The Journal of Machine Learning Research
Volume 17
Print-Archive Edition

The Journal of Machine Learning Research (JMLR) is an open access journal. All articles published in JMLR are freely available via electronic distribution. This Print-Archive Edition is published annually as a means of archiving the contents of the journal in perpetuity. The contents of this volume are articles published electronically in JMLR in 2016.

JMLR is abstracted in ACM Computing Reviews, INSPEC, and Psychological Abstracts/PsycINFO.

JMLR is a publication of Journal of Machine Learning Research, Inc. For further information regarding JMLR, including open access to articles, visit <http://www.jmlr.org/>.

JMLR Print-Archive Edition is a publication of Microtome Publishing under agreement with Journal of Machine Learning Research, Inc. For further information regarding the Print-Archive Edition, including subscription and distribution information and background on open-access print archiving, visit Microtome Publishing at <http://www.mtome.com/>.

Collection copyright © 2016 The Journal of Machine Learning Research, Inc. and Microtome Publishing. Copyright of individual articles remains with their respective authors.

ISSN 1532-4435 (print)
ISSN 1533-7928 (online)

JMLR Editorial Board

Editor-in-Chief

Bernhard Schölkopf, MPI for Intelligent Systems, Germany

Editor-in-Chief

Kevin Murphy, Google Research, USA

Managing Editor

Aron Culotta, Illinois Institute of Technology, USA

Production Editor

Charles Sutton, University of Edinburgh, UK

JMLR Web Master

Chiyuan Zhang, Massachusetts Institute of Technology, USA

JMLR Action Editors

Edoardo M. Airoldi, Harvard University, USA **Peter Auer**, University of Leoben, Austria **Francis Bach**, INRIA, France **Andrew Bagnell**, Carnegie Mellon University, USA **David Barber**, University College London, UK **Mikhail Belkin**, Ohio State University, USA **Yoshua Bengio**, Université de Montréal, Canada **Samy Bengio**, Google Research, USA **Jeff Bilmes**, University of Washington, USA **David Blei**, Princeton University, USA **Karsten Borgwardt**, MPI For Intelligent systems, Germany **Léon Bottou**, Microsoft Research, USA **Michael Bowling**, University of Alberta, Canada **Lawrence Carin**, Duke University, USA **Francois Caron**, University of Bordeaux, France **David Maxwell Chickering**, Microsoft Research, USA **Andreas Christmann**, University of Bayreuth, Germany **Alexander Clark**, King's College London, UK **William W. Cohen**, Carnegie-Mellon University, USA **Corinna Cortes**, Google Research, USA **Koby Crammer**, Technion, Israel **Sanjoy Dasgupta**, University of California, San Diego, USA **Rina Dechter**, University of California, Irvine, USA **Inderjit S. Dhillon**, University of Texas, Austin, USA **David Dunson**, Duke University, USA **Charles Elkan**, University of California at San Diego, USA **Rob Fergus**, New York University, USA **Nando de Freitas**, Oxford University, UK **Kenji Fukumizu**, The Institute of Statistical Mathematics, Japan **Sara van de Geer**, ETH Zürich, Switzerland **Amir Globerson**, The Hebrew University of Jerusalem, Israel **Moises Goldszmidt**, Microsoft Research, USA **Russ Greiner**, University of Alberta, Canada **Arthur Gretton**, University College London, UK **Maya Gupta**, Google Research, USA **Isabelle Guyon**, ClopiNet, USA **Moritz Hardt**, Google Research, USA **Matthias Hein**, Saarland University, Germany **Thomas Hofmann**, ETH Zurich, Switzerland **Bert Huang**, Virginia Tech, Virginia **Aapo Hyvärinen**, University of Helsinki, Finland **Alex Ihler**, University of California, Irvine, USA **Tommi Jaakkola**, Massachusetts Institute of Technology, USA **Samuel Kaski**, Aalto University, Finland **Sathiya Keerthi**, Microsoft Research, USA **Andreas Krause**, ETH Zurich, Switzerland **Christoph Lampert**, Institute of Science and Technology, Austria **Gert Lanckriet**, University of California, San Diego, USA **Pavel Laskov**, University of Tübingen, Germany **Neil Lawrence**, University of Sheffield, UK **Guy Lebanon**, LinkedIn, USA **Daniel Lee**, University of Pennsylvania, USA **Jure Leskovec**, Stanford University, USA **Qiang Liu**, Dartmouth College, USA **Gábor Lugosi**, Pompeu Fabra University, Spain **Ulrike von Luxburg**, University of Hamburg, Germany **Shie Mannor**, Technion, Israel **Robert E. McCulloch**, University of Chicago, USA **Chris Meek**, Microsoft Research, USA **Nicolai Meinshausen**, University of Oxford, UK **Vahab Mirrokni**, Google Research, USA **Mehryar Mohri**, New

York University, USA **Sebastian Nowozin**, Microsoft Research, Cambridge, UK **Una-May O'Reilly**, Massachusetts Institute of Technology, USA **Laurent Orseau**, Google Deepmind, USA **Manfred Opper**, Technical University of Berlin, Germany **Martin Pelikan**, Google Inc, USA **Jie Peng**, University of California, Davis, USA **Jan Peters**, Technische Universitaet Darmstadt, Germany **Avi Pfeffer**, Charles River Analytics, USA **Joelle Pineau**, McGill University, Canada **Massimiliano Pontil**, University College London, UK **Yuan (Alan) Qi**, Purdue University, USA **Luc de Raedt**, Katholieke Universiteit Leuven, Belgium **Alexander Rakhlin**, University of Pennsylvania, USA **Ben Recht**, University of California, Berkeley, USA **Saharon Rosset**, Tel Aviv University, Israel **Ruslan Salakhutdinov**, University of Toronto, Canada **Sujay Sanghavi**, University of Texas, Austin, USA **Marc Schoenauer**, INRIA Saclay, France **Matthias Seeger**, Amazon, Germany **John Shawe-Taylor**, University College London, UK **Xi-aotong Shen**, University of Minnesota, USA **Yoram Singer**, Google Research, USA **David Sontag**, New York University, USA **Peter Spirtes**, Carnegie Mellon University, USA **Nathan Srebro**, Toyota Technical Institute at Chicago, USA **Ingo Steinwart**, University of Stuttgart, Germany **Amos Storkey**, University of Edinburgh, UK **Csaba Szepesvari**, University of Alberta, Canada **Yee Whye Teh**, University of Oxford, UK **Olivier Teytaud**, INRIA Saclay, France **Ivan Titov**, University of Amsterdam, Netherlands **Koji Tsuda**, National Institute of Advanced Industrial Science and Technology, Japan **Zhuowen Tu**, University of California at San Diego, USA **Nicolas Vayatis**, Ecole Normale Supérieure de Cachan, France **S V N Vishwanathan**, Purdue University, USA **Manfred Warmuth**, University of California at Santa Cruz, USA **Stefan Wrobel**, Fraunhofer IAIS and University of Bonn, Germany **Eric Xing**, Carnegie Mellon University, USA **Bin Yu**, University of California at Berkeley, USA **Tong Zhang**, Rutgers University, USA **Zhihua Zhang**, Shanghai Jiao Tong University, China **Hui Zou**, University of Minnesota, USA

JMLR MLOSS Editors

Geoffrey Holmes, University of Waikato, New Zealand **Antti Honkela**, University of Helsinki, Finland **Balázs Kégl**, University of Paris-Sud, France **Cheng Soon Ong**, University of Melbourne, Australia **Mark Reid**, Australian National University, Australia

Journal of Machine Learning Research

Volume 17, 2017

Part A

- 17(1):1–42 **On the Complexity of Best-Arm Identification in Multi-Armed Bandit Models**
Emilie Kaufmann, Olivier Cappé, Aurélien Garivier
- 17(2):1–51 **Multiscale Dictionary Learning: Non-Asymptotic Bounds and Robustness**
Mauro Maggioni, Stanislav Minsker, Nate Strawn
- 17(3):1–32 **Consistent Algorithms for Clustering Time Series**
Azadeh Khaleghi, Daniil Ryabko, Jérémie Mary, Philippe Preux
- 17(4):1–26 **Random Rotation Ensembles**
Rico Blaser, Piotr Fryzlewicz
- 17(5):1–10 **Should We Really Use Post-Hoc Tests Based on Mean-Ranks?**
Alessio Benavoli, Giorgio Corani, Francesca Mangili
- 17(6):1–31 **Minimax Rates in Permutation Estimation for Feature Matching**
Olivier Collier, Arnak S. Dalalyan
- 17(7):1–33 **Consistency and Fluctuations For Stochastic Gradient Langevin Dynamics**
Yee Whye Teh, Alexandre H. Thiery, Sebastian J. Vollmer
- 17(8):1–32 **Knowledge Matters: Importance of Prior Information for Optimization**
Çağlar Gülçehre, Yoshua Bengio
- 17(9):1–5 **Harry: A Tool for Measuring String Similarity**
Konrad Rieck, Christian Wressnegger
- 17(10):1–29 **Herded Gibbs Sampling**
Yutian Chen, Luke Bornn, Nando de Freitas, Mareija Eskelin, Jing Fang, Max Welling
- 17(11):1–28 **Complexity of Representation and Inference in Compositional Models with Part Sharing**
Alan Yuille, Roozbeh Mottaghi
- 17(12):1–41 **Noisy Sparse Subspace Clustering**
Yu-Xiang Wang, Huan Xu
- 17(13):1–36 **Learning the Variance of the Reward-To-Go**
Aviv Tamar, Dotan Di Castro, Shie Mannor

- 17(14):1–45 **Convex Calibration Dimension for Multiclass Loss Matrices**
Harish G. Ramaswamy, Shivani Agarwal
- 17(15):1–24 **LLORMA: Local Low-Rank Matrix Approximation**
Joonseok Lee, Seungyeon Kim, Guy Lebanon, Yoram Singer, Samy Bengio
- 17(16):1–26 **A Consistent Information Criterion for Support Vector Machines in Diverging Model Spaces**
Xiang Zhang, Yichao Wu, Lan Wang, Runze Li
- 17(17):1–51 **Extremal Mechanisms for Local Differential Privacy**
Peter Kairouz, Sewoong Oh, Pramod Viswanath
- 17(18):1–40 **Loss Minimization and Parameter Estimation with Heavy Tails**
Daniel Hsu, Sivan Sabato
- 17(19):1–30 **Analysis of Classification-based Policy Iteration Algorithms**
Alessandro Lazaric, Mohammad Ghavamzadeh, Rémi Munos
- 17(20):1–54 **Operator-valued Kernels for Learning from Functional Response Data**
Hachem Kadri, Emmanuel Duflos, Philippe Preux, Stéphane Canu, Alain Rakotomamonjy, Julien Audiffren
- 17(21):1–5 **MEKA: A Multi-label/Multi-target Extension to WEKA**
Jesse Read, Peter Reutemann, Bernhard Pfahringer, Geoff Holmes
- 17(22):1–34 **Gradients Weights improve Regression and Classification**
Samory Kpotufe, Abdeslam Boularias, Thomas Schultz, Kyoungok Kim
- 17(23):1–21 **A Closer Look at Adaptive Regret**
Dmitry Adamskiy, Wouter M. Koolen, Alexey Chernov, Vladimir Vovk
- 17(24):1–42 **Learning Using Anti-Training with Sacrificial Data**
Michael L. Valenzuela, Jerzy W. Rozenblit
- 17(25):1–72 **A Unifying Framework in Vector-valued Reproducing Kernel Hilbert Spaces for Manifold Regularization and Co-Regularized Multi-view Learning**
Hà Quang Minh, Loris Bazzani, Vittorio Murino
- 17(26):1–41 **Quantifying Uncertainty in Random Forests via Confidence Intervals and Hypothesis Tests**
Lucas Mentch, Giles Hooker
- 17(27):1–57 **Statistical-Computational Tradeoffs in Planted Problems and Submatrix Localization with a Growing Number of Clusters and Submatrices**
Yudong Chen, Jiaming Xu

- 17(28):1–39 **Non-linear Causal Inference using Gaussianity Measures**
Daniel Hernández-Lobato, Pablo Morales-Mombiela, David Lopez-Paz, Alberto Suárez
- 17(29):1–54 **Consistent Distribution-Free K -Sample and Independence Tests for Univariate Random Variables**
Ruth Heller, Yair Heller, Shachar Kaufman, Barak Brill, Malka Gorfine
- 17(30):1–39 **A Gibbs Sampler for Learning DAGs**
Robert J. B. Goudie, Sach Mukherjee
- 17(31):1–32 **Dimension-free Concentration Bounds on Hankel Matrices for Spectral Learning**
Francois Denis, Mattias Gybels, Amaury Habrard
- 17(32):1–102 **Distinguishing Cause from Effect Using Observational Data: Methods and Benchmarks**
Joris M. Mooij, Jonas Peters, Dominik Janzing, Jakob Zscheischler, Bernhard Schölkopf
- 17(33):1–30 **Multi-task Sparse Structure Learning with Gaussian Copula Models**
André R. Goncalves, Fernando J. Von Zuben, Arindam Banerjee
- 17(34):1–7 **MLlib: Machine Learning in Apache Spark**
Xiangrui Meng, Joseph Bradley, Burak Yavuz, Evan Sparks, Shivaram Venkataraman, Davies Liu, Jeremy Freeman, DB Tsai, Manish Amde, Sean Owen, Doris Xin, Reynold Xin, Michael J. Franklin, Reza Zadeh, Matei Zaharia, Ameet Talwalkar
- 17(35):1–5 **OLPS: A Toolbox for On-Line Portfolio Selection**
Bin Li, Doyen Sahoo, Steven C.H. Hoi
- 17(36):1–39 **A Bounded p -norm Approximation of Max-Convolution for Sub-Quadratic Bayesian Inference on Additive Factors**
Julianus Pfeuffer, Oliver Serang
- 17(37):1–33 **Hybrid Orthogonal Projection and Estimation (HOPE): A New Framework to Learn Neural Networks**
Shiliang Zhang, Hui Jiang, Lirong Dai
- 17(38):1–15 **The Optimal Sample Complexity of PAC Learning**
Steve Hanneke
- 17(39):1–40 **End-to-End Training of Deep Visuomotor Policies**
Sergey Levine, Chelsea Finn, Trevor Darrell, Pieter Abbeel
- 17(40):1–45 **On Quantile Regression in Reproducing Kernel Hilbert Spaces with the Data Sparsity Constraint**
Chong Zhang, Yufeng Liu, Yichao Wu
- 17(41):1–6 **BayesPy: Variational Bayesian Inference in Python**
Jaakko Luttinen

- 17(42):1–62 **Variational Inference for Latent Variables and Uncertain Inputs in Gaussian Processes**
Andreas C. Damianou, Michalis K. Titsias, Neil D. Lawrence
- 17(43):1–28 **On the Estimation of the Gradient Lines of a Density and the Consistency of the Mean-Shift Algorithm**
Ery Arias-Castro, David Mason, Bruno Pelletier
- 17(44):1–35 **Scalable Learning of Bayesian Network Classifiers**
Ana M. Martínez, Geoffrey I. Webb, Shenglei Chen, Nayyar A. Zaidi
- 17(45):1–32 **A Unified View on Multi-class Support Vector Classification**
Ürün Doğan, Tobias Glasmachers, Christian Igel
- 17(46):1–31 **Addressing Environment Non-Stationarity by Repeating Q-learning Updates**
Sherief Abdallah, Michael Kaisers
- 17(47):1–43 **Large Scale Online Kernel Learning**
Jing Lu, Steven C.H. Hoi, Jialei Wang, Peilin Zhao, Zhi-Yong Liu
- 17(48):1–41 **Kernel Mean Shrinkage Estimators**
Krikamol Muandet, Bharath Sriperumbudur, Kenji Fukumizu, Arthur Gretton, Bernhard Schölkopf
- 17(49):1–49 **SPSD Matrix Approximation via Column Selection: Theories, Algorithms, and Extensions**
Shusen Wang, Luo Luo, Zhihua Zhang
- 17(50):1–33 **Combinatorial Multi-Armed Bandit and Its Extension to Probabilistically Triggered Arms**
Wei Chen, Yajun Wang, Yang Yuan, Qinshi Wang
- 17(51):1–42 **Differentially Private Data Releasing for Smooth Queries**
Ziteng Wang, Chi Jin, Kai Fan, Jiaqi Zhang, Junliang Huang, Yiqiao Zhong, Liwei Wang
- 17(52):1–21 **Subspace Learning with Partial Information**
Alon Gonen, Dan Rosenbaum, Yonina C. Eldar, Shai Shalev-Shwartz
- 17(53):1–38 **Iterative Hessian Sketch: Fast and Accurate Solution Approximation for Constrained Least-Squares**
Mert Pilanci, Martin J. Wainwright
- 17(54):1–23 **Estimating Causal Structure Using Conditional DAG Models**
Chris. J. Oates, Jim Q. Smith, Sach Mukherjee
- 17(55):1–46 **Adaptive Lasso and group-Lasso for functional Poisson regression**
Stéphane Ivanoff, Franck Picard, Vincent Rivoirard
- 17(56):1–53 **Causal Inference through a Witness Protection Program**
Ricardo Silva, Robin Evans

- 17(57):1–47 **Structure Discovery in Bayesian Networks by Sampling Partial Orders**
Teppo Niinimäki, Pekka Parviainen, Mikko Koivisto
- 17(58):1–47 **Estimation from Pairwise Comparisons: Sharp Minimax Bounds with Topology Dependence**
Nihar B. Shah, Sivaraman Balakrishnan, Joseph Bradley, Abhay Parekh, Kannan Ramchandran, Martin J. Wainwright
- 17(59):1–35 **Domain-Adversarial Training of Neural Networks**
Yaroslav Ganin, Evgeniya Ustinova, Hana Ajakan, Pascal Germain, Hugo Larochelle, François Laviolette, Mario Marchand, Victor Lempitsky
- 17(60):1–34 **Probabilistic Low-Rank Matrix Completion from Quantized Measurements**
Sonia A. Bhaskar
- 17(61):1–35 **DSA: Decentralized Double Stochastic Averaging Gradient Algorithm**
Aryan Mokhtari, Alejandro Ribeiro
- 17(62):1–29 **The Statistical Performance of Collaborative Inference**
Gérard Biau, Kevin Bleakley, Benoît Cadre
- 17(63):1–53 **Convergence of an Alternating Maximization Procedure**
Andreas Andreassen, Vladimir Spokoiny
- 17(64):1–5 **StructED: Risk Minimization in Structured Prediction**
Yossi Adi, Joseph Keshet
- 17(65):1–32 **Stereo Matching by Training a Convolutional Neural Network to Compare Image Patches**
Jure Žbontar, Yann LeCun
- 17(66):1–53 **Bayesian Policy Gradient and Actor-Critic Algorithms**
Mohammad Ghavamzadeh, Yaakov Engel, Michal Valko
- 17(67):1–70 **Practical Kernel-Based Reinforcement Learning**
André M.S. Barreto, Doina Precup, Joelle Pineau
- 17(68):1–30 **An Information-Theoretic Analysis of Thompson Sampling**
Daniel Russo, Benjamin Van Roy
- 17(69):1–26 **Compressed Gaussian Process for Manifold Regression**
Rajarshi Guhaniyogi, David B. Dunson
- 17(70):1–32 **On the Characterization of a Class of Fisher-Consistent Loss Functions and its Application to Boosting**
Matey Neykov, Jun S. Liu, Tianxi Cai
- 17(71):1–19 **Exact Inference on Gaussian Graphical Models of Arbitrary Topology using Path-Sums**
P.-L. Giscard, Z. Choo, S. J. Thwaite, D. Jaksch

- 17(72):1–54 **Challenges in multimodal gesture recognition**
Sergio Escalera, Vassilis Athitsos, Isabelle Guyon
- 17(73):1–29 **An Emphatic Approach to the Problem of Off-policy Temporal-Difference Learning**
Richard S. Sutton, A. Rupam Mahmood, Martha White
- 17(74):1–25 **Learning Algorithms for Second-Price Auctions with Reserve**
Mehryar Mohri, Andres Munoz Medina
- 17(75):1–25 **Distributed Coordinate Descent Method for Learning with Big Data**
Peter Richtárik, Martin Takáč
- 17(76):1–36 **Scaling-up Empirical Risk Minimization: Optimization of Incomplete U -statistics**
Stephan Cléménçon, Igor Colin, Aurélien Bellet
- 17(77):1–38 **Iterative Regularization for Learning with Convex Loss Functions**
Junhong Lin, Lorenzo Rosasco, Ding-Xuan Zhou
- 17(78):1–41 **Latent Space Inference of Internet-Scale Networks**
Qirong Ho, Junming Yin, Eric P. Xing
- 17(79):1–23 **Patient Risk Stratification with Time-Varying Parameters: A Multitask Learning Approach**
Jenna Wiens, John Guttag, Eric Horvitz
- 17(80):1–33 **Multiplicative Multitask Feature Learning**
Xin Wang, Jinbo Bi, Shipeng Yu, Jiangwen Sun, Minghu Song
- 17(81):1–32 **The Benefit of Multitask Representation Learning**
Andreas Maurer, Massimiliano Pontil, Bernardino Romera-Paredes
- 17(82):1–24 **Model-free Variable Selection in Reproducing Kernel Hilbert Space**
Lei Yang, Shaogao Lv, Junhui Wang
- 17(83):1–5 **CVXPY: A Python-Embedded Modeling Language for Convex Optimization**
Steven Diamond, Stephen Boyd
- 17(84):1–42 **Lenient Learning in Independent-Learner Stochastic Cooperative Games**
Ermo Wei, Sean Luke
- 17(85):1–15 **Structure-Leveraged Methods in Breast Cancer Risk Prediction**
Jun Fan, Yirong Wu, Ming Yuan, David Page, Jie Liu, Irene M. Ong, Peggy Peissig, Elizabeth Burnside

- 17(86):1–5 **LIBMF: A Library for Parallel Matrix Factorization in Shared-memory Systems**
Wei-Sheng Chin, Bo-Wen Yuan, Meng-Yuan Yang, Yong Zhuang, Yu-Chin Juan, Chih-Jen Lin
- 17(87):1–37 **L1-Regularized Least Squares for Support Recovery of High Dimensional Single Index Models with Gaussian Designs**
Matey Neykov, Jun S. Liu, Tianxi Cai
- 17(88):1–45 **Spectral Ranking using Seriation**
Fajwel Fogel, Alexandre d'Aspremont, Milan Vojnovic
- 17(89):1–34 **Sparsity and Error Analysis of Empirical Feature-Based Regularization Schemes**
Xin Guo, Jun Fan, Ding-Xuan Zhou
- 17(90):1–29 **Estimating Diffusion Networks: Recovery Conditions, Sample Complexity and Soft-thresholding Algorithm**
Manuel Gomez-Rodriguez, Le Song, Hadi Daneshmand, Bernhard Schölkopf
- 17(91):1–42 **Rounding-based Moves for Semi-Metric Labeling**
M. Pawan Kumar, Puneet K. Dokania
- 17(92):1–27 **Rate Optimal Denoising of Simultaneously Sparse and Low Rank Matrices**
Dan Yang, Zongming Ma, Andreas Buja
- 17(93):1–50 **Hierarchical Relative Entropy Policy Search**
Christian Daniel, Gerhard Neumann, Oliver Kroemer, Jan Peters
- 17(94):1–31 **Convex Regression with Interpretable Sharp Partitions**
Ashley Petersen, Noah Simon, Daniela Witten
- 17(95):1–5 **JCLAL: A Java Framework for Active Learning**
Oscar Reyes, Eduardo Pérez, María del Carmen Rodríguez-Hernández, Habib M. Fardoun, Sebastián Ventura
- 17(96):1–37 **Integrated Common Sense Learning and Planning in POMDPs**
Brendan Juba
- 17(97):1–37 **Cells in Multidimensional Recurrent Neural Networks**
Gundram Leifert, Tobias Strauß, Tobias Grüning, Welf Wustlich, Roger Labahn
- 17(98):1–37 **Learning Taxonomy Adaptation in Large-scale Classification**
Rohit Babbar, Ioannis Partalas, Eric Gaussier, Massih-Reza Amini, Cécile Amblard
- 17(99):1–61 **How to Center Deep Boltzmann Machines**
Jan Melchior, Asja Fischer, Laurenz Wiskott

- 17(100):1–35 **Control Function Instrumental Variable Estimation of Nonlinear Causal Effect Models**
Zijian Guo, Dylan S. Small
- 17(101):1–54 **Structure Learning in Bayesian Networks of a Moderate Size by Efficient Sampling**
Ru He, Jin Tian, Huaiqing Wu
- 17(102):1–44 **Spectral Methods Meet EM: A Provably Optimal Algorithm for Crowdsourcing**
Yuchen Zhang, Xi Chen, Dengyong Zhou, Michael I. Jordan
- 17(103):1–38 **Bayesian Leave-One-Out Cross-Validation Approximations for Gaussian Latent Variable Models**
Aki Vehtari, Tommi Mononen, Ville Tolvanen, Tuomas Sivula, Ole Winther
- 17(104):1–32 **e-PAL: An Active Learning Approach to the Multi-Objective Optimization Problem**
Marcela Zuluaga, Andreas Krause, Markus Püschel
- 17(105):1–41 **Trend Filtering on Graphs**
Yu-Xiang Wang, James Sharpnack, Alexander J. Smola, Ryan J. Tibshirani
- 17(106):1–37 **Multi-Task Learning for Straggler Avoiding Predictive Job Scheduling**
Neeraja J. Yadwadkar, Bharath Hariharan, Joseph E. Gonzalez, Randy Katz
- 17(107):1–31 **Interleaved Text/Image Deep Mining on a Large-Scale Radiology Database for Automated Image Interpretation**
Hoo-Chang Shin, Le Lu, Lauren Kim, Ari Seff, Jianhua Yao, Ronald M. Summers
- 17(108):1–30 **Distribution-Matching Embedding for Visual Domain Adaptation**
Mahsa Baktashmotlagh, Mehrtash Harandi, Mathieu Salzmann
- 17(109):1–47 **Monotonic Calibrated Interpolated Look-Up Tables**
Maya Gupta, Andrew Cotter, Jan Pfeifer, Konstantin Voevodski, Kevin Canini, Alexander Mangylov, Wojciech Moczydlowski, Alexander van Esbroeck
- 17(110):1–5 **Are Random Forests Truly the Best Classifiers?**
Michael Wainberg, Babak Alipanahi, Brendan J. Frey
- 17(111):1–43 **Minimax Adaptive Estimation of Nonparametric Hidden Markov Models**
Yohann De Castro, Élisabeth Gassiat, Claire Lacour

- 17(112):1–30 **Decrypting “Cryptogenic” Epilepsy: Semi-supervised Hierarchical Conditional Random Fields For Detecting Cortical Lesions In MRI-Negative Patients**
Bilal Ahmed, Thomas Thesen, Karen E. Blackmon, Ruben Kuzniecky, Orrin Devinsky, Carla E. Brodley
- 17(113):1–23 **Fused Lasso Approach in Regression Coefficients Clustering – Learning Parameter Heterogeneity in Data Integration**
Lu Tang, Peter X.K. Song
- 17(114):1–5 **The LRP Toolbox for Artificial Neural Networks**
Sebastian Lapuschkin, Alexander Binder, Grégoire Montavon, Klaus-Robert Müller, Wojciech Samek
- 17(115):1–21 **Equivalence of Graphical Lasso and Thresholding for Sparse Graphs**
Somayeh Sojoudi
- 17(116):1–13 **A Network That Learns Strassen Multiplication**
Veit Elser
- 17(117):1–65 **Revisiting the Nystrom Method for Improved Large-scale Machine Learning**
Alex Gittens, Michael W. Mahoney
- 17(118):1–20 **Improving Structure MCMC for Bayesian Networks through Markov Blanket Resampling**
Chengwei Su, Mark E. Borsuk
- 17(119):1–34 **Volumetric Spanners: An Efficient Exploration Basis for Learning**
Elad Hazan, Zohar Karnin
- 17(120):1–38 **Quasi-Monte Carlo Feature Maps for Shift-Invariant Kernels**
Haim Avron, Vikas Sindhwani, Jiyang Yang, Michael W. Mahoney

Part B

- 17(121):1–36 **Variational Dependent Multi-output Gaussian Process Dynamical Systems**
Jing Zhao, Shiliang Sun
- 17(122):1–35 **Multiple Output Regression with Latent Noise**
Jussi Gillberg, Pekka Marttinen, Matti Pirinen, Antti J. Kangas, Pasi Soinen, Mehreen Ali, Aki S. Havulinna, Marjo-Riitta Järvelin, Mika Ala-Korpela, Samuel Kaski
- 17(123):1–22 **The Constrained Dantzig Selector with Enhanced Consistency**
Yinfei Kong, Zemin Zheng, Jinchi Lv
- 17(124):1–29 **Bootstrap-Based Regularization for Low-Rank Matrix Estimation**
Julie Josse, Stefan Wager

- 17(125):1–47 **Bayesian Optimization for Likelihood-Free Inference of Simulator-Based Statistical Models**
Michael U. Gutmann, Jukka Corander

Abstract

This paper presents a dependent multi-output Gaussian process (GP) for modeling complex dynamical systems. The outputs are dependent in this model, which is largely different from previous GP dynamical systems. We adopt convolved multi-output GPs to model the outputs, which are provided with a flexible multi-output covariance function. We adapt the variational inference method with inducing points for learning the model. Conjugate gradient based optimization is used to solve parameters involved by maximizing the variational lower bound of the marginal likelihood. The proposed model has superiority on modeling dynamical systems under the more reasonable assumption and the fully Bayesian learning framework. Further, it can be flexibly extended to handle regression problems. We evaluate the model on both synthetic and real-world data including motion capture data, traffic flow data and robot inverse dynamics data. Various evaluation methods are taken on the experiments to demonstrate the effectiveness of our model, and encouraging results are observed.

Keywords: Gaussian process, variational inference, dynamical system, multi-output modeling

1. Introduction

Dynamical systems are widespread in the research area of machine learning. Multi-output time series such as motion capture data, traffic flow data and video sequences are typical examples generated from these systems. Data generated from these dynamical systems usually have the following characteristics. 1) Implicit dynamics exist in the data, and the relationship between the observations and the time indices is nonlinear. For example, the transformation of the frames of a video over time is complex. 2) Possible dependency exists among multiple outputs. For example, for motion capture data, the position of the hand is often closely related to the position of the arm. A simple and straightforward method to model this kind of dynamical systems is to use Gaussian processes (GPs), since GPs provide an elegant method for modeling nonlinear mappings in the Bayesian nonparametric learning framework (Rasmussen and Williams, 2006). Some extensions of GPs have been developed in recent years to better model the dynamical systems. The dynamical systems

modeled by GPs are called the Gaussian process dynamical systems (GPDSs). However, the existing GPDSs have a limitation of ignoring the dependency among the multiple outputs, that is, they may not make full use of the characteristics of data. Our work aims to model the complex dynamical systems more reasonably and flexibly.

Gaussian process dynamical models (GPDMS) as extensions of the GP latent variable model (GP-LVM) (Lawrence, 2004, 2005) were proposed to model human motion (Wang et al., 2006, 2008). The GP-LVM is a nonlinear extension of the probabilistic principal component analysis (Tipping and Bishop, 1999) and is a probabilistic model where the outputs are observed while the inputs are hidden. It introduces latent variables and performs a nonlinear mapping from the latent space to the observation space. The GP-LVM provides an unsupervised non-linear dimensionality reduction method by optimizing the latent variables with the maximum a posteriori (MAP) solution. The GPDM allows to model nonlinear dynamical systems by adding a Markov dynamical prior on the latent space in the GP-LVM. It captures the variability of outputs by constructing the variance of outputs with different parameters. Some research of adapting GPDMs to specific applications was developed, such as object tracking (Urtasun et al., 2006), activity recognition (Gamage et al., 2011) and synthesis, and computer animation (Henter et al., 2012).

Similarly, Damianou et al. (2011, 2014) extended the GP-LVM by imposing a dynamical prior on the latent space to the variational GP dynamical system (VGPDS). The nonlinear mapping from the latent space to the observation space in the VGPDS allows the model to capture the structures and characteristics of data in a relatively low dimensional space. Instead of seeking a MAP solution for the latent variables as in GPDMs, VGPDSs used a variational method for model training. This follows the variational Bayesian method for training the GP-LVM (Titsias and Lawrence, 2010), in which a lower bound of the logarithmic marginal likelihood is computed by variationally integrating out the latent variables that appear nonlinearly in the inverse kernel matrix of the model. The variational Bayesian method was built on the method of variational inference with inducing points (Titsias, 2009). The VGPDS approximately marginalizes out the latent variables and leads to a rigorous lower bound on the logarithmic marginal likelihood. The model and variational parameters of the VGPDS can be learned through maximizing the variational lower bound. This variational method with inducing points was also employed to integrate out the warping functions in the warped GP (Snelson et al., 2003; Lázaro-gredilla, 2012). Park et al. (2012) developed an almost direct application of VGPDSs to phoneme classification, in which a variance constraint in the VGPDS was introduced to eliminate the sparse approximation error in the kernel matrix. Besides variational approaches, expectation propagation based methods (Deisenroth and Mohamed, 2012) are also capable of conducting approximate inference in GPDSs.

However, all the models mentioned above for GPDSs ignore the dependency among multiple outputs, which usually assume that the outputs are conditionally independent. Actually, modeling the dependency among outputs is necessary in many applications such as sensor networks, geostatistics and time-series forecasting, which helps to make better predictions (Boyle, 2007). Indeed, there are some recent works that explicitly considered the dependency of multiple outputs in GPs (Álvarez et al., 2009; Álvarez and Lawrence, 2011; Wilson et al., 2012). Latent force models (LFMs) (Álvarez et al., 2009) are a recent state-of-the-art modeling framework, which can model multi-output dependencies. Later, a

*. The authors contributed equally to this work.

series of extensions of LFMs were presented such as linear, nonlinear, cascaded and switching dynamical LFMs (Álvarez et al., 2011, 2013). In addition, sequential inference methods for LFMs have also been developed (Hartikainen and Särkkä, 2012). Álvarez and Lawrence (2011) employed convolution processes to account for the correlations among outputs to construct a convolved multiple outputs GP (CMOGP) which can be regarded as a specific case of LFMs. To overcome the difficulty of time and storage complexities for large data sets, some efficient approximations for the CMOGP were constructed through the convolution formalism (Álvarez et al., 2010; Álvarez and Lawrence, 2011). This leads to a form of covariance similar in spirit to the so called deterministic training conditional (DTC) approximation (Csató and Oppner, 2001), fully independent training conditional (FITC) approximation (Quinero-Candela and Rasmussen, 2005; Snelson and Ghahramani, 2006) and partially independent training conditional (PITC) approximation (Quinero-Candela and Rasmussen, 2005) for a single output (Lawrence, 2007). The CMOGP is then enhanced and extended to the collaborative multi-output Gaussian process (COGP) for handling large scale cases (Nguyen and Bonilla, 2014). Besides CMOGPs, Wilson et al. (2012) combined neural networks with GPs to construct a GP regression network (GPRN). Outputs in the GPRN are linear combinations of the shared adaptive latent basis functions with input dependent weights. However, these two models are neither introduced nor directly suitable for complex dynamical system modeling. When a dynamical prior is imposed, marginalizing over the latent variables is needed, which can be very challenging.

In this paper, we propose a variational dependent multi-output GP dynamical system (VDM-GPDS). It is a hierarchical Gaussian process model in which the dependency among all the observations is well captured. Specifically, the convolved process covariance function (Álvarez and Lawrence, 2011) is employed to capture the dependency among all the data points across all the outputs. To learn the VDM-GPDS, we first approximate the latent functions in the convolution processes, and then variationally marginalize out the latent variables in the model. This leads to a convenient lower bound of the logarithmic marginal likelihood, which is then maximized by the scaled conjugate gradient method to find out the optimal parameters.

The highlights of this paper are summarized as follows. 1) We explicitly take the dependency among multiple outputs into consideration while other methods (Damiannou et al., 2011; Park et al., 2012) for GPDS modeling assume that the outputs are conditionally independent. In particular, the convolved process covariance functions are used to construct the covariance matrix of the outputs. 2) We use the variational method to compute a lower bound of the logarithmic marginal likelihood of the GPDS model. Compared to Damiannou et al. (2011), our model is more reasonable in specific practical settings, and more challenging as a result of involving complex formulations and computations. 3) Our model can be seen as a multi-layer regression model which regards time indices as inputs and observations as outputs. It can be flexibly extended to handle regression problems. Compared with other dependent multi-output models such as the CMOGP, the VDM-GPDS can achieve much better performance attributed to its latent layers. 4) Our model is applicable to general dependent multi-output dynamical systems and multi-output regression tasks, rather than being specially tailored to a particular application. In this paper, we adapt the model to different applications and obtain promising results.

An earlier short version of this work appeared in Zhao and Sun (2014). In this paper, we add detailed derivations of the variational inference and provide the gradients of the objective function with respect to the parameters. Moreover, we analyze the performance and efficiency of the proposed model. In addition, we supplement experiments on real-world data and all the experimental results are measured under various evaluation criteria.

The rest of the paper is organized as follows. First, we give the model for nonlinear dynamical systems in Section 2, where we use convolution process covariance functions to construct the covariance matrix of the dependent multi-output latent variables. Section 3 gives the derivation of the variational lower bound of the marginal likelihood function and optimization methods. Prediction formulations are introduced in Section 4. Related work is analyzed and compared in Section 5. Experimental results are reported in Section 6 and finally conclusions are presented in Section 7.

2. The Proposed Model

Suppose we have multi-output time series data $\{Y_n, t_n\}_{n=1}^N$, where $Y_n \in \mathbb{R}^D$ is an observation at time $t_n \in \mathbb{R}^+$. We assume that there are low dimensional latent variables that govern the generation of the observations and a GP prior for the latent variables conditional on time captures the dynamical driving force of the observations, as in Damiannou et al. (2011). However, a large difference compared with their work is that we explicitly model the dependency among the outputs through convolution processes (Álvarez and Lawrence, 2011).

Our model is a four-layer GP dynamical system. Here $\mathbf{t} \in \mathbb{R}^N$ represents the input variables in the first layer. The matrix $X \in \mathbb{R}^{N \times Q}$ represents the low dimensional latent variables in the second layer with element $x_{nq} = x_q(t_n)$. Similarly, the matrix $F \in \mathbb{R}^{N \times D}$ denotes the latent variables in the third layer, with element $f_{nd} = f_d(\mathbf{x}_n)$ and the matrix $Y \in \mathbb{R}^{N \times D}$ denotes the observations in the fourth layer whose n th row corresponds to Y_n . The model is composed of an independent multi-output GP mapping from \mathbf{t} to X , a dependent multi-output GP mapping from X to F , and a linear mapping from F to Y .

Specifically, for the first mapping, \mathbf{x} is assumed to be a multi-output GP indexed by time t similarly to Damiannou et al. (2011), that is

$$x_q(t) \sim GP(0, \kappa_x(t, t')), \quad q = 1, \dots, Q, \quad (1)$$

where individual components of the latent function $\mathbf{x}(t)$ are independent sample paths drawn from a GP with a certain covariance function $\kappa_x(t, t')$ parameterized by θ_x . There are several commonly used covariance functions such as the squared exponential covariance function (RBF), the Matérn $3/2$ function and the periodic covariance function (RBFperiodic), which can be adopted to model the time evolution of sequences. For example, an RBF or a Matérn $3/2$ function is usually appropriate for a long time dependent sequence, which will lead to a full covariance matrix. For modeling the evolution of multiple independent sequences, a block-diagonal covariance matrix should be chosen, where each block can be constructed by an RBF or a Matérn $3/2$ function. RBFperiodic is useful to capture the periodicity of the sequences, and multiple kernels can be used to model different time cycles. These kernel

functions take the following forms.

$$\begin{aligned} \kappa_x(RBF)(t_i, t_j) &= \sigma_{rbf}^2 \frac{(t_i - t_j)^2}{2t^2}, \\ \kappa_x(\text{Matérn3/2})(t_i, t_j) &= \sigma_{mat}^2 \left(1 + \frac{\sqrt{3}|t_i - t_j|}{\ell}\right) e^{-\frac{\sqrt{3}|t_i - t_j|}{\ell}}, \\ \kappa_x(\text{RBFperiodic})(t_i, t_j) &= \sigma_{per}^2 \frac{1 - \sin^2(\frac{2\pi}{\ell}(t_i - t_j))}{\ell}. \end{aligned} \quad (2)$$

According to the conditional independency assumption among the latent variables $\{\mathbf{x}_q\}_{q=1}^Q$, we have

$$p(\mathbf{X}|\mathbf{t}) = \prod_{q=1}^Q p(\mathbf{x}_q|\mathbf{t}) = \prod_{q=1}^Q \mathcal{N}(\mathbf{x}_q|\mathbf{0}, \mathbf{K}_{\mathbf{t},\mathbf{t}}), \quad (3)$$

where $\mathbf{K}_{\mathbf{t},\mathbf{t}}$ is the covariance matrix constructed by $\kappa_x(\mathbf{t}, \mathbf{t}')$.

For the second mapping, we assume that \mathbf{f} is another multi-output GP indexed by \mathbf{x} , whose outputs are dependent, that is

$$f_d(\mathbf{x}) \sim \mathcal{GP}(0, \kappa_{f_d, f_{d'}}(\mathbf{x}, \mathbf{x}')), \quad d, d' = 1, \dots, D, \quad (4)$$

where $\kappa_{f_d, f_{d'}}(\mathbf{x}, \mathbf{x}')$ is a convolved process covariance function. The convolved process covariance function captures the dependency among all the data points across all the outputs with parameters $\boldsymbol{\theta}_f = \{\{\Lambda_k\}, \{P_d\}, \{S_{d,k}\}\}$. The detailed formulation of this covariance function will be given in Section 2.1. From the conditional dependency among the latent variables $\{f_{nd}\}_{n=1, d=1}^{N, D}$, we have

$$p(F|X) = p(\mathbf{f}|X) = \mathcal{N}(\mathbf{f}|\mathbf{0}, \mathbf{K}_{\mathbf{f},\mathbf{f}}), \quad (5)$$

where \mathbf{f} is a shorthand for $[\mathbf{f}_1^\top, \dots, \mathbf{f}_D^\top]^\top$ and $\mathbf{K}_{\mathbf{f},\mathbf{f}}$ sized $ND \times ND$ is the covariance matrix in which the elements are calculated by the covariance function $\kappa_{f_d, f_{d'}}(\mathbf{x}, \mathbf{x}')$.

The third mapping, which is from the latent variable f_{nd} to the observation y_{nd} , can be written as

$$y_{nd} = f_{nd} + \epsilon_{nd}, \quad \epsilon_{nd} \sim \mathcal{N}(0, \beta^{-1}). \quad (6)$$

Since the observations $\{y_{nd}\}_{n=1, d=1}^{N, D}$ are conditionally independent on F , we get

$$p(Y|F) = \prod_{d=1}^D \prod_{n=1}^N \mathcal{N}(y_{nd}|f_{nd}, \beta^{-1}). \quad (7)$$

Given the above setting, the graphical model for the proposed VDM-GPDS on the training data $\{\mathbf{y}_n, t_n\}_{n=1}^N$ can be depicted as Figure 1. From (3), (5) and (7), the joint probability distribution for the VDM-GPDS model is given by

$$p(\mathbf{Y}, F, X|\mathbf{t}) = p(\mathbf{Y}|F)p(F|X)p(X|\mathbf{t}) = p(\mathbf{f}|X) \prod_{d=1}^D \prod_{n=1}^N p(y_{nd}|f_{nd}) \prod_{q=1}^Q p(\mathbf{x}_q|\mathbf{t}). \quad (8)$$

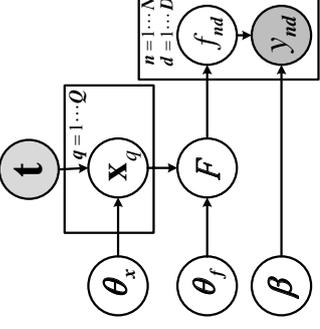

Figure 1: The graphical model for VDM-GPDS.

2.1 Convolved Process Covariance Function

Since the outputs in our model are dependent, we need to capture the correlations among all the data points across all the outputs. Bonilla et al. (2007) and Luttinen and Ilin (2012) used a Kronecker product covariance matrix with the form of $K_{FF} = K_{DD} \otimes K_{NN}$, where K_{DD} is the covariance matrix among the output dimensions, and K_{NN} is the covariance matrix calculated solely from the data inputs. This Kronecker form kernel is constructed from the processes which involve some form of instantaneous mixing of a series of independent processes. This is very limited and actually a special case of some general covariances when covariances calculated from outputs and inputs are independent (Álvarez et al., 2012). For example, if we want to model two output processes in such a way that one process was a blurred version of the other, we cannot achieve this through the instantaneous mixing (Álvarez and Lawrence, 2011). In this paper, we use a more general and flexible kernel in which K_{DD} and K_{NN} are not separated. In particular, the convolution processes (Álvarez and Lawrence, 2011) are employed to model the latent function $F(X)$.

Now we introduce how to construct the convolved process covariance functions. By using independent latent functions $\{u_k(\mathbf{x})\}_{k=1}^K$ and smoothing kernels $\{G_{d,k}(\mathbf{x})\}_{d=1, k=1}^{D, K}$ in the convolution processes, each latent function in (4) in the VDM-GPDS is expressed through a convolution integral,

$$f_d(\mathbf{x}) = \sum_{k=1}^K \int_{\mathbf{X}} G_{d,k}(\mathbf{x} - \tilde{\mathbf{x}}) u_k(\tilde{\mathbf{x}}) d\tilde{\mathbf{x}}. \quad (9)$$

The most common construction is to use Gaussian forms for $\{u_k(\mathbf{x})\}_{k=1}^K$ and $\{G_{d,k}(\mathbf{x})\}_{d=1, k=1}^{D, K}$. So the smoothing kernel is assumed to be

$$\tilde{G}_{d,k}(\mathbf{x}) = S_{d,k} \mathcal{N}(\mathbf{x}|\mathbf{0}, P_d), \quad (10)$$

where $S_{d,k}$ is a scalar value that depends on the output index d and the latent function index k , and P_d is assumed to be diagonal. The latent process $u_k(\mathbf{x})$ is assumed to be

Gaussian with covariance function

$$\kappa_k(\mathbf{x}, \mathbf{x}') = \mathcal{N}(\mathbf{x} - \mathbf{x}' | \mathbf{0}, \Lambda_k). \quad (11)$$

Thus, the covariance between $f_d(\tilde{\mathbf{x}})$ and $f_{d'}(\mathbf{x}')$ is

$$\kappa_{f_d, f_{d'}}(\mathbf{x}, \mathbf{x}') = \sum_{k=1}^K S_{d, k} S_{d', k} \mathcal{N}(\mathbf{x} | \mathbf{x}', P_d + P_{d'} + \Lambda_k). \quad (12)$$

The covariance between $f_d(\mathbf{x})$ and $u_k(\mathbf{x}')$ is

$$\kappa_{f_d, u_k}(\mathbf{x}, \mathbf{x}') = S_{d, k} \mathcal{N}(\mathbf{x} - \mathbf{x}' | \mathbf{0}, P_d + \Lambda_k). \quad (13)$$

These covariance functions (11), (12) and (13) will later be used for approximate inference in Section 3. Compared with Kronecker form kernels, our used convolved kernels have the following advantages. From the perspective of constructing the process f_d , convolved kernels are constructed using the convolution process f_d in which the smoothing kernels $G_{d, k}(\mathbf{x})$ related to \mathbf{x} are employed while Kronecker form kernels are constructed using $f_d(x) = \mathbf{a}_d \mathbf{u}_k(\mathbf{x})$ in which \mathbf{a}_d has no relation to \mathbf{x} (Álvarez and Lawrence, 2011). From the perspective of kernels, for different dimensions d and d' , convolved kernels allow that the covariances $\{\kappa_{f_d, f_{d'}}(\mathbf{x}, \mathbf{x}')\}$ are related to different terms $\mathcal{N}(\mathbf{x} | \mathbf{x}', P_d + P_{d'} + \Lambda_k)$ while Kronecker form kernels indicate that different covariances $\{\kappa_{f_d, f_{d'}}(\mathbf{x}, \mathbf{x}')\}$ share the same term $\kappa_k(\mathbf{x}, \mathbf{x}')$. Thus, our used convolved kernels are more general.

3. Inference and Optimization

As described above, the proposed VDM-GPPDS explicitly models the dependency among multiple outputs, which makes it largely distinct to the previous VGPDS and other GP dynamical systems. In order to make it easy to implement by extending the existing framework of the VGPDS, in the current and the following sections, we will deduce the variational lower bound for the logarithmic marginal likelihood and the posterior distribution for prediction in a formulation similar to the VGPDS. However, many details as described in the paper are specific to our model, and some calculations are more involved.

The fully Bayesian learning for our model requires maximizing the logarithm of the marginal likelihood (Bishop, 2006)

$$p(Y|\mathbf{t}) = \int p(Y|F)p(F|X)p(X|\mathbf{t})dXdF. \quad (14)$$

Note that the integration w.r.t X is intractable, because X appears nonlinearly in the inverse of the matrix $\mathbf{K}_F F$. We attempt to make some approximations for (14).

To begin with, we approximate $p(F|X)$ which is constructed by convolution process $f_d(\mathbf{x})$ in (9). Similarly to Álvarez and Lawrence (2011), a generative approach is used to approximate $f_d(\mathbf{x})$ as follows. We first draw a sample, $\mathbf{u}_k(Z) = [u_k(\mathbf{z}_1), \dots, u_k(\mathbf{z}_M)]^\top$, where $Z = \{\mathbf{z}_m\}_{m=1}^M$ are introduced as a set of input vectors for $u_k(\tilde{\mathbf{x}})$ and will be learned as parameters. We next sample $u_k(\tilde{\mathbf{x}})$ from the conditional prior $p(u_k(\tilde{\mathbf{x}})|\mathbf{u}_k)$. According to the above generating process, $u_k(\tilde{\mathbf{x}})$ in (9) can be approximated by the expectation

$\mathcal{E}(u_k(\tilde{\mathbf{x}})|\mathbf{u}_k)$. Let $U = \{\mathbf{u}_k\}_{k=1}^K$ and $\mathbf{u} = [\mathbf{u}_1^\top, \dots, \mathbf{u}_K^\top]^\top$. The probability distribution of \mathbf{u} can be expressed as

$$p(\mathbf{u}|Z) = \mathcal{N}(\mathbf{0}, \mathbf{K}_{\mathbf{u}, \mathbf{u}}), \quad (15)$$

where $\mathbf{K}_{\mathbf{u}, \mathbf{u}}$ is constructed by $\kappa_k(\mathbf{x}, \mathbf{x}')$ in (11). Combining (9) and (15), we get the probability distribution of \mathbf{f} conditional on \mathbf{u}, X, Z as

$$p(\mathbf{f}|\mathbf{u}, X, Z) = \mathcal{N}(\mathbf{f} | \mathbf{K}_F \mathbf{u}, \mathbf{K}_{\mathbf{u}, \mathbf{u}}^{-1} \mathbf{u}, \mathbf{K}_F F - \mathbf{K}_F \mathbf{u}, \mathbf{K}_{\mathbf{u}, \mathbf{u}}^{-1} \mathbf{K}_F F), \quad (16)$$

where $\mathbf{K}_F \mathbf{u}$ is the cross-covariance matrix between $f_d(\mathbf{x})$ and $u_k(\mathbf{z})$ with element $\kappa_{f_d, u_k}(\mathbf{x}, \mathbf{x}')$ in (13), the block-diagonal matrix $\mathbf{K}_{\mathbf{u}, \mathbf{u}}$ is the covariance matrix between $u_k(\mathbf{z})$ and $u_k(\mathbf{z}')$ with element $\kappa_k(\mathbf{x}, \mathbf{x}')$ in (11), and $\mathbf{K}_F F$ is the covariance matrix between $f_d(\mathbf{x})$ and $f_{d'}(\mathbf{x}')$ with element $\kappa_{f_d, f_{d'}}(\mathbf{x}, \mathbf{x}')$ in (12). Therefore, $p(F|X)$ is approximated by

$$p(F|X) \approx p(\mathbf{f}|\mathbf{u}, X, Z) = \int p(\mathbf{f}|\mathbf{u}, X, Z)p(\mathbf{u}|Z)d\mathbf{u}, \quad (17)$$

and $p(Y|\mathbf{t})$ is converted to

$$p(Y|\mathbf{t}) \approx p(Y|\mathbf{t}, Z) = \int p(Y|\mathbf{f})p(\mathbf{f}|\mathbf{u}, X, Z)p(\mathbf{u}|Z)p(X|\mathbf{t})dFdUdX, \quad (18)$$

where $p(\mathbf{u}|Z) = \mathcal{N}(\mathbf{0}, \mathbf{K}_{\mathbf{u}, \mathbf{u}})$ and $\mathbf{y} = [\mathbf{y}_1^\top, \dots, \mathbf{y}_D^\top]^\top$. It is worth noting that the marginal likelihood in (18) is still intractable as the integration with respect to X remains difficult.

Then, we introduce a lower bound of the logarithmic marginal likelihood $\log p(Y|\mathbf{t})$ using variational methods. We construct a variational distribution $q(F, U, X|Z)$ to approximate the posterior distribution $p(F, U, X|Y, \mathbf{t})$ and compute the Jensen's lower bound on $\log p(Y|\mathbf{t})$ as

$$\mathcal{L} = \int q(F, U, X|Z) \log \frac{p(Y, F, U, X|\mathbf{t}, Z)}{q(F, U, X|Z)} dXdUdF. \quad (19)$$

The variational distribution is assumed to be factorized as

$$q(F, U, X|Z) = p(\mathbf{f}|\mathbf{u}, X, Z)q(\mathbf{u}|Z)q(X). \quad (20)$$

The distribution $p(\mathbf{f}|\mathbf{u}, X, Z)$ in (20) is the same as the second term in (18), which will be eliminated in the term $\log \frac{p(Y, F, U, X|\mathbf{t}, Z)}{q(F, U, X|Z)}$ in (19). The distribution $q(\mathbf{u})$ is an approximation to the posterior distribution $p(\mathbf{u}|\mathbf{u}, X, Y)$, which is arguably Gaussian by maximizing the variational lower bound (Titsias and Lawrence, 2010; Damaniou et al., 2011). The distribution $q(X)$ is an approximation to the posterior distribution $p(X|Y)$, which is assumed to be a product of independent Gaussian distributions $q(X) = \prod_{q=1}^Q \mathcal{N}(\mathbf{x}_q | \boldsymbol{\mu}_q, S_0)$.

After some calculations and simplifications, the lower bound with X, U and F integrated out becomes

$$\begin{aligned} \mathcal{L} = & \log \left[\frac{\beta^{\frac{ND}{2}} |\mathbf{K}_{\mathbf{u}, \mathbf{u}}|^{-\frac{1}{2}}}{(2\pi)^{\frac{ND}{2}} |\beta\psi_2 + \mathbf{K}_{\mathbf{u}, \mathbf{u}}|^{-\frac{1}{2}}} \exp\left\{-\frac{1}{2} \mathbf{y}^\top W \mathbf{y}\right\} \right] \\ & - \frac{\beta\psi_0}{2} + \frac{\beta}{2} \text{Tr}(\mathbf{K}_{\mathbf{u}, \mathbf{u}}^{-1} \psi_2) - \mathbf{KL}[q(X) \| p(X|\mathbf{t})], \end{aligned} \quad (21)$$

where $W = \beta I - \beta^2 \psi_1 (\beta \psi_2 + \mathbf{K}_{u,u})^{-1} \psi_1^\top$, $\psi_0 = \text{Tr}(\mathbf{K}_{f,f} q(X))$, $\psi_1 = (\mathbf{K}_{f,u})_{q(X)}$ and $\psi_2 = (\mathbf{K}_{u,f} \mathbf{K}_{f,u})_{q(X)}$. $\mathbf{KL}[q(X) \| p(X|\mathbf{t})]$ defined by $\int q(X) \log \frac{q(X)}{p(X|\mathbf{t})} dX$ is expressed as

$$\begin{aligned} \mathbf{KL}[q(X) \| p(X|\mathbf{t})] &= \frac{Q}{2} \log |\mathbf{K}_{t,t}| - \frac{1}{2} \sum_{q=1}^Q \log |S_q| \\ &\quad + \frac{1}{2} \sum_{q=1}^Q [\text{Tr}(\mathbf{K}_{t,t}^{-1} S_q) + \text{Tr}(\mathbf{K}_{t,t}^{-1} \boldsymbol{\mu}_q \boldsymbol{\mu}_q^\top)] + \text{const}. \end{aligned} \quad (22)$$

The detailed derivation of this variational lower bound is described in Appendix A where \mathcal{L} is expressed as $\mathcal{L} = \hat{\mathcal{L}} - \mathbf{KL}[q(X) \| p(X|\mathbf{t})]$.

Note that although the lower bound in (21) and the one in VGPPDS (Damianou et al., 2011) look similar, they are essentially distinct and have different meanings. In particular, the variables U in this paper are the samples of the latent functions $\{u_k(\mathbf{x})\}_{k=1}^K$ in the convolution process while in VGPPDS they are samples of the latent variables F . Moreover, the covariance functions of F involved in this paper are multi-output covariance functions while VGPPDS adopts single-output covariance functions. As a result, our model is more flexible and challenging. For example, the calculation of statistics of ψ_0 , ψ_1 and ψ_2 is more complex, as well as the derivatives of the parameters.

3.1 Computation of ψ_0 , ψ_1 , ψ_2

Recall that the lower bound in (21) requires computing the statistics $\{\psi_0, \psi_1, \psi_2\}$. We now detail how to calculate them. ψ_0 is a scalar that can be calculated as

$$\begin{aligned} \psi_0 &= \sum_{n=1}^N \sum_{d=1}^D \sum_{k=1}^K \kappa_{f_d, f_d}(\mathbf{x}_n, \mathbf{x}_n) \mathcal{N}(\mathbf{x}_n | \boldsymbol{\mu}_n, S_n) d\mathbf{x}_n \\ &= \sum_{d=1}^D \sum_{k=1}^K \frac{N S_{d,k} S_{dk}}{(2\pi)^{\frac{D}{2}} |2P_d + \Lambda_k|^{\frac{1}{2}}}. \end{aligned} \quad (23)$$

ψ_1 is a $V \times W$ matrix whose elements are calculated as¹

$$\begin{aligned} (\psi_1)_{v,w} &= \int \kappa_{f_d, u_k}(\mathbf{x}_n, \mathbf{z}_m) \mathcal{N}(\mathbf{x}_n | \boldsymbol{\mu}_n, S_n) d\mathbf{x}_n \\ &= S_{d,k} \mathcal{N}(\mathbf{z}_m | \boldsymbol{\mu}_n, P_d + \Lambda_k + S_n), \end{aligned} \quad (24)$$

where $V = N \times D$, $W = M \times K$, $d = \lfloor \frac{v-1}{N} \rfloor + 1$, $n = v - (d-1)N$, $k = \lfloor \frac{w-1}{M} \rfloor + 1$ and $m = w - (k-1)M$. Here the symbol “ $\lfloor \cdot \rfloor$ ” means rounding down. ψ_2 is a $W \times W$ matrix whose elements are calculated as

$$\begin{aligned} (\psi_2)_{w,w'} &= \sum_{d=1}^D \sum_{n=1}^N \sum_{n'=1}^N \int \kappa_{f_d, u_k}(\mathbf{x}_n, \mathbf{z}_m) \kappa_{f_d, u_{k'}}(\mathbf{x}_n, \mathbf{z}_{m'}) \mathcal{N}(\mathbf{x}_n | \boldsymbol{\mu}_n, S_n) d\mathbf{x}_n \\ &= \sum_{d=1}^D \sum_{n=1}^N \sum_{n'=1}^N S_{d,k} S_{d,k'} \mathcal{N}(\mathbf{z}_m | \mathbf{z}_{m'}, 2P_d + \Lambda_k + \Lambda_{k'}) \mathcal{N}\left(\frac{\mathbf{z}_m + \mathbf{z}_{m'}}{2} | \boldsymbol{\mu}_n, \Sigma_{\psi_2}\right), \end{aligned} \quad (25)$$

1. We borrow the density formulations to express ψ_1 as well as ψ_2 .

where $k = \lfloor \frac{w'-1}{M} \rfloor + 1$, $m = w - (k-1)M$, $k' = \lfloor \frac{w'-1}{M} \rfloor + 1$, $m' = w' - (k'-1)M$ and $\Sigma_{\psi_2} = (P_d + \Lambda_k)^{-1} (2P_d + \Lambda_k + \Lambda_{k'})^{-1} (P_d + \Lambda_{k'}) + S_n$.

3.2 Conjugate Gradient Based Optimization

The parameters involved in (21) include the model parameters $\{\beta, \boldsymbol{\theta}_x, \boldsymbol{\theta}_f\}$ and the variational parameters $\{\{\boldsymbol{\mu}_q, S_q\}_{q=1}^Q, Z\}$. In order to reduce the variational parameters to be optimized and speed up convergence, we reparameterize the variational parameters $\boldsymbol{\mu}_q$ and S_q to $\bar{\boldsymbol{\mu}}_q$ and $\boldsymbol{\lambda}_q$ as done in Oppor and Archambeau (2009) and Damianou et al. (2011)

$$\boldsymbol{\mu}_q = \mathbf{K}_{t,t} \bar{\boldsymbol{\mu}}_q, \quad (26)$$

$$S_q = \left(\mathbf{K}_{t,t}^{-1} + \text{diag}(\boldsymbol{\lambda}_q) \right)^{-1}, \quad (27)$$

where $\text{diag}(\boldsymbol{\lambda}_q) = -2 \frac{\partial \hat{\mathcal{L}}}{\partial S_q}$ is an $N \times N$ diagonal, positive matrix whose N -dimensional diagonal is denoted by $\boldsymbol{\lambda}_q$, and $\bar{\boldsymbol{\mu}}_q = \frac{\partial \hat{\mathcal{L}}}{\partial \boldsymbol{\mu}_q}$ is an N -dimensional vector. Now the variational parameters to be optimized are $\{\{\bar{\boldsymbol{\mu}}_q, \boldsymbol{\lambda}_q\}_{q=1}^Q, Z\}$. Then the derivatives of the lower bound \mathcal{L} with respect to the variational parameters $\bar{\boldsymbol{\mu}}_q$ and $\boldsymbol{\lambda}_q$ become

$$\frac{\partial \mathcal{L}}{\partial \bar{\boldsymbol{\mu}}_q} = \mathbf{K}_{t,t} \left(\frac{\partial \hat{\mathcal{L}}}{\partial \boldsymbol{\mu}_q} - \bar{\boldsymbol{\mu}}_q \right), \quad (28)$$

$$\frac{\partial \mathcal{L}}{\partial \boldsymbol{\lambda}_q} = -(S_q \circ S_q) \left(\frac{\partial \hat{\mathcal{L}}}{\partial S_q} + \frac{1}{2} \boldsymbol{\lambda}_q \right). \quad (29)$$

All the parameters are jointly optimized by the scaled conjugate gradient method to maximize the lower bound in (21). The detailed gradients with respect to the parameters are given in Appendix B.

4. Prediction

The proposed model can perform prediction for complex dynamical systems in two situations. One is prediction with only time and the other is prediction with time and partial observations. In addition, it can be adapted to regression models.

4.1 Prediction with Only Time

If the model is learned with training data Y , one can predict new outputs with only given time. In the Bayesian framework, we need to compute the posterior distribution of the predicted outputs $Y_* \in \mathbb{R}^{N_* \times D}$ on some given time instants $\mathbf{t}_* \in \mathbb{R}^{N_*}$. The expectation is used as the estimate and the autocovariance is used to show the prediction uncertainty. With the parameters as well as time \mathbf{t} and \mathbf{t}_* omitted, the posterior density is given by

$$p(Y_* | Y) = \int p(Y_* | F_*) p(F_* | X_*, Y) p(X_* | Y) dF_* dX_*, \quad (30)$$

where $F_* \in \mathbb{R}^{N_* \times D}$ denotes the set of latent variables (the noise-free version of Y_*) and $X_* \in \mathbb{R}^{N_* \times Q}$ represents the latent variables in the low dimensional space.

The distribution $p(F_*|X_*, Y)$ is approximated by the variational distribution

$$p(F_*|X_*, Y) \approx q(\mathbf{f}_*|X_*) = \int p(\mathbf{f}_*|\mathbf{u}, X_*)q(\mathbf{u})d\mathbf{u}, \quad (31)$$

where $\mathbf{f}_*^\top = [\mathbf{f}_{*1}^\top, \dots, \mathbf{f}_{*D}^\top]$, and $p(\mathbf{f}_*|\mathbf{u}, X_*)$ is Gaussian. Since the optimal setting for $q(\mathbf{u})$ in our variational framework is also found to be Gaussian, $q(\mathbf{f}_*|X_*)$ is Gaussian that can be computed analytically. The distribution $p(X_*|Y)$ is approximated by the variational distribution $q(X_*)$ which is Gaussian. Given $p(F_*|X_*, Y)$ approximated by $q(\mathbf{f}_*|X_*)$ and $p(X_*|Y)$ approximated by $q(X_*)$, the posterior density of \mathbf{f}_* (the noise-free version of \mathbf{y}_*) is now approximated by

$$p(\mathbf{f}_*|Y) = \int q(\mathbf{f}_*|X_*)q(X_*)dX_*. \quad (32)$$

The specific formulations of the distributions $p(\mathbf{f}_*|\mathbf{u}, X_*)$, $q(\mathbf{f}_*|X_*)$ and $q(X_*)$ are given in Appendix C as a more comprehensive treatment.

However, the integration of $q(\mathbf{f}_*|X_*)$ w.r.t $q(X_*)$ is not analytically feasible. Following Daniannou et al. (2011), we give the expectation of \mathbf{f}_* as $\mathcal{E}(\mathbf{f}_*)$ and its element-wise autocovariance as vector $\mathcal{C}(\mathbf{f}_*)$ whose $(\tilde{n} \times d)$ th entry is $\mathcal{C}(f_{\tilde{n}d})$ with $\tilde{n} = 1, \dots, N_*$ and $d = 1, \dots, D$.

$$\mathcal{E}(\mathbf{f}_*) = \psi_{1*}\mathbf{b}, \quad (33)$$

$$\mathcal{C}(f_{\tilde{n}d}) = \mathbf{b}^\top (\psi_{2\tilde{n}}^{d2} - (\psi_{1\tilde{n}}^{d1})^\top \psi_{1\tilde{n}}^{d1}) \mathbf{b} + \psi_{0*}^d - \text{Tr} \left[(\mathbf{K}_{\mathbf{u}\mathbf{u}}^{-1} - (\mathbf{K}_{\mathbf{u}\mathbf{u}} + \beta\psi_2) \mathbf{1}^{-1}) \psi_{2*}^d \right], \quad (34)$$

where $\psi_{1*} = \langle \mathbf{K}_{\mathbf{f}_*\mathbf{u}} \rangle_{q(X_*)}$, $\mathbf{b} = \beta \mathbf{K}_{\mathbf{u}\mathbf{u}} + \beta\psi_2 \mathbf{1}^{-1} \psi_{1*}^\top \mathbf{y}$, $\psi_{1\tilde{n}}^{d1} = \langle \mathbf{K}_{f_{\tilde{n}d}\mathbf{u}} \rangle_{q(X_*)}$, $\psi_{2\tilde{n}}^{d2} = \langle \mathbf{K}_{\mathbf{u}f_{\tilde{n}d}} \rangle_{q(X_*)}$, $\psi_{0*}^d = \text{Tr}(\langle \mathbf{K}_{\mathbf{f}_*\mathbf{f}_*} \rangle_{q(X_*)})$ and $\psi_{2*}^d = \langle \mathbf{K}_{\mathbf{u}\mathbf{f}_*} \rangle_{q(X_*)}$. Since \mathbf{y}_* is the noisy version of F_* , the expectation and element-wise autocovariance of \mathbf{y}_* are $\mathcal{E}(\mathbf{y}_*) = \mathcal{E}(\mathbf{f}_*)$ and $\mathcal{C}(\mathbf{y}_*) = \mathcal{C}(\mathbf{f}_*) + \beta^{-1} \mathbf{1}_{N_*D}$, where $\mathbf{y}_*^\top = [\mathbf{y}_{*1}^\top, \dots, \mathbf{y}_{*D}^\top]$.

4.2 Prediction with Time and Partial Observations

Prediction with time and partial observations can be divided into two cases. In one case, we need to predict $Y_*^m \in \mathbb{R}^{N_* \times D_m}$ which represents the outputs on missing dimensions, given $Y_*^m \in \mathbb{R}^{N_* \times D_p}$ which represents the outputs observed on partial dimensions. We call this task reconstruction. In the other case, we need to predict $Y_*^m \in \mathbb{R}^{N_* \times D}$ which means the outputs at the next time, given $Y_*^m \in \mathbb{R}^{N_* \times D}$ which means the outputs observed on all dimensions at the previous time. We call this task forecasting.

For the task of reconstruction, we should compute the posterior density of Y_*^m which is given below (Daniannou et al., 2011)

$$p(Y_*^m|Y_*^p, Y) = \int p(Y_*^m|F_*^m)p(F_*^m|X_*, Y_*^p, Y)p(X_*|Y_*^p, Y)dF_*^m dX_*. \quad (35)$$

$p(X_*|Y_*^p, Y)$ is approximated by a Gaussian distribution $q(X_*)$ whose parameters need to be optimized for the sake of considering the partial observations Y_*^p . This requires maximizing a new lower bound of $\log p(Y, Y_*^p)$ which can be expressed as

$$\begin{aligned} \tilde{\mathcal{L}} = \log & \left[\frac{\beta^{\frac{ND+N_*D_p}{2}} |\mathbf{K}_{\mathbf{u}\mathbf{u}}|^{\frac{1}{2}}}{(2\pi)^{\frac{ND+N_*D_p}{2}} |\beta\psi_2 + \mathbf{K}_{\mathbf{u}\mathbf{u}}|^{\frac{1}{2}}} \exp\left\{-\frac{1}{2} \tilde{\mathbf{y}}^\top \tilde{\mathbf{M}} \tilde{\mathbf{y}}\right\} \right] \\ & - \frac{\beta\psi_0}{2} + \frac{\beta}{2} \text{Tr}(\mathbf{K}_{\mathbf{u}\mathbf{u}}^{-1} \psi_2) - \mathbf{KL}[q(X, X_*)||p(X, X_*)|\mathbf{t}, \mathbf{t}_*], \end{aligned} \quad (36)$$

where $\tilde{\mathbf{W}} = \beta \mathbf{I} - \beta^2 \psi_1 (\beta\psi_2 + \mathbf{K}_{\mathbf{u}\mathbf{u}})^{-1} \psi_1^\top$, $\psi_0 = \text{Tr}(\langle \mathbf{K}_{\mathbf{f}_*\mathbf{f}_*} \rangle_{q(X, X_*)})$, $\psi_1 = \langle \mathbf{K}_{\mathbf{f}_*\mathbf{u}} \rangle_{q(X, X_*)}$ and $\psi_2 = \langle \mathbf{K}_{\mathbf{u}\mathbf{f}_*} \rangle_{q(X, X_*)}$. The vector $\tilde{\mathbf{y}}$ splices the vectorization of matrix Y and the vectorization of matrix Y_*^p , i.e. $\tilde{\mathbf{y}} = [\text{vec}(Y); \text{vec}(Y_*^p)]$. The vector $\tilde{\mathbf{f}}$ corresponds to the noise-free version of $\tilde{\mathbf{y}}$. Moreover, parameters of the new variational distribution $q(X, X_*)$ are jointly optimized because of the coupling of X and X_* . Then the marginal distribution $q(X_*)$ is obtained from $q(X, X_*)$. Note that when multiple sequences such as X_* and X are independent, only the separated variational distribution $q(X_*)$ is optimized.

For the task of forecasting, we focus on real-time forecasting for which the outputs are dependent on the previous ones and the training set Y is not used in the prediction stage. The variational distribution $q(X_*)$ can be directly computed as (70). Then the posterior density of Y_*^m is computed as (66), but with Y_* and Y replaced with Y_*^n and Y_*^p , respectively. $\mathcal{E}(Y_*^m)$ is the estimate of the output Y_*^m . An application for forecasting is given in Section 6.3.

4.3 Adaptation to Regression Models

Since the VDM-GPDS can be seen as a multi-layer regression model which regards time indices as inputs and observations as outputs. It can be flexibly extended to solve regression problems. Specifically, the time indices in the dynamical systems are replaced with the observed input data V . In addition, the kernel functions for the latent variables X are replaced by some appropriate functions such as automatic relevance determination (ARD) kernels:

$$K_{\tilde{n}}(\mathbf{v}, \mathbf{v}') = \sigma_{\tilde{n}}^2 \rho^{\frac{1}{2}} \sum_{p=1}^P \rho^{\frac{1}{2}} \exp(-\rho^p |v_p - v'_p|). \quad (37)$$

Model inference and optimization remain the same except for some changes for model parameters $\theta_{\tilde{n}}$. Compared with other dependent multi-output regression models such as the CMOGP, the VDM-GPDS can achieve much better performance. This could be attributed to its use of latent layers.

5. Related Work

Daniannou et al. (2011) described a GP dynamical system with variational Bayesian inference called VGPDS in which the latent variables X are imposed a GP prior to model the dynamical driving force and capture the high dimensional data's characteristics. After introducing inducing points, the latent variables are variationally integrated out. The outputs of VGPDS are generated from multiple independent GPs with the same latent variables X and the same parameters, resulting in the advantage that VGPDS can handle high dimensional situations. However, the explicit dependency among the multiple outputs is ignored in this model while this kind of dependency is very important for many applications. In contrast, the CMOGP (Alvarez and Lawrence, 2011) and GPRN (Wilson et al., 2012) model the dependency of different outputs through convolved process covariance functions and an adaptive network, respectively. Nevertheless, these two methods are not directly suitable for dynamical system modeling. If applied to dynamical systems with time as inputs, they cannot well capture the complexity of dynamical systems because there is only one nonlinear mapping between the input and output included.

Our model is capable of capturing the dependency among outputs as well as modeling the dynamical characteristics. It is also very different from the GPDM (Wang et al., 2006, 2008) which models the variance of each output with different scale parameters and employs Markov dynamical prior on the latent variables. The Gaussian prior for the latent variables in the VDM-GPDS can model the dynamical characteristics in the systems better than the Markov dynamical prior, since it can model different kinds of dynamics by using different kernels such as using periodic kernels to model periodicity. Moreover, in contrast to the GPDM that estimates the latent variables X through the MAP, the VDM-GPDS integrates out the latent variables with variational methods. This is in the same spirit of the technique used in Damianou et al. (2011), which can provide a principled approach to handle uncertainty in the latent space and determine its principal dimensions automatically. In addition, the multiple outputs in our model are modeled by convolution processes as in Álvarez and Lawrence (2011), which can flexibly capture the correlations among the outputs.

6. Experiments

In this part, we design five experiments to evaluate our model for four different kinds of applications including prediction with only time as inputs, reconstruction of the missing data, real-time forecasting and solving robot inverse dynamics problem. Two experiments are performed on synthetic data and three on real-world data. A number of models such as the CMOGP/COGP, GPDM, VGPDS and VDM-GPDS are tested on the data. The root mean square error (RMSE) and mean standardized log loss (MSLL) (Rasmussen and Williams, 2006) are taken as the performance measures. In particular, let \hat{Y}^* be the estimate of matrix Y^* , and then the RMSE can be formulated as

$$\text{RMSE}(Y^*, \hat{Y}^*) = \left[\frac{1}{D} \frac{1}{N} \sum_d \sum_n (y_n^{*d} - \hat{y}_n^{*d})^2 \right]^{\frac{1}{2}}. \quad (38)$$

MSLL is the mean negative log probability of all the test data under the learned model Γ and training data Y , which can be formulated as

$$\text{MSLL}(Y^*, \Gamma) = \frac{1}{N} \sum_n \{-\log p(\mathbf{Y}_n^* | \Gamma, Y)\}. \quad (39)$$

The lower value of the RMSE and MSLL we get, the better the performance of the model is. Our code is implemented based on the framework of publicly available code for the VGPDS and CMOGP.

6.1 Synthetic Data

In this section, we evaluate our method on synthetic data generated from a complex dynamical system. The latent variables X are independently generated by the Ornstein-Uhlenbeck (OU) process (Archambeau et al., 2007)

$$dx_q = -\gamma x_q dt + \sqrt{\sigma^2} dW, \quad q = 1, \dots, Q, \quad (40)$$

The outputs Y are generated through a multi-output GP

$$y_d(\mathbf{x}) \sim \mathcal{GP}(0, \kappa_{f_d, f_d'}(\mathbf{x}, \mathbf{x}')), \quad d, d' = 1, \dots, D, \quad (41)$$

	Spline	CMOGP	GPDM	VGPDS	VDM-GPDS
RMSE(y_1)	1.91±0.43	1.75±0.38	1.70±0.18	1.51±0.31	1.43 ± 0.23
RMSE(y_2)	4.23±1.01	3.46±0.67	3.32±0.27	2.99±0.53	2.82 ± 0.35
RMSE(y_3)	6.88±1.91	5.19±0.99	4.83±0.28	4.24±0.85	4.09 ± 0.59
RMSE(y_4)	6.99±1.52	7.50±0.94	5.98±0.55	5.16±0.92	5.00 ± 0.60

Table 1: Averaged RMSE (%) with the standard deviation (%) for predictions on the output-dependent synthetic data.

	CMOGP	GPDM	VGPDS	VDM-GPDS
MSLL(y_1)	-2.63±0.22	$2.21 \times 10^4 \pm 4.86 \times 10^4$	-2.73±0.08	-2.79 ± 0.08
MSLL(y_2)	-1.99±0.13	$1.93 \times 10^4 \pm 5.23 \times 10^4$	-2.14±0.15	-2.18 ± 0.15
MSLL(y_3)	-1.49±0.21	$3.92 \times 10^4 \pm 8.17 \times 10^4$	-1.66±0.24	-1.66 ± 0.21
MSLL(y_4)	-1.08±0.21	$9.90 \times 10^4 \pm 1.98 \times 10^5$	-1.31±0.41	-1.32 ± 0.25

Table 2: Averaged MSLL with the standard deviation for predictions on the output-dependent synthetic data.

where $\kappa_{f_d, f_d'}(\mathbf{x}, \mathbf{x}')$ defined in (12) is the multi-output covariance function. In this paper, the number of the latent functions in (9) is set to one, i.e., $K = 1$, which is also the common setting used in Álvarez and Lawrence (2011).

We sample the synthetic data by two steps. First we use the differential equation with parameters $\gamma = 0.5$, $\sigma = 0.01$ to sample $N = 200$, $Q = 2$ latent variables at time interval $[-1, 1]$. Then we sample $D = 4$ dimensional outputs, each of which has 200 observations through the multi-output GP with the following parameters $S_{1,1} = 1$, $S_{2,1} = 2$, $S_{3,1} = 3$, $S_{4,1} = 4$, $P_1 = [5, 1]^\top$, $P_2 = [5, 1]^\top$, $P_3 = [3, 1]^\top$, $P_4 = [2, 1]^\top$ and $\Lambda = [4, 5]^\top$. For approximation, 30 random inducing points are used. In addition, white Gaussian noise is added to each output.

6.1.1 PREDICTION

Here we evaluate the performance of our method for predicting the outputs given only time over the synthetic data. We randomly select 50 points from each output for training with the remaining 150 points for testing. This is repeated for ten times. The CMOGP, GPDM and VGPDS are performed as comparisons. The cubic spline interpolation (spline for short) is also chosen as a baseline. The latent variables X in the GPDM, VGPDS and VDM-GPDS with two dimensions are initialized by using the principal component analysis on the observations. Moreover, the Matérn 3/2 covariance function is used in the VGPDS and VDM-GPDS.

Table 1 and Table 2 present the RMSE and MSLL for predictions, respectively. The best results are shown in bold. From the tables, we can find that for prediction on the data of each dimension, our model obtains the lowest RMSE and MSLL. We analyze the reasons as follows. First, since the data in this experiment are generated from a complex

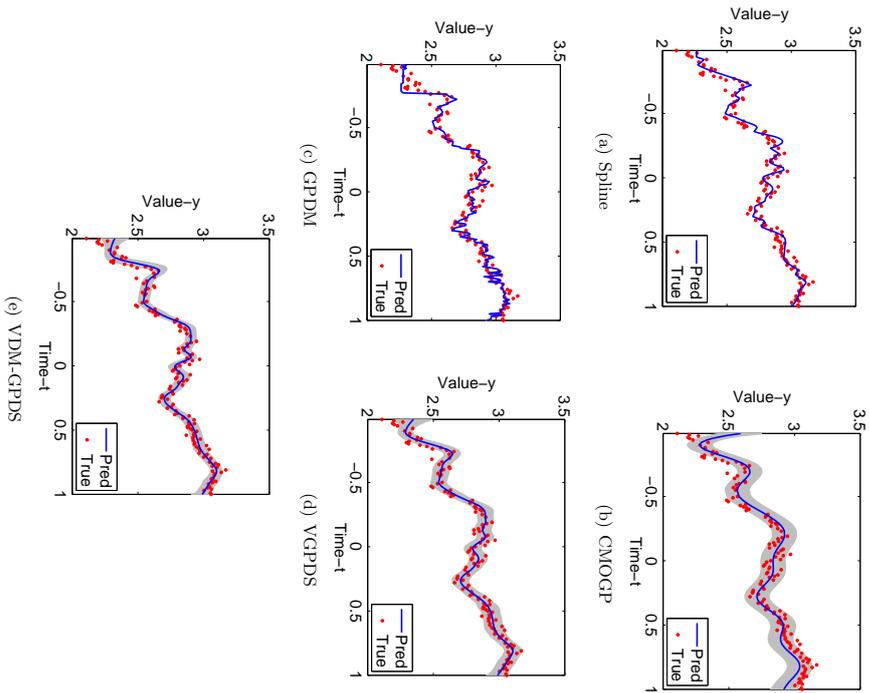

Figure 2: Predictions for $y_4(t)$ with the five methods. Pred and True indicate predicted and observed values, respectively. The shaded regions represent two standard deviations for the predictions.

dynamical system that combines two GP mappings, the CMOGP which consists of only one GP mapping cannot capture the complexity well. Moreover, the VDM-GPDS models the explicit dependency among the multiple outputs while the VGPDS and GPDM do not. The assumption of multi-output dependency is appropriate for the generative model. Further,

Table 3: Averaged RMSE (%) with the standard deviation (%) for predictions on the output-independent synthetic data.

	Spline	CMOGP	GPDM	VGPDS	VDM-GPDS
RMSE(y_1)	3.81±0.82	11.49±0.26	3.82±1.55	2.18 ± 0.06	2.21±0.06

MSLL(y_3)	-2.62±0.05	2.10×10 ² ±3.43×10 ²	-2.50±0.08	-2.52 ± 0.11
MSLL(y_4)	-1.38±0.66	5.19×10 ² ±1.16×10 ³	-1.46±0.17	-1.48 ± 0.18

Table 4: Averaged MSLL with the standard deviation for predictions on the output-independent synthetic data.

the GPDM cannot work well in the case in which data on many time intervals are lost. Prediction with the GPDM results in very high MSLL. To sum up, our model gives the best performance among the five models as expected.

In order to give intuitive representations, we draw one prediction result from the ten experiments in Figure 2 where the shaded regions in 2(b), 2(c), 2(d) and 2(e) represent two standard deviations for the predictions. Through the figures, it is clear that the VDM-GPDS has higher accuracies and smaller variances. Note that the GPDM has very small variances, but low accuracies, which leads to the high MSLL as in Table 2. With all the evaluation measures considered, the VDM-GPDS gives the best performance of prediction with only time as inputs.

In addition, to verify the flexibility of the VDM-GPDS, we perform experiments on the output-independent data which are generated analogously to Section 6.1. In particular, the output-independent data are generated using Equation (41) but with $r_{t,t'}^d(\mathbf{x}, \mathbf{x}') = 0$ for $d \neq d'$ after generating X . Note that the GPDM and VGPDS do not make the assumption of output dependency. The results in terms of RMSE and MSLL are shown in Table 3 and Table 4 where we can see that our model performs as well as the VGPDS and significantly better than the CMOGP and GPDM.

6.1.2 RECONSTRUCTION

In this section, we compare the VDM-GPDS with the k -nearest neighbor best (k -NNbest) method which chooses the best k from $\{1, \dots, 5\}$, the CMOGP, GPDM and VGPDS for recovering missing points given time and partially observed outputs. We set $S_{4,1} = -4$ to generate data in this part, which makes the output y_4 be negatively correlated with the others. We remove all outputs y_1 or y_4 at time interval $[0.5, 1]$ from the 50 training points,

	k -NNbest	CMOGP	GPDM	VGPDs	VDM-GPDS
RMSE(y_1)	1.87±0.62	1.90±0.31	2.69±3.67	1.49±0.94	0.98 ± 0.34
RMSE(y_4)	13.51±2.54	9.31±0.87	12.61±2.43	6.79±6.07	5.56 ± 1.88

Table 5: Averaged RMSE (%) with the standard deviation (%) for reconstructions of the missing points for y_1 and y_4 .

	CMOGP	GPDM	VGPDs	VDM-GPDS
MSLL(y_1)	-1.74±0.20	$1.40 \times 10^3 \pm 5.96 \times 10^4$	-2.29±0.46	-2.86 ± 0.09
MSLL(y_4)	0.31±0.62	$7.40 \times 10^4 \pm 8.34 \times 10^4$	-1.64±0.69	-2.35 ± 0.10

Table 6: Averaged MSLL with the standard deviation for reconstructions of the missing points for y_1 and y_4 .

resulting in 35 points as training data. Note that the CMOGP considers all the present outputs as the training set while the GPDM, VGPDs and VDM-GPDS only consider the outputs at time interval $[-1, 0.5]$ as the training set.

Table 5 and Table 6 show the averaged RMSE and MSLL with the standard deviation for reconstructions of the missing points for y_1 and y_4 . The proposed model performs best with the lowest RMSE and MSLL. Specifically, our model can make full use of the present data on some dimensions to reconstruct the missing data through the dependency among outputs. This advantage is shown by comparing with the GPDM and VGPDs. In addition, the two Gaussian process mappings in the VDM-GPDS help to well model the dynamical characteristics and complexity of the data. This advantage is shown by comparing to the CMOGP.

Figure 3 shows one reconstruction result for y_4 from the ten experiments by five different methods. It can be seen that the results of the VDM-GPDS are the closest to the true values among the compared methods. This indicates the superior performance of our model for the reconstruction task.

6.2 Human Motion Capture Data

In order to demonstrate the validity of the proposed model on real-world data, we employ ten sequences of runs/jogs from subject 35 (see Figure 4 for a skeleton) and two sequences of runs/jogs from subject 16 in the CMU motion capture database for the reconstruction task. In particular, our task is to reconstruct the right leg or the upper body of one test sequence on the motion capture data given training sequences. We preprocess the data as in Lawrence (2007) and divide the sequences into training and test data. Nine independent training sequences are all from subject 35 and the remaining three testing sequences are from subject 35 and subject 16 (one from subject 35 and two from subject 16). The average length of each sequence is 40 frames and the output dimension is 59.

We conduct this reconstruction with six different methods, the nearest neighbor in the angle space (NN) and the scaled space (NN sc.) (Taylor et al., 2006), the CMOGP, GPDM,

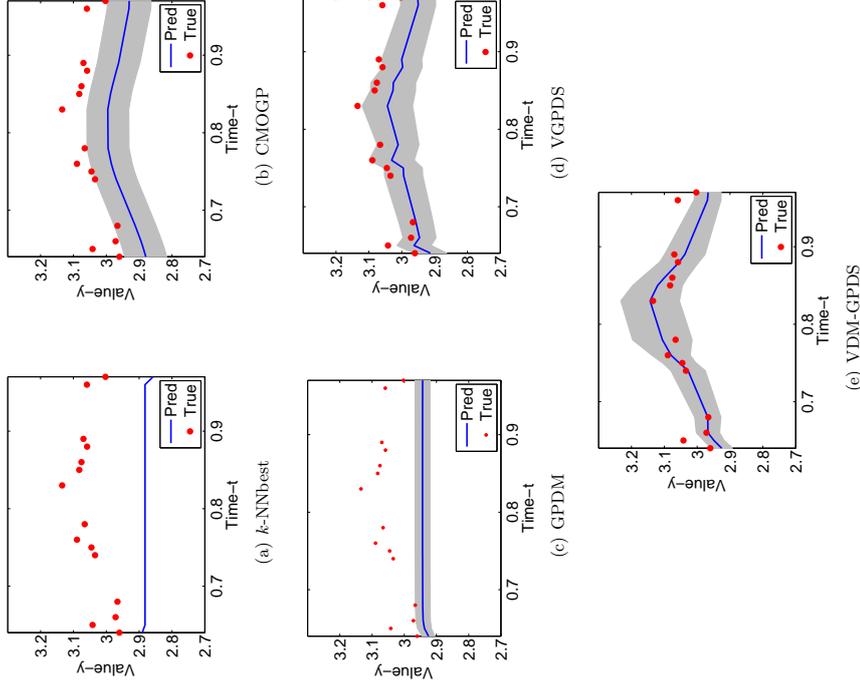

Figure 3: Reconstructions of the missing points for $y_4(t)$ with the five methods. Pred and True indicate predicted and observed values, respectively. The shaded regions represent two standard deviations for the predictions.

VGPDs and VDM-GPDS. For the CMOGP, periodic time indices with different cycles are used as inputs where the length of each sequence is a cycle. For the GPDM, parameters and latent variables are set as in Wang et al. (2006). For the VGPDs and VDM-GPDS, the RBF kernel is adopted in this set of experiments to construct $\mathbf{K}_{t,t}$ which is a block-

Table 9: The RMSE for forecasting results on the traffic flow data.

the historic traffic flows of the four road links to predict the flows of Gd in the next interval. The historic time for forecasting is fixed as four intervals. We compare our model with the Random Walk (RW) and VGPDS. The RW is to forecast the current value using the last value (Williams, 1999), which is chosen as a baseline. According to the descriptions about real-time forecasting in Section 4.2, the VGPDS can be adapted to apply to this experiment. Moreover, in the previous experiments, the VGPDS performs best among the compared models except the VDM-GPDS. Therefore, it is sufficient to compare our model with the RW and VGPDS. Note that the realization of the VGPDS also takes the periodicity into consideration.

Table 9 and Table 10 show the RMSE and MSLL for forecasting results with three methods over the testing sets, respectively. It is obvious that the VDM-GPDS achieves the best performance, even for the road links with large volumes (and large fluctuations) such as Gd . This is attributed to the fact that our model well captures both the temporal and spatial dependency of the traffic flow data. In particular, the relationship between the traffic flows of the objective road link and its upstream links is captured by the multi-

	RW	VGPDS	VDM-GPDS

MSLL(Hi)	.	5.93	5.90
MSLL(Ib)	.	6.33	6.25
MSLL(Jh)	.	6.38	6.30
MSLL(Ka)	.	6.07	5.86

Table 10: The MSLL for forecasting results on the traffic flow data.

output dependency in the VDM-GPDS; the relationship between the traffic flows of the objective road link and its own historical series is captured by the dynamical characteristics modeled in the VDM-GPDS. Therefore, the entire cause information is well collected by the VDM-GPDS to predict the traffic flows of the objective road link.

To be intuitive, we give the final forecasting results of the performed models for the road link Gd in the last three days in Figure 6. The VDM-GPDS has shown great superiority to the compared models. As seen from Figure 6(a) and Figure 6(b), the forecasting results with the RW and VGPDS often lag.

6.4 Robot Inverse Dynamics Problem

The robot inverse dynamics problem is an important task in the robot areas (Sciavicco and Vijayakumar, 2000). For a goal of touching or grasping a subject using a robotic manipulator, it usually needs the following procedures. First, the inverse kinematic calculates the robot joint coordinates given the pose of the end-effector. Then trajectory planning decides a trajectory describing how a robot should move to achieve the desired task. Finally, given the trajectory, i.e., the motion specified by the joint angles, velocities and accelerations, the torques needed at the joints to drive it along the trajectory are computed by the inverse dynamics. What we concerned here is the robot inverse dynamics problem. Analytical models for the inverse dynamics are often infeasible, for example due to uncertainty in the physical parameters of the robot, or the difficulty of modeling frictions. This leads to the need to learn the inverse dynamics by some machine learning methods (Chai et al., 2009; Nguyen and Bonilla, 2014).

We approximate the inverse dynamics model of a 7-degree-of-freedom anthropomorphic robot arm (see Figure 7). The inverse dynamics model of the robot is strongly nonlinear due to a vast amount of superpositions of sine and cosine functions in robot dynamics. The data consist of 21 input dimensions: 7 joint positions, velocities, and accelerations. The goal of learning is to approximate the appropriate torque command of one robot motor in response to the input vector. We choose 4449 data points from the original data set which consists of 48933 data points. We use 100, 300 and 500 points for training, respectively and the rest for testing. All the experiments are repeated for ten times. We consider joint

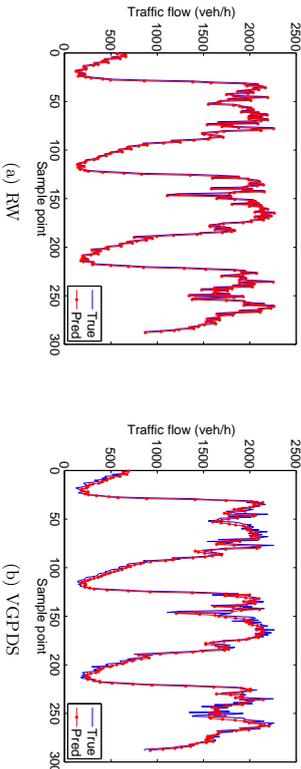

Figure 6: Forecasting results of the performed models for the road link GdI on the last three days.

learning for the two couples, the 2nd and 3rd, the 4th and 7th torques. Note that, the 2nd and 3rd torques are negatively correlated while the 4th and 7th torques are positively correlated.

We adapt our dynamical model to a regression model as described in Section 4.3. In order to demonstrate the performance of our model on the regression problem. We compare our model with the single Gaussian process regression (sGPR), multi-task Gaussian process (MTGP), collaborative multi-output Gaussian process (COGP) and VGPPDS. The sGPR is to learn the torque for each joint separately. The MTGP regards the torques from different joints as different tasks. The COGP is a scalable method which is extended from the CMOGP by introducing stochastic variational inference. As the COGP is an enhanced version of the CMOGP for robot inverse dynamics problems (Nguyen and Bonilla, 2014), we do not include the CMOGP in this experiment. For fairness, we set the batch size in the COGP the same as the number of training points. Note that the exact inference is used for the sGPR and MTGP. For the COGP, VGPDS and VDM-GPDS, variational inference is employed and the same size of inducing points are included. Particularly, 15, 20 and

30 inducing points are used for 100, 300 and 500 training points, respectively. For the VDM-GPDS and VGPDS, the dimensionality of the latent space is set to two. Table 11, 12 and 13 show the results for different methods in terms of averaged RMSE and MSLL. For intuition, we also plot the RMSE results in Figure 8.

From the tables and figures, we find that our model performs best on the whole, which confirms that the VDM-GPDS also works well for regression tasks. Comparing the VDM-

GPDS with the COGP, we further verify the assumption that the latent space can well grasp the characteristics of the data generation. Thus, the VDM-GPDS can well model the inverse dynamics model and make better prediction. Compared with the VGPDs, our model still shows advantages. This is attributed to the assumption of the dependency among

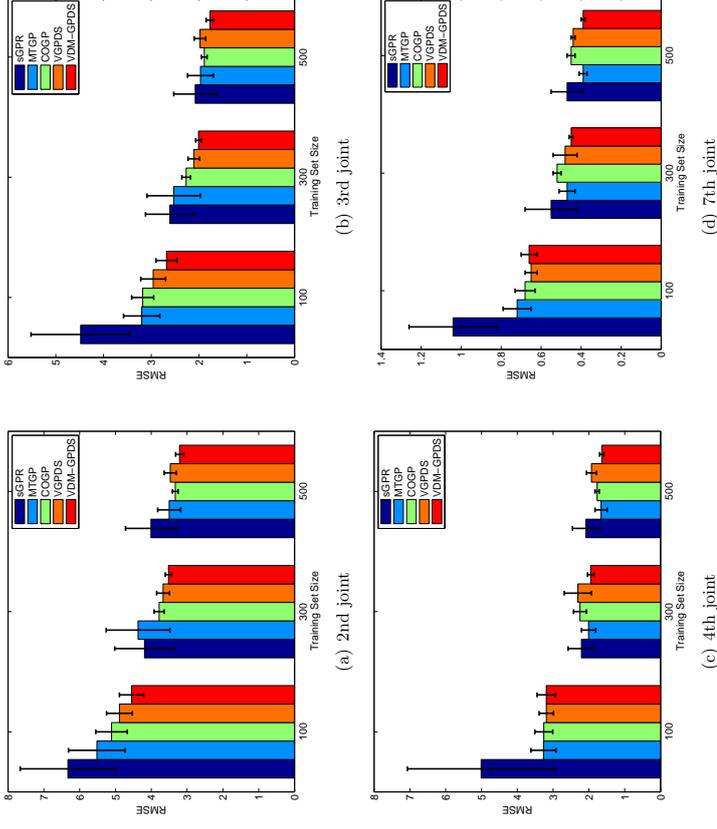

Figure 8: Averaged RMSE with the standard deviation for the 2nd, 3rd, 4th and 7th joint torques prediction. (better in color)

the multiple outputs. No matter for dynamical system modeling or static data regression, the proposed model is reasonable and applicable.

6.5 Performance and Efficiency Analysis

The proposed VDM-GPDS outperforms several previous methods for predicting outputs and recovering missing points for dynamical systems. In order to quantify the superior results, we evaluate the performance increases with the averaged performance increasing ratio to the VGPDs in terms of RMSE. The increasing ratios of the four experiments (Sections 6.1.1, 6.1.2, 6.2, 6.3 and 6.4) are 4.49%, 26.17%, 10.40%, 7.35% and 7.97%, respectively.

However, high effectiveness often comes together with low efficiency. The VDM-GPDS is a four-layer GP system that is more complex than the conventional methods. Particularly,

	CMOGP	GPDM	VGPPDS	VDM-GPDS
computational complexity	$O(D^3N^3)$	$O(N^3)$	$O(M^2NQ)$	$O(M^2NDQK)$
execution time	50.7	26.8	74.2	181.1

Table 14: Computational complexities and execution time (in ms) for different models.

since the proposed method explicitly models the dependency among outputs, the dependent multi-output covariance matrix in the VDM-GPDS is a full matrix with size $ND \times ND$ and operations involving it cannot be factorized. This is in contrast to the independent multi-output covariance matrix in the GPDM and VGPPDS, which is block-diagonal. As in Titsias (2009), inducing points are employed for the variational inference for the VDM-GPDS. The number of the inducing points M is much smaller than that of the data points N , which can improve the computational efficiency. For the VDM-GPDS, the most time-consuming calculation is to compute ψ_2 whose computational complexity is $O(M^2NDQK)$.

In order to give clear comparisons in terms of efficiency, we list the computational complexities of four models and the execution time (in ms) of one step for learning the models on the synthetic data in Table 14. Through the table, we find that the VDM-GPDS costs a lot. Nevertheless, our model can obtain high performance improvements as discussed above. We believe that getting performance improvements is worth the time cost.

7. Conclusion

In this paper, we have proposed a dependent multi-output GP for modeling complex dynamical systems. We give the reasonable assumption that the different outputs of the systems are generally dependent. The convolved process covariance function is employed to model the dependency among all the data points across all the outputs. We adapt the variational inference method involving inducing points to our model so that the latent variables are variationally integrated out. The model and variational parameters are jointly optimized with the scaled conjugate gradient method. Through small adaptations, our model can handle regression problems.

Modeling the possible dependency among multiple outputs can help to make better predictions. The effectiveness of the proposed model for complex dynamical systems is empirically demonstrated through multiple experiments. However, when the dimensionality of the output is very high, our model may take a long time to converge. This opens the possibility for future work to accelerate training for high dimensional dynamical systems.

Appendix A. Derivation of the Lower Bound

In order to approximately compute the marginal likelihood $p(\mathbf{Y}|\mathbf{t})$, we compute the variational lower bound of it by involving the variational distribution $q(F, U, X|Z)$. The variational lower bound \mathcal{L} can be expressed as

$$\begin{aligned} \mathcal{L} &= \int q(F, U, X|Z) \log \frac{p(\mathbf{Y}, F, U, X|\mathbf{t}, Z)}{q(F, U, X|Z)} dX dU dF \\ &= \int p(\mathbf{f}|\mathbf{u}, X, Z) q(\mathbf{u}) q(X) \log \frac{p(\mathbf{y}|\mathbf{f}) p(\mathbf{u}|Z) p(X|\mathbf{t})}{q(\mathbf{u}) q(X)} d\mathbf{f} d\mathbf{u} dX, \end{aligned} \quad (42)$$

since

$$p(\mathbf{Y}, F, U, X|\mathbf{t}, Z) = p(\mathbf{y}|\mathbf{f}) p(\mathbf{f}|\mathbf{u}, X, Z) p(\mathbf{u}|Z) p(X|\mathbf{t}), \quad (43)$$

and

$$q(F, U, X|Z) = p(\mathbf{f}|\mathbf{u}, X, Z) q(\mathbf{u}) q(X). \quad (44)$$

For neatness, the above expression is split into two parts as $\mathcal{L} = \hat{\mathcal{L}} - \mathbf{KL}[q(X)||p(X|\mathbf{t})]$. Specifically, $\hat{\mathcal{L}}$ is expressed by

$$\hat{\mathcal{L}} = \int p(\mathbf{f}|\mathbf{u}, X, Z) q(\mathbf{u}) q(X) \log \frac{p(\mathbf{y}|\mathbf{f}) p(\mathbf{u}|Z)}{q(\mathbf{u})} d\mathbf{f} d\mathbf{u} dX. \quad (45)$$

$\mathbf{KL}[q(X)||p(X|\mathbf{t})]$ is the relative entropy of $q(X)$ and $p(X|\mathbf{t})$, expressed as

$$\begin{aligned} \mathbf{KL}[q(X)||p(X|\mathbf{t})] &= \int q(X) \log \frac{q(X)}{p(X|\mathbf{t})} \\ &= \frac{Q}{2} \log |\mathbf{K}_{\mathbf{t}, \mathbf{t}}| - \frac{1}{2} \sum_{q=1}^Q \log |S_q| \\ &\quad + \frac{1}{2} \sum_{q=1}^Q [\text{Tr}(\mathbf{K}_{\mathbf{t}, \mathbf{t}}^{-1} S_q) + \text{Tr}(\mathbf{K}_{\mathbf{t}, \mathbf{t}}^{-1} \boldsymbol{\mu}_q \boldsymbol{\mu}_q^T)] + \text{const}, \end{aligned} \quad (46)$$

since

$$p(X|\mathbf{t}) = \prod_{q=1}^Q \mathcal{N}(\mathbf{x}_q | \mathbf{0}, \mathbf{K}_{\mathbf{t}, \mathbf{t}}), \quad (47)$$

and

$$q(X) = \prod_{q=1}^Q \mathcal{N}(\mathbf{x}_q | \boldsymbol{\mu}_q, S_q). \quad (48)$$

So far, $\mathbf{KL}[q(X)||p(X|\mathbf{t})]$ can be calculated analytically as the above, we need to calculate $\hat{\mathcal{L}}$. By using the facts that $\log \frac{p(\mathbf{y}|\mathbf{f}) p(\mathbf{u}|Z)}{q(\mathbf{u})} = \log p(\mathbf{y}|\mathbf{f}) + \log \frac{p(\mathbf{u}|Z)}{q(\mathbf{u})}$ and $\int p(\mathbf{f}|\mathbf{u}, X, Z) d\mathbf{f} = 1$, $\hat{\mathcal{L}}$ is converted into

$$\begin{aligned} \hat{\mathcal{L}} &= \int q(\mathbf{u}) q(X) \int p(\mathbf{f}|\mathbf{u}, X, Z) \log p(\mathbf{y}|\mathbf{f}) d\mathbf{f} d\mathbf{u} dX \\ &\quad + \int q(\mathbf{u}) q(X) \log \frac{p(\mathbf{u}|Z)}{q(\mathbf{u})} d\mathbf{u} dX. \end{aligned} \quad (49)$$

We know that $p(\mathbf{y}|\mathbf{f})$ and $p(\mathbf{f}|\mathbf{u}, X, Z)$ are both Gaussian, and then

$$\begin{aligned} & \int p(\mathbf{f}|\mathbf{u}, X, Z) \log p(\mathbf{y}|\mathbf{f}) d\mathbf{f} \\ &= \log \mathcal{N}(\mathbf{y}|\mathbf{K}_{\mathbf{f},\mathbf{u}}\mathbf{K}_{\mathbf{u},\mathbf{u}}^{-1}\mathbf{u}, \beta^{-1}I) - \frac{\beta}{2} \text{Tr}(\mathbf{K}_{\mathbf{f},\mathbf{f}} - \mathbf{K}_{\mathbf{f},\mathbf{u}}\mathbf{K}_{\mathbf{u},\mathbf{u}}^{-1}\mathbf{K}_{\mathbf{u},\mathbf{f}}). \end{aligned} \quad (50)$$

Thus $\hat{\mathcal{L}}$ in (49) can be simplified as

$$\begin{aligned} \hat{\mathcal{L}} &= \int q(\mathbf{u}) q(X) \log \frac{\mathcal{N}(\mathbf{y}|\mathbf{a}, B) p(\mathbf{u})}{q(\mathbf{u})} d\mathbf{u} dX \\ &\quad - \int \frac{\beta}{2} \text{Tr}(\mathbf{K}_{\mathbf{f},\mathbf{f}} - \mathbf{K}_{\mathbf{f},\mathbf{u}}\mathbf{K}_{\mathbf{u},\mathbf{u}}^{-1}\mathbf{K}_{\mathbf{u},\mathbf{f}}) q(X) dX, \end{aligned} \quad (51)$$

where $\mathbf{a} = \mathbf{K}_{\mathbf{f},\mathbf{u}}\mathbf{K}_{\mathbf{u},\mathbf{u}}^{-1}\mathbf{u}$ and $B = \beta^{-1}I$. By changing the integration order, we get

$$\begin{aligned} \hat{\mathcal{L}} &= \int q(\mathbf{u}) \left[\log \frac{e^{(\log \mathcal{N}(\mathbf{y}|\mathbf{a}, B))_{q(X)} p(\mathbf{u})}}{q(\mathbf{u})} \right] d(\mathbf{u}) \\ &\quad - \frac{\beta}{2} \text{Tr}(\langle \mathbf{K}_{\mathbf{f},\mathbf{f}} \rangle_{q(X)} - \langle \mathbf{K}_{\mathbf{f},\mathbf{u}}\mathbf{K}_{\mathbf{u},\mathbf{u}}^{-1}\mathbf{K}_{\mathbf{u},\mathbf{f}} \rangle_{q(X)}). \end{aligned} \quad (52)$$

We compute the optimal bound using the reserved Jensen's inequality as in Titsias and Lawrence (2010). This gives

$$\begin{aligned} \hat{\mathcal{L}} &\leq \log \int e^{(\log \mathcal{N}(\mathbf{y}|\mathbf{a}, B))_{q(X)} p(\mathbf{u})} d\mathbf{u} \\ &\quad - \frac{\beta}{2} \text{Tr}(\langle \mathbf{K}_{\mathbf{f},\mathbf{f}} \rangle_{q(X)}) + \frac{\beta}{2} \text{Tr}(\langle \mathbf{K}_{\mathbf{f},\mathbf{u}}\mathbf{K}_{\mathbf{u},\mathbf{u}}^{-1}\mathbf{K}_{\mathbf{u},\mathbf{f}} \rangle_{q(X)}). \end{aligned} \quad (53)$$

The optimal distribution $q(\mathbf{u})$ that gives rise to this lower bound is given by $q(\mathbf{u}) = e^{(\log \mathcal{N}(\mathbf{y}|\mathbf{K}_{\mathbf{f},\mathbf{u}}\mathbf{K}_{\mathbf{u},\mathbf{u}}^{-1}\mathbf{u}, \beta^{-1}I))_{q(X)} p(\mathbf{u})}$, which is analytically Gaussian

$$q(\mathbf{u}) \propto \mathcal{N}(\beta \mathbf{y}^\top \psi_1 \mathbf{K}_{\mathbf{u},\mathbf{u}} (\beta \psi_2 + \mathbf{K}_{\mathbf{u},\mathbf{u}})^{-1} \psi_1^\top \mathbf{y}, \mathbf{K}_{\mathbf{u},\mathbf{u}} (\beta \psi_2 + \mathbf{K}_{\mathbf{u},\mathbf{u}})^{-1}), \quad (54)$$

where $\psi_0 = \text{Tr}(\langle \mathbf{K}_{\mathbf{f},\mathbf{f}} \rangle_{q(X)})$, $\psi_1 = \langle \mathbf{K}_{\mathbf{f},\mathbf{u}} \rangle_{q(X)}$ and $\psi_2 = \langle \mathbf{K}_{\mathbf{u},\mathbf{u}} \mathbf{K}_{\mathbf{f},\mathbf{u}} \rangle_{q(X)}$. The closed-form of the lower bound of the approximated marginal log-likelihood defined as \mathcal{L} is given by

$$\begin{aligned} \mathcal{L} &= \log \left[\frac{\beta^{\frac{ND}{2}} |\mathbf{K}_{\mathbf{u},\mathbf{u}}|^{\frac{1}{2}}}{2\pi^{\frac{ND}{2}} |\beta \psi_2 + \mathbf{K}_{\mathbf{u},\mathbf{u}}|^{\frac{1}{2}}} \exp\left\{-\frac{1}{2} \mathbf{y}^\top W \mathbf{y}\right\} \right] \\ &\quad - \frac{\beta \psi_0}{2} + \frac{\beta}{2} \text{Tr}(\langle \mathbf{K}_{\mathbf{u},\mathbf{u}} \rangle_{\psi_2}) - \mathbf{KL}[q(X)||p(X|\mathbf{t})], \end{aligned} \quad (55)$$

where $W = \beta I - \beta^2 \psi_1 (\beta \psi_2 + \mathbf{K}_{\mathbf{u},\mathbf{u}})^{-1} \psi_1^\top$. Given the above, we can obtain the final formulation of the lower bound in (21) which has the similar formulation with Damianou et al. (2011). But actually they are not the same.

Appendix B. Gradients with Respect to the Parameters

The parameters involved in the proposed model include the model parameters $\{\beta, \boldsymbol{\theta}_x, \boldsymbol{\theta}_f\}$ and the variational parameters $\{\boldsymbol{\mu}_q, \lambda_q\}_{q=1}^Q$ after reparameterizing $\{\boldsymbol{\mu}_q, S_q\}_{q=1}^Q$. All the parameters are jointly optimized by maximizing the lower bound in (21) with the scaled conjugate gradient method. Here we give the detailed gradients of all the parameters. Note that in our model the dimensionality of the latent variable \mathbf{U} is one ($K=1$). So the statistics such as $S_{d,k}$, Λ_k , W are changed to s_d , Λ , M here. In order to simplify the expressions, we define $\Sigma_{\psi_0} = 2P_d + \Lambda$, $\Sigma_{\psi_1} = P_d + \Lambda + S_n$, $\Sigma_{\psi_{21}} = 2(P_d + \Lambda)$, $\Sigma_{\psi_{22}} = \frac{P_d + \Lambda}{2} + S_n$, $C^{-1} = \beta^{-1} \mathbf{K}_{\mathbf{u},\mathbf{u}} + \psi_2$. \mathbf{z} is equivalent to \mathbf{z}_m and \mathbf{z}' is equivalent to $\mathbf{z}_{m'}$. The symbol $[\cdot]_q$ after a matrix means the q th column of the matrix.

Because of the reparameterization, we need to calculate the gradients of $\hat{\mathcal{L}}$ with respect to $\boldsymbol{\mu}_q$, S_q and then obtain the gradients of \mathcal{L} with respect to $\boldsymbol{\mu}_q$, λ_q using (28) and (29). Given that $\mathbf{KL}[q(X)||p(X|\mathbf{t})]$ does not involve the parameters $\boldsymbol{\theta}_f$, β and Z , its gradients with respect to $\boldsymbol{\theta}_f$, β and Z are zero. Therefore, $\frac{\partial \mathcal{L}}{\partial \boldsymbol{\theta}_f} = \frac{\partial \hat{\mathcal{L}}}{\partial \boldsymbol{\theta}_f}$, $\frac{\partial \mathcal{L}}{\partial \beta} = \frac{\partial \hat{\mathcal{L}}}{\partial \beta}$ and $\frac{\partial \mathcal{L}}{\partial Z} = \frac{\partial \hat{\mathcal{L}}}{\partial Z}$.

First, we give the gradients of $\hat{\mathcal{L}}$ with respect to $\boldsymbol{\mu}_q$, S_q , P_d , s_d through the formulation

$$\frac{\partial \hat{\mathcal{L}}}{\partial \boldsymbol{\theta}} = -\frac{\beta}{2} \frac{\partial \psi_0}{\partial \boldsymbol{\theta}} + \beta \text{Tr} \left[\frac{\partial \psi_1^\top}{\partial \boldsymbol{\theta}} \mathbf{y} \mathbf{y}^\top \psi_1 C \right] + \frac{\beta}{2} \text{Tr} \left[\frac{\partial \psi_2}{\partial \boldsymbol{\theta}} (\mathbf{K}_{\mathbf{u},\mathbf{u}}^{-1} - \frac{C}{\beta} - C \psi_1^\top \mathbf{y} \mathbf{y}^\top \psi_1 C) \right], \quad (56)$$

where $\boldsymbol{\theta}$ represents $\boldsymbol{\mu}_{nq}$, S_{nq} , P_{dq} and s_d . The detailed derivatives of ψ_0 , ψ_1 and ψ_2 with respect to $\boldsymbol{\mu}_{nq}$, S_{nq} , P_{dq} and s_d are different. The derivatives of ψ_0 , $(\psi_1)_{vm}$ and $(\psi_2)_{mm'}$ with respect to $\boldsymbol{\mu}_{nq}$ are

$$\begin{aligned} \frac{\partial \psi_0}{\partial \boldsymbol{\mu}_{nq}} &= 0, \\ \frac{\partial (\psi_1)_{vm}}{\partial \boldsymbol{\mu}_{nq}} &= s_d \mathcal{N}(\mathbf{z}|\boldsymbol{\mu}_n, \Sigma_{\psi_1}) (\mathbf{z} - \boldsymbol{\mu}_n)^\top \Sigma_{\psi_1}^{-1} \mathbf{1}_q, \\ \frac{\partial (\psi_2)_{mm'}}{\partial \boldsymbol{\mu}_{nq}} &= \sum_{d=1}^D s_d^2 \mathcal{N}(\mathbf{z}|\mathbf{z}', \Sigma_{\psi_{21}}) \mathcal{N} \left(\frac{\mathbf{z} + \mathbf{z}'}{2} | \boldsymbol{\mu}_n, \Sigma_{\psi_{22}} \right) \left(\left(\frac{\mathbf{z} + \mathbf{z}'}{2} - \boldsymbol{\mu}_n \right)^\top \Sigma_{\psi_{22}}^{-1} \mathbf{1}_q \right). \end{aligned} \quad (57)$$

The derivatives of ψ_0 , $(\psi_1)_{vm}$ and $(\psi_2)_{mm'}$ with respect to S_{nq} are

$$\begin{aligned} \frac{\partial \psi_0}{\partial S_{nq}} &= 0, \\ \frac{\partial (\psi_1)_{vm}}{\partial S_{nq}} &= s_d \mathcal{N}(\mathbf{z}|\boldsymbol{\mu}_n, \Sigma_{\psi_1}) \left(-\frac{|\Sigma_{\psi_1}^{-1} \partial \Sigma_{\psi_1}|}{2} \frac{1}{\partial S_{nq}} - \frac{1}{2} (\mathbf{z} - \boldsymbol{\mu}_n)^\top \frac{\partial \Sigma_{\psi_1}^{-1}}{\partial S_{nq}} (\mathbf{z} - \boldsymbol{\mu}_n) \right), \\ \frac{\partial (\psi_2)_{mm'}}{\partial S_{nq}} &= \sum_{d=1}^D s_d^2 \mathcal{N}(\mathbf{z}|\mathbf{z}', \Sigma_{\psi_{21}}) \mathcal{N} \left(\frac{\mathbf{z} + \mathbf{z}'}{2} | \boldsymbol{\mu}_n, \Sigma_{\psi_{22}} \right) \\ &\quad \left(-\frac{|\Sigma_{\psi_{22}}^{-1} \partial \Sigma_{\psi_{22}}|}{2} \frac{1}{\partial S_{nq}} - \frac{1}{2} (\mathbf{z} + \mathbf{z}')^\top \frac{\partial \Sigma_{\psi_{22}}^{-1}}{\partial S_{nq}} (\mathbf{z} + \mathbf{z}') - \boldsymbol{\mu}_n \right). \end{aligned} \quad (58)$$

The derivatives of ψ_0 , $(\psi_1)_{om}$ and $(\psi_2)_{mm'}$ with respect to P_{dq} are

$$\begin{aligned} \frac{\partial \psi_0}{\partial P_{dq}} &= \sum_{d=1}^D \frac{N}{2} \frac{s_d s_d}{|2\pi|^{\frac{Q}{2}} |\Sigma_{\psi_0}|^{\frac{3}{2}}} \frac{\partial |\Sigma_{\psi_0}|}{\partial P_{dq}}, \\ \frac{\partial (\psi_1)_{om}}{\partial P_{dq}} &= s_d \mathcal{N}(\mathbf{z} | \boldsymbol{\mu}_n, \Sigma_{\psi_1}) \left(-\frac{1}{2} \frac{|\Sigma_{\psi_1}|^{-1} \partial |\Sigma_{\psi_1}|}{\partial P_{dq}} - \frac{1}{2} (\mathbf{z} - \boldsymbol{\mu}_n)^\top \frac{\partial \Sigma_{\psi_1}^{-1}}{\partial P_{dq}} (\mathbf{z} - \boldsymbol{\mu}_n) \right), \\ \frac{\partial (\psi_2)_{mm'}}{\partial P_{dq}} &= \sum_{n=1}^N s_d^2 \mathcal{N}(\mathbf{z} | \boldsymbol{\mu}_n, \Sigma_{\psi_2}) \mathcal{N} \left(\frac{\mathbf{z} + \mathbf{z}'}{2} \middle| \boldsymbol{\mu}_n, \Sigma_{\psi_{22}} \right) \\ &\quad \left(-\frac{|\Sigma_{\psi_{21}}|^{-1} \partial |\Sigma_{\psi_{21}}|}{2 \partial P_{dq}} - \frac{1}{2} (\mathbf{z} - \mathbf{z}')^\top \frac{\partial \Sigma_{\psi_{21}}^{-1}}{\partial P_{dq}} (\mathbf{z} - \mathbf{z}') \right) \\ &\quad - \frac{|\Sigma_{\psi_{22}}|^{-1} \partial |\Sigma_{\psi_{22}}|}{2 \partial P_{dq}} - \frac{1}{2} (\mathbf{z} + \mathbf{z}')^\top \frac{\partial \Sigma_{\psi_{22}}^{-1}}{\partial P_{dq}} (\mathbf{z} + \mathbf{z}') - \boldsymbol{\mu}_n \Big). \end{aligned} \quad (59)$$

The derivatives of ψ_0 , $(\psi_1)_{om}$ and $(\psi_2)_{mm'}$ with respect to s_d are

$$\begin{aligned} \frac{\partial \psi_0}{\partial s_d} &= \frac{2N s_d}{|2\pi|^{\frac{Q}{2}} |\Sigma_{\psi_0}|^{\frac{3}{2}}}, \\ \frac{\partial (\psi_1)_{om}}{\partial s_d} &= \mathcal{N}(\mathbf{z} | \boldsymbol{\mu}_n, \Sigma_{\psi_1}), \\ \frac{\partial (\psi_2)_{mm'}}{\partial s_d} &= \sum_{n=1}^N 2s_d \mathcal{N}(\mathbf{z} | \boldsymbol{\mu}_n, \Sigma_{\psi_{21}}) \mathcal{N} \left(\frac{\mathbf{z} + \mathbf{z}'}{2} \middle| \boldsymbol{\mu}_n, \Sigma_{\psi_{22}} \right). \end{aligned} \quad (60)$$

Then, we give the gradients of \mathcal{L} with respect to Λ and Z through the formulation

$$\begin{aligned} \frac{\partial \mathcal{L}}{\partial \theta} &= -\frac{\beta}{2} \frac{\partial \psi_0}{\partial \theta} + \beta \text{Tr} \left[\frac{\partial \psi_1^\top}{\partial \theta} \mathbf{y} \mathbf{y}^\top \psi_1 C \right] + \frac{\beta}{2} \text{Tr} \left[\frac{\partial \psi_2}{\partial \theta} (\mathbf{K}_{\mathbf{u}, \mathbf{u}}^{-1} - C \psi_1^\top \mathbf{y} \mathbf{y}^\top \psi_1 C - \beta^{-1} C) \right] \\ &\quad + \frac{1}{2} \text{Tr} \left[\frac{\partial \mathbf{K}_{\mathbf{u}, \mathbf{u}}}{\partial \theta} (\mathbf{K}_{\mathbf{u}, \mathbf{u}}^{-1} - C \psi_1^\top \mathbf{y} \mathbf{y}^\top \psi_1 C - \beta^{-1} C - \beta \mathbf{K}_{\mathbf{u}, \mathbf{u}}^{-1} \psi_2 \mathbf{K}_{\mathbf{u}, \mathbf{u}}^{-1}) \right], \end{aligned} \quad (61)$$

where θ represents Λ_q , Z_{mq} . The detailed derivatives of the ψ_0 , ψ_1 , ψ_2 and $\mathbf{K}_{\mathbf{u}, \mathbf{u}}$ with respect to Λ_q , Z_{mq} are given separately. The derivatives of ψ_0 , $(\psi_1)_{om}$, $(\psi_2)_{mm'}$ and $(\mathbf{K}_{\mathbf{u}, \mathbf{u}})_{mm'}$

with respect to Λ_q are

$$\begin{aligned} \frac{\partial \psi_0}{\partial \Lambda_q} &= \sum_{d=1}^D \frac{N}{2} \frac{s_d s_d}{|2\pi|^{\frac{Q}{2}} |\Sigma_{\psi_0}|^{\frac{3}{2}}} \frac{\partial |\Sigma_{\psi_0}|}{\partial \Lambda_q}, \\ \frac{\partial (\psi_1)_{om}}{\partial \Lambda_q} &= s_d \mathcal{N}(\mathbf{z} | \boldsymbol{\mu}_n, \Sigma_{\psi_1}) \left(-\frac{1}{2} \frac{|\Sigma_{\psi_1}|^{-1} \partial |\Sigma_{\psi_1}|}{\partial \Lambda_q} - \frac{1}{2} (\mathbf{z} - \boldsymbol{\mu}_n)^\top \frac{\partial \Sigma_{\psi_1}^{-1}}{\partial \Lambda_q} (\mathbf{z} - \boldsymbol{\mu}_n) \right), \\ \frac{\partial (\psi_2)_{mm'}}{\partial \Lambda_q} &= \sum_{n=1}^N \sum_{d=1}^D s_d^2 \mathcal{N}(\mathbf{z} | \boldsymbol{\mu}_n, \Sigma_{\psi_{21}}) \mathcal{N} \left(\frac{\mathbf{z} + \mathbf{z}'}{2} \middle| \boldsymbol{\mu}_n, \Sigma_{\psi_{22}} \right) \\ &\quad \left(-\frac{\partial |\Sigma_{\psi_{21}}|}{2 |\Sigma_{\psi_{21}}| \partial \Lambda_q} - \frac{1}{2} (\mathbf{z} - \mathbf{z}')^\top \frac{\partial \Sigma_{\psi_{21}}^{-1}}{\partial \Lambda_q} (\mathbf{z} - \mathbf{z}') \right) \\ &\quad - \frac{\partial |\Sigma_{\psi_{22}}|}{2 |\Sigma_{\psi_{22}}| \partial \Lambda_q} - \frac{1}{2} (\mathbf{z} + \mathbf{z}')^\top \frac{\partial \Sigma_{\psi_{22}}^{-1}}{\partial \Lambda_q} (\mathbf{z} + \mathbf{z}') - \boldsymbol{\mu}_n \Big), \\ \frac{\partial (\mathbf{K}_{\mathbf{u}, \mathbf{u}})_{mm'}}{\partial \Lambda_q} &= \mathcal{N}(\mathbf{z} | \boldsymbol{\mu}_n, \Lambda) \left(-\frac{1}{2} |\Lambda|^{-1} \frac{\partial |\Lambda|}{\partial \Lambda_q} - \frac{1}{2} (\mathbf{z} - \mathbf{z}')^\top \frac{\partial \Lambda^{-1}}{\partial \Lambda_q} (\mathbf{z} - \mathbf{z}') \right). \end{aligned} \quad (62)$$

The derivatives of ψ_0 , $(\psi_1)_{om}$, $(\psi_2)_{mm'}$ and $(\mathbf{K}_{\mathbf{u}, \mathbf{u}})_{mm'}$ with respect to z_{mq} are

$$\begin{aligned} \frac{\partial \psi_0}{\partial z_{mq}} &= 0, \\ \frac{\partial (\psi_1)_{om}}{\partial z_{mq}} &= -s_d \mathcal{N}(\mathbf{z} | \boldsymbol{\mu}_n, \Sigma_{\psi_1}) \left((\mathbf{z} - \boldsymbol{\mu}_n)^\top \Sigma_{\psi_1}^{-1} \mathbf{q} \right), \\ \frac{\partial (\psi_2)_{mm'}}{\partial z_{mq}} &= \sum_{d=1}^D s_d^2 \mathcal{N}(\mathbf{z} | \boldsymbol{\mu}_n, \Sigma_{\psi_{21}}) \mathcal{N} \left(\frac{\mathbf{z} + \mathbf{z}'}{2} \middle| \boldsymbol{\mu}_n, \Sigma_{\psi_{22}} \right) \\ &\quad \left(-\frac{1}{2} (\mathbf{z} + \mathbf{z}')^\top \Sigma_{\psi_{22}}^{-1} \mathbf{q} + (\mathbf{z} - \mathbf{z}')^\top \Sigma_{\psi_{21}}^{-1} \mathbf{q} \right), \\ \frac{\partial (\mathbf{K}_{\mathbf{u}, \mathbf{u}})_{mm'}}{\partial z_{mq}} &= -\frac{1}{\Lambda_q} \mathcal{N}(\mathbf{z} | \boldsymbol{\mu}_n, \Lambda) (z_{mq} - z_{m'q}). \end{aligned} \quad (63)$$

Finally, we give the gradients of \mathcal{L} with respect to β and $\boldsymbol{\theta}_x$ as follows.

$$\begin{aligned} \frac{\partial \mathcal{L}}{\partial \beta} &= \frac{1}{2} \text{Tr} (\mathbf{K}_{\mathbf{u}, \mathbf{u}}^{-1} \psi_2) + (Y - M) \beta^{-1} - \text{Tr} (\mathbf{y} \mathbf{y}^\top) + \text{Tr} (C \psi_1^\top \mathbf{y} \mathbf{y}^\top \psi_1) \\ &\quad + \beta^{-2} \text{Tr} (\mathbf{K}_{\mathbf{u}, \mathbf{u}} C) + \beta^{-1} \text{Tr} (\mathbf{K}_{\mathbf{u}, \mathbf{u}} C \psi_1^\top \mathbf{y} \mathbf{y}^\top \psi_1 C), \\ \frac{\partial \mathcal{L}}{\partial \boldsymbol{\theta}_x} &= \sum_{q=1}^Q \text{Tr} \left[-\frac{1}{2} (\hat{\beta}_q \mathbf{K}_{\mathbf{t}, \mathbf{t}} \hat{\beta}_q + \hat{\boldsymbol{\mu}}_q \hat{\boldsymbol{\mu}}_q^\top) + (I - \hat{\beta}_q \mathbf{K}_{\mathbf{t}, \mathbf{t}}) \frac{\partial \hat{\mathcal{L}}}{\partial S_q} (I - \hat{\beta}_q \mathbf{K}_{\mathbf{t}, \mathbf{t}})^\top \frac{\partial \mathbf{K}_{\mathbf{t}, \mathbf{t}}}{\partial \boldsymbol{\theta}_x} \right] \\ &\quad + \left(\frac{\partial \hat{\mathcal{L}}}{\partial \boldsymbol{\mu}_q} \right)^\top \frac{\partial \mathbf{K}_{\mathbf{t}, \mathbf{t}}}{\partial \boldsymbol{\theta}_x} \bar{\boldsymbol{\mu}}_q, \end{aligned} \quad (64)$$

where $\hat{\beta}_q = \Lambda_q^{\frac{1}{2}} (I + \Lambda_q^{\frac{1}{2}} \mathbf{K}_{\mathbf{t}, \mathbf{t}} \Lambda_q^{\frac{1}{2}})^{-1} \Lambda_q^{\frac{1}{2}}$.

Appendix C. Derivations of Prediction with Only Time

With the parameters as well as time \mathbf{t} and \mathbf{t}_* omitted, the posterior density for prediction is given by

$$p(Y_*|Y) = \int p(Y_*|F_*)p(F_*|X_*, Y)p(X_*|Y)dF_*dX_* \quad (66)$$

where $F_* \in \mathbb{R}^{N_* \times D}$ denotes the set of latent variables (the noise-free version of Y_*) and $X_* \in \mathbb{R}^{N_* \times Q}$ represents the latent variables in the low dimensional space.

The distribution $p(F_*|X_*, Y)$ in (66) is approximated by the variational distribution

$$p(F_*|X_*, Y) \approx q(\mathbf{f}_*|X_*) = \int p(\mathbf{f}_*|\mathbf{u}, X_*)q(\mathbf{u})d\mathbf{u} \quad (67)$$

where $\mathbf{f}_*^\top = [\mathbf{f}_{*1}^\top, \dots, \mathbf{f}_{*D}^\top]$, and $p(\mathbf{f}_*|\mathbf{u}, X_*)$ is Gaussian with the formulation

$$p(\mathbf{f}_*|\mathbf{u}, X_*) = \mathcal{N}(\mathbf{f}_*|\mathbf{K}_{\mathbf{f}_*, \mathbf{u}}\mathbf{K}_{\mathbf{u}, \mathbf{u}}^{-1}\mathbf{u}, \mathbf{K}_{\mathbf{f}_*, \mathbf{f}_*} - \mathbf{K}_{\mathbf{f}_*, \mathbf{u}}\mathbf{K}_{\mathbf{u}, \mathbf{u}}^{-1}\mathbf{K}_{\mathbf{u}, \mathbf{f}_*}). \quad (68)$$

Since the optimal setting for $q(\mathbf{u})$ in our variational framework is also found to be Gaussian, $q(\mathbf{f}_*|X_*)$ is Gaussian that can be computed analytically

$$q(\mathbf{f}_*|X_*) = \mathcal{N}(\beta\mathbf{K}_{\mathbf{f}_*, \mathbf{u}}(\mathbf{K}_{\mathbf{u}, \mathbf{u}} + \beta\psi_2)^{-1}\psi_1^\top\mathbf{y}, \mathbf{K}_{\mathbf{f}_*, \mathbf{u}}(\mathbf{K}_{\mathbf{u}, \mathbf{u}} + \beta\psi_2)^{-1}\mathbf{K}_{\mathbf{f}_*, \mathbf{u}}^\top - \mathbf{K}_{\mathbf{f}_*, \mathbf{f}_*} - \mathbf{K}_{\mathbf{f}_*, \mathbf{u}}\mathbf{K}_{\mathbf{u}, \mathbf{u}}^{-1}\mathbf{K}_{\mathbf{u}, \mathbf{f}_*}). \quad (69)$$

The distribution $p(X_*|Y)$ in (66) is approximated by the variational distribution $q(X_*)$ which is Gaussian and can be explicitly formulated as

$$q(X_*) = \mathcal{N}(\boldsymbol{\mu}_{X_*}, \boldsymbol{\Sigma}_{X_*}), \quad (70)$$

where $\boldsymbol{\mu}_{X_*}$ is composed of column vector $\boldsymbol{\mu}_{\mathbf{x}_{*q}}$ and block-diagonal matrix $\boldsymbol{\Sigma}_{X_*}$ has diagonal element $\boldsymbol{\Sigma}_{\mathbf{x}_{*q}}$ with

$$\boldsymbol{\mu}_{\mathbf{x}_{*q}} = \mathbf{K}_{\mathbf{t}_*, \mathbf{t}_*}\mathbf{K}_{\mathbf{t}_*, \mathbf{t}}^{-1}\boldsymbol{\mu}_q, \quad (71)$$

$$\boldsymbol{\Sigma}_{\mathbf{x}_{*q}} = \mathbf{K}_{\mathbf{t}_*, \mathbf{t}_*} - \mathbf{K}_{\mathbf{t}_*, \mathbf{t}}\mathbf{K}_{\mathbf{t}, \mathbf{t}}^{-1}(\mathbf{K}_{\mathbf{t}, \mathbf{t}_*} - \mathbf{S}_q\mathbf{K}_{\mathbf{t}, \mathbf{t}}^{-1}\mathbf{K}_{\mathbf{t}, \mathbf{t}_*}). \quad (72)$$

Given $p(F_*|X_*, Y)$ approximated by $q(\mathbf{f}_*|X_*)$ and $p(X_*|Y)$ approximated by $q(X_*)$, the posterior density of \mathbf{f}_* (the noise-free version of \mathbf{y}_*) is now approximated by

$$p(\mathbf{f}_*|Y) = \int q(\mathbf{f}_*|X_*)q(X_*)dX_*. \quad (73)$$

So far, following Damianou et al. (2011), the expectation of \mathbf{f}_* and its element-wise autocovariance are given in (33) and (34).

Abstract

In high-dimensional data, structured noise caused by observed and unobserved factors affecting multiple target variables simultaneously, imposes a serious challenge for modeling, by masking the often weak signal. Therefore, (1) explaining away the structured noise in multiple-output regression is of paramount importance. Additionally, (2) assumptions about the correlation structure of the regression weights are needed. We note that both can be formulated in a natural way in a latent variable model, in which both the interesting signal and the noise are mediated through the same latent factors. Under this assumption, the signal model then borrows strength from the noise model by encouraging similar effects on correlated targets. We introduce a hyperparameter for the *latent signal-to-noise ratio* which turns out to be important for modelling weak signals, and an ordered infinite-dimensional shrinkage prior that resolves the rotational unidentifiability in reduced-rank regression models. Simulations and prediction experiments with metabolite, gene expression, fMRI measurement, and macroeconomic time series data show that our model equals or exceeds the state-of-the-art performance and, in particular, outperforms the standard approach of assuming independent noise and signal models.

Keywords: Bayesian reduced-rank regression, latent variable models, latent signal-to-noise ratio, multiple-output regression, nonparametric Bayes, shrinkage priors, structured noise, weak effects

1. Introduction

Explaining away structured noise is one of the cornerstones for successful modeling of high-dimensional output data in the regression framework (Fusi et al., 2012; Klami et al., 2013; Rai et al., 2012; Rakitsch et al., 2013; Stegle et al., 2012; Virtanen et al., 2011). The structured noise refers to dependencies between response variables, which are unrelated to the dependencies of interest between the response variables and the covariates. It is noise caused by observed and unobserved confounders that affect multiple variables simultaneously. Common observed confounders in medical and biological data include age and sex of an individual, whereas unobserved confounders include, for example, the state of the cell being measured, measurement artifacts influencing multiple probes, or other unrecorded experimental conditions. When not accounted for, structured noise may both hide interesting relationships and result in spurious findings (Leek and Storey, 2007; Kang et al., 2008).

The effects of known confounders can be removed straightforwardly by using supervised methods. For the unobserved confounders, a routinely used approach for explaining away structured noise has been to assume *a priori* independent effects for the interesting and uninteresting factors. For example, in the factor regression setup (West, 2003; Stegle et al., 2010; Fusi et al., 2012), the target variables Y are assumed to have been generated as

$$Y = X\Theta + H\Lambda + E, \quad (1)$$

where $Y_{N \times K}$ is the matrix of K target variables (or dependent variables) and $X_{N \times P}$ contains the covariates (or independent variables), for the N observations. The model parameter matrix $H_{N \times S_2}$ comprises the unknown latent factors and $\Lambda_{S_2 \times K}$ the factor loadings, which are used to model away the structured noise. The term $E_{N \times K}$ represents independent unstructured noise and the elements of E are independently distributed, $\text{vec}(E) \sim \mathcal{N}(0, I_{NK})$. In this paper we call this model **independent-noise BRRR**. To reduce the effective number of parameters in the regression coefficient matrix $\Theta_{P \times K}$, a low-rank structure may be

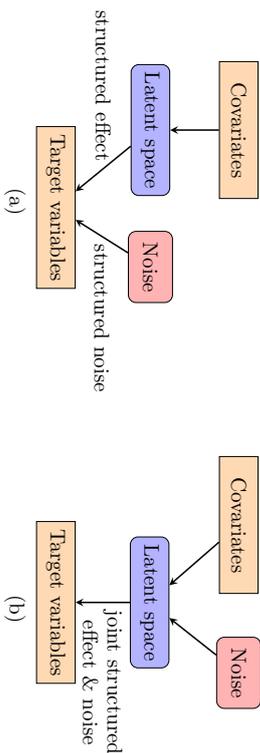

Figure 1: Illustration of (a) *a priori* independent interesting and uninteresting effects and (b) the latent noise assumption. Latent noise is mediated to the target variable measurements through a common subspace with the interesting effects.

assumed:

$$\Theta = \Psi \Gamma, \quad (2)$$

where the rank S_1 of parameters $\Psi_{P \times S_1}$ and $\Gamma_{S_1 \times K}$ is substantially lower than the number of target variables K and covariates P . The low-rank decomposition of the regression coefficient matrix (2) may be given an interpretation whereby the covariates X affect S_1 latent components with coefficients specified in Ψ , and the components, in turn, affect the target Y with coefficients Γ . Another line of work in multiple output prediction has focused on borrowing information from the correlation structure of the target variables when learning the regression model. The intuition stems from the observation that correlated targets are often seen to be affected similarly by the covariates, for example in genetic applications (see, e.g. Davis et al., 2014; Imoye et al., 2012). One popular method, GFlasso (Kim et al., 2009), learns the regression coefficients using

$$\hat{\Theta} = \arg \min_{\Theta} \sum_k (\mathbf{y}_k - X\theta_k)^T (\mathbf{y}_k - X\theta_k) + \lambda \sum_j \sum_k |\theta_{jk}| + \gamma \sum_{(m,j) \in E} r_{mj}^2 \sum_j |\theta_{jm} - \text{sign}(r_{mj})\theta_{jl}|, \quad (3)$$

where the θ_k are the columns of $\hat{\Theta}$. Two regularization parameters are introduced: λ represents the standard Lasso penalty, and γ encourages the effects θ_{jm} and θ_{jl} of the j th covariate on correlated outputs m and l to be similar. Here r_{mj} represents the correlation between the m th and l th phenotypes. The E is an *a priori* specified correlation graph for the output variables, with edges representing correlations to be accounted for in the model.

In this paper we propose a model that simultaneously learns the structured noise and encourages the sharing of information between the noise and the regression models. To motivate the new model, we note that by assuming independent prior distributions on Γ and Λ in model (1), one implicitly assumes independence of the interesting and uninteresting effects, caused by covariates X and unknown factors H , respectively (Fig. 1a). The assumption is appealing for example when explaining away batch effects (Fusi et al., 2012)

in high-dimensional data, but may be inadequate in the presence of other types of noise in molecular biology, where gene expression and metabolomics measurements record concentrations of compounds generated by ongoing latent biological processes. In this kind of situations, a limited set of covariates, such as single nucleotide polymorphisms (SNPs), determines the activity of the latent process only partially and all other activity of the process is due to unrecorded factors. In such cases, the noise affects the measurement levels through the very same process as the interesting signal (Fig. 1b), and rather than assuming independence of the effects, an assumption about parallel effects would be more appropriate. We refer to this type of noise as *latent noise* as it can be considered to affect the same latent subspace as the interesting effects. We note that in practice both types of structured noise are likely to be present. In this work, our main focus is on the latent noise, but we also present a comparison with a model that includes both types of structured noise simultaneously.

A natural way to encode the assumption of latent noise is to use the following model structure:

$$Y = (X\Psi + \Omega) \Gamma + E, \quad (4)$$

where the $\Omega_{N \times S_1}$ is a matrix consisting of unknown latent factors. In (4), Γ mediates the effects of both the interesting and uninteresting signals on the target variables. We note that the change required in the model structure is small, and has in fact been presented earlier (Bo and Sminchisescu 2009; recently extended with an Indian Buffet Process prior on the latent space by Baryg et al. 2014). We now proceed to using the structure (4) for GFlasso-type sharing of information (3) between the regression and noise models while simultaneously explaining away structured noise. To see that the information sharing between noise and regression models follows immediately from model (4), one can consider simulations generated from the model. The *a priori* independence assumption of model (1) results in uncorrelated regression weights regardless of the correlations between target variables (Figure 2a). The assumption of latent noise (4), however, encourages the regression weights to be correlated in a similar way as the target variables are (Figure 2c).

In this work, we focus on modelling weak signals in high-dimensional data with structured noise, where we consider effects that explain a tiny portion, say $< 1\%$, of the variance of the target variables as weak. We have hypothesized above that a model with the structure (4) might be particularly well-suited for this purpose. Additionally, (i) particular emphasis must be put on defining adequate prior distributions to distinguish the weak effects from noise as effectively as possible, and (ii) scalability to large sample size is needed in order to have any chance of learning the weak effects. For (i), we define *latent signal-to-noise ratio* β as a generalization of the standard signal-to-noise ratio in the latent space:

$$\beta = \frac{\text{Trace}(\text{Var}(X\Psi))}{\text{Trace}(\text{Var}(\Omega))}, \quad (5)$$

We use the latent signal-to-noise ratio as a hyperparameter in our model, and show that it is a key parameter affecting model performance. It can be either learned or set using prior knowledge. In addition, we introduce an ordered infinite-dimensional shrinkage prior that resolves the inherent rotational ambiguity in the model (4), by sorting both signal and noise components by their importance. Finally, we present efficient inference methods for the model.

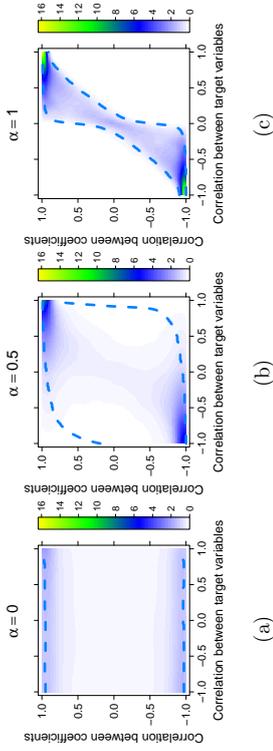

Figure 2: Conditional distribution of the correlation between regression coefficients, given the correlation between the corresponding target variables. In (a) the model (1) assumes *a priori* independent regression and noise models, and in (c) the model (4) makes the latent noise assumption. (b) A mixture of the models in a and c. The data were generated using equation (18), as described in Section 5.3, and α denotes the relative proportion of latent noise in data generation. The dashed lines denote the 95% confidence intervals of the conditional distributions.

2. Related work

Simultaneously solving multiple real-valued prediction tasks with the same set of covariates is called multiple-output regression (Breiman and Friedman, 1997); and more generally sharing of statistical strength between related tasks is called multitask learning (Baxter, 1996; Caruana, 1997). The data consist of N input-output pairs $(\mathbf{x}_n, \mathbf{y}_n)_{n=1, \dots, N}$; the P -dimensional input vectors \mathbf{x} (covariates) are used for predicting K -dimensional vectors \mathbf{y} of target variables. The common approach to dealing with structured noise due to unobserved confounders is to apply factor regression modeling (1) (West, 2003) and to explain away the structured noise using a noise model that is assumed to be *a priori* independent of the regression model (Stegle et al., 2010; Fusi et al., 2012; Rai et al., 2012; Virtanen et al., 2011; Klami et al., 2013; Rakitsch et al., 2013). A recent Bayesian reduced-rank regression (BRRR) model (Marttinen et al., 2014) implements the routine assumption of the independence of the regression and noise models; we will include it in the comparison studies of this paper.

Methods for multiple-output regression without the structured noise model have been proposed in other fields. In the application fields of genomic selection and multi-trait quantitative trait loci mapping, solutions (Yi and Banerjee, 2009; Xu et al., 2009; Calus and Veerkamp, 2011; Stephens, 2013) for low-dimensional target variable vectors ($K < 10$) have been proposed, but these methods do not scale up to the currently emerging needs of analyzing higher-dimensional target variable data. Additionally, sparse multiple-output regression models have been proposed for prediction of phenotypes from genomic data (Kim et al., 2009; Sohn and Kim, 2012).

Many methods for multi-task learning have been proposed in the field of kernel methods (Evgeniou and Pontil, 2007). These methods do not, however, scale up to data sets with

several thousands of samples, required for predicting the weak effects. Other relevant work include a recent method based on the BRRR presented by Foygel et al. (2012), but it does not scale to the dimensionalities of our experiments either. Methods for high-dimensional phenotypes have been proposed in the field of expression quantitative trait loci mapping (Botto et al., 2011) for the related task of finding associations (and avoiding false positives) rather than prediction, which is our main focus. Also functional assumptions (Wang et al., 2012) have been used to constrain related learning problems.

3. Model

In this Section, we present the details of our new model, Bayesian reduced rank regression with latent noise (latent-noise BRRR), show how the hyperparameters can be set using the latent signal-to-noise ratio, and analyze theoretically some properties of the infinite-dimensional shrinkage prior.

3.1 Model details: latent-noise BRRR

Our model is given by

$$Y = (X\Psi + \Omega)\Gamma + E, \quad (6)$$

where $Y_{N \times K}$ contains the K -dimensional response variables for N observations, and $X_{N \times P}$ contains the predictor variables. The product $\Theta = \Psi\Gamma$, of $\Psi_{P \times S_1}$ and $\Gamma_{S_1 \times K}$, results in a regression coefficient matrix with rank S_1 . The $\Omega_{N \times S_1}$ contains unknown latent factors representing the latent noise. Finally, $E_{N \times K} = [e_1, \dots, e_N]^T$, with $e_t \sim N(0, \Sigma)$, where $\Sigma = \text{diag}(\sigma_1^2, \dots, \sigma_K^2)$ is a matrix of uncorrelated target variable-specific noise vectors. Figure 3 displays graphically the structure of the model. In the figure, the node corresponding to the parameter Γ that is shared by the regression and noise models is highlighted with green.

Similarly to a recent BRRR model (Marttinen et al., 2014) and the Bayesian infinite sparse factor analysis model (Bhattacharya and Dunson, 2011), we assume the number of components S_1 connecting the covariates to the targets to be infinite. Accordingly, the number of rows in the weight matrix Γ , and the numbers of columns in Ψ and Ω , are infinite. The low-rank nature of the model is enforced by shrinking the columns of Ψ and rows of Γ and Ω increasingly with the growing column/row index, such that only a small number of columns/rows are influential in practice. The increasing shrinkage also solves any rotational unidentifiability issues by enforcing the model to mediate the strongest effects through the first columns/rows. In Section 3.4 we explore the basic properties of the infinite-dimensional prior, to ensure its soundness. The hierarchical priors for the projection weight matrix Γ , where $\Gamma = [\gamma_{lj}]$, are set as follows:

$$\begin{aligned} \gamma_{lj} | \phi_{lj}^{\Gamma}, \tau_h &\sim N\left(0, (\phi_{lj}^{\Gamma} \tau_h)^{-1}\right), \quad \phi_{lj}^{\Gamma} \sim \text{Ga}(\nu/2, \nu/2), \\ \tau_h &= \prod_{l=1}^h \delta_l, \quad \delta_1 \sim \text{Ga}(a_1, 1), \quad \delta_l \sim \text{Ga}(a_2, 1), \quad l \geq 2. \end{aligned} \quad (7)$$

Here τ_h is a global shrinkage parameter for the h th row of Γ and the ϕ_{lj}^{Γ} s are local shrinkage parameters for the individual elements of Γ , to provide additional flexibility over the global

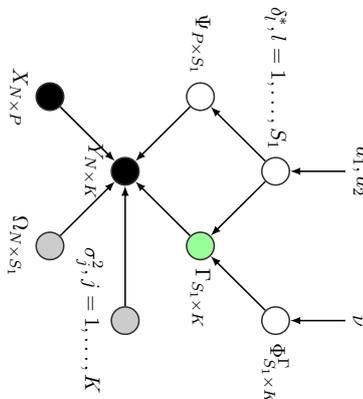

Figure 3: Graphical representation of latent-noise BRRR. The observed data are denoted by black circles, variables related to the reduced-rank regression part of the model by white circles, variables related only to the noise model are denoted by gray circles, and variables related to both the regression and the structured noise model are denoted with green circles. The matrix $\Phi_{S_1 \times K}^T$ comprises the sparsity parameters for the K target variables for the components.

shrinkage priors. The same parameters τ_h are used to shrink the columns of the matrices $\Psi = [\psi_{jh}]$ and $\Omega = [\omega_{jh}]$, because the scales of Γ and Ψ (or Ω) are not identifiable separately:

$$\psi_{jh}|\tau_h \sim N\left(0, (\tau_h)^{-1}\right), \quad \text{and} \quad \omega_{jh}|\tau_h \sim N\left(0, \sigma_\Omega^2 (\tau_h)^{-1}\right),$$

where σ_Ω^2 is a parameter that specifies the amount of latent noise, which is used to regularize the model (see the next Section). With the priors specified, the hidden factors Ω can be integrated out analytically, yielding

$$y_i \sim N\left((\Psi\Gamma)^T x_i, \sigma_\Omega^2 (\Gamma^*)^T (\Gamma^*) + \Sigma\right), \quad i = 1, \dots, N, \quad (8)$$

where Γ^* is obtained from Γ by multiplying the rows of Γ with the shrinkages $(\tau_h)^{-1/2}$ of the columns of Ω .

Finally, conjugate prior distributions

$$\sigma_j^{-2} \sim \text{Ga}(a_\sigma; b_\sigma), \quad j = 1, \dots, K, \quad (9)$$

are placed on the noise parameters of the target variables.

3.2 Regularization of latent-noise BRRR through the variance of Ω

The latent signal-to-noise ratio β in Equation (5) has an intuitive interpretation: given our prior distributions for Ψ and Ω , the prior latent SNR indicates the extent to which we believe

the noise to explain variation in Y , as compared to the variance explained by the covariates X . Thus, the latent SNR acts as a regularization parameter: when the latent variables Ω are allowed to have a large variance, the data will be explained by the noise model rather than the covariates. We note that this approach to regularization is non-standard and it may have favourable characteristics compared to the commonly used L1/L2 regularization of regression weights. First of all, the regression weights remain relatively unbiased as they need not be enforced to zero to control for overfitting. This is important when the effects are weak: if the effects were shrunk towards zero, they might be lost completely.

Secondly, while regularizing with the *a priori* selected latent SNR, the regularization parameter itself remains interpretable: every value of the variance parameter of Ω can be immediately interpreted as the percentage of variance explained by the noise model as compared to the covariates. In our experiments, we use cross-validation to select the variance of Ω and the interpretability of the parameter makes it easy to express beliefs of the plausible values based on prior knowledge. Making similar educated guesses for L1/L2 regularization parameters is not straightforward.

3.3 Difference between latent-noise BRRR and independent-noise BRRR

We call the standard Bayesian reduced rank regression (Equation 1), which assumes independent noise and signal models, the *independent-noise BRRR*. The new latent-noise BRRR differs from it in two ways: in the latent-noise BRRR

1. the structure of the model is different in that the noise model uses the same projection parameters as the regression model, and
2. the model is regularized by modifying the variance of the noise model. This is achieved by learning the latent signal-to-noise ratio parameter β .

In Section 5.5 we show that both of these improvements are needed to reach the performance differences observed.

We emphasize that although the technical difference between the two models is minor, the models are very different from the conceptual point of view, as discussed in the Introduction, as well as from the practical point of view. In particular, it has been reported before that with weak effects the independent-noise BRRR may suffer from severe instability, resulting from a highly multi-modal posterior distribution and, consequently, poor convergence and mixing properties of the learning algorithms (Koop et al., 2006; Marttinen et al., 2014). In Section 5.11, we demonstrate how the latent noise assumption provides just the required additional regularization to make the formal Bayesian inference tractable even with weak effects.

As both independent structured noise and latent noise could be present, a logical extension to the models presented so far is to consider both noise types simultaneously,

$$Y = (X\Psi + \Omega)\Gamma + HA + E, \quad (10)$$

where the distributional assumptions for Ψ , Ω and Γ are the same as in latent-noise BRRR, and for H and Λ they follow independent-noise BRRR. The Gibbs updates for this model are straightforward modifications of those for the latent-noise BRRR and independent-noise BRRR. We have implemented also this model and study its performance in Section 5.9.

We note that the latent-noise model is, in principle, able to express data generated by the independent-noise BRRR model, and vice versa. The latent-noise BRRR model may learn noise components that are independent from the signal in practice, having negligible contribution from the regression part $X\Psi$. On the other hand, nothing prevents the independent noise model to learn some correlated regression and noise components. Therefore, the family of models defined by Equation (10) that simultaneously includes both kinds of structured noise may have redundancy in its parameters. Indeed, the experiments in Section 5.9 demonstrate only minor improvements from this model.

3.4 Proofs of the soundness of the infinite prior

In this Section we verify the sensibility of the infinite non-parametric prior, which we introduce for ordering the components according to decreasing importance, and of a computational approximation resulting from truncation of the infinite model.

It has been proven that in Bayesian factor models $a_1 > 2$ and $a_2 > 3$ (in our case defined in eqn 7) is sufficient for the elements of $\Lambda\Lambda^T$ to have finite variance in a Bayesian factor model (1), even if an infinite number of columns with a prior similar to our model is assumed for Λ (Bhattacharya and Dunson, 2011). In this Section we present similar characteristics for the infinite reduced-rank regression model. The detailed proofs can be found in the Supplementary material. First, in analogy to the infinite Bayesian factor analysis model, we show that

$$a_1 > 2 \quad \text{and} \quad a_2 > 3 \quad (11)$$

is sufficient for the prediction of any of the response variables to have finite variance under the prior distribution (Proposition 1). Second, we show that the underestimation of uncertainty (variance) resulting from using a finite rank approximation to the infinite reduced-rank regression model decays exponentially with the rank of the approximation (Proposition 2). For notational clarity, let Ψ_h denote the h^{th} column of the Ψ matrix in the following. With this notation, the prediction for the i th response variable can be written as

$$\begin{aligned} \tilde{y}_i &= x^T \Theta_i \\ &= x^T \sum_{h=1}^{\infty} \Psi_h \gamma_{hi}. \end{aligned}$$

Furthermore, let $\Gamma(\cdot)$ denote below the gamma function (not to be confused with the matrix Γ used in all other Sections of this paper).

Proposition 1: Finite variance of predictions Suppose that $a_1 > 2$ and $a_2 > 3$. Then

$$\text{Var}(\tilde{y}_i) = \frac{\nu}{\nu-2} \sum_{j=1}^P \text{Var}(x_j) \frac{\Gamma(a_1-2)/\Gamma(a_1)}{1-\Gamma(a_2-2)/\Gamma(a_2)}. \quad (12)$$

A detailed proof is provided in the Supplementary material.

Proposition 2: Truncation error of the finite rank approximation Let $\tilde{y}_i^{S_1}$ denote the prediction for the i th target variable when using an approximation for Ψ and Γ consisting of the first S_1 columns or rows only, respectively. Then,

$$\frac{\text{Var}(\tilde{y}_i) - \text{Var}(\tilde{y}_i^{S_1})}{\text{Var}(\tilde{y}_i)} = \left[\frac{\Gamma(a_2-2)}{\Gamma(a_2)} \right]^{S_1},$$

that is, the reduction in the variance of the prediction resulting from using the approximation, relative to the infinite model, decays exponentially with the rank of the approximation. A detailed proof is provided in the Supplementary material.

4. Efficient computation by reparameterization

For estimating the parameters of the latent-noise BRRR, we use Gibbs sampling, updating the parameters one by one by sampling them from their conditional posterior probability distributions, given the current values of all other parameters. The bottleneck of the computation is in updating the matrix Ψ , and below we present a novel efficient update for this parameter.

4.1 Update of Γ

The conditional distribution of the parameter matrix Γ of latent-noise BRRR can be updated using a standard result for Bayesian linear models (Bishop et al., 2006) which states that if

$$\beta \sim N(0, \Sigma_\beta), \quad \text{and} \quad y|X^*, \beta \sim N(X^* \beta, \Sigma_y), \quad (13)$$

then

$$\beta|y, X^* \sim N(\Sigma_{\beta|y}(X^{*T} \Sigma_y^{-1} y), \Sigma_{\beta|y}), \quad (14)$$

where

$$\Sigma_{\beta|y} = (\Sigma_\beta^{-1} + X^{*T} \Sigma_y^{-1} X^*)^{-1}. \quad (15)$$

Because in our model (6) the columns E_i of the noise matrix are assumed independent with variances $\sigma_1^2, \dots, \sigma_K^2$, we get

$$Y_i \sim N((X\Psi + \Omega)\Gamma_i, \sigma_i^2 I_N). \quad (16)$$

Thus, by substituting

$$X^* \leftarrow X\Psi + \Omega, \quad \beta \leftarrow \Gamma_i, \quad \text{and} \quad \Sigma_y \leftarrow \sigma_i^2 I_N$$

into (13), together with prior covariance Σ_{β} derived from (7), we immediately obtain the posterior of Γ_i from (14) and (15).

4.2 Updates of Φ^1, δ, σ and Ω

The updates of the hyperparameters are the same as in Bayesian Reduced Rank Regression, and the conditional posterior distributions of the hyperparameters can be found in the Supplementary material of Marttinen et al. (2014). The Ω has the same conditional posterior distribution as the model parameter H of Marttinen et al. (2014).

4.3 Improved update of Ψ

The computational bottleneck of the naive Gibbs sampler is the update of parameter Ψ , which has PS_1 elements with a joint multivariate Gaussian distribution, conditionally on the other parameters (Geweke, 1996; Marttinen et al., 2014). Thus, the inversion of the

precision matrix of the joint distribution has a computational cost of $O(P^3 S_1^3)$. To remove the bottleneck, we reparameterize our model after which a linear algebra trick by Stegle et al. (2011) can be used to reduce the computational cost of the bottleneck to $O(P^3 + S_1^3)$. When sampling Ψ we also integrate over the distribution of Ω following the standard result from Equation (8). The reparameterization and the new posteriors are presented in the Supplementary material.

In brief, the trick is that the eigenvalue decomposition of a matrix of the form

$$C \otimes R + \sigma I \quad (17)$$

can be evaluated inexpensively. After reparameterizing the model in the proposed way the posterior covariance matrix of Ψ becomes of the form (17) and the eigenvalue decomposition can then be used to efficiently generate samples from the posterior distribution of Ψ . We note that the trick can also be applied to the original formulation of the Bayesian reduced-rank regression model by Geweke (1996) and the R-code published with this article allows generating samples from the original model as well. In the next Section, we compare the computational cost of the algorithm using the naive Gibbs sampler and the improved version that uses the new parameterization.

4.4 Sampling the maximum rank of the model

The sparse infinite factor analysis model presented by Bhattacharya and Dunson (2011) uses a certain adaptation procedure to update the maximum rank, i.e., the truncation point of their infinite-rank factor model. The idea is to update the maximum rank occasionally during the algorithm such that ranks having all elements of the corresponding projection vectors within some pre-specified distance from zero are removed from the model and, if none of the ranks has all elements within the threshold, another rank is added into the model. We have implemented a modification of this approach where we adapt the maximum rank of our infinite reduced rank regression model using a pre-specified cutoff for the amount of variance explained by the corresponding rank. With a slight abuse of terminology, we shall call this updating of the rank as sampling in the sequel.

5. Experiments

We start with a basic validation of the latent-noise BRRR model, and its relative merits over alternatives in a prediction task, using simulations with the ground truth available (Section 5.3), and a real-world omics dataset (Section 5.4). Section 5.5 analyses these results in more detail and identifies the characteristics of the proposed latent-noise BRRR model that are responsible for the performance differences observed, by considering the impact of each novel model aspect in isolation. Section (5.7) investigates another application domain, the detection of multivariate associations. In order to assess the prediction performance in more general, we analyse several additional real-world data sets from different domains in Section 5.8.

Different aspects of the inference algorithm are considered in three sub-sections: sampling vs. cross-validation of the rank and the latent signal-to-noise ratio (Section 5.6), speedup resulting from the proposed re-parameterization of the algorithm (Section 5.10),

and convergence diagnostics (Section 5.11). To assess the value of further extensions, Section 5.9 considers a model that includes both latent and independent structured noise simultaneously. Finally, Section 5.12 summarizes the findings on all real data sets.

5.1 Data sets

Experiments were performed on the following data sets:

NFBFC1966 [$N = 4702, P = 101, K = 96$, metabolomics prediction from SNPs] The NFBFC1966 data set comprises genome-wide SNP data along with metabolomics measurements for a cohort of 4,702 individuals (Rantakallio, 1969; Soininen et al., 2009). With these data, 96 metabolites belonging to the subclasses VLIDL, IDL, LDL and HDL (Houye et al., 2012) were used as the target variables and SNPs known to be associated with lipid metabolism (Teslovich et al., 2010; Ketunen et al., 2012; Global Lipids Genetics Consortium, 2013) were used as the covariates. Effects of age, sex, and lipid lowering medication were regressed out from the metabolomics data as a preprocessing step. For the genotype data, SNPs with low minor allele frequency (<0.01) were removed as a preprocessing step. For this data set, the comparison method GFLasso required excessive training time and we used 5-fold cross-validation to evaluate test set performances. Where cross-validation was needed for selecting model parameter values, the validation data performance was measured as an average over 3 validation sets, each comprising $\frac{1}{10}$ of the training samples.

DILGOM [$N = 509, P = 65, K = 18 \dots 137$, metabolomics and gene expression prediction from SNPs] The DILGOM data set (Houye et al., 2010) consists of genome-wide SNP data along with metabolomics and gene expression measurements. For details concerning metabolomics and gene expression data collection, see Soininen et al. (2009) and Ketunen et al. (2012). In total 509 individuals had all three measurement types. The DILGOM metabolomics data comprises 137 metabolites, most of which represent NMR-quantified levels of lipoproteins classified into 4 subclasses (VLIDL, IDL, LDL, HDL), together with quantified levels of amino acids, some serum extracts, and a set of quantities derived as ratios of the aforementioned metabolites. All 137 metabolites were used simultaneously as prediction targets. In gene expression prediction, in total 387 probes corresponding to curated gene sets of 8 KEGG lipid metabolism pathways were used as the prediction targets. A separate model was learnt for each pathway. The average number of probes in a pathway was 48. For details about the pathways, see the Supplementary material. On these data sets, 10-fold cross-validation was used to evaluate test set performances. To select values of the parameters that required evaluation on validation data, the training data was then further divided into 9 folds, on which cross-validation was performed to select parameters according to averaged validation set performance.

fMRI [$N = 1307, P = 776, K = 250$, fMRI response prediction from text stimuli] The cognitive neuroscience data set (Wehbe et al., 2014) consists of a time series of fMRI measurements from 8 subjects reading a chapter from ‘‘Harry Potter and the Sorcerers Stone’’ using *Rapid Serial Visual Presentation*: words of the text are presented one by one in the center of a screen. Brain voxel activations were measured

every 2 seconds. The 250 most accurately predictable voxels (see Supplementary material of Wehbe et al., 2014) of the fMRI measurements were used as prediction targets. The fMRI measurements from all patients were predicted simultaneously from features of the words being shown, such as semantic and syntactic properties, visual properties and discourse level features. The data were divided into 10 folds, only two of which were used to measure test data performance. This computational compromise was needed as the preprocessing (Wehbe et al., 2014) for each fold required about 10,000 hours of computation. To select the values of parameters that required evaluation on validation data, the training data were further divided into 10 folds, on which cross-validation was performed to select parameters according to averaged validation set performance.

econ [$N = 120, P = 52, K = 52$, macroeconomic time series prediction] The macroeconomic time series data set (Stock and Watson, 2006) consists of monthly values of 52 macroeconomic indicators. Prediction performance of these values from their earlier values was measured with different lags (1 month, 2 months, etc.). The data were processed as described by Carriero et al. (2011). Data for each month were used as a test set (395 test sets) while using data from the previous 10 years for training. Where cross-validation was needed for learning the values of model parameters, data from the last 2 years before the month-to-be-predicted were used for validation and data from the previous 8 years for training.

5.2 Methods included in comparison

We compared the latent-noise BRRR with a state-of-the-art sparse multiple-output regression method Graph-guided Fused Lasso (GFlasso) (Kim and Xing, 2009), BRRR/factor regression model (Marttinen et al., 2014) with and without the *a priori* independent noise model ('independent-noise BRRR', 'BRRR without noise model'), standard Bayesian linear model ('blm') (Gelman et al., 2004), standard ridge regression ('ridge regression') (Hoerl and Kennard, 1970), elastic-net-penalized multi-task learning (L2/L1 MTL), kernel regression with linear and Gaussian kernels combined with a process for removing confounding factors (Stegle et al., 2012) ('KRR with linear kernel + PEER', 'KRR with Gaussian kernel + PEER') and a baseline method of predicting with target data mean. GFlasso constitutes a suitable comparison as it encourages sharing of information between correlated responses, as our model, but does that within the Lasso-type penalized regression framework without the use of a noise model to explain away the structured noise. L2/L1 MTL is a multitask regression method implemented in the `glmnet` package (Friedman et al., 2010) that allows elastic net regularization. It does not use a noise model to explain away confounders either. The blm method and ridge regression were selected as a simple single-task baselines.

In one of the experiments, on an association study, latent-noise BRRR is compared with independent-noise BRRR and canonical correlation analysis ('cca'), considered the state-of-the-art methods for the detection of multivariate associations (Marttinen et al., 2013, 2014). Additionally, the simple univariate linear model ('lm') is included as it represents the common baseline in association analysis.

We compare latent-noise BRRR also with two other new models for structured noise modeling. In the simulations, we study the performance of correlated Bayesian reduced

rank regression ('correlated BRRR'), which is presented in more detail in the Supplementary material. In brief, in the correlated BRRR, the correlation structure of the target variables learnt by an *a priori* independent noise model is used as a prior for the regression weight parameters. With the NFBC1966 data and the macroeconomic time series data sets, we also study the performance of the method presented in Equation (10) in Section 3.3 that explicitly models both latent and independent structured noise, abbreviated as 'latent+independent-noise BRRR'.

Parameters for the different methods were specified as follows:

GFlasso: The regularization parameters of the `gw2` model were selected from the default grid using cross-validation. The method has been developed for genomic data indicating the default values should be appropriate. However, for NFBC1966 data, we were unable to run the method with the smallest values of the regularization parameters {110, 60, 10} due to lengthy runtime with these values. With this computational compromise of leaving out these three values, the average training time for the largest training data sets was ~ 650 h. With NFBC1966 data, the pre-specified correlation network required by the GFlasso was constructed to match the VLDL, IDL, LDL, and HDL metabolite clusters from Inouye et al. (2012). Within these clusters, the correlation network was fixed to the empirical correlations, and to 0 otherwise. With DILGOM data, we used the empirical correlation network, with correlations below 0.8 fixed to 0 to reduce the number of edges in the network for computational speedup.

independent-noise BRRR, BRRR without noise model: Hyperparameters α_1 and α_2 of all the BRRR models were fixed to 10 and 4, respectively. In total 1,000 MCMC samples were generated and 500 were discarded as burn-in. In preliminary tests similar results were obtained with 50,000 samples. The remaining samples, thinned by a factor of 10, were used for prediction. The maximum rank of the infinite-rank BRRR model was learned using cross-validation from the set of values {5, 10, 15} for the NFBC1966 data set, {2, 4, 8} for the metabolomics prediction task on the DILGOM data set and {2, 5, 10, 20} for the gene expression prediction task on the DILGOM data set. These grids were selected based on initial experiments. For the fMRI response prediction, the possible values for the maximal rank were limited to {2, 4} in order to save computational time. For the econometrics data set, maximum ranks of {5, 10, 20} were used. In the association detection task, the rank of independent noise BRRR was fixed to 1 as this was already sufficient for the task.

latent-noise BRRR: With the NFBC1966 data, the latent signal-to-noise ratio β was selected using cross-validation from a range of values from 100 to $\frac{1}{100}$, $\beta = \{100, 10, 2, 1, \frac{1}{7.5}, \frac{1}{15}, \frac{1}{30}, \frac{1}{60}, \frac{1}{100}\}$, in order to thoroughly evaluate the sensitivity of the model to this parameter. For the other data sets and tasks, the sets of values were as follows: DILGOM metabolomics prediction: $\beta = \{10, 2, 1, \frac{1}{7.5}, \frac{1}{15}, \frac{1}{30}, \frac{1}{60}, \frac{1}{100}\}$, DILGOM gene expression prediction $\beta = \{10, 1, \frac{1}{2}, \frac{1}{10}, \frac{1}{30}, \frac{1}{50}, \frac{1}{100}, \frac{1}{300}\}$ and for macroeconomic time series prediction $\beta = \{10, 2, 1, \frac{1}{7.5}, \frac{1}{15}, \frac{1}{30}, \frac{1}{60}, \frac{1}{100}\}$. For fMRI response prediction, the set of values was limited to $\beta = \{10, 1, \frac{1}{10}\}$ to save computation time. Other parameters, including the number of iterations, were set as for the independent-noise BRRR. The performance of the model was evaluated both by sampling the

maximum rank and by learning it with cross-validation from the same range of values as with independent-noise BRRR. Shrinkage hyperparameters were set to non-informative values, $a_1 = 10$ and $a_2 = 4$, similarly to the corresponding parameters a_3 and a_4 of independent-noise BRRR.

blm: The variance hyperparameter of BLM was integrated over using MCMC. The variance hyperparameter was assigned a Gamma prior with both shape and rate parameters set to 1. In total 1,000 posterior samples were generated and 500 were discarded as burn-in.

ridge regression: Ridge regression was used as implemented in the `glmnet` package with default parameters. The default convergence threshold parameters of `glmnet` were used and no warnings/numerical problems occurred.

L1/L2 MTL: The effects of different types of regularization penalties are an active research topic and we ran a continuum of mixtures of L1 and L2 penalties ranging from group lasso to ridge regression. The mixture parameter α controlling the balance between L1 and L2 regularization was evaluated on the grid $[0, 0.1, \dots, 0.9, 1.0]$ and selected using a 10-fold cross validation. The default convergence threshold parameters of `glmnet` were used and neither warnings nor numerical problems occurred.

KRR with linear kernel + PEER: First, the PEER software (Stegle et al., 2012) was used to remove the effects of confounders using 15 components. Then kernel ridge regression with a normalized linear kernel (Bishop et al., 2006) was applied using the residuals from PEER as the target variables. Kernel ridge regression was regularized according to the standard approach of adding parameter λ to the diagonal elements of the kernel. The value of λ was selected using cross-validation from a set of 10 values ranging from 0.1 to 100, $[10^{-1}, 10^{-0.66}, \dots, 10^{1.67}, 10^2]$. To share information between the different target variables, the approach of using the same kernel for all target variables was adopted.

KRR with Gaussian kernel + PEER: Kernel ridge regression using a Gaussian kernel was used. Regularization and the use of PEER were otherwise similar to KRR with linear kernel + PEER. The radius parameter of the Gaussian kernel was selected using cross-validation from a set of 30 values ranging from 0.001 to 1000, $[10^{-3}, 10^{-2.79}, \dots, 10^{2.79}, 10^3]$

cca: This is the conventional classical correlation analysis that attempts to identify linear combinations of the columns of the input and output matrices that are maximally correlated with each other.

correlated BRRR: Rank and hyperparameters a_1, a_2, a_3 and a_4 were set as with the independent-noise BRRR. This model is presented in detail in Supplementary Section 1.

latent+independent-noise BRRR: With the NFBG1966 data, the hyperparameters a_1, a_2, a_3 and a_4 were set as with the independent-noise BRRR. The latent signal-to-noise ratio β was selected using cross-validation from a range of values from 100 to $\frac{1}{100}$, $\beta = \{100, 10, 2, 1, \frac{1}{7.5}, \frac{1}{30}, \frac{1}{60}, \frac{1}{100}\}$ and the maximum rank was fixed to 10. For the econometrics data set, maximum ranks of $\{5, 10, 20\}$ were used and the signal-to-noise ratio β was selected using cross-validation from the values $\beta = \{10, 2, 1, \frac{1}{5}, \frac{1}{10}, \frac{1}{30}\}$. For both data sets, the variance parameter of the *a priori* independent noise H was selected from values $\{10^{-6}, 1\}$, value 10^{-6} corresponding to the extreme case of latent-noise BRRR.

5.3 Simulation experiment: impact of the noise model assumptions

In this Section, we study the implications of different noise model assumptions. Performances of models with different noise model assumptions are measured on simulated data sets generated from a continuum of models between the two extremes of assuming either latent noise, or *a priori* independent regression and noise models. The synthetic data are generated according to

$$Y = (X\Psi + \alpha\Omega)\Gamma + (1 - \alpha)HA + E, \quad (18)$$

where $\text{vec}(E) \sim \mathcal{N}(0, I_{NK})$ and the parameter $\alpha \in [0, 1]$ defines the proportion of variance attributed to the latent noise versus independent noise. We study a continuum of problems using the values of parameter $\alpha = 0, 0.1, \dots, 1$. The parameters Γ and Λ are orthogonalized using Gram-Schmidt orthogonalization. The parameters are scaled so that covariates X explain 3 % of the variance of Y through $X\Psi\Gamma$, the diagonal Gaussian noise $\mathcal{N}(0, I_{NK})$ explains 20 % of the total variance of Y and the structured noise $\alpha\Omega + (1 - \alpha)HA$ explains the remaining 77 % of the total variance of Y . The simulation was repeated 100 times and training data sets of 500 and 2000 samples were generated for each replicate. To compare the methods, performance in mean squared error (MSE) of the models learned with each method was compared to that of the true model on a test set of 15 000 samples. The number of covariates was fixed to 30 and the number of dependent variables to 60. Rank of the regression coefficient matrix and structured noise was set to 3 when simulating the data sets.

For independent-noise BRRR, the rank of the regression coefficient parameters Ψ and Γ was fixed to the true value while the rank of the noise model was learnt from the data. For latent-noise BRRR, the performance of the model was evaluated both by fixing the rank of the regression coefficient matrix to its true value and by learning it from the data. The variance of Ω was selected using 10-fold cross-validation. The grid for latent signal-to-noise ratios β was $\beta = \frac{1}{5}$ to $\frac{1}{15}$, $\beta = \{\frac{1}{5}, \frac{1}{7.5}, \frac{1}{10}, \frac{1}{12.5}, \frac{1}{15}\}$. More specifically, $\text{Var}(\text{vec}(\Omega)) = \sigma_{\Omega}^2 I_{NK}$ where $\sigma_{\Omega}^2 = \frac{1}{2} \times \text{Trace}(\text{Var}(X))$. The grid was chosen according to the interpretation given in Section 3.2, it corresponds to assuming that the latent noise explains 5 to 15 times the variance explained by the covariates.

Figures 4 (a) and (b) present the results of a simulation study with training sets of 500 and 2000 samples, respectively. When the structured noise is generated according to the conventional assumption of independent signal and noise, the model making the independence assumption (i.e., the independent-noise BRRR) performs equally well to the true

model with both 500 and 2000 samples. However, when the assumption is violated and the proportion of latent noise increases, the performance of the independent-noise BRRR breaks down, whereas the latent-noise BRRR performs consistently well. The method that does not explain away the structured noise at all (BRRR without noise model) is always inferior to the null model with the training set of 500 samples. When the number of training samples is increased to 2000 and the noise is generated according to the latent-noise assumption, the model, however, outperforms even the independent-noise BRRR. Thus, having no noise model is in this case better than having the noise model based on the incorrect independence assumption, which emphasizes the importance of the assumptions on which the noise model is based. Interestingly, with $n=2000$ the BRRR without noise model is among the best performing methods whereas with $n=500$ it is clearly the worst, highlighting the fact that the smaller n gets, the more important the right assumptions become.

The latent-noise end of the continuum appears to be more difficult for the methods that do not account for the structured noise (blm, BRRR without noise model). This weak but consistent trend can be seen in Figure 4(a,b) where the difference between the oracle and these methods increases with the percentage of latent noise. This behaviour is, however, rather intuitive in terms of Equation (18); by rewriting

$$\begin{aligned} Y &= (X\Psi + \alpha\Omega)\Gamma + (1 - \alpha)HA + E, \\ &= X\Psi\Gamma + \alpha\Omega\Gamma + (1 - \alpha)HA + E \end{aligned}$$

it is obvious that as $\alpha \rightarrow 1$, the structured noise (coming from Ω and H) will with certainty be projected on the particular target variables that are affected by the covariates X . In other words, latent noise blurs exactly the relationships of interest, being very disruptive.

Figure 4 shows results also for an alternative novel model that shares information between the noise and regression models (correlated BRRR, see Supplementary material for a detailed description). The model includes a separate noise model for the structured noise, as in (1), but achieves the information sharing by assuming a joint prior for the noise and regression models. In detail, conditional on the noise model, the current residual correlation matrix between the response variables is used as a prior for the rows of Γ . This way the correlations between target variables are propagated into the corresponding regression weights; however, the strongest noise components are not automatically coupled with the strongest signal components. Notably, the performance of the correlated BRRR model is very similar to the regular BRRR model that does not have any dependence between the noise and signal components.

5.4 NFBC1966: metabolomics prediction

In this Section, the models accounting for latent noise are evaluated in terms of predictive performance on the NFBC1966 data with different training set sizes. Figure 5 presents the test data MSE for the different methods. With the larger training set sizes, latent-noise BRRR outperforms the other methods. With the smallest training data size, ridge regression and latent-noise BRRR perform equally outperforming all other methods. However, ridge regression is unable to improve its performance as the number of training data points increases, and with the larger training sets it is outperformed by the more complex methods.

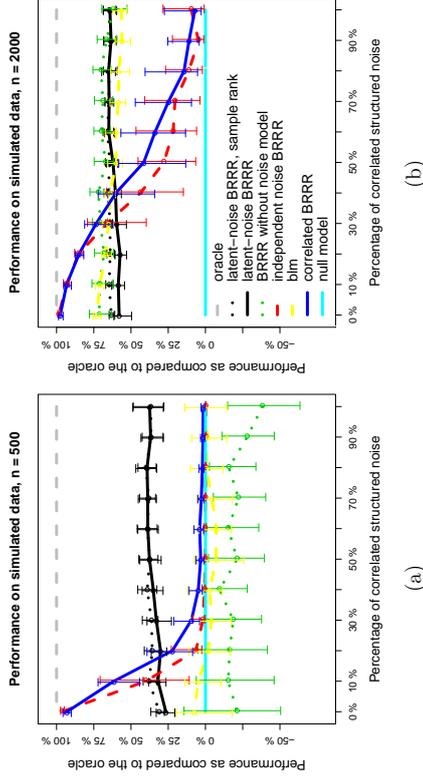

Figure 4: Performance of different methods, compared to the true model, as a function of the proportion of latent noise with a training set of (a) 500 and (b) 2000 samples. The x-axis indicates the proportion of noise generated according to the latent noise assumptions (100% corresponds to $\alpha = 1$). Bars denote ± 1 standard deviation, computed independently for each x-coordinate. The performance of 100% means the amount of variance explained by the model is equal to the amount explained by the true model. The performance of 0% means that the method does not explain any variance of the target variables, whereas negative values indicate the variance actually increases after taking the predictions into account.

Method blm performs worse than the baseline (null model, prediction with training set mean), even with the largest training data set containing 3761 individuals, and BRRR without noise model requires the largest training set size in order to outperform the baseline. A paired t-test for the performance difference between latent-noise BRRR and independent-noise BRRR yields a p-value of 0.03 suggesting a statistically significant difference.

5.5 Differences between latent-noise BRRR and independent-noise BRRR on NFBC1966 metabolomics prediction

The two differences between our new approach, latent-noise BRRR, and independent-noise BRRR are (1) model structure (latent-noise BRRR shares parameters between the regression and noise models) and (2) using the latent signal-to-noise ratio parameter β to regularize the model. In order to identify how these developments lead to the observed performance differences on the NFBC1966 data, we performed a sensitivity analysis for the two methods with respect to the assumed amount of variance attributed to the noise model.

Figure 6 presents the results of this sensitivity analysis. For latent-noise BRRR, the assumed variance of the noise model controlled by the *a priori* signal-to-noise ratio β affects

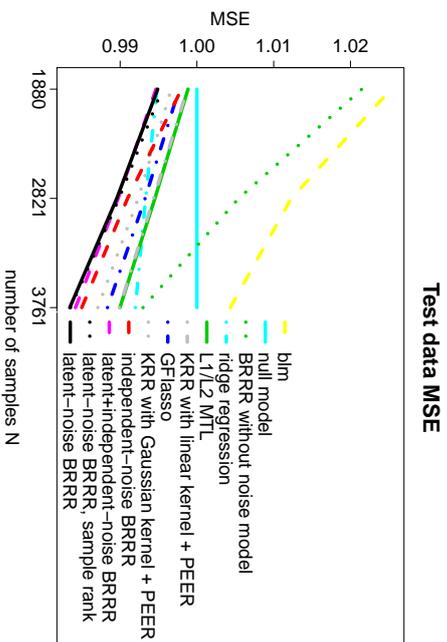

Figure 5: Test data MSE for different amounts of training data on the NFBG1966 metabolomics data. The MSEs have been scaled to give the null model a MSE of 1.

performance in a consistent way, whereas for independent-noise BRRR the impact appears random. If the performance difference stemmed mainly from controlling the variance of the noise model, controlling that parameter for both models should lead to similar results. On the other hand, if the difference in the model structure alone sufficed to explain the performance difference, the difference should not be sensitive to the variance of the noise model. Hence, we conclude that, on this data set, both the new model structure and regularization by using the latent signal-to-noise ratio are required for improved performance.

We also studied the variability of the estimated latent SNR on different folds. The optimal L-SNR was estimated very consistently; the results are presented in Supplementary Figure 3.

5.6 Evaluation of the chosen inference procedures for rank and noise parameters

Inference for the proposed model could naturally be done in several alternative ways. In this Section we justify the proposed inference procedure.

In the simulations (Section 5.3), sampling the maximum rank of the infinite prior worked well, measured in terms of predictive performance. Figure 4 shows that sampling the maximum rank actually improves performance, as compared to fixing it to the value used in the generative process, when the latent noise assumption is wrong (left end), both when $N = 500$ and when $N = 2000$. When the latent noise assumption holds (right end), the two

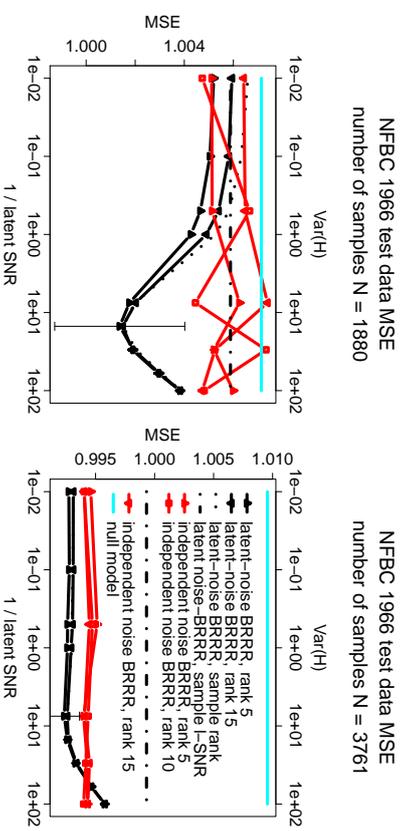

Figure 6: Sensitivity of latent-noise BRRR and independent-noise BRRR to the variance of the structured noise with different maximum ranks. The results are on NFBG1966 test data MSE ($N = 1880$ and $N = 3761$) as a function of the noise model variance. Lower axis: $a \text{ priori}$ latent signal-to-noise ratio of latent-noise BRRR. The upper axis: variance of the model parameter H of independent-noise BRRR. The bar denotes the standard deviation of the test set performance difference observed between the two models in cross-validation. The figures also present the unscaled performance of the null model and the performance of the latent-noise BRRR when using sampling to infer the latent signal-to-noise ratio (latent-noise BRRR, sample L-SNR) and when using sampling to infer the maximum rank (latent-noise BRRR, sample rank). When $N = 3761$, sampling the rank results in similar performance as obtained with the fixed values and thus the curves overlap.

inference procedures perform equally well. With the NFBG1966 data set (Figure 5), learning the maximum rank of the infinite prior by sampling (latent-noise BRRR, sample rank) or by cross-validation (latent-noise BRRR) results in very similar test set performances, similarly to in the simulation experiment in Section 5.3. Hence, we conclude that for learning the maximum rank, both sampling and cross-validation are appropriate techniques. We also ran the independent-noise BRRR so that the rank was sampled instead of selecting it using cross-validation on this data. However, the results were poor, with the test data MSE equal to 1.019 with $N = 1880$ and 1.005 with $N = 3761$. The lines were omitted for clarity. We hypothesize that the problems with the instability of the model (see Section 5.11) were accentuated when the rank was sampled.

The key parameter of our model, the latent signal-to-noise ratio, was estimated using cross-validation. In the simulations, the cross-validation based scheme allowed estimation of the latent signal-to-noise ratio to a reasonable accuracy. The estimated values are included in Figure 2 in the Supplementary material. While the latent signal-to-noise ratio of the

generative process was $\approx 1/25$, the estimated posterior latent signal-to-noise ratios ranged from $\frac{1}{14}$ to $\frac{1}{19}$ in the parts of the domain where the percentage of correlated structured noise was 100-80%. When the percentage of correlated structured noise was 0-10 %, the model correctly learnt lower variance for the latent noise and a corresponding stronger latent signal-to-noise ratio β .

We also studied the performance of latent-noise BRRR while sampling the variance of the noise model. A non-informative prior was assigned for the variance of Ω , $\Omega \sim \mathcal{N}(0, \sigma_\Omega^2)$ and $\sigma_\Omega^2 \sim \text{Gamma}(\text{shape} = 0.001, \text{rate} = 0.001)$. The performance of this model is presented in Figure 6. The performance of latent-noise BRRR when sampling the variance of Ω is consistently worse than when using cross-validation to select the value of the latent signal-to-noise ratio. Hence, we conclude that, as opposed to other parameters, cross-validation is needed to learn the latent-signal to ratio to reach the improved performance.

5.7 NFBC1966: multivariate association detection

Detection of associations between multiple SNPs and metabolites is a topic that has received attention recently (see, e.g., Kim et al., 2009; Inouye et al., 2012; Marttinen et al., 2014). Here we demonstrate the potential of the new method in this task using two illustrative example genes for which ground truth is available. Associations between SNPs within two genes, *LIPC* and *XRCC4*, and the metabolites in the NFBC1966 data are investigated in the experiment. Note that the covariates (SNPs) used in this experiment are different from the ones used in the prediction experiment: here SNPs in individual genes are used, whereas in the prediction experiment all known lipid-associated SNPs were used. *LIPC* was selected as a reference, because it is one of the most strongly lipid-associated genes. On the contrary, *XRCC4* was discovered only recently using three cohorts of individuals (Marttinen et al., 2014), and it was selected to serve as an example of a complex association detectable only by associating multiple SNPs with multiple metabolites, and not visible using simpler methods.

We use the proportion of total variance explained (PTVE) as the test score (Marttinen et al., 2014), and sample 100 permutations to measure the power to detect the associations. Furthermore, we use downsampling to evaluate the impact of the amount of training data. For comparison, we select the BRRR, the exhaustive pairwise (univariate) linear regression ('lm'), and canonical correlation analysis (CCA) (Ferreira and Purcell, 2009), these being the methods that have been proposed for the task and having a sensible runtime in putative genome-wide applications. For lm, the minimum p-value of the regression coefficient over all SNP-metabolite pairs, and for the CCA, the minimum p-value over all SNPs (each SNP associated with all metabolites jointly) are used as the test scores. The association involving the *XRCC4* gene was originally detected using the BRRR model; however, unlike here, informative priors were used for the regression coefficients.

Table 1 presents the ranking of the original data among the permuted data with different sample sizes and methods. Ten MCMC chains were computed for both models to account for sampling variability on this difficult and relatively strongly collinear data. The association score was obtained by averaging over the scores for different chains. As expected, all methods were able to detect the association involving *LIPC* with both training set sizes. However, latent-noise BRRR had the highest power to detect the *XRCC4* gene.

Table 1: Power of different methods to detect the association between metabolomics profiles and *XRCC4* or *LIPC* genes with $N = 4702$ and $N = 2351$ samples. Power is measured as the proportion of association test scores in permuted data sets smaller than the test score in the original data set. Value 1 indicates that the association score of the unpermuted data was higher than the score in any permutation.

	<i>XRCC4</i>		<i>LIPC</i>	
	$N = 4702$	$N = 2351$	$N = 4702$	$N = 2351$
latent-noise BRRR	0.98	0.94	1	1.00
independent-noise BRRR	0.41	0.32	1	0.99
lm	0.62	0.74	1	1.00
cca	0.20	0.24	1	1.00

5.8 Results: other real-world data sets

To thoroughly study the empirical value of the new method, we compared it to alternative methods on macroeconomic time series prediction, metabolomics and gene expression prediction experiments on the DILGOM data set and the fMRI response prediction. In these domains, explaining away structured noise is of crucial importance.

With the DILGOM data, the prediction of the weak effects was challenging for all methods. Indeed, we noticed that the null model using the average training data value for prediction was better than any other method in terms of MSE over all target variables with the single exception of L1/L2 MTL, which set all regression coefficients to zero thus reducing to the null model. However, a detailed investigation of the results revealed that while many of the target variables could not be predicted at all (as indicated by the worse than null model MSE) some of the target variables could still be predicted better than the null model, and by focusing the analysis on the MSE computed over the predictable target variables (*i.e.*, those that could be predicted better than the null by at least one method), comparisons regarding the model performances could still be made. For consistency, both metrics were computed also with the fMRI and econometrics data sets. To save computation time, we chose to evaluate only the cross-validation based variant of our model for the fMRI data, as this approach had already been identified as the most promising implementation of our method.

Table 2 and supplementary Table 1 present the results of the macroeconomic time series prediction experiment, metabolomics and gene expression prediction experiments on the DILGOM data set and the fMRI response prediction experiments. The results have been normalized so that the score for the null model (prediction using the mean) is 1. Table 2 presents the results for the predictable target variables and supplementary Table 1 presents the results obtained by averaging test data MSE over all target variables.

Latent-noise BRRR outperforms independent-noise BRRR consistently on the gene expression (on 8/10 folds), metabolomics (10/10 folds) and fMRI response prediction (2/2 folds) tasks on both scores. In the fMRI response prediction, the latent-noise BRRR and L1/L2 MTL are the only methods that outperform the null model. With the DILGOM data none of the methods outperformed the null model when averaged over all target variables and when concentrating on the predictable target variables, only the latent-noise BRRR and

KRR with Gaussian kernel were able to outperform the null model. With gene expression prediction, latent noise BRRR (sample rank), GFlasso and the kernel methods outperform the null model, latent-noise BRRR being the best. The economics data is the only case in which the independent-noise BRRR is more accurate than the latent-noise BRRR on both metrics, and the latent-noise BRRR is the third best method. In this data set, however, the effects appear rather strong as different methods explain up to 10-32% of the variance of the target variables and the best method is, in fact, ridge regression.

On the small DLGOM data sets, L1/L2 MTL sets all regression weights to zero as hypothesized in Section 3.2. This demonstrates the need to develop new alternatives to L1/L2 regularization: when modeling weak effects on small data sets, using L1/L2 penalties can prevent analysis altogether. Ridge regression appears to suffer from the same problem on the NFBC data set: although shrinking weights towards zero efficiently avoids overfitting, the model is only able to learn the strongest effects. Thus ridge regression outperforms most methods on the smallest training set (where the complex methods easily overfit), but heavily loses as the training set increases and the more complex methods become able to also benefit from the weak effects. Regularization by making the noise model stronger as in latent-noise BRRR avoids this problem.

The standard method blm performs surprisingly poorly especially as compared to ridge regression. The implementation was checked carefully. Predictive performance with the standard least squares linear model was also evaluated for some of the data sets (results not shown) and we found that it performed even worse than the blm. We hypothesize that the collinearity present in all of the data sets analyzed harmed the performance of blm and lm more than that of ridge regression.

5.9 Results: simultaneous modeling of both latent and independent structured noise

As both latent and independent structured noise can be present simultaneously, we evaluated the possible gains from taking both noise types simultaneously into account. A model that incorporates both latent and independent structured noise, here called latent+independent-noise BRRR, was evaluated for the metabolomics prediction task on the NFBC1966 data and on the macroeconomic time series prediction task, the strong domains of the methods of interest.

Results of this experiment are presented in Table 3. In metabolomics prediction, accounting for both noise types improved results slightly on the smallest training data size as compared to the best performing method latent-noise BRRR. On the larger training data sets, the more flexible latent+independent-noise BRRR model performed worse than the latent-noise BRRR that only accounts for latent noise. On the macroeconomic time series prediction task, accounting for both noise types improved performance as compared to only accounting for the dominant noise type (independent structured noise) on the smaller training data set. For summary, even though slight performance improvements were seen with the smallest training set sizes, the results indicate that as the size of the training data set increases, the advantages disappear. We hypothesize that the potential under-identifiability issues discussed in Section 3.3 hinder model performance more than the increased flexibility improves it.

	economics	DLGOM: gene expression	DLGOM: metabolomics	FMRI

5.10 Improvement in computational efficiency resulting from the reparameterization of model

To confirm the computational speed-up resulting from the reparameterization presented in Section 4, we performed an experiment where the algorithm implementing the naive

	NFBC $N = 3761$	NFBC $N = 1880$	econometrics $N = 120$	econometrics $N = 60$
latent-noise BRRR	0.9833±0.0077	0.9949±0.0037	0.7536±0.2143	0.8374±0.1816
latent+independent- noise BRRR	0.9840±0.0072	0.9947±0.0019	0.7445±0.1918	0.7889±0.1561
independent- noise BRRR	0.9849±0.0078	0.9980±0.0059	0.7339±0.1977	0.8097±0.2085

Table 3: Performance of the most flexible modeling assumptions. Test data MSE on the NFBC and econometrics data sets. On the larger training data sets, latent-noise BRRR and independent noise BRRR outperform the model that accounts for both noise types, latent+independent-noise BRRR. On the smaller training data sets, however, this model outperforms the models that only account for one noise type.

Gibbs sampling updates for the Bayesian reduced-rank regression (Geweke, 1996; Karlsson, 2012) was compared with the new algorithm that uses the reparameterization. Similar improvements were achieved with all other BRRR models as well.

Ten simulated data replicates were generated from the prior. The number of samples in the training set was fixed to 5000 and the number of target variables was set to 12. Rank of the regression coefficient matrix was 2. Runtime was measured as a function of the number of covariates, which was varied from 100 to 300; 1000 posterior samples were generated. The new algorithm that reparameterizes the model clearly outperformed the naïve Gibbs sampler (Figure 7). As a sanity check, the regression coefficient matrices estimated by the algorithms were compared, and found to be similar.

5.11 Efficiency of the algorithm

To investigate the efficiency of the proposed algorithm and to compare it with the alternative methods, we recorded the wall-clock run times with the NFBC1966 data set, shown in Figure 8. In addition, we studied the conventional convergence diagnostics. To assess convergence and mixing, we re-computed four MCMC chains of 2000 posterior samples each, for each of the BRRR methods. Averaged effective sample sizes (ESS) and potential scale reduction factors (PSRF) were computed for 200 randomly selected parameters of the regression coefficient matrix (Gelman et al., 2004). These results are presented in Table 4.

All BRRR methods, except for independent-noise BRRR, converge (PSRF < 1.1) and mix acceptably efficiently ($\frac{N_{\text{effective}}}{N_{\text{samples}}} \approx \frac{40}{1000}$). Independent noise BRRR, however, showed poor mixing and convergence. In initial experiments we observed that the PSRF for the independent-noise BRRR did not necessarily ever reach values indicating convergence even when sampled for 15,000 iterations. Thus, we decided to simply use the same number of MCMC iterations for each method in our experiments. The reason for the bad behaviour was the multimodality of the posterior distribution, caused by the too flexible model structure of the independent noise model, and the resulting convergence of the different chains into different modes.

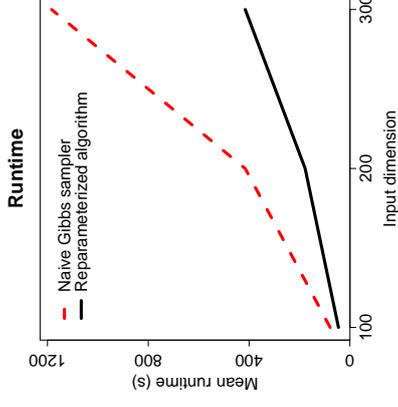

Figure 7: Runtime of the algorithm implementing the naïve Gibbs sampler with computational complexity and the new algorithm that reparameterizes the model. The naïve algorithm has a computational complexity of $O(P^3S_1^3)$ and the new algorithm $O(P^3 + S_1^3)$. Random variation over the repetitions was minimal and the error bars were omitted for clarity.

	independent-noise BRRR	BRRR without noise model	latent-noise BRRR	latent-noise BRRR, sample rank
1000 samples	4.46 ± 0.32	1.03 ± 0.03	1.06 ± 0.05	1.01 ± 0.004
2000 samples	3.42 ± 0.18	1.02 ± 0.02	1.05 ± 0.05	1.01 ± 0.003

Table 4: Averaged PSRF.

To further demonstrate the difference between the latent-noise and independent-noise BRRR methods, we visualized the MCMC trace of the association metric used in Section 5.7. The instability of independent-noise BRRR is strikingly visible in Figure 9. The chains converge to different modes and mix very slowly. On the other hand, the latent-noise BRRR appears to mix adequately and always converges to the same mode, except for one of the ten chains with the XRCC4 gene, which converges to a mode with a lower value of the explained variance.

5.12 Results: summary of the results with the real data sets

To provide an overview of the performances of the different methods on the various data sets and tasks, the methods' performances were ranked for each task/data set. For the prediction tasks, methods were ranked according to the MSE on the test set. When none of the methods outperformed the null model, the scores on the predictable target variables

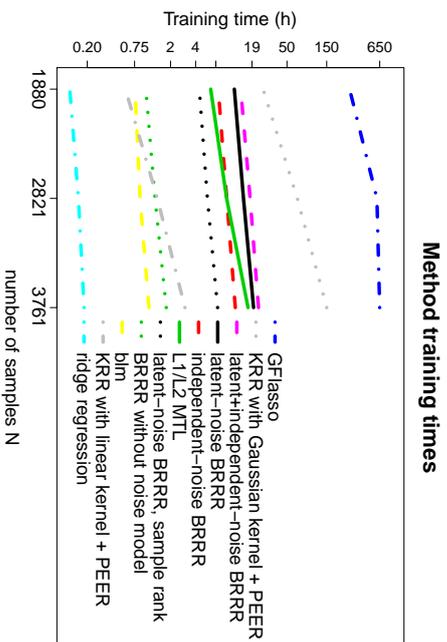

Figure 8: Computation times of the methods for different training set sizes N on the NFBG1966 metabolomics data.

	independent-noise BRRR	BRRR without noise model	latent-noise BRRR	latent-noise BRRR, sample rank
1000 samples	4.32 ± 0.32	43.88 ± 0.93	44.83 ± 0.25	40.74 ± 1.18
2000 samples	5.15 ± 0.66	84.39 ± 1.61	86.40 ± 0.43	77.77 ± 1.25

Table 5: Effective sample sizes for the Bayesian reduced rank regression methods. Independent-noise BRRR mixes substantially worse than the other methods.

were compared instead. In the association detection task, estimated statistical power was used as the ranking criterion. Table 6 presents the overview results.

Averaged over all data sets and tasks, latent-noise BRRR outperforms the comparison methods. In particular, the latent-noise BRRR outperforms the independent-noise BRRR on all setups except for the macroeconomic time series prediction task, where independent-noise BRRR is the best method and the two variants of latent-noise BRRR follow. The difference between the latent-noise BRRR and the independent-noise BRRR is consistent, present on 4/5 test folds on the NFBG1966 metabolite prediction, 8/10 test folds on the DLGOM gene expression prediction, 10/10 test folds on DLGOM metabolite prediction and on 2/2 folds on the FMRI response prediction. On macroeconomic time series prediction, independent-noise BRRR is better on 218/395 test folds. In the association detection task the latent-noise BRRR has higher power with both training set sizes on the challenging XRCC4 gene (0.94 vs. 0.32 with $n=2,351$; 0.98 vs. 0.41 with $n=4,702$).

Simultaneously accounting for both latent and independent structured noise improves performance on the smallest training data sets considered in the macroeconomic time series prediction and metabolomics prediction (NFBG1966) as compared to accounting for only one type of noise. On the other hand, with the larger training set sizes, the models with just the dominant noise type present perform better than the model including both noise types simultaneously.

Selecting the rank for latent-noise BRRR by sampling or by cross-validation results in comparable performance. Average performance ranks for cross-validation based and sampling-based inferences are 2.5 and 3.5, respectively. For the NFBG1966 data set and gene expression prediction task on the DLGOM data set, cross-validation yields better performance. On metabolomics prediction on DLGOM and the macroeconomic time series prediction, on the other hand, the sampling-based approach works better. It is also intriguing that similarly to the simulations, the sampling based variant of the model works better with independent structured noise (macroeconomic time series prediction) than the cross-validation based approach.

Latent-noise BRRR outperforms the null model on all test cases except for the metabolomics prediction on the DLGOM data. Even on that data set, however, the variant of the model that samples the maximum rank of the infinite prior outperforms the null model. We hypothesize that the poor performance may have resulted from convergence to some inferior mode of the posterior distribution; this can happen to latent-noise BRRR (as demonstrated in Figure 9) although the sharing of information between the signal and noise models makes it substantially more stable than the independent-noise BRRR.

6. Discussion

In this work, we evaluated the performance of multiple-output regression with different assumptions for the structured noise. While most existing methods assume *a priori* independence of the interesting effects and the uninteresting structured noise, we started from the opposite assumption of strong dependence between the components of the model. This assumption may be deemed appropriate for instance with the molecular biological data sets often analyzed with such methods. Using simulations we demonstrated the harmfulness of the independence assumption when latent noise was present. In real data experiments the model assuming latent noise outperformed state-of-the-art methods in prediction of metabolite measurements from genotype (SNP) data and FMRI response prediction, and showed consistently good performance in the different domains. In an illustrative multivariate association detection task, the latent noise model had increased power to detect associations invisible to other methods. To better address the computational needs, we presented a new algorithm reducing the runtime considerably, and improving the scalability of the BRRR models as the number of variables increases. The prior distributions were parameterized in terms of the new concept of *latent signal-to-noise ratio*, which was a key ingredient for optimal model performance. In addition, the rotational unidentifiability of the model was solved using ordered infinite-dimensional shrinkage priors. We also demonstrated that the two modifications (model structure, regularization through the latent signal-to-noise ratio) made to the existing state-of-the-art noise modeling approach were both needed in order to reach the optimal performance.

Table 6: Summary: ranking of methods according to performance in each studied data set and task.

In real data both latent and independent structured noise can be present. We studied a model incorporating both types simultaneously, and, based on these results, we concluded that the possible gains in predictive power as compared to modeling only the dominant type of noise were not worthwhile. In fact, results were also found to degrade when both noise types were included, which we hypothesize to be the result of poor identifiability of the corresponding model.

The new model implementing the concept of latent noise was studied using high-dimensional data containing weak signal (weak effects). The new model exploits a ubiquitous character-

istic of such data: while the interesting effects are weak, the noise is strong. Latent-noise BRRR borrows statistical strength from the noise model so as to alleviate learning of the weak effects, by automatically enforcing the regression coefficients on correlated target variables to be correlated. This intuitive characteristic can be seen as a counterpart of the powered correlation priors (Krishna et al., 2009) in the target variable space: Krishna et al. used the correlation structure of the covariates as a prior for the regression weights to enforce correlated covariates to have correlated weights.

The latent-noise BRRR is an extension of several common model families. By removing the covariates, the model reduces to a standard factor analysis model, which explains the output data with underlying factors. Thus, the latent-noise BRRR can be seen as a reversed analogy of PCA regression (West, 2003), in which components of the input space are used as covariates in prediction; in latent-noise BRRR components derived from the output space are predicted using the covariates (see Bo and Sminchisescu, 2009). Allowing the noise term to affect the latent space directly results in interesting connections to *linear mixed models* (LMMs) and *best linear unbiased prediction* (BLUP) (Robinson, 1991); using the latent noise formulation, the model can explain away bias in the residuals as in BLUP. On the other hand, LMMs have a random term for each sample and target variable. While LMMs are not computationally feasible to generalize for high-dimensional targets due to the NK random effect parameters and the associated inversion of an $NK \times NK$ covariance matrix, the latent-noise BRRR can be seen as a low-rank generalization of LMMs for high-dimensional target variables: the covariates are used for prediction in the latent space and in this space there is a noise term for each sample and dimension. Therefore, the number of random effect parameters stays at NS_1 and inference remains tractable.

In summary, our findings extend the existing literature on modeling structured noise in an important way by showing that structured noise can, and should, be taken advantage of when learning the interesting effects between the covariates and the target variables, and how this can be done. Code in R for the new method is available for download at <http://research.cs.aalto.fi/pml/software/latentNoise/>.

Abstract

The Dantzig selector has received popularity for many applications such as compressed sensing and sparse modeling, thanks to its computational efficiency as a linear programming problem and its nice sampling properties. Existing results show that it can recover sparse signals mimicking the accuracy of the ideal procedure, up to a logarithmic factor of the dimensionality. Such a factor has been shown to hold for many regularization methods. An important question is whether this factor can be reduced to a logarithmic factor of the sample size in ultra-high dimensions under mild regularity conditions. To provide an affirmative answer, in this paper we suggest the constrained Dantzig selector, which has more flexible constraints and parameter space. We prove that the suggested method can achieve convergence rates within a logarithmic factor of the sample size of the oracle rates and improved sparsity, under a fairly weak assumption on the signal strength. Such improvement is significant in ultra-high dimensions. This method can be implemented efficiently through sequential linear programming. Numerical studies confirm that the sample size needed for a certain level of accuracy in these problems can be much reduced.

Keywords: Sparse Modeling, Compressed Sensing, Ultra-high Dimensionality, Dantzig Selector, Regularization Methods, Finite Sample

1. Introduction

Due to the advances of technologies, big data problems appear increasingly common in the domains of molecular biology, machine learning, and economics. It is appealing to design procedures that can provide a recovery of important signals, among a pool of potentially huge number of signals, to a desired level of accuracy. As a powerful tool for producing interpretable models, sparse modeling via regularization has gained popularity for analyzing large-scale data sets. A common feature of the theories for many regularization methods is that the rates of convergence under the prediction or estimation loss usually involve the logarithmic factor of the dimensionality $\log p$; see, for example, Bickel et al. (2009), van de Geer et al. (2011), and Fan and Lv (2013), among many others. From the asymptotic point of view, such a factor may be negligible or insignificant when p is not too large. It can, however, become no longer negligible or even significant in finite samples with large dimensionality, particularly when a relatively small sample size is considered or preferred. In such cases, the recovered signals and sparse models may tend to be noisy. Another consequence of this effect is that many noise variables tend to appear together with recovered important ones (Candès et al., 2008). An important and interesting question is whether such a factor can be reduced, say, to a logarithmic factor of the sample size $\log n$, from ultra-high dimensions under mild regularity conditions.

In high-dimensional variable selection, there is a fast growing literature for different kinds of regularization methods with well established rates of convergence under the estimation and prediction losses. For instance, Candès and Tao (2007) proposed the L_1 -regularization approach of the Dantzig selector by relaxing the normal equation to allow for correlation between the residual vector and all the variables, which can recover sparse signals as accurately as the ideal procedure, knowing the true underlying sparse model, up to a logarithmic factor $\log p$. Later, Bickel et al. (2009) showed that the popularly used Lasso estimator (Tibshirani, 1996) exhibits similar behavior as the Dantzig selector with a $\log p$ factor in the oracle inequalities for the prediction risk and bounds on the estimation losses in general nonparametric regression models. Furthermore, it has been proved in Raskutti et al. (2011) that the minimax rates of convergence for estimating the true coefficient vector in the high-dimensional linear regression model involve a logarithmic factor $\log p$ in the L_2 -loss and prediction loss, under some regularity conditions on the design matrix. Other work for desired properties such as the oracle property on the L_1 and more general regularization includes Fan and Li (2001), Fan and Peng (2004), Zou and Hastie (2005), Zou (2006), van de Geer (2008), Lv and Fan (2009), Antoniadis et al. (2010), Städler et al. (2010), Fan and Lv (2011), Negahban et al. (2012), Chen et al. (2013), and Fan and Tang (2013), among many others.

A typical way for reducing the logarithmic factor $\log p$ to $\log n$ is through model selection consistency, where the estimator selects exactly the support of the true coefficient vector, that is, the set of variables with nonzero coefficients. We refer the reader to Zhao and Yu (2006), Wainwright (2009), Zhang (2010), and Zhang (2011) for analysis of model selection consistency of regularization methods. Since the true parameters are assumed to be sparse in the high-dimensional setting, consistent variable selection can greatly lessen the analytical complexity from large dimensionality p to around oracle model size. Once model selection consistency is established for the estimator with significant probability, an analysis

constrained on that event will give a factor $\log n$ instead of $\log p$ in the rates of convergence under various estimation and prediction losses. However, to obtain model selection consistency it usually requires a uniform signal strength condition that the minimum magnitude of nonzero coefficients is at least of order $\{s(\log p)/n\}^{1/2}$ (Fan and Lv, 2013) and (Zheng et al., 2014), where s stands for the size of the low-dimensional parameter vector. We doubt the necessity of the model selection consistency and the uniform signal strength of order $\{s(\log p)/n\}^{1/2}$ for achieving the logarithmic factor $\log n$ in ultra-high dimensionality.

In this paper, we suggest the constrained Dantzig selector to study the rates of convergence with weaker signal strength assumption. The constrained Dantzig selector replaces the constraint Dantzig constraint on correlations between the variables and the residual vector by a more flexible one, and considers a constrained parameter space distinguishing between zero parameters and significantly nonzero parameters. The main contributions of this paper are threefold. First, the convergence rates for the constrained Dantzig selector are shown to be within a factor of $\log n$ of the oracle rates instead of $\log p$, a significant improvement in the case of ultra-high dimensionality and relatively small sample size. It is appealing that such an improvement is made with a fairly weak assumption on the signal strength without requiring model selection consistency. To the best of our knowledge, this assumption seems to be the weakest one in the literature of similar results; see, for example, Bickel et al. (2009) and Zheng et al. (2014). Two parallel theorems, under the uniform uncertainty principle condition and the restricted eigenvalue assumption, are established on the properties of the constrained Dantzig selector for compressed sensing and sparse modeling, respectively. Second, compared to the Dantzig selector, theoretical results of this paper show that the number of falsely discovered signs of our new selector, with an explicit inverse relationship to the signal strength, is controlled as a possibly asymptotically vanishing fraction of the true model size. Third, an active-set based algorithm is introduced to implement the constrained Dantzig selector efficiently. An appealing feature of this algorithm is that its convergence can be checked easily.

The rest of the paper is organized as follows. In Section 2, we introduce the constrained Dantzig selector. We present its compressed sensing and sampling properties in Section 3. In Section 4, we discuss the implementation of the method and present several simulation and real data examples. We provide some discussions of our results and some possible extensions of our method in Section 5. All technical details are relegated to the Appendix.

2. The Constrained Dantzig selector

To simplify the technical presentation, we adopt the model setting in Candès and Tao (2007) and present the main ideas focusing on the linear regression model

$$y = \mathbf{X}\beta + \epsilon, \quad (1)$$

where $y = (y_1, \dots, y_n)^T$ is an n -dimensional response vector, $\mathbf{X} = (\mathbf{X}_1, \dots, \mathbf{X}_p)$ is an $n \times p$ design matrix consisting of p covariate vectors \mathbf{x}_j^T 's, $\beta = (\beta_1, \dots, \beta_p)^T$ is a p -dimensional regression coefficient vector, and $\epsilon = (\epsilon_1, \dots, \epsilon_n)^T \sim N(\mathbf{0}, \sigma^2 \mathbf{I}_n)$ for some positive constant σ is an n -dimensional error vector independent of \mathbf{X} . The normality assumption is considered for simplicity, and all the results in the paper can be extended to the cases of bounded errors

or light-tailed error distributions without much difficulty. See, for example, the technical analysis in Fan and Lv (2011) and Fan and Lv (2013).

In both problems of compressed sensing and sparse modeling, we are interested in recovering the support and nonzero components of the true regression coefficient vector $\beta_0 = (\beta_{0,1}, \dots, \beta_{0,p})^T$, which we assume to be sparse with s nonzero components, for the case when the dimensionality p may greatly exceed the sample size n . Throughout this paper, p is implicitly understood as $\max\{n, p\}$ and $s \leq \min\{n, p\}$ to ensure model identifiability. To align the scale of all covariates, we assume that each column of \mathbf{X} , that is, each covariate vector \mathbf{x}_j , is rescaled to have L_2 -norm $n^{1/2}$, matching that of the constant covariate vector $\mathbf{1}$. The Dantzig selector (Candès and Tao, 2007) is defined as

$$\hat{\beta}_{\text{DS}} = \operatorname{argmin}_{\beta \in \mathbb{R}^p} \|\beta\|_1 \quad \text{subject to} \quad \|n^{-1}\mathbf{X}^T(y - \mathbf{X}\beta)\|_\infty \leq \lambda_1, \quad (2)$$

where $\lambda_1 \geq 0$ is a regularization parameter. The above constant Dantzig selector constraint on correlations between all covariates and the residual vector may not be flexible enough to differentiate important covariates and noise covariates. We introduce an extension of the Dantzig selector, the constrained Dantzig selector, defined as

$$\begin{aligned} \hat{\beta}_{\text{CDS}} = \operatorname{argmin}_{\beta \in \mathbb{R}^p} \quad & \|\beta\|_1 \\ \text{subject to} \quad & |n^{-1}\mathbf{x}_j^T(y - \mathbf{X}\beta)| \leq \lambda_0 \mathbf{1}_{\{|\beta_j| \geq \lambda\}} + \lambda_1 \mathbf{1}_{\{|\beta_j| = 0\}} \\ & \text{for } j = 1, \dots, p, \end{aligned} \quad (3)$$

where $\lambda_0 \geq 0$ is a regularization parameter and $\mathcal{B}_\lambda = \{\beta \in \mathbb{R}^p : \beta_j = 0 \text{ or } |\beta_j| \geq \lambda \text{ for each } j\}$ is the constrained parameter space for some $\lambda \geq 0$. When we choose $\lambda = 0$ and $\lambda_0 = \lambda_1$, the constrained Dantzig selector becomes the Dantzig selector. Throughout this paper, we choose the regularization parameters λ_0 and λ_1 as $c_0\{(\log n)/n\}^{1/2}$ and $c_1\{(\log p)/n\}^{1/2}$, respectively, with $\lambda_0 \leq \lambda_1$ as well as c_0 and c_1 two sufficiently large positive constants, and assume that λ is a parameter greater than λ_1 . The two parameters λ_0 and λ_1 differentially bound two types of correlations: on the support of the constrained Dantzig selector, the correlations between covariates and residuals are bounded, up to a common scale, by λ_0 ; on its complement, however, the correlations are bounded through λ_1 . In the ultra-high dimensional case, meaning $\log p = O(n^\alpha)$ for some $0 < \alpha < 1$, the constraints involving λ_0 are tighter than those involving λ_1 , in which λ_1 is a universal regularization parameter for the Dantzig selector; see Candès and Tao (2007) and Bickel et al. (2009).

We now provide more insights into the new constraints in the constrained Dantzig selector. First, it is worthwhile to notice that if $\beta_0 \in \mathcal{B}_\lambda$, β_0 can satisfy new constraints with large probability in model setting (1); see the proof of Theorem 1. With the tighter constraints, the feasible set of the constrained Dantzig selector problem is a subset of that of the Dantzig selector problem, resulting in a search of the solution in a reduced space. Second, it is appealing to extract more information in important covariates, leading to lower correlations between those variables and the residual vector. In this spirit, the constrained Dantzig selector puts tighter constraints on the correlations between selected variables and residuals. Third, the constrained Dantzig selector is defined on the constrained parameter space \mathcal{B}_λ , which has been introduced in Fan and Lv (2013). Such a space also shares some similarity to the union of coordinate subspaces considered in Fan and Lv (2011) for characterizing the restricted global optimality of nonconcave penalized likelihood estimators.

The threshold λ in \mathcal{B}_λ distinguishes between important covariates with strong effects and noise covariates with weak effects. As shown in Fan and Lv (2013), this feature can lead to improved sparsity and effectively prevent overfitting by making it harder for noise covariates to enter the model.

3. Main results

In this section, two parallel theoretical results are introduced based on the uniform uncertainty principle (UUP) condition and restricted eigenvalue assumption, respectively. Although the UUP condition may be relatively stringent in some applications, we still present one theorem for our method under this condition in Section 3.1 for the purpose of comparison with the original Dantzig selector.

3.1 Nonasymptotic compressed sensing properties

Since the Dantzig selector was introduced partly for applications in compressed sensing, we first study the nonasymptotic compressed sensing properties of the constrained Dantzig selector by adopting the theoretical framework in Candès and Tao (2007). They introduced the uniform uncertainty principle condition defined as follows. Denote by \mathbf{X}_T a submatrix of \mathbf{X} consisting of columns with indices in a set $T \subset \{1, \dots, p\}$. For the true model size s , define the s -restricted isometry constant of \mathbf{X} as the smallest constant δ_s such that

$$(1 - \delta_s) \|\mathbf{h}\|_2^2 \leq n^{-1} \|\mathbf{X}_T \mathbf{h}\|_2^2 \leq (1 + \delta_s) \|\mathbf{h}\|_2^2$$

for any set T with size at most s and any vector \mathbf{h} . This condition requires that each submatrix of \mathbf{X} with at most s columns behaves similarly as an orthonormal system. Another constant, the s -restricted orthogonality constant, is defined as the smallest quantity $\theta_{s,2s}$ such that

$$n^{-1} |(\mathbf{X}_T \mathbf{h}, \mathbf{X}_{T'} \mathbf{h}')| \leq \theta_{s,2s} \|\mathbf{h}\|_2 \|\mathbf{h}'\|_2$$

for all pairs of disjoint sets $T, T' \subset \{1, \dots, p\}$ with $|T| \leq s$ and $|T'| \leq 2s$ and any vectors \mathbf{h}, \mathbf{h}' . The uniform uncertainty principle condition is simply stated as

$$\delta_s + \theta_{s,2s} < 1. \quad (4)$$

For notational simplicity, we drop the subscripts and denote these two constants by δ and θ , respectively. Without loss of generality, assume that $\text{supp}(\beta_0) = \{1 \leq j \leq p : \beta_{0,j} \neq 0\} = \{1, \dots, s\}$ hereafter. To evaluate the sparse recovery accuracy, we consider the number of falsely discovered signs defined as $\text{FS}(\hat{\beta}) = |\{j = 1, \dots, p : \text{sgn}(\hat{\beta}_j) \neq \text{sgn}(\beta_{0,j})\}|$ for an estimator $\hat{\beta} = (\hat{\beta}_1, \dots, \hat{\beta}_p)^T$. Now we are ready to present the nonasymptotic compressed sensing properties of the constrained Dantzig selector.

Theorem 1 *Assume that the uniform uncertainty principle condition (4) holds and $\beta_0 \in \mathcal{B}_\lambda$ with $\lambda \geq C^{1/2}(1 + \lambda_1/\lambda_0)\lambda_1$ for some positive constant C . Then with probability at least*

$1 - O(n^{-c})$ for $c = (c_0^2 \wedge c_1^2)/(2\sigma^2) - 1$, the constrained Dantzig selector $\hat{\beta}$ satisfies that

$$\begin{aligned} \|\hat{\beta} - \beta_0\|_1 &\leq 2\sqrt{5}(1 - \delta - \theta)^{-1} c_0 s \sqrt{(\log n)/n}, \\ \|\hat{\beta} - \beta_0\|_2 &\leq \sqrt{5}(1 - \delta - \theta)^{-1} c_0 \sqrt{s(\log n)/n}, \\ \text{FS}(\hat{\beta}) &\leq C c_1^2 s (\log p) / (n \lambda^2). \end{aligned}$$

If in addition $\lambda > \sqrt{5}(1 - \delta - \theta)^{-1} c_0 \sqrt{s(\log n)/n}$, then with the same probability, it also holds that $\text{sgn}(\hat{\beta}) = \text{sgn}(\beta_0)$ and $\|\hat{\beta} - \beta_0\|_\infty \leq 2c_0 \|(n^{-1} \mathbf{X}_1^T \mathbf{X}_1)^{-1}\|_\infty \sqrt{(\log n)/n}$, where \mathbf{X}_1 is an $n \times s$ submatrix of \mathbf{X} corresponding to s nonzero $\beta_{0,j}$'s.

The constant c in the above probability bound can be sufficiently large since both constants c_0 and c_1 are assumed to be large, while the constant C comes from Theorem 1.1 in Candès and Tao (2007); see the proof in the Appendix for details. In the above bound on the L_∞ -estimation loss, it holds that $\|(n^{-1} \mathbf{X}_1^T \mathbf{X}_1)^{-1}\|_\infty \leq s^{1/2} \|(n^{-1} \mathbf{X}_1^T \mathbf{X}_1)^{-1}\|_2 \leq (1 - \delta)^{-1} s^{1/2}$. See Section 3.2 for more discussion on this quantity.

From Theorem 1, we see improvements of the constrained Dantzig selector over the Dantzig selector, which has a convergence rate, in terms of the L_2 -estimation loss, up to a factor $\log p$ of that for the ideal procedure. However, the sparsity property of the Dantzig selector was not investigated in Candès and Tao (2007). In contrast, the constrained Dantzig selector is shown to have an inverse quadratic relationship between the number of falsely discovered signs and the threshold λ , revealing that its model selection accuracy increases with the signal strength. The number of falsely discovered signs can be controlled below or as an asymptotically vanishing fraction of the true model size, since $\text{FS}(\hat{\beta}) \leq Cs(\lambda_1/\lambda)^2 \leq (1 + \lambda_1/\lambda)^{-2} s < s$ by assuming $\lambda > C^{1/2}(1 + \lambda_1/\lambda_0)\lambda_1$.

Another advantage of the constrained Dantzig selector lies in its convergence rates. In the case of ultra-high dimensionality which is typical in compressed sensing applications, its prediction and estimation losses can be reduced from the logarithmic factor $\log p$ to $\log n$ with overwhelming probability. In particular, only a fairly weak assumption on the signal strength is imposed to attain such improved convergence rates. In fact, it has been shown in Raskutti et al. (2011) that without any condition on the signal strength, the minimax convergence rate of L_2 risk has an upper bound of order $O\{s^{1/2}(\log p)/n\}$. Especially, they claimed that the Dantzig selector can achieve such minimax rate, but requires a relatively stronger condition on the design matrix than nonconvex optimization algorithms to determine the minimax upper bounds. We push a step forward that the constrained Dantzig selector, with additional signal strength conditions, can attain the L_2 -estimation loss of a smaller order than $O\{s^{1/2}(\log p)/n\}$ in ultra-high dimensions.

There exist other methods which have been shown to enjoy convergence rates of the same order as well, for example, in Zheng et al. (2014) for high-dimensional thresholded regression. However, these results usually rely on a stronger condition on signal strength, such as, the minimum signal strength is at least of order $\{s(\log p)/n\}^{1/2}$. In another work, Fan and Lv (2011) showed that the nonconcave penalized estimator can have a consistency rate of $O_p\{s^{1/2} n^{-\gamma} \log n\}$ for some $\gamma \in (0, 1/2]$ under the L_2 -estimation loss, which can be slower than our rate of convergence. More detailed discussion on the relationship between the faster rates of convergence and the assumptions on the signal strength and sparsity can be found in Section 3.2. A main implication of our improved convergence rates is that

a smaller number of observations will be needed for the constrained Dantzig selector to attain the same level of accuracy in compressed sensing, as the Dantzig selector, which is demonstrated in Section 4.2.

3.2 Sampling properties

The properties of the Dantzig selector have also been extensively investigated in Bickel et al. (2009). They introduced the restricted eigenvalue assumption with which the oracle inequalities under various prediction and estimation losses were derived. We adopt their theoretical framework and study the sampling properties of the constrained Dantzig selector under the restricted eigenvalue assumption stated below. A positive integer m is said to be in the same order of s if m/s can be bounded from both above and below by some positive constants.

Condition 1 For some positive integer m in the same order of s , there exists some positive constant κ such that $\|n^{-1/2}\mathbf{X}\boldsymbol{\delta}\|_2 \geq \kappa \max\{\|\boldsymbol{\delta}\|_{1/2}, \|\boldsymbol{\delta}'_1\|_2\}$ for all $\boldsymbol{\delta} \in \mathbb{R}^p$ satisfying $\|\boldsymbol{\delta}_2\|_1 \leq \|\boldsymbol{\delta}'_1\|_1$, where $\boldsymbol{\delta} = (\boldsymbol{\delta}'_1, \boldsymbol{\delta}'_2)^T$, $\boldsymbol{\delta}_1$ is a subvector of $\boldsymbol{\delta}$ consisting of the first s components, and $\boldsymbol{\delta}'_1$ is a subvector of $\boldsymbol{\delta}_2$ consisting of the $\max\{m, C_m s(\lambda_1/\lambda)^2\}$ largest components in magnitude, with C_m some positive constant.

Condition 1 is a basic assumption on the design matrix \mathbf{X} for deriving the oracle inequalities of the Dantzig selector. Since we assume that $\text{supp}(\boldsymbol{\beta}_0) = \{1, \dots, s\}$, Condition 1 indeed plays the same role as the restricted eigenvalue assumption $\text{RE}(s, m, 1)$ in Bickel et al. (2009), which assumes the inequality in Condition 1 holds for any subset with size no larger than s to cover all possibilities of $\text{supp}(\boldsymbol{\beta}_0)$. See (10) in the Appendix for insights into the basic inequality $\|\boldsymbol{\delta}_2\|_1 \leq \|\boldsymbol{\delta}'_1\|_1$ and Bickel et al. (2009) for more detailed discussions on this assumption.

Theorem 2 Assume that Condition 1 holds and $\boldsymbol{\beta}_0 \in \mathcal{B}_\lambda$ with $\lambda \geq C_m^{1/2}(1 + \lambda_1/\lambda_0)\lambda_1$. Then the constrained Dantzig selector $\widehat{\boldsymbol{\beta}}$ satisfies with the same probability as in Theorem 1 that

$$\begin{aligned} n^{-1/2}\|\mathbf{X}(\widehat{\boldsymbol{\beta}} - \boldsymbol{\beta}_0)\|_2 &= O(\kappa^{-1}\sqrt{s(\log n)/n}), & \|\widehat{\boldsymbol{\beta}} - \boldsymbol{\beta}_0\|_1 &= O(\kappa^{-2}s\sqrt{(\log n)/n}), \\ \|\widehat{\boldsymbol{\beta}} - \boldsymbol{\beta}_0\|_2 &= O(\kappa^{-2}\sqrt{s(\log n)/n}), & \text{FS}(\widehat{\boldsymbol{\beta}}) &\leq C_m c_1^2 s(\log \rho)/(n\lambda^2). \end{aligned}$$

If in addition $\lambda > 2\sqrt{5}\kappa^{-2}c_0s^{1/2}\sqrt{(\log n)/n}$, then with the same probability it also holds that $\text{sgn}(\widehat{\boldsymbol{\beta}}) = \text{sgn}(\boldsymbol{\beta}_0)$ and $\|\widehat{\boldsymbol{\beta}} - \boldsymbol{\beta}_0\|_\infty = O\{(n^{-1}\mathbf{X}_1^T\mathbf{X}_1)^{-1}\|_\infty\sqrt{(\log n)/n}$.

Theorem 2 establishes asymptotic results on the sparsity and oracle inequalities for the constrained Dantzig selector under the restricted eigenvalue assumption. This assumption, which is an alternative to the uniform uncertainty principle condition, has also been widely employed in high-dimensional settings. In Bickel et al. (2009), an approximate equivalence of the Lasso estimator (Tibshirani, 1996) and Dantzig selector was proved under this assumption, and the Lasso estimator was shown to be sparse with size $O(\phi_{\max}^s)$, where ϕ_{\max} is the largest eigenvalue of the Gram matrix $n^{-1}\mathbf{X}^T\mathbf{X}$. In contrast, the constrained Dantzig selector gives a sparser model under the restricted eigenvalue assumption, since its number

of falsely discovered signs $\text{FS}(\widehat{\boldsymbol{\beta}}) \leq C_m s(\lambda_1/\lambda)^2 = o(s)$ when $\lambda_1 = o(\lambda)$. Similar as in Theorem 1, the constrained Dantzig selector improves over both Lasso and the Dantzig selector in terms of convergence rates, a reduction of the log p factor to log n .

Let us now take a closer look at the relationship between the faster rates of convergence and the assumptions on the signal strength and sparsity. Observe that the enhanced consistency results require the minimum signal strength to be at least of order $(\log p)/\sqrt{n \log n}$, in view of the assumption $\lambda \geq C_m^{1/2}(1 + \lambda_1/\lambda_0)\lambda_1$. Assume for simplicity that $\|\boldsymbol{\beta}_0\|_2$ is bounded away from both zero and ∞ . Then the order of the minimum signal strength yields an upper bound on the sparsity level $s = O\{n(\log n)/(\log p)^2\}$, which means that the sparsity s is required to be smaller when the dimensionality p becomes larger. In the ultra-high dimensional setting of $\log p = O(n^\alpha)$ with $0 < \alpha < 1$, we then have $s = O(n^{1-2\alpha} \log n)$. Thus the classical convergence rates involving $s(\log p)/n = O(n^{-\alpha} \log n)$ still go to zero asymptotically, while the rates established in our paper are improved with $s(\log p)/n$ replaced by $s(\log n)/n = O\{n^{-2\alpha}(\log n)^2\}$. We see a gain on the convergence rate of a factor $n^\alpha/(\log n)$ at the cost of the aforementioned signal strength and sparsity assumptions.

One can see that results in Theorems 1 and 2 are approximately equivalent, while the latter presents an additional oracle inequality on the prediction loss. An interesting phenomenon is that if adopting a simpler version, that is, the Dantzig selector equipped with the thresholding constraint only, we can also obtain similar results as in Theorems 1 and 2, but with a stronger condition on signal strength such as $\lambda \gg s^{1/2}\lambda_1$. In this sense, the constrained Dantzig selector is also an extension of the Dantzig selector equipped with the thresholding constraint only, but enjoys better properties. Some comprehensive results on the prediction and variable selection properties have also been established in Fan and Lv (2013) for various regularization methods, revealing their asymptotic equivalence in the thresholded parameter space. However, as mentioned in Section 3.1, improved rates as in Theorem 2 commonly require a stronger assumption on the signal strength, which is $\boldsymbol{\beta}_0 \in \mathcal{B}_\lambda$ with $\lambda \gg s^{1/2}\lambda_1$; see, for example, Theorem 2 of Fan and Lv (2013).

For the quantity $\|(n^{-1}\mathbf{X}_1^T\mathbf{X}_1)^{-1}\|_\infty$ in the above bound on the L_∞ -estimation loss, if \mathbf{X}_1 takes the form of a common correlation matrix $(1 - \rho)\mathbf{I}_s + \rho\mathbf{1}_s\mathbf{1}_s^T$ for some $\rho \in [0, 1)$, it is easy to check that $\|(n^{-1}\mathbf{X}_1^T\mathbf{X}_1)^{-1}\|_\infty = (1 - \rho)^{-1}\{1 + (2s - 3)\rho\}/(1 + (s - 1)\rho)$, which is bounded regardless of the value of s .

3.3 Asymptotic properties of computable solutions

The nonasymptotic and sampling properties of the constrained Dantzig selector, as the global minimizer, have been established in Sections 3.1 and 3.2, respectively. However, it is not guaranteed that the global minimizer can be generated by a computational algorithm. Moreover, a computable solution, generated by any algorithm, may only be a local minimizer in many cases. Under certain regularity conditions, we demonstrate that the local minimizer of our method can still share the same nice asymptotic properties as the global one.

Theorem 3 Let $\widehat{\boldsymbol{\beta}}$ be a computable local minimizer of (3). Assume that there exist some positive constants c_2, κ_0 and sufficiently large positive constant c_3 such that $\|\widehat{\boldsymbol{\beta}}\|_0 \leq c_2s$ and $\min_{\|\boldsymbol{\delta}\|_2=1, \|\boldsymbol{\delta}'_0\|_{\leq c_3s}} n^{-1/2}\|\mathbf{X}\boldsymbol{\delta}\|_2 \geq \kappa_0$. Then under conditions of Theorem 2, $\widehat{\boldsymbol{\beta}}$ enjoys the same properties as the global minimizer in Theorem 2.

In Section 4.1, we introduce an efficient algorithm that gives us a local minimizer. Theorem 3 indicates that the obtained solution can also enjoy the asymptotic properties in Theorem 2 under the extra assumptions that $\widehat{\beta}$ is a sparse solution with the number of nonzero components comparable with s and the design matrix \mathbf{X} satisfies a sparse eigenvalue condition. Similar results for the computable solution can be found in Fan and Lv (2013, 2014), where the local minimizer is additionally assumed to satisfy certain constraint on the correlation between the residual vector and all the covariates.

4. Numerical studies

In this section, we first introduce an algorithm which can efficiently implement the constrained Dantzig selector. Then several simulation studies and two real data examples are presented to evaluate the performance of our method.

4.1 Implementation

The constrained Dantzig selector defined in (3) depends on tuning parameters λ_0 , λ_1 , and λ . We suggest some fixed values for λ_0 and λ to simplify the computation, since the proposed method is generally not that sensitive to λ_0 and λ as long as they fall in certain ranges. In simulation studies to be presented, a value around $\{(\log p)/n\}^{1/2}$ for λ and a smaller value for λ_0 , say $0.05\{(\log p)/n\}^{1/2}$ or $0.1\{(\log p)/n\}^{1/2}$, can provide us nice prediction and estimation results. The value of λ_0 is chosen to be smaller than $\{(\log p)/n\}^{1/2}$ to mitigate the selection of noise variables and facilitate sparse modeling. The performance of our method with respect to different values of λ_0 and λ is shown in simulation Example 2 in Section 4.2, which is a typical example that illustrates the robustness of the proposed method with respect to λ_0 and λ .

For fixed λ_0 and λ , we exploit the idea of sequential linear programming to produce the solution path of the constrained Dantzig selector as λ_1 varies. Choose a grid of values for the tuning parameter λ_1 in decreasing order with the first one being $\|n^{-1}\mathbf{X}^T\mathbf{y}\|_\infty$. It is easy to check that $\beta = \mathbf{0}$ satisfies all the constraints in (3) for $\lambda_1 = \|n^{-1}\mathbf{X}^T\mathbf{y}\|_\infty$, and thus the solution is $\widehat{\beta}_{\text{CNS}} = \mathbf{0}$ in this case. For each λ_1 in the grid, we use the solution from the previous one in the grid as an initial value to speed up the convergence. For a given λ_1 , we define an active set, iteratively update this set, and solve the constrained Dantzig selector problem. We name this algorithm as the CDS algorithm which is detailed in four steps below.

1. For a fixed λ_1 in the grid, denote by $\widehat{\beta}_{\lambda_1}^{(0)}$ the initial value. Let $\widehat{\beta}_{\lambda_1}^{(0)}$ be zero when $\lambda_1 = \|n^{-1}\mathbf{X}^T\mathbf{y}\|_\infty$, and the estimate from previous λ_1 in the grid otherwise.
2. Denote by $\widehat{\beta}_{\lambda_1}^{(k)}$ the estimate from the k th iteration. Define the active set \mathcal{A} as the support of $\widehat{\beta}_{\lambda_1}^{(k)}$ and \mathcal{A}^c its complement. Let \mathbf{b} be a vector with constant components λ_0 on \mathcal{A} and λ_1 on \mathcal{A}^c . For the $(k+1)$ th iteration, update \mathcal{A} as $\mathcal{A} \cup \{j \in \mathcal{A}^c : |n^{-1}\mathbf{x}_j^T(\mathbf{y} - \mathbf{X}\widehat{\beta}_{\lambda_1}^{(k)})| > \lambda_1\}$, where the subscript \mathcal{A} indicates a subvector restricted on

4. Solve the following linear program on the new set \mathcal{A} :

$$\widehat{\beta}_{\mathcal{A}} = \operatorname{argmin} \|\beta_{\mathcal{A}}\|_1 \text{ subject to } |n^{-1}\mathbf{X}_{\mathcal{A}}^T(\mathbf{y} - \mathbf{X}_{\mathcal{A}}\beta_{\mathcal{A}})| \leq \mathbf{b}_{\mathcal{A}}, \quad (5)$$

where \leq is understood as componentwise no larger than and the subscript \mathcal{A} also indicates a submatrix with columns corresponding to \mathcal{A} . For the solution obtained in (5), set all its components smaller than λ in magnitude to zero.

3. Update the active set \mathcal{A} as the support of $\widehat{\beta}_{\mathcal{A}}$. Solve the Dantzig selector problem on this active set with λ_0 as the regularization parameter:

$$\widehat{\beta}_{\mathcal{A}} = \operatorname{argmin} \|\beta_{\mathcal{A}}\|_1 \text{ subject to } \|n^{-1}\mathbf{X}_{\mathcal{A}}^T(\mathbf{y} - \mathbf{X}_{\mathcal{A}}\beta_{\mathcal{A}})\|_\infty \leq \lambda_0. \quad (6)$$

Let $\widehat{\beta}_{\mathcal{A}}^{(k+1)} = \widehat{\beta}_{\mathcal{A}}$ and $\widehat{\beta}_{\mathcal{A}^c}^{(k+1)} = \mathbf{0}$, which give the solution for the $(k+1)$ th iteration.

4. Repeat steps 2 and 3 until convergence for a fixed λ_1 and record the estimate from the last iteration as $\widehat{\beta}_{\lambda_1}$. Jump to the next λ_1 if $\widehat{\beta}_{\lambda_1} \in \mathcal{B}_{\lambda_1}$, and stop the algorithm otherwise.

With the solution path produced, we use the cross-validation to select the tuning parameter λ_1 . One can also tune λ_0 and λ similarly as for λ_1 , but as suggested before, some fixed values for them suffice to obtain satisfactory results.

The rationales of the constrained Dantzig selector algorithm are as follows. Step 1 defines the initial value (0th iteration) for each λ_1 in the grid. In step 2, starting with a smaller active set, we add variables that violate the constrained Dantzig selector constraints to eliminate such conflict. As a consequence, some components of $\mathbf{b}_{\mathcal{A}}$ are of value λ_1 instead of λ_0 . Therefore, we need to further solve (6) in step 3 by noting that restricted on its support, the constrained Dantzig selector should be a solution to the Dantzig selector problem with parameter λ_0 . An early stopping of the solution path is imposed in step 4 to make this algorithm computationally more efficient.

An appealing feature of this algorithm is that its convergence can be checked easily. Once there are no more variables violating the constrained Dantzig selector constraints, that is, $\{j \in \mathcal{A}^c : |n^{-1}\mathbf{x}_j^T(\mathbf{y} - \mathbf{X}\widehat{\beta}_{\mathcal{A}})| > \lambda_1\} = \emptyset$, the iteration stops and the algorithm converges. In other words, the convergence of the algorithm is equivalent to that of the active set which can be checked directly. When the algorithm converges, the solution lies in the feasible set of the constrained Dantzig selector problem and is a global minimizer restricted on the active set, and is thus a local minimizer.

In simulation Example 2 of Section 4.2, we tracked the convergence property of the algorithm on 100 data sets for $p = 1000$, 5000, and 10000, respectively. In all cases, we observe that the algorithm always converged over all 100 simulations, indicating considerable stability of this algorithm. Another advantage of the algorithm is that it is built upon the Dantzig selector in lower dimensions, so it inherits the computational efficiency.

4.2 Simulation studies

To better illustrate the performance of the constrained Dantzig selector, we consider the thresholded Dantzig selector which simply sets components of the Dantzig selector estimate to zeros if smaller than a threshold in magnitude. We evaluated the performance

of the constrained Dantzig selector in comparison with the Dantzig selector, thresholded Dantzig selector, Lasso, elastic net (Zou and Hastie, 2005), and adaptive Lasso (Zou, 2006). Two simulation studies were considered, with the first one investigating sparse recovery for compressed sensing and the second one examining sparse modeling.

The setting of the first simulation example is similar to that of the sparse recovery example in Lv and Fan (2009). The noiseless sparse recovery example is considered here since the Dantzig selector problem originated from compressed sensing. We want to evaluate the capability of our constrained Dantzig selector in recovering sparse signals as well. We generated 100 data sets from model (1) without noise, that is, the linear equation $\mathbf{y} = \mathbf{X}\boldsymbol{\beta}_0$ with $(s, p) = (7, 1000)$. The nonzero components of $\boldsymbol{\beta}_0$ were set to be $(1, -0.5, 0.7, -1.2, -0.9, 0.3, 0.55)^T$ lying in the first seven components, and n were chosen to be even integers between 30 and 80. The rows of the design matrix \mathbf{X} were sampled as independent and identically distributed (i.i.d.) copies from $N(\mathbf{0}, \mathbf{I}_r)$, with \mathbf{I}_r a $p \times p$ matrix with diagonal elements being 1 and off-diagonal elements being r , and then each column was rescaled to have L_2 -norm $\sqrt{\pi}$. Three levels of population collinearity, $r = 0, 0.2$, and 0.5 , were considered. Let λ_0 and λ be in two small grids $\{0.001, 0.005, 0.01, 0.05, 0.1\}$ and $\{0.05, 0.1, 0.15, 0.2\}$, respectively. We chose two grids of values for them since in the literature of compressed sensing, it is desirable to have the true support included among a set of estimators. The value 0.2 was chosen because it is close to $\{(\log p)/n\}^{1/2}$, which is about $\{(\log 1000)/80\}^{1/2}$ in this example. Smaller values for λ and λ_0 are also included in the grid for conservativeness. We set the grid of values for λ_1 as described in Section 4.1. If any of the solutions in the path had exactly the same support as $\boldsymbol{\beta}_0$, it is counted as successful recovery. This criterion was applied to all other methods in this example for fair comparison.

Figure 1 presents the probabilities of exact recovery of sparse $\boldsymbol{\beta}_0$ based on 100 simulations by all methods. We see that all methods performed well in relatively large samples and had lower probability of successful sparse recovery when the sample size becomes smaller. The constrained Dantzig selector performed better than other methods over different sample sizes and three levels of population collinearity. In particular, the thresholded Dantzig selector performed similarly to the Dantzig selector, revealing that simple thresholding alone, instead of flexible constraints as in the constrained Dantzig selector, does not help much on signal recovery in this case.

The second simulation example adopts a similar setting to that in Zheng et al. (2014). We generated 100 data sets from the linear regression model (1) with Gaussian error $\boldsymbol{\varepsilon} \sim N(\mathbf{0}, \sigma^2 \mathbf{I}_n)$. The coefficient vector $\boldsymbol{\beta}_0 = (\mathbf{v}^T, \dots, \mathbf{v}^T, \mathbf{0}^T)^T$ with the pattern $\mathbf{v} = (\boldsymbol{\beta}_{\text{strong}}^T, \boldsymbol{\beta}_{\text{weak}}^T)^T$ repeated three times, where $\boldsymbol{\beta}_{\text{strong}} = (0.6, 0, 0, -0.6, 0, 0)^T$ and $\boldsymbol{\beta}_{\text{weak}} = (0.05, 0, 0, -0.05, 0, 0)^T$. The coefficient subvectors $\boldsymbol{\beta}_{\text{strong}}$ and $\boldsymbol{\beta}_{\text{weak}}$ stand for the strong signals and weak signals in $\boldsymbol{\beta}_0$, respectively. The sample size and noise level were chosen as $(n, \sigma) = (100, 0.4)$, while the dimensionality p was set to be 1000, 5000, and 10000. The rows of the $n \times p$ design matrix \mathbf{X} were sampled as i.i.d. copies from a multivariate normal distribution $N(\mathbf{0}, \boldsymbol{\Sigma})$ with $\boldsymbol{\Sigma} = (0.5^{|i-j|})_{1 \leq i, j \leq p}$. We applied all methods as in simulation example 1 and set $\lambda_0 = 0.01$ and $\lambda = 0.2$ for our method. Similarly as before, the value of 0.2 was selected since it is close to $\{(\log 1000)/100\}^{1/2}$. The ideal procedure, which knows the true underlying sparse model in advance, was also used as a benchmark.

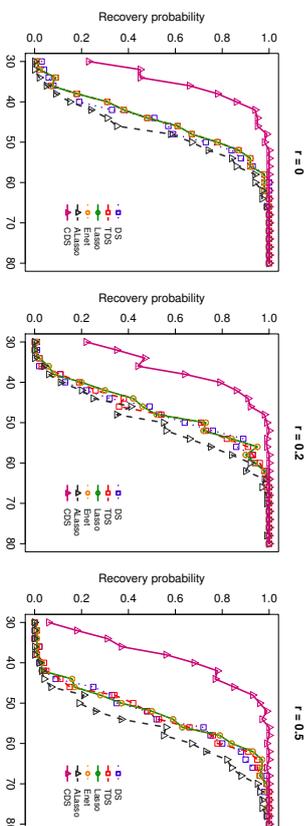

Figure 1: Probabilities of exact sparse recovery for the Dantzig selector (DS), thresholded Dantzig selector (TDS), Lasso, elastic net (Enet), adaptive Lasso (ALasso), and constrained Dantzig selector (CDS) in simulation example 1 of Section 4.2.

To compare these methods, we considered several performance measures: the prediction error, the L_q -estimation loss with $q = 1, 2, \infty$, number of false positives, and number of false negatives for strong or weak signals. The prediction error is defined as $E\|\mathbf{Y} - \mathbf{X}^T \hat{\boldsymbol{\beta}}\|^2$ with $\hat{\boldsymbol{\beta}}$ an estimate and (\mathbf{x}^T, Y) an independent observation, and the expectation was calculated using an independent test sample of size 10000. A false positive means a falsely selected noise covariate in the model, while a false negative means a missed true covariate. Table 1 summarizes the comparison results by all methods. We observe that most weak covariates were missed by all methods. This is reasonable since the weak signals are around the noise level, making it difficult to distinguish them from the noise covariates. However, the constrained Dantzig selector outperformed other methods in terms of other prediction and estimation measures, and followed very closely the ideal procedure in all cases of $p = 1000, 5000$, and 10000. In particular, the L_∞ -estimation loss for the constrained Dantzig selector was similar to that for the oracle procedure, confirming tight bounds on this loss in Theorems 1 and 2. As the dimensionality grows higher, the constrained Dantzig selector performed similarly, while other methods suffered from high dimensionality. In particular, the thresholded Dantzig selector has been shown to improve over the Dantzig selector, but was still outperformed by the adaptive Lasso and constrained Dantzig selector in this example, revealing the necessity to introduce more flexible constraints instead of simple thresholding.

Recall that we have fixed $\lambda_0 = 0.01$ and $\lambda = 0.2$ in the simulation example 2 across all settings. We now study the robustness of the constrained Dantzig with respect to λ_0 and λ in this typical example. For simplicity, we only consider Example 2 with dimensionality $p = 1000$. Instead of fixing $\lambda_0 = 0.01$ and $\lambda = 0.2$, we let λ_0 be a value in the grid $\{0.001, 0.005, 0.01, 0.015, 0.02, 0.025, 0.03\}$ and λ a value in $\{0.1, 0.15, 0.2, 0.25, 0.3, 0.35\}$, respectively. Therefore, we study $7 \times 6 = 42$ different combinations of λ_0 and λ in total to

evaluate the robustness. The same performance measures were calculated. Here we only present the prediction error results to save space, and the other results are available upon request. The tuning parameter λ_1 was chosen by cross-validation, similar as in Example 2. We can see from Table 2 that for all $\lambda \geq 0.15$ and all λ_0 in the grids, the means and standard errors of the prediction error are very close or even identical to those for $\lambda_0 = 0.01$ and $\lambda = 0.2$. The prediction error in the case of $\lambda = 0.1$ is slightly higher since when the threshold becomes lower, some noise variables can be included. For the results on estimation losses as well as false positives and false negatives, we observe similar patterns confirming the robustness of our method with respect to the choices of λ_0 and λ .

4.3 Real data analyses

We applied the same methods as in Section 4.2 to two real data sets: one real PCR data set and another gene expression data set, both in the high-dimensional setting with relatively small sample size. In both data sets, we found that the proposed method enjoys smaller prediction errors and the differences are statistically significant.

Table 2: Means and standard errors (in parentheses) of prediction error of the constrained Dantzig selector for different choices of λ_0 and λ in simulation example 2 with $p = 1000$.

