We consider first the case in which all the black-box functions f, c_1, \dots, c_K are evaluated at the same time (coupled). Let $\mathbb{H}[\mathbf{x}_*|\mathcal{D}]$ denote the differential entropy of $p(\mathbf{x}_*|\mathcal{D})$ and let $y_f, y_{c_1}, \dots, y_{c_K}$ denote the measurements obtained by querying the black-boxes for f, c_1, \dots, c_K at the input location \mathbf{x} . We encode these measurements in vector form as $\mathbf{y} = (y_f, y_{c_1}, \dots, y_{c_K})^T$. Note that \mathbf{y} contains the result of the evaluation of all the functions at \mathbf{x} , that is, the objective f and the constraints c_1, \dots, c_K . We aim to collect data at the location that maximizes the expected information gain or the expected reduction in the entropy of $p(\mathbf{x}_*|\mathcal{D})$. The corresponding acquisition function is

$$\alpha(\mathbf{x}) = \mathbb{H}[\mathbf{x}_*|\mathcal{D}] - \mathbb{E}_{\mathbf{y}|\mathcal{D}, \mathbf{x}}[\mathbb{H}[\mathbf{x}_*|\mathcal{D} \cup \{(\mathbf{x}, \mathbf{y})\}]]. \quad (7)$$

In this expression, $\mathbb{H}[\mathbf{x}_*|\mathcal{D} \cup \{(\mathbf{x}, \mathbf{y})\}]$ is the amount of information on \mathbf{x}_* that is available once we have collected new data \mathbf{y} at the input location \mathbf{x} . However, this new \mathbf{y} is unknown because it has not been collected yet. To circumvent this problem, we take the expectation with respect to the predictive distribution for \mathbf{y} given \mathbf{x} and \mathcal{D} . This produces an expression that does not depend on \mathbf{y} and could in principle be readily computed.

A direct computation of Eq. (7) is challenging because it requires evaluating the entropy of the intractable distribution $p(\mathbf{x}_*|\mathcal{D})$ when different pairs (\mathbf{x}, \mathbf{y}) are added to the data. To simplify computations, we note that Eq. (7) is the mutual information between \mathbf{x}_* and \mathbf{y} given \mathcal{D} and \mathbf{x} , which we denote by $\text{MI}(\mathbf{x}_*, \mathbf{y})$. The mutual information operator is symmetric, that is, $\text{MI}(\mathbf{x}_*, \mathbf{y}) = \text{MI}(\mathbf{y}, \mathbf{x}_*)$. Therefore, we can follow Houthby et al. (2012) and swap the random variables \mathbf{y} and \mathbf{x}_* in Eq. (7). The result is a reformulation of the original equation that is now expressed in terms of entropies of predictive distributions, which are easier to approximate:

$$\alpha(\mathbf{x}) = \mathbb{H}[\mathbf{y}|\mathcal{D}, \mathbf{x}] - \mathbb{E}_{\mathbf{x}_*|\mathcal{D}}[\mathbb{H}[\mathbf{y}|\mathcal{D}, \mathbf{x}, \mathbf{x}_*]]. \quad (8)$$

This is the same reformulation used by Predictive Entropy Search (PES) (Hernández-Lobato et al., 2014) for unconstrained Bayesian optimization, but extended to the case where \mathbf{y} is a vector rather than a scalar. Since we focus on constrained optimization problems, we call our method Predictive Entropy Search with Constraints (PESC). Eq. (8) is used by PESC to efficiently solve constrained Bayesian optimization problems with decoupled function evaluations. In the following section we describe how to obtain a computationally efficient approximation to Eq. (8). We also show that the resulting approximation is separable.

4.1 The PESC Acquisition Function

We assume that the functions f, c_1, \dots, c_K are independent samples from Gaussian process (GP) priors and that the noisy measurements \mathbf{y} returned by the black-boxes are obtained by adding Gaussian noise to the noise-free function evaluations at \mathbf{x} . Under this Bayesian model for the data, the first term in Eq. (8) can be computed exactly. In particular,

$$\mathbb{H}[\mathbf{y}|\mathcal{D}, \mathbf{x}] = \sum_{i=1}^{K+1} \frac{1}{2} \log \sigma_i^2(\mathbf{x}) + \frac{K+1}{2} \log(2\pi\epsilon), \quad (9)$$

where $\sigma_i^2(\mathbf{x})$ is the predictive variance for y_i at \mathbf{x} and y_i is the i -th entry in \mathbf{y} . To obtain this formula we have used the fact that f, c_1, \dots, c_K are generated independently, so that $\mathbb{H}[\mathbf{y}|\mathcal{D}, \mathbf{x}] = \sum_{i=1}^{K+1} \mathbb{H}[y_i|\mathcal{D}, \mathbf{x}]$, and that $p(y_i|\mathcal{D}, \mathbf{x})$ is Gaussian with variance parameter $\sigma_i^2(\mathbf{x})$ given by the GP predictive variance (Rasmussen and Williams, 2006):

$$\sigma_i^2(\mathbf{x}) = k_i(\mathbf{x}) - \mathbf{k}_i(\mathbf{x})^T \mathbf{K}_i^{-1} \mathbf{k}_i(\mathbf{x}) + \nu_i, \quad i = 1, \dots, K+1, \quad (10)$$

where ν_i is the variance of the additive Gaussian noise in the i -th black-box, with f being the first one and c_K the last one. The scalar $k_i(\mathbf{x})$ is the prior variance of the noise-free black-box evaluations at \mathbf{x} . The vector $\mathbf{k}_i(\mathbf{x})$ contains the prior covariances between the black-box values at \mathbf{x} and at those locations for which data from the black-box is available. Finally, \mathbf{K}_i is a matrix with the prior covariances for the noise-free black-box evaluations at those locations for which data is available.

The second term in Eq. (8), that is, $\mathbb{E}_{\mathbf{x}_*|\mathcal{D}}[\mathbb{H}[\mathbf{y}|\mathcal{D}, \mathbf{x}, \mathbf{x}_*]]$, cannot be computed exactly and needs to be approximated. We do this operation as follows. ①: The expectation with respect to $p(\mathbf{x}_*|\mathcal{D})$ is approximated with an empirical average over M samples drawn from $p(\mathbf{x}_*|\mathcal{D})$. These samples are generated by following the approach proposed by Hernández-Lobato et al. (2014) for sampling \mathbf{x}_* in the unconstrained case. We draw approximate posterior samples of f, c_1, \dots, c_K , as described by Hernández-Lobato et al. (2014, Appendix A), and then solve Eq. (1) to obtain \mathbf{x}_* given the sampled functions. More details can be found in Appendix B.3 of this document. Note that this approach only applies for stationary kernels, but this class includes popular choices such as the squared exponential and Matérn kernels. ②: We assume that the components of \mathbf{y} are independent given \mathcal{D} , \mathbf{x} and \mathbf{x}_* , that is, we assume that the evaluations of f, c_1, \dots, c_K at \mathbf{x} are independent given \mathcal{D} and \mathbf{x}_* . This factorization assumption guarantees that the acquisition function used by PESC is additive across the different functions that are being evaluated. ③: Let \mathbf{x}_j^* be the j -th sample from $p(\mathbf{x}_*|\mathcal{D})$. We then find a Gaussian approximation to each $p(y_i|\mathcal{D}, \mathbf{x}, \mathbf{x}_j^*)$ using expectation propagation (EP) (Minka, 2001a). Let $\sigma_i^2(\mathbf{x}|\mathbf{x}_j^*)$ be the variance of the Gaussian

approximation to $p(y_i | \mathcal{D}, \mathbf{x}, \mathbf{x}_i^j)$ given by EP. Then, we obtain

$$\begin{aligned} \mathbb{E}_{\mathbf{x}_* | \mathcal{D}} [\mathbb{H}[y_i | \mathcal{D}, \mathbf{x}, \mathbf{x}_*]] &\stackrel{\textcircled{1}}{\approx} \frac{1}{M} \sum_{j=1}^M \mathbb{H}[y_i | \mathcal{D}, \mathbf{x}, \mathbf{x}_*^j] \stackrel{\textcircled{2}}{\approx} \frac{1}{M} \sum_{j=1}^M \left[\sum_{i=1}^{K+1} \mathbb{H}[y_i | \mathcal{D}, \mathbf{x}, \mathbf{x}_*^j] \right] \\ &\stackrel{\textcircled{3}}{\approx} \sum_{i=1}^{K+1} \left\{ \frac{1}{M} \sum_{j=1}^M \frac{1}{2} \log \sigma_i^2(\mathbf{x} | \mathbf{x}_*^j) \right\} + \frac{K+1}{2} \log(2\pi e), \end{aligned} \quad (11)$$

where each of the approximations has been numbered with the corresponding step from the description above. Note that in step $\textcircled{3}$ of Eq. (11) we have swapped the sums over i and j .

The acquisition function used by PESC is then given by the difference between Eq. (9) and the approximation shown in the last line of Eq. (11). In particular, we obtain

$$\alpha_{\text{PESC}}(\mathbf{x}) = \sum_{i=1}^{K+1} \tilde{\alpha}_i(\mathbf{x}), \quad (12)$$

where

$$\tilde{\alpha}_i(\mathbf{x}) = \frac{1}{M} \sum_{j=1}^M \underbrace{\frac{1}{2} \log \sigma_i^2(\mathbf{x}) - \frac{1}{2} \log \sigma_i^2(\mathbf{x} | \mathbf{x}_*^j)}_{\tilde{\alpha}_i(\mathbf{x} | \mathbf{x}_*^j)}, \quad i = 1, \dots, K+1. \quad (13)$$

Interestingly, the factorization assumption that we made in step $\textcircled{2}$ of Eq. (11) has produced an acquisition function in Eq. (12) that is the sum of $K+1$ function-specific acquisition functions, given by the $\tilde{\alpha}_i(\mathbf{x})$ in Eq. (13). Each $\tilde{\alpha}_i(\mathbf{x})$ measures how much information we gain on average by only evaluating the i -th black box, where the first black-box evaluates f and the last one evaluates c_{K+1} . Furthermore, $\tilde{\alpha}_i(\mathbf{x})$ is the empirical average of $\tilde{\alpha}_i(\mathbf{x} | \mathbf{x}_*^j)$ across M samples from $p(\mathbf{x}_* | \mathcal{D})$. Therefore, we can interpret each $\tilde{\alpha}_i(\mathbf{x} | \mathbf{x}_*^j)$ in Eq. (13) as a function-specific acquisition function conditioned on \mathbf{x}_* . Crucially, by using bits of information about the minimizer as a common unit of measurement, our acquisition function can make meaningful comparisons between the usefulness of evaluating the objective and constraints.

We now show how PESC can be used to obtain the task-specific acquisition functions required by the general algorithm from Section 3.3. Let us assume that we plan to evaluate only a subset of the functions f, c_1, \dots, c_K and let $t \subseteq \{1, \dots, K+1\}$ contain the indices of the functions to be evaluated, where the first function is f and the last one is c_K . We assume that the functions indexed by t are coupled and require joint evaluation. In this case t encodes a *task* according to the definition from Section 3.2. We can then approximate the expected gain of information that is obtained by evaluating this task at input \mathbf{x} . The process is similar to the one used above when all the black-boxes are evaluated at the same time. However, instead of working with the full vector \mathbf{y} , we now work with the components of \mathbf{y} indexed by t . One can then show that the expected information gain obtained after evaluating task t at input \mathbf{x} can be approximated as

$$\alpha_t(\mathbf{x}) = \sum_{i \in t} \tilde{\alpha}_i(\mathbf{x}), \quad (14)$$

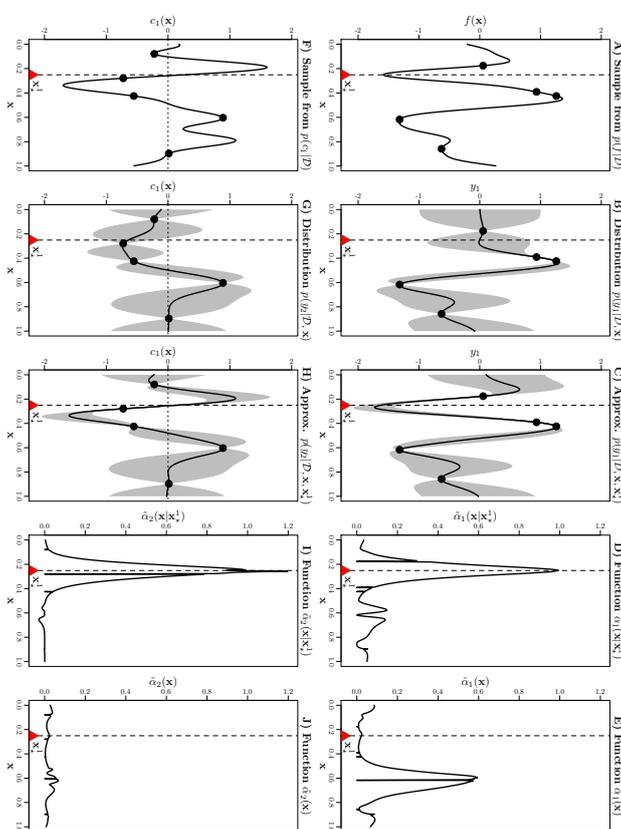

Figure 2: Illustration of the process followed to compute the function-specific acquisition functions given by Eq. (13). See the main text for details.

where the $\tilde{\alpha}_i$ are given by Eq. (13). PESC’s acquisition function is therefore separable since Eq. (14) can be used to obtain an acquisition function for each possible task. The process for constructing these task-specific acquisition functions is also efficient since it requires only to use the individual acquisition functions from Eq. (13) as building blocks. These two properties make PESC an effective solution for the practical implementation of the general algorithm from Section 3.3.

Fig. 2 illustrates with a toy example the process for computing the function-specific acquisition functions from Eq. (13). In this example there is only one constraint function. Therefore, the functions in the optimization problem are only f and c_1 . The search space \mathcal{X} is the unit interval $[0, 1]$ and we have collected four measurements for each function. The data for f are shown as black points in panels A, B and C. The data for c_1 are shown as black points in panels F, G and H. We assume that f and c_1 are independently sampled from a GP with zero mean function and squared exponential covariance function with unit amplitude and length-scale 0.07. The noise variance for the black-boxes that evaluate f and c_1 is zero. Let y_1 and y_2 be the black-box evaluations for f and c_1 at input \mathbf{x} . Under the assumed GP model we can analytically compute the predictive distributions for y_1 and

y_2 , that is, $p(y_1|\mathcal{D}, \mathbf{x})$ and $p(y_2|\mathcal{D}, \mathbf{x})$. Panels B and G show the means of these distributions with confidence bands equal to one standard deviation. The first step to compute the $\tilde{\alpha}_i(\mathbf{x})$ from Eq. (13) is to draw M samples from $p(\mathbf{x}_*|\mathcal{D})$. To generate each of these samples, we first approximately sample f and c_1 from their posterior distributions $p(f|\mathcal{D})$ and $p(c_1|\mathcal{D})$ using the method described by Hernández-Lobato et al. (2014, Appendix A). Panels A and F show one of the samples obtained for f and c_1 , respectively. We then solve the optimization problem given by Eq. (1) when f and c_1 are known and equal to the samples obtained. The solution to this problem is the input that minimizes f subject to c_1 being positive. This produces a sample \mathbf{x}_*^1 from $p(\mathbf{x}_*|\mathcal{D})$ which is shown as a discontinuous vertical line with a red triangle in all the panels. The next step is to find a Gaussian approximation to the predictive distributions when we condition to \mathbf{x}_*^1 , that is, $p(y_1|\mathcal{D}, \mathbf{x}, \mathbf{x}_*^1)$ and $p(y_2|\mathcal{D}, \mathbf{x}, \mathbf{x}_*^1)$. This step is performed using expectation propagation (EP) as described in Section 4.2 and Appendix A. Panels C and H show the approximations produced by EP for $p(y_1|\mathcal{D}, \mathbf{x}, \mathbf{x}_*^1)$ and $p(y_2|\mathcal{D}, \mathbf{x}, \mathbf{x}_*^1)$, respectively. Panel C shows that conditioning to \mathbf{x}_*^1 decreases the posterior mean of y_1 in the neighborhood of \mathbf{x}_*^1 . The reason for this is that \mathbf{x}_*^1 must be the global feasible solution and this means that $f(\mathbf{x}_*^1)$ must be lower than any other feasible point. Panel H shows that conditioning to \mathbf{x}_*^1 increases the posterior mean of y_2 in the neighborhood of \mathbf{x}_*^1 . The reason for this is that $c_1(\mathbf{x}_*^1)$ must be positive because \mathbf{x}_*^1 has to be feasible. In particular, by conditioning to \mathbf{x}_*^1 we are giving zero probability to all c_1 such that $c_1(\mathbf{x}_*^1) < 0$. Let $\sigma_1^2(\mathbf{x}|\mathbf{x}_*^1)$ and $\sigma_2^2(\mathbf{x}|\mathbf{x}_*^1)$ be the variances of the Gaussian approximations to $p(y_1|\mathcal{D}, \mathbf{x}, \mathbf{x}_*^1)$ and $p(y_2|\mathcal{D}, \mathbf{x}, \mathbf{x}_*^1)$ and let $\sigma_1^2(\mathbf{x})$ and $\sigma_2^2(\mathbf{x})$ be the variances of $p(y_1|\mathcal{D}, \mathbf{x})$ and $p(y_2|\mathcal{D}, \mathbf{x})$. We use these quantities to obtain $\hat{\alpha}_1(\mathbf{x}|\mathbf{x}_*^1)$ and $\hat{\alpha}_2(\mathbf{x}|\mathbf{x}_*^1)$ according to Eq. (13). These two functions are shown in panels D and I. The whole process is repeated $M = 50$ times and the resulting $\hat{\alpha}_1(\mathbf{x}|\mathbf{x}_*^j)$ and $\hat{\alpha}_2(\mathbf{x}|\mathbf{x}_*^j)$, $j = 1, \dots, M$, are averaged according to Eq. (13) to obtain the function-specific acquisition functions $\hat{\alpha}_1(\mathbf{x})$ and $\hat{\alpha}_2(\mathbf{x})$, whose plots are shown in panels E and J. These plots indicate that evaluating the objective f is in this case more informative than evaluating the constraint c_1 . But this is certainly not always the case, as will be demonstrated in the experiments later on.

4.2 How to Compute the Gaussian Approximation to $p(y_i|\mathcal{D}, \mathbf{x}, \mathbf{x}_*^j)$

We briefly describe the process followed to find a Gaussian approximation to $p(y_i|\mathcal{D}, \mathbf{x}, \mathbf{x}_*^j)$ using expectation propagation (EP) (Minka, 2001b). Recall that the variance of this approximation, that is, $\sigma_i^2(\mathbf{x}|\mathbf{x}_*^j)$, is used to compute $\hat{\alpha}_i(\mathbf{x}|\mathbf{x}_*^j)$ in Eq. (13). Here we only provide a sketch of the process; full details can be found in Appendix A.

We start by assuming that the search space has finite size, that is, $\mathcal{X} = \{\tilde{\mathbf{x}}_1, \dots, \tilde{\mathbf{x}}_{|\mathcal{X}|}\}$. In this case the functions f , c_1, \dots, c_K are encoded as finite dimensional vectors denoted by \mathbf{f} , $\mathbf{c}_1, \dots, \mathbf{c}_K$. The i -th entries in these vectors are the result of evaluating f , c_1, \dots, c_K at the i -th element of \mathcal{X} , that is, $f(\tilde{\mathbf{x}}_i)$, $c_1(\tilde{\mathbf{x}}_i), \dots, c_K(\tilde{\mathbf{x}}_i)$. Let us assume that \mathbf{x}_*^j and \mathbf{x} are in \mathcal{X} . Then $p(\mathbf{y}|\mathcal{D}, \mathbf{x}, \mathbf{x}_*^j)$ can be defined by the following rejection sampling process. First, we sample \mathbf{f} , $\mathbf{c}_1, \dots, \mathbf{c}_K$ from their posterior distribution given the assumed GP models. We then solve the optimization problem given by Eq. (1). For this, we find the entry of \mathbf{f} with lowest value subject to the corresponding entries of $\mathbf{c}_1, \dots, \mathbf{c}_K$ being positive. Let $i \in \{1, \dots, |\mathcal{X}|\}$ be the index of the selected entry. Then, if $\mathbf{x}_*^j \neq \tilde{\mathbf{x}}_i$, we reject the sampled \mathbf{f} , $\mathbf{c}_1, \dots, \mathbf{c}_K$ and start again. Otherwise, we take the entries of \mathbf{f} , $\mathbf{c}_1, \dots, \mathbf{c}_K$

indexed by \mathbf{x} , that is, $f(\mathbf{x})$, $c_1(\mathbf{x}), \dots, c_K(\mathbf{x})$ and then obtain \mathbf{y} by adding to each of these values a Gaussian random variable with zero mean and variance ν_1, \dots, ν_{K+1} , respectively. The probability distribution implied by this rejection sampling process can be obtained by first multiplying the posterior for \mathbf{f} , $\mathbf{c}_1, \dots, \mathbf{c}_K$ with indicator functions that take value zero when \mathbf{f} , $\mathbf{c}_1, \dots, \mathbf{c}_K$ should be rejected and one otherwise. We can then multiply the resulting quantity by the likelihood for \mathbf{y} given \mathbf{f} , $\mathbf{c}_1, \dots, \mathbf{c}_K$. The desired distribution is finally obtained by marginalizing out \mathbf{f} , $\mathbf{c}_1, \dots, \mathbf{c}_K$.

We introduce several indicator functions to implement the approach described above. The first one $\Gamma(\mathbf{x})$ takes value one when \mathbf{x} is a feasible solution and value zero otherwise, that is,

$$\Gamma(\mathbf{x}) = \prod_{k=1}^K \Theta[c_k(\mathbf{x})], \quad (15)$$

where $\Theta[\cdot]$ is the Heaviside step function which is equal to one if its input is non-negative and zero otherwise. The second indicator function $\Psi(\mathbf{x})$ takes value zero if \mathbf{x} is a better solution than \mathbf{x}_*^j according to the sampled functions. Otherwise $\Psi(\mathbf{x})$ takes value one. In particular,

$$\Psi(\mathbf{x}) = \Gamma(\mathbf{x})[\Theta[f(\mathbf{x}) - f(\mathbf{x}_*^j)] + (1 - \Gamma(\mathbf{x}))]. \quad (16)$$

When \mathbf{x} is infeasible, this expression takes value one. In this case, \mathbf{x} is not a better solution than \mathbf{x}_*^j (because \mathbf{x} is infeasible) and we do not have to reject. When \mathbf{x} is feasible, the factor $\Theta[f(\mathbf{x}) - f(\mathbf{x}_*^j)]$ in Eq. (16) is zero when \mathbf{x} takes lower objective value than \mathbf{x}_*^j . This will allow us to reject \mathbf{f} , $\mathbf{c}_1, \dots, \mathbf{c}_K$ when \mathbf{x} is a better solution than \mathbf{x}_*^j . Using Eq. (15) and Eq. (16), we can then write $p(\mathbf{y}|\mathcal{D}, \mathbf{x}, \mathbf{x}_*^j)$ as

$$p(\mathbf{y}|\mathcal{D}, \mathbf{x}, \mathbf{x}_*^j) \propto \underbrace{p(\mathbf{y}|\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K, \mathbf{x}) p(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K|\mathcal{D}) \Gamma(\mathbf{x}_*^j)}_{f(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K|\mathbf{x}_*^j)} \left\{ \prod_{\mathbf{x}' \in \mathcal{X}} \Psi(\mathbf{x}') \right\} df d\mathbf{c}_1 \dots d\mathbf{c}_K, \quad (17)$$

where $p(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K|\mathcal{D})$ is the GP posterior distribution for the noise-free evaluations of f , c_1, \dots, c_K at \mathcal{X} and $p(\mathbf{y}|\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K, \mathbf{x})$ is the likelihood function, that is, the distribution of the noisy evaluations produced by the black-boxes with input \mathbf{x} given the true function values:

$$p(\mathbf{y}|\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K, \mathbf{x}) = \mathcal{N}(y_1|f(\mathbf{x}), \nu_1) \mathcal{N}(y_2|c_1(\mathbf{x}), \nu_2) \dots \mathcal{N}(y_{K+1}|c_K(\mathbf{x}), \nu_{K+1}). \quad (18)$$

The product of the indicator functions Γ and Ψ in Eq. (17) takes value zero whenever \mathbf{x}_*^j is not the best feasible solution according to $\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K$. The indicator Γ in Eq. (17) guarantees that \mathbf{x}_*^j is a feasible location. The product of all the Ψ in Eq. (17) guarantees that no other point in \mathcal{X} is better than \mathbf{x}_*^j . Therefore, the product of Γ and the Ψ in Eq. (17) rejects any value of $\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K$ for which \mathbf{x}_*^j is not the optimal solution to the constrained optimization problem.

The factors $p(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K|\mathcal{D})$ and $p(\mathbf{y}|\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K, \mathbf{x})$ in Eq. (17) are Gaussian. Thus, their product is also Gaussian and tractable. However, the integral in Eq. (17) does not

have a closed form solution because of the complexity introduced by the the product of indicator functions Γ and Ψ . This means that Eq. (17) cannot be exactly computed and has to be approximated. For this, we use EP to fit a Gaussian approximation to the product of $p(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K | \mathcal{D})$ and the indicator functions Γ and Ψ in Eq. (17), which we have denoted by $f(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K | \mathbf{x}_i^j)$, with a tractable Gaussian distribution given by

$$q(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K | \mathbf{x}_i^j) = \mathcal{N}(\mathbf{f} | \mathbf{m}_1, \mathbf{V}_1) \mathcal{N}(\mathbf{c}_1 | \mathbf{m}_2, \mathbf{V}_2) \dots \mathcal{N}(\mathbf{c}_K | \mathbf{m}_{K+1}, \mathbf{V}_{K+1}), \quad (19)$$

where $\mathbf{m}_1, \dots, \mathbf{m}_{K+1}$ and $\mathbf{V}_1, \dots, \mathbf{V}_{K+1}$ are mean vectors and covariance matrices to be determined by the execution of EP. Let $v_i(\mathbf{x})$ be the diagonal entry of \mathbf{V}_i corresponding to the evaluation location given by \mathbf{x} , where $i = 1, \dots, K+1$. Similarly, let $m_i(\mathbf{x})$ be the entry of \mathbf{m}_i corresponding to the evaluation location \mathbf{x} for $i = 1, \dots, K+1$. Then, by replacing $f(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K | \mathbf{x}_i^j)$ in Eq. (17) with $q(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K | \mathbf{x}_i^j)$, we obtain

$$p(\mathcal{Y} | \mathcal{D}, \mathbf{x}, \mathbf{x}_i^j) \approx \prod_{k=1}^{K+1} \mathcal{N}(y_k | m_k(\mathbf{x}), v_k(\mathbf{x}) + v_k). \quad (20)$$

Consequently, $\sigma_k^2(\mathbf{x} | \mathbf{x}_i^j) = v_k(\mathbf{x}) + v_k$ can be used to compute $\tilde{\alpha}_k(\mathbf{x} | \mathbf{x}_i^j)$ in Eq. (13).

The previous approach does not work when the search space \mathcal{X} has infinite size, for example when $\mathcal{X} = [0, 1]^d$ with d being the dimension of the inputs to f, c_1, \dots, c_K . In this case the product of indicators in Eq. (17) includes an infinite number of factors $\Psi(\mathbf{x}^i)$, one for each possible $\mathbf{x}^i \in \mathcal{X}$. To solve this problem we perform an additional approximation. For the computation of Eq. (17), we consider that \mathcal{X} is well approximated by the finite set \mathcal{Z} , which contains only the locations at which the objective f has been evaluated so far, the value of \mathbf{x}_i^j and \mathbf{x} . Therefore, we approximate the factor $\prod_{\mathbf{x}^i \in \mathcal{X}} \Psi(\mathbf{x}^i)$ in Eq. (17) with the factor $\prod_{\mathbf{x}^i \in \mathcal{Z}} \Psi(\mathbf{x}^i)$, which has now finite size. We expect this approximation to become more and more accurate as we increase the amount of data collected for f . Note that our approximation to \mathcal{X} is finite, but it is also different for each location \mathbf{x} at which we want to evaluate Eq. (17) since \mathcal{Z} is defined to contain \mathbf{x} . A detailed description of the resulting EP algorithm, indicating how to compute the variance functions $v_k(\mathbf{x})$ shown in Eq. (20), is given in Appendix A.

The EP approximation to Eq. (20), performed after replacing \mathcal{X} with \mathcal{Z} , depends on the values of \mathcal{D} , \mathbf{x}_i^j and \mathbf{x} . Having to re-run EP for each value of \mathbf{x} at which we may want to evaluate the acquisition function given by Eq. (12) is a very expensive operation. To avoid this, we split the EP computations between those that depend only on \mathcal{D} and \mathbf{x}_i^j , which are the most expensive ones, and those that depend only on the value of \mathbf{x} . We perform the former computations only once and then reuse them for each different value of \mathbf{x} . This allows us to evaluate the EP approximation to Eq. (17) at different values of \mathbf{x} in a computationally efficient way. See Appendix A for further details.

4.3 Efficient Marginalization of the Model Hyper-parameters

So far we have assumed to know the optimal hyper-parameter values; that is, the amplitude and the length-scales for the GPs and the noise variances for the black-boxes. However, in practice, the hyper-parameter values are unknown and have to be estimated from data. This can be done for example by drawing samples from the posterior distribution of the

hyper-parameters under some non-informative prior. Ideally, we should then average the GP predictive distributions with respect to the generated samples before approximating the information gain. However, this approach is too computationally expensive in practice. Instead, we follow Snoek et al. (2012) and average the PESC acquisition function with respect to the generated hyper-parameter samples. In our case, this involves marginalizing each of the function-specific acquisition functions from Eq. (13). For this, we follow the method proposed by Hernández-Lobato et al. (2014) to average the acquisition function of Predictive Entropy Search in the unconstrained case. Let Θ denote the model hyper-parameters. First, we draw M samples $\Theta^1, \dots, \Theta^M$ from the posterior distribution of Θ given the data \mathcal{D} . Typically, for each of the posterior samples Θ^j of Θ we draw a single corresponding sample \mathbf{x}_i^j from the posterior distribution of \mathbf{x}_* given Θ^j , that is, $p(\mathbf{x}_* | \mathcal{D}, \Theta^j)$. Let $\sigma_k^2(\mathbf{x} | \Theta^j)$ be the variance of the GP predictive distribution for y_i when the hyper-parameter values are fixed to Θ^j , that is, $p(y_i | \mathcal{D}, \mathbf{x}, \Theta^j)$, and let $\sigma_k^2(\mathbf{x} | \mathbf{x}_i^j, \Theta^j)$ be the variance of the Gaussian approximation to the predictive distribution for y_i when we condition to the solution of the optimization problem being \mathbf{x}_i^j and the hyper-parameter values being Θ^j . Then, the version of Eq. (13) that marginalizes out the model hyper-parameters is given by

$$\tilde{\alpha}_k(\mathbf{x}) = \frac{1}{M} \sum_{j=1}^M \left\{ \frac{1}{2} \log \sigma_k^2(\mathbf{x} | \Theta^j) - \frac{1}{2} \log \sigma_k^2(\mathbf{x} | \mathbf{x}_i^j, \Theta^j) \right\}, \quad i = 1, \dots, K+1. \quad (21)$$

Note that j is now an index over joint posterior samples of the model hyper-parameters Θ and the constrained minimizer \mathbf{x}_* . Therefore, we can marginalize out the hyper-parameter values without adding any additional computational complexity to our method because a loop over M samples of \mathbf{x}_* is just replaced with a loop over M joint samples of (Θ, \mathbf{x}_*) . This is a consequence of our reformulation of Eq. (7) into Eq. (8). By contrast, other techniques that work by approximating the original form of the acquisition function used in Eq. (7) do not have this property. An example in the unconstrained setting is Entropy Search (Hennig and Schuler, 2012), which requires re-computing an approximation to the acquisition function for each hyper-parameter sample Θ^j .

4.4 Computational Complexity

In the coupled setting, the complexity of PESC is $\mathcal{O}(MK^2N^3)$, where M is the number of posterior samples of the global constrained minimizer \mathbf{x}_* , K is the number of constraints, and N is the number of collected data points. This cost is determined by the cost of each EP iteration, which requires computing the inverse of the covariance matrices $\mathbf{V}_1, \dots, \mathbf{V}_{K+1}$ in Eq. (20). The dimensionality of each of these matrices grows with the size of \mathcal{Z} , which is determined by the number N of objective evaluations (see the last paragraph of Section 4.2). Therefore each EP iteration has cost $\mathcal{O}(KN^3)$ and we have to run an instance of EP for each of the M samples of \mathbf{x}_* . If M is also the number of posterior samples for the GP hyperparameters, as explained in Section 4.3, this is the same computational complexity as in EIC. However, in practice PESC is slower than EIC because of the cost of running multiple iterations of the EP algorithm.

In the decoupled setting the cost of PESC is $\mathcal{O}(M \sum_{k=2}^{K+1} (N_1 + N_k)^3)$ where N_1 is the number of evaluations of the objective and N_k is the number of evaluations for constraint

$k-1$. The origin of this cost is again the size of the matrices $\mathbf{V}_1, \dots, \mathbf{V}_{k+1}$ in Eq. (20). While \mathbf{V}_1 still scales as a function of $|\mathcal{Z}|$, we have that $\mathbf{V}_2, \dots, \mathbf{V}_{k+1}$ scale now as a function of $|\mathcal{Z}|$ plus the number of observations for the corresponding constraint function. The reason for this is that $\prod_{\mathbf{x}' \in \mathcal{Z}} \Psi(\mathbf{x}')$ is used to approximate $\prod_{\mathbf{x}' \in \mathcal{X}} \Psi(\mathbf{x}')$ in Eq. (17) and each factor in $\prod_{\mathbf{x}' \in \mathcal{Z}} \Psi(\mathbf{x}')$ represents then a virtual data point for each GP. See Appendix A for details.

The cost of sampling the GP hyper-parameters is $\mathcal{O}(MKN^3)$ and therefore, it does not affect the overall computational complexity of PESC.

4.5 Relationship between PESC and PES

PESC can be applied to unconstrained optimization problems. For this we only have to set $K=0$ and ignore the constraints. The resulting technique is very similar to the method PES proposed by Hernández-Lobato et al. (2014) as an information-based approach for unconstrained Bayesian optimization. However, PESC without constraints and PES are not identical. PES approximates $p(y|\mathcal{D}, \mathbf{x}, \mathbf{x}_k^*)$ by multiplying the GP predictive distribution by additional factors that enforce \mathbf{x}_k^* to be the location with lowest objective value. These factors guarantee that 1) the value of the objective at \mathbf{x}_k^* is lower than the minimum of the values for the objective collected so far, 2) the gradient of the objective is zero at \mathbf{x}_k^* and 3) the Hessian of the objective is positive definite at \mathbf{x}_k^* . We do not enforce the last two conditions since the global optimum may be on the boundary of a feasible region and thus conditions 2) and 3) do not necessarily hold (this issue also arises in PES because the optimum may be on the boundary of the search space \mathcal{X}). Condition 1) is implemented in PES by taking the minimum observed value for the objective, denoted by η , and then imposing the soft condition $f(\mathbf{x}_k^*) < \eta + \epsilon$, where $\epsilon \sim \mathcal{N}(0, \nu)$ accounts for the additive Gaussian noise with variance ν in the black-box that evaluates the objective. In PESC this is achieved in a more principled way by using the indicator functions given by Eq. (16).

4.6 Summary of the Approximations Made in PESC

We describe here all the approximations performed in the practical implementation of PESC. PESC approximates the expected reduction in the posterior entropy of \mathbf{x}_* (see Eq. 7) with the acquisition function given by Eq. (12). This involves the following approximations:

1. The expectation over \mathbf{x}_* in Eq. (8) is approximated with Monte Carlo sampling.
2. The Monte Carlo samples of \mathbf{x}_* come from samples of f, c_1, \dots, c_K drawn approximately using a finite basis function approximation to the GP covariance function, as described by Hernández-Lobato et al. (2014, Appendix A).
3. We approximate the factor $\prod_{\mathbf{x}' \in \mathcal{X}} \Psi(\mathbf{x}')$ in Eq. (17) with the factor $\prod_{\mathbf{x}' \in \mathcal{Z}} \Psi(\mathbf{x}')$. Unlike the original search space \mathcal{X} , \mathcal{Z} has now finite size and the corresponding product of Ψ indicators is easier to approximate. The set \mathcal{Z} is formed by the locations of the current observations for the objective f and the current evaluation location \mathbf{x} of the acquisition function.
4. After replacing $\prod_{\mathbf{x}' \in \mathcal{X}} \Psi(\mathbf{x}')$ with $\prod_{\mathbf{x}' \in \mathcal{Z}} \Psi(\mathbf{x}')$ in Eq. (17), we further approximate the factor $f(\mathbf{f}, c_1, \dots, c_K; \mathbf{x}_k^*)$ in this equation with the Gaussian approximation given

by the right-hand-side of Eq. (20). We use the method expectation propagation (EP) for this task, as described in Appendix A. Because the EP approximation in Eq. (19) factorizes across $\mathbf{f}, c_1, \dots, c_K$, the execution of EP implicitly includes the factorization assumption performed in step ② of Eq. (11).

5. As described in the last paragraph of Section 4.2, in the execution of EP we separate the computations that depend on \mathcal{D} and \mathbf{x}_k^* , which are very expensive, from those that depend on the location \mathbf{x} at which the PESC acquisition function will be evaluated. This allows us to evaluate the approximation to Eq. (17) at different values of \mathbf{x} in a computationally efficient way.
6. To deal with unknown hyper-parameter values, we marginalize the acquisition function over posterior samples of the hyper-parameters. Ideally, we should instead marginalize the predictive distributions with respect to the hyper-parameters before computing the entropy, but this is too computationally expensive in practice.

In Section 6.1, we assess the accuracy of these approximations (except the last one) and show that PESC performs on par with a ground-truth method based on rejection sampling.

Note that in addition to the mathematical approximations described above, additional sources of error are introduced by the numerical computations involved. In addition to the usual roundoff error, etc., we draw the reader's attention to the fact that the \mathbf{x}_* samples are the result of numerical global optimization of the approximately drawn samples of f, c_1, \dots, c_K , and then the suggestion is chosen by another numerical global optimization of the acquisition function. At present, we do not have guarantees that the true global optimum is found by our numerical methods in each case.

5. PESC-F: Speeding Up the BO Computations

One disadvantage of PESC is that sampling \mathbf{x}_* and then computing the corresponding EP approximation can be slow. If PESC is slow with respect to the evaluation of the black-box functions f, c_1, \dots, c_K , the entire Bayesian optimization (BO) procedure may be inefficient. For the BO approach to be useful, the time spent doing meta-computations has to be significantly shorter than the time spent actually evaluating the objective and constraints. This issue can be avoided in the coupled case by, for example, switching to a faster acquisition function like EIC or abandoning BO entirely for methods such as the popular CMA-ES (Hansen and Ostermeier, 1996) evolutionary strategy. However, in the decoupling setting, one can encounter problems in which some tasks are fast and others are slow. In this case, a cumbersome BO method might be undesirable because it would be unreasonable to spend minutes making a decision about a task that only takes seconds to complete; and, yet, a method that is fast but inefficient in terms of function evaluations would be ill-suited to making decisions about a task that takes hours complete. This situation calls for an optimization algorithm that can adaptively adjust its own decision-making time. For this reason, we introduce additional approximations in the computations made by PESC to reduce their cost when necessary. The new method that adaptively switches between fast and slow decision-making computations is called PESC-F. The two main challenges are how to speed up the original computations made by PESC and how to

decide when to switch between the slow and the fast versions of those computations. In the following paragraphs we address these issues.

We propose ways to reduce the cost of the computations performed by PESC after collecting each new data point. These computations include

1. Drawing posterior samples of the GP hyper-parameters and then for each sample computing the Cholesky decomposition of the kernel matrix.
2. Drawing approximate posterior samples of \mathbf{x}_* and then running an EP algorithm for each of these samples.
3. Globally maximizing the resulting acquisition functions.

We shorten each of these steps. First, we reduce the cost of step 1 by skipping the sampling of the GP hyper-parameters and instead considering the hyper-parameter samples already used at an earlier iteration. This also allows for additional speedups by using fast ($\mathcal{O}(N^2)$) updates of the Cholesky decomposition of the kernel matrix instead of recomputing it from scratch. Second, we shorten step 2 by skipping the sampling of \mathbf{x}_* and instead considering the samples used at the previous iteration. We also reuse the EP solutions computed at the previous iteration (see Appendix A for further details on how to reuse the EP solutions). Finally, we shorten step 3 by using a coarser termination condition tolerance when maximizing the acquisition function. This allows the optimization process to converge faster but with reduced precision. Furthermore, if the acquisition function is maximized using a local optimizer with random restarts and/or a grid initialization, we can shorten the computation further by reducing the number of restarts and/or grid size.

5.1 Choosing When to Run the Fast or the Slow Version

The motivation for PESC-F is that the time spent in the BO computations should be small compared to the time spent evaluating the black-box functions. Therefore, our approach is to switch between two distinct types of BO computations: the full (slow) and the partial (fast) PESC computations. Our goal is to approximately keep constant the fraction of total wall-clock time consumed by such computations. To achieve this, at each iteration of the BO process, we use the slow version of the computations if and only if

$$\frac{\tau_{\text{now}} - \tau_{\text{last}}}{\tau_{\text{slow}}} > \gamma, \quad (22)$$

where τ_{now} is the current time, τ_{last} is the time at which the last slow BO computations were complete, τ_{slow} is the duration of the last execution of the slow BO computations (this includes the time passed since the actual collection of the data until the maximization of the acquisition function) and $\gamma > 0$ is a constant called the rationality level. The larger the value of γ , the larger the amount of time spent in rational decision making, that is, in performing BO computations. Algorithm 2 shows the steps taken by PESC-F for the decoupled competitive case. In this case each function f, c_1, \dots, c_K represents a different task, that is, the different functions can be evaluated in a decoupled manner and in addition to this, all of them compete for using a single computational resource.

One could replace τ_{slow} with an average over the durations of past slow computations. While this approach is less noisy, we opt for using only the duration of the most recent

Algorithm 2 PESC-F for competitive decoupled functions.

- 1: **Inputs:** $\mathcal{T} = \{f, \{c_1, \dots, c_K\}, \mathcal{D}, \gamma, \delta$.
 - 2: $\tau_{\text{last}} \leftarrow 0$
 - 3: $\tau_{\text{slow}} \leftarrow 0$
 - 4: **repeat**
 - 5: $\tau_{\text{now}} \leftarrow$ current time
 - 6: **if** $(\tau_{\text{now}} - \tau_{\text{last}})/\tau_{\text{slow}} > \gamma$ **then**
 - 7: Sample GP hyper-parameters
 - 8: Fit GP to \mathcal{D}
 - 9: Generate new samples of \mathbf{x}_*
 - 10: Compute the EP solutions from scratch
 - 11: $\tau_{\text{slow}} \leftarrow$ current time $- \tau_{\text{now}}$
 - 12: $\tau_{\text{last}} \leftarrow$ current time
 - 13: $\{\mathbf{x}^*, t^*\} \leftarrow \arg \max_{\mathbf{x} \in \mathcal{X}, t \in \mathcal{T}} \alpha_t(\mathbf{x})$ (expensive optimization)
 - 14: **else**
 - 15: Update fit of GP to \mathcal{D}
 - 16: Reuse previous EP solutions
 - 17: $\{\mathbf{x}^*, t^*\} \leftarrow \arg \max_{\mathbf{x} \in \mathcal{X}, t \in \mathcal{T}} \alpha_t(\mathbf{x})$ (cheap optimization)
 - 18: **end if**
 - 19: Add to \mathcal{D} the evaluation of the function in task t^* at input \mathbf{x}^*
 - 20: **until** termination condition is met
 - 21: **Output:** $\arg \min_{\mathbf{x} \in \mathcal{X}} \text{EGr}[f(\mathbf{x})]$ s.t. $p(c_1(\mathbf{x})) \geq 0, \dots, c_K(\mathbf{x}) \geq 0, \text{GP} \geq 1 - \delta$
-

slow update since these durations may exhibit deterministic trends. For example, the cost of computations tends to increase at each iteration due to the increase in data set size. If indeed the update duration increases monotonically, then the duration of the most recent update would be a more accurate estimate of the duration of the next slow update than the average duration of all past updates.

PESC-F can be used as a generalization of PESC, since it reduces to PESC in the case of sufficiently slow function evaluations. To see this, note that the time spent in a function evaluation will be upper bounded by $\tau_{\text{now}} - \tau_{\text{last}}$ and according to Eq. (22), the slow computations are performed when $\tau_{\text{now}} - \tau_{\text{last}} > \gamma \tau_{\text{slow}}$. When the function evaluation takes a very large amount of time, we have that τ_{slow} will always be smaller than that amount of time and the condition $\tau_{\text{now}} - \tau_{\text{last}} > \gamma \tau_{\text{slow}}$ will always be satisfied for reasonable choices of γ . Thus, PESC-F will always perform slow computations as we would expect. On the other hand, if the evaluation of the black-box function is very fast, PESC-F will mainly perform fast computations but will still occasionally perform slow ones, with a frequency roughly proportional to the function evaluation duration.

5.2 Setting the Rationality Level in PESC-F

PESC-F is designed so that the ratio of time spent in BO computations to time spent in function evaluations is at most γ . This notion is approximate because the time spent in function evaluations includes the time spent doing fast computations. The optimal value of γ may be problem-dependent, but we propose values of γ on the order of 0.1 to 1, which

correspond to spending roughly 50–90% of the total time performing function evaluations. The optimal γ may also change at different stages of the BO process. Selecting the optimal value of γ is a subject for future research. Note that in PESC-F we are making sub-optimal decisions because of time constraints. Therefore, PESC-F is a simple example of *bounded rationality*, which has its roots in the traditional AI literature. For example, Russell (1991) proposes to treat computation as a possible action that consumes time but increases the expected utility of future actions.

5.3 Bridging the Gap Between Fast and Slow Computations

As discussed above, PESC-F can be applied even when function evaluations are very slow, as it automatically reverts to standard PESC when $\tau_{\text{eval}} > \tau_{\text{slow}}$. However, if the function evaluations are extremely fast, that is, faster even than the fast PESC updates, then even PESC-F violates the condition that the decision-making should take less time than the function evaluations. We have already defined τ_{slow} as the duration of the slow BO computations. Let us also define τ_{fast} as the duration of the fast BO computations and τ_{eval} as the duration of the evaluation of the functions. Then, the intuition described above can be put into symbols by saying that PESC-F is most useful when $\tau_{\text{fast}} < \tau_{\text{eval}} < \tau_{\text{slow}}$.

Many aspects of PESC-F are not specific to PESC and could easily be adapted to other acquisition functions like EIC or even unconstrained acquisition functions like PES and EI. In particular, lines 9, 10 and 16 of Algorithm 2 are specific to PESC, whereas others are common to other techniques. For example, when using vanilla unconstrained EI, the computational bottleneck is likely to be the sampling of the GP hyper-parameters (Algorithm 2, line 7) and maximizing the acquisition function (Algorithm 2, line 13). The ideas presented above, namely to skip the hyper-parameter sampling and to optimize the acquisition function with a smaller grid and/or coarser tolerances, are applicable in this situation and might be useful in the case of a fairly fast objective function. However, as mentioned above, in the single-task case one retains the option to abandon BO entirely for a faster method, whereas in the multi-task case considered here, neither a purely slow nor a purely fast method suits the nature of the optimization problem. An interesting direction for future research is to further pursue this notion of optimization algorithms that bridge the gap between those designed for optimizing cheap (fast) functions and those designed for optimizing expensive (slow) functions.

6. Empirical Analyses in the Coupled Case

We first evaluate the performance of PESC in experiments with different types of coupled optimization problems. First, we consider synthetic problems of functions sampled from the GP prior distribution. Second, we consider analytic benchmark problems that were previously used in the literature on Bayesian optimization with unknown constraints. Finally, we address the meta-optimization of machine learning algorithms with unknown constraints.

For the first synthetic case, we follow the experimental setup used by Hennig and Schuler (2012) and Hernández-Lobato et al. (2014). The search space is the unit hypercube of dimension D , and the ground truth objective f is a sample from a zero-mean GP with a squared exponential covariance function of unit amplitude and length scale $\ell = 0.1$ in each dimension. We represent the function f by first sampling from the GP prior on a

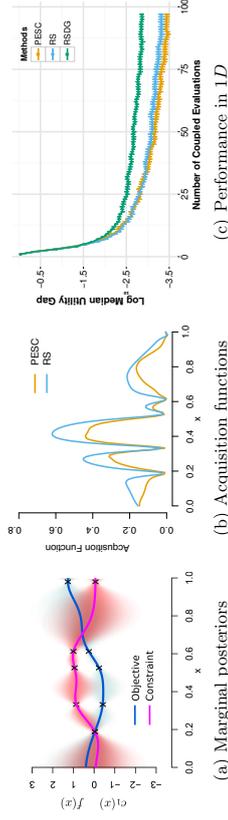

Figure 3: Accuracy of the PESC approximation. (a) Marginal posterior distributions for the objective and constraint given some collected data denoted by \times 's. (b) PESC and RS acquisition functions given the data in (a). (c) Median utility gap for PESC, RS and RSDG in the experiments with synthetic functions sampled from the GP prior with $D = 1$.

grid of 1000 points generated using a Halton sequence (see Leobacher and Pillichshammer, 2014) and then defining f as the resulting GP posterior mean. We use a single constraint function c_1 whose ground truth is sampled in the same way as f . The evaluations for f and c_1 are contaminated with i.i.d. Gaussian noise with variance $\nu_1 = \nu_2 = 0.01$.

6.1 Assessing the Accuracy of the PESC Approximation

We first analyze the accuracy of the PESC approximation to the acquisition function shown in Eq. (8). We compare the PESC approximation with a ground truth for the acquisition function obtained by rejection sampling (RS). The RS method works by discretizing the search space using a fine uniform grid. The expectation with respect to $p(\mathbf{x}_* | \mathcal{D})$ in Eq. (8) is then approximated by Monte Carlo. To achieve this, f, c_1, \dots, c_K are sampled on the grid and the grid cell with non-negative c_1, \dots, c_K (feasibility) and the lowest value of f (optimality) is selected. For each sample of \mathbf{x}_* , $\mathbb{H} [y^f, y^1, \dots, y^K | \mathcal{D}, \mathbf{x}_*, \mathbf{x}_*]$ is approximated by rejection sampling: we sample f, c_1, \dots, c_K on the grid and select those samples whose corresponding feasible optimal solution is the sampled \mathbf{x}_* and reject the other samples. We assume that the selected samples for f, c_1, \dots, c_K have a multivariate Gaussian distribution. Under this assumption, $\mathbb{H} [y^f, y^1, \dots, y^K | \mathcal{D}, \mathbf{x}_*, \mathbf{x}_*]$ can be approximated using the formula for the entropy of a multivariate Gaussian distribution, with the covariance parameter in the formula being equal to the empirical covariance of the selected samples for f and c_1, \dots, c_K at \mathbf{x} plus the corresponding noise variances ν_1 and ν_2, \dots, ν_{K+1} in its diagonal. In our experiments, this approach produces entropy estimates that are very similar, faster to obtain and less noisy than the ones obtained with non-parametric entropy estimators. We compared this implementation of RS with another version that ignores correlations in the samples of f and c_1, \dots, c_K . In practice, both methods produced equivalent results. Therefore, to speed up the method, we ignore correlations in our implementation of RS.

Figure 3(a) shows the posterior distribution for f and c_1 given 5 observations sampled from the GP prior with $D = 1$. The posterior is computed using the optimal GP hyper-

parameters. The corresponding approximations to the acquisition function generated by PESG and RS are shown in Fig. 3(b). In the figure, both PESG and RS use a total of $M = 50$ samples from $p(\mathbf{x}_* | \mathcal{D})$ when approximating the expectation in Eq. (8). The PESG approximation is quite accurate, and importantly its maximum value is very close to the maximum value of the RS approximation. The approximation produced by the version of RS that does not ignore correlations in the samples of f, c_1, \dots, c_K (not shown) cannot be visually distinguished from the one shown in Fig. 3(b).

One disadvantage of the RS method is its high cost, which scales with the size of the grid used. This grid has to be large to guarantee good performance, especially when D is large. An alternative is to use a small dynamic grid that changes as data is collected. Such a grid can be obtained by sampling from $p(\mathbf{x}_* | \mathcal{D})$ using the same approach as in PESG to generate these samples (a similar approach is taken by Hennig and Schuler (2012), in which the dynamic grid is sampled from the EI acquisition function). The samples obtained then form the dynamic grid, with the idea that grid points are more concentrated in areas that we expect $p(\mathbf{x}_* | \mathcal{D})$ to be high. The resulting method is called Rejection Sampling with a Dynamic Grid (RSDG).

We compare the performance of PESG, RS and RSDG in experiments with synthetic data corresponding to 500 pairs of f and c_1 sampled from the GP prior with $D = 1$. RS and RSDG draw the same number of samples of \mathbf{x}_* as PESG. We assume that the GP hyper-parameters are known to each method and fix $\delta = 0.05$, that is, recommendations are made by finding the location with highest posterior mean for f such that c_1 is non-negative with probability at least $1 - \delta$. For reporting purposes, we set the utility $u(\mathbf{x})$ of a recommendation \mathbf{x} to be $f(\mathbf{x})$ if \mathbf{x} satisfies the constraint, and otherwise a penalty value of the worst (largest) objective function value achievable in the search space. For each recommendation \mathbf{x} , we compute the utility gap $|u(\mathbf{x}) - u(\mathbf{x}_*)|$, where \mathbf{x}_* is the true solution to the optimization problem. Each method is initialized with the same three random points drawn with Latin hypercube sampling.

Figure 3(c) shows the median of the utility gap for each method for the 500 realizations of f and c_1 . The x -axis in this plot is the number of joint function evaluations for f and c_1 . We report the median because the empirical distribution of the utility gap is heavy-tailed and in this case the median is more representative of the location of the bulk of the data than the mean. The heavy tails arise because we are averaging over 500 different optimization problems with very different degrees of difficulty. In this and all of the following experiments, unless otherwise specified, error bars are computed using the bootstrap method. The plot shows that PESG and RS are better than RSDG. Furthermore, PESG is very similar to RS, with PESG even performing slightly better, perhaps because PESG is not confined to a grid as RS is. These results seem to indicate that PESG yields an accurate approximation of the information gain.

6.2 Synthetic Functions in 2 and 8 Input Dimensions

We compare the performance of PESG and RSDG with EIG using the same experimental protocol as in the previous section, but with dimensionalities $D = 2$ and $D = 8$. We do not compare with RS here because its use of grids does not scale to higher dimensions. Fig. 4 shows the utility gap for each method across 500 different samples of f and c_1 from the

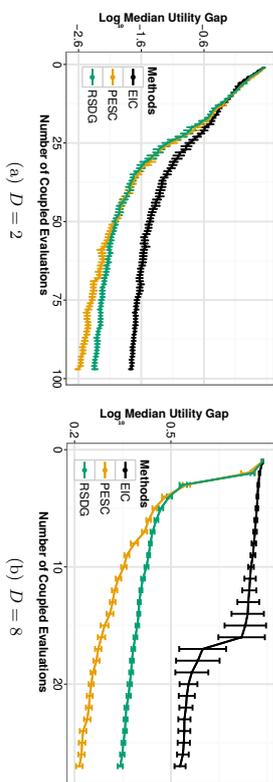

Figure 4: Optimizing samples from the GP prior with (a) $D = 2$ and (b) $D = 8$.

GP prior with (a) $D = 2$ and (b) $D = 8$. Overall, PESG is the best method, followed by RSDG and EIG. RSDG performs similarly to PESG when $D = 2$, but is significantly worse when $D = 8$. This shows that, when D is high, grid based approaches (e.g. RSDG) are at a disadvantage with respect to methods that do not require a grid (e.g. PESG).

6.3 A Toy Problem

Next, we compare PESG with EIG and AL (Gramacy et al. (2016), Section 2.4) on the toy problem described by Gramacy et al. (2016), namely,

$$\begin{aligned} \min_{\mathbf{x} \in [0,1]^2} f(\mathbf{x}) \text{ s.t. } c_1(\mathbf{x}) &\geq 0, c_2(\mathbf{x}) \geq 0, \\ f(\mathbf{x}) &= x_1 + x_2, \\ c_1(\mathbf{x}) &= 0.5 \sin(2\pi(x_1^2 - 2x_2)) + x_1 + 2x_2 - 1.5, \\ c_2(\mathbf{x}) &= -x_1^2 - x_2^2 + 1.5. \end{aligned} \quad (23)$$

This optimization problem has two local minimizers and one global minimizer. At the global solution, which is at $\mathbf{x}_* \approx [0.1954, 0.4404]$, only one of the two constraints (c_1) is active. Since the objective is linear and c_2 is not active at the solution, learning about c_1 is the main challenge of this problem. Fig. 5(a) shows a visualization of the linear objective function and the feasible and infeasible regions, including the location of the global constrained minimizer \mathbf{x}_* .

In this case, the evaluations for f , c_1 and c_2 are noise-free. To produce recommendations in PESG and EIG, we use the confidence value $\delta = 0.05$. We also use a squared exponential GP kernel. PESG uses $M = 10$ samples of \mathbf{x}_* when approximating the expectation in Eq. (8). We use the AL implementation provided by Gramacy et al. (2016) in the R package *laGP*, which is based on the squared exponential kernel and assumes the objective f is known. Thus, in order for this implementation to be used, AL has an advantage over other methods in that it has access to the true objective function. In all three methods, the GP hyperparameters are estimated by maximum likelihood.

Figure 5(b) shows the mean utility gap for each method across 500 repetitions. Each repetition corresponds to a different initialization of the methods with three data points

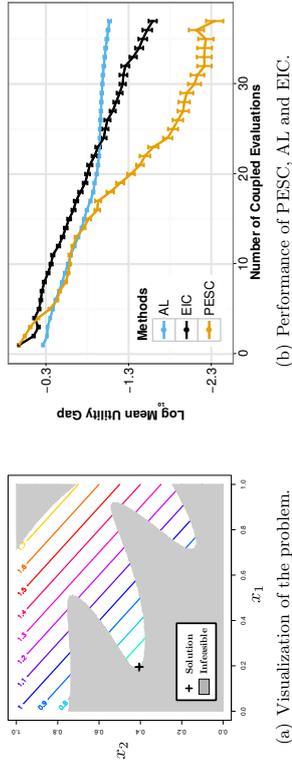

Figure 5: Comparing PESC, AL, and EIC in the toy problem described by Gramacy et al. (2016). (a) Visualization of the linear objective function and the feasible and infeasible regions. (b) Results obtained by PESC, AL and EIC on the toy problem.

selected with Latin hypercube sampling. The results show that PESC is significantly better than EIC and AL for this problem. EIC is superior to AL, which performs slightly better at the beginning, possibly because it has access to the ground truth objective f .

6.4 Finding a Fast Neural Network

In this experiment, we tune the hyper-parameters of a three-hidden-layer neural network subject to the constraint that the prediction time must not exceed 2 ms on an NVIDIA GeForce GTX 580 GPU (also used for training). We use the Matérn 5/2 kernel for the GP priors. The search space consists of 12 parameters: 2 learning rate parameters (initial value and decay rate), 2 momentum parameters (initial and final values, with linear interpolation), 2 dropout parameters (for the input layer and for other layers), 2 additional regularization parameters (weight decay and max weight norm), the number of hidden units in each of the 3 hidden layers, and the type of activation function (RELU or sigmoid). The network is trained using the *deepnet* package¹, and the prediction time is computed as the average time of 1000 predictions for mini-batches of size 128. The network is trained on the MNIST digit classification task with momentum-based stochastic gradient descent for 5000 iterations. The objective is reported as the classification error rate on the standard validation set. For reporting purposes, we treat constraint violations as the worst possible objective value (a classification error of 1.0). This experiment is inspired by a real need for neural networks that can make fast predictions with high accuracy. An example is given by computer vision problems in which the prediction time of the best performing neural network is not fast enough to keep up with the fast rate at which new data is available (e.g., YouTube, connectomics).

Figure 6(a) shows the results of 50 iterations of the Bayesian optimization process. In this experiment and in the next one, the y -axis represents the best objective value observed

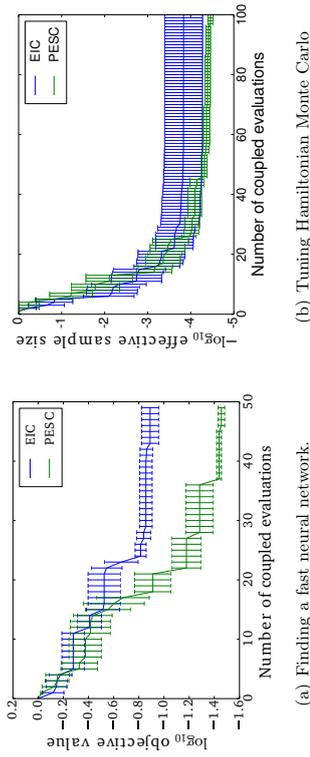

Figure 6: Results for PESC and EIC on the tuning of machine learning methods with coupled constraints. (a) Tuning a neural network subject to the constraint that it makes predictions in under 2 ms. (b) Tuning Hamiltonian Monte Carlo to maximize the number of effective samples within 5 minutes of compute time, subject to the constraints passing the Geweke and Gelman-Rubin convergence diagnostics and integrator stability.

so far, with recommendations produced using $\delta = 0.05$ and observed constraint violations resulting in objective values equal to 1.0. Curves show averages over five independent experiments. In this case, PESC performs significantly better than EIC.

When the constraints are noisy, reporting the best observation is an overly optimistic metric because the best feasible observation might be infeasible in practice. On the other hand, ground-truth is not available. Therefore, to validate our results further, we used the recommendations made at the final iteration of the Bayesian optimization process for each method (EIC and PESC) and evaluated the functions with these recommended parameters. We repeated the evaluation 10 times for each of the 5 repeated experiments. The result is a ground-truth score obtained as the average of 50 function evaluations. This procedure yields a score of $7.0 \pm 0.6\%$ for PESC and $49 \pm 4\%$ for EIC (as in the figure, constraint violations are treated as a classification error of 100%), where the numbers after the \pm symbol denote the empirical standard deviation. This result is consistent with Fig. 6(a) in that PESC performs significantly better than EIC.

6.5 Tuning Markov Chain Monte Carlo

Hamiltonian Monte Carlo (HMC) (Duane et al., 1987) is a popular MCMC technique that takes advantage of gradient information for rapid mixing. HMC contains several parameters that require careful tuning. The two basic parameters are the number of leapfrog steps and the step size. HMC may also include a mass matrix which introduces $\mathcal{O}(D^2)$ additional parameters for problems in D dimensions, although the matrix is often fixed to be diagonal (D parameters) or a multiple of the identity matrix (1 parameter) (Neal, 2011). In this experiment, we optimize the performance of HMC. We use again the Matérn 5/2 kernel for

the GP priors. We tune the following parameters: the number of leapfrog steps, the step size, a mass parameter and the fraction of the allotted computation time spent burning in the chain. Our experiment measures the number of effective samples obtained in a fixed computation time. We impose the constraints that the generated samples must pass the Geweke (Geweke, 1992) and Gelman-Rubin (Gelman and Rubin, 1992) convergence diagnostics. In particular, we require the worst (largest absolute value) Geweke test score across all variables and chains to be at most 2.0, and the worst (largest) Gelman-Rubin score between chains and across all variables to be at most 1.2. We use the *coda* R package (Plummer et al., 2006) to compute the effective sample size and the Geweke convergence diagnostic, and the *PyMCMC* python package (Patil et al., 2010) to compute the Gelman-Rubin diagnostic over two independent traces.

The HMC integration may also diverge for large values of the step size. We treat this as a hidden constraint, and set $\delta = 0.05$. We use HMC to sample from the posterior of a logistic regression binary classification problem using the German credit data set from the UCI repository (Frank and Asuncion, 2010). The data set contains 1000 data points, and is normalized to have zero mean unit variance for each feature. We initialize each chain randomly with $D = 25$ independent draws from a Gaussian distribution with mean zero and standard deviation 10^{-3} . For each set of inputs, we compute two chains, each one with five minutes of computation time on a single core of a compute node.

Figure 6(b) compares EIC and PESCG on this task, averaged over ten realizations of the experiment. As above, we perform a ground-truth assessment of the final recommendations. For each method (EIC and PESCG), we used the recommendations made at the final iteration of the Bayesian optimization process and evaluated the functions with these recommended parameters multiple times. The resulting average effective sample size is 3300 ± 1200 for PESCG and 2300 ± 900 for EIC, where the number after the \pm symbol denotes the empirical standard deviation. Here, the difference between the two methods is within the margin of error. When we compare these results with the ones in Fig. 6(b) we observe that the latter results are overly optimistic, indicating that this experiment is very noisy. The noise presumably comes from the randomness in the initialization and the execution of HMC, which causes the passing or the failure of the convergence diagnostics to be highly stochastic.

7. Empirical Analyses with Decoupled Functions

Section 6 focused on the evaluation of the performance of PESCG in experiments with coupled functions. Here, we evaluate the performance of PESCG in the decoupled case, where the different functions can be evaluated independently.

7.1 Accuracy of the PESCG Approximation

We first evaluate the accuracy of PESCG when approximating the function-specific acquisition functions from Eq. (13). We consider a synthetic problem with input dimension $D = 1$ and including an objective function and a single constraint function, both drawn from the GP prior distribution. Figure 7(a) shows the marginal posterior distributions for f and c_1 given 7 observations for the objective and 3 for the constraint. Figures 7(b) and 7(c) show the PESCG approximations to the acquisition functions for the objective and the constraint,

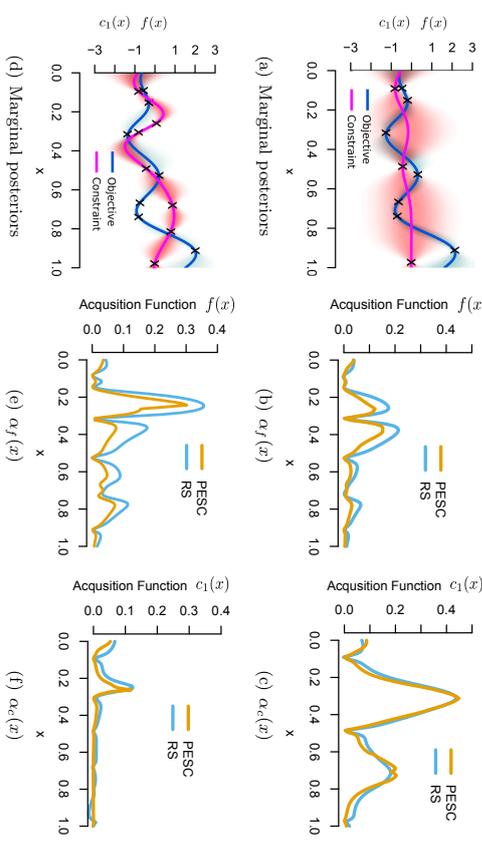

Figure 7: Assessing the accuracy of the decoupled PESCG approximation for the partial acquisition functions for $\alpha_f(x)$ and $\alpha_c(x)$. Between the top and bottom rows, three additional observations of the constraint have been made.

respectively. These functions approximate how much information we would obtain by the individual evaluation of the objective or the constraint at any given location. We also include in Figs. 7(b) and 7(c) the value of a ground truth obtained by rejection sampling (RS). The RS solution is obtained in the same way as in Section 6.1. Both PESCG and RS use a total of $M = 50$ samples from $p(\mathbf{x}_* | \mathcal{D})$. The PESCG approximation is quite accurate, and importantly its maximum value is very close to the maximum value of the RS approximation. Figures 7(b) and 7(c) indicate that the highest expected gain of information is obtained by evaluating the constraint at $x \approx 0.3$. The reason for this is that, as Fig. 7(a) shows, the objective is low near $x \approx 0.3$ but the constraint has not been evaluated at that location yet.

Figure 7(d) shows the marginal posterior distributions for f and c_1 when three more observations have been collected for the constraint. The corresponding approximations given by PESCG and RS to the function-specific acquisition functions are shown in Figs. 7(e) and 7(f). As before, the PESCG approximation is very similar to the RS one. In this case, evaluating the constraint is no longer as informative as before and the highest expected gain of information is obtained by evaluating the objective at $x \approx 0.25$. Intuitively, as we collect more constraint observations the constraint becomes well determined and the optimizer turns its attention to the objective.

7.2 Comparing Coupled and Decoupled PESC

We now compare the performance of coupled and decoupled versions of PESC in the same decoupled optimization problem. This allows us to empirically demonstrate the benefits of treating a decoupled problem as such.

We first consider the toy problem from Section 6.3 given by Eq. (23). We assume that there are three decoupled tasks: one for the objective and another one for each constraint function. We further assume that there is a single resource r with capacity $\omega_{\max}(r) = 3$. Each task requires to use resource r for its evaluation and the evaluation of each task takes always the same amount of time, which is assumed to be much larger than the BO computations. At each iteration resource r is used to evaluate 3 functions in parallel. We compare the performance of four versions of PESC, which differ in how they select the 3 parallel evaluations that will be performed at each iteration. The first method is a coupled approach (Coupled) which, at each iteration, evaluates jointly the three tasks at the same input. The second method is a non-competitive decoupling approach (NCD) which, at each iteration, evaluates all the different tasks once but not necessarily at the same input. This is equivalent to assuming that there are 3 resources with capacity 1 and each task can only be evaluated in one resource: the tasks do not have to compete because each one can only be evaluated in its corresponding resource. The third method is a competitive-decoupling approach (CD) which allows the different tasks to compete such that, at each iteration, three not necessarily unique functions are evaluated at three not necessarily unique locations. We also consider an implementation of CD that is not based on PESC and uses the EIC-D approach, as described in Section 2.5. We call this method EIC-CD. EIC-CD works like CD, with the difference that, at each step, we first determine the next evaluation location \mathbf{x} by maximizing the EIC acquisition function. After this, the next task to be evaluated at \mathbf{x} is chosen according to the expected reduction in the entropy of the global feasible minimizer \mathbf{x}_* . The original description of this method given by Gelbart et al. (2014) approximates the expected reduction in entropy using Monte Carlo sampling. This is in general computationally very expensive. To speed up EIC-CD, we replace the Monte Carlo sampling step by the approximation of the expected reduction in entropy given by PESC.

All the methods have to update the GP model, the posterior samples of \mathbf{x}_* , and the EP solutions just after collecting the data from resource r . However, the method CD and EIC-CD have to do two additional update operations after sending the first and the second evaluations to resource r , respectively. These updates correspond to step 11 in Algorithm 1 and they allow CD and EIC-CD to condition on pending evaluations that are not complete yet. In our experiments we use the Kriging believer approach, in which we pretend that the pending function evaluations have completed and returned the values of the GP predictive mean at those locations. This allows the methods CD and EIC-CD to update the GP model in a fast way, at the cost of ignoring uncertainty in the predictions of the GP model. The samples of \mathbf{x}_* and the EP solutions are, however, recomputed from scratch once the GP model has been updated. This can be expensive in practice. To address this problem we introduce the method CD-F, which works like CD, but replaces the full updates for the samples of \mathbf{x}_* and the EP solutions with the corresponding fast updates used by PESC-F in Section 5. Therefore, by comparing CD and CD-F, we can evaluate the loss in performance that is obtained by using the fast PESC-F updates. Note that CD-F uses the fast updates

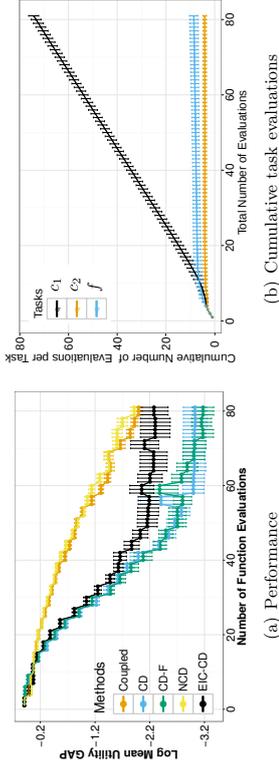

Figure 8: Results for the decoupled toy problem (Eq. (23)) when using a resource r that can evaluate 3 tasks (f , c_1 or c_2) in parallel. (a) Performance comparison of Coupled (orange), NCD (yellow), CD (blue), CD-F (green) and EIC-CD (black) approaches. (b) Cumulative number of evaluations for each task performed by CD-F. The algorithm automatically discovers that the constraint c_1 is much more important than the objective f or the other constraint c_2 .

only after sending the first and the second evaluations to resource r . Once the new data is collected, CD-F uses the original slow updates.

Figure 8(a) shows the results obtained by each method across 500 repetitions of the experiment starting from random initializations. Recommendations are computed with $\delta = 0.01$. The horizontal axis in the plot denotes the number of function evaluations performed so far. Since $\omega_{\max}(r) = 3$, these evaluations are performed in parallel in blocks of three. The vertical axis denotes the average utility gap, computed as in Section 6.1. Overall, CD and CD-F perform the best; the fact that CD and CD-F obtain similar results implies that the fast PESC-F updates incur no significant performance loss in this synthetic optimization problem. EIC-CD is worse than these two methods. This is a result of the sub-optimal two-stage decision process used by EIC-CD to select the next evaluation location and the next task to be evaluated at that location; see Section 2.5 for more details. NCD performs about the same as Coupled which means that, in this problem, the benefits of decoupling come from choosing an unequal distribution of tasks to evaluate, rather than from the additional freedom of evaluating the three tasks at potentially different locations. This hypothesis is corroborated by Fig. 8(b), which shows the average cumulative number of evaluations performed by CD for each task (f , c_1 or c_2) at each iteration. CD chooses to evaluate the constraint c_1 far more often than the objective or the other constraint c_2 . This makes sense since the objective is a linear function and c_1 , which has a complicated form, is the only active constraint at the global solution. Thus, the PESC algorithm has automatically discovered that the constraint c_1 is much more important (both in the sense of being complicated and in the sense of being active at the true solution) than the objective f or the other constraint c_2 . This demonstrates the true power of competitive decoupling,

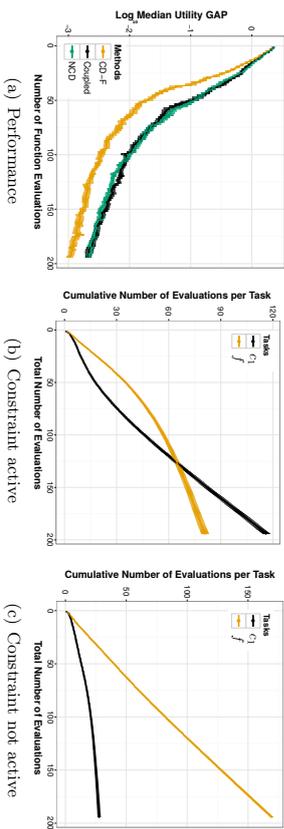

Figure 9: Results on synthetic problems with $D = 2$ sampled from the GP prior as in Section 6.2 when using a resource r that can evaluate 2 tasks (f or c_1) in parallel. (a) Performance comparison of Coupled (black), NCD (green), and CD-F (orange) approaches. (b) Cumulative number of task evaluations performed by CD-F when c_1 is active at the solution. (c) Cumulative number of task evaluations performed by CD-F when c_1 is not active at the solution.

as the algorithm avoids wasting time on uninteresting tasks that might be, in the worst case scenario, even more expensive than the interesting ones.

We perform another comparison of the methods Coupled, NCD and CD-F in synthetic problems in which the objective f and a single constraint function c_1 are drawn from the GP prior with $D = 2$. This is done in the same way as in Section 6.2. We set $\delta = 0.05$ and follow an experimental protocol similar to the one from the previous experiment: we assume that there are two tasks, given by f and c_1 , which can be evaluated at a resource r with capacity $\omega_{\max}(r) = 2$. Therefore, at any iteration we will be evaluating 2 tasks in parallel. Figure 9(a) shows the median utility gap obtained by each method across 500 different realizations of the experiment. As in the previous toy problem, CD-F outperforms Coupled, while Coupled performs similar to NCD. Again, decoupling is useful when we can choose the tasks to evaluate (CD-F) and evaluating the tasks at potentially different locations (NCD) does not seem to produce significant improvements with respect to the coupled approach.

In the previous toy problem, CD-F outperformed NCD and Coupled because it learned that evaluating the constraint c_1 is much more useful than evaluating the objective f or the constraint c_2 . We perform a similar analysis here by plotting the cumulative number of evaluations for each task performed by CD-F. We divide the 500 realizations into those cases in which the constraint c_1 is active at the true solution (Fig. 9(b)) and those in which c_1 is not active at the true solution (Fig. 9(c)). The plots in Figs. 9(b) and 9(c) show that when the constraint c_1 is active at the solution, CD-F chooses to evaluate c_1 much more frequently. By contrast, when the constraint is not active, c_1 is evaluated much less. Presumably, in the latter case c_1 need only be evaluated until it is determined that it is very unlikely to be active at the solution. After this point, further evaluations of c_1 are not

very informative. These results indicate that the task-specific acquisition functions used by PESC and given by Eq. (14) are able to successfully measure the usefulness of evaluating each different task.

7.3 Performance of PESC-F with Respect to Wall-clock Time

We now evaluate the performance of PESC with fast BO computations (PESC-F, Section 5) while considering the wall-clock time of each experiment. Again, we focus on the toy problem from Section 6.3 given by Eq. (23). To highlight what can go wrong in decoupled optimization problems, we will assume that evaluating the objective is instantaneous, evaluating c_1 takes 2 seconds, and evaluating c_2 takes 1 minute. Each of these functions forms a different task so that all of them can be evaluated independently. We also consider that there is a single resource r with $\omega_{\max}(r) = 1$, that is, only one task can be evaluated at any given time with no possible parallelism. This setup corresponds to the competitive decoupling scenario from Fig. 1. We limit each experiment time to 15 minutes and consider the following methods: Coupled, and competitive decoupled (CD) with PESC-F and rationality levels $\gamma = \{\infty, 1, 0.1, 0\}$. According to Eq. (22), setting $\gamma = \infty$ is simply another way of saying that fast BO computations are not used.

Figure 10(a) shows the average utility gap of each method as a function of elapsed time. The coupled approach is the worst performing one, being outperformed by all the versions of PESC-F with different γ . This illustrates the advantages of the decoupled approach. The performance of PESC-F is improved as γ moves from ∞ to 1 and then to 0.1. The reason for this is that, as γ is reduced, less time is spent in the BO computations and more time is spent in the actual collection of data. However, reducing γ too much is detrimental as $\gamma = 0$ performs significantly worse than $\gamma = 0.1$ and $\gamma = 1$. The reason for this is that $\gamma = 0$ performs too many fast BO computations, which produce suboptimal decisions.

Figures 10(b) to 10(f) and Section 7.3 are useful to understand the results obtained by the different methods in Fig. 10(a). These figures show, for each method, the cumulative number of evaluations per task as a function of the elapsed time. The coupled approach performs very few evaluations of the different tasks. The reason for this is that it always evaluates all the tasks the same number of times and this leads to wasting a lot of time by evaluating too often the slowest task, that is, constraint c_2 , which is not very informative about the solution to the problem. The different versions of PESC-F with $\gamma = \{\infty, 1, 0.1, 0\}$ evaluate more often the most informative task, that is, c_1 and less frequently all the other tasks. As the rationality level γ is decreased, less time is spent in the BO computations, and thus more task evaluations are performed. These correspond to increases in performance. However, this trend does not continue indefinitely as γ is decreased. When $\gamma = 0$, performance is significantly diminished. By not performing slow BO computations, the $\gamma = 0$ method is not able to learn that c_2 is uninformative and continues to spend time evaluating it, thus performing many fewer evaluations of the most informative task c_1 . The configuration files for running this experiment are available at <https://github.com/HIPS/Spearmint/tree/PESC/examples/toy-fast-slow>.

Section 7.3 shows the time spent by each method in fast and slow BO computations and in the evaluation of tasks c_1 and c_2 . We do not include the time spent in the evaluation of task f because it is always zero. Note that the total time spent in the BO computations

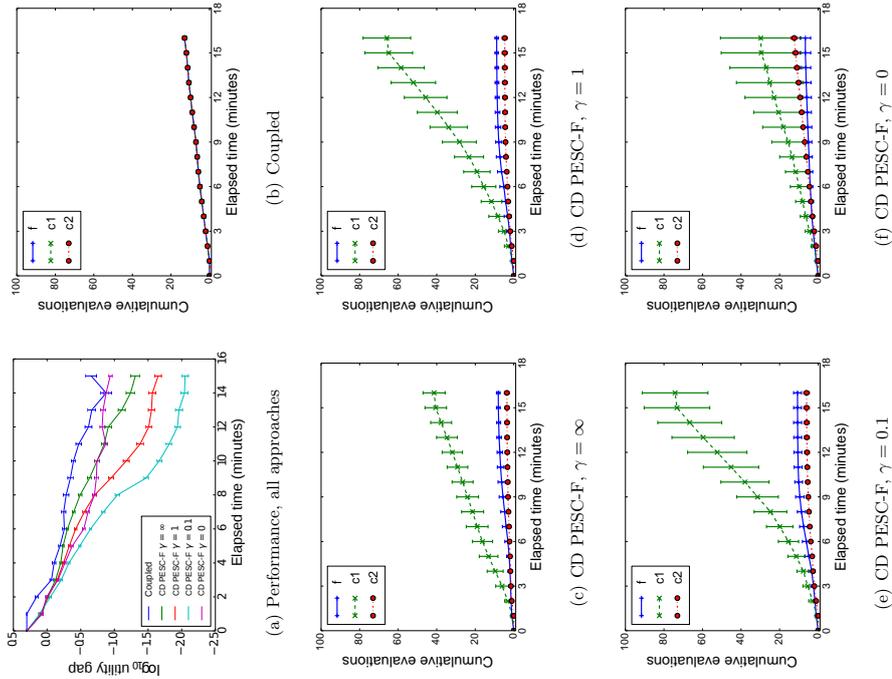

Figure 10: Results for Coupled and CD PESC-F with $\gamma = \{\infty, 1, 0.1, 0\}$ on the toy problem given by Eq. (23). Evaluations of f are instantaneous, evaluations of c_1 take 2 sec. and evaluations of c_2 take 1 min. The maximum experiment time is 15 min. (a) log utility gap versus wall-clock time. (b-f) Cumulative function evaluations for (b) Coupled, (c) CD PESC-F with $\gamma = \infty$ (no fast computations), (d) CD PESC-F with $\gamma = 1.0$, (e) CD PESC-F with $\gamma = 0.1$, and (f) CD PESC-F with $\gamma = 0$ (no slow computations). Curves reflect the mean over 100 trials. Error bars in (b-f) are given by the empirical standard deviations.

Method	Slow BO Comp.	Fast BO Comp.	Total BO Comp.	$c_1(\mathbf{x})$	$c_2(\mathbf{x})$	Total Evaluation
Coupled	2.0	0.0	2.0	0.4	13.0	13.4
CD PESC-F, $\gamma = \infty$	10.2	0.0	10.2	1.4	3.6	5.0
CD PESC-F, $\gamma = 1$	5.2	3.0	8.2	2.2	4.7	6.9
CD PESC-F, $\gamma = 0.1$	1.5	5.1	6.6	2.5	6.0	8.5
CD PESC-F, $\gamma = 0.0$	0.2	1.8	2.0	1.0	12.5	13.5

Table 1: Time spent by each method in BO computations and in task evaluations. For each method, the table reports the mean time in minutes, over 100 independent runs, spent in fast and slow BO computations and in the evaluation of tasks c_1 and c_2 .

and in the evaluation of the different tasks does not add up exactly to 15 minutes because, in our implementation, the current iteration is allowed to finish after the 15-minute mark is reached. As expected, the time spent in the BO computations decreases monotonically as γ is decreased. The coupled approach spends a small amount of time doing BO computations. The reason for this is that this method does not have to perform step 11 in Algorithm 1 and step 4 is performed less frequently than in the PESC-F methods because Coupled spends most of its time in the evaluation of c_2 .

The fifth column in Section 7.3 corresponds to the time spent in the evaluation of c_1 . The entries in this column are indicative of the relative performances of each method, since c_1 is the most important function in this optimization problem. From these entries we may conclude that this problem exhibits an optimal value of γ close to 0.1. This represents an optimal ratio of time spent in the BO computations to time spent in the evaluation of the different tasks. We leave to future work the issue of selecting the optimal value for γ . In a highly sophisticated approach this could be done in an online fashion by using reinforcement learning.

8. Conclusions and Future Work

We have presented a general framework for solving Bayesian optimization (BO) problems with unknown constraint functions. In these problems the objective and the constraints can only be evaluated via expensive queries to black boxes that may provide noisy values. Our framework allows for problems in which the objective and the constraints can be split into subsets of functions that require *coupled* evaluation, meaning that these functions have to be jointly evaluated at the same input. We call these subsets of coupled functions *tasks*. Different tasks may, however, be evaluated independently at different locations, that is, in a *decoupled* way. Furthermore, the tasks may or may not compete for a limited set of resources during their evaluation. Based on this, we have then introduced the notions of *competitive decoupling* (CD), where two or more tasks compete for the same resource, and *non-competitive decoupling* (NCD), where the tasks require to use different resources and can therefore be evaluated in parallel. The notion of *parallel* BO is a special case in which

one task requires a specific resource, of which many instances are available. We have then presented a general procedure, given by Algorithm 1, to solve problems with an arbitrary combination of coupling and decoupling. This algorithm receives as input a bipartite graph \mathcal{G} whose nodes are resources and tasks and whose edges connect each task with the resource at which it can be evaluated. Algorithm 1 relies on an acquisition function that can measure the utility of evaluating any arbitrary subset of functions, that is, of any possible task. An acquisition function that satisfies this requirement is said to be *separable*.

To implement Algorithm 1, we have proposed a new information-based approach called Predictive Entropy Search with Constraints (PESC). At each iteration, PESC collects data at the location that is expected to provide the highest amount of information about the solution to the optimization problem. By introducing a factorization assumption, we obtain an acquisition function that is additive over the subset of functions to be evaluated. That is, the amount of information that we approximately gain by jointly evaluating a set of functions is equal to the sum of the gains of information that we approximately obtain by the individual evaluation of each of the functions. This property means that the acquisition function of PESC is separable. Therefore, PESC can be used to solve general constrained BO problems with decoupled evaluation, something that has not been previously addressed.

We evaluated the performance of PESC in coupled problems, where all the functions (objective and constraints) are always jointly evaluated at the same input location. This is the standard setting considered by most prior approaches to constrained BO. The results of our experiments show that PESC achieves state-of-the-art results in this scenario. We also evaluated the performance of PESC in the decoupled setting, where the different tasks can be evaluated independently at arbitrary input locations. We considered scenarios with competition (CD) and with non-competition (NCD) and compared the performances of two versions of PESC: one with decoupling (decoupled PESC) and another one that always performs coupled evaluations (coupled PESC). Decoupled PESC is significantly better than coupled PESC when there is competition, that is, in the CD setting. The reason for this is that some functions can be more informative than others and decoupled PESC exploits this to make optimal decisions when deciding which function to evaluate next with limited resources. In particular, decoupled PESC avoids wasting time in function evaluations that are unlikely to improve the current estimate of the solution to the optimization problem. However, when there is no competition, that is, in the NCD setting, coupled and decoupled PESC perform similarly. Therefore, in our experiments, the main advantages of considering decoupling seem to come from choosing an unequal distribution of tasks to evaluate, rather than from the additional freedom of evaluating the different tasks at potentially arbitrary locations. In our experiments we have assumed that the evaluation of all the functions takes the same amount of time. However, NCD is expected to perform better than the coupled approach in other settings in which some functions are much faster to evaluate than others. Evaluating the performance of NCD in these settings is left as future work.

For the BO approach to be useful, the time spent performing BO computations (such as computing and globally optimizing the acquisition function) has to be significantly shorter than the time spent collecting data. However, decoupled optimization problems may include some tasks that are fast to evaluate. When these tasks are informative and their evaluation time is comparable to that of the BO computations, the BO approach may be inefficient. To address this issue, we follow a bounded rationality approach and introduce additional

approximations in the computations made by PESC to reduce their cost when necessary. The new method is called PESC-F and it is able to automatically switch between fast, but approximate, and slow, but accurate, operations. A parameter called the *rationality level* is used in PESC-F to balance the amount of time that is spent in the BO computations and in the actual collection of data. Experiments with wall-clock time in a CD scenario show that PESC-F can be significantly better than the original version of PESC.

In summary, PESC is an effective algorithm for BO problems with unknown constraints and the separability of its acquisition function makes it a promising direction towards a unified solution for constrained BO problems. As new acquisition functions are proposed in the future, they will hopefully be developed with separability in mind as an important and desirable property.

The code for PESC, including decoupling and PESC-F, is available in PESC branch of the open-source Bayesian optimization package *Spearmint* at <https://github.com/HIPS/Spearmint/tree/PESC>.

One potential line of future work includes extensions to settings where tasks require more than one resource to run. This could, for example, be formalized using a framework similar to the one presented in Section 3, but where the resource dependencies for each task t are represented as a set of edges $\mathcal{E}_t = \{t \sim r\}$ for the i th potential allocation of resources. This can be interpreted as the statement that all resource nodes $V_t = \{r : (t \sim r) \in \mathcal{E}_t\}$ are required in order to initiate task t using allocation i . Note that the union of these edges now specifies a multigraph with edges $\mathcal{E} = \bigcup_i \mathcal{E}_i$ due to the fact there may be resources that are required across multiple allocations of a particular task. This also modifies the pseudo-code for Algorithm 1 where the loop over resources r becomes a loop over potential allocations such that $\omega(r) < \omega_{\max}(r)$ for $r \in V_t$ for some (t, i) pair. In the case where each task requires only a single resource this reduces to the earlier formulation. Another possibility is for allocations where the resources are time or iteration dependent. This would require some form of temporal planning. To make such a procedure feasible, however, it may be necessary to consider greedy decisions at each point in time.

Another direction for future work is concerned with the use of *bounded rationality* in Bayesian optimization. Here we have used a simple heuristic for selecting between two levels (fast and slow) of computations in PESC-F. However, we could consider a larger number of levels with increasingly more accurate computations (Hay et al., 2012). The Bayesian optimization algorithm would then have to optimally select one of these to determine the next evaluation location. We could also consider different modeling approaches for the collected data, with different trade-offs between accuracy and computational cost. We also leave for future work a theoretical analysis of PESC. This would be in the line of the work of Russo and Van Roy (2014) on information-directed sampling. However, they use simpler models for the data and do not consider problems with constraints.

Finally, we would like to point out that the approach described here can be applied in a straightforward manner to address multi-objective Bayesian optimization problems (Knowles, 2006). In the multi-objective case the different tasks would be given by groups of objective functions that have to be evaluated in a coupled manner. An extension of PESC for working with multiple objectives is given by Hernández-Lobato et al. (2016).

Appendix A. The Expectation Propagation Method Used by PESC

We describe here the expectation propagation (EP) method that is used by PESC to adjust a Gaussian approximation to the non-Gaussian factor $f(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K | \mathbf{x}^j)$ in Eq. (17). This is done after replacing the infinite set \mathcal{X} with the finite set \mathcal{Z} , which contains only the locations at which the objective f has been evaluated so far, the value of \mathbf{x}^j and \mathbf{x} . Recall that \mathbf{x} is the input to the acquisition function, that is, it contains the location at which we are planning to evaluate $f, \mathbf{c}_1, \dots, \mathbf{c}_K$. When \mathcal{X} is replaced with \mathcal{Z} we have that the vectors $\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K$ contain now the result of the noise-free evaluations of $f, \mathbf{c}_1, \dots, \mathbf{c}_K$ at \mathcal{Z} , that is,

$$\mathbf{f} = [f(\mathbf{x}_f^1), \dots, f(\mathbf{x}_f^{N_f}), f(\mathbf{x}^j), f(\mathbf{x})]^T, \quad (24)$$

$$\mathbf{c}_k = [c_k(\mathbf{x}_f^1), \dots, c_k(\mathbf{x}_f^{N_f}), c_k(\mathbf{x}^j), c_k(\mathbf{x})]^T, \quad \text{for } k = 1, \dots, K. \quad (25)$$

where $\mathbf{x}_f^1, \dots, \mathbf{x}_f^{N_f}$ are the locations at which the objective f has been evaluated so far. That is, the first N_f entries in $\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K$ contain the function values at the locations for which there is data for the objective. These entries are then followed by the function values at \mathbf{x}^j and at \mathbf{x} . When we replace \mathcal{X} with \mathcal{Z} we have that

$$f(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K | \mathbf{x}^j) = p(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K | \mathcal{D}) \Gamma(\mathbf{x}^j) \left\{ \prod_{i=1}^{N_f} \Psi(\mathbf{x}_f^i) \right\} \Psi(\mathbf{x}). \quad (26)$$

In this expression we should have included a factor $\Psi(\mathbf{x}^j)$ since $\mathbf{x}^j \in \mathcal{Z}$. We ignore such factor because it is always equal to 1 according to Eq. (16). In Eq. (26) we have separated the non-Gaussian factor that depends on \mathbf{x} , that is, $\Psi(\mathbf{x})$ from those factors that do not depend on \mathbf{x} , that is, $\Gamma(\mathbf{x}^j), \Psi(\mathbf{x}_f^1), \dots, \Psi(\mathbf{x}_f^{N_f})$. All these non-Gaussian factors are approximated with Gaussians using EP.

Finding the next *suggestion* involves maximizing the acquisition function. This requires to evaluate the acquisition function at many different \mathbf{x} and recomputing the complete EP approximation for each value of \mathbf{x} can be excessively expensive. To avoid this, we first compute the EP approximation for the factors that do not depend on \mathbf{x} in isolation, store it and then reuse it as we compute the EP approximation for the remaining factors. Since most of the factors do not depend on \mathbf{x} , this leads to large speedups when we have to evaluate the acquisition function at many different \mathbf{x} . Therefore, we start by finding a Gaussian approximation to the factors that do not depend on \mathbf{x} , that is, $\Gamma(\mathbf{x}^j), \Psi(\mathbf{x}_f^1), \dots, \Psi(\mathbf{x}_f^{N_f})$, while ignoring the other factor that does depend on \mathbf{x} , that is, $\Psi(\mathbf{x})$.

A.1 Approximating the Non-Gaussian Factors that do not Depend on \mathbf{x}

We use EP to find a Gaussian approximation to $\Gamma(\mathbf{x}^j), \Psi(\mathbf{x}_f^1), \dots, \Psi(\mathbf{x}_f^{N_f})$ in Eq. (26) when $\Psi(\mathbf{x}_1), \dots, \Psi(\mathbf{x}_{K+1})$ are assumed to be constant and equal to 1. Because the data is assumed to be generated from independent GPs, we have that $p(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K | \mathcal{D})$ in Eq. (26) is

$$p(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K | \mathcal{D}) = \mathcal{N}(\mathbf{f} | \mathbf{m}_1^{\text{pred}}, \mathbf{V}_1^{\text{pred}}) \prod_{k=1}^K \left\{ \mathcal{N}(\mathbf{c}_k | \mathbf{m}_{k+1}^{\text{pred}}, \mathbf{V}_{k+1}^{\text{pred}}) \right\}, \quad (27)$$

where $\mathbf{m}_1^{\text{pred}}$ and $\mathbf{V}_1^{\text{pred}}$ are the mean and covariance matrix of the posterior distribution of \mathbf{f} given the data for the objective and $\mathbf{m}_{k+1}^{\text{pred}}$ and $\mathbf{V}_{k+1}^{\text{pred}}$ are the mean and covariance matrix of the posterior distribution of \mathbf{c}_k given the data for constraint k . In particular, from Eqs. (2.22) to (2.24) of (Rasmussen and Williams, 2006) we have that

$$\mathbf{m}_i^{\text{pred}} = \mathbf{K}_*^i (\mathbf{K}_*^i + \nu_i \mathbb{I})^{-1} \mathbf{y}^i, \quad (28)$$

$$\mathbf{V}_i^{\text{pred}} = \mathbf{K}_*^i - \mathbf{K}_*^i (\mathbf{K}_*^i + \nu_i \mathbb{I})^{-1} [\mathbf{K}_*^i]^T, \quad \text{for } i = 1, \dots, K+1, \quad (29)$$

where \mathbf{y}^i is an N_i -dimensional vector with the data for the i -th function in $\{f, \mathbf{c}_1, \dots, \mathbf{c}_K\}$, \mathbf{K}_*^i is an $(N_i + 2) \times N_i$ matrix with the prior cross-covariances between the entries of the i -th vector in $\{f, \mathbf{c}_1, \dots, \mathbf{c}_K\}$ and the value of the corresponding function at the locations for which there is data available for that function and $\mathbf{K}_*^{i,*}$ is an $(N_i + 2) \times (N_i + 2)$ matrix with the prior covariances between entries of the i -th vector in $\{f, \mathbf{c}_1, \dots, \mathbf{c}_K\}$ and ν_i is the noise variance at the black-box for the i -th function in $\{f, \mathbf{c}_1, \dots, \mathbf{c}_K\}$.

The exact factors $\Gamma(\mathbf{x}^j), \Psi(\mathbf{x}_f^1), \dots, \Psi(\mathbf{x}_f^{N_f})$ from Eq. (26) are then approximated with the corresponding Gaussian factors $\tilde{\Gamma}(\mathbf{x}^j), \tilde{\Psi}(\mathbf{x}_f^1), \dots, \tilde{\Psi}(\mathbf{x}_f^{N_f})$. Let $\beta_n(\mathbf{f}) = [f(\mathbf{x}_f^1), f(\mathbf{x}_f^2)]^T$, where \mathbf{x}_f^i is the n -th location for which there is data for the objective f . Then, we define

$$\tilde{\Psi}(\mathbf{x}_f^j) \propto \exp \left\{ -\frac{1}{2} \beta_n(\mathbf{f})^T \tilde{\mathbf{A}}_n \beta_n(\mathbf{f}) + \beta_n(\mathbf{f})^T \tilde{\mathbf{b}}_n \right\} \prod_{k=1}^K \exp \left\{ -\frac{1}{2} c_k(\mathbf{x}_f^j)^2 \tilde{d}_n^k + c_k(\mathbf{x}_f^j) \tilde{e}_n^k \right\}, \quad (30)$$

where $\tilde{\mathbf{A}}_n$ and $\tilde{\mathbf{b}}_n$ are the natural parameters of a bivariate Gaussian distribution on $\beta_n(\mathbf{f})$ and \tilde{d}_n^k and \tilde{e}_n^k are the natural parameters of a Gaussian distribution on $c_k(\mathbf{x}_f^j)$, that is, the value of constraint k at the n -th location for which there is data for the objective. We also define

$$\tilde{\Gamma}(\mathbf{x}^j) \propto \prod_{k=1}^K \exp \left\{ -\frac{1}{2} c_k(\mathbf{x}^j) \tilde{g}_k + c_k(\mathbf{x}^j) \tilde{h}_k \right\},$$

where \tilde{g}_k and \tilde{h}_k are the natural parameters of a Gaussian distribution on $c_k(\mathbf{x}^j)$, that is, the value of constraint k at the current posterior sample of \mathbf{x} .

The parameters $\tilde{\mathbf{A}}_n, \tilde{\mathbf{b}}_n, \tilde{d}_n^k, \tilde{e}_n^k, \tilde{g}_k$ and \tilde{h}_k are fixed by running EP. Once the value of these parameters has been fixed, we replace the exact factors $\Gamma(\mathbf{x}^j), \Psi(\mathbf{x}_f^1), \dots, \Psi(\mathbf{x}_f^{N_f})$ in Eq. (26) with their corresponding Gaussian approximations to obtain an approximation to $f(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K | \mathbf{x}^j)$. We denote this approximation by $q(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K)$, where

$$q(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K) \propto p(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K | \mathcal{D}) \tilde{\Gamma}(\mathbf{x}^j) \left\{ \prod_{i=1}^{N_f} \tilde{\Psi}(\mathbf{x}_f^i) \right\} \left\{ \prod_{k=1}^{K+1} \tilde{\Psi}(\mathbf{x}_k) \right\}. \quad (31)$$

Since the approximate factors are Gaussian and $p(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K | \mathcal{D})$ is also Gaussian, we have that $q(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K)$ is also Gaussian:

$$q(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K) = \mathcal{N}(\mathbf{f} | \mathbf{m}_1, \mathbf{V}_1) \prod_{k=1}^K \mathcal{N}(c_k | \mathbf{m}_{k+1}, \mathbf{V}_{k+1}), \quad (32)$$

where, by applying the formula for products of Gaussians, we obtain

$$\mathbf{V}_i = \left[\mathbf{V}_i^{\text{pred}} \right]^{-1} + \tilde{\mathbf{S}}_i^{-1}, \quad (33)$$

$$\mathbf{m}_i = \mathbf{V}_i \left[\mathbf{V}_i^{\text{pred}} \right]^{-1} \mathbf{m}_i^{\text{pred}} + \tilde{\mathbf{t}}_i, \quad \text{for } i = 1, \dots, K+1, \quad (34)$$

with the following definitions for $\tilde{\mathbf{S}}_i$ and $\tilde{\mathbf{t}}_i$:

- $\tilde{\mathbf{S}}_1$ is an $(N_1 + 2) \times (N_1 + 2)$ matrix whose non-zero entries are
 - $[\tilde{\mathbf{S}}_1]_{h,n} = [\mathbf{A}_n]_{1,1}$ for $n = 1, \dots, N_1$,
 - $[\tilde{\mathbf{S}}_1]_{N_1+1,n} = [\tilde{\mathbf{S}}_1]_{n,N_1+1} = [\mathbf{A}_n]_{1,2}$ for $n = 1, \dots, N_1$,
 - $[\tilde{\mathbf{S}}_1]_{N_1+1,N_1+1} = \sum_{n=1}^{N_1} [\mathbf{A}_n]_{2,2}$.
- $\tilde{\mathbf{S}}_{k+1}$, for $k = 1, \dots, K$, is an $(N_1 + 2) \times (N_1 + 2)$ matrix whose non-zero entries are
 - $[\tilde{\mathbf{S}}_{k+1}]_{n,n} = d_n$ for $n = 1, \dots, N_1$,
 - $[\tilde{\mathbf{S}}_{k+1}]_{N_1+1,N_1+1} = g_n$ for $n = 1, \dots, N_1$.
- $\tilde{\mathbf{t}}_1$ is an $(N_1 + 2)$ -dimensional vector whose non-zero entries are
 - $[\tilde{\mathbf{t}}_1]_n = [\tilde{\mathbf{b}}_n]_1$ for $n = 1, \dots, N_1$,
 - $[\tilde{\mathbf{t}}_1]_{N_1+1} = \sum_{n=1}^{N_1} [\tilde{\mathbf{b}}_n]_2$.
- $\tilde{\mathbf{t}}_{k+1}$, for $k = 1, \dots, K$, is an $(N_1 + 2)$ -dimensional vector whose non-zero entries are
 - $[\tilde{\mathbf{t}}_{k+1}]_n = \tilde{c}_n^k$ for $n = 1, \dots, N_1$,
 - $[\tilde{\mathbf{t}}_{k+1}]_{N_1+1} = \tilde{h}_k$.

We now explain how to obtain the values of all the $\tilde{\mathbf{A}}_n$, $\tilde{\mathbf{b}}_n$, \tilde{d}_n^k , \tilde{c}_n^k , \tilde{g}_n , \tilde{h}_k and \tilde{h}_k using EP.

A.1.1 ADJUSTING $\tilde{\Psi}(\mathbf{x}_i^j)$ BY EP

We explain how to adjust the parameters $\tilde{\mathbf{A}}_n$, $\tilde{\mathbf{b}}_n$, \tilde{d}_n^k and \tilde{c}_n^k of the approximate factor $\tilde{\Psi}(\mathbf{x}_i^j)$ using EP. EP performs this operation by minimizing the following Kullback-Leibler divergence:

$$\text{KL}[\Psi(\mathbf{x}_i^j) q^{-n}(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K) \| \tilde{\Psi}(\mathbf{x}_i^j) q^{-n}(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K)], \quad (35)$$

where $q^{-n}(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K)$ is the cavity distribution given by

$$q^{-n}(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K) = q(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K) [\tilde{\Psi}(\mathbf{x}_i^j)]^{-1}, \quad (36)$$

If we marginalize out all variables except those which $\tilde{\Psi}(\mathbf{x}_i^j)$ depends on, namely $\beta_n(\mathbf{f})$ and $c_1(\mathbf{x}_i^j), \dots, c_K(\mathbf{x}_i^j)$, then q^{-n} takes the form

$$q^{-n}[\beta_n(\mathbf{f}), c_1(\mathbf{x}_i^j), \dots, c_K(\mathbf{x}_i^j)] \propto \mathcal{N}(\beta_n(\mathbf{f}) | \mathbf{b}^{-n}, \mathbf{A}^{-n}) \left\{ \prod_{k=1}^K \mathcal{N}(c_k | \mathbf{x}_i^j) \right\} [e_k^{-n}, d_k^{-n}], \quad (37)$$

where the parameters \mathbf{b}^{-n} , \mathbf{A}^{-n} , e_k^{-n} and d_k^{-n} of these Gaussian distributions are obtained from the ratio of q and $\tilde{\Psi}(\mathbf{x}_i^j)$ by using the formula for dividing Gaussians:

$$\mathbf{A}^{-n} = \left\{ \mathbf{V}_{\beta_n(\mathbf{f})}^{-1} - \tilde{\mathbf{A}}_n \right\}^{-1}, \quad \mathbf{b}^{-n} = \mathbf{A}^{-n} \left\{ \mathbf{V}_{\beta_n(\mathbf{f})}^{-1} \mathbf{m}_{\beta_n(\mathbf{f})} - \tilde{\mathbf{b}}_n \right\}, \quad (38)$$

$$d_k^{-n} = \left\{ v_{c_k(\mathbf{x}_i^j)}^{-1} - \tilde{d}_k \right\}^{-1}, \quad e_k^{-n} = d_k^{-n} \left\{ v_{c_k(\mathbf{x}_i^j)}^{-1} m_{c_k(\mathbf{x}_i^j)} - \tilde{e}_k \right\}^{-1}, \quad (39)$$

where $\mathbf{V}_{\beta_n(\mathbf{f})}$ is the 2×2 covariance matrix for $\beta_n(\mathbf{f})$ given by $q(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K)$ in Eq. (32), $\mathbf{m}_{\beta_n(\mathbf{f})}$ is the corresponding 2-dimensional mean vector, $v_{c_k(\mathbf{x}_i^j)}$ is the variance for $c_k(\mathbf{x}_i^j)$ given by $q(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K)$ in Eq. (32) and $m_{c_k(\mathbf{x}_i^j)}$ is the corresponding mean parameter.

To minimize Eq. (35) we match the 1st and 2nd moments of $\Psi(\mathbf{x}_i^j) q^{-n}(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K)$ and $\tilde{\Psi}(\mathbf{x}_i^j) q^{-n}(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K)$. The moments of $\Psi(\mathbf{x}_i^j) q^{-n}(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K)$ can be obtained from the derivatives of the logarithm of its normalization constant Z , which is given by

$$Z = \int \Psi(\mathbf{x}_i^j) q^{-n}(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K) d\mathbf{f} dc_1 \dots dc_K = \Phi(\alpha_n) \prod_{k=1}^K \Phi[\alpha_n^k] + 1 - \prod_{k=1}^K \Phi[\alpha_n^k], \quad (40)$$

where $\alpha_n^k = m_{c_k(\mathbf{x}_i^j)} v_{c_k(\mathbf{x}_i^j)}^{-1/2}$ and $\alpha_n = [1, -1] \mathbf{m}_{\beta_n(\mathbf{f})} ([1, -1] \mathbf{V}_{\beta_n(\mathbf{f})} [1, -1]^\top)^{-1/2}$ and Φ is the standard Gaussian cdf. We follow Eqs. (5.12) and (5.13) in (Minka, 2001b) to update \tilde{d}_n^k and \tilde{c}_n^k in Eq. (30). However, we use the second partial derivative with respect to e_k^{-n} rather than first partial derivative with respect to d_k^{-n} for numerical robustness. These derivatives are given by

$$\frac{\partial \log Z}{\partial e_k^{-n}} = \frac{(Z-1) \phi(\alpha_n^k)}{Z \Phi(\alpha_n^k) \sqrt{d_k^{-n}}}, \quad \frac{\partial^2 \log Z}{\partial [e_k^{-n}]^2} = -\frac{\partial \log Z}{\partial e_k^{-n}} \cdot \frac{\alpha_n^k}{\sqrt{d_k^{-n}}} - \left[\frac{\partial \log Z}{\partial e_k^{-n}} \right]^2, \quad (41)$$

where ϕ is the standard Gaussian pdf. The update equations for the parameters \tilde{d}_n^k and \tilde{c}_n^k of the approximate factor $\tilde{\Psi}(\mathbf{x}_i^j)$ are then

$$[\tilde{d}_n^k]_{\text{new}} = - \left\{ \frac{\partial^2 \log Z}{\partial [e_k^{-n}]^2} + d_k^{-n} \right\}^{-1}, \quad [\tilde{c}_n^k]_{\text{new}} = \left\{ d_k^{-n} - \left[\frac{\partial^2 \log Z}{\partial [e_k^{-n}]^2} \right]^{-1} \frac{\partial \log Z}{\partial e_k^{-n}} \right\} [\tilde{d}_n^k]_{\text{new}}, \quad (42)$$

We now perform the analogous operations to update $\tilde{\mathbf{A}}_n$ and $\tilde{\mathbf{b}}_n$. We need to compute

$$\frac{\partial \log Z}{\partial \mathbf{b}^{-n}} = \frac{\left\{ \prod_{k=1}^K \Phi[\alpha_n^k] \right\} \phi(\alpha_n)}{Z \sqrt{s}} [1, -1], \quad (43)$$

$$\frac{\partial \log Z}{\partial \mathbf{A}^{-n}} = -\frac{1}{2} [1, -1]^\top [1, -1] \frac{\left\{ \prod_{k=1}^K \Phi[\alpha_n^k] \right\} \phi(\alpha_n) \alpha_n}{Z s}, \quad (44)$$

where $s = [-1, 1] \mathbf{A}^{-m} [-1, 1]^\top$. We then compute the mean vector and covariance matrix for $\beta_n(\mathbf{f})$ with respect to $\Psi(\mathbf{x}_k^j) q^{-m}(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K)$:

$$[\mathbf{V}_{\beta_n(\mathbf{f})}]_{\text{new}} = \mathbf{A}^{-m} - \mathbf{A}^{-m} \left[\frac{\partial \log Z}{\partial \mathbf{b}^{-m}} \left(\frac{\partial \log Z}{\partial \mathbf{b}^{-m}} \right)^\top - 2 \frac{\partial \log Z}{\partial \mathbf{A}^{-m}} \right] \mathbf{A}^{-m}, \quad (45)$$

$$[\mathbf{m}_{\beta_n(\mathbf{f})}]_{\text{new}} = \mathbf{b}^{-m} + \mathbf{A}^{-m} \frac{\partial \log Z}{\partial \mathbf{b}^{-m}}. \quad (46)$$

Next, we divide the Gaussian with mean and covariance parameters given by Eqs. (45) and (46) by the marginal for $\beta(\mathbf{f})$ in the cavity distribution $q^{-m}(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K)$. Therefore, the new parameters $\tilde{\mathbf{A}}_n$ and $\tilde{\mathbf{b}}_n$ of the approximate factor $\Psi(\mathbf{x}_k^j)$ are obtained using the formula for the ratio of two Gaussians:

$$\tilde{\mathbf{A}}_n^{\text{new}} = [\mathbf{V}_{\beta_n(\mathbf{f})}]_{\text{new}}^{-1} - [\mathbf{A}^{-m}]^{-1}, \quad (47)$$

$$\tilde{\mathbf{b}}_n^{\text{new}} = [\mathbf{V}_{\beta_n(\mathbf{f})}]_{\text{new}}^{-1} [\mathbf{m}_{\beta_n(\mathbf{f})}]_{\text{new}} - [\mathbf{A}^{-m}]^{-1} \mathbf{b}^{-m}. \quad (48)$$

A.1.2 ADJUSTING $\tilde{\Gamma}(\mathbf{x}_k^j)$ BY EP

We explain how to adjust the parameters \tilde{g}_k and \tilde{h}_k of the approximate factor $\tilde{\Gamma}(\mathbf{x}_k^j)$ using EP. EP performs this operation by minimizing the following Kullback-Leibler divergence:

$$\text{KL}[\tilde{\Gamma}(\mathbf{x}_k^j) q^{-m}(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K) \| \tilde{\Gamma}(\mathbf{x}_k^j) q^{-m}(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K)], \quad (49)$$

where $q^{-m}(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K)$ is the cavity distribution given by

$$q^{-m}(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K) = q(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K) [\tilde{\Gamma}(\mathbf{x}_k^j)]^{-1}, \quad (50)$$

We integrate out in q^{-m} all the variables except those which $\tilde{\Gamma}(\mathbf{x}_k^j)$ does depend on, namely, $c_1(\mathbf{x}_k^j), \dots, c_K(\mathbf{x}_k^j)$. Then q^{-m} takes the form

$$q^{-m}[c_1(\mathbf{x}_k^j), \dots, c_K(\mathbf{x}_k^j)] \propto \prod_{k=1}^K \mathcal{N}(c_k(\mathbf{x}_k^j) | h_k^-, g_k^-), \quad (51)$$

where the parameters h_k^- and g_k^- of these Gaussian distributions are obtained by using the formula for dividing Gaussians:

$$g_k^- = \left\{ v_{c_k(\mathbf{x}_k^j)}^{-1} - \tilde{g}_k^- \right\}^{-1}, \quad h_k^- = g_k^- \left\{ v_{c_k(\mathbf{x}_k^j)}^{-1} m_{c_k}(\mathbf{x}_k^j) - \tilde{e}_k^- \right\}^{-1}, \quad (52)$$

where $v_{c_k(\mathbf{x}_k^j)}$ is the variance for $c_k(\mathbf{x}_k^j)$ given by $q(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K)$ in Eq. (32) and $m_{c_k}(\mathbf{x}_k^j)$ is the corresponding mean parameter.

To minimize Eq. (49) we match the 1st and 2nd moments of $\tilde{\Gamma}(\mathbf{x}_k^j) q^{-m}(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K)$ and $\tilde{\Gamma}(\mathbf{x}_k^j) q^{-m}(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K)$. The moments of $\tilde{\Gamma}(\mathbf{x}_k^j) q^{-m}(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K)$ can be obtained from the derivatives of the logarithm of its normalization constant Z , which is given by

$$Z = \int \Gamma(\mathbf{x}_k^j) q^{-m}(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K) d\mathbf{f} d\mathbf{c}_1 \dots d\mathbf{c}_K = \prod_{k=1}^K \Phi \left[\frac{c_k}{\sigma_k} \right], \quad (53)$$

where $\alpha_n^k = m_{c_k(\mathbf{x}_k^j)} v_{c_k(\mathbf{x}_k^j)}^{-1/2}$. We follow Eqs. (5.12) and (5.13) in (Minka, 2001b) to update \tilde{g}_k and \tilde{h}_k in Eq. (31). However, we use the second partial derivative with respect to g_k^- rather than first partial derivative with respect to h_k^- for numerical robustness. These derivatives are given by

$$\frac{\partial \log Z}{\partial h_k^-} = \frac{(Z-1)\rho(\alpha_n^k)}{Z\Phi(\alpha_n^k)\sqrt{g_k^-}}, \quad \frac{\partial^2 \log Z}{\partial [h_k^-]^2} = -\frac{\partial \log Z}{\partial h_k^-} \cdot \frac{\alpha_n^k}{\sqrt{g_k^-}} - \left[\frac{\partial \log Z}{\partial h_k^-} \right]^2. \quad (54)$$

The update equations for the parameters \tilde{g}_k and \tilde{h}_k of the approximate factor $\tilde{\Gamma}(\mathbf{x}_k^j)$ are

$$[\tilde{g}_k]_{\text{new}} = - \left\{ \left(\frac{\partial^2 \log Z}{\partial [h_k^-]^2} \right)^{-1} + g_k^- \right\}^{-1}, \quad [\tilde{h}_k]_{\text{new}} = \left\{ g_k^- - \left[\frac{\partial^2 \log Z}{\partial [h_k^-]^2} \right] \frac{\partial \log Z}{\partial h_k^-} \right\} [\tilde{g}_k]_{\text{new}}.$$

A.2 Approximating the Non-Gaussian Factor that Depends on \mathbf{x}

Expectation propagation performs the operations described in Appendices A.1.1 and A.1.2 until the Gaussian approximations to $\Gamma(\mathbf{x}_k^j)$, $\Psi(\mathbf{x}_k^j), \dots, \Psi(\mathbf{x}_f^{N_f})$ converge. Importantly the EP operations described in Appendices A.1.1 and A.1.2 can be implemented independently of the value of \mathbf{x} , that is, the location at which we will be evaluating PESC's acquisition function. After EP has converged, the next step is to approximate with Gaussians the other factor in Eq. (26) that does depend on \mathbf{x} , that is, $\Psi(\mathbf{x})$. For this, we first replace the exact factors $\Gamma(\mathbf{x}_k^j)$, $\Psi(\mathbf{x}_k^j), \dots, \Psi(\mathbf{x}_f^{N_f})$ in Eq. (26) with their Gaussian approximations. This results in the following approximation:

$$f(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K | \mathbf{x}_k^j) \approx \tilde{f}(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K | \mathbf{x}_k^j) = q(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K) \Psi(\mathbf{x}), \quad (55)$$

where $q(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K)$, as given by Eq. (32), approximates the product of $p(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K | \mathcal{D})$ and $\Gamma(\mathbf{x}_k^j)$, $\Psi(\mathbf{x}_k^j), \dots, \Psi(\mathbf{x}_f^{N_f})$ in Eq. (26). Next, we find a Gaussian approximation to the right-hand-side of Eq. (55). For this, we first marginalize out in q all the variables except those which $\Psi(\mathbf{x})$ does depend on, that is, $\gamma(\mathbf{f})$ and $c_1(\mathbf{x}), \dots, c_K(\mathbf{x})$, where $\gamma(\mathbf{f}) = [f(\mathbf{x}), f(\mathbf{x}_k^j)]^\top$, we obtain

$$q[\gamma(\mathbf{f}), c_1(\mathbf{x}), \dots, c_K(\mathbf{x})] = \mathcal{N}(\gamma(\mathbf{f}) | \mathbf{m}_{\gamma(\mathbf{f})}, \mathbf{V}_{\gamma(\mathbf{f})}) \left\{ \prod_{k=1}^K \mathcal{N}(c_k(\mathbf{x}) | m_{c_k(\mathbf{x})}, v_{c_k(\mathbf{x})}) \right\}, \quad (56)$$

where $\mathbf{V}_{\gamma(\mathbf{f})}$ is the 2×2 covariance matrix for $\gamma(\mathbf{f})$ given by $q(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K)$ in Eq. (32), $\mathbf{m}_{\gamma(\mathbf{f})}$ is the corresponding 2-dimensional mean vector, $v_{c_k(\mathbf{x})}$ is the variance for $c_k(\mathbf{x})$ given by $q(\mathbf{f}, \mathbf{c}_1, \dots, \mathbf{c}_K)$ in Eq. (32) and $m_{c_k(\mathbf{x})}$ is the corresponding mean parameter.

Let \mathbf{m}_i^j and \mathbf{V}_i^j be the mean vector and covariance matrices for the first $N_1 + 1$ elements of \mathbf{f} in Eq. (24), according to q in Eq. (32). Similarly, \mathbf{m}_{k+1}^j and \mathbf{V}_{k+1}^j be the mean vector and covariance matrices for the first $N_1 + 1$ elements of \mathbf{c}_k in Eq. (25), according to q in Eq. (32), for $k = 1, \dots, K$. After the execution of EP, we compute and store \mathbf{m}_i^j and \mathbf{V}_i^j , for $i = 1, \dots, K$. These parameters can then be used to efficiently compute $\mathbf{V}_{\gamma(\mathbf{f})}$, $\mathbf{m}_{\gamma(\mathbf{f})}$, $v_{c_1(\mathbf{x})}, \dots, v_{c_K(\mathbf{x})}$ and $m_{c_1(\mathbf{x})}, \dots, m_{c_K(\mathbf{x})}$ for any arbitrary value of \mathbf{x} . For this, we use Eqs.

(3.22) and (3.24) in (Rasmussen and Williams, 2006) to obtain

$$\begin{aligned}
 [\mathbf{m}_{\gamma(\mathbf{f})}]_1 &= \mathbf{k}^1(\mathbf{x})^\top [\mathbf{K}_{k_*}^1]^{-1} \mathbf{m}'_1, \\
 [\mathbf{m}_{\gamma(\mathbf{f})}]_2 &= [\mathbf{m}'_1]_{N_1+1}, \\
 [\mathbf{V}_{\gamma(\mathbf{f})}]_{1,1} &= \mathbf{k}^1(\mathbf{x}, \mathbf{x}) - \mathbf{k}^1(\mathbf{x})^\top \left\{ [\mathbf{K}_{k_*}^1]^{-1} + [\mathbf{K}_{k_*}^1]^{-1} \mathbf{V}_1 [\mathbf{K}_{k_*}^1]^{-1} \right\} \mathbf{k}^1(\mathbf{x}), \\
 [\mathbf{V}_{\gamma(\mathbf{f})}]_{2,2} &= [\mathbf{V}'_1]_{N_1+1, N_1+1}, \\
 [\mathbf{V}_{\gamma(\mathbf{f})}]_{1,2} &= \mathbf{k}^1(\mathbf{x}, \mathbf{x}_i^j) - \mathbf{k}^1(\mathbf{x})^\top \left\{ [\mathbf{K}_{k_*}^1]^{-1} + [\mathbf{K}_{k_*}^1]^{-1} \mathbf{V}_1 [\mathbf{K}_{k_*}^1]^{-1} \right\} \mathbf{k}^1(\mathbf{x}_i^j), \\
 m_{\alpha_k(\mathbf{x})} &= \mathbf{k}^{k+1}(\mathbf{x})^\top [\mathbf{K}_{k_*}^{k+1}]^{-1} \mathbf{m}'_{k+1}, \\
 v_{\alpha_k(\mathbf{x})} &= \mathbf{k}^{k+1}(\mathbf{x}, \mathbf{x}) - \mathbf{k}^{k+1}(\mathbf{x})^\top \left\{ [\mathbf{K}_{k_*}^{k+1}]^{-1} + [\mathbf{K}_{k_*}^{k+1}]^{-1} \mathbf{V}'_{k+1} [\mathbf{K}_{k_*}^{k+1}]^{-1} \right\} \mathbf{k}^{k+1}(\mathbf{x}),
 \end{aligned}$$

for $k = 1, \dots, K$, where $\mathbf{k}^k(\mathbf{x})$ is the $(N_1 + 1)$ -dimensional vector with the prior cross-covariances between the value of the i -th function in $\{f, c_1, \dots, c_K\}$ at \mathbf{x} and the values of that function at $\mathbf{x}_f^1, \dots, \mathbf{x}_f^{N_1}, \mathbf{x}_x^1, \dots, \mathbf{x}_x^{N_1}$. $\mathbf{K}_{k_*}^k$ is an $(N_1 + 1) \times (N_1 + 1)$ matrix with the prior covariances between the values of that function at $\mathbf{x}_f^1, \dots, \mathbf{x}_f^{N_1}, \mathbf{x}_x^1, \dots, \mathbf{x}_x^{N_1}$ and $\mathbf{k}^k(\mathbf{x}, \mathbf{x})$ contains the prior variance of the values of that function at \mathbf{x} , for $i = 1, \dots, K + 1$. Finally, $\mathbf{k}^1(\mathbf{x}, \mathbf{x}_i^j)$ contains the prior covariance between $f(\mathbf{x})$ and $f(\mathbf{x}_i^j)$.

Once we have computed the parameters of $q[\gamma(\mathbf{f})|c_1(\mathbf{x}), \dots, c_K(\mathbf{x})]$ in Eq. (56) using the formulas above, we obtain the marginal means and variances for $f(\mathbf{x}), c_1(\mathbf{x}), \dots, c_K(\mathbf{x})$ with respect to $q[\gamma(\mathbf{f}), c_1(\mathbf{x}), \dots, c_K(\mathbf{x})|\Psi(\mathbf{x})]$. Let $m_1(\mathbf{x}), \dots, m_{K+1}(\mathbf{x})$ and $v_1(\mathbf{x}), \dots, v_{K+1}(\mathbf{x})$ be these marginal means and variances. Then, we have the approximation

$$\int q[\gamma(\mathbf{f}), c_1(\mathbf{x}), \dots, c_K(\mathbf{x})|\Psi(\mathbf{x})d\mathbf{f}d\mathbf{x}_i^j] \approx \mathcal{N}(f(\mathbf{x})|m_1(\mathbf{x}), v_1(\mathbf{x})) \prod_{k=1}^K \mathcal{N}(c_k(\mathbf{x})|m_{k+1}(\mathbf{x}), v_{k+1}(\mathbf{x})),$$

where $m_1(\mathbf{x}), \dots, m_{K+1}(\mathbf{x})$ and $v_1(\mathbf{x}), \dots, v_{K+1}(\mathbf{x})$ can be obtained from the normalization constant of $q[\gamma(\mathbf{f}), c_1(\mathbf{x}), \dots, c_K(\mathbf{x})|\Psi(\mathbf{x})]$ using Eqs. (5.12) and (5.13) in (Minka, 2001b). This normalization constant is given by

$$Z = \int q[\gamma(\mathbf{f}), c_1(\mathbf{x}), \dots, c_K(\mathbf{x})|\Psi(\mathbf{x})d\gamma(\mathbf{f})dc_1(\mathbf{x})dc_K(\mathbf{x})] = \Phi(\alpha) \prod_{k=1}^K \Phi(\alpha_k) + 1 - \prod_{k=1}^K \Phi(\alpha_k),$$

where

$$\alpha_k = \frac{m_{\alpha_k(\mathbf{x})}}{\sqrt{v_{\alpha_k(\mathbf{x})}}}, \quad \alpha = \frac{[1, -1]\mathbf{m}_{\gamma(\mathbf{f})}}{\sqrt{s}}, \quad s = [\mathbf{V}_{\gamma(\mathbf{f})}]_{1,1} + [\mathbf{V}_{\gamma(\mathbf{f})}]_{2,2} - 2[\mathbf{V}_{\gamma(\mathbf{f})}]_{1,2}. \quad (57)$$

Given Z , we then compute $m_1(\mathbf{x}), \dots, m_{K+1}(\mathbf{x})$ and $v_1(\mathbf{x}), \dots, v_{K+1}(\mathbf{x})$ using Eqs. (5.12) and (5.13) in (Minka, 2001b):

$$v_1(\mathbf{x}) = [\mathbf{V}_{\gamma(\mathbf{f})}]_{1,1} - \frac{\beta}{s} (\beta + \alpha) \left\{ [\mathbf{V}_{\gamma(\mathbf{f})}]_{1,1} - [\mathbf{V}_{\gamma(\mathbf{f})}]_{1,2} \right\}^2, \quad (58)$$

$$m_1(\mathbf{x}) = [\mathbf{m}_{\gamma(\mathbf{f})}]_1 + \left\{ [\mathbf{V}_{\gamma(\mathbf{f})}]_{1,1} - [\mathbf{V}_{\gamma(\mathbf{f})}]_{1,2} \right\} \frac{\beta}{\sqrt{s}}, \quad (59)$$

$$v_{k+1}(x) = \left\{ v_{\alpha_k(\mathbf{x})}^{-1} + \tilde{\alpha}_k \right\}^{-1}, \quad \text{for } k = 1, \dots, K, \quad (60)$$

$$m_{k+1}(x) = v_{k+1}(x) \left\{ m_{\alpha_k(\mathbf{x})} v_{\alpha_k(\mathbf{x})}^{-1} + \tilde{b}_k \right\}, \quad \text{for } k = 1, \dots, K, \quad (61)$$

where

$$\beta = Z^{-1} \phi(\alpha) \prod_{k=1}^K \Phi(\alpha_k), \quad \tilde{\alpha}_k = - \left\{ \frac{\partial^2 \log Z}{\partial m_{\alpha_k(\mathbf{x})}^2} + v_{\alpha_k(\mathbf{x})} \right\}^{-1}, \quad (62)$$

$$\tilde{b}_k = \tilde{\alpha}_k \left\{ m_{\alpha_k(\mathbf{x})} + \frac{\sqrt{v_{\alpha_k(\mathbf{x})}}}{\alpha_k + \beta_k} \right\}, \quad \frac{\partial^2 \log Z}{\partial m_{\alpha_k(\mathbf{x})}^2} = - \frac{\beta_k \{ \alpha_k + \beta_k \}}{v_{\alpha_k(\mathbf{x})}}, \quad (63)$$

$$\beta_k = \frac{\phi(\alpha_{n_i})}{Z\Phi(\alpha_{n_i})} (Z - 1). \quad (64)$$

Eqs. (58) to (61) are the output of our EP algorithm. These quantities are used in Eq. (20) to evaluate PESOC's acquisition function.

Appendix B. Implementation Considerations

We give details on the practical implementation of PESOC.

B.1 Initialization, Convergence of EP and Parallel EP Updates

We start by fixing the parameters of all the approximate factors $\tilde{\Gamma}(\mathbf{x}_i^j), \tilde{\Psi}(\mathbf{x}_f^1), \dots, \tilde{\Psi}(\mathbf{x}_f^{N_1})$ to be zero. We stop EP when the absolute change in the means and covariance matrices for the first $N_1 + 1$ elements of \mathbf{f} and c_1, \dots, c_K in Eqs. (24) and (25), according to q in Eq. (32), is below 10^{-4} . The approximate factors $\tilde{\Gamma}(\mathbf{x}_i^j), \tilde{\Psi}(\mathbf{x}_f^1), \dots, \tilde{\Psi}(\mathbf{x}_f^{N_1})$ are updated in parallel to speed up convergence (Gerwen et al., 2009). With parallel updates q in Eq. (20) is only updated once per iteration, after all the approximate factors have been refined.

B.2 EP with Damping

To improve the convergence of EP, we use damping (Minka and Laferrière, 2002). If $\tilde{\Psi}(\mathbf{x}_f^j)^{\text{new}}$ is the value of an approximate factor that minimizes the KL-divergence, damping entails using instead $\tilde{\Psi}(\mathbf{x}_f^j)^{\text{damped}}$ as the new factor value, as defined below:

$$\tilde{\Psi}(\mathbf{x}_f^j)^{\text{damped}} = [\tilde{\Psi}(\mathbf{x}_f^j)^{\text{new}}]^\epsilon + [\tilde{\Psi}(\mathbf{x}_f^j)^{\text{old}}]^{1-\epsilon}, \quad (65)$$

where $\tilde{\Psi}(\mathbf{x}_f^j)^{\text{old}}$ is the factor value before performing the update. We do the same for $\tilde{\Gamma}(\mathbf{x}_i^j)$. The parameter ϵ controls the amount of damping, with $\epsilon = 1$ corresponding to no damping. We initialize ϵ to 1 and multiply it by a factor of 0.99 at each iteration.

During the execution of EP, some covariance matrices in q or in the cavity distributions may become non-positive-definite due to an excessively large step size (i.e. large ϵ). If this issue is encountered during an EP iteration, the damping parameter is reduced by half and the iteration is repeated.

B.3 Sampling \mathbf{x}_* in PESC

We sample \mathbf{x}_* from its posterior distribution using an extension of the method described by Hernández-Lobato et al. (2014) to sample \mathbf{x}_* in the unconstrained setting. We perform a finite basis approximation to the GPs used to describe the data for the objective and the constraints. This allows us to sample analytic approximate samples from the GP posterior distribution. We then solve the optimization problem given by Eq. (1), when the functions f, c_1, \dots, c_K are replaced by the generated samples. For this, we use a numerical method for solving constrained optimization problems: the Method of Moving Asymptotes (MMA) (Svanberg, 2002) as implemented in the NLOpt package (Johnson, 2014). We evaluate the sampled functions in a uniform grid of size 10^3 and obtain the best feasible result in that grid. We add to the points in the uniform grid the evaluation locations for which we have already collected data. This is then used as the initial point for the MMA method. The number of basis functions in the approximation to the GP is 10^3 . The NLOpt convergence tolerance is 10^{-6} in the scaled input space units.

The finite basis approximation to the GP is given by a Bayesian Gaussian linear model build on top of a collection of basis functions (Hernández-Lobato et al., 2014). Drawing an approximate sample from the GP posterior distribution involves then sampling from the posterior distribution of that linear model given the observed data. When the number of basis functions is larger than the observed data points, this can be done efficiently as described by Hernández-Lobato et al. (2014). In this case, the covariance matrix of the Gaussian posterior distribution for the linear model is the sum of a low rank matrix and a diagonal matrix, we can then use an efficient method to sample from that Gaussian posterior distribution. This method is outlined in Appendix B.2 of Seeger (2008). The cost is $\mathcal{O}(N^2M)$ where N is the number of collected data points and M is the number of basis functions. Sampling with the naive method takes $\mathcal{O}(M^3)$ operations because we must take the Cholesky decomposition of an $M \times M$ covariance matrix. Given that in our implementation $M = 10^3$ and typically $N < 100$, this method can speed up this sampling procedure by orders of magnitude. A more efficient implementation could also be obtained by using quasi-random numbers to generate the basis functions, thus reducing the number of basis functions needed to attain the same approximation quality (Yang et al., 2014).

B.4 Cholesky Update in PESC-F

In PESC-F, during the fast BO computations, the GP hyperparameters (and in particular the length scales) are not changed from the ones used during last iteration. Because of this, the GP kernel matrix is unchanged except for the addition of a new row and column. Given this, we can compute the Cholesky decomposition of the new kernel matrix with a rank-one update of the Cholesky decomposition of the current kernel matrix. The $\mathcal{O}(N^3)$ computation of the Cholesky decomposition of the kernel matrix is the main bottleneck for GP-based Bayesian optimization. As N gets large, this trick can significantly speed

up the fast BO computations in PESC-F. In fact, this trick applies more generally beyond PESC-F or even any fast-update method: any Bayesian optimization method that does not update the GP hyperparameters at every iteration can take advantage of the rank-one Cholesky update. This update technique is described in more detail by Gill et al. (1974) and is commonly used in the setting of Bayesian optimization as seen in (Osborne, 2010).

Abstract

Biclustering structures in data matrices were first formalized in a seminal paper by John Hartigan (Hartigan, 1972) where one seeks to cluster cases and variables simultaneously. Such structures are also prevalent in block modeling of networks. In this paper, we develop a theory for the estimation and completion of matrices with biclustering structures, where the data is a partially observed and noise contaminated matrix with a certain underlying biclustering structure. In particular, we show that a constrained least squares estimator achieves minimax rate-optimal performance in several of the most important scenarios. To this end, we derive unified high probability upper bounds for all sub-Gaussian data and also provide matching minimax lower bounds in both Gaussian and binary cases. Due to the close connection of graphon to stochastic block models, an immediate consequence of our general results is a minimax rate-optimal estimator for sparse graphons.

Keywords: Biclustering, graphon, matrix completion, missing data, stochastic block models, sparse network

1. Introduction

In a range of important data analytic scenarios, we encounter matrices with biclustering structures. For instance, in gene expression studies, one can organize the rows of a data matrix to correspond to individual cancer patients and the columns to transcripts. Then the patients are expected to form groups according to different cancer subtypes and the genes are also expected to exhibit clustering effect according to the different pathways they belong to. Therefore, after appropriate reordering of the rows and the columns, the data matrix is expected to have a biclustering structure contaminated by noises (Lee et al., 2010). Here, the observed gene expression levels are real numbers. In a different context, such a biclustering structure can also be present in network data. For example, stochastic block model (SBM for short) (Holland et al., 1983) is a popular model for exchangeable networks. In SBMs, the graph nodes are partitioned into k disjoint communities and the probability that any pair of nodes are connected is determined entirely by the community memberships of the nodes. Consequently, if one rearranges the nodes from the same communities together in

the graph adjacency matrix, then the mean adjacency matrix, where each off-diagonal entry equals the probability of an edge connecting the nodes represented by the corresponding row and column, also has a biclustering structure.

The goal of the present paper is to develop a theory for the estimation (and completion when there are missing entries) of matrices with biclustering structures. To this end, we propose to consider the following general model

$$X_{ij} = \theta_{ij} + \epsilon_{ij}, \quad i \in [n_1], j \in [n_2], \quad (1)$$

where for any positive integer m , we let $[m] = \{1, \dots, m\}$. Here, for each (i, j) , $\theta_{ij} = \mathbb{E}[X_{ij}]$ and ϵ_{ij} is an independent piece of mean zero sub-Gaussian noise. Moreover, we allow entries to be missing completely at random (Rubin, 1976). Thus, let E_{ij} be i.i.d. Bernoulli random variables with success probability $p \in (0, 1]$ indicating whether the (i, j) th entry is observed, and define the set of observed entries

$$\Omega = \{(i, j) : E_{ij} = 1\}. \quad (2)$$

Our final observations are

$$X_{ij}, \quad (i, j) \in \Omega. \quad (3)$$

To model the biclustering structure, we focus on the case where there are k_1 row clusters and k_2 column clusters, and the values of $\{\theta_{ij}\}$ are taken as constant if the rows and the columns belong to the same clusters. The goal is then to recover the signal matrix $\theta \in \mathbb{R}^{n_1 \times n_2}$ from the observations (3). To accommodate most interesting cases, especially the case of undirected networks, we shall also consider the case where the data matrix X is symmetric with zero diagonals. In such cases, we also require $X_{ij} = X_{ji}$ and $E_{ij} = E_{ji}$ for all $i \neq j$.

Main contributions In this paper, we propose a unified estimation procedure for partially observed data matrix generated from model (1) – (3). We establish high probability upper bounds for the mean squared errors of the resulting estimators. In addition, we show that these upper bounds are minimax rate-optimal in both the continuous case and the binary case by providing matching minimax lower bounds. Furthermore, SBM can be viewed as a special case of the symmetric version of (1). Thus, an immediate application of our results is the network completion problem for SBMs. With partially observed network edges, our method gives a rate-optimal estimator for the probability matrix of the whole network in both the dense and the sparse regimes, which further leads to rate-optimal graphon estimation in both regimes.

Connection to the literature If only a low rank constraint is imposed on the mean matrix θ , then (1) – (3) becomes what is known in the literature as the matrix completion problem (Recht et al., 2010). An impressive list of algorithms and theories have been developed for this problem, including but not limited to Candès and Recht (2009); Keshavan et al. (2009); Candès and Tao (2010); Candès and Plan (2010); Cai et al. (2010); Keshavan et al. (2010); Recht (2011); Koltchinskii et al. (2011). In this paper, we investigate an alternative biclustering structural assumption for the matrix completion problem, which was first proposed by John Hartigan (Hartigan, 1972). Note that a biclustering structure

automatically implies low-rankness. However, if one applies a low rank matrix completion algorithm directly in the current setting, the resulting estimator suffers an inferior error bound to the minimax rate-optimal one. Thus, a full exploitation of the biclustering structure is necessary, which is the focus of the current paper.

The results of our paper also imply rate-optimal estimation for sparse graphons. Previous results on graphon estimation include Airolidi et al. (2013); Wolfe and Olhede (2013); Olhede and Wolfe (2014); Borgs et al. (2015); Choi (2015) and the references therein. The minimax rates for dense graphon estimation were derived by Gao et al. (2015a). During the time when this paper was written, we became aware of an independent result on optimal sparse graphon estimation by Klopp et al. (2015).

There are also an interesting line of works on biclustering (Flynn and Perry, 2012; Role et al., 2012; Choi and Wolfe, 2014). While these papers aim to recover the clustering structures of rows and columns, the goal of the current paper is to estimate the underlying mean matrix with optimal rates.

Organization After a brief introduction to notation, the rest of the paper is organized as follows. In Section 2, we introduce the precise formulation of the problem and propose a constrained least squares estimator for the mean matrix θ . In Section 3, we show that the proposed estimator leads to minimax optimal performance for both Gaussian and binary data. Section 4 presents some extensions of our results to sparse graphon estimation and adaptation. Implementation and simulation results are given in Section 5. In Section 6, we discuss the key points of the paper and propose some open problems for future research. The proofs of the main results are laid out in Section 7, with some auxiliary results deferred to the appendix.

Notation For a vector $z \in [k]^n$, define the set $z^{-1}(a) = \{i \in [n] : z(i) = a\}$ for $a \in [k]$. For a set S , $|S|$ denotes its cardinality and $\mathbf{1}_S$ denotes the indicator function. For a matrix $A = (A_{ij}) \in \mathbb{R}^{n_1 \times n_2}$, the ℓ_2 norm and ℓ_∞ norm are defined by $\|A\| = \sqrt{\sum_{ij} A_{ij}^2}$ and $\|A\|_\infty = \max_{ij} |A_{ij}|$, respectively. The inner product for two matrices A and B is $\langle A, B \rangle = \sum_{ij} A_{ij} B_{ij}$. Given a subset $\Omega \in [n_1] \times [n_2]$, we use the notation $\langle A, B \rangle_\Omega = \sum_{(i,j) \in \Omega} A_{ij} B_{ij}$ and $\|A\|_\Omega = \sqrt{\sum_{(i,j) \in \Omega} A_{ij}^2}$. Given two numbers $a, b \in \mathbb{R}$, we use $a \vee b = \max(a, b)$ and $a \wedge b = \min(a, b)$. The floor function $\lfloor a \rfloor$ is the largest integer no greater than a , and the ceiling function $\lceil a \rceil$ is the smallest integer no less than a . For two positive sequences $\{a_n\}, \{b_n\}$, $a_n \lesssim b_n$ means $a_n \leq C b_n$ for some constant $C > 0$ independent of n , and $a_n \gtrsim b_n$ means $a_n \gtrsim b_n$ and $b_n \lesssim a_n$. The symbols \mathbb{P} and \mathbb{E} denote generic probability and expectation operators whose distribution is determined from the context.

2. Constrained least squares estimation

Recall the generative model defined in (1) and also the definition of the set Ω in (2) of the observed entries. As we have mentioned, throughout the paper, we assume that the ϵ_{ij} 's are independent sub-Gaussian noises with sub-Gaussianity parameter uniformly bounded from above by $\sigma > 0$. More precisely, we assume

$$\mathbb{E} e^{\lambda \epsilon_{ij}} \leq e^{\lambda^2 \sigma^2 / 2}, \quad \text{for all } i \in [n_1], j \in [n_2] \text{ and } \lambda \in \mathbb{R}. \quad (4)$$

We consider two types of biclustering structures. One is rectangular and asymmetric, where we assume that the mean matrix belongs to the following parameter space

$$\Theta_{k_1 k_2}(M) = \left\{ \theta = (\theta_{ij}) \in \mathbb{R}^{n_1 \times n_2} : \theta_{ij} = Q_{z_1(i)z_2(j)}, z_1 \in [k_1]^{n_1}, z_2 \in [k_2]^{n_2}, \right. \\ \left. Q \in [-M, M]^{k_1 \times k_2} \right\}. \quad (5)$$

In other words, the mean values within each bicluster is homogenous, i.e., $\theta_{ij} = Q_{ab}$ if the i th row belongs to the a th row cluster and the j th column belong to the b th column cluster. The other type of structures we consider is the square and symmetric case. In this case, we impose symmetry requirement on the data generating process, i.e., $n_1 = n_2 = n$ and

$$X_{ij} = X_{ji}, E_{ij} = E_{ji}, \text{ for all } i \neq j. \quad (6)$$

Since the case is mainly motivated by undirected network data where there is no edge linking any node to itself, we also assume $X_{ii} = 0$ for all $i \in [n]$. Finally, the mean matrix is assumed to belong to the following parameter space

$$\Theta_k^s(M) = \left\{ \theta = (\theta_{ij}) \in \mathbb{R}^{n \times n} : \theta_{ii} = 0, \theta_{ij} = \theta_{ji} = Q_{z(i)z(j)} \text{ for } i > j, z \in [k]^n, \right. \\ \left. Q = Q^T \in [-M, M]^{k \times k} \right\}. \quad (7)$$

We proceed by assuming that we know the parameter space Θ which can be either $\Theta_{k_1 k_2}(M)$ or $\Theta_k^s(M)$ and the rate p of an independent entry being observed. The issues of adaptation to unknown numbers of clusters and unknown observation rate p are addressed later in Section 4.1 and Section 4.2. Given Θ and p , we propose to estimate θ by the following program

$$\min_{\theta \in \Theta} \left\{ \|\theta\|^2 - \frac{2}{p} \langle X, \theta \rangle_\Omega \right\}. \quad (8)$$

If we define

$$Y_{ij} = X_{ij} E_{ij} / p, \quad (9)$$

then (8) is equivalent to the following constrained least squares problem

$$\min_{\theta \in \Theta} \|Y - \theta\|^2, \quad (10)$$

and hence the name of our estimator. When the data is binary, $\Theta = \Theta_k^s(1)$ and $p = 1$, the problem specializes to estimating the mean adjacency matrix in stochastic block models, and the estimator defined as the solution to (10) reduces to the least squares estimator in Gao et al. (2015a).

3. Main results

In this section, we provide theoretical justifications of the constrained least squares estimator defined as the solution to (10). Our first result is the following universal high probability upper bounds.

Theorem 1. For any global optimizer of (10) and any constant $C' > 0$, there exists a constant $C > 0$ only depending on C' such that

$$\|\hat{\theta} - \theta\|^2 \leq C \frac{M^2 \vee \sigma^2}{p} (k_1 k_2 + n_1 \log k_1 + n_2 \log k_2),$$

with probability at least $1 - \exp(-C'(k_1 k_2 + n_1 \log k_1 + n_2 \log k_2))$ uniformly over $\theta \in \Theta_{k_1, k_2}(M)$ and all error distributions satisfying (4). For the symmetric parameter space $\Theta_k^s(M)$, the bound is simplified to

$$\|\hat{\theta} - \theta\|^2 \leq C \frac{M^2 \vee \sigma^2}{p} (k^2 + n \log k),$$

with probability at least $1 - \exp(-C'(k^2 + n \log k))$ uniformly over $\theta \in \Theta_k^s(M)$ and all error distributions satisfying (4).

When $(M^2 \vee \sigma^2)$ is bounded, the rate in Theorem 1 is $(k_1 k_2 + n_1 \log k_1 + n_2 \log k_2)/p$ which can be decomposed into two parts. The part involving $k_1 k_2$ reflects the number of parameters in the biclustering structure, while the part involving $(n_1 \log k_1 + n_2 \log k_2)$ results from the complexity of estimating the clustering structures of rows and columns. It is the price one needs to pay for not knowing the clustering information. In contrast, the minimax rate for matrix completion under low rank assumption would be $(n_1 \vee n_2)(k_1 \wedge k_2)/p$ (Koltchinskii et al., 2011; Ma and Wu, 2015), since without any other constraint the biclustering assumption implies that the rank of the mean matrix θ is at most $k_1 \wedge k_2$. Therefore, we have $(k_1 k_2 + n_1 \log k_1 + n_2 \log k_2)/p \ll (n_1 \vee n_2)(k_1 \wedge k_2)/p$ as long as both $n_1 \vee n_2$ and $k_1 \wedge k_2$ tend to infinity. Thus, by fully exploiting the biclustering structure, we obtain a better convergence rate than only using the low rank assumption.

In the rest of this section, we discuss two most representative cases, namely the Gaussian case and the symmetric Bernoulli case. The latter case is also known in the literature as stochastic block models.

The Gaussian case Specializing Theorem 1 to Gaussian random variables, we obtain the following result.

Corollary 2. Assume $\epsilon_{ij} \stackrel{iid}{\sim} N(0, \sigma^2)$ and $M \leq C_1 \sigma$ for some constant $C_1 > 0$. For any constant $C' > 0$, there exists some constant C only depending on C_1 and C' such that

$$\|\hat{\theta} - \theta\|^2 \leq C \frac{\sigma^2}{p} (k_1 k_2 + n_1 \log k_1 + n_2 \log k_2),$$

with probability at least $1 - \exp(-C'(k_1 k_2 + n_1 \log k_1 + n_2 \log k_2))$ uniformly over $\theta \in \Theta_{k_1, k_2}(M)$. For the symmetric parameter space $\Theta_k^s(M)$, the bound is simplified to

$$\|\hat{\theta} - \theta\|^2 \leq C \frac{\sigma^2}{p} (k^2 + n \log k),$$

with probability at least $1 - \exp(-C'(k^2 + n \log k))$ uniformly over $\theta \in \Theta_k^s(M)$.

We now present a rate matching lower bound in the Gaussian model to show that the result of Corollary 2 is minimax optimal. To this end, we use $\mathbb{P}_{(\theta, \sigma^2, p)}$ to indicate the probability distribution of the model $X_{ij} \stackrel{iid}{\sim} N(\theta_{ij}, \sigma^2)$ with observation rate p .

Theorem 3. Assume $\frac{\sigma^2}{p} \left(\frac{k_1 k_2}{n_1 n_2} + \frac{\log k_1}{n_2} + \frac{\log k_2}{n_1} \right) \lesssim M^2$. There exist some constants $C, c > 0$, such that

$$\inf_{\hat{\theta}} \sup_{\theta \in \Theta_{k_1, k_2}(M)} \mathbb{P}_{(\theta, \sigma^2, p)} \left(\|\hat{\theta} - \theta\|^2 > C \frac{\sigma^2}{p} (k_1 k_2 + n_1 \log k_1 + n_2 \log k_2) \right) > c,$$

when $\log k_1 \asymp \log k_2$, and

$$\inf_{\hat{\theta}} \sup_{\theta \in \Theta_k^s(M)} \mathbb{P}_{(\theta, \sigma^2, p)} \left(\|\hat{\theta} - \theta\|^2 > C \frac{\sigma^2}{p} (k^2 + n \log k) \right) > c.$$

The symmetric Bernoulli case When the observed matrix is symmetric with zero diagonal and Bernoulli random variables as its super-diagonal entries, it can be viewed as the adjacency matrix of an undirected network and the problem of estimating its mean matrix with missing data can be viewed as a network completion problem. Given a partially observed Bernoulli adjacency matrix $\{X_{ij}\}_{(i,j) \in \Omega}$, one can predict the unobserved edges by estimating the whole mean matrix θ . Also, we assume that each edge is observed independently with probability p .

Given a symmetric adjacency matrix $X = X^T \in \{0, 1\}^{n \times n}$ with zero diagonals, the stochastic block model (Holland et al., 1983) assumes $\{X_{ij}\}_{i>j}$ are independent Bernoulli random variables with mean $\theta_{ij} = Q_{z(i)z(j)} \in [0, 1]$ with some matrix $Q \in [0, 1]^{k \times k}$ and some label vector $z \in [k]^n$. In other words, the probability that there is an edge between the i th and the j th nodes only depends on their community labels $z(i)$ and $z(j)$. The following class then includes all possible mean matrices of stochastic block models with n nodes and k clusters and with edge probabilities uniformly bounded by ρ :

$$\Theta_k^+(\rho) = \left\{ \theta \in [0, 1]^{n \times n} : \theta_{ii} = 0, \theta_{ij} = \theta_{ji} = Q_{z(i)z(j)}, Q = Q^T \in [0, \rho]^{k \times k}, z \in [k]^n \right\}. \quad (11)$$

By the definition in (7), $\Theta_k^+(\rho) \subset \Theta_k^s(\rho)$.

Although the tail probability of Bernoulli random variables does not satisfy the sub-Gaussian assumption (4), a slightly modification of the proof of Theorem 1 leads to the following result. The proof of Corollary 4 will be given in Section A in the appendix.

Corollary 4. Consider the optimization problem (10) with $\Theta = \Theta_k^s(\rho)$. For any global optimizer $\hat{\theta}$ and any constant $C' > 0$, there exists a constant $C > 0$ only depending on C' such that

$$\|\hat{\theta} - \theta\|^2 \leq C \frac{\rho}{p} (k^2 + n \log k),$$

with probability at least $1 - \exp(-C'(k^2 + n \log k))$ uniformly over $\theta \in \Theta_k^s(\rho) \supset \Theta_k^+(\rho)$.

When $\rho = p = 1$, Corollary 4 implies Theorem 2.1 in Gao et al. (2015a). A rate matching lower bound is given by the following theorem. We denote the probability distribution of a stochastic block model with mean matrix $\theta \in \Theta_k^+(\rho)$ and observation rate p by $\mathbb{P}_{(\theta, p)}$.

Theorem 5. For stochastic block models, we have

$$\inf_{\hat{\theta}} \sup_{\theta \in \Theta_k^+(\rho)} \mathbb{P}_{(\theta, p)} \left(\|\hat{\theta} - \theta\|^2 > C \left(\frac{\rho(k^2 + n \log k)}{p} \wedge \rho^2 n^2 \right) \right) > c,$$

for some constants $C, c > 0$.

The lower bound is the minimum of two terms. When $\rho \geq \frac{k^2+n \log k}{pn^2}$, the rate becomes $\frac{\rho(k^2+n \log k)}{p} \wedge \rho^2 n^2 \asymp \frac{\rho(k^2+n \log k)}{p}$. It is achieved by the constrained least squares estimator according to Corollary 4. When $\rho < \frac{k^2+n \log k}{pn^2}$, the rate is dominated by $\rho^2 n^2$. In this case, a trivial zero estimator achieves the minimax rate.

In the case of $p = 1$, a comparable result has been found independently by Klopp et al. (2015). However, our result here is more general as it accommodates missing observations. Moreover, the general upper bounds in Theorem 1 even hold for networks with weighted edges.

4. Extensions

In this section, we extend the estimation procedure and the theory in Sections 2 and 3 toward three directions: adaptation to unknown observation rate, adaptation to unknown model parameters, and sparse graphon estimation.

4.1 Adaptation to unknown observation rate

The estimator (10) depends on the knowledge of the observation rate p . When p is not too small, such a knowledge is not necessary for achieving the desired rates. Define

$$\hat{p} = \frac{\sum_{i=1}^{n_1} \sum_{j=1}^{n_2} E_{ij}}{n_1 n_2} \quad (12)$$

for the asymmetric and

$$\hat{p} = \frac{\sum_{1 \leq i < j \leq n} E_{ij}}{\frac{1}{2}n(n-1)} \quad (13)$$

for the symmetric case, and redefine

$$Y_{ij} = X_{ij} E_{ij} / \hat{p} \quad (14)$$

where the actual definition of \hat{p} is chosen between (12) and (13) depending on whether one is dealing with the asymmetric or symmetric parameter space. Then we have the following result for the solution to (10) with Y redefined by (14).

Theorem 6. For $\Theta = \Theta_{k_1 k_2}(M)$, suppose for some absolute constant $C_1 > 0$,

$$p \geq C_1 \frac{[\log(n_1 + n_2)]^2}{k_1 k_2 + n_1 \log k_1 + n_2 \log k_2}.$$

Let $\hat{\theta}$ be the solution to (10) with Y defined as in (14). Then for any constant $C' > 0$, there exists a constant $C > 0$ only depending on C' and C_1 such that

$$\|\hat{\theta} - \theta\|^2 \leq C \frac{M^2 \vee \sigma^2}{p} (k_1 k_2 + n_1 \log k_1 + n_2 \log k_2),$$

with probability at least $1 - (n_1 n_2)^{-C'}$ uniformly over $\theta \in \Theta$ and all error distributions satisfying (4).

For $\Theta = \Theta_k^s(M)$, the same result holds if we replace n_1 and n_2 with n and k_1 and k_2 with k in the foregoing statement.

4.2 Adaptation to unknown model parameters

We now provide an adaptive procedure for estimating θ without assuming the knowledge of the model parameters k_1, k_2 and M . The procedure can be regarded as a variation of a 2-fold cross validation (Wold, 1978). We give details on the procedure for the asymmetric parameter spaces $\Theta_{k_1 k_2}(M)$, and that for the symmetric parameter spaces $\Theta_k^s(M)$ can be obtained similarly.

To adapt to k_1, k_2 and M , we split the data into two halves. Namely, sample i.i.d. T_{ij}^b from $\text{Bernoulli}(\frac{1}{2})$. Define $\Delta = \{(i, j) \in [n_1] \times n_2 : T_{ij} = 1\}$. Define $Y_{ij}^\Delta = 2X_{ij} E_{ij} T_{ij} / p$ and $Y_{ij}^{\Delta^c} = 2X_{ij} E_{ij} (1 - T_{ij}) / p$ for all $(i, j) \in [n_1] \times [n_2]$. Then, for some given (k_1, k_2, M) , the least squares estimators using Y^Δ and Y^{Δ^c} are given by

$$\hat{\theta}_{k_1 k_2 M}^\Delta = \underset{\theta \in \Theta_{k_1 k_2}(M)}{\operatorname{argmin}} \|Y^\Delta - \theta\|^2, \quad \hat{\theta}_{k_1 k_2 M}^{\Delta^c} = \underset{\theta \in \Theta_{k_1 k_2}(M)}{\operatorname{argmin}} \|Y^{\Delta^c} - \theta\|^2.$$

Select the parameters by

$$(\hat{k}_1, \hat{k}_2, \hat{M}) = \underset{(k_1, k_2, M) \in [n_1] \times [n_2] \times \mathcal{M}}{\operatorname{argmin}} \|\hat{\theta}_{k_1 k_2 M}^\Delta - Y^{\Delta^c}\|_{\Delta^c}^2,$$

where $\mathcal{M} = \left\{ \frac{h}{n_1 + n_2} : h \in [(n_1 + n_2)^b] \right\}$, and define $\hat{\theta}^\Delta = \hat{\theta}_{\hat{k}_1 \hat{k}_2 \hat{M}}^\Delta$. Similarly, we can also define $\hat{\theta}^{\Delta^c}$ to validate the parameters using Y^{Δ^c} . The final estimator is given by

$$\hat{\theta}_{ij} = \begin{cases} \hat{\theta}_{ij}^{\Delta^c}, & (i, j) \in \Delta; \\ \hat{\theta}_{ij}^\Delta, & (i, j) \in \Delta^c. \end{cases}$$

Theorem 7. Assume $(n_1 + n_2)^{-1} \leq M \leq (n_1 + n_2)^5 - (n_1 + n_2)^{-1}$. For any constant $C' > 0$, there exists a constant $C > 0$ only depending on C' such that

$$\|\hat{\theta} - \theta\|^2 \leq C \frac{M^2 \vee \sigma^2}{p} \left(k_1 k_2 + n_1 \log k_1 + n_2 \log k_2 + \frac{\log(n_1 + n_2)}{p} \right),$$

with probability at least $1 - \exp(-C'(k_1 k_2 + n_1 \log k_1 + n_2 \log k_2)) - (n_1 n_2)^{-C'}$ uniformly over $\theta \in \Theta_{k_1 k_2}(M)$ and all error distributions satisfying (4).

Compared with Theorem 1, the rate given by Theorem 7 has an extra $p^{-1} \log(n_1 + n_2)$ term. A sufficient condition for this extra term to be inconsequential is $p \gtrsim \frac{\log(n_1 + n_2)}{n_1 \wedge n_2}$. Theorem 7 is adaptive for all $(k_1, k_2) \in [n_1] \times [n_2]$ and for $(n_1 + n_2)^{-1} \leq M \leq (n_1 + n_2)^5 - (n_1 + n_2)^{-1}$. In fact, by choosing a larger M , we can extend the adaptive region for M to $(n_1 + n_2)^{-a} \leq M \leq (n_1 + n_2)^b$ for arbitrary constants $a, b > 0$.

4.3 Sparse graphon estimation

Consider a random graph with adjacency matrix $\{X_{ij}\} \in \{0, 1\}^{n \times n}$, whose sampling procedure is determined by

$$(\xi_1, \dots, \xi_n) \sim \mathbb{P}_\xi, \quad X_{ij} | (\xi_i, \xi_j) \sim \text{Bernoulli}(\theta_{ij}), \quad \text{where } \theta_{ij} = f(\xi_i, \xi_j). \quad (15)$$

For $i \in [n]$, $X_{ii} = \theta_{ii} = 0$. Conditioning on (ξ_1, \dots, ξ_n) , $X_{ij} = X_{ji}$ is independent across $i > j$. The function f on $[0, 1]^2$, which is assumed to be symmetric, is called a graphon. The concept of graphon is originated from graph limit theory (Hoover, 1979; Lovász and Szegedy, 2006; Diaconis and Janson, 2007; Lovász, 2012) and the studies of exchangeable arrays (Aldous, 1981; Kallenberg, 1989). It is the underlying nonparametric object that generates the random graph. Statistical estimation of graphon has been considered by Wolfe and Olhede (2013); Olhede and Wolfe (2014); Gao et al. (2015a,b); Lu and Zhou (2015) for dense networks. Using Corollary 4, we present a result for sparse graphon estimation.

Let us start with specifying the function class of graphons. Define the derivative operator by

$$\nabla_{jk} f(x, y) = \frac{\partial^{j+k}}{(\partial x)^j (\partial y)^k} f(x, y),$$

and we adopt the convention $\nabla_{00} f(x, y) = f(x, y)$. The Hölder norm is defined as

$$\|f\|_{\mathcal{H}_\alpha} = \max_{j+k \leq [\alpha]} \sup_{x, y \in \mathcal{D}} |\nabla_{jk} f(x, y)| + \max_{j+k = [\alpha]} \sup_{(x, y) \neq (x', y') \in \mathcal{D}} \frac{|\nabla_{jk} f(x, y) - \nabla_{jk} f(x', y')|}{\|(x - x', y - y')\|_{\alpha - [\alpha]}},$$

where $\mathcal{D} = \{(x, y) \in [0, 1]^2 : x \geq y\}$. Then, the sparse graphon class with Hölder smoothness α is defined by

$$\mathcal{F}_\alpha(\rho, L) = \{0 \leq f \leq \rho : \|f\|_{\mathcal{H}_\alpha} \leq L\sqrt{\rho}, f(x, y) = f(y, x) \text{ for all } x \in \mathcal{D}\},$$

where $L > 0$ is the radius of the class, which is assumed to be a constant. As argued in Gao et al. (2015a), it is sufficient to approximate a graphon with Hölder smoothness by a piecewise constant function. In the random graph setting, a piecewise constant function is the stochastic block model. Therefore, we can use the estimator defined by (10). Using Corollary 4, a direct bias-variance tradeoff argument leads to the following result. An independent finding of the same result is also made by Klopp et al. (2015).

Corollary 8. *Consider the optimization problem (10) where $Y_{ij} = X_{ij}$ and $\Theta = \Theta_k^*(M)$ with $k = \lceil \frac{1}{n^{1-\alpha}} \rceil$ and $M = \rho$. Given any global optimizer $\hat{\theta}$ of (10), we estimate f by $\hat{f}(\xi_i, \xi_j) = \hat{\theta}_{ij}$. Then, for any constant $C' > 0$, there exists a constant $C > 0$ only depending on C' and L such that*

$$\frac{1}{n^2} \sum_{i, j \in [n]} \left(\hat{f}(\xi_i, \xi_j) - f(\xi_i, \xi_j) \right)^2 \leq C\rho \left(n^{-\frac{2\alpha}{\alpha+1}} + \frac{\log n}{n} \right),$$

with probability at least $1 - \exp(-C'(n^{\frac{1}{\alpha+1}} + n \log n))$ uniformly over $f \in \mathcal{F}_\alpha(\rho, L)$ and \mathbb{P}_ξ .

Corollary 8 implies an interesting phase transition phenomenon. When $\alpha \in (0, 1)$, the rate becomes $\rho(n^{-\frac{2\alpha}{\alpha+1}} + \frac{\log n}{n}) \asymp \rho n^{-\frac{2\alpha}{\alpha+1}}$, which is the typical nonparametric rate times a sparsity index of the network. When $\alpha \geq 1$, the rate becomes $\rho(n^{-\frac{2\alpha}{\alpha+1}} + \frac{\log n}{n}) \asymp \frac{\rho \log n}{n}$, which does not depend on the smoothness α . Corollary 8 extends Theorem 2.3 of Gao et al. (2015a) to the case $\rho < 1$. In Wolfe and Olhede (2013), the graphon f is defined in a different way. Namely, they considered the setting where (ξ_1, \dots, ξ_n) are i.i.d. Unif $[0, 1]$ random variables under \mathbb{P}_ξ . Then, the adjacency matrix is generated with

Bernoulli random variables having means $\theta_{ij} = \rho f(\xi_i, \xi_j)$ for a nonparametric graphon f satisfying $\int_0^1 \int_0^1 f(x, y) dx dy = 1$. For this setting, with appropriate smoothness assumption, we can estimate f by $\hat{f}(\xi_i, \xi_j) = \hat{\theta}_{ij}/\rho$. The rate of convergence would be $\rho^{-1}(n^{-\frac{2\alpha}{\alpha+1}} + \frac{\log n}{n})$.

Using the result of Theorem 7, we present an adaptive version for Corollary 8. The estimator we consider is a symmetric version of the one introduced in Section 4.2. The only difference is that we choose the set \mathcal{M} as $\{m/n : m \in [n+1]\}$. The estimator is fully data driven in the sense that it does not depend on α or ρ .

Corollary 9. *Assume $\rho \geq n^{-1}$. Consider the adaptive estimator $\hat{\theta}$ introduced in Theorem 7, and we set $\hat{f}(\xi_i, \xi_j) = \hat{\theta}_{ij}$. Then, for any constant $C' > 0$, there exists a constant $C > 0$ only depending on C' and L such that*

$$\frac{1}{n^2} \sum_{i, j \in [n]} \left(\hat{f}(\xi_i, \xi_j) - f(\xi_i, \xi_j) \right)^2 \leq C\rho \left(n^{-\frac{2\alpha}{\alpha+1}} + \frac{\log n}{n} \right),$$

with probability at least $1 - n^{-C}$ uniformly over $f \in \mathcal{F}_\alpha(\rho, L)$ and \mathbb{P}_ξ .

5. Numerical Studies

To introduce an algorithm solving (8) or (10), we write (10) in an alternative way,

$$\min_{z_1 \in [k_1]^{n_1}, z_2 \in [k_2]^{n_2}, Q \in [u, l]^{k_1 \times k_2}} L(Q, z_1, z_2),$$

where l and u are the lower and upper constraints of the parameters and

$$L(Q, z_1, z_2) = \sum_{(i, j) \in [n_1] \times [n_2]} (Y_{ij} - Q_{z_1(i)z_2(j)})^2.$$

For biclustering, we set $l = -M$ and $u = M$. For SBM, we set $l = 0$ and $u = \rho$. We do not impose symmetry for SBM to gain computational convenience without losing much statistical accuracy. The simple form of $L(Q, z_1, z_2)$ indicates that we can iteratively optimize over (Q, z_1, z_2) with explicit formulas. This motivates the following algorithm.

