s}_j$ had occurred. In this case we would end up with one matrix $\mathbf{D}^a$ for each action $a \in A$. Note though that this formulation of the method is not practical, because the computation of the matrices $\mathbf{D}^a$ would require a transition $(\cdot) \xrightarrow{a} \bar{s}_j$ for each $a \in A$ and each $\bar{s}_j \in \bar{S}$. Clearly, such a requirement is hard to fulfill even if we have a generative model available to generate sample transitions.

In this section we take a closer look at KBSF's approximation, and provide two interpretations that support the way the matrices involved are built. We argue that KBSF can be seen as a kernel-based approximation of both the model and the value function computed by KBRL. Based on these interpretations we later discuss how KBSF can potentially be beneficial from a statistical point of view.

6.1.1 Approximating the model

We start by looking at how KBRL constructs its model. As shown in Figure 2a, for each action $a \in A$ the state $\hat{s}_i^b$ has an associated stochastic vector $\hat{\mathbf{p}}_j^a \in \mathbb{R}^{1\times n}$ whose nonzero entries correspond to the kernel $\kappa_\tau^a(\hat{s}_i^b, \cdot)$ evaluated at $s_k^a, k = 1, 2, \ldots, n_a$. Since we are dealing with a continuous state space, it is possible to compute an analogous vector for any $s \in \mathbb{S}$ and any $a \in A$. Focusing on the nonzero entries of $\hat{\mathbf{p}}_j^a$, we define the function

$$\begin{aligned} \hat{\mathcal{P}}_{S^a}: \quad & \mathbb{S} \mapsto \mathbb{R}^{1\times n_a} \\ & \hat{\mathcal{P}}_{S^a}(s) = \hat{\mathbf{p}}^a \iff \hat{p}_i^a = \kappa_\tau^a(s, s_i^a) \text{ for } i = 1, 2, ..., n_a. \end{aligned} \tag{23}$$

Clearly, full knowledge of the function $\hat{\mathcal{P}}_{S^a}$ allows for an exact computation of KBRL's transition matrix $\hat{\mathbf{P}}^a$. Now suppose we do not know $\hat{\mathcal{P}}_{S^a}$ and we want to compute an approximation of this function in the points $\hat{s}_i^a \in S^a$, for all $a \in A$. Suppose further that we are only given a "training set" composed of m pairs $(\bar{s}_j, \hat{\mathcal{P}}_{S^a}(\bar{s}_j))$. One possible way of approaching this problem is to resort to kernel smoothing techniques. In this case, a particularly common choice is the so-called Nadaraya-Watson kernel-weighted estimator (Hastie et al., 2002, Chapter 6):

$$\bar{\mathcal{P}}_{S^a}(s) = \frac{\sum_{j=1}^m \bar{\mathrm{k}}_{\bar{\tau}}(s, \bar{s}_j)\hat{\mathcal{P}}_{S^a}(\bar{s}_j)}{\sum_{j=1}^m \bar{\mathrm{k}}_{\bar{\tau}}(s, \bar{s}_j)} = \sum_{j=1}^m \bar{\kappa}_{\bar{\tau}}(s, \bar{s}_j)\hat{\mathcal{P}}_{S^a}(\bar{s}_j). \tag{24}$$

Contrasting the expression above with (10), we see that this is exactly how KBSF computes its approximation $\mathbf{D}\mathbf{K}^a \approx \hat{\mathbf{P}}^a$, with $\bar{\mathcal{P}}_{S^a}$ evaluated at the points $\hat{s}_i^b \in S^b$, $b = 1, 2, ..., |A|$. In this case, $\bar{\kappa}_{\bar{\tau}}(\hat{s}_i^b, \bar{s}_j)$ are the elements of matrix $\mathbf{D}$, and $\hat{\mathcal{P}}_{S^a}(\bar{s}_j)$ is the j^{th} row of matrix $\dot{\mathbf{K}}^a$. Thus, in some sense, KBSF uses KBRL's own kernel approximation principle to compute a stochastic factorization of $\hat{M}$. One can easily extend the reasoning above to also include rewards by defining a function $\hat{\mathcal{M}}_{S^a} : \mathbb{S} \mapsto \mathbb{R}^{1 \times n_a + 1}$ such that $\hat{\mathcal{M}}_{S^a}(s) = [\hat{\mathcal{P}}_{S^a}(s), \hat{\mathcal{P}}_{S^a}(s)^\top \mathbf{r}^a]$.

The exposition above also makes it clear that it is possible to build the matrices $\dot{\mathbf{D}}^a$ using different sets of representative states $\bar{S}^a$ (this corresponds to having $|A|$ training sets composed of pairs $(\bar{s}_j^a, \hat{\mathcal{P}}_{S^a}(\bar{s}_j^a))$). As long as all the sets $\bar{S}^a$ have the same cardinality m, the stochastic-factorization trick can still be applied. However, in order for the approximation computed by KBSF to make sense, we would have to have one matrix $\mathbf{D}^a$ for each action $a \in A$ (see in Figure 2b how matrix $\mathbf{D}$ is computed). Unfortunately, when different matrices $\mathbf{D}^a$ are used, our "core" theoretical result, Proposition 2, no longer applies. Although alternative error bounds are possible, as shown by Barreto (2014), they are in general significantly looser than (8). In any case, the extension of KBSF to use different sets of representative states $\bar{S}^a$ may be an interesting topic for future research.

6.1.2 Approximating the value function

We now turn our attention to the way KBRL computes its value function, and show an intuitive way to derive KBSF's update equations. Based on (4) and (5), we see that value iteration's update rule for KBRL's MDP, $\hat{\Delta}\Gamma$, is

$$\hat{Q}_{t+1}(\hat{s}_i^c, a) = \sum_{j=1}^{n_a} \kappa_\tau^a(\hat{s}_i^c, s_j^a) \left[r_j^a + \gamma \max_b \hat{Q}_t(\hat{s}_j^a, b) \right], \tag{25}$$

where $a, b, c \in A$. Note that at any time step t the equation above can be used to compute an approximation of the t-step value function over the entire state space $\mathbb{S}$; after convergence to $\hat{Q}^*$ equation (25) gives rise to (7).

From a computational point of view, the potential problem with rule (25) is the fact that updating $\hat{Q}$ takes $O(n\hat{n}|A|)$ operations (recall that $n = \sum_a n_a$ and $\hat{n} = \max_a n_a$). KBRL makes it possible to compute an approximate solution for an MDP with continuous state space $\mathbb{S}$ by only updating the value of a finite subset $\hat{S} \subset \mathbb{S}$. It is reasonable to ask whether similar strategy can come to the rescue when $\hat{S}$ is itself too large. Specifically, if the values of the states $\hat{s}_i^a \in \hat{S}$ can be approximated based on the values of a small set of states $\bar{S} \subset \mathbb{S}$, with $|\bar{S}| = m$, then only the latter must be updated during dynamic programming's iterative process. Following this reasoning, we can replace $\hat{Q}_t(\hat{s}_j^a, b)$ with $\sum_{l=1}^m \bar{\kappa}_{\bar{\tau}}(\hat{s}_j^a, \bar{s}_l)\hat{Q}_t(\bar{s}_l, b)$ and rewrite (25) as

$$\begin{aligned}
\hat{Q}'_{t+1}(\bar{s}_i, a) &= \sum_{j=1}^{n_a} \kappa_\tau^a(\bar{s}_i, s_j^a) \left[r_j^a + \gamma \max_b \sum_{l=1}^{m} \bar{\kappa}_{\bar{\tau}}(\hat{s}_j^a, \bar{s}_l)\hat{Q}'_t(\bar{s}_l, b) \right] \\
&= \sum_{j=1}^{n_a} \kappa_\tau^a(\bar{s}_i, s_j^a) r_j^a + \gamma \sum_{j=1}^{n_a} \kappa_\tau^a(\bar{s}_i, s_j^a) \max_b \sum_{l=1}^{m} \bar{\kappa}_{\bar{\tau}}(\hat{s}_j^a, \bar{s}_l)\hat{Q}'_t(\bar{s}_l, b).
\end{aligned} \tag{26}$$

Updating $\hat{Q}'$ through (26) is $O(m\hat{n}|A|)$. This is already an improvement over the computational complexity of (25), but the dependence on $\hat{n}$ still precludes the use of (26) in

scenarios involving many sample transitions, such as on-line problems, for example. Now, if we *swap* the positions of the 'max' operator and the kernel $\bar{\kappa}_{\bar{\tau}}$ in (26), we can get rid of the dependence on the number of transitions, in the following way:

$$\begin{aligned}
\bar{Q}_{t+1}(\bar{s}_i, a) &= \sum_{j=1}^{n_a} \kappa_\tau^a(\bar{s}_i, s_j^a) r_j^a + \gamma \sum_{j=1}^{n_a} \kappa_\tau^a(\bar{s}_i, s_j^a) \sum_{l=1}^{m} \bar{\kappa}_{\bar{\tau}}(\hat{s}_j^a, \bar{s}_l) \max_b \bar{Q}_t(\bar{s}_l, b) \\
&= \sum_{j=1}^{n_a} \kappa_\tau^a(\bar{s}_i, s_j^a) r_j^a + \gamma \sum_{l=1}^{m} \sum_{j=1}^{n_a} \kappa_\tau^a(\bar{s}_i, s_j^a) \bar{\kappa}_{\bar{\tau}}(\hat{s}_j^a, \bar{s}_l) \max_b \bar{Q}_t(\bar{s}_l, b) \\
&= \bar{r}_i^a + \gamma \sum_{l=1}^{m} \bar{p}_{il}^a \max_b \bar{Q}_t(\bar{s}_l, b).
\end{aligned} \tag{27}$$

Updating $\bar{Q}$ through (27) takes only $O(m^2|A|)$ operations. It is not difficult to see that (27) is value iteration's update rule for the MDP $\bar{M}$ defined by KBSF, $\bar{\Delta}\Gamma$ (see Algorithm 1).

Summarizing, if we use a local kernel approximation in the update rule of KBRL's MDP, potentially introducing some error, we get (26), which is faster to compute than (25). If in addition we change the order in which the operations are applied, we get KBSF's update rule (27), which is in some sense a greater deviation from (25) than (26), but is even faster to compute. Therefore, KBSF can be interpreted as a computationally efficient way of applying kernel approximation, the basic principle behind KBRL, to KBRL itself.

6.1.3 Curse of dimensionality

In this paper we emphasized the role of KBSF as a technique to reduce KBRL's computational cost. However, it is equally important to ask whether our algorithm provides benefits from a statistical point of view. In particular, instead of trying to approximate KBRL's solution, it may be possible to compute *better* solutions using the same amount of data.

Ormoneit and Sen (2002) showed that, in general, the number of sample transitions needed by KBRL to achieve a certain approximation accuracy grows exponentially with the dimension of the state space—a phenomenon usually referred to as the "curse of dimensionality" (Bellman, 1961). As with other methods, the only way to avoid such an exponential dependency is to exploit some sort of regularity in the problem's structure—paraphrasing Ormoneit and Sen (2002), one can only "break" the curse of dimensionality by incorporating prior knowledge into the approximation. In this section we argue that KBSF can be seen as a strategy to do so. In particular, the definition of the representative states can be seen as a practical mechanism to incorporate additional assumptions about the continuous MDP besides the sample transitions.

The fact that KBRL's sample complexity is exponential in $d_{\mathbb{S}}$ is not surprising. As noted by Ernst et al. (2005), KBRL can be seen as a particular case of the fitted Q-iteration algorithm, which solves a reinforcement learning problem by breaking it into a succession of supervised learning problems. If the MDP defined by KBRL is solved through value iteration, for example, each iteration of this algorithm can be seen as a non-parametric kernel-based regression (Barreto, 2014). It is well known that non-parametric kernel methods suffer from the curse of dimensionality (Stone, 1982; Györfi et al., 2002).

As mentioned above, one can circumvent the curse of dimensionality associated with non-parametric methods by exploiting regularities of the learning problem (Györfi et al.,

2002). For example, Kveton and Theocharous (2013) showed that, when the dynamics of the underlying MDP are factored, incorporating this knowledge into KBRL leads to a dramatic reduction on the number of sample transitions needed for learning a good decision policy. Another type of regularity arises when the "intrinsic dimension" of the state space is much smaller than $d_{\mathbb{S}}$—that is, when the data lies close to a low-dimensional manifold. Farahmand et al. (2007) have shown that simple k-nearest neighborhood regression is manifold-adaptive, meaning that it naturally exploits this type of regularity in the approximation problem. Since KBRL's approximation scheme is very similar to k-nearest neighborhood regression, it is likely that this algorithm also has such a property.

Another way to avoid the curse of dimensionality is to resort to parametric methods. Parametric methods circumvent the exponential growth of the number of samples by restricting the space of functions spanned by the approximator—which corresponds to making assumptions about the target function (Györfi et al., 2002). Since in KBRL the structure of the approximator is defined by the sampled states $\hat{s}_i^a$, one has little flexibility in controlling the induced function space (see (25)). Based on the discussions in Sections 6.1.1 and 6.1.2, one can see that KBSF can be cast as a kernel-based approximation in which the structure of the approximator is defined by the representative states—that is, the representative states play the role of basis functions or "features"(this architecture is similar to that of radial basis function networks, see Chapter 7 of Györfi et al.'s book, 2002). It should be clear, then, that when the representative states are fixed KBSF can be seen as a parametric model—and thus as a potential tool for helping KBRL circumvent the curse of dimensionality.

Parametric regression methods have a serious drawback, though: if the target function cannot be well approximated by any function in the space induced by the parametric model, the approximation error will be large regardless of the data. A popular strategy to overcome this issue without incurring in unacceptable sample complexity is to resort to adaptive methods that use the available data to adjust the complexity of the approximator to the problem at hand (Farahmand and Szepesvári, 2011). In the case of KBRL, the complexity of the induced function space can be controlled via the kernel's width τ (Györfi et al., 2002). KBSF provides an alternative way of controlling the complexity of the approximator through the parameter m (this is akin to limiting the depth of a regression tree, for example—see Barreto's paper for a detailed discussion, 2014). If we think in terms of the classical bias-variance analysis of statistical estimators, intuitively we are decreasing bias and increasing variance as $m \to n$—assuming that the representative states are systematically defined by a reasonable method; see Section 6.2.2 (Hastie et al., 2002). Note that, unlike τ, m has a clear effect on the method's computational cost.

Therefore, KBSF provides both a way of determining the structure of the approximator and extra flexibility in controlling the complexity of the resulting model. Of course, this does not automatically translate into reduced sample complexity. Even if the structural assumptions induced by KBSF arise in problems of interest, we must develop methods to configure the parameters of the algorithm appropriately (see Section 6.2.2). New theoretical results regarding the approximation properties of KBSF would probably be needed as well, since the current results were derived under the interpretation of our algorithm as a computational device to accelerate KBRL (and thus use its solution as a reference point). These might be interesting directions for future investigations.

6.2 Practical issues

During the execution of our experiments we observed several interesting facts about KBSF which are not immediate from its conceptual definition. In this section we share some of the lessons learned with the reader. We start by discussing the impact of deviating from the theoretical assumptions over the performance of our algorithm. We then present general guidelines on how to configure KBSF to solve reinforcement learning problems.

6.2.1 KBSF's applicability

The theoretical guarantees regarding KBRL's solution assume that the initial states s_i^a in the transitions $(s_i^a, r_i^a, \hat{s}_i^a)$ are uniformly sampled from $\mathbb{S}$ (Ormoneit and Sen, 2002, see Assumption 3). This is somewhat restrictive because it precludes the collection of data through direct interaction with the environment. Ormoneit and Sen conjectured that sampling the states s_i^a from an uniform distribution is not strictly necessary, and indeed later Ormoneit and Glynn (2002) relaxed this assumption for the case in which KBRL is applied to an average-reward MDP. In this case, it is only required that the exploration policy used to collect data chooses all actions with positive probability. As described in Sections 4.2 and 5.2, in our computational experiments we collected data through an ϵ-greedy policy (in many cases with $\epsilon = 1$). The good performance of KBSF corroborates Ormoneit and Sen's conjecture and suggests that Ormoneit and Glynn's results can be generalized to the discounted reward case, but more theoretical analysis is needed.

Ormoneit and Sen (2002) also make some assumptions regarding the smoothness of the reward function and the transition kernel of the continuous MDP (Assumptions 1 and 2). Unfortunately, such assumptions are usually not verifiable in practice. Empirically, we observed that KBSF indeed performs better in problems with "smooth dynamics"—loosely speaking, problems in which a small perturbation in s_i^a results in a small perturbation in $\hat{s}_i^a$, such as the pole balancing task. In problems with "rougher" dynamics, like the epilepsy-suppression task, it is still possible to get good results with KBSF, but in this case it is necessary to use more representative states and narrower kernels (that is, smaller values for $\bar{\tau}$). As a result, in problems of this type KBSF is less effective in reducing KBRL's computational cost.

6.2.2 KBSF's configuration

KBSF depends on two basic definitions: the set of representative states and the widths of the kernels. As discussed in Section 6.1, the former can be seen as the definition of the "structure" of the approximator, while the latter are parameters of the approximation. In what follows we discuss the impact of each of them on KBSF's performance.

Definition of Representative States In order to define the representative states we must determine their number, m, and their "position" in the state space. Both theory and practice indicate that KBSF's performance gets closer to KBRL's as m increases. Thus, a "rule of thumb" to define the number of representative states is to simply set m to the largest value allowed by the available computational resources (but see Section 6.1.3 for an alternative view).

As for the position of the representative states, looking at expression (24) we see that ideally $\bar{s}_j$ would be such that the rows of the matrices $\mathbf{K}^a$ would form a convex hull containing the rows of the corresponding $\hat{\mathbf{P}}^a$. However, it is easy to see that when $m < n$ such a set of states may not exist. Besides, even when it does exist, finding this set is not a trivial problem.

Instead of insisting on finding representative states that allow for an exact representation of the matrices $\hat{\mathbf{P}}^a$, it sounds more realistic to content oneself with an approximate solution for this problem. Assuming the dynamics of the underlying MDP are reasonably smooth, one strategy is to guarantee that every sampled state $\hat{s}_i^a$ is close to at least one representative state $\bar{s}_j$. Since covering the entire state space is generally impractical, we want $\bar{s}_j$ to reflect the distribution of the data, that is, we want the representative states to be in the regions of the state space where the data lies. This is why in our experiments we clustered the states $\hat{s}_i^a$ and used the clusters's centers as our representative states (this method is also used in the configuration of radial basis function networks, as discussed by Györfi et al., 2002). Despite its simplicity, this strategy usually results in good performance, as shown in Sections 4.2 and 5.2.

In our experiments we clustered the data using the popular k-means algorithm, which minimizes the average square distance from a given point to the center of the corresponding cluster. However, Proposition 6 states that KBSF's approximation error can be controlled by $\max_{a,i} dist(\hat{s}_i^a, w)$, the maximum distance from a sampled state $\hat{s}_i^a$ to the w^{th} nearest representative state. It is reasonable to ask whether KBSF's performance would improve if we used a clustering method that directly minimizes this quantity.

In the k-center clustering problem one seeks a set of k clusters that minimize the maximum distance from a point to the corresponding cluster center (Gonzales, 1985). Thus, in this case we would be minimizing $\max_{a,i} dist(\hat{s}_i^a, 1)$. Although finding an exact solution for this problem is NP hard, there exist fast algorithms that compute good approximations in time linear in the number of points (Feder and Greene, 1988). In order to provide some intuition on how k-center clustering compares to k-means, we implemented an algorithm by Gonzales (1985) which is extremely simple: at each iteration one selects a new cluster center by simply picking the point whose distance to the closest cluster center is maximal. Although simple, this method provides a solution for the k-center problem whose cost is within a factor of two from the optimal solution, which is the best one can hope for in polynomial time (Feder and Greene, 1988).

Figure 11 shows the performance of KBSF on the puddle-world task using different strategies to define the representative states. The experiment was carried out exactly as the one described in Section 4.2.1. In addition to the results provided by k-means and k-centers, we also show KBSF's performance when using representative states sampled uniformly at random and evenly distributed over the state space. As expected, the worst results correspond to the case in which representative states are picked at random. On the opposite extreme, representative states evenly distributed over $\mathbb{S}$ result in the best performance. Unfortunately, in more realistic scenarios it is impractical to cover the entire state space with representative states, and this is precisely why one may have to resort to strategies like k-means and k-centers. The results shown in Figure 11 suggest that k-centers clustering may indeed be a better choice than k-means, although the difference in the resulting performance is not very significant. One advantage of k-center clustering is that

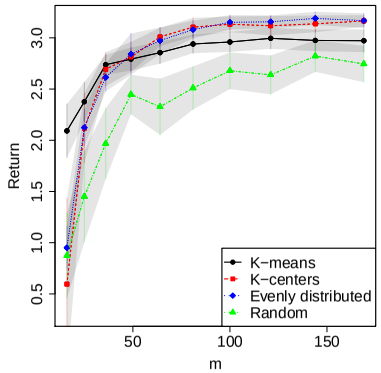


Figure 11: Comparison of different strategies to define the representative states. Results on the puddle-world task averaged over 50 runs. The errors around the mean correspond to the 99% confidence intervals. See Figure 3 for details.

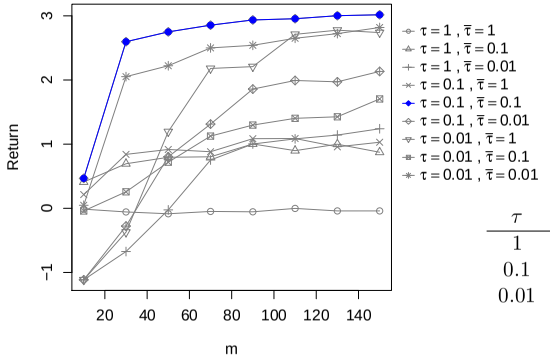
it is very simple to implement and is also very fast. Besides, there are algorithms available that compute an approximation on-line, which allows their use with *i*KBSF (Charikar et al., 1997; Beygelzimer et al., 2006).

Clustering methods are a natural choice for defining the representative states because they summarize the distribution of the data, but of course they are not the only way to solve the problem. Ideally, we want a set of representative states that summarize the *dynamics* of the underlying dynamical system, and this may not reflect the spatial distribution of the data, regardless of the strategy used to collect transitions. As discussed in Section 6.1, the problem of defining representative states is in some sense akin to the problem of defining features in supervised learning (Guyon and Elisseeff, 2003). Such a connection emphasizes the difficulty of the problem and suggests that the best solution may be domain-dependent. On the other hand, as with the definition of features, the definition of representative states can be seen as an opportunity to incorporate prior knowledge about the domain of interest into the approximation model. For example, if one knows that some regions of the state space are more important than others, this information can be used to allocate more representative states to those regions. Similar reasoning applies to tasks in which the level of accuracy required from the decision policy varies across the state space.

Definition of Kernels's Widths Given a well-defined strategy to select representative states, the use of KBSF requires the definition of two parameters, τ and $\bar{\tau}$. The kernels's widths τ and $\bar{\tau}$ may have a strong effect on KBSF's performance. To illustrate this point, we show in Figure 12 the results of this algorithm on the puddle world task when τ and $\bar{\tau}$ are varied in the set $\{0.01, 0.1, 1\}$ (these were the results used to generate Figure 3).



(a) Performance of KBSF(8000, ·)

τ	Average return
1	1.47 ± 0.42
0.1	3.01 ± 0.08
0.01	3.00 ± 0.08

(b) Performance of KBRL(8000). Errors around the mean correspond to 99% confidence intervals.

Figure 12: The impact of the kernels's widths on the performance of KBSF and KBRL. Results on the puddle-world task averaged over 50 runs. See Figure 3 for details.

Of course, the best combination of values for τ and $\bar{\tau}$ depends on the specific problem at hand and on the particular choice of kernels. Here we give some general advice as to how to set these parameters, based on both theory in practice. Since τ is the same parameter used by KBRL, it should decrease with the number of sample transitions n at an "admissible rate" (see Ormoneit and Sen's Lemma 2, 2002). Analogously, Proposition 6 suggests that $\bar{\tau}$ should get smaller as $m \to n$ (details in the proof of the proposition in Appendix A). Empirically, we found out that a simple strategy that usually facilitates the configuration of KBSF is to rescale the data so that all the variables have approximately the same magnitude—which corresponds to using a weighted norm in the computation of the kernels. Using this strategy we were able to obtain good results with KBSF on all problems by performing a coarse search in the space of parameters in which we only varied the order of magnitude of τ and $\bar{\tau}$ (see Table 1).

Alternatively, one can fix τ and $\bar{\tau}$ and define the neighborhood used to compute $\mathrm{k}_\tau(\bar{s}_j, \cdot)$ and $\bar{\mathrm{k}}_{\bar{\tau}}(\hat{s}_i^a, \cdot)$. As explained in Appendix B.2, in some of our experiments we only computed $\mathrm{k}_\tau(\bar{s}_j, \cdot)$ for the μ closest sampled states s_i^a from $\bar{s}_j$, and only computed $\bar{\mathrm{k}}_{\bar{\tau}}(\hat{s}_i^a, \cdot)$ for the $\bar{\mu}$ closest representative states from $\hat{s}_i^a$. When using this approach, a possible way of configuring KBSF is to set τ and $\bar{\tau}$ to sufficiently large values (so as to guarantee a minimum level of overlap between the kernels) and then adjust μ and $\bar{\mu}$. The advantage is that adjusting μ and $\bar{\mu}$ may be more intuitive than directly configuring τ and $\bar{\tau}$ (*cf.* Table 1).

7. Previous work

In our experiments we compared KBSF with KBRL, LSPI, fitted Q-iteration, and SARSA, both in terms of computational cost and in terms of the quality of the resulting decision policies. In this section we situate our algorithm in the broader context of approximate reinforcement learning. Approximation in reinforcement learning is an important topic that has generated a huge body of literature. For a broad overview of the subject, we refer the reader to the books by Sutton and Barto (1998), Bertsekas and Tsitsiklis (1996), and Szepesvári (2010). Here we will narrow our attention to *kernel-based* approximation techniques.

We start by noting that the label "kernel based" is used with two different meanings in the literature. On one side we have kernel smoothing techniques like KBRL and KBSF, which use local kernels essentially as a device to implement smooth instance-based approximation (Hastie et al., 2002). On the other side we have methods that use reproducing kernels to implicitly represent an inner product in a high-dimensional state space (Schölkopf and Smola, 2002). Although these two frameworks can give rise to approximators with similar structures, they rest on different theoretical foundations. Since reproducing-kernels methods are less directly related to KBSF, we will only describe them briefly. We will then discuss the kernel smoothing approaches in more detail.

The basic idea of reproducing-kernel methods is to apply the "kernel trick" in the context of reinforcement learning (Schölkopf and Smola, 2002). Roughly speaking, the approximation problem is rewritten in terms of inner products only, which are then replaced by a properly-defined kernel. This modification corresponds to mapping the problem to a high-dimensional feature space, resulting in more expressiveness of the function approximator. Perhaps the most natural way of applying the kernel trick in the context of reinforcement learning is to "kernelize" some formulation of the value-function approximation problem (Xu et al., 2005; Engel et al., 2005; Farahmand, 2011). Another alternative is to approximate the *dynamics* of an MDP using a kernel-based regression method (Rasmussen and Kuss, 2004; Taylor and Parr, 2009). Following a slightly different line of work, Bhat et al. (2012) propose to kernelize the linear programming formulation of dynamic programming. However, this method is not directly applicable to reinforcement learning, since it is based on the assumption that one has full knowledge of the MDP. A weaker assumption is to suppose that only the reward function is known and focus on the approximation of the transition function. This is the approach taken by Grunewalder et al. (2012), who propose to embed the conditional distributions defining the transitions of an MDP into a Hilbert space induced by a reproducing kernel.

We now turn our attention to kernel-smoothing techniques, which are more closely related to KBRL and KBSF. Kroemer and Peters (2011) propose to apply kernel density estimation to the problem of policy evaluation. They call their method *non-parametric dynamic programming* (NPDP). If we use KBRL to compute the value function of a fixed policy, we see many similarities with NPDP, but also some important differences. Like KBRL, NPDP is statistically consistent. Unlike KBRL, which assumes a finite action space A and directly approximates the conditional density functions $P^a(s'|s)$, NPDP assumes that A is continuous and models the joint density $P(s, a, s')$. Kroemer and Peters (2011) showed that the value function of NPDP has a Nadaraya-Watson kernel regression form. Not

surprisingly, this is also the form of KBRL's solution if we fix the policy being evaluated (*cf.* equation (7)). In both cases, the coefficients of the kernel-based approximation are derived from the value function of the approximate MDP. The key difference is the way the transition matrices are computed in each algorithm. As shown in (4), the transition probabilities of KBRL's model are given by the kernel values themselves. In contrast, the computation of each element of NDPD's transition matrix requires an integration over the continuous state space $\mathbb{S}$. In practice, this is done by numerical integration techniques that may be very computationally demanding (see for example the experiments performed by Grunewalder et al., 2012).

We directly compared NPDP with KBRL because both algorithms build a model whose number of states is dictated by the number of sample transitions n, and neither method explicitly attempts to keep n small. Since in this case each application of the Bellman operator is $O(n^2)$, these methods are not suitable for problems in which a large number of transitions is required, nor are they applicable to on-line reinforcement learning.[5] There are however kernel-smoothing methods that try to avoid this computational issue by either keeping n small or by executing a number of operations that grows only linearly with n. These algorithms are directly comparable with KBSF.

One of the first attempts to adapt KBRL to the on-line scenario was that of Jong and Stone (2006). Instead of collecting a batch of sample transitions before the learning process starts, the authors propose to grow such a set incrementally, based on an exploration policy derived from KBRL's current model. To avoid running a dynamic-programming algorithm to completion in between two transitions, which may not be computationally feasible, Jong and Stone (2006) resort to Moore and Atkeson's (1993) "prioritized sweeping" method to propagate the changes in the value function every time the model is modified. The idea of exploiting the interpretation of KBRL as the derivation of a finite MDP in order to use tabular exploration methods is insightful. However, it is not clear whether smart exploration is sufficient to overcome the computational difficulties arising from the fact that the size of the underlying model is inexorably linked to the number of sample transitions. For example, even using sparse kernels in their experiments, Jong and Stone (2006) had to fix an upper limit for the size of KBRL's model. In this case, once the number of sample transitions has reached the upper limit, all subsequent data must be ignored.

Following the same line of work, Jong and Stone (2009) later proposed to guide KBRL's exploration of the state space using Brafman and Tennenholtz's (2003) R-MAX algorithm. In this new paper the authors address the issue with KBRL's scalability more aggressively. First, they show how to combine their approach with Dietterich's (2000) MAX-Q algorithm, allowing the decomposition of KBRL's MDP into a hierarchy of simpler models. While this can potentially reduce the computational burden of finding a policy, such a strategy transfer to the user the responsibility of identifying a useful decomposition of the task. A more practical approach is to combine KBRL with some stable form of value-function approximation. For that, Jong and Stone (2009) suggest the use of Gordon's (1995) averagers. As shown in Appendix A.2, this setting corresponds to a particular case of KBSF in which representative states are selected among the set of sampled states $\hat{s}_i^a$. It should be noted that, even when using temporal abstraction and function approximation, Jong and Stone's (2009) approach

5. We note that, incidentally, all the reproducing-kernel methods discussed in this section also have a computational complexity super-linear in n.

requires recomputing KBRL's transition probabilities at each new sample, which can be infeasible in reasonably large problems.

Kveton and Theocharous (2012) propose a more practical algorithm to reduce KBRL's computational cost. Their method closely resembles the batch version of KBSF. As with our algorithm, Kveton and Theocharous's method defines a set of representative states $\bar{s}_i$ that give rise to a reduced MDP. The main difference in the construction of the models is that, instead of computing a similarity measure between each sampled state $\hat{s}_i^a$ and all representative states $\bar{s}_j$, their algorithm associates each $\hat{s}_i^a$ with a single $\bar{s}_j$—which comes down to computing a hard aggregation of the state space $\hat{S}$. Such an aggregation corresponds to having a matrix $\mathbf{D}$ with a single nonzero element per row. In fact, it is possible to rewrite Kveton and Theocharous's (2012) algorithm using KBSF's formalism. In this case, the elements of $\dot{\mathbf{D}}^a$ and $\dot{\mathbf{K}}^a$ would be defined as:

$$\dot{k}_{ij}^a = \kappa_\tau^a(\bar{s}_i, rs(s_j^a, 1)), \quad \text{and} \quad \dot{d}_{ij}^a = \bar{\kappa}_0(rs(\hat{s}_i^a, 1), \bar{s}_j) \tag{28}$$

where $\bar{\kappa}_0$ is the normalized kernel induced by an infinitely "narrow kernel $\bar{\mathrm{k}}_0(s, s')$ whose value is greater than zero if and only if $s = s'$ (recall from Section 4.1 that $rs(s, 1)$ gives the closest representative state from s). It is easy to see that we can make matrix $\mathbf{D}$ computed by KBSF as close as desired to a hard aggregation by setting $\bar{\tau}$ to a sufficiently small value (see Lemma 5). More practically, we can simply plug (28) in place of (10) in Algorithm 1 to exactly recover Kveton and Theocharous's method. Note though that, by replacing $\kappa_\tau^a(\bar{s}_i, s_j^a)$ with $\kappa_\tau^a(\bar{s}_i, rs(s_j^a, 1))$ in the computation of $\dot{\mathbf{K}}^a$, we would be in some sense deviating from KBRL's framework. To see why this is so, observe that if the representative states $\bar{s}_i$ are sampled from the set of states $\hat{s}_i^a$, the rows of matrix $\mathbf{K}^a$ computed by KBSF would coincide with a subset of the rows of the corresponding KBRL's matrix $\hat{\mathbf{P}}^a$ (*cf.* (23)). However, this property is lost if one uses (28) instead of (10).[6]

8. Conclusion

This paper presented KBSF, a reinforcement learning algorithm that results from the application of the stochastic-factorization trick to KBRL. KBSF summarizes the information contained in KBRL's MDP in a model of fixed size. By doing so, our algorithm decouples the structure of the model from its configuration. This makes it possible to build an approximation which accounts for both the difficulty of the problem *and* the computational resources available.

One of the main strengths of KBSF is its simplicity. As shown in the paper, its uncomplicated mechanics can be unfolded into two update rules that allow for a fully incremental version of the algorithm. This makes the amount of memory used by KBSF independent of the number of sample transitions. Therefore, with a few lines of code one has a reinforcement-learning algorithm that can be applied to large-scale problems, in both off-line and on-line regimes.

KBSF is also a sound method from a theoretical point of view. As discussed, the distance between the value function computed by this algorithm and the one computed by KBRL

6. Note that this observation only means that KBSF is closer to KBRL in this strict sense; in particular, it does not imply that Kveton and Theocharous's algorithm is not a principled method, nor does it mean that it will perform worse than KBSF.

is bounded by two factors: the quality and the level of stochasticity of the underlying stochastic factorization. We showed that both factors can be made arbitrarily small, which implies that, in theory, we can make KBSF's solution as close to KBRL's solution as desired.

Theoretical guarantees do not always translate into good performance in practice, though, either because they are built upon unrealistic assumptions or because they do not account for procedural difficulties that arise in practical situations. To ensure that this is not the case with our algorithm, we presented an extensive empirical study in which KBSF was successfully applied to different problems, some of them quite challenging. We also presented general guidelines on how to configure KBSF to solve a reinforcement learning problem.

For all the reasons listed above, we believe that KBSF has the potential of becoming a valuable resource for the solution of reinforcement learning problems. This is not to say that the subject has been exhausted. There are several possibilities for future research, some of which we now briefly discuss.

From an algorithmic point of view, perhaps the most pressing demand is for more principled methods to define the representative states. Incidentally, this also opens up the possibility of an automated procedure to set the kernel's widths $\bar{\tau}$ based solely on data. Taking the idea one step further, one can think of having one distinct $\bar{\tau}_i$ associated with each kernel $\bar{\kappa}_{\bar{\tau}}(\cdot, \bar{s}_i)$ (which would make the similarity between KBSF's approximation and radial basis function networks even stronger). Another important advance would be to endow *i*KBSF with more elaborate exploration strategies, maybe following the line of research initiated by Jong and Stone (2006, 2009).

From a theoretical perspective, it may be desirable to "detach" KBSF from KBRL and analyze the former on its own. In this paper we emphasized the view of our algorithm as a tool to apply KBRL in practice. This view is clearly reflected in our theoretical results, which show how KBSF's solution deviates from KBRL's and how we can control such a deviation. But KBRL is itself an approximation, so perhaps it makes sense to analyze KBSF independently from its precursor. This possibility is particularly appealing when we look at KBSF as an intermediate approach between fully nonparametric and parametric models, as discussed in Section 6.1.3.

Looking at KBSF against a broader context, a subject that deserves further investigation is the possibility of building an approximation based on multiple models. Model averaging is not inherently linked to KBSF, and in principle it can be used with virtually any reinforcement learning algorithm. However, KBSF's low computational cost makes it particularly amenable to this technique. Since our algorithm is significantly faster than any method whose complexity per iteration is a function of the number of sample transitions, we can afford to compute several approximations and still have a solution in comparable time (see Section 4.2.3 and Barreto's paper, 2014). Understanding how we can randomize the construction of the individual models and to what extend this can improve the quality of the resulting decision policy is a matter of interest.

We conclude by noting that KBSF represents one particular way in which the stochastic-factorization trick can be exploited in the context of reinforcement learning. In principle, any algorithm that builds a model based on sample transitions can resort to the same trick to leverage the use of the data. The basic idea remains the same: instead of estimating the transition probabilities between every pair of states, one focuses on a small set of representative states whose values are propagated throughout the state space based on some

notion of similarity. We believe that this general framework can potentially be materialized into a multitude of useful reinforcement learning algorithms.

Acknowledgments

The authors would like to thank Amir-massoud Farahmand and Yuri Grinberg for interesting discussions about approximation in reinforcement learning and related subjects. We also thank Branislav Kveton for insightful comments regarding the theory underlying kernel-based reinforcement learning, which were essential for the derivation of our Proposition 8. We are grateful to Keith Bush for making the epilepsy simulator available, and to Alicia Bendz and Ryan Primeau for helping in some of the computational experiments. Finally, we thank the anonymous reviewers for their valid comments and helpful suggestions to improve the paper. Funding for this research was provided by the NSERC Discovery Grant program.

Appendix A. Theoretical Results

A.1 Proofs

Proposition 2

Proof Let $\check{M} \equiv (S, A, \check{\mathbf{P}}^a, \check{\mathbf{r}}^a, \gamma)$, with $\check{\mathbf{P}}^a = \mathbf{D}\mathbf{K}^a$ and $\check{\mathbf{r}}^a = \mathbf{D}\bar{\mathbf{r}}^a$. From the triangle inequality, we know that

$$\left\|\mathbf{v}^* - \Gamma\mathbf{D}\bar{\mathbf{Q}}^*\right\|_\infty \leq \left\|\mathbf{v}^* - \check{\mathbf{v}}^*\right\|_\infty + \left\|\check{\mathbf{v}}^* - \Gamma\mathbf{D}\bar{\mathbf{Q}}^*\right\|_\infty, \tag{29}$$

where $\check{\mathbf{v}}^*$ is the optimal value function of $\check{M}$. Our strategy will be to bound $\|\mathbf{v}^* - \check{\mathbf{v}}^*\|_\infty$ and $\left\|\check{\mathbf{v}}^* - \Gamma\mathbf{D}\bar{\mathbf{Q}}^*\right\|_\infty$. In order to find an upper bound for $\|\mathbf{v}^* - \check{\mathbf{v}}^*\|_\infty$, we apply Whitt's (1978) Theorem 3.1 and Corollary (b) of his Theorem 6.1, with all mappings between M and $\check{M}$ taken to be identities, to obtain

$$\|\mathbf{v}^* - \check{\mathbf{v}}^*\|_\infty \leq \frac{1}{1-\gamma}\left(\max_a \|\mathbf{r}^a - \mathbf{D}\bar{\mathbf{r}}^a\|_\infty + \frac{\gamma\bar{R}_{\text{dif}}}{2(1-\gamma)}\max_a \|\mathbf{P}^a - \mathbf{D}\mathbf{K}^a\|_\infty\right), \tag{30}$$

where we used the fact that $\max_{a,i} \check{r}_i^a - \min_{a,i} \check{r}_i^a \leq \bar{R}_{\text{dif}}$. It remains to bound $\left\|\check{\mathbf{v}}^* - \Gamma\mathbf{D}\bar{\mathbf{Q}}^*\right\|_\infty$. Since $\check{\mathbf{r}}^a = \mathbf{D}\bar{\mathbf{r}}^a$ and $\mathbf{D}\bar{\mathbf{P}}^a = \mathbf{D}\mathbf{K}^a\mathbf{D} = \check{\mathbf{P}}^a\mathbf{D}$ for all $a \in A$, the stochastic matrix $\mathbf{D}$ satisfies Sorg and Singh's (2009) definition of a *soft homomorphism* between $\check{M}$ and $\bar{M}$ (see equations (25)–(28) in their paper). Applying Theorem 1 by the same authors, we know that

$$\left\|\Gamma(\check{\mathbf{Q}}^* - \mathbf{D}\bar{\mathbf{Q}}^*)\right\|_\infty \leq \frac{1}{1-\gamma}\sup_{i,t}(1 - \max_j d_{ij})\ \bar{\delta}_i^{(t)}, \tag{31}$$

where $\bar{\delta}_i^{(t)} = \max_{j:d_{ij}>0,k} \bar{q}_{jk}^{(t)} - \min_{j:d_{ij}>0,k} \bar{q}_{jk}^{(t)}$ and $\bar{q}_{jk}^{(t)}$ are elements of $\bar{\mathbf{Q}}^{(t)}$, the optimal t-step action-value function of $\bar{M}$. Since $\|\Gamma\check{\mathbf{Q}}^* - \Gamma\mathbf{D}\bar{\mathbf{Q}}^*\|_\infty \leq \|\Gamma(\check{\mathbf{Q}}^* - \mathbf{D}\bar{\mathbf{Q}}^*)\|_\infty$ and, for all

$t > 0$, $\bar{\delta}_i^{(t)} \leq (1-\gamma)^{-1}(\max_{a,k} \bar{r}_k^a - \min_{a,k} \bar{r}_k^a)$, we can write

$$\left\|\check{\mathbf{v}}^* - \Gamma \mathbf{D}\bar{\mathbf{Q}}^*\right\|_\infty \leq \frac{\bar{R}_{\text{dif}}}{(1-\gamma)^2}\max_i (1 - \max_j d_{ij}) = \frac{\bar{R}_{\text{dif}}}{(1-\gamma)^2}\sigma(\mathbf{D}). \tag{32}$$

Substituting (30) and (32) back into (29), we obtain (8). ■

Lemma 4
Proof Define the function

$$\psi_{\tau,s}^{a,i}(s') = \left| \frac{\mathrm{k}_\tau(s, s_i^a)}{\sum_{j=1}^{n_a} \mathrm{k}_\tau(s, s_j^a)} - \frac{\mathrm{k}_\tau(s', s_i^a)}{\sum_{j=1}^{n_a} \mathrm{k}_\tau(s', s_j^a)} \right| = \left| \frac{\phi\left(\|s - s_i^a\|/\tau\right)}{\sum_{j=1}^{n_a} \phi\left(\|s - s_j^a\|/\tau\right)} - \frac{\phi\left(\|s' - s_i^a\|/\tau\right)}{\sum_{j=1}^{n_a} \phi\left(\|s' - s_j^a\|/\tau\right)} \right|.$$

Since ϕ is continuous, it is obvious that $\psi_{\tau,s}^{a,i}(s')$ is also continuous in s'. The property follows from the fact that $\lim_{s' \to s} \psi_{\tau,s}^{a,i}(s') = 0$. ■

Lemma 5† *Let $s \in \mathbb{S}$, let $m > 1$, and assume there is a $w \in \{1, 2, ..., m-1\}$ such that $dist(s,w) < dist(s, w+1)$. Define $W^w(s) \equiv \{k \mid \|s - \bar{s}_k\| \leq dist(s,w)\}$ and $\bar{W}^w(s) \equiv \{1, 2, ..., m\} - W^w(s)$. Then, for any $\alpha > 0$, we can guarantee that*

$$\sum_{k \in \bar{W}^w(s)} \bar{\kappa}_{\bar{\tau}}(s, \bar{s}_k) < \alpha \sum_{k \in W^w(s)} \bar{\kappa}_{\bar{\tau}}(s, \bar{s}_k) \tag{33}$$

by making $\bar{\tau} < \varphi(s, w, m, \alpha)$, where

$$\varphi(s, w, m, \alpha) = \min(\varphi_1(s,w), \varphi_2(s, w, m, \alpha)) \tag{34}$$

and

$$\varphi_1(s,w) = \begin{cases} \frac{dist(s,w)}{B_{\bar{\phi}}}, \text{ if } B_{\bar{\phi}} > 0, \\ \infty, \text{ otherwise,} \end{cases} \quad \varphi_2(s,w,m,\alpha) = \begin{cases} \frac{dist(s,w) - dist(s,w+1)}{\ln(\alpha w/(m-w)\lambda_{\bar{\phi}})}, \text{ if } \frac{\alpha w}{(m-w)\lambda_{\bar{\phi}}} < 1, \\ \infty, \text{ otherwise.} \end{cases}$$

Proof Expression (33) can be rewritten as

$$\frac{\sum_{k \in \bar{W}^w(s)} \bar{\mathrm{k}}_{\bar{\tau}}(s, \bar{s}_k)}{\sum_{i=1}^m \bar{\mathrm{k}}_{\bar{\tau}}(s, \bar{s}_i)} < \alpha \frac{\sum_{k \in W^w(s)} \bar{\mathrm{k}}_{\bar{\tau}}(s, \bar{s}_k)}{\sum_{i=1}^m \bar{\mathrm{k}}_{\bar{\tau}}(s, \bar{s}_i)} \iff \sum_{k \in \bar{W}^w(s)} \bar{\mathrm{k}}_{\bar{\tau}}(s, \bar{s}_k) < \alpha \sum_{k \in W^w(s)} \bar{\mathrm{k}}_{\bar{\tau}}(s, \bar{s}_k), \tag{35}$$

which is equivalent to

$$\sum_{k \in \bar{W}^w(s)} \bar{\phi}\left(\frac{\|s - \bar{s}_k\|}{\bar{\tau}}\right) < \alpha \sum_{k \in W^w(s)} \bar{\phi}\left(\frac{\|s - \bar{s}_k\|}{\bar{\tau}}\right). \tag{36}$$

†. We restate the lemma here showing explicitly how to define $\bar{\tau}$. This detail was omitted in the main body of the text to improve clarity.

Based on Assumption (i), we know that a sufficient condition for (36) to hold is

$$\bar{\phi}\left(\frac{dist(s, w+1)}{\bar{\tau}}\right) < \frac{\alpha w}{m-w}\bar{\phi}\left(\frac{dist(s,w)}{\bar{\tau}}\right). \tag{37}$$

Let $\beta = \alpha w/(m-w)$. If $\beta > 1$, then (37) is always true, regardless of the value of $\bar{\tau}$. We now show that, when $\beta \leq 1$, it is always possible to set $\bar{\tau}$ in order to guarantee that (37) holds. Let $z = dist(s,w)$ and let $\delta = dist(s, w+1) - z$. From Assumption (ii), we know that, if $B_{\bar{\phi}} = 0$ or $\bar{\tau} < z/B_{\bar{\phi}}$,

$$\frac{\bar{\phi}((z+\delta)/\bar{\tau})}{\bar{\phi}(z/\bar{\tau})} \leq \frac{\lambda_{\bar{\phi}} A_{\bar{\phi}} \exp(-(z+\delta)/\bar{\tau})}{A_{\bar{\phi}} \exp(-z/\bar{\tau})} = \frac{\lambda_{\bar{\phi}} \exp(-(z+\delta)/\bar{\tau})}{\exp(-z/\bar{\tau})}.$$

Thus, in order for the result to follow, it suffices to show that

$$\frac{\exp(-(z+\delta)/\bar{\tau})}{\exp(-z/\bar{\tau})} < \frac{\beta}{\lambda_{\bar{\phi}}}. \tag{38}$$

We know that, since $\delta > 0$, if $\beta/\lambda_{\bar{\phi}} = 1$ inequality (38) is true. Otherwise,

$$\frac{\exp(-(z+\delta)/\bar{\tau})}{\exp(-z/\bar{\tau})} < \frac{\beta}{\lambda_{\bar{\phi}}} \iff \ln\left(\frac{\exp(-(z+\delta)/\bar{\tau})}{\exp(-z/\bar{\tau})}\right) < \ln\left(\frac{\beta}{\lambda_{\bar{\phi}}}\right)$$
$$\iff -\frac{\delta}{\bar{\tau}} < \ln\left(\frac{\beta}{\lambda_{\bar{\phi}}}\right) \iff \bar{\tau} < -\frac{\delta}{\ln(\beta/\lambda_{\bar{\phi}})}.$$

Thus, by taking $\bar{\tau} < -\delta/\ln(\beta/\lambda_{\bar{\phi}})$ if $B_{\bar{\phi}} > 0$, or $\bar{\tau} < \min(-\delta/\ln(\beta/\lambda_{\bar{\phi}}), z/B_{\bar{\phi}})$ otherwise, the result follows. ■

Proposition 6
Proof From (6) and (11), we know that

$$\|\hat{\mathbf{r}}^a - \mathbf{D}\bar{\mathbf{r}}^a\|_\infty = \|\hat{\mathbf{P}}^a\mathbf{r} - \mathbf{D}\mathbf{K}^a\mathbf{r}\|_\infty = \|(\hat{\mathbf{P}}^a - \mathbf{D}\mathbf{K}^a)\mathbf{r}\|_\infty \leq \|\hat{\mathbf{P}}^a - \mathbf{D}\mathbf{K}^a\|_\infty \|\mathbf{r}\|_\infty. \tag{39}$$

Thus, plugging (39) back into (8), it is clear that there is a $\nu > 0$ such that $\xi_v < \epsilon$ if

$$\max_a \|\hat{\mathbf{P}}^a - \mathbf{D}\mathbf{K}^a\|_\infty < \nu \tag{40}$$

and

$$\max_i (1 - \max_j d_{ij}) < \nu. \tag{41}$$

We start by showing that there is a $\delta > 0$ and a $\theta > 0$ such that expression (40) is true if $\max_{a,i} dist(\hat{s}_i^a, w) < \delta$ and $\bar{\tau} < \theta$. Let $\check{\mathbf{P}}^a = \mathbf{D}\mathbf{K}^a$ and let $\hat{\mathbf{p}}_i^a \in \mathbb{R}^{1\times n}$ and $\check{\mathbf{p}}_i^a \in \mathbb{R}^{1\times n}$ be the i^{th} rows of $\hat{\mathbf{P}}^a$ and $\check{\mathbf{P}}^a$, respectively. Then,

$$\begin{aligned} \|\hat{\mathbf{p}}_i^a - \check{\mathbf{p}}_i^a\|_\infty &= \textstyle\sum_{j=1}^{n_a} |\hat{p}_{ij}^a - \sum_{k=1}^m \dot{d}_{ik}^a \dot{\kappa}_{kj}^a| \\ &= \textstyle\sum_{j=1}^{n_a} |\kappa_\tau^a(\hat{s}_i^a, s_j^a) - \sum_{k=1}^m \bar{\kappa}_{\bar{\tau}}(\hat{s}_i^a, \bar{s}_k)\kappa_\tau^a(\bar{s}_k, s_j^a)| \\ &= \textstyle\sum_{j=1}^{n_a} |\sum_{k=1}^m \bar{\kappa}_{\bar{\tau}}(\hat{s}_i^a, \bar{s}_k)\kappa_\tau^a(\hat{s}_i^a, s_j^a) - \sum_{k=1}^m \bar{\kappa}_{\bar{\tau}}(\hat{s}_i^a, \bar{s}_k)\kappa_\tau^a(\bar{s}_k, s_j^a)| \\ &= \textstyle\sum_{j=1}^{n_a} |\sum_{k=1}^m \bar{\kappa}_{\bar{\tau}}(\hat{s}_i^a, \bar{s}_k)[\kappa_\tau^a(\hat{s}_i^a, s_j^a) - \kappa_\tau^a(\bar{s}_k, s_j^a)]| \\ &\leq \textstyle\sum_{j=1}^{n_a} \sum_{k=1}^m \bar{\kappa}_{\bar{\tau}}(\hat{s}_i^a, \bar{s}_k) \left|\kappa_\tau^a(\hat{s}_i^a, s_j^a) - \kappa_\tau^a(\bar{s}_k, s_j^a)\right|. \end{aligned} \tag{42}$$

Our strategy will be to show that, for any a, i, and j, there is a $\delta^{a,i,j} > 0$ and a $\theta^{a,i,j} > 0$ such that

$$\sum_{k=1}^{m} \bar{\kappa}_{\bar{\tau}}(\hat{s}_i^a, \bar{s}_k)|\kappa_\tau^a(\hat{s}_i^a, s_j^a) - \kappa_\tau^a(\bar{s}_k, s_j^a)| = \sum_{k=1}^{m} \bar{\kappa}_{\bar{\tau}}(\hat{s}_i^a, \bar{s}_k)\varsigma_k^{a,i,j} < \frac{\nu}{n_a} \tag{43}$$

if $dist(\hat{s}_i^a, w) < \delta^{a,i,j}$ and $\bar{\tau} < \theta^{a,i,j}$ (recall that $\varsigma_k^{a,i,j}$ had already been defined in (16)). To simplify the notation, we will use the superscript 'z' meaning 'a, i, j'. From Lemma 4 we know that there is a $\delta^z > 0$ such that $\varsigma_k^z < \nu/n_a$ if $\|\hat{s}_i^a - \bar{s}_k\| < \delta^z$. Let $W^z \equiv \{k \mid \|\hat{s}_i^a - \bar{s}_k\| < \delta^z\}$ and $\bar{W}^z \equiv \{1, 2, ..., m\} - W^z$. Since we are assuming that $dist(\hat{s}_i^a, w) < \delta^z$, we know that $W^z \neq \emptyset$. In this case, we can write:

$$\sum_{k=1}^{m} \bar{\kappa}_{\bar{\tau}}(\hat{s}_i^a, \bar{s}_k)\varsigma_k^z = \sum_{k \in W^z} \bar{\kappa}_{\bar{\tau}}(\hat{s}_i^a, \bar{s}_k)\varsigma_k^z + \sum_{k \in \bar{W}^z} \bar{\kappa}_{\bar{\tau}}(\hat{s}_i^a, \bar{s}_k)\varsigma_k^z.$$

Let

$$\varsigma_{\min}^z = \begin{cases} \min\limits_{k \in W^z} \{\varsigma_k^z | \varsigma_k^z > 0\} \text{ if } \max\limits_{k \in W^z} \varsigma_k^z > 0, \\ 0 \text{ otherwise} \end{cases} \quad \text{and} \quad \bar{\varsigma}_{\max}^z = \begin{cases} \max\limits_{k \in \bar{W}^z} \varsigma_k^z \text{ if } |W^z| < m, \\ 0 \text{ otherwise.} \end{cases}$$

If $\bar{\varsigma}_{\max}^z = 0$, inequality (43) is necessarily true, since $\sum_{k \in W^z} \bar{\kappa}_{\bar{\tau}}(\hat{s}_i^a, \bar{s}_k)\varsigma_k^z \leq \max\limits_{k \in W^z} \varsigma_k^z < \nu/n_a$. We now turn to the case in which $\bar{\varsigma}_{\max}^z > 0$. Suppose first that $\varsigma_{\min}^z = 0$. In this case, we have to show that there is a $\bar{\tau}$ that yields

$$\textstyle\sum_{k \in \bar{W}^z} \bar{\kappa}_{\bar{\tau}}(\hat{s}_i^a, \bar{s}_k)\varsigma_k^z < \frac{\nu}{n_a}. \tag{44}$$

A sufficient condition for (44) to be true is

$$\sum_{k \in \bar{W}^z} \bar{\kappa}_{\bar{\tau}}(\hat{s}_i^a, \bar{s}_k) < \frac{\nu}{n_a \bar{\varsigma}_{\max}^z} \iff \frac{1}{\sum_{j=1}^m \bar{\mathrm{k}}_{\bar{\tau}}(\hat{s}_i^a, \bar{s}_j)} \sum_{k \in \bar{W}^z} \bar{\mathrm{k}}_{\bar{\tau}}(\hat{s}_i^a, \bar{s}_k) < \frac{\nu}{n_a \bar{\varsigma}_{\max}^z}. \tag{45}$$

Obviously, if $\bar{\varsigma}_{\max}^z \leq \nu/n_a$ inequality (45) is always true, regardless of the value of $\bar{\tau}$. Otherwise, we can rewrite (45) as

$$\sum_{k \in \bar{W}^z} \bar{\mathrm{k}}_{\bar{\tau}}(\hat{s}_i^a, \bar{s}_k) < \frac{\nu}{n_a \bar{\varsigma}_{\max}^z} \left(\sum_{j \in W^z} \bar{\mathrm{k}}_{\bar{\tau}}(\hat{s}_i^a, \bar{s}_j) + \sum_{k \in \bar{W}^z} \bar{\mathrm{k}}_{\bar{\tau}}(\hat{s}_i^a, \bar{s}_k) \right),$$

and, after a few algebraic manipulations, we obtain

$$\sum_{k \in \bar{W}^z} \bar{\mathrm{k}}_{\bar{\tau}}(\hat{s}_i^a, \bar{s}_k) < \frac{\nu}{n_a \bar{\varsigma}_{\max}^z - \nu} \sum_{k \in W^z} \bar{\mathrm{k}}_{\bar{\tau}}(\hat{s}_i^a, \bar{s}_k) \iff \sum_{k \in \bar{W}^z} \bar{\kappa}_{\bar{\tau}}(\hat{s}_i^a, \bar{s}_k) < \frac{\nu}{n_a \bar{\varsigma}_{\max}^z - \nu} \sum_{k \in W^z} \bar{\kappa}_{\bar{\tau}}(\hat{s}_i^a, \bar{s}_k). \tag{46}$$

We can guarantee that (46) is true by applying Lemma 5. Before doing so, though, lets analyze the case in which $\varsigma_{\min}^z > 0$. Define

$$\beta^z = \frac{\nu}{n_a \sum_{k \in W^z} \bar{\kappa}_{\bar{\tau}}(\hat{s}_i^a, \bar{s}_k)\varsigma_k^z} - 1 \tag{47}$$

(note that $\beta^z > 0$ because $\sum_{k \in W^z} \bar{\kappa}_{\bar{\tau}}(\hat{s}_i^a, \bar{s}_k)\varsigma_k^z < v/n_a$). In order for (43) to hold, we must show that there is a $\bar{\tau}$ that guarantees that

$$\textstyle\sum_{k \in \bar{W}^z} \bar{\kappa}_{\bar{\tau}}(\hat{s}_i^a, \bar{s}_k)\varsigma_k^z - \beta^z \sum_{k \in W^z} \bar{\kappa}_{\bar{\tau}}(\hat{s}_i^a, \bar{s}_k)\varsigma_k^z < 0. \tag{48}$$

A sufficient condition for (48) to hold is

$$\textstyle\sum_{k \in \bar{W}^z} \bar{\kappa}_{\bar{\tau}}(\hat{s}_i^a, \bar{s}_k) < \frac{\beta^z \varsigma_{\min}^z}{\bar{\varsigma}_{\max}^z} \sum_{k \in W^z} \bar{\kappa}_{\bar{\tau}}(\hat{s}_i^a, \bar{s}_k). \tag{49}$$

Observe that expressions (46) and (49) only differ in the coefficient multiplying the right-hand side of the inequalities. Let

$$\alpha_1^z = \begin{cases} \nu/(\bar{\varsigma}_{\max}^z n_a - \nu), \text{ if } \bar{\varsigma}_{\max}^z > \nu/n_a \\ \infty, \text{otherwise,} \end{cases}$$

and

$$\alpha_2^z = \begin{cases} \beta^z \varsigma_{\min}^z / \bar{\varsigma}_{\max}^z, \text{ if } \bar{\varsigma}_{\max}^z > 0 \text{ and } \varsigma_{\min}^z > 0, \\ \infty, \text{ otherwise.} \end{cases}$$

Let $\alpha^z < \min(\alpha_1^z, \alpha_2^z)$. Then, if we make $\theta^z = \varphi(\hat{s}_i^a, |W|, m, \alpha^z)$, with φ defined in (34), we can apply Lemma 5 to guarantee that (43) holds. Finally, if we let $\delta = \min_z \delta^z = \min_{a,i,j} \delta^{a,i,j}$ and $\theta = \min_z \theta^z = \min_{a,i,j} \theta^{a,i,j}$, we can guarantee that (43) is true for all a, i, and j, which implies that (40) is also true (see (42)).

It remains to show that there is a $\omega > 0$ such that (41) is true if $\bar{\tau} < \omega$. Recalling that, for any i and any a,

$$\max_j \dot{d}_{ij}^a = \bar{\kappa}_{\bar{\tau}}(\hat{s}_i^a, rs(\hat{s}_i^a, 1)),$$

we want to show that

$$\bar{\mathrm{k}}_{\bar{\tau}}(\hat{s}_i^a, rs(\hat{s}_i^a, 1)) > (1 - \nu) \left[\bar{\mathrm{k}}_{\bar{\tau}}(\hat{s}_i^a, rs(\hat{s}_i^a, 1)) + \sum_{k=2}^{m} \bar{\mathrm{k}}_{\bar{\tau}}(\hat{s}_i^a, rs(\hat{s}_i^a, k)) \right],$$

which is equivalent to

$$(1 - \nu) \sum_{k=2}^{m} \bar{\mathrm{k}}_{\bar{\tau}}(\hat{s}_i^a, rs(\hat{s}_i^a, k)) < \nu \bar{\mathrm{k}}_{\bar{\tau}}(\hat{s}_i^a, rs(\hat{s}_i^a, 1)). \tag{50}$$

If $\nu \geq 1$, inequality (50) is true regardless of the particular choice of $\bar{\tau}$. Otherwise, we can rewrite (50) as

$$\sum_{k=2}^{m} \bar{\mathrm{k}}_{\bar{\tau}}(\hat{s}_i^a, rs(\hat{s}_i^a, k)) < \frac{\nu}{1 - \nu} \bar{\mathrm{k}}_{\bar{\tau}}(\hat{s}_i^a, rs(\hat{s}_i^a, 1)) \iff \sum_{k=2}^{m} \bar{\kappa}_{\bar{\tau}}(\hat{s}_i^a, rs(\hat{s}_i^a, k)) < \frac{\nu}{1 - \nu} \bar{\kappa}_{\bar{\tau}}(\hat{s}_i^a, rs(\hat{s}_i^a, 1)). \tag{51}$$

Let

$$\alpha = \begin{cases} \nu/(1 - \nu), \text{ if } \nu < 1, \\ \infty, \text{ otherwise.} \end{cases}$$

Then, if we make $\omega^{a,i} = \varphi(\hat{s}_i^a, 1, m, \alpha)$, with φ defined in (34), we can resort to Lemma 5 to

guarantee that (51) holds. As before, if we let $\omega = \min_{a,i} \omega^{a,i}$, we can guarantee that (41) is true. Finally, by making $\bar{\tau} = \min(\theta, \omega)$, the result follows. ■

Proposition 8

Proof

We start by plugging (39) into the definition of ξ_v, given in (8), to get:

$$\begin{aligned}
\xi_v &\leq \frac{1}{1-\gamma} \max_a \|\hat{\mathbf{P}}^a - \mathbf{D}\mathbf{K}^a\|_\infty \|\mathbf{r}\|_\infty + \frac{\bar{R}_{\text{dif}}}{(1-\gamma)^2} \left(\frac{\gamma}{2} \max_a \|\mathbf{P}^a - \mathbf{D}\mathbf{K}^a\|_\infty + \sigma(\mathbf{D}) \right) \\
&= \max_a \|\mathbf{P}^a - \mathbf{D}\mathbf{K}^a\|_\infty \left(\frac{\|\mathbf{r}\|_\infty}{1-\gamma} + \frac{\gamma \bar{R}_{\text{dif}}}{2(1-\gamma)^2} \right) + \sigma(\mathbf{D}) \frac{\bar{R}_{\text{dif}}}{(1-\gamma)^2}. \\
&\leq \max_a \|\mathbf{P}^a - \mathbf{D}\mathbf{K}^a\|_\infty \left(\frac{R_{\max}}{1-\gamma} + \frac{\gamma R_{\max}}{(1-\gamma)^2} \right) + \sigma(\mathbf{D}) \frac{R_{\max}}{2(1-\gamma)^2} \\
&= \max_a \|\mathbf{P}^a - \mathbf{D}\mathbf{K}^a\|_\infty \frac{R_{\max}}{(1-\gamma)^2} + \sigma(\mathbf{D}) \frac{R_{\max}}{2(1-\gamma)^2}, \qquad (52)
\end{aligned}$$

where we used the fact that $\bar{R}_{\text{dif}} \leq R_{\max}/2$, which follows trivially from the observation that $\min_{a,i} \bar{r}_i^a \geq \min_{a,i} r_i^a$ and $\max_{a,i} \bar{r}_i^a \leq \max_{a,i} r_i^a$. To simplify the notation, let $\mathcal{R} = R_{\max}/(1-\gamma)^2$. Then, from (42), the definition of $\varsigma_k^{a,i,j}$ in (16), and the definition of $\sigma(\mathbf{D})$ in (9), we can rewrite (52) as

$$\begin{aligned}
\xi_v &\leq \max_{a,i} \left(\sum_{j=1}^{n_a} \sum_{k=1}^{m} \bar{\kappa}_{\bar{\tau}}(\hat{s}_i^a, \bar{s}_k) \varsigma_k^{a,i,j} \right) \mathcal{R} + \max_{a,i} \left[1 - \bar{\kappa}_{\bar{\tau}}(\hat{s}_i^a, rs(\hat{s}_i^a, 1)) \right] \frac{\mathcal{R}}{2} \\
&= \max_{a,i} \left(\sum_{k=1}^{m} \bar{\kappa}_{\bar{\tau}}(\hat{s}_i^a, \bar{s}_k) \sum_{j=1}^{n_a} \varsigma_k^{a,i,j} \right) \mathcal{R} + \max_{a,i} \left[1 - \bar{\kappa}_{\bar{\tau}}(\hat{s}_i^a, rs(\hat{s}_i^a, 1)) \right] \frac{\mathcal{R}}{2}
\end{aligned}$$

Let $W^w(\hat{s}_i^a)$ and $\bar{W}^w(\hat{s}_i^a)$ be defined as in (15). Then,

$$\begin{aligned}
\xi_v &\leq \max_{a,i} \left(\sum_{k \in W^w(\hat{s}_i^a)} \bar{\kappa}_{\bar{\tau}}(\hat{s}_i^a, \bar{s}_k) \sum_{j=1}^{n_a} \varsigma_k^{a,i,j} + \sum_{k \in \bar{W}^w(\hat{s}_i^a)} \bar{\kappa}_{\bar{\tau}}(\hat{s}_i^a, \bar{s}_k) \sum_{j=1}^{n_a} \varsigma_k^{a,i,j} \right) \mathcal{R} + \max_{a,i} \left(1 - \bar{\kappa}_{\bar{\tau}}(\hat{s}_i^a, rs(\hat{s}_i^a, 1)) \right] \frac{\mathcal{R}}{2} \\
&\leq \max_{a,i} \left(\sum_{k \in W^w(\hat{s}_i^a)} \bar{\kappa}_{\bar{\tau}}(\hat{s}_i^a, \bar{s}_k) \sum_{j=1}^{n_a} \varsigma_k^{a,i,j} \right) \mathcal{R} \\
&\quad + \underbrace{\max_{a,i} \left(\sum_{k \in \bar{W}^w(\hat{s}_i^a)} \bar{\kappa}_{\bar{\tau}}(\hat{s}_i^a, \bar{s}_k) \sum_{j=1}^{n_a} \varsigma_k^{a,i,j} \right) \mathcal{R} + \max_{a,i} \left(1 - \bar{\kappa}_{\bar{\tau}}(\hat{s}_i^a, rs(\hat{s}_i^a, 1)) \right] \frac{\mathcal{R}}{2}}_{\mathcal{F}(\bar{\tau}, w)}. \qquad (53)
\end{aligned}$$

We see that the two last terms of (53) coincide with the definition of $\mathcal{F}(\bar{\tau}, w)$, given in (17). Thus, if we make sure that $\bar{\kappa}_{\bar{\tau}}$ is an admissible kernel $\bar{\kappa}_{\bar{\tau}}^{\epsilon,w}$ (see Definition 7), we can

rewrite (53) as

$$\begin{aligned}
\xi_v &\leq \max_{a,i} \left(\sum_{k \in W^w(\hat{s}_i^a)} \bar{\kappa}_{\bar{\tau}}^{\epsilon,w}(\hat{s}_i^a, \bar{s}_k) \sum_{j=1}^{n_a} \varsigma_k^{a,i,j} \right) \mathcal{R} + \epsilon \\
&\leq \max_{a,i} \left(w \max_{k \in W^w(\hat{s}_i^a)} \sum_{j=1}^{n_a} \varsigma_k^{a,i,j} \right) \mathcal{R} + \epsilon \\
&= w \max_{a,i} \left(\max_{k \in W^w(\hat{s}_i^a)} \sum_{j=1}^{n_a} |\kappa_\tau^a(\hat{s}_i^a, s_j^a) - \kappa_\tau^a(\bar{s}_k, s_j^a)| \right) \mathcal{R} + \epsilon. \qquad (54)
\end{aligned}$$

Let $z_i^a = \sum_l \mathrm{k}_\tau(\hat{s}_i^a, s_l^a)$ and $\bar{z}_k^a = \sum_l \mathrm{k}_\tau(\bar{s}_k, s_l^a)$. Then, for fixed a, i, j, and k:

$$\begin{aligned}
|\kappa_\tau^a(\hat{s}_i^a, s_j^a) - \kappa_\tau^a(\bar{s}_k, s_j^a)| &= \left| \frac{\mathrm{k}_\tau(\hat{s}_i^a, s_j^a)}{\sum_l \mathrm{k}_\tau(\hat{s}_i^a, s_l^a)} - \frac{\mathrm{k}_\tau(\bar{s}_k, s_j^a)}{\sum_l \mathrm{k}_\tau(\bar{s}_k, s_l^a)} \right| \\
&= \left| \frac{\mathrm{k}_\tau(\hat{s}_i^a, s_j^a)}{z_i^a} - \frac{\mathrm{k}_\tau(\bar{s}_k, s_j^a)}{\bar{z}_k^a} \right| \\
&= \left| \frac{\bar{z}_k^a \mathrm{k}_\tau(\hat{s}_i^a, s_j^a) - z_i^a \mathrm{k}_\tau(\bar{s}_k, s_j^a)}{z_i^a \bar{z}_k^a} \right| \\
&= \left| \frac{\bar{z}_k^a \mathrm{k}_\tau(\hat{s}_i^a, s_j^a) - z_i^a \mathrm{k}_\tau(\bar{s}_k, s_j^a) + z_i^a \mathrm{k}_\tau(\hat{s}_i^a, s_j^a) - z_i^a \mathrm{k}_\tau(\hat{s}_i^a, s_j^a)}{z_i^a \bar{z}_k^a} \right| \\
&= \left| \frac{\mathrm{k}_\tau(\hat{s}_i^a, s_j^a) - \mathrm{k}_\tau(\bar{s}_k, s_j^a)}{\bar{z}_k^a} + \frac{\mathrm{k}_\tau(\hat{s}_i^a, s_j^a)(\bar{z}_k^a - z_i^a)}{z_i^a \bar{z}_k^a} \right| \\
&\leq \frac{\left| \mathrm{k}_\tau(\hat{s}_i^a, s_j^a) - \mathrm{k}_\tau(\bar{s}_k, s_j^a) \right|}{\bar{z}_k^a} + \frac{\mathrm{k}_\tau(\hat{s}_i^a, s_j^a) |\bar{z}_k^a - z_i^a|}{z_i^a \bar{z}_k^a}.
\end{aligned}$$

Thus,

$$\begin{aligned}
\sum_{j=1}^{n_a} |\kappa_\tau^a(\hat{s}_i^a, s_j^a) - \kappa_\tau^a(\bar{s}_k, s_j^a)| &\leq \sum_{j=1}^{n_a} \frac{\left| \mathrm{k}_\tau(\hat{s}_i^a, s_j^a) - \mathrm{k}_\tau(\bar{s}_k, s_j^a) \right|}{\bar{z}_k^a} + \sum_{j=1}^{n_a} \frac{\mathrm{k}_\tau(\hat{s}_i^a, s_j^a) |\bar{z}_k^a - z_i^a|}{z_i^a \bar{z}_k^a} \\
&= \sum_{j=1}^{n_a} \frac{\left| \mathrm{k}_\tau(\hat{s}_i^a, s_j^a) - \mathrm{k}_\tau(\bar{s}_k, s_j^a) \right|}{\bar{z}_k^a} + \sum_{j=1}^{n_a} \kappa_\tau^a(\hat{s}_i^a, s_j^a) \frac{|\bar{z}_k^a - z_i^a|}{\bar{z}_k^a} \\
&= \sum_{j=1}^{n_a} \frac{\left| \mathrm{k}_\tau(\hat{s}_i^a, s_j^a) - \mathrm{k}_\tau(\bar{s}_k, s_j^a) \right|}{\bar{z}_k^a} + \frac{|\bar{z}_k^a - z_i^a|}{\bar{z}_k^a} \\
&= \frac{1}{\sum_{l=1}^{n_a} \mathrm{k}_\tau(\bar{s}_k, s_l^a)} \left(\sum_{j=1}^{n_a} \left| \mathrm{k}_\tau(\hat{s}_i^a, s_j^a) - \mathrm{k}_\tau(\bar{s}_k, s_j^a) \right| + \left| \sum_{j=1}^{n_a} \mathrm{k}_\tau(\bar{s}_k, s_j^a) - \sum_{j=1}^{n_a} \mathrm{k}_\tau(\hat{s}_i^a, s_j^a) \right| \right) \\
&\leq \frac{1}{\sum_{l=1}^{n_a} \mathrm{k}_\tau(\bar{s}_k, s_l^a)} \left(\sum_{j=1}^{n_a} \left| \mathrm{k}_\tau(\hat{s}_i^a, s_j^a) - \mathrm{k}_\tau(\bar{s}_k, s_j^a) \right| + \sum_{j=1}^{n_a} \left| \mathrm{k}_\tau(\bar{s}_k, s_j^a) - \mathrm{k}_\tau(\hat{s}_i^a, s_j^a) \right| \right) \\
&= \frac{2}{\sum_{l=1}^{n_a} \mathrm{k}_\tau(\bar{s}_k, s_l^a)} \sum_{j=1}^{n_a} \left| \mathrm{k}_\tau(\hat{s}_i^a, s_j^a) - \mathrm{k}_\tau(\bar{s}_k, s_j^a) \right|. \qquad (55)
\end{aligned}$$

In order to derive our result, it suffices to replace (55) in (54). Before doing so, though, note that Assumption (iii) implies that

$$\begin{aligned}\left|\mathrm{k}_\tau(s,s') - \mathrm{k}_\tau(s,s'')\right| &= \left|\phi\left(\frac{\|s-s'\|}{\tau}\right) - \phi\left(\frac{\|s-s''\|}{\tau}\right)\right| \\ &\leq \frac{C_\phi}{\tau}\left|\|s-s'\| - \|s-s''\|\right| \\ &\leq \frac{C_\phi}{\tau}\left|\|s-s''\| + \|s''-s'\| - \|s-s''\|\right| \\ &= \frac{C_\phi}{\tau}\|s''-s'\|. \end{aligned} \tag{56}$$

Proceeding with the substitution mentioned above, we have

$$\begin{aligned}\xi_v &\leq 2w \max_{a,i}\left(\max_{k\in W^w(\hat{s}_i^a)} \frac{1}{\sum_{l=1}^{n_a}\mathrm{k}_\tau(\bar{s}_k, s_l^a)} \sum_{j=1}^{n_a}\left|\mathrm{k}_\tau(\hat{s}_i^a, s_j^a) - \mathrm{k}_\tau(\bar{s}_k, s_j^a)\right|\right)\mathcal{R} + \epsilon \\ &\leq 2w \max_{a,i}\left(\max_{k\in W^w(\hat{s}_i^a)} \frac{1}{\sum_{l=1}^{n_a}\mathrm{k}_\tau(\bar{s}_k, s_l^a)} \frac{C_\phi}{\tau} n_a \|\hat{s}_i^a - \bar{s}_k\|\right)\mathcal{R} + \epsilon \\ &= \frac{2wC_\phi}{\tau}\max_{a,i}\left(\max_{k\in W^w(\hat{s}_i^a)} \frac{n_a\|\hat{s}_i^a - \bar{s}_k\|}{\sum_{l=1}^{n_a}\mathrm{k}_\tau(\bar{s}_k, s_l^a)}\right)\mathcal{R} + \epsilon \\ &\leq \frac{2wC_\phi}{\tau}\max_{a,i}\left(\max_{k\in W^w(\hat{s}_i^a)} \frac{n_a\|\hat{s}_i^a - \bar{s}_k\|}{n_a \mathrm{k}_{\min}}\right)\mathcal{R} + \epsilon \\ &= \frac{2wC_\phi}{\tau\mathrm{k}_{\min}}\max_{a,i}\max_{k\in W^w(\hat{s}_i^a)}\|\hat{s}_i^a - \bar{s}_k\|\mathcal{R} + \epsilon. \end{aligned}$$

■

Lemma 9

Proof Let $\mathbf{q}_*^a, \tilde{\mathbf{q}}_*^a \in \mathbb{R}^{|S|}$ be the a^{th} columns of $\mathbf{Q}^*$ and $\tilde{\mathbf{Q}}^*$, respectively. Then,

$$\begin{aligned}\|\mathbf{q}_*^a - \tilde{\mathbf{q}}_*^a\|_\infty &= \left\|\mathbf{r}^a + \gamma\mathbf{P}^a\mathbf{v}^* - \tilde{\mathbf{r}}^a - \gamma\tilde{\mathbf{P}}^a\tilde{\mathbf{v}}^*\right\|_\infty \\ &\leq \|\mathbf{r}^a - \tilde{\mathbf{r}}^a\|_\infty + \gamma\left\|\mathbf{P}^a\mathbf{v}^* - \tilde{\mathbf{P}}^a\tilde{\mathbf{v}}^*\right\|_\infty \\ &= \|\mathbf{r}^a - \tilde{\mathbf{r}}^a\|_\infty + \gamma\left\|\mathbf{P}^a\mathbf{v}^* - \tilde{\mathbf{P}}^a\mathbf{v}^* + \tilde{\mathbf{P}}^a\mathbf{v}^* - \tilde{\mathbf{P}}^a\tilde{\mathbf{v}}^*\right\|_\infty \\ &\leq \|\mathbf{r}^a - \tilde{\mathbf{r}}^a\|_\infty + \gamma\left\|(\mathbf{P}^a - \tilde{\mathbf{P}}^a)\mathbf{v}^*\right\|_\infty + \gamma\left\|\tilde{\mathbf{P}}^a(\mathbf{v}^* - \tilde{\mathbf{v}}^*)\right\|_\infty \\ &\leq \|\mathbf{r}^a - \tilde{\mathbf{r}}^a\|_\infty + \gamma\left\|(\mathbf{P}^a - \tilde{\mathbf{P}}^a)\mathbf{v}^*\right\|_\infty + \gamma\|\mathbf{v}^* - \tilde{\mathbf{v}}^*\|_\infty, \end{aligned} \tag{57}$$

where in the last step we used the fact that $\tilde{\mathbf{P}}^a$ is stochastic, and thus $\|\tilde{\mathbf{P}}^a\mathbf{v}\|_\infty \leq \|\mathbf{v}\|_\infty$ for any $\mathbf{v}$. We now provide a bound for $\|(\mathbf{P}^a - \tilde{\mathbf{P}}^a)\mathbf{v}^*\|_\infty$. Let $\mathbf{A} = \mathbf{P}^a - \tilde{\mathbf{P}}^a$. Then, for any i, $\sum_j a_{ij} = \sum_j (p_{ij}^a - \tilde{p}_{ij}^a) = \sum_j p_{ij}^a - \sum_j \tilde{p}_{ij}^a = 0$, that is, the elements in each row of $\mathbf{A}$ sum to zero. Let a_i^+ be the sum of positive elements in the i^{th} row of $\mathbf{A}$ and let $a_{\max}^+ = \max_i a_i^+$.

It should be clear that $\|\mathbf{A}\|_\infty = 2a_{\max}^+$. Then, for any i,

$$\begin{aligned}\left|\sum_j a_{ij}v_j^*\right| &\leq \sum_{(j:a_{ij}>0)} a_{ij}v_{\max}^* + \sum_{(j:a_{ij}<0)} a_{ij}v_{\min}^* = a_i^+ v_{\max}^* - a_i^+ v_{\min}^* \leq a_{\max}^+(v_{\max}^* - v_{\min}^*) \\ &\leq \frac{a_{\max}^+}{1-\gamma}(r_{\max}^a - r_{\min}^a) \leq \frac{a_{\max}^+ R_{\text{dif}}}{1-\gamma} = \frac{R_{\text{dif}}}{2(1-\gamma)}\|\mathbf{P}^a - \tilde{\mathbf{P}}^a\|_\infty, \end{aligned} \tag{58}$$

where we used the convention $v_{\max} = \max_i v_i$ (analogously for $v_{\min}$). As done in (30), we can resort to Whitt's (1978) Theorem 3.1 and Corollary (b) of his Theorem 6.1 to obtain a bound for $\|\mathbf{v}^* - \tilde{\mathbf{v}}^*\|_\infty$. Substituting such a bound and expression (58) in (57), we obtain

$$\begin{aligned}\|\mathbf{q}_*^a - \tilde{\mathbf{q}}_*^a\|_\infty &\leq \|\mathbf{r}^a - \tilde{\mathbf{r}}^a\|_\infty + \frac{\gamma R_{\text{dif}}}{2(1-\gamma)}\|\mathbf{P}^a - \tilde{\mathbf{P}}^a\|_\infty + \frac{\gamma}{1-\gamma}\left(\max_a \|\mathbf{r}^a - \tilde{\mathbf{r}}^a\|_\infty + \frac{\gamma R_{\text{dif}}}{2(1-\gamma)}\max_a \|\mathbf{P}^a - \tilde{\mathbf{P}}^a\|_\infty\right) \\ &\leq \max_a \|\mathbf{r}^a - \tilde{\mathbf{r}}^a\|_\infty + \frac{\gamma R_{\text{dif}}}{2(1-\gamma)}\max_a \|\mathbf{P}^a - \tilde{\mathbf{P}}^a\|_\infty + \frac{\gamma}{1-\gamma}\left(\max_a \|\mathbf{r}^a - \tilde{\mathbf{r}}^a\|_\infty + \frac{\gamma R_{\text{dif}}}{2(1-\gamma)}\max_a \|\mathbf{P}^a - \tilde{\mathbf{P}}^a\|_\infty\right). \end{aligned}$$

■

Proposition 10

Proof Let $\check{M}_t \equiv (\hat{S}_t, A, \check{\mathbf{P}}_t^a, \check{\mathbf{r}}_t^a, \gamma)$, with $\check{\mathbf{P}}_t^a = \mathbf{D}_t\mathbf{K}_t^a$ and $\check{\mathbf{r}}_t^a = \mathbf{D}_t\bar{\mathbf{r}}_t^a$. From the triangle inequality, we know that

$$|\hat{Q}_t(s,a) - \tilde{Q}_t(s,a)| \leq |\hat{Q}_t(s,a) - \check{Q}_t^*(s,a)| + |\check{Q}_t^*(s,a) - \tilde{Q}_t^*(s,a)| + |\tilde{Q}_t^*(s,a) - \tilde{Q}_t(s,a)|, \tag{59}$$

where $\hat{Q}_t$ and $\tilde{Q}_t$ are defined in the proposition's statement, $\check{Q}_t^*$ is the optimal action-value function of $\check{M}_t$, and $\tilde{Q}_t^*(s,a) = \sum_{i=1}^m \bar{\kappa}_{\bar{\tau}}(s,\bar{s}_i)\bar{Q}_t^*(\bar{s}_i,a)$ (the reader will forgive a slight abuse of notation here, since in general $\bar{Q}_t^*$ is not the optimal value function of any MDP). Our strategy will be to bound each term on the right-hand side of (59). Since $\hat{M}_t$ is the model constructed by KBRL using all the data seen by iKBSF up to time step t, state s will correspond to one of the states $\hat{s}_i^b$ in this MDP. Thus, from (7), we see that $\hat{Q}_t(s,a) = \hat{Q}_t^*(\hat{s}_i^b, a)$ for some i and some b. Therefore, applying Lemma 9 to $\hat{M}_t$ and $\check{M}_t$, we can write

$$|\hat{Q}_t(s,a) - \check{Q}_t^*(s,a)| \leq \frac{1}{1-\gamma}\max_a \|\hat{\mathbf{r}}_t^a - \mathbf{D}_t\bar{\mathbf{r}}_t^a\|_\infty + \frac{\gamma}{2(1-\gamma)^2}\bar{R}_{\text{dif},t}\max_a \|\hat{\mathbf{P}}_t^a - \mathbf{D}_t\mathbf{K}_t^a\|_\infty. \tag{60}$$

In order to bound $|\check{Q}_t^*(s,a) - \tilde{Q}_t^*(s,a)|$, we note that, since the information contained in the transition to state s has been incorporated to iKBSF's model $\bar{M}$ at time t, $\tilde{Q}_t^*(s,a) = \sum_{i=1}^m d_{ti,t}\bar{Q}_t^*(\bar{s}_i,a)$, for any $a \in A$, where $d_{ti,t}$ is the element in the t^{th} row and i^{th} column of $\mathbf{D}_t$ (see Figure 2b). In matrix form, we have $\tilde{\mathbf{Q}}_t^* = \mathbf{D}_t\bar{\mathbf{Q}}_t^*$. As $\mathbf{D}_t$ is a soft homomorphism between $\bar{M}_t$ and $\bar{M}_t$, we can resort to Sorg and Singh's (2009) Theorem 1, as done in Proposition 2, to write:

$$|\check{Q}_t^*(s,a) - \tilde{Q}_t^*(s,a)| \leq \frac{\bar{R}_{\text{dif},t}}{(1-\gamma)^2}\sigma(\mathbf{D}_t) \tag{61}$$

(see (31) and (32)). Finally,

$$|\tilde{Q}_t^*(s,a) - \tilde{Q}_t(s,a)| = \left|\sum_{i=1}^{m} \bar{\kappa}_{\bar{\tau}}(s,\bar{s}_i)\bar{Q}_t^*(\bar{s}_i,a) - \sum_{i=1}^{m} \bar{\kappa}_{\bar{\tau}}(s,\bar{s}_i)\bar{Q}_t(\bar{s}_i,a)\right|$$
$$\leq \sum_{i=1}^{m} \bar{\kappa}_{\bar{\tau}}(s,\bar{s}_i)\left|\bar{Q}_t^*(\bar{s}_i,a) - \bar{Q}_t(\bar{s}_i,a)\right| \leq \epsilon_{\bar{Q}_t}, \tag{62}$$

where the last step follows from the fact that $\sum_{i=1}^{m} \bar{\kappa}_{\bar{\tau}}(s,\bar{s}_i)$ is a convex combination. Substituting (60), (61), and (62) in (59), we obtain the desired bound. ■

A.2 Alternative error bound

In Section 3 we derived an upper bound for the approximation error introduced by the application of the stochastic-factorization trick. In this section we introduce another bound that has different properties. First, the bound is less applicable, because it depends on quantities that are usually unavailable in a practical situation (the fixed points of two contraction mappings). On the bright side, unlike the bound presented in Proposition 2, the new bound is valid for any norm. Also, it draws an interesting connection with an important class of approximators known as *averagers* (Gordon, 1995).

We start by deriving a theoretical result that only applies to stochastic factorizations of order n. We then generalize this result to the case in which the factorizations are of order $m < n$.

Lemma 11 *Let $M \equiv (S, A, \mathbf{P}^a, \mathbf{r}^a, \gamma)$ be a finite MDP with $|S| = n$ and $0 \leq \gamma < 1$. Let $\mathbf{E}\mathbf{L}^a = \mathbf{P}^a$ be $|A|$ stochastic factorizations of order n and let $\bar{\bar{\mathbf{r}}}^a$ be vectors in $\mathbb{R}^n$ such that $\mathbf{E}\bar{\bar{\mathbf{r}}}^a = \mathbf{r}^a$ for all $a \in A$. Define the MDPs $\check{M} \equiv (S, A, \mathbf{L}^a, \bar{\bar{\mathbf{r}}}^a, \gamma)$ and $\bar{\bar{M}} \equiv (S, A, \bar{\bar{\mathbf{P}}}^a, \bar{\bar{\mathbf{r}}}^a, \gamma)$, with $\bar{\bar{\mathbf{P}}}^a = \mathbf{L}^a\mathbf{E}$. Then,*

$$\|\mathbf{v}^* - T\mathbf{E}\check{\mathbf{v}}^*\| \leq \xi_v' \equiv \frac{2\gamma}{1-\gamma}\|\mathbf{v}^* - \mathbf{u}\| + \frac{\gamma(1+\gamma)}{1-\gamma}\|\mathbf{v}^* - \check{\mathbf{v}}^*\|, \tag{63}$$

where $\|\cdot\|$ is a norm in R^n and $\mathbf{u}$ is a vector in $\mathbb{R}^n$ such that $\mathbf{E}\mathbf{u} = \mathbf{u}$.

Proof The Bellman operators of M, $\check{M}$, and $\bar{\bar{M}}$ are given by $T = \Gamma\Delta$, $\check{T} = \Gamma\check{\Delta}$, and $\bar{\bar{T}} = \Gamma\bar{\bar{\Delta}}$. Note that $\mathbf{q}^a = \mathbf{r}^a + \gamma\mathbf{P}^a\mathbf{v} = \mathbf{E}\bar{\bar{\mathbf{r}}}^a + \gamma\mathbf{E}\mathbf{L}^a\mathbf{v} = \mathbf{E}(\bar{\bar{\mathbf{r}}}^a + \gamma\mathbf{L}^a\mathbf{v})$, where $\mathbf{q}^a$ is the a^{th} column of $\mathbf{Q}$. Thus, $\Delta = \mathbf{E}\check{\Delta}$. Since $\mathbf{E}$ is stochastic, we can think of it as one of Gordon's (1995) averagers given by $A(\mathbf{v}) = \mathbf{E}\mathbf{v}$, and then resort to Theorem 4.1 by the same author to conclude that $\bar{\bar{T}} = \mathbf{E}\check{T}$. Therefore,[7]

$$T\mathbf{v} = \Gamma\mathbf{E}\check{\Delta}\mathbf{v} \quad \text{and} \quad \bar{\bar{T}}\mathbf{v} = \mathbf{E}\Gamma\check{\Delta}\mathbf{v}. \tag{64}$$

7. Interestingly, the effect of swapping matrices $\mathbf{E}$ and $\mathbf{L}^a$ is to also swap the operators Γ and $\mathbf{E}$.

Using (64), it is easy to obtain the desired upper bound by resorting to the triangle inequality, the definition of a contraction map, and Denardo's (1967) Theorem 1:

$$\begin{aligned}
\|\mathbf{v}^* - T\mathbf{E}\bar{\bar{\mathbf{v}}}^*\| &\leq \gamma\|\mathbf{v}^* - \mathbf{E}\bar{\bar{\mathbf{v}}}^*\| \leq \gamma(\|\mathbf{v}^* - \mathbf{u}\| + \|\mathbf{u} - \mathbf{E}\bar{\bar{\mathbf{v}}}^*\|) \leq \gamma(\|\mathbf{v}^* - \mathbf{u}\| + \|\mathbf{u} - \check{\mathbf{v}}^*\|) \\
&\leq \gamma\left(\|\mathbf{v}^* - \mathbf{u}\| + \frac{1}{1-\gamma}\|\mathbf{u} - \mathbf{E}\Gamma\check{\Delta}\mathbf{u}\|\right) \leq \gamma\left(\|\mathbf{v}^* - \mathbf{u}\| + \frac{1}{1-\gamma}\|\mathbf{u} - \Gamma\check{\Delta}\mathbf{u}\|\right) \\
&\leq \gamma\left[\|\mathbf{v}^* - \mathbf{u}\| + \frac{1}{1-\gamma}\left(\|\mathbf{u} - \check{\mathbf{v}}^*\| + \|\check{\mathbf{v}}^* - \Gamma\check{\Delta}\mathbf{u}\|\right)\right] \\
&\leq \gamma\left[\|\mathbf{v}^* - \mathbf{u}\| + \frac{1}{1-\gamma}\left(\|\mathbf{u} - \check{\mathbf{v}}^*\| + \gamma\|\check{\mathbf{v}}^* - \mathbf{u}\|\right)\right] = \gamma\left[\|\mathbf{v}^* - \mathbf{u}\| + \frac{1+\gamma}{1-\gamma}\|\mathbf{u} - \check{\mathbf{v}}^*\|\right] \\
&\leq \gamma\left[\|\mathbf{v}^* - \mathbf{u}\| + \frac{1+\gamma}{1-\gamma}\left(\|\mathbf{u} - \mathbf{v}^*\| + \|\mathbf{v}^* - \check{\mathbf{v}}^*\|\right)\right] \\
&= \gamma\|\mathbf{v}^* - \mathbf{u}\| + \frac{\gamma(1+\gamma)}{1-\gamma}\|\mathbf{v}^* - \mathbf{u}\| + \frac{\gamma(1+\gamma)}{1-\gamma}\|\mathbf{v}^* - \check{\mathbf{v}}^*\| \\
&= \frac{\gamma - \gamma^2 + \gamma + \gamma^2}{1-\gamma}\|\mathbf{v}^* - \mathbf{u}\| + \frac{\gamma(1+\gamma)}{1-\gamma}\|\mathbf{v}^* - \check{\mathbf{v}}^*\|.
\end{aligned}$$

■

The derived upper bound depends on two fixed points: $\mathbf{u}$, a fixed point of $\mathbf{E}$, and $\check{\mathbf{v}}^*$, the unique fixed point of $\check{T} = \Gamma\check{\Delta}$. Since the latter is defined by $\bar{\bar{\mathbf{r}}}^a$ and $\mathbf{L}^a$, the bound is essentially a function of the factorization terms, as expected. Notice that the bound is valid for any norm and any fixed point of $\mathbf{E}$ (we may think of $\mathbf{u}$ as the closest vector to $\mathbf{v}^*$ in $\mathbb{R}^n$ which satisfies this property). Notice also that the first term on the right-hand side of (63) is exactly the error bound derived in Gordon's (1995) Theorem 6.2. When $\mathbf{L}^a = \mathbf{P}^a$ and $\mathbf{r}^a = \bar{\bar{\mathbf{r}}}^a$ for all $a \in A$, the operators T and $\check{T}$ coincide, and hence the second term of (63) vanishes. This makes sense, since in this case $\bar{\bar{T}} = \mathbf{E}T$, that is, the stochastic-factorization trick reduces to the averager $A(\mathbf{v}) = \mathbf{E}\mathbf{v}$.

As mentioned above, one of the assumptions of Lemma 11 is that the factorizations $\mathbf{E}\mathbf{L}^a = \mathbf{P}^a$ are of order n. This is unfortunate, since the whole motivation behind the stochastic-factorization trick is to create an MDP with $m < n$ states. One way to obtain such a reduction is to suppose that matrix $\mathbf{E}$ has $n - m$ columns with zeros only. Define $\mathcal{E} \subset \{1, 2, ..., n\}$ as the set of columns of $\mathbf{E}$ with at least one nonzero element and let $\mathbf{H}$ be a matrix in $\mathbb{R}^{m\times n}$ such that $h_{ij} = 1$ if j is the i^{th} smallest element in $\mathcal{E}$ and $h_{ij} = 0$ otherwise. The following proposition generalizes the previous result to a stochastic factorization of order m:

Proposition 12 *Suppose the assumptions of Lemma 11 hold. Let $\mathbf{D} = \mathbf{E}\mathbf{H}^\intercal$, $\mathbf{K}^a = \mathbf{H}\mathbf{L}^a$, and $\bar{\mathbf{r}}^a = \mathbf{H}\bar{\bar{\mathbf{r}}}^a$, with $\mathbf{H}$ defined as described above. Define the MDP $\bar{M} \equiv (\bar{S}, A, \bar{\mathbf{P}}^a, \bar{\mathbf{r}}^a, \gamma)$, with $|\bar{S}| = m$ and $\bar{\mathbf{P}}^a = \mathbf{K}^a\mathbf{D}$. Then, $\|\mathbf{v}^* - \Gamma\mathbf{D}\bar{\mathbf{Q}}^*\| \leq \xi_v'$, with ξ_v' defined in (63).*

Proof Let $\bar{\mathbf{q}}_*^a \in \mathbb{R}^m$ be the a^{th} column of $\bar{\mathbf{Q}}^*$. Then,

$$\begin{aligned}
\mathbf{D}\bar{\mathbf{q}}_*^a &= \mathbf{D}\left(\bar{\mathbf{r}}^a + \gamma\bar{\bar{\mathbf{P}}}^a\bar{\mathbf{v}}^*\right) = \mathbf{D}\bar{\mathbf{r}}^a + \gamma\mathbf{D}\mathbf{K}^a\mathbf{D}\bar{\mathbf{v}}^* = \mathbf{E}\mathbf{H}^\intercal\mathbf{H}\bar{\bar{\mathbf{r}}}^a + \gamma\mathbf{E}\mathbf{H}^\intercal\mathbf{H}\mathbf{L}^a\mathbf{E}\mathbf{H}^\intercal\bar{\mathbf{v}}^* \\
&= \mathbf{E}\bar{\bar{\mathbf{r}}}^a + \gamma\mathbf{E}\bar{\bar{\mathbf{P}}}^a\mathbf{H}^\intercal\bar{\mathbf{v}}^* = \mathbf{E}\bar{\bar{\mathbf{r}}}^a + \gamma\mathbf{E}\bar{\bar{\mathbf{P}}}^a\bar{\bar{\mathbf{v}}}^* = \mathbf{E}\left(\bar{\bar{\mathbf{r}}}^a + \gamma\bar{\bar{\mathbf{P}}}^a\bar{\bar{\mathbf{v}}}^*\right) = \mathbf{E}\bar{\bar{\mathbf{q}}}_*^a,
\end{aligned} \tag{65}$$

where the equality $\mathbf{E}\mathbf{H}^\intercal\mathbf{H} = \mathbf{E}$ follows from the definition of $\mathbf{H}$. The identity $\bar{\bar{\mathbf{P}}}^a\mathbf{H}^\intercal\bar{\mathbf{v}}^* = \bar{\bar{\mathbf{P}}}^a\bar{\bar{\mathbf{v}}}^*$ is a consequence of the fact that the i^{th} column of $\bar{\bar{\mathbf{P}}}^a$ only contains zeros if $i \notin \mathcal{E}$. Since the i^{th} state of $\bar{\bar{M}}$ is transient, the values of the recurrent states of $\bar{\bar{M}}$, which effectively define the multiplication $\bar{\bar{\mathbf{P}}}^a\bar{\bar{\mathbf{v}}}^*$, will coincide with the values of the states of $\bar{M}$. Expression (65) then leads to $\mathbf{D}\bar{\mathbf{Q}}^* = \mathbf{E}\bar{\bar{\mathbf{Q}}}^*$. Also, since $\mathbf{E}\bar{\bar{\mathbf{q}}}^a_* = \mathbf{E}\bar{\bar{\mathbf{r}}}^a + \gamma\mathbf{E}\mathbf{L}^a\mathbf{E}\bar{\bar{\mathbf{v}}}^* = \mathbf{r}^a + \gamma\mathbf{P}^a\mathbf{E}\bar{\bar{\mathbf{v}}}^*$, we know that $\mathbf{E}\bar{\bar{\mathbf{Q}}}^* = \Delta\mathbf{E}\bar{\bar{\mathbf{v}}}^*$. Putting these results together, we obtain $\|\mathbf{v}^* - \Gamma\mathbf{D}\bar{\mathbf{Q}}^*\| = \|\mathbf{v}^* - \Gamma\Delta\mathbf{E}\bar{\bar{\mathbf{v}}}^*\| = \|\mathbf{v}^* - T\mathbf{E}\bar{\bar{\mathbf{v}}}^*\|$, and Lemma 11 applies. ■

The derived bound can be generalized to the case of approximate stochastic factorizations through the triangle inequality, as done in (29). However, if one resorts to Whitt's (1978) results to bound the distance between $\mathbf{v}^*$ and $\check{\mathbf{v}}^*$—where $\check{\mathbf{v}}^*$ is the optimal value function of $\check{M} \equiv (S, A, \mathbf{D}\mathbf{K}^a, \mathbf{D}\bar{\mathbf{r}}^a, \gamma)$—the compounded bound will no longer be valid for all norms, since (30) only holds for the infinity norm.

Appendix B. Details of the experiments

This appendix describes the details of the experiments omitted in the paper.

B.1 Tasks

Puddle World: The puddle-world task was implemented as described by Sutton (1996), but here the task was modeled as a discounted problem with $\gamma = 0.99$. All the transitions were associated with a zero reward, except those leading to the goal, which resulted in a reward of $+5$, and those ending inside one of the puddles, which lead to a penalty of -10 times the distance to the puddle's nearest edge. If the agent did not reach the goal after 300 steps the episode was interrupted and considered as a failure. The algorithms were evaluated on two sets of states distributed over disjoint regions of the state space surrounding the puddles. The first set was a 3×3 grid defined over $[0.1, 0.3] \times [0.3, 0.5]$ and the second one was composed of four states: $\{0.1, 0.3\} \times \{0.9, 1.0\}$.

Pole Balancing: We implemented the simulator of the three versions of the pole-balancing task using the equations of motion and parameters given in the appendix of Gomez's (2003) PhD thesis. For the integration we used the 4^{th} order Runge-Kutta method with a time step of 0.01 seconds and actions chosen every 2 time steps. The problem was modeled as a discounted task with $\gamma = 0.99$. We considered the version of the task in which the angle between the pole and the vertical plane must be kept within $[-36^o, 36^o]$. In this formulation, an episode is interrupted and the agent gets a reward of -1 if the pole falls past a 36-degree angle or the cart reaches the boundaries of the track, located at 2.4m from its center. At all other steps the agent receives a reward of 0. In all versions of the problem an episode was considered a success if the pole(s) could be balanced for 3000 steps (one minute of simulated time). The test set was comprised of 81 states equally spaced in the region defined by $\pm[1.2\text{m}, 1.2/5\text{m}, 18^o, 75^o/s]$, for the single pole case, and by $\pm[1.2\text{m}, 1.2/5\text{m}, 18^o, 75^o/s, 18^o, 150^o/s]$ for the double-pole version of the problem. These values correspond to a hypercube centered at the origin and covering 50% of the state-space axes in each dimension (since the velocity of the cart and the angular velocity of the poles are theoretically not bounded, we defined the limits of these variables based on samples generated in simple preliminary experiments). For the triple pole-balancing task we performed our simulations using the parameters usually adopted with the two pole version of the problem, but we added a third pole with the same length and mass as the longer pole (Gomez, 2003). In this case the decision policies were evaluated on a test set containing 256 states equally distributed in the region $\pm[1.2\text{m}, 1.2/5\text{m}, 18^o, 75^o/s, 18^o, 150^o/s, 18^o, 75^o/s]$.

HIV drug schedule: The HIV drug schedule task was implemented using the system of ordinary differential equations (ODEs) given by Adams et al. (2004). Integration was carried out by the Euler method using a step size of 0.001 with actions selected at each 5000 steps (corresponding to 5 days of simulated time). As suggested by Ernst et al. (2006), the problem was modeled as a discounted task with $\gamma = 0.98$. All other parameters of the task, as well as the protocol used for the numerical simulations, also followed the suggestions of the same authors. In particular, we assumed the existence of 30 patients who were monitored for 1000 days. During the monitoring period, the content of the drug cocktail administered to each patient could be changed at fixed intervals of 5 days. Thus, in a sample transition $(s_i^a, r_i^a, \hat{s}_i^a)$: s_i^a is the initial patient condition, a is one of the four types of cocktails to be administered for the next 5 days, $\hat{s}_i^a$ is the patient condition 5 days later, and r_i^a is a reward computed based on the amount of drug in the selected cocktail a and on the difference between the patient's condition from s_i^a to $\hat{s}_i^a$ (Ernst et al., 2006). The results reported in Section 4.2.3 correspond to the performance of the greedy policy induced by the value function computed by the algorithms using all available sample transitions. The decision policies (in this case STI treatments) were evaluated for 5000 days starting from an "unhealthy" state corresponding to a basin of attraction of the ODEs describing the problem's dynamics (see the papers by Adams et al. and Ernst et al.).

Epilepsy suppression: We used a generative model developed by Bush et al. (2009) to perform our experiments with the epilepsy suppression task. The model was generated based on labeled field potential recordings of five rat brain slices electrically stimulated at frequencies of 0.0 Hz, 0.5 Hz, 1.0 Hz, and 2.0 Hz. The data was used to construct a manifold embedding which in turn gave rise to the problem's state space. The objective is to minimize the occurrence of seizures using as little stimulation as possible, therefore there is a negative reward associated with both events (see Section 4.2.4). Bush et al.'s generative model is public available as an environment for the RL-Glue package (Tanner and White, 2009). In our experiments the problem was modeled as a discounted task with $\gamma = 0.99$. The decision policies were evaluated on episodes of 10^5 transitions starting from a fixed set of 10 test states drawn uniformly at random from the problem's state space.

Helicopter hovering: In the experiments with the helicopter hovering task we used the simulator developed by Abbeel et al. (2005), which is available as an environment for the RL-Glue package (Tanner and White, 2009). The simulator was built based on data collected from two separate flights of an XCell Tempest helicopter. The data was used to adjust the parameters of an "acceleration prediction model", which is more accurate than the linear model normally adopted by industry. The objective in the problem is to keep the helicopter hovering as close as possible to a specific location. Therefore, at each time step the agent gets a negative reward proportional to the distance from the target position. Since the problem's original action space is $A \equiv [-1, 1]^4$, we discretized each dimension using 4 break points distributed unevenly over $[-1, 1]$. We tried several possible discretizations and picked the one which resulted in the best performance of the SARSA

agent (see Section 5.2.3). After this process, the problem's action space was redefined as $A \equiv \{-0.25, -0.05, +0.05, +0.25\}^4$. The problem was modeled as a discounted task with $\gamma = 0.99$. The decision policies were evaluated in episodes starting from the target position and ending when the helicopter crashed.

B.2 Algorithms

In all experiments, we used

$$\phi(z) \equiv \bar{\phi}(z) \equiv \exp(-z) \tag{66}$$

to define the kernels used by KBRL, LSPI, and KBSF. In the experiments involving a large number of sample transitions we used sparse kernels, that is, we only computed the μ largest values of $\mathrm{k}_\tau(\bar{s}_i, \cdot)$ and the $\bar{\mu}$ largest values of $\bar{\mathrm{k}}_{\bar{\tau}}(\hat{s}_i^a, \cdot)$. In order to implement this feature, we used a KD-tree to find the μ ($\bar{\mu}$) nearest neighbors of $\bar{s}_i$ ($\hat{s}_i^a$) and only computed k_τ ($\bar{\mathrm{k}}_{\bar{\tau}}$) in these states (Bentley, 1975). The value of k_τ and $\bar{\mathrm{k}}_{\bar{\tau}}$ outside this neighborhood was truncated to zero (we used specialized data structures to avoid storing those).

We now list a few details regarding the algorithms's implementations which were not described in the paper:

- **KBRL** and **KBSF**: We used modified policy iteration to compute $\hat{\mathbf{Q}}^*$ (Puterman and Shin, 1978). The value function of a fixed policy π was approximated through value iteration using the stop criterion described by Puterman (1994, Proposition 6.6.5) with $\varepsilon = 10^{-6}$. Table 1 shows the parameters's values used by KBSF across the experiments.

- **LSPI**: As explained above, LSPI used the kernel derived from (66) as its basis function. Following Lagoudakis and Parr (2003), we adopted one block of basis functions for each action $a \in A$. Singular value decomposition was used to avoid eventual numerical instabilities in the system of linear equations constructed at each iteration of LSPI (Golub and Loan, 1993).

- **Fitted Q-iteration and extra trees**: FQIT has four main parameters: the number of iterations, the number of trees composing the ensemble, the number of candidate cut-points evaluated during the generation of the trees, and the minimum number of elements required to split a node, denoted here $\eta_{\min}$. In general, increasing the first three improves performance, while $\eta_{\min}$ has an inverse relation with the quality of the final value function approximation. Our experiments indicate that the following configuration of FQIT usually results in good performance on the tasks considered in this paper: 50 iterations (with the structure of the trees fixed after the 10^{th} one), an ensemble of 30 trees, and $d_{\mathbb{S}}$ candidate cut points, where $d_{\mathbb{S}}$ is the dimension of the state space $\mathbb{S}$. The parameter $\eta_{\min}$ has a particularly strong effect on FQIT's performance and computational cost, and its correct value seems to be more problem-dependent. Therefore, in all of our experiments we fixed the parameters of FQIT as described above and only varied $\eta_{\min}$.

- **SARSA**: We adopted the implementation of SARSA(λ) available in the RL-Glue package (Tanner and White, 2009). The algorithm uses gradient descent temporal-difference learning to configure a tile coding function approximator.

Problem	Section	$\bar{s}_i$	m	τ	$\bar{\tau}$	μ	$\bar{\mu}$
Puddle	4.2.1	k-means	$\{10, 30, ..., 150\}$	$\{0.01, 0.1, 0.1\}$	$\{0.01, 0.1, 0.1\}$	∞	∞
Puddle	5.2.1	evenly	100	$\{0.01, 0.1, 0.1\}$	$\{0.01, 0.1, 0.1\}$	∞	∞
Single Pole	4.2.2	k-means	$\{10, 30, ..., 150\}$	1	$\{0.01, 0.1, 0.1\}$	∞	∞
Double Pole	4.2.2	k-means	$\{20, 40, ..., 200\}$	1	$\{0.01, 0.1, 0.1\}$	∞	∞
Triple Pole	5.2.2	on-line	on-line	100^*	1^*	50^*	10^*
HIV	4.2.3	random	$\{2000, 4000, ..., 10000\}$	1	1	2^*	3^*

S	Generic state space	2
$\mathbb{S}$, $d_{\mathbb{S}}$	Continuous state space, dimension of $\mathbb{S}$	2.2
S^a	Sample transitions associated with action a, $S^a \equiv \{(s_i^a, r_i^a, \hat{s}_i^a) \vert i = 1, 2, ..., n_a\}$	2.2
s, s_i, $s_{(t)}$, s_i^a, $\hat{s}_i^a$	Generic state, i^{th} state of an MDP, state occupied at time t, i^{th} tuple in S^a	2
r, $r_{(t)}$, r_i^a	Generic reward, reward received at time t, i^{th} sampled reward in S^a	2
n_a, n, $\hat{n}$	Number of sample transitions in S^a, $n = \sum_a n_a$, and $\hat{n} = \max_a n_a$	2.2
P^a, P^π, $\mathbf{P}^a$, $\mathbf{P}^\pi$	Transition function associated with a or π and their matrix counterparts	2.1
R^a, R^π, $\mathbf{r}^a$, $\mathbf{r}^\pi$	Reward function associated with a or π and corresponding reward vectors	2.1
M	MDP, $M \equiv (S, A, P^a, R^a, \gamma)$	2.1
π, π^*	Generic decision policy, optimal decision policy in M	2
V^π, V^*, $\mathbf{v}^\pi$, $\mathbf{v}^*$	Value function of π, optimal value function of M, vector counterparts	2.1
Q^π, Q^*, $\mathbf{Q}^\pi$, $\mathbf{Q}^*$	Action-value functions of π and M and matrix counterparts	2.1
Γ	Operator: $\Gamma\mathbf{Q} = \mathbf{v} \iff v_i = \max_j q_{ij},\ \forall i$	2.1
Δ	Operator associated with M: $\Delta\mathbf{v} = \mathbf{Q} \iff q_{ia} = r_i^a + \gamma \sum_{j=1}^{\vert S\vert} p_{ij}^a v_j,\ \forall i, a$	2.1
T	Bellman operator of M, given by $T \equiv \Gamma\Delta$	2.1
ϕ, $\bar{\phi}$	Non-increasing functions in $\mathbb{R}^+ \mapsto \mathbb{R}^+$ used to construct the kernels	2.2, 4
k_τ, $\bar{\mathrm{k}}_{\bar{\tau}}$	Kernel functions: $\mathrm{k}_\tau(s, s') = \phi(\Vert s - s'\Vert/\tau)$ and $\bar{\mathrm{k}}_{\bar{\tau}}(s, s') = \bar{\phi}(\Vert s - s'\Vert/\bar{\tau})$	2.2, 4
τ, $\bar{\tau}$	Scalars defining the "widths" of k_τ and $\bar{\mathrm{k}}_{\bar{\tau}}$	2.2, 4
κ_τ^a, $\bar{\kappa}_{\bar{\tau}}$	Normalized kernels: $\kappa_\tau^a(s, s_i^a) = \frac{\mathrm{k}_\tau(s, s_i^a)}{\sum_{j=1}^{n_a} \mathrm{k}_\tau(s, s_j^a)}$ and $\bar{\kappa}_{\bar{\tau}}(s, \bar{s}_i) = \frac{\bar{\mathrm{k}}_{\bar{\tau}}(s, \bar{s}_i)}{\sum_{j=1}^{m} \bar{\mathrm{k}}_{\bar{\tau}}(s, \bar{s}_j)}$	2.2, 4
$\bar{S}$	Set of representative states, $\bar{S} \equiv \{\bar{s}_1, \bar{s}_2, ..., \bar{s}_m\}$	4
$\bar{s}_i$	i^{th} representative state	4
m	Number of representative states	4
$\mathbf{D}$, $\dot{\mathbf{D}}^a$	Stochastic matrix in $\mathbb{R}^{n \times m}$ and its $n_a \times m$ block associated with a	4
$\mathbf{K}^a$, $\dot{\mathbf{K}}^a$	Stochastic matrix in $\mathbb{R}^{m \times n}$ and its dense version in $\mathbb{R}^{m \times n_a}$	4
rs	Function: $rs(s, i) = \bar{s}_k \iff \bar{s}_k$ is the i^{th} closest representative state to s	4.1
$dist$	Function: $dist(s, i) = \Vert s - rs(s, i)\Vert$	4.1

Table 2: List of main symbols used throughout the paper. We use the same notation to refer to all MDPs and the associated elements, and resort to math accents to distinguish between them. So, for example, if $\bar{M}$ is an MDP, the associated elements are referred to as $\bar{\mathbf{P}}^a$, $\bar{\mathbf{r}}^a$, $\bar{\mathbf{v}}^*$, $\bar{\mathbf{Q}}^*$, $\bar{\pi}^*$, $\bar{\Delta}$, and $\bar{T}$.

Abstract

We provide an information-theoretic analysis of Thompson sampling that applies across a broad range of online optimization problems in which a decision-maker must learn from partial feedback. This analysis inherits the simplicity and elegance of information theory and leads to regret bounds that scale with the entropy of the optimal-action distribution. This strengthens preexisting results and yields new insight into how information improves performance.

Keywords: Thompson sampling, online optimization, mutli–armed bandit, information theory, regret bounds

1. Introduction

This paper considers the problem of repeated decision making in the presence of model uncertainty. A decision-maker repeatedly chooses among a set of possible actions, observes an outcome, and receives a reward representing the utility derived from this outcome. The decision-maker is uncertain about the underlying system and is therefore initially unsure of which action is best. However, as outcomes are observed, she is able to learn over time to make increasingly effective decisions. Her objective is to choose actions sequentially so as to maximize the expected cumulative reward.

We focus on settings with *partial feedback*, under which the decision-maker does not generally observe what the reward would have been had she selected a different action. This feedback structure leads to an inherent tradeoff between *exploration and exploitation*: by experimenting with poorly understood actions one can learn to make more effective decisions in the future, but focusing on better understood actions may lead to higher rewards in the short term. The classical multi–armed bandit problem is an important special case of this formulation. In such problems, the decision–maker only observes rewards she receives, and rewards from one action provide no information about the reward that can be attained by selecting other actions. We are interested here primarily in models and algorithms that accommodate cases where the number of actions is very large and there is a richer

information structure relating actions and observations. This category of problems is often referred to as *online optimization with partial feedback*.