0.025	0.190 (0.002)	0.187 (0.001)	0.185 (0.001)	0.185 (0.001)	0.185 (0.001)	0.185 (0.001)
0.030	0.191 (0.002)	0.187 (0.001)	0.191 (0.007)	0.188 (0.003)	0.185 (0.001)	0.185 (0.001)

The real PCR data set, originally studied in Lan et al. (2006), examines the genetics of two inbred mouse populations. This data set is comprised of $n = 60$ samples with 29 males and 31 females. Expression levels of 22,575 genes were measured. Following Song and Liang (2015), we study the linear relationship between the numbers of Phosphoenolpyruvate carboxykinase (PEPCK), a phenotype measured by quantitative real-time PCR, and the gene expression levels. Both the phenotype and predictors are continuous. As suggested in Song and Liang (2015), we only picked $p = 2000$ genes having the highest marginal correlations with PEPCK as predictors. The response was standardized to have zero mean and unit variance before we conducted the analysis. The 2000 predictors were standardized to have zero mean and L_2 -norm \sqrt{n} in each column. Then the data set was randomly split into a training set of 55 samples and a test set with the remaining 5 samples for 100 times. We set $\lambda_0 = 0.001$ and $\lambda = 0.02$ in this real data analysis as well as the other one below for conservativeness. Methods under comparison are the same as in the simulation studies.

Table 3 reports the means and standard errors of the prediction error on the test data as well as the median model size for each method. We see that the method CDS gave the lowest mean prediction error. Paired t -tests were conducted for the prediction errors of CDS versus DS, TDS, Lasso, and Enet, respectively, to test the differences in performance across various methods. The corresponding p -values were 0.0243, 0.0014, 0.0081, 0.0001, and 0.0102, respectively, indicating significantly different prediction error from that for CDS.

The second data set has been studied in Scheetz et al. (2006) and Huang et al. (2008). In this data set, 120 twelve-week-old male rats were selected for tissue harvesting from the eyes and for microarray analysis. There are 31,042 different probe sets in the microarrays from the RNA of those rat eyes. Following Huang et al. (2008), we excluded the probes that were not expressed sufficiently or that lacked sufficient variation, leaving 18,976 probes which satisfy these two criteria. The response variable TRIM32, which was recently found to cause Bardet-Biedl syndrome, is one of the selected 18,976 probes. We then selected 3,000 probes with the largest variances from the remaining 18,975 probes. The goal of our analysis is to identify the genes that are most relevant to the expression level of TRIM32 from the 3,000 candidate genes.

Table 3: Means and standard errors of the prediction error and median model size over 100 random splits for the real PCR data set.

Method	PE	Model Size
DS	0.773 (0.040)	54
TDS	0.897 (0.063)	14
Lasso	0.802 (0.043)	58
ALasso	0.922 (0.056)	5
Enet	0.793 (0.041)	58
CDS	0.660 (0.036)	21

Similarly as in the analysis of the first real data set, we standardized the response and predictors beforehand. The training set contains 100 samples and was sampled randomly 100 times from the full data set. The remaining 20 samples at each time served as the test set. Results of prediction errors and median model sizes are presented in Table 4. It is clear that the proposed method CDS enjoys the lowest prediction error with a small model size. We conducted the same paired t -tests as in the real PCR data set for comparison. The corresponding p -values were 0.0351, 0.0058, 0.0164, 0.0004, and 0.0344, respectively, showing significant improvement.

Table 4: Means and standard errors of the prediction error and median model size over 100 random splits for the gene expression data set of rat eyes.

Method	PE	Model Size
DS	0.582 (0.044)	28.5
TDS	0.627 (0.051)	9
Lasso	0.590 (0.043)	33
ALasso	0.652 (0.051)	8.5
Enet	0.576 (0.040)	67.5
CDS	0.520 (0.025)	9

5. Discussion

We have shown that the suggested constrained Dantzig selector can achieve convergence rates within a logarithmic factor of the sample size of the oracle rates in ultra-high dimensions under a fairly weak assumption on the signal strength. Our work provides a partial answer to an interesting question of whether convergence rates involving a logarithmic factor of the dimensionality are optimal for regularization methods in ultra-high dimensions. It would be interesting to investigate such a phenomenon for more general regularization methods.

Our formulation of the constrained Dantzig selector uses the L_1 -norm of the parameter vector. A natural extension of the method is to exploit the weighted L_1 -norm of the

parameter to allow for different regularization on different covariates, as is in the adaptive Lasso (Zou, 2006). It would be interesting to investigate the behavior of these methods in more general model settings including generalized linear models and survival analysis. These problems are beyond the scope of the current paper and will be interesting topics for future research.

Appendix: Proofs of main results

Proof of Theorem 1

High probability event \mathcal{E} . Recall that $\lambda_0 = c_0 \sqrt{(\log n)/n}$ and $\lambda_1 = c_1 \sqrt{(\log p)/n}$. All the results in Theorems 1 and 2 will be shown to hold on a key event

$$\mathcal{E} = \{\|n^{-1}\mathbf{X}_1^T \boldsymbol{\epsilon}\|_\infty \leq \lambda_0 \text{ and } \|n^{-1}\mathbf{X}_2^T \boldsymbol{\epsilon}\|_\infty \leq \lambda_1\}, \quad (7)$$

where \mathbf{X}_1 is a submatrix of \mathbf{X} consisting of columns corresponding to $\text{supp}(\beta_0)$ and \mathbf{X}_2 consists of the remaining columns. Thus we will have the same probability bound in both theorems. The probability bound on the event \mathcal{E} in (7) can be easily calculated, using the classical Gaussian tail probability bound (see, for example, (Dudley, 1999)) and the Bonferroni inequality, as

$$\begin{aligned} \text{pr}(\mathcal{E}) &\geq 1 - \{\text{pr}(\|n^{-1}\mathbf{X}_1^T \boldsymbol{\epsilon}\|_\infty > \lambda_0) + \text{pr}(\|n^{-1}\mathbf{X}_2^T \boldsymbol{\epsilon}\|_\infty > \lambda_1)\} \\ &= 1 - \{s(2/\pi)^{1/2} \sigma \lambda_0^{-1} n^{-1/2} e^{-\lambda_0^2 n / (2\sigma^2)} + (p-s)(2/\pi)^{1/2} c \lambda_1^{-1} n^{-1/2} e^{-\lambda_1^2 n / (2c^2 \sigma^2)} - 1\} \\ &= 1 - O\{s n^{-c_0^2 / (2\sigma^2)} (\log n)^{-1/2} + (p-s) p^{-c_1^2 / (2\sigma^2)} (\log p)^{-1/2}\}, \end{aligned} \quad (8)$$

where the last equality follows from the definitions of λ_0 and λ_1 . Let $c = (c_0^2 \wedge c_1^2) / (2\sigma^2) - 1$ be a sufficiently large positive constant, since the two positive constants c_0 and c_1 are chosen large enough. Recall that p is understood implicitly as $\max\{n, p\}$ throughout the paper. Thus it follows from (8), $s \leq n$, and $n \leq p$ that

$$\text{pr}(\mathcal{E}) = 1 - O(n^{-c}). \quad (9)$$

From now on, we derive all the bounds on the event \mathcal{E} . In particular, in light of (7) and $\beta_0 \in \mathcal{B}_\lambda$, it is easy to verify that conditional on \mathcal{E} , the true regression coefficient vector β_0 satisfies the constrained Dantzig selector constraints; in other words, β_0 lies in the feasible set in (3).

Nonasymptotic properties of $\hat{\beta}$. We first make a simple observation on the constrained Dantzig selector $\hat{\beta} = (\hat{\beta}_1, \dots, \hat{\beta}_p)^T$. Recall that without loss of generality, we assume $\text{supp}(\beta_0) = \{1, \dots, s\}$. Let $\beta_0 = (\beta_1^T, \mathbf{0}^T)^T$ with each component of β_1 being nonzero, and $\hat{\beta} = (\hat{\beta}_1^T, \hat{\beta}_2^T)^T$ with $\hat{\beta}_1$ a subvector of $\hat{\beta}$ consisting of its first s components. Denote by $\boldsymbol{\delta} = (\boldsymbol{\delta}_1^T, \boldsymbol{\delta}_2^T)^T = \hat{\beta} - \beta_0$ the estimation error, where $\boldsymbol{\delta}_1 = \hat{\beta}_1 - \beta_1$ and $\boldsymbol{\delta}_2 = \hat{\beta}_2$. It follows from the global optimality of $\hat{\beta}$ that $\|\beta_1\|_1 + \|\beta_2\|_1 = \|\hat{\beta}\|_1 \leq \|\beta_0\|_1 = \|\beta_1\|_1$, which entails that

$$\|\boldsymbol{\delta}_2\|_1 = \|\hat{\beta}_2\|_1 \leq \|\beta_1\|_1 - \|\hat{\beta}_1\|_1 \leq \|\hat{\beta}_1 - \beta_1\|_1 = \|\boldsymbol{\delta}_1\|_1. \quad (10)$$

We will see that this basic inequality $\|\delta_2\|_1 \leq \|\delta_1\|_1$ plays a key role in the technical derivations of both Theorem 1 and 2. Equipped with this inequality and conditional on \mathcal{E} , we are now able to start the derivation of all results in Theorem 1 as follows.

The main idea is to first prove its sparsity property which will be presented in the next paragraph. Then, with the control on the number of false positives and false negatives, we derive an upper bound for the L_2 -estimation loss using the conclusion in Lemma 3.1 of Candès and Tao (2007). Results on other types of losses follow accordingly.

(1) Sparsity. Recall that under the assumption of Theorem 1, β_0 lies in its feasible set conditional on \mathcal{E} . Since $\lambda_0 \leq \lambda_1$, by the definition of the constrained Dantzig selector, we have $\|n^{-1}\mathbf{X}^T(\mathbf{y} - \mathbf{X}\hat{\beta})\| \leq \lambda_1$, where \leq is understood as componentwise no larger than. Conditional on the event \mathcal{E} , substituting \mathbf{y} by $\mathbf{X}\beta_0 + \varepsilon$ and applying the triangle inequality yields

$$\|n^{-1}\mathbf{X}^T\mathbf{X}\delta\|_\infty \leq 2\lambda_1. \quad (11)$$

Furthermore, Lemma 3.1 in Candès and Tao (2007) still applies for δ as long as the uniform uncertainty principle condition (4) holds. Together with (10) and (11), by applying the same argument as in the proof of Theorem 1.1 in Candès and Tao (2007), we obtain an L_2 -estimation loss bound of $\|\delta\|_2 \leq (Cs)^{1/2}\lambda_1$ with $C = 4^2/(1 - \delta - \theta)^2$ some positive constant.

Since both the true regression coefficient vector β_0 and the constrained Dantzig selector $\hat{\beta}$ lie in the constrained parameter space \mathcal{B}_λ , the magnitude of any nonzero component in both β_0 and $\hat{\beta}$ is no smaller than λ . It follows that on the set of falsely discovered signs, the component of $\delta = \hat{\beta} - \beta_0$ will be no smaller than λ . Then making use of the obtained L_2 -estimation loss bound $\|\delta\|_2 \leq (Cs)^{1/2}\lambda_1$, it is immediate that the number of falsely discovered signs is bounded from above by $Cs(\lambda_1/\lambda)^2$. Under the assumption of $\lambda \geq C^{1/2}(1 + \lambda_1/\lambda_0)\lambda_1$, we have $Cs(\lambda_1/\lambda)^2 \leq s(1 + \lambda_1/\lambda_0)^{-2} \leq s$.

(2) L_2 -estimation loss. We further exploit the technical tool of Lemma 3.1 in Candès and Tao (2007) to analyze the behavior of the estimation error $\delta = \hat{\beta} - \beta_0$. Let δ'_1 be a subvector of δ_2 consisting of the s largest components in magnitude, $\delta_3 = (\delta'_1, (\delta'_1)^T)^T$, and \mathbf{X}_3 a submatrix of \mathbf{X} consisting of columns corresponding to δ_3 . We emphasize that δ_3 covers all nonzero components of δ since the number of falsely discovered signs is upper bounded by s , as showed in the previous paragraph. Therefore, $\|\delta_3\|_q = \|\delta\|_q$ for all $q > 0$. In view of the uniform uncertainty principle condition (4), an application of Lemma 3.1 in Candès and Tao (2007) results in

$$\|\delta_3\|_2 \leq (1 - \delta)^{-1} \|n^{-1}\mathbf{X}_3^T\mathbf{X}\delta\|_2 + \theta(1 - \delta)^{-1} s^{-1/2} \|\delta_2\|_1. \quad (12)$$

On the other hand, from the basic inequality (10) it is easy to see that $s^{-1/2} \|\delta_2\|_1 \leq s^{-1/2} \|\delta_1\|_1 \leq \|\delta_3\|_2$. Substituting it into (12) leads to

$$\|\delta\|_2 = \|\delta_3\|_2 \leq (1 - \delta - \theta)^{-1} \|n^{-1}\mathbf{X}_3^T\mathbf{X}\delta\|_2 \quad (13)$$

Hence, to develop a bound for the L_2 -estimation loss it suffices to find an upper bound for $\|n^{-1}\mathbf{X}_3^T\mathbf{X}\delta\|_2$.

Denote by A_1 , A_2 , and A_3 the index sets of correctly selected variables, missed true variables, and falsely selected variables, respectively. Let $A_{23} = A_2 \cup A_3$. Then we can

obtain from the definition of the constrained Dantzig selector along with its thresholding feature that $\|n^{-1}\mathbf{X}_{A_1}^T(\mathbf{y} - \mathbf{X}\hat{\beta})\| \leq \lambda_0$, $\|n^{-1}\mathbf{X}_{A_2}^T(\mathbf{y} - \mathbf{X}\hat{\beta})\| \leq \lambda_1$, and $\|n^{-1}\mathbf{X}_{A_3}^T(\mathbf{y} - \mathbf{X}\hat{\beta})\| \leq \lambda_0$. Conditional on \mathcal{E} , substituting \mathbf{y} by $\mathbf{X}\beta_0 + \varepsilon$ and applying the triangle inequality give

$$\|n^{-1}\mathbf{X}_{A_1}^T\mathbf{X}\delta\|_\infty \leq 2\lambda_0 \quad \text{and} \quad \|n^{-1}\mathbf{X}_{A_{23}}^T\mathbf{X}\delta\|_\infty \leq \lambda_0 + \lambda_1. \quad (14)$$

We now make use of the technical result on sparsity. Since A_{23} denotes the index set of false positives and false negatives, its cardinality is also bounded by $Cs(\lambda_1/\lambda)^2$ with probability at least $1 - O(n^{-c})$. Therefore, by (14) we have

$$\begin{aligned} \|n^{-1}\mathbf{X}_3^T\mathbf{X}\delta\|_2^2 &\leq \|n^{-1}\mathbf{X}_{A_1}^T\mathbf{X}\delta\|_2^2 + \|n^{-1}\mathbf{X}_{A_{23}}^T\mathbf{X}\delta\|_2^2 \\ &\leq s\|n^{-1}\mathbf{X}_{A_1}^T\mathbf{X}\delta\|_\infty^2 + Cs(\lambda_1/\lambda)^2\|n^{-1}\mathbf{X}_{A_{23}}^T\mathbf{X}\delta\|_\infty^2 \\ &\leq 4s\lambda_0^2 + Cs(\lambda_1/\lambda)^2(\lambda_0 + \lambda_1)^2. \end{aligned}$$

Substituting this inequality into (13) yields

$$\|\delta\|_2 \leq (1 - \delta - \theta)^{-1} \{4s\lambda_0^2 + Cs(\lambda_1/\lambda)^2(\lambda_0 + \lambda_1)^2\}^{1/2}.$$

Since we assume $\lambda \geq C^{1/2}(1 + \lambda_1/\lambda_0)\lambda_1$, it follows that $C(\lambda_1/\lambda)^2(\lambda_0 + \lambda_1)^2 \leq \lambda_0^2$. Therefore, we conclude that $\|\delta\|_2 \leq (1 - \delta - \theta)^{-1}(5s\lambda_0^2)^{1/2}$.

(3) Other losses. Applying the basic inequality (10), we establish an upper bound for the L_1 -estimation loss

$$\begin{aligned} \|\delta\|_1 &= \|\delta_1\|_1 + \|\delta_2\|_1 \leq 2\|\delta_1\|_1 \leq 2s^{1/2}\|\delta_1\|_2 \\ &\leq 2s^{1/2}\|\delta\|_2 \leq 2(1 - \delta - \theta)^{-1} s(5\lambda_0^2)^{1/2}. \end{aligned}$$

For the L_∞ -estimation loss, we additionally assume that $\lambda > (1 - \delta - \theta)^{-1}(5s\lambda_0^2)$ which can lead to the sign consistency, $\text{sgn}(\hat{\beta}) = \text{sgn}(\beta_0)$, in view of the L_2 -estimation loss inequality above. Therefore, by the constrained Dantzig selector constraints we have $\|n^{-1}\mathbf{X}_1^T(\mathbf{y} - \mathbf{X}_1\hat{\beta}_1)\|_\infty \leq \lambda_0$ and thus $\|n^{-1}\mathbf{X}_1^T(\varepsilon - \mathbf{X}_1\delta_1)\|_\infty \leq \lambda_0$. Then conditional on \mathcal{E} , it follows from the triangle inequality that $\|n^{-1}\mathbf{X}_1^T\mathbf{X}_1\delta_1\|_\infty \leq 2\lambda_0$. Hence, $\|\delta\|_\infty = \|\delta_1\|_\infty \leq 2\|(n^{-1}\mathbf{X}_1^T\mathbf{X}_1)^{-1}\|_\infty\lambda_0$, which completes the proof.

Proof of Theorem 2

We continue to use the technical setup and notation introduced in the proof of Theorem 1. Results are parallel to those in Theorem 1 but presented in the asymptotic manner. The similarity lies in the rationale of the proof as well. The key element is to derive the sparsity and then construct an inequality for L_2 -estimation loss through the bridge $n^{-1}\|\mathbf{X}\delta\|_2^2$. Inequalities for other types of losses are built upon this bound.

(1) Sparsity. Conditional on the event \mathcal{E} , we know that (10) and (11) still hold by the definition of the constrained Dantzig selector. Moreover, Condition I is similar to the restricted eigenvalue assumption $\text{RE}(s, m, 1)$ in Bickel et al. (2009), except that $\text{RE}(s, m, 1)$ assumes the inequality holds for any subset with size no larger than s to cover different possibilities of $\text{supp}(\beta_0)$. Since we assume without loss of generality that $\text{supp}(\beta_0) =$

$\{1, \dots, s\}$, an application of similar arguments as in the proof of Theorem 7.1 in Bickel et al. (2009) yields the L_2 oracle inequality $\|\delta\|_2 \leq (C_m s)^{1/2} \lambda_1$ with C_m some positive constant dependent on m . Therefore, by the same arguments as in the proof of Theorem 1, it can be shown that the number of falsely discovered signs is bounded from above by $C_m s(\lambda_1/\lambda)^2$ and further by $s(1 + \lambda_1/\lambda_0)^{-2}$ since $\lambda \geq C_m^{1/2}(1 + \lambda_1/\lambda_0)\lambda_1$. Next we will go through the proof of Theorem 7.1 in Bickel et al. (2009) in a more cautious manner and make some improvements in some steps with the aid of the obtained bound on the number of false positives and false negatives.

(2) L_2 -estimation loss. By Condition 1, we have a lower bound for $n^{-1}\|\mathbf{X}\delta\|_2^2$. It is also natural to derive an upper bound for it and build an inequality related to the L_2 -estimation loss. It follows from (14) that

$$\begin{aligned} n^{-1}\|\mathbf{X}\delta\|_2^2 &\leq \|n^{-1}\mathbf{X}_A^T \mathbf{X} \delta\|_\infty \|\delta_{A_1}\|_1 + \|n^{-1}\mathbf{X}_{A_{23}}^T \mathbf{X} \delta\|_\infty \|\delta_{A_{23}}\|_1 \\ &\leq 2\lambda_0 \|\delta_{A_1}\|_1 + (\lambda_0 + \lambda_1) \|\delta_{A_{23}}\|_1. \end{aligned} \quad (15)$$

Since the cardinality of A_{23} is bounded by $C_m s(\lambda_1/\lambda)^2$, applying the Cauchy-Schwarz inequality to (15) leads to $n^{-1}\|\mathbf{X}\delta\|_2^2 \leq 2\lambda_0 \|\delta_{A_1}\|_1 + (\lambda_0 + \lambda_1) \|\delta_{A_{23}}\|_1 \leq 2\lambda_0 s^{1/2} \|\delta_{A_1}\|_2 + C_m^{1/2} (\lambda_0 + \lambda_1) s^{1/2} \lambda_1 / \lambda \|\delta_{A_{23}}\|_2$. This gives an upper bound for $n^{-1}\|\mathbf{X}\delta\|_2^2$. Combining this with Condition 1 results in

$$2^{-1} \kappa^{-2} (\|\delta_{A_1}\|_2^2 + \|\delta_{A_{23}}\|_2^2) \leq 2\lambda_0 s^{1/2} \|\delta_{A_1}\|_2 + C_m^{1/2} (\lambda_0 + \lambda_1) s^{1/2} \lambda_1 / \lambda \|\delta_{A_{23}}\|_2. \quad (16)$$

Consider (16) in a two-dimensional space with respect to $\|\delta_{A_1}\|_2$ and $\|\delta_{A_{23}}\|_2$. Then the quadratic inequality (16) defines a circular area centered at $(2\kappa^{-2}\lambda_0 s^{1/2}, \kappa^{-2} C_m^{1/2} (\lambda_0 + \lambda_1) s^{1/2} \lambda_1 / \lambda)$. The term $\|\delta_{A_1}\|_2^2 + \|\delta_{A_{23}}\|_2^2$ is nothing but the squared distance between the point in this circular area and the origin. One can easily identify the largest squared distance which is also the upper bound for the L_2 -estimation loss

$$\|\delta\|_2^2 = \|\delta_{A_1}\|_2^2 + \|\delta_{A_{23}}\|_2^2 \leq 4\kappa^{-4} \left\{ (2\lambda_0 s^{1/2})^2 + [C_m^{1/2} (\lambda_0 + \lambda_1) s^{1/2} \lambda_1 / \lambda]^2 \right\}.$$

With the assumption of $\lambda \geq C_m^{1/2} (1 + \lambda_1/\lambda_0) \lambda_1$, we can show that $\{C_m^{1/2} (\lambda_0 + \lambda_1) s^{1/2} \lambda_1 / \lambda\}^2 \leq s\lambda_0^2$ and thus $\|\delta\|_2 = O(\kappa^{-2} s^{1/2} \lambda_0)$. This bound has significant improvement with the factor $\log p$ reduced to $\log n$ in the ultra-high dimensional setting.

(3) Other losses. With the L_2 oracle inequality at hand, one can derive the L_1 oracle inequality $\|\delta\|_1 \leq s^{1/2} \|\delta\|_2 = O(\kappa^{-2} s \lambda_0)$ in a straightforward manner. For the prediction loss, it follows from (15) that

$$n^{-1}\|\mathbf{X}\delta\|_2^2 \leq 2\lambda_0 s^{1/2} \|\delta_{A_1}\|_2 + C_m^{1/2} (\lambda_0 + \lambda_1) s^{1/2} \lambda_1 / \lambda \|\delta_{A_{23}}\|_2.$$

Consider the problem of minimizing $2\lambda_0 s^{1/2} \|\delta_{A_1}\|_2 + C_m^{1/2} (\lambda_0 + \lambda_1) s^{1/2} \lambda_1 / \lambda \|\delta_{A_{23}}\|_2$ subject to (16). It is simply a two-dimensional linear optimization problem with a circular area as its feasible set. One can easily solve this minimization problem and obtain

$$n^{-1}\|\mathbf{X}\delta\|_2^2 \leq 2\kappa^{-2} \left[(2\lambda_0 s^{1/2})^2 + \{C_m^{1/2} (\lambda_0 + \lambda_1) s^{1/2} \lambda_1 / \lambda\}^2 \right] = O(\kappa^{-2} s \lambda_0^2).$$

Finally, for the L_∞ oracle inequality, it follows from similar arguments as in the proof of Theorem 1 that $\|\delta\|_\infty \leq 2\| (n^{-1} \mathbf{X}_1^T \mathbf{X}_1)^{-1} \|_\infty \lambda_0 = O\{ \| (n^{-1} \mathbf{X}_1^T \mathbf{X}_1)^{-1} \|_\infty \lambda_0 \}$, which concludes the proof.

Proof of Theorem 3

Denote by $\widehat{\beta}_{\text{global}}$ the global minimizer of (3). Under the conditions of Theorem 2, $\widehat{\beta}_{\text{global}}$ enjoys the same oracle inequalities and properties as in Theorem 2 conditional on the event defined in (7). In particular, we have $F_S(\widehat{\beta}_{\text{global}}) = O(s)$. It follows that

$$\|\widehat{\beta}_{\text{global}}\|_0 \leq \|\widehat{\beta}_0\|_0 + F_S(\widehat{\beta}_{\text{global}}) = O(s).$$

Let $\widehat{\beta}$ be a computable local minimizer of (3) produced by any algorithm satisfying $\|\widehat{\beta}\|_0 \leq c_3 s$. Denote by $A = \text{supp}(\widehat{\beta}) \cup \text{supp}(\widehat{\beta}_{\text{global}})$. Then we have

$$|A| \leq \|\widehat{\beta}\|_0 + \|\widehat{\beta}_{\text{global}}\|_0 = O(s) \leq c_3 s$$

for some large enough positive constant c_3 .

We next analyze the difference between the two estimators, that is, $\delta = \widehat{\beta} - \widehat{\beta}_{\text{global}}$. Let \mathbf{X}_A be a submatrix of \mathbf{X} consisting of columns in A and δ_A a subvector of δ consisting of components in A . Since $\|\mathbf{X}^T(\mathbf{y} - \mathbf{X}\widehat{\beta})\|_\infty = O(\lambda_1)$ and $\|\mathbf{X}^T(\mathbf{y} - \mathbf{X}\widehat{\beta}_{\text{global}})\|_\infty = O(\lambda_1)$, we can show that

$$\|n^{-1} \mathbf{X}_A^T \mathbf{X}_A \delta_A\|_2 \leq |A|^{1/2} \|n^{-1} \mathbf{X}_A^T \mathbf{X}_A \delta_A\|_\infty = O(s^{1/2} \lambda_1).$$

By the assumption that $\min_{\|\delta\|_0=1, \|\delta\|_{0 \leq c_3 s}} n^{-1/2} \|\mathbf{X}\delta\|_2 \geq \kappa_0$, the smallest singular value of $n^{-1/2} \mathbf{X}_A$ is bounded from below by κ_0 . Thus we have $\|\delta\|_2 = \|\delta_A\|_2 = O(s^{1/2} \lambda_1)$. Together with the thresholding feature of the constrained Dantzig selector, it follows that the number of different indices between $\text{supp}(\widehat{\beta})$ and $\text{supp}(\widehat{\beta}_{\text{global}})$ is bounded by $O\{s(\lambda_1/\lambda)^2\}$. This sparsity property is essential for our proof and similar sparsity results can be found in Theorem 2.

Based on the aforementioned sparsity property and by the facts that $\|\mathbf{X}_{\widehat{A}_1}^T \mathbf{X}\delta\|_\infty \leq 2\lambda_0$ and $\|\mathbf{X}_{\widehat{A}_{23}}^T \mathbf{X}\delta\|_\infty \leq \lambda_0 + \lambda_1$ with $\widehat{A}_1 = \text{supp}(\widehat{\beta}) \cap \text{supp}(\widehat{\beta}_{\text{global}})$ and $\widehat{A}_{23} = [\text{supp}(\widehat{\beta}) \setminus \text{supp}(\widehat{\beta}_{\text{global}})] \cup [\text{supp}(\widehat{\beta}_{\text{global}}) \setminus \text{supp}(\widehat{\beta})]$, the same arguments as in the proof of Theorem 2 apply to show that $\|\delta\|_2 = O(\kappa^{-2} s^{1/2} \lambda_0)$. It is clear that this bound is of the same order as that for the difference between $\widehat{\beta}_{\text{global}}$ and β_0 in Theorem 2. Thus $\widehat{\beta}$ enjoys the same asymptotic bound on the L_2 -estimation loss. Similarly, the asymptotic bounds for the other losses in Theorem 2 also apply to $\widehat{\beta}$, since those inequalities are rooted on the bounds for the sparsity and L_2 -estimation loss. This completes the proof.

Abstract

We develop a flexible framework for low-rank matrix estimation that allows us to transform noise models into regularization schemes via a simple bootstrap algorithm. Effectively, our procedure seeks an autoencoding basis for the observed matrix that is stable with respect to the specified noise model; we call the resulting procedure a *stable autoencoder*. In the simplest case, with an isotropic noise model, our method is equivalent to a classical singular value shrinkage estimator. For non-isotropic noise models—e.g., Poisson noise—the method does not reduce to singular value shrinkage, and instead yields new estimators that perform well in experiments. Moreover, by iterating our stable autoencoding scheme, we can automatically generate low-rank estimates without specifying the target rank as a tuning parameter.

KEYWORDS: Correspondence analysis, empirical Bayes, Lévy bootstrap, singular-value decomposition.

1. Introduction

Low-rank matrix estimation plays a key role in many scientific and engineering tasks, including collaborative filtering (Koren et al., 2009), genome-wide studies (Leek and Storey, 2007; Price et al., 2006), and magnetic resonance imaging (Candès et al., 2013; Lustig et al., 2008). Low-rank procedures are often motivated by the following statistical model. Suppose that we observe a noisy matrix $X \in \mathbb{R}^{n \times p}$ drawn from some distribution $\mathcal{L}(\mu)$ with $\mathbb{E}_\mu[X] = \mu$, and that we have scientific reason to believe that μ admits a parsimonious, low-rank representation. Then, we can frame our statistical goal as trying to recover the underlying μ from the observed X . D’Aspremont et al. (2012), Candès and Tao (2010), Chatterjee (2015), Gavish and Donoho (2014b), Shabalin and Nobel (2013), and others have studied regimes where it is possible to accurately do so.

Singular-value shrinkage Classical approaches to estimating μ from X are centered around singular-value decomposition (SVD) algorithms. Let

$$X = \sum_{l=1}^{\min\{n,p\}} u_l d_l v_l^\top \quad (1)$$

denote the SVD of X . Then, if we believe that μ should have rank k , the standard SVD estimator $\hat{\mu}_k$ for μ is

$$\hat{\mu}_k = \sum_{l=1}^k u_l d_l v_l^\top. \quad (2)$$

In other words, we estimate μ using the closest rank- k approximation to X . Often, however, the plain rank- k estimator (2) is found to be noisy, and its performance can be improved by regularization. Existing approaches to regularizing $\hat{\mu}_k$ focus on singular value shrinkage, and use

$$\hat{\mu}^{\text{shrink}} = \sum_{l=1}^{\min\{n,p\}} u_l \psi(d_l) v_l^\top, \quad (3)$$

where ψ is a shrinkage function that is usually chosen in a way that makes $\hat{\mu}^{\text{shrink}}$ the closest to μ according to a loss function. Several authors have proposed various choices for ψ (e.g., Candès et al., 2013; Chatterjee, 2015; Gavish and Donoho, 2014a; Josse and Sardy, 2015; Shabalin and Nobel, 2013; Verbanck et al., 2013).

Methods based on singular-value shrinkage have achieved considerable empirical success. They also have provable optimality properties in the Gaussian noise model where $X = \mu + \varepsilon$ and the ε_{ij} are independent and identically distributed Gaussian noise terms (Shabalin and Nobel, 2013). However, in the non-Gaussian case, mere singular-value shrinkage can prove to be limiting, and we may also need to rotate the singular vectors u_l and v_l in order to achieve good performance.

Stable autoencoding In this paper, we propose a new framework for regularized low-rank estimation that does not start from the singular-value shrinkage point of view. Rather, our approach is motivated by a simple plug-in bootstrap idea (Efron and Tibshirani, 1993). It is well known that the classical SVD estimator $\hat{\mu}_k$ can be written as (Boulevard and Kamp, 1988; Baldi and Hornik, 1989)

$$\hat{\mu}_k = X B_k, \quad \text{where } B_k = \operatorname{argmin}_B \left\{ \|X - X B\|_2^2 : \operatorname{rank}(B) \leq k \right\}, \quad (4)$$

where $\|M\|_2^2 = \operatorname{tr}(M^\top M)$ denotes the Frobenius norm. The matrix B , called a linear *autoencoder* of X , allows us to encode the features of X using a low-rank representation.

Now, in the context of our noise model $X \sim \mathcal{L}(\mu)$, we do not just want to compress X , and instead want to recover μ from X . From this perspective, we would much prefer to estimate μ using an oracle encoder matrix that formally provides the best linear approximation of μ given our noise model

$$\hat{\mu}_k^* = X B_k^*, \quad \text{where } B_k^* = \operatorname{argmin}_B \left\{ \mathbb{E}_{X \sim \mathcal{L}(\mu)} \left[\|\mu - X B\|_2^2 \right] : \operatorname{rank}(B) \leq k \right\}. \quad (5)$$

We of course cannot solve for B_k^* because we do not know μ . But we can seek to approximate B_k^* by solving the optimization problem (5) on a well-chosen bootstrap distribution.

More specifically, our goal is to create bootstrap samples $\tilde{X} \sim \tilde{\mathcal{L}}(X)$ such that the distribution of \tilde{X} around X is representative of the distribution of X around μ . Then, we can solve an analogue to (5) on the bootstrap samples \tilde{X} :

$$\hat{\mu}_k^{\text{stable}} = X \hat{B}_k, \quad \text{where } \hat{B}_k = \operatorname{argmin}_B \left\{ \mathbb{E}_{\tilde{X} \sim \tilde{\mathcal{L}}(X)} \left[\|\tilde{X} - \tilde{X} B\|_2^2 \right] : \operatorname{rank}(B) \leq k \right\}. \quad (6)$$

We call this choice of \tilde{B}_k a *stable autoencoder* of X , as it provides a parsimonious encoding of the features of X that is stable when perturbed with bootstrap noise $\mathcal{L}(X)$. The motivation behind this approach is that we want to shrink $\hat{\mu}_k$ aggressively along directions where the bootstrap reveals instability, but do not want to shrink $\hat{\mu}_k$ too much along directions where our measurements are already accurate.

Bootstrap models for stable autoencoding A challenge in carrying out the program (6) is in choosing how to generate the bootstrap samples \tilde{X} . In the classical statistical setting, we have access to $m \gg 1$ independent training samples and can thus create a bootstrap dataset by simply re-sampling the training data with replacement. In our setting, however, we only have a single matrix X , i.e., $m = 1$. Thus, we must find another avenue for creating bootstrap samples \tilde{X} .

To get around this limitation, we use a *Lévy bootstrap* (Wager et al., 2016). Before defining the abstract bootstrap scheme below, we first discuss some simple examples. In the **Gaussian** case $X_{ij} \sim \mathcal{N}(\mu_{ij}, \sigma^2)$, Lévy bootstrapping is equivalent to a parametric bootstrap:

$$\tilde{X}_{ij} = X_{ij} + \tilde{\epsilon}_{ij}, \quad \text{where } \tilde{\epsilon}_{ij} \stackrel{\text{iid}}{\sim} \mathcal{N}\left(0, \frac{\delta}{1-\delta} \sigma^2\right), \quad (7)$$

and $\delta \in (0, 1)$ is a tuning parameter that governs the regularization strength. Meanwhile, in the **Poisson** case $X_{ij} \sim \text{Poisson}(\mu_{ij})$, Lévy bootstrapping involves randomly deleting a fraction δ of the counts comprising the matrix X , and up-weighting the rest:

$$\tilde{X}_{ij} \sim \frac{1}{1-\delta} \text{Binomial}(X_{ij}; 1-\delta), \quad (8)$$

where again $\delta \in (0, 1)$ governs the regularization strength. In the case $\delta = 0.5$, this is equivalent to the “double-or-nothing” bootstrap on the individual counts of X (e.g., Owen and Eckles, 2012).

These two examples already reveal a variety of different phenomena. On one hand, stable autoencoding with the Gaussian noise model (7) reduces to a singular-value shrinkage estimator (Section 2), and thus leads us back to the classical literature on low-rank matrix estimation. Conversely, with the Poisson-adapted bootstrap (8), the method (6) rotates singular vectors instead of just shrinking singular values; and in our experiments, it outperforms several variants of singular-value shrinkage that have been proposed in the literature.

The Lévy bootstrap Having first surveyed our two main examples above, we now present the more general Lévy bootstrap that can be used to carry out stable autoencoding in a wider variety of exponential family models. To motivate this approach, suppose that we can generate our matrix X as a sum of independent components:

$$X = \sum_{b=1}^B X_b^{(B)}, \quad \text{where } X_1^{(B)}, \dots, X_B^{(B)} \quad (9)$$

are independent and identically distributed. For example, if X is Gaussian with $X_{ij} \sim \mathcal{N}(\mu_{ij}, \sigma)$, then (9) holds with $(X_b^{(B)})_{ij} \sim \mathcal{N}(\mu_{ij}/B, \sigma/B)$. If the above construction were to hold and we also knew the individual components $X_b^{(B)}$, we could easily create bootstrap

samples \tilde{X} as

$$\tilde{X} = \frac{1}{1-\delta} \sum_{b=1}^B \tilde{W}_b X_b^{(B)}, \quad \text{where } \tilde{W}_b \stackrel{\text{iid}}{\sim} \text{Bernoulli}(1-\delta), \quad (10)$$

and $\delta \in (0, 1)$ governs the noising strength. Now in reality, we do not know the terms in (9), and so cannot carry out (10).

However, Wager et al. (2016) establish conditions under which this limitation does not matter. Suppose that X is drawn from an exponential family distribution

$$X \sim f_{\Theta}(\cdot), \quad f_{\Theta}(x) = h(X) \exp\left[\sum_{i,j} \Theta_{ij} X_{ij} - \zeta(\Theta)\right], \quad (11)$$

where $\Theta \in \mathbb{R}^{n \times p}$ is an unknown parameter vector, $h(\cdot)$ is a carrier distribution, and $\zeta(\cdot)$ is the log-partition function. Suppose, moreover, that X has an infinitely divisible distribution, or, equivalently, that $X = A(1)$ for some matrix-valued Lévy process $A(t) \in \mathbb{R}^{n \times p}$ for $t > 0$ (e.g., Durrett, 2010). Then, we can always generate bootstrap replicates \tilde{X} distributed as

$$\tilde{X} \sim \tilde{\delta} h(X) := \frac{1}{1-\delta} A(1-\delta) \mid A(1) = X, \quad \text{for any } \delta \in (0, 1), \quad (12)$$

without requiring knowledge of the underlying Θ ; Wäger et al. (2016) provide explicit formulas for carrying out (12) that only depend on the carrier $h(\cdot)$.

The upshot of this bootstrap scheme is that it allows us to preserve the generative structure encoded by Θ without needing to know the true parameter. In the Gaussian and Poisson cases, (12) reduces to (7) and (8) respectively; however, this Lévy bootstrap framework also induces other noising schemes, such as multiplicative noising when X has a Gamma distribution.

Rank selection via iterated stable autoencoding Returning now to our main focus, namely regularized low-rank matrix estimation, we note that one difficulty with the estimator $\hat{\mu}_k^{\text{stable}}$ (6) is that we need to select the rank k of the estimator beforehand in addition to the shrinkage parameter δ . Surprisingly, we can get around this issue by iterating the optimization problem (6) until we converge to a limit:

$$\hat{\mu}^{\text{iter}} = X \hat{B}, \quad \text{where } \hat{B} = \underset{B}{\text{argmin}} \left\{ \mathbb{E}_{\tilde{X} \sim \mathcal{L}(\hat{\mu}^{\text{iter}}, X)} \left[\left\| \hat{\mu}^{\text{iter}} - \tilde{X} \hat{B} \right\|_2^2 \right] \right\}. \quad (13)$$

In Section 3, we establish conditions under which the iterative algorithm implied above in fact converges and, moreover, the resulting fixed point $\hat{\mu}^{\text{iter}}$ is low rank. In our experiments, this *iterated stable autoencoder* does a good job at estimating k of the underlying signal; thus, all the statistician needs to do is to specify a single regularization parameter $\delta \in (0, 1)$ that simultaneously controls both the amount of shrinkage and the rank k of the final estimate $\hat{\mu}$.

To summarize, our approach as instantiated in (6) and (13) provides us with a flexible framework for transforming noise models $\mathcal{L}(\cdot)$ into regularized matrix estimators via the

Lévy bootstrap. In the Gaussian case, our framework yields estimators that resemble best-practice singular-value shrinkage methods. Meanwhile, in the non-Gaussian case, stable autoencoding allows us to learn new singular vectors for $\hat{\mu}$. In our experiments, this allowed us to substantially improve over existing techniques.

Finally, we also discuss extensions to stable autoencoding: In Section 4, we show how to use our method to regularize correspondence analysis (Greenacre, 1984, 2007), which is one of the most popular ways to analyze multivariate count data and underlies several modern machine learning algorithms.

A software implementation of the proposed methods is available through the R-package `denoiseR` (Josse et al., 2016).

1.1 Related work

There is a well-known duality between regularization and feature noising schemes. As shown by Bishop (1995), linear regression with features perturbed with Gaussian noise, i.e.,

$$\hat{\beta} = \operatorname{argmin}_{\beta} \left\{ \mathbb{E}_{\varepsilon_{ij} \stackrel{\text{iid}}{\sim} \mathcal{N}(0, \sigma^2)} \left[\|Y - (X + \varepsilon)\beta\|_2^2 \right] \right\},$$

is equivalent to ridge regularization with Lagrange parameter $\lambda = n\sigma^2$:

$$\hat{\beta}_{\lambda}^{(R)} = \operatorname{argmin}_{\beta} \left\{ \|Y - X\beta\| + \lambda \|\beta\|_2 \right\}.$$

Because ridge regression is equivalent to adding homoskedastic noise to X , we can think of ridge regression as making the estimator robust against round perturbations to the data.

However, if we perturb the features X using non-Gaussian noise or are working with a non-quadratic loss function, artificial feature noising can yield new regularizing schemes with desirable properties (Globerson and Roweis, 2006; Simard et al., 2000; van der Maaten et al., 2013; Wager et al., 2013; Wang et al., 2013). Our proposed estimator $\hat{\mu}_k^{\text{stable}}$ can be seen as an addition to this literature, as we seek to regularize $\hat{\mu}_k$ by perturbing the autoencoder optimization problem. The idea of regularizing via feature noising is also closely connected to the dropout learning algorithm for training neural networks (Srivastava et al., 2014), which aims to regularize a neural network by randomly omitting hidden nodes during training time. Dropout and its generalizations have been found to work well in many large-scale prediction tasks (e.g., Baldi and Sadowski, 2014; Goodfellow et al., 2013; Krizhevsky et al., 2012).

Our method can be interpreted as an empirical Bayes estimator (Efron, 2012; Robbins, 1985), in that the stable autoencoder problem (6) seeks to find the best linear shrinker in an empirically chosen Bayesian model. There is also an interesting connection between stable autoencodings, and more traditional Bayesian modeling such as latent Dirichlet allocation (LDA) (Blei et al., 2003), in that the Lévy bootstrap (12) uses a generalization of the LDA generative model to draw bootstrap samples \tilde{X} . Thus, our method can be seen as benefiting from the LDA generative structure without committing to full Bayesian inference (Kucukelbir and Blei, 2015; Wager et al., 2014, 2016).

There is a large literature on low-rank exponential family estimation (Collins et al., 2001; de Leeuw, 2006; Fithian and Mazumder, 2013; Goodman, 1985; Li and Tao, 2013). In

the simplest form of this idea, each matrix entry is modeled using the generic exponential family distribution (11); the goal is then to maximize the log-likelihood of X subject to a low-rank constraint on the natural parameter matrix Θ , rather than the mean parameter matrix μ as in our setting. The main difficulty with this approach is that the resulting rank-constrained problem is no longer efficiently solvable; one way to avoid this issue is to relax the rank constraint into a nuclear norm penalty. Extending our bootstrap-based regularization framework to low-rank exponential family estimation would present an interesting avenue for further work. We also note the work of Buntine (2002), who seeks to maximize the multinomial log-likelihood of X subject to a low-rank constraint on μ using an approximate variational method.

Finally, one of the advantages of our stable autoencoding approach is that it lets us move beyond singular value shrinkage, and learn better singular vectors than those provided by the SVD. Another approach to way to improve on the quality of the learned singular vectors is to impose structural constraints on them, such as sparsity (Jolliffe et al., 2003; Uçell et al., 2014; Witten et al., 2009; Zou et al., 2006).

2. Fitting stable autoencoders

In this section, we show how to solve (6) under various bootstrap models $\tilde{\mathcal{L}}(\cdot)$. This provides us with estimators $\hat{\mu}_k^{\text{stable}}$ that are interesting in their own right, and also serves as a stepping stone to the iterative solutions from Section 3 that do not require pre-specifying the rank k of the underlying signal.

Isotropic stable autoencoders and singular-value shrinkage At first glance, the estimator $\hat{\mu}_k^{\text{stable}}$ defined in (6) may seem like a surprising idea. It turns out, however, that under the isotropic Gaussian¹ noise model

$$X = \mu + \varepsilon, \quad \text{with } \varepsilon_{ij} \stackrel{\text{iid}}{\sim} \mathcal{N}(0, \sigma^2) \quad \text{for all } i = 1, \dots, n \text{ and } j = 1, \dots, p, \quad (14)$$

$\hat{\mu}_k^{\text{stable}}$ with bootstrap noise as in (7) is equivalent to a classical singular-value shrinkage estimator (3) with $\psi(d) = d/(1 + \lambda/d^2)$ and $\lambda = \delta/(1 - \delta)n\sigma^2$.

Theorem 1 *Let $\hat{\mu}_k^{\text{stable}}$ be the rank- k estimator for μ induced by the stable autoencoder (6) with a bootstrap model $\tilde{\mathcal{L}}_{\delta}(\cdot)$ as defined in (7) with some $0 < \delta < 1$. This estimator can also be written as the solution to a ridge-regularized autoencoder:*

$$\hat{\mu}_k^{\text{stable}} = X\hat{B}_k, \quad \text{where } \hat{B}_k = \operatorname{argmin}_B \left\{ \|X - XB\|_2^2 + \lambda \|B\|_2^2 : \operatorname{rank}(B) \leq k \right\} \quad (15)$$

with $\lambda = \delta/(1 - \delta)n\sigma^2$. Moreover, using notation from (1), we can write $\hat{\mu}_k^{\text{stable}}$ as

$$\hat{\mu}_k^{\text{stable}} = \sum_{l=1}^k u_l \frac{d_l}{1 + \lambda/d_l^2} v_l^{\top}. \quad (16)$$

1. Theorem 1 holds for all isotropic noise models with $\operatorname{Var}[\varepsilon_{ij}] = \sigma^2$ for all i and j , and not just the Gaussian one. However, in practice, isotropic noise is almost always modeled as Gaussian.

In the isotropic Gaussian noise case, singular-value shrinkage methods were shown by Shabalin and Nobel (2013) to have strong optimality properties for estimating μ . Thus, it is reassuring that our framework recovers an estimator of this class in the Gaussian case. In fact, the induced shrinkage function resembles a first-order approximation to the one proposed by Verbanck et al. (2013).

Non-isotropic stable autoencoders Stable autoencoders with isotropic noise are attractive in the sense that we can carefully analyze their behavior in closed form. However, from a practical point of view, our procedure is most useful outside of the isotropic regime, as it induces new estimators $\hat{\mu}$ that do not reduce to singular-value shrinkage. Even in the non-isotropic noise model, low-rank stable autoencoders can still be efficiently solved, as shown below.

Theorem 2 For a generic bootstrap model $\tilde{\mathcal{L}}(\cdot)$, the matrix \hat{B}_k from (6) can be obtained as follows:

$$\hat{B}_k = \operatorname{argmin}_B \left\{ \|X - XB\|_2^2 + \|S^{\frac{1}{2}}B\|_2^2 : \operatorname{rank}(B) \leq k \right\}, \quad (17)$$

where S is a $p \times p$ diagonal matrix with

$$S_{ij} = \sum_{t=1}^n \operatorname{Var}_{\tilde{X} \sim \tilde{\mathcal{L}}(X)} [\tilde{X}_{ij}]. \quad (18)$$

From a computational point of view, we can write the solution \hat{B}_k of (17) as

$$\hat{B}_k = \operatorname{argmin}_B \left\{ \operatorname{tr} \left((B - \hat{B})^\top (X^\top X + S) (B - \hat{B}) \right) : \operatorname{rank}(B) \leq k \right\}, \quad \text{where} \quad (19)$$

$$\hat{B} = (X^\top X + S)^{-1} X^\top X \quad (20)$$

is the solution of (17) without the rank constraint.

The optimization problem in (19) can be easily solved by taking the top k terms from the eigenvalue decomposition of $\hat{B}^\top (X^\top X + S) \hat{B}$: the matrix \hat{B}_k can then be recovered by solving a linear system (e.g., Takane, 2013). Thus, despite what we might have expected, solving the low-rank constrained stable autoencoder problem (6) with a generic noise model is not substantially more computationally demanding than singular-value shrinkage. Note that in (20), the matrix S is not equal to a constant times the identity matrix due to the non-isotropic noise, and so the resulting singular vectors of $\hat{\mu}_k^{\text{stable}} = X\hat{B}_k$ are not in general the same as those of X .

Selecting the tuning parameter Our stable autoencoder depends on a tuning parameter $\delta \in (0, 1)$, corresponding to the fraction of the information in the full data X that we throw away when creating pseudo-datasets \tilde{X} using the Lévy bootstrap (12). More prosaically, the parameter δ manifests itself as a multiplier $\delta/(1 - \delta) \in (0, \infty)$ on the effective stable autoencoding penalty, either explicitly in (15) or implicitly in (18) through the dependence on $\tilde{\mathcal{L}}_\delta(\cdot)$.

Algorithm 1 Low-rank matrix estimation via iterated stable autoencoding.

```

 $\hat{\mu} \leftarrow X$ 
for all  $j = 1, \dots, p$ 
   $S_{jj} \leftarrow \sum_{t=1}^n \operatorname{Var}_{\tilde{X} \sim \tilde{\mathcal{L}}_\delta(X)} [\tilde{X}_{tj}]$ 
while algorithm has not converged do
   $\hat{B} \leftarrow (\hat{\mu}^\top \hat{\mu} + S)^{-1} \hat{\mu}^\top \hat{\mu}$ 
   $\hat{\mu} \leftarrow X \hat{B}$ 
end while
```

One plausible default value is to set $\delta = 1/2$. This corresponds to using half of the information in the full data X to generate each bootstrap sample \tilde{X} , and is closely related to bagging (Breiman, 1996); see Buja and Snetzle (2006) for a discussion of the connections between half-sampling and bagging. Conversely, we could also opt for a data-driven choice of δ . The software implementation of stable autoencoding in `denoiser` (Josse et al., 2016) provides a cell-wise cross-validation algorithm for picking δ .

Finally, we note that our estimator is not in general invariant to transposition $X \rightarrow X^\top$. For example, in the isotropic case (15), we see that λ depends on n but not on p . Meanwhile, in the non-isotropic case (17), transposition may also affect the learned singular vectors. By default, we transpose X such that $n > p$, i.e., we pick the transposition of X that makes the matrix B smaller.

3. Iterated stable autoencoding

One shortcoming of the stable autoencoders discussed in the previous section is that we need to specify the rank k as a tuning parameter. Selecting the rank for multivariate methods is often a difficult problem, and many heuristics are available in the literature (Jolliffe, 2002; Josse and Husson, 2011). The stable autoencoding framework, however, induces a simple solution to the rank-selection problem: As we show here, iterating our estimation scheme from the previous section automatically yields low-rank solutions, and allows us to specify a single tuning parameter δ instead of both δ and k .

At a high level, our goal is to find a solution to

$$\hat{\mu}^{\text{iter}} = X \hat{B}, \quad \text{where } \hat{B} = \operatorname{argmin}_B \left\{ \mathbb{E}_{\tilde{X} \sim \tilde{\mathcal{L}}_\delta(\hat{\mu}^{\text{iter}}, X)} \left[\left\| \hat{\mu}^{\text{iter}} - \tilde{X} B \right\|_2^2 \right] \right\} \quad (21)$$

by iteratively updating \hat{B} and $\hat{\mu}$. As seen in the previous section, stable autoencoding only depends on $\mathcal{L}_\delta(\hat{\mu}, X)$ through the first two moments of \tilde{X} ; here, we simply specify them as

$$\mathbb{E}_{\tilde{X} \sim \tilde{\mathcal{L}}_\delta(\hat{\mu}, X)} [\tilde{X}] = \hat{\mu} \quad \text{and} \quad \operatorname{Var}_{\tilde{X} \sim \tilde{\mathcal{L}}_\delta(\hat{\mu}, X)} [\tilde{X}] = \operatorname{Var}_{\tilde{X} \sim \tilde{\mathcal{L}}_\delta(X)} [\tilde{X}], \quad (22)$$

where $\tilde{\mathcal{L}}_\delta(X)$ is obtained using the Lévy bootstrap as before.

Now, using the unconstrained solution (20) from Theorem 2 to iterate on the relation (21), we get the formal procedure described in Algorithm 1. Note that we do not update the matrix S , which encodes the variance of the noise distribution, and only update $\hat{\mu}$. As shown below, our algorithm converges to a well-defined solution; moreover, the solution is

regularized in that $\hat{\mu}^\top \hat{\mu}$ is smaller than $X^\top X$ with respect to the positive semi-definite cone ordering.

Theorem 3 *Algorithm 1 converges to a fixed point $\hat{\mu} = X\hat{B}$. Moreover,*

$$\hat{\mu}^\top \hat{\mu} \preceq X^\top X.$$

Moreover, iterated stable autoencoding can provide generic low-rank solutions $\hat{\mu}$.

Theorem 4 *Let $\hat{\mu}$ be the limit of our iterative algorithm, and let $u \in \mathbb{R}^p$ be any (normalized) eigenvector of $\hat{\mu}^\top \hat{\mu}$. Then, either*

$$\|\hat{\mu} u\|_2 = 0, \text{ or } \|\hat{\mu} u\|_2 \geq \frac{1}{\|XS^{-1}u\|_2}.$$

The reason our algorithm converges to low-rank solutions is that our iterative scheme does not have any fixed points “near” low-dimensional subspaces. Specifically, as shown in Theorem 4, for any eigenvector of $\hat{\mu}^\top \hat{\mu}$, either $\|\hat{\mu} u\|_2$ must be larger than some cutoff, or it must be exactly zero. Thus, $\hat{\mu}$ cannot have any small but non-zero singular values. In our experiments, we have found that our algorithm in fact conservatively estimates the true rank of the underlying signal.

Finally we note that, in the isotropic case, our iterative algorithm again admits a closed-form solution. Looking at this solution can give us more intuition about what our algorithm does in the general case. In particular, we note that the algorithm never shrinks a singular value by more than a factor $1/2$ without pushing it all the way to 0.

Proposition 5 *In the isotropic Gaussian case (14) with $\delta = 1/2$, our iterative algorithms converges to*

$$\hat{\mu}^{\text{iter}} = \sum_{l=1}^{\min\{n,p\}} u_l \psi(d_l) v_l^\top, \text{ where } \psi(d) = \begin{cases} \frac{1}{2} (d + \sqrt{d^2 - 4n\sigma^2}) & \text{for } d^2 \geq 4n\sigma^2, \\ 0 & \text{else.} \end{cases} \quad (23)$$

Since the isotropic Gaussian matrix estimation problem has been thoroughly studied, we can compare the shrinkage rule $\psi(\cdot)$ with known asymptotically optimal ones. Gavish and Donoho (2014b) provide a comprehensive treatment of optimal singular-value shrinkage for different loss functions in a Marcenko-Pastur asymptotic regime, where n and p both diverge to infinity such that $p/n \rightarrow \beta$ for some $0 < \beta \leq 1$ while the rank and the scale of the signal remains fixed. This specific asymptotic setting has also been investigated by, among others, Johnstone (2001) and Shabalin and Nobel (2013).

In what appears to be a remarkable coincidence, for the square case $\beta = 1$, our shrinkage rule (23) corresponds exactly to the Marcenko-Pastur optimal shrinkage rule under operator-norm loss $\|\hat{\mu} - \mu\|_{\text{op}}$; see the proof of Proposition 5 for a derivation. At the very least, this connection is reassuring as it suggests that our iterative scheme may yield statistically reasonable estimates $\hat{\mu}^{\text{iter}}$ for other noise models too. It remains to be seen whether this connection reflects a deeper theoretical phenomenon.

4. Application: regularizing correspondence analysis

When X contains count data, we have a natural noise model $X_{ij} \sim \text{Poisson}(\mu_{ij})$ that is compatible with the Lévy bootstrap, and so our stable autoencoding framework is easy to apply. In this situation, however, X is often analyzed by correspondence analysis (Greenacre, 1984, 2007) rather than using a direct singular-value decomposition. Correspondence analysis, a classical statistics technique pioneered by Hirschfeld (1935) and Benzécri (1986, 1973), underlies variants of many modern machine learning applications such as spectral clustering on graphs (e.g., Ng et al., 2002; Shi and Malik, 2000) or topic modeling for text data (see Section 6.1). In this section, we show how to regularize correspondence analysis by stable autoencoding. This discussion also serves as a blueprint for extending our method to other low-rank multivariate techniques such as principal component analysis or canonical correlation analysis.

Correspondence analysis involves taking the singular-value decomposition of a transformed matrix M :

$$M = R^{-\frac{1}{2}} \left(X - \frac{1}{N} rc^\top \right) C^{-\frac{1}{2}}, \quad \text{where } R = \text{diag}(r), C = \text{diag}(c), \quad (24)$$

N is the total number of counts, and r and c are vectors containing the row and column sums of X . This transformation M has several motivations. For example, suppose that X is a 2-way contingency table, i.e., that we have N samples for which we measure two discrete features $A \in \{1, \dots, n\}$ and $B \in \{1, \dots, p\}$, and X_{ij} counts the number of samples with $A = i$ and $B = j$. Then M measures the distance between X and a hypothetical contingency table where A and B are independently generated with the same marginal distributions as before; in fact, the standard χ^2 -test for independence of X uses $\|M\|_2^2$ as its test statistic. Meanwhile, if X is the adjacency matrix of a graph, then M is a version of the symmetric normalized graph Laplacian where we have projected out the first trivial eigenvector. Once we have a rank- k estimate of \hat{M}_k obtained as in (2), we get

$$\hat{\mu}_k^{CA} = R^{\frac{1}{2}} \hat{M}_k C^{\frac{1}{2}} + \frac{1}{N} rc^\top. \quad (25)$$

Our goal is to get a better estimator \widehat{M} for the matrix M of the population; we then transform \widehat{M} into an estimate of μ using the same formula (25).

Following (6), we propose regularizing the choice of M as follows:

$$\widehat{M}_k^{\text{stable}} = M \widehat{B}_k, \quad \text{where} \quad (26)$$

$$\widehat{B}_k = \text{argmin}_B \left\{ \mathbb{E}_{\tilde{X} \sim \tilde{\mathcal{L}}_k(X)} \left[\left\| M - R^{-\frac{1}{2}} \left(\tilde{X} - \frac{1}{N} rc^\top \right) C^{-\frac{1}{2}} B \right\|_2^2 \right] : \text{rank}(B) \leq k \right\}.$$

Just as in Theorem 2, we can show that \widehat{B}_k solves

$$\widehat{B}_k = \text{argmin}_B \left\{ \|M - MB\|_2^2 + \left\| S_M^{\frac{1}{2}} B \right\|_2^2 : \text{rank}(B) \leq k \right\}, \quad (27)$$

where S_M is a diagonal matrix with $(S_M)_{jj} = c_j^{-1} \sum_{i=1}^n \text{Var}_{\tilde{X} \sim \tilde{\mathcal{L}}_k(X)}[\tilde{X}_{ij}]/r_i$. We can efficiently solve for (27) using the same method as in (19) and (20). Finally, if we do not want to fix the rank k , we can use an iterative scheme as in Section 3.

Since X contains count data, we generate the bootstrap samples $\tilde{X} \sim \tilde{\mathcal{L}}_{\delta}(X)$ using the Poisson-compatible bootstrap algorithm (8), i.e., $\tilde{X}_{ij} \sim (1 - \delta)^{-1} \text{Binomial}(X_{ij}, 1 - \delta)$. Interestingly, if we had chosen to sample \tilde{X} from an independent contingency table with

$$\mathbb{E}_{\tilde{X} \sim \tilde{\mathcal{L}}_{\delta}}[\tilde{X}] = \frac{1}{N} r c^T, \quad \text{Var}_{\tilde{X} \sim \tilde{\mathcal{L}}_{\delta}}[\tilde{X}_{ij}] = \frac{\delta}{1 - \delta} \frac{r_i c_j}{N}, \quad (28)$$

we would have obtained a regularization matrix $S_M = n\delta/(N(1 - \delta))I_{p \times p}$. Because S_M is diagonal, the resulting estimator \widehat{M}_A could then be obtained from M by singular value shrinkage. Thus, if we want to regularize correspondence analysis applied to a nearly independent table, singular value shrinkage based methods can achieve good performance; however, if the table has strong dependence, our framework provides a more principled way of being robust to sampling noise.

5. Simulation experiments

To assess our proposed methods, we first run comparative simulation studies for different noise models. We begin with a sanity check: in Section 5.1, we reproduce the isotropic Gaussian noise experiments of Candès et al. (2013), and find that our method is competitive with existing approaches on this standard benchmark.

We then move to the non-isotropic case, where we can take advantage of our method’s ability to adapt to different noise structures. In Section 5.2 we show results on experiments with Poisson noise, and find that our method substantially outperforms its competitors. Finally, in Section 6, we apply our method to real-world applications motivated by topic modeling and sensory analysis.

5.1 Gaussian noise

We compare our estimators to existing ones by reproducing the simulations of Candès et al. (2013). For this experiment, we generated data matrices of size 200×500 according to the Gaussian noise model (14) with four signal-to-noise ratios $\text{SNR} \in \{0.5, 1, 2, 4\}$ calculated as $1/(\sigma\sqrt{np})$, and two values for the underlying rank $k \in \{10, 100\}$; results are in Table 1.

Methods under consideration: Our goal is to evaluate the performance of the stable autoencoder (SA) as defined in (6) and the iterated stable autoencoder (ISA) described in Algorithm 1. As discussed in Section 2, we applied our stable autoencoding methods to X^T rather than X , so that n was larger than p ; and set the tuning parameter to $\delta = 1/2$. For ISA, we ran the iterative Algorithm 1 for 100 steps, although the algorithm appeared to become stable after 10 steps already.

In addition to our two methods, we also consider the following estimators:

- Truncated SVD with fixed rank k (TSVD- k). This is the classical approach (2).
- Adaptively truncated SVD (TSVD- τ), using the asymptotically optimal threshold of Gavish and Donoho (2014a).
- Asymptotically optimal singular-value shrinkage (ASYMIP) in the Marchenko-Pastur asymptotic regime given the Frobenius norm loss (Shabalin and Nobel, 2013; Gavish

and Donoho, 2014b), with shrinkage function

$$\psi(d) = \begin{cases} \frac{1}{d} \sqrt{(d^2 - (1 + \beta)n\sigma^2)^2 - 4\beta n^2 \sigma^4} & \text{for } d^2 \geq (1 + \sqrt{\beta})^2 n\sigma^2, \\ 0 & \text{else,} \end{cases} \quad (29)$$

where $\beta = p/n$ is the aspect ratio, assuming without loss of generality that $p \leq n$.

- The shrinkage scheme of Verbanck et al. (2013) motivated by low-noise (LN) asymptotics. It uses for $\psi(d)$ in (3),

$$\psi(d) = \begin{cases} d \left(1 - \frac{\sigma^2}{d^2}\right) & \text{for } l \leq k, \\ 0 & \text{else.} \end{cases} \quad (30)$$

All the estimators are defined assuming the variance of the noise scale σ^2 to be known. In addition, TSVD- k , SA, and LN require the rank k as a tuning parameter. In this case, we set k to the true rank of the underlying signal.

As our simulation study makes clear, the proposed methods have very different strengths and weaknesses. Both methods that apply a hard thresholding rule to the singular values, namely TSVD- k and TSVD- τ , provide accurate MSE when the SNR is high but break down in low SNR settings. Conversely, the SVST behaves well in low SNR settings, but struggles in other regimes. This is not surprising, as the method over-estimates the rank of μ . This behavior is reminiscent of what happens in lasso regression (Tibshirani, 1996) when too many variables are selected (Zou, 2006; Zhang and Huang, 2008).

Meanwhile, the estimators with non-linear singular-value shrinkage functions, namely SA, ISA, ASYMIP, and LN are more flexible and perform well except in the very difficult scenario where the signal is overwhelmed by the noise. Both ASYMIP and ISA estimate the rank accurately except when the signal is nearly indistinguishable from the noise ($\text{SNR} = 0.5$ and $k = 100$).

5.2 Poisson noise

Once we move beyond the isotropic Gaussian case, our method can both learn better singular vectors and out-perform its competitors in terms of MSE. We illustrate this phenomenon with a simple simulation example, where we drew X of size $n = 50$ and $p = 20$ from a Poisson distribution with expectation μ of rank 3 represented in Figure 1. Because the three components of μ have different levels of concentration—the first component is rather diffuse, while the third one is concentrated in a corner—adapting to the Poisson variance structure is important.

We varied the effective signal-to-noise ratio by adjusting the mean number of counts in X , i.e., $N = \sum_{ij} \mu_{ij}$. We then report results for the normalized mean matrix μ/N . We used both SA and ISA to estimate μ from X ; in both cases, we generated \tilde{X} with the Poisson-compatible bootstrap noise model (8), and set $\delta = 1/2$. We also used LN, ASYMIP and

k	SNR	Stable		TSVD		ASYMP	SVST	LN
		SA	ISA	k	τ			
MSE

Table 1: Mean cell-wise squared error (top) and rank estimates (bottom) obtained by the methods described in Section 5.1, averaged over 50 simulation replications. The best results for each row are indicated in bold.

TSVD- τ as baselines, although they are only formally motivated in the Gaussian model. These methods require a value for σ . For LN, we used the method recommended by Josse and Husson (2011):

$$\hat{\sigma}^2 = \frac{\|X - \sum_{l=1}^k u_l d_l v_l\|_2^2}{np - nk - kp + k^2}. \quad (31)$$

For ASYMP and TSVD- τ , we used the estimator suggested in Gavish and Donoho (2014b), $\hat{\sigma} = d_{med} / \sqrt{n\mu_\beta}$, where d_{med} is the median of the singular values of X and μ_β is the median of the Marcenko-Pastur distribution with aspect ratio β .

In addition to providing MSE (Table 2), we also report the alignment of the row/column directions U and V with those of the true mean matrix μ (Table 3). We measured alignment using the RV coefficient, which is a matrix version of Pearson's squared correlation coefficient ρ^2 that takes values between 0 and 1 (Escoufier (1973); see Josse and Holmes (2013) for a review):

$$RV(U, \hat{U}) = \frac{\text{tr}(U^T \hat{U} \hat{U}^T U)}{\sqrt{\text{tr}((U^T U)^2) \text{tr}((\hat{U}^T \hat{U})^2)}}. \quad (32)$$

Finally, we also report the mean estimated ranks in Table 4.

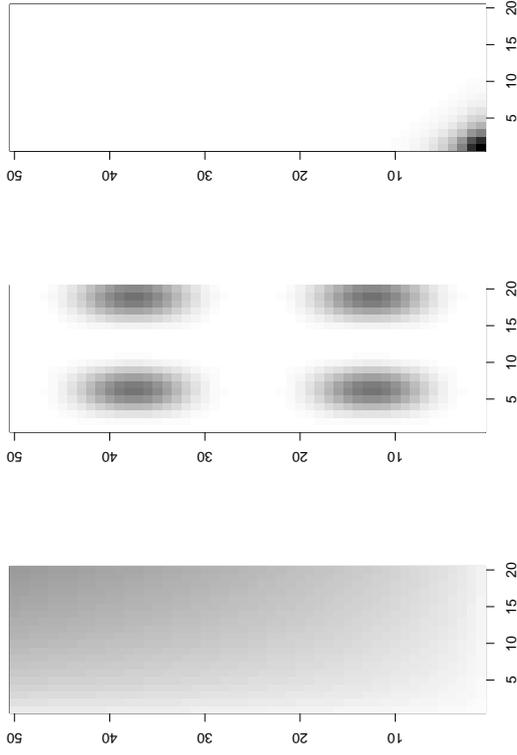

Figure 1: The 3 components of the mean of the underlying Poisson process; the dark arcs have the highest intensity. The corresponding singular values have relative magnitudes 1.1 : 1.4 : 1.

We see that our methods based on stable autoencoding do well across all noise levels. In the high-noise setting (i.e., with a small number of count observations N), the iterated stable autoencoder does particularly well, as it is able to use a lower rank in response to the weaker signal. As seen in Table 3, the ability to learn new singular vectors appears to have been useful here, as the \hat{U} and \hat{V} matrices obtained by stable autoencoding are much better aligned with the population ones than those produced by the SVD arc. We also see that, in the low noise setting where N is large, ISA recovers the true rank $k = 3$ almost exactly, whereas ASYMP and TSVD- τ do not. Finally, we note that all shrinkage methods did better than the baseline, namely the simple rank-3 SVD. Thus, even though LN, ASYMP and TSVD- τ are only formally motivated in the Gaussian noise case, our results suggest that they are still better than no regularization on generic problems.

Table 3: RV coefficients between the estimated and true U and V matrices, averaged over 1000 simulation replications. For ISA, we only averaged performance over examples where the estimated rank was at least 3. In the $N = 200$ case, no results is given for ISA since the estimated rank is always less than 3.

6. Real-world examples

To highlight the wide applicability of our method, we use it on two real-world problems from different fields. We begin with a larger natural language application, where we use the iterated stable autoencoder to improve the quality of topics learned by latent semantic analysis, and evaluate results by end-to-end classifier performance. Next, in Section 6.2, we analyze a smaller dataset from a consumer survey, and show how our regularization schemes can improve the faithfulness of correspondence analysis graphical outputs commonly used by statisticians.

2000	3.23	4.07	3.00

Table 4: Mean rank estimates for the Poisson simulation, averaged over 1000 simulation replications. The true rank of the underlying signal is 3.

	Document Averaged	Corresp. Analysis	Corresp. Analysis + ISA
Accuracy	62.1 %	61.8 %	67.0 %
Times Best	2/10,000	1/10,000	9,997/10,000

Table 5: Test set accuracy of a logistic regression classifier trained on topics learned by latent semantic analysis, averaged over 10,000 train/test splits. The topic models were run only once on all the (unlabeled) data; thus we are in a transductive setting. Each method used $k = 5$ topics; this number was automatically picked by ISA.

6.1 Learning topics for sentiment analysis

Many tasks in natural language processing involve computing a low-rank approximation to a *document/term-frequency* matrix X , i.e., X_{ij} counts the number of times word j appears in document i . The singular rows of X can then be interpreted as *topics* characterized by the prevalence of different words, and each document is described as a mixture of topics. The idea of learning topics using an SVD of (a normalized version of) the matrix X is called latent semantic analysis (Deerwester et al., 1990). Here, we argue that we can make the topics discovered by latent semantic analysis better by regularizing the SVD of X using an iterated stable autoencoder.

To do so, we examine the Rotten Tomatoes movie review dataset collected by Pang and Lee (2004), with $n = 2,000$ documents and $p = 50,921$ unique words. We learned topics with three variants of latent semantic analysis, which involve using different transformations/regularization schemes while taking an SVD.

- Document averaging: in order to avoid large documents dominating the fit, we compute the matrix $\Pi_{ij} = X_{ij} / \sum_j X_{ij}$. We then perform a rank- k SVD of Π .

- Correspondence analysis: we run a rank- k SVD on M from (24). This approach normalizes by both $R^{-\frac{1}{2}}$ and $C^{-\frac{1}{2}}$ in order to counteract the excess influence of both long documents and common words, instead of just using $\Pi = R^{-1}X$ as above.
- ISA-regularized correspondence analysis ($\delta = 0.5$).

Correspondence analysis with ISA picked $k = 5$ topics; we also used $k = 5$ for the other methods. The document averaging method did not appear to benefit much from regularization; presumably, this is because the matrix Π does not up-weight rare words.

Because n and p are both fairly large, it is difficult to evaluate the quality of the learned topics directly. To get around this, we used a more indirect approach and examined the quality of the learned decompositions of X by using them for sentiment classification. Specifically, each method produces a low-rank decomposition UDV^T , where U is an $n \times k$ orthonormal matrix; we then used the columns of U as features in a logistic regression. We trained the logistic regression on one half of the data and then tested it on the other half, repeating this process over 10,000 random splits. We are in a transductive setting because we used all the data (but not the labels) for learning the topics.

The results, shown in Table 5, suggests that ISA substantially improves the performance of latent semantic analysis for this dataset. In a somewhat surprising twist, we may have expected the decomposition based on correspondence analysis to out-perform the baseline that just divides by document length; however, correspondence analysis ended up doing slightly worse. The problem appears to have been that, because correspondence analysis up-weights less common words relative to the common ones, its topics become more vulnerable to noise. Thus, it is not able to beat document-wise averaging although it has a seemingly better normalization scheme. But, once we use ISA to regularize it, correspondence analysis is able to fully take advantage of the down-weighting of common words.

We can visualize the effect of regularization using Figure 2, which shows the distribution of $\log \|U_i\|_2^2$ for the U -matrices produced by correspondence analysis with and without ISA. The quantity $\|U_i\|_2^2$ measures the importance of the i -th document in learning the topics. We see that plain correspondence analysis has some documents that dominate the resulting U matrix, whereas with ISA the magnitudes of the contributions of different documents are more evenly spread out. Thus, assuming that we do not want topics to be dominated by just a few documents, Figure 2 corroborates our intuition that ISA improves the topics learned by correspondence analysis.

Finally, we note that there exist several topic models that do not reduce to an SVD (e.g., Blei et al., 2003; Hofmann, 2001; Xu et al., 2003); in fact, one of the motivations for latent Dirichlet allocation (Blei et al., 2003) was to add regularization to topic modeling using a hierarchical Bayesian approach. Moreover, methods that only rely on unsupervised topic learning do not in general achieve state-of-the-art accuracy for sentiment classification on their own (e.g., Wang and Manning, 2012). Thus, our goal here is not to advocate an end-to-end methodology for sentiment classification, but only to show that stable autoencoding can substantially improve the quality of topics learned by a simple SVD in cases where a practitioner may want to use them.

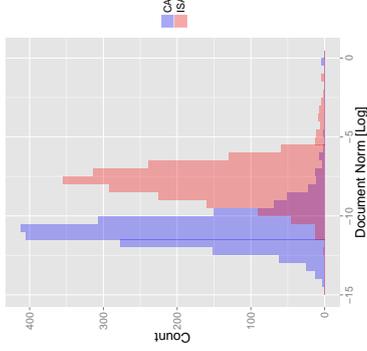

Figure 2: Distribution of $\log \|U_i\|_2^2$ for correspondence analysis with and without ISA. Using ISA increases the influence of the median document in learning topics.

6.2 A sensory analysis of perfumes

Finally, we use stable autoencoding to regularize a sensory analysis of perfumes. The data for the analysis was collected by asking consumers to describe 12 luxury perfumes such as *Chanel Number 5* and *J'adore* with words. The answers were then organized in a 12×39 (39 words unique were used) data matrix where each cell represents the number of times a word is associated to a perfume; a total of $N = 1075$ were used overall. The dataset is available at <http://factominer.free.fr/docs/perfume.txt>. We used correspondence analysis (CA) to visualize the associations between words and perfumes. Here, the technique allows to highlight perfumes that were described using a similar profile of words, and to find words that describe the differences between groups of perfumes.

In order to get a better idea of which regularization method is the most trustworthy here, we ran a small bootstrap simulation study built on top of the perfume dataset. We used the full $N = 1075$ perfume dataset as the population dataset, and then generated samples of size $N = 200$ by subsampling the original dataset without replacement. Then, on each sample, we performed a classical correspondence analysis by performing a rank- k truncated SVD of the matrix M (24), as well as several regularized alternatives described in Section 5.1.

For each estimator, we report its singular values, as well as the RV-coefficients between its row (respectively column) coordinates and the population ones. All the methods except for ISA require us to specify the rank k as an input parameter. Here, of course, k is unknown since we are working with a real dataset; however, examining the full-population dataset suggests that using $k = 2$ components is appropriate. For LN, SA and ISA, we set tuning parameters as in Section 5.2, namely LN uses $\hat{\sigma}$ from (31), while SA is performed with $\delta = 0.5$. For ISA we used $\delta = 0.3$; this latter choice was made to get rank-2 estimates. In practice, one could also consider cross-validation to find a good value for δ .

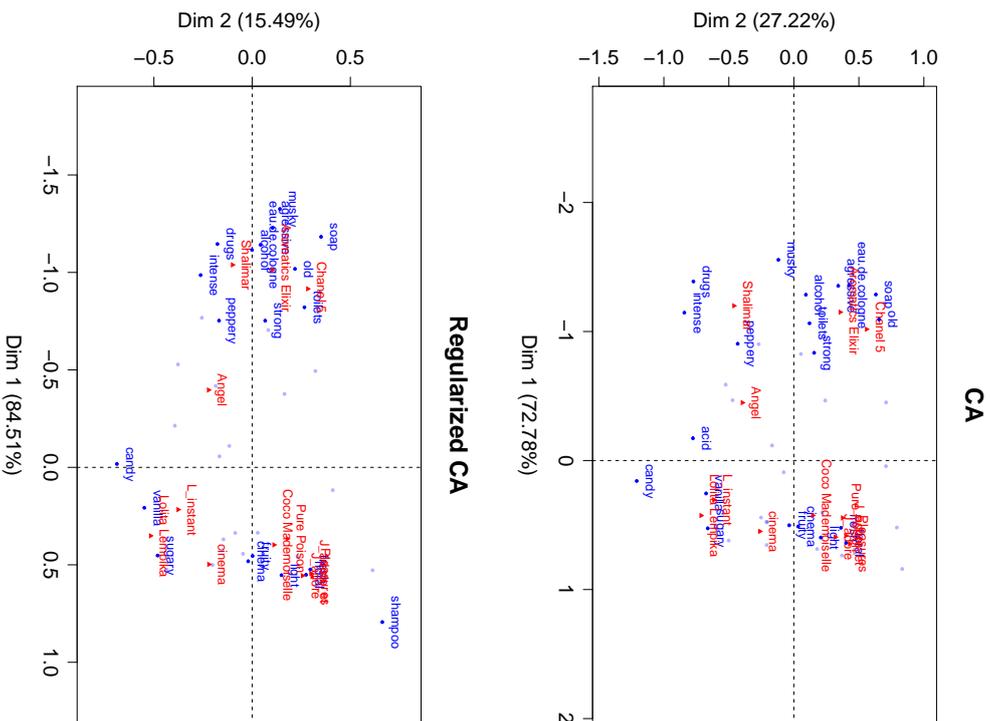

Figure 3: Results for CA on a sample data set (top) and Regularized CA (bottom) using ISA on a single subsample of size $N = 200$. Only the 20 words that contribute the most to the dimensions of variability are represented.

	d_1	d_2	RV _{row}	RV _{col}	k
TRUE	0.44	0.15			
CA	0.62	0.42	0.41	0.72	
LN	0.28	0.11	0.47	0.79	
SA	0.34	0.18	0.50	0.79	
ISA	0.40	0.18	0.52	0.81	2.43

Table 6: Performance of standard correspondence analysis (CA) as well as regularized alternatives on the perfume dataset. We report singular values, RV-coefficients and rank estimates; results correspond to the mean over the 1000 simulations.

Results are shown in Table 6. From a practical point of view, it is also interesting to compare the graphical output of correspondence analysis with and without regularization. Figure 3 (top) shows two-dimensional CA representation on one sample and Figure 3 (bottom) shows the representation obtained with ISA. Only the 20 words that contribute the most to the first two dimensions are represented. The analysis is performed using the R package FactoMineR (Le et al., 2008).

Our results emphasize that, although correspondence analysis is often used as a visualization technique, appropriate regularization is still important, as regularization may substantially affect the graphical output. For example, on the basis of the CA plot, the perfume *Shalimar* looks like an outlier, whereas after regularization it seems to fit in a cluster with *Chanel 5* and *Elixir*. We know from Table 6 that the regularized CA plots are better aligned with the population ones than the unregularized ones are; thus, we may be more inclined to trust insights from the regularized analysis.

7. Discussion

In this paper, we introduced a new framework for low-rank matrix estimation that works by transforming noise models into regularizers via a bootstrap scheme. Our method can adapt to non-isotropic noise structures, thus enabling it to substantially outperform its competitors on problems with, e.g., Poisson noise.

At a high level, our framework works by creating pseudo-datasets \tilde{X} from X using the bootstrap distribution $\tilde{\mathcal{L}}(X)$. If two pseudo-datasets \tilde{X}_1 and \tilde{X}_2 are both likely given $\tilde{\mathcal{L}}(X)$, then we want the induced mean estimates $\hat{\mu}_n^1 = \tilde{X}_1 \hat{B}_n$ and $\hat{\mu}_n^2 = \tilde{X}_2 \hat{B}_n$ to be close to each other. The stable autoencoder (6) enables us to turn this intuition into a concrete regularizer by using the Lévy bootstrap. It remains to be seen whether this idea of regularization via bootstrapping pseudo-datasets can be extended to other classes of low-rank matrix algorithms, e.g., those discussed by Collins et al. (2001), de Leeuw (2006), or Udell et al. (2014).

8. Appendix: Proofs

8.1 Proof of Theorem 1

We begin by establishing the equivalence between (6) and (15). By bias-variance decomposition, we can check that

$$\begin{aligned} \mathbb{E}_{\varepsilon_{ij} \stackrel{iid}{\sim} \mathcal{N}(0, \sigma^2)} \left[\|X - (X + \varepsilon)B\|_2^2 \right] &= \|X - XB\|_2^2 + \mathbb{E}_\varepsilon \left[\|\varepsilon B\|_2^2 \right] \\ &= \|X - XB\|_2^2 + \sum_{i,j,k} \text{Var}[\varepsilon_{ij}] B_{jk}^2 \\ &= \|X - XB\|_2^2 + n \frac{\delta \sigma^2}{1 - \delta} \|B\|_2^2, \end{aligned}$$

and so the two objectives are equivalent.

To show that $\hat{\mu}_k^{\text{stable}}$ can be written as (16), we solve for $\hat{\mu}_k^{\text{stable}} = X\hat{B}_k$ explicitly, where

$$\hat{B}_k = \text{argmin}_B \left\{ \|X - XB\|_2^2 + \lambda \|B\|_2^2 : \text{rank}(B) \leq k \right\}.$$

Let $X = UDV^\top$ be the SVD of X . For any matrix M of the same dimension as D , $\|UMV^\top\|_2^2 = \|M\|_2^2$. Thus, we can equivalently write the problem

$$\hat{B}_k = V\hat{Q}_kV^\top, \text{ where } \hat{Q}_k = \text{argmin}_Q \left\{ \|D - DQ\|_2^2 + \lambda \|Q\|_2^2 : \text{rank}(Q) \leq k \right\}.$$

Now, because D is diagonal, $(DQ)_{ij} = D_{ii}Q_{ij}$. Thus, we conclude that $\hat{Q}_{ij} = 0$ for all $i \neq j$, while the problem separates for all the diagonal terms. Without the rank constraint on Q , we find that the diagonal terms \hat{Q}_{ii} are given by

$$\hat{Q}_{ii} = \text{argmin}_{Q_{ii}} \left\{ (1 - Q_{ii})^2 D_{ii}^2 + \lambda Q_{ii}^2 \right\} = \frac{D_{ii}^2}{\lambda + D_{ii}^2}.$$

Meanwhile, we can check that adding the rank constraint amounts to zeroing out all but the k largest of the \hat{Q}_{ii} . Thus, plugging this into our expression of $\hat{\mu}$, we get that

$$\hat{\mu}_k^{\text{stable}} = \sum_{i=1}^k \frac{U_i}{1 + \lambda/D_{ii}^2} V_i^\top.$$

8.2 Proof of Theorem 2

We start by showing that \hat{B} is the solution to the unconstrained version of (17). Let V be a matrix defined by

$$V_{ij} = \text{Var}_{\tilde{X} \sim \tilde{\mathcal{L}}(X)} \left[\tilde{X}_{ij} \right].$$

Because \tilde{X} has mean X , we can check that

$$\mathbb{E}_{\tilde{X} \sim \tilde{\mathcal{L}}(X)} \left[\left\| X - \tilde{X}B \right\|_2^2 \right] = \|X - XB\|_2^2 + \sum_{i,j,k} V_{ij} B_{jk}^2.$$

Thus,

$$\frac{1}{2} \frac{\partial}{\partial B_{jk}} \mathbb{E}_{\tilde{X} \sim \tilde{\mathcal{L}}(X)} \left[\left\| X - \tilde{X}B \right\|_2^2 \right] = - \sum_i X_{ij} (X - XB)_{ik} + \sum_i V_{ij} B_{jk}.$$

Setting gradients to zero, we find an equilibrium

$$X^\top X = X^\top XB + SB, \text{ where } S_{jk} = \begin{cases} \sum_{i=1}^n V_{ij} & \text{for } j = k, \\ 0 & \text{else.} \end{cases}$$

Thus, we conclude that

$$\hat{B} = (X^\top X + S)^{-1} X^\top X$$

is in fact the solution to (17) without the rank constraint.

Next, we show how we can get from \hat{B} to \hat{B}_k using (19). For any matrix B , we can verify by quadratic expansion that

$$\begin{aligned} \|X - XB\|_2^2 &= \|X - X\hat{B}\|_2^2 + \|X(\hat{B} - B)\|_2^2 + 2 \text{tr} \left((X - X\hat{B})^\top (X\hat{B} - XB) \right) \\ &= \|X - X\hat{B}\|_2^2 + \|X(\hat{B} - B)\|_2^2 \\ &\quad + 2 \text{tr} \left((X^\top X (X^\top X + S)^{-1} X^\top X - X^\top X) (B - \hat{B}) \right) \end{aligned}$$

Meanwhile,

$$\begin{aligned} \|S^{\frac{1}{2}}B\|_2^2 &= \|S^{\frac{1}{2}}\hat{B}\|_2^2 + \|S^{\frac{1}{2}}(B - \hat{B})\|_2^2 + 2 \text{tr} \left(\hat{B}^\top S (B - \hat{B}) \right) \\ &= \|S^{\frac{1}{2}}\hat{B}\|_2^2 + \|S^{\frac{1}{2}}(B - \hat{B})\|_2^2 + 2 \text{tr} \left(X^\top X (X^\top X + S)^{-1} S (B - \hat{B}) \right). \end{aligned}$$

Summing everything together, we find that

$$\|X - XB\|_2^2 + \|S^{\frac{1}{2}}B\|_2^2 = \|X(B - \hat{B})\|_2^2 + \|S^{\frac{1}{2}}(B - \hat{B})\|_2^2 + R(\hat{B}, X)$$

where R is a residual term that does not depend on B . Thus, we conclude that

$$\begin{aligned} \hat{B}_k &= \text{argmin}_B \left\{ \|X - XB\|_2^2 + \|S^{\frac{1}{2}}B\|_2^2 : \text{rank}(B) \leq k \right\} \\ &= \text{argmin}_B \left\{ \text{tr} \left((B - \hat{B})^\top (X^\top X + S) (B - \hat{B}) \right) : \text{rank}(B) \leq k \right\}. \end{aligned}$$

As shown in, e.g., Takane (2013), we can solve this last problem by taking the top k terms of the eigendecomposition of $\hat{B}^\top (X^\top X + S)^{-1} \hat{B}$.

8.3 Proof of Theorem 3

For iterates $t = 0, 1, \dots$, define $M_t = \hat{\mu}_t^\top \hat{\mu}_t$. Here, we will show that M_t converges to a fixed point M^* , and that $M^* \preceq X^\top X$; the desired conclusion then follows immediately. First, by construction, we have that

$$M_0 = X^\top X \quad \text{and} \quad M_t = X^\top X \left(X^\top X + S \right)^{-1} X^\top X \left(X^\top X + S \right)^{-1} X^\top X,$$

and so we immediately see that $M_t \preceq M_0$. The general update for M_t is

$$M_{t+1} = g(M_t)^\top g(M_t), \quad \text{where } g(M) = \Sigma^{\frac{1}{2}} (M + S)^{-1} M, \quad (33)$$

where $\Sigma^{\frac{1}{2}}$ is a positive semi-definite solution to $(\Sigma^{\frac{1}{2}})^\top \Sigma^{\frac{1}{2}} = X^\top X$. Now, because matrix inversion is a monotone decreasing function over the positive semi-definite cone and $S \succ 0$, we find that

$$g(M) = \Sigma^{\frac{1}{2}} \left(I - (M + S)^{-1} S \right)$$

is monotone increasing in M over the positive semi-definite cone. In particular

$$\text{if } M_t \leq M_{t-1}, \text{ then } M_{t+1} \leq M_t.$$

By induction, the sequence M_t is monotone decreasing with respect to the positive semi-definite cone order; by standard arguments, it thus follows that this sequence must converge to a limit M^* . Finally, we note that convergence of M_t also implies convergence of $\hat{\mu}_t$, since $\hat{\mu}_{t+1} = X \hat{B}_t$ and \hat{B}_t only depends on $\hat{\mu}_t$ through M_t .

8.4 Proof of Theorem 4

As in the proof of Theorem 3, let $M^* = \hat{\mu}^\top \hat{\mu}$. Because M^* is a fixed point, we know that

$$M^* = M^* (M^* + S)^{-1} X^\top X (M^* + S)^{-1} M^*.$$

Now, because M^* is symmetric with eigenvector u , we can decompose it as

$$M^* = M^\perp + \lambda_u u u^\top, \quad \text{where } \lambda_u = u^\top M^* u \quad \text{and} \quad \|M^\perp u\|_2 = 0.$$

By combining these equalities and using the monotonicity of matrix inversion, we find that

$$\begin{aligned} \lambda_u &= u^\top M^* u \\ &= \lambda_u^2 u^\top (M^* + S)^{-1} X^\top X (M^* + S)^{-1} u \\ &\leq \lambda_u^2 u^\top S^{-1} X^\top X S^{-1} u. \end{aligned}$$

This relation can only hold if $\lambda_u = 0$, or $1 \leq \lambda_u u^\top S^{-1} X^\top X S^{-1} u$, and so our desired conclusion must hold.

8.5 Proof of Proposition 5

First, we note that in the setting (14) with $\delta = 1/2$, we have $S = n\sigma^2 I$. Using Theorem 1, we can verify that the singular vectors of $\hat{\mu}_t$ are the same as those of X for each iterate $t = 1, 2, \dots$ of our algorithm; and so we can write the limit $\hat{\mu}^{\text{iter}}$ as singular value shrinker

$$\hat{\mu}^{\text{iter}} = \sum_{i=1}^{\min\{n, p\}} u_i \psi(d_i) v_i^\top.$$

It remains to derive the form of ψ . Now, using (16), we can verify that the fixed point condition on $\hat{\mu}^{\text{iter}}$ can be expressed in terms of ψ as

$$\psi(d) = \frac{\psi^2(d)}{\lambda + \psi^2(d)} d, \quad \text{with } \lambda = n\sigma^2.$$

This is a cubic equation, with solutions

$$\psi(d) = 0, \quad \text{and} \quad \psi(d) = \frac{1}{2} \left(d \pm \sqrt{d^2 - 4n\sigma^2} \right) \quad \text{for } d^2 \geq 4n\sigma^2.$$

Finally, we can verify that our iterative procedure cannot jump over the largest root, thus resulting in the claimed shrinkage function.

We also check here that, in the case $n = p$, our shrinker $\psi(\cdot)$ is equivalent to the asymptotically optimal shrinker for operator loss $\psi_{\text{opt}}^*(d)$ (Gavish and Donoho, 2014b) which is 0 for $d^2 < 4n\sigma^2$, and else

$$\begin{aligned} \psi_{\text{opt}}(d) &= \frac{1}{\sqrt{2}} \sqrt{d^2 - 2n\sigma^2 + \sqrt{(d^2 - 2n\sigma^2)^2 - 4n^2\sigma^4}} \\ &= \frac{1}{\sqrt{2}} \sqrt{d^2 - 2n\sigma^2 + d \sqrt{d^2 - 4n\sigma^2}}. \end{aligned}$$

Squaring our iterative shrinker, we see that

$$\psi^2(d) = \frac{1}{2} \left(d^2 - 2n\sigma^2 + d \sqrt{d^2 - 4n\sigma^2} \right) = \psi_{\text{opt}}^2(d)$$

for $d^2 \geq 4n\sigma^2$, and 0 else.

Abstract

Our paper deals with inferring simulator-based statistical models given some observed data. A simulator-based model is a parametrized mechanism which specifies how data are generated. It is thus also referred to as generative model. We assume that only a finite number of parameters are of interest and allow the generative process to be very general; it may be a noisy nonlinear dynamical system with an unrestricted number of hidden variables. This weak assumption is useful for devising realistic models but it renders statistical inference very difficult. The main challenge is the intractability of the likelihood function. Several likelihood-free inference methods have been proposed which share the basic idea of identifying the parameters by finding values for which the discrepancy between simulated and observed data is small. A major obstacle to using these methods is their computational cost. The cost is largely due to the need to repeatedly simulate data sets and the lack of knowledge about how the parameters affect the discrepancy. We propose a strategy which combines probabilistic modeling of the discrepancy with optimization to facilitate likelihood-free inference. The strategy is implemented using Bayesian optimization and is shown to accelerate the inference through a reduction in the number of required simulations by several orders of magnitude.

Keywords: intractable likelihood, latent variables, Bayesian inference, approximate Bayesian computation, computational efficiency

1. Introduction

We consider the statistical inference of a finite number of parameters of interest $\theta \in \mathbb{R}^d$ of a simulator-based statistical model for observed data \mathbf{y}_0 which consist of m possibly dependent data points. A simulator-based statistical model is a parametrized stochastic data generating mechanism. Formally, it is a family of probability density functions (pdfs) $\{p_{\mathbf{y}|\theta}\}_{\theta}$ of unknown analytical form which allow for exact sampling of data $\mathbf{y}\theta \sim p_{\mathbf{y}|\theta}$. In practical terms, it is a computer program which takes a value of θ and a state of the random number generator as input and returns data $\mathbf{y}\theta$ as output. Simulator-based models are also called implicit models because the pdf of $\mathbf{y}\theta$ is not specified explicitly (Diggle and Gratton, 1984), or generative models because they specify how data are generated.

Simulator-based models are useful because they interface easily with models typically encountered in the natural sciences. In particular, hypotheses of how the observed data \mathbf{y}_0 were generated can be implemented without making excessive compromises in order to have an analytically tractable model pdf $p_{\mathbf{y}|\theta}$.

Since the analytical form of $p_{\mathbf{y}|\theta}$ is unknown, inference using the likelihood function $\mathcal{L}(\theta)$,

$$\mathcal{L}(\theta) = p_{\mathbf{y}|\theta}(\mathbf{y}_0|\theta), \quad (1)$$

is not possible. The likelihood function is also not available for a large class of other statistical models which are known as unnormalized models. In these models, $p_{\mathbf{y}|\theta}$ is only known up to a normalizing scaling factor (the partition function) which guarantees that $p_{\mathbf{y}|\theta}$ is a valid pdf for all values of θ . Simulator-based models differ from unnormalized models in that not only is the scaling factor unknown but also the shape of $p_{\mathbf{y}|\theta}$. Likelihood-free inference methods developed for unnormalized models (for example Hinton, 2002; Hyvärinen, 2005; Pihlaja et al., 2010; Gutmann and Hirayama, 2011; Gutmann and Hyvärinen, 2012) are thus not applicable to simulator-based models.

For simulator-based models, likelihood-free inference methods have emerged in multiple disciplines. “Indirect inference” originated in economics (Gouriéroux et al., 1993), “approximate Bayesian computation” (ABC) in genetics (Beaumont et al., 2002; Marjoram et al., 2003; Sisson et al., 2007), or the “synthetic likelihood” approach in ecology (Wood, 2010), for an overview, see, for example, the review by Hartig et al. (2011). The different methods share the basic idea to identify the model parameters by finding values which yield simulated data that resemble the observed data.

The generality of simulator-based models comes with the expense of two major difficulties in the inference. One difficulty is the assessment of the discrepancy between the observed and simulated data (Joyce and Marjoram, 2008; Wegmann et al., 2009; Nunes and Balding, 2010; Fearnhead and Prangle, 2012; Aeschbacher et al., 2012; Gutmann et al., 2014). The other difficulty is that the inference methods tend to be slow due to the need to simulate a large collection of data sets and due to the lack of knowledge about the relation between the model parameters and the corresponding discrepancies.

In this paper, we address the computational difficulty of the likelihood-free inference methods. We propose a strategy which combines probabilistic modeling of the discrepancies with optimization to facilitate likelihood-free inference. The strategy is implemented using Bayesian optimization (see, for example, Brochu et al., 2010). We show that using Bayesian optimization in likelihood-free inference (BOLFI) can reduce the number of required simulations by several orders of magnitude, which accelerates the inference substantially.¹

The rest of the paper is organized as follows: In Section 2, we present examples of simulator-based statistical models to help clarify their properties. In Section 3, we provide a unified review of existing inference methods for simulator-based models, and use the examples to point out computational issues. The computational difficulties are summarized in Section 4, and a framework to address them is outlined in Section 5. Section 6 implements

1. Preliminary results were presented at “Approximate Bayesian Computation in Rome”, 2013, and MCMCski IV, 2014, as a poster “Bayesian optimization for efficient likelihood-free inference”, and at the NIPS workshop “ABC in Montreal”, 2014, as part of an oral presentation.

the framework using Bayesian optimization. Applications of the developed methodology are given in Section 7, and Section 8 concludes the paper.

2. Examples of Simulator-Based Statistical Models

We present here three examples of simulator-based statistical models. The first example is an artificial one, but useful because it allows us to illustrate the central concepts. The other two are examples from real data analysis with intractable models (Wood, 2010; Numminen et al., 2013). The examples will be used throughout the paper and the model details can be looked up here when needed.

Example 1 (Normal distribution). A standard way to sample data $\mathbf{y}_\theta = (y_\theta^{(1)}, \dots, y_\theta^{(n)})$ from a normal distribution with mean θ and variance one is to sample n standard normal random variables $\boldsymbol{\omega} = (\omega^{(1)}, \dots, \omega^{(n)})$ and to add θ to the obtained samples,

$$\mathbf{y}_\theta = \theta + \boldsymbol{\omega}, \quad \boldsymbol{\omega} \sim \mathcal{N}(0, \mathbf{I}_n). \quad (2)$$

The symbol $\mathcal{N}(0, \mathbf{I}_n)$ denotes a n -variate normal distribution with mean zero and identity covariance matrix. After sampling of the random quantities $\boldsymbol{\omega}$, the observed data \mathbf{y}_θ are a deterministic transformation of $\boldsymbol{\omega}$ and the parameter θ . For more general simulators, the same principle applies. In particular, the data \mathbf{y}_θ are a deterministic transformation of θ if the random quantities are kept fixed, for example by fixing the seed of the random number generator.

Example 2 (Ricker model). In this example, the simulator consists of a latent stochastic time series and an observation model. The latent time series is a stochastic version of the Ricker map which is a classical model in ecology (Ricker, 1954). The stochastic version can be described as a nonlinear autoregressive model,

$$\log N^{(t)} = \log r + \log N^{(t-1)} - N^{(t-1)} + \sigma e^{(t)}, \quad t = 1, \dots, n, \quad N^{(0)} = 0, \quad (3)$$

where $N^{(t)}$ is the size of some animal population at time t and the $e^{(t)}$ are independent standard normal random variables. The latent time series has two parameters: $\log r$ which is related to the log growth rate and σ for the standard deviation of the innovations. A Poisson observation model is assumed, such that given $N^{(t)}$, $y_\theta^{(t)}$ is drawn from a Poisson distribution with mean $\varphi N^{(t)}$,

$$y_\theta^{(t)} | N^{(t)}, \varphi \sim \text{Poisson}(\varphi N^{(t)}), \quad (4)$$

where φ is a scaling parameter. The model is thus in total parametrized by $\boldsymbol{\theta} = (\log r, \sigma, \varphi)$. Figure 1(a) shows example data generated from the model. Inference of $\boldsymbol{\theta}$ is difficult because the $N^{(t)}$ are not directly observed and because of the strong nonlinearity in the autoregressive model. Wood (2010) used this example to illustrate his “synthetic likelihood” approach to inference.

Example 3 (Bacterial infections in day care centers). The data generating process is here defined via a latent continuous-time Markov chain and an observation model. The model was developed by Numminen et al. (2013) to infer the transmission dynamics of bacterial infections in day care centers.

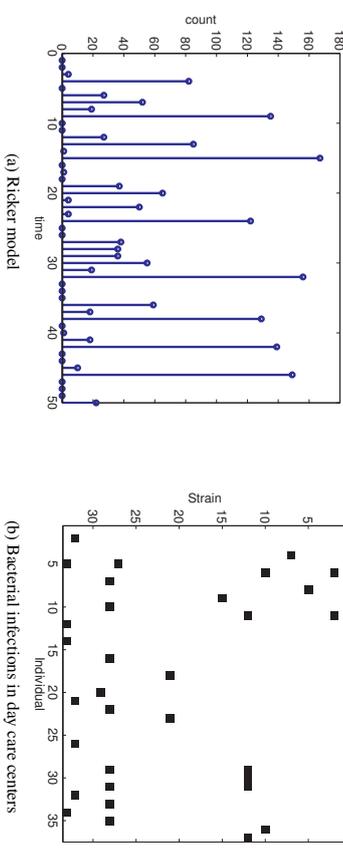

Figure 1: Examples of simulator-based statistical models. (a) Data generated from the Ricker model in Example 2 with $n = 50$ and $\boldsymbol{\theta}_0 = (\log r_0, \sigma_0, \varphi_0) = (3.8, 0.3, 10)$. (b) Data generated from the model in Example 3 on bacterial infections in day care centers. There are 33 different strains of the bacterium in circulation and $M_{\text{DCC}} = 36$ of the 53 attendees of the day care center were sampled (Numminen et al., 2013). Each black square indicates a sampled attendee who is infected with a particular strain. The data were generated with $\boldsymbol{\theta}_0 = (\beta_0, \Delta_0, \theta_0) = (3.6, 0.6, 0.1)$.

The variables of the latent Markov chain are the binary indicator variables I_{is}^t which specify whether attendee i of a day care center is infected with the bacterial strain s at time t ($I_{is}^t = 1$), or not ($I_{is}^t = 0$). Starting with zero infected individuals, $I_{is}^0 = 0$ for all i and s , the states evolve in a stochastic manner according to the rate equations

$$P(I_{is}^{t+h} = 0 | I_{is}^t = 1) = h + o(h), \quad (5)$$

$$P(I_{is}^{t+h} = 1 | I_{is}^t = 0 \forall s') = R_s(t)h + o(h), \quad (6)$$

$$P(I_{is}^{t+h} = 1 | I_{is}^t = 0, \exists s' : I_{is}^t = 1) = \theta R_s(t)h + o(h), \quad (7)$$

where h is a small time interval and $R_s(t)$ the rate of infection with strain s at time t . The three equations model the probability to clear a strain s during time t and $t+h$ (Equation 5), the probability to be infected with a strain s if not colonized by other strains (Equation 6), and the probability to be infected if colonized with other strains (Equation 7). The rate of infection is a weighted combination of the probability P_s for an infection happening outside the day care center and the probability $E_s(t)$ for an infection from within,

$$R_s(t) = \beta E_s(t) + \Delta P_s. \quad (8)$$

We refer the reader to the original publication by Numminen et al. (2013) for more details and the expression for $E_s(t)$. The observation model was random sampling of M_{DCC} individuals without replacement from all the individuals attending a day care center at some sufficiently large random time (endemic situation). The model has three parameters

$\theta = (\beta, \Lambda, \theta)$: the internal infection parameter β , the external infection parameter Λ , and the co-infection parameter θ . Figure 1(b) shows an example of data generated from the model.

Numminen et al. (2013) applied the model to data on colonizations with the bacterium *Streptococcus pneumoniae*. The observed data \mathbf{y}_o were the states of the sampled attendees of 29 day care centers, that is, 29 binary matrices as in Figure 1(b) but with varying numbers of sampled attendees per day care center. Inference of the parameters is difficult because the data are a snapshot of the state of some of the attendees at a single time point only. Since the process evolves in continuous-time, the modeled system involves infinitely many correlated unobserved variables. \blacktriangle

3. Inference Methods for Simulator-Based Statistical Models

This section organizes the foundations and the previous work. We first point out properties common to all inference methods for simulator-based models, one being the general manner of constructing approximate likelihood functions. We then explain parametric and nonparametric approximations of the likelihood and discuss the relation between the two approaches. This is followed by a summary of currently used posterior inference schemes.

3.1 General Properties of the Different Inference Methods

Inference of simulator-based statistical models is generally based on some measurement of discrepancy $\Delta\theta$ between the observed data \mathbf{y}_o and data \mathbf{y}_θ simulated with parameter value θ . The discrepancy is used to define an approximation $L(\theta)$ of the likelihood $\mathcal{L}(\theta)$. The approximation happens on multiple levels.

On a statistical level, the approximation consists of reducing the observed data \mathbf{y}_o to some features, or summary statistics Φ_o , before performing inference. The purpose of the summary statistics is to reduce the dimensionality and to filter out information which is not deemed relevant for the inference of θ . That is, in this first approximation, the likelihood $\mathcal{L}(\theta)$ is replaced with $L(\theta)$,

$$L(\theta) = p_{\Phi|\theta}(\Phi_o|\theta), \tag{9}$$

where $p_{\Phi|\theta}$ is the pdf of the summary statistics. The function $L(\theta)$ is a valid likelihood function, but for the inference of θ given Φ_o , and not for the inference of θ given \mathbf{y}_o , in contrast to $\mathcal{L}(\theta)$, unless the chosen summary statistics happened to be sufficient in the standard statistical sense.

The likelihood function $L(\theta)$, however, is also not known, because the pdf $p_{\Phi|\theta}$ is of unknown analytical form, which is a property inherited from $p_{\mathbf{y}|\theta}$. Thus, $L(\theta)$ needs to be approximated by some method. We denote practical approximations obtained with finite computational resources by $\hat{L}(\theta)$. Limiting approximations if infinitely many computational resources were available will be denoted by $\tilde{L}(\theta)$.

In the paper, we will encounter several methods to construct $\hat{L}(\theta)$. They all base the approximation on simulated summary statistics Φ_θ , generated with parameter value θ . The simulation of summary statistics is generally done by simulating a data set \mathbf{y}_θ , followed by its reduction to summary statistics. Table 1 provides an overview of the different “likelihoods” appearing in the paper.

Symbol	Meaning	Definition
\mathcal{L}	true likelihood based on observed data	Eq (1)
L	true likelihood based on summary statistics	Eq (9)
\tilde{L}	approximation of L requiring infinite computing power	Sec 3.1
$\tilde{L}_s(\tilde{\ell}_s)$	parametric approx/synthetic (log) likelihood	Eq (13)
\tilde{L}_κ	nonparametric approx with kernel κ	Eq (22)
\tilde{L}_u	nonparametric approx with uniform kernel	Eq (25)
\hat{L}	computable approximation of L	Sec 3.1
$\hat{L}_s^N(\hat{\ell}_s^N)$	parametric approx/synthetic (log) likelihood with sample averages	Eq (15)
\hat{L}_κ^N	nonparametric approx with kernel κ and sample averages	Eq (21)
\hat{L}_u^N	nonparametric approx with uniform kernel and sample averages	Eq (24)
$\hat{L}_s^{(t)}(\hat{\ell}_s^{(t)})$	parametric approx/synthetic (log) likelihood with regression	Sec 5.2
$\hat{L}_\kappa^{(t)}$	nonparametric approx with kernel κ and regression	Sec 5.3
$\hat{L}_u^{(t)}$	nonparametric approx with uniform kernel and regression	Sec 5.3

Table 1: The main (approximate) likelihood functions appearing in the paper. The superscript “ N ” indicates that the sample average is computed using N simulated data sets per model parameter θ . The superscript “ (t) ” indicates that regression is performed with a training set containing t simulated data sets. The parametric approximations will be used together with the Gaussian and the Ricker model, the nonparametric approximations together with the Gaussian and the day care center model.

After construction of \hat{L} , inference can be performed in the usual manner by replacing \mathcal{L} with \hat{L} . Approximate posterior inference can be performed via Markov chain Monte Carlo (MCMC) algorithms or via an importance sampling approach (see, for example, Robert and Casella, 2004). The posterior expectation of a function $g(\theta)$ given \mathbf{y}_o can be computed via importance sampling with auxiliary pdf $q(\theta)$,

$$E(g(\theta)|\mathbf{y}_o) \approx \sum_{m=1}^M g(\theta^{(m)})w^{(m)}, \quad w^{(m)} = \frac{\mathcal{L}(\theta^{(m)})p_{\theta}(\theta^{(m)})}{\sum_{i=1}^M \mathcal{L}(\theta^{(i)})p_{\theta}(\theta^{(i)})}, \quad \theta^{(m)} \stackrel{i.i.d.}{\sim} q(\theta), \tag{10}$$

where p_θ denotes the prior pdf. This approach also yields an estimate of the posterior distribution via the “particles” $\theta^{(m)}$ and the associated weights $w^{(m)}$. A computable version is obtained by replacing \mathcal{L} with \hat{L} , giving $E(g(\theta)|\mathbf{y}_o) \approx E(g(\theta)|\Phi_o)$,

$$E(g(\theta)|\Phi_o) \approx \sum_{m=1}^M g(\theta^{(m)})\hat{w}^{(m)}, \quad \hat{w}^{(m)} = \frac{\hat{L}(\theta^{(m)})p_{\theta}(\theta^{(m)})}{\sum_{i=1}^M \hat{L}(\theta^{(i)})p_{\theta}(\theta^{(i)})}, \quad \theta^{(m)} \stackrel{i.i.d.}{\sim} q(\theta). \tag{11}$$

There is some flexibility in the choice of the auxiliary pdf $q(\theta)$ in Equations (10) and (11) which enables iterative adaptive algorithms where the accepted $\theta^{(m)}$ of one iteration are used to define the auxiliary distribution $q(\theta)$ of the next iteration (population or sequential Monte Carlo algorithms; Cappé et al., 2004; Del Moral et al., 2006).

3.2 Parametric Approximation of the Likelihood

The pdf $p_{\Phi\theta}$ of the summary statistics is of unknown analytical form but it may be reasonably assumed that it belongs to a certain parametric family. For instance, if Φ_θ is obtained via averaging, the central limit theorem suggests that the pdf may be well approximated by a Gaussian distribution if the number of samples n is sufficiently large,

$$p_{\Phi\theta}(\phi|\theta) \approx \frac{1}{(2\pi)^{p/2} |\det \Sigma_\theta|^{1/2}} \exp\left(-\frac{1}{2}(\phi - \mu_\theta)^\top \Sigma_\theta^{-1}(\phi - \mu_\theta)\right), \quad (12)$$

where p is the dimension of Φ_θ . The corresponding likelihood function is $\hat{L}_s = \exp(\hat{\ell}_s)$,

$$\hat{\ell}_s(\theta) = -\frac{p}{2} \log(2\pi) - \frac{1}{2} \log |\det \Sigma_\theta| - \frac{1}{2} (\Phi_o - \mu_\theta)^\top \Sigma_\theta^{-1} (\Phi_o - \mu_\theta), \quad (13)$$

which is an approximation of $L(\theta)$ unless the summary statistics are indeed Gaussian. The mean μ_θ and the covariance matrix Σ_θ are generally not known. But the simulator can be used to estimate them via a sample average E^N over N independently generated summary statistics,

$$\hat{\mu}_\theta = E^N[\Phi_\theta] = \frac{1}{N} \sum_{i=1}^N \Phi_\theta^{(i)}, \quad \Phi_\theta^{(i)} \stackrel{i.i.d.}{\sim} p_{\Phi\theta}, \quad \hat{\Sigma}_\theta = E^N[(\Phi_\theta - \hat{\mu}_\theta)(\Phi_\theta - \hat{\mu}_\theta)^\top]. \quad (14)$$

A computable estimate \hat{L}_s^N of the likelihood function $L(\theta)$ is then given by $\hat{L}_s^N = \exp(\hat{\ell}_s^N)$,

$$\hat{\ell}_s^N(\theta) = -\frac{p}{2} \log(2\pi) - \frac{1}{2} \log |\det \hat{\Sigma}_\theta| - \frac{1}{2} (\Phi_o - \hat{\mu}_\theta)^\top \hat{\Sigma}_\theta^{-1} (\Phi_o - \hat{\mu}_\theta). \quad (15)$$

This approximation was named synthetic likelihood (Wood, 2010), hence our subscript “s”. Due to the approximation of the expectation with a sample average, $\hat{\ell}_s^N$ is a stochastic process (a random function). We illustrate this in Example 4 below. We there also show that the number of simulated summary statistics (data sets) N is a trade-off parameter: The computational cost decreases as N decreases but the variability of the estimate increases as a consequence. It further turns out that the sample curves of $\hat{\ell}_s^N$ may not be smooth for finite N and that decreasing N may worsen their roughness. We illustrate this in Example 5 using the Ricker model.

Example 4 (Synthetic likelihood for the mean of a normal distribution). The sample average is a sufficient statistic for the task of inferring the mean θ from a sample $\mathbf{y}_o = (y_o^{(1)}, \dots, y_o^{(n)})$ of a normal distribution with assumed variance one. We thus reduce the observed and simulated data \mathbf{y}_o and \mathbf{y}_θ to the empirical means Φ_o and Φ_θ , respectively,

$$\Phi_o = \frac{1}{n} \sum_{i=1}^n y_o^{(i)}, \quad \Phi_\theta = \frac{1}{n} \sum_{i=1}^n y_\theta^{(i)}. \quad (16)$$

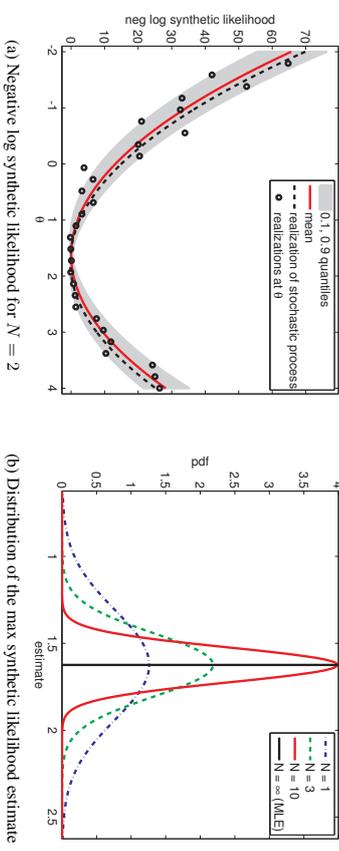

Figure 2: Estimation of the mean of a Gaussian. (a) The figure shows the negative log synthetic likelihood $-\hat{\ell}_s^N$. It illustrates that $\hat{\ell}_s^N$ is a random function. (b) The randomness makes the estimate $\hat{\theta} = \operatorname{argmax}_\theta \hat{\ell}_s^N(\theta)$ a random variable. Its variability increases as N decreases.

In this special case, no information is lost with the reduction to the summary statistic, that is, $L(\theta) \propto \mathcal{L}(\theta)$. Furthermore, the distribution of the summary statistic Φ_θ is here known, $\Phi_\theta \sim \mathcal{N}(\theta, 1/n)$ so that the Gaussian model assumption holds and $L_s(\theta) = L(\theta)$.

Using for simplicity the true variance of Φ_θ , we have $\hat{\ell}_s^N(\theta) = -1/2 \log(2\pi/n) - n/2(\Phi_o - \hat{\mu}_\theta)^2$. Since $\hat{\mu}_\theta$ is an average of N realizations of Φ_θ , $\hat{\mu}_\theta \sim \mathcal{N}(\theta, 1/(nN))$, and we can write $\hat{\ell}_s^N$ as a quadratic function subject to a random shift g ,

$$\hat{\ell}_s^N(\theta) = -\frac{1}{2} \log\left(\frac{2\pi}{n}\right) - \frac{n}{2} (\Phi_o - \theta - g)^2, \quad g \sim \mathcal{N}\left(0, \frac{1}{nN}\right). \quad (17)$$

Each realization of g yields a different mapping $\theta \rightarrow \hat{\ell}_s^N$ which illustrates that the (log) synthetic likelihood is a random function. Figure 2(a) shows the 0.1 and 0.9 quantiles of $-\hat{\ell}_s^N$ for $N=2$. The dashed curve visualizes $\theta \rightarrow -\hat{\ell}_s^N$ for a fixed realization of g . The circles show values of $-\hat{\ell}_s^N(\theta)$ when g is not kept fixed as θ changes. The results are for sample size $n=10$.

The optimizer $\hat{\theta}$ of each realization of $\hat{\ell}_s^N$ depends on g , $\hat{\theta} = \Phi_o - g$. That is, $\hat{\theta}$ is a random variable with distribution $\mathcal{N}(\Phi_o, 1/(Nn))$. In the limit of an infinite amount of available computational resources, that is $N \rightarrow \infty$, g equals zero, and the distribution has a point-mass at $\hat{\theta}_{\text{MLE}} = \Phi_o$ which is indicated with the black vertical line in Figure 2(b). As N decreases, variance is added to the point-estimate $\hat{\theta}$. This added variability is due to the use of finite computational resources; it does not reflect uncertainty about θ due to the finite sample size n . The variability causes an inflation of the mean squared estimation error by a factor of $(1 + 1/N)$, $E((\hat{\theta} - \theta_o)^2) = 1/n(1 + 1/N)$. \blacktriangle

Example 5 (Synthetic likelihood for the Ricker model). Wood (2010) used the synthetic likelihood to perform inference of the Ricker model and other simulator-based models with

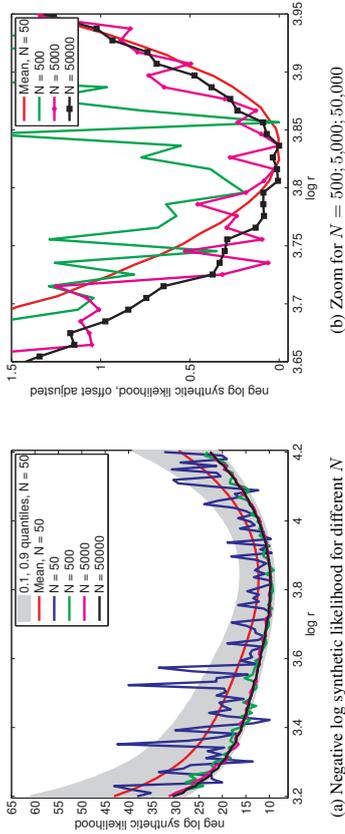

Figure 3: Using less computational resources may reduce the smoothness of the approximate likelihood function. The figures show the negative log synthetic likelihood $-\hat{\ell}_s^N$ for the Ricker model. Only the first parameter ($\log r$) was varied, the others were kept fixed at the data generating values. (a) The use of simulations makes the synthetic likelihood a stochastic process. Realizations of $-\hat{\ell}_s^N$ for different N are shown together with the variability for $N = 50$. (b) The curves become more and more smooth as the number N of simulated data sets increases even though the curve for $N = 50,000$ is still rugged. It is reasonable to assume though that the limit for $N \rightarrow \infty$ is smooth.

complex dynamics. Time series data $\mathbf{y}_\theta = (y_\theta^{(T_0+1)}, \dots, y_\theta^{(T_0+n)})$ from the Ricker model after some “burn-in” time T_0 were summarized in the form of the coefficients of the autocorrelation function and the coefficients of fitted nonlinear autoregressive models, thereby reducing the data to fourteen summary statistics Φ_θ (see the supplementary material of Wood, 2010, for their exact definition).

Figure 3 shows the negative log synthetic likelihood $-\hat{\ell}_s^N$ for the Ricker model as a function of the log growth rate $\log r$ for \mathbf{y}_o in Figure 1(a). The parameters σ and φ were kept fixed at the values $\sigma_o = 0.3$ and $\varphi_o = 10$ which we used to generate \mathbf{y}_o ($\log r^o$ was 3.8). The figures show that the realizations of the synthetic likelihood become less smooth as N decreases.

The lack of smoothness makes the minimization of the different realizations of $-\hat{\ell}_s^N$ difficult. A grid-search is feasible for very large N but this approach does not scale to higher dimensions. Gradient-based optimization is tricky because the functional form of $\hat{\ell}_s^N$ is unknown. Finite differences may not yield a reliable approximation of the gradient because of the lack of smoothness. Instead of optimizing a single realization of the objective, one could use an approximate stochastic gradient approach. That is, approximate gradients are computed with different random seeds at different values of the parameter. For small N , however, the gradients are unreliable so that the stepsize has to be very small, which makes the optimization rather costly again. To resolve the issue, we suggest a more efficient approach by combining probabilistic modeling with optimization. \blacktriangleleft

3.3 Nonparametric Approximation of the Likelihood

An alternative to assuming a parametric model for the pdf $p_{\Phi|\theta}$ of the summary statistics is to approximate it by a kernel density estimate (Rosenblatt, 1956; Parzen, 1962; Mack and Rosenblatt, 1979; Wand and Jones, 1995),

$$p_{\Phi|\theta}(\phi|\theta) \approx \mathbb{E}^N [K(\phi, \Phi_\theta)], \quad (18)$$

where K is a suitable kernel and \mathbb{E}^N denotes empirical expectation as before,

$$\mathbb{E}^N [K(\phi, \Phi_\theta)] = \frac{1}{N} \sum_{i=1}^N K(\phi, \Phi_\theta^{(i)}), \quad \Phi_\theta^{(i)} \stackrel{i.i.d.}{\sim} p_{\Phi|\theta}. \quad (19)$$

An approximation of the likelihood function $L(\theta)$ is given by $\hat{L}_K^N(\theta)$,

$$\hat{L}_K^N(\theta) = \mathbb{E}^N [K(\Phi_o, \Phi_\theta)]. \quad (20)$$

We may re-write $K(\Phi_o, \Phi)$ in another form as $\kappa(\Delta_\theta)$ where $\Delta_\theta \geq 0$ depends on Φ_o and Φ_θ , and κ is a univariate non-negative function not depending on θ . The kernels K are generally such that κ has a maximum at zero (the maximum may be not unique though). Taking the empirical expectation in Equation (20) with respect to Δ_θ instead of Φ_θ , we have $\hat{L}_K^N(\theta) = \hat{L}_\kappa^N(\theta)$,

$$\hat{L}_\kappa^N(\theta) = \mathbb{E}^N [\kappa(\Delta_\theta)]. \quad (21)$$

As the number N grows, \hat{L}_κ^N converges to \bar{L}_κ ,

$$\bar{L}_\kappa(\theta) = \mathbb{E}[\kappa(\Delta_\theta)], \quad (22)$$

which is \hat{L}_κ^N where the empirical average \mathbb{E}^N is replaced by the expectation \mathbb{E} . The limiting approximate likelihood $\bar{L}_\kappa(\theta)$ does not necessarily equal the likelihood $L(\theta) = p_{\Phi|\theta}(\Phi_o|\theta)$. For example, if $\kappa(\Delta_\theta)$ is obtained from a translation invariant kernel K , that is, $\kappa(\Delta_\theta) = K(\Phi_o - \Phi_\theta)$, \bar{L}_κ is the likelihood for a summary statistics whose pdf is obtained by convolving $p_{\Phi|\theta}$ with K .

For convex functions κ , Jensen’s inequality yields a lower bound for \hat{L}_κ^N and its logarithm,

$$\hat{L}_\kappa^N(\theta) \geq \kappa(\hat{J}^N(\theta)), \quad \log \hat{L}_\kappa^N(\theta) \geq \log \kappa(\hat{J}^N(\theta)), \quad \hat{J}^N(\theta) = \mathbb{E}^N [\Delta_\theta]. \quad (23)$$

Since κ is maximal at zero, the lower bound is maximized by minimizing the conditional empirical expectation $\hat{J}^N(\theta)$. The advantage of the lower bound is that it can be maximized irrespective of κ , which is often difficult to choose in practice.

A popular choice of κ for likelihood-free inference is the uniform kernel $\kappa = \kappa_u$ which yields the approximate likelihood \hat{L}_u^N ,

$$\kappa_u(u) = c \chi_{[0,h)}(u), \quad \hat{L}_u^N(\theta) = c \mathbb{P}^N(\Delta_\theta < h), \quad (24)$$

where the indicator function $\chi_{[0,h)}(u)$ equals one if $u \in [0, h)$ and zero otherwise. The scaling parameter c does not depend on θ , and the positive scalar h is the bandwidth of

the kernel and acts as acceptance/rejection threshold. The approximate likelihood \hat{L}_n^N is proportional to the empirical probability that the discrepancy is below the threshold. The limiting approximate likelihood is denoted by $\bar{L}_n(\theta)$,

$$\bar{L}_n(\theta) = c \mathbb{P}(\Delta_\theta < h). \quad (25)$$

The lower bound for convex κ is not applicable but we can obtain an equivalent bound by Markov's inequality,

$$\hat{L}_n^N(\theta) = c \left[1 - \mathbb{P}^N(\Delta_\theta^2 \geq h) \right] \geq c \left[1 - \frac{1}{h} \mathbb{E}^N[\Delta_\theta] \right]. \quad (26)$$

The lower bound of the approximate likelihood can be maximized by minimizing $\hat{J}^N(\theta)$ as for convex κ .

We illustrate the approximation of the likelihood via \hat{L}_n^N in Example 6 below. It is pointed out that good approximations are computationally very expensive because of the very small probability for Δ_θ to be below small thresholds h , or, in other words, because of the large rejection probability. We then use the model for bacterial infections in day care centers to show in Example 7 that the minimizer of $\hat{J}^N(\theta)$ can provide a good approximation of the maximizer of $\hat{L}_n^N(\theta)$. This is important because \hat{J}^N does not require choosing the bandwidth h or involve any rejections.

Example 6 (Approximate likelihood for the mean of a Gaussian). For the inference of the mean of a Gaussian, we can use as discrepancy Δ_θ the squared difference between the empirical mean of the observed and simulated data \mathbf{y}_o and \mathbf{y}_θ , that is the squared difference between the two summary statistics Φ_o and Φ_θ in Example 4: $\Delta_\theta = (\Phi_o - \Phi_\theta)^2$. Because of the use of simulated data, like the synthetic likelihood, the discrepancy Δ_θ is a stochastic process. We visualize its distribution in Figure 4(a). The observed data \mathbf{y}_o were the same as in Example 4.

For this simple example, we can compute the limiting approximate likelihood \bar{L}_n in Equation (25) in closed form,

$$\bar{L}_n(\theta) \propto F\left(\sqrt{n}(\Phi_o - \theta) + \sqrt{nh}\right) - F\left(\sqrt{n}(\Phi_o - \theta) - \sqrt{nh}\right), \quad (27)$$

where $F(x)$ is the cumulative distribution function (cdf) of a standard normal random variable,

$$F(x) = \int_{-\infty}^x \frac{1}{\sqrt{2\pi}} \exp\left(-\frac{1}{2}u^2\right) du. \quad (28)$$

For small nh , $\bar{L}_n(\theta)$ becomes proportional to the likelihood $L(\theta)$. This is visualized in Figure 4(b).² However, the probability to actually observe a realization of Δ_θ which is below the threshold h becomes vanishingly small. For realistic models, \bar{L}_n is not available in closed form but needs to be estimated. The vanishingly small probability indicates that the inference procedure will be computationally expensive when \bar{L}_n is estimated via the sample average approximation \hat{L}_n^N . \blacktriangle

Example 7 (Approximate univariate likelihoods for the day care centers). In the model for bacterial infections in day care centers, the observed data were centered to summary

² Using $h = 0.1$ for illustrative purposes. For threshold choice in real applications, see Example 7 and Section 5.3.

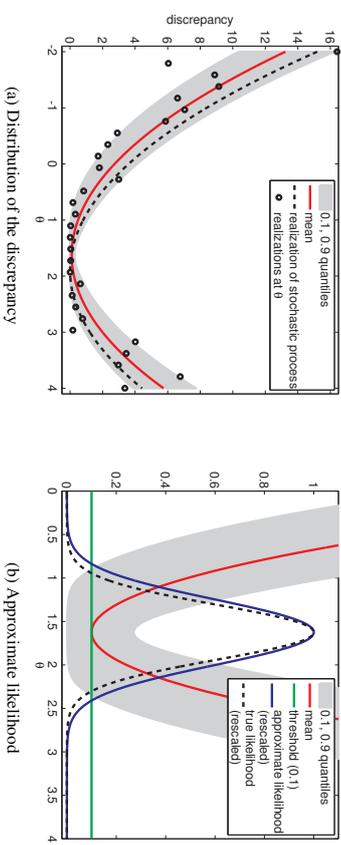

Figure 4: Nonparametric approximation of the likelihood to estimate the mean θ of a Gaussian. The discrepancy Δ_θ is the squared difference between the empirical means of the observed and simulated data. (a) The discrepancy is a random function. (b) The probability that the discrepancy is below some threshold h approximates the likelihood. Note the different range of the axes.

statistics Φ_o by representing each day care center (binary matrix) with four statistics. This gives $4 \cdot 29 = 116$ summary statistics in total (see Numminen et al., 2013, for details).

Since the day care centers can be considered to be independent, the 29 observations can be used to estimate the distribution of the four statistics and their cdfs. Numminen et al. (2013) assessed the difference between Φ_θ and Φ_o by the L_1 distance between the estimated cdfs. Each L_1 distance had its own uniform kernel and corresponding bandwidth, which means that a product kernel was used overall. We here work with a simplified discrepancy measure: The different scales of the four statistics were normalized by letting the maximal value of each of the four statistics be one for \mathbf{y}_o . The discrepancy Δ_θ was then the L_1 norm between Φ_θ and Φ_o divided by their dimension, $\Delta_\theta = 1/116 \|\Phi_\theta - \Phi_o\|_1$.

Figure 5 shows the distributions of the discrepancies Δ_θ if one of the three parameters is varied at a time. The results are for the real data used by Numminen et al. (2013). The parameters were varied on a grid around the (rounded) mean (3.6, 0.6, 0.1) which was inferred by Numminen et al. (2013). The distributions were estimated using $N = 300$ realizations of Δ_θ per parameter value. The red solid lines show the empirical average \hat{L}_n^N . The black lines with circles show \hat{L}_n^N with bandwidths (thresholds) equal to the 0.1 quantile of the sampled discrepancies. While subjective, this is a customary choice (Marin et al., 2012). The thresholds were $h_g = 1.16$, $h_\lambda = 1.18$, and $h_\theta = 1.20$, and are marked with green lines. It can be seen that the optima of \hat{J}^N and L_n^N are attained at about the same parameter values which is advantageous because \hat{J}^N is independent of kernel and bandwidth.

Since the functional form of \hat{J}^N and its gradients are, however, not known, the minimization becomes a difficult problem in higher dimensions. We will show that the idea of

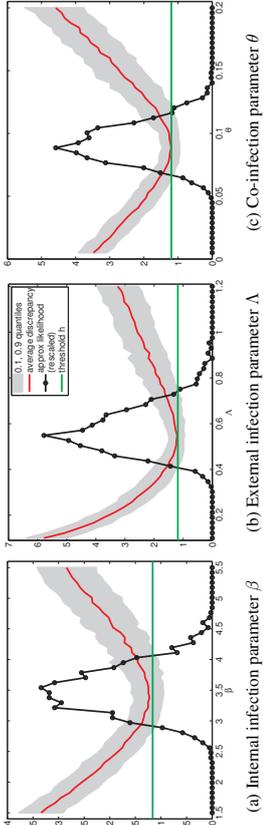

Figure 5: Approximate likelihoods \hat{L}_u^N and distributions of the discrepancy Δ_θ for the day care center example. The green horizontal lines indicate the thresholds used. The optima of the average discrepancies and the approximate likelihoods occur at about the same parameter values.

combining probabilistic modeling with optimization, which we mentioned in Example 5 for the log synthetic likelihood, is also helpful here. \blacktriangle

3.4 Relation between Nonparametric and Parametric Approximation

Kernel density estimation with Gaussian kernels is interesting for two reasons in the context of likelihood-free inference. First, the Gaussian kernel is positive definite, so that the estimated density is a member of a reproducing kernel Hilbert space. This means that more robust approximations of $p_{\Phi|\theta}$ than the one in Equation (18) would exist (Kim and Scott, 2012), and that there might be connections to the inference approach of Fukumizu et al. (2013). Second, it allows us to embed the synthetic likelihood approach of Section 3.2 into the nonparametric approach of Section 3.3.

For the Gaussian kernel, we have that $K(\Phi_o, \Phi_\theta) = K_g(\Phi_o, -\Phi_\theta)$,

$$K_g(\Phi_o - \Phi_\theta) = \frac{1}{(2\pi)^{p/2}} \frac{1}{|\det \mathbf{C}_\theta|^{1/2}} \exp\left(-\frac{(\Phi_o - \Phi_\theta)^\top \mathbf{C}_\theta^{-1} (\Phi_o - \Phi_\theta)}{2}\right), \quad (29)$$

where \mathbf{C}_θ is a positive definite bandwidth matrix possibly depending on θ . The kernel K_g corresponds to $\kappa = \kappa_g$ and $\Delta_\theta = \Delta_\theta^g$,

$$\kappa_g(u) = \frac{1}{(2\pi)^{p/2}} \exp\left(-\frac{u}{2}\right), \quad \Delta_\theta^g = \log|\det \mathbf{C}_\theta| + (\Phi_o - \Phi_\theta)^\top \mathbf{C}_\theta^{-1} (\Phi_o - \Phi_\theta). \quad (30)$$

The function κ_g is convex so that Equation (23) yields a lower bound for $\hat{L}_g^N(\theta) = \hat{L}_g^N(\theta)$ and its logarithm,

$$\log \hat{L}_g^N(\theta) \geq -\frac{p}{2} \log(2\pi) - \frac{1}{2} j_g^N(\theta), \quad (31)$$

$$j_g^N(\theta) = \mathbb{E}^N \left[\log|\det \mathbf{C}_\theta| + (\Phi_o - \Phi_\theta)^\top \mathbf{C}_\theta^{-1} (\Phi_o - \Phi_\theta) \right]. \quad (32)$$

We used the subscript “g” to highlight that \hat{j}^N in Equation (23) is computed for the particular discrepancy Δ_θ^g . The form of \hat{j}_g^N is reminiscent of the log synthetic likelihood $\hat{\ell}_s^N$ in Equation (15). The following proposition shows that there is indeed a connection.

Proposition 1 (Synthetic likelihood as lower bound). For $\mathbf{C}_\theta = \hat{\Sigma}_\theta$,

$$\hat{\ell}_s^N(\theta) = \frac{p}{2} - \frac{p}{2} \log(2\pi) - \frac{1}{2} \hat{j}_g^N(\theta), \quad (33)$$

$$\log \hat{L}_g^N(\theta) \geq -\frac{p}{2} + \hat{\ell}_s^N(\theta) \quad (34)$$

The proposition is proved in Appendix A. It shows that maximizing the synthetic log-likelihood corresponds to maximizing a lower bound of a nonparametric approximation of the log likelihood. The proposition embeds the parametric approach to likelihood approximation conceptually in the nonparametric one and shows furthermore that $\hat{\ell}_s^N$ can be computed via an empirical expectation over Δ_θ^g .

3.5 Posterior Inference using Sample Average Approximations of the Likelihood

Several computable approximations \hat{L} of the likelihood L were constructed in the previous two sections. Table 1 provides an overview. Intractable expectations were replaced with sample averages using N simulated data sets which we denoted by the superscript “ N ” in the symbols for the approximations.

Wood (2010) used the synthetic likelihood \hat{L}_s^N together with a Metropolis MCMC algorithm for posterior computations. We here focus on posterior inference via importance sampling. Using \hat{L}_u^N as \hat{L} in Equation (11), we have

$$\mathbb{E}(g(\theta) | \Phi_o) \approx \sum_{m=1}^M g(\theta^{(m)}) \hat{w}_u^{(m)}, \quad \hat{w}_u^{(m)} = \frac{\sum_{j=1}^N \chi_{[0,h)}(\Delta_\theta^{(j,m)}) \frac{p_{\Phi}(\theta^{(m)})}{q(\theta^{(m)})}}{\sum_{i=1}^M \sum_{j=1}^N \chi_{[0,h)}(\Delta_\theta^{(j,i)}) \frac{p_{\Phi}(\theta^{(i)})}{q(\theta^{(i)})}}, \quad (35)$$

where $\chi_{[0,h)}$ is the indicator function of the interval $[0, h)$ as before, and the $\Delta_\theta^{(j,m)}$, $j = 1, \dots, N$, are the observed discrepancies for the sampled parameter $\theta^{(m)} \sim q(\theta)$. Instead of sampling several discrepancies for the same $\theta^{(m)}$, sampling M' pairs $(\Delta_\theta^{(i)}, \theta^{(i)})$ with $N = 1$ is also possible and corresponds to an asymptotically equivalent solution. With $q = p_\theta$, the approximation is a Nadaraya–Watson kernel estimate of the conditional expectation (see, for example, Wasserman, 2004, Chapter 21).

Approximate Bayesian computation (ABC) is intrinsically linked to kernel density estimation and kernel regression (Blum, 2010). A basic ABC rejection sampler (Pritchard et al., 1999; Marin et al., 2012, Algorithm 2) is obtained from Equation (35) with $N = 1$, $q = p_\theta$, and $\Delta_\theta = \|\Phi_o - \Phi_\theta\|$ where $\|\cdot\|$ is some norm. Approximate samples from the posterior pdf of θ given Φ_o can thus be obtained by retaining those $\theta^{(m)}$ for which the $\Phi_\theta^{(m)}$ are within distance h from Φ_o . In an iterative approach, the accepted particles can be used to define the auxiliary pdf $q(\theta)$ of the next iteration by letting it be a mixture of Gaussians with weights $\hat{w}_u^{(m)}$, center points $\theta^{(m)}$, and a covariance determined by the $\theta^{(m)}$ (Beaumont et al., 2009). This gives the population Monte Carlo (PMC) ABC algorithm (Marin et al., 2012, Algorithm 4). Related sequential Monte Carlo (SMC) ABC algorithms were proposed

by Sisson et al. (2007) and Toni et al. (2009). Working with $q = p_\theta$, Beaumont et al. (2002) introduced ABC with more general kernels, which corresponds to using L_κ^N instead of L_n^N .

Example 6 showed that approximating the likelihood via sample averages is computationally expensive because of the required small thresholds. The auxiliary pdf $q(\theta)$ specifies where in the parameter space the likelihood is predominantly evaluated. The following example shows that avoiding regions in the parameter space where the likelihood is vanishingly small allows for considerable computational savings.

Example 8 (Univariate approximate posteriors for the day care centers). For the inference of the model of bacterial infections in day care centers, Numminen et al. (2013) used uniform priors for the parameters $\beta \in (0, 11)$, $\Lambda \in (0, 2)$, and $\theta \in (0, 1)$. The likelihoods \hat{L}_n^N shown in Figure 5 are thus proportional to the posterior pdfs. The posterior pdfs of the univariate unknowns are conditional on the remaining fixed parameters. For example, the posterior pdf for β is conditional on $(\Lambda, \theta) = (\Lambda_\theta, \theta_\theta) = (0.6, 0.1)$. In Section 7, we consider inference of all three parameters at the same time.

In Figure 5, each parameter is evaluated on a sub-interval of the domain of the prior. The sub-intervals were chosen such that the fat tails of the likelihoods were excluded. Parameter β , for example, was evaluated on the interval (1.5, 5.5) only. Evaluating the discrepancy Δ_θ on the complete interval (0, 11) is not very meaningful since the probability that it is above the chosen threshold is vanishingly small outside the interval (1.5, 5.5). In fact, out of $M = 5,000$ discrepancies Δ_θ which we simulated for β uniformly on (0, 11), not a single one was accepted for $\beta \notin (1.5, 5.5)$. Hence, taking for instance a uniform distribution on (1.5, 5.5) instead of the prior as auxiliary distribution leads to considerable computational savings. Motivated by this, we propose a method which automatically avoids regions in the parameter space where the likelihood is vanishingly small. \blacktriangle

4. Computational Difficulties in the Standard Inference Approach

We have seen that the approximate likelihood functions $\hat{L}(\theta)$ which are used to infer simulator-based statistical models are stochastic processes indexed by the model parameters θ . Their properties, in particular their functional form and gradients, are generally not known: they behave like stochastic black-box functions. The stochasticity is due to the use of simulations to approximate intractable expectations. In the standard approach presented in the previous section, the expectations are approximated by sample averages so that a single evaluation of \hat{L} requires the simulation of N data sets. The standard approach makes minimal assumptions but suffers from a couple of limiting factors.

1. There is an inherent trade-off between computational and statistical efficiency: Reducing N reduces the computational cost of the inference methods, but it can also decrease the accuracy of the estimates (Figure 2).
2. For finite N , the approximate likelihoods may not be smooth (Figure 3).
3. Simulating N data sets uniformly in the parameter space is an inefficient use of computational resources and particularly costly if simulating a single data set already takes a long time. In some regions in the parameter space, far fewer simulations suffice to conclude that it is very unlikely for the approximate likelihood to take a significant value (Figures 2 to 5).

5. Framework to Increase the Computationally Efficiency

We present a framework which combines optimization with probabilistic modeling in order to increase the efficiency of likelihood-free inference of simulator-based statistical models.

5.1 From Sample Average to Regression Based Approximations

The standard approach to obtain a computable approximate likelihood function \hat{L} relies on sample averages, yielding the parametric approximation $\hat{L}_\kappa^N = \exp(\hat{\ell}_\kappa^N)$ in Equation (15) or the nonparametric approximation \hat{L}_κ^N in Equation (21). The approximations are computable versions of $\hat{L}_s = \exp(\hat{\ell}_s)$ in Equation (13) and \hat{L}_κ in Equation (22), which both involve intractable expectations. But sample averages are not the only way to approximate the intractable expectations. We here consider approximations based on regression.

Equation (22) shows that $\hat{L}_\kappa(\theta)$ has a natural interpretation as a regression function where the model parameters θ are the covariates (the independent variables) and $\kappa(\Delta_\theta)$ is the response variable. The expectation can thus also be approximated by solving a regression problem. Further, \hat{J}^N in Equation (23) can be seen as the sample average approximation of the regression function $J(\theta)$,

$$J(\theta) = \mathbb{E}[\Delta_\theta], \quad (36)$$

where the discrepancy Δ_θ is the response variable. The arguments which we used to show that \hat{J}^N provides a lower bound for \hat{L}_κ carry directly over to J and \hat{L}_κ : J provides a lower bound for \hat{L}_κ if κ is convex or the uniform kernel.

Proposition 1 establishes a relation between the sample average quantities \hat{J}_g^N in Equation (32) and \hat{J}_s^N in Equation (15). In the proof of the proposition in Appendix A, we show that the relation extends to the limiting quantities $J_g(\theta) = \mathbb{E}[\Delta_\theta^g]$ and \hat{L}_s in Equation (13). Thus, for $\mathbf{C}_\theta = \Sigma_\theta$ and up to constants and the sign, $\hat{\ell}_s(\theta)$ can be seen as a regression function with the particular discrepancy Δ_θ^g as the response variable.

We next discuss the general strategy to infer the regression functions while avoiding unnecessary computations. For nonparametric approximations to the likelihood, inferring J is simpler than inferring \hat{L}_κ since the function κ and its corresponding bandwidth do not need to be chosen. We thus propose to first infer the regression function J of the discrepancies and then, in a second step, to leverage the obtained solution to infer \hat{L}_κ . For the parametric approximation to the likelihood, this extra step is not needed since J_g is a special instance of the regression function J .

5.2 Inferring the Regression Function of the Discrepancies

Inferring $J(\theta)$ via regression requires training data in the form of tuples $(\theta^{(i)}, \Delta_\theta^{(i)})$. Since we are mostly interested in the region of the parameter space where Δ_θ tends to be small, we propose to actively construct the training data such that they are more densely clustered around the minimizer of $J(\theta)$. As $J(\theta)$ is unknown in the first place, our proposal amounts to performing regression and optimization at the same time: Given an initial guess that the minimizer is in some bounded subset of the parameter space, we can sample some evidence $\mathcal{E}^{(i)}$ of the relation between θ and Δ_θ ,

$$\mathcal{E}^{(i)} = \left\{ (\theta^{(1)}, \Delta_\theta^{(1)}), \dots, (\theta^{(i)}, \Delta_\theta^{(i)}) \right\}, \quad (37)$$

and use this evidence to obtain an estimate $\hat{J}^{(t)}$ of J via regression. The estimated $\hat{J}^{(t)}$ and some measurement of uncertainty about it can then be used to produce a new guess about the potential location of the minimizer, from where the process re-starts. In some cases, it may be advantageous to include the prior pdf of the parameters in the process. We explore this topic in Appendix B.

The evidence set $\mathcal{E}^{(t)}$ grows at every iteration and we may stop at $t = T$. The value of T can be chosen based on computational considerations, by checking whether the learned model predicts the acquired points reasonably well, or by monitoring the change in the minimizer $\hat{\theta}_J^{(t)}$ of $\hat{J}^{(t)}$ as the evidence set grows,

$$\hat{\theta}_J^{(t)} = \operatorname{argmin}_{\theta} \hat{J}^{(t)}(\theta). \quad (38)$$

Given our examples so far, it is further reasonable to assume that J is a smooth function. Even for the Ricker model, the mean objective was smooth although the individual realizations were not (Figure 3). The smoothness assumption about J can be used in the regression and enables its efficient minimization.

For the special case where $\bar{\ell}_s$ is the target, several observed values of $\Delta_{\theta} = \Delta_{\theta}^g$ may be available for any given $\theta^{(t)}$. This is because the covariance matrix Σ_{θ} may be still estimated as a sample average so that multiple simulated summary statistics, and hence discrepancies, are available per $\theta^{(t)}$. They can be used as discussed above with the only minor modification that the training data are updated with several tuples at a time. But it is also possible to only use the average value of the observed discrepancies, which amounts to using the observed values of $\bar{\ell}_s^V$ for training. The estimated regression function $\hat{J}^{(t)}$ provides an estimate for $\bar{\ell}_s$ in either case. We denote the estimate by $\bar{\ell}_s^{(t)}$ and the corresponding estimate of \bar{L}_s by $\bar{L}_s^{(t)}$.

Combining nonlinear regression with the acquisition of new evidence in order to optimize a black-box function is known as Bayesian optimization (see, for example, Brochu et al., 2010). We can thus leverage results from Bayesian optimization to implement the proposed approach, which we will do in Section 6.

5.3 Inferring the Regression Function for Nonparametric Likelihood Approximation

The evidence set $\mathcal{E}^{(t)}$ can be used in two possible ways in the nonparametric setting: The first possibility is to compute for each $\Delta_{\theta}^{(t)}$ in $\mathcal{E}^{(t)}$ the value $\kappa^{(t)} = \kappa(\Delta_{\theta}^{(t)})$ and to thereby produce a new evidence set which can be used to approximate \bar{L}_{κ} by fitting a regression function. The second possibility is to estimate a probabilistic model of Δ_{θ} from the evidence $\mathcal{E}^{(t)}$. The estimated model can be used to approximate \bar{L}_{κ} by replacing the expectation in Equation (22) with the expectation under the model. We denote either approximation by $\bar{L}_{\kappa}^{(t)}$ where the superscript “ (t) ” indicates that the approximation was obtained via regression with t training points. Since $\mathcal{E}^{(t)}$ is such that the approximation of the regression function is accurate where it takes small values, the approximation of \bar{L}_{κ} will be accurate where it takes large values; that is, in the modal areas.

For nonparametric likelihood approximation, kernels and bandwidths need to be selected (see Section 3.3). The choice of the kernel is generally thought to be less critical than the choice of the bandwidth (Wand and Jones, 1995). Bandwidth selection has received considerable attention in the literature on kernel density estimation (for an introduction,

see, for example, Wand and Jones, 1995). The results from that literature are, however, not straightforwardly applicable to our work: We may only be given a certain discrepancy measure Δ_{θ} without underlying summary statistics Φ_{θ} (Gutmann et al., 2014). And even if the discrepancy Δ_{θ} is constructed via summary statistics, the kernel density estimate is only evaluated at Φ_{θ} which is kept fixed while θ is varied. Furthermore, we usually only have very few observations available for any given θ which is generally not the case in kernel density estimation. These differences warrant further investigations into which extend the bandwidth selection methods from the kernel density estimation literature are applicable to likelihood-free inference. We focus in this paper on the uniform kernel and generally choose h via the quantiles of the $\Delta_{\theta}^{(t)}$, which is common practice in approximate Bayesian computation (see, for example, Marin et al., 2012). The approximate likelihood function for the uniform kernel will be denoted by $\hat{L}_u^{(t)}$.

5.4 Benefits and Limitations of the Proposed Approach

The difference between the proposed approach and the standard approach to likelihood-free inference of simulator-based statistical models lies in the way the intractable J and \bar{L} are approximated. We use regression with actively acquired training data while the standard approach relies on computing sample averages. Our approach allows to incorporate a smoothness assumption about J and \bar{L} in the region of their optima. The smoothness assumption allows to “share” observed Δ_{θ} among multiple θ which suggests that fewer $\Delta_{\theta}^{(t)}$, that is, fewer simulated data sets $\mathbf{y}_{\theta}^{(t)}$, are needed to reach a certain level of accuracy. A second benefit of the proposed approach is that it directly targets the region in the parameter space where the discrepancy Δ_{θ} tends to be small, which is very important if simulating data sets is time consuming.

Regression and deciding on the training data are not free of computational cost. While the additional expense is often justified by the net savings made, it goes without saying that if simulating the model is very cheap, methods for regression and decision making need to be used which are not disproportionately costly. Furthermore, prioritizing the low-discrepancy areas of the parameter space is often meaningful, but it also implies that the tails of the likelihood (posterior) will not be as well approximated as the modal areas. The proposed approach thus had to be modified if the computation of small probability events was of primary interest.

Section 4 lists three computational difficulties occurring in the standard approach. Our approach addresses the smoothness issues via smooth regression. The inefficient use of resources is addressed by focusing on regions in the parameter space where Δ_{θ} tends to be small. The trade-off between computational and statistical performance is still present but in modified form: The trade-off is the size of the training set $\mathcal{E}^{(t)}$ used in the regression. The regression functions can be estimated more accurately as the size of the training set grows but this also requires more computation. The size of the training set as trade-off parameter has the advantage that we are free to choose in which areas of the parameter space we would like to approximate the regression function more accurately and in which areas an accurate approximation is not needed. This is in contrast to the standard approach where a computational cost of N simulated data sets needs to be paid per θ irrespective of its value.

6. Implementing the Framework with Bayesian Optimization

We start with introducing Bayesian optimization and then use it to implement our framework. This is followed by a discussion of possible extensions.

6.1 Brief Introduction to Bayesian Optimization

We briefly introduce the elements of Bayesian optimization which are needed in the paper. A more thorough introduction can be found in the review articles by Jones (2001) and Brochu et al. (2010). While the presented version of Bayesian optimization is rather straightforward and textbook-like, our framework can also be implemented with more advanced versions, see Section 6.4.

Bayesian optimization comprises a set of methods to minimize black-box functions $f(\boldsymbol{\theta})$. With a black-box function, we mean a function which we can evaluate but whose form and gradients are unknown. The basic idea in Bayesian optimization is to use a probabilistic model of f to select points where the objective is evaluated, and to use the obtained values to update the model by Bayes' theorem.

The objective f is often modeled as a Gaussian process which is also done in this paper: We assume that f is a Gaussian process with prior mean function $m(\boldsymbol{\theta})$ and covariance function $k(\boldsymbol{\theta}, \boldsymbol{\theta}')$ subject to additive Gaussian observation noise with variance σ_n^2 . The joint distribution of f at any t points $\boldsymbol{\theta}^{(1)}, \dots, \boldsymbol{\theta}^{(t)}$ is thus assumed Gaussian with mean \mathbf{m}_t and covariance \mathbf{K}_t ,

$$(f^{(1)}, \dots, f^{(t)})^\top \sim \mathcal{N}(\mathbf{m}_t, \mathbf{K}_t), \quad (39)$$

$$\mathbf{m}_t = \begin{pmatrix} m(\boldsymbol{\theta}^{(1)}) \\ \vdots \\ m(\boldsymbol{\theta}^{(t)}) \end{pmatrix}, \quad \mathbf{K}_t = \begin{pmatrix} k(\boldsymbol{\theta}^{(1)}, \boldsymbol{\theta}^{(1)}) & \dots & k(\boldsymbol{\theta}^{(1)}, \boldsymbol{\theta}^{(t)}) \\ \vdots & \ddots & \vdots \\ k(\boldsymbol{\theta}^{(t)}, \boldsymbol{\theta}^{(1)}) & \dots & k(\boldsymbol{\theta}^{(t)}, \boldsymbol{\theta}^{(t)}) \end{pmatrix} + \sigma_n^2 \mathbf{I}_t. \quad (40)$$

We used $f^{(t)}$ to denote $f(\boldsymbol{\theta}^{(t)})$ and \mathbf{I}_t is the $t \times t$ identity matrix. While other choices are possible, we assume that $m(\boldsymbol{\theta})$ is either a constant or a sum of convex quadratic polynomials in the elements θ_j of $\boldsymbol{\theta}$, cross-terms were not included, and that $k(\boldsymbol{\theta}, \boldsymbol{\theta}')$ is a squared exponential covariance function,

$$m(\boldsymbol{\theta}) = \sum_j a_j \theta_j^2 + b_j \theta_j + c, \quad k(\boldsymbol{\theta}, \boldsymbol{\theta}') = \sigma_f^2 \exp\left(\sum_j \frac{1}{\lambda_j^2} (\theta_j - \theta'_j)^2\right). \quad (41)$$

These are standard choices (see, for example, Rasmussen and Williams, 2006, Chapter 2). Since we are interested in minimization, we constrain the a_j to be non-negative. In the last equation, θ_j and θ'_j are the elements of $\boldsymbol{\theta}$ and $\boldsymbol{\theta}'$, respectively; σ_f^2 is the signal variance, and the λ_j are the characteristic length scales. The length scales control the amount of correlation between $f(\boldsymbol{\theta})$ and $f(\boldsymbol{\theta}')$, in other words, they control the wiggliness of the realizations of the Gaussian process. The signal variance is the marginal variance of f at a point $\boldsymbol{\theta}$ if the observation noise was zero.

The quantities a_j , b_j , c , σ_f^2 , λ_j , and σ_n^2 are hyperparameters. For the results in this paper, they were learned by maximizing the leave-one-out log predictive probability (a form

of cross-validation, see Rasmussen and Williams, 2006, Section 5.4.2). The hyperparameters were slowly updated as new data were acquired, as done in previous work, for example by Wang et al. (2013). This yielded satisfactory results but there are several alternatives, including Bayesian methods to learn the hyperparameters (for an overview, see Rasmussen and Williams, 2006, Chapter 5), and we did not perform any systematic comparison.

Given evidence $\mathcal{E}_f^{(t)} = \{(\boldsymbol{\theta}^{(1)}, f^{(1)}), \dots, (\boldsymbol{\theta}^{(t)}, f^{(t)})\}$, the posterior pdf of f at a point $\boldsymbol{\theta}$ is Gaussian with posterior mean $\mu_t(\boldsymbol{\theta})$ and posterior variance $v_t(\boldsymbol{\theta}) + \sigma_n^2$,

$$f(\boldsymbol{\theta}) | \mathcal{E}_f^{(t)} \sim \mathcal{N}(\mu_t(\boldsymbol{\theta}), v_t(\boldsymbol{\theta}) + \sigma_n^2), \quad (42)$$

where (see, for example, Rasmussen and Williams, 2006, Section 2.7),

$$\mu_t(\boldsymbol{\theta}) = m(\boldsymbol{\theta}) + \mathbf{k}_t(\boldsymbol{\theta})^\top \mathbf{K}_t^{-1} (\mathbf{f}_t - \mathbf{m}_t), \quad v_t(\boldsymbol{\theta}) = k(\boldsymbol{\theta}, \boldsymbol{\theta}) - \mathbf{k}_t(\boldsymbol{\theta})^\top \mathbf{K}_t^{-1} \mathbf{k}_t(\boldsymbol{\theta}), \quad (43)$$

$$\mathbf{f}_t = (f^{(1)}, \dots, f^{(t)})^\top, \quad \mathbf{k}_t(\boldsymbol{\theta}) = (k(\boldsymbol{\theta}, \boldsymbol{\theta}^{(1)}), \dots, k(\boldsymbol{\theta}, \boldsymbol{\theta}^{(t)}))^\top. \quad (44)$$

The posterior mean μ_t emulates f and can be minimized with powerful gradient-based optimization methods.

The evidence set can be augmented by selecting a new point $\boldsymbol{\theta}^{(t+1)}$ where f is next evaluated. The point is chosen based on the posterior distribution of f given $\mathcal{E}_f^{(t)}$. While other choices are equally possible, we use the acquisition function $\mathcal{A}_t(\boldsymbol{\theta})$ to select the next point,

$$\mathcal{A}_t(\boldsymbol{\theta}) = \mu_t(\boldsymbol{\theta}) - \sqrt{\eta_t^2 v_t(\boldsymbol{\theta})}, \quad (45)$$

where $\eta_t^2 = 2 \log[\rho^{d/2+2} \pi^2 / (3\epsilon_\eta)]$ with ϵ_η being a small constant (we used $\epsilon_\eta = 0.1$). This acquisition function is known as the lower confidence bound selection criterion (Cox and John, 1992, 1997; Srinivas et al., 2010, 2012).³ Classically, $\boldsymbol{\theta}^{(t+1)}$ is chosen deterministically as the minimizer of $\mathcal{A}_t(\boldsymbol{\theta})$. The minimization of $\mathcal{A}_t(\boldsymbol{\theta})$ yields a compromise between exploration and exploitation: Minimization of the posterior mean $\mu_t(\boldsymbol{\theta})$ corresponds to exploitation of the current belief and ignores its uncertainty. Minimization of $-\sqrt{v_t(\boldsymbol{\theta})}$, on the other hand, corresponds to exploration where we seek a point where we are uncertain about f . The coefficient η_t implements the trade-off between these two desiderata.

There is usually no restriction that $\boldsymbol{\theta}^{(t+1)}$ must be different from previously acquired $\boldsymbol{\theta}^{(t)}$. We found, however, that this may result in a poor exploration of the parameter space (see Figure 7 and Example 10 below). Employing a stochastic acquisition rule avoids getting stuck at one point. We used the simple heuristic that $\boldsymbol{\theta}^{(t+1)}$ is sampled from a Gaussian with diagonal covariance matrix and mean equal to the minimizer of the acquisition function. The standard deviations were determined by finding the end-points of the interval where the acquisition function was within a certain (relative) tolerance. Other stochastic acquisition rules, like for example Thompson sampling (Thompson, 1933; Chapelle and Li, 2011; Russo and Van Roy, 2014), could alternatively be used.

The algorithm was initialized with an evidence set $\mathcal{E}_f^{(0)}$ where the parameters $\boldsymbol{\theta}^{(1)}, \dots, \boldsymbol{\theta}^{(k_0)}$ were chosen as a Sobol quasi-random sequence (see, for example, Niederreiter, 1988). Compared to uniformly distributed (pseudo) random numbers, the Sobol sequence covers the

³ In the literature, maximization instead of minimization problems are often considered. For maximization problems, the acquisition function becomes $\mu_t(\boldsymbol{\theta}) + \sqrt{\eta_t^2 v_t(\boldsymbol{\theta})}$ and needs to be maximized. The formula for η_t^2 is used in the review by Brochu et al. (2010) and is part of Theorem 2 of Srinivas et al. (2010).

parameter space in a more even fashion. This kind of initialization is, however, not critical to our approach, and only few initial points were used in our simulations.

6.2 Inferring the Regression Function of the Discrepancies

Letting $f(\theta) = \Delta_\theta$, Bayesian optimization yields immediately an estimate of $J(\theta)$ in Equation (36). Since Δ_θ is non-negative, working with $f = \log \Delta_\theta$ seems to be theoretically more sound. In practice, however, both approaches were found to work well, albeit we do not aim at any systematic comparison here. If $f = \Delta_\theta$, the estimate $\hat{J}^{(t)}$ of J is given by the posterior mean μ_t , and if $f = \log \Delta_\theta$, the estimate is given by the mean of a log-normal random variable,

$$\hat{J}^{(t)}(\theta) = \begin{cases} \mu_t(\theta) & \text{if } f(\theta) = \Delta_\theta, \\ \exp\left(\mu_t(\theta) + \frac{1}{2}(\sigma_t(\theta) + \sigma_n^2)\right) & \text{if } f(\theta) = \log \Delta_\theta. \end{cases} \quad (46)$$

As discussed in Section 5.2, in the parametric approach to likelihood approximation, $\hat{J}^{(t)}$ equals the computable approximation $\hat{\ell}_s^{(t)}$ of $\bar{\ell}_s$.

We illustrate the basic principles of Bayesian optimization in Example 9 below. In Example 10, we illustrate log-Gaussian modeling and the stochastic acquisition rule.

Example 9 (Bayesian optimization to infer the mean of a Gaussian). For inference of the mean of a univariate Gaussian, the squared difference of the empirical means was used as the discrepancy measure Δ_θ , as in Example 6. We modeled the discrepancy Δ_θ as a Gaussian process with constant prior mean and performed Bayesian optimization with the deterministic acquisition rule. Figure 6 shows the first iterations: When only a single observation of Δ_θ is available, $t = 1$ and Δ_θ is believed to be constant but there is considerable uncertainty about it (upper-left panel). The posterior distribution of the Gaussian process yields the acquisition function $\mathcal{A}_1(\theta)$ according to Equation (45) (curve in magenta). Its minimization gives the value $\theta^{(2)}$ where Δ_θ is evaluated next (blue rectangle). After including the observed value of Δ_θ into the evidence set, $t = 2$ and the posterior distribution of the Gaussian process is re-calculated using Equation (42), that is, the belief about Δ_θ is updated using Bayes' theorem (upper-right panel). The updated belief becomes the current belief and the process restarts. A movie showing the process over several iterations is available at <http://www.jmlr.org/papers/volume17/15-017/supplementary/Gauss.avi>. \blacktriangle

Example 10 (Bayesian optimization to infer the growth rate in the Ricker model). Example 5 introduced the synthetic likelihood for the Ricker model. We have seen that individual realizations of $\hat{\ell}_s^N$ are rather noisy, in particular for $N = 50$, but that their average, which represents an estimate of $\bar{\ell}_s$, is smooth with its optimum in the right region (Figure 3). We here obtain estimates $\hat{\ell}_s^{(t)}$ of $\bar{\ell}_s$ with Bayesian optimization. The maximal training data are $T = 150$ tuples $(\log r, \hat{\ell}_s^N)$, where the first nine are from the initialization. The log synthetic likelihood was computed using code of Wood (2010) which only returned $\hat{\ell}_s^N$ and not the multiple discrepancies prior to averaging.

Figures 7(a) and (b) show $-\hat{\ell}_s^{(t)}$ after initialization without and with log-transformation, respectively (black solid lines). In both cases, we used a quadratic prior mean function. The estimated limiting negative log synthetic likelihood $-\bar{\ell}_s$ from Figure 3 is shown in red for

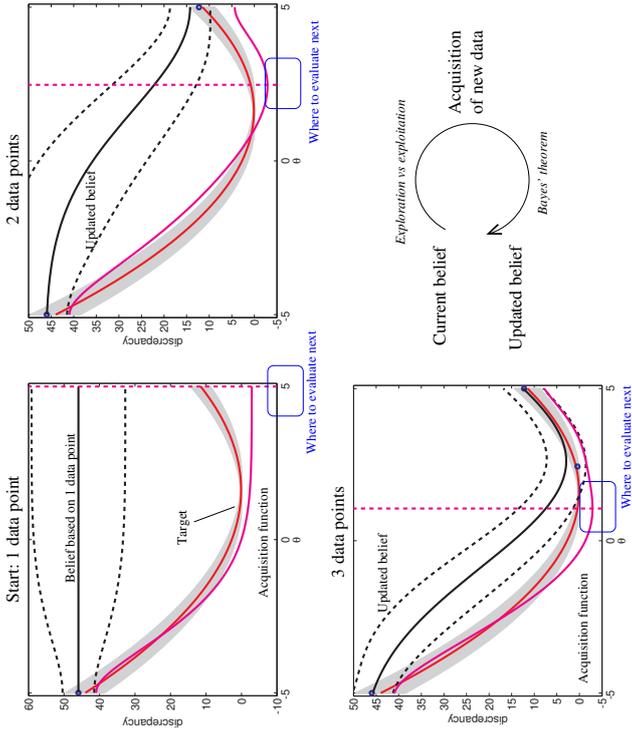

Figure 6: The first iterations of Bayesian optimization to estimate the mean of a Gaussian. The distribution of Δ_θ and its regression function $J(\theta)$ are reproduced from Figure 4 for reference (labeled “Target”). Bayesian optimization consists in acquiring new data based on the current belief, followed by an update of the belief by Bayes’ theorem. The acquisition of new data is based on an acquisition function which implements a trade-off between exploration and exploitation. Exploitation after two data points would consist in evaluating the objective again at $\theta = 5$. Exploration would consist in evaluating it where the posterior variance is large, that is, somewhere between minus five and zero. The point selected (blue rectangle) strikes a compromise between the two extremes.

reference. Figure 7(c) shows that the deterministic decision rule can lead to acquisitions with very little spatial exploration. The reason for the poor exploration is presumably the rather large variance of $\hat{\ell}_s^N$ for $N = 50$. Working with a log-Gaussian process leads to a better exploration and also to a better approximation (Figure 7(d)). The acquisitions happen, however, still in a cluster-like manner, which can also be seen in Figure 14 in Appendix C where we provide a more detailed analysis. Working with a stochastic decision rule leads to acquired points which are spread out more evenly in the area of interest. This results in both more stable and more accurate approximations (Figures 7(e-f) and Figure 15 in Appendix C). \blacktriangle

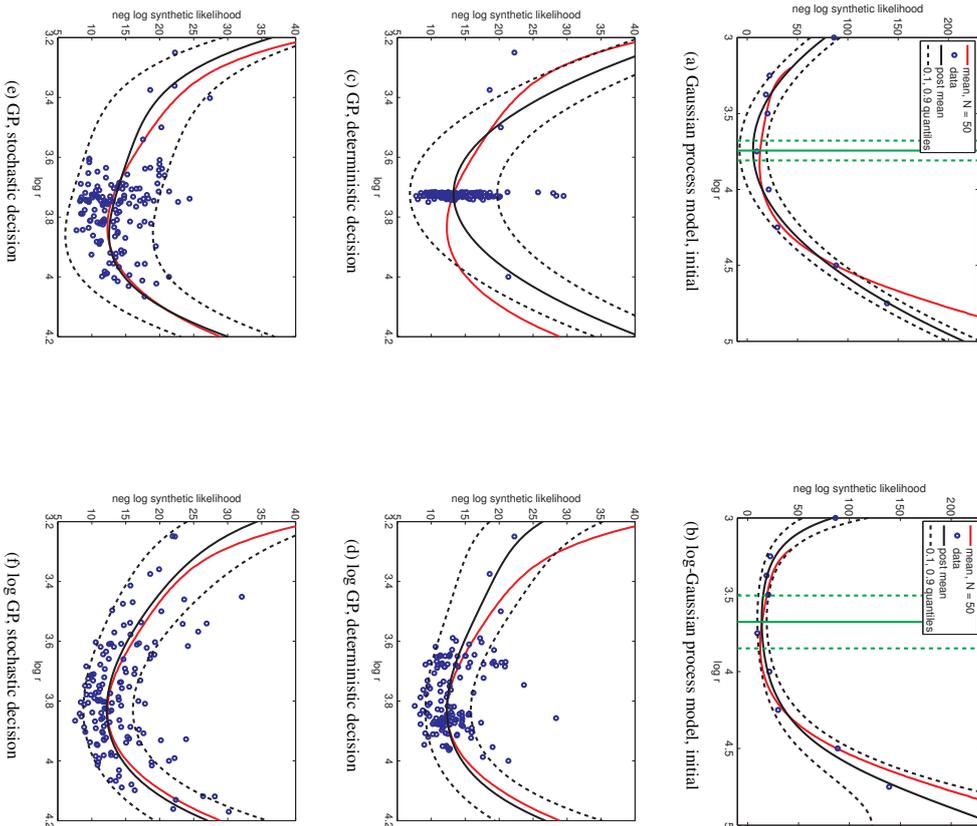

Figure 7. Approximation of the limiting negative log synthetic likelihood $-\hat{\ell}_s$ for the Ricker example. The approximations are shown as black solid curves. The black dashed curves indicate the variability of $-\hat{\ell}_s^N$, and the red curves show $-\hat{\ell}_s$ from Figure 3 for reference. (a–b) The approximation after initialization with 9 data points. The green vertical lines indicate the minimizer of the acquisition function. The dashed vertical lines show the mean plus-or-minus one standard deviation in the stochastic decision rule. (c–f) The approximations are based on 150 data points (blue circles).

6.3 Model-Based Nonparametric Likelihood Approximation

Bayesian optimization yields a probabilistic model for the discrepancy Δ_θ . As discussed in Section 5.3, we can use this model to obtain the computable likelihood approximation $\hat{L}_n^{(t)}$,

$$\hat{L}_n^{(t)}(\theta) \propto \begin{cases} F\left(\frac{h - \mu_t(\theta)}{\sqrt{v_t(\theta) + \sigma_n^2}}\right) & \text{if } f(\theta) = \Delta_\theta, \\ F\left(\frac{\log h - \mu_t(\theta)}{\sqrt{v_t(\theta) + \sigma_n^2}}\right) & \text{if } f(\theta) = \log \Delta_\theta, \end{cases} \quad (47)$$

where h is the bandwidth (threshold). The function $F(x)$ was defined in Equation (28) and denotes the cdf of a standard normal random variable, and μ_t and $v_t + \sigma_n^2$ are the posterior mean and variance of the Gaussian process.

Both $\hat{L}_n^{(t)}$ in the nonparametric approach and $\hat{\ell}_s^{(t)} = \exp(-\hat{\ell}_s^{(t)})$ in the parametric approach are computable approximations \hat{L} of the likelihood L . Evaluating them is cheap since no further runs of the simulator are needed. Derivatives can also be computed since the derivatives of the posterior mean and variance are tractable for Gaussian processes. A given approximate likelihood function can thus be used in various ways for inference: We can maximize it and compute its curvature (Hessian matrix) to obtain error bars, we can perform inference with a hybrid Monte Carlo algorithm in a MCMC framework, or use it according to Equation (11) in an importance sampling approach.

For the results in this paper, we used iterative importance sampling where in each iteration, the auxiliary pdf q was a mixture of Gaussians as in Section 3.5. The initial auxiliary pdf was defined as a mixture of Gaussians in the same manner by associating uniform weights with the $\theta^{(i)}$ acquired in the Bayesian optimization step. Samples from the prior pdf p_θ are not needed in such an approach, which can be advantageous if obtaining them is expensive.

We next illustrate model-based likelihood approximation using the example about bacterial infections in day care centers.

Example 11 (Model-based approximate univariate likelihoods for the day care centers). We inferred the likelihood function via Bayesian optimization using a Gaussian process model with quadratic prior mean and $T = 50$ data points (10 initial points and 40 acquisitions). The bandwidths and general setup were as in Example 7. The left column of Figure 8 shows the estimated models of the discrepancies for the different parameters and compares them with the empirical distributions reported in Figure 5. The right column of Figure 8 shows the estimated likelihood functions $\hat{L}_n^{(t)}$, $t = 50$ (blue solid curves), and compares them with the sample average based approximations $\hat{L}_n^{(t)}$ from Figure 5 (black dots). For Bayesian optimization, the computational cost for an entire likelihood curve was 50 simulations. This is in stark contrast to the computational cost of $N = 300$ simulations for a single evaluation of \hat{L}_n in the sample-based approach. Since \hat{L}_n was evaluated on a grid of 50 points, the model-based results required 300 times fewer simulations. The computational savings were achieved through the use of smooth regression and the active construction of the training data in Bayesian optimization. \blacktriangle

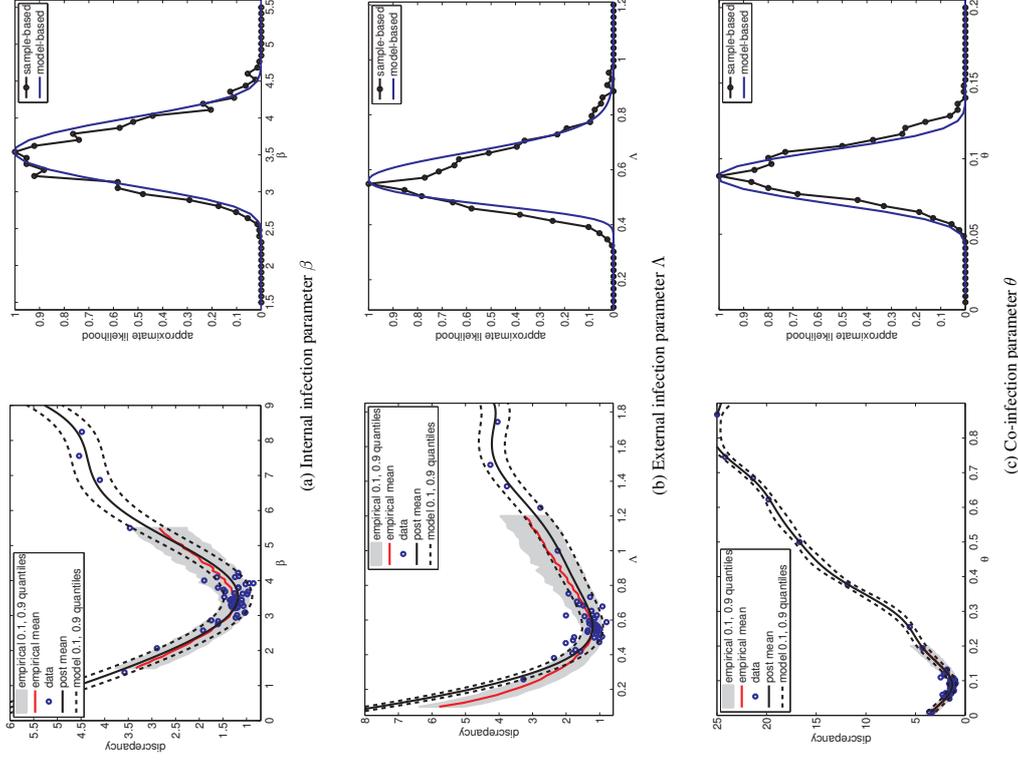

Figure 8: Distributions of the discrepancies and approximate likelihoods for the day care center example. For reference, the sample average results are reproduced from Figure 5. In the standard sample average approach, each likelihood curve required 15,000 simulations (right column, black lines with markers). In the proposed model-based approach, each likelihood curve required 50 simulations (right column, blue solid lines). This yields a factor of 300 in computational savings.

6.4 Possible Extensions

We use in this paper a basic version of Bayesian optimization to do likelihood-free inference. But more advanced versions exist which opens up a range of possible extensions.

6.4.1 SCALABILITY WITH THE NUMBER OF ACQUISITIONS

The straightforward approach of Section 6.1 to Bayesian optimization with a Gaussian process model requires the inversion of the $t \times t$ matrix \mathbf{K}_t . The inversion has complexity $\mathcal{O}(t^3)$ which limits the number of acquisitions to a few thousands. For the applications in this paper, this has not been an issue but we would like to be able to acquire more than a few thousand points if necessary.

Research on Gaussian processes has produced numerous methods to deal with the inversion of \mathbf{K}_t (for an overview, see Rasmussen and Williams, 2006, Chapter 8). Importantly, we can directly use any of these methods for the purpose of likelihood-free inference. For example, sparse Gaussian process regression employs $m < t$ “inducing variables” to reduce the complexity from $\mathcal{O}(t^3)$ to $\mathcal{O}(tm^2)$ (see, for example, Quinero-Candela and Rasmussen, 2005). The inducing variables and the hyperparameters of the Gaussian process can be optimized using variational learning (Titsias, 2009), which is also amenable to stochastic optimization to further reduce the computational cost (Hensman et al., 2013).

An alternative approach to Gaussian process regression is Bayesian linear regression with a set of $m < t$ suitably chosen basis functions. The two approaches are closely related (see, for example, Rasmussen and Williams, 2006, Chapter 2), but instead of a $t \times t$ matrix, a $m \times m$ matrix needs to be inverted. This reduces the computational complexity again to $\mathcal{O}(tm^2)$. In order to keep the number of required basis functions small, adaptive basis regression with deep neural networks has been employed to perform Bayesian optimization (Snoek et al., 2015).

6.4.2 HIGH-DIMENSIONAL INFERENCE

Likelihood-free inference is in general very difficult when the dimensionality d of the parameter space is large. This difficulty manifests itself in our approach in the form of a nonlinear regression problem which needs to be solved. While we are only interested in accurate regression results in the areas of the parameter space where the discrepancy is small, discovering these areas becomes more difficult as the dimension increases.

In general, more training data are needed with increasing dimensions so that a method which can handle a large number of acquisitions is likely required (see above). Furthermore, the optimization of acquisition functions is also more difficult in higher dimensions.

Bayesian optimization in high dimensions typically relies on structural assumptions about the objective function. In recent work, it was assumed that the objective varies along a low dimensional subspace only (Chen et al., 2012; Wang et al., 2013; Djolonga et al., 2013), or that it takes the form of an additive model (Kandasamy et al., 2015). This work and further developments in high-dimensional Bayesian optimization can be leveraged for the challenging problem of high-dimensional likelihood-free inference.

6.4.3 PARALLELIZATION AND ACQUISITION RULES

Bayesian optimization lends itself to parallelization. In particular the acquisition of new data points can be performed in parallel. While several well-known acquisition rules are sequential, they can also be parallelized. Our stochastic acquisition rule provides an easy mechanism by using a sequential rule to define a probability distribution for the location of the next acquisition. Several points can then be drawn in parallel from that distribution. We employ the lower confidence bound selection criterion in Equation (45) to drive the stochastic acquisitions, but alternative rules, for example the maximization of expected improvement, can be used in an analogous way. Other stochastic acquisition rules, like for instance Thompson sampling (Thompson, 1933; Chapelle and Li, 2011; Russo and Van Roy, 2014), enable similarly the concurrent acquisition of multiple data points.

A more elaborate way to parallelize a sequential acquisition rule is to design the joint acquisitions such that the resulting algorithm behaves as if the points are chosen sequentially (Azimi et al., 2010), or to integrate out the possible outcomes of the pending function evaluations (Snoek et al., 2012). Moreover, parallel versions of the lower/upper confidence bound criterion have been proposed by Cortal et al. (2013) and Desautels et al. (2014).

In most theoretical studies on acquisition rules, the objective function in Bayesian optimization is modeled as a Gaussian process with uncorrelated Gaussian observation noise. The distribution of the (log) discrepancy, however, may not follow this assumption. This implies on the one hand that the probabilistic modeling of the discrepancy could be improved (see below). On the other hand, it also means that further research would be needed about optimal acquisition rules in the context of likelihood-free inference.

6.4.4 PROBABILISTIC MODEL

We modeled the discrepancy $\Delta\theta$ as a Gaussian or log-Gaussian process using a squared exponential covariance function and uncorrelated Gaussian observation noise. While simple and often used, we are not limited to these choices. The literature on Gaussian process regression and Bayesian optimization provides several alternatives and extensions (for an overview, see Rasmussen and Williams, 2006). Modeling of $\Delta\theta$ is important because the model affects the inferences made.

In the employed model, a stationary prior distribution is assumed. However, depending on the simulator, the discrepancy may behave differently in different parameter regions. In particular its variance may be input dependent (heteroscedasticity). Such cases can be handled by non-stationary covariance functions or by using different stationary processes in different regions of the parameter space (see, for example, Rasmussen and Williams, 2006, Chapters 6 and 9).

Equation (42) shows that for the Gaussian process model, the posterior variance does not depend on the observed function values but only on the acquisition locations. As more points are acquired in a neighborhood of a point, the posterior variance may shrink even if the observed function values have a larger than expected spread. A dependency on the observed values can be obtained indirectly by updating the hyperparameters of the covariance function. But a more direct dependency may be preferable. An option is to use Student's t processes instead where the posterior variance depends on the observed function values through a global scaling factor (Shah et al., 2014).

7. Applications

We here apply the developed methodology to infer the complete Ricker model and the complete model of bacterial infections in day care centers. As in the previous section, using Bayesian optimization in likelihood-free inference (BOLEFI) reduces the amount of required simulations by several orders of magnitude.

7.1 Ricker Model

We introduced the Ricker model in Example 2. It has three parameters: $\log r$, σ , and ϕ . The difficulty in the inference stems from the dynamics of the latent time series and the unobserved variables. We inferred the parameters using the synthetic likelihood of Wood (2010) from the data shown in Figure 1(a) which were generated with $\theta_0 = (3.8, 0.3, 10)$.

Wood (2010) inferred the model with a random walk Markov chain Monte Carlo algorithm using $\hat{\ell}_s^N(\theta)$ with $N = 500$. The random walk was defined on the log-parameters due to their positivity. In a baseline study with the computer code made publicly available by Wood (2010), we were not able to infer the parameters with the settings in the original publication (Wood, 2010, Section 1.1 in the supplementary material). Reducing the proposal standard deviation for σ by a factor of ten enabled inference even though different Markov chains still led to rather different marginal posterior pdfs for σ . These issues were observed for $N \in \{500, 1000, 5000\}$ and for Markov chains run twice as long as in the original publication (100,000 versus 50,000 iterations). In addition to the usual random effects in MCMC, the variability in the outcomes of the different chains may be due to his approach of working on a single realization of the random log synthetic likelihood function (see Figure 3 for example realizations when only $\log r$ is varied). The results of our baseline study are reported in Appendix D. Given the nature of the baseline results, we should not expect that the results from our method match them exactly.

For BOLEFI, we modeled the random log synthetic likelihood $\hat{\ell}_s^N$ as a log-Gaussian process with a quadratic prior mean function (using $N = 500$ as Wood, 2010). Bayesian optimization was performed with the stochastic acquisition rule and 20 initial data points. Figure 9 shows $-\hat{\ell}_s^N(\theta)$ for $t \in \{50, 150, 500\}$. The results for $t = 50$ and $t = 500$ differ more in the shape of the estimated regression functions than in the location of the optima. As the evidence set grows, the algorithm learns that the log synthetic likelihood is less confined along σ and that the curvature along the other dimensions should be larger. The plot also shows that there is a negative correlation between $\log r$ and ϕ (conditional on σ). This is reasonable since a larger growth rate r can be compensated with a smaller value of the observation scalar ϕ and vice versa.

The approximation $\hat{\ell}_s^N$ was used to perform posterior inference of the parameters via the iterative importance sampling scheme of Section 6.3 (using three iterations with 25,000 samples each). This sampling is purely model-based and does not require further runs of the simulator. The computed marginal posterior pdfs are shown in Figure 10 (curves in gray) together with a MCMC solution for reference (blue dashed). It can be seen that already after $t = 150$ acquired data points, we obtain a solution which matches the MCMC solution well at a fraction of the computational cost. About 600 times fewer calls to the simulator were needed.

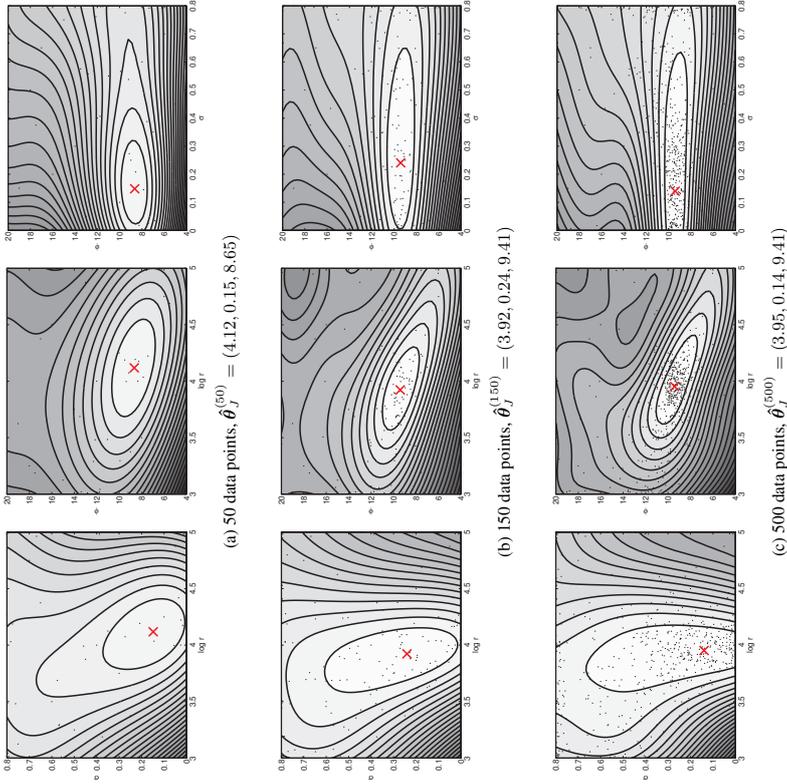

Figure 9: Isocontours of the estimated negative log synthetic likelihood function for the Ricker model. Each panel shows slices of $-\hat{\ell}_s^{(t)}$ with $\text{argmax} \hat{\ell}_s^{(t)}$ as center point when two of the three variables are varied at a time. The center points are marked with a red cross. The dots mark the location of the acquired parameters $\theta^{(t)}$ (projected onto the plane). The intensity map is the same in all figures; white corresponds to the smallest value.

The largest differences between the model-based and the MCMC solution occur for parameter σ (Figure 10(b)). But we have seen that this is a difficult parameter to infer and that the MCMC solution may actually not correspond to ground truth. The two posteriors inferred by MCMC have, for instance, posterior means (blue diamonds) which are further from the data generating parameter $\sigma_o = 0.3$ (green circle) than our model-based solution (black square). For the other parameters, the posterior means of the model-based solution are also closer to ground truth than the posterior means of the MCMC solution.

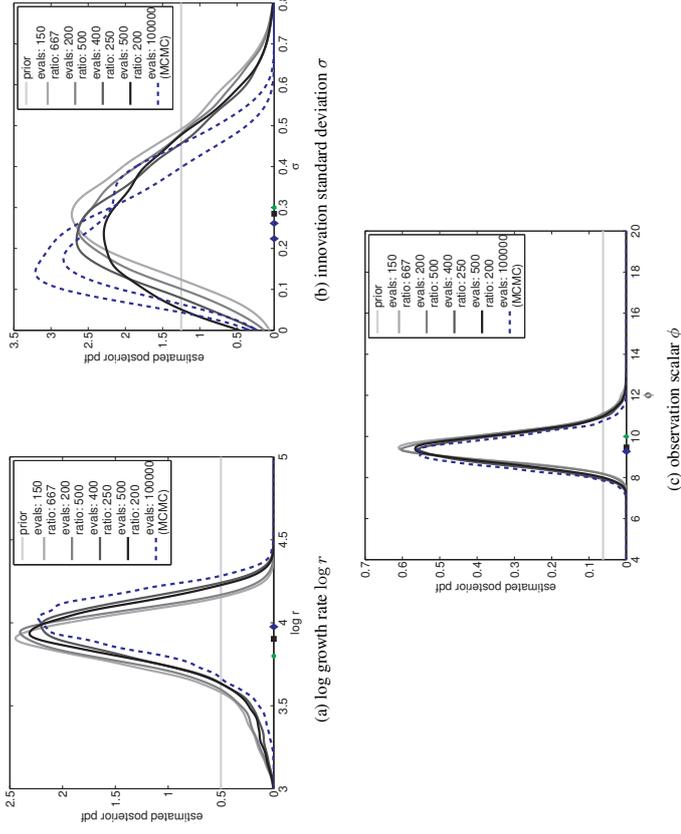

Figure 10: Marginal posterior pdfs for the Ricker model. The model-based solutions are shown in gray, the blue dashed curves are the MCMC solution. The green circles on the x-axes mark the location of $\theta_o = (3.8, 0.3, 10)$. The blue diamonds mark the value of the posterior mean for the MCMC solution while the black squares indicate the posterior means of the model-based solution. For the MCMC solution, 100,000 simulated data sets are needed. Bayesian optimization yields informative solutions using 150 simulated data sets only, which corresponds to 667 times fewer simulations than with MCMC.

7.2 Bacterial Infections in Day Care Centers

The model for bacterial infections in day care centers was described in Example 3. It has three parameters of interest: β , Λ , and θ . The likelihood function is intractable due to the infinitely many unobserved correlated variables. We inferred the model using the discrepancy Δ_θ described in Example 7 from the same real data as Numminen et al. (2013).

For BOLEFI, we modeled the discrepancy Δ_θ as a Gaussian process with a quadratic prior mean function and used the stochastic acquisition rule. The algorithm was initialized with 20 data points. Figure 11 shows the estimated regression functions $\hat{J}^{(t)}$ for

$t \in \{50, 100, 150, 500\}$. For $t = 50$, the optimal co-infection parameter θ is at a boundary of the parameter space. As more training data are acquired, the shape of the estimated regression function changes. The algorithm learns that the optimal θ is located away from the boundary, and the isocontours become oblique which indicates a negative (conditional) correlation between all three parameters. A negative correlation between β and Λ given the estimate of θ is reasonable because an increase in transmissions inside the day care centers (increase of β) can be compensated with a decrease of transmissions from an outside source (decrease of Λ). The co-infection parameter θ is negatively correlated with β given the estimate of Λ because a decrease in the tendency to be infected by multiple strains of the bacterium (decrease of θ) can be offset by an increase of the transmission rate (increase of β). The same reasoning applies to Λ given a fixed value of β .

We used the Gaussian process model of the discrepancy to compute the model-based likelihood $\hat{L}_h^{(t)}$. The threshold h was chosen as the 0.05 quantile of the modeled discrepancy at the minimizer of the estimated regression function. Model-based posterior inference was then performed via iterative importance sampling as described in Section 6:3 (using three iterations with 25,000 samples each). Figure 12 (left column) shows the inferred marginal posterior pdfs. They stabilize quickly as the amount of acquired data increases.

The right column in Figure 12 compares our model-based results with the solution by Numminen et al. (2013) (blue horizontal lines with triangles) and with results by the population Monte Carlo (PMC) ABC algorithm of Section 3.5 (black curves with diamonds). Numminen et al. (2013) used a PMC-ABC algorithm as well but with a slightly different discrepancy measure (see Example 7). Both PMC results were obtained using 10,000 initial simulations to set the initial threshold, followed by four more iterations with shrinking thresholds where in each iteration, data sets were simulated till 10,000 accepted parameters were obtained. It can be seen that the posterior mean and the credibility intervals of the two PMC results match in the fourth generation, which indicates that our modification of the discrepancy measurement had a negligible influence. For the PCM results shown in black, iteration one to four required 121,374; 277,997; 572,007; and 1,218,382 simulations each, giving a total computational cost of 2,199,760 simulations for the results of iteration four. In terms of computing time, the PMC computations took about 4.5 days on a cluster with 200 cores. Our model-based results for $t = 1,000$ were obtained with one tenth of the initial simulations of the reference methods and took only about 1.5 hours on a desktop computer.⁴ Out of the computing time, 93% were spent on simulating the day care centers, and 7% on regression and optimization of the acquisition function.

The posterior means of our model-based approach match quickly the reference results (red curves with circles versus blue curves with triangles). The focus on the modal region yields, however, broader credibility intervals. The broader model-based posterior pdfs suggest that they could be used as auxiliary pdf for PMC-ABC or other iterative ABC algorithms which are based on importance sampling. Moreover, one could evaluate the discrepancy at the sampled points to obtain additional training data in order to refine the model.

⁴ The simulation of the 29 day care centers in the model was partly parallelized by means of seven cores.

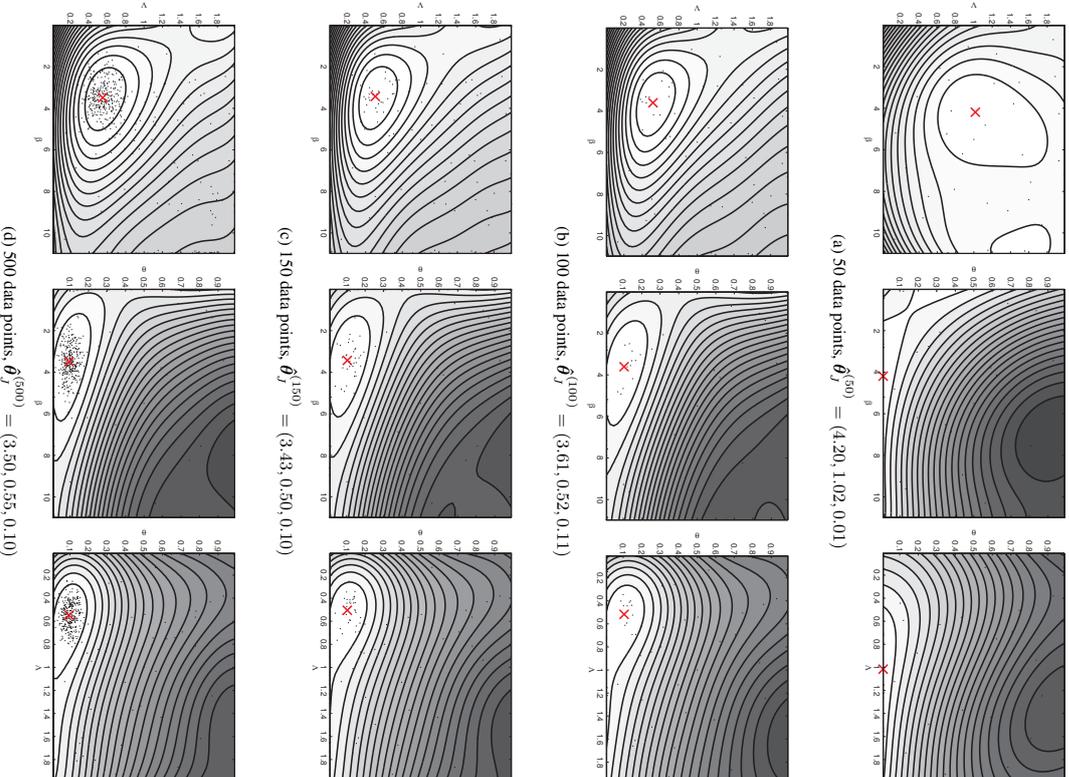

Figure 11: Isocontours of the estimated regression function $\hat{J}^{(t)}$ for the day care center model. Visualization is as in Figure 9.

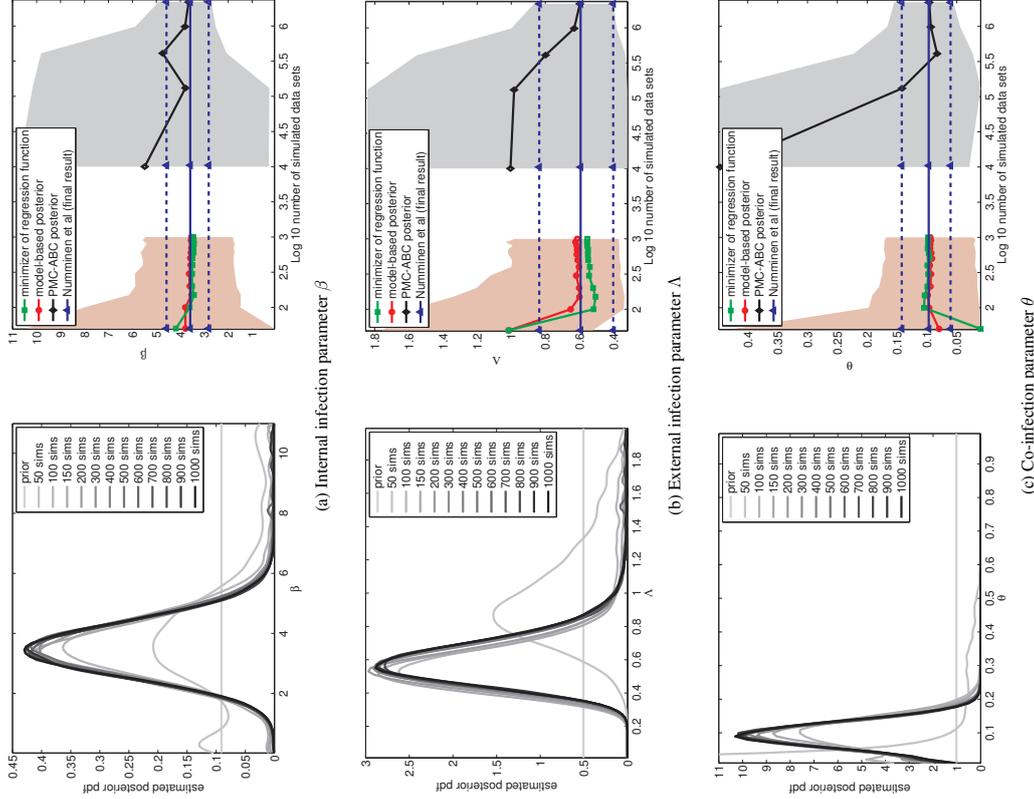

Figure 12: Marginal posterior results for the day care center model. The left column shows the obtained model-based posterior pdfs. The right column compares the posterior mean and the 95% credibility interval with results from PMc-ABC algorithms. We obtain conservative estimates of the model parameters at a fraction of the computational cost. Posterior means are shown as solid lines with markers, credibility intervals as shaded areas or dashed lines.

8. Conclusions

Our paper dealt with inferring the parameters of simulator-based (generative) statistical models. Inference is difficult for such models because of the intractability of the likelihood function. While it is an open question whether variational principles are also applicable, the parameters of simulator-based statistical models are typically inferred by finding values for which the discrepancy between simulated and observed data tends to be small. We have seen that such an approach is computationally costly. The high cost is largely due to a lack of knowledge about the functional relation between the model parameters and the discrepancies. We proposed to use regression to infer the relation using training data which are actively acquired. The acquisition is performed such that the focus in the regression is on regions in the parameter space where the discrepancy tends to be small. We implemented the proposed strategy using Bayesian optimization where the discrepancy is modeled with a Gaussian process. The posterior distribution of the Gaussian process was used to construct a model-based approximation of the intractable likelihood. This combination of probabilistic modeling and optimization reduced the number of simulated data sets by several orders of magnitude in our applications. The reduction in the number of required simulations accelerated the inference substantially.

Our approach is related to the work by Rasmussen (2003) and the two recent papers by Wilkinson (2014) and Meeds and Welling (2014) (which became only available after we first proposed our approach at “ABC in Rome” in 2013): Rasmussen (2003) used a Gaussian process to model the logarithm of the target pdf in a hybrid Monte Carlo algorithm. There are two main differences to our work. First, a scenario was considered where the target can be evaluated exactly at a finite computational cost, even though the cost might be high. In our case, exact evaluation of the likelihood function is not assumed possible at finite cost. This difference is important because approximate likelihood evaluations might be rather noisy. The second difference is that we used Bayesian optimization to focus on the modal areas of the target.

Related to the approach of Rasmussen (2003), Wilkinson (2014) modeled the log likelihood as a Gaussian process. This is different from our work where we model the discrepancies. We believe that modeling the discrepancies is advantageous because it allows to delay the selection of the kernel and bandwidth which are needed in the nonparametric setting. This is important because it enables one to make use of all simulated data. In the parametric setting, the two modeling strategies lead to identical solutions. We found further that accurate point estimates can be obtained by modeling the discrepancies only. In particular, minimizing their regression function corresponds to maximizing a lower bound of the approximate nonparametric likelihood under mild conditions. As a second difference, Wilkinson (2014) used space-filling points together with a plausibility criterion to obtain the parameter values for the regression. This is in contrast to Bayesian optimization where powerful optimization methods are employed to quickly identify the areas of interest.

Meeds and Welling (2014) proposed an alternative to the sample average approximation of the (limiting) synthetic likelihood by modeling each element of the intractable mean and covariance matrix of the summary statistics with a Gaussian process. The resulting likelihood approximation was used together with a Markov chain Monte Carlo algorithm for

posterior inference. The differences to our approach lie in the quantities modeled and in the use Bayesian optimization to actively design the training data for the Gaussian processes.

There are also connections to the body of work on Bayesian analysis of computer codes (for an introduction to this field of research, see for example the paper by O’Hagan, 2006): Sacks et al. (1989) and Currin et al. (1991) modeled the outputs of general deterministic computer codes as Gaussian processes. The computer codes were, for example, solving complex partial differential equations, and the papers were about finding an emulator for the heavy computations. Inference of unknown parameters of the computer codes given observed data was only considered later by Cox et al. (2001) and Kennedy and O’Hagan (2001). The observed and simulated data were modeled using Gaussian processes, and space-filling points were used to choose the parameters for which the computer code was run. The main differences to our approach are again the quantities modeled, and the use of Bayesian optimization.

We employed a rather basic algorithm to perform Bayesian optimization. This does, however, not mean that Bayesian optimization for likelihood-free inference is limited to that particular algorithm. We discussed a number of alternatives, as well as more advanced algorithms which could be used instead, and outlined a general framework for increasing the computational efficiency of likelihood-free inference.

Our paper opens up a wide range of extensions and opportunities for future research. One possibility is to use the tools provided by Bayesian optimization to tackle the challenging problem of likelihood-free inference in high dimensions. More foundational research topics would revolve around the modeling of the discrepancies and the development of acquisition rules which are tailored to the problem of likelihood-free inference. We focused on approximating the modal areas of the intractable likelihoods more accurately than the tails. It is an open question of how to best increase the accuracy in the tail areas. One possibility is to use the samples from the approximate posterior to update the training data for the regression, which would naturally lead to a recursion where the current method would only provide the initial approximation.

Appendix A. Proof of Proposition 1

We split the objective \hat{J}_g^N , defined in Equation (32), into two terms,

$$\hat{J}_g^N(\boldsymbol{\theta}) = T_1(\boldsymbol{\theta}) + T_2(\boldsymbol{\theta}), \quad (48)$$

$$T_1(\boldsymbol{\theta}) = \log |\det \mathbf{C}_{\theta_1}|, \quad (49)$$

$$T_2(\boldsymbol{\theta}) = E^N \left[(\Phi_o - \Phi_{\theta})^\top \mathbf{C}_{\theta}^{-1} (\Phi_o - \Phi_{\theta}) \right]. \quad (50)$$

Term T_2 can be rewritten using the empirical mean $\hat{\boldsymbol{\mu}}_{\theta}$ and the covariance matrix $\hat{\boldsymbol{\Sigma}}_{\theta}$ in Equation (14),

$$T_2(\boldsymbol{\theta}) = E^N \left[(\Phi_o - \hat{\boldsymbol{\mu}}_{\theta} + \hat{\boldsymbol{\mu}}_{\theta} - \Phi_{\theta})^\top \mathbf{C}_{\theta}^{-1} (\Phi_o - \hat{\boldsymbol{\mu}}_{\theta} + \hat{\boldsymbol{\mu}}_{\theta} - \Phi_{\theta}) \right] \quad (51)$$

$$= E^N \left[(\Phi_o - \hat{\boldsymbol{\mu}}_{\theta})^\top \mathbf{C}_{\theta}^{-1} (\Phi_o - \hat{\boldsymbol{\mu}}_{\theta}) + (\hat{\boldsymbol{\mu}}_{\theta} - \Phi_{\theta})^\top \mathbf{C}_{\theta}^{-1} (\hat{\boldsymbol{\mu}}_{\theta} - \Phi_{\theta}) \right. \\ \left. + 2(\Phi_o - \hat{\boldsymbol{\mu}}_{\theta})^\top \mathbf{C}_{\theta}^{-1} (\hat{\boldsymbol{\mu}}_{\theta} - \Phi_{\theta}) \right] \quad (52)$$

$$= (\Phi_o - \hat{\boldsymbol{\mu}}_{\theta})^\top \mathbf{C}_{\theta}^{-1} (\Phi_o - \hat{\boldsymbol{\mu}}_{\theta}) + \text{tr} \left(\mathbf{C}_{\theta}^{-1} E^N \left[(\hat{\boldsymbol{\mu}}_{\theta} - \Phi_{\theta}) (\hat{\boldsymbol{\mu}}_{\theta} - \Phi_{\theta})^\top \right] \right) \quad (53)$$

$$= (\Phi_o - \hat{\boldsymbol{\mu}}_{\theta})^\top \mathbf{C}_{\theta}^{-1} (\Phi_o - \hat{\boldsymbol{\mu}}_{\theta}) + \text{tr} \left(\mathbf{C}_{\theta}^{-1} \hat{\boldsymbol{\Sigma}}_{\theta} \right), \quad (54)$$

where we have used that $E^N[\Phi_{\theta}] = \hat{\boldsymbol{\mu}}_{\theta}$. For $\mathbf{C}_{\theta} = \hat{\boldsymbol{\Sigma}}_{\theta}$, we have

$$T_2(\boldsymbol{\theta}) = (\Phi_o - \hat{\boldsymbol{\mu}}_{\theta})^\top \hat{\boldsymbol{\Sigma}}_{\theta}^{-1} (\Phi_o - \hat{\boldsymbol{\mu}}_{\theta}) + p. \quad (55)$$

Hence, for $\mathbf{C}_{\theta} = \hat{\boldsymbol{\Sigma}}_{\theta}$, \hat{J}_g^N equals

$$\hat{J}_g^N(\boldsymbol{\theta}) = \log |\det \hat{\boldsymbol{\Sigma}}_{\theta}| + (\Phi_o - \hat{\boldsymbol{\mu}}_{\theta})^\top \hat{\boldsymbol{\Sigma}}_{\theta}^{-1} (\Phi_o - \hat{\boldsymbol{\mu}}_{\theta}) + p. \quad (56)$$

On the other hand, the log synthetic likelihood $\hat{\ell}_s^N$ is

$$\hat{\ell}_s^N(\boldsymbol{\theta}) = -\frac{p}{2} \log(2\pi) - \frac{1}{2} \log |\det \hat{\boldsymbol{\Sigma}}_{\theta}| - \frac{1}{2} (\Phi_o - \hat{\boldsymbol{\mu}}_{\theta})^\top \hat{\boldsymbol{\Sigma}}_{\theta}^{-1} (\Phi_o - \hat{\boldsymbol{\mu}}_{\theta}), \quad (57)$$

so that

$$\hat{J}_g^N(\boldsymbol{\theta}) = p - p \log(2\pi) - 2\hat{\ell}_s^N(\boldsymbol{\theta}). \quad (58)$$

The claimed result follows now from Equation (31),

$$\log L_g^N(\boldsymbol{\theta}) \geq -\frac{p}{2} + \hat{\ell}_s^N(\boldsymbol{\theta}). \quad (59)$$

Replacing the empirical average E^N with the expectation shows that the limiting quantities $\hat{\ell}_s$ and $J_g(\boldsymbol{\theta})$,

$$J_g(\boldsymbol{\theta}) = E[\Delta_{\theta_1}^g], \quad (60)$$

are related by an analogous result. In more detail,

$$J_g(\boldsymbol{\theta}) = \log |\det \mathbf{C}_{\theta_1}| + E \left[(\Phi_o - \Phi_{\theta})^\top \mathbf{C}_{\theta}^{-1} (\Phi_o - \Phi_{\theta}) \right] \quad (61)$$

$$= \log |\det \mathbf{C}_{\theta_1}| + (\Phi_o - \boldsymbol{\mu}_{\theta})^\top \mathbf{C}_{\theta}^{-1} (\Phi_o - \boldsymbol{\mu}_{\theta}) + \text{tr} \left(\mathbf{C}_{\theta}^{-1} \boldsymbol{\Sigma}_{\theta} \right), \quad (62)$$

where we used the same development which led to Equation (54) but with the expectation instead of E^N . Hence, for $\mathbf{C}_\theta = \Sigma_\theta$, we have the analogous result by definition of $\tilde{\ell}_s$ in Equation (13),

$$J_g(\theta) = p - p \log(2\pi) - 2\tilde{\ell}_s(\theta). \quad (63)$$

It follows by definition of J_g that $\tilde{\ell}_s$ can be seen as a regression function where θ is the vector of covariates and Δ_θ^g is, up to constants and the sign, the response variable.

Appendix B. Using the Prior Distribution of the Parameters in Bayesian Optimization

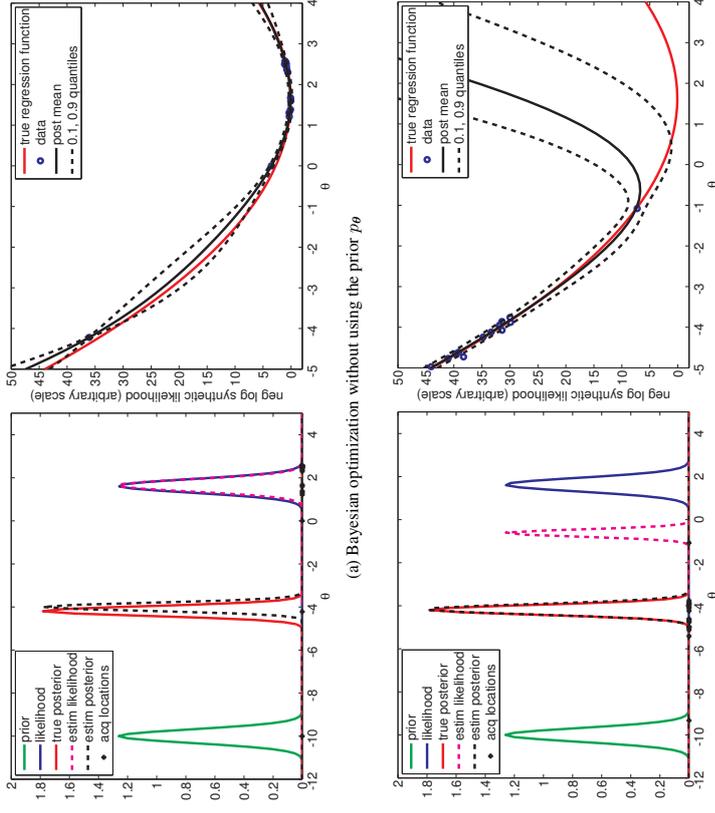

In the main text, we focused on acquiring training data in regions in the parameter space where the discrepancy Δ_θ tends to be small, which corresponds to the modal regions of the approximate likelihoods. For highly informative priors p_θ with modal regions far away from the peaks of the likelihood such an approach is suboptimal for posterior inference. Since the prior is typically fairly broad and the likelihood peaked, this situation is not usual. But if it happens, it is better to directly acquire the training data in the modal areas of the posterior. For inference via the synthetic likelihood, this can be straightforwardly done by approximating $\tilde{\ell}_s + \log p_\theta$. In Bayesian optimization with Δ_θ^g as the response variable, the posterior mean μ_t in Equation (43) would then be replaced by $\hat{\mu}_t(\theta) = \mu_t(\theta) - 2 \log p_\theta$. For inference via a nonparametric approximation of the likelihood, the same approach may also work but this warrants further investigations because the regression function J provides only a lower bound for the likelihood. We also note that using the prior p_θ can be helpful if it is known that the parameters do not influence the model independently, causing for instance the discrepancy to be nearly constant along certain directions in the parameter space.

Figure 13 illustrates the basic idea using Example 1 and a prior pdf p_θ (blue curve) which has practically no overlap with the true likelihood L (green curve). The results are for Bayesian optimization with 20 deterministic acquisitions and a Gaussian process model with constant mean function.

Appendix C. Bayesian Optimization with a Deterministic versus a Stochastic Acquisition Rule

Example 10 illustrated log-Gaussian modeling and the stochastic acquisition rule by means of the Ricker model with the log growth rate $\log r$ as only unknown. We here show the differences between stochastic and deterministic acquisitions in greater detail. The results are for a log-Gaussian process model.

Figure 14 shows the estimated regression functions $\hat{J}^{(t)}$ as obtained with a deterministic acquisition rule like in Figure 7(d) for different t . The acquired data points are vertically clustered because the acquisition rule often proposed nearly identical parameters. Figure 15 shows $\hat{J}^{(t)}$ obtained with a stochastic acquisition rule as in Figure 7(f). While both methods lead to a satisfactory approximation of the negative log synthetic likelihood around its minimum, the result with the stochastic acquisition rule seems more stable because the acquired training data are spread out more evenly in the interval of interest.

(a) Bayesian optimization without using the prior p_θ

(b) Bayesian optimization with the prior p_θ during the acquisitions

Figure 13: Using the prior density p_θ in Bayesian optimization. (a) If p_θ is not used (or if uniform), the focus is on the modal region of the likelihood. If the prior is far from the mode of the likelihood, the learned model is less accurate in the modal areas of the posterior (black dashed versus red solid curve). (b) The prior pdf p_θ was used to shift the data acquisitions in Bayesian optimization to the modal area of the posterior (see the circles in the figures on the right or on the x-axes on the left). This results in a more accurate approximation of the posterior pdf but a less accurate approximation of the mode of the likelihood (dashed magenta versus blue solid curve).

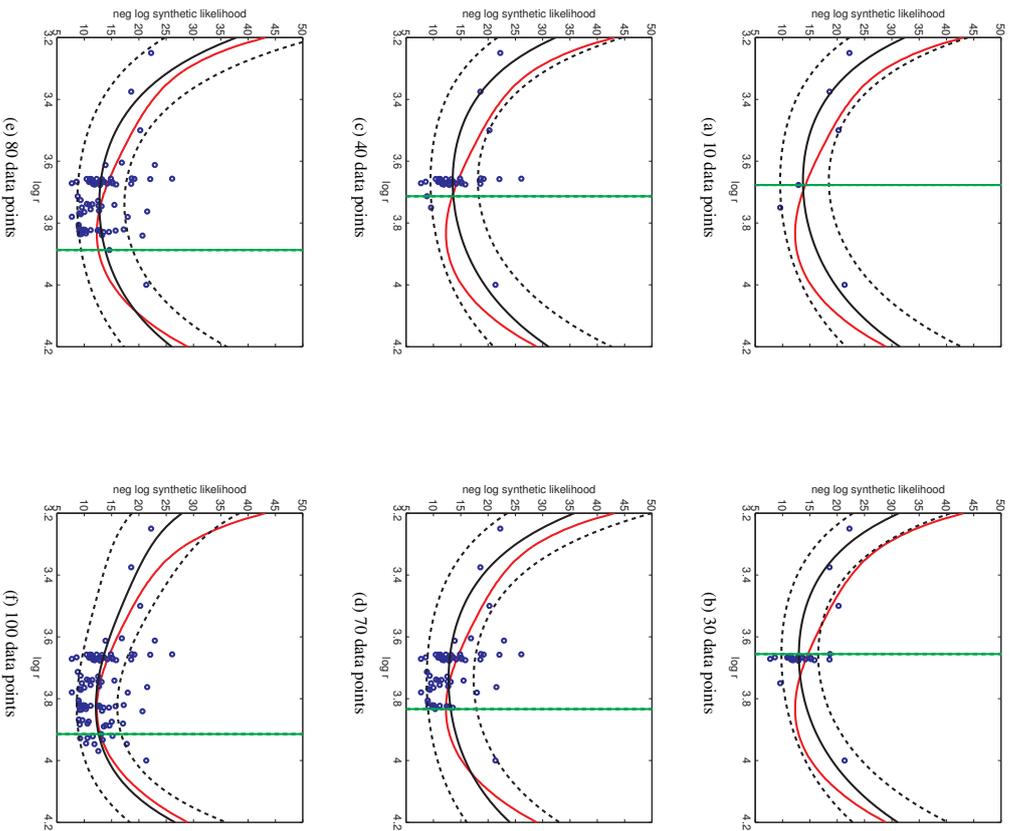

Figure 14: Log-Gaussian process model for the log synthetic likelihood of the Ricker model with $\log r$ as only unknown. The results are for the deterministic acquisition rule consisting of minimization of the acquisition function in Equation (45). Note the vertical clusters. The visualization is as in Figure 7. The plot range was restricted to $(3.2, 4.2)$ so that not all acquisition may be shown.

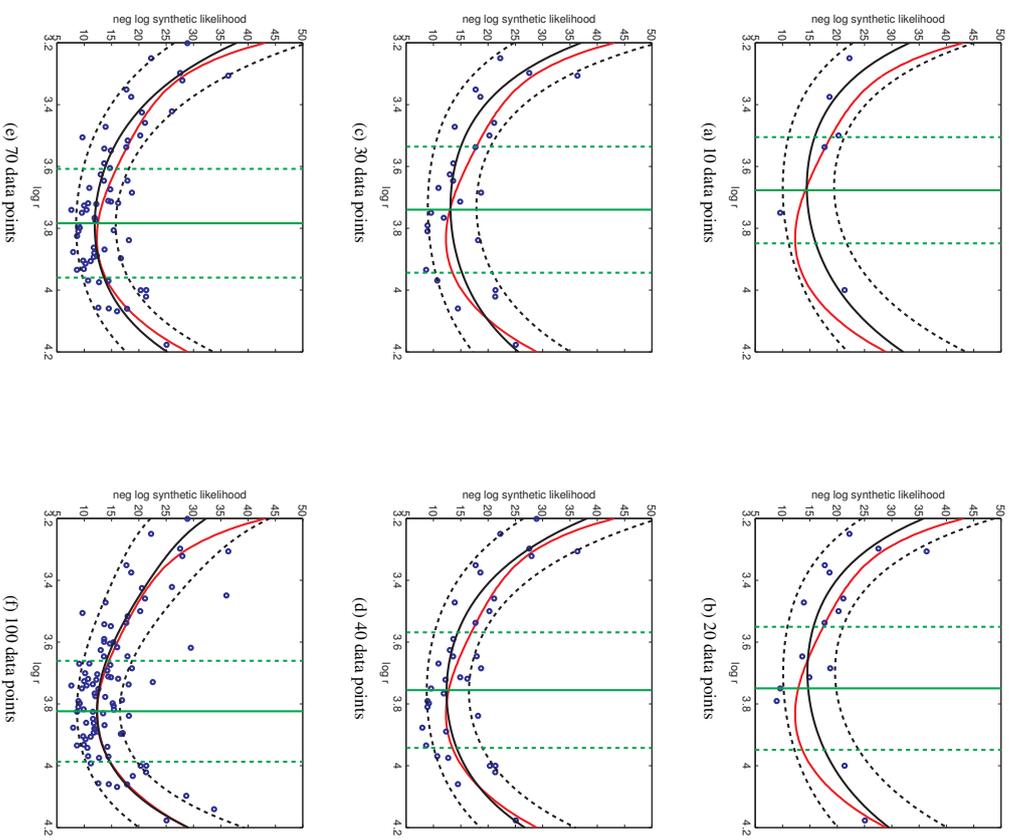

Figure 15: Log-Gaussian process model for the log synthetic likelihood of the Ricker model with $\log r$ as only unknown. The setup and visualization is as in Figure 14 but the stochastic acquisition rule is used. A movie showing the acquisitions and the updating of the model is available at <http://www.jmlr.org/papers/volume17/15-017/supplementary/RickerID.avi>.

Appendix D. Ricker Model Inferred with a Markov Chain Monte Carlo Algorithm

We here report the simulation results for the Ricker model inferred with the log synthetic likelihood \hat{L}_s^N and a random walk MCMC algorithm with the code made publicly available by Wood (2010). We ran the algorithm for 100,000 iterations, starting at $\theta_0 = (3.8, 0.3, 10)$. The first 25,000 samples were discarded. In the work by Wood (2010), the proposal standard deviation for σ was 0.1. Figure 16 shows that this choice led to a chain which got stuck close to $\sigma = 0$ even when $N = 5,000$ (blue, squares). Reducing the proposal standard deviation by a factor of 10 allowed us to obtain reasonable results (red, circles). The proposal standard deviations for the remaining parameters were the same as in the original publication. We then investigated the stability of the inferred posteriors when N is reduced from $N = 5,000$ to $N = 500$ and when the simulator is run with different realizations of the random log synthetic likelihood. Figure 17 shows that the posteriors are stable for $\log r$ and ϕ but that there is some variation for σ .

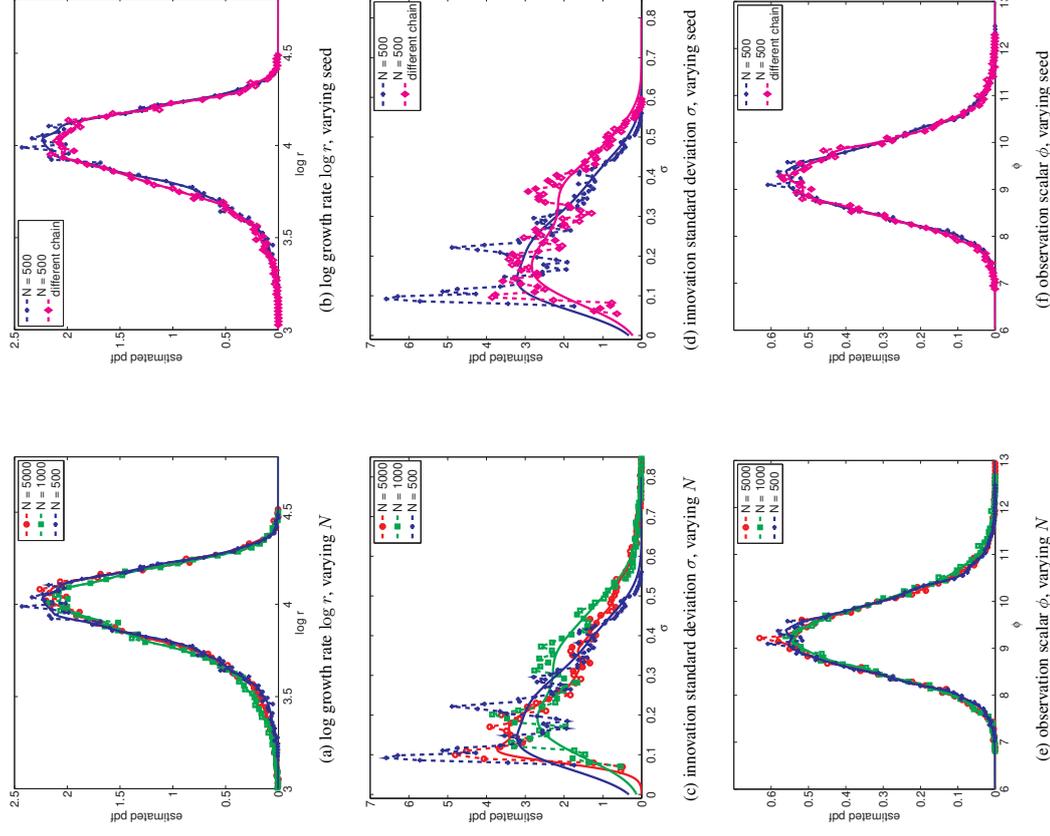

Figure 17: Effect of the number of simulated data sets N (left column) and the seed of the random number generator (right column) for the Ricker example when inferred with the method by Wood (2010). Visualization is as in Figure 16.

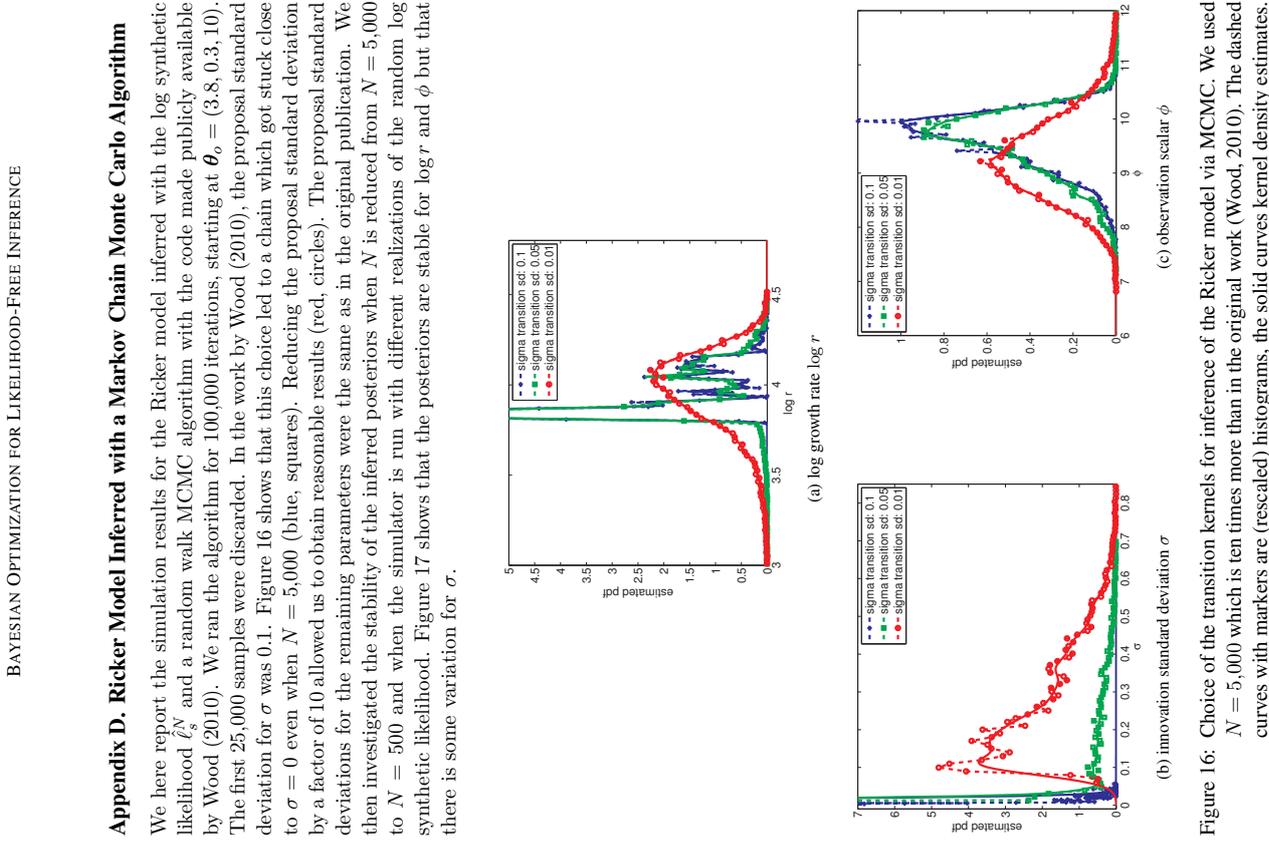

Figure 16: Choice of the transition kernels for inference of the Ricker model via MCMC. We used $N = 5,000$ which is ten times more than in the original work (Wood, 2010). The dashed curves with markers are (rescaled) histograms, the solid curves kernel density estimates.

Abstract

We develop a novel framework to study smooth and strongly convex optimization algorithms. Focusing on quadratic functions we are able to examine optimization algorithms as a recursive application of linear operators. This, in turn, reveals a powerful connection between a class of optimization algorithms and the analytic theory of polynomials whereby new lower and upper bounds are derived. Whereas existing lower bounds for this setting are only valid when the dimensionality scales with the number of iterations, our lower bound holds in the natural regime where the dimensionality is fixed. Lastly, expressing it as an optimal solution for the corresponding optimization problem over polynomials, as formulated by our framework, we present a novel systematic derivation of Nesterov's well-known Accelerated Gradient Descent method. This rather natural interpretation of AGD contrasts with earlier ones which lacked a simple, yet solid, motivation.

Keywords: smooth and strongly convex optimization, full gradient descent, accelerated gradient descent, heavy ball method

1. Introduction

In the field of mathematical optimization one is interested in efficiently solving a minimization problem of the form

$$\min_{\mathbf{x} \in X} f(\mathbf{x}), \quad (1)$$

where the *objective function* f is some real-valued function defined over the *constraints set* X . Many core problems in the field of Computer Science, Economic, and Operations Research can be readily expressed in this form, rendering this minimization problem far-reaching. That being said, in its full generality this problem is just too hard to solve or

even to approximate. As a consequence, various structural assumptions on the objective function and the constraints set, along with better-suited optimization algorithms, have been proposed so as to make this problem viable.

One such case is smooth and strongly convex functions over some d -dimensional Euclidean space¹. Formally, we consider continuously differentiable $f : \mathbb{R}^d \rightarrow \mathbb{R}$ which are L -smooth, i.e.,

$$\|\nabla f(\mathbf{x}) - \nabla f(\mathbf{y})\| \leq L \|\mathbf{x} - \mathbf{y}\|, \quad \forall \mathbf{x}, \mathbf{y} \in \mathbb{R}^d,$$

and μ -strongly convex, that is,

$$f(\mathbf{y}) \geq f(\mathbf{x}) + \langle \mathbf{y} - \mathbf{x}, \nabla f(\mathbf{x}) \rangle + \frac{\mu}{2} \|\mathbf{y} - \mathbf{x}\|^2, \quad \forall \mathbf{x}, \mathbf{y} \in \mathbb{R}^d.$$

A wide range of applications together with very efficient solvers have made this family of problems very important. Naturally, an interesting question arises: how fast can these kind of problems be solved? better said, what is the computational complexity of minimizing smooth and strongly-convex functions to a given degree of accuracy?² Prior to answering these, otherwise ill-defined, questions, one must first address the exact nature of the underlying computational model.

Although being a widely accepted computational model in the theoretical computer sciences, the Turing Machine Model presents many obstacles when analyzing optimization algorithms. In their seminal work, Nemirovsky and Yudin (1983) evaded some of these difficulties by proposing the *black box computational model*, according to which information regarding the objective function is acquired iteratively by querying an *oracle*. This model does not impose any computational resource constraints³. Nemirovsky and Yudin showed that for any optimization algorithm which employs a first-order oracle, i.e. receives $(f(\mathbf{x}), \nabla f(\mathbf{x}))$ upon querying at a point $\mathbf{x} \in \mathbb{R}^d$, there exists an L -smooth μ -strongly convex quadratic function $f : \mathbb{R}^d \rightarrow \mathbb{R}$, such that for any $\epsilon > 0$ the number of oracle calls needed for obtaining an ϵ -optimal solution $\bar{\mathbf{x}}$, i.e.,

$$f(\bar{\mathbf{x}}) < \min_{\mathbf{x} \in \mathbb{R}^d} f(\mathbf{x}) + \epsilon, \quad (2)$$

must satisfy

$$\# \text{ Oracle Calls} \geq \tilde{\Omega} \left(\min \{d, \sqrt{\kappa} \ln(1/\epsilon)\} \right), \quad (3)$$

where $\kappa \triangleq L/\mu$ denotes the so-called *condition number*.

1. More generally, one may consider smooth and strongly convex functions over some Hilbert space.
2. Natural as these questions might look today, matters were quite different only few decades ago. In his book 'Introduction to Optimization' which dates back to 87', Polyak B.T devotes a whole section as to: 'Why Are Convergence Theorems Necessary?' (See section 1.6.2 in Polyak (1987)).
3. In a sense, this model is dual to the Turing Machine model where all the information regarding the parameters of the problem is available prior to the execution of the algorithm, but the computational resources are limited in time and space.

The result of Nemirovsky and Yudin can be seen as the starting point of the present paper. The restricted validity of this lower bound to the first $\mathcal{O}(d)$ iterations is not a mere artifact of the analysis. Indeed, from an information point of view, a minimizer of any convex quadratic function can be found using no more than $\mathcal{O}(d)$ first-order queries. Noticing that this bound is attained by the Conjugate Gradient Descent method (CGD, see Polyak 1987), it seems that one cannot get a non-trivial lower bound once the number of queries exceeds the dimension d . Moreover, a similar situation can be shown to occur for more general classes of convex functions. However, the known algorithms which attain such behavior (such as CGD and the center-of-gravity method, e.g., Nemirovski 2005) require computationally intensive iterations, and are quite different than many common algorithms used for large-scale optimization problems, such as gradient descent and its variants. Thus, to capture the attainable performance of such algorithms, we must make additional assumptions on their structure. This can be made more solid using the following simple observation.

When applied on quadratic functions, the update rule of many optimization algorithms reduces to a recursive application of a linear transformation which depends, possibly randomly, on the previous p query points.

Indeed, the update rule of CGD for quadratic functions is *non-stationary*, i.e. uses a different transformation at each iteration, as opposed to other optimization algorithms which utilize less complex update rules such as: stationary updates rule, e.g., Gradient Descent, Accelerated Gradient Descent, Newton's method (see Nesterov 2004), The Heavy Ball method Polyak (1987), SDCA (see Shalev-Shwartz and Zhang 2013) and SAG (see Roux et al. 2012); cyclic update rules, e.g., SVRG (see Johnson and Zhang 2013); and piecewise-stationary update rules, e.g., Accelerated SDCA. Inspired by this observation, in the present work we explore the boundaries of optimization algorithms which admit stationary update rules. We call such algorithms p -Stationary Canonical Linear Iterative optimization algorithms (abbr. p -SCLI), where p designates the number of previous points which are necessary to generate new points. The quantity p may be instructively interpreted as a limit on the amount of memory at the algorithm's disposal.

Similar to the analysis of power iteration methods, the convergence properties of such algorithms are intimately related to the eigenvalues of the corresponding linear transformation. Specifically, as the convergence rate of a recursive application of a linear transformation is essentially characterized by its largest magnitude eigenvalue, the asymptotic convergence rate of p -SCLI algorithms can be bounded from above and from below by analyzing the spectrum of the corresponding linear transformation. It should be noted that the technique of linearizing iterative procedures and analyzing their convergence behavior accordingly, which dates back to the pioneering work of the Russian mathematician Lyapunov, has been successfully applied in the field of mathematical optimization many times, e.g., Polyak (1987) and more recently Lessard et al. (2014). However, whereas previous works were primarily concerned with deriving upper bounds on the magnitude of the corresponding eigenvalues, in this work our reference point is lower bounds.

As eigenvalues are merely roots of characteristic polynomials⁴, our approach involves establishing a lower bound on the maximal modulus (absolute value) of the roots of polynomials. Clearly, in order to find a meaningful lower bound, one must first find a condition which is satisfied by all characteristic polynomials that correspond to p -SCLIs. We show that such condition does exist by proving that characteristic polynomials of consistent p -SCLIs, which correctly minimize the function at hand, must have a specific evaluation at $\lambda = 1$. This in turn allows us to analyze the convergence rate purely in terms of the analytic theory of polynomials, i.e.,

$$\mathbf{Find} \quad \min \{ \rho(q(z)) \mid q(z) \text{ is a real monic polynomial of degree } p \text{ and } q(1) = r^p \}, \quad (4)$$

where $r \in \mathbb{R}$ and $\rho(q(z))$ denotes the maximum modulus over all roots of $q(z)$. Although a vast range of techniques have been developed for bounding the moduli of roots of polynomials (e.g., Marden 1966; Rahman and Schmeisser 2002; Mhovanovic et al. 1994; Walsh 1922; Mhovanovic and Rassias 2000; Fell 1980), to the best of our knowledge, few of them address lower bounds (see Higham and Tisseur 2003). Minimization problem (4) is also strongly connected with the question of bounding the spectral radius of 'generalized' companion matrices from below. Unfortunately, this topic too lacks an adequate coverage in the literature (see Volkovitz and Stryan 1980; Zhong and Huang 2008; Horne 1997; Huang and Wang 2007). Consequently, we devote part of this work to establish new tools for tackling (4). It is noteworthy that these tools are developed by using elementary arguments. This sharply contrasts with previously proof techniques used for deriving lower bounds on the convergence rate of optimization algorithms which employed heavy machinery from the field of extremal polynomials, such as Chebyshev polynomials (e.g., Mason and Handscomb 2002).

Based on the technique described above we present a novel lower bound on the convergence rate of p -SCLI optimization algorithms. More formally, we prove that any p -SCLI optimization algorithm over \mathbb{R}^d , whose iterations can be executed efficiently, requires

$$\#\text{Oracle Calls} \geq \tilde{\Omega} \left(\sqrt[p]{\kappa} \ln(1/\epsilon) \right) \quad (5)$$

in order to obtain an ϵ -optimal solution, *regardless of the dimension of the problem*. This result partially complements the lower bound presented earlier in Inequality (3). More specifically, for $p = 1$, we show that the runtime of algorithms whose update rules do not depend on previous points (e.g. Gradient Descent) and can be computed efficiently scales linearly with the condition number. For $p = 2$, we get the optimal result for smooth and strongly convex functions. For $p > 2$, this lower bound is clearly weaker than the lower bound shown in (3) at the first d iterations. However, we show that it can be indeed attained by p -SCLI schemes, some of which can be executed efficiently for certain classes of quadratic functions. Finally, we believe that a more refined analysis of problem (4) would show that this technique is powerful enough to meet the classical lower bound $\sqrt[p]{\kappa}$ for any p , in the worst-case over all quadratic problems.

4. In fact, we will use a polynomial matrix analogous of characteristic polynomials which will turn out to be more useful for our purposes.

The last part of this work concerns a cornerstone in the field of mathematical optimization, i.e., Nesterov's well-known Accelerated Gradient Descent method (AGD). Prior to the work of Nemirovsky and Yudin, it was known that full Gradient Descent (FGD) obtains an ϵ -optimal solution by issuing no more than

$$\mathcal{O}(\kappa \ln(1/\epsilon))$$

first-order queries. The gap between this upper bound and the lower bound shown in (3) has intrigued many researchers in the field. Eventually, it was this line of inquiry that led to the discovery of AGD by Nesterov (see Nesterov 1983), a slight modification of the standard GD algorithm, whose iteration complexity is

$$\mathcal{O}(\sqrt{\kappa} \ln(1/\epsilon)).$$

Unfortunately, AGD lacks the strong geometrical intuition which accompanies many optimization algorithms, such as FGD and the Heavy Ball method. Primarily based on sophisticated algebraic manipulations, its proof strives for a more intuitive derivation (e.g. Beck and Teboulle 2009; Baes 2009; Tseng 2008; Sutskever et al. 2013; Allen-Zhu and Orecchia 2014). This downside has rendered the generalization of AGD to different optimization scenarios, such as constrained optimization problems, a highly non-trivial task which up to the present time does not admit a complete satisfactory solution. Surprisingly enough, by designing optimization algorithms whose characteristic polynomials are optimal with respect to a constrained version of (4), we have uncovered a novel simple derivation of AGD. This reformulation as an optimal solution for a constrained optimization problem over polynomials, shows that AGD and the Heavy Ball are essentially two sides of the same coin.

To summarize, our main contributions, in order of appearance, are the following:

- We define a class of algorithms (p -SCLI) in terms of linear operations on the last p iterations, and show that they subsume some of the most interesting algorithms used in practice.
- We prove that any p -SCLI optimization algorithm must use at least
$$\tilde{\Omega}(\sqrt{\kappa} \ln(1/\epsilon))$$
 iterations in order to obtain an ϵ -optimal solution. As mentioned earlier, unlike existing lower bounds, our bound holds for every fixed dimensionality.
- We show that there exist matching p -SCLI optimization algorithms which attain the convergence rates stated above for all p . Alas, for $p \geq 3$, an expensive pre-calculation task renders these algorithms inefficient.
- As a result, we focus on a restricted subclass of p -SCLI optimization algorithms which can be executed efficiently. This yields a novel systematic derivation of Full Gradient Descent, Accelerated Gradient Descent, The Heavy-Ball method (and potentially other efficient optimization algorithms), each of which corresponds to an optimal solution of optimization problems on the moduli of polynomials' roots.

- We present new schemes which offer better utilization of second-order information by exploiting breaches in existing lower bounds. This leads to a new optimization algorithm which obtains a rate of $\sqrt[3]{\kappa} \ln(1/\epsilon)$ in the presence of large enough spectral gaps.

1.1 Notation

We denote scalars with lower case letters and vectors with bold face letters. We use \mathbb{R}^{++} to denote the set of all positive real numbers. All functions in this paper are defined over Euclidean spaces equipped with the standard Euclidean norm and all matrix-norms are assumed to denote the spectral norm.

We denote a block-diagonal matrix whose blocks are A_1, \dots, A_k by the conventional direct sum notation, i.e., $\oplus_{i=1}^k A_k$. We devote a special operator symbol for scalar matrices $\text{Diag}(a_1, \dots, a_d) = \oplus_{i=1}^d a_i$. The spectrum of a square matrix A and its spectral radius, the maximum magnitude over its eigenvalues, are denoted by $\sigma(A)$ and $\rho(A)$, respectively. Recall that the eigenvalues of a square matrix $A \in \mathbb{R}^{d \times d}$ are exactly the roots of the characteristic polynomial which is defined as follows

$$\chi_A(\lambda) = \det(A - \lambda I_d),$$

where I_d denotes the identity matrix. Since polynomials in this paper have their origins as characteristic polynomials of some square matrices, by a slight abuse of notation, we will denote the roots of a polynomial $q(z)$ and its root radius, the maximum modulus over its roots, by $\sigma(q(z))$ and $\rho(q(z))$, respectively, as well.

The following notation for quadratic functions and matrices will be of frequent use,

$$\begin{aligned} \mathcal{S}^d(\Sigma) &\triangleq \left\{ A \in \mathbb{R}^{d \times d} \mid A \text{ is symmetric and } \sigma(A) \subseteq \Sigma \right\}, \\ \mathcal{Q}^d(\Sigma) &\triangleq \left\{ f_{A,\mathbf{b}}(\mathbf{x}) \mid A \in \mathcal{S}^d(\Sigma), \mathbf{b} \in \mathbb{R}^d \right\}, \end{aligned}$$

where Σ denotes a non-empty set of positive reals, and where $f_{A,\mathbf{b}}(\mathbf{x})$ denotes the following quadratic function

$$f_{A,\mathbf{b}}(\mathbf{x}) \triangleq \frac{1}{2} \mathbf{x}^\top A \mathbf{x} + \mathbf{b}^\top \mathbf{x}, \quad A \in \mathcal{S}^d(\Sigma).$$

2. Framework

In the sequel we establish our framework for analyzing optimization algorithms for minimizing smooth and strongly convex functions. First, to motivate this technique, we show that the analysis of SDCA presented in Shalev-Shwartz and Zhang (2013) is tight by using a similar method. Next, we lay the foundations of the framework by generalizing and formalizing various aspects of the SDCA case. We then examine some popular optimization algorithms through this formulation. Apart from setting the boundaries for this work, this inspection gives rise to, otherwise subtle, distinctions between different optimization algorithms. Lastly, we discuss the computational complexity of p -SCLIs, as well as their convergence properties.

2.1 Case Study - Stochastic Dual Coordinate Ascent

We consider the optimization algorithm Stochastic Dual Coordinates Ascent (SDCA⁵) for solving Regularized Loss Minimization (RLM) problems (6), which are of great significance for the field of Machine Learning. It is shown that applying SDCA on quadratic loss functions allows one to reformulate it as a recursive application of linear transformations. The relative simplicity of such processes is then exploited to derive a lower bound on the convergence rate.

A smooth-RLM problem is an optimization task of the following form:

$$\min_{\mathbf{w} \in \mathbb{R}^n} P(\mathbf{w}) \triangleq \frac{1}{n} \sum_{i=1}^n \phi_i(\mathbf{w}^\top \mathbf{x}_i) + \frac{\lambda}{2} \|\mathbf{w}\|^2, \quad (6)$$

where ϕ_i are $1/\gamma$ -smooth and convex, $\mathbf{x}_1, \dots, \mathbf{x}_n$ are vectors in \mathbb{R}^d and λ is a positive constant. For ease of presentation, we further assume that ϕ_i are non-negative, $\phi_i(0) \leq 1$ and $\|\mathbf{x}_i\| \leq 1$ for all i .

The optimization algorithm SDCA works by minimizing an equivalent optimization problem

$$\min_{\alpha \in \mathbb{R}^n} D(\alpha) \triangleq \frac{1}{n} \sum_{i=1}^n \phi_i^*(\alpha_i) + \frac{1}{2\lambda n^2} \left\| \sum_{i=1}^n \alpha_i \mathbf{x}_i \right\|^2,$$

where ϕ_i^* denotes the Fenchel conjugate of ϕ_i , by repeatedly picking $z \sim \mathcal{U}([n])$ uniformly and minimizing $D(\alpha)$ over the z 'th coordinate. The latter optimization problem is referred to as the *dual problem*, while the problem presented in (6) is called the *primal problem*. As shown in Shalev-Shwartz and Zhang (2013), it is possible to convert a high quality solution of the dual problem into a high quality solution of the primal problem. This allows one to bound from above the number of iterations required for obtaining a prescribed level of accuracy $\epsilon > 0$ by

$$\tilde{O}\left(\left(n + \frac{1}{\lambda\gamma}\right) \ln(1/\epsilon)\right).$$

We now show that this analysis is indeed tight. First, let us define the following 2-smooth functions:

$$\phi_i(y) = y^2, \quad i = 1, \dots, n$$

and let us define $\mathbf{x}_1 = \mathbf{x}_2 = \dots = \mathbf{x}_n = \frac{1}{\sqrt{n}} \mathbb{1}$. This yields

$$D(\alpha) = \frac{1}{2} \alpha^\top \left(\frac{1}{2n} I + \frac{1}{\lambda n^2} \mathbb{1} \mathbb{1}^\top \right) \alpha. \quad (7)$$

⁵ For a detailed analysis of SDCA, please refer to Shalev-Shwartz and Zhang 2013.

Clearly, the unique minimizer of $D(\alpha)$ is $\alpha^* \triangleq 0$. Now, given $i \in [n]$ and $\alpha \in \mathbb{R}^n$, it is easy to verify that

$$\operatorname{argmin}_{\alpha' \in \mathbb{R}^n} D(\alpha_1, \dots, \alpha_{i-1}, \alpha', \alpha_{i+1}, \dots, \alpha_n) = \frac{-2}{2 + \lambda n} \sum_{j \neq i} \alpha_j. \quad (8)$$

Thus, the next test point α^+ , generated by taking a step along the i 'th coordinate, is a linear transformation of the previous point, i.e.,

$$\alpha^+ = (I - \mathbf{e}_i \mathbf{u}_i^\top) \alpha, \quad (9)$$

where

$$\mathbf{u}_i^\top \triangleq \left(\frac{2}{2 + \lambda n}, \dots, \frac{2}{2 + \lambda n}, \underbrace{\frac{1}{2 + \lambda n}}_{i's \text{ entry}}, \frac{2}{2 + \lambda n}, \dots, \frac{2}{2 + \lambda n} \right).$$

Let α^k , $k = 1, \dots, K$ denote the k 'th test point. The sequence of points $(\alpha^k)_{k=1}^K$ is randomly generated by minimizing $D(\alpha)$ over the z_k 'th coordinate at the k 'th iteration, where $z_1, z_2, \dots, z_K \sim \mathcal{U}([n])$ is a sequence of K uniform distributed i.i.d random variables. Applying (9) over and over again starting from some initialization point α^0 we obtain

$$\alpha^k = (I - \mathbf{e}_{z_K} \mathbf{u}_{z_K}^\top) (I - \mathbf{e}_{z_{K-1}} \mathbf{u}_{z_{K-1}}^\top) \dots (I - \mathbf{e}_{z_1} \mathbf{u}_{z_1}^\top) \alpha^0.$$

To compute $\mathbb{E}[\alpha^k]$ note that by the i.i.d hypothesis and by the linearity of the expectation operator,

$$\begin{aligned} \mathbb{E}[\alpha^k] &= \mathbb{E} \left[(I - \mathbf{e}_{z_K} \mathbf{u}_{z_K}^\top) (I - \mathbf{e}_{z_{K-1}} \mathbf{u}_{z_{K-1}}^\top) \dots (I - \mathbf{e}_{z_1} \mathbf{u}_{z_1}^\top) \alpha^0 \right] \\ &= \mathbb{E} \left[(I - \mathbf{e}_{z_K} \mathbf{u}_{z_K}^\top) \right] \mathbb{E} \left[(I - \mathbf{e}_{z_{K-1}} \mathbf{u}_{z_{K-1}}^\top) \right] \dots \mathbb{E} \left[(I - \mathbf{e}_{z_1} \mathbf{u}_{z_1}^\top) \right] \alpha^0 \\ &= \mathbb{E} \left[(I - \mathbf{e}_z \mathbf{u}_z^\top) \right]^K \alpha^0. \end{aligned} \quad (10)$$

The convergence rate of the latter is governed by the spectral radius of

$$E \triangleq \mathbb{E} \left[I - \mathbf{e}_z \mathbf{u}_z^\top \right].$$

A straightforward calculation shows that the eigenvalues of E , ordered by magnitude, are

$$\underbrace{1 - \frac{1}{2/\lambda + n}, \dots, 1 - \frac{1}{2/\lambda + n}}_{n-1 \text{ times}}, 1 - \frac{2 + \lambda}{2 + \lambda n}. \quad (11)$$

By choosing α^0 to be the following normalized eigenvector which corresponds to the largest eigenvalue

$$\alpha^0 = \left(\frac{1}{\sqrt{2}}, -\frac{1}{\sqrt{2}}, 0, \dots, 0 \right),$$

and plugging it into Equation (10), we can now bound from below the distance of $\mathbb{E}[\boldsymbol{\alpha}^k]$ to the optimal point $\boldsymbol{\alpha}^* = 0$,

$$\begin{aligned} \|\mathbb{E}[\boldsymbol{\alpha}^k] - \boldsymbol{\alpha}^*\| &= \left\| \mathbb{E} \left[\left(I - \mathbf{e}_z \mathbf{u}_z^\top \right)^K \boldsymbol{\alpha}^0 \right] \right\| \\ &= \left(1 - \frac{1}{2/\lambda + n} \right)^K \|\boldsymbol{\alpha}^0\| \\ &= \left(1 - \frac{2}{(4/\lambda + 2n - 1) + 1} \right)^K \\ &\geq \left(\exp \left(\frac{-1}{2/\lambda + n - 1} \right) \right)^K, \end{aligned} \quad (12)$$

where the last inequality is due to the following inequality,

$$1 - \frac{2}{x+1} \geq \exp \left(\frac{-2}{x-1} \right), \quad \forall x \geq 1.$$

We see that the minimal number of iterations required for obtaining a solution whose distance from the $\boldsymbol{\alpha}^*$ is less than $\epsilon > 0$ must be greater than

$$(2/\lambda + n - 1) \ln(1/\epsilon),$$

thus showing that, up to logarithmic factors, the analysis of the convergence rate of SDCA is tight.