The iteration steps (16), (17) and (18) of Algorithm 1 can be equivalently expressed as

$$\begin{aligned} Q &= \operatorname{argmin}_{Q \in [u, l]^{k_1 \times k_2}} L(Q, z_1, z_2); \\ z_1 &= \operatorname{argmin}_{z_1 \in [k_1]^{n_1}} L(Q, z_1, z_2); \\ z_2 &= \operatorname{argmin}_{z_2 \in [k_2]^{n_2}} L(Q, z_1, z_2). \end{aligned}$$

Thus, each iteration will reduce the value of the objective function. It is worth noting that Algorithm 1 can be viewed as a two-way extension for the ordinary k -means algorithm. Since the objective function is non-convex, one cannot guarantee convergence to global optimum. We initialize the algorithm via a spectral clustering step using multiple random starting points, which worked well on simulated datasets we present below.

Now we present some numerical results to demonstrate the accuracy of the error rate behavior suggested by Theorem 1 on simulated data.

Algorithm 1: A Biclustering Algorithm

Input : $\{X_{ij}\}_{(i,j) \in \Omega}$, the numbers of column and row clusters (k_1, k_2) , lower and upper constraints (l, u) and the number of random starting points m .

Output: An $n_1 \times n_2$ matrix θ with $\theta_{ij} = Q_{z_1(i)z_2(j)}$.

Preprocessing: Let $X_{ij} = 0$ for $(i, j) \notin \Omega$, $\hat{p} = |\Omega|/(n_1 n_2)$ and $Y = X/\hat{p}$.

1 Initialization Step

Apply singular value decomposition and obtain $Y = UDV^T$.

Run k -means algorithm on the first k_1 columns of U with m random starting points to get z_1 .

Run k -means algorithm on the first k_2 columns of V with m random starting points to get z_2 .

while not converge do

2 Update Q : for each $(a, b) \in [k_1] \times [k_2]$,

$$Q_{ab} = \frac{1}{|z_1^{-1}(a)||z_2^{-1}(b)|} \sum_{i \in z_1^{-1}(a)} \sum_{j \in z_2^{-1}(b)} Y_{ij}. \quad (16)$$

If $Q_{ab} > u$, let $Q_{ab} = u$. If $Q_{ab} < l$, let $Q_{ab} = l$.

3 Update z_1 : for each $i \in [n_1]$,

$$z_1(i) = \operatorname{argmin}_{a \in [k_1]} \sum_{j=1}^{n_2} (Q_{az_2(j)} - A_{ij})^2. \quad (17)$$

4 Update z_2 : for each $j \in [n_2]$,

$$z_2(j) = \operatorname{argmin}_{b \in [k_2]} \sum_{i=1}^{n_1} (Q_{z_1(i)b} - A_{ij})^2. \quad (18)$$

Bernoulli case. Our theoretical result indicates the rate of recovery is $\sqrt{\frac{p}{n} \left(\frac{k_1^2}{n_1^2} + \frac{\log k_1}{n} \right)}$

for the root mean squared error (RMSE) $\frac{1}{n} \|\hat{\theta} - \theta\|$. When k is not too large, the dominating term is $\sqrt{\frac{p \log k}{pn}}$. We are going to confirm this rate by simulation. We first generate our data from SBM with the number of blocks $k \in \{2, 4, 8, 16\}$. The observation rate $p = 0.5$. For every fixed k , we use four different $Q = 0.5\mathbf{1}_k \mathbf{1}_k^T + 0.1\mathbf{I}_k$ with $t = 1, 2, 3, 4$ and generate the community labels z uniformly on $[k]$. Then we calculate the error $\frac{1}{n} \|\hat{\theta} - \theta\|$. Panel (a) of Figure 1 shows the error versus the sample size n . In Panel (b), we rescale the x-axis to $N = \sqrt{\frac{pn}{\log k}}$. The curves for different k align well with each other and the error decreases at the rate of $1/N$. This confirms our theoretical results in Theorem 1.

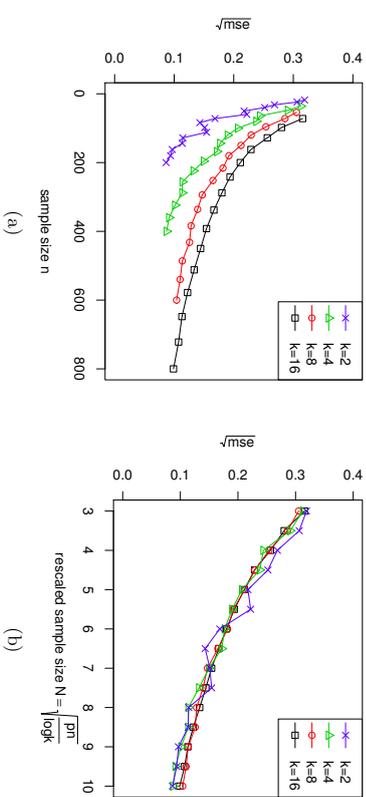

Figure 1: Plots of $\frac{1}{n} \|\hat{\theta} - \theta\|$ when using our algorithm on SBM. Each curve corresponds to a different sample size n with a fixed k . (a) Plots of error against the raw sample size n . (b) Plots of the same error against rescaled sample size $\sqrt{pn/\log k}$.

Gaussian case. We simulate data with Gaussian noise under four different settings of k_1 and k_2 . For each $(k_1, k_2) \in \{(4, 4), (4, 8), (8, 8), (8, 12)\}$, the entries of matrix Q are independently and uniformly generated from $\{1, 2, 3, 4, 5\}$. The cluster labels z_1 and z_2 are uniform on $[k_1]$ and $[k_2]$ respectively. After generating Q , z_1 and z_2 , we add an $N(0, 1)$ noise to the data and observe X_{ij} with probability $p = 0.1$. For each number of rows n_1 , we set the number of columns as $n_2 = n_1 \log k_1 / \log k_2$. Panel (a) of Figure 2 shows the error versus n_1 . In Panel (b), we rescale the x-axis by $N = \sqrt{\frac{pn_1}{\log k_2}}$. Again, the plots for different (k_1, k_2) align fairly well and the error decreases roughly at the rate of $1/N$.

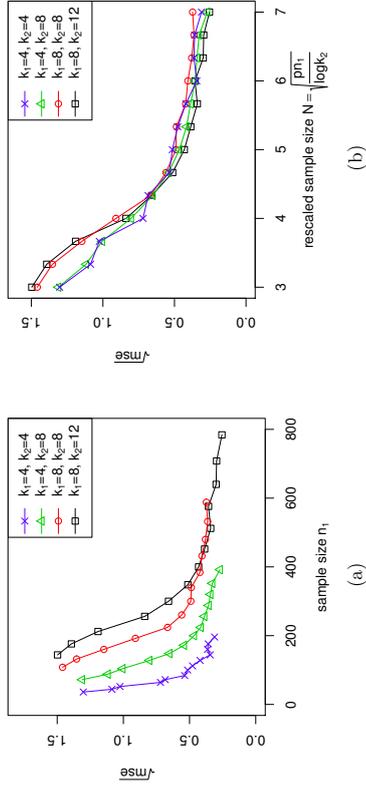

Figure 2: Plots of error $\frac{1}{\sqrt{n_1 n_2}} \|\hat{\theta} - \theta\|$ when using our algorithm on biclustering data with gaussian noise. Each curve corresponds to a fixed (k_1, k_2) . (a) Plots of error against n_1 . (b) Plots of the same error against $\sqrt{pn_1}/\log k_2$.

Sparse Bernoulli case. We also study recovery of sparse SBMs. We do the same simulation as the Bernoulli case except that we choose $Q = 0.02\mathbf{1}_k\mathbf{1}_k^T + 0.05\mathbf{I}_k$ for $t = 1, 2, 3, 4$. The results are shown in Figure 3.

Adaptation to unknown parameters. We use the 2-fold cross validation procedure proposed in Section 4.2 to adaptively choose the unknown number of clusters k and the sparsity level ρ . We use the setting of sparse SBM with the number of block $k \in \{4, 6\}$ and $Q = 0.05\mathbf{1}_k\mathbf{1}_k^T + 0.1\mathbf{I}_k$ for $t = 1, 2, 3, 4$. When running our algorithms, we search over all the (k, ρ) pair for $k \in \{2, 3, \dots, 8\}$ and $\rho \in \{0.2, 0.3, 0.4, 0.5\}$. In Table 1, we report the errors for different configurations of Q . The first row is the error obtained by our adaptive procedure and the second row is the error using the true k and ρ . Consistent with our Theorem 7, the error from the adaptive procedure is almost the same as the oracle error.

rescaled sample size	6	12	18	24
($k=4$) adaptive \sqrt{mse}	0.084	0.066	0.058	0.058
oracle \sqrt{mse}	0.085	0.069	0.060	0.053
($k=6$) adaptive \sqrt{mse}	0.074	0.061	0.051	0.050
oracle \sqrt{mse}	0.078	0.067	0.056	0.048

Table 1: Errors of the adaptive procedure versus the oracle.

The effect of constraints. The optimization (10) and Algorithm 1 involves the constraint $Q \in [l, u]^{k_1 \times k_2}$. It is curious whether this constraint really helps reduce the error or

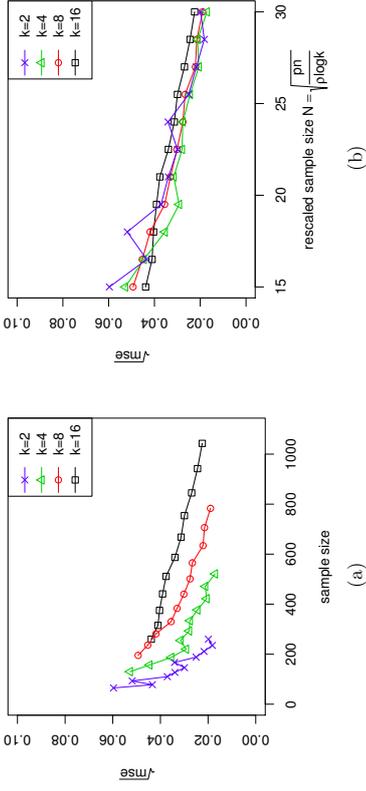

Figure 3: Plots of error $\frac{1}{n} \|\hat{\theta} - \theta\|$ when using our algorithm on sparse SBM. Each curve corresponds to a fixed k . (a) Plots of error against the raw sample size n . (b) Plots of the same error against rescaled sample size $\sqrt{pn}/\log k$.

merely an artifact of the proof. We investigate the effect of this constraint on simulated data by comparing Algorithm 1 with its variation without the constraint for both Gaussian case and sparse Bernoulli case. Panel (a) of Figure 4 shows the plots of sparse SBM with 8 communities. Panel (b) is the plots of Gaussian case with $(k_1, k_2) = (4, 8)$. For both panels, when the rescaled sample size is small, the effect of constraint is significant, while as the rescaled sample size increases, the performance of two estimators become similar.

6. Discussion

This paper studies the optimal rates of recovering a matrix with biclustering structure. While the recent progresses in high-dimensional estimation mainly focus on sparse and low rank structures, the study of biclustering structure does not gain much attention. This paper fills in the gap. In what follows, we discuss some key points of the paper and some possible future directions of research.

Difference from low-rankness. A biclustering structure is implicitly low-rank. Therefore, we show that by exploring the stronger biclustering assumption, one can achieve better rates of convergence in estimation and completion. The minimax rates derived in this paper precisely characterize how much one can gain by taking advantage of this structure.

Relation to other structures. A natural question to investigate is whether there is similarity between the biclustering structure and the well-studied sparsity structure. The paper Gao et al. (2015b) gives a general theory of structured estimation in linear models that puts both sparse and biclustering structures in a unified theoretical framework. According

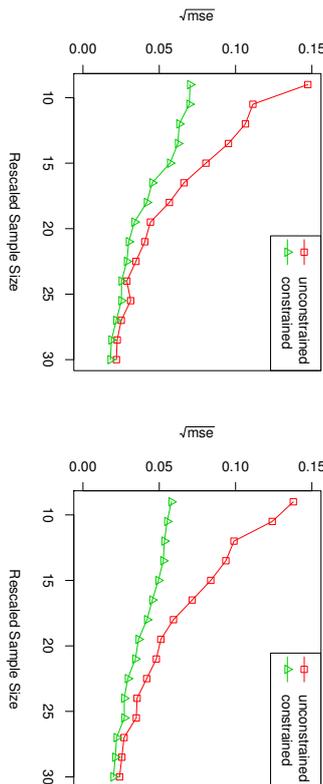

Figure 4: Constrained versus unconstrained least-squares
 (a) Sparse SBM with $k = 8$ (b) Gaussian biclustering with $(k_1, k_2) = (4, 8)$

to this general theory, the $k_1 k_2$ part in the minimax rate is the complexity of parameter estimation and the $n_1 \log k_1 + n_2 \log k_2$ part is the complexity of structure estimation.

Open problems. The optimization problem (10) is not convex, thus causing difficulty in devising a provably optimal polynomial-time algorithm. An open question is whether there is a convex relaxation of (10) that can be solved efficiently without losing much statistical accuracy. Another interesting problem for future research is whether the objective function in (10) can be extended beyond the least squares framework.

7. Proofs

7.1 Proof of Theorem 1

Below, we focus on the proof for the asymmetric parameter space $\Theta_{k_1, k_2}(M)$. The result for the symmetric parameter space $\Theta_k^s(M)$ can be obtained by letting $k_1 = k_2$ and by taking care of the diagonal entries. Since $\hat{\theta} \in \Theta_{k_1, k_2}(M)$, there exists $\hat{z}_1 \in [k_1]^{n_1}$, $\hat{z}_2 \in [k_2]^{n_2}$ and $\hat{Q} \in [-M, M]^{k_1 \times k_2}$ such that $\hat{\theta}_{ij} = \hat{Q}_{\hat{z}_1(i)\hat{z}_2(j)}$. For this (\hat{z}_1, \hat{z}_2) , we define a matrix $\tilde{\theta}$ by

$$\tilde{\theta}_{ij} = \frac{1}{|\hat{z}_1^{-1}(a)| |\hat{z}_2^{-1}(b)|} \sum_{(i,j) \in \hat{z}_1^{-1}(a) \times \hat{z}_2^{-1}(b)} \theta_{ij},$$

for any $(i, j) \in \hat{z}_1^{-1}(a) \times \hat{z}_2^{-1}(b)$ and any $(a, b) \in [k_1] \times [k_2]$. To facilitate the proof, we need to following three lemmas, whose proofs are given in the supplementary material.

Lemma 10. For any constant $C' > 0$, there exists a constant $C_1 > 0$ only depending on C' , such that

$$\|\hat{\theta} - \tilde{\theta}\|^2 \leq C_1 \frac{M^2 \vee \sigma^2}{p} (k_1 k_2 + n_1 \log k_1 + n_2 \log k_2),$$

with probability at least $1 - \exp(-C'(k_1 k_2 + n_1 \log k_1 + n_2 \log k_2))$.

Lemma 11. For any constant $C' > 0$, there exists a constant $C_2 > 0$ only depending on C' , such that the inequality $\|\hat{\theta} - \theta\|^2 \geq C_2 (M^2 \vee \sigma^2) (n_1 \log k_1 + n_2 \log k_2) / p$ implies

$$\left\langle \frac{\hat{\theta} - \theta}{\|\hat{\theta} - \theta\|}, Y - \theta \right\rangle \leq \sqrt{C_2 \frac{M^2 \vee \sigma^2}{p} (k_1 k_2 + n_1 \log k_1 + n_2 \log k_2)},$$

with probability at least $1 - \exp(-C'(k_1 k_2 + n_1 \log k_1 + n_2 \log k_2))$.

Lemma 12. For any constant $C' > 0$, there exists a constant $C_3 > 0$ only depending on C' , such that

$$\left| \langle \hat{\theta} - \tilde{\theta}, Y - \theta \rangle \right| \leq C_3 \frac{M^2 \vee \sigma^2}{p} (k_1 k_2 + n_1 \log k_1 + n_2 \log k_2),$$

with probability at least $1 - \exp(-C'(k_1 k_2 + n_1 \log k_1 + n_2 \log k_2))$.

Proof of Theorem 1. Applying union bound, the results of Lemma 10-12 hold with probability at least $1 - 3 \exp(-C'(k_1 k_2 + n_1 \log k_1 + n_2 \log k_2))$. We consider the following two cases.

Case 1: $\|\tilde{\theta} - \theta\|^2 \leq C_2 (M^2 \vee \sigma^2) (k_1 k_2 + n_1 \log k_1 + n_2 \log k_2) / p$. Then we have

$$\|\hat{\theta} - \theta\|^2 \leq 2\|\hat{\theta} - \tilde{\theta}\|^2 + 2\|\tilde{\theta} - \theta\|^2 \leq 2(C_1 + C_2) \frac{M^2 \vee \sigma^2}{p} (k_1 k_2 + n_1 \log k_1 + n_2 \log k_2)$$

by Lemma 10.

Case 2: $\|\tilde{\theta} - \theta\|^2 > C_2 (M^2 \vee \sigma^2) (k_1 k_2 + n_1 \log k_1 + n_2 \log k_2) / p$.

By the definition of the estimator, we have $\|\hat{\theta} - Y\|^2 \leq \|\hat{\theta} - Y\|^2$. After rearrangement, we have

$$\begin{aligned} \|\hat{\theta} - \theta\|^2 &\leq 2 \langle \hat{\theta} - \theta, Y - \theta \rangle \\ &= 2 \langle \hat{\theta} - \tilde{\theta}, Y - \theta \rangle + 2 \langle \tilde{\theta} - \theta, Y - \theta \rangle \\ &\leq 2 \langle \hat{\theta} - \tilde{\theta}, Y - \theta \rangle + 2\|\tilde{\theta} - \theta\| \left\langle \frac{\tilde{\theta} - \theta}{\|\tilde{\theta} - \theta\|}, Y - \theta \right\rangle \\ &\leq 2 \langle \hat{\theta} - \tilde{\theta}, Y - \theta \rangle + 2(\|\tilde{\theta} - \theta\| + \|\hat{\theta} - \theta\|) \left\langle \frac{\hat{\theta} - \theta}{\|\hat{\theta} - \theta\|}, Y - \theta \right\rangle \\ &\leq 2(C_2 + C_3 + \sqrt{C_1 C_2}) \frac{M^2 \vee \sigma^2}{p} (k_1 k_2 + n_1 \log k_1 + n_2 \log k_2) + \frac{1}{2} \|\hat{\theta} - \theta\|^2, \end{aligned}$$

which leads to the bound

$$\|\hat{\theta} - \theta\|^2 \leq 4(C_2 + C_3 + \sqrt{C_1 C_2}) \frac{M^2 \vee \sigma^2}{p} (k_1 k_2 + n_1 \log k_1 + n_2 \log k_2).$$

Combining the two cases, we have

$$\|\hat{\theta} - \theta\|^2 \leq C \frac{M^2 \vee \sigma^2}{p} (k_1 k_2 + n_1 \log k_1 + n_2 \log k_2),$$

with probability at least $1 - 3 \exp(-C'(k_1 k_2 + n_1 \log k_1 + n_2 \log k_2))$ for $C = 4(C_2 + C_3 + \sqrt{C_1 C_2}) \vee 2(C_1 + C_2)$. \square

7.2 Proof of Theorem 7

We first present a lemma for the tail behavior of sum of independent products of sub-Gaussian and Bernoulli random variables. Its proof is given in the supplementary material.

Lemma 13. *Let $\{X_i\}$ be independent sub-Gaussian random variables with mean $\theta_i \in [-M, M]$ and $\mathbb{E}e^{\lambda(X_i - \theta_i)} \leq e^{\lambda^2 \sigma^2 / 2}$. Let $\{E_i\}$ be independent Bernoulli random variables with mean p . Assume $\{X_i\}$ and $\{E_i\}$ are all independent. Then for $|\lambda| \leq p/(M \vee \sigma)$ and $Y_i = X_i E_i / p$, we have*

$$\mathbb{E}e^{\lambda(Y_i - \theta_i)} \leq 2e^{(M^2 + 2\sigma^2)\lambda^2 / p}.$$

Moreover, for $\sum_{i=1}^n c_i^2 = 1$,

$$\mathbb{P} \left\{ \left| \sum_{i=1}^n c_i (Y_i - \theta_i) \right| \geq t \right\} \leq 4 \exp \left\{ - \min \left(\frac{pt^2}{4(M^2 + 2\sigma^2)}, 2(M \vee \sigma) \|c\|_\infty \right) \right\} \quad (19)$$

for any $t > 0$.

Proof of Theorem 7. Consider the mean matrix θ that belongs to the space $\Theta_{k_1, k_2}(M)$. By the definition of $(\hat{k}_1, \hat{k}_2, \hat{M})$, we have $\|\hat{\theta}_{\hat{k}_1, \hat{k}_2, \hat{M}}^\Delta - Y^{\Delta^c}\|_{\Delta^c}^2 \leq \|\hat{\theta}_{\hat{k}_1, \hat{k}_2, \hat{M}}^\Delta - Y^{\Delta^c}\|_{\Delta^c}^2$, where k_1 and k_2 are true numbers of row and column clusters and m is chosen to be the smallest element in \mathcal{M} that is no smaller than M . After rearrangement, we have

$$\begin{aligned} & \|\hat{\theta}_{\hat{k}_1, \hat{k}_2, \hat{M}}^\Delta - \theta\|_{\Delta^c}^2 \\ & \leq \|\hat{\theta}_{\hat{k}_1, \hat{k}_2, \hat{M}}^\Delta - \theta\|_{\Delta^c}^2 + 2\|\hat{\theta}_{\hat{k}_1, \hat{k}_2, \hat{M}}^\Delta - \hat{\theta}_{\hat{k}_1, \hat{k}_2, \hat{M}}^\Delta\|_{\Delta^c} \left\langle \frac{\hat{\theta}_{\hat{k}_1, \hat{k}_2, \hat{M}}^\Delta - \hat{\theta}_{\hat{k}_1, \hat{k}_2, \hat{M}}^\Delta}{\|\hat{\theta}_{\hat{k}_1, \hat{k}_2, \hat{M}}^\Delta - \hat{\theta}_{\hat{k}_1, \hat{k}_2, \hat{M}}^\Delta\|_{\Delta^c}}, Y^{\Delta^c} - \theta \right\rangle_{\Delta^c} \\ & \leq \|\hat{\theta}_{\hat{k}_1, \hat{k}_2, \hat{M}}^\Delta - \theta\|_{\Delta^c}^2 + 2\|\hat{\theta}_{\hat{k}_1, \hat{k}_2, \hat{M}}^\Delta - \hat{\theta}_{\hat{k}_1, \hat{k}_2, \hat{M}}^\Delta\|_{\Delta^c} \max_{(l_1, l_2) \in [n_1] \times [n_2]} \left\langle \frac{\hat{\theta}_{l_1 l_2 h}^\Delta - \hat{\theta}_{\hat{k}_1, \hat{k}_2, \hat{M}}^\Delta}{\|\hat{\theta}_{l_1 l_2 h}^\Delta - \hat{\theta}_{\hat{k}_1, \hat{k}_2, \hat{M}}^\Delta\|_{\Delta^c}}, Y^{\Delta^c} - \theta \right\rangle_{\Delta^c}. \end{aligned}$$

By Lemma 13 and the independence structure, we have

$$\max_{(l_1, l_2, h) \in [n_1] \times [n_2] \times \mathcal{M}} \left| \left\langle \frac{\hat{\theta}_{l_1 l_2 h}^\Delta - \hat{\theta}_{\hat{k}_1, \hat{k}_2, \hat{M}}^\Delta}{\|\hat{\theta}_{l_1 l_2 h}^\Delta - \hat{\theta}_{\hat{k}_1, \hat{k}_2, \hat{M}}^\Delta\|_{\Delta^c}}, Y^{\Delta^c} - \theta \right\rangle_{\Delta^c} \right| \leq C(M \vee \sigma) \frac{\log(n_1 + n_2)}{p},$$

with probability at least $1 - (n_1 n_2)^{-C'}$. Using triangle inequality and Cauchy-Schwarz inequality, we have

$$\|\hat{\theta}_{\hat{k}_1, \hat{k}_2, \hat{M}}^\Delta - \theta\|_{\Delta^c}^2 \leq \frac{3}{2} \|\hat{\theta}_{\hat{k}_1, \hat{k}_2, \hat{M}}^\Delta - \theta\|_{\Delta^c}^2 + \frac{1}{2} \|\hat{\theta}_{\hat{k}_1, \hat{k}_2, \hat{M}}^\Delta - \theta\|_{\Delta^c}^2 + 4C^2(M^2 \vee \sigma^2) \left(\frac{\log(n_1 + n_2)}{p} \right)^2.$$

By rearranging the above inequality, we have

$$\|\hat{\theta}_{\hat{k}_1, \hat{k}_2, \hat{M}}^\Delta - \theta\|_{\Delta^c}^2 \leq 3\|\hat{\theta}_{\hat{k}_1, \hat{k}_2, \hat{M}}^\Delta - \theta\|_{\Delta^c}^2 + 8C^2(M^2 \vee \sigma^2) \left(\frac{\log(n_1 + n_2)}{p} \right)^2.$$

A symmetric argument leads to

$$\|\hat{\theta}_{\hat{k}_1, \hat{k}_2, \hat{M}}^{\Delta^c} - \theta\|_{\Delta}^2 \leq 3\|\hat{\theta}_{\hat{k}_1, \hat{k}_2, \hat{M}}^{\Delta^c} - \theta\|_{\Delta}^2 + 8C^2(M^2 \vee \sigma^2) \left(\frac{\log(n_1 + n_2)}{p} \right)^2.$$

Summing up the above two inequalities, we have

$$\|\hat{\theta} - \theta\|^2 \leq 3\|\hat{\theta}_{\hat{k}_1, \hat{k}_2, \hat{M}}^\Delta - \theta\|^2 + 3\|\hat{\theta}_{\hat{k}_1, \hat{k}_2, \hat{M}}^{\Delta^c} - \theta\|^2 + 16C^2(M^2 \vee \sigma^2) \left(\frac{\log(n_1 + n_2)}{p} \right)^2. \quad (20)$$

Using Theorem 1 to bound $\|\hat{\theta}_{\hat{k}_1, \hat{k}_2, \hat{M}}^\Delta - \theta\|^2$ and $\|\hat{\theta}_{\hat{k}_1, \hat{k}_2, \hat{M}}^{\Delta^c} - \theta\|^2$ can be bounded by $C \frac{m^2 \vee \sigma^2}{p} (k_1 k_2 + n_1 \log k_1 + n_2 \log k_2)$. Given that $m = M \left(1 + \frac{M}{m}\right) \leq 2M$ by the choice of m , the proof is complete. \square

7.3 Proof of Theorem 6

Recall the augmented data $Y_{ij} = X_{ij} E_{ij} / p$. Define $\mathcal{Y}_{ij} = X_{ij} E_{ij} / \hat{p}$. Let us give two lemmas to facilitate the proof.

Lemma 14. *Assume $p \gtrsim \frac{\log(n_1 + n_2)}{n_1 n_2}$. For any $C' > 0$, there is some constant $C > 0$ such that*

$$\|Y - \mathcal{Y}\|^2 \leq C \left[M^2 + \sigma^2 \log(n_1 + n_2) \right] \frac{\log(n_1 + n_2)}{p^2},$$

with probability at least $1 - (n_1 n_2)^{-C'}$.

Lemma 15. *The inequalities in Lemma 10-12 continue to hold with bounds*

$$\begin{aligned} C_1 \frac{M^2 \vee \sigma^2}{p} (k_1 k_2 + n_1 \log k_1 + n_2 \log k_2) + 2\|Y - \mathcal{Y}\|^2, \\ \sqrt{C_2 \frac{M^2 \vee \sigma^2}{p} (k_1 k_2 + n_1 \log k_1 + n_2 \log k_2) + \|Y - \mathcal{Y}\|}, \\ C_3 \frac{M^2 \vee \sigma^2}{p} (k_1 k_2 + n_1 \log k_1 + n_2 \log k_2) + \|\hat{\theta} - \tilde{\theta}\| \|Y - \mathcal{Y}\|, \end{aligned}$$

and

respectively.

Proof of Theorem 6. The proof is similar to that of Theorem 1. We only need to replace Lemma 10-12 by Lemma 14 and Lemma 15 to get the desired result. \square

7.4 Proofs of Theorem 3 and Theorem 5

This section gives proofs of the minimax lower bounds. We first introduce some notation. For any probability measures \mathbb{P}, \mathbb{Q} , define the Kullback-Leibler divergence by $D(\mathbb{P} \parallel \mathbb{Q}) = \int \left(\log \frac{d\mathbb{P}}{d\mathbb{Q}} \right) d\mathbb{P}$. The chi-squared divergence is defined by $\chi^2(\mathbb{P} \parallel \mathbb{Q}) = \int \left(\frac{d\mathbb{P}}{d\mathbb{Q}} - 1 \right)^2 d\mathbb{P} - 1$. The main tool we will use is the following proposition.

Proposition 16. *Let (Ξ, ℓ) be a metric space and $\{\mathbb{P}_\xi : \xi \in \Xi\}$ be a collection of probability measures. For any totally bounded $T \subseteq \Xi$, define the Kullback-Leibler diameter and the chi-squared diameter of T by*

$$d_{KL}(T) = \sup_{\xi, \xi' \in T} D(\mathbb{P}_\xi \parallel \mathbb{P}_{\xi'}), \quad d_{\chi^2}(T) = \sup_{\xi, \xi' \in T} \chi^2(\mathbb{P}_\xi \parallel \mathbb{P}_{\xi'}).$$

Then

$$\inf_{\xi \in \Xi} \sup_{\mathbb{P}^\xi} \mathbb{P}^\xi \left\{ \rho^2(\hat{\xi}(X), \xi) \geq \frac{\epsilon^2}{4} \right\} \geq 1 - \frac{d_{KL}(T) + \log 2}{\log \mathcal{M}(\epsilon, T, \theta)}, \quad (21)$$

$$\inf_{\xi \in \Xi} \sup_{\mathbb{P}^\xi} \left\{ \rho^2(\hat{\xi}(X), \xi) \geq \frac{\epsilon^2}{4} \right\} \geq 1 - \frac{1}{\mathcal{M}(\epsilon, T, \theta)} - \sqrt{\frac{d_{\chi^2}(T)}{\mathcal{M}(\epsilon, T, \theta)}}, \quad (22)$$

for any $\epsilon > 0$, where the packing number $\mathcal{M}(\epsilon, T, \theta)$ is the largest number of points in T that are at least ϵ away from each other.

The inequality (21) is the classical Fano's inequality. The version we present here is by Yu (1997). The inequality (22) is a generalization of the classical Fano's inequality by using chi-squared divergence instead of KL divergence. It is due to Guntuboyina (2011).

The following proposition bounds the KL divergence and the chi-squared divergence for both Gaussian and Bernoulli models.

Proposition 17. For the Gaussian model, we have

$$D(\mathbb{P}^{(\theta, \sigma^2, \rho)} \| \mathbb{P}^{(\theta', \sigma'^2, \rho)}) \leq \frac{p}{2\sigma^2} \|\theta - \theta'\|^2, \quad \chi^2(\mathbb{P}^{(\theta, \sigma^2, \rho)} \| \mathbb{P}^{(\theta', \sigma'^2, \rho)}) \leq \exp\left(\frac{p}{\sigma^2} \|\theta - \theta'\|^2\right) - 1.$$

For the Bernoulli model with any $\theta, \theta' \in [\rho/2, 3\rho/4]^{n_1 \times n_2}$, we have

$$D(\mathbb{P}^{(\theta, \rho)} \| \mathbb{P}^{(\theta', \rho)}) \leq \frac{8\rho}{\rho} \|\theta - \theta'\|^2, \quad \chi^2(\mathbb{P}^{(\theta, \rho)} \| \mathbb{P}^{(\theta', \rho)}) \leq \exp\left(\frac{8\rho}{\rho} \|\theta - \theta'\|^2\right) - 1.$$

Finally, we need the following Varshamov-Gilbert bound. The version we present here is due to (Massart, 2007, Lemma 4.7).

Lemma 18. There exists a subset $\{\omega_1, \dots, \omega_N\} \subset \{0, 1\}^d$ such that

$$H(\omega_i, \omega_j) \triangleq \|\omega_i - \omega_j\|^2 \geq \frac{d}{4}, \quad \text{for any } i \neq j \in [N], \quad (23)$$

for some $N \geq \exp(d/8)$.

Proof of Theorem 3. We focus on the proof for the asymmetric parameter space $\Theta_{k_1 k_2}(M)$. The result for the symmetric parameter space $\Theta_k^*(M)$ can be obtained by letting $k_1 = k_2 = k$ and by taking care of the diagonal entries. Let us assume n_1/k_1 and n_2/k_2 are integers without loss of generality. We first derive the lower bound for the nonparametric rate $\sigma^2 k_1 k_2 / p$. Let us fix the labels by $z_1(i) = [ik_1/n_1]$ and $z_2(j) = [jk_2/n_2]$. For any $\omega \in \{0, 1\}^{k_1 \times k_2}$, define

$$Q_{ab}^\omega = c \sqrt{\frac{\sigma^2 k_1 k_2}{pn_1 n_2}} \omega_{ab}. \quad (24)$$

By Lemma 18, there exists some $T \subset \{0, 1\}^{k_1 k_2}$ such that $|T| \geq \exp(k_1 k_2 / 8)$ and $H(\omega, \omega') \geq k_1 k_2 / 4$ for any $\omega, \omega' \in T$ and $\omega \neq \omega'$. We construct the subspace

$$\Theta(z_1, z_2, T) = \left\{ \theta \in \mathbb{R}^{n_1 \times n_2} : \theta_{ij} = Q_{z_1(i)z_2(j)}^\omega, \omega \in T \right\}.$$

By Proposition 17, we have

$$\sup_{\theta, \theta' \in \Theta(z_1, z_2, T)} \chi^2(\mathbb{P}^{(\theta, \sigma^2, \rho)} \| \mathbb{P}^{(\theta', \sigma'^2, \rho)}) \leq \exp(c^2 k_1 k_2).$$

For any two different θ and θ' in $\Theta(z_1, z_2, T)$ associated with $\omega, \omega' \in T$, we have

$$\|\theta - \theta'\|^2 \geq \frac{c^2 \sigma^2}{p} H(\omega, \omega') \geq \frac{c^2 \sigma^2}{4p} k_1 k_2.$$

Therefore, $\mathcal{M}\left(\sqrt{\frac{c^2 \sigma^2}{4p}} k_1 k_2, \Theta(z_1, z_2, T), \|\cdot\|\right) \geq \exp(k_1 k_2 / 8)$. Using (22) with an appropriate c , we have obtained the rate $\frac{c^2}{p} k_1 k_2$ in the lower bound.

Now let us derive the clustering rate $\sigma^2 n_2 \log k_2 / p$. Let us pick $\omega_1, \dots, \omega_{k_2} \in \{0, 1\}^{k_1}$ such that $H(\omega_a, \omega_b) \geq \frac{k_1}{4}$ for all $a \neq b$. By Lemma 18, this is possible when $\exp(k_1/8) \geq k_2$. Then, define

$$Q_{*a} = c \sqrt{\frac{\sigma^2 n_2 \log k_2}{pn_1 n_2}} \omega_a. \quad (25)$$

Define $z_1(i) = [ik_1/n_1]$. Fix Q and z_1 and we are going to let z_2 vary. Select a set $\mathcal{Z}_2 \subset [k_2]^{n_2}$ such that $|\mathcal{Z}_2| \geq \exp(Cn_2 \log k_2)$ and $H(z_2, z'_2) \geq \frac{n_2}{6}$ for any $z_2, z'_2 \in \mathcal{Z}_2$ and $z_2 \neq z'_2$. The existence of such \mathcal{Z}_2 is proved by Gao et al. (2015a). Then, the subspace we consider is

$$\Theta(z_1, \mathcal{Z}_2, Q) = \left\{ \theta \in \mathbb{R}^{n_1 \times n_2} : \theta_{ij} = Q_{z_1(i)z_2(j)}, z_2 \in \mathcal{Z}_2 \right\}.$$

By Proposition 17, we have

$$\sup_{\theta, \theta' \in \Theta(z_1, \mathcal{Z}_2, Q)} D(\mathbb{P}^{(\theta, \sigma^2, \rho)} \| \mathbb{P}^{(\theta', \sigma'^2, \rho)}) \leq c^2 n_2 \log k_2.$$

For any two different θ and θ' in $\Theta(z_1, \mathcal{Z}_2, Q)$ associated with $z_2, z'_2 \in \mathcal{Z}_2$, we have

$$\|\theta - \theta'\|^2 = \sum_{j=1}^{n_2} \|\theta_{z_2(j)} - \theta'_{z_2(j)}\|^2 \geq H(z_2, z'_2) \frac{c^2 \sigma^2 n_2 \log k_2 n_1}{pn_1 n_2} \geq \frac{c^2 \sigma^2 n_2 \log k_2}{24p}.$$

Therefore, $\mathcal{M}\left(\sqrt{\frac{c^2 \sigma^2 n_2 \log k_2}{24p}}, \Theta(z_1, \mathcal{Z}_2, Q), \|\cdot\|\right) \geq \exp(Cn_2 \log k_2)$. Using (21) with some appropriate c , we obtain the lower bound $\frac{c^2 n_2 \log k_2}{p}$.

A symmetric argument gives the rate $\frac{c^2 n_1 \log k_1}{p}$. Combining the three parts using the same argument in Gao et al. (2015a), the proof is complete. \square

Proof of Theorem 5. The proof is similar to that of Theorem 3. The only differences are (24) replaced by

$$Q_{ab}^\omega = \frac{1}{2} \rho + \left(c \sqrt{\frac{\rho k^2}{pn^2} \wedge \frac{1}{2} \rho} \right) \omega_{ab}$$

and (25) replaced by

$$Q_{*a} = \frac{1}{2} \rho + \left(c \sqrt{\frac{\rho \log k}{pn} \wedge \frac{1}{2} \rho} \right) \omega_a.$$

It is easy to check that the constructed subspaces are subsets of $\Theta_k^+(\rho)$. Then, a symmetric modification of the proof of Theorem 3 leads to the desired conclusion. \square

7.5 Proofs of Corollary 8 and Corollary 9

The result of Corollary 8 can be derived through a standard bias-variance trade-off argument by combining Corollary 4 and Lemma 2.1 in Gao et al. (2015a). The result of Corollary 9 follows Theorem 7. By studying the proof of Theorem 7, (20) holds for all k . Choosing the best k to trade-off bias and variance gives the result of Corollary 9. We omit the details here.

Appendix A. Proofs of auxiliary results

In this section, we give proofs of Lemma 10-14. We first introduce some notation. Define the set

$$\mathcal{Z}_{k_1, k_2} = \{z = (z_1, z_2) : z_1 \in [k_1]^{n_1}, z_2 \in [k_2]^{n_2}\}.$$

For a matrix $G \in \mathbb{R}^{n_1 \times n_2}$ and some $z = (z_1, z_2) \in \mathcal{Z}_{k_1, k_2}$, define

$$\bar{G}_{ab}(z) = \frac{1}{|z_1^{-1}(a)||z_2^{-1}(b)|} \sum_{(i,j) \in z_1^{-1}(a) \times z_2^{-1}(b)} G_{ij},$$

for all $a \in [k_1]$, $b \in [k_2]$. To facilitate the proof, we need the following two results.

Proposition 19. For the estimator $\hat{\theta}_{ij} = \hat{Q}_{z_1(i)z_2(j)}$, we have

$$\hat{Q}_{ab} = \text{sign}(\bar{Y}_{ab}(\hat{z})) (\bar{Y}_{ab}(\hat{z}) \wedge M),$$

for all $a \in [k_1]$, $b \in [k_2]$.

Lemma 20. Under the setting of Lemma 13, define $S = \frac{1}{\sqrt{n}} \sum_{i=1}^n (Y_i - \theta_i)$ and $\tau = 2(M^2 + 2\sigma^2)/(M \vee \sigma)$. Then we have the following results:

- Let $T = \mathbf{S}\mathbf{1}\{|S| \leq \tau\sqrt{n}\}$, then $\mathbb{E}e^{T^2/(8(M^2+2\sigma^2))} \leq 5$;
- Let $R = \tau\sqrt{n}\mathbf{S}\mathbf{1}\{|S| > \tau\sqrt{n}\}$, then $\mathbb{E}e^{R^2/(8(M^2+2\sigma^2))} \leq 9$.

Proof. By (19),

$$\mathbb{P}(|S| > t) \leq 4 \exp \left\{ -\min \left(\frac{pt^2}{4(M^2 + 2\sigma^2)}, \frac{\sqrt{np}t}{2(M \vee \sigma)} \right) \right\}.$$

Then

$$\begin{aligned} \mathbb{E}e^{M^2} &= \int_0^\infty \mathbb{P}(e^{M^2} > u) du \leq 1 + \int_1^\infty \mathbb{P}(|T| > \sqrt{\frac{\log u}{\lambda}}) du \\ &= 1 + \int_1^{e^{\lambda^2 n}} \mathbb{P}(|S| > \sqrt{\frac{\log u}{\lambda}}) du = 1 + 4 \int_1^{e^{\lambda^2 n}} u^{-p/(4\lambda(M^2+2\sigma^2))} du. \end{aligned}$$

Choosing $\lambda = p/(8(M^2 + 2\sigma^2))$, we get $\mathbb{E}e^{pT^2/(8(M^2+2\sigma^2))} \leq 5$. We proceed to prove the second claim.

$$\begin{aligned} \mathbb{E}e^{\lambda R} &= \mathbb{P}(R=0) + \mathbb{P}(R>0)\mathbb{E}[e^{\lambda R_1} | R>0] \\ &= \mathbb{P}(R=0) + \mathbb{P}(R>0) \int_0^\infty \mathbb{P}(e^{\lambda R} > u | R > 0) du \\ &= \int_0^\infty \mathbb{P}(e^{\lambda R} > u, R > 0) du \\ &\leq \mathbb{P}(R=0) + \mathbb{P}(R>0)e^{\lambda\tau^2 n} + \int_{e^{\lambda\tau^2 n}}^\infty \mathbb{P}(e^{\lambda R} > u) du \\ &\leq 1 + 4e^{-p\tau^2 n/(4(M^2+2\sigma^2)) + \lambda\tau^2 n} + \int_{e^{\lambda\tau^2 n}}^\infty \mathbb{P}(e^{\sqrt{n}\lambda\tau|S|} > u) du \\ &= 1 + 4e^{-p\tau^2 n/(4(M^2+3\sigma^2)) + \lambda\tau^2 n} + 4 \int_{e^{\lambda\tau^2 n}}^\infty u^{-p/(2\lambda\tau(M\vee\sigma))} du \end{aligned}$$

Choosing $\lambda = p/(8(M^2 + 2\sigma^2))$, we get $\mathbb{E}e^{pR/(8(M^2+2\sigma^2))} \leq 9$. \square

Proof of Lemma 10. By the definitions of $\hat{\theta}_{ij}$ and $\tilde{\theta}_{ij}$ and Proposition 19, we have

$$\hat{\theta}_{ij} - \tilde{\theta}_{ij} = \begin{cases} M - \bar{\theta}_{ab}(\hat{z}), & \text{if } \bar{Y}_{ab}(\hat{z}) \geq M; \\ \bar{Y}_{ab}(\hat{z}) - \bar{\theta}_{ab}(\hat{z}), & \text{if } -M \leq \bar{Y}_{ab}(\hat{z}) < M; \\ -M - \bar{\theta}_{ab}(\hat{z}), & \text{if } \bar{Y}_{ab}(\hat{z}) < -M \end{cases}$$

for any $(i, j) \in \hat{z}_1^{-1}(a) \times \hat{z}_2^{-1}(b)$. Define $W = Y - \theta$, and it is easy to check that

$$|\hat{\theta}_{ij} - \tilde{\theta}_{ij}| \leq |\bar{W}_{ab}(\hat{z})| \wedge 2M \leq |\bar{W}_{ab}(\hat{z})| \wedge \tau,$$

where $\hat{z} = (\hat{z}_1, \hat{z}_2)$ and τ is defined in Lemma 20. Then

$$\begin{aligned} \|\hat{\theta} - \tilde{\theta}\|^2 &\leq \sum_{a \in [k_1], b \in [k_2]} |\hat{z}_1^{-1}(a)| |\hat{z}_2^{-1}(b)| \left(|\bar{W}_{ab}(\hat{z})| \wedge \tau \right)^2 \\ &\leq \max_{z \in \mathcal{Z}_{k_1, k_2}} \sum_{a \in [k_1], b \in [k_2]} |z_1^{-1}(a)| |z_2^{-1}(b)| \left(|\bar{W}_{ab}(z)| \wedge \tau \right)^2. \end{aligned} \quad (26)$$

For any $a \in [k_1]$, $b \in [k_2]$ and $z_1 \in [k_1]^{n_1}$, $z_2 \in [k_2]^{n_2}$, define $n_1(a) = |z_1^{-1}(a)|$, $n_2(b) = |z_2^{-1}(b)|$ and

$$\begin{aligned} V_{ab}(z) &= \sqrt{n_1(a)n_2(b)} |\bar{W}_{ab}(z)| \mathbf{1}\{|\bar{W}_{ab}(z)| \leq \tau\}, \\ R_{ab}(z) &= n_1(a)n_2(b)\tau |\bar{W}_{ab}(z)| \mathbf{1}\{|\bar{W}_{ab}(z)| > \tau\}. \end{aligned}$$

Then,

$$\|\hat{\theta} - \tilde{\theta}\|^2 \leq \max_{z \in \mathcal{Z}_{k_1, k_2}} \sum_{a \in [k_1], b \in [k_2]} (V_{ab}^2(z) + R_{ab}(z)). \quad (27)$$

By Markov's inequality and Lemma 20, we have

$$\begin{aligned} \mathbb{P} \left(\sum_{\alpha \in [k_1], \beta \in [k_2]} V_{\alpha\beta}^2(z) > t \right) &\leq e^{-pt/(8(M^2+2\sigma^2))} \prod_{\alpha \in [k_1], \beta \in [k_2]} e^{pV_{\alpha\beta}^2(z)/(8(M^2+2\sigma^2))} \\ &\leq \exp \left\{ -\frac{pt}{8(M^2+2\sigma^2)} + k_1 k_2 \log 5 \right\}, \end{aligned}$$

and

$$\begin{aligned} \mathbb{P} \left(\sum_{\alpha \in [k_1], \beta \in [k_2]} R_{\alpha\beta}(z) > t \right) &\leq e^{-pt/(8(M^2+2\sigma^2))} \prod_{\alpha \in [k_1], \beta \in [k_2]} e^{pR_{\alpha\beta}(z)/(8(M^2+2\sigma^2))} \\ &\leq \exp \left\{ -\frac{pt}{8(M^2+2\sigma^2)} + k_1 k_2 \log 9 \right\}, \end{aligned}$$

Applying union bound and using the fact that $\log |k_1|^{n_1} + \log |[k_2]^{n_2}| = n_1 \log k_1 + n_2 \log k_2$,

$$\mathbb{P} \left(\max_{z \in \mathcal{Z}_{k_1, k_2}} \sum_{\alpha \in [k_1], \beta \in [k_2]} V_{\alpha\beta}^2(z) > t \right) \leq \exp \left\{ -\frac{pt}{8(M^2+2\sigma^2)} + k_1 k_2 \log 5 + n_1 \log k_1 + n_2 \log k_2 \right\}.$$

For any given constant $C' > 0$, we choose $t = C_1 \frac{M^2 \vee \sigma^2}{p} (k_1 k_2 + n_1 \log k_1 + n_2 \log k_2)$ for some sufficiently large $C_1 > 0$ to obtain

$$\max_{z \in \mathcal{Z}_{k_1, k_2}} \sum_{\alpha \in [k_1], \beta \in [k_2]} V_{\alpha\beta}^2(z) \leq C_1 \frac{M^2 \vee \sigma^2}{p} (k_1 k_2 + n_1 \log k_1 + n_2 \log k_2) \quad (28)$$

with probability at least $1 - \exp(-C'(k_1 k_2 + n_1 \log k_1 + n_2 \log k_2))$. Similarly, for some sufficiently large $C_2 > 0$, we have

$$\max_{z \in \mathcal{Z}_{k_1, k_2}} \sum_{\alpha \in [k_1], \beta \in [k_2]} R_{\alpha\beta}(z) \leq C_2 \frac{M^2 \vee \sigma^2}{p} (k_1 k_2 + n_1 \log k_1 + n_2 \log k_2) \quad (29)$$

with probability at least $1 - \exp(-C'(k_1 k_2 + n_1 \log k_1 + n_2 \log k_2))$. Plugging (28) and (29) into (27), we complete the proof. \square

Proof of Lemma 11. Note that

$$\tilde{\theta}_{ij} - \theta_{ij} = \sum_{\alpha \in [k_1], \beta \in [k_2]} \bar{\theta}_{\alpha\beta}(\hat{\mathbf{z}}) \mathbf{1}\{(i, j) \in \hat{\mathbf{z}}_1^{-1}(\alpha) \times \hat{\mathbf{z}}_2^{-1}(\beta)\} - \theta_{ij}$$

is a function of $\hat{\mathbf{z}}_1$ and $\hat{\mathbf{z}}_2$. Then we have

$$\left| \sum_{i,j} \frac{\tilde{\theta}_{ij} - \theta_{ij}}{\sqrt{\sum_{i,j} (\tilde{\theta}_{ij} - \theta_{ij})^2}} (\mathbf{Y}_{ij} - \theta_{ij}) \right| \leq \max_{z \in \mathcal{Z}_{k_1, k_2}} \left| \sum_{i,j} \gamma_{ij}(z) (\mathbf{Y}_{ij} - \theta_{ij}) \right|,$$

where

$$\gamma_{ij}(z) \propto \sum_{\alpha \in [k_1], \beta \in [k_2]} \bar{\theta}_{\alpha\beta}(z) \mathbf{1}\{(i, j) \in z_1^{-1}(\alpha) \times z_2^{-1}(\beta)\} - \theta_{ij}$$

satisfies $\sum_{i,j} \gamma_{ij}(z)^2 = 1$. Consider the event $\|\tilde{\theta} - \theta\|^2 \geq C_2(M^2 \vee \sigma^2)(k_1 k_2 + n_1 \log k_1 + n_2 \log k_2)/p$ for some C_2 to be specified later; we have

$$|\gamma_{ij}(z)| \leq \frac{2M}{\|\tilde{\theta} - \theta\|} \leq \sqrt{C_2(M^2 \vee \sigma^2)(k_1 k_2 + n_1 \log k_1 + n_2 \log k_2)}.$$

By Lemma 13 and union bound, we have

$$\begin{aligned} &\mathbb{P} \left(\max_{z \in \mathcal{Z}_{k_1, k_2}} \left| \sum_{i,j} \gamma_{ij}(z) (\mathbf{Y}_{ij} - \theta_{ij}) \right| > t \right) \\ &\leq \sum_{z_1 \in [k_1]^{n_1}, z_2 \in [k_2]^{n_2}} \mathbb{P} \left(\left| \sum_{i,j} \gamma_{ij}(z) (\mathbf{Y}_{ij} - \theta_{ij}) \right| > t \right) \\ &\leq \exp(-C'(k_1 k_2 + n_1 \log k_1 + n_2 \log k_2)), \end{aligned}$$

by setting $t = \sqrt{C_2(M^2 \vee \sigma^2)(k_1 k_2 + n_1 \log k_1 + n_2 \log k_2)/p}$ for some sufficiently large C_2 depending on C' . Thus, the lemma is proved. \square

Proof of Lemma 12. By definition,

$$\begin{aligned} &\left| \langle \hat{\theta} - \tilde{\theta}, \mathbf{Y} - \theta \rangle \right| \\ &= \left| \sum_{\alpha \in [k_1], \beta \in [k_2]} \left(\text{sign}(\bar{\mathbf{Y}}_{\alpha\beta}(\hat{\mathbf{z}})) (\bar{\mathbf{Y}}_{\alpha\beta}(\hat{\mathbf{z}}) \wedge \mathbf{M}) - \bar{\theta}_{\alpha\beta}(\hat{\mathbf{z}}) \right) \bar{\mathbf{W}}_{\alpha\beta}(\hat{\mathbf{z}}) |z_1^{-1}(\alpha)| |z_2^{-1}(\beta)| \right| \\ &\leq \max_{z \in \mathcal{Z}_{k_1, k_2}} \left| \sum_{\alpha \in [k_1], \beta \in [k_2]} \left(\text{sign}(\bar{\mathbf{Y}}_{\alpha\beta}(z)) (\bar{\mathbf{Y}}_{\alpha\beta}(z) \wedge \mathbf{M}) - \bar{\theta}_{\alpha\beta}(z) \right) \bar{\mathbf{W}}_{\alpha\beta}(z) |z_1^{-1}(\alpha)| |z_2^{-1}(\beta)| \right|. \end{aligned}$$

By definition, we have

$$\left(\text{sign}(\bar{\mathbf{Y}}_{\alpha\beta}(z)) (\bar{\mathbf{Y}}_{\alpha\beta}(z) \wedge \mathbf{M}) - \bar{\theta}_{\alpha\beta}(z) \right) \bar{\mathbf{W}}_{\alpha\beta}(z) \leq |\bar{\mathbf{W}}_{\alpha\beta}(z)|^2 \wedge \tau |\bar{\mathbf{W}}_{\alpha\beta}(z)|.$$

For any fixed $z_1 \in [k_1]^{n_1}$, $z_2 \in [k_2]^{n_2}$, define $n_1(a) = |z_1^{-1}(a)|$ for $a \in [k_1]$, $n_2(b) = |z_2^{-1}(b)|$ for $b \in [k_2]$ and $V_{\alpha\beta}(z) = \sqrt{n_1(a)n_2(b)} |\bar{\mathbf{W}}_{\alpha\beta}(z)| \mathbf{1}\{|\bar{\mathbf{W}}_{\alpha\beta}(z)| \leq \tau\}$, $R_{\alpha\beta}(z) = \tau n_1(a)n_2(b) |\bar{\mathbf{W}}_{\alpha\beta}(z)| \mathbf{1}\{|\bar{\mathbf{W}}_{\alpha\beta}(z)| > \tau\}$. Then

$$\left| \langle \hat{\theta} - \tilde{\theta}, \mathbf{Y} - \theta \rangle \right| \leq \max_{z \in \mathcal{Z}_{k_1, k_2}} \left\{ \sum_{\alpha \in [k_1], \beta \in [k_2]} V_{\alpha\beta}^2(z) + \sum_{\alpha \in [k_1], \beta \in [k_2]} R_{\alpha\beta}(z) \right\}.$$

Following the same argument in the proof of Lemma 10, a choice of $t = C_3(M^2 \vee \sigma^2)(k_1 k_2 + n_1 \log k_1 + n_2 \log k_2)/p$ for some sufficiently large $C_3 > 0$ will complete the proof. \square

Proof of Lemma 13. When $|\lambda| \leq p/(M \vee \sigma)$, $|\lambda\theta_i/p| \leq 1$ and $\lambda^2\sigma^2/p^2 \leq 1$. Then

$$\begin{aligned} \mathbb{E}e^{\lambda(Y_i - \theta_i)} &= p\mathbb{E}e^{\lambda(X_i/p - \theta_i)} + (1-p)\mathbb{E}e^{-\lambda\theta_i} \\ &\leq pe^{\frac{\lambda^2\sigma^2}{2p^2} + \frac{1-\lambda^2}{p}\lambda\theta_i} + (1-p)e^{-\lambda\theta_i} \\ &\leq p \left(1 + \frac{1-p}{p}\lambda\theta_i + \frac{2(1-p)^2}{p^2}\lambda^2\theta_i^2 \right) + (1-p)(1 - \lambda\theta_i + 2\lambda^2\theta_i^2) \\ &\leq 1 + \frac{2(1-p)\theta_i^2 + \sigma^2}{p}\lambda^2 + \frac{1-p}{p^2}\lambda^3\theta_i\sigma^2 + \frac{2(1-p)^2}{p^3}\lambda^4\sigma^2\theta_i^2 + 2(1-p)\lambda^2\theta_i^2 \\ &\leq 2 + (2M^2 + \sigma^2)\lambda^2/p + \lambda^3\theta_i\sigma^2/p^2 + 2\lambda^4\sigma^2\theta_i^2/p^3 \\ &\leq 2 + (2M^2 + \sigma^2)\lambda^2/p + \lambda^2\sigma^2/p + 2\lambda^2\sigma^2/p \\ &\leq 2 + (2M^2 + 4\sigma^2)\lambda^2/p \\ &\leq 2e^{(M^2 + 2\sigma^2)\lambda^2/p}. \end{aligned}$$

The second inequality is due to the fact that $e^x \leq 1 + 2x$ for all $x \geq 0$ and $e^x \leq 1 + x + 2x^2$ for all $|x| \leq 1$. Then for $|\lambda|(M \vee \sigma) \leq p$, Markov inequality implies

$$\mathbb{P} \left(\sum_{i=1}^n e_i(Y_i - \theta_i) \geq t \right) \leq 2 \exp \left\{ -\lambda t + \frac{\lambda^2}{p}(M^2 + 2\sigma^2)t \right\}.$$

By choosing $\lambda = \min \left\{ \frac{pt}{2(M^2 + 2\sigma^2)}, \frac{p}{(M \vee \sigma)\|c\|_\infty} \right\}$, we get (19). \square

Proof of Corollary 4. For independent Bernoulli random variables $X_i \sim \text{Ber}(\theta_i)$ with $\theta_i \in [0, \rho]$ for $i \in [n]$. Let $Y_i = X_i E_i/p$, where $\{E_i\}$ are independent Bernoulli random variables and $\{E_i\}$ and $\{X_i\}$ are independent. Note that $\mathbb{E}Y_i = p_i$, $\mathbb{E}Y_i^2 \leq \rho/p$ and $|Y_i| \leq 1/p$. Then Bernstein's inequality (Massart, 2007, Corollary 2.10) implies

$$\mathbb{P} \left\{ \left| \frac{1}{\sqrt{n}} \sum_{i=1}^n (Y_i - \theta_i) \right| \geq t \right\} \leq 2 \exp \left\{ -\min \left(\frac{pt^2}{4\rho}, \frac{3\sqrt{np}t}{4} \right) \right\} \quad (30)$$

for any $t > 0$. Let $S = \frac{1}{\sqrt{n}} \sum_{i=1}^n (Y_i - \theta_i)$, $T = S\mathbf{1}\{|S| \leq 3\rho\sqrt{n}\}$ and $R = 3\rho\sqrt{n}\mathbf{1}\{|S| > 3\rho\sqrt{n}\}$. Following the same arguments as in the proof of Lemma 20, we have $\mathbb{E}e^{pT/(8\rho)} \leq 5$ and $\mathbb{E}e^{pR/(8\rho)} \leq 9$. Consequently, Lemma 10, Lemma 11 and Lemma 12 hold for the Bernoulli case. Then the rest of the proof follows from the proof of Theorem 1. \square

Proof of Lemma 14. By the definitions of Y and \mathcal{Y} , we have

$$\|Y - \mathcal{Y}\|^2 \leq (\hat{p}^{-1} - p^{-1})^2 \max_{i,j} X_{ij}^2 \sum_{i,j} E_{ij}.$$

Therefore, it is sufficient to bound the three terms. For the first term, we have

$$|\hat{p}^{-1} - p^{-1}| \leq |\hat{p}^{-1} - p^{-1}| \frac{|\hat{p} - p|}{p} + \frac{|\hat{p} - p|}{p^2},$$

which leads to

$$|\hat{p}^{-1} - p^{-1}| \leq \left(1 - \frac{|\hat{p} - p|}{p} \right)^{-1} \frac{|\hat{p} - p|}{p^2}. \quad (31)$$

Bernstein's inequality implies $|\hat{p} - p|^2 \leq C \frac{p \log(n_1 + n_2)}{n_1 n_2}$ with probability at least $1 - (n_1 n_2)^{-C'}$ under the assumption that $p \gtrsim \frac{\log(n_1 + n_2)}{n_1 n_2}$. Plugging the bound into (31), we get

$$(\hat{p}^{-1} - p^{-1})^2 \leq C_1 \frac{\log(n_1 + n_2)}{p^3 n_1 n_2}.$$

The second term can be bounded by a union bound with the sub-Gaussian tail assumption of each X_{ij} . That is,

$$\max_{i,j} X_{ij}^2 \leq C_2(M^2 + \sigma^2 \log(n_1 + n_2)),$$

with probability at least $1 - (n_1 n_2)^{-C'}$. Finally, using Bernstein's inequality again, the third term is bounded as

$$\sum_{i,j} E_{ij} \leq C_3 n_1 n_2 \left(p + \sqrt{\frac{p \log(n_1 + n_2)}{n_1 n_2}} \right) \leq C'_3 n_1 n_2 p,$$

with probability at least $1 - (n_1 n_2)^{-C'}$ under the assumption that $p \gtrsim \frac{\log(n_1 + n_2)}{n_1 n_2}$. Combining the three bounds, we have obtained the desired conclusion. \square

Proof of Lemma 15. For the second and the third bounds, we use

$$\left\langle \frac{\tilde{\theta} - \theta}{\|\tilde{\theta} - \theta\|}, \mathcal{Y} - \theta \right\rangle \leq \left\langle \frac{\tilde{\theta} - \theta}{\|\tilde{\theta} - \theta\|}, Y - \theta \right\rangle + \|\mathcal{Y} - Y\|,$$

and

$$\left| \left\langle \frac{\tilde{\theta} - \theta}{\|\tilde{\theta} - \theta\|}, \mathcal{Y} - \theta \right\rangle \right| \leq \left| \left\langle \tilde{\theta} - \theta, Y - \theta \right\rangle \right| + \|\tilde{\theta} - \theta\| \|Y - \mathcal{Y}\|,$$

followed by the original proofs of Lemma 11 and Lemma 12. To prove the first bound, we introduce the notation $\hat{\theta}_{ij} = \hat{Q}_{\hat{z}_i(t)\hat{z}_j(t)}$ with $\hat{Q}_{ab} = \text{sign}(\hat{Y}_{ab}(\hat{z})) (\hat{Y}_{ab}(\hat{z}) \wedge M)$. Recall the definition of \hat{Q} in Proposition 19 with Y replaced by \mathcal{Y} . Then, we have

$$\|\hat{\theta} - \tilde{\theta}\|^2 \leq 2\|\hat{\theta} - \theta\|^2 + 2\|\hat{\theta} - \tilde{\theta}\|^2.$$

Since $\|\hat{\theta} - \tilde{\theta}\|$ can be bounded by the exact argument in the proof of Lemma 10, it is sufficient to bound $\|\hat{\theta} - \theta\|^2$. By Jensen inequality,

$$\|\hat{\theta} - \tilde{\theta}\|^2 \leq \sum_{ab} |\hat{z}^{-1}(a)| |\hat{z}^{-1}(b)| (\hat{Y}_{ab}(\hat{z}) - \tilde{\mathcal{Y}}_{ab}(\hat{z}))^2 \leq \|Y - \mathcal{Y}\|^2.$$

Thus, the proof is complete. \square

Abstract

Teaching dimension is a learning theoretic quantity that specifies the minimum training set size to teach a target model to a learner. Previous studies on teaching dimension focused on version-space learners which maintain all hypotheses consistent with the training data, and cannot be applied to modern machine learners which select a specific hypothesis via optimization. This paper presents the first known teaching dimension for ridge regression, support vector machines, and logistic regression. We also exhibit optimal training sets that match these teaching dimensions. Our approach generalizes to other linear learners.

Keywords: Optimization based learner, Karush-Kuhn-Tucker conditions, VC-dimension

1. Introduction

Consider a teacher who knows both a target model and the learning algorithm used by a machine learner. The teacher wants to teach the target model to the learner by *constructing* a training set. The training set does not need to contain independent and identically distributed items drawn from some distribution. Furthermore, the teacher can construct any item in the input space. How many training items are needed? This is the question addressed by the *teaching dimension* (Goldman and Kearns, 1995; Shinohara and Miyano, 1991). We give the precise definition in section 2, but first illustrate the intuition with an example.

Consider integers $x \in \{1 \dots 10\}$ and threshold classifiers h_θ on them, so that $h_\theta(x)$ returns -1 if $x < \theta$ and 1 if $x \geq \theta$. Now let the hypothesis space \mathcal{H} consist of eleven classifiers $\mathcal{H} = \{h_\theta \mid \theta \in \{1 \dots 11\}\}$. Let the learner be a version-space learner, namely it maintains a version space $\{h_\theta \in \mathcal{H} \mid h_\theta \text{ consistent with the training set}\}$. Equivalently, the learner is a 0-1 loss empirical risk minimizer (ERM) which finds all models with zero training error. If we want to teach a target model (in this paper we use hypothesis and model interchangeably), say h_θ , to such a learner, we can construct a training set that results in a singleton version space $\{h_\theta\}$. It is easy to see that the training set $D = \{(x_1 = 8, y_1 = -1), (x_2 = 9, y_2 = 1)\}$ is the smallest set for this purpose. We say that the teaching dimension of h_θ with respect

to \mathcal{H} is $TD(h_\theta) = |D| = 2$. Similarly, $TD(h_{11}) = 1$ because $D = \{(x_1 = 10, y_1 = -1)\}$ suffices. In fact, $TD(h_\theta^*) = 1$ for target model $\theta^* = 1$ or 11, and 2 for $\theta^* = 2, 3, \dots, 10$.

The astute reader may notice that this example does not apply to continuous spaces. To see this, let us extend $x \in \mathbb{R}$ and $\mathcal{H} = \{h_\theta \mid \theta \in \mathbb{R}\}$. The learner's version space under any linearly separable training set would now be represented by the interval between the two closest oppositely labeled items. It is impossible for the version-space learner to pick out a unique target model h_{θ^*} with a finite training set. In other words, $TD(h_{\theta^*}) = \infty$ for all target models θ^* . This is counterintuitive because ostensibly we can teach any one of the "modern" machine learning algorithms such as a support vector machine (SVM) with only two training items: $D = \{(x_1 = \theta^* - \epsilon, y_1 = -1), (x_2 = \theta^* + \epsilon, y_2 = 1)\}$ with any $\epsilon > 0$.

The issue here is that a version-space learner is not equipped with the ability to pick the max-margin (or any other specific) hypothesis from the version space. In contrast, an SVM is *not* a version-space learner in our terminology; we have stronger knowledge from optimization on how it picks a specific hypothesis from the hypothesis space. This paper will utilize such knowledge to derive teaching dimensions that are distinct from classic teaching dimension analysis (e.g. Doliwa et al. (2014)). Specifically, we extend teaching dimension to linear learners that learn by regularized surrogate-loss empirical risk minimization:

$$\mathcal{A}_{\text{opt}}(D) := \underset{\theta \in \mathbb{R}^d}{\text{Argmin}} \underbrace{\sum_{i=1}^n \ell(\mathbf{x}_i^\top \theta; y_i) + \frac{\lambda}{2} \|\theta\|_A^2}_{=: f(\theta)}. \quad (1)$$

Here, we identify \mathcal{H} with \mathbb{R}^d , h with θ , the surrogate loss function ℓ is either smooth or convex in the first argument, $\lambda > 0$ is the regularization coefficient, and A is a positive semidefinite matrix. $\|\cdot\|_A$ is the Mahalanobis norm: $\|\theta\|_A := \sqrt{\theta^\top A \theta}$. This covers both homogeneous (e.g. $A = I$) and inhomogeneous (e.g. $A = [I, 0; 0, I]$) learners. We follow the convention in optimization when we use the capitalized Argmin to emphasize that it returns a *set* that achieves the minimum. The teacher can construct a training set with any items in \mathbb{R}^d . The alternative pool-based teaching setting, where the teacher is given a finite pool of candidate training items and must select items from that pool, is not studied in this paper. By linear learners we mean the input \mathbf{x} and the parameter θ interact only via their inner product $\mathbf{x}^\top \theta$. Linear learners include SVMs, logistic regression, and linear regression. Our analysis technique involves a novel application of the Karush-Kuhn-Tucker (KKT) conditions.

	homogeneous			inhomogeneous		
	ridge	SVM	logistic	ridge	SVM	logistic
exact parameter	1	$\lceil \lambda \ \theta^*\ ^2 \rceil$	$\lceil \frac{\lambda \ \theta^*\ ^2}{2\tau_{\max}} \rceil$	2	$2 \lceil \frac{\lambda \ \mathbf{w}^*\ ^2}{2} \rceil$	$2 \lceil \frac{\lambda \ \mathbf{w}^*\ ^2}{2\tau_{\max}} \rceil$
decision boundary	-	1	1	-	2	2

Table 1: The teaching dimension of ridge regression, SVM, and logistic regression. ($\lceil \cdot \rceil$: up to rounding effect, see section 3.3).

To our knowledge, this paper gives the first known values of teaching dimension for ridge regression, SVM, and logistic regression. We summarize our main results in Table 1. The table separately lists homogeneous (without a bias term) and inhomogeneous (with a bias term) versions of the linear learners. The teaching goal refers to the intention of the teacher: is teaching considered successful only when the learner learns the exact target parameter, or when the learner learns the correct decision boundary (which can be achieved by any positive scaling of the target parameter)? See section 3 for definition of the target parameters θ^* , w^* and the constant τ_{\max} . The target parameters are assumed to be nonzero. We will also present the corresponding minimum teaching set construction in section 3.

2. Classic Teaching Dimension and its Limitations

Let \mathcal{X} denote the input space and $\mathcal{Y} \subseteq \mathbb{R}$ the output space. A hypothesis is a function $h : \mathcal{X} \rightarrow \mathcal{Y}$. In this section we identify a hypothesis h_θ with its model parameter θ . The hypothesis space \mathcal{H} is a set of hypotheses. By training item we mean a pair $(x, y) \in \mathcal{X} \times \mathcal{Y}$. A training set is a multiset $D = \{(x_1, y_1), \dots, (x_n, y_n)\}$ where repeated items are allowed. Importantly, for the purpose of teaching we do *not* assume that D be drawn *i.i.d.* from a distribution. Let $\mathbb{D} = \cup_{n=1}^{\infty} (\mathcal{X} \times \mathcal{Y})^n$ denote the set of all training sets of all sizes. A learning algorithm $\mathcal{A} : \mathbb{D} \rightarrow 2^{\mathcal{H}}$ takes in a training set $D \in \mathbb{D}$ and outputs a subset of the hypothesis space \mathcal{H} . That is, \mathcal{A} does not necessarily return a unique hypothesis.

Classic teaching dimension analysis is restricted to the version-space learner \mathcal{A}_{vs} :

$$\mathcal{A}_{vs}(D) = \{h \in \mathcal{H} \mid \forall (x, y) \in D, h(x) = y\}. \quad (2)$$

That is, the learner \mathcal{A}_{vs} keeps track of the version space consisting of all hypotheses h that are consistent with D . Let the target model be $h_{\theta^*} \in \mathcal{H}$. Teaching is successful if the teacher identifies a training set $D \in \mathbb{D}$ such that $\mathcal{A}_{vs}(D) = \{h_{\theta^*}\}$ the singleton set. Such a D is called a **teaching set** of h_{θ^*} with respect to \mathcal{H} . The teaching dimension of the hypothesis h_{θ^*} is the minimum size of the teaching set:

$$TD(h_{\theta^*}) = \begin{cases} \min_{D \in \mathbb{D}} |D|, & \text{for } D \text{ a teaching set of } h_{\theta^*} \\ \infty, & \text{if no teaching set exists} \end{cases}$$

Furthermore, the teaching dimension of the whole hypothesis space \mathcal{H} is defined by the hardest hypothesis: $TD(\mathcal{H}) = \max_{h \in \mathcal{H}} TD(h)$. In this paper we will focus on the fine-grained teaching dimension of individual hypothesis $TD(h)$.

Classic teaching dimension analysis has several limitations: the learner is assumed to be a version-space learner \mathcal{A}_{vs} , and the hypothesis space is typically finite or countably infinite. As the example in section 1 showed, these fail to capture the teaching dimension of “modern” machine learners which has \mathbb{R}^d as input space and picks a unique hypothesis via regularized empirical risk minimization (1). Furthermore, the target model can be ambiguous when the learner is a classifier: should the learner learn the exact target parameter θ^* , or the target decision boundary? In linear models any scaled parameter $c\theta^*$ with $c > 0$ produces the same target decision boundary. These limitations motivate us to generalize the teaching dimension in the next section.

3. Main Results

To make our teaching dimension’s dependency on the learning algorithm explicit, henceforth we write teaching dimension with two arguments as

$$TD(h^*, \mathcal{A})$$

where $h^* \in \mathcal{H}$ is the target model, and $\mathcal{A} : \mathbb{D} \rightarrow 2^{\mathcal{H}}$ is the learning algorithm which given a training set $D \in \mathbb{D}$ returns a set of hypotheses $\mathcal{A}(D)$. We define teaching dimension to be the size of the smallest training set D such that $\mathcal{A}(D) = \{h^*\}$, the singleton set containing the target model. With this notation, the classic teaching dimension is $TD(h^*, \mathcal{A}_{vs})$ where \mathcal{A}_{vs} is the version space learning algorithm (2). In this paper we focus on \mathcal{A}_{opt} in (1) instead, namely linear learners in \mathbb{R}^d . Linear learners include many popular members such as both homogeneous and inhomogeneous versions of linear regression, SVM, and logistic regression. In addition, the linear interaction between \mathbf{x} and θ makes the loss function subgradient easy to compute, though in principle our analysis technique is applicable to other optimization-based learners, too. In this section our goal is to teach the exact parameter θ^* , consequently our teaching dimension of interest is

$$TD(\theta^*, \mathcal{A}_{opt}).$$

Later in section 4 for classification we will teach the decision boundary instead.

How to reason about our teaching dimension $TD(\theta^*, \mathcal{A}_{opt})$? It is the size of the *smallest* training set D with which (1) has a unique solution θ^* . Our strategy is to first establish a number of lower bounds $LB \leq TD(\theta^*, \mathcal{A}_{opt})$ by showing that any training set with which (1) has a unique solution θ^* must have at least LB items. Section 3.1 is devoted to such lower bounds. The actual teaching dimension is learner dependent. In sections 3.2 and 3.3 we construct specific teaching sets for three popular learners: ridge regression, SVM, and logistic regression. These teaching sets uniquely returns θ^* via (1). By definition, the size of these teaching sets is an upper bound on $TD(\theta^*, \mathcal{A}_{opt})$, respectively. If the lower and upper bounds match, we would have identified the teaching dimension $TD(\theta^*, \mathcal{A}_{opt})$.

3.1 Lower Bounds on Teaching Dimension $TD(\theta^*, \mathcal{A}_{opt})$

In this section we provide three general lower bounds on the teaching dimension. These lower bounds capture different aspects of a teaching set, and should be used in conjunction (i.e. taking the maximum) when applicable. We will instantiate these lower bounds for specific learners in section 3.2. In the following let \mathcal{X} and \mathcal{Y} be the feasible region of all \mathbf{x}_i ’s and y_i ’s respectively. We will use the notation $\partial_t \ell(\cdot, \cdot)$ in the following way: if $\ell(\cdot, \cdot)$ is smooth, then it denotes a singleton set only containing the gradient w.r.t. the first argument; if $\ell(\cdot, \cdot)$ is convex, then it denotes the subdifferential w.r.t the first argument.

LBI comes from a degree-of-freedom perspective. It is necessary to have this amount of training items for a unique solution to exist in (1).

Theorem 1 *Given any target model θ^* , there is a degree-of-freedom lower bound on the number of training items to obtain a unique solution θ^* from solving (1):*

$$LBI = \begin{cases} d - \text{Rank}(A) + 1, & \text{if } A\theta^* \neq \mathbf{0} \\ d - \text{Rank}(A), & \text{otherwise.} \end{cases} \quad (3)$$

Proof Let n^* be the minimal number of training items to ensure a unique solution $\boldsymbol{\theta}^*$. First consider the case $n^* = 0$. It happens if and only if $\boldsymbol{\theta}^* = \mathbf{0}$ and $\text{Rank}(A) = d$, which is a special case of $A\boldsymbol{\theta}^* = \mathbf{0}$. Clearly, this case is consistent with LB1. Next consider the case $n^* \geq 1$. Since $\boldsymbol{\theta}^*$ solves (1), the KKT condition holds:

$$-\lambda A\boldsymbol{\theta}^* \in \sum_{i=1}^{n^*} \partial_1 \ell(\mathbf{x}_i^\top \boldsymbol{\theta}^*, y_i) \mathbf{x}_i. \quad (4)$$

We seek all $\boldsymbol{\delta}$ such that $\boldsymbol{\theta}^* + \boldsymbol{\delta}$ satisfies

$$A(\boldsymbol{\theta}^* + \boldsymbol{\delta}) = A\boldsymbol{\theta}^* \quad \text{and} \quad \mathbf{x}_i^\top (\boldsymbol{\theta}^* + \boldsymbol{\delta}) = \mathbf{x}_i^\top \boldsymbol{\theta}^* \quad \forall i = 1, \dots, n^*, \quad (5)$$

For any such $\boldsymbol{\delta}$, simple algebra verifies that $\boldsymbol{\theta}^* + t\boldsymbol{\delta}$ satisfies the KKT condition (4) for any $t \in [0, 1]$. Consequently, $\boldsymbol{\theta}^* + \boldsymbol{\delta}$ also solves the problem in (1). To see this, we consider two situations:

- If the loss function $\ell(\cdot, \cdot)$ is convex in the first argument, the KKT condition is a sufficient optimality condition, which means that $\boldsymbol{\theta}^* + \boldsymbol{\delta}$ solves (1).
- If the loss function $\ell(\cdot, \cdot)$ is smooth (not necessary convex) in the first argument, we have $f(\boldsymbol{\theta}^*) = f(\boldsymbol{\theta}^* + \boldsymbol{\delta})$ by using the Taylor expansion (recall f is defined in equation 1):

$$\begin{aligned} f(\boldsymbol{\theta}^* + \boldsymbol{\delta}) &= f(\boldsymbol{\theta}^*) + \langle \nabla f(\boldsymbol{\theta}^* + t\boldsymbol{\delta}), \boldsymbol{\delta} \rangle \quad (\text{for some } t \in [0, 1]) \\ &= f(\boldsymbol{\theta}^*) + \left\langle \sum_{i=1}^{n^*} \nabla_1 \ell(\mathbf{x}_i^\top (\boldsymbol{\theta}^* + t\boldsymbol{\delta}), y_i) \mathbf{x}_i + \lambda A(\boldsymbol{\theta}^* + t\boldsymbol{\delta}), \boldsymbol{\delta} \right\rangle \\ &= f(\boldsymbol{\theta}^*) + \underbrace{\left\langle \sum_{i=1}^{n^*} \nabla_1 \ell(\mathbf{x}_i^\top \boldsymbol{\theta}^*, y_i) \mathbf{x}_i + \lambda A\boldsymbol{\theta}^*, \boldsymbol{\delta} \right\rangle}_{=0 \text{ due to the KKT condition (4)}} \\ &= f(\boldsymbol{\theta}^*). \end{aligned}$$

Therefore, $\boldsymbol{\theta}^* + \boldsymbol{\delta}$ also solves (1). However, the uniqueness of $\boldsymbol{\theta}^*$ requires $\boldsymbol{\delta} = \mathbf{0}$ to be the only value satisfying (5). This is equivalent to say

$$\text{Null}(A) \cap \text{Null}(\text{Span}\{\mathbf{x}_1, \dots, \mathbf{x}_{n^*}\}) = \{\mathbf{0}\}. \quad (6)$$

It indicates that

$$\text{Rank}(A) + \text{Dim}(\text{Span}\{\mathbf{x}_1, \dots, \mathbf{x}_{n^*}\}) \geq d.$$

From $n^* \geq \text{Dim}(\text{span}\{\mathbf{x}_1, \dots, \mathbf{x}_{n^*}\})$, we have $n^* \geq d - \text{Rank}(A)$. We proved the general case for LB1.

If we have $A\boldsymbol{\theta}^* \neq \mathbf{0}$, we can further improve LB1. Let $\mathbf{g}^* = (g_1^*, \dots, g_{n^*}^*)^\top$ be the vector satisfying

$$-\lambda A\boldsymbol{\theta}^* = \sum_{i=1}^{n^*} g_i^* \mathbf{x}_i \quad \text{and} \quad g_i^* \in \partial_1 \ell(\mathbf{x}_i^\top \boldsymbol{\theta}^*, y_i) \quad \forall i = 1, 2, \dots, n^*. \quad (7)$$

Since $\boldsymbol{\theta}^*$ satisfies the KKT condition, such vector \mathbf{g}^* must exist. Applying $A\boldsymbol{\theta}^* \neq \mathbf{0}$ to (7), we have $\mathbf{g}^* \neq \mathbf{0}$ and

$$\text{Dim}(\text{Span}\{A_{1,1}, A_{2,1}, \dots, A_{d,1}\} \cap \text{Span}\{\mathbf{x}_1, \dots, \mathbf{x}_{n^*}\}) \geq 1. \quad (8)$$

To satisfy (6), we must have

$$d = \text{Dim}(\text{Span}\{A_{1,1}, A_{2,1}, \dots, A_{d,1}, \mathbf{x}_1, \dots, \mathbf{x}_{n^*}\}).$$

Using the fact in linear algebra

$$\begin{aligned} & \text{Dim}(\text{Span}\{A_{1,1}, A_{2,1}, \dots, A_{d,1}, \mathbf{x}_1, \dots, \mathbf{x}_{n^*}\}) \\ &= \underbrace{\text{Dim}(\text{Span}\{A_{1,1}, A_{2,1}, \dots, A_{d,1}\})}_{=\text{Rank}(A)} + \\ & \underbrace{\text{Dim}(\text{Span}\{\mathbf{x}_1, \dots, \mathbf{x}_{n^*}\})}_{\leq n^*} - \\ & \underbrace{\text{Dim}(\text{Span}\{A_{1,1}, A_{2,1}, \dots, A_{d,1}\} \cap \text{Span}\{\mathbf{x}_1, \dots, \mathbf{x}_{n^*}\})}_{\geq 1 \text{ (from (8))}} \end{aligned}$$

We conclude that $n^* \geq d - \text{Rank}(A) + 1$. We completed the proof for LB1. ■

LB2 observes that the regularizer acts as a prior. If λ is large, more items are needed to sway the prior toward the target $\boldsymbol{\theta}^*$.

Theorem 2 Given any target model $\boldsymbol{\theta}^*$, there is a strength-of-regularization lower bound on the required number of training items to obtain a unique solution $\boldsymbol{\theta}^*$ from solving (1):

$$LB2 = \begin{cases} \lambda \left(\sup_{\alpha \in \mathbb{R}, y \in \mathcal{Y}} -\partial_1 \ell(\alpha \|\boldsymbol{\theta}^*\|_A^2, y) \right)^{-1}, & \text{if } A \text{ has full rank and } \boldsymbol{\theta}^* \neq \mathbf{0} \\ 0, & \text{otherwise.} \end{cases} \quad (9)$$

Proof When A has full rank we have an equivalent expression for the KKT condition (4):

$$-\lambda A^{\frac{1}{2}} \boldsymbol{\theta}^* \in \sum_{i=1}^{n^*} A^{-\frac{1}{2}} \mathbf{x}_i \partial_1 \ell(\mathbf{x}_i^\top \boldsymbol{\theta}^*, y_i) \quad \forall i = 1, \dots, n^*. \quad (10)$$

Let us decompose $A^{-\frac{1}{2}} \mathbf{x}_i$ for all $i = 1, \dots, n^*$ into $A^{-\frac{1}{2}} \mathbf{x}_i = \alpha_i A^{\frac{1}{2}} \boldsymbol{\theta}^* + \mathbf{u}_i$, where \mathbf{u}_i is orthogonal to $A^{\frac{1}{2}} \boldsymbol{\theta}^*$: $\mathbf{u}_i^\top A^{\frac{1}{2}} \boldsymbol{\theta}^* = 0$. Equivalently $\mathbf{x}_i = \alpha_i A \boldsymbol{\theta}^* + A^{\frac{1}{2}} \mathbf{u}_i$. Applying this decomposition, we have

$$\mathbf{x}_i^\top \boldsymbol{\theta}^* = \alpha_i \|\boldsymbol{\theta}^*\|_A^2 + \mathbf{u}_i^\top A^{\frac{1}{2}} \boldsymbol{\theta}^* = \alpha_i \|\boldsymbol{\theta}^*\|_A^2.$$

Putting it back in (10) we obtain

$$-\lambda A^{\frac{1}{2}} \boldsymbol{\theta}^* \in \sum_{i=1}^{n^*} (\alpha_i A^{\frac{1}{2}} \boldsymbol{\theta}^* + \mathbf{u}_i) \partial_1 \ell(\alpha_i \|\boldsymbol{\theta}^*\|_A^2, y_i) \quad \forall i = 1, \dots, n^*. \quad (11)$$

Since \mathbf{u}_i is orthogonal to $A^{\frac{1}{2}}\boldsymbol{\theta}^*$, (11) can be rewritten as

$$\exists \alpha_i \in \mathbb{R}, \exists y_i \in \mathcal{Y}; \exists g_i \in \partial_1 \ell(\alpha_i \|\boldsymbol{\theta}^*\|_A, y_i) \quad \forall i = 1, \dots, n^*$$

satisfying
$$\sum_{i=1}^{n^*} g_i \mathbf{u}_i = 0$$

$$-\lambda A^{\frac{1}{2}}\boldsymbol{\theta}^* = A^{\frac{1}{2}}\boldsymbol{\theta}^* \sum_{i=1}^{n^*} \alpha_i g_i \quad (12)$$

Since $A\boldsymbol{\theta}^* \neq 0$, we have $A^{\frac{1}{2}}\boldsymbol{\theta}^* \neq 0$ and (12) is equivalent to $-\lambda = \sum_{i=1}^{n^*} \alpha_i g_i$. It follows that

$$\lambda = -\sum_{i=1}^{n^*} \alpha_i g_i \leq n^* \sup_{\alpha \in \mathbb{R}, y \in \mathcal{Y}, g \in \partial_1 \ell(\alpha \|\boldsymbol{\theta}^*\|_A, y)} -\alpha g = n^* \sup_{\alpha \in \mathbb{R}, y \in \mathcal{Y}, g \in \partial_1 \ell(\alpha \|\boldsymbol{\theta}^*\|_A, y)} \alpha g$$

It indicates the lower bound for n^*

$$n^* \geq \left\lfloor \frac{\lambda}{\sup_{\alpha \in \mathbb{R}, y \in \mathcal{Y}, g \in \partial_1 \ell(\alpha \|\boldsymbol{\theta}^*\|_A, y)} \alpha g} \right\rfloor. \quad \blacksquare$$

LB1 and LB2 apply to all generalized linear learners. Due to the popularity of inhomogeneous margin-based linear learners (which include the standard form of SVM and logistic regression), we provide a tighter lower bound LB3 for such learners in Theorem 3. For inhomogeneous margin-based linear learners the learning algorithm A_{opt} solves a special form of (1):

$$A_{opt}(\mathcal{D}) = \text{Argmin}_{\mathbf{w}, b} \sum_{i=1}^n \ell(y_i(\mathbf{x}_i^\top \mathbf{w} + b)) + \frac{\lambda}{2} \|\mathbf{w}\|_A^2. \quad (13)$$

LB3 will prove to be instrumental in computing the teaching dimension for those learners. Following standard notation, we define $\boldsymbol{\theta} = [\mathbf{w}; b]$ where $\mathbf{w} \in \mathbb{R}^d$ is the weight vector and $b \in \mathbb{R}$ the bias (offset) term. Note $\boldsymbol{\theta} \in \mathbb{R}^{d+1}$ now. The $d \times d$ regularization matrix A applies only to \mathbf{w} while b is not regularized. Furthermore, margin-based linear learners have loss functions defined on the margin $y(\mathbf{x}^\top \mathbf{w} + b)$. This loss function structure will play a key role in obtaining LB3.

Theorem 3 *Assume matrix A in (13) has full rank and $\mathbf{w}^* \neq \mathbf{0}$. Given any target model $[\mathbf{w}^*; b^*]$, there is an inhomogeneous-margin lower bound on the required number of training items to obtain a unique solution $[\mathbf{w}^*; b^*]$ from solving (13):*

$$LB3 = \left\lfloor \lambda \left(\sup_{\alpha \in \mathbb{R}, g \in -\partial \ell(\alpha \|\mathbf{w}^*\|_A^2)} \alpha g \right)^{-1} \right\rfloor. \quad (14)$$

Proof Let $\mathcal{D} = \{\mathbf{x}_i, y_i\}_{i=1, \dots, n}$ be a teaching set for $[\mathbf{w}^*; b^*]$. The following KKT condition needs to be satisfied:

$$\mathbf{0} \in \sum_{i=1}^n \partial \ell(y_i(\mathbf{x}_i^\top \mathbf{w}^* + b^*)) y_i \begin{bmatrix} \mathbf{x}_i \\ 1 \end{bmatrix} + \begin{bmatrix} \lambda A \mathbf{w}^* \\ 0 \end{bmatrix}. \quad (15)$$

If we construct a new training set

$$\tilde{\mathcal{D}} = \left\{ \tilde{\mathbf{x}}_i = \mathbf{x}_i + \frac{b^*}{\|\mathbf{w}^*\|_A^2} A \mathbf{w}^*, \tilde{y}_i = y_i \right\}_{i=1, \dots, n}$$

then $[\mathbf{w}^*; 0]$ satisfies the KKT condition defined on $\tilde{\mathcal{D}}$. This can be verified as follows:

$$\begin{aligned} & \sum_{i=1}^n \partial \ell(y_i(\tilde{\mathbf{x}}_i^\top \mathbf{w}^*)) y_i \begin{bmatrix} \tilde{\mathbf{x}}_i \\ 1 \end{bmatrix} + \begin{bmatrix} \lambda A \mathbf{w}^* \\ 0 \end{bmatrix} \\ &= \sum_{i=1}^n \partial \ell(y_i(\mathbf{x}_i^\top \mathbf{w}^* + b^*)) y_i \begin{bmatrix} \mathbf{x}_i + \frac{b^*}{\|\mathbf{w}^*\|_A^2} A \mathbf{w}^* \\ 1 \end{bmatrix} + \begin{bmatrix} \lambda A \mathbf{w}^* \\ 0 \end{bmatrix} \\ &= \underbrace{\sum_{i=1}^n \partial \ell(y_i(\mathbf{x}_i^\top \mathbf{w}^* + b^*)) y_i \begin{bmatrix} \mathbf{x}_i \\ 1 \end{bmatrix} + \begin{bmatrix} \lambda A \mathbf{w}^* \\ 0 \end{bmatrix}}_{\geq 0 \text{ from (15)}} + \underbrace{\sum_{i=1}^n \partial \ell(y_i(\mathbf{x}_i^\top \mathbf{w}^* + b^*)) y_i \begin{bmatrix} \frac{b^*}{\|\mathbf{w}^*\|_A^2} A \mathbf{w}^* \\ 0 \end{bmatrix}}_{\geq 0 \text{ from (15)}} \\ & \geq 0 \end{aligned}$$

where $0 \in \sum_{i=1}^n \partial \ell(y_i(\mathbf{x}_i^\top \mathbf{w}^* + b^*)) y_i$ is from the bias dimension in (15). It follows that

$$\mathbf{0} \in \sum_{i=1}^n \partial \ell(\tilde{y}_i \tilde{\mathbf{x}}_i^\top \mathbf{w}^*) \tilde{y}_i \tilde{\mathbf{x}}_i + \lambda A \mathbf{w}^*$$

which is equivalent to

$$\begin{aligned} \mathbf{0} & \in \sum_{i=1}^n \partial \ell(\tilde{y}_i \tilde{\mathbf{x}}_i^\top \mathbf{w}^*) A^{-\frac{1}{2}} \underbrace{\tilde{y}_i \tilde{\mathbf{x}}_i}_{=: \mathbf{z}_i} + \lambda A^{\frac{1}{2}} \mathbf{w}^* \\ &= \sum_{i=1}^n \partial \ell(\mathbf{z}_i^\top \mathbf{w}^*) A^{-\frac{1}{2}} \mathbf{z}_i + \lambda A^{\frac{1}{2}} \mathbf{w}^*. \end{aligned} \quad (16)$$

We decompose $A^{-\frac{1}{2}} \mathbf{z}_i = \alpha_i A^{\frac{1}{2}} \mathbf{w}^* + \mathbf{u}_i$ where \mathbf{u}_i satisfies $\mathbf{u}_i^\top A^{\frac{1}{2}} \mathbf{w}^* = 0$. Applying this decomposition to (16), we have

$$\lambda A^{\frac{1}{2}} \mathbf{w}^* \in \sum_{i=1}^n -\partial \ell(\alpha_i \|\mathbf{w}^*\|_A^2) (\alpha_i A^{\frac{1}{2}} \mathbf{w}^* + \mathbf{u}_i). \quad (17)$$

Since \mathbf{u}_i is orthogonal to $A^{\frac{1}{2}} \mathbf{w}^*$, (17) implies that

$$\lambda A^{\frac{1}{2}} \mathbf{w}^* \in \sum_{i=1}^n -\partial \ell(\alpha_i \|\mathbf{w}^*\|_A^2) \alpha_i A^{\frac{1}{2}} \mathbf{w}^*.$$

Since $\mathbf{w}^* \neq \mathbf{0}$ we have

$$\lambda \in \sum_{i=1}^n -\partial \ell(\alpha_i \|\mathbf{w}^*\|_A^2) \alpha_i.$$

Together with

$$\sum_{i=1}^n -\partial \ell(\alpha_i \|\mathbf{w}^*\|_A^2) \alpha_i \leq n \sup_{\alpha \in \mathbb{R}, g \in -\partial \ell(\alpha \|\mathbf{w}^*\|_A^2)} \alpha g,$$

we obtain LB3. \blacksquare

3.2 The Teaching Dimension $TD(\boldsymbol{\theta}^*, \mathcal{A}_{opt})$ of Three Homogeneous Learners

We now turn to upper bounding teaching dimension by constructing teaching sets. To prove that we indeed have a teaching set for a target $\boldsymbol{\theta}^*$, we need to show that $\boldsymbol{\theta}^*$ is a solution of (1), and the solution is unique. The size of any such teaching set is an upper bound on the teaching dimension. The teaching dimension itself is determined if such an upper bound matches the corresponding lower bound. We show that this is indeed the case for our constructed teaching sets. For the sake of reference we preview in Table 2 the instantiated lower bounds that we will use in this section; their derivation will be shown below.

lower bound	homogeneous			inhomogeneous		
	ridge	SVM	logistic	ridge	SVM	logistic
LB1	1	1	1	2	2	2
LB2	0	$\lceil \lambda \ \boldsymbol{\theta}^*\ ^2 \rceil$	$\frac{\lambda \ \boldsymbol{\theta}^*\ ^2}{\tau_{\max}}$	0	0	0
LB3	-	-	-	-	$\lceil \lambda \ \mathbf{w}^*\ ^2 \rceil$	$\frac{\lambda \ \mathbf{w}^*\ ^2}{\tau_{\max}}$

Table 2: Lower bounds of teaching dimension $TD(\boldsymbol{\theta}^*, \mathcal{A}_{opt})$ for homogeneous and inhomogeneous versions of ridge regression, SVM, and logistic regression.

Teaching dimension is learner-dependent. We choose three learners to study their teaching dimension due to these learners' popularity in machine learning: ridge regression, SVM, and logistic regression. It turns out that homogeneous and inhomogeneous versions of these learners require different analysis. We devote this section to the homogeneous version where the regularizer matrix $A = I$ the identity matrix, and the next section to the inhomogeneous version. It is possible to extend our analysis to other linear learners of the form (1).

It is easy to see that if the target model $\boldsymbol{\theta}^* = \mathbf{0}$, we do not need any training data to uniquely obtain the target model from (1). In the following, we only consider the nontrivial case $\boldsymbol{\theta}^* \neq \mathbf{0}$.

Homogeneous ridge regression solves the following optimization problem:

$$\min_{\boldsymbol{\theta} \in \mathbb{R}^d} \sum_{i=1}^n \frac{1}{2} (\mathbf{x}_i^\top \boldsymbol{\theta} - y_i)^2 + \frac{\lambda}{2} \|\boldsymbol{\theta}\|^2. \quad (18)$$

We only need one training item to uniquely obtain any nonzero target model $\boldsymbol{\theta}^*$, as the following construction shows.

Proposition 1 *Given any target model $\boldsymbol{\theta}^* \neq \mathbf{0}$, the following is a teaching set for homogeneous ridge regression (18):*

$$\mathbf{x}_1 = a\boldsymbol{\theta}^*, \quad y_1 = \frac{\lambda + \|\mathbf{x}_1\|^2}{a} \quad (19)$$

where a can be any nonzero real number.

Proof We simply verify the KKT condition to see that $\boldsymbol{\theta}^*$ is a solution to (18) by applying the construction in (19). The uniqueness of $\boldsymbol{\theta}^*$ is guaranteed by the strong convexity of (18). \blacksquare

It is worth to note that the teaching set is inconsistent with the target model, that is, $\mathbf{x}_1^\top \boldsymbol{\theta}^* = a\|\boldsymbol{\theta}^*\|^2 \neq y_1 = \frac{\lambda}{a} + a\|\boldsymbol{\theta}^*\|^2$, unless the regularization is absent $\lambda = 0$. The teacher intentionally overshoots the target in order to precisely counter the learner's regularizer. This has been observed before for Bayesian learners, too (Zhu, 2013).

We encourage the reader to distinguish two senses of uniqueness. The teaching set itself is not necessarily unique. In the construction (19), any $a \neq 0$ leads to a valid teaching set. Nonetheless, any one of the teaching sets will lead to the unique solution $\boldsymbol{\theta}^*$ in (18).

Corollary 1 *The teaching dimension $TD(\boldsymbol{\theta}^*, \mathcal{A}_{ridge}^{hom}) = 1$ for homogeneous ridge regression and target $\boldsymbol{\theta}^* \neq \mathbf{0}$.*

Proof Substituting A by I in LB1 (3), we obtain the lower bound $d - \text{Rank}(I) + 1 = 1$ which matches the teaching set size in (19). \blacksquare

Homogeneous SVM solves the problem:

$$\min_{\boldsymbol{\theta} \in \mathbb{R}^d} \sum_{i=1}^n \max(1 - y_i \mathbf{x}_i^\top \boldsymbol{\theta}, 0) + \frac{\lambda}{2} \|\boldsymbol{\theta}\|^2. \quad (20)$$

To teach this learner one training item is in general not enough: we will show that we need $\lceil \lambda \|\boldsymbol{\theta}^*\|^2 \rceil$ training items. In fact, we will construct such a teaching set consisting of *identical* training items. It is well-known in the teaching literature that a teaching set does not need to consist of *i.i.d.* samples from a distribution, and can look unusual. It is possible to incorporate additional constraints into a teaching problem if one wants the training items to be diverse, but we do not consider that in the present paper.

Proposition 2 *Given any target model $\boldsymbol{\theta}^* \neq \mathbf{0}$, the following is a teaching set for homogeneous SVM (20). There are $n = \lceil \lambda \|\boldsymbol{\theta}^*\|^2 \rceil$ identical training items, each taking the form*

$$\mathbf{x}_i = \frac{\lambda \boldsymbol{\theta}^*}{\lceil \lambda \|\boldsymbol{\theta}^*\|^2 \rceil}, \quad y_i = 1. \quad (21)$$

Proof We only need to verify that the KKT condition holds for $\boldsymbol{\theta}^*$. Due to the strong convexity of (20) uniqueness is guaranteed automatically. We denote the subgradient

$\partial_a \max(1 - a, 0) = -\partial_1 \max(1 - a, 0) = -\mathbf{I}(a)$, where

$$\mathbf{I}(a) = \begin{cases} 1, & \text{if } a < 1 \\ [0, 1], & \text{if } a = 1 \\ 0, & \text{otherwise} \end{cases}. \quad (22)$$

The KKT condition is

$$\begin{aligned} & \sum_{i=1}^n -y_i \mathbf{x}_i \partial_1 \max(1 - y_i \mathbf{x}_i^\top \boldsymbol{\theta}^*, 0) + \lambda \boldsymbol{\theta}^* \\ &= \sum_{i=1}^n -y_i \mathbf{x}_i \mathbf{I}(y_i \mathbf{x}_i^\top \boldsymbol{\theta}^*) + \lambda \boldsymbol{\theta}^* \\ &= -n \frac{\lambda \|\boldsymbol{\theta}^*\|^2}{[\lambda \|\boldsymbol{\theta}^*\|^2]} \mathbf{I} \left(\frac{\lambda \|\boldsymbol{\theta}^*\|^2}{[\lambda \|\boldsymbol{\theta}^*\|^2]} \right) + \lambda \boldsymbol{\theta}^* \\ &= -\lambda \boldsymbol{\theta}^* \mathbf{I} \left(\frac{\lambda \|\boldsymbol{\theta}^*\|^2}{[\lambda \|\boldsymbol{\theta}^*\|^2]} \right) + \lambda \boldsymbol{\theta}^* \\ &\geq \mathbf{0} \end{aligned}$$

where the last line is due to $\mathbf{I} \left(\frac{\lambda \|\boldsymbol{\theta}^*\|^2}{[\lambda \|\boldsymbol{\theta}^*\|^2]} \right)$ giving either the set $[0, 1]$ or the value 1. \blacksquare

Corollary 2 *The teaching dimension $TD(\boldsymbol{\theta}^*, \mathcal{A}_{\text{sym}}^{\text{hom}}) = [\lambda \|\boldsymbol{\theta}^*\|^2]$ for homogeneous SVM and target $\boldsymbol{\theta}^* \neq \mathbf{0}$.*

Proof We show this number matches LB2. Let $A = I$, $\ell(a, b) = \max(1 - ab, 0)$, and consider the denominator of (9):

$$\begin{aligned} \sup_{\alpha \in \mathbb{R}, y \in \mathcal{Y}, g \in -\partial_1 \ell(\alpha \|\boldsymbol{\theta}^*\|^2, y)} \alpha g &= \sup_{\alpha, y \in \{-1, 1\}, g \in \partial_1 \ell(g \alpha \|\boldsymbol{\theta}^*\|^2)} \alpha g \\ &= \sup_{\alpha, g \in \mathbf{I}(\alpha \|\boldsymbol{\theta}^*\|^2)} \alpha g \\ &= \frac{1}{\|\boldsymbol{\theta}^*\|^2} \end{aligned}$$

where the first equality is due to $\partial_1 \ell(a, b) = -b \mathbf{I}(ab)$. Therefore, $LB2 = [\lambda \|\boldsymbol{\theta}^*\|^2]$ which matches the construction in (21). \blacksquare

Homogeneous logistic regression solves the problem:

$$\min_{\boldsymbol{\theta} \in \mathbb{R}^d} \sum_{i=1}^n \log(1 + \exp(-y_i \mathbf{x}_i^\top \boldsymbol{\theta})) + \frac{\lambda}{2} \|\boldsymbol{\theta}\|^2 \quad (23)$$

where \log has base e . The situation is similar to homogeneous SVM. However, due to the negative log likelihood term we have a coefficient defined by the Lambert W function (Corless et al., 1996), which we denote by W_{lam} . Recall the defining equation for Lambert W

function is $W_{\text{lam}}(x)e^{W_{\text{lam}}(x)} = x$. We further define

$$\tau_{\max} := \max \frac{t}{1 + e^t} = W_{\text{lam}}(1/e) \approx 0.2785,$$

where the equality can be derived in following: The optimal t^* satisfies

$$1 + e^{t^*} = t^* e^{t^*} \Leftrightarrow (t^* - 1)e^{t^* - 1} = 1/e$$

which suggests $t^* = W_{\text{lam}}(1/e) + 1$. We apply the optimality condition above and the optimal value of t^* to obtain

$$\max_t \frac{t}{1 + e^t} = \frac{t^*}{1 + e^{t^*}} = \frac{1}{e^{t^*}} = \frac{1}{e \cdot e^{W_{\text{lam}}(1/e)}} = W_{\text{lam}}(1/e).$$

For any value $a \leq \tau_{\max}$, we define $\tau^{-1}(a)$ as the solution to $a = \frac{t}{1 + e^t}$. By using the Lambert W function $\tau^{-1}(a)$ can be expressed as $\tau^{-1}(a) \equiv a - W_{\text{lam}}(-ae^a)$, which can be derived from

$$\frac{t}{1 + e^t} = \frac{a - W_{\text{lam}}(-ae^a)}{1 + e^{a - W_{\text{lam}}(-ae^a)}} = \frac{a + ae^a/e^{W_{\text{lam}}(-ae^a)}}{1 + e^a - W_{\text{lam}}(-ae^a)} = a.$$

Proposition 3 *Given any target model $\boldsymbol{\theta}^* \neq \mathbf{0}$, the following is a teaching set for homogeneous logistic regression (23). There are $n = \left\lceil \frac{\lambda \|\boldsymbol{\theta}^*\|^2}{\tau_{\max}} \right\rceil$ identical training items, each taking the form*

$$\mathbf{x}_i = \tau^{-1} \left(\lambda \|\boldsymbol{\theta}^*\|^2 \left\lceil \frac{\lambda \|\boldsymbol{\theta}^*\|^2}{\tau_{\max}} \right\rceil^{-1} \right) \frac{\boldsymbol{\theta}^*}{\|\boldsymbol{\theta}^*\|^2}, \quad y_i = 1. \quad (24)$$

Proof We first verify that $\boldsymbol{\theta}^*$ is a solution to (23) based on the teaching set construction in (24). We only need to verify the gradient of (23) is zero. Computing the gradient of (23), we have

$$\begin{aligned} & \sum_{i=1}^n \frac{-y_i \mathbf{x}_i}{1 + \exp\{y_i \mathbf{x}_i^\top \boldsymbol{\theta}^*\}} + \lambda \boldsymbol{\theta}^* \\ &= -n \frac{\mathbf{x}_i}{1 + \exp \left\{ \tau^{-1} \left(\lambda \|\boldsymbol{\theta}^*\|^2 \left\lceil \frac{\lambda \|\boldsymbol{\theta}^*\|^2}{\tau_{\max}} \right\rceil^{-1} \right) \right\}} + \lambda \boldsymbol{\theta}^* \\ &= -n \frac{\tau^{-1} \left(\lambda \|\boldsymbol{\theta}^*\|^2 \left\lceil \frac{\lambda \|\boldsymbol{\theta}^*\|^2}{\tau_{\max}} \right\rceil^{-1} \right) \boldsymbol{\theta}^*}{\left(\lambda \|\boldsymbol{\theta}^*\|^2 \left\lceil \frac{\lambda \|\boldsymbol{\theta}^*\|^2}{\tau_{\max}} \right\rceil^{-1} \right) \|\boldsymbol{\theta}^*\|^2} + \lambda \boldsymbol{\theta}^* \\ &= -n \lambda \|\boldsymbol{\theta}^*\|^2 \left\lceil \frac{\lambda \|\boldsymbol{\theta}^*\|^2}{\tau_{\max}} \right\rceil^{-1} \frac{\boldsymbol{\theta}^*}{\|\boldsymbol{\theta}^*\|^2} + \lambda \boldsymbol{\theta}^* \\ &= \mathbf{0}, \end{aligned}$$

where the third equality uses the fact $\lambda \|\boldsymbol{\theta}^*\|^2 \left\lceil \frac{\lambda \|\boldsymbol{\theta}^*\|^2}{\tau_{\max}} \right\rceil^{-1} \leq \tau_{\max}$ and the property $a = \frac{\tau^{-1}(a)}{1 + e^{\tau^{-1}(a)}}$. The strong convexity of (23) automatically implies uniqueness. \blacksquare

Corollary 3 The teaching dimension $TD(\boldsymbol{\theta}^*, \mathcal{A}_{\log}^{\text{hom}}) = \left\lceil \frac{\lambda \|\boldsymbol{\theta}^*\|^2}{\tau_{\max}} \right\rceil$ for homogeneous logistic regression and target $\boldsymbol{\theta}^* \neq \mathbf{0}$.

Proof We show that the number matches LB2. In (9) let $A = I$ and $\ell(a, b) = \log(1 + \exp(-ab))$. The denominator of LB2 is:

$$\begin{aligned} \sup_{\alpha \in \mathbb{R}, \beta \in \mathcal{Y}} \sup_{\beta \in \mathcal{Y}} \ell(\alpha \|\boldsymbol{\theta}^*\|^2, \beta) &= \sup_{\alpha, \beta \in \{-1, 1\}, \beta = y(1 + \exp\{\beta \alpha \|\boldsymbol{\theta}^*\|^2\})^{-1}} \alpha \beta \\ &= \sup_{\alpha, \beta = (1 + \exp\{\alpha \|\boldsymbol{\theta}^*\|^2\})^{-1}} \alpha \beta \\ &= \sup_{\alpha} \frac{\alpha}{1 + \exp\{\alpha \|\boldsymbol{\theta}^*\|^2\}} \\ &= \|\boldsymbol{\theta}^*\|^{-2} \sup_t \frac{\alpha}{1 + \exp\{t\}} \\ &= \frac{\tau_{\max}}{\|\boldsymbol{\theta}^*\|^2}, \end{aligned}$$

which implies $LB2 = \left\lceil \frac{\lambda \|\boldsymbol{\theta}^*\|^2}{\tau_{\max}} \right\rceil$. ■

3.3 The Teaching Dimension $TD(\boldsymbol{\theta}^*, \mathcal{A}_{\text{opt}})$ of Three Inhomogeneous Learners

Inhomogeneous learners are defined by $\boldsymbol{\theta} = [w; b]$ where the weight vector $w \in \mathbb{R}^d$ and the scalar offset $b \in \mathbb{R}$. The offset b is not regularized. Similar to the previous section, we need to instantiate the teaching dimension lower bounds and design the teaching sets. We show that the size of our teaching set exactly matches the lower bound for inhomogeneous ridge regression, and differs from the lower bound of inhomogeneous SVM and logistic regression by at most one due to rounding. Therefore, up to rounding we also establish the teaching dimension for these inhomogeneous learners.

Inhomogeneous ridge regression solves the problem:

$$\min_{w \in \mathbb{R}^d, b \in \mathbb{R}} \sum_{i=1}^n \frac{1}{2} (\mathbf{x}_i^\top w + b - y_i)^2 + \frac{\lambda}{2} \|w\|^2 \quad (25)$$

Proposition 4 Given any target model $[w^*; b^*]$, if $w^* = \mathbf{0}$ (b^* can be an arbitrary value), the following is a teaching set for inhomogeneous ridge regression (25) with $n = 1$:

$$\mathbf{x}_1 = \mathbf{0}, \quad y_1 = b^*. \quad (26)$$

If $w^* \neq \mathbf{0}$, any $n = 2$ items satisfying the following are a teaching set for $a \neq 0$:

$$\mathbf{x}_1 - \mathbf{x}_2 = a w^*, \quad y_1 = \mathbf{x}_1^\top w^* + b^* + \frac{\lambda}{a}, \quad y_2 = y_1 - a \|w^*\|^2 - 2 \frac{\lambda}{a}. \quad (27)$$

Proof We first prove the case for $w^* = \mathbf{0}$. We can verify that the KKT condition is satisfied by designing \mathbf{x}_1 and y_1 as in (26):

$$\begin{aligned} (\mathbf{x}_1^\top w^* + b^* - y_1) \mathbf{x}_1 + \lambda w^* &= \mathbf{0} \\ \mathbf{x}_1^\top w^* + b^* - y_1 &= 0. \end{aligned}$$

The uniqueness of $[w^*; b^*]$ is indicated by the strong convexity of (25) when $n = 1$.

We then prove the case for $w^* \neq \mathbf{0}$. With simple algebra, we can verify the KKT condition holds via the construction in (27):

$$\begin{aligned} (\mathbf{x}_1^\top w^* + b^* - y_1) \mathbf{x}_1 + (\mathbf{x}_2^\top w^* + b^* - y_2) \mathbf{x}_2 + \lambda w^* &= \mathbf{0} \\ (\mathbf{x}_1^\top w^* + b^* - y_1) + (\mathbf{x}_2^\top w^* + b^* - y_2) &= 0. \end{aligned}$$

Similarly, the uniqueness is implied by the strong convexity of (25) when $n = 2$. ■

Corollary 4 The teaching dimension for inhomogeneous ridge regression with target $\boldsymbol{\theta}^* = [w^*; b^*]$ is $TD(\boldsymbol{\theta}^*, \mathcal{A}_{\text{ridge}}^{\text{inh}}) = 1$ if target $w^* = \mathbf{0}$, or $TD(\boldsymbol{\theta}^*, \mathcal{A}_{\text{ridge}}^{\text{inh}}) = 2$ if $w^* \neq \mathbf{0}$, regardless of the target offset b^* .

Proof We match the lower bound LB1 in (3). Note $\boldsymbol{\theta}^* = [w^*; b^*] \in \mathbb{R}^{d+1}$, and A in this case is a $(d+1) \times (d+1)$ matrix with the $d \times d$ identity matrix I_d padded with one additional row and column of zeros for the offset. Therefore $\text{Rank}(A) = \text{Rank}(I_d) = d$. When $w^* = \mathbf{0}$, $A\boldsymbol{\theta}^* = \mathbf{0}$ and $LB1 = (d+1) - \text{Rank}(A) = 1$. When $w^* \neq \mathbf{0}$, $A\boldsymbol{\theta}^* \neq \mathbf{0}$ and $LB1 = (d+1) - \text{Rank}(A) + 1 = 2$. These lower bounds match the teaching set sizes in (26) and (27), respectively. ■

Inhomogeneous SVM solves the problem:

$$\min_{w \in \mathbb{R}^d, b \in \mathbb{R}} \max_{i=1}^n \max(1 - y_i (\mathbf{x}_i^\top w + b), 0) + \frac{\lambda}{2} \|w\|^2. \quad (28)$$

Proposition 5 Given any target model $[w^*; b^*]$ with $w^* \neq \mathbf{0}$, the following is a teaching set for inhomogeneous SVM (28). We need $n = 2 \left\lceil \frac{\lambda \|w^*\|^2}{2} \right\rceil$ training items, half of which are identical positive items $\mathbf{x}_i = \mathbf{x}_+$, $y_i = 1$, $\forall i \in \{1, \dots, \frac{n}{2}\}$ and half identical negative items $\mathbf{x}_i = \mathbf{x}_-$, $y_i = -1$, $\forall i \in \{\frac{n}{2} + 1, \dots, n\}$. \mathbf{x}_+ and \mathbf{x}_- can be designed as any vectors satisfying

$$\mathbf{x}_+^\top w^* = 1 - b^*, \quad \mathbf{x}_- = \mathbf{x}_+ - \frac{2w^*}{\|w^*\|^2}. \quad (29)$$

Proof Unlike in previous learners (including homogeneous SVM), we no longer have strong convexity w.r.t. b . In order to prove that (29) is a teaching set, we need to verify the KKT condition and verify solution uniqueness.

We first verify the KKT condition to show that the solution under (29) includes the target model $[w^*; b^*]$. From (29), we have

$$\mathbf{x}_+^\top w^* + b^* = 1, \quad \mathbf{x}_-^\top w^* + b^* = -1. \quad (30)$$

Applying them to the KKT condition and using the notation in (22) we obtain

$$\begin{aligned}
& -\frac{n}{2}\mathbf{I}(\mathbf{x}_+^\top \mathbf{w}^* + b^*) \begin{bmatrix} \mathbf{x}_+ \\ 1 \end{bmatrix} + \frac{n}{2}\mathbf{I}(-\mathbf{x}_-^\top \mathbf{w}^* - b^*) \begin{bmatrix} \mathbf{x}_- \\ 1 \end{bmatrix} + \begin{bmatrix} \lambda \mathbf{w}^* \\ 0 \end{bmatrix} \\
& = -\frac{n}{2}\mathbf{I}(1) \begin{bmatrix} \mathbf{x}_+ \\ 1 \end{bmatrix} + \frac{n}{2}\mathbf{I}(1) \begin{bmatrix} \mathbf{x}_- \\ 1 \end{bmatrix} + \begin{bmatrix} \lambda \mathbf{w}^* \\ 0 \end{bmatrix} \\
& \supseteq \frac{n}{2}\mathbf{I}(1) \begin{bmatrix} \mathbf{x}_- - \mathbf{x}_+ \\ 0 \end{bmatrix} + \begin{bmatrix} \lambda \mathbf{w}^* \\ 0 \end{bmatrix} \quad \text{setting the last dimension to 0} \\
& = \mathbf{I}(1) \begin{bmatrix} -\frac{n}{\|\mathbf{w}^*\|^2} \mathbf{w}^* \\ 0 \end{bmatrix} + \begin{bmatrix} \lambda \mathbf{w}^* \\ 0 \end{bmatrix} \quad \text{applying (29)} \\
& \supseteq \mathbf{I}(1) \begin{bmatrix} -\lambda \mathbf{w}^* \\ 0 \end{bmatrix} + \begin{bmatrix} \lambda \mathbf{w}^* \\ 0 \end{bmatrix} \quad \text{observing } n \geq \lambda \|\mathbf{w}^*\|^2 \\
& \ni \mathbf{0}.
\end{aligned}$$

It proves that $[\mathbf{w}^*; b^*]$ solves (28) by our teaching set construction.

Next we prove uniqueness by contradiction. We use $f(\mathbf{w}, b)$ to denote the objective function in (28) under the teaching set. It is easy to verify that $f(\mathbf{w}^*, b^*) = \frac{\lambda}{2}\|\mathbf{w}^*\|^2$. Assume that there exists another solution $[\bar{\mathbf{w}}; \bar{b}]$ different from $[\mathbf{w}^*; b^*]$. We can obtain $\|\bar{\mathbf{w}}\|^2 \leq \|\mathbf{w}^*\|^2$ due to

$$\frac{\lambda}{2}\|\mathbf{w}^*\|^2 = f(\mathbf{w}^*, b^*) = f(\bar{\mathbf{w}}, \bar{b}) \geq \frac{\lambda}{2}\|\bar{\mathbf{w}}\|^2.$$

The second equality is due to $[\bar{\mathbf{w}}; \bar{b}]$ being a solution; the inequality is due to whole-part relationship. Therefore, there are only two possibilities for the norm of $\bar{\mathbf{w}}$: $\|\bar{\mathbf{w}}\| = \|\mathbf{w}^*\|$ or $\|\bar{\mathbf{w}}\| = t\|\mathbf{w}^*\|$ for some $0 \leq t < 1$. Next we will show that both cases are impossible.

(Case 1) For the case $\|\bar{\mathbf{w}}\| = \|\mathbf{w}^*\|$, we have

$$\begin{aligned}
f(\bar{\mathbf{w}}, \bar{b}) &= \frac{n}{2} \max \left(1 - (\mathbf{x}_+^\top \bar{\mathbf{w}} + \bar{b}), 0 \right) + \frac{n}{2} \max \left(1 + (\mathbf{x}_-^\top \bar{\mathbf{w}} + \bar{b}), 0 \right) + \frac{\lambda}{2} \|\bar{\mathbf{w}}\|^2 \\
&= \frac{n}{2} \max \left(\underbrace{\mathbf{x}_+^\top (\mathbf{w}^* - \bar{\mathbf{w}})}_{=: \Delta_+} + (\bar{b}^* - \bar{b}), 0 \right) + \frac{n}{2} \max \left(\underbrace{-\mathbf{x}_-^\top (\mathbf{w}^* - \bar{\mathbf{w}})}_{=: \Delta_-} - (\bar{b}^* - \bar{b}), 0 \right) \\
&\quad + \frac{\lambda}{2} \|\mathbf{w}^*\|^2 \\
&= \frac{n}{2} \max(\Delta_+, 0) + \frac{n}{2} \max(\Delta_-, 0) + f(\mathbf{w}^*, b^*).
\end{aligned}$$

From $f(\bar{\mathbf{w}}, \bar{b}) = f(\mathbf{w}^*, b^*)$, it follows $\Delta_+ \leq 0$ and $\Delta_- \leq 0$. Since

$$0 \geq \Delta_+ + \Delta_- = (\mathbf{x}_+ - \mathbf{x}_-)^\top (\mathbf{w}^* - \bar{\mathbf{w}}) = \frac{2(\mathbf{w}^*)^\top (\mathbf{w}^* - \bar{\mathbf{w}})}{\|\mathbf{w}^*\|^2} = 2 - 2 \frac{\bar{\mathbf{w}}^\top \mathbf{w}^*}{\|\mathbf{w}^*\|^2},$$

we have $\bar{\mathbf{w}}^\top \mathbf{w}^* \geq \|\mathbf{w}^*\|^2$. But because $\|\bar{\mathbf{w}}\| = \|\mathbf{w}^*\|$, we must have $\bar{\mathbf{w}} = \mathbf{w}^*$. Applying this new observation to $\Delta_+ \leq 0$ and $\Delta_- \leq 0$, we obtain $\bar{b}^* = b$. It means that $[\mathbf{w}^*; b^*] = [\bar{\mathbf{w}}; \bar{b}]$, contradicting our assumption $[\mathbf{w}^*; b^*] \neq [\bar{\mathbf{w}}; \bar{b}]$.

(Case 2) Next we turn to the case $\|\bar{\mathbf{w}}\| = t\|\mathbf{w}^*\|$ for some $t \in [0, 1)$. Recall our assumption that $[\bar{\mathbf{w}}; \bar{b}]$ solves (28). Then it follows that the following specific construction $[\hat{\mathbf{w}}; \hat{b}]$ solves (28) as well:

$$\hat{\mathbf{w}} = t\mathbf{w}^*, \quad \hat{b} = tb^*. \quad (31)$$

To see this, we consider the following optimization problem:

$$\begin{aligned}
& \min_{\mathbf{w}, b} L(\mathbf{w}, b) := \frac{n}{2} \max(1 - (\mathbf{x}_+^\top \mathbf{w} + b), 0) + \frac{n}{2} \max(1 + (\mathbf{x}_-^\top \mathbf{w} + b), 0) \\
& \text{s.t. } \|\mathbf{w}\| \leq t\|\mathbf{w}^*\|.
\end{aligned} \quad (32)$$

Since $[\bar{\mathbf{w}}; \bar{b}]$ solves (28), it is easy to see that $[\bar{\mathbf{w}}; \bar{b}]$ solves (32) too, otherwise there exists a solution for (32) which gives a lower function value on (28). Then we can verify that $[\bar{\mathbf{w}}; \bar{b}]$ solves (32) as well by showing the following geometric optimality condition holds:

$$-\left[\frac{\partial L(\mathbf{w}, b)}{\partial \mathbf{w}} \right]_{[\bar{\mathbf{w}}; \bar{b}]} \cap \underbrace{\mathcal{N}_{\|\mathbf{w}\| \leq t\|\mathbf{w}^*\|}(\hat{\mathbf{w}}, \hat{b})}_{\text{Normal cone to the set } \{\mathbf{w}; \hat{b} : \|\mathbf{w}\| \leq t\|\mathbf{w}^*\| \text{ at } [\bar{\mathbf{w}}; \bar{b}]} \neq \emptyset.$$

Given a convex closed set Ω and a point $\theta \in \Omega$, the normal cone at point θ is defined to be a set

$$\mathcal{N}_\Omega(\theta) = \{\phi : \langle \phi, \psi - \theta \rangle \leq 0 \forall \psi \in \Omega\}.$$

The optimality condition basically suggests that at the optimal point, the negative (sub)gradient direction overlaps with the normal cone. In other words, there does not exist any valid direction to decrease the objective at the optimal point. Readers can refer to Nocedal and Wright (2006) or Bertsekas and Nedic (2003) for more explanations about the geometric optimality condition.

Because of (30) and (31), we have $\mathbf{x}_+^\top \hat{\mathbf{w}} + \hat{b} = t < 1$. Thus at $[\hat{\mathbf{w}}; \hat{b}]$ the subgradient is

$$-\left[\frac{\partial L(\mathbf{w}, b)}{\partial \mathbf{w}} \right]_{[\hat{\mathbf{w}}; \hat{b}]} = \frac{n}{2} \begin{bmatrix} \mathbf{x}_+ - \mathbf{x}_- \\ 0 \end{bmatrix} = \begin{bmatrix} \frac{n\mathbf{w}^*}{\|\mathbf{w}^*\|^2} \\ 0 \end{bmatrix}$$

And the normal cone is

$$\mathcal{N}_{\|\mathbf{w}\| \leq t\|\mathbf{w}^*\|}(\hat{\mathbf{w}}, \hat{b}) = \left\{ s \begin{bmatrix} \mathbf{w}^* \\ 0 \end{bmatrix} \mid s \geq 0 \right\}.$$

The intersection is non-empty by choosing $s = \frac{n}{\|\mathbf{w}^*\|^2}$. Since both $[\hat{\mathbf{w}}; \hat{b}]$ and $[\bar{\mathbf{w}}; \bar{b}]$ solve (32), we have $L(\hat{\mathbf{w}}, \hat{b}) = L(\bar{\mathbf{w}}, \bar{b})$. Together with $\|\hat{\mathbf{w}}\| = \|\bar{\mathbf{w}}\|$, we have

$$f(\hat{\mathbf{w}}, \hat{b}) = L(\hat{\mathbf{w}}, \hat{b}) + \frac{\lambda}{2} \|\hat{\mathbf{w}}\|^2 = f(\bar{\mathbf{w}}, \bar{b}) = f(\mathbf{w}^*, b^*).$$

Therefore, we proved that $(\hat{\mathbf{w}}, \hat{b})$ solves (28) as well. To see the contradiction, let us check the function value of $f(\hat{\mathbf{w}}, \hat{b})$ via a different route:

$$\begin{aligned}
f(\hat{\mathbf{w}}, \hat{b}) &= f(\hat{\mathbf{w}}^*, t\hat{b}^*) \\
&= \sum_{i=1}^{\frac{n}{2}} \max \left(1 - t(\mathbf{x}_+^\top \hat{\mathbf{w}}^* + b^*), 0 \right) + \sum_{i=1}^{\frac{n}{2}} \max \left(1 + t(\mathbf{x}_-^\top \hat{\mathbf{w}}^* + b^*), 0 \right) + \frac{\lambda}{2} \|\hat{\mathbf{w}}^*\|^2 t^2 \\
&= \sum_{i=1}^{\frac{n}{2}} \max(1 - t, 0) + \sum_{i=1}^{\frac{n}{2}} \max(1 + t, 0) + \frac{\lambda}{2} \|\hat{\mathbf{w}}^*\|^2 t^2 \\
&\geq n(1 - t) - \frac{\lambda}{2} \|\hat{\mathbf{w}}^*\|^2 (1 - t^2) + \frac{\lambda}{2} \|\hat{\mathbf{w}}^*\|^2 \\
&\geq n(1 - t) - \frac{n}{2} (1 - t^2) + \frac{\lambda}{2} \|\hat{\mathbf{w}}^*\|^2 \\
&= \frac{n}{2} (1 - t)^2 + f(\hat{\mathbf{w}}^*, b^*) \\
&> f(\hat{\mathbf{w}}^*, b^*),
\end{aligned}$$

where the first inequality uses the fact that $n \geq \lambda \|\hat{\mathbf{w}}^*\|^2$. It contradicts our early assertion $f(\hat{\mathbf{w}}, \hat{b}) = f(\hat{\mathbf{w}}^*, b^*)$. Putting cases 1 and 2 together we prove uniqueness. \blacksquare

Our construction of the teaching set in (29) requires $n = 2 \left\lceil \frac{\lambda \|\mathbf{w}^*\|^2}{2} \right\rceil$ training items. This is an upper bound on the teaching dimension. Meanwhile, we show below that the inhomogeneous SVM lower bound is $LB3 = \lceil \lambda \|\mathbf{w}^*\|^2 \rceil$. There can be a difference of at most one between the lower and upper bounds, which we call the ‘‘rounding effect.’’ We suspect that this small gap is a technicality and not intrinsic. However, at present we do not have a teaching set construction that bridges this gap. Therefore, we state the teaching dimension as an interval in the following corollary and leave the precise value as an open question for future research.

Corollary 5 *The teaching dimension for inhomogeneous SVM and target $\boldsymbol{\theta}^* = [\mathbf{w}^*; b^*]$ where $\mathbf{w}^* \neq \mathbf{0}$ is in the interval $\lceil \lambda \|\mathbf{w}^*\|^2 \rceil \leq TD(\boldsymbol{\theta}^*, \mathcal{A}_{svm}^{inh}) \leq 2 \left\lceil \frac{\lambda \|\mathbf{w}^*\|^2}{2} \right\rceil$.*

Proof The upper bound directly follows Proposition 5. We only need to show the lower bound $LB3 = \lceil \lambda \|\mathbf{w}^*\|^2 \rceil$ in Theorem 3. Let $A = I$, $\ell(a) = \max(1 - a, 0)$, and consider the denominator of (14):

$$\sup_{\alpha \in \mathbb{R}, g \in -\partial \ell(\alpha \|\mathbf{w}^*\|^2)} \alpha g = \sup_{\alpha, g \in \mathbf{I}(\alpha \|\mathbf{w}^*\|^2)} \alpha g = \frac{1}{\|\mathbf{w}^*\|^2}$$

where the first equality is due to $\partial \ell(a) = -\mathbf{I}(a)$. Therefore, $LB3 = \lceil \lambda \|\mathbf{w}^*\|^2 \rceil$ which proves the lower bound. \blacksquare

Inhomogeneous logistic regression solves the problem

$$\min_{\mathbf{w} \in \mathbb{R}^d, b \in \mathbb{R}} \sum_{i=1}^n \log(1 + \exp\{-y_i(\mathbf{x}_i^\top \mathbf{w} + b)\}) + \frac{\lambda}{2} \|\mathbf{w}\|^2. \quad (33)$$

Proposition 6 *To create a teaching set for target model $[\mathbf{w}^*; b^*]$ with nonzero \mathbf{w}^* for inhomogeneous logistic regression (33), we can use $n = 2 \left\lceil \frac{\lambda \|\mathbf{w}^*\|^2}{2\tau_{\max}} \right\rceil$ training items where $\mathbf{x}_i = \mathbf{x}_+$, $y_i = 1$, $\forall i \in \{1, \dots, \frac{n}{2}\}$ and $\mathbf{x}_i = \mathbf{x}_-$, $y_i = -1$, $\forall i \in \{\frac{n}{2} + 1, \dots, n\}$. \mathbf{x}_+ and \mathbf{x}_- can be designed as any vectors satisfying*

$$\mathbf{x}_+^\top \mathbf{w}^* = t - b^*, \quad \mathbf{x}_- = \mathbf{x}_+ - \frac{2t}{\|\mathbf{w}^*\|^2} \mathbf{w}^*, \quad (34)$$

where the constant t is defined by $t := \tau^{-1} \left(\frac{\lambda \|\mathbf{w}^*\|^2}{n} \right)$.

Proof We first point out that for t to be well-defined the argument to $\tau^{-1}(\cdot)$ has to be bounded $\frac{\lambda \|\mathbf{w}^*\|^2}{n} \leq \tau_{\max}$. This implies $n \geq \frac{\lambda \|\mathbf{w}^*\|^2}{\tau_{\max}}$. The size of our proposed teaching set is the smallest among all such symmetric construction that satisfy this constraint.

We verify that the KKT condition to show the construction in (34) includes the solution $[\mathbf{w}^*; b^*]$. From (34), we have

$$\mathbf{x}_+^\top \mathbf{w}^* + b^* = t \quad \mathbf{x}_-^\top \mathbf{w}^* + b^* = -t.$$

We apply them and the teaching set construction to compute the gradient of (33):

$$\begin{aligned}
& -\frac{n}{2} \frac{1}{1 + \exp\{\mathbf{x}_+^\top \mathbf{w}^* + b^*\}} \begin{bmatrix} \mathbf{x}_+ \\ 1 \end{bmatrix} + \frac{n}{2} \frac{1}{1 + \exp\{-\mathbf{x}_-^\top \mathbf{w}^* - b^*\}} \begin{bmatrix} \mathbf{x}_- \\ 1 \end{bmatrix} + \begin{bmatrix} \lambda \mathbf{w}^* \\ 0 \end{bmatrix} \\
&= -\frac{n}{2} \frac{1}{1 + \exp\{t\}} \begin{bmatrix} \mathbf{x}_+ \\ 1 \end{bmatrix} + \frac{n}{2} \frac{1}{1 + \exp\{t\}} \begin{bmatrix} \mathbf{x}_- \\ 1 \end{bmatrix} + \begin{bmatrix} \lambda \mathbf{w}^* \\ 0 \end{bmatrix} \\
&= -\frac{n}{\|\mathbf{w}^*\|^2} \frac{t}{1 + \exp\{t\}} \begin{bmatrix} \mathbf{w}^* \\ 0 \end{bmatrix} + \begin{bmatrix} \lambda \mathbf{w}^* \\ 0 \end{bmatrix} \\
&= -\frac{n}{\|\mathbf{w}^*\|^2} \frac{\lambda \|\mathbf{w}^*\|^2}{n} \begin{bmatrix} \mathbf{w}^* \\ 0 \end{bmatrix} + \begin{bmatrix} \lambda \mathbf{w}^* \\ 0 \end{bmatrix} \\
&= 0.
\end{aligned}$$

This verifies the KKT condition.

Finally we show uniqueness. The Hessian matrix of the objective function (33) under our training set (34) is:

$$\frac{n}{2} \underbrace{\frac{\exp\{t\}}{(1 + \exp\{t\})^2} \begin{bmatrix} \mathbf{x}_+ \mathbf{x}_+^\top + \mathbf{x}_- \mathbf{x}_-^\top & \mathbf{x}_+ + \mathbf{x}_- \\ \mathbf{x}_+ + \mathbf{x}_-^\top & 2 \end{bmatrix}}_{:=A} + \lambda \underbrace{\begin{bmatrix} I & \mathbf{0} \\ \mathbf{0}^\top & 0 \end{bmatrix}}_{:=B}.$$

Note $a > 0$ and $A = \begin{bmatrix} \mathbf{x}_+ & \\ & 1 \end{bmatrix} \begin{bmatrix} \mathbf{x}_- \\ 1 \end{bmatrix} + \begin{bmatrix} \mathbf{x}_- \\ 1 \end{bmatrix} \begin{bmatrix} \mathbf{x}_+ & \\ & 1 \end{bmatrix}$ is positive semi-definite. We show that $aA + \lambda B$ is positive definite. Suppose not. Then there exists $[\mathbf{u}; v] \neq \mathbf{0}$ such that $[\mathbf{u}; v]^\top (aA + \lambda B) [\mathbf{u}; v] = 0$. This implies $[\mathbf{u}; v]^\top (aA) [\mathbf{u}; v] + \lambda \mathbf{u}^\top \mathbf{u} = 0$. Since the first term is non-negative due to A being positive semi-definite, $\mathbf{u} = \mathbf{0}$. But then we have $2av^2 = 0$ which implies $[\mathbf{u}; v] = \mathbf{0}$, a contradiction. Therefore uniqueness is guaranteed. \blacksquare

Corollary 6 *The teaching dimension for inhomogeneous logistic regression and target θ^* = $\lfloor \mathbf{w}^*; b^* \rfloor$ where $\mathbf{w}^* \neq \mathbf{0}$ is in the interval $\left\lfloor \frac{\lambda \|\mathbf{w}^*\|^2}{T_{\max}} \right\rfloor \leq TD(\theta^*, \mathcal{A}_{log}^{inh}) \leq 2 \left\lfloor \frac{\lambda \|\mathbf{w}^*\|^2}{2\tau_{\max}} \right\rfloor$.*

Proof The upper bound directly follows Proposition 6. We only need to show the lower bound $\left\lfloor \frac{\lambda \|\mathbf{w}^*\|^2}{T_{\max}} \right\rfloor$ by applying $LB3$ in Theorem 3. Let $A = I$ and $\ell(a) = \log(1 + \exp\{-a\})$ and consider the denominator of (14):

$$\begin{aligned} \sup_{\alpha \in \mathbb{R}, g \in \mathcal{H}(\alpha \|\mathbf{w}^*\|^2)} \alpha g &= \sup_{\alpha, g = (1 + \exp\{\alpha \|\mathbf{w}^*\|^2\})^{-1}} \alpha g \\ &= \sup_{\alpha} \frac{\alpha}{1 + \exp\{\alpha \|\mathbf{w}^*\|^2\}} \\ &= \|\mathbf{w}^*\|^{-2} \sup_t \frac{t}{1 + \exp\{t\}} \\ &= \frac{\tau_{\max}}{\|\mathbf{w}^*\|^2}, \end{aligned}$$

which implies $LB3 = \left\lfloor \frac{\lambda \|\mathbf{w}^*\|^2}{T_{\max}} \right\rfloor$. ■

4. Teaching a Decision Boundary Instead of a Parameter

In section 3 we considered the teaching goal where the learner is required to learn the exact *target parameter* θ^* . But when the learner is a classifier often a weaker teaching goal is sufficient, namely teaching the learner a *target decision boundary*. In this section we consider this teaching goal. Equivalently, such a goal is defined by the set of parameters that produce the target decision boundary. Teaching is successful if the learner arrives at any one parameter within that set.

In the case of inhomogeneous linear learners, the linear decision boundary $\{\mathbf{x} \mid \mathbf{x}^\top \mathbf{w}^* + b^* = 0\}$ is identified with the parameter set $\{t[\mathbf{w}^*; b^*] : t > 0\}$. Here we assume \mathbf{w}^* is nonzero. The parameter $\theta^* = \lfloor \mathbf{w}^*; b^* \rfloor$ is just a representative member of the set. Inhomogeneous linear learners are similar without b^* . We denote the corresponding “decision boundary” teaching dimension by $TD(\{\theta^*\}, \mathcal{A}_{opt})$. This notation extends our earlier definition of TD by allowing the first argument to be a set, with the understanding that the teaching goal is for the learned model to be an element in the set. It immediately follows that

$$TD(\{\theta^*\}, \mathcal{A}_{opt}) = \min_{t > 0} TD(t\theta^*, \mathcal{A}_{opt}).$$

Since it is sufficient to teach the parameter $t\theta^*$ for some $t > 0$ in order to teach the decision boundary, we can choose the best t that minimizes $TD(t\theta^*, \mathcal{A}_{opt})$. For SVM and logistic regression — either homogeneous or inhomogeneous — the teaching dimension $TD(t\theta^*, \mathcal{A}_{opt})$ depends on $\|\theta^*\|$ (see Table 1). We can choose t sufficiently small to drive down the teaching set size toward its possible minimum indicated by the LBI value in Table 2 (which is nonzero because of the ceiling function). Specifically, for any fixed parameter θ^* representing the target decision boundary:

- (homogeneous SVM): we choose $t \leq \frac{1}{\sqrt{\lambda \|\theta^*\|}}$ so that $TD(\{t\theta^*\}, \mathcal{A}_{svm}^{hom}) = 1$;

- (homogeneous logistic regression): we choose $t \leq \frac{\sqrt{\tau_{\max}}}{\sqrt{\lambda \|\theta^*\|}}$ so that $TD(\{t\theta^*\}, \mathcal{A}_{log}^{hom}) = 1$;
- (inhomogeneous SVM): we choose $t \leq \frac{\sqrt{2}}{\sqrt{\lambda \|\mathbf{w}^*\|}}$ so that $TD(\{t\theta^*\}, \mathcal{A}_{svm}^{inh}) = 2$ (note LBI=2 in Table 2);
- (inhomogeneous logistic regression): we choose $t \leq \frac{\sqrt{2\tau_{\max}}}{\sqrt{\lambda \|\mathbf{w}^*\|}}$ so that $TD(\{t\theta^*\}, \mathcal{A}_{log}^{inh}) = 2$ (note LBI=2 in Table 2).

The resulting teaching dimension $TD(\{t\theta^*\}, \mathcal{A}_{opt})$ is listed in Table 1 on the row marked by “decision boundary.” The teaching set construction is the same as in sections 3.2 and 3.3, respectively, but with θ^* .

5. Related Work

Teaching dimension as a learning-theoretic quantity has attracted a long history of research. It was proposed independently in Goldman and Kearns (1995); Shinohara and Miyano (1991). Subsequent theoretical developments can be found in e.g. Zilles et al. (2011); Balbach and Zeugmann (2009); Angluin (2004); Angluin and Krikis (1997); Goldman and Mathias (1996); Mathias (1997); Balbach and Zeugmann (2006); Balbach (2008); Kobayashi and Shinohara (2009); Angluin and Krikis (2003); Rivest and Yin (1995); Ben-David and Eiron (1998); Doliwa et al. (2014). Many of them assume little extra knowledge on the learner other than that it is consistent with the training data, though Zilles et al. (2011); Balbach (2008) allow the teacher and the learner to cooperate. These theoretically elegant teaching definitions diverge from the practice of modern machine learning where the learner solves an optimization problem to find a single model that is not necessarily the 0-1 loss ERM. Teaching such modern learners is our goal. Section 6 discusses a new view to unify our work and some existing optimal teaching work.

Teaching dimension is distinct from VC dimension. For a finite hypothesis space \mathcal{H} , Goldman and Kearns (1995) proved the relation

$$VC(\mathcal{H}) / \log(|\mathcal{H}|) \leq TD(\mathcal{H}) \leq VC(\mathcal{H}) + |\mathcal{H}| - 2^{VC(\mathcal{H})}.$$

These inequalities are somewhat weak, as Goldman and Kearns had shown both cases where one quantity is much larger than the other. The distinction between TD and VC dimension is also present in our setting. For example, by inspecting the inhomogeneous SVM column in Table 1 we note that TD does not depend on the dimensionality d of the feature space \mathbb{R}^d . To see why this makes intuitive sense, note two d -dimensional points are sufficient to specify any bisecting hyperplane in \mathbb{R}^d . On the other hand, recall that the VC dimension for inhomogeneous hyperplanes in \mathbb{R}^d is $d + 1$. Furthermore, there is an interesting connection to sample compression in Floyd and Warmuth (1995). Our teaching set can be viewed as the compressed sample, but with two generalizations: (i) the original “sample” is the whole input space, and (ii) the labels is allowed to diverge from the target model. Further quantification of these connections remains an open research question.

The teaching setting we considered is also distinct from active learning. In teaching the teacher knows the target model *a priori* and her goal is to *encode* the target model as a

training set, knowing that the decoder is special (namely a specific machine learning algorithm). This communication perspective highlights the difference to active learning, which must explore the hypothesis space to find the target model. Consequently, the teaching dimension can be dramatically smaller than the active learning query complexity for the same learner and hypothesis space. For example, Zhu (2013) demonstrated that to learn a 1D threshold classifier within ϵ error, the teaching dimension is a constant $\text{TD}=2$ regardless of ϵ , while active learning would require $O(\log \frac{1}{\epsilon})$ queries which can be arbitrarily larger than TD .

While the present paper focused on the theory of optimal teaching, there are practical applications, too. One such application is computer-aided personalized education. The human student is modeled by a computational cognitive model, or equivalently the learning algorithm. The educational goal is specified by the target model. The optimal teaching set is then well-defined, and represents the best personalized lesson for the student (Zhu, 2015, 2013; Khan et al., 2011). In one experiment, Patil *et al.* showed that real human students learn statistically significantly better under such optimal teaching set compared to an *i.i.d.* training set (Patil et al., 2014). Because contemporary cognitive models often employ optimization-based machine learners, our teaching dimension study helps to characterize these optimal lessons.

Another application of optimal teaching is in computer security. In particular, optimal teaching is the mathematical formalism to study the so-called data poisoning attacks (Barreno et al., 2010; Mei and Zhu, 2015a,b; Alfeld et al., 2016). Here the “teacher” is an attacker who has a nefarious target model in mind. The “student” is a learning agent (such as a spam filter) which accepts data and adapts itself. The attacker wants to minimally manipulate the input data in order to manipulate the learning agent toward the attacker’s target model. Teaching dimension quantifies the difficulty of data-poisoning attacks, and supports research on defenses.

Teaching dimension also has applications in interactive machine learning to quantify the minimum human interaction necessary (Suh et al., 2016; Cakmak and Thomaz, 2011), and in formal synthesis to generate computer programs satisfying a specification (Jha and Seshia, 2015).

6. A New View on Teaching

The optimal teaching literature has been cautious about the so-called collusion or coding tricks between the teacher and the learner. Nonetheless, what constitutes collusion does not have a fully satisfactory definition. Goldman and Mathias (1996) defined the teacher and the learner as collusion-free if (i) the teaching set is consistent with the target concept; (ii) any superset of the teaching set will make the learner learn the target concept, too. While this definition of collusion-free is useful, it does not capture all interesting learning behaviors. For example, Zilles et al. (2011, section 4) had to introduce a different notion of collusion in order to allow benign cooperation between the teacher and the learner. As another example, standard machine learning algorithms such as ridge regression does not satisfy either of the two properties: the teaching set (19) is inconsistent in that $y_t \neq \mathbf{x}_t^\top \boldsymbol{\theta}^*$, and adding more consistent training items will in general produce a different model due to regularization.

We advance an alternative view on the relation between the teacher and the learner. Under this view, the learner publishes his learning algorithm $\mathcal{A} : \mathbb{D} \rightarrow 2^{\mathcal{H}}$. Recall \mathcal{A} takes in a training set $D \in \mathbb{D}$ and outputs a subset of the hypothesis space \mathcal{H} . The teacher then uses a fixed strategy: she simply solves the training set cardinality minimization problem under the constraint that \mathcal{A} returns the target hypothesis set Θ^* . For example, to teach a specific parameter vector $\boldsymbol{\theta}^*$ the target is the singleton set $\Theta^* = \{\boldsymbol{\theta}^*\}$; to teach a decision boundary the target is the set $\Theta^* = \{\boldsymbol{\theta}^* \mid t > 0\}$. More precisely, the teacher’s strategy is to solve the following optimization problem, whose objective value is the (learner-dependent) teaching dimension $\text{TD}(\Theta^*, \mathcal{A})$:

$$\begin{aligned} \min_{D \in \mathbb{D}} \quad & |D| \\ \text{s.t.} \quad & \Theta^* = \mathcal{A}(D). \end{aligned} \tag{35}$$

Our teaching dimension for linear learners clearly fits this view, with \mathcal{A}_{opt} being a regularized empirical risk minimizer (1). Let us look at a few other interesting learners \mathcal{A} under this view. We will use the following hypothesis space as it is historically used to contrast those learners (Goldman and Kearns, 1995; Zilles et al., 2011). Let $\mathcal{X} = \{x_1, \dots, x_n\}$. Let $h_i(x) = 1$ if $x = x_i$ and 0 otherwise, for $i = 1 \dots n$. In other words, h_i is the indicator concept on x_i . Let the all-negative concept be $h_0(x) = 0$ for all x . Let $\mathcal{H} = \{h_0, h_1, \dots, h_n\}$.

- **The version-space learner \mathcal{A}_{vs} as defined by (2).** This is the learner behind the teaching dimension defined by Goldman and Kearns (1995). We have $\mathcal{A}_{vs}(\{(x_i, 1)\}) = \{h_i\}$ for $i = 1 \dots n$, such that these target concepts have classic teaching dimension $\text{TD}(h_i, \mathcal{A}_{vs}) = 1$. But note that $\mathcal{A}_{vs}(\{(x_i, 0)\}) = \{h_0, \dots, h_{i-1}, h_{i+1}, \dots\}$ which does not reduce the version space to a single element. To specify the all-negative concept we need $\mathcal{A}_{vs}(\{(x_1, 0), \dots, (x_n, 0)\}) = \{h_0\}$. That is, h_0 ’s classic teaching dimension is $\text{TD}(h_0, \mathcal{A}_{vs}) = n$. These teaching dimensions are the objective values in our view (35) when we plug in \mathcal{A}_{vs} .

- **The Balbach learner \mathcal{A}_B (Balbach, 2008).** Balbach noticed that h_1, \dots, h_n can each be taught with one item. The reasoning goes that as soon as the teaching set contains more than one item, it must be a helpful teacher’s hint that the target concept is h_0 . That is, the size of the training set carries useful information about the target concept. In the view of (35), we may define $\mathcal{A}_B(\{(x_i, 1)\}) = \{h_i\}$ for $i = 1 \dots n$, and $\mathcal{A}_B(\{(x_i, 0), (x_j, 0)\}) = \{h_0\}$ for any $i \neq j$. For the sake of completeness, here and below for all other $D \in \mathbb{D}$ not explicitly mentioned we simply define $\mathcal{A}(D) = \{h\}$ consistent with D . When we plug \mathcal{A}_B into (35) we obtain Balbach’s teaching dimension $\text{TD}(h_i, \mathcal{A}_B)$ of 1 for h_1, \dots, h_n , and 2 for h_0 .

- **The subset learner \mathcal{A}_s (Zilles et al., 2011).** Since the teaching sets for h_1, \dots, h_n each contain a positive item, it stands to reason that h_0 is the target concept as soon as a single negative training item is observed. We can define $\mathcal{A}_s(\{(x_i, 1)\}) = \{h_i\}$ and $\mathcal{A}_s(\{(x_i, 0)\}) = \{h_0\}$ for $i = 1 \dots n$. When we plug \mathcal{A}_s into (35) we obtain the subset teaching dimension of $\text{TD}(h_i, \mathcal{A}_s) = 1$ for all $h \in \mathcal{H}$, which is an improvement over the Balbach teaching dimension by a certain benign cooperation.

- **A coding-trick learner \mathcal{A}_{c1} .** This ‘learner’ uses x to encode hypothesis: $\mathcal{A}_{c1}(\{(x_i, y)\}) = \{h_i\}$ for $i = 1 \dots n$ regardless of y , and all non-singleton training set maps to h_0 : $\mathcal{A}_{c1}(D) = \{h_0\}$ if $|D| \neq 1$. \mathcal{A}_{c1} is mathematically well-defined for teaching in (35), but one can argue that it does not seem like a reasonable learner: it ignores y completely and thus is inconsistent (although recall modern regularized empirical risk minimizers (1) can be inconsistent, too).

- **Another coding-trick learner \mathcal{A}_{c2} .** This ‘learner’ uses training set size to encode the hypothesis, while ignoring the content of the training set: $\mathcal{A}_{c2}(D) = \{h_{|D|}\}$ if $|D| \leq n$, and \emptyset if $|D| > n$. Again, \mathcal{A}_{c2} is mathematically well-defined but does not seem like a reasonable learner.

As the examples above show, our alternative view of teaching in (35) does not resolve the issue of what constitutes coding-tricks. All the learners \mathcal{A} are well-defined functions mapping a training set to a subset of hypotheses, so that the optimization problem (35) is also well-defined even for ‘unreasonable’ learners like \mathcal{A}_{c1} and \mathcal{A}_{c2} . However, our alternative view does provide two benefits:

- Because the teacher employs a fixed strategy (35), this view removes the notion of ‘collusion’ altogether. Instead, the question becomes what learning algorithm \mathcal{A} one would consider as admissible. This view point can be more natural when we extend teaching to richer, more complex learners.
- There can be a misconception that the classic teaching dimension defined by Goldman and Kearns (1995) is learner-independent and a property of \mathcal{H} only, in part perhaps fueled by the original notation $TD(\mathcal{H})$. Our view highlights classic teaching dimension’s dependency on the version space learner \mathcal{A}_{vs} . It is true that \mathcal{A}_{vs} is a particularly simple and elegant learner with very nice properties. But, as others have observed (e.g. Balbach (2008); Zilles et al. (2011)), it does not capture all natural teaching and learning behaviors.

7. Conclusion

We have presented a generalization on teaching dimension to optimization-based learners. To the best of our knowledge, our teaching dimension for ridge regression, SVM, and logistic regression is new; so are the lower bounds and our analysis technique in general.

There are many possible extensions to the present work. For example, one may extend our analysis to nonlinear learners. This can potentially be achieved by using the kernel trick on the linear learners. As another example, one may allow ‘approximate teaching’ by relaxing the teaching goal, such that teaching is considered successful if the learner arrives at a model close enough to the target model. Taken together, the present paper and its extensions are expected to enrich our understanding of optimal teaching and enable novel applications.

Abstract

To infer multilayer deep representations of high-dimensional discrete and nonnegative real vectors, we propose an augmentable gamma belief network (GBN) that factorizes each of its hidden layers into the product of a sparse connection weight matrix and the nonnegative real hidden units of the next layer. The GBN's hidden layers are jointly trained with an upward-downward Gibbs sampler that solves each layer with the same subroutine. The gamma-negative binomial process combined with a layer-wise training strategy allows inferring the width of each layer given a fixed budget on the width of the first layer. Example results illustrate interesting relationships between the width of the first layer and the inferred network structure, and demonstrate that the GBN can add more layers to improve its performance in both unsupervisedly extracting features and predicting heldout data. For exploratory data analysis, we extract trees and subnetworks from the learned deep network to visualize how the very specific factors discovered at the first hidden layer and the increasingly more general factors discovered at deeper hidden layers are related to each other, and we generate synthetic data by propagating random variables through the deep network from the top hidden layer back to the bottom data layer.

Keywords: Bayesian nonparametrics, deep learning, multilayer representation, Poisson factor analysis, topic modeling, unsupervised learning

1. Introduction

There has been significant recent interest in deep learning. Despite its tremendous success in supervised learning, inferring a multilayer data representation in an unsupervised manner remains a challenging problem (Bengio and LeCun, 2007; Ranzato et al., 2007; Bengio et al., 2015). To generate data with a deep network, it is often unclear how to set the structure of the network, including the depth (number of layers) of the network and the width (number of hidden units) of each layer. In addition, for some commonly used deep

generative models, including the sigmoid belief network (SBN), deep belief network (DBN), and deep Boltzmann machine (DBM), the hidden units are often restricted to be binary. More specifically, the SBN, which connects the binary units of adjacent layers via the sigmoid functions, infers a deep representation of multivariate binary vectors (Neal, 1992; Saul et al., 1996); the DBN (Hinton et al., 2006) is a SBN whose top hidden layer is replaced by the restricted Boltzmann machine (RBM) (Hinton, 2002) that is undirected; and the DBM is an undirected deep network that connects the binary units of adjacent layers using the RBMs (Salakhutdinov and Hinton, 2009). All these three deep networks are designed to model binary observations, without principled ways to set the network structure. Although one may modify the bottom layer to model Gaussian and multinomial observations, the hidden units of these networks are still typically restricted to be binary (Salakhutdinov and Hinton, 2009; Larochelle and Lauly, 2012; Salakhutdinov et al., 2013). To generalize these models, one may consider the exponential family harmoniums (Welling et al., 2004; King et al., 2005) to construct more general networks with non-binary hidden units, but often at the expense of noticeably increased complexity in training and data fitting. To model real-valued data without restricting the hidden units to be binary, one may consider the general framework of nonlinear Gaussian belief networks (Frey and Hinton, 1999) that constructs continuous hidden units by nonlinearly transforming Gaussian distributed latent variables, including as special cases both the continuous SBN of Frey (1997a,b) and the rectified Gaussian nets of Hinton and Ghahramani (1997). More recent scalable generalizations under that framework include variational auto-encoders (Kingma and Welling, 2014) and deep latent Gaussian models (Rezende et al., 2014).

Moving beyond conventional deep generative models using binary or nonlinearly transformed Gaussian hidden units and setting the network structure in a heuristic manner, we construct deep networks using gamma distributed nonnegative real hidden units, and combine the gamma-negative binomial process (Zhou and Carin, 2015; Zhou et al., 2015b) with a greedy-layer wise training strategy to automatically infer the network structure. The proposed model is called the augmentable gamma belief network, referred to hereafter for brevity as the GBN, which factorizes the observed or latent count vectors under the Poisson likelihood into the product of a factor loading matrix and the gamma distributed hidden units (factor scores) of layer one; and further factorizes the shape parameters of the gamma hidden units of each layer into the product of a connection weight matrix and the gamma hidden units of the next layer. The GBN together with Poisson factor analysis can unsupervisedly infer a multilayer representation from multivariate count vectors, with a simple but powerful mechanism to capture the correlations between the visible/hidden features across all layers and handle highly overdispersed counts. With the Bernoulli-Poisson link function (Zhou, 2015), the GBN is further applied to high-dimensional sparse binary vectors by truncating latent counts, and with a Poisson randomized gamma distribution, the GBN is further applied to high-dimensional sparse nonnegative real data by randomizing the gamma shape parameters with latent counts.

For tractable inference of a deep generative model, one often applies either a sampling based procedure (Neal, 1992; Frey, 1997a) or variational inference (Saul et al., 1996; Frey, 1997b; Ranganath et al., 2014b; Kingma and Welling, 2014). However, conjugate priors on the model parameters that connect adjacent layers are often unknown, making it difficult to develop fully Bayesian inference that infers the posterior distributions of these parameters.

*. Correspondence should be addressed to M. Zhou or B. Chen.

It was not until recently that a Gibbs sampling algorithm, imposing priors on the network connection weights and sampling from their conditional posteriors, was developed for the SBN by Gan et al. (2015b), using the Pólya-Gamma data augmentation technique developed for logistic models (Polson et al., 2012). In this paper, we will develop data augmentation technique unique for the augmentable GBN, allowing us to develop a fully Bayesian upward-downward Gibbs sampling algorithm to infer the posterior distributions of not only the hidden units, but also the connection weights between adjacent layers.

Distinct from previous deep networks that often require tuning both the width (number of hidden units) of each layer and the network depth (number of layers), the GBN employs nonnegative real hidden units and automatically infers the widths of subsequent layers given a fixed budget on the width of its first layer. Note that the budget could be infinite and hence the whole network can grow without bound as more data are being observed. Similar to other belief networks that can often be improved by adding more hidden layers (Hinton et al., 2006; Sutskever and Hinton, 2008; Bengio et al., 2015), for the proposed model, when the budget on the first layer is finite and hence the ultimate capacity of the network could be limited, our experimental results also show that a GBN equipped with a narrower first layer could increase its depth to match or even outperform a shallower one with a substantially wider first layer.

The gamma distribution density function has the highly desired strong non-linearity for deep learning, but the existence of neither a conjugate prior nor a closed-form maximum likelihood estimate (Choi and Wette, 1969) for its shape parameter makes a deep network with gamma hidden units appear unattractive. Despite seemingly difficult, we discover that, by generalizing the data augmentation and marginalization techniques for discrete data modeled with the Poisson, gamma, and negative binomial distributions (Zhou and Carin, 2015), one may propagate latent counts one layer at a time from the bottom data layer to the top hidden layer, with which one may derive an efficient upward-downward Gibbs sampler that, one layer at a time in each iteration, upward samples Dirichlet distributed connection weight vectors and then downward samples gamma distributed hidden units, with the latent parameters of each layer solved with the same subroutine.

With extensive experiments in text and image analysis, we demonstrate that the deep GBN with two or more hidden layers clearly outperforms the shallow GBN with a single hidden layer in both unsupervisedly extracting latent features for classification and predicting heldout data. Moreover, we demonstrate the excellent ability of the GBN in exploratory data analysis: by extracting trees and subnetworks from the learned deep network, we can follow the paths of each tree to visualize various aspects of the data, from very general to very specific, and understand how they are related to each other.

In addition to constructing a new deep network that well fits high-dimensional sparse binary, count, and nonnegative real data, developing an efficient upward-downward Gibbs sampler, and applying the learned deep network for exploratory data analysis, other contributions of the paper include: 1) proposing novel link functions, 2) combining the gamma-negative binomial process (Zhou and Carin, 2015; Zhou et al., 2015b) with a layer-wise training strategy to automatically infer the network structure; 3) revealing the relationship between the upper bound imposed on the width of the first layer and the inferred widths of subsequent layers; 4) revealing the relationship between the depth of the network and the model’s ability to model overdispersed counts; and 5) generating multivariate high-

dimensional discrete or nonnegative real vectors, whose distributions are governed by the GBN, by propagating the gamma hidden units of the top hidden layer back to the bottom data layer. We note this paper significantly extends our recent conference publication (Zhou et al., 2015a) that proposes the Poisson GBN.

2. Augmentable Gamma Belief Networks

Denoting $\theta_j^{(t)} \in \mathbb{R}_+^{K_t}$ as the K_t hidden units of sample j at layer t , where $\mathbb{R}_+ = \{x : x \geq 0\}$, the generative model of the augmentable gamma belief network (GBN) with T hidden layers, from top to bottom, is expressed as

$$\begin{aligned} \theta_j^{(T)} &\sim \text{Gam}\left(\mathbf{r}, 1/c_j^{(T+1)}\right), \\ &\vdots \\ \theta_j^{(t)} &\sim \text{Gam}\left(\Phi^{(t+1)}\theta_j^{(t+1)}, 1/c_j^{(t+1)}\right), \\ &\vdots \\ \theta_j^{(1)} &\sim \text{Gam}\left(\Phi^{(2)}\theta_j^{(2)}, p_j^{(2)}/(1-p_j^{(2)})\right), \end{aligned} \quad (1)$$

where $x \sim \text{Gam}(a, 1/c)$ represents a gamma distribution with mean a/c and variance a/c^2 . For $t = 1, 2, \dots, T-1$, the GBN factorizes the shape parameters of the gamma distributed hidden units $\theta_j^{(t)} \in \mathbb{R}_+^{K_t}$ of layer t into the product of the connection weight matrix $\Phi^{(t+1)} \in \mathbb{R}_+^{K_t \times K_{t+1}}$ and the hidden units $\theta_j^{(t+1)} \in \mathbb{R}_+^{K_{t+1}}$ of layer $t+1$; the top layer’s hidden units $\theta_j^{(T)}$ share the same vector $\mathbf{r} = (r_1, \dots, r_{K_T})^\top$ as their gamma shape parameters; and the $p_j^{(2)}$ are probability parameters and $\{1/c^{(t)}\}_{3:T+1}$ are gamma scale parameters, with $c_j^{(2)} := (1-p_j^{(2)})/p_j^{(2)}$. We will discuss later how to measure the connection strengths between the nodes of adjacent layers and the overall popularity of a factor at a particular hidden layer.

For scale identifiability and ease of inference and interpretation, each column of $\Phi^{(t)} \in \mathbb{R}_+^{K_{t-1} \times K_t}$ is restricted to have a unit L_1 norm and hence $0 \leq \Phi^{(t)}(k', k) \leq 1$. To complete the hierarchical model, for $t \in \{1, \dots, T-1\}$, we let

$$\phi_k^{(t)} \sim \text{Dir}(\eta^{(t)}, \dots, \eta^{(t)}), \quad \tau_k \sim \text{Gam}(\gamma_0/K_T, 1/c_0) \quad (2)$$

where $\phi_k^{(t)} \in \mathbb{R}_+^{K_{t-1}}$ is the k th column of $\Phi^{(t)}$; we impose $c_0 \sim \text{Gam}(e_0, 1/f_0)$ and $\gamma_0 \sim \text{Gam}(a_0, 1/b_0)$; and for $t \in \{3, \dots, T+1\}$, we let

$$p_j^{(2)} \sim \text{Beta}(a_0, b_0), \quad c_j^{(t)} \sim \text{Gam}(e_0, 1/f_0). \quad (3)$$

We expect the correlations between the K_t rows (latent features) of $(\theta_1^{(t)}, \dots, \theta_j^{(t)})$ to be captured by the columns of $\Phi^{(t+1)}$. Even if $\Phi^{(t)}$ for $t \geq 2$ are all identity matrices, indicating no correlations between the latent features to be captured, our analysis in Section 3.2 will show that a deep structure with $T \geq 2$ could still benefit data fitting by better modeling the variability of the latent features $\theta_j^{(1)}$. Before further examining the network structure, below we first introduce a set of distributions that will be used to either model different types of data or augment the model for simple inference.

2.1 Distributions for Count, Binary, and Nonnegative Real Data

Below we first describe some useful count distributions that will be used later.

2.1.1 USEFUL COUNT DISTRIBUTIONS AND THEIR RELATIONSHIPS

Let the Chinese restaurant table (CRT) distribution $l \sim \text{CRT}(n, r)$ represent the random number of tables seated by n customers in a Chinese restaurant process (Blackwell and MacQueen, 1973; Antoniak, 1974; Aldous, 1985; Pitman, 2006) with concentration parameter r . Its probability mass function (PMF) can be expressed as

$$P(l | n, r) = \frac{\Gamma(r)^r}{\Gamma(n+r)} |s(n, l)|,$$

where $l \in \mathbb{Z}$, $\mathbb{Z} := \{0, 1, \dots, n\}$, and $|s(n, l)|$ are unsigned Stirling numbers of the first kind. A CRT distributed sample can be generated by taking the summation of n independent Bernoulli random variables as

$$l = \sum_{i=1}^n b_i, \quad b_i \sim \text{Bernoulli}[r/(r+i-1)].$$

Let $u \sim \text{Log}(p)$ denote the logarithmic distribution (Fisher et al., 1943; Anscombe, 1950; Johnson et al., 1997) with PMF

$$P(u | p) = \frac{1}{-\ln(1-p)} \frac{p^u}{u},$$

where $u \in \{1, 2, \dots\}$, and let $n \sim \text{NB}(r, p)$ denote the negative binomial (NB) distribution (Greenwood and Yule, 1920; Bliss and Fisher, 1953) with PMF

$$P(n | r, p) = \frac{\Gamma(n+r)}{n! \Gamma(r)} p^r (1-p)^r,$$

where $n \in \mathbb{Z}$. The NB distribution $n \sim \text{NB}(r, p)$ can be generated as a gamma mixed Poisson distribution as

$$n \sim \text{Pois}(\lambda), \quad \lambda \sim \text{Gam}[r, p/(1-p)],$$

where $p/(1-p)$ is the gamma scale parameter.

As shown in (Zhou and Carin, 2015), the joint distribution of n and l given r and p in

$$l \sim \text{CRT}(n, r), \quad n \sim \text{NB}(r, p),$$

where $l \in \{0, \dots, n\}$ and $n \in \mathbb{Z}$, is the same as that in

$$n = \sum_{t=1}^l u_t, \quad u_t \sim \text{Log}(p), \quad l \sim \text{Pois}[-r \ln(1-p)], \quad (4)$$

which is called the Poisson-logarithmic bivariate distribution, with PMF

$$P(n, l | r, p) = \frac{|s(n, l)| r^l}{n!} p^n (1-p)^r.$$

We will exploit these relationships to derive efficient inference for the proposed models.