A large and growing literature treats the design and analysis of algorithms for such problems. An online optimization algorithm typically starts with two forms of prior knowledge. The first – *hard knowledge* – posits that the mapping from action to outcome distribution lies within a particular family of mappings. The second – *soft knowledge* – concerns which of these mappings are more or less likely to match reality. Soft knowledge evolves with observations and is typically represented in terms of a probability distribution or a confidence set.

Much recent work concerning online optimization algorithms focuses on establishing performance guarantees in the form of *regret bounds*. Surprisingly, virtually all of these regret bounds depend on hard knowledge but not soft knowledge, a notable exception being the bounds of Srinivas et al. (2012) which we discuss further in Section 1.2. Regret bounds that depend on hard knowledge yield insight into how an algorithm's performance scales with the complexity of the family of mappings and are useful for delineating algorithms on that basis, but if a regret bound does not depend on soft knowledge, it does not have much to say about how future performance should improve as data is collected. The latter sort of insight should be valuable for designing better ways of trading off between exploration and exploitation, since it is soft knowledge that is refined as a decision-maker learns. Another important benefit to understanding how performance depends on soft knowledge arises in practical applications: when designing an online learning algorithm, one may have access to historical data and want to understand how this prior information benefits future performance.

In this paper, we establish regret bounds that depend on both hard and soft knowledge for a simple online learning algorithm alternately known as *Thompson sampling*, *posterior sampling*, or *probability matching*. The bounds strengthen results from prior work not only with respect to Thompson sampling but relative to regret bounds for *any* online optimization algorithm. Further, the bounds offer new insight into how regret depends on soft knowledge. Indeed, forthcoming work of ours leverages this to produce an algorithm that outperforms Thompson sampling.

We found information theory to provide tools ideally suited for deriving our new regret bounds, and our analysis inherits the simplicity and elegance enjoyed by work in that field. Our formulation encompasses a broad family of information structures, including as special cases multi–armed bandit problems with independent arms, online optimization problems with full information, linear bandit problems, and problems with combinatorial action sets and "semi–bandit" feedback. We leverage information theory to provide a unified analysis that applies to each of those special cases.

A novel feature of our bounds is their dependence on the entropy of the optimal-action distribution. To our knowledge, these are the first bounds on the expected regret of *any* algorithm that depend on the magnitude of the agent's uncertainty about which action is optimal. The fact that our bounds only depend on uncertainties relevant to optimizing performance highlights the manner in which Thompson sampling naturally exploits complex information structures. Further, in practical contexts, a decision-maker may begin with an understanding that some actions are more likely to be optimal than others. For example, when dealing with a shortest path problem, one might expect paths that traverse fewer

edges to generally incur less cost. Our bounds are the first to formalize the performance benefits afforded by such an understanding.

1.1 Preview of Results

Our analysis is based on a general probabilistic, or Bayesian, formulation in which uncertain quantities are modeled as random variables. In principle, the optimal strategy for such a problem could be calculated via dynamic programing, but for problem classes of practical interest this would be computationally intractable. *Thompson sampling* serves as a simple and elegant heuristic strategy. In this section, we provide a somewhat informal problem statement, and a preview of our main results about Thompson sampling. In the next subsection we discuss how these results relate to the existing literature.

A decision maker repeatedly chooses among a finite set of possible actions $\mathcal{A}$ and upon taking action $a \in \mathcal{A}$ at time $t \in \mathbb{N}$ she observes a random outcome $Y_{t,a} \in \mathcal{Y}$. She associates a reward with each outcome as specified by a reward function $R : \mathcal{Y} \to \mathbb{R}$. The outcomes $(Y_{t,a})_{t\in\mathbb{N}}$ are drawn independently over time from a fixed probability distribution p_a^* over $\mathcal{Y}$. The decision maker is uncertain about the distribution of outcomes $p^* = (p_a^*)_{a\in\mathcal{A}}$, which is itself distributed according to a prior distribution over a family $\mathcal{P}$ of such distributions. However, she is able to learn about p^* as the outcomes of past decisions are observed, and this allows her to learn over time to attain improved performance.

We first present a special case of our main result that applies to online linear optimization problems under bandit feedback. This result applies when each action is associated with a d–dimensional feature vector and the mean reward of each action is the inner product between an unknown parameter vector and the action's known feature vector. More precisely, suppose $\mathcal{A} \subset \mathbb{R}^d$ and that for every $p \in \mathcal{P}$ there is a vector $\theta_p \in \mathbb{R}^d$ such that

$$\mathop{\mathbb{E}}_{y\sim p_a}[R(y)] = a^T\theta_p \tag{1}$$

for all $a \in \mathcal{A}$. When an action is sampled, a random reward in $[0, 1]$ is received, where the mean reward is given by (1). Then, our analysis establishes that the expected cumulative regret of Thompson sampling up to time T is bounded by

$$\sqrt{\frac{\text{Entropy}(A^*)dT}{2}}, \tag{2}$$

where $A^* \in \arg\max_{a\in\mathcal{A}} \mathbb{E}[R(Y_{t,a})|p^*]$ denotes the optimal action. This bound depends on the time horizon, the entropy of the of the prior distribution of the optimal action A^*, and the dimension d of the linear model.

Because the entropy of A^* is always less than $\log|\mathcal{A}|$, (2) yields a bound of order $\sqrt{\log(|\mathcal{A}|)dT}$, and this scaling cannot be improved in general (see Section 6.5). The bound (2) is stronger than this worst–case bound, since the entropy of A^* can be much smaller than $\log(|\mathcal{A}|)$.

Thompson sampling incorporates prior knowledge in a flexible and coherent way, and the benefits of this are reflected in two distinct ways by the above bound. First, as in past work (see e.g. Dani et al., 2008; Rusmevichientong and Tsitsiklis, 2010), the bound depends on the dimension of the linear model instead of the number of actions. This reflects that the

algorithm is able to learn more rapidly by exploiting the known model, since observations from selecting one action provide information about rewards that would have been generated by other actions. Second, the bound depends on the entropy of the prior distribution of A^* instead of a worst case measure like the logarithm of the number of actions. This highlights the benefit of prior knowledge that some actions are more likely to be optimal than others. In particular, this bound exhibits the natural property that as the entropy of the prior distribution of A^* goes to zero, expected regret does as well.

Our main result extends beyond the class of linear bandit problems. Instead of depending on the linear dimension of the model, it depends on a more general measure of the problem's information complexity: what we call the problem's *information ratio*. By bounding the information ratio in specific settings, we recover the bound (2) as a special case, along with bounds for problems with full feedback and problems with combinatorial action sets and "semi–bandit" feedback.

1.2 Related Work

Though Thompson sampling was first proposed in 1933 (Thompson, 1933), until recently it was largely ignored in the academic literature. Interest in the algorithm grew after empirical studies (Scott, 2010; Chapelle and Li, 2011) demonstrated performance exceeding state of the art. Over the past several years, it has also been adopted in industry.[1] This has prompted a surge of interest in providing theoretical guarantees for Thompson sampling.

One of the first theoretical guarantees for Thompson sampling was provided by May et al. (2012), but they showed only that the algorithm converges asymptotically to optimality. Agrawal and Goyal (2012); Kauffmann et al. (2012); Agrawal and Goyal (2013a) and Korda et al. (2013) studied on the classical multi-armed bandit problem, where sampling one action provides no information about other actions. They provided frequentist regret bounds for Thompson sampling that are asymptotically optimal in the sense defined by Lai and Robbins (1985). To attain these bounds, the authors fixed a specific uninformative prior distribution, and studied the algorithm's performance assuming this prior is used.

Our interest in Thompson sampling is motivated by its ability to incorporate rich forms of prior knowledge about the actions and the relationship among them. Accordingly, we study the algorithm in a very general framework, allowing for an *arbitrary* prior distribution over the true outcome distributions $p^* = (p_a^*)_{a\in\mathcal{A}}$. To accommodate this level of generality while still focusing on finite–time performance, we study the algorithm's *expected regret* under the prior distribution. This measure is sometimes called *Bayes risk* or *Bayesian regret*.

Our recent work (Russo and Van Roy, 2014) provided the first results in this setting. That work leverages a close connection between Thompson sampling and upper confidence bound (UCB) algorithms, as well as existing analyses of several UCB algorithms. This confidence bound analysis was then extended to a more general setting, leading to a general regret bound stated in terms of a new notion of model complexity – what we call the eluder dimension. While the connection with UCB algorithms may be of independent interest,

1. Microsoft (Graepel et al., 2010), Google analytics (Scott, 2014) and Linkedin (Tang et al., 2013) have used Thompson sampling.

it's desirable to have a simple, self–contained, analysis that does not rely on the–often complicated–construction of confidence bounds.

Agrawal and Goyal (2013a) provided the first "distribution independent" bound for Thompson sampling. They showed that when Thompson sampling is executed with an independent uniform prior and rewards are binary the algorithm satisfies a frequentist regret bound[2] of order $\sqrt{|\mathcal{A}|T\log(T)}$. Russo and Van Roy (2014) showed that, for an arbitrary prior over bounded reward distributions, the expected regret of Thompson sampling under this prior is bounded by a term of order $\sqrt{|\mathcal{A}|T\log(T)}$. Bubeck and Liu (2013) showed that this second bound can be improved to one of order $\sqrt{|\mathcal{A}|T}$ using more sophisticated confidence bound analysis, and also studied a problem setting where the regret of Thompson sampling is bounded uniformly over time. In this paper, we are interested mostly in results that replace the explicit $\sqrt{|\mathcal{A}|}$ dependence on the number of actions with a more general measure of the problem's information complexity. For example, as discussed in the last section, for the problem of linear optimization under bandit feedback one can provide bounds that depend on the dimension of the linear model instead of the number of actions.

To our knowledge, Agrawal and Goyal (2013b) are the only other authors to have studied the application of Thompson sampling to linear bandit problems. They showed that, when the algorithm is applied with an uncorrelated Gaussian prior over θ_{p^*}, it satisfies frequentist regret bounds of order $\frac{d^2}{\epsilon}\sqrt{T^{1+\epsilon}}(\log(Td)$. Here ϵ is a parameter used by the algorithm to control how quickly the posterior concentrates. Russo and Van Roy (2014) allowed for an arbitrary prior distribution, and provided a bound on expected regret (under this prior) of order $d\log(T)\sqrt{T}$. Unlike the bound (2), these results hold whenever $\mathcal{A}$ is a compact subset of $\mathbb{R}^d$, but we show in Appendix D.1 that through discretization argument the bound (2) also yields a similar bound whenever $\mathcal{A}$ is compact. In the worst case, that bound is of order $d\sqrt{T\log(T)}$.

Other very recent work (Gopalan et al., 2014) provided a general asymptotic guarantee for Thompson sampling. They studied the growth rate of the cumulative number of times a suboptimal action is chosen as the time horizon T tends to infinity. One of their asymptotic results applies to the problem of online linear optimization under "semi–bandit" feedback, which we study in Section 6.6.

An important aspect of our regret bound is its dependence on soft knowledge through the entropy of the optimal-action distribution. One of the only other regret bounds that depends on soft–knowledge was provided very recently by Li (2013). Inspired by a connection between Thompson sampling and exponential weighting schemes, that paper introduced a family of Thompson sampling like algorithms and studied their application to contextual bandit problems. While our analysis does not currently treat contextual bandit problems, we improve upon their regret bound in several other respects. First, their bound depends on the entropy of the prior distribution of mean rewards, which is never smaller, and can be much larger, than the entropy of the distribution of the optimal action. In addition, their bound has an order $T^{2/3}$ dependence on the problem's time horizon, and, in order to guarantee each action is explored sufficiently often, requires that actions are frequently selected uniformly at random. In contrast, our focus is on settings where the number of actions is large and the goal is to learning without sampling each one.

2. They bound regret conditional on the true reward distribution: $\mathbb{E}\left[\text{Regret}(T,\pi^{\text{TS}})|p^*\right]$.

Another regret bound that to some extent captures dependence on soft knowledge is that of Srinivas et al. (2012). This excellent work focuses on extending algorithms and expanding theory to address multi-armed bandit problems with arbitrary reward functions and possibly an infinite number of actions. In a sense, there is no hard knowledge while soft knowledge is represented in terms of a Gaussian process over a possibly infinite dimensional family of functions. An upper-confidence-bound algorithm is proposed and analyzed. Our earlier work (Russo and Van Roy, 2014) showed similar bounds also apply to Thompson sampling. Though our results here do not treat infinite action spaces, it should be possible to extend the analysis in that direction. One substantive difference is that our results apply to a much broader class of models: distributions are not restricted to Gaussian and more complex information structures are allowed. Further, the results of Srinivas et al. (2012) do not capture the benefits of soft knowledge to the extent that ours do. For example, their regret bounds do not depend on the mean of the reward function distribution, even though mean rewards heavily influence the chances that each action is optimal. Our regret bounds, in contrast, establish that regret vanishes as the probability that a particular action is optimal grows.

Our review has discussed the recent literature on Thompson sampling as well as two papers that have established regret bounds that depend on soft knowledge. There is of course an immense body of work on alternative approaches to efficient exploration, including work on the Gittins index approach (Gittins et al., 2011), Knowledge Gradient strategies (Ryzhov et al., 2012), and upper-confidence bound strategies (Lai and Robbins, 1985; Auer et al., 2002). In an adversarial framework, authors often study exponential-weighting shemes or, more generally, strategies based on online stochastic mirror descent. Bubeck and Cesa-Bianchi (2012) provided a general review of upper–confidence strategies and algorithms for the adversarial multi-armed bandit problem.

2. Problem Formulation

The decision–maker sequentially chooses actions $(A_t)_{t\in\mathbb{N}}$ from the action set $\mathcal{A}$ and observes the corresponding outcomes $(Y_{t,A_t})_{t\in\mathbb{N}}$. To avoid measure-theoretic subtleties, we assume the space of possible outcomes $\mathcal{Y}$ is a subset of a finite dimensional Euclidean space. There is a random outcome $Y_{t,a}\in\mathcal{Y}$ associated with each $a\in\mathcal{A}$ and time $t\in\mathbb{N}$. Let $Y_t\equiv(Y_{t,a})_{a\in\mathcal{A}}$ be the vector of outcomes at time $t\in\mathbb{N}$. The "true outcome distribution" p^* is a distribution over $\mathcal{Y}^{|\mathcal{A}|}$ that is itself randomly drawn from the family of distributions $\mathcal{P}$. We assume that, conditioned on p^*, $(Y_t)_{t\in\mathbb{N}}$ is an iid sequence with each element Y_t distributed according to p^*. Let p^*_a be the marginal distribution corresponding to $Y_{t,a}$.

The agent associates a reward $R(y)$ with each outcome $y\in\mathcal{Y}$, where the reward function $R:\mathcal{Y}\to\mathbb{R}$ is fixed and known. Uncertainty about p^* induces uncertainty about the true optimal action, which we denote by $A^*\in\arg\max_{a\in\mathcal{A}}\mathbb{E}\left[R(Y_{t,a})|p^*\right]$. The T period *regret* of the sequence of actions $A_1,..,A_T$ is the random variable,

$$\text{Regret}(T):=\sum_{t=1}^{T}\left[R(Y_{t,A^*})-R(Y_{t,A_t})\right], \tag{3}$$

which measures the cumulative difference between the reward earned by an algorithm that always chooses the optimal action, and actual accumulated reward up to time T. In this paper we study expected regret

$$\mathbb{E}\left[\text{Regret}(T)\right] = \mathbb{E}\left[\sum_{t=1}^{T}\left[R(Y_{t,A^*}) - R(Y_{t,A_t})\right]\right], \tag{4}$$

where the expectation is taken over the randomness in the actions A_t and the outcomes Y_t, and over the prior distribution over p^*. This measure of performance is commonly called *Bayesian regret* or *Bayes risk*.

Filtrations and randomized policies: We define all random variables with respect to a probability space $(\Omega, \mathcal{F}, \mathbb{P})$. Actions are chosen based on the history of past observations and possibly some external source of randomness. To represent this external source of randomness more formally, we introduce a sequence of random variables $(U_t)_{t\in\mathbb{N}}$, where for each $i \in \mathbb{N}$, U_i is jointly independent of $\{U_t\}_{t\neq i}$, the outcomes $\{Y_{t,a}\}_{t\in\mathbb{N},a\in\mathcal{A}}$, and p^*. We fix the filtration $(\mathcal{F}_t)_{t\in\mathbb{N}}$ where $\mathcal{F}_t \subset \mathcal{F}$ is the sigma–algebra generated by $\left(A_1, Y_{1,A_1}, ..., A_{t-1}, Y_{t-1,A_{t-1}}\right)$. The action A_t is measurable with respect to the sigma–algebra generated by $(\mathcal{F}_t, U_t)$. That is, given the history of past observations, A_t is random only through its dependence on U_t.

The objective is to choose actions in a manner that minimizes expected regret. For this purpose, it's useful to think of the actions as being chosen by a *randomized policy* π, which is an $\mathcal{F}_t$–adapted sequence $(\pi_t)_{t\in\mathbb{N}}$. An action is chosen at time t by randomizing according to $\pi_t(\cdot) = \mathbb{P}(A_t \in \cdot|\mathcal{F}_t)$, which specifies a probability distribution over $\mathcal{A}$. We explicitly display the dependence of regret on the policy π, letting $\mathbb{E}\left[\text{Regret}(T, \pi)\right]$ denote the expected value given by (4) when the actions $(A_1, .., A_T)$ are chosen according to π.

Further Assumptions: To simplify the exposition, our main results will be stated under two further assumptions. The first requires that rewards are uniformly bounded, effectively controlling the worst-case variance of the reward distribution. In particular, this assumption is used only in proving Fact 9. In the technical appendix, we show that Fact 9 can be extended to the case where reward distributions are sub-Gaussian, which yields results in that more general setting.

Assumption 1 $\sup_{\overline{y}\in\mathcal{Y}} R(\overline{y}) - \inf_{\underline{y}\in\mathcal{Y}} R(\underline{y}) \leq 1.$

Our next assumption requires that the action set is finite. In the technical appendix we show that some cases where $\mathcal{A}$ is infinite can be addressed through discretization arguments.

Assumption 2 *$\mathcal{A}$ is finite.*

Because the Thompson sampling algorithm only chooses actions from the support of A^*, all of our results hold when the finite set $\mathcal{A}$ denotes only the actions in the support of A^*. This difference can be meaningful. For example, when $\mathcal{A}$ is a polytope and the objective function is linear, the support of A^* contains only extreme points of the polytope: a finite set.

3. Basic Measures and Relations in Information Theory

Before proceeding, we will define several common information measures – entropy, mutual information, and Kullback-Leibler divergence — and state several facts about these measures that will be referenced in our analysis. When all random variables are discrete, each of these facts is shown in chapter 2 of Cover and Thomas (2012). A treatment that applies to general random variables is provided in chapter 5 of Gray (2011).

Before proceeding, we will define some simple shorthand notation. Let $P(X) = \mathbb{P}(X \in \cdot)$ denote the distribution function of random variable X. Similarly, define $P(X|Y) = \mathbb{P}(X \in \cdot|Y)$ and $P(X|Y = y) = \mathbb{P}(X \in \cdot|Y = y)$.

Throughout this section, we will fix random variables X, Y, and Z that are defined on a joint probability space. We will allow Y and Z to be general random variables, but will restrict X to be supported on a finite set $\mathcal{X}$. This is sufficient for our purposes, as we will typically apply these relations when X is A^*, and is useful, in part, because the entropy of a general random variable can be infinite.

The *Shannon entropy* of X is defined as

$$H(X) = -\sum_{x\in\mathcal{X}} \mathbb{P}(X = x)\log\mathbb{P}(X = x).$$

The first fact establishes uniform bounds on the entropy of a probability distribution.

Fact 1 $0 \leq H(X) \leq \log(|\mathcal{X}|)$.

If Y is a discrete random variable, the entropy of X conditional on $Y = y$ is

$$H(X|Y = y) = \sum_{x\in\mathcal{X}} \mathbb{P}\left(X = x|Y = y\right)\log\mathbb{P}(X = x|Y = y)$$

and the conditional entropy is of X given Y is

$$H(X|Y) = \sum_{y} H(X|Y = y)\mathbb{P}(Y = y).$$

For a general random variable Y, the conditional entropy of X given Y is,

$$H(X|Y) = \mathbb{E}_Y\left[-\sum_{x\in\mathcal{X}} \mathbb{P}\left(X = x|Y\right)\log\mathbb{P}(X = x|Y)\right],$$

where this expectation is taken over the marginal distribution of Y. For two probability measures P and Q, if P is absolutely continuous with respect to Q, the *Kullback–Leibler divergence* between them is

$$D(P||Q) = \int \log\left(\frac{dP}{dQ}\right) dP \tag{5}$$

where $\frac{dP}{dQ}$ is the Radon–Nikodym derivative of P with respect to Q. This is the expected value under P of the log-likelihood ratio between P and Q, and is a measure of how different P and Q are. The next fact establishes the non-negativity of Kullback–Leibler divergence.

Fact 2 *(Gibbs' inequality) For any probability distributions P and Q such that P is absolutely continuous with respect to Q, $D(P||Q) \geq 0$ with equality if and only if $P = Q$ P–almost everywhere.*

The *mutual information* between X and Y

$$I(X;Y) = D\left(P(X,Y) \,||\, P(X)\, P(Y)\right) \tag{6}$$

is the Kullback–Leibler divergence between the joint distribution of X and Y and the product of the marginal distributions. From the definition, it's clear that $I(X;Y) = I(Y;X)$, and Gibbs' inequality implies that $I(X;Y) \geq 0$ and $I(X;Y) = 0$ when X and Y are independent.

The next fact, which is Lemma 5.5.6 of Gray (2011), states that the mutual information between X and Y is the expected reduction in the entropy of the posterior distribution of X due to observing Y.

Fact 3 *(Entropy reduction form of mutual information)*

$$I(X;Y) = H(X) - H(X|Y)$$

The mutual information between X and Y, conditional on a third random variable Z is

$$I(X;Y|Z) = H(X|Z) - H(X|Y,Z),$$

the expected additional reduction in entropy due to observing Y given that Z is also observed. This definition is also a natural generalization of the one given in (6), since

$$I(X;Y|Z) = \mathbb{E}_Z\left[D\left(P\left((X,Y)|Z\right) \,||\, P(X|Z)\, P(Y|Z)\right)\right].$$

The next fact shows that conditioning on a random variable Z that is independent of X and Y does not affect mutual information.

Fact 4 *If Z is jointly independent of X and Y, then $I(X;Y|Z) = I(X;Y)$.*

The mutual information between a random variable X and a collection of random variables $(Z_1, ..., Z_T)$ can be expressed elegantly using the following "chain rule."

Fact 5 *(Chain Rule of Mutual Information)*

$$I(X;(Z_1, ...Z_T)) = I(X;Z_1) + I(X;Z_2|\, Z_1) + ... + I(X;Z_T|\, Z_1, ..., Z_{T-1}).$$

We provide some details related to the derivation of Fact 6 in the appendix.

Fact 6 *(KL divergence form of mutual information)*

$$\begin{aligned} I(X;Y) &= \mathbb{E}_X\left[D\left(P(Y|X) \,||\, P(Y)\right)\right] \\ &= \sum_{x \in \mathcal{X}} \mathbb{P}(X=x) D\left(P(Y|X=x) \,||\, P(Y)\right) \end{aligned}$$

While Facts 1 and 6, are standard properties of mutual information, it's worth highlighting their surprising power. It's useful to think of X as being A^*, the optimal action, and Y as being $Y_{t,a}$, the observation when selecting some action a. Then, combining these properties, we see that the next observation Y is expected to greatly reduce uncertainty about the optimal action A^* if and only if the distribution of Y varies greatly depending on the realization of A^*, in the sense that $D\left(P(Y|A^*=a^*) \,||\, P(Y)\right)$ is large on average. This fact is crucial to our analysis.

One implication of the next fact is that the expected reduction in entropy from observing the outcome $Y_{t,a}$ is always at least as large as that from observing the reward $R(Y_{t,a})$.

Fact 7 *(Weak Version of the Data Processing Inequality) If $Z = f(Y)$ for a deterministic function f, then $I(X;Y) \geq I(X;Z)$. If f is invertible, so Y is also a deterministic function of Z, then $I(X;Y) = I(X;Z)$.*

We close this section by stating a fact that guarantees $D\left(P(Y|X=x) \,||\, P(Y)\right)$ is well defined. It follows from a general property of conditional probability: for any random variable Z and event $E \subset \Omega$, if $\mathbb{P}(E) = 0$ then $\mathbb{P}(E|Z) = 0$ almost surely.

Fact 8 *For any $x \in \mathcal{X}$ with $\mathbb{P}(X=x) > 0$, $P(Y|X=x)$ is absolutely continuous with respect to $P(Y)$.*

3.1 Notation Under Posterior Distributions

As shorthand, we let

$$\mathbb{P}_t(\cdot) = \mathbb{P}(\cdot|\mathcal{F}_t) = \mathbb{P}(\cdot|\, A_1, Y_{1,A_1}, ..., A_{t-1}, Y_{t-1,A_{t-1}})$$

and $\mathbb{E}_t[\cdot] = \mathbb{E}[\cdot|\mathcal{F}_t]$. As before, we will define some simple shorthand notation for the distribution function of a random variable under $\mathbb{P}_t$. Let $P_t(X) = \mathbb{P}_t(X \in \cdot)$, $P_t(X|Y) = \mathbb{P}_t(X \in \cdot|Y)$ and $P_t(X|Y=y) = \mathbb{P}_t(X \in \cdot|Y=y)$.

The definitions of entropy and mutual information implicitly depend on some base measure over the sample space Ω. We will define special notation to denote entropy and mutual information under the posterior measure $\mathbb{P}_t(\cdot)$. Define

$$\begin{aligned} H_t(X) &= -\sum_{x \in \mathcal{X}} \mathbb{P}_t(X=x) \log \mathbb{P}_t(X=x) \\ H_t(X|Y) &= \mathbb{E}_t\left[-\sum_{x \in \mathcal{X}} \mathbb{P}_t(X=x|Y) \log \mathbb{P}_t(X=x|Y)\right] \\ I_t(X;Y) &= H_t(X) - H_t(X|Y). \end{aligned}$$

Because these quantities depend on the realizations of $A_1, Y_{1,A_1}, ..., A_{t-1}, Y_{t-1,A_{t-1}}$, they are random variables. By taking their expectation, we recover the standard definition of conditional entropy and conditional mutual information:

$$\begin{aligned} \mathbb{E}[H_t(X)] &= H(X|A_1, Y_{1,A_1}, ..., A_{t-1}, Y_{t-1,A_{t-1}}) \\ \mathbb{E}[I_t(X;Y)] &= I\left(X;Y|A_1, Y_{1,A_1}, ..., A_{t-1}, Y_{t-1,A_{t-1}}\right). \end{aligned}$$

4. Thompson Sampling

The Thompson sampling algorithm simply samples actions according to the posterior probability they are optimal. In particular, actions are chosen randomly at time t according to the sampling distribution $\pi_t^{\text{TS}} = \mathbb{P}(A^* = \cdot|\mathcal{F}_t)$. By definition, this means that for each $a \in \mathcal{A}$, $\mathbb{P}(A_t = a|\mathcal{F}_t) = \mathbb{P}(A^* = a|\mathcal{F}_t)$. This algorithm is sometimes called *probability matching* because the action selection distribution is *matched* to the posterior distribution of the optimal action.

This conceptually elegant probability matching scheme often admits a surprisingly simple and efficient implementation. Consider the case where $\mathcal{P} = \{p_\theta\}_{\theta\in\Theta}$ is some parametric family of distributions. The true outcome distribution p^* corresponds to a particular random index $\theta^* \in \Theta$ in the sense that $p^* = p_{\theta^*}$ almost surely. Practical implementations of Thompson sampling typically use two simple steps at each time t to randomly generate an action from the distribution α_t. First, an index $\hat{\theta}_t \sim \mathbb{P}(\theta^* \in \cdot|\mathcal{F}_t)$ is sampled from the posterior distribution of the true index θ^*. Then, the algorithm selects the action $A_t \in \arg\max_{a\in\mathcal{A}} \mathbb{E}\left[R(Y_{t,a})|\theta^* = \hat{\theta}_t\right]$ that would be optimal if the sampled parameter were actually the true parameter. We next provide an example of a Thompson sampling algorithm designed to address the problem of online linear optimization under bandit feedback.

4.1 Example of Thompson Sampling

Suppose each action $a \in \mathcal{A} \subset \mathbb{R}^d$ is defined by a d-dimensional feature vector, and almost surely there exists $\theta^* \in \mathbb{R}^d$ such that for each $a \in \mathcal{A}$, $\mathbb{E}\left[R(Y_{t,a})|p^*\right] = a^T\theta^*$. Assume θ^* is drawn from a normal distribution $N(\mu_0, \Sigma_0)$. When a is selected, only the realized reward $Y_{t,a} = R(Y_{t,a}) \in \mathbb{R}$ is observed. For each action a, reward noise $R(Y_{t,a}) - \mathbb{E}\left[R(Y_{t,a})|p^*\right]$ follows a Gaussian distribution with known variance. One can show that, conditioned on the history of observed data $\mathcal{F}_t$, θ^* remains normally distributed. Algorithm 1 provides an implementation of Thompson sampling for this problem. The expectations in step 3 can be computed efficiently via Kalman filtering.

Algorithm 1 Linear–Gaussian Thompson Sampling

1: **Sample Model**:
   $\hat{\theta}_t \sim N(\mu_{t-1}, \Sigma_{t-1})$
2: **Select Action**:
   $A_t \in \arg\max_{a\in\mathcal{A}}\langle a, \hat{\theta}_t\rangle$
3: **Update Statistics**:
   $\mu_t \leftarrow \mathbb{E}[\theta^*|\mathcal{F}_t]$
   $\Sigma_t \leftarrow \mathbb{E}[(\theta^* - \mu_t)(\theta^* - \mu_t)^\top|\mathcal{F}_t]$
4: **Increment t and Goto Step 1**

Algorithm 1 is efficient as long as the linear objective $\langle a, \hat{\theta}_t\rangle$ can be maximized efficiently over the action set $\mathcal{A}$. For this reason, the algorithm is implementable in important cases where other popular approaches, like the ConfidenceBall$_2$ algorithm of Dani et al. (2008),

are computationally intractable. Because the posterior distribution of θ^* has a closed form, Algorithm 1 is particularly efficient. Even when the posterior distribution is complex, however, one can often generate samples from this distribution using Markov chain Monte Carlo algorithms, enabling efficient implementations of Thompson sampling. A more detailed discussion of the strengths and potential advantages of Thompson sampling can be found in earlier work (Scott, 2010; Chapelle and Li, 2011; Russo and Van Roy, 2014; Gopalan et al., 2014).

5. The Information Ratio and a General Regret Bound

Our analysis will relate the expected regret of Thompson sampling to its expected information gain: the expected reduction in the entropy of the posterior distribution of A^*. The relationship between these quantities is characterized by what we call the *information ratio*,

$$\Gamma_t := \frac{\mathbb{E}_t\left[R(Y_{t,A^*}) - R(Y_{t,A_t})\right]^2}{I_t\left(A^*; (A_t, Y_{t,A_t})\right)}$$

which is the ratio between the square of expected regret and information gain in period t. Recall that, as described in Subsection 3.1, the subscript t on $\mathbb{E}_t$ and I_t indicates that these quantities are evaluated under the posterior measure $\mathbb{P}_t(\cdot) = \mathbb{P}(\cdot|\mathcal{F}_t)$.

Notice that if the information ratio is small, Thompson sampling can only incur large regret when it is expected to gain a lot of information about which action is optimal. This suggests its expected regret is bounded in terms of the maximum amount of information any algorithm could expect to acquire, which is at most the entropy of the prior distribution of the optimal action. Our next result shows this formally. We provide a general upper bound on the expected regret of Thompson sampling that depends on the time horizon T, the entropy of the prior distribution of A^*, $H(A^*)$, and any worst–case upper bound on the information ratio Γ_t. In the next section, we will provide bounds on Γ_t for some of the most widely studied classes of online optimization problems.

Proposition 1 *For any $T \in \mathbb{N}$, if $\Gamma_t \leq \overline{\Gamma}$ almost surely for each $t \in \{1, .., T\}$,*

$$\mathbb{E}\left[\text{Regret}(T, \pi^{\text{TS}})\right] \leq \sqrt{\overline{\Gamma} H(A^*) T}.$$

Proof Recall that $\mathbb{E}_t[\cdot] = \mathbb{E}[\cdot|\mathcal{F}_t]$ and we use I_t to denote mutual information evaluated under the base measure $\mathbb{P}_t(\cdot) = \mathbb{P}(\cdot|\mathcal{F}_t)$. Then,

$$\begin{aligned}
\mathbb{E}\left[\text{Regret}(T, \pi^{\text{TS}})\right] \overset{(a)}{=} \mathbb{E}\sum_{t=1}^{T}\mathbb{E}_t\left[R(Y_{t,A^*}) - R(Y_{t,A_t})\right] &= \mathbb{E}\sum_{t=1}^{T}\sqrt{\Gamma_t I_t\left(A^*; (A_t, Y_{t,A_t})\right)} \\
&\leq \sqrt{\overline{\Gamma}}\left(\mathbb{E}\sum_{t=1}^{T}\sqrt{I_t\left(A^*; (A_t, Y_{t,A_t})\right)}\right) \\
&\overset{(b)}{\leq} \sqrt{\overline{\Gamma} T \mathbb{E}\sum_{t=1}^{T} I_t\left(A^*; (A_t, Y_{t,A_t})\right)},
\end{aligned}$$

where (a) follows from the tower property of conditional expectation, and (b) follows from the Cauchy-Schwartz inequality. We complete the proof by showing that expected information gain cannot exceed the entropy of the prior distribution. For the remainder of this proof, let $Z_t = (A_t, Y_{t,A_t})$. Then, as discussed in Subsection 3.1,

$$\mathbb{E}\left[I_t\left(A^*; Z_t\right)\right] = I\left(A^*; Z_t | Z_1, ..., Z_{t-1}\right),$$

and therefore

$$\begin{aligned}\mathbb{E}\sum_{t=1}^{T} I_t\left(A^*; Z_t\right) = \sum_{t=1}^{T} I\left(A^*; Z_t | Z_1, ..., Z_{t-1}\right) &\overset{(c)}{=} I\left(A^*;\, (Z_1, ...Z_T)\right) \\ &= H(A^*) - H(A^* | Z_1, ...Z_T) \\ &\overset{(d)}{\leq} H(A^*),\end{aligned}$$

where (c) follows from the chain rule for mutual information (Fact 5), and (d) follows from the non-negativity of entropy (Fact 1). ■

6. Bounding the Information Ratio

This section establishes upper bounds on the information ratio in several important settings. This yields explicit regret bounds when combined with Proposition 1, and also helps to clarify the role the information ratio plays in our results: it roughly captures the extent to which sampling some actions allows the decision maker to make inferences about *different* actions. In the worst case, the information ratio depends on the number of actions, reflecting the fact that actions could provide no information about others. For problems with full information, the information ratio is bounded by a numerical constant, reflecting that sampling one action perfectly reveals the rewards that would have been earned by selecting any other action. The problems of online linear optimization under "bandit feedback" and under "semi–bandit feedback" lie between these two extremes, and the information ratio provides a natural measure of each problem's information structure. In each case, our bounds reflect that Thompson sampling is able to automatically exploit this structure.

We will compare our upper bounds on expected regret with known lower bounds. Some of these lower bounds were developed and stated in an adversarial framework, but were proved using the *probabilistic method*; authors fixed a family of distributions $\mathcal{P}$ and an initial distribution over p^* and lower bounded the expected regret under this environment of any algorithm. This provides lower bounds on $\inf_\pi \mathbb{E}\left[\text{Regret}(T, \pi)\right]$ in our framework at least for particular problem instances. Unfortunately, we are not aware of any general prior-dependent lower bounds, and this remains an important direction for the field.

Our bounds on the information ratio Γ_t will hold at any time t and under any posterior measure $\mathbb{P}_t$. To simplify notation, in our proofs we will omit the subscript t from $\mathbb{E}_t, \mathbb{P}_t, P_t, A_t, Y_t, H_t$, and I_t.

6.1 An Alternative Representation of the Information Ratio

Recall that the information ratio is defined to be

$$\frac{\mathbb{E}\left[R(Y_{A^*}) - R(Y_A)\right]^2}{I\left(A^*; (A, Y_A)\right)}.$$

The following proposition expresses the information ratio of Thompson sampling in a form that facilitates further analysis. The proof uses that Thompson sampling matches the action selection distribution to the posterior distribution of the optimal action, in the sense that $\mathbb{P}\left(A^* = a\right) = \mathbb{P}\left(A = a\right)$ for all $a \in \mathcal{A}$.

Proposition 2

$$\begin{aligned}I\left(A^*; (A, Y_A)\right) &= \sum_{a \in \mathcal{A}} \mathbb{P}(A = a) I(A^*; Y_a) \\ &= \sum_{a, a^* \in \mathcal{A}} \mathbb{P}(A^* = a)\mathbb{P}(A^* = a^*)\left[D\left(P(Y_a | A^* = a^*) \,||\, P(Y_a)\right)\right].\end{aligned}$$

and

$$\mathbb{E}\left[R(Y_{A^*}) - R(Y_A)\right] = \sum_{a \in \mathcal{A}} \mathbb{P}(A^* = a)\left(\mathbb{E}\left[R(Y_a) | A^* = a\right] - \mathbb{E}[R(Y_a)]\right.$$

The numerator of the information ratio measures the average difference between rewards generated from $P(Y_a)$, the posterior predictive distribution at a, and $P(Y_a | A^* = a)$, the posterior predictive distribution at a conditioned on a being the optimal action. It roughly captures how much knowing that the *selected action is optimal* influences the expected reward observed. The denominator measures how much, on average, knowing *which action is optimal* changes the observations at the selected action. Intuitively, the information ratio tends to be small when knowing which action is optimal significantly influences the anticipated observations at many other actions.

It's worth pointing out that this form of the information ratio bears a superficial resemblance to fundamental complexity terms in the multi-armed bandit literature. The results of Lai and Robbins (1985) and Agrawal et al. (1989) show the optimal asymptotic growth rate of regret is characterized by a ratio where the numerator depends on the difference between means of the reward distributions and the denominator depends on Kullback–Leibler divergences.

Proof Both proofs will use that the action A is selected based on past observations and independent random noise. Therefore, conditioned on the history, A is jointly independent

of A^* and the outcome vector $Y \equiv (Y_a)_{a\in\mathcal{A}}$.

$$\begin{aligned}
I(A^*;(A,Y_A)) &\overset{(a)}{=} I(A^*;A) + I(A^*;Y_A|A) \\
&\overset{(b)}{=} I(A^*;Y_A|A) \\
&= \sum_{a\in\mathcal{A}} \mathbb{P}(A=a) I(A^*;Y_A|A=a) \\
&\overset{(c)}{=} \sum_{a\in\mathcal{A}} \mathbb{P}(A=a) I(A^*;Y_a) \\
&\overset{(d)}{=} \sum_{a\in\mathcal{A}} \mathbb{P}(A=a) \left(\sum_{a^*\in\mathcal{A}} \mathbb{P}(A^*=a^*) D\left(P(Y_a|A^*=a^*) \,||\, P(Y_a)\right)\right) \\
&= \sum_{a,a^*\in\mathcal{A}} \mathbb{P}(A^*=a)\mathbb{P}(A^*=a^*) \left[D\left(P(Y_a|A^*=a^*) \,||\, P(Y_a)\right)\right],
\end{aligned}$$

where (a) follows from the chain rule for mutual information (Fact 5), (b) uses that A and A^* are independent and the mutual information between independent random variables is zero (Fact 4), (c) uses Fact 4 and that A is jointly independent of Y and A^*, and equality (d) uses Fact 6. Now, the numerator can be rewritten as,

$$\begin{aligned}
\mathbb{E}\left[R(Y_{A^*}) - R(Y_A)\right] &= \sum_{a\in\mathcal{A}} \mathbb{P}(A^*=a)\mathbb{E}\left[R(Y_a)|A^*=a\right] - \sum_{a\in\mathcal{A}} \mathbb{P}(A=a)\mathbb{E}[R(Y_a)|A=a] \\
&= \sum_{a\in\mathcal{A}} \mathbb{P}(A^*=a)\left(\mathbb{E}\left[R(Y_a)|A^*=a\right] - \mathbb{E}[R(Y_a)]\right),
\end{aligned}$$

where the second equality uses that $\mathbb{P}(A=a) = \mathbb{P}(A^*=a)$ by the definition of Thompson sampling, and that Y is independent of the chosen action A. ■

6.2 Preliminaries

Here we state two basic facts that are used in bounding the information ratio. Proofs of both results are provided in the appendix for completeness.

The first fact lower bounds the Kullback–Leibler divergence between two bounded random variables in terms of the difference between their means. It follows trivially from an application of Pinsker's inequality.

Fact 9 *For any distributions P and Q such that that P is absolutely continuous with respect to Q, any random variable $X : \Omega \to \mathcal{X}$ and any $g : \mathcal{X} \to \mathbb{R}$ such that* $\sup g - \inf g \leq 1$*,*

$$\mathbb{E}_P\left[g(X)\right] - \mathbb{E}_Q\left[g(X)\right] \leq \sqrt{\frac{1}{2} D\left(P||Q\right)},$$

where $\mathbb{E}_P$ and $\mathbb{E}_Q$ denote the expectation operators under P and Q.

Because of Assumption 1, this fact shows

$$\mathbb{E}\left[R(Y_a)|A^*=a^*\right] - \mathbb{E}\left[R(Y_a)\right] \leq \sqrt{\frac{1}{2} D\left(P(Y_a|A^*=a^*) \,||\, P(Y_a)\right)}.$$

By the Cauchy–Schwartz inequality, for any vector $x \in \mathbb{R}^n$, $\sum_i x_i \leq \sqrt{n}\|x\|_2$. The next fact provides an analogous result for matrices. For any rank r matrix $M \in \mathbb{R}^{n\times n}$ with singular values $\sigma_1, ..., \sigma_r$, let

$$\|M\|_* := \sum_{i=1}^{r} \sigma_i, \qquad \|M\|_F := \sqrt{\sum_{k=1}^{m}\sum_{j=1}^{n} M_{i,j}^2} = \sqrt{\sum_{i=1}^{r}\sigma_i^2}, \qquad \text{Trace}(M) := \sum_{i=1}^{n} M_{ii},$$

denote respectively the Nuclear norm, Frobenius norm and trace of M.

Fact 10 *For any matrix $M \in \mathbb{R}^{k\times k}$,*

$$\text{Trace}\left(M\right) \leq \sqrt{\text{Rank}(M)}\|M\|_{\text{F}}.$$

6.3 Worst Case Bound

The next proposition provides a bound on the information ratio that holds whenever rewards are bounded, but that has an explicit dependence on the number of actions. This scaling cannot be improved in general, but we go on to show tighter bounds are possible for problems with different *information structures*.

Proposition 3 *For any $t \in \mathbb{N}$, $\Gamma_t \leq |\mathcal{A}|/2$ almost surely.*

Proof We bound the numerator of the information ratio by $|\mathcal{A}|/2$ times its denominator:

$$\begin{aligned}
\mathbb{E}\left[R(Y_{A^*}) - R(Y_A)\right]^2 &\overset{(a)}{=} \left(\sum_{a\in\mathcal{A}} \mathbb{P}(A^*=a)\left(\mathbb{E}\left[R(Y_a)|A^*=a\right] - \mathbb{E}[R(Y_a)]\right)\right)^2 \\
&\overset{(b)}{\leq} |\mathcal{A}| \sum_{a\in\mathcal{A}} \mathbb{P}(A^*=a)^2 \left(\mathbb{E}\left[R(Y_a)|A^*=a\right] - \mathbb{E}[R(Y_a)]\right)^2 \\
&\leq |\mathcal{A}| \sum_{a,a^*\in\mathcal{A}} \mathbb{P}(A^*=a)\mathbb{P}(A^*=a^*) \left(\mathbb{E}\left[R(Y_a)|A^*=a^*\right] - \mathbb{E}[R(Y_a)]\right)^2 \\
&\overset{(c)}{\leq} \frac{|\mathcal{A}|}{2} \sum_{a,a^*\in\mathcal{A}} \mathbb{P}(A^*=a)\mathbb{P}(A^*=a^*) D\left(P(Y_a|A^*=a^*) \,||\, P(Y_a)\right) \\
&\overset{(d)}{=} \frac{|\mathcal{A}| I(A^*;(A,Y))}{2}
\end{aligned}$$

where (b) follows from the Cauchy–Schwarz inequality, (c) follows from Fact 9, and (a) and (d) follow from Proposition 2. ■

Combining Proposition 3 with Proposition 1 shows that $\mathbb{E}\left[\text{Regret}(T,\pi^{\text{TS}})\right] \leq \sqrt{\frac{1}{2}|\mathcal{A}|H(A^*)T}$. Bubeck and Liu (2013) show $\mathbb{E}\left[\text{Regret}(T,\pi^{\text{TS}})\right] \leq 14\sqrt{|\mathcal{A}|T}$ and that this bound is order optimal, in the sense that for any time horizon T and number of actions $|\mathcal{A}|$ there exists a prior distribution over p^* such that $\inf_\pi \mathbb{E}\left[\text{Regret}(T,\pi)\right] \geq \frac{1}{20}\sqrt{|\mathcal{A}|T}$.

6.4 Full Information

Our focus in this paper is on problems with *partial feedback*. For such problems, what the decision maker observes depends on the actions selected, which leads to a tension between exploration and exploitation. Problems with full information arise as an extreme point of our formulation where the outcome $Y_{t,a}$ is perfectly revealed by observing $Y_{t,\tilde{a}}$ for any $\tilde{a} \neq a$; what is learned does not depend on the selected action. The next proposition shows that under full information, the information ratio is bounded by 1/2.

Proposition 4 *Suppose for each $t \in \mathbb{N}$ there is a random variable $Z_t : \Omega \to \mathcal{Z}$ such that for each $a \in \mathcal{A}$, $Y_{t,a} = (a, Z_t)$. Then for all $t \in \mathbb{N}$, $\Gamma_t \leq 1/2$ almost surely.*

Proof As before we bound the numerator of Γ_t by $\sqrt{1/2}$ times the denominator:

$$\begin{aligned}
\mathbb{E}\left[R(Y_{A^*}) - R(Y_A)\right] &\overset{(a)}{=} \sum_{a\in\mathcal{A}} \mathbb{P}(A^* = a)\left(\mathbb{E}\left[R(Y_a)|A^* = a\right] - \mathbb{E}[R(Y_a)]\right) \\
&\overset{(b)}{\leq} \sum_{a\in\mathcal{A}} \mathbb{P}(A^* = a)\sqrt{\frac{1}{2} D\left(P(Y_a|A^* = a) \,||\, P(Y_a)\right)} \\
&\overset{(c)}{\leq} \sqrt{\frac{1}{2}\sum_{a\in\mathcal{A}} \mathbb{P}(A^* = a) D\left(P(Y_a|A^* = a) \,||\, P(Y_a)\right)} \\
&\overset{(d)}{=} \sqrt{\frac{1}{2}\sum_{a,a^*\in\mathcal{A}} \mathbb{P}(A^* = a)\mathbb{P}(A^* = a^*) D\left(P(Y_a|A^* = a^*) \,||\, P(Y_a)\right)} \\
&\overset{(e)}{=} \sqrt{\frac{I(A^*;(A,Y))}{2}},
\end{aligned}$$

where again (a) and (e) follow from Proposition 2, (b) follows from Fact 9 and (c) follows from Jensen's inequality. Equality (d) follows because $D\left(P(Y_a|A^* = a^*) \,||\, P(Y_a)\right) = D\left(P(Z|A^* = a^*) \,||\, P(Z)\right)$ does not depend on the sampled action a under full information. ■

Combining this result with Proposition 1 shows $\mathbb{E}\left[\text{Regret}(T, \pi^{\text{TS}})\right] \leq \sqrt{\frac{1}{2}H(A^*)T}$. Further, a worst–case bound on the entropy of A^* shows that $\mathbb{E}\left[\text{Regret}(T, \pi^{\text{TS}})\right] \leq \sqrt{\frac{1}{2}\log(|\mathcal{A}|)T}$. The bound here improves upon this worst case bound since $H(A^*)$ can be much smaller than $\log(|\mathcal{A}|)$ when the prior distribution is informative.

6.5 Linear Optimization Under Bandit Feedback

The stochastic linear bandit problem has been widely studied (e.g Dani et al., 2008; Rusmevichientong and Tsitsiklis, 2010; Abbasi-Yadkori et al., 2011) and is one of the most important examples of a multi-armed bandit problem with "correlated arms." In this setting, each action is associated with a finite dimensional feature vector, and the mean reward generated by an action is the inner product between its known feature vector and some unknown parameter vector. Because of this structure, observations from taking one action allow the decision–maker to make inferences about other actions. The next proposition

bounds the information ratio for such problems. Its proof is essentially a generalization of the proof of Proposition 3.

Proposition 5 *If $\mathcal{A} \subset \mathbb{R}^d$ and for each $p \in \mathcal{P}$ there exists $\theta_p \in \mathbb{R}^d$ such that for all $a \in \mathcal{A}$*

$$\mathop{\mathbb{E}}_{y\sim p_a}[R(y)] = a^T\theta_p,$$

then for all $t \in \mathbb{N}$, $\Gamma_t \leq d/2$ almost surely.

Proof Write $\mathcal{A} = \{a_1, ..., a_K\}$ and, to reduce notation, for the remainder of this proof let $\alpha_i = \mathbb{P}(A^* = a_i)$. Define $M \in \mathbb{R}^{K\times K}$ by

$$M_{i,j} = \sqrt{\alpha_i\alpha_j}\left(\mathbb{E}[R(Y_{a_i})|A^* = a_j] - \mathbb{E}[R(Y_{a_i})]\right),$$

for all $i, j \in \{1, .., K\}$. Then, by Proposition 2,

$$\mathbb{E}\left[R(Y_{A^*}) - R(Y_A)\right] = \sum_{i=1}^{K} \alpha_i\left(\mathbb{E}[R(Y_{a_i})|A^* = a_i] - \mathbb{E}[R(Y_{a_i})]\right) = \text{Trace(M)}.$$

Similarly, by Proposition 2,

$$\begin{aligned}
I(A^*;(A,Y_A)) &= \sum_{i,j} \alpha_i\alpha_j D\left(P(Y_{a_i}|A^* = a_j) \,||\, P(Y_{a_i})\right) \\
&\overset{(a)}{\geq} 2\sum_{i,j} \alpha_i\alpha_j\left(\mathbb{E}[R(Y_{a_i})|A^* = a_j] - \mathbb{E}[R(Y_{a_i})]\right)^2 \\
&= 2\|M\|_{\text{F}}^2,
\end{aligned}$$

where inequality (a) uses Fact 9. This shows, by Fact 10, that

$$\frac{\mathbb{E}\left[R(Y_{A^*}) - R(Y_A)\right]^2}{I(A^*;(A,Y_A))} \leq \frac{\text{Trace(M)}^2}{2\|M\|_{\text{F}}^2} \leq \frac{\text{Rank}(M)}{2}.$$

We now show $\text{Rank}(M) \leq d$. Define

$$\mu = \mathbb{E}\left[\theta_{p^*}\right] \qquad \mu^j = \mathbb{E}\left[\theta_{p^*}|A^* = a_j\right].$$

Then, by the linearity of the expectation operator,

$$M_{i,j} = \sqrt{\alpha_i\alpha_j}((\mu^j - \mu)^T a_i)$$

and therefore

$$M = \begin{bmatrix} \sqrt{\alpha_1}\left(\mu^1 - \mu\right)^T \\ \vdots \\ \vdots \\ \sqrt{\alpha_K}\left(\mu^k - \mu\right)^T \end{bmatrix} \begin{bmatrix} \sqrt{\alpha_1}a_1 & \cdots & \cdots & \sqrt{\alpha_K}a_K \end{bmatrix}.$$

This shows M is the product of a K by d matrix and a d by K matrix, and hence has rank at most d. ■

This result shows that $\mathbb{E}\left[\text{Regret}(T, \pi^{\text{TS}})\right] \leq \sqrt{\frac{1}{2} H(A^*) dT} \leq \sqrt{\frac{1}{2} \log(|\mathcal{A}|) dT}$ for linear bandit problems. Dani et al. (2007) show this bound is order optimal, in the sense that for any time horizon T and dimension d if the actions set is $\mathcal{A} = \{0,1\}^d$, there exists a prior distribution over p^* such that $\inf_\pi \mathbb{E}\left[\text{Regret}(T, \pi)\right] \geq c_0 \sqrt{\log(|\mathcal{A}|) dT}$ where c_0 is a constant the is independent of d and T. The bound here improves upon this worst case bound since $H(A^*)$ can be much smaller than $\log(|\mathcal{A}|)$ when the prior distribution is informative.

6.6 Combinatorial Action Sets and "Semi–Bandit" Feedback

To motivate the information structure studied here, consider a simple resource allocation problem. There are d possible projects, but the decision–maker can allocate resources to at most $m \leq d$ of them at a time. At time t, project $i \in \{1, .., d\}$ yields a random reward $\theta_{t,i}$, and the reward from selecting a subset of projects $a \in \mathcal{A} \subset \{a' \subset \{0, 1, ..., d\} : |a'| \leq m\}$ is $m^{-1} \sum_{i \in \mathcal{A}} \theta_{t,i}$. In the linear bandit formulation of this problem, upon choosing a subset of projects a the agent would only observe the overall reward $m^{-1} \sum_{i \in a} \theta_{t,i}$. It may be natural instead to assume that the outcome of each selected project $(\theta_{t,i} : i \in a)$ is observed. This type of observation structure is sometimes called "semi–bandit" feedback (Audibert et al., 2013).

A naive application of Proposition 5 to address this problem would show $\Gamma_t \leq d/2$. The next proposition shows that since the entire parameter vector $(\theta_{t,i} : i \in a)$ is observed upon selecting action a, we can provide an improved bound on the information ratio. The proof of the proposition is provided in the appendix.

Proposition 6 *Suppose $\mathcal{A} \subset \{a \subset \{0, 1, ..., d\} : |a| \leq m\}$, and that there are random variables $(\theta_{t,i} : t \in \mathbb{N}, i \in \{1, ..., d\})$ such that*

$$Y_{t,a} = (\theta_{t,i} : i \in a) \quad \textit{and} \quad R\left(Y_{t,a}\right) = \frac{1}{m} \sum_{i \in a} \theta_{t,i}.$$

Assume that the random variables $\{\theta_{t,i} : i \in \{1, ..., d\}\}$ are independent conditioned on $\mathcal{F}_t$ and $\theta_{t,i} \in [\frac{-1}{2}, \frac{1}{2}]$ almost surely for each (t, i). Then for all $t \in \mathbb{N}$, $\Gamma_t \leq \frac{d}{2m^2}$ almost surely.

In this problem, there are as many as $\binom{d}{m}$ actions, but because Thompson sampling exploits the structure relating actions to one another, its regret is only polynomial in m and d. In particular, combining Proposition 6 with Proposition 1 shows $\mathbb{E}\left[\text{Regret}(T, \pi^{\text{TS}})\right] \leq \frac{1}{m} \sqrt{dH(A^*)T}$. Since $H(A^*) \leq \log |\mathcal{A}| = O(m \log(\frac{d}{m}))$ this also yields a bound of order $\sqrt{\frac{d}{m} \log\left(\frac{d}{m}\right) T}$. As shown by Audibert et al. (2013), the lower bound for this problem is of order $\sqrt{\frac{d}{m} T}$, so our bound is order optimal up to a $\sqrt{\log(\frac{d}{m})}$ factor.[3] It's also worth

3. In their formulation, the reward from selecting action a is $\sum_{i \in a} \theta_{t,i}$, which is m times larger than in our formulation. The lower bound stated in their paper is therefore of order $\sqrt{mdT}$. They don't provide a complete proof of their result, but note that it follows from standard lower bounds in the bandit literature. In the proof of Theorem 5 in that paper, they construct an example in which the decision

pointing that, although there may be as many as $\binom{d}{m}$ actions, the action selection step of Thompson sampling is computationally efficient whenever the offline decision problem $\max_{a \in \mathcal{A}} \theta^T a$ can be solved efficiently.

7. Conclusion

This paper has provided a new analysis of Thompson sampling based on tools from information theory. As such, our analysis inherits the simplicity and elegance enjoyed by work in that field. Further, our results apply to a much broader range of information structures than those studied in prior work on Thompson sampling. Our analysis leads to regret bounds that highlight the benefits of soft knowledge, quantified in terms of the entropy of the optimal-action distribution. Such regret bounds yield insight into how future performance depends on past observations. This is key to assessing the benefits of exploration, and as such, to the design of more effective schemes that trade off between exploration and exploitation. In forthcoming work, we leverage this insight to produce an algorithm that outperforms Thompson sampling.

While our focus has been on providing theoretical guarantees for Thompson sampling, we believe the techniques and quantities used in the analysis may be of broader interest. Our formulation and notation may be complex, but the proofs themselves essentially follow from combining known relations in information theory with the tower property of conditional expectation, Jensen's inequality, and the Cauchy–Schwartz inequality. In addition, the information theoretic view taken in this paper may provide a fresh perspective on this class of problems.

Appendix A. Proof of Basic Facts

A.1 Proof of Fact 9

This result is a consequence of *Pinsker's inequality*, (see Lemma 5.2.8 of Gray (2011)) which states that

$$\sqrt{\frac{1}{2} D(P||Q)} \geq \|P - Q\|_{\text{TV}} \tag{7}$$

maker plays m bandit games in parallel, each with d/m actions. Using that example, and the standard bandit lower bound (see Theorem 3.5 of Bubeck and Cesa-Bianchi (2012)), the agent's regret from each component must be at least $\sqrt{\frac{d}{m} T}$, and hence her overall expected regret is lower bounded by a term of order $m\sqrt{\frac{d}{m} T} = \sqrt{mdT}$.

where $\|P-Q\|_{\text{TV}}$ is the total variation distance between P and Q. When Ω is countable, $\|P-Q\|_{\text{TV}} = \frac{1}{2}\sum_{\omega}|P(\omega)-Q(\omega)|$. More generally, if P and Q are both absolutely continuous with respect to some base measure μ, then $\|P-Q\|_{\text{TV}} = \frac{1}{2}\int_{\Omega}|\frac{dP}{d\mu} - \frac{dQ}{d\mu}|d\mu$, where $\frac{dP}{d\mu}$ and $\frac{dQ}{d\mu}$ are the Radon–Nikodym derivatives of P and Q with respect to μ. We now prove Fact 9.

Proof Choose a base measure μ so that P and Q are absolutely continuous with respect to μ. This is always possible: since P is absolutely continuous with respect to Q by hypothesis, one could always choose this base measure to be Q. Let $f(\omega) = g(X(\omega)) - \inf_{\omega'} g(X(\omega')) - 1/2$ so that $f : \Omega \to [-1/2, 1/2]$ and f and $g(X)$ differ only by a constant. Then,

$$\begin{aligned}
\sqrt{\frac{1}{2}D(P||Q)} \geq \frac{1}{2}\int\left|\frac{dP}{d\mu} - \frac{dQ}{d\mu}\right|d\mu &\geq \frac{1}{2}\int\left|2\left(\frac{dP}{d\mu} - \frac{dQ}{d\mu}\right)f\right|d\mu \\
&\geq \int\left(\frac{dP}{d\mu} - \frac{dQ}{d\mu}\right)f d\mu \\
&= \int f dP - \int f dQ \\
&= \mathbb{E}_P[g(X)] - \mathbb{E}_Q[g(X)],
\end{aligned}$$

where the first inequality is Pinsker's inequality. ■

A.2 Proof of Fact 10

Proof Fix a rank r matrix $M \in \mathbb{R}^{k\times k}$ with singular values $\sigma_1 \geq ... \geq \sigma_r$. By the Cauchy Shwartz inequality,

$$\|M\|_* \overset{\text{Def}}{=} \sum_{i=1}^{r}\sigma_i \leq \sqrt{r}\sqrt{\sum_{i=1}^{r}\sigma_i^2} \overset{\text{Def}}{=} \sqrt{r}\|M\|_F. \tag{8}$$

Now, we show

$$\begin{aligned}
\text{Trace}(M) = \text{Trace}\left(\frac{1}{2}M + \frac{1}{2}M^T\right) \overset{(a)}{\leq} \left\|\frac{1}{2}M + \frac{1}{2}M^T\right\|_* &\overset{(b)}{\leq} \frac{1}{2}\|M\|_* + \frac{1}{2}\left\|M^T\right\|_* \\
&\overset{(c)}{=} \|M\|_* \overset{(d)}{\leq} \sqrt{r}\|M\|_F.
\end{aligned}$$

Here (b) follows from the triangle inequality and the fact that norms are homogeneous of degree one. Inequality (c) uses that the singular values of M and M^T are the same, and inequality (d) follows from equation (8).

To justify inequality (a), we show that for any symmetric matrix W, $\text{Trace}(W) \leq \|W\|_*$. To see this, let W be a rank r matrix and let $\tilde{\sigma}_1 \geq ... \geq \tilde{\sigma}_r$ denote its singular values. Since W is symmetric, it has r nonzero real valued eigenvalues $\lambda_1, .., \lambda_r$. If these are sorted so that $|\lambda_1| \geq ... \geq |\lambda_r|$ then $\tilde{\sigma}_i = |\lambda_i|$ for each $i \in \{1, .., r\}$.[4] This shows $\text{Trace}(M) = \sum_{i=1}^{r}\lambda_i \leq \sum_{i=1}^{r}\tilde{\sigma}_i = \|M\|_*$. ■

4. This fact is stated, for example, in Appendix A.5 of Boyd and Vandenberghe (2004).

Appendix B. Proof of Proposition 6

The proof relies on the following lemma, which lower bounds the information gain due to selecting an action a. The proof is provided below, and relies on the chain–rule of Kullback–Leibler divergence.

Lemma 1 *Under the conditions of Proposition 6, for any $a \in \mathcal{A}$,*

$$I(A^*; Y_a) \geq 2\sum_{i\in a}\mathbb{P}(i \in A^*)\left(\mathbb{E}\left[\theta_i | i \in A^*\right] - \mathbb{E}\left[\theta_i\right]\right)^2$$

Proof In the proof of this lemma, for any $i \in a$ we let $\theta_{<i} = (\theta_j : j < i, j \in a)$. Since $a \in \mathcal{A}$ is fixed throughout this proof, we do not display the dependence of $\theta_{<i}$ on a. Recall that by Fact 6,

$$I(A^*; Y_a) = \sum_{a^*\in\mathcal{A}}\mathbb{P}(A^* = a^*)D\left(P(Y_a|A^* = a^*)\,||\,P(Y_a)\right).$$

where here,

$$\begin{aligned}
D\left(P(Y_a|A^* = a^*)\,||\,P(Y_a)\right) &= D\left(P\left((\theta_i : i \in a)|A^* = a^*\right)\;||\;P\left((\theta_i : i \in a)\right)\right) \\
&\overset{(a)}{=} \sum_{i\in a}\mathbb{E}\left[D\left(P\left(\theta_i|A^* = a^*, \theta_{<i}\right)\;||\;P\left(\theta_i|\theta_{<i}\right)\right)\middle|A^* = a^*\right] \\
&\overset{(b)}{\geq} 2\sum_{i\in a}\mathbb{E}\left[\left(\mathbb{E}\left[\theta_i|A^* = a^*, \theta_{<i}\right] - \mathbb{E}\left[\theta_i|\theta_{<i}\right]\right)^2\middle|A^* = a^*\right] \\
&\overset{(c)}{=} 2\sum_{i\in a}\mathbb{E}\left[\left(\mathbb{E}\left[\theta_i|A^* = a^*, \theta_{<i}\right] - \mathbb{E}\left[\theta_i\right]\right)^2\middle|A^* = a^*\right] \\
&\overset{(d)}{\geq} 2\sum_{i\in a}\left(\mathbb{E}\left[\theta_i|A^* = a^*\right] - \mathbb{E}\left[\theta_i\right]\right)^2.
\end{aligned}$$

Equality (a) follows from the chain rule of Kullback–Leibler divergence, (b) follows from Fact 9, (c) follows from the assumption that $(\theta_i : 1 \leq i \leq d)$ are independent conditioned on any history of observations, and (d) follows from Jensen's inequality and the tower property

of conditional expectation. Now, we can show

$$\begin{aligned}
I(A^*;Y_a) &\geq 2\sum_{i\in a}\sum_{a^*\in\mathcal{A}}\mathbb{P}(A^*=a^*)\left(\mathbb{E}\left[\theta_i|A^*=a^*\right]-\mathbb{E}\left[\theta_i\right]\right)^2\\
&= 2\sum_{i\in a}\mathbb{P}(i\in A^*)\sum_{a^*\in\mathcal{A}}\frac{\mathbb{P}(A^*=a^*)}{\mathbb{P}(i\in A^*)}\left(\mathbb{E}\left[\theta_i|A^*=a^*\right]-\mathbb{E}\left[\theta_i\right]\right)^2\\
&\geq 2\sum_{i\in a}\mathbb{P}(i\in A^*)\sum_{a^*:i\in a^*}\frac{\mathbb{P}(A^*=a^*)}{\mathbb{P}(i\in A^*)}\left(\mathbb{E}\left[\theta_i|A^*=a^*\right]-\mathbb{E}\left[\theta_i\right]\right)^2\\
&= 2\sum_{i\in a}\mathbb{P}(i\in A^*)\sum_{a^*:i\in a^*}\mathbb{P}(A^*=a^*|i\in A^*)\left(\mathbb{E}\left[\theta_i|A^*=a^*\right]-\mathbb{E}\left[\theta_i\right]\right)^2\\
&\overset{(e)}{\geq} 2\sum_{i\in a}\mathbb{P}(i\in A^*)\left(\sum_{a^*:i\in a^*}\mathbb{P}(A^*=a^*|i\in A^*)\left(\mathbb{E}\left[\theta_i|A^*=a^*\right]-\mathbb{E}\left[\theta_i\right]\right)\right)^2\\
&\overset{(f)}{=} 2\sum_{i\in a}\mathbb{P}(i\in A^*)\left(\mathbb{E}\left[\theta_i|i\in A^*\right]-\mathbb{E}\left[\theta_i\right]\right)^2,
\end{aligned}$$

where (e) and (f) follow from Jensen's inequality and the tower property of conditional expectation, respectively. ■

Lemma 2 *Under the conditions of Proposition 6,*

$$I(A^*;(A,Y_A))\geq 2\sum_{i=1}^{d}\mathbb{P}(i\in A^*)^2\left(\mathbb{E}\left[\theta_i|i\in A^*\right]-\mathbb{E}\left[\theta_i\right]\right)^2.$$

Proof By Lemma 1 and the tower property of conditional expectation,

$$\begin{aligned}
I(A^*;(A;Y_A)) &= \mathbb{P}(A^*=a)I(A^*;Y_a)\\
&\geq 2\sum_{a\in\mathcal{A}}\mathbb{P}(A^*=a)\left[\sum_{i\in a}\mathbb{P}(i\in A^*)\left(\mathbb{E}\left[\theta_i|i\in A^*\right]-\mathbb{E}\left[\theta_i\right]\right)^2\right]\\
&= 2\sum_{i=1}^{d}\sum_{a:i\in a}\mathbb{P}(A^*=a)\left(\mathbb{P}(i\in A^*)\left(\mathbb{E}\left[\theta_i|i\in A^*\right]-\mathbb{E}\left[\theta_i\right]\right)^2\right)\\
&= 2\sum_{i=1}^{d}\mathbb{P}(i\in A^*)^2\left(\mathbb{E}\left[\theta_i|i\in A^*\right]-\mathbb{E}\left[\theta_i\right]\right)^2.
\end{aligned}$$

■

Now, we complete the proof of Proposition 6.

Proof The proof establishes that the numerator of the information ratio is less than $d/2m^2$ times its denominator:

$$\begin{aligned}
m\mathbb{E}[R(Y_{A^*})-R(Y_A)] &= \mathbb{E}\sum_{i\in A^*}\theta_i-\mathbb{E}\sum_{i\in A}\theta_i\\
&= \sum_{i=1}^{d}\mathbb{P}(i\in A^*)\mathbb{E}[\theta_i|i\in A^*]-\sum_{i=1}^{d}\mathbb{P}(i\in A)\mathbb{E}[\theta_i|i\in A]\\
&= \sum_{i=1}^{d}\mathbb{P}(i\in A^*)\left(\mathbb{E}[\theta_i|i\in A^*]-\mathbb{E}[\theta_i]\right)\\
&\leq \sqrt{d}\sqrt{\sum_{i=1}^{d}\mathbb{P}(i\in A^*)^2\left(\mathbb{E}[\theta_i|i\in A^*]-\mathbb{E}[\theta_i]\right)^2}\\
&\leq \sqrt{\frac{dI(A^*;(A,Y_A))}{2}}.
\end{aligned}$$

■

Appendix C. Proof of Fact 6

We could not find a reference that proves Fact 6 in a general setting, and will therefore provide a proof here.

Consider random variables $X:\Omega\to\mathcal{X}$ and $Y:\Omega\to\mathcal{Y}$ where $\mathcal{X}$ is assumed to be a finite set but Y is a general random variable. We show

$$I(X;Y)=\sum_{x\in\mathcal{X}}\mathbb{P}\left(X=x\right)D\left(\mathbb{P}\left(Y\in\cdot|X=x\right)||\,\mathbb{P}\left(Y\in\cdot\right)\right).$$

When Y has finite support this result follows easily by using that $\mathbb{P}(X=x,Y=y)=\mathbb{P}(X=x)\mathbb{P}(Y=y|X=x)$. For an extension to general random variables Y we follow chapter 5 of Gray (2011).

The extension follows by considering quantized versions of the random variable Y. For a finite partition $\mathcal{Q}=\{Q_i\subset\mathcal{Y}\}_{i\in I}$, we denote by $Y_{\mathcal{Q}}$ the quantization of Y defined so that $Y_{\mathcal{Q}}(\omega)=i$ if and only if $Y(\omega)\in Q_i$. As shown in Gray (2011), for two probability measures P_1 and P_2 on $(\Omega,\mathcal{F})$,

$$D\left(P_1(Y\in\cdot)||P_2(Y\in\cdot)\right)=\sup_{\mathcal{Q}}D\left(P_1(Y_{\mathcal{Q}}\in\cdot)||P_2(Y_{\mathcal{Q}}\in\cdot)\right),\tag{9}$$

where the supremum is taken over all finite partitions of $\mathcal{Y}$, and whenever $\overline{\mathcal{Q}}$ is a refinement of $\mathcal{Q}$,

$$D\left(P_1(Y_{\overline{\mathcal{Q}}}\in\cdot)||P_2(Y_{\overline{\mathcal{Q}}}\in\cdot)\right)\geq D\left(P_1(Y_{\mathcal{Q}}\in\cdot)||P_2(Y_{\mathcal{Q}}\in\cdot)\right).\tag{10}$$

Since $I(X;Y)=D\left(\mathbb{P}(X\in\cdot,Y\in\cdot)\,||\,\mathbb{P}(X\in\cdot)\mathbb{P}(Y\in\cdot)\right)$ these properties also apply to $I(X;Y_{\mathcal{Q}})$. Now, for each $x\in\mathcal{X}$ we can introduce a sequence of successively refined partitions $(\mathcal{Q}_n^x)_{n\in\mathbb{N}}$

so that

$$\begin{aligned} D\left(\mathbb{P}\left(Y \in \cdot | X = x\right) || \mathbb{P}\left(Y \in \cdot\right)\right) &= \lim_{n\to\infty} D\left(\mathbb{P}\left(Y_{\mathcal{Q}_n^x} \in \cdot | X = x\right) || \mathbb{P}\left(Y_{\mathcal{Q}_n^x} \in \cdot\right)\right) \\ &= \sup_{\mathcal{Q}} D\left(\mathbb{P}\left(Y_{\mathcal{Q}} \in \cdot | X = x\right) || \mathbb{P}\left(Y_{\mathcal{Q}} \in \cdot\right)\right). \end{aligned}$$

Let the finite partition $\mathcal{Q}_n$ denote the refinement of the partitions $\{\mathcal{Q}_n^x\}_{x\in\mathcal{X}}$. That is, for each x, every set in Q_n^x can be written as the union of sets in $\mathcal{Q}_n$. Then,

$$\begin{aligned} I(X;Y) &\geq \lim_{n\to\infty} I(X; Y_{\mathcal{Q}_n}) \\ &= \lim_{n\to\infty} \sum_{x\in\mathcal{X}} \mathbb{P}\left(X = x\right) D\left(\mathbb{P}\left(Y_{\mathcal{Q}_n} \in \cdot | X = x\right) || \mathbb{P}\left(Y_{\mathcal{Q}_n} \in \cdot\right)\right) \\ &\geq \lim_{n\to\infty} \sum_{x\in\mathcal{X}} \mathbb{P}\left(X = x\right) D\left(\mathbb{P}\left(Y_{\mathcal{Q}_n^x} \in \cdot | X = x\right) || \mathbb{P}\left(Y_{\mathcal{Q}_n^x} \in \cdot\right)\right) \\ &= \sum_{x\in\mathcal{X}} \mathbb{P}\left(X = x\right) D\left(\mathbb{P}\left(Y \in \cdot | X = x\right) || \mathbb{P}\left(Y \in \cdot\right)\right) \\ &= \sum_{x\in\mathcal{X}} \mathbb{P}\left(X = x\right) \sup_{\mathcal{Q}^x} D\left(\mathbb{P}\left(Y_{\mathcal{Q}^x} \in \cdot | X = x\right) || \mathbb{P}\left(Y_{\mathcal{Q}^x} \in \cdot\right)\right) \\ &\geq \sup_{\mathcal{Q}} \sum_{x\in\mathcal{X}} \mathbb{P}\left(X = x\right) D\left(\mathbb{P}\left(Y_{\mathcal{Q}} \in \cdot | X = x\right) || \mathbb{P}\left(Y_{\mathcal{Q}} \in \cdot\right)\right) \\ &= \sup_{\mathcal{Q}} I(X; Y_{\mathcal{Q}}) = I(X;Y), \end{aligned}$$

hence the inequalities above are equalities and our claim is established.

Appendix D. Technical Extensions

D.1 Infinite Action Spaces

In this section, we discuss how to extend our results to problems where the action space is infinite. For concreteness, we will focus on linear optimization problems. Specifically, throughout this section our focus is on problems where $\mathcal{A} \subset \mathbb{R}^d$ and for each $p \in \mathcal{P}$ there is some $\theta_p \in \Theta \subset \mathbb{R}^d$ such that for all $a \in \mathcal{A}$

$$\mathop{\mathbb{E}}_{y\sim p_a}\left[R(y)\right] = a^T\theta_p.$$

We assume further that there is a fixed constant $c \in \mathbb{R}$ such that $\sup_{a\in\mathcal{A}} \|a\|_2 \leq c$ and $\sup_{\theta\in\Theta} \|\theta\|_2 \leq c$. Because $\mathcal{A}$ is compact, it can be extremely well approximated by a finite set. In particular, we can choose a finite cover $\mathcal{A}_\epsilon \subset \mathcal{A}$ with $\log|A_\epsilon| = O(d\log(dc/\epsilon))$ such that for every $a \in \mathcal{A}$, $\min_{\tilde{a}\in\mathcal{A}_\epsilon} \|a - \tilde{a}\|_2 \leq \epsilon$. By the Cauchy-Schwartz inequality, this implies that $|\left(a - \tilde{a}\right)^T \theta_P| \leq c\epsilon$ for every θ_P.

We introduce a quantization A_Q^* of the random variable A^*. A_Q^* is supported only on the set $\mathcal{A}_\epsilon$, but satisfies $\|A^*(\omega) - A_Q^*(\omega)\|_2 \leq \epsilon$ for each $\omega \in \Omega$.

Consider a variant of Thompson sampling that randomizes according to the distribution of A_Q^*. That is, for each $a \in \mathcal{A}_\epsilon$, $\mathbb{P}\left(A_t = a|\mathcal{F}_t\right) = \mathbb{P}\left(A_Q^* = a|\mathcal{F}_t\right)$. Then, our analysis shows,

$$\begin{aligned} \mathbb{E}\sum_{t=1}^T \left[R(Y_{t,A^*}) - R(Y_{t,A_t})\right] &= \mathbb{E}\sum_{t=1}^T \left[R(Y_{t,A^*}) - R(Y_{t,A_Q^*})\right] + \mathbb{E}\sum_{t=1}^T \left[R(Y_{t,A_Q^*}) - R(Y_{t,A_t})\right] \\ &\leq \epsilon T + \sqrt{dTH\left(A_Q^*\right)}. \end{aligned}$$

This new bound depends on the time horizon T, the dimension d of the linear model, the entropy of the prior distribution of the quantized random variable A_Q^* and the discretization error ϵT. Since $H(A_Q^*) \leq \log\left(|\mathcal{A}_\epsilon|\right)$, by choosing $\epsilon = (cT)^{-1}$ and choosing a finite cover with $\log\left(|\mathcal{A}_\epsilon|\right) = O(d\log(dcT))$ we attain a regret bound of order $d\sqrt{T\log(dcT)}$. Note that for $d \leq T$, this bound is of order $d\sqrt{T\log(cT)}$, but for $d > T \geq 1$, we have a trivial regret bound of $T < \sqrt{dT}$.

Here, for simplicity, we have considered a variant of Thompson sampling that randomizes according to the posterior distribution of the quantized random variable A_Q^*. However, with a somewhat more careful analysis, one can provide a similar result for an algorithm that randomizes according to the posterior distribution of A^*.

D.2 Unbounded Noise

In this section we relax Assumption 1, which requires that reward distributions are uniformly bounded. This assumption is required for Fact 9 to hold, but otherwise was never used in our analysis. Here, we show that an analogue to Fact 9 holds in the more general setting where reward distributions are *sub–Gaussian*. This yields more general regret bounds.

A random variable is sub–Gaussian if its moment generating function is dominated by that of a Gaussian random variable. Gaussian random variables are sub–Gaussian, as are real-valued random varaibles with bounded support.

Definition 1 *Fix a deterministic constant $\sigma \in \mathbb{R}$. A real–valued random variable X is σ sub–Gaussian if for all $\lambda \in \mathbb{R}$*

$$\mathbb{E}\left[\exp\{\lambda X\}\right] \leq \exp\{\lambda^2\sigma^2/2\}.$$

More generally X is σ sub–Gaussian conditional on a sigma-algebra $\mathcal{G} \subset \mathcal{F}$ if for all $\lambda \in \mathbb{R}$,

$$\mathbb{E}\left[\exp\{\lambda X\}|\mathcal{G}\right] \leq \exp\{\lambda^2\sigma^2/2\}$$

almost surely.

The next lemma extends Fact 9 to sub-Gaussian random variables.

Lemma 3 *Suppose there is a $\mathcal{F}_t$ measurable random variable σ such that for each $a \in \mathcal{A}$, $R(Y_{t,a}))$ is σ sub-Gaussian conditional on $\mathcal{F}_t$. Then for every $a, a^* \in \mathcal{A}$*

$$\mathbb{E}_t[R(Y_{t,a})|A^* = a^*] - \mathbb{E}_t[R(Y_{t,a})] \leq \sigma\sqrt{2D\left(P_t(Y_{t,a}|A* = a^*) \,||\, P_t(Y_{t,a})\right)},$$

almost surely.

Using this Lemma in place of Fact 9 in our analysis leads to the following corollary.

Corollary 1 *Fix a deterministic constant $\sigma \in \mathbb{R}$. Suppose that conditioned on $\mathcal{F}_t$, $R(Y_{t,a}) - \mathbb{E}\left[R(Y_{t,a})|\mathcal{F}_t\right]$ is σ sub–Gaussian. Then*

$$\Gamma_t \leq 2|\mathcal{A}|\sigma^2$$

almost surely for each $t \in \mathbb{N}$. Furthermore, $\Gamma_t \leq 2\sigma^2$ under the conditions of Proposition 4, $\Gamma_t \leq 2d\sigma^2$ under the conditions of Proposition 5, and $\Gamma_t \leq \frac{2d\sigma^2}{m^2}$ under the conditions of Proposition 6.

It's worth highlighting two cases under which the conditions of Corollary 1 are satisfied. The first is a setting with a Gaussian prior and Guassian reward noise. The second case is when under any model $p \in \mathcal{P}$ expected rewards lie in a bounded interval and reward noise is sub–Gaussian.

1. Suppose that for each $a \in \mathcal{A}$, $R(Y_{t,a})$ follows a Guassian distribution with variance less than σ^2, $Y_{t,a} = R(Y_{t,a})$ and, reward noise $R(Y_{t,a}) - \mathbb{E}[R(Y_{t,a})|p^*]$ is Gaussian with known variance. Then, the posterior predictive distribution of $R(Y_{t,a})$, $\mathbb{P}\left(R(Y_{t,a}) \in \cdot|\mathcal{F}_t\right)$ is Gaussian with variance less than σ^2 for each $a \in \mathcal{A}$ and $t \in \mathbb{N}$.
2. Fix constants $C \in \mathbb{R}$ and $\sigma \in \mathbb{R}$. Suppose that almost surely $\mathbb{E}\left[R(Y_{t,a})|p^*\right] \in \left[\frac{-C}{2}, \frac{C}{2}\right]$ and reward noise is $R(Y_{t,a}) - \mathbb{E}\left[R(Y_{t,a})|p^*\right]$ is σ sub–Gaussian. Then, conditioned on the history, $R(Y_{t,a}) - \mathbb{E}\left[R(Y_{t,a})|\mathcal{F}_t\right]$ is $\sqrt{C^2 + \sigma^2}$ sub-Gaussian almost surely.

The first case relies on the fact that $\mathbb{E}[R(Y_{t,a})|p^*]$ is C–sub-Gaussain, as well as the following fact about sub-Gaussian random variables.

Fact 11 *Consider random variables $(X_1, ..., X_K)$. If for each X_i there is a deterministic σ_i such that X_i is σ_i sub–Gaussian conditional on $X_1, .., X_{i-1}$, then $\sum_{i=1}^K X_i$ is $\sqrt{\sum_{i=1}^K \sigma_i^2}$ sub-Gaussian.*

Proof For any $\lambda \in \mathbb{R}$,

$$\begin{aligned}\mathbb{E}\left[\exp\{\lambda \sum_{i=1}^K X_i\}\right] = \mathbb{E}\left[\prod_{i=1}^K \exp\{\lambda X_i\}\right] &= \mathbb{E}\left[\prod_{i=1}^K \mathbb{E}\left[\exp\{\lambda X_i\}\middle| X_1, ..X_{i-1}\right]\right] \\ &\leq \prod_{i=1}^K \exp\left\{\frac{\lambda^2\sigma_i^2}{2}\right\} = \exp\left\{\frac{\lambda^2(\sum_i \sigma_i^2)}{2}\right\}.\end{aligned}$$

■

The proof of Lemma 3 relies on the following property of Kullback–Leibler divergence.

Fact 12 *(Variational form of KL–Divergence given in Theorem 5.2.1 of Gray (2011)) Fix two probability distributions P and Q such that P is absolutely continuous with respect to Q. Then,*

$$D(P||Q) = \sup_X \left\{\mathbb{E}_P\left[X\right] - \log \mathbb{E}_Q\left[\exp\{X\}\right]\right\},$$

where $\mathbb{E}_P$ and $\mathbb{E}_Q$ denote the expectation operator under P and Q respectively, and the supremum is taken over all real valued random variables X such that $\mathbb{E}_P\left[X\right]$ is well defined and $\mathbb{E}_Q\left[\exp\{X\}\right] < \infty$.

We now show that Lemma 3 follows from the variational form of KL–Divergence.

Proof Define the random variable $X = R\left(Y_{t,a}\right) - \mathbb{E}_t\left[R\left(Y_{t,a}\right)\right]$. Then, for abitrary $\lambda \in \mathbb{R}$, applying Fact 12 to λX yields

$$\begin{aligned}D\left(P_t\left(Y_{t,a}|A^* = a^*\right) \,||\, P_t(Y_{t,a})\right) &\geq \lambda\mathbb{E}_t\left[X|A^* = a^*\right] - \log \mathbb{E}_t\left[\exp\{\lambda X\}\right] \\ &= \lambda\left(\mathbb{E}_t[R\left(Y_{t,a}\right)|A^* = a^*] - \mathbb{E}_t\left[R\left(Y_{t,a}\right)\right]\right) - \log \mathbb{E}\left[\exp\{\lambda X\}|\mathcal{F}_t\right] \\ &\geq \lambda\left(\mathbb{E}_t[R\left(Y_{t,a}\right)|A^* = a^*] - \mathbb{E}_t\left[R\left(Y_{t,a}\right)\right]\right) - (\lambda^2\sigma^2/2).\end{aligned}$$

Maximizing over λ yields the result. ■

Abstract

Nonparametric regression for large numbers of features (p) is an increasingly important problem. If the sample size n is massive, a common strategy is to partition the feature space, and then separately apply simple models to each partition set. This is not ideal when n is modest relative to p, and we propose an alternative approach relying on random compression of the feature vector combined with Gaussian process regression. The proposed approach is particularly motivated by the setting in which the response is conditionally independent of the features given the projection to a low dimensional manifold. Conditionally on the random compression matrix and a smoothness parameter, the posterior distribution for the regression surface and posterior predictive distributions are available analytically. Running the analysis in parallel for many random compression matrices and smoothness parameters, model averaging is used to combine the results. The algorithm can be implemented rapidly even in very large p and moderately large n nonparametric regression, has strong theoretical justification, and is found to yield state of the art predictive performance.

Keywords: Compressed regression; Gaussian process; Gaussian random projection; Large p; Manifold regression.

1. Introduction

With recent technological progress, it is now routine in many disciplines to collect data containing large numbers of features, ranging from thousands to millions. To account for complex nonlinear relationships between the features and the response, nonparametric regression models are employed. For example,

$$y = \mu_0(\boldsymbol{x}) + \epsilon, \ \epsilon \sim N(0, \sigma^2),$$

where $\boldsymbol{x} \in \mathcal{R}^p$, $\mu_0(\cdot)$ is the unknown regression function and ϵ is a residual. When p is large, estimating μ_0 can lead to a statistical and computational curse of dimensionality. One strategy for combatting this curse is dimensionality reduction via variable selection or (more broadly) subspace learning, with the high-dimensional features replaced with their projection to a d-dimensional subspace or manifold with $d \ll p$. In many applications, the relevant information about the high-dimensional features can be encoded in such low dimensional coordinates.

There is a vast frequentist literature on subspace learning for regression, typically employing a two stage approach. In the first stage, a dimensionality reduction technique is used to obtain lower dimensional features that can "faithfully" represent the higher dimensional features. Examples include principal components analysis and more elaborate methods that accommodate non-linear subspaces, such as isomap (Tenenbaum et al., 2000) and Laplacian eigenmaps (Belkin and Niyogi, 2003; Guerrero et al., 2011). Once lower dimensional features are obtained, the second stage uses these features in standard regression and classification procedures as if they were observed initially. Such two stage approaches rely on learning the manifold structure embedded in the high dimensional features, which adds unnecessary computational burden when inferential interest lies mainly in prediction.

Another thread of research focuses on prediction using divide-and-conquer techniques. As the number of features increases, the problem of finding the best splitting attribute becomes intractable, so that CART (Breiman et al., 1984), MARS and multiple tree models, such as Random Forest (Breiman, 2001), cannot be efficiently applied. A much simpler approach is to apply high dimensional clustering techniques, such as metis, cover trees and spectral clustering. Once the observations are clustered into a few groups, simple models (glm, Lasso etc) are fitted in each cluster (Zhang et al., 2013). Such methods are sensitive to clustering, do not characterize predictive uncertainty, and may lack efficiency, an important consideration outside the $n \gg p$ setting. There is also a recent literature on scaling up sparse optimization methods, such as Lasso, to large p and n settings relying on algorithms that can exploit multiple processors in a distributed manner e.g., (Boyd et al., 2011). However, such methods are yet to be developed for non-linear manifold regression, which is the central focus of this article.

This naturally motivates Bayesian models that simultaneously learn the mapping to the lower-dimensional subspace along with the regression function in the coordinates on this subspace, providing a characterization of predictive uncertainties. Tokdar et al. (2010) proposes a logistic Gaussian process approach, while Reich et al. (2011) use finite mixture models for sufficient dimension reduction. Page et al. (2013) propose a Bayesian nonparametric model for learning of an affine subspace in classification problems. These approaches have the disadvantages of being limited to linear subspaces, lacking scalability beyond a few dozen features and having potential sensitivity to features corrupted with noise. There is also a literature on Bayesian methods that accommodate non-linear subspaces, ranging from Gaussian process latent variable models (GP-LVMs) (Lawrence, 2005) for probabilistic nonlinear PCA to mixture factor models Chen et al. (2010). However, such methods similarly face barriers in scaling up to large p and/or n. There is a heavy computational price for learning the number of latent variables, the distribution of the latent variables, and the mapping functions while maintaining identifiability restrictions.

Recently, Yang and Dunson (2013) show that this computational burden can be largely bypassed by using usual Gaussian process (GP) regression without attempting to learn the mapping to the lower-dimensional subspace. They showed that when the features lie on a d-dimensional manifold embedded in the p-dimensional feature space with $d \ll p$ and the regression function is not highly smooth, the optimal rate can be obtained using GP regression with a squared exponential covariance in the original high-dimensional feature

space. This is an exciting theoretical result, which provides motivation for the approach in this article, which is focused on scalable Bayesian nonparametric regression in large p settings. For broader applicability than Yang and Dunson (2013), we accommodate features that are contaminated by noise and hence do not lie exactly on a low-dimensional manifold. In addition, we facilitate computational efficiency by bypassing MCMC and reducing matrix inversion bottlenecks via random projections. Sensitivity to the random projection and to tuning parameters is reduced through the use of Bayesian model averaging. The proposed approach that accommodates all these features is coined as the *compressed Gaussian process* (CGP).

Snelson and Ghahramani (2012) also considered manifold regression for big data, comprising feature vectors via pre-multiplying with a short and fat projection matrix. Their approach involves estimating a total of $(M+p)m$ parameters in a feature compression matrix and input points, with M the number of input points, leading to intractability as p increases. We demonstrate substantial advantages of our random compression approach in Section 5 in terms of computational scalability and predictive performance. In addition, SG lacks theory guarantees, while we show that CGP has a minimax optimal adaptive convergence rate dependent only on the true manifold dimension (assumed small). Calandra et al. (2014) instead use a neural network-like mapping of the input space, requiring non-convex optimization in high-dimensions. Scaling to moderate n, such as $n \sim 5,000 - 10,000$, is problematic. Other manifold regression methods (see Bickel and Li, 2007; Aswani et al., 2011) either lack scalability even for moderate p and n, or fail to characterize predictive uncertainties.

Section 2 proposes the model and computational approach in large p settings. Section 3 describes extensions to moderately large n, and Section 4 develops theoretical justification. Section 5 contains simulation examples relative to state-of-the-art competitors. Section 6 presents an image data application, and Section 7 concludes the paper with a discussion.

2. Compressed Gaussian process regression

This section details out compressed Gaussian process model with the associated prior and posterior distributions of the parameters.

2.1 Model

For subjects $i = 1, \ldots, n$, let $y_i \in \mathcal{Y}$ denote a response with associated features $\boldsymbol{x}_i = (x_{i1}, \ldots, x_{ip})' = (z_{i1}, \ldots, z_{ip})' + (\delta_{i1}, \ldots, \delta_{ip})' = \boldsymbol{z}_i + \boldsymbol{\delta}_i$, $\boldsymbol{z}_i \in \mathcal{M}$, $\boldsymbol{\delta}_i \in \mathcal{R}^p$, where $\mathcal{M}$ is a d-dimensional manifold embedded in the ambient space $\mathcal{R}^p$. We assume that the response $y \in \mathcal{Y}$ is continuous. The measured features do not fall exactly on the manifold $\mathcal{M}$ but are corrupted by noise. We assume a compressed nonparametric regression model

$$y_i = \mu\big(\boldsymbol{\Psi}\boldsymbol{x}_i\big) + \epsilon_i, \quad \epsilon_i \sim N(0, \sigma^2), \tag{1}$$

with the residuals modeled as Gaussian with variance σ^2, though other distributions including heavy-tailed ones can be accommodated. $\boldsymbol{\Psi}$ is an $m \times p$ matrix that compresses p-dimensional features to dimension m. Following a Bayesian approach, we choose a prior distribution for the regression function μ and residual variance σ^2, while randomly generating $\boldsymbol{\Psi}$ following precedence in the literature on feature compression (Maillard and Munos, 2009; Fard et al., 2012; Guhaniyogi and Dunson, 2013). These earlier approaches differ from ours in focusing on parametric regression. We independently draw elements $\{\Psi_{ij}\}$ of $\boldsymbol{\Psi}$ from $N(0,1)$, and then normalize the rows using Gram-Schmidt orthogonalization.

We assume that $\mu \in \mathcal{H}_s$ is a continuous function belonging to $\mathcal{H}_s$, a Holder class with smoothness s. To allow μ to be unknown, we use a Gaussian process (GP) prior, $\mu \sim \text{GP}(0, \sigma^2\kappa)$ with the covariance function chosen to be squared exponential

$$\kappa(\boldsymbol{x}_i, \boldsymbol{x}_j; \lambda) = \exp\left(-\lambda||\boldsymbol{x}_i - \boldsymbol{x}_j||^2\right), \tag{2}$$

with λ a smoothness parameter and $||\cdot||^2$ the Euclidean norm. To additionally allow the residual variance σ^2 and smoothness λ to be unknown, we let

$$\sigma^2 \sim IG(a, b), \quad \lambda^d \sim Ga(a_0, b_0),$$

with $IG()$ and $Ga()$ denoting the inverse-gamma and gamma densities, respectively. The powered gamma prior for λ is motivated by the result of van der Vaart and van Zanten (2009) showing minimax adaptive rates of $n^{-s/(2s+p)}$ for a GP prior with squared exponential covariance and powered gamma prior. This is the optimal rate for nonparametric regression in the original p-dimensional ambient space. The rate can be improved to $n^{-s/(2s+d)}$ when $\boldsymbol{x}_i \in \mathcal{M}$, with $\mathcal{M}$ a d-dimensional manifold. Yang and Dunson (2013) shows that a GP prior with powered gamma prior on the smoothness can achieve this rate. In practice, replacing the powered gamma prior for λ with a gamma prior has essentially no impact on the results in examples we have considered.

In many applications, features may not lie exactly on $\mathcal{M}$ due to noise and corruption in the data. We apply random compression in (1) to de-noise the features, obtaining $\boldsymbol{\Psi}\boldsymbol{x}_i$ much more concentrated near a lower-dimensional subspace than the original $\boldsymbol{x}_i$. With this enhanced concentration, the theory in Yang and Dunson (2013) suggests excellent performance for an appropriate GP prior. In addition to de-noising, this approach has the major advantage of bypassing estimation of a geodesic distance along the unknown manifold $\mathcal{M}$ between any two data points $\boldsymbol{x}_i$ and $\boldsymbol{x}_{i'}$.

2.2 Posterior form

Let $\boldsymbol{\mu} = (\mu(\boldsymbol{\Psi}\boldsymbol{x}_1), ..., \mu(\boldsymbol{\Psi}\boldsymbol{x}_n))'$ and $\boldsymbol{K}_1 = (\kappa(\boldsymbol{\Psi}\boldsymbol{x}_i, \boldsymbol{\Psi}\boldsymbol{x}_j; \lambda))_{i,j=1}^n$. The prior distribution on μ, σ^2 induces a normal-inverse gamma (NIG) prior on $(\boldsymbol{\mu}, \sigma^2)$,

$$(\boldsymbol{\mu} \,|\, \sigma^2) \sim N(\boldsymbol{0}, \sigma^2\boldsymbol{K}_1),\ \sigma^2 \sim IG(a, b),$$

leading to a NIG posterior distribution for $(\boldsymbol{\mu}, \sigma^2)$ given $y, \boldsymbol{\Psi}\boldsymbol{x}, \lambda$. In the special case in which $a, b \to 0$, we obtain Jeffrey's prior and the posterior distribution is

$$\boldsymbol{\mu} \,|\, \boldsymbol{y} \sim t_n(\boldsymbol{m}, \boldsymbol{\Sigma}) \tag{3}$$

$$\sigma^2 \,|\, \boldsymbol{y} \sim IG(a_1, b_1), \tag{4}$$

where $a_1 = n/2$, $b_1 = \boldsymbol{y}'\left(\boldsymbol{K}_1 + \boldsymbol{I}\right)^{-1}\boldsymbol{y}/2$, $\boldsymbol{m} = \left[\boldsymbol{I} + \boldsymbol{K}_1^{-1}\right]^{-1}\boldsymbol{y}$, $\boldsymbol{\Sigma} = (2b_1/n)\left[\boldsymbol{I} + \boldsymbol{K}_1^{-1}\right]^{-1}$, and $t_\nu(\boldsymbol{m}, \boldsymbol{\Sigma})$ denotes a multivariate-t distribution with ν degrees of freedom, mean $\boldsymbol{m}$ and covariance $\boldsymbol{\Sigma}$.

Hence, the exact posterior distribution of $(\boldsymbol{\mu}, \sigma^2)$ conditionally on $(\boldsymbol{\Psi}, \lambda)$ is available analytically. The predictive of $\boldsymbol{y}^* = (y_1^*, ..., y_{n_{pred}}^*)'$ given $\boldsymbol{X}^* = \left(\boldsymbol{x}_1^{*'}, ..., \boldsymbol{x}_{n_{pred}}^{*'}\right)'$ and $\boldsymbol{\Psi}, \lambda$ for new n_{pred} subjects marginalizing out $(\boldsymbol{\mu}, \sigma^2)$ over their posterior distribution is available analytically as

$$\boldsymbol{y}^* | \boldsymbol{x}_1^*, ..., \boldsymbol{x}_{n_{pred}}^*, \boldsymbol{y} \sim t_n\left(\mu_{pred}, \sigma^2_{pred}\right), \tag{5}$$

where $\boldsymbol{K}_{pred} = \{\kappa(\boldsymbol{x}_i^*, \boldsymbol{x}_j^*; \lambda)\}_{i,j=1}^{n_{pred}}$, $\boldsymbol{K}_{pred,1} = \{\kappa(\boldsymbol{x}_i^*, \boldsymbol{x}_j; \lambda)\}_{i=1,j=1}^{i=n_{pred},j=n}$, $\boldsymbol{K}_{1,pred} = \boldsymbol{K}'_{pred,1}$, $\mu_{pred} = \boldsymbol{K}_{pred,1}\left(\boldsymbol{I} + \boldsymbol{K}_1\right)^{-1}\boldsymbol{y}$, $\sigma^2_{pred} = (2b_1/n)\left[\boldsymbol{I} + \boldsymbol{K}_{pred} - \boldsymbol{K}_{pred,1}\left\{\boldsymbol{I} + \boldsymbol{K}_1\right\}^{-1}\boldsymbol{K}_{1,pred}\right]$.

2.3 Model averaging

The approach described in the previous section can be used to obtain a posterior distribution for $\boldsymbol{\mu}$ and a predictive distribution for $\boldsymbol{y}^* = (y_1^*, ..., y_{n_{pred}}^*)$ given $\boldsymbol{X}^*$ for a new set of n_{pred} subjects *conditionally* on the $m \times p$ random projection matrix $\boldsymbol{\Psi}$ and the scaling parameter λ. To accomplish robustness with respect to the choice of $(\boldsymbol{\Psi}, \lambda)$ and the subspace dimension m, following Guhaniyogi and Dunson (2013), we propose to generate s random matrices having different m, s and λ from the marginal posterior distribution, $(\Psi^{(l)}, \lambda^{(l)})$, $l = 1, ..., s$, and then use model averaging to combine the results. To make matters more clear, let $\mathcal{M}_l$, $l = 1, \ldots, s$, represent (1) with m_l number of rows. Corresponding to the model $\mathcal{M}_l$, we denote $\boldsymbol{\Psi}$, λ, $\boldsymbol{\mu}$ and σ^2 by $\boldsymbol{\Psi}^{(l)}$, $\lambda^{(l)}$, $\boldsymbol{\mu}^{(l)}$ and $\sigma^{2(l)}$ respectively. Given $\boldsymbol{\Psi}^{(l)}$, we draw a few $\lambda_1, ..., \lambda_k$ randomly from $U(3/dmax, 3/dmin)$ where $dmax = \max_{i,j} ||\boldsymbol{x}_i - \boldsymbol{x}_j||^2$ and $dmin = \min_{i,j} ||\boldsymbol{x}_i - \boldsymbol{x}_j||^2$. Next we use the fact that the marginal posterior distribution of $\lambda | \boldsymbol{\Psi}^{(l)}, \boldsymbol{y}$ is given by

$$f(\lambda | \boldsymbol{y}, \boldsymbol{\Psi}^{(l)}) \propto \frac{1}{|\boldsymbol{K}_1 + \boldsymbol{I}|^{\frac{1}{2}}} \frac{2^{\frac{n}{2}}\Gamma(\frac{n}{2})}{\left[\boldsymbol{y}'\left(\boldsymbol{K}_1 + \boldsymbol{I}\right)^{-1}\boldsymbol{y}\right]^{\frac{n}{2}}(\sqrt{2\pi})^n} \times \pi(\lambda),$$

where $\pi(\lambda)$ is the prior distribution of λ. Clearly, a discrete approximation of $\lambda | \boldsymbol{\Psi}^{(l)}, \boldsymbol{y}$ is given by $\sum_{i=1}^k w_i \delta_{\lambda_i}$, where $w_i = \frac{f(\lambda_i | \boldsymbol{y}, \boldsymbol{\Psi}^{(l)})}{\sum_{j=1}^k f(\lambda_j | \boldsymbol{y}, \boldsymbol{\Psi}^{(l)})}$ and δ_{λ_i} is the Dirac Delta function at λ_i. Finally, $\lambda^{(l)}$ is drawn from $\sum_{i=1}^k w_i \delta_{\lambda_i}$. Although Section 4 shows minimax optimality of CGP with $\lambda^d \sim Gamma(a, b)$, we use $d = 1$ in practical implementations with no practical loss in cases we have considered.

Let $\mathcal{M} = \{\mathcal{M}_1, \ldots, \mathcal{M}_s\}$ denote the set of models corresponding to different random projections, $\mathcal{D} = \{(y_i, \boldsymbol{x}_i), i = 1, \ldots, n\}$ denote the observed data, and $\boldsymbol{y}^*$ denote the data for future subjects with features $\boldsymbol{X}^*$. Then, the predictive density of $\boldsymbol{y}^*$ given $\boldsymbol{X}^*$ is

$$f(\boldsymbol{y}^* | \boldsymbol{X}^*, \mathcal{D}) = \sum_{l=1}^s f(\boldsymbol{y}^* | \boldsymbol{X}^*, \mathcal{M}_l, \mathcal{D}) P(\mathcal{M}_l \,|\, \mathcal{D}), \tag{6}$$

where the predictive density of $\boldsymbol{y}^*$ given $\boldsymbol{X}^*$ under projection $\mathcal{M}_l$ is given in (9) and the posterior probability weight on projection $\mathcal{M}_l$ is

$$P(\mathcal{M}_l \,|\, \mathcal{D}) = \frac{P(\mathcal{D} \,|\, \mathcal{M}_l) P(\mathcal{M}_l)}{\sum_{h=1}^s P(\mathcal{D} \,|\, \mathcal{M}_h) P(\mathcal{M}_h)}.$$

Assuming equal prior weights for each random projection, $P(\mathcal{M}_l) = 1/s$. In addition, the marginal likelihood under $\mathcal{M}_l$ is

$$P(\mathcal{D} \,|\, \mathcal{M}_l) = \int P(\mathcal{D} \,|\, \mathcal{M}_l, \boldsymbol{\mu}^{(l)}, \sigma^{2(l)}) \pi(\boldsymbol{\mu}^{(l)}, \sigma^{2(l)}). \tag{7}$$

After a little algebra, one observes that for (1) with $(\boldsymbol{\mu} \,|\, \sigma^2) \sim N(\boldsymbol{0}, \sigma^2 \boldsymbol{K}_1)$, $\pi(\sigma^2) \propto \frac{1}{\sigma^2}$,

$$P(\mathcal{D} \,|\, \mathcal{M}_l) = \frac{1}{|\boldsymbol{K}_1 + \boldsymbol{I}|^{\frac{1}{2}}} \frac{2^{\frac{n}{2}}\Gamma(\frac{n}{2})}{\left[\boldsymbol{y}'\left(\boldsymbol{K}_1 + \boldsymbol{I}\right)^{-1}\boldsymbol{y}\right]^{\frac{n}{2}}(\sqrt{2\pi})^n}.$$

Plugging in the above expressions in (6), one obtains the posterior predictive distribution as a weighted average of t densities. Given that the computation over different sets of $\boldsymbol{\Psi}, \lambda$ are not dependent on each other, the calculations are embarrassingly parallel with a trivial expense for combining. The main computational expense comes from the inversion of an $n \times n$ matrix under the lth random projection. There is a vast literature on obtaining rapid approximations to such inversions under low rank assumptions. In the next section, we describe one such approach for enabling scaling to moderate n. Other recent methods can be easily substituted to scale to very large or massive n.

3. Scaling to moderately large n

Fitting (1) using model averaging requires computing inverses and determinants of covariance matrices of the order $n \times n$. In problems with even moderate n, this adds a heavy computational burden of the order of $O(n^3)$. Additionally, as dimension increases, matrix inversion becomes more unstable with the propagation of errors due to finite machine precision. This problem is further exacerbated if the covariance matrix is nearly rank deficient.

To address such issues, existing solutions rely on approximating $\mu(\cdot)$ by another process $\tilde{\mu}(\cdot)$, which is more tractable computationally. One popular approach constructs $\tilde{\mu}(\cdot)$ as a finite basis approximation via kernel convolution (Higdon, 2002) or kalman filtering (Wikle and Cressie, 1999). Alternatively, one can let $\tilde{\mu}(\cdot) = \mu(\cdot)\eta(\cdot)$, where $\eta(\cdot)$ is a Gaussian process having compactly supported correlation function that essentially makes the covariance matrix of $(\tilde{\mu}(\boldsymbol{x}_1), ..., \tilde{\mu}(\boldsymbol{x}_n))$ sparse (Kaufman et al., 2008), facilitating inversion through efficient sparse solvers.

Banerjee et al. (2008) proposes a low rank approach that imputes $\mu(\cdot)$ conditionally on a few knot-points, closely related to subset of regressor methods in machine learning (Smola and Schölkopf, 2000). Subsequently, Finley et al. (2009) in statistics and Snelson and Ghahramani (2006) in machine learning report bias in both variance and length-scale parameter estimation which affects predictive estimates for the proposed approaches (Banerjee et al., 2008; Smola and Schölkopf, 2000). They also suggest possible remedies for bias adjustments. To avoid sensitivity to knot selection in the low rank approaches, Banerjee et al. (2013) approximates $\mu(\cdot)$ using $\tilde{\mu}(\cdot) = E[\mu(\cdot) \,|\, \boldsymbol{\Phi}\mu(\boldsymbol{X})] + \epsilon_{\boldsymbol{\Phi}}(\cdot)$, with $\boldsymbol{\Phi}$ an $m \times n$, $m \ll n$ random matrix with $\Phi_{ij} \sim N(0, 1)$. $\epsilon_{\boldsymbol{\Phi}}(\boldsymbol{x})$ are independent feature specific noises with $\epsilon_{\boldsymbol{\Phi}}(\boldsymbol{x}) \sim N(\boldsymbol{0}, \mathrm{var}(\mu(\boldsymbol{x})) - \mathrm{var}(\tilde{\mu}(\boldsymbol{x})))$, which are introduced for bias correction similar to Finley et al. (2009). There is a parallel literature on nearest neighbor Gaussian processes which is built upon approximating a multivariate high dimensional Gaussian distribution

by a product of lower dimensional conditional distributions. Such an idea was first pursued by Vecchia (1988) and Stein et al. (2004), and has recently gained traction in the computer experiments literature (Gramacy and Apley, 2015) and in spatial geo-statistics (Emery, 2009; Stroud et al., 2014; Datta et al., 2014). Some of the recent versions of the this idea are found to be amenable to parallel computations as well.

We adapt Banerjee et al. (2013) from usual GP regression to our compressed manifold regression setting. In particular, let

$$y = \tilde{\mu}_{\boldsymbol{\Phi}}(\boldsymbol{\Psi x}) + \epsilon_{\boldsymbol{\Phi}}(\boldsymbol{\Psi x}) + \epsilon,\ \epsilon \sim N(0, \sigma^2), \tag{8}$$

where $\tilde{\mu}_{\boldsymbol{\Phi}}(\boldsymbol{\Psi x}) = E[\mu(\boldsymbol{\Psi x}) \,|\, \boldsymbol{\Phi}\mu(\boldsymbol{X\Psi}')]$, $\epsilon_{\boldsymbol{\Phi}}(\boldsymbol{\Psi x}) \,|\, \sigma^2 \sim N(0, \sigma^2_\epsilon(\boldsymbol{x}))$, $\sigma^2_\epsilon(\boldsymbol{x}) = \sigma^2\left[\kappa(\boldsymbol{\Psi x}, \boldsymbol{\Psi x}; \lambda) - (\boldsymbol{\Phi k_x})'\left\{\boldsymbol{\Phi K}_1\boldsymbol{\Phi}'\right\}^{-1}(\boldsymbol{\Phi k_x})\right]$ and $\boldsymbol{k_x} = (\kappa(\boldsymbol{\Psi x}, \boldsymbol{\Psi x}_1; \lambda), ..., \kappa(\boldsymbol{\Psi x}, \boldsymbol{\Psi x}_n; \lambda))'$. Denoting $\boldsymbol{H}_1 = diag(\boldsymbol{K}_1 - \boldsymbol{K}_1\boldsymbol{\Phi}'(\boldsymbol{\Phi K}_1\boldsymbol{\Phi}')^{-1}\boldsymbol{\Phi K}_1) + \boldsymbol{I}$ and $\boldsymbol{H}_2 = \boldsymbol{K}_1\boldsymbol{\Phi}'(\boldsymbol{\Phi K}_1\boldsymbol{\Phi}')^{-1}\boldsymbol{\Phi}$, marginal posterior distributions of μ and σ^2 are available in analytical forms

$$\boldsymbol{\mu} \,|\, \boldsymbol{y} \sim t_n(\boldsymbol{m}_{RGP}, \boldsymbol{\Sigma}_{RGP}),\quad \sigma^2 \,|\, \boldsymbol{y} \sim IG(a_2, b_2),$$

where $a_2 = n/2$, $b_2 = \boldsymbol{y}'\left(\boldsymbol{H}_1 + \boldsymbol{H}_2\boldsymbol{K}_1\right)^{-1}\boldsymbol{y}/2$, $\boldsymbol{m}_{RGP} = \left[\boldsymbol{H}_2'\boldsymbol{H}_1^{-1}\boldsymbol{H}_2 + \boldsymbol{K}_1^{-1}\right]^{-1}\boldsymbol{H}_2'\boldsymbol{H}_1^{-1}\boldsymbol{y}$, $\boldsymbol{\Sigma}_{RGP} = (2b_2/n)\left[\boldsymbol{H}_2'\boldsymbol{H}_1^{-1}\boldsymbol{H}_2 + \boldsymbol{K}_1^{-1}\right]^{-1}$. Owing to the special structure of $\boldsymbol{\Sigma}_{RGP}$ and $\boldsymbol{m}_{RGP}$, $n \times n$ matrix inversion can be efficiently achieved by Sherman-Woodbury-Morrison matrix inversion technique.

Attention now turns to prediction from (8). The predictive of $\boldsymbol{y}^* = (y_1^*, ..., y_{n_{pred}}^*)'$ given $\boldsymbol{X}^* = \left(\boldsymbol{x}_1^{*'}, ..., \boldsymbol{x}_{n_{pred}}^{*'}\right)'$ and $\boldsymbol{\Psi}, \lambda$ for new n_{pred} subjects marginalizing out $(\boldsymbol{\mu}, \sigma^2)$ over their posterior distribution is available analytically as

$$\boldsymbol{y}^* | \boldsymbol{x}_1^*, ..., \boldsymbol{x}_{n_{pred}}^*, \boldsymbol{y} \sim t_n\left(\mu_{pred}, \sigma^2_{pred}\right), \tag{9}$$

where $\boldsymbol{K}_{pred} = \{\kappa(\boldsymbol{x}_i^*, \boldsymbol{x}_j^*; \lambda)\}_{i,j=1}^{n_{pred}}$, $\boldsymbol{K}_{pred,1} = \{\kappa(\boldsymbol{x}_i^*, \boldsymbol{x}_j; \lambda)\}_{i=1,j=1}^{i=n_{pred},j=n}$, $\boldsymbol{K}_{1,pred} = \boldsymbol{K}_{pred,1}'$, $H_3 = \boldsymbol{I} + diag(K_{pred} - K_{pred,1}\boldsymbol{\Phi}'(\boldsymbol{\Phi K}_1\boldsymbol{\Phi})^{-1}\boldsymbol{\Phi}K_{1,pred})$, $\mu_{pred} = \boldsymbol{K}_{pred,1}\boldsymbol{H}_2'\left(\boldsymbol{H}_1 + \boldsymbol{H}_2\boldsymbol{K}_1\right)^{-1}\boldsymbol{y}$, $\sigma^2_{pred} = (2b_1/n)\left[\boldsymbol{H}_3 + \boldsymbol{K}_{pred,1}\boldsymbol{\Phi}'(\boldsymbol{\Phi K}_1\boldsymbol{\Phi}')^{-1}\boldsymbol{\Phi K}_{1,pred} - \boldsymbol{K}_{pred,1}\boldsymbol{H}_2'(\boldsymbol{H}_1 + \boldsymbol{H}_2\boldsymbol{K}_1)^{-1}\boldsymbol{H}_2\boldsymbol{K}_{1,pred}\right]$. Evaluating the above expression requires inverting matrices of order $m_{\boldsymbol{\Phi}} \times m_{\boldsymbol{\Phi}}$. Model averaging is again employed to limit sensitivity over the choices of $\boldsymbol{\Psi}, \lambda$. Following similar calculations as in Section 2.3, model averaging weights are found to be

$$P(\mathcal{D} \,|\, \mathcal{M}_l) = \frac{1}{|\boldsymbol{H}_2\boldsymbol{K}_1 + \boldsymbol{H}_1|^{\frac{1}{2}}} \frac{2^{\frac{n}{2}}\Gamma(\frac{n}{2})}{\left[\boldsymbol{y}'\left(\boldsymbol{H}_2\boldsymbol{K}_1 + \boldsymbol{H}_1\right)^{-1}\boldsymbol{y}\right]^{\frac{n}{2}}(\sqrt{2\pi})^n}.$$

Model averaging is performed on a wide interval of possible m values determined by the "compressed sample size" $m_{\boldsymbol{\Phi}}$ and p, analogous to Section 2.3.

Although we focus in this article on using the Banerjee et al. (2013) approach within CGP for scaling to moderately large n, alternative low rank or scalable approximations to Gaussian processes can be substituted essentially without complication. For example, there has been a recent emphasis on methods that break the data into exhaustive and mutually exclusive subsets (Parikh and Boyd, 2011), run computation separately for each subset and then combine the results; such methods have been applied to GPs (Deisenroth and Ng, 2015) and have complexity that scales as $O\left(\left(\frac{n}{K}\right)^3\right)$, where K is the number of subsets. Choosing K large enough, with this approach, one can compute CGP with moderate sized subset in each processor followed by combining inferences from different subsets. This can be further reduced by using low rank approximations to the GPs within each subset.

An important question that remains is how much information is lost in compressing the high-dimensional feature vector to a much lower dimension? In particular, one would expect to pay a price for the huge computational gains in terms of predictive performance or other metrics. We address this question in two ways. First we argue satisfactory theoretical performance in prediction in a large p asymptotic paradigm in Section 4. Then, we will consider practical performance in finite samples using simulated and real data sets.