2.2 Definitions

In the sequel we introduce the framework of p -SCLI optimization algorithms which generalizes the analysis shown in the preceding section.

We denote the set of $d \times d$ symmetric matrices whose spectrum lies in $\Sigma \subseteq \mathbb{R}^{++}$ by $\mathcal{S}^d(\Sigma)$ and denote the following set of quadratic functions

$$f_{A,\mathbf{b}}(\mathbf{x}) \triangleq \frac{1}{2} \mathbf{x}^\top A \mathbf{x} + \mathbf{b}^\top \mathbf{x}, \quad A \in \mathcal{S}^d(\Sigma),$$

by $\mathcal{Q}^d(\Sigma)$. Note that since twice continuous differentiable functions $f(\mathbf{x})$ are L -smooth and μ -strongly convex if and only if

$$\sigma(\nabla^2 f(\mathbf{x})) \subseteq [\mu, L] \subseteq \mathbb{R}^{++}, \quad \mathbf{x} \in \mathbb{R}^d,$$

we have that $\mathcal{Q}^d(\mu, L)$ comprises L -smooth μ -strongly convex quadratic functions. Thus, any optimization algorithm designed for minimizing smooth and strongly convex functions can be used to minimize functions in $\mathcal{Q}^d(\mu, L)$. The key observation here is that since the gradient of $f_{A,\mathbf{b}}(\mathbf{x})$ is linear in \mathbf{x} , when applied to quadratic functions, the update rules of many optimization algorithms also become linear in \mathbf{x} . This formalizes as follows.

Definition 1 (p -SCLI optimization algorithms) An optimization algorithm \mathcal{A} is called a p -stationary canonical linear iterative (abbr. p -SCLI) optimization algorithm over \mathbb{R}^d if there exist $p+1$ mappings $C_0(X), C_1(X), \dots, C_{p-1}(X), N(X)$ from $\mathbb{R}^{d \times d}$ to $\mathbb{R}^{d \times d}$ -valued random variables, such that for any $f_{A,\mathbf{b}}(\mathbf{x}) \in \mathcal{Q}^d(\Sigma)$ the corresponding initialization and update rules take the following form:

$$\mathbf{x}^0, \mathbf{x}^1, \dots, \mathbf{x}^{p-1} \in \mathbb{R}^d \quad (13)$$

$$\mathbf{x}^k = \sum_{j=0}^{p-1} C_j(A) \mathbf{x}^{k-p+j} + N(A) \mathbf{b}, \quad k = p, p+1, \dots \quad (14)$$

We further assume that in each iteration $C_j(A)$ and $N(A)$ are drawn independently of previous realizations⁶, and that $\mathbb{E}C_i(A)$ are finite and simultaneously triangularizable⁷.

Let us introduce a few more definitions and terminology which will be used throughout this paper. The number of previous points p by which new points are generated is called the lifting factor. The matrix-valued random variables $C_0(X), C_1(X), \dots, C_{p-1}(X)$ and $N(X)$ are called coefficient matrices and inversion matrix, respectively. The term inversion matrix refers to the mapping $N(X)$, as well as to a concrete evaluation of it. It will be clear from the context which interpretation is being used. The same holds for coefficient matrices.

As demonstrated by the following definition, coefficients matrices of p -SCLIs can be equivalently described in terms of polynomial matrices⁸. This correspondence will soon play a pivotal role in the analysis of p -SCLIs.

Definition 2 The characteristic polynomial of a given p -SCLI optimization algorithm \mathcal{A} is defined by

$$\mathcal{L}_{\mathcal{A}}(\lambda, X) \triangleq I_d \lambda^p - \sum_{j=0}^{p-1} \mathbb{E}C_j(X) \lambda^j, \quad (15)$$

where $C_j(X)$ denote the coefficient matrices. Moreover, given $X \in \mathbb{R}^{d \times d}$ we define the root radius of $\mathcal{L}_{\mathcal{A}}(\lambda, X)$ by

$$\rho_{\mathcal{A}}(\mathcal{L}_{\mathcal{A}}(\lambda, X)) = \rho(\det \mathcal{L}_{\mathcal{A}}(\lambda, X)) = \max \{ |\lambda| \mid \det \mathcal{L}_{\mathcal{A}}(\lambda, X) = 0 \}.$$

For the sake of brevity, we sometimes specify a given p -SCLI optimization algorithm \mathcal{A} using an ordered pair of a characteristic polynomial and an inversion matrix as follows

$$\mathcal{A} \triangleq (\mathcal{L}_{\mathcal{A}}(\lambda, X), N(X)).$$

Furthermore, we may omit the subscript \mathcal{A} , when it is clear from the context.

6. We shall refer to this assumption as *stationarity*.

7. Intuitively, having this technical requirement is somewhat similar to assuming that the coefficients matrices commute (see Draxin et al. 1951 for a precise statement), and as such does not seem to restrict the scope of this work. Indeed, it is common to have $\mathbb{E}C_i(A)$ as polynomials in A or as diagonal matrices, in which case the assumption holds true.

8. For a detailed cover of polynomial matrices see Golberg et al. (2009).

Lastly, note that nowhere in the definition of p -SCLIs did we assume that the optimization process converges to the minimizer of the function under consideration - an assumption which we refer to as *consistency*.

Definition 3 (Consistency of p -SCLI optimization algorithms) A p -SCLI optimization algorithm \mathcal{A} is said to be consistent with respect to a given $A \in \mathbf{S}^d(\Sigma)$ if for any $\mathbf{b} \in \mathbb{R}^d$, \mathcal{A} converges to the minimizer of $f_{A,\mathbf{b}}(\mathbf{x})$, regardless of the initialization point. That is, for $(\mathbf{x}^k)_{k=1}^\infty$ as defined in (13,14) we have that

$$\mathbf{x}^k \rightarrow -A^{-1}\mathbf{b},$$

for any $\mathbf{b} \in \mathbb{R}^d$. Furthermore, if \mathcal{A} is consistent with respect to all $A \in \mathbf{S}^d(\Sigma)$, then we say that \mathcal{A} is consistent with respect to $\mathcal{Q}^d(\Sigma)$.

2.3 Specifications for Some Popular Optimization Algorithms

Having defined the framework of p -SCLI optimization algorithms, a natural question now arises: how broad is the scope of this framework and what does characterize optimization algorithms which it applies to? Loosely speaking, any optimization algorithm whose update rules depend linearly on the first and the second order derivatives of the function under consideration is eligible for this framework. Instead of providing a precise characterization for such algorithms, we apply various popular optimization algorithms on a general quadratic function $f_{A,\mathbf{b}}(\mathbf{x}) \in \mathcal{Q}^d(\mu, L)$ and then express them as p -SCLI optimization algorithms.

Full Gradient Descent (FGD) is a 1-SCLI optimization algorithm with

$$\begin{aligned} \mathbf{x}^0 &\in \mathbb{R}^d, \\ \mathbf{x}^{k+1} &= \mathbf{x}^k - \beta \nabla f(\mathbf{x}^k) = \mathbf{x}^k - \beta(A\mathbf{x}^k + \mathbf{b}) = (I - \beta A)\mathbf{x}^k - \beta\mathbf{b}, \\ \beta &= \frac{2}{\mu + L}. \end{aligned}$$

See Nesterov (2004) for more details.

Newton method is a 0-SCLI optimization algorithm with

$$\begin{aligned} \mathbf{x}^0 &\in \mathbb{R}^d, \\ \mathbf{x}^{k+1} &= \mathbf{x}^k - (\nabla^2 f(\mathbf{x}^k))^{-1} \nabla f(\mathbf{x}^k) = \mathbf{x}^k - A^{-1}(A\mathbf{x}^k + \mathbf{b}) \\ &= (I - A^{-1}A)\mathbf{x}^k - A^{-1}\mathbf{b} = -A^{-1}\mathbf{b}. \end{aligned}$$

Note that Newton method can be also formulated as a degenerate p -SCLI for some $p \in \mathbb{N}$, whose coefficients matrices vanish. See Nesterov (2004) for more details.

The Heavy Ball Method is a 2-SCLI optimization algorithm with

$$\begin{aligned} \mathbf{x}^{k+1} &= \mathbf{x}^k - \alpha \nabla f(\mathbf{x}^k) + \beta(\mathbf{x}^k - \mathbf{x}^{k-1}) \\ &= \mathbf{x}^k - \alpha(A\mathbf{x}^k + \mathbf{b}) + \beta(\mathbf{x}^k - \mathbf{x}^{k-1}) \\ &= ((1 + \beta)I - \alpha A)\mathbf{x}^k - \beta I\mathbf{x}^{k-1} - \alpha\mathbf{b}, \\ \alpha &= \frac{4}{(\sqrt{L} + \sqrt{\mu})^2}, \quad \beta = \left(\frac{\sqrt{L} - \sqrt{\mu}}{\sqrt{L} + \sqrt{\mu}} \right)^2. \end{aligned}$$

See Polyak (1987) for more details.

Accelerated Gradient Descent (AGD) is a 2-SCLI optimization algorithm with

$$\begin{aligned} \mathbf{x}^0 &= \mathbf{y}^0 \in \mathbb{R}^d, \\ \mathbf{y}^{k+1} &= \mathbf{x}^k - \frac{1}{L} \nabla f(\mathbf{x}^k), \\ \mathbf{x}^{k+1} &= (1 + \alpha)\mathbf{y}^{k+1} - \alpha\mathbf{y}^k, \\ \alpha &= \frac{\sqrt{L} - \sqrt{\mu}}{\sqrt{L} + \sqrt{\mu}}, \end{aligned}$$

which can be rewritten as follows:

$$\begin{aligned} \mathbf{x}^0 &\in \mathbb{R}^d, \\ \mathbf{x}^{k+1} &= (1 + \alpha) \left(\mathbf{x}^k - \frac{1}{L} \nabla f(\mathbf{x}^k) \right) - \alpha \left(\mathbf{x}^{k-1} - \frac{1}{L} \nabla f(\mathbf{x}^{k-1}) \right) \\ &= (1 + \alpha) \left(\mathbf{x}^k - \frac{1}{L}(A\mathbf{x}^k + \mathbf{b}) \right) - \alpha \left(\mathbf{x}^{k-1} - \frac{1}{L}(A\mathbf{x}^{k-1} + \mathbf{b}) \right) \\ &= (1 + \alpha) \left(I - \frac{1}{L}A \right) \mathbf{x}^k - \alpha \left(I - \frac{1}{L}A \right) \mathbf{x}^{k-1} - \frac{1}{L}\mathbf{b}. \end{aligned}$$

Note that here we employ a stationary variant of AGD. See Nesterov (2004) for more details.

Stochastic Coordinate Descent (SCD) is a 1-SCLI optimization algorithm. This is a generalization of the example shown in Section 2.1. SCD acts by repeatedly minimizing a uniformly randomly drawn coordinate in each iteration. That is,

$$\begin{aligned} \mathbf{x}^0 &\in \mathbb{R}^d, \\ \text{Pick } i &\sim \mathcal{U}([d]) \text{ and set } \mathbf{x}^{k+1} = \left(I - \frac{1}{A_{i,i}} \mathbf{e}_i \mathbf{a}_{i,*}^\top \right) \mathbf{x}^k - \frac{b_i}{A_{i,i}} \mathbf{e}_i, \end{aligned}$$

where $\mathbf{a}_{i,*}^\top$ denotes the i 'th row of A and $\mathbf{b} \triangleq (b_1, b_2, \dots, b_d)$. Note that the expected update rule of this method is equivalent to the well-known Jacobi's iterative method.

We now describe some popular optimization algorithms which do not fit this framework, mainly because the stationarity requirement fails to hold. The extension of this framework to cyclic and piecewise stationary optimization algorithms is left to future work.

Conjugate Gradient Descent (CGD) can be expressed as a non-stationary iterative method

$$\mathbf{x}^{k+1} = ((1 + \beta_k)I - \alpha_k A) \mathbf{x}^k - \beta_k I \mathbf{x}^{k-1} - \alpha_k \mathbf{b},$$

where α_k and β_k are computed at each iteration based on $\mathbf{x}^k, \mathbf{x}^{k-1}, A$ and \mathbf{b} . Note the similarity of CGD and the heavy ball method. See Polyak (1987); Nemirovski (2005) for more details. In the context of this framework, CGD forms the ‘most non-stationary’ kind of method in that its coefficients α_k, β_k are highly dependent on time and the function at hand.

Stochastic Gradient Descent (SGD) A straightforward extension of the deterministic FGD. Specifically, let $(\Omega, \mathcal{F}, \mathcal{P})$ be a probability space and let $G(\mathbf{x}, \omega) : \mathbb{R}^d \times \Omega \rightarrow \mathbb{R}^d$ be an unbiased estimator of $\nabla f(\mathbf{x})$ for any \mathbf{x} . That is,

$$\mathbb{E}[G(\mathbf{x}, \omega)] = \nabla f(\mathbf{x}) = A\mathbf{x} + \mathbf{b}, \quad \mathbf{x} \in \mathbb{R}^d.$$

Equivalently, define $\mathbf{e}(\mathbf{x}, \omega) = G(\mathbf{x}, \omega) - (A\mathbf{x} + \mathbf{b})$ and assume $\mathbb{E}[\mathbf{e}(\mathbf{x}, \omega)] = 0, \mathbf{x} \in \mathbb{R}^d$. SGD may be defined using a suitable sequence of step sizes $(\gamma_i)_{i=1}^\infty$ as follows:

$$\begin{aligned} \text{Generate } \omega_k \text{ randomly and set } \mathbf{x}^{k+1} &= \mathbf{x}^k - \gamma_k G(\mathbf{x}^k, \omega_k) \\ &= (I - \gamma_k A) \mathbf{x}^k - \gamma_k \mathbf{b} - \gamma_k \mathbf{e}(\mathbf{x}, \omega). \end{aligned}$$

Clearly, some types of noise may not form a p -SCLI optimization algorithm. However, for some instances, e.g., quadratic learning problems, we have

$$\mathbf{e}(\mathbf{x}, \omega) = A_\omega \mathbf{x} + \mathbf{b}_\omega,$$

such that

$$\mathbb{E}[A_\omega] = 0, \quad \mathbb{E}[\mathbf{b}_\omega] = 0.$$

If, in addition, the step size is fixed then we get a 1-SCLI optimization algorithm. See Kushner and Yin (2003); Spall (2005); Nemirovski (2005) for more details.

2.4 Computational Complexity

The stationarity property of general p -SCLIs optimization algorithms implies that the computational cost of minimizing a given quadratic function $f_{A,\mathbf{b}}(\mathbf{x})$, assuming $\Theta(1)$ cost for all arithmetic operations, is

$$\# \text{ Iterations} \times \begin{cases} \text{Generating coefficient and inversion matrices randomly} \\ + \\ \text{Executing update rule (14) based on the previous } p \text{ points} \end{cases}$$

The computational cost of the execution of update rule (14) scales quadratically with d , the dimension of the problem, and linearly with p , the lifting factor. Thus, the running time of p -SCLIs is mainly affected by the iterations number and the computational cost of

randomly generating coefficient and inversion matrices each time. Notice that for deterministic p -SCLIs one can save running time by computing the coefficient and inversion matrices once, prior to the execution of the algorithm. Not surprisingly, but interesting nonetheless, there is a law of conservation which governs the total amount of computational cost invested in both factors: the more demanding is the task of randomly generating coefficient and inversion matrices, the less is the total number of iterations required for obtaining a given level of accuracy, and vice versa. Before we can make this statement more rigorous, we need to present a few more facts about p -SCLIs. For the time being, let us focus on the *iteration complexity*, i.e., the total number iterations, which forms our analogy for black box complexity.

The *iteration complexity* of a p -SCLI optimization algorithm \mathcal{A} with respect to an accuracy level ϵ , initialization points \mathcal{X}^0 and a quadratic function $f_{A,\mathbf{b}}(\mathbf{x})$, symbolized by

$$\mathcal{IC}_{\mathcal{A}}(\epsilon, f_{A,\mathbf{b}}(\mathbf{x}), \mathcal{X}^0),$$

is defined to be the minimal number of iterations K such that

$$\|\mathbb{E}[\mathbf{x}^k - \mathbf{x}^*]\| < \epsilon, \quad \forall k \geq K,$$

where $\mathbf{x}^* = -A^{-1}\mathbf{b}$ is the minimizer of $f_{A,\mathbf{b}}(\mathbf{x})$, assuming \mathcal{A} is initialized at \mathcal{X}^0 . We would like to point out that although iteration complexity is usually measured through

$$\mathbb{E}\|\mathbf{x}^k - \mathbf{x}^*\|,$$

here we employ a different definition. We will discuss this issue shortly.

In addition to showing that the iteration complexity of p -SCLI algorithms scales logarithmically with $1/\epsilon$, the following theorem provides a characterization for the iteration complexity in terms of the root radius of the characteristic polynomial.

Theorem 4 *Let \mathcal{A} be a p -SCLI optimization algorithm over \mathbb{R}^d and let $f_{A,\mathbf{b}}(\mathbf{x}) \in \mathcal{Q}^d(\Sigma)$, $(\Sigma \subseteq \mathbb{R}^{++})$ be a quadratic function. Then, there exists $\mathcal{X}^0 \in (\mathbb{R}^d)^p$ such that*

$$\mathcal{IC}_{\mathcal{A}}(\epsilon, f_{A,\mathbf{b}}(\mathbf{x}), \mathcal{X}^0) = \tilde{\Omega}\left(\frac{\rho}{1-\rho} \ln(1/\epsilon)\right),$$

and for all $\mathcal{X}^0 \in (\mathbb{R}^d)^p$, it holds that

$$\mathcal{IC}_{\mathcal{A}}(\epsilon, f_{A,\mathbf{b}}(\mathbf{x}), \mathcal{X}^0) = \tilde{\mathcal{O}}\left(\frac{1}{1-\rho} \ln(1/\epsilon)\right),$$

where ρ denotes the root radius of the characteristic polynomial evaluated at $X = A$.

The full proof for this theorem is somewhat long and thus provided in Section C.1. Nevertheless, the intuition behind it is very simple and may be sketched as follows:

- First, we express update rule (14) as a single step rule by introducing new variables in some possibly higher-dimensional Euclidean space $(\mathbb{R}^d)^p$,

$$\mathbf{z}^0 = (\mathbf{x}^0, \mathbf{x}^1, \dots, \mathbf{x}^{p-1})^\top \in \mathbb{R}^{pd}, \quad \mathbf{z}^k = M(X)\mathbf{z}^{k-1} + UN(X)\mathbf{b}, \quad k = 1, 2, \dots$$

Recursively applying this rule and taking expectation w.r.t. the coefficient matrices and the inversion matrix yields

$$\mathbb{E}[\mathbf{z}^k - \mathbf{z}^*] = \mathbb{E}[M]^k (\mathbf{z}^0 - \mathbf{z}^*).$$

- Then, to derive the lower bound, we use the Jordan form of $\mathbb{E}[M]$ to show that there exists some non-zero vector $\mathbf{r} \in (\mathbb{R}^d)^p$ such that if $\langle \mathbf{z}^0 - \mathbf{z}^*, \mathbf{r} \rangle \neq 0$, then $\|\mathbb{E}[M]^k (\mathbf{z}^0 - \mathbf{z}^*)\|$ is asymptotically bounded from below by some geometric sequence. The upper bound follows similarly.
- Finally, we express the bound on the convergence rate of $\langle \mathbf{z}^k \rangle$ in terms of the original space.

Carefully inspecting the proof idea shown above reveals that the lower bound remains valid even in cases where the initialization points are drawn randomly. The only condition for this to hold is that the underlying distribution is reasonable, in the sense that it is absolutely continuous w.r.t. the Lebesgue measure, which implies that $\Pr[\langle \mathbf{z}^0 - \mathbf{z}^*, \mathbf{r} \rangle \neq 0] = 1$.

We remark that the constants in the asymptotic behavior above may depend on the quadratic function under consideration, and that the logarithmic terms depend on the distance of the initialization points from the minimizer, as well as the lifting factor and the spectrum of the Hessian. For the sake of clarity, we omit the dependency on these quantities.

There are two, rather subtle, issues regarding the definition of iteration complexity which we would like to address. First, observe that in many cases a given point $\bar{\mathbf{x}} \in \mathbb{R}^d$ is said to be ϵ -optimal w.r.t. some real function $f: \mathbb{R}^d \rightarrow \mathbb{R}$ if

$$f(\bar{\mathbf{x}}) < \min_{\mathbf{x} \in \mathbb{R}^d} f(\mathbf{x}) + \epsilon.$$

However, here we employ a different measure for optimality. Fortunately, in our case either can be used without essentially affecting the iteration complexity. That is, although in general the gap between these two definitions can be made arbitrarily large, for L -smooth μ -strongly convex functions we have

$$\frac{\mu}{2} \|\mathbf{x} - \mathbf{x}^*\|^2 \leq f(\mathbf{x}) - f(\mathbf{x}^*) \leq \frac{L}{2} \|\mathbf{x} - \mathbf{x}^*\|^2.$$

Combining these two inequalities with the fact that the iteration complexity of p -SCLIs depends logarithmically on $1/\epsilon$ implies that in this very setting these two distances are interchangeable, up to logarithmic factors.

Secondly, here we measure the sub-optimality of the k 'th iteration by $\|\mathbb{E}[\mathbf{x}^k - \mathbf{x}^*]\|$, whereas in many other stochastic settings it is common to derive upper and lower bounds on $\mathbb{E}[\|\mathbf{x}^k - \mathbf{x}^*\|]$. That being the case, by

$$\mathbb{E}[\|\mathbf{x}^k - \mathbf{x}^*\|^2] = \mathbb{E}[\|\mathbf{x}^k - \mathbb{E}\mathbf{x}^k\|^2] + \|\mathbb{E}[\mathbf{x}^k - \mathbf{x}^*]\|^2,$$

we see that if the variance of the k 'th point is of the same order of magnitude as the norm of the expected distance from the optimal point, then both measures are equivalent. Consequently, our upper bounds imply upper bounds on $\mathbb{E}[\|\mathbf{x}^k - \mathbf{x}^*\|^2]$ for deterministic algorithms (where the variance term is zero), and our lower bounds imply lower bounds on $\mathbb{E}[\|\mathbf{x}^k - \mathbf{x}^*\|^2]$, for both deterministic and stochastic algorithms (since the variance is non-negative). We defer a more adequate treatment for this matter to future work.

3. Deriving Bounds for p -SCLI Algorithms

The goal of the following section is to show how the framework of p -SCLI optimization algorithms can be used to derive lower and upper bounds. Our presentation follows from the simplest setting to the most general one. First, we present a useful characterization of consistency (see Definition 3) of p -SCLIs using the characteristic polynomial. Next, we demonstrate the importance of consistency through a simplified one dimensional case. This line of argument is then generalized to any finite dimensional space and is used to explain the role of the inversion matrix. Finally, we conclude this section by providing a schematic description of this technique for the most general case which is used both in Section (4) to establish lower bounds on the convergence rate of p -SCLIs with diagonal inversion matrices, and in Section (5) to derive efficient p -SCLIs.

3.1 Consistency

Closely inspecting various specifications for p -SCLI optimization algorithms (see Section (2.3)) reveals that the coefficient matrices always sum up to $I + \mathbb{E}N(X)X$, where $N(X)$ denotes the inversion matrix. It turns out that this is not a mere coincidence, but an extremely useful characterization for consistency of p -SCLIs. To see why this condition must hold, suppose \mathcal{A} is a deterministic p -SCLI algorithm over \mathbb{R}^d whose coefficient matrices and inversion matrix are $C_0(X), \dots, C_{p-1}(X)$ and $N(X)$, respectively, and suppose that \mathcal{A} is consistent w.r.t. some $A \in S^d(\Sigma)$. Recall that every $p + 1$ consecutive points generated by \mathcal{A} are related by (14) as follows

$$\mathbf{x}^k = \sum_{j=0}^{p-1} C_j(A)\mathbf{x}^{k-p+j} + N(A)\mathbf{b}, \quad k = p, p+1, \dots$$

Taking limit of both sides of the equation above and noting that by consistency

$$\mathbf{x}^k \rightarrow -A^{-1}\mathbf{b}$$

for any $\mathbf{b} \in \mathbb{R}^d$, yields

$$-A^{-1}\mathbf{b} = -\sum_{j=0}^{p-1} C_j(A)A^{-1}\mathbf{b} + N(A)\mathbf{b}.$$

Thus,

$$-A^{-1} = -\sum_{j=0}^{p-1} C_j(A)A^{-1} + N(A).$$

Multiplying by A and rearranging, we obtain

$$\sum_{j=0}^{p-1} C_j(A) = I_d + N(A)A. \quad (16)$$

On the other hand, if instead of assuming consistency we assume that \mathcal{A} generates a convergent sequence of points and that Equation (16) holds, then the arguments used above show that the limit point must be $-A^{-1}\mathbf{b}$. In terms of the characteristic polynomial of p -SCLIs, this is formalized as follows.

Theorem 5 (Consistency via Characteristic Polynomials) *Suppose $\mathcal{A} \triangleq (\mathcal{L}(\lambda, X), N(X))$ is a p -SCLI optimization algorithm. Then, \mathcal{A} is consistent with respect to $A \in \mathcal{S}^d(\Sigma)$ if and only if the following two conditions hold:*

1. $\mathcal{L}(1, A) = -\mathbb{E}N(A)A$ (17)
2. $\rho_\lambda(\mathcal{L}(\lambda, A)) < 1$ (18)

The proof for the preceding theorem is provided in Section C.2. This result will be used extensively throughout the remainder of this work.

3.2 Simplified One-Dimensional Case

To illustrate the significance of consistency in the framework of p -SCLIs, consider the following simplified case. Suppose \mathcal{A} is a deterministic 2-SCLI optimization algorithm over $\mathcal{Q}^1(\mu, L)$, such that its inversion matrix $N(x)$ is some constant scalar $\nu \in \mathbb{R}$ and its coefficient matrices $c_0(x), c_1(x)$ are free to take any form. The corresponding characteristic polynomial is

$$\mathcal{L}(\lambda, x) = \lambda^2 - c_1(x)\lambda - c_0(x).$$

Now, let $f_{a,b}(x) \in \mathcal{Q}^1(\mu, L)$ be a quadratic function. By Theorem 4, we know that \mathcal{A} converges to the minimizer of $f_{a,b}(x)$ with an asymptotic geometric rate of $\rho_\lambda(\mathcal{L}(\lambda, a))$, the maximal modulus root. Thus, ideally we would like to set $c_j(x) = 0$, $j = 0, 1$. However, this might violate the consistency condition (17), according to which, one must maintain

$$\mathcal{L}(1, a) = -\nu a.$$

That being the case, how little can $\rho_\lambda(\mathcal{L}(\lambda, a))$ be over all possible choices for $c_j(a)$ which satisfy $\mathcal{L}(1, a) = -\nu a$? Formally, we seek to solve the following minimization problem

$$\rho_* = \min \{ \rho_\lambda(\mathcal{L}(\lambda, a)) \mid \mathcal{L}(\lambda, a) \text{ is a real monic quadratic polynomial in } \lambda \text{ and } \mathcal{L}(1) = -\nu a \}.$$

By consistency we also have that ρ_* must be strictly less than one. This readily implies that $-\nu a > 0$. In which case, Lemma 6 below gives

$$\rho_* \geq \rho \left((\lambda - 1 - \sqrt{-\nu a})^2 \right) = \left| \sqrt{-\nu a} - 1 \right|. \quad (19)$$

The key observation here is that ν cannot be chosen so as to be optimal for all $\mathcal{Q}^1(\mu, L)$ simultaneously. Indeed, the preceding inequality holds in particular for $a = \mu$ and $a = L$, by which we conclude that

$$\rho_* \geq \max \left\{ \left| \sqrt{-\nu\mu} - 1 \right|, \left| \sqrt{-\nu L} - 1 \right| \right\} \geq \frac{\sqrt{\kappa} - 1}{\sqrt{\kappa} + 1}, \quad (20)$$

where $\kappa \triangleq L/\mu$. Plugging in Inequality (20) into Theorem 4 implies that there exists $f_{a,b}(x) \in \mathcal{Q}^1(\mu, L)$ such that the iteration complexity of \mathcal{A} for minimizing it is

$$\tilde{\Omega} \left(\frac{\sqrt{\kappa} - 1}{2} \ln(1/\epsilon) \right).$$

To conclude, by applying this rather natural line of argument we have established a lower bound on the convergence rate of any 2-SCLI optimization algorithms for smooth and strongly convex function over \mathbb{R} , e.g., AGD and HB.

3.3 The General Case and the Role of the Inversion Matrix

We now generalize the analysis shown in the previous simplified case to any deterministic p -SCLI optimization algorithm over any finite dimensional space. This generalization relies on a useful decomposability property of the characteristic polynomial, according to which deriving a lower bound on the convergence rate of p -SCLIs over \mathbb{R}^d is essentially equivalent for deriving d lower bounds on the maximal modulus of the roots of d polynomials over \mathbb{R} .

Let $\mathcal{A} \triangleq (\mathcal{L}(\lambda, X), N(X))$ be a consistent deterministic p -SCLI optimization algorithm and let $f_{A,\mathbf{b}}(\mathbf{x}) \in \mathcal{Q}^d(\Sigma)$ be a quadratic function. By consistency (see Theorem 5) we have

$$\mathcal{L}(1, A) = -NA$$

(for brevity we omit the functional dependency on X). Since coefficient matrices are assumed to be simultaneously triangularizable, there exists an invertible matrix $Q \in \mathbb{R}^{d \times d}$ such that

$$T_j \triangleq Q^{-1}C_jQ, \quad j = 0, 1, \dots, p-1$$

are upper triangular matrices. Thus, by the definition of the characteristic polynomial (Definition 2) we have

$$\det \mathcal{L}(\lambda, X) = \det (Q^{-1}\mathcal{L}(\lambda, X)Q) = \det \left(I_d \lambda^p - \sum_{j=0}^{p-1} T_j \lambda^j \right) = \prod_{j=1}^d \ell_j(\lambda), \quad (21)$$

where

$$\ell_j(\lambda) = \lambda^p - \sum_{k=0}^{p-1} \sigma_k^j \lambda^k, \quad (22)$$

and where $\sigma_0^j, \dots, \sigma_{d-1}^j$, $j = 0, \dots, p-1$ denote the elements on the diagonal of \mathcal{T}_j , or equivalently the eigenvalues of G_j ordered according to Q_j . Hence, the root radius of the characteristic polynomial of \mathcal{A} is

$$\rho_\lambda(\mathcal{L}(\lambda, X)) = \max\{|\lambda| \mid \ell_i(\lambda) = 0 \text{ for some } i \in [d]\}. \quad (23)$$

On the other hand, by consistency condition (17) we get that for all $i \in [d]$,

$$\ell_i(1) = \sigma_i(\mathcal{L}(1)) = \sigma_i(-NA). \quad (24)$$

It remains to derive a lower bound on the maximum modulus of the roots of $\ell_i(\lambda)$, subject to constraint (24). To this end, we employ the following lemma whose proof can be found in Section C.3.

Lemma 6 *Suppose $q(z)$ is a real monic polynomial of degree p . If $q(1) < 0$, then*

$$\rho(q(z)) > 1.$$

Otherwise, if $q(1) \geq 0$, then

$$\rho(q(z)) \geq \left| \sqrt[p]{q(1)} - 1 \right|.$$

In which case, equality holds if and only if

$$q(z) = \left(z - (1 - \sqrt[p]{q(1)}) \right)^p.$$

We remark that the second part of Lemma 6 implies that subject to constraint (24), the lower bound stated above is unimprovable. This property is used in Section 5 where we aim to obtain optimal p -SCLIs by designing $\ell_j(\lambda)$ accordingly. Clearly, in the presence of additional constraints, one might be able to improve on this lower bound (see Section 4.2).

Since \mathcal{A} is assumed to be consistent, Lemma 6 implies that $\sigma(-N(A)A) \subseteq \mathbb{R}^{++}$, as well as the following lower bound on the root radius of the characteristic polynomial,

$$\rho_\lambda(\mathcal{L}(\lambda, X)) \geq \max_{i \in [d]} \left| \sqrt[p]{\sigma_i(-N(A)A)} - 1 \right|. \quad (25)$$

Noticing that the reasoning above can be readily applied to stochastic p -SCLI optimization algorithms, we arrive at the following corollary which combines Theorem 4 and Inequality (25).

Corollary 7 *Let \mathcal{A} be a consistent p -SCLI optimization algorithm with respect to some $A \in \mathcal{S}^d(\Sigma)$, let $N(X)$ denote the corresponding inversion matrix and let*

$$\rho^* = \max_{i \in [d]} \left| \sqrt[p]{\sigma_i(-\mathbb{E}N(A)A)} - 1 \right|,$$

then the iteration complexity of \mathcal{A} for any $f_{A,b}(\mathbf{x}) \in \mathcal{Q}^d(\Sigma)$ is lower bounded by

$$\tilde{\Omega} \left(\frac{\rho^*}{1 - \rho^*} \ln(1/\epsilon) \right). \quad (26)$$

Using Corollary 7, we are now able to provide a concise ‘plug-and-play’ scheme for deriving lower bounds on the iteration complexity of p -SCLI optimization algorithms. To motivate this scheme, note that the effectiveness of the lower bound stated in Corollary 7 is directly related to the magnitude of the eigenvalues of $-N(X)X$. To exemplify this, consider the inversion matrix of Newton method (see Section 2.3)

$$N(X) = -X^{-1}.$$

Since

$$\sigma(-N(X)X) = \{1\},$$

the lower bound stated above is meaningless for this case. Nevertheless, the best computational cost for computing the inverse of $d \times d$ regular matrices known today is super-quadratic in d . As a result, this method might become impractical in large scale scenarios where the dimension of the problem space is large enough. A possible solution is to employ inversion matrices whose dependence on X is simpler. On the other hand, if $N(X)$ approximates $-X^{-1}$ very badly, then the root radius of the characteristic polynomial might get too large. For instance, if $N(X) = 0$ then

$$\sigma(-N(X)X) = \{0\},$$

contradicting the consistency assumption, regardless of the choice of the coefficient matrices.

In light of the above, many optimization algorithms can be seen as strategies for balancing the computational cost of obtaining a good approximation for the inverse of X and executing large number of iterations. Put differently, various structural restrictions on the inversion matrix yield different $\sigma(-N(X)X)$, which in turn lead to a lower bound on the root radius of the corresponding characteristic polynomial. This gives rise to the following scheme:

Scheme 1	Lower bounds
Parameters:	<ul style="list-style-type: none"> • A family of quadratic functions $\mathcal{Q}^d(\Sigma)$ • An inversion matrix $N(X)$
Choose	• A lifting factor $p \in \mathbb{N}$,
Verify	$S' \subseteq \mathcal{S}^d(\Sigma)$
Bound	$\forall A \in S', \sigma(-\mathbb{E}N(A)A) \subseteq (0, 2^p)$ to ensure consistency (Theorem 5)
Lower bound:	$\max_{A \in S', i \in [d]} \left \sqrt[p]{\sigma_i(-\mathbb{E}N(A)A)} - 1 \right $ from below by some $\rho^* \in [0, 1)$
Lower bound:	$\tilde{\Omega} \left(\frac{\rho^*}{1 - \rho^*} \ln(1/\epsilon) \right)$

This scheme is implicitly used in the previous Section (3.2), where we established a lower bound on the convergence rate of 2-SCLI optimization algorithms over \mathbb{R} with constant inversion matrix and the following parameters

$$\Sigma = [\mu, L], \quad S' = \{\mu, L\}.$$

In Section 4 we will make this scheme concrete for scalar and diagonal inversion matrices.

3.4 Bounds Schemes

In spite of the fact that Scheme 1 is expressive enough for producing meaningful lower bounds under various structures of the inversion matrix, it does not allow one to incorporate other lower bounds on the root radius of characteristic polynomials whose coefficient matrices admit certain forms, e.g., linear coefficient matrices (see 35 below). Abstracting away from Scheme 1, we now formalize one of the main pillars of this work, i.e., the relation between the amount of computational cost one is willing to invest in executing each iteration and the total number of iterations needed for obtaining a given level of accuracy. We use this relation to form two schemes for establishing lower and upper bounds for p -SCLIs.

Given a compatible set of parameters: a lifting factor p , an inversion matrix $N(X)$, set of quadratic functions $\mathcal{Q}^d(\Sigma)$ and a set of coefficient matrices \mathcal{C} , we denote by $\mathfrak{A}(p, N(X), \mathcal{Q}^d(\Sigma), \mathcal{C})$ the set of consistent p -SCLI optimization algorithms for $\mathcal{Q}^d(\Sigma)$ whose inversion matrix are $N(X)$ and whose coefficient matrices are taken from \mathcal{C} . Furthermore, we denote by $\mathfrak{L}(p, N(X), \mathcal{Q}^d(\Sigma), \mathcal{C})$ the following set of polynomial matrices

$$\left\{ \mathcal{L}(\lambda, X) \triangleq I_d \lambda^p - \sum_{j=0}^{p-1} \mathbb{E} C_j(X) \lambda^j \mid C_j(X) \in \mathcal{C}, \mathcal{L}(1, A) = -N(A)A, \forall A \in \mathcal{S}^d(\Sigma) \right\}.$$

Since both sets are determined by the same set of parameters, the specifications of which will be occasionally omitted for brevity. The natural one-to-one correspondence between these two sets, as manifested by Theorem 4 and Corollary 5, yields

$$\boxed{\min_{A \in \mathfrak{A}} \max_{f, \lambda, b(x) \in \mathcal{Q}^d(\Sigma)} \rho_\lambda(\mathcal{L}_A(\lambda, A)) = \min_{\mathcal{L}(\lambda, X) \in \mathfrak{L}} \max_{A \in \mathcal{S}^d(\Sigma)} \rho_\lambda(\mathcal{L}(\lambda, A))} \quad (27)$$

The importance of Equation (27) stems from its ability to incorporate any bound on the maximal modulus root of polynomial matrices into a general scheme for bounding the iteration complexity of p -SCLIs. This is summarized by the following scheme.

Scheme 2	Lower bounds
Given	a set of p -SCLI optimization algorithms $\mathfrak{A}(p, N(X), \mathcal{Q}^d(\Sigma), \mathcal{C})$
Find	$\rho_* \in [0, 1)$ such that
	$\min_{\mathcal{L}(\lambda, X) \in \mathfrak{L}} \max_{A \in \mathcal{S}^d(\Sigma)} \rho_\lambda(\mathcal{L}(\lambda, A)) \geq \rho_*$
Lower bound:	$\tilde{\Omega} \left(\frac{\rho_*}{1-\rho_*} \ln(1/\epsilon) \right)$

Thus, Scheme 1 is in effect an instantiation of the scheme shown above using Lemma 6. This correspondence of p -SCLI optimization algorithms and polynomial matrices can be also used contrarily to derive efficient algorithm optimization. Indeed, in Section 2.3 we show how FGD, HB and AGD can be formed as optimal instantiations of the following dual scheme.

Scheme 3	Optimal p -SCLI Optimization Algorithms
Given	a set of polynomial matrices $\mathfrak{L}(p, N(X), \mathcal{Q}^d(\Sigma), \mathcal{C})$
Compute	$\rho^* = \min_{\mathcal{L}(\lambda, X) \in \mathfrak{L}} \max_{A \in \mathcal{S}^d(\Sigma)} \rho_\lambda(\mathcal{L}(\lambda, A))$ and denote its minimizer by $\mathcal{L}^*(\lambda, A)$
Upper bound:	The corresponding p -SCLI algorithm for $\mathcal{L}^*(\lambda, A)$
Convergence rate:	$\mathcal{O} \left(\frac{1}{1-\rho^*} \ln(1/\epsilon) \right)$

4. Lower Bounds

In the sequel we derive lower bounds on the convergence rate of p -SCLI optimization algorithms whose inversion matrices are scalar or diagonal, and discuss the assumptions under which these lower bounds meet matching upper bounds. It is likely that this approach can be also effectively applied for block-diagonal inversion, as well as for a much wider set of inversion matrices whose entries depend on a relatively small set of entries of the matrix to be inverted.

4.1 Scalar and Diagonal Inversion Matrices

We derive a lower bound on the convergence rate of p -SCLI optimization algorithms for L -smooth μ -strongly convex functions over \mathbb{R}^d with a scalar inversion matrix $N(X)$ by employing Scheme 1 (see Section 3.3). Note that since the one-dimensional case was already proven in Section 3.2, we may assume that $d \geq 2$.

First, we need to pick a ‘hard’ matrix in $\mathcal{S}^d([\mu, L])$. It turns out that any positive-definite matrix $A \in \mathcal{S}^d([\mu, L])$ for which

$$\{\mu, L\} \subseteq \sigma(A), \quad (28)$$

will meet this criterion. For the sake of concreteness, let us define

$$A \triangleq \text{Diag}(L, \underbrace{\mu, \dots, \mu}_{d-1 \text{ times}}).$$

In which case,

$$-\nu\{\mu, L\} = \sigma(-\mathbb{E}N(A)A),$$

where $\nu I = \mathbb{E}[N(A)]$. Thus, to maintain consistency, it must hold that⁹

$$\nu \in \left(\frac{-2\rho}{L}, 0 \right). \quad (29)$$

9. On a side note, this reasoning also implies that if the spectrum of a given matrix A contains both positive and negative eigenvalues then $A^{-1}b$ cannot be computed using p -SCLIs with scalar inversion matrices.

Next, to bound from below

$$\rho_* \triangleq \max_{\kappa \in [\underline{\mu}]} \left| \frac{\sqrt{\sigma_i}(\sqrt{-\nu}A) - 1}{\sqrt{\sigma_i}} \right| = \max \left\{ \sqrt{\kappa^{-\nu}\mu} - 1, \left| \sqrt{\kappa^{-\nu}L} - 1 \right| \right\},$$

we split the feasible range of ν (29) into three different sub-ranges as follows:

$\sqrt{\kappa^{-\nu}\mu} - 1 < 0$	Case 1 Range: $[-1/L, 0)$ Minimizer: $\nu^* = -1/L$ Lower bounds: $1 - \sqrt{\frac{\mu}{L}}$	$\sqrt{\kappa^{-\nu}\mu} - 1 \geq 0$	N/A
$\sqrt{\kappa^{-\nu}L} - 1 \leq 0$	Case 2 Range: $(-1/\mu, -1/L)$ Minimizer: $-\left(\frac{\sqrt{\kappa^{-\nu}L} + \sqrt{\mu}}{2}\right)^p$ Lower bound: $\frac{\sqrt{\kappa^{-\nu}L/\mu} - 1}{\sqrt{\kappa^{-\nu}L/\mu} + 1}$	Case 3 (requires: $p \geq \log_2 \kappa$) Range: $(-2^p/L, -1/\mu]$ Minimizer: $-1/\mu$ Lower Bound: $\sqrt{\frac{\mu}{L}} - 1$	
$\sqrt{\kappa^{-\nu}L} - 1 > 0$			

Table 1: Lower bound for ρ_* by subranges of ν

Therefore,

$$\rho_* \geq \min \left\{ 1 - \sqrt{\frac{\mu}{L}}, \frac{\sqrt{\kappa^{-\nu}L/\mu} - 1}{\sqrt{\kappa^{-\nu}L/\mu} + 1}, \sqrt{\frac{L}{\mu}} - 1, \sqrt{\frac{\kappa}{\mu}} - 1 \right\} = \frac{\sqrt{\kappa} - 1}{\sqrt{\kappa} + 1}, \quad (30)$$

where $\kappa \triangleq L/\mu$, upper bounds the condition number of functions in $\mathcal{Q}^d(\mu, L)$. Thus, by Scheme 1, we get the following lower bound on the worse-case iteration complexity,

$$\tilde{\Omega} \left(\frac{\sqrt{\kappa} - 1}{2} \ln(1/\epsilon) \right). \quad (31)$$

As for the diagonal case, it turns out that for any quadratic $f_{A,b}(\mathbf{x}) \in \mathcal{Q}^d(\mu, L)$ which has

$$\begin{pmatrix} \frac{L+\mu}{2} & \frac{L-\mu}{2} \\ \frac{L-\mu}{2} & \frac{L+\mu}{2} \end{pmatrix} \quad (32)$$

as a principal sub-matrix of A , the best p -SCLI optimization algorithm with a diagonal inversion matrix does not improve on the optimal asymptotic convergence rate achieved by scalar inversion matrices (see Section C.4). Overall, we obtain the following theorem.

Theorem 8 *Let A be a consistent p -SCLI optimization algorithm for L -smooth μ -strongly convex functions over \mathbb{R}^d . If the inversion matrix of A is diagonal, then there exists a quadratic function $f_{A,b}(\mathbf{x}) \in \mathcal{Q}^d(\mu, L)$ such that*

$$\mathcal{IC}_A(\epsilon, f_{A,b}(\mathbf{x})) = \tilde{\Omega} \left(\frac{\sqrt{\kappa} - 1}{2} \ln(1/\epsilon) \right), \quad (33)$$

where $\kappa = L/\mu$.

4.2 Is This Lower Bound Tight?

A natural question now arises: is the lower bound stated in Theorem 8 tight? In short, it turns out that for $p = 1$ and $p = 2$ the answer is positive. For $p > 2$, the answer heavily depends on whether a suitable spectral decomposition is within reach. Obviously, computing the spectral decomposition for a given positive definite matrix A is at least as hard as finding the minimizer of a quadratic function whose Hessian is A . To avoid this, we will later restrict our attention to linear coefficient matrices which allow efficient implementation.

A matching upper bound for $p = 1$ In this case the lower bound stated in Theorem 8 is simply attained by FGD (see Section 2.3).

A matching upper bound for $p = 2$ In this case there are two 2-SCLI optimization algorithms which attain this bound, namely, Accelerated Gradient Descent and The Heavy Ball method (see Section 2.3), whose inversion matrices are scalar and correspond to Case 1 and Case 2 in Table 1, i.e.,

$$N_{\text{HB}} = - \left(\frac{2}{\sqrt{L} + \sqrt{\mu}} \right)^2 I_d, \quad N_{\text{AGD}} = \frac{-1}{L} I_d.$$

Although HB obtains the best possible convergence rate in the class of 2-SCLIs with diagonal inversion matrices, it has a major disadvantage. When applied to general smooth and strongly-convex functions, one cannot guarantee global convergence. That is, in order to converge to the corresponding minimizer, HB must be initialized close enough to the minimizer (see Section 3.2.1 in Polyak 1987). Indeed, if the initialization point is too far from the minimizer then HB may diverge as shown in Section 4.5 in Lessard et al. (2014). In contrast to this, AGD attains a global linear convergence with a slightly worse factor. Put differently, the fact HB is highly adapted to quadratic functions prevents it from converging globally to the minimizers of general smooth and strongly convex functions.

A matching upper bound for $p > 2$ In Subsection A we show that when no restriction on the coefficient matrices is imposed, the lower bound shown in Theorem 8 is tight, i.e., for any $p \in \mathbb{N}$ there exists a matching p -SCLI optimization algorithm with scalar inversion matrix whose iteration complexity is

$$\tilde{\mathcal{O}} \left(\frac{\sqrt{\kappa} - 1}{2} \ln(1/\epsilon) \right). \quad (34)$$

In light of the existing lower bound which scales according to $\sqrt{\kappa}$, this result may seem surprising at first. However, there is a major flaw in implementing these seemingly ideal p -SCLIs. In order to compute the corresponding coefficients matrices one has to obtain a very good approximation for the spectral decomposition of the positive definite matrix which defines the optimization problem. Clearly, this approach is rarely practical. To remedy this situation we focus on linear coefficient matrices which admit a relatively low computational cost per iteration. That is, we assume that there exist real scalars $\alpha_1, \dots, \alpha_{p-1}$ and $\beta_1, \dots, \beta_{p-1}$ such that

$$C_j(X) = \alpha_j X + \beta_j I_d, \quad j = 0, 1, \dots, p-1, \quad (35)$$

We believe that for these type of coefficient matrices the lower bound derived in Theorem 8 is not tight. Precisely, we conjecture that for any $0 < \mu < L$ and for any consistent p -SCLI optimization algorithm \mathcal{A} with diagonal inversion matrix and linear coefficients matrices, there exists $f_{A,B}(\mathbf{x}) \in \mathcal{Q}^d([\mu, L])$ such that

$$\rho_\lambda(\mathcal{L}_A(\lambda, X)) \geq \frac{\sqrt{\kappa} - 1}{\sqrt{\kappa} + 1},$$

where $\kappa \triangleq L/\mu$. Proving this may allow to derive tight lower bounds for many optimization algorithm in the field of machine learning. Using Scheme 2, which allows to incorporate various lower bounds on the root radius of polynomials, one is able to equivalently express this conjecture as follows: suppose $q(z)$ is a p -degree monic real polynomial such that $q(1) = 0$. Then, for any polynomial $r(z)$ of degree $p-1$ and for any $0 < \mu < L$, there exists $\eta \in [\mu, L]$ such that

$$\rho(q(z) - \eta r(z)) \geq \frac{\sqrt{L/\mu} - 1}{\sqrt{L/\mu} + 1}.$$

That being so, can we do better if we allow families of quadratic functions $\mathcal{Q}^d(\Sigma)$ where Σ are not necessarily continuous intervals? It turns out that the answer is positive. Indeed, in Section B we present a 3-SCLI optimization algorithm with linear coefficient matrices which, by being intimately adjusted to quadratic functions whose Hessian admits large enough spectral gap, beats the lower bound of Nemirovsky and Yudin (3). This apparently contradicting result is also discussed in Section B, where we show that lower bound (3) is established by employing quadratic functions whose Hessian admits spectrum which densely populates $[\mu, L]$.

5. Upper Bounds

Up to this point we have projected various optimization algorithms on the framework of p -SCLI optimization algorithms, thereby converting questions on convergence properties into questions on moduli of roots of polynomials. In what follows, we shall head in the opposite direction. That is, first we define a polynomial (see Definition (2)) which meets a prescribed set of constraints, and then we form the corresponding p -SCLI optimization algorithm. As stressed in Section 4.2, we will focus exclusively on linear coefficient matrices which admit low per-iteration computational cost and allow a straightforward extension to general smooth and strongly convex functions. Surprisingly enough, this allows a systematic recovering of FGD, HB, AGD, as well as establishing new optimization algorithms which allow better utilization of second-order information. This line of inquiry is particularly important due to the obscure nature of AGD, and further emphasizes its algebraic characteristic. We defer stochastic coefficient matrices, as in SDCA, (Section 2.1) to future work.

This section is organized as follows. First we apply Scheme 3 to derive general p -SCLIs with linear coefficients matrices. Next, we recover AGD and HB as optimal instantiations under this setting. Finally, although general p -SCLI algorithms are exclusively specified for quadratic functions, we show how p -SCLIs with linear coefficient matrices can be extended to general smooth and strongly convex functions.

5.1 Linear Coefficient Matrices

In the sequel we instantiate Scheme 3 (see Section 3.4) for $\mathcal{C}_{\text{Linear}}$, the family of deterministic linear coefficient matrices.

First, note that due to consistency constraints, inversion matrices of constant p -SCLIs with linear coefficient matrices must be either constant scalar matrices or else be computationally equivalent to A^{-1} . Therefore, since our motivation for resorting to linear coefficient matrices was efficiency, we can safely assume that $N(X) = \nu I_d$ for some $\nu \in (-2^p/L, 0)$. Following Scheme 3, we now seek the optimal characteristic polynomial in $\mathfrak{E}_{\text{Linear}} \triangleq \mathfrak{E}(p, \nu I_d, \mathcal{Q}^d([\mu, L]), \mathcal{C}_{\text{Linear}})$ with a compatible set of parameters (see Section 3.4). In the presence of linearity, the characteristic polynomials takes the following simplified form

$$\mathcal{L}(\lambda, X) = \lambda^p - \sum_{j=0}^{p-1} (a_j X + b_j I_d) \lambda^j, \quad a_j, b_j \in \mathbb{R}.$$

By (23) we have

$$\rho_\lambda(\mathcal{L}(\lambda, X)) = \max\{|\lambda| \mid \exists i \in [d], \ell_i(\lambda) = 0\},$$

where $\ell_i(\lambda)$ denote the factors of the characteristic polynomial as in (22). That is, denoting the eigenvalues of X by $\sigma_1, \dots, \sigma_d$ we have

$$\ell_i(\lambda) = \lambda^p - \sum_{j=0}^{p-1} (a_j \sigma_i + b_j) \lambda^j = \lambda^p - \sigma_i \sum_{j=0}^{p-1} a_j \lambda^j + \sum_{j=0}^{p-1} b_j \lambda^j.$$

Thus, we can express the maximal root radius of the characteristic polynomial over $\mathcal{Q}^d([\mu, L])$ in terms of the following polynomial

$$\ell(\lambda, \eta) = \lambda^p - (\eta a(\lambda) + b(\lambda)), \quad (36)$$

for some real univariate $p-1$ degree polynomials $a(\lambda)$ and $b(\lambda)$, whereby

$$\max_{A \in \mathfrak{S}^d(\Sigma)} \rho_\lambda(\mathcal{L}(\lambda, A)) = \max_{\eta \in [\mu, L]} \rho(\ell(\lambda, \eta)).$$

That being the case, finding the optimal characteristic polynomial in $\mathfrak{E}_{\text{Linear}}$ translates to the following minimization problem,

$\begin{aligned} & \text{minimize} && \max_{\eta \in [\mu, L]} \rho_\lambda(\ell(\lambda, \eta)) \\ & \text{s.t.} && \ell(1, \eta) = -\nu\eta, \quad \eta \in [\mu, L] \end{aligned} \quad (37)$ $\rho_\lambda(\ell(\lambda, \eta)) < 1 \quad (38)$

(Note that in this case we think of $\mathfrak{E}_{\text{Linear}}$ as a set of polynomials whose variable assumes scalars).

This optimization task can be readily solved for the setting where the lifting factor is $p = 1$, the family of quadratic functions under considerations is $\mathcal{Q}^d(\mu, L)$ and the inversion matrix is $N(X) = \nu I_d$, $\nu \in (-2/L, 0)$. In which case (36) takes the following form

$$\ell(\lambda, \eta) = \lambda - \eta a_0 - b_0,$$

where a_0, b_0 are some real scalars. In order to satisfy (37) for all $\eta \in [\mu, L]$, we have no other choice but to set

$$a_0 = \nu, \quad b_0 = 1,$$

which implies

$$\rho_\lambda(\ell(\lambda, \eta)) = 1 + \nu\eta.$$

Since $\nu \in (-2/L, 0)$, condition 38 follows, as well. The corresponding 1-SCLI optimization algorithm is

$$\mathbf{x}^{k+1} = (I + \nu A)\mathbf{x}^k + \nu \mathbf{b},$$

and its first-order extension (see Section 5.3 below) is precisely FGD (see Section 2.3). Finally, note that the corresponding root radius is bounded from above by

$$\frac{\kappa - 1}{\kappa}$$

for $\nu = -1/L$, the minimizer in Case 2 of Table 1, and by

$$\frac{\kappa - 1}{\kappa + 1}$$

for $\nu = \frac{-2}{\mu+L}$, the minimizer in Case 3 of Table 1. This proves that FGD is optimal for the class of 1-SCLIs with linear coefficient matrices. Figure 5.1 shows how the root radius of the characteristic polynomial of FGD is related to the eigenvalues of the Hessian of the quadratic function under consideration.

5.2 Recovering AGD and HB

Let us now calculate the optimal characteristic polynomial for the setting where the lifting factor is $p = 2$, the family of quadratic functions under considerations is $\mathcal{Q}^d(\mu, L)$ and the inversion matrix is $N(X) = \nu I_d$, $\nu \in (-4/L, 0)$ (recall that the restricted range of ν is due to consistency). In which case (36) takes the following form

$$\ell(\lambda, \eta) = \lambda^2 - \eta(a_1\lambda + a_0) - (b_1\lambda + b_0), \quad (39)$$

for some real scalars a_0, a_1, b_0, b_1 . Our goal is to choose a_0, a_1, b_0, b_1 so as to minimize

$$\max_{\eta \in [\mu, L]} \rho_\lambda(\ell(\lambda, \eta))$$

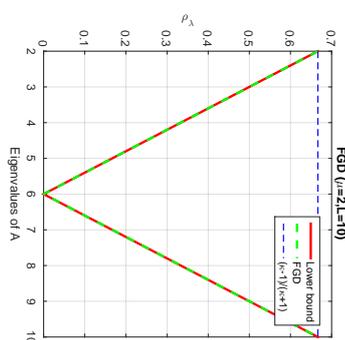

Figure 1: The root radius of FGD vs. various eigenvalues of the corresponding Hessian.

while preserving conditions (37) and (38). Note that $\ell(\lambda, \eta)$, when seen as a function of η , forms a linear path of quadratic functions. Thus, a natural way to achieve this goal is to choose $\ell(\lambda, \eta)$ so that $\ell(\lambda, \mu)$ and $\ell(\lambda, L)$ take the form of the ‘economic’ polynomials introduced in Lemma 6, namely

$$(\lambda - (1 - \sqrt{\tau}))^2$$

for $\tau = -\nu\mu$ and $\tau = -\nu L$, respectively, and hope that for others $\eta \in (\mu, L)$, the roots of $\ell(\lambda, \eta)$ would still be of small magnitude. Note that due to the fact that $\ell(\lambda, \eta)$ is linear in η , condition (37) readily holds for any $\eta \in (\mu, L)$. This yields the following two equations

$$\begin{aligned} \ell(\lambda, \mu) &= (\lambda - (1 - \sqrt{-\nu\mu}))^2, \\ \ell(\lambda, L) &= (\lambda - (1 - \sqrt{-\nu L}))^2. \end{aligned}$$

Substituting (39) for $\ell(\lambda, \eta)$ and expanding the r.h.s. of the equations above we get

$$\begin{aligned} \lambda^2 - (a_1\mu + b_1)\lambda - (a_0\mu + b_0) &= \lambda^2 - 2(1 - \sqrt{-\nu\mu})\lambda + (1 - \sqrt{-\nu\mu})^2, \\ \lambda^2 - (a_1L + b_1)\lambda - (a_0L + b_0) &= \lambda^2 - 2(1 - \sqrt{-\nu L})\lambda + (1 - \sqrt{-\nu L})^2. \end{aligned}$$

Which can be equivalently expressed as the following system of linear equations

$$-(a_1\mu + b_1) = -2(1 - \sqrt{-\nu\mu}), \quad (40)$$

$$-(a_0\mu + b_0) = (1 - \sqrt{-\nu\mu})^2, \quad (41)$$

$$-(a_1L + b_1) = -2(1 - \sqrt{-\nu L}), \quad (42)$$

$$-(a_0L + b_0) = (1 - \sqrt{-\nu L})^2. \quad (43)$$

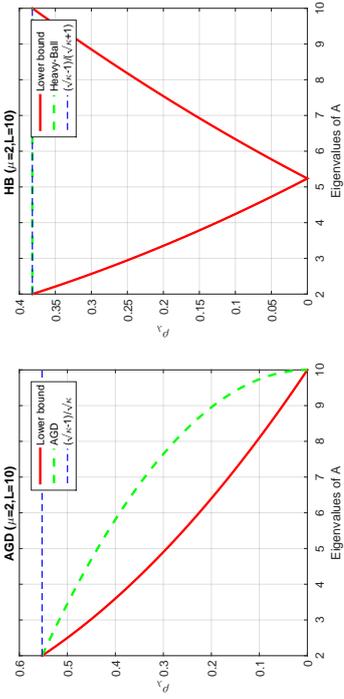

Figure 2: The root radius of AGD and HB vs. various eigenvalues of the corresponding Hessian.

Multiplying Equation (40) by -1 and add to it Equation (42). Next, multiply Equation (41) by -1 and add to it Equation (43) yields

$$\begin{aligned} a_1(\mu - L) &= 2\sqrt{-\nu}(\sqrt{L} - \sqrt{\mu}), \\ a_0(\mu - L) &= (1 - \sqrt{-\nu L})^2 - (1 - \sqrt{-\nu\mu})^2. \end{aligned}$$

Thus,

$$a_1 = \frac{-2\sqrt{-\nu}}{\sqrt{\mu} + \sqrt{L}}, \quad a_0 = \frac{2\sqrt{-\nu}}{\sqrt{\mu} + \sqrt{L}} + \nu.$$

Plugging in $\nu = -1/L$ (see Table 1) into the equations above and solving for b_1 and b_0 yields a 2-SCLI optimization algorithm whose extension (see Section 5.3 below) is precisely AGD. Following the same derivation only this time by setting (see again Table 1)

$$\nu = -\left(\frac{2}{\sqrt{L} + \sqrt{\mu}}\right)^2$$

yields the Heavy-Ball method.

Moreover, using standard formulae for roots of quadratic polynomials one can easily verify that

$$\rho_\lambda(\ell(\lambda, \eta)) \leq \frac{\sqrt{\kappa} - 1}{\sqrt{\kappa}}, \quad \eta \in [\mu, L],$$

for AGD, and

$$\rho_\lambda(\ell(\lambda, \eta)) \leq \frac{\sqrt{\kappa} - 1}{\sqrt{\kappa} + 1}, \quad \eta \in [\mu, L],$$

for HB. In particular, Condition 38 holds. Figure 5.2 shows how the root radii of the characteristic polynomials of AGD and HB are related to the eigenvalues of the Hessian of the quadratic function under consideration.

Unfortunately, finding the optimal p -SCLIs for $p > 2$ is open and is closely related to the conjecture presented in the end of Section 4.2.

5.3 First-Order Extension for p -SCLIs with Linear Coefficient Matrices

As mentioned before, since the coefficient matrices of p -SCLIs can take any form, it is not clear how to use a given p -SCLI algorithm, efficient as it may be, for minimizing general smooth and strongly convex functions. That being the case, one could argue that recovering the specifications of, say, AGD for quadratic functions does not necessarily imply how to recover AGD itself. Fortunately, consistent p -SCLIs with linear coefficients can be reformulated as optimization algorithms for general smooth and strongly convex functions in a natural way by substituting $\nabla f(\mathbf{x})$ for $A\mathbf{x} + \mathbf{b}$, while preserving the original convergence properties to a large extent. In the sequel we briefly discuss this appealing property, namely, canonical first-order extension, which completes the path from the world of polynomials to the world optimization algorithm for general smooth and strongly convex functions.

Let $\mathcal{A} \triangleq (\mathcal{L}_A(\lambda, X), N(X))$ be a consistent p -SCLI optimization algorithm with a scalar inversion matrix, i.e., $N(X) \triangleq \nu I_d$, $\nu \in (-2^p/L, 0)$, and linear coefficient matrices

$$C_j(X) = a_j X + b_j I_d, \quad j = 0, \dots, p-1, \quad (44)$$

where $a_0, \dots, a_{p-1} \in \mathbb{R}$ and $b_0, \dots, b_{p-1} \in \mathbb{R}$ denote real scalars. Recall that by consistency, for any $f_{A,\mathbf{b}}(\mathbf{x}) \in \mathcal{Q}^d(\Sigma)$, it holds that

$$\begin{aligned} \text{Thus,} \quad & \sum_{j=0}^{p-1} C_j(A) = I + \nu A. \\ & \sum_{j=0}^{p-1} b_j = 1 \text{ and } \sum_{j=0}^{p-1} a_j = \nu. \end{aligned} \quad (45)$$

By the definition of p -SCLIs (Definition 1), we have that

$$\mathbf{x}^k = C_0(A)\mathbf{x}^{k-p} + C_1(A)\mathbf{x}^{k-(p-1)} + \dots + C_{p-1}(A)\mathbf{x}^{k-1} + \nu \mathbf{b}.$$

Substituting $C_j(A)$ for (44), gives

$$\mathbf{x}^k = (a_0 A + b_0)\mathbf{x}^{k-p} + (a_1 A + b_1)\mathbf{x}^{k-(p-1)} + \dots + (a_{p-1} A + b_{p-1})\mathbf{x}^{k-1} + \nu \mathbf{b}.$$

Rearranging and plugging in 45, we get

$$\begin{aligned} \mathbf{x}^k &= a_0(A\mathbf{x}^{k-p} + \mathbf{b}) + a_1(A\mathbf{x}^{k-(p-1)} + \mathbf{b}) + \dots + a_{p-1}(A\mathbf{x}^{k-1} + \mathbf{b}) \\ &\quad + b_0\mathbf{x}^{k-p} + b_1\mathbf{x}^{k-(p-1)} + \dots + b_{p-1}\mathbf{x}^{k-1}. \end{aligned}$$

Finally, by substituting $A\mathbf{x} + \mathbf{b}$ for its analog $\nabla f(\mathbf{x})$, we arrive at the following canonical first-order extension of \mathcal{A}

$$\mathbf{x}^k = \sum_{j=0}^{p-1} b_j \mathbf{x}^{k-(p-j)} + \sum_{j=0}^{p-1} a_j \nabla f(\mathbf{x}^{k-(p-j)}). \quad (46)$$

Being applicable to a much wider collection of functions, how well should we expect the canonical extensions to behave? The answer is that when initialized close enough to the minimizer, one should expect a linear convergence of essentially the same rate. A formal statement is given by the theorem below which easily follows from Theorem 1 in Section 2.1, Polyak (1987) for

$$g(\mathbf{x}^{k-p}, \mathbf{x}^{k-(p-1)}, \dots, \mathbf{x}^{k-1}) = \sum_{j=0}^{p-1} b_j \mathbf{x}^{k-(p-j)} + \sum_{j=0}^{p-1} a_j \nabla f(\mathbf{x}^{k-(p-j)}).$$

Theorem 9 *Suppose $f : \mathbb{R}^d \rightarrow \mathbb{R}$ is an L -smooth μ -strongly convex function and let \mathbf{x}^* denotes its minimizer. Then, for every $\epsilon > 0$, there exist $\delta > 0$ and $C > 0$ such that if*

$$\|\mathbf{x}^j - \mathbf{x}^*\| \leq \delta, \quad j = 0, \dots, p-1,$$

then

$$\|\mathbf{x}^k - \mathbf{x}^0\| \leq C(\rho^* + \epsilon)^k, \quad k = p, p+1, \dots,$$

where

$$\rho^* = \sup_{\eta \in \Sigma} \rho \left(\lambda^p - \sum_{j=0}^{p-1} (a_j \eta + b_j) \lambda^j \right).$$

Unlike general p -SCLIs with linear coefficient matrices which are guaranteed to converge only when initialized close enough to the minimizer, AGD converges linearly, regardless of the initialization points, for any smooth and strongly convex function. This fact merits further investigation as to the precise principles which underlie p -SCLIs of this kind.

Appendix A. Optimal p -SCLI for Unconstrained Coefficient Matrices

In the sequel we use Scheme 3 (see Section 3.4) to show that, when no constraints are imposed on the functional dependency of the coefficient matrices, the lower bound shown in Theorem 8 is tight. To this end, recall that in Lemma 6 we showed that the lower bound on the maximal modulus of roots of a polynomials which evaluate at $z = 1$ to some $r \geq 0$ is uniquely attained by the following polynomial

$$q_r^*(z) \triangleq (z - (1 - \sqrt[r]{r}))^p$$

Thus, by choosing coefficient matrices which admit the same form, we obtain the optimal convergence rate as stated in Theorem 8.

Concretely, let $p \in \mathbb{N}$ be some lifting factor, let $N(X) = \nu L$, $\nu \in (-2^p/L, 0)$ be a fixed scalar matrix and let $f_{A,\mathbf{b}}(\mathbf{x}) \in \mathcal{Q}^d(2)$ be some quadratic function. Lemma 6 implies that for each $\eta \in \sigma(-\nu A)$ we need the corresponding factor of the characteristic polynomial to be

$$\begin{aligned} \ell_j(\lambda) &= (\lambda - (1 - \sqrt[p]{\eta}))^p \\ &= \sum_{k=0}^p \binom{p}{k} (\sqrt[p]{-\nu\eta} - 1)^{p-k} \lambda^k \end{aligned} \quad (47)$$

This is easily accomplished using the spectral decomposition of A by

$$\Lambda \triangleq U^T A U$$

where U is an orthogonal matrix and Λ is a diagonal matrix. Note that since A is a positive definite matrix such a decomposition must always exist. We define p coefficient matrices C_0, C_1, \dots, C_{p-1} in accordance with Equation (47) as follows

$$C_k = U \begin{pmatrix} -\binom{p}{k} (\sqrt[p]{-\nu\Lambda_{11}} - 1)^{p-k} & & & \\ & -\binom{p}{k} (\sqrt[p]{-\nu\Lambda_{22}} - 1)^{p-k} & & \\ & & \ddots & \\ & & & -\binom{p}{k} (\sqrt[p]{-\nu\Lambda_{dd}} - 1)^{p-k} \end{pmatrix} U^T.$$

By using Theorem 5, it can be easily verified that these coefficient matrices form a consistent p -SCLI optimization algorithm whose characteristic polynomial's root radius is

$$\max_{j=1, \dots, d} \left| \sqrt[p]{-\nu \mu_j} - 1 \right|.$$

Choosing

$$\nu = - \left(\frac{2}{\sqrt[p]{L} + \sqrt[p]{\mu}} \right)^p$$

according to Table 1, produces an optimal p -SCLI optimization algorithm for this set of parameters. It is noteworthy that other suitable decompositions can be used for deriving optimal p -SCLIs, as well.

As a side note, since the cost of computing each iteration in \mathbb{R}^{pd} grows linearly with the lifting factor p , the optimal choice of p with respect to the condition number κ yields a p -SCLI optimization algorithm whose iteration complexity is $\Theta(\ln(\kappa) \ln(1/\epsilon))$. Clearly, this result is of theoretical interest only, as this would require a spectral decomposition of A , which, if no other structural assumptions are imposed, is an even harder task than computing the minimizer of $f_{A,\mathbf{b}}(\mathbf{x})$.

Appendix B. Lifting Factor ≥ 3

In Section 4.2 we conjecture that for any p -SCLI optimization algorithm $\mathcal{A} \triangleq (\mathcal{L}(\lambda, X), N(X))$, with diagonal inversion matrix and linear coefficient matrices there exists some $A \in \mathcal{Q}^d([\mu, L])$ such that

$$\rho_\lambda(\mathcal{L}(\lambda, X)) \geq \frac{\sqrt{\kappa} - 1}{\sqrt{\kappa} + 1}, \quad (48)$$

where $\kappa \triangleq L/\mu$. However, it may be possible to overcome this barrier by focusing on a subclass of $\mathcal{Q}^d([\mu, L])$. Indeed, recall that the polynomial analogy of this conjecture states that for any monic real p degree polynomial $q(z)$ such that $q(1) = 0$ and for any polynomial $r(z)$ of degree $p - 1$, there exists $\eta \in [\mu, L]$ such that

$$\rho(q(z) - \eta r(z)) \geq \frac{\sqrt{\kappa} - 1}{\sqrt{\kappa} + 1}.$$

This implies that we may be able to tune $q(z)$ and $r(z)$ so as to obtain a convergence rate, which breaks Inequality (48), for quadratic function whose Hessian's spectrum does not spread uniformly across $[\mu, L]$.

Let us demonstrate this idea for $p = 3$, $\mu = 2$ and $L = 100$. Following the exact same derivation used in the last section, let us pick

$$q(z, \eta) \triangleq z^3 - (\eta a(z) + b(z))$$

numerically, so that

$$\begin{aligned} q(z, \mu) &= \left(z - (1 - \sqrt[3]{-\nu\mu}) \right)^3 \\ q(z, L) &= \left(z - (1 - \sqrt[3]{-\nu\mu}) \right)^3 \end{aligned}$$

where

$$\nu = - \left(\frac{2}{\sqrt[3]{L} + \sqrt[3]{\mu}} \right)^3$$

The resulting 3-CLI optimization algorithm \mathcal{A}_3 is

$$\mathbf{x}^k = C_2(X)\mathbf{x}^{k-1} + C_1(X)\mathbf{x}^{k-2} + C_0(X)\mathbf{x}^{k-3} + N(X)b$$

where

$$\begin{aligned} C_0(X) &\approx 0.1958L_d - 0.0038X \\ C_1(X) &\approx -0.9850L_d \\ C_2(X) &\approx 1.7892L_d - 0.0351X \\ N(X) &\approx -0.0389L_d \end{aligned}$$

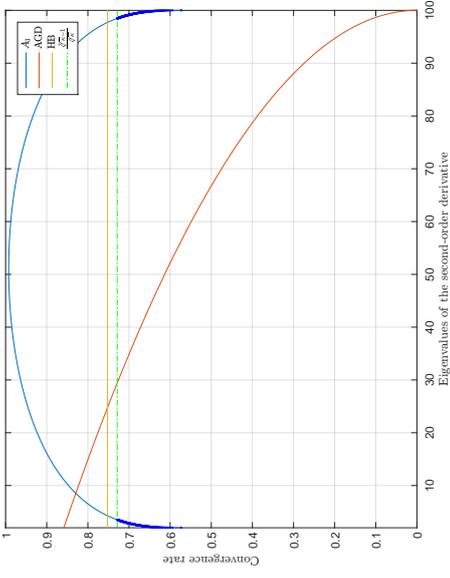

Figure 3: The convergence rate of AGD and \mathcal{A}_3 vs. the eigenvalues of the second-order derivatives. It can be seen that the asymptotic convergence rate of \mathcal{A}_3 for quadratic functions whose second-order derivative comprises eigenvalues which are close to the edges of $[2, 100]$, is faster than AGD and goes below the theoretical lower bound for first-order optimization algorithm $\frac{\sqrt{\kappa}-1}{\sqrt{\kappa}+1}$.

As opposed to the algorithm described in Section A, when employing linear coefficient matrices no knowledge regarding the eigenvectors of A is required. As each eigenvalue of the second-order derivative corresponds to a bound on the convergence rate, one can verify by Figure 3 that

$$\rho_\lambda(\mathcal{L}_{\mathcal{A}_3}(\lambda, X)) \leq \frac{\sqrt[3]{\kappa} - 1}{\sqrt[3]{\kappa}}$$

for any $X \in \mathcal{Q}^d([2, 100])$ which satisfies

$$\sigma(A) \subseteq \hat{\Sigma} \triangleq [2, 2 + \epsilon] \cup [100 - \epsilon, 100], \quad \epsilon \approx 1.5.$$

Thus, \mathcal{A}_3 outperforms AGD for this family of quadratic functions.

Let us demonstrate the gain in the performance allowed by \mathcal{A}_3 in a very simple setting. Define A to be $\text{Diag}(\mu, L)$ rotated counter-clockwise by 45° , that is

$$A = \mu \begin{pmatrix} \frac{1}{\sqrt{2}} & \\ & \frac{1}{\sqrt{2}} \end{pmatrix} \begin{pmatrix} \frac{1}{\sqrt{2}} & \\ & \frac{1}{\sqrt{2}} \end{pmatrix}^\top + L \begin{pmatrix} \frac{1}{\sqrt{2}} & \\ & \frac{1}{\sqrt{2}} \end{pmatrix} \begin{pmatrix} \frac{1}{\sqrt{2}} & \\ & \frac{1}{\sqrt{2}} \end{pmatrix}^\top = \begin{pmatrix} \frac{\mu+L}{2} & \\ & \frac{\mu-L}{2} \end{pmatrix}.$$

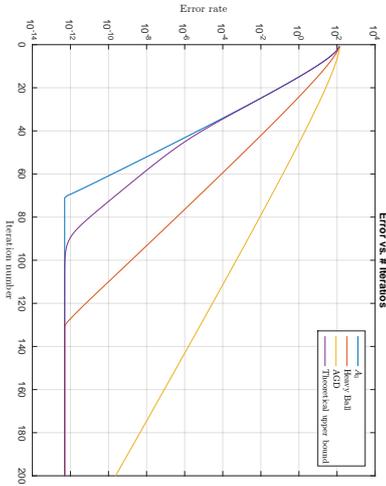

Figure 4: The error rate of \mathcal{A}_3 , AGD and HB vs. # iterations for solving a simple quadratic minimization task. The convergence rate of \mathcal{A}_3 is bounded from above by $\frac{\sqrt[3]{\kappa}-1}{\sqrt[3]{\kappa}}$ as implied by theory.

Furthermore, define $\mathbf{b} = -\mathbf{A}(100, 100)^\top$. Note that $f_{\mathbf{A}, \mathbf{b}}(\mathbf{x}) \in \mathcal{Q}^2(\hat{\Sigma})$ and that its minimizer is simply $(100, 100)^\top$. Figure 4 shows the error of \mathcal{A}_3 , AGD and HB vs. iteration number. All algorithms are initialized at $\mathbf{x}^0 = 0$. Since \mathcal{A}_3 is a first-order optimization algorithm, by the lower bound shown in (3) there must exist some quadratic function $f_{\mathbf{A}_{\text{lb}}, \mathbf{b}_{\text{lb}}}(\mathbf{x}) \in \mathcal{Q}^2(\mu, L)$ such that

$$\mathcal{EC}_{\mathcal{A}_3}(\epsilon, f_{\mathbf{A}_{\text{lb}}, \mathbf{b}_{\text{lb}}}(\mathbf{x})) \geq \tilde{\Omega}(\sqrt{\kappa} \ln(1/\epsilon)). \tag{49}$$

But, since

$$\mathcal{EC}_{\mathcal{A}_3}(\epsilon, f_{\mathbf{A}, \mathbf{b}}(\mathbf{x})) \leq \mathcal{O}(\sqrt[3]{\kappa} \ln(1/\epsilon)) \tag{50}$$

for every $f_{\mathbf{A}, \mathbf{b}}(\mathbf{x}) \in \mathcal{Q}^2(\hat{\Sigma})$, we must have $f_{\mathbf{A}_{\text{lb}}, \mathbf{b}_{\text{lb}}}(\mathbf{x}) \in \mathcal{Q}^2(\mu, L) \setminus \mathcal{Q}^2(\hat{\Sigma})$. Indeed, in the somewhat simpler form of the general lower bound for first-order optimization algorithms,

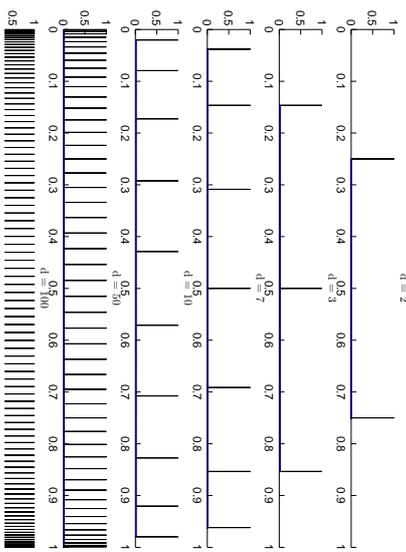

Figure 5: The spectrum of \mathbf{A}_{lb} , as used in the derivation of Nesterov’s lower bound, for problem space of various dimensions.

Nesterov (see Nesterov 2004) considers the following 1-smooth 0-strongly convex function¹⁰

$$\mathbf{A}_{\text{lb}} = \frac{1}{4} \begin{pmatrix} 2 & -1 & 0 & \cdots & 0 \\ -1 & 2 & -1 & 0 & \cdots & 0 \\ 0 & -1 & 2 & -1 & 0 & \cdots & 0 \\ \cdots & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\ 0 & \cdots & 0 & -1 & 2 & -1 \\ 0 & \cdots & \cdots & 0 & -1 & 2 \end{pmatrix}, \mathbf{b}_{\text{lb}} = - \begin{pmatrix} 1 \\ 0 \\ \vdots \\ 0 \end{pmatrix}.$$

As demonstrated by Figure 5, $\sigma(\mathbf{A}_{\text{lb}})$ densely fills $[\mu, L]$.

Consequently, we expect that whenever adjacent eigenvalues of the second-order derivatives are relatively distant, one should be able to minimize the corresponding quadratic function faster than the lower bound stated in 3. This technique can be further generalized to $p > 3$ using the same ideas. Also, a different approach is to use quadratic (or even higher degree) coefficient matrices to exploit other shapes of spectra. Clearly, the applicability of both approaches heavily depends the existence of spectra of this type in real applications.

¹⁰. Although $f_{\mathbf{A}_{\text{lb}}, \mathbf{b}_{\text{lb}}}(\mathbf{x})$ is not strongly convex, the lower bound for strongly convex function is obtained by shifting the spectrum using a regularization term $\mu/2 \|\mathbf{x}\|^2$. In which case, the shape of the spectrum is preserved.

Appendix C. Proofs

C.1 Proof of Theorem 4

The simple idea behind proof of Theorem 4 is to express the dynamic of a given p -SCLI optimization algorithm as a recurrent application of linear operator. To analyze the latter, we employ the Jordan form which allows us to bind together the maximal magnitude eigenvalue and the convergence rate. Prior to proving this theorem, we first need to introduce some elementary results in linear algebra.

C.1.1 LINEAR ALGEBRA PRELIMINARIES

We prove two basic lemmas which allow to determine under what conditions does a recurrence application of linear operators over finite dimensional spaces converge, as well as to compute the limit of matrices powers series. It is worth noting that despite of being a very elementary result in Matrix theory and in the theory of power methods, the lower bound part of the first lemma does not seem to appear in this form in standard linear algebra literature.

Lemma 10 *Let A be a $d \times d$ square matrix.*

- *If $\rho(A) > 0$ then there exists $C_A > 0$ such that for any $\mathbf{u} \in \mathbb{R}^d$ and for any $k \in \mathbb{N}$ we have*

$$\|A^k \mathbf{u}\| \leq C_A k^{m-1} \rho(A)^k \|\mathbf{u}\|,$$

where m denotes the maximal index of eigenvalues whose modulus is maximal.

In addition, there exists $c_A > 0$ and $\mathbf{r} \in \mathbb{R}^d$ such that for any $\mathbf{u} \in \mathbb{R}^d$ which satisfies $\langle \mathbf{u}, \mathbf{r} \rangle \neq 0$ we have

$$\|A^k \mathbf{u}\| \geq c_A k^{m-1} \rho(A)^k \|\mathbf{u}\|,$$

for sufficiently large $k \in \mathbb{N}$.

- *If $\rho(A) = 0$ then A is a nilpotent matrix. In which case, both lower and upper bounds mentioned above hold trivially for any $\mathbf{u} \in \mathbb{R}^d$ for sufficiently large k .*

Proof Let P be a $d \times d$ invertible matrix such that

$$P^{-1}AP = J,$$

where J is a Jordan form of A , namely, J is a block-diagonal matrix such that $J = \bigoplus_{i=1}^s J_{k_i}(\lambda_i)$ where $\lambda_1, \lambda_2, \dots, \lambda_s$ are eigenvalues of A in a non-increasing order, whose indices are k_1, \dots, k_s , respectively. w.l.o.g. we may assume that $|\lambda_1| = \rho(A)$ and that the corresponding index, which we denote by m , is maximal over all eigenvalues of maximal magnitude. Let Q_1, Q_2, \dots, Q_s and R_1, R_2, \dots, R_s denote partitioning of the columns of P and the rows of P^{-1} , respectively, which conform with the Jordan blocks of A .

Note that for all $i \in [d]$, $J_{k_i}(0)$ is a nilpotent matrix of an order k_i . Therefore, for any (λ_i, k_i) and $k \geq k_i - 1$ we have

$$\begin{aligned} J_{k_i}(\lambda_i)^k &= (\lambda_i J_{k_i} + J_{k_i}(0))^k \\ &= \sum_{j=0}^k \binom{k}{j} \lambda_i^{k-j} J_{k_i}(0)^j \\ &= \sum_{j=0}^{k_i-1} \binom{k}{j} \lambda_i^{k-j} J_{k_i}(0)^j. \end{aligned}$$

Thus, for non-zero eigenvalues we have

$$\begin{aligned} J_{k_i}(\lambda_i)^k / (k^{m-1} \lambda_i^k) &= \sum_{j=0}^{k_i-1} \frac{\binom{k}{j} \lambda_i^{k-j} J_{k_i}(0)^j}{k^{m-1} \lambda_i^k} \\ &= \sum_{j=0}^{k_i-1} \binom{k}{j} \left(\frac{\lambda_i}{\lambda_1} \right)^k \frac{J_{k_i}(0)^j}{\lambda_i^j}. \end{aligned} \quad (51)$$

The rest of the proof pivots around the following equality which holds for any $\mathbf{u} \in \mathbb{R}^{pd}$,

$$\begin{aligned} \|A^k \mathbf{u}\| &= \|PJ^k P^{-1} \mathbf{u}\| \\ &= \left\| \sum_{i=1}^{s'} Q_i J_{k_i}(\lambda_i)^k R_i \mathbf{u} \right\| \\ &= k^{m-1} \rho(A)^k \left\| \sum_{i=1}^{s'} Q_i \left(J_{k_i}(\lambda_i) / (k^{m-1} \lambda_i^{k_i}) \right) R_i \mathbf{u} \right\|, \end{aligned} \quad (52)$$

where s' denotes the smallest index such that $\lambda_i = 0$ for $i > s'$, in case there are zero eigenvalues. Plugging in 51 yields,

$$\|A^k \mathbf{u}\| = k^{m-1} \rho(A)^k \underbrace{\left\| \sum_{i=1}^{s'} Q_i \left(\sum_{j=0}^{k_i-1} \frac{\binom{k}{j}}{k^{m-1}} \left(\frac{\lambda_i}{\lambda_1} \right)^k \frac{J_{k_i}(0)^j}{\lambda_i^j} \right) R_i \mathbf{u} \right\|}_{\mathbf{w}_k}. \quad (53)$$

Let us denote the sequence of vectors in the r.h.s of the preceding inequality by $\{\mathbf{w}_k\}_{k=1}^\infty$. Showing that the norm of $\{\mathbf{w}_k\}_{k=1}^\infty$ is bounded from above and away from zero will conclude the proof. Deriving an upper bound is straightforward.

$$\begin{aligned} \|\mathbf{w}_k\| &\leq \sum_{i=1}^{s'} \left\| Q_i \left(\sum_{j=0}^{k_i-1} \frac{\binom{k}{j}}{k^{m-1}} \left(\frac{\lambda_i}{\lambda_1} \right)^k \frac{J_{k_i}(0)^j}{\lambda_i^j} \right) R_i \mathbf{u} \right\| \\ &\leq \|\mathbf{u}\| \sum_{i=1}^{s'} \|Q_i\| \|R_i\| \sum_{j=0}^{k_i-1} \left\| \frac{\binom{k}{j}}{k^{m-1}} \left(\frac{\lambda_i}{\lambda_1} \right)^k \frac{J_{k_i}(0)^j}{\lambda_i^j} \right\|. \end{aligned} \quad (54)$$

Since for all $i \in [d]$ we have

$$\frac{\binom{k}{i}}{k^{m-1}} \left(\frac{\lambda_i}{\lambda_1}\right)^k \rightarrow 0 \quad \text{or} \quad \left| \frac{\binom{k}{i}}{k^{m-1}} \left(\frac{\lambda_i}{\lambda_1}\right)^k \right| \rightarrow 1$$

it holds that Inequality (54) can be bounded from above by some positive scalar C_A . Plugging it in into 53 yields

$$\|A^k \mathbf{u}\| \leq C_A k^{m-1} \rho(A)^k \|\mathbf{u}\|.$$

Deriving a lower bound on the norm of $\{\mathbf{w}_k\}$ is a bit more involved. First, we define the following set of Jordan blocks which govern the asymptotic behavior of $\|\mathbf{w}_k\|$

$$\mathcal{I} \triangleq \{i \in [s] \mid |\lambda_i| = \rho(A) \text{ and } k_i = m\}.$$

Equation (51) implies that for all $i \notin \mathcal{I}$

$$J_{k_i}(\lambda_i)^k / (k^{m-1} \lambda_i^k) \rightarrow 0 \text{ as } k \rightarrow \infty.$$

As for $i \in \mathcal{I}$, the first $k_i - 1$ terms in Equation (51) tend to zero. The last term is a matrix whose entries are all zeros, except for the last entry in the first row which equals

$$\frac{\binom{k}{m-1}}{k^{m-1}} \left(\frac{\lambda_i}{\lambda_1}\right)^k \frac{1}{(\lambda_i^{m-1})} \sim \left(\frac{\lambda_i}{\lambda_1}\right)^k \frac{1}{(\lambda_i^{m-1})}$$

(here, two positive sequences a_k, b_k are asymptotic equivalence, i.e., $a_k \sim b_k$, if $a_k/b_k \rightarrow 1$). By denoting the first column of each Q_i by \mathbf{q}_i and the last row in each R_i by \mathbf{r}_i^\top , we get

$$\begin{aligned} \|\mathbf{w}_k\| &\sim \left\| \sum_{i \in \mathcal{I}} \left(\frac{\lambda_i}{\lambda_1}\right)^k \frac{1}{\lambda_i^{m-1}} Q_i J_m(0)^{m-1} R_i \mathbf{u} \right\| \\ &= \left\| \sum_{i \in \mathcal{I}} \left(\frac{\lambda_i}{\lambda_1}\right)^k \frac{\mathbf{q}_i \mathbf{r}_i^\top \mathbf{u}}{\lambda_i^{m-1}} \right\|. \end{aligned}$$

Now, if \mathbf{u} satisfies $\mathbf{r}_1^\top \mathbf{u} \neq 0$ then since $\mathbf{q}_1, \mathbf{q}_2, \dots, \mathbf{q}_I$ are linearly independent, we see that the preceding can be bounded from below by some positive constant $c_A > 0$ which does not depend on k . That is, there exists $c_A > 0$ such that $\|\mathbf{w}_k\| > c_A$ for sufficiently large k . Plugging it in into Equation (53) yields

$$\|A \mathbf{u}\| \geq c_A k^{m-1} \rho(A)^k \|\mathbf{u}\|$$

for any $\mathbf{u} \in \mathbb{R}^d$ such that $\langle \mathbf{u}, \mathbf{r}_1 \rangle \neq 0$ and for sufficiently large k . ■

The following is a well-known fact regarding *Neuman series*, sum of powers of square matrices, which follows easily from Lemma 10.

Lemma 11 *Suppose A is a square matrix. Then, the following statements are equivalent:*

1. $\rho(A) < 1$.
2. $\lim_{k \rightarrow \infty} A^k = 0$.
3. $\sum_{k=0}^{\infty} A^k$ converges.

In which case, $(I - A)^{-1}$ exists and $(I - A)^{-1} = \sum_{k=0}^{\infty} A^k$.

Proof First, note that all norms on a finite-dimensional space are equivalent. Thus, the claims stated in (2) and (3) are well-defined.

The fact that (1) and (2) are equivalent is a direct implication of Lemma 10. Finally, the equivalence of (2) and (3) may be established using the following identity

$$(I - A) \sum_{k=0}^{m-1} A^k = I - A^m, \quad m \in \mathbb{N}.$$

■

C.1.2 CONVERGENCE PROPERTIES

Let us now analyze the convergence properties of p -SCLI optimization algorithms. First, note that update rule (14) can be equivalently expressed as a single step rule by introducing new variables in some possibly higher-dimensional Euclidean space \mathbb{R}^{pd} ,

$$\mathbf{z}^0 = (\mathbf{x}^0, \mathbf{x}^1, \dots, \mathbf{x}^{p-1})^\top \in \mathbb{R}^{pd}, \quad \mathbf{z}^k = M(X) \mathbf{z}^{k-1} + U N(X) \mathbf{b}, \quad k = 1, 2, \dots \quad (55)$$

where

$$U \triangleq \underbrace{(0_d, \dots, 0_d, I_d)}_{p-1 \text{ times}}^\top \in \mathbb{R}^{pd \times d}, \quad (56)$$

and where $M(X)$ is a mapping from $\mathbb{R}^{d \times d}$ to $\mathbb{R}^{pd \times pd}$ -valued random variables which admits the following generalized form of companion matrices

$$\begin{pmatrix} 0_d & I_d & & & \\ & 0_d & I_d & & \\ & & \ddots & \ddots & \\ & & & 0_d & \ddots \\ C_0(X) & \dots & C_{p-2}(X) & C_{p-1}(X) & I_d \end{pmatrix}. \quad (57)$$

Following the convention in the field of linear iterative methods, we call $M(X)$ the *iteration matrix*. Note that in terms of the formulation given in (55), consistency w.r.t. $A \in \mathcal{S}^d(\Sigma)$ is equivalent to

$$\mathbb{E} \mathbf{z}^k \rightarrow \underbrace{(-A^{-1} \mathbf{b}, \dots, -A^{-1} \mathbf{b})^\top}_{p \text{ times}} \quad (58)$$

regardless of the initialization points and for any $\mathbf{b} \in \mathbb{R}^d$ and $\mathbf{z}^0 \in \mathbb{R}^{pd}$.

To improve readability, we shall omit the functional dependency of the iteration, inversion and coefficient matrices on X in the following discussion. Furthermore, Equation (55) can be used to derive a simple expression of \mathbf{z}^k , in terms of previous iterations as follows

$$\begin{aligned} \mathbf{z}^1 &= M^{(0)}\mathbf{z}^0 + UN^{(0)}\mathbf{b}, \\ \mathbf{z}^2 &= M^{(1)}\mathbf{z}^1 + UN^{(1)}\mathbf{b} = M^{(1)}M^{(0)}\mathbf{z}^0 + M^{(1)}UN^{(0)}\mathbf{b} + UN^{(1)}\mathbf{b}, \\ \mathbf{z}^3 &= M^{(2)}\mathbf{z}^2 + UN^{(2)}\mathbf{b} = M^{(2)}M^{(1)}M^{(0)}\mathbf{z}^0 + M^{(2)}M^{(1)}UN^{(0)}\mathbf{b} + M^{(2)}UN^{(1)}\mathbf{b} + UN^{(2)}\mathbf{b}, \\ &\vdots \\ \mathbf{z}^k &= \prod_{j=0}^{k-1} M^{(j)}\mathbf{z}^0 + \sum_{m=1}^{k-1} \prod_{j=m}^{k-1} M^{(j)}UN^{(m-1)}\mathbf{b} + UN^{(k-1)}\mathbf{b}, \\ &= \prod_{j=0}^{k-1} M^{(j)}\mathbf{z}^0 + \sum_{m=1}^k \left(\prod_{j=m}^{k-1} M^{(j)} \right) UN^{(m-1)}\mathbf{b}. \end{aligned}$$

where $(M^{(0)}, N^{(0)}), \dots, (M^{(k-1)}, N^{(k-1)})$ are k i.i.d realizations of the corresponding iteration matrix and inversion matrix, respectively. We follow the convention of defining an empty product as the identity matrix and defining the multiplication order of factors of abbreviated product notation as multiplication from the highest index to the lowest, i.e., $\prod_{j=1}^k M^{(j)} = M^{(k)} \dots M^{(1)}$. Taking the expectation of both sides yields

$$\mathbb{E}\mathbf{z}^k = \mathbb{E}[M]^{k-1}\mathbf{z}^0 + \left(\sum_{j=0}^{k-1} \mathbb{E}[M]^j \right) \mathbb{E}[UN]\mathbf{b}. \quad (59)$$

By Lemma 11, if $\rho(\mathbb{E}M) < 1$ then the first term in the r.h.s of Equation (59) vanishes for any initialization point \mathbf{z}^0 , whereas the second term converges to

$$(I - \mathbb{E}M)^{-1} \mathbb{E}[UN]\mathbf{b},$$

the fixed point of the update rule. On the other hand, suppose that $(\mathbb{E}z^k)_{k=0}^\infty$ converges for any $\mathbf{z}^0 \in \mathbb{R}^d$. Then, this is also true for $\mathbf{z}^0 = 0$. Thus, the second summand in the r.h.s of Equation (59) must converge. Consequently, the sequence $\mathbb{E}[M]^k\mathbf{z}^0$, being a difference of two convergent sequences, converges for all \mathbf{z}^0 , which implies $\rho(\mathbb{E}[M]) < 1$. This proves the following theorem.

Theorem 12 *With the notation above, $(\mathbb{E}z^k)_{k=0}^\infty$ converges for any $\mathbf{z}^0 \in \mathbb{R}^d$ if and only if $\rho(\mathbb{E}[M]) < 1$. In which case, for any initialization point $\mathbf{z}^0 \in \mathbb{R}^d$, the limit is*

$$\mathbf{z}^* \triangleq (I - \mathbb{E}M)^{-1} \mathbb{E}[UN]\mathbf{b}. \quad (60)$$

We now address the more delicate question as to how fast do p -SCLIs converge. To this end, note that by Equation (59) and Theorem 12 we have

$$\begin{aligned} \mathbb{E}[\mathbf{z}^k - \mathbf{z}^*] &= \mathbb{E}[M]^{k-1}\mathbf{z}^0 + \left(\sum_{i=0}^{k-1} \mathbb{E}[M]^i \right) \mathbb{E}[UN]\mathbf{b} - (I - \mathbb{E}M)^{-1} \mathbb{E}[UN]\mathbf{b} \\ &= \mathbb{E}[M]^{k-1}\mathbf{z}^0 + (I - \mathbb{E}M)^{-1} \left((I - \mathbb{E}M) \sum_{i=0}^{k-1} \mathbb{E}[M]^i - I \right) \mathbb{E}[UN]\mathbf{b} \\ &= \mathbb{E}[M]^{k-1}\mathbf{z}^0 - (I - \mathbb{E}M)^{-1} (\mathbb{E}M)^k \mathbb{E}[UN]\mathbf{b} \\ &= \mathbb{E}[M]^{k-1}(\mathbf{z}^0 - \mathbf{z}^*). \end{aligned} \quad (61)$$

Hence, to obtain a full characterization of the convergence rate of $\|\mathbb{E}[\mathbf{z}^k - \mathbf{z}^*]\|$ in terms of $\rho(\mathbb{E}M)$, all we need is to simply apply Lemma 10 with $\mathbb{E}M$.

C.1.3 PROOF

We are now in position to prove Theorem 4. Let $\mathcal{A} \triangleq (\mathcal{L}(\lambda, X), N(X))$ be a p -SCLI algorithm over \mathbb{R}^d , let $M(X)$ denote its iteration matrix and let $f_{A,\mathbf{b}}(\mathbf{x})$ be some quadratic function. According to the previous discussion, there exist $m \in \mathbb{N}$ and $C(A), c(A) > 0$ such that the following hold:

1. For any initialization point $\mathbf{z}^0 \in \mathbb{R}^{pd}$, we have that $(\mathbb{E}z^k)_{k=1}^\infty$ converges to $\mathbf{z}^* \triangleq (I - \mathbb{E}M(A))^{-1} \mathbb{E}[UN(A)]\mathbf{b}$. (62)
2. For any initialization point $\mathbf{z}^0 \in \mathbb{R}^{pd}$ and for any $h \in \mathbb{N}$, (63)

$$\|\mathbb{E}[\mathbf{z}^k - \mathbf{z}^*]\| \leq C_A k^{m-1} \rho(M(A))^k \|\mathbf{z}^0 - \mathbf{z}^*\|.$$
3. There exists $\mathbf{r} \in \mathbb{R}^{pd}$ such that for any initialization point $\mathbf{z}^0 \in \mathbb{R}^{pd}$ which satisfies $\langle \mathbf{z}^0 - \mathbf{z}^*, \mathbf{r} \rangle \neq 0$ and sufficiently large $k \in \mathbb{N}$, (64)

$$\|\mathbb{E}[\mathbf{x}^k - \mathbf{x}^*]\| \geq c_A k^{m-1} \rho(M(A))^k \|\mathbf{z}^0 - \mathbf{z}^*\|.$$

Since iteration complexity is defined over the problem space, we need to derive the same inequalities in terms of

$$\mathbf{x}^k = U^\top \mathbf{z}^k.$$

Note that by linearity we have $\mathbf{x}^* = U^\top \mathbf{z}^*$. For bounding $(\mathbf{x}^k)_{k=1}^\infty$ from above we use (63),

$$\begin{aligned} \|\mathbb{E}[\mathbf{x}^k - \mathbf{x}^*]\| &= \|\mathbb{E}[U^\top \mathbf{z}^k - U^\top \mathbf{z}^*]\| \\ &\leq \|U^\top\| \|\mathbb{E}[\mathbf{z}^k - \mathbf{z}^*]\| \\ &\leq \|U^\top\| C_A k^{m-1} \rho(M)^k \|\mathbf{z}^0 - \mathbf{z}^*\| \\ &= \|U^\top\| C_A k^{m-1} \rho(M)^k \|U\mathbf{x}^0 - U\mathbf{x}^*\| \\ &\leq \|U^\top\| \|U\| C_A k^{m-1} \rho(M)^k \|\mathbf{x}^0 - \mathbf{x}^*\|. \end{aligned} \quad (65)$$

Thus, the same rate as in (63), with a different constant, holds in the problem space. Although the corresponding lower bound takes a slightly different form, its proof is done similarly. Pick $\mathbf{x}^0, \mathbf{x}^1, \dots, \mathbf{x}^{p-1}$ such that the corresponding \mathbf{z}^0 is satisfied the condition in (64). For sufficiently large $k \in \mathbb{N}$, it holds that

$$\begin{aligned} \max_{k=0, \dots, p-1} \left\| \mathbb{E} \mathbf{x}^{k+j} - \mathbb{E} \mathbf{x}^* \right\| &\geq \frac{1}{\sqrt{p}} \sqrt{\sum_{j=0}^{p-1} \left\| \mathbb{E} \mathbf{x}^{k+j} - \mathbb{E} \mathbf{x}^* \right\|^2} \\ &= \frac{1}{\sqrt{p}} \left\| \mathbb{E} [\mathbf{z}^k] - \mathbf{z}^* \right\| \\ &\geq \frac{c_A}{\sqrt{p}} k^{m-1} \rho(M)^k \|\mathbf{z}^0 - \mathbf{z}^*\| \\ &= \frac{c_A}{\sqrt{p}} k^{m-1} \rho(M)^k \sum_{j=0}^{p-1} \|\mathbf{x}^j - \mathbf{x}^*\|^2. \end{aligned} \quad (66)$$

We arrived at the following corollary which states that the asymptotic convergence rate of any p -SCLI optimization algorithm is governed by the spectral radius of its iteration matrix.

Theorem 13 *Suppose \mathcal{A} is a p -SCLI optimization algorithm over $\mathcal{Q}^d(\Sigma)$ and let $M(X)$ denotes its iteration matrix. Then, there exists $m \in \mathbb{N}$ such that for any quadratic function $f_{\mathcal{A},b}(\mathbf{x}) \in \mathcal{Q}^d(\Sigma)$ it holds that*

$$\left\| \mathbb{E} [\mathbf{x}^k - \mathbf{x}^*] \right\| = \mathcal{O} \left(k^{m-1} \rho(M(X))^k \|\mathbf{x}^0 - \mathbf{x}^*\| \right),$$

where \mathbf{x}^* denotes the minimizer of $f_{\mathcal{A},b}(\mathbf{x})$. Furthermore, there exists an initialization point $\mathbf{x}^0 \in \mathbb{R}^d$, such that

$$\max_{k=0, \dots, p-1} \left\| \mathbb{E} \mathbf{x}^{k+j} - \mathbb{E} \mathbf{x}^* \right\| = \Omega \left(\frac{k^{m-1}}{\sqrt{p}} \rho(M(X))^k \|\mathbf{x}^0 - \mathbf{x}^*\| \right).$$

Finally, in the next section we prove that the spectral radius of the iteration matrix equals the root radius of the determinant of the characteristic of polynomial by showing that

$$\det(\lambda I - M(X)) = \det(\mathcal{L}(\lambda, X)).$$

Combining this with the corollary above and by applying Inequality (12) and the like, concludes the proof for Theorem 4.

C.1.4 THE CHARACTERISTIC POLYNOMIAL OF THE ITERATION MATRIX

The following lemma provides an explicit expression for the characteristic polynomial of iteration matrices. The proof is carried out by applying elementary determinant manipulation rules.

Lemma 14 *Let $M(X)$ be the matrix defined in (57) and let A be a given $d \times d$ square matrix. Then, the characteristic polynomial of $\mathbb{E}M(A)$ can be expressed as the following matrix polynomial*

$$\chi_{\mathbb{E}M(A)}(\lambda) = (-1)^{pd} \det \left(\lambda^p I_d - \sum_{k=0}^{p-1} \lambda^k \mathbb{E} C_k(A) \right). \quad (67)$$

Proof As usual, for the sake of readability we omit the functional dependency on A , as well as the expectation operator symbol. For $\lambda \neq 0$ we get,

$$\begin{aligned} \chi_M(\lambda) &= \det(M - \lambda I_{pd}) \\ &= \det \begin{pmatrix} -\lambda I_d & I_d & & & \\ & -\lambda I_d & I_d & & \\ & & \ddots & \ddots & \\ & & & -\lambda I_d & I_d \\ C_0 & & \dots & C_{p-2} & C_{p-1} - \lambda I_d \end{pmatrix} \\ &= \det \begin{pmatrix} -\lambda I_d & I_d & & & \\ & -\lambda I_d & I_d & & \\ & & \ddots & \ddots & \\ & & & -\lambda I_d & I_d \\ 0_d & C_1 + \lambda^{-1} C_0 & \dots & C_{p-2} & C_{p-1} - \lambda I_d \end{pmatrix} \\ &= \det \begin{pmatrix} -\lambda I_d & I_d & & & \\ & -\lambda I_d & I_d & & \\ & & \ddots & \ddots & \\ & & & -\lambda I_d & I_d \\ 0_d & 0_d & C_2 + \lambda^{-1} C_1 + \lambda^{-2} C_0 & \dots & C_{p-2} & C_{p-1} - \lambda I_d \end{pmatrix} \\ &= \det \begin{pmatrix} -\lambda I_d & I_d & & & \\ & -\lambda I_d & I_d & & \\ & & \ddots & \ddots & \\ & & & -\lambda I_d & I_d \\ 0_d & \dots & 0_d & \dots & \sum_{k=1}^p \lambda^{k-p} C_{k-1} - \lambda I_d \end{pmatrix} \\ &= \det(-\lambda I_d)^{p-1} \det \left(\sum_{k=1}^p \lambda^{k-p} C_{k-1} - \lambda I_d \right) \end{aligned}$$

$$\begin{aligned}
&= (-1)^{(p-1)d} \det \left(\sum_{k=1}^p \lambda^{k-1} C_{k-1} - \lambda^p I_d \right) \\
&= (-1)^{pd} \det \left(\lambda^p I_d - \sum_{k=0}^{p-1} \lambda^k C_k \right).
\end{aligned}$$

By continuity we have that the preceding equality holds for $\lambda = 0$ as well. \blacksquare

C.2 Proof of Theorem 5

We prove that consistent p -SCLI optimization algorithms must satisfy conditions (17) and (18). The reverse implication is proven by reversing the steps of the proof.

First, note that (18) is an immediate consequence of Corollary 13, according to which p -SCLIs converge if and only if the root radius of the characteristic polynomial is strictly smaller than 1. As for (18), let $\mathcal{A} \triangleq (\mathcal{L}(\lambda, X), N(X))$ be a consistent p -SCLI optimization algorithm over $\mathcal{Q}^d(\Sigma)$ and let $f_{A, \mathbf{b}}(\mathbf{x}) \in \mathcal{Q}^d(\Sigma)$ be a quadratic function. Furthermore, let us denote the corresponding iteration matrix by $M(X)$ as in (57). By Theorem 12, for any initialization point we have

$$\mathbb{E} \mathbf{z}^k \rightarrow (I - \mathbb{E}M(A))^{-1} U \mathbb{E}[N(A)] \mathbf{b},$$

where U is as defined in (56), i.e.,

$$U \triangleq \underbrace{(0_d, \dots, 0_d, I_d)^\top}_{p-1 \text{ times}} \in \mathbb{R}^{pd \times d}.$$

For the sake of readability we omit the functional dependency on A , as well as the expectation operator symbol. Combining this with Equation (58) yields

$$U^\top (I - M)^{-1} U N \mathbf{b} = -A^{-1} \mathbf{b}.$$

Since this holds for any $\mathbf{b} \in \mathbb{R}^d$, we get

$$U^\top (I - M)^{-1} U N = -A^{-1}.$$

Evidently, N is an invertible matrix. Therefore,

$$U^\top (I - M)^{-1} U = -(NA)^{-1}. \quad (68)$$

Now, recall that

$$M = \begin{pmatrix} 0_d & I_d & & & \\ 0_d & I_d & & & \\ & & \ddots & & \\ & & & \ddots & \\ C_0 & \dots & C_{p-2} & C_{p-1} \end{pmatrix},$$

where C_j denote the coefficient matrices. We partition M as follows

$$\left(\begin{array}{c|c|c} M_{11} & M_{12} & \\ \hline M_{21} & M_{22} & \\ \hline C_0 & \dots & C_{p-2} \end{array} \middle| \begin{array}{c} I_d \\ I_d \\ \vdots \\ 0_d \\ C_{p-1} \end{array} \right).$$

The l.h.s of Equation (68) is in fact the inverse of the Schur Complement of $I - M_{11}$ in $I - M$, i.e.,

$$\begin{aligned}
(I - M_{22} - M_{21}(I - M_{11})^{-1}M_{12})^{-1} &= -(NA)^{-1} \\
I - M_{22} - M_{21}(I - M_{11})^{-1}M_{12} &= -NA \\
M_{22} + M_{21}(I - M_{11})^{-1}M_{12} &= I + NA.
\end{aligned} \quad (69)$$

Moreover, it is straightforward to verify that

$$(I - M_{11})^{-1} = \begin{pmatrix} I_d & I_d & & \\ & I_d & I_d & \\ & & \ddots & \\ & & & I_d \end{pmatrix}$$

Plugging in this into (69) yields

$$\sum_{i=0}^{p-1} C_i = I + NA,$$

or equivalently,

$$\mathcal{L}(1, A) = -NA \quad (70)$$

This concludes the proof.

C.3 Proof of Lemma 6

First, we prove the following Lemma. Let us denote

$$q_r^*(z) \triangleq (z - (1 - \sqrt[r]{r}))^p,$$

where r is some non-negative constant.

Lemma 15 Suppose $q(z)$ is a monic polynomial of degree p with complex coefficients. Then,

$$\rho(q(z)) \leq \left| \sqrt[p]{|q(1)|} - 1 \right| \iff q(z) = q_{|q(1)|}^*(z).$$

Proof As the \Leftarrow statement is clear, we prove here only the \Rightarrow part. By the fundamental theorem of algebra $q(z)$ has p roots. Let us denote these roots by $\zeta_1, \zeta_2, \dots, \zeta_p \in \mathbb{C}$. Equivalently,

$$q(z) = \prod_{i=1}^p (z - \zeta_i).$$

Let us denote $r \triangleq |q(1)|$. If $r \geq 1$ we get

$$\begin{aligned} r &= \left| \prod_{i=1}^p (1 - \zeta_i) \right| = \prod_{i=1}^p |1 - \zeta_i| \leq \prod_{i=1}^p (1 + |\zeta_i|) \\ &\leq \prod_{i=1}^p (1 + |\zeta_i|^r) = \prod_{i=1}^p (1 + \zeta_i^r - 1) = r. \end{aligned} \tag{71}$$

Consequently, Inequality (71) becomes an equality. Therefore,

$$|1 - \zeta_i| = 1 + |\zeta_i| = \zeta_i^r, \quad \forall i \in [p]. \tag{72}$$

Now, for any two complex numbers $w, z \in \mathbb{C}$ it holds that

$$|w + z| = |w| + |z| \iff \text{Arg}(w) = \text{Arg}(z).$$

Using this fact in the first equality of Equation (72), we get that $\text{Arg}(-\zeta_i) = \text{Arg}(1) = 0$, i.e., ζ_i are negative real numbers. Writing $-\zeta_i$ in the second equality of Equation (72) instead of $|\zeta_i|$, yields $1 - \zeta_i = \zeta_i^r$, concluding this part of the proof.

The proof for $r \in [0, 1)$ follows along the same lines, only this time we use the reverse triangle inequality,

$$\begin{aligned} r &= \prod_{i=1}^p |1 - \zeta_i| \geq \prod_{i=1}^p (1 - |\zeta_i|) \geq \prod_{i=1}^p (1 - |\zeta_i|^r) \\ &= \prod_{i=1}^p (1 - (1 - \zeta_i^r)) = r. \end{aligned}$$

Note that in the first inequality, we used the fact that $r \in [0, 1) \implies |\zeta_i| \leq 1$ for all i . ■

The proof for Lemma 6 now follows easily. In case $q(1) \geq 0$, if $q(z) = (z - (1 - \zeta^r))^p$ then, clearly,

$$\rho(q(z)) = \rho((z - (1 - \zeta^r))^p) = |1 - \zeta^r|.$$

Otherwise, according to Lemma 15

$$\rho(q(z)) > |1 - \zeta^r|.$$

In case $q(1) \leq 0$, we must use the assumption that the coefficients are reals (see Remark 16), in which case the mere fact that

$$\lim_{z \in \mathbb{R}, z \rightarrow \infty} q(z) = \infty$$

combined with the Mean-Value theorem implies $\rho(q(z)) \geq 1$. This concludes the proof.

Remark 16 The requirement that the coefficients of $q(z)$ should be real is inevitable. To see why, consider the following polynomial,

$$u(z) = \left(z - \left(1 - 0.5e^{\frac{ix}{3}} \right) \right)^3.$$

Although $u(1) = \left(1 - \left(1 - 1/2e^{\frac{ix}{3}} \right) \right)^3 = -1/8 \leq 0$, it holds that $\rho(u(z)) < 1$. Indeed, not all the coefficients of $u(z)$ are real. Notice that the claim does hold for degree ≤ 3 , regardless of the additional assumption on the coefficients of $u(z)$.

C.4 Bounding the Spectral Radius of Diagonal Inversion Matrices from below Using Scalar Inversion Matrices

We prove a lower bound on the convergence rate of p -SCLI optimization algorithm with diagonal inversion matrices. In particular, we show that for any p -SCLI optimization algorithm whose inversion matrix is diagonal there exists a quadratic function for which it does not perform better than p -SCLI optimization algorithms with scalar inversion matrix. We prove the claim for $d = 2$. The general case follows by embedding the 2-dimensional case as a principal sub-matrix in some higher dimensional matrix in $S^d(\mu, L)$. Also, although here we prove for deterministic p -SCLIs, the stochastic case is straightforward.

Let \mathcal{A} be a p -SCLI optimization algorithm with iteration matrix $M(X)$ (defined in (57)) and diagonal inversion matrix $N(X)$. Define the following positive definite matrix

$$B = \begin{pmatrix} \frac{L+\mu}{2} & \frac{L-\mu}{2} \\ \frac{L-\mu}{2} & \frac{L+\mu}{2} \end{pmatrix}, \tag{73}$$

and note that $\sigma(B) = \{\mu, L\}$. As usual, we wish to derive a lower bound on $\rho(M(B))$. To this end, denote

$$N \triangleq N(B) = \begin{pmatrix} \alpha & 0 \\ 0 & \beta \end{pmatrix},$$

where $\alpha, \beta \in \mathbb{R}$. By a straightforward calculation we get that the eigenvalues of $-NB$ are

$$\begin{aligned} \sigma_{1,2}(\alpha, \beta) &= \frac{-(\alpha + \beta)(L + \mu)}{4} \pm \sqrt{\left(\frac{(\alpha + \beta)(L + \mu)}{4} \right)^2 - \alpha\beta L\mu} \\ &= \frac{-(\alpha + \beta)(L + \mu)}{4} \pm \sqrt{(\alpha + \beta)^2 \frac{(L - \mu)^2}{16} + \frac{1}{4}(\alpha - \beta)^2 L\mu}. \end{aligned} \tag{74}$$

Using similar arguments to the ones which were applied in the scalar case, we get that both eigenvalues of $-NB$ must be strictly positive as well as satisfy

$$\rho(M) \geq \min_{\alpha, \beta} \max \left\{ \left| \sqrt{\sigma_1(\alpha, \beta)} - 1 \right|, \left| \sqrt{\sigma_2(\alpha, \beta)} - 1 \right| \right\}. \quad (75)$$

Equation (74) shows that the minimum of the preceding is obtained for $\nu = \frac{\alpha+\beta}{2}$, which simplifies to

$$\begin{aligned} \max \left\{ \left| \sqrt{\sigma_1(\alpha, \beta)} - 1 \right|, \left| \sqrt{\sigma_2(\alpha, \beta)} - 1 \right| \right\} &\geq \max \left\{ \left| \sqrt{\sigma_1(\nu, \nu)} - 1 \right|, \left| \sqrt{\sigma_2(\nu, \nu)} - 1 \right| \right\} \\ &= \max \left\{ \left| \sqrt{-\nu\mu} - 1 \right|, \left| \sqrt{-\nu L} - 1 \right| \right\}. \end{aligned}$$

The rest of the analysis is carried out similarly to the scalar case, resulting in

$$\rho(M(B)) \geq \frac{\sqrt{\kappa} - 1}{\sqrt{\kappa} + 1}.$$

Abstract

Control of non-episodic, finite-horizon dynamical systems with uncertain dynamics poses a tough and elementary case of the exploration-exploitation trade-off. Bayesian reinforcement learning, reasoning about the effect of actions and future observations, offers a principled solution, but is intractable. We review, then extend an old approximate approach from control theory—where the problem is known as *dual control*—in the context of modern regression methods, specifically generalized linear regression. Experiments on simulated systems show that this framework offers a useful approximation to the intractable aspects of Bayesian RL, producing structured exploration strategies that differ from standard RL approaches. We provide simple examples for the use of this framework in (approximate) Gaussian process regression and feedforward neural networks for the control of exploration.

Keywords: reinforcement learning, control, Gaussian processes, filtering, Bayesian inference

1. Introduction

The exploration-exploitation trade-off is a central problem of learning in interactive settings, where the learner’s actions influence future observations. In episodic settings, where the control problem is re-instantiated repeatedly with unchanged dynamics, comparably simple notions of exploration can succeed. E.g., assigning an *exploration bonus* to uncertain options (Macready and Wolpert, 1998; Audibert et al., 2009) or acting optimally under one sample from the current probabilistic model of the environment (*Thompson sampling*, see Thompson, 1933; Chapelle and Li, 2011), can perform well (Dearden et al., 1999; Kolter and Ng, 2009; Srinivas et al., 2010). Such approaches, however, do not model the effect of actions on future beliefs, which limits the potential for the balancing of exploration and exploitation. This issue is most drastic in the non-episodic case, the control of a single, ongoing trial. Here, the controller cannot hope to be returned to known states, and exploration must be carefully controlled to avoid disaster.

A principled solution to this problem is offered by *Bayesian reinforcement learning* (Duff, 2002; Poupart et al., 2006; Hennig, 2011): A probabilistic belief over the dynamics and cost of the environment can be used not just to simulate and plan trajectories, but also to reason about changes to the belief from future observations, and their influence on future decisions. An elegant formulation is to combine the physical state with the parameters of the probabilistic model into an augmented dynamical description, then aim to control this system. Due to the inference, the augmented system invariably has strongly nonlinear dynamics, causing prohibitive computational cost—even for finite state spaces and discrete time (Poupart et al., 2006), all the more for continuous space and time (Hennig, 2011).

The idea of augmenting the physical state with model parameters was noted early, and termed *dual control*, by Feldbaum (1960–1961). It seems both conceptual and—by the standards of the time—computational complexity hindered its application. An exception is a strand of several works by Meier, Bar-Shalom, and Tse (Tse et al., 1973; Tse and Bar-Shalom, 1973; Bar-Shalom and Tse, 1976; Bar-Shalom, 1981). These authors developed techniques for limiting the computational cost of dual control that, from a modern perspective, can be seen as a form of approximate inference for Bayesian reinforcement learning. While the Bayesian reinforcement learning community is certainly aware of their work (Duff, 2002; Hennig, 2011), it has not found widespread attention. The first purpose of this paper is to cast their dual control algorithm as an approximate inference technique for Bayesian RL in parametric Gaussian (general least-squares) regression. We then extend the framework with ideas from contemporary machine learning. Specifically, we explain how it can in principle be formulated non-parametrically in a Gaussian process context, and then investigate simple, practical finite-dimensional approximations to this result. We also give a simple, small-scale example for the use of this algorithm for dual control if the environment model is constructed with a feedforward neural network rather than a Gaussian process.

2. Model and Notation

Throughout, we consider discrete-time, finite-horizon dynamic systems (POMDPs) of form

$$x_{k+1} = f_k(x_k, u_k) + \xi_k \quad (\text{state dynamics}) \quad y_k = Cx_k + \gamma_k \quad (\text{observation model}).$$

At time $k \in \{0, \dots, T\}$, $x_k \in \mathbb{R}^n$ is the state, $\xi_k \sim \mathcal{N}(0, Q)$ is a Gaussian disturbance. The control input (continuous action) is denoted u_k ; for simplicity we will assume scalar $u_k \in \mathbb{R}$ throughout. Measurements $y_k \in \mathbb{R}^d$ are observations of x_k , corrupted by Gaussian noise $\gamma_k \sim \mathcal{N}(0, R)$. The generative model thus reads $p(x_{k+1} | x_k, u_k) = \mathcal{N}(x_{k+1}; f_k(x_k, u_k), Q)$ and $p(y_k | x_k) = \mathcal{N}(y_k; Cx_k, R)$, with a linear map $C \in \mathbb{R}^{d \times n}$. Trajectories are vectors $\mathbf{x} = [x_0, \dots, x_T]$, and analogously for \mathbf{u}, \mathbf{y} . We will occasionally use the subset notation $\mathbf{y}_{k:j} = [y_k, \dots, y_j]$. We further assume that dynamics f_k are not known, but can be described up to Gaussian uncertainty by a general linear model with nonlinear features $\phi: \mathbb{R}^n \rightarrow \mathbb{R}^m$ and uncertain matrices A_k, B_k .

$$x_{k+1} = A_k \phi(x_k) + B_k u_k + \xi_k, \quad A_k \in \mathbb{R}^{n \times m}, B_k \in \mathbb{R}^{n \times 1}. \quad (1)$$

To simplify notation, we reshape the elements of A_k and B_k into a parameter vector $\theta_k = [\text{vec}(A_k); \text{vec}(B_k)] \in \mathbb{R}^{(m+1)n}$, and define the reshaping transformations $A(\theta_k): \theta_k \mapsto A_k$

and $B(\theta_k) : \theta_k \mapsto B_k$. At initialization, $k = 0$, the belief over states and parameters is assumed to be Gaussian

$$p \left(\begin{bmatrix} x_0 \\ \theta_0 \end{bmatrix} \right) = \mathcal{N} \left(\begin{bmatrix} x_0 \\ \theta_0 \end{bmatrix}; \begin{bmatrix} \hat{x}_0 \\ \hat{\theta}_0 \end{bmatrix}, \begin{bmatrix} \Sigma_{x_0}^{xx} & \Sigma_{x_0}^{x\theta} \\ \Sigma_{\theta_0}^{x0} & \Sigma_{\theta_0}^{\theta\theta} \end{bmatrix} \right). \quad (2)$$

The control response $B_k u_k$ is linear, a common assumption for physical systems. Nonlinear mappings can be included in a generic form $\phi(x_k, u_k)$, but complicate the following derivations and raise issues of identifiability. For simplicity, we also assume that the dynamics do not change through time: $p(\theta_{k+1} | \theta_k) = \delta(\theta_{k+1} - \theta_k)$. This could be relaxed to an autoregressive model $p(\theta_{k+1} | \theta_k) = \mathcal{N}(\theta_{k+1}; D\theta_k, \Xi)$, which would give additive terms in the derivations below. Throughout, we assume a finite horizon with terminal time T and a quadratic cost function in state and control

$$\mathcal{L}(\mathbf{x}, \mathbf{u}) = \left[\sum_{k=0}^{T-1} (x_k - r_k)^\top W_k (x_k - r_k) + \sum_{k=0}^{T-1} u_k^\top U_k u_k \right],$$

where $\mathbf{r} = [r_0, \dots, r_{T-1}]$ is a target trajectory. W_k and U_k define state and control cost, they can be time-varying. The goal, in line with the standard in both optimal control and reinforcement learning, is to find the control sequence \mathbf{u} that, at each k , minimizes the *expected cost* to the horizon

$$J_k(\mathbf{u}_{k:T-1}; p(x_k)) = \mathbb{E}_{x_k} \left[(x_k - r_k)^\top W_k (x_k - r_k) + u_k^\top U_k u_k + J_{k+1}(\mathbf{u}_{k+1:T-1}; p(x_{k+1})) \right] | p(x_k), \quad (3)$$

where past measurements $\mathbf{y}_{1:k}$, controls $\mathbf{u}_{1:k-1}$ and prior information $p(x_0)$ are incorporated into the belief $p(x_k)$, relative to which the expectation is calculated. Effectively, $p(x_k)$ serves as a bounded rationality approximation to the true information state. Since the equation above is recursive, the final element of the cost has to be defined differently, as

$$J_T(p(x_T)) = \mathbb{E}_{x_T} \left[(x_T - r_T)^\top W_T (x_T - r_T) \right] | p(x_T)$$

(that is, without control input and future cost). The optimal control sequence minimizing this cost will be denoted \mathbf{u}^* , with associated cost

$$J_k^*(p(x_k)) = \min_{\mathbf{u}_k} \mathbb{E}_{x_k} \left[(x_k - r_k)^\top W_k (x_k - r_k) + u_k^\top U_k u_k + J_{k+1}^*(p(x_{k+1})) \right] | p(x_k). \quad (4)$$

This recursive formulation, if written out, amounts to alternating minimization and expectation steps. As u_k influences x_{k+1} and y_{k+1} , it enters the latter expectation nonlinearly. Classic optimal control is the linear base case ($\phi(x) = x$) with known θ , where \mathbf{u}^* can be found by dynamic programming (Bellman, 1961; Bertsekas, 2005).

3. Bayesian RL and Dual Control

Feldbaum (1960–1961) coined the term *dual control* to describe the idea now also known as Bayesian reinforcement learning in the machine learning community: While adaptive control only considers past observations, dual control also takes future observations into account. This is necessary because all other ways to deal with uncertain parameters have substantial

drawbacks. Robust controllers, for example, sacrifice performance due to their conservative design; adaptive controllers based on *certainly equivalence* (where the uncertainty of the parameters is not taken into account but only their mean estimates) do not move exploration, so that all learning is purely passive. For most systems it is obvious that more excitation leads to better estimation, but also to worse control performance. Attempts at finding a compromise between exploration and exploitation are generally subsumed under the term “dual control” in the control literature. It can only be achieved by taking the future effect of current actions into account.

It has been shown that optimal dual control is practically unsolvable for most cases (Aoki, 1967), with a few examples where solutions were found for simple systems (e.g., Sternby, 1976). Instead, a large number of *approximate* formulations of the dual control problem were formulated in the decades since then. This includes the introduction of perturbation signals (e.g., Jacobs and Patchell, 1972), constrained optimization to limit the minimal control signal or the maximum variance, serial expansion of the loss function (e.g., Tse et al., 1973) or modifications of the loss function (e.g., Fliatow and Unbehauen, 2004). A comprehensive overview of dual control methods is given by Wittemark (1995). A historical side-effect of these numerous treatments is that the meaning of the term “dual control” has evolved over time, and is now applied both to the fundamental concept of optimal exploration, and to methods that only approximate this notion to varying degree. Our treatment below studies one such class of practical methods that aim to approximate the true dual control solution.

The central observation in Bayesian RL / dual control is that both the states x and the parameters θ are subject to uncertainty. While part of this uncertainty is caused by randomness, part by lack of knowledge, both can be captured in the same way by probability distributions. States and parameters can thus be subsumed in an *augmented state* (Feldbaum, 1960–1961; Duff, 2002; Pompart et al., 2006) $z_k^\top = (x_k^\top \ \theta_k^\top) \in \mathbb{R}^{(m+2)n}$. In this notation, the optimal exploration–exploitation trade-off—relative to the probabilistic priors defined above—can be written compactly as optimal control of the augmented system with a new observation model $p(y_k | z_k) = \mathcal{N}(y_k; \tilde{C}z_k, R)$ using $\tilde{C} = [C \ \mathbf{0}]$ and a cost analogous to Eq. (3).

Unfortunately, the dynamics of this new system are nonlinear, even if the original physical system is linear. This is because inference is always nonlinear and future states influence future parameter beliefs, and vice versa. A first problem, not unique to dual control, is thus that inference is not analytically tractable to use under the Gaussian assumptions above (Aoki, 1967). The standard remedy is to get approximations, most popularly the linearization of the extended Kalman filter (e.g., Särkkä, 2013). This gives a sequence of approximate Gaussian likelihood terms. But even so, incorporating these Gaussian likelihood terms into future dynamics is still intractable, because it involves expectations over rational polynomial functions, whose degree increases with the length of the prediction horizon. The following section provides an intuition for this complexity, but also the descriptive power of the augmented state space.

As an aside, we note that several authors (Kaippen, 2011; Hennig, 2011) have previously pointed out another possible construction of an augmented state: incorporating not the actual *value* of the parameters θ_k in the state, but the parameters μ_k, Σ_k of a Gaussian belief $p(\theta_k | \mu_k, \Sigma_k) = \mathcal{N}(\theta_k; \mu_k, \Sigma_k)$ over them. The advantage of this is that, if the state x_k is observed without noise, these belief parameters follow stochastic differential equations—more

precisely, Σ_k follows an ordinary (deterministic) differential equation, while μ_k follows a stochastic differential equation—and it can then be attempted to solve the control problem for these differential equations more directly.

While it can be a numerical advantage, this formulation of the augmented state also has some drawbacks, which is why we have here decided not to adopt it: First, the simplicity of the directly formalizable SDE vanishes in the POMDP settings, i.e. if the state is not observed without noise. If the state observations are corrupted, the exact belief state is not a Gaussian process, so that the parameters μ_k and Σ_k have no natural meaning. Approximate methods can be used to retain a Gaussian belief (and we will do so below), but the dynamics of μ_k , Σ_k are then intertwined with the chosen approximation (i.e. changing the approximation changes their dynamics), which causes additional complication. More generally speaking, it is not entirely natural to give differing treatment to the state x_k and parameters θ_k : Both state and parameters should thus be treated within the same framework; this also allows extending the framework to the case where also the parameters do follow an SDE.

3.1 A Toy Problem

To provide an intuition for sheer complexity of optimal dual control, consider the perhaps simplest possible example: the linear, scalar system

$$x_{k+1} = ax_k + bu_k + \xi_k, \quad (5)$$

with target $r_k = 0$ and noise-free observations ($R = 0$). If a and b are known, the optimal u_k to drive the current state x_k to zero in one step can be trivially verified to be

$$u_{k,\text{oracle}}^* = -\frac{abx_k}{U + b^2}.$$

Let now parameter b be uncertain, with current belief $p(b) = \mathcal{N}(b; \mu_k, \sigma_k^2)$ at time k . The naive option of simply replacing the parameter with the current mean estimate is known as *certainty equivalence (CE)* control in the dual control literature (e.g., Bar-Shalom and Tse, 1974). The resulting control law is

$$u_{k,\text{CE}}^* = -\frac{a\mu_k x_k}{U + \mu_k^2}.$$

It is used in many adaptive control settings in practice, but has substantial deficiencies: If the uncertainty is large, the mean is not a good estimate, and the CE controller might apply completely useless control signals. This often results in large overshoots at the beginning or after parameter changes.

A slightly more elaborate solution is to compute the expected cost $\mathbb{E}_b[x_{k+1}^2 + Uu_k^2 | \mu_k, \sigma_k^2]$ and then optimize for u_k . This gives *optimal feedback (OF)* or “cautious” control (Dreyfus, 1964)¹:

$$u_{k,\text{OF}}^* = -\frac{a\mu_k x_k}{U + \sigma_k^2 + \mu_k^2}. \quad (6)$$

1. Dreyfus used the term “open loop optimal feedback” for his approach, a term that is misleading to modern readers, because it is in fact a closed-loop algorithm.

This control law reduces control actions in cases of high parameter uncertainty. This mitigates the main drawback of the CE controller, but leads to another problem: Since the OF controller decreases control with rising uncertainty, it can entirely prevent learning. Consider the posterior on b after observing x_{k+1} , which is a closed-form Gaussian (because u_k is chosen by the controller and has no uncertainty):

$$p(b | \mu_{k+1}, \sigma_{k+1}^2) = \mathcal{N}\left(b; \frac{\sigma_k^2 u_k (bu_k + \xi_k) + \mu_k Q}{u_k^2 \sigma_k^2 + Q}, \frac{\sigma_k^2 Q}{u_k^2 \sigma_k^2 + Q}\right) \quad (7)$$

(b shows up in the fully observed $x_{k+1} = ax_k + bu_k + \xi_k$). The dual effect here is that the updated σ_{k+1}^2 depends on u_k . For large values of σ_k^2 , according to (6), $u_{k,\text{OF}} \rightarrow 0$, and the new uncertainty $\sigma_{k+1}^2 \rightarrow \sigma_k^2$. The system thus will never learn or act, even for large x_k . This is known as the “turn-off phenomenon” (Aoki, 1967; Bar-Shalom, 1981).

However, the derivation for OF control above amounts to minimizing Eq. (3) for the myopic controller, where the horizon is only a single step long ($T = 1$). Therefore, OF control is indeed optimal for this case. By the optimality principle (e.g., Bertsekas, 2005), this means that Eq. (6) is the optimal solution for the last step of every controller. But since it does not show any form of exploration or “probing” (Bar-Shalom and Tse, 1976), a myopic controller is not enough to show the dual properties.

In order to expose the dual features, the horizon has to be at least of length $T = 2$. Since the optimal controller follows Bellman’s equation, the solution proceeds backwards. The solution for the second control action u_1 is identical to the solution of the myopic controller (6); but after applying the first control action u_0 , the belief over the unknown parameter b needs an update according to Eq. (7), resulting in

$$u_1^* = -\left[U + \frac{\sigma_0^2 Q}{u_0^2 \sigma_0^2 + Q} + \left(\frac{\sigma_0^2 u_0 (bu_0 + \xi_0) + \mu_0 Q}{u_0^2 \sigma_0^2 + Q} \right)^2 \right]^{-1} \left[a \frac{\sigma_0^2 u_0 (bu_0 + \xi_0) + \mu_0 Q}{u_0^2 \sigma_0^2 + Q} x_1 \right]. \quad (8)$$

Inserting into Eq. (4) gives

$$\begin{aligned} J_0^*(x_0) &= \min_{u_0} \mathbb{E}_{x_0} \left[Wx_0^2 + Uu_0^2 + \min_{u_1} \mathbb{E}_{x_1} \left[Wx_1^2 + Uu_1^2 + \mathbb{E}_{x_2} [Wx_2^2] \right] \right] \\ &= \min_{u_0} \left[Wx_0^2 + Uu_0^2 + \mathbb{E}_{\xi_1, b} [Wx_1^2 + U(u_1^*)^2 + \mathbb{E}_{\xi_1, b} [W(x_1 + bu_1^* + \xi_1)^2 | \mu_1, \sigma_1] | \mu_0, \sigma_0] \right]. \end{aligned} \quad (9)$$

Since u_1^* from Eq. (8) is already a rational function of fourth order in b , and shows up quadratically in Eq. (9), the relevant expectations cannot be computed in closed form (Aoki, 1967). For this simple case though, it is possible to compute the optimal dual control by performing the expectation through sampling b, ξ_0, ξ_1 from the prior. Fig. 1 shows such samples of $\mathcal{L}(u_0)$ (in gray; one single sample highlighted in orange), and the empirical expectation $J(u_0)$ in dashed green. Each sample is a rational function of even leading order. In contrast to the CE cost, the dual cost is much narrower, leading to more cautious behavior of the dual controller. The average dual cost has its minima not at zero, but to either side of it, reflecting the optimal amount of exploration in this particular belief state.

While it is not out of the question that the Monte Carlo solution can remain feasible for larger horizons, we are not aware of successful solutions for continuous state spaces

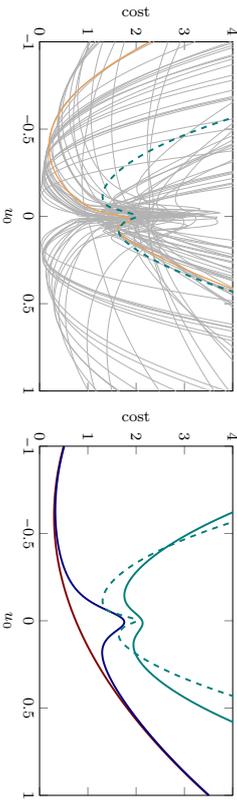

Figure 1: **Left:** Computing the $T = 2$ dual cost for the simple system of Eq. (5). Costs $\mathcal{L}(u_0)$ under optimal control on u_1 for sampled parameter b (thin gray; one sample highlighted, orange). Expected dual cost $J(u_0)$ under u_1^* (dashed green). The optimal u_0^* lies at the minimum of the dashed green line. **Right:** Comparison of sampling (dashed green; thin gray; samples) to three approximations: CE (red) and CE with Bayesian exploration bonus (blue). The solid green line is the approximate dual control constructed in Section 4. See also Sec. 6.1 for details.

(however, see Pompart et al., 2006, for a sampling solution to Bayesian reinforcement learning in discrete spaces, including notes on the considerable computational complexity of this approach). The next section describes a tractable *analytic* approximation that does not involve samples.

4. Approximate Dual Control for Linear Systems

In 1973, Tse et al. (1973) constructed theory and an algorithm (Tse and Bar-Shalom, 1973) for approximate dual (AD) control, based on the series expansion of the cost-to-go. This is related to differential dynamic programming for the control of nonlinear dynamic systems (Mayne, 1966). It separates into three conceptual steps (described in Sec. 4.1–4.3), which together yield what, from a contemporary perspective, amounts to a structured Gaussian approximation to Bayesian RL.

- ① Find an optimal trajectory for the deterministic part of the system under the mean model: the *nominal* trajectory under certainty equivalent control. For linear systems this is easy (see below), for nonlinear ones it poses a nontrivial, but feasible nonlinear model predictive control problem (Allgöwer et al., 1999; Diehl et al., 2009). It yields a nominal trajectory, relative to which the following step constructs a tractable quadratic expansion.
- ② Around the nominal trajectory, construct a local *quadratic expansion* that approximates the effects of future observations. Because the expansion is quadratic, an optimal control law relative to the deterministic system—the *perturbation control*—can be constructed by dynamic programming. Plugging this perturbation control into the residual dynamics of the approximate quadratic system gives an approximation for the cost-to-go. This step adds the cost of uncertainty to the deterministic control cost.

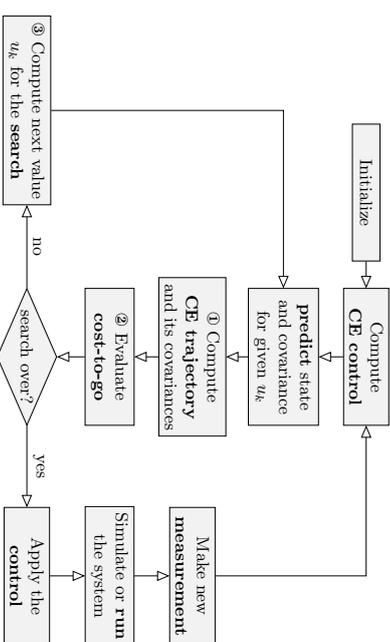

Figure 2: Flow-chart of the approximate dual control algorithm to show the overall structure. Adapted from Tse and Bar-Shalom (1973). The left cycle is the inner loop, performing the nonlinear optimization.

- ③ In the current time step k , perform the prediction for an arbitrary control input u_k (as opposed to the analytically computed control input for later steps). Optimize u_k numerically by repeated computation of steps ① and ② at varying u_k to minimize the approximate cost.

These three steps will be explained in detail in the subsequent sections. The interplay between the different parts of the algorithm is shown in Figure 2.

The abstract introductory work Tse et al. (1973) is relatively general, but the explicit formulation in Tse and Bar-Shalom (1973) only applies to linear systems. Since both works are difficult to parse for contemporary readers, the following sections thus first provide a short review, before we extend to more modern concepts. In this section, we follow the more transparent case of a linear system from Tse and Bar-Shalom (1973), i.e. $\phi(x) = x$ in Eq. (1). For the augmented state z , this still gives a nonlinear system, because θ and x interact multiplicatively

$$z_{k+1} = \begin{pmatrix} x_{k+1} \\ \theta_{k+1} \end{pmatrix} = \begin{pmatrix} A(\theta_k) & 0 \\ 0 & \mathbf{I} \end{pmatrix} z_k + \begin{pmatrix} B(\theta_k) \\ 0 \end{pmatrix} u_k + \begin{pmatrix} \xi_k \\ 0 \end{pmatrix} =: \tilde{f}(z_k, u_k). \quad (10)$$

The parameters θ are assumed to be deterministic, but not known to the controller. This uncertainty is captured by the distribution $p(\theta)$ representing the lack of knowledge.

4.1 Certainty Equivalent Control Gives a Nominal Reference Trajectory

The certainty equivalent model is built on the assumption that the uncertain θ coincide with their most likely value, the mean $\bar{\theta}$ of $p(\theta)$, and that the system propagates deterministically without noise. This means that the nominal parameters $\bar{\theta}$ are the current mean values $\hat{\theta}$,

which decouples θ entirely from x in Eq. (10), and the optimal control for the finite horizon problem can be computed by dynamic programming (DP) (Aoki, 1967), yielding an optimal linear control law

$$\bar{u}_j^* = -(\bar{B}^\top \bar{K}_{j+1} \bar{B} + U_j)^{-1} \bar{B}^\top [\bar{K}_{j+1} \bar{A} \bar{x}_j + \bar{p}_{j+1}],$$

where we have momentarily simplified notation to $\bar{A} = A(\bar{\theta}_j)$, $\bar{B} = B(\bar{\theta}_j)$, $\forall j$, because the $\bar{\theta}_j$ are constant. The \bar{K}_j and \bar{p}_j for $j = k+1, \dots, T$ are defined and computed recursively as

$$\begin{aligned} \bar{K}_j &= \bar{A}^\top (\bar{K}_{j+1} - \bar{K}_{j+1} \bar{B} (\bar{B}^\top \bar{K}_{j+1} \bar{B} + U_j)^{-1} \bar{B}^\top \bar{K}_{j+1}) \bar{A} + W_j & \bar{K}_T &= W_T \\ \bar{p}_j &= \bar{A}^\top (\bar{p}_{j+1} - \bar{K}_{j+1} \bar{B} (\bar{B}^\top \bar{K}_{j+1} \bar{B} + U_j)^{-1} \bar{B}^\top \bar{K}_{j+1}) \bar{p}_{j+1} - W_j r_j & \bar{p}_T &= -W_T r_T, \end{aligned}$$

where r is the reference trajectory to be followed. This CE controller gives the *nominal trajectory* of inputs $\bar{u}_{k:T-1}$ and states $\bar{x}_{k:T}$, from the current time k to the horizon T . The true future trajectory is subject to stochasticity and uncertainty, but the deterministic nominal trajectory \bar{x} , with its optimal control \bar{u}^* and associated nominal cost $\bar{J}_k^* = \mathcal{L}(\bar{x}_{k:T}, \bar{u}_{k:T}^*)$ provides a base, relative to which an approximation will be constructed.

4.2 Quadratic Expansion Around the Nominal Defines Cost of Uncertainty

The central idea of AD control is to project the nonlinear objective $J_k(\mathbf{u}_{k:T-1}, p(x_k))$ of Eq. (3) into a quadratic, by locally linearizing around the nominal trajectory \mathbf{x} and maintaining a joint Gaussian belief.

To do so, we introduce small perturbations around nominal cost, states, and control: $\Delta J_j = J_j - \bar{J}_j$, $\Delta z_j = z_j - \bar{z}_j$, and $\Delta u_j = u_j - \bar{u}_j$. These perturbations arise from both the stochasticity of the state and the parameter uncertainty. Note that a change in the state results in a change of the control signal, because the optimal control signal in each step depends on the state. Even though the origin of the uncertainties is different (Δx arises from stochasticity and $\Delta \theta$ from the lack of knowledge), both can be modeled in a joint probability distribution.

Approximate Gaussian filtering ensures that beliefs over Δz remain Gaussian:

$$p(\Delta z_j) = \mathcal{N} \left[\begin{pmatrix} \Delta x_j \\ \Delta \theta_j \end{pmatrix}; \begin{pmatrix} \Sigma_{xx} & \Sigma_{x\theta} \\ 0 & \Sigma_{\theta\theta} \end{pmatrix} \right].$$

Note that shifting the mean to the nominal trajectory does not change the uncertainty. Note further that the expected perturbation in the parameters is nil. This is because the parameters are assumed to be deterministic and are not affected by any state or input.

Calculating the Gaussian filtering updates is in principle not possible for future measurements, since it violates the causality principle (Glad and Ljung, 2000). Nonetheless, it is possible to use the *expected* measurements to simulate the effects of the future measurements on the uncertainty, since these effects are deterministic. This is sometimes referred to as preposterior analysis (Raiffa and Schlaifer, 1961).

To second order around the nominal trajectory, the cost is approximated by

$$J_k(\mathbf{u}_{k:T-1}, p(x_k)) = \bar{J}_k^* + \Delta J_k \approx \bar{J}_k^* + \Delta \bar{J}_k,$$

where \bar{J}_k^* is the optimal cost for the nominal system and $\Delta \bar{J}_k$ is the approximate additional cost from the perturbation:

$$\Delta \bar{J}_k := \mathbb{E}_{\mathbf{x}_{k:T}} \left[\sum_{j=k}^T \left\{ (\hat{x}_j - r_j)^\top W_j \Delta x_j + \frac{1}{2} \Delta \hat{x}_j^\top W_j \Delta x_j \right\} + \sum_{j=k}^{T-1} \left\{ \bar{u}_j^\top U_j \Delta u_j + \frac{1}{2} \Delta \bar{u}_j^\top U_j \Delta u_j \right\} \right]. \quad (12)$$

Although the uncertain parameters θ do not show up explicitly in the above equation, this step captures dual effects: The uncertainty of the trajectory $\Delta \mathbf{x}$ depends on θ via the dynamics. Higher uncertainty over θ at time $j-1$ causes higher predictive uncertainty over Δx_j (for each j), and thus increases the expectation of the quadratic term $\Delta \bar{u}_j^\top W_j \Delta x_j$. Control that decreases uncertainty in θ can lower this approximate cost, modeling the benefit of exploration. For the same reason, Eq. (12) is in fact still not a quadratic function and has no closed form solution. To make it tractable, Tse and Bar-Shalom (1973) make the ansatz that all terms in the expectation of Eq. (12) can be written as $g_j + p_j^\top \Delta z_j + 1/2 \Delta z_j^\top K_j \Delta z_j$. This amounts to applying dynamic programming on the perturbed system. Expectations over the cost under Gaussian beliefs on Δz can then be computed analytically. Because all $\Delta \theta$ have zero mean, linear terms in these quantities vanish in the expectation. This allows analytic minimization of the approximate optimal cost for each time step

$$\begin{aligned} \Delta \bar{J}_j^*(p(x_j)) &= \min_{\Delta u_j} \left\{ (x_j - r_j)^\top W_j \Delta \hat{x}_{j|j} + \frac{1}{2} \Delta \hat{x}_{j|j}^\top W_j \Delta \hat{x}_{j|j} + u_j^\top U \Delta u_j + \frac{1}{2} \Delta \bar{u}_j^\top U \Delta u_j \right. \\ &\quad \left. + \frac{1}{2} \text{tr} \left[W_j \Sigma_{j-1|j}^{xx} \right] + \mathbb{E}_{\Delta \bar{x}_{j+1}} \left[\Delta \bar{J}_{j+1}^*(\mathbf{y}_{1:j+1}) \mid p(x_j) \right] \right\}, \quad (13) \end{aligned}$$

which is feasible given an explicit description of the Gaussian filtering update. It is important to note that, assuming extended Kalman filtering, the update to the mean from *expected* future observations y_{j+1} is nil. This is because we expect to see measurements consistent with the current mean estimate. Nonetheless, the (co-)variance changes depending on the control input u_j , which is the dual effect.

Following the dynamic programming equations for the perturbed problem, including the additional cost from uncertainty, the resulting cost amounts to (Tse et al., 1973)

$$\begin{aligned} \Delta \bar{J}_k^*(p(x_k)) &= \hat{g}_{k+1} + \bar{p}_{k+1}^\top \Delta \hat{z}_k + \frac{1}{2} \Delta \hat{z}_k^\top \bar{K}_{k+1} \Delta \hat{z}_k \\ &\quad + \frac{1}{2} \text{tr} \left\{ W_T \Sigma_{T|T}^{xx} + \sum_{j=k}^{T-1} \left[W_j \Sigma_{j|j}^{xx} + (\Sigma_{j+1|j} - \Sigma_{j+1|j+1}) \bar{K}_{j+1} \right] \right\} \end{aligned}$$

(where we have neglected second-order effects of the dynamics). Recalling that $\Delta \hat{z} = 0$ and dropping the constant part, the dual cost can be approximated to be

$$J_k^d = \frac{1}{2} \text{tr} \left\{ W_T \Sigma_{T|T}^{xx} + \sum_{j=k}^{T-1} \left[W_j \Sigma_{j|j}^{xx} + (\Sigma_{j+1|j} - \Sigma_{j+1|j+1}) \bar{K}_{j+1} \right] \right\} \quad (= \Delta \bar{J}_k^* - \text{const})$$

where the recursive equation

$$\bar{K}_j = \bar{A}^\top (\bar{K}_{j+1} - \bar{K}_{j+1} \bar{B} (\bar{B}^\top \bar{K}_{j+1} \bar{B} + U_j)^{-1} \bar{B}^\top \bar{K}_{j+1}) \bar{A} + \bar{W}_j \quad \bar{K}_T = \bar{W}_T$$

is defined for the augmented system (10), with $\tilde{A} = \frac{\partial \tilde{f}}{\partial \tilde{x}}$, $\tilde{B} = \frac{\partial \tilde{f}}{\partial \tilde{u}}$ and $\tilde{W}_j = \text{blkdiag}(W_j, \mathbf{0})$. The approximation to the overall cost is then $J_k^* + J_k^d$, which is used in the subsequent optimization procedure.

4.3 Optimization of the Current Control Input Gives Approximate Dual Control

The last step ③ amounts to the outer loop of the overall algorithm. A gradient-free black-box optimization algorithm is used to find the minimum of the dual cost function. In every step, this algorithm proposes a control input u_k for which the dual cost is evaluated.

Depending on u_k , approximate filtering is carried out to the horizon. The perturbation control is plugged into Eq. (13) to give an analytic, recursive definition for K_j , and an approximation for the dual cost J_k^d as a function of the current control input u_k .

Nonlinear optimization—through repetitions of steps ① and ② for proposed locations u_k —then yields an approximation to the optimal dual control u_k^* . Conceptually the simplest part of the algorithm, this outer loop dominates computational cost, because for every location u_k the whole machinery of ① and ② has to be evaluated.

5. Extension to Contemporary Machine Learning Models

The preceding section reviewed the treatment of dual control in linear dynamical systems from Tse and Bar-Shalom (1973). In this section, we extend the approach to inference on, and dual control of, the dynamics of *nonlinear* dynamical systems. This extension is guided by the desire to use a number of popular, standard regression frameworks in machine learning: Parametric general least-squares regression, nonparametric Gaussian process regression, and feedforward neural networks (including the base case of logistic regression).

5.1 Parametric Nonlinear Systems

We begin with the generalized linear model mentioned in Eq. (1). The nonlinear features ϕ can in principle be any function (popular choices include sines and cosines, radial basis functions, sigmoids, polynomials and others), with the caveat that their structure crucially influences the properties of the model. From a modeling perspective, this approach is quite standard for machine learning. However, the dynamical learning setting requires a few adaptations: First, to allow the modeling of higher-order dynamical systems, the original states must be included. This gives features of the form $\phi(x)^T = (x^T \ \varphi(x)^T)$, consisting of the linear representation, augmented by general features φ .

The next challenge is that the optimal control for nonlinear dynamical systems cannot be optimized in closed form using dynamic programming, not even for the deterministic nominal system. Instead, we find the nominal reference trajectory using nonlinear model predictive control (Allgöwer et al., 1999; Diehl et al., 2009). In our case, we begin with a dynamic programming on a locally linearized system, then optimize nonlinearly with a numerical method across the trajectory. This adds computational cost, and requires some care to achieve stable optimization performance for specific system setups.

Filtering from observations is also more involved in the case of nonlinear dynamics. In the experiments reported below, we stayed within the extended Kalman filtering framework

to retain Gaussian beliefs over the states and parameters. Extensions of this approach to more elaborate filtering methods are an interesting direction for future work. This includes relatively standard options like unscented Kalman filtering (Uhlmann, 1995), but also more recent developments in machine learning and probabilistic control, such as analytic moment propagation where the features φ allow this (e.g., Deisenroth and Rasmussen, 2011).

The final problem is the generalization of the derivations from the preceding sections to the nonlinear dynamics. We take a relatively simplistic approach, which nevertheless turns out to work well. A linearization gives locally linear dynamics whose structure closely matches Eq. (10):

$$\begin{aligned} z_{k+1} &= \begin{pmatrix} \bar{x}_{k+1} + \Delta x_{k+1} \\ \bar{\theta}_{k+1} + \Delta \theta_{k+1} \end{pmatrix} = \begin{pmatrix} A(\theta_k) & 0 \\ 0 & I \end{pmatrix} \begin{pmatrix} \phi(\bar{x}_k + \Delta x_k) \\ \bar{\theta}_k + \Delta \theta_k \end{pmatrix} + \begin{pmatrix} B(\theta_k) \\ 0 \end{pmatrix} u_k + \begin{pmatrix} \xi_k \\ 0 \end{pmatrix} \\ &\approx \begin{pmatrix} A(\bar{\theta}_k) & 0 \\ 0 & I \end{pmatrix} \begin{pmatrix} \phi(\bar{x}_k) \\ \bar{\theta}_k \end{pmatrix} + \begin{pmatrix} B(\bar{\theta}_k) \\ 0 \end{pmatrix} u_k + \begin{pmatrix} \xi_k \\ 0 \end{pmatrix} \\ &\quad + \begin{pmatrix} A(\bar{\theta}_k) \frac{\partial}{\partial \bar{x}_k} \phi(\bar{x}_k) & \frac{\partial}{\partial \bar{\theta}_k} (A(\bar{\theta}_k) \phi(\bar{x}_k) + B(\bar{\theta}_k) u_k) \\ 0 & I \end{pmatrix} \begin{pmatrix} \Delta x_k \\ \Delta \theta_k \end{pmatrix}. \end{aligned}$$

This essentially amounts to extended Kalman filtering on the augmented state. Using this linearization, the approximation described in Sec. 4 can be applied analogously.

5.2 Nonparametric Gaussian Process Dynamics Models

The above treatment of parametric linear models makes it comparably easy to extend the description from finitely many feature functions to an infinite-dimensional feature space defining a Gaussian process (GP) dynamics model: Assume that the true dynamics function f is a draw from a Gaussian process prior $p(f) = \mathcal{GP}(f; m, \bar{\kappa})$ with prior mean function $m: \mathbb{R}^n \rightarrow \mathbb{R}^n$, and prior covariance function (kernel) $\bar{\kappa}: \mathbb{R}^n \times \mathbb{R}^n \rightarrow \mathbb{R}^n \times \mathbb{R}^n$. This is using the widely used notion of “multi-output regression” (Rasmussen and Williams, 2006, § 9.1), i.e. formulating the covariance as

$$\text{cov}(f_k(x), f_j(x')) = \bar{\kappa}_{kj}(x, x').$$

To simplify the treatment, we will assume that the covariance factors between inputs and outputs, i.e. $\bar{\kappa}_{ij}(x, x') = V_{ij} \kappa(x, x')$ with a univariate kernel $\kappa: \mathbb{R}^n \times \mathbb{R}^n \rightarrow \mathbb{R}$ and a positive semi-definite matrix $V \in \mathbb{R}^{m \times m}$ of output covariances. By Mercer’s theorem (e.g., König, 1986; Rasmussen and Williams, 2006), the kernel can be decomposed into a converging series over eigenfunctions $\phi(x)$, as

$$\kappa(x, x') = \sum_{\ell=1}^{\infty} \lambda_{\ell} \phi_{\ell}(x) \phi_{\ell}^*(x'), \quad (14)$$

where $\phi_{\ell}: \mathbb{R}^n \rightarrow \mathbb{R}$ are functions that are orthonormal relative to some measure μ over \mathbb{R}^n (the precise choice of which is irrelevant for the time being), with the property

$$\int \kappa(x, x') \phi_{\ell}(x') d\mu(x') = \lambda_{\ell} \phi_{\ell}(x).$$

Precisely in this sense, Gaussian process regression can be written as “infinite-dimensional” Bayesian linear regression. We will use the suggestive, and somewhat abusive notation $f_k(x_k) = L\Omega_k\Phi(x_k)$ for this generative model, defined as

$$f_k^i(x_k) = \sum_{j=1}^T L_{ij} \sum_{\ell=1}^{\infty} \Omega_k^{\ell} \phi_{\ell}(x_k) \quad (15)$$

where L is a matrix satisfying $LL^{\top} = V$ (e.g., the Cholesky decomposition), and the elements of Ω are draws from the “white” Gaussian process $\Omega_k^{\ell} \sim \mathcal{N}(0, \lambda_{\ell})$. Because of Mercer’s theorem above, Eq. (15) exists in μ^2 expectation, and is well-defined in this sense. This notation allows writing Eq. (2) as a nonparametric prior with mean θ_0 and covariance $\Sigma_k^{\theta_0} = V \otimes (\Phi\Lambda\Phi^{\top})$ where Λ is an infinite diagonal matrix with diagonal elements $\Lambda_{\ell\ell} = \lambda_{\ell}$ (the matrix multiplication $\Phi\Lambda\Phi^{\top}$ is here defined as in Eq. (15)).

Using this notation, a tedious but straightforward linear algebra derivation (see Appendix A) shows that the posterior over $z^{\top} = (x^{\top} \ \theta^{\top})$ after a number k of EKF-linearized Gaussian observations is a tractable Gaussian process, for which the Gram matrix

$$\mathcal{G} = \mathcal{P} + \mathcal{Q} + \mathcal{K} + \mathcal{F}^{-1}\mathcal{R}\mathcal{F}^{-\top}$$

consists of the parts

$$\mathcal{P} = \begin{bmatrix} R_0 & 0 \\ 0 & 0 \end{bmatrix} \quad \mathcal{Q} = (\mathcal{Q} \otimes I) \quad \mathcal{K} = \kappa(\mathbf{y}_{1:m}, \mathbf{y}_{1:m}) \quad \mathcal{R} = (R \otimes I)$$

of appropriate size, depending on the current time k . The multi-step state transition matrix

$$\mathcal{F} = \begin{bmatrix} I & 0 & 0 & \dots & 0 \\ A_1 & I & 0 & \dots & 0 \\ A_2 A_1 & A_2 & I & \dots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ A_m \dots A_1 & A_m \dots A_2 & \dots & \dots & I \end{bmatrix} \quad \text{with} \quad \mathcal{F}^{-1} = \begin{bmatrix} I & 0 & 0 & \dots & 0 \\ -A_1 & I & 0 & \dots & 0 \\ 0 & -A_2 & I & \dots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & \dots & 0 & -A_m & I \end{bmatrix}$$

is needed to account for the effect of the measurement noise R over time. The A -matrices are the Jacobians $\nabla_x f(x)_{|x_k}$.

The posterior mean now evaluates to

$$\begin{bmatrix} \hat{x}_k \\ \hat{\theta}_k \end{bmatrix} = \begin{bmatrix} \hat{x}_{k-1} \\ 0 \end{bmatrix} + \begin{bmatrix} \Phi(\hat{x}_{k-1})\Lambda\Phi(\mathbf{y}_{1:k-1})^{\top} \\ \Lambda\Phi(\mathbf{y}_{1:k-1})^{\top} \end{bmatrix} \mathcal{G}^{-1} [\Phi(\mathbf{y}_{1:k-1})\Lambda\Phi(\hat{x}_{k-1})^{\top} \ \Phi(\mathbf{y}_{1:k-1})\Lambda] \quad (16)$$

and the posterior covariance is comprised of

$$\bar{\Sigma}_k^{xx} = A_k \Sigma_k^{xx} A_k^{\top} + Q + \Phi_k \Sigma_k^{\theta_0} A_k^{\top} + A_k \Sigma_k^{\theta_0} \Phi_k^{\top} + \Phi_k \Sigma_k^{\theta_0} \Phi_k^{\top} \quad (17a)$$

$$\Sigma_k^{xx} = \bar{\Sigma}_{k-1}^{xx} - \bar{\Sigma}_{k-1}^{xx} [\bar{\Sigma}_{k-1}^{xx} + R]^{-1} \bar{\Sigma}_{k-1}^{xx} \quad (17b)$$

$$\Sigma_k^{\theta_0} = \mathcal{F}_k \Phi_k \Phi_k^{\top} \Lambda - \mathcal{F}_k; [\mathcal{P} + \mathcal{K} + \mathcal{Q}] \mathcal{G}^{-1} \Phi_k \Lambda \quad (17c)$$

$$\Sigma_k^{\theta_0} = (\Sigma_k^{\theta_0})^{\top} \quad (17d)$$

$$\Sigma_k^{\theta_0} = \Lambda - \Lambda \Phi(\mathbf{y})^{\top} \mathcal{G}^{-1} \Phi(\mathbf{y}) \Lambda. \quad (17e)$$

This formulation, together with the expositions in the preceding sections, defines a nonparametric dual control algorithm for Gaussian process priors. It is important to stress that this posterior is indeed “tractable” in so far as it depends only on a Gram matrix of size $nT \times nT$, and the posterior over any $f(x)$ can be computed in time $\mathcal{O}((nT)^3)$, despite the infinite-dimensional state space.

5.2.1 AN APPROXIMATION OF CONSTANT COST

In practical control applications, continuously rising inference cost is rarely acceptable. It is thus necessary to project the GP belief onto a finite representation, replacing the infinite sum in Eq. (14) with a finite one, to bound the computational cost of the matrix inversion in Eqs. (16), (17c) and (17e). We do so by projecting into a pre-defined finite basis of functions drawn from the eigen-spectrum of the kernel with respect to the Lebesgue measure. This approach has been recently popular elsewhere in regression (Rahimi and Recht, 2008). For readers unaware of this line of work, here is a short, self-contained introduction:

By Bochner’s theorem (e.g., Stein, 1999; Rasmussen and Williams, 2006), the covariance function $k(r)$ (with $r = |x - x'|$) of a stationary μ^2 continuous random process can be represented as the Fourier transform of a positive finite measure and, if that measure has a density $S(s)$, as the Fourier dual of S :

$$\kappa(r) = \int S(s) e^{2\pi i s r} ds,$$

This means that the eigenfunctions of the kernel are trigonometric functions, and stationary covariance functions, like the commonly used square exponential kernel

$$\kappa_{\text{SE}}(x, x') = \exp\left(-\frac{(x - x')^2}{2\lambda^2}\right),$$

can be approximated by sine and cosine basis functions as

$$\kappa(x, x') \approx \tilde{\kappa}(x, x') = \sqrt{\frac{2}{F}} \sum_{i=1}^{F/2} \sin(\omega_{2i-1}|x - x'|) + \cos(\omega_{2i}|x - x'|),$$

where the frequencies ω_i of the feature functions is sampled from the power spectrum of the process. An example of such kernel approximation is shown in Fig. 3. With increasing number of features, the approximation can be chosen as closely to the true covariance function as needed, while keeping the number of features in a range that is still feasible within the time constraints of the control algorithm.

5.3 Dual Control of Feedforward Neural Networks

Another extension of the parametric linear models of Section 5.1 is to allow for a nonlinear parametrization of the dynamics function:

$$f(x; \theta) = \sum_{\ell} \theta_{\ell}^{\text{lin}} \phi_{\ell}(x; \theta_{\ell}^{\text{nonlin}}).$$

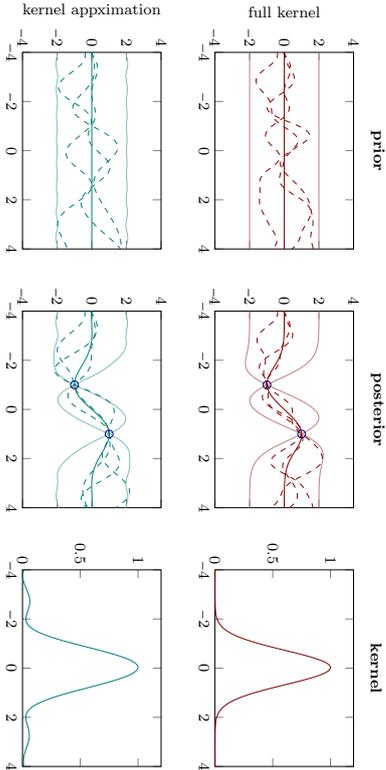

Figure 3: Prior (left), posterior (middle) and kernel function (right) of both the full kernel function (top row) and the approximate kernel (bottom row). The thick lines represent the mean and the thin lines show two standard deviations. The dashed lines are samples from the shown distributions.

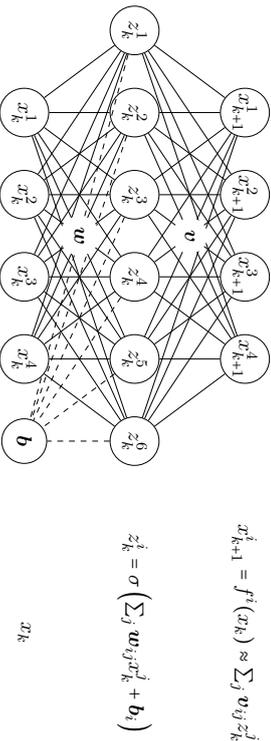

Figure 4: A two-layer feedforward neural network. Sketch to illustrate the structure of Eq. (18).

A particularly interesting example of this structure are multilayer perceptrons. Consider a two-layer network with logistic link function

$$f(x) = \sum_i v_i \sigma(\mathbf{w}_i x + \mathbf{b}_i), \quad (18)$$

where \mathbf{v} are the weights from the latent to the output layer, \mathbf{w} are the weights from input to hidden units, and \mathbf{b} are the biases of the hidden units (see Fig. 4).

Neural networks are used in control quite regularly, see e.g., Nguyen and Widrow (1990). Instead of using backpropagation and stochastic gradient descent as in most applications of neural networks (Rumelhart et al., 1986; Robbins and Monro, 1951), the EKF inference procedure can be used to train the weights as well (Singhal and Wu, 1989). This is possible because the EKF linearization can also be applied for the nonlinear link function, e.g., the logistic function. Speaking in terms of feature functions, not only the weight of each feature but also the shape (steepness) can be inferred. A limiting factor for this inference naturally is the number of data points: the more features and parameters are introduced, the more data points are necessary to learn.

Using the state augmentation $z^T = (x^T \ v^T \ w^T)$, and linearizing w.r.t. all parameters in each step, the EKF inference on the neural network parameters allows us not only to apply relatively cheap inference on them, but also to use the dual control framework to plan control signals, accounting for the effect of future observations and the subsequent change in the belief. This means the adaptive dual controller described in Sec. 4 can identify those parts of the neural net that are relevant for applying optimal control to the problem at hand. In Sec. 6.3, we show an experiment with these properties.

6. Experiments

A series of experiments on single-episode tasks with continuous state space highlights qualitative differences between the adaptive dual (AD) controller and three other controllers: An oracle controller with access to the true parameters, which provides an unattainable lower bound (LB) on the achievable performance, a certainty equivalent (CE) controller as described in Sec. 4.1, and a controller minimizing the sum of GE cost and the Bayesian exploration bonus (BEB) (see Köler and Ng, 2009):

$$l_{\text{BEB}} = \tau \left[\text{sqrt}(\text{diag}(\Sigma^{t\theta})) \right]^T \left[\text{sqrt}(\text{diag}(\Sigma^{t\theta})) \right]$$

(τ is a scalar exploration weight). The additional cost term l_{BEB} is evaluated for the predicted parameter covariance where the prediction time is chosen according to the order of the system such that the effect of the current control signal shows up in the belief over the parameters. This type of controller is sometimes also called dual control, while being referred to as *explicit dual control*, where the dual features are obtained by a modified cost function (Filiatov and Ushbaevan, 2000).

Every experiment was repeated 50 times with different random seeds, which were shared across controllers for comparability. All systems presented below are very simple setups. Their primary point is to show qualitative differences of the controllers' behavior. The experiments were done with different approximations from the preceding section to show experimental feasibility for each of them.

The feature set used for a specific application is part of the prior assumptions for that application. Large uncertainty requires flexible models (which take longer to converge, and require more exploration). Feature selection is important, but since it is independent of the dual control framework itself and a broad topic on its own, it is beyond the scope of this paper. In the following experiments, different feature sets are used both as examples for the flexibility of the framework, but also to model different structural knowledge about the problems at hand.

6.1 On a Simple Scalar System, AD Control Matches Exact Dual Control Well

For the noise-free linear system of Sec. 3.1, ($a = 1$ (known), $b = 2$, $p(b) = \mathcal{N}(b; 1, 10)$, $Q = 10^{-1}$, $R = 0$, $W = 1$, $\Lambda = 1$, $T = 2$), Fig. 1, right, compares the cost functions of the various controllers and the approximately exact sampling solution (which is only available for this very simple setup). All cost functions are shifted by an irrelevant constant. The CE cost is quadratic and indifferent about zero. The BEB ($\tau = 0.1$) gives additional structure near zero that encourages learning. While qualitatively similar to the dual cost, its global minimum is almost at the same location as that of CE. The dual control approximates the sampling solution much closer.

6.2 Faced with Time-Varying State Cost, AD Control Holds Off Exploration Until Suitable

A cart on a rail is a simple example for a dynamical system. Combined with a nonlinearly varying slope, a simple but nonlinear system can be constructed. The dynamics, prior beliefs, and true values for the parameters are chosen to be

$$x_{k+1} = \begin{bmatrix} 1 & 0.4 \\ 0 & 1 \end{bmatrix} x_k + \begin{bmatrix} 0 & 0 \\ \theta^1 & \theta^2 \end{bmatrix} \begin{bmatrix} \varphi^1(x_k^1) \\ \varphi^2(x_k^1) \end{bmatrix} + \begin{bmatrix} 0 \\ 1 \end{bmatrix} u_k \quad \theta \sim \mathcal{N} \left(\begin{bmatrix} 0 \\ 1 \end{bmatrix}, \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \right) \quad \theta_{\text{true}} = \begin{bmatrix} 0.8 \\ 0.4 \end{bmatrix},$$

$$\varphi^1(x) = -\frac{1}{1 + e^{-(x+5)}} \quad \varphi^2(x) = \frac{1}{1 + e^{-(x-5)}}, \quad (19)$$

where superscripts denote vector elements. The nonlinear functions φ are shifted logistic functions of the form

and disturbance/noise is chosen to be $R = Q = 10^{-2}I$. We use this setup as a testbed for a time-structured exploration problem. The actual system and its dynamics are relatively irrelevant here, as we will focus on a complication caused by the cost function: The reference to be tracked is

$$\mathbf{r}_{0:11} = \begin{bmatrix} 0 \\ 0 \end{bmatrix} \quad \mathbf{r}_{12:14} = \begin{bmatrix} 10 \\ 0 \end{bmatrix} \quad \mathbf{r}_{15} = \begin{bmatrix} 0 \\ 0 \end{bmatrix} \quad \mathbf{r}_{16:18} = \begin{bmatrix} -10 \\ 0 \end{bmatrix} \quad \mathbf{r}_{19:20} = \begin{bmatrix} 0 \\ 0 \end{bmatrix};$$

it is also shown in each plot of Fig. 5 as dashed orange line. The state weighting is time-dependent

$$\mathbf{W}_{0:5} = \begin{bmatrix} 10 & 0 \\ 0 & 0 \end{bmatrix} \quad \mathbf{W}_{5:10} = \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix} \quad \mathbf{W}_{11:20} = \begin{bmatrix} 100 & 0 \\ 0 & 0 \end{bmatrix},$$

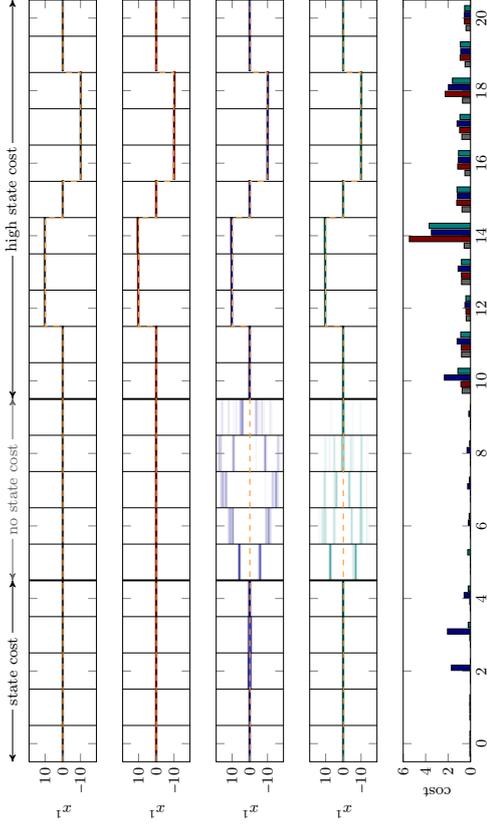

Figure 5: **Top four:** Density estimate for 50 trajectories (first state). From top to bottom: optimal oracle control (gray), certainty equivalent control (red), CE with Bayesian exploration bonus (blue), approximate dual control (green). Reference trajectory in dashed orange. **Bottom:** The mean cost per time step is shown in the bottom plot, with colors matching the controllers noted above.

and control cost is relatively low: $\Lambda = 10^{-3}$. The task, thus, is to first keep the cart fixed in the starting position to high precision, for the first 4 time steps. This is followed by a “loose” period between time steps 5 and 10. Then, the cart has to be moved to one side, back to the center, to the other side, and back again, all at high cost. A good exploration strategy in this setting is to act cautiously for the first 5 time steps, then aggressively explore in the “loose” phase, to finally be able to control the motion with high precision.

The inference model is a GP with approximated SE kernel, as described in Sec. 5.2.1. We use 30 alternating sine and cosine features that are distributed according to the power spectrum of the full SE kernel. Since the true nonlinearity of Eq. (19) is not of this form, the approximation is out of model and the lower bound controller only represents a perfectly learned, but still not exact, model.

Fig. 5 shows a density estimated from 50 state trajectories for the four different controllers. The lower bound controller (top) controls precisely at times of high cost, and does nothing for times with zero cost, controlling perfectly up to the measurement and state disturbances. The certainty equivalent controller (second from top) never explores actively, it only learns “accidentally” from observations arising during the run. Since the initial trajectory requires little action, it is left with a bad model when the reference starts to move at time step 12. The exploration bonus controller (second from bottom) continuously explores, because it

has no way of knowing about the “loose” phase ahead. Of course, this strategy incurs a higher cost initially. The dual controller (bottom) efficiently holds off exploration until it reaches the “loose” phase, where it explores aggressively.

6.3 AD Control Distinguishes Necessary and Unnecessary Parameter Exploration

The system including nonlinearities for this experiment is the same as before, although with noise parameters $R = Q = 10^{-3}I$. The reference trajectory and state weighting are much simpler, though:

$$r_{0:11} = \begin{bmatrix} 0 \\ 0 \end{bmatrix} \quad r_{12:18} = \begin{bmatrix} 10 \\ 0 \end{bmatrix} \quad r_{18:20} = \begin{bmatrix} 0 \\ 0 \end{bmatrix},$$

with the time-dependent weighting

$$W_{0:10} = \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix} \quad W_{11:20} = \begin{bmatrix} 10 & 0 \\ 0 & 0 \end{bmatrix},$$

allowing for identification in the beginning, while penalizing deviations of the first state in later time steps.

Important to note here is that the reference trajectory only passes areas of the state space where φ^1 is strong, and φ^2 is negligible. Good exploration thus will ignore θ^2 , but this can only be found through reasoning about future trajectories.

In this experiment, the learned model is of the neural network form described in Sec. 5.3. We use 4 logistic features (see Eq. (18)) with two free parameters each (w_i and v_i) and equally spaced b_i between -5 and 5 , the locations of the true nonlinear features. This means it is possible to learn the perfect model in this case.

Fig. 6 shows a density estimated from 50 state trajectories for the four different controllers. Because of symmetry in the cost function and feature functions, BEB (with $\tau = 1$) cannot “decide” between the relevant θ^1 and the irrelevant θ^2 , choosing the exploration direction stochastically. It thus sometimes reduces the uncertainty on θ^2 , which does not help the subsequent control. The AD controller ignores θ^2 completely and only identifies θ^1 in early phases, leading to good control performance.

6.4 AD Control Maintains Only Useful Knowledge

The last experiment is again similar to Sec. 6.2, but uses a different set of nonlinear functions, namely shifted Gaussian functions (a.k.a. radial basis functions)

$$\varphi^1(x) = e^{-\frac{(x-2)^2}{2}} \quad \varphi^2(x) = e^{-\frac{(x+2)^2}{2}} \quad \theta_{\text{true}} = \begin{bmatrix} 1.0 \\ 0.8 \end{bmatrix}.$$

For this experiment, the model is learned with parametric linear regression, according to Sec. 5.1. The fundamental difference to the other experimental setups is that the model now assumes *parameter drift*. This results in growing uncertainty for the parameters over time. (The true parameters are kept constant for simplicity.)

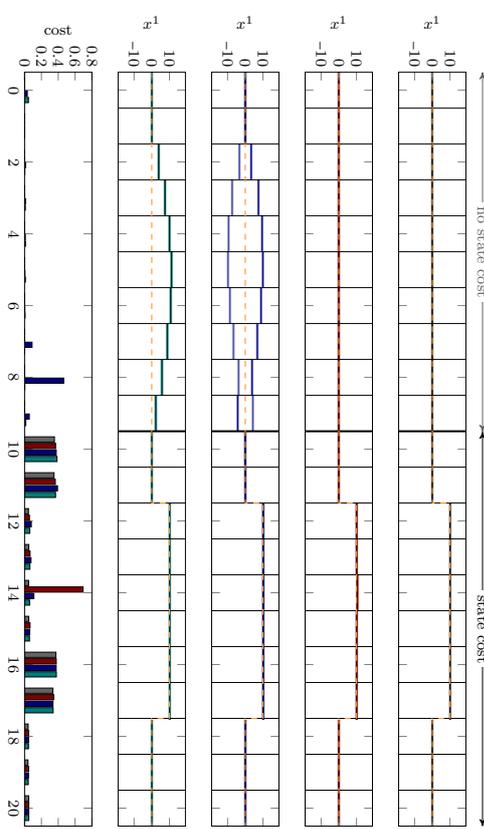

Figure 6: **Top four:** Density estimate for 50 trajectories (second state). From top to bottom: optimal oracle control (gray), certainty equivalent control (red), CE with Bayesian exploration bonus (blue), approximate dual control (green). Reference trajectory in dashed orange. **Bottom:** The mean cost per time step is shown in the bottom plot, with colors matching the controllers noted above.

The reference to be tracked passes through both nonlinear features but then stays at one of them:

$$r_{0:6} = \begin{bmatrix} -5 \\ 0 \end{bmatrix} \quad r_7 = \begin{bmatrix} -4 \\ 0 \end{bmatrix} \quad r_8 = \begin{bmatrix} -2 \\ 0 \end{bmatrix} \quad r_9 = \begin{bmatrix} 0 \\ 0 \end{bmatrix} \quad r_{10:20} = \begin{bmatrix} 2 \\ 0 \end{bmatrix}.$$

The cost structure is

$$W_{0:5} = \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix} \quad W_{6:20} = \begin{bmatrix} 10 & 0 \\ 0 & 0 \end{bmatrix},$$

such that there is cost starting with the linear reference trajectory at time instant 6.

Fig. 7 shows the parameter belief and relevant state of a single run of this experiment over time. It shows clearly that the in the beginning necessary parameter θ^1 is learned early by BEB and the AD controller, while CE learns only “accidentally”. The BEB controller also learns the second parameter in the beginning, even though the knowledge will be lost over time. When the trajectory reaches the zone of the second parameter, the BEB controller tries to lower the growing uncertainty every now and then (visible by the drops in state x^1), incurring high cost. AD control completely ignores the growing uncertainty on θ^1 after reaching the area of θ^2 , thus preventing unnecessary exploration.

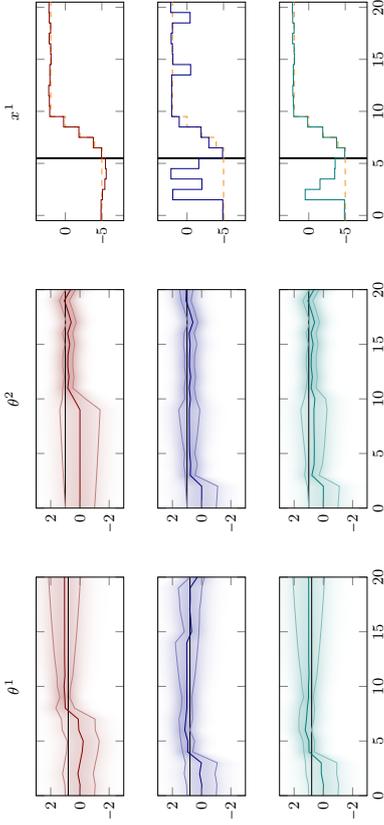

Figure 7: Parameter knowledge (left, middle) and state trajectory (right) for different controllers. From top to bottom: certainty equivalent control (red), CE with Bayesian exploration bonus (blue), approximate dual control (green). The true parameters are the black lines.

	Exp. 6.1		Exp. 6.2		Exp. 6.3		Exp. 6.4	
	mean	std	mean	std	mean	std	mean	std
Oracle	0.67	0.23	1.75	0.33	7.15	3.85	0.66	0.51
CE	0.84	0.73	2.49	0.74	15.72	5.20	1.76	0.90
CE-BEB	0.99	0.92	2.64	0.37	20.88	6.74	84.91	6.77
AD	0.77	0.43	1.96	0.34	14.33	5.40	1.62	0.56

Table 1: Average and standard deviation of costs in the experiments for 50 runs.

6.5 Quantitative Comparison

The above experiments aim to emphasize qualitative strengths of AD control over simpler approximations. It is desirable for a controllers to deal with flexible models of many parameters, many of which will invariably be superfluous. For reference, Table 6.5 also shows quantitative results: Averages and standard deviations of the cost, from the 50 runs for each controller. The AD controller shows good performance overall; interestingly, it also has low variance. CE and BEB were more prone to instabilities.

7. Conclusion

Bayesian reinforcement learning, or dual control, offers an elegant answer to the exploration-exploitation trade-off, relative to prior probabilistic beliefs. Its intricate, intractable structure requires approximations to balance another kind of trade-off, between computation and performance. This work investigated an old approximate framework from control, re-phrased

it in the language of reinforcement learning, and extended it to apply to contemporary inference methods from machine learning, including approximate Gaussian process regression and multi-layer networks. The result is a tractable approximation that captures notions of structured exploration, like the value of waiting for future exploration opportunities, and distinguishing relevant from irrelevant model parameters.

The dual control framework, in its now clearer form, offers interesting directions for research in reinforcement learning, including its combination with recent new developments in learning and planning. Following this conceptual work, the main challenge for further development is the still comparably high (but tractable) numerical load of dual control, particularly in problems of higher dimensionality.

Appendix A. Nonparametric EKF Form

The standard Kalman filter (KF) can be found in many textbooks (e.g., Särkkä, 2013) and therefore will not be restated here. Starting from the standard equations, we derive a general multi-step formulation of the classic KF with

$$p(z_k) = \mathcal{N}(z_k; m_k, P_k).$$

From there, state augmentation with an infinite-dimensional weight vector gives the expected result.

A.1 Derivation of the Multi-Step KF Formulation

Assuming that the result of the KF and the Gaussain process framework should be identical under certain circumstances, we wish to transform the KF to a formulation with full Gram matrix. Therefore, the prediction and update step have to be combined to

$$P_1 = (A_0 P_0 A_0^\top + Q) - (A_0 P_0 A_0^\top + Q) H^\top S_1^{-1} H (A_0 P_0 A_0^\top + Q)^\top$$

$$S_1 = H (A_0 P_0 A_0^\top + Q) H^\top + R,$$

which is pretty straightforward. We're adopting a standard notation, where P_k is the covariance at time step k , A_k is the Jacobian, Q is the drift and R is the measurement covariance. The same can be done for the second time step, but it is beneficial introducing a compact notation for the predictive covariance first

$$\begin{aligned} & (A_1 P_1 A_1^\top + Q) \\ &= (A_1 \left[(A_0 P_0 A_0^\top + Q) - (A_0 P_0 A_0^\top + Q) H^\top S_1^{-1} H (A_0 P_0 A_0^\top + Q)^\top \right] A_1^\top + Q) \\ &= \underbrace{A_1 (A_0 P_0 A_0^\top + Q) A_1^\top}_{=:g_{11}} + \underbrace{Q - A_1 (A_0 P_0 A_0^\top + Q) H^\top (S_1^{-1})^{-1} H (A_0 P_0 A_0^\top + Q) A_1^\top}_{=:g_{10}} \\ &= g_{11} - g_{10} H^\top g_{00}^{-1} H g_{01}. \end{aligned}$$

Using the compact notation and defining S_2 analogously to S_1 , we can write the two-step update as

$$\begin{aligned} P_2 &= (g_{11} - g_{10} H^\top S_1^{-1} H g_{01}) - (g_{11} - g_{10} H^\top S_1^{-1} H g_{01}) H^\top S_2^{-1} H (g_{11} - g_{10} H^\top S_1^{-1} H g_{01}) \\ P_2 &= g_{11} - g_{10} H^\top S_1^{-1} H g_{01} - g_{11} H^\top S_2^{-1} H g_{11} - g_{10} H^\top S_1^{-1} H g_{01} H^\top S_2^{-1} H g_{10} H^\top S_1^{-1} H g_{01} \\ &\quad + g_{11} H^\top S_2^{-1} H g_{10} H^\top S_1^{-1} H g_{01} + g_{10} H^\top S_1^{-1} H g_{01} H^\top S_2^{-1} H g_{11} \\ P_2 &= g_{11} - \underbrace{[g_{10} H^\top \quad g_{11} H^\top]}_{=:G^{-\top}} \begin{bmatrix} S_1^{-1} + S_1^{-1} H g_{01} H^\top S_2^{-1} H g_{01} H^\top S_1^{-1} & -S_1^{-1} H g_{01} H^\top S_2^{-1} \\ -S_2^{-1} H g_{10} H^\top S_1^{-1} & S_2^{-1} \end{bmatrix} \begin{bmatrix} H g_{01} \\ H g_{11} \end{bmatrix}. \end{aligned}$$

Application of Schur's lemma gives

$$G = \begin{bmatrix} H g_{00} H^\top + R & H g_{01} H^\top \\ H g_{10} H^\top & H g_{11} H^\top + R \end{bmatrix}.$$

Assuming full state measurement ($H = I$) for compactness of notation, the two-step update is

$$\begin{aligned} P_2 &= g_{11} - \begin{bmatrix} g_{10}^\top & g_{11}^\top \end{bmatrix} \begin{bmatrix} g_{00} + R & g_{01} \\ g_{10} & g_{11} + R \end{bmatrix}^{-1} \begin{bmatrix} g_{01} \\ g_{11} \end{bmatrix} \\ &= A_1 (A_0 P_0 A_0^\top + Q) A_1^\top + Q - [A_1 (A_0 P_0 A_0^\top + Q) \quad (A_1 (A_0 P_0 A_0^\top + Q) A_1^\top + Q)] \\ &\quad \cdot \begin{bmatrix} (A_0 P_0 A_0^\top + Q) + R & (A_0 P_0 A_0^\top + Q) A_1^\top \\ A_1 (A_0 P_0 A_0^\top + Q) A_1^\top + Q + R \end{bmatrix}^{-1} \begin{bmatrix} (A_0 P_0 A_0^\top + Q) A_1^\top \\ (A_1 (A_0 P_0 A_0^\top + Q) A_1^\top + Q) \end{bmatrix}, \end{aligned} \quad (20)$$

which already looks similar to GP inference. We can now generalize this two-step result to the general form by building the Gram matrix according to

$$G = \mathcal{F} \mathcal{P} \mathcal{F}^\top + \mathcal{F} \mathcal{Q} \mathcal{F}^\top + \mathcal{R},$$

where the individual parts are

$$\mathcal{P} = \begin{bmatrix} P_0 & 0 \\ 0 & 0 \end{bmatrix} \quad \mathcal{Q} = (Q \otimes I) \quad \mathcal{R} = (R \otimes I)$$

of appropriate size, depending on the current time k . The multi-step state transition matrix

$$\mathcal{F} = \begin{bmatrix} I & 0 & 0 & \dots & 0 \\ A_1 & I & 0 & \dots & 0 \\ A_2 & A_1 & A_2 & \dots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ A_m \dots A_1 & A_m \dots A_2 & \dots & I \end{bmatrix}, \quad \text{with} \quad \mathcal{F}^{-1} = \begin{bmatrix} I & 0 & 0 & \dots & 0 \\ -A_1 & I & 0 & \dots & 0 \\ 0 & -A_2 & I & \dots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & \dots & 0 & -A_m & I \end{bmatrix},$$

is also needed so shift the initial covariance and drift covariances through time. Put together, this results in

$$P_k = \mathcal{F}_{k,:} (\mathcal{P} + \mathcal{Q}) \mathcal{F}_{k,:}^\top - \mathcal{F}_{k,:} (\mathcal{P} + \mathcal{Q}) \mathcal{F} (\mathcal{F} \mathcal{P} \mathcal{F}^\top + \mathcal{F} \mathcal{Q} \mathcal{F}^\top + \mathcal{R})^{-1} \mathcal{F}^\top (\mathcal{P} + \mathcal{Q}) \mathcal{F}_{k,:}$$

A more compact notation can be achieved by using \mathcal{F}^{-1} to obtain

$$P_k = \mathcal{F}_{k,:} (\mathcal{P} + \mathcal{Q}) \mathcal{F}_{k,:}^\top - \mathcal{F}_{k,:} (\mathcal{P} + \mathcal{Q}) (\mathcal{P} + \mathcal{Q} + \mathcal{F}^{-1} \mathcal{R} \mathcal{F}^{-\top})^{-1} (\mathcal{P} + \mathcal{Q}) \mathcal{F}_{k,:} \quad (21)$$

Calculating the mean prediction is done analogously:

$$m_k = \mathcal{F}_{k,0} m_0 + \mathcal{F}_{k,:} (\mathcal{P} + \mathcal{Q}) (\mathcal{P} + \mathcal{Q} + \mathcal{F}^{-1} \mathcal{R} \mathcal{F}^{-\top})^{-1} \mu.$$

A.2 Augmenting the State

Instead of tracking only the state covariance, in the GP setting also the dynamics function has to be inferred. The system equations of the nonlinear system are now

$$\begin{aligned} x_k &= f(x_{k-1}) + q_{k-1} & q_{k-1} &\sim \mathcal{N}(0, Q) \\ y_k &= H x_k + r_k & r_k &\sim \mathcal{N}(0, R), \end{aligned}$$

where $f \sim \mathcal{GP}(0, k)$. The inference in this model can be done through the EKF with augmented state. We adopt the weight-space view with $f = \Phi^\top w$ (see Rasmussen and Williams, 2006) to augment the state with the infinite-dimensional weight vector w :

$$z = \begin{pmatrix} x \\ w \end{pmatrix} \quad \Sigma = \begin{pmatrix} P & \Sigma^{vw} \\ \Sigma^{wx} & \Sigma^{ww} \end{pmatrix} \quad J_A = \begin{pmatrix} \frac{\partial f}{\partial x} & \frac{\partial f}{\partial w} \\ 0 & I \end{pmatrix} = \begin{pmatrix} A & \Phi \\ 0 & I \end{pmatrix},$$

where, in (20), the original x is replaced by the augmented z , P by Σ and A by J_A .

Choosing $H = [I \ 0]$ so that H recovers the original states from the augmented state vector, we obtain, after calculations similar to those above, a Gram matrix with additional terms including feature functions and the prior on them:

$$G^* = G + \begin{pmatrix} \Phi_0 \Sigma_0^{ww} \Phi_0^\top & \Phi_0 \Sigma_0^{vw} \Phi_0^\top \\ (A_1 \Phi_0 + \Phi_1) \Sigma_0^{vw} \Phi_0^\top & (A_1 \Phi_0 + \Phi_1) \Sigma_0^{ww} (\Phi_0^\top A_1^\top + \Phi_1^\top) \end{pmatrix}.$$

At this point it is important to note that the infinite inner product $\Phi_k \Sigma_k^{ww} \Phi_k^\top$ corresponds to an evaluation of the kernel

$$\Phi(x) \Sigma_0^{ww} \Phi(x')^\top = \sum \phi_i(x) \Sigma_{0,i,j}^{ww} \phi_j(x') = \kappa(x, x').$$

This means we can write the Gram matrix as

$$G^* = G + \begin{pmatrix} \kappa_{00} & \kappa_{00} A_1^\top + \kappa_{01} \\ A_1 \kappa_{00} + \kappa_{10} & A_1 \kappa_{00} A_1^\top + \kappa_{10} A_1^\top + A_1 \kappa_{01} + \kappa_{11} \end{pmatrix},$$

where we have written κ_{\cdot} for $\kappa(\cdot, \cdot)$ to save space. In total, the Gram matrix is then

$$G^* = \mathcal{F} \mathcal{P} \mathcal{F}^\top + \mathcal{F} \mathcal{Q} \mathcal{F}^\top + \mathcal{F} \mathcal{K} \mathcal{F}^\top + \mathcal{R},$$

with $\mathcal{K} = \kappa(\mathbf{y}_{1:m}, \mathbf{y}_{1:m})$. Since inference is more compact and numerically stable if we absorb \mathcal{F} into the Gram matrix as in Eq. (21), we define

$$\mathcal{G} = \mathcal{P} + \mathcal{Q} + \mathcal{K} + \mathcal{F}^{-1} \mathcal{R} \mathcal{F}^{-\top}.$$

Inference is done according to

$$P_k = \mathcal{F}_{k,\cdot} (\mathcal{P} + \mathcal{Q} + \mathcal{K}) \mathcal{F}_{k,\cdot}^\top - \mathcal{F}_{k,\cdot} (\mathcal{P} + \mathcal{Q} + \mathcal{K}) \mathcal{G}^{-1} (\mathcal{P} + \mathcal{Q} + \mathcal{K}) \mathcal{F}_{\cdot,k}$$

$$\Sigma_k^{wx} = (\Sigma_k^{ww})^\top = \mathcal{F}_{k,\cdot} \Phi(\mathbf{y}) \Sigma_0^{ww} - \mathcal{F}_{k,\cdot} (\mathcal{P} + \mathcal{K} + \mathcal{Q}) \mathcal{G}^{-1} \Phi(\mathbf{y}) \Sigma_0^{ww}$$

$$\Sigma_k^{ww} = \Sigma_0^{ww} - \Sigma_0^{ww} \Phi(\mathbf{y})^\top \mathcal{G}^{-1} \Phi(\mathbf{y}) \Sigma_0^{ww}$$

for the covariance and

$$m_k = \mathcal{F}_{k,0} m_0 + \mathcal{F}_{k,\cdot} (\mathcal{P} + \mathcal{Q} + \mathcal{K}) \mathcal{G}^{-1} \mathbf{y}$$

$$\bar{w}_k = \bar{w}_0 + \Sigma_0^{ww} \Phi(\mathbf{y})^\top \mathcal{G}^{-1} \mathbf{y}$$

for the mean.

Appendix B. Gradients and Hessians of Dynamics Functions

B.1 Neural Network Basis Functions

The neural network dynamics function is

$$f(x) = \sum_{i=1}^F v_i \sigma(w_i(x - b_i)), \quad \sigma(a) = \frac{1}{1 + e^{-a}},$$

with the well-known derivatives of the logistic

$$\frac{\partial}{\partial a} \sigma(a) = \sigma(a)(1 - \sigma(a)), \quad \frac{\partial^2}{\partial a^2} \sigma(a) = \sigma(a)(1 - \sigma(a))(3 - 2\sigma(a)).$$

The gradient of $f(x)$ can easily found to be

$$\nabla f(x) = \begin{bmatrix} \sum_{i=1}^F v_i w_i \sigma(w_i(x - b_i))(1 - \sigma(w_i(x - b_i))) \\ \sigma(w_1(x - b_1)) \\ \vdots \\ v_1(x - b_1) \sigma(w_1(x - b_1))(1 - \sigma(w_1(x - b_1))) \\ \vdots \\ v_F(x - b_F) \sigma(w_F(x - b_F))(1 - \sigma(w_F(x - b_F))) \end{bmatrix}.$$

The Hessian, written in parts, using $a_i = w_i x + b_i$, is:

$$\nabla_x^2 f(x) = \sum_{i=1}^F v_i w_i^2 \sigma(a_i)(1 - \sigma(a_i))(3 - 2\sigma(a_i))$$

$$\nabla_x \nabla_{v_i} f(x) = w_i \sigma(a_i)(1 - \sigma(a_i))$$

$$\nabla_x \nabla_{w_i} f(x) = v_i \sigma(a_i)(1 - \sigma(a_i)) + (x - b_i) w_i v_i \sigma(a_i)(1 - \sigma(a_i))(1 - 2\sigma(a_i))$$

$$\nabla_{v_i} \nabla_{v_i} f(x) = 0$$

$$\nabla_{v_i} \nabla_{w_i} f(x) = (x - b_i) \sigma(a_i)(1 - \sigma(a_i))$$

$$\nabla_{w_i} \nabla_{w_i} f(x) = v_i (x - b_i)^2 \sigma(a_i)(1 - \sigma(a_i))(3 - 2\sigma(a_i)).$$

B.2 Fourier Basis Functions

The Fourier approximation to the dynamics function has the form

$$f(x) = \sqrt{\frac{F}{2}} \sum_{i=1}^{F/2} v_{2i-1} \sin(\omega_{2i-1} x) + v_{2i} \cos(\omega_{2i} x).$$

The gradient of $f(x)$ can easily verified to be

$$\nabla f(x) = \begin{bmatrix} \sqrt{\frac{2}{F}} \sum_{i=1}^{F/2} v_{2i-1} \omega_{2i-1} \cos(\omega_{2i-1} x) - v_{2i} \omega_{2i} \sin(\omega_{2i} x) \\ \sqrt{\frac{2}{F}} \sin(\omega_1 x) \\ \sqrt{\frac{2}{F}} \cos(\omega_2 x) \\ \vdots \\ \sqrt{\frac{2}{F}} \sin(\omega_{F-1} x) \\ \sqrt{\frac{2}{F}} \cos(\omega_F x) \end{bmatrix}.$$

The Hessian, written in parts, using $c = \sqrt{2/F}$ for normalization, is:

$$\begin{aligned} \nabla_x^2 f(x) &= c \sum_{i=1}^{F/2} -v_{2i-1} \omega_{2i-1}^2 \sin(\omega_{2i-1} x) - v_{2i} \omega_{2i}^2 \cos(\omega_{2i} x) \\ \nabla_x \nabla_{v_i} f(x) &= \begin{cases} c \omega_i \cos(\omega_i x) & i \text{ odd} \\ -c \omega_i \sin(\omega_i x) & i \text{ even} \end{cases} \\ \nabla_{v_i} \nabla_{v_i} f(x) &= 0. \end{aligned}$$

B.3 Radial Basis Functions

With radial basis function features, the dynamics function is

$$f(x) = \sum_{i=1}^F v_i \exp\left(-\frac{(x-c_i)^2}{2\lambda^2}\right).$$

The gradient of $f(x)$ is

$$\nabla f(x) = \begin{bmatrix} \sum_{i=1}^F v_i \exp\left(-\frac{(x-c_i)^2}{2\lambda^2}\right) \frac{(c_i-x)}{2\lambda^2} \\ \exp\left(-\frac{(x-c_1)^2}{2\lambda^2}\right) \\ \vdots \\ \exp\left(-\frac{(x-c_F)^2}{2\lambda^2}\right) \end{bmatrix}.$$

The Hessian, written in parts, is:

$$\begin{aligned} \nabla_x^2 f(x) &= \sum_{i=1}^F v_i \exp\left(-\frac{(x-c_i)^2}{2\lambda^2}\right) \left[\left(\frac{c_i-x}{2\lambda^2}\right)^2 - \frac{1}{\lambda^2} \right] \\ \nabla_x \nabla_{v_i} f(x) &= \exp\left(-\frac{(x-c_i)^2}{2\lambda^2}\right) \frac{c_i-x}{2\lambda^2} \\ \nabla_{v_i} \nabla_{v_i} f(x) &= 0 \end{aligned}$$

Abstract

We propose a new theoretical framework for analyzing the multiple-instance learning (MIL) setting. In MIL, training examples are provided to a learning algorithm in the form of labeled sets, or “bags,” of instances. Applications of MIL include 3-D quantitative structure–activity relationship prediction for drug discovery and content-based image retrieval for web search. The goal of an algorithm is to learn a function that correctly labels new bags or a function that correctly labels new instances. We propose that bags should be treated as latent distributions from which samples are observed. We show that it is possible to learn accurate instance- and bag-labeling functions in this setting as well as functions that correctly rank bags or instances under weak assumptions. Additionally, our theoretical results suggest that it is possible to learn to rank efficiently using traditional, well-studied “supervised” learning approaches. We perform an extensive empirical evaluation that supports the theoretical predictions entailed by the new framework. The proposed theoretical framework leads to a better understanding of the relationship between the MI and standard supervised learning settings, and it provides new methods for learning from MI data that are more accurate, more efficient, and have better understood theoretical properties than existing MI-specific algorithms.

Keywords: multiple-instance learning, learning theory, ranking, classification

1. Introduction

The standard supervised learning setting, in which labeled training examples are represented with individual feature vectors, is well-studied with numerous applications. However, there remain many compelling real-world problems that require learning from more structured data. For example, in text categorization, a document might contain a set of passages or paragraphs. A typical approach is to simply ignore the internal structure within the document by treating it as a “bag of words,” then to represent the document with a single feature vector based on word frequencies. However, because such an approach destroys the internal structure of the document, it becomes challenging to determine *which* passages or paragraphs correspond to the category of interest. Similarly, for the content-based image retrieval (CBIR) domain, the goal is to learn to retrieve images that contain some object of interest to the user. One approach is to use a flat feature vector representation of each

image given pixel color values. Again, using such an approach, it is not clear how one might identify *which* object in or region of the image was of interest to a user.

For such problems, the multiple-instance (MI) setting offers a richer representation for structure objects as sets, or “bags,” of feature vectors, each of which is called an “instance” (Dietterich et al., 1997). In the text categorization example above, a document is a bag of passages or paragraphs, which are the instances. For CBIR, an image is a bag of segments or objects. The MI setting further assumes that labels exist at both the level of instances and bags, where a bag’s label is the logical conjunction of Boolean instance labels. That is, a bag is positive if *at least one* instance in the bag is positive and negative if *all* of the instances in the bag are negative. This logical relationship corresponds to the fact that a document or an image is of the class of interest if and only if at least one of the passages or objects it contains is of the class of interest.

In the standard supervised setting, there is typically only one target concept of interest. For MI learning, one might be interested in learning either a bag or an instance concept from MI data. For example, in the 3-Dimensional Quantitative Structure–Activity Relationship (3D-QSAR) domain, the goal is to learn to predict whether a molecule will bind to a given target receptor (Dietterich et al., 1997). Because a molecule has flexible bonds, it exists in multiple shapes, or *conformations*, in solution. Thus, mapping this problem into the MI setting, conformations are instances and molecules are bags. A *bag-labeling* function can be used to predict whether a given molecule will bind to a target receptor. On the other hand, an *instance-labeling* function can be used to predict which specific conformations will bind to a receptor, providing useful, difficult-to-measure information about the receptor’s physical structure.

Despite the importance of these two learning tasks, only the bag-labeling task has received much attention in recent prior work characterizing the learnability of MI concepts (Sabato and Tishby, 2012). When learnability of instance concepts has been addressed, it has been under the strict, unrealistic assumption that instances across all bags are independent and identically distributed (IID) samples *from the same underlying distribution* (Blum and Kalai, 1998). However, as far as we know, the result of Blum and Kalai (1998) has remained the only positive result on instance concept learnability in the MI setting for over a decade. In this paper, we describe new *positive* results for both instance- and bag-concept learnability. Our contributions are summarized as follows:

1. We describe a new generative model for MI data and show that it subsumes some previously proposed generative models for MI learning (MIL).
2. We provide novel results for learning accurate bag-level concepts from MI data.
3. We describe the first positive instance concept learnability results since those of Blum and Kalai (1998).¹
4. We prove the first results, to our knowledge, that formally describe the ability to rank both instances and bags in the MI setting.
5. We empirically evaluate a surprising implication of our theoretical results: that *standard supervised approaches* can effectively rank both instances and bags in the MI setting.

¹. These results were also presented in Doran and Ray (2014).

setting. Our evaluation uses 55 data sets from a wide variety of domains, and supports both our theoretical results as well as the assumptions made by our generative model.

2. Bags as Distributions

In this section, we describe a generative model for MI data in which bags are viewed as *distributions over instances* rather than as sets of instances. We show that the proposed generative model actually encompasses previous, standard models of MI learning in which bags are sets or tuples. The choice of framing a problem within a particular theoretical model has significant practical consequences for designing or selecting an algorithm to solve the problem. This section provides a theoretical framework in which the MI classification problem can be analyzed. The model allows us to derive positive instance- and bag-concept learnability results for the MI setting as described in Section 3. Furthermore, as Section 4 shows, the generative model leads to a surprising yet testable hypothesis that standard supervised algorithms can learn from MI data. This hypothesis is evaluated experimentally, supporting the assumptions made by the model.

2.1 The Generative Model

At the heart of this work is the claim that bags are best viewed as distributions rather than as finite sets of instances. Below, we formally define what we mean by this statement. But first, the example domain of drug activity prediction provides an intuitive justification for this claim. As described in Section 1, in the drug activity prediction domain, the goal is to predict the ability of molecules to activate, or bind to, a receptor. To cast the problem as binary classification, we select some threshold so that each molecule’s activity level either corresponds to an “active” or “inactive” label. In this case, we can think of each molecule (bag) as being drawn from a distribution D_B over molecules. Ignoring for the moment that each molecule has numerous conformations, this molecule either activates the receptor or not, so in nature the labeling function is defined at the level of bags. Prior models represent each molecule as a set or multiset of conformations, so they implicitly assume that each molecule exists in only a finite number of conformations. In reality, a molecule can transform continuously from conformation to conformation, producing an infinite set of conformations. In particular, each molecule exists in a state of dynamic equilibrium in which the amount of time it spends in each conformation is distributed according to Gibbs free energy such that low-energy conformations are preferred. Hence, the molecule (bag) corresponds to a *distribution over instances*. Constructing a bag from low-energy conformations, the common procedure for constructing bags in the drug activity domain, can be thought of as sampling instances from this distribution. Note that each molecule will have a *unique* distribution over conformations; thus, prior generative models for MIL that assume all instances are drawn from the *same* distribution are not applicable (Blum and Kalai, 1998). In Section 2.5, we describe how this view of the MI generative process can be applied to other problem domains.

More abstractly, our generative process needs several components. First, *bags are distributions over instances*, and we will assume that these bags are sampled from a *distribution over bags* and labeled according to a *bag-labeling function*. In addition to the bag-labeling

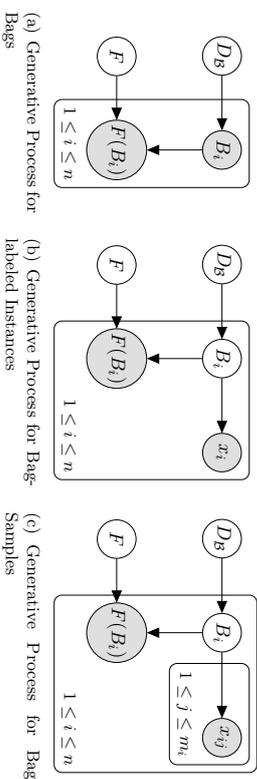

Figure 1: A comparison of the generative processes for bags, individual bag-labeled instances, and bag samples.

function, in the MI setting there is also an *instance-labeling* function with the standard *MI assumption* relating the bag- and instance-labeling functions. We describe the *instance distribution* that is consistent with the generative process, which will be useful for discussing instance concept learnability. In addition to these essential components, we introduce two *additional weak assumptions* that make efficient learning in this setting possible.

Bags as Distributions. To formalize the intuition above, suppose we have an instance space \mathcal{X} . Typically, the space of bags is some subset of \mathcal{X}^* , the set of all finite subsets of \mathcal{X} . However, here, we let the space of bags be $\mathcal{B} = \mathcal{P}(\mathcal{X})$, the set of probability distributions on the input space. Hence, each bag $B \in \mathcal{B}$ is a probability distribution over instances, denoted $P(x | B)$.

Bag Distribution. We propose that, at the level of bags, the MI generative process is similar to that for supervised learning. In particular, bags are sampled from some fixed distribution D_B , which is a distribution over instance distributions ($D_B \in \mathcal{P}(\mathcal{P}(\mathcal{X}))$). From this distribution D_B , we sample some set of bags $\{B_i\}_{i=1}^n$, as illustrated by the plate model in Figure 1(a).

Bag-Labeling Function. As in supervised learning, we assume that there exists some labeling function $F : \mathcal{B} \rightarrow \{0, 1\}$ that labels bags. Thus, a supervised data set $\{(B_i, F(B_i))\}_{i=1}^n$ could be produced by sampling bags IID from D_B and applying the labeling function F .

Instance-Labeling Function. In the MI setting, we assume that in addition to the bag-labeling function F , there also exists an *instance-labeling* function $f : \mathcal{X} \rightarrow \{0, 1\}$. A key component of the MI setting is not only the existence of both bag and instance labeling functions, but the relationship between the two as well. Traditionally, the MI assumption is stated with respect to particular sets of instances so that a bag label $F(B_i)$ is the logical OR (for boolean labels), or maximum (for numerical labels), of its instances’ labels: $F(B_i) = \max_j f(x_{ij})$. However, in the proposed generative model, bags are distributions with *a priori* labels regardless of the instances sampled from them. Therefore, our generative model requires a more nuanced description of the relationship between bag and instance labels.

The MI Assumption. We state the relationship between F and f at the level of the generative model. Accordingly, a bag is negative ($F(B) = 0$) if and only if probability of sampling a positive instance within the bag is zero: $\mathbb{P}_{x \sim B}[f(x) = 1] = 0$. In measure theoretic terms, instances sampled within negative bags are almost surely negative, which implies that positive instances are almost surely sampled only within positive bags. This condition corresponds to the standard MI assumption that negative bags contain only negative instances.

Instance Distribution. In order to talk about the learnability of f , we must define some instance distribution with respect to which we will measure risk. An instance distribution naturally arises from our generative model if we first sample a bag B randomly from D_B , then sample an instance x randomly from the distribution corresponding to B . The instance distribution D_X resulting from this two-level sampling procedure is effectively the distribution that marginalizes out the individual bag distributions. That is, given a probability distribution P_B over bags corresponding to D_B , we can define a distribution P_X corresponding to D_X as

$$P_X(x) = \int_B P(x | B) dP_B(B). \quad (1)$$

Given that “ x ” is used to denote instances and “ B ” is used to denote bags, we subsequently drop subscripts from P when the sample space can be inferred from context. As we discuss in Section 3.4, the ability to marginalize out bag-specific distributions in our model plays a vital role in proving the learnability of instance- and bag-labeling functions. Given a bag distribution, the existence of such an instance distribution is guaranteed under relatively weak assumptions on the instance space \mathcal{X} (Diestel and Uhl, 1977). Furthermore, note that while we can view instances in our generative model as being sampled IID from D_X , this does not require the assumption that instances are IID across all bag distributions, as in prior generative models for MIL (Blum and Kalai, 1998). We discuss this point in detail in Section 3.6.

Additional Assumptions. As is the case in the standard MI framework, in our generative model, only bag labels are observed. Suppose we sample individual instances as illustrated in Figure 1(b) where we first sample a bag, record its label, and then sample an instance from the bag-specific distribution $P(x | B)$ and assign the bag label to the instance. Then the resulting bag-labeled instances $\{(x_{i1}, F(B_i))\}_{i=1}^n$ are distributed according to D_X , and will appear in positive bags some of the time and negative bags the remaining fraction of the time. Therefore, each instance will have some probability $c(x) \in [0, 1]$ of appearing with a positive label, which can be formally expressed as a probabilistic concept (p -concept) like the kind described by Kearns and Schapire (1994):

$$c(x) \triangleq \mathbb{P}[F(B) = 1 | x]. \quad (2)$$

That is, the probability of observing a positive label for instance x is the conditional probability that the bag B in the two-level sampling procedure was positive, given that x was observed within B . This conditional probability can be derived from the joint distribution over instances and bag labels corresponding to the generative process in Figure 1(b).

It follows from the previously-stated relationship between F and f that for any positive instance x_+ , $c(x_+) = 1$, since each positive instance is observed almost surely (with probability 1) within a positive bag. In order to distinguish positive and negative instances, we

make the following weak assumption: there exists some $\gamma > 0$ such that for every negative instance x_- , $c(x_-) \leq 1 - \gamma$. Intuitively, this corresponds to the assumption that every negative instance is observed with some nonzero probability in a negative bag.

To see why negative instances must appear in negative bags in order to learn a concept, consider trying to learn the instance concept “spoon” in the CBIR domain, as described in Section 1. To learn this concept, you are given a set of images containing spoons, and a set of images not containing spoons. However, suppose that in every image containing a spoon, there is also a fork nearby. Furthermore, forks never appear alone in images without spoons. In this unfortunate scenario, you have no means of determining which of the fork or spoon is the positive instance given only image-level labels. However, if there is a guarantee that eventually you will see a negative image containing a fork but not a spoon, you will be able to learn that the fork is not the positive instance. We discuss learnability further in Section 3 and Section 4.

Finally, for learning bag-level concepts, we show in Section 3.2 that we require one additional assumption that there is some minimum fraction π of positive instances in each positive bag. That is, for every positive bag B_+ , $\mathbb{P}[f(x) = 1 | B_+] \geq \pi$. Without this assumption, there might be positive bags that only contain negative instances. However, this would make them indistinguishable during bag labeling from negative bags, which by definition only contain negative instances. Interestingly, this assumption is not required if we are only interested in learning an instance-level concept.

Now, we can formally define MI-GEN, the set of generative processes for MI data consistent with the assumptions described above,

Definition 1 (MI-GEN) *Given any $\gamma \in (0, 1]$ and $\pi \in [0, 1]$, MI-GEN(γ, π) is the set of all tuples (D_X, D_B, f, F) , each consisting of an instance distribution D_X (with corresponding $P(x)$), bag distribution D_B (with corresponding $P(B)$), instance-labeling function f , and bag-labeling function F , that satisfy the conditions:*

1. $\mathbb{P}(x) = \int_B \mathbb{P}(x | B) dP(B)$
2. $\forall x : f(x) = 1 \implies \mathbb{P}[F(B) = 0 | x] = 0$
3. $\forall x : f(x) = 0 \implies \mathbb{P}[F(B) = 0 | x] \geq \gamma$
4. $\forall B : F(B) = 1 \implies \mathbb{P}[f(x) = 1 | B] \geq \pi$.

For simplicity, we will write MI-GEN(γ) for the case when $\pi = 0$, which corresponds to the weakest Condition 4. That is, for any fixed γ , MI-GEN(γ) \supseteq MI-GEN(γ, π) for every $\pi \geq 0$. Such notation will be used when discussing instance-concept learnability, which does not require the $\pi > 0$ assumption. That is, instance-concept learning under our model is naturally tolerant to “bag label noise” of the form where positive bags contain only negative instances.

Finally, note that for any $\gamma \in (0, 1]$, $\pi \in [0, 1]$, MI-GEN(γ, π) \supseteq MI-GEN(1, 1). That is, $\gamma = \pi = 1$ corresponds to the strongest constraints on the generative process. Even in this case, for any D_X and f , there exist D_B and F such that $(D_X, D_B, f, F) \in \text{MI-GEN}(1, 1)$. In particular, given a point mass δ_x centered on x , we can define D_B so that $P_B(\delta_x) = P_X(x)$ and F such that $F(\delta_x) = f(x)$. This choice of (D_B, F) corresponds to supervised learning

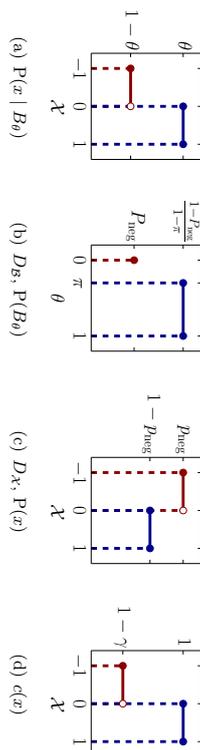

Figure 2: An example generative process for MI data. Each bag distribution (a) is parameterized by θ , and the distribution over bags (b) corresponds to a distribution over values of θ . The resulting distribution over instance (c) is derived in Equation 4 and Equation 5. The probability of instances appearing in positive bags (d) is derived in Equation 6 and Equation 7.

expressed in our generative model. That is, sampling from our generative process in that case is indistinguishable from sampling directly from D_X with labels assigned according to f . Below, we discuss the relationship between our generative model and other proposed models for MI learning.

2.2 An Example of the Generative Process

As a concrete example, suppose the instance space is the closed real-valued interval $\mathcal{X} = [-1, 1]$ and each bag B_θ is a distribution parameterized by a single real-valued parameter $\theta \in [0, 1]$. As illustrated in Figure 2(a), the bag distribution $P(x | B_\theta)$ assigns $(1 - \theta)$ of the probability mass uniformly to the interval $[-1, 0)$, and θ of the mass uniformly to the interval $[0, 1]$. Each value of θ corresponds to a different bag, which is a different distribution over instances.

In this example, a distribution over bags is essentially a distribution over the bag parameter θ . Such a distribution is illustrated in Figure 2(b), and assigns P_{neg} of the mass to the set $\{0\}$ and the remaining $1 - P_{\text{neg}}$ portion of the mass uniformly to the interval $[\pi, 1]$. The probability of sampling a bag, $P(B_\theta)$, corresponds to the probability of sampling the corresponding value of θ . Similarly, a bag-labeling function F can be defined in terms of θ as follows:

$$F(B_\theta) = \begin{cases} 0 & \text{if } \theta = 0 \\ 1 & \text{if } \theta > 0. \end{cases} \quad (3)$$

Thus, for this example, $P_{\text{neg}} = P[F(B_\theta) = 0]$.

For the sake of the example, we choose the instance-labeling function to be

$$f(x) = \begin{cases} 0 & \text{if } x < 0 \\ 1 & \text{if } x \geq 0. \end{cases}$$

This choice is consistent with the bag-labeling function defined in Equation 3, since $F(B_\theta) = 0$ implies $\theta = 0$, which implies that the probability of sampling a positively labeled $x \in [0, 1]$ is zero as required.

If we marginalize out the bag distribution, we obtain the single instance distribution in Figure 2(c). Analytically, for any $x_- \in [-1, 0)$, we have

$$\begin{aligned} P(x_-) &= \int_0^1 P(x_- | B_\theta) P(B_\theta) d\theta \\ &= 1 \cdot P_{\text{neg}} + \int_\pi^1 (1 - \theta) \frac{1 - P_{\text{neg}}}{1 - \pi} d\theta \\ &= P_{\text{neg}} + \frac{1}{2}(1 - P_{\text{neg}})(1 - \pi) \triangleq P_{\text{neg}}. \end{aligned} \quad (4)$$

Similarly, for $x_+ \in [0, 1]$,

$$\begin{aligned} P(x_+) &= \int_0^1 P(x_+ | B_\theta) P(B_\theta) d\theta \\ &= 0 \cdot P_{\text{neg}} + \int_\pi^1 \frac{\theta - P_{\text{neg}}}{1 - \pi} d\theta \\ &= \frac{1}{2}(1 - P_{\text{neg}})(1 + \pi) = 1 - P_{\text{neg}}. \end{aligned} \quad (5)$$

Since probability density functions exist for this example, we can analytically compute $c(x)$ given the following expression:

$$c(x) = P[F(B) = 1 | x] = \frac{\int_{B_+} P(x | B) dP(B)}{P(x)},$$

where $B_+ = \{B : F(B) = 1\}$. As described, for positive instances $x_+ \in [0, 1]$, we have

$$c(x_+) = \frac{\int_\pi^1 P(x_+ | B_\theta) P(B_\theta) d\theta}{\frac{1}{2}(1 - P_{\text{neg}})(1 + \pi)} = 1, \quad (6)$$

since positive instances always appear in positive bags. On the other hand, for negative instances,

$$\begin{aligned} c(x_-) &= \frac{\int_\pi^1 P(x_- | B_\theta) P(B_\theta) d\theta}{P_{\text{neg}} + \frac{1}{2}(1 - P_{\text{neg}})(1 - \pi)} \\ &= \frac{\frac{1}{2}(1 - P_{\text{neg}})(1 - \pi)}{P_{\text{neg}} + \frac{1}{2}(1 - P_{\text{neg}})(1 - \pi)} \triangleq 1 - \gamma. \end{aligned} \quad (7)$$

The resulting values of $c(x)$ are shown in Figure 2(d). Note that for this generative process, except for the trivial case in which $P_{\text{neg}} = 0$, $1 - \gamma = c(x_-) < 1$, so $\gamma > 0$. Thus, the assumption that negative instances appear in negative bags is automatically satisfied for the example in Figure 2. By construction, this example also satisfies the $\pi > 0$ assumption since there is zero probability of sampling a bag with $\theta \in (0, \pi)$ mass over positive bags. Hence, this example is an element of MI-GEN.

2.3 The Empirical Bag-Labeling Function

In MI-GEN, the instance- and bag-labeling functions are defined independently at the level of the generative model, and must satisfy the relationships indicated in Definition 1.

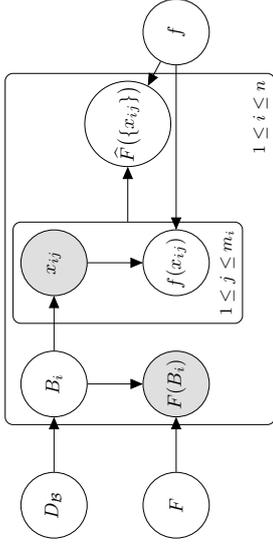

Figure 3: An illustration of the instance-, bag-, and empirical bag-labeling functions in MI-GEN.

However, in the standard MI setting, bag labels are typically viewed as being derived from instance labels. That is, if a bag is a set, then it is positive if it contains at least one positive instance, and negative otherwise.

Unlike the plate model in Figure 1(a), we do not typically observe bags directly in the MI setting. In the typical case, we only have access to samples $X_i = \{x_{ij}\}_{j=1}^{m_i}$, each drawn independently according to the distribution corresponding to each bag B_i , so that $\{\{x_{ij}\}_{j=1}^{m_i}, F(B_i)\}_{i=1}^n$ is the observed MI data set, as shown in Figure 1(c). Each bag can be a different size, but we will use $m_l \leq m_i \leq m_u$ to denote the lower and upper bounds on bag sizes, respectively.

If we think of “bags” (in the sense of the standard generative model) of instances $\{x_{ij}\}_{j=1}^{m_i}$ as empirical samples drawn from the underlying bag distributions B_i in our model, then it is possible that samples from positive bags do not contain any positive instances. Hence, such “bags” would be negative in the sense of the standard model. To more harmoniously account for the standard notion of bag labels within our model, we introduce the empirical bag-labeling function, $\widehat{F} : \mathcal{X}^* \rightarrow \{0, 1\}$:

$$\widehat{F}(X_i) = \max_j f(x_{ij}), \tag{8}$$

where $X_i = \{x_{ij}\}_{j=1}^{m_i}$ is any finite set of instances.

We can think of \widehat{F} as the bag labels that would be assigned by an oracle that had perfect information about the instance-labeling function f , but only an empirical sample from each bag. An illustration of the empirical bag-labeling function is shown in Figure 3. Figure 3 is a version of Figure 1(c) that shows the contributions of the instance-labeling and empirical bag-labeling functions. For every instance x_{ij} in an empirical bag sample, f assigns the label $f(x_{ij})$ to x_{ij} . On the other hand, \widehat{F} is a function of the entire bag sample $X_i = \{x_{ij}\}_{j=1}^{m_i}$ as well as the instance-labeling function f , as specified in Equation 8.

The labeling functions F and \widehat{F} will always agree on negative bags, since only negative instances are observed in negative bags. However, there might be some discrepancy between

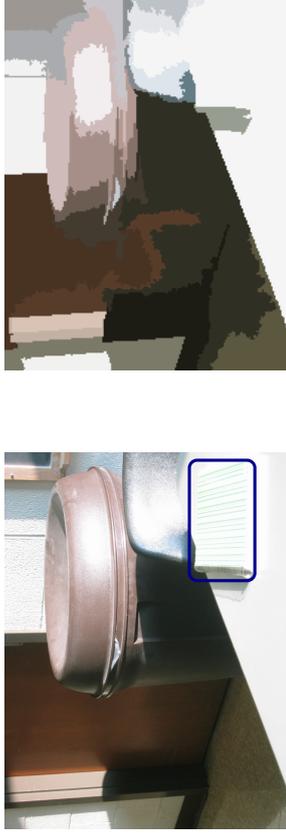

Figure 4: An example from the CBIR domain when a positive image does not contain a positive instance (the notebook, annotated in blue) after segmentation.

F and \widehat{F} on positive bags if only negative instances are sampled within a positive bag. We return to characterizing the discrepancy between F and \widehat{F} in Section 3.2.

The discrepancy between F and \widehat{F} is essentially bag-label noise that naturally results from our generative model. Previous generative models do not account for this potential source of label noise, despite its presence in some domains. For example, in the drug activity prediction domain, even if it is known that a molecule activates a receptor, a sample of conformations from this molecule might not contain the particular positive conformation that causes activation. Likewise, for the CBIR domain, extracting a set of objects from images is often performed using segmentation achieved through local optimization (Andrews et al., 2003; Carson et al., 2002). Therefore, it is possible that no single instance in a bag generated from a positive image will correspond to the positive instance. Figure 4 shows an example from the SIVAL data set when, due to lighting conditions, the positive “notebook” instance in the image is grouped with the table during segmentation (Settles et al., 2008). This kind of “noise” is naturally captured by our generative model as the discrepancy between \widehat{F} and F .

2.4 Relationship to Prior Models

The most general model in which instance learnability results have been previously shown is the “IID r -tuple” model (Blum and Kalai, 1998). The model, illustrated in Figure 5(a), assumes that each bag is generated by randomly sampling r instances in every bag from the same underlying instance distribution, D_X . However, this is an unrealistic assumption for many domains. For example, consider the drug activity prediction setting. In this domain, that would mean that the conformations of every molecule are sampled independently from the same distribution, which is not true as it requires that different molecules share the same conformations. Likewise, for CBIR, the IID assumption asserts that all segments in *all* images are sampled from the same distribution, when the distributions over objects/segments clearly change between images.

To show that our model is more general than the IID r -tuple model, we now describe how to simulate this model within our model. First, we define each bag to be a probability distribution parameterized by an r -tuple of instances $B_{(x_1, \dots, x_r)}$. This distribution will be a weighted sum of point masses over each of the r instances: $\mathbf{P}(x | B_{(x_1, \dots, x_r)}) = \frac{1}{r} \sum_{i=1}^r \delta_{x_i}(x)$. Then, for any distribution D_X over instances (with $\mathbf{P}(x)$ and instance-labeling function f), we let the distribution over bags D_B be defined as $\mathbf{P}(B_{(x_1, \dots, x_r)}) \triangleq \prod_{i=1}^r \mathbf{P}(x_i)$, which is the probability that the corresponding r -tuple would have been sampled from D_X , and the bag-labeling function F to be $F(B_{(x_1, \dots, x_r)}) = \max_{1 \leq i \leq r} f(x_i)$. Let $p_{\text{neg}} = \mathbf{P}[f(x) = 0]$, then we claim that the (D_X, D_B, f, F) described above is in ML-GEN $(\mu_{\text{neg}}^{\text{at}}, \frac{1}{r})$.

First, we need to show that D_B as defined satisfies Condition 1 of Definition 1:

$$\begin{aligned} \mathbf{P}(x) &\stackrel{?}{=} \int_B \mathbf{P}(x | B) d\mathbf{P}(B) \\ &= \int_B \frac{1}{r} \sum_{i=1}^r \delta_{x_i}(x) d\mathbf{P}(B_{(x_1, \dots, x_r)}) \\ &= \frac{1}{r} \sum_{i=1}^r \int_{\mathcal{X}} \dots \int_{\mathcal{X}} \delta_{x_i}(x) d\mathbf{P}(x_r) \dots d\mathbf{P}(x_1) \\ &= \frac{1}{r} \sum_{i=1}^r \left(\prod_{j \neq i} \int_{\mathcal{X}} d\mathbf{P}(x_j) \right) \left(\int_{\mathcal{X}} \delta_{x_i}(x) d\mathbf{P}(x_i) \right) \\ &= \frac{1}{r} \sum_{i=1}^r (1^{r-1}) \mathbf{P}(x) = \mathbf{P}(x). \end{aligned}$$

So sampling instances under our two-step generative process is equivalent to sampling according to the original instance distribution.

Condition 2 of Definition 1 is trivially satisfied, since by the definition of F , positive instances never appear in negative bags. To show that Condition 3 holds, we must compute the probability that negative instances appear in a negative bag. Using the definition of conditional probability, this is,

$$\mathbf{P}[F(B) = 0 | x] = \frac{\int_B \mathbf{P}(x | B) d\mathbf{P}(B)}{\mathbf{P}(x)}.$$

Using the fact that in a negative bag $B_{(x_1, \dots, x_r)}$, all instances must be negative, we can compute the numerator for a negative instance as

$$\begin{aligned} \int_B \mathbf{P}(x | B) d\mathbf{P}(B) &= \int_B \frac{1}{r} \sum_{i=1}^r \delta_{x_i}(x) d\mathbf{P}(B_{(x_1, \dots, x_r)}) \\ &= \frac{1}{r} \sum_{i=1}^r \int_{\mathcal{X}} \dots \int_{\mathcal{X}} \delta_{x_i}(x) d\mathbf{P}(x_r) \dots d\mathbf{P}(x_1) \\ &= \frac{1}{r} \sum_{i=1}^r \left(\prod_{j \neq i} \int_{\mathcal{X}} d\mathbf{P}(x_j) \right) \left(\int_{\mathcal{X}} \delta_{x_i}(x) d\mathbf{P}(x_i) \right) \\ &= \frac{1}{r} \sum_{i=1}^r (p_{\text{neg}}^{r-1}) \mathbf{P}(x) = p_{\text{neg}}^{r-1} \mathbf{P}(x). \end{aligned}$$

Thus, $\mathbf{P}[F(B) = 0 | x] = \frac{p_{\text{neg}}^{r-1} \mathbf{P}(x)}{\mathbf{P}(x)} = p_{\text{neg}}^{r-1}$. Since this probability is the same across all negative instances, this means that $\gamma = p_{\text{neg}}^{r-1}$. This quantity is positive as long as $p_{\text{neg}} > 0$. Otherwise, all instances are positive, so the $\gamma > 0$ assumption is vacuously satisfied.

Finally, to show that Condition 4 of Definition 1 is satisfied, we see that for a positive bag, B_i ,

$$\begin{aligned} \mathbf{P}[f(x) = 1 | B] &= \int_{\mathcal{X}} f(x) \left(\frac{1}{r} \sum_{i=1}^r \delta_{x_i}(x) \right) dx \\ &= \frac{1}{r} \sum_{i=1}^r \int_{\mathcal{X}} f(x_i) \geq \frac{1}{r} = \pi, \end{aligned} \tag{9}$$

since at least one instance in the bag is such that $f(x) = 1$. Therefore, the IID r -tuple model is a special case of our model in which γ and π are positive, and determined by the fraction of negative instances and bag size r .

Another generative model, used to show the learnability of bag-level concepts (Sabato and Tishby, 2012), allows arbitrary distributions over r -tuples. The model further relaxes the r -tuple model by allowing bag sizes to vary from 1 to R , some maximum bag size. The model is illustrated in Figure 5(b), where D_X^* denotes the distribution over tuples of size at most R . However, this model is also restrictive for many problem domains like drug activity prediction, since it enforces that bag sizes are finite and bounded, whereas molecules can exist in infinitely many conformations.

We can also represent the generative model of Sabato and Tishby (2012) in a similar way as for the IID r -tuple model. We simplify the space of bags to be atomic distributions over $r \leq R$ tuples, and allow an arbitrary distribution D_B over bags rather than requiring that $\mathbf{P}(B_{(x_1, \dots, x_r)}) = \prod_{i=1}^r \mathbf{P}(x_i)$. Now, D_X is not fixed, so we can define it in terms of Condition 1 of ML-GEN so that that condition is automatically satisfied. The bag-labeling function F is still defined in terms of the arbitrary instance-labeling function f , so Condition 2 is still trivially satisfied. Furthermore, by similar reasoning as in Equation 9, $\pi = \frac{1}{r}$ in this generative model, so Condition 4 is satisfied. However, the $\gamma > 0$ assumption (Condition 3) is no longer automatically satisfied by this generative process, since arbitrary distributions over tuples are allowed. Hence, while Sabato and Tishby (2012) analyze bag

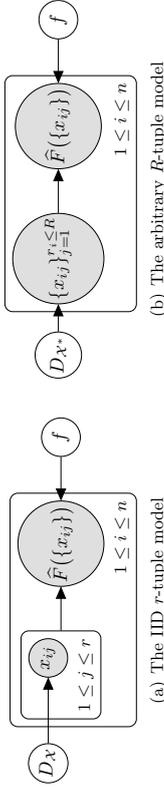

Figure 5: Previous generative models for MI data.

concept learnability with MI-GEN $(0, \frac{1}{R})$, we require MI-GEN $(\gamma, \frac{1}{R}) \subset$ MI-GEN $(0, \frac{1}{R})$ for instance concept learnability.

Babenko et al. (2011) propose treating bags in the MI setting as *manifolds* in the instance space \mathcal{X} . While this allows describing a bag with an infinite number of instances, it assigns an equal “weight” to every instance. However, for a domain like drug activity prediction, a molecule is more likely to exist in certain conformations than in others. The varying weight of instances is naturally handled in our setting, but we do not treat bags as manifolds over instances, so our results may not apply to the generative process in which bags are manifolds.

Some prior work proposes additional generative models for MIL, some of which model bags as distributions over instances. For example, some work uses Gaussian distributions (Maron and Lozano-Pérez, 1998; Xu, 2003) or mixture models (Foulds and Smyth, 2011) to represent distributions over instances, while other work uses more complex graphical (Yang et al., 2009; Adel et al., 2013; Kandemir and Hamprecht, 2014) or hierarchical Bayesian (Kueck and de Freitas, 2005) models. However, our work differs from these prior investigations in two important ways. First, we focus on the theoretical properties of our generative model, whereas prior work has only empirically explored the performance of algorithms tailored to specific generative models. Secondly, while prior generative models require that bags or instances are sampled from specific, parametric probability distributions, our generative model does not require such assumptions. Thus, the theoretical results presented below apply to more general scenarios than the models previously explored.

2.5 Applicability to Problem Domains

At the beginning of this section, we motivated MI-GEN using the 3D-QSAR domain. In this section, we elaborate on how bags can naturally be viewed as distributions in various other problem domains and which labeling tasks illustrated in Figure 3 are of interest in each domain. Of course, as described in Section 2.4, standard generative models are special cases of MI-GEN; so previous applications of MIL for which it is most natural to think of bags as finite sets of instances can still be incorporated in this model.

2.5.1 DRUG ACTIVITY PREDICTION

For the drug activity prediction or the 3D-QSAR problem, it is natural to think of each molecule as a distribution over conformations. While it is natural to view learning molecule-level activity F as the ultimate goal of 3D-QSAR, it is also important to learn the instance-

labeling function f . Knowing whether an individual conformation binds to a receptor provides information about the structure of the receptor’s binding site, which is practically difficult to measure directly. Hence, learning both instance- and bag-labeling functions are important in the 3D-QSAR domain.

2.5.2 TEXT CATEGORIZATION

While it is popular to represent documents as a flat “bag of words” using a single feature vector comprised of word frequencies (Salton and McGill, 1983), prior work has acknowledged the benefits of representing document-specific structure. In particular, latent Dirichlet allocation (LDA) models each document as a mixture of distributions over words (Blei et al., 2003). Of course, LDA can also be applied to a coarser-grained representation in which documents are distributions over n -grams or paragraphs, which are like individual instances in the MI setting (Blei et al., 2003). Other work attempts to infer the level of granularity in a document in addition to modeling the distributions over the discovered “segments” (Du et al., 2013). Hence, treating documents as distributions is already a natural and popular representation for text. On the other hand, LDA treats each document distribution as taking a specific parametric form, whereas our results and analysis do not make any parametric assumptions about bag-level distributions.

As for 3D-QSAR, both document-level and instance-level categorization is important in the text categorization domain. For example, if certain types of documents like survey articles discuss various subjects, then it might be important to determine not just that the document as a whole discusses a particular subject, but also which specific passage or paragraph discusses the subject.

2.5.3 CONTENT-BASED IMAGE RETRIEVAL

Applying our generative framework to the CBIR task requires viewing images as distributions over objects such that the objects in each image are a sample from the corresponding distribution. As with LDA for the text categorization domain, analogous probabilistic models have been proposed for categorizing natural scenes (Fei-Fei and Perona, 2005). Thus, while treating images as distributions is not unprecedented, our analysis is novel in that it discusses learnability under such a model without assuming that image distributions take a specific parametric form.

Furthermore, as for the other domains discussed, the bag-labeling function F is not the only latent variable of interest in CBIR. In addition to labeling new images, a CBIR system might be interested in determining the location of the object of interest within an image, which requires learning the instance-labeling function f .

3. Learning Accurate Concepts from MI Data

In this section, we describe new theoretical results that highlight the advantages of the generative model proposed in Section 2. In particular, the new generative model allows new results about instance- and bag-concept learnability that previously only held under a much stronger set of assumptions. As we describe in Section 4, additional theoretical results imply the surprising but testable ability of standard supervised approaches to learn

Table 1: A summary of the learnability results in Section 3 and Section 4.

	Accuracy		AUC
Instance	f	Theorem 1	Theorem 4
	\hat{F}	Theorem 2	Theorem 5
Bag	F	Theorem 3	Theorem 6

Table 2: Legend of the basic notation used in Section 3.

Symbol	Description/Definition
\mathcal{X}	Space of instances
\mathcal{B}	Space of bags (distributions over instances)
\mathcal{X}^*	Set of bag samples (sets of instances)
x_{ij}	Instance $x_{ij} \in \mathcal{X}$
B_i	Bag $B_i \in \mathcal{B}$
X_i	Bag sample $\{x_{ij}\}_{j=1}^{m_i} \in \mathcal{X}^*$, $x_{ij} \sim B_i$
m_i	Bag Sample Size $(m_i \leq X_i \leq m_u)$
f	Instance-Labeling Concept $m_i = X_i $
F	Bag-Labeling Concept
\hat{F}	Empirical Bag-Labeling Concept $\hat{F}(X_i) \triangleq \max_j f(x_{ij})$
g	Instance-Labeling Hypothesis
\hat{G}	Empirical Bag-Labeling Hypothesis $\hat{G}(X_i) \triangleq \max_j g(x_{ij})$
\mathcal{F}	Instance-Labeling Concept Class
$\text{VC}(\mathcal{F})$	Vapnik-Chervonenkis (VC) Dimension (Vapnik and Chervonenkis, 1971)

to rank instances and bags from MI data. Table 1 summarizes the theoretical contributions made in this and the following sections, which demonstrate the learnability of the instance concept f , empirical bag-labeling function \hat{F} , and bag-labeling function F with respect to both accuracy and ranking as measured by area under ROC (AUC). The results in this section and the following section use a model of the instance labeling function f to derive models for the bag-labeling functions \hat{F} and F .

Defining the ability of an algorithm to learn a good approximation of a target concept requires some metric by which the quality of the approximation is to be measured. Traditionally, the quality of a classifier is measured in terms of expected 0–1 loss. We begin by investigating the ability of algorithms to learn accurate concepts from MI data in this sense. While there is only one learning task in the supervised setting, there are now both instance- and bag-concept learning tasks in the MI setting, which we explore separately in the following sections. Table 2 shows the notation used for the concepts in this section.

3.1 Learning Accurate Instance Concepts

The probably approximately correctly (PAC) framework describes one sense in which it is possible to learn accurate concepts from supervised data. Since the generative process

described in Section 2 differs from that for supervised learning, we must restate what it means to “PAC” learn an accurate instance concept under this model.

In the supervised setting, the learnability of some fixed concept class \mathcal{F} is discussed without making any assumptions about the distribution over instances. The definition of MI-GEN in Definition 1 similarly allows any instance distribution, with which many bag distributions are consistent in the sense of Condition 1. To ensure that the target concept f is a member of the concept class \mathcal{F} , we must further restrict the set of models allowed by the generative process as follows:

Definition 2 (MI-GEN \mathcal{F}) For any $\gamma \in (0, 1]$ and $\pi \in [0, 1]$:

$$\text{MI-GEN}_{\mathcal{F}(\gamma, \pi)} \triangleq \{(D_X, D_B, f, F) \in \text{MI-GEN}(\gamma, \pi) : f \in \mathcal{F}\}.$$

Now, we can formally define PAC learnability for the MI setting:

Definition 3 (Instance MI PAC-learning) We say that an algorithm \mathcal{A} MI PAC-learns instance concept class \mathcal{F} from MI data when for any $(D_X, D_B, f, F) \in \text{MI-GEN}_{\mathcal{F}(\gamma)}$ with $\gamma > 0$, and $\epsilon_1, \delta > 0$, \mathcal{A} requires $O(\text{poly}(\frac{1}{\epsilon_1}, \frac{1}{\delta}))$ bag-labeled instances sampled independently from the MI generative process in Figure 1(b) to produce an instance hypothesis g with risk $R_I(g) < \epsilon_1$ with probability at least $1 - \delta$ over samples.²

Note that because our generative model allows us to discuss the marginalized instance distribution D_X , the risk $R_I(g) = \mathbb{E}_{x \sim D_X} [\mathbb{1}[f(x) \neq g(x)]]$ is measured with respect to this distribution as in the supervised setting. Now we show that instance concepts are MI PAC-learnable in the sense of Definition 3:

Theorem 1 An instance concept class \mathcal{F} with VC dimension $\text{VC}(\mathcal{F})$ is Instance MI PAC-learnable using $O\left(\frac{1}{\epsilon_1 \gamma} \left(\text{VC}(\mathcal{F}) \log \frac{1}{\epsilon_1 \gamma} + \log \frac{1}{\delta}\right)\right)$ examples.

Proof By Condition 1 in Definition 1, we can treat bag-labeled instances as being drawn from the underlying instance distribution D_X . Instances are observed with some label noise with respect to true labels given by f . Since positive instances never appear in negative bags (by Condition 2 of Definition 1), noise on instances is one-sided. If every negative instance appears in negative bags at least some γ fraction of the time (by Condition 3), then the maximum one-sided noise rate is $\eta = 1 - \gamma$. Since $\gamma > 0$, $\eta < 1$, which is required for learnability. Under our generative assumptions, the noise is “semi-random” in that noise rate might vary across instances, but is bounded by $\eta < 1$. Thus, learning an instance concept is equivalent to learning from data with one-sided label noise in this sense.

The result of Simon (2012) shows that in the presence of one-sided, semi-random noise, when a concept class \mathcal{F} has a VC dimension of $\text{VC}(\mathcal{F})$, \mathcal{F} is PAC-learnable from $O\left(\frac{1}{\epsilon_1(1-\eta)} \left(\text{VC}(\mathcal{F}) \log \frac{1}{\epsilon_1(1-\eta)} + \log \frac{1}{\delta}\right)\right)$ examples using a “minimum one-sided disagreement” strategy. This strategy entails choosing a classifier that minimizes the number of disagreements on positively-labeled examples while perfectly classifying all negatively-labeled examples. This strategy also works in the special case that all instances and bags are positive ($\eta = 0$, or $\gamma = 1$, since there are no negative instances). Substituting $1 - \gamma$ for η in the

² Alternate definitions of PAC-learnability require that \mathcal{A} also take at most polynomial time to produce hypothesis g . We defer the discussion of time complexity to Section 3.5.

bound of Simon (2012) yields the bound in terms of γ . ■

We note that Theorem 1 allows for “noisy” positive bags without positive instances ($\pi = 0$), since the additional bag-level noise is essentially absorbed into η .

3.2 Learning Accurate Bag Concepts

As for instance concept learnability, we must formally define what we mean to learn accurate bag concepts in the MI setting. As described in Section 2, there are two bag-labeling functions we might be interested in learning. In our generative model, we assume that the MI relationship between bag and instance labels holds at the level of the generative process. That is, bags are directly assigned labels by a bag concept F . On the other hand, given a set of instances sampled from a bag, we might be interested in learning the more traditional bag-labeling concept in the MI setting, $\widehat{F}(X_i) = \max_j f(x_{ij})$, which we have called the empirical bag-labeling function (Equation 8). We will first analyze learnability with respect to the empirical bag-labeling function and then extend this result to the true bag-labeling function.

We can define the risk of a bag-labeling concept \widehat{G} with respect to the underlying empirical bag-labeling concept \widehat{F} as follows:

$$R_{\widehat{F}}(\widehat{G}) = \mathbb{E}[\mathbb{1}[\widehat{F}(X) \neq \widehat{G}(X)]] \tag{10}$$

$$= \int_B \int_{\mathcal{X}^*} \mathbb{1}[\widehat{F}(X) \neq \widehat{G}(X)] d\mathbb{P}(X | B) d\mathbb{P}(B),$$

where $\mathbb{P}(X | B)$ is the probability of sampling the set of instances X from bag B . Since we assume that instances are sampled IID according to B , $\mathbb{P}(X | B) = \prod_{x \in X} \mathbb{P}(x | B)$. Given a formal definition of the risk of an empirical bag-labeling function, we can define learnability with respect to this function below:

Definition 4 (Empirical Bag MI PAC-learning) *We say that an algorithm \mathcal{A} MI PAC-learns empirical bag-labeling functions derived from instance concept class \mathcal{F} when for any $(D_{\mathcal{X}}, D_B, f, F) \in \text{MI-GEN}_{\mathcal{F}}(\gamma)$ with $\gamma > 0$, and $\epsilon_B, \delta > 0$, \mathcal{A} requires $O(\text{poly}(\frac{1}{\gamma}, \frac{1}{\epsilon_B}, \frac{1}{\delta}))$ bag-labeled instances sampled independently from the MI generative process in Figure 1(b) to produce an empirical bag-labeling function \widehat{G} with risk $R_{\widehat{F}}(\widehat{G}) < \epsilon_B$ with probability at least $1 - \delta$ over samples.*

To show empirical bag concept learnability under our generative model, we will show that by learning an accurate enough instance concept g , the resulting empirical bag-labeling concept given by $\widehat{G}(X_i) = \max_j g(x_{ij})$ will have low risk with respect to \widehat{F} . Thus, we start with a bound on $R_{\widehat{F}}(\widehat{G})$ in terms of $R_f(g)$.

Lemma 1 *Let $R_f(g)$ be the risk of an instance labeling concept g , and $R_{\widehat{F}}(\widehat{G})$ be the risk of the empirical bag-labeling function $\widehat{G}(X_i) = \max_j g(x_{ij})$. Then if bag sample sizes are bounded by m_o ($\forall i : |X_i| \leq m_o$), $R_{\widehat{F}}(\widehat{G}) \leq m_o R_f(g)$.* ■

Proof See Appendix A.

Given the bound demonstrated in Lemma 1, we can derive the following result:

Theorem 2 *Empirical bag-labeling functions derived from instance concept class \mathcal{F} with VC dimension $\text{VC}(\mathcal{F})$ are PAC-learnable from MI data using*

$$O\left(\frac{m_u}{\epsilon_B \gamma} \left(\text{VC}(\mathcal{F}) \log \frac{m_u}{\epsilon_B \gamma} + \log \frac{1}{\delta}\right)\right)$$

examples.

Proof The general strategy is to learn an approximation g for $f \in \mathcal{F}$ using minimum one-sided disagreement as mentioned in the proof of Theorem 1 and then to derive an empirical bag-labeling function \widehat{G} from g .

For a desired bound ϵ_B on $R_{\widehat{F}}(\widehat{G})$, by using $\epsilon_1 = \frac{\epsilon_B}{m_u}$ in Theorem 1, this ensures that the resulting instance classifier is such that $R_f(g) < \frac{\epsilon_B}{m_u}$ with high probability. Combined with the result in Lemma 1, this implies that $R_{\widehat{F}}(\widehat{G}) \leq m_u R_f(g) < m_u \left(\frac{\epsilon_B}{m_u}\right) = \epsilon_B$, so $R_{\widehat{F}}(\widehat{G}) < \epsilon_B$ as desired. Substituting $\epsilon_1 = \frac{\epsilon_B}{m_u}$ into the bound in Theorem 1 gives the bound as stated in Theorem 2. ■

Again, Theorem 2 allows for noisy positive bags without positive instances ($\pi = 0$). Furthermore, in the special case when every bag sample is a singleton $X = \{x\}$, then $m_u = 1$ and $\widehat{F}(\{x\}) = f(x)$. Thus, the instance concept learnability result in Theorem 1 is really just a special case of learning an empirical bag-labeling function with bags of size 1 as in Theorem 2.