2.1.2 BERNOULLI-POISSON LINK AND TRUNCATED POISSON DISTRIBUTION

As in Zhou (2015), the Bernoulli-Poisson (BerPo) link thresholds a random count at one to obtain a binary variable as

$$b = \mathbf{1}(m \geq 1), \quad m \sim \text{Pois}(\lambda), \quad (5)$$

where $b = 1$ if $m \geq 1$ and $b = 0$ if $m = 0$. If m is marginalized out from (5), then given λ , one obtains a Bernoulli random variable as $b \sim \text{Ber}(1 - e^{-\lambda})$. The conditional posterior of the latent count m can be expressed as

$$(m | b, \lambda) \sim b \cdot \text{Pois}_+(\lambda),$$

where $x \sim \text{Pois}_+(\lambda)$ follows a truncated Poisson distribution, with $P(x = k) = (1 - e^{-\lambda})^{-1} \lambda^k e^{-\lambda} / k!$ for $k \in \{1, 2, \dots\}$. Thus if $b = 0$, then $m = 0$ almost surely (a.s.), and if $b = 1$, then $m \sim \text{Pois}_+(\lambda)$, which can be simulated with a rejection sampler that has a minimal acceptance rate of 63.2% at $\lambda = 1$ (Zhou, 2015). Given the latent count m and a gamma prior on λ , one can then update λ using the gamma-Poisson conjugacy. The BerPo link shares some similarities with the probit link that thresholds a normal random variable at zero, and the logistic link that lets $b \sim \text{Ber}[e^x / (1 + e^x)]$. We advocate the BerPo link as an alternative to the probit and logistic links since if $b = 0$, then $m = 0$ a.s., which could lead to significant computational savings if the binary vectors are sparse. In addition, the conjugacy between the gamma and Poisson distributions makes it convenient to construct hierarchical Bayesian models amenable to posterior simulation.

2.1.3 POISSON RANDOMIZED GAMMA AND TRUNCATED BESSEL DISTRIBUTIONS

To model nonnegative data that include both zeros and positive observations, we introduce the Poisson randomized gamma (PRG) distribution as

$$x \sim \text{PRG}(\lambda, c),$$

whose distribution has a point mass at $x = 0$ and is continuous for $x > 0$. The PRG distribution is generated as a Poisson mixed gamma distribution as

$$x \sim \text{Gam}(n, 1/c), \quad n \sim \text{Pois}(\lambda),$$

in which we define $\text{Gam}(0, 1/c) = 0$ a.s. and hence $x = 0$ if and only if $n = 0$. Thus the PMF of $x \sim \text{PRG}(\lambda, c)$ can be expressed as

$$\begin{aligned} f_X(x | \lambda, c) &= \sum_{n=0}^{\infty} \text{Gam}(x; n, 1/c) \text{Pois}(n; \lambda) \\ &= (e^{-\lambda})^{\mathbf{1}(x=0)} \left[e^{-\lambda - cx} \sqrt{\frac{\lambda c}{x}} I_{-1} \left(2\sqrt{\lambda cx} \right) \right]^{\mathbf{1}(x>0)}, \end{aligned} \quad (6)$$

where

$$I_{-1}(\alpha) = \left(\frac{\alpha}{2} \right)^{-1} \sum_{n=1}^{\infty} \frac{\left(\frac{\alpha^2}{4} \right)^n}{n! \Gamma(n)}, \quad \alpha > 0$$

is the modified Bessel function of the first kind $I_\nu(\alpha)$ with ν fixed at -1 . Using the laws of total expectation and total variance, or using the PMF directly, one may show that

$$\mathbb{E}[x | \lambda, c] = \lambda/c, \quad \text{var}[x | \lambda, c] = 2\lambda/c^2.$$

Thus the variance-to-mean ratio of the PRG distribution is $2/c$, as controlled by c .

The conditional posterior of n given x , λ , and c can be expressed as

$$\begin{aligned} f_N(n | x, \lambda, c) &= \frac{\text{Gam}(x; n, 1/c) \text{Pois}(n; \lambda)}{\text{PRG}(x; \lambda, c)} \\ &= \mathbf{1}(x = 0) \delta_0 + \mathbf{1}(x > 0) \sum_{n=1}^{\infty} \frac{1}{L_{-1}(2\sqrt{\lambda cx})} \frac{(\lambda cx)^{n-\frac{1}{2}}}{n! \Gamma(n)} \delta_n \\ &= \mathbf{1}(x = 0) \delta_0 + \mathbf{1}(x > 0) \sum_{n=1}^{\infty} \text{Bessel}_{-1}(n; 2\sqrt{cx\lambda}) \delta_n, \end{aligned} \quad (7)$$

where we define $n \sim \text{Bessel}_{-1}(\alpha)$ as the truncated Bessel distribution, with PMF

$$\text{Bessel}_{-1}(n; \alpha) = \frac{\left(\frac{\alpha}{2}\right)^{2n-1}}{L_{-1}(\alpha) n! \Gamma(n)}, \quad n \in \{1, 2, \dots\}.$$

Thus $n = 0$ if and only if $x = 0$, and n is a positive integer drawn from a truncated Bessel distribution if $x > 0$. In Appendix A, we plot the probability distribution functions of the proposed PRG and truncated Bessel distributions and show how they differ from the randomized gamma and Bessel distributions (Yuan and Kalbfleisch, 2000), respectively.

2.2 Link Functions for Three Different Types of Observations

If the observations are multivariate count vectors $\mathbf{x}_j^{(1)} \in \mathbb{Z}^V$, where $V := K_0$, then we link the integer-valued visible units to the nonnegative real hidden units at layer one using Poisson factor analysis (PFA) as

$$\mathbf{x}_j^{(1)} \sim \text{Pois}\left(\Phi^{(1)} \theta_j^{(1)}\right). \quad (8)$$

Under this construction, the correlations between the K_0 rows (features) of $(\mathbf{x}_1^{(1)}, \dots, \mathbf{x}_J^{(1)})$ are captured by the columns of $\Phi^{(1)}$. Detailed descriptions on how PFA is related to a wide variety of discrete latent variable models, including nonnegative matrix factorization (Lee and Seung, 2001), latent Dirichlet allocation (Blei et al., 2003), the gamma-Poisson model (Canny, 2004), discrete Principal component analysis (Buntine and Jakulin, 2006), and the focused topic model (Williamson et al., 2010), can be found in Zhou et al. (2012) and Zhou and Carin (2015).

We call PFA using the GBN in (1) as the prior on its factor scores as the Poisson gamma belief network (PGBN), as proposed in Zhou et al. (2015a). The PGBN can be naturally applied to factorize the term-document frequency count matrix of a text corpus, not only extracting semantically meaningful topics at multiple layers, but also capturing the relationships between the topics of different layers using the deep network, as discussed below in both Sections 2.3 and 4.

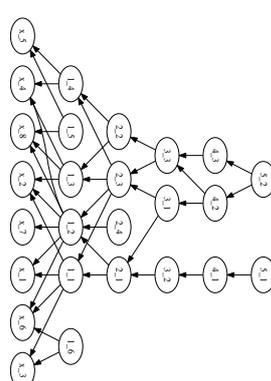

Figure 1: An example directed network of five hidden layers, with $K_0 = 8$ visible units, $[K_1, K_2, K_3, K_4, K_5] = [6, 4, 3, 3, 2]$, and sparse connections between the units of adjacent layers.

If the observations are high-dimensional sparse binary vectors $\mathbf{b}_j^{(1)} \in \{0, 1\}^V$, then we factorize them using Bernoulli-Poisson factor analysis (Ber-PFA) as

$$\mathbf{b}_j^{(1)} = \mathbf{1}(\mathbf{x}_j^{(1)} \geq 0), \quad \mathbf{x}_j^{(1)} \sim \text{Pois}\left(\Phi^{(1)} \theta_j^{(1)}\right). \quad (9)$$

We call Ber-PFA with the augmentable GBN as the prior on its factor scores $\theta_j^{(1)}$ as the Bernoulli-Poisson gamma belief network (BerPo-GBN).

If the observations are high-dimensional sparse nonnegative real-valued vectors $\mathbf{y}_j^{(1)} \in \mathbb{R}_+^V$, then we factorize them using Poisson randomized gamma (PRG) factor analysis as

$$\mathbf{y}_j^{(1)} \sim \text{Gam}(\mathbf{x}_j^{(1)}, 1/q_j), \quad \mathbf{x}_j^{(1)} \sim \text{Pois}\left(\Phi^{(1)} \theta_j^{(1)}\right). \quad (10)$$

We call PRG factor analysis with the augmentable GBN as the prior on its factor scores $\theta_j^{(1)}$ as the PRG gamma belief network (PRG-GBN).

We show in Figure 1 an example directed belief network of five hidden layers, with $K_0 = 8$ visible units, with 6, 4, 3, 3, and 2 hidden units for layers one, two, three, four, and five, respectively, and with sparse connections between the units of adjacent layers.

2.3 Exploratory Data Analysis

To interpret the network structure of the GBN, we notice that

$$\mathbb{E}[\mathbf{x}_j^{(1)} | \theta_j^{(1)}, \{\mathbf{c}_j^{(l)}, c_j^{(l)}\}_{l=1}^t] = \left[\prod_{l=1}^t \Phi^{(l)} \right] \frac{\theta_j^{(1)}}{\prod_{l=2}^t c_j^{(l)}}, \quad (11)$$

$$\mathbb{E}[\theta_j^{(1)} | \{\Phi^{(l)}, c_j^{(l)}\}_{l=1}^T, \mathbf{r}] = \left[\prod_{l=1}^T \Phi^{(l)} \right] \frac{\mathbf{r}}{\prod_{l=1}^{T-1} c_j^{(l)}}. \quad (12)$$

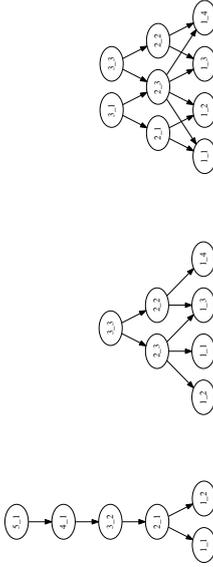

Figure 2: Extracted from the network shown in Figure 1, the left plot is a tree rooted at node 5.1, the middle plot is a tree rooted at node 3.3, and the right plot is a subnetwork consisting of both the tree rooted at node 3.1 and the tree rooted at node 3.3.

Thus for visualization, it is straightforward to project the K_t topics/hidden units/factor loadings/nodes of layer $t \in \{1, \dots, T\}$ to the bottom data layer as the columns of the $V \times K_t$ matrix

$$\prod_{\ell=1}^t \Phi^{(\ell)}, \quad (13)$$

and rank their popularities using the K_t dimensional nonnegative weight vector

$$\mathbf{r}^{(t)} := \left[\prod_{\ell=t+1}^T \Phi^{(\ell)} \right] \mathbf{r}. \quad (14)$$

To measure the connection strength between node k of layer t and node k' of layer $t-1$, we use the value of

$$\Phi^{(t)}(k', k),$$

which is also expressed as $\phi_k^{(t)}(k')$ or $\phi_{k'k}^{(t)}$.

Our intuition is that examining the nodes of the hidden layers, via their projections to the bottom data layer, from the top to bottom layers will gradually reveal less general and more specific aspects of the data. To verify this intuition and further understand the relationships between the general and specific aspects of the data, we consider extracting a tree for each node of layer t , where $t \geq 2$, to help visualize the inferred multilayer deep structure. To be more specific, to construct a tree rooted at a node of layer t , we grow the tree downward by linking the root node (if at layer t) or each leaf node of the tree (if at a layer below layer t) to all the nodes at the layer below that are connected to the root/leaf node with non-negligible weights. Note that a tree in our definition permits a node to have more than one parent, which means that different branches of the tree can overlap with each other. In addition, we also consider extracting subnetworks, each of which consists of multiple related trees from the full deep network. For example, shown in the left of Figure 2 is the tree extracted from the network in Figure 1 using node 5.1 as the root, shown in the middle is the tree using node 3.3 as the root, and shown in the right is a subnetwork consisting of two related trees that are rooted at nodes 3.1 and 3.3, respectively.

2.3.1 VISUALIZING NODES OF DIFFERENT LAYERS

Before presenting the technical details, we first provide some example results obtained with the PGBN on extracting multilayer representations from the 11,269 training documents of the 20newsgroups data set (<http://qwone.com/~jason/20Newsgroups/>). Given a fixed budget of $K_1^{\max} = 800$ on the width of the first layer, with $\eta^{(t)} = 0.1$ for all t , a five-layer deep network inferred by the PGBN has a network structure as $[K_1, K_2, K_3, K_4, K_5] = [386, 63, 58, 54, 51]$, meaning that there are 386, 63, 58, 54, and 51 nodes at layers one to five, respectively.

For visualization, we first relabel the nodes at each layer based on their weights $\{r_k^{(t)}\}_{1, K_t}$, calculated as in (14), with a more popular (larger weight) node assigned with a smaller label. We visualize node k of layer t by displaying its top 12 words ranked according to their probabilities in $(\prod_{\ell=1}^{t-1} \Phi^{(\ell)}) \phi_k^{(t)}$, the k th column of the projected representation calculated as in (13). We set the font size of node k of layer t proportional to $(r_k^{(t)}/r_1^{(t)})^{1/5}$ in each subplot, and color the outside border of a text box as red, green, orange, blue, or black for a node of layer five, four, three, two, or one, respectively. For better interpretation, we also exclude from the vocabulary the top 30 words of node 1 of layer one: “don just like people think know time good make way does writes edu ve want say really article use right did things point going better thing need sure used little,” and the top 20 words of node 2 of layer one: “edu writes article com apr cs ca just know don like think news cc david university john org wrote world.” These 50 words are not in the standard list of stopwords but can be considered as stopwords specific to the 20newsgroups corpus discovered by the PGBN.

For the [386, 63, 58, 54, 51] PGBN learned on the 20newsgroups corpus, we plot 54 example topics of layer one in Figure 3, the top 30 topics of layer three in Figure 4, and the top 30 topics of layer five in Figure 5. Figure 3 clearly shows that the topics of layer one, except for topics 1-3 that mainly consist of common functional words of the corpus, are all very specific. For example, topics 71 and 81 shown in the first row are about “candida yeast symptoms” and “sex,” respectively; topics 53, 73, 83, and 84 shown in the second row are about “printer,” “msg,” “police radar detector,” and “Canadian health care system,” respectively, and topics 46 and 76 shown in third row are about “ice hockey” and “second amendment,” respectively. By contrast, the topics of layers three and five, shown in Figures 4 and 5, respectively, are much less specific and can in general be matched to one or two news groups out of the 20 news groups, including comp.{graphics, os.ms-windows.misc, sys.ibm.pc.hardware, sys.mac.hardware, windows.x}, rec.{autos, motorcycles}, rec.sport.{baseball, hockey}, sci.{crypt, electronics, med, space}, misc.forsale, talk.politics.{misc, guns, mideast}, and {talk.religion.misc, alt.atheism, soc.religion.christian}.

2.3.2 VISUALIZING TREES ROOTED AT THE TOP-LAYER HIDDEN UNITS

While it is interesting to examine the topics of different layers to understand the general and specific aspects of the corpus used to train the PGBN, it would be more informative to further illustrate how the topics of different layers are related to each other. Thus we consider constructing trees to visualize the PGBN. We first pick a node as the root of a tree and grow the tree downward by drawing a line from node k at layer t , the root or a leaf node of the tree, to node k' at layer $t-1$ for all k' in the set $\{k' : \Phi^{(t)}(k', k) > \tau_t/K_{t-1}\}$,

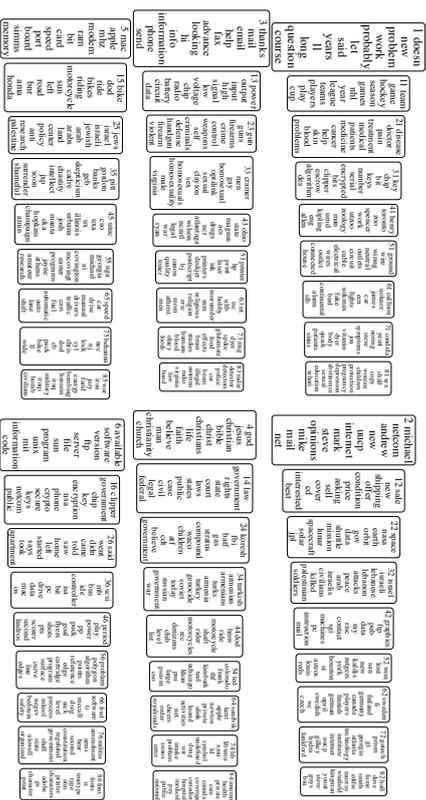

Figure 3: Example topics of layer one of the PGBN trained on the 20newsgrroups corpus.

Figure 4: The top 30 topics of layer three of the PGBN trained on the 20newsgrroups corpus.

Figure 5: The top 30 topics of layer five of the PGBN trained on the 20newsgrroups corpus.

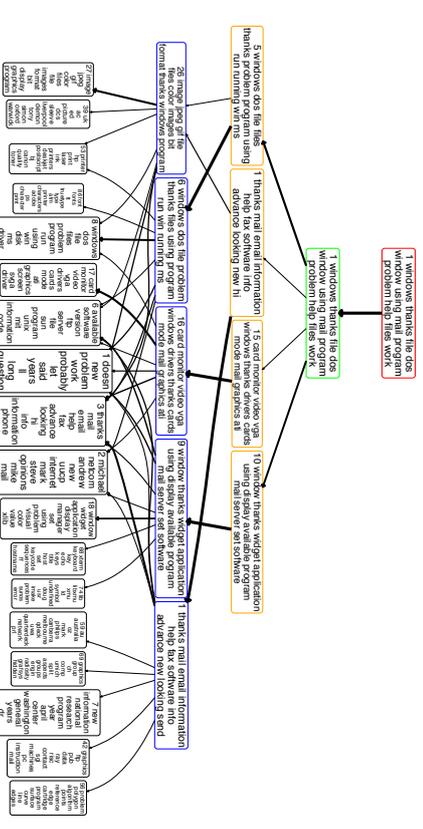

Figure 6: A [18, 5, 4, 1, 1] tree that includes all the lower-layer nodes (directly or indirectly) linked with non-negligible weights to the top ranked node of the top layer, taken from the full [386, 63, 58, 54, 51] network inferred by the PGBN on the 11,269 training documents of the 20newsgrroups corpus, with $\eta^{(t)} = 0.1$ for all t . A line from node k at layer t to node k' at layer $t - 1$ indicates that $\Phi^{(t)}(k', k) > 3/K_{t-1}$, with the width of the line proportional to $\sqrt{\Phi^{(t)}(k', k)}$. For each node, the rank (in terms of popularity) at the corresponding layer and the top 12 words of the corresponding topic are displayed inside the text box, where the text font size monotonically decreases as the popularity of the node decreases, and the outside border of the text box is colored as red, green, orange, blue, or black if the node is at layer five, four, three, two, or one, respectively.

where we set the width of the line connecting node k of layer t to node k' of layer $t - 1$ be proportional to $\sqrt{\Phi^{(t)}(k', k)}$ and use τ_t to adjust the complexity of a tree. In general, increasing τ_t would discard more weak connections and hence make the tree simpler and easier to visualize.

We set $\tau_t = 3$ for all t to visualize both a five-layer tree rooted at the top ranked node of the top hidden layer, as shown in Figure 6, and a five-layer tree rooted at the second ranked node of the top hidden layer, as shown in Figure 7. For the tree in Figure 6, while it is somewhat vague to determine the actual meanings of both node 1 of layer five and node 1 of layer four based on their top words, examining the more specific topics of layers three and two within the tree clearly indicate that this tree is primarily about “windows,” “window system,” “graphics,” “information,” and “software,” which are relatively specific concepts that are all closely related to each other. The similarities and differences between the five nodes of layer two can be further understood by examining the nodes of layer one that are connected to them. For example, while nodes 26 and 16 of layer two share their connections to multiple nodes of layer one, node 27 of layer one on “image” is strongly connected to node 26 of layer two but not to node 16 of layer two, and node 17 of layer one on “video” is strongly connected to node 16 of layer two but not to node 26 of layer two.

The bottom subplot reveals that in layer one, topic 14 on “law & government,” topic 32 on “Israel & Lebanon,” topic 34 on “Turkey, Armenia, Soviet Union, & Russian,” topic 132 on “Greece, Turkey, & Cyprus,” topic 98 on “Bosnia, Serbs, & Muslims,” topic 143 on “Armenia, Azeris, Cyprus, Turkey, & Karabakh,” and several other very specific topics related to Turkey and/or Armenia all tend to co-occur with each other.

We note that capturing the co-occurrence patterns between the topics not only helps exploratory data analysis, but also helps extract better features for classification in an unsupervised manner and improves prediction for held-out data, as will be demonstrated in detail in Section 4.

2.4 Related Models

The structure of the augmentable GBN resembles the sigmoid belief network and recently proposed deep exponential family model (Ranganath et al., 2014b). Such kind of gamma distribution based network and its inference procedure were vaguely hinted in Corollary 2 of Zhou and Carin (2015), and had been exploited by Acharya et al. (2015) to develop a gamma Markov chain to model the temporal evolution of the factor scores of a dynamic count matrix, but have not yet been investigated for extracting multilayer data representations. The proposed augmentable GBN may also be considered as an exponential family harmonium (Welling et al., 2004; Xing et al., 2005).

2.4.1 SIGMOID AND DEEP BELIEF NETWORKS

Under the hierarchical model in (1), given the connection weight matrices, the joint distribution of the observed/latent counts and gamma hidden units of the GBN can be expressed, similar to those of the sigmoid and deep belief networks (Bengio et al., 2015), as

$$P(\mathbf{x}_j^{(1)}, \{\theta_j^{(t)}\}_t | \{\Phi^{(t)}\}_t) = P(\mathbf{x}_j^{(1)} | \Phi^{(1)}, \theta_j^{(1)}) \left[\prod_{t=2}^{T-1} P(\theta_j^{(t)} | \Phi^{(t+1)}, \theta_j^{(t+1)}) \right] P(\theta_j^{(T)}).$$

With ϕ_{vj} representing the v th row Φ , for the gamma hidden units $\theta_{vj}^{(t)}$ we have

$$P(\theta_{vj}^{(t)} | \phi_{vj}^{(t+1)}, \theta_j^{(t+1)}, c_{j+1}^{(t+1)}) = \frac{\binom{c_{j+1}^{(t+1)}}{\theta_{vj}^{(t+1)}} \phi_{vj}^{(t+1)} \theta_j^{(t+1)}}{\Gamma(\phi_{vj}^{(t+1)}) \theta_j^{(t+1)}} \binom{\theta_{vj}^{(t+1)}}{\theta_{vj}^{(t)}} \phi_{vj}^{(t+1)} \theta_j^{(t+1)-1} e^{-\phi_{vj}^{(t+1)} \theta_{vj}^{(t)}}, \quad (19)$$

which are highly nonlinear functions that are strongly desired in deep learning. By contrast, with the sigmoid function $\sigma(x) = 1/(1+e^{-x})$ and bias terms $b_v^{(t+1)}$, a sigmoid/deep belief network would connect the binary hidden units $\theta_{vj}^{(t)} \in \{0, 1\}$ of layer t (for deep belief networks, $t < T-1$) to the product of the connection weights and binary hidden units of the next layer with

$$P(\theta_{vj}^{(t)} = 1 | \phi_{vj}^{(t+1)}, \theta_j^{(t+1)}, b_v^{(t+1)}) = \sigma(b_v^{(t+1)} + \phi_{vj}^{(t+1)} \theta_j^{(t+1)}). \quad (20)$$

Comparing (19) with (20) clearly shows the distinctions between the gamma distributed nonnegative hidden units and the sigmoid link function based binary hidden units. The

limitation of binary units in capturing the approximately linear data structure over small ranges is a key motivation for Frey and Hinton (1999) to investigate nonlinear Gaussian belief networks with real-valued units. As a new alternative to binary units, it would be interesting to further investigate whether the gamma distributed nonnegative real units can in theory carry richer information and model more complex nonlinearities given the same network structure. Note that the rectified linear units have emerged as powerful alternatives of sigmoid units to introduce nonlinearity (Nair and Hinton, 2010). It would be interesting to investigate whether the gamma units can be used to introduce nonlinearity into the positive region of the rectified linear units.

2.4.2 DEEP POISSON FACTOR ANALYSIS

With $T = 1$, the PGBN specified by (1)-(3) and (8) reduces to Poisson factor analysis (PFA) using the (truncated) gamma-negative binomial process (Zhou and Carin, 2015), with a truncation level of K_1 . As discussed in (Zhou et al., 2012; Zhou and Carin, 2015), with priors imposed on neither $\phi_k^{(1)}$ nor $\theta_j^{(1)}$, PFA is related to nonnegative matrix factorization (Lee and Seung, 2001), and with the Dirichlet priors imposed on both $\phi_k^{(1)}$ and $\theta_j^{(1)}$, PFA is related to latent Dirichlet allocation (Blei et al., 2003).

Related to the PGBN and the dynamic model in (Acharya et al., 2015), the deep exponential family model of Ranganath et al. (2014b) also considers a gamma chain under Poisson observations, but it is the gamma scale parameters that are chained and factorized, which allows learning the network parameters using black box variational inference (Ranganath et al., 2014a). In the proposed PGBN, we chain the gamma random variables via the gamma shape parameters. Both strategies worth through investigation. We prefer chaining the shape parameters in this paper, which leads to efficient upward-downward Gibbs sampling via data augmentation and makes it clear how the latent counts are propagated across layers, as discussed in detail in the following sections. The sigmoid belief network has also been recently incorporated into PFA for deep factorization of count data (Gan et al., 2015a), however, that deep structure captures only the correlations between binary factor usage patterns but not the full connection weights. In addition, neither Ranganath et al. (2014b) nor Gan et al. (2015a) provide a principled way to learn the network structure, whereas the proposed GBN uses the gamma-negative binomial process together with a greedy layer-wise training strategy to automatically infer the widths of the hidden layers, which will be described in Section 3.3.

2.4.3 CORRELATED AND TREE-STRUCTURED TOPIC MODELS

The PGBN with $T = 2$ can also be related to correlated topic models (Blei and Lafferty, 2006; Paisley et al., 2012; Chen et al., 2013; Ranganath and Blei, 2015; Linderman et al., 2015), which typically use the logistic normal distributions to replace the topic-proportion Dirichlet distributions used in latent Dirichlet allocation (Blei et al., 2003), capturing the co-occurrence patterns between the topics in the latent Gaussian space using a covariance matrix. By contrast, the PGBN factorizes the topic usage weights (not proportions) under the gamma likelihood, capturing the co-occurrence patterns between the topics of the first layer (i.e., the columns of $\Phi^{(1)}$) in the columns of $\Phi^{(2)}$, the latent weight matrix connecting the hidden units of layers two and one. For the PGBN, the computation does not involve

matrix inversion, which is often necessary for correlated topic models without specially structured covariance matrices, and scales linearly with the number of topics, hence it is suitable to be used to capture the correlations between hundreds of or thousands of topics.

As in Figures 6, 7, and 17-21, trees and subnetworks can be extracted from the inferred deep network to visualize the data. Tree-structured topic models have also been proposed before, such as those in Blei et al. (2010), Adams et al. (2010), and Paisley et al. (2015), but they usually artificially impose the tree structures to be learned, whereas the PGBN learns a directed network, from which trees and subnetworks can be extracted for visualization, without the need to specify the number of nodes per layer, restrict the number of branches per node, and forbid a node to have multiple parents.

3. Model Properties and Inference

Inference for the GBN shown in (1) appears challenging, because not only the conjugate prior is unknown for the shape parameter of a gamma distribution, but also the gradients are difficult to evaluate for the parameters of the (log) gamma probability density function, which, as in (19), includes the parameters inside the (log) gamma function. To address these challenges, we consider data augmentation (van Dyk and Meng, 2001) that introduces auxiliary variables to make it simple to compute the conditional posteriors of model parameters via the joint distribution of the auxiliary and existing random variables. We will first show that each gamma hidden unit can be linked to a Poisson distributed latent count variable, leading to a negative binomial likelihood for the parameters of the gamma hidden unit if it is margined out from the Poisson distribution; we then introduce an auxiliary count variable, which is sampled from the CRT distribution parametrized by the negative binomial latent count and shape parameter, to make the joint likelihood of the auxiliary CRT count and latent negative binomial count given the parameters of the gamma hidden unit amenable to posterior simulation. More specifically, under the proposed augmentation scheme, the gamma shape parameters will be linked to auxiliary counts under the Poisson likelihoods, making it straightforward for posterior simulation, as described below in detail.

3.1 The Upward Propagation of Latent Counts

We break the inference of the GBN of T hidden layers into T related subproblems, each of which is solved with the same subroutine. Thus for implementation, it is straightforward for the GBN to adjust its depth T . Let us denote $\mathbf{x}_j^{(t)} \in \mathbb{Z}^{K_{t-1}}$ as the observed or latent count vector of layer $t \in \{1, \dots, T\}$, and $x_{vj}^{(t)}$ as its v th element, where $v \in \{1, \dots, K_{t-1}\}$.

Lemma 1 (Augment-and-Conquer The Gamma Belief Network) *With $p_j^{(1)} := 1 - e^{-1}$ and*

$$p_j^{(t+1)} := -\ln(1 - p_j^{(t)}) / \left[c_j^{(t+1)} - \ln(1 - p_j^{(t)}) \right] \quad (21)$$

for $t = 1, \dots, T$, one may connect the observed or latent counts $\mathbf{x}_j^{(t)} \in \mathbb{Z}^{K_{t-1}}$ to the product $\Phi^{(t)}(\theta_j^{(t)})$ at layer t under the Poisson likelihood as

$$\mathbf{x}_j^{(t)} \sim \text{Pois} \left[-\Phi^{(t)}(\theta_j^{(t)}) \ln(1 - p_j^{(t)}) \right]. \quad (22)$$

Proof By definition (22) is true for layer $t = 1$. Suppose that (22) is also true for layer $t > 1$, then we can augment each count $x_{vj}^{(t)}$, where $v \in \{1, \dots, K_{t-1}\}$, into the summation of K_t latent counts, which are smaller than or equal to $x_{vj}^{(t)}$ as

$$x_{vj}^{(t)} = \sum_{k=1}^{K_t} x_{vjk}^{(t)}, \quad x_{vjk}^{(t)} \sim \text{Pois} \left[-\phi_{vk}^{(t)} \theta_{kj}^{(t)} \ln(1 - p_j^{(t)}) \right]. \quad (23)$$

Let the \cdot symbol represent summing over the corresponding index and let

$$m_{kj}^{(t)(t+1)} := x_{\cdot jk}^{(t)} := \sum_{v=1}^{K_{t-1}} x_{vjk}^{(t)}$$

represent the number of times that factor $k \in \{1, \dots, K_t\}$ of layer t appears in observation j and $\mathbf{m}_j^{(t)(t+1)} := (x_{\cdot j1}^{(t)}, \dots, x_{\cdot jK_t}^{(t)})'$. Since $\sum_{v=1}^{K_{t-1}} \phi_{vk}^{(t)} = 1$, we can marginalize out $\Phi^{(t)}$ as in (Zhou et al., 2012), leading to

$$\mathbf{m}_j^{(t)(t+1)} \sim \text{Pois} \left[-\theta_j^{(t)} \ln(1 - p_j^{(t)}) \right].$$

Further marginalizing out the gamma distributed $\theta_j^{(t)}$ from the Poisson likelihood leads to

$$m_j^{(t)(t+1)} \sim \text{NB} \left(\Phi^{(t+1)} \theta_j^{(t+1)}, p_j^{(t+1)} \right). \quad (24)$$

Element k of $\mathbf{m}_j^{(t)(t+1)}$ can be augmented under its compound Poisson representation as

$$m_{kj}^{(t)(t+1)} = \sum_{\ell=1}^{x_{\cdot jk}^{(t+1)}} u_\ell, \quad u_\ell \sim \text{Log}(p_j^{(t+1)}), \quad x_{kj}^{(t+1)} \sim \text{Pois} \left[-\phi_{k\cdot}^{(t+1)} \theta_j^{(t+1)} \ln(1 - p_j^{(t+1)}) \right].$$

Thus if (22) is true for layer t , then it is also true for layer $t+1$. ■

Corollary 2 (Propagate the latent counts upward) *Using Lemma 4.1 of (Zhou et al., 2012) on (23) and Theorem 1 of (Zhou and Carin, 2015) on (24), we can propagate the latent counts $x_{vj}^{(t)}$ of layer t upward to layer $t+1$ as*

$$\left\{ \left(x_{vj1}^{(t)}, \dots, x_{vjK_t}^{(t)} \mid x_{vj}^{(t)}, \phi_{v\cdot}^{(t)}, \theta_j^{(t)} \right) \sim \text{Mult} \left(x_{vj}^{(t)}, \frac{\phi_{v1}^{(t)} \theta_{1j}^{(t)}}{\sum_{k=1}^{K_t} \phi_{vk}^{(t)} \theta_{kj}^{(t)}}, \dots, \frac{\phi_{vK_t}^{(t)} \theta_{K_t j}^{(t)}}{\sum_{k=1}^{K_t} \phi_{vk}^{(t)} \theta_{kj}^{(t)}} \right), \quad (25) \right. \\ \left. \left(x_{kj}^{(t+1)} \mid m_{kj}^{(t)(t+1)}, \phi_{k\cdot}^{(t+1)}, \theta_j^{(t+1)} \right) \sim \text{CRT} \left(m_{kj}^{(t)(t+1)}, \phi_{k\cdot}^{(t+1)} \theta_j^{(t+1)} \right). \quad (26) \right.$$

We provide a set of graphical representations in Figure 8 to describe the GBN model and illustrate the augment-and-conquer inference scheme. We provide the upward-downward Gibbs sampler in Appendix B.

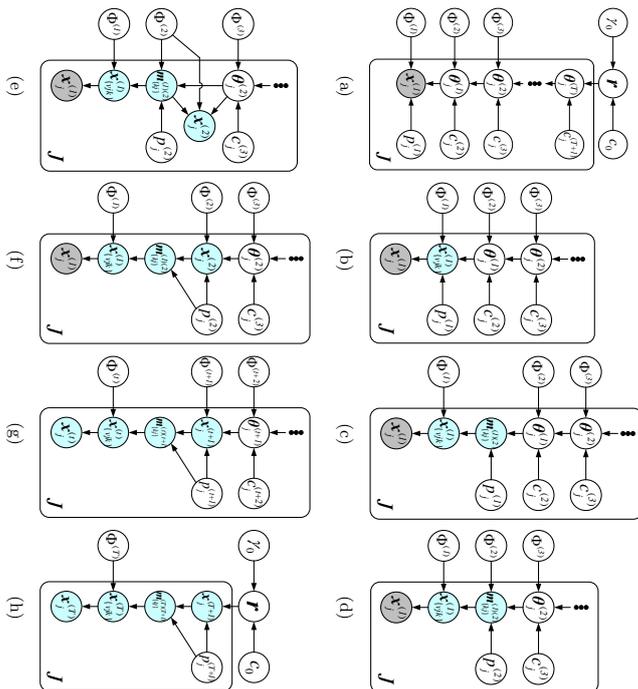

Figure 8: Graphical representations of the model and data augmentation and marginalization based inference scheme. (a) graphical representation of the GBN hierarchical model. (b) an augmented representation of Poisson factor model of layer $t = 1$, corresponding to (23) with $t = 1$. (c) an alternative representation using the relationships between the Poisson and multinomial distributions, obtained by applying Lemma 4.1 of Zhou et al., 2012) on (23) for $t = 1$. (d) a negative binomial distribution based representation that marginalizes out the gamma from the Poisson distributions, corresponding to (24) for $t = 1$. (e) an equivalent representation that introduces CRT distributed auxiliary variables, corresponding to (26) with $t = 1$. (f) an equivalent representation using Theorem 1 of Zhou and Cain, 2015) on (24) and (26) for $t = 1$. (g) An representation obtained by repeating the same augmentation-marginalization steps described in (b)-(f) one layer at a time from layers 1 to t . (h) An representation of the top hidden layer.

Note that $x_{k_j}^{(t)} = m_{k_j}^{(t)(t+1)}$, and as the number of tables occupied by the customers is in the same order as the logarithm of the customer number in a Chinese restaurant process, $x_{k_j}^{(t+1)}$ is in the same order as $\ln(m_{k_j}^{(t)(t+1)})$. Thus the total count of layer $t + 1$ as $\sum_j x_{k_j}^{(t+1)}$ would often be much smaller than that of layer t as $\sum_j x_{k_j}^{(t)}$ (though in general not as small as a count that is in the same order of the logarithm of $\sum_j x_{k_j}^{(t)}$), and hence one may use the total count $\sum_j x_{k_j}^{(T)}$ as a simple criterion to decide whether it is necessary to add more

layers to the GBN. In addition, if the latent count $x_{k',k}^{(t)}$:= $\sum_j x_{k_j}^{(t)k}$ becomes close or equal to zero, then the posterior mean of $\Phi^{(t)}(k', k)$ could become so small that node k' of layer $t - 1$ can be considered to be disconnected from node k of layer t .

3.2 Modeling Data Variability With Distributed Representation

In comparison to a single-layer model with $T = 1$, which assumes that the hidden units of layer one are independent in the prior, the multilayer model with $T \geq 2$ captures the correlations between them. Note that for the extreme case that $\Phi^{(t)} = \mathbf{I}_{K_t}$ for $t \geq 2$ are all identity matrices, which indicates that there are no correlations between the features of $\theta_j^{(t-1)}$ left to be captured, the deep structure could still provide benefits as it helps model latent counts $m_{k_j}^{(1)(2)}$ that may be highly overdispersed. For example, let us assume $\Phi^{(t)} = \mathbf{I}_{K_3}$ for all $t \geq 2$, then from (1) and (24) we have

$$m_{k_j}^{(1)(2)} \sim \text{NB}(\theta_{k_j}^{(2)}, p_j^{(2)}), \dots, \theta_{k_j}^{(t)} \sim \text{Gam}(\theta_{k_j}^{(t+1)}, 1/c_j^{(t+1)}), \dots, \theta_{k_j}^{(T)} \sim \text{Gam}(r_k, 1/c_j^{(T+1)}).$$

Using the laws of total expectation and total variance, we have

$$\mathbb{E}[\theta_{k_j}^{(2)} | r_k] = \frac{r_k}{\prod_{l=3}^{T+1} c_j^{(l)}}, \quad \text{var}[\theta_{k_j}^{(2)} | r_k] = r_k \sum_{l=3}^{T+1} \left[\prod_{l=3}^l (c_j^{(l)})^{-2} \right] \left[\prod_{l=l+1}^{T+1} (c_j^{(l)})^{-1} \right].$$

Further applying the same laws, we have

$$\mathbb{E}[m_{k_j}^{(1)(2)} | r_k] = \frac{r_k p_j^{(2)}}{(1 - p_j^{(2)}) \prod_{l=3}^{T+1} c_j^{(l)}},$$

$$\text{var}[m_{k_j}^{(1)(2)} | r_k] = \frac{r_k p_j^{(2)}}{(1 - p_j^{(2)})^2 \prod_{l=3}^{T+1} c_j^{(l)}} \left\{ 1 + p_j^{(2)} \sum_{l=3}^{T+1} \left[\prod_{l=3}^l (c_j^{(l)})^{-1} \right] \right\}.$$

Thus the variance-to-mean ratio (VMR) of the count $m_{k_j}^{(1)(2)}$ given r_k can be expressed as

$$\text{VMR}[m_{k_j}^{(1)(2)} | r_k] = \frac{1}{(1 - p_j^{(2)})} \left\{ 1 + p_j^{(2)} \sum_{l=3}^{T+1} \left[\prod_{l=3}^l (c_j^{(l)})^{-1} \right] \right\}. \quad (27)$$

In comparison to PFA with $m_{k_j}^{(1)(2)} \sim \text{NB}(r_k, p_j^{(2)})$ given r_k , with a VMR of $1/(1 - p_j^{(2)})$, the GBN with T hidden layers, which mixes the shape of $m_{k_j}^{(1)(2)} \sim \text{NB}(\theta_{k_j}^{(2)}, p_j^{(2)})$ with a chain of gamma random variables, increases $\text{VMR}[m_{k_j}^{(1)(2)} | r_k]$ by a factor of

$$\frac{1 + p_j^{(2)} \sum_{l=3}^{T+1} \left[\prod_{l=3}^l (c_j^{(l)})^{-1} \right]}{1 + (T - 1)p_j^{(2)}}$$

which is equal to

if we further assume $c_j^{(l)} = 1$ for all $l \geq 3$. Therefore, by increasing the depth of the network to distribute the variability into more layers, the multilayer structure could increase its capacity to model data variability.

3.3 Learning The Network Structure With Layer-Wise Training

As jointly training all layers together is often difficult, existing deep networks are typically trained using a greedy layer-wise unsupervised training algorithm, such as the one proposed in (Hinton et al., 2006) to train the deep belief networks. The effectiveness of this training strategy is further analyzed in (Bengio et al., 2007). By contrast, the augmentable GBN has a simple Gibbs sampler to jointly train all its hidden layers, as described in Appendix B, and hence does not necessarily require greedy layer-wise training, but the same as these commonly used deep learning algorithms, it still needs to specify the number of layers and the width of each layer.

In this paper, we adopt the idea of layer-wise training for the GBN, not because of the lack of an effective joint-training algorithm that trains all layers together in each iteration, but for the purpose of learning the width of each hidden layer in a greedy layer-wise manner, given a fixed budget on the width of the first layer. The basic idea is to first train a GBN with a single hidden layer, *i.e.*, $T = 1$, for which we know how to use the gamma-negative binomial process (Zhou and Carin, 2015; Zhou et al., 2015b) to infer the posterior distribution of the number of active factors; we fix the width of the first layer K_1 with the number of active factors inferred at iteration B_1 , prune all inactive factors of the first layer, and continue Gibbs sampling for another C_1 iterations. Now we describe the proposed recursive procedure to build a GBN with $T \geq 2$ layers. With a GBN of $T - 1$ hidden layers that has already been inferred, for which the hidden units of the top layer are distributed as $\theta_j^{(T-1)} \sim \text{Gam}(r, 1/c_j^{(T)})$, where $\mathbf{r} = (r_1, \dots, r_{K_{T-1}})'$, we add another layer by letting $\theta_j^{(T-1)} \sim \text{Gam}(\Phi^{(T)} \theta_j^{(T)}, 1/c_j^{(T)})$, $\theta_j^{(T)} \sim \text{Gam}(r, 1/c_j^{(T+1)})$, where $\Phi^{(T)} \in \mathbb{R}_+^{K_{T-1} \times K_{T \max}^{(T+1)}}$ and \mathbf{r} is redefined as $\mathbf{r} = (r_1, \dots, r_{K_{T \max}^{(T)}})'$. The key idea is with latent counts $m_{kj}^{(T)/(T+1)}$ upward propagated from the bottom data layer, one may marginalize out $\theta_{kj}^{(T)}$, leading to $m_{kj}^{(T)/(T+1)} \sim \text{NB}(r_k, p_j^{(T+1)})$, $r_k \sim \text{Gam}(\gamma_0/K_{T \max}, 1/c_0)$, and hence can again rely on the shrinkage mechanism of a truncated gamma-negative binomial process to prune inactive factors (connection weight vectors, columns of $\Phi^{(T)}$) of layer T , making K_T the inferred layer width for the newly added layer, smaller than $K_{T \max}$ if $K_{T \max}$ is set to be sufficiently large. The newly added layer and all the layers below would be jointly trained, but with the structure below the newly added layer kept unchanged. Note that when $T = 1$, the GBN infers the number of active factors if $K_1 \max$ is set large enough, otherwise, it still assigns the factors with different weights r_k , but may not be able to prune any of them. The details of the proposed layer-wise training strategies are summarized in Algorithm 1 for multivariate count data, and in Algorithm 2 for multivariate binary and nonnegative real data.

4. Experimental Results

In this section, we present experimental results for count, binary, and nonnegative real data.

4.1 Deep Topic Modeling

We first analyze multivariate count data with the Poisson gamma belief network (PGBN). We apply the PGBNs for topic modeling of text corpora, each document of which is represented as a term-frequency count vector. Note that the PGBN with a single hidden layer

is identical to the (truncated) gamma-negative binomial process PFA of Zhou and Carin (2015), which is a nonparametric Bayesian algorithm that performs similarly to the hierarchical Dirichlet process latent Dirichlet allocation of Teh et al. (2006) for text analysis, and is considered as a strong baseline. Thus we will focus on making comparison to the PGBN with a single layer, with its layer width set to be large to approximate the performance of the gamma-negative binomial process PFA. We evaluate the PGBNs' performance by examining both how well they unsupervisedly extract low-dimensional features for document classification, and how well they predict heldout word tokens. Matlab code will be available in <http://mingyuanzhou.github.io/>.

We use Algorithm 1 to learn, in a layer-wise manner, from the training data the connection weight matrices $\Phi^{(1)}, \dots, \Phi^{(T \max)}$ and the top-layer hidden units' gamma shape parameters \mathbf{r} : to add layer T to a previously trained network with $T - 1$ layers, we use B_T iterations to jointly train $\Phi^{(T)}$ and \mathbf{r} together with $\{\Phi^{(t)}\}_{1, T-1}$, prune the inactive factors of layer T , and continue the joint training with another C_T iterations. We set the hyper-parameters as $a_0 = b_0 = 0.01$ and $e_0 = f_0 = 1$. Given the trained network, we apply the upward-downward Gibbs sampler to collect 500 MCMC samples after 500 burnins to estimate the posterior mean of the feature usage proportion vector $\theta_j^{(1)}/\theta_j^{(1)}$ at the first hidden layer, for every document in both the training and testing sets.

4.1.1 FEATURE LEARNING FOR BINARY CLASSIFICATION

We consider the 20newsgroups data set that consists of 18,774 documents from 20 different news groups, with a vocabulary of size $K_0 = 61,188$. It is partitioned into a training set of 11,269 documents and a testing set of 7,505 ones. We first consider two binary classification tasks that distinguish between the *comp.sys.ibm.pc.hardware* and *comp.sys.mac.hardware*, and between the *sci.electronics* and *sci.med* news groups. For each binary classification task, we remove a standard list of stop words and only consider the terms that appear at least five times, and report the classification accuracies based on 12 independent random trials. With the upper bound of the first layer's width set as $K_1 \max \in \{25, 50, 100, 200, 400, 600, 800\}$, and $B_t = C_t = 1000$ and $\eta^{(t)} = 0.01$ for all t , we use Algorithm 1 to train a network with $T \in \{1, 2, \dots, 8\}$ layers. Denote θ_j as the estimated K_1 dimensional feature vector for document j , where $K_1 \leq K_1 \max$ is the inferred number of active factors of the first layer that is bounded by the pre-specified truncation level $K_1 \max$. We use the L_2 regularized logistic regression provided by the LIBLINEAR package (Fan et al., 2008) to train a linear classifier on θ_j in the training set and use it to classify θ_j in the test set, where the regularization parameter is five-fold cross-validated on the training set from $(2^{-10}, 2^{-9}, \dots, 2^{15})$.

As shown in Figure 9, modifying the PGBN from a single-layer shallow network to a multilayer deep one clearly improves the qualities of the unsupervisedly extracted feature vectors. In a random trial, with $K_1 \max = 800$, we infer a network structure of $[K_1, \dots, K_8] = [512, 154, 75, 54, 47, 37, 34, 29]$ for the first binary classification task, and $[K_1, \dots, K_8] = [491, 143, 74, 49, 36, 32, 28, 26]$ for the second one. Figures 9(c)-(d) also show that increasing the network depth in general improves the performance, but the first-layer width clearly plays a critical role in controlling the ultimate network capacity. This insight is further illustrated below.

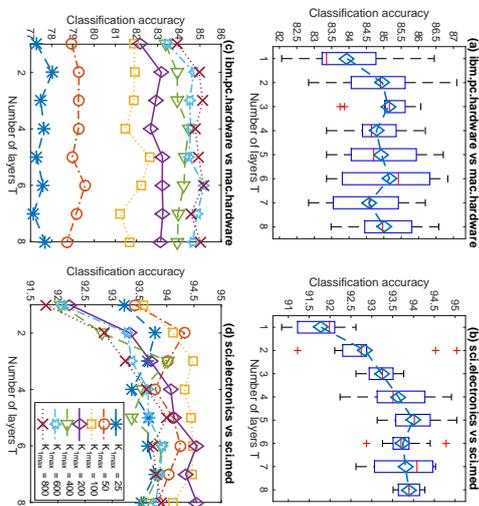

Figure 9: Classification accuracy (%) as a function of the network depth T for two 20news groups binary classification tasks, with $\eta^{(t)} = 0.01$ for all layers. (a)-(b): the boxplots of the accuracies of 12 independent runs with $K_1^{\max} = 800$. (c)-(d): the average accuracies of these 12 runs for various K_1^{\max} and T . Note that $K_1^{\max} = 800$ is large enough to cover all active first-layer topics (inferred to be around 500 for both binary classification tasks), whereas all the first-layer topics would be used if $K_1^{\max} = 25, 50, 100$, or 200.

4.1.2 FEATURE LEARNING FOR MULTI-CLASS CLASSIFICATION

We test the PGBNs for multi-class classification on 20news groups. After removing a standard list of stopwords and the terms that appear less than five times, we obtain a vocabulary with $V = 33,420$. We set $C_t = 500$ and $\eta^{(t)} = 0.05$ for all t ; we set $B_t = 1000$ for all t if $K_1^{\max} \leq 400$, and set $B_t = 1000$ and $B_t = 500$ for $t \geq 2$ if $K_1^{\max} > 400$. We use all 11,269 training documents to infer a set of networks with $T_{\max} \in \{1, \dots, 5\}$ and $K_1^{\max} \in \{50, 100, 200, 400, 600, 800\}$, and mimic the same testing procedure used for binary classification to extract low-dimensional feature vectors, with which each testing document is classified to one of the 20 news groups using the L_2 regularized logistic regression.

Figure 10 shows a clear trend of improvement in classification accuracy by increasing the network depth with a limited first-layer width, or by increasing the upper bound of the width of the first layer with the depth fixed. For example, a single-layer PGBN with $K_1^{\max} = 100$ could add one or more layers to slightly outperform a single-layer PGBN with $K_1^{\max} = 200$, and a single-layer PGBN with $K_1^{\max} = 200$ could add layers to clearly outperform a single-layer PGBN with K_1^{\max} as large as 800.

The proposed Gibbs sampler also exhibits several desirable computational properties. Each iteration of jointly training multiple layers usually only costs moderately more than that of training a single layer, e.g., with $K_1^{\max} = 400$, a training iteration on a single core of an Intel Xeon 2.7 GHz CPU takes about 5.6, 6.7, 7.1 seconds for the PGBN with 1, 3,

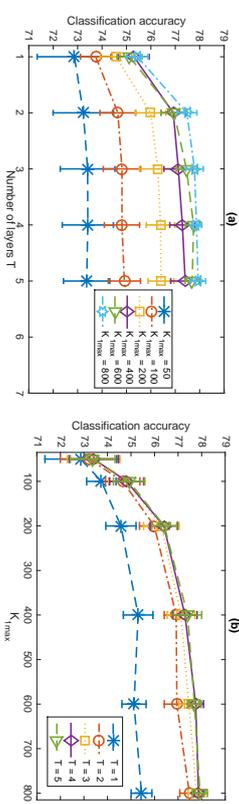

Figure 10: Classification accuracy (%) of the PGBNs with Algorithm 1 for 20news groups multi-class classification (a) as a function of the depth T with various K_1^{\max} and (b) as a function of K_1^{\max} with various depths, with $\eta^{(t)} = 0.05$ for all layers. The widths of the hidden layers are automatically inferred. In a random trial, the inferred network widths $[K_1, \dots, K_5]$ for $K_1^{\max} = 50, 100, 200, 400, 600$, and 800 are $[50, 50, 50, 50, 50]$, $[100, 99, 99, 94, 87]$, $[200, 161, 130, 94, 63]$, $[396, 109, 99, 82, 68]$, $[528, 129, 109, 98, 91]$, and $[608, 100, 99, 96, 89]$, respectively.

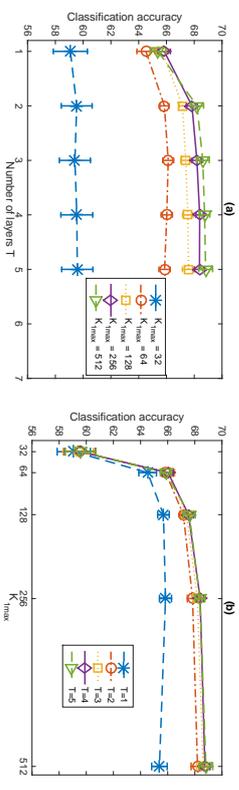

Figure 11: Analogous plots to Figure 10 with the vocabulary size restricted to be 2000, including the most frequent 2000 terms after removing a standard list of stopwords. The widths of the hidden layers are automatically inferred. In a random trial, the inferred network widths $[K_1, \dots, K_5]$ for $K_1^{\max} = 32, 64, 128, 256$, and 512 are $[32, 32, 32, 32, 32]$, $[64, 64, 64, 59, 59]$, $[128, 125, 118, 106, 87]$, $[256, 224, 124, 83, 65]$, and $[512, 187, 89, 78, 62]$, respectively.

and 5 layers, respectively. Since the per iteration cost increases approximately as a linear function of the inferred K_1 and as a linear function of the size of the data set, given a fixed computational budget, one may choose a moderate K_1^{\max} to allow adding a sufficiently large number of hidden layers. In addition, the samplings of $x^{(t)}$, $\phi_k^{(t)}$, and $\theta_{kj}^{(t)}$ in each layer can all be made embarrassingly parallel with blocked Gibbs sampling, and hence can potentially significantly benefit from implementing the algorithm using graphics processing units (GPUs) or other parallel computing architectures.

Examining the inferred network structure also reveals interesting details. For example, in a random trial with Algorithm 1, with $\eta^{(t)} = 0.05$ for all t , the inferred network widths $[K_1, \dots, K_5]$ for $K_1^{\max} = 50, 100, 200, 400, 600$, and 800 are $[50, 50, 50, 50, 50]$, $[100, 99, 99, 94, 87]$, $[200, 161, 130, 94, 63]$, $[396, 109, 99, 82, 68]$, $[528, 129, 109, 98, 91]$, and $[608,$

100, 99, 96, 89], respectively. This indicates that for a network with an insufficient budget on its first-layer width, as the network depth increases, its inferred layer widths decay more slowly than a network with a sufficient or surplus budget on its first-layer width; and a network with a surplus budget on its first-layer width may only need relatively small widths for its higher hidden layers.

In order to make comparison to related algorithms, we also consider restricting the vocabulary to the 2000 most frequent terms of the vocabulary after moving a standard list of stopwords. We repeat the same experiments with the same settings except that we set $K_{1\max} \in \{32, 64, 128, 256, 512\}$, $B_1 = 1000$, $C_1 = 500$, and $B_t = C_t = 500$ for all $t \geq 2$. We show the results in Figure 11. Again, we observe a clear trend of improvement by increasing the network depth with a limited first-layer width, or by increasing the upper bound of the width of the first layer with the depth fixed. In a random trial with Algorithm 1, the inferred network widths $[K_1, \dots, K_5]$ for $K_{1\max} = 32, 64, 128, 256$, and 512 are $[32, 32, 32, 32, 32]$, $[64, 64, 64, 59, 59]$, $[128, 125, 118, 106, 87]$, $[256, 224, 124, 83, 65]$, and $[512, 187, 89, 78, 62]$, respectively.

For comparison, we first consider the same L_2 regularized logistic regression multi-class classifier, trained either on the raw word counts or normalized term-frequencies of the 20newsgroups training documents using five-fold cross-validation. As summarized in Table 1 of Appendix C, when using the raw term-frequency word counts as covariates, the same classifier achieves 69.8% (68.2%) accuracy on the 20newsgroups test documents if using the top 2000 terms that exclude (include) a standard list of stopwords, achieves 75.8% if using all the 61, 188 terms in the vocabulary, and achieves 78.0% if using the 33, 420 terms remained after removing a standard list of stopwords and the terms that appear less than five times; and when using the normalized term-frequencies as covariates, the corresponding accuracies are 70.8% (67.9%) if using the top 2000 terms excluding (including) stopwords, 77.6% with all the 61, 188 terms, and 79.4% with the 33, 420 selected terms.

As summarized in Table 2 of Appendix C, for multi-class classification on the same data set, with a vocabulary size of 2000 that consists of the 2000 most frequent terms after removing stopwords and stemming, the DocNADE (Laroche and Laully, 2012) and the over-replicated softmax (Srivastava et al., 2013) provide the accuracies of 67.0% and 66.8%, respectively, for a feature dimension of $K = 128$, and provide the accuracies of 68.4% and 69.1%, respectively, for a feature dimension of $K = 512$.

As shown in Figure 11 and summarized in Table 3 of Appendix C, with the same vocabulary size of 2000 (but different terms due to different preprocessing), the proposed PGBN provides 65.9% (67.5%) with $T = 1$ ($T = 5$) for $K_{1\max} = 128$, and 65.9% (69.2%) with $T = 1$ ($T = 5$) for $K_{1\max} = 512$, which may be further improved if we also consider the stemming step, as done in these two algorithms, for word preprocessing, or if we set the values of $\eta^{(l)}$ to be smaller than 0.05 to encourage a more complex network structure. We also summarize in Table 3 the classification accuracies shown in Figure 10 for the PGBNs with $V = 33, 420$. Note that the accuracies in Tables 2 and 3 are provided to show that the PGBNs are in the same ballpark as both the DocNADE (Laroche and Laully, 2012) and over-replicated softmax (Srivastava et al., 2013). Note these results are not intended to provide a head-to-head comparison, which is possible if the same data preprocessing and classifier were used and the error bars were shown in Srivastava et al. (2013), or we could obtain the code to replicate the experiments using the same preprocessed data and classifier.

Note that 79.4% achieved using the 33, 420 selected features is the best accuracy reported in the paper, which is unsurprising since all the unsupervisedly extracted latent feature vectors have much lower dimensions and are not optimized for classification (Zhu et al., 2012; Zhou et al., 2015b). In comparison to using appropriately preprocessed high-dimensional features, our experiments show that while text classification performance often clearly deteriorates if one trains a multi-class classifier on the lower-dimensional features extracted using “shallow” unsupervised latent feature models, one could obtain much improved results using appropriate “deep” generalizations. For further improvement, one may consider adding an extra supervised component into the model, which is shown to boost the classification performance for latent Dirichlet allocation (Blei and Mcauliffe, 2008; Zhu et al., 2012), a shallow latent feature model related to the PGBN with a single hidden layer.

4.1.3 PERPLEXITIES FOR HELDOUT WORDS

In addition to examining the performance of the PGBN for unsupervised feature learning, we also consider a more direct approach that we randomly choose 30% of the word tokens in each document as training, and use the remaining ones to calculate per-heldout-word perplexity. We consider both all the 18,774 documents of the 20newsgroups corpus, limiting the vocabulary to the 2000 most frequent terms after removing a standard list of stopwords, and the NIPS12 (<http://www.cs.yyu.edu/~roweis/data.html>) corpus whose stopwords have already been removed, limiting the vocabulary to the 2000 most frequent terms. We set $\eta^{(l)} = 0.05$ and $C_t = 500$ for all t , set $B_1 = 1000$ and $B_t = 500$ for $t \geq 2$, and consider five random trials. Among the $B_t + C_t$ Gibbs sampling iterations used to train layer t , we collect one sample per five iterations during the last 500 iterations, for each of which we draw the topics $\{\phi_k^{(l)}\}_k$ and topics weights $\theta_j^{(l)}$, to compute the per-heldout-word perplexity using Equation (34) of Zhou and Carin (2015). This evaluation method is similar to those used in Newman et al. (2009), Wallach et al. (2009), and Paisley et al. (2012).

As shown in both Figures 12 and 13, we observe a clear trend of improvement by increasing both $K_{1\max}$ and T . We have also examined the topics and network structure learned on the NIPS12 corpus. Similar to the exploratory data analysis performed on the 20newsgroups corpus, as described in detail in Section 2.3, the inferred deep networks also allow us to extract trees and subnetworks to visualize various aspects of the NIPS12 corpus from general to specific and reveal how they are related to each other. We omit these details for brevity and instead provide a brief description: with $K_{1\max} = 200$ and $T = 5$, the PGBN infers a network with $[K_1, \dots, K_5] = [200, 164, 106, 60, 42]$ in one of the five random trials. The ranks, according to the weights $r_k^{(l)}$ calculated in (14), and the top five words of three example topics for layer $T = 5$ are “6 network units input learning training,” “15 data model learning set image,” and “34 network learning model input neural;” while these of five example topics of layer $T = 1$ are “19 likelihood em mixture parameters data,” “37 bayesian posterior prior log evidence,” “62 variables belief networks conditional inference,” “126 boltzmann binary machine energy hinton,” and “127 speech speaker acoustic vowel phonetic.” It is clear that the topics of the bottom hidden layers are very specific whereas these of the top hidden layer are quite general.

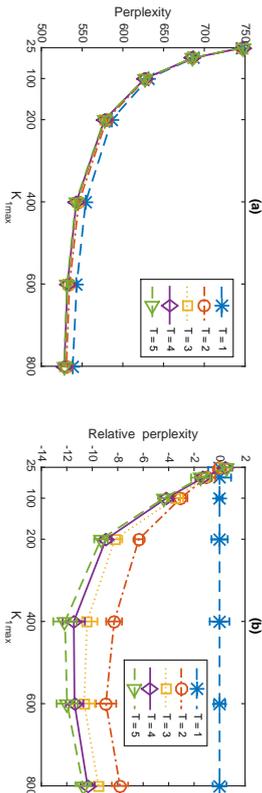

Figure 12: (a) per-held-out-word perplexity (the lower the better) for the NIPS12 corpus (using the 2000 most frequent terms) as a function of the upper bound of the first layer with $K_{1,max}$ and network depth T , with 30% of the word tokens in each document used for training and $\eta^{(l)} = 0.05$ for all l . (b) for visualization, each curve in (a) is reproduced by subtracting its values from the average perplexity of the single-layer network. In a random trial, the inferred network widths $[K_1, \dots, K_5]$ for $K_{1,max} = 25, 50, 100, 200, 400, 600$, and 800 are $[25, 25, 25, 25, 25]$, $[50, 50, 50, 49, 42]$, $[100, 99, 93, 78, 54]$, $[200, 164, 106, 60, 42]$, $[400, 130, 83, 52, 39]$, $[596, 71, 68, 58, 37]$, and $[755, 57, 53, 46, 42]$, respectively.

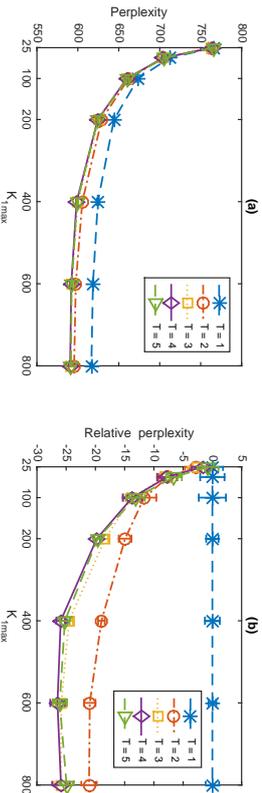

Figure 13: Analogous plots to Figure 12 for the 20newsgroups corpus (using the 2000 most frequent terms after removing a standard list of stopwords). In a random trial, the inferred network widths $[K_1, \dots, K_5]$ for $K_{1,max} = 25, 50, 100, 200, 400, 600$, and 800 are $[25, 25, 25, 25, 25]$, $[50, 50, 50, 50, 50]$, $[100, 99, 99, 97, 97]$, $[200, 194, 177, 152, 123]$, $[398, 199, 140, 116, 105]$, $[557, 156, 133, 118, 103]$, and $[701, 119, 116, 112, 103]$, respectively.

4.1.4 GENERATING SYNTHETIC DOCUMENTS

We have also tried drawing $\theta_j^{(T)} \sim \text{Gann}(\mathbf{r}, 1/c_j^{(T+1)})$ and downward passing it through a T -layer network trained on a text corpus to generate synthetic bag-of-words documents, which are found to be quite interpretable and reflect various general aspects of the corpus used to train the network. We consider the PGBN with $[K_1, \dots, K_5] = [608, 100, 99, 96, 89]$, which is trained on the training set of the 20newsgroups corpus with $K_{1,max} = 800$ and $\eta^{(l)} = 0.05$ for all l . We set $c_j^{(l)}$ as the median of the inferred $\{c_j^{(l)}\}_j$ of the training doc-

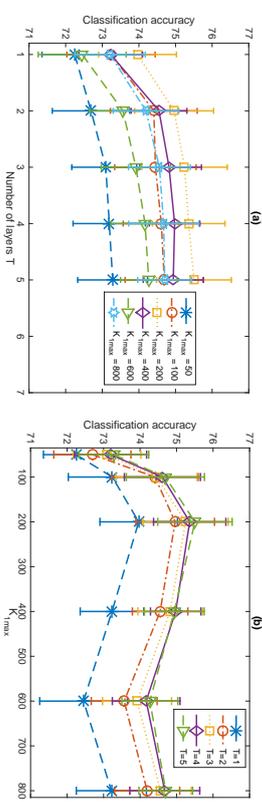

Figure 14: Analogous plots to Figure 10 for the BertPo-GBNs on the binarized 20news-groups term-document count matrix. The widths of the hidden layers are automatically inferred. In a random trial with Algorithm 2, the inferred network widths $[K_1, \dots, K_5]$ for $K_{1,max} = 50, 100, 200, 400, 600$, and 800 are $[50, 50, 50, 50, 50]$, $[100, 97, 95, 90, 82]$, $[178, 145, 122, 97, 72]$, $[184, 139, 119, 101, 75]$, $[172, 165, 158, 138, 110]$, and $[156, 151, 147, 134, 117]$, respectively.

uments for all l . Given $\{\Phi^{(l)}\}_{l,T}$ and \mathbf{r} , we first generate $\theta_j^{(T)} \sim \text{Gann}(\mathbf{r}, 1/c_j^{(T+1)})$ and then downward pass it through the network by drawing nonnegative real random variables, one layer after another, from the gamma distributions as in (1). With the simulated $\theta_j^{(l)}$, we calculate the Poisson rates for all the V words using $\Phi^{(1)}\theta_j^{(1)}$ and display the top 100 words ranked by their Poisson rates. As shown in the text file available at <http://mingyuanzhou.github.io/Results/GBN-BOW.txt>, the synthetic documents generated in this manner are all easy to interpret and reflect various general aspects of the 20newsgroups corpus on which the PGBN is trained.

4.2 Multilayer Representation for Binary Data

We apply the BertPo-GBN to extract multilayer representations for high-dimensional sparse binary vectors. The BertPo link is proposed in Zhou (2015) to construct edge partition models for network analysis, whose computation is mainly spent on pairs of linked nodes and hence is scalable to big sparse relational networks. That link function and its inference procedure have also been adopted by Hu et al. (2015) to analyze big sparse binary tensors.

We consider the same problem of feature learning for multi-class classification studied in detail in Section 4.1.2. We consider the same setting except that the original term-document word count matrix is now binarized into a term-document indicator matrix; the (i, j) element of which is set as one if and only if $n_{ij} \geq 1$ and set as zero otherwise. We test the BertPo-GBNs on the 20newsgroups corpus, with $\eta^{(l)} = 0.05$ for all layers. As shown in Figure 14, given the same upper-bound on the width of the first layer, increasing the depth of the network clearly improves the performance. Whereas given the same number of hidden layers, the performance initially improves and then fluctuates as the upper-bound of the first layer increases. Such kind of fluctuations when $K_{1,max}$ reaches over 200 are expected, since the width of the first layer is inferred to be less than 190 and hence the budget as small as $K_{1,max} = 200$ is already large enough to cover all active factors.

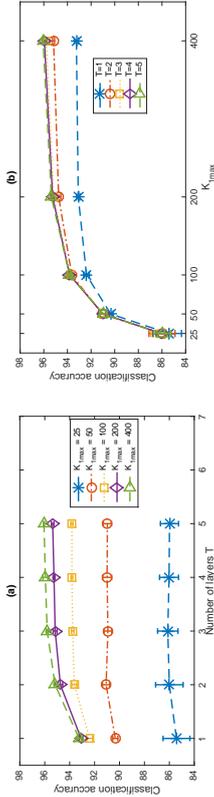

Figure 15: Analogous plots to Figure 10 for the PRG-GBNs on the MNIST data set. In a random trial with Algorithm 2, the inferred network widths $[K_1, \dots, K_5]$ for $K_{1,max} = 50, 100, 200$, and 400 are $[50, 50, 50, 50]$, $[100, 100, 100, 100]$, $[200, 200, 200, 200]$, and $[400, 400, 399, 385, 321]$, respectively.

4.3 Multilayer Representation for Nonnegative Real Data

We use the PRG-GBN to unsupervisedly extract features from nonnegative real data. We consider the MNIST data set (<http://yann.lecun.com/exdb/mnist/>), which consists of 60000 training handwritten digits and 10000 testing ones. We divide the gray-scale pixel values of each 28×28 image by 255 and represent each image as a 784 dimensional nonnegative real vector. We set $\eta^{(1)} = 0.05$ and use all training digits to infer the PRG-GBNs with $T_{max} \in \{1, \dots, 5\}$ and $K_{1,max} \in \{50, 100, 200, 400\}$. We consider the same problem of feature extraction for multi-class classification studied in detail in Section 4.1.2, and we follow the same experimental settings over there. As shown in Figure 15, both increasing the width of the first layer and the depth of the network could clearly improve the performance in terms of unsupervisedly extracting features that are better suited for multi-class classification.

Note that the PRG distribution might not be the best distribution to fit MNIST digits, but nevertheless, displaying the inferred features at various layers as images provides a straightforward way to visualize the latent structures inferred from the data and hence provides an excellent example to understand the properties and working mechanisms of the GBN. We display the projections to the first layer of the factors $\Phi^{(l)}$ at all five hidden layers as images for $K_{1,max} = 100$ and $K_{1,max} = 400$ in Figures 22 and 23, respectively, which clearly show that the inferred latent factors become increasingly more general as the layer increases. In both Figures 22 and 23, the latent factors inferred at the first hidden layer represent filters that are only active at very particular regions of the images, those inferred at the second hidden layer represent larger parts of the hidden-written digits, and those inferred at the third and deeper layers resemble the whole digits.

To visualize the relationships between the factors of different layers, we show in Figure 24 in Appendix C a subset of nodes of each layer and the nodes of the layer below that are connected to them with non-negligible weights.

It is interesting to note that unlike Lee et al. (2009) and many other following works that rely on the convolutional and pooling operations, which are pioneered by LeCun et al. (1989), to extract hierarchical representation for images at different spatial scales, we show that the proposed algorithm, while not breaking the images into spatial patches, is already able to learn the factors that are active on very specific spatial regions of the image in

the bottom hidden layer, and learn these increasingly more general factors covering larger spatial regions of the images as the number of layer increases. However, due to the lack of the ability to discover spatially localized features that can be shared at multiple different spatial regions, our algorithm does not at all exploit the redundancies of the spatially localized features inside a single image and hence may require much more data to train. Therefore, it would be interesting to investigate whether one can introduce convolutional and pooling operations into the GBNs, which may substantially improve their performance on modeling natural images.

5. Conclusions

The augmentable gamma belief network (GBN) is proposed to extract a multilayer representation for high-dimensional count, binary, or nonnegative real vectors, with an efficient upward-downward Gibbs sampler to jointly train all its layers and a layer-wise training strategy to automatically infer the network structure. A GBN of T layers can be broken into T subproblems that are solved by repeating the same subroutine, with the computation mainly spent on training the first hidden layer. When used for deep topic modeling, the GBN extracts very specific topics at the first hidden layer and increasingly more general topics at deeper hidden layers. It provides an excellent way for exploratory data analysis through the visualization of the inferred deep network, whose hidden units of adjacent layers are sparsely connected. Its good performance is further demonstrated in unsupervisedly extracting features for document classification and predicting heldout word tokens. The extracted deep network can also be used to simulate very interpretable synthetic documents, which reflect various general aspects of the corpus that the network is trained on. When applied for image analysis, without using the convolutional and pooling operations, the GBN is already able to extract interpretable factors in the first hidden layer that are active in very specific spatial regions and interpretable factors in deeper hidden layers with increasingly more general spatial patterns covering larger spatial regions. For big data problems, in practice one may rarely have a sufficient budget to allow the first-layer width to grow without bound, thus it is natural to consider a deep network that can use a multilayer deep representation to better allocate its resource and increase its representation power with limited computational power. Our algorithm provides a natural solution to achieve a good compromise between the width of each layer and the depth of the network.

Zhou thanks Texas Advanced Computing Center for computational support. B. Chen thanks the support of the Thousand Young Talent Program of China, NSFC (61372132), NCET-13-0945, and NDRP-9140A07010115DZ01015.

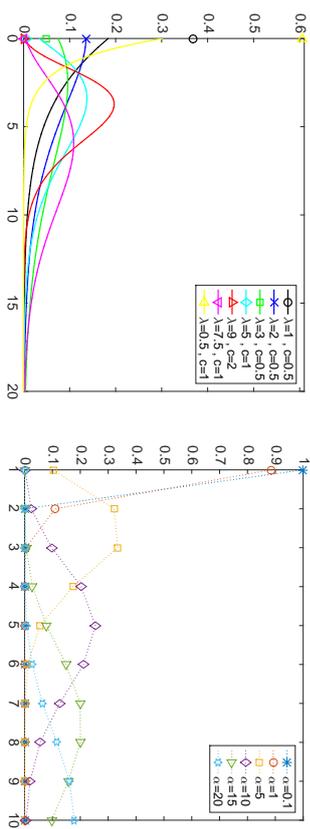

Figure 16: Left: probability distribution functions for the Poisson randomized gamma (PRG) distribution $x \sim \text{PRG}(\lambda, c)$, where the sum of the probability mass at $x = 0$ and the area under the probability density function curve for $x > 0$ is equal to one; Right: probability mass functions for the truncated Bessel distribution $n \sim \text{Bessel}_-(\alpha)$, where $n \in \{1, 2, \dots\}$.

Appendix A. Randomized Gamma and Bessel Distributions

Related to our work, Yuan and Kalbfleisch (2000) proposed the randomized gamma distribution to generate a random positive real number as

$$x | n, \nu \sim \text{Gam}(n + \nu + 1, 1/c), \quad n \sim \text{Pois}(\lambda),$$

where $\nu > -1$ and $c > 0$. As in Yuan and Kalbfleisch (2000), the conditional posterior of n can be expressed as

$$(n | x, \nu, \alpha) \sim \text{Bessel}_\nu(2\sqrt{cx\lambda})$$

where we denote $n \sim \text{Bessel}_\nu(\alpha)$ as the Bessel distribution with parameters $\nu > -1$ and $\alpha > 0$, with PMF

$$\text{Bessel}_\nu(n; \alpha) = \frac{\left(\frac{\alpha}{2}\right)^{2n+\nu}}{\Gamma_\nu(\alpha)n\Gamma(n+\nu+1)}, \quad n \in \{0, 1, 2, \dots\}.$$

Algorithms to draw Bessel random variables can be found in Devroye (2002).

The proposed PRG is different from the randomized gamma distribution of Yuan and Kalbfleisch (2000) in that it models both positive real numbers and exact zeros, and the proposed truncated Bessel distribution $n \sim \text{Bessel}_-(\alpha)$ is different from the Bessel distribution $n \sim \text{Bessel}_\nu(\alpha)$, where $\nu > -1$, in that it is defined only on positive integers. For illustration, we show in Figure 16 the probability distribution functions of both the PRG and truncated Bessel distributions under a variety of parameter settings.

Appendix B. Upward-Downward Gibbs Sampling

Below we first discuss Gibbs sampling for count data and then generalize it for both binary and nonnegative real data.

B.1 Inference for the PGBN

With Lemma 1 and Corollary 2 and the width of the first layer being bounded by $K_{1,\max}$, we first consider multivariate count observations and develop an upward-downward Gibbs sampler for the PGBN, each iteration of which proceeds as follows.

Sample $x_{vj}^{(t)}$. We can sample $x_{vj}^{(t)}$ for all layers using (25). But for the first hidden layer, we may treat each observed count $x_{vj}^{(1)}$ as a sequence of word tokens at the v th term (in a vocabulary of size $V := K_0$) in the j th document, and assign the $x_j^{(1)}$ words $\{v_j^i\}_{i=1, x_j^{(1)}}$ one after another to the latent factors (topics), with both the topics $\Phi^{(1)}$ and topic weights $\theta_j^{(1)}$ marginalized out, as

$$P(z_{ji} = k | -) \propto \frac{\eta_j^{(1)} + x_{vj}^{(1)-ji}}{V\eta_j^{(1)} + x_{\cdot, k}^{(1)-ji}} \left(x_{jk}^{(1)-ji} + \phi_{k\cdot}^{(2)} \theta_j^{(2)} \right), \quad k \in \{1, \dots, K_{1,\max}\}, \quad (28)$$

where z_{ji} is the topic index for v_j^i and $x_{vj}^{(1)} := \sum_i \delta(v_j^i = v, z_{ji} = k)$ counts the number of times that term v appears in document j ; we use x^{-ji} to denote the count x calculated without considering word i in document j . The collapsed Gibbs sampling update equation shown above is related to the one developed in (Zhou, 2014) for PFA using the beta-negative Dirichlet allocation, and the one developed in (Griffiths and Steyvers, 2004) for latent binomial process. When $T = 1$, we would replace the terms $\phi_{k\cdot}^{(2)} \theta_j^{(2)}$ with r_k for PFA built on the gamma-negative binomial process (Zhou and Carin, 2015) (or with $\alpha\pi_k$ for hierarchical Dirichlet process latent Dirichlet allocation, see (Teh et al., 2006) and (Zhou, 2014) for details), and add an additional term to account for the possibility of creating an additional factor (Zhou, 2014). For simplicity, in this paper, we truncate the nonparametric Bayesian model with $K_{1,\max}$ factors and let $r_k \sim \text{Gam}(\gamma_0/K_{1,\max}, 1/c_0)$ if $T = 1$. Note that although we use collapsed Gibbs sampling inference in this paper, if one desires embarrassingly parallel inference and possibly lower computation, then one may consider explicitly sampling $\{\phi_k^{(1)}\}_k$ and $\{\theta_j^{(1)}\}_j$ and sampling $x_{vj}^{(1)}$ with (25).

Sample $\phi_k^{(t)}$. Given these latent counts, we sample the factors/topics $\phi_k^{(t)}$ as

$$(\phi_k^{(t)} | -) \sim \text{Dir} \left(\eta_{1,k}^{(t)} + x_{1,k}^{(t)}, \dots, \eta_{K_{t-1},k}^{(t)} + x_{K_{t-1},k}^{(t)} \right). \quad (29)$$

Sample $x_{vj}^{(t+1)}$. We sample $x_j^{(t+1)}$ using (26), where we replace the term $\phi_{k\cdot}^{(T+1)} \theta_j^{(T+1)}$ with r_v .

Sample \mathbf{r} . Both γ_0 and c_0 are sampled using related equations in (Zhou and Carin, 2015), omitted here for brevity. We sample \mathbf{r} as

$$(r_v | -) \sim \text{Gam} \left(\gamma_0 / K_T + x_{v\cdot}^{(T+1)}, \left[c_0 - \sum_j \ln(1 - p_j^{(T+1)}) \right]^{-1} \right). \quad (30)$$

Sample $\theta_j^{(t)}$. Using (22) and the gamma-Poisson conjugacy, we sample θ_j as

$$\begin{aligned}
 (\theta_j^{(T)} | -) &\sim \text{Gam} \left(\mathbf{r} + \mathbf{m}_j^{(T)(T+1)}, [c_j^{(T)(T+1)} - \ln(1 - p_j^{(T)})]^{-1} \right), \\
 &\vdots \\
 (\theta_j^{(t)} | -) &\sim \text{Gam} \left(\Phi^{(t+1)} \theta_j^{(t+1)} + \mathbf{m}_j^{(t)(t+1)}, [c_j^{(t)(t+1)} - \ln(1 - p_j^{(t)})]^{-1} \right), \\
 &\vdots \\
 (\theta_j^{(1)} | -) &\sim \text{Gam} \left(\Phi^{(2)} \theta_j^{(2)} + \mathbf{m}_j^{(1)(2)}, [c_j^{(1)(2)} - \ln(1 - p_j^{(1)})]^{-1} \right), \tag{31}
 \end{aligned}$$

Sample $c_j^{(t)}$. With $\theta_j^{(t)} := \sum_{k=1}^{K_t} \theta_{kj}^{(t)}$ for $t \leq T$ and $\theta_j^{(T+1)} := \mathbf{r}$, we sample $p_j^{(2)}$ and $\{c_j^{(t)}\}_{t \geq 3}$ as

$$(p_j^{(2)} | -) \sim \text{Beta} \left(a_0 + m_{\cdot j}^{(1)(2)}, b_0 + \theta_j^{(2)} \right), \quad (c_j^{(t)} | -) \sim \text{Gam} \left(\epsilon_0 + \theta_j^{(t)}, [f_0 + \theta_j^{(t-1)}]^{-1} \right), \tag{32}$$

and calculate $c_j^{(2)}$ and $\{p_j^{(t)}\}_{t \geq 3}$ with (21).

B.2 Handling Binary and Nonnegative Real Observations

For binary observations that are linked to the latent counts at layer one as $b_{vj}^{(1)} = \mathbf{1}(x_{vj}^{(1)} \geq 1)$, we first sample the latent counts at layer one from the truncated Poisson distribution as

$$(x_{vj}^{(1)} | -) \sim b_{vj}^{(1)} \cdot \text{Pois}_+ \left(\sum_{k=1}^{K_1} \phi_{ok}^{(1)} \theta_{kj}^{(1)} \right) \tag{33}$$

and then sample $x_{vj}^{(t)}$ for all layers using (25).

For nonnegative real observations $y_{vj}^{(t)}$ that are linked to the latent counts at layer one as

$$y_{vj}^{(1)} \sim \text{Gam}(x_{vj}^{(1)}, 1/a_j),$$

we let $x_{vj}^{(1)} = 0$ if $y_{vj}^{(1)} = 0$ and sample $x_{vj}^{(1)}$ from the truncated Bessel distribution as

$$(x_{vj}^{(1)} | -) \sim \text{Bessel}_{-1} \left(2 \sqrt{a_j y_{vj}^{(1)} \sum_{k=1}^{K_1} \phi_{ok}^{(1)} \theta_{kj}^{(1)}} \right) \tag{34}$$

if $y_{vj}^{(1)} > 0$. We let $a_j \sim \text{Gam}(\epsilon_0, 1/f_0)$ in the prior and sample a_j as

$$(a_j | -) \sim \text{Gam} \left(\epsilon_0 + \sum_v x_{vj}^{(1)}, \frac{1}{f_0 + \sum_v y_{vj}^{(1)}} \right). \tag{35}$$

We then sample $x_{vj}^{(t)}$ for all layers using (25).

Appendix C. Additional Tables and Figures

Algorithm 1 The PGBN upward-downward Gibbs sampler that uses a layer-wise training strategy to train a set of networks, each of which adds an additional hidden layer on top of the previously inferred network, retrains all its layers jointly, and prunes inactive factors from the last layer. **Inputs:** observed counts $\{x_{vj}\}_{v,j}$, upper bound of the width of the first layer $K_{1 \max}$, upper bound of the number of layers T_{\max} , number of iterations $\{B_T, S_T\}_{1:T_{\max}}$, and hyper-parameters.

Outputs: A total of T_{\max} jointly trained PGBNs with depths $T = 1, T = 2, \dots$, and $T = T_{\max}$.

- 1: **for** $T = 1, 2, \dots, T_{\max}$ **do** Jointly train all the T layers of the network
- 2: Set K_{T-1} , the inferred width of layer $T-1$, as $K_{T \max}$, the upper bound of layer T 's width.
- 3: **for** $iter = 1 : B_T + C_T$ **do** Upward-downward Gibbs sampling
- 4: Sample $\{z_{ji}\}_{j,i}$ using collapsed inference; Calculate $\{x_{vjk}^{(1)}\}_{v,k,j}$; Sample $\{x_{vj}^{(2)}\}_{v,j}$;
- 5: **for** $t = 2, 3, \dots, T$ **do**
- 6: Sample $\{x_{vjk}^{(t)}\}_{v,j,k}$; Sample $\{\phi_k^{(t)}\}_k$; Sample $\{x_{vj}^{(t+1)}\}_{v,j}$;
- 7: **end for**
- 8: Sample $p_j^{(2)}$ and Calculate $c_j^{(2)}$; Sample $\{c_j^{(t)}\}_{j,t}$ and Calculate $\{p_j^{(t)}\}_{j,t}$ for $t = 3, \dots, T+1$;
- 9: **for** $t = T, T-1, \dots, 2$ **do**
- 10: Sample \mathbf{r} if $t = T$; Sample $\{\theta_j^{(t)}\}_j$;
- 11: **end for**
- 12: **if** $iter = B_T$ **then**
- 13: Prune layer T 's inactive factors $\{\phi_k^{(T)}\}_{k:z_{\cdot,k}^{(T)}=0}$;
- 14: let $K_T = \sum_k \delta(x_{\cdot,k}^{(T)} > 0)$ and update \mathbf{r} ;
- 15: **end if**
- 16: **end for**
- 17: Output the posterior means (according to the last MCMC sample) of all remaining factors $\{\phi_k^{(t)}\}_{k,t}$ as the inferred network of T layers, and $\{r_k\}_{k=1}^{K_T}$ as the gamma shape parameters of layer T 's hidden units.
- 18: **end for**

Algorithm 2 The upward-downward Gibbs samplers for the Ber-GBN and PRG-GBN are constructed by using Lines 1-8 shown below to substitute Lines 4-11 of the PGBN Gibbs sampler shown in Algorithm 1.

- 1: Sample $\{x_{vj}^{(1)}\}_{v,j}$ using (33) for binary observations; Sample $\{x_{vj}^{(1)}\}_{v,j}$ using (34) and sample a_j using (35) for nonnegative real observations;
- 2: **for** $t = 1, 2, \dots, T$ **do**
- 3: Sample $\{x_{vjk}^{(t)}\}_{v,j,k}$; Sample $\{\phi_k^{(t)}\}_k$; Sample $\{x_{vj}^{(t+1)}\}_{v,j}$;
- 4: **end for**
- 5: Sample $p_j^{(2)}$ and Calculate $c_j^{(2)}$; Sample $\{c_j^{(t)}\}_{j,t}$ and Calculate $\{p_j^{(t)}\}_{j,t}$ for $t = 3, \dots, T+1$;
- 6: **for** $t = T, T-1, \dots, 1$ **do**
- 7: Sample \mathbf{r} if $t = T$; Sample $\{\theta_j^{(t)}\}_j$;
- 8: **end for**

Abstract

We propose a simple framework for estimating derivatives without fitting the regression function in nonparametric regression. Unlike most existing methods that use the symmetric difference quotients, our method is constructed as a linear combination of observations. It is hence very flexible and applicable to both interior and boundary points, including most existing methods as special cases of ours. Within this framework, we define the variance-minimizing estimators for any order derivative of the regression function with a fixed bias-reduction level. For the equidistant design, we derive the asymptotic variance and bias of these estimators. We also show that our new method will, for the first time, achieve the asymptotically optimal convergence rate for difference-based estimators. Finally, we provide an effective criterion for selection of tuning parameters and demonstrate the usefulness of the proposed method through extensive simulation studies of the first- and second-order derivative estimators.

Keywords: Linear combination, Nonparametric derivative estimation, Nonparametric regression, Optimal sequence, Taylor expansion

1. Introduction

Consider the following nonparametric regression model:

$$Y_i = m(x_i) + \varepsilon_i, \quad 1 \leq i \leq n, \quad (1)$$

where x_i are the design points satisfying $0 \leq x_1 < \dots < x_n \leq 1$, $m(x)$ is the regression function, Y_i are the observations, and ε_i are independent and identically distributed random errors with $E(\varepsilon_i) = 0$ and $\text{var}(\varepsilon_i) = \sigma^2 < \infty$. Estimation of $m(x)$ is an important problem in nonparametric regression and has received sustained attention in the literature. Such

methods include, for example, kernel smoothing (Härdle, 1990), spline smoothing (Wahba, 1990), and local polynomial regression (Fan and Gijbels, 1996). It has been noted that the estimation of the first- or higher-order derivatives of $m(x)$ is also important for practical implementations including, but not limited to, the modeling of human growth data (Ramsay and Silverman, 2002), kidney function for a lupus nephritis patient (Ramsay, 2006), and Raman spectra of bulk materials (Charnigo et al., 2011). Derivative estimation is also needed in nonparametric regression to construct confidence intervals for regression functions (Eubank and Speckman, 1993), to select kernel bandwidths (Ruppert et al., 1995), and to compare regression curves (Park and Kang, 2008).

Most existing methods for p th-order derivative estimation can be expressed as a weighted average of the responses,

$$\hat{m}^{(p)}(x) = \sum_{i=1}^n w_i(x) Y_i,$$

where $w_i(x)$ are weights assigned to each observation Y_i . These estimators can be separated into two classes by their ability to directly or indirectly assess the weights, $w_i(x)$. In the indirect methods, the regression function is initially estimated as $\hat{m}(x) = \sum_{i=1}^n c_i(x) Y_i$ by the aforementioned nonparametric smoothing techniques, where $c_i(x)$ are smooth functions. Then, $w_i(x)$ are estimated as $d^p c_i(x)/dx^p$ (Gasser and Müller, 1984; Müller et al., 1987; Fan and Gijbels, 1995; Zhou and Wolfe, 2000; Boente and Rodriguez, 2006; Cao, 2014). We note, however, that the optimal bandwidths may differ for estimating the regression function and for estimating the derivatives, respectively. That is, a good estimate of the regression function may not guarantee the generation of good estimates of the derivatives.

Direct methods lead to the second class, which estimate the derivatives directly without fitting the regression function. The two key steps for such methods are constructing point-wise estimates for the derivatives of each design point and determining the amount of smoothing or the bandwidth. To select the bandwidth, one may refer to some classical methods in Müller et al. (1987), Härdle (1990), Fan and Gijbels (1996), Opsomer et al. (2001), Lahiri (2003), and Kim et al. (2009), among others. In contrast, little attention has been paid to the improvement of the point-wise estimation of the derivatives. One simple point-wise estimator for derivatives uses difference quotients. This method is, however, very noisy. For example, the variance of the first-order difference quotient $(Y_i - Y_{i-1})/(x_i - x_{i-1})$ is of order $O(n^2)$. Charnigo et al. (2011) proposed a variance-reducing linear combination of symmetric difference quotients, called *empirical derivatives*, and applied it to their generalized C_p criterion for tuning parameter selection. De Brabauter et al. (2013) established the L_1 and L_2 convergence rates for the empirical derivatives. Specifically, they defined the empirical derivatives as

$$Y_i^{(L)} = \sum_{j=1}^{k_L} w_{j,L} \left(\frac{Y_{i+j}^{(L-1)} - Y_{i-j}^{(L-1)}}{x_{i+j} - x_{i-j}} \right), \quad L = 1, \dots, p,$$

where $Y_i^{(L)}$ denotes the estimated L th-order derivative at x_i , $Y_i^{(0)} = Y_i$ and $w_{j,L}$ are the associated weights. When $L = 1$, $w_{j,1}$ are chosen as the optimal weights that minimize the estimation variance. For $L \geq 2$, $w_{j,L}$ are determined intuitively instead of by optimizing the estimation variance. As a consequence, their higher-order empirical derivatives may not

be optimally defined. Another attempt was made recently by Wang and Lin (2015). They estimated the derivative as the intercept of a linear regression model through the weighted least squares method. They further showed that their proposed estimators achieve better control of the estimation bias, which makes them superior to empirical derivatives when the signal-to-noise ratio is large. Finally, it is noteworthy that their method only applies to equidistant designs and hence the practical applications are somewhat limited.

In this paper, we propose a simple framework for estimating derivatives in model (1) without fitting the regression function. Our method does not rely on symmetric difference quotients; hence, it is more flexible than existing methods. Within this framework, we define the variance-minimizing estimators for any order derivative of $m(x)$ with a fixed bias-reduction level. For the equidistant design, we derive the asymptotic variance and bias of these estimators. We also show that the proposed estimators perform well on both interior and boundary points and, more importantly, that they achieve the optimal convergence rate for the mean squared error (MSE).

The rest of this paper is organized as follows. In Section 2, we propose a new framework for first-order derivative estimation and show that most existing estimators are special cases of ours. We also investigate the theoretical properties of the proposed estimator, including the optimal sequence, the asymptotic variance and bias, the point-wise consistency, and the boundary behavior. In Section 3, we extend the proposed method to higher-order derivative estimation and provide an effective criterion for the selection of tuning parameters. We then report extensive simulation studies in Section 4 that validate the proposed method. We conclude the paper with a discussion in Section 5. Technical proofs of the theoretical results are given in the Appendix.

2. First-order derivative estimation

In this section, we propose a new framework for estimating derivatives in nonparametric regression. Within this framework, we define the optimal estimator for the first-order derivative by minimizing the estimation variance. Theoretical results including the asymptotic variance and bias, and point-wise consistency are derived for the proposed optimal estimators under the equidistant design. We also investigate the performance of the estimators on the boundaries.

2.1 New framework

Recall that most existing methods are weighted average of symmetric difference quotients, which limits their implementation to some extent. All these estimators can be expressed as a linear combination of the observations for fixed design points. To proceed, we define

$$DY_i = \sum_{k=0}^r d_k Y_{i+k}, \quad 1 \leq i \leq n-r,$$

where (d_0, \dots, d_r) is a sequence of real numbers, and r is referred to as the order of the sequence. Assuming that $m(x)$ is a smooth enough function, we have the following Taylor

expansion at x_{i+l} for each $m(x_{i+k})$,

$$m(x_{i+k}) = m(x_{i+l}) + \sum_{j=1}^{\infty} \frac{(x_{i+k} - x_{i+l})^j}{j!} m^{(j)}(x_{i+l}), \quad 0 \leq l \leq r.$$

Note that x_{i+l} can be any design point within $[x_i, x_{i+r}]$, which frees our method from the symmetric form restriction. If we further assume that x_i are equidistant, then $x_i = i/n$, $i = 1, \dots, n$. Define $C_{j,l} = \sum_{k=0}^r d_k (k-l)^j / (n^j j!)$, $j = 0, 1, \dots$ and $l = 0, \dots, r$. The expectation of DY_i can be expressed as

$$E(DY_i) = \sum_{j=0}^{\infty} C_{j,l} m^{(j)}(x_{i+l}), \quad 1 \leq i \leq n-r. \quad (2)$$

To estimate the first-order derivative at x_{i+l} with DY_i , we let $C_{0,l} = 0$ and $C_{1,l} = 1$ so that

$$E(DY_i) = m'(x_{i+l}) + \sum_{j=2}^{\infty} C_{j,l} m^{(j)}(x_{i+l}),$$

where the second term on the right side is the estimation bias. When the regression function is oscillating around x_{i+l} , we can alter our model by controlling the estimation bias at a higher level. Specifically, if we let

$$C_{1,l} = 1 \text{ and } C_{j,l} = 0, \quad 0 \leq j \neq 1 \leq q-1, \quad (3)$$

then

$$E(DY_i) = m'(x_{i+l}) + \sum_{j=q}^{\infty} C_{j,l} m^{(j)}(x_{i+l}).$$

When $q = 2$, condition (3) reduces to $C_{1,l} = 1$ and $C_{0,l} = 0$. When $q \geq 3$, condition (3) eliminates the estimation bias up to order $q-1$.

2.2 Theoretical results

If we use a sequence with an order $r \geq q$, an infinite number of choices satisfying (3) is available. Among them, we choose the one(s) minimizing the estimation variance, $\text{var}(DY_i) = \sigma^2 \sum_{k=0}^r d_k^2$, which leads to the following optimization problem,

$$(d_0, \dots, d_r)_{1,q} = \underset{(d_0, \dots, d_r) \in \mathbb{R}^{r+1}}{\text{argmin}} \sum_{k=0}^r d_k^2, \quad \text{s.t.} \quad \text{condition (3) holds.}$$

We denote this variance-minimizing sequence as $(d_0, \dots, d_r)_{1,q}$. For simplicity of notation, the dependence of d_k on l is suppressed. In addition, we introduce the following notation:

$$I_i^{(l)} = \sum_{k=0}^r (k-l)^i, \quad l = 0, \dots, r \quad \text{and} \quad i = 0, 1, \dots;$$

$$U^{(l)} \text{ denotes a } q \times q \text{ matrix with } u_{ij}^{(l)} = I_{i+j-2}^{(l)};$$

$V^{(l)} = (U^{(l)})^{-1}$ is the inverse matrix of $U^{(l)}$.

Then, we present the theoretical results for $(d_0, \dots, d_r)_{1,q}$ in the following proposition.

Proposition 1 *Assume that model (1) holds with equidistant design and $m(x)$ has a finite q th-order derivative on $[0, 1]$. For $1 \leq i \leq n - r$ and $0 \leq l \leq r$, the unique variance-minimizing sequence is*

$$(d_k)_{1,q} = n \sum_{j=0}^{q-1} V_{(j+1,2)}^{(l)} (k-l)^j, \quad k = 0, \dots, r,$$

for estimating $m^{(l)}(x_{i+l})$ with an order of accuracy up to $m^{(q)}(x_{i+l})$, $q \geq 2$. Here, $V_{(i,d)}^{(l)}$ denotes the element in the i th row and the j th column of the matrix $V^{(l)}$. *Proof: see Appendix A.*

When q is fixed, the optimal sequence depends only on l , which makes it quite convenient for practical implementation. When r is even and $l = r/2$, we get the symmetric form used in De Brabanter et al. (2013) and Wang and Lin (2015). For this case, it is easy to verify that $d_k = -d_{r-k}$, which eliminates all the even-order derivatives in (2). The sequence is derived for the equidistant design on $[0, 1]$. To extend the result to equidistant designs on an arbitrary interval, $[a, b] \subset \mathbb{R}$, we can simply use $d_k/(b-a)$ instead. We treat the DY_i built on $(d_0, \dots, d_r)_{1,q}$ as the estimator for the first-order derivative with a bias-reduction level of q , denoted by $\hat{m}'_q(x_{i+l})$.

Theorem 1 *Assume that model (1) holds with equidistant design, $m(x)$ has a finite q th-order derivative on $[0, 1]$ and $r = o(n)$, $r \rightarrow \infty$. For $1 \leq i \leq n - r$ and $0 \leq l \leq r$, we have*

$$\begin{aligned} \text{var}[\hat{m}'_q(x_{i+l})] &= n^2 V_{(2,2)}^{(l)} \sigma^2 = O\left(\frac{n^2}{r^3}\right), \\ \text{bias}[\hat{m}'_q(x_{i+l})] &= \frac{1}{q! n^{q-1}} \sum_{j=0}^{q-1} V_{(j+1,2)}^{(l)} m^{(j)}(x_{i+l}) + o\left(\frac{r^{q-1}}{n^{q-1}}\right). \end{aligned}$$

Proof: see Appendix B.

For a larger q , the order of estimation bias is indeed reduced as expected, and the estimation variance surprisingly retains the same order at the same time. Assuming $r = n^\lambda$ and $2/3 < \lambda < 1$, we can establish the point-wise consistency of our estimator, $\hat{m}'_q(x_{i+l}) \xrightarrow{P} m'(x_{i+l})$, where " \xrightarrow{P} " means convergence in probability.

Corollary 1 *Assume that the conditions in Theorem 1 hold. When r is even and $l = r/2$,*

$$\hat{m}'_{2v}(x_{i+r/2}) = \hat{m}'_{2v+1}(x_{i+r/2}), \quad v = 1, 2, \dots, \left\lfloor \frac{q-1}{2} \right\rfloor,$$

where $\lfloor x \rfloor$ denotes the greatest integer less than or equal to x .

This means that, when we employ a symmetric form for our estimator, the optimal sequence is the same for $q = 2v$ and $q = 2v + 1$. In other words, the symmetric form further reduces the order of estimation bias without any increase in the estimation variance. Hence, it is natural to use the symmetric form (r is even and $l = r/2$) for the interior points, $\{x_i : 1 + r/2 \leq i \leq n - r/2\}$, when the design points are equidistant. Also, we can show that the two existing estimators for the first-order derivative (De Brabanter et al., 2013; Wang and Lin, 2015) are special cases of our method.

When $q = 2$ or $q = 3$, we get the same sequence as

$$(d_k)_{1,2} = (d_k)_{1,3} = \frac{6n(2k-r)}{r(r+1)(r+2)}, \quad k = 0, \dots, r.$$

This results in the empirical estimator in De Brabanter et al. (2013), denoted by \hat{m}'_{emp} . Assuming the regression function has a finite third-order derivative on $[0, 1]$, the estimation variance and bias are respectively

$$\text{var}[\hat{m}'_2(x_{i+r/2})] = \frac{12n^2\sigma^2}{r(r+1)(r+2)} \quad \text{and} \quad \text{bias}[\hat{m}'_2(x_{i+r/2})] = \frac{r^2}{40n^2} m^{(3)}(x_{i+r/2}) + o\left(\frac{r^2}{n^2}\right).$$

When $q = 4$ or $q = 5$, we get the same sequence as

$$(d_k)_{1,4} = (d_k)_{1,5} = \frac{n \left[I_6^{(r/2)}(k - \frac{r}{2}) - I_4^{(r/2)}(k - \frac{r}{2}) \right]}{I_2^{(r/2)} I_6^{(r/2)} - I_4^{(r/2)^2}}, \quad k = 0, \dots, r.$$

This results in the least squares estimator in Wang and Lin (2015), denoted by \hat{m}'_{lsq} . Within our framework, it is clear that the least squares estimator can be regarded as a bias-reduction modification of the empirical estimator.

Figure 1 presents an example of $\hat{m}'_q(x_i)$ with different levels of control for the estimation bias ($q = 3, 5$ and 7). We follow the regression function $m(x) = \sqrt{x(1-x)} \cdot \sin[2.1\pi/(x+0.05)]$ for model (1) from De Brabanter et al. (2013) and Wang and Lin (2015). Five hundred design points are equidistant on $[0.25, 1]$ and the random errors are generated from a Gaussian distribution, $N(0, 0.1^2)$. Sequence orders are chosen as $\{50, 100\}$. We observe that the estimation curves are smoother for smaller q , and the bias in oscillating areas decreases significantly for larger q . These results are consistent with our theoretical results. With various levels of bias control, we may achieve a better compromise in the trade-off between the estimation variance and bias.

2.3 Behavior on the boundaries

If we use a sequence with order r , then the boundary region will be $\{x_i : 1 \leq i \leq \lfloor r/2 \rfloor$ or $n - \lfloor r/2 \rfloor + 1 \leq i \leq n\}$. Within our framework, we have two types of estimators for estimating derivatives for the boundary area. One choice is to use a sequence with smaller order, so that we can still use the symmetric estimator as suggested for the interior points. This solution is also suggested by both De Brabanter et al. (2013) and Wang and Lin (2015). The other is to hold the sequence order while using an asymmetric form of the estimator instead.

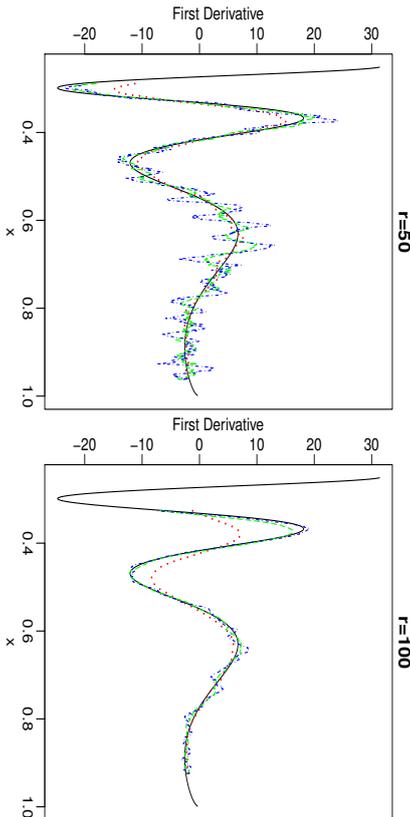

Figure 1: First-order derivative estimates with different levels of bias reduction. Red lines (dotted): $q = 3$; green lines (long dash): $q = 5$; blue lines (dot dash): $q = 7$ and black lines (solid): the true first-order derivative.

For the symmetric estimator, we can choose an even-order t satisfying $1 \leq t/2 \leq \min(i-1, n-i, \lceil r/2 \rceil)$. By Theorem 1, we have

$$\text{var}[\hat{m}'_q(x_i)] = O\left(\frac{n^2}{j^3}\right) \quad \text{and} \quad \text{bias}[\hat{m}'_q(x_i)] = O\left(\frac{t^{q-1}}{n^{q-1}}\right),$$

for $2 \leq i \leq \lceil r/2 \rceil$ or $n - \lceil r/2 \rceil + 1 \leq i \leq n - 1$. The closer x_i locates to the endpoints, the smaller the largest order of the chosen sequence, which means that the information we can incorporate into the estimator becomes very limited. As a consequence, the estimation variance will eventually reach an order of $O(n^2)$, which is rather noisy.

The asymmetric estimator does not require the estimated point to be located at the middle of the interval. We can still use a relatively large sequence order to include as much information as included in the interior points. The theoretical results were provided in Theorem 1:

$$\text{var}[\hat{m}'_q(x_i)] = O\left(\frac{n^2}{r^3}\right) \quad \text{and} \quad \text{bias}[\hat{m}'_q(x_i)] = O\left(\frac{r^{q-1}}{n^{q-1}}\right).$$

With a proper choice of r , we can still get a consistent estimate for the derivatives at the boundary region. Another advantage of this asymmetric form is that it is applicable to all the boundary points including x_1 and x_n , which can never be handled by the symmetric-form estimators.

It is noteworthy that Wang and Lin (2015) also proposed left-side and right-side weighted least squares estimators for the boundary points. Their estimators are, however, two special

cases of our asymmetric estimator with $q = 2$ and $l = 0$ (right-side) or $l = r$ (left-side). The estimation bias for $\hat{m}'_2(x_{i+l})$ is

$$\text{bias}[\hat{m}'_2(x_{i+l})] = \frac{r-2l}{2n} m''(x_{i+l}) + o\left(\frac{r}{n}\right).$$

To minimize the estimation bias on these boundary points, we recommend the following criterion:

$$\hat{m}'_2(x_i) = \begin{cases} DX_1 & 1 \leq i \leq \lceil r/2 \rceil, \\ DY_{n-r} & n - \lceil r/2 \rceil + 1 \leq i \leq n. \end{cases}$$

Then, the smallest absolute estimation bias can be simply derived as

$$|E[\hat{m}'_2(x_i)] - m'(x_i)| = \frac{r - 2\min(i-1, n-i)}{2n} |m''(x_i)| + o\left(\frac{r}{n}\right).$$

In summary, the asymmetric estimator generates a smaller variance, while its estimation bias is of a higher order. Consequently, the sequence order should be selected to achieve the best trade-off between the estimation variance and bias. In view of this, we recommend using the asymmetric estimator when the regression function is flat at the boundary region or when σ^2 is large; otherwise, the symmetric form should be employed.

3. Higher-order derivative estimation

In this section, we extend our method and propose higher-order derivative estimators for model (1). We further demonstrate that the new estimators possess the optimal estimation variance, which is not achieved by the two aforementioned methods (De Brabanter et al., 2013; Wang and Lin, 2015). Our new estimators also achieve the optimal convergence rate for MSE.

3.1. Theoretical results

To define an estimator for $m^{(p)}(x_{i+l})$ with a bias-reduction level up to $m^{(q)}(x_{i+l})$, we construct the new conditions on the coefficients as

$$C_{p,l} = 1 \quad \text{and} \quad C_{j,l} = 0, \quad 0 \leq j \neq p \leq q-1. \quad (4)$$

Then, the optimal sequence can be derived as the solution(s) of the following optimization problem:

$$(d_0, \dots, d_r)_{p,q} = \underset{(d_0, \dots, d_r) \in \mathbb{R}^{r+1}}{\text{argmin}} \sum_{k=0}^r d_k^2, \quad \text{s.t.} \quad \text{condition (4) holds.}$$

We present the result for $(d_0, \dots, d_r)_{p,q}$ in the following proposition.

Proposition 2 Assume that model (1) holds with equidistant design and $m(x)$ has a finite q th-order derivative on $[0, 1]$. For $1 \leq i \leq n-r$ and $0 \leq l \leq r$, the unique variance minimizing sequence is

$$(d_k)_{p,q} = p!r^p \sum_{j=0}^{q-1} V_{(j+1-p+l)}^{(0)} (k-j)^j, \quad k = 0, \dots, r,$$

for estimating $m^{(p)}(x_{i+t})$ with an order of accuracy up to $m^{(q)}(x_{i+t})$, $q \geq p + 1$.
Proof: see Appendix C.

To extend the result to equidistant designs on an arbitrary interval, $[a, b] \subset \mathbb{R}$, we can simply use $(d_k)_{p,q}/(b-a)^p$ instead. We treat the DY_i built on $(d_0, \dots, d_r)_{p,q}$ as the estimator for the p th-order derivative with a bias-reduction level up to $m^{(q)}(x_{i+t})$, denoted as $\hat{m}_q^{(p)}(x_{i+t})$.

Theorem 2 Assume that model (1) holds with equidistant design, $m(x)$ has a finite q th-order derivative on $[0, 1]$ and $r = o(n)$, $\tau \rightarrow \infty$. For $1 \leq i \leq n - r$ and $0 \leq l \leq r$, we have

$$\begin{aligned} \text{var}[\hat{m}_q^{(p)}(x_{i+t})] &= (p!)^2 n^{2p} V_{(p+1, p+1)}^{(l)} \sigma^2 = O\left(\frac{n^{2p}}{r^{2p+1}}\right), \\ \text{bias}[\hat{m}_q^{(p)}(x_{i+t})] &= \frac{p!}{q! n^{q-p}} \sum_{j=0}^{q-1} V_{(j+1, p+1)}^{(l)} I_{j+q}^{(l)} m^{(q)}(x_{i+t}) + o\left(\frac{r^{q-p}}{n^{q-p}}\right). \end{aligned}$$

Proof: see Appendix D.

For a fixed p and an increasing q , we can reduce the estimation bias to a lower order while keeping the order of variance unchanged. Whenever we keep the difference between q and p constant, the convergence rate of the bias is preserved for different p . When r is an even number and $l = r/2$, we can derive that $(d_k)_{p,q} = (-1)^p (d_{n-k})_{p,q}$. Consequently in this case, the optimal sequence remains the same when we increase q from $p + 2\nu - 1$ to $p + 2\nu$, $\nu = 1, 2, \dots$, which means $\hat{m}_{p+2\nu-1}^{(p)}(x_{i+r/2}) = \hat{m}_{p+2\nu}^{(p)}(x_{i+r/2})$. Hence, for this kind of estimator, the symmetric form is also the most favorable choice for the interior points.

The optimal MSE of our estimator is of order $O(n^{-2(q-p)/(2q+1)})$, which achieves the asymptotically optimal rate established by Stone (1980). For comparison, we note that the optimal MSE of the empirical estimator in De Brabanter et al. (2013) is of order $O(n^{-4/(2p+5)})$, that is, their estimator is of the optimal order only when $q = p + 2$. While for the least squares estimator in Wang and Lin (2015), they provided asymptotic results only for the first- and second-order derivative estimator. Their optimal MSE is of order $O(n^{-8/11})$ for $p = 1$ and $O(n^{-8/13})$ for $p = 2$, which corresponds with two special cases, i.e., when $(p, q) = (1, 5)$ or $(2, 6)$. From this point of view, our method has greatly improved the literature in derivative estimation and it achieves the optimal rate of MSE for any (p, q) from Theorem 2.

As mentioned at the beginning of this section, the newly defined estimator is optimal for the estimation variance, which is superior to existing estimators. In what follows, we illustrate this advantage in detail with the second-order derivative estimator, which is usually of greatest interest after the first-order derivative in practice. A similar analysis can be made for other higher-order derivative estimators. For the estimator without bias-control, e.g. \hat{m}_4'' , we derive the following results:

$$\begin{aligned} \text{var}[\hat{m}_4''(x_{i+r/2})] &= \frac{4n^4 \sigma^2 I_0^{(r/2)}}{I_0^{(r/2)} I_4^{(r/2)} - I_2^{(r/2)^2}}, \\ \text{bias}[\hat{m}_4''(x_{i+r/2})] &= \frac{r^2}{14n^2} m^{(4)}(x_{i+r/2}) + o\left(\frac{r^2}{n^2}\right). \end{aligned}$$

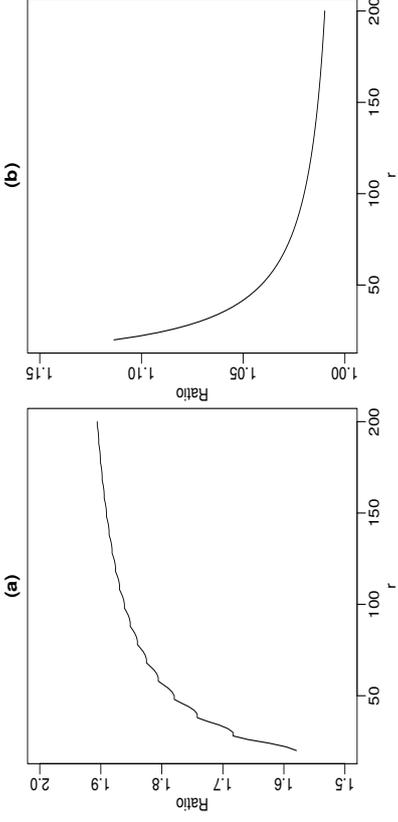

Figure 2: The ratio of estimation variance is plotted against the sequence order, r . Setting: $n = 500$ and r is chosen as an even integer ranging from 20 to 200. (a), $\text{var}(\hat{m}_{\text{emp}}''/\text{var}(\hat{m}_4''))$; (b), $\text{var}(\hat{m}_{\text{isc}}''/\text{var}(\hat{m}_6''))$.

The corresponding method is \hat{m}_{emp}'' in De Brabanter et al. (2013) with regard to the accurate level. Instead of minimizing the estimation variance, they intuitively choose the weight sequences for higher-order derivative estimators, which makes it quite difficult to derive analytical asymptotic results. Hence, we make a finite sample comparison of the variance of the two estimators. We set $n = 500$ and calculate the corresponding sequences for \hat{m}_4'' with an even order r ranging from 20 to 200 and $l = r/2$. For \hat{m}_{emp}'' , we choose (k_1, k_2) , which achieves the smallest estimation variance from $\{(k_1, k_2) : k_1 \leq k_2, k_1 + k_2 = r/2\}$. We do not need a specified form of the regression function, since it is not related with the estimation variance. We illustrate the ratio, $\text{var}(\hat{m}_{\text{emp}}''/\text{var}(\hat{m}_4''))$, in the left panel of Figure 2. Obviously, the new estimator improves the estimation variance significantly, which results in a smaller MSE for smooth regression functions.

A similar comparison is carried out between \hat{m}_{isc}'' and \hat{m}_6'' under the same settings, and the ratio of $\text{var}(\hat{m}_{\text{isc}}''/\text{var}(\hat{m}_6''))$ is presented in the right panel of Figure 2. Wang and Lin (2015) built a linear model with correlated regressors but employed the weighted least squares regression, rather than the generalized least squares technique, to derive the estimator. It can be shown that our method is equivalent with the generalized least squares estimator for their model. As expected, we find that our proposed estimator performs slightly better in terms of the finite sample than the least squares estimator. In addition their asymptotic variances and biases are equivalent for the first-order term. For the boundary points, our second-order estimator also maintains the same advantages over the existing estimators as discussed in Section 2.2 for the first-order estimators.

3.2 Tuning parameter selection

As shown in Figure 1, the order, r , and the bias-reduction level, q , are both critical to the proposed estimators. For practical implementation, (r, q) should be chosen to achieve a better trade-off between the estimation variance and bias.

By Theorem 2, the approximated MSE of $\hat{m}_q^{(p)}(x_{i+h})$ is

$$\text{MSE}[\hat{m}_q^{(p)}(x_{i+h})] \simeq (p!)^2 n^{-2p} V_{(p+1, p+1)}^{(l)} \sigma^2 + \left[\frac{p!}{q! n^{q-p}} \sum_{j=0}^{q-1} V_{(j+1, p+1)}^{(l)} J_{j+q}^{(l)} m^{(q)}(x_{i+h}) \right]^2.$$

We define the averaged mean squared error (AMSE) as a measure of the goodness of fit for all the design points,

$$\text{AMSE}(\hat{m}_q^{(p)}) = \frac{1}{n} \sum_{i=1}^n \text{MSE}[\hat{m}_q^{(p)}(x_i)].$$

A uniform sequence is preferred for the estimate at most points (all the interior points for example) over different sequences for each design point. Hence, we can choose the parameters (r, q) minimizing the AMSE. To achieve this, we replace the unknown quantities, σ^2 and $m^{(q)}(x_{i+h})$, with their consistent estimates. The error variance can be estimated by the method in Tong and Wang (2005) and Tong et al. (2013) and $m^{(q)}(x_i)$ can be estimated by the local polynomial regression of order $q+2$. For the high-order derivatives at the boundary points, we recommend replacing the AMSE for all the points with the following adjusted form:

$$\text{AMSE}_{\text{adj}}(\hat{m}_q^{(p)}) = \frac{1}{n-r} \sum_{i=1+r}^{n-r} \text{MSE}[\hat{m}_q^{(p)}(x_i)] \simeq B_1 \sigma^2 + \frac{B_2}{n-r} \sum_{i=1+r}^{n-r} [m^{(q)}(x_i)]^2, \quad (5)$$

where $B_1 = (p!)^2 n^{2p} V_{(p+1, p+1)}^{(r/2)}$ and $B_2 = \left[\frac{p!}{q! n^{q-p}} \sum_{j=0}^{q-1} V_{(j+1, p+1)}^{(r/2)} J_{j+q}^{(r/2)} \right]^2$. Given all the parameters for a specific problem, B_1 and B_2 are available quantities. The adjusted AMSE includes only derivatives at the interior points that share the identical difference sequence for an even r and $l = r/2$. Another advantage is that we only need $V^{(r/2)}$ and $J_{j+q}^{(r/2)}$ instead of $V^{(l)}$ and $J_{j+q}^{(l)}$ for $l = 0, \dots, r$, which greatly reduces the computation time.

For the tuning parameter space of the sequence order, we recommend $r \in O = \{2l : 1 \leq l \leq k_0\}$, where $k_0 \leq \lfloor n/4 \rfloor$, to keep a symmetric form ($l = r/2$) for the interior points and to make sure that the number of boundary points will be less than that of the interior points. For the bias-reduction level of $\hat{m}_q^{(p)}$, we consider $q \in Q = \{p+2\nu : \nu = 1, 2, \dots, \nu_0\}$, where $p+2\nu_0$ is the highest level chosen by users. Only even differences are considered for $q-p$, since $\hat{m}_{p+2\nu_0-1}^{(p)} = \hat{m}_{p+2\nu_0}^{(p)}$ when we use the recommended symmetric form.

4. Simulation study

In this section, we conduct simulation studies to assess the finite sample performance of the proposed estimators, $\hat{m}_q^{(p)}$, and make comparisons with the empirical estimator, $\hat{m}_{\text{emp}}^{(p)}$.

in De Brabanter et al. (2013) and the least squares estimator, $\hat{m}_{\text{lse}}^{(p)}$, in Wang and Lin (2015). We apply the three methods to both interior (Int) and boundary (Bd) areas, where $\text{Int} = \{x_i : k_0 + 1 \leq i \leq n - k_0\}$ and $\text{Bd} = \{x_i : 1 \leq i \leq k_0 \text{ or } n - k_0 + 1 \leq i \leq n\}$. Throughout the simulation, we set $k_0 = \lfloor n/10 \rfloor$, which means that we treat ten percent of the design points on both sides of the interval as boundary points. We also tried some other proportions and the results were similar. For the interior part, we keep the symmetric form for $\hat{m}_q^{(p)}$ by setting r as an even number and $l = r/2$, as suggested in the theoretical results. For the boundary part, we apply the following criterion for the proposed estimators:

$$\hat{m}_q^{(p)}(x_i) = \begin{cases} DY_1 & 1 \leq i \leq \lfloor r/2 \rfloor, \\ DY_{n-r} & n - \lfloor r/2 \rfloor + 1 \leq i \leq n. \end{cases}$$

The modified version of $\hat{m}_{\text{emp}}^{(p)}$ in De Brabanter et al. (2013) and the one-side weighted least squares estimators in Wang and Lin (2015) are investigated for the empirical and least squares estimators, respectively on the boundary points. We consider estimators for both first- and second-order derivatives, which are of most interest in practice. Similar to De Brabanter et al. (2013) and Wang and Lin (2015), the mean absolute error (MAE) is used as a measure of estimation accuracy. It is defined as follows:

$$\text{MAE} = \frac{1}{\#\mathbb{A}} \sum_{x_i \in \mathbb{A}} |\hat{m}_q^{(p)}(x_i) - m^{(p)}(x_i)|,$$

where $\mathbb{A} = \text{Int}$ or Bd and $\#\mathbb{A}$ denotes the number of elements in set \mathbb{A} .

We consider the following regression function,

$$m(x) = 5 \sin(w\pi x),$$

with $\omega = 1, 2, 4$ corresponding to different levels of oscillations. The $n = 100$ and 500 sample sizes are investigated. We set the design points as $x_i = i/n$ and generate the random errors, ε_i , independently from $N(0, \sigma^2)$. For each regression function, we consider $\sigma = 0.1, 0.5$ and 2 to capture the small, moderate and large variances, respectively. In total, we have 18 combinations of simulation settings. Following the definitions of Int and Bd, we select the sequence order r from $\mathbb{O} = \{2l : 1 \leq l \leq k_0\}$. We choose the bias-reduction level, q , from $\mathbb{Q} = \{p+2, p+4, p+6\}$, with $q = p+2$ and $q = p+4$ corresponding to $\hat{m}_{\text{emp}}^{(p)}$ and $\hat{m}_{\text{lse}}^{(p)}$, respectively, and $q = p+6$ as an even higher level. We denote by $\hat{m}_{\text{opt}}^{(p)}$ the estimator with the selected tuning parameters. For $\hat{m}_{\text{emp}}^{(p)}$ and $\hat{m}_{\text{lse}}^{(p)}$, the parameter k is chosen from $\{l : 1 \leq l \leq k_0\}$. We investigate two scenarios (for the tuning parameters selection criterion): *oracle* and *plug-in* (see below). For each run of the simulation, we compute the MAE of the estimators at both Int and Bd and repeat the procedure 1000 times for each setting. The simulation results for $w = 2$ are reported as box-plot figures. Other results are provided in the supplementary materials.

Oracle parameters

Oracle parameters are selected by assuming that we know the true regression (derivative) function, the purpose of which is to illustrate the possible best performance of each

estimator. Specifically for $\hat{m}_q^{(p)}$, the pair of tuning parameters is chosen as

$$(\tau, q)_{\text{opt}} = \underset{\tau \in \bar{\mathbb{O}}, q \in \mathbb{Q}}{\operatorname{argmin}} \left(\operatorname{MAE}(\hat{m}_q^{(p)}) \right).$$

The bandwidths of $\hat{m}_{\text{emp}}^{(p)}$ and $\hat{m}_{\text{lse}}^{(p)}$ are selected through a similar procedure.

For the first-order derivative, we investigate \hat{m}'_{opt} , \hat{m}'_{emp} and \hat{m}'_{lse} and report the simulation results in Figure 3. On the interior points, \hat{m}'_{opt} always possesses the same MAE as the smaller one of \hat{m}'_{emp} and \hat{m}'_{lse} , due to the fact that \hat{m}'_{emp} and \hat{m}'_{lse} are two special cases of \hat{m}'_q in this area. On the boundary points, \hat{m}'_{opt} is uniformly better than the other two methods. To further explore the reason for the boundary behavior, we use an example from De Brabanter et al. (2013) and Wang and Lin (2015). The fitted results for the three estimators are illustrated in Figure 4, where the red points represent the boundary parts. The empirical estimator suffers a lot from the increasing variance when the estimated points get close to the endpoints of the interval. The least squares estimator simply estimates the boundary parts by shifting the estimates of the interior points nearby, which results in very serious estimation bias. Our estimator fits the boundary points very well, resulting from the flexibility brought by the parameter l , the relative location of the estimated point within the interval $[x_i, x_{i+r}]$.

For the second-order derivative, we include another two estimators, \hat{m}''_4 and \hat{m}''_6 , which have the same bias-reduction level as \hat{m}''_{emp} and \hat{m}''_{lse} , respectively. The sequence order, τ , of the two additional estimators is optimally chosen by minimizing MAE, as well. The simulation results are presented in Figure 5. The relationships between \hat{m}''_{opt} , \hat{m}''_{emp} and \hat{m}''_{lse} remain the same as those observed for the first-order derivative. We also observe that $\operatorname{MAE}(\hat{m}''_4)$ is significantly smaller than $\operatorname{MAE}(\hat{m}''_{\text{emp}})$ and that $\operatorname{MAE}(\hat{m}''_6)$ is almost the same as $\operatorname{MAE}(\hat{m}''_{\text{lse}})$, consistent with our theoretical results in Section 3.

Plug-in parameters

Plug-in parameters are chosen via minimizing the adjusted AMSE in (5) after replacing all the unknown quantities with their consistent estimates. In this simulation, we estimate σ^2 using Tong and Wang's (2005) method with the recommended bandwidth $[n^{1/3}]$. Here, $\hat{m}^{(q)}(x_i)$ ($1 + k_0 \leq i \leq n - k_0$) are calculated with the function *locpol* in the R package *locpol* (Ojeda Cabrera, 2012) with the parameter *deg* = $q + 2$. The bandwidths of $\hat{m}_{\text{emp}}^{(p)}$ and $\hat{m}_{\text{lse}}^{(p)}$ are selected accordingly.

We report the simulation results together with those for the oracle parameters in Figures 6 and 7. From the comparison, we observe that the plug-in parameters lead to quite similar results with those for the oracle parameters, especially on the interior points. Since the tuning parameters are selected based on AMSE of derivative estimates for the interior points, the performance on the boundary is not consistent. Nevertheless, the mutual relationship of the three estimators remains the same for most cases on both interior and boundary points. Overall, the proposed plug-in method is quite effective for choosing the optimal tuning parameters.

In summary, we have demonstrated the superiority of the proposed estimators over the existing estimators through extensive simulation studies. We have further provided an effective criterion for selection of the tuning parameters for the newly defined estimator.

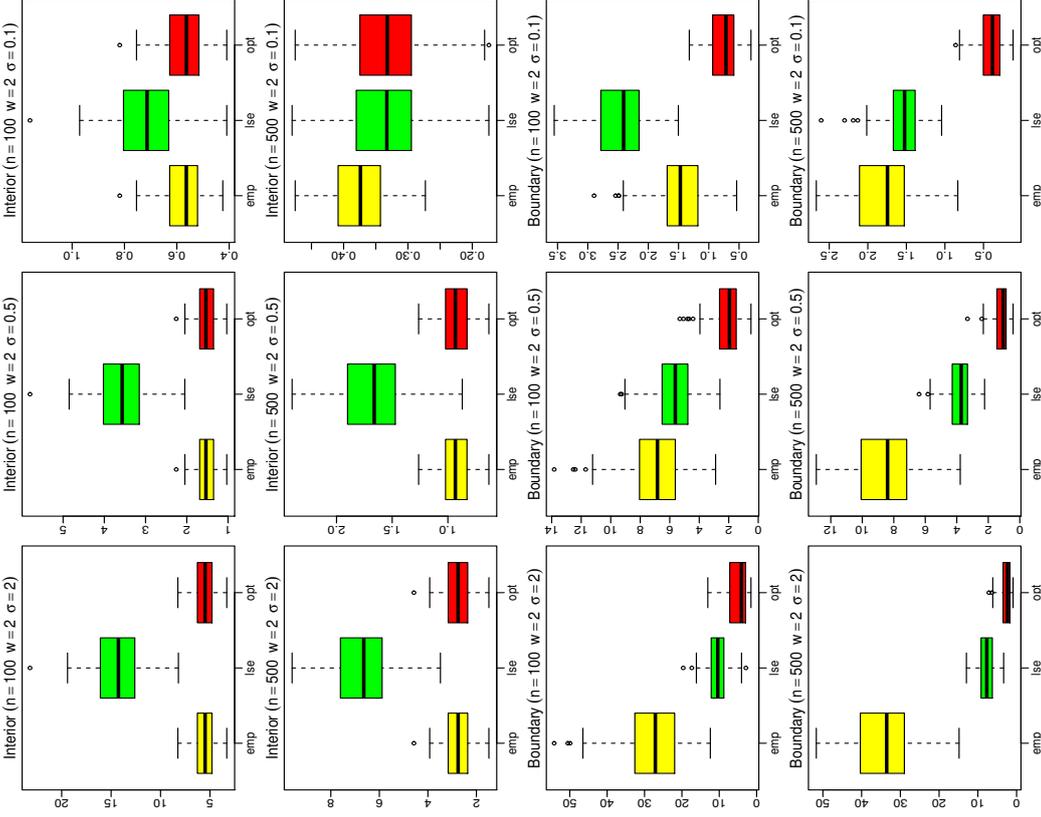

Figure 3: Mean absolute errors of three first-order derivative estimators on both interior (2 top rows) and boundary (2 bottom rows) points for various settings. \hat{m}'_{emp} , yellow box; \hat{m}'_{lse} , green box; \hat{m}'_{opt} , red box. $m(x) = 5 \sin(2\pi x)$ and $\varepsilon \sim N(0, \sigma^2)$.

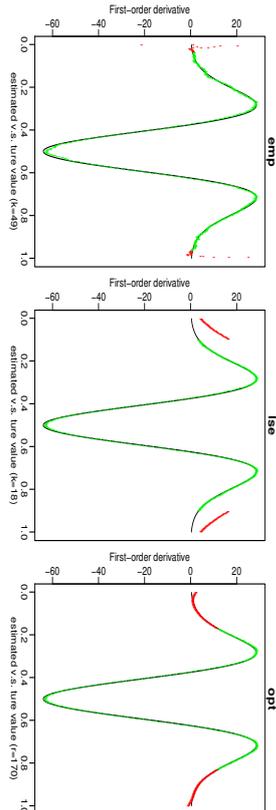

Figure 4: The fitted point-wise derivatives by the three estimators using oracle tuning parameters. $m(x) = 32e^{-8(1-2x)^2(1-2x)}$, ε_i are independent random errors from $N(0, 0.1^2)$ and $n = 500$. Interior points: green points. Boundary points: red points.

5. Conclusion

We proposed a new framework for estimating derivatives without fitting the regression function. Unlike most existing methods using the symmetric difference quotients, our method is constructed as a linear combination of the observations. It is hence very flexible and applicable to both interior and boundary points. We obtained the variance-minimizing estimators for the first- and higher-order derivatives with a fixed bias-reduction level. Under the equidistant design, we derived some theoretical results for the proposed estimators including the optimal sequence, asymptotic variance and bias, point-wise consistency, and boundary behavior. We illustrated that the order of the estimation bias can be reduced while the order of variance remains unchanged. We showed that our method achieves the optimal convergence rate for the MSE. Furthermore, we provided an effective selection procedure for the tuning parameters of the proposed estimators. Simulation studies for the first- and second-order derivative estimators demonstrated the superiority of our proposed method.

The method can be readily extended to unequally spaced designs. In this case, the symmetric form is no longer valid and the choice of l also deserves further consideration. To estimate the point-wise derivatives for unequally spaced designs, we can first find the r nearest neighbors of the estimated point and construct the variance-minimizing estimator with the linear combination of the $r + 1$ points, say $x_i < \dots < x_{i+l} < \dots < x_{i+r}$. Assuming that $m(x)$ is smooth enough and that x_{i+l} is the estimated point, we have the expectation of DY_i as

$$E(DY_i) = m(x_{i+l}) \sum_{k=0}^r d_k + \sum_{j=1}^{\infty} m^{(j)}(x_{i+l}) \sum_{k=0}^r d_k (x_{i+l+k} - x_{i+l})^j / j!$$

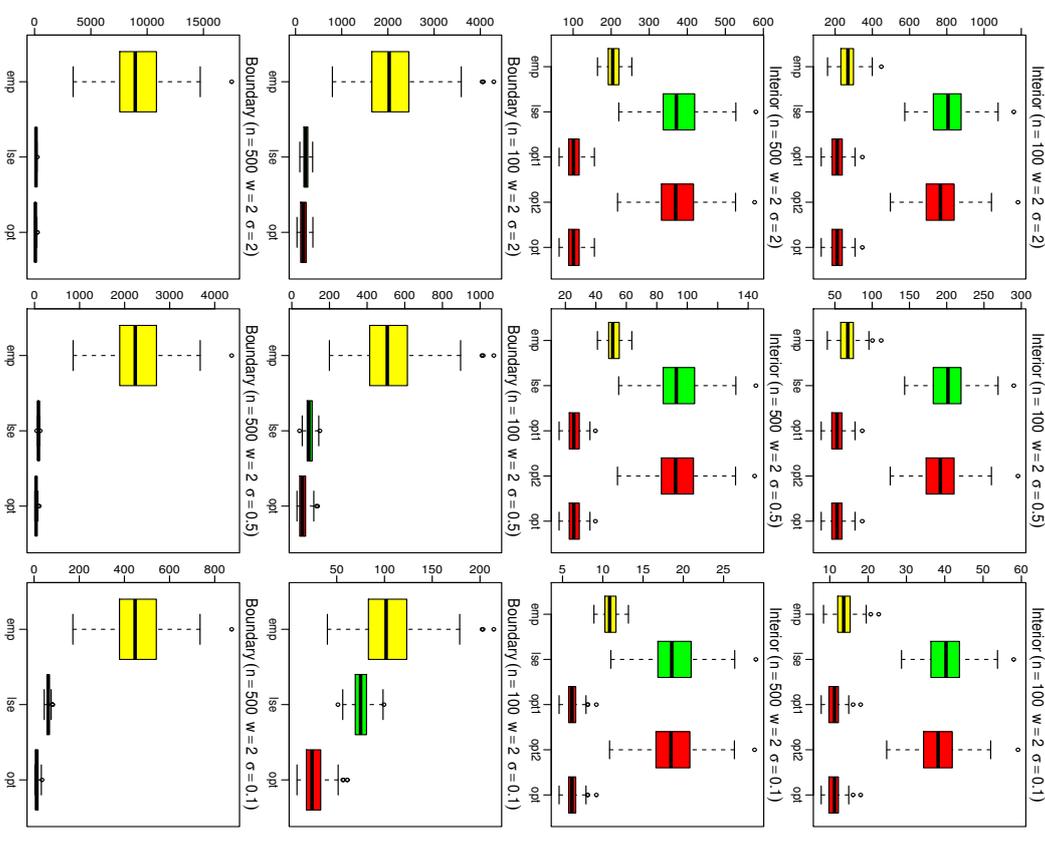

Figure 5: Mean absolute errors of three second-order derivative estimators on both interior (2 top rows) and boundary (2 bottom rows) points for various settings. \hat{m}_{emp}' , yellow box; \hat{m}_{ise}' , green box; \hat{m}_{opt}' , red box. opt1: \hat{m}_{opt}' ; opt2: \hat{m}_{opt}'' ; opt: \hat{m}_{opt}''' . $m(x) = 5 \sin(2\pi x)$ and $\varepsilon \sim N(0, \sigma^2)$.

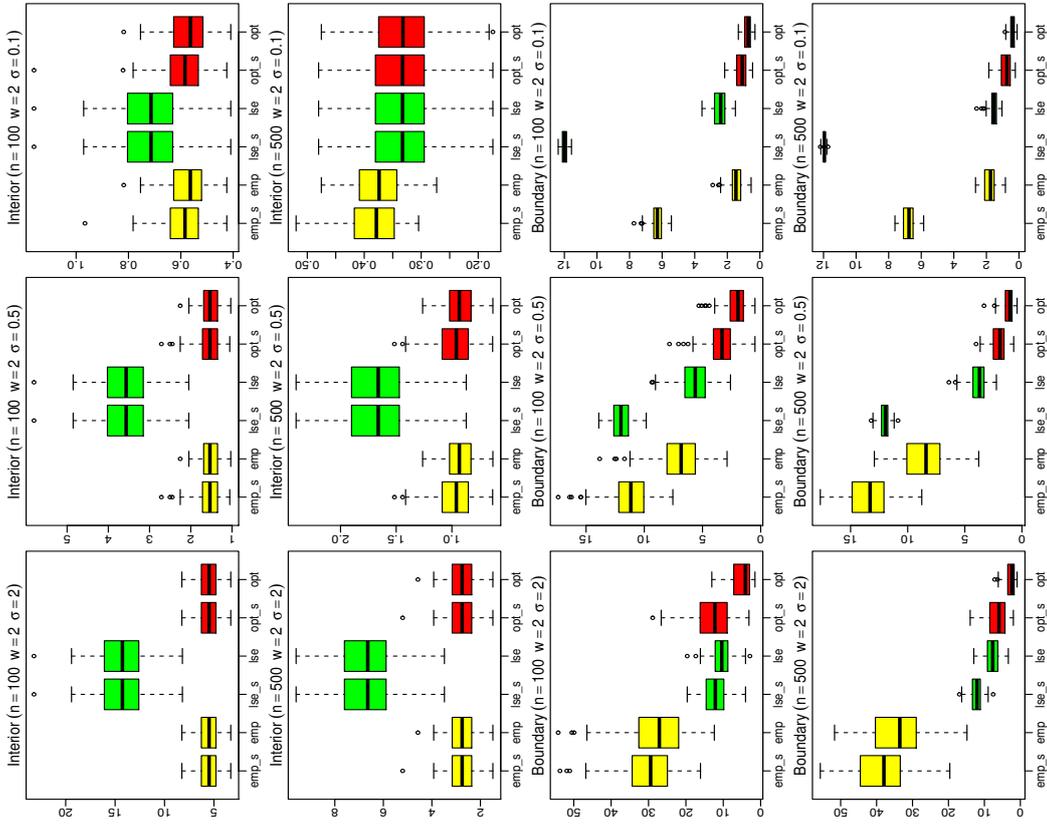

Figure 6: Comparison of the mean absolute errors on both interior (2 top rows) and boundary (2 bottom rows) points between the first-order derivative estimators with oracle tuning parameters and those with plug-in tuning parameters. \hat{m}'_{emp} , yellow box; \hat{m}'_{lse} , green box; \hat{m}'_{opt} , red box. “ s ” denotes estimators using plug-in parameters. $m(x) = 5 \sin(2\pi x)$ and $\varepsilon \sim N(0, \sigma^2)$.

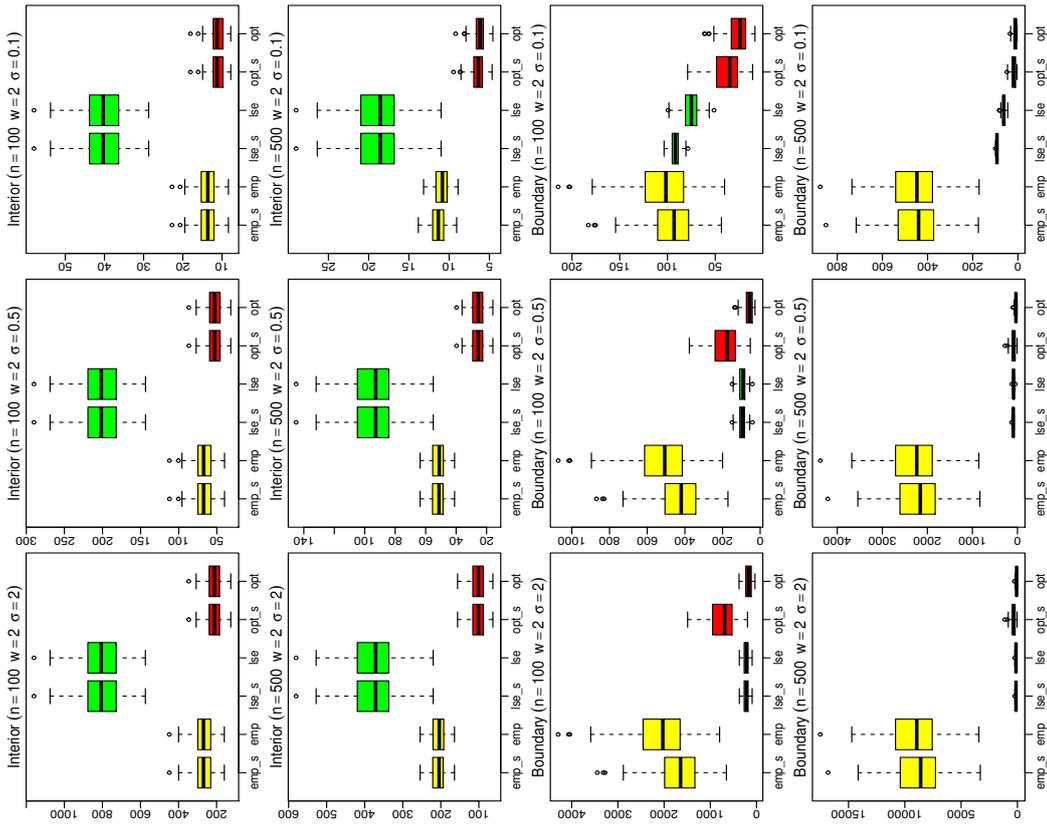

Figure 7: Comparison of the mean absolute errors on both interior (2 top rows) and boundary (2 bottom rows) points between the second-order derivative estimators with oracle tuning parameters and those with plug-in tuning parameters. \hat{m}''_{emp} , yellow box; \hat{m}''_{lse} , green box; \hat{m}''_{opt} , red box. “ s ” denotes estimators using plug-in parameters. $m(x) = 5 \sin(2\pi x)$ and $\varepsilon \sim N(0, \sigma^2)$.

The optimal sequence for estimating $m^{(p)}(x_{i+l})$ with a bias-reduction level q can be decided by solving the following optimization problem:

$$\begin{aligned} (d_0, \dots, d_r)_{pq} = & \underset{(d_0, \dots, d_r) \in \mathbb{R}^{r+1}}{\operatorname{argmin}} \sum_{k=0}^r d_k^2, \\ \text{s.t. } \sum_{k=0}^r d_k \frac{(x_{i+k} - x_{i+l})^j}{j!} = 0, \quad j = 0, \dots, p-1, p+1, \dots, q-1, \quad \sum_{k=0}^r d_k \frac{(x_{i+k} - x_{i+l})^p}{p!} = 1. \end{aligned}$$

The optimal difference sequences are adaptively chosen for each estimated point and they are no longer identical for all the interior design points. As a result, the parameter selection becomes more challenging and we leave this for future research. Finally, other models worthy of investigation include, for example, random design models (De Brabanter and Liu, 2015) and multivariate models (Charrigo et al., 2015; Charrigo and Srinivasan, 2015).

Appendix A. Proof of Proposition 1

To find the optimal sequence for estimating the first-order derivative with q th-order accuracy, we solve the following optimization problem:

$$(d_0, \dots, d_r)_{1q} = \underset{(d_0, \dots, d_r) \in \mathbb{R}^{r+1}}{\operatorname{argmin}} \sum_{k=0}^r d_k^2, \quad \text{s.t.} \quad \text{condition (3) holds.}$$

It is easy to check that condition (3) is equivalent to

$$\sum_{k=0}^r d_k(k-l) = n \quad \text{and} \quad \sum_{k=0}^r d_k(k-l)^j = 0, \quad 0 \leq j \neq 1 \leq q-1.$$

To apply the Lagrange multipliers method to find the optimal sequence, we transform the above problem in the following unconstrained optimization problem:

$$f(d_0, \dots, d_r, \lambda_0, \dots, \lambda_{q-1}) = \sum_{k=0}^r d_k^2 + \lambda_0 C_0 + \sum_{j=2}^{q-1} \lambda_j \sum_{k=0}^r d_k(k-l)^j + \lambda_1 \left[\sum_{k=0}^r d_k(k-l) - n \right].$$

Taking the partial derivative of f with respect to each parameter and setting it to zero, we have

$$\begin{aligned} \frac{\partial f}{\partial d_k} &= 2d_k + \lambda_0 + \sum_{j=1}^{q-1} \lambda_j (k-l)^j = 0, \quad k = 0, \dots, r, \\ \frac{\partial f}{\partial \lambda_j} &= \sum_{k=0}^r d_k (k-l)^j = 0, \quad 0 \leq j \neq 1 \leq q-1, \\ \frac{\partial f}{\partial \lambda_1} &= \sum_{k=0}^r d_k (k-l) = n. \end{aligned} \tag{6}$$

We further make the following transformation:

$$\begin{aligned} \sum_{k=0}^r (k-l)^i \frac{\partial f}{\partial d_k} &= 2 \sum_{k=0}^r d_k (k-l)^i + \lambda_0 \sum_{k=0}^r (k-l)^i + \sum_{j=1}^{q-1} \lambda_j \sum_{k=0}^r (k-l)^{i+j} \\ &= I_i^{(l)} \lambda_0 + \sum_{j=1}^{q-1} I_{i+j}^{(l)} \lambda_j = 0, \quad 0 \leq i \neq 1 \leq q-1. \\ \sum_{k=0}^r (k-l) \frac{\partial f}{\partial d_k} &= 2 \sum_{k=0}^r d_k (k-l) + \lambda_0 \sum_{k=0}^r (k-l) + \sum_{j=1}^{q-1} \lambda_j \sum_{k=0}^r (k-l)^{1+j} \\ &= 2n + I_1^{(l)} \lambda_0 + \sum_{j=1}^{q-1} I_{1+j}^{(l)} \lambda_j = 0, \end{aligned}$$

where $I_i^{(l)} = \sum_{k=0}^r (k-l)^i$ for $i = 1, 2, \dots$.

These results can be expressed as a matrix equation,

$$U^{(l)}(\lambda_0, \dots, \lambda_{q-1})' = -2ne_2,$$

where $U^{(l)}$ is a $q \times q$ matrix with $u_{ij}^{(l)} = I_{i+j-2}^{(l)}$ and e_2 is a $q \times 1$ vector with the second element equal to 1 and the others equal to zero. Noting that $U^{(l)}$ is an invertible matrix, we have

$$(\lambda_0, \dots, \lambda_{q-1})' = -2nV_{(:,2)}^{(l)},$$

where $V^{(l)} = (U^{(l)})^{-1}$ and $V_{(:,2)}^{(l)}$ denotes the second column of $V^{(l)}$. This leads to $\lambda_j = -2pl_n V_{(j+1,2)}^{(l)}$ for $j = 0, \dots, q-1$. Combining this result with (6), we get

$$(d_k)_{1,q} = n \sum_{j=0}^{q-1} V_{(j+1,2)}^{(l)} (k-l)^j, \quad k = 0, \dots, r.$$

This completes the proof of Proposition 1. \square

Appendix B. Proof of Theorem 1

We can easily derive that

$$\begin{aligned} \text{var}[\hat{m}'_q(x_{i+t})] &= \sigma^2 \sum_{k=0}^r d_k^2 = \sigma^2 \sum_{k=0}^r d_k \left[\sum_{j=0}^{q-1} n V_{(j+1,2)}^{(l)}(k-l)^j \right] \\ &= \sigma^2 n \sum_{j=0}^{q-1} V_{(j+1,2)}^{(l)} \sum_{k=0}^r d_k (k-l)^j = \sigma^2 n V_{(2,2)}^{(l)} \sum_{k=0}^r d_k (k-l) \\ &= \sigma^2 n^2 V_{(2,2)}^{(l)}, \\ \text{bias}[\hat{m}'_q(x_{i+t})] &= C_{q,l} m^{(q)}(x_{i+t}) + o(r^{q-1}/n^{q-1}), \end{aligned}$$

where

$$\begin{aligned} C_{q,l} &= \sum_{k=0}^r d_k \frac{(k-l)^q}{n^q q!} = \frac{n}{q! n^q} \sum_{k=0}^r \left[\sum_{j=0}^{q-1} V_{(j+1,2)}^{(l)}(k-l)^j \right] (k-l)^q \\ &= \frac{1}{q! n^{q-1}} \sum_{j=0}^{q-1} V_{(j+1,2)}^{(l)} I_{j+q}^{(l)} = O(r^{q-1}/n^{q-1}). \end{aligned}$$

This completes the proof of Theorem 1. \square

Appendix C. Proof of Proposition 2

To find the optimal sequence for estimating the p th-order derivative with q th-order accuracy, we solve the following optimization problem:

$$(d_0, \dots, d_r)_{p,q} = \underset{(d_0, \dots, d_r) \in \mathbb{R}^{r+1}}{\text{argmin}} \sum_{k=0}^r d_k^2, \quad \text{s.t.} \quad \text{condition (4) holds.}$$

It is easy to check that condition (4) is equivalent to

$$\sum_{k=0}^r d_k (k-l)^p = p! n^p \quad \text{and} \quad \sum_{k=0}^r d_k (k-l)^j = 0, \quad 0 \leq j \neq p \leq q-1.$$

To apply the Lagrange multipliers method to find the optimal sequence, we transform the above problem in the following unconstrained optimization problem:

$$\begin{aligned} f(d_0, \dots, d_r, \lambda_0, \dots, \lambda_{q-1}) &= \sum_{k=0}^r d_k^2 + \lambda_0 C_0 + \left(\sum_{j=1}^{p-1} + \sum_{j=p+1}^{q-1} \right) \lambda_j \sum_{k=0}^r d_k (k-l)^j \\ &\quad + \lambda_p \left[\sum_{k=0}^r d_k (k-l)^p - p! n^p \right]. \end{aligned}$$

Taking the partial derivative of f with respect to each parameter and setting it to zero, we have

$$\begin{aligned} \frac{\partial f}{\partial d_k} &= 2d_k + \lambda_0 + \sum_{j=1}^{q-1} \lambda_j (k-l)^j = 0, \quad k = 0, \dots, r, \\ \frac{\partial f}{\partial \lambda_j} &= \sum_{k=0}^r d_k (k-l)^j = 0, \quad 0 \leq j \neq p \leq q-1, \\ \frac{\partial f}{\partial \lambda_p} &= \sum_{k=0}^r d_k (k-l)^p = p! n^p. \end{aligned} \quad (7)$$

We further make the following transformation:

$$\begin{aligned} \sum_{k=0}^r (k-l)^i \frac{\partial f}{\partial d_k} &= 2 \sum_{k=0}^r d_k (k-l)^i + \lambda_0 \sum_{k=0}^r (k-l)^i + \sum_{j=1}^r \lambda_j \sum_{k=0}^r (k-l)^{i+j} \\ &= I_i^{(l)} \lambda_0 + \sum_{j=1}^{q-1} I_{i+j}^{(l)} \lambda_j = 0, \quad 0 \leq i \neq p \leq q-1. \\ \sum_{k=0}^r (k-l)^p \frac{\partial f}{\partial d_k} &= 2 \sum_{k=0}^r d_k (k-l)^p + \lambda_0 \sum_{k=0}^r (k-l)^p + \sum_{j=1}^r \lambda_j \sum_{k=0}^r (k-l)^{p+j} \\ &= 2p! n^p + I_p^{(l)} \lambda_0 + \sum_{j=1}^{q-1} I_{p+j}^{(l)} \lambda_j = 0, \end{aligned}$$

where $I_i^{(l)} = \sum_{k=0}^r (k-l)^i$ for $i = 1, 2, \dots$.

These results can be expressed as a matrix equation,

$$U^{(l)}(\lambda_0, \dots, \lambda_{q-1})' = -2p! n^p \epsilon_{p+1},$$

where $U^{(l)}$ is a $q \times q$ matrix with $u_{ij}^{(l)} = I_{i+j-2}^{(l)}$ and ϵ_{p+1} is a $q \times 1$ vector with the $(p+1)$ th element equal to 1 and the others equal to zero. Noting that $U^{(l)}$ is an invertible matrix, we have

$$(\lambda_0, \dots, \lambda_{q-1})' = -2p! n^p V_{(-,p+1)}^{(l)},$$

where $V^{(l)} = (U^{(l)})^{-1}$ and $V_{(-,p+1)}^{(l)}$ denotes the $(p+1)$ th column of $V^{(l)}$. This leads to $\lambda_j = -2p! n^p V_{(j+1,p+1)}^{(l)}$ for $j = 0, \dots, q-1$. Combining this result with (7), we get

$$(d_k)_{p,q} = p! n^p \sum_{j=0}^{q-1} V_{(j+1,p+1)}^{(l)} (k-l)^j, \quad k = 0, \dots, r.$$

This completes the proof of Proposition 2. \square

Appendix D. Proof of Theorem 2

We can easily derive that

$$\begin{aligned} \text{var}[\hat{m}_q^{(p)}(x_{i+1})] &= \sigma^2 \sum_{k=0}^r d_k^2 = \sigma^2 \sum_{k=0}^r d_k \left[\sum_{j=0}^{q-1} p!n^p V_{(j+1,p+1)}^{(l)}(k-l)^j \right] \\ &= \sigma^2 p!n^p \sum_{j=0}^{q-1} V_{(j+1,p+1)}^{(l)} \sum_{k=0}^r d_k (k-l)^j = \sigma^2 p!n^p V_{(p+1,p+1)}^{(l)} \sum_{k=0}^r d_k (k-l)^p \\ &= \sigma^2 (p!)^2 n^{2p} V_{(p+1,p+1)}^{(l)}, \\ \text{bias}[\hat{m}_q^{(p)}(x_{i+1})] &= C_{q,l} m^{(q)}(x_{i+1}) + o(r^{q-p}/n^{q-p}), \end{aligned}$$

where

$$\begin{aligned} C_{q,l} &= \sum_{k=0}^r d_k \frac{(k-l)^q}{n^q q!} = \frac{p!n^p}{q!n^q} \sum_{k=0}^r \left[\sum_{j=0}^{q-1} V_{(j+1,p+1)}^{(l)}(k-l)^j \right] (k-l)^q \\ &= \frac{p!}{q!n^{q-p}} \sum_{j=0}^{q-1} V_{(j+1,p+1)}^{(l)} I_{j+q}^{(l)} = O(r^{q-p}/n^{q-p}). \end{aligned}$$

This completes the proof of Theorem 2. \square

Abstract

Crowdsourcing has gained immense popularity in machine learning applications for obtaining large amounts of labeled data. Crowdsourcing is cheap and fast, but suffers from the problem of low-quality data. To address this fundamental challenge in crowdsourcing, we propose a simple payment mechanism to incentivize workers to answer only the questions that they are sure of and skip the rest. We show that surprisingly, under a mild and natural “no-free-lunch” requirement, this mechanism is the one and only incentive-compatible payment mechanism possible. We also show that among all possible incentive-compatible mechanisms (that may or may not satisfy no-free-lunch), our mechanism makes the smallest possible payment to spammers. We further extend our results to a more general setting in which workers are required to provide a quantized confidence for each question. Interestingly, this unique mechanism takes a “multiplicative” form. The simplicity of the mechanism is an added benefit. In preliminary experiments involving over 900 worker-task pairs, we observe a significant drop in the error rates under this unique mechanism for the same or lower monetary expenditure.

Keywords: high-quality labels, supervised learning, crowdsourcing, mechanism design, proper scoring rules

1. Introduction

Complex machine learning tools such as deep learning are gaining increasing popularity and are being applied to a wide variety of problems. These tools require large amounts of labeled data (Hinton et al., 2012; Raykar et al., 2010; Deng et al., 2009; Carlson et al., 2010). These large labeling tasks are being performed by coordinating crowds of semi-skilled workers through the Internet. This is known as crowdsourcing. Generating large labeled data sets through crowdsourcing is inexpensive and fast as compared to employing experts. Furthermore, given the current platforms for crowdsourcing such as Amazon Mechanical Turk and many others, the initial overhead of setting up a crowdsourcing task is minimal. Crowdsourcing as a means of collecting labeled training data has now become indispensable to the engineering of intelligent systems. The crowdsourcing of labels is also often used to supplement automated algorithms, to perform the tasks that are too difficult

to accomplish by machines alone (Khatib et al., 2011; Lang and Rio-Ross, 2011; Bernstein et al., 2010; Von Ahn et al., 2008; Franklin et al., 2011).

Most workers in crowdsourcing are not experts. As a consequence, labels obtained from crowdsourcing typically have a significant amount of error (Kazai et al., 2011; Vuurens et al., 2011; Wais et al., 2010). It is not surprising that there is significant emphasis on having higher quality labeled data for machine learning algorithms, since a higher amount of noise implies requirement of more labels for obtaining the same accuracy in practice. Moreover, several algorithms and settings are not very tolerant of data that is noisy (Long and Servidio, 2010; Hanneke and Yang, 2010; Manwani and Sastry, 2013; Baldrige and Palmer, 2009); for instance, Long and Servidio (2010) conclude that “a range of different types of boosting algorithms that optimize a convex potential function satisfying mild conditions cannot tolerate random classification noise.” Recent efforts have focused on developing statistical techniques to post-process the noisy labels in order to improve its quality (e.g., Raykar et al., 2010; Zhou et al., 2012; Chen et al., 2013; Dawid and Skene, 1979; Karger et al., 2011; Liu et al., 2012; Zhang et al., 2014; Ipeitotis et al., 2014; Zhou et al., 2015; Khetan and Oh, 2016; Shah et al., 2016c). However, when the inputs to these algorithms are highly erroneous, it is difficult to guarantee that the processed labels will be reliable enough for subsequent use by machine learning or other applications. In order to avoid “garbage in, garbage out”, we take a complementary approach to this problem: cleaning the data at the time of collection.

We consider crowdsourcing settings where the workers are paid for their services, such as in the popular crowdsourcing platforms of Amazon Mechanical Turk (mturk.com), Crowdflower (crowdflower.com) and other commercial platforms, as well as internal crowdsourcing platforms of companies such as Google, Facebook and Microsoft. These commercial platforms have gained substantial popularity due to their support for a diverse range of tasks for machine learning labeling, varying from image annotation and text recognition to speech captioning and machine translation. We consider problems that are objective in nature, that is, have a definite answer. Figure 1a depicts an example of such a question where the worker is shown a set of images, and for each image, the worker is required to identify if the image depicts the Golden Gate Bridge.

Our approach builds on the simple insight that in typical crowdsourcing setups, workers are simply paid in proportion to the amount of tasks they complete. As a result, workers attempt to answer questions that they are not sure of, thereby increasing the error rate of the labels. For the questions that a worker is not sure of, her answers could be very unreliable (Wais et al., 2010; Kazai et al., 2011; Vuurens et al., 2011; Jagabathula et al., 2014). To ensure acquisition of only high-quality labels, we wish to encourage the worker to skip the questions about which she is unsure, for instance, by providing an explicit “I’m not sure” option for every question (see Figure 1b). Given this additional option, one must also ensure that the worker is indeed incentivized to skip the questions that she is not confident about. In a more general form, we consider eliciting the confidence of the worker for each question at multiple levels. For instance, in addition to “I’m not sure”, we may also provide options like “absolutely sure”, and “moderately sure” (see Figure 1c). The goal is to design payment mechanisms that incentivize the worker to attempt only those questions for which they are confident enough, or alternatively, report their confidences truthfully. As we will see later, this significantly improves the aggregate quality of the labels that are input to the machine learning algorithms. We will term any payment mechanism that incentivizes the worker to do so as “incentive compatible”.

In addition to incentive compatibility, preventing spammers is another desirable requirement from incentive mechanisms in crowdsourcing. Spammers are workers who answer randomly with-

<p>a Is this the Golden Gate Bridge?</p>  <p><input type="radio"/> Yes <input type="radio"/> No</p>	<p>b Is this the Golden Gate Bridge?</p>  <p><input type="radio"/> Yes <input type="radio"/> No <input type="radio"/> I'm not sure</p>
<p>c Is this the Golden Gate Bridge?</p>  <p><input type="radio"/> Yes <input type="radio"/> Moderately sure <input type="radio"/> Absolutely sure <input type="radio"/> No <input type="radio"/> Moderately sure <input type="radio"/> Absolutely sure <input type="radio"/> I'm not sure</p>	

Figure 1: Different interfaces for a task that requires the worker to answer the question “Is this the Golden Gate Bridge?”: (a) the conventional interface; (b) with an option to skip; (c) with multiple confidence levels.

out regard to the question being asked, in the hope of earning some free money, and are known to exist in large numbers on crowdsourcing platforms (Wais et al., 2010; Bohannon, 2011; Kazai et al., 2011; Vuurens et al., 2011). The presence of spammers can significantly affect the performance of any machine learning algorithm that is trained on this data. It is thus of interest to deter spammers by paying them as low as possible. An intuitive objective, to this end, is to ensure a minimum possible payment to spammers who answer randomly. For instance, in a task with binary-choice questions, a spammer is expected to have half of the attempted answers incorrect; one may thus wish to set the payment to its minimum possible value if half or more of the attempted answers are wrong. In this paper, however, we impose *strictly and significantly weaker requirement*, and then show that there is one and only one incentive-compatible mechanism that can satisfy this weak requirement. Our requirement is referred to as the “no-free-lunch” axiom. In the skip-based setting, it says that if *all* the questions attempted by the worker are answered incorrectly, then the payment must be the minimum possible. The no-free-lunch axiom for the general confidence-based setting is even weaker: if the worker indicates the highest confidence level for *all* the questions she attempts in the gold standard, and furthermore if all these responses are incorrect, then the payment must be the minimum possible. We term this condition the “no-free-lunch” axiom. In the general confidence-based setting, we want to make the minimum possible payment if the worker indicates the *highest confidence level* for *all* the questions she attempts *and* if *all* these responses are incorrect.

In order to test whether our mechanism is practically viable, and to assess the quality of the final labels obtained, we conducted experiments on the Amazon Mechanical Turk crowdsourcing platform. In our preliminary experiments that involved several hundred workers, we found that the quality of data consistently improved by use of our schemes as compared to the standard settings, often by two-fold or higher, with the total monetary expenditure being the same or lower as compared to the conventional baseline.

1.1 Summary of Contributions

We propose a payment mechanism for the aforementioned setting (“incentive compatibility” plus “no-free-lunch”), and show that surprisingly, this is the *only* possible mechanism. We also show that additionally, our mechanism makes the smallest possible payment to spammers among all possible incentive compatible mechanisms that may or may not satisfy the no-free-lunch axiom. Interestingly, our payment mechanism takes a multiplicative form: the evaluation of the worker’s response to each question is a certain score, and the final payment is a *product* of these scores. This mechanism has additional appealing features in that it is simple to compute, and is also simple to explain to the workers. Our mechanism is applicable to any type of objective questions, including multiple choice annotation questions, transcription tasks, etc. In preliminary experiments on Amazon Mechanical Turk involving over 900 worker-task pairs, the quality of data improved significantly under our unique mechanism, with the total monetary expenditure being the same or lower as compared to the conventional baseline.

1.2 Related Literature

The framework of “strictly proper scoring rules” (Brier, 1950; Savage, 1971; Gneiting and Raftery, 2007; Lambert and Shoham, 2009) provides a general theory for eliciting information for settings where this information can subsequently be verified by the mechanism designer, for example, by observing the true value some time in the future. In our work, this verification is performed *via* the presence of some “gold standard” questions in the task. Consequently, our mechanisms can also be called “strictly proper scoring rules”. It is important to note that the framework of strictly proper scoring rules, however, provides a large collection of possible mechanisms and does not guide the choice of a specific mechanism from this collection (Gneiting and Raftery, 2007). In this work, we show that for the crowdsourcing setups considered, under a very mild condition we term the “no-free-lunch” axiom, the mechanism proposed in this paper is the one and only strictly proper scoring rule.

Interestingly, proper scoring rules have another interesting connection with machine learning techniques: quoting Bija et al. (2005), “proper scoring rules comprise most loss functions currently in use: log-loss, squared error loss, boosting loss, and as limiting cases cost-weighted misclassification losses.” The present paper does not investigate this aspect of proper scoring rules, and we refer the reader to Biihmann and Hothorn (2007); Mease et al. (2007); Bija et al. (2005) for more details.

In this paper, we assume the existence of some gold standard questions whose answers are known a priori to the system designer. As a result, the payment to a worker is determined solely by her own work. There are settings where gold standard questions may not be available, for instance, when obtaining gold standard questions is too expensive, or when the questions pertain to subjective preferences (Shah and Wainwright, 2015; Shah et al., 2016b; Chen et al., 2016) instead of labeling data. A parallel line of literature (Miller et al., 2005; Dasgupta and Ghosh, 2013; Prelec, 2004; Wolfers and Zitzewitz, 2004; Conitzer, 2009) addresses such settings without gold standard questions. The idea in the mechanisms designed therein is to reward the agents based on certain criteria that compares certain elicited data from the agents with each other, and typically involves asking agents to predict other agents’ responses. The mechanisms designed often provide weaker guarantees (such as that of truth-telling being a Nash equilibrium) due to the absence of a gold standard answer to compare with. This line of literature includes work on peer-prediction (Miller

et al., 2005; Dasgupta and Ghosh, 2013), the Bayesian truth serum (Prelec, 2004) and prediction markets (Wolfers and Zitewitz, 2004; Conitzer, 2009).

The design of statistical inference algorithms for denoising the data obtained from workers is an active topic of research (Raykar et al., 2010; Zhou et al., 2012; Wauthier and Jordan, 2011; Chen et al., 2013; Khetan and Oh, 2016; Dawid and Skene, 1979; Karger et al., 2011; Liu et al., 2012; Zhang et al., 2014; Vempaty et al., 2014; Ipeirotis et al., 2014; Zhou et al., 2015; Shah et al., 2016c). In addition, several machine learning algorithms accommodating errors in the data have also been designed (Angluin and Laird, 1988; Cano et al., 2001; Lee et al., 2004; Chu et al., 2004). These algorithms are typically oblivious to the elicitation procedure. Our work nicely complements this line of research in that these inference algorithms may now additionally employ the higher quality data and the specific structure of the elicited data for an improved denoising efficiency.

Another relevant problem in crowdsourcing is that of choosing which workers to hire or efficiently matching workers to tasks, and such problems are studied in Yuen et al. (2011); Ho et al. (2013); Zhou et al. (2014); Anari et al. (2014) under different contexts. Our work assumes that a worker is already matched, and focuses on incentivizing that worker to respond in a certain manner. A recent line of work has focused on elicitation of data from multiple agents in order to perform certain specific estimation tasks (Fang et al., 2007; Dekel et al., 2008; Cai et al., 2015). In contrast, our goal is to ensure that workers censor their own low-quality (raw) data, without restricting our attention to any specific downstream algorithm or task.