4. Convergence analysis

This section provides theory supporting the excellent practical performance of the proposed method. In our context the feature vector $\boldsymbol{x}$ is assumed to be $\boldsymbol{x} = \boldsymbol{z} + \boldsymbol{\delta}$, $\boldsymbol{z} \in \mathcal{M}$, $\boldsymbol{\delta} \in \mathcal{R}^p$. Compressing the feature vector results in compressing $\boldsymbol{z}$ and the noise followed by their addition, $\boldsymbol{\Psi x} = \boldsymbol{\Psi z} + \boldsymbol{\Psi\delta}$. The following two directions are used to argue that compression results in near optimal inference.

(A) When features lie on a manifold a two stage estimation procedure (compression followed by a Gaussian process regression) leads to optimal convergence properties. This is used to show that using $\{\boldsymbol{\Psi z}_i\}_{i=1}^n$ as features in the Gaussian process regression yields the optimal rate of convergence.

(B) Noise compression through $\boldsymbol{\Psi}$ mitigates the deleterious effect of noise in $\boldsymbol{x}$ on the resulting performance.

Let $\mu_0(\cdot)$ and $\mu(\cdot)$ be the true and the fitted regression functions respectively. Define $\rho(\mu, \mu_0)^2 = \frac{1}{n}\sum_{i=1}^n(\mu(\boldsymbol{x}_i) - \mu_0(\boldsymbol{x}_i))^2$ as the distance between μ, μ_0 under a fixed design. When the design is random, let $\rho(\mu, \mu_0)^2 = \int_{\mathcal{M}}(\mu(\boldsymbol{x}) - \mu_0(\boldsymbol{x}))^2 F(d\boldsymbol{x})$, where F is the marginal distribution of the features. Denote $\Pi(\cdot|y_1, ..., y_n)$ to be the posterior distribution given $y_1, ..., y_n$. Then the interest lies in the rate at which the posterior contracts around μ_0 under the metric $\rho(\cdot, \cdot)$. This calls for finding a sequence $\{\zeta_n\}_{n\geq 1}$ of lower bounds such that

$$\Pi(\rho(\mu, \mu_0) > \zeta_n \,|\, y_1, ..., y_n) \to 0,\ \text{as } n \to \infty. \tag{10}$$

Definition: Given two manifolds $\mathcal{M}$ and $\mathcal{N}$, a differentiable map $f : \mathcal{M} \to \mathcal{N}$ is called a diffeomorphism if it is a bijection and its inverse $f^{-1} : \mathcal{N} \to \mathcal{M}$ is differentiable. If these functions are r times continuously differentiable, f is called a C^r-diffeomorphism.

Our analysis builds on the following result (Theorem 2.3 in Yang and Dunson (2013)).

Theorem 1 *Assume $\mathcal{M}$ is a d dimensional $\mathcal{C}^{r_1}$ compact sub-manifold of $\mathcal{R}^p$. Let $G : \mathcal{M} \to \mathcal{R}^p$ be the embedding map so that $G(\mathcal{M}) \simeq \mathcal{M}$. Further assume $T : \mathcal{R}^p \to \mathcal{R}^m$ is a dimensionality reducing map s.t. the restriction $T_{\mathcal{M}}$ of T on $G(\mathcal{M})$ is a $\mathcal{C}^{r_2}$-diffeomorphism*

onto its image. Then for any $\mu_0 \in \mathcal{C}^s$ *with* $s \leq \min\{2, r_1 - 1, r_2 - 1\}$*, a Gaussian process prior on* μ *with features* $\{T(\boldsymbol{z}_i)\}_{i=1}^n$*,* $\boldsymbol{z}_i \in \mathcal{M}$*, leads to a posterior contraction rate at least* $\zeta_n = n^{-s/(2s+d)} \log(n)^{d+1}$*.*

This is a huge improvement upon the minimax optimal adaptive rate of $n^{-s/(2s+p)}$ without the manifold structure in the features. We use the above result in our context. Define the linear transformation $T(\boldsymbol{z}) = \boldsymbol{\Psi}\boldsymbol{z}$. Using properties of random projection matrix, we have that, given $\kappa \in (0,1)$, if the projected dimension $m > O(\frac{m}{\kappa^2}\log(Cp\kappa^{-1})\log(\phi_n^{-1}))$ then with probability greater than $1 - \phi_n$, the following relationship holds for every point $\boldsymbol{z}_i, \boldsymbol{z}_j \in \mathcal{M}$,

$$(1-\kappa)\sqrt{\frac{m}{p}}||\boldsymbol{z}_i - \boldsymbol{z}_j|| < ||T(\boldsymbol{z}_i) - T(\boldsymbol{z}_j)|| < (1+\kappa)\sqrt{\frac{m}{p}}||\boldsymbol{z}_i - \boldsymbol{z}_j||, \tag{11}$$

implying that T is a diffeomorphism onto its image with probability greater than $(1 - \phi_n)$. Define $\mathcal{A}_n = \{\text{Equation 11 holds}\}$ so that $P(\mathcal{A}_n) > 1 - \phi_n$.

$$\begin{aligned}
\Pi(d(\mu,\mu_0) > \zeta_n | y_1, ..., y_n) &= \Pi(d(\mu,\mu_0) > \zeta_n | y_1, ..., y_n, \mathcal{A}_n) P(\mathcal{A}_n) \\
&+ \Pi(d(\mu,\mu_0) > \zeta_n | y_1, ..., y_n, \mathcal{A}_n') P(\mathcal{A}_n') \\
&< \Pi(d(\mu,\mu_0) > \zeta_n | y_1, ..., y_n, \mathcal{A}_n) + P(\mathcal{A}_n') \\
&< \Pi(d(\mu,\mu_0) > \zeta_n | y_1, ..., y_n, \mathcal{A}_n) + \phi_n.
\end{aligned}$$

On $\mathcal{A}_n$, T is a diffeomorphism. Therefore, Theorem 1 implies that with features $\{T(\boldsymbol{z}_i)\}_{i=1}^n$ $\Pi(d(\mu,\mu_0) > \zeta_n | y_1, ..., y_n, \mathcal{A}_n) \to 0$. Finally, assuming $\phi_n \to 0$ yields $\Pi(d(\mu,\mu_0) > \zeta_n | y_1, ..., y_n) \to 0$ with features $\{T(\boldsymbol{z}_i)\}_{i=1}^n$. This proves (A).

Let $\boldsymbol{\Psi}^{(l)}$ be the l-th row of $\boldsymbol{\Psi}$, $l = 1, ..., m$. Denote $\boldsymbol{\Delta} = [\boldsymbol{\delta}_1 : \cdots : \boldsymbol{\delta}_n] \in \mathcal{R}^{p \times n}$ and assume $\boldsymbol{z}_i$ is the i-th row of $\boldsymbol{\Delta}$. Using Lemma 2.9.5 in Van der Vaart and Wellner (1996), we obtain

$$\sqrt{p}\sum_{j=1}^{p} \Psi_{lj}\boldsymbol{z}_j \to N(\boldsymbol{0}, \text{Cov}(\boldsymbol{z}_1)).$$

Therefore, $\sum_{j=1}^p \Psi_{lj}\boldsymbol{z}_j = O_p(p^{-1/2})$, reducing the magnitude of noise in the original features. Hence (B) is proved. Thus, even if noise exists, asymptotic performance of $\{T(\boldsymbol{x}_i)\}_{i=1}^n$ will be similar to $\{T(\boldsymbol{z}_i)\}_{i=1}^n$ in the GP regression (which by (A) has "optimal" asymptotic performance).

5. Simulation Examples

We assess the performance of compressed Gaussian process (CGP) regression in a number of simulation examples. We consider various numbers of features (p) and level of noise in the features (τ) to study their impact on the performance. In all the simulations out of sample predictive performance of the proposed CGP regression was compared to that of uncompressed Gaussian process (GP), BART (Bayesian Additive Regression Trees) Chipman et al. (2010), RF (Random Forests) Breiman (2001) and TGP (Treed Gaussian process) Gramacy and Lee (2008). Unfortunately, with massive number of features, traditional BART, RF and TGP are computationally prohibitive. Therefore, we consider compressed versions in

which we generate a single projection matrix to obtain a single set of compressed features, running the analysis with compressed features instead of original features. This idea leads to compressed versions of random forest (CRF), Bayesian additive regression tree (CBART) and Treed Gaussian process (CTGP). These methods entail faster implementation when the number of features is massive.

As a default in these analyses, we use $m = 60$, which seems to be a reasonable choice of upper bound for the dimension of the linear subspace to compress to. In addition, we implement two stage GP (2GP) where the p-dimensional features are projected into smaller dimension by using Laplacian eigenmap (Belkin and Niyogi, 2003; Guerrero et al., 2011) in the first stage and then a GP with projected features is fitted in the second stage. We also compared Lasso and partial least square regression (PLSR) to indicate advantages of our proposed method over linear regularizing methods. However, in presence of strong nonlinear relationship between the response and the features, Lasso and PLSR perform poorly and hence results for them are omitted.

When n is moderately large ~ 5000, to bypass heavy computational price associated with CGP for inverting an $n \times n$ matrix, we employ a low rank approximation of the compressed Gaussian process as described in Section 3. As an uncompressed competitor of CGP in settings with moderately large n, efficient Gaussian random projection technique Banerjee et al. (2013) is implemented. This is also referred to as the GP to avoid needless confusion. Along with GP, CBART and CRF are included as competitors. CTGP with moderately large n poses heavy computational burden and is, therefore, omitted.

As a more scalable competitor, we employ the popular two stage technique of clustering the massive sample into a number of clusters followed by fitting simple model such as Lasso in each of these clusters. To facilitate clustering of high dimensional features in the first stage, we use the spectral clustering algorithm (Ng et al., 2001) described in Algorithm 1. Once observations are clustered, separate Lasso is fitted in each of these clusters. Hence-

Algorithm 1 Spectral Clustering Algorithm

Input: features $\boldsymbol{x}_1, ..., \boldsymbol{x}_n$ and the number of clusters required $n.clust$.

- Form the affinity matrix $\boldsymbol{A} \in \mathcal{R}^{n \times n}$ defined by $A_{ij} = \exp\left(-||\boldsymbol{x}_i - \boldsymbol{x}_j||^2/2\sigma^2\right)$ if $i \neq j$, $A_{ii} = 0$, for some judicious choice of σ^2.
- Define $\boldsymbol{D}$ to be the diagonal matrix whose (i,i)-th entry is the sum of the elements in the i-th row of $\boldsymbol{A}$. Construct $\boldsymbol{L} = \boldsymbol{D}^{-1/2}\boldsymbol{A}\boldsymbol{D}^{-1/2}$.
- Find $\boldsymbol{s}_1, ..., \boldsymbol{s}_{n.clust}$ be the eigenvectors corresponding to the $n.clust$ largest eigenvalues of $\boldsymbol{L}$. Form the matrix $\boldsymbol{S} = [\boldsymbol{s}_1 : \cdots : \boldsymbol{s}_{n.clust}] \in \mathcal{R}^{n \times n.clust}$ by stacking the eigenvectors in column.
- Normalize so that each row of $\boldsymbol{S}$ has unit norm.
- Now treating each row of $\boldsymbol{S}$ as a point in $\mathcal{R}^{n.clust}$ cluster them into $n.clust$ clusters via $K - means$ clustering.
- Finally assign $\boldsymbol{x}_i$ in cluster j if the i th row of $\boldsymbol{S}$ goes to cluster j.

forth, we refer to this procedure as distributed supervised learning (DSL). Along with the above methods, for large moderately n, we also implement the Bayesian analogue of sparse

Gaussian process with dimension reduction (Snelson and Ghahramani, 2012), referred to as the SG method.

The model averaging step in CGP requires choosing a window over the possible values of m. When n is small, we adopt the choice suggested in Guhaniyogi and Dunson (2013) to have a window of $[\lceil 2log(p) \rceil, min(n,p)]$, which implies that the number of possible models to be averaged across is $s = min(n,p) - \lceil 2log(p) \rceil + 1$. When n is moderately large, we choose the window of $[\lceil 2log(p) \rceil, min(m_{\mathbf{\Phi}}, p)]$. The number of rows of $\mathbf{\Phi}$ is fixed at $m_{\mathbf{\Phi}} = 100$ for the simulation study with moderately large n. However, changing $m_{\mathbf{\Phi}}$ moderately does not alter the performance of CGP.

5.1 Manifold Regression on Swiss Roll

To provide some intuition for our model, we start with a concrete example where the distribution of the response is a nonlinear function of the coordinates along a swissroll, which is embedded in a high dimensional ambient space. To be more specific, we sample manifold coordinates, $t \sim U(\frac{3\pi}{2}, \frac{9\pi}{2})$, $h \sim U(0,3)$. A high dimensional feature $\boldsymbol{x} = (x_1, ..., x_p)$ is then sampled following

$$x_1 = t\cos(t) + \delta_1,\ x_2 = h + \delta_2,\ x_3 = t\sin(t) + \delta_3,\ x_i = \delta_i,\ i \geq 4, \delta_1, .., \delta_p \sim N(0, \tau^2).$$

Finally responses are simulated to have nonlinear and non-monotonic relationship with the features

$$y_i = \sin(5\pi t) + h^2 + \epsilon_i,\ \epsilon_i \sim N(0, 0.02^2). \tag{12}$$

Clearly, $\boldsymbol{x}$ and y are conditionally independent given θ, h, which is the low-dimensional signal manifold. In particular, $\boldsymbol{x}$ lives on a (*noise corrupted*) swissroll embedded in a p-dimensional ambient space (see Figure 1(a)), but y is only a function of coordinates along the swissroll $\mathcal{M}$ (see Figure 1(b)).

The geodesic distance between two points in a swiss roll can be substantially different from their Euclidean distance in the ambient space $\mathcal{R}^p$. For example, in Figure 1(c) two points joined by the line segment have much smaller Euclidean distance than geodesic distance. Theorem 1 in Section 4 guarantees optimal performance when the compact submanifold $\mathcal{M}$ is sufficiently smooth, so that the locally Euclidean distance serves as a good approximation of the geodesic distance. The Swiss roll presents a challenging set up for CGP, since points on $\mathcal{M}$ that are close in a Euclidean sense can be quite far in a geodesic sense.

To assess the impact of the number of features (p) and noise levels of the features (τ) on the performance of CGP, a number of simulation scenarios are considered in Table 1. For each of these simulation scenarios, we generate multiple datasets and present predictive inference such as mean squared prediction error (MSPE), coverage and lengths of 95% predictive intervals (PI) averaged over all replicates.

In our experiments, $\boldsymbol{y}$ and $\boldsymbol{X}$ are centered. To implement LASSO, we use `glmnet` (Friedman et al., 2009) package in R with the optimal tuning parameter selected through 10 fold cross validation. CRF, CBART and CTGP in R using `randomForest` (Liaw and Wiener, 2002), `BayesTree` (Chipman et al., 2009) and `tgp` (Gramacy, 2007) packages, respectively.

Simulation	sample size (n)	no. of features (p)	noise in the features (τ)
1	100	10,000	0.02
2	100	20,000	0.02
3	100	10,000	0.05
4	100	20,000	0.05
5	100	10,000	0.10
6	100	20,000	0.10

Figure 1: Simulated features and response on a *noisy* Swiss Roll, $\tau = 0.05$

5.1.1 MSPE Results

Predictive MSE for each of the simulation settings averaged over 50 simulated datasets is shown in Table 2. Subscripted values represent bootstrap standard errors for the averaged

MSPEs, calculated by generating 50 bootstrap datasets resampled from the MSPE values, finding the average MSPE of each, and then computing their standard error.

Table 2 shows that feeding randomly compressed features into any of the nonparametric methods leads to good predictive performance, while Lasso fails to improve much upon the null model (not shown here). For both $p = 10,000$ and $20,000$, when the swiss roll is corrupted with low noise, CGP performs significantly better than GP, while CBART and CRF provide competitive performance with GP. Increasing noise in the features results in deteriorating performances for all the competitors. CGP is an effective tool to reduce the effect of noise in the features, but at a *tipping point* (depending on n) noise distorts the manifold too much, and CGP starts performing similarly to GP. CRF and CTGP perform much worse than CGP in high noise scenarios, while CBART produces competitive performance. Two stage GP (2GP) performs much worse than all the other competitors; perhaps the two stage procedure is considerably more sensitive to noise. Increasing number of features does not alter MSPE for CGP significantly in presence of low noise, consistent with asymptotic results showing posterior convergence rates depend on the intrinsic dimension of $\mathcal{M}$ instead of p when features are concentrated close to $\mathcal{M}$. In the next section, we will study these aspects with increasing sample size and noise in the features.

	Noise in the feature			
		.02	.05	.10
$p = 10000$	CGP	$4.09_{0.08}$	$5.49_{0.08}$	$7.03_{0.11}$
	GP	$4.71_{0.10}$	$5.63_{0.10}$	$7.09_{0.12}$
	CRF	$4.13_{0.11}$	$6.23_{0.09}$	$7.44_{0.11}$
	CBART	$3.73_{0.13}$	$6.14_{0.10}$	$7.34_{0.12}$
	CTGP	$4.24_{0.14}$	$7.13_{0.11}$	$7.72_{0.14}$
	2GP	$5.72_{0.15}$	$6.55_{0.13}$	$7.85_{0.16}$
$p = 20000$	CGP	$4.43_{0.07}$	$6.21_{0.10}$	$7.28_{0.13}$
	GP	$4.86_{0.07}$	$6.25_{0.12}$	$7.18_{0.12}$
	CRF	$5.06_{0.11}$	$6.81_{0.11}$	$7.47_{0.13}$
	CBART	$4.84_{0.15}$	$6.77_{0.11}$	$7.33_{0.11}$
	CTGP	$5.59_{0.11}$	$7.40_{0.11}$	$7.51_{0.15}$
	2GP	$6.05_{0.10}$	$6.69_{0.13}$	$7.09_{0.19}$

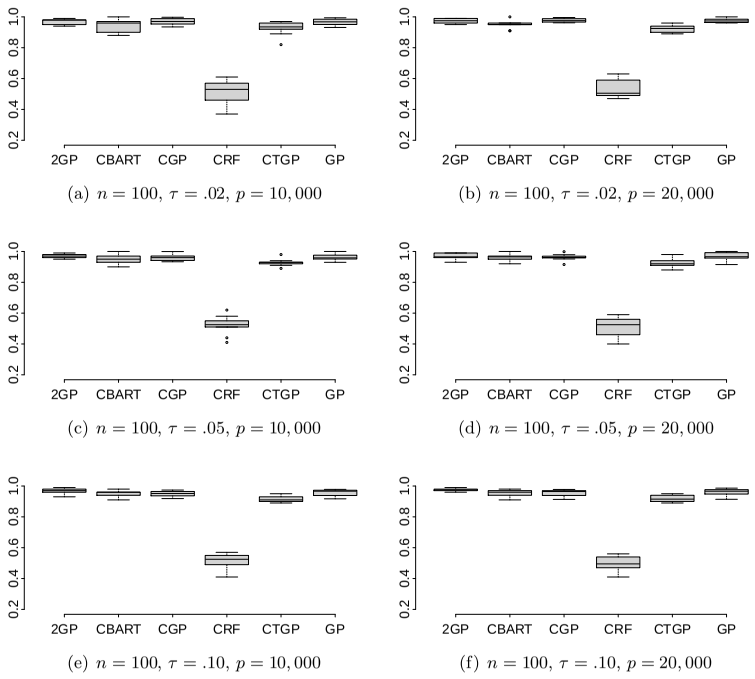
Table 2: Performance comparisons for competitors in terms of mean squared prediction errors (MSPE)

5.1.2 Coverage and Length of PIs

To assess if CGP is well calibrated in terms of uncertainty quantification, we compute coverage and length of 95% predictive intervals (PI) of CGP along with all the competitors. Although most frequentist methods such as CRF are unable to provide such coverage probabilities in producing point estimates, we present a measure of predictive uncertainty for those methods following the popular two stage plug-in approach, (i) estimate the regression function in the first stage; (ii) construct 95% PI based on the normal distribution centered

on the predictive mean from the regression model with variance equal to the estimated variance in the residuals. Boxplots for coverage probabilities in all the simulation cases are presented in Figure 2. Figure 3 presents median lengths of the 95% predictive intervals.

Both these Figures demonstrate that in all the simulation scenarios CGP, uncompressed GP, 2GP and CBART result in predictive coverage of around 95%, while CRF suffers from severe under-coverage. The gross under-coverage of CRF is attributed to the overly narrow predictive intervals. Additionally, CTGP shows some under-coverage, with shorter predictive intervals than CGP, GP, 2GP or CBART. CGP turns out to be an excellent choice among all the competitors in fairly broad simulation scenarios. We consider larger sample sizes and high noise scenarios in the next subsection.



(a) $n = 100$, $\tau = .02$, $p = 10,000$ (b) $n = 100$, $\tau = .02$, $p = 20,000$

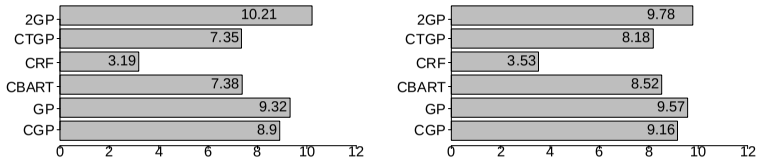
(c) $n = 100$, $\tau = .05$, $p = 10,000$ (d) $n = 100$, $\tau = .05$, $p = 20,000$

(e) $n = 100$, $\tau = .10$, $p = 10,000$ (f) $n = 100$, $\tau = .10$, $p = 20,000$

Figure 2: coverage of 95% PI's for CGP, GP, CBART, CTGP, CRF, 2GP

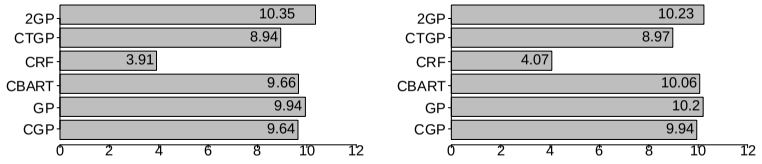
5.2 Manifold Regression on Swiss roll for Larger Samples

To assess how the relative performance of CGP changes for larger sample size, we implement manifold regression on swiss roll using methodologies developed in Section 3. For this simulation example, a data generation scheme similar to Section 5.1 is used. Ideally, larger



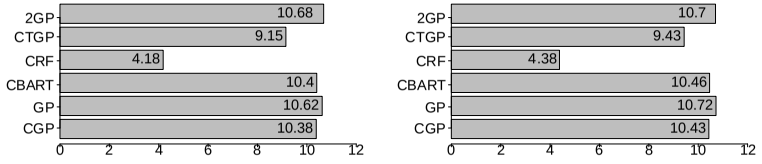
(a) $n = 100$, $\tau = .02$, $p = 10,000$

(b) $n = 100$, $\tau = .02$, $p = 20,000$



(c) $n = 100$, $\tau = .05$, $p = 10,000$

(d) $n = 100$, $\tau = .05$, $p = 20,000$



(e) $n = 100$, $\tau = .10$, $p = 10,000$

(f) $n = 100$, $\tau = .10$, $p = 20,000$

Figure 3: lengths of 95% PI's for CGP, GP, CBART, CRF, CTGP, 2GP

sample size should lead to better predictive performance. Therefore, one would expect more accurate prediction even with higher degree of noise in the features for larger sample size, as long as there is sufficient signal in the data. To accommodate higher signal than in Section 5.1, we simulate manifold coordinates as $t \sim U(\frac{3\pi}{2}, \frac{9\pi}{2})$, $h \sim U(0, 5)$ and sample responses as per (12). We also increase noise variability in the features for all the simulation settings. Simulation scenarios are described in Table 3.

MSPE of all the competing methods are calculated along with their bootstrap standard errors and presented in Table 4. Results in Table 4 provide more evidence supporting our conclusion in Section 5.1. With smaller noise variance, CGP along with other compressed methods outperform uncompressed GP and 2GP. However, when τ exceeds a certain limit, the manifold structure is more and more distorted, with performance of all the competitors worsening. In particular with increasing noise, performance of CGP and GP start becoming more comparable. On the other hand, SG method faces computational issues for $p \sim 10000 - 20000$ features. Therefore, we select only 500 features without disrupting the noisy manifold structure. Even with many fewer features, SG performs worse than CGP with

Simulation	sample size (n)	no. of features (p)	noise in the features (τ)
1	5,000	10,000	.03
2	5,000	20,000	.03
3	5,000	10,000	.06
4	5,000	20,000	.06
5	5,000	10,000	.10
6	5,000	20,000	.10

Table 3: Different Simulation settings for CGP for large n.

MSPE 46.3, 52.2 for $\tau = 0.03, 0.1$ respectively. Our investigation shows that the performance of SG is quite competitive when p is less than a few dozen. However, as p increases over a few hundreds, SG starts performing poorly. This is perhaps due to the fact that SG estimates a large number of poorly identifiable parameters resulting in inaccurate estimation. CGP with random compression of high dimensional features remarkably reduces the number of parameters to be estimated. Comparing results from the last section it is quite evident that with large samples, CGP is able to perform well even with very large number of features and moderate variance of noise in the features. This shows the effectiveness of CGP for large p and moderately large n when features are close to lying on a low-dimensional manifold.

In all the simulation scenarios, DSL is the best performer in terms of MSPE, consistent with the routine use of DSL in large scale settings. However, the performance is extremely sensitive to the choice of clusters. In real data applications often inaccurate clustering leads to suboptimal performance, as will be seen in the data analysis. Additionally, we are not just interested in obtaining a point prediction approach, but want to obtain methods that provide an accurate characterization of predictive uncertainty. With this in mind, we additionally examine coverage probabilities and lengths of 95% predictive intervals (PIs). Boxplots for coverage probabilities of 95% PI's are presented in Figure 4. Figure 5 presents

		Noise in the feature		
		.03	.06	.10
$p = 10,000$	CGP	$0.56_{0.06}$	$1.06_{0.03}$	$2.18_{0.08}$
	GP	$2.05_{0.32}$	$2.37_{0.35}$	$3.35_{0.42}$
	CRF	$1.05_{0.10}$	$2.16_{0.11}$	$3.52_{0.09}$
	CBART	$0.69_{0.07}$	$1.72_{0.11}$	$2.79_{0.13}$
	DSL	$0.50_{0.07}$	$0.52_{0.03}$	$0.50_{0.03}$
	2GP	$3.78_{0.31}$	$3.95_{0.41}$	$4.05_{0.38}$
$p = 20,000$	CGP	$1.17_{0.048}$	$2.11_{0.107}$	$2.57_{0.222}$
	GP	$1.98_{0.418}$	$2.33_{0.321}$	$2.78_{0.330}$

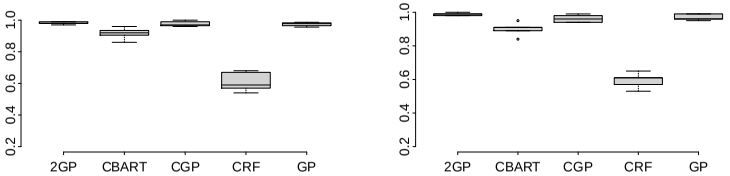
	CBART	$1.22_{0.092}$	$2.53_{0.151}$	$3.84_{0.192}$
	DSL	$0.48_{0.015}$	$0.45_{0.014}$	$0.57_{0.078}$
	2GP	$3.84_{0.581}$	$4.10_{0.370}$	$4.53_{0.481}$

Table 4: $MSPE \times 0.1$ along with the bootstrap $sd \times 0.1$ for all the competitors

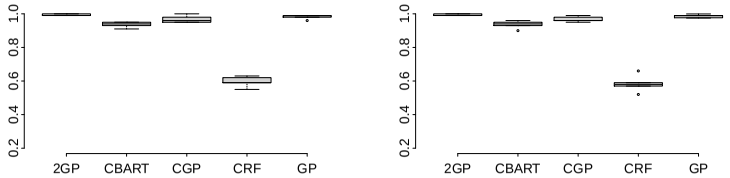
lengths of 95% prediction intervals for all the competitors. As expected, CGP, GP, 2GP

and CBART demonstrate better performance in terms of coverage. However, in low noise cases CGP and CBART achieve similar coverage with a two fold reduction in the length of PIs compared to GP or 2GP. CRF, like in the previous section, shows under-coverage with narrow predictive intervals. The predictive interval for CGP is found to be marginally wider than CBART with comparable coverage. With high noise, it becomes intractable to recover the manifold structure and hence performance is affected for all the competitors. It is observed that with high noise all approaches tend to have wider predictive intervals. DSL presents overly narrow predictive intervals (not shown here) yielding severe under-coverage.



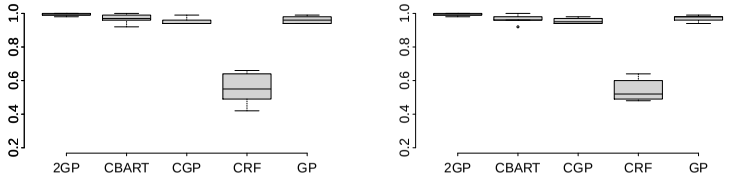
(a) $n = 5,000$, $p = 10,000$, $\tau = 0.03$

(b) $n = 5,000$, $p = 20,000$, $\tau = 0.03$



(c) $n = 5,000$, $p = 10,000$, $\tau = 0.06$

(d) $n = 5,000$, $p = 20,000$, $\tau = 0.06$



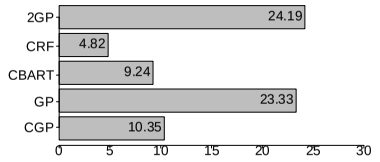
(e) $n = 5,000$, $p = 10,000$, $\tau = 0.10$

(f) $n = 5,000$, $p = 20,000$, $\tau = 0.10$

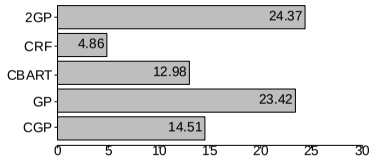
Figure 4: coverage of 95% PI's for CGP, GP, CRF, CBART, 2GP

5.3 Computation Time

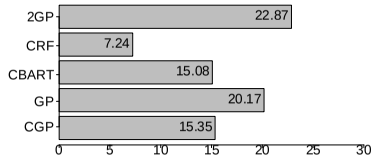
One of the major motivations in developing CGP was to improve computational scalability to large p settings. Clearly, the computational time for nonparametric estimation methods such as BART, TGP or RF applied to the original data will become notoriously prohibitive for large p, and hence we focus on comparisons with more scalable methods. The approach of applying BART, RF and TGP to the compressed features, which is employed in CBART,



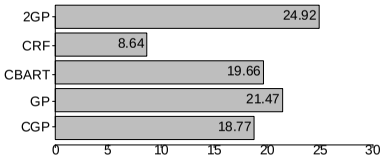
(a) $n = 5,000$, $\tau = .03$, $p = 10,000$



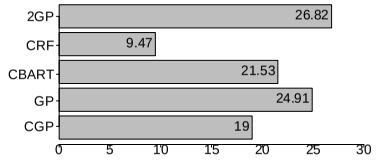
(b) $n = 5,000$, $\tau = .03$, $p = 20,000$



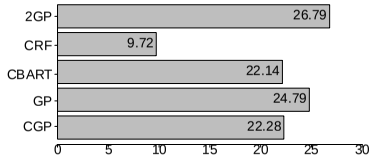
(c) $n = 5,000$, $\tau = .06$, $p = 10,000$



(d) $n = 5,000$, $\tau = .06$, $p = 20,000$



(e) $n = 5,000$, $\tau = .10$, $p = 10,000$



(f) $n = 5,000$, $\tau = .10$, $p = 20,000$

Figure 5: lengths of 95% PI's for CGP, GP, CBART, CRF, 2GP

CRF and CTGP respectively, is faster to implement. Using R code in a standard server, the computing time for 2,000 iterations of CBART for $n = 100$ and $p = 10,000, 20,000$ are only $7.21, 8.36$ seconds, while CGP has run time of $7.48, 8.05$ seconds, respectively. Increasing n moderately, we find CBART and CGP have similar run time. CRF is a bit faster than both of them, while CTGP has run time $37.64, 38.33$ seconds for $p = 10,000, 20,000$ respectively. For moderate n, 2GP is found to have similar run time as CBART.

With large n, CTGP is impractically slow and hence omitted in the comparison. GP needs to calculate and store a distance matrix of p features. Apart from the storage bottleneck, the computational complexity is $O(n^2p)$. CGP instead proposes calculating and storing a distance matrix of m compressed features, with a computational complexity of $O(n^2m)$. Computation time for CGP additionally depends on a number of factors, (i) Gram Schmidt orthogonalization of m rows of $m \times p$ matrices, (ii) inverting an $m_{\mathbf{\Phi}} \times m_{\mathbf{\Phi}}$ matrix, (iii) multiplying $n \times p$ and $p \times m$ matrices. Along with these three steps, one requires multiplying $m_{\mathbf{\Phi}} \times n$ matrix $\mathbf{\Phi}$ with $n \times n$ matrix K_1 at each MCMC iteration that incurs a computation complexity of order $n^2 m_{\mathbf{\Phi}}$. Typically the computation complex-

ity is dominated by n^2 and hence scaling with sample size is computationally feasible for about $n \sim 10000$ observations. For much larger n, one can resort to distributed GP based approaches as mentioned in Section 3. On the other hand, SPGP with dimensionality reduction (SG method) introduces exorbitantly large number of parameters even for moderate p.

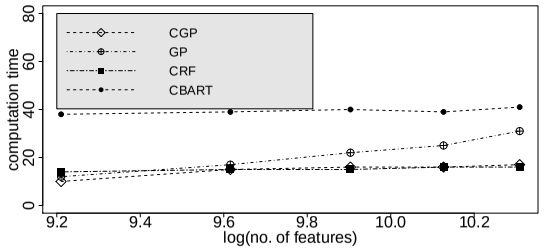
Figure 6 shows the computational speed comparison between CGP, GP, CBART and CRF for various n and p. Computational speed is recorded assuming existence of a number of processors on which parallelization can be executed. As n increases, CGP enjoys substantial computational advantage over competitors. The computational advantage is especially notable over CBART and GP. Run times of DSL are also recorded for $n = 5,000$ and $p = 10,000, 15,000, 20,000, 25,000, 30,000$ and they are $449, 599, 737, 945, 1158$ seconds, respectively. Alternatively, 2GP involves creating adjacency matrices followed by an eigen-decomposition of an $n \times n$ matrix. Both these steps are computationally demanding. We find 2GP takes $602, 723, 856, 983, 1108$ seconds to run for $n = 5000$ and $p = 10000, 15000, 20000, 25000, 30000$, respectively. Therefore, CGP can outperform even a simple two stage estimation procedure such as DSL in terms of computational speed.

6. Application to Face Images

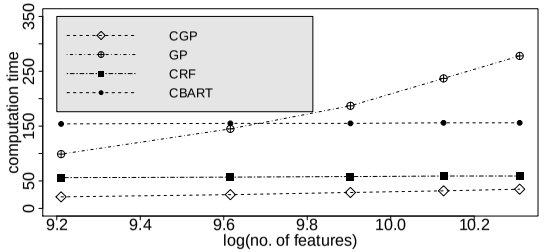
In our simulation examples, the underlying manifold is three dimensional and can be directly visualized. In this section we present an application in which both the dimension and the structure of the underlying manifold is unknown. The dataset consists of 698 images of an artificial face and is referred to as the *Isomap face data* (Tenenbaum et al., 2000). A few such representative images are presented in Figure 7. Each image is labeled with three different variables: illumination-, horizontal- and vertical-orientation. Two dimensional projections of the images are presented in the form of 64×64 pixel matrices. Intuitively, a limited number of additional features are needed for different views of the face. This is confirmed by the recent work of Levina and Bickel (2004); Aswani et al. (2011) where the intrinsic dimensionality is estimated to be small from these images. More details about the dataset can be found in `http://isomap.stanford.edu/datasets.html`.

We apply CGP and all the competitors to the dataset to assess relative performances. To set up the regression problem, we consider horizontal pose angles (vary in $[-75^0, 75^0]$) of the images, after standardization, as the responses. The features are taken $64 \times 64 = 4096$ dimensional vectorized images for each sample. To simulate more realistic situations, $N(0, \tau^2)$ noise is added to each pixel of the images, with varying τ, to make predictive inference more challenging from the noisy images. We carry out random splitting of the data into $n = 648$ training cases and $n_{pred} = 50$ test cases and run all the competitors to obtain predictive inference in terms of MSPE, length and coverage of 95% predictive intervals. To avoid spurious inference due to small validation set, this experiment is repeated 50 times.

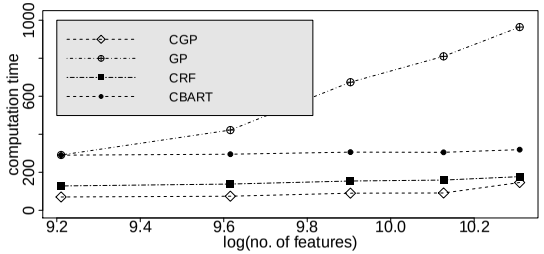
Table 5 presents MSPE for all the competing methods averaged over 50 experiments along with their standard errors computed using 100 bootstrap samples. Note that, because of the standardization, the null model yields MSPE 1. It is clear from Table 5 that CGP along with its compressed competitors explain a lot of variation in the response. DSL and 2GP are the worst performers in terms of MSPE. This is consistent with our experience that, in the presence of a complex and unknown manifold structure along with noise, DSL



(a) $n = 1,000$



(b) $n = 3,000$



(c) $n = 5,000$

Figure 6: Computational time in seconds for CGP, GP, CBART, CRF against log of the number of features.

can be unreliable relative to CGP which tends to be more robust to the type of manifold and noise level. GP also performs much worse than CGP and other compressed competitors especially in presence of small amount of noise in the features. As the noise in the features increases, performance of CGP and GP are found to be comparable. On the other hand

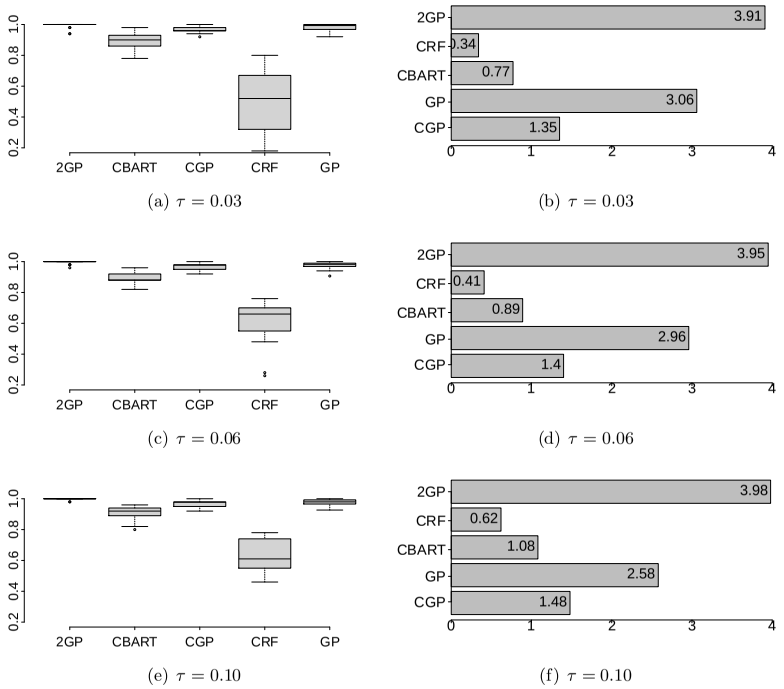
Figure 7: Representative images from the Isomap face data.

τ	CGP	GP	CBART	CRF	DSL	2GP
0.03	$0.07_{0.004}$	$0.85_{0.054}$	$0.07_{0.005}$	$0.06_{0.009}$	$0.70_{0.010}$	$0.98_{0.001}$
0.06	$0.08_{0.008}$	$0.75_{0.043}$	$0.09_{0.008}$	$0.10_{0.012}$	$0.78_{0.015}$	$0.94_{0.022}$
0.10	$0.09_{0.003}$	$0.68_{0.041}$	$0.11_{0.006}$	$0.11_{0.004}$	$0.83_{0.024}$	$0.98_{0.001}$

Table 5: MSPE and standard error (computed using 100 bootstrap samples) for all the competitors over 50 replications

SG implemented with only a subset of 500 features yields much worse performance (MSPE 0.97, 0.98 for $\tau = 0.1, 0.03$) respectively.

To see how well calibrated these methods are, Figure 8 provides coverage probabilities along with the lengths of predictive intervals for all the competitors. It is evident from the Figure that CGP, CBART, GP and 2GP yield excellent coverage. However, for CGP and CBART this coverage is achieved with much narrower predictive intervals compared to GP and 2GP. On the other hand, both CRF and DSL produce extremely narrow predictive intervals resulting in severe under-coverage. In fact for $\tau = 0.03, 0.06, 0.10$, length of 95% predictive intervals for DSL are $0.13, 0.19, 0.21$ respectively. Therefore, both in terms of MSPE and predictive coverage, CGP does a good job. More importantly, these results serve as a testimony of the robust performance demonstrated by compressed Bayesian nonparametric methods (CGP being one of them) even in the presence of unknown and complex manifold structure in the features.



(a) $\tau = 0.03$ (b) $\tau = 0.03$

(c) $\tau = 0.06$ (d) $\tau = 0.06$

(e) $\tau = 0.10$ (f) $\tau = 0.10$

7. Discussion

The overarching goal of this article is to develop nonparametric regression methods that scale to large/very large p and/or moderately large $n \sim 5000$ when features lie on a *noise corrupted* manifold. The statistical and machine learning literature is somewhat limited in robust and flexible methods that can accurately provide predictive inference for large p with moderately large sample size, while taking into account the geometric structure. We develop a method based on nonparametric *low-rank* Gaussian process methods combined with random feature compression to accurately characterize predictive uncertainties quickly, bypassing the need to estimate the underlying manifold. The computational template exploits model averaging to limit sensitivity of the inference to the specific choices of the random

projection matrix $\mathbf{\Psi}$. The proposed method is also guaranteed to yield minimax optimal convergence rates.

There are many future directions motivated by our work. For example, the present work uses Banerjee et al. (2013) that is less suitable for massive n. It is quite straightforward to extend CGP to massive n by directly applying recently developed approaches for distributed computation in GP models (Deisenroth and Ng, 2015). Also the present work is not able to estimate the true dimensionality of the noise corrupted manifold. Arguably, a nonparametric method that can simultaneously estimate the intrinsic dimensionality of the manifold in the ambient space would improve performance both theoretically and practically. One possibility is to simultaneously learn the marginal distribution of the features, accounting for the low-dimensional structure. Other possible directions include adapting to massive streaming data where inference is to be made online. Although random compression both in n and p provides substantial benefit in terms of computation and inference, it might be worthwhile to learn the matrices $\mathbf{\Psi}$, $\mathbf{\Phi}$ while attempting to limit the associated computational burden.

Abstract

Accurate classification of categorical outcomes is essential in a wide range of applications. Due to computational issues with minimizing the empirical 0/1 loss, Fisher consistent losses have been proposed as viable proxies. However, even with smooth losses, direct minimization remains a daunting task. To approximate such a minimizer, various boosting algorithms have been suggested. For example, with exponential loss, the AdaBoost algorithm (Freund and Schapire, 1995) is widely used for two-class problems and has been extended to the multi-class setting (Zhu et al., 2009). Alternative loss functions, such as the logistic and the hinge losses, and their corresponding boosting algorithms have also been proposed (Zou et al., 2008; Wang, 2012). In this paper we demonstrate that a broad class of losses, including non-convex functions, achieve Fisher consistency, and in addition can be used for explicit estimation of the conditional class probabilities. Furthermore, we provide a generic boosting algorithm that is not loss-specific. Extensive simulation results suggest that the proposed boosting algorithms could outperform existing methods with properly chosen losses and bags of weak learners.

Keywords: Boosting, Fisher-Consistency, Multiclass Classification, SAMME

1. Introduction

Accurate classification of multi-class outcomes is essential in a wide range of applications. To construct an accurate classifier for the outcome $C \in \{1, ..., n\}$ based on a predictor vector $\mathbf{X}$, the target is often to minimize a misclassification rate, which corresponds to a 0/1 loss. We assume that the data $(C, \mathbf{X}^T)^T$ is generated from a fixed but unknown distribution $\mathscr{P}$. Specifically, one would aim to identify $\mathbf{f} = \{f_1(\cdot), ..., f_n(\cdot)\}$ that maximizes the misclassification rate

$$\mathbb{L}(\mathbf{f}) = \mathbb{E}\left[\mathbb{1}\{C \neq c_{\mathbf{f}}(\mathbf{X})\}\right] = \mathbb{P}\left\{C \neq c_{\mathbf{f}}(\mathbf{X})\right\}^{1}, \tag{1}$$

under the constraint $\sum_j f_j(\mathbf{X}) = 0$, where $\mathbb{1}(\cdot)$ is the indicator function and for any $\mathbf{f}$, $c_{\mathbf{f}}(\mathbf{X}) = \text{argmax}_j f_j(\mathbf{X})$. Obviously, $\mathbf{f}_{\text{Bayes}} = \{f_{\text{Bayes},j}(\cdot) = \mathbb{P}(C = j \mid \cdot) - n^{-1}, j = 1, ..., n\}$ minimizes (1). In practice, one may approximate the Bayes classifier $c_{\mathbf{f}_{\text{Bayes}}}(\cdot)$ by modeling $\mathbb{P}(C = j \mid \cdot)$ parametrically or non-parametrically. However, due to the curse of dimensionality and potential model mis-specification, such direct modeling may not work well when the underlying conditional risk functions are complex. On the other hand, due to both the discontinuity and the discrete nature of the empirical 0/1 loss, direct minimization is often computationally undesirable.

To overcome these challenges, many novel statistical procedures have been developed by replacing the 0/1 loss with a *Fisher consistent* loss ϕ such that its corresponding minimizer can be used to obtain the Bayes classifier. Lin (2004) showed that a class of smooth convex functions can achieve Fisher consistency (FC) for binary classification problems. Zou et al. (2008) further extended these results to the multi-class setting. Support vector machine (SVM) methods have been shown to yield Fisher consistent results for both binary and multi-class settings (Lin, 2002; Liu, 2007). Relying on these FC results, boosting algorithms for approximating the minimizers of the loss functions have also been proposed for specific choices of losses. Boosting algorithms search for the optimal solution by greedily aggregating a set of "weak-learners" $\mathcal{G}$ via minimization of an empirical risk, based on a loss function ϕ. The classical AdaBoost algorithm (Freund and Schapire, 1995) for example is based on the minimization of the exponential loss, $\phi(x) = e^{-x}$, using the forward stagewise additive modeling (FSAM) approach. Hastie et al. (2009) showed that the population minimizer of the AdaBoost algorithm corresponds to the Bayes rule $c_{\mathbf{f}_{\text{Bayes}}}(\cdot)$ for the two-class setting. Zhu et al. (2009) extended this algorithm and developed the Stagewise Additive Modeling using a Multi-class Exponential (SAMME) algorithm for the multi-class case.

Most existing work on Fisher consistent losses focuses on convex functions such as $\phi(x) = e^{-x}$ and $\phi(x) = |1 - x|_+$. However, there are important papers advocating the usage of non-convex loss functions, which we will briefly discuss here. Inspired by Shen et al. (2003), Collobert et al. (2006) explores SVM type of algorithms with the non-convex "ramp" loss instead of the typical "hinge" loss in order to speed up computations. Bartlett et al. (2006) consider the concept of "classification calibration" in the two-class case. Classification calibration of a loss can be understood as uniform FC, along all possible conditional probabilities on the simplex. They demonstrate that non-convex losses such as $1 - \tan(kx), k > 0$ can be classification calibrated in the two class case. More generally, Tewari and Bartlett (2007) extend classification calibration to the multiclass case, and provide elegant characterization theorems. We will draw a link between our work and the work of Tewari and Bartlett (2007) in Section 2.

Asymptotically, procedures such as the AdaBoost based on FC losses would lead to the optimal Bayes classifier, provided sufficiently large space of weak learner set $\mathcal{G}$. However, in finite samples, the estimated classifiers are often far from optimal, and the choice of the loss ϕ could greatly impact the accuracy of the resulting classifier. In this paper, we consider

1. Here the expectation and probability are both with respect to the unknown true distribution $\mathscr{P}$.

a broad class of loss functions that are potentially non-convex and demonstrate that the minimizer of these losses can lead to the Bayes rules for multi-category classification, and in fact can be used to explicitly restore the conditional probabilities. Moreover, we propose a generic algorithm leading to local minimizers of these potentially non-convex losses, which as we argue, can also recover the Bayes rule. The last observation has important consequences in practice, as global minimization of non-convex losses remains a challenging problem. On the other hand, non-convex losses, although not commonly used in the existing literature, could be more robust to outliers (Masnadi-Shirazi and Vasconcelos, 2008). The rest of the paper is organized as follows. In section 2 we detail the conditions for the losses and their corresponding FC results. In settings where the cost of misclassification may not be exchangeable between classes, we generalize our FC results to a weighted loss that accounts for differential costs. In section 3, we propose a generic boosting algorithm for approximating the minimizers and study some of its numerical convergence aspects. In section 4 we present simulation results and real data analysis comparing the performance of our proposed procedures to that of some existing methods including the SAMME. In addition in Section 4 we apply our proposed algorithms to identify subtypes of diabetic neuropathy with EMR data from the Partners. These numerical studies suggest that our proposed methods, with properly chosen losses, could potentially provide more accurate classification than existing procedures. Additional discussions are given section 5. Proofs of the theorems are provided in Appendix A.

2. Fisher Consistency for a general class of loss functions

In this section we characterize a broad class of loss functions which we deem relaxed Fisher consistent. This class encompasses previous classes of loss functions, provided in Zou et al. (2008), but also admits non-convex loss functions.

2.1 Fisher Consistency for 0/1 Loss

Suppose the training data available consists of N realizations of $(C, \mathbf{X}^T)^T$ drawn from $\mathscr{P}$, and let $\mathscr{D} = \{(C_i, \mathbf{X}_i^T)^T, i = 1, \ldots, N\}$. Moreover, we assume throughout that:

$$\min_{j \in \{1,\ldots,n\}} \mathbb{P}(C = j|\mathbf{X}) > 0 : \text{almost surely in } \mathbf{X}. \tag{2}$$

Assumption (2) states that any class C has a chance to be drawn for all $\mathbf{X}$, except on a set of measure 0, where determinism in the class assignment is allowed. For a given C, define a corresponding $n \times 1$ vector $\mathbf{Y}_C = (\mathbb{1}(C = 1), \ldots, \mathbb{1}(C = n))^T$. Under this notation, clearly $\mathbf{Y}_C^T \mathbf{f}(\mathbf{X}) = f_C(\mathbf{X})$. For identifiability the following constraint is commonly used in the existing literature (Lee et al., 2004; Zou et al., 2008; Zhu et al., 2009, e.g.) :

$$\sum_{j=1}^{n} f_j(\cdot) = 0. \tag{3}$$

To identify optimal $\mathbf{f}(\cdot)$ for classifying C based on $\mathbf{f}(\mathbf{X})$, we consider continuous loss functions ϕ as alternatives to the 0/1 loss and aim to minimize

$$\mathbb{L}_\phi(\mathbf{f}) = \mathbb{E}[\phi\{\mathbf{Y}_C^T \mathbf{f}(\mathbf{X})\}] = \mathbb{E}[\phi\{f_C(\mathbf{X})\}] = \sum_{j=1}^{n} \mathbb{E}[\phi\{f_j(\mathbf{X})\}\mathbb{P}(C = j \mid \mathbf{X})], \tag{4}$$

under the constraint (3). The loss function ϕ is deemed Fisher consistent Fisher consistent if the global minimizer (assuming it exists) $\mathbf{f}_\phi = \text{argmin}_{\mathbf{f}:\sum_j f_j = 0} \mathbb{L}_\phi(\mathbf{f})$ satisfies

$$c_{\mathbf{f}_\phi}(\mathbf{X}) = {}^2 c_{\mathbf{f}_{\text{Bayes}}}(\mathbf{X}). \tag{5}$$

Hence, with a Fisher consistent loss ϕ, the resulting $\text{argmax}_j \mathbf{f}_\phi(x)$ has the nice property of recovering the optimal Bayes classifier for the 0/1 loss. Clearly, the global minimizer $\mathbf{f}_\phi(x)$ also minimizes $\mathbb{E}[\phi\{f_C(\mathbf{X})\} \mid \mathbf{X} = x]$ for almost all x [3]. With a given data $\mathscr{D}$, we may approximate $\mathbf{f}_\phi$ by minimizing the empirical loss function

$$\widehat{L}_\phi(\mathbf{f}) = \frac{1}{N}\sum_{i=1}^{N} \phi\{\mathbf{Y}_{C_i}^T \mathbf{f}(\mathbf{X}_i)\} = \frac{1}{N}\sum_{i=1}^{N} \phi(f_{C_i}(\mathbf{X}_i)) = \frac{1}{N}\sum_{j=1}^{n}\sum_{i=1}^{N} \phi(f_j(\mathbf{X}_i))\mathbb{I}(C_i = j),$$

to obtain $\widehat{\mathbf{f}} = \text{argmin}_{\mathbf{f}:\sum_j f_j = 0} \widehat{L}_\phi(\mathbf{f})$.

Existing literature on the choice of ϕ focuses almost entirely on convex losses other than a few important exceptions (Bartlett et al., 2006; Tewari and Bartlett, 2007, e.g.). Here, we propose a general class of ϕ to include non-convex losses and generalize the concept of FC as we defined in (5). Specifically, we consider all continuous ϕ satisfying the following properties:

$$\phi(x) - \phi(x') \geq (g(x) - g(x'))k(x') \quad \text{for all } x \in \mathbb{R}, x' \in S = \{z \in \mathbb{R} : k(z) \leq 0\}, \tag{6}$$

where g and k are both strictly increasing continuous functions, with $g(0) = 1, \inf_{x\in\mathbb{R}} g(x) = 0, \sup_{x\in\mathbb{R}} g(x) = +\infty$, $k(0) < 0$ and $\sup_{z\in\mathbb{R}} k(z) \geq 0$. This suggests[4] that $\phi\{g^{-1}(\cdot)\}$ is continuously differentiable and convex on the set $g(S) = \{g(z) : z \in S\}$. However, ϕ itself is not required to be convex or differentiable. Extensively studied convex losses such as $\phi(x) = e^{-x}$ and $\phi(x) = \log(1 + e^{-x})$ both satisfy these conditions. For $\phi(x) = e^{-x}$, (6) would hold if we let $g(x) = e^x$ and $k(x) = -e^{-2x}$. For the logistic loss $\phi(x) = \log(1 + e^{-x})$, we may let $g(x) = e^{cx}$ and $k(x) = -\{ce^{cx}(1 + e^x)\}^{-1}$ for any positive constant $c > 0$. Alternatively, $g(x) = e^x(1 + e^x)/2$ and $k(x) = -2\{e^x(1 + e^x)(1 + 2e^x)\}^{-1}$ would also satisfy (6) for the logistic loss. Our class of losses also allows non-convex functions. For example, $\phi(x) = \log(\log(e^{-x} + e))$ is a non-convex loss and (6) holds if $g(x) = e^x$ and $k(x) = -\{e^x(e^{x+1} + 1)\log(e^{-x} + e)\}^{-1}$. On an important note, we would like to mention that all three examples above can be seen to fall into the general class of classification calibrated loss functions in the two class case, as defined by Bartlett et al. (2006) and hence are FC in the two-class case. We will see a more general statement relating condition (6) to the notion of classification calibration in the two class case (see Remark 2.2 below).

Next, we extend the FC property (5), to allow for more generic classification rules. For a loss function ϕ, if there exists a functional $\mathcal{H}$ such that the minimizer of (4) has the property:

$$\underset{j\in\{1,\ldots,n\}}{\text{argmax}}\, \mathcal{H}\{f_{\phi,j}(\mathbf{X})\} = c_{\mathbf{f}_{\text{Bayes}}}(\mathbf{X}), \tag{7}$$

2. Formally the "=" in (5) should be understood as "⊆". For the sake of simplicity, we keep this slight abuse of notation consistent throughout the paper.
3. Provided that this minimizer of $\mathbb{E}[\phi\{f_C(\mathbf{X})\} \mid \mathbf{X}]$ exists on a set of probability 1, and $\mathbb{E}[|\phi\{f_C(\mathbf{X})\}|] < \infty$ so that Fubini's theorem holds.
4. We provide a formal proof of this fact in Appendix A under Lemma A.1.

then we call it *relaxed* Fisher consistent (RFC). Obviously, the RFC property would still recover the Bayes classifier. Moreover FC losses are special cases of the RFC losses with an increasing $\mathcal{H}$.

We will now point out a connection between RFC and multiclass classification calibration as defined by Tewari and Bartlett (2007). Re-casting the definition of multiclass classification calibration to our framework, it requires that for any vector $\mathbf{w}$ on the simplex, the minimizer (assuming that it exists):

$$\widehat{\mathbf{F}}(\mathbf{w}) = \underset{\mathbf{F}:\sum_j F_j=0}{\operatorname{argmin}} \sum_{i=1}^{n} \phi(F_j) w_j \text{ satisfies } \underset{j\in\{1,\ldots,n\}}{\operatorname{argmax}} \mathcal{H}(\phi(\widehat{F}_j)) = \underset{j\in\{1,\ldots,n\}}{\operatorname{argmax}} w_j, \tag{8}$$

for some functional $\mathcal{H}$. In words, classification calibration ensures that regardless of the conditional distribution of $C|\mathbf{X}$, one can recover the Bayes rule. In contrast, RFC requires this to happen for the distribution at hand $C|\mathbf{X}$, for ($\mathscr{P}$ almost) all $\mathbf{X}$. This subtle but important distinction makes a difference. Example 4 in Tewari and Bartlett (2007) shows that if ϕ is positive and convex the conditions in (8) cannot be met for all vectors $\mathbf{w}$ on the simplex, when we have at least 3 classes. On the contrary, in the present paper we argue that in fact condition (8) remains plausible for both convex and non-convex losses, provided that we require that the points $\mathbf{w}$ are not allowed to be vertexes of the simplex (i.e. $w_j > 0$ for all j), which relates back to assumption (2).

The next result justifies that the proposed losses satisfying (6) are RFC with $\mathcal{H}(x) = H_\phi(x) \equiv g(x)k(x)$. We first present in Theorem 2.1 the property of a general constrained minimization problem, which is key to establishing the RFC.

Theorem 2.1 *For a loss ϕ satisfying (6), consider the optimization problem with some given $w_j > 0$:*

$$\min_{\mathbf{F}=(F_1,\ldots,F_n)^T} \sum_{j=1}^{n} \phi(F_j) w_j \quad \textit{under the constraint} \quad \prod_{j=1}^{n} g(F_j) = 1. \tag{9}$$

Assume that there exists a minimum denoted by $\widehat{\mathbf{F}} = (\widehat{F}_1, \ldots, \widehat{F}_n)^T$. Then the minimizer $\widehat{\mathbf{F}}$ must satisfy

$$H_\phi(\widehat{F}_j) w_j = \mathcal{C} \quad \textit{for some } \mathcal{C} < 0. \tag{10}$$

Moreover, if the function $H_\phi(\cdot)$ is strictly monotone there is a unique point with the property described above.

This result indicates that $H_\phi(\widehat{F}_j)$ is inversely proportional to the weight w_j. Now, consider $g(x) = \exp(x)$, $w_j = \mathbb{P}(C = j|\mathbf{X} = x)$, and $F_j = f_j(x)$, where we hold x . Then we can recover $c_{\mathbf{f}_{\text{Bayes}}}(x)$ by classifying C according to $\operatorname{argmax}_j \{-H_\phi(\widehat{F}_j)\}^{-1} = \operatorname{argmax}_j H_\phi(\widehat{F}_j)$ (the negative sign comes in because $\mathcal{C} < 0$), which implies that ϕ is RFC. Note that when $H_\phi(\cdot)$ is not increasing, Theorem 2.1 does not immediately imply that ϕ is a Fisher consistent loss according to definition (5), because the Bayes classifier need not be recovered by $\operatorname{argmax}_j \widehat{F}_j$. Nevertheless, we have the following:

Proposition 2.2 *Assume the same conditions as in Theorem 2.1. Then in addition to (10) we have:*

$$\underset{j\in\{1,\ldots,n\}}{\operatorname{argmax}} \widehat{F}_j = \underset{j\in\{1,\ldots,n\}}{\operatorname{argmax}} w_j,$$

and hence ϕ is also FC in the sense of (5).

The validity of Proposition 2.2 can be deduced from Theorem 2.1 and an application of Lemma 4 of Tewari and Bartlett (2007), but for completeness we include a simple standalone proof in Appendix A. While Proposition 2.2 states that ϕ is FC, Theorem 2.1 suggests that in addition to classification, one can recover conditional probabilities by calculating:

$$w_j = \frac{\{H_\phi(\widehat{F}_j)\}^{-1}}{\sum_{j=1}^{n} \{H_\phi(\widehat{F}_j)\}^{-1}}. \tag{11}$$

It is also worth noting here that the constraint in (9), generalizes the typical identifiability constraint (3), and the two coincide when $g(\cdot) = \exp(\cdot)$. We proceed by formulating a sufficient condition for the optimization problem in Theorem 2.1 to have a minimum without requiring the convexity or differentiability of ϕ.

Theorem 2.3 *The optimization problem in Theorem 2.1 has a minimum if either of the following conditions holds:*

i. ϕ is decreasing on the whole $\mathbb{R}$ and for all $c > 0$:

$$c\phi(g^{-1}(x)) + \phi(g^{-1}(x^{1-n})) \uparrow +\infty, \ \textit{as } x \downarrow 0, \tag{12}$$

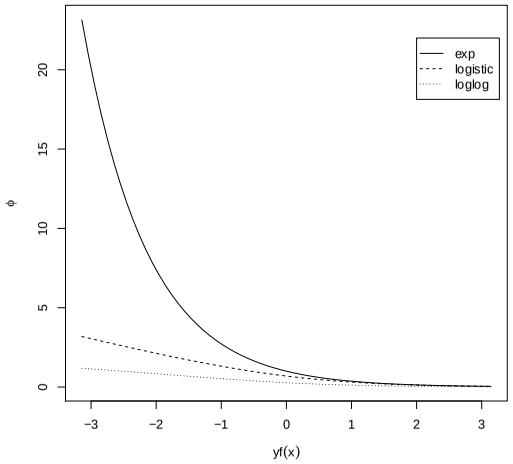
ii. ϕ is not decreasing on the whole $\mathbb{R}$.

Remark 2.1 *It follows that in any case, problem (9) has a minimum when the loss function is bounded from below and unbounded from above.*

Remark 2.2 *Take $g = \exp$ to match the constraint in (9) with the constraint considered by Bartlett et al. (2006). It turns out that a loss function obeying (6) and either i. or ii in Theorem 2.3. is classification calibrated in the two class case. See and Lemma A.2 in Appendix A for a formal proof of this fact.*

Clearly, by Remark 2.1, problem (9) would have a minimum for all three losses suggested earlier — the exponential, logistic (for both $g(x) = e^{cx}$, and $g(x) = e^x \frac{e^x+1}{2}$), and log-log loss.

Finally we conclude this subsection, by noting that the assumptions in both Theorem 1 and 2 in Zou et al. (2008) can be seen to imply that the assumptions in Theorems 2.1 and 2.3 hold, thus rendering these theorems as consequences of the main result shown above. For completeness we briefly recall what these conditions are. In Theorem 1, Zou et al. (2008) require a twice differentiable loss function ϕ such that $\phi'(0) < 0$ and $\phi'' > 0$. In Theorem 2 these conditions are slightly relaxed by allowing for part linear and part constant convex losses.



2.2 Fisher Consistency for Weighted 0/1 Loss

Although the expected 0/1 loss or equivalently the overall misclassification is an important summary for the overall performance of a classification, alternative measures may be preferred when the cost of misclassification is not exchangeable across outcome categories. For such settings, it would be desirable to incorporate the differential cost when evaluating the classification performance and consider a weighted misclassification rate. Consider a cost matrix $\mathcal{W} = [W(j,j)]_{n\times n}$ with $W(j,j)$ representing the cost in classifying the j^{th} class to the j^{th} class. Then, the optimal Bayes classifier is

$$c^{\mathcal{W}}_{\mathbf{f}_{\text{Bayes}}}(\mathbf{X}) = \underset{j}{\operatorname{argmin}} \sum_{j=1}^{n} W(j,j)\mathbb{P}(C=j|\mathbf{X}). \tag{13}$$

Setting $\mathcal{W} = 1-\mathcal{I}$ corresponds to the 0/1 loss and $c^{\mathcal{W}}_{\mathbf{f}_{\text{Bayes}}} = c_{\mathbf{f}_{\text{Bayes}}}$, where $\mathcal{I}$ is the identity matrix. Without loss of generality, we assume that $W(j,j) \geq 0$. For ϕ satisfying (6) and the condition in Theorem 2.3, we next establish the FC results for the weighted 0/1 loss parallel to those given in Theorems 2.1 and 2.3.

Proposition 2.4 *Define the weighted loss $\ell(F_j) = \sum_{j=1}^{n}\phi(F_j)W(j,j)$. Then the optimization problem:*

$$\min_{\mathbf{F}=(F_1,\ldots,F_n)^T:\prod_{j=1}^{n} g(F_j)=1} \sum_{j=1}^{n} \ell(F_j)\mathbb{P}(C=j|\mathbf{X}), \tag{14}$$

has a minimizer $\widehat{\mathbf{F}}^{\mathcal{W}} = (\widehat{F}_1^{\mathcal{W}},\ldots,\widehat{F}_n^{\mathcal{W}})^T$ which satisfies the property that:

$$H_\phi(\widehat{F}_j^{\mathcal{W}})w_j^{\mathcal{W}} = \widetilde{\mathcal{C}} \quad \text{for some } \widetilde{\mathcal{C}} < 0, \tag{15}$$

where $w_j^{\mathcal{W}} = \sum_{j=1}^{n} W(j,j)\mathbb{P}(C=j|\mathbf{X})$ assuming that $w_j^{\mathcal{W}} > 0$.

This proposition is a direct consequence of Theorem 2.1, after exchanging summations:

$$\sum_{j=1}^{n}\sum_{j=1}^{n}\phi(F_j)W(j,j)\mathbb{P}(C=j|\mathbf{X}) = \sum_{j=1}^{n}\phi(F_j)w_j^{\mathcal{W}}.$$

Remark 2.3 *Note that the above result hints on how one can relax assumption (2) by using the loss ℓ constructed with $\mathcal{W} = 1-\mathcal{I}$. Using this particular ℓ, Proposition 2.4 simply requires $w_j^{\mathcal{W}} > 0$, which would be satisfied if we required:*

$$\max_{j\in\{1,\ldots,n\}} \mathbb{P}(C=j|\mathbf{X}) < 1: \text{ almost surely in } \mathbf{X}.$$

This is indeed weaker than (2). If we wanted to recover the conditional probabilities simply note that $\mathbb{P}(C=j|\mathbf{X}) = 1 - w_j^{\mathcal{W}}$, and hence:

$$\mathbb{P}(C=j|\mathbf{X}) = 1 - \frac{\{H_\phi(\widehat{F}_j^{\mathcal{W}})\}^{-1}}{\sum_{j=1}^{n}\{H_\phi(\widehat{F}_j^{\mathcal{W}})\}^{-1}}.$$

The result also suggests that using the modified loss ℓ, we can attain the optimal weighted Bayes classifier $c^{\mathcal{W}}_{\mathbf{f}_{\text{Bayes}}}(\mathbf{X})$ based on $\operatorname{argmin}_j H_\phi(\widehat{F}_j^{\mathcal{W}})$.

3. Generic Algorithm for Constructing the Classifier

In this section we provide a generic boosting algorithm, based on the explicit structure (6) that the RFC loss functions possess, and analyze certain numerical convergence aspects of the algorithm in the special case when $g = \exp$.

3.1 A Generic Boosting Algorithm

The properties of ϕ and the results in Theorem 2.1 and 2.3 also lead to a natural iterative generic boosting algorithm to attain the minimizer.

3.1.1 A Conditional Iteration

In this subsection, we provide an iterative procedure, conditional on $\mathbf{X} = x$, which eventually leeds to a generic boosting algorithm. The usefulness of this conditional iteration is based on the following result.

Theorem 3.1 *Assume that ϕ satisfies (6) and the condition in Theorem 2.3. Starting from $\mathbf{F}^{(0)} \equiv 0$, i.e. $F_j^{(0)} = 0$ for all j, define the following iterative procedure:*

$$\mathbf{F}^{(m+1)} = \underset{\mathbf{F}:\prod g(F_j)=1}{\operatorname{argmax}} \sum_{j=1}^{n}\{g(F_j^{(m)}) - g(F_j)\}k(F_j)w_j. \tag{16}$$

This iteration is guaranteed to converge to a point $\mathbf{F}^*$ *with the following property:*

$$g(F_j^*)k(F_j^*)w_j = H_\phi(F_j^*)w_j = \mathcal{C} < 0.$$

In the theorem above, the iterations are defined conditionally on $\mathbf{X} = x$, and F_j can be understood as $f_j(x)$. If $H_\phi(\cdot)$ turns out to be monotone, the procedure above will converge to the global minimum, as we can conclude straight from Theorem 2.1. Even if the procedure does not converge to a global minimum, because of the property of the point that it converges to, $\mathbf{F}^*$ can be used to recover the Bayes classifier. This observation is particularly useful for minimizing a non-convex loss functions as in such cases it is often hard to arrive at the global minimum. Moreover, as before the point $\mathbf{F}^*$ can be used not only for classification purposes, but also to recover the exact probabilities w_j.

In practice, the procedure described in (16) can be used to derive algorithms for boosting. However, an unconditional version of (16) is needed since w_j are unknown in general. Noting that the expectation of $\mathbb{1}(C = j)$ given $\mathbf{X}$ is w_j, we have

$$\begin{aligned}
&\mathbb{E}\left(\sum_{j=1}^{n}\Big[g\{F_j^{(m)}(\mathbf{X})\} - g\{F_j(\mathbf{X})\}\Big]k\{F_j(\mathbf{X})\}w_j\right)\\
=&\mathbb{E}\left(\sum_{j=1}^{n}\Big[g\{F_j^{(m)}(\mathbf{X})\} - g\{F_j(\mathbf{X})\}\Big]k\{F_j(\mathbf{X})\}\mathbb{1}(C = j)\right)\\
=&\mathbb{E}\left(\Big[g\{\mathbf{Y}_C^T\mathbf{F}^{(m)}(\mathbf{X})\} - g\{\mathbf{Y}_C^T\mathbf{F}(\mathbf{X})\}\Big]k\{\mathbf{Y}_C^T\mathbf{F}(\mathbf{X})\}\right), \qquad (17)
\end{aligned}$$

where recall that $\mathbf{Y}_C = (\mathbb{1}(C = 1), ..., \mathbb{1}(C = n))^T$. We next derive a boosting algorithm iterating based on an empirical version of (17).

3.1.2 The Boosting Algorithm

To derive the boosting algorithm, we let $\mathcal{G} = \{G_b(\cdot), b = 1, ..., B\}$ denote the bag of weak learners with $G(\mathbf{X}) \in \{1, ..., n\}$ denoting the predicted class based on learner G. For the bth classifier in $\mathcal{G}$, define a corresponding vectorized version of G_b, $\mathbf{F}_b = (F_{b1}, ..., F_{bn})$, with

$$F_{bj}(\mathbf{X}) = \mathcal{C}_- + \mathbb{1}\{G_b(\mathbf{X}) = j\}(\mathcal{C}_+ - \mathcal{C}_-),$$

where $\mathcal{C}_- < 0$ and $\mathcal{C}_+ > 0$ are chosen such that $\prod_{j=1}^n g(F_{bj}) = 1$. Obviously, $\mathbf{Y}_C^T\mathbf{F}_b(\cdot) = \mathcal{C}_- + \mathbb{1}(G_b(\cdot) = C)(\mathcal{C}_+ - \mathcal{C}_-)$. Let $\mathcal{G}^* = \{\mathbf{F}_b(\cdot), b = 1, ..., B\}$ denote the bag of vectorized classification functions corresponding to the classifiers in $\mathcal{G}$.

We next propose a generic iterative boosting algorithm that greedily searches for an optimal weight and for which weak learner to aggregate at each iteration. The loss function ϕ is not directly used, and instead we rely on the $g(\cdot)$ and $k(\cdot)$ functions as specified in (6). Specifically, we initialize $\mathbf{F}^{(0)} := 0$. Then for $m = 1, ..., M$ with M being the total number of desired iterations, we obtain the maximizer of

$$\sum_{i=1}^{N} g\{\mathbf{Y}_{Ci}^T\mathbf{F}^{(m-1)}(\mathbf{X}_i)\}\left[1 - g\{\mathbf{Y}_{Ci}^T\mathbf{F}(\mathbf{X}_i)\}^\beta\right]k\left(g^{-1}\left[g\{\mathbf{Y}_{Ci}^T\mathbf{F}^{(m-1)}(\mathbf{X}_i)\}g\{\mathbf{Y}_{Ci}^T\mathbf{F}(\mathbf{X}_i)\}^\beta\right]\right),$$

with respect to $\mathbf{F} \in \mathcal{G}^*$ and $\beta \geq 0$, denoted by $\widehat{\mathbf{F}}$ and $\widehat{\beta}$. Then we update the classifier coordinate-wise as $F_j^{(m)} = g^{-1}\{g(F_j^{(m-1)})g(\widehat{F}_j)^{\widehat{\beta}}\}$ so that we have the following

$g\{\mathbf{Y}_C^T\mathbf{F}^{(m)}\} = g\{\mathbf{Y}_C^T\mathbf{F}^{(m-1)}\}g\{\mathbf{Y}_C^T\widehat{\mathbf{F}}\}^{\widehat{\beta}}$ holding for all C. This will ensure that the property $\prod_{j=1}^n g(F_j^{(m)}) = 1$ continues to hold throughout the iterations. Thus at each iteration, we would be greedily maximizing:

$$\sum_{i=1}^{N}\Big[g\{\mathbf{Y}_{Ci}^T\mathbf{F}^{(m-1)}(\mathbf{X}_i)\} - g\{\mathbf{Y}_{Ci}^T\mathbf{F}^{(m)}(\mathbf{X}_i)\}\Big]k\left\{\mathbf{Y}_{Ci}^T\mathbf{F}^{(m)}(\mathbf{X}_i)\right\},$$

which is exactly the empirical version of (17).

For illustration, consider $g(x) = e^x$ with ϕ being differentiable and hence we may let $k(x) = \dot{\phi}(x)e^{-x}$. In this special case the update of $\mathbf{F}^{(m)}$ simplifies to $\mathbf{F}^{(m)} = \mathbf{F}^{(m-1)} + \widehat{\beta}\widehat{\mathbf{F}}$. Therefore following the iteration described above we have:

$$\underset{\mathbf{F}\in\mathcal{G}^*,\ \beta\geq 0}{\operatorname{argmin}} \sum_{i=1}^{N} -\{e^{-\beta\mathbf{Y}_{Ci}^T\mathbf{F}(\mathbf{X}_i)} - 1\}\dot{\phi}\{\mathbf{Y}_{Ci}^T\mathbf{F}^{(m-1)}(\mathbf{X}_i) + \beta\mathbf{Y}_{Ci}^T\mathbf{F}(\mathbf{X}_i)\}. \qquad (18)$$

Note here, the apparent similarity between a coordinate descent (or gradient descent in a functional space) as proposed in Mason et al. (1999) and Friedman (2001), and the above iteration. Finally, we summarize the algorithm as follows.

Algorithm 1: Generic Boosting Algorithm

1. Set $\mathbf{F}^{(0)} = 0$
2. For $m = 1, \ldots, M$
   (a) Maximize $\sum_{i=1}^N \Big\{g\{\mathbf{Y}_{Ci}^T\mathbf{F}^{(m-1)}(\mathbf{X}_i)\}\left[1 - g\{\mathbf{Y}_{Ci}^T\mathbf{F}(\mathbf{X}_i)\}^\beta\right]\times k\left(g^{-1}\left[g\{\mathbf{Y}_{Ci}^T\mathbf{F}^{(m-1)}(\mathbf{X}_i)\}g\{\mathbf{Y}_{Ci}^T\mathbf{F}(\mathbf{X}_i)\}^\beta\right]\right)\Big\}$ with respect to $\mathbf{F} \in \mathcal{G}^*$, $\beta \geq 0$ to obtain $\widehat{\mathbf{F}}$ and $\widehat{\beta}$
   (b) Update $\mathbf{F}^{(m)}$ coordinate-wise as $F_j^{(m)} = g^{-1}\big\{g(F_j^{(m-1)})g(\widehat{F}_j)^{\widehat{\beta}}\big\}$.
3. Output $\mathbf{F}^{(M)}$ and classify via $\operatorname{argmax}_j H_\phi(F_j^{(M)})$.

3.2 Numerical Convergence of the Algorithm when $g(\cdot) = \exp(\cdot)$

In this subsection we illustrate how algorithm 1 performs in finite samples, if we let it run until convergence (using potentially infinitely many iterations). More specifically, we study the properties of the iteration above in the case when $g(x) = \exp(x)$, or in other words we are concerned with the iteration given by (18). In addition, we also want to explore the relationship between iteration (18) and the following optimization problem:

$$\inf_{\mathbf{F}\in\operatorname{span}\mathcal{G}^*} \sum_{i=1}^{N} \phi(\mathbf{Y}_{C_i}^T\mathbf{F}(\mathbf{X}_i)). \qquad (19)$$

To this end we formulate the following:

Definition 3.1 (Looping closure) *Let* π *be a permutation of the numbers* $\{1, \ldots, n\}$ *into* $\{\pi_1, \ldots, \pi_n\}$. *Consider the following "loop" functions, such that for all* $i = 1, \ldots, n$: $l^{(0)}(\pi_i) =$

$\pi_i, l^{(1)}(\pi_i) = \pi_{i+1}$, $l^{(k)}(\cdot) = l^{(1)}(l^{(k-1)}(\cdot))$, *where the indexing is* $\bmod n$, *and* $k = 1, \ldots, n-1$[5]. *We say that a classifier bag* $\mathcal{G}$ *is closed under "looping" if there exists a permutation* π *such that for all* $G \in \mathcal{G}$ *it follows that* $l^{(k)} \circ G \in \mathcal{G}$ *for all* $k = 0, \ldots, n-1$.

In practice, closure under looping can easily be achieved if it is not already present, by adding the missing classifiers to the bag. Similar bag closures have been considered in the two class case in Mason et al. (1999). We start our discussion with the following proposition, providing a property of the algorithm at its limiting points.

Proposition 3.2 *Suppose that the loss function* ϕ *is decreasing, continuously differentiable, bounded from below and satisfies (6) with* $g = \exp$. *Furthermore assume that, the classifier bag is closed under looping (see Definition 3.1). Then iterating (18), using possibly infinite amount of iterations until a limiting point* $\mathbf{F}^{(\infty)}$ *is reached, guarantees that the following condition holds:*

$$\sum_{i=1}^{N} \mathbf{Y}_{Ci}^T \mathbf{F}(\mathbf{X}_i) \dot{\phi}(\mathbf{Y}_{Ci}^T \mathbf{F}^{(\infty)}(\mathbf{X}_i)) = 0, \tag{20}$$

for all $\mathbf{F} \in \mathcal{G}^*$.

Clearly, all examples of loss functions we considered satisfy the assumptions of Proposition 3.2. In the case when ϕ is convex, (20) shows that by iterating (18) we would arrive at an infimum of problem (19). This can be easily seen along the following lines. Assume that the $\widetilde{\mathbf{F}}$ is a point of infimum of (19) over the span of $\mathcal{G}^*$. By convexity of ϕ we have:

$$\sum_{i=1}^{N} \phi(\mathbf{Y}_{Ci}^T \widetilde{\mathbf{F}}(\mathbf{X}_i)) - \sum_{i=1}^{N} \phi(\mathbf{Y}_{Ci}^T \mathbf{F}^{(\infty)}(\mathbf{X}_i)) \geq \sum_{i=1}^{N} \mathbf{Y}_{Ci}^T [\widetilde{\mathbf{F}}(\mathbf{X}_i) - \mathbf{F}^{(\infty)}(\mathbf{X}_i)] \dot{\phi}(\mathbf{Y}_{Ci}^T \mathbf{F}^{(\infty)}(\mathbf{X}_i)) = 0.$$

The last equality follows from (20) and the fact that $\widetilde{\mathbf{F}} - \mathbf{F}^{(\infty)}$ is in the span of classifiers.

In the case when ϕ is not convex, condition (20) remains meaningful, though it doesn't guarantee convergence to the infimum. In order for us to relate condition (20) to equation (11) in the general (non-convex loss) case, and make it more intuitive, we consider a simple and illustrative example. We restrict our attention to the two class case ($n = 2$), but the example can be easily generalized.

Example 3.1 *Consider a (disjoint) partition of the predictor support:* $\mathcal{X} = \mathcal{X}_1, \ldots, \mathcal{X}_B$. *Construct classifiers based on that partition in the following manner:*

$$G_b(x) = \begin{cases} 1, & \text{if } x \in \mathcal{X}_b \\ 2 & \text{otherwise} \end{cases},$$

and close them under looping. It is easily seen that, under this framework the vector $\mathbf{F}^{(\infty)}(x)$ *is constant for* $x \in \mathcal{X}_b$ *for a fixed* b. *Denote the value of this constant with* $\mathbf{F}_b^{(\infty)}$. *Plugging in the* b^{th} *classifier in equation (20) we obtain:* $N_b \dot{\phi}(\mathbf{Y}_1^T \mathbf{F}_b^{(\infty)}) - (N - N_b) \dot{\phi}(\mathbf{Y}_2^T \mathbf{F}_b^{(\infty)}) = 0$,

5. Note that the loop functions depend on the permutation π, but we suppress this dependence for clarity of exposition.

where N_b *is the number of observations correctly classified by the* b^{th} *classifier, or in other words:*

$$\frac{\{\dot{\phi}(\mathbf{Y}_1^T \mathbf{F}_b^{(\infty)})\}^{-1}}{\{\dot{\phi}(\mathbf{Y}_1^T \mathbf{F}_b^{(\infty)})\}^{-1} + \{\dot{\phi}(\mathbf{Y}_2^T \mathbf{F}_b^{(\infty)})\}^{-1}} = \frac{N_b}{N}.^6 \tag{21}$$

The LHS of (21) is an estimate of the probability $\mathbb{P}(C = 1 | \mathbf{X} \in \mathcal{X}_b)$, *which in turn is a proxy to the Bayes classifier. For the RHS of (21), note that our probability recovering rule (11) with* $g = \exp$ *becomes:*

$$\frac{\{\dot{\phi}(\mathbf{Y}_j^T \mathbf{F}^{(\infty)}(x))\}^{-1}}{\{\dot{\phi}(\mathbf{Y}_1^T \mathbf{F}^{(\infty)}(x))\}^{-1} + \{\dot{\phi}(\mathbf{Y}_2^T \mathbf{F}^{(\infty)}(x))\}^{-1}},$$

in the two class case. This expression is in complete agreement with the RHS of (21).

3.2.1 Convergence Analysis

In the convex loss function case, property (20) will be matched by a gradient descent methods in the function space such as AnyBoost (Mason et al., 1999). This motivates us to consider the question of the convergence rate of the newly suggested algorithm — is it slower, faster or the same as a gradient descent in the convex loss function case? At first glance the rate might appear to be slower as we are not using the "fastest" decrease at each iteration using simply the exp function. In the end of this subsection we establish a geometric rate of convergence under certain assumptions, which matches the convergence rate for gradient descent under similar assumptions.

As we argued in the previous subsection, in the case of a convex loss ϕ, (20) guarantees that iteration (18) converges to the infimum of problem (19). Let $\mathbf{Y}_{C_i}^T \mathbf{F}^{(\infty)}(\mathbf{X}_i)$ be the limiting (allowed to be $\pm\infty$) values achieving the infimum above. Before we formalize the convergence rate result, we will characterize the behavior of $\mathbf{Y}_{C_i}^T \mathbf{F}^{(\infty)}(\mathbf{X}_i)$. This question is of interest in its own right, as this characterization remains valid regardless of what boosting algorithm one decides to use to obtain the minimum/infimum.

For what follows we consider a loss function ϕ which satisfies a mildly strengthened condition (12). Namely, let ϕ be decreasing and for any $\alpha, c > 0$ it satisfies the following condition:

$$\phi(x) + c\phi(-\alpha x) \uparrow +\infty \text{ as } x \uparrow +\infty \tag{22}$$

It is worth noting that if condition (12) is satisfied for all n (recall that $g = \exp$ here) this would imply (22). Denote with B the total number of weak learners in the bag. Let $\mathbf{D} := \{\mathbf{Y}_{Ci}^T \mathbf{F}_j(\mathbf{X}_i)\}_{j,i}$ be a $B \times N$ matrix each entry of which is either $\mathcal{C}_+$ or $\mathcal{C}_-$. Again, we assume that the bag is closed under looping. Let $\mathbf{v} \in \mathbb{R}^N$ be a vector. Consider the equation $\mathbf{D}^T \boldsymbol{\alpha} = \mathbf{v}$ for some vector $\boldsymbol{\alpha} \in \mathbb{R}_{0,+}^B$, where $\mathbb{R}_{0,+} = [0, \infty)$. Note that because of the looping closure[7] the linear equation above has solution iff the equation $\mathbf{D}^T \boldsymbol{\alpha} = \mathbf{v}$ has a solution with $\boldsymbol{\alpha} \in \mathbb{R}^B$, since without loss of generality we can add a large positive constant

6. Here we assume that $\dot{\phi}(\mathbf{Y}_j^T \mathbf{F}_b^{(\infty)}) \neq 0, j \in \{1, 2\}$, which can be ensured if ϕ is unbounded from above
7. Looping closure (Definition 3.1) implies that the column sums of $\mathbf{D}$ are 0.

to the coordinates of $\boldsymbol{\alpha}$. It follows that the equation $\mathbf{D}^T\boldsymbol{\alpha} = \mathbf{v}$ has a solution $\boldsymbol{\alpha} \in \mathbb{R}^B_{0,+}$ iff $\mathbf{v} \in \text{row}(\mathbf{D})$.

To see the connection between the linear equation above and optimization problem (19) consider the following simple example:

Example 3.2 *The function* $\sum_{i=1}^N \phi(\sum_{j=1}^B \alpha_j \mathbf{Y}_{Ci}^T \mathbf{F}_j(\mathbf{X}_i))$ *cannot have a minimum, if there exists a vector* $\mathbf{v} \in \mathbb{R}^N_+$*, such that the equation* $\mathbf{D}^T\boldsymbol{\alpha} = \mathbf{v}$ *has a solution —* $\widehat{\boldsymbol{\alpha}} \in \mathbb{R}^B_{0,+}$*, where* $\mathbb{R}_+ = (0, \infty)$ *. To see this, suppose the contrary, take an arbitrary constant* $R > 0$ *and note that:*

$$\sum_{i=1}^N \phi(\sum_{j=1}^B R\widehat{\alpha}_j \mathbf{Y}_{Ci}^T \mathbf{F}_j(\mathbf{X}_i)) = \sum_{i=1}^N \phi(Rv_i).$$

Take the limit $R \to \infty$*, and it is clear that the infimum* $N\phi(+\infty)$ *is achieved.*

Example 3.2 illustrates that if we want to have a solution smaller than $N\phi(+\infty)$, $\mathbf{D}$ cannot have rank N. Denote the rank of $\mathbf{D}$ with r.

More generally, our next result provides a characterization of how many (and which) of the values $\mathbf{Y}_{C_i}^T \mathbf{F}^{(\infty)}(\mathbf{X}_i)$ are set to $+\infty$ at the infimum of (19). Consider the perp space of the row space of the matrix $\mathbf{D}$, $\mathbf{E} := \text{row}(\mathbf{D})^\perp$. Out of all possible bases of $\mathbf{E}$ including the 0 vector, select the one $\mathbf{e}_1, \ldots, \mathbf{e}_s$ $(s = \min(N, B) - r + 1)$ for which the vector $\mathbf{e}_1$ has the most strictly positive entries at I coordinates and zeros at the rest[8]. We have the following:

Proposition 3.3 *Let* ϕ *be a decreasing loss function satisfying (22). Set* $M := N - I$*, where* $I \in \{0, \ldots, N\}$*. We have that:*

$$(N - M - 1)\phi(0) + (M + 1)\phi(+\infty) < \inf_{\mathbf{F} \in \text{span}\, \mathcal{G}^*} \sum_{i=1}^N \phi(\mathbf{Y}_{Ci}^T \mathbf{F}(\mathbf{X}_i)) \leq (N - M)\phi(0) + M\phi(+\infty).$$

Moreover, exactly M *of the values* $\mathbf{Y}_{C_i}^T \mathbf{F}^{(\infty)}(\mathbf{X}_i)$ *(i will be corresponding to the* 0 *coordinates of* $\mathbf{e}_1$*) will be set to* $+\infty$ *at the infimum.*

Proposition 3.3 characterizes the cases when one should expect problem (19) to have a minimum. In fact, in the cases where $I > 0$, we can simply delete the observations corresponding to the rows of $\mathbf{e}_1$ that are 0, and solve the optimization only on the set of observations left, as it can be seen from the proof.

Next we formulate the speed of the convergence of the algorithm we suggested, in the case when the function ϕ is convex. For simplicity we assume that the matrix of classifier entries, $\mathbf{D}$, is such that there is a strictly positive vector in the perp of the row space of $\mathbf{D}$. If that is not the case as argued we can delete observations that will be set to $+\infty$ at the maximum, and work with the rest. Denote with $\mathcal{S} = \{\mathbf{v} : \mathbf{D}^T\boldsymbol{\alpha} = \mathbf{v} \text{ with } \boldsymbol{\alpha} \geq 0, \sum_{i=1}^N \phi(v_i) \leq N\phi(0)\}$. Proposition 3.3 then implies that, the set $\mathcal{S}$ is bounded coordinate-wise. Next we formulate the result:

Theorem 3.4 *Let the convex, decreasing loss function* ϕ *be strongly convex with Lipchitz and bounded derivative on any compact subset of* $\mathbb{R}$*, and satisfies (22) and (6) with* $g = \exp$*. Furthermore, assume that there is a stricly positive vector in* $\text{row}(\mathbf{D})^\perp$*, and define the set* $\mathcal{S}$ *as above. Let* $\mathbf{F}^* \in \text{span}\, \mathcal{G}^*$ *achieves the minimum in problem (19). Denote with* $\varepsilon_m = \sum_{i=1}^N \phi(\mathbf{Y}_{Ci}^T \mathbf{F}^{(m)}(\mathbf{X}_i)) - \sum_{i=1}^N \phi(\mathbf{Y}_{Ci}^T \mathbf{F}^*(\mathbf{X}_i))$*, where* $\mathbf{F}^{(m)}$ *is produced iteratively using (18). Then there exists a constant* $K < 1$ *depending on the matrix* $\mathbf{D}$*, the sample size* N *and the set* $\mathcal{S}$*, such that:*

$$\varepsilon_{m+1} \leq \varepsilon_m K.$$

As we can see from Theorem 3.4 if we use this algorithm in the convex loss function case, we wouldn't lose convergence speed to gradient descent (see Nesterov (2004) Theorem 2.1.14), but in the non-convex function case which still obeys (6) this algorithm will be converging to a local minimum. In the latter case we will still be capable of recovering the Bayes classifier, as indicated by equation (20).

8. We allow $I = 0$, in which case $\mathbf{e}_1$ would simply represent the 0 vector.

4. Numerical Studies and Data Examples

In this section we validate empirically the performance of the generic boosting algorithm developed in the previous section with various choices of ϕ, comparing it to popular classification algorithms such as SVM and SAMME on simulated datasets, real benchmark datasets from the UCI machine learning, as well as an EMR study on diabetic neuropathy conducted at the Partners Healthcare.

For each dataset, we evaluated our proposed boosting algorithm based on (i) $\phi(x) = \log(1+e^{-x})$ (Logistic) with $g(x) = e^x$ and $k(x) = -\{e^x(1+e^x)\}^{-1}$; (ii) $\phi(x) = \log(\log(e^{-x}+e))$ (LogLog) with $g(x) = e^x$ and $k(x) = \{e^x(e^{x+1}+1)\log(e^{-x}+e)\}^{-1}$. We also experimented with $g(x) = e^{cx}$ for different values of c, and our results (not reported) were robust with respect to the choice of c. We also compare each of these algorithms to the commonly used LASSO (Friedman et al., 2010)/Multinomial Logistic Regression and SVM procedures. The SVM was trained with RBF kernel where the tuning parameter for the kernel function was chosen via the `sigest` function of `ksvm` library. The `sigest` procedure outputs three quantiles — 0.1, 0.5, 0.9 of the distribution of $\|X - X'\|_2^{-2}$ where X and X' are two predictors sampled from the matrix $\mathbf{X}$, and we take the mean of these quantiles as the tunning parameter in the RBF kernel for robustness. The fitting was performed with the `kernlab` `R` package implementation – `ksvm` which uses the "one-against-one"-approach to deal with multi-class problems see Hsu and Lin (2002) for example. The LASSO procedure with $\mathbf{X}$ being the predictors was based on an ℓ_1 penalized logistic regression through the `glmnet` implementation, and the tuning parameter was selected based on 5-fold CV. Throughout, the bag of classifiers for all boosting algorithms consisted of decision trees and multinomial logistic regressions weak learners, the predictors in each of which represented a subsample of the whole predictor set.

4.1 Simulation Studies

To distinguish the performance of our algorithm to the classical SAMME algorithm we chose a simulation setting with a complicated decision boundary. We borrow the idea of this simulation from the celebrated paper by Friedman et al. (2000).

The predictor matrix is generated as follows $\mathbf{X} \sim [N(0, \mathbb{I}_{10\times 10})]^{10}$. Next for each observation $\mathbf{X}_i$ it's ℓ_1 or ℓ_2 norms were calculated. The class assignment was then performed

based on:

$$C_i = \sum_{j=1}^{n} j \mathbb{1}(r_j \leq \|\mathbf{X}_i\|_\ell < r_{j+1}),$$

where $0 = r_1 \leq r_2 \leq \ldots \leq r_{n+1} = \infty$, $\ell \in \{1, 2\}$ and for $\mathbf{X} \in \mathbb{R}^p$ we have $\|\mathbf{X}\|_\ell := \left(\sum_{i=1}^{p} |X_i|^\ell\right)^{1/\ell}$. The thresholds r_j were selected in such a way so that each class got an approximately equal number of observations. Geometrically the classes $C = \{1, \ldots, k\}$ for $k < n$ were observations belonging to a 10 dimensional ℓ_1 or ℓ_2 sphere. Moreover, the more cutoffs r_j, the more classes the problem has, and hence the more complicated classification becomes.

We compared 5 algorithms – the SAMME, our algorithm with the logistic and loglog losses, the SVM and the LASSO logistic regression algorithm. Each simulation, 3200 observations were generated, 200 of which were used for training and 3000 were left out for testing purposes. We performed in total of 500 simulation for each scenario. The results are summarized in the tables 1 and 2 below:

Table 1: Percent misclassification for ℓ_1 Spheres

	$n = 3$	$n = 4$	$n = 5$	$n = 6$
SVM	17.9% (0.46)	29.4% (0.45)	37.6% (0.81)	46.6% (1.21)
LASSO	7.8% (11.6)	27.6% (5.00)	30.4% (20.0)	43.9% (15.9)
SAMME	6.9% (0.31)	10.7% (0.20)	16.4%(0.33)	28.4% (0.34)
Logistic	6.5% (22.6)	10.0% (16.4)	15.1% (22.3)	25.1% (23.6)
LogLog	6.6% (32.7)	9.8% (24.0)	15.0% (33.5)	25.2% (34.5)

Table 2: Percent misclassification for ℓ_2 Spheres

	$n = 3$	$n = 4$	$n = 5$	$n = 6$
SVM	17.0% (0.44)	28.0% (0.78)	36.6% (0.83)	44.1% (1.15)
LASSO	8.7% (11.8)	26.7% (5.70)	31.9% (19.7)	45.0% (14.6)
SAMME	8.2% (0.33)	12.9% (0.46)	19.7% (0.30)	28.9% (0.29)
Logistic	7.5% (23.4)	11.7% (25.3)	17.3% (24.6)	25.4% (23.5)
LogLog	7.7% (33.7)	11.5% (35.6)	17.9% (35.7)	25.8% (35.7)

As we can see our boosting based procedures dominated in all scenarios with the difference becoming more pronounced the more number of classes we have. We observed that our algorithms seem to combine classifiers from the bag more efficiently as compared to the SAMME algorithm in this scenario, especially so when the number of classes was large.

4.2 Experiments with UCI Benchmark Datasets

To present a more comprehensive assessment of our procedure, we analyzed 5 datasets from the UCI machine learning repository. The summaries of the characteristics of the datasets we used can be found in Table 3.

We compare results from SAMME, LogLog and Logistic from our proposed methods, SVM and a multinomial logistic regression (referred to as MLogisticReg). The MLogisticReg

9. Originally 10 classes; Extreme classes were grouped together for balanced class counts.

Table 3: Summary of datasets

	Dataset	Train Set / Test Set Size	# Features	# Classes
IS	Image Segmentation	210/2100	19	7
LED	Led Display	200/5000	7	10
RWQ[9]	Red Wine Quality	700/899	11	4
SE	Seeds	100/110	7	3
EC	Ecoli	100/236	7	8

was used instead of the LASSO procedure, as these datasets have relatively few features, and the LASSO procedure generally performs worse than the standard. As before all boosting algorithms were ran for 50 iterations.

For the analysis of all 5 datasets, the bag of weak learners we used consisted of decision trees and multinomial logistic regressions with subsampled prefixed number of predictors.

Table 4: Percent misclassifications (run time in seconds)

	IS	RWQ	SE	LED	EC
SVM	16.19% (0.44)	29.37% (0.28)	8.18% (0.08)	28.64% (1.26)	37.28% (0.27)
MLogisticReg	10.57% (0.08)	28.59% (0.09)	5.45% (0.04)	28.34% (0.06)	41.52% (0.04)
SAMME	5.09% (0.17)	30.14% (0.74)	4.55% (0.02)	29.36% (0.04)	22.45% (0.02)
Logistic	5.00% (13.6)	27.36% (35.3)	3.64% (1.61)	27.02% (1.53)	19.49% (1.22)
LogLog	4.95% (16.9)	28.36% (48.8)	3.64% (1.30)	27.00% (2.01)	19.49% (1.45)

We observe that in nearly all cases the newly suggested procedure performed better than the SAMME procedure, which typically converged too fast failing to include enough classifiers. The misclassifications rates of both the Logistic and LogLog based boosting algorithms were also better compared to the SVM and logistic regression in all 4 datasets.

4.3 Summary of Simulation Results and Benchmark Data Analyses

The results provided above demonstrate that the suggested algorithms can be used in successfully practice, and can outperform existing algorithms in many cases. The proposed boosting algorithm with LogLog loss appears to perform well across all settings considered with respect to classification accuracy. The robustness and gained accuracy of our proposed procedures come at the price of being more computationally intensive than the competitors. The slow speed is mostly due to the optimization with respect to β (see Algorithm 1) required at each iteration for each classifier in the bag. The SAMME algorithm avoids this search as an explicit solution to its corresponding optimization problem exists.

Further computational complexity in boosting procedures comes from two sources: one of them is the complexity of the classifiers in the bag, and the other is the number of classifiers in the bag. For massive datasets (with both high numbers of observations and of predictors) the optimization involved in our algorithm might be prohibitive if one decides to include a lot of weak learners. The methods we suggest could work in a reasonable time,

if one opts for sampling not too many classifiers. A relaxation of the procedure might be warranted in cases where a lot of classifiers will be used, and such relaxed algorithms are left for future work.

4.4 Application to an EMR Study of Diabetic Neuropathy

To illustrate our proposed generic boosting algorithm and demonstrate the advantage of having multiple losses, we apply our procedures to an electronic medical record (EMR) study, conducted at the Partners Healthcare, aiming to identify patients with different subtypes of diabetic neuropathy. Diabetic neuropathy (DN), a serious complication of diabetes, is the most common neuropathy in industrialized countries with an estimate of about 20-30 million people affected by symptomatic DN worldwide (Said, 2007). Increasing rates of obesity and type 2 diabetes could potentially double the number of affected individuals by the year 2030. The prevalence of DN also increases with time and poor glycemic control (Martin et al., 2006). Although many types of neuropathy can be associated with diabetes, the most common type is diabetic polyneuropathy and pain can develop as a symptom of diabetic polyneuropathy (Thomas and Eliasson, 1984; Galer et al., 2000). Pain in the feet and legs was reported to occur in 11.6% of insulin dependent diabetics and 32.1% of noninsulin dependent diabetics (Ziegler et al., 1992). Unfortunately, risk factors for developing painful diabetic neuropathy (pDN) are generally poorly understood. pDN has been reported as more prevalent in patients with type 2 diabetes and women (Abbott et al., 2011). Prior studies have also reported an association between family history and pDN, suggesting a potential genetic predisposition to pDN (Galer et al., 2000). To enable a genetic study of pDN and non-painful DN (npDN), an EMR study was performed to identify patients with these two subtypes of DN by investigators from the informatics for integrating biology to the bedside (i2b2), a National Center for Biomedical Computing based at Partners HealthCare (Murphy et al., 2006, 2010).

To identify such patients, we created a datamart compromising 20,000 patients in the Partners Healthcare with relevant ICD9 (International Classification of Diseases, version 9) codes. Two sources of information were utilized to classify patients' DN status and subtypes: (i) structured clinical data searchable in the EMR such as ICD9 codes; and (ii) variable identified using natural language processing (NLP) to identify medical concepts in narrative clinical notes. Algorithm development and validation was performed in a training set of 611 patients sampled from the datamart. To obtain the gold standard disease status for these patients, several neurologists performed chart reviews and classified them into no DN, pDN and npDN. The distribution of the classes was $64\%, 14\%, 22\%$ respectively. To train the classification algorithms, we included a total of 85 predictors most of which are NLP variables, counting mentions of medical concepts such as *"pain"*, *"hypersensitivity"*, and *"diabetic neuropathy"*.

We trained boosting classification algorithms to classify these 3 disease classes. We used decision stumps as weak learners. They only have two nodes with the first node deciding between class C_1 vs C_2 and C_3 and the other node deciding between C_2 vs C_3, where $\{C_1, C_2, C_3\}$ is a permutation of {no DN,pDN,npDN}. In order to illustrate the algorithms we used 311 observations as a training set and the rest 300 patients we set off as a test set.

We report the percentage mis-classifications in Table 5. The boosting results show some improvement, as compared to standard methods. We can also see that the generic boosting algorithm performs slightly better than SAMME in this situation with both the logistic and the LogLog losses. It warrants further research whether picking richer tree structures as opposed to using stumps, would yield an even better performance on this dataset.

Table 5: Percent misclassifications (run time in seconds)

	% incorrect
SVM	43.67% (0.26)
LASSO	37.00% (15.8)
SAMME	33.33% (0.21)
Logistic	31.67% (9.55)
LogLog	31.67% (12.5)

5. Discussion

For multi-category classification problems, we described in this paper a class of loss functions that attain FC properties and provided theoretical justifications for how such loss functions can ultimately lead to optimal Bayes classifier. We extended the results to accommodate differential costs in misclassifying different classes. To approximate the minimizer of the empirical losses, we demonstrated that a natural iterative procedure can be used to derive generic boosting algorithms for any of the proposed losses. Numerical results suggest that non-convex losses such as LogLog could potentially lead to algorithms with better classification performance. Although the LogLog loss appears to perform well across different settings considered in the numerical studies, choosing an optimal loss for a given dataset warrants further research. Our preliminary studies (results not shown) suggest that procedures such as the cross-validation can potentially be used for loss selections.

Our proposed algorithm not only depends on the choice of ϕ but also the associated $g(\cdot)$ and $k(\cdot)$ functions as indicated in (6). We can think of g as a positive deformation of the real line and even with the same ϕ, changing g could also change the classifiers. Most existing boosting algorithms correspond to $g(x) = e^x$, in which case the constraint $\prod_{j=1}^n g(F_j) = 1$ simplifies to the commonly seen condition $\sum_j F_j = 0$. Moreover if ϕ is smooth and convex, one may let $k(x) = \dot{\phi}(x)/e^x$. Thus, under convexity, $H_\phi(x) = \dot{\phi}(x) = d\phi(x)/dx$ is an increasing function and ϕ is Fisher consistent in the traditional sense. We also saw, that even when ϕ is not convex, our suggested losses are Fisher consistent in the standard sense. Moreover, we argued that loss functions satisfying (6), can be used to recover the exact conditional probabilities. It would be interesting to develop adaptive boosting procedure where we use different g functions in the process of boosting adaptively. For example, in the suggested logistic loss boosting with $g(x) = e^{cx}$, we can adaptively select the parameter c, for better convergence results of the algorithm which will potentially result in a better classification results. We were provided a property of the limiting point of the algorithm in the case where $g = \exp$. Furthermore, we characterized when the problem has a minimum in the finite sample case under certain assumptions on ϕ. The resemblance of the proposed

generic boosting algorithm with coordinate descent, helped us to establish geometric rate of convergence in the convex loss function case. The consistency of the algorithm under conditions such as finite VC dimension of the classifier bag, warrants future research.

Acknowledgments

The authors would like to thank Alexander Rakhlin and three referees for their valuable suggestions and feedback, which led to improvements in the present manuscript. This research was partially supported by Research Grants NSF DMS1208771, NIH R01GM113242-01, NIH U54HG007963 and NIH RO1HL089778.

Appendix A. Proofs

Lemma A.1 *Assumption (6) implies that the function $\phi(g^{-1}(z))$ is continuously differentiable and convex for all $z \in g(S)$.*

Proof [Proof of Lemma A.1] Set $z := g(x), z' := g(x')$ in (6). When $x, x' \in S$ we have $z, z' \in g(S)$ and vice versa. Now (6) can be rewritten as:

$$\phi(g^{-1}(z)) - \phi(g^{-1}(z')) \geq (z - z')k(g^{-1}(z')). \tag{23}$$

Changing the roles of z and z' and using the fact that both $z, z' \in g(S)$ we obtain:

$$\phi(g^{-1}(z')) - \phi(g^{-1}(z)) \geq (z' - z)k(g^{-1}(z)).$$

The above two inequalities, combined with the fact that k and g^{-1} are increasing, give that for any $z \neq z', z, z' \in g(S)$ we have:

$$\min\{k(g^{-1}(z)), k(g^{-1}(z'))\} \leq \frac{\phi(g^{-1}(z')) - \phi(g^{-1}(z))}{z' - z} \leq \max\{k(g^{-1}(z)), k(g^{-1}(z'))\}. \tag{24}$$

By the continuity of k and g we have that the composition $k(g^{-1}(\cdot))$ is also continuous. Taking the limit $z' \to z$ in (24) shows that the function $\phi(g^{-1}(z))$ is differentiable on $g(S)$ with a continuous derivative equal to $k(g^{-1}(z))$. Now the convexity of $\phi(g^{-1}(z))$ follows from (23). ■

Proof [Proof of Theorem 2.1] To show that $H_\phi(\widehat{F}_j)w_j = \mathcal{C}$ for some $\mathcal{C} < 0$, define $\Omega = \{\mathbf{F} = (F_1, \ldots, F_n) : F_j \in S, j = 1, ..., n\}$, where recall that $S = \{z \in \mathbb{R} : k(z) \leq 0\}$. From (6),

$$\sum_{j=1}^n \phi(\widehat{F}_j)w_j \geq \sum_{j=1}^n \phi(F_j)w_j + \sum_{j=1}^n \{g(\widehat{F}_j) - g(F_j)\}k(F_j)w_j \quad \text{for any } \mathbf{F} \in \Omega. \tag{25}$$

Since $\widehat{\mathbf{F}}$ minimizes $\sum_{j=1}^n \phi(F_j)w_j$, (25) implies that

$$\sum_{j=1}^n g(F_j)k(F_j)w_j \geq \sum_{j=1}^n g(\widehat{F}_j)k(F_j)w_j \quad \text{for any } \mathbf{F} \in \Omega. \tag{26}$$

For any given constant $\mathcal{C} < 0$, let $\widetilde{F}_{\mathcal{C}j}$ be the solution to $g(\widehat{F}_j)k(\widetilde{F}_{\mathcal{C}j})w_j = \mathcal{C}$ or equivalently $\widetilde{F}_{\mathcal{C}j} = k^{-1}[\mathcal{C}/\{g(\widehat{F}_j)w_j\}]$. Obviously $\widetilde{\mathbf{F}}_{\mathcal{C}} \in \Omega$ for all $\mathcal{C} < 0$. We next show that there exists $\mathcal{C}_0 < 0$ such that $\prod_{j=1}^n g(\widetilde{F}_{\mathcal{C}_0 j}) = \prod_{j=1}^n g(k^{-1}[\mathcal{C}_0/\{g(\widehat{F}_j)w_j\}]) = 1$. Since g and k are continuous and strictly increasing functions, it suffices to show that $\prod_{j=1}^n g(\widetilde{F}_{0j}) > 1$ and $\prod_{j=1}^n g(\widetilde{F}_{\mathcal{C}j}) \leq 1$ for some $\mathcal{C}$. Obviously $\prod_{j=1}^n g(\widetilde{F}_{0j}) > 1$ since $g\{k^{-1}(0)\} > g(0) = 1$. Now let $\mathcal{C}_1 = k(0)\max_j\{g(\widehat{F}_j)w_j\} < 0$. Then for all j, $\mathcal{C}_1/\{g(\widehat{F}_j)w_j\} \leq k(0)$ and thus $g(k^{-1}[\mathcal{C}_1/\{g(\widehat{F}_j)w_j\}]) \leq g(0) = 1$. Then by continuity of g and k, there exists $\mathcal{C}_0 \in [\mathcal{C}_1, 0)$ such that $\prod_{j=1}^n g(\widetilde{F}_{\mathcal{C}_0 j}) = 1$. Thus, the constructed $\widetilde{\mathbf{F}}_{\mathcal{C}_0}$ possesses several properties: (i) $g(\widehat{F}_j)k(\widetilde{F}_{\mathcal{C}_0 j})w_j = \mathcal{C}_0$; (ii) $\prod_{j=1}^n g(\widetilde{F}_{\mathcal{C}_0 j}) = 1$; and (iii) $k(\widetilde{F}_{\mathcal{C}_0 j}) < 0$ and hence $\widetilde{\mathbf{F}}_{\mathcal{C}_0} \in \Omega$. It then follows from the AM-GM inequality that

$$\sum_{j=1}^n g(\widetilde{F}_{\mathcal{C}_0 j})\{-k(\widetilde{F}_{\mathcal{C}_0 j})\}w_j \geq n\left[\prod_{j=1}^n g(\widetilde{F}_{\mathcal{C}_0 j})\{-k(\widetilde{F}_{\mathcal{C}_0 j})\}w_j\right]^{n^{-1}} = n\left[\prod_{j=1}^n g(\widehat{F}_j)\{-k(\widetilde{F}_{\mathcal{C}_0 j})\}w_j\right]^{n^{-1}} = -n\mathcal{C}_0,$$

where we used the fact that $\prod_{j=1}^n g(\widetilde{F}_{\mathcal{C}_0 j}) = \prod_{j=1}^n g(\widehat{F}_j) = 1$. This, together with (26), implies that

$$n\mathcal{C}_0 \geq \sum_{j=1}^n g(\widetilde{F}_{\mathcal{C}_0 j})k(\widetilde{F}_{\mathcal{C}_0 j})w_j \geq \sum_{j=1}^n g(\widehat{F}_j)k(\widetilde{F}_{\mathcal{C}_0 j})w_j = n\mathcal{C}_0$$

and hence $n\mathcal{C}_0 = \sum_{j=1}^n g(\widetilde{F}_{\mathcal{C}_0 j})k(\widetilde{F}_{\mathcal{C}_0 j})w_j$. Thus, the equality holds in the AM-GM inequality above, which also implies that $g(\widetilde{F}_{\mathcal{C}_0 j})k(\widetilde{F}_{\mathcal{C}_0 j})w_j = \mathcal{C}_0$. Since $g(\widehat{F}_j)k(\widetilde{F}_{\mathcal{C}_0 j})w_j = \mathcal{C}_0$, $k(\widetilde{F}_{\mathcal{C}_0 j}) \neq 0$ and g is strictly increasing, we have $g(\widehat{F}_j) = g(\widetilde{F}_{\mathcal{C}_0 j})$ and hence $\widehat{F}_j = \widetilde{F}_{\mathcal{C}_0 j}$. Therefore,

$$g(\widehat{F}_j)k(\widehat{F}_j)w_j = H_\phi(\widehat{F}_j)w_j = \mathcal{C}_0. \tag{27}$$

Obviously if $H_\phi(\cdot)$ is strictly monotone then $\widehat{F}_j = H_\phi^{-1}(\mathcal{C}_0/w_j)$ which is unique. ■

Proof [Proof of Proposition 2.2] The function ϕ is strictly decreasing on the set $S' := \{z : k(z) < 0\}$, as from (6) for any $x < x', x, x' \in S'$ we have:

$$\phi(x) - \phi(x') \geq (g(x) - g(x'))k(x') > 0.$$

Furthermore, it follows from Theorem 2.1, that $\widehat{F}_j \in S'$ since by (27) $k(\widehat{F}_j) < 0$ for all j. Next we show that if $w_\jmath > w_j$ we must have $\phi(\widehat{F}_\jmath) \leq \phi(\widehat{F}_j)$. This observation follows since:

$$\phi(\widehat{F}_\jmath)w_\jmath + \phi(\widehat{F}_j)w_j \leq \phi(\widehat{F}_j)w_\jmath + \phi(\widehat{F}_\jmath)w_\jmath,$$

or else $\widehat{\mathbf{F}}$ cannot be a minimum of (9), as we can swap $\widehat{F}_\jmath$ and $\widehat{F}_j$ to obtain a strictly smaller value while still satisfying the constraint. Furthermore by Theorem 2.1, $w_\jmath \neq w_j$ implies that $\widehat{F}_\jmath \neq \widehat{F}_j$ because otherwise $H_\phi(\widehat{F}_\jmath) = H_\phi(\widehat{F}_j)$ and hence $w_\jmath = w_j$ by (10). Since ϕ is strictly decreasing on S' it also implies $\phi(\widehat{F}_\jmath) \neq \phi(\widehat{F}_j)$. Hence $w_\jmath > w_j$ implies $\phi(\widehat{F}_\jmath) < \phi(\widehat{F}_j)$. Finally, the last observation gives:

$$\operatorname*{argmin}_{j\in\{1,\ldots,n\}} \phi(\widehat{F}_j) = {}^{10} \operatorname*{argmax}_{j\in\{1,\ldots,n\}} w_j.$$

The fact that ϕ is decreasing on S' completes the proof. ■

Proof [Proof of Theorem 2.3] To show that a finite minimizer $\widehat{\mathbf{F}}$ exists, it suffices to show that $g(\widehat{F}_j)$ is finite and bounded away from 0, for $j = 1, ..., n$. To this end, we note that the condition (12) is equivalent to,

$$\lim_{x\downarrow 0} c_1\phi(g^{-1}(x)) + c_2\phi(g^{-1}(x^{-(n-1)})) = +\infty \quad \text{for all } c_1, c_2 > 0. \tag{28}$$

We next show that at the minimizer $\widehat{\mathbf{F}}$, $\widehat{m} = \min_j g(\widehat{F}_j) = g(\widehat{F}_{j^*})$ is bounded away from 0, where $j^* = \text{argmin}_j\, g(\widehat{F}_j)$. Since $1 = \prod_{j=1}^n g(\widehat{F}_j) \geq g(\widehat{F}_j)\widehat{m}^{n-1}$, we have $\widehat{F}_j \leq g^{-1}(\widehat{m}^{-(n-1)})$ for $j = 1, ..., n$. If ϕ is *decreasing* over $\mathbb{R}$, then

$$\begin{aligned}\phi(0)\sum_{j=1}^n w_j &\geq \sum_{j=1}^n \phi(\widehat{F}_j)w_j = w_{j^*}\phi\{g^{-1}(\widehat{m})\} + \sum_{j\neq j^*} w_j\phi(\widehat{F}_j)\\ &\geq w_{j^*}\phi\{g^{-1}(\widehat{m})\} + \sum_{j\neq j^*} w_j\phi\{g^{-1}(\widehat{m}^{-(n-1)})\}.\end{aligned}$$

From (28) with $c_1 = w_{j^*}$ and $c_2 = \sum_{j\neq j^*} w_j$, we conclude that $\widehat{m}$ must be bounded away from 0 since $\sum_{j=1}^n \phi(\widehat{F}_j)w_j \to \infty$ if $\widehat{m} \to 0$. Thus, there exists $m_0 > 0$ such that $\widehat{m} \geq m_0$ and consequently

$$0 < m_0 \leq g(\widehat{F}_j) \leq m_0^{-(n-1)} < \infty, \quad j = 1, ..., n.$$

Now, if ϕ is not decreasing on the whole $\mathbb{R}$, then there must exist $F^* < \infty$ such that $k(F^*) = 0$ since ϕ is strictly decreasing on $S' = \{z : k(z) < 0\}$.