Next, we turn our attention to learning the underlying bag-labeling function F . We will still use the instance-labeling function g to derive this bag-labeling function. It is possible to consider learning F without the use of an instance concept g , as we discuss in Section 3.3. During both training and testing, we are only given access to a sample X_i from each bag B_i with which we can estimate $F(B_i)$. Therefore, we will again learn an empirical bag labeling function $\widehat{G}(X_i)$. However, now we will assess the quality of \widehat{G} with respect to the underlying bag-labeling function F as follows:

$$R_F(\widehat{G}) = \mathbb{E}[\mathbb{1}[F(B) \neq \widehat{G}(X)]] \tag{11}$$

$$= \int_B \int_{\mathcal{X}^*} \mathbb{1}[F(B) \neq \widehat{G}(X)] d\mathbb{P}(X | B) d\mathbb{P}(B).$$

The definition of bag concept learnability then takes the same form as that in Definition 4 with the risk as given in Equation 11. As we will show in Lemma 2, we now also require the further assumption that π , minimum fraction of positive instances in positive bags, is nonzero.

Definition 5 (Bag MI PAC-learning) *We say that an algorithm \mathcal{A} MI PAC-learns bag-labeling functions derived from instance concept class \mathcal{F} when for any $(D_{\mathcal{X}}, D_B, f, F) \in \text{MI-GEN}_{\mathcal{F}}(\gamma, \pi)$ with $\gamma, \pi > 0$, and $\epsilon_B, \delta > 0$, algorithm \mathcal{A} requires $O(\text{poly}(\frac{1}{\gamma}, \frac{1}{\pi}, \frac{1}{\epsilon_B}, \frac{1}{\delta}))$ bag-labeled instances sampled independently from the MI generative process in Figure 1(b) to produce an empirical bag-labeling function \widehat{G} with risk $R_F(\widehat{G}) < \epsilon_B$ with probability at least $1 - \delta$ over samples.*

In order to show learnability of the bag-labeling concept F , we adopt a similar strategy as for Theorem 2 in which we first learn an instance-labeling concept g , then use g to derive

an empirical bag-labeling concept \widehat{G} . Since Theorem 2 shows that we can learn a concept G that accurately models F , what remains to be shown is that F is an accurate model of F under some additional conditions. First, we prove the following lemma, which decomposes the risk $R_F(\widehat{G})$ into the discrepancy between \widehat{G} and \widehat{F} , and the discrepancy between \widehat{F} and F .

Lemma 2 For any empirical bag-labeling concept \widehat{G} ,

$$R_F(\widehat{G}) \leq R_{\widehat{F}}(\widehat{G}) + R_F(\widehat{F}).$$

Proof See Appendix A. ■

Now, we derive a bound on the discrepancy between the empirical bag-labeling function \widehat{F} and the underlying bag-labeling function F . Since this discrepancy arises when we do not sample a positive instance within a positive bag, the bound depends on the minimum bag sample size and the minimum fraction π of positive instances in every positive bag.

Lemma 3 Suppose bag samples are of size at least m_i ($\forall i : m_i \leq |X_i|$), then $R_F(\widehat{F}) \leq (1 - \pi)^{m_i}$.

Proof See Appendix A. ■

Finally, we can now show the following learnability result with respect to the underlying bag-labeling function. However, note that in Lemma 3, the error $R_F(\widehat{F})$ decreases with the minimum bag size m_i . Thus, in order to achieve low error with respect to F , we must ensure that bags in the test set are sufficiently large. Therefore, the following result is stated under the additional condition that the test bag sample sizes m_i satisfy some constraints. Note that these constraints arise naturally from the process that samples instances from bag distributions.

Theorem 3 Bag-labeling functions derived from instance concept class \mathcal{F} with VC dimension $VC(\mathcal{F})$ are PAC-learnable from MI data using

$$O\left(\frac{1}{\epsilon_B^2 \pi} \left(VC(\mathcal{F}) \log \frac{1}{\epsilon_B \pi} + \log \frac{1}{\delta}\right)\right) \tag{12}$$

examples when test bag sample sizes are bounded by $m_i \leq m \leq m_u$ and m_i is large enough such that $m_i \geq \frac{1}{\pi} \log \frac{2}{\epsilon_B}$.

Proof Intuitively, we can learn an instance-labeling function g according to Theorem 1 and then use the resulting empirical bag-labeling function \widehat{G} . By combining the previously stated results, we can bound $R_F(\widehat{G})$ as

$$\begin{aligned} R_F(\widehat{G}) &\leq R_{\widehat{F}}(\widehat{G}) + R_F(\widehat{F}) && \text{(by Lemma 2)} \\ &\leq m_u R_g(g) + R_F(\widehat{F}) && \text{(by Lemma 1)} \\ &\leq m_u R_g(g) + (1 - \pi)^{m_i}. && \text{(by Lemma 3)} \end{aligned}$$

In the case that $\pi = 1$, then the second term in the sum is zero. Otherwise, suppose the minimum bag size is such that

$$m_i \geq \frac{1}{\pi} \log \frac{2}{\epsilon_B} \geq \frac{\log \frac{\epsilon_B}{2}}{\log(1 - \pi)} = \log_{1 - \pi} \frac{\epsilon_B}{2},$$

where the second inequality follows from the fact that $\pi \leq -\log(1 - \pi)$ for $\pi \in (0, 1)$. Therefore, since $(1 - \pi) < 1$, we have that

$$(1 - \pi)^{m_i} \leq (1 - \pi)^{\log_{1 - \pi} \frac{\epsilon_B}{2}} = \frac{\epsilon_B}{2}.$$

Furthermore, when learning the instance concept g , we can choose ϵ_l to be such that $\epsilon_l = \frac{\epsilon_B}{2m_u}$. Since g will be such that $R_g(g) < \epsilon_l$ with probability $(1 - \delta)$, with the same probability we have that

$$\begin{aligned} R_F(\widehat{G}) &\leq m_u R_g(g) + (1 - \pi)^{m_i} \\ &< m_u \left(\frac{\epsilon_B}{2m_u}\right) + \frac{\epsilon_B}{2} = \epsilon_B. \end{aligned}$$

Substituting the expression for ϵ_l in terms of ϵ_B into the bound in Theorem 1 gives the sample complexity bound:

$$O\left(\frac{m_u}{\epsilon_B^2 \gamma} \left(VC(\mathcal{F}) \log \frac{m_u}{\epsilon_B \gamma} + \log \frac{1}{\delta}\right)\right),$$

which is the same bound as stated in Theorem 2.

It is also possible to sub-sample large bags such that there is also a conservative upper bound on sample size $m_u = O\left(\frac{1}{\epsilon_B \pi}\right)$, which is consistent with $m_i \geq \frac{1}{\pi} \log \frac{2}{\epsilon_B}$. Then, we can derive an expression for learnability in terms of π : Substituting this bound into that of Theorem 2 gives the second sample complexity bound as stated in Equation 12. ■

3.3 Discussion

The results presented in Section 3.1 and Section 3.2 follow the same basic strategy. First, minimum one-sided disagreement is used to learn an accurate instance concept g in the presence of one-sided noise on bag-labeled instances. Then, for the bag-labeling task, instance labels are aggregated using an empirical bag-labeling function \widehat{G} to approximate the empirical bag-labeling function \widehat{F} or the underlying bag-labeling function F . The idea of combining instance labels to produce a bag-labeling function is used by many existing MI algorithms.

However, under the generative model that treats bags as distributions, the bag-labeling results derived in Section 3.2 are somewhat counterintuitive. On the one hand, if bags are distributions from which we observe samples, then the larger the samples, the more information an algorithm has about the underlying bag distribution. Intuitively, it seems that the better an algorithm can estimate the underlying bag distribution, which is the object of interest for classification, the better it can learn a concept to label new bags. On

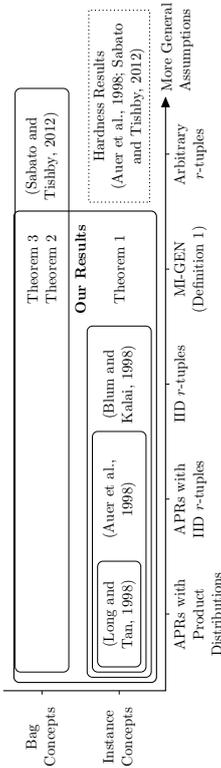

Figure 6: Relation to prior learnability results.

the other hand, the result in Theorem 2 suggests that it is harder to learn from larger bag sizes, since roughly $O(m_n \log m_n)$ more examples are required to learn an accurate concept.

Essentially, the source of this incoherence in reasoning is the use of an instance-labeling concept g to derive the bag-labeling concept \widehat{G} . In the process of combining instance labels to label a bag, small errors in the instance labeling function g compound quickly. For example, g must label *all* instances in a negative bag correctly for \widehat{G} to label the bag correctly. As bag size increases, it becomes less likely that g will agree with f across all instances.

Therefore, despite our positive results suggesting that learning an accurate instance-labeling function is sufficient to learn an accurate bag-labeling function, in practice, it is possible to imagine an alternative approach in which bag-labeling functions are learned directly by representing bags in a supervised fashion. Several practical approaches, such as bag-level kernels (Gärtner et al., 2002; Zhou et al., 2009) and embeddings (Chen et al., 2006; Foulds, 2008) do precisely this, and essentially turn the bag-label learning problem into a supervised learning problem. Further investigating the trade-offs between techniques that classify bags using instance classifiers and those that directly learn bag classifiers is an interesting direction for future work.

3.4 Relation to Prior Learnability Results

An overview of our results in the context of prior work is shown in Figure 6. Early work on instance learnability shows that axis-parallel rectangles (APRs) are learnable from MI data, but under the restrictive assumption that each bag contains r IID instances sampled from a product distribution (Long and Tan, 1998). Later work by Auer et al. (1998) extends these results to the case when the instance distribution is no longer a product distribution, but the instances are still sampled IID from a single distribution across bags. The most recent results on instance concept learnability in the MI setting are described by Blum and Kalai (1998). Like the proof of Theorem 1, Blum and Kalai (1998) also reduce the problem of learning instance concepts to learning from noisy examples. However, the proof in Blum and Kalai (1998) requires that the label noise on negative examples be uniformly random. This condition is met under the strong assumption made in that work, that instances in all bags are drawn IID from the same distribution over instances. On the other hand, the result in Theorem 1 applies to our more general model in which the noise rate can vary

across instances. Hence, our results rely on the recent work of Simon (2012), which shows that it is possible to learn from instances corrupted with semi-random one-sided noise.

The bag learnability results in Section 3.2 show that an accurate bag concept can be learned by learning an accurate instance concept and deriving a bag concept by combining instance labels within a bag. Other recent work on bag concept learnability takes a different approach. The strategy of Sabato and Tishby (2012) is to directly learn empirical bag-labeling concepts using empirical risk minimization (ERM). That is, they suppose that an algorithm selects an instance-labeling function $g \in \mathcal{F}$ that minimizes $R_{\widehat{F}}(\widehat{G})$. Since general sample complexity bounds exist for ERM in terms of capacity measures such as VC dimension of a hypothesis class (Blumer et al., 1989), Sabato and Tishby (2012) proceed by proving that the capacity of the function class $\{\widehat{G} : \widehat{G}(X_i) = \max_j g(x_{ij}), g \in \mathcal{F}\}$ is bounded in terms of the capacity of \mathcal{F} . In fact, the results of Sabato and Tishby (2012) apply to more general cases in which the combining function used to derive a bag-labeling function from an instance-labeling function is other than the max function. However, the results of Sabato and Tishby (2012) do not prove positive results about instance-labeling concepts.

As indicated in Figure 6, the results in Section 3.2 are not a strict generalization of those in Sabato and Tishby (2012), nor are those in Sabato and Tishby (2012) a generalization of those in Section 3.2. In particular, since MI-GEN treats bags as distributions, the results in Section 3.2 apply to cases not considered in Sabato and Tishby (2012), in which bags are assumed to have finite size. On the other hand, while our generative model can encapsulate aspects of the generative model in Sabato and Tishby (2012) (see Section 2.4), arbitrary distributions over r -tuples are not permitted. However, it may be that we are able to prove positive instance learnability results precisely *because* of this constraint on the generative process.

Other recent work has discussed the difficulty, both theoretically and in practice, to relate the performance of the same classifier on the instance- and bag-labeling tasks (Tragante et al., 2011). In contrast, Lemma 1 illustrates a clear connection between the accuracy of an instance concept and that of the resulting empirical bag concept. This new connection is made possible by the relationship between bag and instance distributions in our generative model, as highlighted in Lemma 1. In particular, Condition 1 of Definition 1 is employed to marginalize out the effect of individual bag distributions so that error on bags can be expressed directly in terms of the error on instances. There are at least two reasons why this relationship is not obvious from empirical results. First, contrasting the sample complexity expressions Theorem 1 and Theorem 3, we see that larger samples are required to learn accurate bag concepts. Thus, for a fixed sample size, there might be a significant discrepancy in performance of a single algorithm on the two learning tasks. Secondly, the relationship we demonstrate holds when an accurate instance concept is learned and *then* applied to the bag-labeling task. However, in practice, many algorithms attempt to learn an instance function to label bags using ERM at the *bag-level*. It is not clear that the instance-labeling function found via bag-level ERM in this way will successfully label instances.

3.5 Relation to Prior Hardness Results

The positive learnability results in Section 3.1 and Section 3.2 do not contradict existing hardness results about learning in the MI setting. Essentially, most hardness results are shown under the scenarios that lie on the far right of Figure 6. For example, Sabato and Tishby (2012) observe that if only positive bags are generated, then learning the bag-labeling function is trivial, but no label information about instances is provided. In this case, learning instance labels is equivalent to learning in the *unsupervised learning* setting, for which no PAC-style guarantees can be made. However, the additional assumptions in MI-GEN preclude the case when only positive bags appear, since the negative instances would never appear in negative bags as required by Condition 3 in Definition 1.

Similarly, under the weak assumption in which arbitrary distributions over r -tuples are allowed, Auer et al. (1998) show that that efficiently PAC-learning MI instance concepts is impossible (unless $\text{NP} = \text{RP}^?$). While the results on instance and bag learnability stemming from Theorem 1 show that a polynomial number of examples can be used to learn accurate concepts, they do not bound the computational complexity of learning from the examples. In particular, minimum one-sided disagreement is known to be NP-hard for certain concept classes and loss functions (Simon, 2012). Therefore, for some concept classes, instance and bag concepts are not *efficiently* PAC-learnable: learnable with a polynomial number of examples *in polynomial time*.

The apparent contradiction between our learnability results and the hardness results of Auer et al. (1998) is resolved by observing that MI-GEN precludes the scenario used to reduce learning disjunctive normal form (DNF) formulae to learning APPRs from MI data. In the reduction used by Auer et al. (1998), each instance corresponds to a (variable assignment, clause) pair, and a bag is formed for each variable assignment by including a pair with that variable assignment for each clause. Bags are sampled uniformly over all variable assignments. Suppose a particular variable assignment v satisfies the first clause c_1 , but not the second clause c_2 . Then the instance (v, c_1) is positive, but (v, c_2) is negative. However, (v, c_2) only ever appears in bags along with (v, c_1) ; that is, in positive bags. This violates the condition that $\gamma > 0$, or that negative instances appear with some probability in negative bags, so our results do not apply to this hard scenario.

Similarly, our generative model precludes scenarios used to show the hardness of learning hyperplane concepts for MI data (Kumudacioglu et al., 2010; Dicochos et al., 2012; Doran and Ray, 2013). It is unknown whether there is an algorithm to efficiently learn hyperplanes that minimize one-sided disagreement. However, even ERM under 0–1 loss is NP-hard for the concept class of hyperplanes (Ben-David et al., 2003), which are widely used in practice for supervised learning. Thus, while previous results have characterized the hardness of MI learning as resulting from arbitrary distributions across bags, our results suggest that the hardness arises from cases in which $\gamma = 0$, or when negative instances only occur in negative bags.

3. **RP** is the class of decision problems for which a probabilistic Turing machine terminates in polynomial time, always returns **NO** when the answer is **NO**, and returns **YES** with probability at least $\frac{1}{2}$ when the answer is **YES**.

3.6 Must Instances be Dependent Samples?

As observed in prior work, most real-world examples of MIIL have bags that contain non-IID instances (Zhou et al., 2009). Thus, our assumption that bag samples X_i are drawn IID according to their corresponding bag distributions B_i might seem unrealistic. However, note that our generative model *does* allow for dependencies between instances at the level of bag distributions, B_i . That is, although the samples X_i are drawn from bag distributions independently, we can use such independent samples to *approximate* the behavior of empirical bag-labeling functions on *nonindependent* samples.

The arbitrary R -tuple model, as illustrated in Figure 5(b), allows for arbitrary distributions over tuples of size at most R , which can be used to represent any generative model in which there is a relationship between instances in bags (i.e., bags in which instances are non-IID). As described in Section 2.4, it is possible to represent this model within MI-GEN where each bag is an atomic distribution over the instances in the tuple and the distribution over bags corresponds to the original distribution over tuples. Given this representation, $\pi = \frac{1}{R}$ in our model. In the traditional MI setting, we would directly observe these R instances. Our generative model, on the other hand, assumes that we perform the equivalent of repeatedly sampling an instance from these R instances uniformly and independently at random. In this case, we have the following result:

Corollary 1 (MI PAC-learning from Dependent Instances) *When distributions of instances in bags are defined by a set of R dependent instances sampled from a distribution over R tuples, bag-labeling functions derived from instance concept class \mathcal{F} with VC dimension $\text{VC}(\mathcal{F})$ are PAC-learnable from MI data using*

$$O\left(\frac{R}{\epsilon_B \gamma} \log \frac{1}{\epsilon_B} \left(\text{VC}(\mathcal{F}) \log \frac{R}{\epsilon_B \gamma} + \log \frac{1}{\delta}\right)\right)$$

examples with test bags of size $m = \lceil R \log \frac{2}{\epsilon_B} \rceil$ drawn independently with replacement from the R dependent instances.

Proof Following the same line of reasoning as in Theorem 3, we can derive the sample complexity bound

$$O\left(\frac{m}{\epsilon_B \gamma} \left(\text{VC}(\mathcal{F}) \log \frac{m}{\epsilon_B \gamma} + \log \frac{1}{\delta}\right)\right), \quad (13)$$

when there are m instances per bag. Choosing $m = \lceil R \log \frac{2}{\epsilon_B} \rceil$ satisfies the conditions of that theorem, since $\pi = \frac{1}{R}$. Substituting m into Equation 13 implies the sample complexity as stated in the corollary. ■

Thus, even though the bag distribution is representable using only R dependent instances, when sampling independently, we must sample a factor of $O\left(\log \frac{1}{\epsilon_B}\right)$ more instances to ensure that we can learn an accurate bag-labeling concept with high probability.

4. Learning to Rank from MI Data

Learnability results are often stated as in Section 3 with respect to the accuracy metric. However, other metrics often provide a more useful characterization of algorithm performance in practice. For example, for the 3D-QSAR problem, it is not necessary to accurately

Table 3: Legend of the basic notation used in Section 4.

Symbol	Description/Definition
\mathcal{X}	Space of instances
\mathcal{B}	Space of bags (distributions over instances)
\mathcal{X}^*	Set of bag samples (sets of instances)
x_{ij}	Instance $x_{ij} \in \mathcal{X}$
B_i	Bag $B_i \in \mathcal{B}$
X_i	Bag sample $\{x_{ij}\}_{j=1}^{m_i} \in \mathcal{X}^*$, $x_{ij} \sim B_i$ ($m_i \leq X_i \leq m_u$)
m_i	Bag Sample Size $m_i = X_i $
c	p -concept for bag-labeled instances $c(x) \triangleq \mathbb{P}[F(B) = 1 x]$
h	Instance-Labeling p -concept
\hat{H}	Empirical Bag-Labeling p -concept $\hat{H}(X_i) \triangleq \max_j h(x_{ij})$
p_{neg}, p	$p_{\text{neg}} \triangleq \mathbb{P}[f(x) = 0]$ $p \triangleq \min\{p_{\text{neg}}, 1 - p_{\text{neg}}\}$
$\hat{P}_{\text{neg}}, \hat{P}$	$\hat{P}_{\text{neg}} \triangleq \mathbb{P}[\hat{F}(X) = 0]$ $\hat{P} \triangleq \min\{\hat{P}_{\text{neg}}, 1 - \hat{P}_{\text{neg}}\}$
P_{neg}, P	$P_{\text{neg}} \triangleq \mathbb{P}[F(B) = 0]$ $P \triangleq \min\{P_{\text{neg}}, 1 - P_{\text{neg}}\}$
\mathcal{C}	Instance-Labeling p -concept Class
$\text{PD}(\mathcal{C})$	Pseudo-Dimension of \mathcal{C} (Haussler, 1992)

predict the activity of every molecule. Instead, a classifier can produce a ranked list indicating its confidence that each molecule is active. The set of active molecules with the highest predicted activity can then be investigated further by chemists. Unlike the prior work on learning accurate concepts from MI data as shown in Figure 6, there has been virtually no prior work on learning to rank in the MI setting. That is, although ranking algorithms have been developed for MIL (Bergeron et al., 2008), there is no formal analysis of the performance of such approaches. We provide such an analysis in this section.

In the 3D-QSAR example, a desirable property of a classifier is that it appropriately *rank*s bags or instances. That is, it assigns a higher real-valued confidence that a conformation is positive to actual positive conformations than to negative conformations. The AUC metric is commonly used to measure the ranking performance of a classifier. We show in this section that classifiers with high AUC are also learnable from MI data under our generative model. Furthermore, we show that learning high-AUC concepts from MI data is easier than learning accurate concepts in the sense that it can be achieved using standard ERM approaches. This suggests that standard supervised algorithms can learn high-AUC concepts from MI data generated according to MI-GEN, a surprising hypothesis that we evaluate in the final section.

4.1 Learning High-AUC Instance Concepts

Prior work has shown that the AUC is equivalent to the probability that a randomly selected positive example will be assigned a higher confidence than a randomly selected negative example (Hanley and McNeil, 1982). We can define a corresponding instance AUC error of a real-valued hypothesis h as $1 - \text{AUC}$, or the probability that a negative instance is assigned a higher confidence than a positive instance:

$$\begin{aligned} R_f^{\text{AUC}}(h) &= \int_{\mathcal{X}} \int_{\mathcal{X}} \mathbb{1}[h(x_-) > h(x_+)] d\mathbb{P}(x_+ | f(x_+) = 1) d\mathbb{P}(x_- | f(x_-) = 0) \\ &= \frac{\int_{\mathcal{X}_-} \int_{\mathcal{X}_+} \mathbb{1}[h(x_-) > h(x_+)] d\mathbb{P}(x_+) d\mathbb{P}(x_-)}{\mathbb{P}[f(x) = 1] \mathbb{P}[f(x) = 0]} \\ &= \frac{1}{(1 - p_{\text{neg}}) p_{\text{neg}}} \int_{\mathcal{X}_-} \int_{\mathcal{X}_+} \mathbb{1}[h(x_-) > h(x_+)] d\mathbb{P}(x_+) d\mathbb{P}(x_-). \end{aligned} \quad (14)$$

The first step follows from the definition of conditional probability, and we introduce $p_{\text{neg}} = \mathbb{P}[f(x) = 0]$ for notational convenience (see Table 3 for a list of notation used in this section). By definition, this quantity is zero in the cases when either all instances are positive or all instances are negative.

Given the formal definition of AUC, we can begin to describe how it is possible to learn high-AUC instance concepts from MI data. Since a classifier’s confidence values are relevant for the AUC metric, we will consider the hypothesis class corresponding to a classifier to be a p -concept class \mathcal{C} . The p -concept model is a model for binary classification in which a p -concept $c: \mathcal{X} \rightarrow [0, 1]$ represents the probability that an instance x is observed with a positive label (Kearns and Schapire, 1994). For high-AUC instance learnability, we will show that it is sufficient to learn a p -concept $h \in \mathcal{C}$ that models the p -concept $c(x) = \mathbb{P}[F(B) = 1 | x]$, the probability of observing instance x in a positive bag as defined in Equation 2.

To ensure that the target concept c is also a member of \mathcal{C} , we must formally restrict the set of bag labeling functions and distributions that are permitted by the generative model as follows:

Definition 6 (MI-GEN \mathcal{C}) For any $\gamma \in (0, 1]$ and $\pi \in [0, 1]$:

$$\text{MI-GEN}_{\mathcal{C}}(\gamma, \pi) \triangleq \left\{ (D_{\mathcal{X}}, D_{\mathcal{B}}, f, F) \in \text{MI-GEN}(\gamma, \pi) : (x \mapsto \mathbb{P}[F(B) = 1 | x]) \in \mathcal{C} \right\}.$$

Learnability of a p -concept with high AUC is then defined with respect to p -concept class \mathcal{C} :

Definition 7 (Instance MI AUC-PAC-learning) We say that an algorithm \mathcal{A} MI AUC-PAC-learns instance p -concept class \mathcal{C} from MI data when for any $(D_{\mathcal{X}}, D_{\mathcal{B}}, f, F) \in \text{MI-GEN}_{\mathcal{C}}(\gamma)$ with $\gamma > 0$, and $\epsilon_1, \delta > 0$, algorithm \mathcal{A} requires $O(\text{poly}(\frac{1}{\epsilon_1}, \frac{1}{\delta}))$ bag-labeled instances sampled independently from the MI generative process in Figure 1(b) to produce an instance p -concept hypothesis h with risk $R_f^{\text{AUC}}(h) < \epsilon_1$ with probability at least $1 - \delta$ over samples.

Whereas learning accurate instance concepts as in Definition 3 required the use of minimum one-sided disagreement, we show in Theorem 4 that it is possible to learn high-AUC

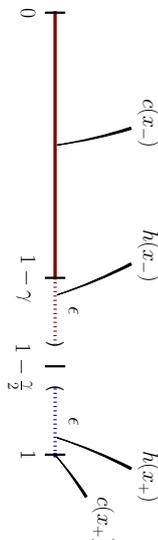

Figure 7: The intuition behind Theorem 4. A hypothesis h that closely approximates c will correctly rank instances with high probability.

concepts using ERM. In particular, the strategy used in the following theorem is to learn a p -concept h that models the concept c defined in Equation 2 using standard ERM. The intuition is that c already achieves perfect AUC; that is, $R_{\text{AUC}}^{\text{AUC}}(c) = 0$. The reason is that for any negative instance x_- and positive instance x_+ , $c(x_-) \leq 1 - \gamma < 1 = c(x_+)$; see Figure 7 for an illustration. If we learn a p -concept h that closely approximates c to within some ϵ , then with high probability, h will also correctly rank instances.

Stating the learnability of a p -concept with ERM requires use of the pseudo-dimension of the concept class \mathcal{C} ; just as VC dimension can be used to characterize the capacity of a deterministic concept class. The pseudo-dimension is similar to the VC dimension, but uses a different notion of “shattering.” In particular, for a set of points with real-valued labels, $\{(x_i, y_i)\}_{i=1}^n$, a p -concept class \mathcal{C} shatters the points if for any binary labeling of the points $\{b_i\}$, there exists some $c \in \mathcal{C}$ such that $c(x_i) \geq y_i$ if $b_i = 1$ and $c(x_i) < y_i$ if $b_i = 0$ (Haussler, 1992). The pseudo-dimension of \mathcal{C} , denoted $\text{PD}(\mathcal{C})$, is the size of the largest set such that \mathcal{C} shatters some set of that size.

Theorem 4 *An instance p -concept class \mathcal{C} with pseudo-dimension $\text{PD}(\mathcal{C})$ is Instance MI AUC-PAC-learnable using $O\left(\frac{1}{(\epsilon\gamma)^p} \left(\text{PD}(\mathcal{C}) \log \frac{1}{\epsilon\gamma p} + \log \frac{1}{\delta}\right)\right)$ examples with standard ERM approaches, where $p = \min\{P_{\text{neg}}, 1 - P_{\text{neg}}\}$.*

Proof See Appendix A. ■

Comparing Theorem 4 with Theorem 1 on learning accurate instance concepts, we see that neither results require that positive instances appear in positive bags ($\pi > 0$). In both cases, the addition label noise affects γ , but is tolerated by the underlying algorithm. The key difference between these results is that high-AUC concepts can be learned via standard ERM approaches, whereas accurate concept learning requires minimum one-sided disagreement. Additionally, the sample complexity bound in Theorem 4 contains an additional factor p that accounts for class imbalance. Intuitively, this factor appears because it is difficult to learn to effectively rank instances from different classes when one class appears very infrequently in the training set (p is small).

4.2 Learning High-AUC Bag Concepts

As for accuracy, we might be interested in learning either high-AUC instance *or* bag concepts from MI data. Following a similar strategy as employed in Section 3.2 for learning accurate bag concepts, here we will consider two measures of bag-level performance of a bag concept \hat{H} derived from an instance concept h . The same combining function as in Section 3, $\hat{H}(X_i) = \max_j h(x_{ij})$, is commonly used to derive real-valued bag-labeling functions in prior work (Ray and Craven, 2005). Following the analysis in Section 3.2, we will measure performance of \hat{H} with respect to both \hat{F} , the empirical bag-labeling function, and later F , the underlying bag-labeling function.

For the empirical bag-labeling function, \hat{F} , the intuitive definition of AUC is the probability that a bag-level hypothesis \hat{H} assigns a higher value to a bag sample given that it is labeled positive by \hat{F} (that is, containing at least one positive instance) than another bag sample labeled negative by \hat{F} (containing no positive instances). Formally, we can define the corresponding AUC-based risk as follows:

$$\begin{aligned} R_{\hat{F}}^{\text{AUC}}(\hat{H}) &= \frac{\int_{\mathcal{B}} \int_{\mathcal{B}} \int_{\mathcal{X}_+} \int_{\mathcal{X}_+} \mathbf{1}[\hat{H}(X_-) > \hat{H}(X_+)] \dots \\ &\quad \dots d\mathbb{P}(X_+ | B_+) d\mathbb{P}(X_- | B_-) d\mathbb{P}(B_+) d\mathbb{P}(B_-)}{\mathbb{P}[\hat{F}(X) = 1] \mathbb{P}[\hat{F}(X) = 0]} \\ &= \frac{\int_{\mathcal{B}} \int_{\mathcal{B}} \int_{\mathcal{X}_+} \int_{\mathcal{X}_+} \mathbf{1}[\hat{H}(X_-) > \hat{H}(X_+)] \dots \\ &\quad \dots d\mathbb{P}(X_+ | B_+) d\mathbb{P}(X_- | B_-) d\mathbb{P}(B_+) d\mathbb{P}(B_-)}{(1 - \hat{P}_{\text{neg}}) \hat{P}_{\text{neg}}}. \end{aligned} \quad (15)$$

Above, \mathcal{X}_+^* is the set of all negative bag samples, and \mathcal{X}_+^* the set of all positive bag samples. The notation $\hat{P}_{\text{neg}} = \Pr[\hat{F}(X) = 0]$ is used for convenience. Now, we can define learnability with respect to this metric:

Definition 8 (Empirical Bag MI AUC-PAC-learning) *We say that an algorithm A MI AUC-PAC-learns empirical bag-labeling functions derived from p -concept class \mathcal{C} when for any $(D_{\mathcal{X}}, D_{\mathcal{B}}, f, F) \in \text{MI-GEN}(\gamma)$ with $\gamma > 0$, and $\epsilon_{\mathcal{B}}, \delta > 0$, algorithm A requires $O(\text{poly}(\frac{1}{\gamma}, \frac{1}{\epsilon_{\mathcal{B}}}, \frac{1}{\delta}))$ bag-labeled instances sampled independently from the MI generative process in Figure 1(b) to produce an empirical bag-labeling function \hat{H} with risk $R_{\hat{F}}^{\text{AUC}}(\hat{H}) < \epsilon_{\mathcal{B}}$ with probability at least $1 - \delta$ over samples.*

We will now show learnability of empirical bag-labeling functions by reducing the problem to learning an accurate model of the p -concept c . Hence, the approach of the proof follows that for learning accurate empirical bag-labeling functions.

Theorem 5 *Empirical bag-labeling functions derived from p -concept class \mathcal{C} with pseudo-dimension $\text{PD}(\mathcal{C})$ are AUC-PAC-learnable from MI data using*

$$O\left(\frac{m_{\mathcal{B}}^4}{(\epsilon_{\mathcal{B}}\gamma)^4} \left(\text{PD}(\mathcal{C}) \log \frac{m_{\mathcal{B}}}{\epsilon_{\mathcal{B}}\gamma} + \log \frac{1}{\delta}\right)\right)$$

examples with standard ERM approaches, where

$$\hat{P} \triangleq \min\{\hat{P}_{\text{neg}}, 1 - \hat{P}_{\text{neg}}\} \geq \min\{P_{\text{neg}}, 1 - P_{\text{neg}}\},$$

and $m_{\mathcal{B}}$ is an upper bound on bag sample size.

Proof See Appendix A. ■

Note that Theorem 4 is a special case of Theorem 5 when $m_u = 1$. In this case $\widehat{P}_{\text{neg}} = p_{\text{neg}}$ when samples all have size 1, so $\widehat{P} = p$ and the sample complexity is the same.

Now, we can examine AUC-learnability with respect to the true bag-labeling function, F . To define AUC with respect to F , we measure the probability that a sample X_+ is labeled higher by \widehat{H} than X_- is, given that X_+ is sampled from a positive bag and X_- is sampled from a negative bag. Formally, the AUC risk of \widehat{H} with respect to F is

$$\begin{aligned} R_F^{\text{AUC}}(\widehat{H}) &= \frac{\int_{\mathcal{B}_-} \int_{\mathcal{B}_+} \int_{\mathcal{X}^*} \mathbb{1}[\widehat{H}(X_-) > \widehat{H}(X_+)] \dots}{\dots \text{dP}(X_+ | B_+) \text{dP}(X_- | B_-) \text{dP}(B_+) \text{dP}(B_-)} \dots \\ &= \frac{\text{P}[F(B) = 1] \text{P}[F(B) = 0]}{\int_{\mathcal{B}_-} \int_{\mathcal{B}_+} \int_{\mathcal{X}^*} \mathbb{1}[\widehat{H}(X_-) > \widehat{H}(X_+)] \dots \dots \text{dP}(X_+ | B_+) \text{dP}(X_- | B_-) \text{dP}(B_+) \text{dP}(B_-)} \dots \end{aligned} \quad (16)$$

The notation $P_{\text{neg}} = \text{P}[F(B) = 0]$ is used to denote the probability of sampling a negative bag from the distribution over bags. We define the risk to be zero in the case that this probability is equal to either 0 or 1.

As for accuracy, the risk of an empirical bag-labeling function now depends on how representative a sample is of the underlying bag. Thus, in the definition of AUC-learnability with respect to F (Definition 9), we now again require an additional assumption that positive instances appear some $\pi > 0$ fraction of the time in positive bags.

Definition 9 (Bag MI AUC-PAC-learning) *We say that an algorithm \mathcal{A} MI AUC-PAC-learns bag-labeling functions derived from the p -concept class \mathcal{C} when for any tuple $(D_X, D_B, f, F) \in \text{MI-GEN}_c(D_X, f, \gamma, \pi)$ with $\gamma, \pi > 0$, and $\epsilon_B, \delta > 0$, algorithm \mathcal{A} requires $O(\text{poly}(\frac{1}{\epsilon_B}, \frac{1}{\pi}, \frac{1}{\delta}, \frac{1}{\delta}))$ bag-labeled instances sampled independently from the MI generative process in Figure 1(b) to produce an empirical bag-labeling function \widehat{H} with risk $R_F^{\text{AUC}}(\widehat{H}) < \epsilon_B$ with probability at least $1 - \delta$ over samples.*

Again, we will learn an instance p -concept h that models c , and then show that a sufficiently accurate p -concept can produce an empirical bag-labeling function \widehat{H} that models F with high AUC. To do this, we will show that the AUC error of \widehat{H} with respect to F , $R_F^{\text{AUC}}(\widehat{H})$, is bounded in terms of the AUC error of \widehat{H} with respect to \widehat{F} , $R_{\widehat{F}}^{\text{AUC}}(\widehat{H})$.

Lemma 4 *Suppose bag samples are of size at least $m_i : m_i \leq |X_i|$, then $R_F^{\text{AUC}}(\widehat{H}) \leq \frac{1}{P_{\text{neg}}} R_{\widehat{F}}^{\text{AUC}}(\widehat{H}) + (1 - \pi)^{m_i}$.* ■

Proof See Appendix A.

Finally, given the bound in Lemma 4, we can derive a result on learning high-AUC bag concepts with respect to the underlying bag-labeling function F . As with the results in Theorem 3, we state the results conditioned on the fact that bag sizes m_i respect some constraints to account for the error that naturally results from insufficiently large samples of instances in positive bags.

Theorem 6 *Bag-labeling functions derived from p -concept class \mathcal{C} with pseudo-dimension $\text{PD}(\mathcal{C})$ are AUC-PAC-learnable from MI data using*

$$O\left(\frac{1}{(\epsilon_B^2 \gamma \pi P_{\text{neg}})^4} \left(\text{PD}(\mathcal{C}) \log \frac{1}{(\epsilon_B \gamma \pi P_{\text{neg}})} + \log \frac{1}{\delta} \right) \right). \quad (17)$$

examples using standard ERM approaches when bag sample sizes are bounded by $m_i \leq m \leq m_u$ and $m_i \geq \frac{1}{\pi} \log \frac{2}{\epsilon_B}$, where $\widehat{P} = \min\{\widehat{P}_{\text{neg}}, 1 - \widehat{P}_{\text{neg}}\}$. ■

Proof See Appendix A.

4.3 Discussion

The results on AUC learnability in the MI setting are surprising, because they imply the testable hypothesis that *standard supervised approaches* can be used to learn about instance and bag labels in the MI setting. The work that introduced the MI setting evaluated the performance, in terms of *accuracy*, of supervised approaches on MI problems and found them to perform poorly (Dietterich et al., 1997). Later empirical work found that supervised algorithms actually performed quite well on MI problems, *in terms of AUC* (Ray and Craven, 2005). This apparent discrepancy can be explained with the results in this section. Supervised approaches can perform well in terms of AUC on MI problems, but not, it seems, with respect to accuracy.

While the results in Section 3 do not formally show that supervised approaches cannot learn high-accuracy concepts, we conjecture that this is the case due to the one-sided noise inherent in learning to discriminate classes. As illustrated in Figure 7, the fact that negative instances appear some $\gamma > 0$ fraction of the time in negative bags means that learning to approximate c can be used to rank instances. However, accurately labeling instances using an approximation of c requires choosing a *threshold* to discriminate between positive and negative instances. If the value of γ were known in advance, then such a threshold might be selected at $1 - \frac{\gamma}{2}$, for example. However, without knowledge of γ or other further assumptions about the generative process, proving that such a threshold might be selected accurately is a direction for future work.

5. Empirical Evaluation

Because the results in this work imply the surprising fact that standard supervised algorithms can be used to learn concepts with high-AUC, but not high accuracy, from MI data, we explicitly evaluate this hypothesis using real-world MI data sets. As always, there are some differences between theory and practice that might confound the experimental results. Below we first explain these two key differences and argue why they do not threaten the validity of our experimental results. Then, we discuss the remainder of our experimental methodology and results.

5.1 Single Instance Learning

In these experiments, we use single-instance learning (SIL) to apply supervised algorithms to MI data. The SIL procedure takes an MI data set and applies to every instance the

label of its bag. Hence, like in the generative model described in Section 2 used to show the theoretical results in this work, the SIL training set consists of bag-labeled instances. However, unlike in the generative model used in this work, SIL samples more than one instance per bag. As a result, SIL potentially introduces some “correlation” between instances in the training set. Figure 1 provides a comparison of the generative model of Section 2 (Figure 1(b)) and that of SIL (Figure 1(c)).

We could make SIL more closely resemble our generative model by randomly discarding all but one instance in every bag. However, this would dramatically reduce the size of most practical MI data sets and would needlessly “throw away” the information associated with the discarded instances. Instead, we use all instances in the data set, and ignore the fact that they are potentially correlated, thereby assuming that every instance is sampled from an independent bag. The correlation could change the training distribution over instances, but this should *hurt* the performance of the supervised algorithm if it has any significant effect at all. Therefore, comparing SIL to MI-specific algorithms provides a comparison that is fair to the MI approaches.

5.2 Risk Minimization Approaches

The results on AUC learnability for MI data use results on learning via empirical risk minimization (ERM). ERM requires that some concept class C is fixed in advance, and a hypothesis $h \in C$ that minimizes empirical risk (in terms of accuracy) is selected. In practice, however, C might not be known *a priori*. Thus, structural risk minimization (SRM) strategies are often used in practice, which simultaneously select a hypothesis h that minimizes empirical risk while controlling the capacity of the class from which h is selected. The standard support vector machine (SVM) is an SRM approach, where the parameter C , selected via cross-validation, controls the trade-off between risk minimization and regularization. Although our theoretical result holds for ERM, we will use the SRM-based SVM for these experiments. The same SRM strategy is used across all of the baseline algorithms.

Similarly, the SVM outputs confidence values that range from $(-\infty, \infty)$ rather than from $[0, 1]$. Thus, the SVM technically does not learn a p -concept. However, prior work has shown how it is possible to fit a logistic regression model to an SVM’s outputs to derive associated probabilities (Platt, 1999). However, since rescaling the data does not affect the relative rankings of the real-valued outputs produced by the SVM, the AUC of the classifier does not change. Accordingly, we report results using the raw confidence values produced by the SVM in these experiments.

5.3 Methodology

To evaluate our hypothesis that a supervised SVM can perform well with respect to AUC for learning instance- and bag-labeling functions, we use a total of 55 real-world data sets across a variety of problem domains, including 3D-QSAR (Dietterich et al., 1997), CBR (Andrews et al., 2003; Maron and Ratan, 1998; Rahmani et al., 2005), text categorization (Andrews et al., 2003; Settles et al., 2008), and audio classification (Briggs et al., 2012). Of the 55 data sets, 45 of them have instance labels, which are only used to test the instance-level performance of classifiers, not for training.

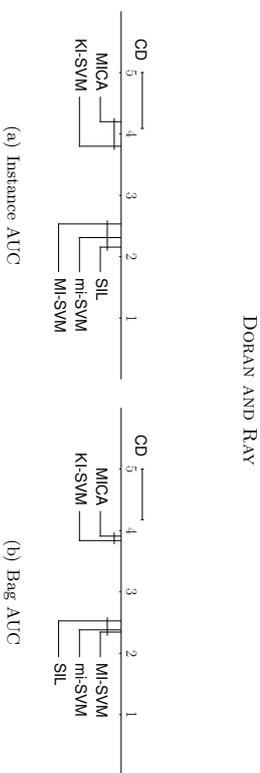

Figure 8: The average ranks (lower is better) of approaches on the instance- and bag-labeling tasks, evaluated using AUC. Statistically insignificant differences in performance are indicated with horizontal lines.

The SIL approach combined with a standard supervised SVM is compared with four popular baseline MI SVM approaches: mi-SVM (Andrews et al., 2003), MICA (Mangasarian and Wild, 2008), and the “instance” variant of KI-SVM (Li et al., 2009), which have been specifically designed to learn bag or instance labels from MI data. Prior empirical results show that these approaches constitute the state-of-the-art in instance-based MI SVM approaches (Doran and Ray, 2013).

The experiments used for this work were implemented in Python using NumPy (Ascher et al., 2001) and SciPy (Jones et al., 2001) for general matrix computations and the CVXOPT library (Dahl and Vandenberghe, 2009) for solving quadratic programs (QPs). We use the authors’ original MATLAB code, found at http://lamba.nju.edu.cn/code-KTSVM_astx, for the key instance SVM (KI-SVM) approach (Lin et al., 2012). We evaluate algorithms using 10-fold stratified cross-validation, with 5-fold inner-validation used to select parameters using random search (Bergstra and Bengio, 2012). Parameter selection is performed with respect to bag-level labels (since instance-level labels are unavailable at training time, even during cross-validation). We use the radial basis function (RBF) kernel with all algorithms, with scale parameter $\gamma \in [10^{-6}, 10^1]$, and regularization-loss trade-off parameter $C \in [10^{-2}, 10^5]$. The L_2 norm is used for regularization in all algorithms.

To statistically compare the classifiers, we use the approach described by Demšar (2006). We use the nonparametric Friedman test to reject the null hypothesis that the algorithms perform equally at an $\alpha = 0.001$ significance level. Finally, we plot the average ranks using a *critical difference* diagram, which uses the Nemenyi test to identify statistically equivalent groups of classifiers at an $\alpha = 0.05$ significance level.

5.4 Results and Discussion

The results are summarized using critical difference diagrams in Figure 8. Using AUC to measure performance, the ranks of the approaches are averaged across the 45 instance-labeled data sets for the instance-level metrics and across the 55 data sets for the bag-level metrics. Lower ranks indicate better performance. Full results can be found in Table 4 and Table 5.

Prior work has found that with respect to accuracy, the naïve SIL approach applied to MI data does not perform well (Dietterich et al., 1997; Doran and Ray, 2014). On the other hand, with respect to AUC, the relative performance of SIL increases significantly, and SIL

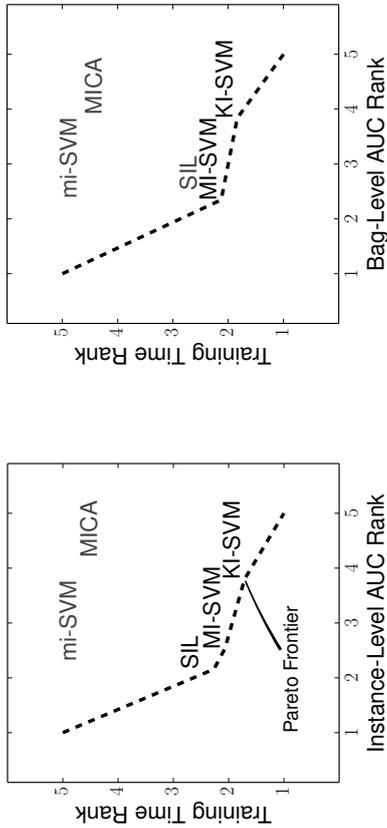

Figure 9: Comparison of supervised and MI-specific approaches in terms of running time and classification performance (AUC). Lower ranks correspond to better performance and faster training time. The Pareto frontier shows algorithms that are not dominated by any other algorithm along both dimensions.

performs as well the best MI approaches. For instance-level AUC, SIL is the highest-ranked approach. For bag-level AUC, SIL is not the best approach on average, but it is statistically equivalent to the top MI approaches. Since more samples are required to learn a bag-level concept using SIL, it could be that performance would improve even more with a larger training sample.

These surprising results support the theoretical framework described in Section 2. In particular, the experimental results suggest that the assumptions made by our generative model hold in practice in many cases. For example, we claim that the assumption that negative instances appear in negative bags ($\gamma > 0$) is weak and reasonable for many MI domains. In CBIR, negative background segments are likely to appear at least some of the time in images without the object of interest. The experimental results provide empirical support for this claim across the four domains on which we evaluate the classifiers. Of course, there might be domains for which this assumption does not hold. Determining whether any learnability results can be derived under weaker assumptions is an interesting question for future work.

There are also several ways that the theoretical and empirical results in this work can inform future work on MI learning. As mentioned earlier, the first work on MIL used accuracy as a performance measure, and found the SIL approach to be inaccurate in the MI setting for labeling bags (Dietterich et al., 1997). As a result, subsequent studies rarely used it as a baseline when evaluating new MI techniques. However, our results suggest that SIL should be used as a baseline when evaluating new MI approaches, especially if the intended application involves ranking bags or instances.

For researchers looking to learn high-AUC instance concepts from MI data, our results suggest that supervised approaches often suffice for this purpose in practice. Since supervised approaches are typically more computationally efficient than their MI counterparts, our theoretical and empirical justification for using supervised approaches with MI data provides a valuable practical benefit. The results in Figure 9 support this claim. The training time required by the algorithms for each data set is ranked with 1 corresponding to the fastest algorithm, and these ranks are averaged across data sets. Then, the combined performance of each approach in terms of both AUC and training time is shown in Figure 9. The Pareto frontier, the set of algorithms for which there does not exist any other algorithm that has better performance along both dimensions, is indicated in the figure. SIL is at or near the Pareto frontier for both instance- and bag-labeling.

For learning high-AUC bag-labeling concepts, MI algorithms still had a slight (but statistically insignificant) advantage over SIL in terms of classifier performance and training time. However, we have observed that even better performance can be attained by applying standard supervised approaches directly to the bag-level learning task using kernel methods (Doran and Ray, 2013).

6. Conclusion

In this work, we describe a new generative model for the MI setting in which bags are viewed as distributions over instances. The sets of instances observed in a training sample are then viewed as samples from each underlying bag distribution. We then introduce several additional assumptions that we show entail instance and bag concept learnability. We discuss the relationship between the proposed model and those found in prior work.

Next, we describe new positive learnability results for learning instance or bag concepts from data generated by MI-GEN. We describe how our generative model allows for learnability while excluding scenarios used to show hardness under other generative models. Nevertheless, our generative process extends prior results on instance concept learnability that are over a decade old (Blum and Kalai, 1998). We also show that MI-GEN can incorporate the non-IID instance assumption within bag-specific distributions over instances, so assuming that samples from individual bags are drawn independently is not a restrictive assumption in our model.

Finally, we argue that for many real-world applications of MIL, it is sufficient to *rank* instances or bags rather than assign accurate binary labels. Accordingly, we derived results demonstrating the ability to learn high-AUC rankings of instances or bags from data generated by a process in MI-GEN. The surprising aspect of these results is that such rankings can be found via *standard supervised approaches*. We evaluate this surprising hypothesis empirically and find that supervised approaches *can* in fact learn to rank from MI data in practice. Thus, the empirical results support the assumptions made by MI-GEN.

Our work provides a starting point for many future investigations of learning in the MI framework. For example, we plan to extend our learnability results to the multi-class and multi-label settings. Furthermore, we plan to investigate generalizations of our generative model that allow for other previously studied instance- and bag-label relationships (Scott et al., 2005). Finally, some recent work has investigated learnability of real-valued bag-level concepts under a similar generative process for MI regression (Szabó et al., 2015). We plan to investigate instance-level learning in the MI regression setting.

Appendix A. Detailed Proofs

Lemma 1 *Let $R_f(g)$ be the risk of an instance labeling concept g , and $R_{\widehat{F}}(\widehat{G})$ be the risk of the empirical bag-labeling function $\widehat{G}(X_i) = \max_j g(x_{ij})$. Then if bag sample sizes are bounded by m_u ($\forall i : |X_i| \leq m_u$), $R_{\widehat{F}}(\widehat{G}) \leq m_u R_f(g)$.*

Proof First, observe that when all elements of an empirical bag X_i are labeled correctly by g , $\widehat{F}(X_i) = \widehat{G}(X_i)$, so when $\widehat{F}(X_i) \neq \widehat{G}(X_i)$, at least one instance in X_i is labeled

incorrectly by g . In set notation, this implication is equivalent to the statement

$$\left\{ X_i : \widehat{F}(X_i) \neq \widehat{G}(X_i) \right\} \subseteq \left\{ X_i : (f(x_{i1}) \neq g(x_{i1})) \vee \dots \vee (f(x_{im}) \neq g(x_{im})) \right\}.$$

Using indicator function ($\mathbb{1}[\cdot]$) notation, the statement above implies

$$\begin{aligned} \mathbb{1}[\widehat{F}(X_i) \neq \widehat{G}(X_i)] &\leq \mathbb{1}[(f(x_{i1}) \neq g(x_{i1})) \vee \dots \vee (f(x_{im}) \neq g(x_{im}))] \\ &= \mathbb{1}\left[\bigvee_{x_{ij} \in X_i} (f(x_{ij}) \neq g(x_{ij}))\right] \\ &\leq \sum_{x_{ij} \in X_i} \mathbb{1}[f(x_{ij}) \neq g(x_{ij})]. \end{aligned}$$

Using this inequality in the definition of risk for empirical bag-labeling functions (Equation 10) yields

$$\begin{aligned} R_{\widehat{F}}(\widehat{G}) &= \int_{\mathcal{B}} \int_{\mathcal{X}^*} \mathbb{1}[\widehat{F}(X_i) \neq \widehat{G}(X_i)] d\mathbb{P}(X_i | B) d\mathbb{P}(B) \\ &\leq \int_{\mathcal{B}} \int_{\mathcal{X}^*} \sum_{x_{ij} \in X_i} \mathbb{1}[f(x_{ij}) \neq g(x_{ij})] d\mathbb{P}(X_i | B) d\mathbb{P}(B). \end{aligned}$$

By the independence of the instances $x_{ij} \in X_i$, and the bound m_u on bag sample sizes, we can rewrite the inner integral to conclude that

$$\begin{aligned} R_{\widehat{F}}(\widehat{G}) &\leq \int_{\mathcal{B}} m_u \int_{\mathcal{X}^*} \mathbb{1}[f(x) \neq g(x)] d\mathbb{P}(x | B) d\mathbb{P}(B) \\ &= m_u \int_{\mathcal{X}^*} \mathbb{1}[f(x) \neq g(x)] d\mathbb{P}(x) \\ &= m_u R_f(g). \end{aligned}$$

Exchanging the order of the integrals and marginalizing out the individual bag distributions to obtain an integral with respect to the instance distribution follows from Condition 1 in Definition 1. \blacksquare

Lemma 2 *For any empirical bag-labeling concept \widehat{G} ,*

$$R_{\widehat{F}}(\widehat{G}) \leq R_{\widehat{F}}(\widehat{G}) + R_{\widehat{F}}(\widehat{F}).$$

Proof First, note that if $\widehat{G}(X) = \widehat{F}(X)$ and $\widehat{F}(X) = F(B)$, then $\widehat{G}(X) = F(B)$. Thus, if $\widehat{G}(X) \neq F(B)$, then either $\widehat{G}(X) \neq \widehat{F}(X)$ or $\widehat{F}(X) \neq F(B)$. In set notation, this is equivalent to the statement

$$\left\{ (X, B) : \widehat{G}(X) \neq F(B) \right\} \subseteq \left\{ (X, B) : (\widehat{G}(X) \neq \widehat{F}(X)) \vee (\widehat{F}(X) \neq F(B)) \right\}.$$

Using indicator function notation, the statement above implies

$$\begin{aligned} \mathbb{1}[\widehat{G}(X) \neq F(B)] &\leq \mathbb{1}[(\widehat{G}(X) \neq \widehat{F}(X)) \vee (\widehat{F}(X) \neq F(B))] \\ &\leq \mathbb{1}[(\widehat{G}(X) \neq \widehat{F}(X))] + \mathbb{1}[(\widehat{F}(X) \neq F(B))]. \end{aligned}$$

Finally, substituting the expression above into the definitions of risk yields

$$\begin{aligned} R_F(\widehat{G}) &= \int_{\mathcal{B}} \int_{\mathcal{X}^*} \mathbb{1}[\widehat{G}(X) \neq F(B)] \, d\mathbb{P}(X | B) \, d\mathbb{P}(B) \\ &\leq \int_{\mathcal{B}} \int_{\mathcal{X}^*} \mathbb{1}[(\widehat{G}(X) \neq \widehat{F}(X))] \, d\mathbb{P}(X | B) \, d\mathbb{P}(B) \\ &\quad + \int_{\mathcal{B}} \int_{\mathcal{X}^*} \mathbb{1}[(\widehat{F}(X) \neq F(B))] \, d\mathbb{P}(X | B) \, d\mathbb{P}(B) \\ &= R_{\widehat{F}}(\widehat{G}) + R_F(\widehat{F}). \end{aligned}$$

■

Lemma 3 *Suppose bag samples are of size at least m_i ($\forall i : m_i \leq |X_i|$), then $R_F(\widehat{F}) \leq (1 - \pi)^{m_i}$.*

Proof Given the definition of $R_F(\widehat{F})$, we can decompose it as such

$$\begin{aligned} R_F(\widehat{F}) &= \int_{\mathcal{B}} \int_{\mathcal{X}^*} \mathbb{1}[F(B_i) \neq \widehat{F}(X_i)] \, d\mathbb{P}(X_i | B_i) \, d\mathbb{P}(B_i) \\ &= \int_{\mathcal{B}_+} \int_{\mathcal{X}^*} \mathbb{1}[F(B_i) \neq \widehat{F}(X_i)] \, d\mathbb{P}(X_i | B_i) \, d\mathbb{P}(B_i) \\ &\quad + \int_{\mathcal{B}_-} \int_{\mathcal{X}^*} \mathbb{1}[F(B_i) \neq \widehat{F}(X_i)] \, d\mathbb{P}(X_i | B_i) \, d\mathbb{P}(B_i). \end{aligned}$$

On the set of negative bags \mathcal{B}_- , F and \widehat{F} always agree, since only negative instances are sampled within negative bags. Therefore, the second term of the decomposition can be eliminated and we are left with

$$R_F(\widehat{F}) = \int_{\mathcal{B}_+} \int_{\mathcal{X}^*} \mathbb{1}[F(B_i) \neq \widehat{F}(X_i)] \, d\mathbb{P}(X_i | B_i) \, d\mathbb{P}(B_i).$$

Now, we observe that for a positive bag B_i , the only way that F and \widehat{F} can disagree is if every instance in X_i is negative. Using basic properties of indicator functions (namely, that $\mathbb{1}[\bigvee_i E_i] = \prod_i \mathbb{1}[E_i^c]$), we can use this fact to rewrite the expression above as

$$\begin{aligned} R_F(\widehat{F}) &= \int_{\mathcal{B}_+} \int_{\mathcal{X}^*} \mathbb{1}[F(B_i) \neq \widehat{F}(X_i)] \, d\mathbb{P}(X_i | B_i) \, d\mathbb{P}(B_i) \\ &= \int_{\mathcal{B}_+} \int_{\mathcal{X}^*} \mathbb{1}[\bigwedge_{x_{ij} \in X_i} (f(x_{ij}) = 0)] \, d\mathbb{P}(X_i | B_i) \, d\mathbb{P}(B_i) \\ &= \int_{\mathcal{B}_+} \int_{\mathcal{X}^*} \prod_{x_{ij} \in X_i} \mathbb{1}[f(x_{ij}) = 0] \, d\mathbb{P}(X_i | B_i) \, d\mathbb{P}(B_i). \end{aligned}$$

Since the instances $x_{ij} \in X_i$ are independent, we can rewrite the integral as

$$\begin{aligned} R_F(\widehat{F}) &= \int_{\mathcal{B}_+} \int_{\mathcal{X}^*} \prod_{x_{ij} \in X_i} \mathbb{1}[f(x_{ij}) = 0] \, d\mathbb{P}(X_i | B_i) \, d\mathbb{P}(B_i) \\ &= \int_{\mathcal{B}_+} \prod_{x_{ij} \in X_i} \left(\int_{\mathcal{X}} \mathbb{1}[f(x_{ij}) = 0] \, d\mathbb{P}(x_{ij} | B_i) \right) \, d\mathbb{P}(B_i) \\ &\leq \int_{\mathcal{B}_+} \prod_{x_{ij} \in X_i} (1 - \pi) \, d\mathbb{P}(B_i) \\ &\leq \int_{\mathcal{B}_+} (1 - \pi)^{m_i} \, d\mathbb{P}(B_i) \\ &= (1 - \pi)^{m_i} \int_{\mathcal{B}_+} \, d\mathbb{P}(B_i) \\ &\leq (1 - \pi)^{m_i}. \end{aligned}$$

■

Theorem 4 *An instance p -concept class \mathcal{C} with pseudo-dimension $\text{PD}(\mathcal{C})$ is Instance MI AUC-P4C-learnable using $O\left(\frac{1}{\epsilon^2 p^2}\left(\text{PD}(\mathcal{C}) \log \frac{1}{\epsilon} + \log \frac{1}{\delta}\right)\right)$ examples with standard ERM approaches, where $p = \min\{p_{\text{neg}}, 1 - p_{\text{neg}}\}$.*

Proof For any $c \in \mathcal{C}$, we can use ERM with respect to the quadratic loss function to learn a hypothesis h such that $\mathbb{E}[|h(x) - c(x)|^2] < \epsilon$ with probability $1 - \delta$ across samples. By Jensen's inequality, this bounds the expected absolute deviation between h and c :

$$\mathbb{E}[|h(x) - c(x)|] \leq \sqrt{\mathbb{E}[|h(x) - c(x)|^2]} < \sqrt{\epsilon}.$$

Then, by Markov's inequality, this expression bounds the probability over examples that $|h(x) - c(x)|$ exceeds some constant t :

$$\mathbb{P}[|h(x) - c(x)| > t] \leq \frac{\mathbb{E}[|h(x) - c(x)|]}{t} < \frac{\sqrt{\epsilon}}{t}. \quad (18)$$

Therefore, with high probability, $|h(x) - c(x)|$ is small for small ϵ .

Now, we can proceed by following the intuition illustrated in Figure 7. In particular, we will show that the AUC risk is bounded when h and c agree on examples with high probability. First, suppose $|h(x) - c(x)| \leq \frac{\gamma}{2}$ for both of a pair (x_+, x_-) of positive and negative instances. Then for the negative instance, x_- , by Definition 1, Condition 3,

$$h(x_-) \leq c(x_-) + \frac{\gamma}{2} \leq (1 - \gamma) + \frac{\gamma}{2} = 1 - \frac{\gamma}{2}.$$

Similarly, for the positive instance, x_+ , by Definition 1, Condition 2,

$$h(x_+) \geq c(x_+) - \frac{\gamma}{2} = 1 - \frac{\gamma}{2}.$$

Hence, we have that $h(x_-) \leq h(x_+)$.

By contraposition of the conclusion above, if $h(x_-) > h(x_+)$, then it is either the case that $|h(x_-) - c(x_-)| > \frac{\gamma}{2}$ or that $|h(x_+) - c(x_+)| > \frac{\gamma}{2}$. In set theoretic terms, this means

$$\{(x_+, x_-) : h(x_-) > h(x_+)\} \subseteq \{(x_+, x_-) : |h(x_-) - c(x_-)| > \frac{\gamma}{2} \vee |h(x_+) - c(x_+)| > \frac{\gamma}{2}\}$$

In indicator function notation, this implies

$$\begin{aligned} \mathbb{1}[h(x_-) > h(x_+)] &\leq \mathbb{1}[|h(x_-) - c(x_-)| > \frac{\gamma}{2} \vee |h(x_+) - c(x_+)| > \frac{\gamma}{2}] \\ &\leq \mathbb{1}[|h(x_-) - c(x_-)| > \frac{\gamma}{2}] + \mathbb{1}[|h(x_+) - c(x_+)| > \frac{\gamma}{2}]. \end{aligned}$$

Substituting this expression into the definition of $R_f^{\text{AUC}}(h)$ (Equation 14) yields

$$\begin{aligned} R_f^{\text{AUC}}(h) &= \frac{\int_{X_-} \int_{X_+} \mathbb{1}[h(x_-) > h(x_+)] d\mathbb{P}(x_+) d\mathbb{P}(x_-)}{(1 - p_{\text{neg}})p_{\text{neg}}} \\ &\leq \frac{\int_{X_-} \int_{X_+} \mathbb{1}[|h(x_-) - c(x_-)| > \frac{\gamma}{2}] d\mathbb{P}(x_+) d\mathbb{P}(x_-)}{(1 - p_{\text{neg}})p_{\text{neg}}} \\ &\quad + \frac{\int_{X_+} \int_{X_+} \mathbb{1}[|h(x_+) - c(x_+)| > \frac{\gamma}{2}] d\mathbb{P}(x_+) d\mathbb{P}(x_-)}{(1 - p_{\text{neg}})p_{\text{neg}}} \\ &= \frac{\int_{X_-} \mathbb{1}[|h(x_-) - c(x_-)| > \frac{\gamma}{2}] d\mathbb{P}(x_-)}{1 - p_{\text{neg}}} \\ &\quad + \frac{\int_{X_+} \mathbb{1}[|h(x_+) - c(x_+)| > \frac{\gamma}{2}] d\mathbb{P}(x_+)}{1 - p_{\text{neg}}}. \end{aligned}$$

Then, using the definition $p = \min\{p_{\text{neg}}, 1 - p_{\text{neg}}\}$, this becomes

$$\begin{aligned} R_f^{\text{AUC}}(h) &\leq \frac{\int_{X_-} \mathbb{1}[|h(x_-) - c(x_-)| > \frac{\gamma}{2}] d\mathbb{P}(x_-)}{p} \\ &\quad + \frac{\int_{X_+} \mathbb{1}[|h(x_+) - c(x_+)| > \frac{\gamma}{2}] d\mathbb{P}(x_+)}{p} \\ &= \frac{\int_{X_-} \mathbb{1}[|h(x_-) - c(x_-)| > \frac{\gamma}{2}] d\mathbb{P}(x_-) + \int_{X_+} \mathbb{1}[|h(x_+) - c(x_+)| > \frac{\gamma}{2}] d\mathbb{P}(x_+)}{p}. \end{aligned}$$

Finally, using the inequality derived in Equation 18, we have

$$R_f^{\text{AUC}}(h) \leq \frac{\mathbb{P}[|h(x) - c(x)| > \frac{\gamma}{2}]}{p} < \frac{2\sqrt{\epsilon}}{\gamma p}.$$

Therefore, it is sufficient to choose $\epsilon = \frac{(\gamma p)^2}{4}$ when learning h via ERM as so that $R_f^{\text{AUC}}(h) < \epsilon$.

Finally, the sample complexity bound results from substituting $\epsilon = \frac{(\gamma p)^2}{4}$ into the existing bound $O(\frac{1}{\epsilon} (\text{PD}(\mathcal{C}) \log \frac{1}{\epsilon} + \log \frac{1}{\delta}))$ for learning p -concepts using ERM (Kearns and Schapire, 1994). ■

Theorem 5 Empirical bag-labeling functions derived from p -concept class \mathcal{C} with pseudo-dimension $\text{PD}(\mathcal{C})$ are AUC-PAC-learnable from MI data using

$$O\left(\frac{m_u}{(\epsilon \gamma \hat{P})^4} \left(\text{PD}(\mathcal{C}) \log \frac{m_u}{(\epsilon \gamma \hat{P})} + \log \frac{1}{\delta}\right)\right)$$

examples with standard ERM approaches, where

$$\hat{P} \triangleq \min\{\hat{P}_{\text{neg}}, 1 - \hat{P}_{\text{neg}}\} \geq \min\{P_{\text{neg}}, 1 - p_{\text{neg}}\},$$

and m_u is an upper bound on bag sample size.

Proof As in Theorem 4, we will learn a p -concept h to model c accurately with high probability. Then, given bag samples X_+ with at least one positive instance and X_- with all negative instances, suppose that $|h(x) - c(x)| \leq \frac{\gamma}{2}$ for all instances across both samples. Then by the same argument as in Theorem 4 as illustrated in Figure 7, at least one instance in X_+ is assigned a label by h that is at least $1 - \frac{\gamma}{2}$, and all instances in X_- are assigned a label by h of at most $1 - \frac{\gamma}{2}$. Therefore, the maximum label assigned in X_+ , $\hat{H}(X_+)$, is greater than or equal to the maximum label in X_- , $\hat{H}(X_-)$.

By contraposition, if $\hat{H}(X_-) > \hat{H}(X_+)$, then the label $h(x)$ of some instance x in either X_+ or X_- deviates by more than $\frac{\gamma}{2}$ from $c(x)$. That is,

$$\begin{aligned} \{(X_+, X_-) : \hat{H}(X_-) > \hat{H}(X_+)\} \\ \subseteq \left\{ (X_+, X_-) : \left(\bigvee_{x \in X_+} |h(x) - c(x)| > \frac{\gamma}{2} \right) \vee \left(\bigvee_{x \in X_-} |h(x) - c(x)| > \frac{\gamma}{2} \right) \right\} \end{aligned}$$

Therefore, in indicator function notation,

$$\mathbb{1}[\hat{H}(X_-) > \hat{H}(X_+)] \leq \sum_{x \in X_+} \mathbb{1}[|h(x) - c(x)| > \frac{\gamma}{2}] + \sum_{x \in X_-} \mathbb{1}[|h(x) - c(x)| > \frac{\gamma}{2}].$$

Using the inequality above in the definition of $R_F^{\text{AUC}}(\hat{H})$ in Equation 15 gives

$$\begin{aligned} R_F^{\text{AUC}}(\hat{H}) &\leq \frac{(1 - \hat{P}_{\text{neg}})\hat{P}_{\text{neg}}}{\dots d\mathbb{P}(X_+ | B_+) d\mathbb{P}(X_- | B_-) d\mathbb{P}(B_+) d\mathbb{P}(B_-)} \\ &\quad \int_{B_-} \int_{B_-} \int_{X_+} \int_{X_+} \mathbb{1}[|h(x) - c(x)| > \frac{\gamma}{2}] \dots \\ &\quad \dots d\mathbb{P}(X_+ | B_+) d\mathbb{P}(X_- | B_-) d\mathbb{P}(B_+) d\mathbb{P}(B_-) \\ &\quad + \frac{(1 - \hat{P}_{\text{neg}})\hat{P}_{\text{neg}}}{\dots d\mathbb{P}(X_+ | B_+) d\mathbb{P}(X_- | B_-) d\mathbb{P}(B_+) d\mathbb{P}(B_-)} \\ &\quad \dots d\mathbb{P}(X_+ | B_+) d\mathbb{P}(X_- | B_-) d\mathbb{P}(B_+) d\mathbb{P}(B_-) \end{aligned}$$

Since the integrands above only depend on X_+ and X_- , we can rewrite the expression using the fact that

$$\begin{aligned} \int_{X_-} d\mathbb{P}(X_- | B_-) d\mathbb{P}(B_-) &= \mathbb{P}[\hat{F}(X) = 0] = \hat{P}_{\text{neg}} \\ \int_{X_+} d\mathbb{P}(X_+ | B_+) d\mathbb{P}(B_+) &= \mathbb{P}[\hat{F}(X) = 1] = 1 - \hat{P}_{\text{neg}}. \end{aligned}$$

The result is

$$\begin{aligned}
 R_{\hat{P}}^{\text{AVC}}(\hat{H}) &\leq \frac{\int_{\mathcal{B}} \int_{\mathcal{X}^*} \sum_{x \in \mathcal{X}_+} \mathbb{1}[|h(x) - c(x)| > \frac{\gamma}{2}] d\mathbb{P}(X_+ | \mathcal{B}_+) d\mathbb{P}(\mathcal{B}_+)}{(1 - \hat{P}_{\text{neg}})} \\
 &\quad + \frac{\int_{\mathcal{B}} \int_{\mathcal{X}^*} \sum_{x \in \mathcal{X}_-} \mathbb{1}[|h(x) - c(x)| > \frac{\gamma}{2}] d\mathbb{P}(X_- | \mathcal{B}_-) d\mathbb{P}(\mathcal{B}_-)}{\hat{P}_{\text{neg}}} \\
 &\leq \frac{\int_{\mathcal{B}} \int_{\mathcal{X}^*} \sum_{x \in \mathcal{X}_+} \mathbb{1}[|h(x) - c(x)| > \frac{\gamma}{2}] d\mathbb{P}(X_+ | \mathcal{B}_+) d\mathbb{P}(\mathcal{B}_+)}{\hat{P}} \\
 &\quad + \frac{\int_{\mathcal{B}} \int_{\mathcal{X}^*} \sum_{x \in \mathcal{X}_-} \mathbb{1}[|h(x) - c(x)| > \frac{\gamma}{2}] d\mathbb{P}(X_- | \mathcal{B}_-) d\mathbb{P}(\mathcal{B}_-)}{\hat{P}} \\
 &= \frac{\int_{\mathcal{B}} \int_{\mathcal{X}^*} \sum_{x \in \mathcal{X}} \mathbb{1}[|h(x) - c(x)| > \frac{\gamma}{2}] d\mathbb{P}(X | \mathcal{B}) d\mathbb{P}(\mathcal{B})}{\hat{P}}.
 \end{aligned}$$

By the independence of instances $x \in \mathcal{X}$, the upper bound m_u on bag size, and Condition 1 in Definition 1, we can rewrite the expression above as

$$\begin{aligned}
 R_{\hat{P}}^{\text{AVC}}(\hat{H}) &\leq \frac{m_u}{\hat{P}} \int_{\mathcal{B}} \int_{\mathcal{X}} \mathbb{1}[|h(x) - c(x)| > \frac{\gamma}{2}] d\mathbb{P}(x | \mathcal{B}) d\mathbb{P}(\mathcal{B}) \\
 &= \frac{m_u}{\hat{P}} \int_{\mathcal{X}} \mathbb{1}[|h(x) - c(x)| > \frac{\gamma}{2}] d\mathbb{P}(x) \\
 &= \frac{m_u}{\hat{P}} \mathbb{P}[|h(x) - c(x)| > \frac{\gamma}{2}].
 \end{aligned}$$

Then, by Markov's inequality in Equation 18,

$$R_{\hat{P}}^{\text{AVC}}(\hat{H}) \leq \frac{m_u}{\hat{P}} \mathbb{P}[|h(x) - c(x)| > \frac{\gamma}{2}] < \frac{2m_u\sqrt{\epsilon}}{\gamma\hat{P}}. \quad (19)$$

Therefore, choosing $\epsilon = \frac{(\gamma\hat{P})^2}{4m_u^2}$, is sufficient to learn \hat{H} with $R_{\hat{P}}^{\text{AVC}}(\hat{H}) < \epsilon\mathcal{B}$. Substituting this ϵ into the bound of Kearns and Schapire (1994) gives the sample complexity of learning \hat{H} as stated in the theorem.

Finally, we show that $\hat{P} \geq \min\{P_{\text{neg}}, 1 - P_{\text{neg}}\}$ as asserted in the theorem, which demonstrates that \hat{P} is independent of the bag size m (so there is no hidden dependence on bag size). First, observe that $\hat{P}_{\text{neg}} \geq P_{\text{neg}}$. The reason is that whenever a negative bag is sampled, a sample of only negative instances is guaranteed to be sampled from the bag. Thus, the probability of a negative sample of instances is at least the probability of sampling a negative bag.

Additionally, $1 - \hat{P}_{\text{neg}} \geq 1 - P_{\text{neg}}$. This is true because the probability of a sample containing a positive instance is at least the probability that the very first instance sampled is positive, which is $1 - P_{\text{neg}}$.

Combining the observations above, we get

$$\begin{aligned}
 \hat{P} &\triangleq \min\{\hat{P}_{\text{neg}}, 1 - \hat{P}_{\text{neg}}\} \\
 &\geq \min\{P_{\text{neg}}, 1 - P_{\text{neg}}\}.
 \end{aligned}$$

Lemma 4 *Suppose bag samples are of size at least m_l ($\forall i: m_l \leq |X_i|$), then $R_{\hat{P}}^{\text{AVC}}(\hat{H}) \leq \frac{1}{P_{\text{neg}}} R_{\hat{P}}^{\text{AVC}}(\hat{H}) + (1 - \pi)^{m_l}$.*

Proof We can derive the inequality in Lemma 4 by transforming the definition of $R_{\hat{P}}^{\text{AVC}}(\hat{H})$ in Equation 16 to that of $R_{\hat{P}}^{\text{AVC}}(\hat{H})$ in Equation 15. Starting from $R_{\hat{P}}^{\text{AVC}}(\hat{H})$, we get

$$\begin{aligned}
 R_{\hat{P}}^{\text{AVC}}(\hat{H}) &= \frac{\int_{\mathcal{B}_-} \int_{\mathcal{B}_+} \int_{\mathcal{X}^*} \int_{\mathcal{X}^*} \mathbb{1}[\hat{H}(X_-) > \hat{H}(X_+)] \dots \\
 &\quad \dots d\mathbb{P}(X_+ | \mathcal{B}_+) d\mathbb{P}(X_- | \mathcal{B}_-) d\mathbb{P}(\mathcal{B}_+) d\mathbb{P}(\mathcal{B}_-)}{(1 - P_{\text{neg}})P_{\text{neg}}} \dots \\
 &= \frac{\int_{\mathcal{B}_-} \int_{\mathcal{B}_+} \int_{\mathcal{X}^*} \int_{\mathcal{X}^*} \mathbb{1}[\hat{H}(X_-) > \hat{H}(X_+)] \dots \\
 &\quad \dots d\mathbb{P}(X_+ | \mathcal{B}_+) d\mathbb{P}(X_- | \mathcal{B}_-) d\mathbb{P}(\mathcal{B}_+) d\mathbb{P}(\mathcal{B}_-)}{(1 - P_{\text{neg}})P_{\text{neg}}} \\
 &\quad + \frac{\int_{\mathcal{B}_-} \int_{\mathcal{B}_+} \int_{\mathcal{X}^*} \int_{\mathcal{X}^*} \mathbb{1}[\hat{H}(X_-) > \hat{H}(X_+)] \dots \\
 &\quad \dots d\mathbb{P}(X_+ | \mathcal{B}_+) d\mathbb{P}(X_- | \mathcal{B}_-) d\mathbb{P}(\mathcal{B}_+) d\mathbb{P}(\mathcal{B}_-)}{(1 - P_{\text{neg}})P_{\text{neg}}}. \quad (B)
 \end{aligned} \quad (A)$$

Starting with (B), we see that since $\mathbb{1}[\hat{H}(X_-) > \hat{H}(X_+)] \leq 1$, we can rewrite this term as

$$\begin{aligned}
 (B) &\leq \frac{\int_{\mathcal{B}_-} \int_{\mathcal{B}_+} \int_{\mathcal{X}^*} \int_{\mathcal{X}^*} d\mathbb{P}(X_+ | \mathcal{B}_+) d\mathbb{P}(X_- | \mathcal{B}_-) d\mathbb{P}(\mathcal{B}_+) d\mathbb{P}(\mathcal{B}_-)}{(1 - P_{\text{neg}})P_{\text{neg}}} \\
 &= \frac{\int_{\mathcal{B}_+} \int_{\mathcal{X}^*} d\mathbb{P}(X_+ | \mathcal{B}_+) d\mathbb{P}(\mathcal{B}_+)}{(1 - P_{\text{neg}})} \\
 &\leq \frac{\int_{\mathcal{B}_+} (1 - \pi)^{m_l} d\mathbb{P}(\mathcal{B}_+)}{(1 - P_{\text{neg}})} = (1 - \pi)^{m_l}.
 \end{aligned}$$

The second step follows from the fact that $\int_{\mathcal{X}^*} d\mathbb{P}(X_+ | \mathcal{B}_+)$ is the probability of sampling only negative instances within a positive bag of size at least m_l , which is at most $(1 - \pi)^{m_l}$. Continuing with term (A), we can rewrite this as

$$\begin{aligned}
 (A) &= \frac{\int_{\mathcal{B}_-} \int_{\mathcal{B}_+} \int_{\mathcal{X}^*} \int_{\mathcal{X}^*} \mathbb{1}[\hat{H}(X_-) > \hat{H}(X_+)] \dots \\
 &\quad \dots d\mathbb{P}(X_+ | \mathcal{B}_+) d\mathbb{P}(X_- | \mathcal{B}_-) d\mathbb{P}(\mathcal{B}_+) d\mathbb{P}(\mathcal{B}_-)}{(1 - P_{\text{neg}})P_{\text{neg}}} \dots \\
 &\quad + \frac{\int_{\mathcal{B}_-} \int_{\mathcal{B}_+} \int_{\mathcal{X}^*} \int_{\mathcal{X}^*} \mathbb{1}[\hat{H}(X_-) > \hat{H}(X_+)] \dots \\
 &\quad \dots d\mathbb{P}(X_+ | \mathcal{B}_+) d\mathbb{P}(X_- | \mathcal{B}_-) d\mathbb{P}(\mathcal{B}_+) d\mathbb{P}(\mathcal{B}_-)}{(1 - P_{\text{neg}})P_{\text{neg}}}. \quad (D)
 \end{aligned} \quad (C)$$

Now, we see that (D) = 0, since it involves an integral over bags with positive instances in negative bags, which occurs with probability zero by Condition 2 in Definition 1. For (C),

An Online Convex Optimization Approach to Blackwell's Approachability

Abstract

The problem of approachability in repeated games with vector payoffs was introduced by Blackwell in the 1950s, along with geometric conditions and corresponding approachability strategies that rely on computing a sequence of *direction vectors* in the payoff space. For convex target sets, these vectors are obtained as projections from the current average payoff vector to the set. A recent paper by Abernethy, Batlett and Hazan (2011) proposed a class of approachability algorithms that rely on Online Linear Programming for obtaining alternative sequences of direction vectors. This is first implemented for target sets that are convex cones, and then generalized to any convex set by embedding it in a higher-dimensional convex cone. In this paper we present a more direct formulation that relies on general Online Convex Optimization (OCO) algorithms, along with basic properties of the support function of convex sets. This leads to a general class of approachability algorithms, depending on the choice of the OCO algorithm and the used norms. Blackwell's original algorithm and its convergence are recovered when Follow The Leader (or a regularized version thereof) is used for the OCO algorithm.

Keywords: approachability, online convex optimization, repeated games with vector payoffs

1. Introduction

Blackwell's approachability theory and the regret-based framework of online learning both address a repeated decision problem in the presence of an arbitrary (namely, unpredictable) adversary. Approachability, as introduced by Blackwell (1956), considers a fundamental feasibility issue for repeated matrix games with vector-valued payoffs. Referring to one player as the *agent* and to the other as *Nature*, a set S in the payoff space is *approachable* by the agent if it can ensure that the average payoff vector converges (with probability 1) to S , irrespectively of Nature's strategy. Blackwell's seminal paper provided geometric conditions for approachability, which are both necessary and sufficient for *convex* target sets S , and a corresponding approachability strategy for the agent. Approachability has found important applications in the theory of learning in games (Aumann and Maschler, 1995; Fudenberg and Levine,

1998; Peyton Young, 2004), and in particular in relation with no-regret strategies in repeated games as further elaborated below. A recent textbook exposition of approachability and some of its applications can be found in Maschler et al. (2013), and a comprehensive survey is provided by Perchet (2014).

Concurrently to Blackwell's paper, Hauman (1957) introduced the concept of no-regret strategies in the context of repeated matrix games. The *regret* of the agent is the shortfall of the cumulative payoff that was actually obtained relative to the one that would have been obtained with the best (fixed) action in hindsight, given Nature's observed action sequence. A no-regret strategy, or algorithm, ensures that the regret grows sub-linearly in time. The no-regret criterion has been widely adopted in the machine learning literature as a standard measure for the performance of online learning algorithms, and its scope has been greatly extended accordingly. Of specific relevance here is the Online Convex Optimization (OCO) framework, where Nature's discrete action is replaced by the choice of a convex function at each stage, and the agent's decision is a point in a convex set. The influential text of Cesa-Bianchi and Lugosi (2006) offers a broad overview of regret in online learning. Extensive surveys of OCO algorithms are provided by Shalev-Shwartz (2011); Hazan (2012, April 2016).

It is well known that no-regret strategies for repeated games can be obtained as particular instances of the approachability problem. A specific scheme was already given by Blackwell (1954), and an alternative formulation that leads to more explicit strategies was proposed by Hart and Mas-Colell (2001). The present paper considers the opposite direction, namely how no-regret algorithms for OCO can be used as a basis for an approachability strategy. Specifically, the OCO algorithm is used to generate a sequence of vectors that replace the projection-based direction vectors in Blackwell's algorithm. This results in a general class of approachability algorithms, that includes Blackwell's algorithm (and some generalizations thereof by Hart and Mas-Colell (2001)) as special cases.

The idea of using an online-algorithm to provide the sequence of direction vectors originated in the work of Abernethy et al. (2011), who showed how any no-regret algorithm for the online *linear* optimization problem can be used as a basis for an approachability algorithm. The scheme suggested in Abernethy et al. (2011) first considers target sets S that are convex cones. The generalization to any convex set is carried out by embedding the original target set as a convex cone in a higher dimensional payoff space. Here, we propose a more direct scheme that avoids the above-mentioned embedding. This construction relies on the *support function* of the target set, which is related to Blackwell's approachability conditions on the one hand, and on the other provides a variational expression for the point-to-set distance. Consequently, the full range of OCO algorithms can be used to provide a suitable sequence of direction vectors.

As we shall see, Blackwell's original algorithm is recovered from our scheme when the standard Follow the Leader (FTL) algorithm is used for the OCO part. Recovering the (known) convergence of this algorithm directly from the OCO viewpoint is a bit

more intricate. First, when the target set has a smooth boundary, we show that FTL converges at a “fast” (logarithmic) rate, hence leading to a correspondingly fast convergence of the average reward to the target set. To address the general case, we further show that Blackwell’s algorithm is still exactly recovered when an appropriately *regularized* version of FTL is used, from which the standard $O(T^{-1/2})$ convergence rate may be deduced.

The basic results of approachability theory have been extended in numerous directions. These include additional theoretical results, such as the characterization of non-convex approachable sets; extended models, such as stochastic (Markov) games and games with partial monitoring; and additional approachability algorithms for the basic model. For concreteness we will expand only on the latter (below, in Subsection 2.1), and refer the reader to the above-mentioned overviews for further information.

The paper proceeds as follows. In Section 2 we review the relevant background on Blackwell’s approachability and Online Convex Optimization. Section 3 presents the proposed scheme, in the form of a meta-algorithm that relies on a generic OCO algorithm, discusses the relation to the scheme of Abernethy et al. (2011), and demonstrates a specific algorithm that is obtained by using Generalized Gradient Descent for the OCO algorithm. In Section 4 we describe the relations with Blackwell’s original algorithm and its convergence. Section 5 outlines the extension of the proposed framework to general (rather than Euclidean) norms, followed by some concluding remarks.

Notation: The standard (dot) inner product in \mathbb{R}^d is denoted by $\langle \cdot, \cdot \rangle$, $\| \cdot \|_2$ is the Euclidean norm, $d(z, S) = \inf_{s \in S} \|z - s\|_2$ denotes the corresponding point-to-set distance, $B_2 = \{w \in \mathbb{R}^d : \|w\|_2 \leq 1\}$ denotes the Euclidean unit ball, $\Delta(I)$ is the set of probability distributions over a finite set I , $\text{diam}(S) = \sup_{s, s' \in S} \|s - s'\|_2$ is the diameter of the set S , and $\|\mathcal{R} - S\|_2 = \sup_{s \in \mathcal{R}, s' \in S} \|s - s'\|_2$ denotes the maximal distance between points in sets \mathcal{R} and S .

2. Model and Background

We start with brief reviews of Blackwell’s approachability theory and Online Convex Programming, focusing on those aspects that are most relevant to this paper.

2.1 Approachability

Consider a repeated game with *vector-valued* rewards that is played by two players, the *agent* and *Nature*. Let I and J denote the finite action sets of these players, respectively, with corresponding mixed actions $x = (x(I), \dots, x(\{I\})) \in \Delta(I)$ and $y = (y(1), \dots, y(\{J\})) \in \Delta(J)$. Let $r : I \times J \rightarrow \mathbb{R}^d$, $d \geq 1$, be the vector-valued reward function of the single-stage game, which is extended to mixed action as usual through the bilinear function

$$r(x, y) = \sum_{i,j} x(i)y(j)r(i, j).$$

Similarly, we denote $r(x, j) = \sum_i x(i)r(i, j)$. The specific meaning of $r(\cdot, \cdot)$ should be clear by its argument.

The game is repeated in stages $t = 1, 2, \dots$, where at stage t actions i_t and j_t are chosen by the players, and the reward vector $r(i_t, j_t)$ is obtained. A pure strategy for the agent is a mapping from each possible history $(i_1, j_1, \dots, i_{t-1}, j_{t-1})$ to an action i_t , and a mixed strategy is a probability distribution over the pure strategies. Nature’s strategies are similarly defined. Any pair of strategies for the agent and Nature thus induce a probability measure on the game sequence $(i_t, j_t)_{t=1}^{\infty}$.

Let

$$\bar{r}_T = \frac{1}{T} \sum_{t=1}^T r(i_t, j_t)$$

denote the T -stage average reward vector. We may now recall Blackwell’s definition of an approachable set.

Definition 1 (Approachability) *A set $S \subset \mathbb{R}^d$ is **approachable** if there exists a strategy for the agent such that \bar{r}_t converges to S with probability 1, at a uniform rate over Nature’s strategies. That is, for any $\epsilon > 0$ and $\delta > 0$ there exists $T \geq 1$ such that*

$$\text{Prob} \left\{ \sup_{t \geq T} d(\bar{r}_t, S) > \epsilon \right\} \leq \delta, \quad (1)$$

for any strategy of Nature. A strategy of the agent that satisfies this property is an approachability strategy for S .

Remarks:

1. It is evident that approachability of a set and its closure are equivalent, hence we shall henceforth consider only closed target sets S .
2. In some treatments of approachability, convergence of the expected distance $E(d(\bar{r}_t, S))$ and its rates are of central interest; see Perchet (2014). We shall consider these rates as well in the following.
3. In some models of interest, the decision variable of the agent may actually be the continuous variable x (in place of i), so that the actual reward is $r(x, j)$. All definitions and results below easily extend to this case, as long as x remains in a compact and convex set, and $r(x, j)$ is linear in x over that set.

For convex sets, approachability is fully characterized by the following result, which also provides an explicit strategy for the agent.

Theorem 2 (Blackwell, 1956) *A closed convex set $S \subset \mathbb{R}^d$ is approachable if and only if either one of the following equivalent conditions holds:*

(i) For each unit vector $u \in \mathbb{R}^d$, there exists a mixed action $x = x_S(u) \in \Delta(I)$ such that

$$\langle u, r(x, j) \rangle \leq \sup_{s \in S} \langle u, s \rangle, \quad \text{for all } j \in J. \quad (2)$$

(ii) For each $y \in \Delta(J)$ there exists $x \in \Delta(I)$ such that $r(x, y) \in S$.

If S is approachable, then the following strategy is an approachability strategy for S : For $z \notin S$, let $u_S(z)$ denote the unit vector that points to z from $\text{Proj}_S(z)$, the closest point to z in S . For $t \geq 2$, if $\bar{r}_{t-1} \notin S$, choose i_t according to the mixed action $x_t = x_S(u_S(\bar{r}_{t-1}))$; otherwise, choose i_t arbitrarily.

Blackwell's approachability strategy relies on the sequence of direction vectors $u_t = u_S(\bar{r}_{t-1})$, obtained through Euclidean projections onto the set S . A number of extensions and alternative algorithms for the basic game model have been proposed since. Most related to the present paper is the use of more general direction vectors. In Hart and Mas-Colell (2001), the direction vectors are obtained as the gradient of a suitable potential function; Blackwell's algorithm is recovered when the potential is taken as the Euclidean distance to the target set, while the use of other norms provides a range of useful variants. We will relate these variants to the present work in Section 5. As mentioned in the introduction, Abernethy et al. (2011) introduced the use of no-regret algorithms to generate the sequence of direction vectors.

A different class of approachability algorithms relies on Blackwell's dual condition in Theorem 2(ii), thereby avoiding the computation of direction vectors as projections (or related operations) to the target set S . Based on that condition, one can define a *response map* that assigns to each mixed action y of Nature a mixed action x of the agent such that the reward vector $r(x, y)$ belongs to S . An approachability algorithm that applies the response map to a *calibrated forecast* of the opponents' actions was proposed in Perchet (2009), and further analyzed in Bernstein et al. (2014). A computationally feasible response-based scheme that avoids the hard computation of calibrated forecasts is provided by Bernstein and Shimkin (2015). This paper also demonstrates the utility of the response-based approach for a class of generalized no-regret problems, where the set S is geometrically complicated, hence computing a projection is hard, but the response function is readily available. The response-based viewpoint is pursued further in the work of Mannor et al. (2014), which aims to approach the best-in-hindsight target set in an unknown game.

2.2 Online Convex Optimization (OCO)

OCO extends the framework of no-regret learning to function minimization. Let W be a convex and compact set in \mathbb{R}^d , and let \mathcal{F} be a set of convex functions $f : W \rightarrow \mathbb{R}$. Consider a sequential decision problem, where at each stage $t \geq 1$ the agent chooses a point $w_t \in W$, and then observes a function $f_t \in \mathcal{F}$. An *Algorithm* for the agent is a rule for choosing w_t , $t \geq 1$, based on the history $\{f_k, w_k\}_{k \leq t-1}$. The regret of an

algorithm \mathcal{A} is defined as

$$\text{Regret}_{\mathcal{T}}(\mathcal{A}) = \sup_{f_1, \dots, f_{\mathcal{T}} \in \mathcal{F}} \left\{ \sum_{t=1}^{\mathcal{T}} f_t(w_t) - \min_{w \in W} \sum_{t=1}^{\mathcal{T}} f_t(w) \right\}, \quad (3)$$

where the supremum is taken over all possible functions $f_t \in \mathcal{F}$. An effective algorithm should guarantee a small regret, and in particular one that grows sub-linearly in \mathcal{T} .

The OCO problem was introduced in this generality in Zinkevich (2003), along with the following Online Gradient Descent algorithm:

$$w_{t+1} = \text{Proj}_W(w_t - \eta_t g_t), \quad g_t \in \partial f_t(w_t). \quad (4)$$

Here $\partial f_t(w_t)$ is the subdifferential of f_t at w_t , (η_t) is a diminishing gain sequence, and Proj_W denotes the Euclidean projection onto the convex set W . To state a regret bound for this algorithm, let $\text{diam}(W)$ denote the diameter of W , and suppose that all subgradients of the functions f_t are uniformly bounded in norm by a constant G .

Proposition 3 (Zinkevich, 2003) For the Online Gradient Descent algorithm in (4) with gain sequence $\eta_t = \frac{\eta}{\sqrt{t}}$, $\eta > 0$, the regret is upper bounded as follows:

$$\text{Regret}_{\mathcal{T}}(\text{OGD}) \leq \left(\frac{\text{diam}(W)^2}{\eta} + 2\eta G^2 \right) \sqrt{\mathcal{T}}. \quad (5)$$

Several classes of OCO algorithms are now known, as surveyed in Cesa-Bianchi and Lugosi (2006); Shalev-Shwartz (2011); Hazan (2012). Of particular relevance here is the Regularized Follow the Leader (RFTL) algorithm, specified by

$$w_{t+1} = \arg \min_{w \in W} \left\{ \sum_{k=1}^t f_k(w) + R_t(w) \right\}, \quad (6)$$

where $R_t(w)$, $t \geq 1$ is a sequence of regularization functions. With $R_t \equiv 0$, the algorithm reduces to the basic Follow the Leader (FTL) algorithm, which does not generally lead to sublinear regret, unless additional requirements such as strong convexity are imposed on the functions f_t (we will revisit the convergence of FTL in Section 4). For RFTL, we will require the following standard convergence result. Recall that a function $R(w)$ over a convex set W is called ρ -strongly convex if $R(w) - \frac{\rho}{2} \|w\|_2^2$ is convex there.

Proposition 4 Suppose that each function f_t is Lipschitz-continuous over W , with Lipschitz coefficient L_f . Let $R_t(w) = \rho_t R(w)$, where $0 < \rho_t < \rho_{t+1}$, and the function $R : W \rightarrow [0, R_{\max}]$ is 1-strongly convex and Lipschitz continuous with coefficient L_R . Then

$$\text{Regret}_{\mathcal{T}}(\text{RFTL}) \leq 2L_f \sum_{t=1}^{\mathcal{T}} \frac{L_f + (\rho_t - \rho_{t-1})L_R}{\rho_t + \rho_{t-1}} + \rho_{\mathcal{T}} R_{\max}. \quad (7)$$

The proof of this bound is outlined in the Appendix.

3. OCO-Based Approachability

In this section we present the proposed OCO-based approachability algorithm. We start by introducing the support function and its relevant properties, and express Blackwell's separation condition in terms of this function. We then present the proposed algorithm, in the form of a meta-algorithm that incorporates a generic OCO algorithm. As a concrete example, we consider the specific algorithm obtained when Online Gradient Descent is used for the OCO part.

3.1 The Support Function

Let set $S \subset \mathbb{R}^d$ be a closed and convex set. The *support function* $h_S : \mathbb{R}^d \rightarrow \mathbb{R} \cup \{\infty\}$ of S is defined as

$$h_S(w) \triangleq \sup_{s \in S} \langle w, s \rangle, \quad w \in \mathbb{R}^d.$$

It is evident that h_S is a convex function (as a pointwise supremum of linear functions), and is positive homogeneous: $h_S(aw) = ah_S(w)$ for $a \geq 0$. Furthermore, the Euclidean distance from a point $z \in \mathbb{R}^d$ to S can be expressed as

$$d(z, S) = \max_{w \in B_2} \{ \langle w, z \rangle - h_S(w) \}, \quad (8)$$

where B_2 is the closed Euclidean unit ball (see, e.g., Boyd and Vandenberghe (2004), Section 8.1.3); see also Lemma 16 below). It follows that

$$\operatorname{argmax}_{w \in B_2} \{ \langle w, z \rangle - h_S(w) \} = \begin{cases} 0 & : z \in S \\ u_S(z) & : z \notin S \end{cases} \quad (9)$$

with $u_S(z)$ as defined in Theorem 2, namely the unit vector pointing from $\operatorname{Proj}_S(z)$ to z .

Blackwell's separation condition in (2) can now be written in terms of the support function as follows:

$$\langle w, r(x, j) \rangle \leq \sup_{s \in S} \langle w, s \rangle \equiv h_S(w).$$

We can now rephrase the primal condition in Theorem 2 in the following form.

Corollary 5 *A closed and convex set S is approachable if and only if for every vector $w \in B_2$ there exists a mixed action $x \in \Delta(I)$ so that*

$$\langle w, r(x, j) \rangle - h_S(w) \leq 0, \quad \forall j \in J. \quad (10)$$

We note that equation (10) defines a linear inequality for x , so that a mixed action $x \in \Delta(I)$ that satisfies (10) for a given direction w can be computed using linear programming. More concretely, existence of a mixed action x that satisfies (10) can be equivalently stated as

$$\operatorname{val}(w \cdot r) \triangleq \min_{x \in \Delta(I)} \max_{j \in J} \langle w, r(x, j) \rangle \leq h_S(w),$$

where $\operatorname{val}(w \cdot r)$ is the minimax value of the matrix game with a scalar payoff that is obtained by projecting the reward vectors $r(i, j)$ onto w . Consequently, the mixed action x that satisfies (10) can be taken as a minimax strategy for the agent in this game.

3.2 The General Algorithm

The proposed algorithm (see Algorithm 1 below) builds on the following idea. First, we apply an OCO algorithm to generate a sequence of *direction vectors* $w_t \in B_2$, so that

$$\sum_{t=1}^T (\langle w_t, r_t \rangle - h_S(w_t)) \geq T \max_{w \in B_2} \{ \langle w, \bar{r} \rangle - h_S(w) \} - a(T), \quad (11)$$

where $r_t = r(x_t, j_t)$ is considered (within the OCO algorithm) an arbitrary vector that is revealed after w_t is specified, and $a(T)$ is of order $o(T)$. The mixed action $x_t \in \Delta(I)$, in turn, is chosen (after w_t is revealed) to satisfy (10), so that $\langle w_t, r(x_t, j_t) \rangle - h_S(w_t) \leq 0$, hence

$$\langle w_t, r_t \rangle - h_S(w_t) \leq \langle w_t, r(x_t, j_t) \rangle \triangleq \delta_t.$$

Using this inequality in (11), and observing the distance formula (8), yields

$$d(\bar{r}, S) \leq \frac{a(T)}{T} + \Delta(T) \rightarrow 0,$$

where $\Delta(T) = \frac{1}{T} \sum_{t=1}^T \delta_t$, a stochastic term that converges to 0, as discussed below.

To secure (11), observe that the function $f(w; r) = -\langle w, r \rangle + h_S(w)$ is convex in w for each vector r . Therefore, an OCO algorithm can be applied to the sequence of convex functions $f_t(w) = -\langle w, r_t \rangle + h_S(w)$, where $r_t = r(x_t, j_t)$ is considered an arbitrary vector which is revealed only after w_t is specified. Applying an OCO algorithm \mathcal{A} with $\operatorname{Regret}_T(\mathcal{A}) \leq a(T)$ to this setup, we obtain a sequence (w_t) such that

$$\sum_{t=1}^T f_t(w_t) \leq \min_{w \in B_2} \sum_{t=1}^T f_t(w) + a(T),$$

where

$$\begin{aligned} \sum_{t=1}^T f_t(w_t) &= -\sum_{t=1}^T (\langle w_t, r_t \rangle - h_S(w_t)), \\ \sum_{t=1}^T f_t(w) &= -\sum_{t=1}^T (\langle w, r_t \rangle - h_S(w)) = -T(\langle w, \bar{r} \rangle - h_S(w)). \end{aligned}$$

This can be seen to imply (11).

The discussion above leads to the following generic approachability algorithm.

Algorithm 1 (OCO-based Approachability Meta-Algorithm)

- Given: A closed, convex and approachable set S ; a procedure (e.g., a linear program) to compute $x \in \Delta(I)$, for a given vector w , so that (10) is satisfied; an OCO algorithm \mathcal{A} for the functions $f_t(w) = -\langle w, r_t \rangle + h_S(w)$, with $\text{Regret}_T(\mathcal{A}) \leq a(T)$.
- Repeat for $t = 1, 2, \dots$:
 1. Obtain w_t from the OCO algorithm applied to the convex functions $f_k(w) = -\langle w, r_k \rangle + h_k(w)$, $k \leq t - 1$, so that inequality (11) is satisfied.
 2. Choose x_t according to (10), so that $\langle w_t, r(x_t, j) \rangle - h_S(w_t) \leq 0$ holds for all $j \in J$.
 3. Observe Nature's action j_t , and set $r_t = r(x_t, j_t)$.

To state our convergence result for this algorithm, we first consider the term Δ_t that arises due to the difference between $r_t = r(i_t, j_t)$ and $r(x_t, j_t)$. The analysis follows by standard convergence results for martingale difference sequences.

Lemma 6 *Let*

$$\Delta_T = \frac{1}{T} \sum_{t=1}^T \delta_t, \quad \delta_t = \langle w_t, r(i_t, j_t) \rangle - r(x_t, j_t).$$

Then $E(\Delta_T) = 0$, and $\Delta_T \rightarrow 0$ w.p. 1, at a uniform rate independent of Nature's strategy. Specifically,

$$P\{|\Delta_T| > \epsilon\} \leq \frac{6\rho_0^2}{\epsilon^2 T}, \quad (12)$$

where $\rho_0 = \max_{j \in J} \max_{i, i' \in I} \|r(i, j) - r(i', j)\|_2$.

Proof Let $H_t = \langle i_t, j_t, w_t \rangle_{1 \leq k \leq t}$. Observe that w_t and j_t are chosen based only on H_{t-1} , hence do not depend on i_t , and similarly i_t is randomly and independently chosen according to x_t . It follows that $E(\delta_t | H_{t-1}) = 0$, which implies that $E(\Delta_T) = 0$. Furthermore, (δ_t) is a Martingale difference sequence, uniformly bounded by

$$|\delta_t| \leq \|w_t\|_2 \|r(i_t, j_t) - r(x_t, j_t)\|_2 \leq \max_{j \in J} \max_{i, i'} \|r(i, j) - r(i', j)\|_2 \triangleq \rho_0,$$

(where $w_t \in B_2$ was used in the second inequality). Convergence of Δ_t now follows by standard results for martingale difference sequences; the specific rate bound in (12) follows from Proposition 4.1 and Equation (4.7) in Shimkin and Shwartz (1993), upon noting that $X_t \triangleq \sum_{k=1}^t \delta_k$ satisfies $E(X_{t+1}^2 | H_t) = X_t^2 + 0 + E(\delta_{t+1}^2 | H_t) \leq X_t^2 + \rho_0^2$. ■

Convergence of Algorithm 1 may now be summarised as follows.

Theorem 7 *Under Algorithm 1, for any $T \geq 1$ and any strategy of the opponent, it holds w.p. 1 that*

$$d(\bar{r}_T, S) \leq \frac{a(T)}{T} + \Delta_T,$$

where Δ_T is defined in Lemma 6 and is a zero-mean random variable that converges to zero at a uniform rate, as specified there. In particular,

$$E(d(\bar{r}_T, S)) \leq \frac{a(T)}{T}.$$

Proof As observed above, application of the OCO algorithm implies (11). Recalling (8), we obtain

$$\begin{aligned} d(\bar{r}_T, S) &= \max_{w \in B_2} \{ \langle w, \bar{r}_T \rangle - h_S(w) \} \\ &\leq \frac{1}{T} \sum_{t=1}^T (\langle w_t, r_t \rangle - h_S(w_t)) + \frac{a(T)}{T} \\ &= \frac{1}{T} \sum_{t=1}^T (\langle w_t, r(x_t, j_t) \rangle - h_S(w_t)) + \frac{a(T)}{T} + \frac{1}{T} \sum_{t=1}^T (w_t, r_t - r(x_t, j_t)). \end{aligned}$$

But since $\langle w_t, r(x_t, j_t) \rangle - h_S(w_t) \leq 0$ by choice of x_t in the algorithm, and using the definition of Δ_t , we obtain that $d(\bar{r}_T, S) \leq \frac{a(T)}{T} + \Delta_T$, as claimed. The rest now follows by the properties of Δ_t , stated in Lemma 6. ■

To recap, any OCO algorithm that guarantees (11) with $\frac{a(T)}{T} \rightarrow 0$, induces an approachability strategy with rate of convergence bounded by the sum of two terms: the first is $\frac{a(T)}{T}$, related to the regret bound of the OCO algorithm, and the second is a zero-mean stochastic term of order $T^{-1/2}$ (at most), which arises due to the difference between the actual rewards $r_t = r(i_t, j_t)$ and their means $r(x_t, j_t)$.

We conclude this subsection with a few remarks. The first two concern instances where the stochastic term Δ_T is nullified.

Remark 8 (Pure Actions) *Suppose that the inequality $\max_j \langle w_t, r(x, j) \rangle - h_S(w_t) \leq 0$ in step 2 of the Algorithm can always be satisfied by pure actions (so that x_t assigns probability 1 to a single action, i_t). Then choosing such x_t 's clearly implies that $r(x_t, j_t) = r(i_t, j_t)$, hence the term Δ_t in Theorem 7 becomes identically zero.*

Remark 9 (Smooth Rewards) *In some problems, the rewards of interest may actually be the smoothed rewards $r(x_t, j_t)$ or $r(x_t, y_t)$, rather than $r(i_t, j_t)$. Focusing on the first case for concreteness, let us redefine r_t as $r(x_t, j_t)$, and assume that this reward vector can be computed or observed by the agent following each stage t . Applying Algorithm 1 with these modified rewards now leads to the same bound as in Theorem 7, but with $\Delta_T = 0$.*

Remark 10 (Convex Cones) The approachability algorithm of Abernethy et al. (2011) starts with target sets S that are restricted to be convex cones. For S a closed convex cone, the support function is given by

$$h_S(w) = \begin{cases} 0 & : w \in S^\circ \\ \infty & : w \notin S^\circ \end{cases}$$

where S° is the polar cone of S . The required inequality in (11) thus reduces to

$$\sum_{t=1}^T \langle u_t, r_t \rangle \geq T \max_{w \in B_2 \cap S^\circ} \langle w, \bar{r}_T \rangle - a(T).$$

The sequence (u_t) can be obtained in this case by applying an online linear optimization algorithm restricted to $w_t \in B_2 \cap S^\circ$. This is the algorithm proposed by Abernethy et al. (2011). The extension to general convex sets is handled there by lifting the problem to a $(d+1)$ -dimensional space, with payoff vector $r^t(x, y) = (\kappa, r^t(x, y))$ and target set $S' = \text{cone}(\kappa \times S)$, where $\kappa = \max_{s \in S} \|s\|_2$, for which it holds that $d(u, S) \leq 2d(u', S')$.

3.3 An OGD-based Approachability Algorithm

As a concrete example, let us apply the Online Gradient Descent algorithm specified in (4) to our problem. With $W = B_2$ and $f_t^i(w) = -\langle w, r_t \rangle - h_S(w)$, we obtain in step 1 of Algorithm 1,

$$w_{t+1} = \text{Proj}_{B_2} \{w_t + \eta_t(r_t - y_t)\}, \quad y_t \in \partial h_S(w_t).$$

Observe that $\text{Proj}_{B_2}(v) = v / \max\{1, \|v\|_2\}$, and (e.g., by Corollary 8.25 in Rockafellar and Wets (1997))

$$\partial h_S(w) = \arg\max_{s \in S} \langle s, w \rangle.$$

To evaluate the convergence rate in (5), observe that $\text{diam}(B_2) = 2$, and, since $y_t \in S$, $\|y_t\|_2 = \|r_t - y_t\|_2 \leq \|\mathcal{R} - S\|_2$, where $\mathcal{R} = \{r(x, y) : x \in \Delta(U), y \in \Delta(U)\}$ is the reward set. Assuming for the moment that the goal set S is bounded, we obtain

$$E(d(\bar{r}_T, S)) \leq \frac{b(\eta)}{\sqrt{T}}, \quad \text{with } b(\eta) = \frac{4}{\eta} + 2\eta \|\mathcal{R} - S\|_2^2.$$

For $\eta = \sqrt{2} \|\mathcal{R} - S\|_2$, we thus obtain $b(\eta) = 4\sqrt{2} \|\mathcal{R} - S\|_2$.

If S is not bounded, it can always be intersected with \mathcal{R} (without affecting its approachability), yielding $\|\mathcal{R} - S\|_2 \leq \text{diam}(\mathcal{R})$. This amounts to modifying the choice of y_t in the algorithm to

$$y_t \in \partial h_{S \cap \mathcal{R}}(w_t) = \arg\max_{y \in S \cap \mathcal{R}} \langle y, w_t \rangle.$$

Alternatively, one may restrict attention (by projection) to vectors u_t in the set $\{w \in B_2 : h_S(w) < \infty\}$, similarly to the case of convex cones mentioned in Remark 10 above; we will not go here into further details.

4. Blackwell's Algorithm and (R)FTL

We next examine the relation between Blackwell's approachability algorithm and the proposed OCO-based scheme. We first show that Blackwell's algorithm coincides with OCO-based approachability when FTL is used as the OCO algorithm. We use this equivalence to establish fast (logarithmic) convergence rates for Blackwell's algorithm when the target set S has a smooth boundary. Interestingly, this equivalence does not provide a convergence result for general convex sets. To complete the picture, we show that Blackwell's algorithm can more generally be obtained via a *regularized* version of FTL, which leads to an alternative proof of convergence of the algorithm in the general case.

4.1 Blackwell's algorithm as FTL

Recall Blackwell's algorithm as specified in Theorem 2, namely x_{t+1} is chosen as a mixed action that satisfies (2) for $u = u_S(\bar{r}_t)$ (with x_{t+1} chosen arbitrarily if $\bar{r}_t \in S$, which is equivalent to setting $u = 0$ in that case).

Similarly, in Algorithm 1, x_{t+1} is chosen as a mixed action that satisfies (2) for $u = w_{t+1}$. Using FTL (i.e., Equation (6) with $R_t = 0$) for the OCO part gives

$$w_{t+1} = \arg\min_{w \in B_2} \sum_{k=1}^t f_k(w), \quad \text{with } f_k(w) = -\langle w, r_k \rangle + h_S(w).$$

Equivalence of the two algorithms now follows directly from the following observation.

Lemma 11 *With $f_k(w)$ as above,*

$$\arg\min_{w \in B_2} \sum_{k=1}^t f_k(w) = \begin{cases} u_S(\bar{r}_t) & : \bar{r}_t \notin S \\ 0 & : \bar{r}_t \in S \end{cases}.$$

Proof Observe that $\sum_{k=1}^t f_k(w) = -t(\langle w, \bar{r}_t \rangle - h_S(w))$, so that

$$\arg\min_{w \in B_2} \sum_{k=1}^t f_k(w) = \arg\max_{w \in B_2} \{w, \bar{r}_t\} - h_S(w).$$

The required equality now follows from (9). \blacksquare

To establish convergence of Blackwell's algorithm via this equivalence, one needs to show that FTL guarantees the regret bound in (11) for an arbitrary reward sequence $(r_t) \subset \mathcal{R}$, with a sublinear rate sequence $a(T)$. It is well known, however, that (unregularized) FTL does not guarantee sublinear regret, without some additional assumptions on the function f_t . A simple counter-example, reformulated to the present case, is devised as follows: Let $S = \{0\} \subset \mathbb{R}$, so that $h_S(w) = 0$, and suppose that

$r_t = -1$ and $r_t = 2(-1)^t$ for $t > 1$. Since $w_t = \text{sign}(\bar{r}_{t-1})$ and $\text{sign}(r_t) = -\text{sign}(\bar{r}_{t-1})$, we obtain that $f_t(w_t) = -r_t w_t = 1$, leading to a linearly-increasing regret.

The failure of FTL in this example is clearly due to the fast changes in the predictors w_t . We now add some smoothness assumptions on the set S that can mitigate such abrupt changes.

Assumption 1 *Let S be a compact and convex set. Suppose that the boundary ∂S of S is smooth with curvature bounded by κ_0 , namely:*

$$\|\bar{\pi}(s_1) - \bar{\pi}(s_2)\|_2 \leq \kappa_0 \|s_1 - s_2\|_2 \quad \text{for all } s_1, s_2 \in \partial S, \quad (13)$$

where $\bar{\pi}(s)$ is the unique unit outer normal to S at $s \in \partial S$.

For example, for a closed Euclidean ball of radius ρ , (13) is satisfied with equality for $\kappa_0 = \rho^{-1}$. The assumed smoothness property may in fact be formulated in terms of an interior sphere condition: For any point in $s \in S$ there exists a ball $B(\rho) \subset S$ with radius $\rho = \kappa_0^{-1}$ such that $s \in B(\rho)$.

Proposition 12 *Let Assumption 1 hold. Consider Blackwell's algorithm as specified in Theorem 2, and denote $w_t = u_S(\bar{r}_{t-1})$ (with w_1 arbitrary). Then, for any time $T \geq 1$ such that $\bar{r}_T \notin S$, (11) holds with*

$$a(T) = C_0(1 + \ln T), \quad (14)$$

where $C_0 = \text{diam}(\mathcal{R}) \|\mathcal{R} - S\|_2 \kappa_0$, and $\ln(\cdot)$ is the natural logarithm. Consequently,

$$E(\text{d}(\bar{r}_T, S)) \leq C_0 \frac{1 + \ln T}{T}, \quad T \geq 1. \quad (15)$$

Proof Observe first that the regret bound in (14) implies (15). Indeed, for $\bar{r}_T \notin S$, $\text{d}(\bar{r}_T, S) \leq a(T)/T$ follows as in Theorem 7, while if $\bar{r}_T \in S$ then $\text{d}(\bar{r}_T, S) = 0$ and (15) holds trivially.

We proceed to establish the logarithmic regret bound in (14). Let $f_t(w) = -\langle w, r_t \rangle + h_S(w)$, $W = B_2$, and denote

$$\text{Regret}_T(f_{1:T}) = \sum_{t=1}^T f_t(w_t) - \min_{w \in W} \sum_{t=1}^T f_t(w) = \sum_{t=1}^T (f_t(w_t) - f_t(w_{T+1})). \quad (16)$$

A standard induction argument (e.g., Lemma 2.1 in Shalev-Shwartz (2011)) verifies that

$$\sum_{t=1}^T (f_t(w_t) - f_t(u)) \leq \sum_{t=1}^T (f_t(w_t) - f_t(w_{t+1})) \quad (17)$$

holds for any $u \in W$, and in particular for $u = w_{T+1}$. It remains to upper-bound the differences in the last sum.

Consider first the case where $\bar{r}_t \notin S$ for all $1 \leq t \leq T$. We first show that $\|w_t - w_{t+1}\|_2$ is small, which implies the same for $|f_t(w_t) - f_t(w_{t+1})|$. By its definition, $w_{t+1} = u_S(\bar{r}_t)$, the unit vector pointing to \bar{r}_t from $c_t \stackrel{\Delta}{=} \text{Proj}_S(\bar{r}_t)$, which clearly coincides with the outer unit normal $\bar{\pi}(c_t)$ to S at c_t . It follows that

$$\|w_t - w_{t+1}\|_2 = \|\bar{\pi}(c_{t-1}) - \bar{\pi}(c_t)\|_2 \leq \kappa_0 \|c_{t-1} - c_t\|_2 \leq \kappa_0 \|\bar{r}_{t-1} - \bar{r}_t\|_2,$$

where the first inequality follows by Assumption 1, and the second due to the shrinking property of the projection. Substituting $\bar{r}_t = \bar{r}_{t-1} + \frac{1}{t}(r_t - \bar{r}_{t-1})$ obtains

$$\|w_t - w_{t+1}\|_2 \leq \frac{\kappa_0}{t} \|\bar{r}_t - \bar{r}_{t-1}\|_2 \leq \frac{\kappa_0}{t} \text{diam}(\mathcal{R}). \quad (18)$$

Next, observe that for any pair of unit vectors w_1 and w_2 ,

$$\begin{aligned} f_t(w_1) - f_t(w_2) &= -\langle w_1 - w_2, r_t \rangle + h_S(w_1) - h_S(w_2) \\ &= -\langle w_1 - w_2, r_t \rangle + \max_{s \in S} \langle w_1, s \rangle - \max_{s \in S} \langle w_2, s \rangle \\ &\leq -\langle w_1 - w_2, r_t \rangle + \langle w_1, s_1 \rangle - \langle w_2, s_1 \rangle \\ &= \langle w_1 - w_2, s_1 - r_t \rangle \leq \|w_1 - w_2\|_2 \|\mathcal{R} - S\|_2, \end{aligned}$$

where $s_1 \in S$ attains the first maximum. Since the same bound holds for $f_t(w_2) - f_t(w_1)$, it holds also for the absolute value. In particular,

$$|f_t(w_t) - f_t(w_{t+1})| \leq \|w_t - w_{t+1}\|_2 \|\mathcal{R} - S\|_2, \quad (19)$$

and together with (18) we obtain

$$|f_t(w_t) - f_t(w_{t+1})| \leq \frac{\kappa_0}{t} \text{diam}(\mathcal{R}) \|\mathcal{R} - S\|_2 = \frac{C_0}{t}.$$

Substituting in (17) and summing over t^{-1} yields the regret bound

$$\text{Regret}_T(f_{1:T}) \leq C_0(1 + \ln T). \quad (20)$$

We next extend this bound to case where $\bar{r}_t \in S$ for some t . In that case $w_{t+1} = 0$, and $w_t - w_{t+1}$ may not be small. However, since $f_t(0) = 0$, such terms will not affect the sum in (17). Recall that we need to establish (14) for T such that $\bar{r}_T \notin S$. In that case, any time t for which $\bar{r}_t \in S$ is followed by some time $m \leq T$ with $\bar{r}_m \notin S$. Let $1 \leq k < m \leq T$ be indices such that $\bar{r}_k, \dots, \bar{r}_{m-1} \in S$, but $\bar{r}_{k-1} \notin S$ (or $k = 1$) and $\bar{r}_m \notin S$. Then $w_{k+1}, \dots, w_m = 0$, and

$$\sum_{t=k}^m (f_t(w_t) - f_t(w_{t+1})) = f_k(w_k) - f_m(w_{m+1}).$$

Proceeding as above, we obtain similarly to (18),

$$\|w_k - w_{m+1}\|_2 \leq \kappa_0 \|\bar{r}_{k-1} - \bar{r}_m\|_2 \leq \text{diam}(\mathcal{R}) \sum_{t=k}^{m-1} \frac{\kappa_0}{t},$$

and the regret bound in (20) may be obtained as above. \blacksquare

The last result establishes a fast convergence rate (of order $\log T/T$) for Blackwell's approachability algorithm, under the assumed smoothness of the target set. We note that conditions for fast approachability (of order T^{-1}) were derived in Perchet and Mannor (2013), but are of different nature than the above.

Logarithmic convergence rates were derived for OCO algorithms in Hazan et al. (2007), under strong convexity conditions on the function f_t . This is apparently related to the present result, especially given the equivalence between strong convexity of a function and strong smoothness of its Legendre-Fenchel transform (cf. Shalev-Shwartz (2011), Lemma 2.19). However, we observe that the support function is *not* strongly convex, so that the logarithmic regret bound in (20) does not seem to follow from existing results. Rather, a basic property which underlies both cases is insensitvity of the maximum point to small perturbations in f_t , which here leads to the inequality (18).

4.2 Blackwell's algorithm as RFTL

The smoothness requirement in Assumption 1 does not hold for important classes of target sets, such as polyhedra and cones. As observed above, in absence of such additional smoothness properties the interpretation of Blackwell's algorithm through an FTL scheme does not entail its convergence, as the regret of FTL (and the corresponding bound $a(T)$ in (11)) might increase linearly in general.

To accommodate general (non-smooth) sets, we show next that Blackwell's algorithm can be identified more generally with a *regularized* version of FTL. This algorithm does guarantee an $O(\sqrt{T})$ regret in (11), and consequently leads to the standard $O(T^{-1/2})$ rate of convergence of Blackwell's approachability algorithm.

Let us apply the RFTL algorithm in equation (6) as the OCO part in Algorithm 1, with a quadratic regularization function $R_t(w) = \frac{\rho_t}{2} \|w\|_2^2$. This gives

$$w_{t+1} = \underset{w \in B_2}{\operatorname{argmin}} \left\{ \sum_{k=1}^t f_k(w) + \frac{\rho_t}{2} \|w\|_2^2 \right\}, \quad f_k(w) = -\langle w, r_k \rangle + h_S(w).$$

The following equality is the key to the required equivalence. It relies essentially on the positive-homogeneity property of the support function h_S , and consequently of the functions f_k above.

Lemma 13 For $\rho_t > 0$, and w_{t+1} as defined above,

$$w_{t+1} = \begin{cases} \beta_t u_S(\bar{r}_t) & : \bar{r}_t \notin S \\ 0 & : \bar{r}_t \in S \end{cases}, \quad (21)$$

where $\beta_t = \min\{1, \frac{t}{\rho_t} d(\bar{r}_t, S)\} > 0$.

Proof Recall that $\sum_{k=1}^t f_k(w) = -t\langle w, \bar{r}_t \rangle - h_S(w)$, so that

$$\underset{w \in B_2}{\operatorname{argmin}} \left\{ \sum_{k=1}^t f_k(w) + \frac{\rho_t}{2} \|w\|_2^2 \right\} = \underset{w \in B_2}{\operatorname{argmax}} \left\{ \langle w, \bar{r}_t \rangle - h_S(w) - \frac{\rho_t}{2t} \|w\|_2^2 \right\}.$$

To compute the right-hand side, we first maximize over $\{w : \|w\|_2 = \beta\}$, and then optimize over $\beta \in [0, 1]$. Denote $z = \bar{r}_t$, and $\eta = \rho_t/t$. Similarly to Lemma 11,

$$\underset{\|w\|_2=\beta}{\operatorname{argmax}} \left\{ \langle w, z \rangle - h_S(w) - \frac{\eta}{2} \|w\|_2^2 \right\} = \underset{\|w\|_2=\beta}{\operatorname{argmax}} \{ \langle w, z \rangle - h_S(w) \} = \begin{cases} \beta u_S(z) & : z \notin S \\ 0 & : z \in S \end{cases}.$$

Now, for $z \notin S$,

$$\max_{\|w\|_2=\beta} \left\{ \langle w, z \rangle - h_S(w) - \frac{\eta}{2} \|w\|_2^2 \right\} = \beta d(z, S) - \frac{\eta}{2} \beta^2.$$

Maximizing the latter over $0 \leq \beta \leq 1$ gives $\beta^* = \min\{1, \frac{d(z,S)}{\eta}\}$. Substituting back z and η gives (21). \blacksquare

This immediately leads to the required conclusion.

Proposition 14 Algorithm 1 with quadratically regularized FTL is equivalent to Blackwell's algorithm.

Proof Observe that the vector w_{t+1} in Equation (21) is equal to $u_S(\bar{r}_t)$ from Blackwell's algorithm in Theorem 2, up to a positive scaling by β_t . This scaling does not affect the choice of x_{t+1} according to (10), as the support function $h_S(w)$ is positive homogeneous. \blacksquare

Compared to non-regularized FTL (or Blackwell's algorithm), we see the direction vectors in Equation (21) are scaled by a positive constant. Essentially, the effect of this scaling is to reduce the magnitude of w_{t+1} when \bar{r}_t is close to S . While such scaling does not affect the choice of action x_t , it does lead to sublinear-regret for the OLO algorithm, and consequently convergence of the approachability algorithm. This is summarized as follows.

Proposition 15 *Let S be a convex and compact set. Consider the RFTL algorithm specified in equation (21), with $\rho_t = \rho\sqrt{t}$, $\rho > 0$. The regret of this algorithm is bounded by*

$$\text{Regret}_T(\text{RFTL}) \leq \left(\frac{2L_f^2}{\rho} + \frac{\rho}{2} \right) \sqrt{T} + \frac{L_f}{2} \ln(T) + 4L_f \triangleq a_0(T),$$

where $L_f = \|\mathcal{R} - S\|_2$. Consequently, if this RFTL algorithm is used in step 1 of Algorithm 1 to compute w_t , we obtain

$$E(\text{d}(\bar{r}_T, S)) \leq \frac{a_0(T)}{T} = O(T^{-\frac{1}{2}}), \quad T \geq 1. \quad (22)$$

Proof The regret bound follows from the one in Proposition 4, evaluated for $f_t(w) = -\langle r_t, w \rangle + h_S(w)$, $W = B_2$, $R(w) = \frac{1}{2}\|w\|_2^2$, and $\rho_t = \rho\sqrt{t}$. Recalling that $\partial f_t(w) = -r_t + \text{argmax}_{s \in S} \langle w, s \rangle$, the Lipschitz constant of f_t is upper bounded by $\|\mathcal{R} - S\|_2 \triangleq L_f$. Furthermore, $R_{\max} = \frac{1}{2}$ and $L_R = 1$. Therefore,

$$\text{Regret}_T(\text{RFTL}) \leq 2L_f \sum_{t=1}^T \frac{L_f + \rho(\sqrt{t} - \sqrt{t-1})}{\rho(\sqrt{t} + \sqrt{t-1})} + \frac{\rho}{2}\sqrt{T}. \quad (23)$$

To upper bound the sum, we note that

$$\sum_{t=1}^T \frac{1}{(\sqrt{t} + \sqrt{t-1})} = \sum_{t=1}^T (\sqrt{t} - \sqrt{t-1}) = \sqrt{T},$$

and

$$\begin{aligned} \sum_{t=1}^T \left(\frac{\sqrt{t} - \sqrt{t-1}}{\sqrt{t} + \sqrt{t-1}} \right) &= \sum_{t=1}^T \frac{1}{(\sqrt{t} + \sqrt{t-1})^2} \leq 2 + \sum_{t=3}^T \frac{1}{(2\sqrt{t-1})^2} \\ &\leq 2 + \frac{1}{4} \int_{t=1}^T \frac{1}{t} dt = 2 + \frac{1}{4} \ln(T). \end{aligned}$$

Substituting in (23) gives the stated regret bound. The second part now follows directly from Theorem 7. \blacksquare

With $\rho = 2L_f$, we obtain in (22) the convergence rate

$$E(\text{d}(\bar{r}_T, S)) \leq \frac{2\|\mathcal{R} - S\|_2}{\sqrt{T}} + o\left(\frac{1}{\sqrt{T}}\right).$$

We emphasize that the algorithm discussed in this section is equivalent to Blackwell's algorithm, hence its convergence is known. The proof of convergence here

is certainly not the simplest, nor does it lead to the best constants in the convergence rate. Indeed, Blackwell's proof (which recursively bounds the square distance $\text{d}(\bar{r}_T, S)^2$) leads to the bound $\sqrt{E(\text{d}(\bar{r}_T, S)^2)} \leq \frac{\|\mathcal{R} - S\|_2}{\sqrt{T}}$. Rather, our main purpose was to provide an alternative view and analysis of Blackwell's algorithm, which rely on a standard OCO algorithm. That said, the logarithmic convergence rate of the expected distance that was obtained under the smoothness Assumption 1 appears to be new.

5. Extensions with General Norms

As was mentioned in Subsection 2.1, a class of approachability algorithms that generalizes Blackwell's strategy was introduced by Hart and Mas-Colell (2001). The direction vectors (u_t) in Blackwell's algorithm, that are defined through Euclidean projection, are replaced in that paper by the gradient of a smooth *potential function*; Blackwell's algorithm is recovered when the potential is taken as the Euclidean distance to the target set. Other instances of interest are obtained by defining the potential through the p -norm distance; this, in turn, was used as a basis for a general class of no-regret algorithms in repeated games.

In this section we provide an extension of the OCO-based approachability algorithm from Section 3, which relies on a general norm rather than the Euclidean one to obtain the direction vectors (w_t) . The proposed algorithms coincide with those of Hart and Mas-Colell (2001) when the RFTL algorithm is used for the OCO part.

Let $\|\cdot\|$ denote some norm on \mathbb{R}^d . The dual norm, denoted $\|\cdot\|_*$, is defined as

$$\|x\|_* = \max_{w \in \mathbb{R}^d: \|w\| \leq 1} \langle w, x \rangle.$$

For example, if the primal norm is the p -norm $\|x\|_p = (\sum_{i=1}^d x_i^p)^{\frac{1}{p}}$ with $p \in (0, 1)$, the dual norm is the q -norm, with $q \in (0, 1)$ that satisfies $\frac{1}{p} + \frac{1}{q} = 1$.

The following relations between the support function h_S and the point-to-set distance d_* will be required. The first is needed to show convergence of the algorithm, and the second for the interpretation of the FTL-based variant.

Lemma 16 *Let S be a closed convex set with support function h_S , and let $d_*(z, S) = \min_{s \in S} \|z - s\|_*$ denote the point-to-set distance with respect to the dual norm. Then, for any $z \in \mathbb{R}^d$,*

$$d_*(z, S) = \max_{\|w\| \leq 1} \{ \langle w, z \rangle - h_S(w) \}, \quad (24)$$

and

$$\partial d_*(z, S) = \text{argmax}_{\|w\| \leq 1} \{ \langle w, z \rangle - h_S(w) \}, \quad (25)$$

where $\partial d_*(z, S)$ is the subgradient of $d_*(\cdot, S)$ at z .

Proof We first note that the maximum in (24) is attained since h_S is a lower semi-continuous function, and $\{\|w\| \leq 1\}$ is a compact set. To establish (24) we invoke the minimax theorem. By definition of h_S ,

$$\max_{\|w\| \leq 1} \langle w, z \rangle - h_S(w) = \max_{\|w\| \leq 1} \inf_{s \in S} \langle w, z - s \rangle.$$

Observe that $\{\|w\| \leq 1\}$ is a convex and compact set, S is convex by definition, and $\langle w, z - s \rangle$ is linear both in w and in s . We may thus apply Sion's minimax theorem to obtain that the last expression equals

$$\inf_{s \in S} \sup_{\|w\| \leq 1} \langle w, z - s \rangle = \inf_{s \in S} \|z - s\|_* = d_*(z, S),$$

where the definition of the dual norm was used in the last step, and (24) is obtained.

Proceeding to (25), we observe (24) implies that $d_*(\cdot, S)$ is the Legendre-Fenchel transform of an appropriately modified function \bar{h}_S , namely $d_*(z, S) = \max_{w \in \mathbb{R}^d} \{\langle w, z \rangle - \bar{h}_S(w)\}$ where $\bar{h}_S(w) = h_S(w)$ if $\|w\| \leq 1$ and $\bar{h}_S(w) = \infty$ for $\|w\| > 1$. Evidently h_S is a convex and lower semi-continuous function, which follows since both S and $\{\|w\| \leq 1\}$ are closed and convex sets. The equality in (25) now follows directly by Proposition 11.3 in Rockafellar and Wets (1997). ■

The algorithm: We can now repeat the blueprints of Subsection 3.2 to obtain an approachability algorithm for a convex target set S , which here relies on any norm $\|\cdot\|$. First, we apply an OCO algorithm to the functions $f_t(w) = -\langle w, \tau_t \rangle + h_S(w)$ over the convex compact set $\{w \in \mathbb{R}^d : \|w\| \leq 1\}$ to obtain, analogously to equation (11), a sequence of vectors (w_t) such that

$$\sum_{t=1}^T (\langle w_t, \tau_t \rangle - h_S(w_t)) \geq T \max_{\|w\| \leq 1} \{\langle w, \bar{\tau} \rangle - h_S(w)\} - a(T). \quad (26)$$

Next, each w_t is used as the direction vector for stage t , and the mixed action x_t is chosen so that $\langle w_t, \tau_t \rangle - h_S(w_t) \leq 0$ holds for any action of Nature. Observing (24), we obtain that

$$d_*(\bar{\tau}, S) \leq \frac{a(T)}{T} \rightarrow 0.$$

Follow the Leader: Consider the specific case that where FTL is used for the OCO algorithm. That is,

$$w_{t+1} \in \operatorname{argmin}_{\|w\| \leq 1} \sum_{k=1}^t f_k(w) \equiv \operatorname{argmax}_{\|w\| \leq 1} \{\langle w, \tau_t \rangle - h_S(w)\}. \quad (27)$$

By (25), this is equivalent to $w_{t+1} \in \partial d_*(\bar{\tau}, S)$. In particular, if $d_*(z, S)$ is differentiable at $z = \bar{\tau}$, then $w_{t+1} = \nabla d_*(\bar{\tau}, S)$. We therefore recover the approachability algorithm of Hart and Mas-Colell (2001) for the potential function $P(z) = d_*(z, S)$.

Convergence of the approachability algorithm of Hart and Mas-Colell (2001) requires the potential function $P(z)$ to be continuously differentiable. As observed there, for $P(z) = d_*(z, S)$ this holds if either the norm $\|\cdot\|_*$ is smooth (e.g., the q -norm for $1 < q < \infty$), or the boundary of S is smooth.

In our framework, convergence analysis of the FTL-based OCO algorithm can be carried out similarly to that of Section 4. In particular, similarly to the procedure of Subsection 4.2, if the norm $\|\cdot\|$ is smooth we can guarantee convergence of the OCO algorithm without affecting the induced approachability algorithm by adding an appropriate regularization term in (27), namely setting

$$w_{t+1} \in \operatorname{argmin}_{\|w\| \leq 1} \left\{ \sum_{k=1}^t f_k(w) - \frac{\rho_t}{2} \|w\|^2 \right\}.$$

By analogy to Lemma 13, the added regularization does not modify the direction of w_t but only its magnitude, hence the choice of actions x_t is the induced approachability algorithm remains the same. Convergence rates can be obtained along the lines of Section 4, and will not be considered in detail here.

Acknowledgments

Appendix A.

Proof of Proposition 4: We follow the outline of the proof of Lemma 2.10 in Shalev-Shwartz (2011), modified to accommodate a non-constant regularization sequence ρ_t . The starting point is the inequality, proved by induction,

$$\sum_{t=1}^T (f_t(w_t) - f_t(u)) \leq \sum_{t=1}^T (f_t(w_t) - f_t(w_{t+1})) + \rho_t R(u), \quad (28)$$

which holds for any $u \in W$. Therefore,

$$\sum_{t=1}^T (f_t(w_t) - f_t(u)) \leq L_T \sum_{t=1}^T \|w_t - w_{t+1}\|_2 + \rho_t R(u). \quad (29)$$

Denote $F_t(w) = \sum_{k=1}^{t-1} f_k(w) + \rho_{t-1} R(w)$. Then F_t is ρ_{t-1} -strongly convex, and w_t is its minimizer by definition. Hence, it holds generally that

$$F_t(w) \geq F_t(w_t) + \frac{\rho_{t-1}}{2} \|w - w_t\|_2^2,$$

and in particular,

$$F_t(w_{t+1}) \geq F_t(w_t) + \frac{\rho_{t-1}}{2} \|w_{t+1} - w_t\|_2^2, \quad (30)$$

$$F_{t+1}(w_t) \geq F_{t+1}(w_{t+1}) + \frac{\rho_t}{2} \|w_t - w_{t+1}\|_2^2. \quad (31)$$

Summing and cancelling terms, we obtain

$$f_t(w_t) - f_t(w_{t+1}) + (\rho_t - \rho_{t-1})(R(w_t) - R(w_{t+1})) \geq \frac{\rho_t + \rho_{t-1}}{2} \|w_{t+1} - w_t\|_2^2.$$

But the left-hand side is upper-bounded by $(L_f + (\rho_t - \rho_{t-1})L_R)\|w_{t+1} - w_t\|_2$, which implies that

$$\|w_{t+1} - w_t\|_2 \leq 2 \frac{L_f + (\rho_t - \rho_{t-1})L_R}{\rho_t + \rho_{t-1}}.$$

Substituting in (29) gives the bound stated in the Proposition. ■

Abstract

We develop a method for estimating well-conditioned and sparse covariance and inverse covariance matrices from a sample of vectors drawn from a sub-Gaussian distribution in high dimensional setting. The proposed estimators are obtained by minimizing the quadratic loss function and joint penalty of l_1 norm and variance of its eigenvalues. In contrast to some of the existing methods of covariance and inverse covariance matrix estimation, where often the interest is to estimate a sparse matrix, the proposed method is flexible in estimating both a sparse and well-conditioned covariance matrix simultaneously. The proposed estimators are optimal in the sense that they achieve the mini-max rate of estimation in operator norm for the underlying class of covariance and inverse covariance matrices. We give a very fast algorithm for computation of these covariance and inverse covariance matrices which is easily scalable to large scale data analysis problems. The simulation study for varying sample sizes and variables shows that the proposed estimators performs better than several other estimators for various choices of structured covariance and inverse covariance matrices. We also use our proposed estimator for tumor tissues classification using gene expression data and compare its performance with some other classification methods.

Keywords: Sparsity, Eigenvalue Penalty, Penalized Estimation

1. Introduction

With the recent surge in data technology and storage capacity, today's statisticians often encounter data sets where sample size n is small and number of variables p is very large: often hundreds, thousands and even million or more. Examples include gene expression data and web search problems [Clarke et al. (2008), Pass et al. (2006)]. For many of the high dimensional data problems, the choice of classical statistical methods becomes inappropriate for making valid inference. The recent developments in asymptotic theory deal with increasing p as long as both p and n tend to infinity at some rate depending upon the parameters of interest.

The estimation of covariance and inverse covariance matrix is a problem of primary interest in multivariate statistical analysis. Some of the applications include: (i) Principal component analysis (PCA) [Johnstone and Lu (2004), Zou et al. (2006)]; where the goal is to project the data on "best" k -dimensional subspace, and where best means the projected data explains as much of the variation in original data without increasing k . (ii) Discriminant analysis [Mardia et al. (1979)]; where the goal is to classify observations into different

classes. Here estimates of covariance and inverse covariance matrices play an important role as the classifier is often a function of these entities. (iii) Regression analysis: If interest focuses on estimation of regression coefficients with correlated (or longitudinal) data, a sandwich estimator of the covariance matrix may be used to provide standard errors for the estimated coefficients that are robust in the sense that they remain consistent under misspecification of the covariance structure. (iv) Gaussian graphical modeling [Meinshausen and Bühlmann (2006), Wainwright et al. (2006), Yuan and Lin (2007), Yuan (2009)]; the relationship structure among nodes can be inferred from inverse covariance matrix. A zero entry in the inverse covariance matrix implies conditional independence between the corresponding nodes.

The estimation of large dimensional covariance matrix based on few sample observations is a difficult problem, especially when $n \asymp p$ (here $a_n \asymp b_n$ means that there exist positive constants c and C such that $c \leq a_n/b_n \leq C$). In these situations, the sample covariance matrix becomes unstable which explodes the estimation error. It is well known that the eigenvalues of sample covariance matrix are over-dispersed which means that the eigen-spectrum of sample covariance matrix is not a good estimator of its population counterpart [Marcenko and Pastur (1967), Karoui (2008a)]. To illustrate this point, consider $\Sigma_p = I_p$, so all the eigenvalues are 1. A result from [Geman (1980)] shows that if entries of X_i 's are i.i.d (let X_i 's have mean zero and variance 1) with a finite fourth moment and if $p/n \rightarrow \theta < 1$, then the largest sample eigenvalue l_1 satisfies:

$$l_1 \rightarrow (1 + \sqrt{\theta})^2, \quad a.s.$$

This suggests that l_1 is not a consistent estimator of the largest eigenvalue σ_1 of population covariance matrix. In particular if $n = p$ then l_1 tends to 4 whereas $\sigma_1 = 1$. This is also evident in the eigenvalue plot in Figure 2.1. The distribution of l_1 also depends on the underlying structure of the true covariance matrix. From Figure 2.1, it is evident that the smaller sample eigenvalues tend to underestimate the true eigenvalues for large p and small n . For more discussion on this topic, see Karoui (2008a).

To correct for this bias, a natural choice would be to shrink the sample eigenvalues towards some suitable constant to reduce the over-dispersion. For instance, Stein (1975) proposed an estimator of the form $\tilde{\Sigma} = \tilde{U}\Lambda(\lambda)\tilde{U}$, where $\Lambda(\lambda)$ is a diagonal matrix with diagonal entries as transformed function of the sample eigenvalues and \tilde{U} is the matrix of the eigen-vectors. In another interesting paper Ledoit and Wolf (2004) proposed an estimator that shrinks the sample covariance matrix towards the identity matrix. In another paper, Karoui (2008b) proposed a non-parametric estimation of spectrum of eigenvalues and show that his estimator is consistent in the sense of weak convergence of distributions.

The covariance matrix estimates based on eigen-spectrum shrinkage are well-conditioned in the sense that their eigenvalues are well bounded away from zero. These estimates are based on the shrinkage of the eigenvalues and therefore invariant under some orthogonal group i.e. the shrinkage estimators shrink the eigenvalues but eigenvectors remain unchanged. In other words, the basis (eigenvector) in which the data are given is not taken advantage of and therefore the methods rely on premise that one will be able to find a good estimate in any basis. In particular, it is reasonable to believe that the basis generating the data is somewhat nice. Often this translates into the assumption that the covariance matrix

has particular structure that one should be able to take advantage of. In these situations, it becomes natural to perform certain form of regularization directly on the entries of the sample covariance matrix.

Much of the recent literature focuses on two broad classes of regularized covariance matrix estimation. i) The one class relies on natural ordering among variables, where one often assumes that the variables far apart are weakly correlated and ii) the other class where there is no assumption on the natural ordering among variables. The first class includes the estimators based on banding and tapering [Bickel and Levina (2008b), Cai et al. (2011)]. These estimators are appropriate for a number of applications for ordered data (time series, spectroscopy, climate data). However for many applications including gene expression data, prior knowledge of any canonical ordering is not available and searching for all permutation of possible ordering would not be feasible. In these situations, an ℓ_1 penalized estimator becomes more appropriate which yields a permutation-invariant estimate.

To obtain a suitable estimate which is both well-conditioned and sparse, we introduce two regularization terms: i) ℓ_1 penalty for each of the off-diagonal elements of matrix and, ii) penalty proportional to the variance of the eigenvalues. The ℓ_1 minimization problems are well studied in the covariance and inverse covariance matrix estimation literature [Friedman et al. (2008), Banerjee et al. (2008), Ravikumar et al. (2011), Bein and Tibshirani (2011), Maurya (2014) etc.]. Rothman (2012) proposes an ℓ_1 penalized log-likelihood estimator and shows that estimator is consistent in Frobenius norm at the rate of $O_p\left(\sqrt{(\bar{p} + s) \log \bar{p}/n}\right)$, as both p and n approach to infinity. Here s is the number of non-zero off-diagonal elements in the true covariance matrix. In another interesting paper Bein and Tibshirani (2011) propose an estimator of covariance matrix as penalized maximum likelihood estimator with a weighted lasso type penalty. In these optimization problems, the ℓ_1 penalty results in sparse and a permutation-invariant estimator as compared to other $\ell_p, q \neq 1$ penalties. Another advantage is that the ℓ_1 norm is a convex function which makes it suitable for large scale optimization problems. A number of fast algorithms exist in the literature for covariance and inverse covariance matrix estimation [Friedman et al. (2008), Rothman et al. (2008)]. The eigenvalues variance penalty overcomes the over-dispersion in the sample covariance matrix so that the estimator remains well-conditioned.

Ladroit and Wolf (2004) proposed an estimator of covariance matrix as a linear combination of sample covariance and identity matrix. Their estimator of covariance matrix is well-conditioned but it is not sparse. Rothman et al. (2008) proposed estimator of covariance matrix based on quadratic loss function and ℓ_1 penalty with a log-barrier on the determinant of covariance matrix. The log-determinant barrier is a valid technique to achieve positive definiteness but it is still unclear whether the iterative procedure proposed in Rothman et al. (2008) actually finds the right solution to the corresponding optimization problem. In another interesting paper, Xie et al. (2012) proposed an estimator of covariance matrix as a minimizer of penalized quadratic loss function over set of positive definite matrices. In their paper, the authors solve a positive definite constrained optimization problem and establish the consistency of estimator. The resulting estimator is sparse and positive definite but whether it overcomes the over-dispersion of the eigen-spectrum of sample covariance matrix, is hard to justify. Maurya (2014) proposed a joint convex penalty as function of ℓ_1 and trace norm (defined as sum of singular values of a matrix) for inverse covariance matrix estimation based on penalized likelihood approach.

In this paper, we propose the JPEN (Joint PENalty) estimators for covariance and inverse covariance matrices estimation and derive an explicit rate of convergence in both the operator and Frobenius norm. The JPEN estimators achieves mini-max rate of convergence under operator norm for the underlying class of sparse covariance and inverse covariance matrices and hence is optimal. For more details see section §3. One of the major advantage of the proposed estimators is that the proposed algorithm is very fast, efficient and easily scalable to a large scale data analysis problem.

The rest of the paper is organized as following. The next section highlights some background and problem set-up for covariance and inverse covariance matrix estimation. In section 3, we describe the proposed estimators and establish their theoretical consistency. In section 4, we give an algorithm and compare its computational time with some other existing algorithms. Section 5 highlights the performance of the proposed estimators on simulated data while an application of proposed estimator to real life data is given in section 6.

Notation: For a matrix M , let $\|M\|_1$ denote its ℓ_1 norm defined as the sum of absolute values of the entries of M , $\|M\|_F$ denote its Frobenius norm, defined as the sum of square of elements of M , $\|M\|$ denote its operator norm (also called spectral norm), defined as the largest absolute eigenvalue of M , M^- denotes matrix M where all diagonal elements are set to zero, M^+ denote matrix M where all off-diagonal elements are set to zero, $\sigma_i(M)$ denote the i^{th} largest eigenvalue of M , $\text{tr}(M)$ denotes its trace, $\det(M)$ denote its determinant, $\sigma_{\min}(M)$ and $\sigma_{\max}(M)$ denote the minimum and maximum eigenvalues of M , $|M|$ be its cardinality, and let $\text{sign}(M)$ be matrix of signs of elements of M . For any real x , let $\text{sign}(x)$ denotes sign of x , and let $|x|$ denotes its absolute value.

2. Background and Problem Set-up

Let $X = (X_1, X_2, \dots, X_p)$ be a zero-mean p -dimensional random vector. The focus of this paper is the estimation of the covariance matrix $\Sigma := \mathbb{E}(XX^T)$ and its inverse Σ^{-1} from a sample of independently and identically distributed data $\{X^{(k)}\}_{k=1}^n$. In this section we provide some background and problem setup more precisely.

The choice of loss function is very crucial in any optimization problem. An optimal estimator for a particular loss function may not be optimal for another choice of loss function. Recent literature in covariance matrix and inverse covariance matrix estimation mostly focuses on estimation based on likelihood function or quadratic loss function [Friedman et al. (2008), Banerjee et al. (2008), Bickel and Levina (2008b), Ravikumar et al. (2011), Rothman et al. (2008), Maurya (2014)]. The maximum likelihood estimation requires a tractable probability distribution of observations whereas quadratic loss function does not have any such requirement and therefore fully non-parametric. The quadratic loss function is convex and due to this analytical tractability, it is a widely applicable choice for many data analysis problems.

2.1 Proposed Estimators

Let S be the sample covariance matrix. Consider the following optimization problem.

$$\hat{\Sigma}_{\lambda,\gamma} = \underset{\Sigma = \Sigma^T, \text{tr}(\Sigma) = \text{tr}(S)}{\text{argmin}} \left[\|\Sigma - S\|_F^2 + \lambda \|\Sigma^{-1}\|_1 + \gamma \sum_{i=1}^p \{\sigma_i(\Sigma) - \sigma_i(S)\}^2 \right], \quad (2.1)$$

where σ_Σ is the mean of eigenvalues of Σ , λ and γ are some positive constants. Note that by penalty function $\|\Sigma^{-1}\|_1$, we only penalize off-diagonal elements of Σ . The eigenvalues of variance penalty term for eigen-spectrum shrinkage is chosen from the following points of interest: i) It is easy to interpret and ii) this choice of penalty function yields a very fast optimization algorithm. By constraint $\text{tr}(\Sigma) = \text{tr}(S)$, the total variation in $\hat{\Sigma}_{\lambda,\gamma}$ is same as that in sample covariance matrix S , however the eigenvalues of $\hat{\Sigma}_{\lambda,\gamma}$ are well-conditioned than those of S . From here onwards we suppress the dependence of λ, γ on Σ and denote $\hat{\Sigma}_{\lambda,\gamma}$ by $\hat{\Sigma}$.

For $\gamma = 0$, the solution to (2.1) is the standard soft-thresholding estimator for quadratic loss function and its solution is given by (see §4 for derivation of this estimator):

$$\begin{aligned} \hat{\Sigma}_{ii} &= s_{ii} \\ \hat{\Sigma}_{ij} &= \text{sign}(s_{ij}) \max \left(|s_{ij}| - \frac{\lambda}{2}, 0 \right), \quad i \neq j. \end{aligned} \quad (2.2)$$

It is clear from this expression that a sufficiently large value of λ will result in sparse covariance matrix estimate. But estimator $\hat{\Sigma}$ of (2.2) is not necessarily positive definite [for more details here see [Xue et al. \(2012\)](#)]. Moreover it is hard to say whether it overcomes the over-dispersion in the sample eigenvalues. The following eigenvalue plot (Figure (2.1)) illustrates this phenomenon for a neighbourhood type (see §5 for details on description of neighbourhood type of covariance matrix) covariance matrix. Here we simulated random vectors from multivariate normal distribution with sample size $n = 50$ and number of covariates $p = 20$. As is evident from Figure 2.1, eigenvalues of sample covariance matrix are over-dispersed as most of them are either too large or close to zero. Eigenvalues of the proposed Joint Penalty (JPEN) estimator and PDSCE (Positive Definite Sparse Covariance Estimator ([Rothman \(2012\)](#))) of the covariance matrix are well aligned with those of true covariance matrix. See §5 for detailed discussion. Another drawback of the estimator (2.2) is that the estimate can be negative definite.

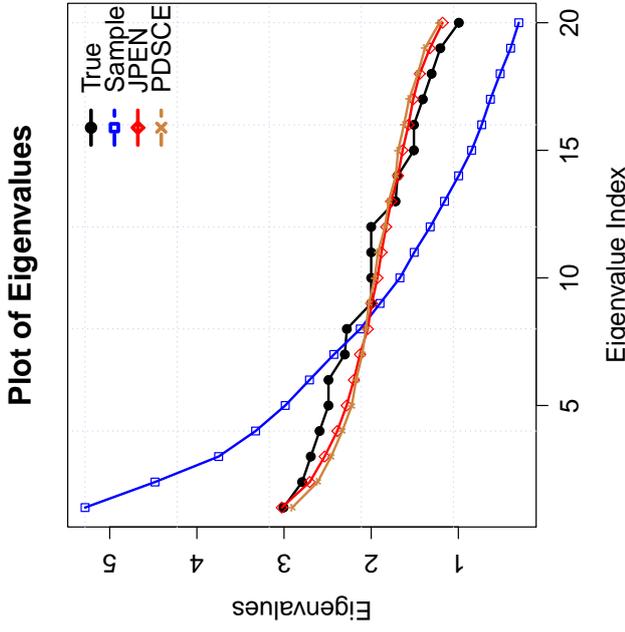

As argued earlier, to overcome the over-dispersion in eigen-spectrum of sample covariance matrix, we include eigenvalues variance penalty. To illustrate its advantage, consider $\lambda = 0$. After some algebra, let $\hat{\Sigma}$ be the minimizer of (2.1), then it is given by:

$$\hat{\Sigma} = (S + \gamma t I)/(1 + \gamma), \quad (2.3)$$

where I is the identity matrix, and $t = \sum_{i=1}^p S_{ii}/p$. After some algebra, conclude that for any $\gamma > 0$:

$$\begin{aligned} \sigma_{\min}(\hat{\Sigma}) &= \sigma_{\min}(S + \gamma t I)/(1 + \gamma) \\ &\geq \frac{\gamma t}{1 + \gamma} > 0 \end{aligned}$$

Figure 2.1: Comparison of Eigenvalues of Covariance Matrices

This means that the eigenvalues variance penalty improves S to a positive definite estimator $\hat{\Sigma}$. However the estimator (2.3) is well-conditioned but need not be sparse. Sparsity can be achieved by imposing ℓ_1 penalty on the entries of covariance matrix. Simulations have shown that, in general the minimizer of (2.1) is not positive definite for all values of $\lambda > 0$ and $\gamma > 0$. Here onwards we focus on correlation matrix estimation, and later generalize the method for covariance matrix estimation.

To achieve both well-conditioned and sparse positive definite estimator we optimize the following objective function in R over specific region of values of (λ, γ) which depends upon sample correlation matrix K and λ, γ . Here the condition $\text{tr}(\Sigma) = \text{tr}(S)$ reduces to $\text{tr}(R) = p$, and $t = 1$. Consider the following optimization problem:

$$\hat{R}_K = \underset{R = R^T, \text{tr}(R) = p(\lambda, \gamma) \in \delta_K^+}{\text{argmin}} \left[\|R - K\|_F^2 + \lambda \|R^{-1}\|_1 + \gamma \sum_{i=1}^p \{\sigma_i(R) - \sigma_i(S)\}^2 \right], \quad (2.4)$$

where

$$\hat{\Sigma}_K^K = \left\{ (\lambda, \gamma) : \lambda, \gamma > 0, \lambda \asymp \gamma \asymp \sqrt{\frac{\log p}{n}}, \forall \epsilon > 0, \sigma_{\min}\{K + \gamma I\} - \frac{\lambda}{2} * \text{sign}(K + \gamma I) > \epsilon \right\},$$

and $\bar{\sigma}_R$ is mean of the eigenvalues of R . For instance when K is diagonal matrix, the set $\hat{\Sigma}_K^K$ is given by:

$$\hat{\Sigma}_K^K = \left\{ (\lambda, \gamma) : \lambda, \gamma > 0, \lambda \asymp \gamma \asymp \sqrt{\frac{\log p}{n}}, \forall \epsilon > 0, \lambda < 2(\gamma - \epsilon) \right\}.$$

The minimization in (2.4) over R is for fixed $(\lambda, \gamma) \in \hat{\Sigma}_K^K$. The proposed estimator of covariance matrix (based on regularized correlation matrix estimator \hat{R}_K) is given by $\hat{\Sigma}_K = (S^+)^{1/2} \hat{R}_K (S^+)^{1/2}$, where S^+ is the diagonal matrix of the diagonal elements of S . Furthermore Lemmas 3.1 and 3.2, respectively show that the objective function (2.4) is convex and estimator given in (2.4) is positive definite.

2.2 Our Contribution

The main contributions are the following:

- i) The proposed estimators are both sparse and well-conditioned simultaneously. This approach allows to take advantage of a prior structure if known on the eigenvalues of the true covariance and the inverse covariance matrices.
- ii) We establish theoretical consistency of proposed estimators in both operator and Frobenius norm. The proposed JPEN estimators achieves the mini-max rate of convergence in operator norm for the underlying class of sparse and well-conditioned covariance and inverse covariance matrices and therefore is optimal.
- iii) The proposed algorithm is very fast, efficient and easily scalable to large scale optimization problems.

3. Analysis of JPEN Method

Def: A random vector X is said to have sub-Gaussian distribution if for each $t \geq 0$ and $y \in \mathbb{R}^p$ with $\|y\|_2 = 1$, there exist $0 < \tau < \infty$ such that

$$\mathbb{P}\{|y^T(X - \mathbb{E}(X))| > t\} \leq e^{-t^2/2\tau} \tag{3.1}$$

Although the JPEN estimators exists for any finite $2 \leq n < p < \infty$, for theoretical consistency in operator norm we require $s \log p = o(n)$ and for Frobenius norm we require $(p + s) \log p = o(n)$ where s is the upper bound on the number of non-zero off-diagonal entries in true covariance matrix. For more details, see the remark after Theorem 3.1.

3.1 Covariance Matrix Estimation

We make the following assumptions about the true covariance matrix Σ_0 .

A0. Let $X := (X_1, X_2, \dots, X_p)$ be a mean zero vector with covariance matrix Σ_0 such that each $X_i/\sqrt{\Sigma_{0ii}}$ has sub-Gaussian distribution with parameter τ as defined in (3.1).

A1. With $E = \{(i, j) : \Sigma_{0ij} \neq 0, i \neq j\}$, the $|E| \leq s$ for some positive integer s .

A2. There exists a finite positive real number $\bar{k} > 0$ such that $1/\bar{k} \leq \sigma_{\min}(\Sigma_0) \leq \sigma_{\max}(\Sigma_0) \leq k$.

Assumption A2 guarantees that the true covariance matrix Σ_0 is well-conditioned (i.e. all the eigenvalues are finite and positive). A well-conditioned means that [Ledoit and Wolf \(2004\)](#)) inverting the matrix does not explode the estimation error. Assumption A1 is more of a definition which says that the number of non-zero off diagonal elements are bounded by some positive integer. Theorem 3.1 gives the rate of convergence of the proposed correlation based covariance matrix estimator (2.4). The following Lemmas show that optimization problem in (2.4) is convex and the proposed JPEN estimator (2.4) is positive definite.

Lemma 1. The optimization problem in (2.4) is convex.

Lemma 2. The estimator given by (2.4) is positive definite for any $2 \leq n < \infty$ and $p < \infty$.

Theorem 3.1. Let $(\lambda, \gamma) \in \hat{\Sigma}_K^K$ and $\hat{\Sigma}_K$ be as defined in (2.4). Under Assumptions A0, A1, A2,

$$\|\hat{R}_K - R_0\|_F = O_P\left(\sqrt{\frac{s \log p}{n}}\right) \quad \text{and} \quad \|\hat{\Sigma}_K - \Sigma_0\| = O_P\left(\sqrt{\frac{(s+1)\log p}{n}}\right), \tag{3.2}$$

where R_0 is true correlation matrix.

Remark 1. The JPEN estimator $\hat{\Sigma}_K$ is mini-max optimal under the operator norm. In [Cai et al. \(2015\)](#), the authors obtain the mini-max rate of convergence in the operator norm of their covariance matrix estimator for the particular construction of parameter space $\mathcal{H}_0(c_{n,p}) := \left\{ \Sigma : \max_{1 \leq i \leq p} \sum_{j=1}^p I(\sigma_{ij} \neq 0) \leq c_{n,p} \right\}$. They show that this rate in operator norm is $c_{n,p} \sqrt{\log p/n}$ which is same as that of $\hat{\Sigma}_K$ for $1 \leq c_{n,p} = \sqrt{s}$.

2. Bickel and Levina (2008a) proved that under the assumption of $\sum_{j=1}^p |\sigma_{ij}|^q \leq c_0(p)$ for some $0 \leq q \leq 1$, the hard thresholding estimator of the sample covariance matrix for tuning parameter $\lambda \asymp \sqrt{(\log p)/n}$ is consistent in operator norm at a rate no worse than $O_P\left(c_0(p) \sqrt{p} (\frac{\log p}{n})^{(1-q)/2}\right)$ where $c_0(p)$ is the upper bound on the number of non-zero elements in each row. Here the truly sparse case corresponds to $q = 0$. The rate of convergence of $\hat{\Sigma}_K$ is same as that of [Bickel and Levina \(2008a\)](#) except in the following cases:

Case (i) The covariance matrix has all off diagonal elements zero except last row which has \sqrt{p} non-zero elements. Then $c_0(p) = \sqrt{p}$ and $\sqrt{s} = \sqrt{2} \sqrt{p} - 1$. The operator norm rate of convergence for JPEN estimator is $O_P\left(\sqrt{\sqrt{p}} (\log p)/n\right)$ where as rate of [Bickel and Levina's](#) estimator is $O_P\left(\sqrt{p} (\log p)/n\right)$.

Case (ii) When the true covariance matrix is tri-diagonal, we have $c_0(p) = 2$ and $s = 2p - 2$, the JPEN estimator has rate of $\sqrt{p} \log p/n$ whereas the [Bickel and Levina's](#) estimator has rate of $\sqrt{\log p/n}$.

For the case $\sqrt{s} \asymp c_0(p)$ and JPEN has the same rate of convergence as that of [Bickel and Levina's](#) estimator.

3. The operator norm rate of convergence is much faster than Frobenius norm. This is due to the fact that Frobenius norm convergence is in terms of all eigenvalues of the covariance matrix whereas the operator norm gives the convergence of the estimators in terms of the largest eigenvalue.

4. Our proposed estimator is applicable to estimate any non-negative definite covariance matrix.

Note that the estimator $\hat{\Sigma}_K$ is obtained by regularization of sample correlation matrix in (2.4). In some application it is desirable to directly regularize the sample covariance matrix. The JPEN estimator of the covariance matrix based on regularization of sample covariance matrix is obtained by solving the following optimization problem:

$$\hat{\Sigma}_S = \arg \min_{\Sigma = \Sigma^T, \text{tr}(\Sigma) = \text{tr}(S)(\lambda, \gamma) \in \hat{S}_S^K} \left[\|\Sigma - S\|_F^2 + \lambda \|\Sigma\|_1 + \gamma \sum_{i=1}^p \{\sigma_i(\Sigma) - \bar{\sigma}_S\}^2 \right], \quad (3.3)$$

where

$$\hat{S}_S^K = \left\{ (\lambda, \gamma) : \lambda, \gamma > 0, \lambda \asymp \gamma \asymp \sqrt{\frac{\log p}{n}}, \forall \epsilon > 0, \sigma_{\min} \left\{ (S + \gamma t I) - \frac{\lambda}{2} * \text{sign}(S + \gamma t I) \right\} > \epsilon \right\},$$

and S is sample covariance matrix. The minimization in (3.3) over Σ is for fixed $(\lambda, \gamma) \in \hat{S}_S^K$. The estimator $\hat{\Sigma}_S$ is positive definite and well-conditioned. Theorem 3.2 gives the rate of convergence of the estimator $\hat{\Sigma}_S$ in Frobenius norm.

Theorem 3.2. *Let $(\lambda, \gamma) \in \hat{S}_S^K$, and let $\hat{\Sigma}_S$ be as defined in (3.3). Under Assumptions A0, A1, A2,*

$$\|\hat{\Sigma}_S - \Sigma_0\|_F = O_P \left(\sqrt{\frac{(s+p)\log p}{n}} \right) \quad (3.4)$$

As noted in Rothman (2012) the worst part of convergence here comes from estimating the diagonal entries.

3.1.1 WEIGHTED JPEN ESTIMATOR FOR THE COVARIANCE MATRIX ESTIMATION

A modification of estimator \hat{R}_K is obtained by adding positive weights to the term $(\sigma_i(R) - \bar{\sigma}_R)^2$. This leads to weighted eigenvalues variance penalty with larger weights amounting to greater shrinkage towards the center and vice versa. Note that the choice of the weights allows one to use any prior structure of the eigenvalues (if known) in estimating the covariance matrix. The weighted JPEN correlation matrix estimator \hat{R}_A is given by :

$$\hat{R}_A = \arg \min_{R = R^T, \text{tr}(R) = \text{tr}(S)(\lambda, \gamma) \in \hat{S}_A^{K,A}} \left[\|R - K\|_F^2 + \lambda \|R\|_1 + \gamma \sum_{i=1}^p a_i \{\sigma_i(R) - \bar{\sigma}_R\}^2 \right], \quad (3.5)$$

where

$$\hat{S}_A^{K,A} = \left\{ (\lambda, \gamma) : \lambda \asymp \gamma \asymp \sqrt{\frac{\log p}{n}}, \lambda \leq \frac{(2 \sigma_{\min}(K)(1+\gamma \max(A_{ii})^{-1}) + \gamma \min(A_{ii}))}{(1+\gamma \min(A_{ii}))^{-p}}}, \right\},$$

and $A = \text{diag}(A_{11}, A_{22}, \dots, A_{pp})$ with $A_{ii} = a_i$. The proposed covariance matrix estimator is $\hat{\Sigma}_{K,A} = (S^+)^{1/2} \hat{R}_A (S^+)^{1/2}$. The optimization problem in (3.5) is convex and yields a positive definite estimator for each $(\lambda, \gamma) \in \hat{S}_A^{K,A}$. A simple exercise shows that the estimator $\hat{\Sigma}_{K,A}$ has same rate of convergence as that of $\hat{\Sigma}_S$.

3.2 Estimation of Inverse Covariance Matrix

We extend the JPEN approach to estimate a well-conditioned and sparse inverse covariance matrix. Similar to the covariance matrix estimation, we first propose an estimator for inverse covariance matrix based on regularized inverse correlation matrix and discuss its rate of convergence in Frobenius and operator norm.

Notation: We shall use Z and Ω for inverse correlation and inverse covariance matrix respectively.

Assumptions: We make the following assumptions about the true inverse covariance matrix Ω_0 . Let $\Sigma_0 = \Omega_0^{-1}$.

B0. Same as the assumption A0.

B1. With $H = \{(i, j) : \Omega_{0ij} \neq 0, i \neq j\}$, the $|H| \leq s$, for some positive integer s .

B2. There exist $0 < \bar{k} < \infty$ large enough such that $(1/\bar{k}) \leq \sigma_{\min}(\Omega_0) \leq \sigma_{\max}(\Omega_0) \leq \bar{k}$.

Let \hat{R}_K be a JPEN estimator for the true correlation matrix. By Lemma 3.2, \hat{R}_K is positive definite. Define the JPEN estimator of inverse correlation matrix as the solution to the following optimization problem,

$$\hat{Z}_K = \arg \min_{Z = Z^T, \text{tr}(Z) = \text{tr}(\hat{R}_K^{-1})(\lambda, \gamma) \in \hat{S}_Z^K} \left[\|Z - \hat{R}_K^{-1}\|^2 + \lambda \|Z\|_1 + \gamma \sum_{i=1}^p \{\sigma_i(Z) - \bar{\sigma}(Z)\}^2 \right] \quad (3.6)$$

where

$$\hat{S}_Z^K = \left\{ (\lambda, \gamma) : \lambda, \gamma > 0, \lambda \asymp \gamma \asymp \sqrt{\frac{\log p}{n}}, \forall \epsilon > 0, \right. \\ \left. \sigma_{\min} \left\{ (\hat{R}_K^{-1} + \gamma t_1 I) - \frac{\lambda}{2} * \text{sign}(\hat{R}_K^{-1} + \gamma t_1 I) \right\} > \epsilon \right\},$$

and t_1 is average of the diagonal elements of \hat{R}_K^{-1} . The minimization in (3.6) over Z is for fixed $(\lambda, \gamma) \in \hat{S}_Z^K$. The proposed JPEN estimator of inverse covariance matrix (based on regularized inverse correlation matrix estimator \hat{Z}_K) is given by $\hat{\Omega}_K = (S^+)^{-1/2} \hat{Z}_K (S^+)^{-1/2}$, where S^+ is a diagonal matrix of the diagonal elements of S . Moreover (3.6) is a convex optimization problem and \hat{Z}_K is positive definite.

Next we state the consistency of estimators \hat{Z}_K and $\hat{\Omega}_K$.

Theorem 3.3. *Under Assumptions B0, B1, B2 and for $(\lambda, \gamma) \in \hat{S}_Z^K$,*

$$\|\hat{Z}_K - R_0^{-1}\|_F = O_P \left(\sqrt{\frac{s \log p}{n}} \right) \quad \text{and} \quad \|\hat{\Omega}_K - \Omega_0\| = O_P \left(\sqrt{\frac{(s+1) \log p}{n}} \right) \quad (3.7)$$

where R_0^{-1} is the inverse of true correlation matrix.

Remark-1. Note that the JPEN estimator $\hat{\Omega}_K$ achieves mini-max rate of convergence for the class of covariance matrices satisfying assumption B_0 , B_1 , and B_2 and therefore optimal. The similar rate is obtained in [Cai et al. \(2015\)](#) for their class of sparse inverse covariance matrices.

Next we give another estimate of inverse covariance matrix based on $\hat{\Sigma}_S$. Consider the following optimization problem:

$$\hat{\Omega}_S = \underset{\Omega \in \Omega^T, \text{tr}(\Omega) = \text{tr}(\hat{\Sigma}_S^{-1}), (\lambda, \gamma) \in \hat{\mathcal{E}}_S^2}{\text{arg min}} \left[\|\Omega - \hat{\Sigma}_S^{-1}\|_F^2 + \lambda \|\Omega^{-1}\|_1 + \gamma \sum_{i=1}^p \{\sigma_i(\Omega) - \sigma_i(R)\}^2 \right], \quad (3.8)$$

where

$$\hat{\mathcal{E}}_S^2 = \left\{ (\lambda, \gamma) : \lambda, \gamma > 0, \lambda \asymp \gamma \asymp \sqrt{\frac{\log p}{n}}, \forall \epsilon > 0, \right. \\ \left. \sigma_{\min}\{(\hat{\Sigma}_S^{-1} + \gamma t_2 I) - \frac{\lambda}{2} * \text{sign}(\hat{\Sigma}_S^{-1} + \gamma t_2 I)\} > \epsilon \right\},$$

and t_2 is average of the diagonal elements of $\hat{\Sigma}_S$. The minimization in (3.8) over Ω is for fixed $(\lambda, \gamma) \in \hat{\mathcal{E}}_S^2$. The estimator in (3.8) is positive definite and well-conditioned. The consistency result of the estimator $\hat{\Omega}_S$ is given in following theorem.

Theorem 3.4. Let $(\lambda, \gamma) \in \hat{\mathcal{E}}_S^2$ and let $\hat{\Omega}_S$ be as defined in (3.8). Under Assumptions B_0 , B_1 , and B_2 ,

$$\|\hat{\Omega}_S - \Omega_0\|_F = O_P \left(\sqrt{\frac{(s+p)\log p}{n}} \right). \quad (3.9)$$

3.2.1 WEIGHTED JPEN ESTIMATOR FOR THE INVERSE COVARIANCE MATRIX

Similar to weighted JPEN covariance matrix estimator $\hat{\Sigma}_{K,A}$, a weighted JPEN estimator of the inverse covariance matrix is obtained by adding positive weights a_i to the term $(\sigma_i(Z) - 1)^2$ in (3.8). The weighted JPEN estimator is $\hat{\Omega}_{K,A} := (S^+)^{-1/2} \hat{Z}_A (S^+)^{-1/2}$, where

$$\hat{Z}_A = \underset{Z = Z^T, \text{tr}(Z) = \text{tr}(R_K^{-1}), (\lambda, \gamma) \in \hat{\mathcal{E}}_{K,A}^2}{\text{arg min}} \left[\|Z - \hat{R}_K^{-1}\|_F^2 + \lambda \|Z^{-1}\|_1 + \gamma \sum_{i=1}^p a_i \{\sigma_i(Z) - 1\}^2 \right], \quad (3.10)$$

with

$$\hat{\mathcal{E}}_{K,A}^2 = \left\{ (\lambda, \gamma) : \lambda \asymp \gamma \asymp \sqrt{\frac{\log p}{n}}, \lambda \leq \frac{(2 \sigma_{\min}(R_K^{-1}) (1 + \gamma \text{max}(A_{ii}))^{-1})}{(1 + \gamma \text{min}(A_{ii}))^{-\gamma}} + \frac{2 \text{min}(A_{ii})}{p} \right\},$$

and $A = \text{diag}(A_{11}, A_{22}, \dots, A_{pp})$ with $A_{ii} = a_i$. The optimization problem in (3.10) is convex and yields a positive definite estimator for $(\lambda, \gamma) \in \hat{\mathcal{E}}_{K,A}^2$. A simple exercise shows that the estimator \hat{Z}_A has similar rate of convergence as that of \hat{Z}_K .

4. An Algorithm

4.1 Covariance Matrix Estimation:

The optimization problem (2.4) can be written as:

$$\hat{R}_K = \underset{R = R^T, (\lambda, \gamma) \in \hat{\mathcal{E}}_K^2}{\text{arg min}} f(R), \quad (4.1)$$

where

$$f(R) = \|R - K\|_F^2 + \lambda \|R^{-1}\|_1 + \gamma \sum_{i=1}^p \{\sigma_i(R) - \sigma_i(R)\}^2.$$

Note that $\sum_{i=1}^p \{\sigma_i(R) - \sigma_i(R)\}^2 = \text{tr}(R^2) - 2 \text{tr}(R) + p$, where we have used the constraint $\text{tr}(R) = p$. Therefore,

$$f(R) = \|R - K\|_F^2 + \lambda \|R^{-1}\|_1 + \gamma \text{tr}(R^2) - 2 \gamma \text{tr}(R) + p \\ = \text{tr}(R^2(1 + \gamma)) - 2\text{tr}\{R(K + \gamma I)\} + \text{tr}(K^T K) + \lambda \|R^{-1}\|_1 + p \\ = (1 + \gamma) \{\text{tr}(R^2) - 2/(1 + \gamma) \text{tr}\{R(K + \gamma I)\} + (1/(1 + \gamma)) \text{tr}(K^T K)\} \\ + \lambda \|R^{-1}\|_1 + p \\ = (1 + \gamma) \{ \|R - (K + \gamma I)/(1 + \gamma) \|_F^2 + (1/(1 + \gamma)) \text{tr}(K^T K) \} \\ + \lambda \|R^{-1}\|_1 + p.$$

The solution of (4.1) is soft thresholding estimator and it is given by:

$$\hat{R}_K = \frac{1}{1 + \gamma} \text{sign}(K) * \text{pmax}\{\text{abs}(K + \gamma I) - \frac{\lambda}{2}, 0\} \quad (4.2)$$

with $(\hat{R}_K)_{ii} = (K_{ii} + \gamma)/(1 + \gamma)$; $\text{pmax}(A, b)_{ij} := \text{max}(A_{ij}, b)$ is elementwise max function for each entry of the matrix A . Note that for each $(\lambda, \gamma) \in \hat{\mathcal{E}}_K^2$, \hat{R}_K is positive definite.

Choice of λ and γ : For a given value of γ , we can find the value of λ satisfying:

$$\sigma_{\min}\{(K + \gamma I) - \frac{\lambda}{2} * \text{sign}(K + \gamma I)\} > 0 \quad (4.3)$$

which can be simplified to

$$\lambda < \frac{\sigma_{\min}(K + \gamma I)}{C_{12} \sigma_{\max}(\text{sign}(K))}.$$

For some $C_{12} \geq 0.5$. Such choice of $(\lambda, \gamma) \in \hat{\mathcal{E}}_K^2$, and the estimator \hat{R}_K is positive definite. Smaller values of C_{12} yield a solution which is more sparse but may not be positive definite.

Choice of weight matrix A : For optimization problem in (3.5), the weights are chosen in following way:

Let \mathcal{E} be the set of sorted diagonal elements of the sample covariance matrix S .

i) Let k be largest index of \mathcal{E} such that k^{th} elements of \mathcal{E} is less than 1. For $i \leq k$, $a_i = \mathcal{E}_i$. For $k < i \leq p$, $a_i = 1/\mathcal{E}_i$.

ii) $A = \text{diag}(a_1, a_2, \dots, a_p)$, where $a_i = a_j / \sum_{i=1}^p a_i$. Such choice of weights allows more shrinkage of extreme sample eigenvalues than the ones in center of eigen-spectrum.

4.2 Inverse Covariance Matrix Estimation:

To get an expression of inverse covariance matrix estimate, we replace K by \hat{R}_K^{-1} in (4.2), where \hat{R}_K is a JPEN estimator of correlation matrix. We chose $(\lambda, \gamma) \in \hat{S}_K^2$. For a given γ , we chose $\lambda > 0$ satisfying:

$$\sigma_{\min}\{(\hat{R}_K^{-1} + \gamma t_1 I) - \frac{\lambda}{2} * \text{sign}(\hat{R}_K^{-1} + \gamma t_1 I)\} > 0 \tag{4.4}$$

which can be simplified to

$$\lambda < \frac{\sigma_{\min}(\hat{R}_K^{-1} + \gamma t_1 I)}{C_{12} \sigma_{\max}(\text{sign}(\hat{R}_K^{-1}))}$$

4.3 Computational Complexity

The JPEN estimator $\hat{\Sigma}_K$ has computational complexity of $O(p^2)$ as there are at most $3p^2$ multiplications for computing the estimator $\hat{\Sigma}_K$. The other existing algorithm Glasso (Friedman et al. (2008)), PDSCE (Rothman (2012)) have computational complexity of $O(p^3)$. We compare the computational timing of our algorithm to some other existing algorithms Glasso (Friedman et al. (2008)), PDSCE (Rothman (2012)). The exact timing of these algorithm also depends upon the implementation, platform etc. (we did our computations in R on a AMD 2.8GHz processor). Following the approach Bickel and Levina (2008a), the optimal tuning parameter (λ, γ) was obtained by minimizing the 5-fold cross validation error

$$(1/5) \sum_{i=1}^5 \|\hat{\Sigma}_i^v - \Sigma_i^{-v}\|_1,$$

where $\hat{\Sigma}_i^v$ is JPEN estimate of the covariance matrix based on $v = 4n/5$ observations, Σ_i^{-v} is the sample covariance matrix using $(n/5)$ observations. Figure 4.1 illustrates the total computational time taken to estimate the covariance matrix by *Glasso*, *PDSCE* and *JPEN* algorithms for different values of p for Toeplitz type of covariance matrix on log-log scale (see section §5 for Toeplitz type of covariance matrix). Although the proposed method requires optimization over a grid of values of $(\lambda, \gamma) \in \hat{S}_K^2$, our algorithm is very fast and easily scalable to large scale data analysis problems.

5. Simulation Results

We compare the performance of the proposed method to other existing methods on simulated data for five types of covariance and inverse covariance matrices.

(i) **Hub Graph:** Here the rows/columns of Σ_0 are partitioned into J equally-sized disjoint groups: $\{V_1 \cup V_2 \cup \dots \cup V_J\} = \{1, 2, \dots, p\}$, each group is associated with a **pivotal** row k . Let size $|V_1| = s$. We set $\sigma_{0k,j} = \sigma_{0j,i} = \rho$ for $i \in V_k$ and $\sigma_{0k,i} = \sigma_{0j,i} = 0$ otherwise. In our experiment, $J = \lfloor p/s \rfloor$, $k = 1, s + 1, 2s + 1, \dots$, and we always take $\rho = 1/(s + 1)$ with $J = 20$.

(ii) **Neighborhood Graph:** We first uniformly sample (y_1, y_2, \dots, y_n) from a unit square. We then set $\sigma_{0k,j} = \sigma_{0j,i} = \rho$ with probability $(\sqrt{2\pi})^{-1} \exp(-4\|y_k - y_j\|^2)$. The remaining entries of Σ_0 are set to be zero. The number of nonzero off-diagonal elements of each row or column is restricted to be smaller than $\lfloor 1/\rho \rfloor$ where ρ is set to be 0.245.

(iii) **Toeplitz Matrix:** We set $\sigma_{0k,j} = 2$ for $i = j$; $\sigma_{0k,j} = \lfloor 0.75 \rfloor^{|i-j|}$ for $|i - j| = 1, 2$; and $\sigma_{0k,j} = 0$ otherwise.

(iv) **Block Diagonal Matrix:** In this setting Σ_0 is a block diagonal matrix with varying block size. For $p = 500$ number of blocks is 4 and for $p = 1000$ the number of blocks is 6. Each block of covariance matrix is taken to be Toeplitz type matrix as in case (iii).

(v) **Cov-I type Matrix:** In this setting, we first simulate a random sample (y_1, y_2, \dots, y_p) from standard normal distribution. Let $x_i = |y_i|^{3/2} * (1 + 1/p)^{1 + \log(1 + 1/p^2)}$. Next we generate multivariate normal random vectors $\tilde{z} = (z_1, z_2, \dots, z_{5p})$ with mean vector zero and identity covariance matrix. Let U be eigenvector corresponding to sample covariance matrix of \tilde{z} . We take $\Sigma_0 = UDU'$, where $D = \text{diag}(x_1, x_2, \dots, x_p)$. This is not a sparse setting but the covariance matrix has most of eigenvalues close to zero and hence allows us to compare the performance of various methods in a setting where most of eigenvalues are close to zero and widely spread as compared to structured covariance matrices in (i)-(iv).

We chose similar structure of Ω_0 for simulations. For all these choices of covariance and inverse covariance matrices, we generate random vectors from multivariate normal distribution with varying n and p . We chose $n = 50, 100$ and $p = 500, 1000$. We compare the performance of proposed covariance matrix estimator $\hat{\Sigma}_K$ to graphical lasso [Friedman et al. (2008)], PDSCE Estimate [Rothman (2012)], Bickel and Levina's thresholding estimator (BLThresh) [Bickel and Levina (2008a)] and Ledoit-Wolf [Ledoit and Wolf (2004)] estimate of covariance matrix. The JPEN estimate $\hat{\Sigma}_K$ was computed using R software (version 3.0.2). The graphical lasso estimate of the covariance matrix was computed using R package "glasso" (<http://statweb.stanford.edu/tibs/glasso/>). The Ledoit-Wolf estimate was obtained using code from (<http://econ.uzh.ch/faculty/wolf/publications.html#9>). The PDSCE estimate was obtained using PDSCE package (<http://cran.r-project.org/web/packages/PDSCE/index.html>). The Bickel and Levina's estimator was computed as per the algorithm given in their paper. For inverse covariance matrix performance comparison

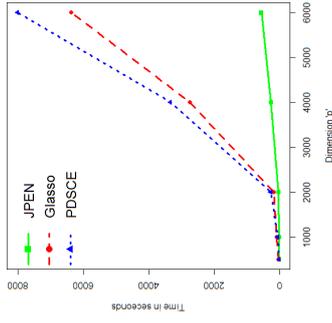

Figure 4.1: Timing comparison of JPEN, Glasso, and PDSCE.

error and their standard deviations (in percentage) for covariance and inverse covariance matrix estimates are given in Table 5.1 and Table 5.2, respectively. The numbers in the bracket are the standard errors of relative error based on the estimates using different methods. Among all the methods JPEN and PDSCe perform similar for most of choices of n and p for all five type of covariance matrices. This is due to the fact that both PDSCe and JPEN use quadratic optimization function with a different penalty function. The behavior of Bickel and Levina's estimator is quite good in Toepfliz case where it performs better than the other methods. For this type of covariance matrix, the entries away from the diagonal decay to zero and therefore soft-thresholding estimators like BLThresh perform better in this setting. However for neighborhood and hub type covariance matrix which are not necessarily banded type, Bickel and Levina estimator is not a natural choice as their estimator would fail to recover the underlying sparsity pattern. The performance of Ledoit-Wolf estimator is not very encouraging for Cov-I type matrix. The Ledoit-Wolf estimator shrinks the sample covariance matrix towards identity and hence the eigenvalues estimates are highly shrunk

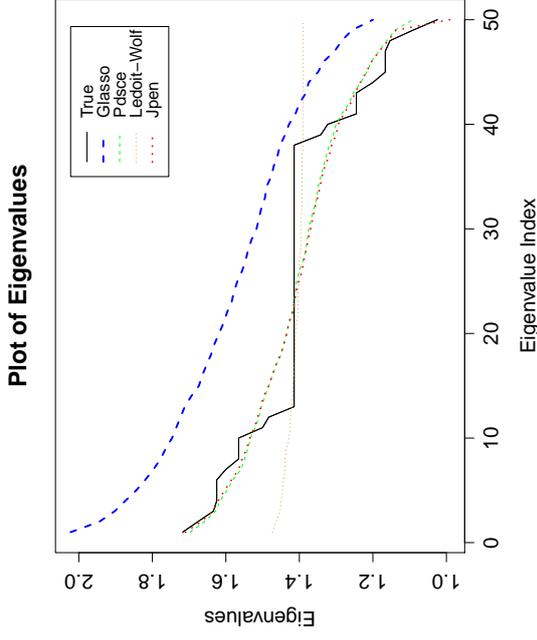

Figure 5.1: Heat-map of zeros identified in covariance matrix out of 50 realizations. White color is 50/50 zeros identified, black color is 0/50 zeros identified.

towards one. This is also visible in eigenvalues plot in Figure 5.2 and Figure 5.3. For Cov-I type covariance matrix where most of eigenvalues are close to zero and widely spread, the performance of JPEN estimator is impressive. The eigenplot in Figure 5.3 shows that among all the methods, estimates of eigenvalues of JPEN estimator are most consistent with true eigenvalues. This clearly shows the advantage of JPEN estimator of covariance matrix when the true eigenvalues are dispersed or close to zero. The eigenvalues plot in Figure 5.2 shows that when eigen-spectrum of true covariance matrix are not highly dispersed, the JPEN and PDSCE estimates of eigenvalues are almost the same. This phenomenon is also apparent in Figure 2.1. Also Ledoit-Wolf estimator heavily shrinks the eigenvalues towards the center and thus underestimates the true eigen-spectrum.

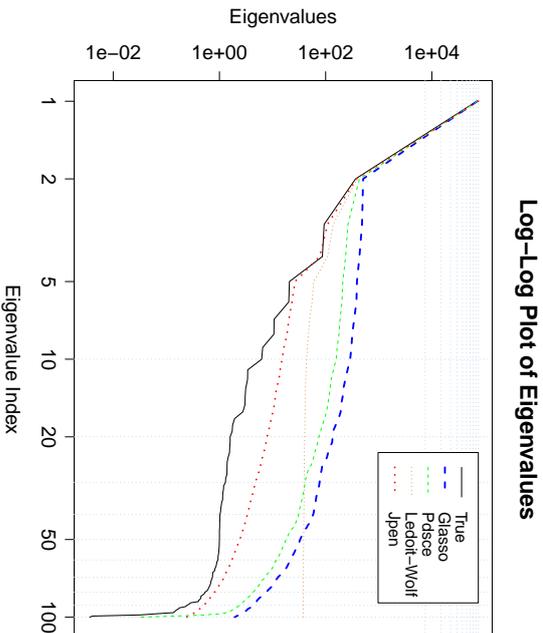

For inverse covariance matrix, we compare glasso, CLIME and PDSCE estimates with proposed JPEN estimator. The JPEN estimator $\hat{\Omega}_K$ outperforms other methods for the most of the choices of n and p for all five types of inverse covariance matrices. Additional simulations (not included here) show that for $n \approx p$, all the underlying methods perform similarly and the estimates of their eigenvalues are also well aligned with true values. However in high dimensional setting, for large p and small n , their performance is different as seen in simulations of Table 5.1 and Table 5.2. Figure 5.1 shows the recovery of non-zero and zero

Figure 5.2: Eigenvalues plot for $n = 100, p = 50$ based on 50 realizations for neighborhood type of covariance matrix

entries of true covariance matrix based on JPEN estimator $\hat{\Sigma}_K$ based on 50 realizations. The estimator recovers the true zeros for about 90% of times for Hub and Neighborhood type of covariance matrix. It also reflect the recovery of true structure of non-zero entries and actual pattern among the rows/columns of covariance matrix. To see the implication of eigenvalues shrinkage penalty as compared to other methods, we plot (Figure 5.2) the eigenvalues of estimated covariance matrix for $n = 100, p = 50$ for neighborhood type of covariance matrix. The JPEN estimates of eigen-spectrum are well aligned with true ones and closest being PDSCE estimates of eigenvalues. Figure 5.3 shows the recovery of eigenvalues based on estimates using different methods for Cov-I type covariance matrix. For this particular simulation, the eigenvalues are chosen differently than the one described in (v) of §5. The eigenvalues of true covariance matrix are taken to be very diverse with maximum about 10^6 and smallest eigenvalue about 10^{-6} . For Cov-I type of matrix, JPEN estimates of eigenvalues are better than other methods.

6. Colon Tumor Classification Example

In this section, we compare performance of JPEN estimator of inverse covariance matrix for tumors classification using Linear Discriminant Analysis (LDA). The gene expression data (Alon et al. (1999)) consists of 40 tumorous and 22 non-tumorous adenocarcinoma tissue. After preprocessing, data was reduced to a subset of 2,000 gene expression values with the largest minimal intensity over the 62 tissue samples (source: <http://genomics-prubz.princeton.edu/oncology/affydata/index.html>). In our analysis, we reduced the number of genes by selecting p most significant genes based on logistic regression. We obtain estimates of inverse covariance matrix for $p = 50, 100, 200$ and then use LDA to classify these tissues as either tumorous or non-tumorous (normal). We classify each test observation x to either class $k = 0$ or $k = 1$ using the LDA rule

$$\hat{\delta}_k(x) = \arg \max_k \left\{ x^T \hat{\Omega} \hat{\mu}_k - \frac{1}{2} \hat{\mu}_k^T \hat{\Omega} \hat{\mu}_k + \log(\hat{\pi}_k) \right\}, \tag{6.1}$$

where $\hat{\pi}_k$ is the proportion of class k observations in the training data, $\hat{\mu}_k$ is the sample mean for class k on the training data, and $\hat{\Omega} := \hat{\Sigma}^{-1}$ is an estimator of the inverse of the common covariance matrix on the training data computed. Tuning parameters λ and γ were

chosen using 5-fold cross validation. To create training and test sets, we randomly split the data into a training and test set of sizes 42 and 20 respectively; following the approach used by Wang et al. (2007), the training set has 27 tumor samples and 15 non-tumor samples. We repeat the split at random 100 times and measure the average classification error. Since

Table 6.1: Averages and standard errors of classification errors over 100 replications in %.

Method	p=50	p=100	p=200
	Logistic Regression	21.0(0.84)	19.31(0.89)
SVM	16.70(0.85)	16.76(0.97)	18.18(0.96)
Naive Bayes	13.3(0.75)	14.33(0.85)	14.63(0.75)
Graphical Lasso	10.9(1.3)	9.4(0.89)	9.8(0.90)
Joint Penalty	9.9(0.98)	8.9(0.93)	8.2(0.81)

we do not have separate validation set, we do the 5-fold cross validation on training data. At each split, we divide the training data into 5 subsets (fold) where 4 subsets are used to estimate the covariance matrix and one subset is used to measure the classifier's performance. For each split, this procedure is repeated 5 times by taking one of the 5 subsets as validation data. An optimal combination of λ and γ is obtained by minimizing the 5-fold cross validation error.

The average classification errors with standard errors over the 100 splits are presented in Table 6.1. Since the sample size is less than the number of genes, we omit the inverse sample covariance matrix as it is not well defined and instead include the naive Bayes' and support vector machine classifiers. Naive Bayes has been shown to perform better than the sample covariance matrix in high-dimensional settings (Bickel and Levina (2004)). Support Vector Machine (SVM) is another popular choice for high dimensional classification tool. Among all the methods covariance matrix based LDA classifiers perform far better than Naive Bayes, SVM and Logistic Regression. For all other classifiers the classification performance deteriorates for increasing p . For larger p , i.e., when more genes are added to the data set, the classification performance of JPEN estimate based LDA classifier initially improves but it deteriorates for large p . For $p = 2000$, the classifier based on inverse covariance matrix has accuracy of 30%. This is due to the fact that as dimension of covariance matrix increases, the estimator does not remain very informative.

7. Summary

We have proposed and analyzed regularized estimation of large covariance and inverse covariance matrix using joint penalty. The proposed JPEN estimators are optimal under spectral norm for underlying classes of sparse and well-conditioned covariance and inverse covariance matrices. We also establish its theoretical consistency in Frobenius norm. One of its biggest advantage is that the optimization carries no computational burden and and the resulting algorithm is very fast and easily scalable to large scale data analysis problems. The extensive simulation shows that the proposed estimators performs well for a number

of structured covariance and inverse covariance matrices. Also when the eigenvalues of underlying true covariance matrix are highly dispersed, it outperforms other methods (based on simulation analysis). The JPEN estimator recovers the sparsity pattern of the true covariance matrix and provides a good approximation of the underlying eigen-spectrum and hence we expect that PCA will be one of the most important application of the method. Although the proposed JPEN estimators of covariance and inverse covariance matrix do not require any assumption on the structure of true covariance and inverse covariance matrices respectively, any prior knowledge of structure of true covariance matrix might be helpful to choose a suitable weight matrix and hence improve estimation.

Acknowledgments

The author would like to express the deep gratitude to Professor Hira L. Koul for his valuable and constructive suggestions during the planning and development of this research work. The author would like to thank Dr. Adam Rothman for his valuable discussion and suggestion. The author would also like to thank the two anonymous referees and the action editor Dr. Jie Peng for insightful reviews that helped to improve the original manuscript substantially.

Appendix A.

Proof of Lemma 3.1

Let

$$f(R) = \|R - K\|^2 + \lambda \|R^{-1}\|_1 + \gamma \sum_{i=1}^p \{\sigma_i(R) - \sigma_{R_i}\}^2. \tag{.1}$$

where $\bar{\sigma}_R$ is the mean of eigenvalues of R . Due to the constraint $\text{tr}(R) = p$, we have $\bar{\sigma}_R = 1$. The third term of (.1) can be written as

$$\sum_{i=1}^p \{\sigma_i(R) - \sigma_{R_i}\}^2 = \text{tr}(R^2) - 2 \text{tr}(R) + p$$

We obtain,

$$\begin{aligned} f(R) &= \text{tr}(R^2) - 2 \text{tr}(RK) + \text{tr}(K^2) + \lambda \|R^{-1}\|_1 + \gamma \{\text{tr}(R^2) - 2 \text{tr}(R) + p\} \\ &= \text{tr}(R^2(1 + \gamma)) - 2 \text{tr}(K + \gamma I) + \text{tr}(K^2) + \lambda \|R^{-1}\|_1 + p \\ &= (1 + \gamma) \|R - (K + \gamma I)/(1 + \gamma)\|^2 + \text{tr}(K^2) + \lambda \|R^{-1}\|_1 + p \end{aligned} \tag{.2}$$

This is quadratic in R with a l_1 penalty to the off-diagonal entries of R , therefore a convex function in R .

Proof of Lemma 3.2 The solution to (.2) satisfies:

$$2(R - (K + \gamma I))(1 + \gamma)^{-1} + \lambda \frac{\partial \|R^{-1}\|_1}{\partial R} = 0 \tag{.3}$$

where $\frac{\partial \|R^{-1}\|_1}{\partial R}$ is given by:

$$\frac{\partial \|R^{-1}\|_1}{\partial R} = \begin{cases} 1 & : \text{if } R_{ij} > 0 \\ -1 & : \text{if } R_{ij} < 0 \\ \tau \in (-1, 1) & : \text{if } R_{ij} = 0 \end{cases}$$

Note that $\|R^{-1}\|_1$ has same value irrespective of sign of R , therefore the right hand side of (.2) is minimum if :

$$\text{sign}(R) = \text{sign}(K + \gamma I) = \text{sign}(K)$$

$\forall \epsilon > 0$, using (.3), $\sigma_{\min}\{K + \gamma I - \frac{\lambda}{2} \text{sign}(K)\} > \epsilon$ gives a $(\lambda, \gamma) \in \hat{S}_\epsilon^K$ and such a choice of (λ, γ) guarantees the estimator to be positive definite.

Remark: Intuitively, a larger γ shrinks the eigenvalues towards center which is 1, a larger γ would result in positive definite estimator, whereas a larger λ results in sparse estimate. A combination of (λ, γ) results in a sparse and well-conditioned estimator. In particular case, when K is diagonal matrix: the $\lambda < 2 * \gamma$.

Proof of Theorem 3.1 Define the function $Q(\cdot)$ as following:

$$Q(R) = f(R) - f(R_0)$$

where R_0 is the true correlation matrix and R is any other correlation matrix. Let $R = UDU^T$ be eigenvalue decomposition of R , D is diagonal matrix of eigenvalues and U is matrix of eigenvectors. We have,

$$Q(R) = \|R - K\|_F^2 + \lambda \|R^-\|_1 + \gamma \operatorname{tr}(D^2 - 2D + p) - \|R_0 - K\|_F^2 - \lambda \|R_0^-\|_1 - \gamma \operatorname{tr}(D_0^2 - 2D_0 + p) \quad (4)$$

$R_0 = U_0 D_0 U_0^T$ is eigenvalue decomposition of R_0 . Let $\Theta_n(M) := \{\Delta : \Delta = \Delta^T, \|\Delta\|_2 = M/n, 0 < M < \infty\}$. The estimate \hat{R} minimizes the $Q(R)$ or equivalently $\hat{\Delta} = \hat{R} - R_0$ minimizes the $G(\Delta) = Q(R_0 + \Delta)$. Note that $G(\Delta)$ is convex and if $\hat{\Delta}$ be its solution, then we have $G(\hat{\Delta}) \leq G(0) = 0$. Therefore if we can show that $G(\Delta)$ is non-negative for $\Delta \in \Theta_n(M)$, this will imply that the $\hat{\Delta}$ lies within sphere of radius M/n . We require $r_n = o\left(\sqrt{(p+s) \log p/n}\right)$.

$$\begin{aligned} \|R - K\|_F^2 - \|R_0 - K\|_F^2 &= \operatorname{tr}(R^T R - 2R^T K + K^T K) - \operatorname{tr}(R_0^T R_0 - 2R_0^T K + K^T K) \\ &= \operatorname{tr}(R^T R - R_0^T R_0) - 2 \operatorname{tr}((R - R_0)^T K) \\ &= \operatorname{tr}((R_0 + \Delta)^T (R_0 + \Delta) - R_0^T R_0) - 2 \operatorname{tr}(\Delta^T K) \\ &= \operatorname{tr}(\Delta^T \Delta) - 2 \operatorname{tr}(\Delta^T (K - R_0)) \end{aligned}$$

Next, we bound term involving K in above expression, we have

$$\begin{aligned} |\operatorname{tr}(\Delta^T (R_0 - K))| &\leq \sum_{i \neq j} |\Delta_{ij} (R_{0ij} - K_{ij})| \\ &\leq \max_{i \neq j} (|R_{0ij} - K_{ij}|) \|\Delta^-\|_1 \\ &\leq C_0 (1 + \tau) \sqrt{\frac{\log p}{n}} \|\Delta^-\|_1 \end{aligned}$$

holds with high probability by a result (Lemma 1) from Ravikumar et al. (2011) on the tail inequality for sample covariance matrix of sub-Gaussian random vectors and where $C_1 = C_0(1 + \tau)$, $C_0 > 0$. Next we obtain upper bound on the terms involving γ in (4). we have,

$$\begin{aligned} &\operatorname{tr}(D^2 - 2D) - \operatorname{tr}(D_0^2 - 2D_0) \\ &= \operatorname{tr}\{R^2 - R_0^2\} - 2 \operatorname{tr}\{R - R_0\} = \operatorname{tr}(R_0 + \Delta)^2 - \operatorname{tr}(R_0^2) \\ &= 2 \operatorname{tr}(R_0 \Delta) + \operatorname{tr}(\Delta^T \Delta) \leq 2 \sqrt{s} \|\Delta\|_F + \|\Delta\|_F^2. \end{aligned}$$

using Cauchy-Schwarz inequality. To bound the term $\lambda(\|R^-\|_1 - \|R_0^-\|_1) = \lambda(\|\Delta^-\|_1 - \|R_0^-\|_1)$, let E be index set as defined in Assumption A.2 of Theorem 3.2. Then using the triangle inequality, we obtain,

$$\begin{aligned} \lambda(\|\Delta^-\|_1 - \|R_0^-\|_1) &= \lambda(\|\Delta_E^-\|_1 + \|\Delta_{E^c}^-\|_1 - \|R_0^-\|_1) \\ &\geq \lambda(\|R_0^-\|_1 - \|\Delta_{E^c}^-\|_1 + \|\Delta_E^-\|_1 - \|R_0^-\|_1) \\ &\geq \lambda(\|\Delta_E^-\|_1 - \|\Delta_{E^c}^-\|_1) \end{aligned}$$

Let $\lambda = (C_1/\epsilon) \sqrt{\log p/n}$, $\gamma = (C_1/\epsilon_1) \sqrt{\log p/n}$, where $(\lambda, \gamma) \in \hat{S}_K^K$, we obtain,

$$\begin{aligned} G(\Delta) &\geq \operatorname{tr}(\Delta^T \Delta) (1 + \gamma) - 2C_1 \left\{ \sqrt{\frac{\log p}{n}} (\|\Delta^-\|_1) + \frac{1}{\epsilon_1} \sqrt{\frac{s \log p}{n}} \|\Delta\|_F \right\} \\ &\quad + \frac{C_1}{\epsilon} \sqrt{\frac{\log p}{n}} (\|\Delta_E^-\|_1 - \|\Delta_{E^c}^-\|_1) \\ &\geq \|\Delta\|_F^2 (1 + \gamma) - 2C_1 \sqrt{\frac{\log p}{n}} (\|\Delta_E^-\|_1 + \|\Delta_{E^c}^-\|_1) \\ &\quad - \frac{C_1}{\epsilon} \sqrt{\frac{\log p}{n}} (\|\Delta_E^-\|_1 - \|\Delta_{E^c}^-\|_1) - \frac{2C_1}{\epsilon_1} \sqrt{\frac{s \log p}{n}} \|\Delta\|_F. \end{aligned}$$

Also because $\|\Delta_E^-\|_1 = \sum_{(i,j) \in E, i \neq j} \Delta_{ij} \leq \sqrt{s} \|\Delta^-\|_F$,

$$-2C_1 \sqrt{\frac{\log p}{n}} \|\Delta_E^-\|_1 + \frac{C_1}{\epsilon} \sqrt{\frac{\log p}{n}} \|\Delta_{E^c}^-\|_1 \geq \sqrt{\frac{\log p}{n}} \|\Delta_{E^c}^-\|_1 (-2C_1 + \frac{C_1}{\epsilon}) \geq 0$$

for sufficiently small ϵ . Therefore,

$$\begin{aligned} G(\Delta) &\geq \|\Delta\|_F^2 (1 + \frac{C_1}{\epsilon_1} \sqrt{\frac{\log p}{n}}) - C_1 \sqrt{\frac{s \log p}{n}} \|\Delta^+\|_F \{1 + 1/\epsilon + 2/\epsilon_1\} \\ &\geq \|\Delta\|_F^2 \left[1 + \frac{C_1}{\epsilon_1} \sqrt{\frac{\log p}{n}} - \frac{C_1}{M} \{1 + 1/\epsilon + 2/\epsilon_1\} \right] \\ &\geq 0, \end{aligned}$$

for all sufficiently large n and M . Which proves the first part of theorem. To prove the operator norm consistency, we have,

$$\begin{aligned} \|\hat{\Sigma}_K - \Sigma_0\| &= \|\hat{W} \hat{R} \hat{W} - W K W\| \\ &\leq \|\hat{W} - W\| \|\hat{R} - K\| \|\hat{W} - W\| \\ &\quad + \|\hat{W} - W\| (\|\hat{R}\| \|W\| + \|\hat{W}\| \|K\|) + \|\hat{R} - K\| \|\hat{W}\| \|W\|. \end{aligned}$$

using sub-multiplicative norm property $\|AB\| \leq \|A\| \|B\|$. Since $\|K\| = O(1)$ and $\|\hat{R} - K\|_F = O(\sqrt{\frac{s \log p}{n}})$ these together implies that $\|\hat{R}\| = O(1)$. Also,

$$\begin{aligned} \|\hat{W} - W\| &= \max_{1 \leq i \leq p} \sum_{i=1}^p (|\hat{w}_i^2 - w_i^2|) x_i^2 \leq \max_{1 \leq i \leq p} (|\hat{w}_i^2 - w_i^2|) \sum_{i=1}^p x_i^2 \\ &= \max_{1 \leq i \leq p} (|\hat{w}_i^2 - w_i^2|) = O\left(\sqrt{\frac{\log p}{n}}\right). \end{aligned}$$

holds with high probability by using a result (Lemma 1) from Ravikumar et al. (2011). Next we shall show that $\|\hat{W} - W\| \asymp \|\hat{W}^2 - W^2\|$, (where $A \succ B$ means $A = O_P(B)$ and

$B=O_p(A)$). We have,

$$\begin{aligned} \|\hat{W} - W\| &= \max_{\|x\|_2=1} \sum_{i=1}^p |(\hat{w}_i - w_i)x_i^2| = \max_{\|x\|_2=1} \sum_{i=1}^p \left(\frac{\hat{w}_i^2 - w_i^2}{\hat{w}_i + w_i} \right) |x_i^2| \\ &\asymp \sum_{i=1}^p |(\hat{w}_i^2 - w_i^2)| x_i^2 = C_3 \|\hat{W}^2 - W^2\|. \end{aligned}$$

where we have used the fact that the true standard deviations are well above zero, i.e., $\exists 0 < C_3 < \infty$ such that $1/C_3 \leq w_i^{-1} \leq C_3 \forall i = 1, 2, \dots, p$, and sample standard deviation are all positive, i.e, $\hat{w}_i > 0 \forall i = 1, 2, \dots, p$. Now since $\|\hat{W}^2 - W^2\| \asymp \|\hat{W} - W\|$, this follows that $\|\hat{W}\| = O(1)$ and we have $\|\sum_{i=1}^p \sigma_i(\Sigma) - \sigma_\Sigma\|^2 = O\left(\frac{s \log p}{n} + \frac{\log p}{n}\right)$. This completes the proof.

Proof of Theorem 3.2 Let

$$f(\Sigma) = \|\Sigma - S\|_F^2 + \lambda \|\Sigma^-\|_1 + \gamma \sum_{i=1}^p \{\sigma_i(\Sigma) - \sigma_\Sigma\}^2,$$

Similar to the proof of theorem (3.1), define the function $Q_1(\cdot)$ as following:

$$Q_1(\Sigma) = f(\Sigma) - f(\Sigma_0)$$

where Σ_0 is the true covariance matrix and Σ is any other covariance matrix. Let $\Sigma = UDU^T$ be eigenvalue decomposition of Σ , D is diagonal matrix of eigenvalues and U is matrix of eigenvectors. We have,

$$\begin{aligned} Q_1(\Sigma) &= \|\Sigma - S\|_F^2 + \lambda \|\Sigma^-\|_1 + \gamma \operatorname{tr}(D^2) - (\operatorname{tr}(D))^2/p \\ &\quad - \|\Sigma_0 - S\|_F^2 - \lambda \|\Sigma_0^-\|_1 - \gamma \operatorname{tr}(D_0^2) - (\operatorname{tr}(D_0))^2/p \end{aligned} \tag{.5}$$

where $A = \operatorname{diag}(a_1, a_2, \dots, a_p)$ and $\Sigma_0 = U_0 D_0 U_0^T$ is eigenvalue decomposition of Σ_0 . Write $\Delta = \Sigma - \Sigma_0$, and let $\Theta_n(M) := \{\Delta : \Delta = \Delta^T, \|\Delta\|_2 = M r_n, 0 < M < \infty\}$. The estimate $\hat{\Sigma}$ minimizes the $Q(\Sigma)$ or equivalently $\hat{\Delta} = \hat{\Sigma} - \Sigma_0$ minimizes the $G(\Delta) = Q(\Sigma_0 + \Delta)$. Note that $G(\Delta)$ is convex and if $\hat{\Delta}$ be its solution, then we have $G(\Delta) \leq G(0) = 0$. Therefore if we can show that $G(\Delta)$ is non-negative for $\Delta \in \Theta_n(M)$, this will imply that the $\hat{\Delta}$ lies within sphere of radius $M r_n$. We require $\sqrt{(p+s) \log p} = o(\sqrt{r_n})$.

$$\begin{aligned} \|\Sigma - S\|_F^2 - \|\Sigma_0 - S\|_F^2 &= \operatorname{tr}(\Sigma^T \Sigma - 2\Sigma^T S + S^T S) - \operatorname{tr}(\Sigma_0^T \Sigma_0 - 2\Sigma_0^T S + S^T S) \\ &= \operatorname{tr}(\Sigma^T \Sigma - \Sigma_0^T \Sigma_0) - 2 \operatorname{tr}(\Sigma - \Sigma_0) S \\ &= \operatorname{tr}((\Sigma_0 + \Delta)^T (\Sigma_0 + \Delta) - \Sigma_0^T \Sigma_0) - 2 \operatorname{tr}(\Delta^T S) \\ &= \operatorname{tr}(\Delta^T \Delta) - 2 \operatorname{tr}(\Delta^T (S - \Sigma_0)) \end{aligned}$$

Next, we bound term involving S in above expression, we have

$$\begin{aligned} |\operatorname{tr}(\Delta(\Sigma_0 - S))| &\leq \sum_{i \neq j} |\Delta_{ij}(\Sigma_{0ij} - S_{ij})| + \sum_{i=1}^p |\Delta_{ii}(\Sigma_{0ii} - S_{ii})| \\ &\leq \max_{i \neq j} (|\Sigma_{0ij} - S_{ij}|) \|\Delta^-\|_1 + \sqrt{p} \max_{i=1}^p (|\Sigma_{0ii} - S_{ii}|) \sqrt{\sum_{i=1}^p \Delta_{ii}^2} \\ &\leq C_0(1 + \tau) \max(\Sigma_{0ii}) \left\{ \sqrt{\frac{\log p}{n}} \|\Delta^-\|_1 + \sqrt{\frac{p \log p}{n}} \|\Delta^+\|_2 \right\} \\ &\leq C_1 \left\{ \sqrt{\frac{\log p}{n}} \|\Delta^-\|_1 + \sqrt{\frac{p \log p}{n}} \|\Delta^+\|_2 \right\} \end{aligned}$$

holds with high probability by a result (Lemma 1) from Ravikumar et al. (2011) where $C_1 = C_0(1 + \tau) \max(\Sigma_{0ii})$, $C_0 > 0$ and Δ^+ is matrix Δ with all off-diagonal elements set to zero. Next we obtain upper bound on the terms involving γ in (3.7). we have,

$$\begin{aligned} \text{(i)} \quad &\operatorname{tr}(D^2) - (\operatorname{tr}(D))^2/p - \operatorname{tr}(D_0^2) - (\operatorname{tr}(D_0))^2/p \\ &= \operatorname{tr}(\Sigma^2) - \operatorname{tr}(\Sigma_0^2) - (\operatorname{tr}(\Sigma))^2/p + (\operatorname{tr}(\Sigma_0))^2/p \\ &\leq \operatorname{tr}(\Sigma_0 + \Delta)^2 - \operatorname{tr}(\Sigma_0)^2 \\ &= \operatorname{tr}(\Delta)^2 + 2 \operatorname{tr}(\Delta^2 \Sigma_0) \leq \operatorname{tr}(\Delta)^2 + C_1 \sqrt{s} \|\Delta\|_F \end{aligned}$$

$$\begin{aligned} \text{(ii)} \quad &\operatorname{tr}(\Sigma^2) - (\operatorname{tr}(\Sigma_0))^2 \\ &= (\operatorname{tr}(\Sigma_0 + \Delta))^2 - (\operatorname{tr}(\Sigma_0))^2 \\ &\leq (\operatorname{tr}(\Delta))^2 + 2 \operatorname{tr}(\Sigma_0) \operatorname{tr}(\Delta) \leq p \|\Delta\|_F^2 + 2 \bar{k} p \sqrt{p} \|\Delta^+\|_F. \end{aligned}$$

Therefore the γ term can be bounded by $2\|\Delta\|_F^2 + (C_1 \sqrt{s} + 2\sqrt{p} \bar{k}) \|\Delta\|_F$. We bound the term involving λ as in similar to the proof of Theorem 3.1. For $\lambda > \gamma \asymp \sqrt{\frac{\log p}{n}}$, the proof follows very similar to Theorem 3.1.

Proof of Theorem 3.3. To bound the cross product term involving Δ and \hat{R}_K^{-1} , we have,

$$\begin{aligned} |\operatorname{tr}((R_0^{-1} - \hat{R}_K^{-1})\Delta)| &= |\operatorname{tr}(R_0^{-1}(\hat{R}_K - R_0)\hat{R}_K^{-1}\Delta)| \\ &\leq \sigma_1(R_0^{-1}) |\operatorname{tr}((\hat{R}_K - R_0)\hat{R}_K^{-1}\Delta)| \\ &\leq \bar{k} \sigma_1(\hat{R}_K^{-1}) |\operatorname{tr}((\hat{R}_K - R_0)\Delta)| \\ &\leq \bar{k} \bar{k}_1 |\operatorname{tr}((\hat{R}_K - R_0)\Delta)|. \end{aligned}$$

where $\sigma_{\min}(\hat{R}_K) \geq (1/\bar{k}_1) > 0$, is a positive lower bound on the eigenvalues of JPEN estimate \hat{R}_K of correlation matrix R_0 . Such a constant exist by Lemma 3.2. Rest of the proof closely follows as that of Theorem 3.1.

Proof of Theorem 3.4. We bound the term $\operatorname{tr}((\hat{\Omega}_S - \Omega_0)\Delta)$ similar to that in proof of Theorem 3.3. Rest of the proof closely follows to that Theorem 3.2.

String and Membrane Gaussian Processes

nonstationary covariance functions, the development of which is still an active subject of research. Secondly, inference under GP priors often consists of looking at the values of the GP at all input points as a jointly Gaussian vector with fully dependent coordinates, which induces a memory requirement and time complexity respectively squared and cubic in the training data size, and thus is intractable for large data sets. We refer to this approach as the *standard GP paradigm*. The framework we introduce in this paper addresses both of the above limitations.

Our work is rooted in the observation that, from a Bayesian nonparametric perspective, it is inefficient to define a stochastic process through *fully-dependent* marginals, as it is the case for Gaussian processes. Indeed, if a stochastic process $(f(x))_{x \in \mathbb{R}^d}$ has fully dependent marginals and exhibits no additional conditional independence structure then, when f is used as functional prior and some observations related to $(f(x_1), \dots, f(x_n))$ are gathered, namely (y_1, \dots, y_n) , the *additional* memory required to take into account an additional piece of information (y_{n+1}, x_{n+1}) grows in $\mathcal{O}(n)$, as one has to keep track of the extent to which y_{n+1} informs us about $f(x_i)$ for every $i \leq n$, typically through a covariance matrix whose size will increase by $2n + 1$ terms. Clearly, this is inefficient, as y_{n+1} is unlikely to be informative about $f(x_i)$, unless x_i is sufficiently close to x_{n+1} . More generally, the larger n , the less information a single additional pair (y_{n+1}, x_{n+1}) will add to existing data, and yet the increase in memory requirement will be much higher than that required while processing earlier and more informative data. This inefficiency in resource requirements extends to computational time, as the *increase* in computational time resulting from adding (y_{n+1}, x_{n+1}) typically grows in $\mathcal{O}(n^2)$, which is the difference between the numbers of operations required to invert a $n \times n$ matrix and to invert a $(n+1) \times (n+1)$ matrix. A solution for addressing this inefficiency is to appropriately limit the extent to which values $f(x_1), \dots, f(x_n)$ are related to each other. Existing approaches such as sparse Gaussian processes (see [Quinero-Candela and Rasmussen \(2005\)](#) for a review), resort to an *ex-post* approximation of fully-dependent Gaussian marginals with multivariate Gaussians exhibiting conditional independence structures. Unfortunately, these approximations trade-off accuracy for scalability through a control variable, namely the number of inducing points, whose choice is often left to the user. The approach we adopt in this paper consists of going back to stochastic analysis basics, and constructing stochastic processes whose finite-dimensional marginals exhibit suitable conditional independence structures so that we need not resorting to *ex-post* approximations. Incidentally, unlike sparse GP techniques, the conditional independence structures we introduce also allow for flexible and principled learning of local patterns, and this increased flexibility does not come at the expense of scalability.

The contributions of this paper are as follows. We introduce a novel class of stochastic processes, string Gaussian processes (*string GPs*), that may be used as priors over latent functions within a Bayesian nonparametric framework, especially for large scale problems and in the presence of possibly multiple types of local patterns. We propose a framework for analysing the flexibility of random functions and surfaces, and prove that our approach yields more flexible stochastic processes than isotropic Gaussian processes. We demonstrate that exact inference under a *string GP* prior scales considerably better than in the *standard GP paradigm*, and is amenable to distributed computing. We illustrate that popular stationary kernels can be well approximated within our framework, making *string GPs* a scalable alternative to commonly used GP models. We derive the joint law of a *string GP* and its gradient, thereby allowing for explanatory analysis on the learned latent function. We propose a reversible-jump Markov Chain Monte Carlo sampler for automatic learning of model complexity and local patterns from data.

Abstract

In this paper we introduce a novel framework for making exact nonparametric Bayesian inference on latent functions that is particularly suitable for *Big Data* tasks. Firstly, we introduce a class of stochastic processes we refer to as *string Gaussian processes (string GPs)* which are not to be mistaken for Gaussian processes operating on text). We construct *string GPs* so that their finite-dimensional marginals exhibit suitable *local* conditional independence structures, which allow for *scalable, distributed, and flexible* nonparametric Bayesian inference, without resorting to approximations, and while ensuring some mild global regularity constraints. Furthermore, *string GP* priors naturally cope with heterogeneous input data, and the gradient of the learned latent function is readily available for explanatory analysis. Secondly, we provide some theoretical results relating our approach to the *standard GP paradigm*. In particular, we prove that some *string GPs* are Gaussian processes, which provides a complementary *global* perspective on our framework. Finally, we derive a scalable and distributed MCMC scheme for supervised learning tasks under *string GP* priors. The proposed MCMC scheme has computational time complexity $\mathcal{O}(N)$ and memory requirement $\mathcal{O}(dN)$, where N is the data size and d the dimension of the input space. We illustrate the efficacy of the proposed approach on several synthetic and real-world data sets, including a data set with 6 millions input points and 8 attributes.

Keywords: String Gaussian processes, scalable Bayesian nonparametrics, Gaussian processes, nonstationary kernels, reversible-jump MCMC, point process priors

1. Introduction

Many problems in statistics and machine learning involve inferring a latent function from training data (for instance regression, classification, inverse reinforcement learning, inference on point processes to name but a few). Real-valued stochastic processes, among which Gaussian processes (GPs), are often used as functional priors for such problems, thereby allowing for a full Bayesian nonparametric treatment. In the machine learning community, interest in GPs grew out of the observation that some Bayesian neural networks converge to GPs as the number of hidden units approaches infinity ([Neal \(1996\)](#)). Since then, other similarities have been established between GPs and popular models such as Bayesian linear regression, Bayesian basis function regression, spline models and support vector machines ([Rasmussen and Williams \(2006\)](#)). However, they often perform poorly on *Big Data* tasks primarily for two reasons. Firstly, large data sets are likely to exhibit multiple types of local patterns that should appropriately be accounted for by flexible and possibly

The rest of the paper is structured as follows. In Section 2 we review recent advances on Gaussian processes in relation to inference on large data sets. In Section 3 we formally construct *string* GPs and derive some important results. In Section 4 we provide detailed illustrative and theoretical comparisons between *string* GPs and the *standard GP paradigm*. In Section 5 we propose methods for inferring latent functions under *string* GP priors with time complexity and memory requirement that are linear in the size of the data set. The efficacy of our approach compared to competing alternatives is illustrated in Section 6. Finally, we finish with a discussion in Section 7.

2. Related Work

The two primary drawbacks of the *standard GP paradigm* on large scale problems are the lack of scalability resulting from postulating a full multivariate Gaussian prior on function values at *all* training inputs, and the difficulty postulating *a priori* a class of covariance functions capable of capturing intricate and often local patterns likely to occur in large data sets. A tremendous amount of work has been published that attempt to address either of the aforementioned limitations. However, scalability is often achieved either through approximations or for specific applications, and nonstationarity is usually introduced at the expense of scalability, again for specific applications.

2.1 Scalability Through Structured Approximations

As far as scalability is concerned, sparse GP methods have been developed that approximate the multivariate Gaussian probability density function (pdf) over training data with the marginal over a smaller set of inducing points multiplied by an approximate conditional pdf (Smola and Bartlett (2001); Lawrence et al. (2003); Seeger (2003b,a); Snelson and Ghahramani (2006)). This approximation yields a time complexity linear—rather than cubic—in the data size and squared in the number of inducing points. We refer to Quinero-Candela and Rasmussen (2005) for a review of sparse GP approximations. More recently, Hensman et al. (2013, 2015) combined sparse GP methods with Stochastic Variational Inference (Hoffman et al. (2013)) for GP regression and GP classification. However, none of these sparse GP methods addresses the selection of the number of inducing points (and the size of the minibatch in the case of Hensman et al. (2013, 2015)), although this may greatly affect scalability. More importantly, although these methods do not impose strong restrictions on the covariance function of the GP model to approximate, they do not address the need for flexible covariance functions inherent to large scale problems, which are more likely to exhibit intricate and local patterns, and applications considered by the authors typically use the vanilla squared exponential kernel.

Lazaro-Gredilla et al. (2010) proposed approximating stationary kernels with truncated Fourier series in Gaussian process regression. An interpretation of the resulting sparse spectrum Gaussian process model as Bayesian basis function regression with a finite number K of trigonometric basis functions allows making inference in time complexity and memory requirement that are both linear in the size of the training sample. However, this model has two major drawbacks. Firstly, it is prone to over-fitting. In effect, the learning machine will aim at inferring the K major spectral frequencies evidenced in the training data. This will only lead to appropriate prediction out-of-sample when the underlying latent phenomenon can be appropriately characterised by a finite discrete spectral decomposition that is expected to be the same everywhere on the domain. Secondly, this model implicitly postulates that the covariance between the values of the GP at two points does not vanish as the distance between the points becomes arbitrarily large. This imposes *a priori* the

view that the underlying function is highly structured, which might be unrealistic in many real-life non-periodic applications. This approach is generalised by the so-called *random Fourier features* methods (Rahimi and Recht (2007); Le et al. (2013); Yang et al. (2015)). Unfortunately all existing random Fourier features methods give rise to stationary covariance functions, which might not be appropriate for data sets exhibiting local patterns.

The bottleneck of inference in the *standard GP paradigm* remains inverting and computing the determinant of a covariance matrix, normally achieved through the Cholesky decomposition or Singular Value Decomposition. Methods have been developed that speed-up these decompositions through low rank approximations (Williams and Seeger (2001)) or by exploiting specific structures in the covariance function and in the input data (Satchi (2011); Wilson et al. (2014)), which typically give rise to Kronecker or Toeplitz covariance matrices. While the Kronecker method used by Satchi (2011) and Wilson et al. (2014) is restricted to inputs that form a Cartesian grid and to separable kernels,¹ low rank approximations such as the Nyström method used by Williams and Seeger (2001) modify the covariance function and hence the functional prior in a non-trivial way. Methods have also been proposed to interpolate the covariance matrix on a uniform or Cartesian grid in order to benefit from some of the computational gains of Toeplitz and Kronecker techniques even when the input space is not structured (Wilson and Nickisch (2015)). However, none of these solutions is general as they require that either the covariance function be separable (Kronecker techniques), or the covariance function be stationary and the input space be one-dimensional (Toeplitz techniques).

2.2 Scalability Through Data Distribution

A family of methods have been proposed to scale-up inference in GP models that are based on the observation that it is more computationally efficient to compute the pdf of K independent small Gaussian vectors with size n than to compute the pdf of a single bigger Gaussian vector of size nK . For instance, Kim et al. (2005) and Gramacy and Lee (2008) partitioned the input space, and put independent stationary GP priors on the restrictions of the latent function to the subdomains forming the partition, which can be regarded as independent *local GP experts*. Kim et al. (2005) partitioned the domain using Voronoi tessellations, while Gramacy and Lee (2008) used tree based partitioning. These two approaches are provably equivalent to postulating a (nonstationary) GP prior on the whole domain that is discontinuous along the boundaries of the partition, which might not be desirable if the latent function we would like to infer is continuous, and might affect predictive accuracy. The more local experts there are, the more scalable the model will be, but the more discontinuities the latent function will have, and subsequently the less accurate the approach will be.

Mixtures of Gaussian process experts models (MoE) (Tresp (2001); Rasmussen and Ghahramani (2001); Meeds and Osindero (2006); Ross and Dy (2013)) provide another implementation of this idea. MoE models assume that there are multiple latent functions to be inferred from the data, on which it is placed independent GP priors, and each training input is associated to one latent function. The number of latent functions and the repartition of data between latent functions can then be performed in a full Bayesian nonparametric fashion (Rasmussen and Ghahramani (2001); Ross and Dy (2013)). When there is a single continuous latent function to be inferred, as it is the case for most regression models, the foregoing Bayesian nonparametric approach will learn a single latent function, thereby leading to a time complexity and a memory requirement that are the same as in the *standard GP paradigm*, which defies the scalability argument.

¹. That is multivariate kernel that can be written as product of univariate kernels.

The last implementation of the idea in this section consists of distributing the training data over multiple independent but identical GP models. In regression problems, examples include the *Bayesian Committee Machines* (BCM) of [Tresp \(2000\)](#), the *generalized product of experts* (gPoE) model of [Cao and Fleet \(2014\)](#), and the *robust Bayesian Committee Machines* (rBCM) of [Deisenroth and Ng \(2015\)](#). These models propose splitting the training data in small subsets, each subset being assigned to a different GP regression model—referred to as an expert—that has the same hyper-parameters as the other experts, although experts are assumed to be mutually independent. Training is performed by maximum marginal likelihood, with time complexity (resp. memory requirement) linear in the number of experts and cubic (resp. squared) in the size of the largest data set processed by an expert. Predictions are then obtained by aggregating the predictions of all GP experts in a manner that is specific to the method used (that is the BCM, the gPoE or the rBCM). However, these methods present major drawbacks in the training and testing procedures. In effect, the assumption that experts have identical hyper-parameters is inappropriate for data sets exhibiting local patterns. Even if one would allow GP experts to be driven by different hyper-parameters as in [Nguyen and Bonilla \(2014\)](#) for instance, learned hyper-parameters would lead to overly simplistic GP experts and poor aggregated predictions when the number of training inputs assigned to each expert is small—this is a direct consequence of the (desirable) fact that maximum marginal likelihood GP regression abides by Occam’s razor. Another critical pitfall of BCM, gPoE and rBCM is that their methods for aggregating expert predictions are Kolmogorov *inconsistent*. For instance, denoting \hat{p} the predictive distribution in the BCM, it can be easily seen from Equations (2.4) and (2.5) in [Tresp \(2000\)](#) that the predictive distribution $\hat{p}(f(x_1^*)|\mathcal{D})$ (resp. $\hat{p}(f(x_2^*)|\mathcal{D})$)² provided by the aggregation procedure of the BCM is *not* the marginal over $f(x_2^*)$ (resp. over $f(x_1^*)$) of the multivariate predictive distribution $\hat{p}(f(x_1^*), f(x_2^*)|\mathcal{D})$ obtained from experts multivariate predictions $p_k(f(x_1^*), f(x_2^*)|\mathcal{D})$ using the same aggregation procedure: $\hat{p}(f(x_1^*)|\mathcal{D}) \neq \int \hat{p}(f(x_1^*), f(x_2^*)|\mathcal{D}) df(x_2^*)$. Without Kolmogorov consistency, it is impossible to make principled Bayesian inference of latent function values. A principled Bayesian nonparametric model should not provide predictions about $f(x_1^*)$ that differ depending on whether or not one is also interested in predicting other values $f(x_2^*)$ simultaneously. This pitfall might be the reason why [Cao and Fleet \(2014\)](#) and [Deisenroth and Ng \(2015\)](#) restricted their expositions to predictive distributions about a single function value at a time $\hat{p}(f(x^*)|\mathcal{D})$, although their procedures (Equation 4 in [Cao and Fleet \(2014\)](#) and Equation 20 in [Deisenroth and Ng \(2015\)](#)) are easily extended to posterior distributions over multiple function values. These extensions would also be Kolmogorov *inconsistent*, and restricting the predictions to be of exactly one function value is unsatisfactory as it does not allow determining the posterior covariance between function values at two test inputs.

2.3 Expressive Stationary Kernels

In regards to flexibly handling complex patterns likely to occur in large data sets, [Wilson and Adams \(2013\)](#) introduced a class of expressive stationary kernels obtained by summing up convolutions of Gaussian basis functions with Dirac delta functions in the spectral domain. The sparse spectrum kernel can be thought of as the special case where the convolving Gaussian is degenerate. Although such kernels perform particularly well in the presence of globally repeated patterns in the data, their stationarity limits their utility on data sets with local patterns. Moreover the proposed covariance

2. Here f is the latent function to be inferred, x_1^*, x_2^* are test points and \mathcal{D} denotes training data.

functions generate infinitely differentiable random functions, which might be too restrictive in some applications.

2.4 Application-Specific Nonstationary Kernels

As for nonstationary kernels, [Paciorek and Schervish \(2004\)](#) proposed a method for constructing nonstationary covariance functions from any stationary one that involves introducing n input dependent $d \times d$ covariance matrices that will be inferred from the data. [Plagemann et al. \(2008\)](#) proposed a faster approximation to the model of [Paciorek and Schervish \(2004\)](#). However, both approaches scale poorly with the input dimension and the data size as they have time complexity $\mathcal{O}(\max(n d^3, n^3))$. [MacKay \(1998\)](#), [Schmidt and O’Hagan \(2003\)](#), and [Calandra et al. \(2014\)](#) proposed kernels that can be regarded as stationary after a non-linear transformation d on the input space: $k(x, x') = h(\|d(x) - d(x')\|)$, where h is positive semi-definite. Although for a given deterministic function d the kernel k is nonstationary, [Schmidt and O’Hagan \(2003\)](#) put a GP prior on d with mean function $m(x) = x$ and covariance function invariant under translation, which unfortunately leads to a kernel that is (unconditionally) stationary, albeit more flexible than $h(\|x - x'\|)$. To model nonstationarity, [Adams and Stegle \(2008\)](#) introduced a functional prior of the form $g(x) = f(x) \exp g(x)$ where f is a stationary GP and g is some scaling function on the domain. For a given non-constant function g such a prior indeed yields a nonstationary Gaussian process. However, when a stationary GP prior is placed on the function g as [Adams and Stegle \(2008\)](#) did, the resulting functional prior $g(x) = f(x) \exp g(x)$ becomes stationary. The piecewise GP ([Kim et al. \(2005\)](#)) and treed GP ([Gramacy and Lee \(2008\)](#)) models previously discussed also introduce nonstationarity. The authors’ premise is that heterogeneous patterns might be locally homogeneous. However, as previously discussed such models are inappropriate for modelling continuous latent functions.

2.5 Our Approach

The approach we propose in this paper for inferring latent functions in large scale problems, possibly exhibiting locally homogeneous patterns, consists of constructing a novel class of *smooth, nonstationary* and *flexible* stochastic processes we refer to as *string Gaussian processes* (*string GPs*), whose finite dimensional marginals are structured enough so that full Bayesian nonparametric inference scales linearly with the sample size, without resorting to approximations. Our approach is analogous to MoE models in that, when the input space is one-dimensional, a *string GP* can be regarded as a *collaboration of local GP experts* on non-overlapping supports, that implicitly exchange messages with one another, and that are independent conditional on the aforementioned messages. Each local GP expert only shares just enough information with adjacent local GP experts for the whole stochastic process to be sufficiently smooth (for instance continuously differentiable), which is an important improvement over MoE models as the latter generate discontinuous latent functions. These messages will take the form of boundary conditions, conditional on which each local GP expert will be independent from any other local GP expert. Crucially, unlike the BCM, the gPoE and the rBCM, we do not assume that local GP experts share the same prior structure (that is mean function, covariance function, or hyper-parameters). This allows each local GP expert to flexibly learn local patterns from the data if there are any, while preserving global smoothness, which will result in improved accuracy. Similarly to MoEs, the computational gain in our approach stems from the fact that the conditional independence of the local GP experts conditional on shared boundary

conditions will enable us to write the joint distribution over function and derivative values at a large number of inputs as the product of pdfs of much smaller Gaussian vectors. The resulting effect on time complexity is a decrease from $\mathcal{O}(N^3)$ to $\mathcal{O}(\max_k n_k^3)$, where $N = \sum_k n_k$, $n_k \ll N$. In fact, in Section 5 we will propose Reversible-Jump Monte Carlo Markov Chain (RJ-MCMC) inference methods that achieve memory requirement and time complexity $\mathcal{O}(N)$, without any loss of flexibility. All these results are preserved by our extension of *string GPs* to multivariate input spaces, which we will occasionally refer to as *membrane Gaussian processes* (or membrane GPs). Unlike the BCM, the gPbE and the rBCM, the approach we propose in this paper, which we will refer to as the *string GP paradigm*, is Kolmogorov consistent, and enables principled inference of the posterior distribution over the values of the latent function at multiple test inputs.

3. Construction of String and Membrane Gaussian Processes

In this section we formally construct *string* Gaussian processes, and we provide some important theoretical results including smoothness, and the joint law of *string GPs* and their gradients. We construct *string GPs* indexed on \mathbb{R} , before generalising to *string GPs* indexed on \mathbb{R}^d , which we will occasionally refer to as *membrane GPs* to stress that the input space is multivariate. We start by considering the joint law of a differentiable GP on an interval and its derivative, and introducing some related notions that we will use in the construction of *string GPs*.

Proposition 1 (Derivative Gaussian processes)

Let I be an interval, $k : I \times I \rightarrow \mathbb{R}$ a \mathcal{C}^2 symmetric positive semi-definite function,³ $m : I \rightarrow \mathbb{R}$ a \mathcal{C}^1 function.

(A) There exists a \mathbb{R}^2 -valued stochastic process $(D_t)_{t \in I}$, $D_t = (z_t, z'_t)$, such that for all $t_1, \dots, t_n \in I$, $(z_{t_1}, \dots, z_{t_n}, z'_{t_1}, \dots, z'_{t_n})$ is a Gaussian vector with mean $(m(t_1), \dots, m(t_n), \frac{dm}{dt}(t_1), \dots, \frac{dm}{dt}(t_n))$ and covariance matrix such that

$$\text{cov}(z_{t_1}, z_{t_2}) = k(t_1, t_2), \quad \text{cov}(z_{t_1}, z'_{t_2}) = \frac{\partial k}{\partial y}(t_1, t_2), \quad \text{and} \quad \text{cov}(z'_{t_1}, z'_{t_2}) = \frac{\partial^2 k}{\partial x^2 \partial y^2}(t_1, t_2),$$

where $\frac{\partial}{\partial x}$ (resp. $\frac{\partial}{\partial y}$) refers to the partial derivative with respect to the first (resp. second) variable of k . We herein refer to $(D_t)_{t \in I}$ as a **derivative Gaussian process**.

(B) $(z_t)_{t \in I}$ is a Gaussian process with mean function m , covariance function k and that is \mathcal{C}^1 in the L^2 (mean square) sense.

(C) $(z'_t)_{t \in I}$ is a Gaussian process with mean function $\frac{dm}{dt}$ and covariance function $\frac{\partial^2 k}{\partial x^2 \partial y^2}$. Moreover, $(z'_t)_{t \in I}$ is the L^2 derivative of the process $(z_t)_{t \in I}$.

Proof Although this result is known in the Gaussian process community, we provide a proof for the curious reader in Appendix B. ■

We will say of a kernel k that it is **degenerate at a** when a *derivative Gaussian process* $(z_t, z'_t)_{t \in I}$

³. \mathcal{C}^1 (resp. \mathcal{C}^2) functions denote functions that are once (resp. twice) continuously differentiable on their domains.

with kernel k is such that z_a and z'_a are perfectly correlated,⁴ that is

$$|\text{corr}(z_a, z'_a)| = 1.$$

As an example, the linear kernel $k(u, v) = \sigma^2(u - c)(v - c)$ is degenerate at 0. Moreover, we will say of a kernel k that it is **degenerate at b given a** when it is not degenerate at a and when the *derivative Gaussian process* $(z_t, z'_t)_{t \in I}$ with kernel k is such that the variances of z_b and z'_b conditional on (z_a, z'_a) are both zero.⁵ For instance, the periodic kernel proposed by MacKay (1998) with period T is degenerate at $u + T$ given u .

An important subclass of *derivative Gaussian processes* in our construction are the processes resulting from conditioning paths of a *derivative Gaussian process* to take specific values at certain times (t_1, \dots, t_c) . We herein refer to those processes as **conditional derivative Gaussian process**. As an illustration, when k is \mathcal{C}^3 on $I \times I$ with $I = [a, b]$, and neither degenerate at a nor degenerate at b given a , the *conditional derivative Gaussian process* on $I = [a, b]$ with unconditional mean function m and unconditional covariance function k that is conditioned to start at $(\tilde{z}_a, \tilde{z}'_a)$ is the *derivative Gaussian process* with mean function

$$\forall t \in I, \quad m_c^a(t; \tilde{z}_a, \tilde{z}'_a) = m(t) + \tilde{\mathbf{K}}_{t;a} \mathbf{K}_{a;a}^{-1} \begin{bmatrix} \tilde{z}_a - m(a) \\ \tilde{z}'_a - \frac{dm}{dt}(a) \end{bmatrix}, \quad (1)$$

and covariance function k_c^a that reads

$$\forall t, s \in I, \quad k_c^a(t, s) = k(t, s) - \tilde{\mathbf{K}}_{t;a} \mathbf{K}_{a;a}^{-1} \tilde{\mathbf{K}}_{s;a}^T \quad (2)$$

where $\mathbf{K}_{a;a} = \begin{bmatrix} k(a, a) & \frac{\partial k}{\partial x}(a, a) \\ \frac{\partial k}{\partial x}(a, a) & \frac{\partial^2 k}{\partial x^2 \partial y^2}(a, a) \end{bmatrix}$, and $\tilde{\mathbf{K}}_{t;a} = \begin{bmatrix} k(t, a) & \frac{\partial k}{\partial y}(t, a) \end{bmatrix}$. Similarly, when the process is conditioned to start at $(\tilde{z}_a, \tilde{z}'_a)$ and to end at $(\tilde{z}_b, \tilde{z}'_b)$, the mean function reads

$$\forall t \in I, \quad m_c^{a,b}(t; \tilde{z}_a, \tilde{z}'_a, \tilde{z}_b, \tilde{z}'_b) = m(t) + \tilde{\mathbf{K}}_{t;(a,b)} \mathbf{K}_{(a,b);(a,b)}^{-1} \begin{bmatrix} \tilde{z}_a - m(a) \\ \tilde{z}'_a - \frac{dm}{dt}(a) \\ \tilde{z}_b - m(b) \\ \tilde{z}'_b - \frac{dm}{dt}(b) \end{bmatrix}, \quad (3)$$

and the covariance function $k_c^{a,b}$ reads

$$\forall t, s \in I, \quad k_c^{a,b}(t, s) = k(t, s) - \tilde{\mathbf{K}}_{t;(a,b)} \mathbf{K}_{(a,b);(a,b)}^{-1} \tilde{\mathbf{K}}_{s;(a,b)}^T \quad (4)$$

where $\mathbf{K}_{(a,b);(a,b)} = \begin{bmatrix} \mathbf{K}_{a;a} & \mathbf{K}_{a;b} \\ \mathbf{K}_{b;a} & \mathbf{K}_{b;b} \end{bmatrix}$, and $\tilde{\mathbf{K}}_{t;(a,b)} = [\tilde{\mathbf{K}}_{t;a} \quad \tilde{\mathbf{K}}_{t;b}]$. It is important to note that both $\mathbf{K}_{a;a}$ and $\mathbf{K}_{(a,b);(a,b)}$ are indeed invertible because the kernel is assumed to be neither degenerate at a nor degenerate at b given a . Hence, the support of (z_a, z'_a, z_b, z'_b) is \mathbb{R}^4 , and any function and derivative values can be used for conditioning. Figure 1 illustrates example independent draws from a *conditional derivative Gaussian process*.

⁴. Or equivalently when the Gaussian vector (z_a, z'_a) is degenerate.

⁵. Or equivalently when the Gaussian vector (z_a, z'_a) is not degenerate but (z_a, z'_a, z_b, z'_b) is.

3.1 String Gaussian Processes on \mathbb{R}

The intuition behind string Gaussian processes on an interval comes from the analogy of collaborative local GP experts we refer to as *strings* that are connected but independent of each other conditional on some regularity boundary conditions. While each string is tasked with representing local patterns in the data, a string only shares the *states* of its extremities (value and derivative) with adjacent strings. Our aim is to preserve global smoothness and limit the amount of information shared between strings, thus reducing computational complexity. Furthermore, the conditional independence between strings will allow for distributed inference, greater flexibility and principled nonstationarity construction.

The following theorem at the core of our framework establishes that it is possible to connect together GPs on a partition of an interval I , in a manner consistent enough that the newly constructed stochastic object will be a stochastic process on I and in a manner restrictive enough that any two connected GPs will share just enough information to ensure that the constructed stochastic process is continuously differentiable (\mathcal{C}^1) on I in the L^2 sense.

Theorem 2 (String Gaussian process)

Let $a_0 < \dots < a_k < \dots < a_K, I = [a_0, a_K]$ and let $p_{\mathcal{N}}(x; \mu, \Sigma)$ be the multivariate Gaussian density with mean vector μ and covariance matrix Σ . Furthermore, let $(m_k : [a_{k-1}, a_k] \rightarrow \mathbb{R})_{k \in [1..K]}$ be \mathcal{C}^1 functions, and $(k_k : [a_{k-1}, a_k] \times [a_{k-1}, a_k] \rightarrow \mathbb{R})_{k \in [1..K]}$ be \mathcal{C}^3 symmetric positive semi-definite functions, neither degenerate at a_{k-1} , nor degenerate at a_k , given a_{k-1} .

(A) There exists an \mathbb{R}^2 -valued stochastic process $(SD_t)_{t \in I}$, $SD_t = (z_t, \dot{z}_t)$ satisfying the following conditions:

1) The probability density of $(SD_{a_0}, \dots, SD_{a_K})$ reads:

$$p_k(x_0, \dots, x_K) := \prod_{k=0}^K p_{\mathcal{N}}\left(x_k; \mu_k, \Sigma_k\right) \quad (5)$$

where: $\Sigma_0 = {}_1\mathbf{K}_{a_0; a_0}$, $\forall k > 0$ $\Sigma_k^b = {}_k\mathbf{K}_{a_k; a_k} - {}_k\mathbf{K}_{a_k; a_{k-1}} {}_k\mathbf{K}_{a_{k-1}; a_{k-1}}^{-1} {}_k\mathbf{K}_{a_{k-1}; a_k}^T$, (6)

$\mu_0^b = {}_1\mathbf{M}_{a_0}$, $\forall k > 0$ $\mu_k^b = {}_k\mathbf{M}_{a_k} + {}_k\mathbf{K}_{a_k; a_{k-1}} {}_k\mathbf{K}_{a_{k-1}; a_{k-1}}^{-1} (x_{k-1} - {}_k\mathbf{M}_{a_{k-1}})$, (7)

$$\text{with } {}_k\mathbf{K}_{a;v} = \begin{bmatrix} k_k(u, v) & \frac{\partial k_k}{\partial v}(u, v) \\ \frac{\partial k_k}{\partial x}(u, v) & \frac{\partial^2 k_k}{\partial x \partial y}(u, v) \end{bmatrix}, \text{ and } {}_k\mathbf{M}_u = \begin{bmatrix} m_k(u) \\ \frac{dm_k}{dt}(u) \end{bmatrix}.$$

2) Conditional on $(SD_{a_k} = x_k, k \in [0..K])$, the restrictions $(SD_t)_{t \in [a_{k-1}, a_k]}$, $k \in [1..K]$ are independent conditional derivative Gaussian processes, respectively with unconditional mean function m_k and unconditional covariance function k_k and that are conditioned to take values x_{k-1} and x_k at a_{k-1} and a_k respectively. We refer to $(SD_t)_{t \in I}$ as a **string derivative Gaussian process**, and to its first coordinate $(z_t)_{t \in I}$ as a **string Gaussian process** namely,

$$(z_t)_{t \in I} \sim \text{SGP}(\{a_k\}, \{m_k\}, \{k_k\}).$$

(B) The **string Gaussian process** $(z_t)_{t \in I}$ defined in (A) is \mathcal{C}^1 in the L^2 sense and its L^2 derivative is the process $(\dot{z}_t)_{t \in I}$ defined in (A).

Proof See Appendix C. ■

In our collaborative local GP experts analogy, Theorem 2 stipulates that each local expert takes as message from the previous expert its left hand side boundary conditions, conditional on which it generates its right hand side boundary conditions, which it then passes on to the next expert. Conditional on their boundary conditions local experts are independent of each other, and resemble vibrating pieces of string on fixed extremities, hence the name *string Gaussian process*.

3.2 Pathwise Regularity

Thus far we have dealt with regularity only in the L^2 sense. However, we note that a sufficient condition for the process $(z_t)_{t \in I}$ in Theorem 2 to be almost surely continuous (i.e. sample paths are continuous with probability 1) and to be the almost sure derivative of the string Gaussian process $(z_t)_{t \in I}$, is that the Gaussian processes on $I_k = [a_{k-1}, a_k]$ with mean and covariance functions $m_{ok}^{a_{k-1}, a_k}$ and $k_{ok}^{a_{k-1}, a_k}$ (as per Equations 3 and 4 with $m := m_k$ and $k := k_k$) are themselves almost surely \mathcal{C}^1 for every boundary condition.⁶ We refer to (Adler and Taylor, 2011, Theorem 2.5.2) for a sufficient condition under which a \mathcal{C}^1 in L^2 Gaussian process is also almost surely \mathcal{C}^1 . As the above question is provably equivalent to that of the almost sure continuity of a Gaussian process (see Adler and Taylor, 2011, p. 30), Kolmogorov's continuity theorem (see Øksendal, 2003, Theorem 2.2.3) provides a more intuitive, albeit stronger, sufficient condition than that of (Adler and Taylor, 2011, Theorem 2.5.2).

3.3 Illustration

Algorithm 1 illustrates sampling jointly from a string Gaussian process and its derivative on an interval $I = [a_0, a_K]$. We start off by sampling the string boundary conditions (z_{a_k}, \dot{z}_{a_k}) sequentially, conditional on which we sample the values of the stochastic process on each string. This we may do in parallel as the strings are independent of each other conditional on boundary conditions. The resulting time complexity is the sum of $\mathcal{O}(\max_k n_k^2)$ for sampling values within strings, and $\mathcal{O}(n)$ for sampling boundary conditions, where the sample size is $n = \sum_k n_k$. The memory requirement grows as the sum of $\mathcal{O}(\sum_k n_k^2)$, required to store conditional covariance matrices of the values within strings, and $\mathcal{O}(K)$ corresponding to the storage of covariance matrices of boundary conditions. In the special case where strings are all empty, that is inputs and boundary times are the same, the resulting time complexity and memory requirement are $\mathcal{O}(n)$. Figure 2 illustrates a sample from a string Gaussian process, drawn using this approach.

3.4 String Gaussian Processes on \mathbb{R}^d

So far the input space has been assumed to be an interval. We generalise *string GPs* to hyperrectangles in \mathbb{R}^d as stochastic processes of the form:

$$f(t_1, \dots, t_d) = \phi\left(z_{t_1}^1, \dots, z_{t_d}^d\right), \quad (10)$$

where the *link function* $\phi : \mathbb{R}^d \rightarrow \mathbb{R}$ is a \mathcal{C}^1 function and (z_t^i) are d independent (\perp) latent string Gaussian processes on intervals. We will occasionally refer to *string GPs* indexed on \mathbb{R}^d with $d > 1$ as *membrane GPs* to avoid any ambiguity. We note that when $d = 1$ and when the link function

⁶ The proof is provided in Appendix D.

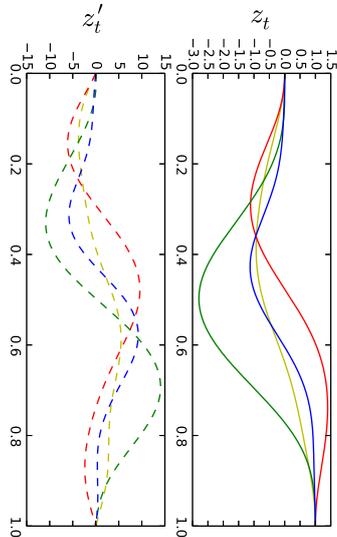

Figure 1: Draws from a conditional derivative GP conditioned to start at 0 with derivative 0 and to finish at 1.0 with derivative 0.0. The unconditional kernel is the squared exponential kernel with variance 1.0 and input scale 0.2.

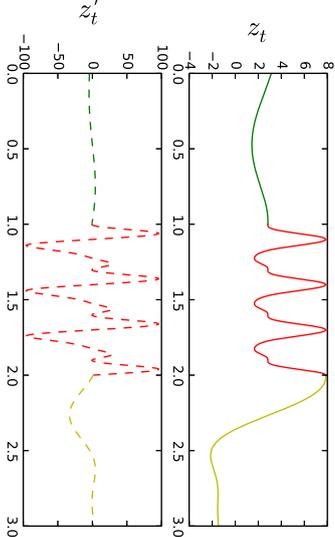

Figure 2: Draw from a *string GP* (z_t) with 3 strings and its derivative (z'_t), under squared exponential kernels (green and yellow strings), and the periodic kernel of MacKay (1998) (red string).

Algorithm 1 Simulation of a string derivative Gaussian process

Inputs: boundary times $a_0 < \dots < a_K$, string times $\{t_j^k \in [a_{k-1}, a_k] \mid j \in [1, n_k], k \in [1, K]\}$, unconditional mean (resp. covariance) functions m_k (resp. k_k)

Output: $\{\dots, z_{a_k}, z'_{a_k}, \dots, z_{t_j^k}, z'_{t_j^k}, \dots\}$.