1.3 Organization

The organization of this paper is as follows. We present the formal problem setting in Section 2. In Section 3 we consider the skip-based setting: We present our proposed mechanism and show that it is the only mechanism which satisfies the requirements discussed above. In Section 4, we then consider the more general setting of eliciting a quantized value of the worker’s confidence. We construct a mechanism for this setting, which also takes a multiplicative form, and prove its uniqueness. In Section 5 we prove that imposing a requirement that is only slightly stronger than our proposed no-free-lunch axiom leads to impossibility results. In Section 6 we present synthetic simulations and real-world experiments on Amazon Mechanical Turk to evaluate the potential of our setting and algorithm to work in practice. We conclude the paper with a discussion on the various modeling choices, future work, and concluding remarks in Section 7.

The paper contains three appendices. In Appendix A we prove all theoretical results whose proofs are not presented in the main text. We provide more details of the experiments in Appendix B. In Appendix C we extend our results to a setting where workers aim to maximize the expected value of some “utility” of their payments.

2. Setting and Notation

In the crowdsourcing setting that we consider, one or more workers perform a *task*, where a task consists of multiple *questions*. The questions are objective, by which we mean, each question has precisely one correct answer. Examples of objective questions include multiple-choice classification questions such as Figure 1, questions on transcribing text from audio or images, etc.

For any possible answer to any question, we define the worker’s *confidence about an answer* as the probability, according to her belief, of this answer being correct. In other words, one can assume that the worker has (in her mind) a probability distribution over all possible answers to a question,

and the confidence for an answer is the probability of that answer being correct. As a shorthand, we also define the *confidence about a question* as the confidence for the answer that the worker is most confident about for that question. We assume that the worker’s confidences for different questions are independent. Our goal is that for every question, the worker should be incentivized to skip if her confidence for that question is below a certain pre-defined threshold, otherwise select the answer that she is most confident about, and if asked, also indicate a correct (quantized) value of her confidence for the answer.

Specifically, we consider two settings:

- **Skip-based.** For each question, the worker can either choose to ‘skip’ the question or provide an answer (Figure 1b).
- **Confidence-based.** For each question, the worker can either ‘skip’ the question or provide an answer, and in the latter case, indicate her confidence for this answer as a number in $\{1, \dots, L\}$ (Figure 1c). We term this indicated confidence as the ‘confidence-level’. Here, L represents the highest confidence-level, and ‘skip’ is considered to be a confidence-level of 0.¹

One can see from the aforementioned definition that the confidence-based setting is a generalization of the skip-based setting (the skip-based setting corresponds to $L = 1$). The goal is to ensure that for a given set of intervals that partition $[0, 1]$, for every question the worker is incentivized to indicate ‘skip’ or choose the appropriate confidence-level when her confidence for that question falls in the corresponding interval. The choice of these intervals will be defined subsequently in the skip-based and confidence-based sections (Section 3 and Section 4) respectively.

Let N denote the total number of questions in the task. Among these questions, we assume the existence of some “gold standard” questions, that is, a set of questions whose answers are known to the requester. Let G ($1 \leq G \leq N$) denote the number of gold standard questions. The G gold standard questions are assumed to be distributed uniformly at random in the pool of N questions (of course, the worker does not know which G of the N questions form the gold standard). The payment to a worker for a task is computed after receiving her responses to all the questions in the task. The payment is based on the worker’s performance on the gold standard questions. Since the payment is based on known answers, the payments to different workers do not depend on each other, thereby allowing us to consider the presence of only one worker without any loss in generality.

We will employ the following standard notation. For any positive integer K , the set $\{1, \dots, K\}$ is denoted by $[K]$. The indicator function is denoted by $\mathbf{1}$, i.e., $\mathbf{1}\{z\} = 1$ if z is true, and 0 otherwise. Let x_1, \dots, x_G denote the evaluations of the answers that the worker gives to the G gold standard questions, and let f denote the scoring rule, i.e., a function that determines the payment to the worker based on these evaluations x_1, \dots, x_G .

In the skip-based setting, $x_i \in \{-1, 0, +1\}$ for all $i \in [G]$. Here, “0” denotes that the worker skipped the question, “-1” denotes that the worker attempted to answer the question and that answer was incorrect, and “+1” denotes that the worker attempted to answer the question and that answer was correct. The payment function is $f : \{-1, 0, +1\}^G \rightarrow \mathbb{R}$.

In the confidence-based setting, $x_i \in \{-L, \dots, +L\}$ for all $i \in [G]$. Here, we set $x_i = 0$ if the worker skipped the question, and for $l \in \{1, \dots, L\}$, we set $x_i = l$ if the question was answered

1. When the task is presented to the workers, the word ‘skip’ or the numbers $\{1, \dots, L\}$ are replaced by more comprehensible phrases such as “I don’t know”, “moderately sure”, “absolutely sure”, etc.

correctly with confidence l and $x_i = -l$ if the question was answered incorrectly with confidence l . The function $f : \{-L, \dots, +L\}^G \rightarrow \mathbb{R}$ specifies the payment to be made to the worker.

The payment is further associated to two parameters, μ_{\max} and μ_{\min} . The parameter μ_{\max} denotes the *budget*, i.e., the maximum amount that is paid to any individual worker for this task:

$$\max_{x_1, \dots, x_G} f(x_1, \dots, x_G) = \mu_{\max}.$$

The amount μ_{\max} is thus the amount of compensation paid to a perfect worker for her work. Further, one may often also have the requirement of paying a certain minimum amount to any worker. The parameter μ_{\min} ($\leq \mu_{\max}$) denotes this minimum payment: the payment function must also satisfy

$$\min_{x_1, \dots, x_G} f(x_1, \dots, x_G) \geq \mu_{\min}.$$

For instance, crowdsourcing platforms today allow payments to workers, but do not allow imposing penalties: this condition gives $\mu_{\min} = 0$.

We assume that the worker attempts to maximize her overall expected payment. In what follows, the expression ‘the worker’s expected payment’ will refer to the expected payment from the worker’s point of view, and the expectation will be taken with respect to the worker’s confidences about her answers and the uniformly random choice of the G gold standard questions among the N questions in the task. A payment function f is called *incentive compatible* if the expected payment of the worker under this payment function is *strictly* maximized when the worker answers in the manner desired.² The specific requirements of the skip-based and the confidence-based settings are discussed subsequently in their respective sections to follow. In the remainder of this section, we formally define the concepts of the worker’s expected payment and incentive compatibility; the reader interested in understanding the paper at a higher level may skip directly to the next section without loss in continuity.

Let Ω denote the set of options for each question. We assume that Ω is a finite set, for instance, the set $\{\text{Yes}, \text{No}\}$ for a task with binary-choice questions, or the set of all strings of at most a certain length for a task with textual responses. Let $Q \in [0, 1]^{|\Omega| \times N}$ denote the beliefs of a worker for the N questions asked. Specifically, for any question $i \in [N]$ and any option $\omega \in \Omega$, let $Q_{\omega, i}$ represent the probability, according to the worker’s belief, that option ω is the correct answer to question i . Then from the law of total probability, any valid Q must have $\sum_{\omega \in \Omega} Q_{\omega, i} = 1$ for every $i \in [N]$. The value of Q is unknown to the mechanism.

Let us first define the notion of the expected payment (from the worker’s point of view) for any given response of the worker to the questions. For any question $i \in [N]$, suppose the worker indicates the confidence-level $\xi_i \in \{0, \dots, L\}$. For every question $i \in [N]$ such that $\xi_i \neq 0$, let $\omega_i \in \Omega$ denote the option selected by the worker; whenever $\xi_i = 0$, indicating a skip, we let ω_i take any arbitrary value in Ω . Furthermore, let $p_i = Q_{\omega_i, i}$ denote the probability, according to the worker’s belief, that the chosen option ω_i is the correct answer to question i . For notational purposes, we also define a vector $E = (\epsilon_1, \dots, \epsilon_G) \in \{-1, 1\}^G$. Then for the given responses, for the worker beliefs Q , and under payment mechanism f , the worker’s expected payment $\Gamma_{Q, f} : (\{0, \dots, L\} \times \Omega)^N \rightarrow \mathbb{R}$

is given by the expression:

$$\begin{aligned} \Gamma_{Q, f}(\xi_1, \omega_1, \dots, \xi_N, \omega_N) &= \frac{1}{\binom{L}{G}} \sum_{\substack{(j_1, \dots, j_G) \\ \subseteq \{1, \dots, N\}}} \sum_{E \in \{-1, 1\}^G} \left(f(\epsilon_1 \xi_{j_1}, \dots, \epsilon_G \xi_{j_G}) \prod_{i=1}^G (p_{j_i})^{\frac{1+\epsilon_i}{2}} (1-p_{j_i})^{\frac{1-\epsilon_i}{2}} \right). \end{aligned} \quad (1)$$

In the expression (1), the outermost summation corresponds to the expectation with respect to the randomness arising from the unknown positions of the gold standard questions. The inner summation corresponds to the expectation with respect to the worker’s beliefs about the correctness of her responses. Note that the right hand side of (1) implicitly depends on $(\omega_1, \dots, \omega_N)$ through the values (p_1, \dots, p_N) . Also note that for every question i such that $\xi_i = 0$, the right hand side of (1) does not depend on the values of ω_i and p_i ; this is because the choice $\xi_i = 0$ of skipping question i implies that the worker did not select any particular option.

We will now use the the definition of the expected payment of the worker to define the notion of incentive compatibility. To this end, for any valid probabilities Q , let $\mathcal{A}(Q) \subseteq \{0, \dots, L\} \times \Omega^N$ denote an associated set of ‘‘desired’’ responses. By this we mean that every $a \in \{0, \dots, L\} \times \Omega^N$ represents a possible response to the set of N questions, and the goal is to incentivize the worker to provide any one response in the set $\mathcal{A}(Q)$. Then a mechanism f is termed *incentive compatible* if

$$\Gamma_{Q, f}(a) > \Gamma_{Q, f}(a') \quad \text{for every } a \in \mathcal{A}(Q), \text{ every } a' \notin \mathcal{A}(Q), \text{ and every valid } Q.$$

The goal is to design mechanisms that are incentive compatible, that is, incentivize the workers to respond in a certain manner. The specific choice of ‘‘desired responses’’ for the skip-based and the confidence-based settings are discussed subsequently in their respective sections. We begin with the skip-based setting.

3. Skip-based Setting

In this section, we consider the setting where for every question, the worker can choose to either answer the question or to skip it; no additional information is asked from the worker. See Figure 1b for an illustration.

3.1 Setting

Let $T \in (0, 1)$ be a predefined value. The goal is to design payment mechanisms that incentivize the worker to skip the questions for which her confidence is lower than T , and answer those for which her confidence is higher than T .³ Moreover, for the questions that she attempts to answer, she must be incentivized to select the answer that she believes is most likely to be correct. The value of T is chosen a priori based on factors such as budget constraints, the targeted quality of labels, and/or the choice of the algorithm used to subsequently aggregate the responses of multiple workers. In this paper, we assume that the value of the threshold T is specified to us.

Now the space of all possible mechanisms for this problem may be rather wide. Thus in order to narrow down our search, we impose the following additional simple and natural requirement:

2. Such a notion of incentive compatibility is often called ‘‘strict incentive compatibility’’, we drop the prefix term ‘‘strict’’ for brevity.

3. In the event that the confidence about a question is exactly equal to T , the worker may choose to answer or skip.

Axiom 1 (No-free-lunch Axiom) *If all the answers attempted by the worker in the gold standard are wrong, then the payment is the minimum possible. More formally, $f(x_1, \dots, x_G) = \mu_{\min}$ for every evaluation (x_1, \dots, x_G) such that $0 < \sum_{i=1}^G \mathbf{1}\{x_i \neq 0\} = \sum_{i=1}^G \mathbf{1}\{x_i = -1\}$.*

One may expect a payment mechanism to impose the restriction of minimum payment to spammers who answer randomly. For instance, in a task with binary-choice questions, a spammer is expected to have 50% of the attempted answers incorrect; one may thus wish to set a the minimum possible payment if 50% or more of the attempted answers were incorrect. The no-free-lunch axiom which we impose is however a *significantly weaker condition*, mandating minimum payment if *all* attempted answers are incorrect.

3.2 Payment Mechanism

We now present our proposed payment mechanism in Algorithm 1.

Algorithm 1: Incentive mechanism for skip-based setting

- Inputs:
 - ▶ Threshold T
 - ▶ Budget parameters μ_{\max} and μ_{\min}
 - ▶ Evaluations $(x_1, \dots, x_G) \in \{-1, 0, +1\}^G$ of the worker's answers to the G gold standard questions
- Set $\alpha_{-1} = 0$, $\alpha_0 = 1$, $\alpha_{+1} = \frac{1}{T}$
- The payment is

$$f(x_1, \dots, x_G) = \kappa \prod_{i=1}^G \alpha_{x_i} + \mu_{\min},$$

where $\kappa = (\mu_{\max} - \mu_{\min})/T^G$.

The proposed mechanism has a *multiplicative* form: each answer in the gold standard is given a score based on whether it was correct (score = $\frac{1}{T}$), incorrect (score = 0) or skipped (score = 1), and the final payment is simply a product of these scores (scaled and shifted by constants). The mechanism is easy to describe to workers: For instance, if $T = \frac{1}{2}$, $G = 3$, $\mu_{\max} = 80$ cents and $\mu_{\min} = 0$ cents, then the description reads:

“The reward starts at 10 cents. For every correct answer in the 3 gold standard questions, the reward will double. However, if any of these questions are answered incorrectly, then the reward will become zero. So please use the ‘I’m not sure’ option wisely.”

Observe how this payment rule is similar to the popular ‘double or nothing’ paradigm (Double or Nothing, 2014).

The algorithm makes a minimum payment if *one or more* attempted answers in the gold standard are wrong. Note that this property is significantly stronger than the no-free-lunch axiom which we originally required, where we wanted a minimum payment only when *all* attempted answers were wrong. Surprisingly, as we prove shortly, Algorithm 1 is the only incentive-compatible mechanism that satisfies no-free-lunch.

The following theorem shows that this mechanism indeed incentivizes a worker to skip the questions for which her confidence is below T , while answering those for which her confidence is greater than T . In the latter case, the worker is incentivized to select the answer which she thinks is most likely to be correct.

Theorem 2 *The mechanism of Algorithm 1 is incentive-compatible and satisfies the no-free-lunch axiom.*

In the remainder of this subsection, we present the proof of Theorem 2. The reader may go directly to subsection 3.3 without loss in continuity.

Proof of Theorem 2. The proposed payment mechanism satisfies no-free-lunch since the payment is μ_{\min} when there are one or more wrong answers in the gold standard. It remains to show that the mechanism is incentive compatible. To this end, observe that the property of incentive-compatibility does not change upon any shift of the mechanism by a constant value or any scaling by a positive constant value. As a result, for the purposes of this proof, we can assume without loss of generality that $\mu_{\min} = 0$.

We will first assume that, for every question that the worker does not skip, she selects the answer which she believes is most likely to be correct. Under this assumption we will show that the worker is incentivized to skip the questions for which her confidence is smaller than T and attempt if it is greater than T . Finally, we will show that the mechanism indeed incentivizes the worker to select the answer which she believes is most likely to be correct for the questions that she doesn't skip. In what follows, we will employ the notation $\kappa = \mu_{\max} T^G$.

Let us first consider the case when $G = N$. Let p_1, \dots, p_N be the confidences of the worker for questions $1, \dots, N$ respectively. Further, let $p_{(1)} \geq \dots \geq p_{(m)} > T > p_{(m+1)} \geq \dots \geq p_{(N)}$ be the ordered permutation of these confidences (for some number m). Let $\{(1), \dots, (N)\}$ denote the corresponding permutation of the N questions. If the mechanism is incentive compatible, then the expected payment received by this worker should be maximized when the worker answers questions $(1), \dots, (m)$ and skips the rest. Under the mechanism proposed in Algorithm 1, this action fetches the worker an expected payment of

$$\frac{p_{(1)}}{\kappa} \dots \frac{p_{(m)}}{T}.$$

Alternatively, if the worker answers the questions $\{i_1, \dots, i_\beta\}$, with $p_{i_1} > \dots > p_{i_\nu} > T > p_{i_{\nu+1}} > \dots > p_{i_\beta}$ for some value ν , then the expected payment is

$$p_{i_1} \dots p_{i_\beta} T^\beta = \kappa \frac{p_{i_1}}{T} \dots \frac{p_{i_\beta}}{T} \tag{2}$$

$$\leq \kappa \frac{p_{i_1}}{T} \dots \frac{p_{i_\nu}}{T} \tag{3}$$

$$\leq \kappa \frac{p_{(1)}}{T} \dots \frac{p_{(m)}}{T}, \tag{4}$$

where inequality (3) holds because $\frac{p_{i_j}}{T} \leq 1 \forall j > \nu$ and holds with equality only when $\beta = \nu$. Inequality (4) is a result of $\frac{p_{i_j}}{T} \geq 1 \forall j \leq m$ and holds with equality only when $\nu = m$. It follows that the expected payment is (strictly) maximized when $i_1 = (1), \dots, i_\beta = (m)$ as required.

The case of $G < N$ is a direct consequence of the result for $G = N$, as follows. When $G < N$, from a worker's point of view, the set of G questions is distributed uniformly at random in

the superset of N questions. However, for every set of G questions, the relations (2), (3), (4) and their associated equality/strict-inequality conditions hold. The expected payment is thus (strictly) maximized when the worker answers the questions for which her confidence is greater than T and skips those for which her confidence is smaller than T .

One can see that for every question that the worker chooses to answer, the expected payment increases with an increase in her confidence. Thus, the worker is incentivized to select the answer that she thinks is most probably correct.

Finally, since $\kappa = \mu_{\max} T^C > 0$ and $T \in (0, 1)$, the payment is always non-negative and satisfies the μ_{\max} -budget constraint.

3.3 Uniqueness of this Mechanism

While we started out with a very weak condition of no-free-lunch that requires a minimum payment when *all* attempted answers are wrong, the mechanism proposed in Algorithm 1 is significantly more strict and pays the minimum amount when *any* of the attempted answers is wrong. A natural question that arises is: can we design an alternative mechanism satisfying incentive compatibility and no-free-lunch that operates somewhere in between? The following theorem answers this question in the negative.

Theorem 3 *The mechanism of Algorithm 1 is the only incentive-compatible mechanism that satisfies the no-free-lunch axiom.*

Theorem 3 gives a strong result despite imposing very weak requirements. To see this, recall our earlier discussion on deterring spammers, that is, making a low payment to workers who answer randomly. For instance, when the task comprises binary-choice questions, one may wish to design mechanisms which make the minimum possible payment when the responses to 50% or more of the questions in the gold standard are incorrect. The no-free-lunch axiom is a much weaker requirement, and the only mechanism that can satisfy this requirement is the mechanism of Algorithm 1.

The proof of Theorem 3 is based on the following key lemma, establishing a condition that any incentive-compatible mechanism must necessarily satisfy. Note that this lemma does *not* require the no-free-lunch axiom.

Lemma 4 *Any incentive-compatible mechanism f must satisfy, for every gold standard question $i \in \{1, \dots, G\}$ and every $(y_1, \dots, y_{i-1}, y_{i+1}, \dots, y_G) \in \{-1, 0, 1\}^{G-1}$,*

$$\begin{aligned} T f(y_1, \dots, y_{i-1}, 1, y_{i+1}, \dots, y_G) + (1 - T) f(y_1, \dots, y_{i-1}, -1, y_{i+1}, \dots, y_G) \\ = f(y_1, \dots, y_{i-1}, 0, y_{i+1}, \dots, y_G). \end{aligned}$$

The proof of Lemma 4 is provided in Appendix A.1. Using this lemma, we will now prove Theorem 3. The reader interested in further results and not the proof may feel free to jump to Subsection 3.4 without any loss in continuity.

Proof of Theorem 3. The property of incentive-compatibility does not change upon any shift of the mechanism by a constant value or any scaling by a positive constant value. As a result, for the purposes of this proof, we can assume without loss of generality that $\mu_{\min} = 0$.

We will first prove that any incentive-compatible mechanism satisfying the no-free-lunch axiom must make a zero payment if one or more answers in the gold standard are incorrect. The proof proceeds by induction on the number of skipped questions S in the gold standard. Let us assume for now that in the G questions in the gold standard, the first question is answered incorrectly, the next $(G - 1 - S)$ questions are answered by the worker and have arbitrary evaluations, and the remaining S questions are skipped. The proof proceeds by an induction on S . Suppose $S = G - 1$. In this case, the only attempted question is the first question and the answer provided by the worker to this question is incorrect. The no-free-lunch axiom necessitates a zero payment in this case, thus satisfying the base case of our induction hypothesis. Now we prove the hypothesis for some S under the assumption of it being true when the number of questions skipped in the gold standard is $(S + 1)$ or more. From Lemma 4 (with $i = G - S - 1$) we have

$$\begin{aligned} T f(-1, y_2, \dots, y_{G-S-2}, 1, 0, \dots, 0) + (1 - T) f(-1, y_2, \dots, y_{G-S-2}, -1, 0, \dots, 0) \\ = f(-1, y_2, \dots, y_{G-S-2}, 0, 0, \dots, 0) \\ = 0, \end{aligned}$$

where the final equation is a consequence of our induction hypothesis: The induction hypothesis is applicable since $f(-1, y_2, \dots, y_{G-S-2}, 0, 0, \dots, 0)$ corresponds to the case when the last $(S + 1)$ questions are skipped and the first question is answered incorrectly. Now, since the payment f must be non-negative and since $T \in (0, 1)$, it must be that

$$f(-1, y_2, \dots, y_{G-S-2}, 1, 0, \dots, 0) = 0,$$

and

$$f(-1, y_2, \dots, y_{G-S-2}, -1, 0, \dots, 0) = 0.$$

This completes the proof of our induction hypothesis. Furthermore, each of the arguments above hold for any permutation of the G questions, thus proving the necessity of zero payment when any one or more answers are incorrect.

We will now prove that when no answers in the gold standard are incorrect, the payment must be of the form described in Algorithm 1. Let κ be the payment when all G questions in the gold standard are skipped. Let C be the number of questions answered correctly in the gold standard. Since there are no incorrect answers, it follows that the remaining $(G - C)$ questions are skipped. Let us assume for now that the first C questions are answered correctly and the remaining $(G - C)$ questions are skipped. We repeatedly apply Lemma 4, and the fact that the payment must be zero when one or more answers are wrong,

$$\begin{aligned} f(\underbrace{1, \dots, 1}_{C-1}, \underbrace{1, 0, \dots, 0}_{G-C}) &= \frac{1}{T} f(\underbrace{1, \dots, 1}_{C-1}, \underbrace{0, 0, \dots, 0}_{G-C}) - \frac{1 - T}{T} f(\underbrace{1, \dots, 1}_{C-1}, \underbrace{-1, 0, \dots, 0}_{G-C}) \\ &= \frac{1}{T} f(\underbrace{1, \dots, 1}_{C-1}, \underbrace{0, 0, \dots, 0}_{G-C}), \end{aligned}$$

and so on to obtain

$$\begin{aligned} f(\underbrace{1, \dots, 1}_{C-1}, \underbrace{1, 0, \dots, 0}_{G-C}) &= \frac{1}{T^C} f(\underbrace{0, \dots, 0}_C) \\ &= \frac{1}{T^C} \kappa. \end{aligned}$$

In order to abide by the budget, we must have the maximum payment as $\mu_{\max} = \kappa \frac{1}{T^G}$. It follows that $\kappa = \mu_{\max} T^G$. Finally, the arguments above hold for any permutation of the G questions, thus proving the uniqueness of the mechanism of Algorithm 1.

3.4 Optimality against Spamming Behavior

As discussed earlier, crowdsourcing tasks, especially those with multiple choice questions, often encounter spammers who answer randomly without heed to the question being asked. For instance, under a binary-choice setup, a spammer will choose one of the two options uniformly at random for every question. A highly desirable objective in crowdsourcing settings is to deter spammers. To this end, one may wish to impose a condition of making the minimum possible payment when the responses to 50% or more of the attempted questions in the gold standard are incorrect. A second desirable metric could be to minimize the expenditure on a worker who simply skips all questions. While the aforementioned requirements were deterministic functions of the worker's responses, one may alternatively wish to impose requirements that depend on the distribution of the worker's answering process. For instance, a third desirable feature would be to minimize the expected payment to a worker who answers all questions uniformly at random. We now show that interestingly, our unique multiplicative payment mechanism *simultaneously* satisfies all these requirements. The result is stated assuming a multiple-choice setup, but extends trivially to non-multiple-choice settings.

Theorem 5.A (Distributional) *Consider any value $A \in \{0, \dots, G\}$. Among all incentive-compatible mechanisms (that may or may not satisfy no-free-lunch), Algorithm 1 pays strictly the smallest amount to a worker who skips some A of the questions in the gold standard, and chooses answers to the remaining $(G - A)$ questions uniformly at random.*

Theorem 5.B (Deterministic) *Consider any value $B \in (0, 1]$. Among all incentive-compatible mechanisms (that may or may not satisfy no-free-lunch), Algorithm 1 pays strictly the smallest amount to a worker who gives incorrect answers to a fraction B or more of the questions attempted in the gold standard.*

We see from this result that the multiplicative payment mechanism of Algorithm 1 thus possesses very useful properties geared to deter spammers, while ensuring that a good worker will be paid a high enough amount. To illustrate this point, let us compare the mechanism of Algorithm 1 with the popular additive class of payment mechanisms.

Example 1 *Consider the popular class of “additive” mechanisms, where the payments to a worker are added across the gold standard questions. This additive payment mechanism offers a reward of $\frac{\mu_{\max}}{G}$ for every correct answer in the gold standard, $\frac{\mu_{\max} T}{G}$ for every question skipped, and 0 for every incorrect answer. Importantly, the final payment to the worker is the sum of the rewards across the G gold standard questions. One can verify that this additive mechanism is incentive compatible. One can also see that that as guaranteed by our theory, this additive payment mechanism does not satisfy the no-free-lunch axiom.*

Suppose each question involves choosing from two options. Let us compute the payment that these two mechanisms make under a spamming behavior of choosing the answer randomly to each question. Given the 50% likelihood of each question being correct, one can compute that the additive

mechanism makes a payment of $\frac{\mu_{\max}}{2}$ in expectation. On the other hand, our mechanism pays an expected amount of only $\mu_{\max} 2^{-G}$. The payment to spammers thus reduces exponentially with the number of gold standard questions under our mechanism, whereas it does not reduce at all in the additive mechanism.

Now, consider a different means of exploiting the mechanism(s) where the worker simply skips all questions. To this end, observe that if a worker skips all the questions then the additive payment mechanism will make a payment of $\mu_{\max} T$. On the other hand, the proposed payment mechanism of Algorithm 1 pays an exponentially smaller amount of $\mu_{\max} T^G$ (recall that $T < 1$).

We prove Theorem 5 in the rest of this subsection. The reader may feel free to jump directly to Section 4 without any loss in continuity.

Proof of Theorem 5. The property of incentive-compatibility does not change upon any shift of the mechanism by a constant value or any scaling by a positive constant value. As a result, for the purposes of this proof, we can assume without loss of generality that $\mu_{\min} = 0$.

Part A (Distributional). Let m denote the number of options in each question. One can verify that under the mechanism of Algorithm 1, a worker who skips A questions and answers the rest uniformly at random will get a payment of $\frac{\mu_{\max} T^A}{m^{G-A}}$ in expectation. This expression arises due to the fact that Algorithm 1 makes a zero payment if any of the attempted answers are incorrect, and a payment of $\mu_{\max} T^A$ if the worker skips A questions and answers the rest correctly. Under uniformly random answers, the probability of the latter event is $\frac{1}{m^{G-A}}$.

Now consider any other mechanism, and denote it as f' . Let us suppose without loss of generality that the worker attempts the first $(G - A)$ questions. Since the payment must be non-negative, a repeated application of Lemma 4 gives

$$f'(1, \dots, 1, 0, \dots, 0) \geq T f'(1, \dots, 1, 0, \dots, 0) \quad (5)$$

$$\begin{aligned} & \vdots \\ & \geq T^A f'(1, \dots, 1) \\ & = T^A \mu_{\max}, \end{aligned} \quad (6)$$

where (6) is a result of the μ_{\max} -budget constraint. Since there is a $\frac{1}{m^{G-A}}$ chance of the $(G - A)$ attempted answers being correct, the expected payment under any other mechanism f' must be at least $\frac{\mu_{\max} T^A}{m^{G-A}}$.

We will now show that if any mechanism f' that makes an expected payment of $\frac{\mu_{\max} T^A}{m^{G-A}}$ to such a spammer, then the mechanism must be identical to Algorithm 1. We split the proof of this part into two cases, depending on the value of the parameter A .

Case I ($A < G$): In order to make an expected payment of $\frac{\mu_{\max} T^A}{m^{G-A}}$, the mechanism must achieve the bound (6) with equality, and furthermore, the mechanism must have zero payment if any of the $(G - A)$ attempted questions are answered incorrectly. In other words, the mechanism f' under consideration must satisfy

$$f'(y_1, \dots, y_{G-A}, 0, \dots, 0) = 0 \quad \forall (y_1, \dots, y_{G-A}) \in \{-1, 1\}^{G-A}.$$

A repeated application of Lemma 4 then implies

$$f'(0, 0, \dots, 0, \dots, -1) = 0. \quad (7)$$

Note that so far we considered the case when the worker attempts the first $(G - A)$ questions. The arguments above hold for any choice of the $(G - A)$ attempted questions, and consequently the results shown so far in this proof hold for all permutations of the arguments to f' . In particular, the mechanism f' must make a zero payment when any $(G - 1)$ questions in the gold standard are skipped and the remaining question is answered incorrectly. Another repeated application of Lemma 4 to this result gives

$$f'(y_1, \dots, y_G) = 0 \quad \forall (y_1, \dots, y_G) \in \{0, -1\}^G \setminus \{0\}^G.$$

This condition is precisely the no-free-lunch axiom, and in Theorem 3 we had shown that Algorithm 1 is the only incentive-compatible mechanism that satisfies this axiom. It follows that our mechanism, Algorithm 1 strictly minimizes the expected payment in the setting under consideration.

Case II ($A = G$): In order to achieve the bound (6) with equality, the mechanism f' must also achieve the bound (5) with equality. Noting that we have $A = G$ in this case, it follows that the mechanism f' must satisfy

$$f'(-1, 0, \dots, 0) = 0.$$

This condition is identical to (7) established for Case I earlier, and the rest of the argument now proceeds in a manner identical to the subsequent arguments in Case I.

Part B (Deterministic). Given our result of Theorem 3, the proof for the deterministic part is straightforward. Algorithm 1 makes a payment of zero when one or more of the answers to questions in the gold standard are incorrect. Consequently, for every value of parameter $B \in (0, 1]$, Algorithm 1 makes a zero payment when a fraction B or more of the attempted answers are incorrect. Any other mechanism doing so must satisfy the no-free-lunch axiom. In Theorem 3 we had shown that Algorithm 1 is the only incentive-compatible mechanism that satisfies this axiom. It follows that our mechanism, Algorithm 1, strictly minimizes the payment in the event under consideration.

4. Confidence-based Setting

In this section, we will discuss incentive mechanisms when the worker is asked to select from more than one confidence-level for every question (Figure 1c). In particular, for some $L \geq 1$, the worker is asked to indicate a confidence-level in the range $\{0, \dots, L\}$ for every answer. Level 0 is the ‘skip’ level, and level L denotes the highest confidence. Note that we do not solicit an answer if the worker indicates a confidence-level of 0 (skip), but the worker must provide an answer if she indicates a confidence-level of 1 or higher. This makes the case of having only a ‘skip’ as considered in Section 3 a special case of this setting, and corresponds to $L = 1$.

We generalize the requirement of no-free-lunch to the confidence-based setting as follows.

Axiom 6 (Generalized-no-free-lunch axiom) *If all the answers attempted by the worker in the gold standard are selected as the highest confidence-level (level L), and all of them turn out to be wrong, then the payment is μ_{\min} . More formally, we require the mechanism f to satisfy $f(x_1, \dots, x_G) = \mu_{\min}$ for every evaluation (x_1, \dots, x_G) that satisfies $0 < \sum_{i=1}^G \mathbf{1}\{x_i \neq 0\} = \sum_{i=1}^G \mathbf{1}\{x_i = -L\}$.*

In the confidence-based setting, we require specification of a set of thresholds $\{S_l, T_l\}_{l=1}^L$ that determine the confidence-levels that the workers should indicate. These thresholds are used to choose the payment mechanism in a principled manner. In particular, we will require specification of two reference points for each confidence level, and this specification generalizes the skip-based setting.

- The first set of thresholds specifies a comparison of any confidence level with the skipping option as a fixed reference. To this end, recall that in the skip-based setting, the threshold T specified when the worker should skip a question and when she should attempt to answer. This is generalized to the confidence-based setting where for every level $l \in [L]$, a fixed threshold S_l specifies the ‘strength’ of confidence-level l . If restricted to only the two options of skipping or selecting confidence-level l for any question, the worker should be incentivized to select confidence-level l if her confidence is higher than S_l and skip if her confidence is lower than S_l .

- The second set of thresholds specifies a comparison of any confidence level with its neighbors. If a worker decides to not skip a question, she must choose one of multiple confidence-levels. A set $\{T_l\}_{l=1}^L$ of thresholds specify the boundaries between different confidence-levels. In particular, when the confidence of the worker for a question lies in (T_{l-1}, T_{l+1}) , then the worker must be incentivized to indicate confidence-level $(l - 1)$ if her confidence is lower than T_l and to indicate confidence-level l if her confidence is higher than T_l . This includes selecting level L if her confidence is higher than T_L and selecting level 0 if her confidence is lower than T_1 .

We will call a payment mechanism as incentive-compatible if it satisfies the two requirements listed above, and also incentivizes the worker to select the answer that she believes is most likely to be correct for every question for which her confidence is higher than T_1 .

The problem setting inherently necessitates certain restrictions in the choice of the thresholds. Since we require the worker to choose a higher level when her confidence is higher, the thresholds must necessarily be monotonic and satisfy $0 < S_1 < S_2 < \dots < S_L < 1$ and $0 < T_1 < T_2 < \dots < T_L < 1$. Also observe that the definitions of S_l and T_l coincide, and hence $S_1 = T_1$. Additionally, we can show (Proposition 18 in Appendix A.5) that for incentive-compatible mechanisms to exist, it must be that $T_l > S_l \forall l \in \{2, \dots, L\}$. As a result, the thresholds must also satisfy $T_1 = S_1, T_2 > S_2, \dots, T_L > S_L$. These thresholds may be chosen based on various factors of the problem at hand, for example, on the post-processing algorithms, any statistics on the distribution of worker abilities, budget constraints, etc. In this paper, we will assume that these values are given to us.

4.1 Payment Mechanism

In this section, we present our proposed payment mechanism, and prove that it is guaranteed to satisfy our requirements. We begin with a description of the mechanism in Algorithm 2.

Algorithm 2: Incentive mechanism for the confidence-based setting

- Inputs:
 - ▶ Thresholds S_1, \dots, S_L and T_1, \dots, T_L
 - ▶ Budget parameters μ_{\max} and μ_{\min}
 - ▶ Evaluations $(x_1, \dots, x_G) \in \{-L, \dots, +L\}^G$ of the worker's answers to the G gold standard questions
- Set $\alpha_{-L}, \dots, \alpha_L$ as
 - ▶ $\alpha_L = \frac{1}{S_L}, \alpha_{-L} = 0$
 - ▶ For $l \in \{L-1, \dots, 1\}$,

$$\alpha_l = \frac{(1-S_l)T_{l+1}\alpha_{l+1} + (1-S_l)(1-T_{l+1})\alpha_{-(l+1)} - (1-T_{l+1})}{T_{l+1} - S_l} \quad \text{and} \quad \alpha_{-l} = \frac{1 - S_l \alpha_l}{1 - S_l}$$

- ▶ $\alpha_0 = 1$

- The payment is

$$f(x_1, \dots, x_G) = \kappa \prod_{i=1}^G \alpha_{x_i} + \mu_{\min}$$

where $\kappa = (\mu_{\max} - \mu_{\min}) \left(\frac{1}{\alpha_L}\right)^G$.

The following theorem shows that this mechanism indeed incentivizes a worker to select answers and confidence-levels as desired.

Theorem 7 *The mechanism of Algorithm 2 is incentive-compatible and satisfies the generalized-no-free-lunch axiom.*

The proof of Theorem 7 follows in a manner similar to that of the proof of Theorem 2, and is provided in Appendix A.2.

Remark 8 *The mechanism of Algorithm 2 also ensures a condition stronger than the 'boundary-based' definition of the thresholds $\{T_l\}_{l \in [L]}$ given earlier. Under this mechanism, for every $l \in [L-1]$ the worker is incentivized to select confidence-level 1 (over all else) whenever her confidence lies in the interval (T_l, T_{l+1}) , select confidence-level 0 (over all else) whenever her confidence is lower than T_l and select confidence-level L (over all else) whenever her confidence is higher than T_L .*

4.2 Uniqueness of this Mechanism

We prove that the mechanism of Algorithm 2 is unique, that is, no other incentive-compatible mechanism can satisfy the generalized-no-free-lunch axiom.

Theorem 9 *The payment mechanism of Algorithm 2 is the only incentive-compatible mechanism that satisfies the generalized-no-free-lunch axiom.*

The proof of Theorem 9 is provided in Appendix A.3. The proof is conceptually similar to that of Theorem 9 but involves resolving several additional complexities that arise due to elicitation from multiple confidence levels.

5. A Stronger No-free-lunch Axiom: Impossibility Results

Recall that the no-free-lunch axiom under the skip-based mechanism of Section 3 requires the payment to be the minimum possible if all attempted answers in the gold standard are incorrect. However, a worker who skips all the questions may still receive a payment. The generalization under the confidence-based mechanism of Section 4 requires the payment to be the minimum possible if all attempted answers in the gold standard were selected with the highest confidence-level and were incorrect. However, a worker who marked all questions with a lower confidence level may be paid even if her answers to all the questions in the gold standard turn out to be incorrect. One may thus wish to impose a stronger requirement instead, where the minimum payment is made to workers who make no useful contribution. This is the primary focus of this section.

Consider the skip-based setting. Define the following axiom which is slightly stronger than the no-free-lunch axiom defined previously.

Strong-no-free-lunch: If none of the answers in the gold standard are correct, then the payment is μ_{\min} . More formally, strong-no-free-lunch imposes the condition $f(x_1, \dots, x_G) = \mu_{\min}$ for every evaluation (x_1, \dots, x_G) that satisfies $\sum_{i=1}^G \mathbf{1}\{x_i > 0\} = 0$.

The strong-no-free-lunch axiom is only slightly stronger than the no-free-lunch axiom proposed in Section 3 for the skip-based setting. The strong-no-free-lunch axiom can equivalently be written as imposing requiring the payment to be the minimum possible for every evaluation that satisfies $\sum_{i=1}^G \mathbf{1}\{x_i \neq 0\} = \sum_{i=1}^G \mathbf{1}\{x_i = -1\}$. From this interpretation, one can see that to the set of events necessitating the minimum payment under the no-free-lunch axiom, the strong-no-free-lunch axiom adds only one extra event, the event of the worker skipping all questions. Unfortunately, it turns out that this minimal strengthening of the requirements is associated to impossibility results.

In this section we show that no mechanism satisfying the strong-no-free-lunch axiom can be incentive compatible in general. The only exception is the case when (a) all questions are in the gold standard ($G = N$), and (b) it is guaranteed that the worker has a confidence greater than T for at least one of the N questions. These conditions are, however, impractical for the crowdsourcing setup under consideration in this paper. We will first prove the impossibility results under the strong-no-free-lunch axiom. For the sake of completeness (and also to satisfy mathematical curiosity), we will then provide a (unique) mechanism that is incentive-compatible and satisfies the strong-no-free-lunch axiom for the skip-based setting under the two conditions listed above. The proofs of each of the claims made in this section are provided in Appendix A.6.

Let us continue to discuss the skip-based setting. In this section, we will call any worker whose confidences for all of the N questions is lower than T as an *unknowledgeable worker*, and call the worker a *knowledgeable worker* otherwise.

Proposition 10 *No payment mechanism satisfying the strong-no-free-lunch axiom can incentivize an unknowledgeable worker to skip all questions. As a result, no mechanism satisfying the strong-no-free-lunch axiom can be incentive-compatible.*

The proof of this proposition, and that of all other theoretical claims made in this section, are presented in Appendix A.6.

The impossibility result of Proposition 10 relies on trying to incentivize an unknowledgeable worker to act as desired. Since no mechanism can be incentive compatible for unknowledgeable workers, we will now consider only workers who are knowledgeable. The following proposition shows that the strong-no-free-lunch axiom is too strong even for this relaxed setting.

Proposition 11 *When $G < N$, there exists no mechanism that is incentive-compatible for knowledgeable workers and satisfies the strong-no-free-lunch axiom.*

Given this impossibility result for $G < N$, we are left with $G = N$ which means that the true answers to all the questions are known a priori. This condition is clearly not applicable to a crowdsourcing setup; nevertheless, it is mathematically interesting and may be applicable to other scenarios such as testing and elicitation of beliefs about future events.

Proposition 12 below presents a mechanism for this case and proves its uniqueness. We previously saw that an unknowledgeable worker cannot be incentivized to skip all the questions (even when $G = N$). Thus, in our payment mechanism, we do the next best thing: Incentivize the unknowledgeable worker to answer only one question, that which she is most confident about, while incentivizing the knowledgeable worker to answer questions for which her confidence is greater than T and skip those for which her confidence is smaller than T .

Proposition 12 *Let C be the number of correct answers and W be the number of wrong answers (in the gold standard). Let the payment be μ_{\min} if $W > 0$ or $C = 0$, and be $(\mu_{\max} - \mu_{\min})T^{G-C} + \mu_{\min}$ otherwise. Under this mechanism, when $G = N$, an unknowledgeable worker is incentivized to answer only one question, that for which her confidence is the maximum, and a knowledgeable worker is incentivized to answer the questions for which her confidence is greater than T and skip those for which her confidence is smaller than T . Furthermore, when $G = N$, this mechanism is the one and only mechanism that obeys the strong-no-free-lunch axiom and is incentive-compatible for knowledgeable workers.*

The following proposition shows that the strong-no-free-lunch axiom leads to negative results in the confidence-based setting ($L > 1$) as well. The strong-no-free-lunch axiom is still defined as in the beginning of Section 5, i.e., the payment is zero if none of the answers are correct.

Proposition 13 *When $L > 1$, for any values of N and G ($\leq N$), it is impossible for any mechanism to satisfy the strong-no-free-lunch axiom and be incentive-compatible even when the worker is knowledgeable.*

6. Simulations and Experiments

In this section, we present synthetic simulations and real-world experiments to evaluate the effects of our setting and our mechanism on the final label quality.

6.1 Synthetic Simulations

We employ synthetic simulations to understand the effects of various distributions of the confidences and labeling errors. We consider binary-choice questions in this set of simulations. Whenever a worker answers a question, her confidence for the correct answer is drawn from a distribution \mathcal{P} independent of all else. We investigate the effects of the following five choices of the distribution \mathcal{P} :

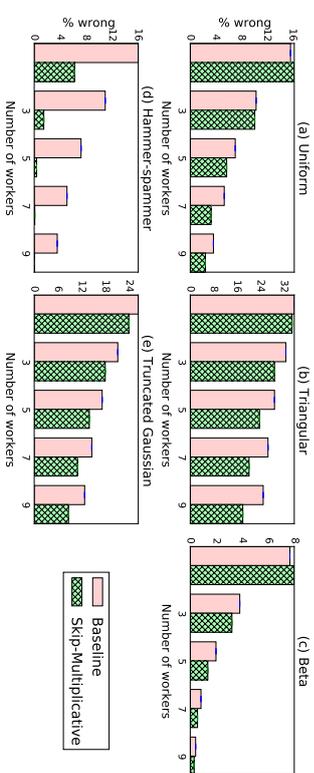

Figure 2: Error under different interfaces for synthetic simulations of five distributions of the workers' error probabilities.

- The uniform distribution on the support $[0.5, 1]$.
- A triangular distribution with lower end-point 0.2, upper end-point 1 and a mode of 0.6.
- A beta distribution with parameter values $\alpha = 5$ and $\beta = 1$.
- The hammer-spammer distribution (Karger et al., 2011): uniform on the discrete set $\{0.5, 1\}$.
- A truncated Gaussian distribution: a truncation of $\mathcal{N}(0.75, 0.5)$ to the interval $[0, 1]$.

We compare (a) the setting where workers attempt every question, with (b) the setting where workers skip questions for which their confidence is below a certain threshold T . In this set of simulations, we set $T = 0.75$. In either setting, we aggregate the labels obtained from the workers for each question via a majority vote on the two classes. Ties are broken by choosing one of the two options uniformly at random.

Figure 2 depicts the results from these simulations. Each bar represents the fraction of questions that are labeled incorrectly, and is an average across 50,000 trials. (The standard error of the mean is too small to be visible.) We see that the skip-based setting consistently outperforms the conventional setting, and the gains obtained are moderate to high depending on the underlying distribution of the workers' errors. In particular, the gains are quite striking under the hammer-spammer model: this result is not surprising since the mechanism (ideally) screens the spammers out and leaves only the hammers who answer perfectly.

The setup of the simulations described above assumes that the workers' confidences equal the true error probabilities. In practice, however, the workers may have incorrect beliefs. The setup also assumes that ties are broken randomly; however in practice, ties may be broken in a more systematic manner by eliciting additional labels for only these hard questions. We now present a second set of simulations that mitigates these biases. In particular, when a worker has a confidence of p , the actual probability of error is assumed to be drawn from a Gaussian distribution with mean p and standard deviation 0.1, truncated to $[0, 1]$. In addition, when evaluating the performance of the

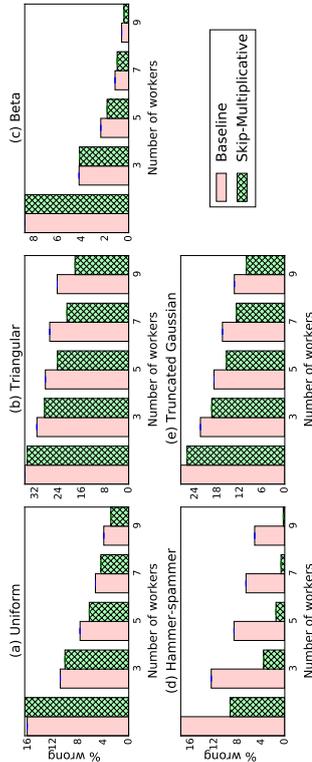

Figure 3: Errors under a model that is a perturbation of the first experiment, where the worker’s confidence is a noisy version of the true error probability and where ties are considered different from random decisions.

majority voting procedure, we consider a tie as having an error of 0.4. Figure 3 depicts the results of these simulations. We observe that the results from these simulations are very similar to those obtained in the earlier simulation setup of Figure 2.

6.2 Experiments on Amazon Mechanical Turk

We conducted preliminary experiments on the Amazon Mechanical Turk commercial crowdsourcing platform (`mturk.com`) to evaluate our proposed scheme in real-world scenarios. The complete data, including the interface presented to the workers in each of the tasks, the results obtained from the workers, and the ground truth solutions, are available on the website of the first author.

6.2.1 GOAL

Before delving into details, we first note certain caveats relating to such a study of mechanism design on crowdsourcing platforms. When a worker encounters a mechanism for only a small amount of time (a handful of tasks in typical research experiments) and for a small amount of money (at most a few dollars in typical crowdsourcing tasks), we cannot expect the worker to completely understand the mechanism and act precisely as required. For instance, we wouldn’t expect our experimental results to change significantly even upon moderate modifications in the promised amounts, and furthermore, we do expect the outcomes to be noisy. Incentive compatibility kicks in when the worker encounters a mechanism across a longer term, for example, when a proposed mechanism is adopted as a standard for a platform, or when higher amounts are involved. This is when we would expect workers or others (e.g., bloggers or researchers) to design strategies that can game the mechanism. The theoretical guarantee of incentive compatibility then prevents such gaming in the long run.

We thus regard these experiments as preliminary. Our intentions towards this experimental exercise were (a) to evaluate the potential of our algorithms to work in practice, (b) to investigate

the effect of the proposed algorithms on the net error in the collected labeled data, and (c) to identify if there is any major issue of dissatisfaction among the workers.

6.2.2 EXPERIMENTAL SETUP

We conducted our experiments on the “Amazon Mechanical Turk” commercial crowdsourcing platform (`mturk.com`). On this platform, individuals or businesses (called ‘requesters’) can post tasks, and any individual (called a ‘worker’) may complete the task over the Internet in exchange for a pre-specified payment. The payment may comprise of two parts: a fixed component which is identical for all workers performing that task, and a ‘bonus’ which may be different for different workers and is paid at the discretion of the requester.

We designed nine experiments (tasks) ranging from image annotation to text and speech recognition. The individual experiments are described in more detail in Appendix B. All experiments involved objective questions, and the responses elicited were multiple choice in five of the experiments and free-form text in the rest. For each experiment, we tested three settings: (i) the baseline conventional setting (Figure 1a) with a mechanism of paying a fixed amount per correct answer, (ii) our skip-based setting (Figure 1b) with our multiplicative mechanism, and (iii) our confidence-based setting (Figure 1c) with our confidence-based mechanism. For each mechanism in each experiment, we specified the requirement of 35 workers independently performing the task. This amounts to a total of 945 worker-tasks (315 worker-tasks for each mechanism). We also set the following constraints for a worker to attempt our tasks: the worker must have completed at least 100 tasks previously, and must have a history of having at least 95% of her prior work approved by the respective requesters. In each experiment, we offered a certain small fixed payment (in order to attract the workers in the first place) and executed the variable part of our mechanisms via a bonus payment.

6.2.3 RESULTS: RAW DATA

Figure 4 plots, for the baseline, skip-based and confidence-based mechanisms for all nine experiments, the (i) fraction of questions that were answered incorrectly, (ii) fraction of questions that were answered incorrectly among those that were attempted, (iii) the average payment to a worker (in cents), and (iv) break up of the answers in terms of the fraction of answers in each confidence level. The payment for various tasks plotted in Figure 4 is computed as the average of the payments across 100 (random) selections of the gold standard questions, in order to prevent any distortion of the results due to the randomness in the choice of the gold standard questions.

The figure shows that the amount of errors among the attempted questions is much lower in the skip and the confidence-based settings than the baseline setting. Also observe that in the confidence-based setting, as expected, the answers selected with higher confidence-levels are more correct. The total money spent under each of these settings is similar, with the skip and the confidence-based settings faring better in most cases. We also elicited feedback from the workers, in which we received several positive comments (and no negative comments). Examples of comments that we received: “I was wondering if it would be possible to increase the maximum number of HTTs I may complete for you. As I said before, they were fun to complete. I think I did a good job completing them, and it would be great to complete some more for you.”; “I am eagerly waiting for your bonus.”; “Enjoyable. Thanks.”

6.2.4. RESULTS: AGGREGATED DATA

We saw in the previous section that under the skip-based setting, the amount of error among the attempted questions was significantly lower than the amount of error in the baseline setting. However, the skip-based setting was also associated, by design, to lesser amount of data by virtue of questions being skipped by the workers. A natural question that arises is how the baseline and the skip-based mechanisms will compare in terms of the final data quality, i.e., the amount of error once data from multiple workers is aggregated.

To this end, we considered the five experiments that consisted of multiple-choice questions. We let a parameter `num_workers` take values in {3, 5, 7, 9, 11}. For each of the five experiments and for each of the five values of `num_workers`, we perform the following actions 1,000 times: for each question, we choose `num_workers` workers and perform a majority vote on their responses. If the correct answer for that question does not lie in the set of options given by the majority, we consider it as an accuracy of zero. Otherwise, if there are m options tied in the majority vote, and the correct answer is one of these m , then we consider it as an accuracy of $\frac{100\%}{m}$ (hence, 100% if the correct answer is the only answer picked by the majority vote). We average the accuracy across all questions and across all iterations.

We choose majority voting as the means of aggregation since (a) it is the simplest and still most popular aggregation method, and (b) to enable an apples-to-apples comparison design since while more advanced aggregation algorithms have been developed for the baseline setting without the skip (Raykar et al., 2010; Zhou et al., 2012; Wauthier and Jordan, 2011; Chen et al., 2013; Khetani and Oh, 2016; Dawid and Skene, 1979; Karger et al., 2011; Liu et al., 2012; Vempaty et al., 2014; Zhang et al., 2014; Ipeirotis et al., 2014; Zhou et al., 2015; Shah et al., 2016c), but design of analogous algorithms for the new skip-based setting is still open.

The results are presented in Figure 5. We see that in most cases, our skip-based mechanism induces a lower labeling error at the aggregate level than the baseline. Furthermore, in many of the instances, the reduction is two-fold or higher.

All in all, in the experiments, we observe a substantial reduction in the error-rates while expending the same or lower amounts and receiving no negative comments from the workers, suggesting that these mechanisms can work; the fundamental theory underlying the mechanisms ensures that the system cannot be gamed in the long run. Our proposed settings and mechanisms thus have the potential to provide much higher quality labeled data as input to machine learning algorithms.

7. Discussion and Conclusions

In this concluding section, we first discuss the modeling assumptions that we made in this paper, followed by a discussion on future work and concluding remarks.

7.1 Modeling Assumptions

When forming the model for our problem, as in any other field of theoretical research, we had to make certain assumptions and choices. In what follows, we discuss the reasons for the modeling choices we made.

- *Use of gold standard questions:* We assume the existence of gold standard questions in the task, i.e., a subset of questions to which the answers are known to the system designer. The existence of gold standard is commonplace in crowdsourcing platforms (Le et al., 2010; Chen et al., 2011).

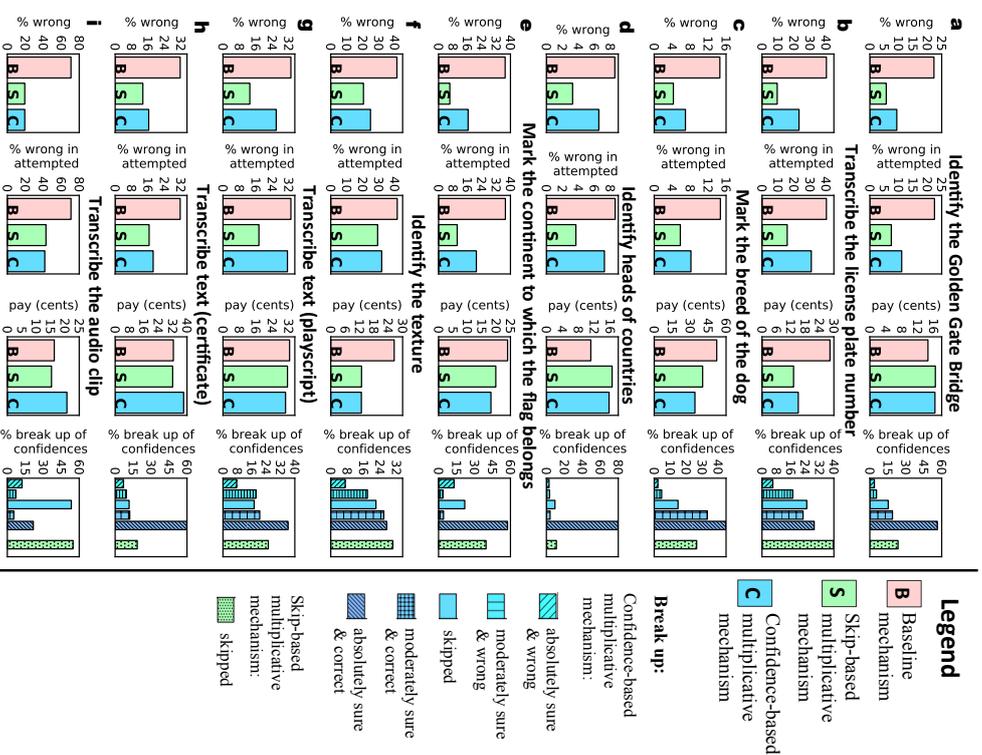

Figure 4: The error-rates in the raw data and payments in the nine experiments. Each individual bar in the plots corresponds to one mechanism in one experiment and is generated from 35 distinct workers (this totals to 945 worker-tasks).

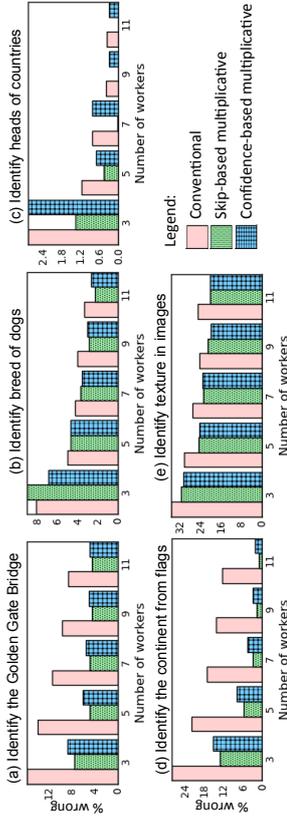

Figure 5: Error-rates in the aggregated data in the five experiments involving multiple-choice tasks.

- Workers aiming to maximize their expected payments:** We assume that the workers aim to maximize their expected payments. In many other problems in game theory, one often makes the assumption that people are “risk-averse”, and aim to maximize the expected value of some “utility function” of their payments. While we extend our results to general utility functions in Appendix C in order to accommodate such requirements, we also think that the assumption of workers maximizing their expected payments is a perfectly reasonable assumption for the crowdsourcing settings considered here. The reason is that each such task lasts for a handful of minutes and is worth a few tens of cents. Workers typically perform tens to hundreds of tasks per day, and consequently their empirical hourly wages very quickly converge to their expectation.
- Workers knowing their confidences:** We understand that in practice the workers will have noisy or granular estimates of their own beliefs. The mathematical assumption of workers knowing their precise confidences is an idealization intended for mathematical tractability. This is one of the reasons why we only elicit a quantized value of the workers’ beliefs (in terms of skipping or choosing one of a finite number of confidence levels), and not try to ask for a precise value.
- Eliciting a quantized version of the beliefs:** We do not directly attempt to elicit the values of the beliefs of the workers, but instead ask them to indicate only a quantization (e.g., “I’m not sure” or “moderately confident”, etc.). We prefer this quantization to direct assessment to real-valued probability, motivated by the extensive literature in psychology on the coarseness of human perception and processing (e.g., (Miller, 1956; Shiffrin and Nosofsky, 1994; Jones and Loe, 2013; Shah et al., 2016a)) establishing that humans are more comfortable at providing quantized responses. This notion is verified by experiments on Amazon Mechanical Turk in Shah et al. (2016a) where it is observed that people are more consistent when giving ordinal answers (comparing pairs of items) as opposed to when they are asked for numeric evaluations.
- Choosing the number of confidence levels L :** In the paper we assume that the number of confidence levels L is specified to us, and we provide mechanisms for any given choice of L . It is an interesting and challenging open problem to choose L for any given application in a principled manner. Up on increasing L , on one hand, we obtain additional nuanced information about the workers’ beliefs, while on the other hand, workers require a greater time and effort to provide

select the confidence level and their answers also tend to get noisier. In other words, both the “signal” and the “noise” in the data increase with an increase in the value of L , and lead to an interesting trade-off.

7.2 Open problems

We discuss two sets of open problems, one from the practical perspective and another on the theoretical front.

First, in the paper, we assumed that the number of total questions N in a task, the number of gold standard questions G , and the threshold T for skipping (or the number and thresholds of the different confidence levels) were provided to the mechanism. While these parameters may be chosen by hand by a system designer based on her own experience, a more principled design of these parameters is an important question. The choices for these parameters may have to be made based on certain tradeoffs. For instance, a higher value of G reduces the variance in the payments but uses more resources in terms of gold standard questions. Or for instance, more number of threshold levels L would increase the amount of information obtained about the workers’ beliefs, but also increase the noise in the workers’ estimates of her own beliefs.

A second open problem is the design of inference algorithms that can exploit the specific structure of the skip-based setting. There are several algorithms and theoretical analyses in the literature for aggregating data from multiple workers in the baseline setting (Raykar et al., 2010; Zhou et al., 2012; Wauthier and Jordan, 2011; Chen et al., 2013; Khetian and Oh, 2016; Dawid and Skene, 1979; Karger et al., 2011; Liu et al., 2012; Vempaty et al., 2014; Zhang et al., 2014; Ipeirotis et al., 2014; Zhou et al., 2015; Shah et al., 2016c). A useful direction of research in the future is to develop algorithms and the theoretical guarantees that incorporate information about the workers’ confidences. For instance, for the skip-based setting, the missing labels are not missing “at random” but are correlated with the difficulty of the task; in the confidence-based setting, we elicit information about the workers’ perceived confidence levels. Designing algorithms that can exploit this information judiciously (e.g., via confidence-weighted worker/item constraints in the minimax entropy method of Zhou et al. (2015)) is a useful direction of future research.

7.3 Conclusions

Despite remarkable progress in machine learning and artificial intelligence, many problems are still not solvable by either humans or machines alone. In recent years, crowdsourcing has emerged as a powerful tool to combine both human and machine intelligence. Crowdsourcing is also a standard means of collecting labeled data for machine learning algorithms. However, crowdsourcing is often plagued with the problem of poor-quality output from workers.

We designed a reward mechanism for crowdsourcing to ensure collection of high-quality data. Under a very natural “no-free-lunch” axiom, we mathematically prove that surprisingly, our mechanism is the only feasible reward mechanism. We further show that among all possible incentive-compatible mechanisms, our “multiplicative” mechanism makes the strictly smallest expenditure on spammers. In preliminary experiments, we observe a significant drop in the error rates under this unique mechanism as compared to basic baseline mechanisms, suggesting that our mechanism has the potential to work well in practice. Our mechanisms offer some additional benefits. The pattern of skips or confidence levels of the workers provide a reasonable estimate of the difficulty of each question. In practice, the questions that are estimated to be more difficult may now be delegated

to an expert or to more non-expert workers. Secondly, the theoretical guarantees of the mechanism may allow for better post-processing of the data, incorporating the confidence information and improving the overall accuracy. The simplicity of the rules of our mechanisms may facilitate an easier adoption among the workers.

In conclusion, given the uniqueness in theory, simplicity, and good performance observed in practice, we envisage our ‘multiplicative’ mechanisms to be of interest to machine learning researchers and practitioners who use crowdsourcing to collect labeled data.

We also thank John C. Platt and Martin J. Wainwright for helping in proof-reading and polishing parts of the manuscript. This work was done when Nihar B. Shah was an intern at Microsoft Research.

Appendix A. Proofs

In this section, we prove the claimed theoretical results whose proofs are not included in the main text of the paper.

The property of incentive-compatibility does not change upon any shift of the mechanism by a constant value or any scaling by a positive constant value. As a result, for the purposes of these proofs, we can assume without loss of generality that $\mu_{\min} = 0$.

A.1 Proof of Lemma 4: The Workhorse Lemma

First we consider the case of $G = N$. In the set $\{y_1, \dots, y_{i-1}, y_{i+1}, \dots, y_G\}$, for some $(\eta, \gamma) \in \{0, \dots, G-1\}^2$ such that $\eta + \gamma + 1 \leq G$, suppose there are η elements with a value $1, \gamma$ elements with a value -1 , and $(G-1-\eta-\gamma)$ elements with a value 0 . Let us assume for now that $i = \eta + \gamma + 1, y_1 = 1, \dots, y_\eta = 1, y_{\eta+1} = -1, \dots, y_{\eta+\gamma} = -1, y_{\eta+\gamma+2} = 0, \dots, y_G = 0$.

Suppose the worker has confidences $(p_1, \dots, p_{\eta+\gamma}) \in (T, 1]^{\eta+\gamma}$ for the first $(\eta + \gamma)$ questions, a confidence of $q \in (0, 1]$ for the next question, and confidences smaller than T for the remaining $(G - \eta - \gamma - 1)$ questions. The mechanism must incentivize the worker to answer the first $(\eta + \gamma)$ questions and skip the last $(G - \eta - \gamma - 1)$ questions; for question $(\eta + \gamma + 1)$, it must incentivize the worker to answer if $q > T$ and skip if $q < T$. Supposing the worker indeed attempts the first $(\eta + \gamma)$ questions and skips the last $(G - \eta - \gamma - 1)$ questions, let $x = \{x_1, \dots, x_{\eta+\gamma}\} \in \{-1, 1\}^{\eta+\gamma}$ denote the evaluation of the worker’s answers to the first $(\eta + \gamma)$ questions. Define quantities $\{r_j\}_{j \in [\eta+\gamma]}$ as $r_j = 1 - p_j$ for $j \in \{1, \dots, \eta\}$, and $r_j = p_j$ for $j \in \{\eta + 1, \eta + \gamma\}$. The requirement

of incentive compatibility necessitates

$$\begin{aligned} & q \sum_{x \in \{-1, 1\}^{\eta+\gamma}} \left(f(x_1, \dots, x_\eta, -x_{\eta+1}, \dots, -x_{\eta+\gamma}, 1, 0, \dots, 0) \prod_{j \in [\eta+\gamma]} \frac{1-x_j}{r_j} (1-r_j)^{\frac{1+x_j}{2}} \right) \\ & + (1-q) \sum_{x \in \{-1, 1\}^{\eta+\gamma}} \left(f(x_1, \dots, x_\eta, -x_{\eta+1}, \dots, -x_{\eta+\gamma}, -1, 0, \dots, 0) \prod_{j \in [\eta+\gamma]} \frac{1-x_j}{r_j} (1-r_j)^{\frac{1+x_j}{2}} \right) \\ & \stackrel{q < T}{\leq} \sum_{q > T} \sum_{x \in \{-1, 1\}^{\eta+\gamma}} \left(f(x_1, \dots, x_\eta, -x_{\eta+1}, \dots, -x_{\eta+\gamma}, 0, 0, \dots, 0) \prod_{j \in [\eta+\gamma]} \frac{1-x_j}{r_j} (1-r_j)^{\frac{1+x_j}{2}} \right). \end{aligned}$$

The left hand side of this expression is the expected payment if the worker chooses to answer question $(\eta + \gamma + 1)$, while the right hand side is the expected payment if she chooses to skip it. For any real-valued variable q , and for any real-valued constants a, b and c ,

$$aq \stackrel{q < c}{\leq} b \stackrel{q > c}{\Rightarrow} ac = b.$$

As a result,

$$\begin{aligned} & T \sum_{x \in \{-1, 1\}^{\eta+\gamma}} \left(f(x_1, \dots, x_\eta, -x_{\eta+1}, \dots, -x_{\eta+\gamma}, 1, 0, \dots, 0) \prod_{j \in [\eta+\gamma]} \frac{1-x_j}{r_j} (1-r_j)^{\frac{1+x_j}{2}} \right) \\ & + (1-T) \sum_{x \in \{-1, 1\}^{\eta+\gamma}} \left(f(x_1, \dots, x_\eta, -x_{\eta+1}, \dots, -x_{\eta+\gamma}, -1, 0, \dots, 0) \prod_{j \in [\eta+\gamma]} \frac{1-x_j}{r_j} (1-r_j)^{\frac{1+x_j}{2}} \right) \\ & - \sum_{x \in \{-1, 1\}^{\eta+\gamma}} \left(f(x_1, \dots, x_\eta, -x_{\eta+1}, \dots, -x_{\eta+\gamma}, 0, 0, \dots, 0) \prod_{j \in [\eta+\gamma]} \frac{1-x_j}{r_j} (1-r_j)^{\frac{1+x_j}{2}} \right) = 0. \end{aligned} \tag{8}$$

The left hand side of (8) represents a polynomial in $(\eta + \gamma)$ variables $\{r_j\}_{j=1}^{\eta+\gamma}$ which evaluates to zero for all values of the variables within a $(\eta + \gamma)$ -dimensional solid Euclidean ball. Thus, the coefficients of the monomials in this polynomial must be zero. In particular, the constant term must be zero. The constant term appears when $x_j = 1 \forall j$ in the summations in (8). Setting the constant term to zero gives

$$\begin{aligned} & T f(x_1 = 1, \dots, x_\eta = 1, -x_{\eta+1} = -1, \dots, -x_{\eta+\gamma} = -1, 1, 0, \dots, 0) \\ & + (1-T) f(x_1 = 1, \dots, x_\eta = 1, -x_{\eta+1} = -1, \dots, -x_{\eta+\gamma} = -1, -1, 0, \dots, 0) \\ & - f(x_1 = 1, \dots, x_\eta = 1, -x_{\eta+1} = -1, \dots, -x_{\eta+\gamma} = -1, 0, 0, \dots, 0) = 0, \end{aligned}$$

as desired. Since the arguments above hold for any permutation of the G questions, this completes the proof for the case of $G = N$.

Now consider the case $G < N$. Let $g : \{-1, 0, 1\}^N \rightarrow \mathbb{R}_+$ represent the expected payment given an evaluation of all the N answers, when the identities of the gold standard questions are

unknown. Here, the expectation is with respect to the (uniformly random) choice of the G gold standard questions. If $(x_1, \dots, x_N) \in \{-1, 0, 1\}^N$ are the evaluations of the worker's answers to the N questions then the expected payment is

$$g(x_1, \dots, x_N) = \frac{1}{\binom{N}{G}} \sum_{\{i_1, \dots, i_G\} \subseteq \{1, \dots, N\}} f(x_{i_1}, \dots, x_{i_G}). \quad (9)$$

Notice that when $G = N$, the functions f and g are identical.

In the set $\{y_1, \dots, y_{\eta-1}, y_{\eta+1}, \dots, y_G\}$, for some $(\eta, \gamma) \in \{0, \dots, G-1\}^2$ with $\eta + \gamma < G$, suppose there are η elements with a value 1, γ elements with a value -1 , and $(G-1-\eta-\gamma)$ elements with a value 0. Let us assume for now that $i = \eta + \gamma + 1$, $y_i = 1, \dots, y_\eta = 1, y_{\eta+1} = -1, \dots, y_{\eta+\gamma} = -1, y_{\eta+\gamma+2} = 0, \dots, y_G = 0$.

Suppose the worker has confidences $\{p_1, \dots, p_{\eta+\gamma}\} \in (T, 1]^{\eta+\gamma}$ for the first $(\eta + \gamma)$ of the N questions, a confidence of $q \in (0, 1]$ for the next question, and confidences smaller than T for the remaining $(N - \eta - \gamma - 1)$ questions. The mechanism must incentivize the worker to answer the first $(\eta + \gamma)$ questions and skip the last $(N - \eta - \gamma - 1)$ questions; for the $(\eta + \gamma + 1)^{\text{th}}$ question, the mechanism must incentivize the worker to answer if $q > T$ and skip if $q < T$. Supposing the worker indeed attempts the first $(\eta + \gamma)$ questions and skips the last $(N - \eta - \gamma - 1)$ questions, let $x = \{x_1, \dots, x_{\eta+\gamma}\} \in \{-1, 1\}^{\eta+\gamma}$ denote the evaluations of the worker's answers to the first $(\eta + \gamma)$ questions. Define quantities $\{r_j\}_{j \in [\eta+\gamma]}$ as $r_j = 1 - p_j$ for $j \in \{1, \dots, \eta\}$, and $r_j = p_j$ for $j \in \{\eta + 1, \eta + \gamma\}$. The requirement of incentive compatibility necessitates

$$\begin{aligned} q & \sum_{x \in \{-1, 1\}^{\eta+\gamma}} \left(g(x_1, \dots, x_\eta, -x_{\eta+1}, \dots, -x_{\eta+\gamma}, 1, 0, \dots, 0) \prod_{j \in [\eta+\gamma]} r_j^{\frac{1-x_j}{2}} (1-r_j)^{\frac{1+x_j}{2}} \right) \\ & + (1-q) \sum_{x \in \{-1, 1\}^{\eta+\gamma}} \left(g(x_1, \dots, x_\eta, -x_{\eta+1}, \dots, -x_{\eta+\gamma}, -1, 0, \dots, 0) \prod_{j \in [\eta+\gamma]} r_j^{\frac{1-x_j}{2}} (1-r_j)^{\frac{1+x_j}{2}} \right) \\ & \sum_{q < T} \sum_{q > T} \left(g(x_1, \dots, x_\eta, -x_{\eta+1}, \dots, -x_{\eta+\gamma}, 0, 0, \dots, 0) \prod_{j \in [\eta+\gamma]} r_j^{\frac{1-x_j}{2}} (1-r_j)^{\frac{1+x_j}{2}} \right). \end{aligned} \quad (10)$$

Again, applying the fact that for any real-valued variable q and for any real-valued constants a, b and $c, aq \sum_{q < c} b \sum_{q > c} b \Rightarrow ac = b$, we get that

$$\begin{aligned} Tg(x_1 = 1, \dots, x_\eta = 1, -x_{\eta+1} = -1, \dots, -x_{\eta+\gamma} = -1, 1, 0, \dots, 0) \\ + (1-T)g(x_1 = 1, \dots, x_\eta = 1, -x_{\eta+1} = -1, \dots, -x_{\eta+\gamma} = -1, -1, 0, \dots, 0) \\ - g(x_1 = 1, \dots, x_\eta = 1, -x_{\eta+1} = -1, \dots, -x_{\eta+\gamma} = -1, 0, 0, \dots, 0) = 0. \end{aligned} \quad (11)$$

The proof now proceeds via induction on the quantity $(G - \eta - \gamma - 1)$, i.e., on the number of skipped questions in $\{y_1, \dots, y_{\eta-1}, y_{\eta+1}, \dots, y_G\}$. We begin with the case of $(G - \eta - \gamma - 1) = G - 1$ which implies $\eta = \gamma = 0$. In this case (11) simplifies to

$$Tg(1, 0, \dots, 0) + (1-T)g(-1, 0, \dots, 0) = g(0, 0, \dots, 0).$$

Applying the expansion of function g in terms of function f from (9) gives

$$\begin{aligned} T(c_1 f(1, 0, \dots, 0) + c_2 f(0, 0, \dots, 0)) + (1-T)(c_1 f(-1, 0, \dots, 0) + c_2 f(0, 0, \dots, 0)) \\ = (c_1 f(0, 0, \dots, 0) + c_2 f(0, 0, \dots, 0)) \end{aligned}$$

for constants $c_1 > 0$ and $c_2 > 0$ that respectively denote the probabilities that the first question is picked and not picked in the set of G gold standard questions. Canceling out the common terms on both sides of the equation, we get the desired result

$$Tf(1, 0, \dots, 0) + (1-T)f(-1, 0, \dots, 0) = f(0, 0, \dots, 0).$$

Next, we consider the case when $(G - \eta - \gamma - 1)$ questions are skipped in the gold standard, and assume that the result is true when more than $(G - \eta - \gamma - 1)$ questions are skipped in the gold standard. In (11), the functions g decompose into a sum of the constituent f functions. These constituent functions f are of two types: the first where all of the first $(\eta + \gamma + 1)$ questions are included in the gold standard, and the second where one or more of the first $(\eta + \gamma + 1)$ questions are not included in the gold standard. The second case corresponds to situations where there are more than $(G - \eta - \gamma - 1)$ questions skipped in the gold standard and hence satisfies our induction hypothesis. The terms corresponding to these functions thus cancel out in the expansion of (11). The remainder comprises only evaluations of function f for arguments in which the first $(\eta + \gamma + 1)$ questions are included in the gold standard: since the last $(N - \eta - \gamma - 1)$ questions are skipped by the worker, the remainder evaluates to

$$\begin{aligned} Tc_3 f(y_1, \dots, y_{\eta+\gamma}, 1, 0, \dots, 0) + (1-T)c_3 f(y_1, \dots, y_{\eta+\gamma}, -1, 0, \dots, 0) \\ = c_3 f(y_1, \dots, y_{\eta+\gamma}, 0, 0, \dots, 0) \end{aligned}$$

for some constant $c_3 > 0$. Dividing throughout by c_3 gives the desired result.

Finally, the arguments above hold for any permutation of the first G questions, thus completing the proof.

A.2 Proof of Theorem 7: Working of Algorithm 2

We first state three properties that the constants $\{\alpha_l\}_{l=-L}^L$ defined in Algorithm 2 must satisfy. We will use these properties subsequently in the proof of Theorem 7.

Lemma 14 For every $l \in \{0, \dots, L-1\}$

$$T_{l+1}\alpha_{l+1} + (1-T_{l+1})\alpha_{-(l+1)} = T_{l+1}\alpha_l + (1-T_{l+1})\alpha_{-l}, \quad (12a)$$

and

$$S_{l+1}\alpha_{l+1} + (1-S_{l+1})\alpha_{-(l+1)} = \alpha_0 = 1. \quad (12b)$$

Lemma 15 $\alpha_L > \alpha_{L-1} > \dots > \alpha_{-L} = 0$.

Lemma 16 For any $m \in \{1, \dots, L\}$, any $p > T_m$ and any $z < m$,

$$p\alpha_m + (1-p)\alpha_{-m} > p\alpha_z + (1-p)\alpha_{-z}, \quad (13a)$$

and for any $m \in \{0, \dots, L-1\}$, any $p < T_{m+1}$ and any $z > m$,

$$p\alpha_m + (1-p)\alpha_{-m} > p\alpha_z + (1-p)\alpha_{-z}. \quad (13b)$$

The proof of these results are available at the end of this subsection. Assuming these lemmas hold, we will now complete the proof of Theorem 7.

The choice of $\alpha_{-L} = 0$ made in Algorithm 2 ensures that the payment is zero whenever any answer in the gold standard evaluates to $-L$. This choice ensures that the no-free-lunch axiom is satisfied. One can easily verify that the payment lies in the interval $[0, \mu_{\max}]$. It remains to prove that the proposed mechanism is incentive-compatible.

Define $E = (\epsilon_1, \dots, \epsilon_G) \in \{-1, 1\}^G$ and $E_{\setminus 1} = (\epsilon_2, \dots, \epsilon_G)$. Suppose the worker has confidences p_1, \dots, p_N for her N answers. For some $(s(1), \dots, s(N)) \in \{0, \dots, L\}^N$ suppose $p_i \in (T_{s(i)}; T_{s(i+1)}) \forall i \in \{1, \dots, N\}$, i.e., $s(1), \dots, s(N)$ are the correct confidence-levels for her answers. Consider any other set of confidence-levels $s'(1), \dots, s'(N)$. When the mechanism of Algorithm 2 is employed, the expected payment (from the point of view of the worker) on selecting confidence-levels $s(1), \dots, s(N)$ is

$$\mathbb{E}[\text{Pay}] = \frac{1}{\binom{N}{G}} \sum_{\substack{(j_1, \dots, j_G) \\ \subseteq \{1, \dots, N\}}} \sum_{E \in \{-1, 1\}^G} \prod_{i=1}^G \alpha_{\epsilon_i s(j_i)} (p_{j_i})^{\frac{1+\epsilon_i}{2}} (1-p_{j_i})^{\frac{1-\epsilon_i}{2}} \quad (14a)$$

$$= \frac{1}{\binom{N}{G}} \sum_{\substack{(j_1, \dots, j_G) \\ \subseteq \{1, \dots, N\}}} \sum_{E_{\setminus 1} \in \{-1, 1\}^{G-1}} (p_{j_1} \alpha_{s(j_1)} + (1-p_{j_1}) \alpha_{-s(j_1)}) \prod_{i=2}^G \alpha_{\epsilon_i s(j_i)} (p_{j_i})^{\frac{1+\epsilon_i}{2}} (1-p_{j_i})^{\frac{1-\epsilon_i}{2}} \quad (14b)$$

⋮

$$= \frac{1}{\binom{N}{G}} \sum_{\substack{(j_1, \dots, j_G) \\ \subseteq \{1, \dots, N\}}} \prod_{i=1}^G (p_{j_i} \alpha_{s(j_i)} + (1-p_{j_i}) \alpha_{-s(j_i)}) \quad (14c)$$

$$> \frac{1}{\binom{N}{G}} \sum_{\substack{(j_1, \dots, j_G) \\ \subseteq \{1, \dots, N\}}} \prod_{i=1}^G (p_{j_i} \alpha_{s'(j_i)} + (1-p_{j_i}) \alpha_{-s'(j_i)}) \quad (14d)$$

which is the expected payment under any other set of confidence-levels $s'(1), \dots, s'(N)$. The last inequality is a consequence of Lemma 16.

An argument similar to the above also proves that for any $m \in \{1, \dots, L\}$, if allowed to choose level m over skip if her confidence is greater S_{m_m} and choose skip over level m if her confidence is smaller than S_{m_m} . Finally, from Lemma 15 we have $\alpha_{-L} > \dots > \alpha_{-L} = 0$. It follows that the expected payment (14c) is strictly increasing in each of the values p_1, \dots, p_N . Thus the worker is incentivized to report the answer that she thinks is most likely to be correct.

A.2.1. PROOF OF LEMMA 14

Algorithm 2 states that $\alpha_{-l} = \frac{1-\alpha_l S_l}{1-S_l}$ for all $l \in [L]$. A simple rearrangement of the terms in this expression gives (12b).

Towards the goal of proving (12a), we will first prove an intermediate result:

$$\alpha_l > 1 > \alpha_{-l} \forall l \in \{L, \dots, 1\}. \quad (15)$$

The proof proceeds via an induction on $l \in \{L, \dots, 2\}$. The case of $l = 1$ will be proved separately. The induction hypothesis involves two claims: $\alpha_l > 1 > \alpha_{-l}$ and $T_l \alpha_l + (1-T_l) \alpha_{-l} > 1$. The base case is $l = L$ for which we know that $\alpha_L = \frac{1}{S_L} > 1 > 0 = \alpha_{-L}$ and $T_l \alpha_l + (1-T_l) \alpha_{-l} = \frac{T_l}{S_l} > 1$. Now suppose that the induction hypothesis is true for $(l+1)$. Rearranging the terms in the expression defining α_l in Algorithm 2 and noting that $1 > T_{l+1} > S_l$, we get

$$\begin{aligned} \alpha_l &= \frac{(1-S_l)(T_{l+1} \alpha_{l+1} + (1-T_{l+1}) \alpha_{-(l+1)}) - (1-T_{l+1})}{(1-S_l) - (1-T_{l+1})} \\ &> \frac{(1-S_l) - (1-T_{l+1})}{(1-S_l) - (1-T_{l+1})} \\ &= 1. \end{aligned} \quad (16)$$

From (12b) we see that the value 1 is a convex combination of α_l and α_{-l} . Since $\alpha_l > 1$ and $S_l \in (0, 1)$, it must be that $\alpha_{-l} < 1$. Furthermore, since $T_l > S_l$ we get

$$\begin{aligned} T_l \alpha_l + (1-T_l) \alpha_{-l} &> S_l \alpha_l + (1-S_l) \alpha_{-l} \\ &= 1. \end{aligned}$$

This proves the induction hypothesis. Let us now consider $l = 1$. If $L = 1$ then we have $\alpha_L = \frac{1}{S_L} > 1 > 0 = \alpha_{-L}$ and we are done. If $L > 1$ then we have already proved that $\alpha_2 > 1 > \alpha_{-2}$ and $T_2 \alpha_2 + (1-T_2) \alpha_{-2} > 1$. An argument identical to (16) onwards proves that $\alpha_1 > 1 > \alpha_{-1}$.

Now that we have proved $\alpha_l > \alpha_{-l} \forall l \in [L]$, we can rewrite the expression defining α_{-l} in Algorithm 2 as

$$S_l = \frac{1-\alpha_{-l}}{\alpha_l - \alpha_{-l}}.$$

Substituting this expression for S_l in the definition of α_l in Algorithm 2 and making some simple rearrangements gives the desired result (12a).

A.2.2. PROOF OF LEMMA 15

We have already shown (15) in the proof of Lemma 14 above that $\alpha_l > 1 > \alpha_{-l} \forall l \in [L]$.

Next we will show that $\alpha_{l+1} > \alpha_l$ and $\alpha_{-(l+1)} < \alpha_{-l} \forall l \geq 0$. First consider $l = 0$, for which Algorithm 2 sets $\alpha_0 = 1$, and we have already proved that $\alpha_1 > 1 > \alpha_{-1}$.

Now consider some $l > 0$. Observe that since $S_l \alpha_l + (1-S_l) \alpha_{-l} = 1$ (Lemma 14), $S_{l+1} > S_l$ and $\alpha_l > \alpha_{-l}$, it must be that

$$S_{l+1} \alpha_l + (1-S_{l+1}) \alpha_{-l} > 1. \quad (17)$$

From Lemma 14, we also have

$$S_{l+1} \alpha_{l+1} + (1-S_{l+1}) \alpha_{-(l+1)} = 1. \quad (18)$$

Subtracting (17) from (18) we get

$$S_{l+1} (\alpha_{l+1} - \alpha_l) + (1-S_{l+1}) (\alpha_{-(l+1)} - \alpha_{-l}) < 0. \quad (19)$$

From Lemma 14 we also have

$$T_{l+1}\alpha_{l+1} + (1 - T_{l+1})\alpha_{-(l+1)} = T_{l+1}\alpha_l + (1 - T_{l+1})\alpha_{-l} \quad (20)$$

$$\Rightarrow T_{l+1}(\alpha_{l+1} - \alpha_l) + (1 - T_{l+1})(\alpha_{-(l+1)} - \alpha_{-l}) = 0. \quad (21)$$

Subtracting (19) from (21) gives

$$(T_{l+1} - S_{l+1})(\alpha_{l+1} - \alpha_l) + (\alpha_{-l} - \alpha_{-(l+1)}) > 0. \quad (22)$$

Since $T_{l+1} > S_{l+1}$ by definition, it must be that

$$\alpha_{l+1} - \alpha_l > \alpha_{-(l+1)} - \alpha_{-l}. \quad (23)$$

Now, rearranging the terms in (20) gives

$$(\alpha_{l+1} - \alpha_l)T_{l+1} = -(\alpha_{-(l+1)} - \alpha_{-l})(1 - T_{l+1}). \quad (24)$$

Since $T_{l+1} \in (0, 1)$, it follows that the terms $(\alpha_{l+1} - \alpha_l)$ and $(\alpha_{-(l+1)} - \alpha_{-l})$ have opposite signs. Using (23) we conclude that $\alpha_{l+1} - \alpha_l > 0$ and $\alpha_{-(l+1)} - \alpha_{-l} < 0$.

A.2.3 PROOF OF LEMMA 16

Let us first prove (13a). First consider the case $z = m - 1$. From Lemma 14 we know that

$$T_m\alpha_{m-1} + (1 - T_m)\alpha_{-(m-1)} = T_m\alpha_m + (1 - T_m)\alpha_{-m},$$

and hence

$$\begin{aligned} 0 &= T_m(\alpha_m - \alpha_{m-1}) + T_m(\alpha_{-(m-1)} - \alpha_{-m}) - (\alpha_{-(m-1)} - \alpha_{-m}) \\ &< p(\alpha_m - \alpha_{m-1}) + p(\alpha_{-(m-1)} - \alpha_{-m}) - (\alpha_{-(m-1)} - \alpha_{-m}), \end{aligned} \quad (25)$$

where (25) is a consequence of $p > T_m$ and Lemma 15. A simple rearrangement of the terms in (25) gives (13a). Now, for any $z < m$, recursively apply this result to get

$$\begin{aligned} p\alpha_m + (1 - p)\alpha_{-m} &> p\alpha_{m-1} + (1 - p)\alpha_{-(m-1)} \\ &> p\alpha_{m-2} + (1 - p)\alpha_{-(m-2)} \\ &\vdots \\ &> p\alpha_z + (1 - p)\alpha_{-z}. \end{aligned}$$

Let us now prove (13b). We first consider the case $z = m + 1$. From Lemma 14 we know that

$$T_{m+1}\alpha_m + (1 - T_{m+1})\alpha_{-m} = T_{m+1}\alpha_{m+1} + (1 - T_{m+1})\alpha_{-(m+1)},$$

and hence

$$\begin{aligned} 0 &= T_{m+1}(\alpha_{m+1} - \alpha_m) + T_{m+1}(\alpha_{-m} - \alpha_{-(m+1)}) - (\alpha_{-m} - \alpha_{-(m+1)}) \\ &> p(\alpha_{m+1} - \alpha_m) + p(\alpha_{-m} - \alpha_{-(m+1)}) - (\alpha_{-m} - \alpha_{-(m+1)}), \end{aligned} \quad (26)$$

where (26) is a consequence of $p < T_{m+1}$ and Lemma 15. A simple rearrangement of the terms in (26) gives (13b). For any $z > m$, applying this result recursively gives

$$\begin{aligned} p\alpha_m + (1 - p)\alpha_{-m} &> p\alpha_{m+1} + (1 - p)\alpha_{-(m+1)} \\ &> p\alpha_{m+2} + (1 - p)\alpha_{-(m+2)} \\ &\vdots \\ &> p\alpha_z + (1 - p)\alpha_{-z}. \end{aligned}$$

A.3 Proof of Theorem 9: Uniqueness of Algorithm 2

We will first define one additional piece of notation. Let $g : \{-L, \dots, L\}^N \rightarrow \mathbb{R}_+$ denote the expected payment given an evaluation of the N answers, where the expectation is with respect to the (uniformly random) choice of the G gold standard questions. If $(x_1, \dots, x_N) \in \{-L, \dots, L\}^N$ are the evaluations of the worker's answers to the N questions then the expected payment is

$$g(x_1, \dots, x_N) = \frac{1}{\binom{N}{G}} \sum_{\{i_1, \dots, i_G\} \subseteq \{1, \dots, N\}} f(x_{i_1}, \dots, x_{i_G}). \quad (27)$$

Notice that when $G = N$, the functions f and g are identical.

The proof of uniqueness is based on a certain condition necessitated by incentive-compatibility stated in the form of Lemma 17 below. Note that this lemma does *not* require the generalized-no-free-lunch axiom, and may be of independent interest.

Lemma 17 *Any incentive-compatible mechanism must satisfy, for every question $i \in \{1, \dots, G\}$, every*

$$(y_1, \dots, y_{i-1}, y_{i+1}, \dots, y_G) \in \{-L, \dots, L\}^{G-1}, \text{ and every } m \in \{1, \dots, L\},$$

$$\begin{aligned} T_m f(y_1, \dots, y_{i-1}, m, y_{i+1}, \dots, y_G) + (1 - T_m) f(y_1, \dots, y_{i-1}, -m, y_{i+1}, \dots, y_G) \\ = T_m f(y_1, \dots, y_{i-1}, m - 1, y_{i+1}, \dots, y_G) + (1 - T_m) f(y_1, \dots, y_{i-1}, -(m - 1), y_{i+1}, \dots, y_G) \end{aligned} \quad (28a)$$

and

$$\begin{aligned} S_m f(y_1, \dots, y_{i-1}, m, y_{i+1}, \dots, y_G) + (1 - S_m) f(y_1, \dots, y_{i-1}, -m, y_{i+1}, \dots, y_G) \\ = f(y_1, \dots, y_{i-1}, 0, y_{i+1}, \dots, y_G). \end{aligned} \quad (28b)$$

Note that (28a) and (28b) coincide when $m = 1$, since $T_1 = S_1$ by definition.

We first prove that any incentive compatible mechanism that satisfies the no-free-lunch axiom must give a zero payment when one or more questions are selected with a confidence L and turn out to be incorrect. Let us assume for now that in the G questions in the gold standard, the first question is answered incorrectly with a confidence of L , the next $(G - 1 - S)$ questions are answered by the worker and have arbitrary evaluations, and the remaining S questions are skipped. The proof proceeds by an induction on S . If $S = G - 1$, the only attempted question is the first question and this is incorrect with confidence L . The no-free-lunch axiom necessitates a zero payment in this

case, thus satisfying the base case of our induction hypothesis. Now we prove the hypothesis for some S under the assumption that the hypothesis is true for every $S' > S$. From Lemma 4 with $m = 1$, we have

$$\begin{aligned} T_1 f(-L, y_2, \dots, y_{G-S-1}, 1, 0, \dots, 0) + (1 - T_1) f(-L, y_2, \dots, y_{G-S-1}, -1, 0, \dots, 0) \\ = T_1 f(-L, y_2, \dots, y_{G-S-1}, 0, 0, \dots, 0) + (1 - T_1) f(-L, y_2, \dots, y_{G-S-1}, 0, 0, \dots, 0) \\ = f(-L, y_2, \dots, y_{G-S-1}, 0, 0, \dots, 0) \\ = 0, \end{aligned} \quad (29)$$

where the final equation (29) is a consequence of our induction hypothesis given the fact that $f(-L, y_2, \dots, y_{G-S-1}, 0, 0, \dots, 0)$ corresponds to the case when the last $(S + 1)$ questions are skipped and the first question is answered incorrectly with confidence L . Now, since the payment f must be non-negative and since $T \in (0, 1)$, it must be that

$$f(-L, y_2, \dots, y_{G-S-1}, 1, 0, \dots, 0) = 0 \quad (30a)$$

and

$$f(-L, y_2, \dots, y_{G-S-1}, -1, 0, \dots, 0) = 0. \quad (30b)$$

Repeatedly applying the same argument to $m = 2, \dots, L$ gives that for every value of m , it must be that $f(-L, y_2, \dots, y_{G-S-1}, m, 0, \dots, 0) = f(-L, y_2, \dots, y_{G-S-1}, -m, 0, \dots, 0) = 0$. This completes the proof of our induction hypothesis. Observe that each of the aforementioned arguments hold for any permutation of the G questions, thus proving the necessity of zero payment when any one or more answers are incorrect.

We will now prove that when no answers in the gold standard are incorrect with confidence L , the payment must be of the form described in Algorithm 1. Let κ denote the payment when all G questions in the gold standard are skipped, i.e.,

$$\kappa = f(0, \dots, 0).$$

Now consider any $S \in \{0, \dots, G - 1\}$ and any $(y_1, \dots, y_{G-S-1}, m) \in \{-L, \dots, L\}^{G-S}$. The payments $\{f(y_1, \dots, y_{G-S-1}, m, 0, \dots, 0)\}_{m=-L}^L$ must satisfy the $(2L - 1)$ linear constraints arising out of Lemma 17 and must also satisfy $f(y_1, \dots, y_{G-S-1}, -L, 0, \dots, 0) = 0$. This set of conditions comprises a total of $2L$ linearly independent constraints on the set of $(2L + 1)$ values $\{f(y_1, \dots, y_{G-S-1}, m, 0, \dots, 0)\}_{m=-L}^L$. The only set of solutions that meet these constraints are

$$f(y_1, \dots, y_{G-S-1}, m, 0, \dots, 0) = \alpha_m f(y_1, \dots, y_{G-S-1}, 0, 0, \dots, 0),$$

where the constants $\{\alpha_m\}_{m=-L}^L$ are as specified in Algorithm 2. Applying this argument G times, starting from $S = 0$ to $S = G - 1$, gives

$$f(y_1, \dots, y_G) = \kappa \prod_{j=1}^G \alpha_{y_j}.$$

Finally, the budget requirement necessitates $\mu_{\max} = \kappa (\alpha_L)^G$, which mandates the value of κ to be $\mu_{\max} \left(\frac{1}{\alpha_L}\right)^G$. This is precisely the mechanism described in Algorithm 2.

A.4 Proof of Lemma 17: Necessary condition for any incentive-compatible mechanism

First consider the case of $G = N$. For every $j \in \{1, \dots, i - 1, i + 1, \dots, G\}$, define

$$r_j = \begin{cases} 1 - p_j & \text{if } y_j \geq 0 \\ p_j & \text{if } y_j < 0. \end{cases}$$

Define $E_{y_i} = \{\epsilon_1, \dots, \epsilon_{i-1}, \epsilon_{i+1}, \dots, \epsilon_G\}$. For any $l \in \{-L, \dots, L\}$ let $\Lambda_l \in \mathbb{R}_+$ denote the expected payment (from the worker's point of view) when her answer to the i^{th} question evaluates to l :

$$\Lambda_l = \sum_{E_{y_i} \in \{-1, 1\}^{G-1}} \left(f(y_1 \epsilon_1, \dots, y_{i-1} \epsilon_{i-1}, l, y_{i+1} \epsilon_{i+1}, \dots, y_G \epsilon_G) \prod_{j \in [G] \setminus \{i\}} r_j^{\frac{1-\epsilon_j}{2}} (1 - r_j)^{\frac{1+\epsilon_j}{2}} \right). \quad (31)$$

Consider a worker who has confidences $\{p_1, \dots, p_{i-1}, p_{i+1}, \dots, p_G\} \in (0, 1)^{G-1}$ for questions $\{1, \dots, i - 1, i + 1, \dots, G\}$ respectively, and for question i suppose she has a confidence of $q \in (T_{m-1}, T_{m+1})$. For question i , we must incentivize the worker to select confidence-level m if $q > T_m$, and to select $(m - 1)$ if $q < T_m$. This necessitates

$$q \Lambda_m + (1 - q) \Lambda_{-m} \stackrel{q < T_m}{\leq} \sum_{q > T_m} q \Lambda_{m-1} + (1 - q) \Lambda_{-(m-1)}. \quad (32)$$

Also, for question i , the requirement of level m having a higher incentive as compared to skipping when $q > S_m$ and vice versa when $q < S_m$ necessitates

$$q \Lambda_m + (1 - q) \Lambda_{-m} \stackrel{q < S_m}{\leq} \sum_{q > S_m} \Lambda_0. \quad (33)$$

Now, note that for any real-valued variable q , and for any real-valued constants a, b and c ,

$$aq \stackrel{q < c}{\leq} b \Rightarrow ac = b, \quad aq \stackrel{q > c}{\geq} b$$

Applying this fact to (32) and (33) gives

$$(T_m \Lambda_m + (1 - T_m) \Lambda_{-m}) - (T_m \Lambda_{m-1} + (1 - T_m) \Lambda_{-(m-1)}) = 0, \quad (34a)$$

$$(S_m \Lambda_m + (1 - S_m) \Lambda_{-m}) - \Lambda_0 = 0. \quad (34b)$$

From the definition of Λ_l in (31), we see that the left hand sides of (34a) and (34b) are both polynomials in $(G - 1)$ variables $\{r_j\}_{j \in [G] \setminus \{i\}}$ and take a value of zero for all values of the variables in a $(G - 1)$ -dimensional solid ball. Thus, each of the coefficients (of the monomials) in both polynomials must be zero, and in particular, the constant terms must also be zero. Observe that in both these polynomials, the constant term arises only when $\epsilon_j = 1 \forall j \in [G] \setminus \{i\}$ (which makes the

exponent of r_j to be 0 and that of $(1 - r_j)$ to be 1). Thus, setting the constant term to zero in the two polynomials results in

$$\begin{aligned} & T_m f(y_1, \dots, y_{i-1}, m, y_{i+1}, \dots, y_G) + (1 - T_m) f(y_1, \dots, y_{i-1}, -m, y_{i+1}, \dots, y_G) \\ &= T_m f(y_1, \dots, y_{i-1}, m-1, y_{i+1}, \dots, y_G) + (1 - T_m) f(y_1, \dots, y_{i-1}, -(m-1), y_{i+1}, \dots, y_G) \end{aligned} \quad (35a)$$

and

$$\begin{aligned} & S_m f(y_1, \dots, y_{i-1}, m, y_{i+1}, \dots, y_G) + (1 - S_m) f(y_1, \dots, y_{i-1}, -m, y_{i+1}, \dots, y_G) \\ &= f(y_1, \dots, y_{i-1}, 0, y_{i+1}, \dots, y_G) \end{aligned} \quad (35b)$$

thus proving the claim for the case of $G = N$.

Now consider the case when $G < N$. In order to simplify notation, let us assume $i = 1$ without loss of generality (since the arguments presented hold for any permutation of the questions). Suppose a worker's answers to questions $\{2, \dots, G\}$ evaluate to $(y_2, \dots, y_G) \in \{-L, \dots, L\}^{G-1}$, and further suppose that the worker skips the remaining $(N - G)$ questions. By going through arguments identical to those for $G = N$, but with f replaced by g , we get the necessity of

$$\begin{aligned} & T_m g(m, y_2, \dots, y_G, 0, \dots, 0) + (1 - T_m) g(-m, y_2, \dots, y_G, 0, \dots, 0) \\ &= T_m g(m-1, y_2, \dots, y_G, 0, \dots, 0) + (1 - T_m) g(-(m-1), y_2, \dots, y_G, 0, \dots, 0) \end{aligned} \quad (36a)$$

and

$$\begin{aligned} & S_m g(m, y_2, \dots, y_G, 0, \dots, 0) + (1 - S_m) g(-m, y_2, \dots, y_G, 0, \dots, 0) = g(0, y_2, \dots, y_G, 0, \dots, 0). \end{aligned} \quad (36b)$$

We now use this result in terms of function g to get an equivalent result in terms of function f . For some $S \in \{0, \dots, G-1\}$, suppose $y_{G-S+1} = 0, \dots, y_G = 0$. The remaining proof proceeds via an induction on S . We begin with $S = G-1$. In this case, (36a) and (36b) simplify to

$$\begin{aligned} & T_m g(m, 0, \dots, 0) + (1 - T_m) g(-m, 0, 0, \dots, 0) \\ &= T_m g(m-1, 0, \dots, 0) + (1 - T_m) g(-(m-1), 0, \dots, 0) \end{aligned} \quad (37a)$$

and

$$S_m g(m, 0, \dots, 0) + (1 - S_m) g(-m, 0, \dots, 0) = g(0, 0, \dots, 0). \quad (37b)$$

Applying the definition of function g from (27) leads to

$$\begin{aligned} & T_m (c_1 f(m, 0, \dots, 0) + c_2 f(0, 0, \dots, 0)) + (1 - T_m) (c_1 f(-m, 0, \dots, 0) + c_2 f(0, 0, \dots, 0)) \\ &= T_m (c_1 f(m-1, 0, \dots, 0) + c_2 f(0, 0, \dots, 0)) \\ &\quad + (1 - T_m) (c_1 f(-(m-1), 0, \dots, 0) + c_2 f(0, 0, \dots, 0)), \end{aligned} \quad (38a)$$

and

$$\begin{aligned} & S_m (c_1 f(m, 0, \dots, 0) + c_2 f(0, 0, \dots, 0)) + (1 - S_m) (c_1 f(-m, 0, \dots, 0) + c_2 f(0, 0, \dots, 0)) \\ &= (c_1 f(0, 0, \dots, 0) + c_2 f(0, 0, \dots, 0)) \end{aligned} \quad (38b)$$

for constants $c_1 > 0$ and $c_2 > 0$ that respectively denote the probabilities that the first question is picked and not picked in the set of G gold standard questions. Can calling out the common terms on both sides of the equation, we get the desired results

$$\begin{aligned} & T_m f(m, 0, \dots, 0) + (1 - T_m) f(-m, 0, \dots, 0) \\ &= T_m f(m-1, 0, \dots, 0) + (1 - T_m) f(-(m-1), 0, \dots, 0) \end{aligned}$$

and

$$S_m f(m, 0, \dots, 0) + (1 - S_m) f(-m, 0, \dots, 0) = f(0, 0, \dots, 0).$$

Next, we consider the case of a general $S \in \{0, \dots, G-2\}$ and assume that the result is true when $y_{G-S} = 0, \dots, y_G = 0$. In (36a) and (36b), the functions g decompose into a sum of the constituent f functions. These constituent functions f are of two types: the first where all of the first $(G-S)$ questions are included in the gold standard, and the second where one or more of the first $(G-S)$ questions are not included in the gold standard. The second case corresponds to situations where there are more than S questions skipped in the gold standard, i.e., when $y_{G-S} = 0, \dots, y_G = 0$, and hence satisfies our induction hypothesis. The terms corresponding to these functions thus cancel out in the expansion of (36a) and (36b). The remainder comprises only evaluations of function f for arguments in which the first $(G-S)$ questions are included in the gold standard: since the last $(N-G+S)$ questions are skipped by the worker, the remainder evaluates to

$$\begin{aligned} & T_m c_3 f(y_1, \dots, y_{i-1}, m, y_{i+1}, \dots, y_G) + (1 - T_m) c_3 f(y_1, \dots, y_{i-1}, -m, y_{i+1}, \dots, y_G) \\ &= T_m c_3 f(y_1, \dots, y_{i-1}, m-1, y_{i+1}, \dots, y_G) \\ &\quad + (1 - T_m) c_3 f(y_1, \dots, y_{i-1}, -(m-1), y_{i+1}, \dots, y_G), \end{aligned}$$

and

$$\begin{aligned} & S_m c_3 f(y_1, \dots, y_{i-1}, m, y_{i+1}, \dots, y_G) + (1 - S_m) c_3 f(y_1, \dots, y_{i-1}, -m, y_{i+1}, \dots, y_G) \\ &= c_3 f(y_1, \dots, y_{i-1}, 0, y_{i+1}, \dots, y_G), \end{aligned}$$

for some constant $c_3 > 0$. Dividing throughout by c_3 gives the desired result.

Finally, the arguments above hold for any permutation of the first G questions, thus completing the proof.

A.5 Necessity of $T_1 > S_l$ for the Problem to be Well Defined

We now show that the restriction $T_1 > S_l$ was necessary when defining the thresholds in Section 4.

Proposition 18 *Incentive-compatibility necessitates $T_1 > S_l \forall l \in \{2, \dots, L\}$, even in the absence of the generalized-no-free-lunch axiom.*

First observe that the proof of Lemma 17 did not employ the generalized-no-free-lunch axiom, neither did it assume $T_1 > S_l$. We will thus use the result of Lemma 17 to prove our claim.

Suppose the confidence of the worker for all but the first question is lower than T_1 and that the worker decides to skip all these questions. Suppose the worker attempts the first question. In order to ensure that the worker selects the answer that she believes is most likely to be true, it must be that

$$f(l, 0, \dots, 0) > f(-l, 0, \dots, 0) \quad \forall l \in [L].$$

We now call upon Lemma 17 where we set $i = 1$, $m = l$, $y_2 = \dots$, $y_G = 0$. Using the fact that $T_1 > T_{l-1} \forall l \in \{2, \dots, L\}$, we get

$$\begin{aligned} T_1 f(l, 0, \dots, 0) &+ (1 - T_1) f(-l, 0, \dots, 0) \\ &= T_1 f(l - 1, 0, \dots, 0) + (1 - T_1) f(-(l - 1), 0, \dots, 0) \\ &> T_{l-1} f(l - 1, 0, \dots, 0) + (1 - T_{l-1}) f(-(l - 1), 0, \dots, 0) \\ &= T_{l-1} f(l - 2, 0, \dots, 0) + (1 - T_{l-1}) f(-(l - 2), 0, \dots, 0) \\ &> T_{l-2} f(l - 2, 0, \dots, 0) + (1 - T_{l-2}) f(-(l - 2), 0, \dots, 0) \\ &\vdots \\ &> T_1 f(1, 0, \dots, 0) + (1 - T_1) f(-1, 0, \dots, 0) \\ &= f(0, \dots, 0) \\ &= S_l f(l, 0, \dots, 0) + (1 - S_l) f(-l, 0, \dots, 0). \end{aligned}$$

Since $f(l, 0, \dots, 0) > f(-l, 0, \dots, 0)$, we have the claimed result.

A.6 A Stronger No-free-lunch Axiom: Impossibility Results

In this section, we prove the various claims regarding the strong no-free-lunch axiom studied in Section 5.

A.6.1 PROOF OF PROPOSITION 10

If the worker skips all questions, then the expected payment is zero under the strong-no-free-lunch axiom. On the other hand, in order to incentivize knowledgeable workers to select answers whenever their confidences are greater than T , there must exist some situation in which the payment is strictly larger than zero. Suppose the payment is strictly positive when questions $\{1, \dots, z\}$ are answered correctly, questions $\{z + 1, \dots, z'\}$ are answered incorrectly, and the remaining questions are skipped. If the confidence of the unknowledgeable worker is in the interval $(0, T)$ for every question, then attempting to answer questions $\{1, \dots, z'\}$ and skipping the rest fetches her a payment that is strictly positive in expectation. Thus, this unknowledgeable worker is incentivized to answer at least one question.

A.6.2 PROOF OF PROPOSITION 11

Consider a (knowledgeable) worker who has a confidence of $p \in (T, 1]$ for the first question, $q \in (0, 1)$ for the second question, and confidences in the interval $(0, T)$ for the remaining questions. Suppose the worker attempts to answer the first question (and selects the answer she believes is most likely to be correct) and skips the last $(N - 2)$ questions as desired. Now, in order to incentivize her to answer the second question if $q > T$ and skip the second question if $q < T$, the payment

mechanism must satisfy

$$\begin{aligned} pqg(1, 1, 0, \dots, 0) &+ (1 - p)qg(-1, 1, 0, \dots, 0) + p(1 - q)g(1, -1, 0, \dots, 0) \\ &+ (1 - p)(1 - q)g(-1, -1, 0, \dots, 0) \stackrel{q < T}{\leq} pq(1, 0, 0, \dots, 0) + (1 - p)g(-1, 0, 0, \dots, 0). \end{aligned}$$

For any real-valued variable g , and for any real-valued constants a, b and c ,

$$aq \sum_{q > T}^{q < c} b \Rightarrow ac = b.$$

As a result,

$$\begin{aligned} pTg(1, 1, 0, \dots, 0) &+ (1 - p)Tg(-1, 1, 0, \dots, 0) + p(1 - T)g(1, -1, 0, \dots, 0) \\ &+ (1 - p)(1 - T)g(-1, -1, 0, \dots, 0) - pqg(1, 0, 0, \dots, 0) - (1 - p)g(-1, 0, 0, \dots, 0) = 0. \end{aligned}$$

The left hand side of this equation is a polynomial in variable p and takes a value of zero for all values of p in a one-dimensional box $(T, 1]$. It follows that the monomials of this polynomial must be zero, and in particular the constant term must be zero:

$$Tg(-1, 1, 0, \dots, 0) + (1 - T)g(-1, -1, 0, \dots, 0) - g(-1, 0, 0, \dots, 0) = 0.$$

The strong-no-free-lunch axiom implies $f(-1, -1, 0, \dots, 0) = f(-1, 0, \dots, 0) = f(0, \dots, 0) = 0$, and hence $g(-1, -1, 0, \dots, 0) = g(-1, 0, 0, \dots, 0) = 0$. Since $T \in (0, 1]$, we have

$$\begin{aligned} 0 &= g(-1, 1, 0, \dots, 0) \\ &= c_1 f(-1, 1, 0, \dots, 0) + c_2 f(-1, 0, \dots, 0) + c_2 f(1, 0, \dots, 0), \end{aligned} \quad (39)$$

for some constants $c_1 > 0$ and $c_2 > 0$ that represent the probability that the first two questions are included in the gold standard, and the probability that the first (or, second) but not the second (or, first) questions are included in the gold standard. Since f is a non-negative function, it must be that

$$f(1, 0, \dots, 0) = 0.$$

Now suppose a (knowledgeable) worker has a confidence of $p \in (T, 1]$ for the first question and confidences lower than T for the remaining $(N - 1)$ questions. Suppose the worker chooses to skip the last $(N - 1)$ questions as desired. In order to incentivize the worker to answer the first question, the mechanism must satisfy for all $p \in (T, 1]$,

$$\begin{aligned} 0 &< pg(1, 0, \dots, 0) + (1 - p)g(-1, 0, \dots, 0) - g(0, 0, \dots, 0) \\ &= pc_3 f(1, 0, \dots, 0) + pc_4 f(0, 0, \dots, 0) + (1 - p)c_3 f(-1, 0, \dots, 0) \\ &\quad + (1 - p)c_4 f(0, 0, \dots, 0) - f(0, 0, \dots, 0) \\ &= 0, \end{aligned}$$

where $c_3 > 0$ and $c_4 > 0$ are some constants. The final equation is a result of the strong-no-free-lunch axiom and the fact that $f(1, 0, \dots, 0) = 0$ as proved above. This yields a contradiction, and hence no incentive-compatible mechanism f can satisfy the strong-no-free-lunch axiom when $G < N$ even when allowed to address only knowledgeable workers.

Finally, as a sanity check, note that if $G = N$ then $c_2 = 0$ in (39). The proof above thus doesn't hold when $G = N$.

A.6.3. PROOF OF PROPOSITION 12

We will first show that the mechanism works as desired.

First consider the case when the worker is unknowledgeable and her confidences are of the form $T > p_{(1)} \geq p_{(2)} \geq p_{(3)} \geq \dots \geq p_{(G)}$. If she answers only the first question, then her expected payment is

$$\frac{p_{(1)}}{\kappa - T}.$$

Let us now see her expected payment if she doesn't follow this answer pattern. The strong-no-free-lunch axiom implies that if the worker doesn't answer any question then her expected payment is zero. Suppose the worker chooses to answer questions $\{i_1, \dots, i_z\}$. In that case, her expected payment is

$$\kappa \frac{p_{i_1} \dots p_{i_z}}{T^z} = \kappa \frac{p_{i_1}}{T} \dots \frac{p_{i_z}}{T} \quad (40)$$

$$\leq \kappa \left(\frac{p_{(1)}}{T} \right)^z \quad (41)$$

$$\leq \kappa \frac{p_{(1)}}{T}, \quad (42)$$

where (42) uses the fact that $p_{(1)} < T$. The inequality in (42) becomes an equality only when $z = 1$. Now when $z = 1$, the inequality in (41) becomes an equality only when $i_1 = (1)$. Thus the unknowledgeable worker is incentivized to answer only one question – the one that she has the highest confidence in.

Now consider a knowledgeable worker and suppose her confidences are of the form $p_{(1)} \geq \dots \geq p_{(m)} > T > p_{(m+1)} \geq \dots \geq p_{(G)}$ for some $m \geq 1$. If the worker answers questions $(1), \dots, (m)$ as desired, her expected payment is

$$\kappa \frac{p_{(1)}}{T} \dots \frac{p_{(m)}}{T}.$$

Now let us see what happens if the worker does not follow this answer pattern. The strong-no-free-lunch axiom implies that if the worker doesn't answer any question then her expected payment is zero. Now, if she answers some other set of questions, say questions $\{i_1, \dots, i_z\}$ with $p_{(1)} \leq p_{i_1} < \dots < p_{i_y} \leq p_{(m)} < p_{i_{y+1}} < \dots < p_{i_z} \leq p_{(G)}$. The expected payment in that case is

$$\kappa \frac{p_{i_1} \dots p_{i_z}}{T^z} = \kappa \frac{p_{i_1}}{T} \dots \frac{p_{i_z}}{T} \quad (43)$$

$$\leq \kappa \frac{p_{i_1}}{T} \dots \frac{p_{i_y}}{T} \quad (44)$$

$$\leq \kappa \frac{p_{(1)}}{T} \dots \frac{p_{(m)}}{T}$$

where inequality (43) is a result of $\frac{p_{i_j}}{T} \leq 1 \ \forall j > y$ and holds with equality only when $y = z$. Inequality (44) is a result of $\frac{p_{i_j}}{T} \geq 1 \ \forall j \leq m$ and holds with equality only when $y = m$. Thus the expected payment is maximized when $i_1 = (1), \dots, i_z = (m)$ as desired. Finally, the payment strictly increases with an increase in the confidences, and hence the worker is incentivized to always consider the answer that she believes is most likely to be correct.

We now show that this mechanism is unique.

The necessary conditions derived in Lemma 4, when restricted to the case of $G = N$ and $(y_1, \dots, y_{i-1}, y_{i+1}, \dots, y_G) \neq \{0\}^{N-1}$, is also applicable to the present setting. This is because the strong-no-free-lunch axiom assumed here is a stronger condition than the no-free-lunch axiom considered in Lemma 4, and moreover, $(y_1, \dots, y_{i-1}, y_{i+1}, \dots, y_G) \neq \{0\}^{N-1}$ avoids the use of unknowledgeable workers in the proof of Lemma 4. It follows that for every question $i \in \{1, \dots, G\}$ and every $(y_1, \dots, y_{i-1}, y_{i+1}, \dots, y_G) \in \{-1, 0, 1\}^{G-1} \setminus \{0\}^{G-1}$, it must be that

$$\begin{aligned} Tf(y_1, \dots, y_{i-1}, 1, y_{i+1}, \dots, y_G) + (1 - T)f(y_1, \dots, y_{i-1}, -1, y_{i+1}, \dots, y_G) \\ = f(y_1, \dots, y_{i-1}, 0, y_{i+1}, \dots, y_G). \end{aligned} \quad (45)$$

We claim that the payment must be zero whenever the number of incorrect answers $W > 0$. The proof proceeds by induction on the number of correct answers C . First suppose $C = 0$ (and $W > 0$). Then all questions are either wrong or skipped, and hence by the strong-no-free-lunch axiom, the payment must be zero. Now suppose the payment is necessarily zero whenever $W > 0$ and the total number of correct answers is $(C - 1)$ or lower, for some $C \in [G - 1]$. Consider any evaluation $(y_1, \dots, y_G) \in \{-1, 0, 1\}^G$ in which the number of incorrect answers is more than zero and the number of correct answers is C . Suppose $y_i = 1$ for some $i \in [G]$, and $y_j = -1$ for some $j \in [G] \setminus \{i\}$. Then from the induction hypothesis, we have $f(y_1, \dots, y_{i-1}, -1, y_{i+1}, \dots, y_G) = f(y_1, \dots, y_{i-1}, 0, y_{i+1}, \dots, y_G) = 0$. Applying (45) and noting that $T \in (0, 1)$, we get that $f(y_1, \dots, y_{i-1}, 1, y_{i+1}, \dots, y_G) = 0$ as claimed. This result also allows us to simplify (45) to: For every question $i \in \{1, \dots, G\}$ and every $(y_1, \dots, y_{i-1}, y_{i+1}, \dots, y_G) \in \{-1, 0, 1\}^{G-1} \setminus \{0\}^{G-1}$,

$$f(y_1, \dots, y_{i-1}, 1, y_{i+1}, \dots, y_G) = \frac{1}{T} f(y_1, \dots, y_{i-1}, 0, y_{i+1}, \dots, y_G). \quad (46)$$

We now show that when $C > 0$ and $W = 0$, the payment must necessarily be of the form described in the statement of Proposition 12. The proof again proceeds via an induction on the number of correct answers $C (\geq 1)$. Define a quantity $\kappa > 0$ as

$$\kappa = Tf(1, 0, \dots, 0). \quad (47)$$

Now consider the payment $f(1, y_2, \dots, y_G)$ for some $(y_2, \dots, y_G) \in \{0, 1\}^{G-1} \setminus \{0\}^{G-1}$ with C correct answers. Applying (46) repeatedly (once for every i such that $y_i = 1$), we get

$$f(1, y_2, \dots, y_G) = \frac{\kappa}{T^C}.$$

Unlike other results in this paper, at this point we cannot claim the result to hold for all permutations of the questions. This is because we have defined the quantity κ in an asymmetric manner (47), in terms of the payment function when the *first* question is correct and the rest are skipped. In what follows, we will prove that the result claimed in the statement of Proposition 12 indeed holds for all permutations of the questions.

From (46) we have

$$\begin{aligned} f(0, 1, 0, \dots, 0) &= Tf(1, 1, 0, \dots, 0) \\ &= f(1, 0, 0, \dots, 0) \\ &= \kappa. \end{aligned}$$

Thus the payment must be κ even if the second answer in the gold standard is correct and the rest are skipped. In fact, the argument holds when any one answer in the gold standard is correct and the rest are skipped. Thus the definition of κ is not restricted to the first question alone as originally defined in (47), but holds for all permutations of the questions. This allows the other arguments above to be applicable to any permutation of the questions. Finally, the budget constraint of μ_{\max} fixes the value of κ to that claimed, thereby completing the proof.

A.6.4 PROOF OF PROPOSITION 13

Proposition 12 proved that under the skip-based setting with the strong-no-free-lunch axiom, the payment must be zero when one or more answers are incorrect. This part of the proof of Proposition 12 holds even when $L > 1$. It follows that for any question, the penalty for an incorrect answer is the same for any confidence-level in $\{1, \dots, L\}$. Thus the worker is incentivized to always select that confidence-level for which the payment is the maximum when the answer is correct, irrespective of her own confidence about the question. This contradicts our requirements.

Appendix B. Details of Experiments

In this section, we provide further details about the experiments described earlier in Section 6.2. The experiments were carried out on the Amazon Mechanical Turk (mturk.com) online crowdsourcing platform in the time period June to October 2013. Figure 6 illustrates the interface shown to the workers for each of the experiments described in Section 6.2, while Figure 7 depicts the instructions given to the workers. The following are more details of each individual experiment. In the description, the notation κ is as defined in Algorithm 1 and Algorithm 2, namely, $\kappa = (\mu_{\max} - \mu_{\min})T^G$ for the skip-based setting and $\kappa = (\mu_{\max} - \mu_{\min}) \left(\frac{1}{\alpha_L}\right)^C$ for the confidence-based setting.

B.1 Recognizing the Golden Gate Bridge

A set of 21 photographs of bridges were shown to the workers, and for each photograph, they had to identify if it depicted the Golden Gate Bridge or not. An example of this task is depicted in Figure 6a, and the instructions provided to the worker under the three mechanisms are depicted in Figure 7. The fixed amount offered to workers was $\mu_{\min} = 3$ cents for the task, and the bonus was based on 3 gold standard questions. We compared (a) the baseline mechanism with 5 cents for each correct answer in the gold standard, (b) the skip-based mechanism with $\kappa = 5.9$ and $\frac{1}{\alpha} = 1.5$, and (c) the confidence-based mechanism with $\kappa = 5.9$ cents, $L = 2$, $\alpha_2 = 1.5$, $\alpha_1 = 1.4$, $\alpha_0 = 1$, $\alpha_{-1} = 0.5$, $\alpha_{-2} = 0$. The results of this experiment are presented in Figure 4a.

B.2 Transcribing Vehicles' License Plate Numbers from Photographs

This task presented the workers with 18 photographs of cars and asked them to transcribe the license plate numbers from each of them (source of photographs: <http://www.coolpic8z.com>). An example of this task is depicted in Figure 6b. The fixed amount offered to workers was $\mu_{\min} = 4$ cents for the task, and the bonus was based on 4 gold standard questions. We compared (a) the baseline mechanism with 10 cents for each correct answer in the gold standard, (b) the skip-based mechanism with $\kappa = 0.62$ and $\frac{1}{\alpha} = 3$, and (c) the confidence-based mechanism with $\kappa = 3.1$ cents, $L = 2$, $\alpha_2 = 2$, $\alpha_1 = 1.95$, $\alpha_0 = 1$, $\alpha_{-1} = 0.5$, $\alpha_{-2} = 0$. The results of this experiment are presented in

Figure 4b. When evaluating, in the worker's answers as well as in the true solutions, we converted all text to upper case, and removed all spaces and punctuations. We then declared a worker's answer to be in error if it did not have an exact match with the true solution.

B.3 Classifying Breeds of Dogs

This task required workers to identify the breeds of dogs shown in 85 images (source of images: Khosla et al. (2011); Deng et al. (2009)). For each image, the worker was given ten breeds to choose from. An example of this task is depicted in Figure 6c. The fixed amount offered to workers was $\mu_{\min} = 5$ cents for the task, and the bonus was based on 7 gold standard questions. We compared (a) the baseline mechanism with 8 cents for each correct answer in the gold standard, (b) the skip-based mechanism with $\kappa = 0.78$ and $\frac{1}{\alpha} = 2$, and (c) the confidence-based mechanism with $\kappa = 0.78$ cents, $L = 2$, $\alpha_2 = 2$, $\alpha_1 = 1.66$, $\alpha_0 = 1$, $\alpha_{-1} = 0.67$, $\alpha_{-2} = 0$. The results of this experiment are presented in Figure 4c.

B.4 Identifying Heads of Countries

Names of 20 personalities were provided and had to be classified as to whether they were ever the (a) President of the USA, (b) President of India, (c) Prime Minister of Canada, or (d) neither of these. An example of this task is depicted in Figure 6d. The fixed amount offered to workers was $\mu_{\min} = 2$ cents for the task, and the bonus was based on 4 gold standard questions. While the ground truth in most other multiple-choice experiments had approximately an equal representation from all classes, this experiment was heavily biased with one of the classes never being correct and another being correct for just 3 of the 20 questions. We compared (a) the baseline mechanism with 2.5 cents for each correct answer in the gold standard, (b) the skip-based mechanism with $\kappa = 0.25$ and $\frac{1}{\alpha} = 3$, and (c) the confidence-based mechanism with $\kappa = 1.3$ cents, $L = 2$, $\alpha_2 = 2$, $\alpha_1 = 1.95$, $\alpha_0 = 1$, $\alpha_{-1} = 0.5$, $\alpha_{-2} = 0$. The results of this experiment are presented in Figure 4d.

B.5 Identifying Flags

This was a relatively long task, with 126 questions. Each question required the workers to identify if a displayed flag belonged to a place in (a) Africa, (b) Asia/Oceania, (c) Europe, or (d) neither of these. An example of this task is depicted in Figure 6e. The fixed amount offered to workers was $\mu_{\min} = 4$ cents for the task, and the bonus was based on 8 gold standard questions. We compared (a) the baseline mechanism with 4 cents for each correct answer in the gold standard, (b) the skip-based mechanism with $\kappa = 0.2$ and $\frac{1}{\alpha} = 2$, and (c) the confidence-based mechanism with $\kappa = 0.2$ cents, $L = 2$, $\alpha_2 = 2$, $\alpha_1 = 1.66$, $\alpha_0 = 1$, $\alpha_{-1} = 0.67$, $\alpha_{-2} = 0$. The results of this experiment are presented in Figure 4e.

B.6 Distinguishing Textures

This task required the workers to identify the textures shown in 24 gray-scale images (source of images: Lazebnik et al. (2005; Data set 1: Textured surfaces)). For each image, the worker had to choose from 8 different options. Such a task has applications in computer vision, where it aids in recognition of objects or their surroundings. An example of this task is depicted in Figure 6f. The fixed amount offered to workers was $\mu_{\min} = 3$ cents for the task, and the bonus was based on 4 gold

standard questions. We compared (a) the baseline mechanism with 10 cents for each correct answer in the gold standard, (b) the skip-based mechanism with $\kappa = 3.1$ and $\frac{1}{\kappa} = 2$, and (c) the confidence-based mechanism with $\kappa = 3.1$ cents, $L = 2$, $\alpha_2 = 2$, $\alpha_1 = 1.66$, $\alpha_0 = 1$, $\alpha_{-1} = 0.67$, $\alpha_{-2} = 0$. The results of this experiment are presented in Figure 4f.

B.7 Transcribing Text from an Image: Film Certificate

The task showed an image containing 11 (short) lines of blurry text which the workers had to decipher. We used text from a certain certificate which movies releasing in India are provided. We slightly modified its text in order to prevent workers from searching a part of it online and obtaining the entire text by searching the first few transcribed lines on the Internet. An example of this task is depicted in Figure 6g. The fixed amount offered to workers was $\mu_{\min} = 5$ cents for the task, and the bonus was based on 2 gold standard questions. We compared (a) the baseline mechanism with 20 cents for each correct answer in the gold standard, (b) the skip-based mechanism with $\kappa = 5.5$ and $\frac{1}{\kappa} = 3$, and (c) the confidence-based mechanism with $\kappa = 12.5$ cents, $L = 2$, $\alpha_2 = 2$, $\alpha_1 = 1.95$, $\alpha_0 = 1$, $\alpha_{-1} = 0.5$, $\alpha_{-2} = 0$. The results of this experiment are presented in Figure 4g. When evaluating, in the worker’s answers as well as in the true solutions, we converted all text to upper case, and removed all spaces and punctuations. We then declared a worker’s answer to be in error if it did not have an exact match with the true solution.

B.8 Transcribing Text from an Image: Script of a Play

The task showed an image containing 12 (short) lines of blurry text which the workers had to decipher. We borrowed a paragraph from Shakespeare’s play ‘As You Like It.’ We slightly modified the text of the play in order to prevent workers from searching a part of it online and obtaining the entire text by searching the first few transcribed lines on the internet. An example of this task is depicted in Figure 6h. The fixed amount offered to workers was 5 cents for the task, and the bonus was based on 2 gold standard questions. We compared (a) the baseline mechanism with $\mu_{\min} = 20$ cents for each correct answer in the gold standard, (b) the skip-based mechanism with $\kappa = 5.5$ and $\frac{1}{\kappa} = 3$, and (c) the confidence-based mechanism with $\kappa = 12.5$ cents, $L = 2$, $\alpha_2 = 2$, $\alpha_1 = 1.95$, $\alpha_0 = 1$, $\alpha_{-1} = 0.5$, $\alpha_{-2} = 0$. The results of this experiment are presented in Figure 4h. When evaluating, in the worker’s answers as well as in the true solutions, we converted all text to upper case, and removed all spaces and punctuations. We then declared a worker’s answer to be in error if it did not have an exact match with the true solution.

B.9 Transcribing Text from Audio Clips

The workers were given 10 audio clips which they had to transcribe to text. Each audio clip was 3 to 6 seconds long, and comprised of a short sentence, e.g., “my favorite topics of conversation are sports, politics, and movies.” Each of the clips were recorded in different accents using a text-to-speech converter. An example of this task is depicted in Figure 6i. The fixed amount offered to workers was $\mu_{\min} = 5$ cents for the task, and the bonus was based on 2 gold standard questions. We compared (a) the baseline mechanism with 20 cents for each correct answer in the gold standard, (b) the skip-based mechanism with $\kappa = 5.5$ and $\frac{1}{\kappa} = 3$, and (c) the confidence-based mechanism with $\kappa = 12.5$ cents, $L = 2$, $\alpha_2 = 2$, $\alpha_1 = 1.95$, $\alpha_0 = 1$, $\alpha_{-1} = 0.5$, $\alpha_{-2} = 0$. The results of this experiment are presented in Figure 4i.

a Recognize the Golden Gate Bridge
 Golden Gate
 NOT Golden Gate
 Answer:

b Transcribe the license plate number
 Answer:

c Mark the breed of the dog
 Afghan Hound
 Doberman
 French Bulldog
 Tibetan Terrier

d Identify heads of countries
 Mohandas Gandhi
 President of the USA
 President of India
 Prime Minister of Canada
 None of these

e Mark the continent to which the flag belongs
 Africa
 Asia/Oceania
 Europe
 None of these

f Identify the texture
 Granite
 Carpet
 Fur
 Glass
 Corduroy
 Wood
 None of these

g Transcribe text (playscript)
 Line 1:
 Line 2:

h Transcribe text (certificate)
 Line 1:
 Line 2:

i Transcribe the audio clip
 Answer:

Figure 6: Various tasks on which the payment mechanisms were tested. The interfaces shown are that of the baseline mechanism, i.e., without the skipping or confidence choices.

a Baseline Mechanism

- *** Instructions for BONUS (Read Carefully) ***
- There are three questions whose answers are known to us, based on which the bonus is calculated
- BONUS (cents) = 5 * number of questions out of these that you correctly answer

b Skip-based multiplicative mechanism

- If you are not sure about any answer, then mark "I'm not sure"
 You need to mark at least something for every question, otherwise your work will be rejected
- *** Instructions for BONUS (Read Carefully) ***
 - You start with 5.9 cents of bonus for this HIT
 - There are three questions whose answers are known to us, based on which the bonus is calculated
 - For each of these questions you answer CORRECTLY, your bonus will INCREASE BY 50% (every 1 cent will become 1.5 cents)
 - If you answer any of these questions WRONG, your bonus will become ZERO
 - So for questions you are not sure of, mark the "I'm not sure" option; this does not affect the bonus

c Confidence-based multiplicative mechanism

- For each answer, you also need to indicate how sure you are about that answer
 If you are not sure about any answer, then mark "I don't know"
 You need to mark at least something for every question, otherwise your work will be rejected
- *** Instructions for BONUS (Read Carefully) ***
 - If an answer marked "absolutely sure" is wrong, your bonus will become ZERO for this entire HIT (you do not get any bonus for this HIT)
 - For every answer marked "absolutely sure" that is correct, your bonus will INCREASE BY 50% (every 1 cent will become 1.5 cents)
 - For every answer marked "moderately sure" that is correct, your bonus will be HALVED (every 1 cent will become half a cent)
 - For every answer marked "moderately sure" that is wrong, your bonus will be INCREASE BY 40% (every 1 cent will become 1.4 cents)
 - Marking "I don't know" for any answer does not change your bonus

Figure 7: An example of the instructions displayed to the worker under the three mechanisms.

Appendix C. General Utility Functions

In this section, we consider a setting where the worker, instead of maximizing her expected payment, aims to maximize the expected value of some *utility function* of her payment. Consider any function $U : \mathbb{R}_+ \rightarrow \mathcal{I}$, where \mathcal{I} is any interval on the real number line. We will require the function U to be strictly increasing and to have an inverse. Examples of such functions include $U(x) = \log(1+x)$ with $\mathcal{I} = \mathbb{R}_+$, $U(x) = \sqrt{x}$ with $\mathcal{I} = \mathbb{R}_+$, and $U(x) = 1 - e^{-x}$ with $\mathcal{I} = [0, 1]$. For any payment f made to the worker (based on the evaluation of her answers to the gold standard questions), her utility for this payment is $U(f)$. The worker aims to maximize the expected value of $U(f)$, where the expectation is with respect to her beliefs regarding correctness of her answers and the uniformly random distribution of the G gold standard questions among the set of N questions. The function U is assumed to be known to the worker as well as the system designer.

Consider the confidence-based setting of Section 4 (of which, the skip-based setting of Section 3 is a special case). Recall the notation $\{x_i\}_{i=1}^G$, $\{\alpha_j\}_{j=-L}^L$ and κ from Algorithm 2. Also recall the (generalized)-no-free-lunch axiom which mandates a zero payment if, in the gold standard, (all attempted questions are marked as the highest confidence L and) the answers to all the attempted questions are incorrect. The following proposition extends the results of the main text in the paper to this setting with utility functions.

Proposition 19 *For a worker who aims to maximize function U of the payment, the one and only mechanism that is incentive-compatible and satisfies the (generalized)-no-free-lunch axiom is*

$$\text{Payment}(x_1, \dots, x_G) = U^{-1} \left(\kappa \prod_{i=1}^G \alpha_{x_i} + U(\mu_{\min}) \right),$$

where the constants $\{\alpha_j\}_{j=-L}^L$ are as defined in Algorithm 2 and $\kappa = (U(\mu_{\max}) - U(\mu_{\min}))\alpha_L^{-G}$.

Note that for the problem to be well defined, the interval $[\mu_{\min}, \mu_{\max}]$ should be contained in the interval \mathcal{I} . The proof of Proposition 19 follows easily from the results proved earlier in the paper, and is provided below for completeness.

Proof of Proposition 19. We will first verify that the proposed payment is always non-negative and satisfies the (generalized)-no-free-lunch axiom. Recall from Theorem 7 that for every evaluation $\{x_1, \dots, x_G\}$ for which the (generalized)-no-free-lunch axiom mandates a zero payment, the value of $\kappa \prod_{i=1}^G \alpha_{x_i}$ is zero. It follows that the payment $U^{-1} \left(\kappa \prod_{i=1}^G \alpha_{x_i} + U(\mu_{\min}) \right) = U^{-1}(0 + U(\mu_{\min})) = \mu_{\min}$, where the final equation is a consequence of the invertibility of U . Further, recall that the value of $\kappa \prod_{i=1}^G \alpha_{x_i}$ in Algorithm 2 is never smaller than zero. Since the function U is increasing, so is U^{-1} , and hence the payment is always non-negative.

We will now prove that the proposed payment is incentive-compatible. To this end, observe that the utility of the proposed payment is

$$\begin{aligned} U(\text{Payment}) &= U \left(U^{-1} \left(\kappa \prod_{i=1}^G \alpha_{x_i} + U(\mu_{\min}) \right) \right) \\ &= \kappa \prod_{i=1}^G \alpha_{x_i} + U(\mu_{\min}). \end{aligned}$$

Noting that $U(0)$ is a constant independent of the worker's answers, the result of Theorem 7 implies that the expectation of $U(\text{Payment})$ behaves exactly as required for incentive-compatibility.

We will now prove uniqueness of this mechanism. Replacing $f(\cdot)$ by $U(\text{Payment}(\cdot))$ in the proof of Theorem 9, we get that the function $U(\text{Payment})$ must be of the form

$$U(\text{Payment}(x_1, \dots, x_G)) = c_1 \prod_{i=1}^G \alpha_{x_i} + c_2,$$

for some constants c_1 and c_2 , where $\{\alpha_{x_j}\}_{j=-L}^L$ are as defined in Algorithm 2. In other words, the payment must be of the form

$$\text{Payment}(x_1, \dots, x_G) = U^{-1} \left(c_1 \prod_{i=1}^G \alpha_{x_i} + c_2 \right).$$

One can evaluate that the maximum value of this payment is $c_1 + c_2$. From our μ_{\max} -budget constraint, we then have $c_1 + c_2 = \mu_{\max}$. Furthermore, when the evaluations x_1, \dots, x_G are such that the (generalized)-no-free-lunch applies, we need $\text{Payment} = \mu_{\min}$. It follows that $c_2 = U(\mu_{\min})$, and consequently $c_1 = U(\mu_{\max}) - U(\mu_{\min})$, thereby completing the proof.

Abstract

Gaussian graphical models capture dependence relationships between random variables through the pattern of nonzero elements in the corresponding inverse covariance matrices. To date, there has been a large body of literature on both computational methods and analytical results on the estimation of a *single* graphical model. However, in many application domains, one has to estimate several *related* graphical models, a problem that has also received attention in the literature. The available approaches usually assume that all graphical models are *globally* related. On the other hand, in many settings different relationships between subsets of the node sets exist between different graphical models. We develop methodology that *jointly* estimates multiple Gaussian graphical models, assuming that there exists prior information on how they are structurally related. For many applications, such information is available from external data sources. The proposed method consists of first applying neighborhood selection with a group lasso penalty to obtain edge sets of the graphs, and a maximum likelihood refit for estimating the nonzero entries in the inverse covariance matrices. We establish consistency of the proposed method for sparse high-dimensional Gaussian graphical models and examine its performance using simulation experiments. Applications to a climate data set and a breast cancer data set are also discussed.

Keywords: Gaussian graphical model, structured sparsity, group lasso penalty, consistency, edge set recovery

1. Introduction

There has been a large amount of work over the last few years on estimating Gaussian graphical models from high-dimensional data. In this family of models, jointly normally distributed random variables are represented by the nodes of a graph, while its edges reflect conditional dependence relationships amongst nodes that are captured through the nonzero entries of the inverse covariance matrix (or precision matrix) (Lauritzen, 1996; Edwards, 2000). Formally, let X be a p -dimensional multivariate normal random vector where

$$X = (X_1, \dots, X_p) \sim \mathcal{N}(\mu, \Sigma).$$

For $1 \leq i \neq j \leq p$, X_i and X_j are said to be conditionally independent given all the remaining variables, if the corresponding entry in the precision matrix $\Omega = \Sigma^{-1}$ is zero. An edge between the nodes X_i and X_j in the graph implies that they are conditionally dependent and corresponds to a nonzero entry in the precision matrix. To identify the graph, one only needs to select the corresponding precision matrix.

Bühlmann and van de Geer (2011, chap. 13) gave an overview of statistical methods developed for estimating a Gaussian graphical model subject to sparsity constraints, an attractive feature that reduces the number of parameters to be estimated and also enhances interpretability of the results. These models have found applications in diverse fields including analysis of omics data (Perraud et al., 2006; Pujana et al., 2007; Putluri et al., 2011), reconstruction of gene regulatory networks (Dehmer and Emmert-Streib, 2008, chap. 6), as well as study of climate networks (Zerener et al., 2014).

More recently, the focus has shifted from estimating a single graphical model to joint estimation of multiple graphs due to the availability of heterogeneous data (see discussion in Guo et al., 2011). For example, climate models capturing relationships between climate defining variables over a large area share common patterns; i.e. there are *shared common links* and also sharing of *absence of links* between the models (networks at different spatial locations). While separate estimation of individual models without taking the known pattern into consideration ignores the common structure, estimating one single model could mask the differences that could prove critical in understanding local climate features.

Several authors have studied the problem of *jointly* estimating multiple graphical models under different assumptions on how the models are related. Guo et al. (2011) introduced a procedure using a hierarchical penalty on the log-likelihood, whose objective is to estimate the common zeros (absence of edges) in the precision matrix across all graphical models under consideration. Thus, the procedure borrows strength across models through the non-connected nodes, but does not impose any structure on the connected ones. Danaher et al. (2014) proposed a joint graphical lasso by maximizing the log-likelihood subject to a generalized fused lasso or group lasso penalty, which can be solved efficiently by a standard alternating directions method of multipliers algorithm (Boyd et al., 2011). When employing a group lasso penalty, the underlying assumption is that the various observed graphical models are *perturbations* of a *single* common connectivity pattern across all graphical models, while when using a fused lasso across all models a similar outcome occurs, although more heterogeneity between estimated graphical models can be obtained depending on the tuning of the penalties. The work by Zhu et al. (2014) investigates the joint estimation problem by introducing a truncated ℓ_1 penalty on the pairwise differences between the precision matrices to achieve entry-wise clustering of the network structure over multiple graphs. Peterson et al. (2015) introduced a Bayesian approach that links the estimation of the graphs via a Markov random field prior for common structures. Further, a spike-and-slab prior is placed on the parameters that measure the similarity between graphs, thus relaxing the assumption on sharing a common structure across all graphical models.

Despite recent advances in joint estimation algorithms, theoretical properties of the resulting estimators have not been fully investigated. Guo et al. (2011) represents an exception, wherein asymptotic properties of the resulting estimator are established for consistent recovery of the common zeros across multiple precision matrices, which is the focus of that procedure. Zhu et al. (2014) focused mainly on efficient computational algorithms when the graphs have disjoint subgraphs, with a brief mention of consistency of precision matrices in a special temporal setting; however, no the-

oretical guarantees are provided for more general settings. Finally, many papers only present algorithms for joint estimation of the Gaussian graphical models under consideration, but no theoretical properties of the estimates (Honorio and Samaras, 2010; Chiquet et al., 2011; Danaher et al., 2014; Mohan et al., 2014).

In this paper, we investigate estimation of multiple graphical models under *complex structural relationships*, assuming that there exists *prior information* on their specification. In many applications, such information is available and may come from prior knowledge in the literature of relationships among different node subsets of the graphical models under consideration, or from clustering of all graphs. The approach allows sharing common sub-graph components between different models and does not require sharing of values for the same element across multiple precision matrices. The proposed method, called the *Joint Structural Estimation Method* (JSEM), leverages structured sparsity patterns as illustrated in Section 2 and is a two-step procedure. In the first step, we infer the sparse graphical models by incorporating the available structure through a group lasso penalty. In the second step, we maximize the Gaussian log-likelihood subject to the edge set constraints obtained from the previous step. Numerically, JSEM demonstrates superior performance in controlling both the number of false positive and false negative edges compared to available methods. When applied to joint modeling of climate networks, our results highlight the different roles climate defining factors play at different regions of the United States. In another application to breast cancer gene expression data, the JSEM methodology reveals interesting differences in the molecular network rewiring between the ER+ and ER- classes (see extensive discussion in Section 5.2). Understanding the rewiring of biological networks under different conditions provides deeper insights into biological mechanisms of disease, especially when combined with topology-based pathway enrichment methods as discussed and illustrated in Ma et al. (2016) and Kaushik et al. (2016).

The contributions of this work are three-fold. First, we develop a general framework for the problem of joint estimation of multiple Gaussian graphical models. The method can incorporate detailed structural information regarding relationships between subsets of the graphical models, while in the absence of such information reduces to the group graphical lasso procedure of Danaher et al. (2014). Further, we establish that the JSEM estimator is consistent with a fast rate of convergence in terms of the Frobenius norm for the estimated precision matrices. We also establish rigorously the consistent recovery of the edge sets for JSEM under suitable regularity conditions. Finally, when the externally provided structured sparsity pattern is moderately misspecified, we provide a modified estimator that reduces the number of false positive edges identified due to prior information misspecification, thus further enhancing the applicability of JSEM.

The paper is organized as follows. Section 2 discusses the structural relationships model used in this work and presents the estimation procedure. Section 3 presents the theoretical properties of the proposed method, followed by simulation studies in Section 4 and two real data applications—climate modeling and genomics of breast cancer—are presented in Section 5. We conclude with a discussion in Section 6. Most details of the theoretical analysis and proofs, additional simulation results as well as additional analyses on the applications are relegated to the Appendix.

2. The Joint Structural Estimation Method

Suppose we are interested in estimating K Gaussian graphical models from their corresponding K independent data sets, assuming that the models exhibit complex relationships between their edge sets. The data in the k -th model are organized in an $n_k \times p$ matrix $\mathbf{X}^k = (\mathbf{X}_1^k, \dots, \mathbf{X}_p^k)$, where each

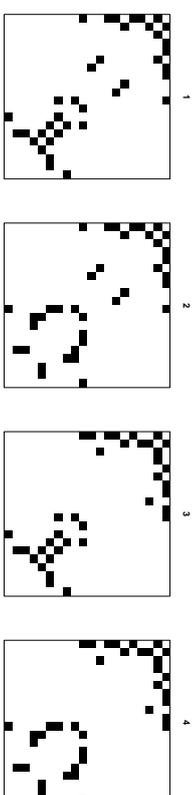

Figure 1: Image plots of the adjacency matrices for four graphical models with vertex set $\{1, \dots, p\}$. The black color represents presence of an edge. The structured sparsity pattern is encoded in $\mathcal{G} = \cup_{1 \leq i < j \leq p} \mathcal{G}^{ij}$, where $\mathcal{G}^{ij} = \{[1, 3], [2, 4]\}$ for $(i, j) \in \{[p/2] + 1, \dots, p\}$ and $\mathcal{G}^{ij} = \{[1, 2], [3, 4]\}$ for all other pairs of (i, j) .

row represents one observation from $\mathcal{N}(\mathbf{0}, \Sigma_0^k)$, $k = 1, \dots, K$. Throughout the remaining sections, we reserve the notations $\Sigma_0, \Omega_0, \dots$ to denote the population parameters in the true model and use Σ, Ω, \dots to denote generic parameters. Without loss of generality, we assume the columns of \mathbf{X}^k are centered and standardized to have mean zero and unit variance. For ease of presentation, it is assumed that the sample size $n_k = n$ for all $k = 1, \dots, K$, but the modeling framework can easily accommodate unequal sample sizes. Our goal is to estimate jointly $\Omega_0^k = (\Sigma_0^k)^{-1}$ for all k , under the assumption that the K corresponding graphs are related via a structured sparsity pattern \mathcal{G} . For example, consider climate models capturing relationships between climate forcing variables defined over a pre-specified spatial domain. Models that belong to the same climate zone may exhibit greater similarity in their graph structures than those from different zones. Thus, one can define \mathcal{G} based on their spatial locations. Figure 1 gives an illustration of the structured sparsity among four graphical models in terms of their adjacency matrices. This pattern indicates that sharing of structures may occur at different subsets of the edge set, which motivates us to develop a joint estimation method that can incorporate such rich and complex structural information.

2.1 Neighborhood Selection

Neighborhood selection was introduced by Meinshausen and Bühlmann (2006) as an efficient method to construct Gaussian graphical models from high-dimensional data. For each node $i = 1, \dots, p$ in the graphical model, consider the optimal prediction of the random variable X_i as a linear combination of the remaining variables:

$$X_i = \sum_{j \neq i} \theta_{ij} X_j + \varepsilon_i$$

where θ_{ij} ($j \neq i$) are the regression coefficients and $\varepsilon_i \perp \{X_j : j \neq i\}$. The matrix $(\theta_{ij})_{1 \leq i, j \leq p}$ is determined by the inverse covariance matrix $\Omega = (\omega_{ij})_{1 \leq i, j \leq p}$. Specifically, it holds that $\theta_{ij} = -\omega_{ij}/\omega_{ii}$, for all $j \neq i$. The set of nonzero coefficients of θ_{ij} ($j \neq i$) is thus the same as the set of nonzero entries in the row vector of ω_{ij} ($j \neq i$), which defines the set of neighbors of node i . Using an l_1 -penalized regression, Meinshausen and Bühlmann (2006) estimated the neighborhood for each node and combined the estimates to obtain the underlying graph.

2.2 An Illustrative Example

We first illustrate how to extend the idea of neighborhood selection to multiple graphical models using the example in Figure 1. For $k = 1, \dots, K$, let $(\theta_{ij}^k)_{p \times p}$ be the matrix of regression coefficients in graph k and θ_i^k the vector of all θ_{ij}^k ($j \neq i$) for node $i = 1, \dots, p$. Unless otherwise stated, all vectors are assumed to be column vectors. For node i in a single graph k , neighborhood selection suggests estimating the coefficients θ_i^k by

$$\min_{\theta_i^k} \frac{1}{n} \|\mathbf{X}_i^k - \mathbf{X}_{-i}^k \theta_i^k\|^2 + 2\lambda \sum_{j \neq i} |\theta_{ij}^k|, \quad (1)$$

where \mathbf{X}_{-i}^k is \mathbf{X}^k with the i -th column removed, $\|\cdot\|$ represents the standard Euclidean norm and λ is the regularization parameter. To achieve joint estimation, consider the following regularized regression problem

$$\min_{\Theta_i} \frac{1}{n} \sum_{k=1}^K \|\mathbf{X}_i^k - \mathbf{X}_{-i}^k \theta_i^k\|^2 + 2P_\lambda(\Theta_i), \quad (1)$$

where $K = 4$, $\Theta_i = (\theta_{i1}^1, \dots, \theta_{i4}^4)$ and $P_\lambda(\Theta_i)$ is a regularization term to be determined next. Note that each column of Θ_i represents the regression coefficients from one graphical model and each row of Θ_i corresponds to the four coefficients at the same (i, j) pair.

The penalty $P_\lambda(\Theta_i)$ is chosen based on information from the structured sparsity pattern \mathcal{G} in Figure 1. For example, for $i = 1$ with grouping $\{[1, 2], [3, 4]\}$,

$$\Theta_1 = \begin{pmatrix} \theta_{12}^1 & \theta_{12}^2 & \theta_{12}^3 & \theta_{12}^4 \\ \vdots & \vdots & \vdots & \vdots \\ \theta_{1p}^1 & \theta_{1p}^2 & \theta_{1p}^3 & \theta_{1p}^4 \end{pmatrix}.$$

As indicated by the colors, we can then group the coefficients in the j -th row of Θ_1 ($j = 2, \dots, p$) as

$$\underbrace{(\theta_{1j}^1, \theta_{1j}^2, \theta_{1j}^3, \theta_{1j}^4)}_{\theta_{1j}^{\{1,2\}}} \underbrace{(\theta_{1j}^3, \theta_{1j}^4)}_{\theta_{1j}^{\{3,4\}}}$$

and set $P_\lambda(\Theta_1)$ to be the group lasso penalty

$$\sum_{j=2, \dots, p} \sum_{g=\{1,2\}, \{3,4\}} \lambda_{ij}^g \|\theta_{1j}^g\|.$$

The group lasso penalty forces the two coefficients in each group to be zero or nonzero at the same time, leading to the same structure for graphical models belonging to the same group.

The solution Θ_1 to (1) for $i = 1, \dots, p$ can then be used for graph selection.

2.3 The General Case

Denote the structured sparsity pattern by $\mathcal{G} = \cup_{1 \leq i < j \leq p} \mathcal{G}^{ij}$, where the union is over all $p(p-1)/2$ pairs of potential edges. Each \mathcal{G}^{ij} is a partition of the set $\{1, 2, \dots, K\}$ and consists of prior

knowledge on the structural similarity for the (i, j) -th pair across models. For example in Figure 1, $\mathcal{G}^{12} = \{[1, 2], [3, 4]\}$ means that the graphs 1 and 2 exhibit the same structure at (i, j) , whereas 3 and 4 behave the same at (i, j) . It is possible for all four graphs to have the edge (i, j) or not have the edge (i, j) at the same time, but we do not impose this restriction. Taking the union over all pairs, $\mathcal{G} = \{[1, 2], [3, 4], [1, 3], [2, 4]\}$ in Figure 1. Therefore the pattern \mathcal{G} allows a more flexible structural relationships among multiple graphical models. Further, the sparsity pattern in \mathcal{G} is symmetric as we require $\mathcal{G}^{ji} = \mathcal{G}^{ij}$ for $i < j$.

For $1 \leq i < j \leq p$ and a group $g \in \mathcal{G}^{ij}$, denote by θ_{ij}^g the vector $(\theta_{ij}^k)_{k \in g}$, a concatenation of all regression coefficients from graphs in g . The grouping for the regression coefficients $(\theta_{ij}^1, \dots, \theta_{ij}^K)$ is determined by \mathcal{G}^{ij} . Under correctly specified \mathcal{G} , all coefficients in the same group should be zero or nonzero simultaneously. For $k = 1, \dots, K$, let $E^k = \{(i, j) : \theta_{ij}^k \neq 0\}$ be the set of undirected edges in graph k and $E_{E^k}^+ = \{\Omega : \Omega \succ 0 \text{ and } \omega_{ij} = 0 \text{ for all } (i, j) \notin E^k \text{ where } i \neq j\}$.

The *Joint Structural Estimation Method* (JSEM) proceeds with the following two steps.

- (I) For $k = 1, \dots, K$, we infer the sparse graphs \hat{E}^k through the following group lasso estimator.
For $i = 1, \dots, p$,

$$\min_{\Theta_i} \left\{ \frac{1}{n} \sum_{k=1}^K \|\mathbf{X}_i^k - \mathbf{X}_{-i}^k \theta_i^k\|^2 + 2 \sum_{j \neq i, g \in \mathcal{G}^{ij}} \lambda_{ij}^g \|\theta_{ij}^g\| \right\}. \quad (2)$$

\hat{E}^k is estimated to be the set

$$\{(i, j) : 1 \leq i < j \leq p, \hat{\theta}_{ij}^k \neq 0 \text{ OR } \hat{\theta}_{ji}^k \neq 0\}. \quad (3)$$

- (II) We refit the model by

$$\min_{\Omega^k \in S_{E^k}^+} \left\{ \text{tr}(\hat{\Sigma}^k \Omega^k) - \log \det(\Omega^k) \right\}, \quad k = 1, \dots, K. \quad (4)$$

Note the grouped variables in (2) are non-overlapping because \mathcal{G}^{ij} partitions the set $\{1, \dots, K\}$ into disjoint subsets. The ‘OR’ rule defined in (3) can be replaced by the ‘AND’ rule. The problems in (2) and (4) are both convex and can thus be solved by available convex optimization algorithms. In this work, we use the R-package `gprreg` (Breheny and Huang, 2009) for implementation of the group lasso penalized optimization (2) and the `glasso` (Friedman et al., 2008) one for solving (4). The computational complexity for step (II) is $O(Kp^3)$ using the standard graphical lasso algorithm. Since `gprreg` uses a coordinate descent algorithm, the computational complexity for step (I) can be as fast as $O(nKp^2)$ if the number of graphs K does not exceed the sample size n , or $O(K^2p^2)$ otherwise. Thus, the overall computational complexity of JSEM is $O(Kp^3)$ if $p > K$, and $O(K^2p^2)$ otherwise.

2.4 Choice of Tuning Parameters

Like any other penalty-based method, JSEM requires selection of the tuning parameters λ_{ij}^g for all p regressions in (2). One can customize λ_{ij}^g for each 3-tuple (i, j, g) based on prior knowledge on graph similarity or simply use the same λ for all 3-tuples (i, j, g) . In the sequel, we present results

based on the latter approach. We recommend choosing the tuning parameters via the Bayesian information criterion (BIC). Specifically, for a given λ , we define BIC for the proposed method as

$$\text{BIC}(\lambda) = \sum_{k=1}^K \left\{ \text{tr}(\hat{\Sigma}^k \hat{Q}_i^k) - \log \det(\hat{Q}_i^k) + \frac{\log(n_k)}{n_k} |\hat{E}^k| \right\},$$

where \hat{Q}_i^k ($k = 1, \dots, K$) are the estimated precision matrices from the data. The optimal tuning parameter is thus $\lambda^* = \arg \min_{\lambda \in \mathcal{D}_n} \text{BIC}(\lambda)$, where the set of values \mathcal{D}_n is chosen such that for every $\lambda_j \in \mathcal{D}_n$ ($n_k = n$):

$$\lambda_j = c_j \left(|g_{\max}| + \sqrt{\log G_0} \right) / \sqrt{n}, \quad c_j = 0.02 * j, \quad j = 1, \dots, 20.$$

Here $|g_{\max}|$ and G_0 refer, respectively, to the maximum size of groups in \mathcal{G} and maximum total number of groups in all regressions. They can be conveniently defined by the input sparsity pattern. In practice, it is also recommended to apply the stability selection procedure (Meinshausen and Bühlmann, 2010; Shah and Samworth, 2013) to select graphical models that are both stable and interpretable.

3. Theoretical Results

The JSEM estimator enjoys nice theoretical properties under certain regularity conditions. Specifically, we establish the norm consistency of the estimated precision matrices, as well as the consistent recovery of the edge sets of the various graphical models under consideration based on the structured sparsity pattern \mathcal{G} .

3.1 Estimation Consistency

Let $\mathbb{N}_{(p-1)K}^i = \{(j, k) : j \neq i, k = 1, \dots, K\}$ be the variable index set for equation (2) with a fixed node i . Given the structural information \mathcal{G} , the grouped variable index set $\{(j, g) : j \neq i, g \in \mathcal{G}^{ij}\}$ defines a partition of $\mathbb{N}_{(p-1)K}^i$. Denote by G_i the cardinality of the set $\{(j, g) : j \neq i, g \in \mathcal{G}^{ij}\}$. Then $1 \leq G_i \leq (p-1)K$. Let $J(\Theta_{0,i}) = \{(j, g) : j \neq i, g \in \mathcal{G}^{ij}, \theta_{0,i}^{[jg]} \neq 0\}$ be the set of nonzero groups in the i -th regression. We assume an overall sparsity at the group level, that is, the size of $J(\Theta_{0,i})$ is $s_i \ll G_i$. Let

$$G_0 = \max_{i=1, \dots, p} G_i, \quad s_0 = \max_{i=1, \dots, p} s_i, \quad S_0 = \sum_{i=1}^p s_i,$$

and also let $|g|$ be the size of the group g with $|g_{\max}| = \max_{g \in \mathcal{G}} |g|$.

Let $\mathbb{M}(p, K)$ represent the set of all $p \times K$ matrices. For $\Delta = (\delta^1, \dots, \delta^K) \in \mathbb{M}(p, K)$ and a group $g \subset \{1, \dots, K\}$, denote by $\delta_j^{[g]}$ the vector composed of all δ_j^k for which $k \in g$. Write $\mathcal{J} = \{J(\Theta_{0,1}), \dots, J(\Theta_{0,p})\}$, the collection of sets of nonzero groups in all p regressions. For any $J \in \mathcal{J}$, denote Δ_J the nonzero matrix in $\mathbb{M}(p, K)$, which has the same coordinates as Δ on J and zero elsewhere. Let J^c denote the complement of the index set J . Write $\underline{0}$ as the zero matrix in $\mathbb{M}(p, K)$. We make the following assumptions.

$$(A1) \quad \text{For } 0 < s < G_0, \text{ there exists } \kappa = \kappa(s) > 0, \text{ such that}$$

$$\min_{J \in \mathcal{J}, |J| \leq s} \min_{\Delta \in \mathcal{F}_J} \frac{\sum_{k=1}^K \|\mathbf{X}^k \delta^k\|^2 / n}{\|\Delta_J\|^2} \geq \kappa^2(s),$$

where for i satisfying $J(\Theta_{0,i}) = J$, \mathcal{F}_J is defined as

$$\mathcal{F}_J = \{\Delta : \Delta \in \mathbb{M}(p, K) \setminus \{0\}, \sum_{(j,g) \in J^c} \lambda_{ij}^g \|\delta_j^{[g]}\| \leq 3 \sum_{(j,g) \in J} \lambda_{ij}^g \|\delta_j^{[g]}\|\}.$$

$$(A2) \quad \text{For every } k = 1, \dots, K \text{ and } i = 1, \dots, p, \text{Var}(X_i^k) = 1. \text{ Further, there exist constants } c_0 \text{ and } d_0 \text{ such that for every } k,$$

$$0 < 1/c_0 \leq \phi_{\min}(\Sigma_0^k) \leq \phi_{\max}(\Sigma_0^k) \leq 1/d_0 < \infty,$$

where $\phi_{\min}(\Sigma_0^k)$ and $\phi_{\max}(\Sigma_0^k)$ are the minimum and maximum eigenvalues of the matrix Σ_0^k , respectively.

Assumption (A1) is a generalization of the Restricted Eigenvalue assumption for the Lasso in Bickel et al. (2009) to the group lasso setting in our problem and requires the super design matrix $\text{diag}(\mathbf{X}^1, \dots, \mathbf{X}^K)$ to be well conditioned over the restricted set of vectors under consideration. One sufficient condition is that the eigenvalues of the Gram matrix of $\text{diag}(\mathbf{X}^1, \dots, \mathbf{X}^K)$ is positive when restricted to the subset of sparse vectors with cardinality no greater than $2s$.

The equal variance requirement in assumption (A2) can be easily achieved by appropriate scaling of the data. The second part of the assumption explicitly excludes singular or nearly singular covariance matrices and guarantees that Ω_0^k exists for every model $k = 1, \dots, K$. We are now ready to state our first result.

Theorem 1 Consider $\hat{\Omega}^k$ ($k = 1, \dots, K$) defined in (4). Let Assumption (A1) with $s = 2s_0$ and Assumption (A2) be satisfied. For every regression defined in (2), choose

$$\chi_{ij}^g = \frac{2}{\sqrt{nd_0}} \left(\sqrt{|g_{\max}|} + \frac{\pi}{\sqrt{2}} \sqrt{q \log G_0} \right),$$

with $q > 1$. Then, with probability at least $1 - 2pG_0^{1-q}$, we have

$$\frac{1}{K} \sum_{k=1}^K \|\hat{\Omega}^k - \Omega_0^k\|_F \leq O \left(\sqrt{\frac{S_0}{nK}} \left\{ \sqrt{|g_{\max}|} + \frac{\pi}{\sqrt{2}} \sqrt{q \log G_0} \right\} \right), \quad (5)$$

where G_0 is the maximum number of groups in all regressions, S_0 is the total number of relevant groups and $|g_{\max}|$ is the maximum group size.

Proof of Theorem 1 is available in Appendix A. Note the rate in (5) improves over estimating each precision matrix separately, as long as the sparsity pattern \mathcal{G} is appropriately specified and nontrivial, i.e. there exists structural similarity among the considered graphical models. Further, the proposed procedure obtains a faster convergence rate than that of Guo et al. (2011) in some scenarios.

For example, if all K graphs share the same structure, then $|g_{\max}| = K$ and $G_0 = p - 1$. Thus, JSEM achieves a convergence rate of the order of

$$O\left(\sqrt{\frac{S_0}{n}} \left\{ 1 + \frac{\pi}{\sqrt{2}} \sqrt{\frac{q \log(p-1)}{K}} \right\}\right). \quad (6)$$

In contrast, separate estimation of Ω^k is known to be of the order of

$$O\left(\sqrt{\sum_k \|\Omega_0^{k-}\|_0 \frac{\log p}{nK}}\right),$$

where $\|\Omega_0^{k-}\|_0$ denotes the number of nonzero off-diagonal entries in Ω_0^k and \sum_k is short-hand notation for $\sum_{k=1}^K$. The joint estimation method by Guo et al. (2011) has the following convergence rate

$$O\left(\sqrt{(p+m) \frac{\log p}{nK}}\right),$$

where $m = |\cup \{k = 1, \dots, K : \omega_{0,ij}^k \neq 0\}|$. Under correctly specified \mathcal{G} , we have $S_0 = m$. Thus, JSEM has a lower estimation error rate than the joint estimation method of Guo et al. (2011). JSEM also outperforms separate estimation if $S_0 \asymp \|\Omega_0^{k-}\|_0$, where \asymp means that the expressions on both sides are of the same order. On the other hand, the rate in (6) could be worse if the sparsity pattern \mathcal{G} is highly misspecified such that the number of nonzero parameters $S_0 > \sum_k \|\Omega_0^{k-}\|_0 \geq m$. The issue of sparsity pattern misspecification is addressed in the next section.

3.2 Graph Selection Consistency

To understand how JSEM performs in selecting the edge sets of the graphical models, it suffices to focus on each of the group lasso estimation problems (2), as consistent graph selection relies on consistent variable selection in all p regressions. Unlike the sign consistency in the lasso setting (Zhao and Yu, 2006), variable selection properties with a group lasso penalty are much more complicated because the latter selects whole groups rather than individual variables (see Basu et al., 2015, and the discussion therein). The Basu et al. (2015) paper offers a generalization and introduces the notion of direction consistency for the group lasso. Specifically, for a nonzero vector ξ , its direction vector is defined as $D(\xi) = \xi/\|\xi\|$ and $D(\mathbf{0}) = \mathbf{0}$. An estimator $\hat{\Theta}_i$ of (2) is *direction consistent* at rate α_n if for a sequence of positive real numbers $\alpha_n \rightarrow 0$,

$$\mathbb{P}(\|D(\hat{\Theta}_{0,ij}^{[g]}) - D(\theta_{0,ij}^{[g]})\| < \alpha_n, \forall (j,g) \in J(\Theta_{0,i}); \hat{\theta}_{ij}^{[g]} = \mathbf{0}, \forall (j,g) \notin J(\Theta_{0,i})) \rightarrow 1,$$

as $n, p \rightarrow \infty$. In general, direction consistency does not guarantee sign consistency, especially when there are multiple members within one group. However, if the group is selected, all the members within the group are selected, which is sufficient for joint neighborhood selection for each node and subsequent selection of graphs. Motivated by the above idea, we establish the graph selection consistency property of JSEM in Theorem 2, which can be conveniently modified to adjust for the misspecification in the prior information \mathcal{G} . Before we present the main result, we need more notations.