Now we show that $\widehat{\mathbf{F}} \in \Omega \equiv \{\mathbf{F} = (F_1, \ldots, F_n) : F_j \in S, j = 1, \ldots, n\}$ as defined in Theorem 2.1. To this end, we note that ϕ is strictly decreasing on S' and $(-\infty, 0] \subset S'$. We next argue by contradiction that $\widehat{F}_j \in S$ or equivalently $\widehat{F}_j \leq F^*$ for all j. For any $F > F^*$, $\phi(F) - \phi(F^*) \geq \{g(F) - g(F^*)\}k(F^*) = 0$ by (6). Let $\mathcal{A} = \{j : \widehat{F}_j > F^*\}$ and $\widehat{F}_j^* = \mathbb{1}(j \in \mathcal{A})F^* + \mathbb{1}(j \notin \mathcal{A})\widehat{F}_j$. If $\mathcal{A}$ is not an empty set, then $\sum_{j=1}^n \phi(\widehat{F}_j^*)w_j \leq \sum_{j=1}^n \phi(\widehat{F}_j)w_j$ and $\prod_{j=1}^n g(\widehat{F}_j^*) < 1$. Since $g(F^*) > 1$, there must exist some $\widehat{F}_j^{**}$ with $F^* \geq \widehat{F}_j^{**} \geq \widehat{F}_j$ for $j \notin \mathcal{A}$ and $\widehat{F}_j^{**} = F^*$ for $j \in \mathcal{A}$ such that $\prod_{j=1}^n g(\widehat{F}_j^{**}) = 1$ and $F^* \geq \widehat{F}_j^{**} > \widehat{F}_j$ for some $j \notin \mathcal{A}$. Since ϕ is strictly decreasing on S, $\sum_{j=1}^n \phi(\widehat{F}_j^{**})w_j < \sum_{j=1}^n \phi(\widehat{F}_j^*)w_j \leq \sum_{j=1}^n \phi(\widehat{F}_j)w_j$, which contradicts that $\widehat{\mathbf{F}}$ is the minimum. Therefore, $\widehat{\mathbf{F}} \in \Omega$.

Hence $\widehat{F}_j \leq F^*$ and $g(\widehat{F}_j) \leq g(F^*) = m_1 \in (0, \infty)$. On the other hand, since $\prod_{j=1}^n g(\widehat{F}_j) = 1$, we have $g(\widehat{F}_j) \geq m_1^{-(n-1)}$ and thus $g(\widehat{F}_j)$ is also bounded away from 0 and finite.

Remark A.1 *As a useful remark we mention that the same argument shows that given any finite vector $\widehat{\mathbf{F}}$, the vectors $\mathbf{F}$ with $\sum_j \phi(F_j)w_j \leq \sum_j \phi(\widehat{F}_j)w_j$ are located on a compact set (provided that $\widehat{F}_j < F^*$ for all j in the second case).*

■

10. Recall that "=" should be interpreted as "⊆".

Lemma A.2 *Any loss function ϕ satisfying (6) with $g = \exp$, and either i. or ii. from Theorem 2.3 is classification calibrated in the two class case.*

Remark A.2 *Recall that a loss function ϕ is classification calibrated in the two class case if, for any point $w_1 + w_2 = 1$ with $w_1 \neq \frac{1}{2}$ and $w_1, w_2 > 0$, we have:*

$$\inf_{x\in\mathbb{R}}(w_1\phi(x) + w_2\phi(-x)) > \inf_{x:x(2w_1-1)\leq 0}(w_1\phi(x) + w_2\phi(-x)).$$

Proof [Proof of Lemma A.2] Denote the two (distinct) class probabilities with $w_1 + w_2 = 1$. Without loss of generality we distinguish two cases: $w_1 > w_2 > 0$ and $w_1 = 1, w_2 = 0$. First, consider the case when $w_1 > w_2 > 0$. Since the conditions of Theorem 2.3 hold, we know that the optimization problem (9) has a minimum, and hence by Proposition 2.2 we have that $\text{argmax}_{j\in\{1,2\}} \widehat{F}_j \subseteq \{1\}$. Hence it follows that $\widehat{F}_1 > 0, \widehat{F}_2 < 0$ at the minimum. This implies that inequality in Remark A.2 is strict.

Next assume that $w_1 = 1, w_2 = 0$. This case is not covered by our results as we assume that the probabilities are bounded away from 0. As we argued earlier ϕ is strictly decreasing on the set S' and by assumption $(-\infty, 0] \subsetneq S'$. Thus by:

$$\widehat{\mathbf{F}} = \text{argmin}_{\mathbf{F}:F_1+F_2=0}\, w_1\phi(F_1) + w_2\phi(F_2) = \text{argmin}_{\mathbf{F}:F_1+F_2=0}\, \phi(F_1),$$

we must have $\widehat{F}_1 > 0$ and hence $\phi(0) > \phi(\widehat{F}_1)$. This finishes the proof. ■

Lemma A.3 *Let $\mathbf{F}^{(m)}$ be defined as in iteration (16) starting from $\mathbf{F}^{(0)} = 0$. Then we must have $\mathbf{F}^{(m)} \in \Omega$ for all m, where $\Omega = \{\mathbf{F} = (F_1, \ldots, F_n) : F_j \in S, j = 1, ..., n\}$.*

Proof [Proof of Lemma A.3] If $S = \mathbb{R}$ there is nothing to prove. Assume that there exists $F^* \in \mathbb{R}$ such that $k(F^*) = 0$. We show the statement by induction. By definition $\mathbf{F}^{(0)} \in \Omega$. Assume that $\mathbf{F}^{(m-1)} \in \Omega$ for some $m \geq 1$. We now show that $\mathbf{F}^{(m)} \in \Omega$. To arrive at a contradiction, assume the contrary. Let $\mathcal{A} = \{j : F_j^{(m)} > F^*\} \neq \varnothing$. Define $F_j^{*(m)} = \mathbb{1}(j \in \mathcal{A})F_j^{(m-1)} + \mathbb{1}(j \notin \mathcal{A})F_j^{(m)}$. Since $\mathbf{F}^{(m-1)} \in \Omega$, it follows that $\mathbf{F}^{*(m)} \in \Omega$ and $\prod_{j=1}^n g(\mathbf{F}_j^{*(m)}) < 1$. More importantly, observe that for all $j \in \mathcal{A}$ we have:

$$0 = (g(F_j^{(m-1)}) - g(F_j^{*(m)}))k(F_j^{*(m)})w_j > (g(F_j^{(m-1)}) - g(F_j^{(m)}))k(F_j^{(m)})w_j,$$

as $g(F_j^{(m-1)}) \leq g(F^*) < g(F_j^{(m)})$ and $k(F_j^{(m)}) > k(F^*) = 0$, and hence:

$$\sum_{j=1}^n (g(F_j^{(m-1)}) - g(F_j^{*(m)}))k(F_j^{*(m)})w_j > \sum_{j=1}^n (g(F_j^{(m-1)}) - g(F_j^{(m)}))k(F_j^{(m)})w_j.$$

Define the index set $\mathcal{B} = \{j : F_j^{*(m)} < F_j^{(m-1)}\}$. Since $\prod_{j=1}^n g(\mathbf{F}_j^{*(m)}) < 1$ and $\mathbf{F}^{(m-1)} \in \Omega$ it follows that $\mathcal{B}$ is not empty and $\mathcal{A} \cap \mathcal{B} = \varnothing$. Next for $\lambda \in [0, 1]$ define for all j:

$$F_j^{*(m),\lambda} := [\mathbb{1}(j \in \mathcal{A}) + \mathbb{1}(j \notin \mathcal{A})\mathbb{1}(j \notin \mathcal{B})]F_j^{*(m)} + \mathbb{1}(j \in \mathcal{B})((1-\lambda)F_j^{*(m)} + \lambda F_j^{(m-1)}).$$

Note that when $\lambda = 0$, we have $F_j^{*(m),0} \equiv F_j^{*(m)}$. Now we show that for any $\lambda \in [0,1]$ the following inequality holds:

$$\sum_{j=1}^{n}(g(F_j^{(m-1)}) - g(F_j^{*(m),\lambda}))k(F_j^{*(m),\lambda})w_j \geq \sum_{j=1}^{n}(g(F_j^{(m-1)}) - g(F_j^{*(m)}))k(F_j^{*(m)})w_j. \quad (29)$$

For any $\lambda \in (0,1]$: $F_j^{*(m),\lambda} \neq F_j^{*(m),\lambda}$ iff $j \in \mathcal{B}$. Next note that for any j the function $(g(F_j^{(m-1)}) - g(x))k(x)w_j$ is an increasing function for $x \leq F_j^{(m-1)}$. The last two observations imply (29). Finally since $\prod_{j=1}^n g(F_j^{*(m),0}) = \prod_{j=1}^n g(F_j^{*(m)}) < 1$ and $\prod_{j=1}^n g(F_j^{*(m),1}) \geq \prod_{j=1}^n g(F_j^{(m-1)}) = 1$, by the continuity of g there exists a $\lambda \in (0,1]$ such that $\prod_{j=1}^n g(F_j^{*(m),\lambda}) = 1$. These facts and inequality (29) imply that $\mathbf{F}^{(m)}$ would not be a maximum in the iteration which is a contradiction. ■

Proof [Proof of Theorem 3.1] By construction we have that on the m^{th} iteration the value $\mathbf{F}^{(m)}$ satisfies $\prod_{j=1}^m g(F_j^{(m)}) = 1$, and Lemma A.3 guarantees that $\mathbf{F}^{(m)} \in \Omega$ for all m. Hence, since $F_j^{(m)}$ are viable values for $F_j^{(m+1)}$, the iteration also guarantees that:

$$\sum_{j=1}^{n}\{\phi(F_j^{(m)}) - \phi(F_j^{(m+1)})\}w_j \geq \sum_{j=1}^{n}\{g(F_j^{(m)}) - g(F_j^{(m+1)})\}k(F_j^{(m+1)})w_j \geq 0.$$

Now, from Remark A.1, $F_j^{(m+1)}$ lie on a compact set for all j, since for our starting point we have $\mathbf{F}_j^{(0)} \equiv 0 \in \Omega$. Therefore there must exist a subsequence $\{m_\ell, \ell = 1, ...\}$ such that $\mathbf{F}^{(m_\ell)}$ converges coordinate-wise on this subsequence, and denote with $\mathbf{F}^*$ its limit.

The function ϕ is continuous and hence we have that $\sum_{j=1}^n \phi(F_j^{(m_\ell)})w_j - \sum_{j=1}^n \phi(F_j^{(m_{\ell+1})})w_j \to 0$. However by the construction of our iteration, the sequences $\sum_{j=1}^n \phi(F_j^{(m_{\ell+1})})w_j$ are decreasing for all ℓ. Therefore we have that: $\sum_{j=1}^n \phi(F_j^{(m)})w_j - \sum_{j=1}^n \phi(F_j^{(m+1)})w_j \to 0$ holds for all m, not only on the subsequence. But this implies that $\sum_{j=1}^n (g(F_j^{(m)}) - g(F_j^{(m+1)}))k(F_j^{(m+1)})w_j \to 0$, which again by the construction is non-negative for all m. Take m_ℓ in place of m in the limit above, and let L be the set of all limit points $\lim_{\ell\to\infty} \mathbf{F}^{(m_\ell+1)}$. By our construction we have the following inequality holding for any point $\mathbf{F}^l \in L$:

$$0 = \sum_{j=1}^{n}\{g(F_j^*) - g(F_j^l)\}k(F_j^l)w_j \geq \sum_{j=1}^{n}\{g(F_j^*) - g(F_j)\}k(F_j)w_j, \quad (30)$$

for any $\mathbf{F} \in \Omega$ with $\prod_{j=1}^n g(F_j) = 1$. Just as in the proof of Theorem 2.1 select $\widetilde{\mathbf{F}}$ so that $g(F_j^*)k(\widetilde{F}_j)w_j = \mathcal{C}$ for all j for some $\mathcal{C} < 0$. By the AM-GM inequality we get:

$$\sum_{j=1}^{n} g(\widetilde{F}_j)\{-k(\widetilde{F}_j)\}w_j \geq n\left[\prod_{j=1}^{n} g(\widetilde{F}_j)\{-k(\widetilde{F}_j)\}w_j\right]^{n^{-1}} = n\left[\prod_{j=1}^{n} g(F_j^*)\{-k(\widetilde{F}_j)\}w_j\right]^{n^{-1}}$$
$$= \sum_{j=1}^{n} g(F_j^*)\{-k(\widetilde{F}_j)\}w_j = -n\mathcal{C}.$$

Now by (30) it follows that equality must be achieved in the preceding display, which implies that $g(F_j^*)k(\widetilde{F}_j)w_j = \mathcal{C} = g(\widetilde{F}_j)k(\widetilde{F}_j)w_j$ and yields $\widetilde{F}_j = F_j^*$ for all j. Hence $g(F_j^*)k(F_j^*)w_j = \mathcal{C}$ for all j.

Thus we showed that on subsequences the iteration converges to points satisfying the equality described above. We are left to show, that all these subsequences converge to the same point. Next, take equation (30). By what we showed it follows that for any $\mathbf{F}^l \in L$, we have that $g(F_j^l)k(F_j^l)w_j = \mathcal{C}^l$ for some $\mathcal{C}^l < 0$. Then we have:

$$\sum_{j=1}^{n} g(F_j^*)\{-k(F_j^l)\}w_j \geq n\left[\prod_{j=1}^{n} g(F_j^*)\{-k(F_j^l)\}w_j\right]^{n^{-1}} = n\left[\prod_{j=1}^{n} g(F_j^l)\{-k(F_j^l)\}w_j\right]^{n^{-1}}$$
$$= \sum_{j=1}^{n} g(F_j^l)\{-k(F_j^l)\}w_j = -n\mathcal{C}^l.$$

Equation (30) implies that the above inequality is in fact equality which shows that:

$$g(F_j^*)k(F_j^l) = g(F_j^l)k(F_j^l) \quad \text{for all } j.$$

Thus since $k(F_j^l) \neq 0$ (recall that all values on the iteration $\mathbf{F}^{(m)} \in \Omega$) we conclude that $g(F_j^*) = g(F_j^l)$, and hence $\mathbf{F}^* = \mathbf{F}^l$. This shows that for any converging subsequence m_ℓ the limiting value coincides with that of the sequence $m_\ell + 1$, which finishes our proof. ■

Proof [Proof of Proposition 3.2.] It is sufficient to show that for all $\mathbf{F} \in \mathcal{G}^*$ we have:

$$\sum_{i=1}^{N} \mathbf{Y}_{C_i}^T \mathbf{F}(\mathbf{X}_i)\dot{\phi}(\mathbf{Y}_{C_i}^T \mathbf{F}^{(\infty)}(\mathbf{X}_i)) \geq 0.$$

The condition above is sufficient, because of the looping closure of $\mathcal{G}$. Writing the inequality for all "looped" versions of $\mathbf{F}$ and noting that they sum up to 0, gives us that the inequality is in fact an equality.

Note that with each iteration (18), we decrease the value of the target function. This can be seen by the following inequality:

$$\sum_{i=1}^{N}\phi(\mathbf{Y}_{C_i}^T\mathbf{F}^{(m-1)}(\mathbf{X}_i)) - \sum_{i=1}^{N}\phi(\mathbf{Y}_{C_i}^T\mathbf{F}^{(m)}(\mathbf{X}_i)) \geq \sum_{i=1}^{N}[\exp(-\beta\mathbf{Y}_{C_i}^T\mathbf{F}(\mathbf{X}_i)) - 1]\dot{\phi}(\mathbf{Y}_{C_i}^T\mathbf{F}^{(m)}(\mathbf{X}_i)) \geq 0,$$

where $\mathbf{F}^{(m)} = \mathbf{F}^{(m-1)} + \beta\mathbf{F}$. As a remark, the inequality in the preceding display holds, since ϕ is decreasing and thus by (6) we have $S = \mathbb{R}$.

Take a limiting point[11] $\mathbf{F}^{(\infty)}$ of iteration (18), where it is possible having coordinates of $\mathbf{F}^{(\infty)}(\mathbf{X}_i)$ equal to $\pm\infty$ for some i. Since ϕ is bounded from below, by our previous observation we have that for any $\beta \geq 0$ and $\mathbf{F} \in \mathcal{G}^*$:

$$\sum_{i=1}^{N}\phi(\mathbf{Y}_{C_i}^T\mathbf{F}^{(\infty)}(\mathbf{X}_i)) - \sum_{i=1}^{N}\phi(\mathbf{Y}_{C_i}^T\mathbf{F}^{(\infty)}(\mathbf{X}_i) + \beta\mathbf{Y}_{C_i}^T\mathbf{F}(\mathbf{X}_i)) \leq 0.$$

11. The existence of a limiting point is guaranteed as any sequence contains a monotone subsequence.

Let $\mathcal{A} = \{i : |\mathbf{Y}_{C_i}^T \mathbf{F}^{(\infty)}(\mathbf{X}_i)| \neq \infty\}$. Then the latter inequality also implies that:

$$\sum_{i \in \mathcal{A}} \phi(\mathbf{Y}_{C_i}^T \mathbf{F}^{(\infty)}(\mathbf{X}_i)) - \sum_{i \in \mathcal{A}} \phi(\mathbf{Y}_{C_i}^T \mathbf{F}^{(\infty)}(\mathbf{X}_i) + \beta \mathbf{Y}_{C_i}^T \mathbf{F}(\mathbf{X}_i)) \leq 0.^{12}$$

Applying inequality (6) the above implies:

$$\sum_{i \in \mathcal{A}} [\exp(-\beta \mathbf{Y}_{C_i}^T \mathbf{F}(\mathbf{X}_i)) - 1] \dot{\phi}(\mathbf{Y}_{C_i}^T \mathbf{F}^{(\infty)}(\mathbf{X}_i) + \beta \mathbf{Y}_{C_i}^T \mathbf{F}(\mathbf{X}_i)) \leq 0,$$

and after a Taylor expansion of the exponent, and division by $\beta \geq 0$ we get:

$$\begin{aligned}
&\sum_{i \in \mathcal{A}} -\mathbf{Y}_{C_i}^T \mathbf{F}(\mathbf{X}_i) \dot{\phi}(\mathbf{Y}_{C_i}^T \mathbf{F}^{(\infty)}(\mathbf{X}_i)) \\
&+ \sum_{i \in \mathcal{A}} -\mathbf{Y}_{C_i}^T \mathbf{F}(\mathbf{X}_i) [\dot{\phi}(\mathbf{Y}_{C_i}^T \mathbf{F}^{(\infty)}(\mathbf{X}_i) + \beta \mathbf{Y}_{C_i}^T \mathbf{F}(\mathbf{X}_i)) - \dot{\phi}(\mathbf{Y}_{C_i}^T \mathbf{F}^{(\infty)}(\mathbf{X}_i))] \\
&+ O(\beta) \sum_{i \in \mathcal{A}} \dot{\phi}(\mathbf{Y}_{C_i}^T \mathbf{F}^{(\infty)}(\mathbf{X}_i) + \beta \mathbf{Y}_{C_i}^T \mathbf{F}(\mathbf{X}_i)) \leq 0.
\end{aligned}$$

Letting $\beta \to 0$, by the continuity of $\dot{\phi}$ we get:

$$\sum_{i \in \mathcal{A}} \mathbf{Y}_{C_i}^T \mathbf{F}(\mathbf{X}_i) \dot{\phi}(\mathbf{Y}_{C_i}^T \mathbf{F}^{(\infty)}(\mathbf{X}_i)) \geq 0. \tag{31}$$

Next we argue that $\dot{\phi}(+\infty) = \lim_{x \to +\infty} \dot{\phi}(x) = 0$. As stated in the main text $\dot{\phi}(x) = k(x)e^x$. Let $K = \inf_{x \in \mathbb{R}} \phi(x)$. For any $\varepsilon > 0$, take a point x' such that $\phi(x') - K \leq \varepsilon$. Then for any $x \in \mathbb{R}$, by (6):

$$\varepsilon \geq \phi(x') - \phi(x) \geq (e^{x'} - e^x) k(x),$$

and thus $\varepsilon - e^{x'} k(x) \geq -\dot{\phi}(x) \geq 0$. Taking the limit $x \to +\infty$ and letting $\varepsilon \to 0$ shows that $\dot{\phi}(+\infty) = 0$.

Now consider two cases for ϕ. Suppose that ϕ is unbounded from above. We argue that $\mathbf{Y}_{C_i}^T \mathbf{F}^{(\infty)}(\mathbf{X}_i) \neq -\infty$ for all i. Since we start form the point 0, and as we argued we are decreasing the target function we have that:

$$N\phi(0) \geq \sum_{i=1}^{N} \phi(\mathbf{Y}_{C_i}^T \mathbf{F}^{(\infty)}(\mathbf{X}_i)) \geq \max_i \phi(\mathbf{Y}_{C_i}^T \mathbf{F}^{(\infty)}(\mathbf{X}_i)) + (N-1)K,$$

and hence $\max_i \phi(\mathbf{Y}_{C_i}^T \mathbf{F}^{(\infty)}(\mathbf{X}_i)) \leq N\phi(0) - (N-1)K$. Since ϕ is decreasing and unbounded from above it follows that $\mathbf{Y}_{C_i}^T \mathbf{F}^{(\infty)}(\mathbf{X}_i) \neq -\infty$ for all i. In the second case suppose that ϕ is bounded from above, and let $M = \sup_{x \in \mathbb{R}} \phi(x)$. We show that $\dot{\phi}(-\infty) = 0$. For any $\varepsilon > 0$ take x so that $\varepsilon \geq M - \phi(x)$. Applying (6) for any $x' \in \mathbb{R}$ yields:

$$\varepsilon \geq \phi(x') - \phi(x) \geq (e^{x'} - e^x) k(x).$$

This gives $\varepsilon - e^{x'} k(x) \geq -\dot{\phi}(x) \geq 0$. Taking $x' \to -\infty$ gives that $\varepsilon \geq -\dot{\phi}(x) \geq 0$ for any x such that $\varepsilon \geq M - \phi(x)$. Since ϕ is decreasing we are allowed to take the limit $x \to -\infty$, and

12. Observe that since ϕ is bounded from below the values of ϕ at infinite points of the iteration i.e. $\phi(\pm\infty)$ have to be bounded.

taking $\varepsilon \to 0$ shows that $\dot{\phi}(-\infty) = 0$. In any case, all of the above arguments imply that we can substitute $\mathcal{A}$ in (31) to the whole index set $\{1, \ldots, N\}$, to finally conclude:

$$\sum_{i=1}^{N} \mathbf{Y}_{C_i}^T \mathbf{F}(\mathbf{X}_i) \dot{\phi}(\mathbf{Y}_{C_i}^T \mathbf{F}^{(\infty)}(\mathbf{X}_i)) \geq 0,$$

for all $\mathbf{F} \in \mathcal{G}^*$. As argued in the beginning the looping closure gives us that in fact the "$\geq$" can be replaced with "=". This concludes the proof.

■

Proof [Proof of Proposition 3.3] First consider the case when $I = N$. Denote with $e_1^1, e_1^2, \ldots, e_1^N$ the positive coordinates of $\mathbf{e}_1$. For any vector $\mathbf{v}$ which is a solution to $\mathbf{D}^T \boldsymbol{\alpha} = \mathbf{v}$ we must have $\sum_{i=1}^N e_1^i v_i = 0$. Clearly then, if $\mathbf{v}$ is non-zero some of the v_i need to be negative. Let $l = \min v_i$. We know that $l < 0$. This immediately implies an upper bound on the maximal positive v_i — $\max_j v_i \leq |l|[\sum_{i=1}^N e_1^i / \min_j e_1^j - 1]$. We now show that $|l|$ is bounded, for all vectors $\mathbf{v}$ such that $\sum_{i=1}^N \phi(v_i) \leq N\phi(0)$. Note that $\sum_{i=1}^N \phi(v_i) \geq \phi(l) + (N-1)\phi(|l|[\sum_{i=1}^N e_1^i / \min_j e_1^j - 1])$, and thus (22) gives that $|l|$ is bounded. This in turn shows that all v_i are bounded as well.

We next consider the case where $I < N$. Without loss of generality, upon rearrangement, we can assume that the positive coordinates of $\mathbf{e}_1$ are located at the first I places. Let $\mathbf{E}_{N \times s} = (\mathbf{e}_1, \ldots, \mathbf{e}_s)$. Let $\widetilde{\mathbf{E}}_{(N-I) \times (s-1)}$ denote the sub-matrix corresponding to the 0 entries of $\mathbf{e}_1$ (excluding $\mathbf{e}_1$) (see (32) for a visualization). Note that the matrix $\widetilde{\mathbf{E}}$ cannot be of full column rank, because otherwise we would have that a vector with positive coordinates is inside the column space which is a contradiction (we can always scale it by a small number and add to $\mathbf{e}_1$). Thus we can eliminate all extra columns that do not contribute to the rank of $\widetilde{\mathbf{E}}$, by doing a linear manipulation on the columns of the whole matrix $\mathbf{E}$ (see (32)). In doing so, we can eliminate extra columns of the matrix $\widetilde{\mathbf{E}}$ so that we end up with a $\widetilde{\widetilde{\mathbf{E}}}$ matrix where the number of non-zero columns matches the rank, and some columns of $\mathbf{E}$ have 0 coefficients on the lower part. Here, observe that the columns of $\mathbf{E}$ with 0 sub-columns in $\widetilde{\mathbf{E}}$, are part of the space $\text{row}(\mathbf{D}_-)^\perp$, where $\mathbf{D}_-$ corresponds to the matrix $\mathbf{D}$ with observations corresponding to 0's of $\mathbf{e}_1$ removed.

We next note that if we discard the observations corresponding to 0 coordinates in e_1, and optimize the problem on the rest of the observations we will obtain some optimal solution $\mathbf{v} = (\hat{v}_1, \ldots, \hat{v}_I)^T$, the entries of which are bounded as argued in the first case. We next show that we can populate the vector $\mathbf{v}$ with positive numbers $p_1, \ldots, p_{N-I}$ to $\boldsymbol{\nu} = (\hat{v}_1, \ldots, \hat{v}_I, p_1, \ldots, p_{N-I})^T$, so that $\boldsymbol{\nu}$ is "perpendicular" to the matrix $\mathbf{E}$ (i.e. $\mathbf{E}^T \boldsymbol{\nu} = 0$), and thus can be written in the form $\mathbf{D}^T \boldsymbol{\alpha}$. Moreover, we will show that $p_1, \ldots, p_{N-I}$, can become arbitrarily large, which will complete the proof.

$$\mathbf{E} = \begin{array}{c} \\ I \\ \\ N-I \end{array} \begin{array}{|c|c|} \hline \mathbf{e}_1 & \mathbf{e}_2 \ \ldots \ \mathbf{e}_s \\ \hline e_1^1 \\ \vdots \\ e_1^I & \\ \hline 0 \\ \vdots \\ 0 & \widetilde{\mathbf{E}} \\ \hline \end{array} \quad \rightarrow \quad \begin{array}{|c|c|c|} \hline \mathbf{e}_1 & \ldots \ \widetilde{\mathbf{e}}_{l+1} & \widetilde{\mathbf{e}}_{l+2} \ \ldots \ \widetilde{\mathbf{e}}_s \\ \hline e_1^1 \\ \vdots \\ e_1^I & \mathbf{G} & \\ \hline 0 & & 0 \ \ldots \ 0 \\ \vdots & \widetilde{\widetilde{\mathbf{E}}} & \vdots \ \ldots \ \vdots \\ 0 & & 0 \ \ldots \ 0 \\ \hline \end{array} \tag{32}$$

Note that the only part of the matrix $\mathbf{E}$ that would be potentially non-zero upon multiplication by $\boldsymbol{\nu}$ would be the part corresponding to the non-zero parts of $\widetilde{\mathbf{E}}$, because as we argued earlier the columns of $\mathbf{E}$ with 0 sub-columns in $\widetilde{\mathbf{E}}$ belong to $\text{row}(\mathbf{D}_-)^\perp$ and on the other hand $\mathbf{v} \in \text{row}(\mathbf{D}_-)$. Denote with $\widetilde{\widetilde{\mathbf{E}}}_{(N-I)\times l}$ the full-rank sub-matrix of $\widetilde{\mathbf{E}}$, where l is the rank of $\widetilde{\mathbf{E}}$, and let $\mathbf{G}_{I\times l}$ be the sub-matrix of $\mathbf{E}$ above $\widetilde{\widetilde{\mathbf{E}}}$ (see (32)). Clearly $l < N - I$ as otherwise there is a positive vector in the column space, and we argued previously that would be a contradiction with the maximality property of $\mathbf{e}_1$. We need to find a positive vector $\mathbf{p}$ such that $(\widetilde{\widetilde{\mathbf{E}}}_{(N-I)\times l})^T \mathbf{p}_{(N-I)\times 1} = -(\mathbf{G}_{I\times l})^T \mathbf{v}_{I\times 1} = \mathbf{K}_{l\times 1}$. Therefore the proof will be completed, if we can find arbitrary large positive vectors $\mathbf{p}$ solving the system $\widetilde{\widetilde{\mathbf{E}}}^T \mathbf{p} = \mathbf{K}$, where $l < N - I$ and $\widetilde{\widetilde{\mathbf{E}}}^T$ has the property that any non-zero linear combination of its rows results into a vector with at least one positive and one negative entry.

Since $\widetilde{\widetilde{\mathbf{E}}}$ is full-rank and $l < N - I$, the linear system $\widetilde{\widetilde{\mathbf{E}}}^T \mathbf{p} = \mathbf{K}$ has a solution. Consider the homogeneous system $\widetilde{\widetilde{\mathbf{E}}}^T \mathbf{p} = 0$. We will show that the homogeneous equation admits arbitrary large positive solutions, which would complete the proof. Fix the value of the i^{th} parameter to be 1. The system then becomes $\widetilde{\widetilde{\mathbf{E}}}^T_{-i} \mathbf{p}_{-i} = -\widetilde{\widetilde{\mathbf{e}}}_i$, where by indexing with $-i$ we mean removing the i^{th} column or element and $\widetilde{\widetilde{\mathbf{e}}}_i$ is the i^{th} column of $\widetilde{\widetilde{\mathbf{E}}}^T$. Next we apply Farkas's lemma to show that the last equation has a non-negative solution. Assume that there is a vector $\mathbf{y}_{l\times 1}$ such that $\widetilde{\widetilde{\mathbf{E}}}_{-i}\mathbf{y} \geq 0$ (coordinate-wise) and $-\widetilde{\widetilde{\mathbf{e}}}_i^T \mathbf{y} < 0$. This is clearly a violation with the property that $\widetilde{\widetilde{\mathbf{E}}}$ satisfies. Therefore by Farkas's lemma the equation $\widetilde{\widetilde{\mathbf{E}}}^T_{-i} \mathbf{p}_{-i} = -\widetilde{\widetilde{\mathbf{e}}}_i$ has a non-negative solution. Since we can achieve this for any index i, averaging these solutions yields a positive solution to the homogeneous system $\widetilde{\widetilde{\mathbf{E}}}^T \mathbf{p} = 0$, and thus this system admits arbitrarily large positive solutions.

■

Proof [Proof of Theorem 3.4] Without loss of generality for the purposes of the proof we will consider $\mathcal{C}_+ = 1$ and $\mathcal{C}_- = -1/(n-1)$ (it's equivalent to rescaling the β in the iteration).

By the iteration's construction we know:

$$\varepsilon_m - \varepsilon_{m+1} \geq \max_{\beta\geq 0, \mathbf{F}\in\mathcal{G}^*} \sum_{i=1}^N \{e^{-\beta \mathbf{Y}_{C_i}^T \mathbf{F}(\mathbf{X}_i)} - 1\} \dot{\phi}\{\mathbf{Y}_{C_i}^T \mathbf{F}^{(m)}(\mathbf{X}_i) + \beta \mathbf{Y}_{C_i}^T \mathbf{F}(\mathbf{X}_i)\}.$$

Note that we have the following simple inequality holding for $\exp(-x) \leq 1 - x + x^2$ for values of $-1/2 \leq x \leq 1/2$. Since $|\mathbf{Y}_{C_i}^T \mathbf{F}(\mathbf{X}_i)| \leq \mathcal{C}_+ = 1$ and ϕ is decreasing, for values of $0 \leq \beta \leq 1/2$ we have that:

$$\begin{aligned}
&\sum_{i=1}^N \{e^{-\beta \mathbf{Y}_{C_i}^T \mathbf{F}(\mathbf{X}_i)} - 1\} \dot{\phi}\{\mathbf{Y}_{C_i}^T \mathbf{F}^{(m)}(\mathbf{X}_i) + \beta \mathbf{Y}_{C_i}^T \mathbf{F}(\mathbf{X}_i)\} \\
&\geq -\sum_{i=1}^N (\beta \mathbf{Y}_{C_i}^T \mathbf{F}(\mathbf{X}_i) - \beta^2) \dot{\phi}\{\mathbf{Y}_{C_i}^T \mathbf{F}^{(m)}(\mathbf{X}_i) + \beta \mathbf{Y}_{C_i}^T \mathbf{F}(\mathbf{X}_i)\}.
\end{aligned}$$

Let L denote the Lipschitz constant of $\dot{\phi}$ on the set $\mathcal{S}$. Consequently we have:

$$\begin{aligned}
-\sum_{i=1}^N (\beta \mathbf{Y}_{C_i}^T \mathbf{F}(\mathbf{X}_i) - \beta^2) \dot{\phi}\{\mathbf{Y}_{C_i}^T \mathbf{F}^{(m)}(\mathbf{X}_i) + \beta \mathbf{Y}_{C_i}^T \mathbf{F}(\mathbf{X}_i)\} &= \sum_{i=1}^N -(\beta \mathbf{Y}_{C_i}^T \mathbf{F}(\mathbf{X}_i) - \beta^2) \dot{\phi}\{\mathbf{Y}_{C_i}^T \mathbf{F}^{(m)}(\mathbf{X}_i)\} \\
&- \sum_{i=1}^N (\beta \mathbf{Y}_{C_i}^T \mathbf{F}(\mathbf{X}_i) - \beta^2)[\dot{\phi}\{\mathbf{Y}_{C_i}^T \mathbf{F}^{(m)}(\mathbf{X}_i) + \beta \mathbf{Y}_{C_i}^T \mathbf{F}(\mathbf{X}_i)\} - \dot{\phi}\{\mathbf{Y}_{C_i}^T \mathbf{F}^{(m)}(\mathbf{X}_i)\}] \geq \\
&\sum_{i=1}^N -(\beta \mathbf{Y}_{C_i}^T \mathbf{F}(\mathbf{X}_i) - \beta^2) \dot{\phi}\{\mathbf{Y}_{C_i}^T \mathbf{F}^{(m)}(\mathbf{X}_i)\} - L\left|\beta \mathbf{Y}_{C_i}^T \mathbf{F}(\mathbf{X}_i) - \beta^2\right| \left|\beta \mathbf{Y}_{C_i}^T \mathbf{F}(\mathbf{X}_i)\right| \geq \\
&\sum_{i=1}^N -(\beta \mathbf{Y}_{C_i}^T \mathbf{F}(\mathbf{X}_i) - \beta^2) \dot{\phi}\{\mathbf{Y}_{C_i}^T \mathbf{F}^{(m)}(\mathbf{X}_i)\} - \frac{3}{2} LN\beta^2.
\end{aligned}$$

Thus we have established:

$$\varepsilon_m - \varepsilon_{m+1} \geq \beta \left(\sum_{i=1}^N (-\mathbf{Y}_{C_i}^T \mathbf{F}(\mathbf{X}_i) + \beta) \dot{\phi}\{\mathbf{Y}_{C_i}^T \mathbf{F}^{(m)}(\mathbf{X}_i)\} - \frac{3}{2} LN\beta \right),$$

for any $0 \leq \beta \leq 1/2$. We select β so that we maximize the RHS in the expression above. It turns out that this happens for:

$$\beta_0 = \frac{\frac{1}{2}\sum_{i=1}^N \mathbf{Y}_{C_i}^T \mathbf{F}(\mathbf{X}_i) \dot{\phi}\{\mathbf{Y}_{C_i}^T \mathbf{F}^{(m)}(\mathbf{X}_i)\}}{-\frac{3}{2}LN + \sum_{i=1}^N \dot{\phi}\{\mathbf{Y}_{C_i}^T \mathbf{F}^{(m)}(\mathbf{X}_i)\}}.$$

Since $\dot{\phi}$ is always negative and as we mentioned $\left|\mathbf{Y}_{C_i}^T \mathbf{F}(\mathbf{X}_i)\right| \leq 1$, provided that the numerator is ≤ 0, we have that $0 \leq \beta_0 \leq 1/2$. Then we would have:

$$\varepsilon_m - \varepsilon_{m+1} \geq -\frac{1}{2}\beta_0 \sum_{i=1}^N \mathbf{Y}_{C_i}^T \mathbf{F}(\mathbf{X}_i) \dot{\phi}\{\mathbf{Y}_{C_i}^T \mathbf{F}^{(m)}(\mathbf{X}_i)\}. \tag{33}$$

Next we show that there exists a classifier, such that the above expression is strictly positive, which will also ensure that $0 \leq \beta_0 \leq 1/2$ is in the correct range. Denote with B the total number of classifiers in the bag. Consider the representation $\mathbf{F}^*(\cdot) - \mathbf{F}^{(m)}(\cdot) = \sum_{j=1}^B \alpha_j \mathbf{F}_j(\cdot)$. Here the $\boldsymbol{\alpha}$ vector is any vector that yields a correct representation (note that we will have many possible $\boldsymbol{\alpha}$ vectors, in the case when $B > N$).

By convexity of ϕ we have:

$$\begin{aligned}
-\varepsilon_m = \sum_{i=1}^N \phi(\mathbf{Y}_{C_i}^T \mathbf{F}^*(\mathbf{X}_i)) - \phi(\mathbf{Y}_{C_i}^T \mathbf{F}^{(m)}(\mathbf{X}_i)) &\geq \sum_{i=1}^N [\mathbf{Y}_{C_i}^T \mathbf{F}^*(\mathbf{X}_i) - \mathbf{Y}_{C_i}^T \mathbf{F}^{(m)}(\mathbf{X}_i)] \dot{\phi}(\mathbf{Y}_{C_i}^T \mathbf{F}^{(m)}(\mathbf{X}_i)) \\
&= \sum_{j=1}^B \sum_{i=1}^N \alpha_j \mathbf{Y}_{C_i}^T \mathbf{F}_j(\mathbf{X}_i) \dot{\phi}(\mathbf{Y}_{C_i}^T \mathbf{F}^{(m)}(\mathbf{X}_i)).
\end{aligned}$$

By the pigeonhole principle it is clear that there exists an index $j \in \{1, \ldots, B\}$ such that:

$$\frac{\varepsilon_m}{B \max_j |\alpha_j|} \leq \frac{\varepsilon_m}{B|\alpha_j|} \leq -\text{sign}(\alpha_j) \sum_{i=1}^N \mathbf{Y}_{C_i}^T \mathbf{F}_j(\mathbf{X}_i) \dot{\phi}(\mathbf{Y}_{C_i}^T \mathbf{F}^{(m)}(\mathbf{X}_i)).$$

Now if $\text{sign}(\alpha_j) = 1$ we already have a "decent" lower bound. Otherwise if $\text{sign}(\alpha_j) = -1$, using the fact that the loop closed classifiers wrt to $\mathbf{F}_j$ sum up to 0, we can claim that for one of the looped classifiers $\mathbf{F}_j^l$ we would have a bound:

$$\frac{\varepsilon_m}{B(n-1)\max_j|\alpha_j|} \leq -\sum_{i=1}^{N}\mathbf{Y}_{C_i}^T\mathbf{F}_j^l(\mathbf{X}_i)\dot{\phi}(\mathbf{Y}_{C_i}^T\mathbf{F}^{(m)}(\mathbf{X}_i)).$$

So that in both cases we established the existence of a classifier such that $\mathbf{F} \in \mathcal{G}^*$ and:

$$\frac{\varepsilon_m}{B(n-1)\max_j|\alpha_j|} \leq -\sum_{i=1}^{N}\mathbf{Y}_{C_i}^T\mathbf{F}(\mathbf{X}_i)\dot{\phi}(\mathbf{Y}_{C_i}^T\mathbf{F}^{(m)}(\mathbf{X}_i))$$

We then know from (33) that:

$$\begin{aligned}\varepsilon_m - \varepsilon_{m+1} &\geq -\frac{1}{2}\beta_0\sum_{i=1}^{N}\mathbf{Y}_{C_i}^T\mathbf{F}(\mathbf{X}_i)\dot{\phi}\{\mathbf{Y}_{C_i}^T\mathbf{F}^{(m)}(\mathbf{X}_i)\}\\ &\geq \frac{1}{4}\frac{\varepsilon_m^2}{B^2(n-1)^2\max_j\alpha_j^2(\frac{3}{2}LN - \sum_{i=1}^{N}\dot{\phi}\{\mathbf{Y}_{C_i}^T\mathbf{F}^{(m)}(\mathbf{X}_i)\})}.\end{aligned}$$

Notice that the derivative is bounded on the set $\mathcal{S}$ and therefore collapsing all constants above into one constant say T we get the following:

$$\varepsilon_m - \varepsilon_{m+1} \geq \frac{\varepsilon_m^2}{T\max_j\alpha_j^2}.$$

Here T depends on the number of classifiers, number of classes, and the bound on the first derivative $\dot{\phi}$ on the set $\mathcal{S}$. We will proceed to bound the $\max_j\alpha_j^2$ for some of the representations from above.

Because on the set $\mathcal{S}$, ϕ is also strongly convex (with a constant say l), we have the following:

$$\begin{aligned}\varepsilon_m &= \sum_{i=1}^{N}\phi(\mathbf{Y}_{C_i}^T\mathbf{F}^{(m)}(\mathbf{X}_i)) - \sum_{i=1}^{N}\phi(\mathbf{Y}_{C_i}^T\mathbf{F}^*(\mathbf{X}_i))\\ &\geq \sum_{i=1}^{N}[\mathbf{Y}_{C_i}^T\mathbf{F}^{(m)}(\mathbf{X}_i) - \mathbf{Y}_{C_i}^T\mathbf{F}^*(\mathbf{X}_i)]\dot{\phi}(\mathbf{Y}_{C_i}^T\mathbf{F}^*(\mathbf{X}_i))\\ &+ l\sum_{i=1}^{N}\left(\sum_{j=1}^{B}\alpha_j\mathbf{Y}_{C_i}^T\mathbf{F}_j(\mathbf{X}_i)\right)^2.\end{aligned}$$

The expression $\sum_{i=1}^{N}[\mathbf{Y}_{C_i}^T\mathbf{F}^{(m)}(\mathbf{X}_i) - \mathbf{Y}_{C_i}^T\mathbf{F}^*(\mathbf{X}_i)]\dot{\phi}(\mathbf{Y}_{C_i}^T\mathbf{F}^*(X_i))$ is 0, as $\mathbf{F}^*$ is the minimum, ϕ is convex and the classifier bag is closed under looping. Let $\mathbf{D} = \{\mathbf{Y}_{C_i}^T\mathbf{F}_j(\mathbf{X}_i)\}_{j,i}$ is the $B\times N$ matrix, each entry of which is either $\mathcal{C}_+$ or $\mathcal{C}_-$. Let the rank of $\mathbf{D}$ is $r \leq \min(N, B)$. We then have $\sum_{i=1}^{N}\left(\sum_{j=1}^{B}\alpha_j\mathbf{Y}_{C_i}^T\mathbf{F}_j(\mathbf{X}_i)\right)^2 = \boldsymbol{\alpha}^T\mathbf{D}\mathbf{D}^T\boldsymbol{\alpha}$. Since, all the bounds above are true for any of the $\boldsymbol{\alpha}$ representations, we could have picked the representation corresponding to the $r\times N$ sub matrix of $\mathbf{D}$, $\mathbf{D}_r$ with rank r for which the smallest eigenvalue of $\mathbf{D}_r\mathbf{D}_r^T$ is the largest. Let this eigenvalue be $\lambda_r > 0$. For this eigenvalue and this choice of $\boldsymbol{\alpha}$ we clearly have $\boldsymbol{\alpha}^T\mathbf{D}\mathbf{D}^T\boldsymbol{\alpha} = \boldsymbol{\alpha}^T\mathbf{D}_r\mathbf{D}_r^T\boldsymbol{\alpha} \geq \lambda_r||\boldsymbol{\alpha}||_2^2 \geq \lambda_r\max_j\alpha_j^2$. (in the second equality we abuse notation deleting zeros from the $\boldsymbol{\alpha}$). Consequently we get:

$$\varepsilon_m \geq l\lambda_r\max_j\alpha_j^2.$$

Thus:

$$\begin{aligned}\varepsilon_{m+1} &\leq \varepsilon_m - \frac{\varepsilon_m^2}{T\max_j\alpha_j^2}\\ &\leq \varepsilon_m\left(1 - \frac{l\lambda_r}{T}\right).\end{aligned}$$

Since both $\varepsilon_{m+1}, \varepsilon_m \geq 0$ we must have $1 - \frac{l\lambda_r}{T} \geq 0$. Furthermore, by construction we have $\frac{l\lambda_r}{T} > 0$, which concludes the proof. ■

Remark A.3 *Since $\mathcal{S}$ is bounded we did not need to require that the first derivative — $\dot{\phi}$ is bounded since we already assumed its Lipschitz continuity.*

Abstract

We present the path-sum formulation for exact statistical inference of marginals on Gaussian graphical models of arbitrary topology. The path-sum formulation gives the covariance between each pair of variables as a branched continued fraction of finite depth and breadth. Our method originates from the closed-form resummation of infinite families of terms of the walk-sum representation of the covariance matrix. We prove that the path-sum formulation always exists for models whose covariance matrix is positive definite: i.e. it is valid for both walk-summable and non-walk-summable graphical models of arbitrary topology. We show that for graphical models on trees the path-sum formulation is equivalent to Gaussian belief propagation. We also recover, as a corollary, an existing result that uses determinants to calculate the covariance matrix. We show that the path-sum formulation formulation is valid for arbitrary partitions of the inverse covariance matrix. We give detailed examples demonstrating our results.

Keywords: Gaussian graphical models, belief propagation, path-sum, walk-sum, graphs of arbitrary topology, block matrices

1. Introduction

A Gaussian Markov random field (GMRF) is a random vector that follows a multivariate normal (or Gaussian) distribution and satisfies *conditional independence* assumptions, hence the *Markov* property. If X_1, X_2, X_3 are random variables with a joint probability density function (or joint probability mass function in a discrete case), we say that X_1 is *conditionally independent* of X_2 given X_3, denoted $X_1 \perp\!\!\!\perp X_2|X_3$, if (Lauritzen, 1996)

$$f(x_1, x_2|x_3) = f(x_1|x_3)f(x_2|x_3).$$

Here we use f as a generic symbol for the probability density function of the random variables corresponding to its arguments. GMRFs have a simple interpretation and find their applications, for example, in image analysis, spatial statistics, structural time series analysis and analysis of longitudinal and survival data (Rue and Held, 2005).

Consider a random vector $\mathbf{X} = (X_1, X_2, \ldots, X_n)$ following a multivariate normal distribution with mean μ and covariance matrix Σ, denoted $\mathbf{X} \sim \mathcal{N}(\mu, \Sigma)$. The probability density function of $\mathbf{X}$ is given as

$$f(x) = \frac{1}{\sqrt{(2\pi)^n \det(\Sigma)}} \exp\left[-\frac{1}{2}(x-\mu)^T\Sigma^{-1}(x-\mu)\right].$$

Here Σ is a symmetric and positive definite matrix. We write $A \succ 0$ to denote that the matrix A is positive definite. Alternatively the probability density function of $\mathbf{X}$ can be expressed in a *canonical form*

$$\begin{aligned} f(x) &= g(x)\exp\left[-\frac{1}{2}x^TJx + h^Tx - k(\mu,\Sigma)\right] \\ &\propto \exp\left[-\frac{1}{2}x^TJx + h^Tx\right], \end{aligned} \tag{1}$$

where $J = \Sigma^{-1}$, $h = J\mu$, $g(x) = (2\pi)^{-\frac{n}{2}}$ and $k(\mu,\Sigma) = \frac{1}{2}\mu^TJ\mu - \frac{1}{2}\ln(\det(J))$. We call J the *information matrix* (or precision matrix) and h the *potential vector*.

One advantage of using the form of parametrization in (1) is that J admits a graphical model in the following sense. Let $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ be an undirected graph with the vertex set $\mathcal{V}$ and the set of edges $\mathcal{E}$. Let $\mathbf{X}_{\setminus ij}$ denote the set of variables with X_i and X_j removed from $\mathbf{X}$. If $J = (J_{ij})_{i,j\in\mathcal{V}}$ is positive definite, then for $i, j \in \mathcal{V}$, where $i \neq j$, we have (Proposition 5.2, Lauritzen, 1996)

$$X_i \perp\!\!\!\perp X_j|\mathbf{X}_{\setminus ij} \Leftrightarrow J_{ij} = 0.$$

Then we define a GMRF as follows.

Definition 1 (Definition 2.1, Rue and Held, 2005) *A random vector* $\mathbf{X}$ *is called a GMRF* with respect to a graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ *with information matrix* J *and potential vector* h *if and only if its density has the form of (1) and* $J_{ij} \neq 0 \Leftrightarrow (i,j) \in \mathcal{E}$*, for all* i *and* j*.*

It is known that X satisfies the Markov property on $\mathcal{G}$ (see Theorem 2.4 by Rue and Held, 2005)[1]. Note that by Definition 1, there is a one-to-one correspondence between the structure of J and the structure of $\mathcal{G}$. Most information matrices J for GMRFs are sparse, i.e. there are $O(n)$ non-zero entries in J. The sparsity structure of J facilitates the simulation of GMRFs through J (Rue and Held, 2005).

Another advantage of using the canonical form concerns the estimation of $\mathbf{X}$ given noisy observations $\mathbf{Y}$ (Johnson, 2002). Indeed, assume that $\mathbf{Y} = C\mathbf{X} + \varepsilon$, where C is an $n \times n$ real matrix and $\varepsilon \sim \mathcal{N}(0, M)$. Then the conditional distribution of $\mathbf{X}|\mathbf{Y}$ is given by

$$\begin{aligned} f(x|y) &= \frac{f(y|x)f(x)}{f(y)} \\ &\propto f(y|x)f(x) \\ &\propto \exp\left[-\frac{1}{2}x^T\tilde{J}x + \tilde{h}^T x\right], \end{aligned}$$

where $\tilde{J} = J + C^T M^{-1} C$ and $\tilde{h} = h + C^T M^{-1} y$. Thus given noisy observations, one only needs to update the information matrix and the potential vector to construct a graphical model for $f(x|y)$. For simplicity, we use J and h to denote the parameters after absorption of observations.

Given the canonical form, one needs both the covariance matrix $\Sigma = J^{-1}$ and the mean vector $\mu = J^{-1}h$ to obtain the marginal distributions of $\mathbf{X}$ or $\mathbf{X}|\mathbf{Y}$. Since knowing J^{-1} is sufficient to recover μ, we focus our efforts on calculating J^{-1}. Direct inversion of J has complexity $O(n^3)$ and does not exploit the sparsity of J.[2] In a simple situation where the graph $\mathcal{G}$ of a GMRF is a tree, belief propagation (BP) efficiently calculates the correct marginals (Malioutov et al., 2006; Pearl, 1988). For graphs with cycles (also called loopy graphs), the method of loopy belief propagation (LBP) can be used to efficiently *approximate* the marginals. However, it was shown in Weiss and Freeman (2001) that while LBP gives correct means for the marginals, the estimates of the covariance matrices it provides are generally incorrect.

In this article, we present a novel approach to the calculation of the marginals of $\mathbf{X}$ or $\mathbf{X}|\mathbf{Y}$, which we term *method of path-sums*. This approach is a generalization and completion of the walk-sum formulation developed in Malioutov et al. (2006). The method of path-sums is based on results established by Giscard et al. (2012) concerning the algebraic structure of walk sets, which permit the systematic resummation of infinite families of walks in any walk-sum. These resummations transform a walk-sum into a branched continued fraction comprising only a *finite* number of terms. Furthermore, these terms have an elementary interpretation as simple paths and simple cycles on $\mathcal{G}$. A simple path is a walk (i.e. a trajectory on $\mathcal{G}$) whose vertices are all distinct. A simple cycle is a walk whose endpoints

1. For a GMRF, the pairwise Markov property, the local Markov property and the global Markov property are equivalent. This is proven by using Proposition 3.8 of Lauritzen (1996), in conjunction with the Hammersley-Clifford Theorem (Theorem 3.9, Lauritzen, 1996).
2. Algorithms that compute *some* entries (either diagonal entries or certain off-diagonal entries) of a symmetric sparse matrix with complexity less than $O(n^3)$ do exist (see Eastwood and Wan, 2013; Li et al., 2008; Lin et al., 2011; Tang and Saad, 2012). The path-sum representation achieves this as well, computing the covariance of a pair of variables with complexity $O(n)$ whenever $\mathcal{G}$ is a tree: see §5 and Giscard et al. (2013).

are identical and intermediate vertices (from the second to the penultimate) are all distinct and different from the endpoints. An important consequence of these observations is that if J is positive definite[3], the path-sum formulation of J^{-1} is convergent.

Consequently, one does not need the walk-summability of a model, which was devised by Malioutov et al. (2006) to guarantee the convergence of the infinite walk-sum representation of the covariance matrix $\Sigma = J^{-1}$. Let $R := I - J$ be the partial correlations matrix and $|R|$ be the entrywise absolute value of this matrix, i.e. $(|R|)_{ij} = |R_{ij}|$. The authors showed that a GMRF is walk-summable if and only if the spectral radius $\rho(|R|)$ is strictly less than 1, which implies $J \succ 0$. However, the converse does not hold: that is, there are positive definite information matrices which are not walk-summable. In contrast to the walk-summability criterion, our formulation only requires positive definiteness of J. Most importantly, the path-sum formulation gives the *correct* marginals when the graph $\mathcal{G}$ is loopy, and is equivalent to BP when $\mathcal{G}$ is a tree.

The rest of this article is organized as follows. In §2, we introduce the context and arguments underlying the path-sum formulation. We present the path-sum result in §2.2 and show its validity for all positive definite matrices, irrespective of the walk-summability criterion. In the following section, §3, we relate the path-sum representation of a covariance matrix to existing approaches. In §4 we prove that the path-sum representation can be applied to arbitrary partitions of the information matrix J. We give an example demonstrating this claim. Finally in §5 we briefly discuss the computational cost of our approach as well as future prospects. The proof of the path-sum result is deferred to Appendix A.

2. Path-Sum Representation

2.1 Context

The *"most basic result of algebraic graph theory"* (as described in Flajolet and Sedgewick, 2009) states that the powers of the adjacency matrix $A_{\mathcal{G}}$ of a graph $\mathcal{G}$ generate all the walks on this graph (Biggs, 1993). This result extends to weighted graphs if $A_{\mathcal{G}}$ is replaced by a weighted adjacency matrix R, with R_{ij} the weight of the edge from vertex j to vertex i on $\mathcal{G}$. Then $(R^\ell)_{ij}$ is the sum of the weights of all the walks of length ℓ from j to i (Flajolet and Sedgewick, 2009). The weight of a walk is simply the ordered product of the weight of the edges it traverses. (Note that the indices of a matrix are written right-to-left, but correspond to an edge written left-to-right. This is due to unfortunate conventions). We index the entries of R by the labels of the vertices in $\mathcal{G}$. We write these labels with roman letters, Greek letters, or numbers, as convenient. Now – assuming that the Taylor series converges – we have $(I - R)^{-1} = \sum_\ell R^\ell$. It follows that $(I - R)^{-1}_{ij}$ can be interpreted as the sum of the weights of all the walks from j to i. This directly implies the walk-sum interpretation advocated by Malioutov et al. (2006) for $J^{-1} = (I - R)^{-1}$, with $R = I - J$ and $\mathcal{G}$ the graphical model of the GMRF constructed by using Definition 1. Further, it follows that the calculation of J^{-1} is susceptible to a particular resummation technique from graph theory based on the structure of sets of walks, called the method of path-sums.

In its most general form, the method of path-sums stems from a fundamental algebraic property of the set of all walks on any weighted graph: namely, that any walk factorizes

3. $J \succ 0$ is equivalent to J being non-singular for a GMRF.

uniquely into products of prime walks, which are the simple paths and simple cycles of $\mathcal{G}$ (see §1 for the definitions). The path-sum representation of the series of all walks on the graph $\mathcal{G}$ is thus the representation of this series that only involves the prime walks.[4] Since a finite graph sustains only finitely many primes, the walk series (which is typically infinite) thus has an exact representation involving only finitely many terms. An important consequence of this observation is that the path-sum expression of J^{-1} is *convergent* as long as $J \succ 0$.

For a full exposition of the algebraic structure of walk sets at the origin of path-sums and its applications in linear algebra, the interested reader can refer to Giscard et al. (2012) and Giscard et al. (2013). In §2.2 we give the *explicit* and universal path-sum formulation for J^{-1}. This expression takes the form of a branched continued fraction of finite depth and breadth.

2.2 Path-Sum Formulation of the Covariance Matrix

Let $\mathcal{G} \setminus \{\alpha, \beta \dots\}$ denote the subgraph of $\mathcal{G}$ obtained by deleting from $\mathcal{G}$ the vertices $\{\alpha, \beta \dots\} \subset \mathcal{V}$ and the edges incident to them. For simplicity, we write $J^{-1}_{\alpha\beta}$ for $(J^{-1})_{\alpha\beta}$. The path-sum expression for $\Sigma = J^{-1}$ is presented in Theorem 2 below. We defer its proof to Appendix A.

Theorem 2 *Let $J \succ 0$ be an information matrix. Let $\Pi_{\mathcal{G};\,\alpha\omega}$ and $\Gamma_{\mathcal{G};\,\alpha}$ be the sets of simple paths from α to ω on $\mathcal{G}$ and the set of simple cycles from α to itself on $\mathcal{G}$, respectively. If $\mathcal{G}$ has finitely many vertices and edges, these two sets are finite.*

Then each entry of the covariance matrix $\Sigma = J^{-1}$ admits an expression involving only weighted prime walks, called a path-sum representation. It is explicitly given by

$$J^{-1}_{\omega\alpha} = \sum_{p \in \Pi_{\mathcal{G};\,\alpha\omega}} (-1)^{\ell(p)} \prod_{j=1}^{\ell(p)+1} \left\{ \left(J_{\mathcal{G}\setminus\{\alpha,\nu_2,\dots,\nu_{j-1}\}}\right)^{-1}_{\nu_j\nu_j} J_{\nu_{j+1}\nu_j} \right\} J^{-1}_{\alpha\alpha}\,, \tag{2}$$

$$J^{-1}_{\alpha\alpha} = \left(\sum_{\gamma \in \Gamma_{\mathcal{G};\,\alpha\alpha}} (-1)^{\ell(\gamma)+1} J_{\mu_1\mu_{\ell(\gamma)}} \prod_{j=2}^{\ell(\gamma)} \left\{ \left(J_{\mathcal{G}\setminus\{\alpha,\mu_2,\dots,\mu_{j-1}\}}\right)^{-1}_{\mu_j\mu_j} J_{\mu_j\mu_{j-1}} \right\} \right)^{-1}, \tag{3}$$

where the products are right-to-left (i.e. $\prod_{i=1}^{m} a_i = a_m \cdots a_1$), $p = (\nu_1, \nu_2, \dots, \nu_{\ell(p)+1})$ is a simple path of length $\ell(p)$ with $\alpha \equiv \nu_1$ and $\omega \equiv \nu_{\ell(p)+1}$ for convenience; and $\gamma = (\mu_1, \mu_2, \dots, \mu_{\ell_\gamma}, \mu_1)$ is a simple cycle of length $\ell(\gamma)$ from $\alpha \equiv \mu_1$ to itself.

Note that $J^{-1}_{\alpha\alpha}$ is obtained recursively through Eq. (3). Indeed it is expressed in terms of entries of inverses of submatrices of J, such as $(J_{\mathcal{G}\setminus\{\alpha,\mu_2,\dots,\mu_{j-1}\}})^{-1}_{\mu_j\mu_j}$, which is in turn obtained through Eq. (3) but on the subgraph $\mathcal{G}\setminus\{\alpha, \dots, \mu_{j-1}\}$ of $\mathcal{G}$. The recursion stops when vertex μ_j has no neighbor on this subgraph, in which case $(J_{\mathcal{G}\setminus\{\alpha,\mu_2,\dots,\mu_{j-1}\}})^{-1}_{\mu_j\mu_j} = 1/J_{\mu_j\mu_j}$ (note that $J_{\mu_j\mu_j} \neq 0$ since $J \succ 0$). The entry $J^{-1}_{\alpha\alpha}$ is therefore expressed as a branched continued fraction which terminates at a finite depth, and $J^{-1}_{\alpha\omega}$ is a finite sum of such continued fractions.

4. Since path-sums are the prime representations of walk series, they are the graph-theoretic analog of Euler product formulas for the Riemann zeta function and other totally multiplicative functions in number theory.

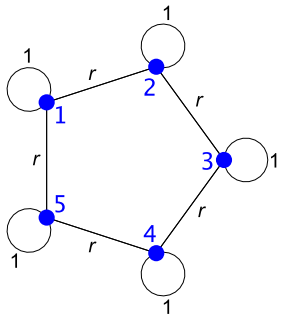

Figure 1: The circle graph on 5 vertices $\mathcal{C}_5$ *associated with* J in Example 1. The edge-weights are indicated next to the edges and the vertices are labeled 1 to 5.

Remark 3 Theorem 2 is valid even when $\mathcal{G}$ is loopy and/or J is not walk-summable. In particular there is no restriction on the spectrum of J as long as $J \succ 0$. An example showing this is given below.

Example 1 (An illustrative example) To illustrate Theorem 2, we consider an example taken from Malioutov et al. (2006), where J has the structure of a circle graph on 5 vertices, denoted $\mathcal{C}_5$, see Figure 1. The information matrix is

$$J = \begin{pmatrix} 1 & r & 0 & 0 & r \\ r & 1 & r & 0 & 0 \\ 0 & r & 1 & r & 0 \\ 0 & 0 & r & 1 & r \\ r & 0 & 0 & r & 1 \end{pmatrix}.$$

Then J is positive definite for $\frac{2}{1-\sqrt{5}} \leq r \leq \frac{2}{1+\sqrt{5}}$ (approximately $-1.618 \leq r \leq 0.618$), and walk-summable if and only if $-1/2 \leq r \leq 1/2$. This example thus provides a test case for both the walk-summable and non-walk-summable situations, depending on the value of r. Here we obtain J^{-1} correctly for all values of r such that J is not singular.

By the symmetry of $\mathcal{C}_5$, all the diagonal entries of J^{-1} are identical, and we choose to calculate J^{-1}_{11} without loss of generality. There are five simple cycles from vertex 1 to itself on $\mathcal{C}_5$: i) the self-loop $1 \to 1$; ii) the two backtracks $1 \to 2 \to 1$ and $1 \to 5 \to 1$; and iii) the two pentagons $1 \to 2 \to 3 \to 4 \to 5 \to 1$ and $1 \to 5 \to 4 \to 3 \to 2 \to 1$. By symmetry, the

two backtracks and the two pentagons have the same weights. Consequently Eq. (3) gives

$$(J^{-1})_{11} = \Bigg(\underbrace{1}_{\text{Self-loop}} - \underbrace{2\,r^2\left(J_{\mathcal{C}_5\setminus\{1\}}\right)^{-1}_{22}}_{\text{Backtracks}} + \underbrace{2\,r^5\left(J_{\mathcal{C}_5\setminus\{1,2,3,4\}}\right)^{-1}_{55}\left(J_{\mathcal{C}_5\setminus\{1,2,3\}}\right)^{-1}_{44}\left(J_{\mathcal{C}_5\setminus\{1,2\}}\right)^{-1}_{33}\left(J_{\mathcal{C}_5\setminus\{1\}}\right)^{-1}_{22}}_{\text{Pentagons}} \Bigg)^{-1}.$$

The required entries $(J_{\mathcal{C}_5\setminus\{1\}})^{-1}_{22}, \cdots, (J_{\mathcal{C}_5\setminus\{1,2,3,4\}})^{-1}_{55}$ remain to be calculated. To this end, we use again Eq. (3) of Theorem 2. For example, consider calculating $(J_{\mathcal{C}_5\setminus\{1\}})^{-1}_{22}$. Since the graph associated with $J_{\mathcal{C}_5\setminus\{1\}}$ is $\mathcal{C}_5$ with vertex 1 removed, the only simple cycles from vertex 2 to itself on $\mathcal{C}_5\setminus\{1\}$ are the self-loop $2\to 2$ and the backtrack $2\to 3\to 2$. We thus find

$$\left(J_{\mathcal{C}_5\setminus\{1\}}\right)^{-1}_{22} = \Bigg(\underbrace{1}_{\text{Self-loop}} - \underbrace{r^2\left(J_{\mathcal{C}_5\setminus\{1,2\}}\right)^{-1}_{33}}_{\text{Backtrack}} \Bigg)^{-1},$$

Similarly we obtain $(J_{\mathcal{C}_5\setminus\{1,2\}})^{-1}_{33} = \left(1-r^2(J_{\mathcal{C}_5\setminus\{1,2,3\}})^{-1}_{44}\right)^{-1}$, $(J_{\mathcal{C}_5\setminus\{1,2,3\}})^{-1}_{44} = \left(1-r^2(J_{\mathcal{C}_5\setminus\{1,2,3,4\}})^{-1}_{55}\right)^{-1}$ and finally $(J_{\mathcal{C}_5\setminus\{1,2,3,4\}})^{-1}_{55} = 1$. Combining these equations gives

$$\begin{aligned}
(J_{\mathcal{C}_5\setminus\{1,2,3,4\}})^{-1}_{55} = 1 &\Rightarrow \left(J_{\mathcal{C}_5\setminus\{1,2,3\}}\right)^{-1}_{44} = \frac{1}{1-r^2} \\
&\Rightarrow \left(J_{\mathcal{C}_5\setminus\{1,2\}}\right)^{-1}_{33} = \frac{1-r^2}{1-2r^2} \\
&\Rightarrow \left(J_{\mathcal{C}_5\setminus\{1\}}\right)^{-1}_{22} = \frac{1-2r^2}{1-3r^2+r^4}, \\
&\Rightarrow (J^{-1})_{11} = \frac{1-3r^2+r^4}{1-5r^2+5r^4+2r^5}.
\end{aligned}$$

As noted, the last equation gives the value of every diagonal entry of J^{-1}. We now consider the off-diagonal entries. We note again that, by the symmetry of $\mathcal{C}_5$, there are only two different entries, and we choose to calculate $(J^{-1})_{21}$ and $(J^{-1})_{31}$ without loss of generality. Following Theorem 2, these two entries are given by a sum over simple paths from vertex 1 to vertex 2, and vertex 1 to vertex 3, respectively. In each case there are only two simple paths: for example from 1 to 2, we have $1\to 2$ and $1\to 5\to 4\to 3\to 2$. Then Eq. (2)

yields

$$\left(J^{-1}\right)_{21} = \underbrace{-\,r\left(J_{\mathcal{C}_5\setminus\{1\}}\right)^{-1}_{22}\left(J^{-1}\right)_{11}}_{\text{Simple path}} + \underbrace{r^4\left(J_{\mathcal{C}_5\setminus\{1,5,4,3\}}\right)^{-1}_{22}\left(J_{\mathcal{C}_5\setminus\{1,5,4\}}\right)^{-1}_{33}\left(J_{\mathcal{C}_5\setminus\{1,5\}}\right)^{-1}_{44}\left(J_{\mathcal{C}_5\setminus\{1\}}\right)^{-1}_{55}\left(J^{-1}\right)_{11}}_{\text{Simple path}}.$$

By the symmetry of $\mathcal{C}_5$, we have $(J_{\mathcal{C}_5\setminus\{1,5,4,3\}})^{-1}_{22} = (J_{\mathcal{C}_5\setminus\{1,2,3,4\}})^{-1}_{55}$, $(J_{\mathcal{C}_5\setminus\{1,5,4\}})^{-1}_{33} = (J_{\mathcal{C}_5\setminus\{1,2,3\}})^{-1}_{44}$, $(J_{\mathcal{C}_5\setminus\{1,5\}})^{-1}_{44} = (J_{\mathcal{C}_5\setminus\{1,2\}})^{-1}_{33}$ and $(J_{\mathcal{C}_5\setminus\{1\}})^{-1}_{55} = (J_{\mathcal{C}_5\setminus\{1\}})^{-1}_{22}$. The previously obtained results then immediately give

$$(J^{-1})_{21} = \frac{r^4+2r^3-r}{1-5r^2+5r^4+2r^5},$$

and similarly

$$(J^{-1})_{31} = \frac{r^2-r^3-r^4}{1-5r^2+5r^4+2r^5}.$$

Piecing these results together, we finally obtain

$$J^{-1} = \frac{r^2}{2r^3+3r^2-r-1}\begin{pmatrix} \frac{(r-1)r-1}{r^2} & 1+r^{-1} & -1 & -1 & 1+r^{-1} \\ 1+r^{-1} & \frac{(r-1)r-1}{r^2} & 1+r^{-1} & -1 & -1 \\ -1 & 1+r^{-1} & \frac{(r-1)r-1}{r^2} & 1+r^{-1} & -1 \\ -1 & -1 & 1+r^{-1} & \frac{(r-1)r-1}{r^2} & 1+r^{-1} \\ 1+r^{-1} & -1 & -1 & 1+r^{-1} & \frac{(r-1)r-1}{r^2} \end{pmatrix}.$$

We now verify that this expression is correct in both the walk-summable and non-walk-summable situations:

(a) Walk-summable and $J \succ 0$: set $r = 0.3$. Then to 5 decimal places we have $(J^{-1})_{11} = 1.23975$, $(J^{-1})_{21} = -0.39959$ and $(J^{-1})_{31} = 0.09221$, so that

$$J^{-1} = \begin{pmatrix} 1.23975 & -0.39959 & 0.09221 & 0.09221 & -0.39959 \\ -0.39959 & 1.23975 & -0.39959 & 0.09221 & 0.09221 \\ 0.09221 & -0.39959 & 1.23975 & -0.39959 & 0.09221 \\ 0.09221 & 0.09221 & -0.39959 & 1.23975 & -0.39959 \\ -0.39959 & 0.09221 & 0.09221 & -0.39959 & 1.23975 \end{pmatrix}.$$

One can verify that this result obtained by using the path-sum formulation coincides with the one obtained by direct inversion of J.

(b) Non walk-summable and $J \succ 0$: set $r = 0.6$. Then to 5 decimal places, we have $(J^{-1})_{11} = 14.09091$, $(J^{-1})_{21} = -10.90909$ and $(J^{-1})_{31} = 4.09091$, and so

$$J^{-1} = \begin{pmatrix} 14.09091 & -10.90909 & 4.09091 & 4.09091 & -10.90909 \\ -10.90909 & 14.09091 & -10.90909 & 4.09091 & 4.09091 \\ 4.09091 & -10.90909 & 14.09091 & -10.90909 & 4.09091 \\ 4.09091 & 4.09091 & -10.90909 & 14.09091 & -10.90909 \\ -0.39959 & 4.09091 & 4.09091 & -0.39959 & 14.09091 \end{pmatrix}.$$

This result is again easily verified through direct inversion of J.

Remark 4 First, one could have calculated everything with numerical values from the start, as opposed to evaluating the analytic expression of J^{-1} for a specific value of r as we did here. This gives the same results, as expected. Second, the analytical formula for J^{-1} remains valid even when J is not positive definite and only fails for those values of r such that J is singular. The main *mathematical* role of the condition $J \succ 0$ in the path-sum representation is to guarantee that J is not singular.[5]

In the following section, we discuss the relations between Theorem 2 and two existing approaches.

3. Relation to Existing Approaches

Malioutov et al. (2006) provided a walk-sum derivation for Gaussian belief propagation on trees. Jones and West (2005) presented an expression for the entries of J^{-1} as a sum of simple paths. In this section, we show that these results are corollaries of Theorem 2 arising as special cases.

3.1 Path-Sums on Trees

The recursive structure of the path-sum representation of J^{-1} is especially simple on trees, for which we recover the Gaussian belief propagation results of Malioutov et al. (2006).

Let $J \succ 0$ be an information matrix associated with a tree model $\mathcal{T}$. For any vertex α of $\mathcal{T}$, let $\mathcal{N}(\alpha)$ be the set of neighbors of α on $\mathcal{T}$. Observe that since $\mathcal{T}$ is a tree, the only simple cycles from α to itself are the self-loop $\alpha \to \alpha$ with weight $J_{\alpha\alpha}$, and the backtracks to the neighbors of α on $\mathcal{T}$, e.g. $\alpha \to \beta \to \alpha$, $\beta \in \mathcal{N}(\alpha)$. Then Eq. (3) of Theorem 2 gives

$$\Sigma_{\alpha\alpha} = J^{-1}_{\alpha\alpha} = \left(J_{\alpha\alpha} + \sum_{\beta \in \mathcal{N}(\alpha)} -J_{\alpha\beta} (J_{\mathcal{T}\setminus\{\alpha\}})^{-1}_{\beta\beta} J_{\beta\alpha} \right)^{-1}. \tag{4a}$$

The quantity $(J_{\mathcal{T}\setminus\{\alpha\}})^{-1}_{\beta\beta}$ satisfies a similar relation on the subtree $\mathcal{T}\setminus\{\alpha\}$,

$$(J_{\mathcal{T}\setminus\{\alpha\}})^{-1}_{\beta\beta} = \left(J_{\beta\beta} + \sum_{\delta \in \mathcal{N}(\beta)\setminus\alpha} -J_{\beta\delta} (J_{\mathcal{T}\setminus\{\alpha,\beta\}})^{-1}_{\delta\delta} J_{\delta\beta} \right)^{-1}.$$

5. A path-sum result for singular matrices also exists, but it necessitates additional mathematical machinery. In this case the path-sum formulation yields a pseudo-inverse for the singular matrix, see Giscard et al. (2013).

Let $\mathcal{C}_{\mathcal{T}\setminus\{\beta\};\,\delta}$ be the connected component of $\mathcal{T}\setminus\{\beta\}$ that contains the vertex $\delta \in \mathcal{N}(\alpha)$. Similarly define $\mathcal{C}_{\mathcal{T}\setminus\{\alpha,\beta\};\,\delta}$ to be the connected component of $\mathcal{T}\setminus\{\alpha,\beta\}$ that contains the vertex δ. Since $\mathcal{T}$ is a tree, these components are identical: $\mathcal{C}_{\mathcal{T}\setminus\{\beta\};\,\delta} = \mathcal{C}_{\mathcal{T}\setminus\{\alpha,\beta\};\delta}$, and therefore $(J_{\mathcal{T}\setminus\{\beta\}})^{-1}_{\delta\delta} = (J_{\mathcal{T}\setminus\{\alpha,\beta\}})^{-1}_{\delta\delta}$. Thus, we have

$$(J_{\mathcal{T}\setminus\{\alpha\}})^{-1}_{\beta\beta} = \left(J_{\beta\beta} + \sum_{\delta \in \mathcal{N}(\beta)\setminus\alpha} -J_{\beta\delta} (J_{\mathcal{T}\setminus\{\beta\}})^{-1}_{\delta\delta} J_{\delta\beta} \right)^{-1}. \tag{4b}$$

In order to show that Eqs. (4a, 4b) are the Gaussian belief propagation results, we introduce some notation from Malioutov et al. (2006). Let $\hat{J}_\alpha := 1/\Sigma_{\alpha\alpha}$ and $\hat{J}^{-1}_{\beta\setminus\alpha} := (J_{\mathcal{T}\setminus\{\alpha\}})^{-1}_{\beta\beta}$. With these notations, Eqs. (4a, 4b) become

$$\hat{J}_\alpha = J_{\alpha\alpha} + \sum_{\beta \in \mathcal{N}(\alpha)} \Delta J_{\beta\to\alpha}, \quad \text{and} \quad \hat{J}_{\beta\setminus\alpha} = J_{\beta\beta} + \sum_{\delta \in \mathcal{N}(\beta)\setminus\alpha} \Delta J_{\delta\to\beta},$$

with

$$\Delta J_{\delta\to\beta} = -J_{\beta\delta} \hat{J}^{-1}_{\delta\setminus\beta} J_{\delta\beta}.$$

These are the Gaussian belief propagation equations (Eqs. 7, 8 and 9 in Malioutov et al., 2006), which immediately imply Propositions 16 and 17 in Malioutov et al. (2006) with the further definitions $r_{\beta\alpha} := R_{\beta\alpha} = -J_{\beta\alpha}$, $\gamma_{\beta\setminus\alpha} := (J_{\mathcal{T}\setminus\{\alpha\}})^{-1}_{\beta\beta}$. Note that $r_{\alpha\beta} = r_{\beta\alpha}$ since J is symmetric.

3.2 An Approach using Determinants

A determinant-based approach to the calculation of the covariance matrix $\Sigma = J^{-1}$ was demonstrated by Jones and West (2005). Here we show that this result follows from Eq. (2) by using the adjugate formula for the matrix inverse. We then point out the fundamental limitation of determinant-based approaches. We overcome this limitation using the path-sum formulation in §4.

We recall the adjugate formula for matrix inverses:

Proposition 5 (Adjugate formula, Strang, 2005) *Let $M \in \mathbb{C}^{n\times n}$ be a $n \times n$ non-singular complex matrix. Then*

$$\left(M^{-1}\right)_{ij} = (-1)^{i+j} \frac{\det M^i_j}{\det M}, \text{ and in particular } \left(M^{-1}\right)_{ii} = \frac{\det M^i}{\det M},$$

where M^i_j is the matrix M with its ith column and jth row removed and $M^i = M^i_i$.

To obtain this result we start with Eq. (2), which gives here

$$J^{-1}_{\omega\alpha} = \sum_{p \in \Pi_{\mathcal{G};\,\alpha\omega}} (-1)^{\ell(p)} (J_{\mathcal{G}\setminus\{\alpha,\,\nu_2,\ldots,\nu_{\ell(p)}\}})^{-1}_{\omega\omega} J_{\omega\nu_{\ell(p)}} \cdots J_{\nu_3\nu_2} (J_{\mathcal{G}\setminus\{\alpha\}})^{-1}_{\nu_2\nu_2} J_{\nu_2\alpha} (J^{-1})_{\alpha\alpha},$$

with $p = (\alpha, \nu_2, \ldots \nu_{\ell(p)}\omega)$ is a simple path of length $\ell(p)$. Since all the entries of J commute, we can reorganize the weights in the above expression to get

$$J^{-1}_{\omega\alpha} = \sum_{p \in \Pi_{\mathcal{G};\,\alpha\omega}} (-1)^{\ell(p)} \phi[p] \times (J_{\mathcal{G}\setminus\{\alpha,\nu_2,\ldots,\nu_{\ell(p)}\}})^{-1}_{\omega\omega} \times \ldots \times (J_{\mathcal{G}\setminus\{\alpha\}})^{-1}_{\nu_2\nu_2} \times (J^{-1})_{\alpha\alpha},$$

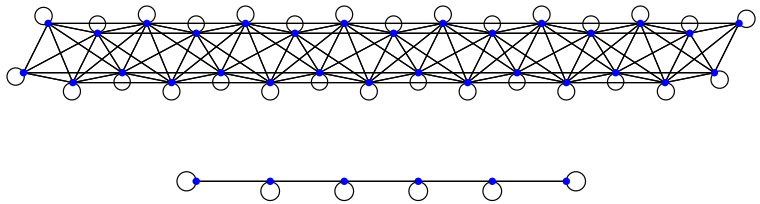

Figure 2: top: the graphical model associated with a 5-banded 30×30 positive definite information matrix. The weights of the edges are the entries of J. Bottom: the graphical model associated with a partition of J into 5×5 blocks. The edge weights are the blocks constituting J.

where $\phi[p] = J_{\omega\nu_{\ell(p)}} \dots J_{\nu_3\nu_2} J_{\nu_2\alpha}$ is the weight of the simple path p. Using the adjugate formula in Proposition 5, we have

$$J^{-1}_{\omega\alpha} = \sum_{p \in \Pi_{\mathcal{G};\,\alpha\omega}} (-1)^{\ell(p)} \phi[p] \times \frac{\det J^{\alpha,\nu_2,\dots,\nu_{\ell(p)},\omega}}{\det J^{\alpha,\nu_2,\dots,\nu_{\ell(p)}}} \times \dots \frac{\det J^{\alpha,\nu_2}}{\det J^{\alpha}} \times \frac{\det J^{\alpha}}{\det J},$$

since $J_{\mathcal{G}\setminus\{\alpha,\nu_2,\dots,\nu_j\}} = J^{\alpha,\nu_2,\dots,\nu_j}$. This simplifies to

$$J^{-1}_{\omega\alpha} = \sum_{p \in \Pi_{\mathcal{G};\,\alpha\omega}} (-1)^{\ell(p)} \phi[p] \frac{\det J^{\alpha,\nu_2,\dots,\omega}}{\det J}. \tag{5}$$

The last equation is given as Theorem 1 in Jones and West (2005). Note that we only used Eq. (2) in Theorem 2 to obtain this result. Jones and West (2005) did not give an expression equivalent to Eq. (3) in Theorem 2, which provides an explicit formula for the necessary determinants in terms of simple cycles on the graph associated with J.

The requirement that the entries of J be commutative to obtain Eq. (5) from Eq. (2) may seem trivial, but in fact it excludes the very important case of *block matrices*. In the next section, we demonstrate the use of Theorem 2 in the case where J is a block matrix.

4. Path-Sums for Arbitrary Partitions of J

An information matrix J may have a sparsity structure that is best exploited by partitioning J into blocks. For example, consider an $n \times n$ information matrix J which is banded: i.e. $J_{ij} = 0$ if and only if $|i - j| > b$ for some $b < n$. We say that J is b-banded. Then J is simply block-tridiagonal when partitioned $b \times b$ blocks. Consequently, the graph $\mathcal{G}$ associated with this partition of J is simpler than the graph associated with the full matrix: see for example Figure 2. It is therefore desirable to develop a method capable of exploiting these simplifications.

A fundamental impediment to determinant-based approaches to J^{-1} is that the notion of determinant itself does not extend to matrices with non-commutative blocks (Silvester, 2000). In contrast, the path-sum formulation for J^{-1} does not require the commutativity of the entries of J. For this reason, it continues to hold even when these entries do not commute, see (Giscard et al., 2012) and (Giscard et al., 2013).

Let J be an $n \times n$ information matrix and $I_1, \dots, I_B$ for some $1 \leq B \leq n$ be B disjoint subsets of $\{1, \dots, n\}$. Then we write $J_{I_i I_j}$ for the minor (i.e. block) of J that corresponds to the rows indexed by I_i and the columns indexed by I_j. We form a new graph $\mathcal{G}' = (\mathcal{V}', \mathcal{E}')$ associated with this partition of J, such that $J_{I_i I_j} \neq \mathbf{0} \iff (j,i) \in \mathcal{E}'$, where $\mathbf{0}$ is a zero matrix. The block $J_{I_i I_j}$ is now the weight associated with the edge (j,i). With these conventions, Theorem 2 extends to block matrices without modification.

Remark 6 For a GMRF $\mathbf{X}$, the partition of J given above is equivalent to a partition of the set of random variables $\mathbf{X}$ into $B > 1$ disjoint subsets $\mathbf{X}_1, \dots, \mathbf{X}_B$. Let $\mathbf{X}' = (\mathbf{X}_1, \dots, \mathbf{X}_B)$ be a GMRF with respect to a new graph $\mathcal{G}' = (\mathcal{V}', \mathcal{E}')$ with information matrix J'. Note that each $\mathbf{X}_i$ is now a random vector instead of a random variable. Following Definition 1:

$$\mathbf{X}_i \perp\!\!\!\perp \mathbf{X}_j | \mathbf{X}'_{\setminus ij} \iff J'_{ij} = \mathbf{0} \iff (j,i) \notin \mathcal{E}', \tag{6}$$

with $\mathbf{X}'_{\setminus ij}$ the set of variables with $\mathbf{X}_i$ and $\mathbf{X}_j$ removed from $\mathbf{X}'$. Note that $\mathbf{X}_i \perp\!\!\!\perp \mathbf{X}_j | \mathbf{X}'_{\setminus ij}$ implies the global Markov property (GMP), which, for GMRFs, is equivalent to the pairwise Markov property (PMP) (Lauritzen, 1996). However for a general distribution, the PMP does not imply the GMP (Lauritzen, 1996). Hence in this case, the partition of $\mathbf{X}$ as per Eq. (6) may not correspond to the partition of J.

Below we give a detailed synthetic example demonstrating the path-sum formulation of the covariance matrix $\Sigma = J^{-1}$ using a partition of J.

Example 2 (Non walk-summable block matrix on a loopy graph) Consider the following positive definite information matrix J of a thin membrane model

$$J = \tag{7}$$
$$\begin{pmatrix}
a+5b & -b & 0 & -b & -b & 0 & -b & -b & 0 \\
-b & a+5b & -b & -b & 0 & -b & -b & 0 & -b \\
0 & -b & a+5b & 0 & -b & -b & 0 & -b & -b \\
-b & -b & 0 & a+5b & -b & 0 & -b & -b & 0 \\
-b & 0 & -b & -b & a+5b & -b & -b & 0 & -b \\
0 & -b & -b & 0 & -b & a+5b & 0 & -b & -b \\
-b & -b & 0 & -b & -b & 0 & a+5b & -b & 0 \\
-b & 0 & -b & -b & 0 & -b & -b & a+5b & -b \\
0 & -b & -b & 0 & -b & -b & 0 & -b & a+5b
\end{pmatrix},$$

where $a, b > 0$. Recall that walk-summability is equivalent to the condition $\rho(|R|) < 1$, where $|R|$ is the entry-wise absolute value of $R := I - J$ (Malioutov et al., 2006). Here we have $\rho(|R|) = |a + 5b - 1| + \sqrt{19}\, b + b$, and thus—depending on the values of a and b—walk-summability does not always hold. For example, when $a = b = 1$ we have $\rho(|R|) \simeq 10.36$, $\rho(J) \simeq 9.36$ and $\rho(R) \simeq 8.36$ and J is not walk-summable.

The graph $\mathcal{G}$ associated to J is shown on the left of Figure 3. Instead of working on this complicated graph, we may partition the matrix into 3×3 blocks as follows

$$J = \begin{pmatrix} L & E & E \\ E & L & E \\ E & E & L \end{pmatrix}, \tag{8}$$

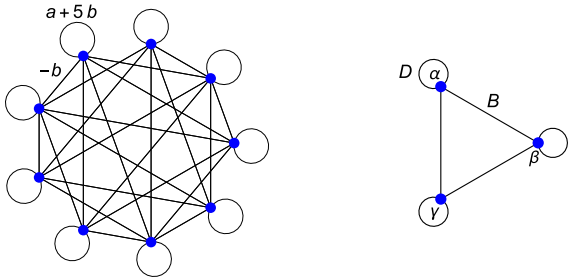

Figure 3: left: graphical model associated with the thin membrane model matrix J of Eq. (7). Every edge has weight $-b$ and every self-loop has weight $a+5b$. Right: triangular graphical model $\mathcal{K}_3$ associated with the partition of J given in Eq. (8). Edges and self-loops have matrix weights E and L, respectively. The vertices are labeled α, β and γ for convenience.

with

$$E := \begin{pmatrix} -b & -b & 0 \\ -b & 0 & -b \\ 0 & -b & -b \end{pmatrix}, \quad L := \begin{pmatrix} a+5b & -b & 0 \\ -b & a+5b & -b \\ 0 & -b & a+5b \end{pmatrix}.$$

The graph $\mathcal{G}'$ associated with this partition of J is a triangle, denoted $\mathcal{K}_3$ and shown on the right of Figure 3. Accordingly, the edge-weights are now the matrices E and L for edges and self-loops, respectively. Note that these weights do not commute: $[E, L] = EL - LE \neq 0$.

The only simple cycles from any vertex (say, α) to itself on this graph are the self-loop $\alpha \to \alpha$, the two backtracks $\alpha \to \beta \to \alpha$ and $\alpha \to \gamma \to \alpha$ and the two triangles $\alpha \to \beta \to \gamma \to \alpha$ and $\alpha \to \gamma \to \beta \to \alpha$. Theorem 2 therefore yields

$$J^{-1}_{\alpha\alpha} = \Big(\underbrace{L}_{\text{Self loop}} - \underbrace{E \,.\, (J_{\mathcal{K}_3\setminus\{\alpha\}})^{-1}_{\beta\beta} \,.\, E}_{\text{Backtrack}} - \underbrace{E \,.\, (J_{\mathcal{K}_3\setminus\{\alpha\}})^{-1}_{\gamma\gamma} \,.\, E}_{\text{Backtrack}} \tag{9a}$$

$$+ \underbrace{E \,.\, (J_{\mathcal{K}_3\setminus\{\alpha,\beta\}})^{-1}_{\gamma\gamma} \,.\, E \,.\, (J_{\mathcal{K}_3\setminus\{\alpha\}})^{-1}_{\beta\beta} \,.\, E}_{\text{Triangle}} + \underbrace{E \,.\, (J_{\mathcal{K}_3\setminus\{\alpha,\gamma\}})^{-1}_{\beta\beta} \,.\, E \,.\, (J_{\mathcal{K}_3\setminus\{\alpha\}})^{-1}_{\gamma\gamma} \,.\, E}_{\text{Triangle}} \Big)^{-1},$$

where, by Eq. (3),

$$(J_{\mathcal{K}_3\setminus\{\alpha\}})^{-1}_{\beta\beta} = \Big(\underbrace{L}_{\text{Self loop}} - \underbrace{E \,.\, (J_{\mathcal{K}_3\setminus\{\alpha,\beta\}})^{-1}_{\gamma\gamma} \,.\, E}_{\text{Backtrack}} \Big)^{-1} \text{ and } (J_{\mathcal{K}_3\setminus\{\alpha,\beta\}})^{-1}_{\gamma\gamma} = \underbrace{L^{-1}}_{\text{Self loop}}. \tag{9b}$$

Since $(J_{\mathcal{K}_3\setminus\{\alpha\}})^{-1}_{\gamma\gamma} = (J_{\mathcal{K}_3\setminus\{\alpha\}})^{-1}_{\beta\beta}$ and $(J_{\mathcal{K}_3\setminus\{\alpha,\gamma\}})^{-1}_{\beta\beta} = (J_{\mathcal{K}_3\setminus\{\alpha,\beta\}})^{-1}_{\gamma\gamma}$, Eqs. (9a, 9b) completely determine $J^{-1}_{\alpha\alpha}$. Thus, we have

$$J^{-1}_{\alpha\alpha} = \frac{b}{a^2+8ab-3b^2} \times \begin{pmatrix} \frac{a}{b} + \frac{a}{a+3b} + \frac{5a}{3(a+6b)} + \frac{1}{3} & 1 & \frac{3b}{a+3b} \\ 1 & \frac{a}{b} + \frac{12a}{5(a+5b)} + \frac{3}{5} & 1 \\ \frac{3b}{a+3b} & 1 & \frac{a}{b} + \frac{a}{a+3b} + \frac{5a}{3(a+6b)} + \frac{1}{3} \end{pmatrix}.$$

By symmetry of J, this gives also $J^{-1}_{\beta\beta}$ and $J^{-1}_{\gamma\gamma}$. The off-diagonal blocks, which are all identical because of the symmetry of the matrix, now follow easily. For example, we have

$$(J^{-1})_{\beta\alpha} = \underbrace{(J_{\mathcal{K}_3\setminus\{\alpha\}})^{-1}_{\beta\beta} \,.\, E \,.\, (J^{-1})_{\alpha\alpha}}_{\text{Path}} - \underbrace{E \,.\, (J_{\mathcal{K}_3\setminus\{\alpha,\gamma\}})^{-1}_{\beta\beta} \,.\, E \,.\, (J_{\mathcal{K}_3\setminus\{\alpha\}})^{-1}_{\gamma\gamma} \,.\, E \,.\, (J^{-1})_{\alpha\alpha}}_{\text{Path}},$$

$$= \frac{b}{a^2+8ab-3b^2} \begin{pmatrix} \frac{a}{a+3b} - \frac{5a}{6(a+6b)} + \frac{5}{6} & 1 & \frac{3b}{a+3b} \\ 1 & \frac{6b}{a+5b} & 1 \\ \frac{3b}{a+3b} & 1 & \frac{a}{a+3b} - \frac{5a}{6(a+6b)} + \frac{5}{6} \end{pmatrix}.$$

As long as $a, b > 0$ (which implies $J \succ 0$), these results hold regardless of the values of a and b. For example setting $a = b = 1$, we obtain the correct covariance matrix even though J is not walk-summable.

5. Conclusion

We have presented an approach for exact inference of marginals in Gaussian graphical models, called the path-sum formulation. This approach represents the covariance matrix Σ of a Gaussian Markov Random Field (GMRF) as a continued fraction of finite depth and breadth, and which only involves the simple paths and simple cycles on the graphical model of the GMRF. For GMRFs, we have shown that the path-sum formulation only requires $J \succ 0$. It also extends to arbitrary partitions of J, thereby providing the flexibility necessary to exploit the sparsity structure of the information matrix $J = \Sigma^{-1}$.

From an algorithmic point of view, the computational cost associated with the calculation of any entry of a $n \times n$ covariance matrix using a path-sum is known to be $O(n)$ on trees,

see Giscard et al. (2013). The $O(n)$ complexity is achieved for the most general situation; if J or $\mathcal{G}$ has symmetries, the complexity would be lower. Evaluating the complexity of the path-sum approach on a graph with an arbitrary topology remains an open problem. In practice, finding the simple paths and simple cycles required for the computation of a path-sum can be achieved using standard depth-first or breadth-first algorithms (Johnson, 1975). In addition, we have consistently observed in numerical experiments that the contribution of a simple cycle/path to any path-sum decays exponentially with its length. The method we propose is therefore likely to find practical applications on sufficiently sparse yet large Gaussian graphical models where the increase in the number of simple cycles/paths with the length ℓ is offset by the decay of their contributions with ℓ.

Alternatively, path-sums can be used to enhance existing walk-sum calculations. To this end, we first factorise the walks involved in the walk-sum using an algorithm provided by Giscard et al. (2012). The typical computational cost of this operation grows linearly, and at worst quadratically, with the length of the walks. This yields a set of simple cycles/paths, from which a path-sum can be constructed. This path-sum is guaranteed to contain all the walks present in the original walk-sum as well as (infinitely) many more walks, all of which are valid walks on the graphical model. Since the method of path-sums arises from exact resummations on walk-sums, every problem that has a walk-sum interpretation is susceptible to these resummations and therefore admits a path-sum expression. Consequently, every algorithm that has a walk-sum interpretation (see e.g. Chandrasekaran et al., 2008) necessarily has a path-sum formulation.

The interpretation of the entries of the covariance matrix as walk-sums and the existence of the path-sum formulation opens the door to many more walk-based methods, which are intermediary between these two approaches. The central idea is to exploit recent results regarding the algebraic structure of the set of walks on graphs with arbitrary topology (Thwaite, 2014) to identify certain infinite geometric series of terms appearing in a walk-sum. These geometric series can then be exactly resummed, thereby reducing the sum of all walk weights to a sum over the weights of a certain (yet infinite) subset of 'irreducible' walks. Each term in this sum is 'dressed' so as to exactly include the contributions of the infinite families of resummed terms. The exact form of both the dressing and the irreducible terms remaining in the sum depend on the structure of the resummed terms: choosing a different family of terms produces a different series.

Viewed in this context, the walk-sum and path-sum formulations of a given problem can be seen to be the extrema of a hierarchy of possible resummations: a walk-sum corresponds to the case where *no* terms are exactly resummed, such that an explicit summation over all walks remains to be carried out, while the path-sum expression corresponds to the case where *all possible* geometric series have been resummed, leaving behind only a (finite) sum over simple paths. In between these extremes lie many intermediate formulations, whose mathematical properties such as complexity and convergence are expected to interpolate between those of walk-sums and path-sums.

Appendix A.

In this appendix we prove Theorem 2.

Proof The proof of the theorem is organized in two steps. First, assuming walk-summability, we obtain the path-sum formulation for J^{-1}. Second, we show that path-sum expression thus obtained is the unique analytic continuation of the sum of all walks, and continues to exist in the absence of walk-summability. Consequently, the path-sum remains a valid representation of J^{-1} when walk-summability fails.

Step 1: the path-sum expression for J^{-1} is a special case of the more general result concerning the path-sum formulation of the matrix inverse function presented and proved in Giscard et al. (2013). Below we briefly recount how we obtain result for the specific case of J^{-1}. Let $R := I - J$ and $|R|$ be the entry-wise absolute value of R, i.e. $|R|_{ij} = |R_{ij}|$. Let $\rho(|R|)$ be the spectral radius of $|R|$, i.e. the largest eigenvalue of $|R|$. As established by Malioutov et al. (2006), $\rho(|R|) < 1$ is equivalent to to walk-summability, and is enough to guarantee absolute convergence of the series $\sum_{n\geq 0} R^n = (I-R)^{-1} = J^{-1}$. This power series can be seen as a sum of walk weights on the graph $\mathcal{G}$ associated with R (Flajolet and Sedgewick, 2009), that is

$$\Big(\sum_{n\geq 0} R^n\Big)_{\omega\alpha} = \sum_{w\in\mathcal{W}_{\mathcal{G};\,\alpha\omega}} \phi[w], \tag{10}$$

with $\phi[w]$ the weight of the walk w, which is defined to be the product of the weights of the edges traversed by w, where the weight of an edge from α to β is given by

$$\phi[\alpha\beta] := R_{\beta\alpha} = \begin{cases} -J_{\beta\alpha} & \text{if } \alpha \neq \beta, \\ 1 - J_{\alpha\alpha} & \text{if } \alpha = \beta. \end{cases} \tag{11}$$

Note that since we assumed walk-summability, the right-hand side of Eq. (10) exists. We then use the result by Giscard et al. (2012), which reduces a series of weighted walks, such as the one of Eq. (10), to a sum of weighted simple paths and simple cycles. This result is reproduced here for the sake of completeness:

Theorem 7 (Path-sum, Giscard et al., 2012) *Let $\mathcal{G}$ be a graph and $\phi[.]$ be the weight function of Eq. (11). Suppose that the walk-sum $\sum_{w\in\mathcal{W}_{\mathcal{G};\alpha\omega}} \phi[w]$ exists. Then this sum is given by the weighted path-sum*

$$\sum_{w\in\mathcal{W}_{\mathcal{G};\alpha\omega}} \phi[w] = \sum_{p\in\Pi_{\mathcal{G};\,\alpha\omega}} \prod_{j=1}^{\ell(p)+1} \Big\{ \phi_{\mathcal{G}\setminus\{\alpha,\,\nu_2,\ldots,\nu_{j-1}\};\,\nu_j}\, \phi[\nu_{j+1}\nu_j] \Big\}\, \phi_{\mathcal{G};\,\alpha},$$

where $\phi_{\mathcal{G};\alpha} := \sum_{w \in \mathcal{W}_{\mathcal{G};\alpha\alpha}} \phi[w]$ *is the weighted sum of all walks from* α *to itself on* $\mathcal{G}$ *and is explicitly given by*

$$\phi_{\mathcal{G};\alpha} = \left(1 - \sum_{\gamma \in \Gamma_{\mathcal{G};\alpha\alpha}} \phi[\mu_1 \mu_{\ell(\gamma)}] \prod_{j=2}^{\ell(\gamma)} \left\{ \phi_{\mathcal{G}\setminus\{\alpha,\mu_2,\ldots,\mu_{j-1}\};\mu_j} \, \phi[\mu_j \mu_{j-1}] \right\}\right)^{-1},$$

and similarly for all $\phi_{\mathcal{G}\setminus\{\alpha,\nu_2,\ldots,\nu_{j-1}\};\nu_j}$ *and* $\phi_{\mathcal{G}\setminus\{\alpha,\mu_2,\ldots,\mu_{j-1}\};\mu_j}$*. In these expressions, the products are right-to-left,* $p = (\nu_1, \nu_2, \ldots, \nu_{\ell(p)+1})$ *is a simple path of length* $\ell(p)$ *with* $\alpha \equiv \nu_1$ *and* $\omega \equiv \nu_{\ell(p)+1}$ *for convenience; and* $\gamma = (\mu_1, \mu_2, \ldots, \mu_{\ell_\gamma}, \mu_1)$ *is a simple cycle of length* $\ell(\gamma)$ *from* $\alpha \equiv \mu_1$ *to itself.*

By using the edge weights of Eq. (11), we obtain $\phi_{\mathcal{G};\alpha} = J^{-1}_{\alpha\alpha}$ and similarly $\phi_{\mathcal{G}\setminus\{\alpha,\nu_2,\ldots,\nu_{j-1}\};\nu_j} = (J_{\mathcal{G}\setminus\{\alpha,\nu_2,\ldots,\nu_{j-1}\}})^{-1}_{\nu_j\nu_j}$ and Theorem 7 yields Eqs. (2, 3). Next we prove that Eqs. (2, 3) yield J^{-1} for any matrix $J \succ 0$, even when walk-summability does not hold and the walk-sum of Eq. (10) does not converge. Central to our proof is the (well-established) theory of analytic continuation (Priestley, 2003).

Step 2: we consider the three following functions of a complex variable z into $\mathbb{C}^{n\times n}$, $g_1(z) := (I - zR)^{-1}$, $g_2(z) := \sum_{n\geq 0} z^n R^n$ and, since $g_2(z)$ is a walk-sum, it has a path-sum expression which we denote $g_3(z)$. (The path-sum expression $g_3(z)$ is obtained from Theorem 2 on using the edge-weights $zR_{\beta\alpha}$ for an edge from α to β).

The first function, $g_1(z)$, is analytic on $z \in \mathbb{C}\backslash \mathrm{Sp}^{-1}(R)$ with $\mathrm{Sp}^{-1}(R)$ the inverse of the spectrum of R. The second function, $g_2(z)$, is analytic on the disk D_R of the complex plane where $z < 1/\rho(|R|)$. The third function, $g_3(z)$, comprises only a finite number of terms (since there are finitely many simple paths and simple cycles on a finite graph). Consequently $g_3(z)$ exists for $z \in \mathbb{C}\backslash \mathrm{Sp}^{-1}(R)$. Evidently g_1 and g_2 agree on D_R and by construction g_2 and g_3 agree on D_R as well. It follows that g_1 and g_3 constitute two *direct analytic continuations* of g_2 outside of D_R (Priestley, 2003) (also called *extensions* of g_2, Kreyszig, 1989). By the Uniqueness Theorem (Theorem 15.9, Priestley, 2003) only one such analytic continuation exists and $g_1(z) = g_3(z)$ on the domain $\mathbb{C}\backslash \mathrm{Sp}^{-1}(R)$.

We conclude the proof by showing that the point $z = 1$, for which $g_1(z)$ and $g_3(z)$ yield J^{-1}, is also in this domain. Indeed, the covariance matrix Σ of a Gaussian distribution must be positive definite, implying that it is non-singular (Corollary 7.17 in Horn and Johnson, 2013). Consequently, J is not singular: so J^{-1} exists exists and 1 is not an eigenvalue of $R = I - J$, i.e. $1 \in \mathbb{C}\backslash \mathrm{Sp}^{-1}(R)$. Then g_1 and g_3 exist at $z = 1$, in particular $g_3(1)$ is a valid representation of J^{-1}, even though $z = 1$ may not be in D_R (i.e. J is not walk-summable). This completes the proof of Theorem 2. ■

Abstract

This paper surveys the state of the art on multimodal gesture recognition and introduces the JMLR special topic on gesture recognition 2011-2015. We began right at the start of the Kinect^{TM} revolution when inexpensive infrared cameras providing image depth recordings became available. We published papers using this technology and other more conventional methods, including regular video cameras, to record data, thus providing a good overview of uses of machine learning and computer vision using multimodal data in this area of application. Notably, we organized a series of challenges and made available several datasets we recorded for that purpose, including tens of thousands of videos, which are available to conduct further research. We also overview recent state of the art works on gesture recognition based on a proposed taxonomy for gesture recognition, discussing challenges and future lines of research.

Keywords: Gesture Recognition, Time Series Analysis, Multimodal Data Analysis, Computer Vision, Pattern Recognition, Wearable sensors, Infrared Cameras, Kinect^{TM}.

1. Introduction

Gestures are naturally performed by humans. Gestures are produced as part of deliberate actions, signs or signals, or subconsciously revealing intentions or attitude. They may involve the motion of all parts of the body, but the arms and hands, which are essential for action and communication, are often the focus of studies. Facial expressions are also considered gestures and provide important cues in communication.

Gestures are present in most daily human actions or activities, and participate to human communication by either complementing speech or substituting themselves to spoken language in environments requiring silent communication (under water, noisy environments, secret communication, etc.) or for people with hearing disabilities. The importance of gestures in communication is rooted in primal behaviors: the gesture-first theory, supported by the analysis of mirror neurons in primates (Hewes, 1973), indicated that the first steps of language phylogenetically were not speech, nor speech with gesture, but were gestures alone (McNeil, 2012; Hewes, 1973). See examples of primate communication by means of gestures in Figure 1.

Given the indubitable importance of gestures in human activities, there has been huge interest by the Computer Vision and Machine Learning communities to analyze human gestures from visual data in order to offer new non-intrusive technological solutions. For completeness, in this paper we also review some gesture recognition systems with data acquired from wearable sensors, although the comprehensive review of papers focus on the analysis of different visual modalities.

Figure 1: Example of possible bonobo iconic gestures. (a) Start of swing gesture (or shove); (b) End of swing gesture (or shove); (c) Start of iconic swing, other bonobo starts to move; (d) End of iconic swing, other moving. Image from (McNeil, 2012).

Applications are countless, like Human Computer Interaction (HCI), Human Robot Interaction (HRI) (also named human machine interaction HMI), communication, entertainment, security, art, semiotics, commerce and sports, while having an important social impact in assistive technologies for the handicapped and the elderly. Some examples of applications are illustrated in Fig. 2.

In addition to the recent advances in human and gesture recognition from classical RGB visual data, the automatic analysis of human body from sensor data keeps making rapid progress with the constant improvement of (i) new published methods that constantly push the state-of-the-art and (ii) the recent availability of inexpensive 3D video sensors such as Kinect^{TM}, providing a complementary source of information, and thus allowing the computation of new discriminative feature vectors and improved recognition by means of fusion strategies. In section 2 we review the state of the art in gesture recognition.

In order to push research and analyze the gain of multimodal methods for gesture recognition, in 2011 and 2012, ChaLearn organized a challenge on single user one-shot-learning gesture recognition with data recorded with Kinect^{TM} in which 85 teams competed. Starting from baseline methods making over 50% error (measured in Leveinshtein distance, a metric counting the number of substitutions, insertions and deletions, analogous to an error rate), the winners brought the error rate below 10%. While there was still some margin of improvement on such tasks to reach human performance (which is below 2% error), we were encouraged to make the task harder to push the state of the art in computer vision. In our second ChaLearn challenge on Multimodal Gesture Recognition in 2013, we proposed a user-independent task with data recorded with Kinect^{TM}, with a larger vocabulary and continuously performed gestures. Of 60 participating teams, the winner attained an error rate of 10% on this data set, in terms of Leveinshtein distance. In 2014, we used the same Multimodal Gesture Recognition dataset with the objective of performing gesture spotting. The winner of the competition, with a deep learning architecture, obtained an overlapping near 0.9. Lastly, in 2014 and 2015 we ran an action spotting challenge with a new dataset consisting of RGB sequences of actors performing different isolated and collaborative actions in outdoor environments. Future challenges we are planning include the analysis of gestures taking into account face and contextual information, involving many modalities in the recognition process. In this paper we also review other existing international challenges related to gesture recognition.

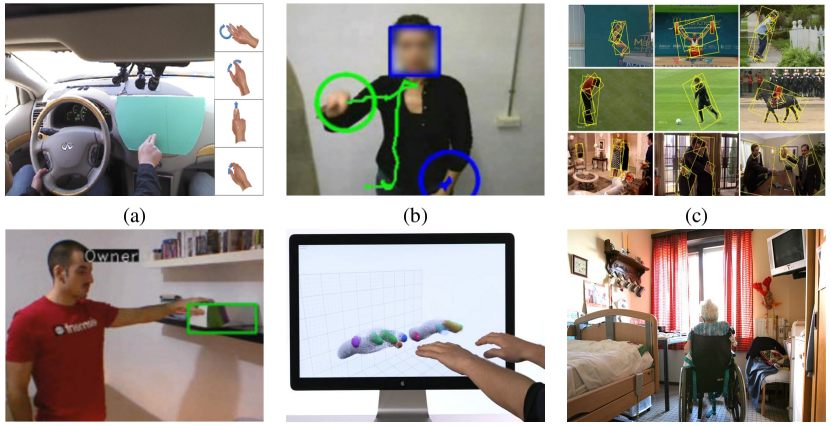

Figure 2: Some applications of gesture recognition. (a) Gesture recognition for driver assistance, from (Ohn-Bar and Trivedi, 2014), (b) Sign Language Recognition, (c) action/gesture recognition for content retrieval and categorization, from (Ma et al., 2013), (d) surveillance, (e) Human Computer/Robot/Machine Interaction, and (f) Assistive technology for people with reduced autonomy.

Our first workshop at CVPR from our 2011 challenge emphasized mostly 2D video data meanwhile our second and third workshops at CVPR, ICPR, ICMI, ECCV conferences from our 2012, 2013, and 2014 challenges were focused on affordable 3D sensors for gesture recognition research, also including audio information. In ECCV 2014 and CVPR 2015 workshops we also promoted different aspects of looking at people, including pose recovery, activity recognition, and scene understanding where humans are present. In addition to best challenge results, many research papers devoted to gesture recognition were published and presented in our challenge workshops. We also invited keynote speakers in diverse areas of pose and gesture research, including sign language recognition, body posture analysis, action and activity recognition, and facial expression or emotion recognition.

In this special topic on gesture recognition, extension of best challenge and workshop papers from previous events have been published. In addition, new description and learning strategies papers related to gesture recognition have been published. All of them will be shortly reviewed in the following sections.

The rest of the paper is organized as follows: Section 2 reviews the state of the art on gesture recognition, defining a taxonomy to describe existing works as well as available databases for gesture and action recognition. Section 3 describes the series of gesture and action recognition challenges organized by ChaLearn, describing the data, objectives, schedule, and achieved results by the participants. For completeness we also review other existing gesture challenge organizations. In Section 4 we review the published papers in this gesture recognition topic which are

related to ChaLearn competitions. Section 5 describes special topic published papers related to gesture recognition which are not based on ChaLearn competitions. Finally, Section 6 discusses main observations about the published papers.

2. Related Work in Gesture Recognition

In this section we present a taxonomy for action/gesture recognition, we review most influential works in the field, and finally we review existing datasets for action/gesture recognition together with the performance obtained by state of the art methods.

2.1 Taxonomy for gesture recognition

Fig. 3 is an attempt to create a taxonomy of the various components involved in conducting research in action/gesture recognition. We include various aspects relating to the problem setting, the data acquisition, the tools, the solutions, and the applications.

First, regarding the problem setting, the interpretation of gestures critically depends on a number of factors, including the environment in which gestures are performed, their span in time and space, and the intentional meaning in terms of symbolic description and/or the subconscious meaning revealing affective/emotional states. The problem setting also involves different actors who may participate in the execution of gestures and actions: human(s) and/or machine(s) (robot, computer, etc.), performing with or without tools or interacting or not with objects. Additionally, independently of the considered modality, for some gestures/actions different parts of the body are involved. While many gesture recognition systems only focus on arms and hands, full body motion/configuration and facial expressions can also play a very important role. Another aspect of the problem setting involves whether recognized gestures are static or dynamic. For the first case, just considering features from an input frame or any other acquisition device describing spatial configuration of body limbs, a gesture can be recognized. In the second case, the trajectory and pose of body limbs provide the highest discriminative information for gesture recognition. In some settings, gestures are defined based not only on the pose and motion of the human, but also on the surrounding context, and more specifically on the objects that the human interacts with. For such settings, one approach for achieving context awareness is scene analysis, where information is extracted from the scene around the subject (e.g., Pieropan et al. (2014); Shapovalova et al. (2011)). Another approach is to have the subject interact with intelligent objects. Such objects use embedded hardware and software to facilitate object recognition/localization, and in some cases to also monitor interactions between such objects and their environment (e.g., Czabke et al. (2010))

Second, the data are, of course, of very central importance, as in every machine learning application. The data sources may vary: when recognizing gestures, input data can come from different modalities, visual (RGB, 3D, or thermal, among others), audio, or wearable sensors (magnetic field trackers, instrumented (data) gloves, or body suits, among others). In the case of gloves, they can be active or passive. Active ones make use of a variety of sensors on a glove to measure the flexing of joints or the acceleration and communicates data to the host device using wired or wireless technology. Passive ones consist only of markers or colored gloves for finger detection by an external device such as a camera. Although most gestures are recognized by means of ambient intelligent systems, looking at the person from outside, some gesture recognition approaches are based on egocentric computing, using wearable sensors or wearable cameras that analyze, for instance, hand behaviors. Additionally, it is well-known that context provides rich information that can be useful

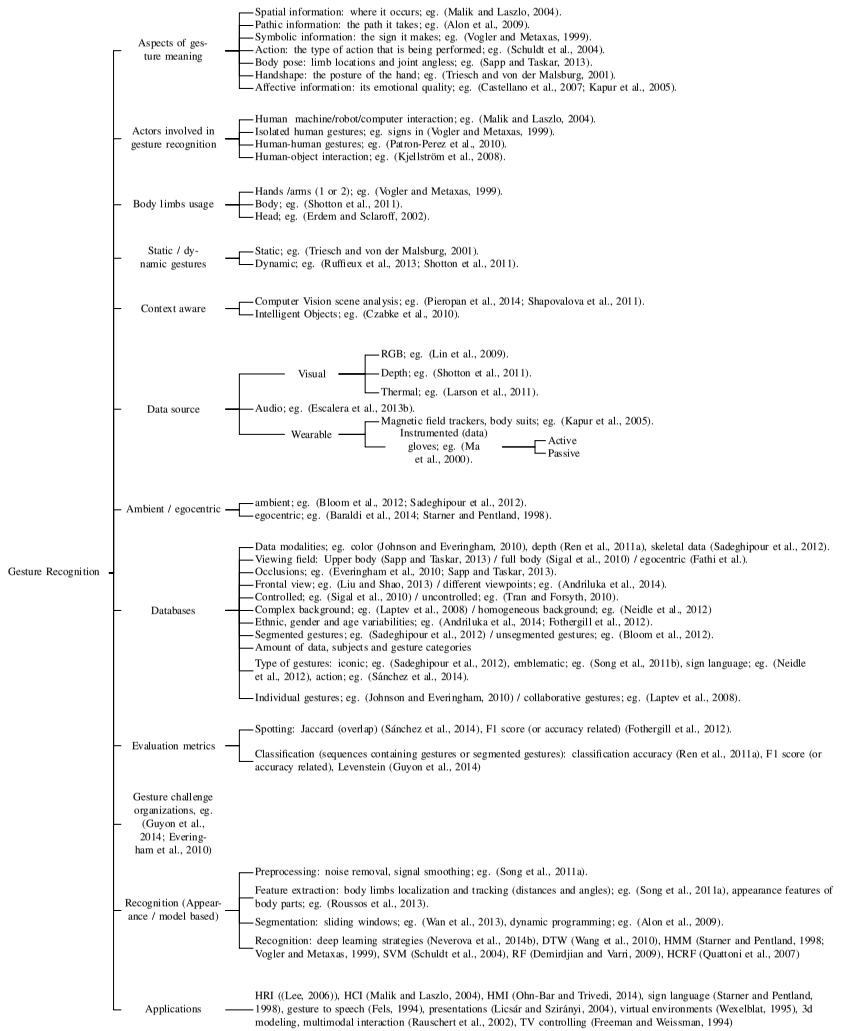

Figure 3: Taxonomy for gesture recognition.

to better infer the meaning of some gestures. Context information can be obtained by means of computer vision scene analysis, interaction with objects, but also via intelligent objects in the scene

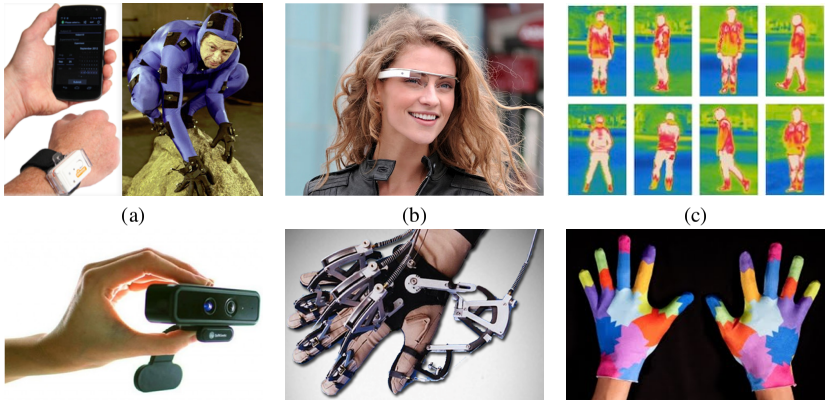

Figure 4: Some examples of acquisition devices for gesture recognition. (a) left: mobile with GPS and accelerometer, right: inertial sensor with accelerometer and gyroscope, (b) Google Glasses for egocentric computing, (c) thermal imagery for action recognition, (d) audio-RGB-depth device, (e) active glove, and (f) passive glove.