Step 1: sample the boundary conditions sequentially.

for $k = 0$ to K do

Sample $(z_{a_k}, z'_{a_k}) \sim \mathcal{N}(\mu_k^b, \Sigma_k^b)$, with μ_k^b and Σ_k^b as per Equations (7) and (6).

end for

Step 2: sample the values on each string conditional on the boundary conditions in parallel.

parfor $k = 1$ to K do

Let ${}_k M_{a_k}$ and ${}_k K_{a_k; y}$ be as in Theorem 2.

$${}_k \Lambda = \begin{bmatrix} {}_k \mathbf{K}_{t_1^k; a_k-1} & \dots & {}_k \mathbf{K}_{t_1^k; a_k} \\ \dots & \dots & \dots \\ {}_k \mathbf{K}_{t_{n_k}^k; a_k-1} & \dots & {}_k \mathbf{K}_{t_{n_k}^k; a_k} \end{bmatrix}^{-1} \begin{bmatrix} {}_k \mathbf{K}_{a_{k-1}; a_k-1} & \dots & {}_k \mathbf{K}_{a_{k-1}; a_k} \\ \dots & \dots & \dots \\ {}_k \mathbf{K}_{a_k; a_k-1} & \dots & {}_k \mathbf{K}_{a_k; a_k} \end{bmatrix}^{-1},$$

$$\mu_k^s = \begin{bmatrix} {}_k \mathbf{M}_{t_1^k} \\ \dots \\ {}_k \mathbf{M}_{t_{n_k}^k} \end{bmatrix} + {}_k \Lambda \begin{bmatrix} z_{a_{k-1}}^{2a_{k-1}} - m_k(a_{k-1}) \\ z_{a_{k-1}}^{2a_k} - m_k(a_k) \\ z_{a_k}^{2a_k} - \frac{dm_k}{dt}(a_k) \end{bmatrix}, \quad (8)$$

$$\Sigma_k^s = \begin{bmatrix} {}_k \mathbf{K}_{t_1^k; t_1^k} & \dots & {}_k \mathbf{K}_{t_1^k; t_{n_k}^k} \\ \dots & \dots & \dots \\ {}_k \mathbf{K}_{t_{n_k}^k; t_1^k} & \dots & {}_k \mathbf{K}_{t_{n_k}^k; t_{n_k}^k} \end{bmatrix} - {}_k \Lambda \begin{bmatrix} {}_k \mathbf{K}_{a_{k-1}; a_k-1} & \dots & {}_k \mathbf{K}_{a_{k-1}; a_k} \\ \dots & \dots & \dots \\ {}_k \mathbf{K}_{a_k; a_k-1} & \dots & {}_k \mathbf{K}_{a_k; a_k} \end{bmatrix}^T. \quad (9)$$

Sample $(z_{t_1^k}, z'_{t_1^k}, \dots, z_{t_{n_k}^k}, z'_{t_{n_k}^k}) \sim \mathcal{N}(\mu_k^s, \Sigma_k^s)$.

end parfor

is $\phi(x) = x$, we recover *string GPs* indexed on an interval as previously defined. When the *string GPs* (z_t^j) are a.s. \mathcal{C}^1 , the *membrane GP* f in Equation (10) is also a.s. \mathcal{C}^1 , and the partial derivative with respect to the j -th coordinate reads:

$$\frac{\partial f}{\partial t_j}(t_1, \dots, t_d) = z_{t_j}^{j'} \frac{\partial \phi}{\partial t_j}(z_{t_1}^1, \dots, z_{t_d}^d). \quad (11)$$

Thus in high dimensions, *string GPs* easily allow an explanation of the sensitivity of the learned latent function to inputs.

3.5 Choice of Link Function

Our extension of *string GPs* to \mathbb{R}^d departs from the *standard GP paradigm* in that we did not postulate a covariance function on $\mathbb{R}^d \times \mathbb{R}^d$ directly. Doing so usually requires using a metric on \mathbb{R}^d , which is often problematic for heterogeneous input dimensions, as it introduces an arbitrary comparison between distances in each input dimension. This problem has been partially addressed by approaches such as Automatic Relevance Determination (ARD) kernels, that allow for a linear rescaling of input dimensions to be learned jointly with kernel hyper-parameters. However, inference under a *string GP* prior can be thought of as learning a coordinate system in which the latent function f resembles the link function ϕ through non-linear rescaling of input dimensions. In particular, when ϕ is symmetric, the learned univariate *string GPs* (being interchangeable in ϕ) implicitly aim at normalizing input data across dimensions, making *string GPs* naturally cope with heterogeneous data sets.

An important question arising from our extension is whether or not the link function ϕ needs to be learned to achieve a flexible functional prior. The flexibility of a *string GP* as a functional prior depends on both the *link function* and the covariance structures of the underlying *string GP* building blocks (z_t^j). To address the impact of the choice of ϕ on flexibility, we constrain the *string GP* building blocks by restricting them to be independent identically distributed *string GPs* with one string each (i.e. (z_t^j) are i.i.d Gaussian processes). Furthermore, we restrict ourselves to isotropic kernels as they provide a consistent basis for putting the same covariance structure in \mathbb{R} and \mathbb{R}^d . One question we might then ask, for a given *link function* ϕ_0 , is whether or not an isotropic GP indexed on \mathbb{R}^d with covariance function k yields more flexible random surfaces than the stationary *string GP* $f(t_1, \dots, t_d) = \phi_0(z_{t_1}^1, \dots, z_{t_d}^d)$, where (z_t^j) are stationary GPs indexed on \mathbb{R} with the same covariance function k . If we find a *link function* ϕ_0 generating more flexible random surfaces than isotropic GP counterparts it would suggest ϕ need not to be inferred in dimension $d > 1$ to be more flexible than any GP using one of the large number of commonly used isotropic kernels, among which squared exponential kernels, rational quadratic kernels, and Matérn kernels to name but a few.

Before discussing whether such a ϕ_0 exists, we need to introduce a rigorous meaning to ‘flexibility’. An intuitive qualitative definition of the flexibility of a stochastic process indexed on \mathbb{R}^d is the ease with which it can generate surfaces with varying shapes from one random sample to another independent one. We recall that the tangent hyperplane to a \mathcal{C}^1 surface $y = f(x) = 0$, $x \in \mathbb{R}^d$ at some point $x_0 = (t_1^0, \dots, t_d^0)$ has equation $\nabla f(x_0)^T (x - x_0) - (y - f(x_0)) = 0$ and admits as normal vector $(\frac{\partial f}{\partial t_1}(t_1^0), \dots, \frac{\partial f}{\partial t_d}(t_d^0), -1)$. As tangent hyperplanes approximate a surface locally, a first criterion of flexibility for a random surface $y = f(x) = 0$, $x \in \mathbb{R}^d$ is the proclivity of the (random) direction of its tangent hyperplane at any point x —and hence the proclivity of $\nabla f(x)$ —to vary.

This criterion alone, however, does not capture the difference between the local shapes of the random surface at two distinct points. A complementary second criterion of flexibility is the proclivity of the (random) directions of the tangent hyperplanes at any two distinct points $x_0, x_1 \in \mathbb{R}^d$ —and hence the proclivity of $\nabla f(x_0)$ and $\nabla f(x_1)$ —to be independent. The first criterion can be measured using the entropy of the gradient at a point, while the second criterion can be measured through the mutual information between the two gradients. The more flexible a stochastic process, the higher the entropy of its gradient at any point, and the lower the mutual information between its gradients at any two distinct points. This is formalised in the definition below.

Definition 3 (Flexibility of stochastic processes)

Let f and g be two real valued, almost surely \mathcal{C}^1 , stochastic processes indexed on \mathbb{R}^d , and whose gradients have a finite entropy everywhere (i.e. $\forall x, H(\nabla f(x)), H(\nabla g(x)) < \infty$). We say that f is more flexible than g if the following conditions are met:

- 1) $\forall x, H(\nabla f(x)) \geq H(\nabla g(x))$,
 - 2) $\forall x \neq y, I(\nabla f(x); \nabla f(y)) \leq I(\nabla g(x); \nabla g(y))$,
- where H is the entropy operator, and $I(X; Y) = H(X) + H(Y) - H(X, Y)$ stands for the mutual information between X and Y .

The following proposition establishes that the *link function* $\phi_s(x_1, \dots, x_d) = \sum_{i=j}^d x_j$ yields more flexible stationary *string GPs* than their isotropic GP counterparts, thereby providing a theoretical underpinning for not inferring ϕ .

Proposition 4 (Additively separable string GPs are flexible)

Let $k(x, y) := \rho(\|x - y\|_{L^2}^2)$ be a stationary covariance function generating a.s. \mathcal{C}^1 GP paths indexed on \mathbb{R}^d , $d > 0$, and ρ a function that is \mathcal{C}^2 on $]0, +\infty[$ and continuous at 0. Let $\phi_s(x_1, \dots, x_d) = \sum_{j=1}^d x_j$; let $(z_t^j)_{t \in \mathbb{R}, j \in \{1, \dots, d\}}$ be independent stationary Gaussian processes with mean 0 and covariance function k (where the L^2 norm is on \mathbb{R}), and let $f(t_1, \dots, t_d) = \phi_s(z_{t_1}^1, \dots, z_{t_d}^d)$ be the corresponding stationary *string GP*. Finally, let g be an isotropic Gaussian process indexed on \mathbb{R}^d with mean 0 and covariance function k (where the L^2 norm is on \mathbb{R}^d). Then:

- 1) $\forall x \in \mathbb{R}^d, I(\nabla f(x)) = H(\nabla g(x))$,
- 2) $\forall x \neq y \in \mathbb{R}^d, I(\nabla f(x); \nabla f(y)) \leq I(\nabla g(x); \nabla g(y))$.

■ See Appendix E.

Although the link function need not be inferred in a full nonparametric fashion to yield comparable if not better results than most isotropic kernels used in the *standard GP paradigm*, for some problems certain link functions might outperform others. In Section 4.2 we analyse a broad family of link functions, and argue that they extend successful anisotropic approaches such as the Automatic Relevance Determination (MacKay (1998)) and the additive kernels of Duvenaud et al. (2011). Moreover, in Section 5 we propose a scalable inference scheme applicable to any link function.

4. Comparison with the Standard GP Paradigm

We have already established that sampling *string GPs* scales better than sampling GPs under the *standard GP paradigm* and is amenable to distributed computing. We have also established that

stationary additively separable *string GPs* are more flexible than their isotropic counterparts in the *standard GP paradigm*. In this section, we provide further theoretical results relating the *string GP paradigm* to the *standard GP paradigm*. Firstly we establish that *string GPs* with link function $\phi_s(x_1, \dots, x_d) = \sum_{j=1}^d x_j$ are GPs. Secondly, we derive the global mean and covariance functions induced by the *string GP* construction for a variety of link functions. Thirdly, we provide a sense in which the *string GP paradigm* can be thought of as extending the *standard GP paradigm*. And finally, we show that the *string GP paradigm* may serve as a scalable approximation of commonly used stationary kernels.

4.1 Some String GPs are GPs

On one hand we note from Theorem 2 that the restriction of a *string GP* defined on an interval to the support of the first string—in other words the first local GP expert—is a Gaussian process. On the other hand, the messages passed on from one local GP expert to the next are not necessarily consistent with the unconditional law of the receiving local expert, so that overall a *string GP* defined on an interval, that is when looked at globally and unconditionally, might not be a Gaussian process. However, the following proposition establishes that some *string GPs* are indeed Gaussian processes.

Proposition 5 (Additively separable string GPs are GPs)

String Gaussian processes on \mathbb{R} are Gaussian processes. Moreover, string Gaussian processes on \mathbb{R}^d with link function $\phi_s(x_1, \dots, x_d) = \sum_{j=1}^d x_j$ are also Gaussian processes.

Proof. The intuition behind this proof lies in the fact that if X is a multivariate Gaussian, and if conditional on X , Y is a multivariate Gaussian, providing that the conditional mean of Y depends linearly on X and the conditional covariance matrix of Y does not depend on X , the vector (X, Y) is jointly Gaussian. This will indeed be the case for our collaboration of local GP experts as the boundary conditions picked up by an expert from the previous will not influence the conditional covariance structure of the expert (the conditional covariance structure depends only on the partition of the domain, not the values of the boundary conditions) and will affect the mean linearly. See Appendix H for the full proof. ■

The above result guarantees that commonly used closed form predictive equations under GP priors are still applicable under some *string GP* priors, providing the global mean and covariance functions, which we derive in the following section, are available. Proposition 5 also guarantees stability of the corresponding *string GPs* in the GP family under addition of independent Gaussian noise terms as in regression settings. Moreover, it follows from Proposition 5 that inference techniques developed for Gaussian processes can be readily used under *string GP* priors. In Section 5 we provide an additional MCMC scheme that exploits the conditional independence between strings to yield greater scalability and distributed inference.

4.2 String GP kernels and String GP Mean Functions

The approach we have adopted in the construction of *string GPs* and *membrane GPs* did not require explicitly postulating a global mean function or covariance function. In Appendix I we derive the global mean and covariance functions that result from our construction. The global covariance function could be used for instance as a stand-alone kernel in any kernel method, for instance GP

models under the *standard GP paradigm*, which would provide a flexible and nonstationary alternative to commonly used kernels that may be used to learn local patterns in data sets—some successful example applications are provided in Section 5. That being said, adopting such a global approach should be limited to small scale problems as the conditional independence structure of *string GPs* does not easily translate into structures in covariance matrices over *string GP* values (without derivative information) that can be exploited to speed-up SVD or Cholesky decomposition. Crucially, marginalising out all derivative information in the distribution of *derivative string GP* values at some inputs would destroy any conditional independence structure, thereby limiting opportunities for scalable inference. In Section 5 we will provide a RJ-MCMC inference scheme that fully exploits the conditional independence structure in *string GPs* and scales to very large data sets.

4.3 Connection Between Multivariate String GP kernels and Existing Approaches

We recall that for $n \leq d$, the n -th order *elementary symmetric polynomial* (Macdonald (1995)) is given by

$$e_0(x_1, \dots, x_d) := 1, \quad \forall 1 \leq n \leq d \quad e_n(x_1, \dots, x_d) = \sum_{1 \leq i_1 < i_2 < \dots < i_n \leq d} \prod_{k=1}^n x_{i_k}. \quad (12)$$

As an illustration,

$$\begin{aligned} e_1(x_1, \dots, x_d) &= \sum_{j=1}^d x_j = \phi_s(x_1, \dots, x_d), \\ e_2(x_1, \dots, x_d) &= x_1 x_2 + x_1 x_3 + \dots + x_1 x_d + \dots + x_{d-1} x_d, \\ &\dots \\ e_d(x_1, \dots, x_d) &= \prod_{j=1}^d x_j = \phi_p(x_1, \dots, x_d). \end{aligned}$$

Covariance kernels of *string GPs*, using as link functions *elementary symmetric polynomials* e_n , extend most popular approaches that combine unidimensional kernels over features for greater flexibility or cheaper design experiments.

The first-order polynomial e_1 gives rise to additively separable Gaussian processes, that can be regarded as Bayesian nonparametric *generalised additive models* (GAM), particularly popular for their interpretability. Moreover, as noted by Durrande et al. (2012), additively separable Gaussian processes are considerably cheaper than alternate transformations in design experiments with high-dimensional input spaces. In addition to the above, additively separable *string GPs* also allow postulating the existence of local properties in the experimental design process at no extra cost.

The d -th order polynomial e_d corresponds to a product of unidimensional kernels, also known as separable kernels. For instance, the popular squared exponential kernel is separable. Separable kernels have been successfully used on large scale inference problems where the inputs form a grid (Saatchi, 2011; Wilson et al., 2014), as they yield covariance matrices that are Kronecker products, leading to maximum likelihood inference in linear time complexity and with linear memory requirement. Separable kernels are often used in conjunction with the *automatic relevance determination* (ARD) model, to learn the relevance of features through global linear rescaling. However, ARD

kernels might be limited in that we might want the relevance of a feature to depend on its value. As an illustration, the market value of a watch can be expected to be a stronger indicator of its owner's wealth when it is in the top 1 percentile, than when it is in the bottom 1 percentile; the rationale being that possessing a luxurious watch is an indication that one can afford it, whereas possessing a cheap watch might be either an indication of lifestyle or an indication that one cannot afford a more expensive one. Separable *string GP* kernels extend ARD kernels, in that strings between input dimensions and within an input dimension may have unconditional kernels with different hyperparameters, and possibly different functional forms, thereby allowing for *automatic local relevance determination* (ALRD).

More generally, using as link function the n -th order elementary symmetric polynomial e_n corresponds to the n -th order interaction of the *additive kernels* of Duvenaud et al. (2011). We also note that the class of link functions $\phi(x_1, \dots, x_d) = \sum_{i=1}^d \sigma_i e_i(x_1, \dots, x_d)$ yield full *additive kernels*. Duvenaud et al. (2011) noted that such kernels are 'exceptionally well-suited' to learn non-local structures in data. *String GPs* complement *additive kernels* by allowing them to learn local structures as well.

4.4 String GPs as Extension of the Standard GP Paradigm

The following proposition provides a perspective from which *string GPs* may be considered as extending Gaussian processes on an interval.

Proposition 6 (Extension of the standard GP paradigm)

Let $K \in \mathbb{N}^*$, let $I = [a_0, a_K]$ and $I_k = [a_{k-1}, a_k]$ be intervals with $a_0 < \dots < a_K$. Furthermore, let $m : I \rightarrow \mathbb{R}$ be a C^1 function, m_k the restriction of m to I_k , $h : I \times I \rightarrow \mathbb{R}$ a C^3 symmetric positive semi-definite function, and h_k the restriction of h to $I_k \times I_k$. If

$$(z_t)_{t \in I} \sim \mathcal{SGP}(\{a_k\}, \{m_k\}, \{h_k\}),$$

then

$$\forall k \in [1..K], (z_t)_{t \in I_k} \sim \mathcal{GP}(m, h).$$

Proof. See Appendix F. ■

We refer to the case where unconditional string mean and kernel functions are restrictions of the same functions as in Proposition 6 as *uniform string GPs*. Although uniform *string GPs* are not guaranteed to be as much regular at boundary times as their counterparts in the *standard GP paradigm*, we would like to stress that they may well generate paths that are. In other words, the functional space induced by a uniform *string GP* on an interval extends the functional space of the GP with the same mean and covariance functions m and h taken globally and unconditionally on the whole interval as in the *standard GP paradigm*. This allows for (but does not enforce) less regularity at the boundary times. When *string GPs* are used as functional prior, the posterior mean can in fact have more regularity at the boundary times than the continuous differentiability enforced in the *string GP paradigm*, providing such regularity is evidenced in the data.

We note from Proposition 6 that when m is constant and h is stationary, the restriction of the uniform *string GP* $(z_t)_{t \in I}$ to any interval whose interior does not contain a boundary time, the largest of which being the intervals $[a_{k-1}, a_k]$, is a stationary GP. We refer to such cases as *partition stationary string GPs*.

4.5 Commonly Used Covariance Functions and their String GP Counterparts

Considering the superior scalability of the *string GP paradigm*, which we may anticipate from the scalability of sampling *string GPs*, and which we will confirm empirically in Section 5, a natural question that comes to mind is whether or not kernels commonly used in the *standard GP paradigm* can be well approximated by *string GP* kernels, so as to take advantage of the improved scalability of the *string GP paradigm*. We examine the distortions to commonly used covariance structures resulting from restricting strings to share only C^1 boundary conditions, and from increasing the number of strings.

Figure 3 compares some popular stationary kernels on $[0, 1] \times [0, 1]$ (first column) to their uniform *string GP* kernel counterparts with 2, 4, 8 and 16 strings of equal length. The popular kernels considered are the squared exponential kernel (SE), the rational quadratic kernel $k_{RQ}(u, v) = \left(1 + \frac{2(u-v)^2}{\alpha}\right)^{-\alpha}$ with $\alpha = 1$ (RQ 1) and $\alpha = 5$ (RQ 5), the Matérn 3/2 kernel (MA 3/2), and the Matérn 5/2 kernel (MA 5/2), each with output scale (variance) 1 and input scale 0.5. Firstly, we observe that each of the popular kernels considered coincides with its uniform *string GP* counterparts regardless of the number of strings, so long as the arguments of the covariance function are less than an input scale apart. Except for the Matérn 3/2, the loss of information induced by restricting strings to share only C^1 boundary conditions becomes noticeable when the arguments of the covariance function are more than 1.5 input scales apart, and the effect is amplified as the number of strings increases. As for the Matérn 3/2, no loss of information can be noticed, as further attests Table 1. In fact, this comes as no surprise given that stationary Matérn 3/2 GP are 1-Markov, that is the corresponding derivative Gaussian process is a Markov process so that the vector (z_t, \dot{z}_t) contains as much information as all *string GP* or derivative values prior to t (see Doob (1944)). Table 1 provides some statistics on the absolute errors between each of the popular kernels considered and uniform *string GP* counterparts.

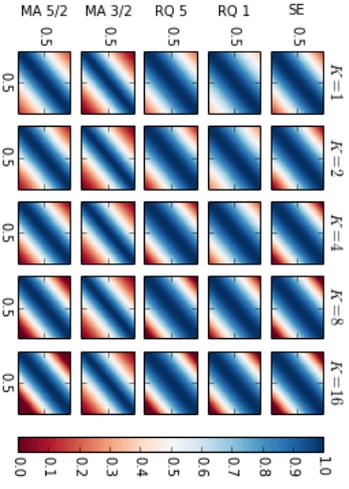

Figure 3: Commonly used covariance functions on $[0, 1] \times [0, 1]$ with the same input and output scales (first column) and their uniform *string GP* counterparts with $K > 1$ strings of equal length.

	$K = 2$			$K = 4$			$K = 8$			$K = 16$

Table 1: Minimum, average, and maximum absolute errors between some commonly used stationary covariance functions on $[0, 1] \times [0, 1]$ (with unit variance and input scale 0.5) and their uniform *string GP* counterparts with $K > 1$ strings of equal length.

5. Inference under String and Membrane GP Priors

In this section we move on to developing inference techniques for Bayesian nonparametric inference of latent functions under *string GP* priors. We begin with marginal likelihood inference in regression problems. We then propose a novel reversible-jump MCMC sampler that enables automatic learning of model complexity (that is the number of different unconditional kernel configurations) from the data, with a time complexity and memory requirement both linear in the number of training inputs.

5.1 Maximum Marginal Likelihood for Small Scale Regression Problems

Firstly, we leverage the fact that additively separable *string GPs* are Gaussian processes to perform Bayesian nonparametric regressions in the presence of local patterns in the data, using standard Gaussian process techniques (see [Rasmussen and Williams, 2006](#), p.112 §5.4.1). We use as generative model

$$y_i = f(x_i) + \epsilon_i, \quad \epsilon_i \sim \mathcal{N}(0, \sigma_{k_i}^2), \quad \sigma_{k_i}^2 > 0, \quad x_i \in I^1 \times \dots \times I^d, \quad y_i, \epsilon_i \in \mathbb{R}$$

we are given the training data set $\mathcal{D} = \{\tilde{x}_i, \tilde{y}_i\}_{i \in [1..N]}$, and we place a mean-zero additively separable *string GP* prior on f , namely

$$f(x) = \sum_{j=1}^d z_{x[j]}, \quad (z_i^j \sim \text{SGP}(\{a_k^j\}, \{0\}, \{k_k^j\})), \quad \forall j < l, \quad (z_i^j \perp (z_i^l))$$

which we assume to be independent of the measurement noise process. Moreover, the noise terms are assumed to be independent, and the noise variance $\sigma_{k_i}^2$ affecting $f(x_i)$ is assumed to be the same for any two inputs whose coordinates lie on the same string intervals. Such a heteroskedastic noise model fits nicely within the *string GP paradigm*, can be very useful when the dimension of the input space is small, and may be replaced by the typical constant noise variance assumption in high-dimensional input spaces.

Let us define $\mathbf{y} = (\tilde{y}_1, \dots, \tilde{y}_N)$, $\mathbf{X} = (\tilde{x}_1, \dots, \tilde{x}_N)$, $\mathbf{f} = (f(\tilde{x}_1), \dots, f(\tilde{x}_N))$ and let $\bar{\mathbf{K}}_{\mathbf{X};\mathbf{X}}$ denote the auto-covariance matrix of \mathbf{f} (which we have derived in [Section 4.2](#)), and let $\mathbf{D} = \text{diag}(\{\sigma_{k_i}^2\})$ denote the diagonal matrix of noise variances. It follows that \mathbf{y} is a Gaussian vector with mean $\mathbf{0}$ and auto-covariance matrix $\mathbf{K}_{\mathbf{y}} := \bar{\mathbf{K}}_{\mathbf{X};\mathbf{X}} + \mathbf{D}$ and that the log marginal likelihood reads:

$$\log p(\mathbf{y} | \mathbf{X}, \{\sigma_{k_i}\}, \{\theta_k^j\}, \{a_k^j\}) = -\frac{1}{2} \mathbf{y}^T \mathbf{K}_{\mathbf{y}}^{-1} \mathbf{y} - \frac{1}{2} \log \det(\mathbf{K}_{\mathbf{y}}) - \frac{n}{2} \log 2\pi. \quad (13)$$

We obtain estimates of the string measurement noise standard deviations $\{\hat{\sigma}_{k_i}\}$ and estimates of the string hyper-parameters $\{\hat{\theta}_k^j\}$ by maximising the marginal likelihood for a given domain partition $\{a_k^j\}$, using gradient-based methods. We deduce the predictive mean and covariance matrix of the latent function values \mathbf{f}^* at test points \mathbf{X}^* , from the estimates $\{\hat{\theta}_k^j\}, \{\hat{\sigma}_{k_i}\}$ as

$$\mathbf{E}(\mathbf{f}^* | \mathbf{y}) = \bar{\mathbf{K}}_{\mathbf{X}^*; \mathbf{X}} \mathbf{K}_{\mathbf{y}}^{-1} \mathbf{y} \quad \text{and} \quad \text{cov}(\mathbf{f}^* | \mathbf{y}) = \bar{\mathbf{K}}_{\mathbf{X}^*; \mathbf{X}^*} - \bar{\mathbf{K}}_{\mathbf{X}^*; \mathbf{X}} \mathbf{K}_{\mathbf{y}}^{-1} \bar{\mathbf{K}}_{\mathbf{X}; \mathbf{X}^*}, \quad (14)$$

using the fact that $(\mathbf{f}^*, \mathbf{y})$ is jointly Gaussian, and that the cross-covariance matrix between \mathbf{f}^* and \mathbf{y} is $\bar{\mathbf{K}}_{\mathbf{X}^*; \mathbf{X}}$ as the additive measurement noise is assumed to be independent from the latent process f .

5.1.1 REMARKS

The above analysis and equations still hold when a GP prior is placed on f with one of the multivariate *string GP* kernels derived in [Section 4.2](#) as covariance function.

It is also worth noting from the derivation of *string GP* kernels in [Appendix I](#) that the marginal likelihood [Equation \(13\)](#) is continuously differentiable in the locations of boundary times. Thus, for a given number of boundary times, the positions of the boundary times can be determined as part of the marginal likelihood maximisation. The derivatives of the marginal log-likelihood ([Equation 13](#)) with respect to the aforementioned locations $\{\sigma_{k_i}^2\}$ can be determined from the recursions of [Appendix I](#), or approximated numerically by finite differences. The number of boundary times in each input dimension can then be learned by trading off model fit (the maximum marginal log likelihood) and model simplicity (the number of boundary times or model parameters), for instance using information criteria such as AIC and BIC. When the input dimension is large, it might be advantageous to further constrain the hypothesis space of boundary times before using information criteria, for instance by assuming that the number of boundary times is the same in each dimension. An alternative Bayesian nonparametric approach to learning the number of boundary times will be discussed in [section 5.4](#).

This method of inference cannot exploit the structure of *string GPs* to speed-up inference, and as a result it scales like the *standard GP paradigm*. In fact, any attempt to marginalize out univariate derivative processes, including in the prior, will inevitably destroy the conditional independence structure. Another perspective to this observation is found by noting from the derivation of global *string GP* covariance functions in [Appendix I](#) that the conditional independence structure does not easily translate in a matrix structure that may be exploited to speed-up matrix inversion, and that marginalizing out terms relating to derivatives processes as in [Equation \(13\)](#) can only make things worse.

5.2 Generic Reversible-Jump MCMC Sampler for Large Scale Inference

More generally, we consider learning a smooth real-valued latent function f , defined on a d -dimensional hyper-rectangle, under a generative model with likelihood $p(\mathcal{D} | \mathbf{f}, \mathbf{u})$, where \mathbf{f} denotes values of f at training inputs points and \mathbf{u} denotes other likelihood parameters that are not related to f . A large class of machine learning problems aiming at inferring a latent function have a likelihood model of this form. Examples include celebrated applications such as nonparametric regression and nonparametric binary classification problems, but also more recent applications such as learning a profitable portfolio generating-function in *stochastic portfolio theory* ([Karatzas and Fernholz \(2009\)](#)) from the data. In particular, we do not assume that $p(\mathcal{D} | \mathbf{f}, \mathbf{u})$ factorizes over training inputs. Extensions to likelihood models that depend on the values of multiple latent functions are straight-forward and will be discussed in [Section 5.3](#).

5.2.1 PRIOR SPECIFICATION

We place a prior $p(\mathbf{u})$ on other likelihood parameters. For instance, in regression problems under a Gaussian noise model, \mathbf{u} can be the noise variance and we may choose $p(\mathbf{u})$ to be the inverse-Gamma distribution for conjugacy. We place a mean-zero *string GP* prior on f

$$f(x) = \phi \left(z_{x[1]}^1, \dots, z_{x[d]}^d \right), \quad (z_i^j \sim \text{SGP}(\{a_k^j\}, \{0\}, \{k_k^j\})), \quad \forall j < l, \quad (z_i^j \perp (z_i^l)). \quad (15)$$

As discussed in Section 3.5, the link function ϕ need not be inferred as the symmetric sum was found to yield a sufficiently flexible functional prior. Nonetheless, in this section we do not impose any restriction on the link function ϕ other than continuous differentiability. Denoting \mathbf{z} the vector of univariate *string GP* processes and their derivatives, evaluated at all distinct input coordinate values, we may re-parametrize the likelihood as $p(\mathcal{D}|\mathbf{z}, \mathbf{u})$, with the understanding that \mathbf{f} can be recovered from \mathbf{z} through the link function ϕ . To complete our prior specification, we need to discuss the choice of boundary times $\{a_k^j\}$ and the choice of the corresponding unconditional kernel structures $\{k_k^j\}$. Before doing so, we would like to stress that key requirements of our sampler are that i) it should decouple the need for scalability from the need for flexibility, ii) it should scale linearly with the number of training and test inputs, and iii) the user should be able to express prior views on model complexity/flexibility in an intuitive way, but the sampler should be able to validate or invalidate the prior model complexity from the data. While the motivations for the last two requirements are obvious, the first requirement is motivated by the fact that a massive data set may well be more homogeneous than a much smaller data set.

5.2.2 SCALABLE CHOICE OF BOUNDARY TIMES

To motivate our choice of boundary times that achieves great scalability, we first note that the evaluation of the likelihood, which will naturally be needed by the MCMC sampler, will typically have at least linear time complexity and linear memory requirement, as it will require performing computations that use each training sample at least once. Thus, the best we can hope to achieve overall is linear time complexity and linear memory requirement. Second, in MCMC schemes with functional priors, the time complexity and memory requirements for sampling from the posterior

$$p(\mathbf{f}|\mathcal{D}) \propto p(\mathcal{D}|\mathbf{f})p(\mathbf{f})$$

are often the same as the resource requirements for sampling from the prior $p(\mathbf{f})$, as evaluating the model likelihood is rarely the bottleneck. Finally, we note from Algorithm 1 that, when each input coordinate in each dimension is a boundary time, the sampling scheme has time complexity and memory requirement that are linear in the maximum number of unique input coordinates across dimensions, which is at most the number of training samples. In effect, each univariate derivative *string GP* is sampled in *parallel* at as many times as there are unique input coordinates in that dimension, before being combined through the link function. In a given input dimension, univariate derivative *string GP* values are sampled sequentially, one boundary time conditional on the previous. The foregoing sampling operation is very scalable not only asymptotically but also in absolute terms: it merely requires storing and inverting at most as many 2×2 matrices as the number of input points. We will evaluate the actual overall time complexity and memory requirement when we discuss our MCMC sampler in greater detail. For now, we would like to stress that i) choosing each distinct input coordinate value as a boundary time in the corresponding input dimension before training is a perfectly valid choice, ii) we expect this choice to result in resource requirements that grow linearly with the sample size and iii) in the *string GP* theory we have developed thus far there is no requirement that two adjacent strings be driven by different kernel hyper-parameters.

5.2.3 MODEL COMPLEXITY LEARNING AS A CHANGE-POINT PROBLEM

The remark iii) above pertains to model complexity. In the simplest case, all strings are driven by the same kernel and hyper-parameters as it was the case in Section 4.5, where we discussed how this

setup departs from postulating the unconditional string covariance function k_k^j globally similarly to the *standard GP paradigm*. The more distinct unconditional covariance structures there are, the more complex the model is, as it may account for more types of local patterns. Thus, we may identify model complexity to the number of different kernel configurations across input dimensions. In order to learn model complexity, we require that some (but not necessarily all) strings share their kernel configuration.⁷ Moreover, we require kernel membership to be dimension-specific in that two strings in different input dimensions may not explicitly share a kernel configuration in the prior specification, although the posterior distribution over their hyper-parameters might be similar if the data support it.

In each input dimension j , kernel membership is defined by a partition of the corresponding domain operated by a (possibly empty) set of change-points,⁸ as illustrated in Figure 4. When there is no change-point as in Figure 4-(a), all strings are driven by the same kernel and hyper-parameters. Each change-point c_b^j induces a new kernel configuration θ_b^j that is shared by all strings whose boundary times a_k^j and a_{k+1}^j both lie in $[c_b^j, c_{b+1}^j]$.⁹ When one or multiple change-points c_b^j occur between two adjacent boundary times as illustrated in Figures 4-(b-d), for instance $a_k^j \leq c_b^j \leq a_{k+1}^j$, the kernel configuration of the string defined on $[a_k^j, a_{k+1}^j]$ is that of the largest change-point that lies in $[a_k^j, a_{k+1}^j]$ (see for instance Figure 4-(d)). For consistency, we denote θ_b^j the kernel configuration driving the first string in the j -th dimension; it also drives strings that come before the first change-point, and all strings when there is no change-point.

To place a prior on model complexity, it suffices to define a joint probability measure on the set of change-points and the corresponding kernel configurations. As kernel configurations are not shared across input dimensions, we choose these priors to be independent across input dimensions. Moreover, $\{c_b^j\}$ being a random collection of points on an interval whose number and positions are both random, it is *de facto* a point process (Daley and Vere-Jones (2008)). To keep the prior specification of change-points uninformative, it is desirable that conditional on the number of change-points, the positions of change-points be i.i.d. uniform on the domain. As for the number of change-points, it is important that the support of its distribution not be bounded, so as to allow for an arbitrarily large model complexity if warranted. The two requirements above are satisfied by a homogeneous Poisson process or HPP (Daley and Vere-Jones (2008)) with constant intensity λ^j . More precisely, the prior probability measure on $(\{c_b^j, \theta_b^j\}, \lambda^j)$ is constructed as follows:

$$\begin{cases} \lambda^j \sim \Gamma(\alpha^j, \beta^j), \\ \{c_b^j\} | \lambda^j \sim \text{HPP}(\lambda^j) \\ \theta_b^j | \{c_b^j\}, \lambda^j \stackrel{\text{i.i.d.}}{\sim} \log \mathcal{N}(0, \rho^j) \\ \forall (j, p) \neq (1, q) \quad \theta_b^j \perp \theta_q^j \end{cases} \quad (16)$$

where we choose the Gamma distribution Γ as prior on the intensity λ^j for conjugacy, we assume all kernel hyper-parameters are positive as is often the case in practice,⁹ the coordinates of the hyper-parameters of a kernel configuration are assumed i.i.d., and kernel hyper-parameters are assumed

⁷ That is, the functional form of the unconditional kernel k_k^j and its hyper-parameters.

⁸ We would like to stress that change-points do not introduce new input points or boundary times, but solely define a partition of the domain of each input dimension.

⁹ This may easily be relaxed if needed, for instance by putting normal priors on parameters that may be negative and log-normal priors on positive parameters.

independent between kernel configurations. Denoting the domain of the j -th input $[a^j, b^j]$, it follows from applying the laws of total expectation and total variance on Equation (16) that the expected number of change-points in the j -th dimension under our prior is

$$E(\#\{c_p^j\}) = (b^j - a^j) \frac{\alpha^j}{\beta^j}, \tag{17}$$

and the variance of the number of change-points in the j -dimension under our prior is

$$\text{Var}(\#\{c_p^j\}) = (b^j - a^j) \frac{\alpha^j}{\beta^j} \left(1 + \frac{(b^j - a^j)}{\beta^j} \right). \tag{18}$$

The two equations above may guide the user when setting the parameters α^j and β^j . For instance, these values may be set so that the expected number of change-points in a given input dimension be a fixed fraction of the number of boundary times in that input dimension, and so that the prior variance over the number of change-points be large enough that overall the prior isn't too informative.

We could have taken a different approach to construct our prior on change-points. In effect, assuming for the sake of the argument that the boundaries of the domain of the j -th input, namely a^j and b^j , are the first and last change-point in that input dimension, we note that the mapping

$$(\dots, c_p^j, \dots) \rightarrow (\dots, p_p^j, \dots) := \left(\dots, \frac{c_{p+1}^j - c_p^j}{b^j - a^j}, \dots \right)$$

defines a bijection between the set of possible change-points in the j -th dimension and the set of all discrete probability distributions. Thus, we could have placed as prior on (\dots, p_p^j, \dots) a Dirichlet process (Ferguson (1973)), a Pitman-Yor process (Pitman and Yor (1997)), more generally *normalized completely random measures* (Kingman (1967)) or any other probability distribution over partitions. We prefer the point process approach primarily because it provides an easier way of expressing prior belief about model complexity through the expected number of change-points $\#\{c_p^j\}$, while remaining uninformative about positions thereof.

One might also be tempted to regard change-points in an input dimension j as inducing a partition, not of the domain $[a^j, b^j]$, but of the set of boundary times a_k^j in the same dimension, so that one may define a prior over kernel memberships through a prior over partitions of the set of boundary times. However, this approach would be inconsistent with the aim to learn local patterns in the data if the corresponding random measure is *exchangeable*. In effect, as boundary times are all input coordinates, local patterns may only arise in the data as a result of adjacent strings sharing kernel configurations. An exchangeable random measure would postulate a priori that two kernel membership assignments that have the same kernel configurations (i.e. the same number of configurations and the same set of hyper-parameters) and the same *number* of boundary times in each kernel cluster (although not exactly the same boundary times), are equally likely to occur, thereby possibly putting more probability mass on kernel membership assignments that do not respect boundary time adjacency. Unfortunately, *exchangeable* random measures (among which the Dirichlet process and the Pitman-Yor process) are by far more widely adopted by the machine learning community than non-exchangeable random measures. Thus, this approach might be perceived as overly complex. That being said, as noted by Foti and Williamson (2015), non-exchangeable normalized random measures may be regarded as Poisson point processes (with varying intensity functions) on some

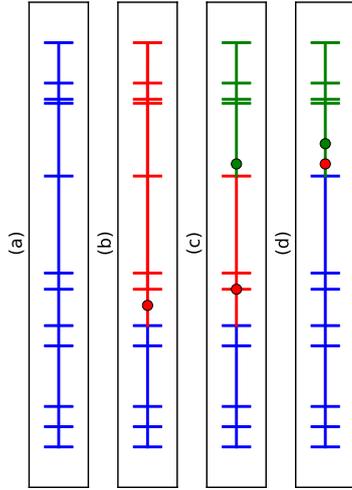

Figure 4: Effects of domain partition through change-points (coloured circles), on kernel membership. Each vertical bar corresponds to a distinct boundary time a_k^j . For the same collection of boundary times, we consider four scenarios: (a) no partition, (b) partition of the domain in two by a single change-point that does not coincide with any existing boundary time, (c) partition of the domain in three by two change-points, one of which coincides with an existing boundary time, and (d) partition of the domain in two by two distinct change-points. In each scenario, kernel membership is illustrated by colour-coding. The colour of the interval between two consecutive boundary times a_k^j and a_{k+1}^j reflects what kernel configuration drives the corresponding string; in particular, the colour of the vertical bar corresponding to boundary time a_{k+1}^j determines what kernel configuration should be used to compute the conditional distribution of the value of the derivative string GP (z_t^j, z_t^j) at a_{k+1}^j , given its value at a_k^j .

augmented spaces, which makes this choice of prior specification somewhat similar, but stronger (that is more informative) than the one we adopt in this paper.

Before deriving the sampling algorithm, it is worth noting that the prior defined in Equation (16) does not admit a density with respect to the same base measure,¹⁰ as the number of change-points $\#\{d_j^i\}$, and subsequently the number of kernel configurations, may vary from one sample to another. Nevertheless, the joint distribution over the data \mathcal{D} and all other model parameters is well defined and, as we will see later, we may leverage reversible-jump MCMC techniques (Green (1995); Green and Hastie (2009)) to construct a Markov chain that converges to the posterior distribution.

5.2.4 OVERALL STRUCTURE OF THE MCMC SAMPLER

To ease notations, we denote \mathbf{c} the set of all change-points in all input dimensions, we denote $\mathbf{n} = (\dots, \#\{d_j^i\}, \dots) \in \mathbb{N}^d$ the vector of the numbers of change-points in each input dimension, we denote $\boldsymbol{\theta}$ the set of kernel hyper-parameters,¹¹ and $\boldsymbol{\rho} := (\dots, \rho^1, \dots)$ the vector of variances of the independent log-normal priors on $\boldsymbol{\theta}$. We denote $\boldsymbol{\lambda} := (\dots, \lambda^1, \dots)$ the vector of change-points intensities, we denote $\boldsymbol{\alpha} := (\dots, \alpha^d, \dots)$ and $\boldsymbol{\beta} := (\dots, \beta^1, \dots)$ the vectors of parameters of the Gamma priors we placed on the change-points intensities across the d input dimensions, and we recall that \mathbf{u} denotes the vector of likelihood parameters other than the values of the latent function f .

We would like to sample from the posterior distribution $p(\mathbf{f}, \mathbf{f}^*, \nabla \mathbf{f}, \nabla \mathbf{f}^* | \mathcal{D}, \boldsymbol{\alpha}, \boldsymbol{\beta}, \boldsymbol{\rho})$, where \mathbf{f} and \mathbf{f}^* are the vectors of values of the latent function f at training and test inputs respectively, and $\nabla \mathbf{f}, \nabla \mathbf{f}^*$ the corresponding gradients. Denoting \mathbf{z} the vector of univariate *string GP* processes and their derivatives, evaluated at all distinct training and test input coordinate values, we note that to sample from $p(\mathbf{f}, \mathbf{f}^*, \nabla \mathbf{f}, \nabla \mathbf{f}^* | \mathcal{D}, \boldsymbol{\alpha}, \boldsymbol{\beta}, \boldsymbol{\rho})$, it suffices to sample from $p(\mathbf{z} | \mathcal{D}, \boldsymbol{\alpha}, \boldsymbol{\beta}, \boldsymbol{\rho})$, compute \mathbf{f} and \mathbf{f}^* using the link function, and compute the gradients using Equation (11). To sample from $p(\mathbf{z} | \mathcal{D}, \boldsymbol{\alpha}, \boldsymbol{\beta}, \boldsymbol{\rho})$, we may sample from the target distribution

$$\pi(\mathbf{n}, \mathbf{c}, \boldsymbol{\theta}, \boldsymbol{\lambda}, \mathbf{z}, \mathbf{u}) := p(\mathbf{n}, \mathbf{c}, \boldsymbol{\theta}, \boldsymbol{\lambda}, \mathbf{z}, \mathbf{u} | \mathcal{D}, \boldsymbol{\alpha}, \boldsymbol{\beta}, \boldsymbol{\rho}), \quad (19)$$

and discard variables that are not of interest. As previously discussed, π is not absolutely continuous with respect to the same base measure, though we may still decompose it as

$$\pi(\mathbf{n}, \mathbf{c}, \boldsymbol{\theta}, \boldsymbol{\lambda}, \mathbf{z}, \mathbf{u}) = \frac{1}{p(\mathcal{D} | \boldsymbol{\alpha}, \boldsymbol{\beta}, \boldsymbol{\rho})} p(\mathbf{n} | \boldsymbol{\lambda}) p(\boldsymbol{\lambda} | \boldsymbol{\alpha}, \boldsymbol{\beta}) p(\mathbf{c} | \mathbf{n}) p(\boldsymbol{\theta} | \mathbf{n}, \boldsymbol{\rho}) p(\mathbf{u} | \mathbf{z}, \mathbf{c}, \boldsymbol{\theta}) p(\mathcal{D} | \mathbf{z}, \mathbf{u}), \quad (20)$$

where we use the notation $p(\cdot)$ and $p(\cdot | \cdot)$ to denote probability measures rather than probability density functions or probability mass functions, and where product and scaling operations are usual measure operations. Before proceeding any further, we will introduce a slight re-parametrization of Equation (20) that will improve the inference scheme.

Let $\mathbf{n}_a = (\dots, \#\{d_k^j\}, \dots)$ be the vector of the numbers of unique boundary times in all d input dimensions. We recall from our prior on f that

$$p(\mathbf{z} | \mathbf{c}, \boldsymbol{\theta}) = \prod_{j=1}^d p \left(\begin{matrix} z_{a_0^j}^j, z_{a_0^j}^{j'} \\ z_{a_k^j}^j, z_{a_k^j}^{j'} \end{matrix} \middle| \begin{matrix} z_{a_{k-1}^j}^j, z_{a_{k-1}^j}^{j'} \\ z_{a_{k-1}^j}^j, z_{a_{k-1}^j}^{j'} \end{matrix} \right), \quad (21)$$

10. That is the joint prior probability measure is neither discrete, nor continuous.

11. To simplify the exposition, we assume without loss of generality that each kernel configuration has the same kernel functional form, so that configurations are defined by kernel hyper-parameters.

where each factor in the decomposition above is a bivariate Gaussian density whose mean vector and covariance matrix is obtained from the partitions \mathbf{c} , the kernel hyper-parameters $\boldsymbol{\theta}$, and the kernel membership scheme described in Section 5.2.3 and illustrated in Figure 4, and using Equations (6-7). Let \mathbf{K}_{cov} be the unconditional covariance matrix between $\begin{pmatrix} z_{a_0^j}^j, z_{a_0^j}^{j'} \end{pmatrix}$ and $\begin{pmatrix} z_{a_k^j}^j, z_{a_k^j}^{j'} \end{pmatrix}$ as per the unconditional kernel structure driving the string defined on the interval $[a_k^j, a_{k+1}^j]$. Let $\Sigma_k^j := {}^0 \mathbf{K}_{a_0^j, a_0^j}$ be the auto-covariance matrix of $\begin{pmatrix} z_{a_0^j}^j, z_{a_0^j}^{j'} \end{pmatrix}$. Let

$$\Sigma_k^j := {}^j \mathbf{K}_{a_k^j, a_k^j} - {}^j \mathbf{K}_{a_k^j, a_{k-1}^j} {}^j \mathbf{K}_{a_{k-1}^j, a_{k-1}^j}^{-1} {}^j \mathbf{K}_{a_{k-1}^j, a_k^j}^T$$

be the covariance matrix of $\begin{pmatrix} z_{a_k^j}^j, z_{a_k^j}^{j'} \end{pmatrix}$ given $\begin{pmatrix} z_{a_{k-1}^j}^j, z_{a_{k-1}^j}^{j'} \end{pmatrix}$, and

$$M_k^j := {}^j \mathbf{K}_{a_k^j, a_{k-1}^j} {}^j \mathbf{K}_{a_{k-1}^j, a_{k-1}^j}^{-1}$$

Finally, let $L_k^j := U_k^j (D_k^j)^{\frac{1}{2}}$ with $\Sigma_k^j = U_k^j D_k^j (U_k^j)^T$ the singular value decomposition (SVD) of Σ_k^j . We may choose to represent $\begin{pmatrix} z_{a_0^j}^j, z_{a_0^j}^{j'} \end{pmatrix}$ as

$$\begin{bmatrix} z_{a_0^j}^j \\ z_{a_0^j}^{j'} \end{bmatrix} = L_0^j \mathbf{x}_{a_0^j}^j, \quad (22)$$

and for $k > 0$ we may also choose to represent $\begin{pmatrix} z_{a_k^j}^j, z_{a_k^j}^{j'} \end{pmatrix}$ as

$$\begin{bmatrix} z_{a_k^j}^j \\ z_{a_k^j}^{j'} \end{bmatrix} = M_k^j \begin{bmatrix} z_{a_{k-1}^j}^j \\ z_{a_{k-1}^j}^{j'} \end{bmatrix} + L_k^j \mathbf{x}_{a_k^j}^j, \quad (23)$$

where $\{\mathbf{x}_{a_k^j}^j\}$ are independent bivariate standard normal vectors. Equations (22-23) provide an equivalent representation. In effect, we recall that if $Z = M + LX$, where $X \sim \mathcal{N}(0, I)$ is a standard multivariate Gaussian, M is a real vector, and L is a real matrix, then $Z \sim \mathcal{N}(M, LL^T)$. Equations (22-23) result from applying this result to $\begin{pmatrix} z_{a_0^j}^j, z_{a_0^j}^{j'} \end{pmatrix}$ and $\begin{pmatrix} z_{a_k^j}^j, z_{a_k^j}^{j'} \end{pmatrix} \middle| \begin{pmatrix} z_{a_{k-1}^j}^j, z_{a_{k-1}^j}^{j'} \end{pmatrix}$. We note that at training time, M_k^j and L_k^j only depend on kernel hyper-parameters. Denoting \mathbf{x} the vector of all $\mathbf{x}_{a_k^j}^j$, \mathbf{x} is a so-called ‘whitened’ representation of \mathbf{z} , which we prefer for reasons we will discuss shortly. In the whitened representation, the target distribution π is re-parameterized as

$$\pi(\mathbf{n}, \mathbf{c}, \boldsymbol{\theta}, \boldsymbol{\lambda}, \mathbf{x}, \mathbf{u}) = \frac{1}{p(\mathcal{D} | \boldsymbol{\alpha}, \boldsymbol{\beta}, \boldsymbol{\rho})} p(\mathbf{n} | \boldsymbol{\lambda}) p(\boldsymbol{\lambda} | \boldsymbol{\alpha}, \boldsymbol{\beta}) p(\mathbf{c} | \mathbf{n}) p(\boldsymbol{\theta} | \mathbf{n}, \boldsymbol{\rho}) p(\mathbf{u} | \mathbf{x}) p(\mathcal{D} | \mathbf{x}, \mathbf{c}, \boldsymbol{\theta}, \mathbf{u}), \quad (24)$$

where the dependency of the likelihood term on the partitions and the hyper-parameters stems from the need to recover \mathbf{z} and subsequently \mathbf{f} from \mathbf{x} through Equations (22) and (23). The whitened representation Equation (24) has two primary advantages. Firstly, it is robust to ill-conditioning of

Σ_k^j , which would typically occur when two adjacent boundary times are too close to each other. In the representation of Equation (20), as one needs to evaluate the density $p(\mathbf{z}|\mathbf{c}, \boldsymbol{\theta})$, ill-conditioning of Σ_k^j would result in numerical instabilities. In contrast, in the whitened representation, one needs to evaluate the density $p(\mathbf{x})$, which is that of i.i.d. standard Gaussians and as such can be evaluated robustly. Moreover, the SVD required to evaluate L_k^j is also robust to ill-conditioning of Σ_k^j , so that Equations (22) and (23) hold and can be robustly evaluated for degenerate Gaussians too. The second advantage of the whitened representation is that it improves mixing by establishing a link between kernel hyper-parameters and the likelihood.

Equation (24) allows us to cast our inference problem as a Bayesian model selection problem under a countable family of models indexed by $\mathbf{n} \in \mathbb{N}^d$, each defined on a different parameter subspace $\mathcal{C}_{\mathbf{n}}$, with cross-model normalizing constant $p(\mathcal{D}|\boldsymbol{\alpha}, \boldsymbol{\beta}, \boldsymbol{\rho})$, model probability driven by $p(\mathbf{n}|\boldsymbol{\lambda})p(\boldsymbol{\lambda}|\boldsymbol{\alpha}, \boldsymbol{\beta})$, model-specific prior $p(\mathbf{c}|\mathbf{n})p(\boldsymbol{\theta}|\mathbf{n}, \boldsymbol{\rho})p(\mathbf{u}|\mathbf{x})$, and likelihood $p(\mathcal{D}|\mathbf{x}, \mathbf{c}, \boldsymbol{\theta}, \mathbf{u})$. Critically, it can be seen from Equation (24) that the conditional probability distribution

$$\pi(\mathbf{c}, \boldsymbol{\theta}, \boldsymbol{\lambda}, \mathbf{x}, \mathbf{u}|\mathbf{n})$$

admits a density with respect to Lebesgue's measure on $\mathcal{C}_{\mathbf{n}}$.

Our setup is therefore analogous to that which motivated the seminal paper Green (1995), so that to sample from the posterior $\pi(\mathbf{c}, \boldsymbol{\theta}, \boldsymbol{\lambda}, \mathbf{x}, \mathbf{u}, \mathbf{n})$ we may use any Reversible-Jump Metropolis-Hastings (RJ-MH) scheme satisfying detailed balance and dimension-matching as described in section 3.3 of Green (1995). To improve mixing of the Markov chain, we will alternate between a *between-models* RJ-MH update with target distribution $\pi(\mathbf{n}, \mathbf{c}, \boldsymbol{\theta}, \boldsymbol{\lambda}, \mathbf{x}, \mathbf{u})$, and a *within-model* MCMC-within-Gibbs sampler with target distribution $\pi(\mathbf{c}, \boldsymbol{\theta}, \boldsymbol{\lambda}, \mathbf{x}, \mathbf{u}|\mathbf{n})$. Constructing reversible-jump samplers by alternating between within-model sampling and between-models sampling is standard practice, and it is well-known that doing so yields a Markov chain that converges to the target distribution of interest (see Brooks et al., 2011, p. 50).

In a slight abuse of notation, in the following we might use the notations $p(\cdot|\cdot)$ and $p(\cdot)$, which we previously used to denote probability measures, to refer to the corresponding probability density functions or probability mass functions.

5.2.5 WITHIN-MODEL UPDATES

We recall from Equation (24) that $\mathbf{c}, \boldsymbol{\theta}, \boldsymbol{\lambda}, \mathbf{x}, \mathbf{u}|\mathcal{D}, \boldsymbol{\alpha}, \boldsymbol{\beta}, \boldsymbol{\rho}, \mathbf{n}$ has probability density function

$$p(\mathbf{n}|\boldsymbol{\lambda})p(\boldsymbol{\lambda}|\boldsymbol{\alpha}, \boldsymbol{\beta})p(\mathbf{c}|\mathbf{n})p(\boldsymbol{\theta}|\mathbf{n}, \boldsymbol{\rho})p(\mathbf{u}|\mathbf{x})p(\mathcal{D}|\mathbf{x}, \mathbf{c}, \boldsymbol{\theta}, \mathbf{u}), \quad (25)$$

up to a normalizing constant.

Updating $\boldsymbol{\lambda}$: By independence of the priors over $(\boldsymbol{\lambda}[j], \mathbf{n}[j])$, the distributions $\boldsymbol{\lambda}[j] | \mathbf{n}[j]$ are also independent, so that the updates may be performed in *parallel*. Moreover, recalling that the prior number of change-points in the j -th input dimension is Poisson distributed with intensity $\boldsymbol{\lambda}[j](b^j - a^j)$, and by conjugacy of the Gamma distribution to the Poisson likelihood, it follows that

$$\boldsymbol{\lambda}[j] | \mathbf{n}[j] \sim \Gamma\left(\frac{\mathbf{n}[j]}{b^j - a^j} + \boldsymbol{\alpha}[j], 1 + \boldsymbol{\beta}[j]\right). \quad (26)$$

This update step has memory requirement and time complexity both constant in the number of training and test samples.

Updating \mathbf{u} : When the likelihood has additional parameters \mathbf{u} , they may be updated with a Metropolis-Hastings step. Denoting $q(\mathbf{u} \rightarrow \mathbf{u}')$ the proposal probability density function, the acceptance ratio reads

$$r_{\mathbf{u}} = \min\left(1, \frac{p(\mathbf{u}')p(\mathcal{D}|\mathbf{x}, \mathbf{c}, \boldsymbol{\theta}, \mathbf{u}')q(\mathbf{u} \rightarrow \mathbf{u}')}{p(\mathbf{u})p(\mathcal{D}|\mathbf{x}, \mathbf{c}, \boldsymbol{\theta}, \mathbf{u})q(\mathbf{u}' \rightarrow \mathbf{u})}\right). \quad (27)$$

In some cases however, it might be possible and more convenient to choose $p(\mathbf{u})$ to be conjugate to the likelihood $p(\mathcal{D}|\mathbf{x}, \mathbf{c}, \boldsymbol{\theta}, \mathbf{u})$. For instance, in regression problems under a Gaussian noise model, we may take \mathbf{u} to be the noise variance on which we may place an inverse-gamma prior. Either way, the computational bottleneck of this step is the evaluation of the likelihood $p(\mathcal{D}|\mathbf{x}, \mathbf{c}, \boldsymbol{\theta}, \mathbf{u}')$, which in most cases can be done with a time complexity and memory requirement that are both linear in the number of training samples.

Updating \mathbf{c} : We update the positions of change-points sequentially using the Metropolis-Hastings algorithm, one input dimension j at a time, and for each input dimension we proceed in increasing order of change-points. The proposal new position for the change-point c_j^b is sampled uniformly at random on the interval $[c_{j-p-1}^b, c_{j+p+1}^b]$, where c_{j-p-1}^b (resp. c_{j+p+1}^b) is replaced by a^j (resp. b^j) for the first (resp. last) change-point. The acceptance probability of this proposal is easily found to be

$$r_{c_j^b} = \min\left(1, \frac{p(\mathcal{D}|\mathbf{x}, \mathbf{c}', \boldsymbol{\theta}, \mathbf{u})}{p(\mathcal{D}|\mathbf{x}, \mathbf{c}, \boldsymbol{\theta}, \mathbf{u})}\right), \quad (28)$$

where \mathbf{c}' is identical to \mathbf{c} except for the change-point to update. This step requires computing the factors $\{J_k^j, M_k^j\}$ corresponding to inputs in j -th dimension whose kernel configuration would change if the proposal were to be accepted, the corresponding vector of *derivative string GP* values \mathbf{z} , and the observation likelihood under the proposal $p(\mathcal{D}|\mathbf{x}, \mathbf{c}, \boldsymbol{\theta}, \mathbf{u})$. The computational bottleneck of this step is therefore once again the evaluation of the new likelihood $p(\mathcal{D}|\mathbf{x}, \mathbf{c}', \boldsymbol{\theta}, \mathbf{u})$.

Updating \mathbf{x} : The target conditional density of \mathbf{x} is proportional to

$$p(\mathbf{x})p(\mathcal{D}|\mathbf{x}, \mathbf{c}, \boldsymbol{\theta}, \mathbf{u}). \quad (29)$$

Recalling that $p(\mathbf{x})$ is a multivariate standard normal, it follows that the form of Equation (29) makes it convenient to use elliptical slice sampling (Murray et al. (2010)) to sample from the unnormalized conditional $p(\mathbf{x})p(\mathcal{D}|\mathbf{x}, \mathbf{c}, \boldsymbol{\theta}, \mathbf{u})$. The two bottlenecks of this update step are sampling a new proposal from $p(\mathbf{x})$ and evaluating the likelihood $p(\mathcal{D}|\mathbf{x}, \mathbf{c}, \boldsymbol{\theta}, \mathbf{u})$. Sampling from the multivariate standard normal $p(\mathbf{x})$ may be *massively parallelized*, for instance by using GPU Gaussian random number generators. When no parallelism is available, the overall time complexity reads $\mathcal{O}\left(\sum_{j=1}^d \mathbf{n}_a[j]\right)$, where we recall that $\mathbf{n}_a[j]$ denotes the number of distinct training and testing input coordinates in the j -th dimension. In particular, if we denote N the total number of training and testing d -dimensional input samples, then $\sum_{j=1}^d \mathbf{n}_a[j] \leq dN$, although for many classes of data sets with sparse input values such as images, where each input (single-colour pixel value) may have at most 256 distinct values, we might have $\sum_{j=1}^d \mathbf{n}_a[j] \ll dN$. As for the memory required to sample from $p(\mathbf{x})$, it grows proportionally to the size of \mathbf{x} , that is in $\mathcal{O}\left(\sum_{j=1}^d \mathbf{n}_a[j]\right)$. In regards to the evaluation of the likelihood $p(\mathcal{D}|\mathbf{x}, \mathbf{c}, \boldsymbol{\theta}, \mathbf{u})$, as previously discussed its resource requirements are application-specific, but it will typically have time complexity that grows in $\mathcal{O}(N)$ and memory requirement that grows in $\mathcal{O}(dN)$. For instance, the foregoing resource requirements always hold

for i.i.d. observation models such as in nonparametric regression and nonparametric classification problems.

Updating θ . We note from Equation (25) that the conditional distribution of θ given everything else has unnormalized density

$$p(\theta|n, \rho)p(\mathcal{D}|\mathbf{x}, c, \theta, \mathbf{u}), \quad (30)$$

which we may choose to represent as

$$p(\log \theta|n, \rho)p(\mathcal{D}|\mathbf{x}, c, \log \theta, \mathbf{u}). \quad (31)$$

As we have put independent log-normal priors on the coordinates of θ (see Equation 16), we may once again use elliptical slice sampling to sample from $\log \theta$ before taking the exponential. The time complexity of generating a new sample from $p(\log \theta|n, \rho)$ will typically be at most linear in the total number of distinct kernel hyper-parameters. Overall, the bottleneck of this update is the evaluation of the likelihood $p(\mathcal{D}|\mathbf{x}, c, \log \theta, \mathbf{u})$. In this update, the latter operation requires recomputing the factors M_k^i and L_k^j of Equations (22) and (23), which requires computing and taking the SVD of unrelated 2×2 matrices, computations we may perform in *parallel*. Once the foregoing factors have been computed, we evaluate \mathbf{z} , the *derivative string GP* values at boundary times, parallelizing over input dimensions, and running a sequential update within an input dimension using Equations (22) and (23). Updating \mathbf{z} therefore has time complexity that is, in the worst case where no distributed computing is available, $\mathcal{O}(dN)$, and $\mathcal{O}(N)$ when there are up to d computing cores. The foregoing time complexity will also be that of this update step, unless the observation likelihood is more expensive to evaluate. The memory requirement, as in previous updates, is $\mathcal{O}(dN)$.

Overall resource requirement. To summarize previous remarks, the overall computational bottleneck of a *within-model* iteration is the evaluation of the likelihood $p(\mathcal{D}|\mathbf{x}, c, \theta, \mathbf{u})$. For i.i.d. observation models such as classification and regression problems for instance, the corresponding time complexity grows in $\mathcal{O}(N)$ when d computing cores are available, or $\mathcal{O}(dN)$ otherwise, and the memory requirement grows in $\mathcal{O}(dN)$.

5.2.6 BETWEEN-MODELS UPDATES

Our reversible-jump Metropolis-Hastings update proceeds as follows. We choose an input dimension, say j , uniformly at random. If j has no change-points, that is $\mathbf{n}[j] = 0$, we randomly choose between not doing anything, and adding a change-point, each outcome having the same probability. If $\mathbf{n}[j] > 0$, we either do nothing, add a change-point, or delete a change-point, each outcome having the same probability of occurrence.

Whenever we choose not to do anything, the acceptance ratio is easily found to be one:

$$r_{j0} = 1. \quad (32)$$

Whenever we choose to add a change-point, we sample the position c_k^j of the proposal new change-point uniformly at random on the domain $[a^j, b^j]$ of the j -th input dimension. This proposal will almost surely break an existing kernel membership cluster, say the p -th, into two: that is $c_p^j < c_k^j < c_{p+1}^j$ where we may have $a^j = c_p^j$ and/or $b^j = c_{p+1}^j$. In the event c_k^j coincides with an existing change-point, which should happen with probability 0, we do nothing. When adding a change-point, we sample a new vector of hyper-parameters θ_k^j from the log-normal prior of Equation (16), and we

propose as hyper-parameters for the tentative new clusters $[c_p^j, c_k^j]$ and $[c_k^j, c_{p+1}^j]$ the vectors $\theta_{\text{add-left}}^j$ and $\theta_{\text{add-right}}^j$ defined as

$$\log \theta_{\text{add-left}}^j := \cos(\alpha) \log \theta_p^j - \sin(\alpha) \log \theta_k^j \quad (33)$$

and

$$\log \theta_{\text{add-right}}^j := \sin(\alpha) \log \theta_p^j + \cos(\alpha) \log \theta_k^j \quad (34)$$

respectively, where $\alpha \in [0, \frac{\pi}{2}]$ and θ_p^j is the vector of hyper-parameters currently driving the kernel membership defined by the cluster $[c_p^j, c_{p+1}^j]$. We note that if θ_p^j is distributed as per the prior in Equation (16) then $\theta_{\text{add-left}}^j$ and $\theta_{\text{add-right}}^j$ are i.i.d. distributed as per the foregoing prior. More generally, this elliptical transformation determines the extent to which the new proposal kernel configurations should deviate from the current configuration θ_p^j . α is restricted to $[0, \frac{\pi}{2}]$ so as to give a positive weight to the current vector of hyper-parameters θ_p^j . When $\alpha = 0$, the left hand-side cluster $[c_p^j, c_k^j]$ will fully exploit the current kernel configuration, while the right hand-side cluster $[c_k^j, c_{p+1}^j]$ will use the prior to explore a new set of hyper-parameters. When $\alpha = \frac{\pi}{2}$ the reverse occurs. To preserve symmetry between the left and right hand-side kernel configurations, we choose

$$\alpha = \frac{\pi}{4}. \quad (35)$$

Whenever we choose to delete a change-point, we choose an existing change-point uniformly at random, say c_p^j . Deleting c_p^j would merge the clusters $[c_{p-1}^j, c_p^j]$ and $[c_p^j, c_{p+1}^j]$, where we may have $a^j = c_{p-1}^j$ and/or $b^j = c_{p+1}^j$. We propose as vector of hyper-parameters for the tentative merged cluster $[c_{p-1}^j, c_{p+1}^j]$ the vector $\theta_{\text{del-merged}}^j$ satisfying:

$$\log \theta_{\text{del-merged}}^j = \cos(\alpha) \log \theta_{p-1}^j + \sin(\alpha) \log \theta_p^j, \quad (36)$$

which together with

$$\log \theta_{\text{del}*}^j = -\sin(\alpha) \log \theta_{p-1}^j + \cos(\alpha) \log \theta_p^j, \quad (37)$$

constitute the inverse of the transformation defined by Equations (33) and (34).

Whenever a proposal to add or delete a change-point occurs, the factors L_k^j and M_k^i that would be affected by the change in kernel membership structure are recomputed, and so are the affected coordinates of \mathbf{z} .

This scheme satisfies the reversibility and dimension-matching requirements of Green (1995). Moreover, the absolute value of the Jacobian of the mapping

$$(\log \theta_p^j, \log \theta_k^j) \rightarrow (\log \theta_{\text{add-left}}^j, \log \theta_{\text{add-right}}^j)$$

of the move to add a change-point in $[c_p^j, c_{p+1}^j]$ reads

$$\left| \frac{\partial (\log \theta_{\text{add-left}}^j, \log \theta_{\text{add-right}}^j)}{\partial (\log \theta_p^j, \log \theta_k^j)} \right| = 1. \quad (38)$$

Similarly, the absolute value of the Jacobian of the mapping corresponding to a move to delete change-point c_p^j , namely

$$\begin{aligned} & \left(\log \theta_{p-1}^j, \log \theta_p^j \right) \rightarrow \left(\log \theta_{\text{del-merged}}^j, \log \theta_{\text{del}^*}^j \right), \\ & \text{reads:} \\ & \left| \frac{\partial \left(\log \theta_{\text{del-merged}}^j, \log \theta_{\text{del}^*}^j \right)}{\partial \left(\log \theta_{p-1}^j, \log \theta_p^j \right)} \right| = 1. \end{aligned} \quad (39)$$

Applying the standard result Equation (8) of Green (1995), the acceptance ratio of the move to add a change-point is found to be

$$r_{j+} = \min \left(1, \frac{p(\mathcal{D}|\mathbf{x}, c_+, \theta_+, \mathbf{u}) \lambda[j] (b^j - a^j) p_{\log \theta_+} \left(\log \theta_{\text{add-left}}^j \right) p_{\log \theta_+} \left(\log \theta_{\text{add-right}}^j \right)}{p(\mathcal{D}|\mathbf{x}, c, \theta, \mathbf{u}) \left(1 + \mathbf{n}[j] p_{\log \theta_+} \left(\log \theta_p^j \right) p_{\log \theta_+} \left(\log \theta_c^j \right) \right)} \right) \quad (40)$$

where $p_{\log \theta_+}$ is the prior over log hyper-parameters in the j -th input dimension (as per the prior specification Equation 16), which we recall is i.i.d. centred Gaussian with variance $\rho[j]$, and c_+ and θ_+ denote the proposal new vector of change-points and the corresponding vector of hyper-parameters. The three coloured terms in the acceptance probability are very intuitive. The green term $\frac{p(\mathcal{D}|\mathbf{x}, c_+, \theta_+, \mathbf{u})}{p(\mathcal{D}|\mathbf{x}, c, \theta, \mathbf{u})}$ represents the fit improvement that would occur if the new proposal is accepted.

In the red term $\frac{\lambda[j](b^j - a^j)}{1 + \mathbf{n}[j]}$, $\lambda[j] (b^j - a^j)$ represents the average number of change-points in the j -th input dimension as per the HPP prior, while $1 + \mathbf{n}[j]$ corresponds to the proposal new number of change-points in the j -th dimension, so that the whole red term acts as a complexity regulariser. Finally, the blue term $\frac{p_{\log \theta_+} \left(\log \theta_{\text{add-left}}^j \right) p_{\log \theta_+} \left(\log \theta_{\text{add-right}}^j \right)}{p_{\log \theta_+} \left(\log \theta_p^j \right) p_{\log \theta_+} \left(\log \theta_c^j \right)}$ plays the role of hyper-parameters regulariser.

Similarly, the acceptance ratio of the move to delete change-point c_p^j , thereby changing the number of change-points in the j -th input dimension from $\mathbf{n}[j]$ to $\mathbf{n}[j] - 1$, is found to be

$$r_{j-} = \min \left(1, \frac{p(\mathcal{D}|\mathbf{x}, c_-, \theta_-, \mathbf{u}) \mathbf{n}[j] p_{\log \theta_-} \left(\log \theta_{\text{del-merged}}^j \right) p_{\log \theta_-} \left(\log \theta_{\text{del}^*}^j \right)}{p(\mathcal{D}|\mathbf{x}, c, \theta, \mathbf{u}) \lambda[j] (b^j - a^j) p_{\log \theta_-} \left(\log \theta_{p-1}^j \right) p_{\log \theta_-} \left(\log \theta_c^j \right)} \right), \quad (41)$$

where c_- and θ_- denote the proposal new vector of change-points and the corresponding vector of hyper-parameters. Once more, each coloured term plays the same intuitive role as its counterpart in Equation (40).

Overall resource requirement: The bottleneck of between-models updates is the evaluation of the new likelihoods $p(\mathcal{D}|\mathbf{x}, c_+, \theta_+, \mathbf{u})$ or $p(\mathcal{D}|\mathbf{x}, c_-, \theta_-, \mathbf{u})$, whose resource requirements, which are the same as those of within-models updates, we already discussed.

Algorithm 2 summarises the proposed MCMC sampler.

5.3 Multi-Output Problems

Although we have restricted ourselves to cases where the likelihood model depends on a single real-valued function for brevity and to ease notations, cases where the likelihood depends on vector-valued functions, or equivalently multiple real-valued functions, present no additional theoretical or

Algorithm 2 MCMC sampler for nonparametric Bayesian inference of a real-valued latent function under a string GP prior

Inputs: Likelihood model $p(\mathcal{D}|\mathbf{f}, \mathbf{u})$, link function ϕ , training data \mathcal{D} , test inputs, type of unconditional kernel, prior parameters α, β, ρ .

Outputs: Posterior samples of the values of the latent function at training and test inputs \mathbf{f} and \mathbf{f}^* , and the corresponding gradients $\nabla \mathbf{f}$ and $\nabla \mathbf{f}^*$.

Step 0: Set $n = 0$ and $c = \emptyset$, and sample $\theta, \lambda, \mathbf{x}, \mathbf{u}$ from their priors.

repeat

Step 1: Perform a within-model update.

1.1: Update each $\lambda[j]$ by sampling from the Gamma distribution in Equation (26).

1.2: Update \mathbf{u} , the vector of other likelihood parameters, if any, using Metropolis-Hastings (MH) with proposal q and acceptance ratio Equation (27) or by sampling directly from the posterior when $p(\mathbf{u})$ is conjugate to the likelihood model.

1.3: Update θ , using elliptical slice sampling (ESS) with target distribution Equation (31), and record the newly computed factors $\{L_k^j, M_k^j\}$ that relate \mathbf{z} to its whitened representation \mathbf{x} .

1.4: Update \mathbf{x} using ESS with target distribution Equation (29).

1.5: Update change-point positions \mathbf{c} sequentially using MH, drawing a proposal update for c_p^j uniformly at random on $\{c_{p-1}^j, c_{p+1}^j\}$, and accepting the update with probability $r_{c_p^j}$ (defined Equation 28). On accept, update the factors $\{L_k^j, M_k^j\}$.

Step 2: Perform a between-models update.

2.1: Sample a dimension to update, say j , uniformly at random.

2.2: Consider adding or deleting a change-point

if $\mathbf{n}[j] = 0$ **then**

Randomly choose to add a change-point with probability $1/2$.

if we should consider adding a change-point **then**

Construct proposals to update following Section 5.2.6.

Accept proposals with probability r_+^j (see Equation 40).

end if

else

Randomly choose to add/delete a change-point with probability $1/3$.

if we should consider adding a change-point **then**

Construct proposals to update following Section 5.2.6.

Accept proposals with probability r_+^j (see Equation 40).

else if we should consider deleting a change-point **then**

Construct proposals to update following Section 5.2.6.

Accept proposals with probability r_-^j (see Equation 41).

else

Continue.

end if

end if

Step 3: Compute $\mathbf{f}, \nabla \mathbf{f}$ and $\nabla \mathbf{f}^*$, first recovering \mathbf{z} from \mathbf{x} , and then recalling that $f(x) =$

$$\phi \left(z_{x[1]}, \dots, z_{x[d]} \right) \text{ and } \nabla f(x) = \left(z_{x[1]} \frac{\partial \phi}{\partial x[1]}(x), \dots, z_{x[d]} \frac{\partial \phi}{\partial x[d]}(x) \right).$$

until enough samples are generated after mixing.

practical challenge. We may simply put independent *string GP* priors on each of the latent functions. An MCMC sampler almost identical to the one introduced herein may be used to sample from the posterior. All that is required to adapt the proposed MCMC sampler to multi-outputs problems is to redefine \mathbf{z} to include all univariate *derivative string GP* values across input dimensions and across latent functions, perform step 1.1 of Algorithm 2 for each of the latent function, and update step 2.1 so as to sample uniformly at random not only what dimension to update but also what latent function. Previous analyses and derived acceptance ratios remain unchanged. The resource requirements of the resulting multi-outputs MCMC sampler on a problem with K latent functions, N training and test d -dimensional inputs, are the same as those of the MCMC sampler for a single output (Algorithm 2) with N training and test dK -dimensional inputs. The time complexity is $\mathcal{O}(N)$ when dK computing cores are available, $\mathcal{O}(dKN)$ when no distributed computing is available, and the memory requirement becomes $\mathcal{O}(dKN)$.

5.4 Flashback to Small Scale GP Regressions with String GP Kernels

In Section 5.1 we discussed maximum marginal likelihood inference in Bayesian nonparametric regressions under additively separable *string GP* priors, or GP priors with *string GP* covariance functions. We proposed learning the positions of boundary times, conditional on their number, jointly with kernel hyper-parameters and noise variances by maximizing the marginal likelihood using gradient-based techniques. We then suggested learning the number of strings in each input dimension by trading off goodness-of-fit with model simplicity using information criteria such as AIC and BIC. In this section, we propose a fully Bayesian nonparametric alternative.

Let us consider the Gaussian process regression model

$$y_i = f(x_i) + \epsilon_i, \quad f \sim \mathcal{GP}(0, k_{\text{SGP}}(\cdot, \cdot)), \quad \epsilon_i \sim \mathcal{N}(0, \sigma^2), \quad (42)$$

$$x_i \in [a^1, b^1] \times \dots \times [a^d, b^d], \quad y_i, \epsilon_i \in \mathbb{R}, \quad (43)$$

where k_{SGP} is the covariance function of some *string GP* with boundary times $\{a_k^j\}$ and corresponding unconditional kernels $\{k_k^j\}$ in the j -th input dimension. It is worth stressing that we place a GP (not *string GP*) prior on the latent function f , but the covariance function of the GP is a *string GP* covariance function (as discussed in Section 4.2 and as derived in Appendix I). Of course when the *string GP* covariance function k_{SGP} is separably additive, the two functional priors are the same. However, we impose no restriction on the link function of the *string GP* that k_{SGP} is the covariance function of, other than continuous differentiability. To make full Bayesian nonparametric inference, we may place on the boundary times $\{a_k^j\}$ independent homogeneous Poisson process priors, each with intensity λ^j . Similarly to the previous section (Equation 16) our full prior specification of the *string GP* kernel reads

$$\begin{cases} \lambda^j \sim \Gamma(\alpha^j, \beta^j), \\ \{a_k^j\} | \lambda^j \sim \text{HPP}(\lambda^j) \\ \theta_k^j | \{a_k^j\}, \lambda^j \stackrel{\text{i.i.d.}}{\sim} \log \mathcal{N}(0, \rho^j) \\ \forall (j, k) \neq (l, p) \theta_k^j \perp \theta_p^l \end{cases}, \quad (44)$$

where θ_k^j is the vector of hyper-parameters driving the unconditional kernel k_k^j . The method developed in the previous section and the resulting MCMC sampling scheme (Algorithm 2) may be

reused to sample from the posterior over function values, pending the following two changes. First, gradients ∇f and ∇f^* are no longer necessary. Second, we may work with function values (f, f^*) directly (that is in the original as opposed to whitened space). The resulting (Gaussian) distribution of function values (f, f^*) conditional on all other variables is then analytically derived using standard Gaussian identities. Like it is done in vanilla Gaussian process regression, so that the within-model update of (f, f^*) is performed using a single draw from a multivariate Gaussian.

This approach to model complexity learning is advantageous over the information criteria alternative of Section 5.1 in that it scales better with large input-dimensions. Indeed, rather than performing complete maximum marginal likelihood inference a number of times that grows exponentially with the input dimension, the approach of this section alternates between exploring a new combination of numbers of kernel configurations in each input dimension, and exploring function values and kernel hyper-parameters (given their number). That being said, this approach should only be considered as an alternative to commonly used kernels for *small scale* regression problems to enable the learning of local patterns. Crucially, it scales as poorly as the *standard GP paradigm*, and Algorithm 2 should be preferred for large scale problems.

6. Experiments

We now move on to presenting empirical evidence for the efficacy of *string GPs* in coping with local patterns in data sets, and in doing so in a scalable manner. Firstly we consider maximum marginal likelihood inference on two small scale problems exhibiting local patterns. We begin with a toy experiment that illustrates the limitations of the *standard GP paradigm* in extrapolating and interpolating simple local periodic patterns. Then, we move on to comparing the accuracy of Bayesian nonparametric regression under a *string GP* prior to that of the standard Gaussian process regression model and existing mixture-of-experts alternatives on the motorcycle data set of Silverman (1985), commonly used for the local patterns and heteroskedasticity it exhibits. Finally, we illustrate the performance of the previously derived MCMC sampler on two large scale Bayesian inference problems, namely the prediction of U.S. commercial airline arrival delays of Hensman et al. (2013) and a new large scale dynamic asset allocation problem.

6.1 Extrapolation and Interpolation of Synthetic Local Patterns

In our first experiment, we illustrate a limitation of the standard approach consisting of postulating a global covariance structure on the domain, namely that this approach might result in unwanted global extrapolation of local patterns, and we show that this limitation is addressed by the *string GP paradigm*. To this aim, we use 2 toy regression problems. We consider the following functions:

$$f_0(t) = \begin{cases} \sin(60\pi t) & t \in [0, 0.5] \\ \frac{1}{2} \sin(16\pi t) & t \in [0.5, 1] \end{cases}, \quad f_1(t) = \begin{cases} \sin(16\pi t) & t \in [0, 0.5] \\ \frac{1}{2} \sin(32\pi t) & t \in [0.5, 1] \end{cases}. \quad (45)$$

f_0 (resp. f_1) undergoes a sharp (resp. mild) change in frequency and amplitude at $t = 0.5$. We consider using their restrictions to $[0.25, 0.75]$ for training. We sample those restrictions with frequency 300, and we would like to extrapolate the functions to the rest of their domains using Bayesian non-parametric regression.

We compare marginal likelihood *string GP* regression models, as described in Section 5.1, to vanilla GP regression models using popular and expressive kernels. All *string GP* models have two strings and the partition is learned in the marginal likelihood maximisation. Figure 5 illustrates

plots of the posterior means for each kernel used, and Table 2 compares predictive errors. Overall, it can be noted that the *string GP kernel* with the periodic kernel (MacKay (1998)) as building block outperforms competing kernels, including the expressive spectral mixture kernel

$$k_{SM}(\tau) = \sum_{k=1}^K \sigma_k^2 \exp(-2\pi^2 \tau^2 \gamma_k^2) \cos(2\pi \tau \mu_k)$$

of Wilson and Adams (2013) with $K = 5$ mixture components.¹²

The comparison between the spectral mixture kernel and the string spectral mixture kernel is of particular interest, since spectral mixture kernels are pointwise dense in the family of stationary kernels, and thus can be regarded as flexible enough for learning *stationary* kernels from the data. In our experiment, the *string spectral mixture kernel* with a single mixture component per string significantly outperforms the spectral mixture kernel with 5 mixture components. This intuitively can be attributed to the fact that, regardless of the number of mixture components in the spectral mixture kernel, the learned kernel must account for both types of patterns present in each training data set. Hence, each local extrapolation on each side of 0.5 will attempt to make use of both amplitudes and both frequencies evidenced in the corresponding training data set, and will struggle to recover the true local sine function. We would expect that the performance of the spectral mixture kernel in this experiment will not improve drastically as the number of mixture components increases. However, under a *string GP* prior, the left and right hand side strings are independent conditional on the (unknown) boundary conditions. Therefore, when the *string GP* domain partition occurs at time 0.5, the training data set on $[0.25, 0.5]$ influences the hyper-parameters of the string to the right of 0.5 only to the extent that both strings should agree on the value of the latent function and its derivative at 0.5. To see why this is a weaker condition, we consider the family of pair of functions:

$$(\alpha\omega_1 \sin(\omega_2 t), \alpha\omega_2 \sin(\omega_1 t)), \quad \omega_i = 2\pi k_i, \quad k_i \in \mathbb{N}, \quad \alpha \in \mathbb{R}.$$

Such functions always have the same value and derivative at 0.5, regardless of their frequencies, and they are plausible GP paths under a spectral mixture kernel with one single mixture component ($\mu_k = k_i$ and $\gamma_k \ll 1$), and under a periodic kernel. As such it is not surprising that extrapolation under a string spectral mixture kernel or a string periodic kernel should perform well.

To further illustrate that *string GPs* are able to learn local patterns that GPs with commonly used and expressive kernels can't, we consider interpolating two bivariate functions f_2 and f_3 that exhibit local patterns. The functions are defined as:

$$\forall u, v \in [0.0, 1.0] \quad f_2(u, v) = f_0(u)f_1(v), \quad f_3(u, v) = \sqrt{f_0(u)^2 + f_1(v)^2}. \quad (46)$$

We consider recovering the original functions as the posterior mean of a GP regression model trained on $[0.0, 0.4] \cup [0.6, 1.0] \times [0.0, 0.4] \cup [0.6, 1.0]$. Each bivariate kernel used is a product of two univariate kernels in the same family, and we used standard Kronecker techniques to speed-up inference (see Saatchi, 2011, p.134). The univariate kernels we consider are the same as previously. Each univariate *string GP* kernel has one change-point (two strings) whose position is learned by maximum marginal likelihood. Results are illustrated in Figures 6 and 7. Once again it can be seen that unlike any competing kernel, the product of string periodic kernels recover both functions almost perfectly. In particular, it is impressive to see that, despite f_3 not being a separable function,

a product of string periodic kernels recovered it almost perfectly. The interpolations performed by the spectral mixture kernel (see Figures 6 and 7) provide further evidence for our previously developed narrative: the spectral mixture kernel tries to blend all local patterns found in the training data during the interpolation. The periodic kernel learns a single global frequency characteristic of the whole data set, ignoring local patterns, while the squared exponential, Matérn and rational quadratic kernels merely attempt to perform interpolation by smoothing.

Although we used synthetic data to ease illustrating our argument, it is reasonable to expect that in real-life problems the bigger the data set, the more likely there might be local patterns that should not be interpreted as noise and yet are not indicative of the data set as whole.

12. The sparse spectrum kernel of Lazaro-Gredilla et al. (2010) can be thought of as the special case $\gamma_k \ll 1$.

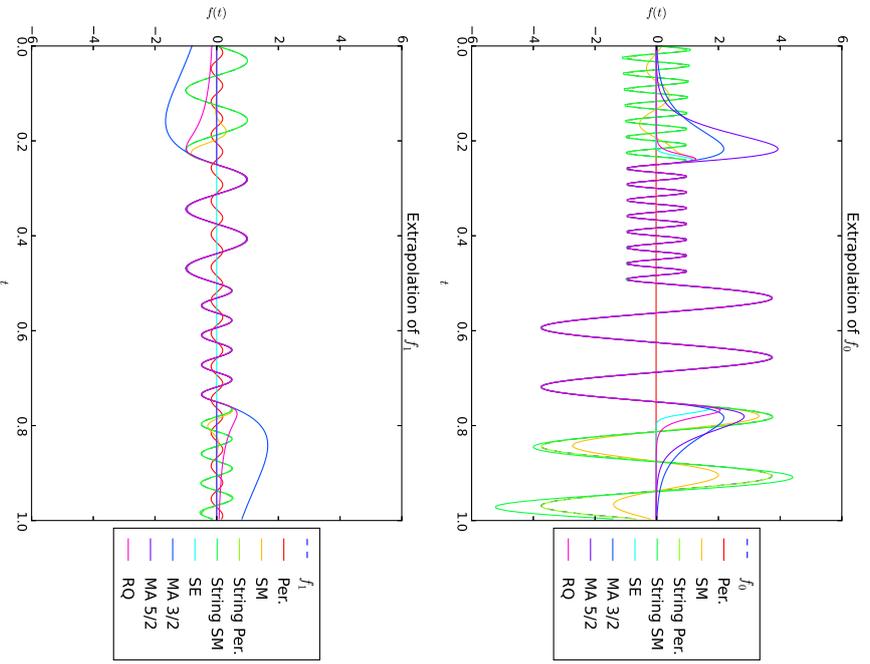

Figure 5: Extrapolation of two functions f_0 and f_1 through Bayesian nonparametric regression under *string GP* priors and vanilla GP priors with popular and expressive kernels. Each model is trained on $[0.25, 0.5]$ and extrapolates to $[0, 1.0]$.

Kernel	Absolute Error		Squared Error	
	f_0	f_1	f_0	f_1
Squared exponential	1.44 ± 2.40	0.48 ± 0.58	3.50 ± 9.20	0.31 ± 0.64
Rational quadratic	1.39 ± 2.31	0.51 ± 0.83	3.28 ± 8.79	0.43 ± 1.15
Matérn 3/2	1.63 ± 2.53	1.26 ± 1.37	4.26 ± 11.07	2.06 ± 3.55
Matérn 5/2	1.75 ± 2.77	0.48 ± 0.58	5.00 ± 12.18	0.31 ± 0.64
Periodic	1.51 ± 2.45	0.53 ± 0.60	3.79 ± 9.62	0.37 ± 0.72
Spec. Mix. (5 comp.)	0.75 ± 1.15	0.39 ± 0.57	0.94 ± 2.46	0.24 ± 0.58
String Spec. Mix. (2 strings, 1 comp.)	0.23 ± 0.84	0.01 ± 0.03	0.21 ± 1.07	0.00 ± 0.00
String Periodic	0.02 ± 0.02	0.00 ± 0.01	0.00 ± 0.00	0.00 ± 0.00

Table 2: Predictive accuracies in the extrapolation of the two functions f_0 and f_1 of Section 6.1 through Bayesian nonparametric regression under *string GP* priors and vanilla GP priors with popular and expressive kernels. Each model is trained on $[0.25, 0.5]$ and extrapolates to $[0, 1.0]$. The predictive errors are reported as average ± 2 standard deviations.

6.2 Small Scale Heteroskedastic Regression

In our second experiment, we consider illustrating the advantage of the *string GP paradigm* over the *standard GP paradigm*, but also over the alternatives of Kim et al. (2005), Gramacy and Lee (2008), Tresp (2000) and Deisenroth and Ng (2015) that consist of considering independent GP experts on disjoint parts of the domain or handling disjoint subsets of the data. Using the motorcycle data set of Silverman (1985), commonly used for the local patterns and heteroskedasticity it exhibits, we show that our approach outperforms the aforementioned competing alternatives, thereby providing empirical evidence that the collaboration between consecutive GP experts introduced in the *string GP paradigm* vastly improves predictive accuracy and certainty in regression problems with local patterns. We also illustrate learning of the derivative of the latent function, solely from noisy measurements of the latent function.

The observations consist of accelerometer readings taken through time in an experiment on the efficacy of crash helmets. It can be seen at a glance in Figure 8 that the data set exhibits roughly 4 regimes. Firstly, between 0ms and 15ms the acceleration was negligible. Secondly, the impact slowed down the helmet, resulting in a sharp deceleration between 15ms and 28ms. Thirdly, the helmet seems to have bounced back between 28ms and 32ms, before it finally gradually slowed down and came to a stop between 32ms and 60ms. It can also be noted that the measurement noise seems to have been higher in the second half of the experiment.

We ran 50 independent random experiments, leaving out 5 points selected uniformly at random from the data set for prediction, the rest being used for training. The models we considered include the vanilla GP regression model, the *string GP* regression model with marginal maximum likelihood inference as described in Section 5.1, mixtures of independent GP experts acting on disjoint subsets of the data both for training and testing, the Bayesian committee machine (Tresp (2000)), and the robust Bayesian committee machine (Deisenroth and Ng (2015)). We considered *string GPs* with 4 and 6 strings whose boundary times are learned as part of the maximum likelihood inference. For consistency, we used the resulting partitions of the domain to define the independent experts in the competing alternatives we considered. The Matérn 3/2 kernel was used throughout. The results are reported in Table 3. To gauge the ability of each model to capture the physics of the helmets crash experiment, we have also trained all models with all data points. The results are illustrated in Figures 8 and 9.

It can be seen at a glance from Figure 9 that mixtures of independent GP experts are inappropriate for this experiment as i) the resulting posterior means exhibit discontinuities (for instance at $t = 30$ ms and $t = 40$ ms) that are inconsistent with the physics of the underlying phenomenon, and ii) they overfit the data towards the end. The foregoing discontinuities do not come as a surprise as each GP regression expert acts on a specific subset of the domain that is disjoint from the ones used by the other experts, both for training and prediction. Thus, there is no guarantee of consistency between expert predictions at the boundaries of the domain partition. Another perspective to this observation is found in noting that postulating independent GP experts, each acting on an element of a partition of the domain, is equivalent to putting as prior on the whole function a stochastic process that is discontinuous at the boundaries of the partition. Thus, the posterior stochastic process should not be expected to be continuous at the boundaries of the domain either.

This discontinuity issue is addressed by the Bayesian committee machine (BCM) and the robust Bayesian committee machine (rBCM) because, despite each independent expert being trained on a disjoint subset of the data, each expert is tasked with making predictions about all test inputs, not

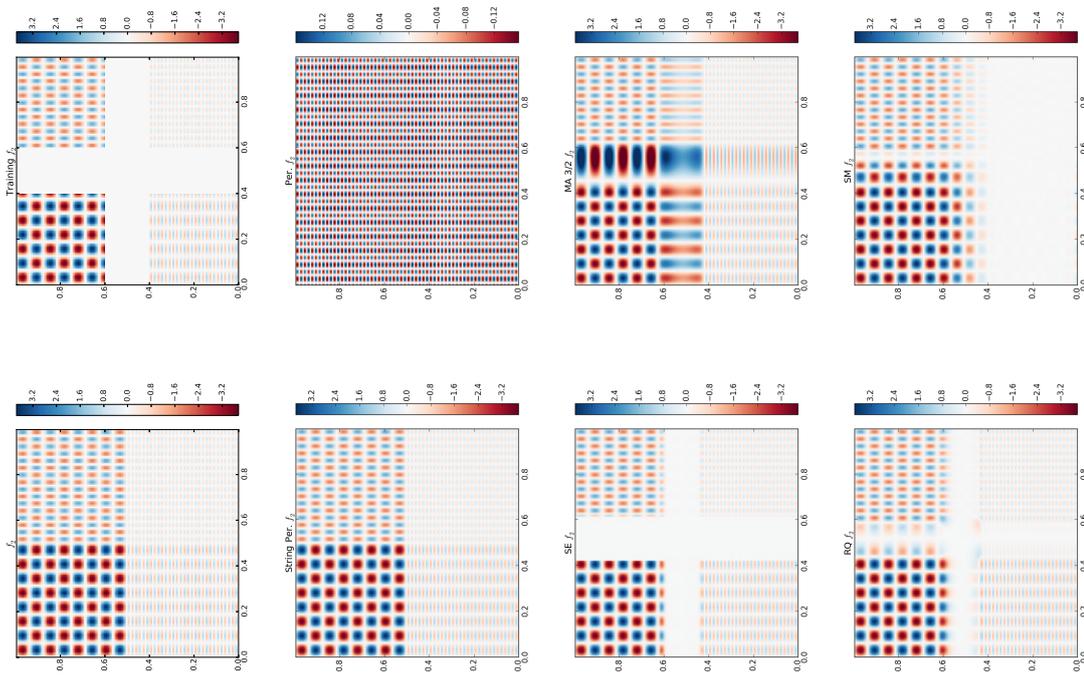

Figure 6: Extrapolation of a synthetic function f_2 (top left corner), cropped in the middle for training (top right corner), using *string GP* regression and vanilla GP regression with various popular and expressive kernels.

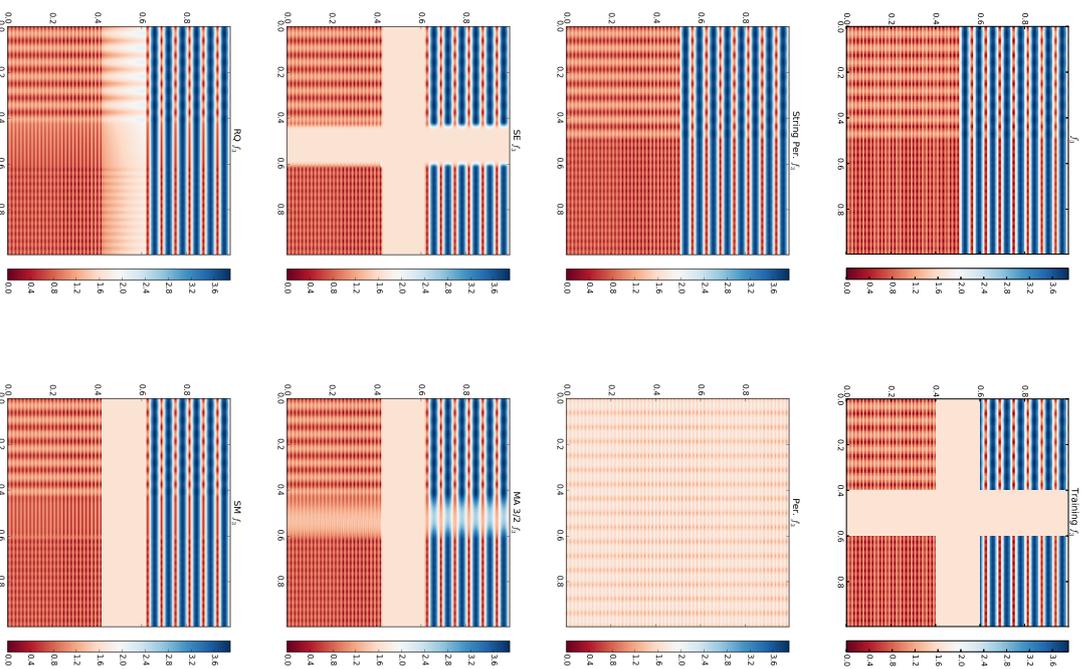

Figure 7: Extrapolation of a synthetic function f_3 (top left corner), cropped in the middle for training (top right corner), using *string GP* regression and vanilla GP regression with various popular and expressive kernels.

just the ones that fall into its input subspace. Each GP expert prediction is therefore continuous on the whole input domain,¹³ and the linear weighting schemes operated by the BCM and the rBCM on expert predictions to construct the overall predictive mean preserve continuity. However, we found that the BCM and the rBCM suffer from three pitfalls. First, we found them to be less accurate than any other alternative out-of-sample on this data set (see Table 3). Second, their predictions of latent function values are overly uncertain. This might be due to the fact that, each GP expert being trained only with training samples that lie on its input subspace, its predictions about test inputs that lie farther away from its input subspace will typically be much more uncertain, so that, despite the weighting scheme of the Bayesian committee machine putting more mass on ‘confident’ experts, overall the posterior variance over latent function values might still be much higher than in the *standard GP paradigm* for instance. This is well illustrated by both the last column of Table 3 and the BCM and rBCM plots in Figure 9. On the contrary, no *string GP* model suffers from this excess uncertainty problem. Third, the posterior means of the BCM, the rBCM and the vanilla GP regression exhibit oscillations towards the end ($t > 40$ ms) that are inconsistent with the experimental setup; the increases in acceleration as the helmet slows down suggested by these posterior means would require an additional source of energy after the bounce.

In addition to being more accurate and more certain about predictions than vanilla GP regression, the BCM and the rBCM (see Table 3), *string GP* regressions yield posterior mean acceleration profiles that are more consistent with the physics of the experiment: steady speed prior to the shock, followed by a deceleration resulting from the shock, a brief acceleration resulting from the change in direction after the bounce, and finally a smooth slow down due to the dissipation of kinetic energy. Moreover, unlike the vanilla GP regression, the BCM and the BCM, *string GP* regressions yield smaller posterior variances towards the beginning and the end of the experiment than in the middle, which is consistent with the fact that the operator would be less uncertain about the acceleration at the beginning and at the end of the experiment—one would indeed expect the acceleration to be null at the beginning and at the end of the experiment. This desirable property can be attributed to the heteroskedasticity of the noise structure in the *string GP* regression model.

We also learned the derivative of the latent acceleration with respect to time, purely from noisy acceleration measurements using the joint law of a *string GP* and its derivative (Theorem 2). This is illustrated in Figure 8.

¹³. So long as the functional prior is continuous, which is the case here.

		Prediction	
		Absolute Error	Squared Error
		Log. lik.	Pred. Std
Training			
String GP (4 strings)	-388.36 ± 0.36	15.70 ± 1.05	0.70/2.25/3.39

rBCM with 4 GPs	-419.08 ± 0.30	17.29 ± 1.11	546.95 ± 61.21
rBCM with 6 GPs	-422.15 ± 0.30	16.79 ± 1.12	542.95 ± 61.95

Table 3: Performance comparison between *string GPs*, vanilla GPs, mixture of independent GPs, the Bayesian committee machine (Tresp (2000)) and the robust Bayesian committee machine (Deisenroth and Ng (2015)) on the motorcycle data set of Silverman (1985). The Matérn 3/2 kernel was used throughout. The domain partitions were learned in the *string GP* experiments by maximum likelihood. The learned partitions were then reused to allocate data between GP experts in other models. 50 random runs were performed, each run leaving 5 data points out for testing and using the rest for training. All results (except for predictive standard deviations) are reported as average over the 50 runs ± standard error. The last column contains the minimum, average and maximum of the predictive standard deviation of the values of the latent (noise-free) function at all test points across random runs.

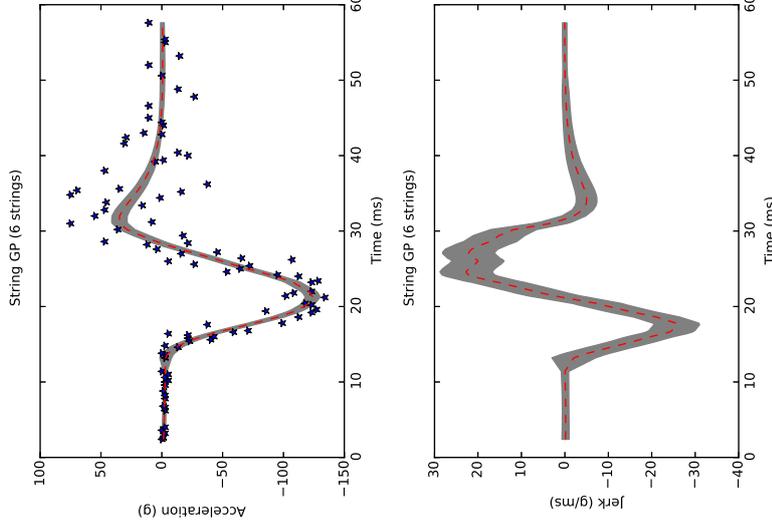

Figure 8: Posterior mean ± 2 predictive standard deviations on the motorcycle data set (see Silverman, 1985), under a Matérn 3/2 derivative *string GP* prior with 6 learned strings. The top figure shows the noisy accelerations measurements and the learned latent function. The bottom function illustrates the derivative of the acceleration with respect to time learned from noisy acceleration samples. Posterior credible bands are over the latent functions rather than noisy measurements, and as such they do not include the measurement noise.

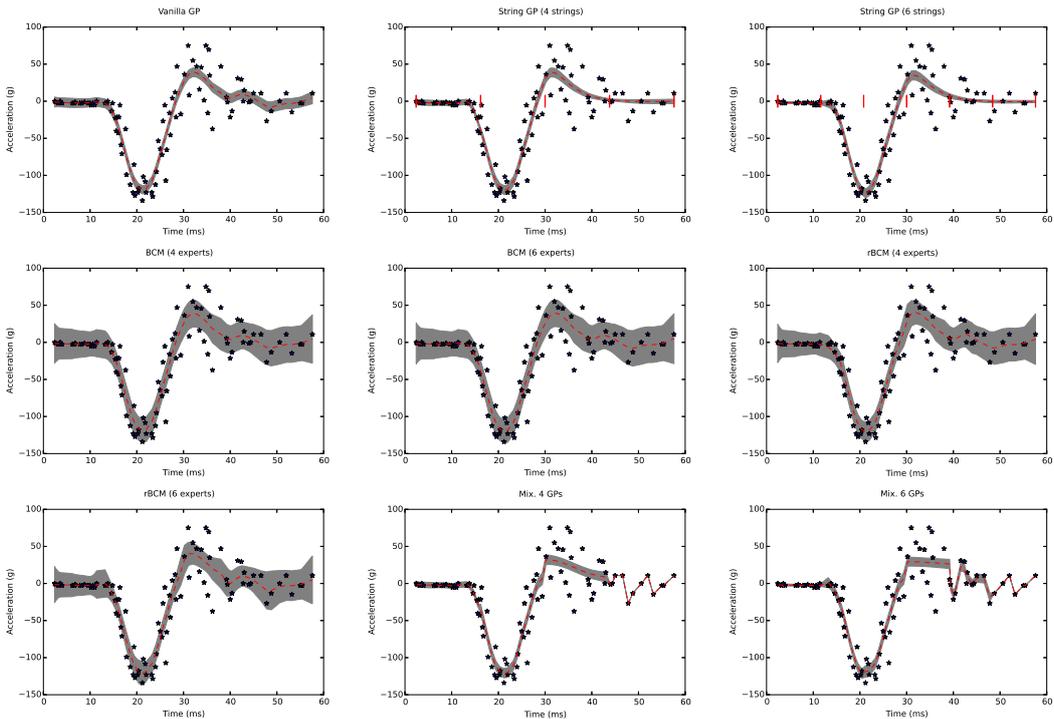

Figure 9: Bayesian nonparametric regressions on the motorcycle data set of Silverman (1985). Models compared are *string GP* regression, vanilla GP regression, mixture of independent GP regression experts on a partition of the domain, the Bayesian committee machine (BCM) and the robust Bayesian committee machine (rBCM). Domain partitions were learned during *string GP* maximum likelihood inference (red vertical bars), and reused in other experiments. Blue stars are noisy samples, red lines are posterior means of the latent function and grey bands correspond to ± 2 predictive standard deviations of the (noise-free) latent function about its posterior mean.

6.3 Large Scale Regression

To illustrate how our approach fares against competing alternatives on a standard large scale problem, we consider predicting arrival delays of commercial flights in the USA in 2008 as studied by Hensman et al. (2013). We choose the same covariates as in Hensman et al. (2013), namely the age of the aircraft (number of years since deployment), distance that needs to be covered, airline, departure time, arrival time, day of the week, day of the month and month. Unlike Hensman et al. (2013) who only considered commercial flights between January 2008 and April 2008, we consider commercial throughout the whole year, for a total of 5.93 million records. In addition to the whole data set, we also consider subsets so as to empirically illustrate the sensitivity of computational time to the number of samples. Selected subsets consist of 10,000, 100,000 and 1,000,000 records selected uniformly at random. For each data set, we use $2/3$ of the records selected uniformly at random for training and we use the remaining $1/3$ for testing. In order to level the playing field between stationary and nonstationary approaches, we normalize training and testing data sets.¹⁴ As competing alternatives to *string GPs* we consider the SVIGP of Hensman et al. (2013), the Bayesian committee machines (BCM) of Tresp (2000), and the robust Bayesian committee machines (rBCM) of Deisenroth and Ng (2015).

As previously discussed the prediction scheme operated by the BCM is Kolmogorov-inconsistent in that the resulting predictive distributions are not consistent by marginalization.¹⁵ Moreover, jointly predicting all function values by using the set of all test inputs as query set, as originally suggested in Tresp (2000), would be impractical in this experiment given that the BCM requires inverting a covariance matrix of the size of the query set which, considering the numbers of test inputs in this experiment (which we recall can be as high as 1.97 million), would be computationally intractable. To circumvent this problem we use the BCM algorithm to query one test input at a time. This approach is in-line with that adopted by Deisenroth and Ng (2015), where the authors did not address determining joint predictive distributions over multiple latent function values. For the BCM and rBCM, the number of experts is chosen so that each expert processes 200 training points. For SVIGP we use the implementation made available by the The GPy authors (2012–2016), and we use the same configuration as in Hensman et al. (2013). As for *string GPs*, we use the symmetric sum as link function, and we run two types of experiments, one allowing for inference of change-points (String GP), and the other enforcing a single kernel configuration per input dimension (String GP*). The parameters α and β are chosen so that the prior mean number of change-points in each input dimension is 5% of the number of distinct training and testing values in that input dimension, and so that the prior variance of the foregoing number of change-points is 50 times the prior mean—the aim is to be uninformative about the number of change-points. We run 10,000 iterations of our R1-MCMC sampler and discarded the first 5,000 as ‘burn-in’. After burn-in we record the states of the Markov chains for analysis using a 1-in-100 thinning rate. Predictive accuracies are reported in Table 4 and CPU time requirements¹⁶ are illustrated in Figure 10. We stress that all experiments were run on a multi-core machine, and that we prefer using the cumulative CPU clock resource

14. More precisely, we subtract from every feature sample (both in-sample and out-of-sample) the in-sample mean of the feature and we divide the result by the in-sample standard deviation of the feature.

15. For instance the predictive distribution of the value of the latent function at a test input x_1 , namely $f(x_1)$, obtained by using $\{x_1\}$ as set of test inputs in the BCM, differs from the predictive distribution obtained by using $\{x_1, x_2\}$ as set of test inputs in the BCM and then marginalising with respect to the second input x_2 .

16. We define CPU time as the cumulative CPU clock resource usage of the whole experiment (training and testing), across child processes and threads, and across CPU cores.

as time complexity metric, instead of wall-clock time, so as to be agnostic to the number of CPU cores used in the experiments. This metric has the merit of illustrating how the number of CPU cores required grows as a function of the number of training samples for a fixed/desired wall-clock execution time, but also how the wall-clock execution time grows as a function of the number of training samples for a given number of available CPU cores.

The BCM and the rBCM perform the worst in this experiment both in terms of predictive accuracy (Table 4) and total CPU time (Figure 10). The poor scalability of the BCM and the rBCM is primarily due to the testing phase. Indeed, if we denote M the total number of experts, then $M = \lceil \frac{N}{300} \rceil$, as each expert processes 200 training points, of which there are $\frac{2}{3}N$. In the prediction phase, each expert is required to make predictions about all $\frac{1}{3}N$ test inputs, which requires evaluating M products of an $\frac{1}{3}N \times 200$ matrix with a 200×200 matrix, which results in a total CPU time requirement that grows in $\mathcal{O}(M \frac{1}{3} N 200^2)$, which is the same as $\mathcal{O}(N^2)$. Given that training CPU time grows linearly in N the cumulative training and testing CPU time grows quadratically in N . This is well illustrated in Figure 10, where it can be seen that the slopes of total CPU time profiles of the BCM and the rBCM in log-log scale are approximately 2. The airline delays data set was also considered by Deisenroth and Ng (2015), but the authors restricted themselves to a fixed size of the test set of 100,000 points. However, this limitation might be restrictive as in many ‘smoothing’ applications, the test data set can be as large as the training data set—neither the BCM nor the rBCM would be sufficiently scalable in such applications.

As for SVIGP, although it was slightly more accurate than *string GPs* on this data set, it can be noted from Figure 10 that *string GPs* required 10 times less CPU resources. In fact we were unable to run the experiment on the full data set with SVIGP—we gave up after 500 CPU hours, or more than a couple of weeks wall-clock time given that the GPy implementation of SVIGP makes little use of multiple cores. As a comparison, the full experiment took 91.0 hours total CPU time (≈ 15 hours wall-clock time on our 8 cores machine) when change-points were inferred and 83.11 hours total CPU time (≈ 14 hours wall-clock time on our 8 cores machine) when change-points were not inferred. Another advantage of additively separable *string GPs* over GPs, and subsequently over SVIGP, is that they are more interpretable. Indeed, one can determine at a glance from the learned posterior mean *string GPs* of Figure 11 the effect of each of the 8 covariates considered on arrival delays. It turns out that the three most informative factors in predicting arrival delays are departure time, distance and arrival time, while the age of the aircraft, the day of the week and the day of the month seem to have little to no effect. Finally, posterior distributions of the number of change-points are illustrated in Figure 12, and posterior distributions of the locations of change-points are illustrated in Figure 13.

N	String GP	String GP*	BCM	rBCM	SVIGP
10,000	1.03 ± 0.10	1.06 ± 0.10	1.06 ± 0.10	1.06 ± 0.10	0.90 ± 0.09
100,000	0.93 ± 0.03	0.96 ± 0.03	1.66 ± 0.03	1.04 ± 0.04	0.88 ± 0.03
1,000,000	0.93 ± 0.01	0.92 ± 0.01	N/A	N/A	0.82 ± 0.01
5,929,413	0.90 ± 0.01	0.93 ± 0.01	N/A	N/A	N/A

Table 4: Predictive mean squared errors (MSEs) \pm one standard error on the airline arrival delays experiment. Squared errors are expressed as fraction of the sample variance of airline arrival delays, and hence are unitless. With this normalisation, a MSE of 1.00 is as good as using the training mean arrival delays as predictor. The * in String GP* indicates that inference was performed without allowing for change-points. N/A entries correspond to experiments that were not over after 500 CPU hours.

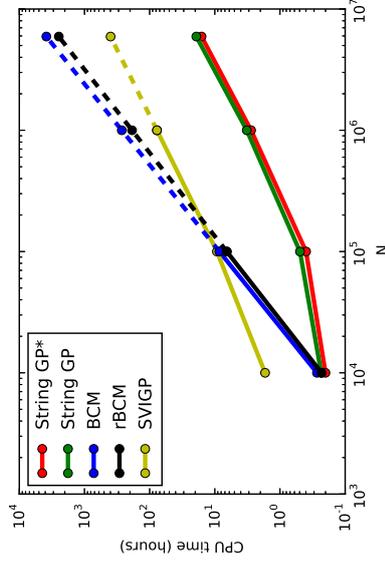

Figure 10: Total CPU time (training and testing) taken by various regression approaches on the airline delays data set as a function of the size of the subset considered, in log-log scale. The experimental setup is described in Section 6.3. The CPU time reflects actual CPU clock resource usage in each experiment, and is therefore agnostic to the number of CPU cores used. It can be regarded as the wall-clock time the experiment would have taken to complete on a single-core computer (with the same CPU frequency). Dashed lines are extrapolated values, and correspond to experiments that did not complete after 500 hours of CPU time.

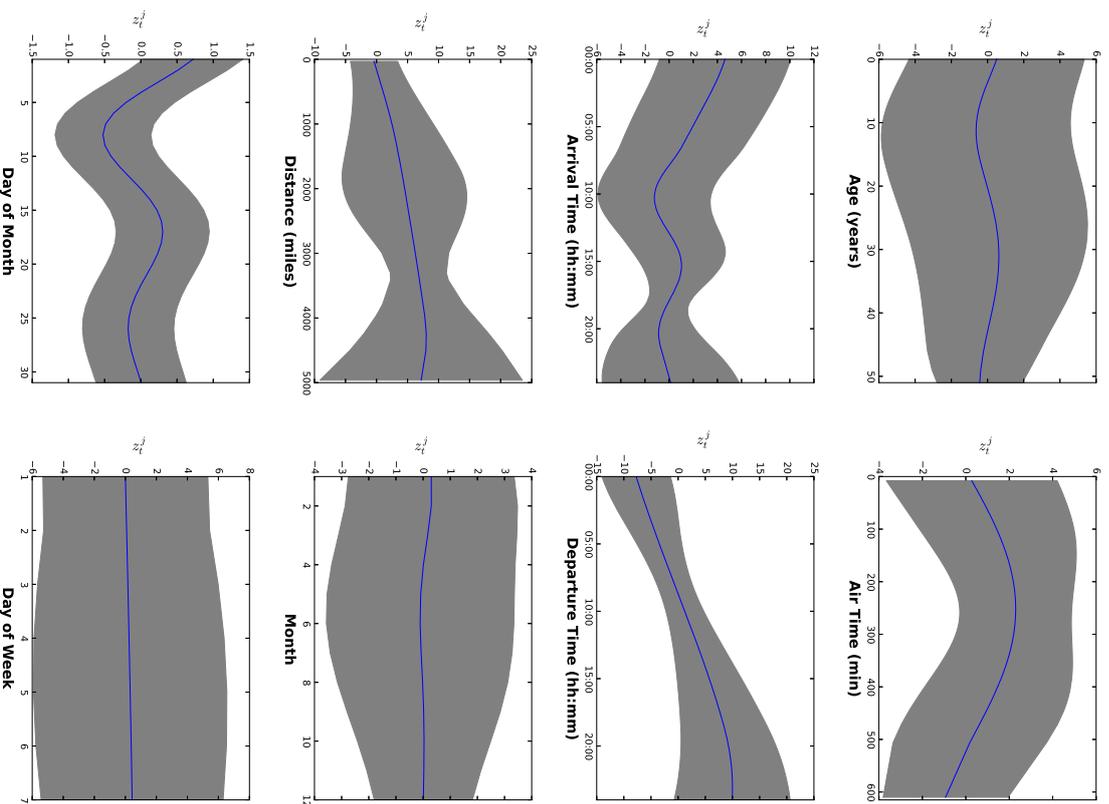

Figure 11: Posterior mean \pm one posterior standard deviation of univariate *string GPs* in the airline delays experiment of Section 6.3. Change-points were automatically inferred in this experiment

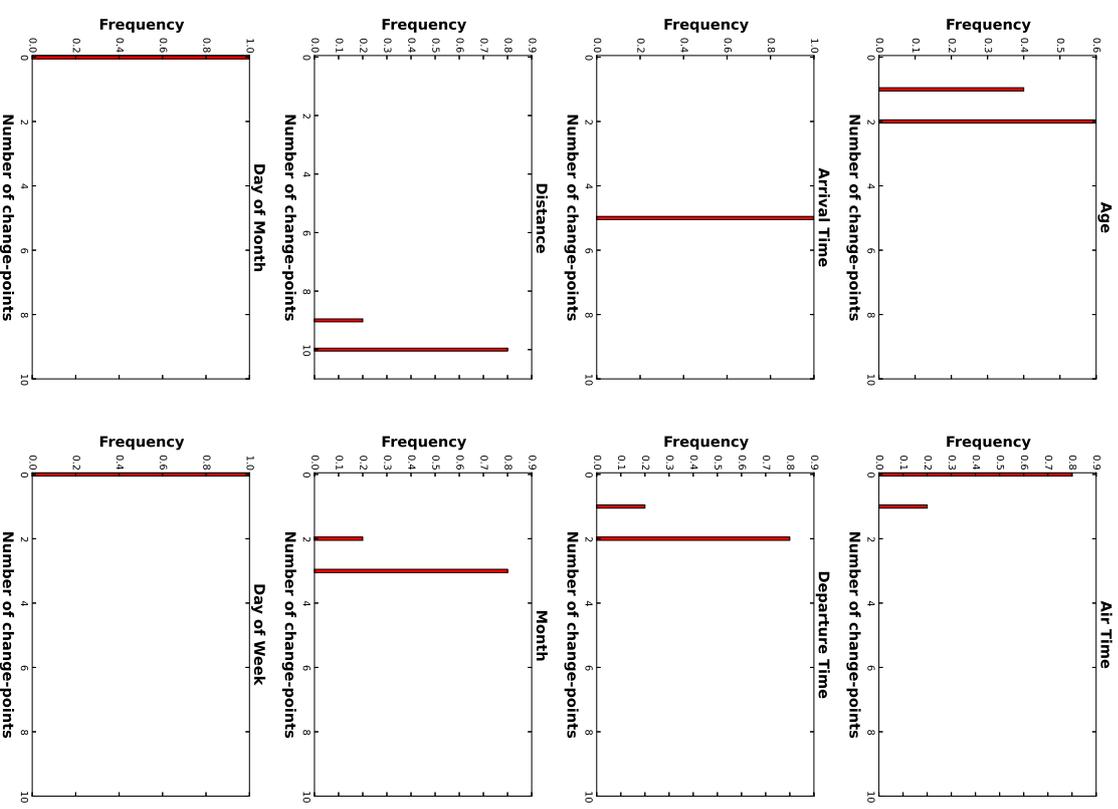

Figure 12: Posterior distributions of the numbers of change-points in each input dimension in the airline delays experiment of Section 6.3.

6.4 Large Scale Dynamic Asset Allocation

An important feature of our proposed RJ-MCMC sampler (Algorithm 2) is that, unlike the BCM, the rBCM and SVIGP, which are restricted to Bayesian nonparametric regression and classification, Algorithm 2 is agnostic with regard to the likelihood model, so long as it takes the form $p(D|\mathbf{u})$. Thus, it may be used as is on a wide variety of problems that go beyond classification and regression. In this experiment we aim to illustrate the efficacy of our approach on one such large scale problem in quantitative finance.

6.4.1 BACKGROUND

Let $(x_i(t))_{t>0}$ for $i = 1, \dots, n$ be n stock price processes. Let $(X_i(t))_{t>0}$ for $i = 1, \dots, n$ denote the market capitalisation processes, that is $X_i(t) = n_i(t)x_i(t)$ where $n_i(t)$ is the number of shares in company i trading in the market at time t . We call long-only portfolio any vector-valued stochastic process $\pi = (\pi_1, \dots, \pi_n)$ taking value on the unit simplex on \mathbb{R}^n , that is

$$\forall i, t, \pi_i(t) \geq 0 \text{ and } \sum_{i=1}^n \pi_i(t) = 1.$$

Each process π_i represents the proportion of an investor's wealth invested in (holding) shares in asset i . An example long-only portfolio is the market portfolio $\mu = (\mu_1, \dots, \mu_n)$ where

$$\mu_i(t) = \frac{X_i(t)}{X_1(t) + \dots + X_n(t)} \tag{47}$$

is the market weight of company i at time t , that is its size relative to the total market size (or that of the universe of stocks considered). The market portfolio is very important to practitioners as it is often perceived not to be subject to idiosyncracies, but only to systemic risk. It is often used as an indicator of how the stock market (or a specific universe of stocks) performs as a whole. We denote Z_π the value process of a portfolio π with initial capital $Z_\pi(0)$. That is, $Z_\pi(t)$ is the wealth at time t of an investor who had an initial wealth of $Z_\pi(0)$, and dynamically re-allocated all his wealth between the n stocks in our universe up to time t following the continuous-time strategy π .

A mathematical theory has recently emerged, namely *stochastic portfolio theory* (SPT) (see Karatzas and Fernholz, 2009) that studies the stochastic properties of the wealth processes of certain portfolios called *functionally-generated portfolio* under realistic assumptions on the market capitalisation processes $(X_i(t))_{t>0}$. Functionally-generated portfolios are rather specific in that the allocation at time t , namely $(\pi_1(t), \dots, \pi_n(t))$, solely depends on the market weights vector $(\mu_1(t), \dots, \mu_n(t))$. Nonetheless, some functionally-generated portfolios π^* have been found that, under the mild (so-called diversity) condition

$$\exists \mu_{\max}, 0 < \mu_{\max} < 1 \text{ s.t. } \forall i \leq n, t \leq T, \mu_i(t) \leq \mu_{\max}, \tag{48}$$

outperform the market portfolio over the time horizon $[0, T]$ with probability one (see Vervuurt and Karatzas, 2015; Karatzas and Fernholz, 2009). More precisely,

$$\mathbb{P}(Z_{\pi^*}(T) \geq Z_\mu(T)) = 1 \text{ and } \mathbb{P}(Z_{\pi^*}(T) > Z_\mu(T)) > 0. \tag{49}$$

Galvanized by this result, we here consider the inverse problem consisting of learning from historical market data a portfolio whose wealth process has desirable user-specified properties. This

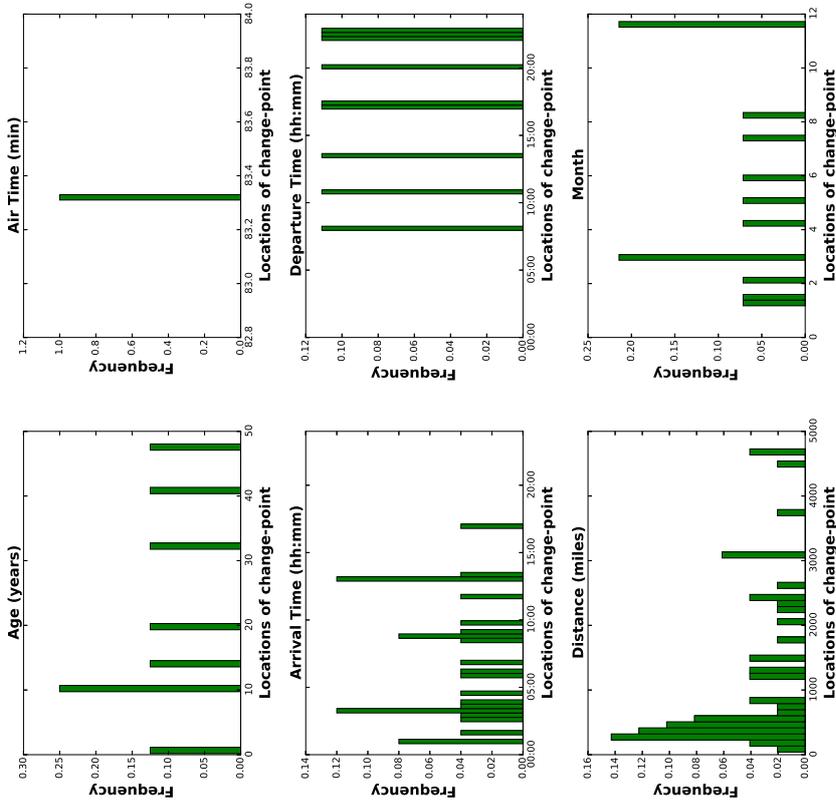

Figure 13: Posterior distributions of the locations of change-points in each input dimension in the airline delays experiment of Section 6.3. Dimensions that were learned to exhibit no change-point have been omitted here.

inverse problem is perhaps more akin to the problems faced by investment professionals: i) their benchmarks depend on the investment vehicles pitched to investors and may vary from one vehicle to another, ii) they have to take into account liquidity costs, and iii) they often find it more valuable to go beyond market weights and leverage multiple company characteristics in their investment strategies.

6.4.2. MODEL CONSTRUCTION

We consider portfolios $\pi^f = (\pi_1^f, \dots, \pi_n^f)$ of the form

$$\pi_i^f(t) = \frac{f(c_i(t))}{f(c_1(t)) + \dots + f(c_n(t))}, \quad (50)$$

where $c_i(t) \in \mathbb{R}^d$ are some quantifiable characteristics of asset i that may be observed in the market at time t , and f is a positive-valued function. Portfolios of this form include all functionally-generated portfolios studied in SPT as a special case.¹⁷ A crucial departure of our approach from the aforementioned type of portfolios is that the market characteristics processes c_i need not be restricted to size-based information, and may contain additional information such as social media sentiments, stock price path-properties, but also characteristics relative to other stocks such as performance relative to the best/worst performing stock last week/month/year etc. We place a mean-zero *string GP* prior on $\log f$. Given some historical data \mathcal{D} corresponding to a training time horizon $[0, T]$, the likelihood model $p(\mathcal{D}|\pi^f)$ is defined by the investment professional and reflects the extent to which applying the investment strategy π^f over the training time horizon would have achieved a specific investment objective. An example investment objective is to achieve a high excess return relative to a benchmark portfolio α

$$U_{\text{ER}}(\pi^f) = \log Z_{\pi^f}(T) - \log Z_{\alpha}(T). \quad (51)$$

α can be the market portfolio (as in SPT) or any stock index. Other risk-adjusted investment objectives may also be used. One such objective is to achieve a high Sharpe-ratio, defined as

$$U_{\text{SR}}(\pi^f) = \frac{\bar{r} \sqrt{252}}{\sqrt{\frac{1}{T} \sum_{t=1}^T (\bar{r}(t) - \bar{r})^2}}, \quad (52)$$

where the time t is in days, $\bar{r}(t) := \log Z_{\pi^f}(t) - \log Z_{\pi^f}(t-1)$ are the daily returns the portfolio π^f and $\bar{r} = \frac{1}{T} \sum_{t=1}^T \bar{r}(t)$ its average daily return. More generally, denoting $\mathcal{U}(\pi^f)$ the performance of the portfolio π^f over the training horizon $[0, T]$ (as per the user-defined investment objective), we may choose as likelihood model a distribution over $\mathcal{U}(\pi^f)$ that reflects what the investment professional considers good and bad performance. For instance, in the case of the excess return relative to a benchmark portfolio or the Sharpe ratio, we may choose $\mathcal{U}(\pi^f)$ to be supported on $]0, +\infty[$ (for instance $\mathcal{U}(\pi^f)$ can be chosen to be Gamma distributed) so as to express that portfolios that do not outperform the benchmark or loose money overall in the training data are not of interest. We may then choose the mean and standard deviation of the Gamma distribution based on our

expectation as to what performance a good candidate portfolio can achieve, and how confident we feel about this expectation. Overall we have,

$$p(\mathcal{D}|\pi^f) = \gamma(\mathcal{U}(\pi^f); \alpha_{\epsilon_1}, \beta_{\epsilon_2}), \quad (53)$$

where $\gamma(\cdot; \alpha, \beta)$ is the probability density function of the Gamma distribution. Noting, from Equation (50) that $\pi_i^f(t)$ only depends on f through its values at $(c_1(t), \dots, c_n(t))$, and assuming that $\mathcal{U}(\pi^f)$ only depends on π^f evaluated at a finite number of times (as it is the case for excess returns and the Sharpe ratio), it follows that $\mathcal{U}(\pi^f)$ only depends on \mathbf{f} , a vector of values of f at a finite number of points. Hence the likelihood model, which we may rewrite as

$$p(\mathcal{D}|\mathbf{f}) = \gamma(\mathcal{U}(\pi_i^f); \alpha_{\epsilon_1}, \beta_{\epsilon_2}), \quad (54)$$

is of the form required by the RL-MCMC sampler previously developed. By sampling from the posterior distribution $p(\mathbf{f}, \mathbf{f}^*, \mathbb{V}\mathbf{f}, \mathbb{V}\mathbf{f}^*|\mathcal{D})$, the hope is to learn a portfolio that did well during the training horizon, to analyse the sensitivity of its investment strategy to the underlying market characteristics through the gradient of f , and to evaluate the learned investment policy on future market conditions.

6.4.3. EXPERIMENTAL SETUP

The universe of stocks was considered for this experiment are the constituents of the S&P 500 index, accounting for changes in constituents over time and corporate events. We used the period 1st January 1990 to 31st December 2004 for training and we tested the learned portfolio during the period 1st January 2005 to 31st December 2014. We rebalanced the portfolio daily, for a total of 2,52 million input points at which the latent function f must be learned. We considered as market characteristics the market weight (CAP), the latest return on asset (ROA) defined as the ratio between the net yearly income and the total assets as per the latest balance sheet of the company known at the time of investment, the previous close-to-close return (PR), the close-to-close return before the previous (PR2), and the S&P long and short term credit rating (LCR and SCR). While the market weight is a company size characteristic, the ROA reflects how well a company performs relative to its size, and we hope that S&P credit ratings will help further discriminate successful companies from others. The close-to-close returns are used to learn possible ‘momentum’ patterns from the data. The data originate from the CRSP and Compustat databases. In the experiments we considered as performance metric the annualised excess return $U_{\text{ER-EMP}}$ relative to the equally-weighted portfolio. We found the equally-weighted portfolio to be a harder benchmark to outperform than the market portfolio. We chose α_{ϵ} and β_{ϵ} in Equation (54) so that the mean of the Gamma distribution is 10.0 and its variance 0.5, which expresses a very greedy investment target.

It is worth pointing out that none of the scalable GP alternatives previously considered can cope with our likelihood model Equation (54). We compared the performance of the learned *string GP* portfolio out-of-sample to those of the best three SPT portfolios studied in [Vervuurt and Karatzas \(2015\)](#), namely the equally weighted portfolio

$$\pi_i^{\text{EMP}}(t) = \frac{1}{n}, \quad (55)$$

and the diversity weighted portfolios

$$\pi_i^{\text{DWP}}(t; p) = \frac{\mu_i(t)^p}{\mu_1(t)^p + \dots + \mu_n(t)^p}, \quad (56)$$

¹⁷ We refer the reader to [Karatzas and Fernholz \(2009\)](#) for the definition of functionally-generated portfolios.

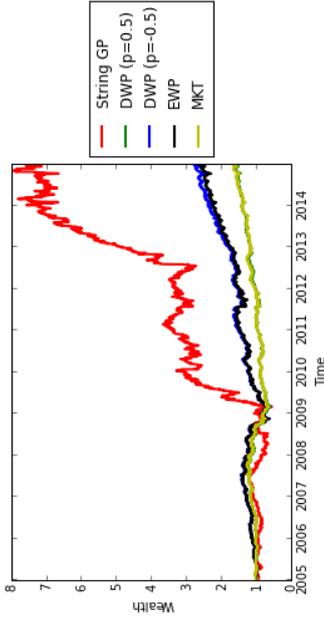

Figure 14: Evolution of the wealth processes of various long-only trading strategies on the S&P 500 universe of stocks between 1st January 2005 (where we assume a starting wealth of 1) and 31st December 2014. The String GP strategy was learned using market data from 1st January 1990 to 31st December 2004 as described in Section 6.4. EWP refers to the equally-weighted portfolio, MKT refers to the market portfolio (which weights stocks proportionally to their market capitalisations) and DWP (p) refers to the diversity-weighted portfolio with exponent p (which weights stocks proportionally to the p -th power of their market weights).

with parameter p equals to -0.5 and 0.5 , and the market portfolio. Results are provided Table 5, and Figure 14 displays the evolution of the wealth process of each strategy. It can be seen that the learned *string GP* strategy considerably outperforms the next best SPT portfolio. This experiment not only demonstrates (once more) that *string GPs* scale to large scale problems, it also illustrates that our inference scheme is able to unlock commercial value in new intricate large scale applications where no alternative is readily available. In effect, this application was first introduced by Kom Samo and Vervuurt (2016), where the authors used a Gaussian process prior on a Cartesian grid and under a separable covariance function so as to speed up inference with Kronecker techniques. Although the resulting inference scheme has time complexity that is linear in the total number of points on the grid, for a given grid resolution, the time complexity grows *exponentially* in the dimension of the input space (that is the number of trading characteristics), which is impractical for $d \geq 4$. On the other hand, *string GPs* allow for a time complexity that grows linearly with the number of trading characteristics, thereby enabling the learning of subtler market inefficiencies from the data.

Strategy	Sharpe Ratio	$Z_\pi(T)/Z_{\text{EWP}}(T)$	Avg. Ann. Ret.
String GP	0.73	2.87	22.07%
DWP ($p = -0.5$)	0.55	1.07	10.56%
EWP	0.53	1.00	9.84%
MKT	0.34	0.62	4.77%
DWP ($p = 0.5$)	0.33	0.61	4.51%

Table 5: Performance of various long-only trading strategies on the S&P 500 universe of stocks between 1st January 2005 (where we assume a starting wealth of 1) and 31st December 2014. The String GP strategy was learned using market data from 1st January 1990 to 31st December 2004 as described in Section 6.4. EWP refers to the equally-weighted portfolio, MKT refers to the market portfolio (which weights stocks proportionally to their market capitalisations) and DWP (p) refers to the diversity-weighted portfolio with exponent p (which weights stocks proportionally to the p -th power of the market weight of the asset). $Z_\pi(T)$ denotes the terminal wealth of strategy π , and Avg. Ann. Ret. is the strategy's equivalent constant annual return over the test horizon.

7. Discussion

In this paper, we introduce a novel class of smooth functional priors (or stochastic processes), which we refer to as *string GPs*, with the aim of simultaneously addressing the lack of scalability and the lack of flexibility of Bayesian kernel methods. Unlike existing approaches, such as Gaussian process priors (Rasmussen and Williams (2006)) or student-t process priors (Shah et al. (2014)), which are parametrised by *global* mean and covariance functions, and which postulate *fully dependent* finite-dimensional marginals, the alternative construction we propose adopts a *local* perspective and the resulting finite-dimensional marginals exhibit *conditional independence* structures. Our local approach to constructing *string GPs* provides a principled way of postulating that the latent function we wish to learn might exhibit locally homogeneous patterns, while the conditional independence structures constitute the core ingredient needed for developing scalable inference methods. Moreover, we provide theoretical results relating our approach to Gaussian processes, and we illustrate that our approach can often be regarded as a more scalable and/or more flexible extension. We argue and empirically illustrate that *string GPs* present an unparalleled opportunity for learning local patterns in small scale regression problems using nothing but standard Gaussian process regression techniques. More importantly, we propose a novel *scalable* RJ-MCMC inference scheme to learn latent functions in a wide variety of machine learning tasks, while simultaneously determining *whether* the data set exhibits local patterns, *how many* types of local patterns the data might exhibit, and *where* do changes in these patterns are likely to occur. The proposed scheme has time complexity and memory requirement that are both *linear* in the sample size N . When the number of available computing cores is at least equal to the dimension d of the input space, the time complexity is independent from the dimension of the input space. Else, the time complexity grows in $\mathcal{O}(dN)$. The memory requirement grows in $\mathcal{O}(dN)$. We empirically illustrate that our approach scales considerably better than competing alternatives on a standard benchmark data set, and is able to process data sizes that competing approaches cannot handle in a reasonable time.

7.1 Limitations

The main limitation of our approach is that, unlike the *standard GP paradigm* in which the time complexity of marginal likelihood evaluation does not depend on the dimension of the input space (other than through the evaluation of the Gram matrix), the *string GP paradigm* requires a number of computing cores that increases linearly with the dimension of the input space, or alternatively has a time complexity linear in the input space dimension on single-core machines. This is a by-product of the fact that in the *string GP paradigm*, we jointly infer the latent function and its gradient. If the gradient of the latent function is inferred in the *standard GP paradigm*, the resulting complexity will also be linear in the input dimension. That being said, overall our RJ-MCMC inference scheme will typically scale better per iteration to large input dimensions than gradient-based marginal likelihood inference in the *standard GP paradigm*, as the latter typically requires numerically evaluating an Hessian matrix, which requires computing the marginal likelihood a number of times per iterative update that grows quadratically with the input dimension. In contrast, a Gibbs cycle in our MCMC sampler has worst case time complexity that is linear in the input dimension.

7.2 Extensions

Some of the assumptions we have made in the construction of *string GPs* and *membrane GPs* can be relaxed, which we consider in detail below.

7.2.1 STRONGER GLOBAL REGULARITY

We could have imposed more (multiple continuous differentiability) or less (continuity) regularity as boundary conditions in the construction of *string GPs*. We chose continuous differentiability as it is a relatively mild condition guaranteed by most popular kernels, and yet the corresponding treatment can be easily generalised to other regularity requirements. It is also possible to allow for discontinuity at a boundary time a_k by replacing μ_k^b and Σ_k^b in Equation (5) with ${}_k M_{a_k}$ and ${}_k \mathbf{K}_{a_k, a_k}$ respectively, or equivalently by preventing any communication between the k -th and the $(k+1)$ -th strings. This would effectively be equivalent to having two independent *string GPs* on $[a_0, a_k]$ and $[a_k, a_k]$.

7.2.2 DIFFERENTIAL OPERATORS AS LINK FUNCTIONS

Our framework can be further extended to allow differential operators as link functions, thereby considering the latent multivariate function to infer as the response of a differential system to independent univariate *string GP* excitations. The RJ-MCMC sampler we propose in Section 5 would still work in this framework, with the only exception that, when the differential operator is of first order, the latent multivariate function will be continuous but not differentiable, except if global regularity is upgraded as discussed above. Moreover, Proposition 5 can be generalised to first order linear differential operators.

7.2.3 DISTRIBUTED STRING GPs

The RJ-MCMC inference scheme we propose may be easily adapted to handle applications where the data set is so big that it has to be stored across multiple clusters, and inference techniques have to be developed as data flow graphs¹⁸ (for instance using libraries such as TensorFlow).

To do so, the choice of string boundary times can be adapted so that each string has the same number of inner input coordinates, and such that in total there are as many strings across dimensions as a target number of available computing cores. We may then place a prior on kernel memberships similar to that of previous sections. Here, the change-points may be restricted to coincide with boundary times, and we may choose priors such that the sets of change-points are independent between input dimensions. In each input dimension the prior on the number of change-points can be chosen to be a truncated Poisson distribution (truncated to never exceed the total number of boundary times), and conditional on their number we may choose change-points to be uniformly distributed in the set of boundary times. In so doing, any two strings whose shared boundary time is not a change-point will be driven by the same kernel configuration.

This new setup presents no additional theoretical or practical challenges, and the RJ-MCMC techniques previously developed are easily adaptable to jointly learn change-points and function values. Unlike the case we developed in previous sections where an update of the univariate *string GP* corresponding to an input dimension, say the j -th, requires looping through all distinct j -th input coordinates, here no step in the inference scheme requires a full view of the data set in any input dimension. Full RJ-MCMC inference can be constructed as a data flow graph. An example such graph is constructed as follows. The leaves correspond to computing cores responsible for generating change-points and kernel configurations, and mapping strings to kernel configurations. The following layer is made of compute cores that use kernel configurations coming out of the previous layer to sequentially compute boundary conditions corresponding to a specific input dimension—there are d such compute cores, where d is the input dimension. These compute cores then pass computed boundary conditions to subsequent compute cores we refer to as string compute cores. Each string compute core is tasked with computing *derivative string GP* values for a specific input dimension and for a specific string in that input dimension, conditional on previously computed boundary conditions. These values are then passed to a fourth layer of compute cores, each of which being tasked with computing function and gradient values corresponding to a small subset of training inputs from previously computed *derivative string GP* values. The final layers then computes the log-likelihood using a distributed algorithm such as Map-Reduce when possible. This proposal data flow graph is illustrated Figure 15.

We note that the approaches of Kim et al. (2005), Gramacy and Lee (2008), Tresp (2000), and Deisenroth and Ng (2015) also allow for fully-distributed inference on regression problems. Distributed *string GP* RJ-MCMC inference improves on these in that it places little restriction on the type of likelihood. Moreover, unlike Kim et al. (2005) and Gramacy and Lee (2008) that yield discontinuous latent functions, *string GPs* are continuously differentiable, and unlike Tresp (2000) and Deisenroth and Ng (2015), local experts in the *string GP paradigm* (i.e. strings) are driven by possibly different sets of hyper-parameters, which facilitates the learning of local patterns.

¹⁸ A data flow graph is a computational (directed) graph whose nodes represent calculations (possibly taking place on different computing units) and directed edges correspond to data flowing between calculations or computing units.

7.2.4 APPROXIMATE MCMC FOR I.I.D. OBSERVATIONS LIKELIHOODS

As discussed in Section 5.2, the bottleneck of our proposed inference scheme is the evaluation of likelihood. When the likelihood factorises across training samples, the linear time complexity of our proposed approach can be further reduced using a Monte Carlo approximation of the log-likelihood (see for instance [Bardenet et al. \(2014\)](#) and references therein). Although the resulting Markov chain will typically not converge to the true posterior distribution, in practice its stationary distribution can be sufficiently close to the true posterior when reasonable Monte Carlo sample sizes are used. Convergence results of such approximations have recently been studied by [Bardenet et al. \(2014\)](#) and [Alquier et al. \(2016\)](#). We expect this extension to speed-up inference when the number of compute cores is in the order of magnitude of the input dimension, but we would recommend the previously mentioned fully-distributed string GP inference extension when compute cores are not scarce.

7.2.5 VARIATIONAL INFERENCE

It would be useful to develop suitable variational methods for inference under *string GP* priors, that we hope will scale similarly to our proposed RJ-MCMC sampler but will converge faster. We anticipate that the main challenge here will perhaps be the learning of model complexity, that is the number of distinct kernel configurations in each input dimension.

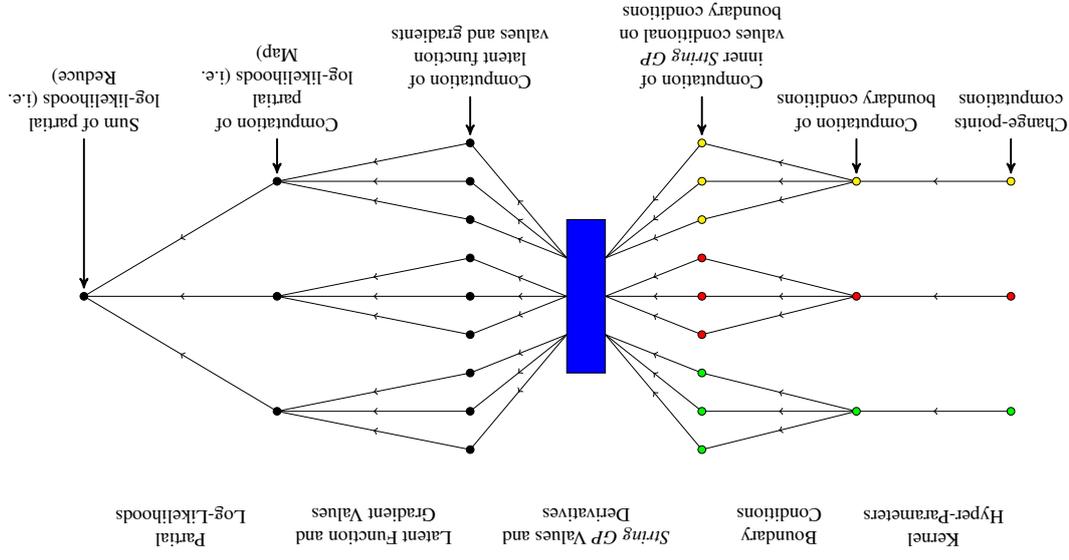

Figure 15: Example data flow graph for fully-distributed *string GP* inference under an i.i.d observations likelihood model. Here the input space is three-dimensional to ease illustration. Filled circles represent compute cores, and edges correspond to flows of data. Compute cores with the same colour (green, red or yellow) perform operations pertaining to the same input dimension, while black-filled circles represent compute cores performing cross-dimensional operations. The blue rectangle plays the role of a hub that relays *string GP* values to the compute cores that need them to compute the subset of latent function values and gradients they are responsible for. These values are then used to compute the log-likelihood in a distributed fashion using the Map-Reduce algorithm. Each calculation in the corresponding RJ-MCMC sampler would be initiated at one of the compute cores, and would trigger updates of all edges accessible from that compute core.

Wharton Research Data Services (WRDS) was used in preparing the data for Section 6.4 of this paper. This service and the data available thereon constitute valuable intellectual property and trade secrets of WRDS and/or its third-party suppliers.

Appendix A.

We begin by recalling Kolmogorov's extension theorem, which we will use to prove the existence of derivative Gaussian processes and string Gaussian processes.

Theorem 7 (Kolmogorov's extension theorem, (Øksendal, 2003, Theorem 2.1.5))

Let I be an interval, let all $t_1, \dots, t_i \in I$, $i, n \in \mathbb{N}^*$, let ν_{t_1, \dots, t_i} be probability measures on \mathbb{R}^{ni} such that:

$$\nu_{\pi(1), \dots, \pi(i)}(F_{\pi(1)}, \dots, F_{\pi(i)}) = \nu_{t_1, \dots, t_i}(F_{t_1}, \dots, F_{t_i}) \quad (57)$$

for all permutations π on $\{1, \dots, i\}$ and

$$\nu_{t_1, \dots, t_i}(F_{t_1}, \dots, F_{t_i}) = \nu_{t_1, \dots, t_i, t_{i+1}, \dots, t_{i+m}}(F_{t_1}, \dots, F_{t_i}, \mathbb{R}^n, \dots, \mathbb{R}^n) \quad (58)$$

for all $m \in \mathbb{N}^*$ where the set on the right hand side has a total of $i + m$ factors. Then there exists a probability space $(\Omega, \mathcal{F}, \mathbb{P})$ and an \mathbb{R}^n -valued stochastic process $(X_t)_{t \in I}$ on Ω ,

$$X_t : \Omega \rightarrow \mathbb{R}^n$$

such that

$$\nu_{t_1, \dots, t_i}(F_{t_1}, \dots, F_{t_i}) = \mathbb{P}(X_{t_1} \in F_{t_1}, \dots, X_{t_i} \in F_{t_i}) \quad (59)$$

for all $t_1, \dots, t_i \in I$, $i \in \mathbb{N}^*$ and for all Borel sets F_1, \dots, F_i .

It is easy to see that every stochastic process satisfies the permutation and marginalisation conditions (57) and (58). The power of Kolmogorov's extension theorem is that it states that those two conditions are sufficient to guarantee the existence of a stochastic process.

Appendix B. Proof of Proposition 1

In this section we prove Proposition 1, which we recall below.

Proposition 1 (Derivative Gaussian processes)

Let I be an interval, $k : I \times I \rightarrow \mathbb{R}$ a C^2 symmetric positive semi-definite function,¹⁹ $m : I \rightarrow \mathbb{R}$ a C^1 function.

(A) There exists a \mathbb{R}^2 -valued stochastic process $(D_t)_{t \in I}$, $D_t = (z_t, z'_t)$, such that for all $t_1, \dots, t_n \in I$,

$$(z_{t_1}, \dots, z_{t_n}, z'_{t_1}, \dots, z'_{t_n})$$

¹⁹ C^1 (resp. C^2) functions denote functions that are once (resp. twice) continuously differentiable on their domains.

is a Gaussian vector with mean

$$\begin{pmatrix} m(t_1), \dots, m(t_n), \frac{dm}{dt}(t_1), \dots, \frac{dm}{dt}(t_n) \end{pmatrix}$$

and covariance matrix such that

$$\text{cov}(z_{t_i}, z_{t_j}) = k(t_i, t_j), \quad \text{cov}(z_{t_i}, z'_{t_j}) = \frac{\partial k}{\partial y}(t_i, t_j), \quad \text{and} \quad \text{cov}(z'_{t_i}, z'_{t_j}) = \frac{\partial^2 k}{\partial x \partial y}(t_i, t_j).$$

We herein refer to $(D_t)_{t \in I}$ as a **derivative Gaussian process**.

(B) $(z_t)_{t \in I}$ is a Gaussian process with mean function m , covariance function k and that is C^1 in the L^2 (mean square) sense.

(C) $(z'_t)_{t \in I}$ is a Gaussian process with mean function $\frac{dm}{dt}$ and covariance function $\frac{\partial^2 k}{\partial x \partial y}$. Moreover, $(z'_t)_{t \in I}$ is the L^2 derivative of the process $(z_t)_{t \in I}$.

Proof

Appendix B.1 Proof of Proposition 1 (A)

Firstly, we need to show that the matrix suggested in the proposition as the covariance matrix of $(z_{t_1}, \dots, z_{t_n}, z'_{t_1}, \dots, z'_{t_n})$ is indeed positive semi-definite. To do so, we will show that it is the limit of positive definite matrices (which is sufficient to conclude it is positive semi-definite, as $x^T M_n x \geq 0$ for a convergent sequence of positive definite matrices implies $x^T M_\infty x \geq 0$).

Let k be as in the proposition, h such that $\forall i \leq n$, $t_i + h \in I$ and $(\tilde{z}_i)_{i \in I}$ be a Gaussian process with covariance function k . The vector

$$\begin{pmatrix} \tilde{z}_{t_1}, \dots, \tilde{z}_{t_n}, \frac{\tilde{z}_{t_1+h} - \tilde{z}_{t_1}}{h}, \dots, \frac{\tilde{z}_{t_n+h} - \tilde{z}_{t_n}}{h} \end{pmatrix}$$

is a Gaussian vector whose covariance matrix is positive definite and such that

$$\text{cov}(\tilde{z}_{t_i}, \tilde{z}_{t_j}) = k(t_i, t_j), \quad (60)$$

and

$$\text{cov}\left(\tilde{z}_{t_i}, \frac{\tilde{z}_{t_i+h} - \tilde{z}_{t_i}}{h}\right) = \frac{k(t_i, t_j + h) - k(t_i, t_j)}{h}, \quad (61)$$

$$\begin{aligned} & \text{cov}\left(\frac{\tilde{z}_{t_i+h} - \tilde{z}_{t_i}}{h}, \frac{\tilde{z}_{t_j+h} - \tilde{z}_{t_j}}{h}\right) \\ &= \frac{1}{h^2} (k(t_i + h, t_j + h) - k(t_i + h, t_j) - k(t_i, t_j + h) + k(t_i, t_j)). \end{aligned} \quad (62)$$

As k is C^2 , $h \rightarrow k(x, y + h)$ admits a second order Taylor expansion about $h = 0$ for every x , and we have:

$$k(x, y + h) = k(x, y) + \frac{\partial k}{\partial y}(x, y)h + \frac{1}{2} \frac{\partial^2 k}{\partial y^2}(x, y)h^2 + o(h^2) = k(y + h, x). \quad (63)$$

Similarly, $h \rightarrow k(x+h, y+h)$ admits a second order Taylor expansion about $h=0$ for every x, y and we have:

$$k(x+h, y+h) = k(x, y) + \left[\frac{\partial k}{\partial x}(x, y) + \frac{\partial k}{\partial y}(x, y) \right] h + \left[\frac{\partial^2 k}{\partial x \partial y}(x, y) + \frac{1}{2} \frac{\partial^2 k}{\partial x^2}(x, y) \right. \\ \left. + \frac{1}{2} \frac{\partial^2 k}{\partial y^2}(x, y) \right] h^2 + o(h^2). \quad (64)$$

Hence,

$$k(t_i, t_j+h) - k(t_i, t_j) = \frac{\partial k}{\partial y}(t_i, t_j)h + o(h), \quad (65)$$

and

$$k(t_i+h, t_j+h) - k(t_i+h, t_j) - k(t_i, t_j+h) + k(t_i, t_j) = \frac{\partial^2 k}{\partial x \partial y}(t_i, t_j)h^2 + o(h^2). \quad (66)$$

Dividing Equation (65) by h , dividing Equation (66) by h^2 , and taking the limits, we obtain:

$$\lim_{h \rightarrow 0} \text{cov} \left(\frac{\tilde{z}_{t_i} + h - \tilde{z}_{t_j}}{h}, \frac{\tilde{z}_{t_j} + h - \tilde{z}_{t_i}}{h} \right) = \frac{\partial k}{\partial y}(t_i, t_j),$$

and

$$\lim_{h \rightarrow 0} \text{cov} \left(\frac{\tilde{z}_{t_i+h} - \tilde{z}_{t_i}}{h}, \frac{\tilde{z}_{t_j+h} - \tilde{z}_{t_j}}{h} \right) = \frac{\partial^2 k}{\partial x \partial y}(t_i, t_j),$$

which corresponds to the covariance structure of Proposition 1. In other words the proposed covariance structure is indeed positive semi-definite.

Let ν_{t_1, \dots, t_n}^N be the Gaussian probability measure corresponding to the joint distribution of $(z_{t_1}, \dots, z_{t_n}, z'_{t_1}, \dots, z'_{t_n})$ as per the Proposition 1, and let ν_{t_1, \dots, t_n}^D be the measure on the Borel σ -algebra $\mathcal{B}(\mathbb{R}^2 \times \dots \times \mathbb{R}^2)$ such that for any $2n$ intervals $I_{11}, I_{12}, \dots, I_{n1}, I_{n2}$,

$$\nu_{t_1, \dots, t_n}^D(I_{11} \times I_{12} \times \dots \times I_{n1} \times I_{n2}) := \nu_{t_1, \dots, t_n}^N(I_{11}, \dots, I_{n1}, I_{12}, \dots, I_{n2}). \quad (67)$$

The measures ν_{t_1, \dots, t_n}^D are the finite dimensional measures corresponding to the stochastic object $(D_t)_{t \in I}$ sampled at times t_1, \dots, t_n . They satisfy the time permutation and marginalisation conditions of Kolmogorov's extension theorem as the Gaussian measures ν_{t_1, \dots, t_n}^N do. Hence, the \mathbb{R}^2 -valued stochastic process $(D_t)_{t \in I}$ defined in Proposition 1 does exist.

Appendix B.2 Proof of Proposition 1 (B)

That $(z_t)_{t \in I}$ is a Gaussian process results from the fact that the marginals $(z_{t_1}, \dots, z_{t_n})$ are Gaussian vectors with mean $(m(t_1), \dots, m(t_n))$ and covariance matrix $[k(t_i, t_j)]_{i, j \in [1, n]}$. The fact that $(z_t)_{t \in I}$ is \mathcal{C}^1 in the L^2 sense is a direct consequence of the twice continuous differentiability of k .

Appendix B.3 Proof of Proposition 1 (C)

In effect, it follows from Proposition 1(A) that $\frac{z_{t+h} - z_t}{h} - z'_t$ is a Gaussian random variable with mean

$$\frac{m(t+h) - m(t)}{h} - \frac{dm}{dt}(t)$$

and variance

$$\frac{k(t+h, t+h) - 2k(t+h, t) + k(t, t) - 2\frac{\partial k}{\partial y}(t+h, t)h + 2\frac{\partial k}{\partial y}(t, t)h + \frac{\partial^2 k}{\partial x \partial y}(t, t)h^2}{h^2}.$$

Taking the second order Taylor expansion of the numerator in the fraction above about $h=0$ we get $o(h^2)$, hence

$$\lim_{h \rightarrow 0} \text{Var} \left(\frac{z_{t+h} - z_t}{h} - z'_t \right) = 0.$$

We also have

$$\lim_{h \rightarrow 0} \mathbb{E} \left(\frac{z_{t+h} - z_t}{h} - z'_t \right) = \frac{dm}{dt}(t) - \mathbb{E}(z'_t) = 0.$$

Therefore,

$$\lim_{h \rightarrow 0} \mathbb{E} \left[\left(\frac{z_{t+h} - z_t}{h} - z'_t \right)^2 \right] = 0,$$

which proves that (z'_t) is the L^2 derivative of (z_t) . The fact that (z'_t) is a Gaussian process with mean function $\frac{dm}{dt}$ and covariance function $\frac{\partial^2 k}{\partial x \partial y}$ is a direct consequence of the distribution of the marginals $(z'_{t_1}, \dots, z'_{t_n})$. Moreover, the continuity of (z'_t) in the L^2 sense is a direct consequence of the continuity of $\frac{\partial^2 k}{\partial x \partial y}$ (see Rasmussen and Williams, 2006, p. 81 4.1.1). ■

Appendix C. Proof of Theorem 2

In this section we prove Theorem 2 which we recall below.

Theorem 2 (String Gaussian process)

Let $a_0 < \dots < a_k < \dots < a_K < \dots < a_K$ and let $p_N(x; \mu, \Sigma)$ be the multivariate Gaussian density with mean vector μ and covariance matrix Σ . Furthermore, let $(m_k : [a_{k-1}, a_k] \rightarrow \mathbb{R})_{k \in [1, K]}$ be \mathcal{C}^1 functions, and $(k_k : [a_{k-1}, a_k] \times [a_{k-1}, a_k] \rightarrow \mathbb{R})_{k \in [1, K]}$ be \mathcal{C}^3 symmetric positive semi-definite functions, neither degenerate at a_{k-1} , nor degenerate at a_k given a_{k-1} .

(A) There exists an \mathbb{R}^2 -valued stochastic process $(SD_t)_{t \in I}$, $SD_t = (z_t, z'_t)$ satisfying the following conditions:

1) The probability density of $(SD_{a_0}, \dots, SD_{a_K})$ reads:

$$p_0(x_0, \dots, x_K) := \prod_{k=0}^K p_N \left(x_k; \mu_k^b, \Sigma_k^b \right)$$

where: $\Sigma_0^b = \mathbf{1} \mathbf{K}_{a_0; a_0}$, $\forall k > 0$ $\Sigma_k^b = \mathbf{K}_{a_k; a_k} - \mathbf{K}_{a_k; a_{k-1}} \mathbf{K}_{a_{k-1}; a_{k-1}}^{-1} \mathbf{K}_{a_{k-1}; a_k}^T$,

$$\begin{aligned} \mu_0^k &= \mathbf{1}_{\mathbf{M}_{a_0}}, \quad \forall k > 0 \quad \mu_k^k = k \mathbf{M}_{a_k} + k \mathbf{K}_{a_k; a_{k-1}} \mathbf{K}_{a_{k-1}}^{-1} (x_{k-1} - k \mathbf{M}_{a_{k-1}}), \\ &\text{with } k \mathbf{K}_{uv} = \begin{bmatrix} k_k(u, v) & \frac{\partial k_k}{\partial u}(u, v) \\ \frac{\partial k_k}{\partial x}(u, v) & \frac{\partial^2 k_k}{\partial x \partial y}(u, v) \end{bmatrix}, \quad \text{and } k \mathbf{M}_u = \begin{bmatrix} m_k(u) \\ \frac{dm_k}{du}(u) \end{bmatrix}. \end{aligned}$$

2) Conditional on $(SD)_{a_k} = x_{a_k} \in [0, K_1]$, the restrictions $(SD)_{t_i \in [a_{k-1}, a_k]}$, $k \in [1..K]$ are **independent conditional derivative Gaussian processes**, respectively with unconditional mean function m_k and unconditional covariance function k_k and that are conditioned to take values x_{k-1} and x_k at a_{k-1} and a_k respectively. We refer to $(SD)_{t_i \in I}$ as a **string derivative Gaussian process**, and to its first coordinate $(z)_{t_i \in I}$ as a **string Gaussian process** namely,

$$(z)_{t_i \in I} \sim \mathcal{SGP}(\{a_k\}, \{m_k\}, \{k_k\}).$$

(B) The **string Gaussian process** $(z)_{t_i \in I}$ defined in (A) is C^1 in the L^2 sense and its L^2 derivative is the process $(z')_{t_i \in I}$ defined in (A).

Proof

Appendix C.1 Proof of Theorem 2 (A)

We will once again turn to Kolmogorov's extension theorem to prove the existence of the stochastic process $(SD)_{t_i \in I}$. The core of the proof is in the finite dimensional measures implied by Theorem 2 (A-1) and (A-2). Let $\{t_i^k \in [a_{k-1}, a_k]\}_{i \in [1..N_k], k \in [1..K]}$ be n times. We first formally construct the finite dimensional measures implied by Theorem 2 (A-1) and (A-2), and then verify that they satisfy the conditions of Kolmogorov's extension theorem.

Let us define the measure $\nu_{t_1^1, \dots, t_1^K, \dots, t_n^1, \dots, t_n^K}^{SD}$ as the probability measure having density with respect to the Lebesgue measure on $\mathcal{E}(\mathbb{R}^2 \times \dots \times \mathbb{R}^2)$ that reads:

$$\begin{aligned} p_{SD}(x_1^1, \dots, x_{N_1}^1, \dots, x_1^K, \dots, x_{N_K}^K, x_{a_0}, \dots, x_{a_K}) &= p_b(x_{a_0}, \dots, x_{a_K}) \times \\ &\prod_{k=1}^K p_{N_k}^{x_{a_{k-1}}, x_{a_k}}(x_{t_1^k}, \dots, x_{t_{N_k}^k}) \end{aligned} \quad (68)$$

where p_b is as per Theorem 2 (A-1) and $p_{N_k}^{x_{a_{k-1}}, x_{a_k}}(x_{t_1^k}, \dots, x_{t_{N_k}^k})$ is the (Gaussian) pdf of the joint distribution of the values at times $\{t_i^k \in [a_{k-1}, a_k]\}$ of the *conditional derivative Gaussian process* with unconditional mean functions m_k and unconditional covariance functions k_k that is conditioned to take values $x_{a_{k-1}} = (z_{a_{k-1}}, z'_{a_{k-1}})$ and $x_{a_k} = (z_{a_k}, z'_{a_k})$ at times a_{k-1} and a_k respectively (the corresponding—conditional—mean and covariance functions are derived from Equations 3 and 4). Let us extend the family of measures ν^{SD} to cases where some or all boundary times a_k are missing, by integrating out the corresponding variables in Equation (68). For instance when a_0 and a_1 are missing

$$\begin{aligned} \nu_{t_1^1, \dots, t_{N_1}^1, \dots, t_1^K, \dots, t_{N_K}^K, a_2, \dots, a_K}^{SD} & (T_1^1, \dots, T_{N_1}^1, \dots, T_1^K, \dots, T_{N_K}^K, A_2, \dots, A_K) \\ &= \nu_{t_1^1, \dots, t_{N_1}^1, \dots, t_1^K, \dots, t_{N_K}^K, a_0, \dots, a_K}^{SD} (T_1^1, \dots, T_{N_1}^1, \dots, T_1^K, \dots, T_{N_K}^K, \mathbb{R}^2, \mathbb{R}^2, A_2, \dots, A_K) \end{aligned} \quad (69)$$

where A_i and T_j^i are rectangle in \mathbb{R}^2 . Finally, we extend the family of measures ν^{SD} to any arbitrary set of indices $\{t_1, \dots, t_n\}$ as follows:

$$\nu_{t_1, \dots, t_n}^{SD}(T_1, \dots, T_n) := \nu_{t_{\pi^*(1)}, \dots, t_{\pi^*(n)}}^{SD}(T_{\pi^*(1)}, \dots, T_{\pi^*(n)}), \quad (70)$$

where π^* is a permutation of $\{1, \dots, n\}$ such that $\{t_{\pi^*(1)}, \dots, t_{\pi^*(n)}\}$ verify the following conditions:

1. $\forall i, j$, if $t_i \in [a_{k_1-1}, a_{k_1}]$, $t_j \in [a_{k_2-1}, a_{k_2}]$, and $k_1 < k_2$, then $\text{Idx}(t_i) < \text{Idx}(t_j)$. Where $\text{Idx}(t_i)$ stands for the index of t_i in $\{t_{\pi^*(1)}, \dots, t_{\pi^*(n)}\}$;
2. if $t_i \notin \{a_0, \dots, a_K\}$ and $t_j \in \{a_0, \dots, a_K\}$ then $\text{Idx}(t_i) < \text{Idx}(t_j)$;
3. if $t_i \in \{a_0, \dots, a_K\}$ and $t_j \in \{a_0, \dots, a_K\}$ then $\text{Idx}(t_i) < \text{Idx}(t_j)$ if and only if $t_i < t_j$.

Any such measure $\nu_{t_{\pi^*(1)}, \dots, t_{\pi^*(n)}}^{SD}$ will fall in the category of either Equation (68) or Equation (69). Although π^* is not unique, any two permutations satisfying the above conditions will only differ by a permutation of times belonging to the same string interval $[a_{k-1}, a_k]$. Moreover, it follows from Equations (68) and (69) that the measures $\nu_{t_{\pi^*(1)}, \dots, t_{\pi^*(n)}}^{SD}$ are invariant by permutation of times belonging to the same string interval $[a_{k-1}, a_k]$, and as a result any two π^* satisfying the above conditions will yield the same probability measure.

The finite dimensional probability measures $\nu_{t_1, \dots, t_n}^{SD}$ are the measures implied by Theorem 2. The permutation condition (57) of Kolmogorov's extension theorem is met by virtue of Equation (70). In effect for every permutation π of $\{1, \dots, n\}$, if we let $\pi' : \{\pi(1), \dots, \pi(n)\} \rightarrow \{1, \dots, n\}$, then

$$\begin{aligned} \nu_{\pi(1), \dots, \pi(n)}^{SD} (T_{\pi(1)}, \dots, T_{\pi(n)}) &:= \nu_{t_{\pi^*(\pi(1))}, \dots, t_{\pi^*(\pi(n))}}^{SD} (T_{\pi^*(\pi(1))}, \dots, T_{\pi^*(\pi(n))}) \\ &= \nu_{t_{\pi^*(1)}, \dots, t_{\pi^*(n)}}^{SD} (T_{\pi^*(1)}, \dots, T_{\pi^*(n)}) \\ &= \nu_{t_1, \dots, t_n}^{SD} (T_1, \dots, T_n). \end{aligned}$$

As for the marginalisation condition (58), it is met for every boundary time by virtue of how we extended ν^{SD} to missing boundary times. All we need to prove now is that the marginalisation condition is also met at any non-boundary time. To do so, it is sufficient to prove that the marginalisation condition holds for t_1^1 , that is:

$$\begin{aligned} \nu_{t_1^1, \dots, t_1^1, \dots, t_1^K, \dots, t_{N_K}^K, a_0, \dots, a_K}^{SD} & (\mathbb{R}^2, T_1^1, T_2^1, \dots, T_{N_1}^1, \dots, T_1^K, \dots, T_{N_K}^K, A_0, \dots, A_K) \\ &= \nu_{t_2^1, \dots, t_{N_1}^1, \dots, t_1^K, \dots, t_{N_K}^K, a_0, \dots, a_K}^{SD} (T_2^1, \dots, T_{N_1}^1, \dots, T_1^K, \dots, T_{N_K}^K, A_0, \dots, A_K) \end{aligned} \quad (71)$$

for every rectangles A_i and T_j^i in \mathbb{R}^2 . In effect, cases where some boundary times are missing are special cases with the corresponding rectangles A_j set to \mathbb{R}^2 . Moreover, if we prove Equation (71), the permutation property (57) will allow us to conclude that the marginalisation also holds true for any other (single) non-boundary time. Furthermore, if Equation (71) holds true, it can be shown that the marginalisation condition will also hold over multiple non-boundary times by using the permutation property (57) and marginalising one non-boundary time after another.

By Fubini's theorem, and considering Equation (68), showing that Equation (71) holds true is equivalent to showing that:

$$\int_{\mathbb{R}^2} p_{\mathcal{N}}^{x_0, x_{a_1}}(x_{t_1}^1, \dots, x_{t_{N_1}}^1) dx_{t_1}^1 = p_{\mathcal{N}}^{x_0, x_{a_1}}(x_{t_2}^1, \dots, x_{t_{N_1}}^1) \quad (72)$$

which holds true as $p_{\mathcal{N}}^{x_0, x_{a_1}}(x_{t_1}^1, \dots, x_{t_{N_1}}^1)$ is a multivariate Gaussian density, and the corresponding marginal is indeed the density of the same *conditional derivative Gaussian process* at times $t_2^1, \dots, t_{N_1}^1$.

This concludes the proof of the existence of the stochastic process $(SD_t)_{t \in I}$.

Appendix C.2 Proof of Theorem 2 (B)

As conditional on boundary conditions the restriction of a *string derivative Gaussian process* on a string interval $[a_{k-1}, a_k]$ is a *derivative Gaussian process*, it follows from Proposition 1 (C) that

$$\forall \tilde{x}_{a_0}, \dots, \tilde{x}_{a_K}, \forall t, t+h \in [a_{k-1}, a_k], \quad \lim_{h \rightarrow 0} \mathbf{E} \left(\left[\frac{z_{t+h} - z_t}{h} - z'_t \right]^2 \middle| x_{a_0} = \tilde{x}_{a_0}, \dots, x_{a_K} = \tilde{x}_{a_K} \right) = 0, \quad (73)$$

or equivalently that:

$$\Delta z'_h := \mathbf{E} \left(\left[\frac{z_{t+h} - z_t}{h} - z'_t \right]^2 \middle| x_{a_0}, \dots, x_{a_K} \right) \xrightarrow{a.s.} 0. \quad (74)$$

Moreover,

$$\Delta z_h = \text{Var} \left(\frac{z_{t+h} - z_t}{h} - z'_t \middle| x_{a_0}, \dots, x_{a_K} \right) + \mathbf{E} \left(\frac{z_{t+h} - z_t}{h} - z'_t \middle| x_{a_0}, \dots, x_{a_K} \right)^2. \quad (75)$$

As both terms in the sum of the above equation are non-negative, it follows that

$$\text{Var} \left(\frac{z_{t+h} - z_t}{h} - z'_t \middle| x_{a_0}, \dots, x_{a_K} \right) \xrightarrow{a.s.} 0 \quad \text{and} \quad \mathbf{E} \left(\frac{z_{t+h} - z_t}{h} - z'_t \middle| x_{a_0}, \dots, x_{a_K} \right)^2 \xrightarrow{a.s.} 0.$$

From which we deduce

$$\mathbf{E} \left(\frac{z_{t+h} - z_t}{h} - z'_t \middle| x_{a_0}, \dots, x_{a_K} \right) \xrightarrow{a.s.} 0.$$

As $\mathbf{E} \left(\frac{z_{t+h} - z_t}{h} - z'_t \middle| x_{a_0}, \dots, x_{a_K} \right)$ depends linearly on the boundary conditions, and as the boundary conditions are jointly-Gaussian (see Appendix H step 1), it follows that

$$\mathbf{E} \left(\frac{z_{t+h} - z_t}{h} - z'_t \middle| x_{a_0}, \dots, x_{a_K} \right)$$

is Gaussian. Finally we note that

$$\text{Var} \left(\frac{z_{t+h} - z_t}{h} - z'_t \middle| x_{a_0}, \dots, x_{a_K} \right)$$

does not depend on the values of the boundary conditions x_{a_k} (but rather on the boundary times), and we recall that convergence almost sure of Gaussian random variables implies convergence in L^2 . Hence, taking the expectation on both side of Equation (75) and then the limit as h goes to 0 we get

$$\mathbf{E} \left(\left[\frac{z_{t+h} - z_t}{h} - z'_t \right]^2 \right) = \mathbf{E}(\Delta z'_h) \xrightarrow{h \rightarrow 0} 0,$$

which proves that the *string GP* $(z_t)_{t \in I}$ is differentiable in the L^2 sense on I and has derivative $(z'_t)_{t \in I}$.

We prove the continuity in the L^2 sense of $(z'_t)_{t \in I}$ in a similar fashion, noting that conditional on the boundary conditions, $(z'_t)_{t \in I}$ is a Gaussian process whose mean function $\frac{d \text{tr}_{\text{ck}}}{dt} a_{k-1, a_k}$ and covariance function $\frac{\partial^2 \text{ck}_{a_{k-1}, a_k}}{\partial z_t \partial y_t}$ are continuous, thus is continuous in the L^2 sense on $[a_{k-1}, a_k]$ (conditional on the boundary conditions). We therefore have that:

$$\forall \tilde{x}_{a_0}, \dots, \tilde{x}_{a_K}, \forall t, t+h \in [a_{k-1}, a_k], \quad \lim_{h \rightarrow 0} \mathbf{E} \left((z'_{t+h} - z'_t)^2 \middle| x_{a_0} = \tilde{x}_{a_0}, \dots, x_{a_K} = \tilde{x}_{a_K} \right) = 0, \quad (76)$$

from which we get that:

$$\Delta z'_h := \mathbf{E} \left([z'_{t+h} - z'_t]^2 \middle| x_{a_0}, \dots, x_{a_K} \right) \xrightarrow{a.s.} 0. \quad (77)$$

Moreover,

$$\Delta z'_h = \text{Var} \left(z'_{t+h} - z'_t \middle| x_{a_0}, \dots, x_{a_K} \right) + \mathbf{E} \left(z'_{t+h} - z'_t \middle| x_{a_0}, \dots, x_{a_K} \right)^2, \quad (78)$$

which implies that

$$\text{Var} \left(z'_{t+h} - z'_t \middle| x_{a_0}, \dots, x_{a_K} \right) \xrightarrow{a.s.} 0$$

and

$$\mathbf{E} \left(z'_{t+h} - z'_t \middle| x_{a_0}, \dots, x_{a_K} \right)^2 \xrightarrow{a.s.} 0,$$

as both terms in the sum in Equation (78) are non-negative. Finally,

$$\text{Var} \left(z'_{t+h} - z'_t \middle| x_{a_0}, \dots, x_{a_K} \right)$$

does not depend on the values of the boundary conditions, and

$$\mathbf{E} \left(z'_{t+h} - z'_t \middle| x_{a_0}, \dots, x_{a_K} \right)$$

is Gaussian for the same reason as before. Hence, taking the expectation on both sides of Equation (78), we get that

$$\mathbf{E} \left([z'_{t+h} - z'_t]^2 \right) = \mathbf{E}(\Delta z'_h) \xrightarrow{h \rightarrow 0} 0,$$

which proves that (z'_t) is continuous in the L^2 sense. ■

Appendix D. Proof of the Condition for Pathwise Regularity Upgrade of String GPs from L^2

In this section we prove that a sufficient condition for the process $(z_t^j)_{t \in I}$ in Theorem 2 to be almost surely continuous and to be the almost sure derivative of the string Gaussian process $(z_t^j)_{t \in I}$, is that the Gaussian processes on $I_k = [a_{k-1}, a_k]$ with mean and covariance functions m_{a_{k-1}, a_k}^k and k_{a_{k-1}, a_k}^k (as per Equations 3 and 4 with $m := m_k$ and $k := k_k$) are themselves almost surely C^1 for every boundary condition.

Firstly we note that the above condition guarantees that the result holds at non-boundary times. As for boundary times, the condition implies that the string GP is almost surely right differentiable (resp. left differentiable) at every left (resp. right) boundary time, including a_0 and a_K . Moreover, the string GP being differentiable in L^2 , the right hand side and left hand side almost sure derivatives are the same, and are equal to the L^2 derivative, which proves that the L^2 derivatives at inner boundary times are also in the almost sure sense. A similar argument holds to conclude that the right (resp. left) hand side derivative at a_0 (resp. a_K) is also in the almost sure sense. Moreover, the derivative process $(z_t^j)_{t \in I}$ admits an almost sure right hand side limit and an almost sure left hand side limit at every inner boundary time and both are equal as the derivative is continuous in L^2 , which proves its almost sure continuity at inner boundary times. Almost sure continuity of $(z_t^j)_{t \in I}$ on the right (resp. left) of a_0 (resp. a_K) is a direct consequence of the above condition.

Appendix E. Proof of Proposition 4

In this section, we prove Proposition 4, which we recall below.

Proposition 4 (Additively separable string GPs are flexible)

Let $k(x, y) := \rho(|x - y|_{I^d}^2)$ be a stationary covariance function generating a.s. C^1 GP paths indexed on \mathbb{R}^d , $d > 0$, and ρ a function that is C^2 on $[0, +\infty[$ and continuous at 0. Let $\phi_s(x_1, \dots, x_d) = \sum_{j=1}^d \phi_s(z_j^1)_{j \in [1, d]}$ be independent stationary Gaussian processes with mean 0 and covariance function k (where the L^2 norm is on \mathbb{R}), and let $f(t_1, \dots, t_d) = \phi_s(z_{t_1}^1, \dots, z_{t_d}^d)$ be the corresponding stationary string GP. Finally, let g be an isotropic Gaussian process indexed on $I^1 \times \dots \times I^d$ with mean 0 and covariance function k (where the L^2 norm is on \mathbb{R}^d). Then:

- 1) $\forall x \in I^1 \times \dots \times I^d$, $H(\nabla f(x)) = H(\nabla g(x))$,
- 2) $\forall x \neq y \in I^1 \times \dots \times I^d$, $I(\nabla f(x); \nabla f(y)) \leq I(\nabla g(x); \nabla g(y))$.

To prove Proposition 4 we need a lemma, which we state and prove below.

Lemma 8 Let X_n be a sequence of Gaussian random vectors with auto-covariance matrix Σ_n and mean μ_n , converging almost surely to X_∞ . If $\Sigma_n \rightarrow \Sigma_\infty$ and $\mu_n \rightarrow \mu_\infty$ then X_∞ is Gaussian with mean μ_∞ and auto-covariance matrix Σ_∞ .

Proof We need to show that the characteristic function of X_∞ is

$$\phi_{X_\infty}(t) := \mathbb{E}(e^{it^T X_\infty}) = e^{it^T \mu_\infty - \frac{1}{2} t^T \Sigma_\infty t}.$$

As Σ_n is positive semi-definite, $\forall n$, $|e^{it^T \mu_n - \frac{1}{2} t^T \Sigma_n t}| = e^{-\frac{1}{2} t^T \Sigma_n t} \leq 1$. Hence, by Lebesgue's dominated convergence theorem,

$$\begin{aligned} \phi_{X_\infty}(t) &= \mathbb{E}(\lim_{n \rightarrow +\infty} e^{it^T X_n}) = \lim_{n \rightarrow +\infty} \mathbb{E}(e^{it^T X_n}) = \lim_{n \rightarrow +\infty} e^{it^T \mu_n - \frac{1}{2} t^T \Sigma_n t} = e^{it^T \mu_\infty - \frac{1}{2} t^T \Sigma_\infty t}. \end{aligned}$$

Appendix E.1 Proof of Proposition 4.1)

Let $x = (t_1^1, \dots, t_1^d) \in I^1 \times \dots \times I^d$. We want to show that $H(\nabla f(x)) = H(\nabla g(x))$ where f and g are as per Proposition 4, and H is the entropy operator. Firstly, we note from Equation (11) that

$$\nabla f(x) = \begin{pmatrix} z_{t_1^1}^1 \\ \vdots \\ z_{t_1^d}^d \end{pmatrix}, \quad (79)$$

where the joint law of the GP $(z_t^j)_{t \in I^j}$ and its derivative $(z_t^j)_{t \in I^j}$ is provided in Proposition 1. As the processes $\left(z_t^j, z_t^j \right)_{t \in I^j}$, $j \in [1, d]$ are assumed to be independent of each other, $\nabla f(x)$ is a Gaussian vector and its covariance matrix reads:

$$\Sigma_{\nabla f(x)} = -2 \frac{dp}{dx}(0) \mathbf{I}_d, \quad (80)$$

where \mathbf{I}_d is the $d \times d$ identity matrix. Hence,

$$H(\nabla f(x)) = \frac{d}{2} (1 + \ln(2\pi)) + \frac{1}{2} \ln |\Sigma_{\nabla f(x)}|. \quad (81)$$

Secondly, let e_j denote the d -dimensional vector whose j -th coordinate is 1 and every other coordinate is 0, and let $h \in \mathbb{R}$. As the proposition assumes the covariance function k generates almost surely C^1 surfaces, the vectors $\left(\frac{g(x+he_1) - g(x)}{h}, \dots, \frac{g(x+he_d) - g(x)}{h} \right)$ are Gaussian vectors converging almost surely as $h \rightarrow 0$. Moreover, their mean is 0 and their covariance matrices have as element on the i -th row and j -th column ($i \neq j$):

$$\text{cov} \left(\frac{g(x+he_i) - g(x)}{h}, \frac{g(x+he_j) - g(x)}{h} \right) = \frac{\rho(2h^2) - 2\rho(h^2) + \rho(0)}{h^2} \quad (82)$$

and as diagonal terms:

$$\text{Var} \left(\frac{g(x+he_j) - g(x)}{h} \right) = 2 \frac{\rho(0) - \rho(h^2)}{h^2}. \quad (83)$$

Taking the limit of Equations (82) and (83) using the first order Taylor expansion of ρ (which the Proposition assumes is C^2), we get that:

$$\Sigma_{\nabla g(x)} = -2 \frac{dp}{dx}(0) \mathbf{I}_d = \Sigma_{\nabla f(x)}, \quad (84)$$

It then follows from Lemma 8 that the limit $\nabla g(x)$ of

$$\left(\frac{g(x+he_1) - g(x)}{h}, \dots, \frac{g(x+he_d) - g(x)}{h} \right)$$

is also a Gaussian vector, which proves that $H(\nabla f(x)) = H(\nabla g(x))$.

Appendix E.2 Proof of Proposition 4.2)

We start by stating and proving another lemma we will later use.

Lemma 9 *Let A and B be two d -dimensional jointly Gaussian vectors with diagonal covariance matrices Σ_A and Σ_B respectively. Let $\Sigma_{A,B}$ be the cross-covariance matrix between A and B , and let $\text{diag}(\Sigma_{A,B})$ be the diagonal matrix whose diagonal is that of $\Sigma_{A,B}$. Then:*

$$\det \left(\begin{array}{c|c} \Sigma_A & \text{diag}(\Sigma_{A,B}) \\ \hline \text{diag}(\Sigma_{A,B}) & \Sigma_B \end{array} \right) \geq \det \left(\begin{array}{c|c} \Sigma_A & \Sigma_{A,B} \\ \hline \Sigma_{A,B}^T & \Sigma_B \end{array} \right).$$

Proof Firstly we note that

$$\det \left(\begin{array}{c|c} \Sigma_A & \text{diag}(\Sigma_{A,B}) \\ \hline \text{diag}(\Sigma_{A,B}) & \Sigma_B \end{array} \right) = \det(\Sigma_A) \det(\Sigma_B - \text{diag}(\Sigma_{A,B}) \Sigma_A^{-1} \text{diag}(\Sigma_{A,B}))$$

and

$$\det \left(\begin{array}{c|c} \Sigma_A & \Sigma_{A,B} \\ \hline \Sigma_{A,B} & \Sigma_B \end{array} \right) = \det(\Sigma_A) \det(\Sigma_B - \Sigma_{A,B}^T \Sigma_A^{-1} \Sigma_{A,B}).$$

As the matrix Σ_A is positive semi-definite, $\det(\Sigma_A) \geq 0$. The case $\det(\Sigma_A) = 0$ is straight-forward. Thus we assume that $\det(\Sigma_A) > 0$, so that all we need to prove is that

$$\det(\Sigma_B - \text{diag}(\Sigma_{A,B}) \Sigma_A^{-1} \text{diag}(\Sigma_{A,B})) \geq \det(\Sigma_B - \Sigma_{A,B}^T \Sigma_A^{-1} \Sigma_{A,B}).$$

Secondly, the matrix $\Sigma_{B|A}^{\text{diag}} := \Sigma_B - \text{diag}(\Sigma_{A,B}) \Sigma_A^{-1} \text{diag}(\Sigma_{A,B})$ being diagonal, its determinant is the product of its diagonal terms:

$$\det(\Sigma_{B|A}^{\text{diag}}) = \prod_{i=1}^d \Sigma_{B|A}[i, i] = \prod_{i=1}^d \left(\Sigma_B[i, i] - \frac{\Sigma_{A,B}[i, i]^2}{\Sigma_A[i, i]} \right).$$

As for the matrix $\Sigma_{B|A} := \Sigma_B - \Sigma_{A,B}^T \Sigma_A^{-1} \Sigma_{A,B}$, we note that it happens to be the covariance matrix of the (Gaussian) distribution of B given A , and thus is positive semi-definite and admits a Cholesky decomposition $\Sigma_{B|A} = LL^T$. It follows that

$$\begin{aligned} \det(\Sigma_{B|A}) &= \prod_{i=1}^d L[i, i]^2 \leq \prod_{i=1}^d \Sigma_{B|A}[i, i] = \prod_{i=1}^d \left(\Sigma_B[i, i] - \sum_{j=1}^d \frac{\Sigma_{A,B}[j, i]^2}{\Sigma_A[j, j]} \right) \\ &\leq \prod_{i=1}^d \left(\Sigma_B[i, i] - \frac{\Sigma_{A,B}[i, i]^2}{\Sigma_A[i, i]} \right) = \det(\Sigma_{B|A}^{\text{diag}}), \end{aligned} \quad (85)$$

where the first inequality results from the fact that $\Sigma_{B|A}[i, i] = \sum_{j=1}^d L[j, i]^2$ by definition of the Cholesky decomposition. This proves that

$$\det(\Sigma_B - \text{diag}(\Sigma_{A,B}) \Sigma_A^{-1} \text{diag}(\Sigma_{A,B})) \geq \det(\Sigma_B - \Sigma_{A,B}^T \Sigma_A^{-1} \Sigma_{A,B}),$$

which as previously discussed concludes the proof of the lemma. \blacksquare

Proof of Proposition 4.2): Let $x = (t_1^x, \dots, t_d^x)$, $y = (t_1^y, \dots, t_d^y) \in I^1 \times \dots \times I^d$, $x \neq y$. We want to show that $I(\nabla f(x); \nabla f(y)) \leq I(\nabla g(x); \nabla g(y))$ where f and g are as per Proposition 4, and

$$I(X; Y) = H(X) + H(Y) - H(X, Y)$$

is the mutual information between X and Y . As we have proved that $\forall x, H(\nabla f(x)) = H(\nabla g(x))$, all we need to prove now is that

$$H(\nabla f(x), \nabla f(y)) \geq H(\nabla g(x), \nabla g(y)).$$

Firstly, it follows from Equation (79) and the fact that the *derivative Gaussian processes* $(z_t^f, z_t^g)_{t \in I^d}$ are independent that $(\nabla f(x), \nabla f(y))$ is a jointly Gaussian vector. Moreover, the cross-covariance matrix $\Sigma_{\nabla f(x), \nabla f(y)}$ is diagonal with diagonal terms:

$$\Sigma_{\nabla f(x), \nabla f(y)}[i, i] = -2 \left[\frac{d\rho}{dx} (\|x - y\|_{L^2}^2) + 2(t_i^x - t_i^y)^2 \frac{d^2\rho}{dx^2} (\|x - y\|_{L^2}^2) \right]. \quad (86)$$

Secondly, it follows from a similar argument to the previous proof that $(\nabla g(x), \nabla g(y))$ is also a jointly Gaussian vector, and the terms $\Sigma_{\nabla g(x), \nabla g(y)}[i, j]$ are evaluated as limit of the cross-covariance terms $\text{cov} \left(\frac{g(x+he_i) - g(x)}{h}, \frac{g(y+he_j) - g(y)}{h} \right)$ as $h \rightarrow 0$. For $i = j$,

$$\begin{aligned} \text{cov} \left(\frac{g(x+he_i) - g(x)}{h}, \frac{g(y+he_i) - g(y)}{h} \right) &= \frac{1}{h^2} \left\{ 2\rho \left(\sum_{k \neq i} (t_k^x - t_k^y)^2 \right) \right. \\ &\quad \left. - \rho \left(\sum_{k \neq i} (t_k^x - t_k^y)^2 + (t_i^x + h - t_i^y)^2 \right) - \rho \left(\sum_{k \neq i} (t_k^x - t_i^y)^2 + (t_i^x - h - t_k^y)^2 \right) \right\}, \end{aligned} \quad (87)$$

As ρ is assumed to be \mathcal{C}^2 , the below Taylor expansions around $h = 0$ hold true:

$$\rho \left(\sum_k (t_k^x - t_k^y)^2 \right) - \rho \left(\sum_{k \neq i} (t_k^x - t_k^y)^2 + (t_i^x - h - t_i^y)^2 \right) = 2(t_i^x - t_i^y) h \frac{d\rho}{dx} \left(\sum_k (t_k^x - t_k^y)^2 \right) \quad (88)$$

$$- \left[\frac{d\rho}{dx} \left(\sum_k (t_k^x - t_k^y)^2 \right) + 2(t_i^x - t_i^y)^2 \frac{d^2\rho}{dx^2} \left(\sum_k (t_k^x - t_k^y)^2 \right) \right] h^2 + o(h^2)$$

$$\rho \left(\sum_k (t_k^x - t_k^y)^2 \right) - \rho \left(\sum_{k \neq i} (t_k^x - t_k^y)^2 + (t_i^x + h - t_i^y)^2 \right) = -2(t_i^x - t_i^y) h \frac{d\rho}{dx} \left(\sum_k (t_k^x - t_k^y)^2 \right) \quad (89)$$

$$- \left[\frac{d\rho}{dx} \left(\sum_k (t_k^x - t_k^y)^2 \right) + 2(t_i^x - t_i^y)^2 \frac{d^2\rho}{dx^2} \left(\sum_k (t_k^x - t_k^y)^2 \right) \right] h^2 + o(h^2)$$

Plugging Equations (88) and (89) into Equation (87) and taking the limit we obtain:

$$\begin{aligned} \Sigma_{\nabla g(x), \nabla g(y)}[i, j] &= -2 \left[\frac{d\rho}{dx} (|x - y|_{L^2}^2) + 2(t_i^x - t_j^y)^2 \frac{d^2\rho}{dx^2} (|x - y|_{L^2}^2) \right] \\ &= \Sigma_{\nabla f(x), \nabla f(y)}[i, j]. \end{aligned} \quad (90)$$

Similarly for $i \neq j$,

$$\begin{aligned} \text{cov} \left(\frac{g(x + h e_i) - g(x)}{h}, \frac{g(y + h e_j) - g(y)}{h} \right) \\ &= \frac{1}{h^2} \left\{ \rho \left(\sum_{k \neq i, j} (t_k^x - t_k^y)^2 + (t_i^x + h - t_j^y)^2 + (t_j^x - h - t_i^y)^2 \right) \right. \\ &\quad - \rho \left(\sum_{k \neq i} (t_k^x - t_k^y)^2 + (t_i^x + h - t_j^y)^2 \right) - \rho \left(\sum_{k \neq j} (t_k^x - t_k^y)^2 + (t_i^x - h - t_j^y)^2 \right) \\ &\quad \left. + \rho \left(\sum_k (t_k^x - t_k^y)^2 \right) \right\}, \end{aligned} \quad (91)$$

and

$$\begin{aligned} &\rho \left(\sum_{k \neq i, j} (t_k^x - t_k^y)^2 + (t_i^x + h - t_j^y)^2 + (t_j^x - h - t_i^y)^2 \right) - \rho \left(\sum_k (t_k^x - t_k^y)^2 \right) \\ &= \left[2 \frac{d\rho}{dx} \left(\sum_k (t_k^x - t_k^y)^2 \right) + 2 \left((t_i^x - t_j^y) - (t_j^x - t_i^y) \right)^2 \times \frac{d^2\rho}{dx^2} \left(\sum_k (t_k^x - t_k^y)^2 \right) \right] h^2 \\ &\quad + 2 \left(t_i^x - t_j^y - t_j^x + t_i^y \right) \frac{d\rho}{dx} \left(\sum_k (t_k^x - t_k^y)^2 \right) h + o(h^2). \end{aligned} \quad (92)$$

Plugging Equations (88), (89) and (92) in Equation (91) and taking the limit we obtain:

$$\Sigma_{\nabla g(x), \nabla g(y)}[i, j] = -4(t_i^x - t_j^y)(t_j^x - t_i^y) \frac{d^2\rho}{dx^2} (|x - y|_{L^2}^2). \quad (93)$$

To summarize, $(\nabla f(x), \nabla f(y))$ and $(\nabla g(x), \nabla g(y))$ are both jointly Gaussian vectors; $\nabla f(x)$, $\nabla g(x)$, $\nabla f(y)$, and $\nabla g(y)$ are (Gaussian) identically distributed with a diagonal covariance matrix; $\Sigma_{\nabla f(x), \nabla f(y)}$ is diagonal; $\Sigma_{\nabla g(x), \nabla g(y)}$ has the same diagonal as $\Sigma_{\nabla f(x), \nabla f(y)}$ but has possibly non-zero off-diagonal terms. Hence, it follows from Lemma 9 that the determinant of the auto-covariance matrix of $(\nabla f(x), \nabla f(y))$ is higher than that of the auto-covariance matrix of $(\nabla g(x), \nabla g(y))$; or equivalently the entropy of $(\nabla f(x), \nabla f(y))$ is higher than that of $(\nabla g(x), \nabla g(y))$ (as both are Gaussian vectors), which as previously discussed is sufficient to conclude that the mutual information between $\nabla f(x)$ and $\nabla f(y)$ is smaller than that between $\nabla g(x)$ and $\nabla g(y)$.

Appendix F. Proof of Proposition 6

In this section, we prove Proposition 6, which we recall below.

Proposition 6 (Extension of the standard GP paradigm)

Let $K \in \mathbb{N}^*$, let $I = [a_0, a_K]$ and $I_k = [a_{k-1}, a_k]$ be intervals with $a_0 < \dots < a_K$. Furthermore, let $m : I \rightarrow \mathbb{R}$ be a C^1 function, m_k the restriction of m to I_k , $h : I \times I \rightarrow \mathbb{R}$ a C^3 symmetric positive semi-definite function, and h_k the restriction of h to $I_k \times I_k$. If

$$(z_t)_{t \in I} \sim \text{SGP}(\{a_k\}, \{m_k\}, \{h_k\}),$$

then

$$\forall h \in [1, K], (z_t)_{t \in I_k} \sim \text{GP}(m, h).$$

Proof

To prove Proposition 6, we consider the string derivative Gaussian process (Theorem 2) $(SD_t)_{t \in I}$, $SD_t = (z_t, \dot{z}_t)$ with unconditional string mean and covariance functions as per Proposition 6 and prove that its restrictions on the intervals $I_k = [a_{k-1}, a_k]$ are derivative Gaussian processes with the same mean function m and covariance function h . Proposition 1(B) will then allow us to conclude that $(z_t)_{t \in I_k}$ are GPs with mean m and covariance function h .

Let $t_1, \dots, t_n \in [a_{k-1}, a_k]$ and let $p_D(x_{a_{k-1}})$ (respectively $p_D(x_{a_k} | x_{a_{k-1}})$) and $p_D(x_{t_1}, \dots, x_{t_n} | x_{a_{k-1}}, x_{a_k})$ denote the pdf of the derivative Gaussian process with mean function m and covariance function h at a_{k-1} (respectively its value at a_k conditional on its value at a_{k-1} , and its values at t_1, \dots, t_n conditional on its values at a_{k-1} and a_k). Saying that the restriction of the string derivative Gaussian process (SD_t) on $[a_{k-1}, a_k]$ is the derivative Gaussian process with mean m and covariance h is equivalent to saying that all finite dimensional marginals of the string derivative Gaussian process $PSD(x_{a_{k-1}}, x_{t_1}, \dots, x_{t_n}, x_{a_k})$, $t_i \in [a_{k-1}, a_k]$, factorise as²⁰:

$$p_{PSD}(x_{a_{k-1}}, x_{t_1}, \dots, x_{t_n}, x_{a_k}) = p_D(x_{a_{k-1}}) p_D(x_{t_1}, \dots, x_{t_n} | x_{a_{k-1}}, x_{a_k}).$$

Moreover, we know from Theorem 2 that by design, $p_{PSD}(x_{a_{k-1}}, x_{t_1}, \dots, x_{t_n}, x_{a_k})$ factorises as

$$p_{PSD}(x_{a_{k-1}}, x_{t_1}, \dots, x_{t_n}, x_{a_k}) = p_{SD}(x_{a_{k-1}} | x_{a_{k-1}}) p_D(x_{t_1}, \dots, x_{t_n} | x_{a_{k-1}}, x_{a_k}).$$

In other words, all we need to prove is that

$$p_{SD}(x_{a_k}) = p_D(x_{a_k})$$

for every boundary time, which we will do by induction. We note by integrating out every boundary condition but the first in p_k (as per Theorem 2 (a-1)) that

$$p_{SD}(x_{a_0}) = p_D(x_{a_0}).$$

If we assume that $p_{SD}(x_{a_{k-1}}) = p_D(x_{a_{k-1}})$ for some $k > 0$, then as previously discussed the restriction of the string derivative Gaussian process on $[a_{k-1}, a_k]$ will be the derivative Gaussian process with the same mean and covariance functions, which will imply that $p_{SD}(x_{a_k}) = p_D(x_{a_k})$. This concludes the proof. \blacksquare

²⁰ We emphasize that the terms on the right hand-side of this equation involve p_D not p_{SD} .

Appendix G. Proof of Lemma 10

In this section, we will prove Lemma 10 that we recall below.

Lemma 10 Let \tilde{X} be a multivariate Gaussian with mean μ_X and covariance matrix Σ_X . If conditional on \tilde{X} , Y is a multivariate Gaussian with mean $M\tilde{X} + A$ and covariance matrix Σ_Y^c , where M , A and Σ_Y^c do not depend on \tilde{X} , then (X, Y) is a jointly Gaussian vector with mean

$$\mu_{X;Y} = \begin{bmatrix} \mu_X \\ M\mu_X + A \end{bmatrix},$$

and covariance matrix

$$\Sigma_{X;Y} = \begin{bmatrix} \Sigma_X & \Sigma_X M^T \\ M\Sigma_X & \Sigma_Y^c + M\Sigma_X M^T \end{bmatrix}.$$

Proof To prove this lemma we introduce two vectors \tilde{X} and \tilde{Y} whose lengths are the same as those of X and Y respectively, and such that (\tilde{X}, \tilde{Y}) is jointly Gaussian with mean $\mu_{X;Y}$ and covariance matrix $\Sigma_{X;Y}$. We then prove that the (marginal) distribution of \tilde{X} is the same as the distribution of X and that the distribution of $\tilde{Y}|\tilde{X} = x$ is the same as $Y|X = x$ for any x , which is sufficient to conclude that (X, Y) and (\tilde{X}, \tilde{Y}) have the same distribution.

It is obvious from the joint (\tilde{X}, \tilde{Y}) that \tilde{X} is Gaussian distribution with mean μ_X and covariance matrix Σ_X . As for the distribution of \tilde{Y} conditional on $\tilde{X} = x$, it follows from the usual Gaussian identities that it is Gaussian with mean

$$M\mu_X + c + M\Sigma_X \Sigma_X^{-1}(x - \mu_X) = Mx + c,$$

and covariance matrix

$$\Sigma_Y^c + M\Sigma_X M^T - M\Sigma_X \Sigma_X^{-1} \Sigma_X^T M^T = \Sigma_Y^c,$$

which is the same distribution as that of $Y|X = x$ since the covariance matrix Σ_X is symmetric. This concludes our proof. \blacksquare

Appendix H. Proof of Proposition 5

In this section we will prove that *string GPs* with link function ϕ_s are GPs, or in other words that if f is a *string GP* indexed on \mathbb{R}^d , $d > 0$ with link function $\phi_s(x_1, \dots, x_d) = \sum_{j=1}^d x_j$, then $(f(x_1), \dots, f(x_n))$ has a multivariate Gaussian distribution for every set of distinct points $x_1, \dots, x_n \in \mathbb{R}^d$.

Proof As the sum of independent Gaussian processes is a Gaussian process, a sufficient condition for additively separable *string GPs* to be GPs in dimensions $d > 1$ is that *string GPs* be GPs in dimension 1. Hence, all we need to do is to prove that *string GPs* are GPs in dimension 1.

Let $(z_t^j, z_t^j)_{t \in \mathcal{I}^j}$ be a string derivative GP in dimension 1, with boundary times $a_0^j, \dots, a_{K^j}^j$, and unconditional string mean and covariance functions m_k^j and k_k^j respectively. We want to prove that $(z_{t_1}^j, \dots, z_{t_n}^j)$ is jointly Gaussian for any $t_1, \dots, t_n \in \mathcal{I}^j$.

APPENDIX H.0.1 STEP 1 $(z_{a_0^j}^j, z_{a_0^j}^j, \dots, z_{a_{K^j}^j}^j, z_{a_{K^j}^j}^j)$ IS JOINTLY GAUSSIAN

We first prove recursively that the vector $(z_{a_0^j}^j, z_{a_0^j}^j, \dots, z_{a_{K^j}^j}^j, z_{a_{K^j}^j}^j)$ is jointly Gaussian. We note from Theorem 2 that $(z_t^j, z_t^j)_{t \in [a_0, a_1]}$ is the *derivative Gaussian process* with mean m_1^j and covariance function k_1^j . Hence, $(z_{a_0^j}^j, z_{a_0^j}^j, \dots, z_{a_1^j}^j, z_{a_1^j}^j)$ is jointly Gaussian. Moreover, let us assume that $\mathcal{B}_{k-1} := (z_{a_0^j}^j, z_{a_0^j}^j, \dots, z_{a_{k-1}^j}^j, z_{a_{k-1}^j}^j)$ is jointly Gaussian for some $k > 1$. Conditional on \mathcal{B}_{k-1} , $(z_{a_k^j}^j, z_{a_k^j}^j)$ is Gaussian with covariance matrix independent of \mathcal{B}_{k-1} , and with mean

$$\begin{bmatrix} m_k^j(a_k^j) \\ \frac{dm_k^j}{dt}(a_k^j) \end{bmatrix} + {}^j\mathbf{K}_{a_k^j, a_{k-1}^j} {}^j\mathbf{K}_{a_{k-1}^j, a_{k-1}^j}^{-1} \begin{bmatrix} z_{a_{k-1}^j}^j - m_k^j(a_{k-1}^j) \\ z_{a_{k-1}^j}^j - \frac{dm_k^j}{dt}(a_{k-1}^j) \end{bmatrix},$$

which depends linearly on $(z_{a_0^j}^j, z_{a_0^j}^j, \dots, z_{a_{k-1}^j}^j, z_{a_{k-1}^j}^j)$. Hence by Lemma 10,

$$(z_{a_0^j}^j, z_{a_0^j}^j, \dots, z_{a_k^j}^j, z_{a_k^j}^j)$$

is jointly Gaussian.

APPENDIX H.0.2 STEP 2 $(z_{a_0^j}^j, z_{a_0^j}^j, \dots, z_{a_{K^j}^j}^j, z_{a_{K^j}^j}^j, \dots, z_{t_k^j}^j, z_{t_k^j}^j, \dots)$ IS JOINTLY GAUSSIAN

Let $t_k^j, \dots, t_n^j \in]a_{k-1}^j, a_k^j[$, $k \leq K^j$ be distinct string times. We want to prove that the vector $(z_{a_0^j}^j, z_{a_0^j}^j, \dots, z_{a_{K^j}^j}^j, z_{a_{K^j}^j}^j, \dots, z_{t_k^j}^j, z_{t_k^j}^j, \dots)$ where all boundary times are represented, and for any finite number of string times is jointly Gaussian. Firstly, we have already proved that

$(z_{a_0^j}^j, z_{a_0^j}^j, \dots, z_{a_{K^j}^j}^j, z_{a_{K^j}^j}^j)$ is jointly Gaussian. Secondly, we note from Theorem 2 that conditional on $(z_{a_0^j}^j, z_{a_0^j}^j, \dots, z_{a_{K^j}^j}^j, z_{a_{K^j}^j}^j)$, $(\dots, z_{t_k^j}^j, z_{t_k^j}^j, \dots)$ is a Gaussian vector whose covariance matrix does not depend on $(z_{a_0^j}^j, z_{a_0^j}^j, \dots, z_{a_{K^j}^j}^j, z_{a_{K^j}^j}^j)$, and whose mean depends linearly on

$$(z_{a_0^j}^j, z_{a_0^j}^j, \dots, z_{a_{K^j}^j}^j, z_{a_{K^j}^j}^j).$$

Hence,

$$(z_{a_0^j}^j, z_{a_0^j}^j, \dots, z_{a_{K^j}^j}^j, z_{a_{K^j}^j}^j, \dots, z_{t_k^j}^j, z_{t_k^j}^j, \dots)$$

is jointly Gaussian (by Lemma 10).

APPENDIX H.0.3 STEP 3 $(z_{t_1}^j, \dots, z_{t_n}^j)$ IS JOINTLY GAUSSIAN

$(z_{t_1}^j, z_{t_1}^j, \dots, z_{t_n}^j, z_{t_n}^j)$ is jointly Gaussian as it can be regarded as the marginal of some joint distribution of the form $(z_{a_0^j}^j, z_{a_0^j}^j, \dots, z_{a_{K^j}^j}^j, z_{a_{K^j}^j}^j, \dots, z_{t_k^j}^j, z_{t_k^j}^j, \dots)$. Hence, its marginal $(z_{t_1}^j, \dots, z_{t_n}^j)$ is also jointly Gaussian, which concludes our proof. \blacksquare

Appendix I. Derivation of Global String GP Mean and Covariance Functions

We begin with *derivative string GPs* indexed on \mathbb{R} . Extensions to *membrane GPs* are easily achieved for a broad range of link functions. In our exposition, we focus on the class of *elementary symmetric*

polynomials (Macdonald (1995)). In addition to containing the link function ϕ_s previously introduced, this family of polynomials yields global covariance structures that have many similarities with existing kernel approaches, which we discuss in Section 4.3.

For $n \leq d$, the n -th order elementary symmetric polynomial is given by

$$e_0(x_1, \dots, x_d) := 1, \quad \forall 1 \leq n \leq d \quad e_n(x_1, \dots, x_d) = \sum_{1 \leq i_1 < i_2 < \dots < i_n \leq d} \prod_{k=1}^n x_{i_k}. \quad (94)$$

As an illustration,

$$\begin{aligned} e_1(x_1, \dots, x_d) &= \sum_{j=1}^d x_j = \phi_8(x_1, \dots, x_d), \\ e_2(x_1, \dots, x_d) &= x_1 x_2 + x_1 x_3 + \dots + x_1 x_d + \dots + x_{d-1} x_d, \\ &\dots \\ e_d(x_1, \dots, x_d) &= \prod_{j=1}^d x_j = \phi_9(x_1, \dots, x_d). \end{aligned}$$

Let f denote a *membrane GP* indexed on \mathbb{R}^d with link function e_n and by $(z_1^1), \dots, (z_1^d)$, its independent building block string GPs. Furthermore, let m_k^j and k_k^j denote the unconditional mean and covariance functions corresponding to the k -th string of (z_k^j) defined on $[a_{k-1}^j, a_k^j]$. Finally, let us define

$$\bar{m}^j(t) := \mathbb{E}(z_k^j), \quad \bar{m}^{j'}(t) := \mathbb{E}(z_k^{j'}),$$

the global mean functions of the j -th building block string GP and of its derivative, where $\forall t \in I^j$. It follows from the independence of the building block string GPs that:

$$\bar{m}^f(t_1, \dots, t_d) := \mathbb{E}(f(t_1, \dots, t_d)) = e_n(\bar{m}^1(t_1), \dots, \bar{m}^d(t_d)).$$

Moreover, noting that

$$\frac{\partial e_n}{\partial x_j} = e_{n-1}(x_1, \dots, x_{j-1}, x_{j+1}, \dots, x_d),$$

it follows that:

$$\bar{m}^{\nabla f}(t_1, \dots, t_d) := \mathbb{E}(\nabla f(t_1, \dots, t_d)) = \begin{bmatrix} \bar{m}^{1'}(t_1) e_{n-1}(\bar{m}^2(t_2), \dots, \bar{m}^d(t_d)) \\ \bar{m}^{2'}(t_2) e_{n-1}(\bar{m}^1(t_1), \dots, \bar{m}^{d-1}(t_{d-1})) \\ \dots \\ \bar{m}^{d'}(t_d) e_{n-1}(\bar{m}^1(t_1), \dots, \bar{m}^{d-1}(t_{d-1})) \end{bmatrix}.$$

Furthermore, for any $u_j, v_j \in I^j$ we also have that

$$\text{cov}(f(u_1, \dots, u_d), f(v_1, \dots, v_d)) = e_n(\text{cov}(z_{u_1}^1, z_{v_1}^1), \dots, \text{cov}(z_{u_d}^d, z_{v_d}^d)),$$

$$\text{cov}\left(\frac{\partial f}{\partial x_i}(u_1, \dots, u_d), f(v_1, \dots, v_d)\right) = e_n(\text{cov}(z_{u_1}^{i-1}, z_{v_1}^1), \dots, \text{cov}(z_{u_i}^i, z_{v_i}^i), \dots, \text{cov}(z_{u_d}^d, z_{v_d}^d)),$$

and for $i \leq j$

$$\text{cov}\left(\frac{\partial f}{\partial x_i}(u_1, \dots, u_d), \frac{\partial f}{\partial x_j}(v_1, \dots, v_d)\right) = \begin{cases} e_n(\text{cov}(z_{u_1}^1, z_{v_1}^1), \dots, \text{cov}(z_{u_i}^i, z_{v_i}^i), \dots, \text{cov}(z_{u_d}^d, z_{v_d}^d)), & \text{if } i < j \\ e_n(\text{cov}(z_{u_1}^1, z_{v_1}^1), \dots, \text{cov}(z_{u_i}^i, z_{v_i}^i), \dots, \text{cov}(z_{u_d}^d, z_{v_d}^d)), & \text{if } i = j \end{cases}.$$

Overall, for any elementary symmetric polynomial link function, multivariate mean and covariance functions are easily deduced from the previously boxed equations and the univariate quantities

$$\bar{m}^j(u), \quad \bar{m}^{j'}(u), \quad \text{and } {}^j\mathbf{K}_{uv} := \begin{bmatrix} \text{cov}(z_u^j, z_u^j) & \text{cov}(z_u^j, z_v^j) \\ \text{cov}(z_u^j, z_v^j) & \text{cov}(z_v^j, z_v^j) \end{bmatrix} = {}^j\mathbf{K}_{v;u}^T$$

which we now derive. In this regards, we will need the following lemma.

Lemma 10 *Let X be a multivariate Gaussian with mean μ_X and covariance matrix Σ_X . If conditional on X , Y is a multivariate Gaussian with mean $MX + A$ and covariance matrix Σ_Y^X where M, A and Σ_Y^X do not depend on X , then (X, Y) is a jointly Gaussian vector with mean*

$$\mu_{X;Y} = \begin{bmatrix} \mu_X \\ M\mu_X + A \end{bmatrix},$$

and covariance matrix

$$\Sigma_{X;Y} = \begin{bmatrix} \Sigma_X & \Sigma_X M^T \\ M \Sigma_X & \Sigma_Y^X + M \Sigma_X M^T \end{bmatrix}.$$

Proof See Appendix G. ■

APPENDIX I.0.1 GLOBAL STRING GP MEAN FUNCTIONS

We now turn to evaluating the univariate global mean functions \bar{m}^j and $\bar{m}^{j'}$. We start with boundary times and then generalise to other times.

Boundary times: We note from Theorem 2 that the restriction $(z_k^j, z_k^{j'})_{k \in [a_0^j, a_1^j]}$ is the derivative Gaussian process with mean and covariance functions m_1^j and k_1^j . Thus,

$$\begin{bmatrix} \bar{m}^j(a_0^j) \\ \bar{m}^{j'}(a_0^j) \end{bmatrix} = \begin{bmatrix} m_1^j(a_0^j) \\ \frac{dm_1^j}{dt}(a_0^j) \end{bmatrix}, \quad \text{and} \quad \begin{bmatrix} \bar{m}^j(a_1^j) \\ \bar{m}^{j'}(a_1^j) \end{bmatrix} = \begin{bmatrix} m_1^j(a_1^j) \\ \frac{dm_1^j}{dt}(a_1^j) \end{bmatrix}.$$

For $k > 1$, we recall that conditional on $(z_{a_{k-1}^j}^j, z_{a_{k-1}^j}^{j'})$, $(z_{a_k^j}^j, z_{a_k^j}^{j'})$ is Gaussian with mean

$$\begin{bmatrix} \bar{m}_k^j(a_k^j) \\ \bar{m}_k^{j'}(a_k^j) \end{bmatrix} + {}^j\mathbf{K}_{a_k^j, a_{k-1}^j} \begin{bmatrix} z_{a_{k-1}^j}^j \\ z_{a_{k-1}^j}^{j'} \end{bmatrix} - \begin{bmatrix} m_k^j(a_{k-1}^j) \\ \frac{dm_k^j}{dt}(a_{k-1}^j) \end{bmatrix} + {}^j\mathbf{K}_{a_{k-1}^j, a_k^j} \begin{bmatrix} z_{a_{k-1}^j}^j \\ z_{a_{k-1}^j}^{j'} \end{bmatrix} - \begin{bmatrix} m_k^j(a_{k-1}^j) \\ \frac{dm_k^j}{dt}(a_{k-1}^j) \end{bmatrix},$$

$$\text{with } {}^j\mathbf{K}_{u,v} = \begin{bmatrix} k_k^j(u, v) & \frac{\partial k_k^j}{\partial x}(u, v) \\ \frac{\partial k_k^j}{\partial x}(u, v) & \frac{\partial^2 k_k^j}{\partial x^2}(u, v) \end{bmatrix}.$$

It then follows from the law of total expectations that for all $k > 1$

$$\begin{bmatrix} \bar{m}_k^j(a_k^j) \\ \bar{m}_k^{j'}(a_k^j) \end{bmatrix} = \begin{bmatrix} m_k^j(a_k^j) \\ \frac{dm_k^j}{dt}(a_k^j) \end{bmatrix} + {}^j\mathbf{K}_{a_k^j, a_{k-1}^j} {}^j\mathbf{K}_{a_{k-1}^j}^{-1} \begin{bmatrix} \bar{m}^j(a_{k-1}^j) - m_k^j(a_{k-1}^j) \\ \bar{m}^{j'}(a_{k-1}^j) - \frac{dm_k^j}{dt}(a_{k-1}^j) \end{bmatrix}.$$

String times: As for non-boundary times $t \in]a_{k-1}^j, a_k^j[$, conditional on $(z_{a_{k-1}^j}^j, z_{a_{k-1}^j}^{j'})$ and $(z_{a_k^j}^j, z_{a_k^j}^{j'})$, $(z_t^j, z_t^{j'})$ is Gaussian with mean

$$\begin{bmatrix} m_k^j(t) \\ \frac{dm_k^j}{dt}(t) \end{bmatrix} + {}^j\mathbf{K}_{t, (a_{k-1}^j, a_k^j)} {}^j\mathbf{K}_{(a_{k-1}^j, a_k^j)}^{-1} (a_{k-1}^j, a_k^j); (a_{k-1}^j, a_k^j) \begin{bmatrix} z_{a_{k-1}^j}^j - m_k^j(a_{k-1}^j) \\ z_{a_{k-1}^j}^{j'} - \frac{dm_k^j}{dt}(a_{k-1}^j) \\ z_{a_k^j}^j - m_k^j(a_k^j) \\ z_{a_k^j}^{j'} - \frac{dm_k^j}{dt}(a_k^j) \end{bmatrix},$$

with

$${}^j\mathbf{K}_{(a_{k-1}^j, a_k^j); (a_{k-1}^j, a_k^j)} = \begin{bmatrix} {}^j\mathbf{K}_{a_{k-1}^j, a_{k-1}^j} & {}^j\mathbf{K}_{a_{k-1}^j, a_k^j} \\ {}^j\mathbf{K}_{a_k^j, a_{k-1}^j} & {}^j\mathbf{K}_{a_k^j, a_k^j} \end{bmatrix}$$

and

$${}^j\mathbf{K}_{t, (a_{k-1}^j, a_k^j)} = \begin{bmatrix} {}^j\mathbf{K}_{t, a_{k-1}^j} & {}^j\mathbf{K}_{t, a_k^j} \end{bmatrix}.$$

Hence, using once again the law of total expectation, it follows that for any $t \in]a_{k-1}^j, a_k^j[$,

$$\begin{bmatrix} \bar{m}_k^j(t) \\ \bar{m}_k^{j'}(t) \end{bmatrix} = \begin{bmatrix} m_k^j(t) \\ \frac{dm_k^j}{dt}(t) \end{bmatrix} + {}^j\mathbf{K}_{t, (a_{k-1}^j, a_k^j); (a_{k-1}^j, a_k^j)} {}^j\mathbf{K}_{(a_{k-1}^j, a_k^j)}^{-1} \begin{bmatrix} \bar{m}^j(a_{k-1}^j) - m_k^j(a_{k-1}^j) \\ \bar{m}^{j'}(a_{k-1}^j) - \frac{dm_k^j}{dt}(a_{k-1}^j) \\ \bar{m}^j(a_k^j) - m_k^j(a_k^j) \\ \bar{m}^{j'}(a_k^j) - \frac{dm_k^j}{dt}(a_k^j) \end{bmatrix}.$$

We note in particular that when $\forall j, k, m_k^j = 0$, it follows that $\bar{m}^j = 0, \bar{m}^{j'} = 0, \bar{m} \nabla f = 0$.

APPENDIX I.0.2 GLOBAL STRING GP COVARIANCE FUNCTIONS

As for the evaluation of ${}^j\mathbf{K}_{u,v}$, we start by noting that the covariance function of a univariate *string GP* is the same as that of another *string GP* whose strings have the same unconditional kernels but unconditional mean functions $m_k^j = 0$, so that to evaluate univariate *string GP* kernels we may assume that $\forall j, k, m_k^j = 0$ without loss of generality. We start with the case where u and v are both boundary times, after which we will generalise to other times.

Boundary times: As previously discussed, the restriction $(z_t^j, z_t^{j'})_{t \in \{a_0^j, a_1^j\}}$ is the *derivative Gaussian process* with mean 0 and covariance function $k_{a_0^j}^j$. Thus,

$${}^j\bar{\mathbf{K}}_{a_0^j, a_0^j} = {}^j\mathbf{K}_{a_0^j, a_0^j}, \quad {}^j\bar{\mathbf{K}}_{a_1^j, a_1^j} = {}^j\mathbf{K}_{a_1^j, a_1^j}, \quad {}^j\bar{\mathbf{K}}_{a_0^j, a_1^j} = {}^j\mathbf{K}_{a_0^j, a_1^j}. \quad (95)$$

We recall that conditional on the boundary conditions at or prior to a_{k-1}^j , $(z_{a_k^j}^j, z_{a_k^j}^{j'})$ is Gaussian with mean

$$\begin{bmatrix} z_{a_{k-1}^j}^j \\ z_{a_{k-1}^j}^{j'} \end{bmatrix} \quad \text{with} \quad b_k M = {}^j\mathbf{K}_{a_k^j, a_{k-1}^j} {}^j\mathbf{K}_{a_{k-1}^j, a_{k-1}^j}^{-1},$$

and covariance matrix

$${}^j\mathbf{K}_{a_k^j, a_k^j} = {}^j\mathbf{K}_{a_k^j, a_{k-1}^j} - b_k M {}^j\mathbf{K}_{a_{k-1}^j, a_{k-1}^j}^{-1} b_k M^T.$$

Hence using Lemma 10 with $M = \begin{bmatrix} b_k M & 0 & \dots & 0 \end{bmatrix}$ where there are $(k-1)$ null block 2×2 matrices, and noting that $(z_{a_0^j}^j, z_{a_0^j}^{j'}, \dots, z_{a_{k-1}^j}^j, z_{a_{k-1}^j}^{j'})$ is jointly Gaussian, it follows that the vector

$(z_{a_0^j}^j, z_{a_0^j}^{j'}, \dots, z_{a_k^j}^j, z_{a_k^j}^{j'})$ is jointly Gaussian, that $(z_{a_k^j}^j, z_{a_k^j}^{j'})$ has covariance matrix

$${}^j\bar{\mathbf{K}}_{a_k^j, a_k^j} = \begin{bmatrix} b_k \Sigma & b_k M {}^j\bar{\mathbf{K}}_{a_{k-1}^j, a_{k-1}^j}^{-1} b_k M^T \\ b_k M {}^j\bar{\mathbf{K}}_{a_{k-1}^j, a_{k-1}^j}^{-1} b_k M^T & {}^j\mathbf{K}_{a_{k-1}^j, a_{k-1}^j} \end{bmatrix},$$

and that the covariance matrix between the boundary conditions at a_k^j and at any earlier boundary time $a_l^j, l < k$ reads:

$${}^j\bar{\mathbf{K}}_{a_l^j, a_k^j} = \begin{bmatrix} b_l M & b_l M {}^j\bar{\mathbf{K}}_{a_{k-1}^j, a_{k-1}^j}^{-1} b_k M^T \\ b_l M {}^j\bar{\mathbf{K}}_{a_{k-1}^j, a_{k-1}^j}^{-1} b_k M^T & {}^j\mathbf{K}_{a_{k-1}^j, a_{k-1}^j} \end{bmatrix}.$$

String times: Let $u \in]a_{p-1}^j, a_p^j[$, $v \in]a_{q-1}^j, a_q^j[$. By the law of total expectation, we have that

$${}^j\bar{\mathbf{K}}_{u,v} := \mathbb{E} \left(\begin{bmatrix} z_u^j \\ z_u^{j'} \end{bmatrix} \begin{bmatrix} z_v^j \\ z_v^{j'} \end{bmatrix} \right) = \mathbb{E} \left(\mathbb{E} \left(\begin{bmatrix} z_u^j \\ z_u^{j'} \end{bmatrix} \begin{bmatrix} z_v^j \\ z_v^{j'} \end{bmatrix} \middle| \mathcal{B}(p, q) \right) \right),$$

where $\mathcal{B}(p, q)$ refers to the boundary conditions at the boundaries of the p -th and q -th strings, in other words $\left\{ z_x^j, z_x^{j'} \mid x \in \{a_{p-1}^j, a_p^j, a_{q-1}^j, a_q^j\} \right\}$. Furthermore, using the definition of the covariance matrix under the conditional law, it follows that

$$\mathbb{E} \left(\begin{bmatrix} z_u^j \\ z_u^{j'} \end{bmatrix} \begin{bmatrix} z_v^j \\ z_v^{j'} \end{bmatrix} \middle| \mathcal{B}(p, q) \right) = {}^j\bar{\mathbf{K}}_{u,v} + \mathbb{E} \left(\begin{bmatrix} z_u^j \\ z_u^{j'} \end{bmatrix} \mathcal{B}(p, q) \right) \mathbb{E} \left(\begin{bmatrix} z_v^j \\ z_v^{j'} \end{bmatrix} \middle| \mathcal{B}(p, q) \right), \quad (96)$$

where ${}^j\bar{\mathbf{K}}_{u,v}$ refers to the covariance matrix between $(z_u^j, z_u^{j'})$ and $(z_v^j, z_v^{j'})$ conditional on the boundary conditions $\mathcal{B}(p, q)$, and can be easily evaluated from Theorem 2. In particular,

$$\text{if } p \neq q, \quad {}^j\bar{\mathbf{K}}_{u,v} = 0, \quad \text{and if } p = q, \quad {}^j\bar{\mathbf{K}}_{u,v} = {}^j\mathbf{K}_{u,v} - \begin{bmatrix} {}^j\mathbf{K}_{u, a_{p-1}^j}^T \\ {}^j\mathbf{K}_{u, a_{p-1}^j} \end{bmatrix}, \quad (97)$$

where

$$\forall x, l, \quad {}^j\Delta_x = \begin{bmatrix} {}^j\mathbf{K}_{x:\alpha^j} \\ {}^j\mathbf{K}_{x:\alpha^j} \end{bmatrix} \begin{bmatrix} {}^j\mathbf{K}_{\alpha^j-1:\alpha^j-1} & {}^j\mathbf{K}_{\alpha^j-1:\alpha^j} \\ {}^j\mathbf{K}_{\alpha^j:\alpha^j-1} & {}^j\mathbf{K}_{\alpha^j:\alpha^j} \end{bmatrix}^{-1}$$

We also note that

$$\mathbb{E} \left(\begin{bmatrix} z_{\alpha^j}^j \\ z_{\beta^j}^j \end{bmatrix} \middle| \mathcal{B}(p, q) \right) = {}^j\Lambda_u \begin{bmatrix} z_{\alpha^j-1}^j & z_{\alpha^j-1}^j \\ z_{\alpha^j-1}^j & z_{\alpha^j-1}^j \\ z_{\alpha^j}^j & z_{\alpha^j}^j \\ z_{\alpha^j}^j & z_{\alpha^j}^j \\ z_{\beta^j}^j & z_{\beta^j}^j \\ z_{\beta^j}^j & z_{\beta^j}^j \end{bmatrix} \text{ and } \mathbb{E} \left(\begin{bmatrix} z_v^j \\ z_{\beta^j}^j \end{bmatrix} \middle| \mathcal{B}(p, q) \right) = \begin{bmatrix} z_{\alpha^j-1}^j & z_{\beta^j}^j & z_{\beta^j}^j \\ z_{\alpha^j-1}^j & z_{\alpha^j}^j & z_{\alpha^j}^j \\ z_{\alpha^j}^j & z_{\alpha^j}^j & z_{\beta^j}^j \\ z_{\alpha^j}^j & z_{\alpha^j}^j & z_{\beta^j}^j \end{bmatrix} {}^j\Lambda_v^T.$$

Hence, taking the expectation with respect to the boundary conditions on both sides of Equation (96), we obtain:

$$\forall u \in [\alpha_{p-1}^j, \alpha_{p-1}^j], v \in [\alpha_{q-1}^j, \alpha_{q-1}^j], \quad {}^j\bar{\mathbf{K}}_{u:v} = {}^j\bar{\mathbf{K}}_{u:v} + {}^j\Lambda_u \begin{bmatrix} {}^j\bar{\mathbf{K}}_{\alpha^j-1:\alpha^j-1} & {}^j\bar{\mathbf{K}}_{\alpha^j-1:\alpha^j} \\ {}^j\bar{\mathbf{K}}_{\alpha^j:\alpha^j-1} & {}^j\bar{\mathbf{K}}_{\alpha^j:\alpha^j} \end{bmatrix} {}^j\Lambda_v^T,$$

where ${}^j\bar{\mathbf{K}}_{u:v}$ is provided in Equation (97).

Abstract

Systematic reviews underpin Evidence Based Medicine (EBM) by addressing precise clinical questions via comprehensive synthesis of all relevant published evidence. Authors of systematic reviews typically define a Population/Problem, Intervention, Comparator, and Outcome (a *PICO* criteria) of interest, and then retrieve, appraise and synthesize results from all reports of clinical trials that meet these criteria. Identifying *PICO* elements in the full-texts of trial reports is thus a critical yet time-consuming step in the systematic review process. We seek to expedite evidence synthesis by developing machine learning models to automatically extract sentences from articles relevant to *PICO* elements. Collecting a large corpus of training data for this task would be prohibitively expensive. Therefore, we derive *distant supervision* (DS) with which to train models using previously conducted reviews. DS entails heuristically deriving 'soft' labels from an available structured resource. However, we have access only to unstructured, free-text summaries of *PICO* elements for corresponding articles; we must derive from these the desired sentence-level annotations.

To this end, we propose a novel method – *supervised distant supervision* (SDS) – that uses a small amount of direct supervision to better exploit a large corpus of distantly labeled instances by *learning* to pseudo-annotate articles using the available DS. We show that this approach tends to outperform existing methods with respect to automated *PICO* extraction.

Keywords: Evidence-based medicine, distant supervision, data extraction, text mining, natural language processing

1. Introduction and Motivation

Evidence-based medicine (EBM) looks to inform patient care using the totality of the available evidence. Typically, this evidence comprises the results of Randomized Control Trials (RCTs) that investigate the efficacy of a particular treatment (or treatments) in people with a specific clinical problem. *Systematic reviews* are transparently undertaken, rigorous statistical syntheses of such evidence; these underpin EBM by providing quantitative summaries of the entirety of the current evidence base pertaining to particular conditions, treatments and populations.

Systematic reviews are especially critical in light of the data deluge in biomedicine: over 27,000 clinical trials were published in 2012 alone, or roughly 74 per day on average (Bastian et al., 2010). There is thus simply no way that a physician could keep current with the body of primary evidence. Reviews mitigate this problem by providing up-to-date, comprehensive summaries of all evidence addressing focused clinical questions. These reviews are considered the highest level of evidence and now inform all aspects of healthcare, from bedside treatment decisions to national policies and guidelines.

However, the same deluge of clinical evidence that has made reviews indispensable has made producing and maintaining them increasingly onerous. An estimate from 1999 suggests that producing a single review requires thousands of person hours (Allen and Olkin, 1999); this has surely increased since. Producing and keeping evidence syntheses current is thus hugely expensive, especially because reviews are performed by highly-trained individuals (often doctors). Machine learning methods to automate aspects of the systematic review process are therefore needed if EBM is to keep pace with the torrent of newly published evidence (Tsafnat et al., 2013; Bastian et al., 2010; Elliott et al., 2014; Wallace et al., 2013).

A cornerstone of the systematic review paradigm is the notion of precise clinical questions. These are typically formed by decomposing queries into *PICO frames* that define the Population, Intervention, Comparison, and Outcome of interest. Interventions and comparison treatments (e.g., placebo) are often discussed together: we therefore group I and C for the remainder of this paper, and refer to these jointly as simply *interventions*. Once specified, these criteria form the basis for retrieval and inclusion of published evidence in a systematic review. The *PICO* framework is an invaluable tool in the EBM arsenal generally (Huang et al., 2006), and is specifically a pillar of the systematic review process.

Unfortunately, results from RCTs are predominantly disseminated as unstructured free text in scientific publications. This makes identifying relevant studies and extracting the target data for evidence syntheses burdensome. For example, free text does not lend itself to structured search over PICO elements. Structured PICO summaries of articles describing clinical trials would vastly improve access to the biomedical literature base. Additionally, methods to extract PICO elements for subsequent inspection could facilitate inclusion assessments for systematic reviews by allowing reviewers to rapidly judge relevance with respect to each PICO element. Furthermore, automated PICO identification could expedite *data extraction* for systematic reviews, in which reviewers manually extract structured data to be reported and synthesized. Consider the task of extracting dosage information for a given clinical trial: currently reviewers must identify passages in the article that discuss the interventions and then extract from these the sought after information. This is time-consuming and tedious; a tool that automatically identified PICO related sentences and guided the reviewer to these would expedite data extraction.

In this work we present a novel machine learning approach that learns to automatically extract sentences pertaining to PICO elements from full-text articles describing RCTs. We exploit an existing (semi-)structured resource – the Cochrane Database of Systematic Reviews (CDSR) – to derive *distant supervision* (DS) with which to train our PICO extraction model. DS is generated by using heuristics to map from existing structured data \mathcal{D} to pseudo-annotations that approximate the target labels \mathcal{Y} . These derived labels will be imperfect, because the structured data to which we have access comprises free-text summaries describing each PICO element; this text does not appear verbatim in the corresponding articles. Thus, using simple string matching methods to induce supervision will introduce noise. We therefore propose a new method that *learns* to map from \mathcal{D} to \mathcal{Y} using a small amount of direct supervision, thus deriving from the free-text summaries in the CDSR the desired sentence-level annotations. We refer to this as *supervised distant supervision* (SDS).

We empirically evaluate our approach both retrospectively (using previously collected data) and via a prospective evaluation. We demonstrate that SDS consistently improves performance with respect to baselines that exploit *only* distant or (a small amount of) direct supervision. We also show that our flexible SDS approach performs at least as well – and usually better – than a previously proposed model for jointly learning from distant and direct supervision. While our focus here is on the particular task of PICO identification in biomedical texts, we believe that the proposed SDS method represents a generally useful new paradigm for distantly supervised machine learning.

The remainder of this paper is structured as follows. We review related work in the following section. We introduce our source of distant supervision, the CDSR, in Section 3. This motivates the development of our SDS model, which we present in Section 4. We discuss experimental details (including features and baseline methods to which we compare) in Section 5, and report experimental results in Section 6. Finally, we conclude with additional discussion in Section 7.

2. Related Work

We briefly review two disparate threads of related work: automatic identification of PICO elements for EBM (Section 2.1) and work on *distant supervision* (Section 2.2), paying particular attention to recent efforts to develop models that combine distant and direct supervision.

2.1 Automatic PICO Identification

The practical need for language technologies posed by EBM-related tasks has motivated several recent efforts to identify PICO elements in biomedical text (Denner-Fushman and Lin, 2007; Chung, 2009; Boudin et al., 2010b,a; Kim et al., 2011). However, nearly all of these works have considered only the abstracts of articles, limiting their utility. Such approaches could not be used, for example, to support data extraction for systematic reviews, because clinically salient data is often not available in the abstract. Furthermore, it is likely that identifying PICO elements in the full-texts of articles could support rich information retrieval support, beyond what is achievable using abstracts alone.

Nonetheless, identifying PICO sentences in abstracts has proven quite useful for supporting biomedical literature retrieval. For example, Denner-Fushman and Lin (2007) developed and evaluated a tool that extracts clinically salient snippets (including PICO elements) from MEDLINE abstracts. They showed that these extractions can assist with information retrieval and clinical question answering. Similarly, Boudin et al. (2010b,a) showed that automatically generated PICO annotation of abstracts can improve biomedical information retrieval, even if these annotations are noisy.

Moving beyond abstracts, one system that does operate over full texts to summarize clinical trials is ExaCT (Kiritchenko et al., 2010). ExaCT aims to extract variables describing clinical trials. It requires HTML or XML formatted documents as input. The system splits full-text articles into sentences and classifies these as *relevant* or *not* using a model trained on a small set (132) of manually annotated articles. ExaCT does not attempt to identify PICO sentences, but rather aims to map directly to a semi-structured template describing trial attributes. The work is therefore not directly comparable to the present effort.

Our work here differs from the efforts just reviewed in a few key ways:

1. In contrast to previous work, we aim to identify sentences in *full-text* articles that are pertinent to PICO elements. This may be used to facilitate search, but we are more immediately interested in using this technology to semi-automate data extraction for systematic reviews.
2. Previous work has leveraged small corpora (on the order of tens to hundreds of manually annotated abstracts) to train machine learning systems. By contrast, we exploit a large ‘distantly supervised’ training corpus derived from an existing database. In Section 6 we demonstrate the advantage of this novel approach, and show that using a small set of direct supervision alone fares comparatively poorly here.

Additionally, we introduce a novel paradigm for distantly supervised machine learning, which we review next.

2.2 Distant Supervision

Distant supervision (DS) refers to learning from indirect or weak supervision derived from existing structured resources. These derived ‘labels’ are often noisy, i.e., imperfect. But the advantage is that by exploiting existing resources one can capitalize on a potentially large labeled training dataset effectively ‘for free’. The general approach in DS is to develop heuristics to map existing, structured resources onto the target labels of interest and then use these derived labels to train a model (Figure 1a).

This paradigm was first introduced by Craven and Kumlien (1999) in their work on building models for information extraction for biological knowledge base construction.¹ Specifically they considered the task of extracting relationships between biological entities, such as subcellular-structures and proteins. To generate (noisy) training data for this task they exploited the Yeast Protein Database (YPD), which contains propositions expressing relationships of interest between pairs of biological entities. For each known relationship expressed in the YPD they searched PubMed, a repository of biomedical literature, to identify abstracts that mentioned both entities. They made the simplifying assumption that any such co-occurrence expressed the target relationship (this being the heuristic means of inducing positive instances). They demonstrated that training their model with these pseudo-positive instances resulted in performance comparable to models trained using manually labeled examples.

Much of the more recent work on distant supervision since has been focused on the task of *relation extraction* (Mintz et al., 2009; Nguyen and Moschitti, 2011; Riedel et al., 2010; Bunesco and Mooney, 2007; Angeli et al., 2014) and classification of Twitter/microblog texts (Purver and Battersby, 2012; Marchetti-Bowick and Chambers, 2012). Our focus here aligns with previous attempts to reduce the noise present in distantly labeled datasets, although so far as we are aware these have been exclusively applied for the task of relation extraction (Roth et al., 2013). These methods have tended to exploit a class of generative *latent-variable* models specifically developed for the task of relation extraction (Surdeanu et al., 2012; Min et al., 2013; Takamatsu et al., 2012; Angeli et al., 2014). Unfortunately, these models do not naturally generalize to other tasks because they are predicated on the assumption that the structured resource to be exploited comprises *entity-pairs* to be identified in unlabeled instances. Such entity-pairs have no analog in the case of sentence extraction. For example, Angeli et al. (2014) combine direct and distant supervision for relation extraction by building on the Multi-Instance Multi-Label Learning (MIML-RE) originally proposed by Surdeanu et al. (2012). They estimate the parameters in a fully generative model that includes variables corresponding to entities and their co-occurrences in

1. Craven and Kumlien called this ‘weakly supervised’ learning. The term ‘distant supervision’ was later coined by Mintz et al. (2009).

Target description from the CDSR. Patients ($n = 24$, 15 females) with neck pain of > 3 months’ duration, who had pain in one or more cervical (C3-C7) zygapophysial joints after a car accident and whose pain perception had been confirmed by placebo-controlled diagnostic blocks.

C1: The study patients were selected from among patients whose cervical zygapophysial-joint pain had been confirmed with the use of local anesthetic blocks at either the unit or a private radiology practice in Newcastle.

C2: We studied 24 patients (9 men and 15 women; mean age, 43 years) who had pain in one or more cervical zygapophysial joints after an automobile accident (median duration of pain, 34 months).

C3: The significant rate of response to the control treatment, even among patients who had been tested with placebo-controlled diagnostic blocks to confirm their perceptions of pain, is a sobering reminder of the complex and inconstant dynamics of placebo phenomena.

Table 1: Example *population* target text (summary) from the CDSR and three candidate sentences from the corresponding full-text article generated via distant supervision.

texts. It is not clear how one might modify this model to accommodate our task of *sentence extraction*.

Here we will therefore be interested in guiding DS for general learning tasks using a small set of direct annotations. Most relevant to our work is therefore that of Nguyen and Moschitti (2011), in which they proposed a general method for combining direct and distant supervision. Their approach involves training two conditional models: one trained on directly labeled instances and the other on a mixed set comprising both directly and distantly labeled examples. They then linearly combine probability estimates from these classifiers to produce a final estimate. The key point here is that the derivation of the DS – i.e., the process of moving from extant data to noisy, distant labels – was still a heuristic procedure in this work. By contrast, we propose *learning* an explicit mapping from directly labeled data to distant labels, as we discuss further in Section 4.

3. Learning from the Cochrane Database of Systematic Reviews

We next describe the Cochrane Database of Systematic Reviews (CDSR) (The Cochrane Collaboration, 2014), which is the database we used to derive DS.

3.1 PICO and the CDSR

The CDSR is produced and maintained by the *Cochrane Collaboration*, a global network of 30,000+ researchers who work together to produce systematic reviews. The group has collectively generated nearly 6,000 reviews, which describe upwards of 50,000 clinical trials. These reviews (and the data extracted to produce them) are published as the CDSR.

The CDSR contains structured and semi-structured data for every clinical trial included in each systematic review. To date we have obtained corresponding full-text articles (PDFs) for 12,808 of the clinical trials included in the CDSR. In previous work (Marshall et al., 2014, 2015) we demonstrated that supervision derived from the CDSR on linked full-text

PICO element	Number of distantly labeled articles
<i>Population</i>	12,474
<i>Intervention</i>	12,378
<i>Outcomes</i>	12,572

Table 2: The number of full-text articles for which a corresponding free-text summary is available in the CDSR for each PICO element (studies overlap substantially); this provides our DS.

articles can be exploited to learn models for automated *risk of bias* (RoB) assessment of clinical trials and supporting sentence extraction. However, in the case of RoB, supervision was comparatively easy to derive from the CDSR: this required only literal string matching, because by convention reviewers often store verbatim sentences extracted from articles that support their RoB assessments. In the case of PICO, however, reviewers generate free-text summaries for each element (not verbatim quotes) that are then stored in the CDSR. Therefore, we must map from these summaries to sentence labels (*relevant* or *not*) for each PICO domain.

Table 1 provides an example of a *population* summary stored in the Cochrane database for a specific study, along with potentially ‘positive’ sentence instances from the corresponding article. Such summaries are typically, but not always, generated for articles and this varies somewhat by PICO element. In Table 2 we report the number of studies for which we have access to human-generated summaries for each PICO element.

Articles used for the population, intervention and outcomes domains were (automatically) segmented into 333, 335 and 338 sentences on average, respectively. We adopted a straightforward heuristic approach to generating DS (in turn generating candidate sets) of sentences using the CDSR. Specifically, for a given article a_i and matched PICO element summary s_i stored in the CDSR, we soft-labeled as positive (designated as candidates) up to k sentences in a_i that were most similar to s_i . To mitigate noise, we introduced a threshold such that candidate sentences had to be at least ‘reasonably’ similar to the CDSR text to be included in the candidate set. Operationally, we ranked all sentences in a given article with respect to the raw number of word (nigram) tokens shared with the CDSR summary, excluding stop words. The top 10 sentences that shared at least 4 tokens with the summary were considered positive (members of the candidate set). These were somewhat arbitrary decisions reflecting intuitions gleaned through working with the data; other approaches to generating candidate sets could have of course been used here instead. However, it is likely that any reasonable heuristic based on token similarity would result in DS with similar properties.

7

3.2 Annotation

We labeled a subset of the candidate sets generated via DS from the CDSR for two reasons: (1) this constitutes the *direct* supervision which we aim to combine with DS to train an accurate model; and, (2) cross-fold validation using these labels may be used as a proxy evaluation for different models. We say ‘proxy’ because implicitly we assume that *all* sentences not among the candidate sets are true negatives, which is almost certainly not the case (although given the relatively low threshold for inclusion in the candidate set, this assumption is not entirely unreasonable).

The annotation process involved rating the quality of automatically derived candidate sentences for each PICO element and article. Annotations were on a 3-point scale designed to differentiate between *irrelevant*, *relevant* and *best available* candidate sentences (coded as 0, 1 and 2, respectively). This assessment was made in light of the corresponding summaries for each PICO field published in the CDSR. In Table 1, we show three candidate sentences (distantly labeled ‘positive’ instances) and the target summary. Here, candidate 1 (C_1) is *relevant*, C_2 is the *best available* and C_3 is in fact *irrelevant*.

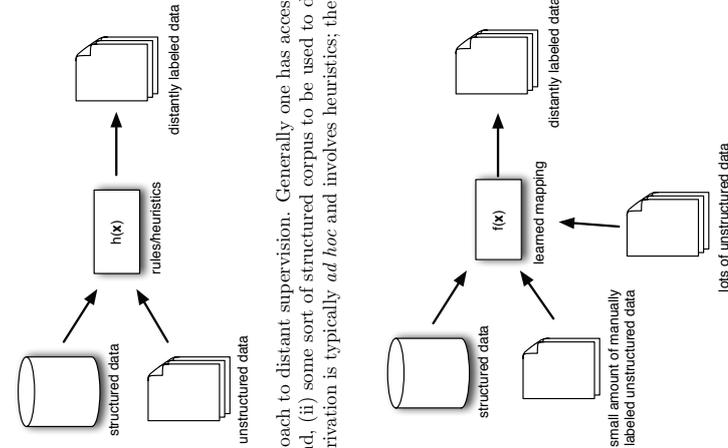

Two of the co-authors (BZ and AS) worked with BW to develop and refine the labeling scheme. This refinement process involved conducting a few pilot rounds to clarify labeling criteria.² We conducted these until what we deemed acceptable pairwise agreement was reached, and subsequently discarded the annotations collected in these early rounds. After this pilot phase, a subset of 1,071 total candidate sentences were labeled independently by both annotators. Additional sentences were later labeled individually. On the multiply labeled subset, observed annotator agreement was high: pairwise $\kappa = 0.74$ overall, and $\kappa = 0.81$ when we group *relevant* sentences with *best available* – in practice, we found distinguishing between these was difficult and so we focus on discriminating between *irrelevant* and *relevant/best available* sentences. Ultimately, we acquired a set of 2,821 labels on sentences from 133 unique articles; these comprise 1009, 1006 and 806 sentences corresponding to ‘participants’, ‘interventions’ and ‘outcomes’, respectively.

4. Supervised Distant Supervision

We now describe the novel approach of *supervised distant supervision* (SDS) that we propose for capitalizing on a small set of directly labeled candidate instances in conjunction with a large set of distantly supervised examples to induce a more accurate model for the target task. Figure 1b describes the idea at a high-level. The intuition is to train a model that maps from the heuristically derived and hence noisy DS to ‘true’ target labels. This may be viewed as learning a filtering model that winnows a candidate set of positive instances automatically generated via DS to a higher-precision subset of (hopefully) true positive

² The annotation guideline developed during our pilot annotation phase is available at: <http://byron.ischool.utexas.edu/stratic/sds-guidelines.pdf>

8

(a) The standard approach to distant supervision. Generally one has access to (i) a (large) set of unlabeled instances and, (ii) some sort of structured corpus to be used to derive distant labels on said instances. This derivation is typically *ad hoc* and involves heuristics; the derived labels are thus usually noisy.

(b) The proposed *supervised distant supervision* (SDS) approach. We aim to leverage a small amount of annotated data – which provides alignments between unlabeled instances with the structured corpus to be used to derive distant labels – to induce a model that maps that from paired entries in the available structured data and unlabeled corpus to the target labels on the latter.

Figure 1: Standard distant supervision (top) and the proposed *supervised distant supervision* approach (bottom).

instances, using attributes derived from instances and the available distant supervision on them.

We will denote instances (documents) by $\mathcal{X} = \{\mathbf{x}_1, \dots, \mathbf{x}_n\}$. Each $\mathbf{x}_i \in \mathcal{X}$ comprises m_i sentences: $\{\mathbf{x}_{i,1}, \dots, \mathbf{x}_{i,m_i}\}$. We will index sentences by j , so $\mathbf{x}_{i,j}$ denotes the (vector

representation of) sentence j in document i . We treat the sentence extraction tasks for the respective PICO elements as independent, and therefore do not introduce notation to differentiate between them.

We will denote the database of semi-structured information from which we are to derive DS by \mathcal{D} . We assume that \mathcal{D} contains an entry for all n linked articles under consideration. We denote the set of distantly derived labels on sentences by $\tilde{\mathcal{Y}} = \{\tilde{y}_{1,1}, \dots, \tilde{y}_{1,m_1}, \dots, \tilde{y}_{n,1}, \dots, \tilde{y}_{n,m_n}\}$, and corresponding true target labels by $\mathcal{Y} = \{y_{1,1}, \dots, y_{1,m_1}, \dots, y_{n,1}, \dots, y_{n,m_n}\}$. The former are assumed to have been derived from \mathcal{D} via the heuristic labeling function h , while the latter are assumed to be unobserved. In DS one generally hopes that $\tilde{\mathcal{Y}}$ and \mathcal{Y} agree well enough to train a model that can predict target labels for future examples.

Our innovation here is to exploit a small amount of direct supervision to *learn* a model to improve DS by filtering the candidates generated by h using a function f that operates over features capturing similarities between entries in \mathcal{D} and instances to generate a more precise label set. Specifically we aim to learn a function $f : (\mathcal{X}, \tilde{\mathcal{Y}}) \rightarrow \mathcal{Y}$, where we have introduced new instance representations \mathcal{X} which incorporate features derived from pairs of instances and database entries (we later enumerate these). We emphasize that this representation differs from \mathcal{X} , which cannot exploit features that rely on \mathcal{D} because DS will not generally be available for new instances. The parameters of f are to be estimated using a small amount of direct (manual) supervision which we will denote by \mathcal{L} . These labels indicate whether or not distantly derived labels are correct. Put another way, this is *supervision for distant supervision*.

We will assume that the heuristic function h can generate a *candidate set* of positive instances, many of which will in fact be negative. This assumption is consistent with previous efforts (Bunescu and Mooney, 2007). In our case, we will have a candidate set of sentence indices \mathcal{C}_i associated with each entry i in \mathcal{D} (note that we will have different candidate sets for each PICO element, but the modeling approach will be the same for each). These are the sentences for which \tilde{y} is positive. The supervision \mathcal{L} will comprise annotations on entries in these candidate sets with respect to target labels y . Thus the learning task that we will be interested in is a mapping between $\mathcal{C}_1, \dots, \mathcal{C}_l$ and corresponding target label sets $\mathcal{Y}_1, \dots, \mathcal{Y}_l$.