Consider the group lasso estimation problem (2) for node i . For simplicity, we discuss the estimation consistency properties with a common tuning parameter λ for all (j,g) . For $k = 1, \dots, K$,

denote \mathbf{X}_k^k the $n \times |I_k|$ sub-matrix consisting of all relevant variables from the k -th model. In other words, for all $j \in I_k$, there exists a group $g \ni k$ such that $(j,g) \in J(\Theta_{0,i})$. Note the dependency of each index set I_k on i is made implicit here for notational convenience. Further, let $\xi^k \in \mathbb{R}^{|I_k|}$ be a vector indexed by I_k . The following assumption adapts the *Uniform Irrepresentability Condition (IC)* in Basu et al. (2015) to our setting:

(A3) There exists a positive constant η such that for all $\xi = ((\xi^1)^T, \dots, (\xi^K)^T)^T \in \mathbb{R}^{\sum_k |I_k|}$ with $\max_{(j,g)} \|\xi_j^{[g]}\| \leq 1$ and all $(j,g) \notin J(\Theta_{0,i})$,

$$\left(\sum_{k \in G} [\mathbf{X}_j^k]^T \mathbf{X}_{I_k}^k \{(\mathbf{X}_{I_k}^k)^T \mathbf{X}_k^k\}^{-1} \xi^k \right]^{1/2} \leq 1 - \eta. \quad (7)$$

Note the group level constraint (7) is required to hold for all p regressions and is less stringent than the IC for the selection consistency of lasso. In general, it is not easy to verify Assumption (A3). One sufficient condition, as suggested in Zhao and Yu (2006), is that the regression coefficients of \mathbf{X}_j^k on \mathbf{X}_k^k ($k = 1, \dots, K$) have Euclidean norm less than 1 for all $(j,g) \notin J(\Theta_{0,i})$.

Theorem 2 Let Assumption (A1) with $s = s_0$, (A2) and (A3) be satisfied. Assume further that the sparsity pattern \mathcal{G} is correctly specified. For every regression defined in (2), choose

$$\lambda \geq \max_{i,(j,g) \notin J(\Theta_{0,i})} \frac{1}{\eta} \frac{1}{\sqrt{nd_0}} \left(\sqrt{|g|} + \frac{\pi}{\sqrt{2}} \sqrt{q \log G_0} \right), \quad (8)$$

$$\alpha_n \geq \max_{i,(j,g) \in J(\Theta_{0,i})} \frac{1}{\kappa(s_0)} \frac{1}{\|\theta_{0,ij}^{[g]}\|} \left\{ \lambda \frac{\sqrt{s_0}}{\kappa(s_0)} + \frac{1}{\sqrt{nd_0}} \left(\sqrt{|g|} + \frac{\pi}{\sqrt{2}} \sqrt{q \log G_0} \right) \right\}, \quad (9)$$

with $q > 1$. Then with probability at least $1 - 4pG_0^{1-q}$, we have simultaneously for all i

1. $\hat{\theta}_{ij}^{[g]} = \mathbf{0}$, for all $(j,g) \notin J(\Theta_{0,i})$,
2. $\|\hat{\theta}_{ij}^{[g]} - \theta_{0,ij}^{[g]}\| < \alpha_n \|\theta_{0,ij}^{[g]}\|$, and hence $\|D(\hat{\Theta}_{0,ij}^{[g]}) - D(\theta_{0,ij}^{[g]})\| < 2\alpha_n$, for all $(j,g) \in J(\Theta_{0,i})$.

Further, if $\alpha_n < 1$, then

$$\mathbb{P}(\hat{E}^k = E_0^k, \forall k = 1, \dots, K) \geq 1 - 4pG_0^{1-q},$$

where \hat{E}^k is defined in (3).

Note the choice of λ in (8) is of the same order as the tuning parameter required for estimation consistency in Theorem 1. With the above choice of λ , α_n can be chosen to be of the order of $O(\sqrt{s_0}(\sqrt{|g_{\max}|} + \sqrt{\log G_0})/\sqrt{\eta})$. A proof of Theorem 2 can be found in Appendix B.

Bach (2008) using a strong irrepresentability assumption also establishes group support recovery. In this work, we take a different route, where a similar strong irrepresentability assumption leads to direction consistency. Then, we leverage the notion of direction consistency to propose *within group thresholding* which allows us to handle successfully moderate misspecification of the group structures, as discussed next. Further, from a technical perspective, we build on the Karush-Kuhn-Tucker (KKT) conditions inversion scheme introduced in Zhao and Yu (2006), and noting

that the $\text{sign}(\cdot)$ function in standard lasso KKT conditions is replaced by the $D(\cdot)$ function in the group lasso KKT conditions. Therefore, sign consistency has a natural generalized counterpart when considering optimization over groups.

When \mathcal{G} is misspecified, it is possible that not all the members within a group have nonzero effects. However, the group lasso penalty may fail to exclude members with actual zero effect within the misspecified group, leading to the recovery of spurious edges. The following result implies that the property of direction consistency helps identify influential members within a group, that is, those with noticeable nonzero effects.

Corollary 3 *Let Assumption (A1) with $s = s_0$, (A2) and (A3) be satisfied. For every regression defined in (2), choose λ and α_n as in Theorem 2. Define*

$$\hat{\theta}_{ij}^{k,thr} = \hat{\theta}_{ij}^k \mathbf{1}\{\|\hat{\theta}_{ij}^k\| / \|\hat{\theta}_{ij}^{[0]}\| > 2\alpha_n\}, \quad \forall k \in g, \forall (i, j) \in J(\Theta_{0,i}),$$

and

$$\hat{E}^{k,thr} = \{(i, j) : 1 \leq i < j \leq p, \hat{\theta}_{ij}^{k,thr} \neq 0 \text{ OR } \hat{\theta}_{ji}^{k,thr} \neq 0\},$$

If for all $g \in \mathcal{G}$, $\min_{k \in g} \hat{\theta}_{i,j}^k / \|\hat{\theta}_{0,i,j}^{[0]}\| > 2\alpha_n$, then

$$\mathbb{P}(\hat{E}^{k,thr} = E_0^k, \forall k = 1, \dots, K) \geq 1 - 4pG_0^{1-q}.$$

The result in Corollary 3 implies immediately that JSEM with an additional thresholding step on the estimated direction vectors $D(\|\hat{\theta}_{ij}^{[0]}\|)$ can be applied to reduce false discoveries and thus improve selection of the edge sets when the structured pattern \mathcal{G} is moderately misspecified (that is, most of the structural relationships specified in \mathcal{G} are reliable). This is illustrated in the third simulation study of Section 4.

4. Performance Evaluation

We present three simulation studies to evaluate the performance of JSEM. Other methods compared include the separate estimation method Glasso, where the *Graphical Lasso* by Friedman et al. (2008) is applied to each graphical model separately, joint estimation by Guo et al. (2011), denoted by JEM-G, the Group Graphical Lasso denoted by GGL by Danaher et al. (2014), and the structural pursuit method MGGM by Zhu et al. (2014). Note we choose MGGM over the Fused Graphical Lasso method (Danaher et al., 2014), as the former has been consistently shown to exhibit better performance.

The first study considers a *single common structure* across all graphical models, while the second one features a *more complex structured sparsity pattern*. Our comparisons are based on the overall performance of different methods in terms of their ROC curves, as well as their finite sample performance in identifying the corresponding graphical models. For the latter, we use BIC to select the tuning parameters for all methods; in addition, the maximum likelihood refitting step (4) is added to all joint estimation methods to ensure fair comparison. We point out that the first study is favorable to existing joint estimation methods due to high degree of structural similarity, while the second one with varying degrees of structural similarity is more favorable to the JSEM procedure. Nevertheless, the results show that JSEM outperforms these competing methods in both settings, even when the structured pattern is moderately misspecified.

The third simulation compares JSEM with its thresholded version under misspecified \mathcal{G} using the experimental settings of the first two studies. In this setting, one also needs to select the within group thresholding α_n besides λ . As in previous simulations, we first select λ via BIC without any thresholding. At the optimal λ , we select α_n from the grid of values

$$\alpha_n(c) = c \left(|g_{\max}| + \sqrt{\log G_0} \right) / \sqrt{\pi}, \quad c \in \{0.1, 0.2, \dots, 1\},$$

where $|g_{\max}|$ and G_0 are defined by the input sparsity pattern. The optimal α_n^* is selected as the one that minimizes the corresponding BIC.

We refer readers to Appendix C for additional simulation results, including comparison of all joint estimation methods with and without maximum likelihood refitting step (4), and large p settings.

4.1 Simulation Study 1

In our first simulation, we set $K = 5$, with each graphical model being of size $p = 100$. The structured pattern is constructed as follows: we first generate a scale-free network with edge set E_0 as the common structure shared across all graphs, shown in the left panel of Figure 2. To generate the edge set E^k , we randomly select a pair of (i, j) , $i < j$ such that $(i, j) \notin E_0$ and add it to E^k . This procedure was repeated $\rho|E_0|$ times for each k , where ρ is a positive number corresponding to the ratio of individual edges to common ones. In this example, we set $\rho = 0.1$ to allow high structural similarity across graphs. Thus, all graphical models have the same degree of sparsity, with 108 or 2.2% of all possible edges present. Note that due to the sparse structure of each graph, the proportion of shared non-edges (common zeros in the adjacency matrices) among all models is 98%.

Given the edge set E^k , we then constructed the inverse covariance matrix with the nonzero off-diagonal entries in Ω^k being uniformly generated from the $[-1, -0.5] \cup [0.5, 1]$ interval. The positive definiteness of Ω^k is guaranteed by setting the diagonal elements to be $[\phi_{\min}(\Omega^k)] + 0.1$. The covariance matrix Σ^k is then determined by

$$\Sigma_{ij}^k = (\Omega^k)_{ij}^{-1} / \sqrt{(\Omega^k)_{ii}^{-1} (\Omega^k)_{jj}^{-1}}.$$

By construction, each Σ^k corresponds to the correlation matrix for the k -th graphical model. The sparsity pattern supplied for JSEM is $\mathcal{G} = \{1, \dots, K\}$, that is assuming all graphical models share the same structure. Note by setting the parameter $\rho = 0.1$, we have created a situation where about 10% of the information in \mathcal{G} is misspecified for JSEM. This is of interest for us to see whether JSEM is robust to pattern misspecification.

To compare the overall performance of all methods, we generated $n_k = 50$ samples from each $k = 1, \dots, K$ and computed the average false positive and true positive rates of the estimated precision matrices over a fine grid of tuning parameters from 20 replications. The resulting ROC curves are shown in the right panel of Figure 2. Since both GGL and MGGM require two tuning parameters, one for controlling the *sparsity* of individual graph and the other for controlling the *similarity* across all graphs, we computed the ROC curves over a fine grid of the sparsity parameter while fixing the similarity regularization at four different levels (from low to high similarity), and plotted the one that has the largest value of area under the curve (AUC). The graph \mathcal{U} supplied for MGGM is a complete graph such that each pair of graphical models is included in the fused lasso

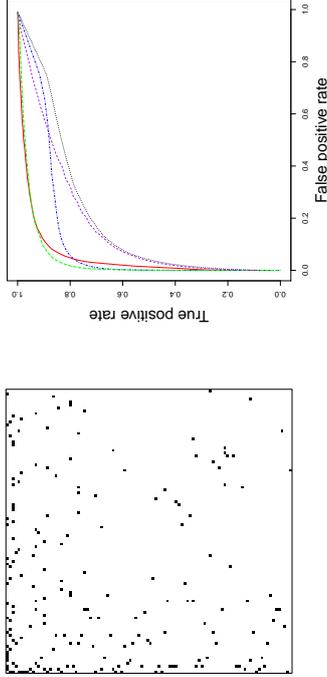

Figure 2: Simulation study 1: left panel shows the image plot of the adjacency matrix corresponding to the shared structure across all graphs. Each black cell indicates presence of an edge. The right panel shows the ROC curves for sample size $n_k = 50$: GGLasso (dotted in black), JEM-G (dotted in blue), GGL (dashed in red), MGGM (dashed in purple), JSEM (long-dash in green).

In this example, it turns out that GGL performs the best when there is only regularization on the similarity, i.e. a *group lasso* penalty on the same entry across all K precision matrices, which we expect to exhibit a similar performance to the proposed JSEM. In the right panel of Figure 2, the ROC curve of GGL falls slightly below that of JSEM. In comparison, MGGM does not perform as well despite the flexible penalty. The best curve we got from MGGM shows some advantage over the separate estimation GGLasso, but mostly falls below curves from other joint estimation methods. JEM-G performs well and is very competitive compared to GGL and JSEM for very low false positive and high true positive rates, but starts falling behind when the false positive rate is greater than 5%. In this example, JSEM performs the best with the highest ROC curve throughout the domain.

Next, we computed the estimators from different methods with $n_k = 50$ samples for each $k = 1, \dots, K$, using the tuning parameters selected by BIC. Results are summarized in Table 1, which compares the estimated precision matrices with the population version in the true model based on 50 replications under falsely discovered edges (FP), falsely deleted edges (FN), structural hamming distance (SHD), F_1 score (F1) and Frobenius norm loss (FL). The F_1 score (based on the effectiveness measure in Rijsbergen, 1979) measures the accuracy of a test by summarizing information from both FP and FN, where it reaches its best value at 1 and worst at 0. The results indicate that although GGL is good at controlling false positives, it tends to produce a high number of false negatives. The performance of MGGM is quite the opposite, with relatively small false negatives, but a huge number of false positive edges. In comparison, the proposed method JSEM achieves

Method	FP	FN	SHD	F1	FL
Glasso	35(6)	81(2)	116(5)	0.32(0.02)	0.73(< 0.01)
JEM-G	22(4)	40(4)	62(6)	0.69(0.03)	0.28(0.02)
GGL	17(6)	73(2)	90(6)	0.44(0.03)	0.29(0.02)
MGGM	286(13)	49(3)	335(13)	0.26(0.01)	0.64(0.02)
JSEM	19(4)	35(3)	54(6)	0.73(0.03)	0.25(0.02)

Table 1: Performance of different regularization methods for estimating graphical models in Simulation Study 1: average FP, FN, SHD, F1 and FL (SE) for sample size $n_k = 50$. The best cases are highlighted in bold.

a balance and obtains the highest F_1 score, as well as the lowest Frobenius norm loss. JEM-G performs slightly worse, but still well above the other three methods.

4.2 Simulation Study 2

In our second study, we consider a more structured pattern with $K = 10$ graphs. Each graphical model consists of $p = 50$ variables. Figure 3 shows the heat maps of the 10 adjacency matrices. This structured pattern is constructed as follows: we first generate the adjacency matrices corresponding to five distinct p -dimensional scale-free networks, so that the adjacency matrices in each column of the plot are the same. Next, we replace the connectivity structure of the bottom right diagonal block of size $p/2$ by $p/2$ in each adjacency matrix with that of another two distinct $p/2$ -dimensional scale-free networks, so that graphical models in each column exhibit the same connectivity pattern except in the bottom right diagonal block of their adjacency matrices. Note that by replacing the connectivity structure among the second half of the nodes, the relationships between the first half and the second half of the nodes are also altered. In summary, this structured pattern illustrates how different subsets of the edge sets across multiple graphical models can be similar, as well as exhibit differences in their topologies. To the best of our knowledge, such complex relationships have not been studied in the literature. In this setting, the proportion of shared non-edges (common zeros in the precision matrices) among all graphical models is about 60%.

Given the adjacency matrix or equivalently the edge set E^k , we generate the covariance and inverse covariance matrices in the same way as in the first simulation study. The input sparsity pattern \mathcal{S} supplied for JSEM and the graph \mathcal{U} required in MGGM are defined according to the pattern in Figure 3. We also study the effect of misspecification in \mathcal{S} by varying $\rho = 0, 0.2, 0.4, 0.6$, each corresponding to having only $(1 - \rho) * 100\%$ of the information in \mathcal{S} being correct for JSEM.

At each level of pattern misspecification, we generated $n_k = 100$ independent samples for each $k = 1, \dots, K$ and compared the ROC curves from different methods based on 20 replications in Figure 4. Again, the ROC curves for GGL and MGGM were optimized first with respect to the similarity regularization in terms of AUC. When $\rho = 0$, the results show a superior performance of JSEM, since it effectively incorporates available prior information across the various graphical models. JEM-G also yields a reasonably high ROC curve by taking advantage of the shared non-edges among all models. The performance of MGGM is comparable to that of JEM-G and much better than that of GGL. This is not surprising since MGGM benefits from knowing which pairs of

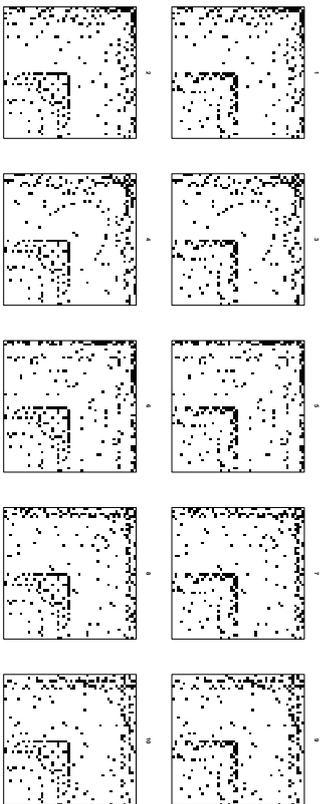

Figure 3: Simulation study 2: image plots of the adjacency matrices from all graphical models. Graphs in the same row share the same connectivity pattern at the bottom right block, whereas graphs in the same column share the same pattern at remaining locations.

graphical models to group. As ρ increases ($0 < \rho \leq 0.4$), JSEM still performs the best despite the incorrectly specified \mathcal{G} , while other methods perform not much better than the separate estimation method *Giaco*. When $\rho = 0.6$, JSEM starts suffering from the large amount of pattern misspecification as well and performing not much better than separate estimation. Note at such high ρ values, the assumption of the presence of any related structures across graphical models becomes tenuous and therefore one is better off employing a separate estimation method for each graph.

Next, we examined the finite sample performance of different methods in identifying the true graphs and estimating the precision matrices at the optimal choice of tuning parameters. Table 2 shows the deviance measures between the estimated and the true precision matrices based on 50 replications for varying levels of pattern misspecification. For $\rho \leq 0.4$, JSEM achieves a good balance between FP and FN, and yields the highest F_1 score and lowest Frobenius norm loss. JEM-G is also very competitive in controlling false positive edges and comes next in overall performance. MGGM benefits from knowing the grouping structures and has comparable performance to JEM-G. In all cases, GGL achieves low FN, but very high FP, thus resulting in low F_1 scores. When $\rho = 0.6$, the advantage of using a joint estimation method begins to diminish due to the high heterogeneity and separate estimation is recommended.

4.3 Simulation Study 3

Finally, we illustrate how direction consistency helps improve the estimation of graphical models using the previous two experimental settings. Table 3 presents the performance of thresholded JSEM when \mathcal{G} is moderately misspecified with individual to common ratio $\rho = 0.3$, based on 50 replications. Note that we used a larger sample size $n_k = 200$ in both settings to ensure that the Uniform IC required for direction consistency holds. The advantage of thresholding within groups is obvious in both settings, where the thresholded JSEM significantly reduces the number of false

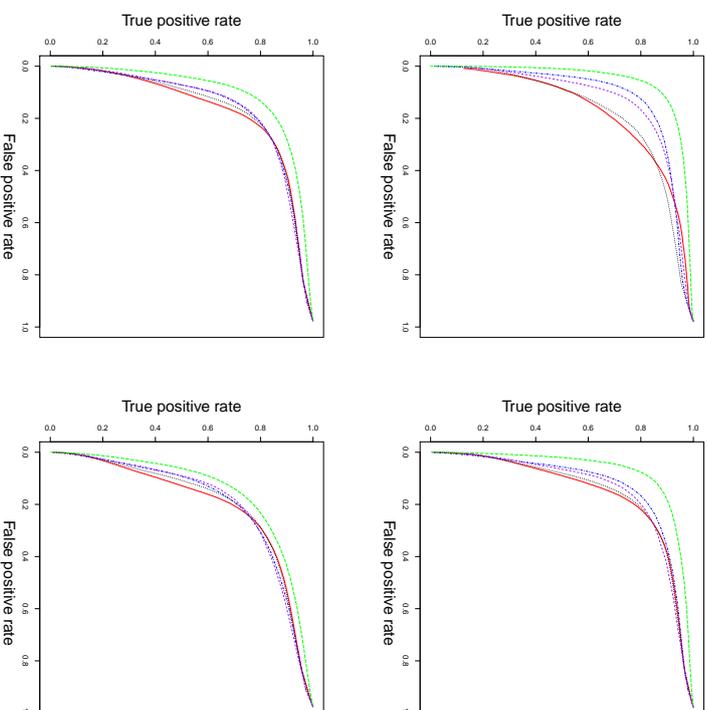

Figure 4: Simulation study 2: ROC curves for sample size $n_k = 100$: *Giaco* (dotted in black), JEM-G (dotted in blue), GGL (solid in red), MGGM (dashed in purple), JSEM (long-dash in green). The misspecification ratio ρ varies from (left to right): 0, 0.2 (top row) and 0.4, 0.6 (bottom row).

positive edges with only a small loss in the presence of false negative edges. One may notice the slight increase in Frobenius norm loss for thresholded JSEM, which is likely due to the increased presence of false negative edges. Nevertheless, the thresholded version of JSEM obtains higher F_1 scores, indicating an overall improvement in the structural estimation of all graphs.

We point out that the JSEM with thresholding procedure is most effective when ρ is moderate to small, such as $\rho < 0.5$ in this example. In other words, one believes most of the structural relationships are fairly reliable. If this is not the case, the numerical work presented strongly suggests that no joint estimation method works well, since the fundamental assumption of structural similarity

ρ	Method	FP	FN	SHD	F1	FL
0	Glasso	154(4)	38(1)	192(4)	0.51(0.01)	0.60(0.005)

among multiple models is violated. Instead, separate estimation is recommended for handling high heterogeneity among multiple graphical models.

5. Applications

To illustrate the proposed joint estimation method in inferring real-world networks, we applied JSEM to a climate data set to study relationships between climate defining variables at multiple locations in North America, as well as a breast cancer gene expression data extracted from The Cancer Genome Atlas project (TCGA, 2012).

5.1 Application to Climate Modeling

Recent assessments from the Intergovernmental Panel on Climate Change (IPCC, Stocker et al., 2013) indicate multiple lines of evidence for climate change in the past century and these changes have caused significant impacts on natural and human systems. One common approach towards understanding the climate system has been attribution studies of detected changes to internal and external forcing mechanisms (such as solar radiation, greenhouse gases, etc.) using simulated climate models. Lozano et al. (2009) used spatial-temporal modeling to study the attribution of climate defining mechanisms from observed data. In this work, we provide an alternative to learning the complex interactions among climate defining factors exhibited across different climate zones based on observed data.

The data used in this study are monthly measurements from January 2001 to June 2005 on 16 variables including mean temperature (TMP), diurnal temperature range (DTR), maximum and minimum temperature (TMX, TMN), precipitation (PRE), vapor pressure (VAP), cloud cover (CLD), rain days (WET), potential evapotranspiration (PET), frost days (FRS), greenhouse gases (carbon dioxide (CO₂), carbon monoxide (CO), methane (CH₄), hydrogen (H₂), aerosols (AER) and solar radiation (SOL) from CRU (<http://www.cru.uea.ac.uk/cru/data>), NOAA (<http://www.esrl.noaa.gov/gmd/dv/ftpdata.html>), NASA (<http://disc.sci.gsfc.nasa.gov/aerosols>) and NCDC (<http://ftp.ncdc.noaa.gov/pub/data/nsrdb-solar/>). The data are organized as a 2.5 degree latitude by 2.5 degree longitude grid across North America. To avoid complications from any seasonality or autocorrelation of the data, we aggregated the monthly time series into bins of 3-month intervals and took first differences of the quarterly data. The data after differencing were further normalized. Details on the pre-processing steps are included in Appendix D. Next, we randomly selected $K = 27$ locations spanning all types of climate from the 2.5 by 2.5 degree grid of North America (see Figure 5). This gives us an $n \times p$ matrix at each of the 27 locations, corresponding to $n = 17$ observations for the $p = 16$ climate defining variables. At each location, the conditional dependency network is of dimension $p \times p$, which has $16 \times 15/2 = 120$ edges to be inferred.

Our goal is to infer the conditional dependency networks for all locations simultaneously based on available spatial information, obtained from the classification of climate zones in Peel et al. (2007). Specifically, we assume that AER and SOL have one common connectivity pattern with other variables in the geographical south of North America and another common pattern in the north. The definition of the south and north is given in Figure 5. Variables on greenhouse gases (CO₂, CO, CH₄ and H₂) are assumed to interact with other variables (except AER and SOL) in the same fashion within each of the four climate groups, that is Mid-latitude Desert, Semiarid Steppe, Humid Subtropical and Humid Continental. The connectivity patterns among all remaining variables are assumed to be the same within each of the six distinct climate zones in Figure 5.

We used BIC on the normalized data to select the tuning parameter λ for the proposed JSEM. At the optimal λ , we applied our method coupled with complementary pairs stability selection (Shah

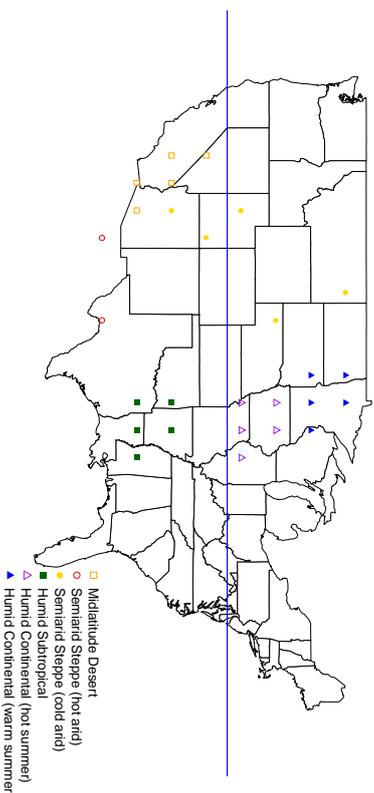

Figure 5: The selected 27 locations based on climate classification. The solid line separates the south and north of North America and corresponds to latitude 39° N.

and Samworth, 2013) to identify the interaction networks at the 27 locations. To perform stability selection, we ran our method 50 times on two randomly drawn complementary pairs of sizes 8 and 9, and kept only edges that are selected over 70% of the time.

Due to space limitation, we present in Figure 6 the estimated networks at the six distinct climate zones. Readers are referred to Appendix D for the complete picture of the 27 networks from all the 27 locations under study, as well as more detailed comparisons. Although we do not impose the assumption on sharing of a single common structure across all locations, there are common edges (solid) identified for all climate zones, reflecting key features of climate defining regardless of geographical location. Such relationships are consistent with how the corresponding climate defining variables are defined, as well as how the data are collected (Harris et al., 2014). The Mid-latitude Desert and Semiarid Steppe climate zones share the edge between DTR and CLD, indicating that they are correlated conditional on all other variables. Similar relationships have also been found over drier regions in Zhou et al. (2009). In addition, one can see that the variable FRS interacts mainly with PET at Mid-latitude Desert and Semiarid Steppe climates, whereas it is partially correlated with both PRE and TMN (or TMX) at Continental climates. This can be explained from the distinction between these climate zones. At Humid Continental climate, precipitation is relatively well distributed year-round in most areas and snowfall occurs in all areas. It is thus not difficult to see why precipitation (PRE) and temperature related variables correlate with the number of frost days (FRS). Further, a primary criterion of an area characterized as Mid-latitude Desert or Semiarid Steppe is that it receives precipitation below potential evapotranspiration (PET), which possibly explains why FRS is partially correlated only with PET for Mid-latitude Desert and Semiarid Steppe climate. Finally, we point out that the inferred networks at neighboring climate zones are more similar, such as Semiarid Steppe (hot arid and cold arid), or Humid Continental (hot summer and

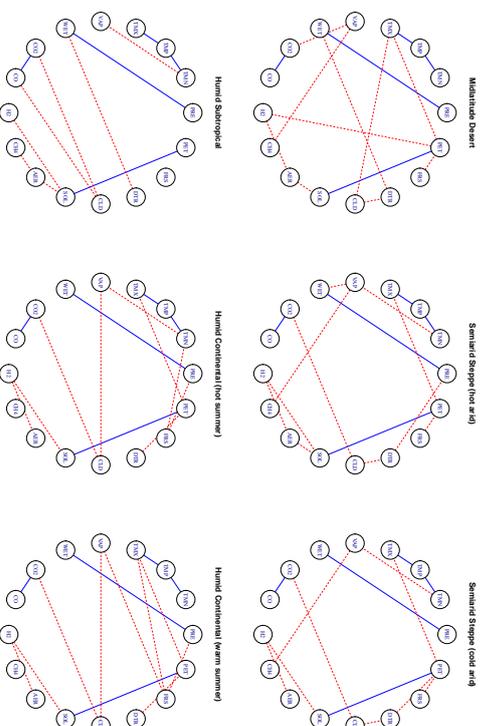

Figure 6: Estimated climate networks at the six distinct climate zones using JSEM, with edges shared across all locations blue solid and differential edges red dashed.

warm summer), whereas those with dramatically different climate show significantly different connectivity patterns. These common and individual interactions can prove critical in understanding the mechanisms of climate defining, and facilitate decision making in maintaining the best environmental results.

5.2 Application to Breast Cancer

Breast cancer is the most common cancer in women worldwide, with nearly 1.7 million new cases diagnosed in 2012 (second most common cancer overall). This represents about 12% of all new cancer cases and 25% of all cancers in women (Ferlay et al., 2013). Breast cancer is hormone related and this leads to a basic classification of cancer cells. Specifically, a cancer is called estrogen-receptor-positive (or ER+) if it has receptors for estrogen, and hence the cells receive signals from estrogen that could promote their growth. It is estimated that about 80% of all breast cancer cases are ER+ and they are more likely to respond to hormone therapy. Further, ER+ status is associated with better survival rates, especially if the cancer is diagnosed early. On the other hand, the ER-status lacks the estrogen receptor and in general exhibits poorer survival rates. Note that the presence/absence of other hormone receptors (progesterone and HER2) also play an important role in breast cancer tumor classification, therapeutic strategies and survival rates.

The breast cancer data set (TCGA, 2012) contains RNA-seq measurements for 17296 genes from 1033 breast cancer specimens, including ER+, ER- and other unevaluated cases. Due to the

overall small sample size, we first reduced the number of variables by focusing on a subset of the genes that are present in the 44 KEGG pathways in Table 4. These pathways correspond to the major signaling and biochemical ones that have been reported in the literature of playing a significant role in all cancer types. This leaves for further consideration 800 genes with 403 samples from the ER+ and 117 from the ER- classes.

The structural similarity between the networks for ER+ and ER- status was defined based on the third column in Table 4, which indicates whether the pathway is significantly enriched when testing ER+ vs ER- status via NetGSA (Ma et al., 2016), and complemented through literature searches. If one pathway is not significantly enriched, then the genes belonging to the pathway are considered to share a common structure under both ER+ and ER- status. However, due to overlaps amongst pathways (since some of their members are assigned to multiple ones in the KEGG database), only genes that did not belong to any of the differential pathways were used to define the common structure. The remaining genes are assumed to have distinct structures under the two conditions.

We then used BIC on the normalized data to select the tuning parameter λ for the proposed JSEM. At the optimal λ , we applied our method coupled with complementary pairs stability selection (Shah and Samworth, 2013) to identify the interaction networks for the ER+ and ER- classes, respectively. Due to the large number of variables, visualization of the estimated networks at the individual gene level is challenging. Instead, we examine the interactions among pathways in Figure 7 to gain insight into their co-regulation behavior. The weighted pathway level network is defined as follows. Let each node in the network represent one pathway, with size proportional to the size of the corresponding pathway. A weighted edge between two pathways P_1 and P_2 is defined as the number of nonzero partial correlations between genes in P_1 and those in P_2 (normalized by the sizes of the two pathways). Links visualized in Figure 7 are the top 5% of the weighted edges, where ranking is based on edge weights. Note pathways that are isolated from all others were removed.

The first thing to note is that structural information provided enables us to estimate a much more dense graph than either separate estimation or an agnostic method like JEM-G (see Figure 12 in Appendix D), which in turn aids biological interpretation. We focus next on the interactions between pathways, as shown in Figure 7. The central role of known cancer related pathways—TGF- β , p53, MAPK and hedgehog—is apparent. Further, we see high degree of interconnections between signaling and biochemical pathways including glycolysis gluconeogenesis, pyrimidine, cysteine and methionine, and tryptophan, which is expected due to the impact of energy metabolism in tumor growth and progression. One surprising finding is that the p53 pathway is connected only in the ER+ class, but we suspect that this may be the case due to the big discrepancy in terms of available samples for the ER+ and ER- classes and the large number of genes present. In summary, the proposed method captures established cross-talk patterns between various signaling and biochemical pathways, which is not the case with competing methods or with separate estimation.

6. Discussion

This work introduces a flexible joint structural estimation method (JSEM) that incorporates *a priori* known structural relationships between multiple graphical models. The proposed method works well in situations where there is a large number of graphical models, but external similarity information is available only for sub-components of the models. In practice, if not all entry-wise structural relationships across multiple graphical models are available, it is recommended to add constraints at mainly edge pairs that are likely to share the same structures instead of providing a highly mis-

specified structured sparsity pattern. On the other hand, if more structural information is available, one may generalize the group lasso penalty to incorporate additional structural constraints.

The theoretical guarantees of JSEM rely on two important, but standard in the literature, assumptions: the restricted eigenvalue assumption (A1) and the uniform IC assumption in (A3). In practice, it might be difficult to verify whether these assumptions are fulfilled, especially the more stringent assumption (A3). For the latter condition, Meinshausen and Yu (2009) observe that the irrepresentability condition (a variant of A3) may be violated in practical settings in the presence of highly correlated variables; nevertheless, the lasso estimates are still ℓ_2 consistent, under (A1).

Appendix A. Proof of Theorem 1

To prove the rate of convergence in Theorem 1, we look at three key steps: nodewise regression in subsection A.1, selecting the edge set in A.2 and maximum likelihood refitting in A.3. More information can be found in Appendix E. When it is clear, we shall use \sum_k as a short notation for $\sum_{k=1}^K$.

A.1 Regression

For $j \neq i, g \in \mathcal{G}^{ij}, k \in g$, let $\epsilon_j^k = \mathbf{X}_j^k - \sum_{j' \neq i} \theta_{0,j'}^k \mathbf{X}_j^k$. Let $\langle a, b \rangle$ represent the inner product between two vectors a and b . Denote $\zeta_{ij}^k = \langle \epsilon_j^k, \mathbf{X}_j^k \rangle / n$ and $\zeta_{ij}^{|\beta|} = \langle \epsilon_j^{|\beta|}, \mathbf{X}_j^k \rangle_{k \in g} \in \mathbb{R}^{|\beta|}$. Consider the random event $\mathcal{A} = \bigcap_{i,j \neq i,g} \mathcal{A}_{ij}^g$, where $\mathcal{A}_{ij}^g = \{2\|\zeta_{ij}^{|\beta|}\| \leq \lambda_{ij}^g\}$. By Lemma E.2, if we choose λ_{ij}^g as

$$\lambda_{ij}^g \geq \max_{k \in g} \frac{2}{\sqrt{n\epsilon_{0,iz}^k}} \left(\sqrt{|\beta|} + \frac{\pi}{\sqrt{2}} \sqrt{q \log G_0} \right) \quad (10)$$

with $q > 1$, then $\mathbb{P}(\mathcal{A}) \geq 1 - 2pG_0^{1-q}$. We first present the following proposition that establishes oracle bounds for $\hat{\Theta}_i - \Theta_{0,i}$ under the chosen λ_{ij}^g .

Proposition A.1 For $i = 1, \dots, p$, consider the problem (2) and choose λ_{ij}^g as in (10). Let $\hat{\Theta}_i$ be the solution to problem (2). If Assumption (A1) holds with $\kappa^2 = \kappa^2(s_0)$, then for any solution $\hat{\Theta}_i$ of problem (2), we have on the event \mathcal{A}

$$\sum_{j \neq i, g \in \mathcal{G}^{ij}} \|\hat{\theta}_{ij}^{|\beta|} - \theta_{0,ij}^{|\beta|}\| \leq \frac{16}{\kappa^2 \lambda_{\min}} \sum_{(j,g) \in J(\Theta_{0,i})} (\lambda_{ij}^g)^2, \quad (11)$$

$$\mathcal{M}(\hat{\Theta}_i) \leq \frac{64\phi_{\max}}{\kappa^2 \lambda_{\min}^2} \sum_{(j,g) \in J(\Theta_{0,i})} (\lambda_{ij}^g)^2, \quad (12)$$

where $\lambda_{\min} = \min_{i,j \neq i, g \in \mathcal{G}^{ij}} \lambda_{ij}^g$, $\mathcal{M}(\hat{\Theta}_i) = |J(\hat{\Theta}_i)|$ and ϕ_{\max} is the maximal eigenvalue of $(\mathbf{X}^k)^T \mathbf{X}^k / n$ for all $k = 1, \dots, K$. If, in addition, Assumption (A1) holds with $\kappa^2(2s_0)$, then for any solution $\hat{\Theta}_i$ of problem (2) we have that

$$\|\hat{\Theta}_i - \Theta_{0,i}\|_F \leq \frac{4\sqrt{10}}{\kappa^2(2s_0)} \sum_{(j,g) \in J(\Theta_{0,i})} (\lambda_{ij}^g)^2 \lambda_{\min} \sqrt{s_i} \quad (13)$$

By Assumption (A2), $\epsilon_{0,iz}^k \geq \phi_{\min}(\Sigma_0^k) = \phi_{\max}^{-1}(\Sigma_0^k) \geq d_0$ for all i, k . Thus, (10) implies that we can choose $\lambda_{ij}^g = \lambda_{\max}$ as

$$\lambda_{\max} = \frac{2}{\sqrt{nd_0}} \left(\sqrt{|\beta|_{\max}} + \frac{\pi}{\sqrt{2}} \sqrt{q \log G_0} \right), \quad (14)$$

with $q > 1$ for all 3-tuples (i, j, g) . Then we can rewrite the oracle inequalities in (12) and (13) as

$$\mathcal{M}(\hat{\Theta}_i) \leq \frac{64\phi_{\max}}{\kappa^2} s_i, \quad (15)$$

$$\|\hat{\Theta}_i - \Theta_{0,i}\|_F \leq \frac{8\sqrt{10}}{\kappa^2(2s_0)\sqrt{d_0}} \left(\sqrt{|g_{\max}|} + \frac{\pi}{\sqrt{2}} \sqrt{q \log G_0} \right) \sqrt{\frac{s_i}{n}}. \quad (16)$$

Detailed proof of Proposition A.1 follows similarly to that of Theorem 3.1 in Lounici et al. (2011) and can be found in Appendix E.

A.2 Selecting Edge Set

Given the estimates $\hat{\Theta}_i$ ($i = 1, \dots, p$), define \hat{E}^k as in (3) the estimated set of edges in graph $k = 1, \dots, K$. For every k , let $\hat{\Omega}^k = \text{diag}(\Omega_0^k) + \Omega_{0, E_0^k \cap \hat{E}^k}$ and $\hat{\Sigma}^k = (\hat{\Omega}^k)^{-1}$. Let

$$C_{\text{bias}} = \frac{8\sqrt{10}c_0}{\kappa^2(2s_0)\sqrt{d_0}}.$$

The following corollary is an immediate result of (15) and (16).

Corollary A.1 Consider \hat{E}^k ($k = 1, \dots, K$) selected in (3). Suppose all conditions in Theorem 1 are satisfied. Choose $\lambda_{ij}^k = \lambda_{\max}$ as defined in (14) with $q > 1$. Then we have on the event \mathcal{A}

$$|\hat{E}^k| \leq \frac{64\phi_{\max}}{\kappa^2(s_0)} S_0, \quad k = 1, \dots, K, \quad (17)$$

and

$$\frac{1}{K} \sum_k \|\hat{\Omega}^k - \Omega_0^k\|_F \leq \frac{1}{\sqrt{K}} \left\{ \sum_k \|\hat{\Omega}^k - \Omega_0^k\|_F^2 \right\}^{1/2} \leq C_{\text{bias}} \sqrt{\frac{S_0}{nK}} \left(\sqrt{|g_{\max}|} + \frac{\pi}{\sqrt{2}} \sqrt{q \log G_0} \right), \quad (18)$$

where G_0 is the maximum number of groups in all p regressions, S_0 is the total number of relevant groups, and $|g_{\max}|$ is the maximum group size.

The bound in (17) says that the cardinality of the estimated set of edges is at most of the order of S_0 and proves essential in controlling the error rate of the maximum likelihood estimate $\hat{\Omega}^k$ in the refitting step. Further, the second inequality in (18) implies

$$\left\{ \sum_k \|\hat{\Omega}^k - \Omega_0^k\|_F^2 \right\}^{1/2} \leq \tau_1 d_0,$$

provided the sample size n satisfies for $0 < \tau_1 < 1$,

$$n \geq S_0 \left(\sqrt{|g_{\max}|} + \frac{\pi}{\sqrt{2}} \sqrt{q \log G_0} \right)^2 \left(\frac{C_{\text{bias}}}{\tau_1 d_0} \right)^2.$$

It follows immediately that on the event \mathcal{A} , we can bound the spectrum of $\hat{\Omega}^k$ ($k = 1, \dots, K$) as follows. For a symmetric matrix A , let $\|A\|$ represent the spectral norm of A , which is equal to $\phi_{\max}(A)$. By definition,

$$\phi_{\min}(\hat{\Omega}^k) = \min_{v: v^T v = 1} v^T \hat{\Omega}^k v = \min_{v: v^T v = 1} \{v^T \hat{\Omega}^k v + v^T (\hat{\Omega}^k - \Omega_0^k) v\} \geq \phi_{\min}(\Omega_0^k) - \|\hat{\Omega}^k - \Omega_0^k\|.$$

Since $\phi_{\min}(\Omega_0^k) \geq d_0$ by Assumption (A2), we have

$$\begin{aligned} \phi_{\min}(\hat{\Omega}^k) &\geq \phi_{\min}(\Omega_0^k) - \|\hat{\Omega}^k - \Omega_0^k\| \geq \phi_{\min}(\Omega_0^k) - \|\hat{\Omega}^k - \Omega_0^k\|_F \\ &\geq \phi_{\min}(\Omega_0^k) - \left\{ \sum_k \|\hat{\Omega}^k - \Omega_0^k\|_F^2 \right\}^{1/2} \geq (1 - \tau_1) d_0 > 0, \end{aligned} \quad (19)$$

In addition, we have an upper bound for the maximum eigenvalue of $\hat{\Omega}^k$,

$$\begin{aligned} \phi_{\max}(\hat{\Omega}^k) &\leq \phi_{\max}(\Omega_0^k) + \|\hat{\Omega}^k - \Omega_0^k\| \leq \phi_{\max}(\Omega_0^k) + \|\hat{\Omega}^k - \Omega_0^k\|_F \\ &\leq \phi_{\max}(\Omega_0^k) + \left\{ \sum_k \|\hat{\Omega}^k - \Omega_0^k\|_F^2 \right\}^{1/2} \leq c_0 + \tau_1 d_0 < \infty. \end{aligned} \quad (20)$$

A.3 Refitting

Let $\hat{\Omega}^k$ ($k = 1, \dots, K$) be defined in (4) and

$$r_n = C_{\text{bias}} \sqrt{\frac{S_0}{n}} \left(\sqrt{|g_{\max}|} + \frac{\pi}{\sqrt{2}} \sqrt{q \log G_0} \right). \quad (21)$$

Proof [of Theorem 1.] In view of Corollary A.1, it suffices to show that

$$\sum_k \|\hat{\Omega}^k - \tilde{\Omega}^k\|_F^2 \leq O(r_n^2),$$

since by Cauchy-Schwarz inequality,

$$\frac{1}{K} \sum_k \|\hat{\Omega}^k - \tilde{\Omega}^k\|_F \leq \frac{1}{\sqrt{K}} \left\{ \sum_k \|\hat{\Omega}^k - \tilde{\Omega}^k\|_F^2 \right\}^{1/2},$$

and by triangle inequality,

$$\frac{1}{K} \sum_k \|\hat{\Omega}^k - \Omega_0^k\|_F \leq \frac{1}{K} \sum_k \|\hat{\Omega}^k - \tilde{\Omega}^k\|_F + \frac{1}{K} \sum_k \|\tilde{\Omega}^k - \Omega_0^k\|_F.$$

For $k = 1, \dots, K$, let $\Delta^k = \Omega^k - \tilde{\Omega}^k \in \mathbb{M}(p, p)$ and $\hat{\Delta}^k = \hat{\Omega}^k - \tilde{\Omega}^k$. Let

$$Q(\Omega) = \sum_k \left\{ \text{tr}(\hat{\Sigma}^k \Omega^k) - \log \det(\Omega^k) - \text{tr}(\hat{\Sigma}^k \tilde{\Omega}^k) + \log \det(\tilde{\Omega}^k) \right\}.$$

Since $(\hat{\Omega}^k)_{k=1}^K$ minimizes $Q(\Omega)$, $(\hat{\Delta}^k)_{k=1}^K$ minimizes $G(\Delta) = Q(\hat{\Omega} + \Delta)$. Recall the definition $S_E^+ = \{\Gamma \in \mathbb{R}^{p \times p} : \Gamma > 0 \text{ and } \Gamma_{ij} = 0, \text{ for all } (i, j) \notin E \text{ where } i \neq j\}$. For $k = 1, \dots, K$, define a sequence of convex sets

$$\mathcal{U}_k(\tilde{\Omega}^k) = \{\Gamma - \tilde{\Omega}^k | \Gamma \in S_E^+\}.$$

The main idea of the proof is as follows. For a sufficiently large $M > 0$, consider the set

$$\mathcal{T}_n = \{(\Delta^1, \dots, \Delta^K) : \Delta^k \in \mathcal{U}_k(\tilde{\Omega}^k), \sum_k \|\Delta^k\|_F^2 = M r_n^2\}.$$

Write $0_{p \times p}$ the zero matrix in $\mathbb{M}(n, p)$. It is clear that $G(\Delta)$ is a convex function and $G(\hat{\Delta}) \leq G(0_{p \times p}) = 0$. Thus if we can show $\inf_{\Delta \in \mathcal{T}_n} G(\Delta) > 0$, the minimizer $\hat{\Delta}$ must be inside the ball defined by \mathcal{T}_n . That is $\sum_k \|\Delta^k\|_F^2 \leq M r_n^2$. To see this, note that the convexity of $Q(\hat{\Omega})$ implies that $\inf_{\Delta \in \mathcal{T}_n} Q(\hat{\Omega} + \Delta) > Q(\hat{\Omega}) = 0$. There exists therefore a local minimizer in the ball $\{\tilde{\Omega}^k + \Delta^k : \sum_k \|\Delta^k\|_F^2 \leq M r_n^2\}$, or equivalently, $\sum_k \|\hat{\Delta}^k\|_F^2 \leq M r_n^2$.

In the remainder of the proof, we focus on

$$G(\Delta) = \sum_k \left\{ \text{tr}(\tilde{\Sigma}^k \Delta^k) - \log \det(\tilde{\Omega}^k + \Delta^k) + \log \det(\tilde{\Omega}^k) \right\}.$$

Applying Taylor expansion to the logarithm terms in the above equation, we have

$$\begin{aligned} & \log \det(\tilde{\Omega}^k + \Delta^k) - \log \det(\tilde{\Omega}^k) \\ &= \text{tr}(\tilde{\Sigma}^k \Delta^k) - \text{vec}(\Delta^k)^T \left\{ \int_0^1 (1-t)(\tilde{\Omega}^k + t\Delta^k)^{-1} \otimes (\tilde{\Omega}^k + t\Delta^k)^{-1} dt \right\} \text{vec}(\Delta^k), \end{aligned}$$

where \otimes is the Kronecker product, and $\text{vec}(\Delta^k)$ is Δ^k vectorized to match the dimensions of the Kronecker product. Therefore, we can rewrite $G(\Delta) = L_1 - L_2 + L_3$, with

$$\begin{aligned} L_1 &= \sum_k \text{tr} \{ (\tilde{\Sigma}^k - \Sigma_0^k) \Delta^k \}, \\ L_2 &= \sum_k \text{tr} \{ (\tilde{\Sigma}^k - \Sigma_0^k) \Delta^k \}, \\ L_3 &= \sum_k \text{vec}(\Delta^k)^T \left\{ \int_0^1 (1-t)(\tilde{\Omega}^k + t\Delta^k)^{-1} \otimes (\tilde{\Omega}^k + t\Delta^k)^{-1} dt \right\} \text{vec}(\Delta^k). \end{aligned}$$

Next we bound each term separately.

Recall for every k , Σ_0^k and $\tilde{\Sigma}^k$ represent the correlation and the sample correlation matrix, respectively. By Lemma 14 of Zhou et al. (2011) [see details on page 3003],

$$\mathbb{P} \left\{ |\hat{\sigma}_{0,ij}^k - \sigma_{0,ij}^k| \geq t \right\} \leq \exp \left(- \frac{3nr t^2}{10t + (\sigma_{0,ij}^k)^2} \right) \leq \exp \left(- \frac{3nr t^2}{20} \right), \quad (22)$$

for $0 \leq t \leq \{1 + (\sigma_{0,ij}^k)^2\}^{1/2}$. Then the union sum inequality and (22) imply that, with probability tending to 1,

$$\begin{aligned} \max_{k,i,j} |\hat{\sigma}_{ij}^k - \sigma_{0,ij}^k| &\leq c_1 \sqrt{\frac{1}{nK}} \left(\sqrt{|g_{\max}|} + \frac{\pi}{\sqrt{2}} \sqrt{q \log G_0} \right), \\ n &\geq \frac{4c_1^2}{K} \left(\sqrt{|g_{\max}|} + \frac{\pi}{\sqrt{2}} \sqrt{q \log G_0} \right)^2, \end{aligned}$$

provided that the sample size satisfies

where $c_1 > 0$ is a constant. Write $\Delta^k = \Delta^{k,+} + \Delta^{k,-}$ such that $\Delta^{k,+} = \text{diag}(\Delta^k)$ and $\Delta^{k,-}$ consists of the off-diagonal entries of Δ^k . Then

$$|L_1| \leq \sum_k \sum_{i \neq j} |\hat{\sigma}_{ij}^k - \sigma_{0,ij}^k| |\Delta_{ij}^k| \leq c_1 \sqrt{\frac{1}{nK}} \left(\sqrt{|g_{\max}|} + \frac{\pi}{\sqrt{2}} \sqrt{q \log G_0} \right) \sum_k \|\Delta^{k,-}\|_1.$$

By Cauchy-Schwarz inequality and the definition of $\Delta^k \in \mathcal{U}_n(\tilde{\Omega}^k)$,

$$\sum_k \|\Delta^{k,-}\|_1 \leq \sum_k (2|\hat{E}^k|)^{1/2} \|\Delta^{k,-}\|_F \leq \max_k (2|\hat{E}^k|)^{1/2} \sqrt{K} \left(\sum_k \|\Delta^k\|_F^2 \right)^{1/2}.$$

Using the bound of \hat{E}^k in (17) and the definition of r_n , we obtain

$$\begin{aligned} |L_1| &\leq c_1 \sqrt{\frac{1}{n}} \left(\sqrt{|g_{\max}|} + \frac{\pi}{\sqrt{2}} \sqrt{q \log G_0} \right) \frac{8\sqrt{2}\phi_{\max}^{\mathcal{S}_0}}{K^{1/2}(s_0)} \left(\sum_k \|\Delta^k\|_F^2 \right)^{1/2} \\ &= \frac{8\sqrt{2}c_1 \sqrt{\phi_{\max}^{\mathcal{S}_0}} r_n (M r_n^2)^{1/2}}{C_{\text{bias}} \kappa(s_0)} = \frac{8\sqrt{2}c_1 \sqrt{\phi_{\max}^{\mathcal{S}_0}} \sqrt{M} r_n^2}{C_{\text{bias}} \kappa(s_0)}, \end{aligned} \quad (23)$$

where the first equality in (23) follows from the definition of r_n in (21).

Using results from (19) and (18) together with Cauchy-Schwarz inequality, the second term L_2 can be bounded by

$$\begin{aligned} |L_2| &\leq \sum_k \langle \tilde{\Sigma}^k - \Sigma_0^k, \Delta^k \rangle \leq \sum_k \|\tilde{\Sigma}^k - \Sigma_0^k\|_F \|\Delta^k\|_F \leq \sum_k \|\Delta^k\|_F \frac{\|\tilde{\Omega}^k - \Omega_0^k\|_F}{\phi_{\min}(\tilde{\Omega}^k) \phi_{\min}(\Omega_0^k)} \\ &\leq \frac{1}{(1-\tau_1)d_0^2} \left(\sum_k \|\Delta^k\|_F^2 \right)^{1/2} \left(\sum_k \|\tilde{\Omega}^k - \Omega_0^k\|_F^2 \right)^{1/2} \leq \frac{\sqrt{M} r_n^2}{(1-\tau_1)d_0^2}, \end{aligned} \quad (24)$$

where the last inequality in (24) comes from the rotation invariant property of the Frobenius norm.

Finally we bound L_3 . Suppose for a small constant $0 < \tau_2 < 1$ such that $\tau_1 + \tau_2 < 1$, the sample size n satisfies

$$n \geq M S_0 \left(\sqrt{|g_{\max}|} + \frac{\pi}{\sqrt{2}} \sqrt{q \log G_0} \right)^2 \left(\frac{C_{\text{bias}}}{\tau_2 d_0} \right)^2,$$

then $\sqrt{M} r_n \leq \tau_2 d_0$. By (20), $\phi_{\max}(\tilde{\Omega}^k)$ is bounded above by $c_0 + \tau_1 d_0$. Therefore for $\Delta \in \mathcal{T}_n$,

$$\begin{aligned} \phi_{\max}(\tilde{\Omega}^k + \Delta^k) &\leq c_0 + \tau_1 d_0 + \|\Delta^k\| \leq c_0 + \tau_1 d_0 + \|\Delta^k\|_F \\ &\leq c_0 + \tau_1 d_0 + \left(\sum_k \|\Delta^k\|_F^2 \right)^{1/2} \leq c_0 + (\tau_1 + \tau_2) d_0, \\ \phi_{\min}(\tilde{\Omega}^k + \Delta^k) &\geq (1 - \tau_1) d_0 - \|\Delta^k\| \geq (1 - \tau_1) d_0 - \|\Delta^k\|_F \\ &\geq (1 - \tau_1) d_0 - \left(\sum_k \|\Delta^k\|_F^2 \right)^{1/2} \geq (1 - \tau_1 - \tau_2) d_0 > 0. \end{aligned}$$

For $\tilde{\Omega}^k$ and Δ^k defined above, Zhou et al. (2011) showed that $\tilde{\Omega}^k + t\Delta^k \succ 0$, $t \in [0, 1]$, for all $k = 1, \dots, K$ on the event \mathcal{A} . Thus, following similar arguments as in Rothman et al. (2008, page 502), we have

$$\begin{aligned} |L_3| &\geq \frac{1}{2} \sum_k \phi_{\min}^2(\tilde{\Omega}^k + \Delta^k)^{-1} \|\Delta^k\|_F^2 = \frac{1}{2} \sum_k \phi_{\max}^{-2}(\tilde{\Omega}^k + \Delta^k) \|\Delta^k\|_F^2 \\ &\geq \frac{M r_n^2}{2(c_0 + \tau_1 d_0 + \tau_2 d_0)^2}. \end{aligned}$$

Combining the above three bounds, we thus have

$$\begin{aligned} G(\Delta) &\geq |L_3| - |L_4| - |L_2| \\ &\geq \frac{Mr_n^2}{2(c_0 + \tau_1 d_0 + \tau_2 d_0)^2} - \frac{8\sqrt{2}c_1\sqrt{\phi_{\max}}}{C_{\text{bias}\kappa}(s_0)}\sqrt{Mr_n^2} - \frac{\sqrt{Mr_n^2}}{(1 - \tau_1)d_0^2} \\ &\geq Mr_n^2 \left\{ \frac{1}{2(c_0 + \tau_1 d_0 + \tau_2 d_0)^2} - \frac{8c_1\sqrt{2\phi_{\max}}}{C_{\text{bias}\kappa}(s_0)}\sqrt{M} - \frac{1}{(1 - \tau_1)d_0^2\sqrt{M}} \right\} > 0, \end{aligned}$$

for M sufficiently large. \blacksquare

Appendix B. Proof of Theorem 2

Consider the group lasso estimator $\hat{\Theta}_i$ defined in (2). Since the problem (2) is a special case of the generic group lasso in Basu et al. (2015), we adapt their results in Theorem 4.1 to our design.

Proof Let \mathcal{X}_i be the block diagonal matrix composed of all variables but \mathbf{X}_i^k ($k = 1, \dots, K$), that is

$$\mathcal{X}_i = \begin{pmatrix} \mathbf{X}_{-i}^1 & & \\ & \ddots & \\ & & \mathbf{X}_{-i}^K \end{pmatrix}.$$

After rearranging the columns of \mathcal{X}_i , we assume without loss of generality $\mathcal{X}_i = (\mathcal{X}_{i(1)}, \mathcal{X}_{i(2)})$ such that

$$\mathcal{X}_{i(1)} = \text{diag}(\mathbf{X}_{I_1}^1, \dots, \mathbf{X}_{I_K}^K)$$

is the sub-matrix consisting of all relevant variables. Denote the Gram matrix

$$C = \frac{1}{n} \mathcal{X}_i^T \mathcal{X}_i = \begin{pmatrix} C_{11} & C_{12} \\ C_{21} & C_{22} \end{pmatrix}$$

with $C_{11} = \mathcal{X}_{i(1)}^T \mathcal{X}_{i(1)}/n$ and $C_{22} = \mathcal{X}_{i(2)}^T \mathcal{X}_{i(2)}/n$. C_{12} and C_{21} are also defined accordingly. Note due to the block diagonal structure of $\mathcal{X}_{i(1)}$, C_{11} is also block diagonal.

Now consider interchanging the columns of \mathcal{X}_i such that

$$\tilde{\mathcal{X}}_i = \mathcal{X}_i \text{diag}(R_1, R_2) = (\mathcal{X}_{i(1)} R_1, \mathcal{X}_{i(2)} R_2) = (\tilde{\mathcal{X}}_{i(1)}, \tilde{\mathcal{X}}_{i(2)}),$$

where the columns of $\tilde{\mathcal{X}}_{i(1)}$ and $\tilde{\mathcal{X}}_{i(2)}$ are ordered in groups of variables. Here R_l is the product of elementary column switching matrices and satisfies $R_l^{-1} = R_l^T$ ($l = 1, 2$). Note $R_1 \in \mathbb{M}(\sum_k |I_k|, \sum_k |I_k|)$. Based on $\tilde{\mathcal{X}}_i$, we can define \tilde{C}_{11} , \tilde{C}_{21} and \tilde{C}_{22} similarly as above. The advantage of using $\tilde{\mathcal{X}}_i$ as the design matrix is that it orders the variables based on the grouping structures, and is in the form of the generic group lasso design in Basu et al. (2015). It is thus more straightforward to adapt their results using $\tilde{\mathcal{X}}_i$. Moreover, since each group of variables (j, g) corresponds to regression coefficients at the same (i, j) position across different models in g , the matrix \tilde{C}_{11} is in fact a block matrix, whose diagonal blocks are all identity matrices. To see this, consider

$g = \{k_1, k_2\}$, the columns of $\tilde{\mathcal{X}}_{i(1)}$ that correspond to the group (j, g) is

$$\mathbf{X}_j^g = \begin{pmatrix} \mathbf{0} & \mathbf{0} \\ \vdots & \vdots \\ \mathbf{X}_j^{k_1} & \mathbf{0} \\ \mathbf{0} & \mathbf{X}_j^{k_2} \\ \vdots & \vdots \\ \mathbf{0} & \mathbf{0} \end{pmatrix}.$$

Hence the (j, g) -th diagonal block $(\tilde{C}_{11})_{[j,g]} = (\mathbf{X}_j^g)^T \mathbf{X}_j^g / n = I_2$.

With the above notations, the Uniform IC in Assumption (A3) is equivalent to saying for all $\xi = ((\xi^1)^T, \dots, (\xi^K)^T)^T \in \mathbb{R}^{\sum_k |I_k|}$ with $\max_{(j,g) \in J(\Theta_{0,i})} \|\xi_{[j,g]}\| \leq 1$ and all $(j, g) \notin J(\Theta_{0,i})$

$$\|[\tilde{C}_{21}(\tilde{C}_{11})^{-1}\tilde{\xi}]_{[j,g]}\| \leq 1 - \eta,$$

where $\tilde{\xi} = R_1^T \xi$.

It remains to select λ and α_n to ensure that the direction consistency results hold simultaneously for all i with probability tending to 1. For any $(j, g) \in J(\Theta_{0,i})$, denote $(\tilde{C}_{11})_{[j,g]}^{-1}$ the diagonal block in \tilde{C}_{11}^{-1} corresponding to the group (j, g) . By Theorem 4.1 of Basu et al. (2015), it suffices to find the upper bounds for $\|\tilde{C}_{11}^{-1}\|$, $\|(\tilde{C}_{11})_{[j,g]}^{-1}\|$, $\|(\tilde{C}_{22})_{[j,g]}\|$ and substitute the constant variance σ with the appropriate bound for $\text{Var}(\mathbf{X}_i^k | \mathbf{X}_{-i}^k) = 1/\omega_{0,ii}^k$ ($k = 1, \dots, K$).

By definition and the fact that the columns of \mathbf{X}^k are centered and standardized to have mean zero and unit variance, $(\tilde{C}_{11})_{[j,g]}$ is the identity matrix of size $|g| \times |g|$. It follows that

$$1 = \phi_{\min}^{-1}((\tilde{C}_{11})_{[j,g]}) \leq \phi_{\max}((\tilde{C}_{11})_{[j,g]}^{-1}) = \|(\tilde{C}_{11})_{[j,g]}^{-1}\| \leq \|(\tilde{C}_{11})^{-1}\|, \quad (25)$$

where the last step is obtained by applying Courant minimax principle since $0 \prec (\tilde{C}_{11})_{[j,g]}^{-1} \preceq (\tilde{C}_{11})^{-1}$. Similarly, for any $(j, g) \notin J(\Theta_{0,i})$, $(\tilde{C}_{22})_{[j,g]}$ is the identity matrix and

$$\|(\tilde{C}_{22})_{[j,g]}\| = 1. \quad (26)$$

Moreover, the variance for the random design in our problem

$$\text{Var}(\mathbf{X}_i^k | \mathbf{X}_{-i}^k) = 1/\omega_{0,ii}^k \leq 1/d_0, \quad \forall k, \quad (27)$$

by Assumption (A2).

It remains to find an upper bound for $\|\tilde{C}_{11}^{-1}\|$. Under Assumption (A1) with $s = s_0$, if we set $\Delta \in \mathcal{F}$ such that $\delta_j^{[g]} = \mathbf{0}$ for any $(j, g) \notin J(\Theta_{0,i})$, then

$$\frac{\sum_k \|\mathbf{X}^k \delta^{[g]}\|^2 / n}{\|\Delta_{J(\Theta_{0,i})}\|_{\mathcal{F}}^2} = \frac{\xi^T C_{11} \xi}{\xi^T \xi},$$

where $\xi = ((\xi^1)^T, \dots, (\xi^k)^T)^T \in \mathbb{R}^{\sum_k |E_i|}$ such that each ξ^k corresponds to the nonzero part of δ^k . If we choose Δ such that ξ is the eigenvector corresponding to the smallest eigenvalue of C_{11} , then

$$\kappa^2(s_0) \leq \frac{\sum_k \|\mathbf{X}^k \delta^k\|^2/n}{\|\Delta_{J(\Theta_{0,j})}\|_F^2} = \frac{\xi^T C_{11} \xi}{\xi^T \xi} = \phi_{\min}(C_{11}).$$

Since $R_1^{-1} = R_1^T$, C_{11} and \tilde{C}_{11} are similar (there exists a non-singular matrix P such that $P^{-1}C_{11}P = \tilde{C}_{11}$) and thus share the same set of eigenvalues. Therefore $\phi_{\min}(\tilde{C}_{11}) \geq \kappa^2(s_0)$ and

$$\|\tilde{C}_{11}^{-1}\| \leq \kappa^{-2}(s_0). \quad (28)$$

Combining the upper bounds in (25), (26), (27) and (28), Theorem 4.1 of Basu et al. (2015) implies that if we select λ and α_n as in (8) and (9), respectively, the direction consistency results follow by considering the union bound on all probabilities made across $i = 1, \dots, p$.

Further, if $\alpha_n < 1$, the direction consistency property of Θ_j implies exact recovery of all nonzero entries in the inverse covariance matrices, provided that the sparsity pattern \mathcal{G} is correctly specified. In other words, the set in (3) estimates correctly the true edge set E_0^k for all k .

The probability statement $1 - 4pC_0^{-1}e^{-q}$ follows from considering the union bound of the above result over all p regressions.

This completes the proof. ■

Appendix C. Additional Simulation Results

C.1 Performance with and without maximum likelihood refitting

In the main paper, we have compared the performance of different methods in estimating multiple Gaussian graphical models under optimally chosen tuning parameters with the results shown in Tables 1 and 2. All joint estimation methods were evaluated by adding the maximum likelihood refitting Step (II) for fair comparisons. To confirm that this is indeed the case, we present in the following additional simulation results for cases evaluated without the maximum likelihood refitting step.

Table 5 presents the complete table of deviance measures for various methods considered in simulation study 1. These methods include the separate estimation method Glasso, where the *Graphical Lasso* by Friedman et al. (2008) is applied to each graphical model separately, joint estimation by Guo et al. (2011), denoted by JEM-G, the Group Graphical Lasso denoted by GGL by Danaher et al. (2014), and the structural pursuit method MGGM by Zhu et al. (2014). For the latter three methods, we also present deviance measures for which the maximum likelihood refitting Step (II) is not included, denoted respectively by JEM-GI, GGL I and MGGM I. For the proposed two-step method JSEM, deviance measures based on Step I only is presented under the name JSEM I. It is clear from Table 5 that the refitting step generally does not introduce more errors in terms of structural estimation, but can significantly reduce the estimation errors in Frobenius norm.

Table 6 presents the performance of different regularization methods in estimating multiple inverse covariance matrices in simulation study 2. Here we observe similar pattern as that in Table 5, which confirms again that contribution from the maximum likelihood refitting step is mainly in reducing the Frobenius norm loss.

Method	FP	FN	SHD	F1	FL
Glasso	35(6)	81(2)	116(5)	0.32(0.02)	0.73(< 0.01)
JEM-GI	22(4)	40(4)	62(6)	0.69(0.03)	0.28(0.03)
JEM-G	22(4)	40(4)	62(6)	0.69(0.03)	0.28(0.02)
GGL I	18(7)	73(2)	91(7)	0.44(0.03)	0.70(0.01)
GGL	17(6)	73(2)	90(6)	0.44(0.03)	0.29(0.02)
MGGM I	291(14)	47(3)	339(14)	0.26(0.01)	0.69(0.02)
MGGM	286(13)	49(3)	335(13)	0.26(0.01)	0.64(0.02)
JSEM I	20(4)	34(3)	54(6)	0.73(0.03)	0.71(0.04)
JSEM	19(4)	35(3)	54(6)	0.73(0.03)	0.25(0.02)

Table 5: Performance of different regularization methods for estimating graphical models in Simulation Study 1: average FP, FN, SHD, F1 and FL (SE) for sample size $n_k = 50$. JEM-GI, GGL I, MGGM I and JSEM I correspond to respective method without the maximum likelihood refitting step. The best cases are highlighted in bold.

C.2 Performance as a function of p and n

Table 7 presents the performance of JSEM for $p = 500$ and $p = 1000$ with sample sizes n varying from 100, 200 to 500. The simulation setup is similar to that in Simulation Study 1: at each p , there are $K = 5$ graphical models sharing a *single* common structure. Individual structures with $p = 0.1$ are added to each graph separately such that about 10% of the edges in each graph are unique to themselves. It is clear that as the sample size n increases, the performance of JSEM also improves with smaller structural hamming distances (SHD), higher F1 score (F1) and smaller Frobenius norm loss (FL). In particular, the number of falsely rejected edges (FN) has decreased significantly.

Appendix D. Real Data Analysis

D.1 Climate data sources and pre-processing

The data we use in this study come from multiple sources and are collected under different resolutions for varying lengths of time periods. Specifically, the sources we consider include:

- (1) CRU: Climate Research Unit provides monthly climatology data (<http://www.cru.uea.ac.uk/cru/data/>) for 10 surface variables including mean temperature (TMP), diurnal temperature range (DTR), maximum and minimum temperature (TMX, TMN), precipitation (PRE), vapor pressure (VAP), cloud cover (CLD), rainy days counts (WET), potential evapotranspiration (PET) and frost days (FRS) from 1901 to 2013 at the 0.5 degree latitude and longitude resolution. Note these high-resolution gridded data sets are constructed using not only directly observed data, but also derived and estimated values with well-known formulae whenever the observed data are not available (see details in Harris et al., 2014).
- (2) NASA: The Goddard Earth Sciences Data and Information Services Center (GES DISC) from the National Aeronautics and Space Administration (NASA) has collected aerosol measurements using Moderate Resolution Imaging Spectroradiometer (MODIS) on satellites. The

data set obtained from Terra satellite consists of monthly average aerosol optical depth (AER) at the 1 degree latitude by 1 degree longitude resolution from March 2000 to August 2014.

- (3) NCDC: The National Solar Radiation Database (NSRDB) 1991–2010 (a collaborative project between The National Renewable Energy Laboratory (NREL) and the National Climatic Data Center (NCDC)) provides statistical summaries for solar data (<ftp://ftp.ncdc.noaa.gov/pub/data/nsrdb-solar/>) from 860 different locations across the United States. The locations are recorded using their latitude, longitude and altitude. We used measurements for global horizontal radiation (SOL) at 242 class I stations that have high-quality data.
 - (4) NOAA: The climate data center of National Oceanic and Atmospheric Administration (NOAA) has archived the trace gases data, including carbon dioxide (CO₂), carbon monoxide (CO), methane (CH₄) and hydrogen (H₂), from 170 worldwide stations (<http://www.esrl.noaa.gov/gmd/dv/ftpdata.html>). These data sets consist of measurements spanning different time periods, with CO₂ ranging from 1968 to 2013 (the longest) and H₂ from 1992 to 2005 (the shortest). In addition, they come with relatively low resolution compared to other variables due to the limited number of stations.
- To ensure compatibility and consistency among multiple data sources, we performed the following pre-processing:
- (1) Normalization: We first transformed each data set into monthly observations in a standard format including longitude, latitude, altitude (when available), date, variable, value, unit, and source. We focus on a 54-month time period from January 2001 to June 2005 where data for all variables are available.
 - (2) Interpolation and smoothing: We interpolated the monthly data from NCDC and NOAA onto a common 2.5 by 2.5 degree grid for North America using thin plate splines. Since the data from CRU and NASA were provided for a finer resolution grid, thin plate splines were used to first interpolate the data onto a grid of the same resolution as the source data. Then we performed spatial averaging to get data on the common 2.5 by 2.5 degree grid.
 - (3) Seasonality and autocorrelation: We reduced the short-term autocorrelation by aggregating the time series for each variable at each location into bins of 3-month intervals and taking

first differences on the quarterly data. The resulting data, consisting of 17 measurements, are assumed to be independent samples for the corresponding variable at the specified location.

The final data are organized as an $n \times p$ matrix at each of the 27 locations considered, where $n = 17$ and $p = 16$.

D.2 Additional results in climate modeling

The inferred networks at the six distinct climate zones using JSEM are presented in Section 5. The estimated networks at the 27 distinct locations are also presented in Figure 8 for reference. For notational convenience, we have renamed the climate zones such that BW for Midlatitude Desert, Cfa for Humid Subtropical, Bsh for Semiarid Steppe (hot arid), Bsk for Semiarid Steppe (cold arid), Dfa for Humid Continental (hot summer), and Dfb for Humid Continental (warm summer).

The networks in Figure 8 are ordered such that those in the same row belong to the same climate zone; further, networks in the third and fourth rows represent those from the Semiarid Steppe group, whereas networks in the last two rows are all from the Humid Continental group. Such an ordering respects how the structural information is defined and helps visualize similarities across networks. Indeed, by comparing networks at locations from geographical south, that is networks entitled ‘South’, we notice that the interactions between AER, SOL, and the remaining variables are very similar. For example, almost all of them share the edges AER—SOL and SOL—H2, except at two locations ‘BW South desert 3’ and ‘BW South desert 7’. In contrast, networks from the geographical north all share the edges AER—H2 and SOL—H2. Further, the interactions between variables on greenhouse gases (CO2, CO, CH4 and H2) and others have four distinct patterns at the four distinct climate groups. For example, greenhouse gases interact with VAP for the desert group, whereas they interact with CLD in the subtropical group. The partial correlation between CLD and greenhouse gases at subtropical climate makes sense because such humid areas are more likely to be cloudy, thereby influencing the concentration of CO2 (Graham et al., 2003). Finally, variables excluding AER, SOL, and those on greenhouse gases show distinct interaction patterns with others at the six distinct climate zones. In particular, one can see that the variable FRS interacts mainly with PET at Desert and Steppe climate, whereas it is partially correlated with both PRE and TMN (or TMX) at Continental climate. This can be explained from the distinction between these climate zones: At Humid Continental climate, precipitation is relatively well distributed year-round in most areas and snowfall occurs in all areas. It is thus not difficult to see why precipitation (PRE) and temperature related variables correlate with the number of frost days (FRS). Further, a primary criterion of an area being Midlatitude Desert or Semiarid Steppe is that it receives precipitation below potential evapotranspiration (PET), which possibly explains why FRS is partially correlated only with PET for Desert and Steppe climate. We also point out that networks at adjacent climate zones are very similar. For example, networks at ‘Bsh Steppe’ and ‘Bsk Steppe’ share similar topologies. As a comparison, we also applied other joint estimation methods JEM-G, GGL and MGGM on the same data set. For each of the three methods considered here, we used BIC on the normalized data to select the optimal tuning parameters and coupled each method with complementary pairs stability selection (Shah and Samworth, 2013) to infer the related climate networks. As in the case of JSEM, we run each method 50 times on two randomly drawn complementary pairs of size 8 and 9 and kept only edges that are selected above a certain threshold. The selection probability used for JSEM is 70%. However, as the second simulation study indicates JEM-G and GGL tend to produce higher false positives, especially GGL, we increased the probability threshold for JEM-G and GGL

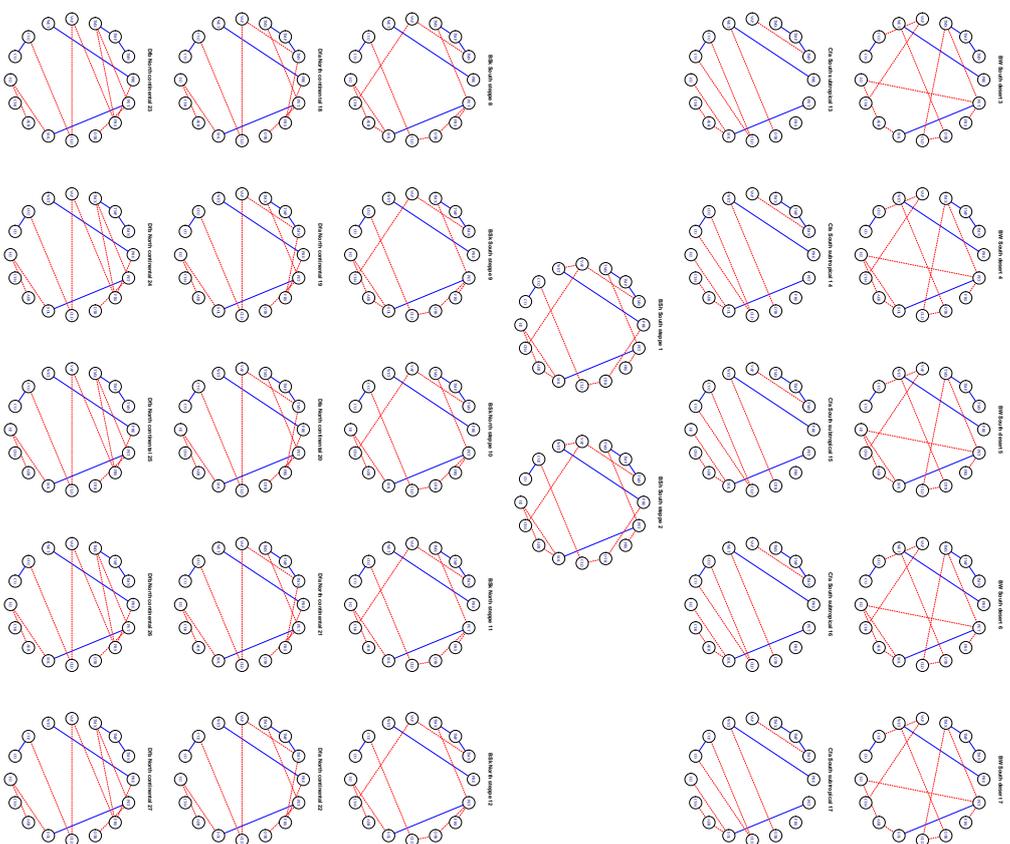

Figure 8: Estimated climate networks at the 27 locations using JSEM, with edges shared across all locations solid and differential edges dashed.

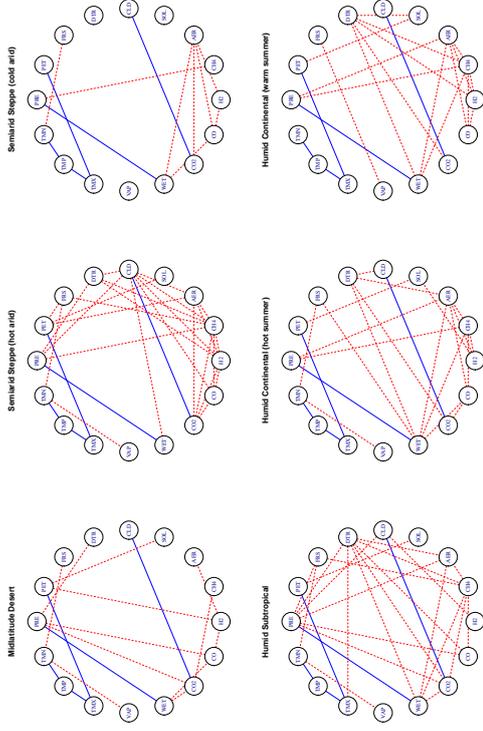

Figure 9: Estimated climate networks at the six distinct climate zones using JEM-G, with edges shared across all locations solid and differential edges dashed.

to 90% and 100%, respectively. On the other hand, we reduced the threshold for MGGM to 50% due to the relatively few edges recovered. The results are shown in Figure 9, 10 and 11.

One can see clearly that the estimated networks using the three methods exhibit quite different connectivity patterns from those inferred from JSEM. In particular, the results from GGL seem to suggest strong conditional dependence among a subset of variables, which distinguishes itself from JEM-G and JSEM. The estimated networks using MGGM, though sparse, bear certain similarity to those recovered using GGL. On the other hand, the results from JEM-G and JSEM are more similar. For example, common edges identified using JEM-G, such as TMN—TMP, TMP—TMX, PRE—WET, also show up under JSEM. The common edge between CLD and CO2 is found at all locations except Midlatitude Desert under JSEM, whereas the edge between PET and SOL identified using JSEM exists everywhere except at Semiarid Steppe (cold arid) under JEM-G. Note although JEM-G does not require external information on the structural relationships across graphs, the inferred networks respect roughly the spatial pattern of all climate zones. For instance, Humid Continental (hot summer and cool summer) are more similar.

D.3 Additional results in analysis of breast cancer

We have presented the inferred pathway level networks under both ER+ and ER- status using JSEM in the main paper. As a comparison, we applied JEM-G with tuning parameters selected via BIC to the same normalized and processed data set. To ensure a stable estimation, we further

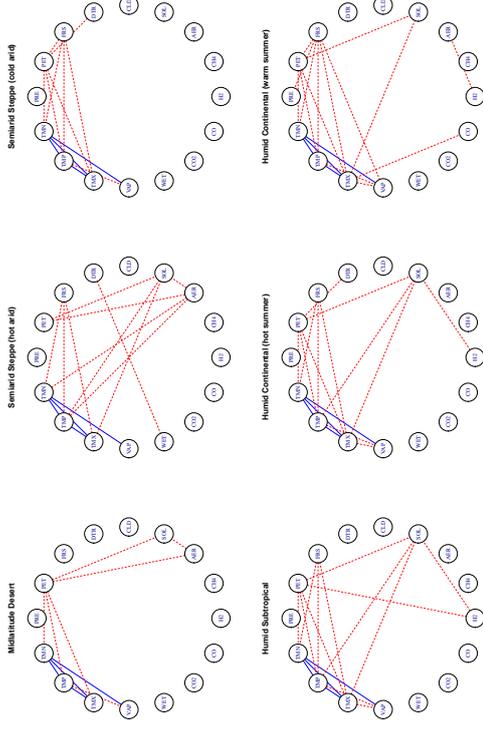

Figure 10: Estimated climate networks at the six distinct climate zones using GGL, with edges shared across all locations solid and differential edges dashed.

coupled JEM-G with complementary pairs stability selection (Shah and Samworth, 2013). Figure 12 shows the pathway level interactions estimated from JEM-G at selection frequency 70%, after removing isolated pathways. One striking difference between Figure 12 and Figure 7 is that Figure 12 sees more edges shared across the two classes (in blue). This is partly due to how JEM-G is implemented directly via the sample covariance matrices and partly to JEM-G being an agnostic method.

We also present estimated gene-level networks (with isolated genes removed) using both JEM-G and JSEM in Figure 13. Similar to what we observe in the pathway level network comparison, the JEM-G recovered gene networks show more edges shared between the two classes. In comparison, JSEM recovers more differential edges for the ER+ class. Apart from the differences, we also observe some similarities between the estimated gene networks. For example, both methods identify a small hub around the gene SFRP1, indicating their potential in regulating the underlying biological process.

Appendix E. Additional Technical Details

We include here some additional lemmas and proofs necessary for establishing the theoretical results in Section 3.

The first lemma is borrowed from Basu et al. (2015, Lemma A.2). We state the result here for completeness. Please refer to their paper for proof of the lemma.

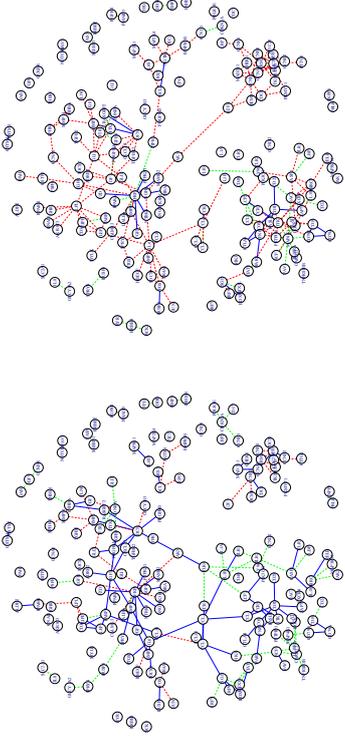

Figure 13: Estimated gene networks combined using JEM-G (left) and JSEM (right), with edges shared between ER+ and ER- blue solid and differential edges red dashed (ER+)/ green dashed (ER-).

Applying Lemma E.1,

$$\begin{aligned} \mathbb{P}(\{\mathcal{A}_{ij}^g\}^c) &\leq \mathbb{P}(\|Z^{[g]}\| - E\|Z^{[g]}\| > \sqrt{n}\lambda_{ij}^g/2 - E\|Z^{[g]}\|) \\ &\leq 2 \exp\left\{-\frac{2}{\pi^2\|\text{Var}(Z^{[g]})\|}\left(\frac{\sqrt{n}\lambda_{ij}^g}{2} - E\|Z^{[g]}\|\right)^2\right\}. \end{aligned}$$

Choose λ_{ij}^g such that the right-hand side of above inequality is less than $2G_0^{-q}$ for some positive parameter q . Then

$$\lambda_{ij}^g \geq \frac{2}{\sqrt{n}} \left(E\|Z^{[g]}\| + \frac{\pi}{\sqrt{2}} \sqrt{q \log G_0} \sqrt{\|\text{Var}(Z^{[g]})\|} \right),$$

and is satisfied if

$$\lambda_{ij}^g \geq \max_{k \in g} \frac{2}{\sqrt{n\omega_{0,ii}^k}} \left(\sqrt{|g|} + \frac{\pi}{\sqrt{2}} \sqrt{q \log G_0} \right),$$

by Lemma E.1. With the above choice of λ_{ij}^g ,

$$\mathbb{P}(\mathcal{A}^c) \leq \sum_{i=1}^p \sum_{j \neq i} \sum_{g \in \mathcal{G}^{ij}} \mathbb{P}(\{\mathcal{A}_{ij}^g\}^c) \leq 2pG_0^{1-q},$$

or equivalently, $\mathbb{P}(\mathcal{A}) \geq 1 - 2pG_0^{1-q}$. \blacksquare

Proof of Proposition A.1

Proof For all $\Theta_i \in \mathbb{M}(p-1, K)$, using a similar argument to that in Lemma 3.1 of Lounici et al. (2011), it is straightforward to verify the following:

$$\begin{aligned} &\sum_{k=1}^K \frac{1}{n} \|\mathbf{X}_{-i}^k(\hat{\theta}_i^k - \theta_{0,i}^k)\|^2 + \sum_{j \neq i, g \in \mathcal{G}^{ij}} \lambda_{ij}^g \|\hat{\theta}_{ij}^{[g]} - \theta_{ij}^{[g]}\| \\ &\leq \sum_{k=1}^K \frac{1}{n} \|\mathbf{X}_{-i}^k(\theta_i^k - \theta_{0,i}^k)\|^2 + 4 \sum_{(j,g) \in \mathcal{I}(\Theta_i)} \lambda_{ij}^g \min\left(\|\theta_{ij}^{[g]}\|, \|\hat{\theta}_{ij}^{[g]} - \theta_{ij}^{[g]}\|\right), \end{aligned} \quad (30)$$

$$\left\{ \sum_{k \in \mathcal{G}^g} (n^{-1} \mathbf{X}_j^k, \mathbf{X}_{-i}^k(\theta_i^k - \theta_{0,i}^k))^2 \right\}^{1/2} \leq \frac{3\lambda_{ij}^g}{2}, \quad (31)$$

$$\mathcal{M}(\hat{\Theta}_i) \leq \frac{4\phi_{\max}}{\lambda_{\min}^2} \sum_{k=1}^K \frac{1}{n} \|\mathbf{X}_{-i}^k(\hat{\theta}_i^k - \theta_{0,i}^k)\|^2, \quad (32)$$

where λ_{\min} and ϕ_{\max} are defined in Proposition A.1.

Let $\Delta = (\delta^1, \dots, \delta^K)$ be a matrix in $\mathbb{M}(p, K)$ such that $\delta_j^k = \hat{\theta}_{ij}^k - \theta_{0,ij}^k$ for $j \neq i$ and $\delta_i^k = 0$ for all k . We would like to first find an upper bound for B^2 , where

$$B^2 := \sum_{k=1}^K \frac{1}{n} \|\mathbf{X}_{-i}^k(\hat{\theta}_i^k - \theta_{0,i}^k)\|^2 = \sum_{k=1}^K \frac{1}{n} \|\mathbf{X}^k \delta^k\|^2.$$

On the event \mathcal{A} , we have

$$\sum_{j \neq i, g \in \mathcal{G}^{ij}} \lambda_{ij}^g \|\delta_j^{[g]}\| \leq B^2 + \sum_{j \neq i, g \in \mathcal{G}^{ij}} \lambda_{ij}^g \|\delta_j^{[g]}\| \leq 4 \sum_{(j,g) \in \mathcal{I}(\Theta_{0,i})} \lambda_{ij}^g \|\delta_j^{[g]}\|, \quad (33)$$

where the second inequality follows from setting $\Theta_i = \Theta_{0,i}$ in (30). Therefore

$$\sum_{(j,g) \in \mathcal{I}(\Theta_{0,i})^c} \lambda_{ij}^g \|\delta_j^{[g]}\| \leq 3 \sum_{(j,g) \in \mathcal{I}(\Theta_{0,i})} \lambda_{ij}^g \|\delta_j^{[g]}\|,$$

which implies that $\Delta \in \mathcal{F}$, the restricted set defined in Assumption (A1). Under Assumption (A1) with $\kappa = \kappa(s_0)$, one has

$$B^2 \geq \kappa^2 \|\Delta_J\|_{\mathcal{F}}^2 = \kappa^2 \sum_{(j,g) \in \mathcal{I}(\Theta_{0,i})} \|\delta_j^{[g]}\|^2. \quad (34)$$

Combing (33) and the Cauchy-Schwarz inequality, we obtain

$$B^2 \leq 4 \sum_{(j,g) \in \mathcal{I}(\Theta_{0,i})} \lambda_{ij}^g \|\delta_j^{[g]}\| \leq 4 \left\{ \sum_{(j,g) \in \mathcal{I}(\Theta_{0,i})} (\lambda_{ij}^g)^2 \right\}^{1/2} \left\{ \sum_{(j,g) \in \mathcal{I}(\Theta_{0,i})} \|\delta_j^{[g]}\|^2 \right\}^{1/2} \quad (35)$$

$$\leq 4 \left\{ \sum_{(j,g) \in \mathcal{I}(\Theta_{0,i})} (\lambda_{ij}^g)^2 \right\}^{1/2} \frac{B}{\kappa}, \quad (36)$$

where the last inequality in (36) comes from (34). Canceling out the extra B in (36), we get

$$B^2 = \sum_k \frac{1}{n} \|\mathbf{X}_{0,i}^k(\hat{\theta}_i^k - \theta_{0,i}^k)\|^2 \leq \frac{16}{\kappa^2} \sum_{(j,g) \in I(\Theta_{0,i})} (\lambda_{ij}^g)^2. \quad (37)$$

To show the inequality in (11), we note by (33), the Cauchy-Schwarz inequality, (34) and (37),

$$\begin{aligned} \sum_{j \neq i} \sum_{g \in \mathcal{G}^{ij}} \|\delta_j^{[g]}\| &\leq \frac{1}{\lambda_{\min}} \sum_{j \neq i} \sum_{g \in \mathcal{G}^{ij}} \lambda_{ij}^g \|\delta_j^{[g]}\| \leq \frac{4}{\lambda_{\min}} \sum_{(j,g) \in I(\Theta_{0,i})} \lambda_{ij}^g \|\delta_j^{[g]}\| \\ &\leq \frac{4}{\lambda_{\min}} \left\{ \sum_{(j,g) \in I(\Theta_{0,i})} \|\delta_j^{[g]}\|^2 \right\}^{1/2} \left\{ \sum_{(j,g) \in I(\Theta_{0,i})} (\lambda_{ij}^g)^2 \right\}^{1/2} \\ &\leq \frac{4}{\lambda_{\min}} \frac{B}{\kappa} \left\{ \sum_{(j,g) \in I(\Theta_{0,i})} (\lambda_{ij}^g)^2 \right\}^{1/2} \\ &\leq \frac{16}{\kappa^2 \lambda_{\min}} \sum_{(j,g) \in I(\Theta_{0,i})} (\lambda_{ij}^g)^2. \end{aligned}$$

(12) follows readily from (32) and (37)

$$\mathcal{M}(\hat{\Theta}_i) \leq \frac{4\phi_{\max}}{\lambda_{\min}^2} B^2 \leq \frac{64\phi_{\max}}{\kappa^2 \lambda_{\min}^2} \sum_{(j,g) \in I(\Theta_{0,i})} (\lambda_{ij}^g)^2.$$

Finally, we prove (13). Let $J_0 = J(\Theta_{0,i})$ and J_1 denote the set of indices in J_0^c corresponding to the s_i largest values of $\lambda_{ij}^g \|\delta_j^{[g]}\|$. The dependence of J_0 and J_1 on i is made implicit here for clarity. Let $J_{01} = J_0 \cup J_1$. So $|J_{01}| \leq 2s_i$. Let (j_ℓ, g_ℓ) be the index of the ℓ th largest element of the set $\{\lambda_{ij}^g \|\delta_j^{[g]}\| : (j, g) \in J_0^c\}$. Then

$$\lambda_{j_\ell g_\ell}^{g_\ell} \|\Delta_{j_\ell}^{[g_\ell]}\| \leq \sum_{(j,g) \in J_0^c} \frac{\lambda_{ij}^g \|\delta_j^{[g]}\|}{\ell}.$$

Combining with the fact that $\Delta \in \mathcal{F}$, we have on the event \mathcal{A}_1 ,

$$\begin{aligned} \sum_{(j,g) \in I_0^c} \left(\lambda_{ij}^g \|\delta_j^{[g]}\| \right)^2 &\leq \sum_{(j,g) \in I_0^c} \left(\lambda_{j_\ell g_\ell}^{g_\ell} \|\delta_{j_\ell}^{[g_\ell]}\| \right)^2 \leq \sum_{\ell=s_i+1}^{\infty} \frac{\left(\sum_{(j,g) \in I_0^c} \lambda_{ij}^g \|\delta_j^{[g]}\| \right)^2}{\ell^2} \\ &\leq \frac{1}{s_i} \left(\sum_{(j,g) \in I_0^c} \lambda_{ij}^g \|\delta_j^{[g]}\| \right)^2 \\ &\leq \frac{9}{s_i} \left(\sum_{(j,g) \in I_0} \lambda_{ij}^g \|\delta_j^{[g]}\| \right)^2 \\ &\leq \frac{9}{s_i} \sum_{(j,g) \in I_0} (\lambda_{ij}^g)^2 \|\Delta_{j_0}\|_F^2 \\ &\leq \frac{9}{s_i} \sum_{(j,g) \in J_0} (\lambda_{ij}^g)^2 \|\Delta_{j_0}\|_F^2, \end{aligned} \quad (38)$$

where (38) comes from the Cauchy-Schwarz inequality. It follows immediately that

$$\lambda_{\min}^2 \sum_{(j,g) \in I_0^c} \|\delta_j^{[g]}\|^2 \leq \frac{9}{s_i} \sum_{(j,g) \in J_0} (\lambda_{ij}^g)^2 \|\Delta_{j_0}\|_F^2.$$

Hence

$$\begin{aligned} \|\hat{\Theta}_i - \Theta_{0,i}\|_F^2 &= \sum_{j \neq i} \sum_{g \in \mathcal{G}^{ij}} \|\delta_j^{[g]}\|^2 = \|\Delta_{j_0}\|_F^2 + \|\Delta_{j_0^c}\|_F^2 \\ &\leq \|\Delta_{j_0}\|_F^2 + \frac{9}{s_i \lambda_{\min}^2} \sum_{(j,g) \in J_0} (\lambda_{ij}^g)^2 \|\Delta_{j_0}\|_F^2 \\ &\leq \frac{10}{s_i \lambda_{\min}^2} \sum_{(j,g) \in J_0} (\lambda_{ij}^g)^2 \|\Delta_{j_0}\|_F^2. \end{aligned} \quad (39)$$

Now we bound $\|\Delta_{j_0}\|_F$. Note (35) implies that

$$B^2 \leq 4 \left\{ \sum_{(j,g) \in J_0} (\lambda_{ij}^g)^2 \right\}^{1/2} \|\Delta_{j_0}\|_F \leq 4 \left\{ \sum_{(j,g) \in J_0} (\lambda_{ij}^g)^2 \right\}^{1/2} \|\Delta_{j_0}\|_F.$$

Further we have $B^2 \geq \kappa^2 (2s_0) \|\Delta_{j_0}\|_F^2$ under Assumption (A1) with $s = 2s_0$. So

$$\|\Delta_{j_0}\|_F^2 \leq \frac{B^2}{\kappa^2 (2s_0)} \leq \frac{4}{\kappa^2 (2s_0)} \left\{ \sum_{(j,g) \in J_0} (\lambda_{ij}^g)^2 \right\}^{1/2} \|\Delta_{j_0}\|_F,$$

which implies

$$\|\Delta_{j_0}\|_F \leq \frac{4}{\kappa^2 (2s_0)} \left\{ \sum_{(j,g) \in J_0} (\lambda_{ij}^g)^2 \right\}^{1/2}. \quad (40)$$

Plugging the bound in (40) into (39), we obtain

$$\|\hat{\Theta}_i - \Theta_{0,i}\|_F^2 \leq \left\{ \frac{4\sqrt{10}}{\kappa^2 (2s_0)} \right\}^2 \left\{ \sum_{(j,g) \in J_0} (\lambda_{ij}^g)^2 \right\}^2,$$

or equivalently

$$\|\hat{\Theta}_i - \Theta_{0,i}\|_F \leq \frac{4\sqrt{10}}{\kappa^2 (2s_0)} \sum_{(j,g) \in I(\Theta_{0,i})} (\lambda_{ij}^g)^2 \lambda_{\min} \sqrt{s_i}.$$

■

Proof of Corollary A.1

Proof By definition, $\omega_{0,ij}^k = -\theta_{0,ij}^k \omega_{0,ii}^k$ for all $j \neq i$ and $k = 1, \dots, K$. Further, under Assumption (A2), $\omega_{0,ii}^k \leq \phi_{\max}(\Omega_0^k) = \phi_{\min}^{-1}(\Sigma_0^k) \leq c_0$ for all i, k . Therefore

$$\begin{aligned} \sum_k \|\tilde{\Omega}^k - \Omega_0^k\|_F^2 &= \sum_k \sum_{i=1}^p \sum_{j \in J(\Theta_{0,i}) \cap J(\hat{\Theta}_i)^c} (\theta_{0,ij}^k \omega_{0,ii}^k)^2 \\ &= \sum_{i=1}^p \sum_{j \in J(\Theta_{0,i}) \cap J(\hat{\Theta}_i)^c} \sum_{g \in \mathcal{G}^{ij}} (\theta_{0,ij}^k \omega_{0,ii}^k)^2 \\ &\leq c_0^2 \sum_{i=1}^p \sum_{j \in J(\Theta_{0,i}) \cap J(\hat{\Theta}_i)^c} \sum_{g \in \mathcal{G}^{ij}} \|\theta_{0,ij}^g\|^2 \\ &\leq c_0^2 \sum_{i=1}^p \sum_{j \neq i} \sum_{g \in \mathcal{G}^{ij}} \|\theta_{0,ij}^g\|^2. \end{aligned}$$

Under Assumption (A1) with $s = 2s_0$, applying Proposition A.1 with $\lambda_{ij}^g = \lambda_{\max}$ in (14),

$$\sum_{\substack{j \neq i \\ g \in \mathcal{G}^{ij}}} \|\theta_{0,ij}^g - \hat{\theta}_{0,ij}^g\|^2 \leq \left\{ \frac{4\sqrt{10}}{r^2(2s_0)} \lambda_{\max} \right\}^2 s_i.$$

Therefore,

$$\sum_k \|\tilde{\Omega}^k - \Omega_0^k\|_F^2 \leq \left\{ \frac{4\sqrt{10}c_0}{r^2(2s_0)} \lambda_{\max} \right\}^2 \sum_{i=1}^p s_i = \left\{ \frac{4\sqrt{10}c_0}{r^2(2s_0)} \lambda_{\max} \right\}^2 S_0.$$

It follows immediately that

$$\begin{aligned} \frac{1}{K} \sum_k \|\tilde{\Omega}^k - \Omega_0^k\|_F &\leq \frac{1}{\sqrt{K}} \left\{ \sum_k \|\tilde{\Omega}^k - \Omega_0^k\|_F^2 \right\}^{1/2} \leq \frac{4\sqrt{10}c_0}{r^2(2s_0)} \lambda_{\max} \sqrt{\frac{S_0}{K}} \\ &\leq C_{\text{bias}} \sqrt{\frac{S_0}{nK}} \left(\sqrt{g_{\max}} + \frac{\pi}{\sqrt{2}} \sqrt{q \log C_0} \right). \end{aligned}$$

To bound the size of the estimated edge set \hat{E}^k , we notice if there exists (i, j, k) such that $\hat{\theta}_{ij}^k \neq 0$, then $\hat{\theta}_{ij}^{[g]} \neq 0$, where $g \ni k$. Hence $\mathcal{M}(\hat{\theta}_i^k) \subseteq \mathcal{M}(\hat{\Theta}_i)$ for all k . By (12), the upper bound for \hat{E}^k is thus

$$|\hat{E}^k| \leq \sum_{i=1}^p \mathcal{M}(\hat{\theta}_i^k) \leq \sum_{i=1}^p \frac{64\phi_{\max}}{r^2(s_0)} \lambda_{\min}^2 \sum_{(j,g) \in J(\Theta_{0,i})} s_i \leq \frac{64\phi_{\max}}{r^2(s_0)} S_0. \quad \blacksquare$$

Abstract

Learning risk scores to predict dichotomous or continuous outcomes using machine learning approaches has been studied extensively. However, how to learn risk scores for time-to-event outcomes subject to right censoring has received little attention until recently. Existing approaches rely on inverse probability weighting or rank-based regression, which may be inefficient. In this paper, we develop a new support vector hazards machine (SVHM) approach to predict censored outcomes. Our method is based on predicting the counting process associated with the time-to-event outcomes among subjects at risk via a series of support vector machines. Introducing counting processes to represent time-to-event data leads to a connection between support vector machines in supervised learning and hazards regression in standard survival analysis. To account for different at risk populations at observed event times, a time-varying offset is used in estimating risk scores. The resulting optimization is a convex quadratic programming problem that can easily incorporate non-linearity using kernel trick. We demonstrate an interesting link from the profiled empirical risk function of SVHM to the Cox partial likelihood. We then formally show that SVHM is optimal in discriminating covariate-specific hazard function from population average hazard function, and establish the consistency and learning rate of the predicted risk using the estimated risk scores. Simulation studies show improved prediction accuracy of the event times using SVHM compared to existing machine learning methods and standard conventional approaches. Finally, we analyze two real world biomedical study data where we use clinical markers and neuroimaging biomarkers to predict age-at-onset of a disease, and demonstrate superiority of SVHM in distinguishing high risk versus low risk subjects.

Keywords: support vector machine, survival analysis, risk bound, risk prediction, neuroimaging biomarkers, early disease detection

1. Introduction

Time-to-event outcome is of interest in many scientific studies in which right censoring occurs when subjects' event times are longer than the duration of studies or subjects drop out of the study prematurely. One important goal in these studies is to use baseline covariates collected on a newly recruited subject to construct an effective risk score to predict likelihood an event of interest. For example, in one of our motivating studies analyzed in Section 4.2 (PREDICT-HD, Paulsen et al. 2008a), the research aim is to combine neuroimaging biomarkers with clinical markers measured at the baseline to provide risk stratification for time-to-onset of Huntington's disease (HD) to facilitate early diagnosis, where subjects who did not experience HD during the study had censored HD onset time. This critical goal of identifying prognostic markers predictive of disease onset is shared by research communities on other neurological disorders such as Alzheimer's disease and Parkinson's disease, and recognized as one of the primary aims in research initiatives such as Alzheimer's Disease Neuroimaging Initiative (Mueller et al., 2005) and Parkinson's Progression Markers Initiative (Marek et al., 2011).

Learning risk scores for binary or continuous outcomes are examined extensively in statistical learning literature (Hastie et al., 2009). However, learning risk scores for occurrence of an event subject to censoring is much less explored. Existing work on survival analysis focuses on estimating population-level quantities such as survival function or association parameters through hazard function. For example, the most popular model for the time-to-event analysis is the Cox proportional hazards model (Cox, 1972), which assumes the hazard ratio between two subjects with different covariate values stays as a constant as time progresses. A Cox partial likelihood function is maximized for estimation. When the proportional hazards assumption is violated, several alternative models have been proposed in statistics literature, including the proportional odds model (Bennett, 1983), the accelerated failure time model (Buckley and James, 1979), the linear transformation models (Dabrowska and Doksum, 1988; Cheng et al., 1995; Chen et al., 2002), and more recently general transformation models (Zeng and Lin, 2006, 2007). The above models are all likelihood-based which impose certain parametric or semiparametric relationship between the underlying hazard function and the covariates. In addition, they are designed to estimate the population-level parameters for the association between covariates and the time-to-event outcomes (and thus uses likelihood as the optimization function), but do not directly focus on individual risk scores for predicting an event time.

For non-censored outcomes, supervised learning plays an important role for risk prediction. In many applications, a large number of input variables with known output values are used to learn an unknown functional relationship between the inputs and outputs through a suitable algorithm, and the learned functional is used to predict the output value for future subjects from their input variables (Steinwart and Christmann, 2008). Many learning approaches have been developed for standard classification and regression problems, such as kernel smoothing, support vector machines (SVM), projection pursuit regression, neural network, and decision trees (Hastie et al., 2009). In particular, support vector machine is among one of the most popular and successful learning methods in practice (Moguerza and Munoz, 2006; Orru et al., 2012). From the training data, support vector machine finds a hyperplane that separates the data into two classes as accurately as possible and has a simple

geometric interpretation. In addition, the algorithm can be written as a strictly convex optimization problem, which leads to a unique global optimum and incorporates non-linearity in an automatic manner using various kernel machines. By reformulating the algorithm into a minimization of regularized empirical risk, Steinwart (2002) established the universal consistency and learning rate on some functional space. Support vector machines have also been applied to continuous outcomes through regression (Shioda and Schölkopf, 2004), multiclass category discrete outcomes (Lee et al., 2004), and structured classification problems (Wang et al., 2011).

For time-to-event outcomes, right censoring makes developing supervised learning techniques challenging due to missing event times for censored subjects and a lack of standard prediction loss function. Ripley and Ripley (2001) and Ripley et al. (2004) discussed models for survival analysis based on neural network. Bou-Hamad et al. (2011) reviewed survival tree approaches in the recent work as non-parametric alternatives to semiparametric models. Compared to survival trees, effectively extending the support vector-based methods to censored data is still an on-going research. Shivswamy et al. (2007) and Khan and Zubek (2008) proposed asymmetric modifications to the ϵ -insensitive loss function of support vector regression (SVR) to handle censoring. Specifically, they penalized the censored and non-censored subjects using different loss functions to extract incomplete information due to censoring. Van Belle et al. (2010) proposed a least-squares support vector machine, where they adopted the concept of concordance index and added rank constraints to handle censored data. In their method, the empirical risk of miss-ranking two data points with respect to their event times was minimized. Furthermore, Van Belle et al. (2011) conducted numerical experiments to compare some recent machine learning methods for censored data and proposed a modified procedure to adjust for censoring based on both rank and regression constraints. Their results indicate that including two types of constraints performs the best regarding the prediction accuracy. None of the above methods has theoretical justification and the relationship between their objective loss functions to be minimized and the goal of predicting survival time remains unclear. The rank-based methods only use feasible pairs of observations whose ranks are comparable so that it may result in potential selection bias when constructing prediction rules, especially when the censoring mechanism is not completely at random (e.g., censoring time depends/correlates with a subject's covariates). Recently, Goldberg and Kosorok (2013) used inverse-probability-of-censoring weighting to adapt standard support vector methods for complete data to censored data. However, inverse weighting is known to be inefficient (Robins et al., 1995) due to the fact that it discards useful information for some subjects known to survive longer than observed times, and in addition, this method may exhibit severe bias when the censoring distribution is misspecified. Additionally, the weights used in the inverse weighting can be large in some situations, and computation of Goldberg and Kosorok (2013) becomes numerically unstable and even infeasible.

In this work, we propose a new support vector hazards machine (SVHM) framework to learn risk scores for survival outcomes using the concept of counting process. We aim to maximally separate event and no-event subjects among all subjects at risk, and allow censoring times to depend on covariates without modeling the censoring distribution. One major challenge in predicting censored event times is the difficulty of defining a sensible loss function for prediction. Because of the equivalence of an event time to its counting process,

if a prediction rule can adequately predict the event time, the same rule should also predict the counting process at any given time that a subject is still at risk. We propose a flexible nonparametric decision function with an additive structure for the counting process, which gives the desirable risk scores but also includes a time-varying offset to account for different at-risk population as time progresses. Empirically, we transform the prediction of an event time to predicting a sequence of binary outcomes for which algorithm such as support vector machine (SVM) is standard and commonly used. This transformation allows for the successful statistical learning tools designed for classification and prediction of binary outcomes to be used for censored outcomes without modeling the censoring distribution. The developed algorithm formulation is similar to the standard support vector machines and can be solved conveniently using any convex quadratic programming packages. In addition, theoretical analysis shows that the optimal rule obtained from SVHM is equivalent to maximizing the difference between the instantaneous subject-specific hazards and population-average hazard, which intuitively links SVHM to the commonly used hazards regression models in traditional survival analysis. The profile loss shares similarity with Cox partial likelihood. Under some regularity conditions, we show the universal consistency of SVHM and derive corresponding finite sample bounds on the deviation from the optimal risk. Numeric simulations and applications to real world studies show superior performance in distinguishing high risk versus low risk subjects.

2. Learning Risk Scores with SVHM

In this section, we first introduce the population loss function that SVHM aims to optimize with infinite sample and its corresponding Bayes risk. Next, we lay out the algorithm to empirically learn the risk scores and assess the empirical risk.

2.1. Review of Survival Analysis and Introduction of Counting Process

Framework for SVHM

We begin by briefly introducing basic concepts and notation of classical survival analysis (c.f. Fleming and Harrington, 1991). Survival analysis focuses on using covariates to predict time to event outcomes. The events of interest can be death, diagnosis of a disease, onset of cancer metastasis, or failure of a machine component. An event time of interest (i.e., age at onset of a disease) is usually denoted by T , and a vector of baseline covariates (e.g., genomic risk factors) is denoted by \mathbf{X} . The main goals of survival analysis are to understand association between \mathbf{X} and T or predicting T from \mathbf{X} . A fundamental problem of survival analysis is to deal with incomplete observation of T due to that the event may not occur in some of the subjects due to study termination or subjects dropping out of the study. For example, in a study on predicting time to cancer metastasis, some subjects may not develop metastasis by the end of study period, and thus their T is not observed. These subjects are termed as being censored and their time to study termination is termed as censoring time, usually denoted by C . For each subject in the study, we observe either their event time T or censoring time C , whichever is smaller. This observation is usually denoted by $T_i \wedge C_i$, where the operator $(a \wedge b)$ denotes taking minimum of a and b . A usual assumption in survival analysis is that the censoring time C is independent of T given covariates \mathbf{X} . From a random sample of n subjects, the observed data consist of $\{T_i \wedge C_i, \Delta_i = I(T_i \leq C_i), \mathbf{X}_i\}$

for $i = 1, \dots, n$, where $I(\cdot)$ is an indicator function and $I(T_i \leq C_i)$ is thus the event indicator. The central quantity of interest in a survival analysis is occurrence of an event over time. Such occurrences are equivalent to point processes described by counting the number of events as they occur by certain time point, termed as counting processes. That is, a counting process of the event on subject i counts the number of events that have occurred up to, and including t , and is denoted as $N_i(t) = I[(T_i \wedge C_i) \leq t]$. Corresponding to the counting process for the events, the at-risk process counts subjects who have not yet had an event by time t and thus who are still "at risk" of experiencing an event. Such process is denoted by $Y_i(t) = I[(T_i \wedge C_i) \geq t]$.

The fundamental idea to learn risk scores for T to distinguish high risk versus low risk subjects is to equivalently learn risk scores for the counting process associated with T at each time point. Since the latter can be treated as a sequence of binary outcomes (event vs. no event) over time, it motivates one to reformulate the problem as deriving the risk score for predicting the jumps of the counting process over a sequence of time points among subjects still at risk at those times. This amounts to developing a classification rule to predict whether a subject will experience an event in the next immediate time point given that the subject has not yet experienced an event. To account for different risk sets as time progresses (i.e., risk set at time t is the subset of subjects with $Y_i(t) = 1$), it is necessary to include a time-varying offset for the nonparametric risk score. Thus, consider the following general form at time t for a subject with $\mathbf{X} = \mathbf{x}$,

$$f(t, \mathbf{x}) = \alpha(t) + g(\mathbf{x}), \quad (1)$$

where both $\alpha(\cdot)$ and $g(\cdot)$ are unknown nonparametric functions, $g(\mathbf{x})$ is the risk score, and $\alpha(t)$ is the time-varying offset. To understand (1), consider a risk score function at time t for a subject with $\mathbf{X} = \mathbf{x}$: if this subject is still at risk at time t , we predict the subject to experience the event at the next immediate time point if $f(t, \mathbf{x}) > 0$, and predict as event-free if $f(t, \mathbf{x}) \leq 0$. Thus, within a small time interval $[t, t + dt)$, where dt denotes a positive infinitesimal unit, a natural prediction loss counting rate of risk-misclassification is given by

$$Y(t)dN(t)I(f(t, \mathbf{X}) < 0) + Y(t)(1 - dN(t))I(f(t, \mathbf{X}) \geq 0),$$

where $Y(t)$ and \mathbf{X} are the at risk process and covariates for a subject drawn from the population, respectively, and $dN(t)$ denotes the number of jumps of the counting process $N(t)$ in a small time interval $[t, t + dt)$. Equivalently, $dN(t) = 1$ if $T \in [t, t + dt)$ and $dN(t) = 0$ otherwise, so it is a binary variable taking value one if an event occurs in the interval $[t, t + dt)$ for subjects who are still at risk for experiencing an event. Thus, summing above loss function over subjects counts the number of at-risk subjects miss-classified by the prediction rule $f(t, \mathbf{X})$. The above prediction loss can be viewed as a natural extension of the 0-1 loss for binary case to capture the same information for an at-risk subject in a survival analysis: if the prediction function and the observed counting process at time t are inconsistent, a loss is incurred. However, at any time t , the probability of $dN(t) = 1$ is almost zero as compared to the probability of $dN(t) = 0$, which implies that the above prediction loss is completely dominated by non-event subjects in the risk set. In order to balance the contribution from subjects with and without events at any given time, borrowing from the weighted SVM for unbalanced classes, a sensible prediction loss is the following

weighted loss, where the ratio of weights for two unbalanced classes is proportional to $E[dN(t)]/E[Y(t)]$:

$$Y(t)dN(t)I(f(t, \mathbf{X}) \leq 0) + \frac{E[dN(t)]}{E[Y(t)]}Y(t)(1 - dN(t))I(f(t, \mathbf{X}) \geq 0). \quad (2)$$

This weighting scheme can also be understood in the context of nested case-control design. That is, select one subject from the event class, $\{i : dN_i(t) = 1\}$, at this interval and another subject from the non-event class, $\{i : dN_i(t) = 0\}$, using $E[dN(t)]/E[Y(t)]$ as the sampling weights for the latter. Consequently, an overall weighted prediction loss for the proposed SVHM, which is the expectation of (2) and ignores infinitesimal terms, is

$$\mathcal{R}_0(f) = E \left(\int Y(t)I(f(t, \mathbf{X}) \leq 0]dN(t) \right) + \int \frac{E(Y(t)I(f(t, \mathbf{X}) \geq 0])}{E(Y(t))}E(dN(t)),$$

where the expectation is with respect to random variables $Y(t)$ and $dN(t)$. Our goal of learning a prediction rule for T , or equivalently, $N(t)$, based on the censored data is to minimize the population loss $\mathcal{R}_0(f)$.

To define the empirical loss, suppose there are m distinct ordered event times, $t_1 < t_2 < \dots < t_m$. We let

$$\delta N_i(t_j) \equiv 2(N_i(t_j) - N_i(t_{j-1})) - 1$$

so $\delta N_i(t_j)$ takes values 1 or -1 depending on whether the i th subject experiences an event at t_j or not. Learning $f(t, \mathbf{x})$ becomes a sequence of binary classification problems over t_j 's. Furthermore, at each t_j and for subject i at risk at t_j , we use the following weight associated with the risk set size at t_j :

$$u_i(t_j) = I \left\{ \delta N_i(t_j) = 1 \right\} \left\{ 1 - \frac{1}{\sum_{i=1}^n Y_i(t_j)} \right\} + I \left\{ \delta N_i(t_j) = -1 \right\} \left\{ \frac{1}{\sum_{i=1}^n Y_i(t_j)} \right\}.$$

Note that the weights $u_i(t_j)$ are the empirical version of the weights used in (2) with similar interpretation as the reciprocal of the empirical probability of remaining event free or experiencing an event at the observed event time. Such weights balance the differential size of event class and non-event class at time t_j . Then an optimal decision function that minimizes the empirical version of $\mathcal{R}_0(f)$ is to minimize the following weighted total misclassification error:

$$\mathcal{R}_{0n}(f) = n^{-1} \sum_{i=1}^n \sum_{j=1}^m u_i(t_j) Y_i(t_j) I(\delta N_i(t_j) f(t_j, \mathbf{X}_i) < 0), \quad (3)$$

where the term $Y_i(t_j)$ reflects that only subjects still at risk will contribute towards prediction.

Directly minimizing (3) is difficult due to non-smoothness of the 0-1 loss in the indicator function. Furthermore, no restriction on the complexity of f leads to potential overfitting. To handle these issues, we adopt the same idea as SVM for supervised learning to replace the 0-1 loss in (1) by the hinge loss, and impose regularization to estimate f . Specifically, we propose to minimize the following regularized SVHM loss:

$$\mathcal{R}_n(f) + \lambda_n \|f\|^2,$$

$$\text{with } \mathcal{R}_n(f) \equiv n^{-1} \sum_{i=1}^n \sum_{j=1}^m w_i(t_j) Y_i(t_j) [1 - f(t_j, \mathbf{X}_i) \delta N_i(t_j)]_+, \quad (4)$$

where $[1 - x]_+ = \max(1 - x, 0)$ is the hinge loss, $\|\cdot\|$ is a suitable norm or semi-norm for f to be discussed in the following sections, and λ_n is the regularization parameter. This minimization is equivalent to maximizing the margin between subjects in the event and non-event classes subject to an upper bound on the misclassification rate. Since this learning method is a weighted version of the standard support vector machines and learning $f(t, \mathbf{x})$ is essentially learning the hazard rate function, we refer our proposed method as ‘‘support vector hazards machine’’.

2.2 Learning Algorithm

Next, we describe the computational algorithm to solve the optimization in (4). We do not impose any restriction on $\alpha(t)$, and assume $g(\mathbf{X})$ lies in a reproducing kernel Hilbert space \mathcal{H}_n with a kernel function $K(\mathbf{x}, \mathbf{x}')$. Commonly used kernels include linear kernel, where $K(\mathbf{x}, \mathbf{x}') = \langle \mathbf{x}, \mathbf{x}' \rangle$; radial basis kernel where $K(\mathbf{x}, \mathbf{x}') = \exp(-\|\mathbf{x} - \mathbf{x}'\|^2/\sigma)$; and l th-degree polynomial kernel, where $K(\mathbf{x}, \mathbf{x}') = (1 + \langle \mathbf{x}, \mathbf{x}' \rangle)^l$. Furthermore, let $\|f\| = \|g\|_{\mathcal{H}_n}$ which is the norm in the reproducing kernel Hilbert space \mathcal{H}_n . The minimization in (3),

$$\min_{\alpha, g} \frac{1}{2} \sum_{i=1}^n \sum_{j=1}^m w_i(t_j) Y_i(t_j) [1 - (\alpha(t_j) + g(\mathbf{X}_i)) \delta N_i(t_j)]_+ + \lambda_n \|g\|_{\mathcal{H}_n}^2, \quad (5)$$

is equivalent to

$$\min_{\alpha, g} \frac{1}{2} \|g\|_{\mathcal{H}_n}^2 + C_n \sum_{i=1}^n \sum_{j=1}^m w_i(t_j) Y_i(t_j) \zeta_i(t_j), \quad (6)$$

subject to $Y_i(t_j) \zeta_i(t_j) \geq 0, i = 1, \dots, n, j = 1, \dots, m$,

$$Y_i(t_j) \delta N_i(t_j) \{\alpha(t_j) + g(\mathbf{X}_i)\} \geq Y_i(t_j) \{1 - \zeta_i(t_j)\}, i = 1, \dots, n, j = 1, \dots, m,$$

where the value $\zeta_i(t_j)$ is the proportional amount by which the prediction is on the wrong side of its margin at time t_j , and C_n is the cost parameter.

The constrained optimization in (6) is usually solved by turning it into its dual form (through including Lagrange multipliers of the constraints into the objective function). We convert the above problem to its dual form by using the corresponding Lagrangian function

$$\begin{aligned} L_p &= \frac{1}{2} \|g\|_{\mathcal{H}_n}^2 + C_n \sum_{i=1}^n \sum_{j=1}^m w_i(t_j) Y_i(t_j) \zeta_i(t_j) - \sum_{i=1}^n \sum_{j=1}^m \mu_{ij} Y_i(t_j) \zeta_i(t_j) \\ &\quad - \sum_{i=1}^n \sum_{j=1}^m \gamma_{ij} [Y_i(t_j) \delta N_i(t_j) \{\alpha(t_j) + g(\mathbf{X}_i)\} - Y_i(t_j) \{1 - \zeta_i(t_j)\}], \end{aligned}$$

where $\mu_{ij} \geq 0$ and $\gamma_{ij} \geq 0$ are the corresponding Lagrange multipliers. Let $\{\phi_1, \phi_2, \dots\}$ be the orthonormal basis system in \mathcal{H}_n and $g(\mathbf{X}) = \sum_{k=1}^{\infty} \beta_k \phi_k(\mathbf{X})$. Then after differentiating

the Lagrangian function with respect to β 's, $\alpha(t_j)$'s and $\zeta_i(t_j)$'s, we obtain

$$\begin{aligned} \beta_k &= \sum_{i=1}^n \sum_{j=1}^m \gamma_{ij} Y_i(t_j) \delta N_i(t_j) \phi_k(\mathbf{X}_i), \quad k = 1, 2, \dots, \\ &\quad \sum_{i=1}^n \gamma_{ij} Y_i(t_j) \delta N_i(t_j) = 0, \end{aligned}$$

$$C_n w_i(t_j) Y_i(t_j) - \mu_{ij} Y_i(t_j) = \gamma_{ij} Y_i(t_j), \quad i = 1, \dots, n, j = 1, \dots, m,$$

as well as the positivity constraints $\gamma_{ij}, \mu_{ij}, \zeta_i(t_j) \geq 0$ for all i and j . By substituting these back to L_p and noting that $\sum_{k=1}^{\infty} \phi_k(\mathbf{X}_i) \phi_k(\mathbf{X}) = K(\mathbf{X}_i, \mathbf{X})$ (Theorem 4.2, Steinwart (2002)), we obtain the dual objective function to be

$$L_D = \sum_{i=1}^n \sum_{j=1}^m \gamma_{ij} Y_i(t_j) - \frac{1}{2} \sum_{i=1}^n \sum_{j=1}^m \sum_{i'=1}^n \sum_{j'=1}^m \gamma_{ij} \gamma_{i'j'} Y_i(t_j) Y_{i'}(t_{j'}) \delta N_i(t_j) \delta N_{i'}(t_{j'}) K(\mathbf{X}_i, \mathbf{X}_{i'}), \quad (7)$$

and the optimization is carried out by maximizing L_D with respect to γ_{ij} subject to $0 \leq \gamma_{ij} \leq w_i(t_j) C_n$ and $\sum_{i=1}^n \sum_{j=1}^m \gamma_{ij} Y_i(t_j) \delta N_i(t_j) = 0$ for $i = 1, \dots, n$ and $j = 1, \dots, m$. This optimization can be solved using quadratic programming packages available in many softwares (for example, MOSEK toolbox in Matlab). The tuning parameter C_n is chosen by cross-validation searching over a grid of values. Denote $\hat{\gamma}_{ij}$ as the solutions for γ_{ij} obtained from the optimization procedure in (7). Comparing (7) with existing standard support vector machine algorithms, we see that the objective function sums across all at-risk subjects and across all time points for which they are at risk. Constraints are placed on those subjects and time points.

Next, from the equalities between β_k 's and γ_{ij} 's in the above duality derivation, the solutions for β_k (denoted as $\hat{\beta}_k$) are given by

$$\hat{\beta}_k = \sum_{i=1}^n \sum_{j=1}^m \hat{\gamma}_{ij} Y_i(t_j) \delta N_i(t_j) \phi_k(\mathbf{X}_i), \quad k = 1, 2, \dots.$$

Thus, the solution for g that minimizes (5), which is the risk score for a future subject with baseline covariates \mathbf{x} , is

$$\begin{aligned} \hat{g}(\mathbf{x}) &= \sum_{k=1}^{\infty} \hat{\beta}_k \phi_k(\mathbf{x}) = \sum_{i=1}^n \sum_{j=1}^m \hat{\gamma}_{ij} Y_i(t_j) \delta N_i(t_j) \sum_{k=1}^{\infty} \phi_k(\mathbf{X}_i) \phi_k(\mathbf{x}) \\ &= \sum_{i=1}^n \sum_{j=1}^m \hat{\gamma}_{ij} \delta N_i(t_j) K(\mathbf{x}, \mathbf{X}_i). \end{aligned} \quad (7)$$

It follows that those data points with $\hat{\gamma}_{ij} > 0$ form support vectors and determine $g(\mathbf{X})$.

Furthermore, to determine the solution to $\alpha(t_j)$ at each t_j , denoted by $\hat{\alpha}(t_j)$, we solve the Karush-Kuhn-Tucker (KKT) conditions

$$\gamma_{ij} [Y_i(t_j) \delta N_i(t_j) \{\alpha(t_j) + g(\mathbf{X}_i)\} - Y_i(t_j) \{1 - \zeta_i(t_j)\}] = 0,$$

$$Y_i(t_j)\zeta_i(t_j) \geq 0,$$

$$Y_i(t_j)\delta N_i(t_j)\{\alpha(t_j) + g(\mathbf{X}_i)\} - Y_i(t_j)\{1 - \zeta_i(t_j)\} \geq 0.$$

Specifically, if there are some support vectors lying on the edge of the margin which are characterized by $0 < \hat{\gamma}_{ij} < w_i(t_j)C_n$, $\hat{\alpha}(t_j) = 1/\delta N_i(t_j) - \hat{g}(\mathbf{X}_i)$ for these points, and we take the average of all the solutions for numerical stability. If all the support vectors at t_j are $\hat{\gamma}_{ij} = C_n w_i(t_j)$, $\hat{\alpha}(t_j)$ is not unique and falls into a range

$$\min_{\substack{Y_i(t_j)=1, \hat{\gamma}_{ij}=C_n w_i(t_j), \\ \delta N_i(t_j)=1}} \{1 - \hat{g}(\mathbf{X}_i)\} \geq \hat{\alpha}(t_j) \geq \max_{\substack{Y_i(t_j)=1, \hat{\gamma}_{ij}=C_n w_i(t_j), \\ \delta N_i(t_j)=-1}} \{-1 - \hat{g}(\mathbf{X}_i)\}.$$

In this case, we take $\hat{\alpha}(t_j) = 1 - \hat{g}(\mathbf{X}_i)$ where $\delta N_i(t_j) = 1$ for some i with $Y_i(t_j) = 1$.

Since a higher value of the prediction function $\hat{\alpha}(t) + \hat{g}(x)$ leads to a greater likelihood of having an event at an earlier time, the magnitude of $\hat{g}(x)$ induces a natural ordering of the risks. Lastly, the learned risk scores can be used to predict the event time for any future subjects using their baseline covariates \mathbf{x} . To this end, consider the nearest-neighbor prediction: for a future subject with $\mathbf{X} = \mathbf{x}$, find k ($k=1$ or 3 in our applications) non-censored subjects in the training data whose predictive scores are closest to $\hat{g}(\mathbf{x})$, denoted as $\hat{g}(\mathbf{X}_j)$. To maintain the monotone relationship between the event times and predictive scores, sort these scores of non-censored subjects in the training data in descending order and identify the rank of $\hat{g}(\mathbf{X}_j)$. Next, sort the event times of the derived scores in the training data in ascending order and find the event times with the same rank as the rank of $\hat{g}(\mathbf{X}_j)$, denoted as $T_{j'}$. The event time for this subject is predicted as $T_{j'}$ (or the average of $T_{j'}$ for $k=3$). We provide a detailed description of SVHM algorithm in Appendix A.

2.3 Connection with Existing Support Vector-Based Approaches

Support vector-based approaches in machine learning literature are motivated by the fact that they are easy to compute and enable estimation under weak or no assumptions on the distribution. Most of these approaches (Shivaswamy et al., 2007; Van Belle et al., 2010, 2011) adapt the ϵ -insensitive loss for SVR to account for incomplete observations in time-to-event data. To improve performance, modified SVR (Van Belle et al., 2011) further places ranking constraints under the ϵ -insensitive loss. The formulation of the problem is

$$\min_{\mathbf{w}, \boldsymbol{\xi}, \boldsymbol{\xi}^*} \frac{1}{2} \mathbf{w}^T \mathbf{w} + \lambda_1 \sum_i \epsilon_i + \lambda_2 \sum_i (\xi_i + \xi_i^*), \quad (8)$$

$$\text{subject to } \mathbf{w}^T(\varphi(\mathbf{X}_i) - \varphi(\mathbf{X}_{j(i)})) \geq Y_i - Y_{j(i)} - \epsilon_i, i = 1, \dots, n,$$

$$\mathbf{w}^T \varphi(\mathbf{X}_i) + b \geq Y_i - \xi_i, i = 1, \dots, n,$$

$$\Delta_i(\mathbf{w}^T \varphi(\mathbf{X}_i) + b) \geq -\Delta_i Y_i - \xi_i^*, i = 1, \dots, n,$$

$$\epsilon_i \geq 0, \xi_i \geq 0, \xi_i^* \geq 0, i = 1, \dots, n,$$

where $Y_i = T_i \wedge C_i$, $\varphi(\cdot)$ is the feature map that does not need to be specified explicitly in a kernel-based method, and $j(i)$ indicates the subject with the largest event time smaller than Z_i . The first set of constraints above aims at ensuring rank consistency to maximize C-index for predicting survival outcomes, and the second and third sets of constraints are the

same as the regression constraints in Shivaswamy et al. (2007) for the modified ϵ -insensitive loss for survival outcomes. One potential problem with the above optimization is that the observations contributing to these three sets of constraints may consist of a selected (non-censored) sample from the full data; thus, the derived prediction rule will likely favor those observations which contribute most.

Furthermore, comparing the modified SVR in (8) with SVHM in (6), we see that the loss function for the former is the ϵ -insensitivity loss plus the loss resulting from violating rank consistency, while for the latter it is sum of a sequence of hinge losses. The objective function and the slack variables (i.e., $\epsilon_i, \xi_i, \xi_i^*$) for the modified SVR, however, are time-invariant, while the slack variables for SVHM (i.e., $\zeta_i(t_j)$ in (8)) are time-sensitive. Thus, we expect better control of the prediction error by SVHM. Note that this advantage stems from the counting process formulation of SVHM transforming prediction of time-to-event outcomes (or survival outcomes) as a sequence of binary prediction problems over time.

2.4 Connection with the Cox Partial Likelihood

In classical survival analysis using Cox regression model (Cox, 1972), partial likelihood plays a central role since it only involves association parameter of interest (i.e., hazard ratios as regression coefficients) but not the nuisance parameter (i.e., baseline hazard function), and maximizing the partial likelihood directly estimates the hazard ratios. The partial likelihood is constructed by multiplying together the conditional probabilities of observing an event for individual i at time t , given the past and given that an event is observed at that time, over all observed event times. This conditional probability formulation shares some similarity with our hazard formulation for SVHM. Since maximizing Cox partial likelihood leads to regression estimators that enjoy optimal statistical property (i.e., being semiparametric efficient, Bickel et al. (1998)), it is worth to draw connection between SVHM and partial likelihood to shed lights on the theoretical properties of SVHM.

To this end, we further explore the optimization in (5) to compare the SVHM objective function and the Cox partial likelihood. First note that the function $\alpha(t)$ in (5) is analogous to the baseline hazard function in the Cox model (Cox, 1972), which is treated as a nuisance parameter and profiled out for inference. Thus, we also profile out $\alpha(t)$ to investigate the profile risk function for SVHM (e.g., substitute fitted $\alpha(t)$ in the original risk function). For a fixed $g(\mathbf{x})$, from the derivation similar to Hastie et al. (2009) (p421) and Abe (2010) (p77), we can show that at each t_j , if there are some support vectors lying on the edge of the margin which are characterized by $0 < \hat{\gamma}_{ij} < w_i(t_j)C_n$, these margin points can be used to solve for $\alpha(t_j)$. This yields

$$\hat{\alpha}(t_j) = 1 - g(\mathbf{X}_i), \quad \delta N_i(t_j) = 1.$$

Note that \mathbf{X}_i is the covariate value for the subject who has an event at t_j . However, if $\hat{\gamma}_{ij}$ is not within $(0, w_i(t_j)C_n)$, $\hat{\alpha}(t_j)$ can be any value satisfying

$$\min_{\substack{\hat{\gamma}_{ij}=C_n w_i(t_j), \\ \delta N_i(t_j)=-1}} \{1 - g(\mathbf{X}_i)\} \geq \alpha(t_j) \geq \max_{\substack{\hat{\gamma}_{ij}=C_n w_i(t_j), \\ \delta N_i(t_j)=-1}} \{-1 - g(\mathbf{X}_i)\}.$$

In this case, taking $\hat{\alpha}(t_j) = 1 - g(\mathbf{X}_i)$ where $\delta N_i(t_j) = 1$ satisfies these constraints. Further note that optimizing (5) is equivalent to minimizing

$$\begin{aligned} & \frac{1}{n} \sum_{i=1}^n \sum_{j=1}^d Y_i(t_j) w_i(t_j) [1 - (\alpha(t) + g(\mathbf{X}_i)) \delta N_i(t_j)]_+ + \lambda_n \|g\|_{\mathcal{H}_n} \\ &= \frac{1}{n} \sum_{i=1}^n \int [1 - (\alpha(t) + g(\mathbf{X}_i))]_+ dN_i(t) + \frac{1}{n} \int \frac{\sum_{i=1}^n Y_i(t) [1 + (\alpha(t) + g(\mathbf{X}_i))]_+ d \left\{ \sum_{i=1}^n N_i(t) \right\}}{\sum_{i=1}^n Y_i(t)} \\ & \quad - \frac{1}{n} \sum_{i=1}^n \int \frac{1}{\sum_{i=1}^n Y_i(t)} ([1 - (\alpha(t) + g(\mathbf{X}_i))]_+ + [1 + (\alpha(t) + g(\mathbf{X}_i))]_+) dN_i(t) + \lambda_n \|g\|_{\mathcal{H}_n}. \end{aligned}$$

After we plug the expression of $\hat{\alpha}(t) = \sum_{i=1}^n (1 - g(\mathbf{X}_i)) I(\delta N_i(t) = 1)$ into the above expression, we obtain

$$\frac{1}{n} \sum_{i=1}^n \int [1 - (\hat{\alpha}(t) + g(\mathbf{X}_i))]_+ dN_i(t) = \frac{1}{n} \sum_{i=1}^n \Delta_i [1 - (1 - g(\mathbf{X}_i) + g(\mathbf{X}_i))]_+ = 0,$$

and similarly,

$$\frac{1}{n} \sum_{i=1}^n \int \frac{1}{\sum_{i=1}^n Y_i(t)} ([1 - (\hat{\alpha}(t) + g(\mathbf{X}_i))]_+ + [1 + (\hat{\alpha}(t) + g(\mathbf{X}_i))]_+) dN_i(t) = \frac{2}{n} \sum_{i=1}^n \int \frac{dN_i(t)}{\sum_{i=1}^n Y_i(t)}.$$

Additionally,

$$\begin{aligned} & \frac{1}{n} \int \frac{\sum_{i=1}^n Y_i(t) [1 + (\hat{\alpha}(t) + g(\mathbf{X}_i))]_+ d \left\{ \sum_{i=1}^n N_i(t) \right\}}{\sum_{i=1}^n Y_i(t)} \\ &= \frac{1}{n} \sum_{k=1}^n \Delta_k \frac{\sum_{i=1}^n I(Y_i \geq Y_k) [1 + (\hat{\alpha}(\mathbf{X}_k) + g(\mathbf{X}_k))]_+}{\sum_{i=1}^n I(Y_i \geq Y_k)} \\ &= \frac{1}{n} \sum_{k=1}^n \frac{\sum_{i=1}^n I(Y_i \geq Y_k) [2 - g(\mathbf{X}_k) + g(\mathbf{X}_i)]_+ \Delta_k}{\sum_{i=1}^n I(Y_i \geq Y_k)}. \end{aligned}$$

The objective function (5) can be written as $\mathcal{P}\mathcal{R}_n(g) + \lambda_n \|g\|_{\mathcal{H}_n}^2$, where

$$\begin{aligned} \mathcal{P}\mathcal{R}_n(g) &= \frac{1}{n} \sum_{i=1}^n \int \frac{\sum_{k=1}^n Y_k(t) [2 - g(\mathbf{X}_i) + g(\mathbf{X}_k)]_+ dN_i(t)}{\sum_{k=1}^n Y_k(t)} - \frac{2}{n} \sum_{i=1}^n \int \frac{dN_i(t)}{\sum_{k=1}^n Y_k(t)} \\ &= \frac{1}{n} \sum_{i=1}^n \Delta_i \frac{\sum_{k=1}^n I(Y_k \geq Y_i) [2 - g(\mathbf{X}_i) + g(\mathbf{X}_k)]_+}{\sum_{k=1}^n I(Y_k \geq Y_i)} - \frac{2}{n} \sum_{i=1}^n \frac{\Delta_i}{\sum_{k=1}^n I(Y_k \geq Y_i)} \\ &= \mathbf{P}_n \left(\Delta \frac{\tilde{\mathbf{P}}_n \{I(\tilde{Y} \geq Y) [2 + g(\tilde{\mathbf{X}}) - g(\mathbf{X})]_+\}}{\tilde{\mathbf{P}}_n [I(\tilde{Y} \geq Y)]} - \frac{2}{n} \mathbf{P}_n \left\{ \frac{\Delta}{\tilde{\mathbf{P}}_n [I(\tilde{Y} \geq Y)]} \right\} \right). \end{aligned}$$

Here, \mathbf{P}_n denotes the empirical measure from n observations and $\tilde{\mathbf{P}}_n$ is the empirical measure applied to $(\tilde{Y}, \tilde{\mathbf{X}}, \tilde{\Delta})$, an i.i.d copy of (Y, \mathbf{X}, Δ) . Thus, $\hat{g}(\mathbf{x})$ minimizes $\mathcal{P}\mathcal{R}_n(g) + \lambda_n \|g\|_{\mathcal{H}_n}^2$.

If we let $\hat{f}(g, t) = \hat{\alpha}(t) + \hat{g}(\mathbf{x})$ be the function minimizing (5) over $g \in \mathcal{H}_n$, then $\mathcal{R}_n(\hat{f}) = \mathcal{P}\mathcal{R}_n(\hat{g})$.

In a Cox partial likelihood function, $g(\mathbf{X})$ is estimated by minimizing

$$\mathbf{P}_n \left(\Delta \log \frac{\tilde{\mathbf{P}}_n \{I(\tilde{Y} \geq Y) \exp\{g(\tilde{\mathbf{X}}) - g(\mathbf{X})\}\}}{\tilde{\mathbf{P}}_n [I(\tilde{Y} \geq Y)]} \right).$$

Therefore, it is worthy to point out one interesting observation: both $\mathcal{P}\mathcal{R}_n(g)$ and the Cox partial likelihood take a similar form which essentially evaluates a loss comparing the risk scores from the subjects at risk versus the one from the subject who has an event at the same time. SVHM uses a hinge loss while Cox partial likelihood uses an exponential loss and a logarithm transformation, which is similar to the contrast between SVM and logistic regression. The robustness of hinge loss compared to exponential loss suggests SVHM will be less sensitive to extreme observations. In addition, this connection sheds lights on the theoretical optimality of SVHM which we prove in the next section.

3. Theoretical Properties

In this section, we study the asymptotic properties of SVHM and the predicted risk. We first derive the population risk function for the proposed SVHM. Next, we derive the optimal fully nonparametric decision rule for this risk function and show that it also optimizes the 0-1 loss corresponding to (3). We highlight important differences in the theoretical proof that distinguish this work from the standard proofs in the statistical learning theories.

3.1 Risk Function and Optimal Risk Classification Rule

To derive the population risk function for SVHM, we first examine the population version (the expectation) of $\mathcal{R}_n(f)$. Recall the definition of $\mathcal{R}_n(f)$ is given in (4) as

$$\begin{aligned} \mathcal{R}_n(f) &= n^{-1} \sum_{i=1}^n \sum_{j=1}^n \frac{I\{\delta N_i(t_j) = 1\} (\sum_{i=1}^n Y_i(t_j) - 1)}{\sum_{i=1}^n Y_i(t_j)} [1 - f(t_j, \mathbf{X}_i)]_+ \\ & \quad + n^{-1} \sum_{i=1}^n \sum_{j=1}^n \frac{I\{\delta N_i(t_j) = 1\}}{\sum_{i=1}^n Y_i(t_j)} [1 + f(t_j, \mathbf{X}_i)]_+, \end{aligned}$$

After re-arranging the terms and adopting counting process notation, we can rewrite $\mathcal{R}_n(f)$ as

$$\begin{aligned} \mathcal{R}_n(f) &= \frac{1}{n} \sum_{i=1}^n \int Y_i(t) [1 - f(t, \mathbf{X}_i)]_+ dN_i(t) + \frac{1}{n} \int \frac{\sum_{i=1}^n Y_i(t) [1 + f(t, \mathbf{X}_i)]_+ d \left\{ \sum_{i=1}^n N_i(t) \right\}}{\sum_{i=1}^n Y_i(t)} \\ & \quad - \frac{1}{n} \sum_{i=1}^n \int \frac{1}{\sum_{i=1}^n Y_i(t)} ([1 - f(t, \mathbf{X}_i)]_+ + [1 + f(t, \mathbf{X}_i)]_+) dN_i(t). \end{aligned}$$

Note that the last term in $\mathcal{R}_n(f)$ is on the order of $O(1/n)$, so it vanishes as n goes to infinity. By the central limit theorem, we obtain the asymptotic limit of $\mathcal{R}_n(f)$, denoted as

$\mathcal{R}(f)$, to be

$$\mathcal{R}(f) = E \left(\int Y(t)[1 - f(t, \mathbf{X})]_+ dN(t) \right) + \int \frac{E(Y(t)[1 + f(t, \mathbf{X})]_+)}{E(Y(t))} E(dN(t)).$$

Likewise, similar arguments show that the empirical risk based on the prediction error in (1), i.e., $\mathcal{R}_n(f)$, converges to $\mathcal{R}_0(f)$.

Let $f^*(t, \mathbf{x})$ denote the limit of the risk function estimated by SVHM (i.e., the optimal function minimizing $\mathcal{R}(f)$). Since the difference between $\mathcal{R}(f)$ and $\mathcal{R}_0(f)$ is the hinge loss versus the zero-one loss, one question is whether $f^*(t, \mathbf{x})$ also minimizes $\mathcal{R}_0(f)$. The following theorem gives such a result for $f^*(t, \mathbf{x})$.

Theorem 3.1 *Let $h(t, \mathbf{x})$ denote the conditional hazard rate function of $T = t$ given $\mathbf{X} = \mathbf{x}$ and let $\bar{h}(t) = E[dN(t)/dt]/E[Y(t)] = E[h(t, \mathbf{X})|Y(t) = 1]$ be the average hazard rate at time t . Then $f^*(t, \mathbf{x}) = \text{sign}(h(t, \mathbf{x}) - \bar{h}(t))$ minimizes $\mathcal{R}(f)$. Furthermore, $f^*(t, \mathbf{x})$ also minimizes $\mathcal{R}_0(f)$ and*

$$\mathcal{R}_0(f^*) = P(T \leq C) - \frac{1}{2} E \left[\int E(Y(t)|\mathbf{X} = \mathbf{x})h(t, \mathbf{x}) - \bar{h}(t) dt \right].$$

In addition, for any $f(t, \mathbf{x}) \in [-1, 1]$,

$$\mathcal{R}_0(f) - \mathcal{R}_0(f^*) \leq \mathcal{R}(f) - \mathcal{R}(f^*),$$

where $h(t, \mathbf{x})$ denotes the conditional hazard rate of $T = t$ given $\mathbf{X} = \mathbf{x}$ and $\bar{h}(t)$ is the population average hazard at time t ,

$$\bar{h}(t) = \frac{E[dN(t)]/dt}{E[Y(t)]} = E[h(t, \mathbf{X})|Y(t) = 1].$$

The proof of Theorem 3.1 is provided in the Appendix B. Theorem 3.1 resembles the excess risk in most learning theories (Bartlett et al., 2006); however, the loss function in our case is some composite expectation, $\mathcal{R}_0(f)$, which is not covered by Bartlett et al. (2006). From Theorem 3.1, we see that the optimal rule is essentially to predict whether an at-risk subject will experience an event by comparing the subject-specific hazard rate depending on the covariate to the population-average hazard rate obtained from all at-risk subjects at a given time point. Since the minimizer of $\mathcal{R}(f)$ also minimizes $\mathcal{R}_0(f)$, this theory justifies the use of hinge-loss in SVHM to minimize the weighted prediction error in $\mathcal{R}_0(f)$. The last inequality in Theorem 3.1 proves that a decision function with a small excess hinge-loss-based risk will lead to a small excess 0-1 loss-based risk.

3.2 Asymptotic Properties

Here, we study the asymptotic properties of SVHM when the decision function takes the form in (1). Specifically, we examine a stochastic bound for the excess risk when using \hat{g} , the estimator from n observations. This bound will be given in terms of the sample size n , the tuning parameter λ_n and the bandwidth of the kernel function σ_n . Denote \mathcal{H}_n as

a reproducing kernel Hilbert space from a Gaussian kernel $k(x, x') = \exp\{-\|x - x'\|^2/\sigma_n\}$. Instead of considering the risk for $\mathcal{R}(f)$, we consider

$$\mathcal{PR}(g) = \min_{\alpha(t)} \mathcal{R}(\alpha(t) + g(\mathbf{x}))$$

and refer it as ‘‘profile risk’’, since $\alpha(t)$ is profiled out from the original risk function. In other words, $\mathcal{PR}(g)$ is the best expected risk for a given score $g(\mathbf{x})$ after accounting for $\alpha(t)$.

To obtain an explicit expression of $\mathcal{PR}(g)$, we first note that

$$\begin{aligned} \mathcal{R}(\alpha(t) + g(\mathbf{x})) &= E \left(\int Y(t)[1 - f(t, \mathbf{X})]_+ dN(t) \right) + \int \frac{E(Y(t)[1 + f(t, \mathbf{X})]_+)}{E(Y(t))} E(dN(t)) \\ &= \int E[Y(t)h(t, \mathbf{X})] \left[\frac{E[Y(t)h(t, \mathbf{X})] - E[Y(t)g(\mathbf{X})h(t, \mathbf{X})]}{E[Y(t)h(t, \mathbf{X})]} - \alpha(t) \right]_+ dt \\ &\quad + \int \bar{h}(t)E[Y(t)] \left[\frac{E[Y(t)] + E[Y(t)g(\mathbf{X})]}{E[Y(t)]} + \alpha(t) \right]_+ dt. \end{aligned}$$

Since $\alpha(t)$ is arbitrary and the integrand in the above expression is a piecewise linear function of $\alpha(t)$, simple algebra gives that

$$\alpha(t) = - \frac{E[Y(t)] + E[Y(t)g(\mathbf{X})]}{E[Y(t)]}$$

minimizes $\mathcal{R}(f)$. Therefore, after replacing $\alpha(t)$ by this minimizer in $\mathcal{R}(\alpha(t) + g(\mathbf{x}))$, we obtain

$$\mathcal{PR}(g) = E \left[\Delta \frac{\tilde{\mathbf{P}}I(\tilde{Y} \geq Y)}{g} [2 - g(\tilde{\mathbf{X}}) + g(\mathbf{X})]_+ \right].$$

Clearly, $\mathcal{PR}(g)$ is the asymptotic limit of $\mathcal{PR}_n(g)$. The following theorem holds for the risk $\mathcal{PR}(\hat{g})$.

Theorem 3.2 *Assume that \mathbf{X} 's support is compact and $E[Y(\tau)|\mathbf{X}]$ is bounded from zero where τ is the study duration. Furthermore, assume λ_n and σ_n satisfies $\lambda_n, \sigma_n \rightarrow 0$, and $n\lambda_n\sigma_n^{(2/p-1/2)d} \rightarrow \infty$ for some $p \in (0, 2)$. Then it holds*

$$\lambda_n \|\hat{g}\|_{\mathcal{H}_n}^2 + \mathcal{PR}(\hat{g}) \leq \inf_g \mathcal{PR}(g) + O_p \left\{ \lambda_n + \frac{\sigma_n^{d/2}}{\sqrt{n}} + \frac{\lambda_n^{-1/2} \sigma_n^{-(1/p-1/4)d}}{\sqrt{n}} \right\}.$$

The proof of Theorem 3.2 mostly follows the machinery for support vector machines. It mainly uses empirical process theories to control the stochastic error of the empirical risk functions and the approximation properties of the reproducing kernel Hilbert space based on the Gaussian kernel function. However, one major difference from the classical proof is that the empirical loss function we study here is some composite statistics instead of the summation of n i.i.d terms. This poses additional challenges to control stochastic variability. The constants in Theorem 3.2 imply that the bandwidth for the Gaussian

kernel and regularization parameter should converge to zero in certain rates depending on \mathbf{X} 's dimension, but not too fast to ensure stochastic variability is under control. Finally, we state two useful observations as remarks below.

Remark 1. From Theorem 3.2, if we choose $\sigma_n = (n\lambda_n)^{-1/2d(1/p+1/4)}$, it gives

$$\mathcal{PR}(\hat{g}) - \mathcal{PR}(g^*) = O_p \{ \lambda_n + (n\lambda_n)^{-q} \},$$

where $q = 1/(4/p + 1)$ and g^* is the function minimizing $\mathcal{PR}(g)$.

Remark 2. Furthermore, if we choose $\lambda_n = n^{-q/(q+1)}$, then the optimal rate obtained from Theorem 3.2 becomes

$$\mathcal{PR}(\hat{g}) - \mathcal{PR}(g^*) = O(n^{-q/(q+1)}).$$

4. Numeric Examples

In this section, we first present simulation results comparing SVHM to existing machine learning approaches and semiparametric approaches based on the Cox proportional hazards regression. Next, we provide applications to two real world empirical studies.

4.1 Simulation Studies

In all scenarios, we generated both event times and censoring times to be dependent on the covariates. First we simulated five covariates $\mathbf{Z} = (Z_1, \dots, Z_5)$ which are marginally normal $N(0, 0.5^2)$ with pairwise correlation $\text{corr}(Z_j, Z_k) = \rho^{|j-k|}$, and $\rho = 0.5$. The event times were generated from the Cox proportional hazards model with true $\beta = (2, -1.6, 1.2, -0.8, 0.4)^T$ and the exponential distribution with $\lambda = 0.25$ was assumed to compute the baseline cumulative hazard function $\Lambda(t) = \int_0^t \lambda_0(s)ds$, where $\lambda_0(s)$ is the baseline hazard function. We simulated two types of censoring distributions. In the first type, the censoring times were generated from an accelerated failure time model following the log-normal distribution, that is, $\log C \sim N(\mathbf{Z}^T \beta_c + a, 0.5^2)$, with true $\beta_c = (1, 1, 1, 1, 1)^T$. In the second type, the distribution of the censoring times follows the Cox proportional hazards model with true $\beta_c = (1, 1, 1, -2, -2)^T$ and the baseline cumulative hazard function $\Lambda_c(t) = bt$ ($b > 0$). The parameters a and b were chosen to obtain the desired censoring ratio. We considered the censoring ratios 40% and 60%. Any event times or censoring times greater than u_0 were truncated at u_0 , where u_0 is the 90th percentile of the event times. Moreover, we explored some generalizations of the above scenarios to include more covariates in the regression models and include additional noise variables. Besides these training data sets (with a sample size of 100 or 200), we use a randomly generated testing data set with 10,000 subjects in each scenario with no censoring to evaluate prediction performance of various methods.

For all scenarios, we compared SVHM with the modified support vector regression for right censored data based on the ranking constraints (modified SVR) (Van Belle et al., 2011) and the inverse-probability-of-censoring weighting with censoring distribution estimated using Kaplan-Meier (IPCW-KM) or estimated under a Cox model (IPCW-Cox) (Goldberg and Kosorok, 2013), whose objective function is defined as

$$n^{-1} \sum_{i=1}^n \frac{\Delta_i}{\tilde{S}(Y_i)} (\log Y_i - \mathbf{x}^T \phi(\mathbf{X}_i))^2$$

with $\tilde{S}(t)$ is the estimated survival probability for the censoring time. We used linear kernel $K(x, x') = \mathbf{x}^T \mathbf{x}'$ in all four methods, and used 5-fold cross-validation to choose the tuning parameters from the grid of $\{2^{-16}, 2^{-15}, \dots, 2^{15}, 2^{16}\}$. As the model comparison criterion, we adapted mean squared error to censored data, which sums up the mean squared differences between the fitted event times and observed event times for uncensored subjects. For censored subjects, we sum up the squared differences between fitted times and censoring times if the former is smaller than the latter. Essentially, for these censored subjects, if their predicted event times were less than the observed censoring times, we imposed a penalty to measure how much under-estimation there is. The mean squared differences were assumed to be zero for censored subjects if their predicted values were greater than the observed censoring times. We divided the total sum of squares by the total number of observations. We repeated the simulation 500 times, since our results show that 500 repetitions are sufficient to obtain stable simulation results to draw conclusions on comparing performance of different methods while still achieving computational efficiency.

Table 1 and 2 give the average Pearson correlations and root mean square errors (RMSE) $\{\sum(\hat{T} - T)^2\}^{1/2}$ based on the fitted event times and observed event times T on the testing data set. Larger correlation and smaller root mean squared error indicate better performance. The results show that SVHM outperforms the other methods for all the simulation cases and sample sizes. The advantages are not affected by including 5 or 15 noise variables, and the improvements become more evident when the censoring rate is 60% or the censoring distribution follows the accelerated failure time model. The columns of the average correlations show that the modified SVR has similar capability to capture the rank information as SVHM. However, it gives less accurate prediction of the exact event times as measured by the higher RMSEs. The IPCW methods have the worst performance, no matter using the Kaplan-Meier estimator or Cox model to estimate the censoring distribution, even when the censoring distribution follows the Cox model. The performances of all the methods are improved as the sample size increases from 100 to 200, and the proposed SVHM has the largest improvement with respect to the ratios of the average RMSEs. The RMSE of SVHM is significantly lower than the best competing method in all simulation settings in Table 1 and 2. Correlation between the risk scores and event times for SVHR is not significantly different from modified SVR, but in the first simulation setting it is significantly higher than two IPW-based methods except when there are 95 noise variables (Table 1). In the second simulation setting, difference between SVHR and IPW is smaller, with the former significantly greater for most cases with $n = 200$ (Table 2).

In conclusion, Table 1 shows that SVHM performs much better than Cox regression when the model assumption does not hold, and Table 2 shows that SVHM still maintains its advantage when the Cox proportional hazards assumption holds. This advantage may be due to that Cox model aims at maximizing the likelihood while SVHM directly aims at discriminating individual's risk and prediction.

We also explored SVHM with a Gaussian kernel for the sample size 100 and the computation is more intensive. The resulting average correlations and RMSEs are similar to those for linear kernel. For example, under the setting in Table 1 with 60% censoring rate, no noise variable and $n = 100$, using Gaussian kernel yields almost similar correlation of 0.48, 0.10, 0.15, and 0.53 for four competing methods (modified SVR, IPCW-KM, IPCW-Cox, SVHM), respectively. The corresponding RMSEs are 6.03, 6.62, 6.75, and 5.26, respectively

Table 2: Comparison of four support vector learning methods for right censored data using a linear kernel, with censoring times following the Cox proportional hazards model

for each method. Under the setting in Table 2 with 60% censoring rate, no noise variable and $n = 100$, the correlations for the four methods are 0.52, 0.42, 0.40, and 0.55, respectively, and the RMSEs are 5.52, 5.76, 5.94, and 5.06.

In our next simulation experiment, we compare SVHM with Cox model based analysis and explore 1-nearest-neighbor (1-NN) prediction and the average of 3-nearest-neighbors (3-NN) prediction. In the first setting we generate five discrete covariates $\mathbf{Z} = (Z_1, \dots, Z_5)$ with equal probability of taking each value: Z_1 takes values $-5, -4, -2, -1$ or 0 ; Z_2 takes values $-1, 0$ or 1 ; Z_3 takes integer values 1 to 10 ; Z_4 has a correlation of 0.5 with Z_1 and is also correlated with a random normal noise variable $N(0, 0.5)$, and Z_5 has a correlation of 0.3 with Z_1 and is also correlated with a random uniform noise variable $U(0, 0.5)$. Similar to the previous simulations, the event times were generated from Cox proportional hazards model with true $\beta = (-2, -1.6, 1.2, -0.8, 0.4)^T$ and the exponential distribution with $\lambda = 0.25$ was assumed for the baseline cumulative hazard function $\Lambda(t)$. The distribution of the censoring times followed Cox proportional hazards model with true $\beta_c = (1, 1, 1, -2, -2)^T$ and the baseline hazard rate was a constant. In the second setting, we generated Z_1, \dots, Z_3 independently from $U(0, 1)$ and Z_4 from a binary distribution with $P(Z_4 = 1) = P(Z_4 = -1) = 0.5$. Furthermore, both the event times and censoring times were generated from accelerated failure time models with both main effects and interactions:

$$\log T = -0.2 - 0.5Z_1 + 0.5Z_2 + 0.3Z_3 + 0.5Z_4 - 0.1Z_1Z_4 - 0.6Z_2Z_4 + 0.1Z_3Z_4 + N(0, 1),$$

$$\log C = 0.5 - 0.8Z_1 + 0.4Z_2 + 0.4Z_3 + 0.5Z_4 - 0.1Z_1Z_4 - 0.6Z_2Z_4 + 0.3Z_3Z_4 + N(0, 1).$$

The censoring ratio was around 30% in both settings. We experimented two sample sizes, 100 or 200, and two numbers of noise variables, 10 or 30.

The simulation results are summarized in Table 3. The same 1-NN or 3-NN method was applied to predict event times using the fitted scores derived from SVHM or Cox model. We can see that 1-NN performs slightly better than 3-NN in terms of a higher correlation and lower RMSE for both methods. In addition, when the event times were simulated from the Cox model, SVHM with 1-NN or 3-NN performs similarly to Cox model-based analysis. This is expected since proportional hazards assumption was satisfied for the Cox model based method. We also compared using 1-NN and 3-NN for prediction with using median survival times under a Cox model. We see 1-NN with SVHM or 1-NN with Cox model leads to superior performance than using median survival time. When the true model for the event times was accelerated failure time model (AFT), SVHM outperforms Cox model based analysis in terms of a higher correlation and lower RMSE. In the AFT model case, using the median survival time from the Cox model for prediction tends to be less accurate since the model assumption does not hold. Lastly, when the number of noise variables was 95, Cox model analysis did not converge in most simulations and thus the results were not included. In summary, results in Table 3 show that nearest neighbor based prediction rule performs better than using median survival time, and SVHM performs better than Cox model based methods when the model assumption does not hold.

4.2 PREDICT-HD Study

In the first real data analysis, we apply various methods to a study on Huntington's disease (HD). HD is a severe dominant genetic disorder for which at risk subjects can be identified

Table 3: Comparison of SVHM with Cox model based methods

through a genetic testing of C-A-G expansion status at the IT15 gene (MacDonald et al., 1993). The availability of genetic testing and virtually complete penetrance of gene provides opportunity for early intervention. Currently a major research interest in HD is to combine salient clinical markers and biological markers sensitive enough to detect early indicators of patient disease diagnosis before evident clinical signs of HD emerge, and thus inform early interventions long before the clinical diagnosis. The hope of such early detection and intervention is to alter the disease course before substantial damage has occurred. The most promising markers thus far are brain imaging biomarkers and some cognitive markers which correlate with future clinical diagnosis (Paulsen, 2011; Paulsen et al., 2014).

We perform analysis using data collected in the PREDICT-HD study (Paulsen et al. 2008b; data available through dbGap: http://www.ncbi.nlm.nih.gov/projects/gap/cgi-bin/study.cgi?study_id=phs000222.v3.p2). PREDICT-HD is by far the largest and most comprehensive study of prodromal HD subjects that collects clinical, cognitive and structural MRI imaging biomarkers predictive of HD onset. Pre-manifest HD subjects in the absence of experimental treatment were recruited and followed to monitor HD symptom progression and assess HD onset. In our analyses, there were 647 subjects and 118 of them developed HD during the course of study. For each subject, a wide range of measures on motor, psychiatric, cognitive signs as well as MRI imaging markers were collected at the baseline visit. The covariates cover important clinical, cognitive, functional, psychiatric and imaging domains of HD including CAP score (a combination of age and C-A-G repeats length, Zhang et al. (2011)), symbol digital modality test (SDMT), STROOP color, word and interference tests, total functional capacity scores, UHDRS total motor scores, various SCL-90 psychiatric scores, demographic variables such as gender and education in years, and imaging measures based on regional brain volumes. The structural MRI T1-weighted imaging analysis of subcortical and cortical segmentations and cortical parcellations were based on a customized FreeSurfer 5.2 pipeline developed at The University of Iowa. The details of imaging preprocessing and analysis are available in the online Supplementary Material of Paulsen et al. (2014). The subcortical volumetric measures of interest include nucleus accumbens, caudate, putamen, hippocampus, and thalamus (Paulsen et al., 2014).

We study the combined prediction capability of 31 baseline markers predicting the age-at-onset of HD diagnosis during the study period, and evaluate the usefulness of the fitted prediction score on performing risk stratification. The covariates are normalized to the same scale to achieve numeric stability and allow for comparing their relative importance. The predicted values of HD onset ages are obtained via three-fold cross validation, and the cost tuning parameter is chosen from the grid $2^{-16}, 2^{-15}, \dots, 2^{16}$. We consider both linear kernel and Gaussian kernel. For the Gaussian kernel $K(x, x') = \exp(-\gamma \|x - x'\|^2)$, the parameter γ is fixed to be 0.005. To compare the prediction capability, we compute several quantities using the predicted values of onset ages and the observed onset ages or censoring ages. Specifically, we report the concordance index defined as the percentage of correctly ordered pairs among all feasible pairs (C-index) when including imaging markers. To evaluate the ability of the fitted scores on performing risk stratification, we separated subjects into two groups (high risk versus low risk group) based on whether their predicted scores are higher or lower than given percentiles computed from all subjects' fitted scores. We then calculate the Chi-square statistics from the logrank test and the hazard ratios comparing the hazard rate of developing HD between two groups.

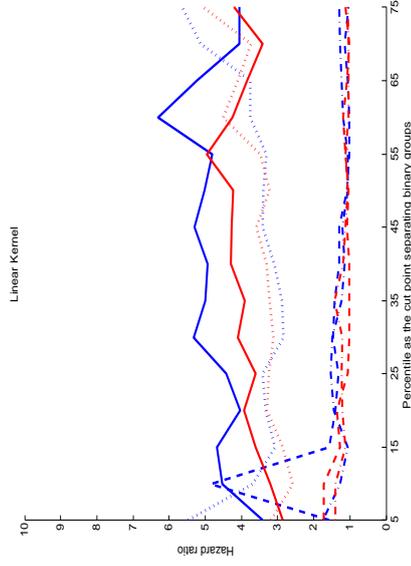

Figure 1: Hazard ratios comparing two groups separated using percentiles of predicted scores as cut points for PREDICT-HD data with linear kernel. Blue curves obtained from analyses with MRI imaging biomarkers and red curves without imaging biomarkers. Solid curve: SVHM; Dotted curve: Modified SVR; Dashed curve: IPCW-KM; Dashed-dotted curve: IPCW-Cox.

The analysis results are given in Table 4. SVHM improves over the other methods with respect to all the quantities for both linear kernel and Gaussian kernel, and the performances are similar using different kernels. For example, the logrank Chi-square statistics and hazard ratios of SVHM are much larger than the competing methods at most quantiles except at the right tail (e.g., over 65th percentile). A higher value of logrank Chi-square and a larger hazard ratio indicate greater difference between high risk and low risk subjects using a given percentile as a cut off value, and thus better discriminant ability of a risk score distinguishing high/low risk subjects. In addition, the predictions from IPCW cannot capture the trend of the original disease onset ages. Figure 1 complements the results in the table by plotting the hazard ratios comparing two groups separated using a series of percentiles of the predicted scores as cut points, and SVHM consistently has the largest hazard ratio across all percentiles among all methods. The improvement of SVHM increases at the higher percentiles, indicating that it is particularly effective in discriminating high risk subjects. This observation is consistent with our theoretical results which reveal that SVHM is optimal in separating the individual covariate-specific hazard function, $h(t, \mathbf{x})$ given \mathbf{x} , from the population average hazard function, $h(t)$.

Additionally, we show the fitted coefficients from SVHM and other competing methods in Table 5 and compare with coefficients obtained from a Cox proportional hazards model.

Table 4: Comparison of prediction capability for different methods using PREDICT-HD data with and without structural MRI imaging measures ($n = 647$)

Modified SVR yields coefficients in the same direction as SVHM, while two IPW methods give several coefficients in the opposite direction of other methods. SVHM suggests the top ranking markers with largest standardized effects to be the baseline total motor score and CAP score, which is consistent with the clinical literature on the importance of these markers on the diagnosis of HD (Zhang et al., 2011; Paulsen et al., 2014; Chen et al., 2014). The baseline total motor score as a measure of motor impairment appears to be more informative than CAP score in terms of predicting future HD diagnosis during the study. Several neuropsychological markers (Stroop color, Stroop word, SDMT) are predictive except for Stroop interference score. The coefficients from Cox model however, suggest that SDMT is not important, which is not consistent with the clinical literature (Paulsen, 2011; Paulsen et al., 2014). Note that SVHM gives psychiatric markers (SCL 90 depression, GSI, PST and PSDI) low weights which is consistent with clinical observations that the psychiatric markers are considered as noisy for predicting HD diagnosis due to reasons such as subjects may seek treatment for their psychiatric symptoms. In contrast, Cox model yields high weights for these markers which are deemed to be less informative.