(objects with sensors that emit signals related to proximity and interaction). Some examples of acquisition devices are shown in Figure 4.

Third, the field of gesture recognition has shaped up thanks to the adoption of standard methodology. In order to advance in the design of robust action/recognition approaches, several datasets with different complexity have been published, and several world challenges helped to push the research in the area. This required the definition of standard evaluation metrics to render methods comparable. Notably, when one wants to recognize actions/gestures from data, common steps involve pre-processing of the acquired data, feature extraction, segmentation of begin-end of gesture and its final gesture/action label classification. Many datasets include preprocessed and/or thoroughly annotated data.

Fourth, gesture recognition has offered many opportunities to algorithm developers to innovate. The approaches, which essentially can be categorized into appearance-based and model-based methods, are going to be reviewed in the next section. We will mention only the most influential works for action/gesture recognition illustrating various aspects of the problem setting, data acquisition, and methodology defined in our taxonomy. Note that although we defined a general taxonomy for gesture recognition, in this paper, we put special emphasis on computer vision and machine learning methods for action/gesture recognition.

Finally, our taxonomy would not be complete without the wide array of applications of gesture/action recognition, already mentioned in the introduction.

2.2 Overview of gesture recognition methods

Different surveys have been published so far reviewing gesture recognition systems (LaViola Jr., 1999; Mitra and Acharya, 2007; Chaudhary et al., 2011; Ibraheem and Khan, 2012; Avci et al., 2010; Khan and Ibraheem; Kausar and Javed, 2011). In this section, we present an up-to-date review of most influential works in the field.

2.2.1 RECOGNIZING STATIC GESTURES AND HAND POSE

In the case of static gestures, frequently hand shape is the important differentiating feature (Cui and Weng, 2000; Freeman and Roth, 1996; Kelly et al., 2010; Ren et al., 2011b; Triesch and von der Malsburg, 2002), although the pose of the rest of the body can also be important, e.g., (Yang et al., 2010; Van den Bergh et al., 2009). For static hand pose classification, some approaches rely on visual markers, such as a color glove with a specific color for each finger, e.g., (Wang and Popović, 2009). Other approaches can recognize the hand pose on unadorned hands. Appearance-based methods, like (Moghaddam and Pentland, 1995; Triesch and von der Malsburg, 2002; Freeman and Roth, 1996; Wu and Huang, 2000), can be used for recognizing static hand postures observed from specific viewpoints.

Model-based methods for hand pose estimation (Oikonomidis et al., 2011; de La Gorce et al., 2011; Oikonomidis et al., 2010; Rehg and Kanade, 1995) typically match visual observations to instances of a predefined hand model. Single frame pose estimation methods try to solve the hand pose estimation problem without relying on temporal information (Athitsos and Sclaroff, 2003). Most recently, due to the advent of commercially available depth sensors, there is an increased interest in methods relying on depth data (Keskin et al., 2012; Mo and Neumann, 2006; Oikonomidis et al., 2011; Pugeault and Bowden, 2011; Lopes et al., 2014).

2.2.2 FROM BODY PART DETECTION TO HOLISTIC PATTERN DETECTION

Dynamic gestures are characterized by both the pose and the motion of the relevant body parts. Much effort has traditionally be put into detecting first **body parts** and then tracking their motion. In color videos, detecting hands can be quite challenging, although better performance can be achieved by placing additional constraints on the scene and the relative position of the subject and the hands with respect to the camera (Cui and Weng, 2000; Isard and Blake, 1998; Kolsch and Turk, 2004; Ong and Bowden, 2004; Stefanov et al., 2005; Stenger et al., 2003; Sudderth et al., 2004). Commonly-used visual cues for hand detection such as skin color, edges, motion, and background subtraction (Chen et al., 2003; Martin et al., 1998) may also fail to unambiguously locate the hands when the face, or other "hand-like" objects are moving in the background.

In (Li and Kitani, 2013) the authors propose a hand segmentation approach from egocentric RGB data by the combination of color and texture features. In(Baraldi et al., 2014), dense features are extracted around regions selected by a new hand segmentation technique that integrates super-pixel classification, temporal and spatial coherence. Bag of visual words and linear SVM are used for final representation and classification.

Depth cameras have become widely available in recent years, and hand detection (in tandem with complete body pose estimation) using such cameras (and also in combination with other visual modalities) can be performed sufficiently reliably for many applications (Shotton et al., 2011; Hernandez-Vela et al., 2012). The authors of (Ren et al., 2013) propose a part-based hand gesture recognition system using Kinect^{TM}sensor. Finger-EarthMover's Distance (FEMD) metric is proposed to measure the dissimilarity between hand shapes. It matches the finger parts while not the whole hand based on hand segmentation and contour analysis. The method is tested on their own 10-gesture dataset.

Instead of estimating hand position and/or body pose before recognizing the gesture, an alternative is to customize the recognition module so that it does not require the exact knowledge of hand positions, but rather accepts as input a list of several candidate hand locations (Alon et al., 2009; Sato and Kobayashi, 2002; Hernandez-Vela et al., 2013b).

Another approach is to use **global image/video features**. Such global features include motion energy images (Bobick and Davis, 2001), thresholded intensity images and difference images (Dreuw et al., 2006), 3D shapes extracted by identifying areas of motion in each video frame (Gorelick et al., 2007) and histograms of pairwise distances of edge pixels (Nayak et al., 2005). Gestures can also be modelled as rigid 3D patterns (Ke et al., 2005), from which features can be extracted using 3D extensions of rectangle filters (Viola and Jones, 2001). The work of (Kong et al., 2015) uses pixel-level attributes in a hierarchical architecture of 3D kernel descriptors, and efficient match kernel is used to recognize gestures from depth data.

Along similar lines, (Ali and Shah, 2010) propose a set of kinematic features that are derived from the optical flow for human action recognition in videos: divergence, vorticity, symmetric and antisymmetric flow fields, second and third principal invariants of flow gradient and rate of strain tensor, and third principal invariant of rate of rotation tensor, which define spatiotemporal patterns. These kinematic features are computed by Principal Component Analysis (PCA). Then multiple instance learning (MIL) is applied for recognition in which each action video is represented by a bag of kinematic modes. The proposal is evaluated on the RGB Weizmann and KTH action data sets, showing comparable result to state of the art performances.

Much effort has also been put into **spatiotemporal invariant features**. In (Yuan et al., 2011) the authors propose a RGB action recognition system based on a pattern matching approach, named naive Bayes mutual information maximization (NBMIM). Each action is characterized by a collection of spatiotemporal invariant features which are matched with an action class by measuring the mutual information between them. Based on this matching criterion, action detection is to localize a subvolume in the volumetric video space that has the maximum mutual information toward a specific action class. A novel spatiotemporal branch-and-bound (STBB) search algorithm is designed to efficiently find the optimal solution. Results show high recognition results on KTH, CMU, and MSR data sets, showing speed up inference in comparison with standard 3D branch-and-bound.

Another example is the paper of (Derpanis et al., 2013) in which a compact local descriptor of video dynamics is proposed for action recognition in RGB data sequences. The descriptor is based on visual spacetime oriented energy measurements. An associated similarity measure is introduced that admits efficient exhaustive search for an action template, derived from a single exemplar video, across candidate video sequences. The method is speeded up by means of a GPU implementation. Method is evaluated on UCF and KTH data sets, showing comparable results to state of the art methods.

The work of (Yang and Tian, 2014b) presents a coding scheme to aggregate low-level descriptors into the super descriptor vector (SDV). In order to incorporate the spatio-temporal information, the super location vector (SLV) models the space-time locations of local interest points in a compact way. SDV and SLV are combined as the super sparse coding vector (SSCV) which jointly models the motion, appearance, and location cues. The approach is tested on HMDB51 and Youtube with higher performance in comparison to state of the art approaches.

2.2.3 SEGMENTATION OF GESTURES AND GESTURE SPOTTING

Dynamic gesture recognition methods can be further categorized based on whether they make the assumption that gestures have already been segmented, so that the start frame and end frame of each gesture is known. Gesture spotting is the task of recognizing gestures in unsegmented video streams, that may contain an unknown number of gestures, as well as intervals were no gesture is being performed. Gesture spotting methods can be broadly classified into two general approaches: the direct approach, where temporal segmentation precedes recognition of the gesture class, and the indirect approach, where temporal segmentation is intertwined with recognition:

- **Direct methods** (also called heuristic segmentation) first compute low-level motion parameters such as velocity, acceleration, and trajectory curvature (Kang et al., 2004) or mid-level motion parameters such as human body activity (Kahol et al., 2004), and then look for abrupt changes (e.g., zero-crossings) in those parameters to identify candidate gesture boundaries.

- **Indirect methods** (also called recognition-based segmentation) detect gesture boundaries by finding, in the input sequence, intervals that give good recognition scores when matched with one of the gesture classes. Most indirect methods (Alon et al., 2009; Lee and Kim, 1999; Oka, 1998) are based on extensions of Dynamic Programming (DP) e.g., Dynamic Time Warping (DTW) (Darrell et al., 1996; Kruskal and Liberman, 1983), Continuous Dynamic Programming (CDP) (Oka, 1998), various forms of Hidden Markov Models (HMMs) (Brand et al., 1997; Chen et al., 2003; Stefanov et al., 2005; Lee and Kim, 1999; Starner and Pentland, 1998; Vogler and Metaxas, 1999; Wilson and Bobick, 1999), and most recently, Conditional Random Fields (Lafferty et al., 2001; Quattoni et al., 2007). Also hybrid probabilistic and dynamic programming approaches have been recently published (Hernandez-Vela et al., 2013a). In those methods, the gesture endpoint is detected by comparing the recognition likelihood score to a threshold. The threshold can be fixed or adaptively computed by a non-gesture garbage model (Lee and Kim, 1999; Yang et al., 2009), equivalent to silence models in speech.

When attempting to recognize unsegmented gestures, a frequently encountered problem is the *subgesture problem*: false detection of gestures that are similar to parts of other longer gestures. (Lee and Kim, 1999) address this issue using heuristics to infer the user's completion intentions, such as moving the hand out of camera range or freezing the hand for a while. An alternative is proposed in (Alon et al., 2009), where a learning algorithm explicitly identifies subgesture/supergesture relationships among gesture classes, from training data.

Another common approach for gesture spotting is to first extract features from each frame of the observed video, and then to provide a sliding window of those features to a recognition module, which performs the classification of the gesture (Corradini, 2001; Cutler and Turk, 1998; Darrell et al., 1996; Oka et al., 2002; Starner and Pentland, 1998; Yang et al., 2002)). Oftentimes, the extracted features describe the position and appearance of the gesturing hand or hands (Cutler and Turk, 1998; Darrell et al., 1996; Starner and Pentland, 1998; Yang et al., 2002)). This approach can be integrated with recognition-based segmentation methods.

2.2.4 ACTION AND ACTIVITY RECOGNITION

The work of (Li et al., 2010) presents an action graph to model explicitly the dynamics of 3D actions and a bag of 3D points to characterize a set of salient postures that correspond to the nodes

in the action graph. The authors propose a projection based sampling scheme to sample the bag of 3D points from the depth maps. In (Sminchisescu et al., 2006) it is proposed the first conditional/discriminative chain model for action recognition.

The work of (Zanfir et al., 2013) propose the non-parametric Moving Pose (MP) framework for low-latency human action and activity recognition. The moving pose descriptor considers both pose information as well as differential quantities (speed and acceleration) of the human body joints within a short time window around the current frame. The descriptor is used with a modified kNN classifier that considers both the temporal location of a particular frame within the action sequence as well as the discrimination power of its moving pose descriptor compared to other frames in the training set. The method shows comparable results to state of the art methods on MSR-Action3D and MSR-DailyActivities3D data sets.

In (Oreifej and Liu, 2013), it is proposed a new descriptor for activity recognition from videos acquired by a depth sensor. The depth sequence is described using a histogram capturing the distribution of the surface normal orientation in the 4D space of time, depth, and spatial coordinates. To build the histogram, 4D projectors are created, which quantize the 4D space and represent the possible directions for the 4D normal. Projectors are initialized using the vertices of a regular polychoron. Projectors are refined using a discriminative density measure, such that additional projectors are induced in the directions where the 4D normals are more dense and discriminative. The proposed descriptor is tested on MSR Actions 3D, MSR Gesture 3D, and MSR Daily Activity 3D, slightly improving state of the art results.

In (Wang et al., 2014), the authors propose to characterize the human actions with an "actionlet" ensemble model, which represents the interaction of a subset of human joints. Authors train an ensemble of SVM classifiers related to actionlet patterns, which includes 3D joint features, Local Occupancy Patterns, and Fourier Temporal Pyramid. Results on CMU MoCap, MSR-Action3D, MSR-DailyActivity3D, Cornell Activity, and Multiview 3D data sets show comparable and better performance than state of the art approaches.

The work of (Yang and Tian, 2014a) presents an approach for activity recognition in depth video sequences. Authors cluster hypersurface normals in a depth sequence to form the polynormal which is used to jointly characterize the local motion and shape information. In order to globally capture the spatial and temporal orders, an adaptive spatio-temporal pyramid is introduced to subdivide a depth video into a set of space-time grids. It is then proposed a scheme of aggregating the low-level polynormals into the super normal vector (SNV) which can be seen as a simplified version of the Fisher kernel representation. Authors validate the proposed approach on MSRAction3D, MSRDailyActivity3D, MSRGesture3D, and MSRActionPairs3D data sets slightly improving in all cases state of the art performances.

In (Yu et al., 2014) the authors propose the orderlets to capture discriminative information for gesture recognition from depth maps. Orderlet features are discovered looking for frequent sets of skeleton joints that provide discriminative information. Adaboost is used for orderlets selection. Results on the ORGBD data set shows a recognition rate of 71.4% mean class average accuracy, improving by near 5% state of the art results on this data set, and near 20% improvement regarding frame level classification. However the results showed on the MSR-DailyActivity3D data set are inferior to the ones reported in (Luo et al., 2014).

The work of (Liang et al., 2014) presents a depth-based method for hand detection and pose recognition by segmentation of different hand parts. Authors based on RF for initial multipart hand

segmentation. Then, a Superpixel-Markov Random Field (SMRF) parsing scheme is used to enforce the spatial smoothness and the label co-occurrence prior to remove the misclassified regions.

2.2.5 APPROACHES USING NON-VIDEO MODALITIES AND MULTIMODAL APPROACHES

In terms of multimodal approaches for gesture recognition, (Luo et al., 2014) propose a sparse coding-based temporal pyramid matching approach (ScTPM) for feature representation using depth maps. The authors also propose the Center-Symmetric Motion Local Ternary Pattern (CS-Mltp) descriptor to capture spatial-temporal features from RGB videos. By fusing both RGB and Depth descriptors, the authors improve state of the art results on MSR-Action3D and MSR-DailyActivity3D data sets, with a 6% and 7% of improvement, respectively.

In (Ionescu et al., 2014), it is presented the Human3.6M data set, consisting of 3.6Million accurate 3D Human poses, acquired by recording the performance of 5 female and 6 male subjects, under 4 different viewpoints, for training realistic human sensing systems and for evaluating the next generation of human pose estimation models and algorithms. Authors also provide a set of large scale statistical models and evaluation baselines for the dataset illustrating its diversity.

In (Xiao et al., 2014) a wearable Immersion CyberGlove II is used to capture the hand posture and the vision-based Microsoft Kinect^{TM}takes charge of capturing the head and arm posture. An effective and real-time human gesture recognition algorithm is also proposed.

In (Liang et al., 2013) it is proposed to detect and segment different body parts using RGB and Depth data sequences. The method uses both temporal constraints and spatial features, and performs hand parsing and 3D fingertip localization for hand pose estimation. The hand parsing algorithm incorporates a spatial-temporal feature into a Bayesian inference framework to assign the correct label to each image pixel. The 3D fingertip localization algorithm adapts is based on geodesic extrema extraction to fingertip detection. The detected 3D fingertip locations are finally used for hand pose estimation with an inverse kinematics solver. The work of (Joshi et al., 2015) use random forest for both segmenting and classifying gesture categories from data coming from different sensors.

Although many works base only on inertial data (Benbasat and Paradiso, 2001; Berlemont et al., 2015), multimodal approaches are often considered in order to combine trajectory information will pose analysis based on visual data. The works of (Liu et al., 2014; Pardo et al., 2013) present approaches for gesture recognition based on the combination of depth and inertial data. In (Liu et al., 2014) skeleton obtained from depth data and data from inertial sensors are train within HMM in order to perform hand gesture recognition. A similar approach is presented in (Pardo et al., 2013), but also recognizing objects present in the scene and using DTW for recognition with the objective of performing ambient intelligent analysis to support people with reduced autonomy. In (Gowing et al., 2014), it is presented a comparison of WIMU aWireless/Wearable Inertial Measurement Unit and Kinect^{TM}. However, comparison is performed independently, without considering a fusion strategy.

The work of (Appenrodt et al., 2009) is one of the few that compare the performance of different segmentation approaches for gesture recognition comparing RGB, depth, and thermal modalities. They propose a simple segmentation approach of faces and one hand for recognizing letters and numbers for HCI. They obtained higher performance by the use of depth maps. Unfortunately no mutimodal fusion approaches are tested in order to analyze when each modality can complement the information provided by the rest of modalities.

The work of (Escalera et al., 2013b) summarizes a 2013 challenge on multimodal gesture recognition, where in addition to RGB and depth data, audio can be used to identify the performed gestures.

Few works considered context information in order to improve gesture/action recognition systems. In (Wilhelm) it is proposed to adapt gesture recognition based on a dialogue manager as a partially observable Markov decision process (POMDP). In (Caon et al., 2011) two Kinect^{TM}devices and smart objects are used to estimate proximity and adapt the recognition prior of some gestures.

The recent emergence of deep learning systems in computer vision have also been applied to action/gesture recognition systems. In (Neverova et al., 2014a), it is presented a deep learning based approach for hand pose estimation, targeting gesture recognition. The method integrates local and global structural information into the training objective. In (Nagi et al., 2011), deep neural network (NN) combining convolution and max-pooling (MPCNN) is proposed for supervised feature learning and classification of RGB hand gestures given by humans to mobile robots using colored gloves. The hand contour is retrieved by color segmentation, then smoothed by morphological image processing which eliminates noisy edges. The system classifies 6 gesture classes with 96% accuracy, improving performance of several state of the art methods. The work of (Duffner et al., 2014) presents an approach that classifies 3D gestures using jointly accelerometer and gyroscope signals from a mobile device using convolutional neural network with a specific structure involving a combination of 1D convolution. In (Molchanov et al., 2015) convolutional deep neural networks are used to fuse data from multiple sensors (short-range radar, a color camera, and a depth camera) and to classify the gestures in a driver assistance scenario.

2.3 Sign language recognition

An important application of gesture recognition is sign language recognition. American Sign Language (ASL) is used by 500,000 to two million people in the U.S. (Lane et al., 1996; Schein, 1989). Overall, national and local sign languages are used all over the world as the natural means of communication in deaf communities.

Several methods exist for recognizing isolated signs, as well as continuous signing. Some researchers have reported results on continuous signing with vocabularies of thousands of signs, using input from digital gloves, e.g., (Yao et al., 2006). However, glove-based interfaces are typically expensive for adoption by the general public, as well as intrusive, since the user has to wear one or two gloves connected with wires to a computer.

Computer vision methods for sign language recognition offer hope for cheaper, non-intrusive interfaces compared to methods using digital gloves. Several such methods have been proposed (Bauer et al., 2000; Cui and Weng, 2000; Dreuw et al., 2006; Kadir et al., 2004; Starner and Pentland, 1998; Vogler and Metaxas, 1999; Wang et al., 2010; Zieren and Kraiss, 2005). However, computer vision methods typically report lower accuracies compared to methods using digital gloves, due to the difficulty of extracting accurate information about the articulated pose and motion of the signer.

An important constraint limiting the accuracy of computer vision methods is the availability of training data. Using more examples per sign typically improves accuracy (see, e.g., (Kadir et al., 2004; Zieren and Kraiss, 2005)). However, existing datasets covering large vocabularies have only a limited number of examples per sign. As an example, the ASLLVD dataset (Athitsos et al., 2008) includes about 3,000 signs, but only two examples are available for most of the signs. Some interest-

ing research has aimed at enabling automated construction of large datasets. For example, (Cooper and Bowden, 2009) aim at automatically generating large corpora by automatically segmenting signs from close-captioned sign language videos. As another example, (Farhadi et al., 2007) propose a method where sign models are learned using avatar-produced data, and then transfer learning is used to create models adapted for specific human signers.

The recent availability of depth cameras such as Kinect^{TM}has changed the methodology and improved performance. Depth cameras provide valuable 3D information about the position and trajectory of hands in signing. Furthermore, detection and tracking of articulated human motion is significantly more accurate in depth video than in color video. Several approaches have been published in recent years that use depth cameras to improve accuracy in sign language recognition Conly et al. (2015); Wang et al. (2015a); Zafrulla et al. (2011).

2.4 Data sets for gesture and action recognition

Tens of gesture recognition datasets have been made available to the research community over the last several years. A summary of available datasets is provided in Table 1. In that table, for each data set we mark some important attributes of the dataset, such as the type of gestures it contains, the data modalities it provides, the viewing field, background, amount of data, and so on. Regarding the "occlusions" attribute in that table, we should clarify that it only refers to occlusions of the subject by other objects (or subjects), and not to self occlusions. Self occlusions are quite common in gestures, and are observed in most datasets. We should also note that, regarding the complexity of the background, dynamic and/or cluttered backgrounds can make gesture recognition challenging in color images and video. At the same time, a complex background can be quite easy to segment if depth or skeletal information is available, as is the case in several datasets on Table 1.

In order to be able to fit Table 1 in a single page, we had to use abbreviations quite heavily. Table 2 defines the different acronyms and abbreviations used in Table 1.

The datasets we have created for our challenges have certain unique characteristics, that differentiate them from other existing datasets. The CDG2011 dataset (Guyon et al., 2014) has a quite diverse collection of gesture types, including static, pantomime, dance, signs, and activities. This is in contrast to other datasets, that typically focus on only one or maybe two gesture types. Furthermore, the CDG2011 dataset uses an evaluation protocol that emphasizes one-shot learning, whereas existing data sets typically have several training examples for each class. The CDG2013 dataset introduces audio data to the mix of color and depth that is available in some other data sets, such as (Sadeghipour et al., 2012; Bloom et al., 2012).

Table 1: Datasets. "Occl." stands for "occlusions". "View. variab." stands for "viewpoint variabilities". "Variab." stands for "variabilities in gender, age, ethnicity". "Seg." stands for "segmented". "Indiv/Collab." stands for "individual or collaborative gestures". "Type" stands for "gesture type". "Eval." stands for "evaluation".

Taxonomy Attribute	Acronym/Abbreviation	Meaning
Actors/Objects	HH	human-human interactions
Actors/Objects	IH	isolated human
Actors/Objects	O	humans with objects
Body parts	F	full body
Body parts	H	hands
Static/Dynamic	SF	Subjects are in motion, but each frame is individually classified
Modalities	6DMG	WorldViz PPT-X4 (position + 3D orientation) + Wii Remote Plus (acceleration and angular speeds)
Modalities	A	audio
Modalities	B	binary segmentation mask
Modalities	C	RGB (color)
Modalities	ChAir	RGB, depth, skeletal, four inertial motion units
Modalities	D	depth
Modalities	G	grayscale
Modalities	MC	multiple cameras
Modalities	S	stereo images
Modalities	ST	skeletal tracking
Viewing field	A	arm and hand
Viewing field	E	egocentric
Viewing field	F	full body
Viewing field	MU	upper body in most cases
Viewing field	U	upper body
Occlusions		
Viewpoints	F	Frontal
Viewpoints	Fixed	Fixed viewpoint for each class
Viewpoints	SV	Fixed viewpoint for some classes, variable for other classes
Viewpoints	V	Variable viewpoint
Controlled/Uncontrolled	C	Controlled
Controlled/Uncontrolled	U	Uncontrolled
Background	CU	some cluttered, some uncluttered
Background	C	cluttered
Background	D	dynamic
Background	SF	each frame is individually classified, so background is seen only from a single frame
Background	SD	static in some cases, dynamic in some cases
Background	ST	static
Background	U	uncluttered
Variabilities in gender/age/ethnicity	A	variabilities in age
Variabilities in gender/age/ethnicity	AU	unspecified whether there are variabilities in age
Variabilities in gender/age/ethnicity	AY	mostly non-senior adults
Variabilities in gender/age/ethnicity	E	variabilities in ethnicity
Variabilities in gender/age/ethnicity	EU	unspecified whether there are variabilities in ethnicity
Variabilities in gender/age/ethnicity	G	variabilities in gender
Variabilities in gender/age/ethnicity	U	unspecified
Segmented/Unsegmented	SF	each frame is individually classified
Amount of data	A	action samples
Amount of data	F	frames
Amount of data	G	gesture samples
Amount of data	V	video clips
Number of subjects	U1	Unspecified, but most subjects appear in only one sample
Number of subjects	UM	Unspecified, but most subjects appear in several samples
Number of subjects	US	Unspecified, but some subjects appear in more than one sample
Classes	CBP	continuous space of body
Classes	CDG11	about 300, but broken into subsets of 8-12 classes
Gesture type	A	action
Gesture type	BP	body pose
Gesture type	D	deictic
Gesture type	E	emblematic
Gesture type	HS	handshape
Gesture type	I	iconic
Gesture type	S	sign
Individual or collaborative	B	both individual and collaborative
Individual or collaborative	C	collaborative
Individual or collaborative	I	individual
Individual or collaborative	MI	mostly individual
Evaluation criteria	ATSR	Defined in (Ruffieux et al., 2013), based on difference between detected and ground truth endpoints, normalized by duration of the gesture
Evaluation criteria	CA	Classification accuracy
Evaluation criteria	F	F-score
Evaluation criteria	Fer.	Defined in (Ferrari et al., 2008), checks if detected endpoints are within distance of half length (of the body part in question) from the ground truth position.
Evaluation criteria	L	Levenshtein distance
Evaluation criteria	MPJPE	Mean per-joint position error (measured as Euclidean distance).
Evaluation criteria	Pascal	At least 50% overlap of bounding boxes on all body parts.
Evaluation criteria	Ram.	Defined in (Ramanan, 2006), average negative log likelihood of correct pose.
Evaluation criteria	RCC	Defined in (Wang et al., 2010), based on rank of the correct class for each test sign. For any R, report percentage of test signs for which the correct class was in the top R classes.
Evaluation criteria	Sap.	Defined in (Sapp and Taskar, 2013), Accuracy is based on (variable) threshold pixel distance between joint location and ground truth, scaled so that the torso length in the ground truth is 100 pixels.

3. Gesture recognition challenges

In this section we review the series of gesture and action recognition challenges organized by ChaLearn from 2011 to 2015, as well as other international challenges related to gesture recognition.

3.1 First ChaLearn Gesture Recognition Challenge (2011-2012): One shot learning

ChaLearn launched in 2012 a challenge with prizes donated by Microsoft using datasets described in (Guyon et al., 2014). We organized two rounds in conjunction with the CVPR conference (Providence, Rhode Island, USA, June 2012) and the ICPR conference (Tsukuba, Japan, November 2012). Details on the challenge setting and results are found in (Guyon et al., 2013). We briefly summarize the setting and results.

3.1.1 2011-2012 CHALLENGE PROTOCOL AND EVALUATION

The task of the challenge was to built a learning system capable of learning a gesture classification problem from a **single training example** per class, from dynamic video data complemented by a depth map obtained with Kinect^{TM}. The rationale behind this setting is that, in many computer interface applications to gesture recognition, users want to customize the interface to use their own gestures. Therefore they should be able to retrain the interface using a small vocabulary of their own gestures. We have also experimented with other use cases in gaming and teaching gesture vocabularies. Additionally, the problem of one-shot-learning is of intrinsic interest in machine learning and the solutions deviced could carry over to other applications. It is in a certain way an extreme case of transfer learning.

To implement this setting in the challenge, we collected a large dataset consisting of batches, each batch corresponding to the video recording of short sequences of gestures performed by the same person. The gestures in one batch pertained to a small vocabulary of gestures taken from a variety of application domains (sign language for the deaf, traffic signals, pantomimes, dance postures, etc.). During the development phase, the participants had access to hundreds of batches of diverse gesture vocabularies. This played the role of "source domain data" in the transfer learning task. The goal of the participants was to get ready to receive new batches from different gesture performers and different gesture vocabularies, playing the role of "transfer domain data". Their system would then need to learn from a single example of gesture performed by the particular performer, before being capable of recognizing the rest of the gestures in that batch. The full dataset is available from `http://gesture.chalearn.org/data`.

More specifically, each batch was split into a training set (of one example for each gesture) and a test set of short sequences of one to 5 gestures. Each batch contained gestures from a different small vocabulary of 8 to 12 gestures, for instance diving signals, signs of American Sign Language representing small animals, Italian gestures, etc. The test data labels were provided for the development data only (source domain data), so the participants could self-evaluate their systems and pre-train parts of it as is expected from transfer learning methods. The data also included 20 validation batches and 20 final evaluation batches as transfer domain data used by the organizers to evaluate the participants. In those batches, only the labels of the training gestures (one example each) was provided, the rest of the gesture sequences were unlabelled and the goal of the participants

was to predict those labels. We used the Kaggle platform to manage submissions[1] The participants received immediate feed-back on validation data on a on-line leaderboard. The final evaluation was carried out on the final evaluation data, and those results were only revealed after the challenge was over. The participants had a few days to train their systems and upload their predictions. Prior to the end of the development phase, the participants were invited to submit executable software for their best learning system to a software vault. This allowed the competition organizers to check their results and ensure the fairness of the competition.

To compare prediction labels for gesture sequences to the truth values, we used the generalized Levenshtein distances (each gesture counting as one token). The final evaluation score was computed as the sum of such distances for all test sequences, divided by the total number of gestures in the test batch. This score is analogous to an error rate. However, it can exceed one. Specifically, for each video, the participants provided an ordered list of labels R corresponding to the recognized gestures. We compared this list to the corresponding list of labels T in the prescribed list of gestures that the user had to play. These are the "true" gesture labels (provided that the users did not make mistakes). We computed the generalized Levenshtein distance $L(R,T)$, that is the minimum number of edit operations (substitution, insertion, or deletion) that one has to perform to go from R to T (or vice versa). The Levenhstein distance is also known as "edit distance". For example: $L([124],[32]) = 2; L([1],[2]) = 1; L([222],[2]) = 2$.

We provided code to browse though the data, a library of computer vision and machine learning techniques written in Matlab featuring examples drawn from the challenge datasets, and an end-to-end baseline system capable of processing challenge data and producing a sample submission. The competition pushed the state of the art considerably. The participants narrowed down the gap in performance between the baseline recognition system initially provided ($\simeq$ 60% error) and human performance ($\simeq$ 2% error) by reaching $\simeq$ 7% error in the second round of the challenge. There remains still much room for improvement, particularly to recognize static postures and subtle finger positions.

3.1.2 2011-2012 CHALLENGE DATA

The datasets are described in details in a companion paper (Guyon et al., 2014). Briefly, the data are organized in batches: development batches devel01-480, validation batches valid01-20, and final evaluation batches final01-20 (for round 1) and final21-40 (for round 2). For the development batches, we provided all the labels. To evaluate the performances on "one-shot-learning" tasks, the valid and final batches were provided with labels only for **one example of each gesture class** in each batch (training examples). The goal was to automatically predict the gesture labels for the remaining unlabelled gesture sequences (test examples).

Each batch includes 100 recorded gestures grouped in sequences of 1 to 5 gestures performed by the same user. The gestures are drawn from a small vocabulary of 8 to 12 unique gestures, which we call a "lexicon". For instance a gesture vocabulary may consist of the signs to referee volleyball games or the signs to represent small animals in the sign language for the deaf. We selected lexicons from nine categories corresponding to various settings or application domains (Figure 5):

1. **Body language** gestures (like scratching your head, crossing your arms).

1. For round 1: `http://www.kaggle.com/c/GestureChallenge`. For round 2: `http://www.kaggle.com/c/GestureChallenge2`.

Team	Public score on validation set	Private score on final set #1	For comparison score on final set #2
Alfnie	0.1426	0.0996	0.0915
Pennect	0.1797	0.1652	0.1231
OneMillionMonkeys	0.2697	0.1685	0.1819
Immortals	0.2543	0.1846	0.1853
Zonga	0.2714	0.2303	0.2190
Balazs Godeny	0.2637	0.2314	0.2679
SkyNet	0.2825	0.2330	0.1841
XiaoZhuwWudi	0.2930	0.2564	0.2607
Baseline method 1	0.5976	0.6251	0.5646

Table 3: Results of round 1. In round 1 the baseline method was a simple template matching method (see text). For comparison, we show the results on the final set number 2 not available in round 1.

2. **Gesticulations** performed to accompany speech.
3. **Illustrators** (like Italian gestures).
4. **Emblems** (like Indian Mudras).
5. **Signs** (from sign languages for the deaf).
6. **Signals** (like referee signals, diving signals, or Marshalling signals to guide machinery or vehicle).
7. **Actions** (like drinking or writing).
8. **Pantomimes** (gestures made to mimic actions).
9. **Dance postures.**

During the challenge, we did not disclose the identity of the lexicons and of the users.

3.1.3 2011-2012 CHALLENGE RESULTS

The results of the top ranking participants were checked by the organizers who reproduced their results using the code provided by the participants before they had access to the final evaluation data. All of them passed successfully the verification process. These results are shown in Tables 3 and 4.

3.1.4 2011-2012 CHALLENGE, SUMMARY OF THE WINNER METHODS

The results of the challenge are analyzed in details, based on papers published in this special topic and on descriptions provided by the top ranking participants in their fact sheets (Guyon et al., 2013). We briefly summarize notable methods below.

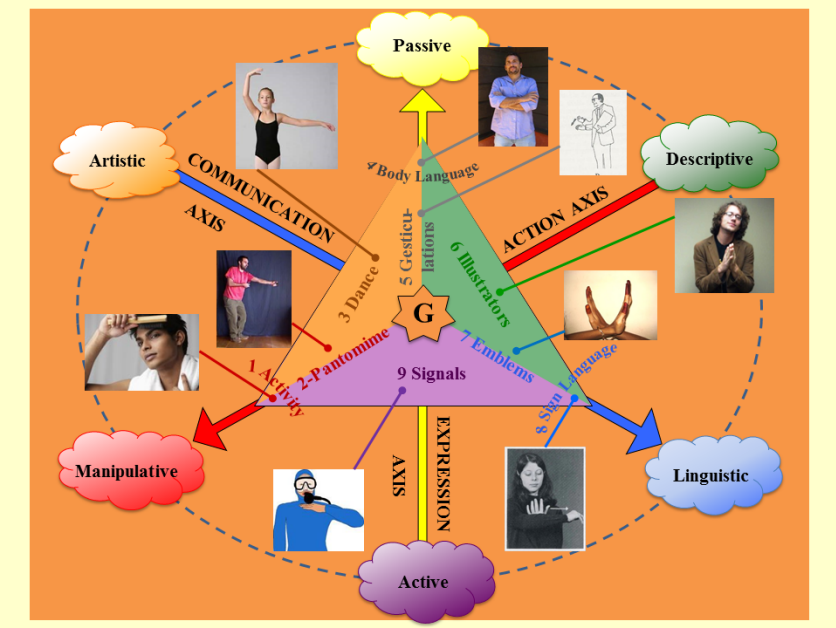

Figure 5: **Types of gestures.** We created a classification of gesture types according to purpose defined by three complementary axes: communication, expression and action. We selected 85 gesture vocabularies, including Italian gestures, Indian Mudras, Sign language for the deaf, diving signals, pantomimes, and body language.

The winner of both rounds (Alfonso Nieto Castañon of Spain, a.k.a. alfnie) used a novel technique called "Motion Signature analyses", inspired by the neural mechanisms underlying information processing in the visual system. This is an unpublished method using a sliding window to perform simultaneously recognition and temporal segmentation, based solely on depth images. The method, described by the authors as a "Bayesian network", is similar to a Hidden Markov Model (HMM). It performs simultaneous recognition and segmentation using the Viterbi algorithm. The preprocessing steps include Wavelet filtering replacement of missing values and outlier detection. Notably, this method is one of the fastest despite the fact that he implemented it in Matlab (close to real time on a regular laptop). The author claims that it has linear complexity in image size, number of frames, and number of training examples.

The second best ranked participants (team Pennect of Universit of Pennsylvania, USA, in round 1 and team Turtle Tamers of Slovakia, in round 2) used very similar methods and performed similarly. The second team published their results in this special topic (Konecny and Hagara, 2014).

Team	Public score on validation set	For comparison score on final set #1	Private score on final set #2
Alfnie	0.0951	0.0734	0.0710
Turtle Tamers	0.2001	0.1702	0.1098
Joewan	0.1669	0.1680	0.1448
Wayne Zhang	0.2814	0.2303	0.1846
Manavender	0.2310	0.2163	0.1608
HIT CS	0.1763	0.2825	0.2008
Vigilant	0.3090	0.2809	0.2235
Baseline method 2	0.3814	0.2997	0.3172

Table 4: Results of round 2. In round 2, the baseline method was the "Principal Motion" method (see text).

Both methods are based on an HMM-style model using HOG/HOF features to represent movie frames. They differ in that Pennect used RGB images only while Turtle Tamers used both RGB and depth. Another difference is that Pennect used HOG/HOF features at 3 different scales while Turtle Tamers created a bag of features using K-means clustering from only 40x40 resolution and 16 orientation bins. Pennect trained a one-vs-all linear classifier for each frame in every model and used the discriminant value as a local state score for the HMM while Turtle Tamers used a quadratic-chi kernel metric for comparing pairs of frames in the training and test movie. As preprocessing, Pennect uses mean subtraction and compensates for body translations while Turtle Tamers replaces the missing values by the median of neighboring values. Both teams claim a linear complexity in number of frames, number of training examples, and image size. They both provided Matlab software that processes all the batches of the final test set on a regular laptop in a few hours.

The next best ranked participants (who won **third place in round 2**), the Joewan team, who published in this special topic (Wan et al., 2013), used a slightly different approach. They relied on the motion segmentation method provided by the organizers to pre-segment videos. They then represented each video as a bag of 3D MOSIFT features (integrating RGB and depth data), and then used a nearest neighbor classifier. Their algorithm is super-quadratic in image size, linear in number of frames per video, and linear in number of training examples. The method is rather slow and takes over a day to process all the batches of the final test set on a regular laptop.

The third best ranked team in round 1 (OneMillionMonkeys) also used an HMM in which a state is created for each frame of the gesture exemplars. This data representation is based on edge detection in each frame. Edges are associated with several attributes including the X/Y coordinates, their orientation, their sharpness, their depth and location in an area of change. To provide a local state score to the HMM for test frames, OneMillionMonkeys calculated the joint probability of all the nearest neighbors in training frames using a Gaussian model. The system works exclusively from the depth images. The system is one of the slowest proposed. Its processing speed is linear in number of training examples but quadratic in image size and number of frames per video. The method is rather slow and takes over a day to process all the batches of the final test set on a regular laptop.

Methods robust against translation include those of Joewan (Wan et al., 2013) and Immortals/Manavender (this is the same author under two different pseudonyms for round 1 and round 2). The team Immortals/Manavender published their method in this special topic (Malgireddy et al., 2013). Their representations are based on a bag of visual words, inspired by techniques used in action recognition (Laptev, 2005). Such representations are inherently shift invariant. The slight performance loss in translated data may be due to partial occlusions.

Although the team Zonga did not end up ranking among top ranking participants, the authors, who published their method in this special topic, proposed a very original method and ended up winning the best paper award. Notably, their outperformed all baseline methods early on in the challenge by applying their method without tuning it to the tasks of the challenge and remained at the top of the leaderboard for several weeks. The used a novel technique based on tensor geometry, which provides a data representation exhibiting desirable invariances and yields a very discriminating structure for action recognition.

ChaLearn also organized demonstration competitions of gesture recognition systems using Kinect^{TM}, in conjunction with those events. Novel data representations were proposed to tackle with success, in real time, the problem of hand and finger posture recognition. The demonstration competition winners showed systems capable of accurately tracking in real time hand postures in application for touch free exploration of 3D medical images for surgeons in the operating room, finger spelling (sign language for the deaf), virtual shopping, and game controlling. Combining the methods proposed in the demonstration competition tackling the problem of hand postures and those of the quantitative evaluation focusing on the dynamics of hand and arm movements is a promising direction of future research. For a long lasting impact, the challenge platform, the data and software repositories have been made available for further research[2].

3.2 ChaLearn Multimodal Gesture Recognition Challenge 2013

The focus of this second challenge was on *multiple instance, user independent learning of gestures from multimodal data*, which means learning to recognize gestures from several instances for each category performed by different users, drawn from a vocabulary of 20 gesture categories(Escalera et al., 2013b,a). A gesture vocabulary is a set of unique gestures, generally related to a particular task. In this challenge we focus on the recognition of a vocabulary of 20 Italian cultural/anthropological signs (Escalera et al., 2013b), see Figure 6 for one example of each Italian gesture.

3.2.1 2013 CHALLENGE DATA

In all the sequences, a single user is recorded in front of a Kinect^{TM}, performing natural communicative gestures and speaking in fluent Italian. The main characteristics of the dataset of gestures are:

- 13.858 gesture samples recorded with the Kinect^{TM} camera, including audio, skeletal model, user mask, RGB, and depth images.
- RGB video stream, 8-bit VGA resolution (640×480) with a Bayer color filter, and depth sensing video stream in VGA resolution (640×480) with 11-bit. Both are acquired in 20 fps on average.
- Audio data is captured using Kinect^{TM} 20 multiarray microphone.
- A total number of 27 users appear in the data set.

2. http://gesture.chalearn.org/

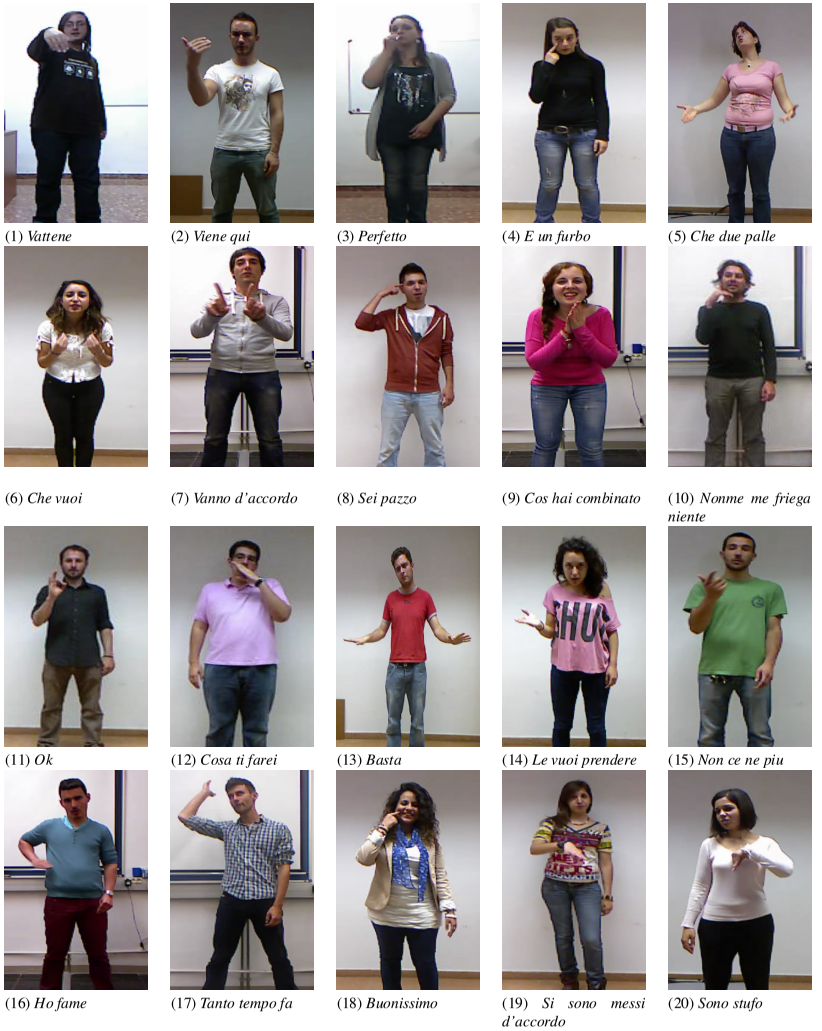

Figure 6: Data set gesture categories.

- The data set contains the following number of sequences, development: 393 (7.754 gestures), validation: 287 (3.362 gestures), and test: 276 (2.742 gestures), each sequence lasts between 1 and 2 minutes and contains between 8 and 20 gesture samples, around 1.800 frames. The total number

Table 5: Easy and challenging aspects of the data.

Easy
Fixed camera
Near frontal view acquisition
Within a sequence the same user
Gestures performed mostly by arms and hands
Camera framing upper body
Several available modalities: audio, skeletal model, user mask, depth, and RGB
Several instances of each gesture for training
Single person present in the visual field
Challenging
Within each sequence:
Continuous gestures without a resting pose
Many gesture instances are present
Distracter gestures out of the vocabulary may be present in terms of both gesture and audio
Between sequences:
High inter and intra-class variabilities of gestures in terms of both gesture and audio
Variations in background, clothing, skin color, lighting, temperature, resolution
Some parts of the body may be occluded
Different Italian dialects

of frames of the data set is 1.720.800.

• All the gesture samples belonging to 20 main gesture categories from an Italian gesture dictionary are annotated at frame level indicating the gesture label.

• 81% of the participants were Italian native speakers, while the remaining 19% of the users were not Italian, but Italian-speakers.

• All the audio that appears in the data is from the Italian dictionary. In addition, sequences may contain distractor words and gestures, which are not annotated since they do not belong to the main dictionary of 20 gestures.

This dataset, available at `http://sunai.uoc.edu/chalearn`, presents various features of interest as listed in Table 5. Examples of the provided visual modalities are shown in Figure 7.

RGB Depth User mask Skeletal model

Figure 7: Different data modalities of the provided data set.

3.2.2 2013 CHALLENGE PROTOCOL AND EVALUATION

As in our previous 2011-2012 challenge, it consisted of two main components: a development phase (April 30th to Aug 1st) and a final evaluation phase (Aug 2nd to Aug 15th). The submission and

evaluation of the challenge entries was via the *Kaggle* platform [3]. The official participation rules were provided on the website of the challenge. In addition, publicity and news on the ChaLearn Multimodal Gesture Recognition Challenge were published in well-known online platforms, such as LinkedIn, Facebook, Google Groups and the ChaLearn website.

During the development phase, the participants were asked to build a system capable of learning from several gesture samples a vocabulary of 20 Italian sign gesture categories. To that end, the teams received the development data to train and self-evaluate their systems. In order to monitor their progress they could use the validation data for which the labels were not provided. The prediction results on validation data could be submitted online to get immediate feed-back. A real-time leaderboard showed to the participants their current standing based on their validation set predictions.

During the final phase, labels for validation data were published and the participants performed similar tasks as those performed in previous phase, using the validation data and training data sets in order to train their system with more gesture instances. The participants had only few days to train their systems and upload them. The organizers used the final evaluation data in order to generate the predictions and obtain the final score and rank for each team. At the end, the final evaluation data was revealed, and authors submitted their own predictions and fact sheets to the platform.

As an evaluation metric we also used the Levenshtein distance described in previous section. A public score appeared on the leaderboard during the development period and was based on the validation data. Subsequently, a private score for each team was computed on the final evaluation data released at the end of the development period, which was not revealed until the challenge was over. The private score was used to rank the participants and determine the prizes.

3.2.3 2013 CHALLENGE RESULTS

The challenge attracted high level of participation, with a total of 54 teams and near 300 total number of entries. This is a good level of participation for a computer vision challenge requiring very specialized skills. Finally, 17 teams successfully submitted their prediction in final test set, while providing also their code for verification and summarizing their method by means of a fact sheet questionnaire.

After verifying the codes and results of the participants, the final scores of the top rank participants on both validation and test sets were made public: these results are shown in Table 6, where winner results on the final test set are printed in bold. In the end, the final error rate on the test data set was around 12%.

3.2.4 2013 CHALLENGE SUMMARY OF THE WINNER METHODS

Table 7 shows the summary of the strategies considered by each of the top ranked participants on the test set. Interestingly, the three top ranked participants agree in the modalities and segmentation strategy considered, although they differ in the final applied classifier. Next, we briefly describe in more detail the approach designed by the three winners of the challenge.

The first ranked team *IVAMM* on the test set used a feature vector based on audio and skeletal information, and applied late fusion to obtain final recognition results. A simple time-domain end-point detection algorithm based on joint coordinates is applied to segment continuous data sequences into candidate gesture intervals. A Gaussian Hidden Markov Model is trained with 39-

dimension MFCC features and generates confidence scores for each gesture category. A Dynamic Time Warping based skeletal feature classifier is applied to provide complementary information. The confidence scores generated by the two classifiers are firstly normalized and then combined to produce a weighted sum. A single threshold approach is employed to classify meaningful gesture intervals from meaningless intervals caused by false detection of speech intervals.

The second ranked team *WWEIGHT* combined audio and skeletal information, using both joint spatial distribution and joint orientation. The method first searches for regions of time with high audio-energy to define 1.8-second-long windows of time that potentially contained a gesture. This had the effect that the development, validation, and test data were treated uniformly. Feature

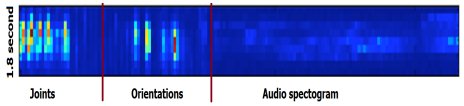

Figure 8: ExtraTreesClassifier Feature Importance.

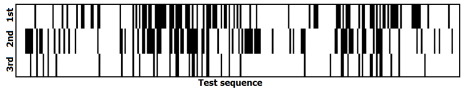

Figure 9: Recognition of test sequence by the three challenge winners. Black bin means that the complete list of ordered gestures has been successfully recognized.

vectors are then defined using a log-spaced audio spectrogram and the joint positions and orientations above the hips. At each time sample the method subtracts the average 3D position of the left and right shoulders from each 3D joint position. Data is down-sampled onto a 5 Hz grid considering 1.8 seconds. There were 1593 features total (9 time samples $\times$ 177 features per time sample). Since some of the detected windows can contain distractor gestures, an extra 21st label is introduced, defining the 'not in the dictionary' gesture category. Python's scikit-learn was used to train two models: an ensemble of randomized decision trees (ExtraTreesClassifier, 100 trees, 40% of features) and a K-Nearest Neighbor model (7 neighbors, L1 distance). The posteriors from these models are averaged with equal weight. Finally, a heuristic is used (12 gestures maximum, no repeats) to convert posteriors to a prediction for the sequence of gestures.

Figure 8 shows the mean feature importance for the windows size of 1.8 seconds for the three sets of features: joint coordinates, joint orientations, and audio spectogram. One can note that features from the three sets are selected as discriminative by the classifier, although skeletal features becomes more useful for the ExtraTreesClassifier. Additionally, the most discriminative features are those in the middle of the windows size, since begin-end features are shared among different gestures (transitions) and thus are less discriminative for the classifier.

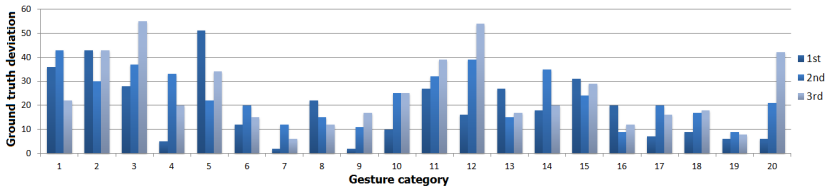

Figure 10: Deviation of the number of gesture samples for each category by the three winners in relation to the GT data.

The third ranked team *ET* combined the output decisions of two designed approaches. In the first approach, they look for gesture intervals (unsupervised) using the audio files and extract these features from intervals (MFCC). Using these features, authors train a random forest and gradient boosting classifier. The second approch uses simple statistics (median, var, min, max) on the first 40

frames for each gesture to build the training samples. The prediction phase uses a sliding window. The authors create a weighted average of the output of these two models. The features considered were skeleton information and audio signal.

Finally, we extracted some statistics from the results of the three challenge winners in order to analyze common points and difficult aspects of the challenge. Figure 9 shows the recognition of the 276 test sequences by the winners. Black bin means that the complete list of ordered gestures was successfully recognized for those sequences. Once can see that there exists some kind of correlation among methods. Taking into account that consecutive sequences belong to the same user performing gestures, it means that some some gestures are easier to recognize than others. Since different users appear in the training and test sequences, it is sometimes difficult for the models to generalize to the style of new users, based on the gesture instances used for training.

We also investigated the difficulty of the problem by gesture category, within each of the 20 Italian gesture categories. Figure 10 shows for each winner method the deviation between the number of gesture instances recognized and the total number of gestures, for each category. This was computed for each sequence independently, and adding the deviation for all the sequences. In that case, a zero value means that the participant method recognized the same number of gesture instances for a category that was recorded in the ground truth data. Although we cannot guarantee with this measure that the order of recognized gesture matches with the ground truth, it gives us an idea of how difficult the gesture sequences were to segment into individual gestures. Additionally, the sum of total deviation for all the gestures for all the teams was 378, 469, and 504, which correlates with the final rank of the winners. The figure suggests a correlation between the performance of the three winners. In particular, categories 6, 7, 8, 9, 16, 17, 18, and 19 were the ones that achieved most accuracy for all the participants, meanwhile 1, 2, 3, 5, and 12 were the ones that introduced the highest recognition error. Note that the public data set provides accurate label annotations of end-begin of gestures, and thus, a more detailed recognition analysis could be performed applying a different recognition measurement to Leveinstein, such as Jaccard overlapping or sensitivity score estimation, which will also allow for confusion matrix estimation based on both inter and intra user and gesture category variability. This is left to future work.

3.3 ChaLearn Multimodal Gesture Spotting Challenge 2014

In ChaLearn LAP 2014 (Escalera et al., 2014) we focused on the user-independent automatic spotting of a vocabulary of 20 Italian cultural/anthropological signs in image sequences, see Figure 6.

3.3.1 2014 GESTURE CHALLENGE DATA

This challenge was based on an Italian gesture data set, called *Montalbano gesture dataset*, an enhanced version of the ChaLearn 2013 multimodal gesture recognition challenge (Escalera et al., 2013b,a) with more ground-truth annotations. In all the sequences, a single user is recorded in front of a Kinect^{TM}, performing natural communicative gestures and speaking in fluent Italian. Examples of the different visual modalities are shown in Figure 7.

The main characteristics of the data set are:

• Largest data set in the literature, with a large duration of each individual performance showing no resting poses and self-occlusions.

• There is no information about the number of gestures to spot within each sequence, and several distracter gestures (out of the vocabulary) are present.

Training seq.	Validation seq.	Test seq.	Sequence duration	FPS
393 (7,754 gestures)	287 (3,362 gestures)	276 (2,742 gestures)	1-2 min	20
Modalities	Num. of users	Gesture categories	Labeled sequences	Labeled frames
RGB, Depth, User mask, Skeleton	27	20	13,858	1,720,800

Table 8: Main characteristics of the *Montalbano* gesture dataset.

• High intra-class variability of gesture samples and low inter-class variability for some gesture categories.

A list of data attributes for data set used in track 3 is described in Table 8.

3.3.2 2014 GESTURE CHALLENGE PROTOCOL AND EVALUATION

The challenge was managed using the Microsoft Codalab platform[4]. We followed a development (February 9 to May 20 2014) and tests phases (May 20th - June 1st 2014)) as in our previous challenges.

To evaluate the accuracy of action/interaction recognition, we use the Jaccard Index, For the n action, interaction, and gesture categories labelled for a RGB/RGBD sequence s, the Jaccard Index is defined as:

$$J_{s,n} = \frac{A_{s,n} \bigcap B_{s,n}}{A_{s,n} \bigcup B_{s,n}}, \quad (1)$$

where $A_{s,n}$ is the ground truth of action/interaction/gesture n at sequence s, and $B_{s,n}$ is the prediction for such an action at sequence s. $A_{s,n}$ and $B_{s,n}$ are binary vectors where 1-values correspond to frames in which the $n-$th action is being performed. The participants were evaluated based on the mean Jaccard Index among all categories for all sequences, where motion categories are independent but not mutually exclusive (in a certain frame more than one action, interaction, gesture class can be active).

In the case of false positives (e.g. inferring an action, interaction or gesture not labelled in the ground truth), the Jaccard Index is 0 for that particular prediction, and it will not count in the mean Jaccard Index computation. In other words n is equal to the intersection of action/interaction/gesture categories appearing in the ground truth and in the predictions.

An example of the calculation for two actions is shown in Figure 11. Note that in the case of recognition, the ground truth annotations of different categories can overlap (appear at the same time within the sequence). Also, although different actors appear within the sequence at the same time, actions/interactions/gestures are labelled in the corresponding periods of time (that may overlap), there is no need to identify the actors in the scene. The example in Figure 11 shows the mean Jaccard Index calculation for different instances of actions categories in a sequence (single red lines denote ground truth annotations and double red lines denote predictions). In the top part of the image one can see the ground truth annotations for actions walk and fight at sequence s. In the center part of the image a prediction is evaluated obtaining a Jaccard Index of 0.72. In the bottom part of the image the same procedure is performed with the action fight and the obtained Jaccard Index is 0.46. Finally, the mean Jaccard Index is computed obtaining a value of 0.59.

3.3.3 2014 GESTURE CHALLENGE RESULTS

Table 10 summarizes the methods of the 17 participants that contributed to the test set of track 3. Although DTW and HMM (and variants) were in the last edition of the ChaLearn Multimodal Gesture competition (Escalera et al., 2013b,a), random forest has been widely applied in this 2014 edition. Also, three participants used deep learning architectures.

3.3.4 2014 GESTURE CHALLENGE SUMMARY OF THE WINNER METHODS

Next, we describe the main characteristics of the three winning methods.

First place: The proposed method was based on a deep learning architecture that iteratively learned and integrated discriminative data representations from individual channels, modelling cross-modality correlations and short- and long-term temporal dependencies. This framework combined three data modalities: depth information, grayscale video and skeleton stream ("articulated pose"). Articulated pose served as an efficient representation of large-scale body motion of the upper body and arms, while depth and video streams contained complementary information about more subtle hand articulation. The articulated pose was formulated as a set of joint angles and normalized distances between upper-body joints, augmented with additional information reflecting speed and acceleration of each joint. For the depth and video streams, the authors did not rely on hand-crafted descriptors, but on discriminatively learning joint depth-intensity data representations with a set of convolutional neural layers. Iterative fusion of data channels was performed at output layers of the neural architecture. The idea of learning at multiple scales was also applied to the temporal dimension, such that a gesture was considered as an ordered set of characteristic motion impulses, or dynamic poses. Additional skeleton-based binary classifier was applied for accurate gesture localization. Fusing multiple modalities at several spatial and temporal scales led to a significant increase in recognition rates, allowing the model to compensate for errors of the individual classifiers as well as noise in the separate channels.

Second place: The approach combined a sliding-window gesture detector with multimodal features drawn from skeleton data, color imagery, and depth data produced by a first-generation Kinect^{TM} sensor. The gesture detector consisted of a set of boosted classifiers, each tuned to a specific gesture or gesture mode. Each classifier was trained independently on labeled training data, employing bootstrapping to collect hard examples. At run-time, the gesture classifiers were evaluated in a one-vs-all manner across a sliding window. Features were extracted at multiple temporal scales to enable recognition of variable-length gestures. Extracted features included descriptive statistics of normalized skeleton joint positions, rotations, and velocities, as well as HOG descriptors of the hands. The full set of gesture detectors was trained in under two hours on a single machine, and was extremely efficient at runtime, operating at 1700 fps using skeletal data.

Third place: The proposed method was based on four features: skeletal joint position feature, skeletal joint distance feature, and histogram of oriented gradients (HOG) features corresponding to left and right hands. Under the naïve Bayes assumption, likelihood functions were independently defined for every feature. Such likelihood functions were non-parametrically constructed from the training data by using kernel density estimation (KDE). For computational efficiency, k-nearest neighbor (kNN) approximation to the exact density estimator was proposed. Constructed likelihood functions were combined to the multimodal likelihood and this serves as a unary term for our pairwise Markov random field (MRF) model. For enhancing temporal coherence, a pairwise term was additionally incorporated to the MRF model. Final gesture labels were obtained via 1D MRF inference efficiently achieved by dynamic programming.

3.4 ChaLearn Action and Interaction Spotting Challenge 2014

The goal of this challenge was to perform automatic action and interaction spotting of people appearing in RGB data sequences.

Training actions	Validation actions	Test actions	Sequence duration	FPS
150	90	95	9× 1-2 min	15
Modalities	**Num. of users**	**Action categories**	**interaction categories**	**Labelled sequences**
RGB	14	7	4	235

Table 11: Action and interaction data characteristics.

3.4.1 2014 ACTION CHALLENGE DATA

We presented a novel fully limb labelled dataset, the Human Pose Recovery and Behavior Analysis *HuPBA* 8k+ dataset (Sánchez et al., 2014). This dataset is formed by more than 8000 frames where 14 limbs are labelled at pixel precision, thus providing 124,761 annotated human limbs. The characteristics of the data set are:

• The images are obtained from 9 videos (RGB sequences) and a total of 14 different actors appear in the sequences. The image sequences have been recorded using a stationary camera with the same static background.

• Each video (RGB sequence) was recorded at 15 fps rate, and each RGB image was stored with resolution 480×360 in BMP file format.

• For each actor present in an image 14 limbs (if not occluded) were manually tagged: Head, Torso, R-L Upper-arm, R-L Lower-arm, R-L Hand, R-L Upper-leg, R-L Lower-leg, and R-L Foot.

• Limbs are manually labelled using binary masks and the minimum bounding box containing each subject is defined.

• The actors appear in a wide range of different poses and performing different actions/gestures which vary the visual appearance of human limbs. So there is a large variability of human poses, self-occlusions and many variations in clothing and skin color.

• Several actions and interactions categories are labelled at frame level.

A key frame example for each gesture/action category is shown in Figure 12. The challenges the participants had to deal with for this new competition are:

• 235 action/interaction samples performed by 14 actors.

• Large difference in length about the performed actions and interactions. Several distracter actions out of the 11 categories are also present.

• 11 action categories, containing isolated and collaborative actions: Wave, Point, Clap, Crouch, Jump, Walk, Run, Shake Hands, Hug, Kiss, Fight. There is a high intra-class variability among action samples.

Table 11 summarizes the data set attributes for the case of action/interaction spotting.

3.4.2 2014 ACTION CHALLENGE PROTOCOL AND EVALUATION

To evaluate the accuracy of action/interaction recognition, we use the Jaccard Index as defined in Section 3.3.2.

3.4.3 2014 ACTION CHALLENGE RESULTS

In this section we summarize the methods proposed by the participants and the winning methods. Six teams submitted their code and predictions for the test sets. Top rows of Table 9 summarizes the approaches of the participants who uploaded their models. One can see that most methods are based on similar approaches. In particular, alternative representations to classical BoW were considered, as Fisher Vector and VLAD (Jegou et al., 2012). Most methods perform sliding windows and SVM

(a) Wave (b) Point (c) Clap

(d) Crouch (e) Jump (f) Walk

(g) Run (h) Shake hands (i) Hug

(j) Kiss (k) Fight (l) Idle

Figure 12: Key frames of the *HuPBA* $8K+$ dataset used in the tracks 1 and 2, showing actions ((a) to (g)), interactions ((h) to (k)) and the idle pose (l).

classification. In addition, to refine the tracking of interest points, 4 participants used improved trajectories (Wang and Schmid, 2013).

3.4.4 2014 ACTION CHALLENGE SUMMARY OF THE WINNER METHODS

Next, we describe the main characteristics of the three winning methods.

First place: The method was composed of two parts: video representation and temporal segmentation. For the representation of video clip, the authors first extracted improved dense trajectories with HOG, HOF, MBHx, and MBHy descriptors. Then, for each kind of descriptor, the participants trained a GMM and used Fisher vector to transform these descriptors into a high dimensional super vector space. Finally, sum pooling was used to aggregate these codes in the whole video clip and normalize them with power L2 norm. For the temporal recognition, the authors resorted to a temporal sliding method along the time dimension. To speed up the processing of detection, the authors designed a temporal integration histogram of Fisher Vector, with which the pooled Fisher Vector was efficiently evaluated at any temporal window. For each sliding window, the authors used the pooled Fisher Vector as representation and fed it into the SVM classifier for action recognition.

Second place: a human action detection framework called "mixture of heterogeneous attribute analyzer" was proposed. This framework integrated heterogeneous attributes learned from various types of video features including static and dynamic, local and global features, to boost the action detection accuracy. The authors first detected a human from the input video by SVM-HOG detector and performed forward-backward tracking. Multiple local human tracks are linked into long trajectories by spatial-temporal graph based matching. Human key poses and local dense motion trajectories were then extracted within the tracked human bounding box sequences. Second, the authors proposed a mining method that learned discriminative attributes from three feature modalities: human trajectory, key pose and local motion trajectory features. The mining framework was based on the exemplar-SVM discriminative middle level feature detection approach. The learned discriminative attributes from the three types of visual features were then mixed in a max-margin learning algorithm which also explores the combined discriminative capability of heterogeneous feature modalities. The learned mixed analyzer was then applied to the input video sequence for action detection.

Third place: The framework for detecting actions in video is based on improved dense trajectories applied on a sliding windows fashion. Authors independently trained 11 one-versus-all kernel SVMs on the labelled training set for 11 different actions. The feature and feature descriptions used are improved dense trajectories, HOG, HOF, MBHx and MBHy. During training, for each action, a temporal sliding window is applied without overlapping. For every action, a segment was labelled 0 (negative) for a certain action only if there is no frame in this segment labelled 1. The feature coding method was bag-of-features. For a certain action, the features associated with those frames which are labelled 0 (negative) are not counted when we code the features of the action for the positive segments with bag-of-features. On the basis of the labelled segments and their features, a kernel SVM was trained for each action. During testing, non-overlap sliding window was applied for feature coding of the video. Every frame in a segment was consistently labelled as the output of SVM for each action. The kernel type, sliding window size and penalty of SVMs were selected during validation. When building the bag-of-features, the clustering method was K-means and the vocabulary size is 4000. For one trajectory feature in one frame, all the descriptors were connected to form one description vector. The bag-of-features were built upon this vector.

3.5 ChaLearn Action and Interaction Spotting Challenge 2015

The goal of this challenge was to perform automatic action and interaction spotting of people appearing in RGB data sequences. This corresponds to the second round of 2014 Action/Interaction challenge (Baró et al., 2015). Data, protocol, and evaluation were defined as explained in Section 3.4.

3.5.1 2015 ACTION CHALLENGE RESULTS

Results of the two top ranked participants are shown in bottom rows of Table 9. One can see that the methods of the participants are similar to the ones applied in the 2014 challenge for the same dataset (Top rows of Table 9). Results of this second competition round improved by 2% the results obtained in the first round of the challenge.

3.5.2 2015 ACTION CHALLENGE SUMMARY OF THE WINNER METHODS

First winner: This method is an improvement of the system proposed in (Peng et al., 2015), which is composed of two parts: video representation and temporal segmentation. For the representation of video clip, the authors first extracted improved dense trajectories with HOG, HOF, MBHx, and MBHy descriptors. Then, for each kind of descriptor, the participants trained a GMM and used Fisher vector to transform these descriptors into a high dimensional super vector space. Finally, sum pooling was used to aggregate these codes in the whole video clip and normalize them with power L2 norm. For the temporal recognition, the authors resorted to a temporal sliding method along the time dimension. To speed up the processing of detection, the authors designed a temporal integration histogram of Fisher Vector, with which the pooled Fisher Vector was efficiently evaluated at any temporal window. For each sliding window, the authors used the pooled Fisher Vector as representation and fed it into the SVM classifier for action recognition. A summary of this method is shown in Figure 13.

Second winner: The method implements an end-to-end generative approach from feature modelling to activity recognition. The system combines dense trajectories and Fisher Vectors with a temporally structured model for action recognition based on a simple grammar over action units. The authors modify the original dense trajectory implementation of (Wang and Schmid, 2013) to avoid the omission of neighborhood interest points once a trajectory is used (the improvement is shown in Figure 14). They use an open source speech recognition engine for the parsing and segmentation of video sequences. Because a large data corpus is typically needed for training such systems, images were mirrored to artificially generate more training data. The final result is achieved by voting over the output of various parameter and grammar configurations.

3.6 Other international competitions for gesture and action recognition

In addition to the series of ChaLearn Looking at People challenges, different international challenges have also been performed in the field of action/gesture recognition. Some of them are reviewed below.

The ChAirGest challenge (Ruffieux et al., 2013) is a research oriented competition designed to compare multimodal gesture recognizers. The provided data came from one Kinect camera and 4 Inertial Motion Units (IMU) attached to the right arm and neck of the subject. The dataset contains 10 different gestures, started from 3 different resting postures and recorded in two different lighting

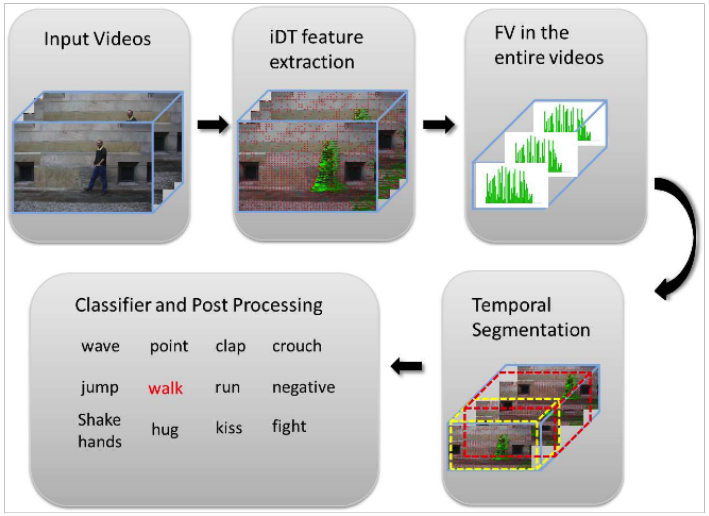

Figure 13: Method summary for MMLAB team (Wang et al., 2015b).

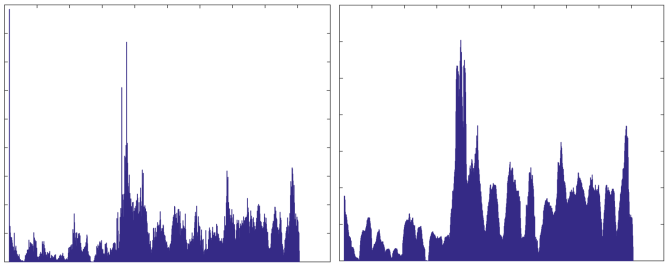

Figure 14: Example of DT feature distribution for the first 200 frames of Seq01 for FKIE team, (a) shows the distribution of the original implementation, (b) shows the distribution of the modified version.

conditions by 10 different subjects. Thus, the total dataset contains 1200 annotated gestures split in continuous video sequences containing a variable number of gestures. The goal of the challenge was to promote research on methods using multimodal data to spot and recognize gestures in the context of close human-computer interaction.

In 2015, OpenCV ran at CVPR different challenges[5], one of them focusing on gesture recognition, using the ChaLearn gesture recognition data. The winner of the competition was also the work that won the ChaLearn challenge at ECCV 2014 (Neverova et al., 2014b).

Another recent action recognition competition is the THUMOS challenge (Gorban et al., 2015). Last round of the competition was ran at CVPR 2015. The last round of the challenge contained a forward-looking data set with over 430 hours of video data and 45 million frames (70% larger than THUMOS'14). All videos were collected from YouTube. Two tracks were performed: 1) Action Classification, for whole-clip action classification on 101 action classes, and 2) Temporal Action Localization, for action recognition and temporal localization on a subset of 20 action classes.

4. Summary of Special Topic Papers Not Related to the Challenges

In this special topic, in addition to the papers that described systems that participated in the ChaLearn gesture challenges, there are also several papers relating to broader aspects of gesture recognition, including topics such as sign language recognition, facial expression analysis, and facilitating development of real-world systems.

Three of these papers propose new methods for gesture and action recognition (Malgireddy et al., 2013; Fanello et al., 2013; Lui, 2012), that were also evaluated on parts of the CDG2011 dataset (Guyon et al., 2014), used in the ChaLearn challenges held in 2011 and 2012. More specifically, (Malgireddy et al., 2013) present an approach for detecting and recognizing activities and gestures. Hierarchical models are built to describe each activity as a combination of other, more simple activities. Each video is recursively divided into segments consisting of a fixed number of frames. The relationship between observed features and latent variables is modelled using a generative model that combines aspects of dynamic Bayesian networks and hierarchical Bayesian models. (Fanello et al., 2013) describe a system for real-time action recognition using depth video. The paper proposes specific features that are well adapted to real-time constraints, based on histograms of oriented gradients and histograms of optical flow. Support vector machines trained on top of such features perform action segmentation and recognition. (Lui, 2012) propose a method for representing gestures as tensors. These tensors are treated as points on a product manifold. In particular, the product manifold is factorized into three manifolds, one capturing horizontal motion, one capturing vertical motion, and one capturing 2D appearance. The difference between gestures is measured using a geodesic distance on the product manifold.

One paper (Wang et al., 2012) studied an action recognition problem outside the scope of the ChaLearn contests, namely recognizing poses and actions from a single image. Hierarchical models are used for modelling body pose. Each model in this hierarchy covers a part of the human body that can range from the entire body to a specific rigid part. Different levels in this hierarchy correspond to different degrees of coarseness vs. detail in the models at each level.

Three papers proposed novel methods within the area of sign language recognition (Cooper et al., 2012; Nayak et al., 2012; Roussos et al., 2013). (Cooper et al., 2012) describe a method for sign language recognition using linguistic subunits that are learned automatically by the system. Different types of such subunits are considered, including subunits based on appearance and local motion of the hand, subunits based on combining tracked 2D hand trajectories and hand shape, and subunits based on tracked 3D hand trajectories. (Nayak et al., 2012) address the problem of learning a model for a sign that occurs multiple times in a set of sentences. One benefit from such an approach

5. http://code.opencv.org/projects/opencv/wiki/VisionChallenge

is that it does not require the start and end frame of each sign as training data. Another benefit is that the method identifies the aspects of a sign that are least affected by movement epenthesis, i.e., by signs immediately preceding or following the sign in question. (Roussos et al., 2013) present a method for classifying handshapes for the purpose of sign language recognition. Cropped hand images are converted to a normalized representation called "shape-appearance images", based on a PCA decomposition of skin pixel colors. Then, active appearance models are used to model the variation in shape and appearance of the hand.

One paper focused on the topic of facial expression analysis (Martinez and Du, 2012). The paper proposes a model for describing how humans perceive facial expressions of emotion. The proposed model consists of multiple distinct continuous spaces. Emotions can be represented using linear combinations of these separate spaces. The paper also discusses how the proposed model can be used to design algorithms for facial expression recognition.

Another set of papers contributed methods that address different practical problems, that are important for building real-world gesture interfaces (Nguyen-Dinh et al., 2014; Gillian and Paradiso, 2014; Kohlsdorf and Starner, 2013). One such problem is obtaining manual annotations and ground truth for large amounts of training data. Obtaining such manual annotations can be time consuming, and can be an important bottleneck in building a real system. Crowdsourcing is a potential solution, but crowdsourced annotations often suffer from noise, in the form of discrepancies in how different humans annotate the same data. In (Nguyen-Dinh et al., 2014), two template-matching methods are proposed, called SegmentedLCSS and WarpingLCSS, that explicitly deal with the noise present in crowdsourced annotations of gestures. These methods are designed for spotting gestures using wearable motion sensors. The methods quantize signals into strings of characters and then apply variations of the longest common subsequence algorithm (LCSS) to spot gestures.

In designing a real-world system, another important problem is rapid development. (Gillian and Paradiso, 2014) present a gesture recognition toolkit, a cross-platform open-source C++ library. The toolkit features a broad range of classification and regression algorithms and has extensive support for building real-time systems. This includes algorithms for signal processing, feature extraction and automatic gesture spotting.

Finally, choosing the gesture vocabulary can be an important implementation parameter. (Kohlsdorf and Starner, 2013) propose a method for choosing a vocabulary of gestures for a human-computer interface, so that gestures in that vocabulary have a low probability of being confused with each other. Candidate gestures for the interface can be suggested both by humans and by the system itself. The system compares examples of each gesture with a large repository of unlabelled sensor/motion data, to check how often such examples resemble typical session/motion patterns encountered in that specific application domain.

5. Summary of Special Topic Papers Related to 2011-2012 Challenges

Next we briefly review the contributions of the accepted papers for the special topic whose methods are applied on the data provided by 2011-2012 ChaLearn gesture recognition challenges. Interestingly, none of the methods proposed in these papers uses skeletal tracking. Instead, these methods use different features based on appearance and/or motion. Where the papers differ is in their choice of specific features, and also in the choice of gesture models that are built on top of the selected features.

(Konecny and Hagara, 2014) combine appearance (Histograms of Oriented Gradients) and motion descriptors (Histogram of Optical Flow) from RGB and depth images for parallel temporal segmentation and recognition. The Quadratic-Chi distance family is used to measure differences between histograms to capture cross-bin relationships. Authors also propose trimming videos by removing unimportant frames based on motion information. Finally, proposed descriptors with different Dynamic Time Warping variants are applied for final recognition.

In contrast to (Konecny and Hagara, 2014), which employes commonly used features, (Wan et al., 2013) proposes a new multimodal descriptor, as well as a new sparse coding method. The multimodal descriptor is called 3D EMoSIFT, is invariant to scale and rotation, and has more compact and richer visual representations than other state-of-the-art descriptors. The proposed sparse coding method is named simulation orthogonal matching pursuit (SOMP), and is a variant of BoW. Using SOMP, each feature can be represented by some linear combination of a small number of codewords.

A different approach is taken in (Jiang et al., 2015), which combines three different methods for classifying gestures. The first method uses an improved principal motion representation. In the second method, a particle-based descriptor and a weighted dynamic time warping are proposed for the location component classification. In the third method, the shape of the human subject is used, extracted from the frame in the gesture that exhibits the least motion. The explicit use of shape in this paper is in contrast to (Konecny and Hagara, 2014; Wan et al., 2013), where shape information is implicitly coded in the extracted features.

In (Goussies et al., 2014), the focus is on transfer learning. The proposed method did not do as well as the previous methods (Konecny and Hagara, 2014; Wan et al., 2013; Jiang et al., 2015) on the CDG 2011 dataset, but nonetheless it contributes novel ideas for transfer learning, that can be useful when the number of training examples per class is limited. This is in contrast to the other papers related to the 2011-2012 challenges, that did not address transfer learning. The paper introduces two mechanisms into the decision forest framework, in order to transfer knowledge from the source tasks to a given target task. The first one is mixed information gain, which is a data-based regularizer. The second one is label propagation, which infers the manifold structure of the feature space. The proposed approach show improvements over traditional decision forests in the ChaLearn Gesture Challenge and on the MNIST dataset.

6. Summary of Special Issue Papers Related to 2013 Challenge

Next we briefly review the contributions of the accepted papers for the special issue whose methods are applied on the data provided by 2013 ChaLearn multimodal gesture recognition challenge. An important difference between this challenge and the previous ChaLearn challenges is the multimodal nature of the data. Thus, a key focus area for methods applied on this data is the problem of fusing information from multiple modalities.

(Wu and Cheng, 2014) propose a Bayesian Co-Boosting framework for multimodal gesture recognition. Inspired by boosting learning and co-training method, the system combines multiple collaboratively trained weak classifiers, Hidden Markov Models in this case, to construct the final strong classifier. During each iteration round, randomly a number of feature subsets are samples and weak classifiers parameters for each subset are estimated. The optimal weak classifier and its corresponding feature subset are retained for strong classifier construction. Authors also define an upper bound of training error and derive the update rule of instance's weight, which guarantees the

error upper bound to be minimized through iterations. This methodology won the ChaLearn 2013 ICMI competition.

(Pitsikalis et al., 2014) present a framework for multimodal gesture recognition that is based on a multiple hypotheses rescoring fusion scheme. Authors employ multiple modalities, i.e., visual cues, such as skeleton data, color and depth images, as well as audio, and extract feature descriptors of the hands movement, handshape, and audio spectral properties. Using a common hidden Markov model framework authors build single-stream gesture models based on which they can generate multiple single stream-based hypotheses for an unknown gesture sequence. By multimodally rescoring these hypotheses via constrained decoding and a weighted combination scheme, authors end up with a multimodally-selected best hypothesis. This is further refined by means of parallel fusion of the monomodal gesture models applied at a segmental level. The proposed methodology is tested on the ChaLearn 2013 ICMI competition data.

7. Discussion

We reviewed the gesture recognition topic, defining a taxonomy to characterize state of the art works on gesture recognition. We also reviewed the gesture and action recognition challenges organized by ChaLearn from 2011 to 2015, as well as other international competitions related to gesture recognition. Finally, we reviewed the papers submitted to the Special Topic on Gesture Recognition 2011-2014 we organized at Journal of Machine Learning Research.

Regarding the ChaLearn gesture recognition challenges, we began right at the start of the Kinect^{TM} revolution when inexpensive infrared cameras providing image depth recordings became available. We published papers using this technology and other more conventional methods, including regular video cameras, to record data, thus providing a good overview of uses of machine learning and computer vision using multimodal data in this area of application. Notably, we organized a series of challenges and made available several datasets we recorded for that purpose, including tens of thousands of videos, which are available to conduct further research [6].

Regarding the papers published in the gesture recognition special topic related to 2011-2012 challenges with the objective of performing one-shot learning, most of the authors proposed new multimodal descriptors taking benefit from both RGB and Depth cues in order to describe human body features, both static and dynamic ones. As the recognition strategies, common techniques used were variants of classical well-known Dynamic Time Warping and Hidden Markov Models. In particular, the most efficient techniques so far have used sequences of features processed by graphical models of the HMM/CRF family, similar to techniques used in speech recognition. Authors also considered a gesture candidate sliding window and motion-based video-cutting approaches. Last approach was frequently used since sign language videos included a resting pose. Also interesting novel classification strategies were proposed, such as multilayered decomposition, where different length gesture units are recognize at different levels ((Jiang et al., 2015)).

Regarding the papers published in the gesture recognition special topic related to 2013 and 2014 challenges with the objective of performing user independent multiple gesture recognition from large volumes of multimodal data (RGB, Depth and audio), different classifiers for gesture recognition were used by the participants. In 2013, the preferred one was Hidden Markov Models (used by the first ranked team of the challenge), followed by Random Forest (used by the second and third winners). Although several state of the art learning and testing gesture techniques were

6. http://gesture.chalearn.org/

applied at the last stage of the methods of the participants, still the feature vector descriptions are mainly based on MFCC audio features and skeleton joint information. The published paper of the winner to the special topic presents a novel coboosting strategy, where a set of HMM classifiers and collaboratively included in a boosting strategy considering random sets of features ((Wu and Cheng, 2014)). In 2014, similar descriptors and classifiers were used, and in particular, three deep learning architectures were considered, including the method of the winner team (Neverova et al., 2014b).

In the case of the ChaLearn action/interaction challenges organized in 2014 and 2015 most methods were based on similar approaches. In particular, alternative representations to classical BoW were considered, as Fisher Vector and VLAD (Jegou et al., 2012). Most methods performed sliding windows and SVM classification. In addition, to refine the tracking of interest points, several participants used improved trajectories (Wang and Schmid, 2013).

From the review of the gesture recognition topic, the achieved results in the performed challenges and the rest of papers published in the gesture recognition Special Topic, one can observe that still it is possible that progress will also be made in feature extraction by making better use of the multimodal development data for better transfer learning. For instance, we think that structural hand information around hand joint could be useful to discriminate among gesture categories that may share similar trajectories of hand/arms. Also recent approaches have shown that Random Forest and Deep Learning, such as considering Convolutional Neural Networks, are powerful alternatives to classical gesture recognition approaches, which still open the door for future the design of new gesture recognition classifiers.

In the case of action detection or spotting, most of the methods are still based on sliding-windows approaches, which makes recognition a time-consuming task. Thus, the research on methods that can generate gesture/action candidates from data in a different fashion are still an open issue.

Acknowledgments

This work has been partially supported by ChaLearn Challenges in Machine Learning `http://chalearn.org`, the Human Pose Recovery and Behavior Analysis Group[7], the Pascal2 network of excellence, NSF grants 1128296, 1059235, 1055062, 1338118, 1035913, 0923494, and Spanish project TIN2013-43478-P. Our sponsors include Microsoft and Texas Instrument who donated prizes and provided technical support. The challenges were hosted by Kaggle.com and Coralab.org who are gratefully acknowledged. We thank our co-organizers of ChaLearn gesture and action recognition challenges: Miguel Reyes, Jordi Gonzalez, Xavier Baro, Jamie Shotton, Victor Ponce, Miguel Angel Bautista, and Hugo Jair Escalante.

Editor: Shie Mannor

Abstract

In this paper we introduce the idea of improving the performance of parametric temporal-difference (TD) learning algorithms by selectively emphasizing or de-emphasizing their updates on different time steps. In particular, we show that varying the emphasis of linear TD(λ)'s updates in a particular way causes its expected update to become stable under off-policy training. The only prior model-free TD methods to achieve this with per-step computation linear in the number of function approximation parameters are the gradient-TD family of methods including TDC, GTD(λ), and GQ(λ). Compared to these methods, our *emphatic TD(λ)* is simpler and easier to use; it has only one learned parameter vector and one step-size parameter. Our treatment includes general state-dependent discounting and bootstrapping functions, and a way of specifying varying degrees of interest in accurately valuing different states.

Keywords: Temporal-difference learning, Off-policy learning, Function approximation, Stability, Convergence.

1. Parametric Temporal-Difference Learning

Temporal-difference (TD) learning is perhaps the most important idea to come out of the field of reinforcement learning. The problem it solves is that of efficiently learning to make a sequence of long-term predictions about how a dynamical system will evolve over time. The key idea is to use the change (temporal difference) from one prediction to the next as an error in the earlier prediction. For example, if you are predicting on each day what the stock-market index will be at the end of the year, and events lead you one day to make a much lower prediction, then a TD method would infer that the predictions made prior to the drop were probably too high; it would adjust the parameters of its prediction function so as to make lower predictions for similar situations in the future. This approach contrasts with conventional approaches to prediction, which wait until the end of the year when the final stock-market index is known before adjusting any parameters, or else make only short-term (e.g., one-day) predictions and then iterate them to produce a year-end prediction. The TD approach is more convenient computationally because it requires less memory and because its computations are spread out uniformly over the year (rather than being bunched together all at the end of the year). A less obvious advantage of the TD approach is that it often produces statistically more accurate answers than conventional approaches (Sutton 1988).

Parametric temporal-difference learning was first studied as the key "learning by generalization" algorithm in Samuel's (1959) checker player. Sutton (1988) introduced the TD(λ) algorithm and proved convergence in the mean of episodic linear TD(0), the simplest parametric TD method. The potential power of parametric TD learning was convincingly demonstrated by Tesauro (1992, 1995) when he applied TD(λ) combined with neural networks and self play to obtain ultimately the world's best backgammon player. Dayan (1992) proved convergence in expected value of episodic linear TD(λ) for all $\lambda \in [0, 1]$, and Tsitsiklis and Van Roy (1997) proved convergence with probability one of discounted continuing linear TD(λ). Watkins (1989) extended TD learning to control in the form of Q-learning and proved its convergence in the tabular case (without function approximation, Watkins & Dayan 1992), while Rummery (1995) extended TD learning to control in an on-policy form as the Sarsa(λ) algorithm. Bradtke and Barto (1996), Boyan (1999), and Nedic and Bertsekas (2003) extended linear TD learning to a least-squares form called LSTD(λ). Parametric TD methods have also been developed as models of animal learning (e.g., Sutton & Barto 1990, Klopf 1988, Ludvig, Sutton & Kehoe 2012) and as models of the brain's reward systems (Schultz, Dayan & Montague 1997), where they have been particularly influential (e.g., Niv & Schoenbaum 2008, O'Doherty 2012). Sutton (2009, 2012) has suggested that parametric TD methods could be key not just to learning about reward, but to the learning of world knowledge generally, and to perceptual learning. Extensive analysis of parametric TD learning as stochastic approximation is provided by Bertsekas (2012, Chapter 6) and Bertsekas and Tsitsiklis (1996).

Within reinforcement learning, TD learning is typically used to learn approximations to the value function of a Markov decision process (MDP). Here the value of a state s, denoted $v_\pi(s)$, is defined as the sum of the expected long-term discounted rewards that will be received if the process starts in s and subsequently takes actions as specified by the decision-making policy π, called the *target policy*. If there are a small number of states, then it may be practical to approximate the function v_π by a table, but more generally a parametric form is used, such as a polynomial, multi-layer neural network, or linear mapping. Also key is the source of the data, in particular, the policy used to interact with the MDP. If the data is obtained while following the target policy π, then good convergence results are available for linear function approximation. This case is called *on-policy* learning because learning occurs while "on" the policy being learned about. In the alternative, *off-policy* case, one seeks to learn about v_π while behaving (selecting actions) according to a different policy called the *behavior policy*, which we denote by μ. Baird (1995) showed definitively that parametric TD learning was much less robust in the off-policy case (for $\lambda < 1$) by exhibiting counterexamples for which both linear TD(0) and linear Q-learning had unstable expected updates and, as a result, the parameters of their linear function approximation diverged to infinity. This is a serious limitation, as the off-policy aspect is key to Q-learning (perhaps the single most popular reinforcement learning algorithm), to learning from historical data and from demonstrations, and to the idea of using TD learning for perception and world knowledge.

Over the years, several different approaches have been taken to solving the problem of off-policy learning with TD learning ($\lambda < 1$). Baird (1995) proposed an approach based on gradient descent in the Bellman error for general parametric function approximation that has the desired computational properties, but which requires access to the MDP for double sampling and which in practice often learns slowly. Gordon (1995, 1996) proposed restricting attention to function approximators that are averagers, but this does not seem to be possible without storing many of the training examples, which would defeat the primary strength that we seek to obtain from parametric function approximation. The LSTD(λ) method was always relatively robust to off-policy training (e.g., Lagoudakis & Parr 2003, Yu 2010, Mahmood, van Hasselt & Sutton 2014), but its per-step computational complexity is quadratic in the number of parameters of the function approximator, as opposed to the linear complexity of TD(λ) and the other methods. Perhaps the most successful approach to date is the gradient-TD approach (e.g., Maei 2011, Sutton et al. 2009, Maei et al. 2010), including hybrid methods such as HTD (Hackman 2012). Gradient-TD methods are of linear complexity and guaranteed to converge for appropriately chosen step-size parameters but are more complex than TD(λ) because they require a second auxiliary set of parameters with a second step size that must be set in a problem-dependent way for good performance. The studies by White (2015), Geist and Scherrer (2014), and Dann, Neumann, and Peters (2014) are the most extensive empirical explorations of gradient-TD and related methods to date.

In this paper we explore a new approach to solving the problem of off-policy TD learning with function approximation. The approach has novel elements but is similar to that developed by Precup, Sutton, and Dasgupta in 2001. They proposed to use importance sampling to reweight the updates of linear TD(λ), emphasizing or de-emphasizing states as they were encountered, and thereby create a weighting equivalent to the stationary distribution under the target policy, from which the results of Tsitsiklis and Van Roy (1997) would apply and guarantee convergence. As we discuss later, this approach has very high variance and was eventually abandoned in favor of the gradient-TD approach. The new approach we explore in this paper is similar in that it also varies emphasis so as to reweight the distribution of linear TD(λ) updates, but to a different goal. The new goal is to create a weighting equivalent to the *followon distribution* for the target policy started in the stationary distribution of the behavior policy. The followon distribution weights states according to how often they would occur prior to termination by discounting *if the target policy was followed*.

Our main result is to prove that varying emphasis according to the followon distribution produces a new version of linear TD(λ), *called emphatic TD(λ)*, that is stable under general off-policy training. By "stable" we mean that the expected update over the ergodic distribution (Tsitsiklis & Van Roy 1997) is a contraction, involving a positive definite matrix. We concentrate on stability in this paper because it is a prerequisite for full convergence of the stochastic algorithm. Demonstrations that the linear TD(λ) is not stable under off-policy training have been the focus of previous counterexamples (Baird 1995, Tsitsiklis & Van Roy 1996, 1997, see Sutton & Barto 1998). Substantial additional theoretical machinery would be required for a full convergence proof. Recent work by Yu (2015a,b) builds on our stability result to prove that the emphatic TD(λ) converges with probability one.

In this paper we first treat the simplest algorithm for which the difficulties of off-policy temporal-difference (TD) learning arise—the TD(0) algorithm with linear function approximation. We examine the conditions under which the expected update of on-policy TD(0) is stable, then why those conditions do not apply under off-policy training, and finally how they can be recovered for off-policy training using established importance-sampling methods together with the emphasis idea. After introducing the basic idea of emphatic algorithms using the special case of TD(0), we then develop the general case. In particular, we consider a case with general state-dependent discounting and bootstrapping functions, and with a user-specified allocation of function approximation resources. Our new theoretical results and the emphatic TD(λ) algorithm are presented fully for this general case. Empirical examples elucidating the main theoretical results are presented in the last section prior to the conclusion.

2. On-policy Stability of TD(0)

To begin, let us review the conditions for stability of conventional TD(λ) under on-policy training with data from a continuing finite Markov decision process. Consider the simplest function approximation case, that of linear TD(λ) with $\lambda = 0$ and constant discount-rate parameter $\gamma \in [0, 1)$. Conventional linear TD(0) is defined by the following update to the parameter vector $\boldsymbol{\theta}_t \in \mathbb{R}^n$, made at each of a sequence of time steps $t = 0, 1, 2, \ldots$, on transition from state $S_t \in \mathcal{S}$ to state $S_{t+1} \in \mathcal{S}$, taking action $A_t \in \mathcal{A}$ and receiving reward $R_{t+1} \in \mathbb{R}$:

$$\boldsymbol{\theta}_{t+1} \doteq \boldsymbol{\theta}_t + \alpha \left(R_{t+1} + \gamma \boldsymbol{\theta}_t^\top \boldsymbol{\phi}(S_{t+1}) - \boldsymbol{\theta}_t^\top \boldsymbol{\phi}(S_t) \right) \boldsymbol{\phi}(S_t), \tag{1}$$

where $\alpha > 0$ is a step-size parameter, and $\boldsymbol{\phi}(s) \in \mathbb{R}^n$ is the feature vector corresponding to state s. The notation "$\doteq$" indicates an equality by definition rather than one that follows from previous definitions. In on-policy training, the actions are chosen according to a target policy $\pi : \mathcal{A} \times \mathcal{S} \to [0, 1]$, where $\pi(a|s) \doteq \mathbb{P}\{A_t = a | S_t = s\}$. The state and action sets $\mathcal{S}$ and $\mathcal{A}$ are assumed to be finite, but the number of states is assumed much larger than the number of learned parameters, $|\mathcal{S}| \doteq N \gg n$, so that function approximation is necessary. We use linear function approximation, in which the inner product of the parameter vector and the feature vector for a state is meant to be an approximation to the value of that state:

$$\boldsymbol{\theta}_t^\top \boldsymbol{\phi}(s) \approx v_\pi(s) \doteq \mathbb{E}_\pi[G_t | S_t = s], \tag{2}$$

where $\mathbb{E}_\pi[\cdot]$ denotes an expectation conditional on all actions being selected according to π, and G_t, the *return* at time t, is defined by

$$G_t \doteq R_{t+1} + \gamma R_{t+2} + \gamma^2 R_{t+3} + \cdots . \tag{3}$$

The TD(0) update (1) can be rewritten to make the stability issues more transparent:

$$\begin{aligned} \boldsymbol{\theta}_{t+1} &= \boldsymbol{\theta}_t + \alpha \Big(\underbrace{R_{t+1} \boldsymbol{\phi}(S_t)}_{\mathbf{b}_t \in \mathbb{R}^n} - \underbrace{\boldsymbol{\phi}(S_t) \left(\boldsymbol{\phi}(S_t) - \gamma \boldsymbol{\phi}(S_{t+1}) \right)^\top}_{\mathbf{A}_t \in \mathbb{R}^{n \times n}} \boldsymbol{\theta}_t \Big) \\ &= \boldsymbol{\theta}_t + \alpha(\mathbf{b}_t - \mathbf{A}_t \boldsymbol{\theta}_t) \\ &= (\mathbf{I} - \alpha \mathbf{A}_t) \boldsymbol{\theta}_t + \alpha \mathbf{b}_t. \end{aligned} \tag{4}$$

The matrix $\mathbf{A}_t$ multiplies the parameter $\boldsymbol{\theta}_t$ and is thereby critical to the stability of the iteration. To develop intuition, consider the special case in which $\mathbf{A}_t$ is a diagonal matrix. If any of the diagonal elements are negative, then the corresponding diagonal element of $\mathbf{I}-\alpha\mathbf{A}_t$ will be greater than one, and the corresponding component of $\boldsymbol{\theta}_t$ will be amplified, which will lead to divergence if continued. (The second term $(\alpha\mathbf{b}_t)$ does not affect the stability of the iteration.) On the other hand, if the diagonal elements of $\mathbf{A}_t$ are all positive, then α can be chosen smaller than one over the largest of them, such that $\mathbf{I}-\alpha\mathbf{A}_t$ is diagonal with all diagonal elements between 0 and 1. In this case the first term of the update tends to shrink $\boldsymbol{\theta}_t$, and stability is assured. In general, $\boldsymbol{\theta}_t$ will be reduced toward zero whenever $\mathbf{A}_t$ is positive definite.[1]

In actuality, however, $\mathbf{A}_t$ and $\mathbf{b}_t$ are random variables that vary from step to step, in which case stability is determined by the steady-state expectation, $\lim_{t\to\infty}\mathbb{E}[\mathbf{A}_t]$. In our setting, after an initial transient, states will be visited according to the steady-state distribution under π (which we assume exists). We represent this distribution by a vector $\mathbf{d}_\pi$, each component of which gives the limiting probability of being in a particular state[2] $[\mathbf{d}_\pi]_s \doteq d_\pi(s) \doteq \lim_{t\to\infty}\mathbb{P}\{S_t{=}s\}$, which we assume exists and is positive at all states (any states not visited with nonzero probability can be removed from the problem). The special property of the steady-state distribution is that once the process is in it, it remains in it. Let $\mathbf{P}_\pi$ denote the $N\times N$ matrix of transition probabilities $[\mathbf{P}_\pi]_{ij} \doteq \sum_a \pi(a|i)p(j|i,a)$ where $p(j|i,a) \doteq \mathbb{P}\{S_{t+1}{=}j|S_t{=}i, A_t{=}a\}$. Then the special property of $\mathbf{d}_\pi$ is that

$$\mathbf{P}_\pi^\top \mathbf{d}_\pi = \mathbf{d}_\pi. \tag{5}$$

Consider any stochastic algorithm of the form (4), and let $\mathbf{A} \doteq \lim_{t\to\infty}\mathbb{E}[\mathbf{A}_t]$ and $\mathbf{b} \doteq \lim_{t\to\infty}\mathbb{E}[\mathbf{b}_t]$. We define the stochastic algorithm to be *stable* if and only if the corresponding deterministic algorithm,

$$\bar{\boldsymbol{\theta}}_{t+1} \doteq \bar{\boldsymbol{\theta}}_t + \alpha(\mathbf{b}-\mathbf{A}\bar{\boldsymbol{\theta}}_t), \tag{6}$$

is convergent to a unique fixed point independent of the initial $\bar{\boldsymbol{\theta}}_0$. This will occur iff the $\mathbf{A}$ matrix has a full set of eigenvalues all of whose real parts are positive. If a stochastic algorithm is stable and α is reduced according to an appropriate schedule, then its parameter vector may converge with probability one. However, in this paper we focus only on stability as a prerequisite for convergence (of the original stochastic algorithm), leaving convergence itself to future work. If the stochastic algorithm converges, it is to a fixed point $\bar{\boldsymbol{\theta}}$ of the deterministic algorithm, at which $\mathbf{A}\bar{\boldsymbol{\theta}}=\mathbf{b}$, or $\bar{\boldsymbol{\theta}}=\mathbf{A}^{-1}\mathbf{b}$. (Stability assures existence of the inverse.) In this paper we focus on establishing stability by proving that $\mathbf{A}$ is positive definite. From definiteness it immediately follows that $\mathbf{A}$ has a full set of eigenvectors (because $\mathbf{y}^\top\mathbf{A}\mathbf{y}>0, \forall\mathbf{y}\neq\mathbf{0}$) and that the corresponding eigenvalues all have real parts.[3]

1. A real matrix $\mathbf{A}$ is defined to be *positive definite* in this paper iff $\mathbf{y}^\top\mathbf{A}\mathbf{y}>0$ for any real vector $\mathbf{y}\neq\mathbf{0}$.
2. Here and throughout the paper we use brackets with subscripts to denote the individual elements of vectors and matrices.
3. To see the latter, let $\mathrm{Re}(x)$ denote the real part of a complex number x, and let $\mathbf{y}^*$ denotes the conjugate transpose of a complex vector $\mathbf{y}$. Then, for any eigenvalue–eigenvector pair $\lambda,\mathbf{y}$: $0<\mathrm{Re}(\mathbf{y}^*\mathbf{A}\mathbf{y}) = \mathrm{Re}(\mathbf{y}^*\lambda\mathbf{y}) = \mathrm{Re}(\lambda)\mathbf{y}^*\mathbf{y} \implies 0<\mathrm{Re}(\lambda)$.

Now let us return to analyzing on-policy TD(0). Its $\mathbf{A}$ matrix is

$$\begin{aligned}
\mathbf{A} = \lim_{t\to\infty}\mathbb{E}[\mathbf{A}_t] &= \lim_{t\to\infty}\mathbb{E}_\pi\Big[\boldsymbol{\phi}(S_t)\left(\boldsymbol{\phi}(S_t)-\gamma\boldsymbol{\phi}(S_{t+1})\right)^\top\Big] \\
&= \sum_s d_\pi(s)\,\boldsymbol{\phi}(s)\left(\boldsymbol{\phi}(s)-\gamma\sum_{s'}[\mathbf{P}_\pi]_{ss'}\boldsymbol{\phi}(s')\right)^\top \\
&= \boldsymbol{\Phi}^\top\mathbf{D}_\pi(\mathbf{I}-\gamma\mathbf{P}_\pi)\boldsymbol{\Phi},
\end{aligned}$$

where $\boldsymbol{\Phi}$ is the $N\times n$ matrix with the $\boldsymbol{\phi}(s)$ as its rows, and $\mathbf{D}_\pi$ is the $N\times N$ diagonal matrix with $\mathbf{d}_\pi$ on its diagonal. This $\mathbf{A}$ matrix is typical of those we consider in this paper in that it consists of $\boldsymbol{\Phi}^\top$ and $\boldsymbol{\Phi}$ wrapped around a distinctive $N\times N$ matrix that varies with the algorithm and the setting, and which we call the *key matrix*. An $\mathbf{A}$ matrix of this form will be positive definite whenever the corresponding key matrix is positive definite.[4] In this case the key matrix is $\mathbf{D}_\pi(\mathbf{I}-\gamma\mathbf{P}_\pi)$.

For a key matrix of this type, positive definiteness is assured if all of its columns sum to nonnegative numbers. This was shown by Sutton (1988, p. 27) based on two previously established theorems. One theorem says that any matrix $\mathbf{M}$ is positive definite if and only if the symmetric matrix $\mathbf{S}=\mathbf{M}+\mathbf{M}^\top$ is positive definite (Sutton 1988, appendix). The second theorem says that any symmetric real matrix $\mathbf{S}$ is positive definite if the absolute values of its diagonal entries are greater than the sum of the absolute values of the corresponding off-diagonal entries (Varga 1962, p. 23). For our key matrix, $\mathbf{D}_\pi(\mathbf{I}-\gamma\mathbf{P}_\pi)$, the diagonal entries are positive and the off-diagonal entries are negative, so all we have to show is that each row sum plus the corresponding column sum is positive. The row sums are all positive because $\mathbf{P}_\pi$ is a stochastic matrix and $\gamma<1$. Thus it only remains to show that the column sums are nonnegative.

Note that the row vector of the column sums of any matrix $\mathbf{M}$ can be written as $\mathbf{1}^\top\mathbf{M}$, where $\mathbf{1}$ is the column vector with all components equal to 1. The column sums of our key matrix, then, are:

$$\begin{aligned}
\mathbf{1}^\top\mathbf{D}_\pi(\mathbf{I}-\gamma\mathbf{P}_\pi) &= \mathbf{d}_\pi^\top(\mathbf{I}-\gamma\mathbf{P}_\pi) \\
&= \mathbf{d}_\pi^\top - \gamma\mathbf{d}_\pi^\top\mathbf{P}_\pi \\
&= \mathbf{d}_\pi^\top - \gamma\mathbf{d}_\pi^\top \qquad \text{(by (5))} \\
&= (1-\gamma)\mathbf{d}_\pi,
\end{aligned}$$

all components of which are positive. Thus, the key matrix and its $\mathbf{A}$ matrix are positive definite, and on-policy TD(0) is stable. Additional conditions and a schedule for reducing α over time (as in Tsitsiklis and Van Roy 1997) are needed to prove convergence with probability one, $\boldsymbol{\theta}_\infty=\mathbf{A}^{-1}\mathbf{b}$, but the analysis above includes the most important steps that vary from algorithm to algorithm.

4. Strictly speaking, positive definiteness of the key matrix assures only that $\mathbf{A}$ is positive *semi*-definite, because it is possible that $\boldsymbol{\Phi}\mathbf{y}=\mathbf{0}$ for some $\mathbf{y}\neq\mathbf{0}$, in which case $\mathbf{y}^\top\mathbf{A}\mathbf{y}$ will be zero as well. To rule this out, we assume, as is commonly done, that the columns of $\boldsymbol{\Phi}$ are linearly independent (i.e., that the features are not redundant), and thus that $\boldsymbol{\Phi}\mathbf{y}=\mathbf{0}$ only if $\mathbf{y}=\mathbf{0}$. If this were not true, then convergence (if it occurs) may not be to a unique $\boldsymbol{\theta}_\infty$, but rather to a subspace of parameter vectors all of which produce the same approximate value function.

3. Instability of Off-policy TD(0)

Before developing the off-policy setting in detail, it is useful to understand informally why TD(0) is susceptible to instability. TD learning involves learning an estimate from an estimate, which can be problematic if there is generalization between the two estimates. For example, suppose there is a transition between two states with the same feature representation except that the second is twice as big:

where here θ and 2θ are the estimated values of the two states—that is, their feature representations are a single feature that is 1 for the first state and 2 for the second (cf. Tsitsiklis & Van Roy 1996). Now suppose that θ is 10 and the reward on the transition is 0. The transition is then from a state valued at 10 to a state valued at 20. If γ is near 1 and α is 0.1, then θ will be increased to approximately 11. But then the next time the transition occurs there will be an even bigger increase in value, from 11 to 22, and a bigger increase in θ, to approximately 12.1. If this transition is experienced repeatedly on its own, then the system is unstable and the parameter increases without bound—it diverges. We call this the $\theta \to 2\theta$ problem.

In on-policy learning, repeatedly experiencing just this single problematic transition cannot happen, because, after the highly-valued 2θ state has been entered, it must then be exited. The transition from it will either be to a lesser or equally-valued state, in which case θ will be significantly decreased, or to an even higher-valued state which in turn must be followed by an even larger decrease in its estimated value or a still higher-valued state. Eventually, the promise of high value must be made good in the form of a high reward, or else estimates will be decreased, and this ultimately constrains θ and forces stability and convergence. In the off-policy case, however, if there is a deviation from the target policy then the promise is excused and need never be fulfilled. Later in this section we present a complete example of how the $\theta \to 2\theta$ problem can cause instability and divergence under off-policy training.

With these intuitions, we now detail our off-policy setting. As in the on-policy case, the data is a single, infinite-length trajectory of actions, rewards, and feature vectors generated by a continuing finite Markov decision process. The difference is that the actions are selected not according to the target policy π, but according to a different *behavior policy* $\mu : \mathcal{A} \times \mathcal{S} \to [0, 1]$, yet still we seek to estimate state values under π (as in (2)). Of course, it would be impossible to estimate the values under π if the actions that π would take were never taken by μ and their consequences were never observed. Thus we assume that $\mu(a|s) > 0$ for every state and action for which $\pi(a|s) > 0$. This is called the assumption of *coverage*. It is trivially satisfied by any ϵ-greedy or soft behavior policy. As before we assume that there is a stationary distribution $d_\mu(s) \doteq \lim_{t\to\infty} \mathbb{P}\{S_t{=}s\} > 0, \forall s \in \mathcal{S}$, with corresponding N-vector $\mathbf{d}_\mu$.

Even if there is coverage, the behavior policy will choose actions with proportions different from the target policy. For example, some actions taken by μ might never be chosen by π. To address this, we use importance sampling to correct for the relative probability of taking the action actually taken, A_t, in the state actually encountered, S_t, under the target

and behavior policies:

$$\rho_t \doteq \frac{\pi(A_t|S_t)}{\mu(A_t|S_t)}.$$

This quantity is called the *importance sampling ratio* at time t. Note that its expected value is one:

$$\mathbb{E}_\mu[\rho_t|S_t{=}s] = \sum_a \mu(a|s)\frac{\pi(a|s)}{\mu(a|s)} = \sum_a \pi(a|s) = 1.$$

The ratio will be exactly one only on time steps on which the action probabilities for the two policies are exactly the same; these time steps can be treated the same as in the on-policy case. On other time steps the ratio will be greater or less than one depending on whether the action taken was more or less likely under the target policy than under the behavior policy, and some kind of correction is needed.

In general, for any random variable Z_{t+1} dependent on S_t, A_t and S_{t+1}, we can recover its expectation under the target policy by multiplying by the importance sampling ratio:

$$\begin{aligned}\mathbb{E}_\mu[\rho_t Z_{t+1}|S_t{=}s] &= \sum_a \mu(a|s)\frac{\pi(a|s)}{\mu(a|s)} Z_{t+1} \\ &= \sum_a \pi(a|s) Z_{t+1} \\ &= \mathbb{E}_\pi[Z_{t+1}|S_t{=}s], \qquad \forall s \in \mathcal{S}. \end{aligned} \tag{7}$$

We can use this fact to begin to adapt TD(0) for off-policy learning (Precup, Sutton & Singh 2000). We simply multiply the whole TD(0) update (1) by ρ_t:

$$\begin{aligned}\boldsymbol{\theta}_{t+1} &\doteq \boldsymbol{\theta}_t + \rho_t\,\alpha\left(R_{t+1} + \gamma\boldsymbol{\theta}_t^\top\boldsymbol{\phi}_{t+1} - \boldsymbol{\theta}_t^\top\boldsymbol{\phi}_t\right)\boldsymbol{\phi}_t \\ &= \boldsymbol{\theta}_t + \alpha\Big(\underbrace{\rho_t R_{t+1}\boldsymbol{\phi}_t}_{\mathbf{b}_t} - \underbrace{\rho_t\boldsymbol{\phi}_t\left(\boldsymbol{\phi}_t - \gamma\boldsymbol{\phi}_{t+1}\right)^\top}_{\mathbf{A}_t}\boldsymbol{\theta}_t\Big),\end{aligned} \tag{8}$$

where here we have used the shorthand $\boldsymbol{\phi}_t \doteq \boldsymbol{\phi}(S_t)$. Note that if the action taken at time t is never taken under the target policy in that state, then $\rho_t = 0$ and there is no update on that step, as desired. We call this algorithm *off-policy TD(0)*.

Off-policy TD(0)'s $\mathbf{A}$ matrix is

$$\begin{aligned}\mathbf{A} = \lim_{t\to\infty}\mathbb{E}[\mathbf{A}_t] &= \lim_{t\to\infty}\mathbb{E}_\mu\Big[\rho_t\boldsymbol{\phi}_t\left(\boldsymbol{\phi}_t - \gamma\boldsymbol{\phi}_{t+1}\right)^\top\Big] \\ &= \sum_s d_\mu(s)\mathbb{E}_\mu\Big[\rho_k\boldsymbol{\phi}_k\left(\boldsymbol{\phi}_k - \gamma\boldsymbol{\phi}_{k+1}\right)^\top\Big|S_k = s\Big] \\ &= \sum_s d_\mu(s)\mathbb{E}_\pi\Big[\boldsymbol{\phi}_k\left(\boldsymbol{\phi}_k - \gamma\boldsymbol{\phi}_{k+1}\right)^\top\Big|S_k = s\Big] \qquad \text{(by (7))} \\ &= \sum_s d_\mu(s)\,\boldsymbol{\phi}(s)\left(\boldsymbol{\phi}(s) - \gamma\sum_{s'}[\mathbf{P}_\pi]_{ss'}\boldsymbol{\phi}(s')\right)^\top \\ &= \boldsymbol{\Phi}^\top\mathbf{D}_\mu(\mathbf{I} - \gamma\mathbf{P}_\pi)\boldsymbol{\Phi},\end{aligned}$$

where $\mathbf{D}_\mu$ is the $N \times N$ diagonal matrix with the stationary distribution $\mathbf{d}_\mu$ on its diagonal. Thus, the key matrix that must be positive definite is $\mathbf{D}_\mu(\mathbf{I} - \gamma\mathbf{P}_\pi)$ and, unlike in the on-policy case, the distribution and the transition probabilities do not match. We do not have an analog of (5), $\mathbf{P}_\pi^\top \mathbf{d}_\mu \neq \mathbf{d}_\mu$, and in fact the column sums may be negative and the matrix not positive definite, in which case divergence of the parameter is likely.