4.1 Intuition

To better motivate this SDS approach, consider a scenario in which one has access to a (very) large set of unlabeled instances \mathcal{X} and a database \mathcal{D} from which noisy, distant supervision $\tilde{\mathcal{Y}}$ may be derived (along with feature vectors jointly describing instances and their entries in \mathcal{D} , \mathcal{X}). In such scenarios, we will be able to efficiently generate a very large training set for ‘free’ by exploiting \mathcal{D} ; hence the appeal of DS. However, if our rule h for deriving $\tilde{\mathcal{Y}}$ is only moderately accurate, we may be introducing excessive noise into the training set, in turn hindering model performance. At the same time, it may be that one

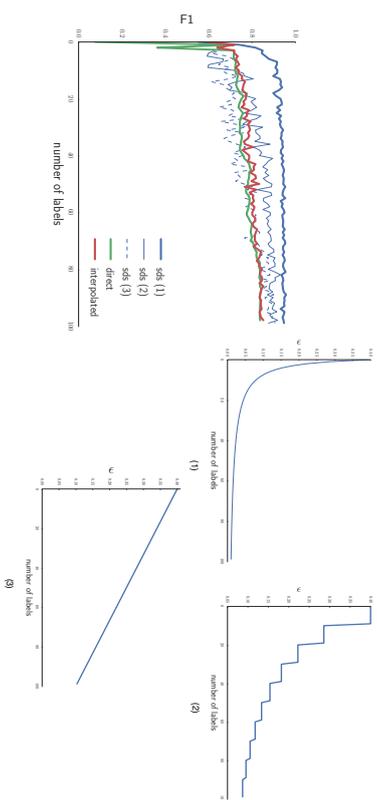

Figure 2: Plots from a simulation highlighting the intuition behind SDS. We consider different learning rates for the SDS task: e.g., in scenario 1 we assume the error ϵ in the distantly derived labels can be reduced drastically with relatively few direct labels. Put another way, this assumes that an accurate heuristic is relatively easy to learn. On this assumption, performance (F1) on the target task can be improved drastically compared to the alternative approach of, e.g., interpolating models trained on the distant and direct label sets. SDS still performs well under less optimistic assumptions, as can be seen in scenarios 2 and 3, which assume step and linear reduction relationships between ϵ and the number of labels provided, respectively. See the text for additional explanation.

can dramatically improve the pseudo-labeling accuracy by *learning* a mapping from a small amount of direct supervision, \mathcal{L} . Providing supervision for the mapping, rather than the actual task at hand, may be worthwhile if the former allows us to effectively exploit the large set of distantly labeled data.

To make this intuition more concrete, we conducted an illustrative simulation experiment using the classic twenty-newsgroups corpus.³ We used the standard train and test splits of the data, and consider the binary classification task of discriminating between messages from the *alt.athletics* and those from the *soc.religion.christian* boards. This subset comprises 1079 messages in the training set and 717 in the testing set.

We assume that a DS heuristic h assigns the true label with probability $1-\epsilon$; thus ϵ encodes the noise present in $\tilde{\mathcal{Y}}$. Intuitively, SDS will work well when we can efficiently learn a model that operates over $\tilde{\mathcal{X}}, \tilde{\mathcal{Y}}$ to better approximate the true labels \mathcal{Y} , i.e., reduce ϵ . This may be possible when the features comprising \mathcal{X} are predictive. We assume $\epsilon = 0.4$ for

3. <http://kdd.ics.uci.edu/databases/20newsgroups/20newsgroups.html>

DS to begin with and we consider three scenarios which differ in their assumed relationship between the number of annotations and the induced reduction in ϵ . Respectively, these simulations assume: (1) a smooth and (2) step-wise exponentially decreasing function (representing rapid learning rates, implying that $\tilde{\mathcal{X}}$ is rich with signal), and (3) a linearly decreasing function. These simulated learning rates are depicted in Figure 2.

We report the performance (F1 score, i.e., the harmonic mean of precision and recall) on the held-out test data using SDS under these three scenarios. That is, we re-label the instances in the large training corpus with noise equal to the corresponding ϵ under each scenario; this simulates re-labeling the (distantly supervised) training corpus using the trained SDS model. We compare this to using direct supervision (no noise) only and to interpolating independent predictions from models trained on direct and distant supervision, respectively (see Section 5.2). We allowed the latter model access to a small validation set with which to tune the interpolation parameter. We simulated annotating (directly, with no noise) up to 100 instances and show learning curves under each strategy/scenario.

As one would expect, SDS works best when one can efficiently reduce the noise in the relatively large set of distantly labeled instances, as in simulations (1) and (2), which assume noise exponentially decays with labeled instances. In these cases, effort is best spent on learning a model to reduce ϵ . However, note that even when the signal is not quite as strong – as in scenario 3 where we assume a linear relationship between noise reduction and collected annotations – we can see that the SDS model ultimately outperforms the other approaches. The comparative advantage of the SDS strategy will depend on the noise introduced by DS to begin with and the efficiency with which a model can be learned to reduce this noise. We emphasize that this scenario is intended to highlight the intuition behind SDS and scenarios in which it might work well, not necessarily to provide empirical evidence for its efficacy.

4.2 Model

We now turn to formally defining an SDS model. This entails first specifying the form of f . Here we use a log-linear model to relate instances comprising candidate sets to their associated label qualities. Specifically, we assume:

$$\hat{p}_{i,j}^{sds} = p(y_{i,j} | \mathcal{C}_i, \tilde{\mathbf{w}}) = \begin{cases} \propto \exp(\tilde{\mathbf{w}} \cdot \tilde{\mathbf{x}}_{i,j}) & \text{if } j \in \mathcal{C}_i \text{ (i.e., } \tilde{y}_{i,j} = 1) \\ 0 & \text{otherwise} \end{cases} \quad (1)$$

where $\tilde{\mathbf{w}}$ is a weight vector to be estimated from the training data \mathcal{L} .⁴ More precisely, we use regularized logistic regression as our conditional probability model for instances comprising the candidate set. Note that for brevity we will denote the estimated conditional

4. Note that $\tilde{\mathbf{w}}$ differs from the weight vector parameterizing the final model, \mathbf{w} , because the former comprises coefficients for features in $\tilde{\mathcal{X}}$ which are at least partially derived from information in the available structured resource. These would not be available at test-time (i.e., in \mathcal{X}).

probability for sentence j in document i by $\hat{p}_{i,j}^{sds}$. The idea is that once we have estimated $\tilde{\mathbf{w}}$ (and hence $\hat{p}_{i,j}^{sds}$ for all i and j) we can use this to improve the quality of DS by effectively filtering the candidate sets.

Consider first a standard objective that aims to directly estimate the parameters \mathbf{w} of a linear model for the target task relying only on the distant supervision:

$$\operatorname{argmin}_{\mathbf{w}} \mathcal{R}(\mathbf{w}) + C \sum_{i=1}^n \sum_{j=1}^{m_i} \operatorname{loss}(\mathbf{w} \cdot \mathbf{x}_{i,j}, \tilde{y}_{i,j}) \quad (2)$$

where a loss function (e.g., hinge or log loss) is used to incur a penalty for disagreement between model predictions and the derived (distant) labels, \mathcal{R} is a regularization penalty (such as the squared ℓ_2 norm) and C is a scalar encoding the emphasis placed on minimizing loss versus achieving model simplicity. We will be concerned primarily with the parameterization of the *loss* function here, and therefore omit the regularization term (and associated hyper-parameter C) for brevity in the following equations.

Again grouping all distantly labeled ‘positive’ sentences for document i in the set \mathcal{C}_i and decomposing the loss into that incurred for false negatives and false positives, we can re-write this as:

$$\sum_{i=1}^n \left\{ \sum_{j \in \mathcal{C}_i} c_{fn} \cdot \operatorname{loss}(\mathbf{w} \cdot \mathbf{x}_{i,j}, 1) + \sum_{j \notin \mathcal{C}_i} c_{fp} \cdot \operatorname{loss}(\mathbf{w} \cdot \mathbf{x}_{i,j}, -1) \right\} \quad (3)$$

Where we are denoting the cost of a false negative by c_{fn} and the cost of a false positive by c_{fp} . Minimizing this objective over \mathbf{w} provides a baseline approach to learning under DS.

We propose an alternative objective that leverages the mapping model discussed above (Equation 1). The most straight-forward approach would be to use binary (0/1) classifier output to completely drop out instances in the candidate set that are deemed likely to be irrelevant by the model, i.e.:

$$\sum_{i=1}^n \left\{ \sum_{j \in \mathcal{C}_i} c_{fn} \cdot \operatorname{sign}^{0/1}(\tilde{\mathbf{w}} \cdot \tilde{\mathbf{x}}_{i,j}) \cdot \operatorname{loss}(\mathbf{w} \cdot \mathbf{x}_{i,j}, 1) + \sum_{j \notin \mathcal{C}_i} c_{fp} \cdot \operatorname{loss}(\mathbf{w} \cdot \mathbf{x}_{i,j}, -1) \right\} \quad (4)$$

Where $\operatorname{sign}^{0/1}$ denotes a sign function that returns 0 when its argument is negative and 1 otherwise. We take a finer-grained approach in which we scale the contribution to the total loss due to ‘positive’ instances by probability estimates that these indeed represent true positive examples, conditioned on the available distant supervision:

$$\sum_{i=1}^n \left\{ \sum_{j \in \mathcal{C}_i} c_{fn} \cdot \hat{p}_{i,j}^{sds} \cdot \operatorname{loss}(\mathbf{w} \cdot \mathbf{x}_{i,j}, 1) + \sum_{j \notin \mathcal{C}_i} c_{fp} \cdot \operatorname{loss}(\mathbf{w} \cdot \mathbf{x}_{i,j}, -1) \right\} \quad (5)$$

We extend this objective to penalize more for mistakes on explicitly labeled instances. Recall that we denote by \mathcal{L} the small set of directly annotated articles; here we assume that this set comprises indices of directly labeled articles. Let us also denote by \mathcal{L}_i^+ and \mathcal{L}_i^- the set of positive and negative sentence indices for labeled article i , respectively. Further, denote by $\tilde{\mathcal{L}}$ the set of article indices for which we *only* have distant supervision (so that $\mathcal{L} \cap \tilde{\mathcal{L}} = \emptyset$ by construction). Putting everything together forms our complete objective:

$$\operatorname{argmin}_{\mathbf{w}} \mathcal{R}(\mathbf{w}) + C \left(\lambda \sum_{i \in \mathcal{L}} \left\{ \sum_{j \in \mathcal{L}_i^+} c_{fn} \cdot \operatorname{loss}(\mathbf{w} \cdot \mathbf{x}_{i,j}, 1) + \sum_{j \in \mathcal{L}_i^-} c_{fp} \cdot \operatorname{loss}(\mathbf{w} \cdot \mathbf{x}_{i,j}, -1) \right\} + \sum_{i \in \tilde{\mathcal{L}}} \left\{ \sum_{j \in \mathcal{C}_i} c_{fn} \cdot \hat{p}_{i,j}^{sds} \cdot \operatorname{loss}(\mathbf{w} \cdot \mathbf{x}_{i,j}, 1) + \sum_{j \notin \mathcal{C}_i} c_{fp} \cdot \operatorname{loss}(\mathbf{w} \cdot \mathbf{x}_{i,j}, -1) \right\} \right) \quad (6)$$

Here we used log loss throughout and ℓ_2 regularization for the penalty \mathcal{R} . The λ and C are hyper-parameters to be tuned via grid-search (details in Section 5.3).

The key element of this objective is the use of the $\hat{p}_{i,j}^{sds}$ (Equation 1) estimates to scale loss contributions from distantly supervised data. This is particularly important because in general there will exist far more distantly supervised instances than directly labeled examples, i.e., $|\tilde{\mathcal{L}}| \gg |\mathcal{L}|$. One practical advantage of this approach is that once training is complete, the model is defined by a single weight-vector \mathbf{w} , even though two models, parameterized independently by \mathbf{w} and $\tilde{\mathbf{w}}$ are used during training.

Recall that $\hat{p}_{i,j}^{sds}$ estimates the probability of a candidate sentence (potentially positive instance, as per the distant supervision heuristic h) indeed being a ‘true’ positive. As mentioned above, the feature space that we use for this task can differ from the feature space used for the target task. That is, the attributes comprising \mathcal{X} need not be the same as those in $\tilde{\mathcal{X}}$. Indeed, features in $\tilde{\mathcal{X}}$ should capture signal gleaned from attributes derived via the available distant supervision \mathcal{D} for any given instance, but at test time we would not be able to capitalize on such features. In the next section we describe the features we used for PICO sentence classification, both for \mathcal{X} and $\tilde{\mathcal{X}}$.

5. Experimental Details and Setup

5.1 Features

Table 3 enumerates the feature sets we use. All models leverage those in the top part of the table. The bottom part describes those features that are derived using \mathcal{D} , our source of DS. Therefore, these are only used in the SDS approach, and only present in $\tilde{\mathcal{X}}$.

5.2 Baselines

We compare the proposed *supervised distant supervision* (SDS) approach to the following baseline methods:

Feature	Description
Bag-of-Words	Term-Frequency Inverse-Document-Frequency (TF-IDF) weighted uni- and bi-gram count features extracted for each sentence. We include up to 50,000 unique tokens that appear in at least three unique sentences.
Positional	Indicator variable coding for the decile (with respect to length) of the article where the corresponding sentence is located.
Line lengths	Variables indicating if a sentence contains 10%, 25% or a greater percentage of 'short' lines (operationally defined as comprising 10 or fewer characters); a heuristic for identifying tabular data
Numbers	Indicators encoding the fraction of numerical tokens in a sentence (fewer than 20% or fewer than 40%).
New-line count	Binned indicators for new-line counts in sentences. Bins were: 0-1, fewer than 20 and fewer than 40 new-line characters.
Drugbank	An indicator encoding whether the sentence contains any known drug names (as enumerated in a stored list of drug names from http://www.drugbank.ca/).
Shared tokens	<i>Additional features used for SDS task (enclosed by X)</i> TF-IDF weighted features capturing the uni- and bi-grams present both in a sentence and in the Cochrane summary for the target field.
Relative similarity score	'Score' (here, token overlap count) for sentences with respect to target summary in the CDSR. Specifically, we use the score for the sentence minus the average score over all candidate sentences.

Table 3: Features we used for the target learning tasks and additional features we used in learning to map from candidate sets (the distant supervision) to 'true' labels. We set discrete ('binned') feature thresholds heuristically, reflecting intuition; we did not experiment at length with alternative coding schemes. Note that separate models were learned for each PICO domain.

- Distant supervision only (DS) (Mintz et al., 2009; Craven and Kunhlen, 1999). This simply relies on the heuristic labeling function h . We define the corresponding objective formally in Equation 3. We also experimented with a variant that naively incorporates the direct labels when available, but does not explicitly distinguish these from the distant labels. These two approaches performed equivalently, likely due to the relative volume of the distantly labeled instances.
- Direct supervision only. This uses only the instances for which we have direct supervision and so represents standard supervised learning.
- Joint distant and direct supervision, via the pooling method due to Nguyen and Moschitti (2011). In this approach one leverages the direct and indirect supervision to estimate separate (probabilistic) models, and then generates a final predicted probability by linearly interpolating the estimates from the two models:

$$\hat{p}_{k,j}^{\text{pooled}} = \alpha \cdot \hat{p}_{k,j}^{\text{direct}} + (1 - \alpha) \cdot \hat{p}_{k,j}^{\text{distant}} \quad (7)$$

Where α is to be tuned on a validation set (Section 5.3).

These baselines allow us to evaluate (1) whether and to what degree augmenting a large set of DS with a small set of direction annotations can improve model performance; (2) the relative accuracy of the proposed SDS approach, in comparison to the pooling mechanism proposed by Nguyen and Moschitti (2011).

5.3 Parameter Estimation and Hyper-Parameter Tuning

We performed parameter estimation for all models concerned with the target task (i.e., estimating \mathbf{w}) via Stochastic Gradient Descent (SGD).⁵ For all models, class weights were set inversely to their prevalences in the training dataset (mistakes on the rare class – positive instances – were thus more severely penalized). For distant and direct only models, we conducted a line-search over C values from 10 up to 10^5 , taking logarithmically spaced steps. We selected from these the value that maximized the harmonic mean of precision and recall (F1 score); this was repeated independently for each fold.

SDS. For the SDS model (Equation 6) we performed grid search over λ and C values. Specifically we searched over $\lambda = \{2, 10, 50, 100, 200, 500\}$ and the same set of C values specified above. For each point on this grid, we assessed performance with respect to squared error on a validation set comprising 25% of the available training data for a given fold. We kept the λ and C values that minimized expected squared error

$$\beta \{y_{k,j} = 1 | \hat{\mathbf{w}}, \mathbf{x}_{k,j}\} - \text{sign}^{0/1}(y_{k,j})^2 \quad (8)$$

⁵ Specifically, we used the implementation in the Python machine learning library `scikit-learn` (Pedregosa et al., 2011) v0.17, with default estimation parameters save for `class_weight` which we set to 'balanced'.

Where $\hat{p}(y_{i,j} = 1|\hat{\mathbf{w}})$ denotes the predicted probability of sentence j in article i being relevant – that is, predicted by the linear model for the target task where $\hat{\mathbf{w}}$ has been selected to maximize the objective parameterized by a specific pair of (λ, C) values. We emphasize that this estimated probability is with respect to the target label, and thus differs from the $\hat{p}_{i,j}^{sds}$ defined in Equation 1, which relies on an estimate of $\tilde{\mathbf{w}}$. We scaled this per-instance error to account for imbalance, so that the total contribution to the overall error that could be incurred from mistakes made on (the relatively few) positive instances was equal to the potential contribution due to mistakes made on negative examples.

We also note that the parameters of the SDS model (i.e., $\tilde{\mathbf{w}}$ in Equation 1) were estimated using LIBLINEAR (Fan et al., 2008);⁶ for this model we searched over a slightly different range of C values, ranging from 10^0 to 10^4 , taking logarithmically spaced steps.

Nguyen. We performed a line-search for α (Equation 7) ranging from 0 to 1 taking 50 equispaced steps using the same strategy and objective as just described for tuning the SDS hyper-parameters. (Note that the two constituent models that form the Nguyen ensemble have their own respective regularizer and associated scalar hyper-parameter; we tune these independently of α , also via line-search as described above).

5.4 Evaluation and Metrics

We performed both retrospective and prospective evaluation. For retrospective evaluation, we performed cross-fold validation of the directly labeled candidate instances (see Section 3). Note that this evaluation is somewhat noisy, due to the way in which the ‘ground truth’ was derived. Therefore, we also conducted a prospective evaluation, which removed noise from the test set but required additional annotation effort. For the latter evaluation we considered only the two most competitive methods. The top-3 sentences retrieved by each of these methods were directly labeled for relevance, using the same criteria as we used in collecting our direct supervision over candidate instances (Section 3.2). The annotator was blinded to which method selected which sentences.

In our retrospective evaluation, we report several standard metrics: Area Under the Receiver Operating Characteristic Curve (AUC) to assess overall discriminative performance and normalized Discounted Cumulative Gain (NDCG) (Järvelin and Kekäläinen, 2000, 2002), which incorporates relevance scores and discounts relative rankings that appear lower in the ranking. More specifically, we report NDCG@20, which evaluates the rankings of the top 20 sentences induced by each method. We also report precision@3, precision@10 and precision@20, which correspond to the fraction of relevant sentences retrieved amongst the top 3, 10 and 20 sentences retrieved by each method, respectively. All metrics are calculated for each article separately and we then report averages and standard deviations over these.

For our prospective evaluation, we report precision@3, which was practical from an annotation vantage point. We allowed the two most competitive models to select three

sentences from as-yet unlabeled articles to be manually assessed for relevance (the assessor was blinded as to which model selected which sentences). We report the average fraction of these (over articles) deemed at least *relevant*.

6. Results

We present retrospective results in Section 6.1 and prospective results in Section 6.2. For the latter, we tasked one of our trained annotators with labeling (for each PICO domain) the three top-ranked sentences selected from 50 held-out articles by the two most competitive approaches, SDS and the pooling approach Nguyen and Moschitti Nguyen and Moschitti (2011).

6.1 Retrospective evaluation

We performed five-fold validation on the 133 articles for which candidate sentences were directly labeled across all three PICO elements (recall that we group Intervention and Comparator together). We treat all explicitly labeled *relevant* and *best available* sentences (as described in Section 3) instances as positive and all other examples as negative, including those that did not score sufficiently high to be included in a candidate set (i.e., distantly labeled negative instances).

We report results averaged over these folds with respect to the metrics discussed in Section 5.4. We report all results observed on the retrospective data in Table 4; we reiterate that these are averages taken across all 133 articles. In general, we note that across all metrics and domains, SDS most often results in the best performance, although the comparative gain is often small.

6. Again with default parameters provided in the interface from scikit-learn (Pedregosa et al., 2011) v0.17, and again specifying a ‘balanced’ *class_weight*.

Method	Mean AUC (SD)	Mean NDCG@20 (SD)	Precision@3 (SD)	Precision@10 (SD)	Precision@20 (SD)
<i>Population</i>					
Direct only	0.904 (0.106)	0.530 (0.270)	0.347 (0.298)	0.183 (0.126)	0.116 (0.070)
DS	0.941 (0.063)	0.484 (0.243)	0.256 (0.242)	0.129 (0.075)	0.117 (0.072)
Ngyuen	0.917 (0.091)	0.537 (0.275)	0.328 (0.281)	0.180 (0.128)	0.117 (0.072)
SDS	0.947 (0.050)	0.548 (0.263)	0.336 (0.276)	0.212 (0.133)	0.132 (0.076)

Ngyuen	0.870 (0.085)	0.339 (0.256)	0.228 (0.288)	0.151 (0.137)	0.106 (0.084)
SDS	0.900 (0.070)	0.333 (0.233)	0.138 (0.212)	0.160 (0.134)	0.124 (0.092)

Table 4: Retrospective results, with respect to: per-article AUC, NDCG@20, precision@10 and precision@20. For each we report the means and standard deviations over the 133 articles for which candidate sets were annotated for the respective domains. All sentences not in candidate sets are assumed to be *irrelevant*, these results are therefore noisy and likely pessimistic. We **bold** cells corresponding to the best performing methods for each metric, PICO element pair.

EXTRACTING PICO SENTENCES FROM CLINICAL TRIAL REPORTS USING SDS

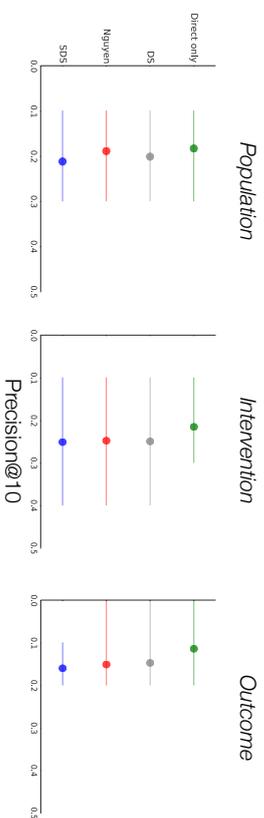

Figure 3: A subset of the retrospective results presented in Table 4 depicted graphically. Top: mean precision@10 for each method and domain (thin lines span the 25th to 75th percentiles, over articles). Bottom: density plots of per-article AUCs. Note that while Ngyuen is the most competitive method with SDS with respect to precision@10, simple DS outperforms this method in terms of overall ranking performance (AUC). SDS maintains a modest but consistent edge over other approaches.

For clarity we also present a subset of the retrospective results graphically in Figure 3. The top row of this figure depicts the mean precision@10 (and 25th/75th percentiles across articles) realized by each model in each domain. The bottom row of this figure describes the distributions of AUCs realized by each strategy for each domain. These are density plots (smoothed histograms) showing the empirical density of AUCs (calculated per-article) achieved by each strategy.

We observe that the top two models with respect to precision@10 (and precision@k in general) are SDS and the interpolation approach proposed by Ngyuen and Moschitti (Ngyuen and Moschitti, 2011). But in terms of overall ranking performance (AUC), vanilla DS outperforms the latter but not the former. Put another way: SDS appears to perform well both in terms of overall ranking and with respect to discriminative performance amongst the top k sentences.

Method	Precision@3
<i>Population</i>	
Nguyen	0.907 (0.222)
SDS	0.927 (0.214)
<i>Interventions</i>	
Nguyen	0.854 (0.254)
SDS	0.903 (0.245)
<i>Outcomes</i>	
Nguyen	0.880 (0.208)
SDS	0.887 (0.196)

Table 5: Averages (and standard deviations) of the proportion of the top-3 sentences extracted via the respective models from 50 prospectively annotated articles that were deemed *relevant* or *best available* by an annotator. The annotator was blinded to which model selected which sentences.

6.2 Prospective results

We prospectively evaluated the top-3 sentences retrieved by the Nguyen and SDS methods (as these were the best performing in our retrospective evaluation). We report precision@3 for each approach in Table 5, calculated over 50 prospectively annotated articles. One can see that here SDS consistently includes *more* relevant sentences among the top-3 than does the pooling approach, and this holds across all domains. The difference is in some cases substantial; e.g., we see a 5% absolute gain in precision@3 for Interventions (a gain of nearly 3% for Population. For Outcomes the difference is less pronounced (nearing 1 point in precision@3).

7. Discussion

We have presented and evaluated a new approach to automating the extraction of sentences describing the PICO elements from the full-texts of biomedical publications that report the conduct and results of clinical trials. As far as we are aware, this is the first effort to build models that automatically extract PICO sentences from full-texts.

We demonstrated the efficacy of using distant supervision (DS) for this task and we introduced *supervised distant supervision* (SDS), a new, flexible approach to distant supervision that capitalizes on a small set of direct annotation to mitigate noise in distantly derived annotations. We demonstrated that this consistently improves performance compared to baseline models that exploit either distant or direct supervision only, and generally also outperforms a previously proposed approach to combining direct and distant supervision. While this work has been motivated by EBM and specifically the task of PICO extraction,

we believe that the proposed SDS approach represents a generally useful strategy for learning jointly from distant and direct supervision.

A natural extension to SDS would be to explore *active* SDS, in which one would aim to selectively acquire the small set of directly annotated instances with which to estimate the parameters of the mapping function f . This may further economize efforts by capitalizing on a small set of examples cleverly selected instances to learn a model that can subsequently ‘clean’ a very large set of distantly generated labels.

For the present application of PICO extraction, we would also like in future work to introduce dependencies across sentences into the model. The model we have proposed ignores such structure. We also note that we hope to extend the present approach by mapping tokens comprising the identified PICO sentences to normalized terms from a structured biomedical vocabulary (namely, MeSH⁷).

With respect to next steps toward automating EBM, we hope to develop models that take as input the PICO sentences extracted from articles to improve ‘downstream’ tasks. For example, we have already incorporated these models into our *RobotReviewer* (Marshall et al., 2015; Kuiper et al., 2014) tool,⁸ which aims to facilitate semi-automated data extraction from full-text articles for biomedical evidence synthesis. This tool uses machine learning models to automatically identify and highlight passages likely to contain the information of interest, thus expediting the extraction process. Additionally, extracted PICO sentences could be used to improve article indexing for search, or fed as input to models for extracting structured bits of information, such as outcome metrics.

Realizing the aim of evidence-based care in an era of information overload necessitates the development of new machine learning and natural language processing technologies to optimize aspects of evidence synthesizes. This work represents one step toward this goal, but much work remains.

Abstract

Patients with developmental disorders, such as autism spectrum disorder (ASD), present with symptoms that change with time even if the named diagnosis remains fixed. For example, language impairments may present as delayed speech in a toddler and difficulty reading in a school-age child. Characterizing these trajectories is important for early treatment. However, deriving these trajectories from observational sources is challenging: electronic health records only reflect observations of patients at irregular intervals and only record what factors are clinically relevant at the time of observation. Meanwhile, caretakers discuss daily developments and concerns on social media.

In this work, we present a fully unsupervised approach for learning disease trajectories from incomplete medical records and social media posts, including cases in which we have only a single observation of each patient. In particular, we use a dynamic topic model approach which embeds each disease trajectory as a path in \mathbb{R}^D . A Pólya-gamma augmentation scheme is used to efficiently perform inference as well as incorporate multiple data sources. We learn disease trajectories from the electronic health records of 13,435 patients with ASD and the forum posts of 13,743 caretakers of children with ASD, deriving interesting clinical insights as well as good predictions.

Keywords: Disease progression model, Dynamic topic model

1. Introduction

Psychiatric conditions that arise in childhood, generally termed developmental disorders, are increasingly common. The parent-reported rates of developmental disorders are now nearly 15%, which includes learning disabilities (affecting 7.66% of children) and attention deficit hyperactivity disorder (ADHD, 6.69% of children) (Boyle et al., 2011). CDC estimates for the prevalence of autism spectrum disorder (ASD) is now 1 in 68 children which is over 1% of the US population (Baio, 2014).

Characterizing these disorders is challenging because, unlike many adult disorders, the symptoms of developmental disorders are inextricably linked to the developmental processes

of childhood. For example, a language-related impairment may present as delayed speech in a toddler and difficulty reading in a school-age child. A neurological condition may manifest as convulsions at age three and intellectual disability at age seven. Characterizing the evolution of distinct disease courses is a critical step toward personalizing treatments; with developmental disorders the early identification of appropriate therapy can significantly increase a child's IQ and ability to communicate (Peters-Scheffer et al., 2011).

However, constructing these trajectories from data is challenging. Clinical studies tend to have the cleanest sources of data: patients are followed regularly, and measurements are consistently recorded. Unfortunately, most clinical studies involve small cohorts—under 200 individuals—which can make it difficult or impossible to distinguish heterogeneous disease courses from variance. In contrast, electronic health records (EHRs) and social media (SM) provide valuable windows to study populations of thousands of individuals. However, these less-structured sources are much more challenging to analyze due to several factors:

- *(Extremely) Partial trajectories.* EHRs are often confined to a single medical system; if a patient switches providers then their history will no longer be available. Similarly, patients and caregivers may be active on social media at some times and not others.
- *Irregular interactions.* Patients generally only visit clinics or post to social media when they have complaints; we do not observe data from patients between these times.
- *Partially structured, noisy, high-dimensional information.* The space of clinical symptoms is large, and with both clinician and caregiver-generated text, information may also be entered or described incorrectly. Clinicians and patients use very different vocabularies when describing the same symptoms.

To address these challenges, we develop an unsupervised approach that models each source—electronic health records and social media—with a cross-corpora dynamic topic model. Our model can be scientifically interpreted as positing that there are a few underlying disease processes that characterize the signs and symptoms that we observe in our patient population. Each disease is a process that evolves over time; we posit that each disease process k at each time t is associated with a distribution over possible signs and symptoms it may emit. The same disease process may be described differently in electronic health records and social media, and multiple diseases may be simultaneously present in a patient.

Specifically, we assume data in the form of (patient , time , sign) tuples. For some patients, we have may have data at multiple times; for other patients, we may only have data at one time. Similarly, some patients may have many signs, others just a few. Our approach derives distinct disease trajectories *without* linking individual identities between social media and electronic health records, and it can also derive disease trajectories in the limit of only a single note per patient. Thus, we do not have to restrict ourselves to patients with longitudinal data; we are able to incorporate all patient data that we have.

For inference in our model, we explore the use of Pólya-gamma augmentation scheme (Polson et al., 2013; Zhou et al., 2012b; Chen et al., 2013; Linderman et al., 2015) to easily adapt the model to have different correlation structures. We detail our approach in Sections 3 and 4, and review related work in Section 6. In Section 5, we apply our approach to a large data set of electronic health records from 13,435 individuals with ASD and 13,743

forum posts by 2,391 caretakers of children with ASD. To our knowledge, this is the first study to jointly model temporal patterns in electronic health record and social media data at this scale.

2. Background

Our technical approach uses Pólya-gamma augmentation to construct an efficient and easily extensible sampler for dynamic topic models and related models. In this section we briefly review topic models and Pólya-gamma augmentation.

2.1 Topic Models and Dynamic Topic Models

Latent Dirichlet Allocation (LDA) The latent Dirichlet allocation (LDA) topic model (Blei et al., 2003) is one of the most successful and widely used models in machine learning. Its basic aim is to decompose a corpus of natural language documents, like a collection of news articles or scientific papers, into an interpretable collection of topics as well as identify what topics are present in each document. For example, a corpus of scientific papers may contain topics like atomic physics, cosmology, and neural chemistry. For modeling purposes, each such topic is identified with a distribution over words: for example, the word “experiment” might have high probability in all three topics, while only the cosmology topic might have frequent occurrences of words like “star” and “galaxy.” In this simplified view, to identify the topics present in a document, it is not necessary to model the details of language or even the order of the words in each document; instead, a document can be summarized by “bag of words:” a histogram counting the words that it contains.

The LDA topic model of Blei et al. (2003) posits that each document can be characterized by a distribution over the topics it contains, and each topic can be characterized by a distribution over the words associated with it. In symbols, each document d has a distribution over topics θ_d ($d = 1, 2, \dots, D$), and each topic β_k ($k = 1, 2, \dots, K$) is a distribution over a vocabulary of V possible words. Given Dirichlet priors on the topics β and topic proportions θ with parameters α_β and α_θ , the full generative model (also illustrated in figure 1a) is

$$\begin{aligned} \beta_k &\sim \text{Dir}(\alpha_\beta), \\ \theta_d &\sim \text{Dir}(\alpha_\theta), \\ z_{n,d} | \theta_d &\sim \text{Cat}(\theta_d), \\ w_{n,d} | z_{n,d}, \{\beta\} &\sim \text{Cat}(\beta_{z_{n,d}}). \end{aligned} \quad (1)$$

where $w_{n,d}$ is n^{th} word in document d , $z_{n,d}$ is the topic associated with the word $w_{n,d}$, $\text{Cat}(\pi)$ draws one sample from a vector of probabilities π , and Dir is the Dirichlet distribution. The Dirichlet-multinomial conjugacy in the generative process makes it straight-forward to perform inference via a blocked Gibbs sampling scheme that, given a set of words $\{w_{n,d}\}$, can sample the latent topic-word distributions $\{\beta_{k_i}\}$, the document-topic proportions $\{\theta_d\}$, and the word-topic assignments $\{z_{n,d}\}$.

Dynamic Topic Model (DTM) Blei and Lafferty (2006b) expand upon LDA to model temporal evolution in the topics β . Each multinomial topic distribution β_k is modeled

through its natural parameter ψ_k ; the mapping from ψ_k to β_k is a multi-class logistic function given by

$$\beta_k(v) \equiv \beta(\psi_k(v)) \equiv \frac{\exp(\psi_k(v))}{\sum_{v'} \exp(\psi_k(v'))}. \quad (2)$$

where $\beta_k(v)$ is the probability of word v in topic k . The natural parameters ψ_k are unconstrained—they can be positive or negative, and they do not need to sum to one.

Next, Blei and Lafferty (2006b) model the evolution of each topic β_k as a random walk on its natural parameters ψ_k . Let $\psi_{k,t}$ denote the values of the natural parameters ψ for topic k at time t . The DTM posits the following generative process on ψ , also illustrated in figure 1b:

$$\begin{aligned} \psi_{k,t} | \psi_{k,t-1} &\sim \mathcal{N}(\psi_{k,t-1}, \sigma^2 I), \\ \theta_d &\sim \text{Dir}(\alpha_\theta), \\ z_{n,d} | \theta_d &\sim \text{Cat}(\theta_d), \\ w_{n,d} | z_{n,d}, \{\psi_{k,t}\} &\sim \text{Cat}(\beta(\psi_{z_{n,d},t}(d))). \end{aligned} \quad (3)$$

Here, $t(d)$ is the time associated with document d and $\beta(\psi_{k,t})$ is the transformation of $\psi_{k,t}$ back to a multinomial using equation 2. We will use $\beta_{k,t}$ as shorthand for $\beta(\psi_{k,t})$.

This DTM construction captures the temporal evolution of topics while retaining the interpretable structure of LDA. However, the DTM construction in equation 3 does not enjoy the conjugacy structure of the original LDA model in equation 1: the DTM replaces LDA’s factored Dirichlet prior on the topics β_k with a Gaussian linear dynamical system (LDS) mapped through a multi-class logistic function. While inference in Gaussian linear dynamical systems coupled with linear Gaussian observations can be performed efficiently using message passing algorithms, the nonlinear mapping in equation 2 does not allow such algorithms to be applied directly.

2.2 Pólya-gamma Augmentation

Pólya-gamma augmentation is an auxiliary variable scheme that allows multinomial observations to appear as Gaussian likelihoods. This scheme has recently been used to develop Gibbs samplers and variational inference algorithms for Bernoulli, binomial, negative binomial, and multinomial regression models with logit link functions (Polson et al., 2013). Chen et al. (2013) use Pólya-gamma augmentation for multinomial models in the context of LDA, but in a way that only provides limited single-site inference updates. More recently, Linderman et al. (2015) extend the Pólya-gamma augmentation scheme for multinomial models in such a way that allows block updates and hence readily extends to dynamic topic models, in which entire state trajectories must be updated as a block for inference to be efficient. Here, we use the augmentation strategy of Linderman et al. (2015) to enable such block updating in our dynamic topic models.

The Pólya-gamma augmentation scheme is based on an integral identity derived from the Laplace transform of the Pólya-gamma distribution. Specifically, if $p(\omega | b, 0)$ is the density of the Pólya-gamma distribution $\text{PG}(b, 0)$, then

$$\frac{(e^\omega)^a}{(1 + e^\omega)^b} = 2^{-b} e^{a\omega} \int_0^\infty e^{-\omega\omega'/2} p(\omega' | b, 0) d\omega', \quad (4)$$

where $\kappa = a - b/2$. The integral on the right-hand side is the Laplace transform of the Pólya-gamma density evaluated at $\psi^2/2$, and the left-hand side is a functional form that often appears in logistic likelihoods. Importantly, viewed as a function of ψ for fixed ω , the right-hand side is an unnormalized Gaussian density. Thus, the identity in equation 4 transforms a logistic likelihood to a Gaussian likelihood conditioned on an auxiliary variable, ω .

While we focus on Gibbs sampling inference here, the Pólya-gamma augmentation scheme also enables efficient mean-field variational inference (Linderman et al., 2015; Zhou et al., 2012b), including scalable stochastic variational inference (Hoffman et al., 2013; Linderman et al., 2015). These algorithms could be adapted to provide scalable inference for the dynamic topic model case that we study here.

Binomial Case For the binomial case, Polson et al. (2013) let $\psi_0 = 0$ and write $\psi_1 = \psi$. Let $x = (x_0, x_1)$ be the number of zeros and ones that have been observed. Then we can write the likelihood of the natural parameter ψ given the data x as

$$p(x | \psi) = \binom{x_0 + x_1}{x_1} \frac{(e^\psi)^{x_1}}{(1 + e^\psi)^{x_0}} = c(x) \frac{(e^\psi)^{a(x)}}{(1 + e^\psi)^{b(x)}}$$

Given a prior $p(\psi)$ on the natural parameter ψ , then the joint density of (ψ, x) can be written as

$$p(\psi, x) = p(\psi) c(x) \frac{(e^\psi)^{a(x)}}{(1 + e^\psi)^{b(x)}} = \int_0^\infty p(\psi) c(x) 2^{-b(x)} e^{\kappa(x)\psi} e^{-\omega\psi^2/2} p(\omega | b(x), 0) d\omega. \quad (5)$$

The integrand of (5) defines a joint density on (ψ, x, ω) . If we condition on the auxiliary variables ω , then the conditional density $p(\psi | x, \omega)$ on the natural Bernoulli parameter ψ is given by

$$p(\psi | x, \omega) \propto p(\psi) e^{\kappa(x)\psi} e^{-\omega\psi^2/2} \quad (6)$$

which is Gaussian if $p(\psi)$ is Gaussian. By the exponential tilting property of the Pólya-gamma distribution, we have $\omega | \psi, x \sim \text{PG}(b(x), \psi)$. Efficient samplers exist for Pólya-gamma distributed variables (Windle et al., 2014), and thus we can alternate between sampling $\omega | \psi, x$ from a Pólya-gamma distribution and sampling $\psi | \omega, x$ from a Gaussian distribution.

Multinomial Case For the multinomial case, Linderman et al. (2015) rewrite the K -dimensional multinomial likelihood recursively in terms of $K - 1$ binomial densities using the following stick-breaking representation. Let β be a vector describing the probability of each outcome $1 \dots K$. Then we can define $\tilde{\beta}_k$ to be probability of choosing option k given that we have not selected any option $j < k$:

$$\tilde{\beta}_k = \frac{\beta_k}{1 - \sum_{j < k} \beta_j} \quad (7)$$

Writing the probabilities β in this way allows us to write the multinomial density as a product of binomial densities:

$$\text{Mult}(\mathbf{x} | N, \beta) = \prod_{k=1}^{K-1} \text{Bin}(x_k | N_k, \tilde{\beta}_k), \quad (8)$$

$$N_k = N - \sum_{j < k} x_j, \quad k = 1, 2, \dots, K, \quad (9)$$

where we can interpret N_k as the number of observations remaining after the observations where $j = 1, 2, \dots, k$ have been removed. Substituting $\tilde{\beta}_k = \sigma(\psi_k)$, we can write the multinomial likelihood as

$$\begin{aligned} \text{Mult}(\mathbf{x} | N, \psi) &= \prod_{k=1}^{K-1} \text{Bin}(x_k | N_k, \sigma(\psi_k)) = \prod_{k=1}^{K-1} \binom{N_k}{x_k} \sigma(\psi_k)^{x_k} (1 - \sigma(\psi_k))^{N_k - x_k} \\ &= \prod_{k=1}^{K-1} \binom{N_k}{x_k} \frac{(e^{\psi_k})^{x_k}}{(1 + e^{\psi_k})^{N_k}}. \end{aligned}$$

Linderman et al. (2015) next let $\mathbf{a}_k(\mathbf{x}) = \mathbf{x}_k$ and $\mathbf{b}_k(\mathbf{x}) = N_k$ for each $k = 1, 2, \dots, K - 1$ and introduce Pólya-gamma auxiliary variables ω_k corresponding to each coordinate ψ_k . Then the probability of the data \mathbf{x} and the auxiliary variables ω given the natural parameters ψ has a diagonal Gaussian likelihood:

$$p(\mathbf{x}, \omega | \psi) \propto \prod_{k=1}^{K-1} e^{(\kappa_k - N_k/2)\psi_k - \omega_k \psi_k^2/2} \propto \mathcal{N}\left(\psi \mid \Omega^{-1} \kappa(\mathbf{x}), \Omega^{-1}\right),$$

where $\Omega \equiv \text{diag}(\omega)$ and $\kappa(\mathbf{x}) \equiv \mathbf{x} - N(\mathbf{x})/2$. Thus, if we begin with a Gaussian prior $p(\psi)$ on the stick-breaking parameters ψ , then the posterior will remain Gaussian.

Finally, given the parameters ψ , we can recover the parameters β through the stick-breaking construction:

$$\begin{aligned} \tilde{\beta}_j &= \sigma(\psi_j) \\ \beta_k &= \tilde{\beta}_k \prod_{j < k} (1 - \tilde{\beta}_j) \end{aligned} \quad (10)$$

We denote this recovery process in equation 10 by the function $\beta \equiv \pi_{\text{SB}}(\psi)$.

3. Model: Stick-breaking Construction for Dynamic Topic Models

The Pólya-gamma augmentation scheme allows us to take a Gaussian graphical model in which efficient inference is well-developed and apply it to models with multinomial likelihoods. However, we must first convert the dynamic topic model from Section 2.1 into the appropriate stick-breaking form. In this section we describe this stick-breaking construction and a natural cross-corpora extension; for completeness we also include the parts of the dynamic topic model that remain unchanged.

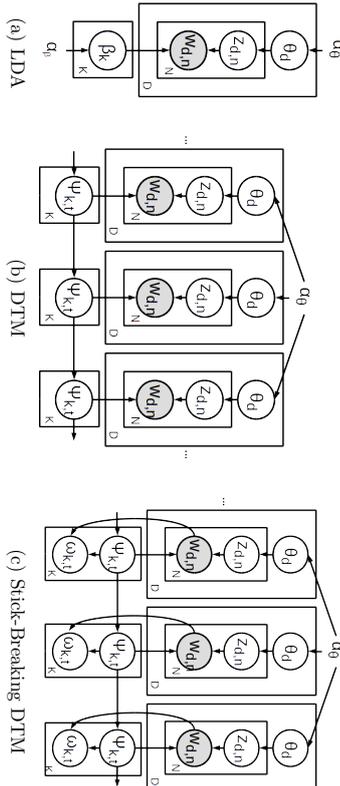

Figure 1: Graphical Models of latent Dirichlet allocation, the dynamic topic model, and our stick-breaking dynamic topic model. The natural parameters ψ are converted to multinomials β through the stick-breaking process in equation 10

3.1 Document-Specific parameters $\{\theta_d\}$ and $\{z_{n,d}\}$

As in the standard LDA approach, we continue to model the proportion of each topic in each document θ_d as being drawn independently from Dirichlet distributions with parameters α_θ , and the topic $z_{n,d}$ for each word $w_{n,d}$ drawn from θ_d :

$$\begin{aligned} \theta_d &\sim \text{Dir}(\alpha_\theta), \\ z_{n,d} | \theta_d &\sim \text{Cat}(\theta_d). \end{aligned}$$

3.2 Topic Parameters $\{\beta_k\}$

Static Stick-Breaking LDA Model In standard LDA, the likelihood associated with each topic β_k depends on the words assigned to that topic:

$$p(\{w_d\}_{d=1}^D | \{z_d\}_{d=1}^D, \{\beta_k\}_{k=1}^K) \propto \prod_{d=1}^D \prod_{k=1}^{N_d} \beta_k^{\mathbb{1}\{z_{d,n}=k\}} \propto \text{Mult} \left(\sum_{d=1}^D \mathbf{b}_{d,k}, \sum_{d=1}^D N_{d,k}, \beta_k \right)$$

where $\{w_{n,d}\}$ are all of the words in document d and $\{z_{n,d}\}$ are all of their assignments. Let N_d be the number of words in document d . The count vectors $\mathbf{b}_{d,k,v}$ and $N_{d,k}$ count the number of occurrences of word v in document d assigned to topic k and the number of occurrences of the topic k in document d , respectively:

$$\begin{aligned} \mathbf{b}_{d,k,v} &= \sum_{n=1}^{N_d} \mathbb{1}\{w_{d,n} = v\} \mathbb{1}\{z_{d,n} = k\}, \\ N_{d,k} &= \sum_{n=1}^{N_d} \mathbb{1}\{z_{d,n} = k\}. \end{aligned} \tag{11}$$

We transform the word probability vectors such that $\beta_k \equiv \pi_{\text{SB}}(\psi_k)$, introduce auxiliary variables ω_k , and set a Gaussian prior $\psi_k \sim \mathcal{N}(\mu, \Sigma)$ on the stick-breaking parameters ψ . Then the posterior over ψ given the counts $\{\mathbf{b}_d\}$ is given by the Gaussian

$$p(\psi_k | \{\mathbf{b}_d\}, \{z_d\}, \omega_k, \mu, \Sigma) \propto \mathcal{N} \left(\psi_k | \Omega_k^{-1} \cdot \kappa \left(\sum_{d=1}^D \mathbf{b}_{d,k} \right), \Omega_k^{-1} \right) \mathcal{N}(\psi_k | \mu, \Sigma) \tag{12}$$

Dynamic Stick-Breaking Topic Model Let $t(d) \in \mathbb{N}$ denote the discrete time index of document d and $\beta_{t,k} \in [0, 1]^V$ denote the word probability vector of topic k at time t . Then we can define the following dynamical system model

$$\begin{aligned} \psi_{t,k} &\sim \mathcal{N}(\mathbf{A}\psi_{t-1,k}, \mathbf{B}\mathbf{B}^\top) \\ \beta_{t,k} &\equiv \pi_{\text{SB}}(\psi_{t,k}) \end{aligned} \tag{13}$$

where $\mathbf{u}_{t,k}$ is a latent state of topic k at time t . Then the likelihood associated with latent state vectors $\{\mathbf{u}_{t,k}\}$ given the word-topic assignments $\{z_{n,d}\}$ is given by the diagonal Gaussian potential

$$p(\mathbf{b}_{d,k} | \{\mathbf{u}_{t(d),k}, \omega_{t(d),k}\}) \propto \mathcal{N} \left(\mathbf{\Omega}^{-1} \cdot \kappa \left(\sum_{t:t(d)=t} \mathbf{b}_{d,k} \right) | \psi_{t(d),k}, \mathbf{\Omega}^{-1} \right). \tag{14}$$

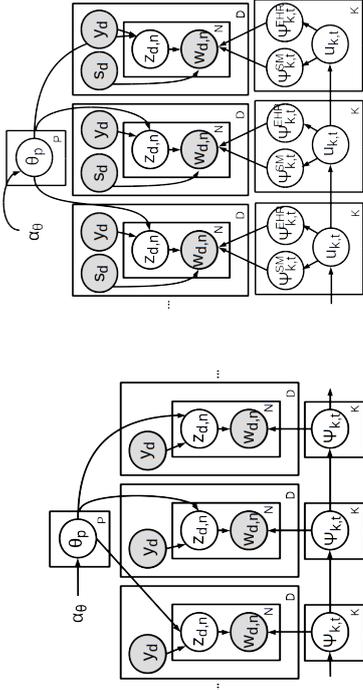

where $\mathbf{\Omega} \equiv \text{diag}(\omega_{t,k})$. As in equation 11, $\mathbf{b}_{d,k}$ counts how often each word v is assigned to topic k in document d , and the likelihood for $\psi_{t,k}$ only depends on the documents for which $t(d) = t$. Figure 1c shows the graphical model of the stick-breaking DTM with the associated Pólya-gamma variables.

3.3 Extensions

Shared Topic Proportions Among Documents In the dynamic topic model, temporal coherence arises due to the smoothness prior on β . While this approach allows us to build temporal models from cross-sectional data, it does not use longitudinal information about whether documents are associated with the same patient when it is available.

One extension we consider is that the proportion of each disease in a patient does not change over time, that is, instead of considering a distinct document-topic vector θ_d for each document, we have a single patient-topic vector θ_p for each patient. However, the probability of a word given the topic— β —will still change with time. This extension is shown in figure 2a, where we introduce the variable y_d to indicate which patient p is associated with each document d ; that is, the indicator y_d selects which θ_p to apply to document d .

Relationships between Multiple Corpora Given multiple corpora, one simple extension of the model from Section 3.2 is to posit that each disease has some canonical temporal process, but the probabilities of the terms associated with that process may vary across different corpora. For example, posts from social media may talk more about the behaviors associated with a disease, while diagnoses may focus on comorbidities. To model differences

(a) DTM with per-patient θ_p ; the observed variable y_d indicates which patient the document came from.
 (b) Cross-corpora extension; the observed variable s_d indicates to which corpus the document belongs.

Figure 2: Graphical Models for the DTMs in which topic proportions are shared across all notes from the same patient (2a) and DTMs that combine multiple corpora (2b). To reduce clutter, we do not include the associated Pólya-gamma variables; these are the same as in figure 1c

in term usage between corpora, we consider a dynamical system structured as

$$\begin{aligned} \mathbf{u}_{t,k} &\sim \mathcal{N}(\mathbf{u}_{t,k} | \mathbf{A}\mathbf{u}_{t-1,k}, \mathbf{B}\mathbf{B}^\top) \\ \epsilon_{t,k,l} &\sim \mathcal{N}(0, \sigma_l^2) \\ \psi_{t,k,l} &\equiv \mathbf{u}_{t,k} + \epsilon_{t,k,l} \\ \beta_{t,k,l} &\equiv \pi\text{SB}(\psi_{t,k,l}) \end{aligned} \quad (15)$$

where now topic proportions $\beta_{t,k,l}$ and their natural parameters $\psi_{t,k,l}$ are associated with a specific corpus l .

Our stick-breaking construction using Pólya-gamma augmentation again renders the relevant likelihoods Gaussian: for each corpus l , the probability of the words associated with the corpus given $\psi_{t,k,l}$ is given by

$$p(\mathbf{b}_{d,k} | \psi_{t(d),k,l(d)}, \boldsymbol{\omega}_{t(d),k,l(d)}) \propto \mathcal{N}\left(\boldsymbol{\Omega}_{t(d),k,l(d)}^{-1} \cdot \boldsymbol{\kappa} \left(\sum_{d:l(d)=l} \mathbf{b}_{d,k} \right) \middle| \psi_{t(d),k,l(d)}, \boldsymbol{\Omega}_{t(d),k,l(d)}^{-1}\right)$$

where $l(d)$ is the corpus associated with document d , $\mathbf{b}_{d,k}$ is again a vector of the number of times each word v is assigned to topic k in document d from equation 11, and $\boldsymbol{\Omega} \equiv \text{diag}(\boldsymbol{\omega}_{t,k})$.

Finally, the likelihood associated with the underlying temporal process $\mathbf{u}_{t,k}$ is simply

$$p(\psi_{t,k}, |\mathbf{u}_{t,k}, \sigma_l^2) = \prod_l \mathcal{N}(\psi_{t,k,l} | \mathbf{u}_{t,k}, \sigma_l^2).$$

The cross-corpora extension of the dynamic topic model is shown in figure 2b, where we explicitly show the parameters $\psi_{t,k}^{SM}$ and $\psi_{t,k}^{EHR}$ for just two corpora. The variable s_d indicates which source— $\psi_{t,k}^{SM}$ or $\psi_{t,k}^{EHR}$ —should be used to model document d .

4. Inference

Given the stick-breaking dynamic topic model construction in Section 3.2, inference is straight-forward; the simplicity of inference is a key advantage of the Pólya-gamma augmentation approach. Below we summarize the inference process for the latent variables in our model: the topic proportions θ_d , the topic assignments $\{z_{nd}\}$, the topic parameters \mathbf{u} (which can be deterministically converted into the topic proportions $\boldsymbol{\beta} = \pi\text{SB}(\mathbf{u})$), and the augmentation variables $\boldsymbol{\omega}$. The variables θ , $\{z_{nd}\}$, and $\boldsymbol{\omega}$ are resampled using Gibbs sampling, and \mathbf{u} is resampled using a Gaussian linear dynamical system.

4.1 Resampling Document-Specific Parameters $\{z_{n,d}\}$ and $\{\theta_d\}$

The word-topic assignments $\{z_{n,d}\}$ are resampled exactly as in the Gibbs sampler for LDA:

$$z_{nd} \sim \text{Mult}(\{\beta_{k,v(w_{nd})} \theta_{d,k}\})$$

where $v(w_{n,d})$ is the word associated with the token $w_{n,d}$. Likewise, the topic proportions θ_d are also sampled exactly as in LDA:

$$\theta_d \sim \text{Dir}(\alpha_\theta + \mathbf{N}_d),$$

where \mathbf{N}_d is the vector of counts with $N_{dk} = \sum_{z_{nd} \in d} \mathbb{I}(z_{nd} = k)$. If we are sampling topic proportions per patient rather than per document, then we simply replace N_{dk} with $N_{pk} = \sum_{z_{nd} \in p} \mathbb{I}(z_{nd} = k)$, the number of times that a topic has been observed with each patient.

4.2 Resampling Topic Parameters

In the static LDA case, we can resample the natural parameters ψ from the Gaussian distribution given equation 12. In the dynamic case, we must incorporate the linear dynamical system prior.

Resampling ψ : Dynamic Topic Model The formulas in equation 13 describe a linear Gaussian system, and the likelihoods in equation 14 are also Gaussian, and thus inference on \mathbf{u} can be performed using off-the-shelf algorithms for linear dynamical systems. For completeness, we write the forward-filtering backward-sampling equations here, setting \mathbf{A} from equation 13 to be the identity \mathbf{I} and $\mathbf{B} = \text{diag}(\sigma_n \dots \sigma_n)$. Define the covariance of the random walk $\boldsymbol{\Sigma} \equiv \mathbf{B}\mathbf{B}^\top = \text{diag}(\sigma_n^2 \dots \sigma_n^2)$. For each topic k , we first compute the mean $q_{t,k}$ and variance $Q_{t,k}$ of the ψ_k in the forward pass:

$$\begin{aligned} q_{t,k} &= q_{t-1,k} + (Q_{t-1,k} + \boldsymbol{\Sigma})(Q_{t-1,k} + \boldsymbol{\Sigma} + \boldsymbol{\Omega}_{t(d),k}^{-1})^{-1}(y_{t,k} - q_{t-1,k}) \\ Q_{t,k} &= (\mathbf{I} - (Q_{t-1,k} + \boldsymbol{\Sigma})(Q_{t-1,k} + \boldsymbol{\Sigma} + \boldsymbol{\Omega}_{t(d),k}^{-1})^{-1})(Q_{t-1,k} + \boldsymbol{\Sigma}) \end{aligned} \quad (16)$$

where we start with some q_1 and Q_1 as the prior mean and variance of $\psi_{t=1,k}$, $\mathbf{\Omega}_{t(0),k}^{-1}$ is computed from the auxiliary variables according to equation 14, and we use $q_{t,k} \equiv \mathbf{\Omega}_{t(0),k}^{-1} \cdot \kappa(\sum_{d:t(d)=t} \mathbf{b}_{d,k})$. Importantly, if the initial covariance Q_1 is diagonal, then because the transition covariance $\mathbf{\Sigma}$ and the likelihood covariance $\mathbf{\Omega}$ are also diagonal, the covariance $Q_{t,k}$ remains diagonal for all times t . Thus the updates in equation 16 can be computed in time linear in the size of the vocabulary $|V|$.

Similarly, the backward sampling pass can be efficiently computed by sampling $\psi_{T,k} \sim \mathcal{N}(q_{T,k}, Q_{T,k})$ and then recursively sampling $\psi_{t,k} \sim \mathcal{N}(q'_{t,k}, Q'_{t,k})$ where the mean $q'_{t,k}$ and variance $Q'_{t,k}$ are given by

$$\begin{aligned} q'_{t,k} &= q_{t,k} + Q_{t,k}(Q_{t,k} + \mathbf{\Sigma})^{-1}(\psi_{t+1,k} - q_{t,k}) \\ Q'_{t,k} &= (\mathbf{I} - Q_{t,k}(Q_{t,k} + \mathbf{\Sigma})^{-1})Q_{t,k} \end{aligned} \quad (17)$$

Resampling ω , ψ : Cross-Corpora Dynamic Topic Model In the cross-corpora dynamic topic model from section 3.3, we have separate variables $\omega_{t,k}$ describing the underlying dynamical system and natural parameters $\psi_{t,k,l}$ for each corpus. Conditioned on $\omega_{t,k}$, the distribution over the parameters for $\psi_{t,k,l}$ for each time t are independent. They can be computed using equation 12 for the static LDA case and substituting the appropriate mean and variance:

$$p(\psi_{t,k,l} | \{z_d\}, \omega_{t,k}, \mathbf{\Sigma}) \propto \mathcal{N} \left(\psi_k | \mathbf{\Omega}_{t,k,l}^{-1} \cdot \kappa \left(\sum_{d \in I} \mathbf{b}_d \right), \mathbf{\Omega}_k^{-1} \right) \cdot \mathcal{N}(\psi_{t,k,l} | \omega_{t,k}, \mathbf{\Sigma})$$

where $\mathbf{\Sigma}$ is the diagonal covariance $\text{diag}(\sigma_1^2 \dots \sigma_l^2)$ from equation 15 and \mathbf{b}_d sums over the word counts for topic k at time t in corpus l in document d .

Conditioned on the topic proportions $\psi_{t,k,l}$, the evolving terms $\omega_{t,k}$ can be resampled using a linear dynamical system with $\psi_{t,k,l}$ as the emissions.

Resampling ω In both the cross-corpora and the standard dynamic topic models, we achieve Gaussian likelihoods by augmenting the model with Pólya-gamma distributed variables $\omega_{t,k}$ or $\omega_{t,k,l}$ respectively. The posterior distributions of these variables are given by

$$\omega_{t,k} | \omega_{t,k}, \sim \text{PG}(\mathbf{N}_{t,k}, \omega_{t,k})$$

where $\mathbf{N}_{t,k}$ is a vector of how often each word appeared in all documents at time t that were assigned to topic k . In the cross-corpora case, this becomes

$$\omega_{t,k,l} | \psi_{t,k,l}, \sim \text{PG}(\mathbf{N}_{t,k,l}, \psi_{t,k,l}).$$

5. Application to Learning Trajectories in Autism Spectrum Disorders

5.1 Data Description

Electronic Health Records We analyze the ICD-9CM diagnostic codes from 13,435 patients with at least one ICD-9CM code for autism spectrum disorder (299.0, 299.8, 299.9) from the Boston Children’s Hospital. The Institutional Review Boards of Boston Children’s

Hospital, Harvard Medical School, and the Harvard Paulson School of Engineering and Applied Sciences reviewed this study and approved it as not-human subjects research.

Each ICD-9CM code was converted into a concept unique identifier (CUIs) using the UMLS (Bodenreider, 2004) and filtered for the semantic type “Disease or Syndrome.” For each code, we computed the age of the patient given the patient’s birth date and the date associated with the visit that produced the code. As current evidence (e.g. Stoner et al. (2014)) suggests that ASD develops from birth, we used the age of the child as the time index for the ICD-9CM code.

To form documents, we grouped all codes associated with a patient for each year of age between the ages 0 and 15 into a “document.” For example, if a patient had three visits that generated a total of ten ICD9-CM codes between ages one and two, and two more visits that generated a total of five ICD9-CM codes between ages two and three, then that patient would be associated with two documents: one at time index “age 1,” with ten codes, and one at time index “age 2,” with five codes. Grouping all diagnostic codes from a year into one document smoothed over variations due to visits to specialties that focused on different aspects of the child’s care. This processing procedure resulted in 63,941 documents with an average of 5.3 CUIs each and 7,037 unique CUIs.

Social Media We scraped all subforums of the websites www.asd-forum.org.uk, www.autismweb.com, and www.asdfriendly.org, resulting in 664,954 posts from 80,927 threads. An example post is given in Appendix A.1. The forum posts contained the date of posting but not the child’s date of birth; thus additional processing was required to determine the age of the child—and thus the time-index—for the documents. Regular expressions (see Appendix A.2) were used to extract ages from the posts, and posts with multiple ages were excluded. This procedure resulted in 13,743 posts with a single mention of age. Approximately 1,000 of these posts were hand-checked for accuracy; the regular expressions were adjusted to avoid any errors that were discovered in the hand-checked posts.

We filtered for patients between 0 and 15 years of age, and as with the electronic health records, we combined all the posts written about the same patient with the same age into one document to smooth over variations due to the caregiver’s particular concerns at the time. This processing resulted in a data set of 5,461 documents (each containing possibly multiple posts written in the same year) by 2,391 unique users.

Clinically-relevant terms were extracted from these posts by finding terms that matched the consumer health vocabulary (Zeng, 2015), which has mappings into the UMLS CUIs. A trie was used to quickly match terms to the dictionary of words, and only terms with the semantic type “Disease or Syndrome” were included. The average number of CUIs per document was 1.8. Of the 7,372 CUIs across the EHR and SM data sets, 284 were unique to the forum posts and 2,407 were unique to the EHR codes.

5.2 Methods

Models We considered three variants of dynamic topic models:

- *SB-DTM- θ* The stick-breaking DTM from Section 3.2.

- **SB-DTM- θ_p** The stick-breaking DTM in which we assume that distribution over diseases in each patient remains constant over time, as described in Section 3.3.
- **SB-ccDTM** The stick-breaking DTM in which the EHR and SM corpora are modeled as having distinct topics with shared underlying dynamics, as described in Section 3.3.

These variants were compared to two versions of LDA: in the first version, LDA-K was trained with K topics that did not evolve over time. LDA-K15 was trained with $15K$ topics, accounting for the fact that the dynamic topic model could have a different topic for each year in ages 0 to 15.¹

Evaluations Our first evaluation metric was simply predictive log-likelihoods. We randomly held-out 10% percent of the words from 10% percent of the documents. Once the model was trained, we had a value of the topic proportions θ_d for every document d . Thus, probability of a held-out word w_{nd} was given by

$$p(w_{nd} | \theta_d, \beta) = \sum_z p(w_{nd} | z, \beta_{z,t(d)}) p(z | \theta_d)$$

Our second evaluation metric simulated the more clinically relevant task of stratifying patient risk for various future outcomes. For this evaluation, we considered only patients with at least one document during early childhood—under the age of five—and one document from later childhood—over the age of seven. For 10% of these patients, we held out *all* the documents for after the child was six years old. The documents from when the child was five years old or younger were included in the DTM training. Following training, we computed the average document-topic proportions θ_p for each patient as

$$\theta_p = \frac{1}{N_p^{<5}} \sum_{ds,t,t(d) \leq 5} \theta_d$$

where $N_p^{<5}$ is the number of documents associated with patient p where $t(d) \leq 5$. This averaging corresponds to the assumption that the patient’s disease proportions do not change over time; note that in the shared-proportions DTM from Section 3.3, we can simply use the learned θ_p .

Given a patient-topic vector θ_p , we can compute the likelihood of the future, *unseen* notes

$$p(w_{nd} | \theta_p, \beta) = \sum_{z, ds,t,t(d) \geq 7} p(w_{nd} | z, \beta_{z,t(d)}) p(z | \theta_p)$$

If our temporal models were capturing time-varying patterns in disease processes, we would expect our model to better predict the content of future documents than a static model.

1. We also ran tests using the C implementation of dynamic topic models available at <https://github.com/balei-1ab/dtm> but were unable to achieve satisfying likelihoods with several parameter settings.

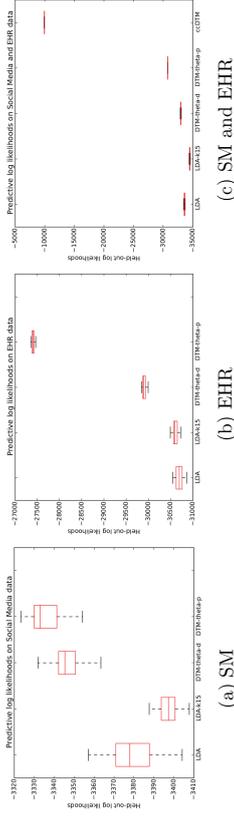

Figure 3: Boxplots of held-out test likelihoods for the different models on SM data alone, EHR data alone, and both data sets combined. Across all versions, the dynamic models have higher predictive performance.

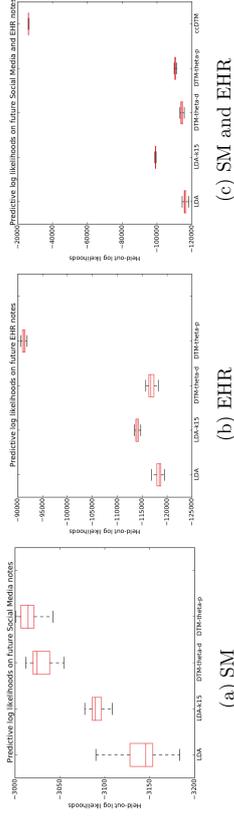

Figure 4: Boxplots of predictions of future patient notes on SM data alone, EHR data alone, and both data sets combined. Models which are trained with the assumption that topic proportions θ_p for each patient remain constant over time do best in the individual data sets, and the transfer learning in the combined case has the best predictive performance.

5.3 Results and Analysis

We completed 10 runs each of LDA, LDA-K15, the standard DTM, the SB-DTM- θ_d , the SB-DTM- θ_p , and the SB-ccDTM. We completed runs on the EHR data alone, the SM data alone, and the SM and EHR data combined. The results of LDA were used to initialize the dynamic topic models, and the results of basic DTM were used to initialize the ccDTM. Preliminary tests of 300 iterations showed that the samplers mixed by around 50 iterations (see figure 9 in appendix B for an example plot); in the results below each sampler was run for 100 iterations. The transition noise parameter in the linear dynamical system was set to $\sigma_n^2 = 0.1$, the cross-corpora noise parameter in SB-ccDTM was set to $\sigma_c^2 = 1$, and the number of topics K was set to 10 based on initial parameter exploration of $K = 5, 10, 15$.

Predictive Performance: Held-out Data Figure 3 shows the held-out test likelihoods for the SM, EHR, and combined cohorts, respectively, for $K = 15$. We see that the dynamic models outperform the static models, including an LDA model with as many topics as the DTM. Indeed, LDA-K15 has the lowest overall predictive likelihoods, suggesting that it may be overfitting. Incorporating links between notes from the same patient (DTM- θ_p)

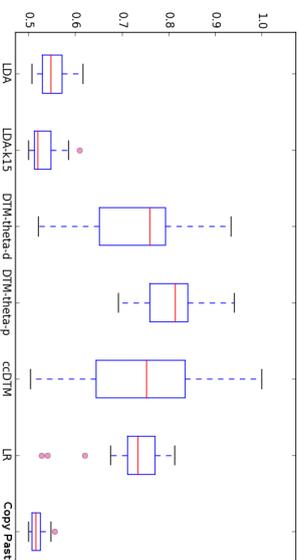

Figure 5: Boxplots of AUCs for predicting future patient conditions for conditions that occurred in at least 10% of the patients. Even without explicitly trying to optimize future predictions, the DTM-based approaches are comparable to—or better than—a discriminative baseline such as logistic regression.

improves prediction quality in both the individual and combined data sets, and the added flexibility of the cross collection ccDTM model further improves prediction accuracy in the combined data set.

Predicting Future notes Figure 4 shows the held-out test likelihoods for the content of *all* patients notes associated with age seven and above given all the notes from that patient under the age of five. Predicting the content of an *entirely* held-out note is much harder than predicting the missing contents of a partially held-out note. We see that training the models with the assumption that topic proportions stay constant—as in the DTM- θ_p model—results in the best predictive performance on these entirely held-out notes in both data sets. In the combined data set, the ccDTM model, which also allows for transfer learning between the SM and EHR data sets, achieves the highest predictive likelihoods.

Figure 5 shows AUCs for the same task of predicting the contents of future notes given current ones. We see that the DTM-based models again perform better than their static counterparts because they are able to imagine what future diseases may occur (the boxplots are over all CTUs with at least 10% prevalence the future notes). The DTM model which takes advantage of the links between patients performs the best, better than the logistic regression discriminative baseline. Finally, we see that simply assuming that a patient’s past condition will continue into the future (copy past) does not produce high AUCs; both the DTM and the logistic regression are learning meaningful predictive relationships.

Transfer Learning between EHR and Social Media The previous analyses showed that our dynamic models better predict held-out and future patient data than a static model. It is also interesting to test whether combining the two data sets increases predictive performance on data from each of the individual data sets, that is, for the same held-out

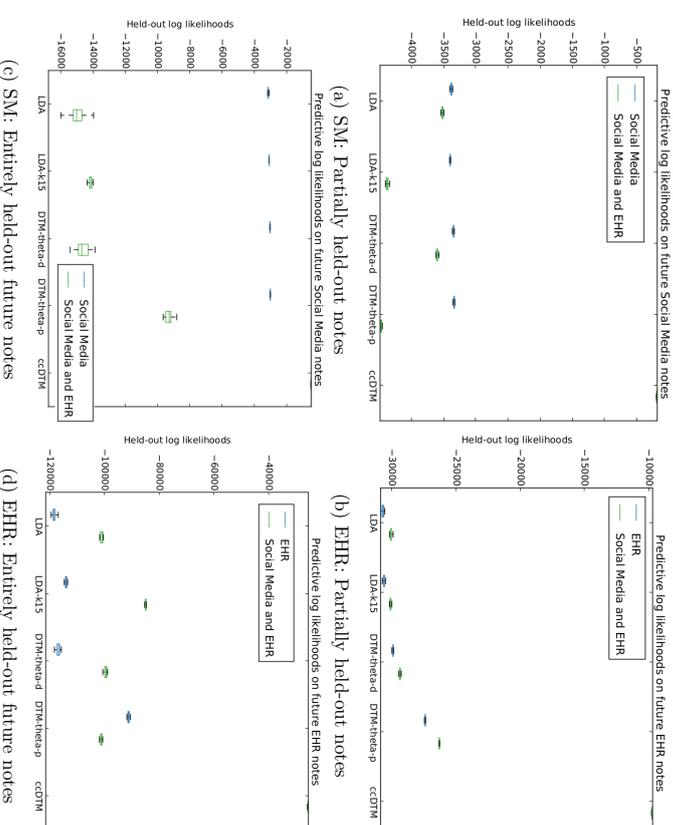

Figure 6: Boxplots comparing of predictions of randomly held-out data and future notes for each cohort vs. the combined cohort. In general, transfer is positive for EHRs and negative for SM; however, the flexibility of the cross-corpora DTM results in positive transfer in all scenarios (tiny bar at the top-right in all the plots).

EHR data, is there a benefit to training on EHR and SM data rather than training on EHR data alone? Likewise, for some held-out SM data, does adding EHR data into the training set benefit predictive performance? (Note that there is no reason, a priori, to assume that combining collections will be beneficial.)

The boxplots in figure 6 show the results of this test for both randomly held-out data and for predicting entire future notes. The blue boxplots correspond to training only on the target data set, and the green boxplots correspond to training on the combined data set. In the EHR cohort, the transfer is positive in almost all cases (the green boxplots are higher than their corresponding blue boxplots), even among models such as standard LDA. The opposite is true in the SM cohort: training on the combined set decreases predictive accuracy among the flat models, likely because the SM data set had many fewer documents than the EHR data set. However, in all cases, we observe that cross-collection DTM (ccDTM)—

whose hierarchy allows greater flexibility in how information is shared across the two data sources—has the highest predictive performance.

Computational Time The static LDA models had the fastest wall-clock times, with a five-topic LDA model on the full corpus taking 0.279 seconds per iteration and the larger LDA-15 taking 0.414 seconds per iteration. The standard DTM- θ_d took 2.00 seconds per iteration, and adding the patient links in the DTM- θ_p increased the per iteration runtime to 2.14 seconds per iteration. Interestingly, the cDTM required only 0.953 seconds per iteration, because the forward-backward pass over the \mathbf{u} variables only had two emissions—the ψ from each corpus—rather than inputs from all of the documents.

Qualitative Examination of Topics: Electronic Health Records We show the top-4 words for the EHR-only θ -p DTM in table 1. (We choose a small K for brevity, larger K have similar and additional patterns.) Topic 0 corresponds to the trajectory of patients with ASD who also have Down’s syndrome. ASD and Down’s syndrome are known to be comorbid with each other (Kent et al., 1999; Rasmussen et al., 2001). Expressive disorder, a feature of both ASD and Down’s syndrome, shows up in the top-4 list as children are learning language at age 2; later the top-4 list is dominated by clinical features such as infections. The overall prevalence of infection-related terms is consistent with associations of immunodeficiency with both Down’s syndrome (Ram and Chinen, 2011) and ASD (Gupta et al., 2010), including increased ear infections specifically (Konstantareas and Homatidis, 1987b). Children with Down’s syndrome are more likely to have a variety of abnormal ocular features such as myopia (Shapiro and France, 1985) and abnormalities of the ear such as eustachian tube dysfunction (Pueschel, 1990; Shott et al., 2001). Sleep apnea is also common in children with Down’s syndrome (Marcus et al., 1991).

Topic 1 corresponds to children with ASD who go on to develop psychiatric disorders, and is very similar to the psychiatric subgroup reported by Doshi-Velez et al. (2013). As expected, there is a progression from ADHD at age 4, anxiety and conduct disorders at age 10, to episodic mood disorders at age 15 (other prevalent, but not top-4 terms at age 15 included depressive disorder and childhood psychoses). Psychiatric disorders are commonly reported among higher functioning children with ASD (Gillott et al., 2001; DeLong and Dwyer, 1988), and the progression of diagnoses makes sense because clinicians will usually avoid giving a young child a diagnosis for a severe psychiatric illness.

Topic 2 contains a combination of intellectual disability and epilepsy. It is similar to neurological subgroup reported by Doshi-Velez et al. (2013). Epilepsy is a common comorbidity of autism (Sherr, 2003a; Mouridsen SE, 1999), affecting close to 20% of children with ASD. Sherr (2003b) suggest that these three disorders—epilepsy, intellectual disability, and ASD—are linked through the ARX gene. Launonnier et al. (2004) find common genes between ASD and intellectual disability, and Sharp et al. (2008) report genomic underpinnings for epilepsy and intellectual disability. Again, a young child is less likely to be given a diagnosis of intellectual disability—it appears in our top-4 list at age 4—but other signs, such as symbolic dysfunction and developmental delays are noted from infancy.

Topic 3 tracks the progression of children with ASD and cerebral palsy. There are known correlations between cerebral palsy and infantile autism (Surén et al., 2012; Talkowski et al., 2012); early infections (seen at age 0) have also been associated with both cerebral palsy and autism spectrum disorders (Konstantareas and Homatidis, 1987a; Rosenhall et al., 1999).

Table 1: Top words from Dynamic Topic Model trained only on Electronic Health Records.

Topic	Year 0	Year 2	Year 4	Year 10	Year 15
Topic 0	Otitis Media, Down Syndrome, Acute upper respiratory infection, Unspecified viral infection	Expressive Language Disorder, Otitis Media, Down Syndrome, Chronic serous otitis media	Otitis Media, Expressive Language Disorder, Down Syndrome, Eustachian tube disorder	Down Syndrome, Eustachian tube disorder, Sensorineural Hearing Loss, Otitis Media	Down Syndrome, Eustachian tube disorder, Sleep Apnea, Myopia
Topic 1	Acute bronchitis, Asthma	Other specified pervasive developmental disorders, Asthma, Urea Cycle Disorders, Autistic Disorder	Other specified pervasive developmental disorders, Attention deficit hyperactivity disorder, Autistic Disorder, Developmental delay (disorder)	Attention deficit hyperactivity disorder, Other specified pervasive developmental disorders, Anxiety state, Conduct Disorder	Attention deficit hyperactivity disorder, Other specified pervasive developmental disorders, Anxiety state, episodic mood disorders
Topic 2	Other specified delays in development, Mixed development disorder, Viral and chlamydial infection, Developmental delay (disorder), Symbolic dysfunction	Infantile autism, Symbolic dysfunction, Developmental delay (disorder), Other specified delays in development	Symbolic dysfunction, Infantile autism, Unspecified intellectual disabilities, Epilepsy	Infantile autism, Unspecified intellectual disabilities, Epilepsy, Symbolic dysfunction	Infantile autism, Unspecified intellectual disabilities, Epilepsy, Unspecified, Generalized convulsive epilepsy,
Topic 3	Infantile cerebral palsy, Gastroesophageal reflux disease, Chronic respiratory disease in perinatal period, Deglutition Disorders	Infantile cerebral palsy, Quadriplegic Infantile Cerebral Palsy, Diplegic Infantile Cerebral Palsy, Deglutition Disorders	Infantile cerebral palsy, Quadriplegic Infantile Cerebral Palsy, Diplegic Infantile Cerebral Palsy, Deglutition Disorders	Quadraplegic Infantile Cerebral Palsy, Infantile cerebral palsy, allergic rhinitis, hay fever	Quadraplegic Infantile Cerebral Palsy, Infantile cerebral palsy, Hemiplegic cerebral palsy, Gastroesophageal reflux disease
Topic 4	Gastroesophageal reflux disease, Atrial septal defect within oval fossa, Hypoplastic Left Heart Syndrome, DiGeorge Syndrome	Gastroesophageal reflux disease, Deglutition Disorders, Asthma, Failure to Thrive	Gastroesophageal reflux disease, Muscle, ligation and fascia disorders, Developmental Coordination Disorder, Deglutition Disorders	Gastroesophageal reflux disease, Hypogammaglobulinemia, Asthma, Hematological Disease	Hypogammaglobulinemia, Gastroesophageal reflux disease, Adjustment Disorder With Mixed Anxiety and Depression, Hypertopia

Children with cerebral palsy are known to have difficulty swallowing (Sochaniwskyj et al., 1986) and reflux (Reyes et al., 1993). Horrath et al. (1999) also note an association between ASD and a number of gastrointestinal symptoms, including increased reflux.

Finally, topic 4 initially contains a variety of more severe multi-system disorders. Many are congenital anomalies (e.g. DigGeorge Syndrome and septal defects), which are more prevalent in ASD (Wier et al., 2006). It makes sense to see “failure to thrive”—usually diagnosed in early childhood—as one of the top diagnoses in this topic of severe illnesses. The later terms contain features common in ASD (GI symptoms, immunodeficiency) seen in earlier topics but without the associated Down’s syndrome or cerebral palsy. This topic is somewhat reminiscent of the multi-system subgroup in Doshi-Velez et al. (2013). More broadly, analyzing the same data set, we recover topics that resemble the subgroups discovered in Doshi-Velez et al. (2013) with the addition of specific trajectories for patients with ASD and Down’s syndrome and ASD and cerebral palsy.

Qualitative Examination of Topics: Social Media Table 2 shows a similar table for the θ_i DTM trained on the social media data alone. Even after filtering for only signs and symptoms, the extracted terms from the forum posts tend to focus more the symptoms of the child’s ASD rather than other comorbid conditions. ² Topic 3 seems to correspond to the most “traditional” ASD trajectory: with speech delays and tantrums early on. Emotional distress is a constant, and we see that bullying makes the top-4 list at age 10. Children with ASD are both more likely to bully (Montes and Haltnerman, 2007; Van Roessel et al., 2010) and be bullied (Lee et al., 2008), especially as they reach later grade school and early middle school years.

In general, terms such as tantrums and mental suffering are common in many of the topics. For example, topic 0 follows the trajectory of children with stereotypics (tic disorder, apraxias) common in ASD (Goldman et al., 2009). Pagramenta et al. (2010) suggest genetic commonalities between ASD and dyslexia, and Gillon and Moriarty (2007) note that children with speech apraxias are also at higher risk for dyslexia. However, there also exists a parallel set of terms starting with mental suffering starting at age 2 and ending with psychiatric problem at age 15. Even if some of the mental suffering terms are a mistaken reference to the challenges experienced by the caregiver, rather than the child, we can still say that forums generally contain more language pertaining to mental health.

Topic 1 describes emotional distress, including nightmares (while nightmares are not reported as common in the clinical literature, sleep disorders are very common and it may be that parents attribute sleep disorders to nightmares (Gail Williams et al., 2004)), as well as reactions that children may have to stress—temper tantrums and aggressive behaviors. These terms turn to phobic anxiety at later ages. We conjecture that this topic is the care-giver analog of EHR Topic 1 above, which followed the trajectories of patients with psychiatric disorders.

Like Topic 2 in the EHR, Topic 2 here describes developmental delays and epilepsy. However, we see abstract thought disorder rather than intellectual disability as well as symptoms such as staring. At age 15, emotional distress again makes the top-4 list, suggesting that most children with ASD face challenges as they grow older and interact more

² We were not able to incorporate clinical notes in this study, but it is possible that the clinical note would also tip the balance toward terms describing the patient’s ASD rather than other comorbidities.

with society. Topic 4 also has some psychiatric disorders, including aggressive behavior turning into emotional distress, bullying, and depression as the child ages.

Table 2: Top words from Dynamic Topic Model trained on only Social Media

Topic	Year 0	Year 2	Year 4	Year 10	Year 15
0	Infection, Apraxias, Developmental delay (disorder), Autistic Disorder	Autistic Disorder, Infection, Apraxias, Mental Suffering	Autistic Disorder, Apraxias, Tic disorder, Mental Suffering	Autistic Disorder, Dyslexia, Apraxias, Mental Suffering	Autistic Disorder, Apraxias, Tic disorder, Psychiatric problem
1	Autistic Disorder, Emotional distress, Abstract thought disorder, Temper tantrum	Autistic Disorder, Emotional distress, Abstract thought disorder, Aggressive behavior	Autistic Disorder, Emotional distress, Abstract thought disorder, Aggressive behavior	Autistic Disorder, Emotional distress, Temper tantrum, Aggressive behavior	Autistic Disorder, Emotional distress, Phobic anxiety disorder, Nightmares

Qualitative Examination of Topics: Cross-corpora model Finally, we show the matching topics of the cross-corpora model in tables 3 and 4, as well as the overall proportions of each topic in figure 7. Again, we limit ourselves to a smaller topic model and show only a few top words, but we emphasize that in a clinical application these choices can be expanded and each topic examined in significantly more detail. What is most interesting for our purposes is the cross-corpora DTM allows us to see where top words in the corpora match, and where they do not.

Overall, the topics are closer to the EHR topics—likely a reflection of the fact that we had more EHR data. For example, topic 0 appears to be epilepsy topic (with pervasive developmental disorders replacing intellectual disability as a topic term, but reflecting a similar set of conditions). Epilepsy-related terms are also present in the social media version of the topic; however, we also see ADHD—also comorbid with epilepsy (Suren et al., 2012; Dunn et al., 2003)—present in both topics, likely because ADHD is commonly discussed on forums. We also dental caries, which are also associated with epilepsy (Anjounshoaa et al.,

2009), in the social media version of the topic. Such dental terms would not occur as often in the clinical records because children see their dentists outside the hospital system.

Topic 1 contains several psychiatric disorders with increasing severity (especially prominent in the EHR version of the topic). These show up as more general emotional distress and mental suffering in the forum topic. While most of the topics are present in similar relative proportions in both corpora (figure 7), topic 1 is the most common topic in the social media source and the least common topic in the electronic health records. We posit this difference may be because caregivers in general may be more focused on the mental health of their children (as seen in the social media-only topics), while the EHRs contain a range of specialties seen by the patient and perhaps disproportionately little about their mental health.

Topic 2 contains many infections, in both the social media and the EHR, which are consistent with the immunodeficiency-related topics discovered from EHR alone. Interestingly, asthma, an autoimmune disease, also appears in this topic; Becker (2007) posits that some ASDs, asthma, and inflammation may have a common autoimmune component. Doshi-Velez et al. (2013) also found a subgroup enriched for asthma. Obesity, associated with asthma (Beuther et al., 2006), also appears in this topic; here it seems that combining the sources resulted in a much clearer infections and autoimmune topic rather than the more diluted multi-system EHR topic 4.

Finally, topic 3 mirrors the cerebral palsy topic from the EHRs and topic 4 mirrors the Down’s syndrome topic. In the cerebral palsy topic (topic 3), we see more differences in the topics early on. Caregivers mention temper tantrums, speech delays, and abstract thought disorder—all features consistent with ASD and cerebral palsy—early on but the term cerebral palsy does not make the top-4 list. Later the terms are more similar across the two sources. Similarly, the caregiver version of the top-4 list for the ASD and Down’s syndrome topic (topic 4) includes more terms like expressive language disorder and symbolic dysfunction early on as well as stereotypic movements.

6. Related Work

Disease Progression Models Disease progression modeling is an important area in medical informatics. When biomarkers of interest are known, or disease stages have been labeled, supervised approaches can be used to predict disease stages given signs and symptoms; such supervised approaches have been applied to modeling the progression of Alzheimer’s disease (Zhou et al., 2012a). Other approaches use physiological models (De Winter et al., 2006) or meta-analyses of existing literature (Ito et al., 2010) to derive disease progression models.

One of the most popular data-driven approaches to learning disease progression models is to fit a hidden Markov Model (HMM) to the observations. The states of the HMM correspond to different stages of chronic diseases, and often left-to-right HMMs are used to model the fact that many disease progression processes are not reversible. Such models have been used to model disease progression in chronic kidney disease (Luo et al., 2013; Yang et al., 2014), Alzheimer’s disease (Sukkar et al., 2012), aneurysm screening (Jackson et al., 2003), and flu (Fan et al., 2015). Yang et al. (2014) allow the patient to have multiple conditions at the same time, treating each patient as having a mixture of disease pathways. Luo et al. (2013) take into account irregular sampling of data.

Table 3: Top words from Dynamic Topic Model trained on both SM and EHR data.

	Year 0	Year 2	Year 4	Year 10	Year 15
EHR Topic 0	Acute upper respiratory infection, Hearing Loss, gastroenteritis, Hirschsprung’s disease	Expressive Language Disorder, Developmental delay, Hearing Loss, Mixed development disorder	Expressive Language Disorder, Developmental delay, Epilepsy, Localization-related epilepsy	Epilepsy, Hearing Loss, Conduct Disorder, ADHD	Generalized intractable convulsive epilepsy, Conduct Disorder, Generalized intractable convulsive epilepsy, Epilepsy

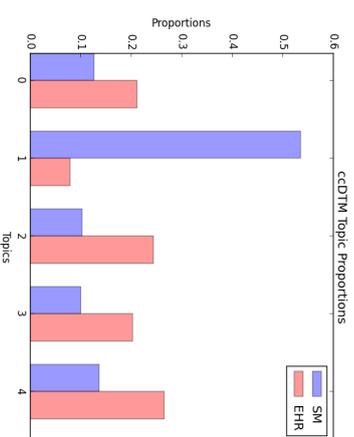

Figure 7: Overall topic popularities in both electronic health record and social media documents. Except for topic 1, most of the topics are present in similar proportions.

Others model disease progression with continuous time processes. Liu et al. (2013) model the progression of glaucoma with continuous-time HMMs, while Wang et al. (2014) use continuous-time Markov jump processes to model the progression of chronic obstructive pulmonary disease. Saeedi and Bouchard-Côté (2011) introduce gamma-exponential processes to model recurrent disease processes multiple sclerosis. These models can be adapted to incorporate individual-specific progression rates and treatment effects (Post et al., 2005).

Whether discrete or continuous time, all of these approaches involve discrete disease stages. However, often diseases evolve slowly over time. While we use a discrete time model in our work, a fundamental difference in our approach from those above is that we do not attempt to divide disease progression into stages, which might be artificial distinctions. Especially in developmental disorders, a more continuous progression model is more natural as a child’s development is a continuously evolving process. In this sense, perhaps closest in spirit to our work is the work of Zhou et al. (2014), which models disease progression with a matrix factorization that is smooth in the time dimension. Che et al. (2015) embed each time point of a patient into a latent space using a deep network.

In addition to being a natural way to model smoothly evolving diseases, our smoothness assumption allows us to easily incorporate cross-sectional data as well as longitudinal data. Requiring multiple visits to derive trajectories is often one of the factors that greatly limits the amount of data that can be used from a cohort: Doshi-Velez et al. (2013) used EHRs from the same hospital as us but were limited to only 4,927 patients with many visits rather than the 13,435 patients we study here (unlike Doshi-Velez et al. (2013) and other clustering-based studies, we do also not rely on ad-hoc patient similarity functions and intensive data pre-processing). Other studies that use smoothness assumptions in similar ways are Ross et al. (2014) and Li et al. (2012). Li et al. (2012) derive trajectories and then define an HMM from cross-sectional data through temporal bootstrap method that connects patients with similar features; their approach has no underlying model but rather

relies on patient similarities to build trajectories. Ross et al. (2014) derive lung capacity trajectories in chronic obstructive pulmonary disease from a cross-sectional cohort using Gaussian processes to encourage smoothness.

Dynamic Topic Models and Dynamical Systems Several techniques exist to model the temporal evolution of topics. Wang and McCallum (2006) consider the case in which the popularity of a topic changes over time, but each topic’s word proportions remain stationary. In contrast, dynamic topic models (Blei and Lafferty, 2006b; Wang et al., 2012) assume a topic’s word proportions smoothly evolve over time. Dynamic topic models have been applied to applications including discovering themes in research communities, (Furukawa et al., 2015), evolving patterns in software programs (Thomas et al., 2014), and the adoption of applications by smart phone users (Chua et al., 2015).

Topic models have also been developed for modeling multiple corpora. Wang et al. (2009) model correlations between the natural parameters for multiple corpora as a Gaussian random field. Paul (2009); Paul and Girju (2009); Zhai et al. (2004) model correlations between multiple corpora through a mixture of base and corpora-specific topics. Zhang et al. (2010) model the changing popularities of topics across three corpora—blogs, news, and message boards—using evolutionary hierarchical Dirichlet processes.

There also exists a related literature on modeling text as dynamical systems. Mikolov (2012) model dependencies in text as a recurrent neural network. Belanger and Kakade (2015) model text as a Gaussian linear dynamical system. Their model is misspecified in that it attributes zero probability mass to any observation, but they note the computational convenience of modeling occurrences of words with Gaussian variables rather than multinomials. While we are not modeling sequences of words, the idea modeling trends as linear dynamical system is close in spirit to our work.

In this context, we emphasize that the models we described in Section 3 are not novel—dynamic topic models and cross-corpora topic models both have well-established literatures. However, each topic model variant above relies on its own bespoke, implementation-intensive inference techniques that are often specific to that model. By using Pólya-gamma augmentation in our inference, we are able easily explore a variety of models. Moreover, to our knowledge, the application of dynamical system models of text to characterize disease progression is novel.

Disease Models from Social Media There exists a large body of work analyzing social media for information related to diseases. Chee et al. (2011) use personal health messages to predict adverse drug events, while Wilson and Brownstein (2009); Paul et al. (2015) use social media for disease surveillance. Elhadad et al. (2014); Jha and Elhadad (2010) characterize the linguistic properties of online forum text and use it to predict the cancer stage of the patient. Coppersmith et al. (2015) describe the task of identifying patients with depression and post-traumatic stress disorder from their Twitter posts. Unlike these works, our objective is understanding disease phenotypes and disease progression from social media, not prevalence or diagnosis.

7. Discussion and Conclusions

Modeling Choices Using dynamic topic models for modeling disease progression offers several advantages over more traditional clustering and HMM-based approaches. We do not require patients to belong to a single cluster or health state; they may have multiple disease processes varying in intensity over time, and each disease process is a smoothly varying, rather than discrete, structure. Because we can combine longitudinal and cross-sectional data, we can take advantage of much larger cohorts. Unlike clustering approaches, no ad-hoc patient similarity metrics are required, and unlike HMM-based approaches, we do not need to perform inference about what may have happened to patients in the gaps between visits.

Using Pólya-gamma augmentation allowed us to explore a variety of model choices without significantly changing our inference procedure: the static LDA, the DTM, and the ccDTM all used the same underlying Gibbs samplers and forward-backward code for Gaussian distributions. It would be interesting to investigate other alternatives, such as correlating intra-document topic proportions with a Pólya-gamma version of the correlated topic model (Blei and Lafferty, 2006a; Linderman et al., 2015) and correlating inter-document topic proportions from the same patient with an author topic model (Rosen-Zvi et al., 2004).

Another interesting direction for exploration is how the same topic appears in different corpora. In our work, we used the simplest approach in which topics for each corpus were isotropically perturbed versions of the latent disease process topic. This approach had the advantage of being able to easily interpret the latent topics probabilities $\mathbf{u}_{t,k}$. However, another option might be to learn a static emission matrix \mathbf{C}_l for each corpus l :

$$\begin{aligned}\beta_{l,k,l} &\equiv \pi_{SB}(\psi_{l,k,l}) \\ \psi_{l,k,l} &\equiv \mathbf{C}_l \mathbf{u}_{t,k} \\ \mathbf{u}_{t,k} &\sim \mathcal{N}(\mathbf{u}_{t,k} \mid \mathbf{A}, \mathbf{u}_{t-1,k}, \mathbf{B}\mathbf{B}^\top)\end{aligned}$$

Such an approach could allow the statistics of the pathological process $\mathbf{u}_{t,k}$ to have much lower dimensionality than the corpus-specific topic-word parameters ψ if \mathbf{C} were rectangular. It could also model systematic differences between document collections. For example, it would be exciting to incorporate general terms from social media that are not diseases or syndromes. However, the statistics $\mathbf{u}_{t,k}$ would be much harder to interpret; we chose our simpler model because $\mathbf{u}_{t,k}$ can readily be interpreted as the key terms of the disease process k . To create interpretable reduced-rank models, one approach might be to require that the emission matrix \mathbf{C}_l respect some clinician-interpretable ontology, as was done for static topic models in Doshi-Velez et al. (2015).

While Pólya-gamma augmentation allows for the exploration of many exciting models, there are some aspects of the inference that must be treated with care. Our application had a much higher dimensionality than the work of Linderman et al. (2015), and numerical errors accumulated during the recursive stick-breaking construction. Ordering the vocabulary by the prevalence of terms had a large impact on inference performance; deeply understanding the limitations of this augmentation approach on high-dimensionality data sets remains an interesting and open question. Our sampler was also fully uncollapsed; it would be interesting to see whether parameters in the cross-corpora models can be collapsed for

faster-mixing inference. As an alternative inference strategy, black-box variational inference (BBVI) (Ranganath et al., 2014) may offer convenient ways to work with such non-conjugate models.

Clinical Relevance: Autism Spectrum Disorders Clinical manifestations of autism spectrum disorders (ASD) beyond the core DSM criteria have been gaining increasing attention in recent years (Ming et al., 2008; Bauman, 2010; Coury, 2010; Smith, 1981; Kohane et al., 2012). Prior work in clustering phenotypes in ASD has largely relied on surveys and diagnostic tests. Miles et al. (2005) divide ASD into two clusters, “essential” and “complex” based on the manifestation of significant dysmorphology or microcephaly. They find that patients with “complex” ASDs have poorer outcomes, including lower IQ and more seizures. Wiggins et al. (2012) find clusters along disease severity, while Lane et al. (2010) discover sensory processing subtypes. Other studies find clusters along cognitive, language, and behavioral criteria (Wing and Gould, 1979; Ben-Sasson et al., 2008; Bitsika et al., 2008; Hu and Steinberg, 2009). Sacco et al. (2012) find patterns among both neurodevelopmental factors as well as immune and circadian dysfunction.

The phenotypes we find are consistent with these studies as well as the neurological, multi-system, and psychiatric disorder clusters characterized by Doshi-Velez et al. (2013). In addition, we find trajectories for patients with ASD and Down’s syndrome and ASD and cerebral palsy, two common comorbidities. Meanwhile, the topics associated with the social media—containing terms such as tantrums and bullying—provide a more complete window in the lives of these children. The fact that mental health terms dominate the social media topics is an indication of important stressors for these children and caregivers.

While it is reassuring that the topics associated with the clinical data are consistent with prior work, this study still has important limitations. Diagnostic codes are extremely noisy measures of disease state, and information extraction from social media is also a challenging process. In particular, our extraction is agnostic to whether a term applies to a current or past condition, to the child or to the caregiver. Our coarse processing was sufficient to discover credible trends, but better extraction methods will be required to validate the patterns we have discussed. Furthermore, while we have shown that our dynamic topic modeling approaches do better at predicting a patient’s future diagnoses than static models, there is still an important gap between improved predictions and clinically-useful predictions. Filling this gap will require using additional features in the models and rigorous data validation (e.g. through chart review).

Other Phenotyping Applications While we have focused on developmental disorders, the approaches described here could be relevant to discover the disease trajectories in other conditions. Indeed, almost all disease processes are likely best modeled as continuously evolving rather than having discrete stages. However, applying our approach to complex, chronic diseases such as chronic obstructive pulmonary disease, chronic kidney disease, or diabetes will have several challenges. First, unlike developmental disorders, which start at birth, one must now infer the age of onset from observational sources. Second, while disease processes are continuous, patients often visit when their situation has changed, leading clinicians to observe discrete changes. We hypothesize that a cross-corpora approach, using patient or caregiver-generated text or even outputs of patient-worn sensors (such as glucose monitors), could help discover these continuously evolving processes between sporadic

patient visits. Finally, many of these adult chronic diseases may have periods of remission between periods of high disease activity; these will also need to be modeled.

Conclusions In this work, we presented a dynamic topic modeling approach to modeling disease evolution. Our application of Poly-r-gamma augmentation to these models created a simple, unified framework for inference in dynamic topic models and cross-collection topic models. Applied to large collection of EHR and online forum posts describing patients with ASD, our models discovered disease trajectories that make sense in the context of the existing autism literature, and our cross-collection dynamic topic model had both high overall predictive performance and high predictive performance on predicting future patient trajectories. We are excited by the opportunity created by our approach to discover cross-corpora patterns of disease evolution in ASD as well as other diseases.

Acknowledgments

We are grateful to John Bickel and the Boston Children’s Hospital i2b2 team for providing the electronic health record data. Joy Ming, Sam Wiseman, and Andy Miller’s work on understanding autism forum data was directly valuable for in our pre-processing pipeline. We would also like to acknowledge support for this project from the National Science Foundation (NSF grant ACl-1544628).

A.1 Example Forum Post

Below is an example of a post. The age and CUIs that we extracted from the post are listed below.

hi my son is 13 nearly 14 and has this year become increasingly anxious and withdrawn in july his psychiatrist said to put him on prozac saying it might take the edge off his anxieties and allow him some positive experiences thus helping to lift the depression he seemed to be in i was not all that keen to be honest but my son who had been reluctant to take his other meds said he wanted to try it so we did he started on a small liquid dose and is now on tab a day will check exact dose if you want to know it despite my reservations his mood has really lifted he is still really challenging aggressive one track mind struggles to leave the house though maybe not so much but

to be honest he is back to where he was before the dip in terms of talking to me etc i am probably not explaining very well in feb half term adn easter hols the only interaction at all was to be negative call us names adn swear at us now he still does that but he also chats and has a laugh again which had stopped i have not seen any side effects and he says he likes taking it cos he feels better he cant explain anymore than that i discussed it with autism outreach recently and she said it is being used effectively in a lot of kids with asd and anxieties to take the edge off the anxieties dont get me wrong it hasn t solved all our issues at all but he just doesnt seem so saddont know if this is of any help at all so hard to put into words lol ps if you google most meds for kids ritalin prozac respiridone etc you get a lot of negatives adn not many positives and not a lot of balanced comment

age: 13

A.2 Forum Data Pre-Processing and Age Extraction

We used BeautifulSoup to obtain and parse all subforums of the websites www.asd-forum.org.uk, www.autismweb.com, and www.asdfriendly.org on June 29, 2015. We extracted the text, the user-id, and the time and date of posting for 21,206 threads from [asd-forum](http://asd-forum.com), 26,807 threads from [asd-friendly](http://asd-friendly.com), and 32,914 threads from [autismweb](http://autismweb.com), for a total of 80,927 threads. These threads contained a total of 664,954 posts. Figure 8 shows the regular expressions used to extract ages from the posts. Next, the outputs were filtered through a trie for a list of error terms such as *sec*, *wks*, *ft*, and *m* that might indicate another unit of measure; posts with such terms after the identified age were excluded. Finally, only posts with only one age were included, to avoid conflating information from multiple ages or multiple people.

Appendix B. MCMC Convergence

Figure 9 show the log-likelihoods for a characteristic run. Based on plots such as these, we determined that 100 iterations seemed to be more than enough for the sampler to find an optima.

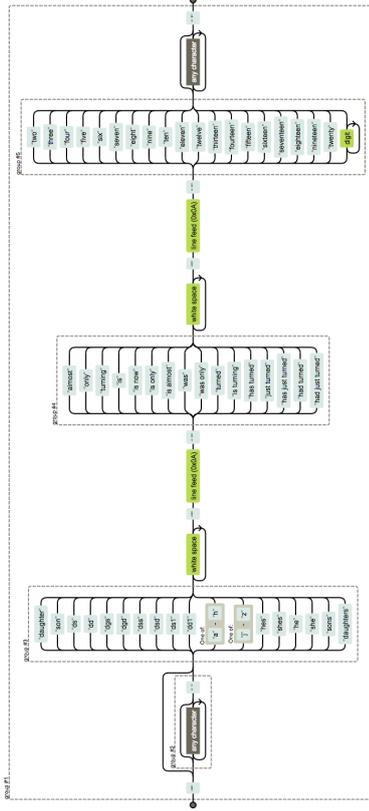

Figure 8: Chart showing the of regular expressions used to extract potential ages from posts. Outputs passing this filter were filtered through a second stage of processing to identify and remove cases where the number corresponded to a unit other than age in years.

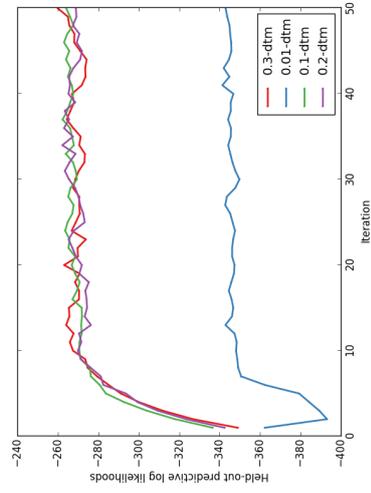

Figure 9: Log-likelihoods for a characteristic run.

Adjusting for Chance Clustering Comparison Measures

Abstract

Adjusted for chance measures are widely used to compare partitions/clustering of the same data set. In particular, the Adjusted Rand Index (ARI) based on pair-counting, and the Adjusted Mutual Information (AMI) based on Shannon information theory are very popular in the clustering community. Nonetheless it is an open problem as to what are the best application scenarios for each measure and guidelines in the literature for their usage are sparse, with the result that users often resort to using both. Generalized Information Theoretic (IT) measures based on the Tsallis entropy have been shown to link pair-counting and Shannon IT measures. In this paper, we aim to bridge the gap between adjustment of measures based on pair-counting and measures based on information theory. We solve the key technical challenge of analytically computing the expected value and variance of generalized IT measures. This allows us to propose adjustments of generalized IT measures, which reduce to well known adjusted clustering comparison measures as special cases. Using the theory of generalized IT measures, we are able to propose the following guidelines for using ARI and AMI as external validation indices: ARI should be used when the reference clustering has large equal sized clusters; AMI should be used when the reference clustering is unbalanced and there exist small clusters.

Keywords: Clustering Comparison, Clustering Validation, Adjustment for Chance, Generalized Information Theoretic Measures, Pair-Counting Measures

1. Introduction

Clustering comparison measures are used to compare partitions/clustering of the same data set. In the clustering community (Aggarwal and Reddy, 2013), they are extensively used for external validation when the ground truth clustering is available. A family of popular clustering comparison measures are measures based on pair-counting (Albatineh et al., 2006). This category comprises the well known similarity measures Rand Index (RI) (Rand, 1971) and the Jaccard coefficient (J) (Ben-Hur et al., 2001). Recently, information theoretic (IT) measures have been also extensively used to compare partitions (Strehl and Ghosh, 2003; Vinh et al., 2010). Given the variety of different possible measures, it is very challenging to identify the best choice for a particular application scenario (Wu et al., 2009).

The picture becomes even more complex if adjusted for chance measures are also considered. Adjusted for chance measures are widely used external clustering validation techniques

because they improve the interpretability of the results. Indeed, two important properties hold true for adjusted measures: they have constant baseline equal to 0 value when the partitions are random and independent, and they are equal to 1 when the compared partitions are identical. Notable examples are the Adjusted Rand Index (ARI) (Hubert and Arabie, 1985) and the Adjusted Mutual Information (AMI) (Vinh et al., 2009). It is common to see published research that validates clustering solutions against a reference ground truth clustering with the ARI or the AMI. Nonetheless there are still open problems: *there are no guidelines for their best application scenarios shown in the literature to date and authors often resort to employing them both and leaving the reader to interpret.*

Moreover, some clustering comparisons measures are susceptible to selection bias: when selecting the most similar partition to a given ground truth partition, clustering comparison measures are more likely to select partitions with many clusters (Romano et al., 2014). In Romano et al. (2014) it was shown that it is beneficial to perform statistical standardization to IT measures to correct for this bias. In particular, standardized IT measures help in decreasing this bias when the number of objects in the data set is small. Statistical standardization has not been applied to pair-counting measures yet in the literature. We solve this challenge in the current paper, and provide further results about the utility of measure adjustment by standardization.

In this work, we aim to *bridge the gap between the adjustment of pair-counting measures and the adjustment of IT measures.* In Furuichi (2006) and Simovici (2007) it has been shown that generalized IT measures based on the Tsallis q -entropy (Tsallis et al., 2009) are a further generalization of IT measures and some pair-counting measures such as RI. In this paper, we will exploit this useful idea to connect ARI and AMI. Furthermore using the same idea, we can perform statistical adjustment by standardization to a broader class of measures, including pair-counting measures.

A key technical challenge is to analytically compute the expected value and variance for generalized IT measures when the clusterings are random. To solve this problem, we propose a technique applicable to a broader class of measures we name \mathcal{L}_ϕ , which includes generalized IT measures as a special case. This generalizes previous work which provided analytical adjustments for narrower classes: measures based on pair-counting from the family \mathcal{L} (Albatineh et al., 2006), and measures based on the Shannon mutual information (Vinh et al., 2009, 2010). Moreover, we define a family of measures \mathcal{N}_ϕ which generalizes many clustering comparison measures. For measures which belong in this family, the expected value can be analytically approximated when the number of objects is large. Figure 1 depicts the families of measures discussed in this paper. Table 1 summarizes the development of this line of work over the past 30 years and positions our contribution. In summary, we make the following contributions:

- We define families of measures for which the expected value and variance can be computed analytically when the clusterings are random;
- We propose generalized adjusted measures to correct for the baseline property and for selection bias. This captures existing well known measures as special cases;
- We provide insights into the open problem of identifying the best application scenarios for clustering comparison measures, in particular the application scenarios for ARI and AMI.

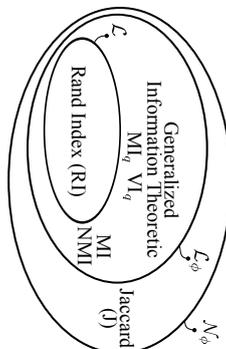

Figure 1: Families of clustering comparison measures discussed in this paper. We show how to analytically adjust measures in \mathcal{L}_ϕ and how to obtain approximations for the family \mathcal{N}_ϕ .

Table 1: Work on adjusting clustering comparison measures carried out over the past 30 years. Information theoretic measures have been only recently adjusted for chance. In this paper, we bridge the gap between adjustment of pair-counting measures and information theoretic measures.

2. Comparing Partitions

Given two partitions (clusterings) U and V of the same data set of N objects, let $\{u_1, \dots, u_r\}$ and $\{v_1, \dots, v_c\}$ be the disjoint sets (clusters) for U and V respectively. Let $|u_i| = a_i$ for $i = 1, \dots, r$ denote the number of objects in the set u_i and $|v_j| = b_j$ for $j = 1, \dots, c$ denote the number of objects in v_j . Naturally, $\sum_{i=1}^r a_i = \sum_{j=1}^c b_j = N$. The overlap between the two partitions U and V can be represented in matrix form by a $r \times c$ contingency table \mathcal{M} where n_{ij} represents the number of objects in both u_i and v_j , i.e. $n_{ij} = |u_i \cap v_j|$. Also, we refer to $a_i = \sum_{j=1}^c n_{ij}$ as the row marginals and to $b_j = \sum_{i=1}^r n_{ij}$ as the column marginals. A contingency table \mathcal{M} is shown in Table 2.

Pair-counting measures between partitions, such as the Rand Index (RI) (Rand, 1971), might be defined using the following quantities: k_{11} , the pairs of objects in the same set in both U and V ; k_{00} the pairs of objects not in the same set in U and not in the same set in V ; k_{10} , the pairs of objects in the same set in U and not in the same set in V ; and k_{01} the pairs of objects not in the same set in U and in the same set in V . All these quantities can

		V				
		b_1	\dots	b_j	\dots	b_c
U	a_1	n_{11}	\dots	\cdot	\dots	n_{1c}
	\vdots	\vdots	\vdots	\vdots	\vdots	\vdots
	a_i	\cdot	\dots	n_{ij}	\cdot	\cdot
	\vdots	\vdots	\vdots	\vdots	\vdots	\vdots
a_r	n_{r1}	\dots	\cdot	\dots	n_{rc}	

Table 2: $r \times c$ contingency table \mathcal{M} related to two clusterings U and V . $a_i = \sum_j n_{ij}$ are the row marginals and $b_j = \sum_i n_{ij}$ are the column marginals.

be computed using the contingency table \mathcal{M} , for example:

$$k_{11} = \frac{1}{2} \sum_{i=1}^r \sum_{j=1}^c n_{ij}(n_{ij} - 1), \quad k_{00} = \frac{1}{2} \left(N^2 + \sum_{i=1}^r \sum_{j=1}^c n_{ij}^2 - \left(\sum_{i=1}^r a_i^2 + \sum_{j=1}^c b_j^2 \right) \right) \quad (1)$$

Using k_{00} , k_{11} , k_{10} , and k_{01} it is possible to compute similarity measures, e.g. RI, or distance measures, e.g. the Mirkin index $\text{MK}(U, V) \triangleq \sum_i a_i^2 + \sum_j b_j^2 - 2 \sum_{i,j} n_{ij}^2$, between partitions (Meiliš, 2007):

$$\text{RI}(U, V) \triangleq (k_{11} + k_{00}) / \binom{N}{2}, \quad \text{MK}(U, V) = 2(k_{10} + k_{01}) = N(N-1)(1 - \text{RI}(U, V)) \quad (2)$$

Information theoretic measures are instead defined for random variables but can also be used to compare partitions when we employ the empirical probability distributions associated to U , V , and the joint partition (U, V) . Let $\frac{a_i}{N}$, $\frac{b_j}{N}$, and $\frac{n_{ij}}{N}$ be the probability that an object falls in the set u_i , v_j , and $u_i \cap v_j$ respectively. We can therefore define the Shannon entropy with natural logarithms for a partition V as follows: $H(V) \triangleq -\sum_j \frac{b_j}{N} \ln \frac{b_j}{N}$. Similarly, we can define the entropy $H(U)$ for the partition U , the joint entropy $H(U, V)$ for the joint partition (U, V) , and the conditional entropies $H(U|V)$ and $H(V|U)$. Shannon entropy can be used to define the well known Mutual Information (MI) and employ it to compute similarity between partitions U and V :

$$\text{MI}(U, V) \triangleq H(U) - H(U|V) = H(V) - H(V|U) = H(U) + H(V) - H(U, V) \quad (3)$$

On contingency tables, MI is linearly related to G -statistics used for likelihood-ratio tests: $G = 2N\text{MI}$. In Meiliš (2007), using the Shannon entropy it was shown that the following distance, namely the Variation of Information (VI) is a metric:

$$\text{VI}(U, V) \triangleq 2H(U, V) - H(U) - H(V) = H(U|V) + H(V|U) = H(U) + H(V) - 2\text{MI}(U, V) \quad (4)$$

Information theoretic measures are extensively used to compare crisp partitions (Strehl and Ghosh, 2003; Vinh et al., 2010). Very recently they have also been used to compare fuzzy partitions (Lei et al., 2014a, 2016).

2.1 Generalized Information Theoretic Measures

Generalized Information Theoretic (IT) measures based on the generalized Tsallis q -entropy (Tsallis, 1988) can be defined for random variables (Furuchi, 2006) and also be applied to the task of comparing partitions (Simovici, 2007). Indeed, these measures have also seen recent application in the machine learning community. More specifically, it has been shown that they can act as proper kernels (Martins et al., 2009). Furthermore, empirical studies demonstrated that careful choice of q yields successful results when comparing the similarity between documents (Vila et al., 2011), decision tree induction (Maszczyk and Duch, 2008; Wang et al., 2015), and reverse engineering of biological networks (Lopes et al., 2011). It is important to note that the Tsallis q -entropy is equivalent to the Havrda-Charvat-Daroczy generalized entropy proposed in Havrda and Charvat (1967); Daroczy (1970). Results available in literature about these generalized entropies are equivalently valid for all the proposed versions.

Given $q \in \mathbb{R}^+ - \{1\}$, the generalized Tsallis q -entropy for a partition V is defined as follows: $H_q(V) \triangleq \frac{1}{q-1} \left(1 - \sum_j \left(\frac{a_j}{N}\right)^q\right)$. Similarly to the case of Shannon entropy, we have the joint q -entropy $H_q(U, V)$ and the conditional q -entropies $H_q(U|V)$ and $H_q(V|U)$. Conditional q -entropy is computed according to a weighted average parametrized on q . More specifically the formula for $H_q(V|U)$ is:

$$H_q(V|U) \triangleq \sum_{i=1}^r \left(\frac{a_i}{N}\right)^q H_q(V|u_i) = \sum_{i=1}^r \left(\frac{a_i}{N}\right)^q \frac{1}{q-1} \left(1 - \sum_{j=1}^c \left(\frac{n_{ij}}{a_i}\right)^q\right) \quad (5)$$

The q -entropy reduces to the Shannon entropy computed in nats for $q \rightarrow 1$.

In Furuchi (2006), using the fact that $q > 1$ implies $H_q(U) \geq H_q(U|V)$, it is shown that non-negative MI can be naturally generalized with q -entropy when $q > 1$:

$$\text{MI}_q(U, V) \triangleq H_q(U) - H_q(U|V) = H_q(V) - H_q(V|U) = H_q(U) + H_q(V) - H_q(U, V) \quad (6)$$

However, q values smaller than 1 are allowed if the assumption that $\text{MI}_q(U, V)$ is always positive can be dropped. In addition, generalized IT measures can be used to define the generalized Variation of Information distance (VI_q) which tends to VI in Eq. (4) when $q \rightarrow 1$:

$$\text{VI}_q(U, V) \triangleq H_q(U|V) + H_q(V|U) = 2H_q(U, V) - H_q(U) - H_q(V) = H_q(U) + H_q(V) - 2\text{MI}_q(U, V) \quad (7)$$

In Simovici (2007) it was shown that VI_q is a proper metric and interesting links were identified between measures for comparing partitions U and V . We state these links in Proposition 1 given that they set the fundamental motivation of our paper:

Proposition 1 (Simovici, 2007) *When $q = 2$ the generalized variation of information, the Minkin index, and the Rand index are linearly related: $\text{VI}_2(U, V) = \frac{1}{N^2} \text{MK}(U, V) = \frac{N-1}{N} (1 - \text{RI}(U, V))$.*

Generalized IT measures are not only a generalization of IT measures in the Shannon sense but also a generalization of pair-counting measures for particular values of q . Note that in literature there exist another well know generalization of entropy: the Renyi entropy (Renyi,

1961). This entropy is again parametrized on a real number q and is defined as follows: $R_q(V) \triangleq \frac{1}{1-q} \ln \left(\sum_j \left(\frac{b_j}{N}\right)^q\right)$. Because of the use of the logarithm for any value of q , the Renyi entropy does enable the generalization of pair-counting measures when $q = 2$. Therefore, in this paper we make use of generalized IT measures based on the Tsallis entropy.

2.2 Normalized Generalized IT Measures

To allow a more interpretable range of variation, a clustering similarity measure should be normalized: it should achieve its maximum at 1 when $U = V$. An upper bound to the generalized mutual information MI_q is used to obtain a normalized measure. MI_q can take different possible upper bounds (Furuchi, 2006). Here, we choose to derive another possible upper bound using Eq. (7) when we use the minimum value of $\text{VI}_q = 0$: $\max \text{MI}_q = \frac{1}{2}(H_q(U) + H_q(V))$. This upper bound is valid for any $q \in \mathbb{R}^+ - \{1\}$ and allows us to link different existing measures as we will show in the next sections of the paper. The Normalized Mutual Information with q -entropy (NMI_q) is defined as follows:

$$\text{NMI}_q(U, V) \triangleq \frac{\text{MI}_q(U, V)}{\max \text{MI}_q(U, V)} = \frac{\text{MI}_q(U, V)}{\frac{1}{2}(H_q(U) + H_q(V))} = \frac{H_q(U) + H_q(V) - H_q(U, V)}{\frac{1}{2}(H_q(U) + H_q(V))} \quad (8)$$

Even if $\text{NMI}_q(U, V)$ achieves its maximum 1 when the partitions U and V are identical, $\text{NMI}_q(U, V)$ is not a suitable clustering comparison measure. Indeed, it does not show constant baseline value equal to 0 when partitions are random. We explore this through an experiment. Given a dataset of $N = 100$ objects, we randomly generate uniform partitions U with $r = 2, 4, 6, 8, 10$ sets and V with $c = 6$ sets *independently* of each others. The average value of NMI_q over 1,000 simulations for different values of q is shown in Figure 2. It is reasonable to expect that when the partitions are independent, the average value of NMI_q is constant irrespectively of the number of sets r of the partition U . This is not the case. This behavior is unintuitive and misleading when comparing partitions. Computing the

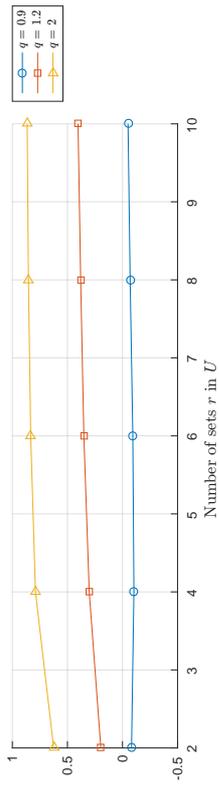

Figure 2: The baseline value of $\text{NMI}_q(U, V)$ between independent random partitions U and V . Despite the partitions are random, the baseline of NMI_q is not constant and depends on the number of sets of the partitions.

analytical expected value of generalized IT measures under the null hypothesis of random and independent U and V is important; it can be subtracted from the measure itself to adjust its baseline for chance such that the result is 0 when U and V are random. Given

Proposition 1, this strategy also allows us to generalize adjusted for chance pair-counting and Shannon IT measures.

3. Baseline Adjustment

In order to adjust the baseline of a similarity measure $S(U, V)$, we have to compute its expected value under the null hypothesis of independent random partitions U and V . We adopt the assumption of randomness used to adjust RI (Hubert and Arabie, 1985) and the Shannon MI (Vinh et al., 2009). This is formalized as follows:

Definition 1 (Random partitions) *The partitions U and V are generated independently and at random fixing the number of objects N and the marginals a_i and b_j .*

This is also denoted as the permutation or the hypergeometric model of randomness. We are able to compute the exact expected value for a similarity measure in the family \mathcal{L}_ϕ :

Definition 2 *Let \mathcal{L}_ϕ be the family of similarity measures $S(U, V) = \alpha + \beta \sum_{ij} \phi_{ij}(r_{ij})$ where α and β do not depend on the entries r_{ij} of the contingency table \mathcal{M} and $\phi_{ij}(\cdot)$ are bounded real functions.*

Intuitively, \mathcal{L}_ϕ represents the class of measures that can be written as a linear combination of $\phi_{ij}(r_{ij})$. A measure between partitions uniquely determines α , β , and ϕ_{ij} . However, not every choice of α , β , and ϕ_{ij} yields a meaningful similarity measure. \mathcal{L}_ϕ is a superset of the set \mathcal{L} defined in Albatineh et al. (2006) as the family of measures $S(U, V) = \alpha + \beta \sum_{ij} r_{ij}^2$, i.e. $S \in \mathcal{L}$ are special cases of measures in \mathcal{L}_ϕ with $\phi_{ij}(\cdot) = (\cdot)^2$. Figure 1 shows a diagram of the similarity measures discussed in Section 2.1 and their relationships.

Lemma 1 *If $S(U, V) \in \mathcal{L}_\phi$, when partitions U and V are random:*

$$E[S(U, V)] = \alpha + \beta \sum_{ij} E[\phi_{ij}(r_{ij})] \quad \text{where} \quad E[\phi_{ij}(r_{ij})] \quad \text{is} \quad (9)$$

$$\sum_{n_{ij}=\max\{0, a_i+b_j-N\}}^{\min\{a_i, b_j\}} \phi_{ij}(r_{ij}) \frac{a_i! b_j! (N - a_i)! (N - b_j)!}{N! n_{ij}! (a_i - n_{ij})! (b_j - n_{ij})! (N - a_i - b_j + n_{ij})!} \quad (10)$$

Lemma 1 extends the results in Albatineh and Niewiadomska-Bęgał (2011) showing exact computation of the expected value of measures in the family \mathcal{L} . Given that generalized IT measures belong in \mathcal{L}_ϕ we can employ this result to adjust them.

3.1 Baseline Adjustment for Generalized IT measures

Using Lemma 1 it is possible to compute the exact expected value of $H_q(U, V)$, $VI_q(U, V)$ and $MI_q(U, V)$:

Theorem 1 *When the partitions U and V are random:*

- i) $E[H_q(U, V)] = \frac{1}{q-1} \left(1 - \frac{1}{N^q} \sum_{ij} E[n_{ij}^q] \right)$ with $E[n_{ij}^q]$ from Eq. (10) with $\phi_{ij}(r_{ij}) = r_{ij}^q$;
- ii) $E[MI_q(U, V)] = H_q(U) + H_q(V) - E[H_q(U, V)]$;

$$\text{ii) } E[VI_q(U, V)] = 2E[H_q(U, V)] - H_q(U) - H_q(V).$$

It is worth noting that this approach is valid for any $q \in \mathbb{R}^+ - \{1\}$. We can use these expected values to adjust for baseline generalized IT measures. We use the method proposed in Hubert and Arabie (1985) to adjust similarity measures, such as MI_q and distance measures, such as VI_q :

$$AMI_q \triangleq \frac{MI_q - E[MI_q]}{\max MI_q - E[MI_q]} \quad AVI_q \triangleq \frac{E[VI_q] - VI_q}{E[VI_q] - \min VI_q} \quad (11)$$

VI_q is a distance measure, thus $\min VI_q = 0$. For MI_q we use the upper bound $\max MI_q = \frac{1}{2}(H_q(U) + H_q(V))$ as for NMI_q in Eq. (8). An exhaustive list of adjusted versions of Shannon MI can be found in Vinh et al. (2010), when the upper bound $\frac{1}{2}(H_q(U) + H_q(V))$ is used the authors named the adjusted MI as AMI_{sum} .

It is important to note that this type of adjustment turns distance measures into similarity measures, i.e., AVI_q is a similarity measure. It is also possible to maintain both the distance properties and the baseline adjustment using $NVI_q \triangleq VI_q/E[VI_q]$ which can be seen as a normalization of VI_q with the stochastic upper bound $E[VI_q]$ (Vinh et al., 2009). It is also easy to see that $AVI_q = 1 - NVI_q$. The adjustments in Eq. (11) also enable the measures to be normalized. AMI_q and AVI_q achieve their maximum at 1 when $U = V$ and their minimum is 0 when U and V are random partitions.

According to the chosen upper bound for MI_q , we obtain the nice analytical form shown in Theorem 2. Our adjusted measures quantify the discrepancy between the values of the actual contingency table and their expected value in relation to the maximum discrepancy possible, i.e. the denominator in Eq. (12). It is also easy to see that all measures in \mathcal{L}_ϕ resemble this form when adjusted.

Theorem 2 *Using $E[n_{ij}^q]$ in Eq. (10) with $\phi_{ij}(r_{ij}) = r_{ij}^q$, the adjustments for chance for $MI_q(U, V)$ and $VI_q(U, V)$ are:*

$$AMI_q(U, V) = AVI_q(U, V) = \frac{\sum_{ij} n_{ij}^q - \sum_{ij} E[n_{ij}^q]}{\frac{1}{2} \left(\sum_i a_i^q + \sum_j b_j^q \right) - \sum_{ij} E[n_{ij}^q]} \quad (12)$$

From now on we only discuss AMI_q given that it is identical to AVI_q . There are notable special cases for our proposed adjusted generalized IT measures. In particular, the Adjusted Rand Index (ARI) (Hubert and Arabie, 1985) is equal to AMI_2 . ARI is a classic measure, heavily used for validation in social sciences and the most popular clustering validity index.

Corollary 1 *It holds true that:*

- i) $\lim_{q \rightarrow 1} AMI_q = \lim_{q \rightarrow 1} AVI_q = AMI = AVI$ with Shannon entropy;
- ii) $AMI_2 = AVI_2 = ARI$.

Therefore, using the permutation model we can perform baseline adjustment to generalized IT measures. Our generalized adjusted IT measures are a further generalization of particular well known adjusted measures such as AMI and ARI. It is worth noting, that ARI is equivalent to other known measures for comparing partitions (Albatineh et al., 2006).

Furthermore, there is also a strong connection between ARI and Cohen's κ statistics used to quantify inter-rater agreement (Warrens, 2008). As final remark, we point out that our baseline adjustments can also be seen as statistical corrections for generalized information theoretic measures. It is indeed well known that information theoretic measures are severely biased when plug-in estimators are used, and many have worked on correcting this bias for decades: there exist in literature frequentist approaches (Paininski, 2003) as well as Bayesian approaches (Archer et al., 2013; Cerqueti, 2014) to reduce bias. In this section, we discussed an adjustment to obtain exact bias correction in particular when U and V are independent.

Computational complexity: The computational complexity of AMI_q in Eq. (12) is dominated by the computation of the sum of the expected value of each cell.

Proposition 2 *The computational complexity of AMI_q is $O(N \cdot \max\{r, c\})$.*

If all the possible contingency tables \mathcal{M} obtained by permutations were generated, the computational complexity of the exact expected value would be $O(N!)$. However, this can be dramatically reduced using properties of the expected value.

3.2 Experiments on Measure Baseline

Here we show that our adjusted generalized IT measures have a baseline value of 0 when comparing random partitions U and V . In Figure 3 we show the behavior of AMI_q , ARI, and AMI on the same experiment proposed in Section 2.2. They are all close to 0 with negligible variation when the partitions are random and independent. Moreover, it is interesting to see the equivalence of AMI_2 and ARI. On the other hand, the equivalence of AMI_q and AMI with Shannon entropy is obtained only at the limit $q \rightarrow 1$.

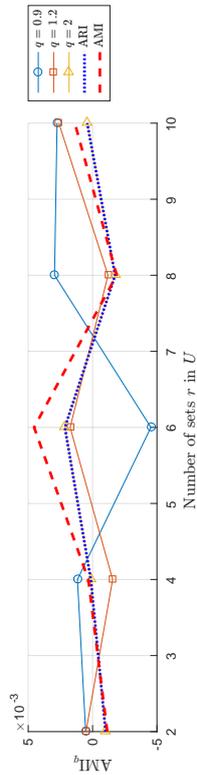

Figure 3: Baseline value of adjusted clustering comparison measures between two random partitions. When varying the number of sets for the random partition U , the value of $\text{AMI}_q(U, V)$ is always very close to 0 with negligible variation for any q .

We also point out that NMI_q does not show constant baseline when the relative size of the sets in U varies when U and V are random. In Figure 4, we generate random partitions V with $c = 6$ sets on $N = 100$ points, and random binary partitions U independently. $\text{NMI}_q(U, V)$ shows different behavior at the variation of the relative size of the biggest set

in U . This is unintuitive given that the partitions U and V are random and independent. We obtain the desired property of a baseline value of 0 with AMI_q .

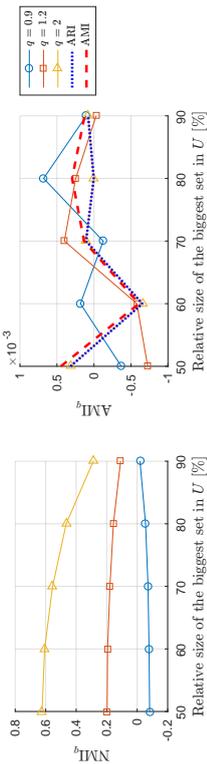

Figure 4: The left panel shows the baseline value of $\text{NMI}_q(U, V)$ between the random partitions U and V at the variation of the size of the sets in U . The right panel shows the baseline value of adjusted clustering comparison measures. When varying the relative size of one cluster for the random partition U , the value of $\text{AMI}_q(U, V)$ is always very close to 0 with negligible variation for any q .

3.3 Large Number of Objects

In this section, we introduce a very general family of measures which includes \mathcal{L}_ϕ . For measures belonging to this family, it is possible to find an approximation of their expected value when the number of objects N is large. This allows us to identify approximations for the expected value of measures in \mathcal{L}_ϕ as well as for measures not in \mathcal{L}_ϕ , such as the Jaccard coefficient as shown in Figure 1.

Let \mathcal{N}_ϕ be the family of measures which are *non-linear* combinations of $\phi_{ij}(n_{ij})$:

Definition 3 *Let \mathcal{N}_ϕ be the family of similarity measures $S(U, V) = \phi(\frac{a_i b_j}{N}, \dots, \frac{n_{ij}}{N}, \dots, \frac{b_i c_j}{N})$ where ϕ is a bounded real function as N reaches infinity.*

Note that \mathcal{N}_ϕ is a generalization of \mathcal{L}_ϕ . At the limit of large number of objects N , it is possible to compute the expected value of measures in \mathcal{N}_ϕ under random partitions U and V using only the marginals of the contingency table \mathcal{M} :

Lemma 2 *If $S(U, V) \in \mathcal{N}_\phi$, then $\lim_{N \rightarrow \infty} E[S(U, V)] = \phi(\frac{a_i b_j}{N}, \dots, \frac{a_i b_j}{N}, \dots, \frac{a_i b_j}{N})$.*

In Morey and Agresti (1984) the expected value of the RI was computed using an approximated value based on the multinomial distribution. It turns out this approximated value is equal to what we obtain for RI using Lemma 2. The authors of Albatineh et al. (2006) noticed that the difference between the approximation and the expected value obtained with the hypergeometric model is small on empirical experiments when N is large. We point out that this is a natural consequence of Lemma 2 given that $\text{RI} \in \mathcal{L}_\phi \subseteq \mathcal{N}_\phi$. Moreover, the multinomial distribution was also used to compute the expected value of the Jaccard coefficient (J) in Albatineh and Niewiadomska-Bugaj (2011), obtaining good results on empirical experiments with many objects. Again, this is a natural consequence of Lemma 2

given that $J \in \mathcal{N}_\phi$ but $J \notin \mathcal{L}_\phi$. Indeed, the Jaccard coefficient does not allow analytical adjustment using the hypergeometric model but it allows an approximation using Lemma 2.

Generalized IT measures belong in $\mathcal{L}_\phi \subseteq \mathcal{N}_\phi$. Therefore we can employ Lemma 2. When the number of objects is large, the expected value under random partitions U and V of $H_q(U, V)$, $MI_q(U, V)$, and $VI_q(U, V)$ in Theorem 1 depends only on the entropy of the partitions U and V , i.e., just the marginals of the contingency table must be taken into account:

Theorem 3 *It holds true that:*

- i) $\lim_{N \rightarrow +\infty} E[H_q(U, V)] = H_q(U) + H_q(V) - (q-1)H_q(U)H_q(V)$;
- ii) $\lim_{N \rightarrow +\infty} E[MI_q(U, V)] = (q-1)H_q(U)H_q(V)$;
- iii) $\lim_{N \rightarrow +\infty} E[VI_q(U, V)] = H_q(U) + H_q(V) - 2(q-1)H_q(U)H_q(V)$.

Result i) recalls the property of non-additivity that holds true for random variables (Furuidi, 2006). Figure 5 shows the behavior of $E[H_q(U, V)]$ when the partitions U and V are generated uniformly at random. V has $c = 6$ sets and U has r sets. In this case, $H_q(U) + H_q(V) - (q-1)H_q(U)H_q(V)$ appears to be a good approximation already for $N = 1000$. In particular, the approximation is good when the number of objects N is big with regards to the number of cells of the contingency table in Table 2: i.e., when $\frac{N}{rc}$ is large enough.

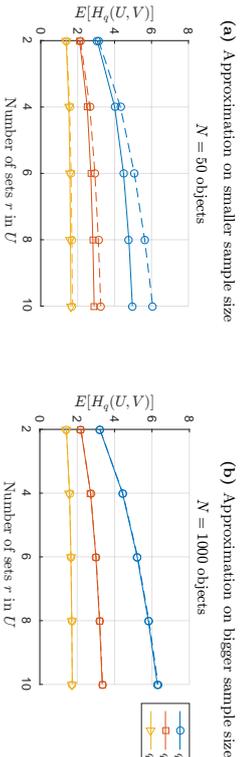

Figure 5: The left panel shows the average value of $E[H_q(U, V)]$ between random partitions U and V when they are induced on $N = 50$ objects. The right panel shows results for $N = 1000$ objects. $E[H_q(U, V)]$ are plotted using a solid line and their limit value $H_q(U) + H_q(V) - (q-1)H_q(U)H_q(V)$ is plotted using a dashed line. The solid line coincides approximately with the dashed one in (4b) when $N = 1000$. The limit value is a good approximation for $E[H_q(U, V)]$ when $\frac{N}{rc}$ is large enough.

From point ii) follows the result proved in Vinh et al. (2010) to connect the adjusted mutual information to the widely used Normalized Mutual Information (NMI) based on Shannon entropy (Strehl and Ghosh, 2003):

Theorem 4 (Vinh et al., 2010) *It holds true that:*

$$\lim_{N \rightarrow +\infty} \text{AMI}(U, V) = \text{NMI}(U, V)$$

NMI is easier to compute than AMI and it is less prone to computer precision errors. The analysis provided in this section aims at broadening the possible clustering comparison measures that can be adjusted: as long as a measure belongs in \mathcal{N}_ϕ , its expected value at large N can be computed and thus it can be adjusted. Moreover, we saw that adjusted measures in $\mathcal{L}_\phi \subseteq \mathcal{N}_\phi$ have simpler formulas at large N . The adjustments at large N are faster to compute and less prone to computer precision errors.

In the next section we put forward a theoretical analysis on the best choice between AMI and ARI when validating clustering solutions. Moreover being NMI equal to AMI at large N , the next section helps also to understand when to use either NMI or ARI.

4. Application Scenarios for AMI_q

In this section we aim to answer to the question: *Given a reference ground truth clustering V , which is the best choice for q in $\text{AMI}_q(U, V)$ to validate the clustering solution U ?* By answering this question, we implicitly identify the application scenarios for ARI and AMI given the results in Corollary 1. This is particularly important for external clustering validation. Nonetheless, there are a number of other applications where the task is to find the most similar partition to a reference ground truth partition: e.g., categorical feature selection (Vinh et al., 2014), decision tree induction (Criminisi et al., 2012), generation of alternative or multi-view clusterings (Miller et al., 2013), or the exploration of the clustering space with the Meta-Clustering algorithm (Caruana et al., 2006; Lei et al., 2014b) to list a few.

Different values for q in AMI_q yield to different biases. The source of these biases can be identified by analyzing the properties of the q -entropy. In Figure 6 we show the q -entropy for a binary partition at the variation of the relative size p of one cluster. This can be analytically computed: $H_q(p) = \frac{1}{q-1}(1-p)^p - (1-p)^q$. *The range of variation for $H_q(p)$ is much bigger if q is small.* More specifically, when q is small, the difference in entropy between an unbalanced partition and a balanced partition is big.

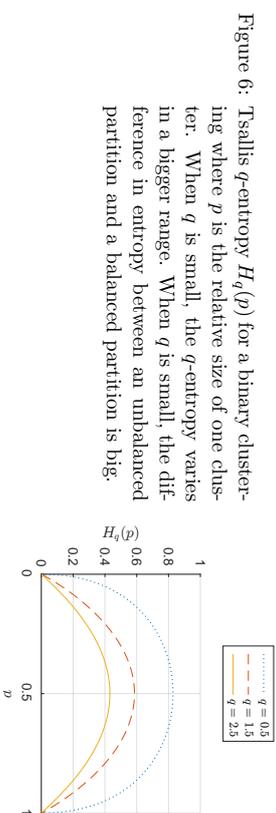

Figure 6: Tsallis q -entropy $H_q(p)$ for a binary clustering where p is the relative size of one cluster. When q is small, the q -entropy varies in a bigger range. When q is small, the difference in entropy between an unbalanced partition and a balanced partition is big.

Let us focus on an example. Let V be a reference clustering with 3 clusters of size 50 each, and let U_1 and U_2 be two clustering solutions with the same number of clusters and same cluster sizes. The contingency tables for U_1 and U_2 are shown on Figure 7. Given that both contingency tables have the same marginals, the only difference between $\text{AMI}_q(U_1, V)$ and $\text{AMI}_q(U_2, V)$ according to Eq. (11) lies in MI_q . Given that both solutions U_1 and U_2

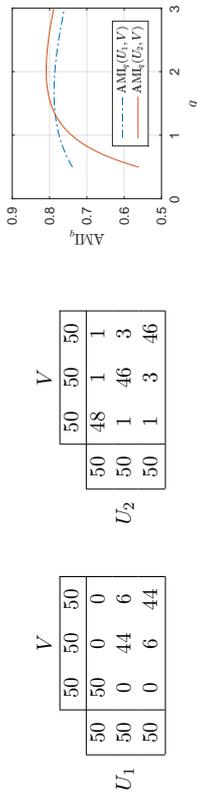

Figure 7: Ground truth clustering V compared in turn to the clustering solutions U_1 and U_2 . AMI_q with small q prefers the solution U_1 because there exists one pure cluster: i.e., there is one cluster which contains elements from only one cluster in the reference clustering V .

are compared against V , the only term that varies in $\text{MI}_q(U, V) = H_q(V) - H_q(V|U)$ is $H_q(V|U)$. In order to identify the clustering solution that maximizes AMI_q we have to analyze the solution that decreases $H_q(V|U)$ the most. $H_q(V|U)$ is a weighted average of the entropies $H_q(V|u_i)$ computed on the rows of the contingency table as shown in Eq. (5), and this is sensitive to values equal to 0. Given the bigger range of variation of H_q for small q , small q implies higher sensitivity to row entropies of 0. Therefore, small values of q tends to decrease $H_q(V|U)$ much more if the clusters in the solution U are pure: i.e., clusters contain elements from only one cluster in the reference clustering V . In other words, AMI_q with *small q prefers pure clusters in the clustering solution*.

When the marginals in the contingency tables for two solutions are different, another important factor in the computation of AMI_q is the normalization coefficient $\frac{1}{2}(H_q(U) + H_q(V))$. Balanced solutions U will be penalized more by AMI_q when q is small. Therefore, AMI_q with *small q prefers unbalanced clustering solutions*. To summarize, AMI_q with small q such as $\text{AMI}_{0.5}$ or $\text{AMI}_1 = \text{AMI}$ with Shannon entropy:

- Is biased towards pure clusters in the clustering solutions;
 - Prefers unbalanced clustering solutions.
- By contrary, AMI_q with bigger q such as $\text{AMI}_{2.5}$ or $\text{AMI}_2 = \text{ARI}$:
- Is less biased towards pure clusters in the clustering solution;
 - Prefers balanced clustering solutions.

Given a reference clustering V , these biases can guide the choice of q in AMI_q to identify more suitable clustering solutions.

4.1 Use AMI_q with small q such as $\text{AMI}_{0.5}$ or $\text{AMI}_1 = \text{AMI}$ when the reference clustering is unbalanced and there exist small clusters

If the reference cluster V is unbalanced and presents small clusters, AMI_q with small q might prefer more appropriate clustering solutions U . For example, in Figure 8 we show two contingency tables associated to two clustering solutions U_1 and U_2 for the reference

clustering V with 4 clusters of size $[10, 10, 10, 70]$ respectively. When there exist small clusters in the reference V their identification has to be *precise* in the clustering solution. In the solution U_1 looks arguably better than U_2 because it shows many pure clusters. In this scenario we advise the use of $\text{AMI}_{0.5}$ or $\text{AMI}_1 = \text{AMI}$ with Shannon entropy because it gives more weight to the clustering solution U_1 .

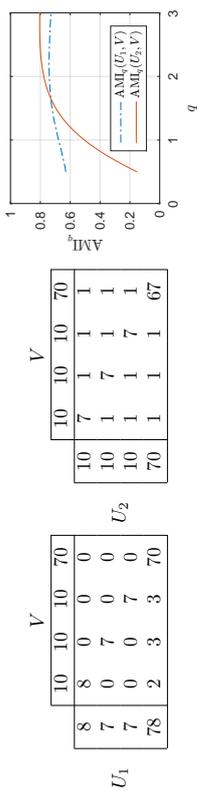

Figure 8: Ground truth clustering V compared in turn to the clustering solutions U_1 and U_2 . V is unbalanced and presents small clusters. When the reference clustering has small clusters their identification in the solution has to be *precise*. Therefore U_1 appears to be a better solution than U_2 . AMI_q with small q prefers the solution U_1 because its clusters are pure. In this scenario we advise the use of $\text{AMI}_{0.5}$ or $\text{AMI}_1 = \text{AMI}$.

If the number of objects N is large, AMI is equivalent to NMI according to Theorem 4. Therefore, when the reference clustering is unbalanced, there exist small clusters, and N is large, it is advisable to use NMI rather than ARI .

4.2 Use AMI_q with big q such as $\text{AMI}_{2.5}$ or $\text{AMI}_2 = \text{ARI}$ when the reference clustering has big equal sized clusters

If V is a reference clustering with big equal size clusters it is less crucial to have precise clusters in the solution. Indeed, precise clusters in the solution penalize the *recall* of clusters from the reference. In this case, AMI_q with bigger q might prefer more appropriate solutions. In Figure 9 we show two clustering solutions U_1 and U_2 for the reference clustering V with 4 equal size clusters of size 25. The solution U_2 looks better than U_1 because each of its clusters identifies more elements from particular clusters in the reference. Moreover, U_2 has to be preferred to U_1 because it consists in 4 equal sized clusters as the reference clustering V consists in equal sized clusters. In this scenario we advise the use of $\text{AMI}_{2.5}$ or $\text{AMI}_2 = \text{ARI}$ because it gives more importance to the solution U_2 .

If the number of objects N is large, AMI is equivalent to NMI according to Theorem 4. Therefore, when the reference clustering is balanced with big equal sized clusters and N is large, it is advisable to use ARI rather than NMI .

5. Standardization of Clustering Comparison Measures

The selection of the most similar partition U to a reference partition V is biased according to the chosen similarity measure, the number of sets r in U , and their relative size.

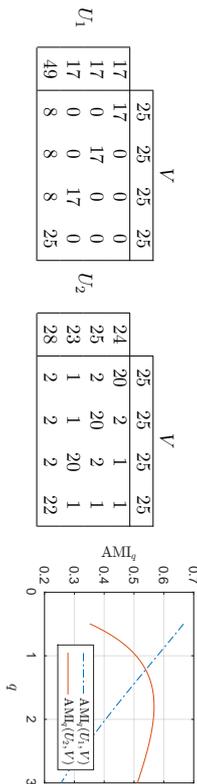

Figure 9: Ground truth clustering V compared in turn to the clustering solutions U_1 and U_2 . V shows equal size clusters. U_2 appears to be a better solution than U_1 because its clusters are more balanced in size than the clusters in U_1 . When the reference clustering has big equal sized clusters their precise identification is less crucial. AMI_q with big q prefers the solution U_2 because it is less biased to pure clusters in the solution. In this scenario we advise the use of $AMI_{2.5}$ or $AMI_2 = ARI$.

This phenomena is known as *selection bias* and it has been extensively studied in decision trees (White and Liu, 1994). Researchers in this area agree that in order to achieve unbiased selection of partitions, distribution properties of similarity measures have to be taken into account (Dobra and Gehrke, 2001; Shih, 2004; Hothorn et al., 2006). Using the permutation model, we proposed in Romano et al. (2014) to analytically standardize the Shannon MI by subtraction of its expected value and division by its standard deviation. In this section, we discuss how to achieve analytical standardization of measures $S \in \mathcal{L}_{\phi^*}$.

In order to standardize a measure, we must analytically compute its variance:

Lemma 3 *If $S(U, V) \in \mathcal{L}_{\phi^*}$, when partitions U and V are random:*

$$\text{Var}(S(U, V)) = \beta^2 \left(E \left[\left(\sum_{i,j} \phi_{ij}(n_{ij}) \right)^2 \right] - \left(\sum_{i,j} E[\phi_{ij}(n_{ij})] \right)^2 \right),$$

where

$$E \left[\left(\sum_{i,j} \phi_{ij}(n_{ij}) \right)^2 \right]$$

is equal to

$$\begin{aligned} & \sum_{i,j} \sum_{\tilde{n}_{i,j}} \phi(n_{ij}) P(n_{ij}) \cdot \left[\phi_{ij}(n_{ij}) + \sum_{\tilde{n}_{i,j} \neq n_{i,j}} \sum_{\tilde{n}_{i,j}} \phi_{ij}(\tilde{n}_{i,j}) P(\tilde{n}_{i,j}) + \right. \\ & \quad \left. + \sum_{\tilde{n}_{i,j} \neq \tilde{n}_{i,j'}} \sum_{\tilde{n}_{i,j'}} P(\tilde{n}_{i,j'}) \left(\phi_{ij}(\tilde{n}_{i,j}) + \sum_{\tilde{n}_{i,j} \neq \tilde{n}_{i,j'}} \sum_{\tilde{n}_{i,j'}} \phi_{ij}(\tilde{n}_{i,j'}) P(\tilde{n}_{i,j'}) \right) \right] \end{aligned} \quad (13)$$

with $n_{ij} \sim \text{HYP}(a_i, b_j, N)$, $\tilde{n}_{i,j} \sim \text{HYP}(b_j - n_{ij}, a_i, N - a_i)$, $\tilde{n}_{i,j'} \sim \text{HYP}(a_i - n_{ij}, b_j', N - b_j)$, $\tilde{n}_{i,j'} \sim \text{HYP}(a_i, b_j', N - a_i)$ *hypergeometric random variables*.

We can use the expected value to standardize measures $S \in \mathcal{L}_{\phi^*}$ such as generalized IT measures.

5.1 Standardization of Generalized IT Measures

The variance under the permutation model of generalized IT measures is:

Theorem 5 *Using Eqs. (10) and (13) with $\phi_{ij}(\cdot) = (\cdot)^q$, when the partitions U and V are random:*

- i) $\text{Var}(H_q(U, V)) = \frac{1}{(q-1)^2 N^{2q}} \left(E[(\sum_{i,j} n_{ij}^q)^2] - (\sum_{i,j} E[n_{ij}^q])^2 \right)$;
- ii) $\text{Var}(MI_q(U, V)) = \text{Var}(H_q(U, V))$
- iii) $\text{Var}(VI_q(U, V)) = 4\text{Var}(H_q(U, V))$

We define the standardized version of the similarity measure MI_q (SMI_q), and the standardized version of the distance measure VI_q (SVI_q) as follows:

$$SMI_q \triangleq \frac{MI_q - E[MI_q]}{\sqrt{\text{Var}(MI_q)}}, \quad SVI_q \triangleq \frac{E[VI_q] - VI_q}{\sqrt{\text{Var}(VI_q)}}, \quad (14)$$

As for the case of AMI_q and AVI_q , it turns out that SMI_q is equal to SVI_q :

Theorem 6 *Using Eqs. (10) and (13) with $\phi_{ij}(\cdot) = (\cdot)^q$, the standardized $MI_q(U, V)$ and the standardized $VI_q(U, V)$ are:*

$$SMI_q(U, V) = SVI_q(U, V) = \frac{\sum_{i,j} n_{ij}^q - \sum_{i,j} E[n_{ij}^q]}{\sqrt{E[(\sum_{i,j} n_{ij}^q)^2] - (\sum_{i,j} E[n_{ij}^q])^2}} \quad (15)$$

This formula shows that we are interested in maximizing the difference between the sum of the cells of the actual contingency table and the sum of the expected cells under randomness. Standardized measures differs from their adjusted counterpart because of the denominator, i.e. the standard deviation of the sums of the cells. Indeed, SMI_q and SVI_q measure the number of standard deviations MI_q and VI_q are from their mean.

There are some notable special cases for particular choices of q . Indeed, our generalized standardization of IT measures allows us to generalize also the standardization of pair-counting measures such as the Rand index. To see this, let us define the Standardized Rand Index (SRI): $SRI \triangleq \frac{RI - E[RI]}{\sqrt{\text{Var}(RI)}}$ and recall that the standardized G -statistic is defined as $SG \triangleq \frac{G - E[G]}{\sqrt{\text{Var}(G)}}$ (Romano et al., 2014):

Corollary 2 *It holds true that:*

- i) $\lim_{q \rightarrow 1} SMI_q = \lim_{q \rightarrow 1} SVI_q = SMI = SVI = SG$ with Shannon entropy;
- ii) $SMI_2 = SVI_2 = SRI$.

Computational complexity: The computational complexity of SMI_q is dominated by computation of the second moment of the sum of the cells defined in Eq. (13):

Proposition 3 *The computational complexity of SMI_q is $O(N^3 c \cdot \max\{c, r\})$.*

Note that the complexity is quadratic in c and linear in r . This happens because of the way we decided to condition the probabilities in Eq. (13) in the proof of Lemma 3. With different conditions, it is possible to obtain a formula symmetric to Eq. (13) with complexity $O(N^3 r \cdot \max\{r, c\})$ (Romano et al., 2014).

Statistical inference: All IT measures computed on *partitions* can be seen as estimators of their true value computed using the random *variables* associated to the partitions U and V . Therefore, SMI_q can be used as non-parametric independence test for MI_q . We formalize this with the following proposition:

Proposition 4 *The p -value associated to the test for independence between U and V using $\text{MI}_q(U, V)$ is smaller than:*

$$\frac{1}{1 + (\text{SMI}_q(U, V))^2}.$$

For example, if SMI_q is equal to 4.46 the associated p -value is smaller than 0.05. Neural time series data is often analyzed making use of the Shannon MI (e.g. see Chapter 29 in Cohen (2014)). It is common practice to test the independence of two time series by computing SMI via Monte Carlo permutations, sampling from the space of $N!$ cardinality. Our SMI_q can be effectively and efficiently used in this application because it is exact and obtains $O(N^3 r \cdot \max\{r, c\})$ complexity.

5.2 Experiments on Selection Bias

In this section, we evaluate the performance of standardized measures on selection bias correction when partitions U are generated at random and independently from the reference partition V . This hypothesis has been employed in previous published research to study selection bias (White and Liu, 1994; Frank and Witten, 1998; Dobra and Gehrké, 2001; Shih, 2004; Hothorn et al., 2006; Romano et al., 2014). In particular, we experimentally demonstrate that NMI_q is biased towards the selection of partitions U with more clusters at any q . Therefore, in this scenario it is beneficial to perform standardization. Mind though that the choice of whether performing standardization or not is application dependent (Romano et al., 2015). For example, it has been argued that in some cases the selection of clustering solutions should be biased towards clusterings with the same number of clusters as in the reference (Amelio and Pizzati, 2015). In this section we aim to show the effects of selection bias when clusterings are independent and that standardization helps in reducing it. Moreover, we will see in Section 5.3 that it is particularly important to correct for selection bias when the number of objects N is small.

Given a reference partition V on $N = 100$ objects with $c = 4$ sets, we generate a pool of random partitions U with r ranging from 2 to 10 sets. Then, we use $\text{NMI}_q(U, V)$ to select the closest partition to the reference V . The plot at the bottom of Figure 10 shows the probability of selection of a partition U with r sets using NMI_q computed on 5000 simulations. We do not expect any partition to be the best given that they are all generated at random: *i.e., the plot is expected to be flat if a measure is unbiased*. Nonetheless, we see that there is a clear bias towards partitions with 10 sets if we use NMI_q with q respectively equal to 1.001, 2, or 3. We can see that the use of the adjusted measures such as AMI_q helps in decreasing this bias, in particular when $q = 2$. On this experiment when $q = 2$, baseline adjustment seems to be effective in decreasing the selection bias because the variance of $\text{AMI}_2 = \text{ARI}$ is almost constant. However for all q , using SMI_q we obtain close to uniform probability of selection of each random partition U .

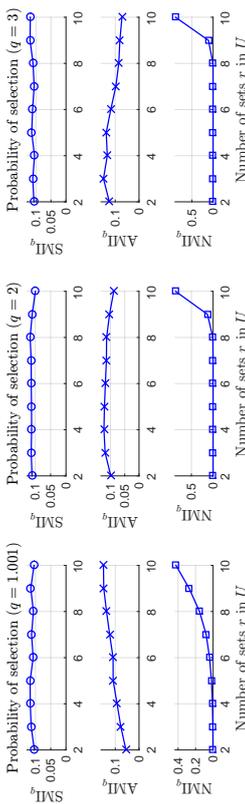

Figure 10: Selection bias towards random partitions U with different number of sets r when compared to a reference V . The probability of selection should be uniform when partitions are random. Using SMI_q we achieve close to uniform probability of selection for q equal to 1.001, 2 and 3 respectively.

5.3 Large Number of Objects

It is likely to expect that the variance of generalized IT measures decreases when partitions are generated on a large number of objects N . Here we prove a general result about measures of the family \mathcal{N}_ϕ .

Lemma 4 *If $S(U, V) \in \mathcal{N}_\phi$, then $\lim_{N \rightarrow +\infty} \text{Var}(S(U, V)) = 0$.*

Given that generalized IT measures belong in the family \mathcal{N}_ϕ , we can prove the following:

Theorem 7 *It holds true that:*

$$\lim_{N \rightarrow +\infty} \text{Var}(H_q(U, V)) = \lim_{N \rightarrow +\infty} \text{Var}(\text{MI}_q(U, V)) = \lim_{N \rightarrow +\infty} \text{Var}(\text{VI}_q(U, V)) = 0 \quad (16)$$

Therefore, SMI_q attains very large values when N is large. In practice of course, N is finite, so the use of SMI_q is beneficial. However, it is less important to correct for selection bias if the number of objects N is big with regards to the number of cells in the contingency table in Table 2: i.e., when $\frac{N}{rc}$ is large. Indeed, when the number of objects is large AMI_q might be sufficient to avoid selection bias and any test for independence between partitions has high power. In this scenario, SMI_q is not needed and AMI_q might be preferred as it can be computed more efficiently.

6. Conclusion

In this paper, we computed the exact expected value and variance of measures of the family \mathcal{L}_ϕ , which contains generalized IT measures. We also showed how the expected value for measures $S \in \mathcal{N}_\phi$ can be computed for large N . Using these statistics, we proposed AMI_q and SMI_q to adjust generalized IT measures both for baseline and for selection bias. AMI_q is a further generalization of well known measures for clustering comparisons such as ARI and AMI. This analysis allowed us to provide guidelines for their best application in different scenarios. In particular ARI might be used as external validation index when the reference

clustering shows big equal sized clusters. AMI can be used when the reference clustering is unbalanced and there exist small clusters. The standardized SMI_q can instead be used to correct for selection bias among many possible candidate clustering solutions when the number of objects is small. Furthermore, it can also be used to test the independence between two partitions. All code has been made available online¹.

Appendix A. Theorem Proofs

Proposition 1 (Simowicz, 2007) *When $q = 2$ the generalized variation of information, the Mfrkin index, and the Rand index are linearly related: $VI_2(U, V) = \frac{1}{N^2}MK(U, V) = \frac{N-1}{N}(1 - RI(U, V))$.*

Proof

$$\begin{aligned} VI_q(U, V) &= 2H_q(U, V) - H_q(U) - H_q(V) \\ &= \frac{2}{q-1} \left(1 - \sum_{i=1}^r \sum_{j=1}^c \binom{n_{ij}}{N} \right)^q - \frac{1}{q-1} \left(1 - \sum_{i=1}^r \binom{a_i}{N} \right)^q - \frac{1}{q-1} \left(1 - \sum_{j=1}^c \binom{b_j}{N} \right)^q \\ &= \frac{1}{(q-1)N^q} \left(\sum_{i=1}^r a_i^q + \sum_{j=1}^c b_j^q - 2 \sum_{i=1}^r \sum_{j=1}^c n_{ij}^q \right) \end{aligned}$$

When $q = 2$, $VI_2(U, V) = \frac{1}{N^2}(\sum_i a_i^2 + \sum_j b_j^2 - 2 \sum_{i,j} n_{ij}^2) = \frac{1}{N^2}MK(U, V) = \frac{N-1}{N}(1 - RI(U, V))$. ■

Lemma 1 *If $S(U, V) \in \mathcal{L}_\phi$, when partitions U and V are random:*

$$E[S(U, V)] = \alpha + \beta \sum_{i,j} E[\phi_{ij}(n_{ij})] \quad \text{where} \quad E[\phi_{ij}(n_{ij})] \quad \text{is} \quad (9)$$

$$\sum_{n_{ij}=\max\{0, a_i+b_j-N\}}^{\min\{a_i, b_j\}} \phi_{ij}(n_{ij}) \frac{a_i! b_j! (N - a_i)! (N - b_j)!}{N! n_{ij}! (a_i - n_{ij})! (b_j - n_{ij})! (N - a_i - b_j + n_{ij})!} \quad (10)$$

Proof The expected value of $S(U, V)$ according to the hypergeometric model of randomness is $E[S(U, V)] = \sum_{\mathcal{M}} S(\mathcal{M}) P(\mathcal{M})$ where \mathcal{M} is a contingency table generated via permutations. This is reduced to $E[S(U, V)] = \sum_{\mathcal{M}} (\alpha + \beta \sum_{i,j} \phi_{ij}(n_{ij})) P(\mathcal{M}) = \alpha + \beta \sum_{\mathcal{M}} \sum_{i,j} \phi_{ij}(n_{ij}) P(\mathcal{M})$. Because of linearity of the expected value, it is possible to swap the summation over \mathcal{M} and the one over cells obtaining $\alpha + \beta \sum_{i,j} \sum_{n_{i,j}} \phi_{ij}(n_{i,j}) P(n_{i,j}) = \alpha + \beta \sum_{i,j} E[\phi_{ij}(n_{i,j})]$ where $n_{i,j}$ is a hypergeometric distribution with the marginals a_i , b_j and N as parameters, i.e. $n_{i,j} \sim \text{Hyp}(a_i, b_j, N)$. ■

Theorem 1 *When the partitions U and V are random:*

- i) $E[H_q(U, V)] = \frac{1}{q-1} \left(1 - \frac{1}{N^q} \sum_{i,j} E[n_{ij}^q] \right)$ with $E[n_{ij}^q] = n_{ij}^q$;
- ii) $E[MI_q(U, V)] = H_q(U) + H_q(V) - E[H_q(U, V)]$;
- iii) $E[VI_q(U, V)] = 2E[H_q(U, V)] - H_q(U) - H_q(V)$.

Proof The results easily follow from Lemma 1 and the hypothesis of fixed marginals. ■

¹ <https://sites.google.com/site/adjgent/>

Theorem 2 Using $E[n_{ij}^q]$ in Eq. (10) with $\phi_{ij}(n_{ij}) = n_{ij}^q$, the adjustments for chance for $\text{MI}_q(U, V)$ and $\text{VI}_q(U, V)$ are:

$$\text{AMI}_q(U, V) = \text{AVI}_q(U, V) = \frac{\sum_{i,j} n_{ij}^q - \sum_{i,j} E[n_{ij}^q]}{\frac{1}{2} \left(\sum_i a_i^q + \sum_j b_j^q \right) - \sum_{i,j} E[n_{ij}^q]} \quad (12)$$

Proof The using the upper bound $\frac{1}{2}(H_q(U) + H_q(V))$ to MI_q , AMI_q and AVI_q are equivalent. Therefore we compute AVI_q . The denominator is equal to $E[\text{VI}_q] = \frac{2}{(q-1)N^q} \left(\frac{1}{2} \sum_i a_i^q + \sum_j b_j^q \right) - \sum_{i,j} E[n_{ij}^q]$. The numerator is instead $\frac{2}{(q-1)N^q} \left(\sum_{i,j} n_{ij}^q - \sum_{i,j} E[n_{ij}^q] \right)$. ■

Corollary 1 It holds true that:

- i) $\lim_{q \rightarrow 1} \text{AMI}_q = \lim_{q \rightarrow 1} \text{AVI}_q = \text{AMI} = \text{AVI}$ with Shannon entropy;
- ii) $\text{AMI}_2 = \text{AVI}_2 = \text{ARI}$.

Proof Point i) follows from the limit of the q -entropy when $q \rightarrow 1$. Point ii) follows from:

$$\text{AVI}_2 = \frac{E[\text{VI}_2] - \text{VI}_2}{E[\text{VI}_2] - \min \text{VI}_2} = \frac{\frac{N-1}{N}(\text{RI} - E[\text{RI}])}{\frac{N-1}{N}(\max \text{RI} - E[\text{RI}])} = \text{ARI}$$

■

Proposition 2 The computational complexity of AMI_q is $O(N \cdot \max\{r, c\})$.

Proof The computation of $P(n_{ij})$ where n_{ij} is a hypergeometric distribution $\text{Hyp}(a_i, b_j, N)$ is linear in N . However, the computation of the expected value $E[n_{ij}^q] = \sum_{n_{ij}} n_{ij}^q P(n_{ij})$ can exploit the fact that $P(n_{ij})$ are computed iteratively: $P(n_{ij}+1) = P(n_{ij}) \frac{(a_i - n_{ij})(b_j - n_{ij})}{(n_{ij}+1)(N - a_i - b_j + n_{ij} + 1)}$. We compute $P(n_{ij})$ only for $\max\{0, a_i + b_j - N\}$. In both cases $P(n_{ij})$ can be computed in $O(\max\{a_i, b_j\})$. We can compute all other probabilities iteratively as shown above in constant time. Therefore:

$$\begin{aligned} \sum_{i=1}^r \sum_{j=1}^c \left(O(\max\{a_i, b_j\}) + \sum_{n_{ij}=0}^{\min\{a_i, b_j\}} O(1) \right) &= \sum_{i=1}^r \sum_{j=1}^c O(\max\{a_i, b_j\}) = \sum_{i=1}^r O(\max\{ca_i, N\}) \\ &= O(\max\{cN, rN\}) = O(N \cdot \max\{c, r\}) \end{aligned}$$

■

Lemma 2 If $S(U, V) \in \mathcal{N}_\phi$, then $\lim_{N \rightarrow +\infty} E[S(U, V)] = \phi\left(\frac{a_1}{N}, \dots, \frac{a_r}{N}, \frac{b_1}{N}, \dots, \frac{b_c}{N}\right)$.

Proof $S(U, V)$ can be written as $\phi\left(\frac{n_{11}}{N}, \dots, \frac{n_{1r}}{N}, \dots, \frac{n_{rc}}{N}\right)$. Let $\mathbf{X} = (X_1, \dots, X_{rc}) = \left(\frac{n_{11}}{N}, \dots, \frac{n_{1r}}{N}, \dots, \frac{n_{rc}}{N}\right)$ be a vector of rc random variables where n_{ij} is a hypergeometric distribution with the marginals as parameters: a_i, b_j and N . The expected value of $\frac{n_{ij}}{N}$ is $E\left[\frac{n_{ij}}{N}\right] = \frac{1}{N} \frac{a_i b_j}{N}$. Let $\boldsymbol{\mu} = (\mu_1, \dots, \mu_{rc}) = (E[X_1], \dots, E[X_{rc}]) = \left(\frac{a_1 b_1}{N}, \dots, \frac{a_1 b_r}{N}, \dots, \frac{a_r b_c}{N}\right)$ be the vector of the expected values. The Taylor approximation of $S(U, V) = \phi(\mathbf{X})$ around $\boldsymbol{\mu}$ is:

$$\phi(\mathbf{X}) \simeq \phi(\boldsymbol{\mu}) + \sum_{t=1}^{rc} (X_t - \mu_t) \frac{\partial \phi}{\partial X_t} + \frac{1}{2} \sum_{t=1}^{rc} \sum_{s=1}^{rc} (X_t - \mu_t)(X_s - \mu_s) \frac{\partial^2 \phi}{\partial X_t \partial X_s} + \dots$$

Its expected value is (see Section 4.3 of (Ang and Tang, 2006)):

$$E[\phi(\mathbf{X})] \simeq \phi(\boldsymbol{\mu}) + \frac{1}{2} \sum_{t=1}^{rc} \sum_{s=1}^{rc} \text{Cov}(X_t, X_s) \frac{\partial^2 \phi}{\partial X_t \partial X_s} + \dots$$

We just analyse the second order remainder given that it dominates the higher order ones. Using the Cauchy-Schwartz inequality we have that $|\text{Cov}(X_t, X_s)| \leq \sqrt{\text{Var}(X_t)\text{Var}(X_s)}$. Each X_t and X_s is equal to $\frac{n_{ij}}{N}$ for some indexes i and j . The variance of each X_t and X_s is therefore equal to $\text{Var}\left(\frac{n_{ij}}{N}\right) = \frac{1}{N^2} \frac{a_i b_j}{N} \frac{N - a_i - b_j}{N - 1}$. When the number of records is large also the marginals increase: $N \rightarrow +\infty \Rightarrow a_i \rightarrow +\infty$, and $b_j \rightarrow +\infty \forall i, j$. However, because of the permutation model, all the fractions $\frac{a_i}{N}$ and $\frac{b_j}{N}$ stay constant $\forall i, j$. Therefore, because $\boldsymbol{\mu}$ is constant. However, at the limit of large N , the variance of $\frac{n_{ij}}{N}$ tends to 0: $\text{Var}\left(\frac{n_{ij}}{N}\right) = \frac{1}{N} \frac{a_i b_j}{N} \left(1 - \frac{a_i}{N}\right) \left(1 + \frac{1}{N-1} - \frac{b_j}{N}\right) \rightarrow 0$. Therefore, at large N :

$$E[\phi(\mathbf{X})] \simeq \phi(\boldsymbol{\mu}) = \phi\left(\frac{a_1}{N}, \frac{b_1}{N}, \dots, \frac{a_r}{N}, \frac{b_c}{N}\right)$$

■

Theorem 3 It holds true that:

- i) $\lim_{N \rightarrow +\infty} E[H_q(U, V)] = H_q(U) + H_q(V) - (q-1)H_q(U)H_q(V)$;
- ii) $\lim_{N \rightarrow +\infty} E[\text{MI}_q(U, V)] = (q-1)H_q(U)H_q(V)$;
- iii) $\lim_{N \rightarrow +\infty} E[\text{VI}_q(U, V)] = H_q(U) + H_q(V) - 2(q-1)H_q(U)H_q(V)$.

Proof $E[H_q(U, V)] = \frac{1}{q-1} \left(1 - \sum_{i,j} E\left[\left(\frac{n_{ij}}{N}\right)^q\right]\right)$ and according to Lemma 2 for large N : $E[H_q(U, V)] \simeq \frac{1}{q-1} \left(1 - \sum_{i,j} \left(\frac{a_i b_j}{N^q}\right)^q\right) = \frac{1}{q-1} \left(1 - \sum_i \left(\frac{a_i}{N}\right)^q \sum_j \left(\frac{b_j}{N}\right)^q\right)$. If we add an subtract

$1 - \sum_i \left(\frac{a_i}{N}\right)^q - \sum_j \left(\frac{b_j}{N}\right)^q$ in the parenthesis above:

$$\begin{aligned} E[H_q(U, V)] &\simeq \frac{1}{q-1} \left(1 - \sum_i \left(\frac{a_i}{N}\right)^q \sum_j \left(\frac{b_j}{N}\right)^q\right. \\ &\quad \left.+ 1 - \sum_i \left(\frac{a_i}{N}\right)^q - \sum_j \left(\frac{b_j}{N}\right)^q\right) \\ &\quad - 1 + \sum_i \left(\frac{a_i}{N}\right)^q + \sum_j \left(\frac{b_j}{N}\right)^q \\ &= \frac{1}{q-1} \left(1 - \sum_i \left(\frac{a_i}{N}\right)^q\right) + \frac{1}{q-1} \left(1 - \sum_j \left(\frac{b_j}{N}\right)^q\right) \\ &\quad + \frac{1}{q-1} \left(-1 - \sum_i \left(\frac{a_i}{N}\right)^q \sum_j \left(\frac{b_j}{N}\right)^q + \sum_i \left(\frac{a_i}{N}\right)^q + \sum_j \left(\frac{b_j}{N}\right)^q\right) \\ &= H_q(U) + H_q(V) + \frac{1}{q-1} \left(\left(1 - \sum_i \left(\frac{a_i}{N}\right)^q\right) \left(\sum_j \left(\frac{b_j}{N}\right)^q\right)\right) \\ &= H_q(U) + H_q(V) - (q-1)H_q(U)H_q(V) \end{aligned}$$

Point *ii*) and *iii*) follow from Equations (6) and (7). \blacksquare

Lemma 3 *If $S(U, V) \in \mathcal{L}_{\phi^*}$, when partitions U and V are random:*

$$\text{Var}(S(U, V)) = \beta^2 \left(E \left[\left(\sum_{i,j} \phi_{ij}(n_{ij}) \right)^2 \right] - \left(\sum_{i,j} E[\phi_{ij}(n_{ij})] \right)^2 \right),$$

where

$$E \left[\left(\sum_{i,j} \phi_{ij}(n_{ij}) \right)^2 \right]$$

is equal to

$$\begin{aligned} &\sum_{i,j} \sum_{n_{ij}} \phi(n_{ij}) P(n_{ij}) \cdot \left[\phi_{ij}(n_{ij}) + \sum_{i' \neq i} \sum_{j' \neq j} \phi_{i'j'}(\tilde{n}_{i'j'}) P(\tilde{n}_{i'j'}) + \right. \\ &\quad \left. + \sum_{j' \neq j} \sum_{i' \neq i} P(\tilde{n}_{i'j'}) \left(\phi_{ij'}(\tilde{n}_{i'j'}) + \sum_{i'' \neq i} \sum_{j'' \neq j} \phi_{i''j''}(\tilde{\tilde{n}}_{i''j''}) P(\tilde{\tilde{n}}_{i''j''}) \right) \right] \end{aligned} \quad (13)$$

with $n_{ij} \sim \text{HYP}(a_i, b_j, N)$, $\tilde{n}_{i'j'} \sim \text{HYP}(b_j - n_{ij}, a_i, N - a_i)$, $\tilde{\tilde{n}}_{i''j''} \sim \text{HYP}(a_i - n_{ij}, b_j, N - b_j)$, $\tilde{n}_{i'j'} \sim \text{HYP}(a_i, b_j - \tilde{n}_{i'j'}, N - a_i)$ hypergeometric random variables.

Proof The proof follows Theorem 1 proof in Romano et al. (2014). Using the properties of the variance we can show that $\text{Var}(S(U, V)) = \beta^2 \text{Var}(\sum_{i,j} \phi_{ij}(n_{ij})) = \beta^2 \left(E[(\sum_{i,j} \phi_{ij}(n_{ij}))^2] -$

$(\sum_{i,j} E[\phi_{ij}(n_{ij})])^2$). $(E[\sum_{i,j} \phi_{ij}(n_{ij})])^2 = (\sum_{i,j} E[\phi_{ij}(n_{ij})])^2$ can be computed using Eq. (10). The first term in the sum is instead:

$$E[(\sum_{i,j} \phi_{ij}(n_{ij}))^2] = \sum_{i,j} \sum_{i',j'} E[\phi_{ij}(n_{ij})\phi_{i'j'}(n_{i'j'})] = \sum_{i,j} \sum_{i',j'} \sum_{n_{ij}} \sum_{n_{i'j'}} \phi_{ij}(n_{ij})\phi_{i'j'}(n_{i'j'}) P(n_{ij}, n_{i'j'})$$

We cannot find the exact form of the joint probability $P(n_{ij}, n_{i'j'})$ thus we rewrite it as $P(n_{ij})P(n_{i'j'}|n_{ij}) = P(n_{ij})P(\tilde{n}_{i'j'})$. The random variable $n_{i'j'}$ is a hypergeometric distribution that simulates the experiment of sampling without replacement the a_i objects in the set u_i from a total of N objects. Sampling one of the b_j objects from v_j is defined as a success: $n_{i'j'} \sim \text{HYP}(a_i, b_j, N)$. The random variable $\tilde{n}_{i'j'}$ has a different distribution depending on the possible combinations of indexes i, i', j, j' . Thus $E[(\sum_{i,j} \phi_{ij}(n_{ij}))^2]$ is equal to:

$$\begin{aligned} &\sum_{i,j} \sum_{n_{ij}} \sum_{i',j'} \sum_{n_{i'j'}} \phi_{ij}(n_{ij})\phi_{i'j'}(n_{i'j'}) P(n_{ij}, n_{i'j'}) = \sum_{i,j} \sum_{n_{ij}} \phi_{ij}(n_{ij}) P(n_{ij}) \sum_{i',j'} \sum_{n_{i'j'}} \phi_{i'j'}(\tilde{n}_{i'j'}) P(\tilde{n}_{i'j'}) \\ &\quad \text{which, by taking care of all possible combinations of } i, i', j, j', \text{ is equal to :} \\ &\sum_{i,j} \sum_{n_{ij}} \phi_{ij}(n_{ij}) P(n_{ij}) \cdot \left[\sum_{i'=i, j'=j} \sum_{\tilde{n}_{i'j'}} \phi_{ij}(\tilde{n}_{i'j'}) P(\tilde{n}_{i'j'}) \right. \\ &\quad \left. + \sum_{i' \neq i, j'=j} \sum_{\tilde{n}_{i'j'}} \phi_{ij}(\tilde{n}_{i'j'}) P(\tilde{n}_{i'j'}) \right] \end{aligned} \quad (17)$$

$$\begin{aligned} &\quad + \sum_{i'=i, j' \neq j} \sum_{\tilde{n}_{i'j'}} \phi_{ij}(\tilde{n}_{i'j'}) P(\tilde{n}_{i'j'}) \\ &\quad + \sum_{i' \neq i, j' \neq j} \sum_{\tilde{n}_{i'j'}} \phi_{ij}(\tilde{n}_{i'j'}) P(\tilde{n}_{i'j'}) \end{aligned} \quad (18)$$

Case 1: $i' = i \wedge j' = j$
 $P(\tilde{n}_{i'j'}) = 1$ if and only if $\tilde{n}_{i'j'} = n_{ij}$ and 0 otherwise. This case produces the first term $\phi_{ij}(n_{ij})$ enclosed in square brackets.

Case 2: $i' = i \wedge j' \neq j$
In this case, the possible successes are the objects from the set v_j . We have already sampled n_{ij} objects and we are sampling from the whole set of objects excluding the set v_j . Thus, $\tilde{n}_{i'j'} \sim \text{HYP}(a_i - n_{ij}, b_j, N - b_j)$.

Case 3: $i' \neq i \wedge j' = j$
This case is symmetric to the previous one where $a_{i'}$ is now the possible number of successes. Therefore $\tilde{n}_{i'j'} \sim \text{HYP}(b_j - n_{ij}, a_i, N - a_i)$.

Case 4: $i' \neq i \wedge j' \neq j$
In order compute $P(\tilde{n}_{i'j'})$, we have to impose a further condition:

$$P(\tilde{n}_{i'j'}) = \sum_{\tilde{n}_{i'j'}} P(\tilde{n}_{i'j'} | \tilde{n}_{i'j'}) P(\tilde{n}_{i'j'}) = \sum_{\tilde{n}_{i'j'}} P(\tilde{\tilde{n}}_{i'j'}) P(\tilde{\tilde{n}}_{i'j'})$$

We are considering sampling the $a_{i'}$ objects in $u_{i'}$ from the whole set of objects excluding the a_i objects from u_i . Just knowing that n_{ij} objects have already been sampled from u_i does not allow us to know how many objects from $v_{i'}$ have also been sampled. If we know that $n_{i'j'}$ is the number of objects sampled from $v_{j'}$, we know there are $b_{j'} - n_{i'j'}$ possible successes and thus $\tilde{n}_{i'j'} | \tilde{n}_{i'j'} \sim \text{Hyp}(a_{i'}, b_{j'} - \tilde{n}_{i'j'}, N - a_i)$. So the last two terms in Eq. (18) can be put together:

$$\begin{aligned} & \sum_{j' \neq i, j' \neq j} \sum_{\tilde{n}_{i'j'}} \phi_{ij'}(\tilde{n}_{i'j'}) P(\tilde{n}_{i'j'}) + \sum_{i' \neq i, j' \neq j} \sum_{\tilde{n}_{i'j'}} \phi_{ij'}(\tilde{n}_{i'j'}) P(\tilde{n}_{i'j'}) \\ &= \sum_{j' \neq j} \sum_{\tilde{n}_{i'j'}} \phi_{ij'}(\tilde{n}_{i'j'}) P(\tilde{n}_{i'j'}) + \sum_{i' \neq i, j' \neq j} \sum_{\tilde{n}_{i'j'}} \phi_{ij'}(\tilde{n}_{i'j'}) P(\tilde{n}_{i'j'}) P(\tilde{n}_{i'j'}) \\ &= \sum_{j' \neq j} \sum_{\tilde{n}_{i'j'}} \phi_{ij'}(\tilde{n}_{i'j'}) P(\tilde{n}_{i'j'}) + \sum_{i' \neq i, j' \neq j} \sum_{\tilde{n}_{i'j'}} \phi_{ij'}(\tilde{n}_{i'j'}) P(\tilde{n}_{i'j'}) P(\tilde{n}_{i'j'}) \\ &= \sum_{j' \neq j} \sum_{\tilde{n}_{i'j'}} P(\tilde{n}_{i'j'}) \phi_{ij'}(\tilde{n}_{i'j'}) + \sum_{i' \neq i, j' \neq j} \sum_{\tilde{n}_{i'j'}} P(\tilde{n}_{i'j'}) \sum_{i' \neq i} \phi_{ij'}(\tilde{n}_{i'j'}) P(\tilde{n}_{i'j'}) \\ &= \sum_{j' \neq j} \sum_{\tilde{n}_{i'j'}} P(\tilde{n}_{i'j'}) \left(\phi_{ij'}(\tilde{n}_{i'j'}) + \sum_{i' \neq i} \sum_{\tilde{n}_{i'j'}} \phi_{ij'}(\tilde{n}_{i'j'}) P(\tilde{n}_{i'j'}) \right) \end{aligned}$$

By putting everything together we get that $E[(\sum_{ij} \phi_{ij}(n_{ij}))^2]$ is equal to:

$$\begin{aligned} & \sum_{ij} \sum_{i'j'} \phi(n_{ij}) P(n_{ij}) \cdot \left[\phi_{ij}(n_{ij}) + \sum_{i' \neq i} \sum_{\tilde{n}_{i'j'}} \phi_{ij}(\tilde{n}_{i'j'}) P(\tilde{n}_{i'j'}) + \right. \\ & \quad \left. + \sum_{j' \neq j} \sum_{\tilde{n}_{i'j'}} P(\tilde{n}_{i'j'}) \left(\phi_{ij'}(\tilde{n}_{i'j'}) + \sum_{i' \neq i} \sum_{\tilde{n}_{i'j'}} \phi_{ij'}(\tilde{n}_{i'j'}) P(\tilde{n}_{i'j'}) \right) \right] \end{aligned}$$

Theorem 5 Using Eqs. (10) and (13) with $\phi_{ij}(\cdot) = (\cdot)^q$, when the partitions U and V are random:

- i) $\text{Var}(H_q(U, V)) = \frac{1}{(q-1)^2 N^q} \left(E[(\sum_{ij} n_{ij}^q)^2] - (\sum_{ij} E[n_{ij}^q])^2 \right)$;
- ii) $\text{Var}(\text{ML}_q(U, V)) = \text{Var}(H_q(U, V))$
- iii) $\text{Var}(\text{VI}_q(U, V)) = 4\text{Var}(H_q(U, V))$

Proof The results follow from Lemma 3, the hypothesis of fixed marginals and properties of the variance. ■

Theorem 6 Using Eqs. (10) and (13) with $\phi_{ij}(\cdot) = (\cdot)^q$, the standardized $\text{ML}_q(U, V)$ and the standardized $\text{VI}_q(U, V)$ are:

$$\text{SMI}_q(U, V) = \text{SVI}_q(U, V) = \frac{\sum_{ij} n_{ij}^q - \sum_{ij} E[n_{ij}^q]}{\sqrt{E[(\sum_{ij} n_{ij}^q)^2] - (\sum_{ij} E[n_{ij}^q])^2}} \quad (15)$$

Proof

For SMI_q , the numerator is equal to $H_q(U, V) - E[H_q(U, V)] = \frac{1}{(q-1)N^q} \left(\sum_{ij} n_{ij}^q - \sum_{i,j} E[n_{ij}^q] \right)$. According Theorem 5, the denominator is instead:

$$\sqrt{\text{Var}(\text{ML}_q(U, V))} = \sqrt{\text{Var}(H_q(U, V))} = \frac{1}{(q-1)N^q} \sqrt{E[(\sum_{ij} n_{ij}^q)^2] - (E[\sum_{ij} n_{ij}^q])^2}.$$

For SVI_q , the numerator is equal to $2H_q(U, V) - 2E[H_q(U, V)] = \frac{2}{(q-1)N^q} \left(\sum_{ij} n_{ij}^q - \sum_{i,j} E[n_{ij}^q] \right)$. According Theorem 5, the denominator is instead:

$$\sqrt{\text{Var}(\text{VI}_q(U, V))} = \sqrt{4\text{Var}(H_q(U, V))} = \frac{2}{(q-1)N^q} \sqrt{E[(\sum_{ij} n_{ij}^q)^2] - (E[\sum_{ij} n_{ij}^q])^2}.$$

Therefore, SMI_q and SVI_q are equivalent. ■

Corollary 2 It holds true that:

- i) $\lim_{q \rightarrow 1} \text{SMI}_q = \lim_{q \rightarrow 1} \text{SVI}_q = \text{SMI} = \text{SVI} = \text{SG}$ with Shannon entropy;
- ii) $\text{SMI}_2 = \text{SVI}_2 = \text{SRI}$.

Proof Point i) follows from the limit of the q -entropy when $q \rightarrow 1$ and the linear relation of G -statistic to MI: $G = 2N\text{MI}$. Point ii) follows from:

$$\text{SVI}_2 = \frac{E[\text{VI}_2] - \text{VI}_2}{\sqrt{\text{Var}(\text{VI}_2)}} = \frac{N-1}{N} \frac{(\text{RI} - E[\text{RI}])}{\sqrt{\text{Var}(\text{RI})}} = \text{SRI}$$

Proposition 3 The computational complexity of SMI_q is $O(N^3 c \cdot \max\{c, r\})$.

Proof Each summation in Eq. (13) can be bounded above by the maximum value of the cell marginals and each sum can be done in constant time. The last summation in Eq. (13) is:

$$\begin{aligned} & \sum_{j'=1}^c \sum_{\tilde{n}_{i'j'=0}} \sum_{i'=1}^r \sum_{\tilde{n}_{i'j'=0}} \sum_{i'=1}^c \max_{\{a_{i'}, b_{j'}\}} \sum_{i'=1}^r \sum_{\tilde{n}_{i'j'=0}} O(\max\{a_{i'}, b_{j'}\}) \\ &= \sum_{j'=1}^c \sum_{\tilde{n}_{i'j'=0}} \sum_{i'=1}^r \sum_{\tilde{n}_{i'j'=0}} O(\max\{N, r b_{j'}\}) \\ &= \sum_{j'=1}^c O(\max\{a_i, b_{j'}\}) \\ &= \sum_{j'=1}^c O(\max\{a_i, a_i r b_{j'}, b_{j'} N, r b_{j'}^2\}) \\ &= O(\max\{c a_i, N, a_i r N, r N^2\}) \end{aligned}$$

The above term is thus the computational complexity of the inner loop. Using the same machinery one can prove that:

$$\sum_{j=1}^c \sum_{i=1}^r \max_{n_{ij}=0}^{\max\{a_i, b_j\}} O(\max\{a_i N, a_j r N, r N^2\}) = O(\max\{c^2 N^3, r c N^3\}) = O(N^3 c \cdot \max\{c, r\})$$

■

Proposition 4 *The p -value associated to the test for independence between U and V using $\text{MI}_q(U, V)$ is smaller than: $\frac{1}{1 + (\text{SMI}_q(U, V))^2}$.*

Proof Let MI_q^0 be the random variable under the null hypothesis of independence between partitions associated to the test statistic $\text{MI}_q(U, V)$. The p -value is defined as:

$$\begin{aligned} p\text{-value} &= P\left(\text{MI}_q^0 \geq \text{MI}_q(U, V)\right) = P\left(\text{MI}_q^0 - E[\text{MI}_q(U, V)] \geq \text{MI}_q(U, V) - E[\text{MI}_q(U, V)]\right) \\ &= P\left(\frac{\text{MI}_q^0 - E[\text{MI}_q(U, V)]}{\sqrt{\text{Var}(\text{MI}_q(U, V))}} \geq \frac{\text{MI}_q(U, V) - E[\text{MI}_q(U, V)]}{\sqrt{\text{Var}(\text{MI}_q(U, V))}}\right) \\ &= P\left(\frac{\text{MI}_q^0 - E[\text{MI}_q(U, V)]}{\sqrt{\text{Var}(\text{MI}_q(U, V))}} \geq \text{SMI}_q(U, V)\right) \end{aligned}$$

Let Z be the standardized random variable $\frac{\text{MI}_q^0 - E[\text{MI}_q(U, V)]}{\sqrt{\text{Var}(\text{MI}_q(U, V))}}$, then using the one side Chebyshev's inequality also known as the Cantelli's inequality (Ross, 2012):

$$p\text{-value} = P(Z \geq \text{SMI}_q(U, V)) < \frac{1}{1 + (\text{SMI}_q(U, V))^2}$$

■

Lemma 4 *If $S(U, V) \in \mathcal{N}_{\phi}$, then $\lim_{N \rightarrow +\infty} \text{Var}(S(U, V)) = 0$.*

Proof Let $\mathbf{X} = (X_1, \dots, X_{rc}) = (\frac{n_{11}}{N}, \dots, \frac{n_{1c}}{N}, \dots, \frac{n_{r1}}{N}, \dots, \frac{n_{rc}}{N})$ be a vector of rc random variables where n_{ij} is a hypergeometric distribution with the marginals as parameters: a_i , b_j and N . Using the Taylor approximation (Ang and Tang, 2006) of $S(U, V) = \phi(\mathbf{X})$, it is possible to show that:

$$\text{Var}(\phi(\mathbf{X})) \simeq \sum_{i=1}^{rc} \sum_{s=1}^{rc} \text{Cov}(X_i, X_s) \frac{\partial \phi}{\partial X_i} \frac{\partial \phi}{\partial X_s} + \dots$$

Using the Cauchy-Schwarz inequality we have that $|\text{Cov}(X_i, X_s)| \leq \sqrt{\text{Var}(X_i) \text{Var}(X_s)}$. Each X_i and X_s is equal to $\frac{n_{ij}}{N}$ for some indexes i and j . The variance of each X_i and X_s is

therefore equal to $\text{Var}\left(\frac{n_{ij}}{N}\right) = \frac{1}{N^2} \frac{a_i b_j}{N} \frac{N - a_i}{N} \frac{N - b_j}{N - 1}$. When the number of records is large also the marginals increase: $N \rightarrow +\infty \Rightarrow a_i \rightarrow +\infty$, and $b_j \rightarrow +\infty \forall i, j$. However because of the permutation model, all the fractions $\frac{a_i}{N}$ and $\frac{b_j}{N}$ stay constant $\forall i, j$. Therefore, at the limit of large N , the variance of $\frac{n_{ij}}{N}$ tends to 0: $\text{Var}\left(\frac{n_{ij}}{N}\right) = \frac{1}{N} \frac{a_i}{N} \frac{b_j}{N} \left(1 - \frac{a_i}{N}\right) \left(1 + \frac{1}{N-1} - \frac{b_j}{N}\right) \rightarrow 0$ and thus $\text{Var}(\phi(\mathbf{X}))$ tends to 0. ■

Theorem 7 *It holds true that:*

$$\lim_{N \rightarrow +\infty} \text{Var}(H_q(U, V)) = \lim_{N \rightarrow +\infty} \text{Var}(\text{MI}_q(U, V)) = \lim_{N \rightarrow +\infty} \text{Var}(\text{VI}_q(U, V)) = 0 \quad (16)$$

Proof Trivially follows from Lemma 4. ■

Refined Error Bounds for Several Learning Algorithms

Steve Hanneke

STEVE.HANNEKE@GMAIL.COM

Editor: John Shawe-Taylor

Abstract

This article studies the achievable guarantees on the error rates of certain learning algorithms, with particular focus on refining logarithmic factors. Many of the results are based on a general technique for obtaining bounds on the error rates of sample-consistent classifiers with monotonic error regions, in the realizable case. We prove bounds of this type expressed in terms of either the VC dimension or the sample compression size. This general technique also enables us to derive several new bounds on the error rates of general sample-consistent learning algorithms, as well as refined bounds on the label complexity of the CAL active learning algorithm. Additionally, we establish a simple necessary and sufficient condition for the existence of a distribution-free bound on the error rates of all sample-consistent learning rules, converging at a rate inversely proportional to the sample size. We also study learning in the presence of classification noise, deriving a new excess error rate guarantee for general VC classes under Tsybakov's noise condition, and establishing a simple and general necessary and sufficient condition for the minimax excess risk under bounded noise to converge at a rate inversely proportional to the sample size.

Keywords: sample complexity, PAC learning, statistical learning theory, active learning, minimax analysis

1. Introduction

Supervised machine learning is a classic topic, in which a learning rule is tasked with producing a classifier that mimics the classifications that would be assigned by an expert for a given task. To achieve this, the learner is given access to a collection of examples (assumed to be i.i.d.) labeled with the correct classifications. One of the major theoretical questions of interest in learning theory is: How many examples are necessary and sufficient for a given learning rule to achieve low classification error rate? This quantity is known as the *sample complexity*, and varies depending on how small the desired classification error rate is, the type of classifier we are attempting to learn, and various other factors. Equivalently, the question is: How small of an error rate can we guarantee a given learning rule will achieve, for a given number of labeled training examples?

A particularly simple setting for supervised learning is the *realizable case*, in which it is assumed that, within a given set \mathcal{C} of classifiers, there resides some classifier that is *always* correct. The optimal sample complexity of learning in the realizable case has recently been completely resolved, up to constant factors, in a sibling paper to the present article (Hanneke, 2016). However, there remains the important task of identifying interesting general families of algorithms achieving this optimal sample complexity. For instance, the best known general upper bounds for the general family of *empirical risk minimization* algorithms differ from the optimal sample complexity by a logarithmic factor, and it is

known that there exist spaces \mathcal{C} for which this is unavoidable (Auer and Ortner, 2007). This same logarithmic factor gap appears in the analysis of several of other learning methods as well. The present article focuses on this logarithmic factor, arguing that for certain types of learning rules, it can be entirely removed in some cases, and for others it can be somewhat refined. The technique leading to these results is rooted in an idea introduced in the author's doctoral dissertation (Hanneke, 2009). By further exploring this technique, we also obtain new results for the related problem of *active learning*. We also derive interesting new results for learning with classification noise, where again the focus is on a logarithmic factor gap between upper and lower bounds.

1.1 Basic Notation

Before further discussing the results, we first introduce some essential notation. Let \mathcal{X} be any nonempty set, called the *instance space*, equipped with a σ -algebra defining the measurable sets; for simplicity, we will suppose the sets in $\{\{x\} : x \in \mathcal{X}\}$ are all measurable. Let $\mathcal{Y} = \{-1, +1\}$ be the label space. A *classifier* is any measurable function $h : \mathcal{X} \rightarrow \mathcal{Y}$. Following Vapnik and Chervonenkis (1971), define the VC dimension of a set \mathcal{A} of subsets of \mathcal{X} , denoted $\text{vc}(\mathcal{A})$, as the maximum cardinality $|S|$ over subsets $S \subseteq \mathcal{X}$ such that $\{S \cap A : A \in \mathcal{A}\} = 2^S$ (the power set of S); if no such maximum cardinality exists, define $\text{vc}(\mathcal{A}) = \infty$. For any set \mathcal{H} of classifiers, denote by $\text{vc}(\mathcal{H}) = \text{vc}(\{\{x\} : h(x) = +1\} : h \in \mathcal{H})$ the VC dimension of \mathcal{H} . Throughout, we fix a set \mathcal{C} of classifiers, known as the *concept space*, and abbreviate $d = \text{vc}(\mathcal{C})$. To focus on nontrivial cases, throughout we suppose $|\mathcal{C}| \geq 3$, which implies $d \geq 1$. We will also generally suppose $d < \infty$ (though some of the results would still hold without this restriction).

For any $L_m = \{(x_1, y_1), \dots, (x_m, y_m)\} \in (\mathcal{X} \times \mathcal{Y})^m$, and any classifier h , define $\text{er}_{L_m}(h) = \frac{1}{m} \sum_{(x,y) \in L_m} \mathbb{1}[h(x) \neq y]$. For completeness, also define $\text{er}_{\mathcal{H}}(h) = 0$. Also, for any set \mathcal{H} of classifiers, denote $\mathcal{H}[L_m] = \{h \in \mathcal{H} : \forall (x, y) \in L_m, h(x) = y\}$, referred to as the set of classifiers in \mathcal{H} *consistent* with L_m ; for completeness, also define $\mathcal{H}[\{\}] = \mathcal{H}$. Fix an arbitrary probability measure \mathcal{P} on \mathcal{X} (called the *data distribution*), and a classifier $f^* \in \mathcal{C}$ (called the *target function*). For any classifier h , denote $\text{er}(h) = \mathcal{P}(x : h(x) \neq f^*(x))$, the *error rate* of h . Let X_1, X_2, \dots be independent \mathcal{P} -distributed random variables. We generally denote $\mathcal{L}_m = \{(X_1, f^*(X_1)), \dots, (X_m, f^*(X_m))\}$, and $V_m = \mathcal{C}[\mathcal{L}_m]$ (called the *version space*). The general setting in which we are interested in producing a classifier \hat{h} with small $\text{er}(\hat{h})$, given access to the data \mathcal{L}_m , is a special case of supervised learning known as the *realizable case* (in contrast to settings where the observed labeling might not be realizable by any classifier in \mathcal{C} , due to label noise or model misspecification, as discussed in Section 6).

We adopt a few convenient notational conventions. For any $m \in \mathbb{N}$, denote $[m] = \{1, \dots, m\}$; also denote $[0] = \{\}$. We adopt a shorthand notation for sequences, so that for a sequence x_1, \dots, x_m , we denote $x_{[m]} = (x_1, \dots, x_m)$. For any \mathbb{R} -valued functions f, g , we write $f(z) \lesssim g(z)$ or $g(z) \gtrsim f(z)$ if there exists a finite numerical constant $c > 0$ such that $f(z) \leq cg(z)$ for all z . For any $x, y \in \mathbb{R}$, denote $x \vee y = \max\{x, y\}$ and $x \wedge y = \min\{x, y\}$. For $x \geq 0$, denote $\text{Log}(x) = \ln(x \vee e)$ and $\text{Log}_2(x) = \log_2(x \vee 2)$. We also adopt the conventions that for $x > 0$, $x/0 = \infty$, and $0\text{Log}(x/0) = 0\text{Log}(\infty) = 0 \cdot \infty = 0$. It will also be convenient to use the notation $\mathcal{Z}^0 = \{\emptyset\}$ for a set \mathcal{Z} , where $(\)$ is the empty sequence.

Throughout, we also make the usual implicit assumption that all quantities required to be measurable in the proofs and lemmas from the literature are indeed measurable. See, for instance, van der Vaart and Wellner (1996, 2011), for discussions of conditions on \mathbb{C} that typically suffice for this.

1.2 Background and Summary of the Main Results

This work concerns the study of the error rates achieved by various *learning rules*: that is, mappings from the data set \mathcal{L}_m to a classifier \hat{h}_m ; for simplicity, we sometimes refer to \hat{h}_m itself as a learning rule, leaving dependence on \mathcal{L}_m implicit. There has been a substantial amount of work on bounding the error rates of various learning rules in the realizable case. Perhaps the most basic and natural type of learning rule in this setting is the family of *consistent* learning rules: that is, those that choose $\hat{h}_m \in V_m$. There is a general upper bound for all consistent learning rules \hat{h}_m , due to Vapnik and Chervonenkis (1974); Blumer, Ehrenfeucht, Haussler, and Warmuth (1989), stating that with probability at least $1 - \delta$,

$$\text{er}(\hat{h}_m) \lesssim \frac{1}{m} \left(d \log \left(\frac{m}{d} \right) + \text{Log} \left(\frac{1}{\delta} \right) \right). \quad (1)$$

This is complemented by a general lower bound of Ehrenfeucht, Haussler, Kearns, and Valiant (1989), which states that for any learning rule (consistent or otherwise), there exists a choice of \mathcal{P} and $f^* \in \mathbb{C}$ such that, with probability greater than δ ,

$$\text{er}(\hat{h}_m) \gtrsim \frac{1}{m} \left(d + \text{Log} \left(\frac{1}{\delta} \right) \right). \quad (2)$$

Resolving the logarithmic factor gap between (2) and (1) has been a challenging subject of study for decades now, with many interesting contributions resolving special cases and proposing sometimes-better upper bounds (e.g., Haussler, Littlestone, and Warmuth, 1994; Giné and Koltchinskii, 2006; Auer and Ortner, 2007; Long, 2003). It is known that the lower bound is sometimes *not* achieved by certain consistent learning rules (Auer and Ortner, 2007). The question of whether the lower bound (2) can always be achieved by *some* algorithm remained open for a number of years (Ehrenfeucht, Haussler, Kearns, and Valiant, 1989; Warmuth, 2004), but has recently been resolved in a sibling paper to the present article (Hanneke, 2016). That work proposes a learning rule \hat{h}_m based on a majority vote of classifiers consistent with carefully-constructed subsamples of the data, and proves that with probability at least $1 - \delta$,

$$\text{er}(\hat{h}_m) \lesssim \frac{1}{m} \left(d + \text{Log} \left(\frac{1}{\delta} \right) \right).$$

However, several avenues for investigation remain open, including identifying interesting general families of learning rules able to achieve this optimal bound under general conditions on \mathbb{C} . In particular, it remains an open problem to determine necessary and sufficient conditions on \mathbb{C} for the entire family of consistent learning rules to achieve the above optimal error bound.

The work of Giné and Koltchinskii (2006) includes a bound that refines the logarithmic factor in (1) in certain scenarios. Specifically, it states that, for any consistent learning rule

\hat{h}_m , with probability at least $1 - \delta$,

$$\text{er}(\hat{h}_m) \lesssim \frac{1}{m} \left(d \log \left(\theta \left(\frac{d}{m} \right) \right) + \text{Log} \left(\frac{1}{\delta} \right) \right), \quad (3)$$

where $\theta(\cdot)$ is the *disagreement coefficient* (defined below in Section 4). The doctoral dissertation of Hanneke (2009) contains a simple and direct proof of this bound, based on an argument which splits the data set in two parts, and considers the second part as containing a subsequence sampled from the conditional distribution given the region of disagreement of the version space induced by the first part of the data. Many of the results in the present work are based on variations of this argument, including a variety of interesting new bounds on the error rates achieved by certain families of learning rules.

As one of the cornerstones of this work, we find that a variant of this argument for consistent learning rules with *monotonic* error regions leads to an upper bound that *matches* the lower bound (2) up to constant factors. For such monotonic consistent learning rules to exist, we would need a very special kind of concept space. However, they do exist in some important cases. In particular, in the special case of learning *intersection-closed* concept spaces, the *Closure* algorithm (Natarajan, 1987; Auer and Ortner, 2004, 2007) can be shown to satisfy this monotonicity property. Thus, this result immediately implies that, with probability at least $1 - \delta$, the Closure algorithm achieves

$$\text{er}(\hat{h}_m) \lesssim \frac{1}{m} \left(d + \text{Log} \left(\frac{1}{\delta} \right) \right),$$

which was an open problem of Auer and Ortner (2004, 2007); this fact was recently also obtained by Darnstädt (2015), via a related direct argument. We also discuss a variant of this result for monotone learning rules expressible as *compression schemes*, where we remove a logarithmic factor present in a result of Littlestone and Warmuth (1986) and Floyd and Warmuth (1995), so that for \hat{h}_m based on a compression scheme of size n , which has monotonic error regions (and is permutation-invariant), with probability at least $1 - \delta$,

$$\text{er}(\hat{h}_m) \lesssim \frac{1}{m} \left(n + \text{Log} \left(\frac{1}{\delta} \right) \right).$$

This argument also has implications for *active learning*. In many active learning algorithms, the *region of disagreement* of the version space induced by m samples, $\text{DIS}(V_m) = \{x \in \mathcal{X} : \exists h, g \in V_m \text{ s.t. } h(x) \neq g(x)\}$, plays an important role. In particular, the label complexity of the CAL active learning algorithm (Cohn, Atlas, and Laderer, 1994) is largely determined by the rate at which $\mathcal{P}(\text{DIS}(V_m))$ decreases, so that any bound on this quantity can be directly converted into a bound on the label complexity of CAL (Hanneke, 2011, 2009, 2014; El-Yaniv and Wiener, 2012). Wiener, Hanneke, and El-Yaniv (2015) have argued that the region $\text{DIS}(V_m)$ can be described as a compression scheme, where the size of the compression scheme, denoted \hat{n}_m , is known as the *version space compression set size* (Definition 6 below). By further observing that $\text{DIS}(V_m)$ is monotonic in m , applying our general argument yields the fact that, with probability at least $1 - \delta$, letting $\hat{n}_{1:m} = \max_{t \in [m]} \hat{n}_t$,

$$\mathcal{P}(\text{DIS}(V_m)) \lesssim \frac{1}{m} \left(\hat{n}_{1:m} + \text{Log} \left(\frac{1}{\delta} \right) \right), \quad (4)$$

which is typically an improvement over the best previously-known general bound by a logarithmic factor.

In studying the distribution-free minimax label complexity of active learning, Hanneke and Yang (2015) found that a simple combinatorial quantity \mathfrak{s} , which they term the *star number*, is of fundamental importance. Specifically (see also Definition 9), \mathfrak{s} is the largest number s of distinct points $x_1, \dots, x_s \in \mathcal{X}$ such that $\exists h_0, h_1, \dots, h_s \in \mathbb{C}$ with $\forall i \in [s]$, $\text{DIS}(\{h_0, h_i\}) \cap \{x_1, \dots, x_s\} = \{x_i\}$, or else $\mathfrak{s} = \infty$ if no such largest s exists. Interestingly, the work of Hanneke and Yang (2015) also establishes that the largest possible value of \hat{h}_m (over m and the data set) is exactly \mathfrak{s} . Thus, (4) also implies a *data-independent* and *distribution-free* bound: with probability at least $1 - \delta$,

$$\mathcal{P}(\text{DIS}(V_m)) \lesssim \frac{1}{m} \left(\mathfrak{s} + \text{Log} \left(\frac{1}{\delta} \right) \right).$$

Now one interesting observation at this point is that the direct proof of (3) from Hanneke (2009) involves a step in which $\mathcal{P}(\text{DIS}(V_m))$ is relaxed to a bound in terms of $\theta(d/m)$. If we instead use (4) in this step, we arrive at a new bound on the error rates of *all* consistent learning rules \hat{h}_m : with probability at least $1 - \delta$,

$$\text{er}(\hat{h}_m) \lesssim \frac{1}{m} \left(d \text{Log} \left(\frac{\hat{h}_{1,m}}{d} \right) + \text{Log} \left(\frac{1}{\delta} \right) \right). \quad (5)$$

Since Hanneke and Yang (2015) have shown that the maximum possible value of $\theta(d/m)$ (over m , \mathcal{P} , and f^*) is also exactly the star number \mathfrak{s} , while $\hat{h}_{1,m}/d$ has as its maximum possible value \mathfrak{s}/d , we see that the bound in (5) sometimes reflects an improvement over (3). It further implies a new data-independent and distribution-free bound for any consistent learning rule \hat{h}_m : with probability at least $1 - \delta$,

$$\text{er}(\hat{h}_m) \lesssim \frac{1}{m} \left(d \text{Log} \left(\frac{\min\{\mathfrak{s}, m\}}{d} \right) + \text{Log} \left(\frac{1}{\delta} \right) \right).$$

Interestingly, we are able to complement this with a *lower bound* in Section 5.1. Though not quite matching the above in terms of its joint dependence on d and \mathfrak{s} (and necessarily so), this lower bound does provide the interesting observation that $\mathfrak{s} < \infty$ is *necessary and sufficient* for there to exist a distribution-free bound on the error rates of all consistent learning rules, converging at a rate $\Theta(1/m)$, and otherwise (when $\mathfrak{s} = \infty$) the best such bound is $\Theta(\text{Log}(m)/m)$.

Continuing with the investigation of general consistent learning rules, we also find a variant of the argument of Hanneke (2009) that refines (3) in a different way: namely, replacing $\theta(\cdot)$ with a quantity based on considering a well-chosen *subregion* of the region of disagreement, as studied by Balcan, Broder, and Zhang (2007); Zhang and Chaudhuri (2014). Specifically, in the context of active learning, Zhang and Chaudhuri (2014) have proposed a general quantity $\varphi_c(\cdot)$ (Definition 15 below), which is never larger than $\theta(\cdot)$, and is sometimes significantly smaller. By adapting our general argument to replace $\text{DIS}(V_m)$ with this well-chosen subregion, we derive a bound for all consistent learning rules \hat{h}_m : with probability at least $1 - \delta$,

$$\text{er}(\hat{h}_m) \lesssim \frac{1}{m} \left(d \text{Log} \left(\varphi_c \left(\frac{d}{m} \right) \right) + \text{Log} \left(\frac{1}{\delta} \right) \right).$$

In particular, as a special case of this general result, we recover the theorem of Balcan and Long (2013) that all consistent learning rules have optimal sample complexity (up to constants) for the problem of learning homogeneous linear separators under isotropic log-concave distributions, as $\varphi_c(d/m)$ is bounded by a finite numerical constant in this case. In Section 6, we also extend this result to the problem of learning with *classification noise*, where there is also a logarithmic factor gap between the known general-case upper and lower bounds. In this context, we derive a new general upper bound under the Bernstein class condition (a generalization of Tsybakov’s noise condition), expressed in terms of a quantity related to $\varphi_c(\cdot)$, which applies to a particular learning rule. This sometimes reflects an improvement over the best previous general upper bounds (Massart and Nédélec, 2006; Giné and Koltchinskii, 2006; Hanneke and Yang, 2012), and again recovers a result of Balcan and Long (2013) for homogeneous linear separators under isotropic log-concave distributions, as a special case.

For many of these results, we also state bounds on the *expected* error rate: $\mathbb{E}[\text{er}(\hat{h}_m)]$. In this case, the optimal distribution-free bound is known to be within a constant factor of d/m (Haussler, Littlestone, and Warmuth, 1994; Li, Long, and Srinivasan, 2001), and this rate is achieved by the one-inclusion graph prediction algorithm of Haussler, Littlestone, and Warmuth (1994), as well as the majority voting method of Hanneke (2016). However, there remain interesting questions about whether other algorithms achieve this optimal performance, or require an extra logarithmic factor. Again we find that *monotone* consistent learning rules indeed achieve this optimal d/m rate (up to constant factors), while a distribution-free bound on $\mathbb{E}[\text{er}(\hat{h}_m)]$ with $\Theta(1/m)$ dependence on m is achieved by all consistent learning rules if and only if $\mathfrak{s} < \infty$, and otherwise the best such bound has $\Theta(\text{Log}(m)/m)$ dependence on m .

As a final interesting result, in the context of learning with classification noise, under the *bounded noise assumption* (Massart and Nédélec, 2006), we find that the condition $\mathfrak{s} < \infty$ is actually *necessary and sufficient* for the *minimax optimal* excess error rate to decrease at a rate $\Theta(1/m)$, and otherwise (if $\mathfrak{s} = \infty$) it decreases at a rate $\Theta(\text{Log}(m)/m)$. This result generalizes several special-case analyses from the literature (Massart and Nédélec, 2006; Raginsky and Rakhlin, 2011). Note that the “necessity” part of this statement is significantly stronger than the above result for consistent learning rules in the realizable case, since this result applies to the best error guarantee achievable by *any* learning rule.

2. Bounds for Consistent Monotone Learning

In order to state our results for monotonic learning rules in an abstract form, we introduce the following notation. Let \mathcal{Z} denote any space, equipped with a σ -algebra defining the measurable subsets. For any collection \mathcal{A} of measurable subsets of \mathcal{Z} , a *consistent monotone rule* is any sequence of functions $\psi_t : \mathcal{Z}^t \rightarrow \mathcal{A}$, $t \in \mathbb{N}$, such that $\forall z_1, z_2, \dots \in \mathcal{Z}$, $\forall t \in \mathbb{N}$, $\psi_t(z_1, \dots, z_t) \cap \{z_1, \dots, z_t\} = \emptyset$, and $\forall t \in \mathbb{N}$, $\psi_{t+1}(z_1, \dots, z_{t+1}) \subseteq \psi_t(z_1, \dots, z_t)$. We begin with the following very simple result, the proof of which will also serve to introduce, in its simplest form, the core technique underlying many of the results presented in later sections below.

Theorem 1 Let \mathcal{A} be a collection of measurable subsets of \mathcal{Z} , and let $\psi_t : \mathcal{Z}^t \rightarrow \mathcal{A}$ (for $t \in \mathbb{N}$) be any consistent monotone rule. Fix any $m \in \mathbb{N}$, any $\delta \in (0, 1)$, and any probability measure P on \mathcal{Z} . Letting Z_1, \dots, Z_m be independent P -distributed random variables, and denoting $A_m = \psi_m(Z_1, \dots, Z_m)$, with probability at least $1 - \delta$,

$$P(A_m) \leq \frac{4}{m} \left(17\text{vc}(\mathcal{A}) + 4 \ln \left(\frac{4}{\delta} \right) \right). \quad (6)$$

Furthermore,

$$\mathbb{E}[P(A_m)] \leq \frac{68(\text{vc}(\mathcal{A}) + 1)}{m}. \quad (7)$$

The overall structure of this proof is based on an argument of Hanneke (2009). The most-significant novel element here is the use of monotonicity to further refine a logarithmic factor. The proof relies on the following classic result. Results of this type are originally due to Vapnik and Chervonenkis (1974); the version stated here features slightly better constant factors, due to Blumer, Ehrenfeucht, Haussler, and Warmuth (1989).

Lemma 2 For any collection \mathcal{A} of measurable subsets of \mathcal{Z} , any $\delta \in (0, 1)$, any $m \in \mathbb{N}$, and any probability measure P on \mathcal{Z} , letting Z_1, \dots, Z_m be independent P -distributed random variables, with probability at least $1 - \delta$, every $A \in \mathcal{A}$ with $A \cap \{Z_1, \dots, Z_m\} = \emptyset$ satisfies

$$P(A) \leq \frac{2}{m} \left(\text{vc}(\mathcal{A}) \text{Log}_2 \left(\frac{2em}{\text{vc}(\mathcal{A})} \right) + \text{Log}_2 \left(\frac{2}{\delta} \right) \right).$$

We are now ready for the proof of Theorem 1.

Proof of Theorem 1 Fix any probability measure P , let Z_1, Z_2, \dots be independent P -distributed random variables, and for each $m \in \mathbb{N}$ denote $A_m = \psi_m(Z_1, \dots, Z_m)$. We begin with the inequality in (6). The proof proceeds by induction on m . If $m \leq 200$, then since $\log_2(400e) < 34$ and $\log_2(\frac{2}{\delta}) < 8 \ln(\frac{4}{\delta})$, and since the definition of a consistent monotone rule implies $A_m \cap \{Z_1, \dots, Z_m\} = \emptyset$, the stated bound follows immediately from Lemma 2 for any $\delta \in (0, 1)$. Now, as an inductive hypothesis, fix any integer $m \geq 201$ such that, $\forall m' \in [m-1]$, $\forall \delta \in (0, 1)$, with probability at least $1 - \delta$,

$$P(A_{m'}) \leq \frac{4}{m'} \left(17\text{vc}(\mathcal{A}) + 4 \ln \left(\frac{4}{\delta} \right) \right).$$

Now fix any $\delta \in (0, 1)$ and define

$$N = |\{Z_{[m/2]+1}, \dots, Z_m\} \cap A_{[m/2]}|,$$

and enumerate the elements of $\{Z_{[m/2]+1}, \dots, Z_m\} \cap A_{[m/2]}$ as $\hat{Z}_1, \dots, \hat{Z}_N$ (retaining their original order).

Note that $N = \sum_{i=[m/2]+1}^m \mathbb{1}_{A_{[m/2]}}(Z_i)$ is conditionally Binomial($[m/2]$, $P(A_{[m/2]})$)-distributed given $Z_1, \dots, Z_{[m/2]}$. In particular, with probability one, if $P(A_{[m/2]}) = 0$, then $N = 0$. Otherwise, if $P(A_{[m/2]}) > 0$, then note that Z_1, \dots, Z_N are conditionally independent and $P(\cdot | A_{[m/2]})$ -distributed given $Z_1, \dots, Z_{[m/2]}$ and N . Thus, since $A_m \cap \{\hat{Z}_1, \dots, \hat{Z}_N\} \subseteq A_m \cap \{Z_1, \dots, Z_m\} = \emptyset$, applying Lemma 2 (under the conditional

distribution given N and $Z_1, \dots, Z_{[m/2]}$), combined with the law of total probability, we have that on an event E_1 of probability at least $1 - \delta/2$, if $N > 0$, then

$$P(A_m | A_{[m/2]}) \leq \frac{2}{N} \left(\text{vc}(\mathcal{A}) \text{Log}_2 \left(\frac{2eN}{\text{vc}(\mathcal{A})} \right) + \log_2 \left(\frac{4}{\delta} \right) \right).$$

Additionally, again since N is conditionally Binomial($[m/2]$, $P(A_{[m/2]})$)-distributed given $Z_1, \dots, Z_{[m/2]}$, applying a Chernoff bound (under the conditional distribution given $Z_1, \dots, Z_{[m/2]}$), combined with the law of total probability, we obtain that on an event E_2 of probability at least $1 - \delta/4$, if $P(A_{[m/2]}) \geq \frac{16}{m} \ln(\frac{4}{\delta})$, then

$$N \geq P(A_{[m/2]}) \lceil m/2 \rceil / 2 \geq P(A_{[m/2]}) m / 4.$$

In particular, if $P(A_{[m/2]}) \geq \frac{16}{m} \ln(\frac{4}{\delta})$, then $P(A_{[m/2]}) m / 4 > 0$, so that if this occurs with E_2 , then we have $N > 0$. Noting that $\text{Log}_2(x) \leq \text{Log}(x) / \ln(2)$, then by monotonicity of $x \mapsto \text{Log}(x)/x$ for $x > 0$, we have that on $E_1 \cap E_2$, if $P(A_{[m/2]}) \geq \frac{16}{m} \ln(\frac{4}{\delta})$, then

$$P(A_m | A_{[m/2]}) \leq \frac{8}{P(A_{[m/2]}) m \ln(2)} \left(\text{vc}(\mathcal{A}) \text{Log} \left(\frac{eP(A_{[m/2]}) m}{2\text{vc}(\mathcal{A})} \right) + \ln \left(\frac{4}{\delta} \right) \right).$$

The monotonicity property of ψ_t implies $A_m \subseteq A_{[m/2]}$. Together with monotonicity of probability measures, this implies $P(A_m) \leq P(A_{[m/2]})$. It also implies that, if $P(A_{[m/2]}) > 0$, then $P(A_m) = P(A_m | A_{[m/2]}) P(A_{[m/2]})$. Thus, on $E_1 \cap E_2$, if $P(A_m) \geq \frac{16}{m} \ln(\frac{4}{\delta})$, then

$$P(A_m) \leq \frac{8}{m \ln(2)} \left(\text{vc}(\mathcal{A}) \text{Log} \left(\frac{eP(A_{[m/2]}) m}{2\text{vc}(\mathcal{A})} \right) + \ln \left(\frac{4}{\delta} \right) \right).$$

The inductive hypothesis implies that, on an event E_3 of probability at least $1 - \delta/4$,

$$P(A_{[m/2]}) \leq \frac{4}{\lceil m/2 \rceil} \left(17\text{vc}(\mathcal{A}) + 4 \ln \left(\frac{16}{\delta} \right) \right).$$

Since $m \geq 201$, we have $\lceil m/2 \rceil \geq (m-2)/2 \geq (199/402)m$, so that the above implies

$$P(A_{[m/2]}) \leq \frac{4 \cdot 402}{199m} \left(17\text{vc}(\mathcal{A}) + 4 \ln \left(\frac{16}{\delta} \right) \right).$$

Thus, on $E_1 \cap E_2 \cap E_3$, if $P(A_m) \geq \frac{16}{m} \ln(\frac{4}{\delta})$, then

$$P(A_m) \leq \frac{8}{m \ln(2)} \left(\text{vc}(\mathcal{A}) \text{Log} \left(\frac{2 \cdot 402e}{199} \left(17 + \frac{4}{\text{vc}(\mathcal{A})} \ln \left(\frac{16}{\delta} \right) \right) \right) + \ln \left(\frac{4}{\delta} \right) \right).$$

Lemma 20 in Appendix A allows us to simplify the logarithmic term here, revealing that the right hand side is at most

$$\begin{aligned} & \frac{8}{m \ln(2)} \left(\text{vc}(\mathcal{A}) \text{Log} \left(\frac{2 \cdot 402e}{199} \left(17 + 4 \ln(4) + \frac{4}{\ln(4/e)} \right) \right) + \left(1 + \ln \left(\frac{4}{e} \right) \right) \ln \left(\frac{4}{\delta} \right) \right) \\ & \leq \frac{4}{m} \left(17\text{vc}(\mathcal{A}) + 4 \ln \left(\frac{4}{\delta} \right) \right). \end{aligned}$$

Since $\frac{16}{m} \ln(\frac{4}{\delta}) \leq \frac{4}{m} (17\text{vc}(\mathcal{A}) + 4 \ln(\frac{4}{\delta}))$, we have that, on $E_1 \cap E_2 \cap E_3$, regardless of whether or not $P(A_m) \geq \frac{16}{m} \ln(\frac{4}{\delta})$, we have

$$P(A_m) \leq \frac{4}{m} \left(17\text{vc}(\mathcal{A}) + 4 \ln\left(\frac{4}{\delta}\right) \right).$$

Noting that, by the union bound, the event $E_1 \cap E_2 \cap E_3$ has probability at least $1 - \delta$, this extends the inductive hypothesis to $m' = m$. By the principle of induction, this completes the proof of the first claim in Theorem 1.

For the bound on the expectation in (7), we note that, letting $\varepsilon_m = \frac{4}{m} (17\text{vc}(\mathcal{A}) + 4 \ln(\frac{4}{\delta}))$, by setting the bound in (6) equal to a value ε and solving for δ , the value of which is in $(0, 1)$ for any $\varepsilon > \varepsilon_m$, the result just established can be restated as: $\forall \varepsilon > \varepsilon_m$,

$$\mathbb{P}(P(A_m) > \varepsilon) \leq 4 \exp\{(17/4)\text{vc}(\mathcal{A}) - \varepsilon m/16\}.$$

Furthermore, for any $\varepsilon \leq \varepsilon_m$, we of course still have $\mathbb{P}(P(A_m) > \varepsilon) \leq 1$. Therefore, we have that

$$\begin{aligned} \mathbb{E}[P(A_m)] &= \int_0^\infty \mathbb{P}(P(A_m) > \varepsilon) d\varepsilon \leq \varepsilon_m + \int_{\varepsilon_m}^\infty 4 \exp\{(17/4)\text{vc}(\mathcal{A}) - \varepsilon m/16\} d\varepsilon \\ &= \varepsilon_m + \frac{4 \cdot 16}{m} \exp\{(17/4)\text{vc}(\mathcal{A}) - \varepsilon_m m/16\} = \frac{4}{m} (17\text{vc}(\mathcal{A}) + 4 \ln(\frac{4}{\delta})) + \frac{16}{m} \\ &= \frac{4}{m} (17\text{vc}(\mathcal{A}) + 4 \ln(\frac{4}{\delta})) \leq \frac{68\text{vc}(\mathcal{A}) + 39}{m} \leq \frac{68\text{vc}(\mathcal{A}) + 1}{m}. \end{aligned}$$

■

We can also state a variant of Theorem 1 applicable to *sample compression schemes*, which will in fact be more useful for our purposes below. To state this result, we first introduce the following additional terminology. For any $t \in \mathbb{N}$, we say that a function $\psi: \mathcal{Z}^t \rightarrow \mathcal{A}$ is *permutation-invariant* if every $z_1, \dots, z_t \in \mathcal{Z}$ and every bijection $\kappa: [t] \rightarrow [t]$ satisfy $\psi(z_{\kappa(1)}, \dots, z_{\kappa(t)}) = \psi(z_1, \dots, z_t)$. For any $n \in \mathbb{N} \cup \{0\}$, a *consistent monotone sample compression rule of size n* is a consistent monotone rule ψ_t with the additional properties that, $\forall t \in \mathbb{N}$, ψ_t is permutation-invariant, and $\forall z_1, \dots, z_t \in \mathcal{Z}$, $\exists n_t(z_{[t]}) \in [\min\{n, t\}] \cup \{0\}$ such that

$$\psi_t(z_1, \dots, z_t) = \phi_{t, n_t(z_{[t]})}(z_{i_1(z_{[t]})}, \dots, z_{i_{n_t(z_{[t]})}(z_{[t]})}(z_{[t]}),$$

where $\phi_{t,k}: \mathcal{Z}^k \rightarrow \mathcal{A}$ is a permutation-invariant function for each $k \in [\min\{n, t\}] \cup \{0\}$, and i_1, \dots, i_{n_t} are functions $\mathcal{Z}^t \rightarrow [t]$ such that $\forall z_1, \dots, z_t \in \mathcal{Z}$, $i_{1,1}(z_{[t]}), \dots, i_{t, n_t}(z_{[t]})(z_{[t]})$ are all distinct. In words, the element of \mathcal{A} mapped to by $\psi_t(z_1, \dots, z_t)$ depends only on the unordered (multi)set $\{z_1, \dots, z_t\}$, and can be specified by an unordered subset of $\{z_1, \dots, z_t\}$ of size at most n . Following the terminology from the literature on sample compression schemes, we refer to the collection of functions $\{(n_t, i_{1,1}, \dots, i_{t, n_t}) : t \in \mathbb{N}\}$ as the *compression function* of ψ_t , and to the collection of permutation-invariant functions $\{\phi_{t,k} : t \in \mathbb{N}, k \in [\min\{n, t\}] \cup \{0\}\}$ as the *reconstruction function* of ψ_t .

This kind of ψ_t is a type of sample compression scheme (see Littlestone and Warmuth, 1986; Floyd and Warmuth, 1995), though certainly not all permutation-invariant compression schemes yield consistent monotone rules. Below, we find that consistent monotone

sample compression rules of a quantifiable size arise naturally in the analysis of certain learning algorithms (namely, the Closure algorithm and the CAL active learning algorithm). With the above terminology in hand, we can now state our second abstract result.

Theorem 3 Fix any $n \in \mathbb{N} \cup \{0\}$, let \mathcal{A} be a collection of measurable subsets of \mathcal{Z} , and let $\psi_t: \mathcal{Z}^t \rightarrow \mathcal{A}$ (for $t \in \mathbb{N}$) be any consistent monotone sample compression rule of size n . Fix any $m \in \mathbb{N}$, $\delta \in (0, 1)$, and any probability measure P on \mathcal{Z} . Letting Z_1, \dots, Z_m be independent P -distributed random variables, and denoting $A_m = \psi_m(Z_1, \dots, Z_m)$, with probability at least $1 - \delta$,

$$P(A_m) \leq \frac{1}{m} \left(21n + 16 \ln\left(\frac{3}{\delta}\right) \right). \quad (8)$$

Furthermore,

$$\mathbb{E}[P(A_m)] \leq \frac{21n + 34}{m}. \quad (9)$$

The proof of Theorem 3 relies on the following classic result due to Littlestone and Warmuth (1986); Floyd and Warmuth (1995) (see also Herbrich, 2002; Wiener, Hanneke, and El-Yaniv, 2015, for a clear and direct proof).

Lemma 4 Fix any collection \mathcal{A} of measurable subsets of \mathcal{Z} , any $m \in \mathbb{N}$ and $n \in \mathbb{N} \cup \{0\}$ with $n < m$, and any permutation-invariant functions $\phi_k: \mathcal{Z}^k \rightarrow \mathcal{A}$, $k \in [n] \cup \{0\}$. For any probability measure P on \mathcal{Z} , letting Z_1, \dots, Z_m be independent P -distributed random variables, for any $\delta \in (0, 1)$, with probability at least $1 - \delta$, every $k \in [n] \cup \{0\}$, and every distinct $i_1, \dots, i_k \in [m]$ with $\phi_k(Z_{i_1}, \dots, Z_{i_k}) \cap \{Z_1, \dots, Z_m\} = \emptyset$ satisfy

$$P(\phi_k(Z_{i_1}, \dots, Z_{i_k})) \leq \frac{1}{m-n} \left(n \text{Log}\left(\frac{em}{n}\right) + \text{Log}\left(\frac{1}{\delta}\right) \right).$$

With this lemma in hand, we are ready for the proof of Theorem 3.

Proof of Theorem 3 The proof follows analogously to that of Theorem 1, but with several additional complications due to the form of Lemma 4 being somewhat different from that of Lemma 2. Let $\{(n_t, i_{1,1}, \dots, i_{t, n_t}) : t \in \mathbb{N}\}$ and $\{\phi_{t,k} : t \in \mathbb{N}, k \in [\min\{n, t\}] \cup \{0\}\}$ be the compression function and reconstruction function of ψ_t , respectively. For convenience, also denote $\psi_0() = \mathcal{Z}$, and note that this extends the monotonicity property of ψ_t to $t \in \mathbb{N} \cup \{0\}$. Fix any probability measure P , let Z_1, Z_2, \dots be independent P -distributed random variables, and for each $m \in \mathbb{N}$ denote $A_m = \psi_m(Z_1, \dots, Z_m)$.

We begin with the inequality in (8). The special case of $n = 0$ is directly implied by Lemma 4, so for the remainder of the proof of (8), we suppose $n \geq 1$. The proof proceeds by induction on m . Since $P(A) \leq 1$ for all $A \in \mathcal{A}$, and since $21 + 16 \ln(3) > 38$, the stated bound is trivially satisfied for all $\delta \in (0, 1)$ if $m \leq \max\{38, 21n\}$. Now, as an inductive hypothesis, fix any integer $m > \max\{38, 21n\}$ such that, $\forall m' \in [m-1]$, $\forall \delta \in (0, 1)$, with probability at least $1 - \delta$,

$$P(A_{m'}) \leq \frac{1}{m'} \left(21m' + 16 \ln\left(\frac{3}{\delta}\right) \right).$$

Fix any $\delta \in (0, 1)$ and define

$$N = \left\lfloor \left\{ Z_{\lfloor m/2 \rfloor + 1}, \dots, Z_m \right\} \cap A_{\lfloor m/2 \rfloor} \right\rfloor,$$

and enumerate the elements of $\{Z_{\lfloor m/2 \rfloor + 1}, \dots, Z_m\} \cap A_{\lfloor m/2 \rfloor}$ as $\hat{Z}_1, \dots, \hat{Z}_N$. Also enumerate the elements of $\{Z_{\lfloor m/2 \rfloor + 1}, \dots, Z_m\} \setminus A_{\lfloor m/2 \rfloor}$ as $\hat{Z}'_1, \dots, \hat{Z}'_{\lfloor m/2 \rfloor - N}$. Now note that, by the monotonicity property of ψ_t , we have $A_m \subseteq A_{\lfloor m/2 \rfloor}$. Furthermore, by permutation-invariance of ψ_t , we have that

$$A_m = \psi_m \left(\hat{Z}_1, \dots, \hat{Z}_N, Z_1, \dots, Z_{\lfloor m/2 \rfloor}, \hat{Z}'_1, \dots, \hat{Z}'_{\lfloor m/2 \rfloor - N} \right).$$

Combined with the monotonicity property of ψ_t , this implies that $A_m \subseteq \psi_N \left(\hat{Z}_1, \dots, \hat{Z}_N \right)$. Altogether, we have that

$$A_m \subseteq A_{\lfloor m/2 \rfloor} \cap \psi_N \left(\hat{Z}_1, \dots, \hat{Z}_N \right). \quad (10)$$

Note that $N = \sum_{i=\lfloor m/2 \rfloor + 1}^m \mathbb{1}_{A_{\lfloor m/2 \rfloor}}(Z_i)$ is conditionally Binomial($\lfloor m/2 \rfloor, P(A_{\lfloor m/2 \rfloor})$)-distributed given $Z_1, \dots, Z_{\lfloor m/2 \rfloor}$. In particular, with probability one, if $P(A_{\lfloor m/2 \rfloor}) = 0$, then $N = 0 \leq n$. Otherwise, if $P(A_{\lfloor m/2 \rfloor}) > 0$, then note that $\hat{Z}_1, \dots, \hat{Z}_N$ are conditionally independent and $P(\cdot | A_{\lfloor m/2 \rfloor})$ -distributed given N and $Z_1, \dots, Z_{\lfloor m/2 \rfloor}$. Since ψ_t is a consistent monotone rule, we have that $\psi_N(\hat{Z}_1, \dots, \hat{Z}_N) \cap \{\hat{Z}'_1, \dots, \hat{Z}'_N\} = \emptyset$. We also have, by definition of ψ_N , that $\psi_N(\hat{Z}_1, \dots, \hat{Z}_N) = \phi_{N, n, N}(\hat{Z}_N) \left(\hat{Z}_{i_{N,1}(\hat{Z}_N)}, \dots, \hat{Z}_{i_{N,n}(\hat{Z}_N)}(\hat{Z}_N) \right)$. Thus, applying Lemma 4 (under the conditional distribution given N and $Z_1, \dots, Z_{\lfloor m/2 \rfloor}$), combined with the law of total probability, we have that on an event E_1 of probability at least $1 - \delta/3$, if $N > n$, then

$$P \left(\psi_N \left(\hat{Z}_1, \dots, \hat{Z}_N \right) \middle| A_{\lfloor m/2 \rfloor} \right) \leq \frac{1}{N-n} \left(n \ln \left(\frac{eN}{n} \right) + \ln \left(\frac{3}{\delta} \right) \right).$$

Combined with (10) and monotonicity of measures, this implies that on E_1 , if $N > n$, then

$$\begin{aligned} P(A_m) &\leq P \left(A_{\lfloor m/2 \rfloor} \cap \psi_N \left(\hat{Z}_1, \dots, \hat{Z}_N \right) \right) = P \left(A_{\lfloor m/2 \rfloor} \cap \psi_N \left(\hat{Z}_1, \dots, \hat{Z}_N \right) \middle| A_{\lfloor m/2 \rfloor} \right) \\ &\leq P \left(A_{\lfloor m/2 \rfloor} \right) \frac{1}{N-n} \left(n \ln \left(\frac{eN}{n} \right) + \ln \left(\frac{3}{\delta} \right) \right). \end{aligned}$$

Additionally, again since N is conditionally Binomial($\lfloor m/2 \rfloor, P(A_{\lfloor m/2 \rfloor})$)-distributed given $Z_1, \dots, Z_{\lfloor m/2 \rfloor}$, applying a Chernoff bound (under the conditional distribution given $Z_1, \dots, Z_{\lfloor m/2 \rfloor}$), combined with the law of total probability, we obtain that on an event E_2 of probability at least $1 - \delta/3$, if $P(A_{\lfloor m/2 \rfloor}) \geq \frac{16}{m} \ln \left(\frac{3}{\delta} \right) \geq \frac{8}{\lfloor m/2 \rfloor} \ln \left(\frac{3}{\delta} \right)$, then

$$N \geq P(A_{\lfloor m/2 \rfloor}) \lfloor m/2 \rfloor / 2 \geq P(A_{\lfloor m/2 \rfloor}) m / 4.$$

Also note that if $P(A_m) \geq \frac{1}{m} (21n + 16 \ln \left(\frac{3}{\delta} \right))$, then (10) and monotonicity of probability measures imply $P(A_{\lfloor m/2 \rfloor}) \geq \frac{1}{m} (21n + 16 \ln \left(\frac{3}{\delta} \right))$ as well. In particular, if this occurs with

E_2 , then we have $N \geq P(A_{\lfloor m/2 \rfloor}) m / 4 > 5n$. Thus, by monotonicity of $x \mapsto \text{Log}(x)/x$ for $x > 0$, we have that on $E_1 \cap E_2$, if $P(A_m) \geq \frac{1}{m} (21n + 16 \ln \left(\frac{3}{\delta} \right))$, then

$$\begin{aligned} P(A_m) &< P(A_{\lfloor m/2 \rfloor}) \frac{1}{N - (N/5)} \left(n \text{Log} \left(\frac{eN}{n} \right) + \ln \left(\frac{3}{\delta} \right) \right) \\ &\leq \frac{5}{m} \left(n \text{Log} \left(\frac{eP(A_{\lfloor m/2 \rfloor}) m}{4n} \right) + \ln \left(\frac{3}{\delta} \right) \right). \end{aligned}$$

The inductive hypothesis implies that, on an event E_3 of probability at least $1 - \delta/3$,

$$P(A_{\lfloor m/2 \rfloor}) \leq \frac{1}{\lfloor m/2 \rfloor} \left(21n + 16 \ln \left(\frac{9}{\delta} \right) \right).$$

Since $m \geq 39$, we have $\lfloor m/2 \rfloor \geq (m-2)/2 \geq (37/78)m$, so that the above implies

$$P(A_{\lfloor m/2 \rfloor}) \leq \frac{78}{37m} \left(21n + 16 \ln \left(\frac{9}{\delta} \right) \right).$$

Thus, on $E_1 \cap E_2 \cap E_3$, if $P(A_m) \geq \frac{1}{m} (21n + 16 \ln \left(\frac{3}{\delta} \right))$, then

$$\begin{aligned} P(A_m) &< \frac{5}{m} \left(n \text{Log} \left(\frac{78e}{4 \cdot 37} \left(21 + \frac{16}{n} \ln \left(\frac{9}{\delta} \right) \right) \right) + \ln \left(\frac{3}{\delta} \right) \right) \\ &\leq \frac{5}{m} \left(n \text{Log} \left(\frac{78 \cdot 20}{37 \cdot 11} \left(\frac{21 \cdot 11e}{16 \cdot 5} + \frac{11e}{5} \ln(3) + \frac{11e}{5n} \ln \left(\frac{3}{\delta} \right) \right) \right) + \ln \left(\frac{3}{\delta} \right) \right). \end{aligned}$$

By Lemma 20 in Appendix A, this last expression is at most

$$\begin{aligned} &\frac{5}{m} \left(n \text{Log} \left(\frac{78 \cdot 20}{37 \cdot 11} \left(\frac{21 \cdot 11e}{16 \cdot 5} + \frac{11e}{5} \ln(3) + e \right) \right) + \frac{16}{5} \ln \left(\frac{3}{\delta} \right) \right) < \frac{1}{m} \left(21n + 16 \ln \left(\frac{3}{\delta} \right) \right), \\ &\text{contradicting the condition } P(A_m) \geq \frac{1}{m} (21n + 16 \ln \left(\frac{3}{\delta} \right)). \text{ Therefore, on } E_1 \cap E_2 \cap E_3, \\ &P(A_m) < \frac{1}{m} \left(21n + 16 \ln \left(\frac{3}{\delta} \right) \right). \end{aligned}$$

Noting that, by the union bound, the event $E_1 \cap E_2 \cap E_3$ has probability at least $1 - \delta$, this extends the inductive hypothesis to $m' = m$. By the principle of induction, this completes the proof of the first claim in Theorem 3.

For the bound on the expectation in (9), we note that (as in the proof of Theorem 1), letting $\varepsilon_m = \frac{1}{m} (21n + 16 \ln(3))$, the result just established can be restated as: $\forall \varepsilon > \varepsilon_m$,

$$\mathbb{P}(P(A_m) > \varepsilon) \leq 3 \exp \{ (21/16)n - \varepsilon m / 16 \}.$$

Specifically, this is obtained by setting the bound in (8) equal to ε and solving for δ , the value of which is in $(0, 1)$ for any $\varepsilon > \varepsilon_m$. Furthermore, for any $\varepsilon \leq \varepsilon_m$, we of course still have $\mathbb{P}(P(A_m) > \varepsilon) \leq 1$. Therefore, we have that

$$\begin{aligned} \mathbb{E}[P(A_m)] &= \int_0^\infty \mathbb{P}(P(A_m) > \varepsilon) d\varepsilon \leq \varepsilon_m + \int_{\varepsilon_m}^\infty 3 \exp \{ (21/16)n - \varepsilon m / 16 \} d\varepsilon \\ &= \varepsilon_m + \frac{3 \cdot 16}{m} \exp \{ (21/16)n - \varepsilon_m m / 16 \} = \frac{1}{m} (21n + 16 \ln(3)) + \frac{16}{m} \\ &= \frac{1}{m} (21n + 16 \ln(3e)) \leq \frac{21n + 34}{m}. \quad \blacksquare \end{aligned}$$

3. Application to the Closure Algorithm for Intersection-Closed Classes

One family of concept spaces studied in the learning theory literature, due to their interesting special properties, is the *intersection-closed* classes (Natarajan, 1987; Helmbold, Sloan, and Warmuth, 1990; Haussler, Littlestone, and Warmuth, 1994; Kuhlmann, 1999; Auer and Ortner, 2007). Specifically, the class \mathbb{C} is called *intersection-closed* if the collection of sets $\{(x : h(x) = +1) : h \in \mathbb{C}\}$ is closed under intersections: that is, for every $h, g \in \mathbb{C}$, the classifier $x \mapsto 2\mathbb{1}[h(x) = g(x)] - 1$ is also contained in \mathbb{C} . For instance, the class of conjunctions on $\{0, 1\}^d$, the class of axis-aligned rectangles on \mathbb{R}^d , and the class $\{h : |\{x : h(x) = +1\}| \leq d\}$ of classifiers labeling at most d points positive, are all intersection-closed.

In the context of learning in the realizable case, there is a general learning strategy, called the *Closure* algorithm, designed for learning with intersection-closed concept spaces, which has been a subject of frequent study. Specifically, for any $m \in \mathbb{N} \cup \{0\}$, given any data set $L_m = \{(x_1, y_1), \dots, (x_m, y_m)\} \in (\mathcal{X} \times \mathcal{Y})^m$ with $\mathbb{C}[L_m] \neq \emptyset$, the Closure algorithm $\mathbb{A}(L_m)$ for \mathbb{C} produces the classifier $\hat{h}_m : \mathcal{X} \rightarrow \mathcal{Y}$ with $\{x : \hat{h}_m(x) = +1\} = \bigcap_{h \in \mathbb{C}[L_m]} \{x : h(x) = +1\}$: that is, $\hat{h}_m(x) = +1$ if and only if every $h \in \mathbb{C}$ consistent with L_m (i.e., $\text{er}_{L_m}(h) = 0$) has $h(x) = +1$.¹ Defining $\bar{\mathbb{C}}$ as the set of all classifiers $h : \mathcal{X} \rightarrow \mathcal{Y}$ for which there exists a nonempty $\mathcal{G} \subseteq \mathbb{C}$ with $\{x : h(x) = +1\} = \bigcap_{g \in \mathcal{G}} \{x : g(x) = +1\}$, Auer and Ortner (2007) have argued that $\bar{\mathbb{C}}$ is an intersection-closed concept space containing \mathbb{C} , with $\text{vc}(\bar{\mathbb{C}}) = \text{vc}(\mathbb{C})$. Thus, for $\hat{h}_m = \mathbb{A}(L_m)$ (where \mathbb{A} is the Closure algorithm), since $\hat{h}_m \in \bar{\mathbb{C}}[L_m]$, Lemma 2 immediately implies that, for any $m \in \mathbb{N}$, with probability at least $1 - \delta$, $\text{er}(\hat{h}_m) \lesssim \frac{1}{m}(d \text{Log}(\frac{m}{\delta}) + \text{Log}(\frac{1}{\delta}))$. However, by a more-specialized analysis, Auer and Ortner (2004, 2007) were able to show that, for intersection-closed classes \mathbb{C} , the Closure algorithm in fact achieves $\text{er}(\hat{h}_m) \lesssim \frac{1}{m}(d \text{Log}(d) + \text{Log}(\frac{1}{\delta}))$ with probability at least $1 - \delta$, which is an improvement for large m . They also argued that, for a special subfamily of intersection-closed classes (namely, those with *homogeneous spans*), this bound can be further refined to $\frac{1}{m}(d + \text{Log}(\frac{1}{\delta}))$, which matches (up to constant factors) the lower bound (2). However, they left open the question of whether this refinement is achievable for general intersection-closed concept spaces (by Closure, or any other algorithm).

In the following result, we prove that the Closure algorithm indeed always achieves the optimal bound (up to constant factors) for intersection-closed concept spaces, as a simple consequence of either Theorem 1 or Theorem 3. This fact was very recently also obtained by Darstadt (2015) via a related direct approach; however, we note that the constant factors obtained here are significantly smaller (by roughly a factor of 15.5, for large d).

Theorem 5 *If \mathbb{C} is intersection-closed and \mathbb{A} is the Closure algorithm, then for any $m \in \mathbb{N}$ and $\delta \in (0, 1)$, letting $\hat{h}_m = \mathbb{A}(\{(X_1, f^*(X_1)), \dots, (X_m, f^*(X_m))\})$, with probability at least $1 - \delta$,*

$$\text{er}(\hat{h}_m) \leq \frac{1}{m} \left(21d + 16 \ln \left(\frac{3}{\delta} \right) \right).$$

1. For simplicity, we suppose \mathbb{C} is such that this set $\bigcap_{h \in \mathbb{C}[L_m]} \{x : h(x) = +1\}$ is measurable for every L_m , which is the case for essentially all intersection-closed concept spaces of practical interest.

Furthermore,

$$\mathbb{E} \left[\text{er}(\hat{h}_m) \right] \leq \frac{21d + 34}{m}.$$

Proof For each $t \in \mathbb{N} \cup \{0\}$ and $x_1, \dots, x_t \in \mathcal{X}$, define $\psi_t(x_1, \dots, x_t) = \{x \in \mathcal{X} : \hat{h}_{x_{[t]}}(x) \neq f^*(x)\}$, where $\hat{h}_{x_{[t]}} = \mathbb{A}(\{(x_1, f^*(x_1)), \dots, (x_t, f^*(x_t))\})$. Fix any $x_1, x_2, \dots \in \mathcal{X}$, let $L_t = \{(x_1, f^*(x_1)), \dots, (x_t, f^*(x_t))\}$ for each $t \in \mathbb{N}$, and note that for any $t \in \mathbb{N}$, the classifier $\hat{h}_{x_{[t]}}$ produced by $\mathbb{A}(L_t)$ is consistent with L_t , which implies $\psi_t(x_1, \dots, x_t) \cap \{x_1, \dots, x_t\} = \emptyset$. Furthermore, since $f^* \in \mathbb{C}[L_t]$, we have that $\{x : \hat{h}_{x_{[t]}}(x) = +1\} \subseteq \{x : f^*(x) = +1\}$, which together with the definition of $\hat{h}_{x_{[t]}}$ implies

$$\begin{aligned} \psi_t(x_1, \dots, x_t) &= \{x \in \mathcal{X} : \hat{h}_{x_{[t]}}(x) = -1, f^*(x) = +1\} \\ &= \bigcup_{h \in \mathbb{C}[L_t]} \{x \in \mathcal{X} : h(x) = -1, f^*(x) = +1\} \end{aligned} \quad (11)$$

for every $t \in \mathbb{N}$. Furthermore, for any $t \in \mathbb{N}$, $\mathbb{C}[L_{t+1}] \subseteq \mathbb{C}[L_t]$. Together with monotonicity of the union, these two observations imply

$$\begin{aligned} \psi_{t+1}(x_1, \dots, x_{t+1}) &= \bigcup_{h \in \mathbb{C}[L_{t+1}]} \{x \in \mathcal{X} : h(x) = -1, f^*(x) = +1\} \\ &\subseteq \bigcup_{h \in \mathbb{C}[L_t]} \{x \in \mathcal{X} : h(x) = -1, f^*(x) = +1\} = \psi_t(x_1, \dots, x_t). \end{aligned}$$

Thus, ψ_t defines a consistent monotone rule. Also, since \mathbb{A} always produces a function in $\bar{\mathbb{C}}$, we have $\psi_t(x_1, \dots, x_t) \in \{\{x \in \mathcal{X} : h(x) \neq f^*(x)\} : h \in \bar{\mathbb{C}}\}$ for every $t \in \mathbb{N}$, and it is straightforward to show that the VC dimension of this collection of sets is exactly $\text{vc}(\bar{\mathbb{C}})$ (see Vidyasagar, 2003, Lemma 4.12), which Auer and Ortner (2007) have argued equals d . From this, we can already infer a bound $\frac{4}{m}(17d + 4 \ln(\frac{4}{\delta}))$ via Theorem 1. However, we can refine the constant factors in this bound by noting that ψ_t can also be represented as a consistent monotone sample compression rule of size d , and invoking Theorem 3. The rest of this proof focuses on establishing this fact.

Fix any $t \in \mathbb{N}$. It is well known in the literature (see e.g., Auer and Ortner, 2007, Theorem 1) that there exist $k \in [d] \cup \{0\}$ and distinct $i_1, \dots, i_k \in [d]$ such that $f^*(x_{i_j}) = +1$ for all $j \in [k]$, and letting $L_{i_{[k]}} = \{(x_{i_1}, +1), \dots, (x_{i_k}, +1)\}$, we have $\bigcap_{h \in \mathbb{C}[L_{i_{[k]}}]} \{x : h(x) = +1\} = \bigcap_{h \in \mathbb{C}[L_t]} \{x : h(x) = +1\}$; in particular, letting $\hat{h}_{x_{[i_{[k]}}]} = \mathbb{A}(L_{i_{[k]}})$, this implies $\hat{h}_{x_{[i_{[k]}}]} = \hat{h}_{x_{[t]}}$. This further implies $\psi_t(x_1, \dots, x_t) = \psi_k(x_{i_1}, \dots, x_{i_k})$, so that defining the compression function $(n_k(x_{i_{[k]}}), i_{k,1}(x_{i_{[k]}}), \dots, i_{k,n_k}(x_{i_{[k]}})(x_{i_{[k]}})) = (k, i_1, \dots, i_k)$ as above, for each $x_1, \dots, x_t \in \mathcal{X}$, and defining the reconstruction function $\phi_{t,k}(x'_1, \dots, x'_k) = \psi_k(x'_1, \dots, x'_k)$ for each $t \in \mathbb{N}$, $k' \in [d] \cup \{0\}$, and $x'_1, \dots, x'_k \in \mathcal{X}$, we have that $\psi_t(x_1, \dots, x_t) = \phi_{t,n_k(x_{i_{[k]}})}(x_{i_{k,1}(x_{i_{[k]}}), \dots, x_{i_{k,n_k}(x_{i_{[k]}})}(x_{i_{[k]}}))$ for all $t \in \mathbb{N}$ and $x_1, \dots, x_t \in \mathcal{X}$. Furthermore, since $(x_1, \dots, x_t) \mapsto \mathbb{C}(\{(x_1, f^*(x_1)), \dots, (x_t, f^*(x_t))\})$ is invariant to permutations of its arguments, it follows from (11) that ψ_t is permutation-invariant for every $t \in \mathbb{N}$; this also means that, for the choice of $\phi_{t,k'}$ above, the function $\phi_{t,k'}$ is also permutation-invariant. Altogether, we have that ψ_t is a consistent monotone sample compression rule of size d . Thus,

since $\text{er}(\hat{h}_m) = \mathcal{P}(\psi_m(X_1, \dots, X_m))$ for $m \in \mathbb{N}$, the stated result follows directly from Theorem 3 (with $\mathcal{Z} = \mathcal{X}$, $\mathcal{P} = \mathcal{P}$, and ψ defined as above). ■

4. Application to the CAL Active Learning Algorithm

As another interesting application of Theorem 3, we derive an improved bound on the label complexity of a well-studied active learning algorithm, usually referred to as CAL after its authors Cohn, Atlas, and Laderer (1994). Formally, in the active learning protocol, the learning algorithm \mathbb{A} is given access to the *unlabeled* data sequence X_1, X_2, \dots (or some sufficiently-large finite initial segment thereof), and then sequentially requests to observe the labels: that is, it selects an index t_1 and requests to observe the label $f^*(X_{t_1})$, at which time it is permitted access to $f^*(X_{t_1})$; it may then select another index t_2 and request to observe the label $f^*(X_{t_2})$, is then permitted access to $f^*(X_{t_2})$, and so on. This continues until at most some given number n of labels have been requested (called the *label budget*), at which point the algorithm should halt and return a classifier h ; we denote this as $h = \mathbb{A}(n)$ (leaving the dependence on the unlabeled data implicit, for simplicity). We are then interested in characterizing a sufficient size for the budget n so that, with probability at least $1 - \delta$, $\text{er}(h) \leq \epsilon$; this size is known as the *label complexity* of \mathbb{A} .