In terms of neuroimaging markers, we see that pallidum, putamen, caudate, and thalamus show relatively strong predictive ability of HD onset, while accumbens and hippocampus show low predictive ability. Comparing SVHM and Cox model analysis, note that SVHM provides coefficients with similar magnitude for imaging measures on the left and right side of the same brain region, but Cox model sometimes produces substantially different results for left and right side. For example, left pallidum area is significant but not right pallidum area in Cox model. This observation suggests that SVHM may lead to more interpretable results especially for correlated variables. Another biomarker, cerebral spinal fluid, appears to be promising for predicting HD onset with a coefficient with moderate magnitude. To assess the added value of MRI imaging measures in terms of risk stratification, in Figure 1 we show the hazard ratio comparing high risk versus low risk group based on percentile split of the fitted scores obtained with and without imaging biomarkers. For SVHM with linear kernel, adding imaging measures leads to a larger hazard ratio and a greater difference between high and low risk groups at all percentiles, which demonstrates the ability of SVHM to extract information from imaging biomarkers and corroborates other findings suggesting their added values in predicting HD onset (Paulsen et al., 2014). When using Gaussian kernel for SVHM, we see further improvement of C-index and logrank chi-square statistics. Other methods such as modified SVR or IPCW do not show an advantage from including imaging measures, which may suggest their limitations in handling correlated biomarkers.

4.3 ARIC Study

As a second real world numeric example, we analyze data from the Atherosclerosis Risk in Communities Study, a prospective investigation of the aetiology of atherosclerosis and its clinical sequelae, as well as the variation in cardiovascular risk factors, medical care and disease by race, gender, location and date (The ARIC investigators, 1989; Lubin et al., 2016). We assess the prediction capability of some common cardiovascular risk factors for incident heart failure until 2005. Specifically, these risk factors include age, diabetes status, body mass index, systolic blood pressure, fasting glucose, serum albumin, serum creatinine, heart

rate, left ventricular hypertrophy, bundle branch block, prevalent coronary heart disease, valvular heart disease, high-density lipoprotein, pack-years of smoking, and current and former smoking status. The analysis sample consists of 624 participants who are African-American males living in Jackson, Mississippi. Incident heart failure occurred in 133 men through 2005, with a median follow-up time 16.2 years. Among those participants who did not develop heart failure, 324 were administratively censored on December 31st, 2005. The analysis follows the same procedure as in Section 4.2. The results for prediction capability of different methods are given in Table 6. SVHM provides more accurate prediction than other methods using the linear kernel or Gaussian kernel. It also has higher logrank test statistic and hazard ratio comparing high risk versus low risk group using various percentiles of the predictive scores as cut off points (Figure 2).

In Table 7, we can see that all the risk factors have positive effects on the incident heart failure except high-density lipoprotein, serum albumin and former smoking status. Risk factors for incident heart failure with largest standardized effects include HDL, age, prevalent CHD, and serum albumin level. We also present estimated coefficients from a Cox proportional hazards model as comparison in Table 7. Most coefficients are comparable in terms of size. However, note that higher fasting glucose level appears to be protective of heart rate failure using Cox model, which is the opposite of the expected direction.

5. Concluding Remarks

In this paper, we propose a new statistical framework to learn risk scores for event times using right-censored data by support vector hazards machine. We propose to view the prediction of time-to-event outcomes from a counting process point of view to avoid complications from specifying a censoring distribution. Asymptotically, we justify the associated universal consistency and learning rate through the structural risk minimization and show a natural link between the fitted decision function and the true hazard function: the fitted decision rule asymptotically minimizes the integrated difference between the covariate-specific hazard function and population average hazard function. Our theory shows that SVHM essentially compares events and non-events among the subjects at risk at each follow-up time; therefore, SVHM is sensitive to temporal difference between events and non-events which may not be reflected in either SVR or inverse weighted approaches. We also reveal a theoretical connection between SVHM and Cox partial likelihood function; the proposed method uses a hinge loss which should be robust to extreme observations in contrast to the exponential loss used in Cox partial likelihood. The simulation studies and real data applications demonstrate satisfactory results in finite samples with improved overall risk prediction accuracy in the presence of noise variables compared to other methods, especially when the censoring rate is high and the distribution of censoring times is unknown. The improved performance of our method is due to introducing counting processes to represent the time-to-event data, which leads to an intuitive connection of the method with both support vector machines in standard supervised learning and hazard regression models in standard survival analysis.

Since SVHM essentially learns hazard functions across subjects conditional on each risk set, the intercept term, $\alpha(t)$, is a non-informative nuisance parameter and allowed to be discontinuous over time. This feature is analogous to the estimation in Cox regression

through maximizing the Cox partial likelihood function, where the baseline hazard function is estimated to be non-continuous. Furthermore, due to the martingale property of the counting process, data from each time point can be viewed as independent in the learning method, despite that they may be from the same individual. Thus, we expect little efficiency loss even though some weighing scheme can be adopted to weight distinct risk sets differently over time.

In the current framework, the time-specific risk score $f(t, \mathbf{X})$ being considered includes a class of additive rules. They can be generalized to be fully nonparametric to learn dynamic risk profiles using a subject's time-varying covariates under the current set up. However, this generalization may lose the similarity of formulation to the standard support vector machines and cause numerical instability in the optimization algorithm. These challenging issues will be further investigated in future work. One limitation of the current nonparametric framework not specifying the event distribution is that no straightforward prediction formulae using distribution exist. We used nearest neighbors to perform prediction and simulation studies show that using less closer neighbors (3-NN instead of 1-NN) has little influence on the results. In our simulation studies, we found that a training sample size of $n = 100$ or $n = 200$ both yield stable estimation of correlation and RMSE (not sensitive to the choice of 1-NN or 3-NN). However, further work is needed to examine alternative prediction methods. Lastly, this work opens possibilities to use other powerful learning algorithms for binary and continuous outcomes to handle censored outcomes. For example, instead of using series of SVM to predict counting process as demonstrated here, other effective tools such as AdaBoosting and random forest can also be used. Gaussian process approaches (Barrett and Coolen, 2013) have been recently applied for survival data with competing risks so it will be interesting to compare SVHM with their approaches in terms of prediction performance and robustness.

Appendix A. SVHM Algorithm

In this section, we provide a detailed description of the SVHM algorithm:

Algorithm: SVHM for Censored Outcomes

Input: Training data $(\mathbf{X}_i, T_i \wedge C_i, Y_i(t_j), \delta N_i(t_j))$ for $i = 1, \dots, n, j = 1, \dots, m$.

Step 1. Solve the quadratic programming problem:

$$\max_{\gamma_{ij}} \sum_{i=1}^n \sum_{j=1}^m \gamma_{ij} Y_i(t_j) - \frac{1}{2} \sum_{i=1}^n \sum_{i'=1}^n \sum_{j=1}^m \sum_{j'=1}^m \gamma_{ij} \gamma_{i'j'} Y_i(t_j) Y_{i'}(t_{j'}) \delta N_i(t_j) \delta N_{i'}(t_{j'}) K(\mathbf{X}_i, \mathbf{X}_{i'})$$

subject to: $0 \leq \gamma_{ij} \leq w_i(t_j) C_{ni}, \sum_{i=1}^n \gamma_{ij} Y_i(t_j) \delta N_i(t_j) = 0, i = 1, \dots, n, j = 1, \dots, m$.

Denote the solutions as $\hat{\gamma}_{ij}$.

Step 2. Compute the risk scores for non-censored subjects in the training data as

$$\hat{g}(\mathbf{X}_s) = \sum_{i=1}^n \sum_{j=1}^m \hat{\gamma}_{ij} \delta N_i(t_j) K(\mathbf{X}_s, \mathbf{X}_i).$$

Step 3. Predicting event time of a future subject with covariates \mathbf{x} by k -nearest-neighbor:

- Compute the risk score for this subject as $\hat{g}(\mathbf{x}) = \sum_{i=1}^n \sum_{j=1}^m \hat{\gamma}_{ij} \delta N_i(t_j) K(\mathbf{x}, \mathbf{X}_i)$.
 - Find k non-censored subjects in the training data whose risk scores are closest to $\hat{g}(\mathbf{x})$ and denote them as $\hat{g}(\mathbf{X}_l)$ for $l = 1, \dots, k$.
 - Sort all $\hat{g}(\mathbf{X}_s)$ in descending order and denote the rank of $\hat{g}(\mathbf{X}_l)$ as r_l .
 - Sort event times T_s of all non-censored subjects in ascending order. Find the r_l -th event time and denote as T_l for $l = 1, \dots, k$.
 - The event time for this subject is predicted as $\hat{T} = \frac{1}{k} \sum_{l=1}^k T_l$.
- Output:** For a subject with covariates \mathbf{x} , predict risk score as $\hat{g}(\mathbf{x})$, and predict event time as \hat{T} .
-

Appendix B. Proof of Theorems

In this section, we prove Theorem 3.1 and Theorem 3.2.

Proof (Theorem 3.1)

Since $f^*(t, \mathbf{x})$ minimizes $\mathcal{R}(f)$, conditional $\mathbf{X} = \mathbf{x}$, $f^*(t, \mathbf{x})$ also minimizes

$$E \left(\int Y(t) [1 - f(t, \mathbf{X})]_+ dN(t) | \mathbf{X} = \mathbf{x} \right) + \int \frac{E(Y(t) [1 + f(t, \mathbf{X})]_+ | \mathbf{X} = \mathbf{x})}{E(Y(t))} E(dN(t)). \quad (A.1)$$

Clearly, the value $f^*(t, \mathbf{x})$ should belong to the interval $[-1, 1]$, because otherwise truncation of f at -1 or 1 gives a lower value. Assuming $-1 \leq f(t, \mathbf{x}) \leq 1$, (A.1) becomes

$$\int E(Y(t) | \mathbf{X} = \mathbf{x}) \{h(t, \mathbf{x}) + \bar{h}(t)\} dt - \int f(t, \mathbf{x}) E(Y(t) | \mathbf{X} = \mathbf{x}) \{h(t, \mathbf{x}) - \bar{h}(t)\} dt,$$

where recall that $h(t, \mathbf{x})$ is the conditional hazard rate of $T = t$ given $\mathbf{X} = \mathbf{x}$ and $\bar{h}(t)$ is the population average hazard at time t ,

$$\bar{h}(t) = \frac{E[dN(t)]/dt}{E[Y(t)]} = E[h(t, \mathbf{X}) | Y(t) = 1].$$

Therefore, one optimal decision function minimizing $\mathcal{R}_L(f)$ is

$$f^*(t, \mathbf{x}) = \text{sign}\{h(t, \mathbf{x}) - \bar{h}(t)\}.$$

On other hand, we note

$$\mathcal{R}_0(f) = \int I[f(t, \mathbf{x}) \leq 0] E(Y(t) | \mathbf{X} = \mathbf{x}) h(t, \mathbf{x}) dt + \int I[f(t, \mathbf{x}) \geq 0] E(Y(t) | \mathbf{X} = \mathbf{x}) \bar{h}(t) dt.$$

Thus, any decision function has the same sign as $(h(t, \mathbf{x}) - \bar{h}(t))$ minimizes $\mathcal{R}_0(f)$ so $f^*(t, \mathbf{x})$ minimizes $\mathcal{R}_0(f)$. Finally, under the optimal rule $f^*(t, \mathbf{x})$, the minimal value of the weighted 0-1 risk is given as

$$\begin{aligned} \mathcal{R}_0(f^*) &= E \left[\int E(Y(t) | \mathbf{X} = \mathbf{x}) \min\{h(t, \mathbf{x}), \bar{h}(t)\} dt \right] \\ &= \frac{1}{2} E \left[\int E(Y(t) | \mathbf{X} = \mathbf{x}) \{h(t, \mathbf{x}) + \bar{h}(t) - |h(t, \mathbf{x}) - \bar{h}(t)|\} dt \right] \\ &= P(T \leq C) - \frac{1}{2} E \left[\int E(Y(t) | \mathbf{X} = \mathbf{x}) |h(t, \mathbf{x}) - \bar{h}(t)| dt \right]. \end{aligned}$$

To show the last inequality in Theorem 3.1, we note that for $-1 \leq f(t, \mathbf{x}) \leq 1$,

$$\begin{aligned} \mathcal{R}(f) &= E \left[\int E(Y(t) | \mathbf{X} = \mathbf{x}) \{h(t, \mathbf{x}) + \bar{h}(t)\} dt - \int f(t, \mathbf{x}) E(Y(t) | \mathbf{X} = \mathbf{x}) \{h(t, \mathbf{x}) - \bar{h}(t)\} dt \right] \\ &= 2P(T \leq C) - E \left[\int f(t, \mathbf{x}) E(Y(t) | \mathbf{X} = \mathbf{x}) \{h(t, \mathbf{x}) - \bar{h}(t)\} dt \right], \end{aligned}$$

and

$$\mathcal{R}(f^*) = 2P(T \leq C) - E \left[\int \text{sign}\{h(t, \mathbf{x}) - \bar{h}(t)\} E(Y(t) | \mathbf{X} = \mathbf{x}) \{h(t, \mathbf{x}) - \bar{h}(t)\} dt \right].$$

Thus,

$$\begin{aligned} \mathcal{R}(f) - \mathcal{R}(f^*) &= E \left[\int E(Y(t) | \mathbf{X} = \mathbf{x}) \{ \text{sign}\{h(t, \mathbf{x}) - \bar{h}(t)\} - f(t, \mathbf{x}) \} \times \{h(t, \mathbf{x}) - \bar{h}(t)\} dt \right] \\ &= E \left[\int E(Y(t) | \mathbf{X} = \mathbf{x}) |f(t, \mathbf{x}) - \text{sign}\{h(t, \mathbf{x}) - \bar{h}(t)\}| \times |h(t, \mathbf{x}) - \bar{h}(t)| dt \right] \end{aligned}$$

On the other hand, for the risk function based on the 0-1 loss, we have

$$\begin{aligned} \mathcal{R}_0(f) - \mathcal{R}_0(f^*) &= E \left[\int E(Y(t) | \mathbf{X} = \mathbf{x}) (I[f(t, \mathbf{x}) \leq 0] h(t, \mathbf{x}) + I[f(t, \mathbf{x}) \geq 0] \bar{h}(t) - \min\{h(t, \mathbf{x}), \bar{h}(t)\}) dt \right] \\ &= E \left[\int E(Y(t) | \mathbf{X} = \mathbf{x}) |h(t, \mathbf{x}) - \bar{h}(t)| \times I\{|h(t, \mathbf{x}) - \bar{h}(t)\} \text{sign}\{f(t, \mathbf{x})\} < 0\} dt \right]. \end{aligned}$$

Note that

$$I(\{h(t, \mathbf{x}) - \bar{h}(t)\} \text{sign}\{f(t, \mathbf{x})\} < 0) \leq |f(t, \mathbf{x}) - \text{sign}\{h(t, \mathbf{x}) - \bar{h}(t)\}|.$$

We then obtain $\mathcal{R}_0(f) - \mathcal{R}_0(f^*) \leq \mathcal{R}(f) - \mathcal{R}(f^*)$. \blacksquare

Proof (Theorem 3.2)

The proof of Theorem 3.2 follows a similar procedure to the standard support vector machine theory. However, the main difference is that the proof handles $\mathcal{P}\mathcal{R}_n(f)$ instead of the simple empirical mean of the hinge-loss in the standard theory. Let g_n be the function in \mathcal{H}_n which minimizes $\lambda_n \|g\|_{\mathcal{H}_n}^2 + \mathcal{P}\mathcal{R}(g)$. The proof consists of the following steps.

First, we derive a preliminary bound for some norms of \hat{g} . Clearly,

$$\lambda_n \|g_{\lambda_n}\|_{\mathcal{H}_n}^2 + \mathcal{P}\mathcal{R}(g_{\lambda_n}) \leq \mathcal{P}\mathcal{R}(0).$$

This gives $\|g_{\lambda_n}\|_{\mathcal{H}_n} \leq \sqrt{c/\lambda}$ for some constant λ_n so by Lemma 4.23 (Steinwart and Christmann, 2008, p124), we obtain $\|g_{\lambda_n}\|_{\infty} \leq \sqrt{c/\lambda_n}$. Furthermore, using the fact

$$\lambda_n \|\hat{g}\|_{\mathcal{H}_n}^2 + \mathcal{P}\mathcal{R}_n(\hat{g}) \leq \lambda_n \|g_{\lambda_n}\|_{\mathcal{H}_n}^2 + \mathcal{P}\mathcal{R}_n(g_{\lambda_n}),$$

we conclude $\|\hat{g}\|_{\mathcal{H}_n} \leq \sqrt{c/\lambda_n}$ so $\|\hat{g}\|_{\infty} \leq \sqrt{c/\lambda_n}$, where c may be another different constant (without confusion, we always use c to denote some constant). Therefore, we can restrict g in the minimization of (2) to be in $\sqrt{c/\lambda_n} \mathcal{B}_{\mathcal{H}_n}$, where $\mathcal{B}_{\mathcal{H}_n}$ be the unit ball in \mathcal{H}_n .

Second, we obtain a key inequality for comparing the risks of \hat{g} and g_{λ_n} . By the definition of \hat{g} , the following fact holds:

$$\begin{aligned} & \lambda_n \|\hat{g}\|_{\mathcal{H}}^2 + \mathcal{P}\mathcal{R}(\hat{g}) - (\lambda_n \|g_{\lambda_n}\| + \mathcal{P}\mathcal{R}(g_{\lambda_n})) \\ & \leq \lambda_n \|\hat{g}\|_{\mathcal{H}}^2 + \mathcal{P}\mathcal{R}(\hat{g}) - (\lambda_n \|g_{\lambda_n}\| + \mathcal{P}\mathcal{R}(g_{\lambda_n})) \\ & \quad - [\lambda_n \|\hat{g}\|_{\mathcal{H}}^2 + \mathcal{P}\mathcal{R}_n(\hat{g}) - (\lambda_n \|g_{\lambda_n}\| + \mathcal{P}\mathcal{R}_n(g_{\lambda_n}))] \\ & = \mathcal{P}\mathcal{R}(\hat{g}) - \mathcal{P}\mathcal{R}_n(\hat{g}) - \{\mathcal{P}\mathcal{R}(g_{\lambda_n}) - \mathcal{P}\mathcal{R}_n(g_{\lambda_n})\}. \end{aligned}$$

From Step 1, we conclude

$$\lambda_n \|\hat{g}\|_{\mathcal{H}}^2 + \mathcal{P}\mathcal{R}(\hat{g}) - (\lambda_n \|g_{\lambda_n}\| + \mathcal{P}\mathcal{R}(g_{\lambda_n})) \leq 2 \sup_{\|g\|_{\mathcal{H}_n} \leq \sqrt{c/\lambda_n}} |\mathcal{P}\mathcal{R}_n(g) - \mathcal{P}\mathcal{R}(g)|. \quad (\text{A.2})$$

We derive a bound for the right-hand side of (A.2). First,

$$\mathcal{P}\mathcal{R}_n(g) - \mathcal{P}\mathcal{R}(g) = (\mathbf{P}_n - \mathbf{P})f_g(Y, \mathbf{X}, \Delta) - \frac{2}{n} \mathbf{P}_n \left\{ \frac{\Delta}{\tilde{\mathbf{P}}_n[I(\tilde{Y} \geq Y)]} \right\},$$

where

$$\begin{aligned} f_g(Y, \mathbf{X}, \Delta) &= \Delta \frac{\tilde{\mathbf{P}}_n\{I(\tilde{Y} \geq Y)[2 + g(\tilde{\mathbf{X}}) - g(\mathbf{X})]_+\}}{\tilde{\mathbf{P}}_n[I(\tilde{Y} \geq Y)]} + \tilde{\mathbf{P}} \left(\frac{\Delta I(Y \geq \tilde{Y})[2 + g(\mathbf{X}) - g(\tilde{\mathbf{X}})]_+}{\tilde{\mathbf{P}}_n[I(\tilde{Y} \geq Y)]} \right) \\ &= \tilde{\mathbf{P}} \left(\frac{\Delta I(Y \geq \tilde{Y}) \mathbf{P}^*\{I(Y^* \geq \tilde{Y})[2 + g(\mathbf{X}^*) - g(\tilde{\mathbf{X}})]_+\}}{\mathbf{P}_n^*\{I(Y^* \geq \tilde{Y})\} \mathbf{P}^*\{I(Y^* \geq \tilde{Y})\}} \right). \end{aligned}$$

Therefore,

$$\sup_{\|g\|_{\mathcal{H}_n} \leq \sqrt{c/\lambda_n}} |\mathcal{P}\mathcal{R}_n(g) - \mathcal{P}\mathcal{R}(g)| \leq \sup_{\|g\|_{\mathcal{H}_n} \leq \sqrt{c/\lambda_n}} |(\mathbf{P}_n - \mathbf{P})f_g| + c/n.$$

On the other hand, from Theorem 3.1 in Steinwart and Scovel (2007), we have

$$\log N(\epsilon, \sqrt{c/\lambda_n} \mathcal{B}_{\mathcal{H}_n}, l_{\infty}) \leq c_{p,d} \sigma_n^{(p/4-1)d} \left(\frac{\epsilon}{\sqrt{c/\lambda_n}} \right)^{-p} \leq c_{p,d} \sigma_n^{(p/4-1)d} \lambda_n^{-p/2} \epsilon^{-p},$$

where $N(\epsilon, \mathcal{F}, l_{\infty})$ is the ϵ -covering number of \mathcal{F} under l_{∞} -norm, d is the dimension of \mathbf{X} , p is any number in $(0, 2)$ and $c_{p,d}$ is a constant only depending on (p, d) . Moreover, we note that by the property of the hinge-loss, f_g is the Lipschitz continuous in g and satisfies

$$|f_{g_1} - f_{g_2}| \leq c|g_1 - g_2|.$$

This implies

$$\log N(\epsilon, \{f_g/a_n : g \in \sqrt{c/\lambda_n} \mathcal{B}_{\mathcal{H}_n}\}, l_{\infty}) \leq c_{p,d} \sigma_n^{(p/4-1)d} \epsilon^{-p},$$

where $a_n = \sqrt{c/\lambda_n} \sigma_n^{-(1-p/4)d/p}$. Therefore, according to Theorem 2.14.10 in van der Vaart and Wellner (1996), we obtain

$$P \left(\sqrt{n} \sup_{\|g\|_{\mathcal{H}_n} \leq \sqrt{c/\lambda_n}} |(\mathbf{P}_n - \mathbf{P})(f_g/a_n)| > x \right) \leq e^{-cx^2}$$

for some constant c only depending on (p, d) . Consequently, (A.2) gives

$$P(\lambda_n \|\hat{g}\|_{\mathcal{H}}^2 + \mathcal{P}\mathcal{R}(\hat{g}) - (\lambda_n \|g_{\lambda_n}\| + \mathcal{P}\mathcal{R}(g_{\lambda_n})) > cn^{-1} + a_n n^{-1/2} x) \leq e^{-cx^2}. \quad (\text{A.3})$$

Hence, we have proved

$$\lambda_n \|\hat{g}\|_{\mathcal{H}_n}^2 + \mathcal{P}\mathcal{R}(\hat{g}) \leq \inf_{g \in \mathcal{H}_n} \{\lambda_n \|g\|_{\mathcal{H}_n} + \mathcal{P}\mathcal{R}(g)\} + O_p \left(\frac{\lambda_n^{-1/2} \sigma_n^{-(1/p-1/4)d}}{\sqrt{n}} \right). \quad (\text{A.3})$$

Let $g^* = \text{argmin} \mathcal{P}\mathcal{R}(g)$. From the expression of $\mathcal{P}\mathcal{R}(g)$, we note

$$|\mathcal{P}\mathcal{R}(g) - \mathcal{P}\mathcal{R}(g^*)| \leq c \|g - g^*\|_{L_1(\mathcal{P})}.$$

Thus, if we define

$$\tilde{g}(\mathbf{x}) = \frac{2\sigma_n^{-d/2}}{\pi^{d/4}} \int e^{-\|x-y\|^2/(2\sigma_n^2)} g^*(y) dy,$$

then $\tilde{g} \in \mathcal{H}_n$ and

$$\|g - g^*\|_{\mathcal{H}_n} \leq \|g - \tilde{g}\|_{L_2(\mathcal{P})} \leq c\sigma_n^{d/2}.$$

Therefore,

$$\inf_{g \in \mathcal{H}_n} \{\lambda_n \|g\|_{\mathcal{H}_n} + \mathcal{P}\mathcal{R}(g)\} \leq \{\lambda_n \|\tilde{g}\|_{\mathcal{H}_n} + \mathcal{P}\mathcal{R}(\tilde{g})\} \leq \mathcal{P}\mathcal{R}(g^*) + c\sigma_n^{d/2} + c\lambda_n,$$

and the result in Theorem 3.2 holds. \blacksquare

Abstract

Stable random variables are motivated by the central limit theorem for densities with (potentially) unbounded variance and can be thought of as natural generalizations of the Gaussian distribution to skewed and heavy-tailed phenomenon. In this paper, we introduce α -stable graphical (α -SG) models, a class of multivariate stable densities that can also be represented as Bayesian networks whose edges encode linear dependencies between random variables. One major hurdle to the extensive use of stable distributions is the lack of a closed-form analytical expression for their densities. This makes penalized maximum-likelihood based learning computationally demanding. We establish theoretically that the *Bayesian information criterion* (BIC) can asymptotically be reduced to the computationally more tractable *minimum dispersion criterion* (MDC) and develop **Stable**, a structure learning algorithm based on MDC. We use simulated datasets for five benchmark network topologies to empirically demonstrate how **Stable** improves upon ordinary least squares (OLS) regression. We also apply **Stable** to microarray gene expression data for lymphoblastoid cells from 727 individuals belonging to eight global population groups. We establish that **Stable** improves test set performance relative to OLS via ten-fold cross-validation. Finally, we develop **SGEX**, a method for quantifying differential expression of genes between different population groups.

Keywords: Bayesian networks, stable distributions, linear regression, structure learning, gene expression, differential expression

1. Introduction

Stable distributions have found applications in modeling several real-life phenomena (Berger and Mandelbrot, 1963; Mandelbrot, 1963; Nikias and Shao, 1995; Gallardo et al., 2000; Achim et al., 2001) and have robust theoretical justification in the form of the generalized central limit theorem (Feller, 1968; Nikias and Shao, 1995; Nolan, 2013). Several special instances of multivariate generalization of stable distributions have also been described in literature (Samorodnitsky and Taqqu, 1994; Nolan and Rajput, 1995). Multivariate stable densities have previously been applied to modeling wavelet coefficients with bivariate α -

stable distributions (Achim and Kuruoglu, 2005), inferring parameters for linear models of network flows (Bickson and Guestrin, 2011) and stock market fluctuations (Bonato, 2012).

In this paper, we describe α -stable graphical (α -SG) models, a new class of multivariate stable densities that can be represented as directed acyclic graphs (DAG) with arbitrary network topologies. We prove that these multivariate densities also correspond to linear regression-based Bayesian networks and establish a model selection criterion that is asymptotically equivalent to the *Bayesian information criterion* (BIC). Using simulated data for five benchmark network topologies, we empirically show how α -SG models improve structure and parameter learning performance for linear regression networks with additive heavy-tailed noise.

One motivation for the present work comes from potential applications to computational biology, especially in genomics, where Bayesian network models of gene expression profiles are a popular tool (Friedman et al., 2000; Ben-Dor et al., 2000; Friedman, 2004). A common approach to network models of gene expression involves learning linear regression-based Gaussian graphical models. However, the distribution of experimental microarray intensities shows a clear skew and may not necessarily be best described by a Gaussian density (Section 3.2). Another aspect of microarray intensities is that they represent the average mRNA concentration in a population of cells. Assuming the number of mRNA transcripts within each cell to be independent and identically distributed, the generalized central limit theorem suggests that the observed shape should asymptotically (for large population size) approach a stable density (Feller, 1968; Nikias and Shao, 1995; Nolan, 2013). Univariate stable distributions have previously been used to model gene expression data (Salas-Gonzalez et al., 2009a,b) and it is therefore natural to consider multivariate α -stable densities as models for mRNA expression for larger sets of genes. In Section 3.2 we provide empirical evidence to support this reasoning. We further develop α -stable graphical (α -SG) models for quantifying differential expression of genes from microarray data belonging to phase III of the HapMap project (International HapMap 3 Consortium and others, 2010; Montgomery et al., 2010; Stranger et al., 2012).

The rest of the paper is structured as follows : Section 2.1 describes the basic notation and background concepts for Bayesian networks and stable densities. Section 2.2 introduces α -SG models and establishes that these models are Bayesian networks that also represent multivariate stable distributions with discrete spectral measures. Section 2.3 establishes the equivalence of the popular but (in this case) computationally challenging *Bayesian information criterion* (BIC) for structure learning and the computationally more tractable *minimum dispersion criterion* (MDC), for all α -SG models that represent symmetric densities. Furthermore, we establish how data samples from any α -SG model can be combined to generate samples from a partner symmetric α -SG model with identical network topology and regression coefficients. Using these theoretical results we design **Stable**, an efficient algorithm that combines ordering-based search (OBS) (Teyssier and Koller, 2005) for structure learning with the iteratively re-weighted least squares (IRLS) algorithm (Byrd and Payne, 1979) for learning the regression parameters via least l_p norm estimation. Finally, in Section 3 we implement the structure and parameter learning algorithm on simulated and expression microarray data sets.

2. Methods

In this section we develop the theory and algorithms for learning α -SG models from data. First, we discuss some well-established results for Bayesian networks and α -stable densities.

2.1 Background

We begin with an introduction to Bayesian network models (Pearl, 1988) for the joint probability distribution of a finite set of random variables $\mathcal{X} = \{X_1, \dots, X_N\}$. A Bayesian network $B(G, \Theta)$ is specified by a directed acyclic graph (DAG) G , whose vertices represent random variables in \mathcal{X} and a set of parameters $\Theta = \{\theta_i | X_i \in \mathcal{X}\}$, that determine the conditional probability distribution $p(X_i | Pa(X_i), \theta_i)$ for each variable $X_i \in \mathcal{X}$ given the state of its parents $Pa(X_i) \subseteq \mathcal{X} \setminus \{X_i\}$ in G (Koller and Friedman, 2009). We will overload the symbols X_i and $Pa(X_i)$ to represent both sets of random variables and their realizations. The directed acyclic graph G implies a factorization of the joint probability density into terms representing each variable X_i and its parents $Pa(X_i)$ (called a *family*) such that :

$$P_B(\mathcal{X}) = \prod_{i=1}^{|\mathcal{X}|} p(X_i | Pa(X_i), \theta_i) \quad (1)$$

The dependence of $p(X_i | Pa(X_i), \theta_i)$ on θ_i is usually specified by an appropriately chosen family of parameterized probability densities for the random variables, such as Gaussian or log-Normal. In this paper, we will use multivariate stable densities to model the random variables in \mathcal{X} . The primary motivation for modeling continuous random variables using stable distributions comes from the generalization of the central limit theorem to distributions with unbounded variance (Feller, 1968; Nikias and Shao, 1995). Stable distributions are parameterized to allow varying degrees of impulsiveness and skewness. The generalized central limit theorem requires that the sums of stable random variables are stable and more generally in the limit of large N , all sums of N independent, identically distributed random variables approach a stable density. A formal definition for stable random variables can be provided in terms of the characteristic function (Fourier transform of the density function)

Definition 1 A stable random variable $X \sim S_{\alpha}(\beta, \gamma, \mu)$, is defined for each $\alpha \in (0, 2]$, $\beta \in [-1, 1]$, $\gamma \in (0, \infty)$ and $\mu \in (-\infty, \infty)$. The probability density $f(X | \alpha, \beta, \gamma, \mu)$ is implicitly specified by a characteristic function $\phi(q | \alpha, \beta, \gamma, \mu)$:

$$\begin{aligned} \phi(q | \alpha, \beta, \gamma, \mu) &\equiv \mathbb{E}[\exp(iqX)] \\ &= \int_{-\infty}^{\infty} f(X | \alpha, \beta, \gamma, \mu) \exp(iqX) dX \\ &= \exp(i\mu q - \gamma |q|^\alpha [1 - i\beta \operatorname{sign}(q)^\gamma r(q, \alpha)]) \end{aligned}$$

where, $r(q, \alpha) = \begin{cases} \tan \frac{\alpha\pi}{2} & \alpha \neq 1 \\ -\frac{2}{\pi} \log |q| & \alpha = 1 \end{cases}$

The parameters α, β, γ and μ will be called the characteristic exponent, skew, dispersion and location respectively. Unfortunately, the density $f(X | \alpha, \beta, \gamma, \mu)$ does not have a closed-form analytical expression except for the three well-known stable distributions (Figure 1 and Table 1).

Distribution	$S_{\alpha}(\beta, \gamma, \mu)$	$f(X \alpha, \beta, \gamma, \mu)$	Support
Lévy(γ, μ)	$S_{0.5}(1, \gamma, \mu)$	$\frac{\sqrt{\gamma}}{\sqrt{2\pi}} \frac{1}{(x-\mu)^{3/2}} \exp\left(-\frac{\gamma^2}{2(x-\mu)}\right)$	$\mu < x < \infty$
Cauchy(γ, μ)	$S_{1.0}(0, \gamma, \mu)$	$\frac{1}{\pi} \frac{\gamma}{\gamma^2 + (x-\mu)^2}$	$-\infty < x < \infty$
Normal(μ, σ)	$S_{2.0}(0, \gamma = \frac{\sigma^2}{2}, \mu)$	$\frac{1}{\sqrt{2\pi\sigma^2}} \exp\left(-\frac{(x-\mu)^2}{2\sigma^2}\right)$	$-\infty < x < \infty$

Table 1: Closed-form analytical expressions for Lévy, Cauchy and Normal densities and the corresponding α -stable parameters.

Except for the Gaussian case, the asymptotic (large x) behavior of univariate α -stable densities shows Pareto or power law tails (Lévy, 1925). The following lemma formalizes this observation (Samorodnitsky and Taqqu, 1994; Nolan, 2013)

Lemma 1 $Hf X \sim S_{\alpha}(\beta, \gamma, 0)$ with $0 < \alpha < 2$, then as $x \rightarrow \infty$

$$Pr(X > x) \sim (1 + \beta)\gamma C_{\alpha} x^{-\alpha}$$

$$C_{\alpha} = (2 \int_0^{\infty} x^{-\alpha} \sin x dx)^{-1} = \frac{1}{\pi} \Gamma(\alpha) \sin\left(\frac{\alpha\pi}{2}\right)$$

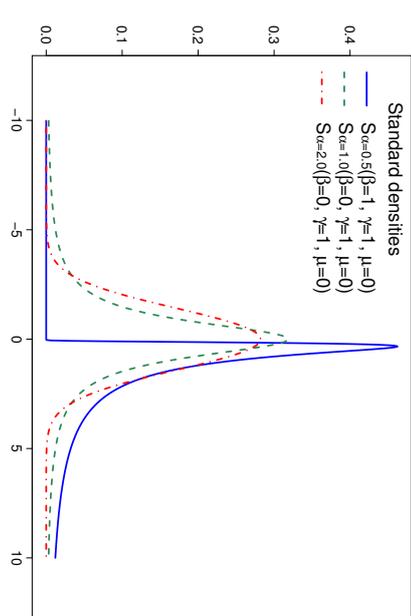

Figure 1: The three instances of analytically known univariate α -stable densities $S_{\alpha}(\beta, \gamma, \mu)$. Lévy(γ, μ) $\sim S_{0.5}(1, \gamma, \mu)$ (solid blue curves), Cauchy(γ, μ) $\sim S_{1.0}(0, \gamma, \mu)$ (dashed green curves) and Normal(μ, σ) $\sim S_{2.0}(0, \frac{\sigma^2}{2}, \mu)$ (dot-dashed red curves).

It is straight forward to use the characterization of stable random variables in Definition 1 to verify the following well-known properties (Samorodnitsky and Taqqu, 1994),

Property 1 If $X_1 \sim S_\alpha(\beta_1, \gamma_1, \mu_1)$ and $X_2 \sim S_\alpha(\beta_2, \gamma_2, \mu_2)$ are independent stable random variables, then $Y = X_1 + X_2 \sim S_\alpha(\beta, \gamma, \mu)$, with

$$\beta = \frac{\beta_1 \gamma_1 + \beta_2 \gamma_2}{\gamma_1 + \gamma_2}, \quad \gamma = (\gamma_1 + \gamma_2), \quad \mu = \mu_1 + \mu_2$$

Property 2 If $X \sim S_\alpha(\beta, \gamma, \mu)$ and $c, d \in \mathbb{R}$, then

$$cX + d \sim \begin{cases} S_\alpha(\text{sign}(c)\beta, |c|^\alpha \gamma, c\mu + d), & \alpha \neq 1 \\ S_\alpha(\text{sign}(c)\beta, |c|\gamma, c(\mu - \frac{2\gamma \beta \ln|c|}{\pi}) + d), & \alpha = 1 \end{cases}$$

A word on the notation used throughout this paper. We will use the symbol $\|Y\|_p = (\sum_\lambda |Y_\lambda|^p)^{1/p}$ to represent the l_p norm of a vector. The l_p norm of a vector representing N realizations of a random variable Z is related to the p^{th} moment $E(|Z|^p) = \|Z\|_p^p/N$. For heavy-tailed α -stable densities, one convenient method for parameter estimation is via fractional lower order moments (FLOM) for $p < \alpha$ (Hardin Jr, 1984; Nikias and Shao, 1995). Later, we will discuss FLOM-based parameter learning in greater detail (Section 2.4.1).

2.2 α -Stable Graphical Models

We can now introduce Bayesian network models reconstructed from stable densities that have compact representations for the characteristic function. Univariate α -stable densities can be generalized to represent multivariate stable distributions that are defined as follows (Samorodnitsky and Taqqu, 1994),

Definition 2 A d -dimensional multivariate stable distribution over $\mathcal{X} = \{X_1, \dots, X_d\}$ is defined by an $\alpha \in (0, 2]$, $\mu \in \mathbb{R}^d$ and a spectral measure Λ over the d -dimensional unit sphere S_d , such that the characteristic function

$$\begin{aligned} \Phi(q|\alpha, \mu, \Lambda) &\equiv \mathbb{E}[\exp(iq^T \mathcal{X})] \\ &= \exp\left(-\int_{S_d} \psi(s^T q|\alpha)\Lambda(ds) + i\mu^T q\right) \end{aligned}$$

where, $\psi(u|\alpha) = |u|^\alpha (1 - i \text{sign}(u)r(u, \alpha))$

Definition 3 An α -stable graphical (α -SG) model $B(G, \Theta)$ is a probability distribution over \mathcal{X} such that

1. $Z_j \equiv X_j - \sum_{X_k \in Pa(X_j)} w_{jk} X_k \sim S_\alpha(\beta_j, \gamma_j, \mu_j)$
2. Z_j is independent of Z_k , if $j \neq k$, $\forall X_j \in \mathcal{X}$

where $Pa(X_i) \subseteq \mathcal{X} \setminus \{X_i\}$ are the parent nodes of X_j in the directed acyclic graph G and Θ describes the distribution parameters

$$\begin{aligned} w_{jk} &\in \mathbb{R}, & W_j &= \{w_{jk} | X_k \in Pa(X_j)\}, \\ \theta_j &= \{\alpha, \beta_j, \gamma_j, \mu_j\} \cup W_j, & \Theta &= \{\theta_i | X_i \in \mathcal{X}\}. \end{aligned}$$

A symmetric α -stable graphical (So-SG) model is a α -SG model with $\beta = 0$.

It is straightforward to see that $B(G, \Theta)$ is indeed a Bayesian network. Note also that the fact that Z_j are stable follows directly from Property 1.

Lemma 2 $B(G, \Theta)$ in Definition 3 represents a Bayesian network

Proof Let $d = |\mathcal{X}|$. First note that every directed acyclic graph can be used to infer an ordering (not necessarily unique) on the variables in \mathcal{X} such that all parents of each variable have a lower order than the variable itself. Suppose we index each variable with its order in an ordering compatible with the DAG, such that X_i has order i . The proof rests on the fact that the transformation matrix from $\{Z_i\}$ to $\{X_i\}$ for such a graph is lower triangular, with each diagonal entry equal to 1. Since the determinant of a triangular matrix equals the product of its diagonal entries, the Jacobian for the transformation (or the determinant of the transformation matrix), $|\frac{\partial(Z_1, \dots, Z_d)}{\partial(X_1, \dots, X_d)}| = 1$. Furthermore, since the noise variables Z_j are independent of each other

$$\begin{aligned} P_B(Z_1, \dots, Z_d) &= \prod_{j=1}^d f(Z_j | \alpha, \beta_j, \gamma_j, \mu_j) \\ \text{also, } p(X_j | Pa(X_j), \theta_j) &= f(Z_j | \alpha, \beta_j, \gamma_j, \mu_j) \\ &\implies P_B(\mathcal{X}) = P_B(Z_1, \dots, Z_d) \frac{\partial(Z_1, \dots, Z_d)}{\partial(X_1, \dots, X_d)} \\ &\implies P_B(\mathcal{X}) = \prod_{j=1}^d p(X_j | Pa(X_j), \theta_j) \frac{\partial(Z_1, \dots, Z_d)}{\partial(X_1, \dots, X_d)} \\ &\implies P_B(\mathcal{X}) = \prod_{j=1}^d p(X_j | Pa(X_j), \theta_j) \end{aligned}$$

Hence, $B(G, \Theta)$ is a Bayesian network. ■

Before establishing the fact that an α -SG model is a multivariate stable density in the sense of Definition 2, we prove the following result (proof is provided in Appendix A) :

Lemma 3 Every d -dimensional distribution with a characteristic function of the form

$$\Phi(q|\alpha, \tilde{\mu}, \Lambda) = \prod_{k=1}^d \phi(c_k^T q | \alpha, \beta_k, \gamma_k, \mu_k) \quad \text{where, } c_k, q \in \mathbb{R}^d$$

represents a multivariate stable distribution with a discrete spectral measure Λ .

We are now in a position to establish that α -SG models imply a multivariate stable density with a spectral measure concentrated on a finite number of points over the unit sphere.

Lemma 4 Every α -SG model represents a multivariate stable distribution with a discrete spectral measure of the form in Lemma 3.

Proof We will prove the lemma by induction. First, observe that every Bayesian network can be used to assign an ordering (not unique) such that $Pa(X_j) \subseteq \{X_1, \dots, X_j - 1\}$. As before, we will use such an ordering to index each random variable in \mathcal{X} , such that $X_{|\mathcal{X}|}$ has no descendants. The base case of the lemma, where $|\mathcal{X}| = 1$ is clearly true. Assume that the lemma is true for all Bayesian networks with $|\mathcal{X}| = m - 1$. Then for any Bayesian network B with $|\mathcal{X}| = m$ random variables

$$\begin{aligned} \Phi_B(q) &\equiv \mathbb{E}[\exp(iq^T \mathcal{X})] \\ &= \int \prod_{j=1}^{|\mathcal{X}|} dX_j f(Z_j | \alpha, \beta_j, \gamma_j, \mu_j) \exp(iq_j X_j) \\ &= \int \left[\prod_{j=1}^{m-1} dX_j f(Z_j | \alpha, \beta_j, \gamma_j, \mu_j) \exp(iq_j X_j) \right] \int dX_m f(Z_m | \alpha, \beta_m, \gamma_m, \mu_m) \exp(iq_m X_m) \\ &= \int \left[\prod_{j=1}^{m-1} dX_j f(Z_j | \alpha, \beta_j, \gamma_j, \mu_j) \exp(iq_j X_j) \right] \int dZ_m f(Z_m | \alpha, \beta_m, \gamma_m, \mu_m) \exp(iq_m Z_m) \\ &= \Phi_{\tilde{B}}(\tilde{q}) \phi(q_m | \alpha, \beta_m, \gamma_m, \mu_m) \\ &\quad \text{where } \tilde{B} \text{ is the Bayes net on } \tilde{\mathcal{X}} = \mathcal{X} \setminus \{X_m\}, \\ &\quad \text{and } \tilde{q}_j = q_j + u_{mj} q_m | Pa(X_m) \cap \{X_j\} \vee X_j \in \tilde{\mathcal{X}} \end{aligned}$$

Since by assumption,

$$\begin{aligned} \Phi_{\tilde{B}}(\tilde{q}) &= \prod_{k=1}^{m-1} \phi(s_k^T \tilde{q} | \alpha, \beta_k, \gamma_k, \mu_k) \\ \implies \Phi_B(q) &= \phi_{\tilde{B}}(\tilde{q}) \phi(q_m | \alpha, \beta_m, \gamma_m, \mu_m) \\ &= \prod_{k=1}^m \phi(s_k^T q | \alpha, \beta_k, \gamma_k, \mu_k), \text{ where :} \\ s_k^T q &= \begin{cases} \sum_{j=1}^{m-1} s_{k,j} q_j + u_{mj} q_m | Pa(X_m) \cap \{X_j\} & k < m \\ q_m & k = m \end{cases} \end{aligned}$$

Therefore, $\Phi_B(q)$ represents a m -dimensional multivariate stable distribution with a discrete spectral measure (Lemma 3). Therefore, by induction, every α -SG model represents a multivariate stable distribution with a discrete spectral measure of the form in Lemma 3. ■

2.3 Learning α -SG Models

A popular method for structure learning in Bayesian network models is based on the *Bayesian information criterion* (BIC) which is also equivalent to the minimum description length (MDL) principle (Schwarz, 1978; Heckerman et al., 2000).

Definition 4 Given a data set $D = \{D_1, \dots, D_N\}$, the *Bayesian Information Score* $S_{BIC}(B|D)$ for a Bayesian network $B(G; \Theta)$ is defined as,

$$S_{BIC}(B|D) = \sum_{D_j \in D} \log [P_B(D_j)] - \sum_{X_i \in \mathcal{X}} \frac{|Pa(X_i)|}{2} \log N$$

The *Bayesian information criterion* (BIC) selects the Bayesian network that maximizes this score over the space of all directed acyclic graphs G and parameters Θ .

The major stumbling block in using stable densities is due to the fact that there is no known closed-form analytical expression for them (apart from special cases representing Gaussian, Cauchy and Levy distributions). This makes BIC based inference computationally demanding due to the marginal likelihood term $P_B[D_\lambda]$. One main contribution of this paper is an efficient method of learning the network structure and parameters for α -SG models. The next lemma establishes a new result that is useful in efficiently solving the learning problem.

Lemma 5 Given a data set $D_Y = \{Y_1, \dots, Y_N\}$ generated from a stable random variable $Y \sim S_\alpha(\beta, \gamma, \mu)$

$$\begin{aligned} \sum_{j=1}^N \log [f(Y_j | \alpha, \beta, \gamma, \mu)] &= -N \left(\log \gamma + h(Y | \alpha, \beta) \right) \\ \text{where, } \lim_{N \rightarrow \infty} h(Y | \alpha, \beta) &= - \int dY f(Y | \alpha, \beta, 1, 0) \log f(Y | \alpha, \beta, 1, 0) \\ &= H[S_\alpha(\beta, 1, 0)] \end{aligned}$$

where, $H[\cdot]$ is the entropy of the corresponding random variable.

Proof Since Y includes samples from a stable distribution, $Y \sim S_\alpha(\beta, \gamma, \mu)$ by definition, performing a change of variable to

$$\begin{aligned} Y \rightarrow \tilde{Y} &= \frac{Y}{\gamma^{1/\alpha}} - \tilde{\mu} \\ \text{where, } \tilde{\mu} &= \begin{cases} \frac{\mu}{\gamma^{1/\alpha}} & \alpha \neq 1 \\ \frac{\mu}{\gamma} + \frac{2\beta \ln 2}{\pi} & \alpha = 1 \end{cases} \end{aligned} \quad (2)$$

we get, the *standard* form density $\tilde{Y} \sim S_\alpha(\beta, 1, 0)$ using Property 2. Furthermore, samples from the transformed data set $\tilde{Y} = \{\tilde{Y}_1, \dots, \tilde{Y}_N\}$ are also distributed according to the following standard density :

$$f(Y | \alpha, \beta, \gamma, \mu) = f(\tilde{Y} | \alpha, \beta, 1, 0) \frac{d\tilde{Y}}{dY} = f(\tilde{Y} | \alpha, \beta, 1, 0) \frac{1}{\gamma^{1/\alpha}}$$

This implies that if we know the parameters α, β, γ and μ for the density generating D_Y

$$\begin{aligned} \log [f(Y|\alpha, \beta, \gamma, \mu)] &= \sum_{j=1}^N \log f(Y_j|\alpha, \beta, \gamma, \mu) \\ &= \sum_{j=1}^N \left\{ -\frac{\log \gamma}{\alpha} + \log f(\tilde{Y}_j|\alpha, \beta, 1, 0) \right\} \\ &= -N \left(\frac{\log \gamma}{\alpha} + h(Y|\alpha, \beta) \right) \end{aligned}$$

where, $h(Y|\alpha, \beta)$ is defined by

$$h(Y|\alpha, \beta) \equiv -\frac{1}{N} \sum_{j=1}^N \log f(\tilde{Y}_j|\alpha, \beta, 1, 0) \quad (3)$$

Here \tilde{Y}_j and Y_j are related via Equation 2 for all $1 \leq j \leq N$. Note that since the transformed variables \tilde{Y}_j are samples from $f(\tilde{Y}|\alpha, \beta, 1, 0)$, we have the following asymptotic result for large N

$$\begin{aligned} \lim_{N \rightarrow \infty} h(Y, \alpha, \beta) &= -\lim_{N \rightarrow \infty} \frac{1}{N} \sum_{j=1}^N \log f(\tilde{Y}_j|\alpha, \beta, 1, 0) \\ &= -\int_{-\infty}^{\infty} f(\tilde{Y}|\alpha, \beta, 1, 0) \log f(\tilde{Y}|\alpha, \beta, 1, 0) dY \\ &= H[S_\alpha(\beta, 1, 0)] \end{aligned}$$

where, $H[\cdot]$ is the entropy of the corresponding random variable. ■

As things stand, the entropy $H[\cdot]$ of stable random variables in the standard form is just as difficult to compute as the original log-likelihood and the previous lemma has just transformed one intractable quantity into another. However, there is an important class of models where we can ignore the entropy term during structure learning; this class of multivariate distributions have a special property that every linear combination of random variables is distributed as a stable distribution $S_\alpha(\beta, \cdot, \cdot)$ with the same α and β . One scenario when this is true is when the noise term is symmetric *i.e.* $\beta_i = 0 \forall X_i \in \mathcal{X}$. This special case is important since we later show (Lemma 8) that every α -SG model can be easily transformed into a partner symmetric α -SG model with identical network topology and regression coefficients. For all practical purposes, learning the structure of symmetric α -SG models is effectively the same as learning structure of arbitrary α -SG models.

Lemma 6 Given a symmetric α -stable graphical model for variables in \mathcal{X} ,

$$Z \equiv w^T \mathcal{X} = \sum_{X_j \in \mathcal{X}} w_j X_j \sim S(\alpha, \beta(w) = 0, \gamma(w), \mu(w)), \quad \forall w \in \mathbb{R}^{|\mathcal{X}|}$$

if, $\beta_i = 0, \forall X_i \in \mathcal{X}$

Proof The dispersion $\gamma(w)$ and skewness $\beta(w)$ for the projection $w^T \mathcal{X}$ of any d -dimensional stable random density are given by (Samorodnitsky and Taqqu, 1994)

$$\begin{aligned} \gamma(w) &= \int_{S_d} |w^T s|^\alpha \Lambda(ds) \\ \beta(w) &= \gamma(w)^{-1} \int_{S_d} \text{sign}(w^T s) |w^T s|^\alpha \Lambda(ds) \end{aligned}$$

Since, \mathcal{X} represents a symmetric α -stable graphical model, Lemma 4 and Lemma 3 imply (substituting the characteristic function in the expression for $\beta(w)$ with the expansion in Lemma 3 :

$$\begin{aligned} \beta(w) &= \sum_{k=1}^d \frac{|w^T c_k|^{\frac{\alpha}{2} \gamma_k}}{2^\gamma(w)} \int_{S_d} \left\{ \delta(s - \frac{c_k}{|c_k|_2}) + \delta(s + \frac{c_k}{|c_k|_2}) \right\} |w^T s|^\alpha \text{sign}(w^T s) ds \\ &= 0 \end{aligned}$$

For a recent reference on multiple regression with stable errors, see also Nolan (2013b).

We are now in a position to present the main contribution of this paper : an alternative criterion for model selection that is both computationally efficient and comes with robust theoretical guarantees (Lemma 7). The criterion is called *minimum dispersion criterion (MDC)* and is a penalized version of a technique previously used in signal processing literature for designing filters for heavy-tailed noise (Stuck, 1978).

Definition 5 Given a data set $D = \{D_1, \dots, D_N\}$, the penalized dispersion score $S_{MDC}(B|D)$ for a Bayesian network $B(G, \Theta)$ is defined as,

$$S_{MDC}(B|D) = - \sum_{X_i \in \mathcal{X}} \left\{ N \frac{\log \gamma_i}{\alpha} + \frac{|Pa(X_i)|}{2} \log N \right\}$$

The minimum dispersion criterion (MDC) selects the Bayesian network that maximizes this score over the space of all directed acyclic graphs G and parameters Θ .

Lemma 7 Given a data set $D = \{D_1, \dots, D_N\}$ generated by a symmetric α -stable graphical model, $B^*(G^*, \Theta^*)$, the minimum dispersion criterion is asymptotically equivalent to the Bayesian information criterion over the search space of all symmetric α -stable graphical models

Proof First consider the contribution to BIC score from each family (ie., each random variable and its parents) separately. Let $Z_j = X_j - \sum_{X_k \in Pa(X_j)} w_{jk} X_k$ be any arbitrary set of regression coefficients for a candidate network $B(G, \Theta)$. Note that the coefficients $W_j = \{w_{jk} | X_k \in Pa(X_j)\}$ need not be the true regression coefficients W_j^* and B need not be the true network B^* . We will use the notation $Z_{i,\lambda}$ for the realization of Z_i in sample $D_\lambda \in D$. Since D includes samples from a symmetric α -stable graphical model, Lemma 6

implies $Z_j \sim S_\alpha(\beta = 0, \gamma_j, \mu_j)$. Therefore, using Lemma 5

$$\begin{aligned} Fam(X_j, Pa(X_j)|D) &\equiv \sum_{\lambda=1}^N \log \left[f(Z_{j,\lambda}|\alpha, \beta = 0, \gamma_j, \mu_j) \right] - \frac{|Pa(X_j)|}{2} \log N \\ &= -N \left(\frac{\log \gamma_j}{\alpha} + h(\tilde{Z}_j|\alpha, \beta = 0) \right) - \frac{|Pa(X_j)|}{2} \log N \end{aligned}$$

where, as in Equation 3, Z_j and \tilde{Z}_j are related by the transformation in Equation 2 and $Fam(X_j, Pa(X_j)|D)$ represents the contribution to BIC score from each family (ie., each random variable and its parents).

$$\begin{aligned} \implies \frac{SBIC(B|D)}{N} &= \sum_{X_j \in \mathcal{X}} \frac{Fam(X_j, Pa(X_j)|D)}{N} \\ &= - \sum_{X_j \in \mathcal{X}} \left(\frac{\log \gamma_j}{\alpha} + h(Z_j|\alpha, \beta = 0) + \frac{|Pa(X_j)|}{2N} \log N \right) \\ \implies \lim_{N \rightarrow \infty} \frac{SBIC(B|D)}{N} &= \lim_{N \rightarrow \infty} \frac{SMDC(B|D)}{N} - |\mathcal{X}|H[S_\alpha(\beta = 0, 1, 0)] \end{aligned}$$

Since, $|\mathcal{X}|H[S_\alpha(\beta = 0, 1, 0)]$ is independent of the candidate network structure and regression parameters $\{W_j|X_j \in \mathcal{X}\}$, we get the result that for any pair of networks B and B'

$$\implies \lim_{N \rightarrow \infty} \frac{1}{N} (SBIC(B|D) - SBIC(B'|D)) = \lim_{N \rightarrow \infty} \frac{1}{N} (SMDC(B|D) - SMDC(B'|D))$$

Therefore, asymptotically, BIC is equivalent to MDC when data is generated by a symmetric α -SG graphical model. ■

We now show how samples from any stable graphical model can be combined to yield samples from a partner symmetric stable graphical model with identical parameters and network topology. This transformation was earlier used by Kurugolu (2001) in order to estimate parameters from skewed univariate stable densities. We should point out that the procedure described above has the drawback that symmetrized data set has half the sample size.

Lemma 8 *Every α -SG model can be associated with a symmetric α -SG model with identical skeleton (graph structure) and regression parameters.*

Proof Given a data set $D = \{D_1, \dots, D_N\}$ representing any α -SG model $B(G, \Theta)$, consider a resampled data set $\tilde{D} = \{\tilde{D}_1, \dots, \tilde{D}_{N_s}\}$ with variable realizations

$$\widehat{X}_{i,\lambda} = X_{i,2\lambda} - X_{i,2\lambda-1}, \quad \forall \lambda \in \{1, \dots, N_s = \lfloor N/2 \rfloor\}$$

These 'bootstrapped' data samples $\tilde{D}_\lambda = \{\widehat{X}_{i,\lambda}|X_i \in \mathcal{X}\}$ represent independent realizations of random variables $\widehat{\mathcal{X}} \equiv \{\widehat{X}_i|X_i \in \mathcal{X}\}$. Similarly, we may use the regression parameters W to define resampled noise variables :

$$\tilde{Z}_j \equiv \widehat{X}_j - \sum_{\widehat{X}_k \in Pa(\widehat{X}_j)} w_{jk} \widehat{X}_k$$

We now make two observations :

1. If $Z_j = X_j - \sum_{X_k \in Pa(X_j)} w_{jk} X_k \sim S_\alpha(\beta_j, \gamma_j, \mu_j)$, then using Property 1

$$\tilde{Z}_j \equiv \widehat{X}_j - \sum_{\widehat{X}_k \in Pa(\widehat{X}_j)} w_{jk} \widehat{X}_k \sim S_\alpha(\beta = 0, 2\gamma_j, 0)$$

2. The transformed noise variables \tilde{Z}_j are independent of each other.

But these conditions define an α -SG model (Definition 3). Therefore, by Lemma 2, the resampled data is distributed according to a Bayesian network $B(G, \Theta)$ such that

$$\begin{aligned} \tilde{Z}_j &\equiv \widehat{X}_j - \sum_{\widehat{X}_k \in Pa(\widehat{X}_j)} w_{jk} \widehat{X}_k \\ P_{\tilde{B}}(\widehat{\mathcal{X}}) &= \prod_{j=1}^{|\mathcal{X}|} f(\tilde{Z}_j|\alpha, 0, 2\gamma_j, 0) \\ \tilde{\theta}_j &= \{\alpha, \beta = 0, 2\gamma_j, 0\} \cup W_j, \quad \widehat{\Theta} = \{\tilde{\theta}_j|X_j \in \mathcal{X}\} \end{aligned}$$

■

The expression for MDC in Definition 5 does not involve the stable pdf and hence one may wonder how the variables of the distribution could be estimated. The answer is given by the following property of stable distributions Kurugolu (2001).

Lemma 9 *If $Z \sim S_\alpha(0, \gamma, 0)$, then*

$$E(|Z|^p) = C(p, \alpha) \gamma^{p/\alpha} \quad \forall -1 < p < \alpha$$

where,

$$C(p, \alpha) = \frac{\Gamma(1 - \frac{p}{\alpha})}{\Gamma(1 - p) \cos(p \frac{\pi}{\alpha})}.$$

2.4 The Stable Algorithm

In this section we describe **Stable**, an algorithm for learning the structure and parameters of α -SG models (Algorithm 1). The first step of **Stable** is to center and symmetrize the entire data matrix D_j in terms of the variables \mathcal{X} , as described in Lemma 8. This is followed by estimating the global parameter α using the method of log statistics (Kurugolu, 2001). Finally, structure learning is performed by a modified version of the *ordering-based search* (OBS) algorithm (Section 2.4.2). The details of parameter estimation and structure learning algorithms are discussed next.

2.4.1 PARAMETER LEARNING

First, we describe the algorithms **Stable** uses to estimate the characteristic exponent α from the data matrix D , as well as the parameters $\Gamma = \{\gamma_j|X_j \in \mathcal{X}\}$ and $W_j = \{w_{jk}|X_k \in Pa(X_j)\}$ for any given directed acyclic graph G .

Algorithm 1 Stable

Input: Input data matrix D_I , number of random restarts N_{reps}
Output: α -SG model $B(G, \Theta)$ over \mathcal{X}
 $D \leftarrow \text{Symmetrized}(D_I)$ // Symmetrize the data as per Lemma 8
Estimate α from D // Use log-statistics, Equation 4
Initialize $B(G, \Theta) = \emptyset$
for $i = 1$ **to** N_{reps} **do**
 Initialize a random ordering σ
 $B_\sigma(G, \Theta) = \text{OBS}(D, \alpha, \sigma)$ // Ordering-based search, Algorithm 4
 if $S_{\text{MDC}}(B_\sigma | D) > S_{\text{MDC}}(B | D)$ **then**
 $B = B_\sigma$
 end if
end for

Estimating the global parameter α : Log statistics can be used to estimate the characteristic exponent α from the centered and symmetrized variables in \mathcal{X} (Kuruoglu, 2001).

Algorithm: Since every linear combination of variables in $\hat{\mathcal{X}}$ has the same α , if we define

$$\begin{aligned} \hat{\mathcal{X}} &= \sum_{i=1}^{|\hat{\mathcal{X}}|} \hat{X}_i, \text{ then} \\ \alpha &= \left(\frac{L_2}{\psi_1} - \frac{1}{2} \right)^{-1/2} \\ L_2 &\equiv \mathbb{E} \left[\left(\log |\hat{\mathcal{X}}| - \mathbb{E}[\log |\hat{\mathcal{X}}|] \right)^2 \right] \\ \psi_1 &\equiv \left. \frac{d^2}{dy^2} \Gamma(y) \right|_{y=1} = \frac{\pi^2}{6} \end{aligned} \quad (4)$$

Estimating the dispersion γ_j , and regression parameters $W_j = \{w_{jk} | X_k \in P_a(X_j)\}$
If $\gamma_j(W_j)$ is the dispersion parameter for the distribution of $Z_j = X_j - \sum_{X_k \in P_a(X_j)} w_{jk} X_k$, then the minimum dispersion criterion selects regression parameters

$$W_j^* = \arg \min_{\alpha} \frac{1}{\alpha} \log \gamma_j(W_j)$$

Minimum dispersion regression coefficients are estimated using a connection between the l_p -norm of a stable random variable and the dispersion parameter γ (Zolotarev, 1957; Kuruoglu, 2001) given above in Lemma 9.

This lemma tells us that within a constant term $\log C(p, \alpha)$, minimizing $\frac{1}{\alpha} \log \gamma_j$ is identical to minimizing the l_p -norm $\|Z_j\|_p \equiv \left(\sum_{\lambda=1}^N |Z_{j,\lambda}|^p \right)^{1/p}$ for $-1 < p < \alpha$.

$$W_j^* = \arg \min \log \left(\|Z_j\|_p \right) \equiv \arg \min \log \left(\sum_{\lambda=1}^N |Z_{j,\lambda}|^p \right)^{1/p}$$

Algorithm 2 IRLS // Find the least l_p norm regression coefficients

Input: N dimensional vector for realizations of the child node Y , $N \times M$ matrix X of realizations of the parent set $P_a(Y)$, tolerance ϵ and $p \in (0, 2]$
Output: M dimensional vector of regression co-efficients $W^* = \arg \min_W \|Y - XW\|_p$
Initialize W with OLS co-efficients $W = (X^T X)^{-1} X^T Y$
repeat
 Initialize buffer for current regression coefficients $\beta = W$
 Initialize a diagonal $N \times N$ matrix Ω from β for weighted least squares regression
 $\Omega_{ij} = \delta_{ij} (Y_i - (XW)_i)^{p-2} \forall i, j \in \{1, \dots, N\}$
 Update regression coefficients vector $W = (X^T \Omega X)^{-1} (X^T \Omega Y)$
until $\|\beta - W\|_2 < \epsilon$ // Change in regression coefficients is within tolerance

Algorithm: Minimization of the l_p norm is performed by the *iteratively least squares* (IRLS) algorithm (Byrd and Payne, 1979). Briefly, the IRLS algorithm repeatedly solves an instance of the weighted least squares problem to achieve successive estimates for the least l_p norm coefficients (Algorithm 2). IRLS is attractive since rigorous convergence guarantees can be given (Daubechies et al., 2010) and the method is easy to implement since several software packages are available for the weighted least squares problem. Even though the IRLS objective is no longer convex for $p < 1.0$, Daubechies et al. (2010) show that under certain sparsity conditions, the algorithm can recover the true solution. Simulations described in Section 3.1 tend to support this observation.

For experiments described in this manuscript, **Stable** used two values of p for l_p -norm estimation. For learning regression coefficients during structure learning, IRLS was implemented with $p = \alpha/1.01$, since lower values tended to give noisier estimates (possibly due to numerical errors). However, we also found that estimating the term $\log C(p, \alpha)$ is prone to numerical errors for small values of $|\alpha - p|$. Therefore, we ignore this constant term during structure learning since it is common to all candidate structures. **Stable** estimates the dispersion parameters γ_j after structure learning, by computing the l_p -norm for p sufficiently smaller than α (e.g. $\alpha/10 \leq p \leq \alpha/2$ and applying Lemma 9).

2.4.2 STRUCTURE LEARNING

Searching the space of all network structures can be performed through any of the popular hill-climbing algorithms. In this paper we used the *ordering-based search* (OBS) algorithm (Teyssier and Koller, 2005) to search for a local optimum in the space of all directed acyclic graphs. The algorithm starts with an initial ordering σ and then learns a DAG consistent with σ (i.e., all parents of each node must have a lower order). This part of structure learning is performed via a subroutine K2Search (Algorithm 3), which is a modified version of the hill-climbing based K2Search algorithm Cooper and Herskovits (1992). K2Search starts with an empty parent set for each node $X_i \in \mathcal{X}$ and greedily adds edges until the MDC based score $FS(X_i, P_a(X_i) | D, \alpha) = -\frac{N}{\alpha} \log \gamma_i - \frac{|P_a(X_i)|}{2} \log N$ reaches a local maximum. The main difference from Gaussian graphical models (Heckerman et al., 2000; Schmidt et al., 2007) is that K2Search scores each family based on least l_p norm instead

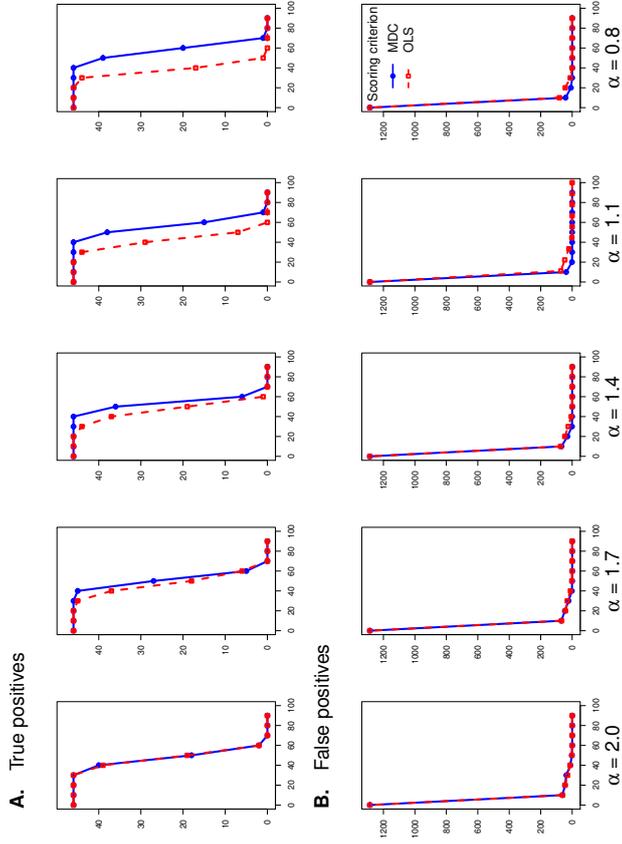

Figure 2: The ALARM network - Inferred structure. Comparative performance of MDC based Stable algorithm (solid blue curves) versus an identical algorithm based on OLS score (dashed red curves). Vertical axes show true positives in **A** and false positives in **B**, for directed edges present in the input network. Horizontal axes show respective confidence (percentage of simulated data sets with the feature)

goal was to assess **Stable** in terms of its performance at structure learning and estimation of stable noise parameters for a variety of regression coefficients.

We performed five sets of experiments for each network, corresponding to different values of $\alpha = 0.8, 1.1, 1.4, 1.7, 2.0$. For each set of experiments, we chose $\rho = 1.0$, $\beta = 0.9$ and $\gamma = 1.0$. We chose such a high skew ($\beta = 0.9$) in the input data to test our algorithm on its ability to symmetrize and correctly learn (possibly) difficult problem instances. Instead of β however, we report a related parameter $\theta = \arctan(\beta \tan \alpha \frac{\rho}{\gamma})$ which can be inferred more robustly in practice since it avoids the singularity near $\alpha = 2$ (Kuruoglu, 2001). We used the zeroth order signed moments based method for estimating θ (Kuruoglu, 2001).

$$\theta_i = \frac{\alpha\pi}{2N} \sum_{\lambda=1}^N \text{sign}(X_{i,\lambda}), \quad \forall X_i \in \mathcal{X} \quad (6)$$

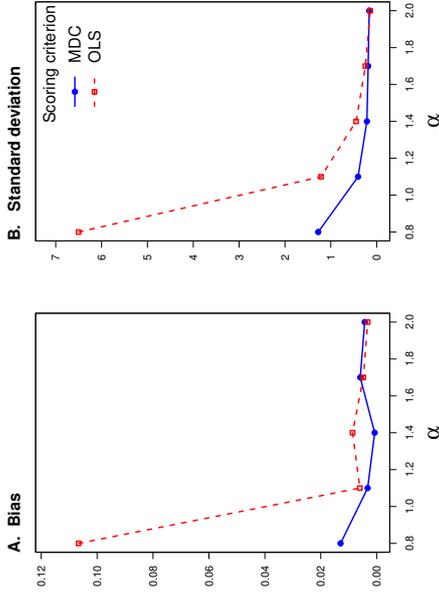

Figure 3: The ALARM network - Estimated regression parameters.

We report two set of results for each network : structure learning and parameter estimation. For convenience, we describe the results for the ALARM network first (results for other data sets are provided in Appendix B).

3.1.1 INFERRED STRUCTURE

Figure 2 shows the comparative performance of MDC and OLS based approaches. Each curve shows the number of inferred directed edges. Figure 2A, B show the number of true positives and true negatives at a given confidence level (percentage of simulated data sets where the directed edge was learnt). Solid (blue) curves show the performance of MDC and dashed (red) curves show OLS based method. The results are along expected lines with the difference between the two getting larger as α is varied away from 2.0. One clear trend is that while the sensitivity to true positive detection degrades for OLS (Type II errors) as α decreases, the MDC based method remain robust to changes in α . Both methods are however quite reliable at not inferring incorrect edges (false positives or Type I errors). Similar behavior is observed for other data sets as well (Appendix B).

3.1.2 ESTIMATED PARAMETERS

Figure 3 shows the comparative performance of MDC and OLS scores in estimating regression coefficients. Figure 3A shows the bias in mean estimates (in absolute magnitude) and Figure 3B, the standard deviation around the mean in estimated coefficients and are averaged over all true positives and all simulated data sets. Note that each of the 100 simulated data set had regression coefficients sampled independently from $[-1/2, 1/2]$. OLS had a much higher standard deviation and bias at low α . As with structure learning, this pattern was consistently observed for other network topologies as well (Appendix B).

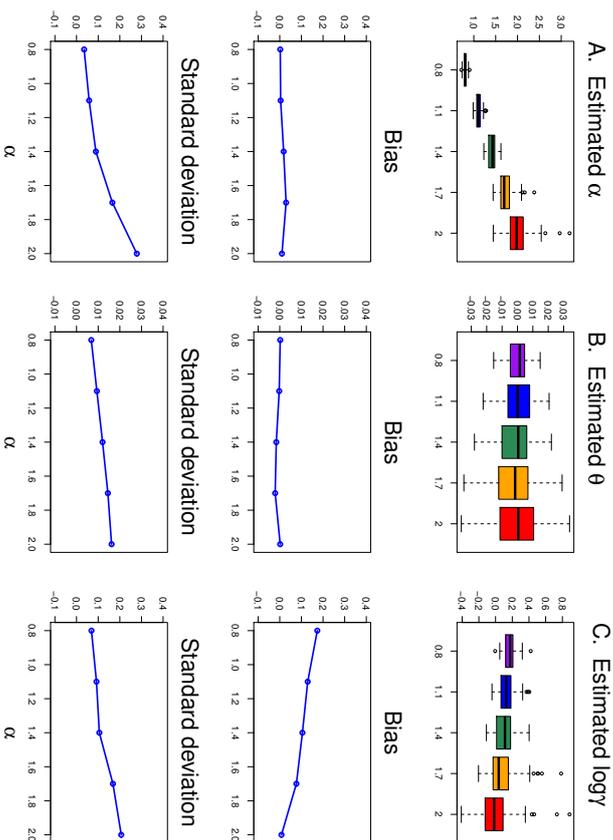

Figure 4: The ALARM network - Estimated noise parameters.

We also assessed the ability of `Stable` to infer α -stable noise parameters accurately and robustly. However, we could not show a comparative performance since OLS scores assume Gaussian noise. Figure 4 shows the box plot and basic statistics for the estimates for α , θ and $\log \gamma$ from the symmetrized data set (node specific parameters θ and $\log \gamma$ are reported as averages).

$$\alpha, \quad \theta \equiv \frac{1}{|X|} \sum_i \arctan(\beta_i \tan \alpha_i^{\frac{\pi}{2}}), \quad \log \gamma = \frac{1}{|X|} \sum_i \log \gamma_i$$

Both α and θ estimates have low bias and standard deviation for each of the five data sets. But, $\log \gamma$ estimates show a clear tendency to overestimate the dispersion in noise at very low α . This is however a difficult parameter domain for most existing methods for parameter estimation, even for univariate α stable densities (Kurugolu, 2001). As with other inferences, the performance of `Stable` is again robust to changes in network topology (Appendix B).

Table 2: The HapMap III population groups and selected microarray probes as reported by Stranger et al. (2012).

3.2 Gene Expression Microarray Data

In this section, we describe two sets of analyses for gene expression microarray data from phase III of the HapMap project³. Our approach models the set of gene expression profiles as a multivariate stable distribution that can be represented by an α -SG model. The first set of experiments aimed at comparing the prediction accuracy of MDC with OLS-based structure learning via ten-fold cross-validation (Section 3.2.2). The results of these experiments establish the utility of heavy-tailed models for gene expression profiles.

Next, we apply α -SG models to the problem of quantifying differential expression (DE) of a gene between samples belonging to different conditions. This is a common task in gene expression-based analyses in contemporary genomics. However, popular methods for detecting differentially expressed genes usually assume the expression profile for each gene to be independent of others. Based on this assumption, DE quantification is performed by testing the null hypothesis that the log-expression of each gene is identical across the observed conditions and using the corresponding p-value as a measure of DE. In Section 3.2.3, we develop `SGEX`, a new technique for quantifying differential expression of each gene that is based on α -SG models. We apply `SGEX` to quantify the DE for a gene in each population group within the HapMap data. Contrary to most existing methods, `SGEX` takes into account both the heavy-tailed behavior of gene expression densities, as well as linear dependencies between mRNA expression of different genes.

3.2.1 DATA NORMALIZATION

We downloaded pre-processed data for 727 individuals from eight global population groups as reported in Stranger et al. (2012). Details about the eight population groups are provided in Table 2. For each individual, the input data represented log-intensities for 21800 microarray probes⁴ that were quantile and median normalized, as described in the original paper (Stranger et al., 2012). These microarray intensities provide a measure for mRNA concen-

3. Data sets can be downloaded from the Array Express database <http://www.ebi.ac.uk/arrayexpress/> using Series Accession Numbers E-MTAB-198 and E-MTAB-264.

4. Each selected probe mapped to a unique, autosomal Ensembl gene. Ensembl gene IDs are available at <http://www.ensembl.org>.

tration within a sample of lymphoblastoid cells from each individual. Before performing structure learning, we further processed each probe intensity as follows :

1. The log-intensity $l(i)$ for each probe i was median-centered to obtain transformed log-intensities $ml(i)$, ie., the number of samples with positive log-intensity was half (or 0.5 less than) the total ($= 363 = \lfloor 727/2 \rfloor$). This is a standard technique for learning Gaussian graphical models from gene expression data and does not affect the network structure.
2. The median-centered log-intensities were used to assign a rank $R(i)$ to each probe i , in decreasing order of variance. Even for α -stable distributions, variance of log transformed data is finite (Kuruoglu, 2001). This is also a standard technique for restricting computing time by selecting a subset of genes with most variation.
3. The median-centered log-intensities $\{ml(i) | R(i) \leq 21800\}$ were exponentiated to $\mathcal{I} = \{2^{ml(i)} | R(i) \leq 21800\}$.
4. The exponentiated-median-centered log-intensities $\mathcal{I}_k = \{2^{ml(i)} | R(i) \leq k \leq 21800\}$ for the top k ranked probes were provided as input to **Stable** (for cross-validation) and **SGEX** (for DE quantification, as described in Section 3.2.3). In the experiments reported here $k = 100$.

We estimated α over 1000 resampled bootstrap replicates of the data. This was meant as a diagnostic to assess the heavy-tailed nature of the intensities. As shown in Figure 5A, the data suggests a clear departure from a Gaussian profile.

3.2.2 CROSS-VALIDATION ANALYSIS

We performed a ten-fold cross-validation for the top 100 ranked probes from the HapMap data. Since we wanted to compare MDC with OLS-based learning, we report goodness of fit of the graphical model B on the test set $T = \{T_1, \dots, T_N\}$ in terms of log fractional lower order moments :

$$LFLOM(T|B, p) = \sum_{X_i \in \mathcal{X}} \left[\frac{1}{p} \log E(|Z_i|^p) \right] = \sum_{X_i \in \mathcal{X}} \left[\frac{1}{p} \log E(|X_i - \sum_{X_j \in \mathcal{P}_A(X_i)} w_{ij} X_j|^p) \right]$$

where, w_{ij} represents the regression co-efficient for the edge (X_j, X_i) . Clearly, if most of the variation in X_i can be explained by the parent set $\mathcal{P}_A(X_i)$, the corresponding $LFLOM$ will be small. For $p = 2$, $LFLOM$ is identical to the negative log-likelihood for Gaussian graphical models⁵. However, the second order moment diverges for $\alpha < 2$ (Lemma 9). Therefore, $LFLOM$ provide a more robust estimate for evaluating the model on test set for heavy-tailed noise ($\alpha < 2$).

Figure 5B shows the average (over the ten-folds) of $LFLOM$ for MDC (blue) and OLS-based (red) models. In each case, the curves show the difference in $LFLOM$ between optimal (MDC or OLS) network and an empty network (NULL). This allows us to also assess the deterioration in test set performance by treating each gene as an independent

5. Note that the noise term Z_i has zero mean, since the data is centro-symmetrized before cross-validation.

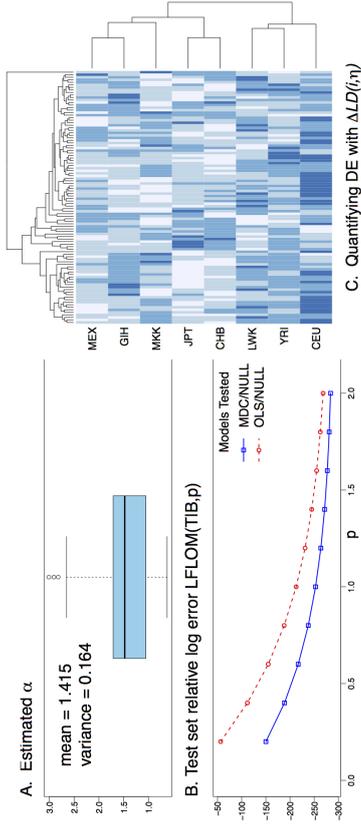

Figure 5: Test set performance and differential expression quantification with **SGEX**. **A** shows a box plot of estimated α over 1000 bootstrap replicates. **B** shows comparative Test set performance for MDC and OLS based networks relative to an empty network (no edges). **C** shows a heat map of ΔLD that quantifies differential expression of a gene. The color for each column is normalized by scaling and centering.

random variable (a common assumption in DE quantification). Although the data set contains only 727 samples, we see a clear improvement in test set performance of α -SG models (MDC curve) relative to Gaussian graphical models (OLS curve).

3.2.3 QUANTIFYING DIFFERENTIAL EXPRESSION WITH SGEX

Finally, we discuss **SGEX**, a new technique for quantifying differential expression using α -SG models. **SGEX** is based on cross-validation for assessing DE of a gene across different conditions. For the HapMap data, we chose each of the eight population groups in turn as the test set and learnt the optimal α -SG model for the rest of the samples. We then estimated $\Delta LD(i, \eta)$, the change in negative log-likelihood per sample between the test set η and the training set as a measure of DE for each probe i

$$\Delta LD(i, \eta) = \frac{1}{p} \left[\log E_{\eta}(|Z_i|^p) - \log E_{\bar{\eta}}(|Z_i|^p) \right], \quad p \in (-1, \alpha)$$

Here, $E_{\eta}(\cdot)$ is the expectation value for population η (test set) and $E_{\bar{\eta}}(\cdot)$ for the rest (training set). Note that Lemma 9 guarantees that RHS of the previous equation is indeed independent of p . For the calculation reported here $p = \alpha/1.01$, just as it was during structure learning. Thus, $\Delta LD(i, \eta)$ measures the average increase (or decrease) in log-dispersion for the noise variable Z_i corresponding to probe i within population η . This density is represented as a heat map in Figure 5C. We should point out that a higher (or lower) dispersion

for the noise variable associated with a gene in the test set does not necessarily imply over (or under) expression of a gene in the test set population. The change in dispersion could also be due to a change in network topology or regression coefficients for the test set population.

4. Discussion

In this paper we have introduced and developed the theory for efficiently learning α -SG models from data. In particular, one of the main contributions of this paper is to show how the BIC can be asymptotically reduced to the MDC for α -SG models. This result makes it feasible to efficiently learn the structure of these models, since the log-likelihood term does not have a closed form expression in general. We have also empirically validated the resultant algorithm `Stable` on both simulated and microarray data. In both cases, the presence of heavy-tailed noise has a clear effect on learning performance of OLS based methods. Based on these results, we recommend a bootstrapped estimation of α as an effective and computationally efficient diagnostic to assess the applicability of OLS based Gaussian graphical models.

We have also described `SGEX`, a new technique for quantifying differential expression from microarray data. α -SG models may also have wider applicability to other aspects of computational biology, especially to data from next-generation sequencing technologies. In addition to mRNA expression measurements (RNA-seq experiments), α -SG models may prove helpful for other experiments, such as protein-DNA binding (ChIP-seq experiments) and DNA accessibility measurements (DNase-seq and FAIRE-seq experiments).

Finally, we should mention that there are several potential applications of α -SG models beyond computational biology. In particular, image processing provides several problem instances where there is a need to relate different regions of the image. For example, functional magnetic resonance imaging (fMRI) experiments generate a series of images highlighting activity sites in the brain in response to stimuli. Bayesian networks are an effective way of modeling statistical relations between different areas of the brain and the stimuli (Li et al., 2011). Stable distributions may provide a better model for such applications. Another image processing application with potentials for α -SG models is remote sensing images of the earth (Mustrafai et al., 2012) where image histograms demonstrate clearly skewed and heavy tailed characteristics (Kuruoglu and Zerbiba, 2004). Traffic modeling (Castillo et al., 2012) and financial data analysis (Bonato, 2012) are also promising application areas.

5. Software Availability

Source code for `Stable` and data sets used here are available at <https://sourceforge.net/projects/sgmodels/>. `SGEX` is available upon request from the first author.

Appendix A

In this section we provide the proof for Lemma 3

Lemma 3 Every d -dimensional distribution with a characteristic function of the form

$$\Phi(q|\alpha, \tilde{\mu}, \Lambda) = \prod_{k=1}^d \phi(c_k^T q|\alpha, \beta_k, \gamma_k, \mu_k) \quad \text{where, } c_k, q \in \mathbb{R}^d$$

represents a multivariate stable distribution with a discrete spectral measure Λ .

Proof Assume the following ansatz for the spectral measure Λ ,

$$\begin{aligned} \Lambda_k &= \frac{\|c_k\|_2^{\alpha} \gamma_k}{2} \left((1 + \beta_k) \delta(s - \frac{c_k}{\|c_k\|_2}) + (1 - \beta_k) \delta(s + \frac{c_k}{\|c_k\|_2}) \right) \\ \Lambda(ds) &= \sum_k \Lambda_k ds \end{aligned}$$

and location vector $\tilde{\mu}$,

$$\begin{aligned} \eta_k(c_k|\alpha, \beta_k, \gamma_k, \mu_k) &= \begin{cases} \mu_k & \alpha \neq 1 \\ \mu_k - \frac{2\beta_k c_k}{\pi} \log \|c_k\|_2 & \alpha = 1 \end{cases} \\ \tilde{\mu} &= \sum_{k=1}^d \eta_k(c_k|\alpha, \beta_k, \gamma_k, \mu_k) c_k \in \mathbb{R}^d \end{aligned}$$

Upon substitution into the parametrization in Definition 2 we get

$$\begin{aligned} \int_{S_d} \psi(s^T q|\alpha) \Lambda_k ds &= \frac{\|c_k\|_2^{\alpha} \gamma_k}{2} \left((1 + \beta_k) \psi\left(\frac{c_k^T q}{\|c_k\|_2}|\alpha\right) + (1 - \beta_k) \psi\left(-\frac{c_k^T q}{\|c_k\|_2}|\alpha\right) \right) \\ &= \frac{\|c_k\|_2^{\alpha} \gamma_k}{2} \frac{\|c_k^T q\|_2^{\alpha}}{\|c_k\|_2^{\alpha}} \left((1 + \beta_k) (1 - \text{sign}(c_k^T q) r\left(\frac{c_k^T q}{\|c_k\|_2}, \alpha\right)) \right. \\ &\quad \left. + (1 - \beta_k) (1 + \text{sign}(c_k^T q) r\left(\frac{c_k^T q}{\|c_k\|_2}, \alpha\right)) \right) \\ \implies \int_{S_d} \psi(s^T q|\alpha) \Lambda_k ds &= \gamma_k |c_k^T q|^{\alpha} \left(1 - \nu \beta_k \text{sign}(c_k^T q) r\left(\frac{c_k^T q}{\|c_k\|_2}, \alpha\right) \right) \\ &= \gamma_k |c_k^T q|^{\alpha} \left(1 - \nu \beta_k \text{sign}(c_k^T q) r\left(\frac{c_k^T q}{\|c_k\|_2}, \alpha\right) \right) \\ &\quad - \nu \beta_k \gamma_k |c_k^T q|^{\alpha} \text{sign}(c_k^T q) \left(r\left(\frac{c_k^T q}{\|c_k\|_2}, \alpha\right) - r\left(-\frac{c_k^T q}{\|c_k\|_2}, \alpha\right) \right) \end{aligned}$$

$$\text{Since, } r\left(\frac{c_k^T q}{\|c_k\|_2}, \alpha\right) - r\left(-\frac{c_k^T q}{\|c_k\|_2}, \alpha\right) = \begin{cases} 0 & \alpha \neq 1 \\ \frac{2}{\pi} \log \|c_k\|_2 & \alpha = 1 \end{cases}$$

$$\begin{aligned} \nu \beta_k \gamma_k |c_k^T q|^{\alpha} \text{sign}(c_k^T q) \left(r\left(\frac{c_k^T q}{\|c_k\|_2}, \alpha\right) - r\left(-\frac{c_k^T q}{\|c_k\|_2}, \alpha\right) \right) &= \begin{cases} 0 & \alpha \neq 1 \\ \nu \beta_k \gamma_k \frac{\|c_k^T q\|_2^{\alpha}}{\|c_k\|_2^{\alpha}} \log \|c_k\|_2 & \alpha = 1 \end{cases} \\ &= \begin{cases} \nu \beta_k \gamma_k \frac{\|c_k^T q\|_2^{\alpha}}{\|c_k\|_2^{\alpha}} \log \|c_k\|_2 & \alpha \neq 1 \\ \nu \beta_k \gamma_k \frac{\|c_k^T q\|_2^{\alpha}}{\|c_k\|_2^{\alpha}} \log \|c_k\|_2 & \alpha = 1 \end{cases} \\ &= \begin{cases} \nu \beta_k \gamma_k \frac{\|c_k^T q\|_2^{\alpha}}{\|c_k\|_2^{\alpha}} \log \|c_k\|_2 & \alpha \neq 1 \\ \nu \beta_k \gamma_k \frac{\|c_k^T q\|_2^{\alpha}}{\|c_k\|_2^{\alpha}} \log \|c_k\|_2 & \alpha = 1 \end{cases} \\ &= \nu \beta_k \gamma_k \left(\mu_k - \eta_k(c_k|\alpha, \beta_k, \gamma_k, \mu_k) \right) \end{aligned}$$

$$\begin{aligned}
 \implies \int_{S_{it}} \psi(s^T q | \alpha) \Lambda_k ds &= -\log \phi(c_k^T q | \alpha, \beta_k, \gamma_k, \mu_k) + \eta_k(c_k | \alpha, \beta_k, \gamma_k, \mu_k) c_k^T q \\
 \implies \log(\Phi(q | \alpha, \tilde{\mu}, \Lambda)) &= -\int_{S_{it}} \psi(s^T q | \alpha) \Lambda(ds) + i \tilde{\mu} q \\
 &= -\sum_{k=1}^d \int_{S_{it}} \psi(s^T q | \alpha) \Lambda_k ds + i \sum_{k=1}^d \eta_k(c_k | \alpha, \beta_k, \gamma_k, \mu_k) c_k^T q \\
 \implies \log(\Phi(q | \alpha, \tilde{\mu}, \Lambda)) &= \sum_{k=1}^d \log \phi(c_k^T q | \alpha, \beta_k, \gamma_k, \mu_k) \\
 \implies \Phi(q | \alpha, \tilde{\mu}, \Lambda) &= \prod_{k=1}^d \phi(c_k^T q | \alpha, \beta_k, \gamma_k, \mu_k)
 \end{aligned}$$

Abstract

Training a multilayer perceptron (MLP) with algorithms employing global search strategies has been an important research direction in the field of neural networks. Despite a number of significant results, an important matter concerning the bounds of the search region—typically defined as a box—where a global optimization method has to search for a potential global minimizer seems to be unresolved. The approach presented in this paper builds on interval analysis and attempts to define guaranteed bounds in the search space prior to applying a global search algorithm for training an MLP. These bounds depend on the machine precision and the term “guaranteed” denotes that the region defined surely encloses weight sets that are global minimizers of the neural network’s error function. Although the solution set to the bounding problem for an MLP is in general non-convex, the paper presents the theoretical results that help deriving a box which is a convex set. This box is an outer approximation of the algebraic solutions to the interval equations resulting from the function implemented by the network nodes. An experimental study using well known benchmarks is presented in accordance with the theoretical results.

Keywords: neural network training, bound constrained global optimization, interval analysis, interval linear equations, algebraic solution

1. Introduction

Multi-layer perceptrons are feed forward neural networks featuring universal approximation properties used both in regression problems and in complex pattern classification tasks. Actually, an MLP is a means used to encode empirical knowledge about a physical phenomenon, i.e., a real world process. This encoding is done in terms of realizing a function F that is close enough to a target function $d = f(x)$ representing the underlying process. The target function is rarely formulated in analytical terms but it is defined as a set of input-output values $\{x_l, d_l\}$, $1 \leq l \leq p$, which is the training set resulting from observations of the underlying process.

More formally, an MLP is used to implement a model $F(x; w)$ about a physical process which is a mapping $F : \mathbb{R}^n \times \mathbb{R}^m \rightarrow \mathbb{R}^k$ whose values $F(x_l; w)$ have minimum distance from their corresponding d_l , where $x_l = (x_{1,l}, x_{2,l}, \dots, x_{n,l})^T$ and $w = (w_1, w_2, \dots, w_m)^T$. Given that x_l are known, this minimum distance depends on the values of the weights w . This formulates a problem of parametric model identification on the basis of the training set composed of the inputs and their corresponding outputs. Determining the values of the weights is done by an iterative process commonly known as network training, which consists in minimizing some cost function $E : \mathbb{R}^k \rightarrow \mathbb{R}$ of the network output.

The dominant approach when training feedforward neural networks has been to adopt local search in the weight space using some gradient descent technique in order to minimize the output error function. Adaptation of the weights is done with the well known error back-propagation (BP) algorithm. A detailed review of BP and other training algorithms based on gradient descent can be found in Haykin (1999). However, local search techniques are, in the general case, unable to detect with certainty a global or a “good” local minimum, and consequently the corresponding minimizer, as they may stuck in “bad” local minima. Researchers in the area of neural networks have tried to overcome this defect by proposing efficient weight initialization techniques (Adam et al., 2014; Nguyen and Widrow, 1990). Moreover, a number of effective search strategies have been proposed (Magoulas et al., 1997, 1999) which concern definition or adaptation of relevant parameters of the search procedure such as the step-size, the momentum term etc.

The counter approach to local search is to use global search of the free parameter space. The techniques based on global optimization can be either exact or heuristic (Horst and Pardalos, 1995). Exact global optimization methods can be roughly defined as deterministic or stochastic (Pál, 2010). Deterministic global search techniques perform exhaustive search of the weight space and they guarantee to locate a global minimizer (Tang and Koehler, 1994). However, often the time needed for this task is unacceptable, especially for real life applications, and usually it is achieved with excessive use of computational resources. This is mainly due to the size of the parameter space which grows with the number of free parameters (weights) of the neural networks. An alternative approach to deterministic search has been the use of stochastic global search methods which are based on random sampling of the search space adopting random or adaptive random search strategies. Such methods include Monte Carlo techniques (Brooks, 1958; Caffisch, 1998) and multistart methods (Boender et al., 1982). On the other hand, heuristic methods include simulated annealing (Engel, 1988; Kirkpatrick et al., 1983) and techniques based on evolutionary computation such as the genetic algorithm (GA) (Castillo et al., 2000; Montana and Davis, 1989), Par-

title Swarm Optimization (PSO) (Gudise and Venayagamoorthy, 2003; van den Bergh and Engelbrecht, 2000) and differential evolution algorithms (Iloen et al., 2003).

Although these methods possess several desirable characteristics and have proven to be effective in several applications, they cannot guarantee—in the general case—that they are able to detect a global minimizer in the first run. Moreover, their performance, in terms of the overall search time, depends on the scale of the problem. To a large extent, this is due to inappropriate initial conditions because the search space is only heuristically known (Parsopoulos and Vrahatis, 2010). A common technique to reduce the uncertainty about the search space and enhance the efficiency of these methods is to define the region of the search space to be “as large as possible”. A survey of global optimization techniques used for neural network training can be found in Duch and Korczak (1998) as well as in Paganakes et al. (2001, 2006). Finally, it is worth noting that a number of research work has focused on combining local and global search in order to alleviate the disadvantages of local search methods or in order to decrease the overall search time in the case of global search of the weight space (Bagirov et al., 2009; Caprani et al., 1993; Ng et al., 2010; Shiang and Wall, 1996; Voglis and Lagaris, 2009; Xu, 2002).

A common characteristic to all global search procedures used for training MLPs is that the bounds of the search region are intuitively defined. This approach, often, proves to be inadequate to support training MLPs with global optimization methods. Hence, defining effective bounds of the search space is a cornerstone for using global search strategies in real life applications of feedforward neural networks. The approach presented in this paper is based on concepts of interval analysis and attempts to define guaranteed bounds of the search space prior to applying a global search procedure for neural network training. The term “guaranteed” denotes that the bounds of the region defined surely enclose weights that are global minimizers of the error function. Once the box is defined, it is up to the global optimization method to explore the region identified by the proposed approach in order to find the set of weights that minimize the error function of the multilayer perceptron.

The rest of the paper is organized as follows. Section 2 is devoted to a detailed description of the problem background and the motivation for the proposed approach. Section 3 presents the solution proposed to tackle this problem. In Section 4 we derive the theoretical results for bounding the feasible solution set of the problem and discuss these results. In Section 5 we validate the proposed method on real world problems and discuss the experimental results. Finally, Section 6 summarizes the paper with some concluding remarks.

2. Problem Formulation in a Global Optimization Context

Hereafter, we consider feed forward neural networks having 3 layers with n , h , and o nodes in the input, the hidden and the output layers, respectively. It has been proved that standard feedforward networks with only a single hidden layer can approximate any continuous function uniformly on any compact set and any measurable function to any desired degree of accuracy (Cybenko, 1989; Hornik et al., 1989; Kreinovich and Shtinsengtaksin, 1993; White, 1990). Hence, it has general importance to study 3-layer neural networks. On the other hand, as it will be shown, the assumption regarding the number of layers is not restrictive, given that the weights of each layer are treated with respect to the output range of the previous layer and the input domain of the next one. Hence, it is straightforward to extend

this analysis to networks with multiple hidden layers. Moreover, despite the variety of activation functions found in the literature (Duch and Jankowski, 1999), in this paper we have retained the most common assumptions adopted for MLPs. This means that the nodes in the hidden layer are supposed to have a sigmoid activation function which may be one of the following:

$$\text{logistic sigmoid} : \sigma_1(\text{net}) = \frac{1}{1 + e^{-\alpha \text{net}}}, \quad (1a)$$

$$\text{hyperbolic tangent} : \sigma_2(\text{net}) = \tanh(\beta \text{net}) = \frac{e^{\beta \text{net}} - e^{-\beta \text{net}}}{e^{\beta \text{net}} + e^{-\beta \text{net}}}, \text{ or} \quad (1b)$$

$$\sigma_2(\text{net}) = \frac{2}{1 + e^{-2\beta \text{net}}} - 1,$$

where net denotes the input to a node and α , β are the slope parameters of the sigmoids. Hereafter, let us assume that $\alpha = \beta = 1$ and note that this assumption has no effect on the theoretical analysis presented in this paper. Nevertheless, for application purposes using different values for the slope parameters has an effect on the results obtained, as it will be explained later in Subsection 3.2. In addition to the previous assumptions, let us suppose that the nodes in the output layer may have either one of the above sigmoid activation functions or the linear one. Finally, we assume that all nodes in the hidden layer use the same activation function and the same stands for the output layer nodes.

With respect to the above assumptions the function computed by a feed forward neural network can be defined as $F : \mathbb{R}^n \times \mathbb{R}^{(n+1)h} \times \mathbb{R}^{(h+1)o} \rightarrow \mathbb{R}^o$, where $F(X, W_1, W_2)$ denotes the actual network output, $X \in \mathbb{R}^n$ refers to the input patterns, $W_1 \in \mathbb{R}^{(n+1)h}$ is the matrix of the input-to-hidden layer connection weights and biases, and $W_2 \in \mathbb{R}^{(h+1)o}$ denotes the matrix of the hidden-to-output layer connection weights and biases. Moreover, let us denote $T \in \mathbb{R}^o$ the target output of the function approximated by the network. Obviously, if any of the parameters, X, W_1, W_2 , and T is interval valued then the network is an interval neural network (Hu et al., 1998).

The process of neural networks training aims to solve the following optimization problem:

$$\text{arg min}_{W_1 \in \mathbb{R}^{(n+1)h}, W_2 \in \mathbb{R}^{(h+1)o}} \|F(X, W_1, W_2) - T\|_q \quad (2)$$

for some appropriate norm $\|\cdot\|_q$, considering that the ideal minimum of $\|F(X, W_1, W_2) - T\|_q$ is 0, which means that $F(X, W_1, W_2) = T$.

As said above, training the network is defining the values of the elements of the matrices W_1 and W_2 that solve the previous unconstrained minimization problem. The domain of these weights is not known in advance and so, in practice, the global optimization procedures used to solve this problem search for the global minimum in a box $\mathbb{D}_w \subset \mathbb{R}^{(n+1)h} \times \mathbb{R}^{(h+1)o}$. This means that the initial unconstrained global optimization problem is arbitrarily converted to an ad-hoc bound constrained optimization one. The bounds of this box and therefore its size are defined intuitively. Such a choice may lead to unsuccessful training or give a computationally expensive solution that is impractical to use in real life problems. The argument that the box \mathbb{D}_w is intuitively defined is supported by a number of examples found in the literature.

For instance, Sarcev (2012) gives an example of interval global optimization for training a network that approximates the function $z = 0.5 \sin(\pi x^2) \sin(2\pi y)$ and defines the initial

box to be $[w]_0 = [-10, 10]^s$, where s is the number of unknown weights. The results reported in the paper indicate that the global optimization technique succeeded in training the network using this initial box. However, the author does not provide any justification on how the initial search box was defined.

Another example is given by the approach formulated by Jamett and Acuña (2006) to solve the problem of weight initialization for an MLP based on interval analysis. These researchers argue that their approach “solves the network weight initialization problem performing an exhaustive global search for minimums in the weight space by means of interval arithmetic. The global minimum is obtained once the search has been limited to the estimated region of convergence.” For the experimental evaluation proposed in Jamett and Acuña (2006) the interval weights are initially defined as wide as necessary, with widths up to 10^6 .

In Hu et al. (1998) the authors consider a 3-layer interval neural network and they propose to adjust the interval weights with the use of the Newton interval method solving a system of nonlinear equations of the $h(n+o)$ unknown weights. This is possible under the hypothesis that the network is, what they call, a Type 1 interval neural network, i.e., a network for which the number l of nonlinear equations, formed using all available patterns x^k , $1 \leq k \leq l$, satisfy the inequality $l \leq h(n+o)$. When this inequality is not true they propose to use an interval branch-and-bound algorithm to solve the minimization problem related to the network training. However, the authors do not provide any kind of concrete experiment where interval global optimization is actually used for training the network.

In addition to the above, one should mention the problems related to the initialization and the bounds of the search region reported with heuristic and population based approaches when solving global optimization problems and more specifically when training MLPs. For instance, Helwig and Wanka (2008) showed that when PSO is used to solve problems with boundary constraints in high-dimensional search spaces, many particles leave the search space at the beginning of the optimization process. This commonly known problem of “particle explosion” (Clerc and Kennedy, 2002) for PSO in high-dimensional bounded spaces highlights the importance of defining bound handling procedures.

Moreover, when dealing with neural network training, one should take into account the remarks reported by Gudise and Venayagamoorthy (2003) regarding the selection of parameters for PSO. The authors report that during their experiments in order to determine the optimal PSO parameters they found that “A small search space range of $[-1, 1]$ did not provide enough freedom for the particles to explore the space and hence they failed to find the best position”. So, they gradually increased the size of the search space from $[-1, 1]$ to $[-200, 200]$ and they observed that a search space range of $[-100, 100]$ was the best range for having optimal performance of the PSO algorithm. Finally, when no limits were set on the search space range, the convergence rate of PSO decreased and there appeared to be even cases of no convergence.

According to the above examples, it is obvious that the outcome of training an MLP with global optimization is unpredictable as there is no information concerning the region where a global minimum of the error function is located. To the best of our knowledge this statement is true no matter the type of the global optimization procedure used. So, researchers and practitioners in the field proceed using random (intuitively defined) bounds which result in trial and error training strategies. This paper argues that it is possible to

derive the bounds of the search region for this type of global optimization task. It will be shown that the box defined by these bounds is guaranteed to enclose some global minimizers of the network output error function. This permits to obtain a value for the global minimum which is at least equal to the “machine ideal global minimum”, that is the best value for the global minimum that can be computed within the limits set by the machine precision. The results obtained in this paper apply to any type of global optimization procedure used to train an MLP.

3. Bounding the Weight Space Using Interval Analysis

The idea underlying our analysis is to consider the bounds of the range of each node in the output, the hidden and the input layer respectively. These bounds are implicit constraints imposed by the type of the activation function for the nodes in the output and the hidden layers. Moreover, explicit constraints are imposed by the values of the input patterns for the input layer. Performing local inversion of the activation function at the level of each node and using the constraints on its inputs imposed by the output of the previous layer results in formulating suitable linear interval equations. The subsequent analysis of the solution sets of these equations permits to derive the bounds of a box enclosing the region where some global minimizers of the network output error function are located. The approach proposed leads to defining a suitable approximation \mathbb{D}_w of the feasible set S for the error function of the network.

3.1 The Interval Analysis Formalism

Interval arithmetic has been defined as a means of setting lower and upper bounds on the effect produced on a computed quantity by different types of mathematical errors. The efficiency of methods built on interval arithmetic is related to these bounds, which need to be as narrow as possible. Thus, the major focus of interval analysis is to develop interval algorithms producing sharp solutions when computing numerical problems. A real interval, or interval number, is a closed interval $[a, b] \subset \mathbb{R}$ of all real numbers between (and including) the endpoints a and b , with $a \leq b$. The terms interval and interval number are used interchangeably. Whenever $a = b$ the interval is said to be degenerate, thin or even point interval. An interval $[a, b]$ where $a = -b$ is called a symmetric interval. Regarding notation, an interval x may be also denoted $[x]$, or $[\underline{x}, \bar{x}]$, or even $[x_L, x_U]$ where subscripts L and U stand for lower and upper bounds respectively. Notation for interval variables may be uppercase or lowercase (Alefeld and Mayer, 2000). Throughout this paper we will use the notation $[x]$ whenever we refer to an interval number, while notation $[\underline{x}, \bar{x}]$ will be used when explicit reference to the interval bounds is required. Moreover, an n -dimensional interval vector, that is a vector having n real interval components $([v_1], [v_2], \dots, [v_n])^T$, will be denoted $[v]$ or even $[\underline{v}, \bar{v}]$. Finally, uppercase letters will be used for matrices with interval elements as for an $n \times m$ interval matrix $[A] = ((a_{ij}))_{\substack{i=1,2,\dots,n \\ j=1,2,\dots,m}}$.

Generally, if $[z] = [\underline{z}, \bar{z}]$ is a real interval then the following notation is used:

$\text{rad}([x]) = (\bar{x} - \underline{x})/2$, is the radius of the interval $[x]$,

$\text{mid}([x]) = (\bar{x} + \underline{x})/2$, is the midpoint (mean value) of the interval $[x]$,

$|[x]| = \max\{|\underline{x}|, |\bar{x}|\}$, is the absolute value (magnitude) of the interval $[x]$,

$d([x]) = \bar{x} - \underline{x}$, is the diameter (width) of the interval $[x]$,

\mathbb{IR} , denotes the set of closed real intervals,

\mathbb{IR}^n , denotes the set of n -dimensional vectors of closed real intervals.

Let \diamond denote one of the elementary arithmetic operators $\{+, -, \times, \div\}$ for the simple arithmetic of real numbers x, y . If $[x] = [\underline{x}, \bar{x}]$ and $[y] = [\underline{y}, \bar{y}]$ denote real intervals then the four elementary arithmetic operations are defined by the rule

$$[x] \diamond [y] = \{x \diamond y \mid x \in [x], y \in [y]\}.$$

This definition guarantees that $x \diamond y \in [x] \diamond [y]$ for any arithmetic operator and any values x and y . In practical calculations each interval arithmetic operation is reduced to operations between real machine numbers. For the intervals $[x]$ and $[y]$ it can be shown that the above definition produces the following intervals for each arithmetic operation:

$$\begin{aligned} [x] + [y] &= [\underline{x} + \underline{y}, \bar{x} + \bar{y}], \\ [x] - [y] &= [\underline{x} - \bar{y}, \bar{x} - \underline{y}], \\ [x] \times [y] &= \{\min(\underline{x}\underline{y}, \underline{x}\bar{y}, \bar{x}\underline{y}, \bar{x}\bar{y}), \max(\underline{x}\underline{y}, \underline{x}\bar{y}, \bar{x}\underline{y}, \bar{x}\bar{y})\}, \\ [x] \div [y] &= [x] \times \frac{1}{[y]}, \text{ with} \\ \frac{1}{[y]} &= \left[\frac{1}{\bar{y}}, \frac{1}{\underline{y}} \right], \text{ provided that } 0 \notin [\underline{y}, \bar{y}]. \end{aligned}$$

The usual algebraic laws of arithmetic operations applied to real numbers need to be re-considered regarding finite arithmetic on intervals. For instance, a non-degenerate (thick) interval has no inverse with respect to addition and multiplication. So, if $[x], [y]$, and $[z]$ are non-degenerate intervals then,

$$\begin{aligned} [x] + [y] &= [z] \not\Rightarrow [x] = [z] - [y], \\ [x] \times [y] &= [z] \not\Rightarrow [x] = [z] \times \frac{1}{[y]}. \end{aligned}$$

The following sub-distributive law holds for non-degenerate intervals $[x], [y]$, and $[z]$,

$$[x] \times ([y] + [z]) \subseteq [x] \times [y] + [x] \times [z].$$

Note that the usual distributive law holds in some particular cases: if $[x]$ is a point interval, if both $[y]$ and $[z]$ are point intervals, or if $[y]$ and $[z]$ lie on the same side of 0. Hereafter, the multiplication operator \times will be omitted as in usual algebraic expressions with

real numbers. Interval arithmetic operations are said to be *inclusion isotonic* or *inclusion monotonic* or even *inclusion monotone* given that the following relations hold,

$$\begin{aligned} \text{if } [a], [b], [c], [d] \in \mathbb{IR} \text{ and } [a] \subseteq [b], [c] \subseteq [d] \\ \text{then } [a] \diamond [c] \subseteq [b] \diamond [d], \text{ for } \diamond \in \{+, -, \times, \div\}. \end{aligned}$$

The property of *inclusion isotony* for interval arithmetic operations is considered to be the fundamental principle of interval analysis. More details on interval arithmetic and its extensions can be found in Alefeld and Mayer (2000); Hansen and Walster (2004), and Neumaier (1990).

Standard interval functions φ are extensions of the corresponding real functions $F = \{\sin(), \cos(), \tan(), \arctan(), \exp(), \ln(), \text{abs}(), \text{sqrt}(), \text{sqrt}()\}$ and they are defined via their range, i.e., $\varphi([x]) = \{\varphi(x) \mid x \in [x]\}$, for $\varphi \in F$, (Alefeld and Mayer, 2000). Given that, these real functions are continuous and piecewise monotone on any compact interval in their domain of definition, the values $\varphi([x])$ can be computed directly from the values at the bounds of $[x]$. For non-monotonic functions such as the trigonometric ones the computation is more complicated. For instance, $\sin(0, \pi) = [0, 1]$ which differs from the interval $[\sin(0), \sin(\pi)]$. In these cases, the computation is carried out using an algorithm (Jaulin et al., 2001). Finally, it must be noted that the standard interval functions are inclusion monotonic.

Let $f : D \subset \mathbb{R} \rightarrow \mathbb{R}$ be a real function and $[x] \subseteq D$ an interval in its domain of definition. The range of values of f over $[x]$ may be denoted by $R(f; [x])$ (Alefeld and Mayer, 2000) or simply $f([x])$. Computing the range $f([x])$ of a real function by interval analysis tools practically comes to enclosing the range $f([x])$ by an interval which is as narrow as possible. This is an important task in interval analysis which can be used for various reasons, such as localizing and enclosing global minimizers and global minima of f on $[x]$, verifying that $f([x]) \subseteq [y]$ for some given interval $[y]$, verifying the nonexistence of a zero of f in $[x]$ etc.

Enclosing the range of f over an interval $[x]$ is achieved by defining a suitable interval function $[f] : \mathbb{IR} \rightarrow \mathbb{IR}$ such that $\forall [x] \in \mathbb{IR}, f([x]) \subset [f]([x])$. This interval function is called an inclusion function of f . What is important when considering an inclusion function $[f]$ is that it permits to compute a box $[f]([x])$ which is guaranteed to contain $f([x])$, whatever the shape of $f([x])$ (Jaulin et al., 2001). Note that the so-called natural inclusion function is defined if $f(x), x \in D$ is computed as a finite composition of elementary arithmetic operators $\{+, -, \times, \div\}$ and standard functions $\varphi \in F$ as above. The natural inclusion function of f is obtained by replacing the real variable x by an interval variable $[x] \subseteq D$, each operator or function by its interval counterpart and evaluating the resulting interval expression using the rules in the previous paragraphs. The natural inclusion function has important properties such as being inclusion monotonic and if f involves only continuous operators and continuous standard functions it is convergent (see Jaulin et al., 2001).

3.2 Weights of Hidden-to-output Layer Connections

Let us compute the bounds of the intervals of the weights for any output node. As we will see the procedure described herein does not depend on the number of inputs to the node but merely on the type of its activation function.

The output z_k of the k -th node in the output layer is given by

$$z_k = \sigma \left(\sum_{j=1}^h w_{kj} y_j + w_{kb} \right), \quad (3)$$

where y_j is the output of the j -th node in the hidden layer. During training the output z_k may be any value in the range of the sigmoid activation function σ used by the output layer nodes. So, $z_k \in [0, 1]$ for the logistic sigmoid and $z_k \in [-1, 1]$ for the hyperbolic tangent.

The activation functions defined in (1) are bijective and so they are invertible. Using the inverse σ^{-1} of the activation function σ on both sides of (3) gives:

$$\sigma^{-1}(z_k) = \sigma^{-1} \left(\sigma \left(\sum_{j=1}^h w_{kj} y_j + w_{kb} \right) \right)$$

and finally the equation,

$$\sum_{j=1}^h w_{kj} y_j + w_{kb} = \sigma^{-1}(z_k). \quad (4)$$

The inverse of the activation functions are

$$\text{for the logistic sigmoid : } \sigma_1^{-1} = -\ln \frac{1-x}{x}, \text{ and}$$

$$\text{for the hyperbolic tangent : } \sigma_2^{-1} = \operatorname{atanh}(x) = \frac{1}{2} \ln \left(\frac{1+x}{1-x} \right).$$

The output of each activation function is an interval. So, the values of the inverse of the activation functions are,

$$\text{for the logistic sigmoid : } \sigma_1^{-1}([0, 1]) = [-\infty, +\infty],$$

$$\text{for the hyperbolic tangent : } \sigma_2^{-1}([-1, 1]) = [-\infty, +\infty].$$

For nodes with sigmoid activation functions when the output value is one of the exact bounds of the intervals $[0, 1]$ or $[-1, 1]$, then the corresponding node is saturated. This implies that connection weights take very large values. However, in practice this is rarely achieved and as Rumelhart et al. (1986) note: "The system cannot actually reach its extreme values of 1 or 0 without infinitely large weights. Therefore, in a practical learning situation in which the desired outputs are binary $\{0, 1\}$, the system can never actually achieve these values. Therefore, we typically use the values of 0.1 and 0.9 as the targets, even though we will talk as if values of $\{0, 1\}$ are sought." This consideration is adopted for the values of the output layer nodes in various practical pattern recognition applications of MLPs as well as in research papers such as Sprinkhuizen-Kuyper and Boers (1999); Yam and Chow (2001).

This means that a node with a sigmoid activation function becomes saturated with input values much greater than $-\infty$ and drastically smaller than $+\infty$, and its output is still considered to be 0 (or -1), and 1, respectively. Hence, as far as saturation of the node is concerned, for practical use instead of the interval $[-\infty, +\infty]$ one may consider a substitute $[-\mathbf{b}, \mathbf{b}]$, where $\mathbf{b} > 0$. In consequence, the node output is not any of the "ideal" intervals

$[0, 1]$ or $[-1, 1]$ but merely some approximation such as $[0 + \varepsilon, 1 - \varepsilon]$ or $[-1 + \varepsilon, 1 - \varepsilon]$ where ε depends on the value of \mathbf{b} and, obviously, it should satisfy the precision required for the problem.

Henceforth, the interval $[-\mathbf{b}, \mathbf{b}]$, for some $\mathbf{b} > 0$, will be used instead of the $[-\infty, +\infty]$ for the input values of the sigmoid activation function of any node in the output, or in the hidden, layer. With this assumption the intervals resulting for the inverse of the activation functions of the output layer nodes are:

$$\text{for the logistic sigmoid : } \sigma_1^{-1}([0 + \varepsilon, 1 - \varepsilon]) = [-\mathbf{b}_1, \mathbf{b}_1], \quad (5a)$$

$$\text{for the hyperbolic tangent : } \sigma_2^{-1}([-1 + \varepsilon, 1 - \varepsilon]) = [-\mathbf{b}_2, \mathbf{b}_2]. \quad (5b)$$

So, \mathbf{b}_1 and \mathbf{b}_2 are such that $\sigma_1([-1 + \varepsilon, 1 - \varepsilon]) = [0 + \varepsilon, 1 - \varepsilon] \triangleq [0, 1]_\varepsilon$ and $\sigma_2([-1 + \varepsilon, 1 - \varepsilon]) \triangleq [-1, 1]_\varepsilon$.

With these results (4) implies that

$$\sum_{j=1}^h w_{kj} y_j + w_{kb} \in [-\mathbf{b}, \mathbf{b}], \quad (6)$$

where $\mathbf{b} = \mathbf{b}_1$ or $\mathbf{b} = \mathbf{b}_2$, depending on the type of the activation function used. Recall that in Section 2 we assumed that the slope parameters α and β of the sigmoids are considered to be equal to 1. If this assumption does not hold then it is easy to see that the bounds \mathbf{b}_1 and \mathbf{b}_2 , defined here, need to be divided by α and β , respectively.

Taking into account the type of the activation function of the hidden layer nodes we have that $y_j \in [0, 1]$ for the logistic sigmoid and $y_j \in [-1, 1]$ for the hyperbolic tangent. However, we note that the above assumptions, regarding the approximations of the interval $[-\infty, +\infty]$, also hold for the sigmoid activation functions of the hidden layer nodes. So, in practical situations, we consider that $y_j \in [0, 1]_\varepsilon$ and $y_j \in [-1, 1]_\varepsilon$, where $[0, 1]_\varepsilon \subset [0, 1]$ and $[-1, 1]_\varepsilon \subset [-1, 1]$. Then, because of the inclusion monotonicity property of the interval arithmetic operators and the activation functions, in the analysis presented in this paper, for the interval equations we use the intervals $[0, 1]$ and $[-1, 1]$ instead of $[0, 1]_\varepsilon$ and $[-1, 1]_\varepsilon$, respectively. This means that any solution set or enclosure of a solution set determined, herein, for an interval equation using the wider intervals $[0, 1]$ and $[-1, 1]$ also constitute enclosures of the solution set of the same equation using the narrower ones, $[0, 1]_\varepsilon$ and $[-1, 1]_\varepsilon$.

Using all these results we may formulate the following two linear interval inequalities for the unknown weights of the hidden-to-output layer connections:

$$\sum_{j=1}^h [w_{kj}] [0, 1] + [w_{kb}] \leq [-\mathbf{b}, \mathbf{b}],$$

$$\sum_{j=1}^h [w_{kj}] [-1, 1] + [w_{kb}] \leq [-\mathbf{b}, \mathbf{b}].$$

Hence, the interval $[-\mathbf{b}, \mathbf{b}]$ determines an enclosure of the intervals $[w_{kj}]$, $1 \leq j \leq h$. However, as the aim of this paper is to bound the box containing the values of w_{kj} which solve

Equation (4), instead of solving the above inequalities we may, equivalently, consider the following equations and define approximations of the corresponding solution sets:

$$\sum_{j=1}^h [w_{kj}] [0, 1] + [w_{kh}] = [-b, b], \quad (7a)$$

$$\sum_{j=1}^h [w_{kj}] [-1, 1] + [w_{kh}] = [-b, b]. \quad (7b)$$

Before, examining solvability issues and the relation of the solutions to these equations with the problem at hand, let us discuss, hereafter, some issues concerning the parameter \mathbf{b} and its relation to ε .

3.2.1 ON THE DEFINITION OF THE PARAMETERS \mathbf{b} AND ε

The previous analysis introduced the interval $[-b, b]$ for the input values of a sigmoid activation function. This interval may also be defined for other types of activation functions and so its bounds depend on the type of the activation function. In the following sections we will show that these bounds, actually, define the volume of the area in the network weight space where global minimizers of the network's error function are located. The analysis presented in this paper does not rely on some specific values of the bounds of the interval $[-b, b]$. Instead, the results obtained depend on the activation functions of the network nodes and the calculation precision set for the problem. So, they have \mathbf{b} 's as parameters.

As noted above, for sigmoid activation functions, the interval $[-b, b]$ implicitly defines the intervals $[0, 1]_\varepsilon$ or $[-1, 1]_\varepsilon$ which approximate the intervals $[0, 1]$ or $[-1, 1]$, respectively. Conversely, by setting some specific value to ε and using the inverse of the activation functions, one is able to define a value for \mathbf{b} , and in consequence the width of the interval $[-b, b]$. As this interval determines enclosures for the intervals $[w_{kj}]$, $1 \leq j \leq h$, it is obvious that its width determines the magnitudes of the corresponding dimensions of the minimizers' search area. Here, this search area is considered to be a hyper-box in the weight space, determined by the intervals $[-b, b]$, for all network nodes. On the other hand, selecting some specific value for ε determines the numerical precision used by the network output for solving the problem at hand. Therefore, an interval $[-b, b]$ defines some ε inducing some numerical precision for the problem, and vice-versa. The smaller the area defined by small values of \mathbf{b} the bigger the values of ε and so the lower the precision. Conversely, the highest the precision for computing the network outputs the smaller the values of ε and so the larger the search area defined by larger \mathbf{b} 's.

This problem can be formulated in the following terms: 'How large can ε be in order to minimize \mathbf{b} and in consequence the search area of global minimizers without compromising the numerical precision for solving the problem'. Hence, some tradeoff between \mathbf{b} (volume of the search area) and ε (numerical precision) seems to be required here. The impact of selecting a value for \mathbf{b} , or equivalently for ε , on the numerical precision of the problem mainly concerns the accuracy required for the network output in order to match the problem requirements. In a classification context and for practical applications, this issue is probably insignificant given that, typically, for such problems an approximate response of the order of

$\varepsilon = 0.1$ is sufficient for the classification task. On the other hand, for function approximation problems where accuracy of the network output is really a prerequisite, the output nodes use linear activation functions as for these kind of problems networks perform regression tasks (Hornik et al., 1989; White, 1990). As we will see, hereafter, such approximation assumptions do not apply to linear activation functions. Moreover, for hidden nodes using sigmoid activation functions, as we will see, approximating the intervals $[0, 1]$ and $[-1, 1]$ by $[0, 1]_\varepsilon$ and $[-1, 1]_\varepsilon$, respectively, where ε is of the order of the machine precision, is sufficient for carrying out the neural computation. Actually, such an approximation is within the numerical precision adopted for neural computations in various contexts.

The problem of numerical precision pertaining neural computations has been addressed by several researchers. For instance, some of the earlier research include the work of Hoelzfeld and Fahlman (1992) who studied the possibility of training a network using the cascade-correlation algorithm in a limited numerical precision learning context. Moreover, Hoi and Hwang (1993) addressed the question of the precision required in order to implement neural network algorithms on low precision hardware. The authors performed a theoretical analysis of the error produced by finite precision computation and investigated the precision that is necessary in order to perform successful neural computations both for training a multilayer perceptron with back-propagation as well as for forward activation and retrieving. A more recent work (Draghici, 2002) deals with the capabilities of neural networks using weights with limited precision and the work of Vassiliadis et al. (2000) states that a representation error of 2^{-10} provides a limit for a safe approximation error in neural functions computations. Such an error is within the limits of machine precision and double precision arithmetic. The most recent research focuses on the numerical precision required for deep neural networks and their hardware implementation (Courbariaux et al., 2014; Gupta et al., 2015; Judd et al., 2016).

The precision level used for a neural network and the problem at hand is a matter that needs to be addressed prior to any implementation, either software or hardware. Following the above literature, in this paper, we may state that double precision floating point arithmetic proposed by the IEEE (754–2008) standard (Higham, 2002; IEEE, 2008) provides a very good precision level as required by modern neural computation applications and hardware implementations. Hence, for the experimental evaluation of the proposed approach the value of the machine epsilon, commonly known as double precision epsilon ($\varepsilon = 2.2204 \times 10^{-16}$) is retained in this paper. This value of ε is the precision (eps) used for the computing environment MATLAB (MATLAB-Documentation, 2014) as well as for the majority of the programming languages according to IEEE (754–2008) standard. As a consequence we have the following values for \mathbf{b} :

$$\text{for the logistic sigmoid : } \mathbf{b}_1 = 36.0437,$$

$$\text{for the hyperbolic tangent : } \mathbf{b}_2 = 18.3684.$$

Note that, under the specific assumptions of Rummelhart et al. (1986) the intervals resulting for the inverse of the activation functions of the output layer nodes are,

$$\text{for the logistic sigmoid : } \sigma_1^{-1}(0.1, 0.9) = [-2.1972, 2.1972],$$

$$\text{for the hyperbolic tangent : } \sigma_2^{-1}(-0.9, 0.9) = [-1.4722, 1.4722].$$

The analysis presented in this subsection relies on the assumption that the activation function of the output nodes is the logistic sigmoid or the hyperbolic tangent. However, when an MLP is used for function approximation or regression then usually linear activations are used in the output nodes. In order to establish a unique formalism for our analysis we need to define an interval of the type $[-\mathbf{b}, \mathbf{b}]$ for a pure linear activation function of the network's output nodes.

The sample of the input data, by default, defines an interval $[\underline{z}_k, \bar{z}_k]$ for the range of values of the k -th output node. A pure linear activation function f_{lin} is invertible in its domain. So, using inversion we obtain an interval of the type $[a_k, b_k] = f_{lin}^{-1}([\underline{z}_k, \bar{z}_k])$ for the input values of the linear activation function. Seemingly, such an interval is not symmetric and so, in order to keep pace with the previous assumptions, we extend it to obtain a symmetric interval of the type $[-\mathbf{b}, \mathbf{b}]$. This is achieved by setting $\mathbf{b}_{3,k} = \max\{a_k, |b_k|\}$ and considering the interval $[-\mathbf{b}_{3,k}, \mathbf{b}_{3,k}]$ instead of $[a_k, b_k]$ which actually permits to adopt the above assumptions and the ensuing conclusions. It is obvious that, during training it depends on the optimization procedure to narrow the search space back to the initial interval $[a_k, b_k]$.

Note that, if sampling of the input space is performed with a distribution which is close to the underlying distribution of the input space then the sample data are representative of the real data and hence the output of any node is reliably set by the values derived from the patterns. If sampling of the input space is not correct then the input data will provide erroneous dimensions of the search area. However, this unfortunate outcome will happen whatever the network or the training algorithm used.

The above considerations are necessary in order to tackle the hidden-to-output connection weights using Equations (7a) and (7b) as the unique formalism for the problem. Hereafter, whatever the activation function of the output nodes its range of values will be considered a symmetric interval of the form $[-\mathbf{b}, \mathbf{b}]$.

3.2.2 ON THE SOLUTION OF THE INTERVAL EQUATIONS

In interval analysis, the formal notation $[A][x] = [b]$ (or $[A]x = [b]$) of an interval linear system, where $[A] \in \mathbb{IR}^{m \times n}$ is an m -by- n matrix of real intervals and $[b] \in \mathbb{IR}^m$ is an m -dimensional vector of real intervals, denotes different interval problems (Shary, 1995). Respectively, the solution or solution set to this interval linear system has been defined in a number of possible ways (Shary, 1997). The paper uses the so-called *algebraic solution*, which is an interval vector $[x^e]$ such that, when substituting into $[A][x] = [b]$ and executing all interval arithmetic operations, results in the valid equality $[A][x^e] = [b]$. Later, in Section 4, we will show the implication of an *algebraic solution* in deriving an outer approximation of the solutions of Equations (7a) and (7b). For a theoretical justification of this choice see Shary (1996, 2002) and references therein. An algebraic solution for the bounding of the weight space is an interval vector of the form $[w_k^a] = ([w_{k1}^a], [w_{k2}^a], \dots, [w_{kb}^a], [w_{kb}^a])^\top$, such that each of the relations,

$$\begin{aligned} [w_{k1}^a][0, 1] + [w_{k2}^a][0, 1] + \dots + [w_{kb}^a][0, 1] + [w_{kb}^a][1, 1] &= [-\mathbf{b}, \mathbf{b}], \\ [w_{k1}^a][-1, 1] + [w_{k2}^a][-1, 1] + \dots + [w_{kb}^a][-1, 1] + [w_{kb}^a][1, 1] &= [-\mathbf{b}, \mathbf{b}], \end{aligned}$$

corresponding to (7a) and (7b), respectively, is a valid interval equality.

A suitable approximation of the feasible solution set to the training problem (2) can be

derived considering the bounds of the interval components of the algebraic solution to each of the Equations (7a) and (7b). In the following section we are defining the bounds of an algebraic solution to each of the aforementioned equations. This is accomplished by taking into account the specific type of these equations and considering the algebraic solutions (Shary, 1997) to these equations. Before proceeding to defining these algebraic solutions let us consider two issues; one concerning solvability of Equations (7a) and (7b) and the other dealing with effectively solving these equations.

Solvability of the above Equations (7a) and (7b) can be studied either considering each equation as an $1 \times (h + 1)$ system and using the results in Rohn (2003), or applying the conclusions of Ratschek and Sauer (1982). Using the latter in our case is more appropriate given that Ratschek and Sauer (1982) have considered the concept of the algebraic solution to an interval linear equation (see also Shary, 1996). Hence, the conclusions concerning the solvability of a single interval equation of the general form $\mathbf{A}_1 \mathbf{x}_1 + \mathbf{A}_2 \mathbf{x}_2 + \dots + \mathbf{A}_n \mathbf{x}_n = \mathbf{B}$, as denoted and studied in Ratschek and Sauer (1982), apply also in our case. The hypotheses of Ratschek and Sauer (1982, Theorem 1) are satisfied and so the above Equations (7a) and (7b) are solvable having eventually multiple solutions.

Solving a linear interval equation or defining an optimal enclosure of the solution set is a matter addressed by several researchers; see for example Beaumont (1998); Hansen (1969); Hansen and Sengupta (1981); Jansson (1997); Kreinovich et al. (1993); Neumaier (1986); Rohn (1989, 1995); Shary (1995) and extensive references therein. However, there is quite a little work done on solving an underdetermined linear interval equation. To the best of our knowledge, for this matter Neumaier (1986) refers to the work of Rump (1983) while the work of Popova (2006) proposes an algorithm which improves the approach used in Hölbig and Krämer (2003) and Krämer et al. (2006). In addition, INTLAB (Rump, 1999) provides an algorithm for solving underdetermined linear systems of interval equations which, however, does not seem to converge in all cases.

Finally, note that Ratschek and Sauer (1982) examined in detail the convexity of the solution set of the equation $\mathbf{A}_1 \mathbf{x}_1 + \mathbf{A}_2 \mathbf{x}_2 + \dots + \mathbf{A}_n \mathbf{x}_n = \mathbf{B}$ if this equation is solvable. According to Ratschek and Sauer (1982, Theorem 6) the solution set to each of the Equations (7a) and (7b) is not convex. However, the approach proposed in the next section results in defining an outer approximation which is a convex set.

3.3 Weights of Input-to-hidden Layer Connections

The output of the j -th node in the hidden layer used in the previous subsection is defined by

$$y_j = \sigma \left(\sum_{i=1}^n w_{ji} x_i + w_{j0} \right), \quad (8)$$

where x_i is the i -th input, i.e., the output of the i -th node in the input layer. Here, let us assume that scaling is applied (Bishop, 1995) to the neural network inputs x_i in order to facilitate training (LeCun, 1993), and so $x_i \in [0, 1]$ or $x_i \in [-1, 1]$. Moreover, the output y_j may be any value in the range of the sigmoid activation function σ used by the hidden layer nodes. So, $y_j \in [0, 1]$ for the logistic sigmoid and $y_j \in [-1, 1]$ for the hyperbolic tangent.

All these hypotheses suggest that defining the intervals of the weights of the input-to-hidden layer connections is a problem formulated exactly as the problem of defining the

weights of the hidden-to-output layer connections of the previous subsection. In consequence, we formulate the following equations:

$$\sum_{i=1}^n [w_{ji}] [0, 1] + [w_j b] = [-b, b], \quad (9a)$$

$$\sum_{i=1}^k [w_{ji}] [-1, 1] + [w_j b] = [-b, b]. \quad (9b)$$

The same arguments as those in the previous subsection apply concerning the solvability of Equations (9a) and (9b). In addition, solving these equations and defining outer approximations of the corresponding solution sets is covered by the same analysis as in the previous subsection.

4. An Algebraic Solution to Bounding the Weight Space

For the neural network training problem defined in (2), the solution set of each of the resulting Equations (7a), (7b) and (9a), (9b) is extremely difficult to be described analytically. Hence, in this section, we derive an outer approximation (an enclosure) of an algebraic solution, that is more practical to define and use. This enclosure is a convex polytope, depending on the MLP architecture, and more specifically on the type of the activation function of the network nodes, and is derived under the assumption that the neural network inputs x_i are scaled in the interval $[0, 1]$ or $[-1, 1]$. First, the theoretical results are derived and then the conditions for their applicability are discussed.

4.1 Theoretical Results

As seen in Subsection 3.2, above, an algebraic solution exists for each of the Equations (7a), (7b) and (9a), (9b). Here, given an algebraic solution $[w^a]$ we proceed with computing limit values for the bounds of the interval components of $[w^a]$. In the sequel, given these limit values we derive outer approximations of the solutions of Equations (7a), (7b) and (9a), (9b).

In order to simplify their representation, we define the outer approximations of the solutions as convex sets or convex polytopes. However, what really matters with these outer approximations for each of the equations is that, they enclose the solutions containing the connection weights which are the global minimizers of the problem defined by (2).

Theorem 1 Consider the equation,

$$[w_1] [0, 1] + [w_2] [0, 1] + \dots + [w_n] [0, 1] + [w_b] [1, 1] = [-b, b]. \quad (10)$$

Then, whenever an algebraic solution is regarded for this equation, the following statements are valid:

- (i) For any variable $[w_i] = [\underline{w}_i, \bar{w}_i]$, $1 \leq i \leq n$ the maximum possible value of \bar{w}_i is $2b$ or the minimum possible value of \underline{w}_i is $-2b$.
- (ii) For the variable $[w_b] = [\underline{w}_b, \bar{w}_b]$ the maximum possible value of \bar{w}_b is b and the minimum possible value of \underline{w}_b is $-b$.

Proof First, let us note that for the product $[x, y] [0, 1]$ the following equalities are valid depending on the values of x and y :

$$[x, y] [0, 1] = [0, y], \quad \text{if } 0 \leq x \leq y, \quad (11a)$$

$$[x, y] [0, 1] = [x, 0], \quad \text{if } x \leq y \leq 0, \quad (11b)$$

$$[x, y] [0, 1] = [x, y], \quad \text{if } x \leq 0 \leq y. \quad (11c)$$

In addition let $[t_j]$ denote the product $[w_j] [0, 1]$, for $1 \leq j \leq n$. Then, with respect to the above Equalities (11) the sum of all terms $[t_j]$ of the left hand side of Equation (10), that is, $[t_1] + [t_2] + \dots + [t_n]$ may be written as the sum of three intervals of the form $[0, s_k] + [-s_l, 0] + [-s_m^L, s_m^H]$ defined as follows:

$$[t_1] + [t_2] + \dots + [t_k] = [0, s_k], \quad 0 \leq k \leq n, \quad (12a)$$

$$[t_1] + [t_2] + \dots + [t_l] = [-s_l, 0], \quad 0 \leq l \leq n, \quad (12b)$$

$$[t_1] + [t_2] + \dots + [t_m] = [-s_m^L, s_m^H], \quad 0 \leq m \leq n, \quad (12c)$$

with $k + l + m = n$, $s_k \geq 0$, $s_l \geq 0$ and $s_m^L, s_m^H \geq 0$.

Statement (i)

Let i be an index such that for the interval $[\underline{w}_i, \bar{w}_i]$ we have $\bar{w}_i > 0$. We will show that $\bar{w}_i \leq 2b$. Excluding the term $[t_i]$ let us consider that the above integers k, l , and m are defined for the sum $[t_1] + [t_2] + \dots + [t_{i-1}] + [t_{i+1}] + \dots + [t_n]$. This means that, $0 \leq k \leq n-1$, $0 \leq l \leq n-1$, $0 \leq m \leq n-1$, and $k + l + m = n-1$. In addition, $[t_j] = [t_j, \bar{t}_j]$ with $\bar{t}_j = \bar{w}_j$ and

$$t_j = \begin{cases} 0 & \text{if } 0 \leq \underline{w}_j \\ \underline{w}_j & \text{if } \underline{w}_j < 0. \end{cases}$$

Then Equation (10) becomes,

$$[0, s_k] + [-s_l, 0] + [-s_m^L, s_m^H] + [t_i, \bar{w}_i] + [\underline{w}_b, \bar{w}_b] = [-b, b],$$

or even,

$$[-s_l - s_m^L - |t_i| + \underline{w}_b, s_k + s_m^H + \bar{w}_i + \bar{w}_b] = [-b, b].$$

This interval equation translates to:

$$s_k + s_m^H + \bar{w}_i + \bar{w}_b = b, \quad (13a)$$

$$-s_l - s_m^L - |t_i| + \underline{w}_b = -b. \quad (13b)$$

Furthermore, let us suppose that $\bar{w}_i > b$. Given that $s_k + s_m^H \geq 0$ then (13a) holds true if $\bar{w}_b < 0$ and $\bar{w}_b \leq b - (s_k + s_m^H + \bar{w}_i)$. Setting $\bar{w}_i = b + x$, where $x > 0$, then the previous inequality gives that $\bar{w}_b \leq b - (s_k + s_m^H + b + x)$, or else, $\bar{w}_b \leq -(s_k + s_m^H) - x < 0$.

On the other hand $[\underline{w}_b, \bar{w}_b]$ is a valid interval if $\underline{w}_b \leq \bar{w}_b$. It follows that $\underline{w}_b < 0$. Using (13b) we have that $\underline{w}_b = -b + s_l + s_m^L + |t_i|$. From this equation we deduce that the minimum possible value for \underline{w}_b is $-b$ attained when $s_l + s_m^L + |t_i| = 0$. In consequence we have $-b \leq \underline{w}_b \leq \bar{w}_b \leq -(s_k + s_m^H) - x$. So, $-b \leq -(s_k + s_m^H) - x$. The last inequality gives that $-b + (s_k + s_m^H) \leq -x$, and finally, $x \leq b - (s_k + s_m^H)$. This suggests that $x \leq b$ and the

maximum value is attained when $s_k + s_m^H = 0$. Hence, $\bar{w}_i \leq 2\mathbf{b}$. Note that $\bar{w}_i = 2\mathbf{b}$ when $[w_1] = [w_2] = \dots = [w_{i-1}] = [w_{i+1}] = \dots = [w_n] = [0]$, $\underline{w}_i = 0$, and $[w_b] = [-\mathbf{b}, -\mathbf{b}]$.

Now, suppose that $\underline{w}_i < -\mathbf{b}$ and $[w_i] = [\underline{w}_i, \bar{w}_i]$. Then following the same reasoning as above we may infer that $-2\mathbf{b} \leq \underline{w}_i$. In this case \underline{w}_b is a positive number that diminishes the excess on the lower bound of the left hand side interval of the Equation (10) produced by \underline{w}_i . Note that $\underline{w}_i = -2\mathbf{b}$ when $[w_1] = [w_2] = \dots = [w_{i-1}] = [w_{i+1}] = \dots = [w_n] = [0]$, $\bar{w}_i = 0$, and $[w_b] = [\mathbf{b}, \mathbf{b}]$.

Statement (ii)

In order to prove this statement let us suppose that $[\underline{w}_b, \bar{w}_b]$ is such that $\bar{w}_b > \mathbf{b}$. In this case $\bar{w}_b = \mathbf{b} + x$ with $x > 0$. Considering Equalities (12) we rewrite Equation (10) as,

$$[0, s_k] + [-s_l, 0] + [-s_m^L, s_m^H] + [\underline{w}_b, \bar{w}_b] = [-\mathbf{b}, \mathbf{b}],$$

which gives,

$$\begin{aligned} s_k + s_m^H + \bar{w}_b &= \mathbf{b}, \\ -s_l - s_m^L + \underline{w}_b &= -\mathbf{b}. \end{aligned}$$

The hypothesis $\bar{w}_b = \mathbf{b} + x$ with $x > 0$ implies that $s_k + s_m^H = \mathbf{b} - \bar{w}_b = -x$. This is impossible given that, by definition, $s_k + s_m^H \geq 0$. Hence, the only possibility for x is to have $x = 0$ which means that $\bar{w}_b \leq \mathbf{b}$. Using the same reasoning we may infer that $-\mathbf{b} \leq \underline{w}_b$. ■

The above theorem defines maximum and minimum values for the bounds of any interval parameter in Equations (7a) and (9a). Moreover, it suggests that in Equation (10) the interval $[w_b]$ acts as a term that cuts off the excess in the upper or the lower bound of the sum of the weight intervals. However, this is true only for either the upper or the lower bound but not for both bounds at the same time. The following Theorem 2 constitutes a generalization of *statement (i)* in the proof of Theorem 1.

Theorem 2 Suppose that the interval vector $([w_1^*], [w_2^*], \dots, [w_n^*], [w_b^*])^\top$ is an algebraic solution of Equation (10) of Theorem 1. If $S \subseteq I_n = \{1, 2, \dots, n\}$ denotes a set of indices $\{i_1, i_2, \dots, i_q\}$ such that all $[w_{i_j}^*] \neq 0$, $1 \leq j \leq q$, then only one of the following two relations can be true:

$$\begin{aligned} (i) \quad -2\mathbf{b} &\leq \sum_{j=1}^q \underline{w}_{i_j}^* < -\mathbf{b}, \text{ or} \\ (ii) \quad \mathbf{b} &< \sum_{j=1}^q \bar{w}_{i_j}^* \leq 2\mathbf{b}. \end{aligned}$$

■ **Proof** The proof is obtained using the same reasoning as for Theorem 1.

Corollary 3 Suppose that the interval vector $([w_1^*], [w_2^*], \dots, [w_n^*], [w_b^*])^\top$ is an algebraic solution of the equation $[w_1][0, 1] + [w_2][0, 1] + \dots + [w_n][0, 1] + [w_b][1, 1] = [-\mathbf{b}, \mathbf{b}]$. Then for any interval $[w_i^*]$ both the upper and the lower bounds of this interval cannot exceed the bounds of the interval $[-\mathbf{b}, \mathbf{b}]$.

Proof Suppose that there exists an index i such that for the interval $[\underline{w}_i^*, \bar{w}_i^*]$ both inequalities $\underline{w}_i^* < -\mathbf{b}$ and $\mathbf{b} < \bar{w}_i^*$ hold true. That is $[-\mathbf{b}, \mathbf{b}] < [\underline{w}_i^*, \bar{w}_i^*]$. Using the reasoning of Theorem 1 in order to reduce the excessive effect produced by $[\underline{w}_i^*, \bar{w}_i^*]$ on the left hand side of the interval of the equation we need to define $[\underline{w}_b, \bar{w}_b]$ with $\underline{w}_b > 0$ and $\bar{w}_b < 0$ which obviously is not a valid interval. Hence, it is impossible for some variable $[\underline{w}_i, \bar{w}_i]$ to have a solution such that $[-\mathbf{b}, \mathbf{b}] < [\underline{w}_i^*, \bar{w}_i^*]$. ■

Theorem 2 and Corollary 3, derived above, show the complexity of the set containing the algebraic solutions of Equations (7a) and (9a). However, the following Corollary defines an outer approximation of this solution set which is a convex set (polytope).

Corollary 4 The algebraic solutions of Equation (10) of Theorem 1 are enclosed in the polytope defined by $[-2\mathbf{b}, 2\mathbf{b}]^n \times [-\mathbf{b}, \mathbf{b}]$.

Proof Let the interval vector $([w_1^*], [w_2^*], \dots, [w_n^*], [w_b^*])^\top$ be a solution of Equation (10). Then for each $[w_j^*]$, $1 \leq j \leq n$ we have that $[w_j^*] < [-2\mathbf{b}, 2\mathbf{b}]$. Moreover $[w_b^*] < [-\mathbf{b}, \mathbf{b}]$. This proves the Corollary. ■

Theorem 5 Consider the equation,

$$[w_1][-1, 1] + [w_2][-1, 1] + \dots + [w_n][-1, 1] + [w_b][1, 1] = [-\mathbf{b}, \mathbf{b}]. \quad (14)$$

Then, whenever an algebraic solution is regarded for this equation, for any variable $[w_i] = [\underline{w}_i, \bar{w}_i]$, $1 \leq i \leq n$ the maximum possible value of \bar{w}_i is \mathbf{b} and the minimum possible value of \underline{w}_i is $-\mathbf{b}$. The same holds for the maximum possible value of \bar{w}_b and the minimum possible value of \underline{w}_b .

Proof First note that any interval multiplied by $[-1, 1]$ gives a symmetric interval. Actually, $[x, y][-1, 1] = [-m, m]$, where $m = \max\{|x|, |y|\}$, for any interval $[x, y]$. If $[t_j]$ denotes $[w_j][-1, 1]$, for $1 \leq j \leq n$, then Equation (14) becomes $[t_1] + [t_2] + \dots + [t_n] + [\underline{w}_b, \bar{w}_b] = [-\mathbf{b}, \mathbf{b}]$, with all $[t_j]$ being symmetric intervals. So, the following two equalities must hold:

$$\underline{t}_1 + \underline{t}_2 + \dots + \underline{t}_n + \underline{w}_b = -\mathbf{b}, \quad (15a)$$

$$\bar{t}_1 + \bar{t}_2 + \dots + \bar{t}_n + \bar{w}_b = \mathbf{b}, \quad (15b)$$

with $\underline{t}_j \leq 0$ and $0 \leq \bar{t}_j$ for $j = 1, 2, \dots, n$.

Let i be an index such that for the interval $[\underline{w}_i, \bar{w}_i]$ we have $\underline{w}_i < -\mathbf{b}$ and $\mathbf{b} < \bar{w}_i$. Thus, the term $[\underline{t}_i, \bar{t}_i] > [-\mathbf{b}, \mathbf{b}]$.

Then (15a) is true if $\underline{t}_1 + \underline{t}_2 + \dots + \underline{t}_{i-1} + \underline{t}_{i+1} + \dots + \underline{t}_n = 0$ and $\underline{w}_b > 0$. In addition (15b) is true if $\bar{t}_1 + \bar{t}_2 + \dots + \bar{t}_{i-1} + \bar{t}_{i+1} + \dots + \bar{t}_n = 0$ and $\bar{w}_b < 0$. The above suggest that $[\underline{w}_b, \bar{w}_b]$ defined so it is not a valid interval. In consequence the interval $[\underline{t}_i, \bar{t}_i] \leq [-\mathbf{b}, \mathbf{b}]$ and so neither $\mathbf{b} < \bar{w}_i$ nor $\underline{w}_i < -\mathbf{b}$. Hence, $[\underline{w}_i, \bar{w}_i] \leq [-\mathbf{b}, \mathbf{b}]$.

For the interval $[\underline{w}_b, \bar{w}_b]$ suppose that $\bar{w}_b < -\mathbf{b}$. This means that $\underline{w}_b = -\mathbf{b} - x$ for some $x > 0$. Under these assumptions (15a) holds true if $\underline{t}_1 + \underline{t}_2 + \dots + \underline{t}_n = x$, which is impossible given that $\underline{t}_1 + \underline{t}_2 + \dots + \underline{t}_n < 0$. The reasoning is the same if we suppose that $\bar{w}_b > \mathbf{b}$. Hence the minimum possible value of \underline{w}_b is $-\mathbf{b}$ and the maximum possible value of \bar{w}_b is \mathbf{b} . ■

The following corollary is a direct conclusion of Theorem 5.

Corollary 6 *The algebraic solutions of Equation (14) of Theorem 5 are enclosed in the hypercube $[-b, b]^{n+1}$.*

Proof Let the interval vector $([w_1^*], [w_2^*], \dots, [w_n^*], [w_b^*])^T$ be a solution of Equation (14). Then for each $[w_j^*]$, $1 \leq j \leq n$ we have that $[w_j^*] \subseteq [-b, b]$. The same stands for $[w_b^*]$. This proves the Corollary. ■

Theorem 5 and Corollary 6 help defining a convex outer approximation of the set of algebraic solutions to Equations (7b) and (9b).

4.2 Evaluation of the Theoretical Results

In the context of our minimization problem, solving the linear interval Equations (7a), (7b), (9a) and (9b) is equivalent to defining a solution in the tolerance solution set of each of these equations. This is achieved considering algebraic solutions for the following reasons. First, such an interval solution is proven to exist (Ratschek and Sauer, 1982) for each of these equations. Moreover, the algebraic solution of a linear interval system is a solution to the corresponding linear interval tolerance problem (Shary, 1996, Proposition 1). Finally, our aim is not to define exact bounds of the algebraic solution interval vector, but to identify the bounds of the algebraic solution.

Recall that Shary (2002) defined the tolerance (or tolerable) solution set of an interval equation $F([a], x) = [b]$ as the set formed by all point vectors $x \in \mathbb{R}^n$ such that for any $\tilde{a} \in [a]$ the image $F(\tilde{a}, x) \in [b]$. This can be written in one of the following two forms:

$$\begin{aligned} \sum_{\text{tol}} (F, [a], [b]) &= \{x \in \mathbb{R}^n \mid (\forall \tilde{a} \in [a]) (\exists \tilde{b} \in [b]) (F(\tilde{a}, x) = \tilde{b})\}, \\ \sum_{\subseteq} (F, [a], [b]) &= \{x \in \mathbb{R}^n \mid F([a], x) \subseteq [b]\}. \end{aligned}$$

The theoretical results of the previous subsection permit to define suitable convex polytopes containing the algebraic solutions of Equations (7a), (9a) and hypercubes for the algebraic solutions of Equations (7b), (9b). The algebraic solutions of the linear interval Equations (7a), (7b) and (9a), (9b), enclosed in their respective convex sets, are also solutions in the corresponding tolerance solution sets of these linear equations which may well be the activation functions of any output node. We are now interested in examining the relation of these convex sets with Equations (3) and (8). Let us consider the following non-linear interval equations:

$$\sigma_1 \left(\sum_{j=1}^h [w_{kj}] [y_j] + [w_{kb}] \right) = [0, 1], \quad (16a)$$

$$\sigma_2 \left(\sum_{j=1}^h [w_{kj}] [y_j] + [w_{kb}] \right) = [-1, 1], \quad (16b)$$

for any node k in the output layer using a sigmoid activation function, as well as the equations:

$$\sigma_1 \left(\sum_{i=1}^n [w_{ji}] [x_i] + [w_{jb}] \right) = [0, 1], \quad (17a)$$

$$\sigma_2 \left(\sum_{i=1}^n [w_{ji}] [x_i] + [w_{jb}] \right) = [-1, 1], \quad (17b)$$

defined for any node j in the hidden layer using a sigmoid activation function. Note that, $[y_j]$ denotes the interval of the output values of the j -th node in the hidden layer and $[x_i]$ denotes the interval of the values of the i -th component of the input patterns. The above equations are the interval counterparts of Equations (3) and (8).

We will show that the convex polytopes, derived in the previous subsection, constitute inner approximations of the tolerance solution sets for the interval Equations (16) and (17), namely the convex polytope for the Equations (16) and (17) having $[y_j] = [0, 1]$ and $[x_i] = [0, 1]$ while the hypercube does it, for the same equations, when $[y_j] = [-1, 1]$ and $[x_i] = [-1, 1]$.

First, let us formulate the following Proposition regarding Equations (16a), (16b) and (17a), (17b).

Proposition 7 *The tolerance solution set corresponding to each of the Equations (16a), (16b) and (17a), (17b) is unbounded.*

Proof Let us consider Equation (16a) and a real vector $w^1 \in \mathbb{R}^{h+1}$ such that

$$\sigma_1 \left(\sum_{j=1}^h w_j^1 [y_j] + w_{h+1}^1 \right) \subseteq [0, 1].$$

Then, there exists a real vector $w^2 \in \mathbb{R}^{h+1}$ for which $w^1 \leq w^2$, where the operator “ \leq ” denotes the component-wise operator “ \leq ”. If instead of the real vectors we consider their interval counterparts, that is, the degenerate interval vectors $[w^1]$ and $[w^2]$, it is obvious that $[w^1] \subseteq [w^2]$. Then, given that the sigmoid σ_1 is inclusion monotonic we have that

$$\sigma_1 \left(\sum_{j=1}^h w_j^1 [y_j] + w_{h+1}^1 \right) \subseteq \sigma_1 \left(\sum_{j=1}^h w_j^2 [y_j] + w_{h+1}^2 \right) \subseteq [0, 1].$$

Hence, for any real vector $[w^1]$ in the tolerance solution set there will always exist a “larger” vector $[w^2]$ for which the output interval produced will enclose the output interval targeted for $[w^1]$. So, the tolerance solution set of Equation (16a) is unbounded. The proof is similar for the other equations. ■

It is obvious that the outcome of this Proposition is due to the asymptotic convergence of each of the sigmoids to its extreme values, i.e., to 0, 1 or to $-1, 1$. Hence, if one aims in finding a suitable inner approximation of each tolerance solution set, then one should define an upper and a lower limit for the output of the corresponding sigmoid. Actually, this is

how we proceeded in Subsection 3.2. Subsequently, the direct consequence of this approach is to consider the solution set of some linear interval equation suitably defined to take into account the input values of a node. So, for each of the non-linear Equations (16a) and (16b) of some node in the output layer two linear interval equations, namely (7a) and (7b), are defined depending on the type of the sigmoid used. In addition, for each of the non-linear interval Equations (17a) and (17b) of any node in the hidden layer the two linear interval equations derived are (9a) and (9b).

For any node with a sigmoid activation function there are two possible types of boxes, as defined by Corollaries 4 and 6, depending on the intervals of the input values. Here, let us examine the range of application of these boxes in terms of their usage in (16a), (16b) and (17a), (17b). The convex polytope $[-2b, 2b]^h \times [-b, b]$ is used whenever the input signals are in the interval $[0, 1]$. Then, from (16a) and (16b) we derive the following relations:

$$\begin{aligned} \sigma_1 \left(\sum_{j=1}^h [-2b_1, 2b_1][0, 1] + [-b_1, b_1] \right) &\subseteq [0, 1], \\ \sigma_2 \left(\sum_{j=1}^h [-2b_2, 2b_2][0, 1] + [-b_2, b_2] \right) &\subseteq [-1, 1]. \end{aligned}$$

A direct conclusion of these relations is that the convex polytope $[-2b_1, 2b_1]^h \times [-b_1, b_1]$ constitutes an inner approximation of the tolerance solution set of the non-linear interval equation (16a). The same stands for the box $[-2b_2, 2b_2]^h \times [-b_2, b_2]$ and the non-linear interval equation (16b). Obviously, the hypercubes $[-b_1, b_1]^{(h+1)}$ and $[-b_2, b_2]^{(h+1)}$ are used instead of the corresponding convex polytopes when the input signals to a node are in the interval $[-1, 1]$. The same reasoning applies to Equations (17a) and (17b).

Besides these conclusions other interesting results are derived, hereafter, for the above convex polytopes. First, it is easy to verify that the following two equations hold true:

$$\begin{aligned} \sum_{j=1}^h [-2b_1, 2b_1][0, 1] + [-b_1, b_1] &= (2h+1)[-b_1, b_1], \\ \sum_{j=1}^h [-2b_2, 2b_2] [-1, 1] + [-b_2, b_2] &= (2h+1)[-b_2, b_2]. \end{aligned}$$

So, we have the relations:

$$\begin{aligned} \sigma_1((2h+1)[-b_1, b_1]) &\subseteq [0, 1], \\ \sigma_2((2h+1)[-b_2, b_2]) &\subseteq [-1, 1]. \end{aligned}$$

If we set $\lambda = \lambda(h)$, a small number, $0 < \lambda \ll 1$, depending on the number of inputs h of the node then we may write that

$$\begin{aligned} \sigma_1((2h+1)[-b_1, b_1]) &= [0 + \lambda, 1 - \lambda] = [0, 1]_\lambda \subseteq [0, 1], \text{ and} \\ \sigma_2((2h+1)[-b_2, b_2]) &= [-1 + \lambda, 1 - \lambda] = [-1, 1]_\lambda \subseteq [-1, 1]. \end{aligned}$$

In consequence, recalling the definition of the intervals $[-b_1, b_1]$ and $[-b_2, b_2]$, in Subsection 3.2, it is obvious that the following two relations hold true:

$$[0, 1]_\varepsilon = [0 + \varepsilon, 1 - \varepsilon] \subset [0 + \lambda, 1 - \lambda] = [0, 1]_\lambda, \quad (18a)$$

$$[-1, 1]_\varepsilon = [-1 + \varepsilon, 1 - \varepsilon] \subset [-1 + \lambda, 1 - \lambda] = [-1, 1]_\lambda. \quad (18b)$$

In consequence we may state that, for any node in the output layer using a sigmoid activation function, having input signals in the interval $[0, 1]$ and connection weights in the convex polytope $[-2b, 2b]^h \times [-b, b]$ then the range of output values are in the interval $[0, 1]_\lambda$ or $[-1, 1]_\lambda$ for some λ smaller than the precision ε used for the problem.

When the inputs to a node are in the interval $[-1, 1]$ then using the box $[-b, b]^{(h+1)}$ we arrive to similar results and formulate a similar statement. Finally, note that, using the same reasoning we get exactly the same results for any node in the hidden layer bringing out the validity of the theoretical results when used in (17a) and (17b) corresponding to Equations (9a) and (9b).

To further advance this reasoning suppose that the real matrices $W_i^s \in \mathbb{R}^{(n+1)h}$ and $W_2^s \in \mathbb{R}^{(h+1)o}$ constitute a global minimizer of the minimization problem (2), i.e., the distance $\|F(X, W_1^s, W_2^s) - T\|_q \leq \varepsilon$, where ε is the machine precision or the best precision set for the problem. Also, suppose that p patterns are available for the problem, which means that $X = \{x_1, x_2, \dots, x_p\}$ and the corresponding target outputs are $T = \{t_1, t_2, \dots, t_p\}$. The input patterns are n -dimensional vectors while the target outputs are o -dimensional. For any input pattern x_l , where $1 \leq l \leq p$, let z_l be the o -dimensional network output for this pattern, that is, $z_l = F(x_l, W_1^s, W_2^s)$.

Now, if the norm q is such that $1 \leq q$ and considering that the total network output error is averaged over all patterns then we can set the network output error for the l -th pattern to be $(\sum_{k=1}^o |z_{k,l} - t_{k,l}|^q)^{1/q} \leq \varepsilon$. From this, for the k -th output node we may consider that $|z_{k,l} - t_{k,l}|^q \leq \sum_{k=1}^o |z_{k,l} - t_{k,l}|^q \leq \varepsilon^q$. Hence, $|z_{k,l} - t_{k,l}|^q \leq \varepsilon^q$, which gives that $|z_{k,l} - t_{k,l}| \leq \varepsilon$. In consequence, $t_{k,l} - \varepsilon \leq z_{k,l} \leq t_{k,l} + \varepsilon$. So, if $t_{k,l} = 0$ or $t_{k,l} = -1$ then $z_{k,l} \in [0, 0 + \varepsilon]$ or $z_{k,l} \in [-1, -1 + \varepsilon]$. Similarly, if $t_{k,l} = 1$ then $z_{k,l} \in [1 - \varepsilon, 1]$. Hence, we may suppose that there exists some small positive constant, say λ , such that $0 + \lambda \leq z_{k,l} \leq 0 + \varepsilon$, or, $-1 + \lambda \leq z_{k,l} \leq -1 + \varepsilon$, and $1 - \varepsilon \leq z_{k,l} \leq 1 - \lambda$. Then, we may deduce that $[0 + \varepsilon, 1 - \varepsilon] \subset [0 + \lambda, 1 - \lambda]$ and $[-1 + \varepsilon, 1 - \varepsilon] \subset [-1 + \lambda, 1 - \lambda]$. This is exactly what has been derived above with relations (18). So, we deduce that the real matrices $W_1^s \in \mathbb{R}^{(n+1)h}$ and $W_2^s \in \mathbb{R}^{(h+1)o}$ supposed to constitute a global minimizer of the minimization problem (2) are, indeed, located in the corresponding convex polytope, as defined above. The reasoning is similar if q is the infinity norm.

Following the above discussion we consider that it is legitimate to argue that the convex polytopes identified by the proposed method are guaranteed, within the machine precision accuracy, to enclose some global minimizers of the network output error function.

4.3 Discussion on the Theoretical Results

The proposed approach operates under the assumption that the input data to a destination node are either in the interval $[0, 1]$ or in $[-1, 1]$. Typically, this happens in pattern recognition or classification applications; for example, this is the case for the interval used for coding the corresponding components of the input patterns if the weights concern input-to-

hidden layer connections. For a weight of a hidden-to-output layer connection this interval is the range of values of the sigmoid activation function of the corresponding hidden node. So, for an input data point in $[0, 1]$, the initial interval for the value of the corresponding weight is $[-2b, 2b]$; otherwise, if the value of the input data point is in $[-1, 1]$ then the initial interval for the corresponding weight is considered to be $[-b, b]$. In all cases, the interval for the value of any bias weight is $[-b, b]$.

Depending on the type of the activation function parameter b is denoted by b_1 for the logistic sigmoid, b_2 for the hyperbolic tangent, and b_3 for the pure linear activation function. Moreover, recall that the specific value in each case is implementation dependent being a function of the precision ε set for the problem. In this paper, we consider that ε is the machine epsilon corresponding to double precision and so the specific values for b should be $b = b_1 \geq 36.05$ and $b = b_2 \geq 18.4$, while the specific value for $b = b_3$ is defined by the problem data. Table 1 summarizes these results for a 3-layer perceptron having n , h and o nodes in the input, the hidden and the output layers respectively, and two possible ranges, $[0, 1]$ and $[-1, 1]$, for the input data coding.

The convex sets in Table 1 are defined according to the above theoretical results and more specifically the conclusions of Corollaries 4 and 6. However, if one adopts a ‘‘proud interpretation’’ of Corollary 3 it would be possible to consider narrower intervals for nodes with inputs in the interval $[0, 1]$. So, instead of the interval $[-2b, 2b]$ one would rather consider the interval $[-b, b]$. Obviously with this argument the convex set defined, in this case, is no longer a polytope, in general terms, but rather a hypercube. However, we should note that this result is based on heuristic considerations, as the complexity of the structure of the solution sets of Equations (7a) and (9a) leaves no space for such a theoretical conclusion. The validity of this heuristic conjecture is tested in the following Section 5.

The values defined, previously, for b and the subsequent volumes of the convex polytopes, though formally proven, are relatively large. So, they may be not convincing regarding the advantage offered to the global optimization based training by the proposed approach. Here, let us recall the assumption that, often, in practical applications, the output values of a node are expected to be in the interval $[0.1, 0.9]$ for the sigmoid activation function or in the interval $[-0.9, 0.9]$ for the hyperbolic tangent. Then according to Paragraph 3.2.1 the corresponding values for b , denoted here by b^* , should be $b^* \geq 2.2 \approx 2.1972$ and $b^* \geq 1.5 \approx 1.4722$. Despite the apparent disagreement of the intervals $[0.1, 0.9]$ and $[-0.9, 0.9]$ with the linear inverse equations (10) and (14), respectively, the previous theoretical results are still valid. As an example, let us compute the bounds of the weights for the k -th output node having a sigmoid activation function with output in the interval $[0.1, 0.9]$ and inputs y_j in the interval $[0.1, 0.9]$ supposing that any node in the hidden layer has the logistic sigmoid activation function, as well. With these hypotheses Equation (7a) becomes

$$\sum_{j=1}^h [w_{kj}] [0.1, 0.9] + [w_{k0}] = [-b^*, b^*], \quad (19)$$

where b^* is the specific b as noted previously. In addition, due to inclusion monotonicity $\sum_{j=1}^h [w_{kj}] [0.1, 0.9] + [w_{k0}] \subseteq \sum_{j=1}^h [w_{kj}] [0, 1] + [w_{k0}]$. On the other hand, at the expense of lower precision, we may have the equation $\sum_{j=1}^h [w_{kj}] [0, 1] + [w_{k0}] = [-b^*, b^*]$. Then, the solution set defined for this specific form of Equation (7a) is a tolerance solution set of

the linear interval equation (19). In consequence, the convex polytope $[-2b, 2b]^h \times [-b, b]$, for any $b = b^* \geq 2.2$, is a tolerance solution set of the linear interval equation (19), and constitutes an inner approximation of the tolerance solution set of the non-linear interval equation

$$\sigma_1 \left(\sum_{j=1}^h [w_{kj}] [y_j] + [w_{k0}] \right) = [0.1, 0.9], \quad (20)$$

where $[y_j] = [0.1, 0.9]$ for $1 \leq j \leq h$. It is obvious that this reasoning applies to any linear interval equation, such as (7a), (7b), (9a) and (9b).

If the scaling assumption of the neural network inputs x_i does not hold (this may happen with function approximation or regression problems), it is still possible to solve the problem; however, the solution does not comply with the algebraic formalism adopted in the previous section. In this case, let us suppose that $x_i \in [x_i^-, x_i^+]$, for $i = 1, 2, \dots, n$ where the value of the functional $\chi([x_i^-, x_i^+]) \in [-1, 1]$ (see Ratschek and Sauer, 1982), which means that the bounds of the interval $[x_i^-, x_i^+]$ may have any value provided that $x_i^- \leq x_i^+$. For the bias we have that the input is $\chi(1, 1) = 1$, so the hypotheses of Ratschek and Sauer (1982, Theorem 1) are satisfied and in consequence even in this case the Equations (9a) and (9b) have a solution. However, it is clear that the resulting equation does not comply with the formalism adopted in the previous subsection for the Equations (7a), (7b) and (9a), (9b). Although a detailed coverage of this issue is considered out-of-the-scope of this paper, it can briefly be stated that this situation can be dealt with by considering the work of Popova (2006) and the algorithm proposed therein.

5. Testing

In this section we give some concrete examples of the approach presented above. Our objective is to perform some tests, using well known benchmarks, in order to show that the convex sets, derived following the analysis of this paper, indeed enclose global minimizers of the cost function associated with the output of the MLP used for each problem. To this end, the interval global optimization software (GOP), provided by Pál and Csendes (2009), is used.

The reason for adopting an interval global optimization procedure instead of some version of PSO or a GA-based approach is easily understood if one takes into account the fact that interval global optimization is a deterministic approach which is guaranteed to locate the best available minimizers and the interval for the corresponding global minimum. On the other hand, convergence capabilities of population based and heuristic approaches depend on a number of heuristically defined random parameters. Hence, a proof of convergence for these methods is either probabilistic (Bertsimas and Tsitsiklis, 1993; Elben et al., 1991), or it relies on empirical results (Pedersen, 2010). This means that, by using a global search method of this class, it is practically impossible to verify that the boxes derived by the proposed approach indeed contain the best available minimizers.