A simple $\theta \to 2\theta$ example of divergence that fits the setting in this section is shown in Figure 1. From each state there are two actions, left and right, which take the process to the left or right states. All the rewards are zero. As before, there is a single parameter θ and the single feature is 1 and 2 in the two states such that the approximate values are θ and 2θ as shown. The behavior policy is to go left and right with equal probability from both states, such that equal time is spent on average in both states, $\mathbf{d}_\mu = (0.5, 0.5)^\top$. The target policy is to go right in both states. We seek to learn the value from each state given that the right action is continually taken. The transition probability matrix for this example is:

$$\mathbf{P}_\pi = \begin{bmatrix} 0 & 1 \\ 0 & 1 \end{bmatrix}.$$

The key matrix is

$$\mathbf{D}_\mu(\mathbf{I} - \gamma\mathbf{P}_\pi) = \begin{bmatrix} 0.5 & 0 \\ 0 & 0.5 \end{bmatrix} \times \begin{bmatrix} 1 & -0.9 \\ 0 & 0.1 \end{bmatrix} = \begin{bmatrix} 0.5 & -0.45 \\ 0 & 0.05 \end{bmatrix}. \tag{9}$$

We can see an immediate indication that the key matrix may not be positive definite in that the second column sums to a negative number. More definitively, one can show that it is not positive definite by multiplying it on both sides by $\mathbf{y} = \mathbf{\Phi} = (1, 2)^\top$:

$$\mathbf{\Phi}^\top \mathbf{D}_\mu(\mathbf{I} - \gamma\mathbf{P}_\pi)\mathbf{\Phi} = \begin{bmatrix} 1 & 2 \end{bmatrix} \times \begin{bmatrix} 0.5 & -0.45 \\ 0 & 0.05 \end{bmatrix} \times \begin{bmatrix} 1 \\ 2 \end{bmatrix} = \begin{bmatrix} 1 & 2 \end{bmatrix} \times \begin{bmatrix} -0.4 \\ 0.1 \end{bmatrix} = -0.2.$$

That this is negative means that the key matrix is not positive definite. We have also calculated here the $\mathbf{A}$ matrix; it is this negative scalar, $\mathbf{A} = -0.2$. Clearly, this expected update and algorithm are not stable.

It is also easy to see the instability of this example more directly, without matrices. We know that only transitions under the right action cause updates, as ρ_t will be zero for the others. Assume for concreteness that initially $\theta_t = 10$ and that $\alpha = 0.1$. On a right transition from the first state the update will be

$$\begin{aligned} \theta_{t+1} &= \theta_t + \rho_t\alpha\left(R_{t+1} + \gamma\boldsymbol{\theta}_t^\top\boldsymbol{\phi}_{t+1} - \boldsymbol{\theta}_t^\top\boldsymbol{\phi}_t\right)\boldsymbol{\phi}_t \\ &= 10 + 2 \cdot 0.1\,(0 + 0.9 \cdot 10 \cdot 2 - 10 \cdot 1)\,1 \\ &= 10 + 1.6, \end{aligned}$$

Figure 1: $\theta \to 2\theta$ example without a terminal state.

whereas, on a right transition from the second state the update will be

$$\begin{aligned} \theta_{t+1} &= \theta_t + \rho_t\alpha\left(R_{t+1} + \gamma\boldsymbol{\theta}_t^\top\boldsymbol{\phi}_{t+1} - \boldsymbol{\theta}_t^\top\boldsymbol{\phi}_t\right)\boldsymbol{\phi}_t \\ &= 10 + 2 \cdot 0.1\,(0 + 0.9 \cdot 10 \cdot 2 - 10 \cdot 2)\,2 \\ &= 10 - 0.8. \end{aligned}$$

These two transitions occur equally often, so the net change will be positive. That is, θ will increase, moving farther from its correct value, zero. Everything is linear in θ, so the next time around, with a larger starting θ, the increase in θ will be larger still, and divergence occurs. A smaller value of α would not prevent divergence, only reduce its rate.

4. Off-policy Stability of Emphatic TD(0)

The deep reason for the difficulty of off-policy learning is that the behavior policy may take the process to a distribution of states different from that which would be encountered under the target policy, yet the states might appear to be the same or similar because of function approximation. Earlier work by Precup, Sutton and Dasgupta (2001) attempted to completely correct for the different state distribution using importance sampling ratios to reweight the states encountered. It is theoretically possible to convert the state weighting from d_μ to d_π using the product of all importance sampling ratios from time 0, but in practice this approach has extremely high variance and is infeasible for the continuing (non-episodic) case. It works in theory because after converting the weighting the key matrix is $\mathbf{D}_\pi(\mathbf{I} - \gamma\mathbf{P}_\pi)$ again, which we know to be positive definite.

Most subsequent works abandoned the idea of completely correcting for the state distribution. For example, the work on gradient-TD methods (e.g., Sutton et al. 2009, Maei 2011) seeks to minimize the mean-squared projected Bellman error weighted by d_μ. We call this an *excursion* setting because we can think of the contemplated switch to the target policy as an excursion from the steady-state distribution of the behavior policy, d_μ. The excursions would start from d_μ and then follow π until termination, followed by a resumption of μ and thus a gradual return to d_μ. Of course these excursions never actually occur during off-policy learning, they are just contemplated, and thus the state distribution in fact never leaves d_μ. It is the excursion view that we take in this paper, but still we use techniques similar to those introduced by Precup et al. (2001) to determine an emphasis weighting that corrects for the state distribution, only toward a different goal (see also Kolter 2011).

The excursion notion suggests a different weighting of TD(0) updates. We consider that at every time step we are beginning a new contemplated excursion from the current state. The excursion thus would begin in a state sampled from d_μ. If an excursion started it would pass through a sequence of subsequent states and actions prior to termination. Some of the actions that are actually taken (under μ) are relatively likely to occur under the target policy as compared to the behavior policy, while others are relatively unlikely; the corresponding states can be appropriately reweighted based on importance sampling ratios. Thus, there will still be a product of importance sampling ratios, but only since the beginning of the excursion, and the variance will also be tamped down by the discounting; the variance will be much less than in the earlier approach. In the simplest case of an off-policy emphatic algorithm, the update at time t is emphasized or de-emphasized proportional to a new scalar

variable F_t, defined by $F_0 = 1$ and

$$F_t \doteq \gamma\rho_{t-1}F_{t-1} + 1, \qquad \forall t > 0, \tag{10}$$

which we call the *followon trace*. Specifically, we define *emphatic TD(0)* by the following update:

$$\begin{aligned}\boldsymbol{\theta}_{t+1} &\doteq \boldsymbol{\theta}_t + \alpha F_t \rho_t \left(R_{t+1} + \gamma \boldsymbol{\theta}_t^\top \boldsymbol{\phi}_{t+1} - \boldsymbol{\theta}_t^\top \boldsymbol{\phi}_t\right) \boldsymbol{\phi}_t \\ &= \boldsymbol{\theta}_t + \alpha\Big(\underbrace{F_t\rho_t R_{t+1}\boldsymbol{\phi}_t}_{\mathbf{b}_t} - \underbrace{F_t\rho_t\boldsymbol{\phi}_t\left(\boldsymbol{\phi}_t - \gamma\boldsymbol{\phi}_{t+1}\right)^\top}_{\mathbf{A}_t}\boldsymbol{\theta}_t\Big).\end{aligned} \tag{11}$$

Emphatic TD(0)'s $\mathbf{A}$ matrix is

$$\begin{aligned}\mathbf{A} = \lim_{t\to\infty}\mathbb{E}[\mathbf{A}_t] &= \lim_{t\to\infty}\mathbb{E}_\mu\Big[F_t\rho_t\boldsymbol{\phi}_t\left(\boldsymbol{\phi}_t - \gamma\boldsymbol{\phi}_{t+1}\right)^\top\Big] \\ &= \sum_s d_\mu(s)\lim_{t\to\infty}\mathbb{E}_\mu\Big[F_t\rho_t\boldsymbol{\phi}_t\left(\boldsymbol{\phi}_t - \gamma\boldsymbol{\phi}_{t+1}\right)^\top\Big|S_t = s\Big] \\ &= \sum_s d_\mu(s)\lim_{t\to\infty}\mathbb{E}_\mu[F_t|S_t = s]\,\mathbb{E}_\mu\Big[\rho_t\boldsymbol{\phi}_t\left(\boldsymbol{\phi}_t - \gamma\boldsymbol{\phi}_{t+1}\right)^\top\Big|S_t = s\Big]\end{aligned}$$

(because, given S_t, F_t is independent of $\rho_t\boldsymbol{\phi}_t\left(\boldsymbol{\phi}_t - \gamma\boldsymbol{\phi}_{t+1}\right)^\top$)

$$\begin{aligned}&= \sum_s \underbrace{d_\mu(s)\lim_{t\to\infty}\mathbb{E}_\mu[F_t|S_t = s]}_{f(s)}\,\mathbb{E}_\mu\Big[\rho_k\boldsymbol{\phi}_k\left(\boldsymbol{\phi}_k - \gamma\boldsymbol{\phi}_{k+1}\right)^\top\Big|S_k = s\Big] \\ &= \sum_s f(s)\mathbb{E}_\pi\Big[\boldsymbol{\phi}_k\left(\boldsymbol{\phi}_k - \gamma\boldsymbol{\phi}_{k+1}\right)^\top\Big|S_k = s\Big] \qquad \text{(by (7))} \\ &= \sum_s f(s)\,\boldsymbol{\phi}(s)\left(\boldsymbol{\phi}(s) - \gamma\sum_{s'}[\mathbf{P}_\pi]_{ss'}\boldsymbol{\phi}(s')\right)^\top \\ &= \boldsymbol{\Phi}^\top\mathbf{F}(\mathbf{I} - \gamma\mathbf{P}_\pi)\boldsymbol{\Phi},\end{aligned}$$

where $\mathbf{F}$ is a diagonal matrix with diagonal elements $f(s) \doteq d_\mu(s)\lim_{t\to\infty}\mathbb{E}_\mu[F_t|S_t{=}s]$, which we assume exists. As we show later, the vector $\mathbf{f} \in \mathbb{R}^N$ with components $[\mathbf{f}]_s \doteq f(s)$ can be written as

$$\begin{aligned}\mathbf{f} &= \mathbf{d}_\mu + \gamma\mathbf{P}_\pi^\top\mathbf{d}_\mu + \left(\gamma\mathbf{P}_\pi^\top\right)^2\mathbf{d}_\mu + \cdots \qquad (12)\\ &= \left(\mathbf{I} - \gamma\mathbf{P}_\pi^\top\right)^{-1}\mathbf{d}_\mu. \qquad (13)\end{aligned}$$

The key matrix is $\mathbf{F}\left(\mathbf{I} - \gamma\mathbf{P}_\pi\right)$, and the vector of its column sums is

$$\begin{aligned}\mathbf{1}^\top\mathbf{F}(\mathbf{I} - \gamma\mathbf{P}_\pi) &= \mathbf{f}^\top(\mathbf{I} - \gamma\mathbf{P}_\pi) \\ &= \mathbf{d}_\mu^\top(\mathbf{I} - \gamma\mathbf{P}_\pi)^{-1}(\mathbf{I} - \gamma\mathbf{P}_\pi) \qquad \text{(using (13))} \\ &= \mathbf{d}_\mu^\top,\end{aligned}$$

all components of which are positive. Thus, the key matrix and the $\mathbf{A}$ matrix are positive definite and the algorithm is stable. Emphatic TD(0) is the simplest TD algorithm with linear function approximation proven to be stable under off-policy training.

The $\theta \to 2\theta$ example presented earlier (Figure 1) provides some insight into how replacing $\mathbf{D}_\mu$ by $\mathbf{F}$ changes the key matrix to make it positive definite. In general, $\mathbf{f}$ is the expected number of time steps that would be spent in each state during an excursion starting from the behavior distribution $\mathbf{d}_\mu$. From (12), it is $\mathbf{d}_\mu$ plus where you would get to in one step from $\mathbf{d}_\mu$, plus where you would get to in two steps, etc., with appropriate discounting. In the example, excursions under the target policy take you to the second state (2θ) and leave you there. Thus you are only in the first state (θ) if you start there, and only for one step, so $f(1) = d_\mu(1) = 0.5$. For the second state, you can either start there, with probability 0.5, or you can get there on the second step (certain except for discounting), with probability 0.9, or on the third step, with probability 0.9^2, etc, so $f(2) = 0.5 + 0.9 + 0.9^2 + 0.9^3 + \cdots = 0.5 + 0.9 \cdot 10 = 9.5$. Thus, the key matrix is now

$$\mathbf{F}(\mathbf{I} - \gamma\mathbf{P}_\pi) = \begin{bmatrix}0.5 & 0\\ 0 & 9.5\end{bmatrix} \times \begin{bmatrix}1 & -0.9\\ 0 & 0.1\end{bmatrix} = \begin{bmatrix}0.5 & -0.45\\ 0 & 0.95\end{bmatrix}.$$

Note that because $\mathbf{F}$ is a diagonal matrix, its only effect is to scale the rows. Here it emphasizes the lower row by more than a factor of 10 compared to the upper row, thereby causing the key matrix to have positive column sums and be positive definite (cf. (9)). The $\mathbf{F}$ matrix emphasizes the second state, which would occur much more often under the target policy than it does under the behavior policy.

5. The General Case

We turn now to a very general case of off-policy learning with linear function approximation. The objective is still to evaluate a policy π from a single trajectory under a different policy μ, but now the value of a state is defined not with respect to a constant discount rate $\gamma \in [0, 1]$, but with respect to a discount rate that varies from state to state according to a *discount function* $\gamma : \mathcal{S} \to [0, 1]$ such that $\prod_{k=1}^{\infty}\gamma(S_{t+k}) = 0$, w.p.1, $\forall t$. That is, our approximation is still defined by (2), but now (3) is replaced by

$$G_t \doteq R_{t+1} + \gamma(S_{t+1})R_{t+2} + \gamma(S_{t+1})\gamma(S_{t+2})R_{t+3} + \cdots. \tag{14}$$

State-dependent discounting specifies a temporal envelope within which received rewards are accumulated. If $\gamma(S_k) = 0$, then the time of accumulation is fully terminated at step $k > t$, and if $\gamma(S_k) < 1$, then it is partially terminated. We call both of these *soft termination* because they are like the termination of an episode, but the actual trajectory is not affected. Soft termination ends the accumulation of rewards into a return, but the state transitions continue oblivious to the termination. Soft termination with state-dependent termination is essential for learning models of options (Sutton et al. 1999) and other applications.

Soft termination is particularly natural in the excursion setting, where it makes it easy to define excursions of finite and definite duration. For example, consider the deterministic MDP shown in Figure 2. There are five states, three of which do not discount at all, $\gamma(s) = 1$, and are shown as circles, and two of which cause complete soft termination, $\gamma(s) = 0$, and are shown as squares. The terminating states do not end anything other

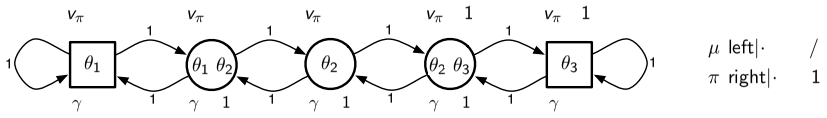

Figure 2: A 5-state chain MDP with soft-termination states at each end.

than the return; actions are still selected in them and, dependent on the action selected, they transition to next states indefinitely without end. In this MDP there are two actions, left and right, which deterministically cause transitions to the left or right except at the edges, where there may be a self transition. The reward on all transitions is +1. The behavior policy is to select left 2/3rds of the time in all states, which causes more time to be spent in states on the left than on the right. The stationary distribution can be shown to be $\mathbf{d}_\mu \approx (0.52, 0.26, 0.13, 0.06, 0.03)^\top$; more than half of the time steps are spent in the leftmost terminating state.

Consider the target policy π that selects the right action from all states. The correct value $v_\pi(s)$ of each state s is written above it in the figure. For both of the two rightmost states, the right action results in a reward of 1 and an immediate termination, so their values are both 1. For the middle state, following π (selecting right repeatedly) yields two rewards of 1 prior to termination. There is no discounting ($\gamma=1$) prior to termination, so the middle state's value is 2, and similarly the values go up by 1 for each state to its left, as shown. These are the correct values. The approximate values depend on the parameter vector $\boldsymbol{\theta}_t$ as suggested by the expressions shown inside each state in the figure. These expressions use the notation θ_i to denote the ith *component* of the current parameter vector $\boldsymbol{\theta}_t$. In this example, there are five states and only three parameters, so it is unlikely, and indeed impossible, to represent v_π exactly. We will return to this example later in the paper.

In addition to enabling definitive termination, as in this example, state-dependent discounting enables a much wider range of predictive questions to be expressed in the form of a value function (Sutton et al. 2011, Modayil, White & Sutton 2014, Sutton, Rafols & Koop 2006), including option models (Sutton, Precup & Singh 1999, Sutton 1995). For example, with state-dependent discounting one can formulate questions both about what will happen during a way of behaving and what will be true at its end. A general representation for predictions is a key step toward the goal of representing world knowledge in verifiable predictive terms (Sutton 2009, 2012). The general form is also useful just because it enables us to treat uniformly many of the most important episodic and continuing special cases of interest.

A second generalization, developed for the first time in this paper, is to explicitly specify the states at which we are most interested is obtaining accurate estimates of value. Recall that in parametric function approximation there are typically many more states than parameters ($N \gg n$), and thus it is usually not possible for the value estimates at all states to be exactly correct. Valuing some states more accurately usually means valuing others less accurately, at least asymptotically. In the tabular case where much of the theory of reinforcement learning originated, this tradeoff is not an issue because the estimates of each state are independent of each other, but with function approximation it is necessary to specify relative interest in order to make the problem well defined. Nevertheless, in the function approximation case little attention has been paid in the literature to specifing the relative importance of different states (an exception is Thomas 2014), though there are intimations of this in the initiation set of options (Sutton et al. 1999). In the past it was typically assumed that we were interested in valuing states in direct proportion to how often they occur, but this is not always the case. For example, in episodic problems we often care primarily about the value of the first state, or of earlier states generally (Thomas 2014). Here we allow the user to specify the relative interest in each state with a nonnegative *interest function* $i : \mathcal{S} \to [0, \infty)$. Formally, our objective is to minimize the Mean Square Value Error (MSVE) with states weighted both by how often they occur and by our interest in them:

$$\text{MSVE}(\boldsymbol{\theta}) \doteq \sum_{s\in\mathcal{S}} d_\mu(s) i(s) \Big(v_\pi(s) - \boldsymbol{\theta}^\top \boldsymbol{\phi}(s) \Big)^2. \tag{15}$$

For example, in the 5-state example in Figure 2, we could choose $i(s) = 1, \forall s \in \mathcal{S}$, in which case we would be primarily interested in attaining low error in the states on the left side, which are visited much more often under the behavior policy. If we want to counter this, we might chose $i(s)$ larger for states toward the right. Of course, with parametric function approximation we presumably do not have access to the states as individuals, but certainly we could set $i(s)$ as a function of the features in s. In this example, choosing $i(s) = 1 + \phi_2(s) + 2\phi_3(s)$ (where $\phi_i(s)$ denotes the ith component of $\boldsymbol{\phi}(s)$) would shift the focus on accuracy to the states on the right, making it substantially more balanced.

The third and final generalization that we introduce in this section is general bootstrapping. Conventional TD(λ) uses a bootstrapping parameter $\lambda \in [0, 1]$; we generalize this to a *bootstrapping function* $\lambda : \mathcal{S} \to [0, 1]$ specifying a potentially different degree of bootstrapping, $1 - \lambda(s)$, for each state s. General bootstrapping of this form has been partially developed in several previous works (Sutton 1995, Sutton & Barto 1998, Maei & Sutton 2010, Sutton et al. 2014, cf. Yu 2012). As a notational shorthand, let us use $\lambda_t \doteq \lambda(S_t)$ and $\gamma_t \doteq \gamma(S_t)$. Then we can define a general notion of bootstrapped return, the λ-return with state-dependent bootstrapping and discounting:

$$G_t^\lambda \doteq R_{t+1} + \gamma_{t+1} \Big[(1 - \lambda_{t+1}) \boldsymbol{\theta}_t^\top \boldsymbol{\phi}_{t+1} + \lambda_{t+1} G_{t+1}^\lambda \Big]. \tag{16}$$

The λ-return plays a key role in the theoretical understanding of TD methods, in particular, in their forward views (Sutton & Barto 1998, Sutton, Mahmood, Precup & van Hasselt 2014). In the forward view, G_t^λ is thought of as the target for the update at time t, even though it is not available until many steps later (when complete termination $\gamma(S_k) = 0$ has occurred for the first time for some $k > t$).

Given these generalizations, we can now specify our final new algorithm, *emphatic TD(λ)*, by the following four equations, for $t \geq 0$:

$$\boldsymbol{\theta}_{t+1} \doteq \boldsymbol{\theta}_t + \alpha \Big(R_{t+1} + \gamma_{t+1} \boldsymbol{\theta}_t^\top \boldsymbol{\phi}_{t+1} - \boldsymbol{\theta}_t^\top \boldsymbol{\phi}_t \Big) \mathbf{e}_t \tag{17}$$

$$\mathbf{e}_t \doteq \rho_t \left(\gamma_t \lambda_t \mathbf{e}_{t-1} + M_t \boldsymbol{\phi}_t \right), \qquad \text{with } \mathbf{e}_{-1} \doteq \mathbf{0} \tag{18}$$

$$M_t \doteq \lambda_t \, i(S_t) + (1 - \lambda_t) F_t \tag{19}$$

$$F_t \doteq \rho_{t-1} \gamma_t F_{t-1} + i(S_t), \qquad \text{with } F_0 \doteq i(S_0), \tag{20}$$

where $F_t \geq 0$ is a scalar memory called the *followon trace*. The quantity $M_t \geq 0$ is termed the *emphasis* on step t. Note that, if desired, M_t can be removed from the algorithm by substituting its definition (19) into (18).

6. Off-policy Stability of Emphatic TD(λ)

As usual, to analyze the stability of the new algorithm we examine its $\mathbf{A}$ matrix. The stochastic update can be written:

$$\begin{aligned}\boldsymbol{\theta}_{t+1} &\doteq \boldsymbol{\theta}_t + \alpha\left(R_{t+1} + \gamma_{t+1}\boldsymbol{\theta}_t^\top \boldsymbol{\phi}_{t+1} - \boldsymbol{\theta}_t^\top \boldsymbol{\phi}_t\right)\mathbf{e}_t \\ &= \boldsymbol{\theta}_t + \alpha\Big(\underbrace{\mathbf{e}_t R_{t+1}}_{\mathbf{b}_t} - \underbrace{\mathbf{e}_t\left(\boldsymbol{\phi}_t - \gamma_{t+1}\boldsymbol{\phi}_{t+1}\right)^\top}_{\mathbf{A}_t}\boldsymbol{\theta}_t\Big).\end{aligned}$$

Thus,

$$\begin{aligned}\mathbf{A} = \lim_{t\to\infty}\mathbb{E}[\mathbf{A}_t] &= \lim_{t\to\infty}\mathbb{E}_\mu\left[\mathbf{e}_t\left(\boldsymbol{\phi}_t - \gamma_{t+1}\boldsymbol{\phi}_{t+1}\right)^\top\right] \\ &= \sum_s d_\mu(s)\lim_{t\to\infty}\mathbb{E}_\mu\left[\mathbf{e}_t\left(\boldsymbol{\phi}_t - \gamma_{t+1}\boldsymbol{\phi}_{t+1}\right)^\top\Big|S_t{=}s\right] \\ &= \sum_s d_\mu(s)\lim_{t\to\infty}\mathbb{E}_\mu\left[\rho_t\left(\gamma_t\lambda_t\mathbf{e}_{t-1} + M_t\boldsymbol{\phi}_t\right)\left(\boldsymbol{\phi}_t - \gamma_{t+1}\boldsymbol{\phi}_{t+1}\right)^\top\Big|S_t{=}s\right] \\ &= \sum_s d_\mu(s)\lim_{t\to\infty}\mathbb{E}_\mu[(\gamma_t\lambda_t\mathbf{e}_{t-1} + M_t\boldsymbol{\phi}_t)|S_t{=}s]\,\mathbb{E}_\mu\left[\rho_t(\boldsymbol{\phi}_t - \gamma_{t+1}\boldsymbol{\phi}_{t+1})^\top\Big|S_t{=}s\right]\end{aligned}$$

(because, given S_t, $\mathbf{e}_{t-1}$ and M_t are independent of $\rho_t(\boldsymbol{\phi}_t - \gamma_{t+1}\boldsymbol{\phi}_{t+1})^\top$)

$$\begin{aligned}&= \sum_s \underbrace{d_\mu(s)\lim_{t\to\infty}\mathbb{E}_\mu[(\gamma_t\lambda_t\mathbf{e}_{t-1} + M_t\boldsymbol{\phi}_t)|S_t{=}s]}_{\mathbf{e}(s)\in\mathbb{R}^n}\mathbb{E}_\mu\left[\rho_k(\boldsymbol{\phi}_k - \gamma_{k+1}\boldsymbol{\phi}_{k+1})^\top\Big|S_k{=}s\right] \\ &= \sum_s \mathbf{e}(s)\mathbb{E}_\pi[\boldsymbol{\phi}_k - \gamma_{k+1}\boldsymbol{\phi}_{k+1}|S_k{=}s]^\top \qquad \text{(by (7))} \\ &= \sum_s \mathbf{e}(s)\left(\boldsymbol{\phi}(s) - \sum_{s'}[\mathbf{P}_\pi]_{ss'}\gamma(s')\boldsymbol{\phi}(s')\right)^\top \\ &= \mathbf{E}(\mathbf{I} - \mathbf{P}_\pi\boldsymbol{\Gamma})\boldsymbol{\Phi}, \qquad (21)\end{aligned}$$

where $\mathbf{E}$ is an $N \times n$ matrix $\mathbf{E}^\top \doteq [\mathbf{e}(1), \cdots, \mathbf{e}(N)]$, and $\mathbf{e}(s) \in \mathbb{R}^n$ is defined by[5]:

$$\begin{aligned}\mathbf{e}(s) &\doteq d_\mu(s)\lim_{t\to\infty}\mathbb{E}_\mu[\gamma_t\lambda_t\mathbf{e}_{t-1} + M_t\boldsymbol{\phi}_t|S_t{=}s] \qquad \text{(assuming this exists)} \\ &= \underbrace{d_\mu(s)\lim_{t\to\infty}\mathbb{E}_\mu[M_t|S_t{=}s]}_{m(s)}\boldsymbol{\phi}(s) + \gamma(s)\lambda(s)d_\mu(s)\lim_{t\to\infty}\mathbb{E}_\mu[\mathbf{e}_{t-1}|S_t{=}s] \\ &= m(s)\boldsymbol{\phi}(s) + \gamma(s)\lambda(s)d_\mu(s)\lim_{t\to\infty}\sum_{\bar{s},\bar{a}}\mathbb{P}\{S_{t-1}{=}\bar{s}, A_{t-1}{=}\bar{a}|S_t{=}s\}\,\mathbb{E}_\mu[\mathbf{e}_{t-1}|S_{t-1}{=}\bar{s}, A_{t-1}{=}\bar{a}]\end{aligned}$$

5. Note that this is a slight abuse of notation; $\mathbf{e}_t$ is a vector random variable, one per time step, and $\mathbf{e}(s)$ is a vector expectation, one per state.

$$\begin{aligned}&= m(s)\boldsymbol{\phi}(s) + \gamma(s)\lambda(s)d_\mu(s)\sum_{\bar{s},\bar{a}}\frac{d_\mu(\bar{s})\mu(\bar{a}|\bar{s})p(s|\bar{s},\bar{a})}{d_\mu(s)}\lim_{t\to\infty}\mathbb{E}_\mu[\mathbf{e}_{t-1}|S_{t-1}{=}\bar{s}, A_{t-1}{=}\bar{a}]\end{aligned}$$

(using the definition of a conditional probability, a.k.a. Bayes rule)

$$\begin{aligned}&= m(s)\boldsymbol{\phi}(s) + \gamma(s)\lambda(s)\sum_{\bar{s},\bar{a}}d_\mu(\bar{s})\mu(\bar{a}|\bar{s})p(s|\bar{s},\bar{a})\frac{\pi(\bar{a}|\bar{s})}{\mu(\bar{a}|\bar{s})}\lim_{t\to\infty}\mathbb{E}_\mu[\gamma_{t-1}\lambda_{t-1}\mathbf{e}_{t-2} + M_{t-1}\boldsymbol{\phi}_{t-1}|S_{t-1}{=}\bar{s}] \\ &= m(s)\boldsymbol{\phi}(s) + \gamma(s)\lambda(s)\sum_{\bar{s}}\left(\sum_{\bar{a}}\pi(\bar{a}|\bar{s})p(s|\bar{s},\bar{a})\right)\mathbf{e}(\bar{s}) \\ &= m(s)\boldsymbol{\phi}(s) + \gamma(s)\lambda(s)\sum_{\bar{s}}[\mathbf{P}_\pi]_{\bar{s}s}\mathbf{e}(\bar{s}).\end{aligned}$$

We now introduce three $N \times N$ diagonal matrices: $\mathbf{M}$, which has the $m(s) \doteq d_\mu(s)\lim_{t\to\infty}\mathbb{E}_\mu[M_t|S_t{=}s]$ on its diagonal; $\boldsymbol{\Gamma}$, which has the $\gamma(s)$ on its diagonal; and $\boldsymbol{\Lambda}$, which has the $\lambda(s)$ on its diagonal. With these we can write the equation above entirely in matrix form, as

$$\begin{aligned}\mathbf{E}^\top &= \boldsymbol{\Phi}^\top\mathbf{M} + \mathbf{E}^\top\mathbf{P}_\pi\boldsymbol{\Gamma}\boldsymbol{\Lambda} \\ &= \boldsymbol{\Phi}^\top\mathbf{M} + \boldsymbol{\Phi}^\top\mathbf{M}\mathbf{P}_\pi\boldsymbol{\Gamma}\boldsymbol{\Lambda} + \boldsymbol{\Phi}^\top\mathbf{M}(\mathbf{P}_\pi\boldsymbol{\Gamma}\boldsymbol{\Lambda})^2 + \cdots \\ &= \boldsymbol{\Phi}^\top\mathbf{M}(\mathbf{I} - \mathbf{P}_\pi\boldsymbol{\Gamma}\boldsymbol{\Lambda})^{-1}.\end{aligned}$$

Finally, combining this equation with (21) we obtain

$$\mathbf{A} = \boldsymbol{\Phi}^\top\mathbf{M}(\mathbf{I} - \mathbf{P}_\pi\boldsymbol{\Gamma}\boldsymbol{\Lambda})^{-1}(\mathbf{I} - \mathbf{P}_\pi\boldsymbol{\Gamma})\boldsymbol{\Phi}, \qquad (22)$$

and through similar steps one can also obtain emphatic TD(λ)'s $\mathbf{b}$ vector,

$$\mathbf{b} = \mathbf{E}\mathbf{r}_\pi = \boldsymbol{\Phi}^\top\mathbf{M}(\mathbf{I} - \mathbf{P}_\pi\boldsymbol{\Gamma}\boldsymbol{\Lambda})^{-1}\mathbf{r}_\pi, \qquad (23)$$

where $\mathbf{r}_\pi$ is the N-vector of expected immediate rewards from each state under π.

Emphatic TD(λ)'s key matrix, then, is $\mathbf{M}(\mathbf{I} - \mathbf{P}_\pi\boldsymbol{\Gamma}\boldsymbol{\Lambda})^{-1}(\mathbf{I} - \mathbf{P}_\pi\boldsymbol{\Gamma})$. To prove that it is positive definite we will follow the same strategy as we did for emphatic TD(0). The first step will be to write the last part of the key matrix in the form of the identity matrix minus a probability matrix. To see how this can be done, consider a slightly different setting in which actions are taken according to π, and in which $1 - \gamma(s)$ and $1 - \lambda(s)$ are considered probabilities of ending by terminating and by bootstrapping, respectively. That is, for any starting state, a trajectory involves a state transition according to $\mathbf{P}_\pi$, possibly terminating according to $\mathbf{I} - \boldsymbol{\Gamma}$, then possibly ending with a bootstrapping event according to $\mathbf{I} - \boldsymbol{\Lambda}$, and then, if neither of these occur, continuing with another state transition and more chances to end, and so on until an ending of one of the two kinds occurs. For any start state $i \in \mathcal{S}$, consider the probability that the trajectory ends in state $j \in \mathcal{S}$ with an ending event of the bootstrapping kind (according to $\mathbf{I} - \boldsymbol{\Lambda}$). Let $\mathbf{P}_\pi^\lambda$ be the matrix with this probability as its

ijth component. This matrix can be written

$$\begin{aligned}
\mathbf{P}_\pi^\lambda &= \mathbf{P}_\pi\mathbf{\Gamma}(\mathbf{I}-\mathbf{\Lambda}) + \mathbf{P}_\pi\mathbf{\Gamma}\mathbf{\Lambda}\mathbf{P}_\pi\mathbf{\Gamma}(\mathbf{I}-\mathbf{\Lambda}) + \mathbf{P}_\pi\mathbf{\Gamma}(\mathbf{\Lambda}\mathbf{P}_\pi\mathbf{\Gamma})^2(\mathbf{I}-\mathbf{\Lambda}) + \cdots \\
&= \left(\sum_{k=0}^{\infty}(\mathbf{P}_\pi\mathbf{\Gamma}\mathbf{\Lambda})^k\right)\mathbf{P}_\pi\mathbf{\Gamma}(\mathbf{I}-\mathbf{\Lambda}) \\
&= (\mathbf{I}-\mathbf{P}_\pi\mathbf{\Gamma}\mathbf{\Lambda})^{-1}\mathbf{P}_\pi\mathbf{\Gamma}(\mathbf{I}-\mathbf{\Lambda}). \\
&= (\mathbf{I}-\mathbf{P}_\pi\mathbf{\Gamma}\mathbf{\Lambda})^{-1}(\mathbf{P}_\pi\mathbf{\Gamma}-\mathbf{P}_\pi\mathbf{\Gamma}\mathbf{\Lambda}) \\
&= (\mathbf{I}-\mathbf{P}_\pi\mathbf{\Gamma}\mathbf{\Lambda})^{-1}(\mathbf{P}_\pi\mathbf{\Gamma}-\mathbf{I}+\mathbf{I}-\mathbf{P}_\pi\mathbf{\Gamma}\mathbf{\Lambda}) \\
&= \mathbf{I}-(\mathbf{I}-\mathbf{P}_\pi\mathbf{\Gamma}\mathbf{\Lambda})^{-1}(\mathbf{I}-\mathbf{P}_\pi\mathbf{\Gamma}),
\end{aligned}$$

or

$$\mathbf{I}-\mathbf{P}_\pi^\lambda = (\mathbf{I}-\mathbf{P}_\pi\mathbf{\Gamma}\mathbf{\Lambda})^{-1}(\mathbf{I}-\mathbf{P}_\pi\mathbf{\Gamma}). \tag{24}$$

It follows then that $\mathbf{M}(\mathbf{I}-\mathbf{P}_\pi^\lambda) = \mathbf{M}(\mathbf{I}-\mathbf{P}_\pi\mathbf{\Gamma}\mathbf{\Lambda})^{-1}(\mathbf{I}-\mathbf{P}_\pi\mathbf{\Gamma})$ is another way of writing emphatic TD(λ)'s key matrix (cf. (22)). This gets us considerably closer to our goal of proving that the key matrix is positive definite. It is now immediate that its diagonal entries are nonnegative and that its off diagonal entries are nonpositive. It is also immediate that its row sums are nonnegative.

There remains what is typically the hardest condition to satisfy: that the column sums of the key matrix are positive. To show this we have to analyze $\mathbf{M}$, and to do that we first analyze the N-vector $\mathbf{f}$ with components $f(s) \doteq d_\mu(s)\lim_{t\to\infty}\mathbb{E}_\mu[F_t|S_t{=}s]$ (we assume that this limit and expectation exist). Analyzing $\mathbf{f}$ will also pay the debt we incurred in Section 4 when we claimed without proof that $\mathbf{f}$ (in the special case treated in that section) was as given by (13). In the general case:

$$\begin{aligned}
f(s) &= d_\mu(s)\lim_{t\to\infty}\mathbb{E}_\mu[F_t|S_t{=}s] \\
&= d_\mu(s)\lim_{t\to\infty}\mathbb{E}_\mu[i(S_t)+\rho_{t-1}\gamma_t F_{t-1}|S_t{=}s] && \text{(by (20))} \\
&= d_\mu(s)i(s) + d_\mu(s)\gamma(s)\lim_{t\to\infty}\sum_{\bar s,\bar a}\mathbb{P}\{S_{t-1}{=}\bar s, A_{t-1}{=}\bar a|S_t{=}s\}\frac{\pi(\bar a|\bar s)}{\mu(\bar a|\bar s)}\mathbb{E}_\mu[F_{t-1}|S_{t-1}{=}\bar s] \\
&= d_\mu(s)i(s) + d_\mu(s)\gamma(s)\sum_{\bar s,\bar a}\frac{d_\mu(\bar s)\mu(\bar a|\bar s)p(s|\bar s,\bar a)}{d_\mu(s)}\frac{\pi(\bar a|\bar s)}{\mu(\bar a|\bar s)}\lim_{t\to\infty}\mathbb{E}_\mu[F_{t-1}|S_{t-1}{=}\bar s] \\
&\quad \text{(using the definition of a conditional probability, a.k.a. Bayes rule)} \\
&= d_\mu(s)i(s) + \gamma(s)\sum_{\bar s,\bar a}\pi(\bar a|\bar s)p(s|\bar s,\bar a)d_\mu(\bar s)\lim_{t\to\infty}\mathbb{E}_\mu[F_{t-1}|S_{t-1}{=}\bar s] \\
&= d_\mu(s)i(s) + \gamma(s)\sum_{\bar s}[\mathbf{P}_\pi]_{\bar s s}f(\bar s).
\end{aligned}$$

This equation can be written in matrix-vector form, letting $\mathbf{i}$ be the N-vector with components $[\mathbf{i}]_s \doteq d_\mu(s)i(s)$:

$$\begin{aligned}
\mathbf{f} &= \mathbf{i} + \mathbf{\Gamma}\mathbf{P}_\pi^\top\mathbf{f} \\
&= \mathbf{i} + \mathbf{\Gamma}\mathbf{P}_\pi^\top\mathbf{i} + (\mathbf{\Gamma}\mathbf{P}_\pi^\top)^2\mathbf{i} + \cdots \\
&= \left(\mathbf{I}-\mathbf{\Gamma}\mathbf{P}_\pi^\top\right)^{-1}\mathbf{i}.
\end{aligned} \tag{25}$$

This proves (13), because there $i(s) \doteq 1, \forall s$ (thus $\mathbf{i} = \mathbf{d}_\mu$), and $\gamma(s) \doteq \gamma, \forall s$.

We are now ready to analyze $\mathbf{M}$, the diagonal matrix with the $m(s)$ on its diagonal:

$$\begin{aligned}
m(s) &= d_\mu(s)\lim_{t\to\infty}\mathbb{E}_\mu[M_t|S_t{=}s] \\
&= d_\mu(s)\lim_{t\to\infty}\mathbb{E}_\mu[\lambda_t\, i(S_t) + (1-\lambda_t)F_t|S_t{=}s] && \text{(by (19))} \\
&= d_\mu(s)\lambda(s)i(s) + (1-\lambda(s))\, f(s),
\end{aligned}$$

or, in matrix-vector form, letting $\mathbf{m}$ be the N-vector with components $m(s)$,

$$\begin{aligned}
\mathbf{m} &= \mathbf{\Lambda}\mathbf{i} + (\mathbf{I}-\mathbf{\Lambda})\mathbf{f} \\
&= \mathbf{\Lambda}\mathbf{i} + (\mathbf{I}-\mathbf{\Lambda})\left(\mathbf{I}-\mathbf{\Gamma}\mathbf{P}_\pi^\top\right)^{-1}\mathbf{i} && \text{(using (25))} \\
&= \left[\mathbf{\Lambda}(\mathbf{I}-\mathbf{\Gamma}\mathbf{P}_\pi^\top) + (\mathbf{I}-\mathbf{\Lambda})\right](\mathbf{I}-\mathbf{\Gamma}\mathbf{P}_\pi^\top)^{-1}\mathbf{i} \\
&= \left(\mathbf{I}-\mathbf{\Lambda}\mathbf{\Gamma}\mathbf{P}_\pi^\top\right)\left(\mathbf{I}-\mathbf{\Gamma}\mathbf{P}_\pi^\top\right)^{-1}\mathbf{i} && (26) \\
&= \left(\mathbf{I}-\mathbf{P}_\pi^{\lambda\top}\right)^{-1}\mathbf{i}. && \text{(using (24))}
\end{aligned}$$

Now we are ready for the final step of the proof, showing that all the columns of the key matrix $\mathbf{M}(\mathbf{I}-\mathbf{P}_\pi^\lambda)$ sum to a positive number. Using the result above, the vector of column sums is

$$\begin{aligned}
\mathbf{1}^\top\mathbf{M}(\mathbf{I}-\mathbf{P}_\pi^\lambda) &= \mathbf{m}^\top(\mathbf{I}-\mathbf{P}_\pi^\lambda) \\
&= \mathbf{i}^\top(\mathbf{I}-\mathbf{P}_\pi^\lambda)^{-1}(\mathbf{I}-\mathbf{P}_\pi^\lambda) \\
&= \mathbf{i}^\top.
\end{aligned}$$

If we further assume that $i(s) > 0, \forall s \in \mathcal{S}$, then the column sums are all positive, the key matrix is positive definite, and emphatic TD(λ) and its expected update are stable. This result can be summarized in the following theorem, the main result of this paper, which we have just proved:

Theorem 1 (Stability of Emphatic TD(λ)) *For any*

- *Markov decision process* $\{S_t, A_t, R_{t+1}\}_{t=0}^\infty$ *with finite state and actions sets* $\mathcal{S}$ *and* $\mathcal{A}$,
- *behavior policy* μ *with a stationary invariant distribution* $d_\mu(s) > 0, \forall s \in \mathcal{S}$,
- *target policy* π *with coverage, i.e., s.t., if* $\pi(a|s) > 0$, *then* $\mu(a|s) > 0$,
- *discount function* $\gamma : \mathcal{S} \to [0,1]$ *s.t.* $\prod_{k=1}^\infty \gamma(S_{t+k}) = 0, w.p.1, \forall t > 0$,
- *bootstrapping function* $\lambda : \mathcal{S} \to [0,1]$,
- *interest function* $i : \mathcal{S} \to (0,\infty)$,
- *feature function* $\boldsymbol{\phi} : \mathcal{S} \to \mathbb{R}^n$ *s.t. the matrix* $\mathbf{\Phi} \in \mathbb{R}^{|\mathcal{S}|\times n}$ *with the* $\boldsymbol{\phi}(s)$ *as its rows has linearly independent columns,*

the $\mathbf{A}$ *matrix of linear emphatic TD(*λ*) (as given by (17–20), and assuming the existence of* $\lim_{t\to\infty}\mathbb{E}[F_t|S_t=s]$ *and* $\lim_{t\to\infty}\mathbb{E}[\mathbf{e}_t|S_t=s]$*,* $\forall s\in\mathcal{S}$*),*

$$\mathbf{A}=\lim_{t\to\infty}\mathbb{E}_\mu[\mathbf{A}_t]=\lim_{t\to\infty}\mathbb{E}_\mu\Big[\mathbf{e}_t\left(\boldsymbol{\phi}_t-\gamma_{t+1}\boldsymbol{\phi}_{t+1}\right)^\top\Big]=\boldsymbol{\Phi}^\top\mathbf{M}(\mathbf{I}-\mathbf{P}_\pi^\lambda)\boldsymbol{\Phi}, \tag{27}$$

is positive definite. Thus the algorithm and its expected update are stable.

As mentioned at the outset, stability is necessary but not always sufficient to guarantee convergence of the parameter vector $\boldsymbol{\theta}_t$. Yu (2015a,b) has recently built on our stability result to show that in fact emphatic TD(λ) converges with probability one under a variety of step-size conditions. Convergence as anticipated is to the unique fixed point $\bar{\boldsymbol{\theta}}$ of the deterministic algorithm (6), in other words, to

$$\mathbf{A}\bar{\boldsymbol{\theta}}=\mathbf{b}\quad\text{ or }\quad\bar{\boldsymbol{\theta}}=\mathbf{A}^{-1}\mathbf{b}. \tag{28}$$

This solution can be characterized as a minimum (in fact, a zero) of the Projected Bellman Error (PBE, Sutton et al. 2009) using the λ-dependent Bellman operator $T^{(\lambda)}:\mathbb{R}^N\to\mathbb{R}^N$ (Tsitiklis & Van Roy 1997) and the weighting of states according to their emphasis. For our general case, we need a version of the $T^{(\lambda)}$ operator extended to state-dependent discounting and bootstrapping. This operator looks ahead to future states to the extent that they are bootstrapped from, that is, according to $\mathbf{P}_\pi^\lambda$, taking into account the reward received along the way. The appropriate operator, in vector form, is

$$T^{(\lambda)}\mathbf{v}\doteq(\mathbf{I}-\mathbf{P}_\pi\boldsymbol{\Gamma}\boldsymbol{\Lambda})^{-1}\mathbf{r}_\pi+\mathbf{P}_\pi^\lambda\mathbf{v}. \tag{29}$$

This operator is a contraction with fixed point $\mathbf{v}=v_\pi$. Recall that our approximate value function is $\boldsymbol{\Phi}\boldsymbol{\theta}$, and thus the difference between $\boldsymbol{\Phi}\boldsymbol{\theta}$ and $T^{(\lambda)}(\boldsymbol{\Phi}\boldsymbol{\theta})$ is a Bellman-error vector. The projection of this with respect to the feature matrix and the emphasis weighting is the emphasis-weighted PBE:

$$\begin{aligned}
\text{PBE}(\boldsymbol{\theta})&\doteq\Pi\left(T^{(\lambda)}(\boldsymbol{\Phi}\boldsymbol{\theta})-\boldsymbol{\Phi}\boldsymbol{\theta}\right)\\
&\doteq\boldsymbol{\Phi}(\boldsymbol{\Phi}^\top\mathbf{M}\boldsymbol{\Phi})^{-1}\boldsymbol{\Phi}^\top\mathbf{M}\left(T^{(\lambda)}(\boldsymbol{\Phi}\boldsymbol{\theta})-\boldsymbol{\Phi}\boldsymbol{\theta}\right) && \text{(see Sutton et al. 2009)}\\
&=\boldsymbol{\Phi}(\boldsymbol{\Phi}^\top\mathbf{M}\boldsymbol{\Phi})^{-1}\boldsymbol{\Phi}^\top\mathbf{M}\left((\mathbf{I}-\mathbf{P}_\pi\boldsymbol{\Gamma}\boldsymbol{\Lambda})^{-1}\mathbf{r}_\pi+\mathbf{P}_\pi^\lambda\boldsymbol{\Phi}\boldsymbol{\theta}-\boldsymbol{\Phi}\boldsymbol{\theta}\right) && \text{(by (29))}\\
&=\boldsymbol{\Phi}(\boldsymbol{\Phi}^\top\mathbf{M}\boldsymbol{\Phi})^{-1}\left(\mathbf{b}+\boldsymbol{\Phi}^\top\mathbf{M}(\mathbf{P}_\pi^\lambda-\mathbf{I})\boldsymbol{\Phi}\boldsymbol{\theta}\right) && \text{(by (23))}\\
&=\boldsymbol{\Phi}(\boldsymbol{\Phi}^\top\mathbf{M}\boldsymbol{\Phi})^{-1}\left(\mathbf{b}-\mathbf{A}\boldsymbol{\theta}\right). && \text{(by (27))}
\end{aligned}$$

From (28), it is immediate that this is vector zero at the fixed point $\bar{\boldsymbol{\theta}}$, thus $\text{PBE}(\bar{\boldsymbol{\theta}})=\mathbf{0}$.

7. Derivation of the Emphasis Algorithm

Emphatic algorithms are based on the idea that if we are updating a state by a TD method, then we should also update each state that it bootstraps from, in direct proportion. For example, suppose we decide to update the estimate at time t with unit emphasis, perhaps because $i(S_t)=1$, and then at time $t+1$ we have $\gamma(S_{t+1})=1$ and $\lambda(S_{t+1})=0$. Because of

the latter, we are fully bootstrapping from the value estimate at $t+1$ and thus we should also make an update of it with emphasis equal to t's emphasis. If instead $\lambda(S_{t+1})=0.5$, then the update of the estimate at $t+1$ would gain a half unit of emphasis, and the remaining half would still be available to allocate to the updates of the estimate at $t+2$ or later times depending on their λs. And of course there may be some emphasis allocated directly updating the estimate at $t+1$ if $i(S_{t+1})>0$. Discounting and importance sampling also have effects. At each step t, if $\gamma(S_t)<1$, then there is some degree of termination and to that extent there is no longer any chance of bootstrapping from later time steps. Another way bootstrapping may be cut off is if $\rho_t=0$ (a complete deviation from the target policy). More generally, if $\rho\neq1$, then the opportunity for bootstrapping is scaled up or down proportionally.

It may seem difficult to work out precisely how each time step's estimates bootstrap from which later states' estimates for all cases. Fortunately, it has already been done. Equation 6 of the paper by Sutton, Mahmood, Precup, and van Hasselt (2014) specifies this in their "forward view" of off-policy TD(λ) with general state-dependent discounting and bootstrapping. From this equation (and their (5)) it is easy to determine the degree to which the update of the value estimate at time k bootstraps from (multiplicatively depends on) the value estimates of each subsequent time t. It is

$$\rho_k\left(\prod_{i=k+1}^{t-1}\gamma_i\lambda_i\rho_i\right)\gamma_t(1-\lambda_t).$$

It follows then that the total emphasis on time t, M_t, should be the sum of this quantity for all times $k<t$, each times the emphasis M_k for those earlier times, plus any intrinsic interest $i(S_t)$ in time t:

$$\begin{aligned}
M_t&\doteq i(S_t)+\sum_{k=0}^{t-1}M_k\rho_k\left(\prod_{i=k+1}^{t-1}\gamma_i\lambda_i\rho_i\right)\gamma_t(1-\lambda_t)\\
&=\lambda_t i(S_t)+(1-\lambda_t)i(S_t)+(1-\lambda_t)\gamma_t\sum_{k=0}^{t-1}\rho_k M_k\prod_{i=k+1}^{t-1}\gamma_i\lambda_i\rho_i\\
&=\lambda_t i(S_t)+(1-\lambda_t)F_t,
\end{aligned}$$

which is (19), where

$$\begin{aligned}
F_t&\doteq i(S_t)+\gamma_t\sum_{k=0}^{t-1}\rho_k M_k\prod_{i=k+1}^{t-1}\gamma_i\lambda_i\rho_i\\
&=i(S_t)+\gamma_t\left(\rho_{t-1}M_{t-1}+\sum_{k=0}^{t-2}\rho_k M_k\prod_{i=k+1}^{t-1}\gamma_i\lambda_i\rho_i\right)\\
&=i(S_t)+\gamma_t\left(\rho_{t-1}M_{t-1}+\rho_{t-1}\lambda_{t-1}\gamma_{t-1}\sum_{k=0}^{t-2}\rho_k M_k\prod_{i=k+1}^{t-2}\gamma_i\lambda_i\rho_i\right)\\
&=i(S_t)+\gamma_t\rho_{t-1}\Bigg(\underbrace{\lambda_{t-1}i(S_{t-1})+(1-\lambda_{t-1})F_{t-1}}_{M_{t-1}}+\lambda_{t-1}\gamma_{t-1}\sum_{k=0}^{t-2}\rho_k M_k\prod_{i=k+1}^{t-2}\gamma_i\lambda_i\rho_i\Bigg)
\end{aligned}$$

$$= i(S_t) + \gamma_t \rho_{t-1} \Bigg(F_{t-1} + \lambda_{t-1} \Bigg(-F_{t-1} + \underbrace{i(S_{t-1}) + \gamma_{t-1} \sum_{k=0}^{t-2} \rho_k M_k \prod_{i=k+1}^{t-2} \gamma_i \lambda_i \rho_i}_{F_{t-1}} \Bigg) \Bigg)$$

$$= i(S_t) + \gamma_t \rho_{t-1} F_{t-1},$$

which is (20), completing the derivation of the emphasis algorithm.

8. Empirical Examples

In this section we present empirical results with example problems that verify and elucidate the formal results already presented. A thorough empirical comparison of emphatic TD(λ) with other methods is beyond the scope of the present article.

The main focus in this paper, as in much previous theory of TD algorithms with function approximation, has been on the stability of the expected update. If an algorithm is unstable, as Q-learning and off-policy TD(λ) are on Baird's (1995) counterexample, then there is no chance of its behaving in a satisfactory manner. On the other hand, even if the update is stable it may be of very high variance. Off-policy algorithms involve products of potentially an infinite number of importance-sampling ratios, which can lead to fluxuations of infinite variance.

As an example of what can happen, let's look again at the $\theta \to 2\theta$ problem shown in Figure 1 (and shown again in the upper left of Figure 3). Consider what happens to F_t in this problem if we have interest only in the first state, and the right action happens to be taken on every step (i.e., $i(S_0) = 1$ then $i(S_t) = 0, \forall t > 0$, and $A_t = \text{right}, \forall t \geq 0$). In this case, from (20),

$$F_t = \rho_{t-1}\gamma_t F_{t-1} + i(S_t) = \prod_{j=0}^{t-1} \rho_j \gamma = (2 \cdot 0.9)^t,$$

which of course goes to infinity as $t \to \infty$. On the other hand, the probability of this specific infinite action sequence is zero, and in fact F_t will rarely take on very high values. In particular, the expected value of F_t remains finite at

$$\begin{aligned} \mathbb{E}_\mu[F_t] &= 0.5 \cdot 2 \cdot 0.9 \cdot \mathbb{E}_\mu[F_{t-1}] + 0.5 \cdot 0 \cdot 0.9 \cdot \mathbb{E}_\mu[F_{t-1}] \\ &= 0.9 \cdot \mathbb{E}_\mu[F_{t-1}] \\ &= 0.9^t, \end{aligned}$$

which tends to zero as $t \to \infty$. Nevertheless, this problem is indeed a difficult case, as the *variance* of F_t *is* infinite:

$$\begin{aligned} \text{Var}[F_t] &= \mathbb{E}\big[F_t^2\big] - (\mathbb{E}[F_t])^2 \\ &= 0.5^t (2^t 0.9^t)^2 - (0.9^t)^2 \\ &= (0.9^2 \cdot 2)^t - (0.9^2)^t \\ &= 1.62^t - 0.81^t, \end{aligned}$$

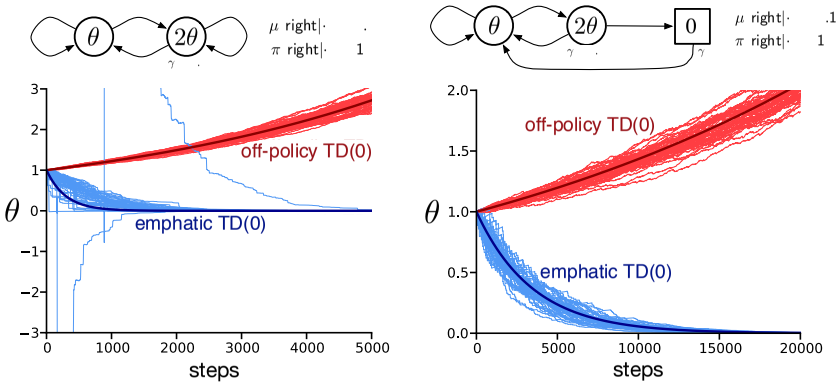

Figure 3: Emphatic TD approaches the correct value of zero, whereas conventional off-policy TD diverges, on fifty trajectories on the $\theta \to 2\theta$ problems shown above each graph. Also shown as a thick line is the trajectory of the deterministic expected-update algorithm (6). On the continuing problem (left) emphatic TD had occasional high variance deviations from zero.

which tends to ∞ as $t \to \infty$.

What does actually happen on this problem? The thin blue lines in Figure 3 (left) show the trajectories of the single parameter θ over time in 50 runs with this problem with $\lambda = 0$ and $\alpha = 0.001$, starting at $\theta = 1.0$. We see that most trajectories of emphatic TD(0) rapidly approached the correct value of $\theta = 0$, but a few made very large steps away from zero and then returned. Because the variance of F_t (and thus of M_t and $\mathbf{e}_t$) grows to infinity as t tends to infinity, there is always a small chance of an extremely large fluxuation taking θ far away from zero. Off-policy TD(0), on the other hand, diverged to infinity in all individual runs.

For comparison, Figure 3 (right) shows trajectories for a $\theta \to 2\theta$ problem in which F_t and all the other variables and their variances are bounded. In this problem, the target policy of selecting right on all steps leads to a soft terminal state ($\gamma(s) = 0$) with fixed value zero, which then transitions back to start again in the leftmost state, as shown in the upper right of the figure. (This is an example of how one can reproduce the conventional notions of terminal state and episode in a soft termination setting.) Here we have chosen the behavior policy to take the action left with probability 0.9, so that its stationary distribution distinctly favors the left state, whereas the target policy would spend equal time in each of the two states. This change increases the variance of the updates, so we used a smaller step size, $\alpha = 0.0001$; other settings were unchanged. Conventional off-policy TD(0) still diverged in this case, but emphatic TD(0) converged reliably to zero.

Finally, Figure 4 shows trajectories for the 5-state example shown earlier (and again in the upper part of the figure). In this case, everything is bounded under the target policy, and both algorithms converged. The emphatic algorithm achieved a lower MSVE in

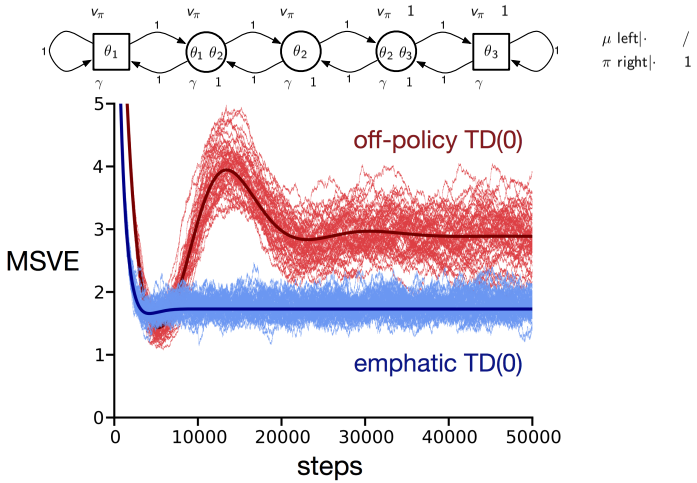

Figure 4: Twenty learning curves and their analytic expectation on the 5-state problem from Section 5, in which excursions terminate promptly and both algorithms converge reliably. Here $\lambda = 0$, $\boldsymbol{\theta}_0 = \mathbf{0}$, $\alpha = 0.001$, and $i(s) = 1, \forall s$. The MSVE performance measure is defined in (15).

this example (nevertheless, we do not mean to claim any general empirical advantage for emphatic TD(λ) at this time).

Also shown in these figures as a thick dark line is the trajectory of the deterministic algorithm: $\bar{\boldsymbol{\theta}}_{t+1} = \bar{\boldsymbol{\theta}}_t + \alpha(\mathbf{b} - \mathbf{A}\bar{\boldsymbol{\theta}}_t)$ (6). Tsitsiklis and Van Roy (1997) argued that, for small step-size parameters and in the steady-state distribution, on-policy TD(λ) follows its expected-update algorithm in an "average" sense, and we see much the same here for emphatic TD(λ).

These examples show that although emphatic TD(λ) is stable for any MDP and all functions λ, γ and (positive) i, for some problems and functions the parameter vector continues to fluxuate with a chance of arbitrarily large deviations (for constant $\alpha > 0$). It is not clear how great of a problem this is. Certainly it is much less of a problem than the positive instability (Baird 1995) that can occur with off-policy TD(λ) (stability of the expected update precludes this). The possibility of large fluxuations may be inherent in any algorithm for off-policy learning using importance sampling with long eligibility traces. For example, the updates of GTD(λ) and GQ(λ) (Maei 2011) with $\lambda = 1$ will tend to infinite variance as $t \to \infty$ on Baird's counterexample and on the example in Figures 1 and 3(left). And, as mentioned earlier, convergence with probability one can still be guaranteed if α is reduced appropriately (Yu 2015a,b).

In practice, however, even when asymptotic convergence can be guaranteed, high variance can be problematic as it may require very small step sizes and slow learning. High

variance frequently arises in off-policy algorithms when they are Monte Carlo algorithms (no TD learning) or they have eligibility traces with high λ (at $\lambda = 1$, TD algorithms become Monte Carlo algorithms). In both cases the root problem is the same: importance sampling ratios that become very large when multiplied together. For example, in the $\theta \to 2\theta$ problem discussed at the beginning of this section, the ratio was only two, but the products of successive twos rapidly produced a very large F_t. Thus, the first way in which variance can be controlled is to ensure that large products cannot occur. We are actually concerned with products of both ρ_ts and γ_ts. Occasional termination ($\gamma_t = 0$), as in the 5-state problem, is thus one reliable way of preventing high variance. Another is through choice of the target and behavior policies that together determine the importance sampling ratios. For example, one could define the target policy to be equal to the behavior policy whenever the followon or eligibility traces exceed some threshold. These tricks can also be done prospectively. White (personal communication) has proposed that the learner compute at each step the variance of what GTD(λ)'s traces would be on the following step. If the variance is in danger of becoming too large, then λ_t is reduced for that step to prevent it. For emphatic TD(λ), the same conditions could be used to adjust γ_t or one of the policies to prevent the variance from growing too large. Another idea for reducing variance is to use *weighted* importance sampling (as suggested by Precup et al. 2001) together with the ideas of Mahmood et al. (2014, 2015a) for extending weighted importance sampling to linear function approximation. Finally, a good solution may even be found by something as simple as bounding the values of F_t or $\mathbf{e}_t$. This would limit variance at the cost of bias, which might be a good tradeoff if done properly (e.g., see Hallak, Tamar, Munos & Mannor 2015).

9. Conclusions and Future Work

We have introduced a way of varying the emphasis or strength of the updates of TD learning algorithms from step to step, based on importance sampling, that should result in much lower variance than previous methods (Precup et al. 2001). In particular, we have introduced the emphatic TD(λ) algorithm and shown that it solves the problem of instability that plagues conventional TD(λ) when applied in off-policy training situations in conjunction with linear function approximation. Compared to gradient-TD methods, emphatic TD(λ) is simpler in that it has a single parameter vector and a single step size rather than two of each. The per-time-step complexities of gradient-TD and emphatic-TD methods are both linear in the number of parameters; both are much simpler than quadratic complexity methods such LSTD(λ) and its off-policy variants. We have also presented a few empirical examples of emphatic TD(0) compared to conventional TD(0) adapted to off-policy training. These examples illustrate some of emphatic TD(λ)'s basic strengths and weaknesses, but a proper empirical comparison with other methods remains for future work. Extensions of the emphasis idea to action-value and control methods such as Sarsa(λ) and Q(λ), to true-online forms (van Seijen & Sutton 2014, Sutton 2015), and to weighted importance sampling (Mahmood et al. 2014, 2015a) are also natural and remain for future work.

Yu (2015a) has recently extended the emphatic idea to a least-squares algorithm and proved that it and our emphatic TD(λ) are convergent with probability one. She has also obtained a stronger result that does not require that the interest be positive in all states,

using an argument similar to that given here about column sums and the Varga (1962) theorem for irreducibly diagonally dominant matrices (Yu 2015a, see also Mahmood et al. 2015b). Yu (2015b) proves convergence for weaker conditions on the step size. Asymptotic bounds on the error of emphatic TD(λ) have been obtained by Hallak et al. (2015).

Two additional ideas for future work deserve special mention.

First, note that the present work has focused on ways of ensuring that the key matrix is positive definite, which implies positive definiteness of the $\mathbf{A}$ matrix and thus that the update is stable. An alternative strategy would be to work directly with the $\mathbf{A}$ matrix. Recall that the $\mathbf{A}$ matrix is vastly smaller than the key matrix; it has a row and column for each *feature*, whereas the key matrix has a row and column for each *state*. It might be feasible then to keep statistics for each row and column of $\mathbf{A}$, whereas of course it would not be feasible for the large key matrix. For example, one might try to use such statistics to directly test for diagonal dominance (and thus positive definiteness) of $\mathbf{A}$. If it were possible to adjust some of the free parameters (e.g., the λ or i functions) to ensure positive definiteness while reducing the variance of F_t, then a substantially improved algorithm might be found.

The second idea for future work is that the emphasis algorithm, by tracing the dependencies among the estimates at various states, is doing something clever that ought to show up as improved bounds on the asymptotic approximation error. The bound given by Tsitsiklis and Van Roy (1997) probably cannot be significantly improved if λ, γ, i, and ρ are all constant, because in this case emphasis asymptotes to a constant that can be absorbed into the step size. But if any of these vary from step to step, then emphatic TD(λ) is genuinely different and may improve over conventional TD(λ). In particular, consider an episodic on-policy case where $i(s) \doteq 1$ and $\lambda(s) \doteq 0$, for all $s \in \mathcal{S}$, and $\gamma(s) \doteq 1$ for all states except for a terminal state where it is zero (and from which a new episode starts). In this case emphasis would increase linearly within an episode to a maximum on the final state, whereas conventional TD(λ) would give equal weight to all steps within the episode. If the feature representation were insufficient to represent the value function exactly, then the emphatic algorithm might improve over the conventional algorithm in terms of asymptotic MSVE (15). Similarly, improvements in asymptotic MSVE over conventional algorithms might be possible whenever i varies from state to state, such as in the common episodic case in which we are interested only in accurately valuing the start state of the episode, and yet we choose $\lambda < 1$ to reduce variance. There may be a wide range of interesting theoretical and empirical work to be done along these lines.

Editor: Kevin Murphy

Abstract

Second-price auctions with reserve play a critical role in the revenue of modern search engine and popular online sites since the revenue of these companies often directly depends on the outcome of such auctions. The choice of the reserve price is the main mechanism through which the auction revenue can be influenced in these electronic markets. We cast the problem of selecting the reserve price to optimize revenue as a learning problem and present a full theoretical analysis dealing with the complex properties of the corresponding loss function. We further give novel algorithms for solving this problem and report the results of several experiments in both synthetic and real-world data demonstrating their effectiveness.

Keywords: Learning Theory, Auctions, Revenue Optimization

1. Introduction

Over the past few years, advertisement has gradually moved away from the traditional printed promotion to the more tailored and directed online publicity. The advantages of online advertisement are clear: since most modern search engine and popular online site companies such as Microsoft, Facebook, Google, eBay, or Amazon may collect information about the users' behavior, advertisers can better target the population sector for which their brand is intended.

More recently, a new method for selling advertisements has gained momentum. Unlike the standard contracts between publishers and advertisers where some amount of impressions are required to be fulfilled by the publisher, an Ad Exchange works in a way similar to a financial exchange where advertisers bid and compete between each other for an ad slot. The winner then pays the publisher and his ad is displayed.

The design of such auctions and their properties are crucial since they generate a large fraction of the revenue of popular online sites. These questions have motivated extensive research on the topic of auctioning in the last decade or so, particularly in the theoretical computer science and economic theory communities. Much of this work has focused on the analysis of mechanism design, either to prove some useful property of an existing auctioning mechanism, to analyze its computational efficiency, or to search for an optimal revenue maximization truthful mechanism (see Muthukrishnan (2009) for a good discussion of key research problems related to Ad Exchange and references to a fast growing literature therein).

One particularly important problem is that of determining an auction mechanism that achieves optimal revenue (Muthukrishnan, 2009). In the ideal scenario where the valuation of the bidders is drawn i.i.d. from a given distribution, this is known to be achievable (see for example (Myerson, 1981)). But, even good approximations of such distributions are not known in practice. Game theoretical approaches to the design of auctions have given a series of interesting results including (Riley and Samuelson, 1981; Milgrom and Weber, 1982; Myerson, 1981; Nisan et al., 2007), all of them based on some assumptions about the distribution of the bidders, e.g., the monotone hazard rate assumption.

The results of these publications have set the basis for most Ad Exchanges in practice: the mechanism widely adopted for selling ad slots is that of a *Vickrey auction* (Vickrey, 1961) or *second-price auction with reserve price* (Easley and Kleinberg, 2010). In such auctions, the winning bidder (if any) pays the maximum of the second-place bid and the reserve price. The reserve price can be set by the publisher or automatically by the exchange. The popularity of these auctions relies on the fact that they are incentive-compatible, i.e., bidders bid exactly what they are willing to pay. It is clear that the revenue of the publisher depends greatly on how the reserve price is set: if set too low, the winner of the auction might end up paying only a small amount, even if his bid was high; on the other hand, if it is set too high, then bidders may not bid higher than the reserve price and the ad slot will not be sold.

We propose a learning approach to the problem of determining the reserve price to optimize revenue in such auctions. The general idea is to leverage the information gained from past auctions to predict a beneficial reserve price. Since every transaction on an Exchange is logged, it is natural to seek to exploit that data. This could be used to estimate the probability distribution of the bidders, which can then be used indirectly to come up with the optimal reserve price (Myerson, 1981; Ostrovsky and Schwarz, 2011). Instead, we will seek a discriminative method making use of the loss function related to the problem and taking advantage of existing user features.

Learning methods have been used in the past for the related problems of designing incentive-compatible auction mechanisms (Balcan et al., 2008; Blum et al., 2004), for algorithmic bidding (Langford et al., 2010; Amin et al., 2012), and even for predicting bid landscapes (Cui et al., 2011). Another closely related problem for which machine learning solutions have been proposed is that of revenue optimization for sponsored search ads and click-through rate predictions (Zhu et al., 2009; He et al., 2013; Devanur and Kakade, 2009). But, to our knowledge, no prior work has used historical data in combination with user features for the sole purpose of revenue optimization in this context. In fact, the only publications we are aware of that are directly related to our objective are (Ostrovsky and Schwarz, 2011) and (Cesa-Bianchi et al., 2013), which considers a more general case than (Ostrovsky and Schwarz, 2011).

The scenario studied by Cesa-Bianchi et al. (2013) is that of censored information, which motivates their use of a regret minimization algorithm to optimize the revenue of the seller. Our analysis assumes instead access to full information. We argue that this is a more realistic scenario since most companies do have access to the full historical data. The learning scenario we consider is also more general since it includes the use of features, as is standard in supervised learning. Since user information is communicated to advertisers and bids are made based on that information, it is only natural to include user features in the formulation of the learning problem. A special case of our analysis coincides with the no-feature scenario considered by Cesa-Bianchi et al. (2013), assuming full information. But, our results further extend those of this paper even in that scenario. In particular, we present an $O(m \log m)$ algorithm for solving a key optimization problem used as a subroutine by these authors, for which they do not seem to give an algorithm. We also do not assume that buyers' bids are sampled i.i.d. from a common distribution. Instead, we only assume that the full outcome of each auction is independent and identically distributed. This subtle distinction makes our scenario closer to reality as it is unlikely for all bidders to follow the same underlying value distribution. Moreover, even though our scenario does not take into account a possible strategic behavior of bidders between rounds, it allows for bidders to be correlated, which is common in practice.

This paper is organized as follows: in Section 2, we describe the setup and give a formal description of the learning problem. We discuss the relations between the scenario we consider and previous work on learning in auctions in Section 3. In particular, we show that, unlike previous work, our problem can be cast as that of minimizing the expected value of a loss function, which is a standard learning problem. Unlike most work in this field, however, the loss function naturally associated to this problem does not admit favorable properties such as convexity or Lipschitz continuity. In fact the loss function is discontinuous. Therefore, the theoretical and algorithmic analysis of this problem raises several non-trivial technical issues. Nevertheless, we use a decomposition of the loss to derive generalization bounds for this problem (see Section 4). These bounds suggest the use of structural risk minimization to determine a learning solution benefiting from strong guarantees. This, however, poses a new challenge: solving a highly non-convex optimization problem. Similar algorithmic problems have been of course previously encountered in the learning literature, most notably when seeking to minimize a regularized empirical 0-1 loss in binary classification. A standard method in machine learning for dealing with such issues consists of resorting to a convex surrogate loss (such as the hinge loss commonly used in linear classification). However, we show in Section 4.2 that no convex loss function is calibrated for the natural loss function for this problem. That is, minimizing a convex surrogate could be detrimental to learning. This fact is further empirically verified in Section 6.

The impossibility results of Section 4.2 prompt us to search for surrogate loss functions with weaker regularity properties such as Lipschitz continuity. We describe a loss function with precisely that property which we further show to be consistent with the original loss. We also provide finite sample learning guarantees for that loss function, which suggest minimizing its empirical value while controlling the complexity

of the hypothesis set. This leads to an optimization problem which, albeit non-convex, admits a favorable decomposition as a difference of two convex functions (DC-programming). Thus, we suggest using the DC-programming algorithm (DCA) introduced by Tao and An (1998) to solve our optimization problem. This algorithm admits favorable convergence guarantees to a *local minimum*. To further improve upon DCA, we propose a combinatorial algorithm to cycle through different local minima with the guarantee of reducing the objective function at every iteration. Finally, in Section 6, we show that our algorithm outperforms several different baselines in various synthetic and real-world revenue optimization tasks.

2. Setup

We start with the description of the problem and our formulation of the learning setup. We study second-price auctions with reserve, the type of auctions adopted in many Ad Exchanges. In such auctions, the bidders submit their bids simultaneously and the winner, if any, pays the maximum of the value of the second-place bid and a reserve price r set by the seller. This type of auctions benefits from the same truthfulness property as second-price auctions (or Vickrey auctions) Vickrey (1961): truthful bidding can be shown to be a dominant strategy in such auctions. The choice of the reserve price r is the only mechanism through which the seller can influence the auction revenue. Its choice is thus critical: if set too low, the amount paid by the winner could be too small; if set too high, the ad slot could be lost. How can we select the reserve price to optimize revenue?

We consider the problem of learning to set the reserve prices to optimize revenue in second-price auctions with reserve. The outcome of an auction can be encoded by the highest and second-highest bids which we denote by a vector $\mathbf{b} = (b^{(1)}, b^{(2)}) \in \mathcal{B} \subset \mathbb{R}^2_+$. We will assume that there exists an upper bound $M \in (0, +\infty)$ for the bids: $\sup_{b \in \mathcal{B}} b^{(1)} = M$. For a given reserve price r and bid pair $\mathbf{b}$, by definition, the revenue of an auction is given by

$$\text{Revenue}(r, \mathbf{b}) = b^{(2)} \mathbb{1}_{r < b^{(2)}} + r \mathbb{1}_{b^{(2)} \leq r \leq b^{(1)}}.$$

We consider the general scenario where a feature vector $\mathbf{x} \in \mathcal{X} \subset \mathbb{R}^N$ is associated with each auction. In the auction theory literature, this feature vector is commonly referred to as *public information*. In the context of online advertisement, this could be for example information about the user's location, gender or age. The learning problem can thus be formulated as that of selecting out of a hypothesis set H of functions mapping $\mathcal{X}$ to $\mathbb{R}$ a hypothesis h with high expected revenue

$$\mathop{\mathbb{E}}_{(\mathbf{x}, \mathbf{b}) \sim D} [\text{Revenue}(h(\mathbf{x}), \mathbf{b})], \tag{1}$$

where D is an unknown distribution according to which pairs $(\mathbf{x}, \mathbf{b})$ are drawn. Instead of the revenue, we will consider a loss function L defined for all $(r, \mathbf{b})$ by $L(r, \mathbf{b}) = -\text{Revenue}(r, \mathbf{b})$, and will equivalently seek a hypothesis h with small expected loss $\mathcal{L}(h) := \mathbb{E}_{(\mathbf{x}, \mathbf{b}) \sim D}[L(h(\mathbf{x}), \mathbf{b})]$. As in standard supervised learning scenarios, we assume access to a training sample $S = ((\mathbf{x}_1, \mathbf{b}_1), \ldots, (\mathbf{x}_m, \mathbf{b}_m))$ of size $m \geq 1$ drawn i.i.d. according to D. We will denote by $\widehat{\mathcal{L}}_S(h)$ the empirical loss $\widehat{\mathcal{L}}_S(h) = \frac{1}{m} \sum_{i=1}^m L(h(\mathbf{x}_i, \mathbf{b}_i))$. Notice that we only assume that the auction outcomes are i.i.d. and not that bidders are independent of each other with the same underlying bid distribution, as in some previous work (Cesa-Bianchi et al., 2013; Ostrovsky and Schwarz, 2011). In the next sections, we will present a detailed study of this learning problem, starting with a review of the related literature.

3. Previous work

Here, we briefly discuss some previous work related to the study of auctions from a learning standpoint. One of the earliest contributions in this literature is that of Blum et al. (2004) where the authors studied a posted-price auction mechanism where a seller offers some good at a certain price and where the buyer decides to either accept that price or reject it. It is not hard to see that this type of auctions is equivalent to second-price auctions with reserve with a single buyer. The authors consider a scenario of repeated interactions with different buyers where the goal is to design an incentive-compatible method of setting prices that is competitive with the best fixed-priced strategy in hindsight. A fixed-price strategy is one that simply offers the same price to all buyers. Using a variant of the EXP3 algorithm of Auer et al. (2002), the authors designed a pricing algorithm achieving a $(1+\epsilon)$-approximation to the best fixed-price strategy. This same scenario was also studied by Kleinberg and Leighton (2003) who gave an online algorithm whose regret after T rounds is in $O(T^{2/3})$.

A step further in the design of optimal pricing strategies was proposed by Balcan et al. (2008). One of the problems considered by the authors was that of setting prices for n buyers in a posted-price auction as a function of their public information. Unlike the on-line scenario of Blum et al. (2004), Balcan et al. (2008) considered a batch scenario where all buyers are known in advance. However, the comparison class considered was no longer that of simple fixed-price strategies but functions mapping public information to prices. This makes the problem more challenging and closer to the scenario we consider. The authors showed that finding a $(1+\epsilon)$-optimal truthful mechanism is equivalent to finding an algorithm to optimize the empirical risk associated to the loss function we consider (in the case $b^{(2)} \equiv 0$). There are multiple connections between this work and our results. In particular, the authors pointed out that the discontinuity and asymmetry of the loss function presented several challenges to their analysis. We will see that, in fact, the same problems appear in the derivation of our learning guarantees. But, we will present an algorithm for minimizing the empirical risk which was a crucial element missing in their results.

A different line of work by Cui et al. (2011) focused on predicting the highest bid of a second-price auction. To estimate the distribution of the highest bid, the authors partitioned the space of advertisers based on their campaign objectives and estimated the distribution for each partition. Within each partition, the distribution of the highest bid was modeled as a mixture of log-normal distributions where the means and standard deviations of the mixtures were estimated as a function of the data features. While it may seem natural to seek to predict the highest bid, we show that this is not necessary and that accurate predictions of the highest bid do not necessarily translate into algorithms achieving large revenue (see Section 6).

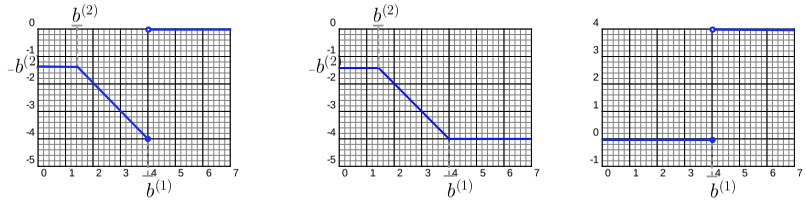
As already mentioned, the closest previous work to ours is that of Cesa-Bianchi et al. (2013), who studied the problem of directly optimizing the revenue under a partial information setting where the learner can only observe the value of the second-highest bid, if it is higher than the reserve price. In particular, the highest bid remains unknown to the learner. This is a natural scenario for auctions such as those of eBay where only the price at which an object is sold is reported. To do so, the authors expressed the expected revenue in terms of the quantity $q(t) = \mathbb{P}[b^{(2)} > t]$. This can be done as follows:

$$\begin{aligned}
\mathop{\mathbb{E}}_{\mathbf{b}}[\text{Revenue}(r, \mathbf{b})] &= \mathop{\mathbb{E}}_{b^{(2)}}[b^{(2)} \mathbb{1}_{r < b^{(2)}}] + r\, \mathbb{P}[b^{(2)} \leq r \leq b^{(1)}] \\
&= \int_0^{+\infty} \mathbb{P}[b^{(2)} \mathbb{1}_{r < b^{(2)}} > t]\, dt + r\, \mathbb{P}[b^{(2)} \leq r \leq b^{(1)}] \\
&= \int_0^{r} \mathbb{P}[r < b^{(2)}]\, dt + \int_r^{\infty} \mathbb{P}[b^{(2)} > t] dt + r\, \mathbb{P}[b^{(2)} \leq r \leq b^{(1)}] \\
&= \int_r^{\infty} \mathbb{P}[b^{(2)} > t]\, dt + r(\mathbb{P}[b^{(2)} > r] + 1 - \mathbb{P}[b^{(2)} > r] - \mathbb{P}[b^{(1)} < r]) \\
&= \int_r^{\infty} \mathbb{P}[b^{(2)} > t]\, dt + r\, \mathbb{P}[b^{(1)} \geq r].
\end{aligned} \tag{2}$$

The main observation of Cesa-Bianchi et al. (2013) was that the quantity $q(t)$ can be estimated from the observed outcomes of previous auctions. Furthermore, if the buyers' bids are i.i.d., then, one can express $\mathbb{P}[b^{(1)} \geq r]$ as a function of the estimated value of $q(r)$. This implies that the right-hand side of (2) can be accurately estimated and therefore an optimal reserve price can be selected. Their algorithm makes calls to a procedure that maximizes the empirical revenue. The authors, however, did not describe an algorithm for that maximization. A by-product of our work is an efficient algorithm for that procedure. The guarantees of Cesa-Bianchi et al. (2013) are similar to those presented in the next section in the special case of learning without features. However, our derivation is different since we consider a batch scenario while Cesa-Bianchi et al. (2013) treated an online setup for which they presented regret guarantees.

4. Learning Guarantees

The problem we consider is an instance of the well known family of supervised learning problems. However, the loss function L does not admit any of the properties such as convexity or Lipschitz continuity often assumed in the analysis of the generalization error, as shown by Figure 1(a). Furthermore, L is discontinuous and, unlike the 0-1 loss function whose discontinuity point is independent of the label, its discontinuity depends on the outcome $\mathbf{b}$ of the auction. Thus, the problem of learning with the loss function L requires a new analysis.



(a) (b)

Figure 1: (a) Plot of the loss function $r \mapsto L(r, \mathbf{b})$ for fixed values of $b^{(1)}$ and $b^{(2)}$; (b) Functions l_1 on the left and l_2 on the right.

4.1 Generalization bound

To analyze the complexity of the family of functions L_H mapping $\mathcal{X} \times \mathcal{B}$ to $\mathbb{R}$ defined by

$$L_H = \{(\mathbf{x}, \mathbf{b}) \mapsto L(h(\mathbf{x}), \mathbf{b}) \colon h \in H\},$$

we decompose L as a sum of two loss functions l_1 and l_2 with more favorable properties than L. We have $L = l_1 + l_2$ with l_1 and l_2 defined for all $(r, \mathbf{b}) \in \mathbb{R} \times \mathcal{B}$ by

$$l_1(r, \mathbf{b}) = -b^{(2)} \mathbb{1}_{r < b^{(2)}} - r \mathbb{1}_{b^{(2)} \leq r \leq b^{(1)}} - b^{(1)} \mathbb{1}_{r > b^{(1)}}$$
$$l_2(r, \mathbf{b}) = b^{(1)} \mathbb{1}_{r > b^{(1)}}.$$

These functions are shown in Figure 1(b). Note that, for a fixed $\mathbf{b}$, the function $r \mapsto l_1(r, \mathbf{b})$ is 1-Lipschitz since the slope of the lines defining the function is at most 1. We will consider the corresponding families of loss functions: $l_{1H} = \{(\mathbf{x}, \mathbf{b}) \mapsto l_1(h(\mathbf{x}), \mathbf{b}) \colon h \in H\}$ and $l_{2H} = \{(\mathbf{x}, \mathbf{b}) \mapsto l_2(h(\mathbf{x}), \mathbf{b}) \colon h \in H\}$ and use the notion of pseudo-dimension as well as those of empirical and average Rademacher complexity to measure their complexities. The pseudo-dimension is a standard complexity measure (Pollard, 1984) extending the notion of VC-dimension to real-valued functions (see also Mohri et al. (2012)). For a family of functions G and finite sample $S = (z_1, \ldots, z_m)$ of size m, the empirical Rademacher complexity is defined by $\widehat{\mathfrak{R}}_S(G) = \mathbb{E}_{\boldsymbol{\sigma}}\left[\sup_{g \in G} \frac{1}{m} \sum_{i=1}^m \sigma_i g(z_i)\right]$, where $\boldsymbol{\sigma} = (\sigma_1, \ldots, \sigma_m)^\top$, with σ_is independent uniform random variables taking values in $\{-1, +1\}$. The Rademacher complexity of G is defined as $\mathfrak{R}_m(G) = \mathbb{E}_{S \sim D^m}[\widehat{\mathfrak{R}}_S(G)]$.

To bound the complexity of L_H, we will first bound the complexity of the family of loss functions l_{1H} and l_{2H}. Since l_1 is 1-Lipschitz, the complexity of the class l_{1H} can be readily bounded by that of H, as shown by the following proposition.

Proposition 1 *For any sample $S = ((\mathbf{x}_1, \mathbf{b}_1), \ldots, (\mathbf{x}_m, \mathbf{b}_m))$, the empirical Rademacher complexity of l_{1H} can be bounded as follows:*

$$\widehat{\mathfrak{R}}_S(l_{1H}) \leq \widehat{\mathfrak{R}}_S(H).$$

Proof By definition of the empirical Rademacher complexity, we can write

$$\widehat{\mathfrak{R}}_S(l_{1H}) = \frac{1}{m} \mathop{\mathbb{E}}_{\boldsymbol{\sigma}}\left[\sup_{h \in H} \sum_{i=1}^m \sigma_i l_1(h(\mathbf{x}_i), \mathbf{b}_i)\right] = \frac{1}{m} \mathop{\mathbb{E}}_{\boldsymbol{\sigma}}\left[\sup_{h \in H} \sum_{i=1}^m \sigma_i (\psi_i \circ h)(\mathbf{x}_i)\right],$$

where, for all $i \in [1, m]$, ψ_i is the function defined by $\psi_i \colon r \mapsto l_1(r, \mathbf{b}_i)$. For any $i \in [1, m]$, ψ_i is 1-Lipschitz, thus, by the contraction lemma of Appendix A (Lemma 14), the following inequality holds:

$$\widehat{\mathfrak{R}}_S(l_{1H}) \leq \frac{1}{m} \mathop{\mathbb{E}}_{\boldsymbol{\sigma}}\left[\sup_{h \in H} \sum_{i=1}^m \sigma_i h(\mathbf{x}_i)\right] = \widehat{\mathfrak{R}}_S(H),$$

which completes the proof. ∎

As shown by the following proposition, the complexity of l_{2H} can be bounded in terms of the pseudo-dimension of H.

Proposition 2 *Let $d = Pdim(H)$ denote the pseudo-dimension of H, then, for any sample $S = ((\mathbf{x}_1, \mathbf{b}_1), \ldots, (\mathbf{x}_m, \mathbf{b}_m))$, the empirical Rademacher complexity of l_{2H} can be bounded as follows:*

$$\widehat{\mathfrak{R}}_S(l_{2H}) \leq M \sqrt{\frac{2d \log \frac{em}{d}}{m}}.$$

Proof By definition of the empirical Rademacher complexity, we can write

$$\widehat{\mathfrak{R}}_S(l_{2H}) = \frac{1}{m} \mathop{\mathbb{E}}_{\boldsymbol{\sigma}}\left[\sup_{h \in H} \sum_{i=1}^m \sigma_i b_i^{(1)} \mathbb{1}_{h(\mathbf{x}_i) > b_i^{(1)}}\right] = \frac{1}{m} \mathop{\mathbb{E}}_{\boldsymbol{\sigma}}\left[\sup_{h \in H} \sum_{i=1}^m \sigma_i \Psi_i(\mathbb{1}_{h(\mathbf{x}_i) > b_i^{(1)}})\right],$$

where, for all $i \in [1, m]$, Ψ_i is the M-Lipschitz function $x \mapsto b_i^{(1)} x$. Thus, by Lemma 14 combined with Massart's lemma (see for example Mohri et al. (2012)), we can write

$$\widehat{\mathfrak{R}}_S(l_{2H}) \leq \frac{M}{m} \mathop{\mathbb{E}}_{\boldsymbol{\sigma}}\left[\sup_{h \in H} \sum_{i=1}^m \sigma_i \mathbb{1}_{h(\mathbf{x}_i) > b_i^{(1)}}\right] \leq M \sqrt{\frac{2d' \log \frac{em}{d'}}{m}},$$

where $d' = \text{VCdim}(\{(\mathbf{x}, \mathbf{b}) \mapsto \mathbb{1}_{h(\mathbf{x}) - b^{(1)} > 0} \colon (\mathbf{x}, \mathbf{b}) \in \mathcal{X} \times \mathcal{B}\})$. Since the second bid component $b^{(2)}$ plays no role in this definition, d' coincides with $\text{VCdim}(\{(\mathbf{x}, b^{(1)}) \mapsto \mathbb{1}_{h(\mathbf{x}) - b^{(1)} > 0} \colon (\mathbf{x}, b^{(1)}) \in \mathcal{X} \times \mathcal{B}_1\})$, where $\mathcal{B}_1$ is the projection of $\mathcal{B} \subseteq \mathbb{R}^2$ onto its first component, and is upper-bounded by $\text{VCdim}(\{(\mathbf{x}, t) \mapsto \mathbb{1}_{h(\mathbf{x}) - t > 0} \colon (\mathbf{x}, t) \in \mathcal{X} \times \mathbb{R}\})$, that is, the pseudo-dimension of H. ∎

Propositions 1 and 2 can be used to derive the following generalization bound for the learning problem we consider.

Theorem 3 *For any $\delta > 0$, with probability at least $1 - \delta$ over the draw of an i.i.d. sample S of size m, the following inequality holds for all $h \in H$:*

$$\mathcal{L}(h) \leq \widehat{\mathcal{L}}_S(h) + 2\mathfrak{R}_m(H) + 2M \sqrt{\frac{2d \log \frac{em}{d}}{m}} + M \sqrt{\frac{\log \frac{1}{\delta}}{2m}}.$$

Proof By a standard property of the Rademacher complexity, since $L = l_1 + l_2$, the following inequality holds: $\mathfrak{R}_m(L_H) \leq \mathfrak{R}_m(l_{1H}) + \mathfrak{R}_m(l_{2H})$. Thus, in view of Propositions 1 and 2, the Rademacher complexity of L_H can be bounded via

$$\mathfrak{R}_m(L_H) \leq \mathfrak{R}_m(H) + M \sqrt{\frac{2d \log \frac{em}{d}}{m}}.$$

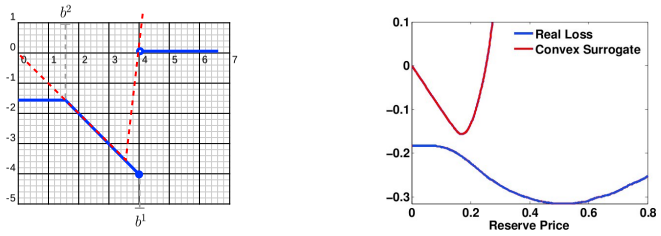
The result then follows by the application of a standard Rademacher complexity bound (Koltchinskii and Panchenko, 2002). ∎

This learning bound invites us to consider an algorithm seeking $h \in H$ to minimize the empirical loss $\widehat{\mathcal{L}}_S(h)$, while controlling the complexity (Rademacher complexity and pseudo-dimension) of the hypothesis set H. In the following section, we discuss the computational problem of minimizing the empirical loss and suggest the use of a surrogate loss leading to a more tractable problem.

4.2 Surrogate Loss

As previously mentioned, the loss function L does not admit most properties of traditional loss functions used in machine learning: for any fixed $\mathbf{b}$, $L(\cdot, \mathbf{b})$ is not differentiable (at two points), it is not convex nor Lipschitz, and in fact it is discontinuous. For any fixed $\mathbf{b}$, $L(\cdot, \mathbf{b})$ is quasi-convex,[1] a property that is often desirable since there exist several solutions for quasi-convex optimization problems. However, in general, a sum of quasi-convex functions, such as the sum $\sum_{i=1}^m L(\cdot, \mathbf{b}_i)$ appearing in the definition of the empirical loss, is not quasi-convex and a fortiori not convex.[2] In general, such a sum may admit exponentially many local minima. This leads us to seek a surrogate loss function with more favorable optimization properties.

1. A function $f \colon \mathbb{R} \to \mathbb{R}$ is said to be *quasi-convex* if for any $\alpha \in \mathbb{R}$ the sub-level set $\{x \colon f(x) \leq \alpha\}$ is convex.
2. It is known that, under some separability condition, if a finite sum of quasi-convex functions on an open convex set is quasi-convex, then all but perhaps one of them is convex (Debreu and Koopmans, 1982).



(a) (b)

Figure 2: (a) Piecewise linear convex surrogate loss L_p. (b) Comparison of the sum of real losses $\sum_{i=1}^m L(\cdot, \mathbf{b}_i)$ for $m = 500$ with the sum of convex surrogate losses. Note that the minimizers are significantly different.

A standard method in machine learning consists of replacing the loss function L with a convex upper bound (Bartlett et al., 2006). A natural candidate in our case is the piecewise linear function L_p shown in Figure 2(a). While this is a convex loss function, and thus convenient for optimization, it is not calibrated. That is, it is possible for $r_p \in \operatorname{argmin} \mathbb{E}_{\mathbf{b}}[L_p(r, \mathbf{b})]$ to have a large expected true loss. Therefore, it does not provide us with a useful surrogate. The calibration problem is illustrated by Figure 2(b) in dimension one, where the true objective function to be minimized $\sum_{i=1}^m L(r, \mathbf{b}_i)$ is compared with the sum of the surrogate losses. The next theorem shows that this problem affects *any* non-constant convex surrogate. It is expressed in terms of the loss $\widetilde{L}\colon \mathbb{R} \times \mathbb{R}_+ \to \mathbb{R}$ defined by $\widetilde{L}(r, b) = -r\mathbb{1}_{r \le b}$, which coincides with L when the second bid is 0.

Definition 4 *We say that a function $L_c\colon [0, M] \times [0, M] \to \mathbb{R}$ is* consistent with $\widetilde{L}$ *if, for any distribution D, there exists a minimizer $r^* \in \operatorname{argmin}_r \mathbb{E}_{b\sim D}[L_c(r, b)]$ such that $r^* \in \operatorname{argmin}_r \mathbb{E}_{b\sim D}[\widetilde{L}(r, b)]$.*

Definition 5 *We say that a sequence of functions $(L_n)_{n\in\mathbb{N}}$ mapping $[0, M] \times [0, M]$ to $\mathbb{R}$ is* weakly consistent with $\widetilde{L}$ *if there exists a sequence $(r_n)_{n\in\mathbb{N}}$ in $\mathbb{R}$ with $r_n \in \operatorname{argmin}_r \mathbb{E}_{b\sim D}[L_n(r, b)]$ for all $n \in \mathbb{N}$ such that $\lim_{n\to+\infty} r_n = r^*$ with $r^* \in \operatorname{argmin} \mathbb{E}_{b\sim D}[\widetilde{L}(r, b)]$.*

Proposition 6 (Convex surrogates) *Let $L_c\colon [0, M] \times [0, M] \to \mathbb{R}$ be a bounded function, convex with respect to its first argument. If L_c is consistent with $\widetilde{L}$, then $L_c(\cdot, b)$ is constant for any $b \in [0, M]$.*

Proof The idea behind the proof is the following: for any two bids $b_1 < b_2$, there exists a distribution D with support $\{b_1, b_2\}$ such that $\mathbb{E}_{b\sim D}[\widetilde{L}(r, b)]$ is minimized at both $r = b_1$ and $r = b_2$. We show this implies that $\mathbb{E}_{b\sim D}[L_c(r, b)]$ must attain a minimum at both points too. By convexity of L_c, it follows that $\mathbb{E}_{b\sim D}[L_c(r, b)]$ must be constant on the interval $[b_1, b_2]$. The main part of the proof will be showing that this implies that the function $L_c(\cdot, b_1)$ must also be constant on the interval $[b_1, b_2]$. Finally, since the value of b_2 was chosen arbitrarily, it will follow that $L_c(\cdot, b_1)$ is constant.

Let $0 < b_1 < b_2 < M$ and, for any $\mu \in [0, 1]$, let D_μ denote the probability distribution with support included in $\{b_1, b_2\}$ defined by $D_\mu(b_1) = \mu$ and let $\mathbb{E}_\mu$ denote the expectation with respect to this distribution. A straightforward calculation shows that the unique minimizer of $\mathbb{E}_\mu[\widetilde{L}(r, b)]$ is given by b_2 if $\mu > \frac{b_2 - b_1}{b_2}$ and by b_1 if $\mu < \frac{b_2 - b_1}{b_2}$. Therefore, if $F_\mu(r) = \mathbb{E}_\mu[L_c(r, b)]$, it must be the case that b_2 is a minimizer of F_μ for $\mu > \frac{b_2 - b_1}{b_2}$ and b_1 is a minimizer of F_μ for $\mu < \frac{b_2 - b_1}{b_2}$.

For a convex function $f\colon \mathbb{R} \to \mathbb{R}$, we denote by f^- its left-derivative and by f^+ its right-derivative, which are guaranteed to exist. We will also denote here, for any $b \in \mathbb{R}$, by $g^-(\cdot, b)$ and $g^+(\cdot, b)$ the left- and right-derivatives of the function $g(\cdot, b)$ and by $g'(\cdot, b)$ its derivative, when it exists. Recall that for a convex function f, if x_0 is a minimizer, then $f^-(x_0) \le 0 \le f^+(x_0)$. In view of that and the minimizing properties

of b_1 and b_2, the following inequalities hold:

$$0 \ge F_\mu^-(b_2) = \mu L_c^-(b_2, b_1) + (1 - \mu) L_c^-(b_2, b_2) \qquad \text{for } \mu > \frac{b_2 - b_1}{b_2}, \tag{3}$$

$$0 \le F_\mu^+(b_1) \le F_\mu^-(b_2) \qquad \text{for } \mu < \frac{b_2 - b_1}{b_2}, \tag{4}$$

where the second inequality in (4) holds by convexity of F_μ and the fact that $b_1 < b_2$. By setting $\mu = \frac{b_2 - b_1}{b_2}$, it follows from inequalities (3) and (4) that $F_\mu^-(b_2) = 0$ and $F_\mu^+(b_1) = 0$. By convexity of F_μ, it follows that F_μ is constant on the interval (b_1, b_2). We now show this may only happen if $L_c(\cdot, b_1)$ is also constant. By rearranging terms in (3) and plugging in the expression of μ, we obtain the equivalent condition

$$(b_2 - b_1) L_c^-(b_2, b_1) = -b_1 L_c^-(b_2, b_2).$$

Since L_c is a bounded function, it follows that $L_c^-(b_2, b_1)$ is bounded for any $b_1, b_2 \in (0, M)$, therefore as $b_1 \to b_2$ we must have $b_2 L_c^-(b_2, b_2) = 0$, which implies $L_c^-(b_2, b_2) = 0$ for all $b_2 > 0$. In view of this, inequality (3) may only be satisfied if $L_c^-(b_2, b_1) \le 0$. However, the convexity of L_c implies $L_c^-(b_2, b_1) \ge L_c^-(b_1, b_1) = 0$. Therefore, $L_c^-(b_2, b_1) = 0$ must hold for all $b_2 > b_1 > 0$. Similarly, by definition of F_μ, the first inequality in (4) implies

$$\mu L_c^+(b_1, b_1) + (1 - \mu) L_c^+(b_1, b_2) \ge 0. \tag{5}$$

Nevertheless, for any $b_2 > b_1$ we have $0 = L_c^-(b_1, b_1) \le L_c^+(b_1, b_1) \le L_c^-(b_2, b_1) = 0$. Consequently, $L_c^+(b_1, b_1) = 0$ for all $b_1 > 0$. Furthermore, $L_c^+(b_1, b_2) \le L_c^+(b_2, b_2) = 0$. Therefore, for inequality (5) to be satisfied, we must have $L_c^+(b_1, b_2) = 0$ for all $b_1 < b_2$.

Thus far, we have shown that for any $b > 0$, if $r \ge b$, then $L_c^-(r, b) = 0$, while $L_c^+(r, b) = 0$ for $r \le b$. A simple convexity argument shows that $L_c(\cdot, b)$ is then differentiable and $L_c'(r, b) = 0$ for all $r \in (0, M)$, which in turn implies that $L_c(\cdot, b)$ is a constant function. ∎

The result of the previous proposition can be considerably strengthened, as shown by the following theorem. As in the proof of the previous proposition, to simplify the notation, for any $b \in \mathbb{R}$, we will denote by $g'(\cdot, b)$ the derivative of a differentiable function $g(\cdot, b)$.

Theorem 7 *Let $(L_n)_{n\in\mathbb{N}}$ denote a sequence of functions mapping $[0, M] \times [0, M]$ to $\mathbb{R}$ that are convex and differentiable with respect to their first argument and satisfy the following conditions:*

- $\sup_{b\in[0,M], n\in\mathbb{N}} \max(|L_n'(0, b)|, |L_n'(M, b)| = K < \infty$*;*
- $(L_n)_n$ *is weakly consistent with $\widetilde{L}$;*
- $L_n(0, b) = 0$ *for all $n \in \mathbb{N}$ and for all b.*

If the sequence $(L_n)_n$ converges pointwise to a function L_c, then $L_n(\cdot, b)$ converges uniformly to $L_c(\cdot, b) \equiv 0$.

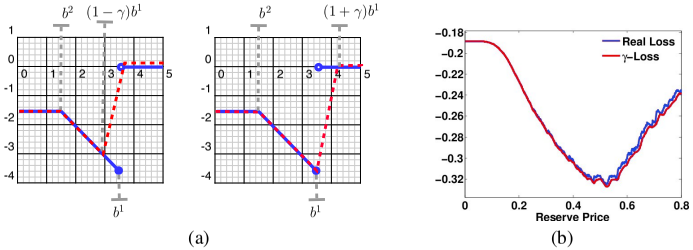
We defer the proof of this theorem to Appendix B and present here only a sketch of the proof. We first show that the convexity of the functions L_n implies that the convergence to L_c must be uniform and that L_c is convex with respect to its first argument. This fact and the weak consistency of the sequence L_n will then imply that L_c is consistent with $\widetilde{L}$ and therefore must be constant by Proposition 6.

The theorem just presented shows that even a weakly consistent sequence of convex losses is uniformly close to a constant function and therefore not helpful to tackle the learning task we consider. This suggests searching for surrogate losses that admit weaker regularity assumptions such as Lipschitz continuity.

Perhaps, the most natural surrogate loss function is then $\overline{L}_\gamma$, an upper bound on L defined for all $\gamma > 0$ by:

$$\overline{L}_\gamma(r, \mathbf{b}) = -b^{(2)}\mathbb{1}_{r \le b^{(2)}} - r\mathbb{1}_{b^{(2)} < r \le \left((1-\gamma)b^{(1)}\right) \vee b^{(2)}} + \left(\frac{1-\gamma}{\gamma} \vee \frac{b^{(2)}}{b^{(1)} - b^{(2)}}\right)(r - b^{(1)})\mathbb{1}_{\left((1-\gamma)b^{(1)}\right) \vee b^{(2)} < r \le b^{(1)}},$$

where $c \vee d = \max(c, d)$. The plot of this function is shown in Figure 3(a). The max terms ensure that the function is well defined if $(1 - \gamma)b^{(1)} < b^{(2)}$. However, this turns out to be also a poor choice as $\overline{L}_\gamma$ is a loose



(a) (b)

Figure 3: (a) Comparison of the true loss L with surrogate loss $\overline{L}_\gamma$ on the left and surrogate loss L_γ on the right, for $\gamma = 0.1$. (b) Comparison of $\sum_{i=1}^{500} L(r, \mathbf{b}_i)$ and $\sum_{i=1}^{500} L_\gamma(r, \mathbf{b}_i)$

upper bound on L in the most critical region, that is around the minimum of the loss L. Thus, instead, we will consider, for any $\gamma > 0$, the loss function L_γ defined as follows:

$$L_\gamma(r, \mathbf{b}) = -b^{(2)} \mathbb{1}_{r \leq b^{(2)}} - r \mathbb{1}_{b^{(2)} < r \leq b^{(1)}} + \frac{1}{\gamma}(r - (1+\gamma)b^{(1)}) \mathbb{1}_{b^{(1)} < r \leq (1+\gamma)b^{(1)}}, \tag{6}$$

whose plot is shown in Figure 3(a).[3] A comparison between the sum of L-losses and the sum of L_γ-losses is shown in Figure 3(b). Observe that the fit is considerably better than that of the piecewise linear convex surrogate loss shown in Figure 2(b). A possible concern associated with the loss function L_γ is that it is a lower bound for L. One might think then that minimizing it would not lead to an informative solution. However, we argue that this problem arises significantly with upper bounding losses such as the convex surrogate, which we showed not to lead to a useful minimizer, or $\overline{L}_\gamma$, which is a poor approximation of L near its minimum. By matching the original loss L in the region of interest, around the minimal value, the loss function L_γ leads to more informative solutions for this problem. In fact, we show that that the expected loss $\mathcal{L}_\gamma(h) \colon = \mathbb{E}_{\mathbf{x},\mathbf{b}}[L_\gamma(h)]$ admits a minimizer close to the minimizer of $\mathcal{L}(h)$. Since $L_\gamma \to L$ as $\gamma \to 0$, this result may seem trivial. However, this convergence is not uniform and therefore calibration is not guaranteed.

Theorem 8 *Let H be a closed, convex subset of a linear space of functions containing 0. Then, the following inequality holds for all $\gamma \geq 0$:*

$$\mathcal{L}(h^*_\gamma) - \mathcal{L}_\gamma(h^*_\gamma) \leq \gamma M.$$

Notice that, since $L \geq L_\gamma$ for all $\gamma \geq 0$, the theorem implies that $\lim_{\gamma \to 0} \mathcal{L}(h^*_\gamma) = \mathcal{L}(h^*)$. Indeed, let h^* denote the best-in-class hypothesis for the loss function L. Then, the following straightforward inequalities hold:

$$\begin{aligned}\mathcal{L}(h^*) &\leq \mathcal{L}(h^*_\gamma) \\ &\leq \mathcal{L}_\gamma(h^*_\gamma) + \gamma M \\ &\leq \mathcal{L}_\gamma(h^*) + \gamma M \leq \mathcal{L}(h^*) + \gamma M.\end{aligned}$$

By letting $\gamma \to 0$, we see that $\mathcal{L}(h^*_\gamma) \to \mathcal{L}(h^*)$. This is a remarkable result as it not only provides a convergence guarantee, but it also gives us an explicit rate of convergence. We will later exploit this fact to derive an optimal choice for γ.

The proof of Theorem 8 is based on the following partitioning of $\mathcal{X} \times \mathcal{B}$ in four regions where L_γ is defined as an affine function:

$$\begin{aligned} I_1 &= \{(\mathbf{x}, \mathbf{b}) | h^*_\gamma(\mathbf{x}) \leq b^{(2)}\} & I_2 &= \{(\mathbf{x}, \mathbf{b}) | h^*_\gamma(\mathbf{x}) \in (b^{(2)}, b^{(1)}]\} \\ I_3 &= \{(\mathbf{x}, \mathbf{b}) | h^*_\gamma(\mathbf{x}) \in (b^{(1)}, (1+\gamma)b^{(1)}]\} & I_4 &= \{(\mathbf{x}, \mathbf{b}) | h^*_\gamma(\mathbf{x}) > (1+\gamma)b^{(1)}\}, \end{aligned}$$

3. Technically, the theoretical and algorithmic results we present for L_γ could be developed in a somewhat similar way for $\overline{L}_\gamma$.

Notice that L_γ and L differ only on I_3. Therefore, we only need to bound the measure of this set which can be done as in Lemma 15 (see Appendix C).

Proof [Theorem 8]. We can express the difference as

$$\begin{aligned}\mathop{\mathbb{E}}_{\mathbf{x},\mathbf{b}}\left[L(h^*_\gamma(\mathbf{x}), \mathbf{b}) - L_\gamma(h^*_\gamma(\mathbf{x}), \mathbf{b})\right] &= \sum_{k=1}^{4} \mathop{\mathbb{E}}_{\mathbf{x},\mathbf{b}}\left[(L(h^*_\gamma(\mathbf{x}), \mathbf{b}) - L_\gamma(h^*_\gamma(\mathbf{x}), \mathbf{b})) \mathbb{1}_{I_k}(\mathbf{x}, \mathbf{b})\right] \\ &= \mathop{\mathbb{E}}_{\mathbf{x},\mathbf{b}}\left[(L(h^*_\gamma(\mathbf{x}), \mathbf{b}) - L_\gamma(h^*_\gamma(\mathbf{x}), \mathbf{b})) \mathbb{1}_{I_3}(\mathbf{x}, \mathbf{b})\right] \\ &= \mathop{\mathbb{E}}_{\mathbf{x},\mathbf{b}}\left[\frac{1}{\gamma}((1+\gamma)b^{(1)} - h^*_\gamma(\mathbf{x})) \mathbb{1}_{I_3}(\mathbf{x}, \mathbf{b}))\right]. \end{aligned} \tag{7}$$

Furthermore, for $(\mathbf{x}, \mathbf{b}) \in I_3$, we know that $b^{(1)} < h^*_\gamma(\mathbf{x})$. Thus, we can bound (7) by $\mathbb{E}_{\mathbf{x},\mathbf{b}}[h^*_\gamma(\mathbf{x}) \mathbb{1}_{I_3}(\mathbf{x}, \mathbf{b})]$, which, by Lemma 15 in Appendix C, is upper bounded by $\gamma \mathbb{E}_{\mathbf{x},\mathbf{b}}\left[h^*_\gamma(\mathbf{x}) \mathbb{1}_{I_2}(\mathbf{x}, \mathbf{b})\right]$. Thus, the following inequalities hold:

$$\mathop{\mathbb{E}}_{\mathbf{x},\mathbf{b}}\left[L(h^*_\gamma(\mathbf{x}), \mathbf{b})\right] - \mathop{\mathbb{E}}_{\mathbf{x},\mathbf{b}}\left[L_\gamma(h^*_\gamma(\mathbf{x}), \mathbf{b})\right] \leq \gamma \mathop{\mathbb{E}}_{\mathbf{x},\mathbf{b}}\left[h^*_\gamma(\mathbf{x}) \mathbb{1}_{I_2}(\mathbf{x}, \mathbf{b})\right] \leq \gamma \mathop{\mathbb{E}}_{\mathbf{x},\mathbf{b}}\left[b^{(1)} \mathbb{1}_{I_2}(\mathbf{x}, \mathbf{b})\right] \leq \gamma M,$$

using the fact that $h^*_\gamma(\mathbf{x}) \leq b^{(1)}$ for $(\mathbf{x}, \mathbf{b}) \in I_2$. ■

The $1/\gamma$-Lipschitzness of L_γ can be used to prove the following generalization bound.

Theorem 9 *Fix $\gamma \in (0, 1]$ and let S denote a sample of size m. Then, for any $\delta > 0$, with probability at least $1 - \delta$ over the choice of the sample S, for all $h \in H$, the following holds:*

$$\mathcal{L}_\gamma(h) \leq \widehat{\mathcal{L}}_\gamma(h) + \frac{2}{\gamma}\mathfrak{R}_m(H) + M\sqrt{\frac{\log \frac{1}{\delta}}{2m}}. \tag{8}$$

Proof Let $L_{\gamma,H}$ denote the family of functions $\{(\mathbf{x}, \mathbf{b}) \to L_\gamma(h(\mathbf{x}), b) \colon h \in H\}$. The loss function L_γ is $\frac{1}{\gamma}$-Lipschitz since the slope of the lines defining it is at most $\frac{1}{\gamma}$. Thus, using the contraction lemma (Lemma 14) as in the proof of Proposition 1, gives $\mathfrak{R}_m(L_{\gamma,H}) \leq \frac{1}{\gamma}\mathfrak{R}_m(H)$. The application of a standard Rademacher complexity bound to the family of functions $L_{\gamma,H}$ then shows that for any $\delta > 0$, with probability at least $1 - \delta$, for any $h \in H$, the following holds:

$$\mathcal{L}_\gamma(h) \leq \widehat{\mathcal{L}}_\gamma(h) + \frac{2}{\gamma}\mathfrak{R}_m(H) + M\sqrt{\frac{\log \frac{1}{\delta}}{2m}}.$$

■

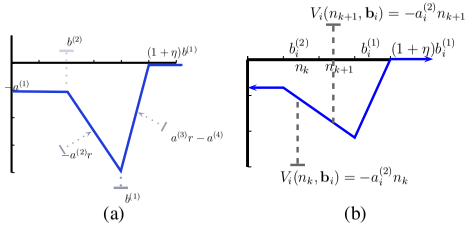
We conclude this section by showing that L_γ admits a stronger form of consistency. More precisely, we prove that the generalization error of the best-in-class hypothesis $\mathcal{L}^* := \mathcal{L}(h^*)$ can be lower bounded in terms of that of the empirical minimizer of L_γ, $\widehat{h}_\gamma \colon = \operatorname{argmin}_{h \in H} \widehat{\mathcal{L}}_\gamma(h)$.

Theorem 10 *Let $M = \sup_{b \in \mathcal{B}} b^{(1)}$ and let H be a hypothesis set with pseudo-dimension $d = Pdim(H)$. Then, for any $\delta > 0$ and a fixed value of $\gamma > 0$, with probability at least $1 - \delta$ over the choice of a sample S of size m, the following inequality holds:*

$$\mathcal{L}^* \leq \mathcal{L}(\widehat{h}_\gamma) \leq \mathcal{L}^* + \frac{2\gamma + 2}{\gamma}\mathfrak{R}_m(H) + \gamma M + 2M\sqrt{\frac{2d \log \frac{em}{d}}{m}} + 2M\sqrt{\frac{\log \frac{2}{\delta}}{2m}}.$$

Proof By Theorem 3, with probability at least $1 - \delta/2$, the following holds:

$$\mathcal{L}(\widehat{h}_\gamma) \leq \widehat{\mathcal{L}}_S(\widehat{h}_\gamma) + 2\mathfrak{R}_m(H) + 2M\sqrt{\frac{2d \log \frac{em}{d}}{m}} + M\sqrt{\frac{\log \frac{2}{\delta}}{2m}}. \tag{9}$$



(a) (b)

Figure 4: (a) Prototypical v-function. (b) Illustration of the fact that the definition of $V_i(r, \mathbf{b}_i)$ does not change on an interval $[n_k, n_{k+1}]$.

Applying Lemma 15 with the empirical distribution induced by the sample, we can bound $\widehat{\mathcal{L}}_S(\widehat{h}_\gamma)$ by $\widehat{\mathcal{L}}_\gamma(\widehat{h}_\gamma) + \gamma M$. The first term of the previous expression is less than $\widehat{\mathcal{L}}_\gamma(h^*_\gamma)$ by definition of $\widehat{h}_\gamma$. Moreover, the same analysis used in the proof of Theorem 9 shows that with probability $1 - \delta/2$,

$$\widehat{\mathcal{L}}_\gamma(h^*_\gamma) \leq \mathcal{L}_\gamma(h^*_\gamma) + \frac{2}{\gamma}\mathfrak{R}_m(H) + M\sqrt{\frac{\log \frac{2}{\delta}}{2m}}.$$

Finally, by definition of h^*_γ and using the fact that L is an upper bound on L_γ, we can write $\mathcal{L}_\gamma(h^*_\gamma) \leq \mathcal{L}_\gamma(h^*) \leq \mathcal{L}(h^*)$. Thus,

$$\widehat{\mathcal{L}}_S(\widehat{h}_\gamma) \leq \mathcal{L}(h^*) + \frac{2}{\gamma}\mathfrak{R}_m(H) + M\sqrt{\frac{\log \frac{2}{\delta}}{2m}} + \gamma M.$$

Replacing this inequality in (9) and applying the union bound yields the result. ■

This bound can be extended to hold uniformly over all γ at the price of a term in $O\Big(\frac{\sqrt{\log \log_2 \frac{1}{\gamma}}}{\sqrt{m}}\Big)$. Thus, for appropriate choices of γ as a function of m (for instance $\gamma = 1/m^{1/4}$) we can guarantee the convergence of $\mathcal{L}(\widehat{h}_\gamma)$ to $\mathcal{L}^*$, a stronger form of consistency (See Appendix C).