The CAL active learning algorithm is based on a very elegant and natural principle: never request a label that can be deduced from information already obtained. CAL is defined solely by this principle, employing no additional criteria in its choice of queries. Specifically, the algorithm proceeds by considering randomly-sampled data points one at a time, and to each it applies the above principle, skipping over the labels that can be deduced, and requesting the labels that cannot be. In favorable scenarios, as the number of label requests grows, the frequency of encountering a sample whose label cannot be deduced should diminish. The key to bounding the label complexity of CAL is to characterize the rate at which this frequency shrinks. To further pursue this discussion with rigor, let us define the *region of disagreement* for any set \mathcal{H} of classifiers:

$$\text{DIS}(\mathcal{H}) = \{x \in \mathcal{X} : \exists h, g \in \mathcal{H} \text{ s.t. } h(x) \neq g(x)\}.$$

Then the CAL active learning algorithm is formally defined as follows.

Algorithm: CAL(n)

0. $m \leftarrow 0$, $t \leftarrow 0$, $V_0 \leftarrow \mathcal{C}$
1. While $t < n$ and $m < 2^n$
 2. $m \leftarrow m + 1$
 3. If $X_m \in \text{DIS}(V_{m-1})$
 4. Request label $Y_m = f^*(X_m)$; let $V_m \leftarrow V_{m-1} \setminus \{(X_m, Y_m)\}$, $t \leftarrow t + 1$
 5. Else $V_m \leftarrow V_{m-1}$
 6. Return any $\hat{h} \in V_m$

This algorithm has several attractive properties. One is that, since it only removes classifiers from V_m upon disagreement with f^* , it maintains the invariant that $f^* \in V_m$.

Another property is that, since it maintains $f^* \in V_m$, and it only refrains from requesting a label if every classifier in V_m agrees on the label (and hence agrees with f^* so that requesting the label would not affect V_m anyway), it maintains the invariant that $V_m = \mathcal{C}[\mathcal{L}_m]$, where $\mathcal{L}_m = \{(X_1, f^*(X_1)), \dots, (X_m, f^*(X_m))\}$.

This algorithm has been studied a great deal in the literature (Cohn, Atlas, and Laderer, 1994; Hanneke, 2009, 2011, 2012, 2014; El-Yaniv and Wiener, 2012; Wiener, Hanneke, and El-Yaniv, 2015), and has inspired an entire genre of active learning algorithms referred to as *disagreement-based* (or sometimes as *mellow*), including several methods possessing desirable properties such as robustness to classification noise (e.g., Balcan, Beygelzimer, and Langford, 2006, 2009; Dasgupta, Hsu, and Monteleoni, 2007; Koltchinskii, 2010; Hanneke and Yang, 2012; Hanneke, 2014). There is a substantial literature studying the label complexity of CAL and other disagreement-based active learning algorithms; the interested reader is referred to the recent survey article of Hanneke (2014) for a thorough discussion of this literature. Much of that literature discusses characterizations of the label complexity in terms of a quantity known as the *disagreement coefficient* (Hanneke, 2007b, 2009). However, Wiener, Hanneke, and El-Yaniv (2015) have recently discovered that a quantity known as the *version space compression set size* (a.k.a. *empirical teaching dimension*) can sometimes provide a smaller bound on the label complexity of CAL. Specifically, the following quantity was introduced in the works of El-Yaniv and Wiener (2010); Hanneke (2007a).

Definition 6 For any $m \in \mathbb{N}$ and $\mathcal{L} \in (\mathcal{X} \times \mathcal{Y})^m$, the version space compression set $\hat{\mathcal{C}}_{\mathcal{L}}$ is a smallest subset of \mathcal{L} satisfying $\mathcal{C}[\hat{\mathcal{C}}_{\mathcal{L}}] = \mathcal{C}[\mathcal{L}]$. We then define $\hat{n}(\mathcal{L}) = |\hat{\mathcal{C}}_{\mathcal{L}}|$, the version space compression set size. In the special case $\mathcal{L} = \mathcal{L}_m$, we abbreviate $\hat{n}_m = \hat{n}(\mathcal{L}_m)$. Also define $\hat{n}_{1:m} = \max_{i \in [m]} \hat{n}_i$, and for any $\delta \in (0, 1)$, define $\hat{n}_m(\delta) = \min\{b \in [m] \cup \{0\} : \mathbb{P}(\hat{n}_m \leq b) \geq 1 - \delta\}$ and $\hat{n}_{1:m}(\delta) = \min\{b \in [m] \cup \{0\} : \mathbb{P}(\hat{n}_m \leq b) \geq 1 - \delta\}$.

The recent work of Wiener, Hanneke, and El-Yaniv (2015) studies this quantity for several concept spaces and distributions, and also identifies general relations between \hat{n}_m and the more-commonly studied disagreement coefficient θ of (Hanneke, 2007b, 2009). Specifically, for any $r > 0$, define $\mathcal{B}(f^*, r) = \{h \in \mathcal{C} : \mathcal{P}(x : h(x) \neq f^*(x)) \leq r\}$. Then the disagreement coefficient is defined, for any $r_0 \geq 0$, as

$$\theta(r_0) = \sup_{r > r_0} \frac{\mathcal{P}(\text{DIS}(\mathcal{B}(f^*, r)))}{r} \vee 1.$$

Both $\hat{n}_{1:m}(\delta)$ and $\theta(r_0)$ are complexity measures dependent on f^* and \mathcal{P} . Wiener, Hanneke, and El-Yaniv (2015) relate them by showing that

$$\theta(1/m) \lesssim \hat{n}_{1:m}(1/20) \vee 1, \quad (12)$$

and for general $\delta \in (0, 1)$,²

$$\hat{n}_{1:m}(\delta) \lesssim \theta(d/m) \left(d \text{Log}(\theta(d/m)) + \text{Log} \left(\frac{\text{Log}(m)}{\delta} \right) \right) \text{Log}(m). \quad (13)$$

² The original claim from Wiener, Hanneke, and El-Yaniv (2015) involved a maximum of minimal $(1 - \delta)$ -confidence bounds on \hat{n}_i over $t \in [m]$, but the same proof can be used to establish this slightly stronger claim.

Wiener, Hanneke, and El-Yaniv (2015) prove that, for $\text{CAL}(n)$ to produce \hat{h} with $\text{er}(\hat{h}) \leq \varepsilon$ with probability at least $1 - \delta$, it suffices to take a budget m of size proportional to

$$\left(\max_{m \in [M(\varepsilon, \delta/2)]} \tilde{n}_m(\delta_m) \text{Log} \left(\frac{m}{\tilde{n}_m(\delta_m)} \right) + \text{Log} \left(\frac{\text{Log}(M(\varepsilon, \delta/2))}{\delta} \right) \right) \text{Log}(M(\varepsilon, \delta/2)), \quad (14)$$

where the values $\delta_m \in (0, 1]$ are such that $\sum_{i=0}^{\lfloor \log_2(M(\varepsilon, \delta/2)) \rfloor} \delta_{2^i} \leq \delta/4$, and $M(\varepsilon, \delta/2)$ is the smallest $m \in \mathbb{N}$ for which $\mathbb{P}(\sup_{h \in \mathbb{C}[\mathcal{L}_m]} \text{er}(h) \leq \varepsilon) \geq 1 - \delta/2$; the quantity $M(\varepsilon, \delta)$ is discussed at length below in Section 5. They also argue that this is essentially a *tight* characterization of the label complexity of CAL, up to logarithmic factors.

The key to obtaining this result is establishing an upper bound on $\mathcal{P}(\text{DIS}(V_m))$ as a function of m , where (as in CAL) $V_m = \mathbb{C}[\mathcal{L}_m]$. One basic observation indicating that $\mathcal{P}(\text{DIS}(V_m))$ can be related to the version space compression set size is that, by exchangeability of the X_i random variables,

$$\begin{aligned} \mathbb{E}[\mathcal{P}(\text{DIS}(V_m))] &= \mathbb{E}[\mathbb{1}[X_{m+1} \in \text{DIS}(\mathbb{C}[\mathcal{L}_m])]] \\ &= \frac{1}{m+1} \sum_{i=1}^{m+1} \mathbb{E}[\mathbb{1}[X_i \in \text{DIS}(\mathbb{C}[\mathcal{L}_{m+1} \setminus \{(X_i, f^*(X_i))\}]]]] \\ &\leq \frac{1}{m+1} \sum_{i=1}^{m+1} \mathbb{E}[\mathbb{1}[(X_i, f^*(X_i)) \in \hat{\mathcal{C}}_{\mathcal{L}_{m+1}}]] = \frac{\mathbb{E}[\hat{n}_{m+1}]}{m+1}, \end{aligned}$$

where the inequality is due to the observation that any $X_i \in \text{DIS}(\mathbb{C}[\mathcal{L}_{m+1} \setminus \{(X_i, f^*(X_i))\}])$ is necessarily in the version space compression set $\hat{\mathcal{C}}_{\mathcal{L}_{m+1}}$, and the last equality is by linearity of the expectation. However, obtaining the bound (14) required a more-involved argument from Wiener, Hanneke, and El-Yaniv (2015), to establish a high-confidence bound on $\mathcal{P}(\text{DIS}(V_m))$, rather than a bound on its expectation. Specifically, by combining a perspective introduced by El-Yaniv and Wiener (2010, 2012), with the observation that $\text{DIS}(V_m)$ may be represented as a sample compression scheme of size \hat{n}_m , and invoking Lemma 4, Wiener, Hanneke, and El-Yaniv (2015) prove that, with probability at least $1 - \delta$,

$$\mathcal{P}(\text{DIS}(V_m)) \lesssim \frac{1}{m} \left(\hat{n}_m \text{Log} \left(\frac{m}{\hat{n}_m} \right) + \text{Log} \left(\frac{1}{\delta} \right) \right). \quad (15)$$

In the present work, we are able to entirely eliminate the factor $\text{Log} \left(\frac{m}{\hat{n}_m} \right)$ from the first term, simply by observing that the region $\text{DIS}(V_m)$ is *monotonic* in m . Specifically, by combining this monotonicity observation with the description of $\text{DIS}(V_m)$ as a compression scheme from Wiener, Hanneke, and El-Yaniv (2015), the refined bound follows from arguments similar to the proof of Theorem 3. Formally, we have the following result.

Theorem 7 For any $m \in \mathbb{N}$ and $\delta \in (0, 1)$, with probability at least $1 - \delta$,

$$\mathcal{P}(\text{DIS}(V_m)) \leq \frac{16}{m} \left(2\hat{n}_{1:m} + \ln \left(\frac{3}{\delta} \right) \right).$$

We should note that, while Theorem 7 indeed eliminates a logarithmic factor compared to (15), this refinement is also accompanied by an increase in the complexity measure, replacing \hat{n}_m with $\hat{n}_{1:m}$. This arises from our proof, since (as in the proof of Theorem 3) the argument relies on $\hat{n}_{1:m}$ being a sample compression set size, not just for the full sample, but also for any prefix of the sample. The effect of this increase is largely benign in this context, since the bound (14) on the label complexity of CAL, derived from (15), involves maximization over the sample size anyway.

Although Theorem 7 follows from the same principles as Theorem 3 (i.e., DIS(V_t) being a consistent monotone rule expressible as a sample compression scheme), it does not quite follow as an immediate consequence of Theorem 3, due fact that the size $\hat{n}_{1:m}$ of the sequence of sample compression schemes can vary based on the specific samples (including their *order*). For this reason, we provide a specialized proof of this result in Appendix B, which follows an argument nearly-identical to that of Theorem 3, with only a few minor changes to account for this variability of $\hat{n}_{1:m}$ using special properties of the sets DIS(V_t).

Based on this result, and following precisely the same arguments as Wiener, Hanneke, and El-Yaniv (2015),³ we arrive at the following bound on the label complexity of CAL. For brevity, we omit the proof, referring the interested reader to the original exposition of Wiener, Hanneke, and El-Yaniv (2015) for the details.

Theorem 8 There is a universal constant $c \in (0, \infty)$ such that, for any $\varepsilon, \delta \in (0, 1)$, for any $n \in \mathbb{N}$ with

$$n \geq c \left(\tilde{n}_{1:M(\varepsilon, \delta/2)}(\delta/4) + \text{Log} \left(\frac{\text{Log}(M(\varepsilon, \delta/2))}{\delta} \right) \right) \text{Log}(M(\varepsilon, \delta/2)),$$

with probability at least $1 - \delta$, the classifier $\hat{h}_n = \text{CAL}(n)$ has $\text{er}(\hat{h}_n) \leq \varepsilon$.

It is also possible to state a distribution-free variant of Theorem 7. Specifically, consider the following definition, from Hanneke and Yang (2015).

Definition 9 The star number \mathfrak{s} is the largest integer s such that there exist distinct points $x_1, \dots, x_s \in \mathcal{X}$ and classifiers $h_0, h_1, \dots, h_s \in \mathbb{C}$ with the property that $\forall i \in [s]$, $\text{DIS}(\{h_0, h_i\}) \cap \{x_1, \dots, x_s\} = \{x_i\}$; if no such largest integer exists, define $\mathfrak{s} = \infty$.

The star number is a natural combinatorial complexity measure, corresponding to the largest possible degree in the data-induced one-inclusion graph. Hanneke and Yang (2015) provide several examples of concept spaces exhibiting a variety of values for the star number (though it should be noted that many commonly-used concept spaces have $\mathfrak{s} = \infty$: e.g., linear separators). As a basic relation, one can easily show that $\mathfrak{s} \geq d$. Hanneke and Yang (2015) also relate the star number to many other complexity measures arising in the learning theory literature, including \hat{n}_m . Specifically, they prove that, for every $m \in \mathbb{N}$ and

3. The only small twist is that we replace $\max_{m \leq M(\varepsilon, \delta/2)} \tilde{n}_m(\delta_m)$ from (14) with $\tilde{n}_{1:M(\varepsilon, \delta/2)}(\delta/4)$. As the purpose of these $\tilde{n}_m(\delta_m)$ values in the original proof is to provide bounds on their respective \hat{n}_m values (which in our context, are $\hat{n}_{1:m}$ values), holding simultaneously for all $m = 2^i \in [M(\varepsilon, \delta/2)]$ with probability at least $1 - \delta/4$, the value $\tilde{n}_{1:M(\varepsilon, \delta/2)}(\delta/4)$ can clearly be used instead. If desired, by a union bound we can of course bound $\tilde{n}_{1:M(\varepsilon, \delta/2)}(\delta/4) \leq \max_{m \in [M(\varepsilon, \delta/2)]} \tilde{n}_m(\delta_m)$, for any sequence δ_m in $(0, 1]$ with $\sum_{m \in [M(\varepsilon, \delta/2)]} \delta_m \leq \delta/4$.

$\mathcal{L} \in (\mathcal{X} \times \mathcal{Y})^m$ with $\mathbb{C}[\mathcal{L}] \neq \emptyset$, $\hat{n}(\mathcal{L}) \leq \mathfrak{s}$, with equality in the worst case (over m and \mathcal{L}). Based on this fact, Theorem 3 implies the following result.

Theorem 10 *For any $m \in \mathbb{N}$ and $\delta \in (0, 1)$, with probability at least $1 - \delta$,*

$$P(\text{DIS}(V_m)) \leq \frac{1}{m} \left(21\mathfrak{s} + 16 \ln \binom{3}{\delta} \right).$$

Proof For every $t \in \mathbb{N}$ and $x_1, \dots, x_t \in \mathcal{X}$, define $\psi_t(x_1, \dots, x_t) = \text{DIS}(\mathbb{C}[\mathcal{L}_{x_t}])$, where $\mathcal{L}_{x_t} = \{(x_1, f^*(x_1)), \dots, (x_t, f^*(x_t))\}$; ψ_t is clearly permutation-invariant, and satisfies $\psi_t(x_1, \dots, x_t) \cap \{x_1, \dots, x_t\} = \emptyset$ (since every $h \in \mathbb{C}[\mathcal{L}_{x_t}]$ agrees with f^* on $\{x_1, \dots, x_t\}$). Furthermore, monotonicity of $\mathcal{L} \mapsto \mathbb{C}[\mathcal{L}]$ and $\mathcal{H} \mapsto \text{DIS}(\mathcal{H})$ imply that any $t \in \mathbb{N}$ and $x_1, \dots, x_{t+1} \in \mathcal{X}$ satisfy $\psi_{t+1}(x_1, \dots, x_{t+1}) \subseteq \psi_t(x_1, \dots, x_t)$, so that ψ_t is a consistent monotone rule. Also define $\phi_{t,k}(x_1, \dots, x_k) = \psi_k(x_1, \dots, x_k)$ for any $k \in [t]$ and $x_1, \dots, x_k \in \mathcal{X}$, and $\phi_{t,0}() = \text{DIS}(\mathbb{C})$. Since ψ_k is permutation-invariant for every $k \in [t]$, so is $\phi_{t,k}$. For any $x_1, \dots, x_t \in \mathcal{X}$, from Definition 6, there exist distinct $i_{t,1}(x_t), \dots, i_{t,\hat{n}(\mathcal{L}_{x_t})}(x_t) \in [t]$ such that $\hat{\mathcal{C}}_{\mathcal{L}_{x_t}} = \{(x_{i_{t,j}}(x_t), f^*(x_{i_{t,j}}(x_t))) : j \in \{1, \dots, \hat{n}(\mathcal{L}_{x_t})\}\}$, and since $\mathbb{C}[\hat{\mathcal{C}}_{\mathcal{L}_{x_t}}] = \mathbb{C}[\mathcal{L}_{x_t}]$, it follows that $\phi_{t,\hat{n}(\mathcal{L}_{x_t})}(x_{i_{t,1}}(x_t), \dots, x_{i_{t,\hat{n}(\mathcal{L}_{x_t})}}(x_t)) = \psi_t(x_1, \dots, x_t)$. Thus, since $\hat{n}(\mathcal{L}_{x_t}) \leq \mathfrak{s}$ for all $t \in \mathbb{N}$ (Hanneke and Yang, 2015), ψ_t is a consistent monotone sample compression rule of size \mathfrak{s} . The result immediately follows by applying Theorem 3 with $\mathcal{Z} = \mathcal{X}$, $\mathcal{P} = \mathcal{P}$, and ψ_t as above. ■

As a final implication for CAL, we can also plug the inequality $\hat{n}(\mathcal{L}) \leq \mathfrak{s}$ into the bound from Theorem 8 to reveal that CAL achieves a label complexity upper-bounded by a value proportional to $\mathfrak{s} \log(M(\varepsilon, \delta/2)) + \log \left(\frac{\log(M(\varepsilon, \delta/2))}{\delta} \right) \log(M(\varepsilon, \delta/2))$.

Remark: In addition to the above applications to active learning, it is worth noting that, combined with the work of El-Yaniv and Wiener (2010), the above results also have implications for the setting of *selective classification*: that is, the setting in which, for each $t \in \mathbb{N}$, given access to $(X_1, f^*(X_1)), \dots, (X_{t-1}, f^*(X_{t-1}))$ and X_t , a learning algorithm is required either to make a prediction \hat{Y}_t for $f^*(X_t)$, or to “abstain” from prediction; after each round t , the algorithm is permitted access to the value $f^*(X_t)$. Then the error rate is the probability the prediction \hat{Y}_t is incorrect (conditioned on $X_{[t-1]}$), given that the algorithm chooses to predict, and the *coverage* is the probability on $X_{[t-1]}$ the algorithm chooses to predict, and the *coverage* is the probability on $X_{[t-1]}$ the algorithm explores an extreme variant, called *perfect selective classification*, in which the algorithm is required to only make predictions that will be correct with *certainly* (i.e., for any data sequence x_1, x_2, \dots , the algorithm will never misclassify a point it chooses to predict for). El-Yaniv and Wiener (2010) find that a selective classification algorithm based on principles analogous to the CAL active learning algorithm obtains the optimal coverage among all perfect selective classification algorithms; the essential strategy is to predict only if $X_t \notin \text{DIS}(V_{t-1})$, taking Y_t as the label agreed-upon by every $h \in V_{t-1}$. In particular, this implies that the optimal coverage rate in perfect selective classification, on round t , is $1 - \mathcal{P}(\text{DIS}(V_{t-1}))$. Thus, combined with Theorem 7 or Theorem 10, we can immediately obtain bounds on the optimal coverage rate for perfect selective classification as well: in particular, this typically refines the bound of

El-Yaniv and Wiener (2010) (and a later refinement by Wiener, Hanneke, and El-Yaniv, 2015) by at least a logarithmic factor (though again, it is not a “pure” improvement, as Theorem 7 uses $\hat{n}_{1:m}$ in place of \hat{n}_m).

5. Application to General Consistent PAC Learners

In general, a *consistent learning algorithm* \mathbb{A} is a learning algorithm such that, for any $m \in \mathbb{N}$ and $L \in (\mathcal{X} \times \mathcal{Y})^m$ with $\mathbb{C}[L] \neq \emptyset$, $\mathbb{A}(L)$ produces a classifier \hat{h} consistent with L (i.e., $\hat{h} \in \mathbb{C}[L]$). In the context of learning in the realizable case, this is equivalent to \mathbb{A} being an instance of the well-studied method of *empirical risk minimization*. The study of general consistent learning algorithms focuses on the quantity $\sup_{h \in V_m} \text{er}(h)$, where $V_m = \mathbb{C}[\mathcal{L}_m]$, as above. It is clear that the error rate achieved by any consistent learning algorithm, given \mathcal{L}_m as input, is at most $\sup_{h \in V_m} \text{er}(h)$. Furthermore, it is not hard to see that, for any given \mathcal{P} and $f^* \in \mathbb{C}$, there exist consistent learning rules obtaining error rates arbitrarily close to $\sup_{h \in V_m} \text{er}(h)$, so that obtaining guarantees on the error rate that hold *generally* for all consistent learning algorithms requires us to bound this value.

Based on Lemma 2 (taking $\mathcal{A} = \{x : h(x) \neq f^*(x)\} : h \in \mathbb{C}\}$), one immediately obtains a classic result (due to Vapnik and Chervonenkis, 1974; Blumer, Ehrenfeucht, Haussler, and Warmuth, 1989), that with probability at least $1 - \delta$,

$$\sup_{h \in V_m} \text{er}(h) \lesssim \frac{1}{m} \left(d \log \left(\frac{m}{d} \right) + \log \left(\frac{1}{\delta} \right) \right).$$

This has been refined by Giné and Koltchinskii (2006),⁴ who argue that, with probability at least $1 - \delta$,

$$\sup_{h \in V_m} \text{er}(h) \lesssim \frac{1}{m} \left(d \log \left(\theta \left(\frac{d}{m} \right) \right) + \log \left(\frac{1}{\delta} \right) \right). \quad (16)$$

In the present work, by combining an argument of Hanneke (2009) with Theorem 7 above, we are able to obtain a new result, which replaces $\theta \left(\frac{d}{m} \right)$ in (16) with $\frac{\mathfrak{s} d}{d}$. Specifically, we have the following result.

Theorem 11 *For any $\delta \in (0, 1)$ and $m \in \mathbb{N}$, with probability at least $1 - \delta$,*

$$\sup_{h \in V_m} \text{er}(h) \leq \frac{8}{m} \left(d \ln \left(\frac{49\mathfrak{s} \hat{n}_{1:m}}{d} + 37 \right) + 8 \ln \left(\frac{6}{\delta} \right) \right).$$

The proof of Theorem 11 follows a similar strategy to the inductive step from the proofs of Theorems 1, 3, and 7. The details are included in Appendix C.

Additionally, since Hanneke and Yang (2015) prove that $\max_{Y \in [m]} \max_{Y \in (\mathcal{X} \times \mathcal{Y})^Y} \hat{n}(L) = \min\{\mathfrak{s}, m\}$, where \mathfrak{s} is the star number, the following new distribution-free bound immediately follows.⁵

4. See also Hanneke (2009), for a simple direct proof of this result.

5. The bound on the expectation follows by integrating the exponential bound on $\mathbb{P}(\sup_{h \in V_m} \text{er}(h) > \varepsilon)$ implied by the first statement in the corollary, as was done, for instance, in the proofs of Theorems 1 and 3. We also note that, by using Theorem 10 in place of Theorem 7 in the proof of Theorem 11, one can obtain mildly better numerical constants in the logarithmic term in this corollary.

Corollary 12 For any $m \in \mathbb{N}$ and $\delta \in (0, 1)$, with probability at least $1 - \delta$,

$$\sup_{h \in V_m} \text{er}(h) \lesssim \frac{1}{m} \left(d \text{Log} \left(\frac{\min\{\mathfrak{s}, m\}}{d} \right) + \text{Log} \left(\frac{1}{\delta} \right) \right).$$

Furthermore,

$$\mathbb{E} \left[\sup_{h \in V_m} \text{er}(h) \right] \lesssim \frac{d}{m} \text{Log} \left(\frac{\min\{\mathfrak{s}, m\}}{d} \right).$$

Let us compare this result to (16). Since Hanneke and Yang (2015) prove that

$$\max_{\mathcal{P}} \max_{f^* \in \mathbb{C}} \theta(r_0) = \min \left\{ \mathfrak{s}, \frac{1}{r_0} \right\},$$

and also (as mentioned) that $\max_{L \in (\mathcal{X} \times \mathcal{Y})} \hat{r}_1(L) = \min\{\mathfrak{s}, m\}$, we see that, at least in some scenarios (i.e., for some choices of \mathcal{P} and f^*), the new bound in Theorem 11 represents an improvement over (16). In particular, the best *distribution-free* bound obtainable from (16) is proportional to

$$\frac{1}{m} \left(d \text{Log} \left(\frac{\min\{d\mathfrak{s}, m\}}{d} \right) + \text{Log} \left(\frac{1}{\delta} \right) \right), \quad (17)$$

which is somewhat larger than the bound stated in Corollary 12 (which has \mathfrak{s} in place of $d\mathfrak{s}$). Also, recalling that Wiener, Hanneke, and El-Yaniv (2015) established that $\theta(1/m) \lesssim \hat{r}_{1,m}(\delta) \lesssim d\theta(d/m) \text{polylog}(m, 1/\delta)$, we should expect that the bound in Theorem 11 is typically not much larger than (16) (and indeed will be smaller in many interesting cases).

5.1 Necessary and Sufficient Conditions for $1/m$ Rates for All Consistent Learners

Corollary 12 provides a sufficient condition for every consistent learning algorithm to achieve error rate with $O(1/m)$ asymptotic dependence on m : namely, $\mathfrak{s} < \infty$. Interestingly, we can show that this condition is in fact also *necessary* for every consistent learner to have a distribution-free bound on the error rate with $O(1/m)$ dependence on m . To be clear, in this context, we only consider m as the asymptotic variable: that is, $m \rightarrow \infty$ while δ and \mathbb{C} (including d and \mathfrak{s}) are held fixed. This result is proven via the following theorem, establishing a worst-case lower bound on $\sup_{h \in V_m} \text{er}(h)$.

Theorem 13 For any $m \in \mathbb{N}$ and $\delta \in (0, 1/100)$, there exists a choice of \mathcal{P} and $f^* \in \mathbb{C}$ such that, with probability greater than δ ,

$$\sup_{h \in V_m} \text{er}(h) \gtrsim \frac{d + \text{Log}(\min\{\mathfrak{s}, m\}) + \text{Log} \left(\frac{1}{\delta} \right)}{m} \wedge 1.$$

Furthermore,

$$\mathbb{E} \left[\sup_{h \in V_m} \text{er}(h) \right] \gtrsim \frac{d + \text{Log}(\min\{\mathfrak{s}, m\})}{m} \wedge 1.$$

Proof Since any $a, b, c \in \mathbb{R}$ have $a + b + c \leq 3 \max\{a, b, c\}$ and $a + b \leq 2 \max\{a, b\}$, it suffices to establish $\frac{d}{m} \wedge 1$, $\frac{\text{Log}(\frac{1}{\delta})}{m} \wedge 1$, and $\frac{\text{Log}(\min\{\mathfrak{s}, m\})}{m}$ as lower bounds separately for the first bound, and $\frac{d}{m} \wedge 1$ and $\frac{\text{Log}(\min\{\mathfrak{s}, m\})}{m}$ as lower bounds separately for the second bound. Lower bounds proportional to $\frac{d}{m} \wedge 1$ (in both bounds) and $\frac{\text{Log}(\frac{1}{\delta})}{m} \wedge 1$ (in the first bound) are known in the literature (Blumer, Ehrenfeucht, Haussler, and Warmuth, 1989; Ehrenfeucht, Haussler, Kearns, and Valiant, 1989; Haussler, Littlestone, and Warmuth, 1994), and in fact hold as lower bounds on the error rate guarantees achievable by *any* learning algorithm.

For the remaining term, note that this term (with appropriately small constant factors) follows immediately from the others if $\mathfrak{s} \leq 56$, so suppose $\mathfrak{s} \geq 57$. Fix any $\varepsilon \in (0, 1/48)$, let $M_\varepsilon = \lfloor \frac{\mathfrak{s} - \varepsilon}{2} \rfloor$, and let $x_1, \dots, x_{\min\{\mathfrak{s}, M_\varepsilon\}} \in \mathcal{X}$ and $h_0, h_1, \dots, h_{\min\{\mathfrak{s}, M_\varepsilon\}} \in \mathbb{C}$ be as in Definition 9. Choose the probability measure \mathcal{P} such that $\mathcal{P}(\{x_i\}) = \varepsilon$ for every $i \in \{2, \dots, \min\{\mathfrak{s}, M_\varepsilon\}\}$, and $\mathcal{P}(\{x_1\}) = 1 - (\min\{\mathfrak{s}, M_\varepsilon\} - 1)\varepsilon \geq 0$. Choose the target function $f^* = h_0$. Then note that, for any $m \in \mathbb{N}$, if $\exists i \in \{2, \dots, \min\{\mathfrak{s}, M_\varepsilon\}\}$ with $x_i \notin \{X_1, \dots, X_m\}$, then $h_i \in V_m$, so that $\sup_{h \in V_m} \text{er}(h) \geq \text{er}(h_i) = \varepsilon$.

Characterizing the probability that $\{x_2, \dots, x_{\min\{\mathfrak{s}, M_\varepsilon\}} \subseteq \{X_1, \dots, X_m\}$ can be approached as an instance of the so-called *coupon collector's problem*. Specifically, let

$$\hat{M} = \min \{m \in \mathbb{N} : \{x_2, \dots, x_{\min\{\mathfrak{s}, M_\varepsilon\}} \subseteq \{X_1, \dots, X_m\}\}.$$

Note that \hat{M} may be represented as a sum $\sum_{k=1}^{\min\{\mathfrak{s}, M_\varepsilon\} - 1} G_k$ of independent geometric random variables $G_k \sim \text{Geometric}(\varepsilon \min\{\mathfrak{s}, M_\varepsilon\} - k)$, where G_k corresponds to the waiting time between encountering the $(k - 1)$ th and k th distinct elements of $\{x_2, \dots, x_{\min\{\mathfrak{s}, M_\varepsilon\}}\}$ in the X_t sequence. A simple calculation reveals that $\mathbb{E}[\hat{M}] = \frac{1}{\varepsilon} H_{\min\{\mathfrak{s}, M_\varepsilon\} - 1}$, where H_t is the t th harmonic number; in particular, $H_t \geq \ln(t)$. Another simple calculation with this sum of independent geometric random variables reveals $\text{Var}(\hat{M}) < \frac{\pi^2}{6\varepsilon^2}$. Thus, Chebyshev's inequality implies that, with probability greater than $1/2$, $\hat{M} \geq \frac{1}{\varepsilon} \ln(\min\{\mathfrak{s}, M_\varepsilon\} - 1) - \frac{\pi}{\sqrt{3}\varepsilon}$. Since $\ln(\min\{\mathfrak{s}, M_\varepsilon\} - 1) \geq \ln(48) > 2\frac{\pi}{\sqrt{3}}$, the right hand side of this inequality is at least $\frac{1}{2\varepsilon} \ln(\min\{\mathfrak{s}, M_\varepsilon\} - 1) = \frac{1}{2\varepsilon} \ln(\min\{\mathfrak{s} - 1, \lfloor \frac{1}{\varepsilon} \rfloor\})$. Altogether, we have that for any $m < \frac{1}{2\varepsilon} \ln(\min\{\mathfrak{s} - 1, \lfloor \frac{1}{\varepsilon} \rfloor\})$, with probability greater than $1/2$, $\sup_{h \in V_m} \text{er}(h) \geq \varepsilon$. By Markov's inequality, this further implies that, for any such m , $\mathbb{E}[\sup_{h \in V_m} \text{er}(h)] > \varepsilon/2$.

For any $m \leq 47$, the $\frac{\text{Log}(\min\{\mathfrak{s}, m\})}{m}$ term in both lower bounds (with appropriately small constant factors) follows from the lower bound proportional to $\frac{d}{m} \wedge 1$, so suppose $m \geq 48$. In particular, for any $c \in (4, \ln(56))$, letting $\varepsilon = \frac{cm}{\ln(\min\{\mathfrak{s} - 1, m\})}$, one can easily verify that $0 < \varepsilon < 1/48$, and $m < \frac{1}{2\varepsilon} \ln(\min\{\mathfrak{s} - 1, \lfloor \frac{1}{\varepsilon} \rfloor\})$. Therefore, with probability greater than $1/2 > \delta$,

$$\sup_{h \in V_m} \text{er}(h) \geq \frac{\ln(\min\{\mathfrak{s} - 1, m\})}{cm},$$

and furthermore,

$$\mathbb{E} \left[\sup_{h \in V_m} \text{er}(h) \right] > \frac{\ln(\min\{\mathfrak{s} - 1, m\})}{2cm}.$$

The result follows by noting $\ln(\min\{\mathfrak{s} - 1, m\}) \geq \ln(\min\{\mathfrak{s}, m\}/2) \geq \ln(\min\{\mathfrak{s}, m\})/2$ for $\mathfrak{s}, m \geq 4$. \blacksquare

Comparing Theorem 13 with Corollary 12, we see that the asymptotic dependences on m are identical, though they differ in their joint dependences on d and m . The precise dependence on both d and m from Corollary 12 can be included in the lower bound of Theorem 13 for certain types of concept spaces \mathbb{C} , but not all: the interested reader is referred to the recent article of Hanneke and Yang (2015) for discussions relevant to this type of gap, and constructions of concept spaces which (one can easily verify) span this gap; that is, for some spaces \mathbb{C} the lower bound is tight, while for other spaces \mathbb{C} the upper bound is tight, up to numerical constant factors.

An immediate corollary of Theorem 13 and Corollary 12 is that $\mathfrak{s} < \infty$ is *necessary and sufficient* for arbitrary consistent learners to achieve $O(1/m)$ rates. Formally, for any $\delta \in (0, 1)$, let $R_m(\delta)$ denote the smallest value such that, for all \mathcal{P} and all $f^* \in \mathbb{C}$, with probability at least $1 - \delta$, $\sup_{h \in V_m} \text{er}(h) \leq R_m(\delta)$. Also let R_m denote the supremum value of $\mathbb{E}[\sup_{h \in V_m} \text{er}(h)]$ over all \mathcal{P} and all $f^* \in \mathbb{C}$. We have the following corollary (which applies to any \mathbb{C} with $0 < d < \infty$).

Corollary 14 $R_m = \Theta\left(\frac{1}{m}\right)$ if and only if $\mathfrak{s} < \infty$, and otherwise $R_m = \Theta\left(\frac{\text{Log}^2(m)}{m}\right)$. Likewise, $\forall \delta \in (0, 1/100)$, $R_m(\delta) = \Theta\left(\frac{1}{m}\right)$ if and only if $\mathfrak{s} < \infty$, and otherwise $R_m(\delta) = \Theta\left(\frac{\text{Log}^2(m)}{m}\right)$.

5.2 Using Subregions Smaller than the Region of Disagreement

In recent work, Zhang and Chandhuri (2014) have proposed a general active learning strategy, which revises the CAL strategy so that the algorithm only requests a label if the corresponding X_m is in a well-chosen *subregion* of $\text{DIS}(V_{m-1})$. This general idea was first explored in the more-specific context of learning linear separators under a uniform distribution by Balcan, Broder, and Zhang (2007) (see also Dasgupta, Kalai, and Monteleoni, 2005, for related arguments). Furthermore, following up on Balcan, Broder, and Zhang (2007), the work of Balcan and Long (2013) has also used this subregion idea to argue that any consistent learning algorithm achieves the optimal sample complexity (up to constants) for the problem of learning linear separators under isotropic log-concave distributions. In this section, we combine the abstract perspective of Zhang and Chandhuri (2014) with our general bounding technique, to generalize the result of Balcan and Long (2013) by expressing a bound holding for arbitrary concept spaces \mathbb{C} , distributions \mathcal{P} , and target functions $f^* \in \mathbb{C}$. First, we need to introduce the following complexity measure $\varphi_c(r_0)$ based on the work of Zhang and Chandhuri (2014). As was true of $\theta(r_0)$ above, this complexity measure $\varphi_c(r_0)$ generally depends on both \mathcal{P} and f^* .

Definition 15 For any nonempty set \mathcal{H} of classifiers, and any $\eta \geq 0$, letting $X \sim \mathcal{P}$, define

$$\Phi(\mathcal{H}, \eta) = \min \left\{ \mathbb{E}[\gamma(X)] : \sup_{h \in \mathcal{H}} \mathbb{E}[\mathbb{1}[h(X) = +1]]\zeta(X) + \mathbb{1}[h(X) = -1]\xi(X) \leq \eta, \right.$$

$$\left. \text{where } \forall x \in \mathcal{X}, \gamma(x) + \zeta(x) + \xi(x) = 1 \text{ and } \gamma(x), \zeta(x), \xi(x) \in [0, 1] \right\}.$$

Then, for any $r_0 \in [0, 1)$ and $c > 1$, define

$$\varphi_c(r_0) = \sup_{r_0 < r \leq 1} \frac{\Phi(\mathbb{B}(f^*, r), r/c)}{r} \vee 1.$$

One can easily observe that, for the optimal choices of γ , ζ , and ξ in the definition of Φ , we have $\gamma(x) = 0$ for (almost every) $x \notin \text{DIS}(\mathcal{H})$. In the special case that γ is binary-valued, the aforementioned well-chosen “subregion” of $\text{DIS}(\mathcal{H})$ corresponds to the set $\{x : \gamma(x) = 1\}$. In general, the definition also allows for $\gamma(x)$ values in between 0 and 1, in which case γ essentially re-weights the conditional distribution $\mathcal{P}(\cdot | \text{DIS}(\mathcal{H}))$.⁶ As an example where this quantity is informative, Zhang and Chandhuri (2014) argue that, for \mathbb{C} the class of homogeneous linear separators in \mathbb{R}^k ($k \in \mathbb{N}$) and \mathcal{P} any isotropic log-concave distribution, $\varphi_c(r_0) \lesssim \text{Log}(c)$ (which follows readily from arguments of Balcan and Long, 2013). Furthermore, they observe that $\varphi_c(r_0) \leq \theta(r_0)$ for any $c \in (1, \infty]$.

Zhang and Chandhuri (2014) propose the above quantities for the purpose of proving a bound on the label complexity of a certain active learning algorithm, inspired both by the work of Balcan, Broder, and Zhang (2007) on active learning with linear separators, and by the connection between selective classification and active learning exposed by El-Yaniv and Wiener (2012). However, since the idea of using well-chosen subregions of $\text{DIS}(V_m)$ in the analysis of consistent learning algorithms lead Balcan and Long (2013) to derive improved sample complexity bounds for these methods in the case of linear separators under isotropic log-concave distributions, and since the corresponding improvements for active learning are reflected in the general results of Zhang and Chandhuri (2014), it is natural to ask whether the sample complexity improvements of Balcan and Long (2013) for that special scenario can also be extended to the general case by incorporating the complexity measure $\varphi_c(r_0)$. Here we provide such an extension. Specifically, following the same basic strategy from Theorem 7, with a few adjustments inspired by Zhang and Chandhuri (2014) to allow us to consider only a *subregion* of $\text{DIS}(V_m)$ in the argument (or more generally, a reweighting of the conditional distribution $\mathcal{P}(\cdot | \text{DIS}(V_m))$), we arrive at the following result. The proof is included in Appendix D.

Theorem 16 For any $\delta \in (0, 1)$ and $m \in \mathbb{N}$, for $c = 16$, with probability at least $1 - \delta$,

$$\sup_{h \in V_m} \text{er}(h) \leq \frac{21}{m} \left(d \ln \left(83\varphi_c \left(\frac{d}{m} \right) \right) + 3 \ln \left(\frac{4}{\delta} \right) \right).$$

In particular, in the special case of \mathbb{C} the space of homogeneous linear separators on \mathbb{R}^k , and \mathcal{P} an isotropic log-concave distribution, Theorem 16 recovers the bound of Balcan and Long (2013) proportional to $\frac{1}{m}(k + \text{Log}(\frac{1}{\delta}))$ as a special case. Furthermore, one can easily construct scenarios (concept spaces \mathbb{C} , distributions \mathcal{P} , and target functions $f^* \in \mathbb{C}$) where $\varphi_c(\frac{d}{m})$ is bounded while $\frac{d_{\text{hom}}}{m} = \frac{d}{m}$ almost surely (e.g., $\mathbb{C} = \{x \mapsto 2\mathbb{1}\{x\} - 1 : t \in \mathbb{R}\}$ the class of impulse functions on \mathbb{R} , and \mathcal{P} uniform on $(0, 1)$), so that Theorem 16 sometimes reflects a significant improvement over Theorem 11.

6. Allowing these more-general values of $\gamma(x)$ typically does not affect the qualitative behavior of the minimal $\mathbb{E}[\gamma(X)]$ value: for instance, we argue in Lemma 24 of Appendix E that the minimal $\mathbb{E}[\gamma(X)]$ value achievable under the additional constraint that $\gamma(x) \in (0, 1)$ is at most $26/74\eta/2$. Thus, we do not lose much by thinking of $\Phi(\mathcal{H}, \eta)$ as describing the measure of a subregion of $\text{DIS}(\mathcal{H})$.

One can easily show that we always have $\varphi_c(r_0) \leq (1 - \frac{1}{c})\theta(r_0)$, so that Theorem 16 is never worse than the bound (16) of Giné and Koltchinskii (2006). However, we argue in Appendix D.1 that $\forall c \geq 2, \forall r_0 \in [0, 1)$,

$$\left(1 - \frac{1}{c}\right) \min \left\{ \mathfrak{s}, \frac{1}{r_0} - \frac{1}{c-1} \right\} \leq \sup_{\mathcal{P}} \sup_{f^* \in \mathbb{C}} \varphi_c(r_0) \leq \left(1 - \frac{1}{c}\right) \min \left\{ \mathfrak{s}, \frac{1}{r_0} \right\}. \quad (18)$$

Thus, at least in some cases, the bound in Theorem 11 is smaller than that in Theorem 16 (as the former leads to Corollary 12 in the worst case, while the latter leads to (17) in the worst case). In fact, if we let $\varphi_c^{01}(r_0)$ be defined identically to $\varphi_c(r_0)$, except that γ is restricted to be $\{0, 1\}$ -valued in Definition 15, then the same argument from Appendix D.1 reveals that, for any $c \geq 4$,

$$\sup_{\mathcal{P}} \sup_{f^* \in \mathbb{C}} \varphi_c^{01}(r_0) = \min \left\{ \mathfrak{s}, \frac{1}{r_0} \right\}.$$

Relation to the Doubling Dimension: To further put Theorem 16 in context, we also note that it is possible to relate $\varphi_c(r_0)$ to the *doubling dimension*. Specifically, the doubling dimension (also known as the local metric entropy) of \mathbb{C} at f^* under \mathcal{P} , denoted $D(r_0)$, is defined as

$$D(r_0) = \max_{r \geq r_0} \log_2 (\mathcal{N}(r/2, \mathbb{B}(f^*, r), \mathcal{P})),$$

for $r_0 > 0$, where $\mathcal{N}(r/2, \mathbb{B}(f^*, r), \mathcal{P})$ is the smallest $n \in \mathbb{N}$ such that there exist classifiers h_1, \dots, h_n for which $\sup_{x \in \mathbb{B}(f^*, r)} \min_{1 \leq i \leq n} \mathcal{P}(x : h_i(x) \neq h_i(x)) \leq r/2$, known as the $(r/2)$ -covering number for $\mathbb{B}(f^*, r)$ under the $L_1(\mathcal{P})$ pseudo-metric. The notion of doubling dimension has been explored in a variety of contexts in the literature (e.g., LeCam, 1973; Yang and Barron, 1999; Gupta, Krauthgamer, and Lee, 2003; Bshouty, Li, and Long, 2009). We always have $D(r_0) \lesssim d\text{Log}(1/r_0)$ (Haussler, 1995), though it can often be smaller than this, and in many interesting contexts, it can even be bounded by an r_0 -invariant value (Bshouty, Li, and Long, 2009). Bshouty, Li, and Long (2009) construct a particular \mathcal{P} -dependent learning rule \mathbb{A} such that, for any $\varepsilon, \delta \in (0, 1)$, and any

$$m \gtrsim \frac{1}{\varepsilon} \left(D(\varepsilon/c) + \text{Log} \left(\frac{1}{\delta} \right) \right), \quad (19)$$

where $c > 0$ is a specific constant, with probability at least $1 - \delta$, the classifier $\hat{h}_m = \mathbb{A}(\mathcal{L}_m)$ satisfies $\text{er}(\hat{h}_m) \leq \varepsilon$. They also establish a weaker bound holding for all consistent learning rules: for any $\varepsilon > 0$, denoting $\varepsilon_0 = \varepsilon \exp \left\{ -\sqrt{\ln(1/\varepsilon)} \right\}$, for any

$$m \gtrsim \frac{1}{\varepsilon} \left(\max \{d, D(\varepsilon_0)\} \sqrt{\text{Log} \left(\frac{1}{\varepsilon} \right)} + \text{Log} \left(\frac{1}{\delta} \right) \right), \quad (20)$$

with probability at least $1 - \delta$, $\sup_{h \in \mathcal{V}_m} \text{er}(h) \leq \varepsilon$.

Hanneke and Yang (2015) have proven that we always have $D(r_0) \lesssim d\text{Log}(\theta(r_0))$, which immediately implies that (19) is never larger than the bound (16) for consistent learning rules (aside from constant factors), though (16) may often offer improvements over the

weaker bound (20). Here we note that a related argument can be used to prove the following bound: for any $r_0 > 0$ and $c \geq 8$,

$$D(r_0) \leq 2d \log_2(96\varphi_c(r_0)). \quad (21)$$

In particular, this implies that the bound (19) is never larger than the bound in Theorem 16 for consistent learning rules (aside from constant factors), though again Theorem 16 may often offer improvements over the weaker bound (20). We also note that, combined with the above mentioned result of Zhang and Chaudhuri (2014) that $\varphi_c(r_0) \lesssim \text{Log}(c)$ for \mathbb{C} the class of homogeneous linear separators in \mathbb{R}^k and \mathcal{P} any isotropic log-concave distribution, (21) immediately implies a bound $D(r_0) \lesssim k$ for the doubling dimension in this scenario (recalling that $d = k$ for this class, from Cover, 1965), which appears to be new to the literature. The proof of (21) is included in Appendix D.2.

6. Learning with Noise

The previous sections demonstrate how variations on the basic technique of Hanneke (2009) lead to refined analyses of certain learning methods, in the *realizable case*, where $\exists f^* \in \mathbb{C}$ with $\text{er}(f^*) = 0$. We can also apply this general technique in the more-general setting of learning with *classification noise*. Specifically, in this setting, there is a *joint* distribution \mathcal{P}_{XY} on $\mathcal{X} \times \mathcal{Y}$, and the error rate of a classifier h is then defined as $\text{er}(h) = \mathbb{P}(h(X) \neq Y)$ for $(X, Y) \sim \mathcal{P}_{XY}$. As above, we denote by \mathcal{P} the marginal distribution $\mathcal{P}_{XY}(\cdot \times \mathcal{Y})$ on \mathcal{X} . We then let $(X_1, Y_1), (X_2, Y_2), \dots$ denote a sequence of independent \mathcal{P}_{XY} -distributed random samples, and denoting $\mathcal{L}_m = \{(X_1, Y_1), \dots, (X_m, Y_m)\}$, we are interested in obtaining bounds on $\text{er}(\hat{h}_m) - \inf_{f \in \mathbb{C}} \text{er}(f)$ (the *excess error rate*), where $\hat{h}_m = \mathbb{A}(\mathcal{L}_m)$ for some learning rule \mathbb{A} . This notation is consistent with the above, which represents the special case in which $\mathbb{P}(Y = f^*(X)|X) = 1$ almost surely (i.e., the *realizable case*). While there are various noise models commonly studied in the literature, for our present discussion, we are primarily interested in two such models.

- For $\beta \in (0, 1/2)$, \mathcal{P}_{XY} satisfies the *β -bounded noise* condition if $\exists h^* \in \mathbb{C}$ such that $\mathbb{P}(Y \neq h^*(X)|X) \leq \beta$ almost surely, where $(X, Y) \sim \mathcal{P}_{XY}$.
- For $a \in [1, \infty)$ and $\alpha \in [0, 1]$, \mathcal{P}_{XY} satisfies the *(a, α) -Bernstein class* condition if, for $h^* = \arg \min_{h \in \mathbb{C}} \text{er}(h)$,⁷ we have $\forall h \in \mathbb{C}, \mathcal{P}(x : h(x) \neq h^*(x)) \leq a(\text{er}(h) - \text{er}(h^*))^\alpha$.

Note that β -bounded noise distributions also satisfy the Bernstein class condition, with $\alpha = 1$ and $a = \frac{1}{1-2\beta}$. These two conditions have been studied extensively in both the passive and active learning literatures (e.g., Massarnau and Tsybakov, 1999; Tsybakov, 2004; Bartlett, Jordan, and McAuliffe, 2006; Massart and Nédélec, 2006; Koltchinskii, 2006; Bartlett and Mendelson, 2006; Giné and Koltchinskii, 2006; Hanneke, 2009, 2011, 2012, 2014; El-Yaniv and Wiener, 2011; Ailon, Begleiter, and Ezra, 2014; Zhang and Chaudhuri, 2014; Hanneke and Yang, 2015). In particular, for passive learning, much of this literature

⁷ For simplicity, we suppose the minimum error rate is achieved in \mathbb{C} . One can easily generalize the condition to the more-general case where the minimum is not necessarily achieved (see e.g., Koltchinskii, 2006), and the results below continue to hold with only minor technical adjustments to the proofs.

focuses on the analysis of *empirical risk minimization*. Specifically, for any $m \in \mathbb{N}$ and $L \in (\mathcal{X} \times \mathcal{Y})^m$, define $\text{ERM}(\mathbb{C}, L) = \{h \in \mathbb{C} : \text{er}_L(h) = \min_{g \in \mathbb{C}} \text{er}_L(g)\}$, the set of *empirical risk minimizers*. Massart and Nédélec (2006) established that, for any \mathcal{P}_{XY} satisfying the (a, α) -Bernstein class condition, for any $\delta \in (0, 1)$, with probability at least $1 - \delta$,

$$\sup_{h \in \text{ERM}(\mathbb{C}, \mathcal{L}_m)} \text{er}(h) - \inf_{h \in \mathbb{C}} \text{er}(h) \lesssim \left(\frac{a \left(d \text{Log} \left(\frac{1}{d} \left(\frac{2m}{d} \right)^{\frac{2-\alpha}{\alpha}} \right) + \text{Log} \left(\frac{1}{\delta} \right) \right)}{m} \right)^{\frac{1}{2-\alpha}}. \quad (22)$$

In the case of β -bounded noise, Giné and Koltchinskii (2006) showed that the logarithmic factor $\text{Log} \left(\frac{m(1-2\beta)^2}{d} \right)$ implied by (22) can be replaced by $\text{Log} \left(\theta \left(\frac{\theta}{m(1-2\beta)^2} \right) \right)$, where the disagreement coefficient $\theta(r_0)$ is defined as above, except with h^* in place of f^* in the definition. Furthermore, applying their arguments to the general case of the (a, α) -Bernstein class condition (see Hanneke and Yang, 2012, for an explicit derivation), one arrives at the fact that, with probability at least $1 - \delta$,

$$\sup_{h \in \text{ERM}(\mathbb{C}, \mathcal{L}_m)} \text{er}(h) - \inf_{h \in \mathbb{C}} \text{er}(h) \lesssim \left(\frac{a \left(d \text{Log} \left(\theta \left(a \left(\frac{2d}{m} \right)^{\frac{2-\alpha}{\alpha}} \right) \right) + \text{Log} \left(\frac{1}{\delta} \right) \right)}{m} \right)^{\frac{1}{2-\alpha}}. \quad (23)$$

Since Hanneke and Yang (2015) have argued that $\theta(r_0) \leq \min \left\{ \mathfrak{s}, \frac{1}{\alpha} \right\}$ (with equality in the worst case), (23) further implies that, with probability at least $1 - \delta$,

$$\sup_{h \in \text{ERM}(\mathbb{C}, \mathcal{L}_m)} \text{er}(h) - \inf_{h \in \mathbb{C}} \text{er}(h) \lesssim \left(\frac{a \left(d \text{Log} \left(\min \left\{ \mathfrak{s}, \frac{1}{\alpha} \left(\frac{2d}{m} \right)^{\frac{2-\alpha}{\alpha}} \right\} \right) + \text{Log} \left(\frac{1}{\delta} \right) \right)}{m} \right)^{\frac{1}{2-\alpha}}. \quad (24)$$

Via the same integration argument used in Corollary 12, this further implies

$$\mathbb{E} \left[\sup_{h \in \text{ERM}(\mathbb{C}, \mathcal{L}_m)} \text{er}(h) - \inf_{h \in \mathbb{C}} \text{er}(h) \right] \lesssim \left(\frac{a d \text{Log} \left(\min \left\{ \mathfrak{s}, \frac{1}{\alpha} \left(\frac{2d}{m} \right)^{\frac{2-\alpha}{\alpha}} \right\} \right)}{m} \right)^{\frac{1}{2-\alpha}}. \quad (25)$$

It is worth noting that the bound (24) does not quite recover the bound of Corollary 12 in the realizable case (corresponding to $a = \alpha = 1$). Specifically, it contains a logarithmic factor $\text{Log} \left(\frac{\min\{d, m\}}{d} \right)$, rather than $\text{Log} \left(\frac{\min\{s, m\}}{d} \right)$. I conjecture that this logarithmic factor in (24) can generally be improved so that, for any a and α , it is bounded by a numerical constant whenever $\mathfrak{s} \lesssim d$. This problem is intimately connected to a conjecture in active learning, proposed by Hanneke and Yang (2015), concerning the joint dependence on \mathfrak{s} and d in the minimax label complexity of active learning under the Bernstein class condition.

6.1 Necessary and Sufficient Conditions for $1/m$ Minimax Rates under Bounded Noise

In the case of bounded noise (where $a = \frac{1}{1-2\beta}$ and $\alpha = 1$), Massart and Nédélec (2006) have shown that for some concept spaces \mathbb{C} , the factor $\text{Log} \left(\frac{m(1-2\beta)^2}{d} \right)$ is present even in

a lower bound on the minimax excess error rate, so that it cannot generally be removed. Raginsky and Rakhlin (2011) further discuss a range of lower bounds on the minimax excess error rate for various spaces \mathbb{C} they construct, where the appropriate factor ranges between $\text{Log} \left(\frac{m(1-2\beta)^2}{d} \right)$ at the highest, to a constant factor at the lowest. The bound in (24) provides a *sufficient* condition for all empirical risk minimization algorithms to achieve excess error rate with $O(1/m)$ asymptotic dependence on m under β -bounded noise: namely $\mathfrak{s} < \infty$. Recall that this condition was both *sufficient and necessary* for $O(1/m)$ error rates to be achievable by every algorithm of this type for all distributions in the realizable case (Corollary 14). It is therefore natural to wonder whether this remains the case for bounded noise as well. In this section, we find this is indeed the case. In fact, following a generalization of the technique of Raginsky and Rakhlin (2011) explored by Hanneke and Yang (2015) for active learning, we are here able to provide a general lower bound on the *minimax* excess error rate of passive learning, expressed in terms of \mathfrak{s} . This immediately implies a corollary that $\mathfrak{s} < \infty$ is both *necessary and sufficient* for the *minimax optimal* bound on the excess error rate to have dependence on m of $\Theta(1/m)$ under bounded noise, and otherwise the minimax optimal bound is $\Theta(\text{Log}(m)/m)$. Note that this is a stronger type of result than that given by Corollary 14, as the lower bounds here apply to *all* learning rules. Formally, we have the following theorem. The proof is included in Appendix E.1.

Theorem 17 *For any $\beta \in (0, 1/2)$, $m \in \mathbb{N}$, and $\delta \in (0, 1/24]$, for any (passive) learning rule Δ , there exists a choice of \mathcal{P}_{XY} satisfying the β -bounded noise condition such that, denoting $\hat{h}_m = \Delta(\mathcal{L}_m)$, with probability greater than δ ,*

$$\text{er}(\hat{h}_m) - \inf_{h \in \mathbb{C}} \text{er}(h) \gtrsim \frac{d + \beta \text{Log} \left(\min \left\{ \mathfrak{s}, (1 - 2\beta)^2 m \right\} \right) + \text{Log} \left(\frac{1}{\delta} \right)}{(1 - 2\beta)m} \wedge (1 - 2\beta).$$

Furthermore,

$$\mathbb{E} \left[\text{er}(\hat{h}_m) \right] - \inf_{h \in \mathbb{C}} \text{er}(h) \gtrsim \frac{d + \beta \text{Log} \left(\min \left\{ \mathfrak{s}, (1 - 2\beta)^2 m \right\} \right)}{(1 - 2\beta)m} \wedge (1 - 2\beta).$$

As was the case in Theorem 13, the joint dependence on d and m in this lower bound does not match that in (24) in the case $\mathfrak{s} = \infty$. One can show that the dependence in this lower bound can be made to nearly match that in (24) for certain specially-constructed spaces \mathbb{C} under bounded noise (Massart and Nédélec, 2006; Raginsky and Rakhlin, 2011; Hanneke and Yang, 2015) (the only gap being that \mathfrak{s} is replaced by \mathfrak{s}/d in (24) to obtain the lower bound); however, there also exist spaces \mathbb{C} where these lower bounds are nearly tight (for β bounded away from 0), so that they cannot be improved in the general case (see Hanneke and Yang, 2015, for construction of spaces \mathbb{C} with arbitrary d and \mathfrak{s} , for which one can show this is the case).

As mentioned above, an immediate corollary of Theorem 17, in combination with (24), is that $\mathfrak{s} < \infty$ is necessary and sufficient for the minimax excess error rate to have $O(1/m)$ dependence on m for bounded noise. Formally, for $m \in \mathbb{N}$, $\beta \in [0, 1/2]$, and $\delta \in (0, 1)$, let $R_m(\delta, \beta)$ denote the smallest value such that there exists a learning rule Δ for which, for all \mathcal{P}_{XY} satisfying the β -bounded noise condition, with probability at least $1 - \delta$, $\text{er}(\Delta(\mathcal{L}_m)) - \inf_{h \in \mathbb{C}} \text{er}(h) \leq R_m(\delta, \beta)$. Also let $\bar{R}_m(\beta)$ denote the smallest value such that

there exists a learning rule \mathbb{A} for which, for all \mathcal{P}_{XY} satisfying the β -bounded noise condition, $\mathbb{E}[\text{er}(\mathbb{A}(\mathcal{L}_m))] - \inf_{h \in \mathbb{C}} \text{er}(h) \leq R_m(\beta)$. We have the following corollary (which applies to any \mathbb{C} with $0 < d < \infty$).

Corollary 18 Fix any $\beta \in (0, 1/2)$. $\bar{R}_m(\beta) = \Theta\left(\frac{1}{m}\right)$ if and only if $\mathfrak{s} < \infty$, and otherwise $\bar{R}_m(\beta) = \Theta\left(\frac{\text{Log}(m)}{m}\right)$. Likewise, $\forall \delta \in (0, 1/24]$, $R_m(\delta, \beta) = \Theta\left(\frac{1}{m}\right)$ if and only if $\mathfrak{s} < \infty$, and otherwise $R_m(\delta, \beta) = \Theta\left(\frac{\text{Log}(m)}{m}\right)$.

Again, note that this is a stronger type of result than Corollary 14 above, which only found $\mathfrak{s} < \infty$ as necessary and sufficient for a *particular family* of learning rules to obtain $O(1/m)$ rates. In contrast, this result applies even to the *minimal optimal* learning rule.

We conclude this section by noting that the technique leading to Theorem 17 appears not to straightforwardly extend to the general (a, α) -Bernstein class condition. Indeed, though one can certainly exhibit specific spaces \mathbb{C} for which the minimax excess risk has $\Theta\left(\frac{\text{Log}(m)}{m}\right)^{\frac{1}{2-\alpha}}$ dependence on m (e.g., impulse functions on \mathbb{R} ; see Hanneke and Yang, 2015, for related discussions), it appears a much more challenging problem to construct general lower bounds describing the range of possible dependences on m . Thus, the more general question of establishing necessary and sufficient conditions for $O\left(\frac{1}{m}\right)^{\frac{1}{2-\alpha}}$ excess error rates under the (a, α) -Bernstein class condition remains open.

6.2 Using Subregions to Achieve Improved Excess Error Bounds

In general, note that plugging into (23) the parameters $a = \alpha = 1$ admitted by the realizable case, (23) recovers the bound (16). Recalling that we were able to refine the bound (16) via techniques from the subregion-based analysis of Zhang and Chaudhuri (2014), yielding Theorem 16 above, it is natural to consider whether we might be able to refine (23) in a similar way. We find that this is indeed the case, though we establish this refinement for a different learning rule (described in Appendix E.2). Letting $c = 128$, for any $r_0 \in [0, 1]$, $a \geq 1$ and $\alpha \in (0, 1]$, define

$$\hat{\varphi}_{a,\alpha}(r_0) = \sup_{h \in \mathbb{C}: r > r_0} \frac{\Phi(\mathbb{B}(h, r), (r/a)^{1/\alpha}/c)}{r} \vee 1.$$

For completeness, also define $\hat{\varphi}_{a,\alpha}(r_0) = 1$ for any $r_0 \geq 1$, $a \geq 1$, and $\alpha \in [0, 1]$. We have the following theorem.

Theorem 19 For any $a \geq 1$ and $\alpha \in (0, 1]$, for any probability measure \mathcal{P} over \mathcal{X} , for any $\delta \in (0, 1)$, there exists a learning rule \mathbb{A} such that, for any \mathcal{P}_{XY} satisfying the (a, α) -Bernstein class condition with marginal distribution \mathcal{P} over \mathcal{X} , for any $m \in \mathbb{N}$, letting $\hat{h}_m = \mathbb{A}(\mathcal{L}_m)$, with probability at least $1 - \delta$,

$$\text{er}(\hat{h}_m) - \inf_{h \in \mathbb{C}} \text{er}(h) \lesssim \left(\frac{a \left(d \text{Log} \left(\hat{\varphi}_{a,\alpha} \left(a \left(\frac{ad}{m} \right)^{\frac{1}{2-\alpha}} \right) \right) + \text{Log} \left(\frac{1}{\delta} \right) \right)^{\frac{1}{2-\alpha}}}{m} \right).$$

The proof is included in Appendix E.2. We should emphasize that the bound in Theorem 19 is established for a particular learning method (described in Appendix E.2), *not* for empirical risk minimization. Thus, whether or not this bound can be established for the general family of empirical risk minimization rules remains an open question. We should also note that $\hat{\varphi}_{a,\alpha}(r_0)$ involves a supremum over $h \in \mathbb{C}$ only so that we may allow the algorithm to explicitly depend on $\hat{\varphi}_{a,\alpha}(r_0)$ (noting that, as stated, Theorem 19 allows \mathcal{P} -dependence in the algorithm). It is conceivable that this dependence on $\hat{\varphi}_{a,\alpha}(r_0)$ in \mathbb{A} can be removed, for instance via a stratification and model selection technique (see e.g., Koltchinskii, 2006), in which case this supremum over h would be replaced by fixing $h = h^*$.

We conclude this section with some basic observations about the bound in Theorem 19. First, in the special case of \mathbb{C} the class of homogeneous linear separators on \mathbb{R}^k and \mathcal{P} any isotropic log-concave distribution, Theorem 19 recovers a bound of Balcan and Long (2013) (established for a closely related method), since a result of Zhang and Chaudhuri (2014) implies $\hat{\varphi}_{a,\alpha}(a\varepsilon^\alpha) \lesssim \text{Log}(a\varepsilon^{\alpha-1})$ in that case. Additionally, we note that a result similar to (24) also generally holds for the method \mathbb{A} from Theorem 19, since (18) implies we always have

$$\frac{\Phi(\mathbb{B}(h, a\varepsilon^\alpha), \varepsilon/c)}{a\varepsilon^\alpha} \leq \left(1 - \frac{1}{ca} \varepsilon^{1-\alpha} \right) \min \left\{ \mathfrak{s}, \frac{1}{a\varepsilon^\alpha} \right\}.$$

Appendix A. A Technical Lemma

The following lemma is useful in the proofs of several of the main results of this paper.⁸

Lemma 20 For any $a, b, c_1 \in [1, \infty)$ and $c_2 \in [0, \infty)$,

$$a \ln \left(c_1 \left(c_2 + \frac{b}{a} \right) \right) \leq a \ln(c_1(c_2 + e)) + \frac{1}{e}b.$$

Proof By subtracting $a \ln(c_1)$ from both sides, we see that it suffices to verify that $a \ln \left(c_2 + \frac{b}{a} \right) \leq a \ln(c_2 + e) + \frac{1}{e}b$. If $\frac{b}{a} \leq e$, then monotonicity of $\ln(\cdot)$ implies

$$a \ln \left(c_2 + \frac{b}{a} \right) \leq a \ln(c_2 + e),$$

which is clearly no greater than $a \ln(c_2 + e) + \frac{1}{e}b$. On the other hand, if $\frac{b}{a} > e$, then

$$a \ln \left(c_2 + \frac{b}{a} \right) \leq a \ln \left(\max\{c_2, 2\} \frac{b}{a} \right) = a \ln(\max\{c_2, 2\}) + a \ln \left(\frac{b}{a} \right).$$

The first term in the rightmost expression is at most $a \ln(c_2 + 2) \leq a \ln(c_2 + e)$. The second term in the rightmost expression can be rewritten as $b \frac{\ln(b/a)}{b/a}$. Since $x \mapsto \ln(x)/x$ is nonincreasing on (e, ∞) , in the case $\frac{b}{a} > e$ this is at most $\frac{1}{e}b$. Together, we have that

$$a \ln \left(c_2 + \frac{b}{a} \right) \leq a \ln(c_2 + e) + \frac{1}{e}b$$

in this case as well. \blacksquare

⁸ This lemma and proof also appear in a sibling paper (Hanneke, 2016).

Appendix B. Proof of Theorem 7

Here we present the proof of Theorem 7.

Proof of Theorem 7 The structure of the proof is nearly identical to that of Theorem 3, with only a few small changes to account for the fact that $\hat{n}_{1:m}$ depends on the specific samples, and in particular, on the order of the samples.

The proof proceeds by induction on m . Since $\mathcal{P}(\text{DIS}(V_m)) \leq 1$ always, the stated bound is trivially satisfied for all $\delta \in (0, 1)$ if $m \leq 16$. Now, as an inductive hypothesis, fix any integer $m \geq 17$ such that, $\forall \delta \in (0, 1)$, with probability at least $1 - \delta$,

$$\mathcal{P}(\text{DIS}(V_{\lfloor m/2 \rfloor})) \leq \frac{16}{\lfloor m/2 \rfloor} \left(2^{\hat{n}_{1:\lfloor m/2 \rfloor}} + \ln \left(\frac{3}{\delta} \right) \right).$$

Fix any $\delta \in (0, 1)$. Define

$$N = \left| \{X_{\lfloor m/2 \rfloor+1}, \dots, X_m\} \cap \text{DIS}(V_{\lfloor m/2 \rfloor}) \right|,$$

and enumerate the elements of $\{X_{\lfloor m/2 \rfloor+1}, \dots, X_m\} \cap \text{DIS}(V_{\lfloor m/2 \rfloor})$ as $\hat{X}_1, \dots, \hat{X}_N$. Let $\mathcal{L}_t = \{(X_1, f^*(X_1)), \dots, (X_t, f^*(X_t))\}$ for every $t \in [m]$, and $\hat{n}'_m = \left| \hat{C}_{\mathcal{L}_m} \setminus \mathcal{L}_{\lfloor m/2 \rfloor} \right|$, and enumerate as $i'_1, \dots, i'_{\hat{n}'_m}$ the indices $i \in \{\lfloor m/2 \rfloor+1, \dots, m\}$ with $(X_i, f^*(X_i)) \in \hat{C}_{\mathcal{L}_m} \setminus \mathcal{L}_{\lfloor m/2 \rfloor}$. In particular, note that $\hat{n}'_m \leq \hat{n}_m$ and $\hat{C}_{\mathcal{L}_m} \subseteq \mathcal{L}_{\lfloor m/2 \rfloor} \cup \{(X_{i'_1}, f^*(X_{i'_1})), \dots, (X_{i'_{\hat{n}'_m}}, f^*(X_{i'_{\hat{n}'_m}}))\}$, so that

$$\mathcal{C} \left[\mathcal{L}_{\lfloor m/2 \rfloor} \cup \{(X_{i'_1}, f^*(X_{i'_1})), \dots, (X_{i'_{\hat{n}'_m}}, f^*(X_{i'_{\hat{n}'_m}}))\} \right] = V_m.$$

Next, let $\hat{n}''_m = \left| \{j \in [\hat{n}'_m] : X_{i'_j} \in \text{DIS}(V_{\lfloor m/2 \rfloor})\} \right|$, and enumerate as $i''_1, \dots, i''_{\hat{n}''_m}$ the indices $i \in [N]$ such that $(\hat{X}_i, f^*(\hat{X}_i)) \in \{(X_{i'_1}, f^*(X_{i'_1})), \dots, (X_{i'_{\hat{n}'_m}}, f^*(X_{i'_{\hat{n}'_m}}))\}$. Note that, since every $j \in [\hat{n}'_m]$ with $X_{i'_j} \notin \text{DIS}(V_{\lfloor m/2 \rfloor})$ has $h(X_{i'_j}) = f^*(X_{i'_j})$ for every $h \in \mathcal{C}[\mathcal{L}_{\lfloor m/2 \rfloor} \cup \{(X_{i'_1}, f^*(X_{i'_1})), \dots, (X_{i'_{\hat{n}'_m}}, f^*(X_{i'_{\hat{n}'_m}}))\}]$ (by definition of DIS and monotonicity of $\mathcal{L} \mapsto \mathcal{C}[\mathcal{L}]$), we have

$$\begin{aligned} \mathcal{C}[\mathcal{L}_{\lfloor m/2 \rfloor} \cup \{(X_{i''_1}, f^*(X_{i''_1})), \dots, (X_{i''_{\hat{n}''_m}}, f^*(X_{i''_{\hat{n}''_m}}))\}] \\ = \mathcal{C} \left[\mathcal{L}_{\lfloor m/2 \rfloor} \cup \{(X_{i'_1}, f^*(X_{i'_1})), \dots, (X_{i'_{\hat{n}'_m}}, f^*(X_{i'_{\hat{n}'_m}}))\} \right] = V_m, \end{aligned}$$

so that $\text{DIS}(V_m)$ may be expressed as a fixed function of $X_1, \dots, X_{\lfloor m/2 \rfloor}$ and $\hat{X}_{i''_1}, \dots, \hat{X}_{i''_{\hat{n}''_m}}$. Furthermore, note that the set $\text{DIS} \left(\mathcal{C}[\mathcal{L}_{\lfloor m/2 \rfloor} \cup \{(X_{i''_1}, f^*(X_{i''_1})), \dots, (X_{i''_{\hat{n}''_m}}, f^*(X_{i''_{\hat{n}''_m}}))\}] \right)$ is invariant to permutations of the $i''_1, \dots, i''_{\hat{n}''_m}$ indices.

Now note that N is conditionally Binomial($\lfloor m/2 \rfloor, \mathcal{P}(\text{DIS}(V_{\lfloor m/2 \rfloor}))$)-distributed given $X_1, \dots, X_{\lfloor m/2 \rfloor}$. In particular, with probability one, if $\mathcal{P}(\text{DIS}(V_{\lfloor m/2 \rfloor})) = 0$, then $N = 0$. Otherwise, if $\mathcal{P}(\text{DIS}(V_{\lfloor m/2 \rfloor})) > 0$, then note that $\hat{X}_1, \dots, \hat{X}_N$ are conditionally independent and $\mathcal{P}(\cdot | \text{DIS}(V_{\lfloor m/2 \rfloor}))$ -distributed given $X_1, \dots, X_{\lfloor m/2 \rfloor}$ and N . Thus, since $\text{DIS}(V_m) \cap \{X_1, \dots, X_N\} = \emptyset$ (since every $h \in V_m$ agrees with f^* on X_1, \dots, X_m), combining the above with Lemma 4 (applied under the conditional distribution given $X_1, \dots, X_{\lfloor m/2 \rfloor}$

and N), combined with the law of total probability, implies that for every $n \in [m] \cup \{0\}$, with probability at least $1 - \delta/(n+3)^2$, if $\hat{n}''_m = n$ and $N > n$, then

$$\mathcal{P}(\text{DIS}(V_m) | \text{DIS}(V_{\lfloor m/2 \rfloor})) \leq \frac{1}{N-n} \left(n \text{Log} \left(\frac{eN}{n} \right) + \text{Log} \left(\frac{(n+3)^2}{\delta} \right) \right).$$

By a union bound, this holds simultaneously for all $n \in [m] \cup \{0\}$ on an event E_1 of probability at least $1 - \sum_{n=0}^m \frac{\delta}{(n+3)^2} > 1 - \frac{2}{3}\delta$. In particular, since the right hand side of the above inequality is nondecreasing in n , and $\hat{n}''_m \leq \hat{n}_m$, and since $\text{DIS}(V_m) \subseteq \text{DIS}(V_{\lfloor m/2 \rfloor})$, we have that on E_1 , if $N > \hat{n}_m$, then

$$\mathcal{P}(\text{DIS}(V_m)) \leq \mathcal{P}(\text{DIS}(V_{\lfloor m/2 \rfloor})) \frac{1}{N - \hat{n}_m} \left(\hat{n}_m \text{Log} \left(\frac{eN}{\hat{n}_m} \right) + \text{Log} \left(\frac{(\hat{n}_m + 3)^2}{\delta} \right) \right).$$

Next, again since N is conditionally Binomial($\lfloor m/2 \rfloor, \mathcal{P}(\text{DIS}(V_{\lfloor m/2 \rfloor}))$)-distributed given $X_1, \dots, X_{\lfloor m/2 \rfloor}$, by a Chernoff bound (applied under the conditional distribution given $X_1, \dots, X_{\lfloor m/2 \rfloor}$), combined with the law of total probability, we obtain that on an event E_2 of probability at least $1 - \delta/3$, if $\mathcal{P}(\text{DIS}(V_{\lfloor m/2 \rfloor})) \geq \frac{16}{m} \ln \left(\frac{3}{\delta} \right) \geq \frac{8}{\lfloor m/2 \rfloor} \ln \left(\frac{3}{\delta} \right)$, then

$$N \geq \mathcal{P}(\text{DIS}(V_{\lfloor m/2 \rfloor})) \lfloor m/2 \rfloor / 2 \geq \mathcal{P}(\text{DIS}(V_{\lfloor m/2 \rfloor})) m/4.$$

Also note that if $\mathcal{P}(\text{DIS}(V_m)) \geq \frac{16}{m} (2\hat{n}_m + \ln \left(\frac{3}{\delta} \right))$, then monotonicity of $t \mapsto \text{DIS}(V_t)$ and monotonicity of probability measures imply $\mathcal{P}(\text{DIS}(V_{\lfloor m/2 \rfloor})) \geq \frac{16}{m} (2\hat{n}_m + \ln \left(\frac{3}{\delta} \right))$ as well. In particular, if this occurs with E_2 , then we have $N \geq \mathcal{P}(\text{DIS}(V_{\lfloor m/2 \rfloor})) m/4 > 8\hat{n}_m$. Thus, by monotonicity of $x \mapsto \text{Log}(x)/x$ for $x > 0$, we have that on $E_1 \cap E_2$, if $\mathcal{P}(\text{DIS}(V_m)) \geq \frac{16}{m} (2\hat{n}_m + \ln \left(\frac{3}{\delta} \right))$, then

$$\begin{aligned} \mathcal{P}(\text{DIS}(V_m)) &< \mathcal{P}(\text{DIS}(V_{\lfloor m/2 \rfloor})) \frac{8}{7N} \left(\hat{n}_m \text{Log} \left(\frac{eN}{\hat{n}_m} \right) + \ln \left(\frac{(\hat{n}_m + 3)^2}{\delta} \right) \right) \\ &\leq \frac{32}{7m} \left(\hat{n}_m \text{Log} \left(\frac{e \mathcal{P}(\text{DIS}(V_{\lfloor m/2 \rfloor})) m}{4\hat{n}_m} \right) + \ln \left(\frac{(\hat{n}_m + 3)^2}{\delta} \right) \right). \end{aligned}$$

The inductive hypothesis implies that, on an event E_3 of probability at least $1 - \delta/4$,

$$\mathcal{P}(\text{DIS}(V_{\lfloor m/2 \rfloor})) \leq \frac{16}{\lfloor m/2 \rfloor} \left(2^{\hat{n}_{1:\lfloor m/2 \rfloor}} + \ln \left(\frac{12}{\delta} \right) \right).$$

Since $m \geq 17$, we have $\lfloor m/2 \rfloor \geq (m-2)/2 \geq (15/34)m$, so that the above implies

$$\mathcal{P}(\text{DIS}(V_{\lfloor m/2 \rfloor})) \leq \frac{544}{15m} \left(2^{2\hat{n}_{1:\lfloor m/2 \rfloor}} + \ln \left(\frac{12}{\delta} \right) \right).$$

Thus, on $E_1 \cap E_2 \cap E_3$, if $\mathcal{P}(\text{DIS}(V_m)) \geq \frac{16}{m} (2\hat{n}_m + \ln \left(\frac{3}{\delta} \right))$, then

$$\begin{aligned} \mathcal{P}(\text{DIS}(V_m)) &< \frac{32}{7m} \left(\hat{n}_m \text{Log} \left(\frac{136e}{15} \left(2^{\frac{\hat{n}_{1:\lfloor m/2 \rfloor}}{\hat{n}_m}} + \frac{1}{\hat{n}_m} \ln \left(\frac{12}{\delta} \right) \right) \right) + \ln \left(\frac{(\hat{n}_m + 3)^2}{\delta} \right) \right) \\ &\leq \frac{32}{7m} \left(\hat{n}_{1:m} \text{Log} \left(\frac{136e}{15} \left(2 + \frac{1}{\hat{n}_{1:m}} \ln(4) + \frac{1}{\hat{n}_{1:m}} \ln \left(\frac{3}{\delta} \right) \right) \right) + \ln \left(\frac{(\hat{n}_{1:m} + 3)^2}{\delta} \right) \right). \end{aligned} \quad (26)$$

By straightforward calculus, one can easily verify that, when $\hat{n}_{1:m} \in \{0, 1\}$, the right hand side of (26) is at most $\frac{16}{m}(2\hat{n}_{1:m} + \ln(\frac{3}{\delta}))$ (recalling our conventions that $1/0 = \infty$ and $0\text{Log}(\infty) = 0$). Otherwise, supposing $\hat{n}_{1:m} \geq 2$, Lemma 20 in Appendix A (applied with $b = \frac{56}{2} \ln(3/\delta)$) implies the right hand side of (26) is at most

$$\begin{aligned} & \frac{32}{7m} \left(\hat{n}_{1:m} \text{Log} \left(\frac{136e}{15} \left(2 + \ln(4) + \frac{2}{5} \right) \right) + 2 \ln(\hat{n}_{1:m} + 3) + \frac{7}{2} \ln \left(\frac{3}{\delta} \right) \right) \\ & \leq \frac{32}{7m} \left(5\hat{n}_{1:m} + 2 \ln(\hat{n}_{1:m} + 3) + \frac{7}{2} \ln \left(\frac{3}{\delta} \right) \right). \end{aligned}$$

Since $5x + 2 \ln(x + 3) < 7x$ for any $x \geq 2$, the above is at most

$$\frac{32}{7m} \left(7\hat{n}_{1:m} + \frac{7}{2} \ln \left(\frac{3}{\delta} \right) \right) = \frac{16}{m} \left(2\hat{n}_{1:m} + \ln \left(\frac{3}{\delta} \right) \right).$$

Thus, since $\frac{16}{m}(2\hat{n}_m + \ln(\frac{3}{\delta})) \leq \frac{16}{m}(2\hat{n}_{1:m} + \ln(\frac{3}{\delta}))$ as well, in either case we have that, on $E_1 \cap E_2 \cap E_3$,

$$\mathcal{P}(\text{DIS}(V_m)) \leq \frac{16}{m} \left(2\hat{n}_{1:m} + \ln \left(\frac{3}{\delta} \right) \right).$$

Noting that, by a union bound, the event $E_1 \cap E_2 \cap E_3$ has probability at least $1 - \frac{2}{3}\delta - \frac{1}{3}\delta - \frac{1}{4}\delta > 1 - \delta$, this extends the result to m . By the principle of induction, this completes the proof of Theorem 7. \blacksquare

Appendix C. Proof of Theorem 11

We now present the proof of Theorem 11.

Proof of Theorem 11 The result trivially holds for $m \leq \lfloor 8(\ln(37) + 8 \ln(6)) \rfloor = 143$, so suppose $m \geq 144$. Let $N = \{X_{\lfloor m/2 \rfloor + 1}, \dots, X_m\} \cap \text{DIS}(V_{\lfloor m/2 \rfloor})$ and enumerate the elements of $\{X_{\lfloor m/2 \rfloor + 1}, \dots, X_m\} \cap \text{DIS}(V_{\lfloor m/2 \rfloor})$ as $\hat{X}_1, \dots, \hat{X}_N$. Note that N is conditionally Binomial($\lfloor m/2 \rfloor, \mathcal{P}(\text{DIS}(V_{\lfloor m/2 \rfloor}))$)-distributed given $X_1, \dots, X_{\lfloor m/2 \rfloor}$. In particular, with probability one, if $\mathcal{P}(\text{DIS}(V_{\lfloor m/2 \rfloor})) = 0$, then $N = 0$. Otherwise, if $\mathcal{P}(\text{DIS}(V_{\lfloor m/2 \rfloor})) > 0$, then note that $\hat{X}_1, \dots, \hat{X}_N$ are conditionally independent $\mathcal{P}(\cdot | \text{DIS}(V_{\lfloor m/2 \rfloor}))$ -distributed random variables, given $X_1, \dots, X_{\lfloor m/2 \rfloor}$ and N . Also, note that (one can easily show) $\text{ve}(\{x : h(x) \neq f^*(x) : h \in \mathbb{C}\}) = d$. Together with Lemma 2 (applied under the conditional distribution given $X_1, \dots, X_{\lfloor m/2 \rfloor}$ and N), combined with the law of total probability, these observations imply that there is an event H_1 of probability at least $1 - \delta/3$, on which, if $N > 0$, then $\forall h \in V_m$,

$$\mathcal{P}(\text{DIS}(\{h, f^*\}) | \text{DIS}(V_{\lfloor m/2 \rfloor})) \leq \frac{2}{N} \left(d \text{Log}_2 \left(\frac{2eN}{d} \right) + \text{Log}_2 \left(\frac{6}{\delta} \right) \right).$$

In particular, noting that $\forall h \in V_m$, since $f^* \in V_m$ as well, $\text{DIS}(\{h, f^*\}) \subseteq \text{DIS}(V_m) \subseteq \text{DIS}(V_{\lfloor m/2 \rfloor})$, we have that on H_1 , $\forall h \in V_m$,

$$\begin{aligned} \text{er}(h) &= \mathcal{P}(\text{DIS}(\{h, f^*\})) = \mathcal{P}(\text{DIS}(\{h, f^*\}) | \text{DIS}(V_{\lfloor m/2 \rfloor})) \mathcal{P}(\text{DIS}(V_{\lfloor m/2 \rfloor})) \\ &\leq \mathcal{P}(\text{DIS}(V_{\lfloor m/2 \rfloor})) \frac{2}{N} \left(d \text{Log}_2 \left(\frac{2eN}{d} \right) + \text{Log}_2 \left(\frac{6}{\delta} \right) \right). \end{aligned}$$

Next, again since N is conditionally Binomial($\lfloor m/2 \rfloor, \mathcal{P}(\text{DIS}(V_{\lfloor m/2 \rfloor}))$)-distributed given $X_1, \dots, X_{\lfloor m/2 \rfloor}$, by a Chernoff bound (applied under the conditional distribution given $X_1, \dots, X_{\lfloor m/2 \rfloor}$), combined with the law of total probability, there is an event H_2 of probability at least $1 - \delta/3$, on which, if $\mathcal{P}(\text{DIS}(V_{\lfloor m/2 \rfloor})) \geq \frac{32}{\lfloor m/2 \rfloor} \ln(\frac{3}{\delta})$, then

$$N \geq (3/4) \mathcal{P}(\text{DIS}(V_{\lfloor m/2 \rfloor})) \lfloor m/2 \rfloor \geq (3/8) \mathcal{P}(\text{DIS}(V_{\lfloor m/2 \rfloor})) m,$$

which (by $\text{Log}_2(x) \leq \text{Log}(x)/\ln(2)$ and monotonicity of $x \mapsto \text{Log}(x)/x$ for $x > 0$) implies

$$\begin{aligned} & \frac{2}{N} \left(d \text{Log}_2 \left(\frac{2eN}{d} \right) + \text{Log}_2 \left(\frac{6}{\delta} \right) \right) \\ & \leq \frac{2}{3 \ln(2) \mathcal{P}(\text{DIS}(V_{\lfloor m/2 \rfloor})) m} \left(d \ln \left(\frac{3e \mathcal{P}(\text{DIS}(V_{\lfloor m/2 \rfloor})) m}{4d} \right) + \ln \left(\frac{6}{\delta} \right) \right). \end{aligned}$$

Also, by Theorem 7, on an event H_3 of probability at least $1 - \delta/3$,

$$\mathcal{P}(\text{DIS}(V_{\lfloor m/2 \rfloor})) \leq \frac{16}{\lfloor m/2 \rfloor} \left(2\hat{n}_{1:\lfloor m/2 \rfloor} + \ln \left(\frac{9}{\delta} \right) \right).$$

Together with the facts that $\frac{16}{3 \ln(2)} < 8$ and $\lfloor m/2 \rfloor \geq \frac{m-2}{m} \frac{m}{2} \geq \frac{142}{144} \frac{m}{2}$, we have that, on $H_1 \cap H_2 \cap H_3$, if $\mathcal{P}(\text{DIS}(V_{\lfloor m/2 \rfloor})) \geq \frac{32}{\lfloor m/2 \rfloor} \ln(\frac{3}{\delta})$, then

$$\begin{aligned} \sup_{h \in V_m} \text{er}(h) &\leq \frac{8}{m} \left(d \ln \left(\frac{e24 \cdot 144 (2\hat{n}_{1:\lfloor m/2 \rfloor} + \ln(9/\delta))}{142d} \right) + \ln \left(\frac{6}{\delta} \right) \right) \\ &= \frac{8}{m} \left(d \ln \left(\frac{24 \cdot 144 \left(\frac{14e\hat{n}_{1:\lfloor m/2 \rfloor} + 7e \ln(3/2)}{d} + \frac{7e \ln(6/\delta)}{d} \right) \right) + \ln \left(\frac{6}{\delta} \right) \right). \end{aligned}$$

By Lemma 20 in Appendix A, this last expression is at most

$$\begin{aligned} & \frac{8}{m} \left(d \ln \left(\frac{24 \cdot 144 \left(\frac{14e\hat{n}_{1:\lfloor m/2 \rfloor} + 7e \ln(3/2)}{d} + e \right) \right) + 8 \ln \left(\frac{6}{\delta} \right) \right) \\ & \leq \frac{8}{m} \left(d \ln \left(\left(\frac{49e\hat{n}_{1:\lfloor m/2 \rfloor}}{d} + 37 \right) \right) + 8 \ln \left(\frac{6}{\delta} \right) \right). \end{aligned}$$

Furthermore, since $\text{DIS}(\{h, f^*\}) \subseteq \text{DIS}(V_{\lfloor m/2 \rfloor})$ for every $h \in V_m$, if $\mathcal{P}(\text{DIS}(V_{\lfloor m/2 \rfloor})) < \frac{32}{\lfloor m/2 \rfloor} \ln(\frac{3}{\delta}) \leq \frac{64}{m} \ln(\frac{3}{\delta})$, then

$$\sup_{h \in V_m} \text{er}(h) < \frac{64}{m} \ln \left(\frac{3}{\delta} \right) < \frac{8}{m} \left(d \text{Log} \left(\frac{49e\hat{n}_{1:\lfloor m/2 \rfloor}}{d} + 37 \right) + 8 \ln \left(\frac{6}{\delta} \right) \right).$$

Thus, in either case, we have that, on $H_1 \cap H_2 \cap H_3$,

$$\sup_{h \in V_m} \text{er}(h) \leq \frac{8}{m} \left(d \text{Log} \left(\frac{49e\hat{n}_{1:\lfloor m/2 \rfloor}}{d} + 37 \right) + 8 \ln \left(\frac{6}{\delta} \right) \right).$$

The proof is completed by noting that $\hat{n}_{1:\lfloor m/2 \rfloor} \leq \hat{n}_{1:m}$, and that, by the union bound, the event $H_1 \cap H_2 \cap H_3$ has probability at least $1 - \delta$. \blacksquare

Appendix D. Proof of Theorem 16

We now present the proof of Theorem 16.

Proof of Theorem 16 The proof essentially combines the argument of Hanneke (2009) (which proves (16)) with the subsample-based ideas of Zhang and Chaudhuri (2014). Fix $c = 16$. The proof proceeds by induction on m . Since $\sup_{h \in \mathcal{C}} \text{er}(h) \leq 1$, the result trivially holds for $m < 21(d \ln(83) + 3 \ln(4))$. Now, as an inductive hypothesis, fix any $m \geq 21(d \ln(83) + 3 \ln(4))$ such that $\forall m' \in [m-1]$, $\forall \delta \in (0, 1)$, with probability at least $1 - \delta$,

$$\sup_{h \in \mathcal{V}_{m'}} \text{er}(h) \leq \frac{21}{m'} \left(d \text{Log} \left(83 \varphi_c \left(\frac{d}{m'} \right) \right) + 3 \text{Log} \left(\frac{4}{\delta} \right) \right).$$

Fix any $\delta \in (0, 1)$ and $\eta \in [0, 1]$. Let γ^*, ζ^*, ξ^* be the functions γ, ζ , and ξ from Definition 13 (each mapping $\mathcal{X} \rightarrow [0, 1]$) with $\gamma^*(x) + \zeta^*(x) + \xi^*(x) = 1$ for all $x \in \mathcal{X}$, and $\mathbb{E}[\gamma^*(X)]X_1, \dots, X_{\lfloor m/2 \rfloor}$ minimal subject to

$$\sup_{h \in \mathcal{V}_{\lfloor m/2 \rfloor}} \mathbb{E}[\mathbb{1}[h(X) = +1][\zeta^*(X) + \mathbb{1}[h(X) = -1]\xi^*(X)]X_1, \dots, X_{\lfloor m/2 \rfloor} \leq \eta,$$

where $X \sim \mathcal{P}$ is independent of X_1, X_2, \dots .⁹ Note that these functions are themselves random, having dependence on $X_1, \dots, X_{\lfloor m/2 \rfloor}$. In particular, $\mathbb{E}[\gamma^*(X)]X_1, \dots, X_{\lfloor m/2 \rfloor} = \Phi(V_{\lfloor m/2 \rfloor}, \eta)$.

Let $\Gamma_{\lfloor m/2 \rfloor+1}, \dots, \Gamma_m$ be conditionally independent random variables given X_1, \dots, X_m , with Γ_i having conditional distribution $\text{Bernoulli}(\gamma^*(X_i))$ given X_1, \dots, X_m , for each $i \in \{\lfloor m/2 \rfloor + 1, \dots, m\}$. Let $N = \{i \in \{\lfloor m/2 \rfloor + 1, \dots, m\} : \Gamma_i = 1\}$, and enumerate the elements of $\{X_i : i \in \{\lfloor m/2 \rfloor + 1, \dots, m\}, \Gamma_i = 1\}$ as $\hat{X}_1, \dots, \hat{X}_N$ (retaining their original order). For $X \sim \mathcal{P}$ independent of X_1, X_2, \dots , let $\Gamma(X)$ denote a random variable that is conditionally $\text{Bernoulli}(\gamma^*(X))$ given X and $X_1, \dots, X_{\lfloor m/2 \rfloor}$. Also define a (random) probability measure $P_{\lfloor m/2 \rfloor}$ such that, given $X_1, \dots, X_{\lfloor m/2 \rfloor}$, $P_{\lfloor m/2 \rfloor}(A) = \mathbb{P}(X \in A | \Gamma(X) = 1, X_1, \dots, X_{\lfloor m/2 \rfloor})$ for all measurable $A \subseteq \mathcal{X}$.

Note that $N = \sum_{i=\lfloor m/2 \rfloor+1}^m \Gamma_i$ is conditionally $\text{Binomial}(\lfloor m/2 \rfloor, \Phi(V_{\lfloor m/2 \rfloor}, \eta))$ given $X_1, \dots, X_{\lfloor m/2 \rfloor}$. In particular, with probability one, if $\Phi(V_{\lfloor m/2 \rfloor}, \eta) = 0$, then $N = 0$. Otherwise, if $\Phi(V_{\lfloor m/2 \rfloor}, \eta) > 0$, then $\hat{X}_1, \dots, \hat{X}_N$ are conditionally i.i.d. given $X_1, \dots, X_{\lfloor m/2 \rfloor}$ and N , each with conditional distribution $P_{\lfloor m/2 \rfloor}$ given $X_1, \dots, X_{\lfloor m/2 \rfloor}$ and N . Thus since every $h \in \mathcal{V}_m$ has $\{x : h(x) \neq f^*(x)\} \cap \{\hat{X}_1, \dots, \hat{X}_N\} \subseteq \{x : h(x) \neq f^*(x)\} \cap \{X_1, \dots, X_m\} = \emptyset$, and (one can easily show) $\text{vc}(\{x : h(x) \neq f^*(x)\} : h \in \mathcal{C}) = d$, applying Lemma 2 (under the conditional distribution given N and $X_1, \dots, X_{\lfloor m/2 \rfloor}$), combined with the law of total probability, we have that on an event E_1 of probability at least $1 - \delta/2$, if $N > 0$, then

$$\sup_{h \in \mathcal{V}_m} P_{\lfloor m/2 \rfloor}(x : h(x) \neq f^*(x)) \leq \frac{2}{N} \left(d \text{Log}_2 \left(\frac{2eN}{d} \right) + \text{Log}_2 \left(\frac{4}{\delta} \right) \right).$$

Next, since N is conditionally $\text{Binomial}(\lfloor m/2 \rfloor, \Phi(V_{\lfloor m/2 \rfloor}, \eta))$ given $X_1, \dots, X_{\lfloor m/2 \rfloor}$, applying a Chernoff bound (under the conditional distribution given $X_1, \dots, X_{\lfloor m/2 \rfloor}$), combined with the law of total probability, we obtain that on an event E_2 of probability at least

⁹ Note that the minimum is actually achieved here, since the objective function is continuous and convex, and the feasible region is nonempty, closed, bounded, and convex (see Bowers and Kalloni, 2014, Proposition 5.50).

$1 - \delta/4$, if $\Phi(V_{\lfloor m/2 \rfloor}, \eta) \geq \frac{18}{\lfloor m/2 \rfloor} \ln \left(\frac{4}{\delta} \right)$, then

$$N \geq (2/3) \Phi(V_{\lfloor m/2 \rfloor}, \eta) \lfloor m/2 \rfloor \geq \Phi(V_{\lfloor m/2 \rfloor}, \eta) m/3.$$

In particular, if $\Phi(V_{\lfloor m/2 \rfloor}, \eta) \geq \frac{18}{\lfloor m/2 \rfloor} \ln \left(\frac{4}{\delta} \right)$, then the right hand side is strictly greater than 0, so that if this occurs with E_2 , then we have $N > 0$. Thus, by the fact that $\text{Log}_2(x) \leq \text{Log}(x)/\ln(2)$, combined with monotonicity of $x \mapsto \text{Log}(x)/x$ for $x > 0$, we have that on $E_1 \cap E_2$, if $\Phi(V_{\lfloor m/2 \rfloor}, \eta) \geq \frac{18}{\lfloor m/2 \rfloor} \ln \left(\frac{4}{\delta} \right)$, then

$$\sup_{h \in \mathcal{V}_m} P_{\lfloor m/2 \rfloor}(x : h(x) \neq f^*(x)) \leq \frac{6/\ln(2)}{\Phi(V_{\lfloor m/2 \rfloor}, \eta) m} \left(d \text{Log} \left(\frac{2e\Phi(V_{\lfloor m/2 \rfloor}, \eta) m}{3d} \right) + \ln \left(\frac{4}{\delta} \right) \right).$$

Next (following an argument of Zhang and Chaudhuri, 2014), note that $\forall h \in \mathcal{V}_m$,

$$\begin{aligned} \text{er}(h) &= \mathbb{E}[\mathbb{1}[h(X) \neq f^*(X)](\gamma^*(X) + \zeta^*(X) + \xi^*(X)) | X_1, \dots, X_{\lfloor m/2 \rfloor}] \\ &= P_{\lfloor m/2 \rfloor}(x : h(x) \neq f^*(x)) \mathbb{P}(\Gamma(X) = 1 | X_1, \dots, X_{\lfloor m/2 \rfloor}) \\ &\quad + \mathbb{E}[\mathbb{1}[h(X) = +1] \mathbb{1}[f^*(X) = -1] \\ &\quad + \mathbb{1}[h(X) = -1] \mathbb{1}[f^*(X) = +1]] (\zeta^*(X) + \xi^*(X)) | X_1, \dots, X_{\lfloor m/2 \rfloor}] \\ &\leq P_{\lfloor m/2 \rfloor}(x : h(x) \neq f^*(x)) \Phi(V_{\lfloor m/2 \rfloor}, \eta) \\ &\quad + \mathbb{E}[\mathbb{1}[h(X) = +1] \zeta^*(X) + \mathbb{1}[h(X) = -1] \xi^*(X) | X_1, \dots, X_{\lfloor m/2 \rfloor}] \\ &\quad + \mathbb{E}[\mathbb{1}[f^*(X) = +1] \zeta^*(X) + \mathbb{1}[f^*(X) = -1] \xi^*(X) | X_1, \dots, X_{\lfloor m/2 \rfloor}]. \end{aligned}$$

Since $h, f^* \in \mathcal{V}_{\lfloor m/2 \rfloor}$, the definition of ζ^* and ξ^* implies this last expression is at most

$$P_{\lfloor m/2 \rfloor}(x : h(x) \neq f^*(x)) \Phi(V_{\lfloor m/2 \rfloor}, \eta) + 2\eta.$$

Therefore, on $E_1 \cap E_2$, if $\Phi(V_{\lfloor m/2 \rfloor}, \eta) \geq \frac{18}{\lfloor m/2 \rfloor} \ln \left(\frac{4}{\delta} \right)$, then

$$\sup_{h \in \mathcal{V}_m} \text{er}(h) \leq 2\eta + \frac{6/\ln(2)}{m} \left(d \text{Log} \left(\frac{2e\Phi(V_{\lfloor m/2 \rfloor}, \eta) m}{3d} \right) + \ln \left(\frac{4}{\delta} \right) \right).$$

The inductive hypothesis implies that, on an event E_3 of probability at least $1 - \delta/4$,

$$\sup_{h \in \mathcal{V}_{\lfloor m/2 \rfloor}} \text{er}(h) \leq \frac{21}{\lfloor m/2 \rfloor} \left(d \text{Log} \left(83 \varphi_c \left(\frac{d}{\lfloor m/2 \rfloor} \right) \right) + 3 \text{Log} \left(\frac{16}{\delta} \right) \right).$$

Since $m \geq \lceil 21(d \ln(83) + 3 \ln(4)) \rceil \geq 181$, we have $\lfloor m/2 \rfloor \geq (m-2)/2 \geq (179/362)m$, so that (together with monotonicity of $\varphi_c(\cdot)$) the above implies $\mathcal{V}_{\lfloor m/2 \rfloor} \subseteq \mathcal{B}(f^*, r_{\lfloor m/2 \rfloor}^c)$, where

$$r_{\lfloor m/2 \rfloor}^c = \frac{21 \cdot 362}{179m} \left(d \ln \left(83 \varphi_c \left(\frac{d}{m} \right) \right) + 3 \ln \left(\frac{16}{\delta} \right) \right).$$

Altogether, plugging in $\eta = (r_{\lfloor m/2 \rfloor}^c/c) \wedge 1$, and noting that $\mathcal{H} \rightarrow \Phi(\mathcal{H}, \eta)$ is nondecreasing in \mathcal{H} , and that $d/m \leq r_{\lfloor m/2 \rfloor}^c$, we have that on $E_1 \cap E_2 \cap E_3$, if $\Phi(V_{\lfloor m/2 \rfloor}, (r_{\lfloor m/2 \rfloor}^c/c) \wedge 1) \geq$

$\frac{18}{\lceil m/2 \rceil} \ln \left(\frac{4}{\delta} \right)$, then

$$\begin{aligned} \sup_{h \in V_m} \text{er}(h) &\leq \frac{2r_{\lceil m/2 \rceil}}{c} + \frac{6/\ln(2)}{m} \left(d \log \left(\frac{2e\Phi(\mathbf{B}(f^*, r_{\lceil m/2 \rceil}) \wedge (r_{\lceil m/2 \rceil}/c) \wedge 1)m}{3d} \right) + \ln \left(\frac{4}{\delta} \right) \right) \\ &\leq \frac{2r_{\lceil m/2 \rceil}}{c} + \frac{6/\ln(2)}{m} \left(d \ln \left(\frac{2e\varphi_c(d/m)r_{\lceil m/2 \rceil}m}{3d} \right) + \ln \left(\frac{4}{\delta} \right) \right). \end{aligned} \quad (27)$$

The second term in this last expression equals

$$\begin{aligned} \frac{6/\ln(2)}{m} \left(d \ln \left(\frac{14 \cdot 362}{179} \varphi_c \left(\frac{d}{m} \right) \right) + e \ln \left(83\varphi_c \left(\frac{d}{m} \right) \right) + \frac{3e}{d} \ln \left(\frac{16}{\delta} \right) \right) + \ln \left(\frac{4}{\delta} \right) \\ \leq \frac{6/\ln(2)}{m} \left(d \ln \left(\frac{14 \cdot 362 \cdot 6}{179 \cdot 7} \varphi_c \left(\frac{d}{m} \right) \right) + \frac{7e}{6} \ln \left(64 \cdot 83\varphi_c \left(\frac{d}{m} \right) \right) + \frac{7e}{2d} \ln \left(\frac{4}{\delta} \right) \right) + \ln \left(\frac{4}{\delta} \right). \end{aligned}$$

Applying Lemma 20 (with $b = (7e/2) \ln(4/\delta)$), this is at most

$$\frac{6/\ln(2)}{m} \left(d \ln \left(\frac{14 \cdot 362 \cdot 6}{179 \cdot 7} \varphi_c \left(\frac{d}{m} \right) \right) + \frac{7e}{6} \ln \left(64 \cdot 83\varphi_c \left(\frac{d}{m} \right) \right) + e \right) + \frac{9}{2} \ln \left(\frac{4}{\delta} \right),$$

and a simple relaxation of the expression in the logarithm reveals this is at most

$$\frac{6/\ln(2)}{m} \left(\frac{3}{2} d \ln \left(83\varphi_c \left(\frac{d}{m} \right) \right) + \frac{9}{2} \ln \left(\frac{4}{\delta} \right) \right) \leq \frac{13}{m} \left(d \ln \left(83\varphi_c \left(\frac{d}{m} \right) \right) + 3 \ln \left(\frac{4}{\delta} \right) \right).$$

Additionally, some straightforward reasoning about numerical constants reveals that

$$\frac{2r_{\lceil m/2 \rceil}}{c} \leq \frac{8}{m} \left(d \ln \left(83\varphi_c \left(\frac{d}{m} \right) \right) + 3 \ln \left(\frac{4}{\delta} \right) \right).$$

Plugging these two facts back into (27), we have that on $E_1 \cap E_2 \cap E_3$, if $\Phi(V_{\lceil m/2 \rceil}, (r_{\lceil m/2 \rceil}/c) \wedge 1) \geq \frac{18}{\lceil m/2 \rceil} \ln \left(\frac{4}{\delta} \right)$, then

$$\sup_{h \in V_m} \text{er}(h) \leq \frac{21}{m} \left(d \ln \left(83\varphi_c \left(\frac{d}{m} \right) \right) + 3 \ln \left(\frac{4}{\delta} \right) \right). \quad (28)$$

On the other hand, if $\Phi(V_{\lceil m/2 \rceil}, (r_{\lceil m/2 \rceil}/c) \wedge 1) < \frac{18}{\lceil m/2 \rceil} \ln \left(\frac{4}{\delta} \right)$, then recalling that (as established above) $\sup_{h \in V_m} \text{er}(h) \leq 2\eta + \sup_{h \in V_m} P_{\lceil m/2 \rceil}(x : h(x) \neq f^*(x))\Phi(V_{\lceil m/2 \rceil}, \eta)$, plugging in $\eta = (r_{\lceil m/2 \rceil}/c) \wedge 1$ and noting that $P_{\lceil m/2 \rceil}(x : h(x) \neq f^*(x)) \leq 1$, we have

$$\begin{aligned} \sup_{h \in V_m} \text{er}(h) &\leq \frac{2r_{\lceil m/2 \rceil}}{c} + \Phi(V_{\lceil m/2 \rceil}, (r_{\lceil m/2 \rceil}/c) \wedge 1) \\ &< \frac{8}{m} \left(d \ln \left(83\varphi_c \left(\frac{d}{m} \right) \right) + 3 \ln \left(\frac{4}{\delta} \right) \right) + \frac{18}{\lceil m/2 \rceil} \ln \left(\frac{4}{\delta} \right) \\ &\leq \frac{21}{m} \left(d \ln \left(83\varphi_c \left(\frac{d}{m} \right) \right) + 3 \ln \left(\frac{4}{\delta} \right) \right). \end{aligned}$$

Thus, in either case, on $E_1 \cap E_2 \cap E_3$, (28) holds. Noting that, by the union bound, the event $E_1 \cap E_2 \cap E_3$ has probability at least $1 - \delta$, this extends the inductive hypothesis to m . The result then follows by the principle of induction. \blacksquare

D.1 The Worst-Case Value of φ_c

Next, we prove (18). Fix any $c \geq 2$. First, suppose $r_0 \in (0, 1)$, and let $m = \min \left\{ \mathfrak{s}, \left\lceil \frac{1}{r_0} \right\rceil \right\}$; note that our assumption that $|C| \geq 3$ implies $\mathfrak{s} \geq 2$, so that $m \geq 2$ here. Let $x_1, \dots, x_m \in \mathcal{X}$ and $h_0, h_1, \dots, h_m \in \mathbb{C}$ be as in Definition 9. Let $\mathcal{P}(\{x_i\}) = 1/m$ for each $i \in [m]$, and take $f^* = h_0$.

Let r_1 be any value satisfying $\max\{1/m, r_0\} < r_1 \leq 1$ chosen sufficiently close to $\max\{1/m, r_0\}$ so that $\frac{mr_1}{c} < 1$. Consider now the definition of $\Phi(\mathbf{B}(f^*, r_1), r_1/c)$ from Definition 15. For any functions $\chi_0, \chi_1 : \mathcal{X} \rightarrow [0, 1]$, let $\zeta(x) = \mathbb{1}[h_0(x) = -1]\chi_0(x) + \mathbb{1}[h_0(x) = +1]\chi_1(x)$ and $\xi(x) = \mathbb{1}[h_0(x) = -1]\chi_1(x) + \mathbb{1}[h_0(x) = +1]\chi_0(x)$. In particular, note that it is possible to specify any functions $\zeta, \xi : \mathcal{X} \rightarrow [0, 1]$ by choosing appropriate χ_0, χ_1 values (namely, $\chi_0(x) = \mathbb{1}[h_0(x) = -1]\zeta(x) + \mathbb{1}[h_0(x) = +1]\xi(x)$ and $\chi_1(x) = \mathbb{1}[h_0(x) = -1]\xi(x) + \mathbb{1}[h_0(x) = +1]\zeta(x)$). Noting that, for any classifier h and any $x \in \mathcal{X}$, $\mathbb{1}[h(x) = -1]\zeta(x) + \mathbb{1}[h(x) = +1]\xi(x) = \mathbb{1}[h(x) \neq h_0(x)]\chi_0(x) + \mathbb{1}[h(x) = h_0(x)]\chi_1(x)$, and $\zeta(x) + \xi(x) = \chi_0(x) + \chi_1(x)$, we may re-express the constraints in the optimization problem defining $\Phi(\mathbf{B}(f^*, r_1), r_1/c)$ in Definition 15 as $\sup_{h \in \mathbf{B}(f^*, r_1)} \mathbb{E}[\mathbb{1}[h(X) \neq h_0(X)]\chi_0(X) + \mathbb{1}[h(X) = h_0(X)]\chi_1(X)] \leq r_1/c$ and $\forall x \in \mathcal{X}, \gamma(x) + \chi_0(x) + \chi_1(x) = 1$ while $\gamma(x), \chi_0(x), \chi_1(x) \in [0, 1]$. We may further simplify the problem by noting that $\gamma(x) = 1 - \chi_0(x) - \chi_1(x)$, so that these last two constraints become $\chi_0(x) + \chi_1(x) \leq 1$ while $\chi_0(x), \chi_1(x) \geq 0$, and the value $\Phi(\mathbf{B}(f^*, r_1), r_1/c)$ is the minimum achievable value of $\mathbb{E}[1 - \chi_0(X) - \chi_1(X)]$ subject to these constraints. Furthermore, noting that $h_i \in \mathbf{B}(f^*, r_1)$ for every $i \in [m]$, we have that

$$\begin{aligned} \Phi(\mathbf{B}(f^*, r_1), r_1/c) &\geq \min \left\{ \mathbb{E}[1 - \chi_0(X) - \chi_1(X)] : \right. \\ &\quad \left. \max_{i \in [m]} \mathbb{E}[\mathbb{1}[h_i(X) \neq h_0(X)]\chi_0(X) + \mathbb{1}[h_i(X) = h_0(X)]\chi_1(X)] \leq \frac{r_1}{c}, \right. \\ &\quad \left. \text{where } \forall x \in \mathcal{X}, \chi_0(x) + \chi_1(x) \leq 1 \text{ and } \chi_0(x), \chi_1(x) \geq 0 \right\} \\ &= \min \left\{ \sum_{i=1}^m \frac{1}{m} (1 - \chi_0(x_i) - \chi_1(x_i)) : \right. \\ &\quad \left. \forall i \in [m], \chi_0(x_i) + \sum_{j \neq i} \chi_1(x_j) \leq \frac{mr_1}{c}, \chi_0(x_i) + \chi_1(x_i) \leq 1, \chi_0(x_i), \chi_1(x_i) \geq 0 \right\}. \end{aligned}$$

This is a simple linear program with linear inequality constraints. We can explicitly solve this problem to find an optimal solution with $\chi_1(x_i) = 0$ and $\chi_0(x_i) = \frac{mr_1}{c}$ for all $i \in [m]$, at which the value of the objective function $\sum_{i=1}^m \frac{1}{m} (1 - \chi_0(x_i) - \chi_1(x_i))$ is $1 - \frac{mr_1}{c}$. One can easily verify that this choice of χ_0 and χ_1 satisfies the constraints above. To see that this is an optimal choice, we note that the objective function can be re-expressed as $\sum_{i=1}^m \frac{1}{m} (1 - \chi_0(x_i) - \chi_1(x_{\sigma(i)}))$, where $\sigma(i) = i + 1$ for $i \in [m-1]$, and $\sigma(m) = 1$. In particular, since $m \geq 2$, we have $\sigma(i) \neq i$ for each $i \in [m]$. Thus, for any χ_0 and χ_1 satisfying the constraints above, we have $\chi_0(x_i) + \chi_1(x_{\sigma(i)}) \leq \chi_0(x_i) + \sum_{j \neq i} \chi_1(x_j) \leq \frac{mr_1}{c}$

for each $i \in [m]$, so that $\sum_{i=1}^m \frac{1}{m} (1 - \chi_0(x_i) - \chi_1(x_i)) \geq 1 - \frac{mm_1}{c}$, which is precisely the value obtained with the above choices of χ_0 and χ_1 .

Thus, since the above argument holds for any choice of $r_1 > \max\{1/m, r_0\}$ sufficiently close to $\max\{1/m, r_0\}$, we have

$$\varphi_c(r_0) = \sup_{r_0 < r \leq 1} \frac{\Phi(\mathcal{B}(f^*, r), r/c)}{r} \vee 1 \geq \lim_{r_1 \searrow \max\{1/m, r_0\}} \frac{1 - \frac{mm_1}{c}}{r_1} = \frac{1 - \frac{1}{c} \max\{1, mm_0\}}{\max\{1/m, r_0\}}.$$

If $s < \frac{1}{r_0}$, then $m = s$, and the rightmost expression above equals $(1 - 1/c)s$. Otherwise, if $s \geq \frac{1}{r_0}$, then $m = \lceil \frac{1}{r_0} \rceil$, and the rightmost expression above equals

$$\left(1 - \frac{1}{c} \left\lceil \frac{1}{r_0} \right\rceil r_0\right) \frac{1}{r_0} \geq \left(1 - \frac{1+r_0}{c}\right) \frac{1}{r_0} = \left(1 - \frac{1}{c}\right) \left(\frac{1}{r_0} - \frac{1}{c-1}\right).$$

Either way, we have

$$\varphi_c(r_0) \geq \left(1 - \frac{1}{c}\right) \min\left\{s, \frac{1}{r_0} - \frac{1}{c-1}\right\}.$$

For the case $r_0 = 0$, we note that $\forall \varepsilon > 0$, any $c \geq 2$ has

$$\sup_{\mathcal{P}} \sup_{f^* \in \mathcal{C}} \varphi_c(0) \geq \sup_{\mathcal{P}} \sup_{f^* \in \mathcal{C}} \varphi_c(\varepsilon) \geq \left(1 - \frac{1}{c}\right) \min\left\{s, \frac{1}{\varepsilon} - \frac{1}{c-1}\right\}.$$

Taking the limit $\varepsilon \rightarrow 0$ yields $\sup_{\mathcal{P}} \sup_{f^* \in \mathcal{C}} \varphi_c(0) \geq (1 - \frac{1}{c})s = (1 - \frac{1}{c}) \min\left\{s, \frac{1}{r_0} - \frac{1}{c-1}\right\}$.

For the upper bound, we clearly have $\varphi_c(r_0) \leq (1 - 1/c)\theta(r_0)$ for every $c > 1$. To see this, take $\zeta(x) = (1/c)\mathbb{1}[x \in \text{DIS}(\mathcal{B}(f^*, r))]\mathbb{1}[f^*(x) = -1] + \mathbb{1}[x \notin \text{DIS}(\mathcal{B}(f^*, r))]\mathbb{1}[f^*(x) = -1]$ and $\xi(x) = (1/c)\mathbb{1}[x \in \text{DIS}(\mathcal{B}(f^*, r))]\mathbb{1}[f^*(x) = +1] + \mathbb{1}[x \notin \text{DIS}(\mathcal{B}(f^*, r))]\mathbb{1}[f^*(x) = +1]$ in the optimization problem defining $\Phi(\mathcal{B}(f^*, r), r/c)$ in Definition 15. With these choices of ζ and ξ , we have $\mathbb{E}[\gamma(X)] = (1 - 1/c)\mathcal{P}(\text{DIS}(\mathcal{B}(f^*, r)))$; also, for any $h \in \mathcal{B}(f^*, r)$, since $\text{DIS}(\{h, f^*\}) \subseteq \text{DIS}(\mathcal{B}(f^*, r))$, we have $\mathbb{E}[\mathbb{1}[h(X) = +1]\zeta(X) + \mathbb{1}[h(X) = -1]\xi(X)] = \mathbb{E}[(1/c)\mathbb{1}[h(X) \neq f^*(X)]] = (1/c)\mathcal{P}(x : h(x) \neq f^*(x)) \leq r/c$; one can easily verify that the remaining constraints are also satisfied. Thus, since Hanneke and Yang (2015) prove $\sup_{\mathcal{P}} \sup_{f^* \in \mathcal{C}} \theta(r_0) = \min\left\{s, \frac{1}{r_0}\right\}$, we have $\sup_{\mathcal{P}} \sup_{f^* \in \mathcal{C}} \varphi_c(r_0) \leq (1 - 1/c) \min\left\{s, \frac{1}{r_0}\right\}$.

We also note that, if we define $\varphi_c^{\text{th}}(r_0)$ identically to $\varphi_c(r_0)$ except that γ is restricted to have *binary* values (i.e., in $\{0, 1\}$), then for $c \geq 4$, this same construction giving the lower bound above must have $\gamma(x_i) = 1$ for every $i \in [m]$, which implies $\varphi_c^{\text{th}}(r_0) \geq \min\left\{s, \frac{1}{r_0}\right\}$ in this case. To see this, consider any $r_1 > \max\{1/m, r_0\}$ sufficiently small so that $\frac{mm_1}{c} < \frac{1}{2}$; then to satisfy the constraints $\chi_0(x_i) + \sum_{j \neq i} \chi_1(x_j) \leq \frac{mm_1}{c} < \frac{1}{2}$ for every $i \in [m]$, while $\chi_0(x_i), \chi_1(x_i) \geq 0$, we must have every $\chi_0(x_i)$ and $\chi_1(x_i)$ strictly less than $\frac{1}{2}$, so that $\gamma(x_i) = 1 - \chi_0(x_i) - \chi_1(x_i) > 0$ (and hence, $\gamma(x_i) = 1$, due to the constraint to binary values). As we always have $\varphi_c^{\text{th}}(r_0) \leq \theta(r_0)$, and Hanneke and Yang (2015) have shown $\sup_{\mathcal{P}} \sup_{f^* \in \mathcal{C}} \theta(r_0) = \min\left\{s, \frac{1}{r_0}\right\}$, this implies $\sup_{\mathcal{P}} \sup_{f^* \in \mathcal{C}} \varphi_c^{\text{th}}(r_0) = \min\left\{s, \frac{1}{r_0}\right\}$ as well.

D.2 Relation of $\varphi_c(r_0)$ to the Doubling Dimension

Here we present the proof of (21), via a modification of an argument of Hanneke and Yang (2015). We in fact prove the following slightly stronger inequality: for any $c \geq 8$ and $r > 0$,

$$\log_2(\mathcal{N}(r/2, \mathcal{B}(f^*, r), \mathcal{P})) \leq 2d \log_2 \left(96 \left(\frac{\Phi(\mathcal{B}(f^*, r), r/c)}{r} \vee 1 \right) \right), \quad (29)$$

which will immediately imply (21) by taking the supremum of both sides over $r > r_0$ (with some careful consideration of the special case $r = r_0$; see below).

Fix any $c > 4$ and $r \in (0, 1]$. Let G_r denote any maximal $(r/2)$ -packing of $\mathcal{B}(f^*, r)$: that is, G_r is a subset of $\mathcal{B}(f^*, r)$ of maximal cardinality such that $\min_{h, g \in G_r: h \neq g} \mathcal{P}(x : h(x) \neq g(x)) > r/2$. It is known that any such set G_r satisfies

$$\mathcal{N}(r/2, \mathcal{B}(f^*, r), \mathcal{P}) \leq |G_r| \leq \mathcal{N}(r/4, \mathcal{B}(f^*, r), \mathcal{P}) \quad (30)$$

(see e.g., Kolmogorov and Tikhomirov, 1959, 1961; Vidyasagar, 2003). In particular, since we have assumed $d < \infty$, in our case this further implies $|G_r| < \infty$ (Haussler, 1995). Also, this implies that if $|G_r| = 1$, then (29) trivially holds, so let us suppose $|G_r| \geq 2$.

Now fix any measurable functions γ, ζ, ξ mapping $\mathcal{X} \rightarrow [0, 1]$ satisfying the constraint $\sup_{h \in \mathcal{B}(f^*, r)} \mathbb{E}[\mathbb{1}[h(X) = +1]\zeta(X) + \mathbb{1}[h(X) = -1]\xi(X)] \leq r/c$, where $X \sim \mathcal{P}$, and $\forall x \in \mathcal{X}$, $\gamma(x) + \zeta(x) + \xi(x) = 1$; for simplicity, also suppose $\mathbb{E}[\gamma(X)] \geq r$. As above, for $m \in \mathbb{N}$, let X_1, \dots, X_m be independent \mathcal{P} -distributed random variables. Then let $\Gamma_1, \dots, \Gamma_m$ be conditionally independent given X_1, \dots, X_m , with the conditional distribution of each Γ_i as Bernoulli($\gamma(X_i)$) given X_1, \dots, X_m . Let $N_m = \{i \in [m] : \Gamma_i = 1\}$, and let $\hat{X}_1, \dots, \hat{X}_m$ denote the subsequence of X_1, \dots, X_m for which the respective $\Gamma_i = 1$.

By two applications of the Chernoff bound, combined with the union bound, the event $E_1 = \{m\mathbb{E}[\gamma(X)]/2 \leq N_m \leq 2m\mathbb{E}[\gamma(X)]\}$ has probability at least $1 - 2\exp\{-m\mathbb{E}[\gamma(X)]/8\}$. Additionally, $\forall f, g \in G_r$ with $f \neq g$, $\forall i \in [m]$,

$$\begin{aligned} \mathbb{P}(f(X_i) \neq g(X_i) \text{ and } \Gamma_i = 0) \\ &= \mathbb{E}[\mathbb{1}[f(X) \neq g(X)](1 - \gamma(X))] = \mathbb{E}[\mathbb{1}[f(X) \neq g(X)](\zeta(X) + \xi(X))] \\ &= \mathbb{E}[\mathbb{1}[f(X) = +1]\mathbb{1}[g(X) = -1] + \mathbb{1}[f(X) = -1]\mathbb{1}[g(X) = +1]](\zeta(X) + \xi(X)) \\ &\leq \mathbb{E}[\mathbb{1}[f(X) = +1]\zeta(X) + \mathbb{1}[f(X) = -1]\xi(X)] + \mathbb{E}[\mathbb{1}[g(X) = -1]\xi(X) + \mathbb{1}[g(X) = +1]\zeta(X)] \\ &\leq \frac{2r}{c} \end{aligned}$$

so that

$$\mathbb{P}(f(X_i) \neq g(X_i) \text{ and } \Gamma_i = 1) = \mathbb{P}(f(X_i) \neq g(X_i)) - \mathbb{P}(f(X_i) \neq g(X_i) \text{ and } \Gamma_i = 0) > \frac{r}{2} - \frac{2r}{c}.$$

In particular, this implies

$$\mathbb{P}(f(X_i) \neq g(X_i) | \Gamma_i = 1) \geq \left(\frac{1}{2} - \frac{2}{c}\right) \frac{r}{\mathbb{E}[\gamma(X)]}.$$

Therefore,

$$\begin{aligned} \mathbb{P}\left(\exists i \in [N_m] : f(\hat{X}_i) \neq g(\hat{X}_i) \mid N_m\right) &= 1 - (1 - \mathbb{P}(f(X_i) \neq g(X_i) | \Gamma_i = 1))^{N_m} \\ &\geq 1 - \left(1 - \left(\frac{1}{2} - \frac{2}{c}\right) \frac{r}{\mathbb{E}[\gamma(X)]}\right)^{N_m} \geq 1 - \exp\left\{-\left(\frac{1}{2} - \frac{2}{c}\right) \frac{r}{\mathbb{E}[\gamma(X)]} N_m\right\}. \end{aligned}$$

On the event E_1 , this is at least $1 - \exp\{-\frac{1}{4} - \frac{1}{c}\}rm$. Altogether, we have that

$$\begin{aligned} \mathbb{P}(E_1 \text{ and } \exists i \in [N_m] : f(\hat{X}_i) \neq g(\hat{X}_i)) &= \mathbb{E}[\mathbb{1}_{E_1} \cdot \mathbb{P}(\exists i \in [N_m] : f(\hat{X}_i) \neq g(\hat{X}_i) | N_m)] \\ &\geq \left(1 - \exp\left\{-\left(\frac{1}{4} - \frac{1}{c}\right)rm\right\}\right) \mathbb{P}(E_1) \\ &\geq 1 - \exp\left\{-\left(\frac{1}{4} - \frac{1}{c}\right)rm\right\} - 2 \exp\{-m\mathbb{E}[\gamma(X)]/8\} \\ &\geq 1 - \exp\left\{-\left(\frac{c-4}{4c}\right)rm\right\} - 2 \exp\{-mr/8\}. \end{aligned}$$

In particular, choosing

$$m = \left\lceil \frac{1}{r} \left(\frac{4c}{c-4} \vee 8\right) \ln(2|G_r|^2) \right\rceil,$$

we have that $\mathbb{P}(E_1 \text{ and } \exists i \in [N_m] : f(\hat{X}_i) \neq g(\hat{X}_i)) \geq 1 - \frac{2}{|G_r|^2}$. By a union bound, this implies that with probability at least $1 - \frac{2}{|G_r|^2}$ ($\frac{|G_r|}{2} > 0$, E_1 holds and, for every $f, g \in G_r$ with $f \neq g$, $\exists i \in [N_m]$ for which $f(\hat{X}_i) \neq g(\hat{X}_i)$): that is, every $f \in G_r$ classifies $\hat{X}_1, \dots, \hat{X}_{N_m}$ distinctly. But for this to be the case, $|G_r|$ can be at most the number of distinct classifications of a sequence of N_m points in \mathcal{X} realizable by classifiers in \mathbb{C} , where (since E_1 also holds) $N_m \leq 2m\mathbb{E}[\gamma(X)]$. Together with the VC-Sauer lemma (Vapnik and Chervonenkis, 1971; Sauer, 1972), this implies that

$$\begin{aligned} \log_2(|G_r|) &\leq d \log_2 \left(\frac{2em\mathbb{E}[\gamma(X)]}{d} \vee 2 \right) \\ &\leq d \log_2 \left(\frac{35 \cdot 4e}{33} \left(\frac{4c}{c-4} \vee 8\right) \frac{\mathbb{E}[\gamma(X)]}{r} \frac{1}{d} (\ln(\sqrt{2}) + \ln(|G_r|)) \vee 2 \right) \\ &= d \log_2 \left(\frac{35 \cdot 4e}{33 \log_2(e)} \left(\frac{4c}{c-4} \vee 8\right) \frac{\mathbb{E}[\gamma(X)]}{r} \frac{1}{d} ((1/2) + \log_2(|G_r|)) \vee 2 \right), \end{aligned}$$

where the second inequality follows from the fact that $8 \ln(2|G_r|^2) > 16.5$ (since $|G_r| \geq 2$), so that $m \leq \frac{17.5}{16.5} \frac{1}{r} \left(\frac{4c}{c-4} \vee 8\right) \ln(2|G_r|^2) = \frac{35}{33} \frac{1}{r} \left(\frac{4c}{c-4} \vee 8\right) \ln(2|G_r|^2)$.

If $\log_2(|G_r|) \leq d$, then together with (30), the inequality (29) trivially holds. Otherwise, if $\log_2(|G_r|) > d$, then letting $K = \frac{1}{2} \log_2(|G_r|) \geq 1$, the above implies

$$\begin{aligned} K &\leq \log_2 \left(\frac{35 \cdot 4e}{33 \log_2(e)} \left(\frac{4c}{c-4} \vee 8\right) \frac{\mathbb{E}[\gamma(X)]}{r} \frac{3}{2} K \right) \\ &= \log_2 \left(\frac{35 \cdot 4e}{22 \log_2(e)} \left(\frac{4c}{c-4} \vee 8\right) \frac{\mathbb{E}[\gamma(X)]}{r} \right) + \log_2(K). \end{aligned}$$

Via some simple calculus (see e.g., Vidyasagar, 2003, Lemma 4.6), this implies

$$K \leq 2 \log_2 \left(\frac{35 \cdot 4e}{22 \log_2(e)} \left(\frac{4c}{c-4} \vee 8\right) \frac{\mathbb{E}[\gamma(X)]}{r} \right).$$

Noting that $\frac{35 \cdot 4e}{22 \log_2(e)} < 12$, together with (30), we have that

$$\log_2(\mathcal{N}(r/2, \mathbb{B}(f^*, r), \mathcal{P})) \leq 2d \log_2 \left(12 \left(\frac{4c}{c-4} \vee 8\right) \frac{\mathbb{E}[\gamma(X)]}{r} \right). \quad (31)$$

This inequality holds for any choice of γ, ζ, ξ satisfying the constraints in the definition of $\Phi(\mathbb{B}(f^*, r), r/c)$ from Definition 15, with the additional constraint that $\mathbb{E}[\gamma(X)] \geq r$. Thus, if $\Phi(\mathbb{B}(f^*, r), r/c) \geq r$, then by minimizing the right hand side of (31) over the choice of γ, ζ, ξ , it follows that

$$\log_2(\mathcal{N}(r/2, \mathbb{B}(f^*, r), \mathcal{P})) \leq 2d \log_2 \left(12 \left(\frac{4c}{c-4} \vee 8\right) \frac{\Phi(\mathbb{B}(f^*, r), r/c)}{r} \right).$$

Otherwise, if $\Phi(\mathbb{B}(f^*, r), r/c) < r$, then we note that, for any functions γ^*, ζ^*, ξ^* satisfying the constraints from the definition of $\Phi(\mathbb{B}(f^*, r), r/c)$ such that $\mathbb{E}[\gamma^*(X)] = \Phi(\mathbb{B}(f^*, r), r/c)$, there exists functions γ, ζ, ξ satisfying the constraints from the definition of $\Phi(\mathbb{B}(f^*, r), r/c)$ for which $\mathbb{E}[\gamma(X)] = r$. For instance, we can take γ based on a convex combination of γ^* and 1: $\gamma(x) = \frac{1-r}{1-\mathbb{E}[\gamma^*(X)]} \gamma^*(x) + \frac{r-\mathbb{E}[\gamma^*(X)]}{1-\mathbb{E}[\gamma^*(X)]}$, $\zeta(x) = (\zeta^*(x) - (\gamma(x) - \gamma^*(x))) \vee 0$, $\xi(x) = 1 - \gamma(x) - \zeta(x)$; one can easily verify that, since $0 \leq \zeta(x) \leq \zeta^*(x)$ and $0 \leq \xi(x) \leq \xi^*(x)$, this choice of γ, ζ, ξ still satisfy the requirements for γ, ζ, ξ above, and that furthermore, $\mathbb{E}[\gamma(X)] = r$. Therefore, (31) implies $\log_2(\mathcal{N}(r/2, \mathbb{B}(f^*, r), \mathcal{P})) \leq 2d \log_2 \left(12 \left(\frac{4c}{c-4} \vee 8\right) \right)$. Thus, either way, we have established that

$$\log_2(\mathcal{N}(r/2, \mathbb{B}(f^*, r), \mathcal{P})) \leq 2d \log_2 \left(12 \left(\frac{4c}{c-4} \vee 8\right) \frac{\Phi(\mathbb{B}(f^*, r), r/c)}{r} \vee 1 \right). \quad (32)$$

Noting that, for any $c \geq 8$, $\frac{4c}{c-4} \leq 8$, this establishes (29) for any $c \geq 8$ and $r \in (0, 1]$.

In the case of $r > 1$, a result of Haussler (1995) implies that

$$\begin{aligned} \log_2(\mathcal{N}(r/2, \mathbb{B}(f^*, r), \mathcal{P})) &\leq \log_2(\mathcal{N}(1/2, \mathbb{C}, \mathcal{P})) \leq d \log_2(4e) + \log_2(\epsilon(d+1)) \\ &\leq d \log_2(4e) + d + \log_2(\epsilon) \leq d \log_2(8e^2) \leq d \log_2(96) \leq 2d \log_2 \left(96 \left(\frac{\Phi(\mathbb{B}(f^*, r), r/c)}{r} \vee 1\right) \right), \end{aligned}$$

so that both (29) and (32) are also valid for $r > 1$. This completes the proof of (29).

As a final step in the proof of (21), we note that there is a slight complication to be resolved, since the definition of $D(r_0)$ includes r_0 in the range of r , while the definition of $\varphi_c(r_0)$ does not. However, we note that, for any $c > 4$, any $r_0 > 0$, and any $r > r_0$ sufficiently close to r_0 , we have $c > cr_0/r > 4$, so that (32) would imply

$$\begin{aligned} \log_2(\mathcal{N}(r_0/2, \mathbb{B}(f^*, r_0), \mathcal{P})) &\leq 2d \log_2 \left(12 \left(\frac{4(cr_0/r)}{(cr_0/r)-4} \vee 8\right) \frac{\Phi(\mathbb{B}(f^*, r_0), r_0/(cr_0/r))}{r_0} \vee 1 \right) \\ &\leq 2d \log_2 \left(12 \left(\frac{4c}{(cr_0/r)-4} \vee \frac{8r}{r_0}\right) \frac{\Phi(\mathbb{B}(f^*, r), r/c)}{r} \vee 1 \right). \end{aligned}$$

Then taking the limit as $r \searrow r_0$ implies

$$\begin{aligned} \log_2(\mathcal{N}(r_0/2, \mathbb{B}(f^*, r_0), \mathcal{P})) &\leq 2d \log_2 \left(12 \left(\frac{4c}{c-4} \vee 8\right) \lim_{r \searrow r_0} \left(\frac{\Phi(\mathbb{B}(f^*, r), r/c)}{r} \vee 1 \right) \right) \\ &\leq 2d \log_2 \left(12 \left(\frac{4c}{c-4} \vee 8\right) \varphi_c(r_0) \right). \end{aligned}$$

In particular, for any $c \geq 8$, $\frac{4c}{c-4} \leq 8$, so that

$$\log_2(\mathcal{N}(r_0/2, \mathcal{B}(f^*, r_0), \mathcal{P})) \leq 2d \log_2(96\varphi_c(r_0)).$$

Together with the above, we therefore have that, for any $c \geq 8$ and $r_0 > 0$,

$$\begin{aligned} D(r_0) &= \max \left\{ \log_2(\mathcal{N}(r_0/2, \mathcal{B}(f^*, r_0), \mathcal{P})), \sup_{r>r_0} \log_2(\mathcal{N}(r/2, \mathcal{B}(f^*, r), \mathcal{P})) \right\} \\ &\leq \max \left\{ 2d \log_2(96\varphi_c(r_0)), \sup_{r>r_0} 2d \log_2 \left(96 \left(\frac{\Phi(\mathcal{B}(f^*, r), r/c)}{r} \vee 1 \right) \right) \right\} \\ &= 2d \log_2(96\varphi_c(r_0)). \end{aligned}$$

Thus, we have established (21).

Appendix E. Proofs of Results on Learning with Noise

This appendix includes the proofs of results in Section 6: namely, Theorems 17 and 19.

E.1 Proof of Theorem 17

We begin with the proof of Theorem 17. The proof follows a technique of Hanneke and Yang (2015), which identifies a subset of classifiers in \mathbb{C} , corresponding to a certain concept space for which Raginsky and Rakhlin (2011) have established lower bounds. Specifically, the following setup is taken directly from Hanneke and Yang (2015). Fix $\zeta \in (0, 1]$, $\beta \in [0, 1/2]$, and $k \in \mathbb{N}$ with $k \leq \min\{1/\zeta, |\mathcal{X}|-1\}$. Let $\mathcal{X}_k = \{x_1, \dots, x_{k+1}\}$ be a set of $k+1$ distinct elements of \mathcal{X} , and define $\mathbb{C}_k = \{x \mapsto 2\mathbb{1}\{x\}(x) - 1 : x \in [k]\}$. Let $\mathcal{P}_{k,\zeta}$ be a probability measure over \mathcal{X} with $\mathcal{P}\{x_i\} = \zeta$ for each $i \in [k]$, and $\mathcal{P}_{k,\zeta}\{x_{k+1}\} = 1 - \zeta k$. For each $t \in [k]$, let $\mathcal{P}'_{k,\zeta,t}$ be a probability measure over $\mathcal{X} \times \mathcal{Y}$ with marginal distribution $\mathcal{P}_{k,\zeta}$ over \mathcal{X} , such that for $(X, Y) \sim \mathcal{P}'_{k,\zeta,t}$ every $i \in [k]$ has $\mathbb{P}\{Y = 2\mathbb{1}\{x_i\}(X) - 1 | X = x_i\} = 1 - \beta$, and $\mathbb{P}\{Y = -1 | X = x_{k+1}\} = 1$. Raginsky and Rakhlin (2011) prove the following result (see the proof of their Theorem 1),¹⁰

Lemma 21 For k, ζ, β as above, with $k \geq 2$, for any $\delta \in (0, 1/4)$, for any (passive) learning rule \mathbb{A} , and any $m \in \mathbb{N}$ with

$$m < \max \left\{ \frac{\beta \ln(\frac{1}{\delta})}{2\zeta(1-2\beta)^2}, \frac{3\beta \ln(\frac{k}{96})}{16\zeta(1-2\beta)^2} \right\},$$

if $\mathbb{C}_k \subseteq \mathbb{C}$, then there exists a $t \in [k]$ such that, if $\mathcal{P}_{XY} = \mathcal{P}'_{k,\zeta,t}$, then denoting $\hat{h}_m = \mathbb{A}(\mathcal{L}_m)$, with probability greater than δ ,

$$\text{er}(\hat{h}_m) - \inf_{h \in \mathbb{C}} \text{er}(h) \geq (\zeta/2)(1-2\beta).$$

10. As noted by Hanneke and Yang (2015), although technically the proof of this result by Raginsky and Rakhlin (2011) relies on a lemma (their Lemma 4) that imposes additional restrictions on k and a parameter ν, μ , one can easily verify that the conclusions of that lemma continue to hold in the special case considered here (corresponding to $d = 1$ and arbitrary $k \in \mathbb{N}$) by defining $\mathcal{M}_{k,1} = \{0, 1\}^k$ in their construction.

Continuing to follow Hanneke and Yang (2015), we embed the above scenario into the general case, so that Lemma 21 provides a lower bound. Fix any $\zeta \in (0, 1]$, $\beta \in [0, 1/2]$, and $k \in \mathbb{N}$ with $k \leq \min\{s-1, \lfloor 1/\zeta \rfloor\}$, and let x_1, \dots, x_{k+1} and h_0, h_1, \dots, h_k be as in Definition 9. Let $\mathcal{P}_{k,\zeta}$ be as above (for this choice of x_1, \dots, x_{k+1}), and for each $t \in [k]$, let $\mathcal{P}_{k,\zeta,t}$ denote a probability measure over $\mathcal{X} \times \mathcal{Y}$ with marginal distribution $\mathcal{P}_{k,\zeta}$ over \mathcal{X} such that, for $(X, Y) \sim \mathcal{P}_{k,\zeta,t}$, $\mathbb{P}\{Y = h_t(X) | X = x_i\} = 1 - \beta$ for every $i \in [k]$, while $\mathbb{P}\{Y = h_0(X) | X = x_{k+1}\} = 1$.

Lemma 22 For k, ζ, β as above, with $k \geq 96e$, for any $\delta \in (0, 1/4)$, for any (passive) learning rule \mathbb{A} , and any $m \in \mathbb{N}$ with

$$m < \frac{3\beta \ln(\frac{k}{96})}{16\zeta(1-2\beta)^2},$$

there exists a $t \in [k]$ such that, if $\mathcal{P}_{XY} = \mathcal{P}_{k,\zeta,t}$, then denoting $\hat{h}_m = \mathbb{A}(\mathcal{L}_m)$, with probability greater than δ ,

$$\text{er}(\hat{h}_m) - \inf_{h \in \mathbb{C}} \text{er}(h) \geq (\zeta/2)(1-2\beta).$$

The proof of Lemma 22 is essentially identical to the proof of Hanneke and Yang (2015, Lemma 26), except that the algorithm \mathbb{A} here is restricted to be a passive learning rule so that Lemma 21 can be applied (in place of Lemma 25 there). As such, we omit the details here for brevity.

We are now ready for the proof of Theorem 17.

Proof of Theorem 17 Fix any $\beta \in (0, 1/2)$, $\delta \in (0, 1/24)$, $m \in \mathbb{N}$, and any (passive) learning rule \mathbb{A} . First consider the case of $s \geq 97e$. Fix $\varepsilon \in (0, (1-2\beta)/(384e^2))$, and let $\zeta = \frac{2\varepsilon}{1-2\beta}$ and $k = \min\{s-1, \lfloor 1/\zeta \rfloor\}$. Then, noting that the distributions $\mathcal{P}_{k,\zeta,t}$ above satisfy the β -bounded noise condition, Lemma 22 implies that if

$$m < \frac{3\beta \ln(\frac{k}{96})}{32\varepsilon(1-2\beta)}, \quad (33)$$

then there exists a choice of \mathcal{P}_{XY} satisfying the β -bounded noise condition such that, with probability greater than δ , the classifier $\hat{h}_m = \mathbb{A}(\mathcal{L}_m)$ has

$$\text{er}(\hat{h}_m) - \inf_{h \in \mathbb{C}} \text{er}(h) \geq \varepsilon.$$

Note that for any $m \in \mathbb{N}$ and $\varepsilon \in (0, (1-2\beta)/(384e^2))$, it holds that (see e.g., Vidyasagar, 2003, Corollary 4.1)

$$\begin{aligned} m &\leq \frac{3\beta}{64\varepsilon(1-2\beta)} \ln \left(\frac{(1-2\beta)^2 m}{18\beta} \right) \\ &\implies m < \frac{3\beta \ln(\frac{1-2\beta}{384\varepsilon})}{32\varepsilon(1-2\beta)} \leq \frac{3\beta \ln(\frac{1/\zeta}{96})}{32\varepsilon(1-2\beta)}. \end{aligned}$$

Thus, the inequality in (33) is satisfied if both

$$m < \frac{3\beta \ln(\frac{s-1}{96})}{32\varepsilon(1-2\beta)}$$

and

$$m \leq \frac{3\beta}{64\epsilon(1-2\beta)} \ln \left(\frac{(1-2\beta)^2 m}{18\beta} \right).$$

Solving for a value $\epsilon \in (0, (1-2\beta)/(384e^2))$ that satisfies both of these, we have that for any $m \in \mathbb{N}$ with $m \geq \frac{18e\beta}{(1-2\beta)^2}$, there is a choice of \mathcal{P}_{XY} satisfying the β -bounded noise condition such that, with probability greater than δ ,

$$\begin{aligned} \text{er}(\hat{h}_m) - \inf_{h \in \mathbb{C}} \text{er}(h) &\geq \frac{3\beta \ln \left(\min \left\{ \frac{s-1}{96}, \frac{(1-2\beta)^2 m}{18\beta} \right\} \right)}{64(1-2\beta)m} \wedge \frac{1-2\beta}{384e^2} \\ &\geq \frac{\beta \text{Log}(\min \{s, (1-2\beta)^2 m\})}{(1-2\beta)m} \wedge (1-2\beta). \end{aligned}$$

Furthermore, for $m < \frac{18e\beta}{(1-2\beta)^2}$, we may also think of \hat{h}_m as the output of $\mathcal{A}'(\mathcal{L}_{m'})$ for $m' = \left\lceil \frac{18e\beta}{(1-2\beta)^2} \right\rceil > m$, for a learning rule \mathcal{A}' which simply discards the last $m' - m$ samples and runs $\mathcal{A}(\mathcal{L}_m)$ to produce its return classifier. Thus, the above result implies that for $m < \frac{18e\beta}{(1-2\beta)^2}$, with probability greater than δ ,

$$\text{er}(\hat{h}_m) - \inf_{h \in \mathbb{C}} \text{er}(h) \geq \frac{3\beta \ln \left(\min \left\{ \frac{s-1}{96}, \frac{(1-2\beta)^2 m'}{18\beta} \right\} \right)}{64(1-2\beta)m'} \wedge \frac{1-2\beta}{384e^2}.$$

Since $m, m' \in \mathbb{N}$ and $m' > m$, we know that $m' \geq 2$, so that $\frac{18e\beta}{(1-2\beta)^2} \leq m' \leq \frac{36e\beta}{(1-2\beta)^2}$. Therefore,

$$\frac{3\beta \ln \left(\min \left\{ \frac{s-1}{96}, \frac{(1-2\beta)^2 m'}{18\beta} \right\} \right)}{64(1-2\beta)m'} \geq \frac{3\beta}{64(1-2\beta)m'} \geq \frac{3(1-2\beta)}{64 \cdot 36e} \frac{(1-2\beta)}{384e^2}.$$

Thus, in this case, we have that with probability greater than δ ,

$$\text{er}(\hat{h}_m) - \inf_{h \in \mathbb{C}} \text{er}(h) \geq \frac{(1-2\beta)}{384e^2} \gtrsim (1-2\beta) \geq \frac{\beta \text{Log}(\min \{s, (1-2\beta)^2 m\})}{(1-2\beta)m} \wedge (1-2\beta).$$

Next, we return to the general case of arbitrary $s \in \mathbb{N} \cup \{\infty\}$. In particular, since any $s < 97e$ has $\frac{\beta \text{Log}(\min \{s, (1-2\beta)^2 m\})}{(1-2\beta)m} \lesssim \frac{d}{(1-2\beta)m}$, to complete the proof it suffices to establish a lower bound

$$\text{er}(\hat{h}_m) - \inf_{h \in \mathbb{C}} \text{er}(h) \gtrsim \frac{1}{(1-2\beta)m} \left(d + \text{Log} \left(\frac{1}{\delta} \right) \right) \wedge (1-2\beta),$$

holding with probability greater than δ . This lower bound is already known, and frequently referred to in the literature; it follows from well-known constructions (see e.g., Anthony and Bartlett, 1999; Massart and Nédélec, 2006; Hanneke, 2011, 2014). The case $\beta < 3/8$ is covered by the classic minimax lower bound of Ehrenfeucht, Haussler, Kearns, and Valiant (1989) for the realizable case, while the case $\beta \geq 3/8$ is addressed by Hanneke (2014, Theorem 3.5). However, it seems an explicit proof of this latter result has not actually

appeared in the literature. As such, for completeness, we include a brief sketch of the argument here.

Suppose $\beta \geq 3/8$. We begin with the term $\frac{1}{(1-2\beta)m} \text{Log} \left(\frac{1}{\delta} \right)$. Since we have assumed $|\mathbb{C}| \geq 3$, there must exist $x_0, x_1 \in \mathcal{X}$ and $h_0, h_1 \in \mathbb{C}$ such that $h_0(x_0) = h_1(x_0)$ while $h_0(x_1) \neq h_1(x_1)$. Now fix $\epsilon = \frac{3}{8(1-2\beta)m} \ln \left(\frac{1}{5\delta} \right) \wedge (1-2\beta)$, let $\mathcal{P}(\{x_1\}) = \frac{\epsilon}{1-2\beta}$, and let $\mathcal{P}(\{x_0\}) = 1 - \mathcal{P}(\{x_1\})$. Then, for $b \in \{0, 1\}$, we let P_b be a distribution on $\mathcal{X} \times \mathcal{Y}$ with marginal \mathcal{P} over \mathcal{X} , and with $P_b(\{(x_0, h_0(x_0))\} \times \mathcal{Y}) = 1$ and $P_b(\{(x_1, h_b(x_1))\} \times \mathcal{Y}) = 1 - \beta$. Then one can easily check that, for $\mathcal{P}_{XY} = P_b$, any classifier h with $h(x_1) \neq h_b(x_1)$ has $\text{er}(h) - \inf_{g \in \mathbb{C}} \text{er}(g) \geq \epsilon$. But since $\text{KL}(P_0^m \| P_1^m) = m \text{KL}(P_0 \| P_1) = m\epsilon \ln \left(\frac{1-\beta}{\beta} \right)$, and $\ln \left(\frac{1-\beta}{\beta} \right) \leq \frac{1-\beta}{\beta} - 1 = \frac{1-2\beta}{\beta} \leq \frac{8}{3}(1-2\beta)$ (since $\beta \geq 3/8$), classic hypothesis testing lower bounds (see Tsybakov, 2009, Theorem 2.2) imply that there exists a choice of $b \in \{0, 1\}$ such that, with $\mathcal{P}_{XY} = P_b$ and $\hat{h}_m = \mathcal{A}(\mathcal{L}_m)$, $\mathbb{P}(\hat{h}_m(x_1) \neq h_b(x_1)) \geq \frac{1}{4} \exp \{-m\epsilon \frac{8}{3}(1-2\beta)\} \geq (5/4)\delta > \delta$. Thus, with probability greater than δ , $\text{er}(\hat{h}_m) - \inf_{g \in \mathbb{C}} \text{er}(g) \geq \epsilon \gtrsim \frac{1}{(1-2\beta)m} \text{Log} \left(\frac{1}{\delta} \right)$.

Next, we present a proof for the term $\frac{1}{(1-2\beta)m}$, again for $\beta \geq 3/8$. This term is trivially implied by the term $\frac{1}{(1-2\beta)m} \text{Log} \left(\frac{1}{\delta} \right)$ in the case $d = 1$, so suppose $d \geq 2$. This time, we let $\{x_0, \dots, x_{d-1}\}$ denote a subset of \mathcal{X} shatterable by \mathbb{C} , fix $\epsilon = \frac{3(d-1)}{64\epsilon(1-2\beta)m} \wedge \frac{1-2\beta}{8e}$, and let $\mathcal{P}(\{x_i\}) = \frac{8\epsilon}{(d-1)(1-2\beta)}$ for $i \in \{1, \dots, d-1\}$, and $\mathcal{P}(\{x_0\}) = 1 - \frac{1-2\beta}{1-2\beta}$. Now for each $\bar{b} = (b_1, \dots, b_{d-1}) \in \{0, 1\}^{d-1}$, let $P_{\bar{b}}$ denote a probability measure on $\mathcal{X} \times \mathcal{Y}$ with marginal \mathcal{P} over \mathcal{X} , and with $P_{\bar{b}}(\{(x_i, 2b_i - 1)\} \times \mathcal{Y}) = 1 - \beta$ for every $i \in \{1, \dots, d-1\}$, and $P_{\bar{b}}(\{(x_0, -1)\} \times \mathcal{Y}) = 1$. In particular, note that any $\bar{b}, \bar{b}' \in \{0, 1\}^{d-1}$ with Hamming distance $\|\bar{b} - \bar{b}'\|_1 = 1$ have $\text{KL}(P_{\bar{b}}^m \| P_{\bar{b}'}^m) = m \text{KL}(P_{\bar{b}} \| P_{\bar{b}'}) = m \frac{8\epsilon}{d-1} \ln \left(\frac{1-\beta}{\beta} \right)$, and as above, $\ln \left(\frac{1-\beta}{\beta} \right) \leq \frac{8}{3}(1-2\beta)$. Now Assouad's lemma (see Tsybakov, 2009, Theorem 2.12) implies that there exists a $\bar{b} \in \{0, 1\}^{d-1}$ such that, with $\mathcal{P}_{XY} = P_{\bar{b}}$ and $\hat{h}_m = \mathcal{A}(\mathcal{L}_m)$, denoting $\hat{b} = ((1 + \hat{h}_m(x_1))/2, \dots, (1 + \hat{h}_m(x_{d-1}))/2)$, we have $\mathbb{E}[\|\hat{b} - \bar{b}\|_1] \geq \frac{d-1}{4} \exp \left\{ -m \frac{8\epsilon}{d-1} \frac{8}{3}(1-2\beta) \right\} \geq \frac{d-1}{4e}$. Noting that $0 \leq \|\hat{b} - \bar{b}\|_1 \leq d-1$, this further implies that $\mathbb{P} \left(\|\hat{b} - \bar{b}\|_1 \geq \frac{d-1}{8e} \right) \geq \frac{1}{8e}$. Furthermore, note that $\text{er}(\hat{h}_m) - \inf_{g \in \mathbb{C}} \text{er}(g) \geq \|\hat{b} - \bar{b}\|_1 \frac{8\epsilon}{d-1}$. Thus, $\mathbb{P} \left(\text{er}(\hat{h}_m) - \inf_{g \in \mathbb{C}} \text{er}(g) \geq \epsilon \right) \geq \frac{1}{8e} > \delta$. Finally, note that $\epsilon \gtrsim \frac{d}{(1-2\beta)m} \wedge (1-2\beta)$.

Altogether, by choosing which ever of these lower bounds is greatest, we have that for any $m \in \mathbb{N}$, there exists a choice of \mathcal{P}_{XY} satisfying the β -bounded noise condition such that, with probability greater than δ ,

$$\text{er}(\hat{h}_m) - \inf_{h \in \mathbb{C}} \text{er}(h) \gtrsim \frac{\max \{d, \beta \text{Log}(\min \{s, (1-2\beta)^2 m\}), \text{Log} \left(\frac{1}{\delta} \right)\}}{(1-2\beta)m} \wedge (1-2\beta).$$

Applying the relaxation $\max\{a, b, c\} \geq (1/3)(a + b + c)$ (for nonnegative values a, b, c) then completes the proof of the first lower bound stated in the theorem.

For the second inequality, note that by taking $\delta = 1/24$, the inequality proven above implies that there exists a distribution \mathcal{P}_{XY} satisfying the β -bounded noise condition such that, with probability greater than $1/24$,

$$\text{er}(\hat{h}_m) - \inf_{h \in \mathbb{C}} \text{er}(h) \gtrsim \frac{d + \beta \text{Log}(\min \{s, (1-2\beta)^2 m\})}{(1-2\beta)m} \wedge (1-2\beta).$$

Furthermore, since bounded noise distributions have $\inf_{h \in \mathcal{C}} \text{er}(h)$ equal the Bayes risk, $\text{er}(h_m) - \inf_{h \in \mathcal{C}} \text{er}(h)$ is always nonnegative. We therefore have

$$\begin{aligned} \mathbb{E} \left[\text{er}(\hat{h}_m) - \inf_{h \in \mathcal{C}} \text{er}(h) \right] &\geq \frac{23}{24} - 0 + \frac{1}{24} \frac{d + \beta \text{Log}(\min\{5, (1 - 2\beta)^2 m\})}{(1 - 2\beta)m} \wedge (1 - 2\beta) \\ &\geq \frac{d + \beta \text{Log}(\min\{5, (1 - 2\beta)^2 m\})}{(1 - 2\beta)m} \wedge (1 - 2\beta). \end{aligned}$$

Finally, since $\inf_{h \in \mathcal{C}} \text{er}(h)$ is nonrandom, $\mathbb{E} \left[\text{er}(\hat{h}_m) \right] - \inf_{h \in \mathcal{C}} \text{er}(h) = \mathbb{E} \left[\text{er}(\hat{h}_m) - \inf_{h \in \mathcal{C}} \text{er}(h) \right]$. ■

E.2 Proof of Theorem 19

Next, we present the proof of Theorem 19. We begin by stating a classic result, due to Ginié and Koltchinski (2006) (see also van der Vaart and Wellner, 2011; Hanneke and Yang, 2012). For any set \mathcal{H} of classifiers, denote $\text{diam}_{\mathcal{P}}(\mathcal{H}) = \sup_{h, g \in \mathcal{H}} \mathcal{P}(x : h(x) \neq g(x))$.

Lemma 23 *There is a universal constant $c_0 \in (1, \infty)$ such that, for any set \mathcal{H} of classifiers, for any $\delta \in (0, 1)$ and $m \in \mathbb{N}$, defining*

$$U(\mathcal{H}, m, \delta; R) = 1 \wedge \inf_{r > \text{diam}_{\mathcal{P}}(\mathcal{H})} c_0 \sqrt{r} \frac{\text{vc}(\mathcal{H}) \text{Log}\left(\frac{\mathcal{P}(R)}{r}\right) + \text{Log}\left(\frac{1}{\delta}\right)}{m} + c_0 \frac{\text{vc}(\mathcal{H}) \text{Log}\left(\frac{\mathcal{P}(R)}{r}\right) + \text{Log}\left(\frac{1}{\delta}\right)}{m}$$

for every measurable $R \subseteq \mathcal{X}$, with probability at least $1 - \delta$, $\forall h \in \mathcal{H}$,

$$\begin{aligned} \text{er}(h) - \inf_{g \in \mathcal{H}} \text{er}(g) &\leq \max \left\{ 2 \left(\text{er}_{\mathcal{L}_m}(h) - \min_{g \in \mathcal{H}} \text{er}_{\mathcal{L}_m}(g) \right), U(\mathcal{H}, m, \delta; \text{DIS}(\mathcal{H})) \right\}, \\ \text{er}_{\mathcal{L}_m}(h) - \min_{g \in \mathcal{H}} \text{er}_{\mathcal{L}_m}(g) &\leq \max \left\{ 2 \left(\text{er}(h) - \inf_{g \in \mathcal{H}} \text{er}(g) \right), U(\mathcal{H}, m, \delta; \text{DIS}(\mathcal{H})) \right\}. \end{aligned}$$

Next, we note that we lose very little by requiring the γ function in Definition 15 to be binary. This allows us to simplify certain parts of the proof of Theorem 19 below.

Lemma 24 *For any set \mathcal{H} of classifiers, and any $\eta \in [0, 1]$, for $X \sim \mathcal{P}$, letting*

$$\begin{aligned} \Phi_{(0,1)}(\mathcal{H}, \eta) &= \inf_{h \in \mathcal{H}} \mathbb{E} \left[\mathbb{I}[\gamma(X)] : \sup_{h \in \mathcal{H}} \mathbb{E} \left[\mathbb{I}[h(X) = +1] \zeta(X) + \mathbb{I}[h(X) = -1] \xi(X) \right] \leq \eta, \right. \\ &\quad \left. \text{where } \forall x \in \mathcal{X}, \gamma(x) + \zeta(x) + \xi(x) = 1 \text{ and } \zeta(x), \xi(x) \in [0, 1], \gamma(x) \in \{0, 1\} \right], \end{aligned}$$

we have that

$$\Phi(\mathcal{H}, \eta) \leq \Phi_{(0,1)}(\mathcal{H}, \eta) \leq 2\Phi(\mathcal{H}, \eta/2).$$

Proof The left inequality is clear from the definitions. For the right inequality, let γ^*, ζ^*, ξ^* be the functions at the optimal solution achieving $\Phi(\mathcal{H}, \eta/2)$ in Definition 15. For every

$x \in \mathcal{X}$, if $\gamma^*(x) \geq 1/2$, define $\gamma(x) = 1$ and $\zeta(x) = \xi(x) = 0$, and otherwise define $\gamma(x) = 0$, $\zeta(x) = \zeta^*(x)/(\zeta^*(x) + \xi^*(x))$, and $\xi(x) = \xi^*(x)/(\zeta^*(x) + \xi^*(x))$. By design, we have that $\gamma(x) \in \{0, 1\}$, $\zeta(x), \xi(x) \in [0, 1]$, and $\gamma(x) + \zeta(x) + \xi(x) = 1$ for every $x \in \mathcal{X}$. Since every $x \in \mathcal{X}$ has $\gamma(x) \leq 2\gamma^*(x)$, we have $\mathbb{E}[\gamma(X)] \leq 2\mathbb{E}[\gamma^*(X)] = 2\Phi(\mathcal{H}, \eta/2)$. Furthermore, for every $x \in \mathcal{X}$, we either have $\zeta(x) = 0 \leq 2\zeta^*(x)$ and $\xi(x) = 0 \leq 2\xi^*(x)$, or else $\gamma^*(x) < 1/2$, in which case $\zeta^*(x) + \xi^*(x) = 1 - \gamma^*(x) > 1/2$, so that $\zeta(x) = \zeta^*(x)/(\zeta^*(x) + \xi^*(x)) \leq 2\zeta^*(x)$ and $\xi(x) = \xi^*(x)/(\zeta^*(x) + \xi^*(x)) \leq 2\xi^*(x)$. Therefore,

$$\begin{aligned} \sup_{h \in \mathcal{H}} \mathbb{E} \left[\mathbb{I}[h(X) = +1] \zeta(X) + \mathbb{I}[h(X) = -1] \xi(X) \right] \\ \leq 2 \sup_{h \in \mathcal{H}} \mathbb{E} \left[\mathbb{I}[h(X) = +1] \zeta^*(X) + \mathbb{I}[h(X) = -1] \xi^*(X) \right] \leq \eta. \end{aligned}$$

Thus, γ, ζ, ξ are functions in the feasible region of the optimization problem defining $\Phi_{(0,1)}(\mathcal{H}, \eta)$, so that $\Phi_{(0,1)}(\mathcal{H}, \eta) \leq \mathbb{E}[\gamma(X)] \leq 2\Phi(\mathcal{H}, \eta/2)$. ■

We will establish the claim in Theorem 19 for the following algorithm (which has the data set \mathcal{L}_m as input). For simplicity, this algorithm is stated in a way that makes it \mathcal{P} -dependent (which is consistent with the statement of Theorem 19). It may be possible to remove this dependence by replacing the \mathcal{P} -dependent quantities with empirical estimates, but we leave this task to future work (e.g., see the work of Koltchinski, 2006, for discussion of empirical estimation of $U(\mathcal{H}, m, \delta; R)$; Zhang and Chandhuri, 2014, additionally discuss estimating the minimizing function γ from the definition of Φ , through some refinement to their concentration arguments would be needed for our purposes). For any $k \in \{0, 1, \dots, \lfloor \log_2(m) \rfloor - 1\}$, define $\delta_k = \frac{\delta}{(\log_2(2m) - \delta_k)^2}$, and fix a value $\eta_k \geq 0$ (to be specified in the proof below).

Algorithm 1:

0. $\mathcal{G}_0 \leftarrow \mathcal{C}$
1. For $k = 0, 1, \dots, \lfloor \log_2(m) \rfloor - 1$
2. Let γ_k be the function γ at the solution defining $\Phi_{(0,1)}(\mathcal{G}_k, \eta_k)$
3. $R_k \leftarrow \{x \in \mathcal{X} : \gamma_k(x) = 1\}$
4. $D_k \leftarrow \{(X_i, Y_i) : 2^k + 1 \leq i \leq 2^{k+1}, X_i \in R_k\}$
5. $\mathcal{G}_{k+1} \leftarrow \left\{ h \in \mathcal{G}_k : 2^{-k} |D_k(\text{er}_{D_k}(h) - \min_{g \in \mathcal{G}_k} \text{er}_{D_k}(g)) \leq \max\{4\eta_k, U(\mathcal{G}_k, 2^k, \delta_k, R_k)\} \right\}$
6. Return any $\hat{h} \in \mathcal{G}_{\lfloor \log_2(m) \rfloor}$

For simplicity, we suppose the function γ_k in Step 2 actually minimizes $\mathbb{E}[\gamma_k(X)]$ subject to the constraints in the definition of $\Phi_{(0,1)}(\mathcal{G}_k, \eta_k)$. However, the proof below would remain valid for any γ_k satisfying these constraints, with $\mathbb{E}[\gamma_k(X)] \leq 2\Phi(\mathcal{G}_k, \eta_k/2)$: for instance, the proof of Lemma 24 reveals this would be satisfied by $\gamma_k(x) = \mathbb{I}[\gamma^*(x) \geq 1/2]$ for the γ^* achieving the minimum value of $\mathbb{E}[\gamma^*(X)]$ in the definition of $\Phi(\mathcal{G}_k, \eta_k/2)$. Indeed, it would even suffice to choose γ_k satisfying the constraints of $\Phi_{(0,1)}(\mathcal{G}_k, \eta_k)$ with $\mathbb{E}[\gamma_k(X)] \leq c^k \Phi(\mathcal{G}_k, \eta_k/2)$, for any finite numerical constant c^k , as this would only affect the numerical constant factors in Theorem 19.

We are now ready for the proof of Theorem 19.

Proof of Theorem 19 The proof is similar to those given above (e.g., that of Theorem 16), except that the stronger form of Lemma 23 (compared to Lemma 2) affords us a simplification that avoids the step in which we lower-bound the sample size under the conditional distribution given $\Gamma_i = 1$.

Fix any $a \geq 1$ and $\alpha \in (0, 1]$, and fix $c = 128$. We establish the claim for Algorithm 1, described above. Define $\eta_0 = 2/c$ and $\tilde{U}_0 = 1$, and for each $k \in \{1, \dots, \lfloor \log_2(m) \rfloor\}$, inductively define

$$\begin{aligned}\tilde{U}_k &= \min \left\{ 1, 2\eta_{k-1} + \max \left\{ 8\eta_{k-1}, 2U(\mathcal{G}_{k-1}, 2^{k-1}, \delta_{k-1}; R_{k-1}) \right\} \right\}, \\ r_k &= ac_1 \left(a2^{1-k} \left(d \text{Log} \left(\hat{\varphi}_{a,\alpha} \left(a \left(ad2^{1-k} \right)^{\frac{\alpha}{2-\alpha}} \right) \right) + \text{Log} \left(\frac{1}{\delta_{k-1}} \right) \right) \right)^{\frac{\alpha}{2-\alpha}}, \\ \eta_k &= \frac{2}{c} \left(\frac{r_k}{a} \right)^{1/\alpha},\end{aligned}$$

where $c_1 = (32c_0)^{\frac{2-\alpha}{\alpha}}$. We proceed by induction on k in the algorithm. Suppose that, for some $k \in \{0, 1, \dots, \lfloor \log_2(m) \rfloor - 1\}$, there is an event E_k of probability at least $1 - \sum_{k'=0}^{k-1} \delta_{k'}$ (or probability 1 if $k = 0$), on which $h^* \in \mathcal{G}_k$, and for some universal constant $c_1 \in (1, \infty)$, every $k' \in \{0, \dots, k\}$ has

$$\tilde{U}_{k'} \leq (c/2)\eta_{k'},$$

and

$$\mathcal{G}_{k'} \subseteq \left\{ h \in \mathbb{C} : \text{er}(h) - \text{er}(h^*) \leq \tilde{U}_{k'} \right\}.$$

In particular, these conditions are trivially satisfied for $k = 0$, so this may serve as a base case for this inductive argument. Next we must extend these conditions to $k + 1$.

For each $h \in \mathcal{G}_k$, define $h_{R_k}(x) = h(x)\mathbb{1}[x \in R_k] + h^*(x)\mathbb{1}[x \notin R_k]$, and denote $\mathcal{H}_k = \{h_{R_k} : h \in \mathcal{G}_k\}$. Noting that $R_k \supseteq \text{DIS}(\mathcal{H}_k)$, and that this implies $U(\mathcal{H}_k, 2^k, \delta_k; R_k) \geq U(\mathcal{H}_k, 2^k, \delta_k; \text{DIS}(\mathcal{H}_k))$, Lemma 23 (applied under the conditional distribution given \mathcal{G}_k) and the law of total probability imply that there exists an event E_{k+1}^* of probability at least $1 - \delta_k$, on which, $\forall h_{R_k} \in \mathcal{H}_k$, denoting $\tilde{\mathcal{L}}_k = \{(X_i, Y_i) : 2^k + 1 \leq i \leq 2^{k+1}\}$ (which is distributionally equivalent to \mathcal{L}_{2^k} but independent of \mathcal{G}_k),

$$\begin{aligned}\text{er}_{\tilde{\mathcal{L}}_k}(h_{R_k}) - \inf_{g_{R_k} \in \mathcal{H}_k} \text{er}(g_{R_k}) &\leq \max \left\{ 2 \left(\text{er}_{\tilde{\mathcal{L}}_k}(h_{R_k}) - \min_{g_{R_k} \in \mathcal{H}_k} \text{er}_{\tilde{\mathcal{L}}_k}(g_{R_k}) \right), U(\mathcal{H}_k, 2^k, \delta_k; R_k) \right\}, \\ \text{er}_{\tilde{\mathcal{L}}_k}(h_{R_k}) - \min_{g_{R_k} \in \mathcal{H}_k} \text{er}_{\tilde{\mathcal{L}}_k}(g_{R_k}) &\leq \max \left\{ 2 \left(\text{er}(h_{R_k}) - \inf_{g_{R_k} \in \mathcal{H}_k} \text{er}(g_{R_k}) \right), U(\mathcal{H}_k, 2^k, \delta_k; R_k) \right\}.\end{aligned}$$

First we note that, since every h_{R_k} and g_{R_k} in \mathcal{H}_k agree on the labels of all samples in $\tilde{\mathcal{L}}_k \setminus D_k$, and they each agree with their respective classifiers h and g in \mathcal{G}_k on D_k , we have that

$$\text{er}_{\tilde{\mathcal{L}}_k}(h_{R_k}) - \min_{g_{R_k} \in \mathcal{H}_k} \text{er}_{\tilde{\mathcal{L}}_k}(g_{R_k}) = 2^{-k}|D_k| \left(\text{er}_{D_k}(h) - \min_{g \in \mathcal{G}_k} \text{er}_{D_k}(g) \right).$$

Next, let ζ_k and ξ_k denote the functions ζ and ξ from the definition of $\Phi_{(0,1)}(\mathcal{G}_k, \eta_k)$ at the solution with γ equal γ_k . Note that ζ_k and ξ_k are themselves random, but are completely

determined by \mathcal{G}_k . The definition of R_k guarantees that for every $h, g \in \mathcal{G}_k$, for $X \sim \mathcal{P}$ (independent from \mathcal{L}_m)

$$\begin{aligned}\mathcal{P}(x \notin R_k : h(x) \neq g(x)) &= \mathbb{E}[\mathbb{1}[h(X) \neq g(X)](\zeta_k(X) + \xi_k(X))|\mathcal{G}_k] \\ &= \mathbb{E}[\mathbb{1}[h(X) = +1]\mathbb{1}[g(X) = -1] + \mathbb{1}[h(X) = -1]\mathbb{1}[g(X) = +1]](\zeta_k(X) + \xi_k(X))|\mathcal{G}_k] \\ &\leq \mathbb{E}[\mathbb{1}[h(X) = +1]\zeta_k(X) + \mathbb{1}[h(X) = -1]\xi_k(X)|\mathcal{G}_k] \\ &\quad + \mathbb{E}[\mathbb{1}[g(X) = +1]\zeta_k(X) + \mathbb{1}[g(X) = -1]\xi_k(X)|\mathcal{G}_k] \leq 2\eta_k.\end{aligned}$$

Therefore,

$$\text{er}(h_{R_k}) - \text{er}(g_{R_k}) \leq \text{er}(h) - \text{er}(g) + \mathcal{P}(x \notin R_k : h(x) \neq g(x)) \leq \text{er}(h) - \text{er}(g) + 2\eta_k,$$

and similarly

$$\text{er}(h_{R_k}) - \text{er}(g_{R_k}) \geq \text{er}(h) - \text{er}(g) - \mathcal{P}(x \notin R_k : h(x) \neq g(x)) \geq \text{er}(h) - \text{er}(g) - 2\eta_k.$$

In particular, noting that $\text{er}(h_{R_k}) - \inf_{g_{R_k} \in \mathcal{H}_k} \text{er}(g_{R_k}) = \sup_{g \in \mathcal{G}_k} \text{er}(h_{R_k}) - \text{er}(g_{R_k})$ and $\sup_{g \in \mathcal{G}_k} \text{er}(h) - \text{er}(g) = \text{er}(h) - \inf_{g \in \mathcal{G}_k} \text{er}(g)$, this implies

$$\text{er}(h) - \inf_{g \in \mathcal{G}_k} \text{er}(g) - 2\eta_k \leq \text{er}(h_{R_k}) - \inf_{g_{R_k} \in \mathcal{H}_k} \text{er}(g_{R_k}) \leq \text{er}(h) - \inf_{g \in \mathcal{G}_k} \text{er}(g) + 2\eta_k.$$

We also note that $\text{vc}(\mathcal{H}_k) \leq \text{vc}(\mathcal{G}_k)$ and $\text{diam}_{\mathcal{P}}(\mathcal{H}_k) \leq \text{diam}_{\mathcal{P}}(\mathcal{G}_k)$, which together imply $U(\mathcal{H}_k, 2^k, \delta_k; R_k) \leq U(\mathcal{G}_k, 2^k, \delta_k; R_k)$. Altogether, we have that on E_{k+1}^* , $\forall h \in \mathcal{G}_k$,

$$\begin{aligned}\text{er}(h) - \inf_{g \in \mathcal{G}_k} \text{er}(g) &\leq 2\eta_k + \max \left\{ 2^{1-k}|D_k| \left(\text{er}_{D_k}(h) - \min_{g \in \mathcal{G}_k} \text{er}_{D_k}(g) \right), U(\mathcal{G}_k, 2^k, \delta_k; R_k) \right\}, \\ 2^{-k}|D_k| \left(\text{er}_{D_k}(h) - \min_{g \in \mathcal{G}_k} \text{er}_{D_k}(g) \right) &\leq \max \left\{ 2 \left(\text{er}(h) - \inf_{g \in \mathcal{G}_k} \text{er}(g) + 2\eta_k \right), U(\mathcal{G}_k, 2^k, \delta_k; R_k) \right\}.\end{aligned}$$

In particular, defining $E_{k+1} = E_{k+1}^* \cap E_k$, we have that on E_{k+1} , $h^* \in \mathcal{G}_k$, and

$$2^{-k}|D_k| \left(\text{er}_{D_k}(h^*) - \min_{g \in \mathcal{G}_k} \text{er}_{D_k}(g) \right) \leq \max \left\{ 4\eta_k, U(\mathcal{G}_k, 2^k, \delta_k; R_k) \right\},$$

so that $h^* \in \mathcal{G}_{k+1}$ as well. Furthermore, combined with the definition of \mathcal{G}_{k+1} , this further implies that on E_{k+1} ,

$$\begin{aligned}\mathcal{G}_{k+1} &\subseteq \left\{ h \in \mathbb{C} : \text{er}(h) - \text{er}(h^*) \leq 2\eta_k + \max \left\{ 8\eta_k, 2U(\mathcal{G}_k, 2^k, \delta_k; R_k) \right\} \right\} \\ &= \left\{ h \in \mathbb{C} : \text{er}(h) - \text{er}(h^*) \leq \tilde{U}_{k+1} \right\}.\end{aligned}$$

It remains only to establish the bound on \tilde{U}_{k+1} . For this, we first note that, combining the inductive hypothesis with the (a, α) -Bernstein class condition, on E_{k+1} we have

$$\mathcal{G}_k \subseteq \mathbb{B} \left(h^*, a\tilde{U}_k^\alpha \right) \subseteq \mathbb{B} \left(h^*, r_k \right).$$

Combining this with Lemma 24 and monotonicity of $\Phi(\cdot, \eta_k/2)$, we have that

$$\mathcal{P}(R_k) \leq 2\Phi \left(\mathbb{B} \left(h^*, r_k \right), \eta_k/2 \right) = 2\Phi \left(\mathbb{B} \left(h^*, r_k \right), (r_k/a)^{1/\alpha}/c \right) \leq 2\hat{\varphi}_{a,\alpha}(r_k)r_k.$$

The above also implies that $\text{diam}_{\mathcal{P}}(\mathcal{G}_k) \leq 2r_k$ on E_{k+1} . Together with the fact that $\text{vc}(\mathcal{G}_k) \leq d$, we have that on E_{k+1} ,

$$\begin{aligned} U(\mathcal{G}_k, 2^k, R_k) &\leq c_0 \sqrt{2r_k 2^{-k} \left(d \text{Log}(\hat{\varphi}_{\alpha, \alpha}(r_k)) + \text{Log}\left(\frac{1}{\delta_k}\right) \right)} \\ &\quad + c_0 2^{-k} \left(d \text{Log}(\hat{\varphi}_{\alpha, \alpha}(r_k)) + \text{Log}\left(\frac{1}{\delta_k}\right) \right). \end{aligned} \quad (34)$$

Furthermore, monotonicity of $\hat{\varphi}_{\alpha, \alpha}(\cdot)$ implies $\hat{\varphi}_{\alpha, \alpha}(r_k) \leq \hat{\varphi}_{\alpha, \alpha}(a(ad2^{-k})^{\frac{2}{2-\alpha}})$. Plugging the definition of r_k into (34) along with this relaxation of $\hat{\varphi}_{\alpha, \alpha}(r_k)$ and simplifying, the minimum of 1 and the right hand side of (34) is at most

$$\begin{aligned} 8c_0 \sqrt{c_1} \left(a 2^{-k} \left(d \text{Log}\left(\hat{\varphi}_{\alpha, \alpha}\left(a(ad2^{-k})^{\frac{2}{2-\alpha}}\right)\right) + \text{Log}\left(\frac{1}{\delta_k}\right) \right) \right)^{\frac{1}{2-\alpha}} \\ = 8c_0 \sqrt{c_1} \left(\frac{r_{k+1}}{c_1 a} \right)^{1/\alpha} = \frac{4c_0 c}{c_1^{\frac{2-\alpha}{2\alpha}}} \eta_{k+1} = \frac{c}{8} \eta_{k+1}. \end{aligned}$$

We may also observe that

$$\eta_k \leq 4^{2^{-\alpha}} \eta_{k+1} \leq 4/\eta_{k+1}.$$

Combining the above with the definition of \tilde{U}_{k+1} , we have that on E_{k+1} ,

$$\tilde{U}_{k+1} \leq 8r_{k+1} + \max\left\{32\eta_{k+1}, \frac{c}{4}\eta_{k+1}\right\} = 40\eta_{k+1} \leq 64\eta_{k+1} = \frac{c}{2}\eta_{k+1}.$$

Finally, noting that the union bound implies E_{k+1} has probability at least $1 - \sum_{k'=0}^k \delta_{k'}$ completes the inductive step.

By the principle of induction, we have thus established that, on an event $E_{\lfloor \log_2(m) \rfloor}$ of probability at least $1 - \sum_{k=0}^{\lfloor \log_2(m) \rfloor - 1} \delta_k > 1 - \delta \sum_{i=2}^{\infty} \frac{1}{i^2} > 1 - \delta$,

$$h^* \in \mathcal{G}_{\lfloor \log_2(m) \rfloor} \subseteq \left\{ h \in \mathcal{C} : \text{er}(h) - \text{er}(h^*) \leq \frac{c}{2} \eta_{\lfloor \log_2(m) \rfloor} \right\}.$$

In particular, this implies that \hat{h} exists in Step 6, and satisfies $\text{er}(\hat{h}) - \inf_{g \in \mathcal{C}} \text{er}(g) = \text{er}(\hat{h}) - \text{er}(h^*) \leq \frac{c}{2} \eta_{\lfloor \log_2(m) \rfloor}$. Noting that

$$\begin{aligned} \frac{c}{2} \eta_{\lfloor \log_2(m) \rfloor} &\leq c_1^{1/\alpha} \left(\frac{4a \left(d \text{Log}\left(\hat{\varphi}_{\alpha, \alpha}\left(a\left(\frac{ad}{m}\right)^{\frac{2}{2-\alpha}}\right)\right) + \text{Log}\left(\frac{4}{\delta}\right) \right)}{m} \right)^{\frac{1}{2-\alpha}} \\ &\leq 6(32c_0)^2 \left(\frac{a \left(d \text{Log}\left(\hat{\varphi}_{\alpha, \alpha}\left(a\left(\frac{ad}{m}\right)^{\frac{2}{2-\alpha}}\right)\right) + \text{Log}\left(\frac{4}{\delta}\right) \right)}{m} \right)^{\frac{1}{2-\alpha}} \end{aligned}$$

completes the proof. \blacksquare

Abstract

This article describes a method for constructing a special rule (we call it synergy rule) that uses as its input information the outputs (scores) of several monotonic rules which solve the same pattern recognition problem. As an example of scores of such monotonic rules we consider here scores of SVM classifiers.

In order to construct the optimal synergy rule, we estimate the conditional probability function based on the direct problem setting, which requires solving a Fredholm integral equation. Generally, solving a Fredholm equation is an ill-posed problem. However, in our model, we look for the solution of the equation in the set of monotonic and bounded functions, which makes the problem well-posed. This allows us to solve the equation accurately even with training data sets of limited size.

In order to construct a monotonic solution, we use the set of functions that belong to Reproducing Kernel Hilbert Space (RKHS) associated with the INK-spline kernel (splines with Infinite Numbers of Knots) of degree zero. The paper provides details of the methods for finding multidimensional conditional probability in a set of monotonic functions to obtain the corresponding synergy rules. We demonstrate effectiveness of such rules for

- 1) solving standard pattern recognition problems,
- 2) constructing multi-class classification rules,
- 3) constructing a method for knowledge transfer from multiple intelligent teachers in the LUPI paradigm.

Keywords: conditional probability, synergy, ensemble learning, intelligent teacher, privileged information, knowledge transfer, support vector machines, SVM+, classification, learning theory, kernel functions, regression

1. Introduction

The standard setting of pattern recognition problem requires, in the given set of functions $f(x, \alpha)$, $\alpha \in \Lambda$ defined in the space $X \in R^n$, to find the function $f(x, \alpha_0)$ such that the indicator function $y = \theta(f(x, \alpha)) \in \{0, 1\}$ (in this paper, the indicator function is defined

as follows: $\theta(x) = 0$ for $x < 0$ and $\theta(x) = 1$ for $x \geq 0$) minimizes the loss functional

$$R(\alpha) = \int |y - f(x, \alpha)| dp(x, y)$$

if the probability measure $p(x, y)$, $x \in X$, $y \in \{0, 1\}$ is unknown but iid data

$$(x_1, y_1), \dots, (x_\ell, y_\ell), \quad x_i \in X, y_i \in \{0, 1\}$$

generated according to $p(x, y) = p(y|x)p(x)$ are given (in the standard pattern recognition terminology, conditional probability $P(y|x)$ defines an unknown law of classification given by Teacher and $P(x)$ defines an unknown generator of events that should be classified by the learning machine).

In this article, we illustrate our approach using Support Vector Machine (SVM) algorithms. The SVM algorithm constructs an approximation of the desired classification function by first mapping vectors $x \in X$ into vectors $z \in Z$ and then constructing a separating hyperplane in space (Z, y) . The obtained rule is used for classification of unknown iid vectors distributed according to the same unknown probability measure $p(x, y)$.

The conditional probability of class $y = 1$ given x depends on the position of vector z relative to the obtained hyperplane

$$s_i = (w, z_i) + b,$$

where w, b are the parameters estimated by SVM: if $s_i \geq 0$, vector z_i belongs to class $y_i = 1$, otherwise it belongs to the opposite class $y_i = 0$.

As Platt (1999) observed, the smaller is the (negative) score s_i for vector z_i , the closer is the conditional probability $P(y = 1|s_i)$ to zero and, the larger is the (positive) score s_i , the closer is the conditional probability $P(y = 1|s_i)$ to one. Platt introduced a method for mapping SVM scores into values of conditional probability based on two hypotheses, a general one and a special one.

The general hypothesis: Conditional probability function $p(y = 1|s)$ is a monotonic function of variable s .

The special hypothesis: Conditional probability function can be approximated well with sigmoid functions with two parameters:

$$P(y = 1|s) = \frac{1}{1 + \exp\{-As + B\}}, \quad A, B \in R^1.$$

Using the maximum likelihood technique, Platt (1999) introduced effective methods to estimate both parameters A, B (see Lin et al., 2007).

Platt's approach was shown to be useful for calibration of SVM scores. Nevertheless, this method has certain drawbacks: even if the conditional probability function for SVM is monotonically increasing, it does not necessarily have the form of a two-parametric sigmoid function.

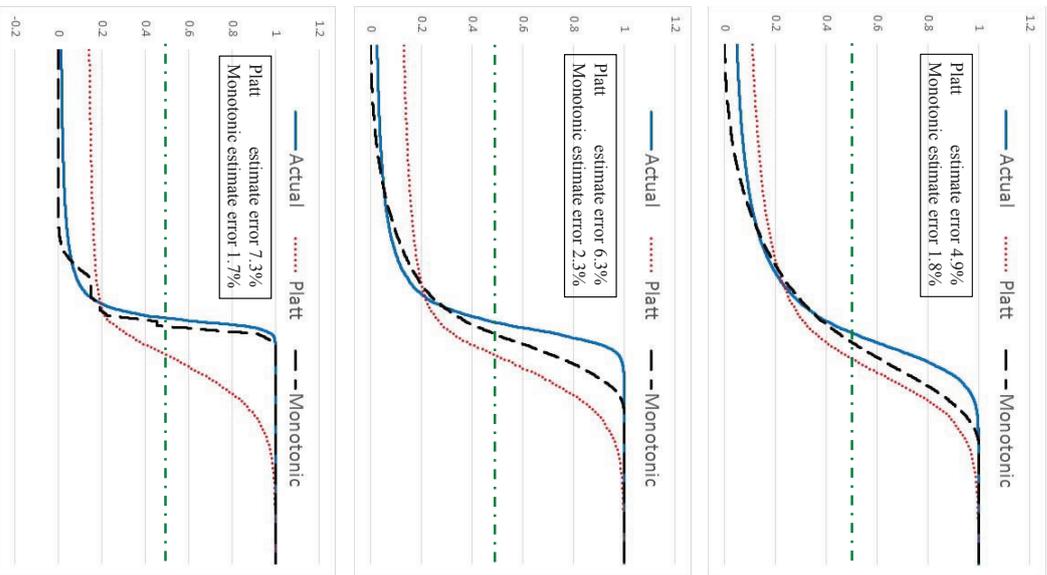

Figure 1: Comparison of conditional probability estimates.

It is easy to construct examples where suggested sigmoid function does not approximate well the desired monotonic conditional probability function. Figure 1 illustrates the conditional probability approximations (for a sample consisting of 96 random numbers that are evenly split between both classes) for Platt’s approach and for the special one-dimensional case of the algorithm described further in this paper.

The one-dimensional problem mentioned in the previous paragraph has the following form: given pairs (values s_i of SVM scores and corresponding classifications y_i)

$$(s_1, y_1), \dots, (s_t, y_t),$$

find an accurate approximation of the monotonic conditional probability function $p(y = 1|s)$. Section 3 describes a technique for construction of a monotonic approximation of the desired function. This approximation provides a more accurate estimate than the one based on sigmoid functions.

In this paper, we consider a more general (and more important) problem than this one-dimensional one. Suppose we have d different SVMs, solving the same classification problem. Also, suppose that the probability of class $y = 1$ given scores $s = (s^1, \dots, s^d)$ of d SVMs is a multidimensional monotonic conditional probability function: for any coordinate k and any fixed values of the other coordinates $(s^1, \dots, s^{k-1}, s^{k+1}, \dots, s^d)$, the higher is the value of score s^k , the higher is the probability $P(y = 1|s)$.

The goal of this article is to find a method for estimation of the *monotonic* conditional probability function $P(y = 1|s)$ for multidimensional vectors $s = (s^1, \dots, s^d)$; that is, to combine, in a single probability value, the results of multiple (namely, d) SVMs. We show that estimating conditional probability function in a set of monotonic functions has a significant advantage over estimating conditional probability function in a general, non-monotonic set of functions: it forms a *well-posed* problem rather than an *ill-posed* problem.

The decision rule for a two-class pattern recognition problem can be obtained using the estimated conditional probability function $P(y = 1|s)$ as

$$y = \theta \left(P(y = 1|s) - \frac{1}{2} \right).$$

This article is organized as follows. In Section 2, we consider the problem of estimating conditional probability function. We show that the problem of conditional probability estimation in general sets of functions is *ill-posed*. However, this problem is *well-posed* for sets of nonnegative bounded (by 1) monotonic functions. Therefore, the problem of estimating the monotonic conditional probability function can be solved more accurately than the general problem of estimating conditional probability function. In Section 3, we describe methods of estimating monotonic conditional probability functions. In Section 4, we apply methods of estimating monotonic conditional probability function based on the scores generated by several different SVMs solving the same pattern recognition problem. Here we estimate monotonic conditional probability function of class $y = 1$ given all the scores and we obtain the so-called *synergy rule* of classification. In Section 5, we consider a method for knowledge transfer from multiple intelligent teachers.

Remark. It is important to note that, in classical machine learning literature, there are *ensemble methods* that combine several rules (see Dietterich (2000), Zhang and Ma (2012),

Tsybakov (2003), Lecué (2007)). The difference between ensemble rules and synergy rules is in the following:

- 1) Ensemble rule is a result of structural combination (such as voting or weighted aggregation) of several classification rules.
- 2) Synergy rule defines the *optimal* solution to the problem of combining several scores of *monotonic rules*. It is based on effective methods of conditional probability estimation in the set of monotonic functions.
- 3) Synergy rule is constructed only for *monotonic rules* (such as SVM) in contrast to ensemble rule which combines *any* rules. Synergy is the property of monotonicity of the solution.

2. Overview of Methods

In this section, we present a short overview of the direct constructive setting of estimation of conditional probability, as presented in (Vapnik and Izmailov, 2015c) and (Vapnik and Izmailov, 2015a). The method is quite general, and, in this section, we do not even assume that the probability has to belong to $[0, 1]$.

2.1 Glivenko-Cantelli Theory

In (Vapnik et al., 2015), (Vapnik and Izmailov, 2015c), (Vapnik and Izmailov, 2015a), we introduced direct constructive methods for solving the main problems of statistical inference. All these methods are based on Glivenko-Cantelli theory, which forms the foundation of classical statistics. This theory states that the *joint cumulative distribution function of several variables* $X = (X^1, \dots, X^n)$

$$F(x) = P\{X^1 \leq x^1, \dots, X^n \leq x^n\}$$

can be estimated from the observations

$$X_1^1, \dots, X_\ell^1$$

by *empirical cumulative distribution function*

$$F_\ell(x) = \frac{1}{\ell} \sum_{k=1}^{\ell} \prod_{i=1}^n \theta(x^k - X_i^i), \quad (1)$$

where $\theta(x^k - X_i^i)$ is the step function (indicator function for $x \geq 0$).

Classical statistical theory provides bounds on the rate of convergence of $F_\ell(x)$ to the desired function $F(x)$ for the one-dimensional case (Massart, 1990):

$$P\left\{\sup_x |F_\ell(x) - F(x)| \geq \varepsilon\right\} \leq 2 \exp\{-2\varepsilon^2 \ell\}. \quad (2)$$

Application of VC theory to n -dimensional case (Vapnik, 1998) gives the bound

$$P\left\{\sup_x |F_\ell(x) - F(x)| \geq \varepsilon\right\} \leq \exp\left\{-\left(\varepsilon^2 - \frac{n \ln \ell}{\ell}\right) \ell\right\}. \quad (3)$$

2.2 Direct Setting of Conditional Probability Estimation

Estimation of cumulative distribution function using empirical data is a foundation for estimation of more sophisticated characteristics of stochastic events such as *density function*, *conditional density function*, *regression function*, *conditional probability function* etc.

1. We call function $p(x)$ the *density function* of the random events $X \sim F(x)$ if its integral defines the cumulative distribution function

$$\int \theta(x - X)p(X)dX = F(x), \quad X \in R^n.$$

2. Let pair (x, y) , $x \in X$, $y \in Y \in R^1$ be a random event. We call

$$p(y|x) = \frac{p(x, y)}{p(x)}, \quad p(x) > 0,$$

the conditional density function; it defines the conditional density of the value of y given observation x .

3. Let pair (x, y) , $x \in X$, $y \in \{0, 1\}$ be a random event. We call

$$p(y = 1|x) = \frac{p(x, y = 1)}{p(x)}, \quad p(x) > 0,$$

the conditional probability function; it defines conditional probability of $y = 1$ given observation x .

4. We call the integral

$$f(x) = \int yp(y|x)dy,$$

the regression function $f(x)$; it defines conditional expectation of value y given observation x .

The definition of conditional probability can be rewritten (see Vapnik and Izmailov (2015c), Vapnik and Izmailov (2015a)) in the form of the solution of integral equation

$$\int \theta(x - X)p(y = 1|X)dF(X) = F(x, y = 1). \quad (4)$$

These papers describe the direct constructive way of estimation of the conditional probability function as solving a multidimensional Fredholm integral equation (4) when cumulative distribution functions $F(x)$ and $F(x, y = 1)$ are unknown but data

$$(x_1, y_1), \dots, (x_\ell, y_\ell)$$

are given. This setting is called *direct* because it is based on the definition of conditional probability. It is called *constructive* because there exists an *empirical cumulative distribution function*, defined as (1), that converges to the real cumulative distribution function with the rates (2) and (3).

In order to find the conditional probability (i.e., to solve equation (4)), we use the approximations $F_k(x)$ and $F_k(x, y = 1) = F_k(x|y = 1)P_k(y = 1)$ instead of unknown functions $F(x)$, $F(x, y = 1)$. As shown in (Vapnik and Izmailov, 2015c) and (Vapnik and Izmailov, 2015a), statistical inference problems, such as (1) conditional density estimation, (2) conditional probability estimation, (3) regression estimation, (4) ratio of two densities estimation, can be formulated as follows: solve the integral equation

$$\int \theta(z - Z)F(z)dF(z) = (E\eta)^{-1}F^*(z)$$

in the situation when the cumulative distribution functions $F(z)$, $F^*(z)$, and the value $E(\eta)$ are unknown but their approximations in the form of empirical cumulative functions $F_k(z)$, $F_k^*(z)$ and empirical average $P_k(y = 1)$ can be obtained using data

$$(z_1, y_1), \dots, (z_\ell, y_\ell).$$

2.3 Fredholm Integral Equations of the First Kind

We consider the linear operator equations

$$Af = \Phi, \tag{5}$$

where A maps elements f of the metric space E_1 into elements Φ of the metric space E_2 . Let A be a continuous one-to-one operator, which maps a set $M \subset E_1$ onto a set $N \subset E_2$, i.e., $AM = N$. The solution of such operator equation exists and is unique, i.e., inverse operator A^{-1} is defined:

$$M = A^{-1}N.$$

The crucial question is whether this inverse operator A^{-1} is continuous. If it is, then close functions in N are mapped by A^{-1} to close functions in M : that is, a ‘‘small’’ change in the right-hand side of (5) results in a ‘‘small’’ change of its solution. In this case, the operator A^{-1} is called *stable* (Tikhonov and Arsenin, 1977). If, however, the inverse operator is discontinuous, then ‘‘small’’ changes in the right-hand side of (5) can cause a significant change of its solution. In this case, the operator A^{-1} is *unstable*.

The equation (5) is *well-posed* if its solution (1) exists, (2) is unique, and (3) is stable. Otherwise, the equation (5) is *ill-posed*.

We are interested in the situation when the solution of operator equation *exists*, and *is unique*. In this case, the *stability* of the operator A^{-1} determines whether (5) is ill-posed or well-posed. If the operator is unstable, then, generally speaking, any numerical solution of (5) is meaningless (a small error in the right-hand side of (5) can cause a large change of its solution).

Here we consider the linear integral operator

$$Af(x) = \int_a^b K(x, u)f(u)du$$

defined by the kernel $K(t, u)$, which is a symmetric positive definite function that is continuous almost everywhere on $a \leq t \leq b$, $c \leq x \leq d$. This kernel maps the set of functions

$\{f(t)\}$, continuous on $[a, b]$, unto the set of functions $\{\Phi(x)\}$, also continuous on $[c, d]$. The corresponding Fredholm equation of the first kind (Tikhonov and Arsenin, 1977)

$$\int_a^b K(x, u)f(u)du = \Phi(x)$$

requires finding the solution $f(u)$ given the right-hand side $\Phi(x)$. It is known that these integral equations are ill-posed.

In our problem, not only the right-hand side of (5) is an approximation but also the operator of (5) is defined approximately. In (Vapnik, 1995), such equations are called stochastic ill-posed problems.

2.4 Methods of Solving Ill-Posed Problems

In this subsection, we consider methods for solving ill-posed operator equations.

2.4.1 INVERSE OPERATOR LEMMA

The following Inverse Operator Lemma (see Tikhonov and Arsenin, 1977) is the key enabler for solving ill-posed problems.

Lemma. *If A is a continuous one-to-one operator defined on a compact set $M^* \subset M$, then the inverse operator A^{-1} is continuous on the set $N^* = AM^*$.*

It is known that bounded monotonic functions form a compact set. Therefore, if we restrict the set of solutions of Fredholm integral equations to the class of bounded monotonic functions, we will make the corresponding equation well-posed. This is exactly the reason of our targeting the *monotonic* solutions in this paper.

Thus, as follows from Inverse Operator Lemma, the conditions of existence and uniqueness of the solution of an operator equation imply that the problem is well-posed on the compact M^* . The third condition (stability of the solution) is automatically satisfied. This lemma is the basis for all constructive ideas of solving ill-posed problems. We describe one of them in the next subsection.

2.4.2 REGULARIZATION METHOD

Suppose that we have to solve the operator equation (4) defined by a continuous one-to-one operator A mapping M into N , where we assume that the solution of (5) exists. Also, suppose that, instead of the right-hand side $\Phi(x)$, we are given its approximations $\Phi_\delta(x)$, where

$$\rho_{E_2}(\Phi(x), \Phi_\delta(x)) \leq \delta.$$

Our goal is to solve the equations

$$Af = \Phi_\delta$$

when $\delta \rightarrow 0$.

Consider a lower semi-continuous functional $W(f)$ (called the *regularizer*) that has the following three properties:

1. the solution of (5) belongs to the domain $D(W)$ of the functional $W(f)$;

2. the values $W(f)$ of W are non-negative in the domain of W ;
3. the sets $\mathcal{M}_c = \{f : W(f) \leq c\}$ are compact for any $c \geq 0$.

The idea of regularization is to find a solution for (5) as an element minimizing the so-called regularized functional

$$R_\gamma(\hat{f}, \Phi_\delta) = \rho_{E_2}^2(A\hat{f}, \Phi_\delta) + \gamma_\delta W(\hat{f}), \quad \hat{f} \in D(W) \quad (6)$$

with regularization parameter $\gamma_\delta > 0$.

The following theorem holds true (Tikhonov and Arsenin, 1977).

Theorem 1. *Let E_1 and E_2 be metric spaces, and suppose that, for $\Phi \in \mathcal{N}$, there exists a solution of (5) that belongs to compact \mathcal{M}_c for some c . Suppose that, instead of the exact right-hand side Φ in (5), its approximations¹ $\Phi_\delta \in E_2$ are such that $\rho_{E_2}(\Phi, \Phi_\delta) \leq \delta$. Consider the sequence of parameters γ such that*

$$\gamma(\delta) \rightarrow 0 \text{ for } \delta \rightarrow 0, \text{ and } \lim_{\delta \rightarrow 0} \frac{\delta^2}{\gamma(\delta)} \leq r < \infty. \quad (7)$$

Then the sequence of solutions $f_\delta^{(\delta)}$ minimizing the functionals $R_{\gamma(\delta)}(f, \Phi_\delta)$ on $D(W)$ converges to the exact solution f (in the metric of space E_1) as $\delta \rightarrow 0$.

In a Hilbert space, the functional $W(f)$ may be chosen as $\|f\|^2$ for a linear operator A . Although the sets \mathcal{M}_c are only weakly compact in this case, regularized solutions converge to the desired one. Such a choice of regularized functional is convenient since its domain $D(W)$ is the whole space E_1 . In this case, however, the conditions on the parameters γ are more restrictive than in the case of Theorem 1: γ should converge to zero slower than δ^2 . Thus the following theorem holds true (Tikhonov and Arsenin, 1977).

Theorem 2. *Let E_1 be a Hilbert space and $W(f) = \|f\|^2$. Then, if $\gamma(\delta)$ satisfies (7) with $r = 0$, the regularized elements $f_\delta^{(\delta)}$ converge to the exact solution f in E_1 as $\delta \rightarrow 0$.*

2.4.3 STOCHASTIC ILL-POSED PROBLEMS

Let A_ℓ be approximations of A and Φ_ℓ be approximations of Φ . In order to solve stochastic ill-posed problems

$$A_\ell f = \Phi_\ell, \quad (8)$$

we will also use the regularization method minimizing the functional

$$T_\ell f = \|A_\ell f - \Phi_\ell\|_{E_2}^2 + \gamma_\ell \Omega(f). \quad (9)$$

Here, with increasing number of observations ℓ , functions Φ_ℓ converge to the actual function Φ and operator A_ℓ converges to the actual operators A in the sense that

$$\|A_\ell - A\|^2 = \sup_{f \in \{\Omega(f) \leq C\}} \frac{\|A_\ell f - A f\|^2}{\Omega(f)} \rightarrow \ell \rightarrow \infty 0. \quad (10)$$

As was shown in (Vapnik (1998)), if the desired solution belongs to one of the compacts $\{f; \Omega(f) \leq C\}$, the sequence of approximations Φ_ℓ of the right-hand side of equation and

¹. The elements Φ_δ do not have to belong to the set \mathcal{N} .

the sequence of approximations A_ℓ of the operators converge in probability to, respectively, Φ and A , and $\gamma_\ell \rightarrow 0$ in (9) is such that

$$\lim_{\ell \rightarrow \infty} \frac{\|A_\ell - A\|^2}{\gamma_\ell} = 0,$$

then the sequence of minima converges to the desired function.

In (Vapnik and Izmailov (2015c)), (Vapnik and Izmailov (2015a)), it was shown that our specific integral equations satisfy the required conditions.

2.5 V-Matrix Method of Estimation of Conditional Probability Function

In order to find the conditional probability from the observations, we solve stochastic ill-posed problem (8) using regularization method (9), where approximations of the right-hand side of equation Φ and operator A are defined. We define two terms of (9) as:

1. the square of the distance $\rho^2(A_\ell f, \Phi_\ell)$ in space E_2 between functions (we omit the common normalizing multiplier $1/\ell$ in these definitions since it does not affect the subsequent derivations):

$$A_\ell f(x) = \sum_{i=1}^{\ell} \theta(x - X_i) f(X_i) \quad \text{and} \quad \Phi_\ell(x) = \sum_{j=1}^{\ell} y_j \theta(x - X_j),$$

where $(X_i, y_i), \dots, i = 1, \dots, \ell, X_i \in R^d, y_i \in \{0, 1\}$ are training data;

2. the regularization functional $\Omega(f)$, to be defined below.

2.5.1 CHOICE OF DISTANCE AND DEFINITION OF V-MATRIX

Below, we use L_2 -distance in space E_2 in the general form

$$\rho^2(A_\ell f, \Phi_\ell) = \int (A_\ell f(x) - \Phi_\ell(x))^2 \sigma(x) d\mu(x),$$

where $\sigma(x)$ is a non-negative function and $\mu(x)$ is a probability measure; some choices for $\sigma(x)$ and $\mu(x)$ were considered in (Vapnik and Izmailov (2015c)), (Vapnik and Izmailov (2015a)). To simplify computations, we chose

$$\sigma(x) = \prod_{k=1}^d \sigma_k(x^k) \quad \text{and} \quad \mu(x) = \prod_{k=1}^d \mu_k(x^k), \quad \text{where } x = (x^1, \dots, x^d).$$

Then we can rewrite the square of distance ρ^2 in the explicit form

$$\int \left(\sum_{i=1}^{\ell} f(X_i) \prod_{k=1}^d \theta(x^k - X_i^k) - \sum_{j=1}^{\ell} y_j \prod_{k=1}^d \theta(x^k - X_j^k) \right)^2 \prod_{k=1}^d \sigma_k(x^k) d\mu_k(x^k) = \sum_{i,j=1}^{\ell} f(X_i) f(X_j) V_{i,j} - 2 \sum_{i,j=1}^{\ell} y_j f(X_i) V_{i,j} + \sum_{i,j=1}^{\ell} y_i y_j V_{i,j},$$

where we have denoted

$$V_{i,j} = \prod_{k=1}^{\ell} V_{k,j}^k, \quad V_{k,j}^k = \int \theta \left(x^k - \min\{X_k^k, X_j^k\} \right) \sigma_k(x^k) d\mu(x^k).$$

We denote by V the $(\ell \times \ell)$ -dimensional matrix of elements $V_{i,j}$, by \mathbf{f} the ℓ -dimensional vector $\mathbf{f} = (f(X_1), \dots, f(X_\ell))^T$, and by Y the ℓ -dimensional vector $Y = (y_1, \dots, y_\ell)^T$. In matrix notations, we can rewrite the square of distance as follows:

$$\rho^2 = \mathbf{f}^T V \mathbf{f} - 2\mathbf{f}^T V Y + Y^T V Y.$$

2.5.2 CHOICE OF REGULARIZATION FUNCTIONAL

Suppose that the solution of our integral equation (4) belongs to the RKHS (Reproducing Kernel Hilbert Space) associated with kernel $K(x, x^*)$ (symmetric positive definite function of vector variables $x, x^* \in X$). This means that RKHS has inner product such that for any function $f(x)$ from the space, the equality

$$(K(\cdot, y), f) = f(y)$$

holds true. According to Mercer theorem, any positive definite kernel $K(x, x^*)$ can be represented as

$$K(x, x^*) = \sum_{k=1}^{\infty} \lambda_k \phi_k(x) \phi_k(x^*),$$

where $\{\phi_k(x)\}$ is a system of orthonormal functions in E_1 and $\{\lambda_k\}$ is a sequence of non-negative values converging to zero, where $k = 1, 2, \dots$

It is easy to check that the functions

$$f(x, a) = \sum_{k=1}^{\infty} a_k \phi_k(x),$$

belong to RKHS associated with kernel $K(x, x^*)$ if the inner product between two functions $f(x, a)$ and $f(x, b)$ has the form

$$(f(x, a), f(x, b)) = \sum_{k=1}^{\infty} \frac{a_k b_k}{\lambda_k},$$

and, therefore, the norm of function $f(x, a)$ is

$$\|f(x, a)\|^2 = \sum_{k=1}^{\infty} \frac{a_k^2}{\lambda_k}. \quad (11)$$

We will chose the norm of function from RKHS as the regularizer $\Omega(f) = \|f\|^2$. As follows from (11), the set of functions with their norm bounded by C

$$\|f(x, a)\|^2 = \sum_{k=1}^{\infty} \frac{a_k^2}{\lambda_k} \leq C$$

is a compact. Therefore, we use as a regularizer in (9) the norm of function in RKHS

$$\rho^2 + \gamma_\ell \|f\|^2 = \mathbf{f}^T V \mathbf{f} - 2\mathbf{f}^T V Y + Y^T V Y + \gamma_\ell \|f\|^2. \quad (12)$$

An important property of RKHS for applications is defined by the so-called Representer Theorem (Kornfeldorff and Wahba (1970)), according to which the minimum of (12) has an expansion on elements $K(x_i, x)$ defined on the training data x_1, \dots, x_ℓ

$$f(x, a) = \sum_{i=1}^{\ell} \alpha_i K(x_i, x), \quad (13)$$

and the norm of function f in RKHS is defined as

$$\|f\|^2 = \sum_{i,j=1}^{\ell} \alpha_i \alpha_j K(x_i, x_j). \quad (14)$$

To simplify the notations, we introduce ℓ -dimensional vector $\Lambda = (\alpha_1, \dots, \alpha_\ell)$, ℓ -dimensional vector functions $K(x) = (K(x_1, x), \dots, K(x_\ell, x))^T$ and $(\ell \times \ell)$ -dimensional matrix $K = (K(x_i, x_j))$.

Using these notations, we can rewrite (13) and (14) as

$$f(x) = K^T(x) \Lambda, \quad \mathbf{f} = K \Lambda, \quad \|f\|^2 = \Lambda^T K \Lambda.$$

2.5.3 V-MATRIX KERNEL REGRESSION

In order to solve our integral equation using the regularization technique, we have to minimize, with respect to vector Λ , the functional

$$W(\Lambda) = \Lambda^T K V K \Lambda - 2\Lambda^T K V Y + \gamma_\ell \Lambda^T K \Lambda; \quad (15)$$

in this functional, the third term of (12) was omitted since it does not depend on Λ . The solution has the form

$$f(x) = \Lambda^T K(x), \quad (16)$$

where one has to minimize functional (15) in order to find Λ .

The minimum of (15) has the closed-form representation

$$\Lambda = (V K + \gamma_\ell I)^{-1} V Y. \quad (17)$$

Note that for $y_i \in \{0, 1\}$ in $Y = (y_1, \dots, y_\ell)^T$, expression (17) estimates the conditional probability; for $y_i \in R^1$, this expression estimates the regression.

2.6 Estimation in a Set of Functions with Bias Term

Below we consider sets of functions $\{f(x) + b\}$, where b is a value of bias (to be estimated from data) and function $f(x)$ belongs to RKHS (note that $f(x) + b$ does not have to belong to RKHS). Replacing $f(x)$ with $f(x) + b$ in (16), we can rewrite (15) in the form

$$W = (K \Lambda + b \mathbf{1}_\ell)^T V (K \Lambda + b \mathbf{1}_\ell) - 2(K \Lambda + b \mathbf{1}_\ell)^T V Y + \gamma_\ell \Lambda^T K \Lambda. \quad (18)$$

Finding the expression for b by minimizing (18)

$$b = \frac{1}{\ell} \mathbf{1}_\ell^T (Y - K\Lambda) \quad (19)$$

and putting it into equation (18), we obtain the functional for minimization:

$$\begin{aligned} W = & \left(K\Lambda + \frac{1}{\ell} \mathbf{1}_\ell \mathbf{1}_\ell^T (Y - K\Lambda) \right)^T \left(K\Lambda + \frac{1}{\ell} \mathbf{1}_\ell \mathbf{1}_\ell^T (Y - K\Lambda) \right) - \\ & 2 \left(K\Lambda + \frac{1}{\ell} \mathbf{1}_\ell \mathbf{1}_\ell^T (Y - K\Lambda) \right)^T VY + \gamma_\ell \Lambda^T K\Lambda. \end{aligned} \quad (20)$$

In order to simplify this expression, we introduce the notations

$$E = I - \frac{1}{\ell} \mathbf{1}_\ell \mathbf{1}_\ell^T \quad \text{and} \quad \mathcal{V} = EV E.$$

Then

$$W = \Lambda^T K \mathcal{V} K \Lambda - 2\Lambda^T K \mathcal{V} Y + \gamma \Lambda^T K \Lambda + C, \quad (21)$$

where C are the terms that do not depend on Λ . Taking the derivative of W over Λ and equating it to zero, we see that, in order to minimize (21), vector Λ has to satisfy the equation

$$2K \mathcal{V} K \Lambda - 2K \mathcal{V} Y + 2\gamma K \Lambda = 0.$$

Solving this equation with respect to Λ , we obtain the closed-form solution

$$\Lambda = (\mathcal{V} K + \gamma I)^{-1} \mathcal{V} Y, \quad (22)$$

which differs from (17) just by using matrix \mathcal{V} instead of matrix V .

Therefore, in order to find the conditional probability in the form $f(x) = \Lambda^T \mathcal{K}(x) + b$, we have to estimate the vector Λ using (22) and estimate the bias b using (19).

Remark. The described solution for conditional probability is also applicable for estimating regression. In that case, coordinates y_i of vector $Y = (y_1, \dots, y_\ell)^T$ belong to \mathbb{R}^1 and the set of functions $f(x, \alpha)$, $\alpha \in \Lambda$ is a set of real-valued functions from RKHS.

2.7 Indirect Methods of Estimation of Conditional Probability

In addition to direct setting of conditional probability problem, indirect settings also exist. They are based on the fact that for some loss functions $\rho(y - f(x, \alpha))$, under a wide range of conditions, the minimum of the functional

$$R = \int \rho(y - f(x, \alpha)) d\rho(x, y) \quad (23)$$

in the set $f(x, \alpha)$, $\alpha \in \Lambda$ defines conditional probability function $f(x, \alpha_0)$ (provided that $\alpha_0 \in \Lambda$). In order to estimate the conditional probability, one has to find the function that minimizes functional (23) if the probability measure $P\rho(x, y)$ is unknown but iid sample

$$(x_1, y_1), \dots, (x_\ell, y_\ell) \quad (24)$$

is given. The standard idea for solving this problem is to minimize the functional

$$\sum_{i=1}^{\ell} \rho(y_i - f(x_i, \alpha)) + \gamma \|f(x, \alpha)\|^2.$$

There are two classical ideas of choosing the term $\rho(y - f(x, \alpha))$:

1. $\rho(y - f(x, \alpha)) = (y - f(x, \alpha))^2$, which leads to regularized *kernel least square* method.
2. $\rho(y - f(x, \alpha)) = |y - f(x, \alpha)|$, which leads to a more robust regularized *kernel least modulo* method.

2.7.1 REGULARIZED KERNEL LEAST SQUARE METHOD

We minimize the functional (23) based on empirical data (24) in the set of functions belonging to RKHS associated with the kernel $K(x, x^*)$. For this set, we minimize the empirical functional

$$\sum_{i=1}^{\ell} (y_i - f(x_i, \alpha) - b)^2 + \gamma \|f(x, \alpha)\|^2.$$

Minimizing this expression over b , we obtain

$$\sum_{i=1}^{\ell} (f(x_i, \alpha) + b) = \sum_{i=1}^{\ell} y_i,$$

where we again assume that functions $f(x, \alpha)$, $\alpha \in \Lambda$ belong to RKHS associated with kernel $K(x, x^*)$. Using the same reasoning as in the previous section, we obtain that the solution has the form (16), with the expansion coefficients $\Lambda = (\alpha_1, \dots, \alpha_\ell)^T$ maximizing the functional

$$W = \Lambda^T K I K \Lambda - 2\Lambda^T K I Y + \gamma \Lambda^T K \Lambda,$$

where we have denoted

$$\mathcal{I} = E I E.$$

The vector of coefficients Λ in closed form is

$$\Lambda = (\mathcal{I} K + \gamma I)^{-1} \mathcal{I} Y.$$

2.7.2 REGULARIZED KERNEL LEAST MODULO METHOD

In classical statistics, besides L_2 -norm loss function for estimating regression, L_1 -norm loss is considered as well. In many situations, L_1 -norm regression has an advantage over L_2 -norm: it provides the so-called *robust regression* (Andersen (2008)). As in previous sections, we estimate the regression in the set of functions $\{f(x, \alpha) + b\}$, where each $f(x, \alpha)$ belongs to RKHS associated with kernel $K(x, x^*)$. In order to do that, we minimize the functional

$$R = C \sum_{i=1}^{\ell} |y_i - f(x_i, \alpha) - b| + \|f(x, \alpha)\|^2.$$

We rewrite this problem in an equivalent form: we map vectors $x \in X$ into Hilbert space $z \in Z$ defined by the inner product $\langle z_i, z_j \rangle = K(x_i, x_j)$ given by a non-negative definite kernel $K(x, x_*)$. We look for a solution in the form $f(x, \alpha) = (w, z) + b$, where $w, z \in Z$. In these notations, we rewrite our minimization problem as follows: minimize the functional

$$R = C \sum_{i=1}^{\ell} \xi_i + (w, w)$$

subject to the constraints

$$-\xi_i \leq y_i - (w, z_i) - b \leq \xi_i, \quad i = 1, \dots, \ell.$$

Using Lagrange multiplier method, we construct the Lagrangian

$$\mathcal{L} = C \sum_{i=1}^{\ell} \xi_i + (w, w) - \sum_{i=1}^{\ell} \alpha_i [y_i - (w, z_i) - b] + \xi_i - \sum_{i=1}^{\ell} \alpha_i^+ [-y_i + (w, z_i) + b] + \xi_i],$$

the saddle point of which (minimum with respect to ξ and w and maximum with respect to α) defines the solution.

The solution has the form

$$f(x, \alpha) = \sum_{i=1}^{\ell} \delta_i K(x_i, x) + b,$$

where, in order to find $\delta_i = \alpha_i^* - \alpha_i$, one has to maximize the functional

$$R = \sum_{i=1}^{\ell} y_i \delta_i - \frac{1}{2} \sum_{i,j=1}^{\ell} \delta_i \delta_j K(x_i, x_j)$$

subject to the constraints

$$-C \leq \delta_i \leq C, \quad \sum_{i=1}^{\ell} \delta_i = 0.$$

The bias b can be computed as

$$b = y_k - \sum_{i=1}^{\ell} \delta_i K(x_i, x_k),$$

where k is an index for which $|\delta_k| \neq C$.

3. Estimation of Monotonic Conditional Probability Functions

Our goal is to minimize functional (15) in the set of monotonically increasing functions. We do this by using expansion of desired function on kernels that generate splines with infinite number of knots (INK-spline) of degree zero. The reason we use these kernels is that they enable an efficient and straightforward construction of multidimensional monotonic functions: it is possible that some other kernels might be used for that purpose as well.

3.1 Kernels for Estimating INK-Splines

According to the definition in the one-dimensional case, splines of degree r with m knots are defined by the expansion (in this section, we assume that $0 \leq x \leq 1$)

$$S(x|r, m) = \sum_{s=0}^r c_s x^s + \sum_{k=0}^m e_k (x - a_k)_+^r, \quad (25)$$

where

$$(x - a_k)_+^r = \begin{cases} (x - a_k)^r & \text{if } x - a_k \geq 0 \\ 0 & \text{otherwise} \end{cases}$$

We generalize expansion (25) using infinite number of knots:

$$S_{\infty}(x) = \sum_{s=0}^r c_s x^s + \int_0^{\infty} g(\tau) (x - \tau)_+^r d\tau.$$

Following the approach from (Vapnik (1998)), (Izmailov et al. (2013)), we define the kernel with infinite number of knots (INK-spline) of degree r for expansion of the function of one variable $x \geq 0$ in the form

$$K_r(x_i, x_j) = \int_0^{\infty} (x_i - \tau)_+^r (x_j - \tau)_+^r d\tau = \sum_{k=0}^r \frac{C_r^k}{2^r - k + 1} [\min\{x_i, x_j\}]^{2r-k+1} |x_i - x_j|^k$$

(here we modified the definition of INK-kernel from (Vapnik (1998)), (Izmailov et al. (2013)) by omitting its polynomial portion).

For $r = 0$, the INK-spline kernel has the form

$$K_0(x_i, x_j) = \min\{x_i, x_j\}; \quad (26)$$

for $r = 1$, the INK-spline kernel has the form

$$K_1(x_i, x_j) = \frac{1}{3} (\min\{x_i, x_j\})^3 + \frac{1}{2} (\min\{x_i, x_j\})^2 |x_i - x_j|.$$

In the multidimensional case, the INK-spline of degree r is defined as

$$K_r(x_i, x_j) = \prod_{k=1}^d K_{r_k}(x_i^k, x_j^k), \quad x = (x^1, \dots, x^d).$$

3.2 Estimating One-Dimensional Monotonic Conditional Probability Function

In classical statistics, there are methods for estimation of monotonic (isotonic) regression (see Best and Chakravarti, Mair et al. (2009), Sysoev et al. (2011), Meyer (2013)), focusing on maintaining the monotonicity on the observed sample points. Below we describe a method of estimating conditional probability that is a monotonic function in the whole space; the method is based on INK-splines with infinite number of knots.

We estimate the monotonic conditional probability function in the set of INK-splines of degree zero (piecewise constant spline function with infinite number of knots). We start with one-dimensional case where $x \geq 0$. For this kernel, the solution is defined as

$$f(x) = \Lambda^T \mathcal{K}(x) + b = \sum_{i=1}^{\ell} \alpha_i \min\{x_i, x\} + b. \quad (27)$$

To specify monotonically increasing function, we impose additional constraints for (27): specifically, we consider the subset of functions (27) for which the inequality

$$\frac{df(x, \alpha)}{dx} \geq 0, \quad \forall x \geq 0 \quad (28)$$

is valid. Since any function (27) is a piecewise linear continuous function, in order for it to be monotonic, it is sufficient for that function to satisfy the constraints

$$\begin{aligned} \frac{df(x_j, \alpha)}{dx} &= \sum_{i=1}^{\ell} \alpha_i \theta(x_i - x_j) \geq 0, \quad j = 1, \dots, \ell, \\ \frac{df(0, \alpha)}{dx} &= \sum_{i=1}^{\ell} \alpha_i \geq 0. \end{aligned} \quad (29)$$

Indeed, consider three possible cases:

1. Let $x \leq \min\{x_1, \dots, x_L\}$. Then, since $\theta(x_i - x) = 1$ for all $i = 1, \dots, L$, the value (28) is non-negative according to the second inequality in (29).
2. Let $\min\{x_1, \dots, x_L\} < x < \max\{x_1, \dots, x_L\}$. Without loss of generality, assume the ordering $x_1 \leq x_2 \leq \dots \leq x_L$ and the position of x within that ordering as $x_j \leq x \leq x_{j+1}$. The function (28) is linear on the interval (x_j, x_{j+1}) and its values at the ends of the interval are

$$\sum_{i=1}^L \alpha_i \theta(x_i - x_j) \quad \text{and} \quad \sum_{i=1}^L \alpha_i \theta(x_i - x_{j+1}),$$

which are non-negative, according to the first inequality in (29). Therefore, the function is also non-negative at any internal point x of the interval (x_j, x_{j+1}) .

3. Let $x \geq \max\{x_1, \dots, x_L\}$. Then, since $\theta(x_i - x) = 0$ for all $i = 1, \dots, L$, the value (28) is zero.

We introduce the notations

$$\Theta(x_j) = (\theta(x_1 - x_j), \dots, \theta(x_\ell - x_j))^T, \quad j = 1, \dots, \ell.$$

Using these notations, we rewrite the constraints (29) in the form

$$\Lambda^T \Theta(0) \geq 0, \quad \Lambda^T \Theta(x_j) \geq 0, \quad j = 1, \dots, \ell. \quad (30)$$

3.2.1 ESTIMATING MONOTONIC CONDITIONAL PROBABILITY USING V-MATRIX METHOD

In order to find a monotonic solution, we use our method for estimating conditional probability function with INK-spline kernel of degree zero with additional ℓ monotonicity constraints (30). That is, we have to minimize the functional

$$W = (K\Lambda + b\mathbf{1}_\ell)^T V(K\Lambda + b\mathbf{1}_\ell) - 2(K\Lambda + b\mathbf{1}_\ell)^T VY + \gamma_\ell \Lambda^T K\Lambda \quad (31)$$

(here coordinates of vector Y are $y_i \in \{0, 1\}$ subject to $\ell + 1$ inequality constraints

$$\Lambda^T \Theta(0) \geq 0, \quad \Lambda^T \Theta(x_j) \geq 0, \quad j = 1, \dots, \ell.$$

Let $x \geq 0$. Then, in order to construct the conditional probability in the set of non-negative monotonic functions bounded by the value 1, we have to enforce the constraint $P(y = 1|x) \leq 1$. Thus, taking into account nonnegativity and monotonicity (31), we add the constraint

$$\Lambda^T \mathcal{K}(x = 1) + b = \Lambda^T \bar{\mathbf{x}} + b \leq 1, \quad (32)$$

where $\bar{\mathbf{x}} = (x_1, \dots, x_\ell)^T$.

3.2.2 ESTIMATING MONOTONIC CONDITIONAL PROBABILITY USING L₂-NORM SVM

Using L_2 -norm SVM for estimating monotonic conditional probability function, we minimize the functional

$$W(\Lambda) = \Lambda^T K K \Lambda - 2\Lambda^T K Y + \gamma_\ell \Lambda^T K \Lambda,$$

with coordinates of Y are $y_i \in \{0, 1\}$ subject to $\ell + 2$ inequality constraints (31), (32).

3.2.3 ESTIMATING MONOTONIC CONDITIONAL PROBABILITY USING L₁-NORM SVM

We look for a solution of the following quadratic optimization problem: minimize the functional

$$C \sum_{i=1}^{\ell} |y_i - f(x_i, \alpha) - b| + \|f(x, \alpha)\|^2$$

subject to $\ell + 2$ inequality constraints (31) and (32), where $f(x, \alpha)$ belongs to RKHS associated with the kernel INK-spline of degree zero $K(x_i, x_j) = \min(x_i, x_j)$.

In matrix form, this problem can be rewritten as follows: minimize the functional

$$R(\xi, \Lambda) = C \mathbf{1}_\ell^T \xi + \gamma \Lambda^T K \Lambda$$

subject to the constraints

$$-\xi \leq Y - K\Lambda - b\mathbf{1}_\ell \leq \xi,$$

and $\ell + 2$ constraints

$$\Lambda^T \Theta(0) \geq 0, \quad \Lambda^T \Theta(x_i) \geq 0, \quad i = 1, \dots, \ell,$$

$$\Lambda^T \bar{\mathbf{x}} + b \leq 1,$$

where we have denoted

$$\bar{\xi} = (\xi_1, \dots, \xi_\ell)^T, \quad \bar{x} = (x_1, \dots, x_\ell)^T, \quad Y = (y_1, \dots, y_\ell)^T.$$

3.3 Estimating Multidimensional Monotonic Conditional Probability Functions

3.3.1 ESTIMATION OF MONOTONIC FUNCTIONS FROM RKHS ASSOCIATED WITH MULTIPLICATIVE KERNELS

In multidimensional case, $x_i = (x_i^1, \dots, x_i^d)^T \in H \subset \mathbb{R}^d$, where we can assume (by proper normalization) that $H = [0, 1]^d$. We consider the solution of the equation in the form

$$f(x) = \sum_{i=1}^{\ell} \alpha_i K(x_i, x) + b,$$

where the kernel generating d -dimensional INK-spline of degree zero has the multiplicative form

$$K(x_i, x) = \prod_{k=1}^d \min(x_i^k, x^k).$$

We have

$$f(x) = \sum_{i=1}^{\ell} \alpha_i \prod_{k=1}^d \min(x_i^k, x^k). \quad (33)$$

Note that the set of functions (33) is monotonic in H if d inequalities

$$\frac{df(x)}{dx^k} = \sum_{i=1}^{\ell} \alpha_i \theta(x_i^k - x^k) \prod_{m \neq k} \min(x_i^m, x^m) \geq 0, \quad k = 1, \dots, d \quad (34)$$

hold true for an function and any $x = (x^1, \dots, x^d) \in H$. To keep the matrix notations, we consider diagonal matrix D_k with diagonal elements h_{ii}

$$h_{ii} = \prod_{m \neq k} \min(x_i^m, x^m), \quad i = 1, \dots, \ell, \quad k = 1, \dots, d.$$

Using this notation, we rewrite (34) as

$$\frac{df(x)}{dx^k} = A^T D_k \Theta(x^k) \geq 0, \quad k = 1, \dots, d \quad (35)$$

for all $x \in H$.

In order to find the monotonic conditional probability function, we minimize

$$R(\Lambda, b) = (K\Lambda + b\mathbf{1}_\ell)^T V (K\Lambda + b\mathbf{1}_\ell) - 2(K\Lambda + b\mathbf{1}_\ell)^T VY + \gamma(A^T K\Lambda) \quad (36)$$

subject to d constrains

$$\inf_{x \in H} A^T D_k \Theta(x^k) \geq 0, \quad k = 1, \dots, d.$$

This is a difficult problem to solve. Instead, one could construct an approximate solution by using Monte Carlo ideas: consider $N \approx n^d$ random (or pseudo-random) elements $x_i =$

$(x_i^1, \dots, x_i^d)^T$, $t = 1, \dots, N$ belonging to H (Sobol points (Jäckel (2004)) could be used, for instance) and instead of d constrains (35) consider Nd constrains

$$A^T D_k \Theta(x_i^k) \geq 0, \quad k = 1, \dots, d, \quad t = 1, \dots, N. \quad (37)$$

As in the one-dimensional case, in order to enforce that the value of conditional probability does not exceed one, we add one more constraint

$$A^T \bar{\mathbf{x}}^* + b \leq 1, \quad (38)$$

where we have denoted by $\bar{\mathbf{x}}^*$ the ℓ -dimensional vector of products

$$\bar{\mathbf{x}}^* = \left[\left(\prod_k x_1^k \right), \dots, \left(\prod_k x_\ell^k \right) \right]^T.$$

Therefore, in order to construct d -dimensional *approximation* of monotonic conditional probability function, one has to minimize functional (36), subject to Nd constrains (37) and one constraint (38).

3.3.2 ESTIMATING MONOTONIC FUNCTIONS FROM RKHS ASSOCIATED WITH ADDITIVE KERNELS

Along with functions defined by (multiplicative) INK-spline kernels of degree zero (26) that can construct approximations to monotonic functions, we consider functions defined by the additive kernel (which is a sum of one-dimensional kernels)

$$f(x) = \sum_{i=1}^{\ell} \sum_{k=1}^d \alpha_i^k \min(x_i^k, x^k) + b. \quad (39)$$

In order to find $d \times \ell$ coefficients α_i^k , $k = 1, \dots, d$, $i = 1, \dots, \ell$ of expansion in estimating conditional probability function in the direct setting, we minimize the functional

$$R(\Lambda_1, \dots, \Lambda_\ell, b) = \left[\sum_{k=1}^d K_k \Lambda_k + b\mathbf{1}_\ell \right]^T V \left[\sum_{k=1}^d K_k \Lambda_k + b\mathbf{1}_\ell \right] - 2 \left[\sum_{k=1}^d K_k \Lambda_k + b\mathbf{1}_\ell \right]^T VY + \gamma \sum_{k=1}^d (\Lambda_k^T K_k \Lambda_k) \quad (40)$$

subject to $d \times (\ell + 1)$ inequality constrains

$$\begin{aligned} \frac{\partial f(x_j, \alpha)}{\partial x^k} &= \sum_{i=1}^{\ell} \alpha_i^k \theta(x_i^k - x^k) = \Lambda_k^T \Theta(x_j^k) \geq 0, \quad j = 1, \dots, \ell, \quad k = 1, \dots, d, \\ \frac{\partial f(\bar{0}, \alpha)}{\partial x^k} &= \sum_{i=1}^{\ell} \alpha_i^k = \Lambda_k^T \Theta(\bar{0}^k) \geq 0, \quad k = 1, \dots, d. \end{aligned} \quad (41)$$

where we have denoted by Λ_k the ℓ -dimensional vector of $\alpha^k = (\alpha_1^k, \dots, \alpha_\ell^k)^T$, $k = 1, \dots, d$, by K_k the $(\ell \times \ell)$ -dimensional matrix of elements $K_k(x_i^k, x_j^k) = \min(x_i^k, x_j^k)$, and by

$$\Theta(x_j^k) = (\theta(x_1^k - x_j^k), \dots, \theta(x_\ell^k - x_j^k))^T, \quad j = 1, \dots, \ell, \quad k = 1, \dots, d$$

we have denoted the $d \times \ell$ vectors of dimensionality ℓ .

Let vector $x = (x^1, \dots, x^d)$ have bounded coordinates $0 \leq x^k \leq c_k$, $k = 1, \dots, d$. Since conditional probability does not exceed 1, we need one more constraint $P(y = 1|c_1, \dots, c_d) \leq 1$. That is, we have to add the constraint

$$\sum_{k=1}^d \Lambda_k^T \mathbf{X}^k + b \leq 1, \quad (42)$$

where we have denoted $\mathbf{X}^k = (x_1^k, \dots, x_\ell^k)^T$. A function satisfying the conditions (41) and (42), is monotonic (it can be proven in the same way it was done in Section 3.2).

3.3.3 ESTIMATION OF MULTIDIMENSIONAL MONOTONIC CONDITIONAL PROBABILITY USING L_2 -NORM SVM

In order to estimate the conditional probability in indirect setting, one minimizes functional (36), subject to constraints (37), (38) for multiplicative kernel (or functional (40) subject to constraints (41), (42) for additive kernel), where V -matrix is replaced with identity matrix (I -matrix).

3.3.4 ESTIMATION OF MULTIDIMENSIONAL MONOTONIC CONDITIONAL PROBABILITY USING L_1 -NORM SVM

In order to estimate multidimensional conditional monotonic function using L_1 -norm and multiplicative INK-spline kernel (33), one minimizes the functional

$$R(\xi, \Lambda) = C \mathbf{1}_\ell^T \xi + \gamma \Lambda^T K \Lambda$$

subject to the constraints

$$-\bar{\xi} \leq Y - K \Lambda - b \mathbf{1}_\ell \leq \bar{\xi},$$

and constraints (37), (38). Here we used the notations

$$\bar{\xi} = (\xi_1, \dots, \xi_\ell)^T, \quad Y = (y_1, \dots, y_\ell)^T.$$

To estimate multidimensional conditional monotonic function using L_1 -norm and additive INK-spline kernel (39), one minimizes the functional

$$R(\xi, \Lambda) = C \mathbf{1}_\ell^T \xi + \gamma \left[\sum_{k=1}^d \Lambda_k^T K_k \Lambda_k \right]$$

subject to the constraints

$$-\bar{\xi} \leq Y - \sum_{k=1}^d K_k \Lambda_k - b \mathbf{1}_\ell \leq \bar{\xi},$$

and constraints (41), (42).

3.3.5 COMPUTATIONAL ISSUES

Quadratic optimization problem. In order to estimate a multidimensional monotonic function using multiplicative kernel, one has to solve a quadratic optimization problem of order ℓ subject to $N = \ell d$ inequality constraints.

With additive kernel, one has to estimate $d \times (\ell + 1)$ parameters under $d \times (\ell + 1)$ constraints. To decrease the computation amount:

1. One can replace V -matrix with I -matrix.
2. For additive kernel, one can estimate multidimensional conditional probability function in the *restricted set of functions* where $\alpha_i^k = \alpha_i$, for some or for all t .
3. One can consider linear structure of the solution using d one-dimensional estimates of conditional probability $P(y = 1|s^t)$ obtained by solving one-dimensional estimation problems as described in Section 3.2.1, and then approximate the multidimensional conditional probability function as

$$P(y = 1|s^1, \dots, s^d) = \sum_{t=1}^d \beta_t P(y = 1|s^t),$$

where its weights $\beta_t \geq 0$, $\sum \beta_t = 1$ are computed by solving an d -dimensional quadratic optimization problem under $d + 1$ constraints. That optimization problem is formulated as follows: minimize the functional

$$B^T P V P B - 2B^T P V Y + \gamma B^T B$$

subject to the constraints

$$B \geq 0, \quad B^T \mathbf{1}_\ell = 1,$$

where we have denoted by B vector of coefficients $B = (\beta_1, \dots, \beta_d)^T$, by P the $(d \times \ell)$ -dimensional matrix $P = p(x_i^t)$, $t = 1, \dots, d$, $i = 1, \dots, \ell$.

Estimation of both the SVMs and the conditional probability using the same data set. In the examples considered in this section, we construct synergy rules for SVMs where we use the same training set both for constructing SVM rules $s_k = f_t(x)$, $t = 1, \dots, d$ and for estimating the conditional probability $P(y = 1|s_1, \dots, s_d)$.

Suppose that our rules were constructed using different SVM kernels $K_t(x, y)$ and the same training set

$$(x_1, y_1), \dots, (x_\ell, y_\ell) \quad (43)$$

and let

$$s_1^t, \dots, s_\ell^t, \quad t = 1, \dots, d$$

be the scores $s^t = f_t(x)$ obtained using vectors x from (43).

Note that these scores are statistically different from the scores obtained using ℓ elements of test set (support vectors s^* are biased: in the separable case, all $|s^*| = 1$). Therefore, it is reasonable to use scores obtained in the procedure of k -fold cross-validation for estimating parameters of SVM algorithm.

Also, note that while individual components of the same d -dimensional vector $S^d = (s_1^d, \dots, s_d^d)$ are interdependent, the vectors S^d themselves are not (they are i.i.d.), so the general theory developed in the previous sections is applicable here for computing conditional probabilities.

4. Synergy of Several SVMs

In this section, we consider several examples of synergy of d SVM rules obtained under different circumstances:

1. Synergy of d rules obtained using the same training data but different kernels.
2. Synergy of d rules obtained using different training data but the same kernel.
3. Synergy of d classes classification problem using d *one versus the rest* rules.

In all these examples, the synergy of the rules is based on estimating the corresponding monotonic conditional probability function from RKHS associated with additive kernel, as described in Section 3.3.2.

4.1 Synergy of SVM Rules with Different Kernels

In this section, we show that the accuracy of classification using synergy of SVM rules that use different kernels can be much higher than the accuracy of a rule based on any kernel.² The effect of synergy, which is estimated by the number of additional training examples in training data required to achieve comparable to synergy level of accuracy, can be significant.

We selected the following 9 calibration data sets from UCI Machine Learning Repository (Lichman (2013)): Covertypе, Adult, Tic-tac-toe, Diabetes, Australian, Spambase, MONK's-1, MONK's-2, and Bank marketing. Our selection of these specific data sets was driven by the desire to ensure statistical reliability of targeted estimates, which translated into availability of relatively large test data set (containing at least 150 samples). Specific breakdowns for the corresponding training and test sets are listed in Table 1.

For each of these 9 data sets, we constructed 10 random realizations of training and test data sets; for each of these 10 realizations, we trained three SVMs with different kernels: with RBF kernel, with INK-Spline kernel, and with linear kernel. The averaged test errors of the constructed SVMs are listed in Table 1.

Constructed SVMs provide binary classifications g and scores s . Additional performance improvements are possible by intelligent leveraging of the results of these classifications.

We compared our approach with the baseline method of voting on classification results of all three classifications obtained from three different kernels (since we had odd number of kernels, we did not need any tie-breaking in that vote). The first column of Table 2 shows the averaged test errors of that voting approach.

The second column of Table 2 shows the averaged test errors of our synergy approach. Specifically, the data in the second column are based on constructing a 3-dimensional mono-

² The idea of using several SVMs as ensemble SVM (such as (Wang et al. (2009)) and Stork et al. (2013)) was used in the past for providing improved classification performance; however, these approaches did not leverage the main monotonicity property of SVM.

Data set	Training	Test	Features
Covertypе	300	3000	54
Adult	300	26147	123
Tic-tac-toe	300	658	27
Diabetes	576	192	8
Australian	517	173	14
Spambase	300	4301	57
MONK's-1	124	432	6
MONK's-2	169	432	6
Bank	300	4221	16

Table 1: Calibration data sets from UCI Machine Learning repository.

Data set	Voting	Synergy	Gain
Covertypе	27.83%	28.96%	-4.05%
Adult	20.07%	19.08%	4.93%
Tic-tac-toe	1.95%	1.75%	10.16%
Diabetes	24.53%	23.39%	4.67%
Australian	12.02%	12.54%	-4.33%
Spambase	8.96%	8.44%	5.80%
MONK's-1	22.80%	20.16%	11.57%
MONK's-2	19.31%	16.23%	15.95%
Bank	12.79%	11.73%	8.29%

Table 2: Synergy of SVMs with RBF, INK-spline, and linear kernels.

tonic conditional probability function from RKHS associated with additive kernel, as described in Section 3.3.2, on triples of SVM scores s . In this column, we assigned the classification labels g based on the sign of the difference between 3-dimensional conditional probability and the threshold value $1/2$.

The last column of Table 2 contains relative performance gain (i.e., relative decrease of error rate) delivered by the proposed synergy approach over the benchmark voting algorithm.

The results demonstrate the consistent performance advantage of synergy approach over its empirical alternative in most of the cases (for 7 data sets out of 9); for some data sets this advantage is relatively small, but for others it is substantial (in relative terms).

This substantial performance improvement of synergy can be also viewed as a viable alternative to brute force approaches relying on accumulation of (big) data. Indeed, for the already considered Adult data set, we compared results of our synergy approach on a training data set consisting of 300 samples to an alternative approach relying on training SVM algorithms on larger training data sets. Specifically, we trained SVMs with RBF kernel and INK-Spline kernel on Adult data sets containing 1,000 and 3,000 samples. The results, shown in Table 3, suggest that synergy of two rules, even on training data set of

Training size	300	1000	3000
RBF	20.95%	19.21%	18.49%
INK-Spline	19.77%	18.72%	18.38%
Synergy	17.92%	-	-

Table 3: Synergy versus training size increase.

limited size, can be better than straightforward SVMs on training data sets of much larger sizes (in this example, equivalent to the increase of training sample by more than a factor of 10).

4.2 Synergy of SVM Rules Obtained on Different Training Data

Suppose we are dealing with “big data” situation, where the number L of elements in the training data set

$$(x_1, y_1), \dots, (x_L, y_L), \quad (44)$$

is large. Consider the SVM method that uses a universal kernel³. Generally speaking, with the increase of size ℓ of training data, the expected error rate of the obtained SVM rule monotonically converges to the Bayesian rule (here the expectation is taken both over the rules obtained from different training data of the same size ℓ and over test data). The typical *learning curve* shows the dependence of that expected error rate on the size ℓ of training data as a hyperbola-looking curve consisting of two parts: the beginning of the curve, where the error rate falls steeply with the increase of ℓ , and the tail of the curve, where the error rate slowly converges to the Bayesian solution. Suppose that the transition from the “steeply falling” part of the curve to the “slowly decreasing” part of the curve (sometimes referred to as the “knee” of the curve) occurs for some ℓ^* . Assuming that large number L in (44) is greater than ℓ^* , we partition the training data (44) into J subsets containing ℓ elements each (here $L = J\ell$ and $\ell > \ell^*$ as well):

$$(x_{(t-1)\ell+1}, y_{(t-1)\ell+1}), \dots, (x_{t\ell}, y_{t\ell}), \quad t = 1, \dots, J \quad (45)$$

On each of these J disjoint training subsets we construct its own SVM rule (independent of other rules)

$$y = \theta(f_t(x, \alpha_\ell)), \quad t = 1, \dots, J.$$

For each of these SVM rules, we construct (as described in Section 3.3.2) its own one-dimensional monotonic conditional probability function $P_t(y = 1|s^t)$, $t = 1, \dots, J$.

Then, using these J one-dimensional monotonic conditional probability functions, we construct the J -dimensional $(s = (s^1, \dots, s^J))$ conditional probability function as follows:

$$P_{syn}(y = 1|s) = \frac{1}{J} \sum_{t=1}^J P_t(y = 1|s^t). \quad (46)$$

3. A universal kernel (for example, RBF) can approximate well any bounded continuous function.

Training size	300	300	300	900	1000	3000
RBF SVM	20.77%	19.06%	21.40%	20.01%	19.21%	18.49%
Voting on 3 subsets	N/A	N/A	N/A	19.44%	-	-
Synergy on 3 subsets	N/A	N/A	N/A	18.52%	-	-

Table 4: Synergy versus training size increase.

The Synergy decision rule in this case has the form

$$y = \theta \left(P_{syn}(y = 1|s) - \frac{1}{2} \right).$$

Note that (46) forms an unbiased estimate of the values of learning curve describing conditional probability for training data of (different) size ℓ . Since the training data (45) for different t are independent, the averaging of J conditional probability values decreases the variance of resulting conditional probability by a factor of J . In this approach, by choosing an appropriate value of ℓ , one can optimally solve the bias-variance dilemma.

To illustrate this approach, we again used Adult data set. Specifically, we trained SVMs with RBF kernel on Adult data sets containing 900, 1,000 and 3,000 samples. For the first of these samples (containing 900 elements), we also executed the following procedure: we split it into three subsets containing 300 elements each, trained RBF SVM on each of them, and then constructed two combined decision rules: (1) voting on the labels of three auxiliary SVMs, and (2) synergy of three SVMs as described in this section. The results, shown in Table 4, suggest that Synergy of rules on disjoint data sets can be better than straightforward SVMs on training data sets of much larger sizes (in this example, equivalent to the increase of training sample by a factor of 3).

Comparison of Table 3 and Table 4 suggests that synergy of SVMs with different SVM kernels obtained on the same data set may be more beneficial (equivalent to ten-fold increase of training sample size) than the synergy of SVMs with the same kernel obtained on different subsets of of that data set (equivalent to three-fold increase of training sample size).

Thus it is reasonable to assume that, for big data set (44), Synergy of SVM rules obtained on different training data and Synergy of SVM rules with different kernels (described in previous Section 4.1) can be unified to create an even more accurate synergy rule. This unification can be implemented in the following manner.

Consider d kernels $K_r(x, x')$, $k = 1, \dots, d$. For each of these kernels, using the method described in Section 3.3.2, we construct the corresponding condition probability function

$$P_{syn}(y = 1|s(r)) = \frac{1}{J} \sum_{t=1}^J P_t(y = 1|s^t(r)),$$

where we have denoted by $P_t(y = 1|s^t(r))$ the conditional probability function estimated for the rule with kernel $K_r(x, x')$ and for the t th subset of training data (44) with the fixed t . Let introduce the vector $p = (p^1, \dots, p^d)$ where

$$p^r = P_{syn}(y = 1|s(r)), \quad r = 1, \dots, d.$$

Using these vectors, we estimate the d -dimensional conditional probability function $P_{sym}(y = 1|p) = P_{sym}(y = 1|p^1, \dots, p^d)$.

The resulting double reinforced Synergy rule has the form

$$y = \theta \left(P_{sym}(y = 1|p) - \frac{1}{2} \right).$$

4.3 Multi-Class Classification Rules

Constructing decision rules for multi-class classification is an important problem in pattern recognition. In contrast to methods for constructing two-class classification rules, which have solid statistical justifications, existing methods for constructing $d > 2$ class classification rules are based on heuristics.

One of the most popular heuristics, *one versus rest* (OVR), suggests first to solve the following d two-class classification problems: in problem number k (where $k = 1, \dots, d$), the examples of class k are considered as examples of the first class and examples of the all other classes $1, \dots, (k - 1), (k + 1), \dots, d$ are considered as the second class. Using OVR approach, one constructs d different two-class classification rules

$$y = \theta(f_k(x)) \quad k = 1, \dots, d.$$

The new object x_* is assigned to the class k , where k th rule provides the maximum score for x_* :

$$k = \operatorname{argmax}\{s_1^1, \dots, s_1^d\}, \quad \text{where } s_i^k = f_i(x_*).$$

This method of d -class classification is not based on a clear statistical foundation⁴.

Here we implement the following multi-class classification procedure. For every k (where $k = 1, \dots, d$), we solve the corresponding OVR SVM problem, for which all the elements with the original label k are marked with $y = 1$, while all the other elements are marked with $y = 0$. Upon solving all these d problems, we can, for any given vector x and any class k , compute its score $s_k(x)$ provided by the k th SVM rule.

After that, for every k (where $k = 1, \dots, d$) we use the obtained scores for estimating conditional probability of the class k based on the scores $(\bar{s}^1, \dots, \bar{s}^d)$ where

$$\bar{s}^m = \begin{cases} s_m & \text{if } m = k \\ -s_m & \text{if } m \neq k \end{cases}$$

This transformation of scores is used to maintain the monotonicity of the overall conditional probability function. To estimate the function

$$P(k) = P(k|\bar{s}^1, \dots, \bar{s}^d),$$

as in Section 3.3.2, we use the representation

$$P(k|\bar{s}^1, \dots, \bar{s}^d) = \sum_{i=1}^d \left[\alpha_i \min\{\bar{s}_i^k, s_i^k\} + \beta_i \sum_{i \neq k} \min\{\bar{s}_i^k, s_i^k\} \right], \quad k = 1, \dots, d.$$

⁴ Another common heuristics called *one versus one* (OVO): it suggests to solve C_2^d two-class classification problems separating all possible pairs of classes. To classify a new object x^* , one uses a voting scheme based on the obtained C_2^d rules.

Data set	Classes	Features	Training	Test	OVR	Synergy	Gain
Vehicle	4	18	709	236	17.45%	14.15%	18.91%
Waveform	3	40	200	4800	20.10%	18.31%	8.90%
Cardiotocography	3	21	300	1826	15.83%	12.05%	23.87%

Table 5: Synergy for multi-class classification.

Finally, we replace the heuristic procedure of choosing the class k based on maximization of underlying scores with the following procedure that is based on the framework described above: this procedure uses estimated d conditional probabilities $P(k|s_1, \dots, s_d)$ (probability of class $k = 1, \dots, d$ given all d scores) and chooses the class t corresponding to the maximum value of the conditional probability:

$$t = \operatorname{argmax}\{P(1|\bar{s}_1^1, \dots, \bar{s}_1^d), \dots, P(d|\bar{s}_1^1, \dots, \bar{s}_1^d)\}.$$

We compared our synergy approach with the standard OVR approach for the data sets Vehicle, Waveform, and Cardiotocography from UCI Machine Learning Repository (Lichman (2013)). Training and test sets were selected randomly from these data sets; the number of elements in each are shown in Table 5; the table also shows the error rates achieved by OVR and synergy algorithm, along with relative performance gain obtained with our approach. The results confirm the viability of our framework.

5. Synergy of Learning from Several Intelligent Teachers

In (Vapnik and Izmailov (2015d)), (Vapnik and Izmailov (2015b)), we introduced the concept of *knowledge transfer* from Intelligent Teacher to student. Knowledge transfer is possible in the framework of Learning Using Privileged Information (LUPI) paradigm introduced in (Vapnik (2006)) and (Vapnik and Vashist (2009)). According to this paradigm, iid training examples are generated by some unknown generator $P(x)$, $x \in X$ and Intelligent Teacher who supplies vectors x with information (x^*, y) according to some (unknown) *Intelligence generator* $P(x^*, y|x)$, $x^* \in X^*$, $y \in \{-1, 1\}$, forming training triples

$$(x_1, x_1^*, y_1), \dots, (x_\ell, x_\ell^*, y_\ell). \quad (47)$$

Vector x_i^* corresponding to vector x_i is called *privileged information*, and generator $P(x^*, y|x)$ is called generator of intelligent (due to x^*) information. Privileged information is available only for training examples and is *not available* for test examples. In contrast to LUPI, classical learning paradigm considers a primitive teacher that just generates classification y for any x according to $P(y|x)$ (with no additional explanation x^*), forming training pairs

$$(x_1, y_1), \dots, (x_\ell, y_\ell).$$

Knowledge transfer mechanism. Consider the second⁵ mechanism in LUPI paradigm the *knowledge transfer mechanism* to construct a better decision rule. Given triplets (47), we can consider two pattern recognition problems:

1. *Pattern recognition problem defined in space X*: Using data, $(x_1, y_1), \dots, (x_\ell, y_\ell)$, find in the set of functions $f(x, \alpha), \alpha \in \Lambda$ the rule $y = \text{sgn}\{f(x)\}$ that minimizes the probability of test errors (in space X).
2. *Pattern recognition problem defined in space X**: Using data, $(x_1^*, y_1), \dots, (x_\ell^*, y_\ell)$, find in the set of functions $f^*(x^*, \alpha^*), \alpha^* \in \Lambda^*$ the rule $y = \text{sgn}\{f^*(x^*)\}$ that minimizes the probability of test errors (in space X*).