Table 1: Approximation of the initial weight set

Activation function	Input Data Interval	
	[0,1]	[-1,1]
HL: logistic sigmoid	$[-2b_1, 2b_1]^{*sh} \times [-b_1, b_1]^h$	$[-b_1, b_1]^{(n+1)*h}$

HL: hyperbolic tangent	$[-2b_2, 2b_2]^{*sh} \times [-b_2, b_2]^h$	$[-b_2, b_2]^{(n+1)*h}$
OL: linear	$[-2b_3, 2b_3]^{*so} \times [-b_3, b_3]^o$	$[-b_3, b_3]^{(h+1)*o}$

- HL : Hidden Layer

- OL : Output Layer

- n, h and o are the number of nodes in the input, hidden and output layer respectively

- b_1 denotes the value of \mathbf{b} in the case of the logistic sigmoid activation function

- b_2 denotes the value of \mathbf{b} in the case of the hyperbolic tangent activation function

- b_3 denotes the value of \mathbf{b} in the case of the linear activation function

5.1 Experimental Setup

In order to perform this experimental verification, we follow the next three steps:

1. Consider an MLP which is typically used for solving the corresponding problem.
2. Write the MATLAB code implementing the natural inclusion function of the MLP mapping, (an example is given in Appendix A).
3. Use the GOP procedure to solve the minimization problem defined for this natural inclusion function, where the bounds for the weights are set by the convex polytope computed by the proposed approach.

Typically, GOP is used for solving a global optimization problem with bound constraints and performs an exhaustive search of the initially defined set of boxes. The criterion used to stop the search process is a tolerance level of the width of the interval computed as the value of the inclusion function. So, given that in this paper we are interested only in verifying the existence of global minimizers and not in effectively locating a global minimum, as this happens when training the MLP, we specify a large value for the tolerance level of the width of the inclusion function interval. Hence, we use GOP to obtain rough estimates of the interval enclosing the global minimum of the network's output error function.

Moreover, GOP uses gradient information of the objective function to perform branch-and-bound computations. In order to comply with this requirement we use the Mean-

Squared-Error (MSE) for computing the distance between the actual network output and the target output. However, using a differentiable distance function such as MSE is not restrictive. Actually, the analysis provided throughout Section 4 makes no assumption regarding the type of the cost function of the network output. What really matters is that the set of boxes defined by the proposed method surely encloses weight vectors that are global minimizers, which means that the range of the error function computed on this set of boxes is an interval enclosing its global minimum.

Note that for all examples the boxes are computed using for \mathbf{b}_1 and \mathbf{b}_2 the values proposed in Paragraph 3.2.1. Obviously, one may set these values according to the precision required for the problem at hand. However, in order to comply with the theoretical considerations of the paper the values chosen for \mathbf{b}_1 and \mathbf{b}_2 should be such that the corresponding sigmoid is driven to the saturation region.

5.2 Experiments and Results

5.2.1 A SIMPLE PROBLEM

The Single Neuron problem: Here, we consider the simplest possible case consisting of a single neuron having one input, a bias and using the logistic sigmoid activation. The advantage of proposing such a rudimentary example is the facility it offers in visualizing its error function. In the following figures one may observe the form of the error functions for two simple artificial mappings with weights in the intervals $[-5.0, 5.0]$ and $[-5.0, 5.0]$. Using GOP it is easy to locate the global minima for each of these functions for various

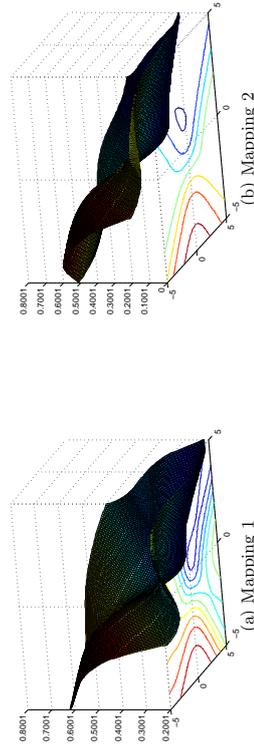

Figure 1: A simple neuron and the error functions for two artificial mappings

boxes of the weights. The results obtained for various trials are given hereafter.

Initial box for the weights: $[-72.1, 72.1][[-36.05, 36.05]$, tolerance = 0.001. Intervals computed by GOP:

Function name: SINGLE NEURON MAPPING 1

The set of global minimizers is located in the union of the following boxes:

c1: [21.75680336914063, 37.45827910156252][20.27820312500000, 36.05010000000000]

c2: [21.54557275390626, 21.68639316406251][19.99656210937500, 20.27820312500000]

c3: [21.12311152343751, 21.40475234375001][19.71492109375000, 19.99656210937500]

The global minimum is enclosed in:
 $[0.176989707623682269, 0.177214552453163560]$
 Function name: SINGLE NEURON MAPPING 2
 The set of global minimizers is located in the union of the following boxes:
 c1: $[-1.44335920410156, -1.05610307617187][1.09140893554687, 1.40825507812500]$
 The global minimum is enclosed in:
 $[0.063025775813289955, 0.093289721540457949]$

In these two cases, it is obvious that the location of the minimizers greatly differs from one error function to the other. Moreover, in the case of the first error function the global minimum is defined exclusively for positive values of the weights. This shows that the input data greatly affect the location of the global minimum.

Let us now consider a narrower interval. Initial box for the weights: $[-5.0, 5.0][-5.0, 5.0]$, tolerance = 0.01. Intervals computed by GOP:

Function name: SINGLE NEURON MAPPING 1
 The set of global minimizers is located in the union of the following boxes:
 c1: $[4.68750000000000, 5.00000000000000][4.21875000000000, 4.68750000000000]$
 The global minimum is enclosed in:
 $[0.215127653743816594, 0.219438417879982417]$
 Function name: SINGLE NEURON MAPPING 2
 The set of global minimizers is located in the union of the following boxes:
 c1: $[-2.03125000000000, -0.62500000000000][0.85837500000000, 1.87500000000000]$
 c2: $[-2.34375000000000, -2.18750000000000][2.03125000000000, 2.18750000000000]$
 The global minimum is enclosed in:
 $[0.089012518962891946, 0.093326904683555062]$

In this trial, narrower intervals were used for the bounds of the weights. As far as the first mapping is concerned, it's easy to notice that, despite the larger value for the tolerance, the intervals used do not enclose the previously detected global minimum. For the intervals specified the so-called global minimum is a local one, despite being the best that GOP was able to locate. For the second mapping, the intervals estimated for both the location of the global minimizers as well as for the global minimum are larger, due to the higher tolerance value, and enclose the intervals computed by GOP in the previous trial.

The main outcome of these examples is that they are consistent with the analysis provided in the paper. These trials provide "good" examples of boxes with global minimizers, as well as "counter-examples" of boxes without global minimizers. The results confirm that heuristic arguments, concerning the weight intervals, are inefficient, whenever global optimization based training is considered for a neural network. Moreover, the convex set defined by the proposed approach provides reliable estimation of these weight intervals.

For bound constrained problems the global optimizer GOP detects the best available minimizers within the box defined for the error function and hence the interval estimate of the corresponding global minimum. Given the size of the search space, in the following experiments it has not been possible to perform exhaustive search of the global minimum and so we tried to obtain rough estimations of the interval enclosing it.

5.2.2 PROBLEMS – NETWORKS WITH LOGISTIC SIGMOID ACTIVATION FUNCTIONS

The XOR problem: Let us consider a 2-2-1 network used for the XOR problem. The purpose of this experiment is to allow us to verify the results of the proposed approach against previous literature (see Haney, 1995, 1998; Sprinkhuizen-Kuyper and Boers, 1999), which has investigated analytically the local and global minima in the XOR problem. All network nodes use the logistic sigmoid activation function, inputs to all nodes are in the interval $[0, 1]$ and the desired outputs are the bounds of the interval $[0, 1]$. The network is fully connected and so there are $2 * 2 + 2 * 1 = 6$ unknown weights as well as $2 + 1 = 3$ bias weights. The interval equation of the weights to any node in the network is one of (7a) or (9a). Thus, if we set $\mathbf{b} = \mathbf{b}_1 = 36.05$ we obtain,

$$[w_1][0, 1] + [w_2][0, 1] + \dots + [w_n][0, 1] + [w_b][1, 1] = [-36.05, 36.05]$$

and so, the initial box where global minimizers are expected to be located is

$$\underbrace{[-72.1, 72.1]^{2*2}}_{\text{Hidden layer}} \times \underbrace{[-36.05, 36.05]^2}_{\text{Output layer}} \times \underbrace{[-72.1, 72.1]^{2*1}}_{\text{Output layer}} \times \underbrace{[-36.05, 36.05]^1}_{\text{Hidden layer}}.$$

The output provided by GOP for the above network is:

Function name: XOR
 The set of global minimizers is located in the union of the following boxes:
 c1: $[-72.09999999999999, 72.09999999999999] \dots$
 $[-36.05000000000000, 36.05000000000000]$
 The global minimum is enclosed in:
 $[0.0000000000000000, 0.250000000000000000]$.

The results of this experiment confirm the theoretical conclusions regarding the location of the global minimizers.

In addition to the previous experiment, it is tentative to examine, here, if the narrower box, defined using a loose interpretation of Corollary 3, is likely to enclose the global minimizers of the network output error. So, if the box $[-36.05, 36.05]^{2*2} \times [-36.05, 36.05]^2$ \times $\underbrace{[-36.05, 36.05]^{2*1}}_{\text{Output layer}} \times \underbrace{[-36.05, 36.05]^1}_{\text{Hidden layer}} = [-36.05, 36.05]^9$ is used as the initial box then the output provided by GOP is:

Function name: XOR
 The set of global minimizers is located in the union of the following boxes:
 c1: $[-36.05000000000000, 36.05000000000000] \dots$
 $[-36.05000000000000, 36.05000000000000]$
 The global minimum is enclosed in:
 $[0.0000000000000000, 0.250000000000000000]$.

The result of this last experiment shows that a narrower box can be effectively used for searching the global minimizers. Nevertheless, we should re-iterate that, as mentioned in

Subsection 4.3, using such a narrower box lacks the necessary theoretical justification.

Finally, if we make the assumption that the outputs of the sigmoids are in the interval $[0.1, 0.9]$ the initial box is considered to be $[-4.4, 4.4]^6 \times [-2.2, 2.2]^3$ which, according to Table 1, is $[-4.4, 4.4]^{2+2} \times [-2.2, 2.2]^2 \times [-4.4, 4.4]^{2+1} \times [-2.2, 2.2]^1$. Then the output provided by GOP is:

Output layer

Function name: XOR

The set of global minimizers is located in the union of the following boxes:

c1: $[-4.4000000000000, 4.4000000000000] \dots$

$[-2.2000000000000, 2.2000000000000]$

The global minimum is enclosed in:

$[0.0000000000000000, 0.160000000000000031]$.

Overall, the outcomes of the three experiments are in line with previous research (Hamey, 1995, 1998; Sprinkhuizen-Kuyper and Boers, 1999). Actually, Hamey (1998) applied to the XOR problem a new methodology for the analysis of the error surface and showed that starting from any point with finite weight values, there exists a finite non-ascending trajectory to a point with error equal to zero. Moreover, Sprinkhuizen-Kuyper and Boers (1999) proved that “the error surface of the two-layer XOR network with two hidden units has a number of regions with local minima” and concluded that “from each finite point in weight space, a strictly decreasing path exists to a point with error zero”. The conclusions of these papers resulted following an exhaustive analysis of the error surface of the network output. Finally, both papers conclude that for a 2-2-1 network using finite weights a global minimum is reachable in the error surface of the XOR problem. This conclusion constitutes a qualitative validation of the results obtained in this paper.

Finally, let us consider the case where a set of boxes does not contain a global minimizer. An example of such a set of boxes is reported by GOP hereafter.

Function name: XOR

The set of global minimizers is located in the union of the following boxes:

c1:

$[-72.09999999999999, 102.09999999999999][[-72.09999999999999, 102.09999999999999]$

$[-72.09999999999999, 102.09999999999999][[-72.09999999999999, 102.09999999999999]$

$[36.05000000000000, 136.05000000000000][36.05000000000000, 136.05000000000000]$

$[72.09999999999999, 102.09999999999999][72.09999999999999, 102.09999999999999]$

$[36.05000000000000, 136.05000000000000]$

The global minimum is enclosed in:

$[0.49882522561647045, 0.5000000000000000111]$.

The IRIS classification problem: Let us consider a 4-5-3 network used for the IRIS classification problem. This benchmark is known as Fisher’s IRIS problem. Based on the values of sepal length and width, petal length and width, the class of IRIS plant needs to be predicted. Inputs are scaled in the interval $[0, 1]$, all network nodes use the logistic sigmoid activation function and the desired outputs are binary $\{0, 1\}$. The network is fully connected and so there are $4 * 5 + 5 * 3 = 35$ unknown weights along with $5 + 3 = 8$ bias

weights. The interval equation of the weights to any node in the network is one of (7a) or (9a) and so if we set $\mathbf{b} = \mathbf{b}_1 = 36.05$ we have again,

$$[w_1][0, 1] + [w_2][0, 1] + \dots + [w_n][0, 1] + [w_b][1, 1] = [-36.05, 36.05].$$

So, one may consider the following initial box for searching the global minimizers,

$$\underbrace{[-72.1, 72.1]^{4*5} \times [-36.05, 36.05]^5}_{\text{Hidden layer}} \times \underbrace{[-72.1, 72.1]^{5*3} \times [-36.05, 36.05]^3}_{\text{Output layer}}.$$

The output provided by GOP for the above network is:

Function name: IRIS

The set of global minimizers is located in the union of the following boxes:

c1: $[-72.09999999999999, 72.09999999999999] \dots$

$[-36.050000000000000, 36.050000000000000]$

The global minimum is enclosed in:

$[0.0000000000000000, 0.75000000000000000]$.

Moreover, under the assumption that the output of the sigmoids are in the interval $[0.1, 0.9]$ the initial box is considered to be $[-4.4, 4.4]^{35} \times [-2.2, 2.2]^8$ which, according to Table 1, is $[-4.4, 4.4]^{4+5} \times [-2.2, 2.2]^5 \times [-4.4, 4.4]^{5+3} \times [-2.2, 2.2]^3$. Then the output provided by GOP is:

Hidden layer

Output layer

Function name: IRIS

The set of global minimizers is located in the union of the following boxes:

c1: $[-4.40000000000000, 4.40000000000000] \dots$

$[-2.20000000000000, 2.20000000000000]$

The global minimum is enclosed in:

$[0.0000000000000000, 0.48000000000000002480]$.

The results of these IRIS experiments are encouraging. Again, the results of the first experiment roughly confirm the theoretical conclusions regarding the location of the global minimizers, while the other experiment indicates that narrower boxes can be effectively used for searching the global minimizers, eventually providing a narrower interval estimate for the global minimum.

5.2.3 A PROBLEM – NETWORK WITH HYPERBOLIC TANGENT ACTIVATION FUNCTIONS

The British vowels recognition problem: Consider the 3-layer 10-20-11 network used for the British vowels data recognition benchmark. This benchmark, known as Deterding Data (Deterding, 1989), is a speaker independent recognition problem of the eleven steady state vowels of British English using a specified training set of 10 lpc (linear prediction coefficients) derived log area ratios. Inputs for this problem are scaled in the interval $[-1, 1]$ and all network nodes use the hyperbolic tangent sigmoid activation function. The network is fully connected and so there are $10 * 20 + 20 * 11 = 420$ unknown weights as well as $20 + 11 = 31$ bias weights. In this case the interval equation of the weights to any node

in the network is one of (7b) or (9b). Setting $\mathbf{b} = \mathbf{b}_2 = 18.04$ one obtains the following equation,

$$[w_1][-1, 1] + [w_2][-1, 1] + \dots + [w_n][-1, 1] + [w_b][1, 1] = [-18.4, 18.4].$$

So, the initial box where global minimizers are potentially located is the hypercube

$$\underbrace{[-18.4, 18.4]^{(10+1)*20}}_{\text{Hidden layer}} \times \underbrace{[-18.4, 18.4]^{(20+1)*11}}_{\text{Output layer}} = [-18.4, 18.4]^{451}.$$

The output provided by GOP for the above network is:

Function name: BRITISH VOWELS

The set of global minimizers is located in the union of the following boxes:

c1: [-18.400000000000000, 18.400000000000000]...

[-18.400000000000000, 18.400000000000000]

The global minimum is enclosed in:
[0.00000000000000000, 11.0000000000000000].

Under the assumption that the output of the sigmoids are in the interval $[-0.9, 0.9]$ the initial box is expected to be $\underbrace{[-1.5, 1.5]^{(10+1)*20}}_{\text{Hidden layer}} \times \underbrace{[-1.5, 1.5]^{(20+1)*11}}_{\text{Output layer}} = [-1.5, 1.5]^{451}$. The

output provided by GOP for the above network is:

Function name: BRITISH VOWELS

The set of global minimizers is located in the union of the following boxes:

c1: [-1.500000000000000, 1.500000000000000]...

[-1.500000000000000, 1.500000000000000]

The global minimum is enclosed in:
[0.00000000000000000, 8.910000000000142251].

The results of the first experiment confirm the theoretical conclusions regarding the location of the global minimizers. In addition, the second experiment confirms the hypothesis that the narrower box derived using the interval $[-0.9, 0.9]$ for the range of the hyperbolic activation functions, can be effectively used for searching the global minimizers of the network learning error.

5.2.4 A PROBLEM – NETWORK WITH HYPERBOLIC TANGENT AND A PURE LINEAR ACTIVATION FUNCTION

A sinusoidal function approximation problem: Consider the 3-layer 2-21-1 network used for approximating the function $y = 0.5 \sin(\pi x_1^2) \sin(2\pi x_2)$ defined in the original paper of Nguyen and Widrow (Nguyen and Widrow, 1990) where they introduce their weight initialization method. Inputs for this problem are in the interval $[-1, 1]$, all nodes in the hidden layer use the hyperbolic tangent sigmoid activation function and nodes in the output layer are linear. The network is fully connected and so there are $2 * 21 + 21 * 1 = 63$ unknown weights as well as $21 + 1 = 22$ bias weights. The interval equation of the weights

to any node in the hidden layer is (7b). Retaining for $\mathbf{b} = \mathbf{b}_2 = 18.04$, as in the previous benchmark, we have

$$[w_1][-1, 1] + [w_2][-1, 1] + \dots + [w_n][-1, 1] + [w_b][1, 1] = [-18.4, 18.4].$$

Moreover, the interval equation of the weights to any node in the output layer is,

$$[w_1][-1, 1] + [w_2][-1, 1] + \dots + [w_n][-1, 1] + [w_b][1, 1] = [-0.5, 0.5].$$

So, the initial box used for searching the global minimizers is

$$\underbrace{[-18.4, 18.4]^{(2+1)*21}}_{\text{Hidden layer}} \times \underbrace{[-0.5, 0.5]^{(21+1)*1}}_{\text{Output layer}}.$$

The output provided by GOP for the above network is:

Function name: FUNCTION APPROXIMATION

The set of global minimizers is located in the union of the following boxes:

c1: [-18.400000000000000, 18.400000000000000]...

[-0.500000000000000, 0.500000000000000]

The global minimum is enclosed in:
[0.00000000000000000, 0.048430679703413922].

5.3 Discussion and Open Problems

The above experiments provide substantial evidence regarding the validity of the theoretical results, showing that the convex set computed by the proposed approach for each problem contains some global minimizers of the network's error function. In addition, it is easy to see that there exist areas in the weight space which do not contain global minimizers.

In all cases the approach for evaluating the theoretical results was based on an interval global optimization procedure. However, the theoretical analysis presented in Section 4 made no assumption regarding the global optimization procedure used to minimize the error function of the MLP. Therefore, the set of boxes enclosing the global minimizers is determined independently of the global optimization method used for training, and so it is also valid for population-based or stochastic global search methods. It is worth noting here that the results reported by Gudise and Venayagamoorthy (2003) constitute an experimental verification of this statement when PSO is used to train an MLP. Moreover, the experimental analysis provided in that paper, concerning the computational cost induced by the training procedure in relation with the width of the search space, may be seen as an evidence of the advantage offered by our approach.

An interesting point of the above experiments concerns the results obtained when the boxes are defined under the assumption that the outputs of the sigmoid and the hyperbolic tangent activation functions are $[0, 1, 0, 9]$ and $[-0.9, 0, 9]$ instead of $[0, 1]$ and $[-1, 1]$. These results indicate that the weight boxes defined so, besides being thinner, also result in a narrower interval enclosing the global minimum. We note here, without further details, that the derivation of these boxes and the entailing results, may be justified using the following theorem by Moore (1966) as formulated in Alefeld and Mayer (2000, Theorem 1).

Theorem 8 *Let $f : D \subset \mathbb{R}^n \rightarrow \mathbb{R}$ be continuous and let $[x] \subseteq [x]^0 \subseteq D$. Then (under mild additional assumptions) $q(R(f; [x]), [f]([x])) \leq \gamma \|d([x])\|_\infty$, $\gamma \geq 0$, and $d([f]([x])) \leq \delta \|d([x])\|_\infty$, $\delta \geq 0$.*

Here, $q(\cdot, \cdot)$ is the Hausdorff distance between intervals which measures the quality of the interval inclusion function $[f]$ as an enclosure of the range of f over an interval $[x]$. This Theorem states that if the inclusion function exists then the Hausdorff distance between $R(f; [x])$ and $[f]([x])$ goes linearly to zero with the diameter $d([x])$ (Alefeld and Mayer, 2000). In addition the diameter of the inclusion function goes linearly to zero if $d([x])$ is approaching zero. The values of parameters γ and δ are very important for defining thinner boxes.

Regarding the previous comment it is important to note that considering narrower intervals for the outputs of the nonlinear activation functions of the nodes cannot be done arbitrarily. Actually, narrowing the intervals of the activation functions' output values causes a decrease in their level of saturation which translates to less sharp values for the network outputs. Obviously, this introduces a degree of uncertainty to the network outputs and thereby to the network function itself. The importance of this outcome seems to be problem dependent. If the underlying problem deals with pattern classification this outcome may have no effect on the classification task and in the best case even increase the generalization ability of the network. On the other hand when dealing with a function approximation or regression problem defining less sharp values for the network outputs is very likely to cause large deviations from the target outputs. To the best of our knowledge there is no research report attempting to define any proper saturation level for the activation functions in order to fit any unknown function with infinite accuracy.

Finally, an issue that needs to be commented concerns the impact of the proposed method on the global optimization procedure, in terms of computational complexity and cost. As the results of the experiments underline, this issue has not been addressed in this paper mainly for two reasons; first the objective of our paper is not to detect the global minimizers of the network error function but merely to delimit the area where a global optimization procedure should search for them. Secondly, evaluating the computational cost of our approach requires either a suitable mathematical formulation or significant computational effort in order to effectively measure the impact of our approach on specific global optimization procedures. Definitely, this issue constitutes our main concern for continuing this research.

6. Conclusion

The approach presented in this paper deals with computing guaranteed bounds for the region where global optimization procedures should search for global minimizers when training an MLP. In contrast to current practice, which defines these bounds heuristically, the proposed approach relies on interval analysis and exploits both the network architecture and information of the input patterns for shaping the search region. The resulting feasible domain of the network's output error function is rather complicated and so a suitable approximation is derived in the form of a convex polytope or a hypercube depending on the network architecture and the problem at hand.

The analysis presented deals with 3-layer feed forward neural networks but the results

can easily be extended to networks with more than one hidden layer. Moreover, this analysis covers the widely used type of feed forward neural networks using some kind of sigmoid activation function for the nodes in the hidden layer. Nodes in the output layer may use either a sigmoid or a linear activation function. The conclusions derived are applicable to both standard MLPs and interval feed forward neural networks.

The examples and the experiments given on well known benchmarks highlight the application of the theoretical results formally derived in the paper. The results of the experiments provide significant evidence that the global minimizers of the considered network error functions fall within the bounds of the polytope defined by our method. Moreover, the proposed approach is not restrictive in terms of the hidden layers considered for the MLP or the bounds of the interval for node's output values.

A thorough performance analysis of global optimization procedures with and without using the proposed approach was not part of the objectives of this paper — this will be considered in future work. Also, we are planning to investigate the possibility of dealing with MLPs that use other types of activation functions as well as explore the applicability of the results to other types of networks such as the radial basis function and the recurrent networks.

Acknowledgments

The authors would like to thank the anonymous reviewers for their valuable suggestions and comments on earlier version of the manuscript, that helped to significantly improve the paper at hand.

Appendix A. Sample Code for an MLP Natural Inclusion Function

Here, we give an example of the MATLAB code used for the natural inclusion function of the function implemented by a 3-layer MLP for the XOR benchmark. It is straightforward to obtain the natural inclusion function by simply replacing real variables by their interval counterparts. So, all variables corresponding to the weights of the MLP, as well as the quantities computed with these variables, are intervals. Interval computations are automatically carried out using INTLAB (Rump, 1999).

```
% the following define the activation functions
avfHL = @(x)[1./(1+exp(-x))]; % for the hidden layer
avfOL = @(x)[1./(1+exp(-x))]; % for the output layer

% the code for the inclusion function
function y = evxor(WO)
% WO is the vector of the weight intervals
% global network parameters and training data
global p t np n h o avfHL avfOL

W1 = reshape(WO(1:h*n,1),h,n);
```

```

b1 = repmat(creshape(W0((h*n)+1:(h*n)+h*1,1),h,1),1,np);
W2 = reshape(W0((h*(n+1))+1:(h*(n+1))+o+h,1),o,h);
b2 = repmat(creshape(W0(h*(n+1)+o+h+1:end,1),o,1),1,np);
y = sum((-avf0L(W2*avfHL(W1*p+b1)+b2)).^-2) ./np;
% end function

```

Abstract

The MLR package provides a generic, object-oriented, and extensible framework for classification, regression, survival analysis and clustering for the R language. It provides a unified interface to more than 160 basic learners and includes meta-algorithms and model selection techniques to improve and extend the functionality of basic learners with, e.g., hyperparameter tuning, feature selection, and ensemble construction. Parallel high-performance computing is natively supported. The package targets practitioners who want to quickly apply machine learning algorithms, as well as researchers who want to implement, benchmark, and compare their new methods in a structured environment.

Keywords: machine learning, hyperparameter tuning, model selection, feature selection, benchmarking, R, visualization, data mining

1. Introduction

R is one of the most popular and widely-used software systems for statistics, data mining, and machine learning. However, it does not define a standardized interface to, e.g., supervised predictive modelling. For any non-trivial experiment one needs to write lengthy, tedious, and error-prone code to unify calling methods and handling output. The MLR package offers a clean, easy-to-use, and flexible domain-specific language for machine learning experiments in R. It supports classification, regression, clustering, and survival analysis with more than 160 modelling techniques. Defining learning tasks, training models, making predictions, and evaluating their performance abstracts from the implementation of the underlying learner through an object-oriented interface. Replacing one learning algorithm with another becomes as easy as changing a string. MLR goes far beyond simply providing a unified interface. It implements a generic architecture that allows the assessment of generalization performance, comparison of different algorithms in a scientifically rigorous way, feature selection, and hyperparameter tuning for any method, as well as extending

the functionality of learners through a wrapper mechanism. Queryable properties provide a reflection mechanism for machine learning objects. Finally, MLR provides sophisticated visualization methods that allow to show effects of partial dependence of models. MLR's long term goal is to provide a high-level domain-specific language to express as many aspects of machine learning experiments as possible.

2. Implemented Functionality

MLR uses R's S3 object system and follows a clear structure. Everything is an object and the classes are as reusable and extensible as possible. This permits to extend the package; e.g., connect a new model from a third-party package or write a custom performance measure.

Tasks and Learners. Tasks encapsulate the data and further relevant information like the name of the target variable for supervised learning problems. They are organized hierarchically, with an abstract Task at the top and specific subclasses. MLR supports regular, multilabel and cost-sensitive classification, regression, survival analysis, and clustering. The integrated learners specialize to these task types. Currently 82 classification learners, 61 regression learners, 13 survival learners, and 9 cluster learners are integrated. Cost-sensitive classification with observation-dependent costs is supported through a cost-sensitive one-versus-one approach, which delegates to ordinary weighted binary classification.

Evaluation and Resampling. MLR provides 46 different performance measures and implements the resampling methods subsampling (including simple holdout), bootstrapping (OOB, B632, B632+), and cross-validation (normal, leave-one-out, repeated). All resampling strategies may be stratified on both target classes and categorical input features. Observations may be partitioned into inseparable blocks (e.g., when observations come from the same image, sound file, or clinic). Moreover, nested resampling is supported and the resampling strategies used in the outer and inner loops can be combined arbitrarily.

Tuning. In practice, successful modelling often depends on a number of choices like the applied learner, its hyperparameter settings, or the data preprocessing. MLR implements joint optimization of hyperparameters of any learning algorithm and any pre- and postprocessing methods for any task, any resampling strategy, and any performance measure, including categorical and conditional hyperparameters. Random search, grid search, evolutionary algorithms, iterated F-racing, and sequential model-based optimization are available.

Feature Selection. Feature selection can improve the interpretability and performance of a learned predictive model. MLR supports *filter* and *wrapper* approaches, while *embedded* techniques like L₁-penalization are included directly in the learners. Supported selection techniques include information gain, MRM, and RELIEF, with forward and backward search. Filter scores and sequential wrapper search results can be visualized.

Wrapper Extensions. MLR's wrapper mechanism allows to extend learners through pre-train, post-train, pre-predict, and post-predict hooks. We provide wrappers for missing value imputation, user-defined preprocessing, class imbalance correction, feature selection, tuning, bagging, and stacking. Wrappers can be nested to combine functionalities. Wrapped learners behave like base learners, with added functionality and expanded hyperparameter set. During resampling, all added steps are carried out in each iteration. During tuning,

the joint parameter space can be optimized. For example thresholds for feature filtering can be tuned jointly with other hyperparameters (Lang et al., 2015).

Benchmarking and Parallelization. The benchmark function evaluates the performance of multiple learners on multiple tasks. As benchmark studies can quickly become very resource-demanding, MLR natively supports parallelization through the PARALLELMAP package (Bischl and Lang, 2015) that can use local multicore, socket, and MPI computation modes. BATCHOBS (Bischl et al., 2015) provides distribution on compute clusters. Operations to be parallelized can be selected explicitly.

Properties and Parameters. Many of the MLR objects have properties that allow them to be used programmatically, e.g., check whether a task has missing values, whether a learner can handle categorical variables, or list all learners suitable for a given task. Every learner includes a description object that defines all hyperparameters, including type, default value, and feasible range. This information is usually not readily available from the implementation of an integrated learning method and may only be listed in its documentation.

3. Example

The following example demonstrates the use of MLR. After loading required packages and the “Sonar” data set (Line 1), we create a classification task and a support vector machine learner (Lines 2–3). The resample description tells MLR to use a 5-fold cross-validation (Line 4). Hyperparameters and box-constraints for tuning are specified in Lines 5–11. We optimize over the choice of a polynomial versus a Gaussian kernel by making their individual parameters dependent on the kernel via the `requires` setting (Lines 9 and 11). We use random search with at most 50 evaluations (Line 12). The values for `C` and `sigma` are sampled on a log-scale through the transformation functions given as the `trafo` argument (Lines 7–8). Line 13 binds everything together and optimizes for mean misclassification error (`mnce`). `res` holds the best configuration and information on the evaluated parameters.

```

1 library(mlr); library(mlbench); data(Sonar)
2 task = makeClassifTask(data=Sonar, target="Class")
3 lrn = makeLearner("Classif.ksvm")
4 rdesc = makeResampleDesc(method="CV", iters=5)
5 ps = makeParamSet(
6   makeDiscretParam("kernel", values=c("polydot", "rbfdot")),
7   makeNumericParam("C", lower=-15, upper=15, trafo=function(x) 2^x),
8   makeNumericParam("sigma", lower=-15, upper=15, trafo=function(x) 2^x,
9     requires = quote(kernel == "rbfdot")),
10  makeIntegerParam("degree", lower = 1, upper = 5,
11    requires = quote(kernel == "polydot"))
12 ctrl = makeTuneControlRandom(maxit=50)
13 res = tuneParams(lrn, task, rdesc, par.set=ps, control=ctrl, measures=mnce)

```

4. Availability, Documentation, Maintenance, and Code Quality Control

The MLR source code is available under the BSD 2-clause license and hosted on GitHub (<https://github.com/mlr-org/mlr>). Stable releases are frequently published on the Contributed R Archive Network (CRAN), which lists MLR in Task View ‘Machine Learning & Statistical Learning’. We provide extensive API documentation through R’s internal help

BISCHL, LANG, KOTTHOFF, SCHIFFNER, RICHTER, STURDERUS, CASALICCHIO AND JONES

system and a very detailed tutorial (Schiffer et al., 2016) that guides the user from very basic tasks to complex applications with worked examples and is continuously extended. An issue tracker, the test framework TESTTHAT (with more than 10,000 lines of tests and more than 1,200 assertions), and the CI systems Travis and Jenkins support the correctness of the code base. In addition, we provide documentation and coding guidelines for developers and contributors.

5. Comparison to Similar Toolkits/Frameworks

Several other R packages provide frameworks for handling prediction models, including CARET (Kuhn, 2008), DMWR (Torgo, 2010), CORELEARN (Robnik-Sikonja and with contributions from John Adeyariju Alao, 2016), RATTLE (Williams, 2011), RMINER (Cortez, 2010), CMA (Slawski et al., 2008), and RPRED (Peters and Hothorn, 2015). The first 5 only support classification and regression, CMA only classification. MLR’s generic wrapper mechanism is not provided by any other package in this form. Although CARET and CMA can fuse a learner with a preprocessing or variable selection method, only MLR can seamlessly tune these methods simultaneously (Koch et al., 2012). Only MLR, RMINER, and CMA support nested cross-validation. A similar degree of flexibility can be achieved in CARET, but requires custom implementations. Only MLR supports ensemble learning through stacking natively. MLR and CARET support bagging natively. Bagging is also available in RPRED and CARETENSEMBLE provides stacking for CARET. Only MLR and CARET have native support for parallel computations. Similar toolkits exist for other languages, e.g., WEKA for Java (Hall et al., 2009) and SCKITR-LEARN for Python (Pedregosa et al., 2011).

6. Conclusions and Outlook

We presented the MLR package, which provides a unified interface to machine learning in R. It implements a generic architecture for a range of common machine learning tasks. MLR is alive and under active development. It has a growing user community and is used for teaching and research.

Major directions for future extensions include better support for large-scale data, a closer connection to the OpenML project (Van Schooren et al., 2013) for open machine learning experiments,¹ and better integration of sequential model-based optimization.²

Abstract

Domain adaptation is the supervised learning setting in which the training and test data are sampled from different distributions: training data is sampled from a source domain, whilst test data is sampled from a target domain. This paper proposes and studies an approach, called feature-level domain adaptation (FLDA), that models the dependence between the two domains by means of a feature-level transfer model that is trained to describe the transfer from source to target domain. Subsequently, we train a domain-adapted classifier by minimizing the expected loss under the resulting transfer model. For linear classifiers and a large family of loss functions and transfer models, this expected loss can be computed or approximated analytically, and minimized efficiently. Our empirical evaluation of FLDA focuses on problems comprising binary and count data in which the transfer can be naturally modeled via a dropout distribution, which allows the classifier to adapt to differences in the marginal probability of features in the source and the target domain. Our experiments on several real-world problems show that FLDA performs on par with state-of-the-art domain-adaptation techniques.

Keywords: Domain adaptation, transfer learning, covariate shift, risk minimization

1. Introduction

Domain adaptation is an important research topic in machine learning and pattern recognition that has applications in, among others, speech recognition (Leggetter and Woodland, 1995), medical image processing (Van Oprooek et al., 2013), computer vision (Saenko et al., 2010), social signal processing (Zen et al., 2014), natural language processing (Peddinti and Chintalapoodi, 2011), and bioinformatics (Borgwardt et al., 2006). Domain adaptation deals with supervised-learning settings in which the common assumption that the training and the test observations stem from the same distribution is dropped. This learning setting may arise, for instance, when the training data is collected with a different measurement device than the test data, or when a model that is trained on one data source is deployed on data that comes from another data source. This creates a learning setting in which the training set contains samples from one distribution (the so-called source domain), whilst the test set constitutes samples from another distribution (the target domain). In domain adaptation, one generally assumes a transductive learning setting: that is, it is assumed that the unlabeled test data are available to us at training time and that the main goal is to predict their labels as well as possible.

The goal of domain-adaptation approaches is to exploit information on the dissimilarity between the source and target domains that can be extracted from the available data in order to make more accurate predictions on samples from the target domain. To this end, many domain adaptation approaches construct a *sample-level transfer model* that assigns weights to observations from the source domain in order to make the source distribution more similar to the target distribution (Shimodaira, 2000; Huang et al., 2006; Cortes et al., 2008; Gretton et al., 2009; Cortes and Mohri, 2011). In contrast to such sample-level reweighing approaches, in this work, we develop a *feature-level transfer model* that describes the shift between the target and the source domain for each feature individually. Such a feature-level approach may have advantages in certain problems: for instance, when one trains a natural language processing model on news articles (the source domain) and applies it to Twitter data (the target domain), the marginal distribution of some of the words or n-grams (the features) is likely to vary between target and source domain. This shift in the marginal distribution of the features cannot be modeled well by sample-level transfer models, but it can be modeled very naturally by a feature-level transfer model.

Our feature-level transfer model takes the form of a conditional distribution that, conditioned on the training data, produces a probability density of the target data. In other words, our model of the target domain thus comprises a convolution of the empirical source distribution and the transfer model. The parameters of the transfer model are estimated by maximizing the likelihood of the target data under the model of the target domain. Subsequently, our classifier is trained as to minimize the expected value of the classification loss under the target-domain model. We show empirically that when the true domain shift can be modeled by the transfer model, under certain assumptions, our domain-adapted classifier converges to a classifier trained on the true target distribution. Our feature-level approach to domain adaptation is general in that it allows the user to choose a transfer model from a relatively large family of probability distributions. This allows practitioners to incorporate domain knowledge on the type of domain shift in their models. In the experimental section of this paper, we focus on a particular type of transfer distribution that is well-suited for

problems in which the features are binary or count data (as often encountered in natural language processing), but the approach we describe is more generally applicable. In addition to experiments on artificial data, we present experiments on several real-world domain adaptation problems, which show that our feature-level approach performs on par with the current state-of-the-art in domain adaptation.

The outline of the remainder of this paper is as follows. In Section 2, we give an overview of related prior work on domain adaptation. Section 3 presents our feature-level domain adaptation (FLDA) approach. In Section 4, we present our empirical evaluation of feature-level domain adaptation and Section 5 concludes the paper with a discussion of our results.

2. Related Work

Current approaches to domain adaptation can be divided into one of three main types. The first type constitutes *importance weighting* approaches that aim to reweigh samples from the source distribution in an attempt to match the target distribution as well as possible. The second type are *sample transformation* approaches that aim to transform samples from the source distribution in order to make them more similar to samples from the target distribution. The third type are *feature augmentation* approaches that aim to extract features that are shared across domains. Our feature-level domain adaptation (FLDA) approach is an example of a sample-transformation approach.

2.1 Importance Weighting

Importance-weighting approaches assign a weight to each source sample in such a way as to make the reweighted version of the source distribution as similar to the target distribution as possible (Shimodaira, 2000; Hwang et al., 2006; Cortes et al., 2008; Gretton et al., 2009; Cortes and Mohri, 2011; Gong et al., 2013; Baktashmoghlagh et al., 2014). If the class posteriors are identical in both domains (that is, the covariate-shift assumption holds) and the importance weights are unbiased estimates of the ratio of the target density to the source density, then the importance-weighted classifier converges to the classifier that would have been learned on the target data if labels for that data were available (Shimodaira, 2000). Despite their theoretic appeal, importance-weighting approaches generally do not to perform very well when the data set is small, or when there is little “overlap” between the source and target domain. In such scenarios, only a very small set of samples from the source domain is assigned a large weight. As a result, the effective size of the training set on which the classifier is trained is very small, which leads to a poor classification model. In contrast to importance-weighting approaches, our approach performs a *feature-level* reweighting. Specifically, FLDA assigns a data-dependent weight to each of the features that represents how informative this feature is in the target domain. This approach effectively uses all the data in the source domain and therefore suffers less from the small sample size problem.

2.2 Sample Transformation

Sample-transformation approaches learn functions that make the source distribution more similar to the target distribution (Blitzer et al., 2006, 2011; Pan et al., 2011; Gopalan et al.,

2011; Gong et al., 2012; Baktashmoghlagh et al., 2013; Dinh et al., 2013; Fernando et al., 2013; Shao et al., 2014). Most sample-transformation approaches learn global (non)linear transformations that map source and target data points into the same, shared feature space in such a way as to maximize the overlap between the transformed source data and the transformed target data (Gopalan et al., 2011; Pan et al., 2011; Gong et al., 2012; Fernando et al., 2013; Baktashmoghlagh et al., 2013). Approaches that learn a shared subspace in which both the source and the target data are embedded often minimize the maximum mean discrepancy (MMD) between the transformed source data and the transformed target data (Pan et al., 2011; Baktashmoghlagh et al., 2013). If used in combination with a universal kernel, the MMD criterion is zero when all the moments of the (transformed) source and target distribution are identical. Most methods minimize the MMD subject to constraints that help to avoid trivial solutions (such as collapsing all data onto the same point) via some kind of spectral analysis. An alternative to the MMD is the subspace disagreement measure (SDM) of Gong et al. (2012), which measures the discrepancy of the angles between the principal components of the transformed source data and the transformed target data. Most current sample-transformation approaches work well for “global” domain shifts such as translations or rotations in the feature space, but they are less effective when the domain shift is “local” in the sense that it strongly nonlinear. Similar limitations apply to the FLDA approach we explore, but it differs in that (1) our transfer model does not learn a subspace but operates in the original feature space and (2) the measure it minimizes to model the transfer is different, namely, the negative log-likelihood of the target data under the transferred source distribution.

2.3 Feature Augmentation

Several domain-adaptation approaches extend the source data and the target data with additional features that are similar in both domains (Blitzer et al., 2006; Li et al., 2014). Specifically, the approach by Blitzer et al. (2006) tries to induce correspondences between the features in both domains by identifying so-called pivot features that appear frequently in both domains but that behave differently in each domain; SVD is applied on the resulting pivot features to obtain a low-dimensional, real-valued feature representation that is used to augment the original features. This approach works well for natural language processing problems due to the natural presence of correspondences between features, e.g. words that signal each other. The approach of Blitzer et al. (2006) is related to many of the instantiations of FLDA that we consider in this paper, but it is different in the sense that we only use information on differences in feature presence between the source and the target domain to reweigh those features (that is, we do not explicitly augment the feature representation). Moreover, the formulation of FLDA is more general, and can be extended through a relatively large family of transfer models.

3. Feature-Level Domain Adaptation

Suppose we wish to train a sentiment classifier for reviews, and we have a data set with book reviews and associated sentiment labels (positive or negative review) available. After having trained a linear classifier on word-count representations of the book reviews, we wish to deploy it to predict the sentiment of kitchen appliance reviews. This leaves us

with a domain-adaptation problem on which the classifier trained on book reviews will likely not work very well: the classifier will assign large positive weights to, for instance, words such as “interesting” and “insightful” as these suggest positive book reviews and will be assigned large positive weights by a linear classifier. But these words hardly ever appear in reviews of kitchen appliances. As a result, a classifier trained naively on the book reviews may perform poorly on kitchen appliance reviews. Since the target domain data (the kitchen appliance reviews) are available at training time, a natural approach to resolving this problem may be to down-weight features corresponding to words that do not appear in the target reviews, for instance, by applying a high level of dropout (Hinton et al., 2012) to the corresponding features in the source data when training the classifier. The use of dropout mimics the target domain scenario in which the “interesting” and “insightful” features are hardly ever observed during the training of the classifier, and prevents that these features are assigned large positive weights during training. Feature-level domain adaptation FLDA aims to formalize this idea in a two-stage approach that (1) fits a probabilistic sample transformation model that aims to model the transfer between source and target domain and (2) trains a classifier by minimizing the risk of the source data under the transfer model.

In the first stage, FLDA models the transfer between the source and the target domain: the transfer model is a data-dependent distribution that models the likelihood of target data conditioned on observed source data. Examples of such transfer models may be a dropout distribution that assigns a likelihood of $1 - \theta$ to the observed feature value in the source data and a likelihood of θ to a feature value of 0, or a Parzen density estimator in which the mean of each kernel is shifted by a particular value. The parameters of the transfer distribution are learned by maximizing the likelihood of target data under the transfer distribution (conditioned on the source data). In the second stage, we train a linear classifier to minimize the expected value of a classification loss under the transfer distribution. For quadratic and exponential loss functions, this expected value and its gradient can be analytically derived whenever the transfer distribution factorizes over features and is in the natural exponential family; for logistic and hinge losses, practical upper bounds and approximations can be derived (Van der Maaten et al., 2013; Wager et al., 2013; Chen et al., 2014).

In the experimental evaluation of FLDA, we focus on applying dropout transfer models to domain-adaptation problems involving binary and count features. These features frequently appear in, for instance, bag-of-words features in natural language processing (Blei et al., 2003) or bag-of-visual-words features in computer vision (Jégou et al., 2012). However, we note that FLDA can be used in combination with a larger family of transfer models; in particular, the expected loss that is minimized in the second stage of FLDA can be computed or approximated efficiently for any transfer model that factorizes over variables and that is in the natural exponential family.

3.1 Notation

We assume a domain adaptation setting in which we receive pairs of samples and labels from the source domain, $S = \{(\mathbf{x}_i, y_i) \mid \mathbf{x}_i \sim p_{\mathcal{X}}, y_i \sim p_{\mathcal{Y}} \mid \mathcal{X}, \mathbf{x}_i \in \mathbb{R}^m, y_i \in Y\}_{i=1}^{|S|}$, at training time. Herein, the set Y is assumed to be a set of discrete classes, $|\cdot|$ denotes the cardinality of the sets and p refers to the probability distribution of its subscripted variable (\mathcal{X} for the source domain variable, \mathcal{Z} for the target domain variable and \mathcal{Y} for the class variable). At test

time, we receive samples from the target domain, $T = \{\mathbf{z}_j \mid \mathbf{z}_j \sim p_{\mathcal{Z}}, \mathbf{z}_j \in \mathbb{R}^m\}_{j=1}^{|T|}$ that need to be classified. Note that we assume samples \mathbf{x}_i and \mathbf{z}_j to lie in the same m -dimensional feature space \mathbb{R}^m , hence, we assume that $p_{\mathcal{X}}$ and $p_{\mathcal{Z}}$ are distributions over the same space. For brevity, we occasionally adopt the notation $\mathbf{X} = [\mathbf{x}_1, \dots, \mathbf{x}_{|S|}]$, $\mathbf{Z} = [\mathbf{z}_1, \dots, \mathbf{z}_{|T|}]$, and $\mathbf{y} = [y_1, \dots, y_{|S|}]$.

3.2 Target Risk

We adopt an empirical risk minimization (ERM) framework for constructing our domain-adapted classifier. The ERM framework proposes a classification function $h: \mathbb{R}^m \rightarrow \mathbb{R}$ and assesses the quality of the hypothesis by comparing its predictions with the true labels on the empirical data using a loss function $L: Y \times \mathbb{R} \rightarrow \mathbb{R}_0^+$. The empirical loss is an estimate of the risk, which is defined as the expected value of the loss function under the data distribution. Below, we show that if the target domain carries no additional information about the label distribution, the risk of a model on the target domain is equivalent to the risk on the source domain under a particular transfer distribution.

We first note that the joint source data, target data and label distribution can be decomposed into two conditional distributions and one marginal source distribution; $p_{\mathcal{Y}, \mathcal{Z}, \mathcal{X}} = p_{\mathcal{Y} \mid \mathcal{Z}, \mathcal{X}} p_{\mathcal{Z} \mid \mathcal{X}} p_{\mathcal{X}}$. The first conditional $p_{\mathcal{Y} \mid \mathcal{Z}, \mathcal{X}}$ describes the full class-posterior distribution given both source and target distribution. Next, we introduce our main assumption: the labels are conditionally independent of the target domain given the source domain ($\mathcal{Y} \perp\!\!\!\perp \mathcal{Z} \mid \mathcal{X}$), which implies: $p_{\mathcal{Y} \mid \mathcal{Z}, \mathcal{X}} = p_{\mathcal{Y} \mid \mathcal{X}}$. In other words, we assume that we can construct an optimal target classifier if (1) we have access to infinitely many labeled source samples—we know $p_{\mathcal{Y} \mid \mathcal{X}}$ —and (2) we know the true domain transfer distribution $p_{\mathcal{Z} \mid \mathcal{X}}$. In this scenario, observing target labels $y_j \sim p_{\mathcal{Y} \mid \mathcal{Z}}$ does not provide us with any new information.

To illustrate our assumption, imagine a sentiment classification problem. If people frequently use the word “nice” in positive reviews about electronics products (the source domain) and we know that electronics and kitchen products (the target domain) are very similar, then we assume that the word “nice” is not predictive of negative reviews of kitchen appliances. In other words, knowing that “nice” is predictive of a positive review and knowing that the domains are similar, it cannot be the case that “nice” is suddenly predictive of a negative review. Under this assumption, learning a good model for the target domain amounts to transferring the source domain to the target domain (that is, altering the marginal probability of observing the word “nice”) and learning a good predictive model on the resulting transferred source domain. Admittedly, there are scenarios in which our assumption is invalid: if people like “small” electronics but dislike “small” cars, the assumption is violated and our domain-adaptation approach will likely work less well. We do note, however, that our assumption is less stringent than the covariate-shift assumption, which assumes that the posterior distribution over classes is identical in the source and the target domain (i.e. that $p_{\mathcal{Y} \mid \mathcal{X}} = p_{\mathcal{Y} \mid \mathcal{Z}}$): the covariate-shift assumption does not facilitate the use of a transfer distribution $p_{\mathcal{Z} \mid \mathcal{X}}$.

Formally, we start by rewriting the risk R_Z on the target domain as follows:

$$\begin{aligned} R_Z(h) &= \int_Z \sum_{y \in \mathcal{Y}} L(y, h(\mathbf{z})) p_{\mathcal{Y}, \mathcal{Z}}(y, \mathbf{z}) \, d\mathbf{z} \\ &= \int_Z \sum_{y \in \mathcal{Y}} \int_{\mathcal{X}} L(y, h(\mathbf{z})) p_{\mathcal{Y}, \mathcal{Z}, \mathcal{X}}(y, \mathbf{z}, \mathbf{x}) \, d\mathbf{x} \, d\mathbf{z} \\ &= \int_Z \sum_{y \in \mathcal{Y}} \int_{\mathcal{X}} L(y, h(\mathbf{z})) p_{\mathcal{Y} | \mathcal{Z}, \mathcal{X}}(y | \mathbf{z}, \mathbf{x}) p_{\mathcal{Z} | \mathcal{X}}(\mathbf{z} | \mathbf{x}) p_{\mathcal{X}}(\mathbf{x}) \, d\mathbf{x} \, d\mathbf{z}. \end{aligned}$$

Using the assumption $p_{\mathcal{Y} | \mathcal{Z}, \mathcal{X}} = p_{\mathcal{Y} | \mathcal{X}}$ (or equivalently, $\mathcal{Y} \perp\!\!\!\perp \mathcal{Z} | \mathcal{X}$) introduced above, we can rewrite this expression as:

$$\begin{aligned} R_Z(h) &= \int_Z \sum_{y \in \mathcal{Y}} \int_{\mathcal{X}} L(y, h(\mathbf{z})) p_{\mathcal{Y} | \mathcal{X}}(y | \mathbf{x}) p_{\mathcal{Z} | \mathcal{X}}(\mathbf{z} | \mathbf{x}) p_{\mathcal{X}}(\mathbf{x}) \, d\mathbf{x} \, d\mathbf{z} \\ &= \int_Z \mathbb{E}_{\mathcal{Y}, \mathcal{X}}[L(y, h(\mathbf{z})) p_{\mathcal{Z} | \mathcal{X}}(\mathbf{z} | \mathbf{x})] \, d\mathbf{z}. \end{aligned}$$

Next, we replace the target risk $R_Z(h)$ with its empirical estimate $\hat{R}_Z(h | S)$ by plugging in source data S for the source joint distribution $p_{\mathcal{Y}, \mathcal{X}}$:

$$\begin{aligned} \hat{R}_Z(h | S) &= \frac{1}{|S|} \int_Z \sum_{(\mathbf{x}_i, y_i) \in S} L(y_i, h(\mathbf{z})) p_{\mathcal{Z} | \mathcal{X}}(\mathbf{z} | \mathbf{x} = \mathbf{x}_i) \, d\mathbf{z} \\ &= \frac{1}{|S|} \sum_{(\mathbf{x}_i, y_i) \in S} \mathbb{E}_{\mathcal{Z} | \mathcal{X} = \mathbf{x}_i}[L(y_i, h(\mathbf{z}))]. \end{aligned} \quad (1)$$

Feature-level domain adaptation (FLDA) trains classifiers by constructing a parametric model of the transfer distribution $p_{\mathcal{Z} | \mathcal{X}}$ and, subsequently, minimizing the expected loss in Equation 1 on the source data with respect to the parameters of the classifier. For linear classifiers, the expected loss in Equation 1 can be computed analytically for quadratic and exponential losses if the transfer distribution factorizes over dimensions and is in the natural exponential family: for the logistic and hinge losses, it can be upper-bounded or approximated efficiently under the same assumptions (Van der Maaten et al., 2013; Wager et al., 2013; Chen et al., 2014). Note that no observed target samples \mathbf{z}_j are involved in Equation 1: the expectation is over the transfer model $p_{\mathcal{Z} | \mathcal{X}}$, conditioned on a particular sample \mathbf{x}_i . The target data is only used to estimate the parameters of the transfer model.

3.3 Transfer Model

The transfer distribution $p_{\mathcal{Z} | \mathcal{X}}$ describes the relation between the source and the target domain: given a particular source sample, it produces a distribution of which target samples are likely to be observed (with the same label). The transfer distribution is modeled by selecting a parametric distribution and learning the parameters of this distribution from the source and target data (without looking at the source labels). Prior knowledge on the relation between source and target domain may be incorporated in the model via the choice

for a particular family of distributions. For instance, if we know that the main variation between two domains consists of particular words that are frequently used in one domain (say, news articles) but infrequently in another domain (say, tweets), then we choose a distribution that alters the relative frequency of words.

Given a model of the transfer distribution $p_{\mathcal{Z} | \mathcal{X}}$ and a model of the source distribution $p_{\mathcal{X}}$, we can work out the marginal distribution over the target domain as

$$q_{\mathcal{Z}}(\mathbf{z} | \theta, \eta) = \int_{\mathcal{X}} p_{\mathcal{Z} | \mathcal{X}}(\mathbf{z} | \mathbf{x}, \theta) p_{\mathcal{X}}(\mathbf{x} | \eta) \, d\mathbf{x}, \quad (2)$$

where θ represents the parameters of the transfer model, and η the parameters of the source model. We learn these parameters separately: first, we learn η by maximizing the likelihood of the source data under the model $p_{\mathcal{X}}(\mathbf{x} | \eta)$ and, subsequently, we learn θ by maximizing the likelihood of the target data under the compound model $q_{\mathcal{Z}}(\mathbf{z} | \theta, \eta)$. Hence, we first estimate the value of η by solving:

$$\hat{\eta} = \arg \max_{\eta} \sum_{\mathbf{x}_i \in T} \log p_{\mathcal{X}}(\mathbf{x}_i | \eta).$$

Subsequently, we estimate the value of θ by solving:

$$\hat{\theta} = \arg \max_{\theta} \sum_{\mathbf{z}_j \in T} \log q_{\mathcal{Z}}(\mathbf{z}_j | \theta, \hat{\eta}). \quad (3)$$

In this paper, we focus primarily on domain-adaptation problems involving binary and count features. In such problems, we wish to encode changes in the marginal likelihood of observing non-zero values in the transfer model. To this end, we employ a dropout distribution as transfer model that can model domain-shifts in which a feature occurs less often in the target domain than in the source domain. Learning a FLDA model with a dropout transfer model has the effect of strongly regularizing weights on features that occur infrequently in the target domain.

3.3.1 DROPOUT TRANSFER

To define our transfer model for binary or count features, we first set up a model that describes the likelihood of observing non-zero features in the source data. This model comprises a product of independent Bernoulli distributions:

$$p_{\mathcal{X}}(\mathbf{x}_i | \eta) = \prod_{d=1}^m \mathbb{1}_{x_{i,d} \neq 0} \eta_d (1 - \eta_d)^{1 - \mathbb{1}_{x_{i,d} \neq 0}}, \quad (4)$$

where $\mathbb{1}$ is the indicator function and η_d is the success probability (probability of non-zero values) of feature d . For this model, the maximum likelihood estimate of η_d is simply the sample average: $\hat{\eta}_d = |S|^{-1} \sum_{\mathbf{x}_i \in S} \mathbb{1}_{x_{i,d} \neq 0}$.

Next, we define a transfer model that describes how often a feature has a value of zero in the target domain when it has a non-zero value in the source domain. We assume an

unbiased dropout distribution (Wager et al., 2013; Rostamizadeh et al., 2011) that sets an observed feature in the source domain to zero in the target domain with probability θ_d :

$$p_{Z|X}(z_{-d} | x = x_{id}, \theta_d) = \begin{cases} \theta_d & \text{if } z_{-d} = 0 \\ 1 - \theta_d & \text{if } z_{-d} = x_{id} / (1 - \theta_d) \end{cases}, \quad (5)$$

where $\forall d : 0 \leq \theta_d \leq 1$, the subscript of z_{-d} denotes the d -th feature for any target sample, and where the outcome of not *dropping out* is scaled by a factor $1/(1 - \theta_d)$ in order to center the dropout distribution on the particular source sample. We assume the transfer distribution factorizes over features to obtain: $p_{Z|X}(\mathbf{z} | \mathbf{x} = \mathbf{x}_i, \theta) = \prod_d^m p_{Z|X}(z_{-d} | x_{-d} = x_{id}, \theta_d)$. The equation above defines a transfer distribution for every source sample. We obtain our final transfer model by sharing the parameters θ between all transfer distributions and averaging over all source samples.

To compute the maximum likelihood estimate of θ , the dropout transfer model from Equation 5 and the source model from Equation 4 are plugged into Equation 2 to obtain (see Appendix A for details):

$$\begin{aligned} q_Z(\boldsymbol{\theta} | \eta) &= \prod_{d=1}^m \int_{\mathcal{X}} p_{Z|X}(z_{-d} | x_{-d}, \theta_d) p_X(x_{-d} | \eta_d) dx_{-d} \\ &= \prod_{d=1}^m \left((1 - \theta_d) \eta_d \right)^{\mathbb{1}_{z_{-d} \neq 0}} \left(1 - (1 - \theta_d) \eta_d \right)^{1 - \mathbb{1}_{z_{-d} \neq 0}}. \end{aligned} \quad (6)$$

Plugging this expression into Equation 3 and maximizing with respect to θ , we obtain:

$$\hat{\theta}_d = \max\{0, 1 - \frac{\hat{\zeta}_d}{\hat{\eta}_d}\},$$

where $\hat{\zeta}_d$ is the sample average of the dichotomized target samples, $|T|^{-1} \sum_{z_d \in T} \mathbb{1}_{z_d \neq 0}$, and where $\hat{\eta}_d$ is the sample average of the dichotomized source samples, $|S|^{-1} \sum_{\mathbf{x}_i \in S} \mathbb{1}_{x_{id} \neq 0}$. We note that our particular choice for the transfer model cannot represent rate changes in the values of non-zero count features, such as whether a word is used on average 10 times in a document versus used on average only 3 times. The only variation that our dropout distribution captures is the variation in whether or not a feature occurs ($z_{-d} \neq 0$).

Because our dropout transfer model factorizes over features and is in the natural exponential family, the expectation in Equation 1 can be analytically computed. In particular, for a transfer distribution conditioned on source sample \mathbf{x}_i , its mean and variance are:

$$\begin{aligned} \mathbb{E}_{Z|X}[\mathbf{z}] &= \mathbf{x}_i \\ \mathbb{V}_{Z|X}[\mathbf{z}] &= \text{diag}\left(\frac{\theta}{1 - \theta}\right) \circ \mathbf{x}_i \mathbf{x}_i^\top, \end{aligned}$$

where \circ denotes the element-wise product of two matrices and we use the shorthand notation $\mathbb{E}_{Z|X=\mathbf{x}_i} = \mathbb{E}_{Z|X}$. The variance is a diagonal matrix due to our assumption of independent transfer distributions per feature. We will use these expressions below in our description of how to learn the parameters of the domain-adapted classifiers.

3.4 Classification

In order to perform classification with the risk formulation in Equation 1, we need to select a loss function L . Popular choices for the loss function include the quadratic loss (used in least-squares classification), the exponential loss (used in boosting), the hinge loss (used in support vector machines) and the logistic loss (used in logistic regression). The formulation in (1) has been studied before in the context of *dropout training* for the quadratic, exponential, and logistic loss by Wäger et al. (2013); Van der Maaten et al. (2013), and for hinge loss by Chen et al. (2014). In this paper, we focus on the quadratic and logistic loss functions, but we note that the FLDA approach can also be used in combination with exponential and hinge losses.

3.4.1 QUADRATIC LOSS

Assuming binary labels $Y = \{-1, +1\}$, a linear classifier $h(\mathbf{z}) = \mathbf{w}^\top \mathbf{z}$ parametrized by \mathbf{w} , and a quadratic loss function $L = (\mathbf{y} - \mathbf{w}^\top \mathbf{z})^2$, the expectation in Equation 1 can be expressed as:

$$\begin{aligned} \hat{R}_Z(\mathbf{w} | S) &= \sum_{(\mathbf{x}_i, y_i) \in S} \mathbb{E}_{Z|X} [y_i - \mathbf{w}^\top \mathbf{z}]^2 \\ &= \mathbf{y}^\top \mathbf{y} - 2 \mathbf{w}^\top \mathbb{E}_{Z|X}[\mathbf{z}] \mathbf{y} + \mathbf{w}^\top (\mathbb{E}_{Z|X}[\mathbf{z}] \mathbb{E}_{Z|X}[\mathbf{z}]^\top + \mathbb{V}_{Z|X}[\mathbf{z}]) \mathbf{w}, \end{aligned}$$

in which the data is augmented with $\mathbf{1}$ to capture the intercept, and in which we denote the $(m+1) \times |S|$ matrix of expectations as $\mathbb{E}_{Z|X=\mathbf{x}}[\mathbf{Z}] = [\mathbb{E}_{Z|X=\mathbf{x}_1}[\mathbf{z}], \dots, \mathbb{E}_{Z|X=\mathbf{x}_{|S|}}[\mathbf{z}]]$ and the $(m+1) \times (m+1)$ diagonal matrix of variances as $\mathbb{V}_{Z|X=\mathbf{x}}[\mathbf{Z}] = \sum_{\mathbf{x}_i \in S} \mathbb{V}_{Z|X=\mathbf{x}_i}[\mathbf{z}]$. Deriving the gradient for this loss function and setting it to zero yields the following closed-form solution for the classifier weights:

$$\mathbf{w} = \left(\mathbb{E}_{Z|X}[\mathbf{z}] \mathbb{E}_{Z|X}[\mathbf{z}]^\top + \mathbb{V}_{Z|X}[\mathbf{z}] \right)^{-1} \mathbb{E}_{Z|X}[\mathbf{z}] \mathbf{y}^\top. \quad (7)$$

In the case of a multi-class problem, i.e. $Y = \{1, \dots, K\}$, K predictors can be built in an one-vs-all fashion or $K(K-1)/2$ predictors in an one-vs-one fashion.

The solution in Equation 7 is very similar to the solution of a standard ridge regression model: $\mathbf{w} = (\mathbf{X}\mathbf{X}^\top + \lambda \mathbf{I})^{-1} \mathbf{X}\mathbf{y}^\top$. The main difference is that, in a standard ridge regressor, the regularization is independent of the data. By contrast, the regularization on the weights of the FLDA solution is determined by the variance of the transfer model: hence, it is different for each dimension and it depends on the transfer from source to target domain. Algorithm 1 summarizes the training of a binary quadratic-loss FLDA classifier with dropout transfer.

Algorithm 1 Binary FLDA with dropout transfer model and quadratic loss function.

```

procedure FLDA-Q( $S, T$ )
  for  $d=1, \dots, m$  do
     $\hat{\eta}_d = |S|^{-1} \sum_{\mathbf{x}_i \in S} \mathbb{1}_{x_i, d \neq 0}$ 
     $\hat{\zeta}_d = |T|^{-1} \sum_{\mathbf{x}_j \in T} \mathbb{1}_{x_j, d \neq 0}$ 
     $\theta_d = \max \{0, 1 - \hat{\zeta}_d / \hat{\eta}_d\}$ 
  end for
   $\mathbf{w} = (\mathbf{X}\mathbf{X}^\top + \text{diag}(\frac{\theta}{1-\theta})) \circ \mathbf{X}\mathbf{X}^\top)^{-1} \mathbf{X}\mathbf{Y}^\top$ 
  return  $\text{sign}(\mathbf{w}^\top \mathbf{Z})$ 
end procedure

```

▷ ◦ Element-wise product

3.4.2 LOGISTIC LOSS

Following the same choice of labels and hypothesis class as for the quadratic loss, the logistic version can be expressed as:

$$\begin{aligned}
 \hat{R}_Z(\mathbf{w} | S) &= \frac{1}{|S|} \sum_{(\mathbf{x}_i, y_i) \in S} \mathbb{E}_Z | \mathbf{x}_i | [-y_i \mathbf{w}^\top \mathbf{z} + \log \sum_{y' \in Y} \exp(y' \mathbf{w}^\top \mathbf{z})] \\
 &= \frac{1}{|S|} \sum_{(\mathbf{x}_i, y_i) \in S} -y_i \mathbf{w}^\top \mathbb{E}_Z | \mathbf{x}_i | \mathbf{z} + \mathbb{E}_Z | \mathbf{x}_i | \left[\log \sum_{y' \in Y} \exp(y' \mathbf{w}^\top \mathbf{z}) \right].
 \end{aligned} \tag{8}$$

This is a convex function in \mathbf{w} because the log-sum-exp of an affine function is convex, and because the expected value of a convex function is convex. However, the expectation cannot be computed analytically. Following Wäger et al. (2013), we approximate the expectation of the log-partition function, $A(\mathbf{w}^\top \mathbf{z}) = \log \sum_{y' \in Y} \exp(y' \mathbf{w}^\top \mathbf{z})$, using a Taylor expansion around the value $a_i = \mathbf{w}^\top \mathbf{x}_i$:

$$\begin{aligned}
 \mathbb{E}_Z | \mathbf{x}_i | [A(\mathbf{w}^\top \mathbf{z})] &\approx A(a_i) + A'(a_i) (\mathbb{E}_Z | \mathbf{x}_i | [\mathbf{w}^\top \mathbf{z}] - a_i) + \frac{1}{2} A''(a_i) (\mathbb{E}_Z | \mathbf{x}_i | [\mathbf{w}^\top \mathbf{z}] - a_i)^2 \\
 &= \text{const} + \sigma(-2\mathbf{w}^\top \mathbf{x}_i) \sigma(2\mathbf{w}^\top \mathbf{x}_i) \mathbf{w}^\top \mathbb{V}_Z | \mathbf{x}_i | \mathbf{z} | \mathbf{w},
 \end{aligned} \tag{9}$$

where $\sigma(x) = 1/(1 + \exp(-x))$ is the sigmoid function. In the Taylor approximation, the first-order term disappears because we chose an unbiased transfer model: $\mathbb{E}_Z | \mathbf{x}_i | [\mathbf{w}^\top \mathbf{z}] = \mathbf{w}^\top \mathbf{x}_i$. The approximation cannot be minimized in closed-form: we repeatedly take steps in the direction of its gradient in order to minimize the approximation of the risk in Equation 8, as described in Algorithm 2 (see Appendix B for the gradient derivation). The algorithm can be readily extended to multi-class problems by replacing \mathbf{w} by a $(m+1) \times K$ matrix and using an one-hot encoding for the labels (see Appendix C).

4. Experiments

In our experiments, we first study the empirical behavior of FLDA on artificial data for which we know the true transfer distribution. Following that, we measure the performance of our method in a “missing data at test time” scenario, as well as on two image data sets and three text data sets with varying amounts of domain transfer.

Algorithm 2 Binary FLDA with dropout transfer model and logistic loss function.

```

procedure FLDA-L( $S, T$ )
  for  $d=1, \dots, m$  do
     $\hat{\eta}_d = |S|^{-1} \sum_{\mathbf{x}_i \in S} \mathbb{1}_{x_i, d \neq 0}$ 
     $\hat{\zeta}_d = |T|^{-1} \sum_{\mathbf{x}_j \in T} \mathbb{1}_{x_j, d \neq 0}$ 
     $\theta_d = \max \{0, 1 - \hat{\zeta}_d / \hat{\eta}_d\}$ 
  end for
   $\mathbf{w} = \arg \min_{\mathbf{w}} - \sum_{(\mathbf{x}_i, y_i) \in S} [y_i \mathbf{w}^\top \mathbf{x}_i]$ 
    +  $\mathbf{w}'^\top (\sum_{(\mathbf{x}_i, y_i) \in S} [\sigma(-2\mathbf{w}^\top \mathbf{x}_i) \sigma(2\mathbf{w}^\top \mathbf{x}_i) \text{diag}(\frac{\theta}{1-\theta}) \mathbf{x}_i \mathbf{x}_i^\top]) \mathbf{w}'$ 
  return  $\text{sign}(\mathbf{w}^\top \mathbf{Z})$ 
end procedure

```

4.1 Artificial Data

We first investigate the behavior of FLDA on a problem in which the model assumptions are satisfied. We create such a problem setting by first sampling a source domain data set from known class-conditional distributions. Subsequently, we construct a target domain data set by sampling additional source data and transforming it using a pre-defined (dropout) transfer model.

4.1.1 ADAPTATION UNDER CORRECT MODEL ASSUMPTIONS

We perform experiments in which the domain-adapted classifier estimates the transfer model and trains on the source data; we evaluate the quality of the resulting classifier by comparing it to an oracle classifier that was trained on the target data (that is, the classifier one would train if labels for the target data were available at training time).

In the first experiment, we generate binary features by drawing 100,000 samples from two bivariate Bernoulli distributions. The marginal distributions are $[0.7 \ 0.7]$ for class one and $[0.3 \ 0.3]$ for class two. The source data is transformed to the target data using a dropout transfer model with parameters $\theta = [0.5 \ 0]$. This means that 50% of the values for feature 1 are set to 0 and the other values are scaled by $1/(1 - 0.5)$. For reference, two naive least-squares classifiers are trained, one on the labeled source data (S-LS) and one on the labeled target data (T-LS), and compared to FLDA-Q. S-LS achieves a misclassification error of 0.40 while T-LS and FLDA-Q achieve an error of 0.30. This experiment is repeated for the same classifiers but with logistic losses: a source logistic classifier (S-LR), a target logistic classifier (T-LR) and FLDA-L. In this experiment, S-LR again achieves an error of 0.40 and T-LR and FLDA-L an error of 0.30. Figure 1 shows the decision boundaries for the quadratic loss classifiers on the left and the logistic loss classifiers on the right. The figure shows that for both loss functions, FLDA has completely adapted to be equivalent to the target classifier in this artificial problem.

In the second experiment, we generate count features by sampling from bivariate Poisson distributions. Herein, we used rate parameters $\lambda = [2 \ 2]$ for the first class and $\lambda = [6 \ 6]$ for the second class. Again, we construct the target domain data by generating new samples

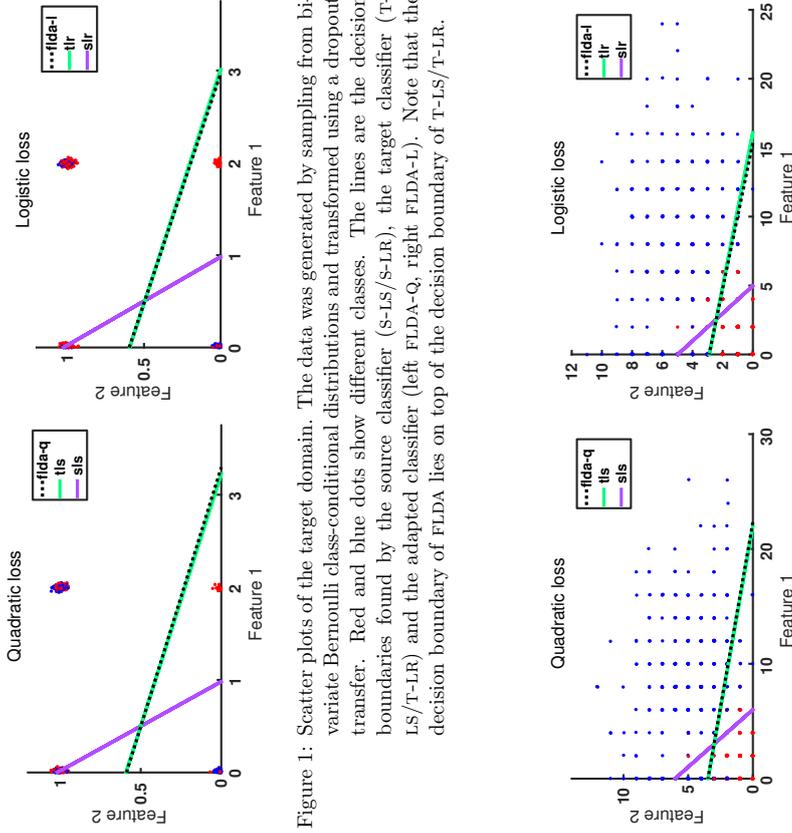

Figure 1: Scatter plots of the target domain. The data was generated by sampling from bivariate Bernoulli class-conditional distributions and transformed using a dropout transfer. Red and blue dots show different classes. The lines are the decision boundaries found by the source classifier (S-LS/S-LR), the target classifier (T-LS/T-LR) and the adapted classifier (left FLDA-Q, right FLDA-L). Note that the decision boundary of FLDA lies on top of the decision boundary of T-LS/T-LR.

Figure 2: Scatter plots of the target domain with decision boundaries of classifiers. The data was generated by sampling from bivariate Poisson class-conditional distributions and the decision boundaries were constructed using the source classifier (S-LS/S-LR), the target classifier (T-LS/T-LR), and the adapted classifiers (left FLDA-Q, right FLDA-L). Note that the decision boundary of FLDA lies on top of the decision boundary of T-LS / T-LR.

and dropping out the values of feature 1 with a probability of 0.5. In this experiment S-LS achieves an error of 0.181 and T-LS / FLDA-Q achieve an error of 0.099, while S-LR achieves an error of 0.170 and T-LR / FLDA-L achieve an error of 0.084. Figure 2 shows the decision boundaries of each of these classifiers and that FLDA has fully adapted to the domain shift.

4.1.2 LEARNING CURVES

One question that arises from the previous experiments is how many samples FLDA needs to estimate the transfer parameters and adapt to be (nearly) identical to the target classifier. To answer it, we performed an experiment in which we computed the classification error rate as a function of the number of training samples. The source training and validation data was generated from the same bivariate Poisson distributions as in Figure 2. The target data was constructed by generating additional source data and dropping out the first feature with a probability of 0.5. Each of the four data sets contained 10,000 samples. First, we trained a naive least-squares classifier on the source data (S-LS) and tested its performance on both the source validation and the target sets as a function of the number of source training samples. Second, we trained a naive least-squares classifier on the labeled target data (T-LS) and tested it on the source validation and another target validation set as a function of the number target training samples. Third, we trained an adapted classifier (FLDA-Q) on equal amounts of labeled source training data and unlabeled target training data and tested it on both the source validation and target validation sets. The experiment was repeated 50 times for every sample size to calculate the standard error of the mean.

The learning curves are plotted in Figure 3, which shows the classification error on the source validation set (top) and the classification error on the target validation (bottom). As expected, the source classifier (S-LS) outperforms the target (T-LS) and adapted (FLDA-Q) classifiers on the source domain (dotted lines), while FLDA-Q and T-LS outperform S-LS on the target domain (solid lines). In this problem, it appears that roughly 20 labeled source samples and 20 unlabeled target samples are sufficient for FLDA to adapt to the domain shift. Interestingly, FLDA-Q is outperforming S-LS and T-LS for small sample sizes. This is most likely due to the fact that the application of the transfer model is acting as a kind of regularization. In particular, when the learning curves are computed with ℓ_2 -regularized classifiers, then the difference in performance disappears.

4.1.3 ROBUSTNESS TO PARAMETER ESTIMATION ERRORS

Another question that arises is how sensitive the approach is to estimation errors in the transfer parameters. To answer this question, we performed an experiment in which we artificially introduce an error in the transfer parameters by perturbing them. As before, we generate 100,000 samples for both domains by sampling from bivariate Poisson distributions with $\lambda = [2 \ 2]$ for class 1 and $\lambda = [6 \ 6]$ for class 2. Again, the target domain is constructed by dropping out feature 1 with a probability of 0.5. We trained a naive classifier on the source data (S-LS), a naive classifier on the target data (T-LS), and an adapted classifier FLDA-Q with four different sets of parameters: the maximum likelihood estimate of the first transfer parameter $\hat{\theta}_1$ with an addition of 0, 0.1, 0.2, and 0.3. Table 1 shows the resulting classification errors, which reveal a relatively small effect of perturbing the estimated transfer parameters: the errors only increase by a few percent in this experiment.

To further illustrate the effect of the transfer parameters, Figure 4 shows the decision boundaries for the perturbed adapted classifiers. The figures show that the linear boundaries start to angle upwards when the error in the transfer parameter estimate increases. Overall, one could describe the effect of a dropout transfer model as steering the direction of the linear classifier. This experiment shows the importance of an accurate estimation of the

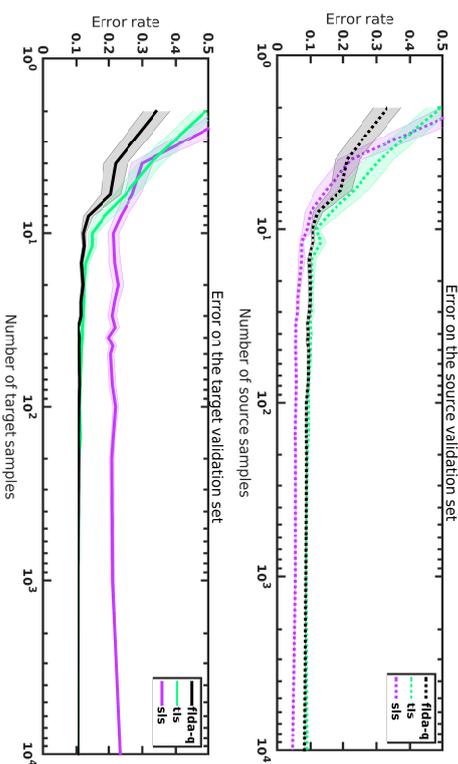

Figure 3: Learning curves of the source classifier (S-SL), the target classifier (T-TL), and adapted classifier (FLDA-Q). The top figure shows the error on a validation set generated from two bivariate Poisson distributions. The bottom figure shows the error on a validation set generated from two bivariate Poisson distributions with the first feature dropped out with a probability of 0.5.

	SL	TL	$\hat{\theta}_1 + 0$	$\hat{\theta}_1 + 0.1$	$\hat{\theta}_1 + 0.2$	$\hat{\theta}_1 + 0.3$
Quadratic loss	0.245	0.137	0.138	0.145	0.149	0.150
Logistic loss	0.264	0.139	0.139	0.140	0.142	0.146

Table 1: Classification errors for a naive source classifier, a naive target classifier, and the adapted classifier with a value of 0, 0.1, 0.2, and 0.3 added to the estimate of the first transfer parameter θ_1 .

transfer parameters to obtain high-quality adaptation. Nonetheless, our results do suggest that FLDA is robust to relatively small perturbations.

4.2 Natural Data

In a second set of experiments, we evaluate FLDA on a series of real-world data sets and compare it with several state-of-the-art methods. The evaluations are performed in the transductive learning setting: we measure the performance of the classifier on the already given, but unlabeled target samples.

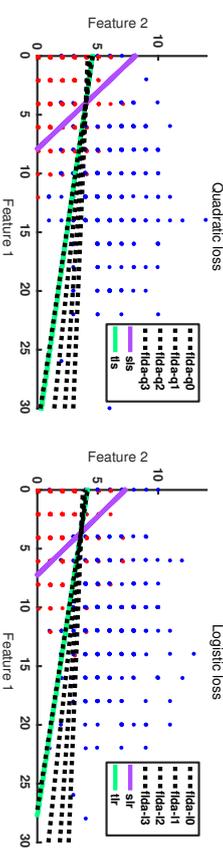

Figure 4: Scatter plots of the target data and decision boundaries of two naive and four adapted classifiers with transfer parameter estimate errors of 0, 0.1, 0.2, and 0.3. Results are shown for both the quadratic loss classifier (FLDA-Q; left) and the logistic loss classifier (FLDA-L; right).

As baselines, we consider eight alternative methods for domain adaptation. All of these employ a two-stage procedure. In the first step, sample weights, domain-invariant features, or a transformation of the feature space is estimated. In the second step, a classifier is trained using the results of the first stage. In all experiments, we estimate the hyperparameters, such as ℓ_2 -regularization parameters, via cross-validation on held-out source data. It should be noted that these values are optimal for generalizing to new source data but not necessarily for generalizing to the target domain (Sugiyama et al., 2007). Each of the eight baseline methods is described briefly below.

4.2.1 NAIVE SUPPORT VECTOR MACHINE (S-SVM)

Our first baseline method is a support vector machine trained on only the source samples and applied on the target samples. We made use of the libsvm package by Chang and Lin (2011) with a radial basis function kernel and we performed cross-validation to estimate the kernel bandwidth and the ℓ_2 -regularization parameter. All multi-class classification is done through an one-vs-one scheme. This method can be readily compared to subspace alignment (SA) and transfer component analysis (TCA) to evaluate the effects of the respective adaptation approaches.

4.2.2 NAIVE LOGISTIC REGRESSION (S-LR)

Our second baseline method is an ℓ_2 -regularized logistic regressor trained on only the source samples. Its main difference with the support vector machine is that it uses a linear model, a logistic loss instead of a hinge loss, and that it has a natural extension to multi-class as opposed to one-vs-one. The value of the regularization parameter was set via cross-validation. This method can be readily compared to kernel mean matching (KMM), structural correspondence learning (SCL), as well as to the logistic loss version of feature-level domain adaptation (FLDA-L).

4.2.3 KERNEL MEAN MATCHING (KMM)

Kernel mean matching (Huang et al., 2006; Gretton et al., 2009) finds importance weights by minimizing the maximum mean discrepancy (MMD) between the reweighted source samples and the target samples. To evaluate the empirical MMD, we used the radial basis function kernel. The weights are then incorporated in an importance weighted ℓ_2 -regularized logistic regressor.

4.2.4 STRUCTURAL CORRESPONDENCE LEARNING (SCL)

In order to build the domain-invariant subspace (Blitzer et al., 2006), the 20 features with the largest proportion of non-zero values in both domains are selected as the pivot features. Their values were dichotomized (1 if $x \neq 0$, 0 if $x = 0$) and predicted using a modified Huber loss (Ando and Zhang, 2005). The resulting classifier weight matrix was subjected to an eigenvalue decomposition and the eigenvectors with the 15 largest eigenvalues are retained. The source and target samples are both projected onto this basis and the resulting subspaces are added as features to the original source and target feature spaces, respectively. Consequently, classification is done by training an ℓ_2 -regularized logistic regressor on the augmented source samples and testing on the augmented target samples.

4.2.5 TRANSFER COMPONENT ANALYSIS (TCA)

For transfer component analysis, the closed-form solution to the parametric kernel map described in Pan et al. (2011) is computed using a radial basis function kernel. Its hyperparameters (kernel bandwidth, number of retained components and trade-off parameter μ) are estimated through cross-validation. After mapping the data onto the transfer components, we trained a support vector machine with an RBF kernel, cross-validating over its kernel bandwidth and the regularization parameter.

4.2.6 GEODESIC FLOW KERNEL (GFK)

The geodesic flow kernel is extracted based on the difference in angles between the principal components of the source and target samples (Gong et al., 2012). The basis functions of this kernel implicitly map the data onto all possible subspaces on the geodesic path between domains. Classification is performed using a kernel 1-nearest neighbor classifier. We used the subspace disagreement measure (SDM) to select an optimal value for the subspace dimensionality.

4.2.7 SUBSPACE ALIGNMENT (SA)

For subspace alignment (Fernando et al., 2013), all samples are normalized by their sum and all features are z-scored before extracting principal components. Subsequently, the Frobenius norm between the transformed source components and target components is minimized with respect to an affine transformation matrix. After projecting the source samples onto the transformed source components, a support vector machine with a radial basis function kernel is trained with cross-validated hyperparameters and tested on the target samples mapped onto the target components.

Missing	75	685	615	130	72	384

Table 2: Summary statistics of the UCI repository data sets with missing data.

4.2.8 TARGET LOGISTIC REGRESSION (T-LR)

Finally, we trained a ℓ_2 -regularized logistic regressor using the normally unknown target labels as the oracle solution. This classifier is included to obtain an upper bound on the performance of our classifiers.

4.2.9 MISSING DATA AT TEST TIME

In this set of experiments, we study "missing data at test time" problems in which we argue that dropout transfer occurs naturally. Suppose that for the purposes of building a classifier, a data set is neatly collected with all features measured for all samples. At test time, however, some features could not be measured, due to for instance sensor failure, and the missing values are replaced by 0. This setting can be interpreted as two distributions over the same space with their transfer characterized by a relative increase in the number of 0 values, which our FLDA with dropout transfer is perfectly suited for. We have collected six data sets from the UCI machine learning repository (Lichman, 2013) with missing data: Hepatitis (hepat.), Ozone (ozone; Zhang and Fan, 2008), Heart Disease (heart; Detraano et al., 1989), Mammographic masses (mam.; Elter et al., 2007), Automobile (auto), and Arrhythmia (arry); Guvenir et al., 1997). Table 2 shows summary statistics for these sets. In the experiments, we construct the training set (source domain) by selecting all samples with no missing data, with the remainder as the test set (target domain). We note that instead of doing 0-imputation, we also could have used methods such as mean-imputation (Rubin, 1976; Little and Rubin, 2014). It is worth noting that the FLDA framework can adapt to such a setting by simply defining a different transfer model (one that replaces a feature value by its mean instead of a 0).

Table 3 reports the classification error rate of all domain-adaptation methods on the before-mentioned data sets. The lowest error rates for a particular data set are bold-faced. From the results presented in the table, we observe that whilst there appears to be little difference between the domains in the Hepatitis and Ozone data sets, there is substantial domain shift in the other data sets: the naive classifiers even perform at chance level on the Arrhythmia and Automobile data sets. On almost all data sets, both FLDA-Q and FLDA-L improve substantially over the S-LR, which suggests that they are successfully adapting to the missing data at test time. By contrast, most of the other domain-adaptation techniques do not consistently improve although, admittedly, sample transformation methods appear to work reasonable well on the Ozone, Mammography, and Arrhythmia data sets.

4.2.10 HANDWRITTEN DIGITS

Handwritten digit data sets have been popular in machine learning due to the large sample size and the interpretability of the images. Generally, the data is acquired by assigning an integer value between 0 and 255 proportional to the amount of pressure that is applied at a particular spatial location on an electronic writing pad. Therefore, the probability of a non-zero value of a pixel informs us how often a pixel is part of a particular digit. For instance, the middle pixel in the digit 8 is a very important part of the digit because it nearly always corresponds to a high-pressure location, but the upper-left corner pixel is not used that often and is less important. Domain shift may be present between digit data sets due to differences in recording conditions. As a result, we may observe pixels that are discriminative in one data set (the source domain) that are hardly ever observed in another data set (the target domain). As a result, these pixels cannot be used to classify digits in the target domain, and we would like to inform the classifier that it should not assign a large weight to such pixels. We created a domain adaptation setting by considering two handwritten digit sets, namely MNIST (LeCun et al., 1998) and USPS (Hull, 1994). In order to create a common feature space, images from both data sets are resized to 16 by 16 pixels. To reduce the discrepancy between the size of MNIST data set (which contains 70,000 examples) and the USPS data set (which contains 9,298 examples), we only use 14,000 samples from the MNIST data set. The classes are balanced in both data sets.

Figure 5 shows a visualization of the probability that each pixel is non-zero for both data sets. The visualization shows that while the digits in the MNIST data set occupy mostly the center region, the USPS digits tend to occupy a substantially larger part of the image, specifically a center column. Figure 6 (left) visualizes the weights of the naive linear classifier (S-LR), (middle) the dropout probabilities θ , and (right) the adapted classifiers weights (FLDA-L). The middle image shows that dropout probabilities are large in regions where USPS pixels are frequent (the white pixels in Figure 5 right) but MNIST pixels are infrequent (the black pixels in Figure 5, left). The weights of the naive classifier appear to be shaped in a somewhat noisy circular pattern in the periphery, with the center containing negative weights (if these center pixels have a low intensity in a new sample, then the image is more likely to be a 0 digit). By contrast, the adapted weights of the FLDA classifier are

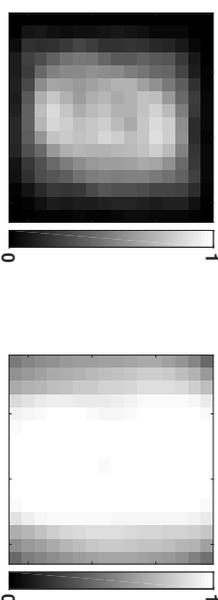

Figure 5: Visualization of the probability of non-zero values for each pixel on the MNIST data set (left) and the USPS data set (right).

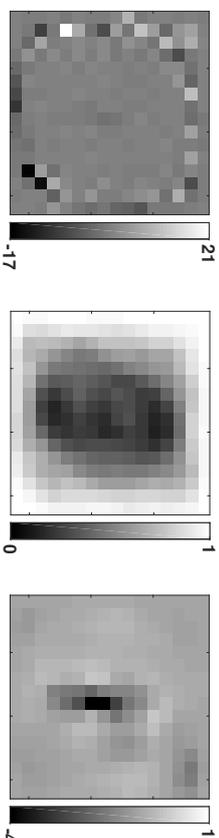

Figure 6: Weights assigned by the naive source classifier to the 0-digit predictor (left), the transfer parameters of the dropout transfer model (middle), and the weights assigned by the adapted classifier to the 0-digit predictor for training on USPS images and testing on MNIST (right; $U \rightarrow M$).

smoothed in the periphery, which indicates that the classifier is placing more value on the center pixels and is essentially ignoring the peripheral ones.

Table 4 shows the classification error rates where the rows correspond to the combinations of treating one data set as the source domain and the other as the target. The results show that there is a large difference between the domain-specific classifiers (S-LR and T-LR), which indicates that the domains are highly dissimilar. We note that the error rates of the target classifier on the MNIST data set are higher than usual for this data set (T-LR has an error rate of 0.234), which is because of the down-sampling of the images to 16×16 pixels and the smaller sample size. The results presented in the table highlight an interesting property of FLDA with dropout transfer: while FLDA performs well in settings in which the domain transfer can be appropriately modeled by the transfer distribution ($U \rightarrow M$ setting where pixels that appear in the USPS do not appear in MNIST), it does not perform well the other way around. The dropout transfer model does not capture pixels appearing *more often* instead of less often in the target domain. To work well in that setting, it is presumably necessary to use a richer transfer model.

Table 5: Classification error rates obtained by ten (domain-adapted) classifiers for all pairwise combinations of domains on the Office-Caltech data set with SURF features (A='Amazon', D='DSLR', W='Webcam', and C='Caltech').

4.2.11 OFFICE-CALTECH

The Office-Caltech data set (Hoffman et al., 2013) consists of images of objects gathered using four different methods: one from images found through a web image search (referred to as 'C'), one from images of products on Amazon (A), one taken with a digital SLR camera (D) and one taken with a webcam (W). Overall, the set contains 10 classes, with 1123 samples from Caltech, 958 samples from Amazon, 157 samples from the DSLR camera, and 295 samples from the webcam. Our first experiment with the Office-Caltech data set is based on features extracted through SURF features (Bay et al., 2006). These descriptors determine a set of interest points by finding local maxima in the determinant of the image Hessian. Weighted sums of Haar features are computed in multiple sub-windows at various scales around each of the interest points. The resulting descriptors are vector-quantized to produce a bag-of-visual-words histogram of the image that is both scale and rotation-invariant. We perform domain-adaptation experiments by training on one domain and testing on another.

Table 5 shows the results of the classification experiments, where compared to competing methods, SA is performing well for a number of domain pairs, which may indicate that the SURF descriptor representation leads to domain dissimilarities that can be accurately

Table 6: Classification error rates obtained by ten (domain-adapted) classifiers for all pairwise combinations of domains on the Office data set with DeCAF₈ features (A='Amazon', D='DSLR', and W='Webcam').

captured by subspace transformations. This result is further supported by the fact that the transformations found by GFK and TCA are also outperforming s-svm. FLDA-Q and FLDA-L are among the best performers on certain domain pairs. In general, FLDA does appear to perform at least as good or better than a naive s-LR classifier. The results on the Office-Caltech data set depend on the type of information the SURF descriptors are extracting from the images. We also studied the performance of domain-adaptation methods on a richer visual representation, produced by a pre-trained convolutional neural network. Specifically, we used a data set provided by Donahue et al., 2014, who extracted 1000-dimensional feature-layer activations (so-called DeCAF₈ features) in the upper layers of the a convolutional network that was pre-trained on the Imagenet data set. Donahue et al. (2014) used a larger superset of the Office-Caltech data set that contains 31 classes with 2817 images from Amazon, 498 from the DSLR camera, and 795 from the webcam. The results of our experiments with the DeCAF₈ features are presented in Table 6. The results show substantially lower error rates overall, but they also show that domain transfer in the DeCAF₈ feature representation is not amenable to effective modeling by subspace transformations. KMM and SCL obtain performances that are similar to the of the naive s-LR classifier but in one experiment, the naive classifier is actually the best-performing model. Whilst achieving the best performance on 2 out of 6 domain pairs, the FLDA-Q and FLDA-L models are not as effective as on other data sets, presumably, because dropout is not a good model for the transfer in a continuous feature space such as the DeCAF₈ feature space.

4.2.12 IMDB

The Internet Movie Database (IMDb) (Pang and Lee, 2004) contains written reviews of movies labeled with a 1-10 star rating, which we dichotomize by setting values > 5 as +1 and values ≤ 5 as -1. Using this dichotomy, both classes are roughly balanced. From the original bag-of-words representation, we selected only the features with more than 100 non-zero values in the entire data set, resulting in 4180 features. To obtain the domains, we split the data set by genre and obtained 3402 reviews of action movies, 1249 reviews of family movies, and 3697 reviews of war movies. We assume that people tend to use different words to review different genres of movies, and we are interested in predicting viewer sentiment after adapting to changes in the word frequencies. To visualize whether this assumption is

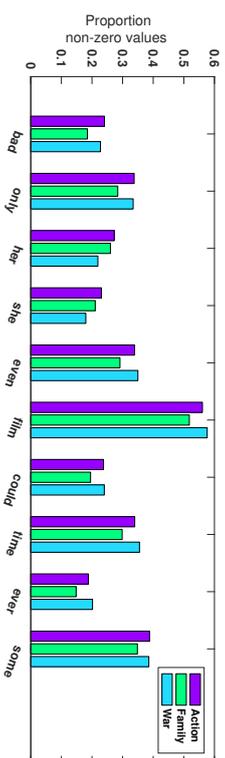

Figure 7: Proportion of non-zero values for a subset of words per domain on the IMDB data set.

	S-SVM	S-LR	KMM	SCL	SA	GFK	TCA	FLDA-Q	FLDA-L	T-LR
A→F	.145	.136	.133	.133	.184	.276	.230	.135	.136	.196
A→W	.158	.155	.155	.165	.163	.249	.266	.158	.154	.163
F→W	.256	.206	.208	.206	.182	.289	.355	.205	.202	.163
F→A	.201	.195	.193	.198	.193	.296	.363	.194	.194	.169
W→A	.168	.160	.159	.159	.167	.238	.222	.155	.157	.169
W→F	.340	.167	.163	.163	.232	.292	.203	.172	.159	.196

Table 7: Classification error rates obtained by ten (domain-adapted) classifiers for all pairwise combinations of domains on the IMDB data set. (A=‘Action’, F=‘Family’, and W=‘War’).

valid, we plot the proportion of non-zero values of 10 randomly chosen words per domain in Figure 7. The figure suggests that action movie and war movie reviews are quite similar, but the word use in family movie reviews does appear to be different.

Table 7 reports the results of the classification experiments on the IMDB database. The first thing to note is that the performances of S-LR and T-LR are quite similar, which suggests that the frequencies of discriminative words do not vary too much between genres. The results also show that GFK and TCA are not as effective on this data set as they were on the handwritten digits and Office-Caltech data sets, which suggests that finding a joint subspace that is still discriminative is hard, presumably, because only a small number of the 4180 words actually carry discriminative information. FLDA-Q and FLDA-L are better suited for such a scenario, which is reflected by their competitive performance on all domain pairs.

4.2.13 SPAM

Domain adaptation settings also arise in spam detection systems. For this experiment, we concatenated two data sets from the UCI machine learning repository: one containing 4205 emails from the Enron spam database (Kilint and Yang, 2004) and one containing 5338 text messages from the SMS-spam data set (Almeida et al., 2011). Both were represented using

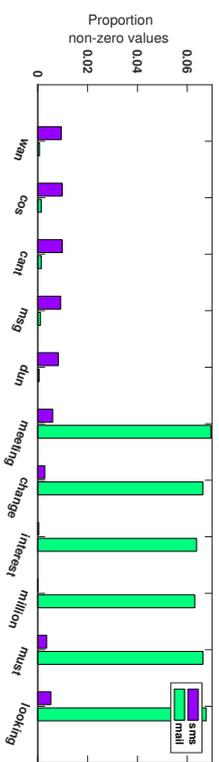

Figure 8: Proportion of non-zero values for a subset of words per domain on the spam data set.

	S-SVM	S-LR	KMM	SCL	SA	GFK	TCA	FLDA-Q	FLDA-L	T-LR
S→M	.460	.522	.521	.524	.445	.491	.508	.511	.521	.073
M→S	.830	.804	.799	.804	.408	.696	.863	.636	.727	.133

Table 8: Classification error rates obtained by ten (domain-adapted) classifiers for both domain pairs on the spam data set. (S=‘SMS’ and M=‘E-Mail’).

bag-of-words vectors over 4272 words that occurred in both data sets. Figure 8 shows the proportions of non-zero values for some example words, and shows that there exist large differences in word frequencies between the two domains. In particular, much of the domain differences are due to text messages using shortened words, whereas email messages tend to be more formal.

Table 8 shows results from our classification experiments on the spam data set. As can be seen from the results of T-LR, fairly good accuracies can be obtained on the spam detection task. However, the domains are so different that the naive classifiers S-SVM and S-LR are performing according to chance or worse. Most of the domain-adaptation models do not appear to improve much over the naive models. For KMM this makes sense, as the importance weight estimator will assign equal values to each sample when the empirical supports of the two domains are disjoint. There might be some features that are shared between domains, *i.e.*, words that are span in both emails and text messages, but considering the performance of SCL these might not be corresponding well with the other features. FLDA-Q and FLDA-L are showing slight improvements over the naive classifiers, but the transfer model we used is too poor as the domains contain a large amount of increased word frequencies.

4.2.14 AMAZON

We performed a similar experiment on the Amazon sentiment analysis data set of product reviews (Blitzer et al., 2007). The data consists of a 30,000 dimensional bag-of-words representations of 27,677 reviews with the labels derived from the dichotomized 5-star rating (ratings > 3 are +1 and ratings ≤ 3 as -1). Each review describes a product from one of four categories: books (6465 reviews), DVDs (5586 reviews), electronics (7681 reviews) and

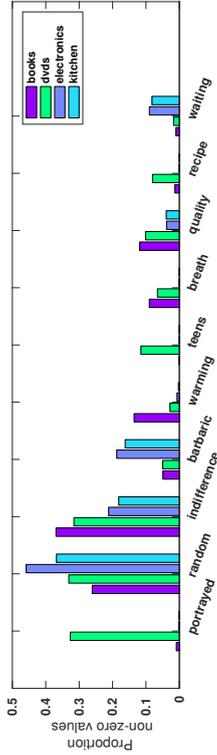

Figure 9: Proportion of non-zero values for a subset of words per domain on the Amazon data set.

kitchen appliances (7945 reviews). Figure 9 shows the probability of a non-zero value for some example words in each category. Some words, such as ‘portrayed’ or ‘barbaric’, are very specific to one or two domains, but the frequencies of many other words do not vary much between domains. We performed experiments on the Amazon data set using the same experimental setup as before.

In Table 9, we report the classification error rates on all pairwise combinations of domains. The difference in classification errors between S-LR and T-LR is up to 10%, which suggests there is potential for success with domain adaptation. However, the domain transfer is not captured well by SA, GFK, TCA: on average, these methods are performing worse than the naive classifiers. We presume this happens because only a small number of words are actually discriminative, and these words carry little weight in the sample transformation measures used. Furthermore, there are significantly less samples than features in each domain which means models with large amounts of parameters are likely to experience estimation errors. By contrast, FLDA-L performs strongly on the Amazon data set, achieving the best performance on many of the domain pairs. FLDA-Q performs substantially worse than FLDA-L, presumably, because of the singular covariance matrix and the fact that least-squares classifiers are very sensitive to outliers.

5. Discussion and Conclusions

We have presented an approach to domain adaptation, called FLDA, that fits a probabilistic model to capture the transfer between the source and the target data and, subsequently, trains a classifier by minimizing the expected loss on the source data under this transfer model. Whilst the FLDA approach is very general, in this paper, we have focused on one particular transfer model, namely, a dropout model. Our extensive experimental evaluation with this transfer model shows that FLDA performs on par with the current state-of-the-art methods for domain adaptation.

An interesting interpretation of our formulation is that the expected loss under the transfer model performs a kind of data-dependent regularization (Wager et al., 2013). For instance, if a quadratic loss function is employed in combination with a Gaussian transfer model, FLDA reduces to a transfer-dependent variant of ridge regression (Bishop, 1995). This transfer-dependent regularizer increases the amount of regularization on features when it

is undesired for the classifier to assign a large weight to that feature. In other words, the regularizer forces the classifier to ignore features that are frequently present in the source domain but very infrequently present in the target domain.

In some of our experiments, the adaptation strategies are producing classifiers that perform worse than a naive classifier trained on the source data. A potential reason for this is that many domain-adaptation models make strong assumptions on the data that are invalid in many real-world scenarios. In particular, it is unclear to what extent the relation between source data and classes ($\mathcal{X} \rightarrow \mathcal{Y}$) truly is informative about the target labels ($\mathcal{Z} \rightarrow \mathcal{Y}$). This issue arises in every domain-adaptation problem: without target labels, there is no way of knowing whether matching the source distribution $p_{\mathcal{X}}$ to the target distribution $p_{\mathcal{Z}}$ will improve the match between $p_{\mathcal{Y}|\mathcal{X}}$ and $p_{\mathcal{Y}|\mathcal{Z}}$.

Appendix A

For some combinations of source and target models, the source domain can be integrated out. For others, we would have to resort to Markov Chain Monte Carlo sampling and subsequently averaging the samples drawn from the *transferred* source distribution q_Z . For the Bernoulli and dropout distributions defined in Equations 4 and 5, the integration as in Equation 6 can be performed by plugging in the specified probabilities and performing the summation:

$$\begin{aligned}
q_Z(\mathbf{z} | \eta, \theta) &= \prod_{d=1}^m \int_{\mathcal{X}} p_Z | \mathcal{X}(z_{-d} | x_{-d}, \theta_d) p_{\mathcal{X}}(x_{-d} | \eta_d) dx_{-d} \\
&= \prod_{d=1}^m \sum_{\mathbb{1}_{x_{-d} \neq 0}} p_Z | \mathcal{X}(z_{-d} | \mathbb{1}_{x_{-d} \neq 0}, \theta_d) p_{\mathcal{X}}(\mathbb{1}_{x_{-d} \neq 0}; \eta_d) \\
&= \prod_{d=1}^m \begin{cases} \sum_{\mathbb{1}_{x_{-d} \neq 0}=0} p_Z | \mathcal{X}(z_{-d} = 0 | \mathbb{1}_{x_{-d} \neq 0}, \theta_d) p_{\mathcal{X}}(\mathbb{1}_{x_{-d} \neq 0}; \eta_d) & \text{if } z_{-d} = 0 \\ \sum_{\mathbb{1}_{x_{-d} \neq 0}=0} p_Z | \mathcal{X}(z_{-d} \neq 0 | \mathbb{1}_{x_{-d} \neq 0}, \theta_d) p_{\mathcal{X}}(\mathbb{1}_{x_{-d} \neq 0}; \eta_d) & \text{if } z_{-d} \neq 0 \end{cases} \\
&= \prod_{d=1}^m \begin{cases} 1(1 - \eta_d) + \theta_d \eta_d & \text{if } z_{-d} = 0 \\ 0(1 - \eta_d) + (1 - \theta_d) \eta_d & \text{if } z_{-d} \neq 0 \end{cases} \\
&= \prod_{d=1}^m (1 - \theta_d) \eta_d^{\mathbb{1}_{z_{-d} \neq 0}} (1 - (1 - \theta_d) \eta_d)^{1 - \mathbb{1}_{z_{-d} \neq 0}},
\end{aligned}$$

where the subscript of x_{-d} refers to the d -th feature of any sample x_{id} . Note that we chose our transfer model such that the probability is 0 for a non-zero target sample value given a zero source sample value; $p_Z | \mathcal{X}(z_{-d} \neq 0 | \mathbb{1}_{x_{-d} \neq 0} = 0, \theta_d) = 0$. In other words, if a word is not used in the source domain, then we expect that it is also not used in the target domain. By setting different values for these probabilities, one models different types of transfer.

Appendix B

The gradient to the second-order Taylor approximation of binary FLDA-L for a general transfer model is:

$$\begin{aligned}
\frac{\partial}{\partial \mathbf{w}} \hat{R}_Z(h | S) &= \frac{1}{|S|} \sum_{(\mathbf{x}_i, y_i) \in S} -y_i \mathbb{E}_{Z | \mathbf{x}_i}[\mathbf{z}] + \sum_{y' \in \mathcal{Y}} y' \frac{\exp(y' \mathbf{w}^\top \mathbf{x}_i)}{\exp(y' \mathbf{w}^\top \mathbf{x}_i)} \mathbf{x}_i + \\
&\left[\left(1 - \left[\frac{\sum_{y' \in \mathcal{Y}} y' \exp(y' \mathbf{w}^\top \mathbf{x}_i)}{\sum_{y' \in \mathcal{Y}} \exp(y' \mathbf{w}^\top \mathbf{x}_i)} \right]^2 \right) \mathbf{w}^\top \mathbf{x}_i + \frac{\sum_{y' \in \mathcal{Y}} y' \exp(y' \mathbf{w}^\top \mathbf{x}_i)}{\sum_{y' \in \mathcal{Y}} \exp(y' \mathbf{w}^\top \mathbf{x}_i)} \left(\mathbb{E}_{Z | \mathbf{x}_i}[\mathbf{z}] - \mathbf{x}_i \right) \right. \\
&\quad \left. + 4\sigma \left(-2 \mathbf{w}^\top \mathbf{x}_i \right) \sigma \left(2 \mathbf{w}^\top \mathbf{x}_i \right) \left[\left(\sigma \left(-2 \mathbf{w}^\top \mathbf{x}_i \right) - \sigma \left(2 \mathbf{w}^\top \mathbf{x}_i \right) \right) \mathbf{w}^\top \mathbf{x}_i + 1 \right] \right) \\
&\mathbf{w}^\top \left(\mathbb{V}_{Z | \mathbf{x}_i}[\mathbf{z}] + \left(\mathbb{E}_{Z | \mathbf{x}_i}[\mathbf{z}] - \mathbf{x}_i \right) \left(\mathbb{E}_{Z | \mathbf{x}_i}[\mathbf{z}] - \mathbf{x}_i \right)^\top \right) \mathbf{w}.
\end{aligned}$$

Appendix C

The second-order Taylor approximation to the expectation over the log-partition function for a multi-class classifier weight matrix \mathbf{W} of size $(m+1) \times K$ around the point $a_i = \mathbf{W}^\top \mathbf{x}_i$ is:

$$\begin{aligned}
\mathbb{E}_{Z | \mathbf{x}_i} [A(\mathbf{W}^\top \mathbf{z})] &\approx A(a_i) + A'(a_i) (\mathbb{E}_{Z | \mathbf{x}_i}[\mathbf{W}^\top \mathbf{z}] - a_i) + \frac{1}{2} A''(a_i) (\mathbb{E}_{Z | \mathbf{x}_i}[\mathbf{W}^\top \mathbf{z}] - a_i)^2 \\
&= \log \sum_{k=1}^K \exp(\mathbf{W}_k^\top \mathbf{x}_i) + \sum_{k=1}^K \frac{\exp(\mathbf{W}_k^\top \mathbf{x}_i)}{\sum_{k=1}^K \exp(\mathbf{W}_k^\top \mathbf{x}_i)} \mathbf{W}_k^\top (\mathbb{E}_{Z | \mathbf{x}_i}[\mathbf{z}] - \mathbf{x}_i) \\
&\quad + \frac{1}{2} \sum_{k=1}^K \left(\frac{\exp(\mathbf{W}_k^\top \mathbf{x}_i)}{\sum_{k=1}^K \exp(\mathbf{W}_k^\top \mathbf{x}_i)} - \frac{\exp(2\mathbf{W}_k^\top \mathbf{x}_i)}{\left(\sum_{k=1}^K \exp(\mathbf{W}_k^\top \mathbf{x}_i) \right)^2} \right) \\
&\quad \mathbf{W}_k^\top \left(\mathbb{V}_{Z | \mathbf{x}_i}[\mathbf{z}] + \left(\mathbb{E}_{Z | \mathbf{x}_i}[\mathbf{z}] - \mathbf{x}_i \right) \left(\mathbb{E}_{Z | \mathbf{x}_i}[\mathbf{z}] - \mathbf{x}_i \right)^\top \right) \mathbf{W}_k.
\end{aligned}$$

The results contains a number of recurring terms which means it can be efficiently implemented. Incorporating the multi-class approximation into the loss, we can derive the following gradient:

$$\begin{aligned}
\frac{\partial}{\partial \mathbf{W}_k} \hat{R}_Z(h | S) &= \frac{1}{|S|} \sum_{(\mathbf{x}_i, y_i) \in S} -y_i \mathbb{E}_{Z | \mathbf{x}_i}[\mathbf{z}] \\
&+ \left[\frac{\exp(\mathbf{W}_k^\top \mathbf{x}_i)}{\sum_{k=1}^K \exp(\mathbf{W}_k^\top \mathbf{x}_i)} - \frac{\exp(2\mathbf{W}_k^\top \mathbf{x}_i)}{\left(\sum_{k=1}^K \exp(\mathbf{W}_k^\top \mathbf{x}_i) \right)^2} \right] \mathbf{x}_i \mathbf{W}_k^\top (\mathbb{E}_{Z | \mathbf{x}_i}[\mathbf{z}] - \mathbf{x}_i) \\
&+ \frac{\exp(\mathbf{W}_k^\top \mathbf{x}_i) \mathbf{x}_i}{\sum_{k=1}^K \exp(\mathbf{W}_k^\top \mathbf{x}_i)} (\mathbb{E}_{Z | \mathbf{x}_i}[\mathbf{z}] - \mathbf{x}_i) \\
&+ \left[\frac{\exp(\mathbf{W}_k^\top \mathbf{x}_i) \mathbf{x}_i}{\sum_{k=1}^K \exp(\mathbf{W}_k^\top \mathbf{x}_i)} - 3 \frac{\exp(2\mathbf{W}_k^\top \mathbf{x}_i) \mathbf{x}_i}{\left(\sum_{k=1}^K \exp(\mathbf{W}_k^\top \mathbf{x}_i) \right)^2} + 2 \frac{\exp(3\mathbf{W}_k^\top \mathbf{x}_i) \mathbf{x}_i}{\left(\sum_{k=1}^K \exp(\mathbf{W}_k^\top \mathbf{x}_i) \right)^3} \right] \\
&\mathbf{W}_k^\top \left(\mathbb{V}_{Z | \mathbf{x}_i}[\mathbf{z}] + \left(\mathbb{E}_{Z | \mathbf{x}_i}[\mathbf{z}] - \mathbf{x}_i \right) \left(\mathbb{E}_{Z | \mathbf{x}_i}[\mathbf{z}] - \mathbf{x}_i \right)^\top \right) \mathbf{W}_k \\
&+ \left[\frac{2 \exp(\mathbf{W}_k^\top \mathbf{x}_i)}{\sum_{k=1}^K \exp(\mathbf{W}_k^\top \mathbf{x}_i)} - \frac{2 \exp(2\mathbf{W}_k^\top \mathbf{x}_i)}{\sum_{k=1}^K \exp(\mathbf{W}_k^\top \mathbf{x}_i)^2} \right] (\mathbb{V}_{Z | \mathbf{x}_i}[\mathbf{z}] + \left(\mathbb{E}_{Z | \mathbf{x}_i}[\mathbf{z}] - \mathbf{x}_i \right) (\mathbb{E}_{Z | \mathbf{x}_i}[\mathbf{z}] - \mathbf{x}_i)^\top) \mathbf{W}_k \\
&- \frac{\exp(\mathbf{W}_k^\top \mathbf{x}_i) \mathbf{x}_i}{\left(\sum_{k=1}^K \exp(\mathbf{W}_k^\top \mathbf{x}_i) \right)^2} \sum_{j \neq k}^K \exp(\mathbf{W}_j^\top \mathbf{x}_i) \mathbf{W}_j^\top (\mathbb{V}_{Z | \mathbf{x}_i}[\mathbf{z}] + \left(\mathbb{E}_{Z | \mathbf{x}_i}[\mathbf{z}] - \mathbf{x}_i \right) (\mathbb{E}_{Z | \mathbf{x}_i}[\mathbf{z}] - \mathbf{x}_i)^\top) \mathbf{W}_j \\
&+ \frac{2 \exp(\mathbf{W}_k^\top \mathbf{x}_i) \mathbf{x}_i}{\left(\sum_{k=1}^K \exp(\mathbf{W}_k^\top \mathbf{x}_i) \right)^3} \sum_{j \neq k}^K \exp(2\mathbf{W}_j^\top \mathbf{x}_i) \mathbf{W}_j^\top (\mathbb{V}_{Z | \mathbf{x}_i}[\mathbf{z}] + \left(\mathbb{E}_{Z | \mathbf{x}_i}[\mathbf{z}] - \mathbf{x}_i \right) (\mathbb{E}_{Z | \mathbf{x}_i}[\mathbf{z}] - \mathbf{x}_i)^\top) \mathbf{W}_j.

Abstract

We introduce the term *semiparametric mean field variational Bayes* to describe the relaxation of mean field variational Bayes in which some density functions in the product density restriction are pre-specified to be members of convenient parametric families. This notion has appeared in various guises in the mean field variational Bayes literature during its history and we endeavor to unify this important topic. We lay down a general framework and explain how previous relevant methodologies fall within this framework. A major contribution is elucidation of numerical issues that impact semiparametric mean field variational Bayes in practice.

Keywords: Bayesian Computing, Factor Graph, Fixed-form Variational Bayes, Fixed-point Iteration, Non-conjugate Variational Message Passing, Nonlinear Conjugate Gradient Method

1. Introduction

We expound *semiparametric mean field variational Bayes*, a powerful combination of the notions of minimum Kullback-Leibler divergence and mean field restriction, that allows fast and often accurate approximate Bayesian inference for a wide range of scenarios. Most of its foundational literature and applications are in Machine Learning. However, semiparametric mean field variational Bayes is also an important paradigm for Statistics in the age of very big sample sizes and models.

Several articles concerned with deterministic approximate Bayesian inference, such as Barber and Bishop (1997), Honkela et al. (2010), Knowles and Minka (2011), Tan and Nott (2013), Wand (2014) and Menictas and Wand (2015), have demonstrated that modification of mean field variational Bayes (e.g. Wainwright and Jordan, 2008) to include pre-specified parametric families in the product density posterior approximation can have great practical benefits. For example, Barber and Bishop (1997) used a pre-specified Multivariate Normal distribution for the posterior density of the vector of adaptive parameters in multilayer neural networks while Tan and Nott (2013) derived a closed form variational approximate

algorithm for Bayesian Poisson mixed models by pre-specifying the fixed and random effects parameters to have Multivariate Normal distributions. Knowles and Minka (2011) took a message passing approach to mean field variational Bayes and explain how their approach to inclusion of pre-specified parametric families allows modular inference algorithms for arbitrary factors. Some recent articles on this topic have used the terms *fixed-form variational Bayes* (Honkela et al., 2010) and *non-conjugate variational message passing* (Knowles & Minka, 2011), to describe this modification of mean field variational Bayes. However, in this article we argue for adoption of the term *semiparametric mean field variational Bayes*.

Although we give a precise mathematical description of semiparametric mean field variational Bayes in Section 2, it simply refers to the relaxation of ordinary mean field variational Bayes in which some of the density functions in the postulated product density form are pre-specified to be particular parametric density functions, often chosen for reasons of tractability. This is a ‘halfway house’ between fully parametric approximation of the joint posterior density function of the model parameters with minimum Kullback-Leibler divergence used for parameter choice and pure mean field variational Bayes in which there is no parametric specification at all – only the product restriction. The following comments apply to our general framework:

- Semiparametric mean field variational Bayes is a modification of mean field variational Bayes that could be carried out via a message passing approach, as done by Knowles and Minka (2011), or by using the more common q -density approach used in, for example, Bishop (2006) and Ormerod and Wand (2010).
- The notion of conjugacy is not intrinsic to semiparametric mean field variational Bayes. The principle may be applied regardless of conjugacy relationships amongst the messages and/or q -densities. Therefore, the ‘non-conjugacy’ label used in recent articles for semiparametric relaxations of mean field variational Bayes is somewhat misleading.
- Contributions such as Knowles and Minka (2011) and Tan and Nott (2013) restrict attention to pre-specification of parametric families that are of exponential family form (e.g. Wainwright and Jordan, 2008). Whilst exponential family density functions have tractability advantages when used in semiparametric mean field variational Bayes, there is no intrinsic reason for only such densities to be used. In Section 5 we illustrate this point using pre-specified Skew-Normal density functions, which are not within the exponential family.
- Recent articles on non-conjugate variational message passing, such as Knowles and Minka (2011), Tan and Nott (2013) and Menictas and Wand (2015) used fixed-point iteration to minimize the Kullback-Leibler divergence or, equivalently, maximize the lower bound on the marginal log-likelihood. Theorem 1 of Knowles and Minka (2011) constitutes such an approach. However, any optimization approach could be used for obtaining the Kullback-Leibler optimal parameters such as Newton-Raphson iteration, quasi-Newton iteration, stochastic gradient descent, the Nelder-Mead simplex method and various hybrids and modifications of such methods.
- Some articles, such as the recent Challis and Barber (2013), are concerned solely with approximate inference via minimum divergence according to the pre-specification that

the posterior is within a parametric family such as Multivariate Normal with banded Cholesky covariance matrix factors. These contributions represent special cases of semiparametric mean field variational Bayes and their findings have relevance to the more general situation.

The main purposes of this article are:

- (1) Bring together the literature on semiparametric mean field variational Bayes and identify its core tenets.
- (2) Lay out and discuss numerical issues that arise in semiparametric mean field variational Bayes, which have a significant practical implications for this body of methodology.

The resulting exposition constitutes the first compendium on semiparametric mean field variational Bayes at its fullest level of generality. It can also be used as a basis for enhancements of semiparametric mean field variational Bayes methodology.

We use two examples to elucidate the general principles and numerical issues. The first, Example 1, involves a Bayesian model with a single parameter and, hence, is such that mean field approximation is not required. The simplicity of Example 1 allows a deep appreciation of the various issues with minimal notational overhead. Example 2 is the Bayesian Poisson mixed model treated in Wand (2014) and benefits from semiparametric mean field variational Bayes methodology. It demonstrates issues with high-dimensional optimization problems that are intrinsic to practical implementation.

One of the main outcomes of our numerical investigations is that fitting exponential family density functions via *natural* fixed-point iteration has some attractive properties. By ‘natural’, we mean a simple version of fixed-point iteration that arises when natural parametrizations are used. As we explain in Section 4, natural fixed-point iterations use *Riemannian* gradients to step through the parameter space, which is generally more efficient than ordinary gradients. The benefits of Riemannian gradient-based algorithms for Machine Learning problems goes back at least to Amari (1998). Such algorithms are the basis of the semiparametric mean field variational Bayes approach of Honkela et al. (2010).

In Section 2 we describe semiparametric mean field variational Bayes in full generality. A general overview of optimization strategies, pertinent to semiparametric mean field variational Bayes, is given in Section 3. The important special case of pre-specified exponential family density functions is treated in Section 4. Section 5 deals with the more difficult non-exponential family case via an illustrative example. Some closing remarks are given in Section 6.

2. General Principles

Semiparametric mean field variational Bayes is an approximate Bayesian inference method based on the principle of minimum Kullback-Leibler divergence. For arbitrary density functions p_1 and p_2 on \mathbb{R}^d ,

$$\text{KL}(p_1 \parallel p_2) \equiv \int_{\mathbb{R}^d} p_1(\mathbf{x}) \log \left\{ \frac{p_1(\mathbf{x})}{p_2(\mathbf{x})} \right\} d\mathbf{x}$$

denotes the *Kullback-Leibler divergence* of p_2 from p_1 . Note that

$$\text{KL}(p_1 \parallel p_2) \geq 0 \quad \text{for any } p_1 \text{ and } p_2. \quad (1)$$

Consider a generic Bayesian model with observed data \mathcal{D} and parameter vector (θ, ϕ) . The reason for this notational decomposition of the parameter vector will soon become apparent. Throughout this section we assume that (θ, ϕ) and \mathcal{D} are continuous random vectors with density functions $p(\theta, \phi)$ and $p(\mathcal{D})$. The situation where some components are discrete has similar treatment with summations replacing integrals. Bayesian inference for θ and ϕ is based on the posterior density function

$$p(\theta, \phi | \mathcal{D}) = \frac{p(\mathcal{D}, \theta, \phi)}{p(\mathcal{D})}.$$

The denominator, $p(\mathcal{D})$, is usually referred to as the *marginal likelihood* or the *model evidence*.

Let $q(\theta, \phi)$ be an arbitrary density function over the parameter space of (θ, ϕ) . The essence of variational approximate inference is to restrict $q(\theta, \phi)$ to some class of density functions \mathcal{Q} and then use the optimal q -density function, given by

$$q^*(\theta, \phi) = \underset{q \in \mathcal{Q}}{\text{argmin}} \text{KL} \left\{ q(\theta, \phi) \parallel p(\theta, \phi | \mathcal{D}) \right\}, \quad (2)$$

as an approximation to the posterior density function $p(\theta, \phi | \mathcal{D})$.

Simple algebraic arguments (e.g. Section 2.1 of Ormerod and Wand, 2010) lead to

$$\log p(\mathcal{D}) = \text{KL} \left\{ q(\theta, \phi) \parallel p(\theta, \phi | \mathcal{D}) \right\} + \log \underline{p}(\mathcal{D}; q) \quad (3)$$

where

$$\underline{p}(\mathcal{D}; q) \equiv \exp \left[\int \int q(\theta, \phi) \log \left\{ \frac{p(q, \theta, \phi)}{q(\theta, \phi)} \right\} d\theta d\phi \right]. \quad (4)$$

From (1) we have

$$\underline{p}(\mathcal{D}; q) \leq p(\mathcal{D}) \quad \text{for any } q(\theta, \phi)$$

showing that $\underline{p}(\mathcal{D}; q)$ is a lower bound on the marginal likelihood. The non-negativity condition (1) means that an equivalent form for the optimal q -density function is

$$q^*(\theta, \phi) = \underset{q \in \mathcal{Q}}{\text{argmax}} \underline{p}(\mathcal{D}; q). \quad (5)$$

This alternative optimization problem has the attractive interpretation of $q^*(\theta, \phi)$ being chosen to maximize a lower bound on the marginal likelihood. For the remainder of this article we work with (5) rather than (2).

Parametric variational approximate inference involves setting

$$\mathcal{Q} = \{q(\theta, \phi; \xi) : \xi \in \Xi\},$$

corresponding to a parametric family of density functions with parameter vector ξ ranging over Ξ . In this case (5) reduces to

$$q^*(\theta, \phi) = \underset{\xi \in \Xi}{\text{argmax}} \underline{p}(\mathcal{D}; q, \xi), \quad (6)$$

where $\underline{p}(\mathcal{D}; q, \xi)$ is the marginal likelihood lower bound defined by (4), but with the dependence on ξ reflected in the notation.

An early contribution of this type is Hinton and van Camp (1993) who used minimum Kullback-Leibler divergence for Gaussian approximation of posterior density functions in neural networks models. Gaussian \mathcal{Q} families have also been used by Lappalainen and Honkela (2000), Archambeau et al. (2007), Raiko et al. (2007), Nickisch and Rasmussen (2008), Honkela and Valpola (2005), Honkela et al. (2007), Honkela et al. (2008) and Opper and Archambeau (2009). The recent contribution by Challis and Barber (2013) is an in-depth coverage of Gaussian minimum Kullback-Leibler approximate inference. Salimans and Knowles (2013) devised a stochastic approximation algorithm for solving (6) when \mathcal{Q} is a parametric family of exponential family form. Gershman et al. (2012) and Zobay (2014) investigated Gaussian-mixture extensions.

In what one may label a *nonparametric* variational approximation approach, ordinary mean field variational Bayes uses restricted q -density spaces such as

$$\mathcal{Q} = \{q(\theta, \phi) : q(\theta, \phi) = q(\theta_1) \cdots q(\theta_M) q(\phi)\} \text{ for some partition } \{\theta_1, \dots, \theta_M\} \text{ of } \theta. \quad (7)$$

The word ‘nonparametric’ is justified by the fact that there is no pre-specification that the q -density, or any of its factors, belong to a particular parametric family. Restriction of $q(\theta, \phi)$ to a product density form is the only pre-specification being made. An iterative scheme for solving (5) under (7) follows from the last displayed equation given in Section 10.1.1 of Bishop (2006). The scheme is listed explicitly as Algorithm 1 of Ormerod and Wand (2010). Note that a simple adjustment that caters for (θ, ϕ) , rather than θ , is required for notation being used here. Gershman et al. (2012) also use the word ‘nonparametric’ to describe a variational approximation approach. However, their methodology is parametric in the sense of the terminology that we are using here.

We propose that the term *semiparametric mean field variational Bayes* be used for restrictions of the form:

$$\mathcal{Q} = \{q(\theta, \phi) : q(\theta, \phi) = q(\theta_1) \cdots q(\theta_M) q(\phi; \xi), \xi \in \Xi\} \quad (8)$$

where $\{q(\phi; \xi) : \xi \in \Xi\}$ is a pre-specified parametric family of density functions in ϕ . Under (8) there is no insistence on the $q(\theta_i)$ having a particular parametric form. For models possessing particular conjugacy properties the optimal q -densities, $q^*(\theta_i)$, will belong to relevant conjugate families. However, in general, the optimal q -densities of the θ_i can assume arbitrary forms; see, for example, Figure 6 of Pham et al. (2013). The quality of a variational approximation is limited by the restrictions imposed by the particular choice of \mathcal{Q} . Semiparametric mean field variational Bayes imposes a product density restriction and then a parametric constraint on one of the factors. The overall quality of the approximation is determined by the combination of these two restrictions. While the estimated nonparametric factors are optimal given the product restriction, a parametric restriction with fewer product assumptions may be more accurate.

We now turn to the practical problem of solving the optimization problem (5) when the q -density restriction is of the form (8). Appropriate strategies for solving (5) depend on the nature of $q(\phi; \xi)$ as a function of ξ and the set Ξ . Some possibilities are:

(A) Ξ is a finite set.

(B) Ξ is an open subset of \mathbb{R}^d for some $d \in \mathbb{N}$ and $q(\phi; \xi)$ is smooth function of ξ over $\xi \in \Xi$.

(C) Ξ is an open subset of \mathbb{R}^d for some $d \in \mathbb{N}$ and $q(\phi; \xi)$ is a non-smooth function of ξ over $\xi \in \Xi$.

(D) Ξ is a complicated set that does not satisfy any of the descriptions given in (A)–(C).

For the vast majority of models in common use and $q(\phi; \xi)$ families (B) applies and most of the remainder of this article is devoted to that case. However, we will first briefly deal with (A) in Section 2.1, since it aids understanding of the semiparametric extension of mean field variational Bayes. To date, we are unaware of any semiparametric mean field variational Bayes contributions where (C) or (D) apply, so these cases are left aside.

2.1 Finite Parameter Space Case

Suppose that Ξ is a finite set. Then Algorithm 1 is the natural extension of the mean field variational Bayes coordinate ascent algorithm given, for example, in Section 10.1.1 of Bishop (2006) and Algorithm 1 of Ormerod and Wand (2010). In Algorithm 1, and elsewhere, the notation $\theta \setminus \theta_i$ denotes the vector θ with the entries of θ_i excluded.

For each $\xi \in \Xi$:

Initialize: $q(\theta_1), \dots, q(\theta_M)$.

Cycle:

$$q(\theta_1) \leftarrow \frac{\exp [E_{q(\theta \setminus \theta_1), q(\phi; \xi)} \{\log p(\mathbf{y}, \theta, \phi)\}]}{\int \exp [E_{q(\theta \setminus \theta_1), q(\phi; \xi)} \{\log p(\mathbf{y}, \theta, \phi)\}] d\theta_1}$$

⋮

$$q(\theta_M) \leftarrow \frac{\exp [E_{q(\theta \setminus \theta_M), q(\phi; \xi)} \{\log p(\mathbf{y}, \theta, \phi)\}]}{\int \exp [E_{q(\theta \setminus \theta_M), q(\phi; \xi)} \{\log p(\mathbf{y}, \theta, \phi)\}] d\theta_M}$$

until the increase in $\underline{p}(\mathcal{D}; q, \xi)$ is negligible.

$$q^*(\theta_i; \xi) \leftarrow q(\theta_i), 1 \leq i \leq M \quad ; \quad \underline{p}(\mathcal{D}; q^*, \xi) \leftarrow \underline{p}(\mathcal{D}; q, \xi).$$

$$\xi^* \leftarrow \operatorname{argmax}_{\xi \in \Xi} \underline{p}(\mathcal{D}; q^*, \xi) \quad ; \quad q^*(\theta_i) \leftarrow q^*(\theta_i; \xi^*), 1 \leq i \leq M.$$

Algorithm 1: *Coordinate ascent algorithm for semiparametric mean field variational Bayes when Ξ is a finite parameter space.*

For each value of ξ in Ξ , Algorithm 1 is essentially the ordinary mean field variational Bayes iterative algorithm — but with the density function of ϕ set to the parametric density function $q(\phi; \xi)$. The optimal ξ is then found by maximizing over the approximate marginal likelihood values that are recorded for each element of Ξ .

2.2 Infinite Parameter Space Case

Algorithm 1 shows how to obtain the Kullback-Leibler-optimal $q(\theta_i)$ and $q(\phi; \xi)$ densities in the case where Ξ is finite. However, for common parametric families such as the Normal and Gamma, Ξ is infinite and the solution of (5) under (8) is more delicate. The coordinate ascent idea used to obtain the $q^*(\theta_i)$ in Algorithm 1 can still be entertained. However, it needs to be combined with an optimization scheme that searches for the optimal ξ over the infinite space Ξ .

For the remainder of this article we focus on the problem of solving (5) under restriction (B) on the q -density parameter space Ξ . We start by studying the criterion function $\underline{p}(\mathcal{G}; q; \xi)$ and special forms that it takes under the mean field restriction. The notions of entropy and factor graphs are shown to be very relevant and useful. We then introduce two running examples, Example 1 and Example 2, to illustrate the issues involved. Since Example 1 has only one parameter requiring inference, this is not a fully-fledged semiparametric mean field variational Bayes problem and the optimization problem is of the form (6). Additionally, (6) for Example 1 is a bivariate optimization problem which allows deeper probing of the numerical analytic issues. Example 2 uses the Poisson mixed model, treated in Section 5.1 of Wand (2014), as our main semiparametric mean field variational Bayes example. It is substantial enough to convey various practical issues but also has a closed form $\log \underline{p}(q; \xi)$ expression that allows purely algebraic exposition.

2.2.1 ENTROPY, FACTOR GRAPHS AND THE MARGINAL LOG-LIKELIHOOD LOWER BOUND

If \mathbf{x} is a random vector having density function p then the corresponding *entropy* is given by

$$\text{Entropy}(p) \equiv E_p\{-\log p(\mathbf{x})\}.$$

For many common distributional families, the entropy admits an algebraic expression in terms of the distribution's parameters. For example, if

$$p(\mathbf{x}; \boldsymbol{\mu}, \boldsymbol{\Sigma}) = (2\pi)^{-d/2} |\boldsymbol{\Sigma}|^{-1/2} \exp\{-\frac{1}{2}(\mathbf{x} - \boldsymbol{\mu})^T \boldsymbol{\Sigma}^{-1}(\mathbf{x} - \boldsymbol{\mu})\}$$

is the Multivariate Normal density function of dimension d with mean vector $\boldsymbol{\mu}$ and covariance matrix $\boldsymbol{\Sigma}$ then

$$\text{Entropy}(p; \boldsymbol{\mu}, \boldsymbol{\Sigma}) = \frac{1}{2} d \{1 + \log(2\pi)\} + \frac{1}{2} \log |\boldsymbol{\Sigma}|. \quad (9)$$

Note that the entropy is independent of the mean vector $\boldsymbol{\mu}$.

Another entropy expression, which arises in many Bayesian models and the example of Section 2.2.3, is that for the Inverse Gamma family of density functions. Let

$$x \sim \text{Inverse-Gamma}(\kappa, \lambda)$$

denote the random variable x having density function

$$p(x; \kappa, \lambda) = \frac{\kappa^\lambda}{\Gamma(\kappa)} x^{-\kappa-1} \exp(-\lambda/x), \quad x > 0,$$

with parameters $\kappa, \lambda > 0$. In this case

$$\text{Entropy}(p; \kappa, \lambda) = \log(\lambda) + \kappa + \log\{\Gamma(\kappa)\} - (\kappa + 1)\text{digamma}(\kappa) \quad (10)$$

where $\text{digamma}(x) \equiv (d/dx) \log \Gamma(x)$ is the digamma function.

The next relevant concept is that of a *factor graph*, which we first explain via an example. Consider the approximate Bayesian inference problem according to the semiparametric mean field variational Bayes restriction (8). Figure 1 is the factor graph for an $M = 9$ example of (8) with the joint density function of all random vectors in the model factorizing as follows:

$$p(\mathbf{x}, \boldsymbol{\theta}, \phi) = f_1(\boldsymbol{\theta}_1) f_2(\boldsymbol{\theta}_1, \boldsymbol{\theta}_2, \phi) f_3(\boldsymbol{\theta}_2) f_4(\boldsymbol{\theta}_1) f_5(\boldsymbol{\theta}_5, \phi) f_6(\boldsymbol{\theta}_2) f_7(\boldsymbol{\theta}_6, \phi) f_8(\boldsymbol{\theta}_6) \\ \times f_9(\boldsymbol{\theta}_7, \boldsymbol{\theta}_8, \boldsymbol{\theta}_9) f_{10}(\boldsymbol{\theta}_2, \boldsymbol{\theta}_3, \boldsymbol{\theta}_4) \quad (11)$$

for *factors* f_1, \dots, f_{10} . Note that some of these factors depend on the data vector \mathbf{x} , but the dependence is suppressed in the f_j notation. Specific examples are given in Sections 2.2.2 and 2.2.3. In Figure 1 the circles correspond to the components of the mean field product restriction

$$q(\phi) \prod_{i=1}^9 q(\theta_i) \quad (12)$$

and are called *stochastic nodes*. The solid squares correspond to the factors f_j , $1 \leq j \leq 10$, and are called *factor nodes*. Edges join each factor node f_j to those stochastic nodes that are included in the f_j function.

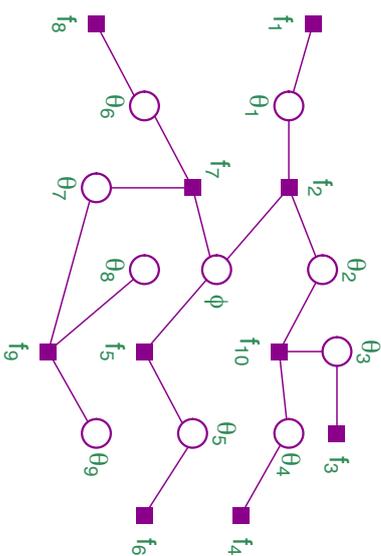

Figure 1: Factor graph corresponding to the model (11) and q -density product restriction (12).

Now consider the general case with semiparametric mean field restriction (8) and suppose that $p(\mathbf{x}, \boldsymbol{\theta}, \phi)$ has N factors f_j , $1 \leq j \leq N$. Then the marginal log-likelihood lower bound admits the following expression in terms of the components of the corresponding factor graph:

$$\log \underline{p}(\boldsymbol{\mathcal{D}}; q, \boldsymbol{\xi}) = \text{Entropy}\{q(\boldsymbol{\theta}_1; \boldsymbol{\xi})\} + \sum_{i=1}^M \text{Entropy}\{q(\boldsymbol{\theta}_i)\} + \sum_{j=1}^N E_q\{\log(f_j)\}. \quad (13)$$

The ϕ -localized component of $\log \underline{p}(\boldsymbol{\mathcal{D}}; q, \boldsymbol{\xi})$, which we denote by $\log \underline{p}(\boldsymbol{\mathcal{D}}; q, \boldsymbol{\xi})^{|\phi|}$, is

$$\log \underline{p}(\boldsymbol{\mathcal{D}}; q, \boldsymbol{\xi})^{|\phi|} \equiv \text{Entropy}\{q(\boldsymbol{\phi}; \boldsymbol{\xi})\} + \sum_{j \in \text{neighbors}(\phi)} E_q\{\log(f_j)\} \quad (14)$$

where

$$\begin{aligned} \text{neighbors}(\phi) &\equiv \{1 \leq j \leq N : f_j \text{ is a neighbor of } \phi \text{ on the factor graph}\} \\ &= \{1 \leq j \leq N : f_j \text{ involves } \phi\}. \end{aligned}$$

For the factor graph shown in Figure 1 $\text{neighbors}(\phi) = \{2, 5, 7\}$ and so have

$$\log \underline{p}(\boldsymbol{\mathcal{D}}; q, \boldsymbol{\xi})^{|\phi|} = \text{Entropy}\{q(\boldsymbol{\phi}; \boldsymbol{\xi})\} + E_q\{\log(f_2)\} + E_q\{\log(f_5)\} + E_q\{\log(f_7)\}.$$

as the ϕ -localized component of $\log \underline{p}(\boldsymbol{\mathcal{D}}; q, \boldsymbol{\xi})$.

For large Bayesian models it is prudent to maximize this localized approximate log-likelihood as part of a coordinate ascent scheme involving all q -density parameters. Such an approach, combined with the *locality property* of mean field variational Bayes (e.g. Wand et al., 2011, Section 3), allows for streamlined handling of arbitrarily large models. We formalize this approach to semiparametric mean field variational Bayes in the shape of Algorithm 2 in the upcoming Section 2.2.4. However, we first give some concrete examples of mean field variational Bayes with pre-specified parametric family q -density functions.

2.2.2 EXAMPLE 1: GUMBEL RANDOM SAMPLE

A Bayesian model for a random sample x_1, \dots, x_n from a Gumbel distribution with location parameter ϕ and unit scale is

$$p(x_1, \dots, x_n | \phi) = \prod_{i=1}^n \exp\{-(x_i - \phi) - e^{-(x_i - \phi)}\}, \quad \phi \sim N(\mu_\phi, \sigma_\phi^2). \quad (15)$$

The posterior density function of ϕ is

$$p(\phi | \mathbf{x}) = \frac{\exp\left\{n\phi - e^\phi \sum_{i=1}^n e^{-x_i} - \frac{1}{2\sigma_\phi^2}(\phi - \mu_\phi)^2\right\}}{\int_{-\infty}^{\infty} \exp\left\{n\phi' - e^{\phi'} \sum_{i=1}^n e^{-x_i} - \frac{1}{2\sigma_\phi^2}(\phi' - \mu_\phi)^2\right\} d\phi'}. \quad (16)$$

The denominator on the right-hand side of (15) is not available in closed form. This implies that numerical methods such as quadrature are required to obtain the Bayes estimate of ϕ

and corresponding credible sets. Instead we consider minimum Kullback-Leibler divergence approximation of $p(\phi | \mathbf{x})$ over a parametric pre-specified family. Let

$$\mathcal{Q} = \{q(\phi; \boldsymbol{\xi}) : \boldsymbol{\xi} \in \Xi\}$$

be such a parametric family. Then the optimal q -density is $q(\phi; \boldsymbol{\xi}^*)$ where

$$\boldsymbol{\xi}^* = \underset{\boldsymbol{\xi} \in \Xi}{\text{argmax}} \underline{p}(q; \boldsymbol{\xi}). \quad (17)$$

Figure 2 shows the factor graph of the model, with factors $p(\phi)$ and $p(\mathbf{x} | \phi)$ neighboring the stochastic node ϕ .

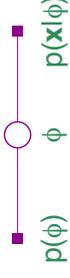

Figure 2: Factor graph for the Example 1 model.

The marginal log-likelihood lower bound is

$$\log \underline{p}(\mathbf{x}; \boldsymbol{\xi}) = \text{Entropy}\{q(\phi; \boldsymbol{\xi})\} + E_q\{\log p(\phi)\} + E_q\{\log p(\mathbf{x} | \phi)\} \quad (18)$$

and the contributions to $\log \underline{p}(\mathbf{x}; \boldsymbol{\xi})$ from the factors are

$$\begin{aligned} E_q\{\log p(\phi)\} &= -\frac{1}{2\sigma_\phi^2} \left\{ E_{q(\phi; \boldsymbol{\xi})}(\phi) - \mu_\phi \right\}^2 + \text{Var}_{q(\phi; \boldsymbol{\xi})}(\phi) \\ \text{and } E_q\{\log p(\mathbf{x} | \phi)\} &= n E_{q(\phi; \boldsymbol{\xi})}(\phi) - M_{q(\phi; \boldsymbol{\xi})}(1) \sum_{i=1}^n e^{-x_i} - n\bar{x} \end{aligned} \quad (19)$$

where $M_{q(\phi; \boldsymbol{\xi})}$ is the moment generating function corresponding to $q(\phi; \boldsymbol{\xi})$.

Now suppose that

$$\mathcal{Q} = \left\{ q(\phi; \mu_{q(\phi)}, \sigma_{q(\phi)}^2) = \frac{1}{\sqrt{2\pi\sigma_{q(\phi)}^2}} \exp\left\{ -\frac{(\phi - \mu_{q(\phi)})^2}{2\sigma_{q(\phi)}^2} \right\} : \mu_{q(\phi)} \in \mathbb{R}, \sigma_{q(\phi)}^2 > 0 \right\}$$

corresponding to the Normal family with q -density parameter vector $\boldsymbol{\xi} = (\mu_{q(\phi)}, \sigma_{q(\phi)}^2)$ and parameter space $\Xi = \mathbb{R} \times \mathbb{R}_+$ where $\mathbb{R}_+ \equiv (0, \infty)$ is the positive half-line. Then, from the entropy result (9) and the well-known expression for the moment generating function of the Normal distribution we obtain

$$\begin{aligned} \log \underline{p}(\mathbf{x}; \mu_{q(\phi)}, \sigma_{q(\phi)}^2) &= \frac{1}{2} \{1 + \log(2\pi)\} + \frac{1}{2} \log(\sigma_{q(\phi)}^2) + n \mu_{q(\phi)} \\ &\quad - \exp(\mu_{q(\phi)} + \frac{1}{2} \sigma_{q(\phi)}^2) \sum_{i=1}^n e^{-x_i} - \frac{1}{2\sigma_\phi^2} \{(\mu_{q(\phi)} - \mu_\phi)^2 + \sigma_{q(\phi)}^2\} - n\bar{x}. \end{aligned}$$

It follows that the Kullback-Leibler optimal Normal q -density function is $q(\phi; \mu_{q(\phi)}^*, \sigma_{q(\phi)}^{2*})$ where

$$\left[\begin{array}{c} \mu_{q(\phi)}^* \\ \sigma_{q(\phi)}^{2*} \end{array} \right] = \underset{\mu_{q(\phi)} \in \mathbb{R}, \sigma_{q(\phi)}^2 > 0}{\text{argmax}} \left\{ f_{\text{ExI}}^N \left(\mu_{q(\phi)}, \sigma_{q(\phi)}^2; n, \sum_{i=1}^n e^{-x_i}, \mu_\phi, \sigma_\phi^2 \right) \right\} \quad (20)$$

and

$$f_{\text{EVI}}^N(x, y; a, b, c, d) = \frac{1}{2} \log(y) + ax - b \exp(x + \frac{1}{2}y) - \frac{1}{2d} \{(x - c)^2 + y\}. \quad (20)$$

The main arguments satisfy $x \in \mathbb{R}$, $y > 0$ and the auxiliary arguments are such that $a, b, d > 0$ and $c \in \mathbb{R}$. From (19) we see that the minimum Kullback-Leibler divergence problem (16), where \mathcal{Q} is the Normal family, reduces to a non-linear bivariate optimization problem. Theory given in Challis and Barber (2013) applies to this example. For example, results given in their Section 3.2 can be used to establish that $f_{\text{EVI}}^N(x, y; a, b, c, d)$ is jointly concave in x and \sqrt{y} .

In Section 3 we study strategies for solving such problems and apply them to this example in Section 4.2.

2.2.3 EXAMPLE 2: POISSON MIXED MODEL

A single variance component *Poisson mixed model* is

$$\begin{aligned} y_i | \beta, \mathbf{u} &\stackrel{\text{ind.}}{\sim} \text{Poisson}[\exp\{(\mathbf{X}\beta + \mathbf{Z}\mathbf{u})_i\}], \quad 1 \leq i \leq n, \\ \mathbf{u} | \sigma^2 &\sim N(0, \sigma^2 \mathbf{I}_K), \quad \sigma^2 | a \sim \text{Inverse-Gamma}(\frac{1}{2}, 1/a), \\ \beta &\sim N(\mathbf{0}, \sigma_\beta^2 \mathbf{I}_p), \quad a \sim \text{Inverse-Gamma}(\frac{1}{2}, 1/A^2) \end{aligned} \quad (21)$$

where \mathbf{X} is an $n \times p$ fixed effects design matrix, \mathbf{Z} is an $n \times K$ random effects design matrix. Note that the prior on σ in (21) is the Half Cauchy distribution with scale parameter A :

$$p(\sigma) = \frac{(2/\pi)}{A[1 + (\sigma/A)^2]}, \quad \sigma > 0.$$

In (21) $\sigma\beta > 0$ and $A > 0$ are hyperparameters to be chosen by the analyst.

A mean field approximation to the joint posterior density function of the model parameters is

$$p(\beta, \mathbf{u}, \sigma^2, a | \mathbf{y}) \approx q(\beta, \mathbf{u}) q(\sigma^2) q(a). \quad (22)$$

As detailed in Appendix A.3, the optimal q -density functions satisfy

$$\begin{aligned} q^*(\sigma^2) \text{ and } q^*(a) &\text{ are both Inverse-Gamma density functions, and} \\ q^*(\beta, \mathbf{u}) &\propto \exp\{\mathbf{y}^T(\mathbf{X}\beta + \mathbf{Z}\mathbf{u}) - \mathbf{1}^T \exp(\mathbf{X}\beta + \mathbf{Z}\mathbf{u}) \\ &\quad - \frac{1}{2}\sigma_\beta^2 \|\beta\|^2 - \frac{1}{2} E_{q(\sigma^2)}(1/\sigma^2) \|\mathbf{u}\|^2\}. \end{aligned} \quad (23)$$

Since $q^*(\beta, \mathbf{u})$ is not a standard form, numerical methods are required to obtain the variational approximate Bayes estimates and credible sets. *Semiparametric* mean field variational Bayes alternatives take the form

$$p(\beta, \mathbf{u}, \sigma^2, a | \mathbf{y}) \approx q(\beta, \mathbf{u}; \xi) q(\sigma^2) q(a) \quad (24)$$

where $\{q(\beta, \mathbf{u}; \xi) : \xi \in \Xi\}$ is a pre-specified parametric family of density functions. The optimal density functions $q(\beta, \mathbf{u}; \xi^*)$, $q^*(\sigma^2)$ and $q^*(a)$ are found by minimizing

$$\text{KL}\{q(\beta, \mathbf{u}; \xi) q(\sigma^2) q(a) \parallel p(\beta, \mathbf{u}, \sigma^2, a | \mathbf{y})\}. \quad (25)$$

We now focus on solving (25).

In Appendix C of Wand (2014) it is shown that

$q^*(\sigma^2)$ is an Inverse-Gamma($\frac{1}{2}(K+1)$, $B_{q(\sigma^2)}$) density function, and $q^*(a)$ is an Inverse-Gamma(1, $B_{q(a)}$) density function

where

$$B_{q(\sigma^2)} = \frac{1}{2} \|\| E_{q(\beta, \mathbf{u}; \xi)}(\mathbf{u}) \|^2 + \text{tr}\{\text{Cov}_{q(\beta, \mathbf{u}; \xi)}(\mathbf{u})\} + \mu_{q(1/a)} \quad (26)$$

and $B_{q(a)} = \mu_{q(1/\sigma^2)} + A^{-2}$ with the definition

$$\mu_{q(1/v)} \equiv E_{q(v)}(1/v)$$

for a generic random variable v .

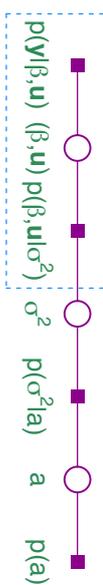

Figure 3: Factor graph for the Example 2 model with stochastic nodes corresponding the mean field restriction (24). The dashed line box contains the stochastic node (β, \mathbf{u}) and its neighboring factors.

It remains to obtain the optimal value of ξ in $q(\beta, \mathbf{u}; \xi)$. Figure 3 shows the factor graph of the current model under mean field restriction (24). The lower bound on the marginal log-likelihood, in terms of the stochastic nodes and factors of Figure 3, is

$$\begin{aligned} \log \underline{p}(\mathbf{y}; q, \xi) &= \text{Entropy}\{q(\beta, \mathbf{u}; \xi)\} + \text{Entropy}\{q(\sigma^2)\} + \text{Entropy}\{q(a)\} \\ &\quad + E_{q\{\log p(\mathbf{y}|\beta, \mathbf{u})\}} + E_q\{\log p(\beta, \mathbf{u} | \sigma^2)\} \\ &\quad + E_{q\{\log p(\sigma^2 | a)\}} + E_q\{\log p(a)\}. \end{aligned} \quad (27)$$

One could substitute (26) into the $\log \underline{p}(\mathbf{y}; q, \xi)$ expression. This resulting marginal log-likelihood lower bound would depend on the q -densities only through ξ and could then be maximized over $\xi \in \Xi$.

An alternative strategy, that scales better to larger models, is to use a coordinate ascent scheme that maximizes $\log \underline{p}(\mathbf{y}; q, \xi)^{(\beta, \mathbf{u})}$, the (β, \mathbf{u}) -localized component of $\log \underline{p}(\mathbf{y}; q, \xi)$, over $\xi \in \Xi$. The relevant factors are those neighboring (β, \mathbf{u}) in Figure 3, corresponding to the dashed line box. The quantity requiring maximization is then

$$\begin{aligned} \log \underline{p}(\mathbf{y}; q, \xi)^{(\beta, \mathbf{u})} &= \text{Entropy}\{q(\beta, \mathbf{u}; \xi)\} + E_{q\{\log p(\mathbf{y}|\beta, \mathbf{u})\}} + E_q\{\log p(\beta, \mathbf{u} | \sigma^2)\} \\ &= \text{Entropy}\{q(\beta, \mathbf{u}; \xi)\} + \mathbf{y}^T \{\mathbf{X} E_{q(\beta, \mathbf{u}; \xi)}(\beta) + \mathbf{Z} E_{q(\beta, \mathbf{u}; \xi)}(\mathbf{u})\} \\ &\quad - \mathbf{1}^T E_{q(\beta, \mathbf{u}; \xi)}\{\exp(\mathbf{X}\beta + \mathbf{Z}\mathbf{u})\} \\ &\quad - \frac{1}{2\sigma_\beta^2} \|\| E_{q(\beta, \mathbf{u}; \xi)}(\beta) \|^2 + \text{tr}\{\text{Cov}_{q(\beta, \mathbf{u}; \xi)}(\beta)\} \\ &\quad - \frac{1}{2} \mu_{q(1/\sigma^2)} \|\| E_{q(\beta, \mathbf{u}; \xi)}(\mathbf{u}) \|^2 + \text{tr}\{\text{Cov}_{q(\beta, \mathbf{u}; \xi)}(\mathbf{u})\} + \text{const} \end{aligned} \quad (28)$$

where ‘const’ denotes terms not depending on ξ .

Next, suppose that \mathcal{Q} corresponds to the family of Multivariate Normal density functions in (β, \mathbf{u}) :

$$\begin{aligned} q(\beta, \mathbf{u}; \boldsymbol{\mu}_{q(\beta, \mathbf{u})}, \boldsymbol{\Sigma}_{q(\beta, \mathbf{u})}) &= (2\pi)^{-(p+K)/2} |\boldsymbol{\Sigma}_{q(\beta, \mathbf{u})}|^{-1/2} \\ &\times \exp \left\{ -\frac{1}{2} \left(\begin{bmatrix} \beta \\ \mathbf{u} \end{bmatrix} - \boldsymbol{\mu}_{q(\beta, \mathbf{u})} \right)^T \boldsymbol{\Sigma}_{q(\beta, \mathbf{u})}^{-1} \left(\begin{bmatrix} \beta \\ \mathbf{u} \end{bmatrix} - \boldsymbol{\mu}_{q(\beta, \mathbf{u})} \right) \right\}. \end{aligned} \quad (29)$$

Then the (β, \mathbf{u}) -localized approximate marginal log-likelihood reduces to

$$\begin{aligned} \log \underline{p}(\mathbf{y}; q, \boldsymbol{\mu}_{q(\beta, \mathbf{u})}, \boldsymbol{\Sigma}_{q(\beta, \mathbf{u})}) &= \frac{1}{2} \log |\boldsymbol{\Sigma}_{q(\beta, \mathbf{u})}| + \mathbf{y}^T \mathbf{C} \boldsymbol{\mu}_{q(\beta, \mathbf{u})} \\ &- \mathbf{1}^T \exp \left\{ \mathbf{C} \boldsymbol{\mu}_{q(\beta)} + \frac{1}{2} \text{diagonal}(\mathbf{C} \boldsymbol{\Sigma}_{q(\beta, \mathbf{u})} \mathbf{C}^T) \right\} \\ &- \frac{1}{2\sigma_\beta^2} \left\{ \|\boldsymbol{\mu}_{q(\beta)}\|^2 + \text{tr}(\boldsymbol{\Sigma}_{q(\beta)}) \right\} \\ &- \frac{1}{2} \mu_{q(1/\sigma^2)} \left\{ \|\boldsymbol{\mu}_{q(\mathbf{u})}\|^2 + \text{tr}(\boldsymbol{\Sigma}_{q(\mathbf{u})}) \right\} + \text{const} \end{aligned}$$

where $\mathbf{C} \equiv [\mathbf{X} \ \mathbf{Z}]$, $\text{diagonal}(\mathbf{M})$ is the vector containing the diagonal entries of the square matrix \mathbf{M} , and $\boldsymbol{\mu}_{q(\beta)}$ is the sub-vector of $\boldsymbol{\mu}_{q(\beta, \mathbf{u})}$ corresponding to β . Analogous definitions apply to $\boldsymbol{\mu}_{q(\mathbf{u})}$, $\boldsymbol{\Sigma}_{q(\beta)}$ and $\boldsymbol{\Sigma}_{q(\mathbf{u})}$. Appendix A.3 provides derivational details for (29).

For this example, the full coordinate ascent scheme has updates as follows:

perform one or more updates of $(\boldsymbol{\mu}_{q(\beta, \mathbf{u})}, \boldsymbol{\Sigma}_{q(\beta, \mathbf{u})})$ within an iterative scheme for the optimization problem:

$$\underset{\boldsymbol{\mu}'_{q(\beta, \mathbf{u})}, \boldsymbol{\Sigma}'_{q(\beta, \mathbf{u})}}{\text{argmax}} \left\{ \log \underline{p}(\mathbf{y}; q, \boldsymbol{\mu}'_{q(\beta, \mathbf{u})}, \boldsymbol{\Sigma}'_{q(\beta, \mathbf{u})})^{|\beta, \mathbf{u}|} \right\}$$

$$B_{q(\alpha)} \leftarrow \mu_{q(1/\sigma^2)} + A^{-2} \quad ; \quad \mu_{q(1/\alpha)} \leftarrow 1/B_{q(\alpha)}$$

$$B_{q(\sigma^2)} \leftarrow \frac{1}{2} \left\{ \|\boldsymbol{\mu}_{q(\mathbf{u})}\|^2 + \text{tr}(\boldsymbol{\Sigma}_{q(\mathbf{u})}) \right\} + \mu_{q(1/\alpha)}$$

$$\mu_{q(1/\sigma^2)} \leftarrow \frac{1}{2} (K + 1) / B_{q(\sigma^2)}.$$

For now, we deliberately leave the form of the $(\boldsymbol{\mu}_{q(\beta, \mathbf{u})}, \boldsymbol{\Sigma}_{q(\beta, \mathbf{u})})$ maximization strategy unspecified. We also allow for one or more updates of an iterative scheme aimed at maximizing $\log \underline{p}(\mathbf{y}; q, \boldsymbol{\mu}'_{q(\beta, \mathbf{u})}, \boldsymbol{\Sigma}'_{q(\beta, \mathbf{u})})^{|\beta, \mathbf{u}|}$, rather than iterating to convergence at every iteration of the full coordinate ascent scheme. Section 3 describes various optimization strategies that could be used for updating $(\boldsymbol{\mu}_{q(\beta, \mathbf{u})}, \boldsymbol{\Sigma}_{q(\beta, \mathbf{u})})$.

Negligible absolute change in $\log \underline{p}(\mathbf{y}; q, \boldsymbol{\mu}_{q(\beta, \mathbf{u})}, \boldsymbol{\Sigma}_{q(\beta, \mathbf{u})})$ can be used as a stopping criterion for the iterations and an algebraic expression for this quantity is given in Appendix A.3.

We return to Example 2 in Section 4.3.

2.2.4 GENERAL SEMIPARAMETRIC MEAN FIELD VARIATIONAL BAYES ALGORITHM

We now treat semiparametric mean field variational Bayes in general, with the set-up laid out in Section 2 and restriction (8). Let $\log \underline{p}(\mathcal{D}; q, \xi)^{|\phi|}$ be defined with respect to the

factor graph of $p(\mathbf{x}, \phi, \boldsymbol{\theta})$ with stochastic nodes $\boldsymbol{\theta}_1, \dots, \boldsymbol{\theta}_M$ and ϕ . Algorithm 2 is a general coordinate ascent algorithm for approximate inference that builds on the standard mean field variational Bayes algorithm.

Initialize: $q(\boldsymbol{\theta}_2), \dots, q(\boldsymbol{\theta}_M)$.

Cycle:

perform one or more updates of ξ within an iterative scheme for the optimization problem:

$$\begin{aligned} &\underset{\xi \in \Xi}{\text{argmax}} \left\{ \log \underline{p}(\mathcal{D}; q, \xi)^{|\phi|} \right\} \\ q(\boldsymbol{\theta}_1) &\leftarrow \frac{\exp \left[E_{q(\boldsymbol{\theta} \setminus \boldsymbol{\theta}_1)} q(\phi; \xi) \left\{ \log p(\mathbf{y}, \boldsymbol{\theta}, \phi) \right\} \right]}{\int \exp \left[E_{q(\boldsymbol{\theta} \setminus \boldsymbol{\theta}_1)} q(\phi; \xi) \left\{ \log p(\mathbf{y}, \boldsymbol{\theta}, \phi) \right\} \right] d\boldsymbol{\theta}_1} \\ &\quad \vdots \\ q(\boldsymbol{\theta}_M) &\leftarrow \frac{\exp \left[E_{q(\boldsymbol{\theta} \setminus \boldsymbol{\theta}_M)} q(\phi; \xi) \left\{ \log p(\mathbf{y}, \boldsymbol{\theta}, \phi) \right\} \right]}{\int \exp \left[E_{q(\boldsymbol{\theta} \setminus \boldsymbol{\theta}_M)} q(\phi; \xi) \left\{ \log p(\mathbf{y}, \boldsymbol{\theta}, \phi) \right\} \right] d\boldsymbol{\theta}_M} \end{aligned}$$

until the absolute change in $\log \underline{p}(\mathcal{D}; q, \xi)$ is negligible.

Algorithm 2: *The general semiparametric mean field variational Bayes algorithm for restriction (8) with $\log \underline{p}(\mathcal{D}; q, \xi)^{|\phi|}$ defined with respect to factor graph of $p(\mathbf{x}, \boldsymbol{\theta}, \phi)$ with stochastic nodes $\boldsymbol{\theta}_1, \dots, \boldsymbol{\theta}_M$ and ϕ .*

For each of these approaches, there remains the practical problem of devising an optimization scheme for $\log \underline{p}(\mathcal{D}; q, \xi)^{|\phi|}$ and ensuring that it leads to the optimal parameters being chosen. Section 3 deals with this problem.

2.3 Relationship to Existing Literature

The general principle of semiparametric mean field variational Bayes that we have laid out in this section is not brand new and, in fact, instances of this principle have made appearances in the literature since the late 1990s — although they are few in number. We now briefly survey articles known to us that have a semiparametric mean field variational Bayes component. As we will see, the terminology varies quite considerably.

Barber and Bishop (1997) uses the terms *ensemble learning* and *hyperparameter adaptation* for what essentially is a semiparametric mean field variational Bayes approach to fitting multi-layer neural networks. They pre-specify Multivariate Normal distributions for the coefficient vector but, in their Section 2.1, allow covariance matrix parameters to be unspecified except for mean field assumptions. However, they do not include numerical details for minimizing Kullback-Leibler divergence over the Multivariate Normal parameters.

Honkela et al. (2010) adopt the phrase *fixed-form variational Bayes* in what is a quite general approach to semiparametric mean field variational Bayes as summarized in their Algorithm 1. Optimization of the pre-specified parametric component parameters is achieved using the *nonlinear conjugate gradient method*, which we describe in Section 3.2. However, Honkela et al. (2010) work with *Riemannian* gradients which, they argue, are more efficient than Euclidean gradients.

In Knowles and Minka (2011) the focus is incorporation of pre-specified exponential family distributions whilst preserving the message passing aspect of a modular approach to mean field variational Bayes, known as *variational message passing*. They arrive at an extension which they label *non-conjugate variational message passing*. The exponential family distribution parameters are chosen via fixed-point iteration, which we describe in detail in Section 3.1.

Tan and Nott (2013) take a semiparametric mean field variational Bayes approach to approximate inference in Bayesian generalized linear mixed models for grouped data. They use pre-specified Multivariate Normal density functions for the random effects of each group with mean field product restrictions and achieve good approximation accuracy via so-called partially noncentered parameterizations.

In the case of pre-specified Multivariate Normal density functions, Wand (2014) obtains an explicit form for the fixed-point iteration scheme of Knowles and Minka (2011) and illustrated its use for the Poisson mixed model described in Section 2.2.3. In Luts and Wand (2015) and Menzies and Wand (2015), semiparametric mean field variational Bayes with Multivariate Normal pre-specification is applied, respectively, to count response semiparametric regression and heteroscedastic semiparametric regression.

2.4 Advantages and Limitations of Algorithm 2

As just described in Section 2.3, Algorithm 2 is a very useful generalization of the ordinary mean field variational Bayes algorithm and allows for tractable handling of a wider class of models. For example, the heteroscedastic nonparametric regression model of Menzies and Wand (2015) is such that ordinary mean field variational Bayes is numerically challenging if one uses the same product restrictions as used in homoscedastic nonparametric regression. The semiparametric mean field variational Bayes extension, based on Multivariate Normal pre-specification of basis function coefficients, leads to an iterative scheme with closed form updates. Simulation studies show very good accuracy compared with Markov chain Monte Carlo-based inference. However Algorithm 2 is not guaranteed to converge and, when it does converge, may result in mediocre approximate Bayesian inference. We close this section by briefly discussing such limitations of Algorithm 2.

In cases where a generic iterative procedure is used to solve $\operatorname{argmax}_{\xi \in \Xi} \{\log p(\mathcal{D}; \eta, \xi')\}$ there is no guarantee that the lower bound is increased in a particular iteration or of convergence in general. As a consequence, the convergence guarantees enjoyed by ordinary mean field variational Bayes algorithms are not shared by their semiparametric extension. As we demonstrate in Section 4.2, convergence does not occur for particular numerical optimization strategies.

Lastly, there is the limitation imposed by the mean field restriction. Even though mean field variational Bayes can lead to very accurate approximate inference, there are

circumstances where its accuracy is quite poor. Some examples, with explanations for the inaccuracy, are given in Wang and Titterton (2005) and Neville et al. (2014). Semiparametric mean field variational Bayes shares this limitation since parametric pre-specification imposes a degradation in accuracy compared with ordinary mean field variational Bayes.

3. Numerical Optimization Strategies

Ordinary mean field variational Bayes, parameter optimization is achieved using a convex optimization algorithm that converges under reasonable assumptions (e.g. Uentberger and Ye, 2008). In the semiparametric extension there is no such convex optimization theory and general numerical optimization has to be called upon to optimize the parameters in the pre-specified parametric density function.