These results are reminiscent of the standard margin bounds with γ playing the role of a margin. The situation here is however somewhat different. Our learning bounds suggest, for a fixed $\gamma \in (0, 1]$, to seek a hypothesis h minimizing the empirical loss $\widehat{\mathcal{L}}_\gamma(h)$ while controlling a complexity term upper bounding $\mathfrak{R}_m(H)$, which in the case of a family of linear hypotheses could be $\|h\|^2_K$ for some PSD kernel K. Since the bound can hold uniformly for all γ, we can use it to select γ out of a finite set of possible grid search values. Alternatively, γ can be set via cross-validation. In the next section, we present algorithms for solving this regularized empirical risk minimization problem.

5. Algorithms

In this section, we show how to minimize the empirical risk under two regimes: first we analyze the no-feature scenario considered in Cesa-Bianchi et al. (2013) and then we present an algorithm to solve the more general feature-based revenue optimization problem.

5.1 No-Feature Case

We now present a general algorithm to optimize sums of functions similar to L_γ or L in the one-dimensional case.

Definition 11 *We will say that function* $V \colon \mathbb{R} \times \mathcal{B} \to \mathbb{R}$ *is a* v-function *if it admits the following form:*

$$V(r, \mathbf{b}) = -a^{(1)}\mathbb{1}_{r \leq b^{(2)}} - a^{(2)} r \mathbb{1}_{b^{(2)} < r \leq b^{(1)}} + (a^{(3)} r - a^{(4)})\mathbb{1}_{b^{(1)} < r < (1+\eta)b^{(1)}},$$

with $a^{(1)} > 0$ *and* $\eta > 0$ *constants and* $a^{(2)}, a^{(3)}, a^{(4)}$ *defined by* $a^{(1)} = \eta a^{(3)} b^{(2)}$, $a^{(2)} = \eta a^{(3)}$, *and* $a^{(4)} = a^{(3)}(1+\eta)b^{(1)}$.

Figure 4(a) illustrates this family of loss functions. A v-function is a generalization of L_γ and L. Indeed, any v-function V satisfies $V(r, \mathbf{b}) \leq 0$ and attains its minimum at $b^{(1)}$. Finally, as can be seen straightforwardly from Figure 3, L_γ is a v-function for any $\gamma > 0$. We consider the following general problem of minimizing a sum of v-functions:

$$\min_{r \geq 0} F(r) := \sum_{i=1}^{m} V_i(r, \mathbf{b}_i). \tag{10}$$

Observe that this is not a trivial problem since, for any fixed $\mathbf{b}_i$, $V_i(\cdot, \mathbf{b}_i)$ is non-convex and that, in general, a sum of m such functions may admit many local minima. Of course, we can seek a solution that is ϵ-close to the optimal reserve via a grid search over points $r_i = i\epsilon$. However, the guarantees for that algorithm would depend on the continuity of the function. In particular, this algorithm might fail for the loss L. Instead, we exploit the particular structure of a v-function to exactly minimize F. The following proposition, which is proven in Appendix D, shows that the minimum is attained at one of the highest bids, which matches the intuition. Notice that for the loss function L this is immediate since if r is not a highest bid, one can raise the reserve price without increasing any of the component losses.

Proposition 12 *Problem* (10) *admits a solution* r^* *that satisfies* $r^* = b_i^{(1)}$ *for some* $i \in [1, m]$.

Problem (10) can thus be reduced to examining the value of the function for the m arguments $b_i^{(1)}$, $i \in [1, m]$. This yields a straightforward method for solving the optimization which consists of computing $F(b_i^{(1)})$ for all i and taking the minimum. But, since the computation of each $F(b_i^{(1)})$ takes $O(m)$, the overall computational cost is in $O(m^2)$, which can be prohibitive for even moderately large values of m.

Instead, we present a combinatorial algorithm to solve the optimization problem (10) in $O(m \log m)$. Let $\mathcal{N} = \bigcup_i \{b_i^{(1)}, b_i^{(2)}, (1+\eta)b_i^{(1)}\}$ denote the set of all *boundary points* associated with the functions $V(\cdot, \mathbf{b}_i)$. The algorithm proceeds as follows: first, sort the set $\mathcal{N}$ to obtain the ordered sequence $(n_1, \ldots, n_{3m})$, which can be achieved in $O(m \log m)$ using a comparison-based sorting algorithm. Next, evaluate $F(n_1)$ and compute $F(n_{k+1})$ from $F(n_k)$ for all k.

The main idea of the algorithm is the following: since the definition of $V_i(\cdot, b_i)$ can only change at boundary points (see also Figure 4(b)), computing $F(n_{k+1})$ from $F(n_k)$ can be achieved in constant time. Indeed, since between n_k and n_{k+1} there are only two boundary points, we can compute $V(n_{k+1}, \mathbf{b}_i)$ from $V(n_k, \mathbf{b}_i)$ by calculating V for only two values of $\mathbf{b}_i$, which can be done in constant time. We now give a more detailed description and proof of correctness of our algorithm.

Proposition 13 *There exists an algorithm to solve the optimization problem* (10) *in* $O(m \log m)$.

Proof The pseudocode of the algorithm is given in Algorithm 1, where $a_i^{(1)}, \ldots, a_i^{(4)}$ denote the parameters defining the functions $V_i(r, \mathbf{b}_i)$. We will prove that, after running Algorithm 1, we can compute $F(n_j)$ in constant time using:

$$F(n_j) = c_j^{(1)} + c_j^{(2)} n_j + c_j^{(3)} n_j + c_j^{(4)}. \tag{11}$$

This holds trivially for n_1 since by definition $n_1 \leq b_i^{(2)}$ for all i and therefore $F(n_1) = -\sum_{i=1}^m a_i^{(1)}$. Now, assume that (11) holds for j, we prove that it must also hold for $j+1$. Suppose $n_j = b_i^{(2)}$ for some i (the cases $n_j = b_i^{(1)}$ and $n_j = (1+\eta)b_i^{(1)}$ can be handled in the same way). Then $V_i(n_j, \mathbf{b}_i) = -a_i^{(1)}$ and we can write

$$\sum_{k \neq i} V_k(n_j, \mathbf{b}_k) = F(n_j) - V(n_j, \mathbf{b}_i) = (c_j^{(1)} + c_j^{(2)} n_j + c_j^{(3)} n_j + c_j^{(4)}) + a_i^{(1)}.$$

Thus, by construction we would have:

$$\begin{aligned} c_{j+1}^{(1)} + c_{j+1}^{(2)} n_{j+1} + c_{j+1}^{(3)} n_{j+1} + c_{j+1}^{(4)} &= c_j^{(1)} + a_i^{(1)} + (c_j^{(2)} - a_i^{(2)}) n_{j+1} + c_j^{(3)} n_{j+1} + c_j^{(4)} \\ &= (c_j^{(1)} + c_j^{(2)} n_{j+1} + c_j^{(3)} n_{j+1} + c_j^{(4)}) + a_i^{(1)} - a_i^{(2)} n_{j+1} \\ &= \sum_{k \neq i} V_k(n_{j+1}, \mathbf{b}_k) - a_i^{(2)} n_{j+1}, \end{aligned}$$

Algorithm 1 Sorting

$\mathcal{N} := \bigcup_{i=1}^m \{b_i^{(1)}, b_i^{(2)}, (1+\eta)b_i^{(1)}\}$;
$n_1, ..., n_{3m}) = \mathbf{Sort}(\mathcal{N})$;
Set $\mathbf{c}_i := (c_i^{(1)}, c_i^{(2)}, c_i^{(3)}, c_i^{(4)}) = 0$ for $i = 1, ..., 3m$;
Set $c_1^{(1)} = -\sum_{i=1}^m a_i^{(1)}$;
for $j = 2, ..., 3m$ **do**
  Set $\mathbf{c}_j = \mathbf{c}_{j-1}$;
  if $n_{j-1} = b_i^{(2)}$ for some i **then**
    $c_j^{(1)} = c_j^{(1)} + a_i^{(1)}$;
    $c_j^{(2)} = c_j^{(2)} - a_i^{(2)}$;
  else if $n_{j-1} = b_i^{(1)}$ for some i **then**
    $c_j^{(2)} = c_j^{(2)} + a_i^{(2)}$;
    $c_j^{(3)} = c_j^{(3)} + a_i^{(3)}$;
    $c_j^{(4)} = c_j^{(4)} - a_i^{(4)}$;
  else
    $c_j^{(3)} = c_j^{(3)} - a_i^{(3)}$;
    $c_j^{(4)} = c_j^{(4)} + a_i^{(4)}$;
  end if
end for

where the last equality holds since the definition of $V_k(r, \mathbf{b}_k)$ does not change for $r \in [n_j, n_{j+1}]$ and $k \neq i$. Finally, since n_j was a boundary point, the definition of $V_i(r, \mathbf{b}_i)$ must change from $-a_i^{(1)}$ to $-a_i^{(2)} r$, thus the last equation is indeed equal to $F(n_{j+1})$. A similar argument can be given if $n_j = b_i^{(1)}$ or $n_j = (1+\eta)b_i^{(1)}$.

We proceed to analyze the complexity of the algorithm: sorting the set $\mathcal{N}$ can be performed in $O(m \log m)$ and each iteration takes only constant time. Thus, the evaluation of all points can be achieved in linear time and, clearly, the minimum can then also be obtained in linear time. Therefore, the overall time complexity of the algorithm is in $O(m \log m)$. ■

The algorithm just proposed can be straightforwardly extended to solve the minimization of F over a set of r-values bounded by Λ, that is $\{r : 0 \leq r \leq \Lambda\}$. Indeed, we need only compute $F(b_i^{(1)})$ for $i \in [1, m]$ such that $b_i^{(1)} < \Lambda$ and of course also $F(\Lambda)$, thus the computational complexity in this regularized case remains in $O(m \log m)$.

5.2 General Case

We now present our main algorithm for revenue optimization in the presence of features. This problem presents new challenges characteristic of non-convex optimization problems in higher dimensions. Therefore, our proposed algorithm can only guarantee convergence to a local minimum. Nevertheless, we provide a simple method for cycling through these local minima with the guarantee of reducing the objective function at each time.

We consider the case of a hypothesis set $H \subset \mathbb{R}^N$ of linear functions $\mathbf{x} \mapsto \mathbf{w} \cdot \mathbf{x}$ with bounded norm, $\|\mathbf{w}\| \leq \Lambda$, for some $\Lambda \geq 0$. This can be immediately generalized to non-linear hypotheses by using a positive definite kernel.

The results of Theorem 9 suggest seeking, for a fixed $\gamma \geq 0$, the vector $\mathbf{w}$ solution to the following optimization problem: $\min_{\|\mathbf{w}\| \leq \Lambda} \sum_{i=1}^m L_\gamma(\mathbf{w} \cdot \mathbf{x}_i, \mathbf{b}_i)$. Replacing the original loss L with L_γ helped us remove the discontinuity of the loss. But, we still face an optimization problem based on a sum of non-convex functions. This problem can be formulated as a DC-programming (difference of convex functions programming) problem which is a well studied problem in non-convex optimization. Indeed, L_γ can be decomposed as follows for all $(r, \mathbf{b}) \in \mathbb{R} \times \mathcal{B}$: $L_\gamma(r, \mathbf{b}) = u(r, \mathbf{b}) - v(r, \mathbf{b})$, with the convex functions u

and v defined by

$$u(r, \mathbf{b}) = -r\mathbb{1}_{r<b^{(1)}} + \frac{r-(1+\gamma)b^{(1)}}{\gamma}\mathbb{1}_{r \geq b^{(1)}}$$
$$v(r, \mathbf{b}) = (-r + b^{(2)})\mathbb{1}_{r<b^{(2)}} + \frac{r-(1+\gamma)b^{(1)}}{\gamma}\mathbb{1}_{r>(1+\gamma)b^{(1)}}.$$

Using the decomposition $L_\gamma = u - v$, our optimization problem can be formulated as follows:

$$\min_{\mathbf{w} \in \mathbb{R}^N} U(\mathbf{w}) - V(\mathbf{w}) \qquad \text{subject to } \|\mathbf{w}\| \leq \Lambda, \tag{12}$$

where $U(\mathbf{w}) = \sum_{i=1}^m u(\mathbf{w} \cdot \mathbf{x}_i, \mathbf{b}_i)$ and $V(\mathbf{w}) = \sum_{i=1}^m v(\mathbf{w} \cdot \mathbf{x}_i, \mathbf{b}_i)$, which shows that it can be formulated as a DC-programming problem. The global minimum of the optimization problem (12) can be found using a cutting plane method (Horst and Thoai, 1999), but that method only converges in the limit and does not admit known algorithmic convergence guarantees.[4] There exists also a branch-and-bound algorithm with exponential convergence for DC-programming (Horst and Thoai, 1999) for finding the global minimum. Nevertheless, in (Tao and An, 1997), it is pointed out that such combinatorial algorithms fail to solve real-world DC-programs in high dimensions. In fact, our implementation of this algorithm shows that the convergence of the algorithm in practice is extremely slow for even moderately high-dimensional problems. Another attractive solution for finding the global solution of a DC-programming problem over a polyhedral convex set is the combinatorial solution of Tuy (1964). However, this method requires explicitly specifying the slope and offsets for the piecewise linear function corresponding to a sum of L_γ losses and incurs an exponential cost in time and space.

An alternative consists of using the DC algorithm (DCA), a primal-dual sub-differential method of Dinh Tao and Hoai An Tao and An (1998), (see also Tao and An (1997) for a good survey). This algorithm is applicable when u and v are proper lower semi-continuous convex functions as in our case. When v is differentiable, the DC algorithm coincides with the CCCP algorithm of Yuille and Rangarajan (2003), which has been used in several contexts in machine learning and analyzed by Sriperumbudur and Lanckriet (2012).

The general proof of convergence of the DC algorithm was given by Tao and An (1998). In some special cases, the DC algorithm can be used to find the global minimum of the problem as in the trust region problem (Tao and An, 1998), but, in general, the DC algorithm or its special case CCCP are only guaranteed to converge to a critical point (Tao and An, 1998; Sriperumbudur and Lanckriet, 2012). Nevertheless, the number of iterations of the DC algorithm is relatively small. Its convergence has been shown to be in fact linear for DC-programming problems such as ours (Yen et al., 2012). The algorithm we are proposing goes one step further than that of Tao and An (1998): we use DCA to find a local minimum but then restart our algorithm with a new seed that is guaranteed to reduce the objective function. Unfortunately, we are not in the same regime as in the trust region problem of Tao and An (1998) where the number of local minima is linear in the size of the input. Indeed, here, the number of local minima can be exponential in the number of dimensions of the feature space and it is not clear to us how the combinatorial structure of the problem could help us rule out some local minima faster and make the optimization more tractable.

In the following, we describe more in detail the solution we propose for solving the DC-programming problem (12). The functions v and V are not differentiable in our context but they admit a sub-gradient at all points. We will denote by $\delta V(\mathbf{w})$ an arbitrary element of the sub-gradient $\partial V(\mathbf{w})$, which coincides with $\nabla V(\mathbf{w})$ at points $\mathbf{w}$ where V is differentiable. The DC algorithm then coincides with CCCP, modulo the replacement of the gradient of V by $\delta V(\mathbf{w})$. It consists of starting with a weight vector $\mathbf{w}_0 \leq \Lambda$ and of iteratively solving a sequence of convex optimization problems obtained by replacing V with its linear approximation giving $\mathbf{w}_t$ as a function of $\mathbf{w}_{t-1}$, for $t = 1, \ldots, T$: $\mathbf{w}_t \in \operatorname{argmin}_{\|\mathbf{w}\| \leq \Lambda} U(\mathbf{w}) - \delta V(\mathbf{w}_{t-1}) \cdot \mathbf{w}$. This problem can be rewritten in our context as the following:

$$\min_{\|\mathbf{w}\|^2 \leq \Lambda^2, \mathbf{s}} \sum_{i=1}^m s_i - \delta V(\mathbf{w}_{t-1}) \cdot \mathbf{w} \tag{13}$$
$$\text{subject to } (s_i \geq -\mathbf{w} \cdot \mathbf{x}_i) \wedge \left[s_i \geq \frac{1}{\gamma}\left(\mathbf{w} \cdot \mathbf{x}_i - (1+\gamma)b_i^{(1)}\right)\right].$$

4. Some claims of Horst and Thoai (1999), e.g., Proposition 4.4 used in support of the cutting plane algorithm, are incorrect (Tuy, 2002).

DC Algorithm

$\mathbf{w} \leftarrow \mathbf{w}_0$ ▷ initialization
while $\mathbf{v} \neq \mathbf{w}$ **do**
  $\mathbf{v} \leftarrow \mathrm{DCA}(\mathbf{w})$ ▷ DC algorithm
  $\mathbf{u} \leftarrow \frac{\mathbf{v}}{\|\mathbf{v}\|}$
  $\eta^* \leftarrow \min_{0 \leq \eta \leq \Lambda} \sum_{\mathbf{u} \cdot \mathbf{x}_i > 0} L_\gamma(\eta \mathbf{u} \cdot \mathbf{x}_i, \mathbf{b}_i)$
  $\mathbf{w} \leftarrow \eta^* \mathbf{v}$
end while

Figure 5: Pseudocode of our DC-programming algorithm.

The problem is equivalent to a QP (quadratic-programming). Indeed, by convex duality, there exists a $\lambda > 0$ such that the above problem is equivalent to

$$\min_{w \in R^N} \lambda \|w\|^2 + \sum_{i=1}^{m} s_i - \delta V(\mathbf{w}_{t-1}) \cdot \mathbf{w}$$
$$\text{subject to } (s_i \geq -\mathbf{w} \cdot \mathbf{x}_i) \wedge \left[s_i \geq \frac{1}{\gamma} \left(\mathbf{w} \cdot \mathbf{x}_i - (1+\gamma) b_i^{(1)} \right) \right]$$

which is a simple QP that can be tackled by one of many off-the-shelf QP solvers. Of course, the value of λ as a function of Λ does not admit a simple expression. Instead, we select λ through validation which is then equivalent to choosing the optimal value of Λ through validation.

We now address the problem of the DC algorithm converging to a local minimum. A common practice is to restart the DC algorithm at a new random point. Instead, we propose an algorithm that iterates along different local minima, with the guarantee of reducing the function at every change of local minimum. The algorithm is simple and is based on the observation that the function L_γ is positive homogeneous. Indeed, for any $\eta > 0$ and $(r, \mathbf{b})$,

$$\begin{aligned} L_\gamma(\eta r, \eta \mathbf{b}) &= -\eta b^{(2)} \mathbb{1}_{\eta r < \eta b^{(2)}} - \eta r \mathbb{1}_{\eta b^{(2)} \leq \eta r \leq \eta b^{(1)}} + \frac{\eta r - (1+\gamma)\eta b^{(1)}}{\gamma} \mathbb{1}_{\eta b^{(1)} < \eta r < \eta(1+\gamma) b^{(1)}} \\ &= \eta L_\gamma(r, \mathbf{b}). \end{aligned}$$

Minimizing the objective function of (12) in a fixed direction $\mathbf{u}$, $\|\mathbf{u}\| = 1$, can be reformulated as follows: $\min_{0 \leq \eta \leq \Lambda} \sum_{i=1}^{m} L_\gamma(\eta \mathbf{u} \cdot \mathbf{x}_i, \mathbf{b}_i)$. Since for $\mathbf{u} \cdot \mathbf{x}_i \leq 0$ the function $\eta \mapsto L_\gamma(\eta \mathbf{u} \cdot \mathbf{x}_i, \mathbf{b}_i)$ is constant and equal to $-b_i^{(2)}$, the problem is equivalent to solving

$$\min_{0 \leq \eta \leq \Lambda} \sum_{\mathbf{u} \cdot \mathbf{x}_i > 0} L_\gamma(\eta \mathbf{u} \cdot \mathbf{x}_i, \mathbf{b}_i).$$

Furthermore, since L_γ is positive homogeneous, for all $i \in [1, m]$ with $\mathbf{u} \cdot \mathbf{x}_i > 0$, $L_\gamma(\eta \mathbf{u} \cdot \mathbf{x}_i, \mathbf{b}_i) = (\mathbf{u} \cdot \mathbf{x}_i) L_\gamma(\eta, \mathbf{b}_i / (\mathbf{u} \cdot \mathbf{x}_i))$. But $\eta \mapsto (\mathbf{u} \cdot \mathbf{x}_i) L_\gamma(\eta, \mathbf{b}_i / (\mathbf{u} \cdot \mathbf{x}_i))$ is a v-function and thus the problem can efficiently be optimized using the combinatorial algorithm for the no-feature case (Section 5.1). This leads to the optimization algorithm described in Figure 5. The last step of each iteration of our algorithm can be viewed as a *line search* and this is in fact the step that reduces the objective function the most in practice. This is because we are then precisely minimizing the objective function even though this is for some fixed direction. Since in general this line search does not find a local minimum (we are likely to decrease the objective value in other directions that are not the one in which the line search was performed) running DCA helps us find a better direction for the next iteration of the line search.

6. Experiments

In this section, we report the results of several experiments with synthetic and real-world data demonstrating the benefits of our algorithm. Since the use of features for reserve price optimization has not been previously studied in the literature, we are not aware of any baseline for comparison with our algorithm. Therefore, its performance is measured against three natural strategies that we now describe.

As mentioned before, a standard solution for solving this problem would be the use of a convex surrogate loss. In view of that, we compare against the solution of the regularized empirical risk minimization of the convex surrogate loss L_α shown in Figure 2(a) parametrized by $\alpha \in [0, 1]$ and defined by

$$L_\alpha(r, \mathbf{b}) = \begin{cases} -r & \text{if } r < b^{(1)} + \alpha(b^{(2)} - b^{(1)}) \\ \left(\frac{(1-\alpha) b^{(1)} + \alpha b^{(2)}}{\alpha (b^{(1)} - b^{(2)})} \right) (r - b^{(1)}) & \text{otherwise.} \end{cases}$$

A second alternative consists of using ridge regression to estimate the first bid and of using its prediction as the reserve price. A third algorithm consists of minimizing the loss while ignoring the feature vectors $\mathbf{x}_i$, i.e., solving the problem $\min_{r \leq \Lambda} \sum_{i=1}^{n} L(r, \mathbf{b}_i)$. It is worth mentioning that this third approach is very similar to what advertisement exchanges currently use to suggest reserve prices to publishers. By using the empirical version of equation (2), we see that this algorithm is equivalent to finding the empirical distribution of bids and optimizing the expected revenue with respect to this empirical distribution as in (Ostrovsky and Schwarz, 2011) and (Cesa-Bianchi et al., 2013).

6.1 Artificial Data Sets

We generated 4 different synthetic data sets with different correlation levels between features and bids. For all our experiments, the feature vectors $\mathbf{x} \in \mathbb{R}^{21}$ were generated in as follows: $\tilde{\mathbf{x}} \in \mathbb{R}^{20}$ was sampled from a standard Gaussian distribution and $\mathbf{x} = (\tilde{\mathbf{x}}, 1)$ was created by adding an offset feature. We now describe the bid generating process for each of the experiments as a function of the feature vector $\mathbf{x}$. For our first three experiments, shown in Figure 6(a)-(c), the highest bid and second highest bid were set to $\max\left(\left| \sum_{i=1}^{21} x_i \right| + \epsilon_1, \left| \sum_{i=1}^{21} \frac{x_i}{2} \right| + \epsilon_2 \right)_+$ and $\min\left(\left| \sum_{i=1}^{21} x_i \right| + \epsilon_1, \left| \sum_{i=1}^{21} \frac{x_i}{2} \right| + \epsilon_2 \right)_+$ respectively, where ϵ_i is a Gaussian random variable with mean 0. The standard deviation of the Gaussian noise was varied over the set $\{0, 0.25, 0.5\}$.

For our last artificial experiment, we used a generative model motivated by previous empirical observations (Ostrovsky and Schwarz, 2011; Lahaie and Pennock, 2007): bids were generated by sampling two values from a log-normal distribution with means $\mathbf{x} \cdot \mathbf{w}$ and $\frac{\mathbf{x} \cdot \mathbf{w}}{2}$ and standard deviation 0.5, with $\mathbf{w}$ a random vector sampled from a standard Gaussian distribution.

For all our experiments, the parameters λ, γ and α were selected respectively from the sets $\{2^i | i \in [-5, 5]\}$, $\{0.1, 0.01, 0.001\}$, and $\{0.1, 0.2, \ldots, 0.9\}$ via validation over a set consisting of the same number of examples as the training set. Our algorithm was initialized using the best solution of the convex surrogate optimization problem. The test set consisted of 5,000 examples drawn from the same distribution as the training set. Each experiment was repeated 10 times and the mean revenue of each algorithm is shown in Figure 6. The plots are normalized in such a way that the revenue obtained by setting no reserve price is equal to 0 and the maximum possible revenue (which can be obtained by setting the reserve price equal to the highest bid) is equal to 1. The performance of the ridge regression algorithm is not included in Figure 6(d) as it was too inferior to be comparable with the performance of the other algorithms.

By inspecting the results in Figure 6(a), we see that, even in the simplest noiseless scenario, our algorithm outperforms all other techniques. The reader could argue that these results are not surprising since the bids were generated by a locally linear function of the feature vectors, thereby ensuring the success of our algorithm. Nevertheless, one would expect this to be the case too for algorithms that leverage the use of features such as the convex surrogate and ridge regression. But one can see that this is in fact not true even for low levels of noise. It is also worth noticing that the use of ridge regression is actually worse than setting the reserve price to 0. This fact can be easily understood by noticing that the square loss used in regression is symmetric. Therefore, we can expect several reserve prices to be above the highest bid, making the revenue of these auctions equal to zero. Another notable feature is that as the noise level increases, the performance of feature-based algorithms decreases. This is true for any learning algorithm: if the features are not relevant to the prediction task, the performance of the algorithm will suffer. However, for the convex surrogate algorithm, a more critical issue occurs: the performance of this algorithm actually decreases as the sample size increases, which shows that in general learning with a convex surrogate is not possible. This is an empirical verification of the inconsistency result provided in Section 4.2. This lack of calibration can also be seen in Figure 6(d), where in fact the performance of this algorithm approaches the use of no reserve price.

In order to better understand the reason behind the performance discrepancy between feature-based algorithms, we analyze the reserve prices offered by each algorithm. In Figure 7 we see that the convex surrogate

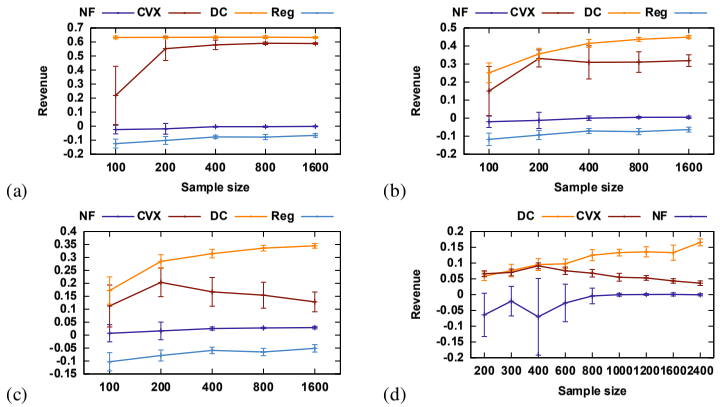


Figure 6: Plots of expected revenue against sample size for different algorithms: DC algorithm (DC), convex surrogate (CVX), ridge regression (Reg) and the algorithm that uses no feature to set reserve prices (NF). For (a)-(c) bids are generated with different noise standard deviation (a) 0, (b) 0.25, (c) 0.5. The bids in (d) were generated using a generative model.

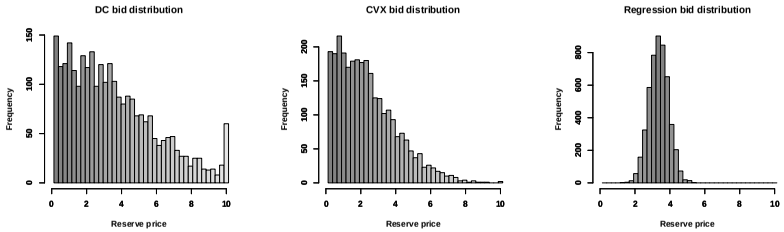

Figure 7: Distribution of reserve prices for each algorithm. The algorithms were trained on 800 samples using noisy bids with standard deviation 0.5.

algorithm tends to offer lower reserve prices. This should be intuitively clear as high reserve prices are over-penalized by the chosen convex surrogate as shown in Figure 2(b). On the other hand, reserve prices suggested by the regression algorithm seem to be concentrated and symmetric around their mean. Therefore we can infer that about 50% of the reserve prices offered will be higher than the highest bid thereby yielding zero revenue. Finally, our algorithm seems to generally offer higher prices. This suggests that the increase in revenue comes from auctions where the highest bid is large but the second bid is small. This bidding phenomenon is in fact commonly observed in practice (Amin et al., 2013).

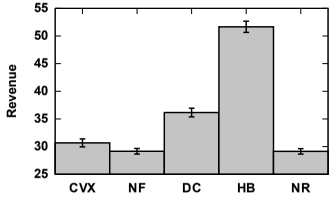

Figure 8: Results of the eBay data set. Comparison of our algorithm (DC) against a convex surrogate (CVX), using no features (NF), setting no reserve (NR) and setting reserve price to highest bid (HB).

6.2 Real-World Data Sets

Due to proprietary data and confidentiality reasons, we cannot present empirical results for AdExchange data. However, we were able to procure an eBay data set consisting of approximately 70,000 second-price auctions of collector sport cards. The full data set can be accessed using the following URL: `http://cims.nyu.edu/~munoz/data`. Some other sources of auction data are accessible (e.g., `http://modelingonlineauctions.com/datasets`), but features are not available for those data sets. To the best of our knowledge, with the exception of the one used here, there is no publicly available data set for online auctions including features that could be readily used with our algorithm. The features used here include information about the seller such as positive feedback percent, seller rating and seller country; as well as information about the card such as whether the player is in the sport's Hall of Fame. The final dimension of the feature vectors is 78. The values of these features are both continuous and categorical. For our experiments we also included an extra offset feature.

Since the highest bid is not reported by eBay, our algorithm cannot be straightforwardly used on this data set. In order to generate highest bids, we calculated the mean price of each object (each card was generally sold more than once) and set the highest bid to be the maximum between this average and the second highest bid.

Figure 8 shows the revenue gained using different algorithms including our DC algorithm, using a convex surrogate, or the algorithm that ignores features. It also shows the results obtained by using no reserve price (NR) and the highest possible revenue obtained by setting the reserve price to the highest bid (HB). We randomly sampled 2,000 examples for training, 2,000 examples for validation and 2,000 examples for testing. This experiment was repeated 10 times. Figure 8(b) shows the mean revenue for each algorithm and their standard deviations. The results of this experiment show that the use of features is crucial for revenue optimization. Indeed, setting an optimal reserve price for all objects seems to achieve the same revenue as no reserve price. Instead, our algorithm achieves a 22% increase on the revenue obtained by not setting a reserve price whereas the non-calibrated convex surrogate algorithm only obtains a 3% revenue improvement. Furthermore, our algorithm is able to obtain as much as 70% of the achievable revenue with knowledge of the highest bid.

7. Conclusion

We presented a comprehensive theoretical and algorithmic analysis of the learning problem of revenue optimization in second-price auctions with reserve. The specific properties of the loss function for this problem required a new analysis and new learning guarantees. The algorithmic solutions we presented are practically applicable to revenue optimization problems for this type of auctions in most realistic settings. Our experimental results further demonstrate their effectiveness. Much of the analysis and algorithms presented, in particular our study of calibration questions, can also be of interest in other learning problems. In particular, they are relevant to the study of learning problems arising in the study of generalized second-price auctions (Mohri and Medina, 2015).

Acknowledgments

We thank Afshin Rostamizadeh and Umar Syed for several discussions about the topic of this work and ICML and JMLR reviewers for useful comments. We also warmly thank Jay Grossman for providing us access to the eBay data set used in this paper. Finally, we thank Le Thi Hoai An for extensive discussions on DC programming. This work was partly funded by the NSF award IIS-1117591.

Appendix A. Contraction Lemma

The following is a version of Talagrand's contraction lemma Ledoux and Talagrand (2011). Since our definition of Rademacher complexity does not use absolute values, we give an explicit proof below.

Lemma 14 *Let H be a hypothesis set of functions mapping $\mathcal{X}$ to $\mathbb{R}$ and $\Psi_1, \ldots, \Psi_m$, μ-Lipschitz functions for some $\mu > 0$. Then, for any sample S of m points $x_1, \ldots, x_m \in \mathcal{X}$, the following inequality holds*

$$\frac{1}{m}\mathop{\mathbb{E}}_{\boldsymbol{\sigma}}\left[\sup_{h\in H}\sum_{i=1}^{m}\sigma_i(\Psi_i\circ h)(x_i)\right] \leq \frac{\mu}{m}\mathop{\mathbb{E}}_{\boldsymbol{\sigma}}\left[\sup_{h\in H}\sum_{i=1}^{m}\sigma_i h(x_i)\right] = \mu\,\widehat{\mathfrak{R}}_S(H).$$

Proof The proof is similar to the case where the functions Ψ_i are all equal. Fix a sample $S = (x_1, \ldots, x_m)$. Then, we can rewrite the empirical Rademacher complexity as follows:

$$\frac{1}{m}\mathop{\mathbb{E}}_{\boldsymbol{\sigma}}\left[\sup_{h\in H}\sum_{i=1}^{m}\sigma_i(\Psi_i\circ h)(x_i)\right] = \frac{1}{m}\mathop{\mathbb{E}}_{\sigma_1,\ldots,\sigma_{m-1}}\left[\mathop{\mathbb{E}}_{\sigma_m}\left[\sup_{h\in H} u_{m-1}(h) + \sigma_m(\Psi_m\circ h)(x_m)\right]\right],$$

where $u_{m-1}(h) = \sum_{i=1}^{m-1}\sigma_i(\Psi_i\circ h)(x_i)$. Assume that the suprema can be attained and let $h_1, h_2 \in H$ be the hypotheses satisfying

$$u_{m-1}(h_1) + \Psi_m(h_1(x_m)) = \sup_{h\in H} u_{m-1}(h) + \Psi_m(h(x_m))$$
$$u_{m-1}(h_2) - \Psi_m(h_2(x_m)) = \sup_{h\in H} u_{m-1}(h) - \Psi_m(h(x_m)).$$

When the suprema are not reached, a similar argument to what follows can be given by considering instead hypotheses that are ϵ-close to the suprema for any $\epsilon > 0$.

By definition of expectation, since σ_m uniform distributed over $\{-1, +1\}$, we can write

$$\begin{aligned}\mathop{\mathbb{E}}_{\sigma_m}\left[\sup_{h\in H} u_{m-1}(h) + \sigma_m(\Psi_m\circ h)(x_m)\right] &= \frac{1}{2}\sup_{h\in H} u_{m-1}(h) + (\Psi_m\circ h)(x_m) + \frac{1}{2}\sup_{h\in H} u_{m-1}(h) - (\Psi_m\circ h)(x_m)\\ &= \frac{1}{2}[u_{m-1}(h_1) + (\Psi_m\circ h_1)(x_m)] + \frac{1}{2}[u_{m-1}(h_2) - (\Psi_m\circ h_2)(x_m)].\end{aligned}$$

Let $s = \operatorname{sgn}(h_1(x_m) - h_2(x_m))$. Then, the previous equality implies

$$\begin{aligned}\mathop{\mathbb{E}}_{\sigma_m}\left[\sup_{h\in H} u_{m-1}(h) + \sigma_m(\Psi_m\circ h)(x_m)\right] &\leq \frac{1}{2}[u_{m-1}(h_1) + u_{m-1}(h_2) + s\mu(h_1(x_m) - h_2(x_m))]\\ &= \frac{1}{2}[u_{m-1}(h_1) + s\mu h_1(x_m)] + \frac{1}{2}[u_{m-1}(h_2) - s\mu h_2(x_m)]\\ &\leq \frac{1}{2}\sup_{h\in H}[u_{m-1}(h) + s\mu h(x_m)] + \frac{1}{2}\sup_{h\in H}[u_{m-1}(h) - s\mu h(x_m)]\\ &= \mathop{\mathbb{E}}_{\sigma_m}\left[\sup_{h\in H} u_{m-1}(h) + \sigma_m\mu h(x_m)\right],\end{aligned}$$

where we used the $\mu-$Lipschitzness of Ψ_m in the first equality and the definition of expectation over σ_m for the last equality. Proceeding in the same way for all other σ_i's ($i \neq m$) proves the lemma. ■

Appendix B. Proof of Theorem 7

Proof We first show that the functions L_n are uniformly bounded for any b:

$$\begin{aligned}|L_n(r,b)| = \left|\int_0^r L_n'(r,b)dr\right| &\leq \int_0^M \max\left(\left|L_n'(0,b)\right|, \left|L_n'(M,b)\right|\right)dr\\ &\leq \int_0^M K dr = MK,\end{aligned}$$

where the first inequality holds since, by convexity, the derivative of L_n with respect to r is an increasing function.

Next, we show that the sequence $(L_n)_{n\in\mathbb{N}}$ is also equicontinuous. It will follow then by the theorem of Arzela-Ascoli that the sequence $L_n(\cdot, b)$ converges uniformly to $L_c(\cdot, b)$. Let $r_1, r_2 \in [0, M]$, for any $b \in [0, M]$ we have

$$\begin{aligned}|L_n(r_1, b) - L_n(r_2, b)| &\leq \sup_{r\in[0,M]} \left|L_n'(r, b)\right| |r_1 - r_2| \\ &= \max\left(\left|L_n'(0, b)\right|, \left|L_n'(M, b))\right|\right) |r_1 - r_2| \\ &\leq K|r_1 - r_2|,\end{aligned}$$

where, again, the convexity of L_n was used for the first equality. Let $F_n(r) = \mathbb{E}_{b\sim D}[L_n(r, b)]$ and $F(r) = \mathbb{E}_{b\sim D}[L_c(r, b)]$. F_n is a convex function as the expectation of a convex function. By the theorem of Arzela-Ascoli, the sequence $(F_n)_n$ admits a uniformly convergent subsequence. Furthermore, by the dominated convergence theorem, we have $(F_n(r))_n$ converges pointwise to $F(r)$. Therefore, the uniform limit of F_n must be F. This implies that

$$\min_{r\in[0,M]} F(r) = \lim_{n\to+\infty} \min_{r\in[0,M]} F_n(r) = \lim_{n\to+\infty} F_n(r_n) = F(r^*),$$

where the first and third equalities follow from the uniform convergence of F_n to F. The last equation implies that L_c is consistent with L. Furthermore, the function $L_c(\cdot, b)$ is convex since it is the uniform limit of convex functions. It then follows by Proposition 6 that $L_c(\cdot, b) \equiv L_c(0, b) = 0$. ■

Appendix C. Consistency of L_γ

Lemma 15 *Let H be a closed, convex subset of a linear space of functions containing 0 and let $h^*_\gamma = \operatorname{argmin}_{h\in H} \mathcal{L}_\gamma(h)$. Then, the following inequality holds:*

$$\mathop{\mathbb{E}}_{\mathbf{x},\mathbf{b}}\left[h^*_\gamma(\mathbf{x})\mathbb{1}_{I_2}(\mathbf{x}, \mathbf{b})\right] \geq \frac{1}{\gamma} \mathop{\mathbb{E}}_{\mathbf{x},\mathbf{b}}\left[h^*_\gamma(\mathbf{x})\mathbb{1}_{I_3}(\mathbf{x}, \mathbf{b})\right].$$

Proof Let $0 < \lambda < 1$. Since H is a convex set, it follows that $\lambda h^*_\gamma \in H$. Furthermore, by the definition of h^*_γ, we must have:

$$\mathop{\mathbb{E}}_{\mathbf{x},\mathbf{b}}\left[L_\gamma(h^*_\gamma(\mathbf{x}), \mathbf{b})\right] \leq \mathop{\mathbb{E}}_{\mathbf{x},\mathbf{b}}\left[L_\gamma(\lambda h^*_\gamma(\mathbf{x}), \mathbf{b})\right]. \tag{14}$$

If $h^*_\gamma(\mathbf{x}) < 0$, then $L_\gamma(h^*_\gamma(\mathbf{x}), \mathbf{b}) = L_\gamma(\lambda h^*_\gamma(\mathbf{x})) = -b^{(2)}$ by definition of L_γ. If on the other hand $h^*_\gamma(\mathbf{x}) > 0$, since $\lambda h^*_\gamma(\mathbf{x}) < h^*_\gamma(\mathbf{x})$, we must have that for $(\mathbf{x}, \mathbf{b}) \in I_1$ $L_\gamma(h^*_\gamma(\mathbf{x}), \mathbf{b}) = L_\gamma(\lambda h^*_\gamma(\mathbf{x}), \mathbf{b}) = -b^{(2)}$ too. Moreover, from the fact that $L_\gamma \leq 0$ and $L_\gamma(h^*_\gamma(\mathbf{x}), \mathbf{b}) = 0$ for $(\mathbf{x}, \mathbf{b}) \in I_4$ it follows that $L_\gamma(h^*_\gamma(\mathbf{x}), \mathbf{b}) \geq L_\gamma(\lambda h^*_\gamma(\mathbf{x}), \mathbf{b})$ for $(\mathbf{x}, \mathbf{b}) \in I_4$, and therefore the following inequality trivially holds:

$$\mathop{\mathbb{E}}_{\mathbf{x},\mathbf{b}}\left[L_\gamma(h^*_\gamma(\mathbf{x}), \mathbf{b})(\mathbb{1}_{I_1}(\mathbf{x}, \mathbf{b}) + \mathbb{1}_{I_4}(\mathbf{x}, \mathbf{b}))\right] \geq \mathop{\mathbb{E}}_{\mathbf{x},\mathbf{b}}\left[L_\gamma(\lambda h^*_\gamma(\mathbf{x}), \mathbf{b})(\mathbb{1}_{I_1}(\mathbf{x}, \mathbf{b}) + \mathbb{1}_{I_4}(\mathbf{x}, \mathbf{b}))\right]. \tag{15}$$

Subtracting (15) from (14) we obtain

$$\mathop{\mathbb{E}}_{\mathbf{x},\mathbf{b}}\left[L_\gamma(h^*_\gamma(\mathbf{x}), \mathbf{b})(\mathbb{1}_{I_2}(\mathbf{x}, \mathbf{b}) + \mathbb{1}_{I_3}(\mathbf{x}, \mathbf{b}))\right] \leq \mathop{\mathbb{E}}_{\mathbf{x},\mathbf{b}}\left[L_\gamma(\lambda h^*_\gamma(\mathbf{x}), \mathbf{b})(\mathbb{1}_{I_2}(\mathbf{x}, \mathbf{b}) + \mathbb{1}_{I_3}(\mathbf{x}, \mathbf{b}))\right].$$

Rearranging terms shows that this inequality is equivalent to

$$\mathop{\mathbb{E}}_{\mathbf{x},\mathbf{b}}\left[(L_\gamma(\lambda h^*_\gamma(\mathbf{x}), \mathbf{b}) - L_\gamma(h^*_\gamma(\mathbf{x}), \mathbf{b}))\mathbb{1}_{I_2}(\mathbf{x}, \mathbf{b})\right] \geq \mathop{\mathbb{E}}_{\mathbf{x},\mathbf{b}}\left[(L_\gamma(h^*_\gamma(\mathbf{x}), \mathbf{b}) - L_\gamma(\lambda h^*_\gamma(\mathbf{x}), \mathbf{b}))\mathbb{1}_{I_3}(\mathbf{x}, \mathbf{b})\right] \tag{16}$$

Notice that if $(\mathbf{x}, \mathbf{b}) \in I_2$, then $L_\gamma(h^*_\gamma(\mathbf{x}), \mathbf{b}) = -h^*_\gamma(\mathbf{x})$. If $\lambda h^*_\gamma(\mathbf{x}) > b^{(2)}$ too then $L_\gamma(\lambda h^*_\gamma(\mathbf{x}), \mathbf{b}) = -\lambda h^*_\gamma(\mathbf{x})$. On the other hand if $\lambda h^*_\gamma(\mathbf{x}) \leq b^{(2)}$ then $L_\gamma(\lambda h^*_\gamma(\mathbf{x}), \mathbf{b}) = -b^{(2)} \leq -\lambda h^*_\gamma(\mathbf{x})$. Thus

$$\mathbb{E}(L_\gamma(\lambda h^*_\gamma(\mathbf{x}), \mathbf{b}) - L_\gamma(h^*_\gamma(\mathbf{x}), \mathbf{b}))\mathbb{1}_{I_2}(\mathbf{x}, \mathbf{b})) \leq (1 - \lambda)\,\mathbb{E}(h^*_\gamma(\mathbf{x})\mathbb{1}_{I_2}(\mathbf{x}, \mathbf{b})) \tag{17}$$

This gives an upper bound for the left-hand side of inequality (16). We now seek to derive a lower bound on the right-hand side. To do so, we analyze two different cases:

1. $\lambda h^*_\gamma(\mathbf{x}) \leq b^{(1)}$;
2. $\lambda h^*_\gamma(\mathbf{x}) > b^{(1)}$.

In the first case, we know that $L_\gamma(h^*_\gamma(\mathbf{x}), \mathbf{b}) = \frac{1}{\gamma}(h^*_\gamma(\mathbf{x}) - (1 + \gamma)b^{(1)}) > -b^{(1)}$ (since $h^*_\gamma(\mathbf{x}) > b^{(1)}$ for $(\mathbf{x}, \mathbf{b}) \in I_3$). Furthermore, if $\lambda h^*_\gamma(\mathbf{x}) \leq b^{(1)}$, then, by definition $L_\gamma(\lambda h^*_\gamma(\mathbf{x}), \mathbf{b}) = \min(-b^{(2)}, -\lambda h^*_\gamma(\mathbf{x})) \leq -\lambda h^*_\gamma(\mathbf{x})$. Thus, we must have:

$$L_\gamma(h^*_\gamma(\mathbf{x}), \mathbf{b}) - L_\gamma(\lambda h^*_\gamma(\mathbf{x}), \mathbf{b}) > \lambda h^*_\gamma(\mathbf{x}) - b^{(1)} > (\lambda - 1)b^{(1)} \geq (\lambda - 1)M, \tag{18}$$

where we used the fact that $h^*_\gamma(\mathbf{x}) > b^{(1)}$ for the second inequality and the last inequality holds since $\lambda - 1 < 0$.

We analyze the second case now. If $\lambda h^*_\gamma(\mathbf{x}) > b^{(1)}$, then for $(\mathbf{x}, \mathbf{b}) \in I_3$ we have $L_\gamma(h^*_\gamma(\mathbf{x}), \mathbf{b}) - L_\gamma(\lambda h^*_\gamma(\mathbf{x}), \mathbf{b}) = \frac{1}{\gamma}(1 - \lambda)h^*_\gamma(\mathbf{x})$. Thus, letting $\Delta(\mathbf{x}, \mathbf{b}) = L_\gamma(h^*_\gamma(\mathbf{x}), \mathbf{b}) - L_\gamma(\lambda h^*_\gamma(\mathbf{x}), \mathbf{b})$, we can lower bound the right-hand side of (16) as:

$$\begin{aligned}\mathop{\mathbb{E}}_{\mathbf{x},\mathbf{b}}\left[\Delta(\mathbf{x}, \mathbf{b})\mathbb{1}_{I_3}(\mathbf{x}, \mathbf{b})\right] &= \mathop{\mathbb{E}}_{\mathbf{x},\mathbf{b}}\left[\Delta(\mathbf{x}, \mathbf{b})\mathbb{1}_{I_3}(\mathbf{x}, \mathbf{b})\mathbb{1}_{\{\lambda h^*_\gamma(\mathbf{x}) > b^{(1)}\}}\right] + \mathop{\mathbb{E}}_{\mathbf{x},\mathbf{b}}\left[\Delta(\mathbf{x}, \mathbf{b})\mathbb{1}_{I_3}(\mathbf{x}, \mathbf{b})\mathbb{1}_{\{\lambda h^*_\gamma(\mathbf{x}) \leq b^{(1)}\}}\right] \\ &\geq \frac{1 - \lambda}{\gamma} \mathop{\mathbb{E}}_{\mathbf{x},\mathbf{b}}\left[h^*_\gamma(\mathbf{x})\mathbb{1}_{I_3}(\mathbf{x}, \mathbf{b})\mathbb{1}_{\{\lambda h^*_\gamma(\mathbf{x}) > b^{(1)}\}}\right] + (\lambda - 1)M\,\mathbb{P}\left[h^*_\gamma(\mathbf{x}) > b^{(1)} \geq \lambda h^*_\gamma(\mathbf{x})\right],\end{aligned} \tag{19}$$

where we have used (18) to bound the second summand. Combining inequalities (16), (17) and (19) and dividing by $(1 - \lambda)$ we obtain the bound

$$\mathop{\mathbb{E}}_{\mathbf{x},\mathbf{b}}\left[h^*_\gamma(\mathbf{x})\mathbb{1}_{I_2}(\mathbf{x}, \mathbf{b})\right] \geq \frac{1}{\gamma} \mathop{\mathbb{E}}_{\mathbf{x},\mathbf{b}}\left[h^*_\gamma(\mathbf{x})\mathbb{1}_{I_3}(\mathbf{x}, \mathbf{b})\mathbb{1}_{\{\lambda h^*_\gamma(\mathbf{x}) > b^{(1)}\}}\right] - M\,\mathbb{P}\left[h^*_\gamma(\mathbf{x}) > b^{(1)} \geq \lambda h^*_\gamma(\mathbf{x})\right].$$

Finally, taking the limit $\lambda \to 1$, we obtain

$$\mathop{\mathbb{E}}_{\mathbf{x},\mathbf{b}}\left[h^*_\gamma(\mathbf{x})\mathbb{1}_{I_2}(\mathbf{x}, \mathbf{b})\right] \geq \frac{1}{\gamma} \mathop{\mathbb{E}}_{\mathbf{x},\mathbf{b}}\left[h^*_\gamma(\mathbf{x})\mathbb{1}_{I_3}(\mathbf{x}, \mathbf{b})\right].$$

Taking the limit inside the expectation is justified by the bounded convergence theorem and $\mathbb{P}[h^*_\gamma(\mathbf{x}) > b^{(1)} \geq \lambda h^*_\gamma(\mathbf{x})] \to 0$ holds by the continuity of probability measures. ■

Proposition 16 *For any $\delta > 0$, with probability at least $1 - \delta$ over the choice of a sample S of size m, the following holds for all $\gamma \in (0, 1]$ and $h \in H$:*

$$\mathcal{L}_\gamma(h) \leq \widehat{\mathcal{L}}_\gamma(h) + \frac{2}{\gamma}\mathfrak{R}_m(H) + M\left[\sqrt{\frac{\log\log_2 \frac{1}{\gamma}}{m}} + \sqrt{\frac{\log \frac{1}{\delta}}{2m}}\right].$$

Proof Consider two sequences $(\gamma_k)_{k\geq 1}$ and $(\epsilon_k)_{k\geq 1}$, with $\epsilon_k \in (0, 1)$. By Theorem 9, for any fixed $k \geq 1$,

$$\mathbb{P}\left[\mathcal{L}_{\gamma_k}(h) - \widehat{\mathcal{L}}_{\gamma_k}(h) > \frac{2}{\gamma_k}\mathfrak{R}_m(H) + M\epsilon_k\right] \leq \exp(-2m\epsilon_k^2).$$

Choose $\epsilon_k = \epsilon + \sqrt{\frac{\log k}{m}}$, then, by the union bound,

$$\begin{aligned}\mathbb{P}\left[\exists k\colon \mathcal{L}_{\gamma_k}(h) - \widehat{\mathcal{L}}_{\gamma_k}(h) > \frac{1}{\gamma_k}\mathfrak{R}_m(H) + M\epsilon_k\right] &\leq \sum_{k\geq 1} \exp\left[-2m(\epsilon + \sqrt{(\log k)/m})^2\right] \\ &\leq \left(\sum_{k\geq 1} 1/k^2\right) \exp(-2m\epsilon^2) \\ &= \frac{\pi^2}{6}\exp(-2m\epsilon^2) \leq 2\exp(-2m\epsilon^2).\end{aligned}$$

For any $\gamma \in (0,1]$, there exists $k \geq 1$ such that $\gamma \in (\gamma_k, \gamma_{k-1})$ with $\gamma_k = 1/2^k$. For such a k, $\frac{1}{\gamma_{k-1}} \leq \frac{1}{\gamma}$, $\gamma_{k-1} \leq \frac{\gamma}{2}$, and $\sqrt{\log(k-1)} = \sqrt{\log\log_2(1/\gamma_{k-1})} \leq \sqrt{\log\log_2(1/\gamma)}$. Since for any $h \in H$, $\mathcal{L}_{\gamma_{k-1}}(h) \leq \mathcal{L}_\gamma(h)$, we can write

$$\mathbb{P}\left[\mathcal{L}(h) - \widehat{\mathcal{L}}_\gamma(h) > \frac{2}{\gamma}\mathfrak{R}_m(H) + M\Big(K(\gamma) + \epsilon\Big)\right] \leq \exp(-2m\epsilon^2),$$

where $K(\gamma) = \sqrt{\frac{\log\log_2 \frac{1}{\gamma}}{m}}$. This concludes the proof. ■

Corollary 17 *Let H be a hypothesis set with pseudo-dimension $d = Pdim(H)$. Then, for any $\delta > 0$ and any $\gamma > 0$, with probability at least $1-\delta$ over the choice of a sample S of size m, the following inequality holds:*

$$\mathcal{L}(\widehat{h}_\gamma) \leq \mathcal{L}^* + \frac{2\gamma+2}{\gamma}\mathfrak{R}_m(H) + \gamma M + M\left[2\sqrt{\frac{2d\log\frac{em}{d}}{m}} + 2\sqrt{\frac{\log\frac{2}{\delta}}{2m}} + \sqrt{\frac{\log\log_2\frac{1}{\gamma}}{m}}\right].$$

The proof follows the same steps as Theorem 10 and uses the results of Proposition 16. Notice that, by setting $\gamma = \frac{1}{m^{1/4}}$, we can guarantee the convergence of $\mathcal{L}(\widehat{h}_\gamma)$ to $\mathcal{L}^*$. Indeed, with this choice, the bound can be expressed as follows:

$$\mathcal{L}(\widehat{h}_\gamma) \leq \mathcal{L}^* + (2+m^{1/4})\mathfrak{R}_m(H) + \frac{1}{m^{1/4}}M + M\left[2\sqrt{\frac{2d\log\frac{em}{d}}{m}} + 2\sqrt{\frac{\log\frac{2}{\delta}}{2m}} + \sqrt{\frac{\log\log_2 m^{1/4}}{m}}\right].$$

Furthermore, when H has finite pseudo-dimension, it is known that $\mathfrak{R}_m(H)$ is in $O\big(\frac{1}{m^{1/2}}\big)$. Thus, this shows that $\mathcal{L}(\widehat{h}_\gamma) = \mathcal{L}^* + O\big(\frac{1}{m^{1/4}}\big)$.

Appendix D. Proof of Proposition 12

Proof From the definition of v-function, it is immediate that V_i is differentiable everywhere except at the three points $n_i^{(1)} = b_i^{(2)}, n_i^{(2)} = b_i^{(1)}$ and $n_i^{(3)} = (1+\eta)b_i^{(1)}$. Let r^* be a minimizer of F. If $r^* \neq n_i^{(j)}$ for every $j \in \{1,2,3\}$ and $i \in \{1,\ldots,m\}$, then F must be differentiable at r^* and $F'(r^*) = 0$. Now, let $n^* = \max\{n_i^{(j)} | n_i^{(j)} < r^*\}$. Since F is a linear function over the interval $(n^*, r^*]$, we must have $F'(r) = F'(r^*) = 0$ for every $r \in (n^*, r^*]$. Thus, F reduces to a constant over this interval and continuity of F implies that $F(n^*) = F(r^*)$.

We conclude the proof by showing that n^* is equal to $b_i^{(1)}$ for some i. Suppose this is not the case and let U be an open interval around n^* satisfying $b_i^{(1)} \notin U$ for all i. It is not hard to verify that V_i is a concave function over every interval not containing $b_i^{(1)}$. In particular V_i is concave over U for any i and, as a sum of concave functions, F is concave too over the interval U. Moreover, by definition, n^* minimizes F restricted to U. This implies that F is constant over U as a non-constant concave function cannot reach its minimum over an open set. Finally, let $b^* = \text{argmin}_i |n^* - b_i^{(1)}|$. Since U was an arbitrary open interval, it follows that there exists r arbitrarily close to b^* such that $F(r) = F(n^*)$. By the continuity of F, we must then have $F(b^*) = F(n^*)$. ■

Abstract

In this paper we develop and analyze Hydra: HYbriD cooRdinAte descent method for solving loss minimization problems with big data. We initially partition the coordinates (features) and assign each partition to a different node of a cluster. At every iteration, each node picks a random subset of the coordinates from those it owns, independently from the other computers, and in parallel computes and applies updates to the selected coordinates based on a simple closed-form formula. We give bounds on the number of iterations sufficient to approximately solve the problem with high probability, and show how it depends on the data and on the partitioning. We perform numerical experiments with a LASSO instance described by a 3TB matrix.

Keywords: stochastic methods, parallel coordinate descent, distributed algorithms, boosting

1. Introduction

Randomized coordinate descent methods (CDMs) are increasingly popular in many learning tasks, including boosting, large scale regression and training linear support vector machines. CDMs update a single randomly chosen coordinate at a time by moving in the direction of the negative partial derivative (for smooth losses). Methods of this type, in various settings, were studied by several authors, including Hsieh et al. (2008); Shalev-Shwartz and Tewari (2009); Nesterov (2012); Richtárik and Takáč (2014); Necoara et al. (2012); Tappenden et al. (2013); Shalev-Shwartz and Zhang (2013b); Lu and Xiao (2015).

It is clear that in order to utilize modern shared-memory parallel computers, more coordinates should be updated at each iteration. One way to approach this is via partitioning the coordinates into blocks, and operating on a single randomly chosen block at a time, utilizing parallel linear algebra libraries. This approach was pioneered by Nesterov (2012) for smooth losses, and was extended to regularized problems in (Richtárik and Takáč, 2014). Another popular approach involves working with a random subset of coordinates (Bradley et al., 2011). These approaches can be combined, and

theory was developed for methods that update a random subset of blocks of coordinates at a time Richtárik and Takáč (2015); Fercoq and Richtárik (2013). Further recent works on parallel coordinate descent include (Richtárik and Takáč, 2012; Mukherjee et al., 2013; Fercoq, 2013; Tappenden et al., 2015; Shalev-Shwartz and Zhang, 2013a).

However, none of these methods are directly scalable to problems of sizes so large that a single computer is unable to store the data describing the instance, or is unable to do so efficiently (e.g., in memory). In a big data scenario of this type, it is imperative to split the data across several nodes (computers) of a cluster, and design efficient methods for this memory-distributed setting.

Hydra. In this work we design and analyze the first distributed coordinate descent method: *Hydra: HYbriD cooRdinAte descent*. The method is "hybrid" in the sense that it uses parallelism at two levels: i) across a number of nodes in a cluster and ii) utilizing the parallel processing power of individual nodes[1].

Assume we have c nodes (computers) available, each with parallel processing power. In Hydra, we initially partition the coordinates $\{1, 2, \dots, d\}$ into c sets, $\mathcal{P}_1, \dots, \mathcal{P}_c$, and assign each set to a single computer. For simplicity, we assume that the partition is balanced: $|\mathcal{P}_k| = |\mathcal{P}_l|$ for all k, l. Each computer *owns* the coordinates belonging to its partition for the duration of the iterative process. Also, these coordinates are stored locally. The data matrix describing the problem is partitioned in such a way that all data describing features belonging to $\mathcal{P}_l$ is stored at computer l. Now, at each iteration, each computer, independently from the others, chooses a random subset of τ coordinates from those they own, and computes and applies updates to these coordinates. Hence, once all computers are done, $c\tau$ coordinates will have been updated. The resulting vector, stored as c vectors of size $s = d/c$ each, in a distributed way, is the new iterate. This process is repeated until convergence. It is important that the computations are done locally on each node, with minimum communication overhead. We comment on this and further details in the text.

The main insight. We show that the parallelization potential of Hydra, that is, its ability to accelerate as τ is increased, depends on two data-dependent quantities: i) the *spectral norm of the data* (σ) and ii) a *partition-induced norm of the data* (σ'). The first quantity completely describes the behavior of the method in the $c = 1$ case. If σ is small, then utilization of more processors (i.e., increasing τ) leads to nearly linear speedup. If σ is large, speedup may be negligible, or there may be no speedup whatsoever. Hence, the size of σ suggests whether it is worth to use more processors or not. The second quantity, σ', characterizes the effect of the initial partition on the algorithm, and as such is relevant in the $c > 1$ case. Partitions with small σ' are preferable. We show that, surprisingly, that as long as $\tau \geq 2$, the effect of a bad partitioning is that it most doubles the number of iterations of Hydra. Hence, data partitioning can be used to optimize for different aspects of the method, such as reducing communication complexity, if needed.

For all of these quantities we derive easily computable and interpretable estimates (ω for σ and ω' for σ'), which may be used by practitioners to gauge, a-priori, whether their problem of interest is likely to be a good fit for Hydra or not. We show that for strongly convex losses, Hydra outputs an ϵ-accurate solution with probability at least $1 - \rho$ after

$$\frac{d\beta}{c\tau\mu} \log\left(\frac{1}{\epsilon\rho}\right)$$

iterations (we ignore some small details here), where a single iteration corresponds to changing of τ coordinates by each of the c nodes; β is a stepsize parameter and μ is a strong convexity constant.

1. We like to think of each node of the cluster as one of the many heads of the mythological Hydra.

square loss (SL)	$\frac{1}{2}(y^j - \mathbf{A}_{j:}x)^2$
logistic loss (LL)	$\log(1 + \exp(-y^j \mathbf{A}_{j:}x))$
square hinge loss (HL)	$\frac{1}{2}\max\{0, 1 - y^j \mathbf{A}_{j:}x\}^2$

Table 1: Examples of loss functions ℓ covered by our analysis.

Outline. In Section 2 we describe the structure of the optimization problem we consider in this paper and state assumptions. We then proceed to Section 3, in which we describe the method. In Section 4 we prove bounds on the number of iterations sufficient for Hydra to find an approximate solution with arbitrarily high probability. A discussion of various aspects of our results, as well as a comparison with existing work, can be found in Section 5. Implementation details of our distributed communication protocol are laid out in Section 6. Finally, we comment on our computational experiments with a big data (3TB matrix) L1 regularized least-squares instance in Section 7.

2. The Problem

We study the problem of minimizing regularized loss,

$$\min_{x \in \mathbb{R}^d} L(x) := f(x) + R(x), \tag{1}$$

where f is a smooth convex loss, and R is a convex (and possibly nonsmooth) regularizer.

2.1 Loss Function f

We assume that there exists a positive definite matrix $\mathbf{M} \in \mathbb{R}^{d \times d}$ such that for all $x, h \in \mathbb{R}^d$,

$$f(x + h) \leq f(x) + (f'(x))^T h + \tfrac{1}{2} h^T \mathbf{M} h, \tag{2}$$

and write $\mathbf{M} = \mathbf{A}^T \mathbf{A}$, where $\mathbf{A}$ is some n-by-d matrix.

Example. These assumptions are natural satisfied in many popular problems. A typical loss function has the form

$$f(x) = \sum_{j=1}^{n} \ell(x, \mathbf{A}_{j:}, y^j), \tag{3}$$

where $\mathbf{A} \in \mathbb{R}^{n \times d}$ is a matrix encoding n examples with d features, $\mathbf{A}_{j:}$ denotes j-th row of $\mathbf{A}$, ℓ is some loss function acting on a single example and $y \in \mathbb{R}^n$ is a vector of labels. For instance, in the case of the three losses ℓ in Table 1, assumption (2) holds with $\mathbf{M} = \mathbf{A}^T \mathbf{A}$ for SL and HL, and $\mathbf{M} = \frac{1}{4}\mathbf{A}^T \mathbf{A}$ for LL (Bradley et al., 2011).

2.2 Regularizer R

We assume that R is separable, i.e., that it can be decomposed as $R(x) = \sum_{i=1}^{d} R_i(x^i)$, where x^i is the i-th coordinate of x, and the functions $R_i : \mathbb{R} \to \mathbb{R} \cup \{+\infty\}$ are convex and closed.

Example. The choice $R_i(t) = 0$ for $t \in [0, 1]$ and $R_i(t) = +\infty$, otherwise, effectively models bound constraints, which are relevant for SVM dual. Other popular choices are $R(x) = \lambda \|x\|_1$ (L1-regularizer) and $R(x) = \frac{\lambda}{2}\|x\|_2^2$ (L2-regularizer).

3. Distributed Coordinate Descent

We consider a setup with c computers (nods) and first partition the d coordinates (features) into c sets $\mathcal{P}_1, \ldots, \mathcal{P}_c$ of equal cardinality, $s := d/c$, and assign set $\mathcal{P}_l$ to node l. Hydra is described in Algorithm 1. Hydra's convergence rate depends on the partition; we comment on this later in Sections 4 and 5. Here we simply assume that we work with a fixed partition. We now comment on the steps.

Algorithm 1: Hydra: HYbriD cooRdinAte descent

Parameters: $x_0 \in \mathbb{R}^d$; $\{\mathcal{P}_1, \ldots, \mathcal{P}_c\}$; $\beta > 0$, τ; $k \leftarrow 0$;
repeat
  $x_{k+1} \leftarrow x_k$;
  for each *computer* $l \in \{1, \ldots, c\}$ **in parallel do**
    Pick a random set of coordinates $\hat{S}_l \subseteq \mathcal{P}_l$, $|\hat{S}_l| = \tau$
    for each $i \in \hat{S}_l$ **in parallel do**
      $h_k^i \leftarrow \arg\min_t f_i'(x_k)t + \frac{M_{ii}\beta}{2}t^2 + R_i(x_k^i + t)$;
      Apply the update: $x_{k+1}^i \leftarrow x_{k+1}^i + h_k^i$;
until *happy*;

Step 3. Here we are just establishing a way of labeling the iterates. Starting with x_k, all c computers modify $c\tau$ entries of x_k in total, in a distributed way, and the result is called x_{k+1}. No computer is allowed to proceed before all computers are done with computing their updates. The resulting vector, x_{k+1}, is the new iterate. Note that, due to this, our method is inherently *synchronous*. In practice, a carefully designed asynchronous implementation will be faster, and our experiments in Section 7 are done with such an implementation.

Steps 4–5. At every iteration, each of the c computers picks a random subset of τ features from those that it owns, uniformly at random, independently of the choice of the other computers. Let $\hat{S}_l$ denote the set picked by node l . More formally, we require that i) $\hat{S}_l \subseteq \mathcal{P}_l$, ii) $\mathbf{Prob}(|\hat{S}_l| = \tau) = 1$, where $1 \leq \tau \leq s$, and that iii) all subsets of $\mathcal{P}_l$ of cardinality τ are chosen equally likely. In summary, at every iteration of the method, features belonging to the random set $\hat{S} := \cup_{l=1}^{c} \hat{S}_l$ are updated. Note that $\hat{S}$ has size $c\tau$, but that, as a sampling from the set $\{1, 2, \ldots, d\}$, it does not choose all cardinality $c\tau$ subsets of $\{1, 2, \ldots, d\}$ with equal probability. Hence, the analysis of parallel coordinate descent methods of Richtárik and Takáč (2015) does not apply. We will say that $\hat{S}$ is a *τ-distributed sampling* with respect to the partition $\{\mathcal{P}_1, \ldots, \mathcal{P}_c\}$.

Step 6. Once computer l has chosen its set of τ coordinates to work on in Step 5, it will *in parallel* compute (Step 7) and apply (Step 8) updates to them.

Step 7. This is a critical step where updates to coordinates $i \in \hat{S}_l$ are computed. By $f_i'(x)$ we denote the i-th partial derivative of f at x. Notice that the formula is very simple as it involves one dimensional optimization.

Closed-form formulas. Often, h_k^i can be computed in closed form. For $R_i(t) = \lambda_i|t|$ (weighted L1 regularizer), h_k^i is the point in the interval

$$\left[\frac{-\lambda_i - f_i'(x_k)}{\mathbf{M}_{ii}\beta}, \frac{\lambda_i - f_i'(x_k)}{\mathbf{M}_{ii}\beta}\right]$$

which is closest to $-x_k^i$. If $R_i(t) = \frac{\lambda_i}{2}t^2$ (weighted L2 regularizer), then $h_k^i = -\frac{f_i'(x_k)+\lambda_i x_k^i}{\lambda_i + \mathbf{M}_{ii}\beta}$.

Choice of β. The choice of the step-size parameter β is of paramount significance for the performance of the algorithm, as argued for different but related algorithms by Richtárik and Takáč (2015); Takáč et al. (2013); Fercoq and Richtárik (2013). We will discuss this issue at length in Sections 4 and 5.

Implementation issues: Note that computer l needs to know the partial derivatives of f at x_k for coordinates $i \in \hat{S}_l \subseteq \mathcal{P}_l$. However, x_k, as well as the data describing f, is distributed among the c computers. One thus needs to devise a fast and communication efficient way of computing these derivatives. This issue will be dealt with in Section 6.

Step 8. Here all the τ updates computed in Step 7 are applied to the iterate. Note that the updates are *local*: computer l only updates coordinates it owns, which are stored locally. Hence, this step is communication-free.

4. Convergence Rate Analysis

Notation: For any $\mathbf{G} \in \mathbb{R}^{d\times d}$, let $D^{\mathbf{G}} = \mathrm{Diag}(\mathbf{G})$. That is, $D_{ii}^{\mathbf{G}} = \mathbf{G}_{ii}$ for all i and $D_{ij}^{\mathbf{G}} = 0$ for $i \neq j$. Further, let $B^{\mathbf{G}} \in \mathbb{R}^{d\times d}$ be the block diagonal of $\mathbf{G}$ associated with the partition $\{\mathcal{P}_1, \ldots, \mathcal{P}_c\}$. That is, $B_{ij}^{\mathbf{G}} = \mathbf{G}_{ij}$ whenever $i, j \in \mathcal{P}_l$ for some l, and $B_{ij}^{\mathbf{G}} = 0$ otherwise.

4.1 Four Important Quantities: $\sigma', \omega', \sigma, \omega$

Here we define two quantities, σ' and σ, which, as we shall see, play an important role in the computation of the stepsize parameter β of Algorithm 1, and through it, in understanding its rate of convergence and potential for speedup by parallelization and distribution. As we shall see, these quantities might not be easily computable. We therefore also provide each with an easily computable and interpretable upper bound, ω' for σ' and ω for σ.

Let

$$\mathbf{Q} := (D^{\mathbf{M}})^{-1/2}\mathbf{M}(D^{\mathbf{M}})^{-1/2}, \tag{4}$$

and notice that, by construction, $\mathbf{Q}$ has ones on the diagonal. Since M is positive definite, $\mathbf{Q}$ is as well. For each $l \in \{1, \ldots, c\}$, let $\mathbf{A}_l \in \mathbb{R}^{n\times s}$ be the column submatrix of $\mathbf{A}$ corresponding to coordinates $i \in \mathcal{P}_l$. The diagonal blocks of $B^{\mathbf{Q}}$ are the matrices $\mathbf{Q}^{ll}$, $l = 1, 2, \ldots, c$, where

$$\mathbf{Q}^{kl} := (D^{\mathbf{A}_k^T\mathbf{A}_k})^{-1/2}\mathbf{A}_k^T\mathbf{A}_l(D^{\mathbf{A}_l^T\mathbf{A}_l})^{-1/2} \in \mathbb{R}^{s\times s} \tag{5}$$

for each $k, l \in \{1, 2, \ldots, c\}$. We now define

$$\sigma' := \max\{x^T\mathbf{Q}x \ : \ x \in \mathbb{R}^d, \ x^T B^{\mathbf{Q}}x \leq 1\}, \tag{6}$$

$$\sigma := \max\{x^T\mathbf{Q}x \ : \ x \in \mathbb{R}^d, \ x^T x \leq 1\}. \tag{7}$$

A useful consequence of (6) is the inequality

$$x^T(\mathbf{Q} - B^{\mathbf{Q}})x \leq (\sigma' - 1)x^T B^{\mathbf{Q}}x. \tag{8}$$

4.1.1 SPARSITY

Let a_{rl} be the r-th row of $\mathbf{A}_l$, and define

$$\omega' := \max_{1\leq r\leq n}\left\{\omega'(r) := |\{l \ : \ l \in \{1, \ldots, c\}, \ a_{rl} \neq 0\}|\right\},$$

where $\omega'(r)$ is the number of matrices $\mathbf{A}_l$ with a nonzero in row r. Likewise, define

$$\omega := \max_{1\leq r\leq n}\left\{\omega(r) := |\{l \ : \ l \in \{1, \ldots, c\}, \ \mathbf{A}_{rl} \neq 0\}|\right\},$$

where $\omega(r)$ is the number of nonzeros in the r-th row of $\mathbf{A}$.

Lemma 1. *The following relations hold:*

$$\max\{1, \tfrac{\sigma}{s}\} \leq \sigma' \leq \omega' \leq c, \qquad 1 \leq \sigma \leq \omega \leq d. \tag{9}$$

The proof can be found in the appendix.

4.2 Choice of the Stepsize Parameter β

We analyze Hydra with stepsize parameter $\beta \geq \beta^*$, where

$$\begin{aligned} \beta^* &:= \beta_1^* + \beta_2^*, \\ \beta_1^* &:= 1 + \frac{(\tau-1)(\sigma-1)}{s_1}, \\ \beta_2^* &:= \left(\frac{\tau}{s} - \frac{\tau-1}{s_1}\right)\frac{\sigma'-1}{\sigma'}\sigma, \end{aligned} \tag{10}$$

and $s_1 = \max(1, s-1)$.

As we shall see in Theorem 5, fixing c and τ, the number of iterations needed by Hydra find a solution is proportional to β. Hence, we would wish to use β which is as small as possible, but not smaller than the safe choice $\beta = \beta^*$, for which convergence is guaranteed. In practice, β can often be chosen smaller than the save but conservative value of β^*, leading to larger steps and faster convergence.

If the quantities σ and σ' are hard to compute, then one can replace them by the easily computable upper bounds ω and ω', respectively. However, there are cases when σ can be efficiently approximated and is much smaller than ω. In some ML data sets with $\mathbf{A} \in \{0,1\}^{n\times d}$, σ is close to the average number of nonzeros in a row of $\mathbf{A}$, which can be significantly smaller than the maximum, ω. On the other hand, if σ is difficult to compute, ω may provide a good proxy. Similar remarks apply to σ'.

More importantly, if $\tau \geq 2$ (which covers all interesting uses of Hydra), we may ignore β_2^* altogether, as implied by the following result.

Lemma 2. *If $\tau \geq 2$, then $\beta^* \leq 2\beta_1^*$.*

Proof. It is enough to argue that $\beta_2^* \leq \beta_1^*$. Notice that β_2^* is increasing in σ'. On the other hand, from Lemma 1 we know that $\sigma' \leq c = \frac{d}{s}$. So, it suffices to show that

$$\left(\frac{\tau}{s} - \frac{\tau-1}{s-1}\right)\left(1 - \frac{s}{d}\right)\sigma \leq 1 + \frac{(\tau-1)(\sigma-1)}{s-1}.$$

After straightforward simplification we observe that this inequality is equivalent to $(s-\tau) + (\tau - 2)\sigma + \frac{\sigma}{d}(s+\tau) \geq 0$, which clearly holds. □

Clearly, $\beta^* \geq \beta_1^*$. Hence, if in Hydra we instead of $\beta = \beta^*$ (best/smallest value prescribed by our theory) use $\beta = 2\beta_1^*$ —eliminating the need to compute σ'—the number of iterations will *at most double*. Since σ', present in β_2^*, captures the effect of the initial partition on the iteration complexity of the algorithm, we conclude that this effect is under control.

4.3 Separable Approximation

We first establish a useful identity for the expected value of a random quadratic form obtained by sampling the rows and columns of the underlying matrix via the distributed sampling $\hat{S}$. Note that the result is a direct generalization of Lemma 1 in (Takáč et al., 2013) to the $c > 1$ case.

For $x \in \mathbb{R}^d$ and $\emptyset \neq S \subseteq [d] := \{1, 2, \ldots, d\}$, we write $x^S := \sum_{i \in S} x^i e_i$, where e_i is the i-th unit coordinate vector. That is, x^S is the vector in $\mathbb{R}^d$ whose coordinates $i \in S$ are identical to those of x, but are zero elsewhere.

Lemma 3. *Fix arbitrary $\mathbf{G} \in \mathbb{R}^{d \times d}$ and $x \in \mathbb{R}^d$ and let $s_1 = \max(1, s-1)$. Then*

$$\mathbf{E}[(x^{\hat{S}})^T \mathbf{G} x^{\hat{S}}] = \frac{\tau}{s}\left[\alpha_1 x^T D^{\mathbf{G}} x + \alpha_2 x^T \mathbf{G} x + \alpha_3 x^T (\mathbf{G} - B^{\mathbf{G}}) x\right], \tag{11}$$

where $\alpha_1 = 1 - \frac{\tau-1}{s_1}$, $\alpha_2 = \frac{\tau-1}{s_1}$, $\alpha_3 = \frac{\tau}{s} - \frac{\tau-1}{s_1}$.

Proof. In the $s = 1$ case the statement is trivially true. Indeed, we must have $\tau = 1$ and thus $\mathbf{Prob}(\hat{S} = \{1, 2, \ldots, d\}) = 1$, $h^{\hat{S}} = h$, and hence

$$\mathbf{E}\left[(h^{\hat{S}})^T \mathbf{Q} h^{\hat{S}}\right] = h^T \mathbf{Q} h.$$

This finishes the proof since $\frac{\tau-1}{s_1} = 0$.

Consider now the $s > 1$ case. From Lemma 3 in Richtárik and Takáč (2015) we get

$$\mathbf{E}\left[(h^{\hat{S}})^T \mathbf{Q} h^{\hat{S}}\right] = \mathbf{E}\left[\sum_{i \in \hat{S}} \sum_{j \in \hat{S}} \mathbf{Q}_{ij} h^i h^j\right] = \sum_{i=1}^{d} \sum_{j=1}^{d} p_{ij} \mathbf{Q}_{ij} h^i h^j, \tag{12}$$

where $p_{ij} = \mathbf{Prob}(i \in \hat{S} \ \& \ j \in \hat{S})$. One can easily verify that

$$p_{ij} = \begin{cases} \frac{\tau}{s}, & \text{if } i = j, \\ \frac{\tau(\tau-1)}{s(s-1)}, & \text{if } i \neq j \text{ and } i \in \mathcal{P}_l,\ j \in \mathcal{P}_l \text{ for some } l, \\ \frac{\tau^2}{s^2}, & \text{if } i \neq j \text{ and } i \in \mathcal{P}_k,\ j \in \mathcal{P}_l \text{ for } k \neq l. \end{cases}$$

In particular, the first case follows from Eq (32) and the second from Eq (37) in Richtárik and Takáč (2015). It only remains to substitute p_{ij} into (12) and transform the result into the desired form. □

We now use the above lemma to compute a separable quadratic upper bound on $\mathbf{E}[(h^{\hat{S}})^T \mathbf{M} h^{\hat{S}}]$.

Lemma 4. *For all $h \in \mathbb{R}^d$,*

$$\mathbf{E}\left[(h^{\hat{S}})^T \mathbf{M} h^{\hat{S}}\right] \leq \frac{\tau}{s} \beta^* \left(h^T D^{\mathbf{M}} h\right). \tag{13}$$

Proof. For $x := (D^{\mathbf{M}})^{1/2} h$, we have $(h^{\hat{S}})^T \mathbf{M} h^{\hat{S}} = (x^{\hat{S}})^T \mathbf{Q} x^{\hat{S}}$. Taking expectations on both sides, and applying Lemma 3, we see that $\mathbf{E}[(h^{\hat{S}})^T \mathbf{M} h^{\hat{S}}]$ is equal to (11) for $\mathbf{G} = \mathbf{Q}$. It remains to bound the three quadratics in (11). Since $D^{\mathbf{Q}}$ is the identity matrix, $x^T D^{\mathbf{Q}} x = h^T D^{\mathbf{M}} h$. In view of (7), the 2nd term is bounded as $x^T \mathbf{Q} x \leq \sigma x^T x = \sigma h^T D^{\mathbf{M}} h$. Finally,

$$\begin{aligned} x^T(\mathbf{Q} - B^{\mathbf{Q}})x &= \frac{\sigma'-1}{\sigma'} x^T(\mathbf{Q} - B^{\mathbf{Q}})x + \frac{1}{\sigma'} x^T(\mathbf{Q} - B^{\mathbf{Q}})x \\ &\overset{(8)}{\leq} \frac{\sigma'-1}{\sigma'} x^T(\mathbf{Q} - B^{\mathbf{Q}})x + \frac{\sigma'-1}{\sigma'} x^T B^{\mathbf{Q}} x \\ &= \frac{\sigma'-1}{\sigma'} x^T \mathbf{Q} x \\ &\overset{(7)}{\leq} \frac{\sigma'-1}{\sigma'} \sigma x^T x \\ &= \frac{\sigma'-1}{\sigma'} \sigma h^T D^{\mathbf{M}} h. \end{aligned}$$

It only remains to plug in these three bounds into (11). □

Inequalities of type (13) were first proposed and studied by Richtárik and Takáč (2015)—therein called Expected Separable Overapproximation (ESO)—and were shown to be important for the convergence of parallel coordinate descent methods. However, they studied a different class of loss functions f (convex smooth and partially separable) and different types of random samplings $\hat{S}$, which did not allow them to propose an efficient distributed sampling protocol leading to a distributed algorithm. An ESO inequality was recently used by Takáč et al. (2013) to design a mini-batch stochastic dual coordinate ascent method (parallelizing the original SDCA methods of Hsieh et al. (2008)) and mini-batch stochastic subgradient descent method (Pegasos of Shalev-Shwartz et al. (2011)), and give bounds on how mini-batching leads to acceleration. While it was long observed that mini-batching often accelerates Pegasos in practice, it was only shown with the help of an ESO inequality that this is so also in theory. Recently, Fercoq and Richtárik (2013) have derived ESO inequalities for smooth approximations of nonsmooth loss functions and hence showed that parallel coordinate descent methods can accelerate on their serial counterparts on a class of structured nonsmooth convex losses. As a special case, they obtain a parallel randomized coordinate descent method for minimizing the logarithm of the exponential loss. Again, the class of losses considered in that paper, and the samplings $\hat{S}$, are different from ours. None of the above methods are distributed.

4.4 Fast Rates for Distributed Learning with Hydra

Let x_0 be the starting point of Algorithm 1, x_* be an optimal solution of problem (1) and let $L^* = L(x_*)$. Further, define $\|x\|_{\mathbf{M}}^2 := \sum_{i=1}^d \mathbf{M}_{ii}(x^i)^2$ (a weighted Euclidean norm on $\mathbb{R}^d$) and assume

that f and R are strongly convex with respect to this norm with convexity parameters μ_f and μ_R, respectively. A function ϕ is strongly convex with parameter $\mu_\phi > 0$ if for all $x, h \in \mathbb{R}^d$,

$$\phi(x+h) \geq \phi(x) + (\phi'(x))^T h + \frac{\mu_\phi}{2}\|h\|^2_{\mathbf{M}},$$

where $\phi'(x)$ is a subgradient (or gradient) for ϕ at x.

We now show that Hydra decreases strongly convex L with an exponential rate in ϵ.

Theorem 5. *Assume L is strongly convex with respect to the norm $\|\cdot\|_{\mathbf{M}}$, with $\mu_f + \mu_R > 0$. Choose $x_0 \in \mathbb{R}^d$, $0 < \rho < 1$, $0 < \epsilon < L(x_0) - L^*$ and*

$$T \quad \geq \quad \frac{d}{c\tau} \times \frac{\beta + \mu_R}{\mu_f + \mu_R} \times \log\left(\frac{L(x_0) - L^*}{\epsilon\rho}\right), \tag{14}$$

where $\beta \geq \beta^*$ and β^* is given by (10)*. If $\{x_k\}$ are the random points generated by Hydra (Algorithm 1), then*

$$\mathbf{Prob}(L(x_T) - L^* \leq \epsilon) \geq 1 - \rho.$$

Proof. We first claim that for all $x, h \in \mathbb{R}^d$,

$$\mathbf{E}\left[f(x + h^{\hat{S}})\right] \leq f(x) + \frac{\mathbf{E}[|\hat{S}|]}{d}\left((f'(x))^T h + \frac{\beta}{2} h^T D^{\mathbf{M}} h\right). \tag{15}$$

To see this, substitute $h \leftarrow h^{\hat{S}}$ into (2), take expectations on both sides and then use Lemma 4 together with the fact that for any vector a, $\mathbf{E}[a^T h^{\hat{S}}] = \frac{\mathbf{E}[|\hat{S}|]}{d} = \frac{\tau c}{sc} = \frac{\tau}{s}$. The rest follows by following the steps in the proof in (Richtárik and Takáč, 2015, Theorem 20). □

A similar result, albeit with the weaker rate $O(\frac{s\beta}{\tau\epsilon})$, can be established in the case when neither f nor R are strongly convex. In big data setting, where parallelism and distribution is unavoidable, it is much more relevant to study the dependence of the rate on parameters such as τ and c. We shall do so in the next section.

5. Discussion

In this section we comment on several aspects of the rate captured in (14) and compare Hydra to selected methods.

5.1 Insights Into the Convergence Rate

Here we comment in detail on the influence of the various design parameters (c = # computers, s = # coordinates owned by each computer, and τ = # coordinates updated by each computer in each iteration), instance-dependent parameters ($\sigma, \omega, \mu_R, \mu_f$), and parameters depending both on the instance and design (σ', ω'), on the stepsize parameter β, and through it, on the convergence rate described in Theorem 5.

special case	β^*	$\beta^*/(c\tau)$
any c $\tau = 1$	$1 + \frac{\sigma}{s}\left(\frac{\sigma' - 1}{\sigma'}\right)$	$s + \sigma\left(\frac{\sigma' - 1}{\sigma'}\right)$
$c = 1$ any τ	$1 + \frac{(\tau - 1)(\sigma - 1)}{d - 1}$	$\frac{d}{\tau}\left(1 + \frac{(\tau - 1)(\sigma - 1)}{d - 1}\right)$
$\tau c = d$	σ	σ

Table 2: Stepsize parameter $\beta = \beta^*$ and the leading factor in the rate (14) (assuming $\mu_R = 0$) for several special cases of Hydra.

5.2 Strong Convexity

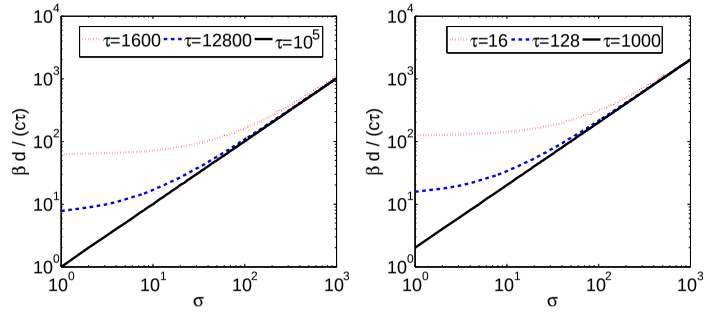
Notice that the size of $\mu_R > 0$ mitigates the effect of a possibly large β on the bound (14). Indeed, for large μ_R, the factor $(\beta + \mu_R)/(\mu_f + \mu_R)$ approaches 1, and the bound (14) is dominated by the term $\frac{d}{c\tau}$, which means that Hydra enjoys linear speedup in c and τ. In the following comments we will assume that $\mu_R = 0$, and focus on studying the dependence of the leading term $d\frac{\beta}{c\tau}$ on various quantities, including τ, c, σ and σ'.

5.3 Search for Small but Safe β

As shown by Takáč et al. (2013, Section 4.1), mini-batch SDCA might *diverge* in the setting with $\mu_f = 0$ and $R(x) \equiv 0$, even for a simple quadratic function with $d = 2$, provided that $\beta = 1$. Hence, small values of β need to be avoided. However, in view of Theorem 5, it is good if β is as small as possible. So, there is a need for a "safe" formula for a small β. Our formula (10), $\beta = \beta^*$, is serving that purpose. For a detailed introduction into the issues related to selecting a good β for parallel coordinate descent methods, we refer the reader to the first 5 pages of (Fercoq and Richtárik, 2013).

5.4 The Effect of σ'

If $c = 1$, then by Lemma 9, $\sigma' = c = 1$, and hence $\beta^*_2 = 0$. However, for $c > 1$ we *may* have $\beta^*_2 > 0$, which can hence be seen as a price we need to pay for using more nodes. The price depends on the way the data is partitioned to the nodes, as captured by σ'. In favorable circumstances, $\sigma' \approx 1$ even if $c > 1$, leading to $\beta^*_2 \approx 0$. However, in general we have the bound $\sigma' \geq \frac{c\sigma}{d}$, which gets worse as c increases and, in fact, σ' can be as large as c. Note also that ξ is decreasing in τ, and that $\xi(s, s) = 0$. This means that by choosing $\tau = s$ (which effectively removes randomization from Hydra), the effect of β^*_2 is eliminated. This may not be always possible as often one needs to solve problems with s vastly larger than the number of updates that can be performed on any given node in parallel. If $\tau \ll s$, the effect of β^*_2 can be controlled, to a certain extent, by choosing a partition



(a) $(c, s) = (1, 10^5)$ (b) $(c, s) = (10^2, 10^3)$

Figure 1: In terms of the number of iterations, very little is lost by using $c > 1$ as opposed to $c = 1$.

with small σ'. Due to the way σ' is defined, this may not be an easy task. However, it may be easier to find partitions that minimize ω', which is often a good proxy for σ'. Alternatively, we may ignore estimating σ' altogether by setting $\beta = 2\beta_1^*$, as mentioned before, at the price of at most doubling the number of iterations.

5.5 Speedup by Increasing τ

Let us fix c and compare the quantities $\gamma_\tau := \frac{\beta^*}{c\tau}$ for $\tau = 1$ and $\tau = s$. We now show that $\gamma_1 \geq \gamma_s$, which means that if all coordinates are updated at every node, as opposed to one only, then Hydra run with $\beta = \beta^*$ will take fewer iterations. Comparing the 1st and 3rd row of Table 2, we see that $\gamma_1 = s + \sigma\frac{\sigma'-1}{\sigma'}$ and $\gamma_s = \sigma$. By Lemma 1, $\gamma_1 - \gamma_s = s - \frac{\sigma}{\sigma'} \geq 0$.

5.6 Price of Distribution

For illustration purposes, consider a problem with $d = 10^5$ coordinates. In Figure 1(a) we depict the size of $\frac{d\beta_1^*}{c\tau}$ for $c = 1$ and several choices of τ, as a function of σ. We see that Hydra works better for small values of σ and that with increasing σ, the benefit of using updating more coordinates diminishes. In Figure 1(a) we consider the same scenario, but with $c = 100$ and $s = 1000$, and we plot $\frac{d2\beta_1^*}{c\tau}$ on the y axis. Note that the red dotted line in both plots corresponds to a parallel update of 1600 coordinates. In (a) all are updated on a single node, whereas in (b) we have 100 nodes, each updating 16 coordinates at a time. Likewise, the dashed blue dashed and solid black lines are also comparable in both plots. Note that the setup with $c = 10$ has a slightly weaker performance, the lines are a bit lower. This is the price we pay for using c nodes as opposed to a single node (obviously, we are ignoring communication cost here). However, in big data situations one simply has no other choice but to utilize more nodes.

5.7 Comparison with Other Methods

While we are not aware of any other *distributed* coordinate descent method, Hydra in the $c = 1$ case is closely related to several existing parallel coordinate descent methods.

5.7.1 HYDRA VS SHOTGUN

The Shotgun algorithm (parallel coordinate descent) of Bradley et al. (2011) is similar to Hydra for $c = 1$. Some of the differences: Bradley et al. (2011) only consider R equal to the $L1$ norm and their method works in dimension $2d$ instead of the native dimension d. Shotgun was not analyzed for strongly convex f, and convergence in expectation was established. Moreover, Bradley et al. (2011) analyze the step-size choice $\beta = 1$, fixed independently of the number of parallel updates τ, and give results that hold only in a "small τ" regime. In contrast, our analysis works for any choice of τ.

5.7.2 HYDRA VS PCDM

For $c = 1$, Hydra reduces to the parallel coordinate descent method (PCDM) of Richtárik and Takáč (2015), but with a *better* stepsize parameter β. We were able to achieve smaller β (and hence better rates) because we analyze a different and more specialized class of loss functions (those satisfying (2)). In comparison, Richtárik and Takáč (2015) look at a general class of partially separable losses. Indeed, in the $c = 1$ case, our distributed sampling $\hat{S}$ reduces to the sampling considered in (Richtárik and Takáč, 2015) (τ-nice sampling). Moreover, our formula for β (see Table 2) is essentially identical to the formula for β provided in (Richtárik and Takáč, 2015, Theorem 14), with the exception that we have σ where they have ω. By (9), we have $\sigma \leq \omega$, and hence our β is smaller.

5.7.3 HYDRA VS SPCDM

SPCDM of Fercoq and Richtárik (2013) is PCDM applied to a smooth approximation of a nonsmooth convex loss; with a special choice of β, similar to β_1. As such, it extends the reach of PCDM to a large class of nonsmooth losses, obtaining $O(\frac{1}{\epsilon^2})$ rates. It is possible to develop accelerated Hydra with $O(\frac{1}{\epsilon})$ rates by combining ideas from this paper, Fercoq and Richtárik (2013) with the APPROX method of Fercoq and Richtárik (2015).

5.7.4 HYDRA VS MINI-BATCH SDCA

Takáč et al. (2013) studied the performance of a mini-batch stochastic dual coordinate ascent for SVM dual ("mini-batch SDCA"). This is a special case of our setup with $c = 1$, convex quadratic f and $R_i(t) = 0$ for $t \in [0, 1]$ and $R_i(t) = +\infty$ otherwise. Our results can thus be seen as a generalization of the results in that paper to a larger class of loss functions f, more general regularizers R, and most importantly, to the distributed setting ($c > 1$). Also, we give $O(\log \frac{1}{\epsilon})$ bounds under strong convexity, whereas (Takáč et al., 2013) give $O(\frac{1}{\epsilon})$ results without assuming strong convexity. However, Takáč et al. (2013) perform a primal-dual analysis, whereas we do not.

6. Distributed Computation of the Gradient

In this section we describe some important elements of our distributed implementation.

loss function ℓ	$f_i'(x)$	$\mathbf{M}_{ii}$
SL	$\sum_{j=1}^{m} -\mathbf{A}_{ji}(y^j - \mathbf{A}_{j:}x)$	$\|\mathbf{A}_{:i}\|_2^2$
LL	$\sum_{j=1}^{m} -y^j\mathbf{A}_{ji}\frac{\exp(-y^j\mathbf{A}_{j:}x)}{1+\exp(-y^j\mathbf{A}_{j:}x)}$	$\frac{1}{4}\|\mathbf{A}_{:i}\|_2^2$
HL	$\sum_{j\,:\,y^j\mathbf{A}_{j:}x<1} \left(-y^j\mathbf{A}_{ji}(1-y^j\mathbf{A}_{j:}x)\right)$	$\|\mathbf{A}_{:i}\|_2^2$

Table 3: Information needed in Step 5 of Hydra for f given by (3) in the case of the three losses ℓ from Table 1.

Note that in Hydra, x_k is stored in a distributed way. That is, the values x_k^i for $i \in \mathcal{P}_l$ are stored on computer l. Moreover, Hydra partitions $\mathbf{A}$ columnwise as $\mathbf{A} = [\mathbf{A}_1, \ldots, \mathbf{A}_c]$, where $\mathbf{A}_l$ consists of columns $i \in \mathcal{P}_l$ of $\mathbf{A}$, and stores $\mathbf{A}_l$ on computer l. So, $\mathbf{A}$ is chopped into smaller pieces with stored in a distributed way in fast memory (if possible) across the c nodes. Note that this allows the method to work with large matrices.

At Step 5 of Hydra, node l at iteration $k+1$ needs to know the partial derivatives $f_i'(x_{k+1})$ for $i \in \hat{S}_l \subseteq \mathcal{P}_l$. We now describe several efficient distributed protocols for the computation of $f_i'(x_{k+1})$ for functions f of the form (3), in the case of the three losses ℓ given in Table 1 (SL, LL, HL). The formulas for $f_i'(x)$ are summarized in Table 3 ($\mathbf{A}_{j:}$ refers to the j-th row of $\mathbf{A}$). Let $D^y := \mathrm{Diag}(y)$.

6.1 Basic Protocol

If we write $h_k^i = 0$ if i is not updated in iteration k, then

$$x_{k+1} = x_k + \sum_{l=1}^{c}\sum_{i\in\hat{S}_l} h_k^i e_i. \tag{16}$$

Now, if we let

$$g_k := \begin{cases} \mathbf{A}x_k - y, & \text{for SL,} \\ -D^y\mathbf{A}x_k, & \text{for LL and HL,} \end{cases} \tag{17}$$

then by combining (16) and (17), we get

$$g_{k+1} = g_k + \sum_{l=1}^{c} \delta g_{k,l}, \qquad \text{where}$$

$$\delta g_{k,l} = \begin{cases} \sum_{i\in\hat{S}_l} h_k^i \mathbf{A}_{:i}, & \text{for SL,} \\ \sum_{i\in\hat{S}_l} -h_k^i D^y \mathbf{A}_{:i}, & \text{for LL and HL.} \end{cases}$$

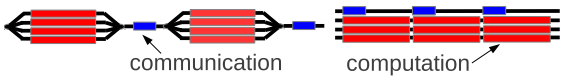


Figure 2: Parallel-serial (PS; left) vs Fully Parallel (FP; right) approach.

Note that the value $\delta g_{k,l}$ can be computed on node l as all the required data is stored locally. Hence, we let each node compute $\delta g_{k,l}$, and then use a *reduce all* operation to add up the updates to obtain g_{k+1}, and pass the sum to all nodes. Knowing g_{k+1}, node l is then able to compute $f_i'(x_{k+1})$ for any $i \in \mathcal{P}_l$ as follows:

$$f_i'(x_{k+1}) = \begin{cases} \mathbf{A}_{:i}^T g_{k+1} = \sum_{j=1}^n \mathbf{A}_{ji} g_{k+1}^j, & \text{for SL,} \\ \sum_{j=1}^n y^j \mathbf{A}_{ji} \frac{\exp(g_{k+1}^j)}{1+\exp(g_{k+1}^j)}, & \text{for LL,} \\ \sum_{j\,:\,g_{k+1}^j>-1} y^j \mathbf{A}_{ji}(1+g_{k+1}^j), & \text{for HL.} \end{cases}$$

6.2 Advanced Protocols

The basic protocol discussed above has obvious drawbacks. Here we identify them and propose modifications leading to better performance.

- *alternating Parallel and Serial regions (PS):* The basic protocol alternates between two procedures: i) a computationally heavy one (done in parallel) with no MPI communication, and ii) MPI communication (serial). An easy fix would be to dedicate 1 thread to deal with communication and the remaining threads within the same computer for computation. We call this protocol *Fully Parallel (FP)*. Figure 2 compares the basic (left) and FP (right) approaches.

- *Reduce All (RA):* In general, reduce all operations may significantly degrade the performance of distributed algorithms. Communication taking place only between nodes close to each other in the network, e.g., nodes directly connected by a cable, is more efficient. Here we propose the *Asynchronous StreamLined (ASL)* communication protocol in which each node, in a given iteration, sends only 1 message (asynchronously) to a nearby computer, and also receives only one message (asynchronously) from another nearby computer. Communication hence takes place in an *Asynchronous Ring*. This communication protocol requires significant changes in the algorithm. Figure 3 illustrates the flow of messages at the end of the k-th iteration for $c = 4$.

  We order the nodes into a ring, denoting l_- and l_+ the two nodes neighboring node l. Node l only receives data from l_-, and sends data to l_+. Let us denote by $\delta G_{k,l}$ the data sent by node l to l_+ at the end of iteration k. When l starts iteration k, it already knows $\delta G_{k-1,l_-}$.[2] Hence, data which will be sent at the end of the k-th iteration by node l is given by

$$\delta G_{k,l} = \delta G_{k-1,l_-} - \delta g_{k-c,l} + \delta g_{k,l}. \tag{18}$$

  This leads to the update rule

$$g_{k+1,l} = g_{k,l} + \delta g_{k,l} + \delta G_{k,l_-} - \delta g_{k-c+1,l}.$$

2. Initially, we let $\delta g_{k,l} = \delta G_{k,l} = 0$ for all $k \le 0$.

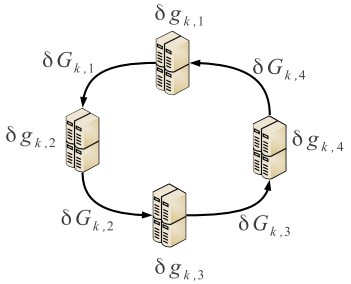

Figure 3: ASL protocol with $c = 4$ nodes. In iteration k, node l computes $\delta g_{k,l}$, and sends $\delta G_{k,l}$ to l_+.

ASL needs less communication per iteration. On the other hand, information is propagated more slowly to the nodes through the ring, which may adversely affect the number of iterations till convergence (note that we do not analyze Hydra with this communication protocol). Indeed, it takes $c-1$ iterations to propagate information to all nodes. Also, storage requirements have increased: at iteration k we need to store the vectors $\delta g_{t,l}$ for $k-c \leq t \leq k$ on computer l.

7. Experiments

In this section we present numerical evidence that Hydra is capable to efficiently solve big data problems. We have a C++ implementation, using Boost::MPI and OpenMP. Experiments were executed on a Cray XE6 cluster with 128 nodes; with each node equipped with two AMD Opteron Interlagos 16-core processors and 32 GB of RAM.

7.1 Performance of Communication Protocols

In this experiment we consider a LASSO problem, i.e., f given by (3) with ℓ being the square loss (SL) and $R(x) = \|x\|_1$. In order to to test Hydra under controlled conditions, we adapted the LASSO generator proposed by Nesterov (2013, Section 6); modifications were necessary as the generator does not work well in the big data setting.

As discussed in Section 6, the advantage of the RA protocol is the fact that Theorem 5 was proved in this setting, and hence can be used as a safe benchmark for comparison with the advanced protocols.

Table 4 compares the average time per iteration for the 3 approaches and 3 choices of τ. We used 128 nodes, each running 4 MPI processes (hence $c = 512$). Each MPI process runs 8 OpenMP threads, giving 4,096 cores in total. The data matrix $\mathbf{A}$ has $n = 10^9$ rows and $d = 5 \times 10^8$ columns, and has 3 TB, double precision. One can observe that in all cases, ASL-FP yields largest gains compared to the benchmark RA-PS protocol. Note that ASL has some overhead in each iteration, and hence in cases when computation per node is small ($\tau = 10$), the speedup is only 1.62. When $\tau = 10^2$ (in this case the durations of computation and communication were comparable), ASL-FP

τ	comm. protocol	organization	avg. time	speedup
10	RA	PS	0.040	—
10	RA	FP	0.035	1.15
10	ASL	FP	0.025	1.62
10^2	RA	PS	0.100	—
10^2	RA	FP	0.077	1.30
10^2	ASL	FP	0.032	3.11
10^3	RA	PS	0.321	—
10^3	RA	FP	0.263	1.22
10^3	ASL	FP	0.249	1.29

Table 4: Duration of a single Hydra iteration for 3 communication protocols. The basic RA-PS protocol is always the slowest, but follows the theoretical analysis. ASL-FP can be $3\times$ faster.

is 3.11 times faster than RA-PS. But the gain becomes again only moderate for $\tau = 10^3$; this is because computation now takes much longer than communication, and hence the choice of strategy for updating the auxiliary vector g_k is less significant. Let us remark that the use of larger τ requires larger $beta$, and hence possibly more iterations (in the worst case).

We now move on to solving an artificial big data LASSO problem with matrix $\mathbf{A}$ in block angular form, depicted in (19).

$$\mathbf{A} = \begin{pmatrix} \mathbf{A}_1^{loc} & 0 & \cdots & 0 \\ 0 & \mathbf{A}_2^{loc} & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ \mathbf{A}_1^{glob} & \mathbf{A}_2^{glob} & \cdots & \mathbf{A}_c^{glob} \end{pmatrix}. \tag{19}$$

Such matrices often arise in stochastic optimization. Each Hydra head (=node) l owns two matrices: $\mathbf{A}_l^{loc} \in \mathbb{R}^{1,952,148 \times 976,562}$ and $\mathbf{A}_l^{glob} \in \mathbb{R}^{500,224 \times 976,562}$. The average number of nonzero elements per row in the local part of $\mathbf{A}_l$ is 175, and $1,000$ for the global part. Optimal solution x_* has exactly $160,000$ nonzero elements. Figure 4 compares the evolution of $L(x_k) - L^*$ for ASL-FP and RA-FP.

Remark: When communicating g_{kl}, only entries corresponding to the global part of $\mathbf{A}_l$ need to be communicated, and hence in RA, a *reduce all* operation is applied to vectors $\delta g_{glob,l} \in \mathbb{R}^{500,224}$. In ASL, vectors with the same length are sent.

7.2 Updating All Coordinates on Each Node in Each Iteration Might not be Optimal

In this section we give an experimental demonstration that it may not be optimal for each node of Hydra to update all coordinates it owns (in each iteration). That is, we will show that the seemingly ideal choice $\tau = s$ is not necessarily optimal.

In the experiment, we use the *astro-ph* data set consisting of abstracts of physics papers (see Shalev-Shwartz et al. (2011)). This data set consists of $d = 29,882$ samples with $n = 32,487$ fea-

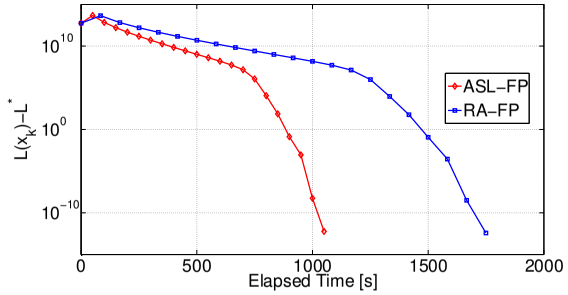

Figure 4: Evolution of $L(x_k) - L^*$ in time. ASL-FP significantly outperforms RA-FP. The loss L is pushed down by 25 degrees of magnitude in less than 30 minutes (3TB problem).

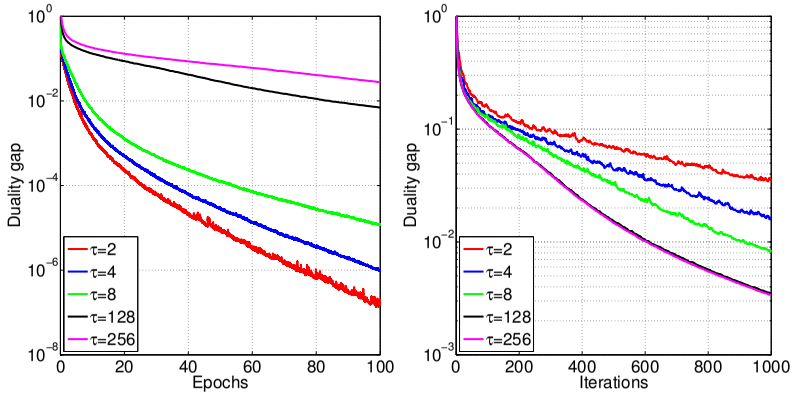

Figure 5: Evolution of the duality gap for several choices of τ.

tures; and hence is a relatively small data set. We have chosen a random partition of the coordinates (=samples) to $c = 32$ nodes, with each partition consisting of $s = 933$ samples (the last partition consists of 959 samples).

In Figure 5 we depict the evolution of the duality gap as a function of effective passes over data (epochs) (left plot) and as a function of iterations (right right). In each plot, we depict the performance of Hydra run with various choices of τ.

With larger τ, i.e., when each node updates more coordinates in a single iteration, more epochs are needed to obtain a solution of any given accuracy. However, if increasing τ by a fair amount only leads to a small increase in computation time within a node (say, because, each node utilizes a multicore processor and τ is proportional to the number of processors), then the increased number of passes over data will not be matched with a similar increase in compute time. The reverse side

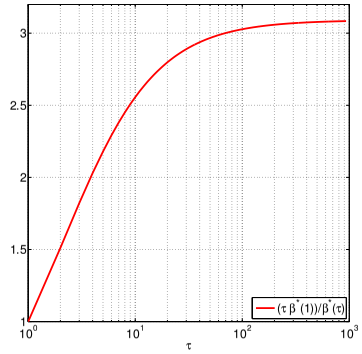

Figure 6: Evolution of the duality gap for several choices of τ.

of this situation is depicted in the right plot. That is, as τ increases, one needs fewer iterations to obtain any given accuracy.

In Figure 6 we depict the theoretical speed-up guarantee, i.e., the fraction $\frac{\tau}{\beta^*}$. Looking at the right plot of Figure 5, we see that the choice $\tau = 256$ does not lead to further speedup when compared to the $\tau = 128$ choice. This phenomenon is also captured in Figure 6, where the line becomes quite flat above $\tau \approx 10^2$.

.

Remark: We have used 10 iterations of the power method in order to estimate parameters σ and σ' which were used to obtain β^* using (10) (note that, in view of Lemma 2, we could have also used $\beta = 2\beta_1^*$). Their values are: $\sigma = 440.61$ and $\sigma' = 29.65$.

7.3 A Simple Model for Communication-Computation Trade-Off: Search for Optimal τ

Assume all c nodes of the cluster are identical. Also assume $s \geq 2$. Further, assume there is a constant $1 \leq K \leq s$ such that while each node is able to compute K coordinate updates in time T_1, the computation of jK updates, for $j = 2, 3, \ldots$ takes jT_1 units of time. This will be approximately true in reality for K sufficiently large, typically a small multiple of the number of cores. It may be useful to think that K is, in fact, equal to the number of cores of each node. Further, assume that the time of updating g_k to g_{k+1} is T_2 (note that this involves communication).

Bases on this simple model, a single iteration of Hydra run with $\tau = jK$ coordinate updates on each node (for $1 \leq j \leq s/K$) takes

$$jT_1 + T_2 \tag{20}$$

units of time.

In what follows, we will assume, for simplicity, that $\mu_R = 0$ (i.e., the regularizer is not strongly convex). The computations simplify with this assumption, but similar computations can be performed in the $\mu_R > 0$ case.

Focusing on the terms which depend on τ, Theorem 5 says that to obtain an ϵ-solution, Hydra needs $\mathcal{O}(\frac{\beta}{\tau})$ iterations. Combining this with the time it takes to perform a single iteration, the overall

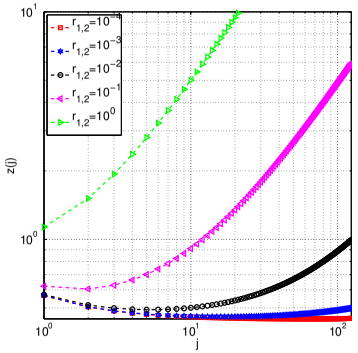

Figure 7: The dependence of the total "time complexity" $T(j)$ on j for various values of the computation-communication ratio $r_{1,2}$.

time, as a function of j, is proportional to

$$\begin{aligned} T(j) &:= \frac{\beta}{jK}(jT_1 + T_2) \\ &\overset{(10)}{=} \frac{1 + \frac{(jK-1)(\sigma-1)}{s_1} + \left(\frac{jK}{s} - \frac{jK-1}{s_1}\right)\frac{\sigma'-1}{\sigma'}\sigma}{jK}(\mathcal{T}_2 + \mathcal{T}_1 j) \\ &= \frac{1 + \frac{(jK-1)(\sigma-1)}{s_1} + \left(\frac{jK}{s} - \frac{jK-1}{s_1}\right)\frac{\sigma'-1}{\sigma'}\sigma}{jK}(1 + jr_{1,2}), \end{aligned}$$

where

$$r_{1,2} := \frac{T_1}{T_2}.$$

Note that $r_{1,2}$ is high if computation is expensive relative to communication, and vice versa. This ratio can be estimated in any particular distributed system.

In Figure 7 we plot $T(j)$ as a function of j for $r_{1,2} \in \{10^{-4}, 10^{-3}, 10^{-2}, 10^{-1}, 10^{0}\}$, $K = 8$ and the rest of the parameters appearing in the definition of $T(j)$ identical to those used in Section 7.2. For large enough $r_{1,2}$, i.e., if communication is relatively cheap, then T is an increasing function of j. This means that it is optimal to choose $j = 1$, which means that it is optimal to only update $\tau = jK$ coordinates on each node in each iteration. This observation is informally summarized as follows:

> *If communication is inexpensive relative to computation, it is optimal for each node to perform a small number of coordinate updates in each iteration. That is, if communication is cheap, do less computation in each iteration.*

For small enough $r_{1,2}$, however, the optimal point j is strictly larger than 1 and smaller than s/K. As $r_{1,2}$ decreases, optimal j increases. This observation is informally summarized as:

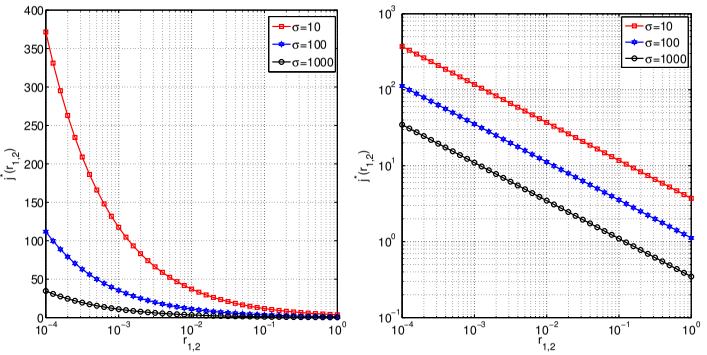

Figure 8: Comparison of $j^*(r_{1,2})$ for various values of parameter σ (left: semilog plot; right: loglog plot).

> *As communication becomes more expensive relative to computation, it is optimal for each node to perform a larger number of coordinate updates in each iteration. That is, if communication is more expensive, do more computation in each iteration.*

Since T is a simple function of j, it is possible to find j^* which minimizes $T(j)$ in closed form (if we relax the requirement of keeping j integral, which is not very important):

$$j^* := \arg\min_j T(j) = \sqrt{\frac{s(s\sigma' - \sigma)}{r_{1,2}K(s\sigma'(\sigma-1) + \sigma - \sigma'\sigma)}}.$$

In Figure 8 we plot j^* as a function of $r_{1,2}$ for $\sigma = 10, 100, 1000$. Recall that smaller σ means less correlated data. This means that less synchronization is needed, and eventually allows us to do more coordinate updates in a single iteration (i.e., j^* is larger). If communication is relatively expensive ($r_{1,2}$ is small), then j^* is big. However, as communication gets cheaper, j^* gets smaller.

7.4 Experiments with a Real Data Set in a Real Distributed Environment

In this section we report on experiments with the WebSpam data set Libsvm. This data set encodes a binary classification problem with $d = 350,000$ samples and $n = 16,609,143$ features. The total size of the data set describing the problem exceeds 23 GB. We split this data into $c = 16$ balanced groups, each containing $s = 21,875$ samples and applied Hydra to the problem (the dual of SVM with hinge loss) for various choices of τ. The results are depicted in Figure 9. As each node in our experiments had an 8-core processor, we have chosen τ in multiples of 8: $\tau \in \{8, 80, 160, 320, 640, 1280, 2560, 5120\}$.