Suppose that, in space X*, one can find a rule $y = \text{sgn}\{f_0^*(x^*)\}$ that is better (more accurate) than the corresponding rule $y = \text{sgn}\{f_0(x)\}$ in space⁶ X.

The question arises: *Can the knowledge about a good rule*

$$f_0^*(x^*) = \sum_{i=1}^{\ell} y_i \alpha_i^* K^*(x_i^*, x^*) + b^* \quad (48)$$

in space X* help to find a good rule

$$f_\ell(x) = \sum_{i=1}^{\ell} y_i \alpha_i K(x_i, x) + b \quad (49)$$

in space X?

Consider the following example. Suppose that our goal is to classify images x_i of biopsy in pixel space X into two categories: cancer and non-cancer.

Suppose that, along with images x_i in pixel space X, we are given description of the images $x_i^* \in X^*$ (privileged information), reflecting the existing model of developing cancer:

- *Aggressive proliferation of A-cells into B-cells.*
- *Absence of any dynamic in standard picture of sells distribution.*

Since pixel space X is universal (it can be used for many problems, for example, in pixel space, one can distinguish male faces from female ones), and space of descriptions X* reflects just the model of cancer development⁷, the VC dimension of the corresponding set of functions in X space has to be larger than the VC dimension of the corresponding set of functions in X*.

Therefore the rule constructed from ℓ examples in space X* will be more accurate than the rule constructed from ℓ examples in space X. That is why transferring the rule from space X* into space X can be helpful.

5. The first mechanism is called *similarity control* described in (Vapnik and Izmailov (2015d)), (Vapnik and Izmailov (2015b)). The second mechanism of knowledge transfer, described there and further in this paper, is related to SVM technology. However, the idea of knowledge transfer is general and can be implemented for other learning algorithms.
6. This is always the case if space X is a subset of X*.
7. In this example, generator $P(x^*, y|x)$ is intelligent since for any *picture* of the event x it describes the *essence* of the event. Using descriptions of the essence of an event makes classification of the event a relatively easy problem.

Knowledge representation in space X*. To transfer knowledge from space X* into space X, we use three elements of knowledge representation developed in 1950's in Artificial Intelligence (see Brachman and Levesque, 2004):

1. Fundamental elements of the knowledge in X*.
2. Main frames (fragments) of the knowledge in X*.
3. Structure of knowledge: combination of the frames in X*.

For LUPI using SVM⁸:

1. The *fundamental elements* are defined by k support vectors of rule (48) in X*.
2. The *frames* in X* are defined by the functions $K^*(x_s^*, x^*)$, $s = 1, \dots, k$.
3. The structure of the knowledge (48) is linear in the frames.

Algorithm for knowledge transfer. In order to transfer knowledge from space X* to space X, one has to make two transformations in the training triplets (47):

1. To transform n -dimensional vectors of $x_i = (x_i^1, \dots, x_i^n)^T$ into k -dimensional vectors $\mathcal{F}x_i = (\phi_1(x_i), \dots, \phi_k(x_i))^T$;
2. Use the target values $f_\ell^*(x_i^*)$ obtained for x_i^* in rule (48) instead of the values y_i , given for x_i in triplet (47).

(1) In order to transform vector x , one constructs k -dimensional space as follows: for any frame $K^*(x_s^*, x_s^*)$, $s = 1, \dots, k$ in space X*, one constructs its image (function) $\phi_s(x)$ in space X that is defined by the relationship

$$\phi_s(x) = \int K(x_s^*, x^*) P(x^*|x) dx^*, \quad s = 1, \dots, k.$$

This requires to solve the following regression estimation problem: given data

$$(x_1, z_1^s), \dots, (x_\ell, z_\ell^s), \quad \text{where } z_i^s = K(x_s^*, x_i^*),$$

find k regression functions $\phi_s(x)$, $s = 1, \dots, k$, forming the space $\mathcal{F}(x) = (\phi_1(x), \dots, \phi_k(x))^T$.
(2) Replace target value y_i in triplets (47) with scores $f_\ell^*(x_i^*)$ given (48).

Therefore the knowledge transfer algorithm transforms the training triplet⁹

$$((\mathcal{F}x_1, x_1^*, f_\ell^*(x_1^*)), \dots, (\mathcal{F}x_\ell, x_\ell^*, f_\ell^*(x_\ell^*))). \quad (50)$$

It uses triplets (50) instead of triplets (47).

Synergy of several Intelligent Teachers. Suppose now that Student tries to learn how to solve the same problem from several (say two) Intelligent Teachers. For simplicity, let both Teachers use the same training data (x_i, y_i) , $i = 1, \dots, \ell$ but different privileged information (different explanations)

$$(x_1, x_1^*, y_1), \dots, (x_\ell, x_\ell^*, y_\ell)$$

and

$$(x_1, x_1^{**}, y_1), \dots, (x_\ell, x_\ell^{**}, y_\ell).$$

Constructing, using these triplets, two different rules and corresponding synergy rule, one obtains the synergy effect of two Intelligent Teachers.

8. Different concepts of fundamental elements, frames, and structure of knowledge can be applied for different algorithms.
9. In the simplified version, pairs $(\mathcal{F}x_i, \delta_i^*)$, $i = 1, \dots, \ell$.

6. Conclusion

In this paper, we showed that:

1. Scores $s = (s^1, \dots, s^d)$ of several monotonic classifiers (for example, SVMs) that solve the same pattern recognition problem can be transformed into multi-dimensional monotonic conditional probability functions $P(y|s)$ (probability of class y given scores s).
2. There exists an effective algorithm for such transformation.
3. Classification rules obtained on the basis of constructed conditional probability functions significantly improve performance, especially in multi-class classification cases.

Abstract

Optimization on manifolds is a class of methods for optimization of an objective function, subject to constraints which are smooth, in the sense that the set of points which satisfy the constraints admits the structure of a differentiable manifold. While many optimization problems are of the described form, technicalities of differential geometry and the laborious calculation of derivatives pose a significant barrier for experimenting with these methods.

We introduce PYMANOPT (available at [pymanopt.github.io](https://github.com/pymanopt)), a toolbox for optimization on manifolds, implemented in Python, that—similarly to the Manopt¹ Matlab toolbox—implements several manifold geometries and optimization algorithms. Moreover, we lower the barriers to users further by using automated differentiation² for calculating derivative information, saving users time and saving them from potential calculation and implementation errors.

Keywords: Riemannian optimization, non-convex optimization, manifold optimization, projection matrices, symmetric matrices, rotation matrices, positive definite matrices

1. Introduction

Optimization on manifolds, or Riemannian optimization, is a method for solving problems of the form

$$\min_{x \in \mathcal{M}} f(x)$$

where $f: \mathcal{M} \rightarrow \mathbb{R}$ is a (cost) function and the search space \mathcal{M} is smooth, in the sense that it admits the structure of a differentiable manifold. Although the definition of differentiable manifold is technical and abstract, many familiar sets satisfy this definition and are therefore compatible with the methods of optimization on manifolds. Examples include the *sphere* (the set of points with unit Euclidean norm) in \mathbb{R}^n , the set of *positive definite matrices*, the set of *orthogonal matrices* as well as the set of p -dimensional subspaces of \mathbb{R}^n with $p < n$, also known as the *Grassmann* manifold.

To perform optimization, the function f needs to be defined for points on the manifold \mathcal{M} . Elements of \mathcal{M} are often represented by elements of \mathbb{R}^n or $\mathbb{R}^{m \times n}$, and f is often well defined on some or all of this “ambient” Euclidean space. If f is also differentiable, it makes sense for an optimization algorithm to use the derivatives of f and adapt them to the manifold setting in order to iteratively refine solutions based on curvature information. This is one of the key aspects of Manopt (Boumal et al., 2014), which allows the user to pass a function’s gradient and Hessian to state of the art

solvers which exploit this information to optimize over the manifold \mathcal{M} . However, working out and implementing gradients and higher order derivatives is a laborious and error prone task, particularly when the objective function acts on matrices or higher rank tensors. Manopt’s state of the art Riemannian Trust Regions solver, described in Absil et al. (2007), requires second order directional derivatives (or a numerical approximation thereof), which are particularly challenging to work out for the average user, and more error prone and tedious even for an experienced mathematician.

It is these difficulties which we seek to address with this toolbox. PYMANOPT supports a variety of modern Python libraries for automated differentiation of cost functions acting on vectors, matrices or higher rank tensors. Combining optimization on manifolds and automated differentiation enables a convenient workflow for rapid prototyping that was previously unavailable to practitioners. All that is required of the user is to instantiate a manifold, define a cost function, and choose one of PYMANOPT’s solvers. This means that the Riemannian Trust Regions solver in PYMANOPT is just as easy to use as one of the derivative-free or first order methods.

2. The Potential of Optimization on Manifolds and Pymanopt Use Cases

Much of the theory of how to adapt Euclidean optimization algorithms to (matrix) manifolds can be found in Smith (1994); Edelman et al. (1998); Absil et al. (2008). The approach of optimization on manifolds is superior to performing free (Euclidean) optimization and projecting the parameters back onto the search space after each iteration (as in the projected gradient descent method), and has been shown to outperform standard algorithms for a number of problems.

Hosseini and Sra (2015) demonstrate this advantage for a well-known problem in machine learning, namely inferring the maximum likelihood parameters of a mixture of Gaussian (MoG) model. Their alternative to the traditional expectation maximization (EM) algorithm uses optimization over a product manifold of positive definite (covariance) matrices. Rather than optimizing the likelihood function directly, they optimize a reparameterized version which shares the same local optima. The proposed method, which is on par with EM and shows less variability in running times, is a striking example why we think a toolbox like PYMANOPT, which allows the user to readily experiment with and solve problems involving optimization on manifolds, can accelerate and pave the way for improved machine learning algorithms.³

Further successful applications of optimization on manifolds include matrix completion tasks (Vandereycken, 2013; Boumal and Absil, 2015), robust PCA (Podosinnikova et al., 2014), dimension reduction for independent component analysis (ICA) (Theis et al., 2009), kernel ICA (Shen et al., 2007) and similarity learning (Shalit et al., 2012).

Many more applications to machine learning and other fields exist. While a full survey on the usefulness of these methods is well beyond the scope of this manuscript, we highlight that at the time of writing, a search for the term “manifold optimization” on the IEEE Xplore Digital Library lists 1065 results; the Manopt toolbox itself is referenced in 90 papers indexed by Google Scholar.

3. Implementation

Our toolbox is written in Python and uses NumPy and SciPy for computation and linear algebra operations. Currently PYMANOPT is compatible with cost functions defined using Autograd (Maclaurin et al., 2015), Theano (AI-Rfou et al., 2016) or TensorFlow (Abadi et al., 2015). PYMANOPT itself and all the required software is open source, with no dependence on proprietary software.

To calculate derivatives, Theano uses symbolic differentiation, combined with rule-based optimizations, while both Autograd and TensorFlow use reverse-mode automatic differentiation. For a discussion of the distinctions between the two approaches and an overview of automatic differentiation in the context of machine learning, we refer the reader to Baydin et al. (2015).

3. A quick example implementation for inferring MoG parameters is available at [pymanopt.github.io/MeG.html](https://github.com/pymanopt/pymanopt/blob/master/MeG.html).

Much of the structure of PYMANOPT is based on that of the Manopt Matlab toolbox. For this early release, we have implemented all of the solvers and a number of the manifolds found in Manopt, and plan to implement more, based on the needs of users. The codebase is structured in a modular way and thoroughly commented to make extension to further solvers, manifolds, or backends for automated differentiation as straightforward as possible. Both a user and developer documentation are available. The GitHub repository at github.com/pymanopt/pymanopt offers a convenient way to ask for help or request features by raising an issue, and contains guidelines for those wishing to contribute to the project.

4. Usage: A Simple Instructive Example

All automated differentiation in PYMANOPT is performed behind the scenes so that the amount of setup code required by the user is minimal. Usually only the following steps are required:

- (a) Instantiation of a manifold \mathcal{M}
- (b) Definition of a cost function $f: \mathcal{M} \rightarrow \mathbb{R}$
- (c) Instantiation of a PYMANOPT solver

We briefly demonstrate the ease of use with a simple example. Consider the problem of finding an $n \times n$ positive semi-definite (PSD) matrix S of rank $k < n$ that best approximates a given $n \times n$ (symmetric) matrix A , where closeness between A and its low-rank PSD approximation S is measured by the following loss function

$$L_\delta(S, A) \triangleq \sum_{i=1}^n \sum_{j=1}^n H_\delta(s_{i,j} - a_{i,j})$$

for some $\delta > 0$ and $H_\delta(x) \triangleq \sqrt{x^2 + \delta^2} - \delta$ the pseudo-Huber loss function. This loss function is robust against outliers as $H_\delta(x)$ approximates $|x| - \delta$ for large values of x while being approximately quadratic for small values of x (Huber, 1964).

This can be formulated as an optimization problem on the manifold of PSD matrices:

$$\min_{S \in \text{PSD}_k^n} L_\delta(S, A)$$

where $\text{PSD}_k^n \triangleq \{M \in \mathbb{R}^{n \times n} : M \succeq 0, \text{rank}(M) = k\}$. This task is easily solved using PYMANOPT:

```
from pymanopt.manifolds import PSDFixedRank
import autograd.numpy as np
from pymanopt import Problem
from pymanopt.solvers import TrustRegions

# Let A be a (n x n) matrix to be approximated

# (a) Instantiation of a manifold
# points on the manifold are parameterized as YY^T
# where Y is a matrix of size n x k
manifold = PSDFixedRank(A.shape[0], k)
# (b) Definition of a cost function (here using autograd.numpy)
def cost(Y):
    S = np.dot(Y, Y.T)
    delta = .5
    return np.sum(np.sqrt((S - A)**2 + delta**2)) - delta
```

```
# define the Pymanopt problem
problem = Problem(manifold=manifold, cost=cost)
# (c) Instantiation of a Pymanopt solver
solver = TrustRegions()

# Let Pymanopt do the rest
Y = solver.solve(problem)
S = np.dot(Y, Y.T)
```

The examples folder within the PYMANOPT toolbox holds further instructive examples, such as performing inference in mixture of Gaussian models using optimization on manifolds instead of the expectation maximization algorithm. Also see the examples section on [pymanopt.github.io](https://github.com/pymanopt/pymanopt).

5. Conclusion

PYMANOPT enables the user to experiment with different state of the art solvers for optimization problems on manifolds, like the Riemannian Trust Regions solver, without any extra effort. Experimenting with different cost functions, for example by changing the pseudo-Huber loss $L_\delta(S, A)$ in the code above to the Frobenius norm $\|S - A\|_F$, a p -norm $\|S - A\|_p$ or some more complex function, requires just a small change in the definition of the cost function. For problems of greater complexity, PYMANOPT offers a significant advantage over toolboxes that require manual differentiation by enabling users to run a series of related experiments without returning to pen and paper each time to work out derivatives. Gradients and Hessians only need to be derived if they are required for other analysis of a problem. We believe that these advantages, coupled with the potential for extending PYMANOPT to large-scale applications using TensorFlow, could lead to significant progress in applications of optimization on manifolds.

Acknowledgments

We would like to thank the developers of the Manopt Matlab toolbox, in particular Nicolas Boumal and Pierre-Antoine Absil, for developing Manopt, and for the generous help and advice they have given. We would also like to thank Helko Strathmann for his thoughtful advice as well as the anonymous reviewers for their constructive feedback and idea for a more suitable application example.

Abstract

There is a widespread need for statistical methods that can analyze high-dimensional datasets without imposing restrictive or opaque modeling assumptions. This paper describes a domain-general data analysis method called CrossCat. CrossCat infers multiple non-overlapping views of the data, each consisting of a subset of the variables, and uses a separate nonparametric mixture to model each view. CrossCat is based on approximately Bayesian inference in a hierarchical, nonparametric model for data tables. This model consists of a Dirichlet process mixture over the columns of a data table in which each mixture component is itself an independent Dirichlet process mixture over the rows; the inner mixture components are simple parametric models whose form depends on the types of data in the table. CrossCat combines strengths of mixture modeling and Bayesian network structure learning. Like mixture modeling, CrossCat can model a broad class of distributions by positing latent variables, and produces representations that can be efficiently conditioned and sampled from for prediction. Like Bayesian networks, CrossCat represents the dependencies and independencies between variables, and thus remains accurate when there are multiple statistical signals. Inference is done via a scalable Gibbs sampling scheme; this paper shows that it works well in practice. This paper also includes empirical results on heterogeneous tabular data of up to 10 million cells, such as hospital cost and quality measures, voting records, unemployment rates, gene expression measurements, and images of handwritten digits. CrossCat infers structure that is consistent with accepted findings and common-sense knowledge in multiple domains and yields predictive accuracy competitive with generative, discriminative, and model-free alternatives.

Keywords: Bayesian nonparametrics, Dirichlet processes, Markov chain Monte Carlo, multivariate analysis, structure learning, unsupervised learning, semi-supervised learning

1. Introduction

High-dimensional datasets containing data of multiple types have become commonplace. These datasets are often presented as tables, where rows correspond to data vectors, columns correspond to observable variables or features, and the whole table is treated as a random subsample from a statistical population (Hastie, Tibshirani, Friedman, and Franklin, 2005). This setting brings new opportunities as well as new statistical challenges (NRC Committee on the Analysis of Massive Data, 2013; Wasserman, 2011). In principle, the dimensionality and coverage of some of these datasets is sufficient to rigorously answer to fine-grained questions about small sub-populations.

This size and richness also enables the detection of subtle predictive relationships, including those that depend on aggregating individually weak signals from large numbers of variables. Challenges include integrating data of heterogeneous types (NRC Committee on the Analysis of Massive Data, 2013), suppressing spurious patterns (Benjamini and Hochberg, 1995; Attia, Ioannidis, et al., 2009), selecting features (Wasserman, 2011; Weston, Mukherjee, et al., 2001), and the prevalence of non-ignorable missing data.

This paper describes CrossCat, a general-purpose Bayesian method for analyzing high-dimensional mixed-type datasets that aims to mitigate these challenges. CrossCat is based on approximate inference in a hierarchical, nonparametric Bayesian model. This model is comprised of an “outer” Dirichlet process mixture over the columns of a table, with components that are themselves independent “inner” Dirichlet process mixture models over the rows. CrossCat is parameterized on a per-table basis by data type specific component models — for example, Beta-Bernoulli models for binary values and Normal-Gamma models for numerical values. Each “inner” mixture is solely responsible for modeling a subset of the variables. Each hypothesis assumes a specific set of marginal dependencies and independencies. This formulation supports scalable algorithms for learning and prediction, specifically a collapsed MCMC scheme that marginalizes out all but the latent discrete state and hyper parameters.

The name “CrossCat” is derived from the combinatorial skeleton of this probabilistic model. Each approximate posterior sample represents a *cross-categorization* of the input data table. In a cross-categorization, the variables are partitioned into a set of *views*, with a separate partition of the entities into *categories* with respect to the variables in each *view*. Each (*category, variable*) pair contains the sufficient statistics or latent state needed by its associated component model. See Figure 1 for an illustration of this structure. From the standpoint of structure learning, CrossCat finds multiple, cross-cutting categorizations or clusterings of the data table. Each non-overlapping system of categories is context-sensitive in that it explains a different subset of the variables. Conditional densities are straightforward to calculate and to sample from. Doing so first requires dividing the conditioning and target variables into views, then sampling a category for each view. The distribution on categories must reflect the values of the conditioning variables. After choosing a category it is straightforward to sample predictions or evaluate predictive densities for each target variable by using the appropriate component model.

Standard approaches for inferring representations for joint distributions from data, such as Bayesian networks, mixture models, and sparse multivariate Gaussians, each exhibit complementary strengths and limitations. Each method exhibits distinct strengths and weaknesses:

1. Bayesian networks and structure learning.

The main advantage offered by Bayesian networks in this setting is that they can use a separate network to model each group of variables. From a statistical perspective, Bayes nets may be effective for sufficiently large, purely discrete datasets where all variables are observed and no hidden variables are needed to accurately model the true data generator. The core modeling difficulty is that many relevant joint distributions are either impossible to represent using a Bayesian network or require prohibitively complex parameterizations. For example, without hidden variables, Bayes nets must emulate the effect of any hidden variables by implicitly marginalizing them out, yielding a dense set of connections. These artificial edges can reduce statistical efficiency: each new parent for a given node can multiplicatively increase

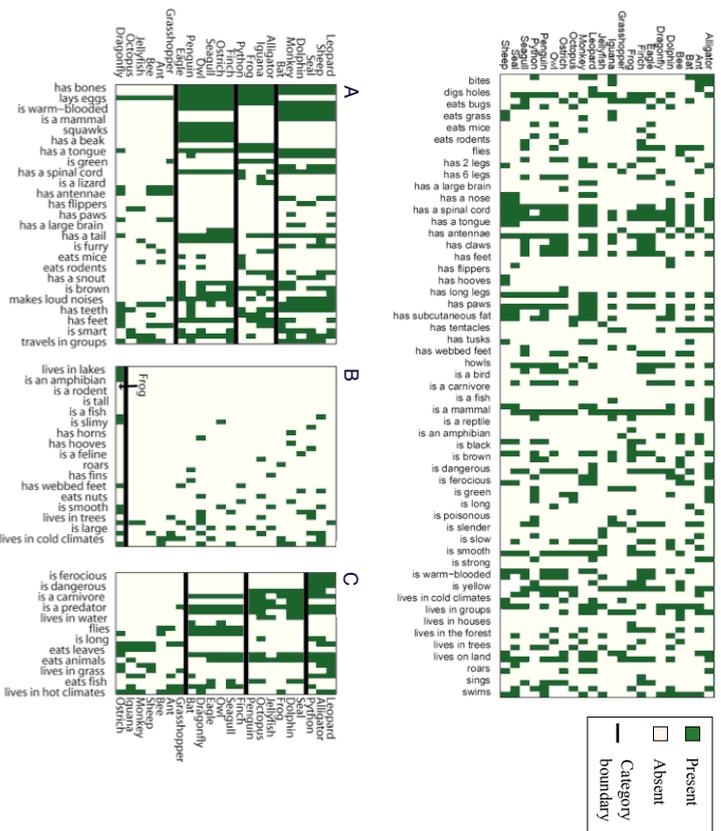

Figure 1: An illustration of the latent structure posited by cross-categorization on a dataset of common-sense judgments about animals. The figure shows the raw input data and one posterior sample from a dataset containing animals and their properties. CrossCat finds three independent signals, or views. A taxonomic clustering (left, A) comprises groups of mammals, amphibians and reptiles, birds, and invertebrates, and explains primarily anatomical and physiological variables. An ecological clustering (right, C) cross-cuts the taxonomic groups and specifies groups of carnivorous land predators, sea animals, flying animals, and other land animals, and explains primarily habitat and behavior variables. Finally all animals (except frogs) are lumped together into a cluster of miscellaneous features (center, B) that accounts for a set of idiosyncratic or sparse “noise” variables.

the number of parameters to estimate (Elidan, Lohner, Friedman, and Koller, 2001; Elidan and Friedman, 2005). There are also computational difficulties. First, there are no known scalable techniques for fully Bayesian learning of Bayesian networks, so posterior uncertainty about the dependence structure is lost. Second, even when the training data is fully observed, i.e. all variables are observed, search through the space of networks is computationally demanding. Third, if the data is incomplete (or hidden variables are posited), a complex inference subproblem needs to be solved in the inner loop of structure search.

2. Parametric and semi-parametric mixture modeling.

Mixtures of simple parametric models have several appealing properties in this setting. First, they can accurately emulate the joint distribution within each group of variables by introducing a sufficiently large number of mixture components. Second, heterogeneous data types are naturally handled using independent parametric models for each variable chosen based on the type of data it contains. Third, learning and prediction can both be done via MCMC techniques that are linear time per iteration, with constant factors and iteration counts that are often acceptable in practice. Unfortunately, mixture models assume that all variables are (marginally) coupled through the latent mixture component assignments. As a result, posterior samples will often contain good categorizations for one group of variables, but these same categories treat all other groups of mutually dependent variables as noise. This can lead to dramatic under-fitting in high dimensions or when missing values are frequent; this paper includes experiments illustrating this failure mode. Thus if the total number of variables is small enough, and the natural cluster structure of all groups of variables is sufficiently similar, and there is enough data, mixture models may perform well.

3. Multivariate Gaussians with sparse inverse covariances.

High-dimensional continuous distributions are often modeled as multivariate Gaussians with sparse conditional dependencies (Meinshausen and Bühlmann, 2006). Several parameter estimation techniques are available; see e.g. (Friedman, Hastie, and Tibshirani, 2008). The pairwise dependencies produced by these methods form an undirected graph. The underlying assumptions are most appropriate when the number of variables and observations are sufficiently large, the data is naturally continuous and fully observed, and the joint distribution is approximately unimodal. A key advantage of these methods is the availability of fast algorithms for parameter estimation (though extensions for handling missing values require solving challenging non-convex optimization problems (Städler and Bühlmann, 2012)). These methods also have two main limitations. First, the assumption of joint Gaussianity is unrealistic in many situations (Wasserman, 2011). Second, discrete values must be transformed into numerical values; this invalidates estimates of predictive uncertainty, and can generate other surprising behaviors.

CrossCat combines key computational and statistical strengths of each of these methods. As with nonparametric mixture modeling, CrossCat admits a scalable MCMC algorithm for posterior sampling, handles incomplete data, and does not impose restrictions on data types. CrossCat also preserves the asymptotic consistency of density estimation via Dirichlet process mixture modeling

(Dunson and Xing, 2009), and can emulate a broad class of generative processes and joint distributions given enough data. However, unlike mixture modeling but like Bayesian network structure learning, CrossCat can also detect independencies between variables. The “outer” Dirichlet process mixture partitions variables into groups that are independent of one another. As with estimation of sparse multivariate Gaussians (but unlike Bayesian network modeling), CrossCat can handle complex continuous distributions and report pairwise measures of association between variables. However, in CrossCat, the couplings between variables can be nonlinear and heteroscedastic, and induce complex, multi-modal distributions. These statistical properties are illustrated using synthetic tests designed to strain the CrossCat modeling assumptions and inference algorithm.

This paper illustrates the flexibility of CrossCat by applying it to several exploratory analysis and predictive modeling tasks. Results on several real-world datasets of up to 10 million cells are described. Examples include measures of hospital cost and quality, voting records, US state-level unemployment time series, and handwritten digit images. These experiments show that CrossCat can extract latent structures that are consistent with accepted findings and common-sense knowledge in multiple domains. They also show that CrossCat can yield favorable predictive accuracy as compared to generative, discriminative, and model-free baselines.

The remainder of this paper is organized as follows. This section concludes with a discussion of related work. Section 2 focuses on generative model and approximate inference scheme behind CrossCat. Section 3 describes empirical results, and section 4 contains a broad discussion and summary of contributions.

1.1 Related Work

The observation that multiple alternative clusterings can often explain data better than a single clustering is not new to this paper. Methods for finding multiple clusterings have been developed in several fields, including by the authors of this paper (see e.g. Niu, Dy, and Jordan, 2010; Cui, Fern, and Dy, 2007; Guan, Dy, Niu, and Ghahramani, 2010; Li and Shafto, 2011; Rodriguez and Ghosh, 2009; Shafto, Kemp, Mansinghka, Gordon, and Tenenbaum, 2006; Shafto, Kemp, Mansinghka, and Tenenbaum, 2011; Ross and Zemel, 2006). For example, Ross and Zemel (2006) used an EM approach to fit a parametric mixture of mixtures and applied it to image modeling. As nonparametric mixtures and model selection over finite mixtures can behave similarly, it might seem that a nonparametric formulation is a small modification. In fact, nonparametric formulation presented here is based on a super-exponentially larger space of model complexities that includes all possible numbers and sizes of views, and for each view, all possible numbers and sizes of categories. This expressiveness is necessary for the broad applicability of CrossCat. Cross-validation over this set is intractable, motivating the nonparametric formulation and sampling scheme used in this paper.

It is instructive to compare and contrast CrossCat with related hierarchical Bayesian models that link multiple Dirichlet process mixture models, such as the nested Dirichlet process (Rodriguez, Dunson, and Gelfand, 2008) and the hierarchical Dirichlet process (Teh, Jordan, Beal, and Blei, 2006). See Jordan (2010) for a thorough review. This section contains a brief discussion of the most important similarities and differences. The hierarchical Dirichlet process applies independent Dirichlet processes to each dataset, whose atoms are themselves draws from a single shared Dirichlet process. It thus enables a single pool of clusters to be shared and sparsely expressed in otherwise independent clusterings of several datasets. The differences are substantial. For example, with the hierarchical Dirichlet process, the number of Dirichlet processes is fixed in advance. In CrossCat,

each atom on one Dirichlet process is associated with its own Dirichlet process, and inference is used to determine the number that will be expressed in a given finite dataset.

The nested Dirichlet process shares this combinatorial structure with CrossCat, but has been used to build very different statistical models. (Rodriguez et al., 2008) introduces it as a model for multiple related datasets. The model consists of a Dirichlet process mixture over datasets where each component is another Dirichlet process mixture models over the items in that dataset. From a statistical perspective, it can be helpful to think of this construction as follows. First, a top-level Dirichlet process is used to cluster datasets. Second, all datasets in the same cluster are pooled and their contents are modeled via a single clustering, provided by the lower-level Dirichlet process mixture model associated with that dataset cluster.

The differences between CrossCat and the nested Dirichlet process are clearest in terms of the nested Chinese restaurant process representation of the nested DP (Blei, Griffiths, Jordan, and Tenenbaum, 2004; Blei, Griffiths, and Jordan, 2010). In a 2-layer nested Chinese restaurant process, there is one customer per data vector. Each customer starts at the top level, sits a table at their current level according to a CRP, and descends to the CRP at the level below that the chosen table contains. In CrossCat, the top level CRP partitions the variables into views, and the lower level CRPs partition the data vectors into categories for each view. If there are K tables in top CRP, i.e. the dataset is divided into K views, then adding one datapoint leads to the seating of K new customers at level 2. Each of these customers is deterministically assigned to a distinct table. Also, whenever a new customer is created at the top restaurant, in addition to creating a new CRP at the level below, R customers are immediately seated below it (one per row in the dataset).

Close relatives of CrossCat have been introduced by the authors of this paper in the cognitive science literature, and also by other authors in machine learning and statistics. This paper goes beyond this previous work in several ways. Guan et al. (2010) uses a variational algorithm for inference, while Rodriguez and Ghosh (2009) uses a sampler for the stick breaking representation for a Pitman-Yor (as opposed to Dirichlet Process) variant of the model. CrossCat is instead based on samplers that (i) operate over the combinatorial (i.e. Chinese restaurant) representation of the model, not the stick-breaking representation, and (ii) perform fully Bayesian inference over all hyper-parameters. This formulation leads to CrossCat’s scalability and robustness. This paper includes results on tables with millions of cells, without any parameter tuning, in contrast to the 148x500 gene expression subsample analyzed in Rodriguez and Ghosh (2009). These other papers include empirical results comparable in size to the authors’ experiments from Shafto et al. (2006) and Mansinghka, Jonas, Petschulat, Cronin, Shafto, and Tenenbaum (2009); these are 10-100x smaller than some of the examples from this paper. Additionally, all the previous work on variants of the CrossCat model focused on clustering, and did not articulate its use as a general model for high-dimensional data generators. For example, Guan et al. (2010) does not include predictions, although Rodriguez and Ghosh (2009) does discuss an example of imputation on a 51x26 table.

To the best of our knowledge, this paper is the first to introduce a fully Bayesian, domain-general, semi-parametric method for estimating the joint distributions of high-dimensional data. This method appears to be the only joint density estimation technique that simultaneously supports heterogeneous data types, detects independencies, and produces representations that support efficient prediction. This paper is also the first to empirically demonstrate the effectiveness of the underlying probabilistic model and inference algorithm on multiple real-world datasets with mixed types, and the first to compare predictions and latent structures from this kind of model against multiple generative, discriminative and model-free baselines.

2. The CrossCat Model and Inference Algorithm

CrossCat is based on inference in a column-wise Dirichlet process mixture of Dirichlet process mixture models (Escobar and West, 1995; Rasmussen, 2000) over the rows. The “outer” or “column-wise” Dirichlet process mixture determines which dimensions/variables should be modeled together at all, and which should be modeled independently. The “inner” or “row-wise” mixtures are used to summarize the joint distribution of each group of dimensions/variables that are stochastically assigned to the same modeling subproblem.

This paper presents the Dirichlet processes in CrossCat via the convenient Chinese restaurant process representation (Pitman, 1996). Recall that the Dirichlet process is a stochastic process that maps an arbitrary underlying base measure into a measure over discrete atoms, where each atom is associated with a single draw from the base measure. In a set of repeated draws from this discrete measure, some atoms are likely to occur multiple times. In nonparametric Bayesian mixture modeling, each atom corresponds to a set of parameters for some mixture component; “popular” atoms correspond to mixture components with high weight. The Chinese restaurant process is a stochastic process that corresponds to the discrete residue of the Dirichlet process. It is sequential, easy to describe, easy to simulate, and exchangeable. It is often used to represent nonparametric mixture models as follows. Each data item is viewed as a customer at a restaurant with an infinite number of tables. Each table corresponds to a mixture component; the customers at each table thus comprise the groups of data that are modeled by the same mixture component. The choice probabilities follow a simple “rich-gets-richer” scheme. Let m_j be the number of customers (data items) seated at a given table j , and z_i be the table assignment of customer i (with the first table $z_0 = 0$), then the conditional probability distribution governing the Chinese restaurant process with concentration parameter α is:

$$Pr(z_i = j) \propto \begin{cases} \alpha & \text{if } j = \max(\bar{z}) + 1 \\ m_j & \text{o.w.} \end{cases}$$

This sequence of conditional probabilities induces a distribution over the partitions of the data that is equivalent to the marginal distribution on equivalence classes of atom assignments under the Dirichlet process. The Chinese restaurant process provides a simple but flexible modeling tool: the number of components in a mixture can be determined by the data, with support over all logically possible clusterings. In CrossCat, the *number* of Chinese restaurant processes (over the table assignment determined by the number of tables in a Chinese restaurant process over the columns. The data itself is modeled by datatype-specific component models for each dimension (column) of the target table.

2.1 The Generative Process

The generative process behind CrossCat unfolds in three steps:

1. **Generating hyper-parameters and latent structure.** First, the hyper-parameters $\tilde{\lambda}_d$ for the component models for each dimension are chosen from a vague hyper-prior V_d that is appropriate¹ for the type of data in d . Second, the concentration parameter α for the outer

¹ The hyper-prior must only assign positive density to valid hyper-parameter values and be sufficiently broad for the marginal distribution for a single data cell has comparable spread to the actual data being analyzed. We have explored multiple hyper-priors that satisfy these constraints on analyses similar to those from this paper; there was little

Chinese restaurant process is sampled from a vague gamma hyper-prior. Third, a partition of the variables into views, \bar{z} , is sampled from this outer Chinese restaurant process. Fourth, for each view, $v \in \bar{z}$, a concentration parameter α_v is sampled from a vague hyper-prior. Fifth, for each view v , a partition of the rows y^v is drawn using the appropriate inner Chinese restaurant process with concentration α_v .

2. **Generating category parameters for uncollapsed variables.** This paper uses u_d as an indicator of whether a given variable/dimension d is uncollapsed ($u_d = 1$) or collapsed ($u_d = 0$). For each uncollapsed variable, parameters θ_c^d must be generated for each category c from a datatype-compatible prior model M_d .

3. **Generating the observed data given hyper-parameters, latent structure, and parameters.** The dataset $\mathbf{X} = \{x^{(i,d)}\}$ is generated separately for each variable d and for each category $c \in \mathcal{Y}^d$ in the view $v = z_d$ for that variable. For uncollapsed dimensions, this is done by repeatedly simulating from a likelihood model L_d . For collapsed dimensions, we use an exchangeably coupled model ML_d to generate all the data in each category at once.

The details of the CrossCat generative process are as follows:

1. Generate α_D , the concentration hyper-parameter for the Chinese Restaurant Process over dimensions, from a generic Gamma hyper-prior: $\alpha_D \sim \text{Gamma}(k = 1, \theta = 1)$.
2. For each dimension $d \in D$:
 - (a) Generate hyper-parameters $\tilde{\lambda}_d$ from a data type appropriate hyper-prior with density $p(\tilde{\lambda}_d) = V_d(\tilde{\lambda}_d)$, as described above. Binary data is handled by an asymmetric Beta-Bernoulli model with pseudocounts $\tilde{\lambda}_d = [\alpha_d, \beta_d]$. Discrete data is handled by a symmetric Dirichlet-Discrete model with concentration parameter $\tilde{\lambda}_d$. Continuous data is handled by a Normal-Gamma model with $\tilde{\lambda}_d = (\mu_d, K_d, \nu_d, \tau_d)$, where μ_d is the mean, K_d is the effective number of observations, ν_d is the degrees of freedom, and τ_d is the sum of squares.
 - (b) Assign dimension d to a view z_d from a Chinese Restaurant Process with concentration hyper-parameter α_D , conditional on all previous draws: $z_d \sim \text{CRP}\{z_0, \dots, z_{d-1}\}; \alpha_D$
3. For each view v in the dimension partition \bar{z} :
 - (a) Generate α_v , the concentration hyper-parameter for the Chinese Restaurant Process over categories in view v , from a generic hyper-prior: $\alpha_v \sim \text{Gamma}(k = 1, \theta = 1)$.
 - (b) For each observed data point (i.e. row of the table) $r \in R$, generate a category assignment y_r^v from a Chinese Restaurant Process with concentration parameter α_v , conditional on all previous draws: $y_r^v \sim \text{CRP}(\{y_0^v, \dots, y_{r-1}^v\}; \alpha_v)$

apparent variation. Examples for strictly positive, real-valued hyper-parameters include vague Gamma($k = 1, \theta = 1$) hyper-prior, uniform priors over a broad range, and both linear and logarithmic discretizations. Our reference implementation uses a set of simple data-dependent heuristics to determine sufficiently broad ranges. Chinese restaurant process concentration parameters are given 100-bin log-scale grid discrete priors; concentration parameters for the finite-dimensional Dirichlet distributions used to generate component parameters for discrete data have the same form. For Normal-Gamma models, $\min(\tilde{K}_{(d)}) \leq \mu_d \leq \max(\tilde{K}_{(d)})$.

- (c) For each category c in the row partition for this view \bar{y}^c :
- i. For each dimension d such that $u_d = 1$ (i.e. its component models are uncollapsed), generate component model parameters θ_c^d from the appropriate prior with density $M_d(\cdot; \bar{\lambda}_d)$ using hyper-parameters $\bar{\lambda}_d$, as follows:
 - A. For binary data, we have a scalar θ_c^d equal to the probability that dimension d is equal to 1 for rows from category c , drawn from a Beta distribution: $\theta_c^d \sim \text{Beta}(\alpha_d, \beta_d)$, where values from the hyper-parameter vector $\bar{\lambda}_d = [\alpha_d, \beta_d]$.
 - B. For categorical data, we have a vector-valued θ_c^d of probabilities, drawn from a symmetric Dirichlet distribution with concentration parameter λ_d : $\theta_c^d \sim \text{Dirichlet}(\lambda_d)$.
 - C. For continuous data, we have $\theta_c^d = (\mu_c^d, \sigma_c^d)$, the mean and variance of the data in the component, drawn from a Normal-Gamma distribution $(\mu_c^d, \sigma_c^d) \sim \text{NormalGamma}(\bar{\lambda}_d)$.
 - ii. Let $\bar{x}_{(\cdot, d)}$ contain all $x_{(r, d)}$ in this component, i.e. for r such that $y_r^d = c$. Generate the data in this component, as follows:
 - A. If $u_d = 1$, i.e. d is uncollapsed, then generate each $x_{(r, d)}$ from the appropriate likelihood model $L_d(\cdot; \theta_c^d)$. For binary data, we have $x_{(r, d)} \sim \text{Bernoulli}(\theta_c^d)$; for categorical data, we have $x_{(r, d)} \sim \text{Multinomial}(\theta_c^d)$; for continuous data, we have $x_{(r, d)} \sim \text{Normal}(\mu_c^d, \sigma_c^d)$.
 - B. If $u_d = 0$, so d is collapsed, generate the entire contents of $\bar{x}_{(\cdot, d)}$ by directly simulating from the marginalized component model that with density $ML_d(\bar{x}_{(\cdot, d)}; \bar{\lambda}_d)$. One approach is to sample from the sequence of predictive distributions $P(x_{(r, d)} | \bar{x}_{(\cdot, d)}^r; \bar{\lambda}_d)$, induced by M_d and L_d , indexing over rows r , in c .
- The key steps in this process can be concisely described:

$$\begin{aligned}
 \alpha_D &\sim \text{Gamma}(k = 1, \theta = 1) \\
 \bar{\lambda}_d &\sim V_d(\cdot) \\
 z_d &\sim \text{CRP}(\{z_i \mid i \neq d\}; \alpha_D) \\
 \alpha_r &\sim \text{Gamma}(k = 1, \theta = 1) \\
 y_r^c &\sim \text{CRP}(\{y_i^c \mid i \neq r\}; \alpha_r) \\
 \bar{\theta}_c^d &\sim M_d(\cdot; \bar{\lambda}_d) \\
 \bar{x}_{(\cdot, d)} = \{x_{(r, d)} \mid y_r^d = c\} &\sim \begin{cases} \prod_r L_d(\bar{\theta}_c^d) & \text{if } u_d = 1 \\ ML_d(\bar{\lambda}_d) & \text{if } u_d = 0 \end{cases}
 \end{aligned}$$

2.2 The Joint Probability Density

Recall that the following dataset-specific information is needed to fully specify the CrossCat model:

1. $V_d(\cdot)$, a generic hyper-prior of the appropriate type for variable/dimension d .
2. $\{u_d\}$, the indicators for which variables are uncollapsed.
3. $M_d(\cdot)$ and $L_D(\cdot) \forall d$ s.t. $u_d = 1$, a datatype-appropriate parameter prior (e.g. a Beta prior for binary data, Normal-Gamma for continuous data, or Dirichlet for discrete data) and likelihood model (e.g. Bernoulli, Normal or Multinomial).
4. $ML_d(\cdot) \forall d$ s.t. $u_d = 0$, a datatype-appropriate marginal likelihood model, e.g. the collapsed version of the conjugate pair formed by some M_d and L_d .
5. $T_d(\{x\})$, the sufficient statistics for the component model for some collapsed dimension d from a subset of the data $\{x\}$. Arbitrary non-conjugate component models can be numerically collapsed by choosing $T_d(\{x\}) = \{x\}$.

This paper will use **CC** to denote the information necessary to capture the dependence of CrossCat on the data \mathbf{X} . This includes the view concentration parameter α_D , the variable-specific hyperparameters $\{\bar{\lambda}_d\}$, the view partition \bar{z} , the view-specific concentration parameters $\{\alpha_r\}$ and row partition $\{y^r\}$, and the category-specific parameters $\{\theta_c^d\}$ or sufficient statistics $T_d(\bar{x}_{(\cdot, d)})$. This paper will also overload ML_d, M_d, V_d, L_d , and CRP to each represent both probability density functions and stochastic simulators; the distinction should be clear based on context. Given this notation, we have:

$$\begin{aligned}
 P(\mathbf{CC}, \mathbf{X}) &= P(\mathbf{X}; \{\theta_c^d\}, \{y^r\}, \{\bar{\lambda}_d\}, \bar{z}, \alpha_D) \\
 &= e^{-\alpha_D (\prod_{d \in D} V_d(\bar{\lambda}_d))} \text{CRP}(\bar{z}; \alpha_D) (\prod_{r \in \bar{z}} e^{-\alpha_r} \text{CRP}(y^r; \alpha_r)) \\
 &\quad \times \prod_{v \in \bar{z}} \prod_{c \in \bar{y}^v} \prod_{d \in \{i \text{ s.t. } z_i = v\}} \begin{cases} ML_d(T_d(\bar{x}_{(\cdot, d)}); \bar{\lambda}_d) & \text{if } u_d = 1 \\ M_d(\theta_c^d; \bar{\lambda}_d) \prod_{r \in c} L_d(x_{(r, d)}; \theta_c^d) & \text{if } u_d = 0 \end{cases}
 \end{aligned}$$

2.3 Hypothesis Space and Modeling Capacity

The modeling assumptions encoded in CrossCat are designed to enable it to emulate a broad class of data generators. One way to assess this class is to study the full hypothesis space of CrossCat, that is, all logically possible cross-categorizations. Figure 2 illustrates the version of this space that is induced by a 4 row, 3 column dataset. Each cross-categorization corresponds to a model structure — a set of dependence and independence assumptions — that is appropriate for some set of statistical situations. For example, conditioned on the hyper-parameters, the dependencies between variables and data values can be either dense or sparse. A group of dependencies will exhibit a unimodal joint distribution if they are modeled using only a single cluster. Strongly bimodal or multi-modal distributions as well as nearly unimodal distributions with some outliers are recovered by varying the number of clusters and their size. The prior favors stochastic relationships between groups of variables, but also supports (nearly) deterministic models; these correspond to structures with a large number of clusters that share low-entropy component models.

The CrossCat generative process favors hypotheses with multiple views and multiple categories per view. A useful rule of thumb is to expect $O(\log(D))$ views with $O(\log(R))$ categories each a priori. Asserting that a dataset has several views and several categories per view corresponds to asserting that the underlying data generator exhibits several important statistical properties. The first is that the dataset contains variables that arise from several distinct causal processes, not just a

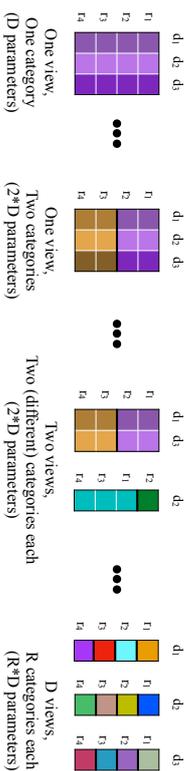

Figure 2. **Model structures drawn from the space of all logically possible cross-categorizations of a 4 row, 3 column dataset.** In each structure, all data values (cells) that are governed by the same parametric model are shown in the same color. If two cells have different colors, they are modeled as conditionally independent given the model structure and hyper-parameters. In general, the space of all cross-categorizations contains a broad class of simple and complex data generators. See the main text for details.

single one. The second is that these processes cannot be summarized by a single parametric model, and thus induce non-Gaussian or multi-modal dependencies between the variables.

2.4 Posterior Inference Algorithm

Posterior inference is carried out by simulating an ergodic Markov chain that converges to the posterior (Gilks, 1999; Neal, 1998). The state of the Markov chain is a data structure storing the cross-categorization, sufficient statistics, and all uncollapsed parameters and hyper-parameters. Figure 3 shows several sampled states from a typical run of the inference scheme on the dataset from Figure 1.

The CrossCat inference Markov chain initializes a candidate state by sampling it from the prior². The transition operator that it iterates consists of an outer cycle of several kernels, each performing cycle sweeps that apply other transition operators to each segment of the latent state. The first is a cycle kernel for inference over the outer CRP concentration parameter α and a cycle of kernels over the inner CRP concentration parameters $\{\alpha_r\}$ for each view. The second is a cycle of kernels for inference over the hyper-parameters $\{\tilde{\lambda}_d\}$ for each dimension. The third is a kernel for inference over any uncollapsed parameters $\{\tilde{\theta}_r^i\}$. The fourth is a cycle over dimensions of an inter-view auxiliary variable Gibbs kernel that shuffles dimensions between views. The fifth is itself a cycle over views of cycles that sweep a single-site Gibbs sampler over all the rows in the given view. This chain corresponds to the default auxiliary variable Gibbs sampler that the Venture probabilistic programming platform (Mansinghka, Selsam, and Perov, 2014) produces when given the CrossCat model written as a probabilistic program.

More formally, the Markov chain used for inference is a cycle over the following kernels:

1. Ancestrally, this initialization appears to yield the best inference performance overall. One explanation can be found by considering a representative subproblem of inference in CrossCat: performing inference in one of the inner CRP mixture models. A maximally dispersed initialization, with each of the N rows in its own category, requires $O(N^2)$ time for its first Gibbs sweep. An initialization that places all rows in a single category requires $O(1)$ time for its first sweep but can spend many iterations stuck in or near the “low resolution” model encoded by this initial configuration.

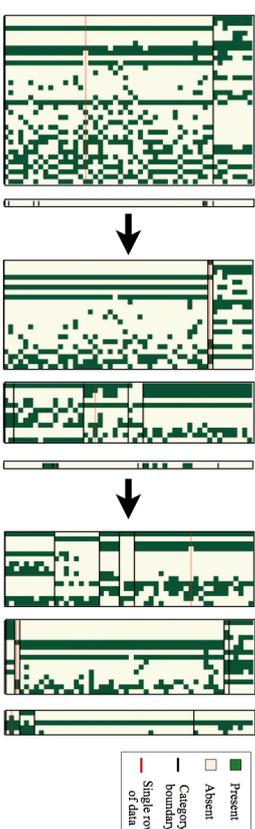

Figure 3. **Snapshots of the Markov chain for cross-categorization on a dataset of human object-feature judgments.** Each of the three states shows a particular cross-categorization that arose during a single Markov chain run, automatically rendered using the latent structure from cross-categorization to inform the layout. Black horizontal lines separate categories within a view. The red horizontal line follows one row of the dataset. Taken from left to right, the three states span a typical run of roughly 100 iterations: the first is while the chain appears to be converging to a high probability region, while the last two illustrate variability within that region.

1. **Concentration hyper-parameter inference: updating α_d and each element of $\{\alpha_r\}$.** Sample α_d and all the $\alpha_{r,s}$ for each view via a discretized Gibbs approximation to the posterior, $\alpha_d \sim P(\alpha_d | \bar{z})$ and $\alpha_r \sim P(\alpha_r | \bar{y}^r)$. For each α , this involves scoring the CRP marginal likelihood at a fixed number of grid points — typically ~ 100 — and then re-normalizing and sampling from the resulting discrete approximation.

2. **Component model hyper-parameter inference: updating the elements of $\{\tilde{\lambda}_d\}$.** For each dimension, for each hyper-parameter, discretize the support of the hyper-prior and numerically sample from an approximate hyper-posterior distribution. That is, implement an appropriately-binned discrete approximation to a Gibbs sampler for $\tilde{\lambda}_d \sim P(\tilde{\lambda}_d | \bar{x}_d, \bar{y}^d)$ (i.e. we condition on the vertical slice of the input table described by the hyper-parameters, and the associated latent variables). For conjugate component models, the probabilities depend only on the sufficient statistics needed to evaluate this posterior. Each hyper-parameter adjustment requires an operation linear in the number of categories, since the scores for each category (i.e. the marginal probabilities) must be recalculated, after each category’s statistics are updated. Thus each application of this kernel takes time proportional to the number of dimensions times the maximum number of categories in any view.

3. **Category inference: updating the elements of $\{y^r\}$ via Gibbs with auxiliary variables.** For each entry in each view, this transition operator samples a new category assignment from its conditional posterior. A variant of Algorithm 8 from (Neal, 1998) (with $m=1$) is used to handle uncollapsed dimensions.

The category inference transition operator will sample y_r^i , the categorization for row r in view v , according to its conditioned distribution given the other category assignments y^r , parameters $\{\tilde{\theta}_r^i\}$ and auxiliary parameters. If $u_d = 0 \forall d$ s.t. $z_d = v$, i.e. there are no uncollapsed dimensions in this view, then this reduces to the usual collapsed Gibbs sampler applied to

the subset of data within the view. Otherwise, let $\{\tilde{\phi}^d\}$ denote auxiliary parameters for each uncollapsed dimension d (where $u_d = 1$) of the same form as θ_c^d . Before each transition, these parameters are chosen as follows:

$$\tilde{\phi}^d \sim \begin{cases} \delta_{\theta_c^d} & \text{if } y_r^+ = y_j^+ \iff r = j \\ M_d(\tilde{\lambda}_d) & \text{o.w. } (y_r^+ \in \tilde{y}_{=r}^-) \end{cases}$$

In this section, c^+ will denote the category associated with the auxiliary variable. If $y_r^+ \in \tilde{y}_{=r}^-$ then $c^+ = \max(\tilde{y}_v^-) + 1$, i.e. a wholly new category will be created, and by sampling $\tilde{\phi}^d$ this category will have newly sampled parameters. Otherwise, $c^+ = y_r^+$, i.e. row r was a singleton, so its previous category assignment and parameters will be reused.

Given the auxiliary variables, we can derive the target density of the transition operator by expanding the joint probability density:

$$\begin{aligned} y_r^+ &\sim P(y_r^+ | \tilde{y}_{=r}^-, \tilde{\lambda}_d, \{x_{(c,d)}\} | d \text{ s.t. } z_d = v), \{\{\theta_c^d | c \in \tilde{y}_{=r}^-\} | d \text{ s.t. } z_d = v \text{ and } u_d = 1\}, \{\tilde{\phi}^d\} \\ &\propto \text{CRP}(y_r^+, \tilde{y}_{=r}^-, \alpha_0) \\ &\quad \times \prod_{d \in \{l \text{ s.t. } z_d = v\}} \begin{cases} M_d(T_d(\tilde{x}_{(c,d)}^-, \tilde{\lambda}_d)) & \text{if } u_d = 0 \\ M_d(\tilde{\theta}_c^d; \tilde{\lambda}_d) \prod_{c \in L_d(x_{(c,d)})} & \text{if } u_d = 1 \text{ and } y_r^+ \in \tilde{y}_{=r}^- \\ M_d(\tilde{\theta}_c^d; \tilde{\lambda}_d) \prod_{c \in L_d(x_{(c,d)})} & \text{if } u_d = 1 \text{ and } y_r^+ = c^+ \notin \tilde{y}_{=r}^- \end{cases} \end{aligned}$$

The probabilities this transition operator needs can be obtained by iterating over possible values for y_r^+ , calculating their joint densities, and re-normalizing numerically. These operations can be implemented efficiently by maintaining and incrementally modifying a representation of CC, updating sufficient statistics and a joint probability accumulator after each change (Mansinghka, 2007). The complexity of resampling y_r^+ for all rows r and views v is $O(VRCD)$, where V is the number of views, R the number of rows, C the maximum number of categories in any view, and D is the number of dimensions.

4. **Inter-view inference: updating the elements of \tilde{z} via Gibbs with auxiliary variables.** For each dimension d , this transition operator samples a new view assignment z_d from its conditional posterior. As with the category inference kernel, this can be viewed as a variant of Algorithm 8 from (Neal, 1998) (with $m = 1$), applied to the ‘‘outer’’ Dirichlet process mixture model in CrossCat. This mixture has uncollapsed, non-conjugate component models that are themselves Dirichlet process mixtures.

Let v^+ be the index of the new view. The auxiliary variables are α_{v^+} , \tilde{y}^{v^+} and $\{\theta_c^d | c \in \tilde{y}^{v^+}\}$ (if $u_d = 1$). If $z_d \in \tilde{z}^{-d}$, then $v^+ = \max(\tilde{z}) + 1$, and the auxiliary variables are sampled from their priors. Otherwise, $v^+ = z_d$, and the auxiliary variables are deterministically set to the values associated with z_d . Given values for these variables, the conditional distribution for z_d can be derived as follows:

$$\begin{aligned} z_d &\sim P(z_d | \alpha_D, \tilde{\lambda}_d, \tilde{z}^{-d}, \alpha_{v^+}, \{\tilde{y}^{v^+}\}, \{\{\theta_c^d | c \in \tilde{y}^c\} | j \in D\}, \mathbf{X}) \\ &\propto \text{CRP}(z_d; \tilde{z}^{-d}, \alpha_D) \prod_{c \in \tilde{y}^{v^+}} \begin{cases} M_{L_d}(T_d(\tilde{x}_{(c,d)}^-, \tilde{\lambda}_d)) & \text{if } u_d = 1 \\ M_d(\tilde{\theta}_c^d; \tilde{\lambda}_d) \prod_{c \in L_d(x_{(c,d)})} & \text{if } u_d = 0 \end{cases} \end{aligned}$$

This transition operator shuffles individual columns between views, weighing their compatibility with each view by multiplying likelihoods for each category. A full sweep thus has time complexity $O(DVCR)$. Note that if a given variable is a poor fit for its current view, its hyper-parameters and parameters will be driven to reduce the dependence of the likelihood for that variable on its clustering. This makes it more likely for row categorizations proposed from the prior to be accepted.

Inference over the elements of \tilde{z} can also be done via a mixture of a Metropolis-Hastings birth-death kernel to create new views with a standard Gibbs kernel to reassign dimensions among pre-existing views. In our experience, both transition operators yield comparable results on real-world data; the Gibbs auxiliary variable kernel is presented here for simplicity.

5. **Component model parameter inference: updating $\{\theta_c^d | u_d = 1\}$.** Each dimension or variable whose component models are uncollapsed must be equipped with a suitable ergodic transition operator T that converges to the local parameter posterior $P(\tilde{\theta}_c^d | x_{(c,d)}^-, \tilde{\lambda}_d)$. Exact Gibbs sampling is often possible when L_d and M_d are conjugate.

CrossCat’s scalability can be assessed by multiplying an estimate of how long each transition takes with an estimate of how many transitions are needed to get good results. The experiments in this paper use ~ 10 -100 independent samples. Each sample was based on runs of the inference Markov chain with ~ 100 -1,000 transitions. Taking these numbers as rough constants, scalability is governed by the asymptotic orders of growth. Let R be the number of rows, D the number of dimensions, V the maximum number of views and C the maximum number of categories. The memory needed to store the latent state is the sum of the memory needed to store the D hyper-parameters and view assignments, the VC parameters/sufficient statistics, and the VR category assignments, or $O(D + VC + VR)$. Assuming a fully dense data matrix, the loops in the transition operator described above scale as $O(DC + RDVC + RDVC + DC) = O(RDVC)$, with the RD terms scaling down following the data density.

This paper shows results from both open-source and commercial implementations on datasets of up to ~ 10 million cells³. Because this algorithm is asymptotically linear in runtime with low memory requirements, a number of performance engineering and distributed techniques can be applied to reach larger scales at low latencies. Performance engineering details are beyond the scope of this paper.

2.5 Exploration and Prediction Using Posterior Samples

Each approximate posterior sample provides an estimate of the full joint distribution of the data. It also contains a candidate latent structure that characterizes the dependencies between variables and provides an independent clustering of the rows with respect to each group of dependent variables. This section gives examples of exploratory and predictive analysis problems that can be solved by using these samples. Prediction is based on calculating or sampling from the conditional densities implied by each sample and then either averaging or resampling from the results. Exploratory queries typically involve Monte Carlo estimation of posterior probabilities that assess structural

3. A variation on CrossCat was the basis of Veritable, a general-purpose machine learning system built by Navia Systems/Prior Knowledge Inc. This implementation became a part of Salesforce.com’s predictive analytics infrastructure. At Navia, CrossCat was applied to proprietary datasets from domains such as operations management for retail, clinical virology, and quantitative finance.

properties of the latent variables posited by CrossCat and the dependencies they imply. Examples include obtaining a global map of the pairwise dependencies between variables, selecting those variables that are probably predictive of some target, and identifying rows that are similar in light of some variables of interest.

2.5.1 PREDICTION

Recall that \mathbf{CC} represents a model for the joint distribution over the variables along with sufficient statistics, parameters, a partition of variables into views, and categorizations of the rows in the data \mathbf{X} . Variables representing the latent structure associated with a particular posterior sample $\mathcal{C}C_s$ will all be indexed by s , e.g. $z_{q_s}^s$. Also let \mathcal{Y}^+ represent the category assignment of a new row in view v , and let $\{t_i\}$ and $\{g_j\}$ be the sets of target variables and given variables in a given predictive query.

To generate predictions by sampling from the conditional density on targets given the data, we must simulate

$$\{\hat{x}_i\} \sim p(\{X_{t_i}\} | \{X_{g_j} = x_{g_j}\}, \mathbf{X})$$

Given a set of models, this can be done in two steps. First, from each model, sample a categorization from each view conditioned on the values of the given variables. Second, sample values for each target variable by simulating from the target variable's component model for the sampled category:

$$\begin{aligned} \mathcal{C}C_s &\sim p(\mathbf{CC} | \mathbf{X}) \\ c_s^v &\sim p(\mathcal{Y}^+ | \{X_{g_j} = x_{g_j} | z_{q_s}^s = v\}) \\ \hat{x}_i^v &\sim p(X_{t_i} | z_{q_s}^s = v) = \int L(x_{t_i}; \hat{\theta}_{c_s^v}^v) M(\hat{\theta}_{c_s^v}^v; \vec{\lambda}_{q_i}, \vec{\mu}) d\hat{\theta} \end{aligned}$$

The category kernel from the MCMC inference algorithm can be re-used to sample from c_s^v . Also, sampling from \hat{x}_i^v can be done directly given the sufficient statistics for data types whose likelihood models and parameter priors are conjugate. In other cases, either θ will be represented as part of $\mathcal{C}C_s$ or sampled on demand.

The same latent variables are also useful for evaluating the conditional density for a desired set of predictions:

$$\begin{aligned} p(\{X_{t_i} = x_{t_i}\} | \{X_{g_j} = x_{g_j}\}, \mathbf{X}) \\ &\approx \frac{1}{N} \sum_s p(\{X_{t_i} = x_{t_i}\} | \{X_{g_j} = x_{g_j}\}, \mathbf{CC} = \mathcal{C}C_s) \\ &= \frac{1}{N} \sum_s \prod_{v \in \mathcal{C}^v} \prod_c p(\{X_{t_i} = x_{t_i} | z_{q_s}^s = v\} | \mathcal{Y}^+ = c) p(\mathcal{Y}^+ = c | \{X_{g_j} = x_{g_j} | z_{q_s}^s = v\}) \end{aligned}$$

Many problems of prediction can be reduced to sampling from and/or calculating conditional densities. Examples include classification, regression and imputation. Each can be implemented by forming estimates $\{X_{t_i}^v\}$ of the target variables. By default, the implementation from this paper implements the mean of the predictive to impute continuous values. This is equivalent to choosing the value that minimizes the expected square loss under the empirical distribution induced by a set of predictive samples. For discrete values, the implementation uses the most probable value.

equivalent to minimizing 0-1 loss, and calculates it by directly evaluating the conditional density of each possible value. This approach to prediction can also handle nonlinear and/or stochastic relationships within the set of target variables $\{X_{t_i}\}$ and between the given variables $\{X_{g_j}\}$ and the targets. It is easy to implement in terms of the same sampling and probability calculation kernels that are necessary for inference.

This formulation of prediction scales linearly in the number of variables, categories, and view. It is also sub-linear in the number of variables when dependencies are sparse, and parallelizable over the views, the posterior samples, and the generated samples from the conditional density. Future work will explore the space of tradeoffs between accuracy, latency and throughput that can be achieved using this basic design.

2.5.2 DETECTING DEPENDENCIES BETWEEN VARIABLES

To detect dependencies between groups of variables, it is natural to use a Monte Carlo estimate of the marginal posterior probability that a set of variables $\{q_i\}$ share the same posterior view. Using s as a superscript to select values from a specific sample, we have:

$$\begin{aligned} Pr[z_{q_0}^s = z_{q_1} = \dots = z_{q_n} | \mathbf{X}] &\approx \frac{1}{N} \sum_s Pr[z_{q_0}^s = z_{q_1}^s = \dots = z_{q_n}^s | \mathcal{C}C_s] \\ &= \frac{\#\{s | z_{q_0}^s = z_{q_1}^s = \dots = z_{q_n}^s\}}{N} \end{aligned}$$

These probabilities also characterize the marginal dependencies and independencies that are explicitly represented by CrossCat. For example, pairwise co-assignment in \vec{z} determines⁴ pairwise marginal independence under the generative model:

$$X_{q_i} \perp\!\!\!\perp X_{q_j} \iff z_{q_i} \neq z_{q_j}$$

The results in this paper often include the “z-matrix” of marginal dependence probabilities $\mathbf{Z} = [Z_{(i,j)}]$, where $Z_{(i,j)} = 1 - Pr[X_i \perp\!\!\!\perp X_j | \mathbf{X}]$. This measure is used primarily for simplicity; other measures of the presence or strength of predictive relationships are possible.

2.5.3 ESTIMATING SIMILARITY BETWEEN ROWS

Exploratory analyses often make use of “similarity” functions defined over pairs of rows. One useful measure of similarity is given by the probability that two pieces of data were generated from the same statistical model (Tenenbaum and Griffiths, 2001; Ghahramani and Heller, 2006). CrossCat naturally induces a context-sensitive similarity measure between rows that has this form: the probability that two items come from the same category in some context. Here, contexts are defined by target variables, and comprise the set of views in which that variable participates (weighted by their probability). This probability is straightforward to estimate given a collection of samples:

⁴ This paper defines independence in terms of the generative process and latent variables. Two variables in different views are explicitly independent, but two variables in the same view are coupled through the latent cluster assignment. This is clear if there are multiple clusters. Even if there is just one cluster, if q_i remains nonzero as N goes to infinity, then eventually there will be more than one cluster. A predictive definition of independence in terms of nonzero mutual information will differ in some cases: a comparison between these candidate measures is beyond the scope of this paper.

$$1 - Pr[x_{(r,c)} \perp x_{(r',c)} | \mathbf{X}, \tilde{\lambda}_c] \approx \frac{\#(\{s|y_{(s,r)}^{sc} = y_{(s,r')}^{sc}\})}{N}$$

This measure relies on CrossCat’s detection of marginal dependencies to determine which variables are relevant in any given context. The component models largely determine how differences in each variable in that view will be weighted when calculating similarity.

2.6 Assessing Inference Quality

A central concern is that the single-site Gibbs sampler used for inference might not produce high-quality models or stable posterior estimates within practical running times. For example, the CrossCat inference algorithm might rapidly converge to a local minimum in which all proposals to create new views are rejected. In this case, even though the Gibbs sampler will appear to have converged, the models it produces could yield poor inference quality.

This section reports four experiments that illustrate key algorithmic and statistical properties of CrossCat. The first experiment gives a rough sense of inference efficiency by comparing the energies of ground truth states to the energies of states sampled from CrossCat on data generated by the model. The second experiment assesses the convergence rate and the reliability of estimates of posterior expectations on a real-world dataset. The third experiment explores CrossCat’s resistance to under-fitting and over-fitting by running inference on datasets of Gaussian noise. The fourth experiment assesses CrossCat’s predictive accuracy in a setting with a large number of distractors and a small number of signal variables. It shows that CrossCat yields favorable accuracy compared to several baseline methods.

The next experiment assesses the stability and efficiency of CrossCat inference on real-world data. Figure 5a shows the evolution of Monte Carlo dependence probability estimates as a function of the number of Markov chain iterations. Figure 5b shows traces of the number of views for each chain in the same set of runs. ~ 100 iterations appears sufficient for initializations to be forgotten, regardless of the number of views sampled from the CrossCat prior. At this point, Monte Carlo estimates appear to stabilize, and the majority of states (~ 40 of 50 total) appear to have 4, 5 or 6 views. This stability is not simply due to a local minimum: after 700 iterations, transitions that create or destroy views are still being accepted. However, the frequency of these transitions does decrease. It thus seems likely that the standard MCMC approach of averaging over a single long chain run might require significantly more computation than parallel chains. This behavior is typical for applications to real-world data. We typically use 10–100 chains, each run for 100–1,000 iterations, and have consistently obtained stable estimates.

The convergence measures from (Geweke, 1992) are also included for comparison, specifically the numerical standard error (NSE) and relative numerical efficiency (RNE) for the view CRP parameter α to assess autocorrelations (LeSage, 1999). NSE values near 0 and RNE values near 1 indicate approximately independent draws. These values were computed using a 0%, 4%, 8%, and 15% autocorrelation taper. NSE values were near zero and did not differ markedly: .023, .021, .018, and .018. Similarly, RSE values were near 1 and did not differ markedly: 1, 1.23, 1.66, and 1.54. These results suggest that there is acceptably low autocorrelation in the sampled values of the hyper-parameters.

The reliability of CrossCat reflects simple but important differences between the way single-site Gibbs sampling is used here and standard MCMC practice in machine learning. First, CrossCat

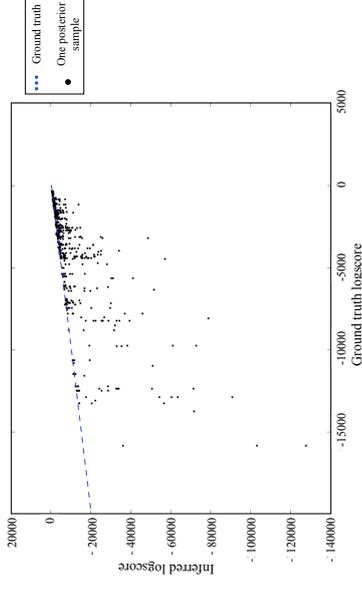

Figure 4: **The joint density of the latent cross-categorization and training data for $\sim 1,000$ samples from CrossCat’s inference algorithm, compared to ground truth.** Each point corresponds to a sample drawn from an approximation of the CrossCat posterior distribution after 200 iterations on data from a randomly chosen CrossCat model. Table sizes range from 10×10 to 512×512 . Points on the blue line correspond to samples with the same joint density as the ground truth state. Points lying above the line correspond to models that most likely underestimate the entropy of the underlying generator, i.e. they have over-fit the data. CrossCat rarely produces such samples. Some points lie significantly below the line, overestimating the entropy of the generator. These do not necessarily correspond to “under-fit” models, as the true posterior will be broad (and may also induce broad predictions) when data is scarce.

uses independent samples from parallel chains, each initialized with an independent sample from the CrossCat prior. In contrast, typical MCMC schemes from nonparametric Bayesian statistics use dependent samples obtained by thinning a single long chain that was deterministically initialized. For example, Gibbs samplers for Dirichlet process mixtures are often initialized to a state with a single cluster; this corresponds to a single-view single-category state for CrossCat. Second, CrossCat performs inference over hyper-parameters that control the expected predictability of each dimension, as well as the concentration parameters of all Dirichlet processes. Many machine learning applications of nonparametric Bayes do not include inference over these hyper-parameters; instead, they are set via cross-validation or other heuristics.

There are mechanisms by which these differences could potentially explain the surprising reliability and speed of CrossCat inference as compared to typical Gibbs samplers. Recall that the regeneration time of a Markov chain started at its equilibrium distribution is the (random) amount of time it needs to “forget” its current state and arrive at an independent sample. For CrossCat, this regeneration time appears to be substantially longer than convergence time from the prior. States from the prior are unlikely to have high energy or be near high energy regions, unlike states drawn from the posterior. Second, hyper-parameter inference — especially those controlling the expected noise in the component models, not just the Dirichlet process concentrations — provides a simple mechanism that helps the sampler exit local minima. Consider a dimension that is poorly explained

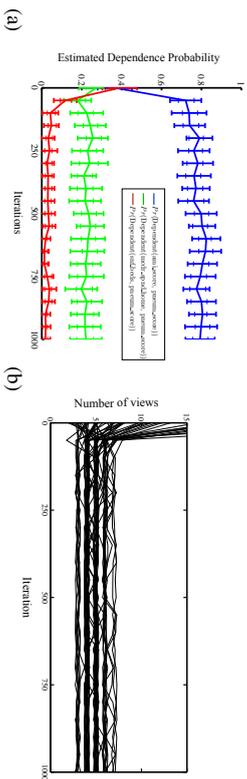

Figure 5: A quantitative assessment of the convergence rate of CrossCat inference and the stability of posterior estimates on a real-world health economics dataset. (a) shows the evolution of simple Monte Carlo estimates of the probability of dependence of three pairs of variables, made from independent chains initialized from the prior, as a function of the number of iterations of inference. Thick error bars show the standard deviation of estimates across 50 repetitions, each with 20 samples; thin lines show the standard deviation of estimates from 40 samples. Estimates stabilize after ~ 100 iterations. (b) shows the number of views for 50 of the same Markov chain runs. After ~ 100 iterations, states with 4, 5 or 6 views dominate the sample, and chains still can switch into and out of this region after 700 iterations.

by the categorization in its current view. Conditioned on such a categorization, the posterior on the hyper-parameter will favor increasing the expected noisiness of the clusters, to better accommodate the data. Once the hyper-parameter enters this regime, the model becomes less sensitive to the specific clustering used to explain this dimension. This therefore also increases the probability that the dimension will be reassigned to any other pre-existing view. It also increases the acceptance probability for proposals that create a new view with a random categorization. Once a satisfactory categorization is found, however, the Bayesian Occam’s Razor favors reducing the expected entropy of the clusters. Similar dynamics were described in (Mansinghka, Kulkarni, Perov, and Tenenbaum, 2013); a detailed study is beyond the scope of this paper.

The third simulation, shown in Figure 7, illustrates CrossCat’s behavior on datasets with low-dimensional signals amidst high-dimensional random noise. In each case, CrossCat rapidly and confidently detects the independence between the “distractor” dimensions, i.e. it does not over-fit. Also, when the signal is strong or there are few distractors, CrossCat confidently detects the true predictive relationships. As the signals become weaker, CrossCat’s confidence decreases, and variance increases. These examples qualitatively support the use of CrossCat’s estimates of dependence probabilities as indicators of the presence or absence of predictive relationships. A quantitative characterization of CrossCat’s sensitivity and specificity, as a function of both sample size and strength of dependence, is beyond the scope of this paper.

Many data analysis problems require sifting through a large pool of candidate variables in settings where only a small fraction are relevant for any given prediction. The fourth experiment, shown in Figure 7, illustrates CrossCat’s behavior in this setting. The test datasets contain 10 “signal” dimensions generated from a 5-component mixture model, plus 10–1,000 “distractor” dimensions generated by an independent 3-component mixture that clusters the data differently. As the number of distractors increases, the likelihood becomes dominated by the distractors. The experiment compares imputation accuracy for several methods — CrossCat, mixture modeling, column-wise averaging, imputation by randomly chosen values, and a popular model-free imputation tech-

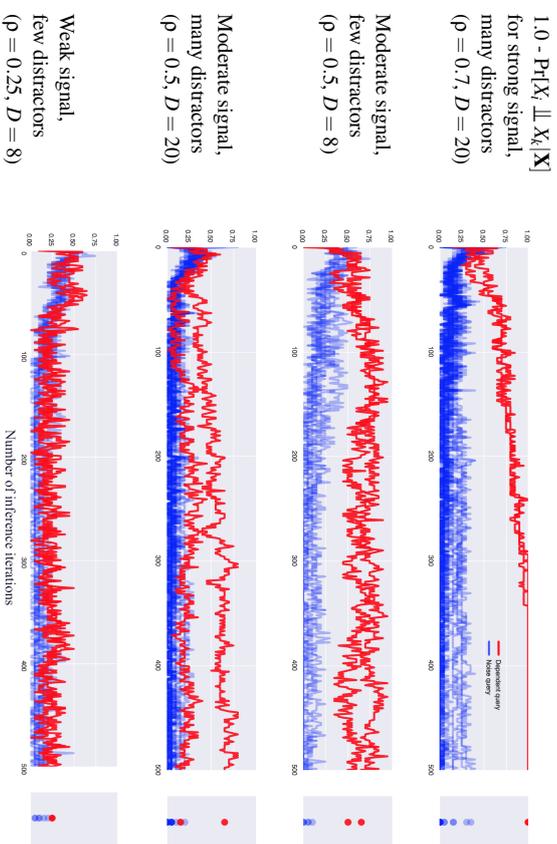

Figure 6: **Detected dependencies given two correlated signal variables and multiple independent distractors.** This experiment illustrates CrossCat’s sensitivity and specificity to pairwise relationships on multivariate Gaussian datasets with 100 rows. In each dataset, two pairs of variables have nonzero correlation ρ . The remaining $D - 4$ dimensions are uncorrelated distractors. Each row shows the inferred dependences between 20 randomly sampled pairs of distractors (blue) and the two pairs of signal variables (red). See main text for further discussion.

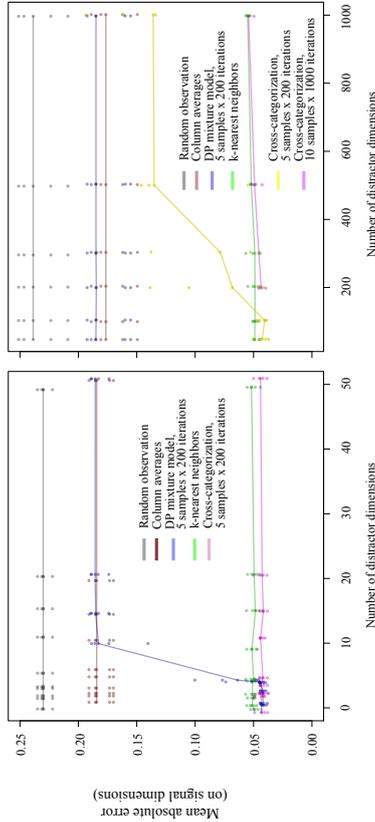

Figure 7: **Predictive accuracy for low-dimensional signals embedded in high-dimensional noise.** The data generator contains 10 “signal” dimensions described by a 5-cluster model to which distractor dimensions described by an independent 3-cluster model have been appended. The left plot shows imputation accuracies for up to 50 distractor dimensions; the right shows accuracies for 50-1,000 distractors. CrossCat is compared to mixture models as well as multiple non-probabilistic baselines (column-wise averaging, imputing via a random value, and a state-of-the-art extension to k-nearest-neighbors). The accuracy of mixture modeling drops when the number of distractors D becomes comparable to the number of signal variables S , i.e. when $D \approx S$. When $D > S$, the distractors get modeled instead of the signal. In contrast, CrossCat remains accurate when the number of distractors is 100 times larger than the number of signal variables. See main text for additional discussion.

nique (Hastie, Tibshirani, Sherlock, Eisen, Brown, and Bostein, 1999) — on problems with varying numbers of distractors. CrossCat remains accurate when the number of distractors is 100x larger than the number of signal variables. As expected, mixtures are effective in low dimensions, but inaccurate in high dimensions. When the number of distractors equals the number of signal variables, the mixture posterior grows bimodal, including one mode that treats the signal variables as noise. This mode dominates when the number of distractors increases further.

3. Empirical Results on Real-World Datasets

This section describes the results from CrossCat-based analyses of several datasets. Examples are drawn from multiple fields, including health economics, pattern recognition, political science, and econometrics. These examples involve both exploratory analysis and predictive modeling. The primary aim is to illustrate CrossCat and assess its efficacy on real-world problems. A secondary aim is to verify that CrossCat produces useful results on data generating processes with diverse statistical characteristics. A third aim is to compare CrossCat with standard generative, discriminative, and model-free methods.

3.1 Dartmouth Atlas of Health Care

The Dartmouth Atlas of Health Care (Fisher, Goodman, Wennberg, and Bronner, 2011) is one output from a long-running effort to understand the efficiency and effectiveness of the US health care system. The overall dataset covers ~4300 hospitals that can be aggregated into ~300 hospital-reporting regions. The extract analyzed here contains 74 variables that collectively describe a hospital’s capacity, quality of care, and cost structure. These variables contain information about multiple functional units of a hospital, such as the intensive care unit (ICU), its surgery department, and any hospice services it offers. For several of these units, the amount each hospital bills to a federal program called Medicare is also available. The continuous variables in this dataset range over multiple orders of magnitude. Specific examples include counts of patients, counts of beds, dollar amounts, percentages that are ratios of counts in the dataset, and numerical aggregates from survey instruments that assess quality of care.

Due to its broad coverage of hospitals and their key characteristics, this dataset illustrates some of the opportunities and challenges described by the NRC Committee on the Analysis of Massive Data (2013). For example, given the range of cost variables and quality surveys it contains, this data could be used to study the relationship between cost and quality of care. The credibility of any resulting inferences would rest partly on the comprehensiveness of the dataset in both rows (hospitals) and columns (variables). However, it can be difficult to establish the absence of meaningful predictive relationships in high-dimensional data on purely empirical grounds. Many possible sets of predictors and forms of relationships need to be considered and rejected, without sacrificing either sensitivity or specificity. If the dataset had fewer variables, a negative finding would be easier to establish, both statistically and computationally, as there are fewer possibilities to consider. However, such a negative finding would be less convincing.

The dependencies detected by CrossCat reflect accepted findings about health care that may be surprising. The inferred pairwise dependence probabilities, shown in Figure 8, depict strong evidence for a dissociation between cost and quality. Specifically, the variables in block A are aggregated quality scores, for congestive heart failure (CHE_SCORE), pneumonia (PNEUM_SCORE), acute myocardial infarction (AMI_SCORE), and an overall quality metric (QUAL_SCORE). The probability that they depend on any other variable in the dataset is low. This finding has been reported consistently across multiple studies and distinct patient populations (Fisher, Goodman, Skinner, and Bronner, 2009). Partly due to its coverage in the popular press (Gawande, 2009), it also informed the design of performance-based funding provisions in the 2009 Affordable Care Act.

CrossCat identifies several other clear, coherent blocks of variables whose dependencies are broadly consistent with common sense. For example, Section B of Figure 8 shows that CrossCat has inferred probable dependencies between three variables that all measure hospice usage. The dependencies within Section C reflect the proposition that the presence of home health aides — often consisting of expensive equipment — and overall equipment spending are probably dependent. The dark green bar for MD_CRFND_AMBLINC with the variables in section C is also intuitive: home health care easily leads to ambulance transport during emergencies. Section D shows probable dependencies between the length of hospital stays, hospital bed usage, and surgery. This section and section E, which contains measures of ICU usage, are probably predictive of the general spending metrics in section F, such as total Medicare reimbursement, use of doctors’ time, and total full time equivalent (FTE) head count. Long hospital stays, surgery, and time in the intensive care unit (ICU) are key drivers of costs, but not quality of care.

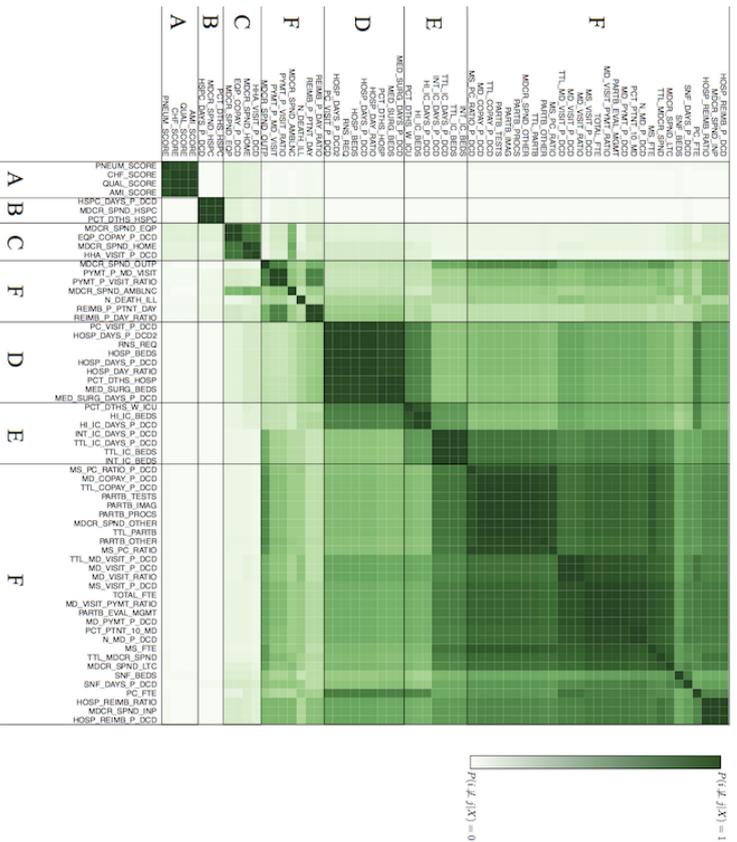

Figure 8: **Dependencies between variables the Dartmouth Atlas data aggregated by hospital federal region.** This figure shows the z-matrix $Z = [Z(i, j)]$ of pairwise dependence probabilities, where darker green represents higher probability. Rows and columns are sorted by hierarchical clustering and several portions of the matrix have been labeled. The isolation of [A] indicates that the quality score variables are almost certainly mutually dependent but independent of the variables describing capacity and cost structure. [B] contains three distinct but dependent measures of hospice cost and capacity: the percent of deaths in hospice, the number of hospice days per decedent, and the total Medicare spending on hospice usage. [C] contains spending on home health aides, equipment, and ambulance care. [D] shows dependencies between hospital stays, surgeries, and in-hospital deaths. [E] contains variables characterizing intensive care, including some that probably interact with surgery, and others that interact with general spending metrics [F], such as usage of doctors' time and total full time equivalency (FTE) head count.

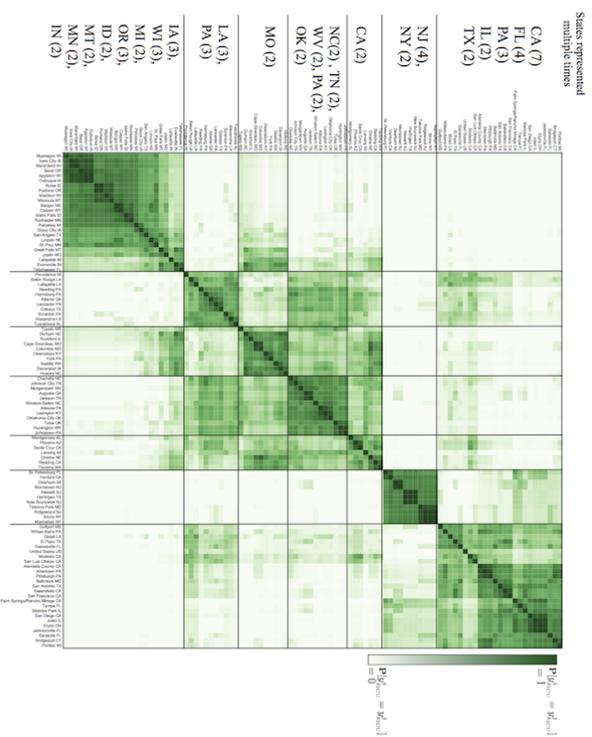

Figure 9: **The pairwise similarity measure inferred by CrossCat in the context of ICU utilization.** Each cell contains an estimate of the marginal probability that the hospital reporting regions corresponding to the row and column come from the same category in the view. The block structure in this matrix reflects regional variation in ICU utilization and in other variables that are probably predictive of it; examples include measures of hospital and intensive care capacity and usage.

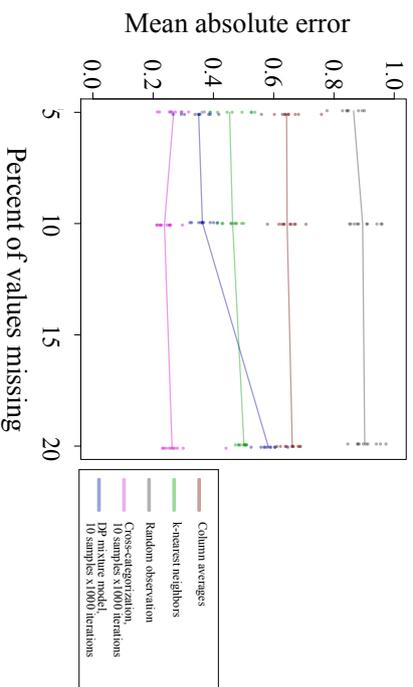

Figure 12: **A comparison of imputation accuracy under random censoring.** The error (y axis) as a function of the fraction of missing values (x axis) is measured on a scale that has been normalized by column-wise variance, so that high-variance variables do not dominate the comparison. CrossCat is more accurate than baselines such as column-wise averaging, imputation using a randomly chosen observation, a state-of-the-art variant of k-nearest-neighbors, and Dirichlet process mixtures of Gaussians. Also note the collapse of mixture modeling to column-wise averaging when the fraction of missing values grows sufficiently large.

3.2 Classifying Images of Handwritten Digits

The MNIST collection of handwritten digit images (LeCun and Cortes, 2011) can be used to explore CrossCat’s applicability to high-dimensional prediction problems from pattern recognition. Figure 13a shows example digits. For all experiments, each image was downsampled to 16x16 pixels and represented as a 256-dimensional binary vector. The digit label was treated as an additional categorical variable, observed for training examples and treated as missing for testing. Figure 13b shows the inferred dependence probabilities among pixels and between the digit label and the pixels. The pixels that are identified as independent of the digit class label lie on the boundary of the image, as shown in Figure 13c.

A set of approximate posterior samples from CrossCat can be used to complete partially observed images by sampling predictions for arbitrary subsets of pixels. Figure 14 illustrates this: each panel shows the data, marginal predictive images, and predicted image completions, for 10 images from the dataset, one per digit. With no data, all 10 predictive distributions are equivalent, but as additional pixels are observed, the predictions for most images concentrate on representations of the correct digit. Some digits remain ambiguous when $\sim 30\%$ of the pixels have been observed. The predictive distributions begin as highly multi-modal distributions when there is little to no data, but concentrate on roughly unimodal distributions given sufficiently many features.

The predictive distribution can also be used to infer the most probable digit, i.e. solve the standard MNIST multi-class classification problem. Figure 15 shows ROC curves for CrossCat on this problem. Each panel shows the tradeoff between true and false positives for each digit, aggregated from the overall performance on the underlying multi-class problem. The figure also includes ROC curves for Support Vector Machines with linear and Gaussian kernels. For these methods, the standard one-vs-all approach was used to reduce the multi-class problem into a set of binary classification problems. The regularization and kernel bandwidth parameters for the SVMs were set via cross-validation using 10% of the training data. 10 posterior samples from CrossCat were used, each obtained after 1,000 iterations of inference from a random initialization. CrossCat was more accurate than the linear discriminative technique; this is expected, as CrossCat induces a nonlinear decision boundary even if classifying based on a single posterior sample. Overall, the 10-sample model used here made less accurate predictions than the Gaussian SVM baseline. Also, in anecdotal runs that were scored by overall 0-1 loss rather than per-digit accuracy, performance was similarly mixed, and less favorable for CrossCat. However, the size of the kernel matrix for the Gaussian SVM scales quadratically, while CrossCat scales linearly. As a classifier, CrossCat thus offers different tradeoffs between accuracy, amount of training data, test-time parallelism (via the number of independent samples), and latency than standard techniques.

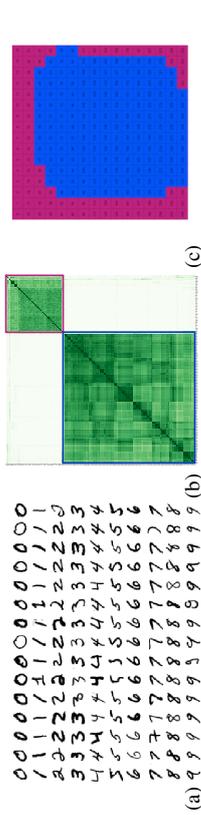

Figure 13: **MNIST handwritten digits, feature z-matrix, and color-coded image pixel locations.** (a) Fifteen visually rendered examples of handwritten digits for each number in the MNIST data set. Each image was converted to a binary feature vector for predictive modeling. CrossCat additionally treated the digit label as an additional feature; this value was observed for training examples and treated as missing for testing. (b) The dependence probabilities between pixel values distinguish two blocks of pixels, one containing the digit label. (c) Coloring the pixels from each block reveals the spatial structure in pixel dependencies. Blue pixels — pixels from the block with a blue border from figure (b) — pick out the foreground, i.e. pixels whose values depend on what digit the image contains. Magenta pixels pick out the common background, i.e. pixels whose values are independent of what digit is drawn.

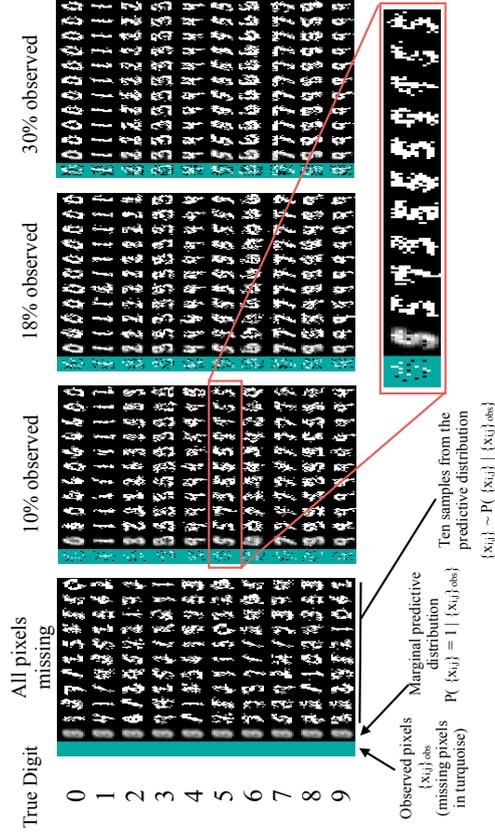

Figure 14: **Predicted images of handwritten digits given sparse observations.** CrossCat can be used to fill in missing pixels by sampling from their conditional density given the observed pixels. Each panel shows completion results for one image per digit; across panels, the fraction of observed pixels grows from 0 to 30%. The leftmost column shows the observed pixels in black and white, with missing pixels in turquoise. The second column from the left shows the marginal probabilities for each pixel. The 10 remaining columns show independent sampled predictions. In the leftmost panel, with no data, all 10 predictive distributions are equivalent. The predictive distribution collapses onto single digit classes (except for 8 and 6) after 18% of the digits have been observed. The marginal images for 1, 7, and 9 become resolvable to a single prototypical example after 10% of the 256 pixels have been observed. Others, such as 8, remain ambiguous.

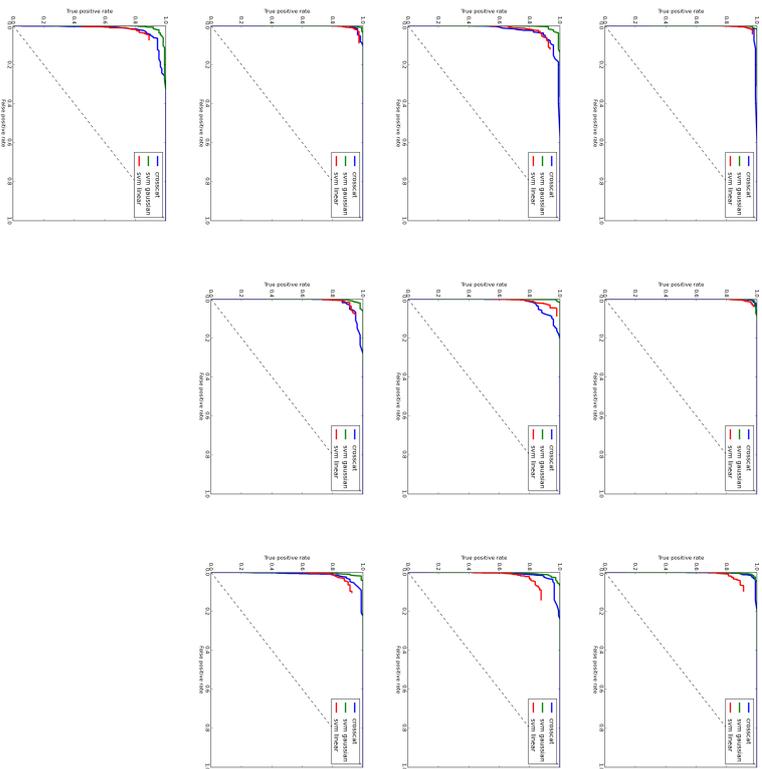

Figure 15: **Classification accuracy on handwritten digits from MNIST.** Each panel shows the true positive/false positive tradeoff curves for classifying each digit from 0 through 9. Digit images were represented as binary vectors, with one dimension per pixel. As with the image completion example from Figure 14, CrossCat was applied directly to this data, with the digit label appended as a categorical variable; no weighting or tuning for the supervised setting was done. Support vector machines (SVMs) with both linear and Gaussian kernels are provided as baselines. Regularization and kernel bandwidth parameters were chosen via cross-validation on 10% of the training data, with multiple classes treated via a one-versus-all reduction. See the main text for further discussion.

3.3 Voting Records for the 111th Senate

Voters are often members of multiple issue-dependent coalitions. For example, US senators sometimes vote according to party lines, and at other times vote according to regional interests. Because this common-sense structure is typical for the CrossCat prior, voting records are an important test case.

This set of experiments describes the results of a CrossCat analysis of the 397 votes held by the 111th Senate during the 2009-2010 session. In this dataset, each column is a vote or bill, and each row is a senator. Figure 16 shows the raw voting data, with several votes and senators highlighted. There are 106 senators; this is senators is larger than the size of the senate by 6, due to deaths, replacement appointments, party switches, and special elections. When a senator did not vote on a given issue, that datum is treated as missing. Figure 16 also includes two posterior samples, one that reflects partisan alignment and another that posits a higher-resolution model for the votes.

This kind of structure is also apparent in estimates that aggregate across samples. Dependence probabilities between votes are shown in Figure 17. The visible independencies between blocks are compatible with a common-sense understanding of US politics. The two votes in orange are partisan issues. The two votes in green have broad bipartisan support. The vote in yellow aimed at removing an energy subsidy for rural areas, an issue that cross-cuts party lines. The vote in purple stipulates that the Department of Homeland Security must spend its funding through competitive processes, with an exception for small businesses and women or minority-owned businesses. This issue subdivides the republican party, isolating many of the most fiscally conservative. Similarity matrices for the senators with respect to S. 160 (orange) and an amendment to H.R. 2997 (yellow) are shown in Figure 18, with the senators whose similarity values changed the most between these two bills highlighted in grey.

It is instructive to compare the latent structure and predictions inferred by CrossCat with structures and predictions from other learning techniques. As an individual voting record can be described by 397 binary variables and the missing values are negligible, Bayesian network structure learning is a suitable benchmark. Figure 19a shows the best Bayesian network structure found by structure learning using the search-and-score method implemented in the Bayes Net Toolbox for MATLAB (Murphy, 2001). This search is based on local moves similar to the transition operators from Gaudici and Green (1999). The highest scoring graphs after 500 iterations contained between 143 and 193 links. Figure 19b shows the marginal dependencies between votes induced by this Bayesian network; these are sparser than those from CrossCat. Figure 19c shows the mean absolute errors for this Bayes net and for CrossCat on a predictive test where 25% of the votes were held out and predicted for senators in the test set. Bayes net CPTs were estimated using a symmetric Beta-Bernoulli model with hyper-parameter $\alpha = 1$. CrossCat predictions were based on four samples, each obtained after 250 iterations of inference. Compared to Bayesian network structure learning, CrossCat makes more accurate predictions and also finds more intuitive latent structures.

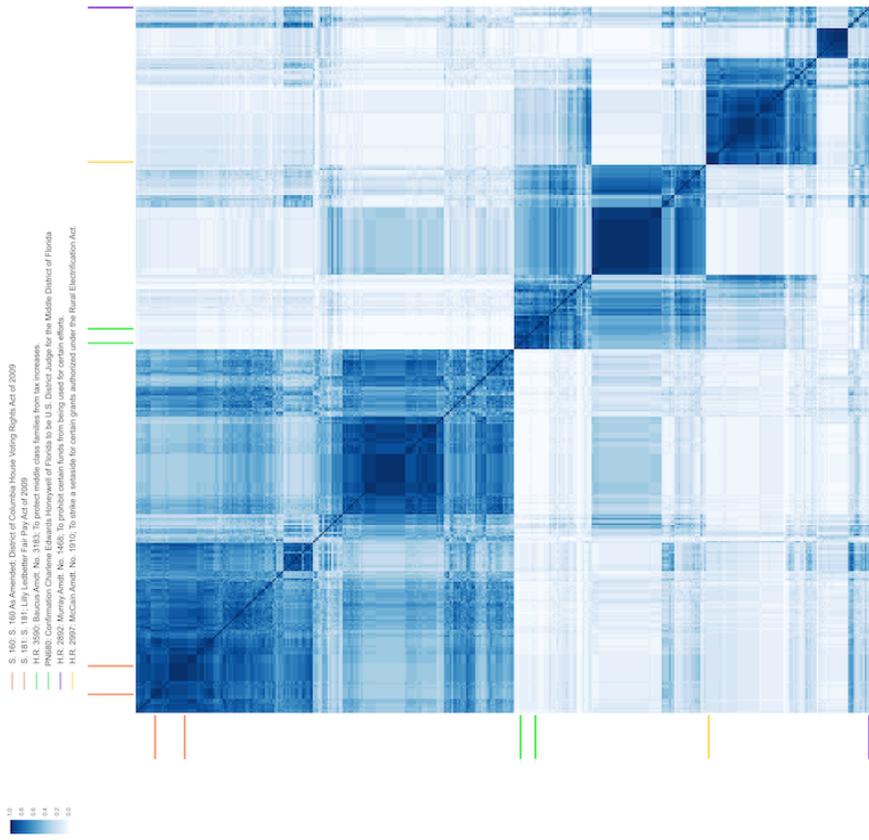

Figure 17: **Pairwise dependence probabilities between bills.** Blocks of bills with high probability of dependence include predominantly partisan issues (orange), issues with broad bipartisan support (green), and bills that divide senators along ideological or regional lines.

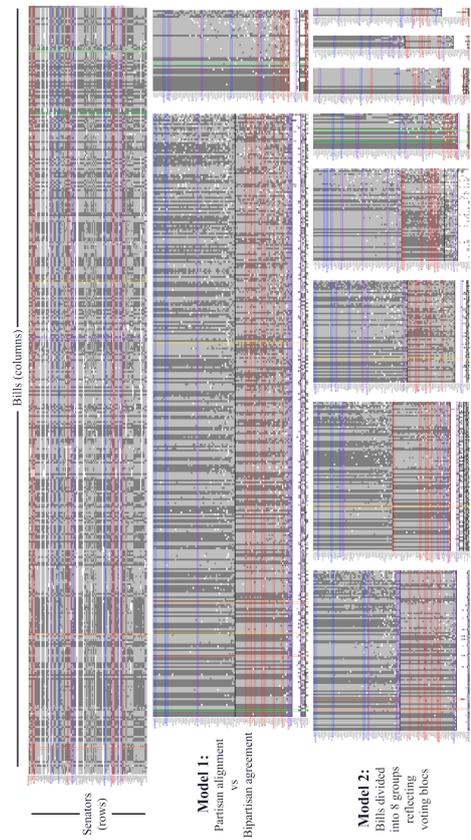

Figure 16: **Voting records for the 111th US Senate (2009).** (top) This includes 397 votes (yea in light grey, nay in dark grey) for 106 senators, including separate records for senators who changed parties or assumed other offices mid-term. Some senators are highlighted in colors based on their generally accepted identification as democrats (blue), moderates (purple), or republicans (red). See main text for an explanation of the colored bills. (middle) This row shows a simple or low resolution posterior sample that divides bills into those that exhibit partisan alignment and those with bipartisan agreement. Clusters of senators, generated automatically, are separated by thick black horizontal lines. (bottom) This row shows a sample that includes additional views and clusters, positing a finer-grained predictive model for votes that are treated as random in the middle row.

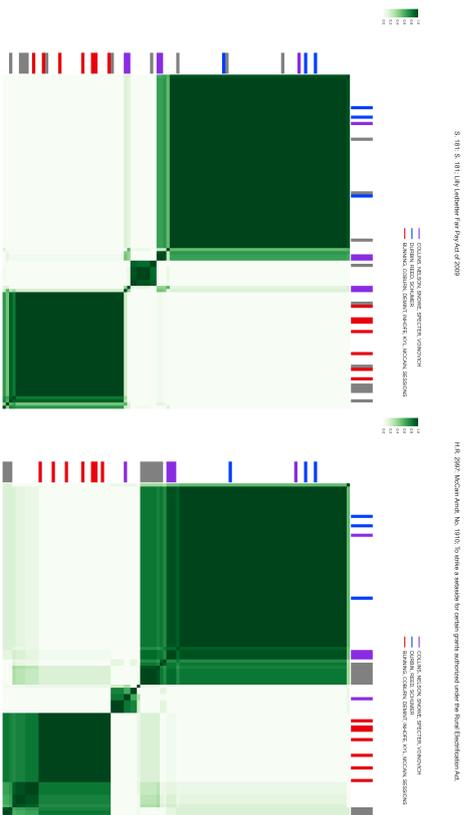

Figure 18: **Context-sensitive similarity measures for senators with respect to partisan and special-interest issues.** The left matrix shows senator similarity for S. 181, the Lilly Ledbetter Fair Pay Act of 2009, a bill whose senator clusters tend to respect party lines. The right matrix is for H.R. 2997, a bill designed to remove a subsidy for energy generation systems in rural areas. The grey senators are those whose similarities changed the most between these two bills.

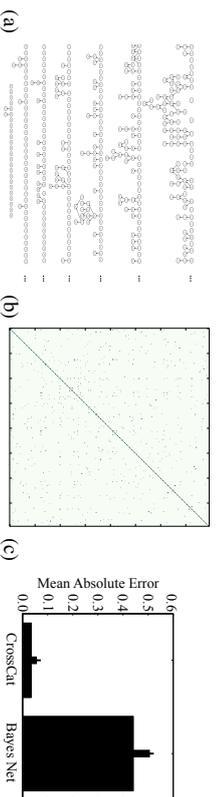

Figure 19: **Comparison of latent structures and predictive accuracy for CrossCat and Bayesian network structure learning.** (a) The Bayesian network structure found by structure learning; each node is a vote, and edge indicates a conditional dependence. (b) The sparse marginal dependencies induced by this Bayes net. (c) A comparison of the predictive accuracy of CrossCat and Bayesian networks. See main text for details and discussion.

High-throughput measurement techniques in modern biology generate datasets of unusually high dimension. The number of variables typically is far greater than the sample size. For example, microarrays can be used to assess the expression levels of 10,000 to 100,000 probe sequences, but due to the cost of clinical data acquisition, typical datasets may have just tens or hundreds of tissue samples. Exploration and analysis of this data can be both statistically and computationally challenging.

3.4 High-Dimensional Gene Expression Data

Individual samples from CrossCat can aid exploration of this kind of data. Figure 20 shows one typical sample obtained from the data in Raponi et al. (2009). The dataset had ~ 1 million cells, with 10,000 probes (columns) and 100 tissue samples (rows). This sample has multiple visually coherent views with ~ 50 genes, each reflecting a particular low-dimensional pattern. Some of these views divide the rows into clusters with “low”, “medium” or “high” expression levels; others reflect more complex patterns. The co-assignment of many probes to a single view could indicate the existence of a latent co-regulating mechanism. The structure in a single sample could thus potentially inform pathway searches and help generate testable hypotheses.

Posterior estimates from CrossCat can also facilitate exploration. CrossCat was applied to estimate dependence probabilities for a subset of the arthritis dataset from (Bienkowska, Dalgin, Battiwalla, Allaire, Roubenoff, Gregersen, and Carulli, 2009) (NCBI GEO accession number GSE15258). This dataset contains expression levels for $\sim 55,000$ probes, each measured for 87 patients. It also contains standard measures of initial and final disease levels and a categorical “response” variable with 3 classes. CrossCat was applied to subsets with 1,000 and 5,000 columns.

Figure 20 shows the 100 variables most probably predictive of a 3-class treatment response variable. The dependence probabilities with response (outlined in red) are all low, i.e. according to CrossCat, there is little evidence in favor of the existence of any prognostic biomarker. At first glance this may seem to contradict (Bienkowska et al., 2009), which reports 8-gene and 24-gene biomarkers with prognostic accuracies of 83%-91%. However, the test set from (Bienkowska et al., 2009) has 11 out-of-sample patients, 9 of whom are responders. Predicting according to class marginal probabilities would yield compatible accuracy. The final disease activation level, outlined in blue, does appear within the selected set of variables. CrossCat infers that it probably depends on many other gene expression levels; these genes could potentially reflect the progression of arthritis in physiologically or clinically useful ways.

3.5 Longitudinal Unemployment Data by State

This experiment explores CrossCat's behavior on data where variables are tracked over time. The data are monthly state-level unemployment rates from 1976 to 2011, without seasonal adjustment, obtained from the US Bureau of Labor Statistics. The data also includes annual unemployment rates for every state. Figure 21 shows time series for 5 states, along with national unemployment rate and real Gross Domestic Product (GDP). Typical analyses of raw macroeconomic time series are built on assumptions about temporal dependence and incorporate multiple model-based smoothing techniques; see e.g. (Bureau of Labor Statistics, 2014). Cyclical macroeconomic dynamics, such as the business cycle, are demarcated using additional formal and informal techniques for assessing agreement across multiple indicators (National Bureau of Economic Research, 2010). For this analysis, the input data was organized as a table, where each row r represents a state, each column c represents a month, and each cell $x_{r,c}$ represents the unemployment rate for state r in month c . This representation removes all temporal cues.

CrossCat posits short-range, common-sense temporal structure in state-level employment rates. The top panel of Figure 21 shows the largest and smallest month in each of the views in a single posterior sample as vertical dashes. Figure 22a shows the frequency of years in each view; each view contains one or two temporally contiguous blocks. Figure 22b shows the raw unemployment rates sorted according to the cross-categorization from this sample. Different groups of states are affected by each phase of the business cycle in different ways, inducing different natural clusterings of unemployment rates.

CrossCat also detects long-range temporal structure that is largely in agreement with the officially designated phases of the business cycle. Figure 23 shows the dependence probabilities for all months, in temporal order, with business cycle peaks in black and troughs in red. The beginning of the 1980 recession aligns closely with a sharp drop in dependence probability; this indicates that during 1980 the states naturally cluster differently than they do in 1979. Three major US recessions — 1980, 1990, and late 2001 — align with these breakpoints. The beginning of the 2008 recession and the end of the 1980s recession (in 1984) both fall near sub-block boundaries; these are best seen at high resolution. Correspondence is not perfect, but this is expected: CrossCat is not analyzing the same data used to determine business cycle peaks and troughs, nor is it explicitly assuming any temporal dynamics.

Time series analysis techniques commonly assume temporal smoothness and sometimes also incorporate the possibility of abrupt changes (Ahn and Thompson, 1988; Wang and Zivot, 2000). CrossCat provides an alternative approach that makes weaker dynamical assumptions: temporal smoothness is not assumed at the outset but must be inferred from the data. This cross-sectional approach to the analysis of natively longitudinal data may open up new possibilities in econometrics. For example, it could be fruitful to apply CrossCat to a longitudinal dataset with multiple macroeconomic variables for each state, or to use CrossCat to combine temporal information at different timescales.

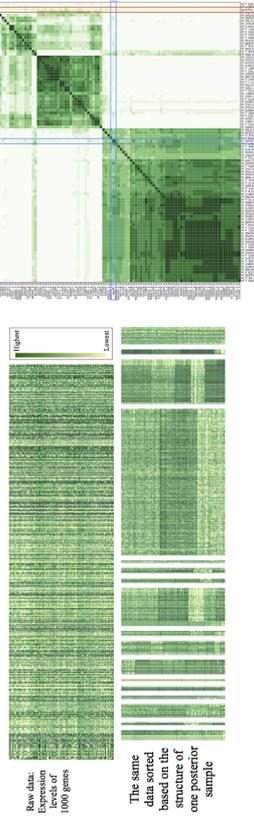

Figure 20: **CrossCat inference results on gene expression data.** (left) Expression levels for the top 1,000 highest-variance genes from Raponi et al. (2009) in original form and in the order induced by a single CrossCat sample. CrossCat was applied to a subset with roughly 1 million cells ($\sim 10,000$ probes by ~ 100 tissue samples). (right) Pairwise dependence probabilities between probe values and treatment response inferred from the GSE15258 dataset. The 100 probes most probably dependent on a 3-class treatment response variable, based on analysis of a subset with 1,000 probes, are shown outlined in red. The low inferred dependence probability suggests that the data does not support the existence of any prognostic biomarker. A standard disease activity score is shown outlined in blue; this measure is naturally dependent on many of the probes.

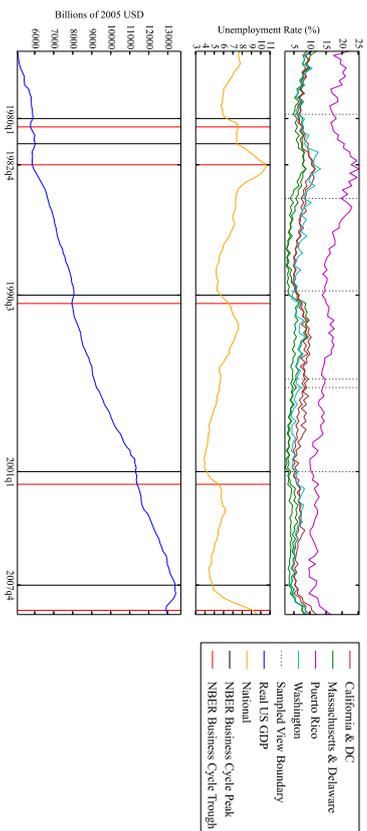

Figure 21: **US state-level unemployment data aligned with official business cycle peaks and troughs.** (top) Unemployment rates for five states from 1976 to 2009, colored according to one posterior sample. (middle) The national unemployment rate and business cycle peaks and troughs during the same period. Business cycle peaks and troughs are identified using multiple macroeconomic signals; see main text for details. Unemployment grows during recessions (intervals bounded on the left by black and on the right by red) and shrinks during periods of growth (intervals bounded on the left by red and on the right by black). (bottom) Real US gross domestic product (GDP) similarly decreases or stays constant during recessions and increases during periods of growth. View boundaries from the CrossCat sample pick out the business cycle turning points around 1980, 1990 and 2001.

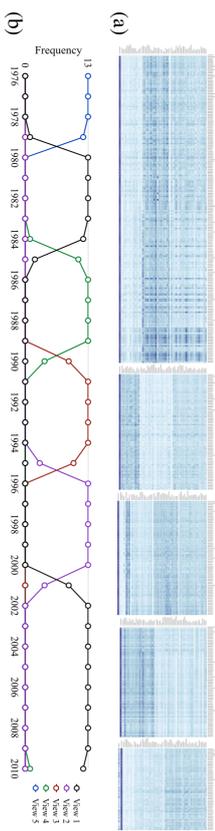

Figure 22: **The temporal structure in a single posterior sample.** (a) The complete state-level monthly employment rate dataset, sorted according to one posterior sample. This sample divides the months into 5 time periods, each inducing a different clustering of the states. (b) The frequency of years and quarters for each view shows that each view reflects temporal contiguity: each view either corresponds to a single, temporally contiguous interval or to the union of two such intervals. This temporal structure is not given to CrossCat, but rather inferred from patterns of unemployment across clusters of states.

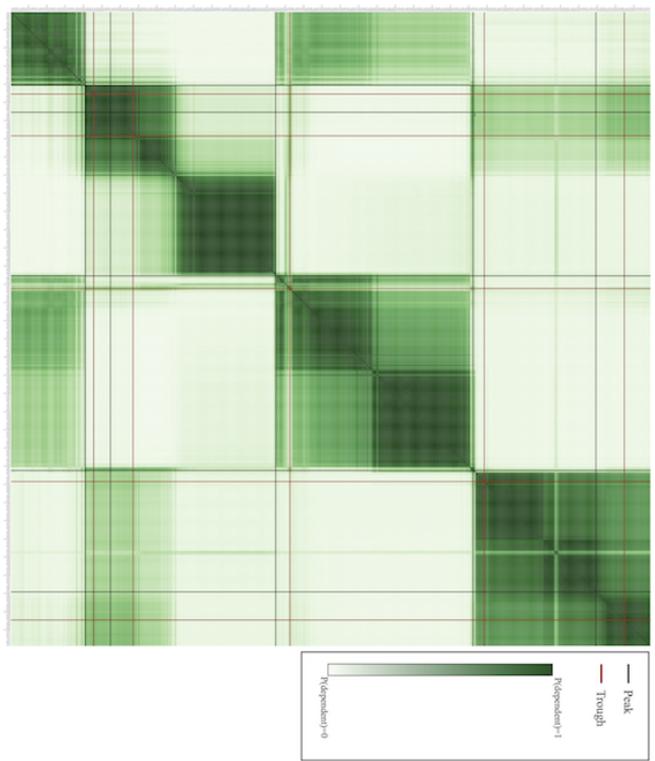

Figure 23: **Dependence probabilities between monthly unemployment rates.** Unemployment rates are sorted by date, beginning with 1976 in the bottom left corner, with business cycle peaks and troughs identified by the NBER in black and red. The beginnings of three major recessions — in the early 1980s, 1990s, and late 2001 — are identified by breaks in dependence probability: unemployment rates are dependent with high probability within these periods, and independent of rates from the previous period. See main text for more discussion.

4. Discussion

This paper contains two contributions. First, it describes CrossCat, a model and inference algorithm that together comprise a domain-general method for characterizing the full joint distribution of the variables in a high-dimensional dataset. CrossCat makes it possible to draw a broad class of Bayesian inferences and to solve prediction problems without domain-specific modeling. Second, it describes applications to real-world datasets and analysis problems from multiple fields. CrossCat finds latent structures that are consistent with accepted findings as well as common-sense knowledge and that can yield favorable predictive accuracy compared to generative and discriminative baselines.

CrossCat is expressive enough to recover several standard statistical methods by fixing its hyperparameters or adding other deterministic constraints:

1. **Semi-supervised naive Bayes:** $\alpha = 0 \implies \#(\text{unique}(\bar{z})) = 1$ and $\alpha_0 = \epsilon$ with $\lambda_{\text{class}} = 0$

Assume that the dimension in the dataset labeled *class* contains categorical class labels, with a multinomial component model and symmetric Dirichlet prior, with concentration parameter λ_{class} . Because the outer CRP concentration parameter is 0, all features as well as the class label will be assigned to a single view. Because $\lambda_{\text{class}} = 0$, each category in this view will have a component model for the class label dimension that constrains the category to only contain data items whose class labels all agree:

$$y_i^j = y_i^j \iff x_{(i,\text{class})} = x_{(j,\text{class})}$$

This yields a model that is appropriate for semi-supervised classification, and related to previously proposed techniques based on EM for mixture models (Nigam, McCallum, Thrun, and Mitchell, 1999). Data from each class will be modeled by a separate set of clusters, with feature hyper-parameters (e.g. overall scales for continuous values, or levels of noise for discrete values) shared across classes. Data items whose class labels are missing will be stochastically assigned to classes based on how compatible their features are with the features for other data items in the same class, marginalizing out parameter uncertainty. Forcing the concentration parameter α_0 for the sole inner CRP to have a sufficiently small value ϵ ensures that there will only be a single cluster per class (with arbitrarily high probability depending on N and ϵ). These restrictions thus recover a version of the naive Bayesian classifier (for discrete data) and linear discriminant analysis (for continuous data), adding hyper-parameter inference.

2. **Nonparametric mixture modeling:** $\alpha = 0 \implies \#(\text{unique}(\bar{z})) = 1$

If the constraints on categorizations are relaxed, but the outer CRP is still constrained to generate a single view, then CrossCat recovers a standard nonparametric Bayesian mixture model. The current formulation of CrossCat additionally enforces independence between features. This assumption is standard for mixtures over high-dimensional discrete data. Mixtures of high-dimensional continuous distributions sometimes support dependence between variables within each component, rather than model all dependence using the latent component assignments. It would be easy and natural to relax CrossCat to support these component models and to revise the calculations of marginal dependence accordingly.

3. **Independent univariate mixtures:** $\alpha = \infty \implies \#(\text{unique}(\bar{z})) = D$

The outer CRP can be forced to assign each variable to a separate view by setting its concentration parameter α to ∞ . With this setting, each customer (variable) will choose a new table (view) with probability 1. In this configuration, CrossCat reduces to a set of independent Dirichlet process mixture models, one per variable. A complex dataset with absolutely no dependencies between variables can induce a CrossCat posterior that concentrates near this subspace.

4. **Clustering with unsupervised feature selection:** $\#(\text{unique}(\bar{z})) = 2$, with $\alpha_0 > 0$ but $\alpha_1 = 0$
- A standard mixture must model noisy or independent variables using the same cluster assignments as the variables that support the clustering. It can therefore be useful to integrate mixture modeling with feature selection, by permitting inference to select variables that should be modeled independently. The “irrelevant” features can be modeled in multiple ways; one natural approach is to use a single parametric model that can independently adjust the entropy of its model for each dimension. CrossCat contains this extension to mixtures as a subspace.

The empirical results suggest that CrossCat’s flexibility in principle manifests in practice. The experiments show that can effectively emulate many qualitatively different data generating processes, including processes with varying degrees of determinism and diverse dependence structures. However, it will still be important to quantitatively characterize CrossCat’s accuracy as a density estimator.

Accuracy assessments will be difficult for two main reasons. First, it is not clear how to define a space of data generators that spans a sufficiently broad class of applied statistics problems. CrossCat itself could be used as a starting point, but key statistical properties such as the marginal and conditional entropies of groups of variables are only implicitly controllable. Second, it is not clear how to measure the quality of an emulator for the full joint distribution. Metrics from collaborative filtering and imputation, such as the mean squared error on randomly censored cells, do not account for predictive uncertainty. Also, the accuracy of estimates of joint distributions and conditional distributions can diverge. Thus the natural metric choice of KL divergence between the emulated and true joint distributions may be misleading in applications where CrossCat is used to respond to a stream of queries of different structures. Because there are exponentially many possible query structures, random sampling will most likely be needed. Modeling the likely query sequences or weighting queries based on their importance seems ultimately necessary but difficult.

In addition to these questions, CrossCat has several known limitations that could be addressed by additional research:

1. *Real-world datasets may contain types and/or shapes of data that CrossCat can only handle by transformation.*

First, several common data types are poorly modeled by the set of component models that CrossCat currently supports. Examples include timestamps, geographical locations, currency values, and categorical variables drawn from open sets. Additional parametric component models — or nonparametric models, e.g. for open sets of discrete values — could be integrated.

Second, it is unclear how to best handle time series data or panel/longitudinal settings. In the analysis of state-level monthly unemployment data, each state was represented as a row, and

each time point was a separate and a priori independent column. The authors were surprised that CrossCat inferred the temporal structure rather than under-fit by ignoring it. In retrospect, this is to be expected in circumstances where the temporal signal is sufficiently strong, such that it can be recovered by inference over the views. However, computational and statistical limitations seem likely to lead to under-fitting on panel data with sufficiently many time points and variables per time point.

One pragmatic approach to resolving this issue is to transform panel data into cross-sectional data by replacing the time series for each member of the population with the parameters of a time-series model. Separately fitting the time-series model could be done as a pre-processing step, or alternated with CrossCat inference to yield a joint Gibbs sampler. Another approach would be to develop a sequential extension to CrossCat. For example, the inner Dirichlet process mixtures could be replaced with nonparametric state machines (Beal, Ghahramani, and Rasmussen, 2001). Each view would share a common state machine, with common states, transition models, and observation models. Each group of dependent variables would thus induce a division of the data into subpopulations, each with a distinct hidden state sequence.

2. Discriminative learning can be more accurate than CrossCat on standard classification and regression problems.

Discriminative techniques can deliver higher predictive accuracy than CrossCat when input features are fully observed during both training and testing and when there is enough labeled training data. One possible remedy is to integrate CrossCat with discriminative techniques, e.g. by allowing “discriminative target” variables to be modeled by generic regressions (e.g. GLMs or Gaussian processes). These regressions would be conditioned on the non-discriminative variables that would still be modeled by CrossCat.

An alternative approach is to distinguish prediction targets within the CrossCat model. At present, the CrossCat likelihood penalizes prediction errors in all features equally. This could be fixed by e.g. deterministically constraining the Dirichlet concentration hyper-parameters for class-label columns to be equal to 0. This forces CrossCat to assign 0 probability density to states that put items from different classes into the same category in the view containing the class label. These purity constraints can be met by using categories that either exactly correspond to the finest-grained classes in the dataset or subdivide these classes. Conditioned on the hyper-parameters, this modification reduces joint density estimation to independent nonparametric Bayesian estimation of class-conditional densities (Mansinghka, Roy, Rifkin, and Tenenbaum, 2007).

3. Natural variations are challenging to test due to the cost and difficulty of developing fast implementations.

The authors found it surprising that a reliable and scalable implementation was possible. Several authors were involved in the engineering of multiple high-performance commercial implementations. One of these can be applied to multiple real-world, million-row datasets with typical runtimes ranging from minutes to hours (Obermeyer, Glidden, and Ionsa, 2014). No fundamental changes to the Gibbs sampling algorithm were necessary to make it possible to do to inference on these scales. Instead, the gains were due to standard software performance engineering techniques. Examples include custom numerical libraries, careful data structure design, and adopting a streaming architecture and compact latent state representation that

reduce the time spent waiting for memory retrieval. The simplicity of the Gibbs sampling algorithm thus turned out to be an asset for achieving high performance. Unfortunately, this implementation took man-years of software engineering, and is harder to extend and modify than slower, research-oriented implementations.

Probabilistic programming technology could potentially simplify the process of prototyping variations on CrossCat and incrementally optimizing them. For example, Venture (Mansinghka et al., 2014) can express the CrossCat model and inference algorithm from this paper in ~ 40 lines of probabilistic code. At the time of writing, the primary open-source implementation of CrossCat is ~ 4000 lines of C++. New datatypes, model variations, and perhaps even more sophisticated inference strategies could potentially be tested this way. However, the performance engineering will still be difficult. As an alternative to careful performance engineering, the authors experimented with more sophisticated algorithms and initializations. Transition operators such as the split-merge algorithm from (Jain and Neal, 2000) and initialization schemes based on high-quality approximations to Dirichlet process posteriors (Li and Shafiq, 2011) did not appear to help significantly. These complex approaches are also more difficult to debug and optimize than single-site Gibbs. This may be a general feature: reductions in the total number of iterations can easily be offset by increases in the computation time required for each transition.

There is a widespread need for statistical methods that are effective in high dimensions but do not rely on restrictive or opaque assumptions (NRC Committee on the Analysis of Massive Data, 2013; Wasserman, 2011). CrossCat attempts to address these requirements via a divide-and-conquer strategy. Each high-dimensional modeling problem is decomposed into multiple independent sub-problems, each of lower dimension. Each of these subproblems is itself decomposed by splitting the data into discrete categories that are separately modeled using parametric Bayesian techniques. The hypothesis space induced by these stochastic decompositions contains proxies for a broad class of data generators, including some generators that are simple and others that are complex. The transparency of simple parametric models is largely preserved, without sacrificing modeling flexibility. It may be possible to design other statistical models around this algorithmic motif.

CrossCat formulates a broad class of supervised, semi-supervised, and unsupervised learning problems in terms of a single set of models and a single pair of algorithms for learning and prediction. The set of models and queries that can be implemented may be large enough to sustain a dedicated probabilistic programming language. Probabilistic programs in such a language could contain modeling constraints, translated into hyper-parameter settings, but leave the remaining modeling details to be filled in via approximate Bayesian inference. Data exploration using CrossCat samples can be cumbersome, and would be simplified by a query language where each query could reference previous results.

This flexibility comes with costs, especially in applications where only a single repeated prediction problem is important. In these cases, it can be more effective to use a statistical procedure that is optimized for this task, such as a discriminative learning algorithm. It seems unlikely that even a highly optimized CrossCat implementation will be able to match the performance of best-in-class supervised learning algorithms when data is plentiful and all features are fully observed.

However, just as with software, sophisticated optimizations also come with costs, and can be premature. For example, some researchers have suggested that there is an “illusion of progress” in classifier technology (Hand, 2006) in which algorithmic and statistical improvements documented

in classification research papers frequently do not hold up in practice. Instead, classic methods seem to give the best and most robust performance. One interpretation is that this is the result of prematurely optimizing based on particular notions of expected statistical accuracy. The choice to formalize a problem as supervised classification may similarly be premature. It is not uncommon for the desired prediction targets to change after deployment, or for the typical patterns of missing values to shift. In both these cases, a collection of CrossCat samples can be used unmodified, while supervised methods need to be retrained.

It is unclear how far this direct Bayesian approach to data analysis can be taken, or how broad is the class of data generating processes that CrossCat can emulate in practice. Some statistical inference problems may be difficult to pose in terms of approximately Bayesian reasoning over a space of proxy generators. Under-fitting may be difficult to avoid, especially for problems with complex couplings between variables that exceed the statistical capacity of fully factored models. Despite these challenges, our experiences with CrossCat have been encouraging. It is fortunate that, paraphrasing Box (1979), the statistical models that CrossCat produces can be simplistic yet still flexible and useful. We thus hope that CrossCat proves to be an effective tool for the analysis of high-dimensional data. We also hope that the results in this paper will encourage the design of other fully Bayesian, general-purpose statistical methods.

Abstract

We study two regularization-based approximate policy iteration algorithms, namely REG-LSPI and REG-BRM, to solve reinforcement learning and planning problems in discounted Markov Decision Processes with large state and finite action spaces. The core of these algorithms are the regularized extensions of the Least-Squares Temporal Difference (LSTD) learning and Bellman Residual Minimization (BRM), which are used in the algorithms' policy evaluation steps. Regularization provides a convenient way to control the complexity of the function space to which the estimated value function belongs and as a result enables us to work with rich nonparametric function spaces. We derive efficient implementations of our methods when the function space is a reproducing kernel Hilbert space. We analyze the statistical properties of REG-LSPI and provide an upper bound on the policy evaluation error and the performance loss of the policy returned by this method. Our bound shows the dependence of the loss on the number of samples, the capacity of the function space, and some intrinsic properties of the underlying Markov Decision Process. The dependence of the policy evaluation bound on the number of samples is minimax optimal. This is the first work that provides such a strong guarantee for a nonparametric approximate policy iteration algorithm.¹

Keywords: reinforcement learning, approximate policy iteration, regularization, nonparametric method, finite-sample analysis

1. Introduction

We study the approximate policy iteration (API) approach to find a close to optimal policy in a Markov Decision Process (MDP), either in a reinforcement learning (RL) or in a planning scenario. The basis of API, which is explained in Section 3, is the policy iteration algorithm that iteratively evaluates a policy (i.e., finding the value function of the policy—the *policy evaluation* step) and then improves it (i.e., computing the *greedy* policy with respect to (w.r.t.) the recently obtained value function—the *policy improvement* step). When the state space is large (e.g., a subset of \mathbb{R}^d or a finite state space that has too many states to be exactly represented), the policy evaluation step cannot be performed exactly, and as a result the use of function approximation is inevitable. The appropriate choice of the function approximation method, however, is far from trivial. The best choice is problem-dependent and it also depends on the number of samples in the input data.

In this paper we propose a *nonparametric regularization*-based approach to API. This approach provides a flexible and easy way to implement the policy evaluation step of API. The advantage of nonparametric methods over parametric methods is that they are flexible: Whereas a parametric model, which has a fixed and finite parameterization, limits the range of functions that can be represented, irrespective of the number of samples, the nonparametric models avoid such undue restrictions by increasing the power of the function approximation as necessary. Moreover, the regularization-based approach to nonparametrics is elegant and powerful: It has a simple algorithmic form and the estimator achieves minimax optimal rates in a number of scenarios. Further discussion of and specific results about nonparametric methods, particularly in the supervised learning scenario, can be found in the books by Györfi et al. (2002) and Wasserman (2007).

The nonparametric approaches to solve RL/Planning problems have received some attention in the RL community. For instance, Petrik (2007); Mahadevan and Maggioni (2007); Parr et al. (2007); Mahadevan and Liu (2010); Geramifard et al. (2011); Farahmand and Precup (2012); Böhrer et al. (2013) and Milani Fard et al. (2013) suggest methods to generate data-dependent basis functions, to be used in general linear models. Ormonett and Sen (2002) use smoothing kernel-based estimate of the model and then use value iteration to find the value function. Barreto et al. (2011, 2012) benefit from “stochastic factorization trick” to provide computationally efficient ways to scale up the approach of Ormonett and Sen (2002). In the context of approximate value iteration, Ernst et al. (2005) consider growing ensembles of trees to approximate the value function. In addition, there have been some works where regularization methods have been applied to the RL/Planning problems, e.g., Engel et al. (2005); Jung and Polani (2006); Loth et al. (2007); Farahmand et al. (2009a,b); Taylor and Parr (2009); Kolter and Ng (2009); Johns et al. (2010); Ghavamzadeh et al. (2011); Farahmand (2011b); Ávila Pires and Szepesvári (2012); Hoffman et al. (2012); Geist and Scherrer (2012). Nevertheless, most of these papers are algorithmic results and do not analyze the statistical properties of these methods (the exceptions are Farahmand et al. 2009a,b; Farahmand 2011b; Ghavamzadeh et al. 2011; Ávila Pires and Szepesvári 2012). We compare these methods with ours in more detail in Sections 5.3.1 and 6.

It is worth mentioning that one might use a regularized estimator alongside a feature generation approach to control the complexity of function space induced by the features. An approach alternative to regularization for controlling the complexity of a function space is to

¹ This work is an extension of the NIPS 2008 conference paper by Farahmand et al. (2009b).

use greedy algorithms, such as Matching Pursuit (Mallat and Zhang, 1993) and Orthogonal Matching Pursuit (Pati et al., 1993), to select features from a large set of features. Greedy algorithms have recently been developed for the value function estimation by Johns (2010); Painter-Wakefield and Parr (2012); Farahmand and Precup (2012); Geramifard et al. (2013). We do not discuss these methods any further.

1.1 Contributions

The algorithmic contribution of this work is to introduce two regularization-based nonparametric approximate policy iteration algorithms, namely *Regularized Least-Squares Policy Improvement (REG-LSPI)* and *Regularized Bellman Residual Minimization (REG-BRM)*. These are flexible methods that, upon the proper selection of their parameters, are sample efficient. Each of REG-BRM and REG-LSPI is formulated as two coupled regularized optimization problems (Section 4). As we argue in Section 4.1, having a regularized objective in both optimization problems is necessary for rich nonparametric function spaces. Despite the unusual coupled formulation of the underlying optimization problems, we prove that the solutions can be computed in a closed-form when the estimated action-value function belongs to the family of *reproducing kernel Hilbert spaces (RKHS)* (Section 4.2).

The theoretical contribution of this work (Section 5) is to analyze the statistical properties of REG-LSPI and to provide upper bounds on the policy evaluation error and the performance difference between the optimal policy and the policy returned by this method (Theorem 14). The result demonstrates the dependence of the bounds on the number of samples, the capacity of the function space to which the estimated action-value function belongs, and some intrinsic properties of the MDP. It turns out that the dependence of the policy evaluation error bound on the number of samples is minimax optimal. This paper, alongside its conference (Farahmand et al., 2009b) and the dissertation (Farahmand, 2011b) versions, is the first work that analyzes a nonparametric regularized API algorithm and provides such a strong guarantee for it.

2. Background and Notation

In the first part of this section, we provide a brief summary of some of the concepts and definitions from the theory of MDPs and RL (Section 2.1). For more information, the reader is referred to Bertsekas and Shreve (1978); Bertsekas and Tsitsiklis (1996); Sutton and Barto (1998); Szepesvári (2010). In addition to this background on MDPs, we introduce the notations we use to denote function spaces and their corresponding norms (Section 2.2) as well as the considered learning problem (Section 2.3).

2.1 Markov Decision Processes

For a space Ω , with a σ -algebra σ_Ω , we define $\mathcal{M}(\Omega)$ as the set of all probability measures over σ_Ω . We let $B(\Omega)$ denote the space of bounded measurable functions w.r.t. σ_Ω and we denote $B(\Omega, L)$ as the space of bounded measurable functions with bound $0 < L < \infty$.

Definition 1 A finite-action discounted MDP is a 4-tuple $(\mathcal{X}, \mathcal{A}, P, \gamma)$, where \mathcal{X} is a measurable state space, \mathcal{A} is a finite set of actions, $P : \mathcal{X} \times \mathcal{A} \rightarrow \mathcal{M}(\mathbb{R} \times \mathcal{X})$ is a mapping with domain $\mathcal{X} \times \mathcal{A}$, and $0 \leq \gamma < 1$ is a discount factor. Mapping P evaluated

at $(x, a) \in \mathcal{X} \times \mathcal{A}$ gives a distribution over $\mathbb{R} \times \mathcal{X}$, which we shall denote by $P(\cdot, \cdot | x, a)$. We denote the marginals of P by the overloaded symbol $P : \mathcal{X} \times \mathcal{A} \rightarrow \mathcal{M}(\mathcal{X})$ defined as $P(\cdot | x, a) = P_{x,a}(\cdot) = \int_{\mathbb{R}} P(dr, \cdot | x, a)$ (transition probability kernel) and $\mathcal{R} : \mathcal{X} \times \mathcal{A} \rightarrow \mathcal{M}(\mathbb{R})$ defined as $\mathcal{R}(\cdot | x, a) = \int_{\mathcal{X}} P(\cdot, dy | x, a)$ (reward distribution).

An MDP together with an initial distribution P_1 of states encode the laws governing the temporal evolution of a discrete-time stochastic process controlled by an agent as follows: The controlled process starts at time $t = 1$ with random initial state $X_1 \sim P_1$ (here and in what follows $X \sim Q$ denotes that the random variable X is drawn from distribution Q). At stage t , action $A_t \in \mathcal{A}$ is selected by the agent controlling the process. In response, the pair (R_t, X_{t+1}) is drawn from $P(\cdot, \cdot | X_t, A_t)$, i.e., $(R_t, X_{t+1}) \sim P(\cdot, \cdot | X_t, A_t)$, where, R_t is the reward that the agent receives at time t and X_{t+1} is the state at time $t + 1$. The process then repeats with the agent selecting action A_{t+1} , etc.

In general, the agent can use all past states, actions, and rewards in deciding about its current action. However, for our purposes it will suffice to consider action-selection procedures, or policies, that select an action deterministically and time-invariantly solely based on the current state:

Definition 2 (Deterministic Markov Stationary Policy) A measurable mapping $\pi : \mathcal{X} \rightarrow \mathcal{A}$ is called a deterministic Markov stationary policy, or just policy in short. Following a policy π in an MDP means that at each time step t it holds that $A_t = \pi(X_t)$.

Policy π induces the transition probability kernels $P^\pi : \mathcal{X} \times \mathcal{A} \rightarrow \mathcal{M}(\mathcal{X} \times \mathcal{A})$ defined as follows: For a measurable subset C of $\mathcal{X} \times \mathcal{A}$, let $(P^\pi)(C | x, a) \triangleq \int P(dy | x, a) \mathbb{1}_C(y, \pi(y)) \in \mathcal{C}$. The m -step transition probability kernels $(P^\pi)^m : \mathcal{X} \times \mathcal{A} \rightarrow \mathcal{M}(\mathcal{X} \times \mathcal{A})$ for $m = 2, 3, \dots$ are defined inductively by $(P^\pi)^m(C | x, a) \triangleq \int_{\mathcal{X}} P(dy | x, a) (P^\pi)^{m-1}(C | y, \pi(y))$. Also given a probability transition kernel $P : \mathcal{X} \times \mathcal{A} \rightarrow \mathcal{M}(\mathcal{X} \times \mathcal{A})$, we define the right-linear operator $P : B(\mathcal{X} \times \mathcal{A}) \rightarrow B(\mathcal{X} \times \mathcal{A})$ by $(PQ)(x, a) \triangleq \int_{\mathcal{X} \times \mathcal{A}} P(dy, da | x, a) Q(y, a)$. For a probability measure $\rho \in \mathcal{M}(\mathcal{X} \times \mathcal{A})$ and a measurable subset C of $\mathcal{X} \times \mathcal{A}$, we define the left-linear operators $\cdot P : \mathcal{M}(\mathcal{X} \times \mathcal{A}) \rightarrow \mathcal{M}(\mathcal{X} \times \mathcal{A})$ by $(\rho P)(C) = \int \rho(dx, da) P(dy, da | x, a) \mathbb{1}_C(y, a) \in \mathcal{C}$. To study MDPs, two auxiliary functions are of central importance: the value and the action-value functions of a policy π .

Definition 3 (Value Functions) For a policy π , the value function V^π and the action-value function Q^π are defined as follows: Let $(R_t; t \geq 1)$ be the sequence of rewards when the Markov chain is started from a state X_1 (or state-action (X_1, A_1) for the action-value function) drawn from a positive probability distribution over \mathcal{X} (or $\mathcal{X} \times \mathcal{A}$) and the agent follows policy π . Then, $V^\pi(x) \triangleq \mathbb{E} \left[\sum_{t=1}^{\infty} \gamma^{t-1} R_t \mid X_1 = x \right]$ and $Q^\pi(x, a) \triangleq \mathbb{E} \left[\sum_{t=1}^{\infty} \gamma^{t-1} R_t \mid X_1 = x, A_1 = a \right]$.

It is easy to see that for any policy π , if the magnitude of the immediate expected reward $r(x, a) = \int r P(dr, dy | x, a)$ is uniformly bounded by R_{\max} , then the functions V^π and Q^π are bounded by $V_{\max} = Q_{\max} = R_{\max} / (1 - \gamma)$, independent of the choice of π .

For a discounted MDP, we define the optimal value and optimal action-value functions by $V^*(x) = \sup_{\pi} V^\pi(x)$ for all states $x \in \mathcal{X}$ and $Q^*(x, a) = \sup_{\pi} Q^\pi(x, a)$ for all state-actions $(x, a) \in \mathcal{X} \times \mathcal{A}$. We say that a policy π^* is optimal if it achieves the best values in every

state, i.e., if $V^{\pi^*} = V^*$. We say that a policy π is *greedy* w.r.t. an action-value function Q if $\pi(x) = \arg\max_{a \in \mathcal{A}} Q(x, a)$ for all $x \in \mathcal{X}$. We define function $\tilde{\pi}(x; Q) \triangleq \arg\max_{a \in \mathcal{A}} Q(x, a)$ (for all $x \in \mathcal{X}$) that returns a greedy policy of an action-value function Q (If there exist multiple maximizers, a maximizer is chosen in an arbitrary deterministic manner). Greedy policies are important because a greedy policy w.r.t. the optimal action-value function Q^* is an optimal policy. Hence, knowing Q^* is sufficient for behaving optimally (cf. Proposition 4.3 of Bertsekas and Shreve 1978).²

Definition 4 (Bellman Operators) For a policy π , the Bellman operators $T^\pi : B(\mathcal{X}) \rightarrow B(\mathcal{X})$ (for value functions) and $T^\pi : B(\mathcal{X} \times \mathcal{A}) \rightarrow B(\mathcal{X} \times \mathcal{A})$ (for action-value functions) are defined as

$$\begin{aligned} (T^\pi V)(x) &\triangleq r(x, \pi(x)) + \gamma \int_{\mathcal{X}} V(y) P(dy|x, \pi(x)), \\ (T^\pi Q)(x, a) &\triangleq r(x, a) + \gamma \int_{\mathcal{X}} Q(y, \pi(y)) P(dy|x, a). \end{aligned}$$

To avoid unnecessary clutter, we use the same symbol to denote both operators. However, this should not introduce any ambiguity: Given some expression involving T^π one can always determine which operator T^π means by looking at the type of function T^π is applied to. It is known that the fixed point of the Bellman operator is the (action-)value function of the policy π , i.e., $T^\pi Q^\pi = Q^\pi$ and $T^\pi V^\pi = V^\pi$, see e.g., Proposition 4.2(b) of Bertsekas and Shreve (1978). We will also need to define the so-called Bellman optimality operators:

Definition 5 (Bellman Optimality Operators) The Bellman optimality operators $T^* : B(\mathcal{X}) \rightarrow B(\mathcal{X})$ (for value functions) and $T^* : B(\mathcal{X} \times \mathcal{A}) \rightarrow B(\mathcal{X} \times \mathcal{A})$ (for action-value functions) are defined as

$$\begin{aligned} (T^* V)(x) &\triangleq \max_a \left\{ r(x, a) + \gamma \int_{\mathcal{X}} V(y) P(dy|x, a) \right\}, \\ (T^* Q)(x, a) &\triangleq r(x, a) + \gamma \int_{\mathcal{X}} \max_{a'} Q(y, a') P(dy|x, a). \end{aligned}$$

Again, we use the same symbol to denote both operators; the previous comment that no ambiguity should arise because of this still applies. The Bellman optimality operators enjoy a fixed-point property similar to that of the Bellman operators. In particular, $T^* V^* = V^*$ and $T^* Q^* = Q^*$, see e.g., Proposition 4.2(a) of Bertsekas and Shreve (1978). The Bellman optimality operator thus provides a vehicle to compute the optimal action-value function and therefore to compute an optimal policy.

² Measurability issues are dealt with in Section 9.5 of the same book. In the case of finitely many actions, no additional condition is needed besides the obvious measurability assumptions on the immediate reward function and the transition kernel (Bertsekas and Shreve, 1978, Corollary 9.17.1), which we will assume from now on.

2.2 Norms and Function Spaces

In what follows we use $\mathcal{F} : \mathcal{X} \rightarrow \mathbb{R}$ to denote a subset of measurable functions. The exact specification of this set will be clear from the context. Further, we let $\mathcal{F}^{\mathcal{A}} : \mathcal{X} \times \mathcal{A} \rightarrow \mathbb{R}^{|\mathcal{A}|}$ to be a subset of vector-valued measurable functions with the identification of

$$\mathcal{F}^{\mathcal{A}} = \{(Q_1, \dots, Q_{|\mathcal{A}|}) : Q_i \in \mathcal{F}, i = 1, \dots, |\mathcal{A}|\}.$$

We shall use $\|Q\|_{p, \nu}$ to denote the $L_p(\nu)$ -norm ($1 \leq p < \infty$) of a measurable function $Q : \mathcal{X} \times \mathcal{A} \rightarrow \mathbb{R}$, i.e., $\|Q\|_{p, \nu} \triangleq \int_{\mathcal{X} \times \mathcal{A}} |Q(x, a)|^p d\nu(x, a)$.

Let $z_{1:n}$ denote the \mathcal{Z} -valued sequence (z_1, \dots, z_n) . For $\mathcal{D}_n = z_{1:n}$, define the empirical norm of function $f : \mathcal{Z} \rightarrow \mathbb{R}$ as

$$\|f\|_{p, \mathcal{D}_n}^p \triangleq \frac{1}{n} \sum_{i=1}^n |f(z_i)|^p. \quad (1)$$

When there is no chance of confusion about \mathcal{D}_n , we may denote the empirical norm by $\|f\|_{p, n}$. Based on this definition, one may define $\|Q\|_{p, \mathcal{D}_n}$ with the choice of $\mathcal{Z} = \mathcal{X} \times \mathcal{A}$. Note that if $\mathcal{D}_n = (Z_i)_{i=1}^n$ is random with $Z_i \sim \nu$, the empirical norm is random too, and for any fixed function f , we have $\mathbb{E}[\|f\|_{p, \mathcal{D}_n}] = \|f\|_{p, \nu}$. When $p = 2$, we simply use $\|\cdot\|_{\mathcal{D}_n}$.

2.3 Offline Learning Problem and Empirical Bellman Operators

We consider the *offline learning* scenario when we are only given a batch of data³

$$\mathcal{D}_n = \{(X_1, A_1, R_1, X'_1), \dots, (X_n, A_n, R_n, X'_n)\}, \quad (2)$$

with $X_i \sim \nu_{\mathcal{X}}$, $A_i \sim \pi_0(\cdot|X_i)$, and $(R_i, X'_i) \sim P(\cdot, \cdot|X_i, A_i)$ for $i = 1, \dots, n$. Here $\nu_{\mathcal{X}} \in \mathcal{M}(\mathcal{X})$ is a fixed distribution over the states and π_0 is the data generating behavior policy, which is a stochastic stationary Markov policy, i.e., given any state $x \in \mathcal{X}$, it assigns a probability distribution over \mathcal{A} . We shall also denote the common distribution underlying (X_i, A_i) by $\nu \in \mathcal{M}(\mathcal{X} \times \mathcal{A})$.

Samples X_i and X'_{i+1} may be sampled independently (we call this the “*Planning scenario*”), or may be coupled through $X'_i = X_{i+1}$ (“*RL scenario*”). In the latter case the data comes from a single trajectory. Under either of these scenarios, we say that the data \mathcal{D}_n meets the *standard offline sampling assumption*. We analyze the Planning scenario, where the states are independent, but one may also analyze dependent processes by considering mixing processes and using tools such as the independent blocks technique (Yu, 1994; Doukhan, 1994), as has been done by Antos et al. (2008b); Farahmand and Szepesvári (2012).

The data set \mathcal{D}_n allows us to define the so-called *empirical Bellman operators*, which can be thought of as empirical approximations to the true Bellman operators.

³ In what follows, when $\{\cdot\}$ is used in connection to a data set, we treat the set as an ordered multiset, where the ordering is given by the time indices of the data points.

Definition 6 (Empirical Bellman Operators) Let \mathcal{D}_n be a data set as above. Define the ordered multiset $S_n = \{(X_1, A_1), \dots, (X_n, A_n)\}$. For a given fixed policy π , the empirical Bellman operator $\hat{T}^\pi : \mathbb{R}^{S_n} \rightarrow \mathbb{R}^n$ is defined as

$$(\hat{T}^\pi Q)(X_i, A_i) \triangleq R_i + \gamma Q(X_i', \pi(X_i')), \quad 1 \leq i \leq n.$$

Similarly, the empirical Bellman optimality operator \hat{T}^* : $\mathbb{R}^{S_n} \rightarrow \mathbb{R}^n$ is defined as

$$(\hat{T}^* Q)(X_i, A_i) \triangleq R_i + \gamma \max_{a'} Q(X_i', a'), \quad 1 \leq i \leq n.$$

In words, the empirical Bellman operators get an n -element list S_n and return an n -dimensional real-valued vector of the single-sample estimate of the Bellman operators applied to the action-value function Q at the selected points. It is easy to see that the empirical Bellman operators provide an unbiased estimate of the Bellman operators in the following sense: For any fixed bounded measurable deterministic function $Q : \mathcal{X} \times \mathcal{A} \rightarrow \mathbb{R}_k$, policy π and $1 \leq i \leq n$, it holds that $\mathbb{E}[\hat{T}^\pi Q(X_i, A_i) | X_i, A_i] = T^\pi Q(X_i, A_i)$ and $\mathbb{E}[\hat{T}^* Q(X_i, A_i) | X_i, A_i] = T^* Q(X_i, A_i)$.

3. Approximate Policy Iteration

The policy iteration algorithm computes a sequence of policies such that the new policy in the iteration is greedy w.r.t. the action-value function of the previous policy. This procedure requires one to compute the action-value function of the most recent policy (policy evaluation step) followed by the computation of the greedy policy (policy improvement step). In API, the exact, but infeasible, policy evaluation step is replaced by an approximate one. Thus, the skeleton of API methods is as follows: At the k^{th} iteration and given a policy π_k , the API algorithm approximately evaluates π_k to find a Q_k . The action-value function Q_k is typically chosen to be such that $Q_k \approx T^{\pi_k} Q_k$, i.e., it is an approximate fixed point of T^{π_k} . The API algorithm then calculates the greedy policy w.r.t. the most recent action-value function to obtain a new policy π_{k+1} , i.e., $\pi_{k+1} = \hat{\pi}(\cdot; Q_k)$. The API algorithm continues by repeating this process again and generating a sequence of policies and their corresponding approximate action-value functions $Q_0 \rightarrow \pi_1 \rightarrow Q_1 \rightarrow \pi_2 \rightarrow \dots$ ⁴.

The success of an API algorithm hinges on the way the approximate policy evaluation step is implemented. Approximate policy evaluation is non-trivial for at least two reasons. First, policy evaluation is an inverse problem,⁵ so the underlying learning problem is unlike a standard supervised learning problem in which the data take the form of input-output pairs. The second problem is the off-policy sampling problem: The distribution of (X_i, A_i) in the data samples (possibly generated by a behavior policy) is typically different from the distribution that would be induced if we followed the to-be-evaluated policy (i.e., target policy). This causes a problem since the methods must be able to handle this mismatch of

distributions.⁶ In the rest of this section, we review generic LSTD and BRM methods for approximate policy evaluation. We introduce our regularized version of LSTD and BRM in Section 4.

3.1 Bellman Residual Minimization

The idea of BRM goes back at least to the work of [Schweitzer and Seidmann \(1985\)](#). It was later used in the RL community by [Williams and Baird \(1994\)](#) and [Baird \(1995\)](#). The basic idea of BRM comes from noticing that the action-value function is the unique fixed point of the Bellman operator: $Q^\pi = T^\pi Q^\pi$ (or similarly $V^\pi = T^\pi V^\pi$ for the value function). Whenever we replace Q^π by an action-value function Q different from Q^π , the fixed-point equation would not hold anymore, and we have a non-zero residual function $Q - T^\pi Q$. This quantity is called the *Bellman residual* of Q . The same is true for the Bellman optimality operator T^* .

The BRM algorithm minimizes the norm of the Bellman residual of Q , which is called the *Bellman error*. It can be shown that if $\|Q - T^* Q\|$ is small, then the value function of the greedy policy w.r.t. Q , that is $V^{\hat{\pi}(\cdot; Q)}$, is also in some sense close to the optimal value function V^* , see e.g., [Williams and Baird \(1994\)](#); [Munos \(2003\)](#); [Antos et al. \(2008b\)](#); [Farahmand et al. \(2010\)](#), and [Theorem 13](#) of this work. The BRM algorithm is defined as the procedure minimizing the following loss function:

$$L_{BRM}(Q; \pi) \triangleq \|Q - T^\pi Q\|_\nu^2,$$

where ν is the distribution of state-actions in the input data. Using the empirical L_2 -norm defined in (1) with samples \mathcal{D}_n defined in (2), and by replacing $(T^\pi Q)(X_i, A_i)$ with the empirical Bellman operator (Definition 6), the empirical estimate of $L_{BRM}(Q; \pi)$ can be written as

$$\hat{L}_{BRM}(Q; \pi, n) \triangleq \|Q - \hat{T}^\pi Q\|_{\mathcal{D}_n}^2 = \frac{1}{n} \sum_{i=1}^n [Q(X_i, A_i) - (R_i + \gamma Q(X_i', \pi(X_i')))]^2. \quad (3)$$

Nevertheless, it is well-known that \hat{L}_{BRM} is not an unbiased estimate of L_{BRM} when the MDP is not deterministic ([Lagoudakis and Parr, 2003](#); [Antos et al., 2008b](#)). To address this issue, [Antos et al. \(2008b\)](#) propose the modified BRM loss that is a new empirical loss function with an extra *de-biasing* term. The idea of the modified BRM is to cancel the unwanted variance by introducing an auxiliary function h and a new loss function

$$L_{BRM}(Q, h; \pi) = L_{BRM}(Q; \pi) - \|h - T^\pi Q\|_\nu^2, \quad (4)$$

and approximating the action-value function Q^π by solving

$$Q_{BRM} = \operatorname{argmin}_{Q \in \mathcal{F}^{\mathcal{A}}} \sup_{h \in \mathcal{F}^{\mathcal{A}}} L_{BRM}(Q, h; \pi), \quad (5)$$

4. In an actual API implementation, one does not need to compute π_{k+1} for all states, which in fact is infeasible for large state spaces. Instead, one uses Q_k to compute π_{k+1} at some select states, as required in the approximate policy evaluation step.

5. Given an operator $\mathcal{L} : \mathcal{F} \rightarrow \mathcal{F}$, the inverse problem is the problem of solving $g = \mathcal{L}f$ for f when g is known. In the policy evaluation problem, $\mathcal{L} = \mathbf{I} - \gamma T^{\pi^*}$, $g(\cdot) = r(\cdot, \pi(\cdot))$, and $f = Q^{\pi^*}$.

6. A number of works in the domain adaptation literature consider this scenario under the name of covariate shift problem, see e.g., [Ben-David et al. 2006](#); [Mansour et al. 2009](#); [Ben-David et al. 2010](#); [Cortes et al. 2015](#).

where the supremum comes from the negative sign of $\|h - T^\pi Q\|_\nu^2$. They have shown that optimizing the new loss function still makes sense and the empirical version of this loss is unbiased.

The min-max optimization problem (5) is equivalent to the following coupled (nested) optimization problems:

$$\begin{aligned} h(\cdot; Q) &= \operatorname{argmin}_{h \in \mathcal{F}^{|\mathcal{A}|}} \|h' - T^\pi Q\|_\nu^2, \\ Q_{BRM} &= \operatorname{argmin}_{Q \in \mathcal{F}^{|\mathcal{A}|}} [\|Q - T^\pi Q\|_\nu^2 - \|h(\cdot; Q) - T^\pi Q\|_\nu^2]. \end{aligned} \quad (6)$$

In practice, the norm $\|\cdot\|_\nu$ is replaced by the empirical norm $\|\cdot\|_{\mathcal{D}_n}$ and $T^\pi Q$ is replaced by its sample-based approximation $\hat{T}^\pi Q$, i.e.,

$$\begin{aligned} \hat{h}_n(\cdot; Q) &= \operatorname{argmin}_{h \in \mathcal{F}^{|\mathcal{A}|}} \|h - \hat{T}^\pi Q\|_{\mathcal{D}_n}^2, \\ \hat{Q}_{BRM} &= \operatorname{argmin}_{Q \in \mathcal{F}^{|\mathcal{A}|}} [\|Q - \hat{T}^\pi Q\|_{\mathcal{D}_n}^2 - \|\hat{h}_n(\cdot; Q) - \hat{T}^\pi Q\|_{\mathcal{D}_n}^2]. \end{aligned} \quad (7) \quad (8)$$

From now on, whenever we refer to the BRM algorithm, we are referring to this modified BRM.

3.2 Least-Squares Temporal Difference Learning

The Least-Squares Temporal Difference learning (LSTD) algorithm for policy evaluation was first proposed by [Bradtke and Barto \(1996\)](#), and later used in an API procedure by [Lagoudakis and Parr \(2003\)](#) and was called Least-Squares Policy Iteration (LSPI).

The original formulation of LSTD finds a solution to the fixed-point equation $Q = \Pi_\nu T^\pi Q$, where Π_ν is the simplified notation for ν -weighted projection operator onto the space of admissible functions $\mathcal{F}^{|\mathcal{A}|}$, i.e., $\Pi_\nu \triangleq \Pi_{\mathcal{F}^{|\mathcal{A}|}} : B(\mathcal{X} \times \mathcal{A}) \rightarrow B(\mathcal{X} \times \mathcal{A})$ is defined by $\Pi_{\mathcal{F}^{|\mathcal{A}|}} Q = \operatorname{argmin}_{h \in \mathcal{F}^{|\mathcal{A}|}} \|h - Q\|_\nu^2$ for $Q \in B(\mathcal{X} \times \mathcal{A})$. We, however, use a different optimization-based formulation. The reason is that whenever ν is not the stationary distribution induced by π , the operator $(\Pi_\nu T^\pi)$ does not necessarily have a fixed point, but the optimization problem is always well-defined.

We define the LSTD solution as the minimizer of the L_2 -norm between Q and $\Pi_\nu T^\pi Q$:

$$L_{LSTD}(Q; \pi) \triangleq \|Q - \Pi_\nu T^\pi Q\|_\nu^2. \quad (9)$$

The minimizer of $L_{LSTD}(Q; \pi)$ is well-defined, and whenever ν is the stationary distribution of π (i.e., on-policy sampling), the solution to this optimization problem is the same as the solution to $Q = \Pi_\nu T^\pi Q$. The LSTD solution can therefore be written as the solution to the following set of coupled optimization problems:

$$\begin{aligned} h(\cdot; Q) &= \operatorname{argmin}_{h \in \mathcal{F}^{|\mathcal{A}|}} \|h' - T^\pi Q\|_\nu^2, \\ Q_{LSTD} &= \operatorname{argmin}_{Q \in \mathcal{F}^{|\mathcal{A}|}} \|Q - h(\cdot; Q)\|_\nu^2, \end{aligned} \quad (10)$$

Algorithm 1 Regularized Policy Iteration($K, \hat{Q}^{(K-1)}, \mathcal{F}^{|\mathcal{A}|}, J, \{(\lambda_{Q_n}^{(k)}, \lambda_{h_n}^{(k)})\}_{k=0}^{K-1}$)

```

// K: Number of iterations
//  $\hat{Q}^{(K-1)}$ : Initial action-value function
//  $\mathcal{F}^{|\mathcal{A}|}$ : The action-value function space
// J: The regularizer
//  $\{(\lambda_{Q_n}^{(k)}, \lambda_{h_n}^{(k)})\}_{k=0}^K$ : The regularization coefficients
for  $k = 0$  to  $K - 1$  do
   $\pi_k(\cdot) \leftarrow \hat{\pi}(\cdot; \hat{Q}^{(k-1)})$ 
  Generate training samples  $\mathcal{D}_n^{(k)}$ 
   $\hat{Q}^{(k)} \leftarrow \text{REG-LSTD/BRM}(\pi_k; \mathcal{D}_n^{(k)}; \mathcal{F}^{|\mathcal{A}|}, J, \lambda_{Q_n}^{(k)}, \lambda_{h_n}^{(k)})$ 
end for
return  $\hat{Q}^{(K-1)}$  and  $\pi_K(\cdot) = \hat{\pi}(\cdot; \hat{Q}^{(K-1)})$ 

```

where the first equation finds the projection of $T^\pi Q$ onto $\mathcal{F}^{|\mathcal{A}|}$, and the second one minimizes the distance of Q and the projection. The corresponding empirical version based on data set \mathcal{D}_n is

$$\hat{h}_n(\cdot; Q) = \operatorname{argmin}_{h \in \mathcal{F}^{|\mathcal{A}|}} \|h - \hat{T}^\pi Q\|_{\mathcal{D}_n}^2, \quad (11)$$

$$\hat{Q}_{LSTD} = \operatorname{argmin}_{Q \in \mathcal{F}^{|\mathcal{A}|}} \|Q - \hat{h}_n(\cdot; Q)\|_{\mathcal{D}_n}^2. \quad (12)$$

For general spaces $\mathcal{F}^{|\mathcal{A}|}$, these optimization problems can be difficult to solve, but when $\mathcal{F}^{|\mathcal{A}|}$ is a linear subspace of $B(\mathcal{X} \times \mathcal{A})$, the minimization problem becomes computationally feasible.

Comparison of BRM and LSTD is noteworthy. The population version of LSTD loss minimizes the distance between Q and $\Pi_\nu T^\pi Q$, which is $\|Q - \Pi_\nu T^\pi Q\|_\nu^2$. Meanwhile, BRM minimizes another distance function that is the distance between $T^\pi Q$ and $\Pi_\nu T^\pi Q$ subtracted from the distance between Q and $T^\pi Q$, i.e., $\|Q - T^\pi Q\|_\nu^2 - \|\hat{h}_n(\cdot; Q) - T^\pi Q\|_\nu^2$. See [Figure 1a](#) for a pictorial presentation of these distances. When $\mathcal{F}^{|\mathcal{A}|}$ is linear, because of the Pythagorean theorem, the solution to the modified BRM (6) coincides with the LSTD solution (10) ([Antos et al., 2008b](#)).

4. Regularized Policy Iteration Algorithms

In this section we introduce two *Regularized Policy Iteration* algorithms, which are instances of the generic API algorithms. These algorithms are built on the regularized extensions of BRM ([Section 3.1](#)) and LSTD ([Section 3.2](#)) for the task of approximate policy evaluation.

The pseudo-code of the Regularized Policy Iteration algorithms is shown in [Algorithm 1](#). The algorithm receives K (the number of API iterations), an initial action-value function $\hat{Q}^{(K-1)}$, the function space $\mathcal{F}^{|\mathcal{A}|}$, the regularizer $J : \mathcal{F}^{|\mathcal{A}|} \rightarrow \mathbb{R}$, and a set of regularization coefficients $\{(\lambda_{Q_n}^{(k)}, \lambda_{h_n}^{(k)})\}_{k=0}^{K-1}$. Each iteration starts with a step of policy improvement, i.e.,

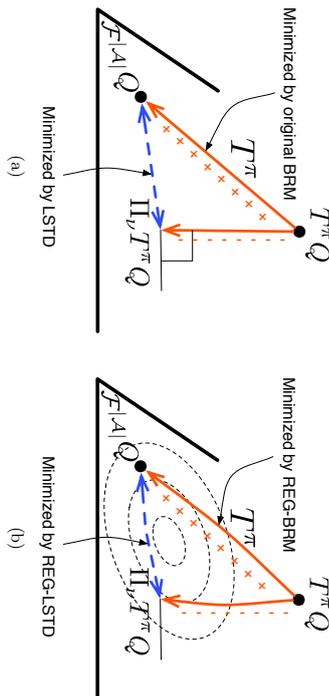

Figure 1: (a) This figure shows the loss functions minimized by the original BRM, the modified BRM, and the LSTD methods: The function space $\mathcal{F}^{|\mathcal{A}|}$ is represented by the plane. The Bellman operator T^π maps an action-value function $Q \in \mathcal{F}^{|\mathcal{A}|}$ to a function $T^\pi Q$. The function $T^\pi Q - \Pi_{\mathcal{F}^{|\mathcal{A}|}} T^\pi Q$ is orthogonal to $\mathcal{F}^{|\mathcal{A}|}$. The original BRM loss function is $\|Q - T^\pi Q\|_2^2$ (solid line), the modified BRM loss is $\|Q - T^\pi Q\|_2^2 - \|\Pi_{\mathcal{F}^{|\mathcal{A}|}} T^\pi Q - \Pi_{\mathcal{F}^{|\mathcal{A}|}} Q\|_2^2$ (the difference of two solid line segments; note the + and - symbols), and the LSTD loss is $\|Q - \Pi_{\mathcal{F}^{|\mathcal{A}|}} T^\pi Q\|_2^2$ (dashed line). LSTD and the modified BRM are equivalent for linear function spaces. (b) REG-LSTD and REG-BRM minimize regularized objective functions. Regularization makes the function $T^\pi Q - \Pi_{\mathcal{F}^{|\mathcal{A}|}} T^\pi Q$ to be non-orthogonal to $\mathcal{F}^{|\mathcal{A}|}$. The dashed ellipsoids represent the level-sets defined by the regularization functional J .

$\pi_k \leftarrow \hat{\pi}(\cdot; \hat{Q}^{(k-1)}) = \operatorname{argmax}_{\sigma \in \mathcal{A}} \hat{Q}^{(k-1)}(\cdot, \sigma)$. For the first iteration ($k=0$), one may ignore this step and provide an initial policy π_0 instead of $\hat{Q}^{(-1)}$. Afterwards, we have a data generating step: At each iteration $k=0, \dots, K-1$, the agent follows the data generating policy π_k to obtain $\mathcal{D}_n^{(k)} = \{(X_t^{(k)}, A_t^{(k)}, R_t^{(k)}, X_{t+1}^{(k)})\}_{1 \leq t \leq n}$. For the k th iteration of the algorithm, we use training samples $\mathcal{D}_n^{(k)}$ to evaluate policy π_k . In practice, one might want to change π_k at each iteration in such a way that the agent ultimately achieves a better performance. The relation between the performance and the choice of data samples, however, is complicated. For simplicity of analysis, in the rest of this work we assume that a fixed behavior policy is used in all iterations, i.e., $\pi_k = \pi_0$.⁷ This leads to K independent data sets $\mathcal{D}_n^{(0)}, \dots, \mathcal{D}_n^{(K-1)}$. From now on, to avoid clutter, we use symbols $\mathcal{D}_n, X_t, \dots$ instead of $\mathcal{D}_n^{(k)}, X_t^{(k)}, \dots$ with the understanding that each \mathcal{D}_n in various iterations is referring to an independent set of data samples, which should be clear from the context.

The approximate policy evaluation step is performed by REG-LSTD/BRM, which will be discussed shortly. REG-LSTD/BRM receives policy π_k , the training samples $\mathcal{D}_n^{(k)}$, the function space $\mathcal{F}^{|\mathcal{A}|}$, the regularizer J , and the regularization coefficients $(\lambda_{Q,n}^{(k)}, \lambda_{h,n}^{(k)})$, and

returns an estimate of the action-value function of policy π_k . This procedure repeats for K iterations.

REG-BRM approximately evaluates policy π_k by solving the following coupled optimization problems:

$$\hat{h}_n(\cdot; Q) = \operatorname{argmin}_{h \in \mathcal{F}^{|\mathcal{A}|}} \left[\|h - \hat{T}^{\pi_k} Q\|_{\mathcal{D}_n}^2 + \lambda_{h,n}^{(k)} J^2(h) \right], \quad (13)$$

$$\hat{Q}^{(k)} = \operatorname{argmin}_{Q \in \mathcal{F}^{|\mathcal{A}|}} \left[\|Q - \hat{T}^{\pi_k} Q\|_{\mathcal{D}_n}^2 - \|\hat{h}_n(\cdot; Q) - \hat{T}^{\pi_k} Q\|_{\mathcal{D}_n}^2 + \lambda_{Q,n}^{(k)} J^2(Q) \right], \quad (14)$$

where $J : \mathcal{F}^{|\mathcal{A}|} \rightarrow \mathbb{R}$ is the regularization functional (or simply regularizer or penalizer), and $\lambda_{h,n}^{(k)}, \lambda_{Q,n}^{(k)} > 0$ are regularization coefficients. The regularizer can be any pseudo-norm defined on $\mathcal{F}^{|\mathcal{A}|}$, and \mathcal{D}_n is defined as (2).⁸ The regularizer is often chosen such that the functions that we believe are more “complex” have larger values of J . The notion of complexity, however, is subjective and depends on the choice of $\mathcal{F}^{|\mathcal{A}|}$ and J . Finally note that we call $J(Q)$ the smoothness of Q , even though it might not coincide with the conventional derivative-based notions of smoothness.

An example of the case that J has a derivative-based interpretation is when the function space $\mathcal{F}^{|\mathcal{A}|}$ is a Sobolev space and the regularizer J is defined as its corresponding norm. In this case, we are penalizing the weak-derivatives of the estimate (Györfi et al., 2002; van de Geer, 2000). One can generalize the notion of smoothness beyond the usual derivative-based ones (cf. Chapter 1 of Triebel 2006) and define function spaces such as the family of Besov spaces (Devore, 1998). The RKHS norm for shift-invariant and radial kernels can also be interpreted as a penalizer of higher-frequency terms of the function (i.e., a low-pass filter Evgenion et al. 1999), so they effectively encourage “smoother” functions. The choice of kernel determines the frequency response of the filter. One may also use other data-dependent regularizers such as manifold regularization (Balkin et al., 2006) and Sample-based Approximate Regularization (Bachman et al., 2014). As a final example, for the functions in the form of $Q(x; a) = \sum_{i \geq 1} \phi_i(x; a) w_i$, if we choose a sparsity-inducing regularizer such as $J(Q) \triangleq \sum_{i \geq 1} |w_i|$ as the measure of smoothness, then a function that has a sparse representation in the dictionary $\{\phi_i\}_{i \geq 1}$ is, by definition, a smooth function—even though there is not necessarily any connection to the derivative-based smoothness.

REG-LSTD approximately evaluates the policy π_k by solving the following coupled optimization problems:

$$\hat{h}_n(\cdot; Q) = \operatorname{argmin}_{h \in \mathcal{F}^{|\mathcal{A}|}} \left[\|h - \hat{T}^{\pi_k} Q\|_{\mathcal{D}_n}^2 + \lambda_{h,n}^{(k)} J^2(h) \right], \quad (15)$$

$$\hat{Q}^{(k)} = \operatorname{argmin}_{Q \in \mathcal{F}^{|\mathcal{A}|}} \left[\|Q - \hat{h}_n(\cdot; Q)\|_{\mathcal{D}_n}^2 + \lambda_{Q,n}^{(k)} J^2(Q) \right]. \quad (16)$$

Note that the difference between (7)-(8) ((11)-(12)) and (13)-(14) ((15)-(16)) is the addition of the regularizers $J^2(h)$ and $J^2(Q)$.

Unlike the non-regularized case described in Section 3, the solutions of REG-BRM and REG-LSTD are not the same. As a result of the *regularized* projection, (13) and

⁷ So we are in the so-called *off-policy sampling* scenario.

(15), the function $\hat{h}_n(\cdot; Q) - \hat{T}^{\pi_k} Q$ is not orthogonal to the function space $\mathcal{F}^{|\mathcal{A}|}$ —even if $\mathcal{F}^{|\mathcal{A}|}$ is a linear space. Therefore, the Pythagorean theorem is not applicable anymore: $\|Q - \hat{h}_n(\cdot; Q)\|^2 \neq \|Q - \hat{T}^{\pi_k} Q\|^2 - \|\hat{h}_n(\cdot; Q) - \hat{T}^{\pi_k} Q\|^2$ (See Figure 1b).

One may ask why we have regularization terms in both optimization problems, as opposed to only in the projection term (15) (similar to the Lasso-TD algorithm [Kolter and Ng 2009](#); [Ghavamzadeh et al. 2011](#)) or only in (16) (similar to [Geist and Scherrer 2012](#); [Ávila Pires and Szepesvári 2012](#)). We discuss this question in Section 4.1. Briefly speaking, for large function spaces such as the Sobolev spaces or the RKHS with universal kernels, if we remove the regularization term in (15), the coupled optimization problems reduces to (unmodified) BRM, which is biased as discussed earlier; whereas if the regularization term in (16) is removed, the solution can be arbitrary bad due to overfitting.

Finally note that the choice of the function space $\mathcal{F}^{|\mathcal{A}|}$, the regularizer J , and the regularization coefficients $\lambda_{Q,n}^{(k)}$ and $\lambda_{h,n}^{(k)}$ all affect the sample efficiency of the algorithms. If one knew $J(Q^\pi)$, the regularization coefficients could be chosen optimally. Nonetheless, the value of $J(Q^\pi)$ is often not known, so one has to use a model selection procedure to set the best function space and the regularization coefficients. The situation is similar to the problem of model selection in supervised learning (though the solutions are different). After developing some tools necessary for discussing this issue in Section 5, we return to the problem of choosing the regularization coefficients after Theorem 11 as well as in Section 6.

Remark 7 *To the best of our knowledge, [Antos et al. \(2008b\)](#) were the first who explicitly considered LSTD as the optimizer of the loss function (9). Their discussion was mainly to prove the equivalence of modified BRM (5) and LSTD when $\mathcal{F}^{|\mathcal{A}|}$ is a linear function space. In their work, the loss function is not used to derive any new algorithm. [Farahmand et al. \(2009b\)](#) used this loss function to develop the regularized variant of LSTD (15)-(16). This loss function was later called mean-square projected Bellman error by [Sutton et al. \(2009\)](#), and was used to derive the GTD2 and TDC algorithms.*

4.1 Why Two Regularizers?

We discuss why using regularizers in both optimization problems (15) and (16) of REG-LSTD is necessary for large function spaces such as the Sobolev spaces and the RKHS with universal kernels. Here we show that for large function spaces, depending on which regularization term we remove, either the coupled optimization problems reduces to the regularized variant of the unmodified BRM, which has a bias, or the solution can be arbitrary bad.

Let us focus on REG-LSTD for a given policy π . Assume that the function space $\mathcal{F}^{|\mathcal{A}|}$ is rich enough in the sense that it is dense in the space of continuous functions w.r.t. the supremum norm. This is satisfied by many large function spaces such as RKHS with universal kernels (Definition 4.52 of [Steinwart and Christmann 2008](#)) and the Sobolev spaces on compact domains. We consider what would happen if instead of the current formulation of REG-LSTD (15)-(16), we only used a regularizer either in the first or second optimization problem. We study each case separately. For notational simplicity, we omit the dependence on the iteration number k .

Case 1. In this case, we only regularize the empirical error $\|Q - \hat{h}_n(\cdot; Q)\|_{\mathcal{D}_n}^2$, but we do not regularize the projection, i.e.,

$$\begin{aligned} \hat{h}_n(\cdot; Q) &= \operatorname{argmin}_{h \in \mathcal{F}^{|\mathcal{A}|}} \|h - \hat{T}^{\pi} Q\|_{\mathcal{D}_n}^2, \\ \hat{Q} &= \operatorname{argmin}_{Q \in \mathcal{F}^{|\mathcal{A}|}} \left[\|Q - \hat{h}_n(\cdot; Q)\|_{\mathcal{D}_n}^2 + \lambda_{Q,n} J^2(Q) \right]. \end{aligned} \quad (17)$$

When the function space $\mathcal{F}^{|\mathcal{A}|}$ is rich enough, there exists a function $\hat{h}_n \in \mathcal{F}^{|\mathcal{A}|}$ that fits perfectly well to its target values at data points $\{(X_i, A_i)\}_{i=1}^n$, that is, $\hat{h}_n(X_i, A_i; Q) = (\hat{T}^{\pi} Q)(X_i, A_i)$ for $i = 1, \dots, n$.⁹ Such a function is indeed the minimizer of the loss $\|Q - \hat{h}_n(\cdot; Q)\|_{\mathcal{D}_n}^2$. The second optimization problem (17) becomes

$$\hat{Q} = \operatorname{argmin}_{Q \in \mathcal{F}^{|\mathcal{A}|}} \left[\|Q - \hat{T}^{\pi} Q\|_{\mathcal{D}_n}^2 + \lambda_{Q,n} J^2(Q) \right].$$

This is the regularized version of the original (i.e., unmodified) formulation of the BRM algorithm. As discussed in Section 3.1, the unmodified BRM algorithm is biased when the MDP is not deterministic. Adding a regularizer does not solve the biasedness problem of the unmodified BRM loss. So without regularizing the first optimization problem, the function \hat{h}_n overfits to the noise and as a result the whole algorithm becomes incorrect.

Case 2. In this case, we only regularize the empirical projection $\|h - \hat{T}^{\pi} Q\|_{\mathcal{D}_n}^2$, but we do not regularize $\|Q - \hat{h}_n(\cdot; Q)\|_{\mathcal{D}_n}^2$, i.e.,

$$\begin{aligned} \hat{h}_n(\cdot; Q) &= \operatorname{argmin}_{h \in \mathcal{F}^{|\mathcal{A}|}} \left[\|h - \hat{T}^{\pi} Q\|_{\mathcal{D}_n}^2 + \lambda_{h,n} J^2(h) \right], \\ \hat{Q} &= \operatorname{argmin}_{Q \in \mathcal{F}^{|\mathcal{A}|}} \|Q - \hat{h}_n(\cdot; Q)\|_{\mathcal{D}_n}^2. \end{aligned} \quad (18)$$

For a fixed Q , the first optimization problem is the standard regularized regression estimator with the regression function $\mathbb{E}[(\hat{T}^{\pi} Q)(X, A) | X = x, A = a] = (T^{\pi} Q)(x, a)$. Therefore, if the function space $\mathcal{F}^{|\mathcal{A}|}$ is rich enough and we set the regularization coefficient $\lambda_{h,n}$ properly, $\|h - T^{\pi} Q\|_{\nu}$ and $\|h - \hat{T}^{\pi} Q\|_{\mathcal{D}_n}$ go to zero as the sample size grows (the rate of convergence depends on the complexity of the target function; cf. Lemma 15 and Theorem 16). So we can expect $\hat{h}_n(\cdot; Q)$ to get closer to $T^{\pi} Q$ as the sample size grows.

For simplicity of discussion, suppose that we are in the ideal situation where for any Q , we have $\hat{h}_n(\cdot; Q) = (T^{\pi} Q)(x, a)$ for all $(x, a) \in \{(X_i, A_i)\}_{i=1}^n \cup \{(X'_i, \pi(X'_i))\}_{i=1}^n$, that

9. To be more precise: First, for an $\varepsilon > 0$, we construct a continuous function $\tilde{h}_\varepsilon(z) = \sum_{z_i \in \{(X_i, A_i)\}_{i=1}^n} \max\left\{1 - \frac{\|z - z_i\|}{\varepsilon}, 0\right\} (\hat{T}^{\pi} Q)(z_i)$. We then use the denseness of the function space $\mathcal{F}^{|\mathcal{A}|}$ in the supremum norm to argue that there exists $h_\varepsilon \in \mathcal{F}^{|\mathcal{A}|}$ such that $\|h_\varepsilon - \tilde{h}_\varepsilon\|_\infty$ is arbitrarily close to zero. So when $\varepsilon \rightarrow 0$, the value of function h_ε is arbitrarily close to $T^{\pi} Q$ at data points. We then choose $\hat{h}_n(\cdot; Q) = h_\varepsilon$. This construction is similar to Theorem 2 of [Nadler et al. \(2009\)](#). See also the argument in Case 2 for more detail.

is, we precisely know $T^\pi Q$ at all data points.¹⁰ Substituting this $\hat{h}_n((x, a), Q)$ in the second optimization problem (17), we get that we are solving the following optimization problem:

$$\hat{Q} = \operatorname{argmin}_{Q \in \mathcal{F}^{\mathcal{A}}} \|Q - T^\pi Q\|_{\mathcal{D}_n}^2. \quad (19)$$

This is the Bellman error minimization problem. We do not have the biasedness problem here as we have $T^\pi Q$ instead of $\hat{T}^\pi Q$ in the loss. Nonetheless, we face another problem: Minimizing this empirical risk minimization without controlling the complexity of the function space might lead to an overfitted solution, very similar to the same phenomenon in supervised learning.

To see it more precisely, we first construct a continuous function

$$\bar{Q}_\varepsilon(z) = \sum_{Z_i \in (\{X_i, A_i\})_{i=1}^n \cup (\{X_i^\dagger, \pi(X_i)\})_{i=1}^n} \max \left\{ 1 - \frac{\|z - Z_i\|}{\varepsilon}, 0 \right\} Q^\pi(Z_i),$$

which for small enough $\varepsilon > 0$ has the property that $\|\bar{Q}_\varepsilon - T^\pi \bar{Q}_\varepsilon\|_{\mathcal{D}_n}^2$ is zero, i.e., it is a minimizer of the empirical loss. Due to the denseness of $\mathcal{F}^{\mathcal{A}}$, we can find a $Q_\varepsilon \in \mathcal{F}^{\mathcal{A}}$ that is arbitrarily close to the continuous function \bar{Q}_ε . Therefore, for small enough ε , the function Q_ε is a minimizer of (19), i.e., the value of $\|Q_\varepsilon - T^\pi Q_\varepsilon\|_{\mathcal{D}_n}^2$ is zero. But Q_ε is not a good approximation of Q^π because Q_ε consists of spikes in the ε -neighbourhood of data points and zero elsewhere. In other words, Q_ε does not generalize well beyond the data points when ε is chosen to be small.

Of course the solution is to control the complexity of $\mathcal{F}^{\mathcal{A}}$ so that spiky functions such as Q_ε are not selected as the solution of the optimization problem. When we regularize both optimization problems, as we do in this work, none of these problems happen.

This argument applies to rich function spaces that can approximate any reasonably complex functions (e.g., continuous functions) arbitrarily well. If the function space $\mathcal{F}^{\mathcal{A}}$ is much more limited, for example if it is a parametric function space, we *may* not need to regularize both optimization problems. An example of such an approach for parametric spaces has been analyzed by [Avila Pires and Szepesvári \(2012\)](#).

4.2 Closed-Form Solutions

In this section we provide a closed-form solution for (13)-(14) and (15)-(16) for two cases: 1) When $\mathcal{F}^{\mathcal{A}}$ is a finite dimensional linear space and $J^2(\cdot)$ is defined as the weighted squared sum of parameters describing the function (a setup similar to the ridge regression [Hoerl and Kennard 1970](#)) and 2) $\mathcal{F}^{\mathcal{A}}$ is an RKHS and $J(\cdot)$ is the corresponding inner-product norm, i.e., $J^2(\cdot) = \|\cdot\|_H^2$. Here we use a generic π and \mathcal{D}_n instead of π_k and $\mathcal{D}_n^{(k)}$ at the k th iteration.

¹⁰. This is an ideal situation because 1) $\|h - \hat{T}^\pi Q\|_v$ is equal to zero only asymptotically and not in finite samples regime, and 2) even if $\|h - \hat{T}^\pi Q\|_v = 0$, it does not imply that $h_n(x, a; Q) = (T^\pi Q)(x, a)$ almost surely on $\mathcal{X} \times \mathcal{A}$. Nonetheless, these simplifications are only in favour of the algorithm considered in this case, so for simplicity of discussion we assume that they hold.

4.2.1 A PARAMETRIC FORMULATION FOR REG-BRM AND REG-LSTD

In this section we consider the case when h and Q are both given as linear combinations of some basis functions:

$$h(\cdot) = \phi(\cdot)^\top \mathbf{u}, \quad Q(\cdot) = \phi(\cdot)^\top \mathbf{w}, \quad (20)$$

where $\mathbf{u}, \mathbf{w} \in \mathbb{R}^p$ are parameter vectors and $\phi(\cdot) \in \mathbb{R}^p$ is a vector of p linearly independent basis functions defined over the space of state-action pairs.¹¹ These basis functions might be predefined (e.g., Fourier ([Kondratiev et al., 2011](#)) or wavelets) or constructed data-dependently by one of already mentioned feature generation methods. We further assume that the regularization terms take the form

$$J^2(h) = \mathbf{u}^\top \Psi \mathbf{u}, \\ J^2(Q) = \mathbf{w}^\top \Psi \mathbf{w}.$$

for some user-defined choice of positive definite matrix $\Psi \in \mathbb{R}^{p \times p}$. A simple and common choice would be $\Psi = \mathbf{I}$. Define $\Phi, \Phi' \in \mathbb{R}^{n \times p}$ and $\mathbf{r} \in \mathbb{R}^n$ as follows:

$$\Phi = \left(\phi(Z_1), \dots, \phi(Z_n) \right)^\top, \quad \Phi' = \left(\phi(Z'_1), \dots, \phi(Z'_n) \right)^\top, \quad \mathbf{r} = \left(R_1, \dots, R_n \right)^\top, \quad (21)$$

with $Z_i = (X_i, A_i)$ and $Z'_i = (X'_i, \pi(X'_i))$.

The solution to REG-BRM is given by the following proposition.

Proposition 8 (Closed-form solution for REG-BRM) *Under the setting of this section, the approximate action-value function returned by REG-BRM is $\hat{Q}(\cdot) = \phi(\cdot)^\top \mathbf{w}^*$, where*

$$\mathbf{w}^* = \left[\mathbf{B}^\top \mathbf{B} - \gamma^2 \mathbf{C}^\top \mathbf{C} + n \lambda_{Q,n} \Psi \right]^{-1} \left(\mathbf{B}^\top + \gamma \mathbf{C}^\top (\Phi \mathbf{A} - \mathbf{D}) \right) \mathbf{r},$$

with $\mathbf{A} = (\Phi^\top \Phi + n \lambda_{h,n} \Psi)^{-1} \Phi^\top$, $\mathbf{B} = \Phi - \gamma \Phi'$, $\mathbf{C} = (\Phi \mathbf{A} - \mathbf{D}) \Phi'$.

Proof Using (20) and (21), we can rewrite (13)-(14) as

$$\mathbf{u}^*(\mathbf{w}) = \operatorname{argmin}_{\mathbf{u} \in \mathbb{R}^p} \left\{ \frac{1}{n} [\Phi \mathbf{u} - (\mathbf{r} + \gamma \Phi' \mathbf{w})]^\top [\Phi \mathbf{u} - (\mathbf{r} + \gamma \Phi' \mathbf{w})] + \lambda_{h,n} \mathbf{u}^\top \Psi \mathbf{u} \right\}, \quad (22)$$

$$\mathbf{w}^* = \operatorname{argmin}_{\mathbf{w} \in \mathbb{R}^p} \left\{ \frac{1}{n} [\Phi \mathbf{w} - (\mathbf{r} + \gamma \Phi' \mathbf{w})]^\top [\Phi \mathbf{w} - (\mathbf{r} + \gamma \Phi' \mathbf{w})] - \frac{1}{n} [\Phi \mathbf{u}^*(\mathbf{w}) - (\mathbf{r} + \gamma \Phi' \mathbf{w})]^\top [\Phi \mathbf{u}^*(\mathbf{w}) - (\mathbf{r} + \gamma \Phi' \mathbf{w})] + \lambda_{Q,n} \mathbf{w}^\top \Psi \mathbf{w} \right\}. \quad (23)$$

Taking the derivative of (22) w.r.t. \mathbf{u} and equating it to zero, we obtain \mathbf{u}^* as a function of \mathbf{w} :

$$\mathbf{u}^*(\mathbf{w}) = \left(\Phi^\top \Phi + n \lambda_{h,n} \Psi \right)^{-1} \Phi^\top (\mathbf{r} + \gamma \Phi' \mathbf{w}) = \mathbf{A} (\mathbf{r} + \gamma \Phi' \mathbf{w}). \quad (24)$$

Plug $\mathbf{u}^*(\mathbf{w})$ from (24) into (23), take the derivative w.r.t. \mathbf{w} and equate it to zero to obtain the parameter vector \mathbf{w}^* as announced above. ■

The solution returned by REG-LSTD is given in the following proposition.

¹¹. At the cost of using generalized inverses, everything in this section extends to the case when the basis functions are not linearly independent.

Proposition 9 (Closed-form solution for REG-LSTD) Under the setting of this section, the approximate action-value function returned by REG-LSTD is $\hat{Q}(\cdot) = \phi(\cdot)^\top \mathbf{w}^*$, where

$$\mathbf{w}^* = [\mathbf{E}^\top \mathbf{E} + n\lambda_{Q,n} \mathbf{\Psi}]^{-1} \mathbf{E}^\top \mathbf{A} \mathbf{r},$$

with $\mathbf{A} = (\mathbf{\Phi}^\top \mathbf{\Phi} + n\lambda_{h,n} \mathbf{\Psi})^{-1} \mathbf{\Phi}^\top$ and $\mathbf{E} = (\mathbf{\Phi} - \gamma \mathbf{A} \mathbf{\Phi}')$.

Proof Using (20) and (21), we can rewrite (15)-(16) as

$$\mathbf{u}^*(\mathbf{w}) = \operatorname{argmin}_{\mathbf{u} \in \mathbb{R}^p} \left\{ \frac{1}{n} [\mathbf{\Phi} \mathbf{u} - (\mathbf{r} + \gamma \mathbf{\Phi}' \mathbf{w})]^\top [\mathbf{\Phi} \mathbf{u} - (\mathbf{r} + \gamma \mathbf{\Phi}' \mathbf{w})] + \lambda_{h,n} \mathbf{u}^\top \mathbf{\Psi} \mathbf{u} \right\}, \quad (25)$$

$$\mathbf{w}^* = \operatorname{argmin}_{\mathbf{w} \in \mathbb{R}^p} \left\{ [\mathbf{\Phi} \mathbf{w} - \mathbf{\Phi} \mathbf{u}^*(\mathbf{w})]^\top [\mathbf{\Phi} \mathbf{w} - \mathbf{\Phi} \mathbf{u}^*(\mathbf{w})] + \lambda_{Q,n} \mathbf{w}^\top \mathbf{\Psi} \mathbf{w} \right\}. \quad (26)$$

Similar to the parametric REG-BRM, we solve (25) and obtain $\mathbf{u}^*(\mathbf{w})$ which is the same as (24). If we plug this $\mathbf{u}^*(\mathbf{w})$ into (26), take derivative w.r.t. \mathbf{w} , and find the minimizer, the parameter vector \mathbf{w}^* will be as announced. \blacksquare

4.2.2 RKHS FORMULATION FOR REG-BRM AND REG-LSTD

The class of reproducing kernel Hilbert spaces provides a flexible and powerful family of function spaces to choose $\mathcal{F}^{|\mathcal{A}|}$ from. An RKHS $\mathcal{H} : \mathcal{X} \times \mathcal{A} \rightarrow \mathbb{R}$ is defined by a positive definite kernel $\kappa : (\mathcal{X} \times \mathcal{A}) \times (\mathcal{X} \times \mathcal{A}) \rightarrow \mathbb{R}$. With such a choice, we can use the corresponding squared RKHS norm $\|\cdot\|_{\mathcal{H}}^2$ as the regularizer $J^2(\cdot)$. REG-BRM with an RKHS function space $\mathcal{F}^{|\mathcal{A}|} = \mathcal{H}$ would be

$$\hat{h}_n(\cdot; Q) = \operatorname{argmin}_{h \in \mathcal{F}^{|\mathcal{A}|} = \mathcal{H}} \left[\|h - \hat{T}^\pi Q\|_{\mathcal{D}_n}^2 + \lambda_{h,n} \|h\|_{\mathcal{H}}^2 \right], \quad (27)$$

$$\hat{Q} = \operatorname{argmin}_{Q \in \mathcal{F}^{|\mathcal{A}|} = \mathcal{H}} \left[\|Q - \hat{T}^\pi Q\|_{\mathcal{D}_n}^2 - \|\hat{h}_n(\cdot; Q) - \hat{T}^\pi Q\|_{\mathcal{D}_n}^2 + \lambda_{Q,n} \|Q\|_{\mathcal{H}}^2 \right], \quad (28)$$

and the coupled optimization problems for REG-LSTD are

$$\hat{h}_n(\cdot; Q) = \operatorname{argmin}_{h \in \mathcal{F}^{|\mathcal{A}|} = \mathcal{H}} \left[\|h - \hat{T}^\pi Q\|_{\mathcal{D}_n}^2 + \lambda_{h,n} \|h\|_{\mathcal{H}}^2 \right], \quad (29)$$

$$\hat{Q} = \operatorname{argmin}_{Q \in \mathcal{F}^{|\mathcal{A}|} = \mathcal{H}} \left[\|Q - \hat{h}_n(\cdot; Q)\|_{\mathcal{D}_n}^2 + \lambda_{Q,n} \|Q\|_{\mathcal{H}}^2 \right]. \quad (30)$$

We can solve these coupled optimization problems by the application of the generalized representer theorem for RKHS (Schölkopf et al., 2001). The result, which is stated in the next theorem, shows that the infinite dimensional optimization problem defined on $\mathcal{F}^{|\mathcal{A}|} = \mathcal{H}$ boils down to a finite dimensional problem with the dimension twice the number of data points.

Theorem 10 Let \tilde{Z} be a vector defined as $\tilde{Z} = (Z_1, \dots, Z_n, Z'_1, \dots, Z'_n)^\top$. Then the optimizer $\hat{Q} \in \mathcal{H}$ of (27)-(28) can be written as $\hat{Q}(\cdot) = \sum_{i=1}^{2n} \tilde{\alpha}_i \kappa(\tilde{Z}_i, \cdot)$ for some values of

$\tilde{\alpha} \in \mathbb{R}^{2n}$. The same holds for the solution to (29)-(30). Further, the coefficient vectors can be obtained in the following form:

$$\begin{aligned} \text{REG-BRM:} \quad \tilde{\alpha}_{BRM} &= (\mathbf{C} \mathbf{K}_Q + n\lambda_{Q,n} \mathbf{I})^{-1} (\mathbf{D}^\top + \gamma \mathbf{C}_2^\top \mathbf{B}) \mathbf{r}, \\ \text{REG-LSTD:} \quad \tilde{\alpha}_{LSTD} &= (\mathbf{F}^\top \mathbf{F} \mathbf{K}_Q + n\lambda_{Q,n} \mathbf{I})^{-1} \mathbf{F}^\top \mathbf{E} \mathbf{r}, \end{aligned}$$

where $\mathbf{r} = (R_1, \dots, R_n)^\top$ and the matrices $\mathbf{K}_Q, \mathbf{B}, \mathbf{C}, \mathbf{C}_2, \mathbf{D}, \mathbf{E}, \mathbf{F}$ are defined as follows: $\mathbf{K}_h \in \mathbb{R}^{n \times n}$ is defined as $[\mathbf{K}_h]_{ij} = \kappa(Z_i, Z_j)$, $1 \leq i, j \leq n$, and $\mathbf{K}_Q \in \mathbb{R}^{2n \times 2n}$ is defined as $[\mathbf{K}_Q]_{ij} = \kappa(\tilde{Z}_i, \tilde{Z}_j)$, $1 \leq i, j \leq 2n$. Let $\mathbf{C}_1 = (\mathbf{I}_{n \times n} \quad \mathbf{0}_{n \times n})$ and $\mathbf{C}_2 = (\mathbf{0}_{n \times n} \quad \mathbf{I}_{n \times n})$. Denote $\mathbf{D} = \mathbf{C}_1 - \gamma \mathbf{C}_2$, $\mathbf{E} = \mathbf{K}_h (\mathbf{K}_h + n\lambda_{h,n} \mathbf{I})^{-1}$, $\mathbf{F} = \mathbf{C}_1 - \gamma \mathbf{E} \mathbf{C}_2$, $\mathbf{B} = \mathbf{K}_h (\mathbf{K}_h + n\lambda_{h,n} \mathbf{I})^{-1} - \mathbf{I}$, and $\mathbf{C} = \mathbf{D}^\top \mathbf{D} - \gamma^2 (\mathbf{B} \mathbf{C}_2)^\top (\mathbf{B} \mathbf{C}_2)$.

Proof See Appendix A. \blacksquare

5. Theoretical Analysis

In this section, we analyze the statistical properties of REG-LSPI and provide a finite-sample upper bound on the performance loss $\|Q^* - Q^{\pi_K}\|_{1,\rho}$. Here, π_K is the policy greedy w.r.t. $\hat{Q}^{(K-1)}$ and ρ is the performance evaluation measure. The distribution ρ is chosen by the user and is often different from the sampling distribution ν .

Our study has two main parts. First, we analyze the policy evaluation error of REG-LSTD in Section 5.1. We suppose that given any policy π , we obtain \hat{Q} by solving (15)-(16) with π_k in these equations being replaced by π . Theorem 11 provides an upper bound on the Bellman error $\|\hat{Q} - T^\pi \hat{Q}\|_{\nu}$. We discuss the optimality of this upper bound for policy evaluation for some general classes of function spaces. We show that the result is not only optimal in its convergence rate, but also in its dependence on $J(Q^\pi)$. After that in Section 5.2, we show how the Bellman errors of the policy evaluation procedure propagate through the API procedure (Theorem 13). The main result of this paper, which is an upper bound on the performance loss $\|Q^* - Q^{\pi_K}\|_{1,\rho}$, is stated as Theorem 14 in Section 5.3, followed by its discussion. We compare this work's statistical guarantee with some other papers' in Section 5.3.1.

To analyze the statistical performance of the REG-LSPI procedure, we make the following assumptions. We discuss their implications and the possible relaxations after stating each of them.

Assumption A1 (MDP Regularity) The set of states \mathcal{X} is a compact subset of \mathbb{R}^d . The random immediate rewards $R_t \sim \mathcal{R}(\cdot | X_t, A_t)$ ($t = 1, 2, \dots$) as well as the expected immediate rewards $r(x, a)$ are uniformly bounded by R_{\max} , i.e., $|R_t| \leq R_{\max}$ ($t = 1, 2, \dots$) and $\|r\|_\infty \leq R_{\max}$.

Even though the algorithms were presented for a general measurable state space \mathcal{X} , the theoretical results are stated for the problems whose state space is a compact subset of \mathbb{R}^d . Generalizing Assumption A1 to other state spaces should be possible under certain regularity conditions. One example could be any Polish space, i.e., separable completely

metrizable topological space. Nevertheless, we do not investigate such generalizations here. The boundedness of the rewards is a reasonable assumption that can be replaced by a more relaxed condition such as its sub-Gaussianity (Vershynin, 2012; van de Geer, 2000). This relaxation, however, increases the technicality of the proofs without adding much to the intuition. We remark on the compactness assumption after stating Assumption A4.

Assumption A2 (Sampling) At iteration k of REG-LSPI (for $k = 0, \dots, K - 1$), n fresh independent and identically distributed (i.i.d.) samples are drawn from distribution $\nu \in \mathcal{M}(\mathcal{X} \times \mathcal{A})$, i.e., $\mathcal{D}_n^{(k)} = \left\{ \left(Z_t^{(k)}, R_t^{(k)}, X_t^{(k)} \right)_{t=1}^n \text{ with } Z_t^{(k)} = (X_t^{(k)}, A_t^{(k)}) \stackrel{\text{i.i.d.}}{\sim} \nu \text{ and } X_t^{(k)} \sim P(\cdot | X_t^{(k)}, A_t^{(k)}) \right\}$.

The i.i.d. requirement of Assumption A2 is primarily used to simplify the proofs. With much extra effort, these results can be extended to the case when the data samples belong to a single trajectory generated by a fixed policy. In the single trajectory scenario, samples are not independent anymore, but under certain conditions on the Markov process, the process (X_t, A_t) gradually “forgets” its past. One way to quantify this forgetting is through mixing processes. For these processes, tools such as the *independent blocks* technique (Yu, 1994; Donkhan, 1994) or information theoretical inequalities (Samson, 2000) can be used to carry on the analysis—as have been done by Amos et al. (2008b) in the API context, by Farahmand and Szepesvári (2012) for analyzing the regularized regression problem, and by Farahmand and Szepesvári (2011) in the context of model selection for RL problems.

It is worthwhile to emphasize that we do not require that the distribution ν to be known. The sampling distribution is also generally different from the distribution induced by the target policy π_* . For example, it might be generated by drawing state samples from a given $\nu_{\mathcal{X}}$ and choosing actions according to a behavior policy π , which is different from the policy being evaluated. So we are in the off-policy sampling setting. Moreover, changing ν at each iteration based on the previous iterations is a possibility with potential practical benefits, which has theoretical justifications in the context of imitation learning (Ross et al., 2011). For simplicity of the analysis, however, we assume that ν is fixed in all iterations. Finally, we note that the proofs work fine if we reuse the same data sets in all iterations. We comment on it later after the proof of Theorem 11 in Appendix B.

Assumption A3 (Regularizer) Define two regularization functionals $J : B(\mathcal{X}) \rightarrow \mathbb{R}$ and $J : B(\mathcal{X} \times \mathcal{A}) \rightarrow \mathbb{R}$ that are pseudo-norms on \mathcal{F} and $\mathcal{F}^{\mathcal{A}}$, respectively.¹² For all $Q \in \mathcal{F}^{\mathcal{A}}$ and $a \in \mathcal{A}$, we have $J(Q(\cdot, a)) \leq J(Q)$.

The regularizer $J(Q)$ measures the complexity of an action-value function Q . The functions that are more complex have larger values of $J(Q)$. We also need to define a related regularizer for value functions $Q(\cdot, a)$ ($a \in \mathcal{A}$). The latter regularizer is not explicitly used in the algorithm, and is only used in the analysis. This assumption imposes some mild restrictions on these regularization functionals. The condition that the regularizers be pseudo-norms is satisfied by many commonly-used regularizers such as the Sobolev norms,

¹² Note that here we are slightly abusing the notations as the same symbol is used for the regularizer over both $B(\mathcal{X})$ and $B(\mathcal{X} \times \mathcal{A})$. However, this should not cause any confusion since in any specific expression the identity of the regularizer should always be clear from the context.

the RKHS norms, and the l_2 -regularizer defined in Section 4.2.1 with a positive semi-definite choice of matrix Ψ . Moreover, the condition $J(Q(\cdot, a)) \leq J(Q)$ essentially states that the complexity of Q should upper bound the complexity of $Q(\cdot, a)$ for all $a \in \mathcal{A}$. If the regularizer $J : B(\mathcal{X} \times \mathcal{A}) \rightarrow \mathbb{R}$ is derived from a regularizer $J' : B(\mathcal{X}) \rightarrow \mathbb{R}$ through $J(Q) = \|(J'(Q(\cdot, a)))_{a \in \mathcal{A}}\|_p$ for some $p \in [1, \infty]$, then J will satisfy the second part of the assumption. From a computational perspective, a natural choice for RKHS is to choose $p = 2$ and to define $J^2(Q) = \sum_{a \in \mathcal{A}} \|Q(\cdot, a)\|_{\mathcal{H}_a}^2$ for \mathcal{H} being the RKHS defined on \mathcal{X} .

Assumption A4 (Capacity of Function Space) For $R > 0$, let $\mathcal{F}_R = \{f \in \mathcal{F} : J(f) \leq R\}$. There exist constants $C > 0$ and $0 < \alpha < 1$ such that for any $u, R > 0$ the following metric entropy condition is satisfied:

$$\log \mathcal{N}_\infty(u, \mathcal{F}_R) \leq C \left(\frac{R}{u} \right)^{2\alpha}.$$

This assumption characterizes the capacity of the ball with radius R in \mathcal{F} . The value of α is an essential quantity in our upper bounds. The metric entropy is precisely defined in Appendix G, but roughly speaking it is the logarithm of the minimum number of balls with radius u that are required to completely cover a ball with radius R in \mathcal{F} . This is a measure of complexity of a function space as it is more difficult to estimate a function when the metric entropy grows fast when u decreases. As a simple example, when the function space is finite, we effectively need to have good estimate of $|\mathcal{F}|$ functions in order not to choose the wrong one. In this case, $\mathcal{N}_\infty(u, \mathcal{F}_R)$ can be replaced by $|\mathcal{F}|$, so $\alpha = 0$ and $C = \log |\mathcal{F}|$. When the state space \mathcal{X} is finite and all functions are bounded by Q_{\max} , we have $\log \mathcal{N}_\infty(u, \mathcal{F}_R) \leq \log \mathcal{N}_\infty(u, \mathcal{F}) = |\mathcal{X}| \log \left(\frac{2Q_{\max}}{u} \right)$. This shows that the metric entropy for problems with finite state spaces grows much slower than what we consider here. Assumption A4 is suitable for large function spaces and is indeed satisfied for the Sobolev spaces and various RKHS. Refer to van de Geer (2000); Zhou (2002, 2003); Steinwart and Christmann (2008) for many examples.

An alternative assumption would be to have a similar metric entropy for the balls in $\mathcal{F}^{\mathcal{A}}$ (instead of \mathcal{F}). This would slightly change a few steps of the proofs, but leave the results essentially the same. Moreover, it makes the requirement that $J(Q(\cdot, a)) \leq J(Q)$ in Assumption A3 unnecessary. Nevertheless, as results on the capacity of \mathcal{F} is more common in the statistical learning theory literature, we stick to the combination of Assumptions A3 and A4.

The metric entropy here is defined w.r.t. the supremum norm. All proofs, except that of Lemma 23, only require the same bound to hold when the supremum norm is replaced by the more relaxed empirical L_2 -norm, i.e., those results require that there exist constants $C > 0$ and $0 < \alpha < 1$ such that for any $u, R > 0$ and all $x_1, \dots, x_n \in \mathcal{X}$, we have $\log \mathcal{N}_2(u, \mathcal{F}_R, x_{1:n}) \leq C \left(\frac{R}{u} \right)^{2\alpha}$. Of course, the metric entropy w.r.t. the supremum norm implies the one with the empirical norm. It is an interesting question to relax the supremum norm assumption in Lemma 23.

We can now remark on the requirement that \mathcal{X} is compact (Assumption A1). We stated that requirement mainly because most of the metric entropy results in the literature are for compact spaces (one exception is Theorem 7.34 of Steinwart and Christmann (2008), which relaxes the compactness requirement by adding some assumptions on the tail of $\nu_{\mathcal{X}}$ on \mathcal{X}).

So we could remove the compactness requirement from Assumption A1 and implicitly let Assumption A4 satisfy it, but we preferred to be explicit about it at the cost of a bit of redundancy in our set of assumptions.

Assumption A5 (Function Space Boundedness) The subset $\mathcal{F}^{|\mathcal{A}|} \subset B(\mathcal{X} \times \mathcal{A}; Q_{\max})$ is a separable and complete Carathéodory set with $R_{\max} \leq Q_{\max} < \infty$.

Assumption A5 requires all the functions in $\mathcal{F}^{|\mathcal{A}|}$ to be bounded so that the solutions of optimization problems (15)-(16) stay bounded. If they are not, they should be truncated, and thus, the truncation argument should be used in the analysis, see e.g., the proof of Theorem 21.1 of Györfi et al. (2002). The truncation argument does not change the final result, but complicates the proof at several places, so we stick to the above assumption to avoid unnecessary clutter. Moreover, in order to avoid the measurability issues resulting from taking supremum over an uncountable function space $\mathcal{F}^{|\mathcal{A}|}$, we require the space to be a separable and complete Carathéodory set (cf. Section 7.3 of Steinwart and Christmann 2008).

Assumption A6 (Function Approximation Property) The action-value function of any policy π belongs to $\mathcal{F}^{|\mathcal{A}|}$, i.e., $Q^\pi \in \mathcal{F}^{|\mathcal{A}|}$.

This “no function approximation error” assumption is standard in analyzing regularization-based nonparametric methods. This assumption is realistic and is satisfied for rich function spaces such as RKHS defined by universal kernels, e.g., Gaussian or exponential kernels (Section 4.6 of Steinwart and Christmann 2008). On the other hand, if the space is not large enough, we might have function approximation error. The behavior of the function approximation error for certain classes of “small” RKHS has been discussed by Smale and Zhou (2003); Steinwart and Christmann (2008). We stick to this assumption to simplify many key steps in the proofs.

Assumption A7 (Expansion of Smoothness) For all $Q \in \mathcal{F}^{|\mathcal{A}|}$, there exist constants $0 \leq L_R, L_P < \infty$, depending only on the MDP and $\mathcal{F}^{|\mathcal{A}|}$, such that for policy π ,

$$J(T^\pi Q) \leq L_R + \gamma L_P J(Q).$$

We require that the complexity of $T^\pi Q$ to be comparable to the complexity of Q itself. In other words, we require that if Q is smooth according to the regularizer J of a function space $\mathcal{F}^{|\mathcal{A}|}$, it stays smooth after the application of the Bellman operator. We believe that this is a reasonable assumption for many classes of MDPs with “sufficient” stochasticity and when $\mathcal{F}^{|\mathcal{A}|}$ is rich enough. The intuition is that if the Bellman operator has a “smoothing” effect, the norm of $T^\pi Q$ does not blow up and the function can still be represented well within $\mathcal{F}^{|\mathcal{A}|}$. Proposition 25 in Appendix F presents the conditions that for the so-called *convolutional* MDPs, Assumption A7 is satisfied. Briefly speaking, the conditions are 1) the transition probability kernel should have a finite gain (in the control-theoretic sense) in its frequency response, and 2) the reward function should be smooth according to the regularizer J . Of course, this is only an example of the class of problems for which this assumption holds.

5.1 Policy Evaluation Error

In this section, we focus on the k^{th} iteration of REG-LSPI. To simplify the notation, we use $\mathcal{D}_n = \{(Z_t, R_t, X_t)\}_{t=1}^n$ to refer to $\mathcal{D}_n^{(k)}$. The policy π_k depends on data used in the earlier iterations, but since we use independent set of samples $\mathcal{D}_n^{(k)}$ for the k^{th} iteration and π_k is independent of $\mathcal{D}_n^{(k)}$, we can safely ignore the randomness of π_k by working on the probability space obtained by conditioning on $\mathcal{D}_n^{(0)}, \dots, \mathcal{D}_n^{(k-1)}$, i.e., the probability space used in the k^{th} iteration is $(\Omega, \sigma_{\Omega}, \mathbb{P}_k)$ with $\mathbb{P}_k = \mathbb{P} \left\{ \cdot \mid \mathcal{D}_n^{(0)}, \dots, \mathcal{D}_n^{(k-1)} \right\}$. In order to avoid clutter, we do not use the conditional probability symbol. In the rest of this section, π refers to a $\sigma(\mathcal{D}_n^{(0)}, \dots, \mathcal{D}_n^{(k-1)})$ -measurable policy and is independent of \mathcal{D}_n ; \hat{Q} and $\hat{h}_n(\cdot) = \hat{h}_n(\cdot; Q)$ refer to the solution to (15)-(16) when $\pi, \lambda_{h,n}$, and $\lambda_{Q,n}$ replace $\pi_k, \lambda_{h,n}$, and $\lambda_{Q,n}$ in that set of equations, respectively.

The following theorem is the main result of this section and provides an upper bound on the statistical behavior of the policy evaluation procedure REG-LSTD.

Theorem 11 (Policy Evaluation) For any fixed policy π , let \hat{Q} be the solution to the optimization problem (15)-(16) with the choice of

$$\lambda_{h,n} = \lambda_{Q,n} = \left[\frac{1}{n J^2(Q^\pi)} \right]^{\frac{1}{1+\alpha}}.$$

If Assumptions A1-A7 hold, there exists $c(\delta) > 0$ such that for any $n \in \mathbb{N}$ and $0 < \delta < 1$, we have

$$\|\hat{Q} - T^\pi \hat{Q}\|_{\nu}^2 \leq c(\delta) n^{-\frac{1}{1+\alpha}},$$

with probability at least $1 - \delta$. Here $c(\delta)$ is equal to

$$c(\delta) = c_1 (1 + (\gamma L_P)^2) J^{\frac{2\alpha}{1+\alpha}}(Q^\pi) \ln(1/\delta) + c_2 \left(L_R^{\frac{2\alpha}{1+\alpha}} + \frac{L_R^2}{[J(Q^\pi)]^{\frac{2\alpha}{1+\alpha}}} \right),$$

for some constants $c_1, c_2 > 0$.

Theorem 11, which is proven in Appendix B, indicates how the number of samples and the difficulty of the problem as characterized by $J(Q^\pi)$, L_P , and L_R influence the policy evaluation error.¹³

This upper bound provides some insights about the behavior of the REG-LSTD algorithm. To begin with, it shows that under the specified conditions, REG-LSTD is a consistent algorithm: As the number of samples increases, the Bellman error decreases and asymptotically converges to zero. This is due to the use of a nonparametric function space and the proper control of its complexity through regularization. A parametric function space, e.g., a linear function approximator with a fixed number of features, does not generally have a similar guarantee unless the value function happens to belong to the span of the features. Achieving consistency for parametric function spaces requires careful choice

13. Without loss of generality and for simplicity we assumed that $J(Q^\pi) > 0$.

of features, and might be difficult. On the other hand, a rich enough nonparametric function space, for example one defined by a universal kernel (cf. Assumption A6), ensures the consistency of the policy evaluation algorithm.

This theorem, however, is much more powerful than a consistency result as it provides a finite-sample upper bound guarantee for the error, too. If the parameters of the REG-LSTD algorithm are selected properly, one may achieve the sample complexity upper bound of $O(n^{-1/(1+\alpha)})$. For the case of the Sobolev space $\mathbb{W}^k(\mathcal{X})$ with \mathcal{X} being an open Euclidean ball in \mathbb{R}^d and $k > d/2$, one may choose $\alpha = d/2k$ to obtain the error upper bound of $O(n^{-d/(2k+d)})$.¹⁴

To study the upper bound a bit closer, let us focus on the special case of $\gamma = 0$. For this choice of the discount factor, $T^\pi Q$ is equal to r^π and $(T^\pi Q)(X_i, A_i)$ is equal to R_i . One can see that the policy evaluation problem becomes a regression problem with the regression function r^π . The guarantee of this theorem would be then on $\|\hat{Q} - T^\pi Q\|_2^2 = \|\hat{Q} - r^\pi\|_2^2$, which is the usual squared error in the regression literature. Hence we reduced a regression problem to a policy evaluation problem. Because of this reduction, any lower bound on the regression would also be a lower bound on the policy evaluation problem.

It is well-known that the convergence rate of $n^{-d/(2k+d)}$ is asymptotically minimax optimal for the regression estimation for target functions belonging to the Sobolev space $\mathbb{W}^k(\mathcal{X})$ as well as some other smoothness classes with the k order of smoothness; cf. e.g., [Nussbaum \(1999\)](#) for the results for the Sobolev spaces, [Stone \(1982\)](#) for a closely related Hölder space $C^{p,\alpha}$, which with the choice of $k = p + \alpha$ ($k \in \mathbb{N}$ and $0 < \alpha \leq 1$) has the same rate, and [Tsybakov \(2009\)](#) for several results on minimax optimality of nonparametric estimators. More generally, the rate of $O(n^{-1/(1+\alpha)})$ is optimal too. For a regression function belonging to a function space \mathcal{F} with a packing entropy in the same form as in the upper bound of Assumption A4, the rate $\Omega(n^{-1/(1+\alpha)})$ is its minimax lower bound ([Yang and Barron, 1999](#)), making the upper bound optimal. Comparing these lower bounds with the upper bound $O(n^{-1/(1+\alpha)})$ (or $O(n^{-d/(2k+d)})$ for the Sobolev space) of this theorem indicates that REG-LSTD algorithm has the optimal error rate as a function of the number of samples n , which is a remarkable result.

Furthermore, to understand the fine behavior of the upper bound, beyond the dependence of the rate on n and α , we focus on the multiplicative term $c(\delta)$. Again we consider the special case of regression estimation as it is the only case we have some known lower bounds. With the choice of $\gamma = 0$, we have $\hat{Q}^\pi = r^\pi$, so $J(\hat{Q}^\pi) = J(r^\pi)$. Moreover, since $T^\pi Q = r^\pi + 0P^\pi Q = r^\pi$, we can choose $L_R = J(r^\pi)$ in Assumption A7. As a result $c(\delta) = c_1 J^{\frac{2\alpha}{1+\alpha}}(r^\pi) \ln(1/\delta)$ for a constant $c_1 > 0$. We are interested in studying the dependence of the upper bound on $J(r^\pi)$. We study its behavior when the function space is the Sobolev space $\mathbb{W}^k([0, 1])$ and $J(\cdot)$ is the corresponding Sobolev space norm. We choose $\alpha = 1/2k$ to get $J^{\frac{2\alpha}{1+\alpha}}(r^\pi)$ dependence of $c(\delta)$. On the other hand, for the regression estimation problem within the subset $\mathcal{F}_T^{\mathcal{A}} = \{Q(\cdot, a) \in \mathbb{W}^k([0, 1]) : J(Q) \leq J(r^\pi), \forall a \in \mathcal{A}\}$ of this Sobolev space, the fine behavior of the asymptotic minimax rate is determined by

the so-called Pinsker constant, whose dependence on J is in fact $J^{\frac{2\alpha}{1+\alpha}}(r^\pi)$, cf. e.g., [Nussbaum \(1999, 1985\)](#), [Golubov and Nussbaum \(1990\)](#), or Section 3.1 of [Tsybakov \(2009\)](#).¹⁵ Therefore, not only the exponent of the rate is optimal for this function space, but also its multiplicative dependence on the smoothness $J(r^\pi)$ is optimal.

For function spaces other than this choice of Sobolev space (i.e., the general case of α), we are not aware of any refined lower bound that indicates the optimality of $J^{\frac{2\alpha}{1+\alpha}}(r^\pi)$. We note that some available upper bounds for regression with comparable assumptions on the metric entropy have the same dependence on $J(r^\pi)$, e.g., [Steinwart et al. \(2009\)](#)¹⁶ or [Farahmand and Szepesvári \(2012\)](#), whose result is for the regression setting with exponential β -mixing input, but can also be shown for i.i.d. data. We conjecture that under our assumptions this dependence is optimal.

One may note that the proper selection of the regularization coefficients to achieve the optimal rate requires the knowledge of an unknown quantity $J(Q^\pi)$. This, however, is not a major concern as a proper model selection procedure finds parameters that result in a performance which is almost the same as the optimal performance. We comment on this issue in more detail in Section 6.

The proof of this theorem requires several auxiliary results, which are presented in the appendices, but the main idea behind the proof is as follows. Since $\|\hat{Q} - T^\pi Q\|_2^2 \leq 2\|\hat{Q} - \hat{h}_n(\cdot; \hat{Q})\|_2^2 + 2\|\hat{h}_n(\cdot; \hat{Q}) - T^\pi \hat{Q}\|_2^2$, we may upper bound the Bellman error by upper bounding each term in the right-hand side (RHS). One can see that for a fixed \hat{Q} , the optimization problem (15) essentially solves a regularized least-squares regression problem, which leads to small value of $\|\hat{h}_n(\cdot; \hat{Q}) - T^\pi \hat{Q}\|_2$, when there are enough samples and under proper conditions. The relation of the optimization problem (16) with $\|\hat{Q} - \hat{h}_n(\cdot; \hat{Q})\|_2$ is evident too. The difficulty, however, is that these two optimization problems are coupled: $\hat{h}_n(\cdot; \hat{Q})$ is a function of \hat{Q} which itself is a function of $\hat{h}_n(\cdot; \hat{Q})$. Thus, \hat{Q} appearing in (15) is not fixed, but is a random function \hat{Q} . The same is true for the other optimization problem as well. The coupling of the optimization problems makes the analysis more complicated than the usual supervised learning type of analysis. The dependencies between all the results that lead to the proof of Theorem 14 is depicted in Figure 2 in Appendix B.

In order to obtain fast convergence rates, we use concepts and techniques from the empirical process theory such as the peeling device, the chaining technique, and the modulus of continuity of the empirical process, cf. e.g., [van de Geer \(2000\)](#). By focusing on the behavior of the empirical process over local subsets of the function space, these techniques allow us to study the deviations of the process in a more refined way compared to a global approach that studies the supremum of the empirical process in the whole function space. These techniques are crucial to obtain a fast rate for large function spaces. We discuss them in more detail as we proceed in the proofs.

15. The Pinsker constant determines the effect of the noise variance too. We do not present such information in our bounds. Also note that most aforementioned results, except [Golubov and Nussbaum \(1990\)](#), consider a normal noise model, which is different from our bounded noise.

16. This is obtained by using Corollary 3 of [Steinwart et al. \(2009\)](#) after substituting $A_2(\lambda)$ by its upper bound $\lambda \|\cdot\|_{\mathcal{H}}^2$, which is valid whenever $f^* \in \mathcal{H}$, as is in our case. This result can be used after one converts the metric entropy condition to the condition on the decay rate of eigenvalues of a certain integral operator.

14. For examples of the metric entropy results for the Sobolev spaces, refer to Section A.5.6 alongside Lemma 6.21 of [Steinwart and Christmann \(2008\)](#), or Theorem 2.4 of [van de Geer \(2000\)](#) for $\mathcal{X} = [0, 1]$ or Lemma 20.6 of [Györfi et al. \(2002\)](#) for $\mathcal{X} = [0, 1]^d$. Also in this paper we use the notation $\mathbb{W}^k(\mathcal{X})$ to refer to $\mathbb{W}^{k,2}(\mathcal{X})$, the Sobolev space defined based on the L_2 -norm of the weak derivatives.

We mentioned earlier that one can actually reuse a single data set in all iterations. To keep the presentation more clear, we keep the current setup. The reason behind this can be explained better after the proof of Theorem 11. But note that from the convergence-rate point of view, the difference between reusing data or not is insignificant. If we have a batch of data with size n and we divide it into K chunks and only use one chunk per iteration of API, the rate would be $O\left(\left(\frac{n}{K}\right)^{-\frac{1}{1+\alpha}}\right)$. For finite K , or slowly growing K , this is essentially the same as $O\left(n^{-\frac{1}{1+\alpha}}\right)$.

5.2 Error Propagation in API

Consider an API algorithm that generates the sequence $\hat{Q}^{(0)} \rightarrow \pi_1 \rightarrow \hat{Q}^{(1)} \rightarrow \pi_2 \rightarrow \dots \rightarrow \hat{Q}^{(K-1)} \rightarrow \pi_K$, where π_k is the greedy policy w.r.t. $\hat{Q}^{(k-1)}$ and $\hat{Q}^{(k)}$ is the approximate action-value function for policy π_k . For the sequence $(\hat{Q}^{(k)})_{k=0}^{K-1}$, denote the Bellman Residual (BR) of the k^{th} action-value function by

$$\varepsilon_k^{\text{BR}} = \hat{Q}^{(k)} - T^{\pi_k} \hat{Q}^{(k)}. \quad (31)$$

The goal of this section is to study the effect of the ν -weighted L_2 -norm of the Bellman residual sequence $(\varepsilon_k^{\text{BR}})_{k=0}^{K-1}$ on the performance loss $\|Q^* - Q^{\pi_K}\|_{1,\rho}$ of the resulting policy π_K . Because of the dynamical nature of the MDP, the performance loss $\|Q^* - Q^{\pi_K}\|_{1,\rho}$ depends on the difference between the sampling distribution ν and the future state-action distribution in the form of $\rho P^{\pi_1} P^{\pi_2} \dots$. The precise form of this dependence is formalized in Theorem 13, which is a slight modification of a result by Farahmand et al. (2010).¹⁷

Before stating the results, we define the following *concentrability* coefficients that are used in a change of measure argument, see e.g., Munos (2007); Antos et al. (2008b); Farahmand et al. (2010).

Definition 12 (Expected Concentrability of Future State-Action Distributions)
Given the distributions $\rho, \nu \in \mathcal{M}(\mathcal{X} \times \mathcal{A})$, an integer $m \geq 0$, and an arbitrary sequence of stationary policies $(\pi_m)_{m \geq 1}$, let $\rho P^{\pi_1} P^{\pi_2} \dots P^{\pi_m} \in \mathcal{M}(\mathcal{X} \times \mathcal{A})$ denote the future state-action distribution obtained when the first state-action is distributed according to ρ and then we follow the sequence of policies $(\pi_k)_{k=1}^m$. Define the following *concentrability coefficients*:

$$c_{PI,\rho,\nu}(m_1, m_2; \pi) \triangleq \left(\mathbb{E} \left[\frac{d(\rho(P^{\pi^*})^{m_1}(P^\pi)^{m_2})}{d\nu} (X, A) \right] \right)^{\frac{1}{2}},$$

with $(X, A) \sim \nu$. If the future state-action distribution $\rho(P^{\pi^*})^{m_1}(P^\pi)^{m_2}$ is not absolutely continuous w.r.t. ν , then we take $c_{PI,\rho,\nu}(m_1, m_2; \pi) = \infty$.

In order to compactly present our results, we define the following notation:

$$a_k = \frac{(1-\gamma)\gamma^{K-k-1}}{1-\gamma^{K+1}}, \quad (0 \leq k < K) \quad (32)$$

17. The difference of these two results is in the way the norm of functions from the space $\mathcal{F}^{\mathcal{A}}$ is defined, which in turn corresponds to whether the distributions ν and ρ are defined over the state space \mathcal{X} , as Farahmand et al. (2010) defined, or over the state-action space $\mathcal{X} \times \mathcal{A}$, as we define here. These differences do not change the general form of the proof. See Theorem 3.2 in Chapter 3 of Farahmand (2011b) for the proof of the current result.

Theorem 13 (Error Propagation for API—Theorem 3 of Farahmand et al. 2010)
Let $p \geq 1$ be a real number, K be a positive integer, and $Q_{\max} \leq \frac{R_{\max}}{1-\gamma}$. Then for any sequence $(\hat{Q}^{(k)})_{k=0}^{K-1} \subset B(\mathcal{X} \times \mathcal{A}, Q_{\max})$ and the corresponding sequence $(\varepsilon_k^{\text{BR}})_{k=0}^{K-1}$ defined in (31), we have

$$\|Q^* - Q^{\pi_K}\|_{p,\rho} \leq \frac{2\gamma}{(1-\gamma)^2} \left[\inf_{r \in [0,1]} C_{PI,\rho,\nu}^{2r}(K; r) \mathcal{E}^{\frac{1}{2r}}(\varepsilon_0^{\text{BR}}, \dots, \varepsilon_{K-1}^{\text{BR}}; r) + \gamma^{\frac{K-1}{p}} R_{\max} \right],$$

where $\mathcal{E}(\varepsilon_0^{\text{BR}}, \dots, \varepsilon_{K-1}^{\text{BR}}; r) = \sum_{k=0}^{K-1} a_k^{2r} \|\varepsilon_k^{\text{BR}}\|_{2p,\nu}^{2r}$ and

$$C_{PI,\rho,\nu}(K; r) = \left(\frac{1-\gamma}{2} \right)^2 \sup_{\pi_0^*, \dots, \pi_{K-1}^*} \left[\sum_{m \geq 0} \gamma^m \left(c_{PI,\rho,\nu}(K-k-1, m+1; \pi_{k+1}^*) + c_{PI,\rho,\nu}(K-k, m; \pi_k^*) \right) \right]^2.$$

For better understanding of the intuition behind the error propagation results in general, refer to Munos (2007); Antos et al. (2008b); Farahmand et al. (2010). The significance of this particular theorem and the ways it improves previous similar error propagation results such as that of Antos et al. (2008b) (for API) and Munos (2007) (for AVI) is thoroughly discussed by Farahmand et al. (2010). We briefly comment on it in Section 5.3.

5.3 Performance Loss of REG-LSPI

In this section, we use the error propagation result (Theorem 13 in Section 5.2) together with the upper bound on the policy evaluation error (Theorem 11 in Section 5.1) to derive an upper bound on the performance loss $\|Q^* - Q^{\pi_K}\|_{1,\rho}$ of REG-LSPI. This is the main theoretical result of this work. Before stating the theorem, let us denote $\hat{\Pi}(\mathcal{F}^{\mathcal{A}})$ as the set of all policies that are greedy w.r.t. a member of $\mathcal{F}^{\mathcal{A}}$, i.e., $\hat{\Pi}(\mathcal{F}^{\mathcal{A}}) = \{\hat{\pi}(\cdot; Q) : Q \in \mathcal{F}^{\mathcal{A}}\}$.

Theorem 14 Let $(\hat{Q}^{(k)})_{k=0}^{K-1}$ be the solutions of the optimization problem (15)-(16) with the choice of

$$\lambda_{h,n}^{(k)} = \lambda_{Q,n}^{(k)} = \left[\frac{1}{nJ^2(Q^{\pi_k})} \right]^{\frac{1}{1+\alpha}}.$$

Let Assumptions A1-A5 hold; Assumptions A6 and A7 hold for any $\pi \in \hat{\Pi}(\mathcal{F}^{\mathcal{A}})$, and $\inf_{r \in [0,1]} C_{PI,\rho,\nu}(K; r) < \infty$. Then there exists $C_{LSPI}(\delta, K, \rho, \nu)$ such that for any $n \in \mathbb{N}$ and $0 < \delta < 1$, we have

$$\|Q^* - Q^{\pi_K}\|_{1,\rho} \leq \frac{2\gamma}{(1-\gamma)^2} \left[C_{LSPI}(\delta, K; \rho, \nu) n^{-\frac{1}{2(1+\alpha)}} + \gamma^{K-1} R_{\max} \right],$$

with probability at least $1 - \delta$.

In this theorem, the function $C_{LSPI}(\delta, K; \rho, \nu) = C_{LSPI}(\delta, K; \rho, \nu; L_R, L_P, \alpha, \beta, \gamma)$ is

$$C_{LSPI}(\delta, K; \rho, \nu; L_R, L_P, \alpha, \beta, \gamma) = C_1^{\frac{1}{2}}(\delta) \inf_{r \in [0,1]} \left\{ \left(\frac{1-\gamma}{1-\gamma^{K+1}} \right)^r \sqrt{\frac{1-(\gamma^{2r})^K}{1-\gamma^{2r}}} C_{PI,\rho,\nu}^{\frac{1}{2}}(K; r) \right\},$$

with $C_1(\delta)$ being defined as

$$C_1(\delta) = \sup_{\pi \in \Pi(\mathcal{F}^{1,4})} \left[c_1 (1 + (\gamma L_P)^2) J^{\frac{2\alpha}{1+\alpha}}(Q^\pi) \ln \left(\frac{K}{\delta} \right) + c_2 \left(L_R^{\frac{2\alpha}{1+\alpha}} + \frac{L_R^2}{[J(Q^\pi)]^{1+\alpha}} \right) \right],$$

in which $c_1, c_2 > 0$ are universal constants.

Proof Fix $0 < \delta < 1$. For each iteration $k = 0, \dots, K-1$, invoke Theorem 11 with the confidence parameter δ/k and take the supremum over all policies to upper bound the Bellman residual error $\|\varepsilon_k^{\text{BR}}\|_\nu$ as

$$\left\| \hat{Q}^{(k)} - T^{\pi_k} \hat{Q}^{(k)} \right\|_\nu^2 \leq \underbrace{\sup_{\pi \in \Pi(\mathcal{F}^{1,4})} c \left(J(Q^\pi), L_R, L_P, \alpha, \beta, \gamma, \frac{\delta}{K} \right)}_{\triangleq c'} n^{-\frac{1}{1+\alpha}},$$

which holds with probability at least $1 - \frac{\delta}{K}$. Here $c(\cdot)$ is defined as in Theorem 11. For any $r \in [0, 1]$, we have

$$\begin{aligned} \mathcal{E}(\varepsilon_0^{\text{BR}}, \dots, \varepsilon_{K-1}^{\text{BR}}; r) &= \sum_{k=0}^{K-1} \frac{2^r}{a_k} \|\varepsilon_k^{\text{BR}}\|_\nu^2 \leq c' n^{-\frac{1}{1+\alpha}} \sum_{k=0}^{K-1} a_k^{\frac{1}{2}} \\ &= c' n^{-\frac{1}{1+\alpha}} \left(\frac{1-\gamma}{1-\gamma^{K+1}} \right)^{2r} \frac{1-(\gamma^{2r})^K}{1-\gamma^{2r}}, \end{aligned}$$

where we used the definition of a_k (32). We then apply Theorem 13 with the choice of $p = 1$ to get that with probability at least $1 - \delta$, we have

$$\|Q^* - Q^{\pi_K}\|_{1,\rho} \leq \frac{2\gamma}{(1-\gamma)^2} \left[C_{\text{LSPI}}(\rho, \nu; K) n^{-\frac{1}{1+\alpha}} + \gamma^{K-1} R_{\max} \right].$$

Here

$$C_{\text{LSPI}}(\rho, \nu; K) = \sqrt{\sup_{\pi \in \Pi(\mathcal{F}^{1,4})} c \left(J(Q^\pi), L_R, L_P, \alpha, \gamma, \frac{\delta}{K} \right) \inf_{r \in [0,1]} \left\{ \left(\frac{1-\gamma}{1-\gamma^{K+1}} \right)^r \sqrt{\frac{1-(\gamma^{2r})^K}{1-\gamma^{2r}}} C_{\text{PI},\rho,\nu}^{\frac{1}{2}}(K; r) \right\}}.$$

■

Theorem 14 upper bounds the performance loss and relates it to the number of samples n , the capacity of the function space quantified by α , the number of iterations K , the concentrability coefficients, and some other properties of the MDP such as L_R, L_P , and γ .

This theorem indicates that the behavior of the upper bound as a function of the number of samples is $O(n^{-\frac{1}{2(1+\alpha)}})$. This upper bound is notable because of its minimax optimality, as discussed in detail after Theorem 11.

The term C_{LSPI} has two main components. The first is $C_{\text{PI},\rho,\nu}(\cdot; r)$, which describes the effect of the sampling distribution ν and the evaluation distribution ρ , as well as the

transition probability kernel of the MDP itself on the performance loss. This term has been thoroughly discussed by Farahmand et al. (2010), but briefly speaking it indicates that ν and ρ affect the performance through a weighted summation of $c_{\text{PI},\rho,\nu}$ (Definition 12). The concentrability coefficients $c_{\text{PI},\rho,\nu}$ is defined as the square root of the expected squared Radon-Nikodym of the future state-action distributions starting from ρ w.r.t. the sampling distribution ν . This may be much tighter compared to the previous results (e.g., Antos et al. 2008b) that depend on the *supremum* of the Radon-Nikodym derivative. One may also notice that Theorem 13 actually provides a stronger result than what is reported in Theorem 14: The effect of errors at earlier iterations on the performance loss is geometrically decayed. So one may potentially use a fewer number of samples in the earlier iterations of REG-LSPI (or any other API algorithm) to get the same guarantee on the performance loss. We ignore this effect to simplify the result.

The other important term is C_1 , which mainly describes the effect of L_R, L_P , and $\sup_{\pi \in \Pi(\mathcal{F}^{1,4})} J(Q^\pi)$ on the performance loss. These quantities depend on the MDP, as well as the function space $\mathcal{F}^{1,4}$. If the function space is “mismatched” with the MDP, these quantities would be small, otherwise they may even be infinity.

Note that C_1 provides an upper bound on the constant in front of REG-LSTD procedure by taking supremum over all policies in $\Pi(\mathcal{F}^{1,4})$. This might be a conservative estimate as the actual encountered policies are the rather restricted random sequence $\pi_0, \pi_1, \dots, \pi_{K-1}$ generated by the REG-LSPI procedure. One might expect that as the sequence $\hat{Q}^{(k-1)}$ converge to a neighbourhood of Q^* , the value function Q^{π_k} of the greedy policy $\pi_k = \hat{\pi}(\cdot; \hat{Q}^{(k-1)})$, which is the policy being evaluated, converges to a neighbourhood of Q^* too. Thus with certain assumptions, one might be able to show that its smoothness $J(Q^{\pi_k})$, the quantity that appears in the upper bound of Theorem 11, belongs to a neighbourhood of $J(Q^*)$. If $J(Q^*)$ is small, the value of $J(Q^{\pi_k})$ in that neighbourhood can be smaller than $\sup_{\pi \in \Pi(\mathcal{F}^{1,4})} J(Q^\pi)$. We postpone the analysis of this finer structure of the problem to future work.

Finally we note that the optimality of the error bound for the policy evaluation task, as shown by Theorem 11, does not necessarily imply that the REG-LSPI algorithm has the optimal sample complexity rate for the corresponding RL/Planning problem as well. The reason is that it is sufficient to get close to the optimal policy, which is the ultimate goal in RL/Planning, even though the estimate of the action-value function is still inaccurate. To act optimally, it is sufficient to have an action-value function whose greedy policy is the same as the optimal policy. This can happen even if there is some error in the estimated action-value function. This is called the *action-gap phenomenon* and has been analyzed in the reinforcement learning context by Farahmand (2011a).

5.3.1 COMPARISON WITH SIMILAR STATISTICAL GUARANTEES

Theorem 14 might be compared with the results of Antos et al. (2008b), who introduced a BRM-based API procedure and studied its statistical properties, Lazarevic et al. (2012), who analyzed LSPI with linear function approximators, Ávila Pires and Szepesvári (2012), who studied a regularized variant of LSTD, and Ghavamzadeh et al. (2011), who analyzed the statistical properties of Lasso-TD. Although these results address different algorithms, comparing them with the results of this work is insightful.

We first focus on [Antos et al. \(2008b\)](#). Their simplified upper bound for $\|Q^* - Q^{\pi_K}\|_{1,\rho}$ is $C_{\rho,\nu}^{1/2} \sqrt{V_{\mathcal{F}} \log(n) + \ln(K/\delta)} n^{-1/4}$, in which $V_{\mathcal{F}}$ is the “effective” dimension of \mathcal{F} and is defined based on the pseudo-dimension of sub-graphs of \mathcal{F} and the so-called “VC-crossing dimension” of \mathcal{F} ; and $C_{\rho,\nu}$ is a concentrability coefficient and plays a similar role to our $C_{\text{PI},\rho,\nu}(K; r)$. In contrast, our simplified upper bound is $C_{\text{LSP1}}(\delta) n^{-\frac{1}{2(1+\tau)}}$, in which $C_{\text{LSP1}}(\delta)$ can roughly be factored into $C_{\text{PI},\rho,\nu}^{\frac{1}{2}}(K; r) C_1(J(Q^r), L_R, L_P) \sqrt{\ln(K/\delta)}$.

One important difference between these two results is that [Antos et al. \(2008b\)](#) considered parametric function spaces, which have finite effective dimension $V_{\mathcal{F}}$, while this work considers nonparametric function spaces, which essentially are infinite dimensional. The way they use the parametric function space assumption is equivalent to assuming that $\log M_1(u, \mathcal{F}, x_{1:n}) \leq V_{\mathcal{F}} \log(\frac{1}{u})$ as opposed to $\log \mathcal{N}_{\infty}(u, \mathcal{F}_B, x_{1:n}) \leq C \left(\frac{B}{u}\right)^{2\alpha}$ of [Assumption A4](#). Our assumption lets us describe the capacity of infinite dimensional function spaces \mathcal{F} . Disregarding this crucial difference, one may also note that our upper bound’s dependence on the number of samples (i.e., $O(n^{-\frac{1}{2(1+\tau)}}$) is much faster than theirs (i.e., $O(n^{-1/4})$). This is more noticeable when we apply our result to a finite dimensional function space, which can be done by letting $\alpha \rightarrow 0$ at a certain rate, to recover the error upper bound of $n^{-1/2}$.¹⁸ This improvement is mainly because of more advanced techniques used in our analysis, i.e., the relative deviation tail inequality and the peeling device in this work in contrast with the uniform deviation inequality of [Antos et al. \(2008b\)](#).

The other difference is in the definition of concentrability coefficients ($C_{\text{PI},\rho,\nu}(K)$ vs. $C_{\rho,\nu}$). In [Definition 12](#), we use the expectation of Radon-Nikodym derivative of two distributions while their definition uses the supremum of a similar quantity. This can be a significant improvement in the multiplicative constant of the upper bound. For more information regarding this improvement, which can be used to improve the result of [Antos et al. \(2008b\)](#) too, refer to [Farahmand et al. \(2010\)](#).

[Lazaric et al. \(2012\)](#) analyzed unregularized LSTD/LSPI specialized for linear function approximators with finite number of basis functions (parametric setting). Their rate of $O(n^{-1/2})$ for $\|V^* - V^{\pi_K}\|_{2,\rho}$ is faster than the rate in the work of [Antos et al. \(2008b\)](#), and is comparable to our rate for $\|Q^* - Q^{\pi_K}\|_{1,\rho}$ when $\alpha \rightarrow 0$. The difference of their work with ours is that they focus on a parametric class of function approximators as opposed to the nonparametric class in this work. Moreover, because they formulate the LSTD as a fixed-point problem, in contrast to this work and that of [Antos et al. \(2008b\)](#), their algorithm and results are only applicable to on-policy sampling scenario.

[Ávila Pires and Szepesvári \(2012\)](#) studied a regularized version of LSTD in the parametric setting that works for both on-policy and off-policy sampling. Beside the difference between the class of function spaces with this work (parametric vs. nonparametric), another algorithmic difference is that they only use a regularizer for the projected Bellman error term, similar to [\(16\)](#), as opposed to using regularizers in both terms of REG-LSTD [\(15\)-\(16\)](#) (cf. [Section 4.1](#)). Also the weight used in their loss function, the matrix M in their paper, is not necessarily the one induced by data. Their result indicates $O(n^{-1/2})$ for the projected Bellman error, which is comparable, though with some subtle differences, to [Lazaric et al.](#)

18. For problems with finite state space, we have $\log \mathcal{N}_{\infty}(u, \mathcal{F}_B) \leq |\mathcal{X}| \log(\frac{Q_{\max}}{u})$, so with a similar $\alpha \rightarrow 0$ argument, we get $O(n^{-1/2})$ error upper bound (disregarding the logarithmic terms).

[\(2012\)](#). It is remarkable that they separate the error bound analysis to deterministic and probabilistic parts. In the deterministic part, they use perturbation analysis to relate the loss to the error in the estimation of certain parameters used by the algorithms. In the probabilistic part, they provide upper bounds on the error in estimation of the parameters. We conjecture that their proof technique, even though simple and elegant, cannot easily be extended to provide the right convergence rate for large function spaces because the current analysis is based on a uniform bound on the error of a noisy matrix. Providing a tight uniform bound for a matrix (or operator) for large state spaces might be difficult or impossible to achieve.

[Ghavamzadeh et al. \(2011\)](#) analyzed Lasso-TD, a policy evaluation algorithm that uses linear function approximators and enforces sparsity by the l_1 -regularization, and provided error upper bounds w.r.t. the empirical measure (or what they call Markov design). Their error upper bound is $O(\|w^*\|_1^2 \log(p))^{1/4} n^{-1/4}$, where w^* is the weight vector describing the projection of Q^{π^*} onto the span of p basis functions. With some extra assumptions on the Gramian of the basis functions, they obtain faster rate of $O(\sqrt{\|w^*\|_0 \log(p)} n^{-1/2})$. These results indicate that by using the sparsity-inducing regularizer, the dependence of the error bound on the number of features becomes logarithmic.

We conjecture that if one uses REG-LSTD with a linear function space (similar to [Section 4.2.1](#)) with $J^2(h) = \|h\|_1$ and $J^2(Q) = \|w\|_1$, the current analysis leads to the error upper bound $O(\|w^*\|_1^{1/2} n^{-1/4})$ with a logarithmic dependence on p . This result might be obtained using [Corollary 5 of Zhang \(2002\)](#) as [Assumption A4](#). To get a faster rate of $O(n^{-1/2})$, one should make extra assumptions on the Gramian—as was done by [Ghavamzadeh et al. \(2011\)](#). We should emphasize that even with the choice of linear function approximators and the l_1 -regularization, REG-LSTD would not be the same algorithm as Lasso-TD since REG-LSTD uses regularization in both optimization problems [\(15\)-\(16\)](#). Also note that the error upper bound of [Ghavamzadeh et al. \(2011\)](#) is on the empirical norm $\|\cdot\|_{2,\mathcal{D}_n}$ as opposed to the norm $\|\cdot\|_{2,\nu}$, which is w.r.t. the measure ν . This means that their result does not provide a generalization upper bound on the quality of the estimated value function over the whole state space, but provides an upper bound only on the training data.

Comparing this work with its conference version ([Farahmand et al., 2009b](#)), we observe that the main difference in the theoretical guarantees is that the current results are for more general function spaces than the Sobolev spaces considered in the conference paper. [Assumption A4](#) specifies the requirement on the capacity of the function space, which is satisfied not only by the Sobolev spaces (with the choice of $\alpha = d/2k$ for $\mathbb{W}^k(\mathcal{X})$ with \mathcal{X} being an open Euclidean ball in \mathbb{R}^d and $k > d/2$; cf. [Section A.5.6](#) alongside [Lemma 6.21 of Steinwart and Christmann \(2008\)](#), or [Theorem 2.4 of van de Geer \(2000\)](#) for $\mathcal{X} = [0, 1]$ or [Lemma 20.6 of Györfi et al. \(2002\)](#) for $\mathcal{X} = [0, 1]^d$), but also many other large function spaces including several commonly-used RKHS.

6. Conclusion and Future Work

We introduced two regularization-based API algorithms, namely REG-LSPI and REG-BRM, to solve RL/Planning problems with large state spaces. Our formulation was general and could incorporate many types of function spaces and regularizers. We specifically showed how these algorithms can be implemented efficiently when the function space is the

span of a finite number of basis functions (parametric model) or an RKHS (nonparametric model).

We then focused on the statistical properties of REG-LSPI and provided its performance loss upper bound (Theorem 14). The error bound demonstrated the role of the sample size, the complexity of function space to which the action-value function belongs (quantified by its metric entropy in Assumption A4), and the intrinsic properties of the MDP such as the behavior of concentrability coefficients and the smoothness-expansion property of the Bellman operator (Definition 12 and Assumption A7). The result indicated that the dependence on the sample size for the task of policy evaluation is optimal.

This work (and its conference (Farahmand et al., 2009b) and the dissertation (Farahmand, 2011b)) versions alongside the work on the Regularized Fitted Q-Iteration algorithm (Farahmand et al., 2008, 2009a) are the first that address the statistical performance of a *regularized* RL algorithm. Nevertheless, there have been a few other work that also used regularization for RL/Planning problems, most often without analyzing their statistical properties.

Jung and Polani (2006) studied adding regularization to BRM, but their solution is restricted to deterministic problems. The main contribution of that work was the development of fast incremental algorithms using the *sparsification* technique. The l_1 -regularization has been considered by Loh et al. (2007), who were similarly concerned with incremental implementations and computational efficiency. Xu et al. (2007) provided a kernel-based, but not regularized, formulation of LSPI. They used sparsification to provide basis functions for the LSTD procedure. Sparsification leads to a selection of only a subset of data points to be used as the basis functions, thus indirectly controls the complexity of the resulting function space. This should be contrasted with a regularization-based approach in which the regularizer interacts with the empirical loss to jointly determine the subset of the function space to which the estimate belongs.

Koller and Ng (2009) formulated an l_1 -regularization fixed-point formulation LSTD, which is called Lasso-TD by Ghavamzadeh et al. (2011), and provided LARS-like algorithm (Efron et al., 2004) to compute the solutions. Johns et al. (2010) considered the same fixed-point formulation and cast it as a linear complementarity problem. The statistical properties of this l_1 -regularized fixed-point formulation is studied by Ghavamzadeh et al. (2011), as discussed earlier. Lasso-TD has a fixed-point formulation, which looks different from our coupled optimization formulation (15)-(16), but under on-policy sampling scenario, it is equivalent to a particular version of REG-LSTD: If we choose a fixed linear function approximator (parametric), use the l_1 -norm in the projection optimization problem (15), but do not regularize optimization problem (16) (i.e., $\lambda_{Q,n} = 0$), we get Lasso-TD. Geist and Scherrer (2012) suggested a different algorithm where the projection is not regularized (i.e., $\lambda_{h,n} = 0$), but the optimization problem (16) is regularized with the l_1 -norm of the parameter weights. The choice of only regularizing (16) is the same as the one in the algorithm introduced and analyzed by Avila Pires and Szepesvári (2012), except that the latter work uses the l_2 -norm. Hofmann et al. (2012) introduced an algorithm similar to that of Geist and Scherrer (2012) with the difference that the projection optimization (15) uses the l_2 -norm (so it is a mixed l_1/l_2 -regularized algorithm). All these algorithms are parametric. Several TD-based algorithms and their regularized variants are discussed in a survey by Dann et al. (2014).

Taylor and Parr (2009) unified several kernelized reinforcement learning algorithms, and showed the equivalence of kernelized value function approximators such as GP-TD (Engel et al., 2005), the work of Xu et al. (2007), and a few other methods with a model-based reinforcement learning algorithm that has certain regularization on the transition kernel estimator, reward estimator, or both. Their result was obtained by considering two separate regularized regression problems: One that predicts the reward function given the current state and the other that predicts the next-state kernel values given the current-state ones. Their formulation is different from our formulation that is stated as a coupled optimization problem in an RKHS.