In the plot on the left we have run the RA variant with $\beta := 2\beta_1^*$ and in the plot on the right we have run the RA with $\beta := \frac{2\beta_1^*}{100}$. By comparing the plots, we can observe that for this particular data set, the theoretically safe choice of β ($\beta := 2\beta_1^*$) is too conservative. Indeed, massive speedups

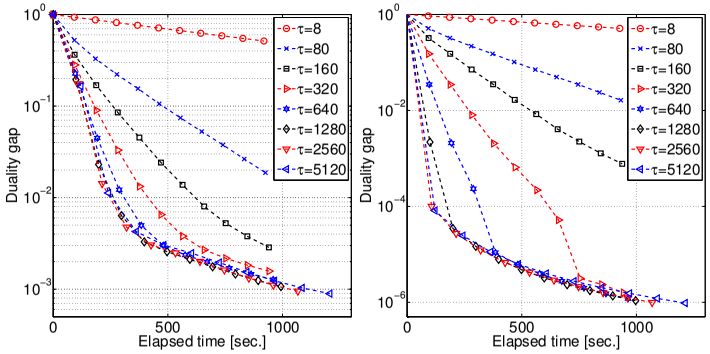

Figure 9: The duality gap evolving in time for Hydra run with various levels of parallelism (as given by τ) within each node.

can be obtained by using a more aggressive stepsize strategy, i.e., by choosing β hundred times smaller than the one recommended by theory. While it is to be expected that particular data sets will tolerate such aggressive stepsize strategies, there are data sets where such stepsizes might lead to a diverging algorithm. However, it is clear that Hydra would benefit from a line-search procedure for the selection of β.

One can also observe from Figure 9 that with beyond some point, increasing τ does not bring much benefit, and only increases the runtime.

8. Extensions

Our results can be extended to the setting where coordinates are replaced by blocks of coordinates, as in (Nesterov, 2012), and to partially separable losses, as in (Richtárik and Takáč, 2015). We expect the block setup to potentially lead to further significant speedups in a practical implementation due to the fact that this will allow us to design data-dependent block norms, which will in turn enable Hydra to use more curvature information the information contained in the diagonal of M. In such a setup, in Step 7 we will instead have a problem of a larger dimension, and the quadratic term can involve a submatrix of M.

Appendix A. Proof Lemma 1

1. The inequality $\omega' \leq c$ is obviously true. By considering x with zeroes in all coordinates except those that belong to $\mathcal{P}_k$ (where k is an arbitrary but fixed index), we see that $x^T\mathbf{Q}x = x^T B^{\mathbf{Q}} x$, and hence $\sigma' \geq 1$.

2. We now establish that $\sigma' \leq \omega'$. Let $\phi(x) = \frac{1}{2}x^T\mathbf{Q}x$, $x \in \mathbb{R}^d$; its gradient is

$$\phi'(x) = \mathbf{Q}x. \tag{21}$$

For each $k = 1, 2, \ldots, c$, define a pair of conjugate norms on $\mathbb{R}^s$ as follows:

$$\|v\|_{(k)}^2 := \langle \mathbf{Q}^{kk} v, v\rangle, \qquad (\|v\|_{(k)}^*)^2 := \max_{\|v'\|_{(k)} \leq 1} \langle v', v\rangle = \langle (\mathbf{Q}^{kk})^{-1} v, v\rangle. \tag{22}$$

Let $\mathbf{U}_k$ be a column submatrix of the d-by-d identity matrix corresponding to columns $i \in \mathcal{P}_k$. Clearly, $\mathbf{A}_k = \mathbf{A}\mathbf{U}_k$ and $\mathbf{U}_k^T\mathbf{Q}\mathbf{U}_k$ is the k-th diagonal block of $\mathbf{Q}$, i.e.,

$$\mathbf{U}_k^T\mathbf{Q}\mathbf{U}_k \overset{(4)}{=} \mathbf{Q}^{kk}. \tag{23}$$

Moreover, for $x \in \mathbb{R}^d$ and $k \in \{1, 2, \ldots, c\}$, let $x^{(k)} = \mathbf{U}_k^T x$ and, fixing positive scalars $w_1, \ldots, w_c$, define a norm on $\mathbb{R}^d$ as follows:

$$\|x\|_w := \left(\sum_{k=1}^c w_k \|x^{(k)}\|_{(k)}^2\right)^{1/2}. \tag{24}$$

Now, we claim that for each k,

$$\|\mathbf{U}_k^T\phi'(x + \mathbf{U}_k h^{(k)}) - \mathbf{U}_k^T\phi'(x)\|_{(k)}^* \leq \|h^{(k)}\|_{(i)}.$$

This means that ϕ' is block Lipschitz (with blocks corresponding to variables in $\mathcal{P}_k$), with respect to the norm $\|\cdot\|_{(k)}$, with Lipschitz constant 1. Indeed, this is, in fact, satisfied with equality:

$$\begin{aligned}
\|\mathbf{U}_k^T\phi'(x + \mathbf{U}_k h^{(k)}) - \mathbf{U}_k^T\phi'(x)\|_{(k)}^* &\overset{(21)}{=} \|\mathbf{U}_k^T\mathbf{Q}(x + \mathbf{U}_k h^{(k)}) - \mathbf{U}_k\mathbf{Q}x\|_{(k)}^* \\
&= \|\mathbf{U}_k^T\mathbf{Q}\mathbf{U}_k h^{(k)}\|_{(k)}^* \\
&\overset{(23)}{=} \|\mathbf{Q}^{kk} h^{(k)}\|_{(k)}^* \\
&\overset{(22)}{=} \langle (\mathbf{Q}^{kk})^{-1}\mathbf{Q}^{kk} h^{(k)}, \mathbf{Q}^{kk} h^{(k)}\rangle \\
&\overset{(22)}{=} \|h^{(k)}\|_{(k)}.
\end{aligned}$$

This is relevant because then, by Richtárik and Takáč (2015, Theorem 7; see comment 2 following the theorem), it follows that ϕ' is Lipschitz with respect to $\|\cdot\|_w$, where $w_k = 1$ for all $k = 1, \ldots, c$, with Lipschitz constant ω' (ω' is the degree of partial block separability of ϕ with respect to the blocks $\mathcal{P}_k$). Hence,

$$\frac{1}{2}x^T\mathbf{Q}x = \phi(x) \leq \phi(0) + (\phi'(0))^T x + \frac{\omega'}{2}\|x\|_w^2 \overset{(22)+(24)}{=} \frac{\omega'}{2}\sum_{k=1}^c \langle \mathbf{Q}^{kk} x^{(k)}, x^{(k)}\rangle = \frac{\omega'}{2}(x^T B^{\mathbf{Q}} x),$$

which establishes the inequality $\sigma' \leq \omega'$.

3. We now show that $\frac{\sigma}{s} \leq \sigma'$. If we let $\theta := \max\{x^T B^{\mathbf{Q}} x : x^T x \leq 1\}$, then $x^T B^{\mathbf{Q}} x \leq \theta x^T x$ and hence $\{x \ : \ x^T x \leq 1\} \subseteq \{x \ : \ x^T B^{\mathbf{Q}} x \leq \theta\}$. This implies that

$$\sigma = \max_x \{x^T \mathbf{Q} x \ : \ x^T x \leq 1\} \leq \max_x \{x^T \mathbf{Q} x \ : \ x^T B^{\mathbf{Q}} x \leq \theta\} = \theta \sigma'.$$

It now only remains to argue that $\theta \leq s$. For $x \in \mathbb{R}^d$, let $x^{(k)}$ denote its subvector in $\mathbb{R}^s$ corresponding to coordinates $i \in \mathcal{P}_k$ and $\Delta = \{p \in \mathbb{R}^c : p \geq 0, \ \sum_{k=1}^c p_k = 1\}$. We can now write

$$\begin{aligned}
\theta &= \max_x \left\{ \sum_{k=1}^c (x^{(k)})^T \mathbf{Q}^{kk} x^{(k)} \ : \ \sum_{k=1}^c (x^{(k)})^T x^{(k)} \leq 1 \right\} \\
&= \max_{p \in \Delta} \sum_{k=1}^c \left\{ \max (x^{(k)})^T \mathbf{Q}^{kk} x^{(k)} \ : \ (x^{(k)})^T x^{(k)} = p_k \right\} \\
&= \max_{p \in \Delta} \sum_{k=1}^c p_k \max \left\{ (x^{(k)})^T \mathbf{Q}^{kk} x^{(k)} \ : \ (x^{(k)})^T x^{(k)} = 1 \right\} \\
&= \max_{1 \leq k \leq c} \max \left\{ (x^{(k)})^T \mathbf{Q}^{kk} x^{(k)} \ : \ (x^{(k)})^T x^{(k)} = 1 \right\} \\
&\leq s.
\end{aligned}$$

In the last step we have used the fact that $\sigma(\mathbf{Q}) = \sigma \leq c = \dim(\mathbf{Q})$, proved in steps 1 and 2, applied to the setting $\mathbf{Q} \leftarrow \mathbf{Q}^{kk}$.

4. The chain of inequalities $1 \leq \sigma \leq \omega \leq c$ is obtained as a special case of the chain $1 \leq \sigma' \leq \omega' \leq d$ (proved above) when $c = d$ (and hence $\mathcal{P}_l = \{l\}$ for $l = 1, \ldots, d$). Indeed, in this case $B^{\mathbf{Q}} = D^{\mathbf{Q}}$, and so $x^T B^{\mathbf{Q}} x = x^T D^{\mathbf{Q}} x = x^T x$, which means that $\sigma' = \sigma$ and $\omega' = \omega$.

Abstract

In a wide range of statistical learning problems such as ranking, clustering or metric learning among others, the risk is accurately estimated by U-statistics of degree $d \geq 1$, *i.e.* functionals of the training data with low variance that take the form of averages over k-tuples. From a computational perspective, the calculation of such statistics is highly expensive even for a moderate sample size n, as it requires averaging $O(n^d)$ terms. This makes learning procedures relying on the optimization of such data functionals hardly feasible in practice. It is the major goal of this paper to show that, strikingly, such empirical risks can be replaced by drastically computationally simpler Monte-Carlo estimates based on $O(n)$ terms only, usually referred to as *incomplete U-statistics*, without damaging the $O_{\mathbb{P}}(1/\sqrt{n})$ learning rate of *Empirical Risk Minimization* (ERM) procedures. For this purpose, we establish uniform deviation results describing the error made when approximating a U-process by its incomplete version under appropriate complexity assumptions. Extensions to model selection, fast rate situations and various sampling techniques are also considered, as well as an application to stochastic gradient descent for ERM. Finally, numerical examples are displayed in order to provide strong empirical evidence that the approach we promote largely surpasses more naive subsampling techniques.

Keywords: big data, empirical risk minimization, U-processes, rate bound analysis, sampling design, stochastic gradient descent

1. Introduction

In classification/regression, empirical risk estimates are sample mean statistics and the theory of *Empirical Risk Minimization* (ERM) has been originally developed in this context, see Devroye et al. (1996). The ERM theory essentially relies on the study of maximal deviations between these empirical averages and their expectations, under adequate complexity assumptions on the set of prediction rule candidates. The relevant tools are mainly concentration inequalities for empirical processes, see Ledoux and Talagrand (1991) for instance.

In a wide variety of problems that received a good deal of attention in the machine learning literature and ranging from clustering to image recognition through ranking or learning on graphs, natural estimates of the risk are not basic sample means but take the form of averages of d-tuples, usually referred to as U-statistics in Probability and Statistics, see Lee (1990). In Clémençon et al. (2005) for instance, ranking is viewed as pairwise classification and the empirical ranking error of any given prediction rule is a U-statistic of order 2, just like the *within cluster point scatter* in cluster analysis (see Clémençon, 2014) or empirical performance measures in metric learning, refer to Cao et al. (2012) for instance. Because empirical functionals are computed by averaging over tuples of sampling observations, they exhibit a complex dependence structure, which appears as the price to be paid for low variance estimates. *Linearization techniques* (see Hoeffding, 1948) are the main ingredient in studying the behavior of empirical risk minimizers in this setting, allowing to establish probabilistic upper bounds for the maximal deviation of collection of centered U-statistics under appropriate conditions by reducing the analysis to that of standard empirical processes. However, while the ERM theory based on minimization of U-statistics is now consolidated (see Clémençon et al., 2008), putting this approach in practice generally leads to significant computational difficulties that are not sufficiently well documented in the machine learning literature. In many concrete cases, the mere computation of the risk involves a summation over an extremely high number of tuples and runs out of time or memory on most machines.

Whereas the availability of massive information in the Big Data era, which machine learning procedures could theoretically now rely on, has motivated the recent development of *parallelized / distributed* approaches in order to scale-up certain statistical learning algorithms, see Bekkerman et al. (2011) or Bianchi et al. (2013) and the references therein, the present paper proposes to use *sampling techniques* as a remedy to the apparent intractability of learning from data sets of explosive size, in order to break the current computational barriers. More precisely, it is the major goal of this article to study how a simplistic sampling technique (*i.e.* drawing with replacement) applied to risk estimation, as originally proposed by Blom (1976) in the context of asymptotic pointwise estimation, may efficiently remedy this issue without damaging too much the "reduced variance" property of the estimates, while preserving the learning rates (including certain "fast-rate" situations). For this purpose, we investigate to which extent a U-process, that is a collection of U-statistics, can be accurately approximated by a Monte-Carlo version (which shall be referred to as an *incomplete U-process* throughout the paper) involving much less terms, provided it is indexed by a class of kernels of controlled complexity (in a sense that will be explained later). A maximal deviation inequality connecting the accuracy of the approximation to the number of terms involved in the approximant is thus established. This result is the key to the analysis of the statistical performance of minimizers of risk estimates when they are in the form of an incomplete U-statistic. In particular, this allows us to show the advantage of using this specific sampling technique, compared to more naive approaches with exactly the same computational cost, consisting for instance in first drawing a subsample and then computing a risk estimate of the form of a (complete) U-statistic based on it. We also show how to incorporate this sampling strategy into iterative statistical learning techniques based on stochastic gradient descent (SGD), see Bottou (1998). The variant of the SGD method we propose involves the computation of an incomplete U-statistic to estimate the gradient at each step. For the estimator thus produced, rate bounds describing its statistical performance are established under mild assumptions. Beyond theoretical results, we

present illustrative numerical experiments on metric learning and clustering with synthetic and real-world data that support the relevance of our approach.

The rest of the article is organized as follows. In Section 2, we recall basic definitions and concepts pertaining to the theory of U-statistics/processes and present important examples in machine learning where natural estimates of the performance/risk measure are U-statistics. We then review the existing results for the empirical minimization of complete U-statistics. In Section 3, we recall the notion of incomplete U-statistic and we derive maximal deviation inequalities describing the error made when approximating a U-statistic by its incomplete counterpart uniformly over a class of kernels that fulfills appropriate complexity assumptions. This result is next applied to derive (possibly fast) learning rates for minimizers of the incomplete version of the empirical risk and to model selection. Extensions to incomplete U-statistics built by means of other sampling schemes than sampling with replacement are also investigated. In Section 4, estimation by means of incomplete U-statistics is applied to stochastic gradient descent for iterative ERM. Section 5 presents some numerical experiments. Finally, Section 6 collects some concluding remarks. Technical details are deferred to the Appendix.

2. Background and Preliminaries

As a first go, we briefly recall some key notions of the theory of U-statistics (Section 2.1) and provide several examples of statistical learning problems for which natural estimates of the performance/risk measure are in the form of U-statistics (Section 2.2). Finally, we review and extend the existing rate bound analysis for the empirical minimization of (complete) generalized U-statistics (Section 2.3). Here and throughout, $\mathbb{N}^*$ denotes the set of all strictly positive integers, $\mathbb{R}_+$ the set of nonnegative real numbers.

2.1 U-Statistics/Processes: Definitions and Properties

For clarity, we recall the definition of generalized U-statistics. An excellent account of properties and asymptotic theory of U-statistics can be found in Lee (1990).

Definition 1 (Generalized U-statistic) *Let $K \geq 1$ and $(d_1, \ldots, d_K) \in \mathbb{N}^{*K}$. Let $\mathbf{X}_{\{1,\ldots,n_k\}} = (X_1^{(k)}, \ldots, X_{n_k}^{(k)})$, $1 \leq k \leq K$, be K independent samples of sizes $n_k \geq d_k$ and composed of i.i.d. random variables taking their values in some measurable space $\mathcal{X}_k$ with distribution $F_k(dx)$ respectively. Let $H : \mathcal{X}_1^{d_1} \times \cdots \times \mathcal{X}_K^{d_K} \to \mathbb{R}$ be a measurable function, square integrable with respect to the probability distribution $\mu = F_1^{\otimes d_1} \otimes \cdots \otimes F_K^{\otimes d_K}$. Assume in addition (without loss of generality) that $H(\mathbf{x}^{(1)}, \ldots, \mathbf{x}^{(K)})$ is symmetric within each block of arguments $\mathbf{x}^{(k)}$ (valued in $\mathcal{X}_k^{d_k}$), $1 \leq k \leq K$. The generalized (or K-sample) U-statistic of degrees $(d_1, \ldots, d_K)$ with kernel H, is then defined as*

$$U_{\mathbf{n}}(H) = \frac{1}{\prod_{k=1}^{K} \binom{n_k}{d_k}} \sum_{I_1} \cdots \sum_{I_K} H(\mathbf{X}_{I_1}^{(1)}, \mathbf{X}_{I_2}^{(2)}, \ldots, \mathbf{X}_{I_K}^{(K)}), \tag{1}$$

where the symbol $\sum_{I_k}$ refers to summation over all $\binom{n_k}{d_k}$ subsets $\mathbf{X}_{I_k}^{(k)} = (X_{i_1}^{(k)}, \ldots, X_{i_{d_k}}^{(k)})$ related to a set I_k of d_k indexes $1 \leq i_1 < \ldots < i_{d_k} \leq n_k$ and $\mathbf{n} = (n_1, \ldots, n_K)$.

The above definition generalizes standard sample mean statistics, which correspond to the case $K = 1 = d_1$. More generally when $K = 1$, $U_{\mathbf{n}}(H)$ is an average over all d_1-tuples of observations, while $K \geq 2$ corresponds to the multi-sample situation with a d_k-tuple for each sample $k \in \{1, \ldots, K\}$. A U-process is defined as a collection of U-statistics indexed by a set $\mathcal{H}$ of kernels. This concept generalizes the notion of empirical process.

Many statistics used for pointwise estimation or hypothesis testing are actually generalized U-statistics (*e.g.* the sample variance, the Gini mean difference, the Wilcoxon Mann-Whitney statistic, Kendall tau). Their popularity mainly arises from their "reduced variance" property: the statistic $U_{\mathbf{n}}(H)$ has minimum variance among all unbiased estimators of the parameter

$$\begin{aligned} \mu(H) &= \mathbb{E}\left[H(X_1^{(1)}, \ldots, X_{d_1}^{(1)}, \ldots, X_1^{(K)}, \ldots, X_{d_K}^{(K)})\right] \\ &= \int_{\mathbf{x}^{(1)} \in \mathcal{X}_1^{d_1}} \cdots \int_{\mathbf{x}^{(K)} \in \mathcal{X}_K^{d_K}} H(\mathbf{x}^{(1)}, \ldots, \mathbf{x}^{(K)}) dF_1^{\otimes d_1}(\mathbf{x}^{(1)}) \cdots dF_K^{\otimes d_K}(\mathbf{x}^{(K)}) = \mathbb{E}\left[U_{\mathbf{n}}(H)\right]. \end{aligned} \tag{2}$$

Classically, the limit properties of these statistics (law of large numbers, central limit theorem, *etc.*) are investigated in an asymptotic framework stipulating that, as the size of the full pooled sample

$$n \stackrel{\text{def}}{=} n_1 + \ldots + n_K \tag{3}$$

tends to infinity, we have:

$$n_k/n \to \lambda_k > 0 \text{ for } k = 1, \ldots, K. \tag{4}$$

Asymptotic results and deviation/moment inequalities for K-sample U-statistics can be classically established by means of specific representations of this class of functionals, see (15) and (27) introduced in later sections. Significant progress in the analysis of U-statistics and U-processes has then recently been achieved by means of decoupling theory, see de la Peña and Giné (1999). For completeness, we point out that the asymptotic behavior of (multisample) U-statistics has been investigated under weaker integrability assumptions than that stipulated in Definition 1, see Lee (1990).

2.2 Motivating Examples

In this section, we review important supervised and unsupervised statistical learning problems where the empirical performance/risk measure is of the form of a generalized U-statistics. They shall serve as running examples throughout the paper.

2.2.1 Clustering

Clustering refers to the unsupervised learning task that consists in partitioning a set of data points $X_1, \ldots, X_n$ in a feature space $\mathcal{X}$ into a finite collection of subgroups depending on their similarity (in a sense that must be specified): roughly, data points in the same subgroup should be more similar to each other than to those lying in other subgroups. One may refer to Chapter 14 in Friedman et al. (2009) for an account of state-of-the-art clustering techniques. Formally, let $M \geq 2$ be the number of desired clusters and consider a symmetric function $D : \mathcal{X} \times \mathcal{X} \to \mathbb{R}_+$ such that $D(x, x) = 0$ for any $x \in \mathcal{X}$. D measures the

dissimilarity between pairs of observations $(x, x') \in \mathcal{X}^2$: the larger $D(x, x')$, the less similar x and x'. For instance, if $\mathcal{X} \subset \mathbb{R}^d$, D could take the form $D(x, x') = \Psi(\|x - x'\|_q)$, where $q \geq 1$, $\|a\|_q = (\sum_{i=1}^d |a_i|^q)^{1/q}$ for all $a \in \mathbb{R}^d$ and $\Psi : \mathbb{R}_+ \to \mathbb{R}_+$ is any borelian nondecreasing function such that $\Psi(0) = 0$. In this context, the goal of clustering methods is to find a partition $\mathcal{P}$ of the feature space $\mathcal{X}$ in a class Π of partition candidates that minimizes the following *empirical clustering risk*:

$$\widehat{W}_n(\mathcal{P}) = \frac{2}{n(n-1)} \sum_{1 \leq i < j \leq n} D(X_i, X_j) \cdot \Phi_{\mathcal{P}}(X_i, X_j), \tag{5}$$

where $\Phi_{\mathcal{P}}(x, x') = \sum_{C \in \mathcal{P}} \mathbb{I}\{(x, x') \in C^2\}$. Assuming that the data $X_1, \ldots, X_n$ are i.i.d. realizations of a generic random variable X drawn from an unknown probability distribution $F(dx)$ on $\mathcal{X}$, the quantity $\widehat{W}_n(\mathcal{P})$, also known as the *intra-cluster similarity* or *within cluster point scatter*, is a one sample U-statistic of degree two ($K = 1$ and $d_1 = 2$) with kernel given by:

$$\forall (x, x') \in \mathcal{X}^2, \quad H_{\mathcal{P}}(x, x') = D(x, x') \cdot \Phi_{\mathcal{P}}(x, x'), \tag{6}$$

according to Definition 1 provided that $\int\int_{(x,x') \in \mathcal{X}^2} D^2(x, x') \cdot \Phi_{\mathcal{P}}(x, x') F(dx) F(dx') < +\infty$. The expectation of the empirical clustering risk $\widehat{W}_n(\mathcal{P})$ is given by

$$W(\mathcal{P}) = \mathbb{E}\left[D(X, X') \cdot \Phi_{\mathcal{P}}(X, X')\right], \tag{7}$$

where X' is an independent copy of the r.v. X, and is named the *clustering risk* of the partition $\mathcal{P}$. The statistical analysis of the clustering performance of minimizers $\widehat{\mathcal{P}}_n$ of the empirical risk (5) over a class Π of appropriate complexity can be found in Clémençon (2014). Based on the theory of U-processes, it is shown in particular how to establish rate bounds for the excess of clustering risk of any empirical minimizer, $W(\widehat{\mathcal{P}}_n) - \inf_{\mathcal{P} \in \Pi} W(\mathcal{P})$ namely, under appropriate complexity assumptions on the cells forming the partition candidates.

2.2.2 Metric Learning

Many problems in machine learning, data mining and pattern recognition (such as the clustering problem described above) rely on a metric to measure the distance between data points. Choosing an appropriate metric for the problem at hand is crucial to the performance of these methods. Motivated by a variety of applications ranging from computer vision to information retrieval through bioinformatics, metric learning aims at adapting the metric to the data and has attracted a lot of interest in recent years (see for instance Bellet et al., 2013, for an account of metric learning and its applications). As an illustration, we consider the metric learning problem for supervised classification. In this setting, we observe independent copies $(X_1, Y_1), \ldots, (X_n, Y_n)$ of a random couple (X, Y), where the r.v. X takes values in some feature space $\mathcal{X}$ and Y in a finite set of labels, $\mathcal{Y} = \{1, \ldots, C\}$ with $C \geq 2$ say. Consider a set $\mathcal{D}$ of distance measures $D : \mathcal{X} \times \mathcal{X} \to \mathbb{R}_+$. Roughly speaking, the goal of metric learning in this context is to find a metric under which pairs of points with the same label are close to each other and those with different labels are far away. The risk of a metric D can be expressed as:

$$R(D) = \mathbb{E}\left[\phi\left((1 - D(X, X') \cdot (2\mathbb{I}\{Y = Y'\} - 1)\right)\right], \tag{8}$$

where $\phi(u)$ is a convex loss function upper bounding the indicator function $\mathbb{I}\{u \geq 0\}$, such as the hinge loss $\phi(u) = \max(0, 1 - u)$. The natural empirical estimator of this risk is

$$R_n(D) = \frac{2}{n(n-1)} \sum_{1 \leq i < j \leq n} \phi\left((D(X_i, X_j) - 1) \cdot (2\mathbb{I}\{Y_i = Y_j\} - 1)\right), \tag{9}$$

which is a one sample U-statistic of degree two with kernel given by:

$$H_D\left((x, y), (x', y)\right) = \phi\left((D(x, x') - 1) \cdot (2\mathbb{I}\{y = y'\} - 1)\right). \tag{10}$$

The convergence to (8) of a minimizer of (9) has been studied in the frameworks of algorithmic stability (Jin et al., 2009), algorithmic robustness (Bellet and Habrard, 2015) and based on the theory of U-processes under appropriate regularization (Cao et al., 2012).

2.2.3 Multipartite Ranking

Given objects described by a random vector of attributes/features $X \in \mathcal{X}$ and the (temporarily hidden) ordinal labels $Y \in \{1, \ldots, K\}$ assigned to it, the goal of *multipartite ranking* is to rank them in the same order as that induced by the labels, on the basis of a training set of labeled examples. This statistical learning problem finds many applications in a wide range of fields (*e.g.* medicine, finance, search engines, e-commerce). Rankings are generally defined by means of a scoring function $s : \mathcal{X} \to \mathbb{R}$, transporting the natural order on the real line onto the feature space and the gold standard for evaluating the ranking performance of $s(x)$ is the ROC manifold, or its usual summary the VUS criterion (VUS standing for *Volume Under the* ROC *Surface*), see Clémençon and Robbiano (2014) and the references therein. In Clémençon et al. (2013), optimal scoring functions have been characterized as those that are optimal for all bipartite subproblems. In other words, they are increasing transforms of the likelihood ratio dF_{k+1}/dF_k, where F_k denotes the class-conditional distribution for the k-th class. When the set of optimal scoring functions is non-empty, the authors also showed that it corresponds to the functions which maximize the volume under the ROC surface

$$VUS(s) = \mathbb{P}\{s(X_1) < \ldots < s(X_K) | Y_1 = 1, \ldots, Y_K = K\}.$$

Given K independent samples $(X_1^{(k)}, \ldots, X_{n_k}^{(k)}) \overset{\text{i.i.d.}}{\sim} F_k(dx)$ for $k = 1, \ldots, K$, the empirical counterpart of the VUS can be written in the following way:

$$\widehat{VUS}(s) = \frac{1}{\prod_{k=1}^K n_k} \sum_{i_1=1}^{n_1} \ldots \sum_{i_K=1}^{n_K} \mathbb{I}\{s(X_{i_1}^{(1)}) < \ldots < s(X_{i_K}^{(K)})\}. \tag{11}$$

The empirical VUS (11) is a K-sample U-statistic of degree $(1, \ldots, 1)$ with kernel given by:

$$H_s(x_1, \ldots, x_K) = \mathbb{I}\{s(x_1) < \ldots < s(x_K)\}. \tag{12}$$

2.3 Empirical Minimization of U-Statistics

As illustrated by the examples above, many learning problems can be formulated as finding a certain rule g in a class $\mathcal{G}$ in order to minimize a risk of the same form as (2), $\mu(H_g)$, with

kernel $H = H_g$. Based on $K \geq 1$ independent i.i.d. samples

$$\mathbf{X}^{(k)}_{\{1,\,\ldots,\,n_k\}} = (X^{(k)}_1,\,\ldots,\,X^{(k)}_{n_k}) \text{ with } 1 \leq k \leq K,$$

the ERM paradigm in statistical learning suggests to replace the risk by the U-statistic estimation $U_{\mathbf{n}}(H_g)$ in the minimization problem. The study of the performance of minimizers $\widehat{g}_{\mathbf{n}}$ of the empirical estimate $U_{\mathbf{n}}(H_g)$ over the class $\mathcal{G}$ of rule candidates naturally leads to analyze the fluctuations of the U-process

$$\{U_{\mathbf{n}}(H_g) - \mu(H_g) :\ g \in \mathcal{G}\}. \tag{13}$$

Given the bound

$$\mu(H_{\widehat{g}_{\mathbf{n}}}) - \inf_{g\in\mathcal{G}} \mu(H_g) \leq 2 \sup_{g\in\mathcal{G}} |U_{\mathbf{n}}(H_g) - \mu(H_g)|, \tag{14}$$

a probabilistic control of the maximal deviation $\sup_{g\in\mathcal{G}} |U_{\mathbf{n}}(H_g) - \mu(H_g)|$ naturally provides statistical guarantees for the generalization ability of the empirical minimizer $\widehat{g}_{\mathbf{n}}$. As shown at length in the case $K = 1$ and $d_1 = 2$ in Clémençon et al. (2008) and in Clémençon (2014) for specific problems, this can be achieved under adequate complexity assumptions of the class $\mathcal{H}_{\mathcal{G}} = \{H_g :\ g \in \mathcal{G}\}$. These results rely on the *Hoeffding's representation* of U-statistics, which we recall now for clarity in the general multisample U-statistics setting. Denote by $\mathfrak{S}_m$ the symmetric group of order m for any $m \geq 1$ and by $\sigma(i)$ the i-th coordinate of any permutation $\sigma \in \mathfrak{S}_m$ for $1 \leq i \leq m$. Let $\lfloor z \rfloor$ be the integer part of any real number z and set

$$N = \min\{\lfloor n_1/d_1 \rfloor,\,\ldots,\,\lfloor n_K/d_K \rfloor\}.$$

Observe that the K-sample U-statistic (1) can be expressed as

$$U_{\mathbf{n}}(H) = \frac{1}{\prod_{k=1}^K n_k!} \sum_{\sigma_1\in\mathfrak{S}_{n_1}} \cdots \sum_{\sigma_K\in\mathfrak{S}_{n_K}} V_H\left(X^{(1)}_{\sigma_1(1)},\,\ldots,\,X^{(K)}_{\sigma_K(n_K)}\right), \tag{15}$$

where

$$\begin{aligned} V_H\left(X^{(1)}_1,\,\ldots,\,X^{(1)}_{n_1},\,\ldots,\,X^{(K)}_1,\,\ldots,\,X^{(K)}_{n_K}\right) = \frac{1}{N}\Big[&H\left(X^{(1)}_1,\,\ldots,\,X^{(1)}_{d_1},\,\ldots,\,X^{(K)}_1,\,\ldots,\,X^{(K)}_{d_K}\right) \\ &+ H\left(X^{(1)}_{d_1+1},\,\ldots,\,X^{(1)}_{2d_1},\,\ldots,\,X^{(K)}_{d_K+1},\,\ldots,\,X^{(K)}_{2d_K}\right) + \ldots \\ &+ H\left(X^{(1)}_{(N-1)d_1+1},\,\ldots,\,X^{(1)}_{Nd_1},\,\ldots,\,X^{(K)}_{(N-1)d_K+1},\,\ldots,\,X^{(K)}_{Nd_K}\right)\Big]. \end{aligned}$$

This representation, sometimes referred to as the *first Hoeffding's decomposition* (see Hoeffding, 1948), allows to reduce a first order analysis to the case of sums of i.i.d. random variables. The following result extends Corollary 3 in Clémençon et al. (2008) to the multisample situation.

Proposition 2 *Let $\mathcal{H}$ be a collection of bounded symmetric kernels on $\prod_{k=1}^K \mathcal{X}_k^{d_k}$ such that*

$$M_{\mathcal{H}} \stackrel{\text{def}}{=} \sup_{(H,x)\in\mathcal{H}\times\mathcal{X}} |H(x)| < +\infty. \tag{16}$$

Suppose also that $\mathcal{H}$ is a VC major class of functions with finite Vapnik-Chervonenkis dimension $V < +\infty$. For all $\delta \in (0,1)$, we have with probability at least $1-\delta$,

$$\sup_{H\in\mathcal{H}} |U_{\mathbf{n}}(H) - \mu(H)| \leq M_{\mathcal{H}} \left\{ 2\sqrt{\frac{2V\log(1+N)}{N}} + \sqrt{\frac{\log(1/\delta)}{N}} \right\}, \tag{17}$$

where $N = \min\{\lfloor n_1/d_1 \rfloor,\,\ldots,\,\lfloor n_K/d_K \rfloor\}$.

Observe that, in the usual asymptotic framework (4), the bound (17) shows that the learning rate is, as expected, of order $O_{\mathbb{P}}(\sqrt{\log n/n})$, where n denotes the size of the pooled sample.

Remark 3 (Uniform boundedness) *We point out that condition (16) is clearly satisfied for the class of kernels considered in the multipartite ranking situation, whatever the class of scoring functions considered. In the case of the clustering example, it is fulfilled as soon as the essential supremum of $D(X,X') \cdot \Phi_{\mathcal{P}}(X,X')$ is uniformly bounded over $\mathcal{P} \in \Pi$, whereas in the metric learning example, it is satisfied when the essential supremum of the r.v. $\phi((D(X,X')-1)\cdot(2\mathbb{I}\{Y=Y'\}-1))$ is uniformly bounded over $D \in \mathcal{D}$. We underline that this simplifying condition can be easily relaxed and replaced by appropriate tail assumptions for the variables $H(X^{(1)}_1,\,\ldots,\,X^{(K)}_{d_K})$, $H \in \mathcal{H}$, combining the arguments of the subsequent analysis with the classical "truncation trick" originally introduced in Fuk and Nagaev (1971).*

Remark 4 (Complexity assumptions) *Following in the footsteps of Clémençon et al. (2008) which considered 1-sample U-statistics of degree 2, define the Rademacher average*

$$\mathcal{R}_N = \sup_{H\in\mathcal{H}} \frac{1}{N} \left| \sum_{l=1}^N \epsilon_l H\left(X^{(1)}_{(l-1)d_1+1},\,\ldots,\,X^{(1)}_{ld_1},\,\ldots,\,X^{(K)}_{(l-1)d_K+1},\,\ldots,\,X^{(K)}_{ld_K}\right) \right|, \tag{18}$$

where $\epsilon_1,\,\ldots,\,\epsilon_N$ are independent Rademacher random variables (random symmetric sign variables), independent from the $X^{(k)}_i$'s. As can be seen by simply examining the proof of Proposition 2 (Appendix A), a control of the maximal deviations similar to (17) relying on this particular complexity measure can be obtained: the first term on the right hand side is then replaced by the expectation of the Rademacher average $\mathbb{E}[\mathcal{R}_N]$, up to a constant multiplicative factor. This expected value can be bounded by standard metric entropy techniques and in the case where $\mathcal{H}$ is a VC major class of functions of dimension V, we have:

$$\mathbb{E}[\mathcal{R}_N] \leq M_{\mathcal{H}} \sqrt{\frac{2V\log(N+1)}{N}}.$$

See Appendix A for further details.

3. Empirical Minimization of Incomplete U-Statistics

We have seen in the last section that the empirical minimization of U-statistics leads to a learning rate of $O_{\mathbb{P}}(\sqrt{\log n/n})$. However, the computational cost required to find the empirical minimizer in practice is generally prohibitive, as the number of terms to be summed up to compute the U-statistic (1) is equal to:

$$\binom{n_1}{d_1} \times \cdots \times \binom{n_K}{d_K}.$$

In the usual asymptotic framework (4), it is of order $O(n^{d_1+\ldots+d_K})$ as $n \to +\infty$. It is the major purpose of this section to show that, in the minimization problem, the U-statistic $U_{\mathbf{n}}(H_g)$ can be replaced by a Monte-Carlo estimation, referred to as an *incomplete* U-*statistic*, whose computation requires to average much less terms, without damaging the learning rate (Section 3.1). We further extend these results to model selection (Section 3.2), fast rates situations (Section 3.3) and alternative sampling strategies (Section 3.4).

3.1 Uniform Approximation of Generalized U-Statistics

As a remedy to the computational issue mentioned above, the concept of *incomplete generalized* U-*statistic* has been introduced in the seminal contribution of Blom (1976). The calculation of such a functional involves a summation over low cardinality subsets of the $\binom{n_k}{d_k}$ d_k-tuples of indices, $1 \leq k \leq K$, solely. In the simplest formulation, the subsets of indices are obtained by *sampling independently with replacement*, leading to the following definition.

Definition 5 (Incomplete Generalized U-statistic) *Let $B \geq 1$. The incomplete version of the U-statistic (1) based on B terms is defined by:*

$$\widetilde{U}_B(H) = \frac{1}{B} \sum_{I=(I_1,\ldots,I_K)\in\mathcal{D}_B} H(\mathbf{X}_{I_1}^{(1)}, \ldots, \mathbf{X}_{I_K}^{(K)}) = \frac{1}{B} \sum_{I\in\mathcal{D}_B} H(\mathbf{X}_I), \tag{19}$$

where $\mathcal{D}_B$ is a set of cardinality B built by sampling with replacement in the set

$$\Lambda = \{((i_1^{(1)}, \ldots, i_{d_1}^{(1)}), \ldots, (i_1^{(K)}, \ldots, i_{d_K}^{(K)})) : 1 \leq i_1^{(k)} < \ldots < i_{d_k}^{(k)} \leq n_k,\ 1 \leq k \leq K\}, \tag{20}$$

and $\mathbf{X}_I = (\mathbf{X}_{I_1}^{(1)}, \ldots, \mathbf{X}_{I_K}^{(K)})$ for all $I = (I_1, \ldots, I_K) \in \Lambda$.

We stress that the distribution of a complete U-statistic built from subsamples of reduced sizes n_k' drawn uniformly at random is quite different from that of an incomplete U-statistic based on $B = \prod_{k=1}^K \binom{n_k'}{d_k}$ terms sampled with replacement in Λ, although they involve the summation of the same number of terms, as depicted by Fig. 1.

In practice, B should be chosen much smaller than the cardinality of Λ, namely $\#\Lambda = \prod_{k=1}^K \binom{n_k}{d_k}$, in order to overcome the computational issue previously mentioned. We emphasize the fact that the cost related to the computation of the value taken by the kernel H at a given point $(x_{I_1}^{(1)}, \ldots, x_{I_K}^{(K)})$ depending on the form of H is not considered here: the focus is on the number of terms involved in the summation solely. As an estimator of $\alpha(H)$, the statistic (19) is still unbiased, *i.e.* $\mathbb{E}[\widetilde{U}_B(H)] = \alpha(H)$, but its variance is naturally larger than that of the complete U-statistic $U_n(H)$. Precisely, writing the variance of the r.v. $\widetilde{U}_B(H)$ as the expectation of its conditional variance given $(\mathbf{X}_I)_{I\in\Lambda}$ plus the variance of its conditional expectation given $(\mathbf{X}_I)_{I\in\Lambda}$, we obtain

$$\mathrm{Var}(\widetilde{U}_B(H)) = \left(1 - \frac{1}{B}\right)\mathrm{Var}(U_{\mathbf{n}}(H)) + \frac{1}{B}\mathrm{Var}(H(X_1^{(1)}, \ldots, X_{d_K}^{(K)})). \tag{21}$$

One may easily check that $\mathrm{Var}(\widetilde{U}_B(H)) \geq \mathrm{Var}(U_{\mathbf{n}}(H))$, and the difference vanishes as B increases. Refer to Lee (1990) for further details (see p. 193 therein). Incidentally,

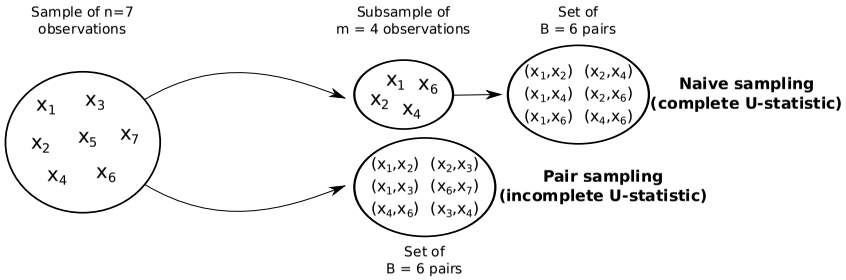

Figure 1: Illustration of the difference between an incomplete U-statistic and a complete U-statistic based on a subsample. For simplicity, we focus on the case $K = 1$ and $d_1 = 2$. In this simplistic example, a sample of $n = 7$ observations is considered. To construct a complete U-statistic of reduced complexity, we first sample a set of $m = 4$ observations and then form all possible pairs from this subsample, *i.e.* $B = m(m-1)/2 = 6$ pairs in total. In contrast, an incomplete U-statistic with the same number of terms is obtained by sampling B pairs directly from the set Λ of all possible pairs based on the original statistical population.

we underline that the empirical variance of (19) is not easy to compute either since it involves summing approximately $\#\Lambda$ terms and bootstrap techniques should be used for this purpose, as proposed in Bertail and Tressou (2006). The asymptotic properties of incomplete U-statistics have been investigated in several articles, see Janson (1984); Brown and Kildea (1978); Enqvist (1978). The angle embraced in the present paper is of very different nature: the key idea we promote here is to use incomplete versions of collections of U-statistics in learning problems such as that described in Section 2.2. The result stated below shows that this approach solves the numerical problem, while not damaging the learning rates under appropriate complexity assumptions on the collection $\mathcal{H}$ of (symmetric) kernels H considered, the complexity being described here in terms of VC dimension for simplicity. In particular, it reveals that concentration results established for U-processes (*i.e.* collections of U-statistics) such as Proposition 2 may extend to their incomplete versions, as shown by the following theorem.

Theorem 6 (Maximal deviation) *Let $\mathcal{H}$ be a collection of bounded symmetric kernels on $\prod_{k=1}^K \mathcal{X}_k^{d_k}$ that fulfills the assumptions of Proposition 2. Then, the following assertions hold true.*

(i) For all $\delta \in (0,1)$, with probability at least $1-\delta$, we have: $\forall \mathbf{n} = (n_1, \ldots, n_K) \in \mathbb{N}^{*K}$, $\forall B \geq 1$,

$$\sup_{H\in\mathcal{H}} \left|\widetilde{U}_B(H) - U_{\mathbf{n}}(H)\right| \leq \mathcal{M}_{\mathcal{H}} \times \sqrt{2\frac{V\log(1+\#\Lambda) + \log(2/\delta)}{B}}$$

(ii) For all $\delta \in (0,1)$, with probability at least $1-\delta$, we have: $\forall \mathbf{n} \in \mathbb{N}^{*K}$, $\forall B \geq 1$,

$$\frac{1}{\mathcal{M}_{\mathcal{H}}} \sup_{H \in \mathcal{H}} \left| \widetilde{U}_B(H) - U(H) \right| \leq 2\sqrt{\frac{2V\log(1+N)}{N}} + \sqrt{\frac{\log(2/\delta)}{N}} + \sqrt{2\frac{V\log(1+\#\Lambda)+\log(4/\delta)}{B}},$$

where $N = \min\{\lfloor n_1/d_1 \rfloor, \ldots, \lfloor n_K/d_K \rfloor\}$.

Remark 7 (Complexity assumptions continued) *We point out that a bound of the same order as that stated above can be obtained under standard metric entropy conditions by means of classical chaining arguments, or under the assumption that the Rademacher average defined by*

$$\widetilde{\mathcal{R}}_B = \sup_{H \in \mathcal{H}} \frac{1}{B} \left| \sum_{b=1}^{B} \epsilon_b \left\{ \sum_{I \in \Lambda} \zeta_b(I) H(\mathbf{X}_I) \right\} \right| \tag{22}$$

has an expectation of the order $O(1/\sqrt{B})$. The quantity $\zeta_b(I)$ indicates whether the subset of indexes I has been picked at the b-th draw ($\zeta_b(I) = +1$) or not ($\zeta_b(I) = 0$), see the calculation at the end of Appendix C. Equipped with this notation, notice that the ζ_b's are i.i.d. multinomial random variables such that $\sum_{I \in \Lambda} \zeta_b(I) = +1$. This assumption can be easily shown to be fulfilled in the case where $\mathcal{H}$ is a VC major class of finite VC dimension (see the proof of Theorem 6 in Appendix B). Notice however that although the variables $\sum_{I \in \Lambda} \zeta_b(I) H(\mathbf{X}_I)$, $1 \leq b \leq B$, are conditionally i.i.d. given $(\mathbf{X}_I)_{I \in \Lambda}$, they are not independent and the quantity (22) cannot be related to complexity measures of the type (18) mentioned in Remark 4.

Remark 8 *We underline that, whereas $\sup_{H \in \mathcal{H}} |U_{\mathbf{n}}(H) - U(H)|$ can be proved to be of order $O_{\mathbb{P}}(1/n)$ under adequate complexity assumptions in the specific situation where $\{U_{\mathbf{n}}(H) : H \in \mathcal{H}\}$ is a collection of degenerate U-statistics (see Section 3.3), the bound (i) in Theorem 6 cannot be improved in the degenerate case. Observe indeed that, conditioned upon the observations $X_i^{(k)}$, the deviations of the approximation (19) from its mean are of order $O_{\mathbb{P}}(1/\sqrt{B})$, since it is a basic average of B i.i.d. terms.*

From the theorem stated above, one may straightforwardly deduce a bound on the excess risk of kernels $\widehat{H}_B$ minimizing the incomplete version of the empirical risk based on B terms, *i.e.* such that

$$\widetilde{U}_B\left(\widehat{H}_B\right) = \min_{H \in \mathcal{H}} \widetilde{U}_B(H). \tag{23}$$

Corollary 9 *Let $\mathcal{H}$ be a collection of symmetric kernels on $\prod_{k=1}^{K} \mathcal{X}_k^{d_k}$ that satisfies the conditions stipulated in Proposition 2. Let $\delta > 0$. For any minimizer $\widehat{H}_B$ of the statistical estimate of the risk (19), the following assertions hold true*

(i) We have with probability at least $1-\delta$: $\forall \mathbf{n} \in \mathbb{N}^{*K}$, $\forall B \geq 1$,

$$U(\widehat{H}_B) - \inf_{H \in \mathcal{H}} U(H) \leq 2\mathcal{M}_{\mathcal{H}} \times \left\{ 2\sqrt{\frac{2V\log(1+N)}{N}} + \sqrt{\frac{\log(2/\delta)}{N}} + \sqrt{2\frac{V\log(1+\#\Lambda)+\log(4/\delta)}{B}} \right\}.$$

Empirical risk criterion	Nb of terms	Rate bound
Complete U-statistic	$O(n^{d_1+\ldots+d_K})$	$O_{\mathbb{P}}(\sqrt{\log(n)/n})$
Complete U-statistic based on subsamples	$O(n)$	$O_{\mathbb{P}}\left(\sqrt{\log(n)/n^{\frac{1}{d_1+\ldots+d_K}}}\right)$
Incomplete U-statistic (our result)	$\mathbf{O(n)}$	$\mathbf{O_{\mathbb{P}}(\sqrt{\log(n)/n})}$

Table 1: Rate bound for the empirical minimizer of several empirical risk criteria *versus* the number of terms involved in the computation of the criterion. For a computational budget of $O(n)$ terms, the rate bound for the incomplete U-statistic criterion is of the same order as that of the complete U-statistic, which is a huge improvement over a complete U-statistic based on a subsample.

(ii) We have: $\forall \mathbf{n} \in \mathbb{N}^{*K}$, $\forall B \geq 1$,

$$\mathbb{E}\left[\sup_{H \in \mathcal{H}} \left| \widetilde{U}_B(H) - U(H) \right| \right] \leq \mathcal{M}_{\mathcal{H}} \left\{ 2\sqrt{\frac{2V\log(1+N)}{N}} + \sqrt{\frac{2(\log 2 + V\log(1+\#\Lambda))}{B}} \right\}.$$

The first assertion of Theorem 6 provides a control of the deviations between the U-statistic (1) and its incomplete counterpart (19) uniformly over the class $\mathcal{H}$. As the number of terms B increases, this deviation decreases at a rate of $O(1/\sqrt{B})$. The second assertion of Theorem 6 gives a maximal deviation result with respect to $U(H)$. Observe in particular that, with the asymptotic settings previously specified, $N = O(n)$ and $\log(\#\Lambda) = O(\log n)$ as $n \to +\infty$. The bounds stated above thus show that, for a number $B = B_n$ of terms tending to infinity at a rate $O(n)$ as $n \to +\infty$, the maximal deviation $\sup_{H \in \mathcal{H}} |\widetilde{U}_B(H) - U(H)|$ is asymptotically of the order $O_{\mathbb{P}}((\log(n)/n)^{1/2})$, just like $\sup_{H \in \mathcal{H}} |U_{\mathbf{n}}(H) - U(H)|$, see bound (17) in Proposition 2. In short, when considering an incomplete U-statistic (19) with $B = O(n)$ terms only, the learning rate for the corresponding minimizer is of the same order as that of the minimizer of the complete risk (1), whose computation requires to average $\#\Lambda = O(n^{d_1+\ldots+d_K})$ terms. Minimizing such incomplete U-statistics thus yields a significant gain in terms of computational cost while fully preserving the learning rate. In contrast, as implied by Proposition 2, the minimization of a complete U-statistic involving $O(n)$ terms, obtained by drawing subsamples of sizes $n_k' = O(n^{1/(d_1+\ldots+d_K)})$ uniformly at random, leads to a rate of convergence of $O(\sqrt{\log(n)/n^{1/(d_1+\ldots+d_K)}})$, which is much slower except in the trivial case where $K = 1$ and $d_1 = 1$. These striking results are summarized in Table 1.

The important practical consequence of the above is that when n is too large for the complete risk (1) to be used, one should instead use the incomplete risk (19) (setting the number of terms B as large as the computational budget allows).

3.2 Model Selection Based on Incomplete U-Statistics

Automatic selection of the model complexity is a crucial issue in machine learning: it includes the number of clusters in cluster analysis (see Clémençon, 2014) or the choice of the number of possible values taken by a piecewise constant scoring function in multipartite ranking for instance (*cf.* Clémençon and Vayatis, 2009). In the present situation, this boils down to choosing the adequate level of complexity of the class of kernels $\mathcal{H}$, measured through its (supposedly finite) VC dimension for simplicity, in order to minimize the (theoretical) risk of the empirical minimizer. It is the purpose of this subsection to show that the incomplete U-statistic (19) can be used to define a penalization method to select a prediction rule with nearly minimal risk, avoiding procedures based on data splitting/resampling and extending the celebrated *structural risk minimization* principle, see Vapnik (1999). Let $\mathcal{H}$ be the collection of all symmetric kernels on $\prod_{k=1}^{K} \mathcal{X}_k^{d_k}$ and set $\mu^* = \inf_{H\in\mathcal{H}} \mu(H)$. Let $\mathcal{H}_1, \mathcal{H}_2, \ldots$ be a sequence of uniformly bounded major subclasses of $\mathcal{H}$, of increasing complexity (VC dimension). For any $m \geq 1$, let V_m denote the VC dimension of the class $\mathcal{H}_m$ and set $\mathcal{M}_{\mathcal{H}_m} = \sup_{(H,x)\in\mathcal{H}_m\times\mathcal{X}} |H(x)| < +\infty$. We suppose that there exists $\mathcal{M} < +\infty$ such that $\sup_{m\geq 1} \mathcal{M}_{\mathcal{H}_m} \leq \mathcal{M}$. Given $1 \leq B \leq \#\Lambda$ and $m \geq 1$, the complexity penalized empirical risk of a solution $\widetilde{U}_{B,m}$ of the ERM problem (23) with $\mathcal{H} = \mathcal{H}_m$ is

$$\widetilde{U}_B(\widehat{H}_{B,m}) + \mathrm{pen}(B, m), \tag{24}$$

where the quantity $\mathrm{pen}(B, m)$ is a *distribution free* penalty given by:

$$\begin{aligned} \mathrm{pen}(B, m) &= 2\mathcal{M}_{\mathcal{H}_m} \left\{ \sqrt{\frac{2V_m \log(1+N)}{N}} + \sqrt{\frac{2(\log 2 + V_m \log(1+\#\Lambda))}{B}} \right\} \\ &+ 2\mathcal{M}\sqrt{\frac{(B+n)\log m}{B^2}}. \end{aligned} \tag{25}$$

As shown in Assertion (ii) of Corollary 9, the quantity above is an upper bound for the expected maximal deviation $\mathbb{E}[\sup_{H\in\mathcal{H}_m} |\widetilde{U}_B(H) - \mu(H)|]$ and is thus a natural penalty candidate to compensate the overfitting within class $\mathcal{H}_m$. We thus propose to select

$$\widehat{m}_B = \arg\min_{m\geq 1} \left\{ \widetilde{U}_B(\widehat{H}_{B,m}) + \mathrm{pen}(B, m) \right\}. \tag{26}$$

As revealed by the theorem below, choosing $B = O(n)$, the prediction rule $\widehat{H}_{\widehat{m}_B}$ based on a penalized criterion involving the summation of $O(n)$ terms solely, achieves a nearly optimal trade-off between the bias and the distribution free upper bound (25) on the variance term.

Theorem 10 (Oracle inequality) *Suppose that Theorem 6's assumptions are fulfilled for all* $m \geq 1$ *and that* $\sup_{m\geq 1} \mathcal{M}_{\mathcal{H}_m} \leq \mathcal{M} < +\infty$. *Then, we have:* $\forall \mathbf{n} \in \mathbb{N}^{*K}$, $\forall B \in \{1, \ldots, \#\Lambda\}$,

$$\mu(\widehat{H}_{B,\widehat{m}}) - \mu^* \leq \inf_{k\geq 1} \left\{ \inf_{H\in\mathcal{H}_m} \mu(H) - \mu^* + \mathrm{pen}(B, m) \right\} + \mathcal{M}\frac{\sqrt{2\pi(B+n)}}{B}.$$

We point out that the argument used to obtain the above result can be straightforwardly extended to other (possibly data-dependent) complexity penalties (*cf.* Massart, 2006), see the proof in Appendix D.

3.3 Fast Rates for ERM of Incomplete U-Statistics

In Clémençon et al. (2008), it has been proved that, under certain "low-noise" conditions, the minimum variance property of the U-statistics used to estimate the ranking risk (corresponding to the situation $K = 1$ and $d_1 = 2$) leads to learning rates faster than $O_{\mathbb{P}}(1/\sqrt{n})$. These results rely on the *Hajek projection*, a linearization technique originally introduced in Hoeffding (1948) for the case of one sample U-statistics and next extended to the analysis of a much larger class of functionals in Hájek (1968). It consists in writing $U_{\mathbf{n}}(H)$ as the sum of the orthogonal projection

$$\widehat{U}_{\mathbf{n}}(H) = \sum_{k=1}^{K} \sum_{i=1}^{n_k} \mathbb{E}\left[U_{\mathbf{n}}(H) \mid X_i^{(k)} \right] - (n-1)\mu(H), \tag{27}$$

which is itself a sum of K independent basic sample means based on i.i.d. r.v.'s (of the order $O_{\mathbb{P}}(1/\sqrt{n})$ each, after recentering), plus a possible negligible term. This representation was used for instance by Grams and Serfling (1973) to refine the CLT in the multisample U-statistics framework. Although useful as a theoretical tool, it should be noticed that the quantity $\widehat{U}_{\mathbf{n}}(H)$ is not of practical interest, since the conditional expectations involved in the summation are generally unknown.

Although incomplete U-statistics do not share the minimum variance property (see Section 3.1), we will show that the same fast rate bounds for the excess risk as those reached by ERM of U-statistics (corresponding to the summation of $O(n^2)$ pairs of observations) can be attained by empirical ranking risk minimizers, when estimating the ranking risk by incomplete U-statistics involving the summation of $o(n^2)$ terms solely.

For clarity (and comparison purpose), we first recall the statistical learning framework considered in Clémençon et al. (2008). Let (X, Y) be a pair of random variables defined on the same probability space, where Y is a real-valued label and X models some input information taking its values in a measurable space $\mathcal{X}$ hopefully useful to predict Y. Denoting by (X', Y') an independent copy of the pair (X, Y). The goal pursued here is to learn how to rank the input observations X and X', by means of an antisymmetric *ranking rule* $r : \mathcal{X}^2 \to \{-1, +1\}$ (*i.e.* $r(x, x') = -r(x'x)$ for any $(x, x') \in \mathcal{X}^2$), so as to minimize the *ranking risk*

$$L(r) = \mathbb{P}\{(Y - Y') \cdot r(X, X') < 0\}. \tag{28}$$

The minimizer of the ranking risk is the ranking rule $r^*(X, X') = 2\mathbb{I}\{\mathbb{P}\{Y > Y' \mid (X, X')\} \geq \mathbb{P}\{Y < Y' \mid (X, X')\}\} - 1$ (see Proposition 1 in Clémençon et al., 2008). The natural empirical counterpart of (28) based on a sample of independent copies $(X_1, Y_1), \ldots, (X_n, Y_n)$ of the pair (X, Y) is the 1-sample U-statistic $U_n(H_r)$ of degree two with kernel $H_r((x, y), (x', y')) = \mathbb{I}\{(y - y') \cdot r(x, x') < 0\}$ for all (x, y) and (x', y')) in $\mathcal{X} \times \mathbb{R}$ given by:

$$L_n(r) = U_n(H_r) = \frac{2}{n(n-1)} \sum_{i<j} \mathbb{I}\{(Y_i - Y_j) \cdot r(X_i, X_j) < 0\}. \tag{29}$$

Equipped with these notations, a statistical version of the excess risk $\Lambda(r) = L(r) - L(r^*)$ is a U-statistic $\lambda_n(r)$ with kernel $q_r = H_r - H_{r^*}$. The key "noise-condition", which allows to exploit the Hoeffding/Hajek decomposition of $\Lambda_n(r)$, is stated below.

Assumption 1 *There exist constants* $c > 0$ *and* $\alpha \in [0,1]$ *such that:*

$$\forall r \in \mathcal{R}, \quad \mathrm{Var}\left(h_r(X,Y)\right) \leq c\Lambda(r)^{\alpha},$$

where we set $h_r(x,y) = \mathbb{E}[q_r((x,y),(X',Y'))]$.

Recall incidentally that very general sufficient conditions guaranteeing that this assumption holds true have been exhibited, see Section 5 in Clémençon et al. (2008) (notice that the condition is void for $\alpha = 0$). Since our goal is to explain the main ideas rather than achieving a high level of generality, we consider a very simple setting, stipulating that the cardinality of the class of ranking rule candidates $\mathcal{R}$ under study is finite, $\#\mathcal{R} = M < +\infty$, and that the optimal rule r^* belongs to $\mathcal{R}$. The following proposition is a simplified version of the fast rate result proved in Clémençon et al. (2008) for the empirical minimizer $\widehat{r}_n = \arg\min_{r\in\mathcal{R}} L_n(r)$.

Proposition 11 *(Clémençon et al. (2008),* Corollary 6*) Suppose that Assumption 1 is fulfilled. Then, there exists a universal constant* $C > 0$ *such that for all* $\delta \in (0,1)$*, we have:* $\forall n \geq 2$*,*

$$L(\widehat{r}_n) - L(r^*) \leq C\left(\frac{\log(M/\delta)}{n}\right)^{\frac{1}{2-\alpha}}. \tag{30}$$

Consider now the minimizer $\widetilde{r}_B$ of the incomplete U-statistic risk estimate

$$\widetilde{U}_B(h_r) = \frac{1}{B}\sum_{k=1}^{B} \sum_{(i,j):1\leq i<j\leq n} \epsilon_k((i,j))\mathbb{I}\{(Y_i - Y_j)\cdot r(X_i,X_j) < 0\} \tag{31}$$

over $\mathcal{R}$, where $\epsilon_k((i,j))$ indicates whether the pair (i,j) has been picked at the k-th draw ($\epsilon_k((i,j)) = 1$ in this case, which occurs with probability $1/\binom{n}{2}$) or not (then, we set $\epsilon_k((i,j)) = 0$). Observe that $\widetilde{r}_B$ also minimizes the empirical estimate of the excess risk $\widetilde{\Lambda}_B(r) = \widetilde{U}_B(q_r)$ over $\mathcal{R}$.

Theorem 12 *Let* $\alpha \in [0,1]$ *and suppose that Assumption 1 is fulfilled. If we set* $B = O(n^{2/(2-\alpha)})$*, there exists some constant* $C < +\infty$ *such that, for all* $\delta \in (0,1)$*, we have with probability at least* $1-\delta$*:* $\forall n \geq 2$*,*

$$L(\widetilde{r}_B) - L(r^*) \leq C\left(\frac{\log(M/\delta)}{n}\right)^{\frac{1}{2-\alpha}}.$$

As soon as $\alpha < 1$, this result shows that the same fast rate of convergence as that reached by $\widehat{r}_n$ can be attained by the ranking rule $\widetilde{r}_B$, which minimizes an empirical version of the ranking risk involving the summation of $O(n^{2/(2-\alpha)})$ terms solely. For comparison purpose, minimization of the criterion (28) computed with a number of terms of the same order leads to a rate bound of order $O_{\mathbb{P}}(n^{1/(2-\alpha)^2})$.

Finally, we point out that fast rates for the clustering problem have been also investigated in Clémençon (2014), see Section 5.2 therein. The present analysis can be extended to the clustering framework by means of the same arguments.

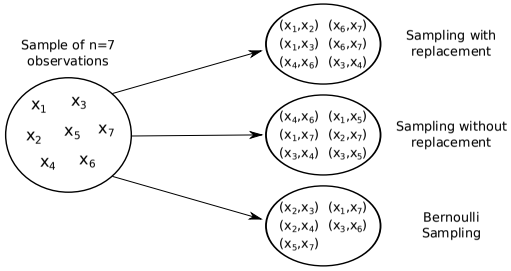

Figure 2: Illustration of different sampling schemes for approximating a U-statistic. For simplicity, consider again the case $K = 1$ and $d_1 = 2$. Here $n = 7$ and the expected number of terms is $B = 6$. Sampling with or without replacement results in exactly B terms, with possible repetitions when sampling with replacement, *e.g.* (x_6, x_7) in this example. In contrast, Bernoulli sampling with $\pi_I = B/\#\Lambda$ results in B terms only in expectation, with individual realizations that may exhibit more or fewer terms.

3.4 Alternative Sampling Schemes

Sampling with replacement is not the sole way of approximating generalized U-statistics with a controlled computational cost. As proposed in Janson (1984), other sampling schemes can be considered, Bernoulli sampling or sampling without replacement in particular (see Figure 2 for an illustration). We now explain how the results of this paper can be extended to these situations. The population of interest is the set Λ and a *survey sample* of (possibly random) size $b \leq n$ is any subset s of cardinality $b = b(s)$ less than $\#\Lambda$ in the power set $\mathcal{P}(\Lambda)$. Here, a general *survey scheme without replacement* is any conditional probability distribution R on the set of all possible samples $s \in \mathcal{P}(\Lambda)$ given $(\mathbf{X}_I)_{I\in\Lambda}$. For any $I \in \Lambda$, the first order *inclusion probability* $\pi_I(R) = \mathbb{P}_R\{I \in S\}$, is the probability that the unit I belongs to a random sample S drawn from distribution R. We set $\boldsymbol{\pi}(R) = (\pi_I(R))_{I\in\Lambda}$. The second order inclusion probabilities are denoted by $\pi_{I,J}(R) = \mathbb{P}_R\{(I,J) \in S^2\}$ for any $I \neq J$ in Λ. When no confusion is possible, we omit to mention the dependence in R when writing the first/second order probabilities of inclusion. The information related to the observed sample $S \subset \Lambda$ is fully enclosed in the random vector $\boldsymbol{\Delta} = (\Delta(I))_{I\in\Lambda}$, where $\Delta(I) = \mathbb{I}\{I \in S\}$ for all $I \in \Lambda$. The 1-d marginal distributions of the sampling scheme $\boldsymbol{\Delta}_n$ are the Bernoulli distributions with parameters π_I, $I \in \Lambda$, and the covariance matrix of the r.v. $\boldsymbol{\Delta}_n$ is given by $\Gamma = \{\pi_{I,J} - \pi_I\pi_J\}_{I,J}$ with the convention $\pi_{I,I} = \pi_I$ for all $I \in \Lambda$. Observe that, equipped with the notations above, $\sum_{I\in\Lambda}\Delta(I) = b(S)$.

One of the simplest survey plans is the Poisson scheme (without replacement), for which the $\Delta(I)$'s are independent Bernoulli random variables with parameters π_I, $I \in \Lambda$, in $(0,1)$. The first order inclusion probabilities fully characterize such a plan. Observe in addition that the size $b(\mathcal{S})$ of a sample generated this way is random with expectation $B = \mathbb{E}[b(S) \mid (\mathbf{X}_I)_{I\in\Lambda}] = \sum_{I\in\Lambda}\pi_I$. The situation where the π_I's are all equal corresponds to the Bernoulli

sampling scheme: $\forall I \in \Lambda$, $\pi_I = B/\#\Lambda$. The Poisson survey scheme plays a crucial role in sampling theory, inso far as a wide range of survey schemes can be viewed as conditional Poisson schemes, see Hájek (1964). For instance, one may refer to Cochran (1977) or Deville (1987) for accounts of survey sampling techniques.

Following in the footsteps of the seminal contribution of Horvitz and Thompson (1951), an estimate of (1) based on a sample drawn from a survey scheme R with first order inclusion probabilities $(\pi_I)_{I\in\Lambda}$ is given by:

$$\bar{U}_{HT}(H) = \frac{1}{\#\Lambda}\sum_{I\in\Lambda}\frac{\Delta(I)}{\pi_I}H(\mathbf{X}_I), \tag{32}$$

with the convention that $0/0 = 0$. Notice that it is an unbiased estimate of (1):

$$\mathbb{E}[\bar{U}_{HT}(H) \mid (\mathbf{X}_I)_{I\in\Lambda}] = U_{\mathbf{n}}(H).$$

In the case where the sample size is deterministic, its conditional variance is given by:

$$\mathrm{Var}(\bar{U}_{HT}(H) \mid (\mathbf{X}_I)_{I\in\Lambda}) = \frac{1}{2}\sum_{I\neq J}\left(\frac{H(\mathbf{X}_I)}{\pi_I} - \frac{H(\mathbf{X}_J)}{\pi_J}\right)^2(\pi_{I,J} - \pi_I\pi_J).$$

We point out that the computation of (32) involves summing over a possibly random number of terms, equal to $B = \mathbb{E}[b(S)] = \sum_{I\in\Lambda}\pi_I$ in average and whose variance is equal to $\mathrm{Var}(b(S)) = \sum_{I\in\Lambda}\pi_I(1-\pi_I) + \sum_{I\neq J}\{\pi_{I,J} - \pi_I\pi_J\}$.

Here, we are interested in the situation where the $\Delta(I)$'s are independent from $(X_I)_{I\in\Lambda}$, and either a sample of size $B \leq \#\Lambda$ fixed in advance is chosen uniformly at random among the $\binom{\#\Lambda}{B}$ possible choices (this survey scheme is sometimes referred to as *rejective sampling* with equal first order inclusion probabilities), or else it is picked by means of a Bernoulli sampling with parameter $B/\#\Lambda$. Observe that, in both cases, we have $\pi_I = B/\#\Lambda$ for all $I \in \Lambda$. The following theorem shows that in both cases, similar results as those obtained for *sampling with replacement* can be derived for minimizers of the Horvitz-Thompson risk estimate (32).

Theorem 13 *Let $\mathcal{H}$ be a collection of bounded symmetric kernels on $\prod_{k=1}^K \mathcal{X}_k^{d_k}$ that fulfills the assumptions involved in Proposition 2. Let $B \in \{1, \ldots, \#\Lambda\}$. Suppose that, for any $H \in \mathcal{H}$, $\bar{U}_{HT}(H)$ is the incomplete U-statistic based on either a Bernoulli sampling scheme with parameter $B/\#\Lambda$ or else a sampling without replacement scheme of size B. For all $\delta \in (0,1)$, we have with probability at least $1-\delta$: $\forall \mathbf{n} \in \mathbb{N}^{*K}$, $\forall B \in \{1, \ldots, \#\Lambda\}$,*

$$\sup_{H\in\mathcal{H}}\left|\bar{U}_{HT}(H) - U_{\mathbf{n}}(H)\right| \leq 2\mathcal{M}_{\mathcal{H}}\sqrt{\frac{\log(2(1+\#\Lambda)^V/\delta)}{B}} + \frac{2\log(2(1+\#\Lambda)^V/\delta)\mathcal{M}_{\mathcal{H}}}{3B},$$

in the case of the Bernoulli sampling design, and

$$\sup_{H\in\mathcal{H}}\left|\bar{U}_{HT}(H) - U_{\mathbf{n}}(H)\right| \leq \sqrt{2}\mathcal{M}_{\mathcal{H}}\sqrt{\frac{\log(2(1+\#\Lambda)^V/\delta)}{B}},$$

in the case of the sampling without replacement design.

We highlight the fact that, from a computational perspective, sampling with replacement is undoubtedly much more advantageous than Bernoulli sampling or sampling without replacement. Indeed, although its expected value is equal to B, the size of a Bernoulli sample is stochastic and the related sampling algorithm requires a loop through the elements I of Λ and the practical implementation of sampling without replacement is generally based on multiple iterations of sampling with replacement, see Tillé (2006).

4. Application to Stochastic Gradient Descent for ERM

The theoretical analysis carried out in the preceding sections focused on the properties of empirical risk minimizers but ignored the issue of finding such a minimizer. In this section, we show that the sampling technique introduced in Section 3 also provides practical means of scaling up iterative statistical learning techniques. Indeed, large-scale training of many machine learning models, such as SVM, Deep Neural Networks or soft K-means among others, is based on stochastic gradient descent (SGD in abbreviated form), see Bottou (1998). When the risk is of the form (2), we now investigate the benefit of using, at each iterative step, a gradient estimate of the form of an incomplete U-statistic, instead of an estimate of the form of a complete U-statistic with exactly the same number of terms based on subsamples drawn uniformly at random.

Let $\Theta \subset \mathbb{R}^q$ with $q \geq 1$ be some parameter space and $H : \prod_{k=1}^K \mathcal{X}_k^{d_k} \times \Theta \to \mathbb{R}$ be a loss function which is convex and differentiable in its last argument. Let $(X_1^{(k)}, \ldots, X_{d_k}^{(k)})$, $1 \leq k \leq K$, be K independent random vectors with distribution $F_k^{\otimes d_k}(dx)$ on $\mathcal{X}_k^{d_k}$ respectively such that the random vector $H(X_1^{(1)}, \ldots, X_{d_1}^{(1)}, \ldots, X_1^{(K)}, \ldots, X_{d_K}^{(K)}; \theta)$ is square integrable for any $\theta \in \Theta$. For all $\theta \in \Theta$, set

$$L(\theta) = \mathbb{E}[H(X_1^{(1)}, \ldots, X_{d_1}^{(1)}, \ldots, X_1^{(K)}, \ldots, X_{d_K}^{(K)}; \theta)] = \mu(H(\cdot; \theta))$$

and consider the *risk minimization* problem $\min_{\theta\in\Theta} L(\theta)$. Based on K independent i.i.d. samples $X_1^{(k)}, \ldots, X_{n_k}^{(k)}$ with $1 \leq k \leq K$, the empirical version of the risk function is $\theta \in \Theta \mapsto \widehat{L}_{\mathbf{n}}(\theta) \overset{\text{def}}{=} U_{\mathbf{n}}(H(\cdot; \theta))$. Here and throughout, we denote by ∇_θ the gradient operator w.r.t. θ.

Gradient descent Many practical machine learning algorithms use variants of the standard gradient descent method, following the iterations:

$$\theta_{t+1} = \theta_t - \eta_t\nabla_\theta\widehat{L}_{\mathbf{n}}(\theta_t), \tag{33}$$

with an arbitrary initial value $\theta_0 \in \Theta$ and a learning rate (step size) $\eta_t \geq 0$ such that $\sum_{t=1}^{+\infty}\eta_t = +\infty$ and $\sum_{t=1}^{+\infty}\eta_t^2 < +\infty$.

Here we place ourselves in a large-scale setting, where the sample sizes $n_1, \ldots, n_K$ of the training data sets are so large that computing the gradient of $\widehat{L}_{\mathbf{n}}$

$$\widehat{g}_{\mathbf{n}}(\theta) = \frac{1}{\prod_{k=1}^K\binom{n_k}{d_k}}\sum_{I_1}\cdots\sum_{I_K}\nabla_\theta H(\mathbf{X}_{I_1}^{(1)}; \mathbf{X}_{I_2}^{(2)}; \ldots; \mathbf{X}_{I_K}^{(K)}; \theta) \tag{34}$$

at each iteration (33) is computationally too expensive. Instead, Stochastic Gradient Descent uses an unbiased estimate $\widetilde{g}(\theta)$ of the gradient (34) that is cheap to compute. A

natural approach consists in replacing (34) by a complete U-statistic constructed from subsamples of reduced sizes $n'_k << n_k$ drawn uniformly at random, leading to the following gradient estimate:

$$\widetilde{g}_{\mathbf{n}'}(\theta) = \frac{1}{\prod_{k=1}^{K} \binom{n'_k}{d_k}} \sum_{I_1} \cdots \sum_{I_K} \nabla_\theta H(\mathbf{X}^{(1)}_{I_1}; \mathbf{X}^{(2)}_{I_2}; \ldots; \mathbf{X}^{(K)}_{I_K}; \theta), \tag{35}$$

where the symbol $\sum_{I_k}$ refers to summation over all $\binom{n'_k}{d_k}$ subsets $\mathbf{X}^{(k)}_{I_k} = (X^{(k)}_{i_1}, \ldots, X^{(k)}_{i_{d_k}})$ related to a set I_k of d_k indexes $1 \leq i_1 < \ldots < i_{d_k} \leq n'_k$ and $\mathbf{n}' = (n'_1, \ldots, n'_K)$.

We propose an alternative strategy based on the sampling scheme described in Section 3, *i.e.* a gradient estimate in the form of an *incomplete* U-statistic:

$$\widetilde{g}_B(\theta) = \frac{1}{B} \sum_{(I_1, \ldots, I_K) \in \mathcal{D}_B} \nabla_\theta H(\mathbf{X}^{(1)}_{I_1}, \ldots, \mathbf{X}^{(K)}_{I_K}; \theta), \tag{36}$$

where $\mathcal{D}_B$ is built by sampling with replacement in the set Λ.

It is well-known that the variance of the gradient estimate negatively impacts on the convergence of SGD. Consider for instance the case where the loss function H is $(1/\gamma)$-smooth in its last argument, *i.e.* $\forall \theta_1, \theta_2 \in \Theta$:

$$\|\nabla_\theta H(\cdot; \theta_1) - \nabla_\theta H(\cdot; \theta_2)\| \leq \frac{1}{\gamma}\|\theta_1 - \theta_2\|.$$

Then one can show that if $\widetilde{g}$ is the gradient estimate:

$$\begin{aligned}
\mathbb{E}[\widehat{L}_{\mathbf{n}}(\theta_{t+1})] &= \mathbb{E}[\widehat{L}_{\mathbf{n}}(\theta_t - \eta_t \widetilde{g}(\theta_t))] \\
&\leq \mathbb{E}[\widehat{L}_{\mathbf{n}}(\theta_t)] - \eta_t \|\mathbb{E}[\widehat{g}_{\mathbf{n}}(\theta_t)]\|^2 + \frac{\eta_t^2}{2\gamma}\mathbb{E}[\|\widetilde{g}(\theta_t)\|^2] \\
&\leq \mathbb{E}[\widehat{L}_{\mathbf{n}}(\theta_t)] - \eta_t \left(1 - \frac{\eta_t}{2\gamma}\right) \mathbb{E}[\|\widehat{g}_{\mathbf{n}}(\theta_t)\|^2] + \frac{\eta_t^2}{2\gamma}\mathrm{Var}[\widetilde{g}(\theta_t)].
\end{aligned}$$

In other words, the smaller the variance of the gradient estimate, the larger the expected reduction in objective value. Some recent work has focused on variance-reduction strategies for SGD when the risk estimates are basic sample means (see for instance Le Roux et al., 2012; Johnson and Zhang, 2013).

In our setting where the risk estimates are of the form of a U-statistic, we are interested in comparing the variance of $\widetilde{g}_{\mathbf{n}'}(\theta)$ and $\widetilde{g}_B(\theta)$ when $B = \prod_{k=1}^{K} \binom{n'_k}{d_k}$ so that their computation requires to average over the same number of terms and thus have similar computational cost.[1] Our result is summarized in the following proposition.

Proposition 14 *Let* $B = \prod_{k=1}^{K} \binom{n'_k}{d_k}$ *for* $n'_k \ll n_k$, $k = 1, \ldots, K$. *In the asymptotic framework* (4)*, we have:*

$$\mathrm{Var}[\widetilde{g}_{\mathbf{n}'}(\theta)] = O\left(\frac{1}{\sum_{k=1}^{K} n'_k}\right), \quad \mathrm{Var}[\widetilde{g}_B(\theta)] = O\left(\frac{1}{\prod_{k=1}^{K} \binom{n'_k}{d_k}}\right),$$

as $n' = n'_1 + \ldots + n'_K \to +\infty$.

1. Note that sampling B sets from Λ to obtain (36) is potentially more efficient than sampling n'_k points from $\mathbf{X}_{\{1,\ldots,n_k\}}$ for each $k = 1, \ldots, K$ and then forming all combinations to obtain (35).

Proposition 14 shows that the convergence rate of $\mathrm{Var}[\widetilde{g}_B(\theta)]$ is faster than that of $\mathrm{Var}[\widetilde{g}_{\mathbf{n}'}(\theta)]$ except when $K = 1$ and $d_1 = 1$. Thus the expected improvement in objective function at each SGD step is larger when using a gradient estimate in the form of (36) instead of (35), although both strategies require to average over the same number of terms. This is also supported by the experimental results reported in the next section.

5. Numerical Experiments

We show the benefits of the sampling approach promoted in this paper on two applications: metric learning for classification, and model selection in clustering.

5.1 Metric Learning

In this section, we focus on the metric learning problem (see Section 2.2.2). As done in much of the metric learning literature, we restrict our attention to the family of pseudo-distance functions $D_M : \mathbb{R}^d \times \mathbb{R}^d \to \mathbb{R}_+$ defined as

$$D_M(x, x') = (x - x')M(x - x')^T,$$

where $M \in \mathbb{S}^d_+$, and $\mathbb{S}^d_+$ is the cone of $d \times d$ symmetric positive-semidefinite (PSD) matrices.

Given a training sample $\{(x_i, y_i)\}_{i=1}^n$ where $x_i \in \mathbb{R}^d$ and $y_i \in \{1, \ldots, C\}$, let $y_{ij} = 1$ if $y_i = y_j$ and 0 otherwise for any pair of samples. Given a threshold $b \geq 0$, we define the empirical risk as follows:

$$R_n(D_M) = \frac{2}{n(n-1)} \sum_{1 \leq i < j \leq n} [y_{ij}(b - D_M(x_i, x_j))]_+, \tag{37}$$

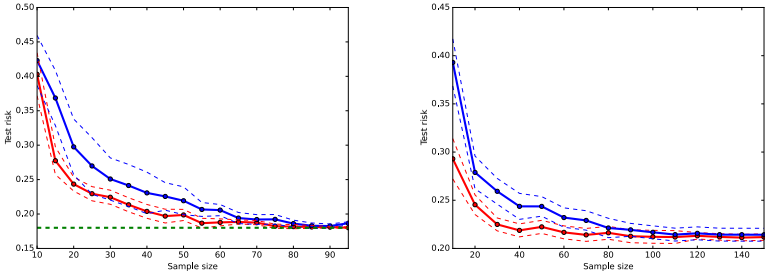
where $[u]_+ = \max(0, 1 - u)$ is the hinge loss. This risk estimate is convex and was used for instance by Jin et al. (2009) and Cao et al. (2012). Our goal is the find the empirical risk minimizer among our family of distance functions, i.e.:

$$\widehat{M} = \arg\min_{M \in \mathbb{S}^d_+} R_n(D_M). \tag{38}$$

In our experiments, we use the following two data sets:

- **Synthetic data set**: some synthetic data that we generated for illustration. X is a mixture of 10 gaussians in $\mathbb{R}^{40}$ – each one corresponding to a class – such that all gaussian means are contained in an subspace of dimension 15 and their shared covariance matrix is proportional to identity with a variance factor such that some overlap is observed. That is, the solution to the metric learning problem should be proportional to the linear projection over the subspace containing the gaussians means. Training and testing sets contain respectively 50,000 and 10,000 observations.
- **MNIST data set**: a handwritten digit classification data set which has 10 classes and consists of 60,000 training images and 10,000 test images.[2] This data set has been used extensively to benchmark metric learning (Weinberger and Saul, 2009). As done by previous authors, we reduce the dimension from 784 to 164 using PCA so as to retain 95% of the variance, and normalize each sample to unit norm.

2. See `http://yann.lecun.com/exdb/mnist/`.



(a) Synthetic data set (b) MNIST data set

Figure 3: Test risk with respect to the sample size p of the ERM when the risk is approximated using complete (blue) or incomplete (red) U-statistics. Solid lines represent means and dashed ones represent standard deviation. For the synthetic data set, the green dotted line represent the performance of the true risk minimizer.

Note that for both data sets, merely computing the empirical risk (37) for a given M involves averaging over more than 10^9 pairs.

We conduct two types of experiment. In Section 5.1.1, we subsample the data before learning and evaluate the performance of the ERM on the subsample. In Section 5.1.2, we use Stochastic Gradient Descent to find the ERM on the original sample, using subsamples at each iteration to estimate the gradient.

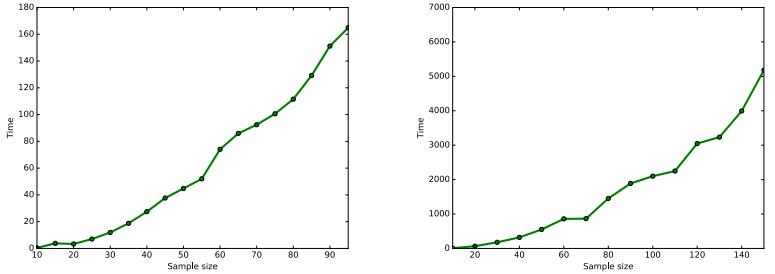
5.1.1 One-Time Sampling

We compare two sampling schemes to approximate the empirical risk:

- Complete U-statistic: p indices are uniformly picked at random in $\{1,\dots,n\}$. The empirical risk is approximated using any possible pair formed by the p indices, that is $\frac{p(p-1)}{2}$ pairs.
- Incomplete U-statistic: the empirical risk is approximated using $\frac{p(p-1)}{2}$ pairs picked uniformly at random in $\{1,\dots,n\}^2$.

For each strategy, we use a projected gradient descent method in order to solve (38), using several values of p and averaging the results over 50 random trials. As the testing sets are large, we evaluate the test risk on 100,000 randomly picked pairs.

Figure 3(a) shows the test risk of the ERM with respect to the sample size p for both sampling strategies on the synthetic data set. As predicted by our theoretical analysis, the incomplete U-statistic strategy achieves a significantly smaller risk on average. For instance, it gets within 5% error of the true risk minimizer for $p = 50$, while the complete U-statistic needs $p > 80$ to reach the same performance. This represents twice more computational time, as shown in Figure 4(a) (as expected, the runtime increases roughly quadratically with



(a) Synthetic data set (b) MNIST data set

Figure 4: Average training time (in seconds) with respect to the sample size p.

p). The incomplete U-statistic strategy also has the advantage of having a much smaller variance between the runs, which makes it more reliable. The same conclusions hold for the MNIST data set, as can be seen in Figure 3(b) and Figure 4(b).

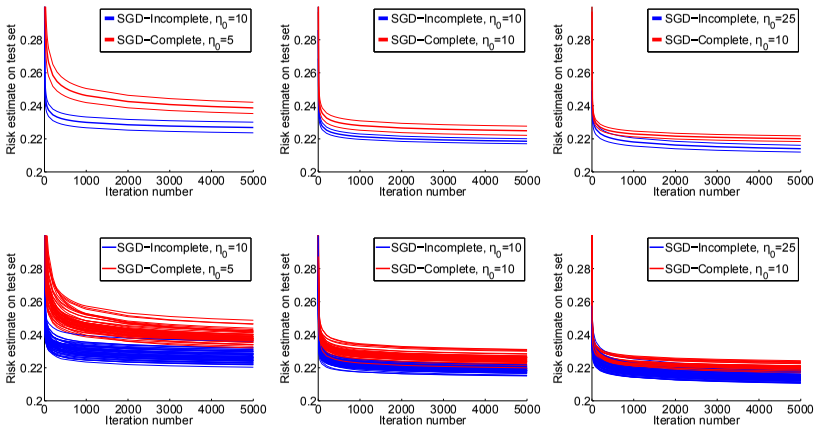
5.1.2 Stochastic Gradient Descent

In this section, we focus on solving the ERM problem (38) using Stochastic Gradient Descent and compare two approaches (analyzed in Section 4) to construct a mini-batch at each iteration. The first strategy, SGD-Complete, is to randomly draw (with replacement) a subsample and use the complete U-statistic associated with the subsample as the gradient estimate. The second strategy, SGD-Incomplete (the one we promote in this paper), consists in sampling an incomplete U-statistic with the same number of terms as in SGD-Complete.

For this experiment, we use the MNIST data set. We set the threshold in (37) to $b = 2$ and the learning rate of SGD at iteration t to $\eta_t = 1/(\eta_0 t)$ where $\eta_0 \in \{1, 2.5, 5, 10, 25, 50\}$. To reduce computational cost, we only project our solution onto the PSD cone at the end of the algorithm, following the "one projection" principle used by Chechik et al. (2010). We try several values m for the mini-batch size, namely $m \in \{10, 28, 55, 105, 253\}$.[3] For each mini-batch size, we run SGD for 10,000 iterations and select the learning rate parameter η_0 that achieves the minimum risk on 100,000 pairs randomly sampled from the training set. We then estimate the generalization risk using 100,000 pairs randomly sampled from the test set.

For all mini-batch sizes, SGD-Incomplete achieves significantly better test risk than SGD-Complete. Detailed results are shown in Figure 5 for three mini-batch sizes, where we plot the evolution of the test risk with respect to the iteration number.[4] We make several comments. First, notice that the best learning rate is often larger for SGD-Incomplete than for SGD-Complete ($m = 10$ and $m = 253$). This confirms that gradient estimates from the

3. For each m, we can construct a complete U-statistic from n' samples with $n'(n'-1)/2 = m$ terms.
4. We point out that the figures look the same if we plot the runtime instead of the iteration number. Indeed, the time spent on computing the gradients (which is the same for both variants) largely dominates the time spent on the random draws.



(a) $m = 10$ (b) $m = 55$ (c) $m = 253$

Figure 5: SGD results on the MNIST data set for various mini-batch size m. The top row shows the means and standard deviations over 50 runs, while the bottom row shows each run separately.

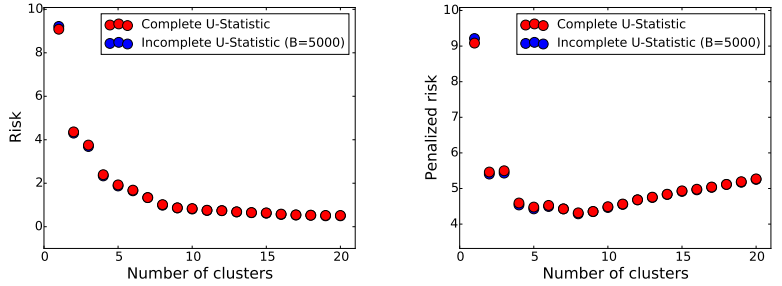
former strategy are generally more reliable. This is further supported by the fact that even though larger learning rates increase the variance of SGD, in these two cases SGD-Complete and SGD-Incomplete have similar variance. On the other hand, for $m = 55$ the learning rate is the same for both strategies. SGD-Incomplete again performs significantly better on average and also has smaller variance. Lastly, as one should expect, the gap between SGD-Complete and SGD-Incomplete reduces as the size of the mini-batch increases. Note however that in practical implementations, the relatively small mini-batch sizes (in the order of a few tens or hundreds) are generally those which achieve the best error/time trade-off.

5.2 Model Selection in Clustering

In this section, we are interested in the clustering problem described in Section 2.2.1. Specifically, let $X_1, \ldots, X_n \in \mathbb{R}^d$ be the set of points to be clustered. Let the clustering risk associated with a partition $\mathcal{P}$ into M groups $\mathcal{C}_1, \ldots, \mathcal{C}_M$ be:

$$\widehat{W}_n(\mathcal{P}) = \frac{2}{n(n-1)} \sum_{m=1}^{M} \sum_{1 \leq i < j \leq n} D(X_i, X_j) \cdot \mathbb{I}\{(X_i, X_j) \in \mathcal{C}_m^2\}. \tag{39}$$

In this experiment, given a set of candidate partitions, we want to perform model selection by picking the partition which minimizes the risk (39) plus some term penalizing the complexity of the partition. When the number of points n is large, the complete risk is very



(a) Risk (b) Penalized risk

Figure 6: Clustering model selection results on the forest cover type data set. Figure 6(a) shows the risk (complete and incomplete with $B = 5,000$ terms) for the first 20 partitions, while Figure 6(b) shows the penalized risk for $c = 1.1$.

expensive to compute. Our strategy is to replace it with an incomplete approximation with much fewer terms. Like in the approach theoretically investigated in Section 3.2, the goal here is to show that using the incomplete approximation instead of the complete version as the goodness-of-fit measure in a complexity penalized criterion does not damage the selection, while reducing the computational cost. For simplicity, the complexity penalty we use below is not of the same type as the structural VC dimension-based penalty considered in Theorem 10, but we will see that the incomplete approximation is very accurate and can thus effectively replace the complete version regardless of the penalty used.

The experimental setup is as follows. We used the forest cover type data set,[5] which is popular to benchmark clustering algorithms (see for instance Kanungo et al., 2004). To be able to evaluate the complete risk, we work with $n = 5,000$ points subsampled at random from the entire data set of 581,012 points in dimension 54. We then generated a hierarchical clustering of these points using agglomerative clustering with Ward's criterion (Ward, 1963) as implemented in the `scikit-learn` Python library (Pedregosa et al., 2011). This defines n partitions $\mathcal{P}_1, \ldots, \mathcal{P}_n$ where $\mathcal{P}_m$ consists of m clusters ($\mathcal{P}_1$ corresponds to a single cluster containing all points, while in $\mathcal{P}_n$ each point has its own cluster).

For each partition size, we first compare the value of the complete risk (39) with $n(n-1) = 24,995,000$ terms with that of an incomplete version with only $B = n = 5,000$ pairs drawn at random. As shown in Figure 6(a), the incomplete U-statistic is a very accurate approximation of the complete one, despite consisting of 5000 times less terms. It will thus lead to similar results in model selection. To illustrate, we use a simple penalty term of the form $\text{pen}(\mathcal{P}_m) = c \cdot \log(m)$ where c is a scaling constant. Figure 6(b) shows that both selection criteria choose the same model $\mathcal{P}_8$. Performing this model selection over $\mathcal{P}_1, \ldots, \mathcal{P}_{20}$

5. See `https://archive.ics.uci.edu/ml/datasets/Covertype`.

took about 66 seconds for the complete U-statistic, compared to only 0.1 seconds for the incomplete version.[6]

Finally, we generated 100 incomplete U-statistics with different random seeds ; all of them correctly identified $\mathcal{P}_8$ as the best model. Using $B = 5,000$ pairs is thus sufficient to obtain reliable results with an incomplete U-statistic for this data set. In contrast, the complete U-statistics based on a subsample (leading to the same number of pairs) selected the correct model in only 57% of cases.

6. Conclusion

In a wide variety of statistical learning problems, U-statistics are natural estimates of the risk measure one seeks to optimize. As the sizes of the samples increase, the computation of such functionals involves summing a rapidly exploding number of terms and becomes numerically unfeasible. In this paper, we argue that for such problems, *Empirical Risk Minimization* can be implemented using statistical counterparts of the risk based on much less terms (picked randomly by means of sampling with replacement), referred to as *incomplete U-statistics*. Using a novel deviation inequality, we have shown that this approximation scheme does not deteriorate the learning rates, even preserving fast rates in certain situations where they are proved to occur. Furthermore, we have extended these results to U-statistics based on different sampling schemes (Bernoulli sampling, sampling without replacement) and shown how such functionals can be used for the purpose of model selection and for implementing ERM iterative procedures based on stochastic gradient descent. Beyond theoretical rate bounds, the efficiency of the approach we promote is illustrated by several numerical experiments.

Acknowledgments

The authors are grateful to the reviewers for their careful reading of the paper, which permitted to improve significantly the presentation of the results.

Appendix A. Proof of Proposition 2

Set $N = \min\{\lfloor n_1/d_1 \rfloor, \ldots, \lfloor n_K/d_K \rfloor\}$ and let

$$V_H\left(X_1^{(1)}, \ldots, X_{n_1}^{(1)}, \ldots, X_1^{(K)}, \ldots, X_{n_K}^{(K)}\right) = \frac{1}{N}\Big[H\left(X_1^{(1)}, \ldots, X_{d_1}^{(1)}, \ldots, X_1^{(K)}, \ldots, X_{d_K}^{(K)}\right) + H\left(X_{d_1+1}^{(1)}, \ldots, X_{2d_1}^{(1)}, \ldots, X_{d_K+1}^{(K)}, \ldots, X_{2d_K}^{(K)}\right) + \ldots + H\left(X_{Nd_1-d_1+1}^{(1)}, \ldots, X_{Nd_1}^{(1)}, \ldots, X_{Nd_K-d_K+1}^{(K)}, \ldots, X_{Nd_K}^{(K)}\right)\Big],$$

6. The $n \times n$ distance matrix was precomputed before running the agglomerative clustering algorithm. The associated runtime is thus not taken into account in these timing results.

for any $H \in \mathcal{H}$ Recall that the K-sample U-statistic $U_{\mathbf{n}}(H)$ can be expressed as

$$U_{\mathbf{n}}(H) = \frac{1}{n_1! \cdots n_K!} \sum_{\sigma_1 \in \mathfrak{S}_{n_1}, \ldots, \sigma_K \in \mathfrak{S}_{n_K}} V_H\left(X_{\sigma_1(1)}^{(1)}, \ldots, X_{\sigma_1(n_1)}^{(1)}, \ldots, X_{\sigma_K(1)}^{(K)}, \ldots, X_{\sigma_K(n_K)}^{(K)}\right), \tag{40}$$

where $\mathfrak{S}_m$ denotes the symmetric group of order m for any $m \geq 1$. This representation as an average of sums of N independent terms is known as the (first) Hoeffding's decomposition, see Hoeffding (1948). Then, using Jensen's inequality in particular, one may easily show that, for any nondecreasing convex function $\psi : \mathbb{R}_+ \to \mathbb{R}$, we have:

$$\mathbb{E}\left[\psi\left(\sup_{H \in \mathcal{H}} \left|U_{\mathbf{n}}(\bar{H})\right|\right)\right] \leq \mathbb{E}\left[\psi\left(\sup_{H \in \mathcal{H}} \left|V_{\bar{H}}(X_1^{(1)}, \ldots, X_{n_1}^{(1)}, \ldots, X_1^{(K)}, \ldots, X_{n_K}^{(K)})\right|\right)\right], \tag{41}$$

where we set $\bar{H} = H - \mu(H)$ for all $H \in \mathcal{H}$. Now, using standard symmetrization and randomization arguments (see Giné and Zinn (1984) for instance) and (41), we obtain that

$$\mathbb{E}\left[\psi\left(\sup_{H \in \mathcal{H}} \left|U_{\mathbf{n}}(\bar{H})\right|\right)\right] \leq \mathbb{E}\left[\psi\left(2\mathcal{R}_N\right)\right], \tag{42}$$

where

$$\mathcal{R}_N = \sup_{H \in \mathcal{H}} \frac{1}{N} \sum_{l=1}^{N} \epsilon_l H\left(X_{(l-1)d_1+1}^{(1)}, \ldots, X_{ld_1}^{(1)}, \ldots, X_{(l-1)d_K+1}^{(K)}, \ldots, X_{ld_K}^{(K)}\right),$$

is a Rademacher average based on the Rademacher chaos $\epsilon_1, \ldots, \epsilon_N$ (independent random symmetric sign variables), independent from the $X_i^{(k)}$'s. We now apply the bounded difference inequality (see McDiarmid (1989)) to the functional $\mathcal{R}_N$, seen as a function of the i.i.d. random variables $(\epsilon_l, X_{(l-1)d_1+1}^{(1)}, \ldots, X_{ld_1}^{(1)}, \ldots, X_{(l-1)d_K+1}^{(K)}, \ldots, X_{ld_K}^{(K)})$, $1 \leq l \leq N$: changing any of these random variables change the value of $\mathcal{R}_N$ by at most $\mathcal{M}_{\mathcal{H}}/N$. One thus obtains from (42) with $\psi(x) = \exp(\lambda x)$, where $\lambda > 0$ is a parameter which shall be chosen later, that:

$$\mathbb{E}\left[\exp\left(\lambda \sup_{H \in \mathcal{H}} \left|U_{\mathbf{n}}(\bar{H})\right|\right)\right] \leq \exp\left(2\lambda \mathbb{E}[\mathcal{R}_N] + \frac{\mathcal{M}_{\mathcal{H}}^2 \lambda^2}{4N}\right). \tag{43}$$

Applying Chernoff's method, one then gets:

$$\mathbb{P}\left\{\sup_{H \in \mathcal{H}} \left|U_{\mathbf{n}}(\bar{H})\right| > \eta\right\} \leq \exp\left(-\lambda\eta + 2\lambda \mathbb{E}[\mathcal{R}_N] + \frac{\mathcal{M}_{\mathcal{H}}^2 \lambda^2}{4N}\right). \tag{44}$$

Using the bound (see Eq. (6) in Boucheron et al. (2005) for instance)

$$\mathbb{E}[\mathcal{R}_N] \leq \mathcal{M}_{\mathcal{H}} \sqrt{\frac{2V \log(1+N)}{N}}$$

and taking $\lambda = 2N(\eta - 2\mathbb{E}[\mathcal{R}_N])/\mathcal{M}_{\mathcal{H}}^2$ in (44), one finally establishes the desired result.

Appendix B. Proof of Theorem 6

For convenience, we introduce the random sequence $\zeta = ((\zeta_k(I))_{I\in\Lambda})_{1\leq k\leq B}$, where $\zeta_k(I)$ is equal to 1 if the tuple $I = (I_1, \ldots, I_K)$ has been selected at the k-th draw and to 0 otherwise: the ζ_k's are i.i.d. random vectors and, for all $(k, I) \in \{1, \ldots, B\} \times \Lambda$, the r.v. $\zeta_k(I)$ has a Bernoulli distribution with parameter $1/\#\Lambda$. We also set $\mathbf{X}_I = (\mathbf{X}_{I_1}^{(1)}, \ldots, \mathbf{X}_{I_K}^{(K)})$ for any I in Λ. Equipped with these notations, observe first that one may write: $\forall B \geq 1$, $\forall \mathbf{n} \in \mathbb{N}^{*K}$,

$$\widetilde{U}_B(H) - U_{\mathbf{n}}(H) = \frac{1}{B}\sum_{k=1}^{B} \mathcal{Z}_k(H),$$

where $\mathcal{Z}_k(H) = \sum_{I\in\Lambda}(\zeta_k(I) - 1/\#\Lambda)H(\mathbf{X}_I)$ for any $(k, I) \in \{1, \ldots, B\} \times \Lambda$. It follows from the independence between the $\mathbf{X}_I$'s and the $\zeta(I)$'s that, for all $H \in \mathcal{H}$, conditioned upon the $\mathbf{X}_I$'s, the variables $\mathcal{Z}_1(H), \ldots, \mathcal{Z}_B(H)$ are independent, centered and almost-surely bounded by $2\mathcal{M}_{\mathcal{H}}$ (notice that $\sum_{I\in\Lambda}\zeta_k(I) = 1$ for all $k \geq 1$). By virtue of Sauer's lemma, since $\mathcal{H}$ is a VC major class with finite VC dimension V, we have, for fixed $\mathbf{X}_I$'s:

$$\#\{(H(\mathbf{X}_I))_{I\in\Lambda} : H \in \mathcal{H}\} \leq (1 + \#\Lambda)^V.$$

Hence, conditioned upon the $\mathbf{X}_I$'s, using the union bound and next Hoeffding's inequality applied to the independent sequence $\mathcal{Z}_1(H), \ldots, \mathcal{Z}_B(H)$, for all $\eta > 0$, we obtain that:

$$\begin{aligned}\mathbb{P}\left\{\sup_{H\in\mathcal{H}}\left|\widetilde{U}_B(H) - U_{\mathbf{n}}(H)\right| > \eta \mid (\mathbf{X}_I)_{I\in\Lambda}\right\} &\leq \mathbb{P}\left\{\sup_{H\in\mathcal{H}}\left|\frac{1}{B}\sum_{k=1}^{B}\mathcal{Z}_k(H)\right| > \eta \mid (\mathbf{X}_I)_{I\in\Lambda}\right\} \\ &\leq 2(1 + \#\Lambda)^V e^{-B\eta^2/(2\mathcal{M}_{\mathcal{H}}^2)}.\end{aligned}$$

Taking the expectation, this proves the first assertion of the theorem. Notice that this can be formulated: for any $\delta \in (0, 1)$, we have with probability at least $1 - \delta$:

$$\sup_{H\in\mathcal{H}}\left|\widetilde{U}_B(H) - U_{\mathbf{n}}(H)\right| \leq \mathcal{M}_{\mathcal{H}} \times \sqrt{2\frac{V\log(1 + \#\Lambda) + \log(2/\delta)}{B}}.$$

Turning to the second part of the theorem, it straightforwardly results from the first part combined with Proposition 2.

Appendix C. Proof of Corollary 9

Assertion (i) is a direct application of Assertion (ii) in Theorem 6 combined with the bound $\mu(\widehat{H}_B) - \inf_{H\in\mathcal{H}}\mu(H) \leq 2\sup_{H\in\mathcal{H}}|\widetilde{U}_B(H) - \mu(H)|$.

Turning next to Assertion (ii), observe that by triangle inequality we have:

$$\mathbb{E}\left[\sup_{H\in\mathcal{H}_m}|\widetilde{U}_B(H) - \mu(H)|\right] \leq \mathbb{E}\left[\sup_{H\in\mathcal{H}_m}|\widetilde{U}_B(H) - U_{\mathbf{n}}(H)|\right] + \mathbb{E}\left[\sup_{H\in\mathcal{H}_m}|U_{\mathbf{n}}(H) - \mu(H)|\right]. \quad (45)$$

The same argument as that used in Theorem 6 (with $\psi(u) = u$ for any $u \geq 0$) yields a bound for the second term on the right hand side of Eq. (45):

$$\mathbb{E}\left[\sup_{H\in\mathcal{H}}|U_{\mathbf{n}}(H) - \mu(H)|\right] \leq 2\mathcal{M}_{\mathcal{H}}\sqrt{\frac{2V\log(1 + N)}{N}}. \quad (46)$$

The first term can be controlled by means of the following lemma, whose proof can be found for instance in Lugosi (2002, Lemmas 1.2 and 1.3).

Lemma 15 *The following assertions hold true.*

(i) Hoeffding's lemma. Let Z be an integrable r.v. with mean zero such that $a \leq Z \leq b$ almost-surely. Then, we have: $\forall s > 0$

$$\mathbb{E}[\exp(sZ)] \leq \exp\left(s^2(b - a)^2/8\right).$$

(ii) Let $M \geq 1$ and $Z_1, \ldots, Z_M$ be real valued random variables. Suppose that there exists $\sigma > 0$ such that $\forall s \in \mathbb{R}$: $\mathbb{E}[\exp(sZ_i)] \leq e^{s^2\sigma^2/2}$ for all $i \in \{1, \ldots, M\}$. Then, we have:

$$\mathbb{E}\left[\max_{1\leq i\leq M}|Z_i|\right] \leq \sigma\sqrt{2\log(2M)}. \quad (47)$$

Assertion (i) shows that, since $-\mathcal{M}_{\mathcal{H}} \leq \mathcal{Z}_k(H) \leq \mathcal{M}_{\mathcal{H}}$ almost surely,

$$\mathbb{E}\left[\exp(s\sum_{k=1}^{B}\mathcal{Z}_k(H)) \mid (\mathbf{X}_I)_{I\in\Lambda}\right] \leq e^{\frac{1}{2}Bs^2\mathcal{M}_{\mathcal{H}}^2}.$$

With $\sigma = \mathcal{M}_{\mathcal{H}}\sqrt{B}$ and $M = \#\{H(\mathbf{X}_I) : H \in \mathcal{H}\} \leq (1 + \#\Lambda)^V$, conditioning upon $(\mathbf{X}_I)_{I\in\Lambda}$, this result yields:

$$\mathbb{E}\left[\sup_{H\in\mathcal{H}}\left|\frac{1}{B}\sum_{k=1}^{B}\mathcal{Z}_k(H)\right| \mid (\mathbf{X}_I)_{I\in\Lambda}\right] \leq \mathcal{M}_{\mathcal{H}}\sqrt{\frac{2(\log 2 + V\log(1 + \#\Lambda))}{B}}. \quad (48)$$

Integrating next over $(\mathbf{X}_I)_{I\in\Lambda}$ and combining the resulting bound with (45) and (46) leads to the inequality stated in (ii).

A bound for the expected value. For completeness, we point out that the expected value of $\sup_{H\in\mathcal{H}}|(1/B)\sum_{k=1}^{B}\mathcal{Z}_k(H)|$ can also be bounded by means of classical symmetrization and randomization devices. Considering a "ghost" i.i.d. sample $\zeta_1', \ldots, \zeta_B'$ independent from $((\mathbf{X}_I)_{I\in\Lambda}, \zeta)$, distributed as ζ, Jensen's inequality yields:

$$\begin{aligned}\mathbb{E}\left[\sup_{H\in\mathcal{H}}\left|\frac{1}{B}\sum_{k=1}^{B}\mathcal{Z}_k(H)\right|\right] &= \mathbb{E}\left[\sup_{H\in\mathcal{H}}\left\{\mathbb{E}\left[\left|\frac{1}{B}\sum_{k=1}^{B}\sum_{I\in\Lambda}H(\mathbf{X}_I)\left(\zeta_k(I) - \zeta_k'(I)\right)\right| \mid (\mathbf{X}_I)_{I\in\Lambda}\right]\right\}\right] \\ &\leq \mathbb{E}\left[\sup_{H\in\mathcal{H}}\left|\frac{1}{B}\sum_{k=1}^{B}\sum_{I\in\Lambda}H(\mathbf{X}_I)\left(\zeta_k(I) - \zeta_k'(I)\right)\right|\right].\end{aligned}$$

Introducing next independent Rademacher variables $\epsilon_1, \ldots, \epsilon_B$, independent from $((\mathbf{X}_I)_{I\in\Lambda}, \zeta, \zeta')$, we have:

$$\mathbb{E}\left[\sup_{H\in\mathcal{H}}\left|\frac{1}{B}\sum_{k=1}^{B}\sum_{I\in\Lambda} H(\mathbf{X}_I)\left(\zeta_k(I)-\zeta'_k(I)\right)\right| \mid (\mathbf{X}_I)_{I\in\Lambda}\right] = \mathbb{E}\left[\sup_{H\in\mathcal{H}}\left|\frac{1}{B}\sum_{k=1}^{B}\epsilon_k\sum_{I\in\Lambda} H(\mathbf{X}_I)\left(\zeta_k(I)-\zeta'_k(I)\right)\right| \mid (\mathbf{X}_I)_{I\in\Lambda}\right] \leq 2\mathbb{E}\left[\sup_{H\in\mathcal{H}}\left|\frac{1}{B}\sum_{k=1}^{B}\epsilon_k\sum_{I\in\Lambda} H(\mathbf{X}_I)\zeta_k(I)\right| \mid (\mathbf{X}_I)_{I\in\Lambda}\right].$$

We thus obtained:

$$\mathbb{E}\left[\sup_{H\in\mathcal{H}}\left|\frac{1}{B}\sum_{k=1}^{B}\mathcal{Z}_k(H)\right|\right] \leq 2\mathbb{E}\left[\sup_{H\in\mathcal{H}}\left|\frac{1}{B}\sum_{k=1}^{B}\epsilon_k\sum_{I\in\Lambda} H(\mathbf{X}_I)\zeta_k(I)\right|\right].$$

Appendix D. Proof of Theorem 10

We start with proving the intermediary result, stated below.

Lemma 16 *Under the assumptions stipulated in Theorem 10, we have:* $\forall m \geq 1$, $\forall \epsilon > 0$,

$$\mathbb{P}\left\{\sup_{H\in\mathcal{H}_m}|\mu(H)-\widetilde{U}_B(H)| > 2\mathcal{M}_{\mathcal{H}_m}\left\{\sqrt{\frac{2V_m\log(1+N)}{N}}+\sqrt{\frac{2(\log 2+V_m\log(1+\#\Lambda))}{B}}\right\}+\epsilon\right\} \leq \exp\left(-B^2\epsilon^2/\left(2(B+n)\mathcal{M}^2_{\mathcal{H}_m}\right)\right).$$

Proof This is a direct application of the bounded difference inequality (see McDiarmid (1989)) applied to the quantity $\sup_{H\in\mathcal{H}_m}|\mu(H)-\widetilde{U}_B(H)|$, viewed as a function of the $(B+n)$ independent random variables $(X_1^{(1)}, X_{n_K}^{(K)}, \epsilon_1, \ldots, \epsilon_B)$ (jumps being bounded by $2\mathcal{M}_H/B$), combined with Assertion (ii) of Corollary 9. ∎

Let $m \geq 1$ and decompose the expected excess of risk of the rule picked by means of the complexity regularized incomplete U-statistic criterion as follows:

$$\mathbb{E}\left[\mu(\widehat{H}_{B,\widehat{m}})-\mu^*_m\right] = \mathbb{E}\left[\mu(\widehat{H}_{B,\widehat{m}})-\widetilde{U}_B(\widehat{H}_{B,\widehat{m}})-\mathrm{pen}(B,\widehat{m})\right] + \mathbb{E}\left[\inf_{j\geq 1}\left\{\widetilde{U}_B(\widehat{H}_{B,j})+\mathrm{pen}(B,j)\right\}-\mu^*_m\right],$$

where we set $\mu^*_m = \inf_{H\in\mathcal{H}_m}\mu(H)$. In order to bound the first term on the right hand side of the equation above, observe that we have: $\forall \epsilon > 0$,

$$\begin{aligned}\mathbb{P}\left\{\mu(\widehat{H}_{B,\widehat{m}})-\widetilde{U}_B(\widehat{H}_{B,\widehat{m}})-\mathrm{pen}(B,\widehat{m})>\epsilon\right\} &\leq \mathbb{P}\left\{\sup_{j\geq 1}\left\{\mu(\widehat{H}_{B,j})-\widetilde{U}_B(\widehat{H}_{B,j})-\mathrm{pen}(B,j)\right\}>\epsilon\right\}\\ &\leq \sum_{j\geq 1}\mathbb{P}\left\{\mu(\widehat{H}_{B,j})-\widetilde{U}_B(\widehat{H}_{B,j})-\mathrm{pen}(B,j)>\epsilon\right\}\\ &\leq \sum_{j\geq 1}\mathbb{P}\left\{\sup_{H\in\mathcal{H}_j}|\mu(\widehat{H})-\widetilde{U}_B(H)|-\mathrm{pen}(B,j)>\epsilon\right\}\\ &\leq \sum_{j\geq 1}\exp\left(-\frac{-B^2}{2(B+n)\mathcal{M}^2}\left(\epsilon+2\mathcal{M}\sqrt{\frac{(B+n)\log j}{B^2}}\right)^2\right)\\ &\leq \exp\left(-\frac{B^2\epsilon^2}{2(B+n)\mathcal{M}^2}\right)\sum_{j\geq 1}1/j^2 \leq 2\exp\left(-\frac{B^2\epsilon^2}{2(B+n)\mathcal{M}^2}\right),\end{aligned}$$

using successively the union bound and Lemma 16. Integrating over $[0,+\infty)$, we obtain that:

$$\mathbb{E}\left[\mu(\widehat{H}_{B,\widehat{m}})-\widetilde{U}_B(\widehat{H}_{B,\widehat{m}})-\mathrm{pen}(B,\widehat{m})\right] \leq \mathcal{M}\frac{\sqrt{2\pi(B+n)}}{B}. \tag{49}$$

Considering now the second term, notice that

$$\mathbb{E}\left[\inf_{j\geq 1}\left\{\widetilde{U}_B(\widehat{H}_{B,j})+\mathrm{pen}(B,j)\right\}-\mu^*_m\right] \leq \mathbb{E}\left[\widetilde{U}_B(\widehat{H}_{B,m})+\mathrm{pen}(B,m)-\mu^*_m\right] \leq \mathrm{pen}(B,m).$$

Combining the bounds, we obtain that: $\forall m \geq 1$,

$$\mathbb{E}\left[\mu(\widehat{H}_{B,\widehat{m}})\right] \leq \mu^*_m + \mathrm{pen}(B,m) + \mathcal{M}\frac{\sqrt{2\pi(B+n)}}{B}.$$

The oracle inequality is thus proved.

Appendix E. Proof of Theorem 12

We start with proving the following intermediary result, based on the U-statistic version of the Bernstein exponential inequality.

Lemma 17 *Suppose that the assumptions of Theorem 12 are fulfilled. Then, for all* $\delta \in (0,1)$*, we have with probability larger than* $1-\delta$*:* $\forall r \in \mathcal{R}$, $\forall n \geq 2$,

$$0 \leq \Lambda_n(r) - \Lambda(r) + \sqrt{\frac{2c\Lambda(r)^\alpha\log(\#\mathcal{R}/\delta)}{n}} + \frac{4\log(\#\mathcal{R}/\delta)}{3n}.$$

Proof The proof is a straightforward application of Theorem A on p. 201 in Serfling (1980), combined with the union bound and Assumption 1. ∎

The same argument as that used to prove Assertion (i) in Theorem 6 (namely, freezing the

$\mathbf{X}_I$'s, applying Hoeffding inequality and the union bound) shows that, for all $\delta \in (0,1)$, we have with probability at least $1-\delta$: $\forall r \in \mathcal{R}$,

$$0 \leq \widetilde{U}_B(q_r) - U_{\mathbf{n}}(q_r) + \sqrt{\frac{M + \log(M/\delta)}{B}}$$

for all $n \geq 2$ and $B \geq 1$ (observe that $\mathcal{M}_{\mathcal{H}} \leq 1$ in this case). Now, combining this bound with the previous one and using the union bound, one gets that, for all $\delta \in (0,1)$, we have with probability larger than $1-\delta$: $\forall r \in \mathcal{R}$, $\forall n \geq 2$, $\forall B \geq 1$,

$$0 \leq \widetilde{U}_B(q_r) - \Lambda(r) + \sqrt{\frac{2c\Lambda(r)^\alpha \log(2M/\delta)}{n}} + \frac{4\log(2M/\delta)}{3n} + \sqrt{\frac{M + \log(2M/\delta)}{B}}.$$