Numerical optimization is a major area of mathematical study with an enormous literature. Recent summaries are given in, for example, Givens and Hoeting (2005) and Ackleh et al. (2010), with the former being geared towards optimization problems arising in Statistics. The choice of optimization method typically is driven by factors such as the smoothness of the function requiring optimization and availability of expressions for low-order derivatives. Optimization methods with derivative information invariably take the form of iterative schemes. Semiparametric mean field variational Bayes often has the luxuries of smoothness and derivative expressions. It is also beneficial to have relatively simple iterative updates given the overarching goal of fast approximate inference. Therefore, we gear our summary of numerical optimization strategies towards simple derivative-based schemes. This is in keeping with the existing literature on parametric and semiparametric variational inference.

Let $f : D \subseteq \mathbb{R}^d \rightarrow \mathbb{R}$ be a function and consider the problem of finding its maximum or minimum value over a set $D_0 \subseteq D$. If all partial derivatives of f exist then a necessary condition for a maximum or minimum in the interior of D_0 is the *stationary point condition*

$$\frac{\partial}{\partial x_j} f(\mathbf{x}) = 0, \quad 1 \leq j \leq d. \quad (30)$$

This converts the optimization problem to a multivariate root-finding problem. However (30) is not a sufficient condition for global optima since local optima and saddle points of f inside D_0 also satisfy (30). Properties of f , such as regions where it is concave or convex, can aid the determination of global optima.

Throughout this section we make use of the derivative matrix and Hessian matrix notation defined in Appendix A.2.

3.1 Fixed-Point Iteration

Assuming that the derivative vector $\mathbf{D}_x f(\mathbf{x})$ (defined formally in Appendix A.1) exists, the stationary point condition (30) can be written

$$\mathbf{D}_x f(\mathbf{x})^T = \mathbf{0} \quad (31)$$

where $\mathbf{0}$ is the vector of zeroes. Fixed-point iteration aims to find points that satisfy (31), which we denote generically by \mathbf{x}^* . Such points are then candidates as maxima or minima

of f . Firstly, (31) is rewritten in the form

$$\mathbf{x} = \mathbf{g}(\mathbf{x}) \quad (32)$$

for some function $\mathbf{g} : D \subseteq \mathbb{R}^d \rightarrow \mathbb{R}^d$. Given this \mathbf{g} , fixed-point iteration simply involves repeated evaluation of \mathbf{g} , as given in Algorithm 3

Initialize: $\mathbf{x} \leftarrow \mathbf{x}_{\text{init}}$ for some $\mathbf{x}_{\text{init}} \in D$.

Cycle:

$$\mathbf{x} \leftarrow \mathbf{g}(\mathbf{x})$$

until convergence.

Algorithm 3: *The fixed-point iteration algorithm in generic form.*

Note, however, the following issues regarding fixed point iteration:

- For a given stationary point condition (31) there are numerous functions \mathbf{g} for which (32) holds. In other words, there are many possible fixed point algorithms available to solve (31).
- Once \mathbf{g} and \mathbf{x}_{init} are chosen then the above algorithm is *not necessarily guaranteed* to converge to a stationary point \mathbf{x}^* . There is a large literature on convergence of fixed-point iterative algorithms and good references on the topic include Section 8.1 of Ortega (1990) and Section 8.2 of Ackleh et al. (2010). For example Theorem 8.1.7 of Ortega (1990) asserts that convergence of Algorithm 3 is guaranteed when \mathbf{x}_{init} is sufficiently close to \mathbf{x}^* , the components of \mathbf{g} are differentiable at \mathbf{x}^* and

$$\rho(D_{\mathbf{x}}\mathbf{g}(\mathbf{x}^*)) < 1.$$

Here $\rho(\mathbf{A})$ denotes the *spectral radius* of the square matrix \mathbf{A} , defined to be

$$\rho(\mathbf{A}) \equiv \text{maximum of the absolute values of the eigenvalues of } \mathbf{A}.$$

Theorem 8.4 of Ackleh et al. (2010) provides a similar condition in terms of the *spectral norm* $\|D_{\mathbf{x}}\mathbf{g}(\mathbf{x}^*)\|_{\text{spec}}$ where

$$\|\mathbf{A}\|_{\text{spec}} \equiv \sqrt{\text{largest eigenvalue of } \mathbf{A}^T \mathbf{A}}.$$

- There are also theorems that guarantee convergence of Algorithm 3 for particular choices of \mathbf{x}_{init} . If D_0 is a closed convex subset of D such that $\mathbf{g} : D_0 \rightarrow D_0$, the entries of $D_{\mathbf{x}}\mathbf{g}(\mathbf{x})$ are each bounded and continuous on D_0 and

$$\sup_{\mathbf{x} \in D_0} \|D_{\mathbf{x}}\mathbf{g}(\mathbf{x})\|_{\text{spec}} \leq \alpha < 1$$

then Algorithm 3 will converge from any initial point $\mathbf{x}_{\text{init}} \in D_0$ (Theorems 8.2 and 8.3 of Ackleh et al., 2010).

Despite this elegant theory, it is difficult to apply in practice with regards to choosing \mathbf{g} and \mathbf{x}_{init} so that Algorithm 3 converges. This is exemplified in Section 4.2 when we return to the Example 1 optimization problem. We also note that $\|D_{\mathbf{x}}\mathbf{g}(\mathbf{x})\|_{\text{spec}} < 1$ near \mathbf{x}^* is a *sufficient* but not *necessary* condition for convergence of fixed point iteration. Nevertheless, the function

$$\rho(D_{\mathbf{x}}\mathbf{g}(\mathbf{x}))$$

is a useful convergence diagnostic for fixed-point iteration. For instance, if $\rho(D_{\mathbf{x}}\mathbf{g}(\mathbf{x})) \gg 1$ during the iterations then this would indicate convergence problems and the possibility of non-existence of a fixed point \mathbf{x}^* .

Various adjustments to fixed-point iteration have been proposed to enhance convergence. For example, in the context of semiparametric mean field variational Bayes, Section 7 of Minka & Knowles (2011) describes a *damping* adjustment.

3.1.1 NEWTON-RAPHSON ITERATION

Newton-Raphson iteration is a special case of fixed-point iteration for optimizing \mathbf{f} with the \mathbf{g} function taking the form

$$\mathbf{g}_{\text{NR}}(\mathbf{x}) = \mathbf{x} - \{H_{\mathbf{x}}\mathbf{f}(\mathbf{x})\}^{-1}D_{\mathbf{x}}\mathbf{f}(\mathbf{x})^T \quad (33)$$

where $H_{\mathbf{x}}\mathbf{f}(\mathbf{x})$ denotes the Hessian matrix of $\mathbf{f}(\mathbf{x})$ as formally defined in Appendix A.1. Assuming existence of $\{H_{\mathbf{x}}\mathbf{f}(\mathbf{x})\}^{-1}$, it is easily shown that $\mathbf{x} = \mathbf{g}_{\text{NR}}(\mathbf{x})$ if and only if $D_{\mathbf{x}}\mathbf{f}(\mathbf{x})^T = \mathbf{0}$. This leads to Algorithm 4, which conveys the generic form of Newton-Raphson iteration.

Initialize: $\mathbf{x} \leftarrow \mathbf{x}_{\text{init}}$ for some $\mathbf{x}_{\text{init}} \in D$.

Cycle:

$$\mathbf{x} \leftarrow \mathbf{x} - \{H_{\mathbf{x}}\mathbf{f}(\mathbf{x})\}^{-1}D_{\mathbf{x}}\mathbf{f}(\mathbf{x})^T$$

until convergence.

Algorithm 4: *The Newton-Raphson algorithm in generic form.*

Some pertinent features of Algorithm 4 are:

- The function \mathbf{g}_{NR} in (33) has the property

$$\rho(D_{\mathbf{x}}\mathbf{g}_{\text{NR}}(\mathbf{x}^*)) = 0 \quad (34)$$

for stationary points \mathbf{x}^* . A proof is given in Appendix A.4. Therefore, via Theorem 8.4 of Ackleh et al. (2010), convergence to \mathbf{x}^* is guaranteed from a sufficiently close \mathbf{x}_{init} .

- If \mathbf{x}_{init} is such that Algorithm 4 is convergent to \mathbf{x}^* then, under certain regularity conditions, convergence is *quadratic*, in that the number of significant figures doubles on each iteration.

- Locating \mathbf{x}_{init} values sufficiently close to \mathbf{x}^* for convergence to occur can be difficult in practice and it is common to combine Newton-Raphson iteration with more robust optimization strategies, such as the Nelder-Mead simplex method.
- A disadvantage of Newton-Raphson iteration compared with other fixed-point iterative schemes is the requirement for second order partial derivatives, corresponding to the entries of the Hessian matrix $\mathbf{H}_x f(\mathbf{x})$. A feeling for the type of additional calculus needed is given in Appendix A.7.
- A variant of Newton-Raphson optimization known as *damped* Newton-Raphson employs line searches (or backtracking) in order to achieve much improved convergence behavior. See, e.g., Section 9.5.2 of Boyd and Vandenberghe (2004).

3.2 Nonlinear Conjugate Gradient Method

The *nonlinear conjugate gradient method* is based on the *conjugate gradient method*, an established iterative approach to solving large systems of linear equations (Hestenes and Stiefel, 1952). The former arises from applying the latter to the linear system that arises from optimization of a multivariate quadratic function. Details of the nonlinear conjugate gradient method are given in Section 10.8 of Press et al. (2007). Algorithm 5 lists the *Polak-Ribière* version of the nonlinear conjugate gradient method for *maximization* of f over D . Since minimization of f is equivalent to maximization of $-f$ it is straightforward to adapt Algorithm 5 to the minimization problem. We choose the Polak-Ribière form here, but another one is the *Fletcher-Reeves* form given by $\beta \leftarrow (\mathbf{v}_{\text{cur}}^T \mathbf{v}_{\text{arr}}) / (\mathbf{v}_{\text{prev}}^T \mathbf{v}_{\text{prev}})$.

Initialize: $\mathbf{x} \leftarrow \mathbf{x}_{\text{init}}$ for some $\mathbf{x}_{\text{init}} \in D$.

$$\mathbf{v}_{\text{prev}} \leftarrow \mathbf{D}_x f(\mathbf{x})^T ; \alpha \leftarrow \underset{\alpha > 0}{\operatorname{argmax}} f(\mathbf{x} + \alpha \mathbf{v}_{\text{prev}})$$

$$\mathbf{x} \leftarrow \mathbf{x} + \alpha \mathbf{v}_{\text{prev}} ; \mathbf{s} \leftarrow \mathbf{v}_{\text{prev}}$$

Cycle:

$$\mathbf{v}_{\text{cur}} \leftarrow \mathbf{D}_x f(\mathbf{x})^T ; \beta \leftarrow \mathbf{v}_{\text{cur}}^T (\mathbf{v}_{\text{cur}} - \mathbf{v}_{\text{prev}}) / (\mathbf{v}_{\text{prev}}^T \mathbf{v}_{\text{prev}})$$

$$\mathbf{s} \leftarrow \beta \mathbf{s} + \mathbf{v}_{\text{cur}} ; \alpha \leftarrow \underset{\alpha > 0}{\operatorname{argmax}} f(\mathbf{x} + \alpha \mathbf{s})$$

$$\mathbf{x} \leftarrow \mathbf{x} + \alpha \mathbf{s} ; \mathbf{v}_{\text{prev}} \leftarrow \mathbf{v}_{\text{cur}}$$

until convergence.

Algorithm 5: *The nonlinear conjugate gradient method for maximization of the function f with the Polak-Ribière form of the β parameter.*

A key aspect of the nonlinear conjugate gradient method is that, on each iteration, it takes a step in the direction $\mathbf{D}f(\mathbf{x})^T$ from the current position at \mathbf{x} . This is the steepest instantaneous direction on the f surface. The parameter denoted by β has several alter-

native forms. Nonlinear conjugate gradient methods have been shown to have good global convergence properties (Dai and Yuan, 1999).

3.3 Other Optimization Strategies

Other popular optimization strategies include *ascent* (or *descent*) *algorithms* (e.g. Boyd and Vandenberghe, 2004, Section 9.3), *quasi-Newton methods* (e.g. Givens and Hoeting, 2005, Section 2.2.2.3), the *Gauss-Newton method* (e.g. Givens and Hoeting, 2005, Section 2.2.3), *stochastic gradient descent* (e.g. Botton, 2004) and the *Nelder-Mead simplex method* (Nelder and Mead, 1965). The last of these has the attraction of not requiring derivatives of f and is generally more robust than derivative-based methods.

3.4 Application to Semiparametric Mean Field Variational Bayes

We now focus on the optimization component of Algorithm 2

$$\underset{\xi \in \Xi}{\operatorname{argmax}} \left\{ \log \underline{p}(\mathcal{Q}; q, \xi)^{|\phi|} \right\} \quad (35)$$

and discuss ways in which numerical optimization strategies described in Sections 3.1–3.3 are applicable.

The stationary condition for the maximizer in (35) is

$$\mathbf{D}_\xi \log \underline{p}(\mathcal{Q}; q, \xi)^{|\phi|} = \mathbf{0}$$

and this may be manipulated in any of a number of ways to produce an equation of the form $\xi = \mathbf{g}(\xi)$ for some function \mathbf{g} . Fixed-point iteration Algorithm 3 can then be entertained but, as discussed in Section 3.1, convergence is not guaranteed for arbitrary \mathbf{g} . We study this issue in the context of Examples 1 and 2 in Sections 4.2 and 4.3.

Newton-Raphson iteration involves iterative updates:

$$\xi \leftarrow \xi - \{\mathbf{H}_\xi \log \underline{p}(\mathcal{Q}; q, \xi)^{|\phi|}\}^{-1} \mathbf{D}_\xi \log \underline{p}(\mathcal{Q}; q, \xi)^{|\phi|}$$

and so is a candidate for insertion into Algorithm 2 for updating the pre-specified parametric q -density parameters.

Another alternative is, of course, updating ξ according to one or more iterations of the nonlinear conjugate gradient method given by Algorithm 5, or any other iterative optimization scheme. However, convergence needs to be monitored. For high-dimensional ξ , speed of convergence may be also be an important factor. Next we discuss an adjustment aimed at improving the convergence speed of gradient-based algorithms.

3.4.1 RIEMANNIAN GEOMETRY ADJUSTMENT

As explained in, for example, Section 6.2 of Murray and Rice (1993) the density function family $\{q(\phi; \xi) : \xi \in \Xi\}$ can be viewed as a *submanifold* of a *Riemannian manifold*. Riemannian manifolds do not necessarily have a *flat* Euclidean geometry. For example, the Riemannian manifold corresponding to the Univariate Normal family:

$$\left\{ \frac{1}{\sqrt{2\pi\sigma_q^2(\phi)}} \exp \left\{ -\frac{(\phi - \mu_{q(\phi)})^2}{2\sigma_q^2(\phi)} \right\} : \mu_{q(\phi)} \in \mathbb{R}, \sigma_q^2(\phi) > 0 \right\} \quad (36)$$

has *hyperbolic geometry* (Murray and Rice, 1993, Example 6.6.2) which is *curved*. Therefore notions such as closeness of two members of (36) and steepness of gradients when searching over the parameter space $\Xi = \mathbb{R} \times \mathbb{R}_+$ are not properly captured by the Euclidean geometry notions of distance and slope. Adjustments for the Riemannian geometry of the family often improve convergence of optimization algorithms for solving problems such as (35). More detailed discussion on this issue is given in Section 2.2 of Honkela et al. (2010) and Section 2.3 of Hoffman et al. (2013).

Consider an optimization method that uses gradients of the form

$$D_{\xi} \log \underline{p}(\mathcal{D}; q, \xi)^{|\phi|^T}$$

to find the direction of steepest descent of the objective function $\log \underline{p}(\mathcal{D}; q, \xi)^{|\phi|}$. The Riemannian geometry adjustment is to instead use

$$[-E\{\mathbf{H}_{\xi} \log q(\phi; \xi)\}]^{-1} D_{\xi} \log \underline{p}(\mathcal{D}; q, \xi)^{|\phi|^T} \quad (37)$$

where the premultiplying matrix is the inverse *Fisher information* of $q(\phi; \xi)$. In the Machine Learning literature (e.g. Amari, 1998) (37) is often labeled the *natural* or *Riemannian gradient* of $\log \underline{p}(\mathcal{D}; q, \xi)^{|\phi|}$ with respect to ξ and the corresponding geometry is called *information geometry*. If $q(\phi; \xi)$ corresponds to the Univariate Normal family (36) then the Fisher information matrix is $\text{diag}(\sigma_{q(\phi)}^{-2}, \frac{1}{2}\sigma_{q(\phi)}^{-4})$. Therefore, from (37), the natural gradient of $\log \underline{p}(q; \mu_{q(\phi)}, \sigma_{q(\phi)}^2)^{|\phi|}$ with respect to $(\mu_{q(\phi)}, \sigma_{q(\phi)}^2)$ is given by

$$\begin{bmatrix} \sigma_{q(\phi)}^2 & \frac{\partial \underline{p}(q; \mu_{q(\phi)}, \sigma_{q(\phi)}^2)^{|\phi|}}{\partial \mu_{q(\phi)}} \\ 2\sigma_{q(\phi)}^4 & \frac{\partial \underline{p}(q; \mu_{q(\phi)}, \sigma_{q(\phi)}^2)^{|\phi|}}{\partial \sigma_{q(\phi)}^2} \end{bmatrix}^T. \quad (38)$$

Honkela et al. (2010) is a major contribution to semiparametric mean field variational Bayes methodology and their Algorithm 1 uses the nonlinear conjugate gradient method (Algorithm 5) with natural gradients rather than ordinary gradients. Via both simple examples and numerical studies, they make a compelling case for the use of natural gradients for optimization of the parameters of the pre-specified parametric q -density function.

3.5 Summary of Semiparametric Mean Field Variational Bayes Ramifications

In this section we have discussed several iterative numerical optimization strategies. Any of these are candidates for the updating ξ in the Algorithm 2 cycle. Special mention has been given to the well-known Newton-Raphson iteration since it can achieve very rapid convergence and the nonlinear conjugate gradient method which has been shown to be effective in semiparametric mean field variational Bayes contexts when the Riemannian geometry adjustment of Section 3.4.1 is employed (Honkela et al., 2010).

General fixed-point iteration has been discussed in detail. It has the advantage of yielding particularly simple iterative updates for ξ in Algorithm 2. Established theory shows that the spectral radius of the derivative matrix of the fixed-point function can be

used to assess the quality of the scheme. In Section 4 we will explain how a particular fixed-point iteration scheme, which we call *natural* fixed-point iteration, has attractive properties when $q(\cdot; \xi)$ is an exponential family density function. We will also revisit Examples 1 and 2 in Section 4 and make some comparisons among various numerical optimization strategies. Natural fixed-point iteration is seen to perform particularly well.

4. Exponential Family Special Case

We now focus on the important special case where the parametric density function family $\{q(\phi; \xi) : \xi \in \Xi\}$ can be expressed in exponential family form:

$$q(\phi; \eta) = \exp\{\mathbf{T}(\phi)^T \eta - A(\eta)\} h(\phi), \quad \eta \in H, \quad (39)$$

where η is a one-to-one transformation of ξ and H is the image of Ξ under this transformation. In (39) $A(\eta)$ is called the *log-partition function* and $h(\phi)$ is called the *base measure*. For example, the Univariate Normal density function family used in Example 1:

$$q(\phi; \mu_{q(\phi)}, \sigma_{q(\phi)}^2) = \frac{1}{\sqrt{2\pi\sigma_{q(\phi)}^2}} \exp\left\{-\frac{(\phi - \mu_{q(\phi)})^2}{2\sigma_{q(\phi)}^2}\right\}, \quad \mu_{q(\phi)} \in \mathbb{R}, \sigma_{q(\phi)}^2 > 0,$$

can be expressed as (39) with

$$\mathbf{T}(\phi) = \begin{bmatrix} \phi \\ \phi^2 \end{bmatrix}, \quad \eta \equiv \begin{bmatrix} \eta_1 \\ \eta_2 \end{bmatrix} = \begin{bmatrix} \mu_{q(\phi)}/\sigma_{q(\phi)}^2 \\ -1/(2\sigma_{q(\phi)}^2) \end{bmatrix}, \quad A(\eta) = -\frac{1}{4}\eta_1^2/\eta_2 - \frac{1}{2}\log(-2\eta_2)$$

and $h(\phi) = (2\pi)^{-1/2}$. The natural parameter space is $H = \{(\eta_1, \eta_2) : \eta_1 \in \mathbb{R}, \eta_2 < 0\}$. Even though semiparametric mean field variational Bayes can involve pre-specification of an arbitrary parametric family, virtually all methodology and examples in the existing literature involves pre-specification within an exponential family. Exponential family distributions also play an important role in the theory of mean field variational Bayes (e.g. Sato, 2001; Beal and Ghahramani, 2006; Wainwright and Jordan, 2008).

Now consider the general factor graph set-up described in Section 2.2.1 with the approximate marginal log-likelihood $\log \underline{p}(\mathcal{D}; q, \eta)^{|\phi|}$ given by (13) but as a function of the natural parameter vector η . Define

$$\text{NonEntropy}\{q(\phi; \eta)\} \equiv \sum_{j \in \text{neighbors}(\phi)} E_{q(\phi; \eta)}\{\log(f_j)\}$$

so that

$$\log \underline{p}(\mathcal{D}; q, \eta)^{|\phi|} = \text{Entropy}\{q(\phi; \eta)\} + \text{NonEntropy}\{q(\phi; \eta)\}.$$

An advantage of working with exponential family density functions is that the entropy takes the simple form:

$$\text{Entropy}\{q(\phi; \eta)\} = A(\eta) - D_{\eta} A(\eta) \eta + E[\exp\{h(\phi)\}]$$

where the notation of Appendix A.2 is being used. Moreover, as shown in Lemma 1 of Appendix A.5, the derivative vector of $\text{Entropy}\{q(\phi; \eta)\}$ is simply

$$D_{\eta} \text{Entropy}\{q(\phi; \eta)\} = -\eta^T \mathbf{H}_{\eta} A(\eta). \quad (40)$$

This implies that the stationary point condition

$$\{D_{\eta} \log \underline{p}(g; \eta)\}^{|\phi|} \}^T = \mathbf{0} \quad (41)$$

is equivalent to

$$\eta = \{H_{\eta} A(\eta)\}^{-1} D_{\eta} \text{NonEntropy}\{q(\phi; \eta)\}^T. \quad (42)$$

Algorithm 1 of Knowles and Minka (2011) is a fixed-point iteration scheme based on (42).

One further interesting and useful connection concerns the *mean parameter* vector

$$\tau \equiv E\{T(\phi)\}$$

which is related to the natural parameter vector via

$$\tau = D_{\eta} A(\eta)^T.$$

Under suitable technical conditions τ is a one-to-one transformation of η . Also the chain rule for differentiation of a smooth function s , listed as Lemma 2 in Appendix A.5, is

$$D_{\eta} s = (D_{\tau} s)(D_{\eta} \tau) = (D_{\tau} s) D_{\eta} \{D_{\eta} A(\eta)^T\} = (D_{\tau} s) H_{\eta} A(\eta).$$

which leads to

$$D_{\tau} s = \{H_{\eta} A(\eta)\}^{-1} D_{\eta} s. \quad (43)$$

Putting all of these relationships together we have:

Result 1 *Let ξ be an arbitrary differentiable one-to-one transformation of η . Then the stationary point condition (41) is equivalent to each the following conditions:*

- (a) $\eta = \{H_{\eta} A(\eta)\}^{-1} D_{\eta} \text{NonEntropy}\{q(\phi; \eta)\}^T$,
- (b) $\eta = \{H_{\eta} A(\eta)\}^{-1} (D_{\eta} \xi)^T D_{\xi} \text{NonEntropy}\{q(\phi; \xi)\}^T$,
- (c) $\eta = D_{\tau} \text{NonEntropy}\{q(\phi; \tau)\}^T$ and
- (d) $\eta = (D_{\tau} \xi)^T D_{\xi} \text{NonEntropy}\{q(\phi; \xi)\}^T$.

We make the following remarks concerning Result 1:

- Result 1(a) immediately gives rise to the following fixed-point iteration scheme in the natural parameter space $\eta \in H$:

$$\eta \leftarrow \{H_{\eta} A(\eta)\}^{-1} D_{\eta} \text{NonEntropy}\{q(\phi; \eta)\}^T. \quad (44)$$

We refer to (44) as the *natural fixed-point iteration scheme* and denote the corresponding fixed-point function by

$$\mathbf{g}_{\text{nat}}(\eta) \equiv \{H_{\eta} A(\eta)\}^{-1} D_{\eta} \text{NonEntropy}\{q(\phi; \eta)\}^T.$$

According to the theory of fixed-point iteration discussed in Section 3.1, convergence of (44) is implied by

$$\rho(D_{\eta} \mathbf{g}_{\text{nat}}(\eta)) < 1$$

in a neighborhood of the maximizer η^* .

- Result 1(b)–(d) offer the possibility of more convenient forms for the fixed-point updates in terms of derivatives of the common parameters or mean parameters. Particularly noteworthy is the fact that Result 1(c)–(d) do not require computation of $\{H_{\eta} A(\eta)\}^{-1}$. We make use of this situation for the Multivariate Normal family in Section 4.1.

- The Fisher information of $q(\phi; \eta)$ is

$$-E\{H_{\eta} \log q(\phi; \eta)\} = H_{\eta} A(\eta)$$

which implies that the natural fixed-point iteration scheme (44) involves updating η according to natural Riemannian gradients of $\text{NonEntropy}(g; \tau)$. From Result 1(c), an equivalent updating scheme is

$$\eta \leftarrow D_{\tau} \text{NonEntropy}\{q(\phi; \tau)\}^T$$

which simply involves updating η according to the direction of maximum slope on the $\text{NonEntropy}(g; \tau)$ surface in the τ space.

- The forms for the stationary point in Result 1 can also be used to derive iterative Newton-Raphson schemes for maximizing $\log \underline{p}(g; \eta)^{|\phi|}$. An example, corresponding to Result 1(a) and optimization within the η space, is

$$\eta \leftarrow \eta - [H_{\eta} \text{NonEntropy}\{q(\phi; \eta)\} - H_{\eta} A(\eta) - (\eta^T \otimes \mathbf{I}) D_{\eta} \text{vec}\{H_{\eta} A(\eta)\}]^{-1} \times [D_{\eta} \text{NonEntropy}\{q(\phi; \eta)\}^T - H_{\eta} A(\eta) \eta].$$

The vec operator flattens a square matrix into a column vector and is defined formally in Appendix A.1.

Any of the other optimization methods mentioned in Section 3 can also be applied to the problem of obtaining

$$\eta^* \equiv \underset{\eta \in H}{\text{argmax}} \{\log \underline{p}(\mathcal{D}; q, \xi)^{|\phi|}\} = \underset{\eta \in H}{\text{argmax}} [A(\eta) - D_{\eta} A(\eta) \eta + \text{NonEntropy}\{q(\phi; \eta)\}]$$

and those involving gradients benefit from the entropy derivative result (40). Additionally, relationship (43) implies that natural (Riemannian) gradients of the objective function in the natural parameter space are equivalent to ordinary Euclidean gradients in the mean parameter space.

4.1 Multivariate Normal Special Case

We now focus on the important special case of $q(\phi; \xi)$ being a d -variate Multivariate Normal density function:

$$q(\phi; \mu_{q(\phi)}, \Sigma_{q(\phi)}) = (2\pi)^{-d/2} |\Sigma_{q(\phi)}|^{-1/2} \exp\{-\frac{1}{2}(\phi - \mu_{q(\phi)})^T \Sigma_{q(\phi)}^{-1} (\phi - \mu_{q(\phi)})\}.$$

Let

$$\xi \equiv \begin{bmatrix} \mu_{q(\phi)} \\ \text{vec}(\Sigma_{q(\phi)}) \end{bmatrix}$$

be the vector of common parameters. An explicit form for the natural fixed point iteration updates in terms of $\mu_{q(\phi)}$ and $\Sigma_{q(\phi)}$ was derived by Wand (2014) and appears as equation (7) there. However Result 1 affords a more direct derivation of the same result, that benefits from (43) and the cancellation of the $H_\eta A(\eta)$ matrix. We can also obtain a neater alternative explicit form by using a differentiation identity, given as Lemma 4 in Appendix A.5. The essence of Lemma 4 is given in the appendix of Oppner and Archambeau (2009).

Result 2 *Natural fixed-point iteration for $q(\phi; \xi)$ corresponding to the $N(\mu_{q(\phi)}, \Sigma_{q(\phi)})$ density function is equivalent to the following updating scheme:*

$$\begin{cases} \mathbf{v}_{q(\phi)} \leftarrow \mathbf{D}_{\mu_{q(\phi)}} \text{NonEntropy}(q; \mu_{q(\phi)}, \Sigma_{q(\phi)})^T \\ \Sigma_{q(\phi)} \leftarrow -\{H_{\mu_{q(\phi)}} \text{NonEntropy}(q; \mu_{q(\phi)}, \Sigma_{q(\phi)})\}^{-1} \\ \mu_{q(\phi)} \leftarrow \mu_{q(\phi)} + \Sigma_{q(\phi)} \mathbf{v}_{q(\phi)}. \end{cases}$$

Appendix A.6 provides details on how Result 2 follows from Result 1.

Result 2 facilitates a semiparametric mean field variational Bayes algorithm that requires only the first and second order derivatives of $\text{NonEntropy}(q; \mu_{q(\phi)}, \Sigma_{q(\phi)})$ with respect to $\mu_{q(\phi)}$. Concrete illustrations are given in Section 4.3 and Appendix A of Menictas and Wand (2015).

In the case where $q(\phi; \xi)$ is the Univariate Normal density function with mean $\mu_{q(\phi)}$ and variance $\sigma_{q(\phi)}^2$ Result 2 leads to the following common parameter updates for the natural fixed point iterative scheme:

$$\begin{cases} \mathbf{v}_{q(\phi)} \leftarrow \frac{\partial \text{NonEntropy}(q; \mu_{q(\phi)}, \sigma_{q(\phi)}^2)}{\partial \mu_{q(\phi)}} \\ \sigma_{q(\phi)}^2 \leftarrow -1 / \left\{ \frac{\partial^2 \text{NonEntropy}(q; \mu_{q(\phi)}, \sigma_{q(\phi)}^2)}{\partial \mu_{q(\phi)}^2} \right\} \\ \mu_{q(\phi)} \leftarrow \mu_{q(\phi)} + \sigma_{q(\phi)}^2 \mathbf{v}_{q(\phi)}. \end{cases} \quad (45)$$

Despite its use of natural gradients, there is no automatic guarantee that iteration of (45) leads to convergence to the maximum of $\log p(\mathcal{D}; q, \xi)^{|\phi|}$ on any given cycle of Algorithm 2. However, the fixed-point iteration theory summarized in Section 3.1 provides some guidance. We now use Example 1 to illustrate this point using the natural fixed-point iteration scheme (45), an alternative simpler fixed-point scheme and a Newton-Raphson scheme.

4.2 Application to Example 1

Consider again the Gumbel random sample example introduced in Section 2.2.2 and the problem of minimum Kullback-Leibler approximation of $p(\phi|\mathbf{x})$ within the Univariate Normal family. As shown there, the optimization problem is encapsulated in (19) and (20). The Newton-Raphson scheme that arises directly from (19) is

$$\begin{bmatrix} \mu_{q(\phi)} \\ \sigma_{q(\phi)}^2 \end{bmatrix} \leftarrow \begin{bmatrix} \mu_{q(\phi)} \\ \sigma_{q(\phi)}^2 \end{bmatrix} - \left\{ H_{\text{Ex1}}^N(\mu_{q(\phi)}, \sigma_{q(\phi)}^2; n, \sum_{i=1}^n e^{-x_i}, \mu_{\phi}, \sigma_{\phi}^2) \right\}^{-1} \\ \times \mathbf{D} f_{\text{Ex1}}^N(\mu_{q(\phi)}, \sigma_{q(\phi)}^2; n, \sum_{i=1}^n e^{-x_i}, \mu_{\phi}, \sigma_{\phi}^2)^T. \quad (46)$$

Differentiation with respect to $(\mu_{\phi}, \sigma_{\phi}^2)$ is suppressed in the \mathbf{D} and \mathbf{H} on the right-hand side of (46). Simple calculus leads to (46) being equivalent to the fixed-point iterative scheme

$$\begin{bmatrix} \mu_{q(\phi)} \\ \sigma_{q(\phi)}^2 \end{bmatrix} \leftarrow \mathbf{g}_{\text{NR}} \left(\begin{bmatrix} \mu_{q(\phi)} \\ \sigma_{q(\phi)}^2 \end{bmatrix}; n, \sum_{i=1}^n e^{-x_i}, \mu_{\phi}, \sigma_{\phi}^2 \right) \quad (47)$$

where

$$\mathbf{g}_{\text{NR}} \left(\begin{bmatrix} x \\ y \end{bmatrix}; a, b, c, d \right) \equiv \begin{bmatrix} x \\ y \end{bmatrix} - \begin{bmatrix} -b e^{x+\frac{1}{2}y} - 1/d & -\frac{1}{2} b e^{x+\frac{1}{2}y} \\ -\frac{1}{2} b e^{x+\frac{1}{2}y} & -\frac{1}{2y^2} - \frac{1}{4} b e^{x+\frac{1}{2}y} \end{bmatrix}^{-1} \\ \times \begin{bmatrix} a - b e^{x+\frac{1}{2}y} - (x-c)/d \\ \frac{1}{2y} - \frac{1}{2} b e^{x+\frac{1}{2}y} - 1/(2d) \end{bmatrix}.$$

According to (45), the natural fixed-point iteration scheme (44) takes the form (47), but with \mathbf{g}_{NR} replaced by \mathbf{g}_{nat} where

$$\mathbf{g}_{\text{nat}} \left(\begin{bmatrix} x \\ y \end{bmatrix}; a, b, c, d \right) \equiv \begin{bmatrix} x + \{a - b e^{x+\frac{1}{2}y} - (x-c)/d\} / (b e^{x+\frac{1}{2}y} + d^{-1}) \\ y / (b e^{x+\frac{1}{2}y} + d^{-1}) \end{bmatrix}.$$

Lastly, there is the very simple fixed-point iteration scheme that arises from full simplification of $\mathbf{D} f_{\text{Ex1}}^N(\mu_{q(\phi)}, \sigma_{q(\phi)}^2; n, \sum_{i=1}^n e^{-x_i}, \mu_{\phi}, \sigma_{\phi}^2)^T = \mathbf{0}$, and corresponds to fixed points of

$$\mathbf{g}_{\text{simp}} \left(\begin{bmatrix} x \\ y \end{bmatrix}; a, b, c, d \right) \equiv \begin{bmatrix} c + d(a - b e^{x+\frac{1}{2}y}) \\ 1 / (b e^{x+\frac{1}{2}y} + d^{-1}) \end{bmatrix}.$$

In Figure 4 we compare \mathbf{g}_{NR} , \mathbf{g}_{nat} and \mathbf{g}_{simp} in terms of the behavior of the spectral norm function $\rho(\mathbf{D} \mathbf{g}(x, y))$ and convergence of the fixed-point iterative scheme. We simulated data from the $n = 20$ version of the Gumbel random sample model (14) with the value of ϕ set to 0. The sufficient statistic $\sum_{i=1}^{20} \exp(-x_i)$ fully determines f_{Ex1}^N and has a mean of 20. In an effort to exhibit typical behavior, we selected a sample that produced a sufficient statistic value close to this mean. The actual value is $\sum_{i=1}^{20} \exp(-x_i) \approx 19.94$. The hyperparameters were set to $\mu_{\phi} = 0$ and $\sigma_{\phi}^2 = 10^{10}$. The optimal parameters in the minimum Kullback-Leibler Univariate Normal approximation to $p(\phi|\mathbf{x})$ are $(\mu_{q(\phi)}^*, (\sigma_{q(\phi)}^2)^*) \approx (0.2260, 0.0500)$. We set up a 101×101 pixel mesh of $(\mu_{q(\phi)}, \log(\sigma_{q(\phi)}^2))$ values around this optimum with limits $(\mu_{q(\phi)}^* - 5, \mu_{q(\phi)}^* + 5)$ and $(\log\{(\sigma_{q(\phi)}^2)^*/5\}^2, \log\{(5\sigma_{q(\phi)}^2)^*\}^2)$. The upper panels of Figure 4 show the

indicator of $\rho(\mathbf{D} \mathbf{g}(\mu_{q(\phi)}, \sigma_{q(\phi)}^2)) < 1$ for $\mathbf{g} \in \{\mathbf{g}_{\text{NR}}, \mathbf{g}_{\text{nat}}, \mathbf{g}_{\text{simp}}\}$.

The lower panels show the

indicator of fixed-point iteration converging when starting from $(\mu_{q(\phi)}, \sigma_{q(\phi)}^2)$.

The top half of Figure 4 shows, via dark grey shading, that both $\rho(\mathbf{D} \mathbf{g}_{\text{NR}}(\mu_{q(\phi)}, \sigma_{q(\phi)}^2))$ and $\rho(\mathbf{D} \mathbf{g}_{\text{nat}}(\mu_{q(\phi)}, \sigma_{q(\phi)}^2))$ are below 1 in regions around the root. The dark grey region for

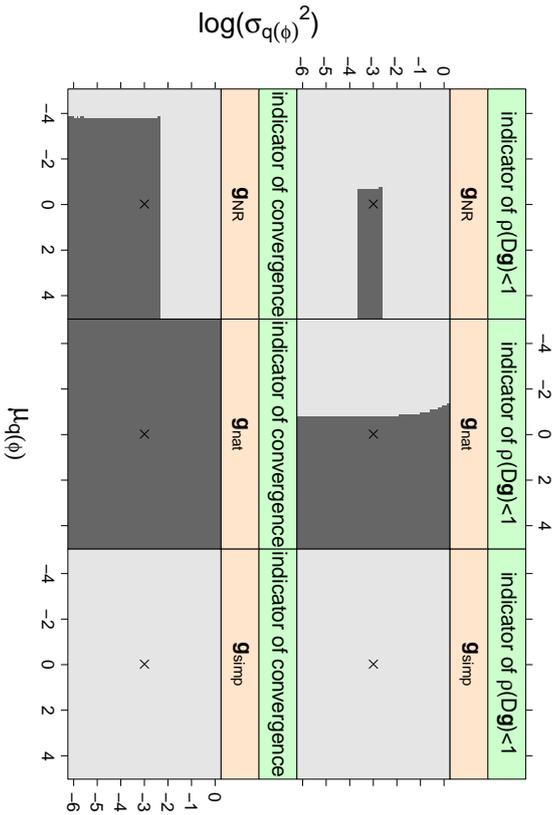

Figure 4: *Upper panels: Dark grey shading shows points where $\rho(\mathbf{Dg}(\mu_{q(\phi)}, \sigma_q^2)) < 1$ for $\mathbf{g} \in \{\mathbf{g}_{\text{NR}}, \mathbf{g}_{\text{nat}}, \mathbf{g}_{\text{simp}}\}$. Lower panels: Dark grey shading shows points from which fixed-point iteration, based on $\mathbf{g} \in \{\mathbf{g}_{\text{NR}}, \mathbf{g}_{\text{nat}}, \mathbf{g}_{\text{simp}}\}$, converges if initialized from that point. The optimum is shown by a cross in each panel and corresponds to minimum Kullback-Leibler divergence for a single $n = 20$ sample of the Gumbel random sample model with hyperparameters set to $\mu_\phi = 0$ and $\sigma_\phi^2 = 10^{10}$.*

\mathbf{g}_{nat} is much larger than that of \mathbf{g}_{NR} , suggesting that the former has better convergence properties according to the theory described in Section 3.1. The lower panels confirm this, with \mathbf{g}_{nat} -based fixed-point iteration converging from every initial value on the pixel mesh, but Newton-Raphson iteration not converging from the sub-region on the top and left-hand side of the mesh. Also note that $\rho(\mathbf{Dg}_{\text{simp}}(\mu_{q(\phi)}, \sigma_q^2)) \geq 1$ over the whole pixel mesh and \mathbf{g}_{simp} -based fixed-point iteration does not converge, regardless of initial point.

Figure 5 shows the iteration trajectories from four different starting values and four iterative schemes based on the same data and hyperparameter values as used in Figure 4. Also shown in each panel is an image plot of the surface being maximized, with a logarithmic scale used for σ_q^2 . In addition to the fixed-point iteration schemes based on \mathbf{g}_{NR} and \mathbf{g}_{nat} we include the nonlinear conjugate gradient method given in Algorithm 5 and

the Riemannian geometry adjustment involving the natural gradients given by (38). In most cases the iterations led to convergence to $(\mu_{q(\phi)}^*, (\sigma_{q(\phi)}^2)^*)$ and the first three iterates are plotted. However, Newton-Raphson failed to converge from the starting values in each of the upper panels and the subsequent iterates are outside of the image plot boundaries.

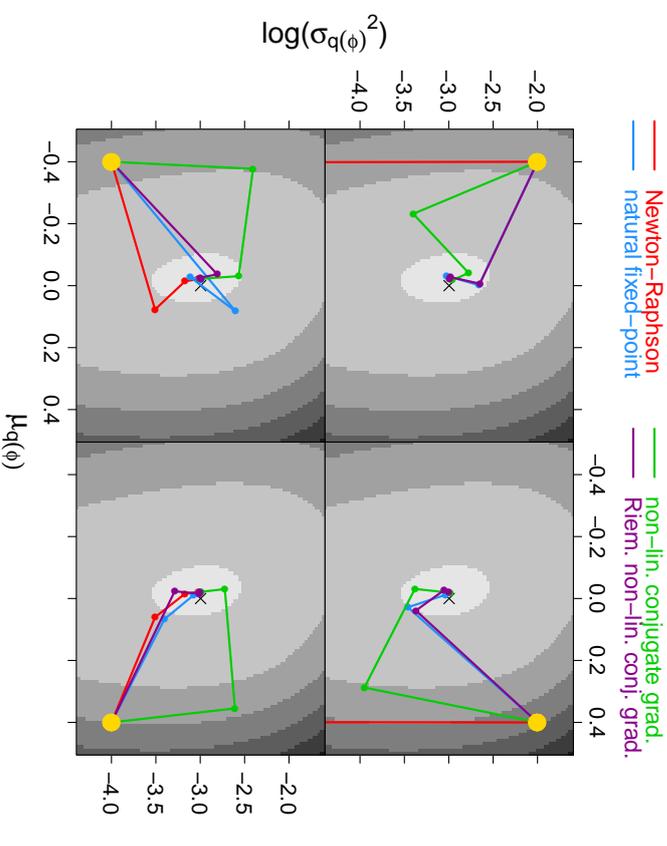

Figure 5: *Iteration trajectories of four iterative algorithms aimed at solving the minimum Kullback-Leibler problem for a Gumbel random sample of size $n = 20$ with hyperparameters $\mu_{q(\phi)} = 0$ and $\sigma_{q(\phi)}^2 = 10^{10}$. The initial value differs for each panel and is shown by the yellow dot. The iterative algorithms are: (1) Newton-Raphson fixed-point iteration based on \mathbf{g}_{NR} , (2) natural fixed-point iteration based on \mathbf{g}_{nat} , (3) ordinary non-linear conjugate gradient method and (4) Riemannian non-linear conjugate gradient method.*

The most striking feature of Figure 5 is the directness with which natural fixed-point iteration and the Riemannian non-linear conjugate gradient method converge from all four starting points and the similarity of their trajectories. This behavior is in keeping with the fact that both work with the more appropriate Riemannian gradients. The ordinary non-linear conjugate gradient trajectories are not as direct. Similar observations are made in Honkela et al. (2010). As demonstrated there, the payoffs from using Riemannian gradients in non-linear conjugate gradient updating are greater in higher-dimensional versions of semiparametric mean field variational Bayes. Based on Figure 5, we anticipate that natural fixed-point iteration is also very good in higher dimensions, and this is corroborated by experiments for Example 2 described in Section 4.3. Newton-Raphson fixed-point iteration is seen to be unreliable for this optimization problem and nowhere near as robust as natural fixed-point iteration. Lastly, we note that the behavior represented in Figures 4 and 5 persists across each of several other samples that we generated.

4.3 Application to Example 2

From (29) and some simple matrix algebra

$$\begin{aligned} \text{NonEntropy}(g; \boldsymbol{\mu}_{q(\beta, \mathbf{u})}, \boldsymbol{\Sigma}_{q(\beta, \mathbf{u})}) &= \mathbf{y}^T \mathbf{C} \boldsymbol{\mu}_{q(\beta, \mathbf{u})} - \mathbf{1}^T \exp \left\{ \mathbf{C} \boldsymbol{\mu}_{q(\beta, \mathbf{u})} + \frac{1}{2} \text{diagonal}(\mathbf{C} \boldsymbol{\Sigma}_{q(\beta, \mathbf{u})} \mathbf{C}^T) \right\} \\ &\quad - \frac{1}{2} \text{tr} \left(\begin{bmatrix} \sigma_\beta^{-2} \mathbf{I}_p & \mathbf{0} \\ \mathbf{0} & \mu_{q(1/\sigma^2)} \mathbf{I}_K \end{bmatrix} \{ \boldsymbol{\mu}_{q(\beta, \mathbf{u})} \boldsymbol{\mu}_{q(\beta, \mathbf{u})}^T + \boldsymbol{\Sigma}_{q(\beta, \mathbf{u})} \} \right) \\ &\quad - \frac{1}{2} (p + K) \log(2\pi) - \frac{1}{2} p \log(\sigma_\beta^2) - \frac{1}{2} K E_q \{ \log(\sigma^2) \} - \mathbf{1}^T \log(\mathbf{y}) \end{aligned}$$

where

$$\mu_{q(1/\sigma^2)} = E_{q(1/\sigma^2)}(1/\sigma^2).$$

The derivatives appearing in Result 2 are

$$\begin{aligned} \mathbf{D}_{\boldsymbol{\mu}_{q(\beta, \mathbf{u})}} \text{NonEntropy}(g; \boldsymbol{\mu}_{q(\beta, \mathbf{u})})^T &= \mathbf{C}^T \left[\mathbf{y} - \exp \left\{ \mathbf{C} \boldsymbol{\mu}_{q(\beta, \mathbf{u})} + \frac{1}{2} \text{diagonal}(\mathbf{C} \boldsymbol{\Sigma}_{q(\beta, \mathbf{u})} \mathbf{C}^T) \right\} \right] \\ &\quad - \begin{bmatrix} \sigma_\beta^{-2} \mathbf{I}_p & \mathbf{0} \\ \mathbf{0} & \mu_{q(1/\sigma^2)} \mathbf{I}_K \end{bmatrix} \boldsymbol{\mu}_{q(\beta, \mathbf{u})} \end{aligned}$$

and

$$\begin{aligned} \mathbf{H}_{\boldsymbol{\mu}_{q(\beta, \mathbf{u})}} \text{NonEntropy}(g; \boldsymbol{\mu}_{q(\beta, \mathbf{u})}) &= \\ - \left(\mathbf{C}^T \text{diag} \left[\exp \left\{ \mathbf{C} \boldsymbol{\mu}_{q(\beta, \mathbf{u})} + \frac{1}{2} \text{diagonal}(\mathbf{C} \boldsymbol{\Sigma}_{q(\beta, \mathbf{u})} \mathbf{C}^T) \right\} \right] \mathbf{C} + \begin{bmatrix} \sigma_\beta^{-2} \mathbf{I}_p & \mathbf{0} \\ \mathbf{0} & \mu_{q(1/\sigma^2)} \mathbf{I}_K \end{bmatrix} \right). \end{aligned}$$

It follows that the updates take the explicit form

$$\begin{cases} \mathbf{w}_{q(\beta, \mathbf{u})} \leftarrow \exp \left\{ \mathbf{C} \boldsymbol{\mu}_{q(\beta, \mathbf{u})} + \frac{1}{2} \text{diagonal}(\mathbf{C} \boldsymbol{\Sigma}_{q(\beta, \mathbf{u})} \mathbf{C}^T) \right\} \\ \boldsymbol{\Sigma}_{q(\beta, \mathbf{u})} \leftarrow \left(\mathbf{C}^T \text{diag} \{ \mathbf{w}_{q(\beta, \mathbf{u})} \} \mathbf{C} + \begin{bmatrix} \sigma_\beta^{-2} \mathbf{I}_p & \mathbf{0} \\ \mathbf{0} & \mu_{q(1/\sigma^2)} \mathbf{I}_K \end{bmatrix} \right)^{-1} \\ \boldsymbol{\mu}_{q(\beta, \mathbf{u})} \leftarrow \boldsymbol{\mu}_{q(\beta, \mathbf{u})} + \boldsymbol{\Sigma}_{q(\beta, \mathbf{u})} \left\{ \mathbf{C}^T (\mathbf{y} - \mathbf{w}_{q(\beta, \mathbf{u})}) - \begin{bmatrix} \sigma_\beta^{-2} \mathbf{I}_p & \mathbf{0} \\ \mathbf{0} & \mu_{q(1/\sigma^2)} \mathbf{I}_K \end{bmatrix} \boldsymbol{\mu}_{q(\beta, \mathbf{u})} \right\}. \end{cases}$$

This is equivalent to the fixed-point iteration scheme

$$\begin{bmatrix} \boldsymbol{\mu}_{q(\beta, \mathbf{u})} \\ \text{vech}(\boldsymbol{\Sigma}_{q(\beta, \mathbf{u})}) \end{bmatrix} \leftarrow \mathbf{g}_{\text{Ex2}} \left(\begin{bmatrix} \boldsymbol{\mu}_{q(\beta, \mathbf{u})} \\ \text{vech}(\boldsymbol{\Sigma}_{q(\beta, \mathbf{u})}) \end{bmatrix} ; \mathbf{y}, \mathbf{C}, \begin{bmatrix} \sigma_\beta^{-2} \mathbf{I}_p & \mathbf{0} \\ \mathbf{0} & \mu_{q(1/\sigma^2)} \mathbf{I}_K \end{bmatrix} \right)$$

where

$$\mathbf{g}_{\text{Ex2}} \left(\begin{bmatrix} \boldsymbol{\mu} \\ \text{vech}(\boldsymbol{\Sigma}) \end{bmatrix} ; \mathbf{y}, \mathbf{C}, \mathbf{M} \right) \equiv \begin{bmatrix} \boldsymbol{\mu} + \left[\mathbf{C}^T \text{diag} \{ \boldsymbol{\omega}(\boldsymbol{\mu}, \boldsymbol{\Sigma}) \} \mathbf{C} + \mathbf{M} \right]^{-1} \\ \times \left[\mathbf{C}^T \{ \mathbf{y} - \boldsymbol{\omega}(\boldsymbol{\mu}, \boldsymbol{\Sigma}) \} - \mathbf{M} \boldsymbol{\mu} \right] \\ \text{vech} \left(\left[\mathbf{C}^T \text{diag} \{ \boldsymbol{\omega}(\boldsymbol{\mu}, \boldsymbol{\Sigma}) \} \mathbf{C} + \mathbf{M} \right]^{-1} \right) \end{bmatrix}$$

and

$$\boldsymbol{\omega}(\boldsymbol{\mu}, \boldsymbol{\Sigma}) \equiv \exp \{ \mathbf{C} \boldsymbol{\mu} + \frac{1}{2} \text{diagonal}(\mathbf{C} \boldsymbol{\Sigma} \mathbf{C}^T) \}.$$

Note that the vech operator stores the unique entries of a symmetric matrix in a column vector. A formal definition of vech is given in Appendix A.1.

We simulated data according to the following special case of the Poisson mixed model:

$$\begin{aligned} y_{ij} | U_i &\sim \text{Poisson} \{ \exp(\beta_0 + \beta_1 x_{ij} + U_i) \}, \quad U_i | \sigma^2 \sim N(0, \sigma^2), \\ 1 \leq i \leq m, \quad 1 \leq j \leq n, \quad \beta &\sim N(\mathbf{0}, \sigma_\beta^2 \mathbf{I}), \\ \sigma^2 | a &\sim \text{Inverse-Gamma}(\tfrac{1}{2}, 1/a), \quad a \sim \text{Inverse-Gamma}(\tfrac{1}{2}, A^{-2}). \end{aligned} \quad (48)$$

The hyperparameters were set at $\sigma_\beta = A = 10^5$ and the sample sizes were $m = 30$, $n = 5$. Note that (48) is a special case of (21) with $\mathbf{Z} = \mathbf{I}_m \otimes \mathbf{I}_n$, where \mathbf{I}_n is the $n \times 1$ vector with all entries equal to one. We then ran Algorithm 2 with $q(\beta, \mathbf{u})$ pre-specified to be the $N(\boldsymbol{\mu}_{q(\beta, \mathbf{u})}, \boldsymbol{\Sigma}_{q(\beta, \mathbf{u})})$ density function and a single natural fixed-point iteration in each cycle based on \mathbf{g}_{Ex2} . The fixed-point iteration search over values of $[\boldsymbol{\mu}_{q(\beta, \mathbf{u})}^T \text{vech}(\boldsymbol{\Sigma}_{q(\beta, \mathbf{u})})]^T$ is within an open subset of \mathbb{R}^{560} .

Figure 6 shows trace plots of $\log \bar{p}(\mathbf{y}; q, \boldsymbol{\mu}_{q(\beta, \mathbf{u})}, \boldsymbol{\Sigma}_{q(\beta, \mathbf{u})})$ and $\rho(\mathbf{D} \mathbf{g}_{\text{Ex2}})$, based on the explicit expressions for $\mathbf{D} \mathbf{g}_{\text{Ex2}}$ given in Appendix A.7. The upper panel indicates that the algorithm becomes close to convergence after 6–10 iterations. After the same number of iterations the values of $\rho(\mathbf{D} \mathbf{g}_{\text{Ex2}})$ fall below 1 and settle at about 0.15.

Before leaving this example we note that numerical checks indicate that the optimal $\boldsymbol{\Sigma}_{q(\beta, \mathbf{u})}$ matrix is approximately sparse, with dominant diagonal entries. This implies the possibility of low-rank approximations to the above semiparametric mean field variational Bayes algorithm given, as described in Section 4.1.3 of Challinor and Barber (2013).

5. A Non-Exponential Family Example

In the previous section it was seen that semiparametric mean field variational Bayes with $q(\phi; \boldsymbol{\xi})$ having an exponential family form (39) leads to simplifications of the Kullback-Leibler minimization problem. However, $q(\phi; \boldsymbol{\xi})$ does not have to be restricted in this way. In this section we illustrate semiparametric mean field variational Bayes with the q -density of ϕ specified to be in a non-exponential family: the family of Skew-Normal density functions (Azzalini and Dalla Valle, 1996). Even though this family has a multivariate extension,

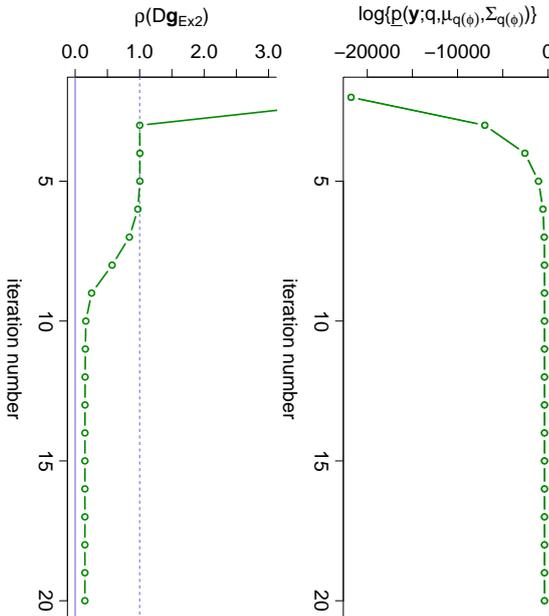

Figure 6: Trace plots of $\log p(\mathbf{y}; q, \boldsymbol{\xi})^{(\beta; u)}$ and $\rho(\mathbf{Dg}_{\text{Ex2}})$ for the version of the Poisson mixed model given by (48) with sample sizes $m = 30$ and $n = 5$.

we restrict attention to the univariate case and, in particular, its use within the context of Example 1.

Specification of $q(\phi; \boldsymbol{\xi})$ being within the family of univariate Skew-Normal density functions entails having

$$q(\phi; \boldsymbol{\xi}) = \sqrt{\frac{2}{\pi\sigma_{q(\phi)}^2}} \exp \left\{ -\frac{(\phi - \mu_{q(\phi)})^2}{2\sigma_{q(\phi)}^2} \right\} \Phi \left\{ \frac{\lambda_{q(\phi)}(\phi - \mu_{q(\phi)})}{\sigma_{q(\phi)}} \right\} \quad (49)$$

where $\Phi(x) \equiv (2\pi)^{-1/2} \int_{-\infty}^x e^{-t^2/2} dt$ is the $N(0, 1)$ cumulative distribution function. The q -density parameter vector is $\boldsymbol{\xi} = (\mu_{q(\phi)}, \sigma_{q(\phi)}^2, \lambda_{q(\phi)})$ and the corresponding parameter space is $\boldsymbol{\Xi} = \mathbb{R} \times \mathbb{R}_+ \times \mathbb{R}$. Now consider the Example 1 setting with $q(\phi; \boldsymbol{\xi})$ restricted to the Skew-Normal family (49). The marginal log-likelihood lower bound, given by (17) and (18),

depends on the explicit expressions

$$E_{q(\phi; \boldsymbol{\xi})}(\phi) = \mu_{q(\phi)} + \frac{\sigma_{q(\phi)} \lambda_{q(\phi)}}{\sqrt{(\pi/2)(1 + \lambda_{q(\phi)}^2)}}, \quad \text{Var}_{q(\phi; \boldsymbol{\xi})}(\phi) = \sigma_{q(\phi)}^2 \left\{ 1 - \frac{2\lambda_{q(\phi)}^2}{\pi(1 + \lambda_{q(\phi)}^2)} \right\}$$

$$\text{and } M_{q(\phi; \boldsymbol{\xi})}(t) = 2 \exp \left(\mu_{q(\phi)} + \frac{1}{2} \sigma_{q(\phi)}^2 t^2 \right) \Phi \left(\frac{\lambda_{q(\phi)} \sigma_{q(\phi)} t}{\sqrt{1 + \lambda_{q(\phi)}^2}} \right)$$

where, as defined in Section 2.2.2, $M_{q(\phi; \boldsymbol{\xi})}$ is the moment generating function corresponding to $q(\phi; \boldsymbol{\xi})$. It also depends on

$$\text{Entropy}\{q(\phi; \boldsymbol{\xi})\} = \frac{1}{2} \{1 + \log(\pi/2) + \log(\sigma_{q(\phi)}^2)\} - \sqrt{\frac{2}{\pi}} \int_{-\infty}^{\infty} \log \Phi(\lambda_{q(\phi)} t) \Phi(\lambda_{q(\phi)} t) e^{-t^2/2} dt$$

which does not simplify any further. Plugging these expressions into (17) and (18) we get the Kullback-Leibler optimal Skew-Normal q -density function is $q(\phi; \mu_{q(\phi)}^*, (\sigma_{q(\phi)}^2)^*, \lambda_{q(\phi)}^*)$ where

$$\begin{bmatrix} \mu_{q(\phi)}^* \\ (\sigma_{q(\phi)}^2)^* \\ \lambda_{q(\phi)}^* \end{bmatrix} = \underset{\substack{\mu_{q(\phi)} \in \mathbb{R}, \sigma_{q(\phi)}^2 \in \mathbb{R} \\ \lambda_{q(\phi)} \in \mathbb{R}}} {\text{argmax}} \left\{ f_{\text{Ex1}}^{\text{SN}} \left(\mu_{q(\phi)}, \sigma_{q(\phi)}^2, \lambda_{q(\phi)}; n, \sum_{i=1}^n e^{-x_i}, \mu_{\phi}, \sigma_{\phi}^2 \right) \right\} \quad (50)$$

and

$$\begin{aligned} f_{\text{Ex1}}^{\text{SN}}(x, y, z; a, b, c, d) &= \frac{1}{2} \log(y) - \sqrt{\frac{2}{\pi}} \int_{-\infty}^{\infty} \log\{\Phi(zt)\} \Phi(zt) e^{-t^2/2} dt \\ &\quad + a \left\{ x + z \sqrt{\frac{2y}{\pi(1+z^2)}} \right\} - 2b \exp\left(x + \frac{1}{2}y\right) \Phi\left(\frac{z\sqrt{y}}{\sqrt{z^2+1}}\right) \\ &\quad - \frac{1}{2d} \left\{ x + z \sqrt{\frac{2y}{\pi(1+z^2)}} - c \right\}^2 + y \left\{ 1 - \frac{2z^2}{\pi(1+z^2)} \right\}. \end{aligned}$$

Optimization problem (50) is considerably more challenging than its Normal counterpart. In particular, evaluations of the objective function and its derivatives require numerical integration.

We solved (50) for three Gumbel random samples of size $n = 5, 10$ and 20 and with $\sum_{i=1}^n e^{-x_i} \approx n$, corresponding to the mean of this sufficient statistic. The intractable integral in $f_{\text{Ex1}}^{\text{SN}}$ was approximated using a trapezoidal quadrature scheme similar to that described in Appendix B.2 of Wand et al. (2011). The limits of the trapezoidal grid were increased until the ratio of the global maximum and minimum absolute values of the integrand fell below 10^{-20} . The number of grid points was then doubled until the relative difference between two successive iterations was less than 10^{-20} . Multiple start locations and simulated annealing were used to locate global optima. Natural fixed-point iteration no

longer applies in this non-exponential family example and optimization of $f_{\text{Ex1}}^{\text{SN}}$ was accomplished using the *Broyden-Fletcher-Goldfarb-Shanno* quasi-Newton method via the `opt.im()` function in the R computing environment (R Development Core Team, 2016).

Figure 7 shows the optimal Skew-Normal q -density functions, together with the exact posterior density functions and those based on the Normal q -density restriction. We see that the Normal approximation is inferior for very low sample sizes, but that the approximations are about the same for moderate to large sample sizes.

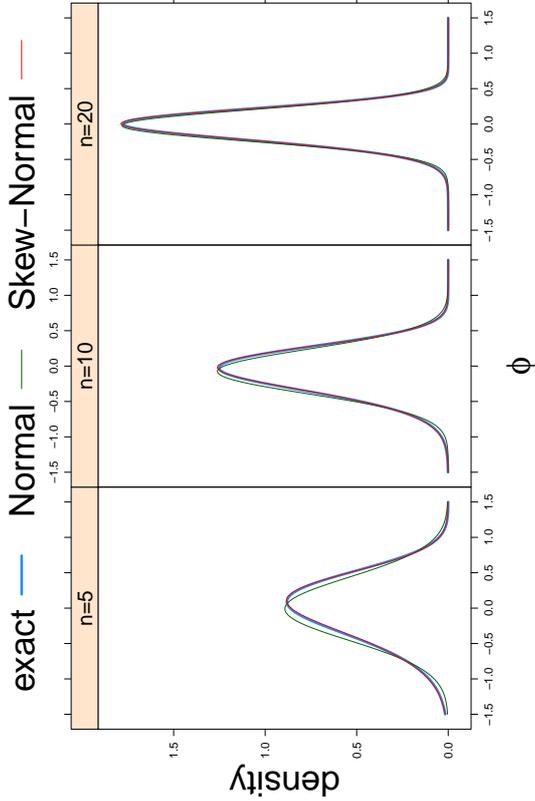

Figure 7: *Skew-Normal minimum Kullback-Leibler approximate posterior density functions for samples of size $n = 5, 10$ and 20 for the Example 1 Gumbel random sample setting. The exact posterior density functions and those based on restriction to the Normal family are also shown.*

6. Closing Remarks

We have taken a broad view of mean field variational Bayes with parametric pre-specification of one of the q -density components and coined the term ‘semiparametric mean field variational Bayes’ for this general approach. As well as laying out the general principles of

semiparametric mean field variational Bayes, we have provided an overview of the numerical issues attached to this methodology. Natural fixed-point iteration has been identified as a promising general approach to dealing with the Kullback-Leibler optimization problem and its attractive Riemannian gradient properties have been elucidated. Proof of convergence of a particular semiparametric mean field variational Bayes strategy appears to be too difficult a goal. However, for fixed-point iteration strategies, the spectral radius of the derivative matrix of the fixed-point update function is a reasonable diagnostic measure for checking convergence.

Appendix A. Definitions and Derivations

A.1 Matrix definitions and identity

If \mathbf{A} is a $d \times d$ matrix then $\text{vec}(\mathbf{A})$ is the $d^2 \times 1$ vector obtained by stacking the columns of \mathbf{A} underneath each other in order from left to right. The inverse vec operator is denoted by vec^{-1} . In addition we let $\text{vech}(\mathbf{A})$ denote the $\frac{1}{2}d(d+1) \times 1$ vector obtained from $\text{vec}(\mathbf{A})$ by eliminating the above-diagonal entries of \mathbf{A} . If \mathbf{A} is symmetric then $\text{vech}(\mathbf{A})$ contains all of the unique entries of \mathbf{A} .

The derivations also require the commutation and duplication matrix notation of Magnus and Neudecker (1999). If \mathbf{A} is an arbitrary $d \times d$ matrix then the *commutation matrix* of order d , denoted by \mathbf{K}_d , is the the $d^2 \times d^2$ matrix of zeroes and ones for which

$$\mathbf{K}_d \text{vec}(\mathbf{A}) = \text{vec}(\mathbf{A}^T).$$

If \mathbf{B} is a symmetric but otherwise arbitrary $d \times d$ matrix then the *duplication matrix* of order d is the $d^2 \times \frac{1}{2}d(d+1)$ matrix of zeroes and ones for which

$$\mathbf{D}_d \text{vech}(\mathbf{B}) = \text{vec}(\mathbf{B}).$$

The Moore-Penrose inverse of \mathbf{D}_d is

$$\mathbf{D}_d^+ \equiv (\mathbf{D}_d^T \mathbf{D}_d)^{-1} \mathbf{D}_d^T.$$

Note that

$$\mathbf{D}_d^+ \text{vec}(\mathbf{B}) = \text{vech}(\mathbf{B}). \quad (51)$$

Another useful notation is

$$\mathbf{Q}(\mathbf{A}) \equiv (\mathbf{A} \otimes \mathbf{1}^T) \odot (\mathbf{1}^T \otimes \mathbf{A})$$

for a general $m \times n$ matrix \mathbf{A} and $\mathbf{1}$ a $n \times 1$ vector of ones. The symbol \odot denotes element-wise product.

The following well-known matrix identity is used several times in the derivations:

$$\text{vec}(\mathbf{ABC}) = (\mathbf{C}^T \otimes \mathbf{A}) \text{vec}(\mathbf{B}). \quad (52)$$

A.2 Derivative Matrix and Hessian Matrix Notation

Our summary of derivative-based optimization, and subsequent discussion, benefits from derivative vector and Hessian matrix notation. Such notation is not universal, and throughout this article we follow the conventions of Magnus and Neudecker (1999).

If \mathbf{h} is a \mathbb{R}^d -valued with argument $\mathbf{x} \in \mathbb{R}^d$ then the *derivative matrix* of \mathbf{h} with respect to \mathbf{x} , denoted by $\mathbf{D}_{\mathbf{x}}\mathbf{h}(\mathbf{x})$, is the $p \times d$ matrix with (i, j) entry

$$\frac{\partial \mathbf{h}(\mathbf{x})}{\partial x_j}$$

A concrete derivative vector example is given in Section 2.3 of Wand (2014).

In the case $p = 1$, the *Hessian matrix* of \mathbf{h} with respect to \mathbf{x} is the $d \times d$ matrix

$$\mathbf{H}_{\mathbf{x}}\mathbf{h}(\mathbf{x}) \equiv \mathbf{D}_{\mathbf{x}}\{\{\mathbf{D}_{\mathbf{x}}\mathbf{h}(\mathbf{x})\}^T\}.$$

A.3 Example 2 Derivational Details

Here provide derivational details pertaining to Example 2 discussed in Section 2.2.3.

According to product restriction (22), the optimal q -density functions satisfy

$$\begin{aligned} q^*(\boldsymbol{\beta}, \mathbf{u}) &\propto \exp[E_{q(\sigma^2, a)}] \log\{p(\mathbf{y}, \boldsymbol{\beta}, \mathbf{u}, \sigma^2, a)\}, \\ q^*(\sigma^2) &\propto \exp[E_{q(\boldsymbol{\beta}, \mathbf{u}, a)}] \log\{p(\mathbf{y}, \boldsymbol{\beta}, \mathbf{u}, \sigma^2, a)\} \\ \text{and } q^*(a) &\propto \exp[E_{q(\boldsymbol{\beta}, \mathbf{u}, \sigma^2)}] \log\{p(\mathbf{y}, \boldsymbol{\beta}, \mathbf{u}, \sigma^2, a)\} \end{aligned}$$

(e.g. Bishop, 2006, Section 10.1.1). Simple algebraic steps lead to the forms given in (23).

First we consider general pre-specified q -density families of the form $q(\boldsymbol{\beta}, \mathbf{u}; \boldsymbol{\xi})$, $\boldsymbol{\xi} \in \Xi$. With the help of (10) each of the terms in (27), can be expressed as follows:

$$\begin{aligned} \text{Entropy}\{q(\boldsymbol{\beta}, \mathbf{u}; \boldsymbol{\xi})\} &= -\int_{\mathbb{R}^{K+2}} \log\{q(\boldsymbol{\beta}, \mathbf{u}; \boldsymbol{\xi})\} q(\boldsymbol{\beta}, \mathbf{u}; \boldsymbol{\xi}) d\boldsymbol{\beta} d\mathbf{u}, \\ \text{Entropy}\{q(\sigma^2)\} &= \log(B_{q(\sigma^2)}) + \frac{1}{2}(K+1) + \log\{\Gamma(\frac{1}{2}(K+1))\} \\ &\quad - \frac{1}{2}(K+3) \text{digamma}\{\frac{1}{2}(K+1)\}, \\ \text{Entropy}\{q(a)\} &= \log(B_{q(a)}) + 1 - 2 \text{digamma}(1), \\ E_{q\{\log p(\mathbf{y}|\boldsymbol{\beta}, \mathbf{u})\}} &= \mathbf{y}^T \{\mathbf{X} E_{q(\boldsymbol{\beta}, \mathbf{u}; \boldsymbol{\xi})}(\boldsymbol{\beta}) + \mathbf{Z} E_{q(\boldsymbol{\beta}, \mathbf{u}; \boldsymbol{\xi})}(\mathbf{u})\} \\ &\quad - \mathbf{1}^T E_{q(\boldsymbol{\beta}, \mathbf{u}; \boldsymbol{\xi})} \{\exp(\mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\mathbf{u})\} - \mathbf{1}^T \log(\mathbf{y}!), \\ E_{q\{\log p(\boldsymbol{\beta}, \mathbf{u}|\sigma^2)\}} &= -\frac{1}{2}(p+K) \log(2\pi) - \frac{1}{2} p \log(\sigma_{\boldsymbol{\beta}}^2) \\ &\quad - \frac{1}{2} K \{\log\{B_{q(\sigma^2)}\} - \text{digamma}\{\frac{1}{2}(K+1)\}\} \\ &\quad - \frac{1}{2\sigma_{\boldsymbol{\beta}}^2} \|\| E_{q(\boldsymbol{\beta}, \mathbf{u}; \boldsymbol{\xi})}(\boldsymbol{\beta})\|^2 + \text{tr}\{\text{Cov}_{q(\boldsymbol{\beta}, \mathbf{u}; \boldsymbol{\xi})}(\boldsymbol{\beta})\} \\ &\quad - \frac{1}{2} \mu_{q(1/\sigma^2)} \|\| E_{q(\boldsymbol{\beta}, \mathbf{u}; \boldsymbol{\xi})}(\mathbf{u})\|^2 + \text{tr}\{\text{Cov}_{q(\boldsymbol{\beta}, \mathbf{u}; \boldsymbol{\xi})}(\mathbf{u})\}, \\ E_{q\{\log p(\sigma^2|a)\}} &= -\frac{1}{2} \log(\pi) - \frac{1}{2} \{\log\{B_{q(a)}\} - \text{digamma}(1)\} \\ &\quad - \frac{1}{2} \{\log\{B_{q(\sigma^2)}\} - \text{digamma}\{\frac{1}{2}(K+1)\}\} \\ &\quad - \mu_{q(1/a)} \mu_{q(1/\sigma^2)} \\ &\quad - \mu_{q(1/a)}^2 / A^2, \\ \text{and } E_{q\{\log p(a)\}} &= -\frac{1}{2} \log(\pi) - \log(A) - \frac{3}{2} \{\log\{B_{q(a)}\} - \text{digamma}(1)\} \\ &\quad - \mu_{q(1/a)} / A^2. \end{aligned} \quad (53)$$

The $(\boldsymbol{\beta}, \mathbf{u})$ -localized approximate marginal log-likelihood expression given by (28) follows immediately from the relevant terms in (53).

If $q(\boldsymbol{\beta}, \mathbf{u}; \boldsymbol{\xi})$ is specified to be the $N(\boldsymbol{\mu}_{q(\boldsymbol{\beta}, \mathbf{u})}, \boldsymbol{\Sigma}_{q(\boldsymbol{\beta}, \mathbf{u})})$ density function then the terms in (27) that depend on $\boldsymbol{\xi} = (\boldsymbol{\mu}_{q(\boldsymbol{\beta}, \mathbf{u})}, \boldsymbol{\Sigma}_{q(\boldsymbol{\beta}, \mathbf{u})})$ are

$$\begin{aligned} \text{Entropy}\{q(\boldsymbol{\beta}, \mathbf{u}; \boldsymbol{\mu}_{q(\boldsymbol{\beta}, \mathbf{u})}, \boldsymbol{\Sigma}_{q(\boldsymbol{\beta}, \mathbf{u})})\} &= \frac{1}{2}(p+K) \{1 + \log(2\pi)\} + \frac{1}{2} \log\|\boldsymbol{\Sigma}_{q(\boldsymbol{\beta}, \mathbf{u})}\|, \\ E_{q\{\log p(\mathbf{y}|\boldsymbol{\beta}, \mathbf{u})\}} &= \mathbf{y}^T \mathbf{C} \boldsymbol{\mu}_{q(\boldsymbol{\beta}, \mathbf{u})} - \mathbf{1}^T \log(\mathbf{y}!) \\ &\quad - \mathbf{1}^T \exp\{\mathbf{C} \boldsymbol{\mu}_{q(\boldsymbol{\beta})} + \frac{1}{2} \text{diagonal}(\mathbf{C} \boldsymbol{\Sigma}_{q(\boldsymbol{\beta}, \mathbf{u})} \mathbf{C}^T)\} \\ \text{and } E_{q\{\log p(\boldsymbol{\beta}, \mathbf{u}|\sigma^2)\}} &= -\frac{1}{2}(p+K) \log(2\pi) - \frac{1}{2} p \log(\sigma_{\boldsymbol{\beta}}^2) \\ &\quad - \frac{1}{2} K \{\log\{B_{q(\sigma^2)}\} - \text{digamma}\{\frac{1}{2}(K+1)\}\} \\ &\quad - \frac{1}{2\sigma_{\boldsymbol{\beta}}^2} \left\{ \|\boldsymbol{\mu}_{q(\boldsymbol{\beta})}\|^2 + \text{tr}(\boldsymbol{\Sigma}_{q(\boldsymbol{\beta})}) \right\} \\ &\quad - \frac{1}{2} \mu_{q(1/\sigma^2)} \left\{ \|\boldsymbol{\mu}_{q(\boldsymbol{\mu})}\|^2 + \text{tr}(\boldsymbol{\Sigma}_{q(\boldsymbol{\mu})}) \right\} \end{aligned} \quad (54)$$

where $\mathbf{C} \equiv [\mathbf{X} \ \mathbf{Z}]$. The $(\boldsymbol{\beta}, \mathbf{u})$ -localized approximate marginal log-likelihood expression given by (29) follows immediately. An explicit expression for $\log p(q; \boldsymbol{\mu}_{q(\boldsymbol{\beta}, \mathbf{u})}, \boldsymbol{\Sigma}_{q(\boldsymbol{\beta}, \mathbf{u})})$, for use as a stopping criterion, can be formed by combining the relevant terms from (53) with those in (54).

A.4 Proof of (34)

In this proof, all appearances of D and H are assumed to be with respect to \mathbf{x} . Let

$$\mathbf{g}_{\text{NR}}(\mathbf{x}) \equiv \mathbf{x} - \{Hf(\mathbf{x})\}^{-1} Df(\mathbf{x})^T.$$

Then, using (52),

$$\begin{aligned} d\mathbf{g}_{\text{NR}}(\mathbf{x}) &= d\mathbf{x} + \{Hf(\mathbf{x})\}^{-1} \{dHf(\mathbf{x})\} \{Hf(\mathbf{x})\}^{-1} Df(\mathbf{x})^T \\ &\quad - \{Hf(\mathbf{x})\}^{-1} dDf(\mathbf{x})^T \\ &= d\mathbf{x} + \{Hf(\mathbf{x})\}^{-1} \text{vec}^{-1} [D\text{vec}\{Hf(\mathbf{x})\} d\mathbf{x}] \{Hf(\mathbf{x})\}^{-1} Df(\mathbf{x})^T \\ &\quad - \{Hf(\mathbf{x})\}^{-1} Hf(\mathbf{x}) d\mathbf{x} \\ &= \{Hf(\mathbf{x})\}^{-1} \text{vec} \left(\mathbf{I} \text{vec}^{-1} [D\text{vec}\{Hf(\mathbf{x})\} d\mathbf{x}] \{Hf(\mathbf{x})\}^{-1} Df(\mathbf{x})^T \right) \\ &= \{Hf(\mathbf{x})\}^{-1} \left([Df(\mathbf{x})\{Hf(\mathbf{x})\}^{-1}] \otimes \mathbf{I} \right) D\text{vec}\{Hf(\mathbf{x})\} d\mathbf{x}. \end{aligned}$$

Therefore

$$D\mathbf{g}_{\text{NR}}(\mathbf{x}) = \{Hf(\mathbf{x})\}^{-1} \left([Df(\mathbf{x})\{Hf(\mathbf{x})\}^{-1}] \otimes \mathbf{I} \right) D\text{vec}\{Hf(\mathbf{x})\}.$$

Since $Df(\mathbf{x}^*) = \mathbf{0}$, we get

$$D\mathbf{g}_{\text{NR}}(\mathbf{x}^*) = \mathbf{O},$$

where \mathbf{O} is the $d \times d$ matrix with all entries equal to zero, and (34) follows immediately.

A.5 Lemmas and Proofs Required for Results 1 and 2

Lemma 1 If

$$q(\mathbf{x}; \boldsymbol{\eta}) = \exp\{\mathbf{T}(\mathbf{x})^T \boldsymbol{\eta} - A(\boldsymbol{\eta})\} h(\mathbf{x})$$

is an exponential family density function then

$$D_{\boldsymbol{\eta}} \text{Entropy}\{q(\mathbf{x}; \boldsymbol{\eta})\} = -\boldsymbol{\eta}^T H_{\boldsymbol{\eta}} A(\boldsymbol{\eta}).$$

Proof of Lemma 1

Since

$$\text{Entropy}\{q(\mathbf{x}; \boldsymbol{\eta})\} = A(\boldsymbol{\eta}) - D_{\boldsymbol{\eta}} A(\boldsymbol{\eta}) \boldsymbol{\eta} - E[\log\{h(\mathbf{x})\}]$$

we then have

$$D_{\boldsymbol{\eta}} \text{Entropy}\{q(\mathbf{x}; \boldsymbol{\eta})\} = D_{\boldsymbol{\eta}} A(\boldsymbol{\eta}) - D_{\boldsymbol{\eta}} \{D_{\boldsymbol{\eta}} A(\boldsymbol{\eta}) \boldsymbol{\eta}\} = D_{\boldsymbol{\eta}} A(\boldsymbol{\eta}) - D_{\boldsymbol{\eta}} \{\boldsymbol{\eta}^T D_{\boldsymbol{\eta}} A(\boldsymbol{\eta})^T\}.$$

Next,

$$\begin{aligned} d\{\boldsymbol{\eta}^T D_{\boldsymbol{\eta}} A(\boldsymbol{\eta})^T\} &= (d\boldsymbol{\eta})^T D_{\boldsymbol{\eta}} A(\boldsymbol{\eta})^T + \boldsymbol{\eta}^T d\{D_{\boldsymbol{\eta}} A(\boldsymbol{\eta})^T\} \\ &= D_{\boldsymbol{\eta}} A(\boldsymbol{\eta}) d\boldsymbol{\eta} + \boldsymbol{\eta}^T D_{\boldsymbol{\eta}} \{D_{\boldsymbol{\eta}} A(\boldsymbol{\eta})^T\} d\boldsymbol{\eta} \\ &= \{D_{\boldsymbol{\eta}} A(\boldsymbol{\eta}) + \boldsymbol{\eta}^T H_{\boldsymbol{\eta}} A(\boldsymbol{\eta})\} d\boldsymbol{\eta} \end{aligned}$$

and so

$$D_{\boldsymbol{\eta}} \{\boldsymbol{\eta}^T D_{\boldsymbol{\eta}} A(\boldsymbol{\eta})^T\} = D_{\boldsymbol{\eta}} A(\boldsymbol{\eta}) + \boldsymbol{\eta}^T H_{\boldsymbol{\eta}} A(\boldsymbol{\eta}).$$

Hence,

$$D_{\boldsymbol{\eta}} \text{Entropy}\{q(\mathbf{x}; \boldsymbol{\eta})\} = D_{\boldsymbol{\eta}} A(\boldsymbol{\eta}) - \{D_{\boldsymbol{\eta}} A(\boldsymbol{\eta}) + \boldsymbol{\eta}^T H_{\boldsymbol{\eta}} A(\boldsymbol{\eta})\} = -\boldsymbol{\eta}^T H_{\boldsymbol{\eta}} A(\boldsymbol{\eta}).$$

Lemma 2 Let s be a differentiable scalar-valued function of $\mathbf{x} \in \mathbb{R}^d$ and let $\mathbf{u} \in \mathbb{R}^k$ be one-to-one transformation of \mathbf{x} . Then

$$D_{\mathbf{x}} s = (D_{\mathbf{u}} s) (D_{\mathbf{x}} \mathbf{u}).$$

Proof of Lemma 2

Lemma 2 is a restatement of Theorem 8, Chapter 5, of Magnus and Neudecker (1999).

Lemma 3 Let $\mathbf{x} \sim N(\boldsymbol{\mu}, \boldsymbol{\Sigma})$ have a d -dimensional Multivariate Normal distribution. The natural statistic is

$$\mathbf{T}(\mathbf{x}) = \begin{bmatrix} \mathbf{x} \\ \text{vech}(\mathbf{x}\mathbf{x}^T) \end{bmatrix}$$

and corresponding mean parameter is $\boldsymbol{\tau} \equiv E\{\mathbf{T}(\mathbf{x})\}$. Then

$$D_{\boldsymbol{\tau}} \begin{bmatrix} \boldsymbol{\mu} \\ \text{vec}(\boldsymbol{\Sigma}) \end{bmatrix} = \begin{bmatrix} \mathbf{I} & \mathbf{0} \\ -(\mathbf{I} + \mathbf{K}_d)(\boldsymbol{\mu} \otimes \mathbf{I}) & D_d \end{bmatrix}.$$

Proof of Lemma 3

The transformation from the common parameters to the mean parameters is

$$\boldsymbol{\tau} \equiv \begin{bmatrix} \boldsymbol{\tau}_1 \\ \boldsymbol{\tau}_2 \end{bmatrix} = \begin{bmatrix} \boldsymbol{\mu} \\ \text{vech}(\boldsymbol{\Sigma} + \boldsymbol{\mu}\boldsymbol{\mu}^T) \end{bmatrix}$$

and the inverse transformation is easily shown to be

$$\begin{bmatrix} \boldsymbol{\mu} \\ \text{vec}(\boldsymbol{\Sigma}) \end{bmatrix} = \begin{bmatrix} D_d \boldsymbol{\tau}_2 - \text{vec}(\boldsymbol{\tau}_1 \boldsymbol{\tau}_1^T) \\ \boldsymbol{\tau}_1 \end{bmatrix}.$$

Hence

$$D_{\boldsymbol{\tau}} \begin{bmatrix} \boldsymbol{\mu} \\ \text{vec}(\boldsymbol{\Sigma}) \end{bmatrix} = \begin{bmatrix} D_{\boldsymbol{\tau}_1} \boldsymbol{\mu} & D_{\boldsymbol{\tau}_2} \boldsymbol{\mu} \\ D_{\boldsymbol{\tau}_1, \text{vec}(\boldsymbol{\Sigma})} & D_{\boldsymbol{\tau}_2, \text{vec}(\boldsymbol{\Sigma})} \end{bmatrix} = \begin{bmatrix} \mathbf{I} & \mathbf{0} \\ -D_{\boldsymbol{\tau}_1, \text{vec}(\boldsymbol{\tau}_1 \boldsymbol{\tau}_1^T)} & D_d \end{bmatrix}.$$

To obtain an explicit expression for the bottom left-hand block we note that

$$d\text{vec}(\boldsymbol{\tau}_1 \boldsymbol{\tau}_1^T) = (\mathbf{I} + \mathbf{K}_d) \text{vec}\{d(\boldsymbol{\tau}_1) \boldsymbol{\tau}_1^T\}.$$

Then, with the help of (52),

$$\text{vec}\{d(\boldsymbol{\tau}_1) \boldsymbol{\tau}_1^T\} = \text{vec}\{\mathbf{I}(d\boldsymbol{\tau}_1) \boldsymbol{\tau}_1^T\} = (\boldsymbol{\tau}_1 \otimes \mathbf{I}) d\boldsymbol{\tau}_1.$$

Hence,

$$D_{\tau_1} \text{vec}(\Sigma) = (\mathbf{I} + \mathbf{K}_d)(\tau_1 \otimes \mathbf{I}) = (\mathbf{I} + \mathbf{K}_d)(\mu \otimes \mathbf{I})$$
and the lemma follows immediately.

Lemma 4 *Let*

$$\phi(\mathbf{x}; \mu, \Sigma) \equiv (2\pi)^{-d/2} |\Sigma|^{-1/2} \exp\left\{-\frac{1}{2}(\mathbf{x} - \mu)^T \Sigma^{-1} (\mathbf{x} - \mu)\right\}$$

denote the d -variate $N(\mu, \Sigma)$ density function. Then

$$\text{vec}^{-1}\left\{D_{\text{vec}(\Sigma)} \phi(\mathbf{x}; \mu, \Sigma)^T\right\} = \frac{1}{2} \mathbf{H}_\mu \phi(\mathbf{x}; \mu, \Sigma).$$

Proof of Lemma 4

First note that

$$(2\pi)^{d/2} \phi(\mathbf{x}; \mu, \Sigma) = |\Sigma|^{-1/2} \exp\left[-\frac{1}{2} \text{tr}\{(\mathbf{x} - \mu)(\mathbf{x} - \mu)^T \Sigma^{-1}\}\right].$$

Then, using the identity $\text{tr}(\mathbf{A}^T \mathbf{B}) = \text{vec}(\mathbf{A})^T \text{vec}(\mathbf{B})$,

$$\begin{aligned} (2\pi)^{d/2} d\Sigma \phi(\mathbf{x}; \mu, \Sigma) &= (d\Sigma |\Sigma|^{-1/2}) \exp\left[-\frac{1}{2} \text{tr}\{(\mathbf{x} - \mu)(\mathbf{x} - \mu)^T \Sigma^{-1}\}\right] \\ &\quad + |\Sigma|^{-1/2} \left(d\Sigma \exp\left[-\frac{1}{2} \text{tr}\{(\mathbf{x} - \mu)(\mathbf{x} - \mu)^T \Sigma^{-1}\}\right]\right) \\ &= -\frac{1}{2} |\Sigma|^{-3/2} \Sigma \left[\text{tr}(\Sigma^{-1} d\Sigma \Sigma) \exp\left[-\frac{1}{2} \text{tr}\{(\mathbf{x} - \mu)(\mathbf{x} - \mu)^T \Sigma^{-1}\}\right]\right] \\ &\quad + |\Sigma|^{-1/2} \exp\left[-\frac{1}{2} \text{tr}\{(\mathbf{x} - \mu)(\mathbf{x} - \mu)^T \Sigma^{-1}\}\right] \\ &\quad \times \left[-\frac{1}{2} \text{tr}\{(\mathbf{x} - \mu)(\mathbf{x} - \mu)^T d\Sigma \Sigma^{-1}\}\right] \\ &= -\frac{1}{2} (2\pi)^{d/2} \phi(\mathbf{x}; \mu, \Sigma) \text{vec}(\Sigma^{-1})^T d\text{vec}(\Sigma) \\ &\quad - \frac{1}{2} (2\pi)^{d/2} \phi(\mathbf{x}; \mu, \Sigma) \text{tr}\{(\mathbf{x} - \mu)(\mathbf{x} - \mu)^T \Sigma^{-1} (d\Sigma) \Sigma^{-1}\} \\ &= -\frac{1}{2} (2\pi)^{d/2} \phi(\mathbf{x}; \mu, \Sigma) \text{vec}(\Sigma^{-1})^T d\text{vec}(\Sigma) \\ &\quad + \frac{1}{2} (2\pi)^{d/2} \phi(\mathbf{x}; \mu, \Sigma) \text{vec}(\Sigma^{-1} (\mathbf{x} - \mu)(\mathbf{x} - \mu)^T \Sigma^{-1})^T d\text{vec}(\Sigma). \end{aligned}$$

Therefore, by Theorem 6, Chapter 5, of Magnus and Neudecker (1999),

$$D_{\text{vec}(\Sigma)} \phi(\mathbf{x}; \mu, \Sigma) = \frac{1}{2} \phi(\mathbf{x}; \mu, \Sigma) \text{vec}[\Sigma^{-1} \{(\mathbf{x} - \mu)(\mathbf{x} - \mu)^T \Sigma^{-1} - \mathbf{I}\}]^T.$$

Also,

$$\begin{aligned} |\Sigma|^{1/2} (2\pi)^{d/2} d\mu \phi(\mathbf{x}; \mu, \Sigma) &= \exp\left[-\frac{1}{2} \text{tr}\{(\mathbf{x} - \mu)(\mathbf{x} - \mu)^T \Sigma^{-1}\}\right] \\ &\quad \times \left[-\frac{1}{2} \text{tr}\{d\mu \{(\mathbf{x} - \mu)(\mathbf{x} - \mu)^T \Sigma^{-1}\}\right] \\ &= |\Sigma|^{1/2} (2\pi)^{d/2} \phi(\mathbf{x}; \mu, \Sigma) \text{tr}\{(\mathbf{x} - \mu)(d\mu)^T \Sigma^{-1}\} \\ &= |\Sigma|^{1/2} (2\pi)^{d/2} \phi(\mathbf{x}; \mu, \Sigma) \Sigma^{-1} (\mathbf{x} - \mu)^T d\mu \end{aligned}$$

which simplifies to

$$d\mu \phi(\mathbf{x}; \mu, \Sigma) = \phi(\mathbf{x}; \mu, \Sigma) \Sigma^{-1} (\mathbf{x} - \mu)^T d\mu.$$

The second differential with respect to μ is then

$$\begin{aligned} d_\mu^2 \phi(\mathbf{x}; \mu, \Sigma) &= \{d_\mu \phi(\mathbf{x}; \mu, \Sigma)\} \Sigma^{-1} (\mathbf{x} - \mu)^T d\mu + \phi(\mathbf{x}; \mu, \Sigma) \Sigma^{-1} (-d\mu)^T d\mu \\ &= \{\phi(\mathbf{x}; \mu, \Sigma) \Sigma^{-1} (\mathbf{x} - \mu)^T d\mu\} \Sigma^{-1} (\mathbf{x} - \mu)^T d\mu + \phi(\mathbf{x}; \mu, \Sigma) \Sigma^{-1} (-d\mu)^T d\mu \\ &= (d\mu)^T \left(\phi(\mathbf{x}; \mu, \Sigma) \Sigma^{-1} \{(\mathbf{x} - \mu)(\mathbf{x} - \mu)^T \Sigma^{-1} - \mathbf{I}\} \right) d\mu. \end{aligned}$$

Hence, using Theorem 6, Chapter 6, of Magnus and Neudecker (1999)

$$\mathbf{H}_\mu \phi(\mathbf{x}; \mu, \Sigma) = \phi(\mathbf{x}; \mu, \Sigma) \Sigma^{-1} \{(\mathbf{x} - \mu)(\mathbf{x} - \mu)^T \Sigma^{-1} - \mathbf{I}\} = 2 \text{vec}^{-1}\left\{D_{\text{vec}(\Sigma)} \phi(\mathbf{x}; \mu, \Sigma)^T\right\}.$$

A.6 Derivation of Result 2

To make the derivation less cumbersome we will suppress the subscripts on the mean μ and covariance matrix Σ . As in Wand (2014) we work with the natural statistic and natural parameter pair

$$\mathcal{T}(\phi) = \begin{bmatrix} \phi \\ \text{vech}(\phi \phi^T) \end{bmatrix} \quad \text{and} \quad \eta = \begin{bmatrix} \Sigma^{-1} \mu \\ -\frac{1}{2} D_d \text{vec}(\Sigma^{-1}) \end{bmatrix}.$$

The mean parameter vector is

$$\tau = E\{\mathcal{T}(\phi)\} = \begin{bmatrix} \mu \\ \text{vech}(\Sigma + \mu \mu^T) \end{bmatrix}.$$

In Lemma 3 in Appendix A.5 we show that

$$D_\tau \begin{bmatrix} \mu \\ \text{vec}(\Sigma) \end{bmatrix} = \begin{bmatrix} \mathbf{I} & \mathbf{0} \\ -(\mathbf{I} + \mathbf{K}_d)(\mu \otimes \mathbf{I}) & D_d \end{bmatrix}$$

and so Result 1(d) becomes

$$\begin{aligned} &\begin{bmatrix} \Sigma^{-1} \mu \\ -\frac{1}{2} D_d^T \text{vec}(\Sigma^{-1}) \end{bmatrix} \\ &= \begin{bmatrix} \mathbf{I} & -(\mu^T \otimes \mathbf{I})(\mathbf{I} + \mathbf{K}_d) \\ \mathbf{0} & D_d^T \end{bmatrix} \begin{bmatrix} D_\mu \text{NonEntropy}\{q(\phi; \mu, \Sigma)\}^T \\ D_{\text{vec}(\Sigma)} \text{NonEntropy}\{q(\phi; \mu, \Sigma)\}^T \end{bmatrix} \end{aligned} \quad (55)$$

where we have used the fact that $\mathbf{K}_d^T = \mathbf{K}_d$. Using (52), and the fact that $\text{vec}^{-1}[D_{\text{vec}(\Sigma)} \text{NonEntropy}\{q(\phi; \mu, \Sigma)\}^T]$

is symmetric, the first component of (55) is equivalent to

$$\begin{aligned}
& \Sigma^{-1} \mu = D_\mu \text{NonEntropy}\{q(\phi; \mu, \Sigma)\}^T \\
& \quad - (\mu^T \otimes \mathbf{I})(\mathbf{I} + \mathbf{K}_a) D_{\text{vec}(\Sigma)} \text{NonEntropy}\{q(\phi; \mu, \Sigma)\}^T \\
& = D_\mu \text{NonEntropy}\{q(\phi; \mu, \Sigma)\}^T \\
& \quad - 2(\mu^T \otimes \mathbf{I})(\mathbf{I} + \mathbf{K}_a) \text{vec}\left(\text{vec}^{-1}[D_{\text{vec}(\Sigma)} \text{NonEntropy}\{q(\phi; \mu, \Sigma)\}^T]\right) \\
& = D_\mu \text{NonEntropy}\{q(\phi; \mu, \Sigma)\}^T \\
& \quad - 2(\mu^T \otimes \mathbf{I}) \text{vec}\left(\text{vec}^{-1}[D_{\text{vec}(\Sigma)} \text{NonEntropy}\{q(\phi; \mu, \Sigma)\}^T]\right) \\
& = D_\mu \text{NonEntropy}\{q(\phi; \mu, \Sigma)\}^T \\
& \quad - 2 \text{vec}\left(\text{vec}^{-1}[D_{\text{vec}(\Sigma)} \text{NonEntropy}\{q(\phi; \mu, \Sigma)\}^T]\right) \mu \\
& = D_\mu \text{NonEntropy}\{q(\phi; \mu, \Sigma)\}^T \\
& \quad - 2 \text{vec}^{-1}[D_{\text{vec}(\Sigma)} \text{NonEntropy}\{q(\phi; \mu, \Sigma)\}^T] \mu.
\end{aligned} \tag{56}$$

The second component (55) is equivalent to

$$-\frac{1}{2} D_d^T \text{vec}(\Sigma) = D_d^T [D_{\text{vec}(\Sigma)} \text{NonEntropy}\{q(\phi; \mu, \Sigma)\}^T]$$

which, under the constraint that Σ is symmetric, is equivalent to

$$\Sigma^{-1} = -2 \text{vec}^{-1}[D_{\text{vec}(\Sigma)} \text{NonEntropy}\{q(\phi; \mu, \Sigma)\}^T]. \tag{57}$$

In view of relationships (56) and (57), the natural fixed-point iteration scheme becomes

$$\begin{cases} \Sigma_{\text{new}}^{-1} \mu_{\text{new}} = [D_\mu \text{NonEntropy}\{q(\phi; \mu, \Sigma)\}]^T_{\mu=\mu_{\text{old}}, \Sigma=\Sigma_{\text{old}}} \\ \quad - 2 \text{vec}^{-1}\left([D_{\text{vec}(\Sigma)} \text{NonEntropy}\{q(\phi; \mu, \Sigma)\}]^T_{\mu=\mu_{\text{old}}, \Sigma=\Sigma_{\text{old}}}\right) \mu_{\text{old}} \\ \Sigma_{\text{new}} = \left\{ -2 \text{vec}^{-1}\left([D_{\text{vec}(\Sigma)} \text{NonEntropy}\{q(\phi; \mu, \Sigma)\}]^T_{\mu=\mu_{\text{old}}, \Sigma=\Sigma_{\text{old}}}\right) \right\}^{-1} \end{cases}$$

where $(\mu_{\text{old}}, \Sigma_{\text{old}})$ and $(\mu_{\text{new}}, \Sigma_{\text{new}})$, respectively, denote the old and new values of (μ, Σ) . The following simplification ensues:

$$\begin{cases} \mu_{\text{new}} = \mu_{\text{old}} + \Sigma_{\text{new}} [D_\mu \text{NonEntropy}\{q(\phi; \mu, \Sigma)\}]^T_{\mu=\mu_{\text{old}}, \Sigma=\Sigma_{\text{old}}} \\ \Sigma_{\text{new}} = \left\{ -2 \text{vec}^{-1}\left([D_{\text{vec}(\Sigma)} \text{NonEntropy}\{q(\phi; \mu, \Sigma)\}]^T_{\mu=\mu_{\text{old}}, \Sigma=\Sigma_{\text{old}}}\right) \right\}^{-1} \end{cases}$$

which is equivalent to the following updating scheme:

$$\begin{cases} \mathbf{v} \leftarrow D_\mu \text{NonEntropy}\{q(\phi; \mu, \Sigma)\}^T \\ \Sigma \leftarrow \left(-2 \text{vec}^{-1}[D_{\text{vec}(\Sigma)} \text{NonEntropy}\{q(\phi; \mu, \Sigma)\}^T] \right)^{-1} \\ \mu \leftarrow \mu + \Sigma \mathbf{v} \end{cases} \tag{58}$$

as given in Wand (2014). However, from Lemma 4 in Appendix A.5 (see also Appendix A of Oppé and Archambeau, 2009) and the fact that $\text{NonEntropy}\{q(\phi; \mu, \Sigma)\}$ is an expectation with respect to the $N(\mu, \Sigma)$ density function we have

$$\text{vec}^{-1}[D_{\text{vec}(\Sigma)} \text{NonEntropy}\{q(\phi; \mu, \Sigma)\}^T] = \frac{1}{2} H_\mu \text{NonEntropy}\{q(\phi; \mu, \Sigma)\}$$

which leads to a somewhat more elegant alternative to (58) given in Result 2.

A.7 Derivation of the Derivative Matrix of g_{Ex2}

From Section 4.3, the fixed-point iteration updating function is of the form

$$g_{\text{Ex2}} \left(\begin{bmatrix} \mu \\ \text{vech}(\Sigma) \end{bmatrix} \right) \equiv \begin{bmatrix} g_{\text{Ex2}, \mu} \\ \text{vech}(\mathbf{G}_{\text{Ex2}, \Sigma}) \end{bmatrix}$$

where

$$\mathbf{G}_{\text{Ex2}, \Sigma} \equiv [\mathbf{C}^T \text{diag}\{\omega(\mu, \Sigma)\} \mathbf{C} + \mathbf{M}]^{-1},$$

$$g_{\text{Ex2}, \mu} \equiv \mu + \mathbf{G}_{\text{Ex2}, \Sigma} [\mathbf{C}^T \{y - \omega(\mu, \Sigma)\} - \mathbf{M} \mu]$$

$$\text{and } \omega(\mu, \Sigma) \equiv \exp\{\mathbf{C} \mu + \frac{1}{2} \text{diagonal}(\mathbf{C} \Sigma \mathbf{C}^T)\}.$$

Note that the dependence of $\mathbf{G}_{\text{Ex2}, \Sigma}$ and g_{Ex2} on y , \mathbf{C} and \mathbf{M} is suppressed here.

The derivative matrix of g_{Ex2} with respect to $[\mu, \text{vech}(\Sigma)]^T$ is

$$D \begin{bmatrix} \mu \\ \text{vech}(\Sigma) \end{bmatrix} g_{\text{Ex2}} = \begin{bmatrix} D_\mu g_{\text{Ex2}, \mu} & D_{\text{vech}(\Sigma)} g_{\text{Ex2}, \mu} \\ D_\mu \text{vech}(\mathbf{G}_{\text{Ex2}, \Sigma}) & D_{\text{vech}(\Sigma)} \text{vech}(\mathbf{G}_{\text{Ex2}, \Sigma}) \end{bmatrix}.$$

We now give explicit expressions for each of these four components of the derivative matrix. It is more efficient, notationally, to first obtain expressions for the derivatives of $\text{vech}(\mathbf{G}_{\text{Ex2}, \Sigma})$.

A.7.1 EXPRESSION FOR $D_\mu \text{vech}(\mathbf{G}_{\text{Ex2}, \Sigma})$

$$D_\mu \text{vech}(\mathbf{G}_{\text{Ex2}, \Sigma}) = -D_{p+K}^+ (\mathbf{G}_{\text{Ex2}, \Sigma} \otimes \mathbf{G}_{\text{Ex2}, \Sigma}) \mathbf{Q}(\mathbf{C})^T \text{diag}\{\omega(\mu, \Sigma)\} \mathbf{C} \tag{59}$$

Derivation:

Using the second rule in Section 3.3.5 of Wand (2002), (52) and (51),

$$\begin{aligned}
D_\mu \text{vech}(\mathbf{G}_{\text{Ex2}, \Sigma}) &= D_{p+K}^+ d_\mu \text{vec}\left([\mathbf{C}^T \text{diag}\{\omega(\mu, \Sigma)\} \mathbf{C} + \mathbf{M}\right]^{-1}) \\
&= -D_{p+K}^+ \text{vec}\left\{\mathbf{G}_{\text{Ex2}, \Sigma} \left(d_\mu [\mathbf{C}^T \text{diag}\{\omega(\mu, \Sigma)\} \mathbf{C} + \mathbf{M}]\right) \mathbf{G}_{\text{Ex2}, \Sigma}\right\} \\
&= -D_{p+K}^+ \left(\mathbf{G}_{\text{Ex2}, \Sigma} \otimes \mathbf{G}_{\text{Ex2}, \Sigma}\right) \text{vec}\left[\mathbf{C}^T \text{diag}\{d_\mu \omega(\mu, \Sigma)\} \mathbf{C}\right].
\end{aligned}$$

From Theorem 2(b) of Wand (2014),

$$\text{vec}[\mathbf{C}^T \text{diag}\{d_\mu \omega(\mu, \Sigma)\} \mathbf{C}] = \mathbf{Q}(\mathbf{C})^T d_\mu \omega(\mu, \Sigma).$$

Lastly, we use the chain rule in Section 3.3.2 of Wand (2002) to get

$$d_{\mu}\omega(\mu, \Sigma) = d_{\mu} \exp\{C\mu + \frac{1}{2} \text{diagonal}(C\Sigma C^T)\} = \text{diag}\{\omega(\mu, \Sigma)\} C d_{\mu}.$$

Combining, we then obtain

$$d_{\mu} \text{vec}(\mathbf{G}_{\text{Ex}2, \Sigma}) = -D_{p+K}^+ \left(\mathbf{G}_{\text{Ex}2, \Sigma} \otimes \mathbf{G}_{\text{Ex}2, \Sigma} \right) \mathbf{Q}(C)^T \text{diag}\{\omega(\mu, \Sigma)\} C d_{\mu}$$

and the stated expression then follow from Theorem 6, Chapter 5, of Magnus and Neudecker (1999).

A.7.2 EXPRESSION FOR $D_{\text{vech}(\Sigma)} \text{vech}(\mathbf{G}_{\text{Ex}2, \Sigma})$

$$\begin{aligned} D_{\text{vech}(\Sigma)} \text{vech}(\mathbf{G}_{\text{Ex}2, \Sigma}) &= -\frac{1}{2} D_{p+K}^+ (\mathbf{G}_{\text{Ex}2, \Sigma} \otimes \mathbf{G}_{\text{Ex}2, \Sigma}) \\ &\quad \times \mathbf{Q}(C)^T \text{diag}\{\omega(\mu, \Sigma)\} \mathbf{Q}(C) D_{p+K}. \end{aligned} \quad (60)$$

Derivation:

The derivation is similar to that for $D_{\mu} \mathbf{G}_{\text{Ex}2, \Sigma}$. It differs in that it requires $d_{\Sigma} \omega(\mu, \Sigma)$ rather than $d_{\mu} \omega(\mu, \Sigma)$. This entails

$$d_{\Sigma} \omega(\mu, \Sigma) = d_{\Sigma} \exp\{C\mu + \frac{1}{2} \text{diagonal}(C\Sigma C^T)\} = \frac{1}{2} \text{diag}\{\omega(\mu, \Sigma)\} d_{\Sigma} \text{diagonal}(C\Sigma C^T).$$

But Theorem 2(a) of Wand (2014) gives

$$d_{\Sigma} \text{diagonal}(C\Sigma C^T) = \mathbf{Q}(C) d_{\Sigma} \text{vec}(\Sigma) = \mathbf{Q}(C) D_{p+K} d_{\Sigma} \text{vech}(\Sigma)$$

which leads to the stated result.

A.7.3 EXPRESSION FOR $D_{\mu} \mathbf{g}_{\text{Ex}2, \mu}$

$$D_{\mu} \mathbf{g}_{\text{Ex}2, \mu} = (C^T \{y - \omega(\mu, \Sigma)\} - M\mu)^T \otimes I) D_{p+K} D_{\mu} \text{vech}(\mathbf{G}_{\text{Ex}2, \Sigma})$$

where $D_{\mu} \text{vech}(\mathbf{G}_{\text{Ex}2, \Sigma})$ is given by (59).

Derivation:

Using the second rule in Section 3.3.4 of Wand (2002) for differentiation of matrix products,

$$\begin{aligned} d_{\mu} \mathbf{g}_{\text{Ex}2, \mu} &= d_{\mu} + d_{\mu} \left(\mathbf{G}_{\text{Ex}2, \Sigma} [C^T \{y - \omega(\mu, \Sigma)\} - M\mu] \right) \\ &= d_{\mu} + (d_{\mu} \mathbf{G}_{\text{Ex}2, \Sigma}) [C^T \{y - \omega(\mu, \Sigma)\} - M\mu] \\ &\quad - \mathbf{G}_{\text{Ex}2, \Sigma} [C^T d_{\mu} \omega(\mu, \Sigma) + M d_{\mu}] \\ &= d_{\mu} + \text{vec}\{I (d_{\mu} \mathbf{G}_{\text{Ex}2, \Sigma}) [C^T \{y - \omega(\mu, \Sigma)\} - M\mu]\} \\ &\quad - \mathbf{G}_{\text{Ex}2, \Sigma} [C^T \text{diag}\{\omega(\mu, \Sigma)\} C + M] d_{\mu}. \end{aligned}$$

where we have used the fact that $(d_{\mu} \mathbf{G}_{\text{Ex}2, \Sigma}) [C^T \{y - \omega(\mu, \Sigma)\} - M\mu]$ is a column vector. Application of (52) leads to

$$\begin{aligned} d_{\mu} \mathbf{g}_{\text{Ex}2, \mu} &= d_{\mu} + ([C^T \{y - \omega(\mu, \Sigma)\} - M\mu]^T \otimes I) d_{\mu} \text{vec}(\mathbf{G}_{\text{Ex}2, \Sigma}) \\ &\quad - \mathbf{G}_{\text{Ex}2, \Sigma} [C^T \text{diag}\{\omega(\mu, \Sigma)\} C + M] d_{\mu} \\ &= \left\{ I + ([C^T \{y - \omega(\mu, \Sigma)\} - M\mu]^T \otimes I) D_{\mu} \text{vec}(\mathbf{G}_{\text{Ex}2, \Sigma}) \right. \\ &\quad \left. - \mathbf{G}_{\text{Ex}2, \Sigma} \mathbf{G}_{\text{Ex}2, \Sigma}^{-1} \right\} d_{\mu} \\ &= ([C^T \{y - \omega(\mu, \Sigma)\} - M\mu]^T \otimes I) D_{p+K} D_{\mu} \text{vech}(\mathbf{G}_{\text{Ex}2, \Sigma}) d_{\mu}. \end{aligned}$$

The given expression follows from Theorem 6, Chapter 5, of Magnus and Neudecker (1999).

A.7.4 EXPRESSION FOR $D_{\text{vech}(\Sigma)} \mathbf{g}_{\text{Ex}2, \mu}$

$$\begin{aligned} D_{\text{vech}(\Sigma)} \mathbf{g}_{\text{Ex}2, \mu} &= \left([C^T \{y - \omega(\mu, \Sigma)\} - M\mu]^T \otimes I \right) D_{p+K} D_{\text{vech}(\Sigma)} \text{vech}(\mathbf{G}_{\text{Ex}2, \Sigma}) \\ &\quad - \frac{1}{2} \mathbf{G}_{\text{Ex}2, \Sigma} C^T \text{diag}\{\omega(\mu, \Sigma)\} \mathbf{Q}(C) D_{p+K} \end{aligned}$$

where $D_{\text{vech}(\Sigma)} \text{vech}(\mathbf{G}_{\text{Ex}2, \Sigma})$ is given by (60).

Derivation:

Dealing with matrix products via the second rule in Section 3.3.4 of Wand (2002) we obtain

$$\begin{aligned} d_{\Sigma} \mathbf{g}_{\text{Ex}2, \mu} &= d_{\Sigma} \left(\mathbf{G}_{\text{Ex}2, \Sigma} [C^T \{y - \omega(\mu, \Sigma)\} - M\mu] \right) \\ &= (d_{\Sigma} \mathbf{G}_{\text{Ex}2, \Sigma}) [C^T \{y - \omega(\mu, \Sigma)\} - M\mu] \\ &\quad - \mathbf{G}_{\text{Ex}2, \Sigma} C^T d_{\Sigma} \omega(\mu, \Sigma) \\ &= \text{vec} \left(I (d_{\Sigma} \mathbf{G}_{\text{Ex}2, \Sigma}) [C^T \{y - \omega(\mu, \Sigma)\} - M\mu] \right) \\ &\quad - \frac{1}{2} \mathbf{G}_{\text{Ex}2, \Sigma} C^T \text{diag}\{\omega(\mu, \Sigma)\} \mathbf{Q}(C) d_{\text{vec}}(\Sigma) \\ &= ([C^T \{y - \omega(\mu, \Sigma)\} - M\mu]^T \otimes I) D_{p+K} d_{\text{vec}}(\mathbf{G}_{\text{Ex}2, \Sigma}) \\ &\quad - \frac{1}{2} \mathbf{G}_{\text{Ex}2, \Sigma} C^T \text{diag}\{\omega(\mu, \Sigma)\} \mathbf{Q}(C) D_{p+K} d_{\text{vec}}(\Sigma) \\ &= ([C^T \{y - \omega(\mu, \Sigma)\} - M\mu]^T \otimes I) \\ &\quad \times D_{p+K} D_{\text{vech}(\Sigma)} \text{vech}(\mathbf{G}_{\text{Ex}2, \Sigma}) d_{\text{vech}}(\Sigma) \\ &\quad - \frac{1}{2} \mathbf{G}_{\text{Ex}2, \Sigma} C^T \text{diag}\{\omega(\mu, \Sigma)\} \mathbf{Q}(C) D_{p+K} d_{\text{vec}}(\Sigma). \end{aligned}$$

Once again we call upon Theorem 6, Chapter 5, of Magnus and Neudecker (1999) to complete the derivation.

Abstract

We investigate the online version of Principle Component Analysis (PCA), where in each trial t the learning algorithm chooses a k -dimensional subspace, and upon receiving the next instance vector \mathbf{x}_t , suffers the “compression loss”, which is the squared Euclidean distance between this instance and its projection into the chosen subspace. When viewed in the right parameterization, this compression loss is linear, i.e. it can be rewritten as $\text{tr}(\mathbf{W}_t \mathbf{x}_t \mathbf{x}_t^\top)$, where \mathbf{W}_t is the parameter of the algorithm and the outer product $\mathbf{x}_t \mathbf{x}_t^\top$ (with $\|\mathbf{x}_t\| \leq 1$) is the instance matrix. In this paper we generalize PCA to arbitrary positive definite instance matrices \mathbf{X}_t with the linear loss $\text{tr}(\mathbf{W}_t \mathbf{X}_t)$.

We evaluate online algorithms in terms of their worst-case regret, which is a bound on the additional total loss of the online algorithm on all instances matrices over the compression loss of the best k -dimensional subspace (chosen in hindsight). We focus on two popular online algorithms for generalized PCA: the Gradient Descent (GD) and Matrix Exponentiated Gradient (MEG) algorithms. We show that if the regret is expressed as a function of the number of trials, then both algorithms are optimal to within a constant factor on worst-case sequences of positive definite instance matrices with trace norm at most one (which subsumes the original PCA problem with outer products). This is surprising because MEG is believed to be suboptimal in this case. We also show that when considering regret bounds as a function of a loss budget, then MEG remains optimal and strictly outperforms GD when the instance matrices are trace norm bounded.

Next, we consider online PCA when the adversary is allowed to present the algorithm with positive semidefinite instance matrices whose largest eigenvalue is bounded (rather than their trace which is the sum of their eigenvalues). Again we can show that MEG is optimal and strictly better than GD in this setting.

Keywords: online learning, regret bounds, expert setting, k -sets, PCA, Gradient Descent, Matrix Exponentiated Gradient algorithm

1. Introduction

In Principle Component Analysis (PCA), the data points $\mathbf{x}_t \in \mathbb{R}^n$ are projected / compressed onto a k -dimensional subspace. Such a subspace can be represented by its projection matrix \mathbf{P} which is a symmetric matrix in $\mathbb{R}^{n \times n}$ with k eigenvalues equal 1 and $n - k$

eigenvalues equal 0. The goal of *uncentered PCA* is to find the rank k projection matrix that minimizes the total *compression loss* $\sum_t \|\mathbf{P} \mathbf{x}_t - \mathbf{x}_t\|^2$, i.e. the sum of the squared Euclidean distances between the original and the projected data points. In *centered PCA* the goal is to minimize $\sum_t \|\mathbf{P}(\mathbf{x}_t - \boldsymbol{\mu}) - (\mathbf{x}_t - \boldsymbol{\mu})\|^2$ where \mathbf{P} is a projection matrix of rank k and $\boldsymbol{\mu} \in \mathbb{R}^n$ is a second mean parameter. For the sake of simplicity we focus on the optimal algorithms for uncentered PCA. However we believe that our results will essentially carry over to the centered case as was already partially done in Warmuth and Kuzmin (2008). Surprisingly, this loss can be written as a linear loss (Warmuth and Kuzmin, 2008):

$$\sum_t \|\mathbf{P} \mathbf{x}_t - \mathbf{x}_t\|^2 = \sum_t \|(\mathbf{P} - \mathbf{I}) \mathbf{x}_t\|^2 = \sum_t \mathbf{x}_t^\top (\mathbf{I} - \mathbf{P})^\top \mathbf{x}_t = \underbrace{\text{tr}((\mathbf{I} - \mathbf{P}) \sum_t \mathbf{x}_t \mathbf{x}_t^\top)}_{\mathbf{C}},$$

where in the 3rd equality we used the fact that $\mathbf{I} - \mathbf{P}$ is a projection matrix and therefore $(\mathbf{I} - \mathbf{P})^2 = \mathbf{I} - \mathbf{P}$. The final expression of the compression loss is linear in the projection matrix $\mathbf{P} - \mathbf{I}$ as well as the covariance matrix $\mathbf{C} = \sum_t \mathbf{x}_t \mathbf{x}_t^\top$. The projection matrix $\mathbf{P} - \mathbf{I}$ is a sum of $n - k$ outer products: $\mathbf{P} - \mathbf{I} = \sum_{i=1}^{n-k} \mathbf{u}_i \mathbf{u}_i^\top$, where the \mathbf{u}_i are unit length and orthogonal. The crucial point to note here is that the compression loss is *linear* in the projection matrix $\mathbf{P} - \mathbf{I}$ but not in the direction vectors \mathbf{u}_i .

The batch version of uncentered PCA is equivalent to finding the eigenvectors $\mathbf{u}_1, \dots, \mathbf{u}_k$ belonging to the k largest eigenvalues of the covariance matrix \mathbf{C} : if $\mathbf{P} = \sum_{i=1}^k \mathbf{u}_i \mathbf{u}_i^\top$ is the k dimensional projection matrix formed from these k eigenvectors, then $\mathbf{I} - \mathbf{P}$ is the complementary $n - k$ dimensional projection matrix minimizing the linear loss $\text{tr}((\mathbf{I} - \mathbf{P})\mathbf{C})$.

In this paper we consider the online version of uncentered PCA (Warmuth and Kuzmin, 2008), where in each trial $t = 1, \dots, T$, the algorithm chooses (based on the previously observed points $\mathbf{x}_1, \dots, \mathbf{x}_{t-1}$) a subspace of dimension k described by its projection matrix \mathbf{P}_t of rank k . Then a next point \mathbf{x}_t (or instance matrix $\mathbf{x}_t \mathbf{x}_t^\top$) is revealed and the algorithm suffers the *compression loss*:

$$\|\mathbf{x}_t - \mathbf{P}_t \mathbf{x}_t\|^2 = \text{tr}((\mathbf{I} - \mathbf{P}_t) \mathbf{x}_t \mathbf{x}_t^\top). \quad (1.1)$$

The goal here is to obtain an online algorithm whose cumulative loss over trials $t = 1, \dots, T$ is close to the cumulative loss of the best rank k projection matrix chosen in hindsight after seeing all T instances. The maximum difference between the cumulative loss of the algorithm and the best off-line comparator is called the (worst-case) *regret*. This regret naturally scales with the maximum square L_2 -norm of the data points \mathbf{x}_t . For the sake of simplicity we assume that all points have L_2 -norm bounded by one, i.e. $\|\mathbf{x}_t\| \leq 1$ for all t . In the paper we find the optimal algorithm for online PCA (and some generalizations), where optimal here means that the upper bounds we prove for the regret of the algorithm is at most a constant factor larger than the lower bound we can prove for the learning problem.

There are two main families of algorithms in online learning, which differ in how the parameter vector/matrix is updated: the Gradient Descent (GD) family (Cesa-Bianchi et al., 1996; Kivinen and Warmuth, 1997; Zinkevich, 2003) and the Exponentiated Gradient (EG) family (Kivinen and Warmuth, 1997). The updated parameters of both families of algorithms are solutions to certain minimization problems which trade off a divergence to

*. A preliminary version of this paper appeared in the 24th International Conference on Algorithmic Learning Theory (2013) (Nie et al., 2013).

the last parameter against the loss on the current instance. The GD family uses the squared Euclidean distance divergence in the trade-off, whereas the Exponentiated Gradient (EG) family is motivated by the relative entropy divergence (Kivinen and Warmuth, 1997). The first family leads to *additive updates* of the parameter vector/matrix. When there are no constraints on the parameter space, then the parameter vector/matrix of the GD family is a linear combination of the instances. However when there are constraints, then after the update the parameter is projected onto the constraints (by a Bregman projection with respect to the squared Euclidean distance). The second family leads to *multiplicative update* algorithms. For that family, the components of the parameter are non-negative and if the parameter space consists of probability vectors, then the non-negativity is already enforced by the relative entropy divergence and less projections are needed.

What is the best parameter space for uncentered PCA? The compression loss (1.1) is linear in the projection matrix $\mathbf{I} - \mathbf{P}_t$ which is of rank $n - k$. An online algorithm has uncertainty over the best projection matrix. Therefore the parameter matrix \mathbf{W}_t of the algorithm is a mixture of such matrices (Warmuth and Kuzmin, 2008) which must be a positive semi-definite matrix of trace $n - k$ whose eigenvalues are capped at 1. The algorithm chooses its projection matrix $\mathbf{I} - \mathbf{P}_t$ by sampling from this mixture \mathbf{W}_t , i.e. $\mathbb{E}[\mathbf{I} - \mathbf{P}_t] = \mathbf{W}_t$. The loss of the algorithm is $\text{tr}((\mathbf{I} - \mathbf{P}_t) \mathbf{x}_t \mathbf{x}_t^\top)$ and its expected loss $\text{tr}(\mathbf{W}_t \mathbf{x}_t \mathbf{x}_t^\top)$.

In Warmuth and Kuzmin (2008), a matrix version of the multiplicative update was applied to PCA, whose regret bound is logarithmic in the dimension n . This algorithm uses the quantum relative entropy in its motivation and is called the *Matrix Exponentiated Gradient* (MEG) algorithm (Tsuda et al., 2005). It does a matrix version of a multiplicative update and then projects onto the “trace equal $n - k$ ” and the “capping” constraints (Here the projections are with respect to the quantum relative entropy).

For the PCA problem, the (expected) loss of the algorithm at trial t is $\text{tr}(\mathbf{W}_t \mathbf{x}_t \mathbf{x}_t^\top)$. Consider the generalization to the loss $\text{tr}(\mathbf{W}_t \mathbf{X}_t)$ where now \mathbf{X}_t is any positive semi-definite symmetric instance matrix and the parameter \mathbf{W}_t is still a convex combination of rank $n - k$ dimensional projection matrices, i.e. $\mathbf{W}_t = \mathbb{E}[\mathbf{I} - \mathbf{P}_t]$ where \mathbf{P}_t is the rank k projection matrix chosen by the algorithm at trial t . The linear loss $\text{tr}(\mathbb{E}[\mathbf{I} - \mathbf{P}_t] \mathbf{X}_t)$ still has a meaning in terms of a compression loss: For any decomposition of \mathbf{X}_t into a linear combination of outer products, i.e. $\mathbf{X}_t = \sum_{q=1}^n \lambda_q \mathbf{z}_q \mathbf{z}_q^\top$ (where the λ_q may be positive or negative and the $\mathbf{z}_q \in \mathbf{R}^n$ don’t have to be orthogonal) we have

$$\text{tr}((\mathbf{I} - \mathbf{P}_t) \mathbf{X}_t) = \sum_q \lambda_q \text{tr}((\mathbf{I} - \mathbf{P}_t) \mathbf{z}_q \mathbf{z}_q^\top) = \sum_q \lambda_q \|\mathbf{z}_q - \mathbf{P}_t \mathbf{z}_q\|^2. \quad (1.2)$$

In this paper we analyze our algorithm for two classes of positive definite instance matrices. Recall that in the vanilla PCA problem the instance matrices are the outer products, i.e. $\mathbf{X}_t = \mathbf{x}_t \mathbf{x}_t^\top$, where $\|\mathbf{x}_t\| \leq 1$. Such instance matrices have a “sparse spectrum” in the sense that they have at most one non-zero eigenvalue. Our first class consists of the convex hull of outer products of length at most one or equivalently all positive semidefinite matrices of trace norm at most one. We call this class L_1 -*bounded* instance matrices. The most important fact to remember is that the case of L_1 -bounded instances contains vanilla PCA with outer product instances as a special case.

Beginning with some of the early work on linear regression (Kivinen and Warmuth, 1997), it is known that multiplicative updates are especially useful when the non-negative

instance vectors are allowed to be “dense”, i.e. their maximum component is bounded by say one but it could contain many components of size up to one. In the matrix context this means that the symmetric positive semi-definite instance matrices \mathbf{X}_t have maximum eigenvalue (or spectral norm) at most one and are thus “spectrally dense”. We call this second class L_∞ -*bounded* instance matrices.

We will show that MEG is optimal for L_∞ -bounded instance matrices and GD is sub-optimal in this case. However for L_1 -bounded instances one might suspect that MEG is not able to fully exploit the spectral sparsity. For example, in the case of linear regression GD is known to have the advantage when the instance vectors¹ have bounded L_2 norm (Kivinen and Warmuth, 1997) and consistently with that, when GD is used for PCA with L_1 -bounded instance matrices, then its regret is bounded by a term that is *independent* of the dimension of the instances. The advantage of GD in the spectrally sparse case is also supported by a general survey of Mirror Descent algorithms (to which GD and MEG belong) for the case when the gradient vectors of the convex loss functions (which may have negative components) lie in certain symmetric norm balls (Srebro et al., 2011). Again when the gradient vectors of the losses are sparse, then GD has the advantage.

Surprisingly, the situation is quite different for PCA: We show that MEG achieves the same regret bound as GD for online PCA with L_1 -bounded instances matrices (despite the spectral sparseness) and the regret bounds for both algorithms are within a constant factor of a new lower bound proved in this paper that holds for any algorithm for PCA with L_1 -bounded instance matrices. This surprising performance of MEG seems to come from the fact that gradients \mathbf{X}_t of the linear loss $\text{tr}(\mathbf{W}_t \mathbf{X}_t)$ of our generalized online PCA problem are restricted to be non-negative. Therefore our results are qualitatively different from the cases studied in Srebro et al. (2011) where the gradients of the loss functions are within a p -norm ball, i.e. symmetric around zero.

Actually, there are two kinds of regret bounds in the literature: bounds expressed as a function of the time horizon T and bounds that depend on an *upper bound* on the loss of the best comparator (which we call a *loss budget* following Aberkane et al. (2008)). In typical applications for PCA, there exists a low dimensional subspace which captures most of the variance in the data and the compression loss is small. Therefore, guarding against the worst-case loss that grows with the number of trials T is overly pessimistic. We can show that when considering regret bounds as a function of a loss budget, MEG is optimal and strictly better than GD by a factor of \sqrt{n} . This suggests that the multiplicative updates algorithm is the best choice for prediction problems in which the parameters are mixtures of projection matrices and the gradients of the losses are non-negative. Note that in this paper we call an algorithm *optimal* for a particular problem if we can prove an upper bound on its worst-case regret that is within a constant factor of the lower bound for the problem (which must hold for any algorithm).

1.1 Related Work and Our Contribution:

The comparison of the GD and MEG algorithms has an extensive history (see, e.g. Kivinen and Warmuth (1997); Warmuth and Vishwanathan (2005); Sridharan and Tewari (2010); Srebro et al. (2011)). It is simplest to compare algorithms in the case when the loss is

¹ Note that for $\mathbf{x} \in \mathbf{R}^n$, $\|\mathbf{x}\|_\infty \leq \|\mathbf{x}\|_2 \leq \|\mathbf{x}\|_1$.

linear. Linear losses are the least convex losses and in the regret bounds, convex losses are often approximated by first-order Taylor approximations which are linear, and the gradient of the loss function serves as the linear “loss/gain vector” (Kivinen and Warmuth, 1997; Zinkevich, 2003). In this case it is often assumed that the gradient of the loss lies in an L_p ball (which is a symmetric constraint) and the results are as expected: EG is optimal when the parameter space is L_1 -bounded and the gradient vectors are L_∞ -bounded, and GD is optimal when the both spaces are L_2 -bounded (Sridharan and Tewari, 2010; Strebrot et al., 2011).

In contrast for PCA, the gradient of the loss $\text{tr}(\mathbf{W}_t \mathbf{X}_t)$ is the instance matrix \mathbf{X}_t which is assumed to be positive semi-definite. None of the previous work exploits this special property of the PCA setup, where the gradient of the loss satisfies some non-negativity property. In this paper we carefully study this case and show that MEG is optimal.

We also made significant technical progress on the lower bounds for online PCA. The previous lower bounds (Warmuth and Kuzmin (2008) and Koolen et al. (2010)) were incomplete in the following three ways: First, the lower bounds only apply to the case of L_∞ -bounded instances and not to the more restricted case of L_1 -bounded instances. Second, the previous lower bounds assume that the dimension k of target subspace is at least $\frac{n}{2}$ and in common PCA problems, k is much smaller than $\frac{n}{2}$. Third, the proofs rely on the Central Limit Theorem and therefore the resulting lower bounds only hold in the limit as T and n go to infinity (See Cesa-Bianchi et al. (1997); Cesa-Bianchi and Lugosi (2006); Abernethy et al. (2009) for details). In this paper, we circumvent all three weak aspects of the previous proofs: We give lower bounds for all four combinations of L_1 or L_∞ -bounded instance matrices versus $k \leq \frac{n}{2}$ or $k \geq \frac{n}{2}$, respectively. All our lower bounds are non-asymptotic, i.e. they hold for all values of the variables T and n . The new lower bounds use a novel probabilistic bounding argument for the minimum of n random variables. Alternate methods for obtaining non-asymptotic lower bound for label efficient learning problems in the expert setting were given in (Audibert and Bubeck, 2010). However those techniques are more complicated and it is not clear how to adapt them to the online PCA problem.

In summary, our contribution consists of proving tight upper bounds on the regret of the two main online PCA algorithms, as well as proving lower bounds on the regret of any algorithm for solving online PCA. For the case when the regret is expressed as a function of the number of trials T , we show that MEG’s and GD’s regret bounds are independent of the dimension n of the problem and are within a constant factor of the lower bound on the regret of any online PCA algorithm. This means the both algorithms are optimal in this case. For the case when the regret is a function of the loss budget, we prove that MEG remains optimal, while we show that the regret of GD is suboptimal by a \sqrt{k} factor.

Furthermore, for the generalization of the PCA with L_∞ -bounded instance matrices, we improve the known regret bound significantly by switching from a loss version to a gain version of MEG depending on the dimension k of the subspace. If $k \geq \frac{n}{2}$, then the gain version of MEG is optimal for L_∞ -bounded instances, and when $k \leq \frac{n}{2}$, then the loss version is optimal. On the other hand, GD is non-optimal for both ranges of k .

A much shorter preliminary version of this manuscript appeared in the 24th International Conference on Algorithmic Learning Theory (2013) (Nie et al., 2013). In this more detailed journal version we give more background and complete proofs of all of our results (mostly omitted or only sketched in the conference version). This paper also has the following

additional material: A proof of the budget bound (3.5) for the gain version of MEG; an extension of the lower bound on the regret of GD (Theorem 4.1) to the case of small budgets; the analysis of the Follow the Regularized Leader variant of GD (Section 4.2) and a discussion of its final parameter matrix (Appendix E); lower bounds on the regret when the number of trials is small (Appendix G).

1.2 Outline of the Paper:

In Section 2, we start with describing the MEG and GD algorithms for online PCA. In particular, we present two versions of the MEG algorithm: the Loss MEG algorithm introduced in (Warmuth and Kuzmin, 2008), and the Gain MEG algorithm, which is the same as Loss MEG except for a sign change in the exponential. Following the description of each algorithm, we then derive in Section 3 their regret bounds expressed as functions of the number of trials T . These bounds are compared in Section 3.2 for all four combinations of L_1 or L_∞ -bounded instance matrices versus $k \leq \frac{n}{2}$ or $k \geq \frac{n}{2}$, respectively (see Table 3.2). Next we consider regret bounds expressed as functions of the loss budget. In Section 4, we prove a lower bound on GD’s regret which shows that the regret of GD is at least \sqrt{k} times larger than the regret of Loss EG. A similar lower bound is proved for the Follow the Regularized Leader variant of GD in Section 4.2. In Section 5 we prove lower bounds for online PCA with L_1 and L_∞ -bounded instances that hold for any online algorithm, and in Section 6 we conclude with a summary of which algorithms are optimal.

2. The Online Algorithms

Online uncentered PCA uses the following protocol in each trial $t = 1, \dots, T$: the algorithm probabilistically chooses a projection matrix $\mathbf{P}_t \in \mathbb{R}^{n \times n}$ of rank k . Then a point $\mathbf{x}_t \in \mathbb{R}^n$ is received and the algorithm suffers the loss $\text{tr}((\mathbf{I} - \mathbf{P}_t)\mathbf{x}_t\mathbf{x}_t^T)$.

We also consider the generalization where the instance matrix is any positive definite matrix \mathbf{X}_t instead of an outer product $\mathbf{x}_t\mathbf{x}_t^T$. In that case the loss of the algorithm is $\text{tr}((\mathbf{I} - \mathbf{P}_t)\mathbf{X}_t)$. As discussed in the introduction (e.g. Equation (1.2)), this linear loss has a compression loss interpretation. It is “complementary” to the gain $\text{tr}(\mathbf{P}_t\mathbf{X}_t)$, i.e.

$$\underbrace{\text{tr}((\mathbf{I} - \mathbf{P}_t)\mathbf{X}_t)}_{\text{loss}} = \underbrace{\text{tr}(\mathbf{X}_t)}_{\text{constant}} - \underbrace{\text{tr}(\mathbf{P}_t\mathbf{X}_t)}_{\text{gain}}$$

and the $n - k$ dimensional projection matrix $\mathbf{I} - \mathbf{P}_t$ is “complementary” to the k dimensional projection matrix \mathbf{P}_t . These two complementations are inherent to our problem and will be present throughout the paper.

In the above protocol, the algorithm is allowed to choose its k dimensional subspace \mathbf{P}_t probabilistically. Therefore we use the expected compression loss $\mathbb{E}[\text{tr}((\mathbf{I} - \mathbf{P}_t)\mathbf{X}_t)]$ as the loss of the algorithm. The regret of the algorithm is then the difference between its cumulative loss and the loss of the best k subspace:

$$\mathcal{R} = \sum_{t=1}^T \mathbb{E}[\text{tr}((\mathbf{I} - \mathbf{P}_t)\mathbf{X}_t)] - \min_{\mathbf{P} \text{ projection matrix of rank } k} \sum_{t=1}^T \text{tr}((\mathbf{I} - \mathbf{P})\mathbf{X}_t).$$

The regret can also be rewritten in terms of gain, but this gives the same value of the regret. Therefore, throughout the paper we use (expected) losses and “loss” regrets (as defined above) to evaluate the algorithms.

Now we rewrite the loss of the algorithm as $\text{tr}(\mathbb{E}[\mathbf{I} - \mathbf{P}_t] \mathbf{X}_t)$ which shows that for any random prediction \mathbf{P}_t of rank k , this loss is fully determined by $\mathbb{E}[\mathbf{I} - \mathbf{P}_t]$, a convex combination of rank $m = n - k$ projection matrices. Hence it is natural to choose the set \mathcal{W}_m of convex combinations of rank m projection matrices as the parameter set of the algorithm. By the definition of projection matrices, \mathcal{W}_m is the set of positive semi-definite matrices of trace m and eigenvalues not larger than 1. The current parameter $\mathbf{W}_t \in \mathcal{W}_m$ of the online algorithm expresses its “uncertainty” about which subspace of rank m is best for the online data stream seen so far and the (expected) loss in trial t becomes $\text{tr}(\mathbf{W}_t \mathbf{X}_t)$. Alternatively, the complementary set \mathcal{W}_k of rank k projection matrices can be used as the parameter set (in that case the loss is $\text{tr}((\mathbf{I} - \mathbf{W}_t) \mathbf{X}_t)$). As discussed, there is a one-to-one correspondence between the two parameter sets: Given $\mathbf{W} \in \mathcal{W}_k$, then $\mathbf{I} - \mathbf{W}$ is the corresponding convex combination in \mathcal{W}_m .

The second reason why convex combinations are natural parameter spaces is that since the loss is linear, the convex combination with the minimum loss occurs at a “pure” projection matrix, i.e.

$$\begin{aligned} \min_{\mathbf{W} \in \mathcal{W}_m} \sum_{t=1}^T \text{tr}(\mathbf{W} \mathbf{X}_t) &= \min_{\substack{\mathbf{P} \\ \text{matrix of rank } k}} \sum_{t=1}^T \text{tr}((\mathbf{I} - \mathbf{P}) \mathbf{X}_t) \quad \text{and} \\ \min_{\mathbf{W} \in \mathcal{W}_k} \sum_{t=1}^T \text{tr}((\mathbf{I} - \mathbf{W}) \mathbf{X}_t) &= \min_{\substack{\mathbf{P} \\ \text{matrix of rank } k}} \sum_{t=1}^T \text{tr}(\mathbf{I} - \mathbf{P}) \mathbf{X}_t. \end{aligned} \quad (2.1)$$

Our protocol requires the algorithm to predict with a rank k projection matrix. Therefore, given a parameter matrix \mathbf{W}_t in say \mathcal{W}_m , the online algorithm still needs to produce a random projection matrix \mathbf{P}_t of rank k at the beginning of trial t such that $\mathbb{E}[\mathbf{I} - \mathbf{P}_t] = \mathbf{W}_t$. A simple greedy algorithm for achieving this is given in (Warmuth and Kuzmin, 2008) (Algorithm 2) which efficiently decomposes \mathbf{W}_t into a convex combination of up to n projection matrices of rank m in general, followed by a *mixture decomposition* of \mathbf{W}_t , which has $O(n^3)$ time complexity in general, followed by a *mixture decomposition* of the eigenvalues which runs in $O(n^2)$ time). Using the mixture coefficients it is now easy to sample a projection matrix $\mathbf{I} - \mathbf{P}_t$ from parameter matrix \mathbf{W}_t .

We now motivate the two main online algorithms used in this paper: the GD and MEG algorithms. The GD algorithm is straightforward and the MEG algorithm was introduced in Tsuda et al. (2005). Both are examples of the *Mirror Descent* family of algorithms developed much earlier in the area of convex optimization (Nemirovski and Yudin, 1978). The Mirror Descent algorithms update their parameter by minimizing a trade-off function of a divergence between the new and old parameter and the loss of the new parameter on the current instance, while constraining the new parameter to lie in the parameter set.

For the problem of online PCA, the update specializes into the following two versions depending on the choice of the parameter set:

Loss update on parameter set \mathcal{W}_m (i.e., $\mathbf{W}_{t+1}, \mathbf{W}, \mathbf{W}_t \in \mathcal{W}_m$):

$$\mathbf{W}_{t+1} = \underset{\mathbf{W} \in \mathcal{W}_m}{\text{argmin}} (\Delta(\mathbf{W}, \mathbf{W}_t) + \eta \text{tr}(\mathbf{W} \mathbf{X}_t)). \quad (2.2)$$

Gain update on parameter set \mathcal{W}_k (i.e., $\mathbf{W}_{t+1}, \mathbf{W}, \mathbf{W}_t \in \mathcal{W}_k$):

$$\begin{aligned} \mathbf{W}_{t+1} &= \underset{\mathbf{W} \in \mathcal{W}_k}{\text{argmin}} (\Delta(\mathbf{W}, \mathbf{W}_t) + \eta \text{tr}((\mathbf{I} - \mathbf{W}) \mathbf{X}_t)) \\ &= \underset{\mathbf{W} \in \mathcal{W}_k}{\text{argmin}} (\Delta(\mathbf{W}, \mathbf{W}_t) - \eta \text{tr}(\mathbf{W} \mathbf{X}_t)). \end{aligned} \quad (2.3)$$

Here $\Delta(\mathbf{W}, \mathbf{W}_t)$ is the motivating Bregman divergence that will be different for the MEG and GD algorithms. The *Loss update* minimizes a trade-off with the expected loss $\text{tr}(\mathbf{W} \mathbf{X}_t)$ which is a matrix version of the dot loss used for motivating the Hedge algorithm (Freund and Schapire, 1995). Note that in the *gain* version, minimizing the loss $-\text{tr}(\mathbf{W} \mathbf{X}_t)$ is the same as maximizing the gain $\text{tr}(\mathbf{W} \mathbf{X}_t)$. Recall that there is a one-to-one correspondence between \mathcal{W}_m and \mathcal{W}_k , i.e. \mathbf{I} minus a parameter in \mathcal{W}_m gives the corresponding parameter in \mathcal{W}_k and vice versa. Therefore, one can for example rewrite the Gain update (2.3) with the parameter set \mathcal{W}_m as well:

$$\widetilde{\mathbf{W}}_{t+1} = \underset{\mathbf{W} \in \mathcal{W}_m}{\text{argmin}} (\Delta(\mathbf{I} - \mathbf{W}, \mathbf{I} - \widetilde{\mathbf{W}}_t) + \eta \text{tr}(\mathbf{W} \mathbf{X}_t)), \quad (2.4)$$

where the above solution $\widetilde{\mathbf{W}}_{t+1} \in \mathcal{W}_m$ of the Gain update is related to the solution $\mathbf{W}_{t+1} \in \mathcal{W}_k$ of (2.3) by the same complementary relationship, i.e. $\widetilde{\mathbf{W}}_{t+1} = \mathbf{I} - \mathbf{W}_{t+1}$, for $t = 1, \dots, T$. Notice that the Loss update is motivated by the divergence $\Delta(\mathbf{W}, \mathbf{W}_t)$ on parameter space \mathcal{W}_m (2.2). On the other hand, when the Gain update is formulated with parameter \mathcal{W}_m , then it is motivated by the divergence $\Delta(\mathbf{I} - \mathbf{W}, \mathbf{I} - \widetilde{\mathbf{W}}_t)$ (2.4).

Now we define the GD and MEG algorithms for online PCA. For the GD algorithm, the motivating Bregman divergence is the squared Frobenius norm between the old and new parameters: $\Delta(\mathbf{W}, \mathbf{W}_t) = \frac{1}{2} \|\mathbf{W} - \mathbf{W}_t\|_F^2$ (Kivinen and Warmuth, 1997; Zinkevich, 2003). With this divergence, the Loss update is solved in the following two steps:

$$\begin{aligned} \text{GD update:} \quad & \text{Descent step:} \quad \widehat{\mathbf{W}}_{t+1} = \mathbf{W}_t - \eta \mathbf{X}_t, \\ & \text{Projection step:} \quad \mathbf{W}_{t+1} = \underset{\mathbf{W} \in \mathcal{W}_m}{\text{argmin}} \|\mathbf{W} - \widehat{\mathbf{W}}_{t+1}\|_F^2. \end{aligned} \quad (2.5)$$

Note, that the split into two steps happens whenever a Bregman divergence is traded off with a linear loss and domain is convex (See Helmbold and Warmuth (2009), Section 5.2, for a discussion). For the squared Frobenius norm, the Gain update is equivalent to the Loss update, since when formulating both updates on parameter set \mathcal{W}_m , then the divergence $\|\mathbf{W} - \mathbf{W}_t\|_F^2$ of the Loss update (2.2) and the divergence $\|(\mathbf{I} - \mathbf{W}) - (\mathbf{I} - \mathbf{W}_t)\|_F^2$ of the Gain update (2.4) are the same. A procedure for projecting $\widehat{\mathbf{W}}_{t+1}$ into \mathcal{W}_m with respect to the squared Frobenius norm is given in Algorithm 2 of Arora et al. (2013). The expensive part of this procedure is obtaining the eigendecomposition of $\widehat{\mathbf{W}}_{t+1}$.

The MEG algorithm uses the (un-normalized) quantum relative entropy $\Delta(\mathbf{W}, \mathbf{W}_t) = \text{tr}(\mathbf{W} (\log \mathbf{W} - \log \mathbf{W}_t) + \mathbf{W}_t - \mathbf{W})$ as its motivating Bregman divergence (Tsuda et al.,

T	Number of trials
n	Dimension of data points $\mathbf{x}_t \in \mathbb{R}^n$ and instance matrices $\mathbf{X}_t \in \mathbb{R}^{n \times n}$
k	Rank of the subspace of PCA into which the data is projected
m	Complement of k , $m = n - k$ (used for the rank of subspace of Loss MEG)
L_1 -bounded instances	positive semi-definite matrices \mathbf{X}_t s.t. $\text{tr}(\mathbf{X}_t) \leq 1$ (subsumes the special case when the \mathbf{X}_t are of the form $\mathbf{x}_t \mathbf{x}_t^\top$, w. $\ \mathbf{x}_t\ \leq 1$)
L_∞ -bounded instances	positive semi-definite matrices \mathbf{X}_t with spectral norm at most one, that is $\lambda_{\max}(\mathbf{X}_t) \leq 1$
B_L	Upper bound on loss of best subspace of rank $n - k$, c.f. (3.1)
B_G	Upper bound on gain of best subspace of rank k , c.f. (3.2).

Table 3.1: Summary of various symbols and terms used in Section 3.

2005) which is based on the matrix logarithm \log . With this divergence the solutions to the Loss update (2.2) and Gain update (2.3) are the following expressions which make use of the matrix exponential \exp (the inverse of \log):

$$\begin{aligned} \text{Loss MEG update:} \quad & \widehat{\mathbf{W}}_{t+1} = \exp(\log \mathbf{W}_t - \eta \mathbf{X}_t), & (2.6) \\ \text{Projection step:} \quad & \mathbf{W}_{t+1} = \underset{\mathbf{W} \in \mathbf{W}_m}{\text{argmin}} \Delta(\mathbf{W}, \widehat{\mathbf{W}}_{t+1}). \end{aligned}$$

$$\begin{aligned} \text{Gain MEG update:} \quad & \widehat{\mathbf{W}}_{t+1} = \exp(\log \mathbf{W}_t + \eta \mathbf{X}_t), & (2.7) \\ \text{Projection step:} \quad & \mathbf{W}_{t+1} = \underset{\mathbf{W} \in \mathbf{W}_k}{\text{argmin}} \Delta(\mathbf{W}, \widehat{\mathbf{W}}_{t+1}). \end{aligned}$$

Note that the only difference between the gain and loss versions of MEG is a sign flip in the exponential. The projection steps in the algorithms are with respect to the quantum relative entropy. An efficient procedure for solving such projections is given in Algorithm 4 of Warmuth and Kuzmin (2008); it does a projection with respect to the standard relative entropy on the vector of eigenvalues of the parameter matrix. Finally note that the computational complexity of all described updates (GD, Loss MEG, Gain MEG) is dominated by the time required for obtaining the eigendecomposition of the parameter matrix \mathbf{W}_{t+1} (or $\widehat{\mathbf{W}}_{t+1}$), which is $O(n^3)$ in general.

3. Upper Bounds on the Regret

Recall that the instance matrices \mathbf{X}_t are always assumed to be positive semi-definite matrices. We call such instance matrices L_1 -bounded, if the trace norm of the instance matrices is at most one, i.e. $\text{tr}(\mathbf{X}_t) \leq 1$ always holds. In particular, this happens for the vanilla PCA setting where the data received at trial is a point $\mathbf{x}_t \in \mathbb{R}^n$ s.t. $\|\mathbf{x}_t\| \leq 1$. In this case the instance matrices have the form $\mathbf{X}_t = \mathbf{x}_t \mathbf{x}_t^\top$ and $\text{tr}(\mathbf{x}_t \mathbf{x}_t^\top) = \mathbf{x}_t^\top \mathbf{x}_t = \|\mathbf{x}_t\|^2 \leq 1$. Note that in the L_1 -bounded case, the sums of the eigenvalues of the \mathbf{X}_t are at most one. We also study the case when the maximum eigenvalue of the instance matrices \mathbf{X}_t is at most one and call the latter the L_∞ -bounded case.

In this section, we present regret upper bounds for the three online algorithms introduced in the previous section, which are Loss MEG, Gain MEG and GD. All three algorithms are examples from the Mirror Descent family of algorithms. Our proof techniques require us to use different restrictions on the worst-case sequences that the adversary can produce. For the Loss MEG algorithm, we give the adversary a *loss budget*, i.e. the adversary must produce a sequence of instances $\mathbf{X}_1 \dots \mathbf{X}_T$ for which the loss of the best subspace is upper bounded by the loss budget B_L :

$$\min_{\substack{\mathbf{P} \text{ projection} \\ \text{matrix of rank } k}} \sum_{t=1}^T \text{tr}((\mathbf{I} - \mathbf{P}) \mathbf{X}_t) \leq B_L. \quad (3.1)$$

We call a regret bound that depends on this parameter a *loss budget dependent* bound. A bound of this type was first proved for Loss MEG in Warmuth and Kuzmin (2008). The latter paper is the precursor of this paper in which the analysis of online algorithms for PCA was started.

For the algorithm of Gain MEG, we give the adversary a *gain budget* B_G , i.e. an upper bound on the gain of the best subspace:

$$\max_{\substack{\mathbf{P} \text{ projection} \\ \text{matrix of rank } k}} \sum_{t=1}^T \text{tr}(\mathbf{P} \mathbf{X}_t) \leq B_G. \quad (3.2)$$

Now the adversary can only produce sequences for which all subspaces have gain at most B_G . We call this type of bound a *gain budget dependent* bound.

Finally we prove regret bounds of a third type for the GD algorithm. For this type the regret is a function of the number of trials T , and we call such a regret bound a *time dependent* regret bound.

We present the three regret bounds in the next subsection and compare them in the following subsection. As we shall see, upper bounds of the regret in terms of a budget imply time dependent bounds, and for lower bounds the implication is reversed. The main symbols and terms used throughout this section are summarized in Table 3.1.

3.1 Upper Bounds on the Regret of Loss MEG, Gain MEG, and GD

The Loss MEG algorithm (2.6) is the original MEG algorithm developed in the precursor paper of Warmuth and Kuzmin (2008) for online PCA. This paper proves a loss budget dependent upper bound on the regret of Loss MEG. This is done by exploiting the fact that PCA learning has the so called expert setting as a special case (See extensive discussion at the beginning of Section 4). More precisely the following bound is proven by lifting a regret bound developed for learning well compared to the best subset of $m = n - k$ experts to the matrix case, where subsets of size m generalize to projection matrices of rank m .

Loss budget dependent bound of Loss MEG:

$$\mathcal{R}_{\text{Loss MEG}} \leq \sqrt{2B_L m \log \frac{n}{m}} + m \log \frac{n}{m}. \quad (3.3)$$

This bound follows from Theorem 6 of Warmuth and Kuzmin (2008), and holds for any sequence of instance matrices (L_∞ as well as L_1 -bounded) for which the total compression loss of the best rank m subspace does not exceed the loss budget B_L (Condition (3.1)).

We begin by showing that the right-hand side of (3.3) is bounded above by an expression that does not depend on the dimension n of the data points:

$$\mathcal{R}_{\text{Loss MEG}} \leq \sqrt{2B_L k} + k. \quad (3.4)$$

This follows immediately from the following inequality and the relationship $m = n - k$ ($n = m + k$):

$$m \log \frac{n}{m} = m \log \left(\frac{k+m}{m} \right) = m \log \left(1 + \frac{k}{m} \right) \leq m \frac{k}{m} = k.$$

As mentioned at the beginning of this subsection (and discussed in more detail later in Section 4), online PCA specializes to the problem of learning well compared to the best set of $m = n - k$ experts. Regret bounds for the expert setting typically depend logarithmically on the number of experts n . Therefore the above dimension free regret bound might seem puzzling at first. However there is no contradiction. In the current setup we have $m = 1$ and $k = n - m = n - 1$ for the vanilla single expert case, and the above dimension free bound (3.4) becomes $\sqrt{2B_L(n-1)}$. This bound is not close to the optimum loss budget dependent regret bound for the single expert case which is $O(\sqrt{B_L \log n} + \log n)$. This latter bound is obtained by plugging $m = 1$ into the *original* regret bound (3.3). Thus for $m = 1$, the above dimension free approximation (3.4) of the original bound is loose. However, when $k \leq \frac{n}{2}$, then as we shall see in Section 5, the dimension free approximation actually is tight. In the precursor paper (Warmuth and Kuzmin, 2008), a different but weaker approximation of the original bound was proved that still has an additional logarithmic dependence when $k \leq \frac{n}{2}$: $O(\sqrt{B_L k \log \frac{n}{k}} + k \log \frac{n}{k})$.

We next develop a regret bound for Gain MEG (2.7). The proof technique is a variation of the original regret bound for Loss MEG (and is given for the sake of completeness in Appendix A).

Gain budget dependent bound of Gain MEG:

$$\mathcal{R}_{\text{Gain MEG}} \leq \sqrt{2B_G k \log \frac{n}{k}}. \quad (3.5)$$

This bound holds for any sequence of instance matrices (L_1 as well as L_∞ -bounded) for which the total gain of the best rank k subspace does not exceed the gain budget B_G (Condition (3.2)).

Finally, we give a simple regret bound for the GD algorithm. This bound (also observed in Arora et al. (2013) and proved for the sake of completeness in Appendix B) is based on two standard techniques: the use of the squared Frobenius norm (Kivinen and Warmuth, 1997) as a measure of progress and the use of the Pythagorean Theorem for handling the projection step (Herbst and Warmuth, 2001).

Time dependent regret bound of GD:

$$\mathcal{R}_{\text{GD}} \leq \begin{cases} \sqrt{\frac{T}{n}} & \text{for } L_1\text{-bounded instances} \\ \sqrt{T k m} & \text{for } L_\infty\text{-bounded instances} \end{cases}. \quad (3.6)$$

Note that each regret bound is expressed as a function of a loss budget, a gain budget or a time bound. They are obtained by setting the fixed learning rate of the algorithm as a function of one of these three parameters. The resulting basic algorithms can be used as sub-modules: For example the algorithm can be stopped as soon as the loss budget is reached and restarted with twice the budget and the corresponding re-tuned learning rate. This heuristic is known as the ‘‘doubling trick’’ (Cesa-Bianchi et al., 1997). Much fancier tuning schemes are explored in (van Erven et al., 2011; de Rooij et al., 2014) and are not the focus of this paper.

3.2 Comparison of the Regret Upper Bounds

Our goal is to find algorithms that achieve the optimal loss budget dependent and time dependent regret bounds where optimal means that the bound is within a constant factor of optimum. We are not interested in *gain dependent* regret bounds per se, i.e. bounds in terms of a gain budget B_G , because the maximal gain is typically much larger than the minimal loss. However when the gain budget restricted regret bounds are converted to time bounds, then for some setting (discussed below) the resulting algorithm becomes the only optimal algorithm we are aware of.

The only known *loss budget dependent* regret bound is bound (3.3) for Loss MEG obtained in the original paper for online learning of PCA (Warmuth and Kuzmin, 2008). We will show later in Section 5 that this upper bound on the regret is optimal. There are no known loss budget dependent upper bounds on the regret of GD. However in Section 4, we prove a lower bound on GD’s regret in terms of the loss budget which shows that GD’s regret is suboptimal by at least a factor of \sqrt{k} when the regret is expressed as a function of the loss budget. The discussion of the *time dependent* regret upper bounds is more involved. We first convert the budget dependent regret bounds of the MEG algorithms into time dependent bounds. We shall see later, for lower bounds on the regret, time dependent bounds lead to budget dependent bounds (see Corollary 5.7). Before we do this, recall that the instance matrices \mathbf{X}_t are L_1 -bounded if their trace is at most one, and for L_∞ -bounded instance matrices, their maximum eigenvalue is at most one. Note that for any vector \mathbf{x}_t of length at most one, $\text{tr}(\mathbf{x}_t \mathbf{x}_t^\top) \leq 1$, and therefore vanilla PCA belongs to the case of L_1 -bounded instance matrices.

Theorem 3.1 *When the instances are L_1 -bounded, then for the online PCA with T trials, the following regret bounds hold for the Loss MEG and Gain MEG algorithms, respectively:*

$$\mathcal{R}_{\text{Loss MEG}} \leq m \sqrt{\frac{2T}{n}} \log \frac{n}{m} + m \log \frac{n}{m}, \quad \mathcal{R}_{\text{Gain MEG}} \leq \sqrt{2T k \log \frac{n}{k}}. \quad (3.7)$$

Similarly, when the instances are L_∞ -bounded, then the following regret bounds hold:

$$\mathcal{R}_{\text{Loss MEG}} \leq m \sqrt{2T \log \frac{n}{m}} + m \log \frac{n}{m}, \quad \mathcal{R}_{\text{Gain MEG}} \leq k \sqrt{2T \log \frac{n}{k}}. \quad (3.8)$$

Proof The theorem will be proved by developing simple upper bounds on the loss/gain of the best rank k subspace that depend on the sequence length T . These upper bounds are then used as budgets in the previously obtained budget dependent bounds.

The best rank k subspace picks k eigenvectors of the covariance matrix $\mathbf{C} = \sum_{t=1}^T \mathbf{X}_t$ with the largest eigenvalues. Hence the total compression loss equals the sum of the smallest m eigenvalues of \mathbf{C} . If $\omega_1, \dots, \omega_n$ denote all the eigenvalues of \mathbf{C} , then:

$$\sum_{i=1}^n \omega_i = \text{tr}(\mathbf{C}) = \sum_{t=1}^T \text{tr}(\mathbf{X}_t) \leq \begin{cases} T & \text{for } L_1\text{-bounded instances} \\ Tn & \text{for } L_\infty\text{-bounded instances} \end{cases},$$

where the inequality follows from our definition of L_1 -bounded and L_∞ -bounded instance matrices. This implies that the sum of the m smallest eigenvalues is upper bounded by $\frac{Tm}{n}$ and Tm , respectively. By using these two bounds as the loss budget B_L in (3.3), we get the time dependent bound for Loss MEG for L_1 -bounded and L_∞ -bounded instances, respectively.

For the regret bounds of Gain MEG, we use the fact that B_G is upper bounded by T when instances are L_1 -bounded and upper bounded by kT when the instances are L_∞ -bounded, and plug these values for B_G into (3.5). ■

Table 3.2 compares time dependent upper bounds for each of the three algorithms (Loss MEG, Gain MEG, GD) where we consider each of the 4 variants of the problem: L_1 -bounded or L_∞ -bounded instance matrices versus $k \leq \frac{n}{2}$ or $k \geq \frac{n}{2}$.

As far as time dependent bounds are concerned, no single algorithm is optimal in all cases. In Table 3.2, the optimum bounds are shown in bold. The lower bounds matching these bold bounds within a constant factor will be proved in Section 5. Note that one version of MEG (either the loss or gain version) is optimal in each case, while GD is optimal only in first case (This is the most important case in practice: vanilla online PCA with $k \ll n$). For the remaining three cases, consider the ratio between the GD's bound and the better of the two MEG bounds, which is

- $\sqrt{\frac{n}{m} / (\log \frac{n}{m})}$, when the instances are L_1 -bounded and $k \geq \frac{n}{2}$,
- $\sqrt{\frac{n}{k} / (\log \frac{n}{k})}$, when the instances are L_∞ -bounded and $k \leq \frac{n}{2}$ and
- $\sqrt{\frac{n}{m} / (\log \frac{n}{m})}$, when the instances are L_∞ -bounded and $k \geq \frac{n}{2}$.

Since none of these three ratios can be upper bounded by a constant, GD is clearly suboptimal in each of the remaining three cases.

	L_1 -bounded instances		L_∞ -bounded instances	
	$k \leq \frac{n}{2}$	$k \geq \frac{n}{2}$	$k \leq \frac{n}{2}$	$k \geq \frac{n}{2}$
Loss MEG	\sqrt{Tk}	$\sqrt{Tm} (\log \frac{n}{m}) / \frac{n}{m}$	\sqrt{Tkm}	$\sqrt{Tm^2 \log \frac{n}{m}}$
Gain MEG	$\sqrt{Tk \log \frac{n}{k}}$	\sqrt{Tm}	$\sqrt{Tk^2 \ln \frac{n}{k}}$	\sqrt{Tkm}
GD	\sqrt{Tk}	\sqrt{Tm}	\sqrt{Tkm}	\sqrt{Tkm}

Table 3.2: Comparison of the time dependent upper bounds on the regret of the Loss MEG, Gain MEG, and GD algorithms. Each column corresponds to one of the four combinations of L_1 -bounded or L_∞ -bounded instance matrices versus $k \leq \frac{n}{2}$ or $k \geq \frac{n}{2}$, respectively. All bounds were given in Section 3.1 and Section 3.2: constants are omitted, we only show the leading term of each bound, and when we compare Loss and Gain MEG bounds, we use $m \ln \frac{n}{m} = \Theta(k)$ when $k \leq \frac{n}{2}$ and $k \ln \frac{n}{k} = \Theta(m)$ when $k \geq \frac{n}{2}$. Recall that m is shorthand for $n - k$. The best (smallest) bound for each case (column) is shown in bold. In Section 5, all bold bounds will be shown to be optimal (within constant factors).

4. Lower Bounds on the Regret of GD

Recall that vanilla online PCA uses L_1 -bounded instance matrices and the subspace dimension k is typically at most $\frac{n}{2}$. In this case Loss MEG has regret $O(\sqrt{Tk})$ and the regret of GD is $O(\sqrt{Tk})$ as well. As for loss budget dependent regret bounds, Loss MEG has regret $O(\sqrt{B_L k} + k)$ and we initially conjectured that GD has the same bound. However, this is not true: we will now show in this section an $\Omega(\max\{B_L, k\sqrt{B_L}, k\})$ lower bound on the regret of GD for L_1 -bounded instance sequences when $k \leq \frac{n}{2}$. In contrast, Loss MEG's regret bound of $O(\sqrt{B_L k} + k)$ will be shown to be optimal in Section 5 for this case. It follows that GD is suboptimal by at least a factor of \sqrt{k} when $B_L = \Omega(k^2)$. A detailed comparison of the lower bound for GD and the optimum upper bound is given in Table 4.1.

It suffices to prove lower bounds on GD's regret on a restricted class of instance matrices: We assume that all instance matrices are in the same eigensystem, i.e. they are diagonal matrices $\mathbf{X} = \text{diag}(\boldsymbol{\ell})$ with $\boldsymbol{\ell} \in \mathbb{R}_{\geq 0}^n$. We call the diagonals $\boldsymbol{\ell}$ the *loss vectors*. All loss vectors in our lower bounds are restricted to be bit vectors in $\{0, 1\}^n$. In the L_1 -bounded instance case, the loss vectors are further restricted to be one of the n unit bit vectors \mathbf{e}_i , i.e. $\mathbf{X} = \text{diag}(\mathbf{e}_i) = \mathbf{e}_i \mathbf{e}_i^\top$. In the L_∞ -bounded instance case, the loss vectors $\boldsymbol{\ell}$ are arbitrary n -dimensional bit vectors.

When all instance matrices are diagonal then the off-diagonal elements in a parameter matrix \mathbf{W} are irrelevant and therefore the algorithm's loss and regret is determined by the diagonals of the parameter matrices \mathbf{W} which is of trace m . Therefore without loss of generality we can assume that the parameter matrices are diagonal as well, i.e. $\mathbf{W} = \text{diag}(\mathbf{w})$ where \mathbf{w} is a *weight vector* in $[0, 1]^n$ with total weight m . Note that the loss becomes

Regret bounds for L_1 -bounded instances, $k \leq \frac{n}{2}$	$B_L \leq k$	$k \leq B_L \leq k^2$	$k^2 \leq B_L$
Upper bound on regret of Loss MEG (see (3.3))	$O(k)$	$O(\sqrt{B_L k})$	$O(\sqrt{B_L k})$
Lower bound on regret of GD (see Theorem 4.1)	$\Omega(k)$	$\Omega(B_L)$	$\Omega(k\sqrt{B_L})$

Table 4.1: Comparison of the loss budget dependent regret bounds for online PCA with $k \leq \frac{n}{2}$. Given dimension k of the subspace, each column shows the values of the two bounds for a specific range of the loss budget B_L . The first row gives the upper bound on the regret of Loss MEG in bold, which will be shown to be optimal in Section 5. The second row gives the lower bound on the regret of GD, which is suboptimal whenever $B_L \geq k$.

a dot product between the weight vector and the loss vector:

$$\text{tr}(\mathbf{W}\mathbf{X}) = \text{tr}(\text{diag}(\mathbf{w}) \text{diag}(\boldsymbol{\ell})) = \mathbf{w} \cdot \boldsymbol{\ell}.$$

What is the prediction of the algorithm with a diagonal parameter matrix $\mathbf{W} = \text{diag}(\mathbf{w})$? It probabilistically predicts with an m dimensional projection matrix \mathbf{P} s.t. $\mathbb{E}[\mathbf{P}] = \text{diag}(\mathbf{w})$. This means \mathbf{P} is a subset of size m from $\{\mathbf{e}_1\mathbf{e}_1^\top, \mathbf{e}_2\mathbf{e}_2^\top, \dots, \mathbf{e}_n\mathbf{e}_n^\top\}$. The diagonals of such projection matrices consists of exactly m ones and $n - m = k$ zeros. In other words the diagonals are indicator vectors of the chosen *subsets* of size m and the expected indicator vector equals the weight vector \mathbf{w} .

We just outlined one of the main insights of (Warmuth and Kuzmin, 2008): The restriction of the PCA problem to diagonal matrices corresponds to learning a subset of size m . The n components of the vectors are usually called *experts*. At trial t the algorithm chooses a subset of m experts. It then receives a loss vector $\boldsymbol{\ell} \in \mathbb{R}_{\geq 0}^n$ for the experts and incurs the total loss of the chosen m experts. The algorithm maintains its uncertainty over the m -sets by means of a parameter vector $\mathbf{w} \in [0, 1]^n$ with total weight m , and it chooses the subset of size m probabilistically so that the expected indicator vector equals \mathbf{w} . We denote the set of such parameter vectors as \mathcal{S}_m . In the L_1 -bounded instance case, the loss vector is a unit bit vector (only one expert incurs a unit of loss). In the L_∞ -bounded instance case, the loss vectors are restricted to be n -dimensional bit vectors.

4.1 Lower Bound on the Regret of the GD Algorithm

The GD algorithm for online PCA (2.5) specializes to the following update of the parameter vector for learning sets:

$$\begin{aligned} \text{Descent step:} \quad \hat{\mathbf{w}}_{t+1} &= \mathbf{w}_t - \eta \boldsymbol{\ell}_t, \\ \text{Projection step:} \quad \mathbf{w}_{t+1} &= \text{argmin}_{\mathbf{w} \in \mathcal{S}_m} \|\mathbf{w} - \hat{\mathbf{w}}_{t+1}\|^2. \end{aligned} \quad (4.1)$$

We now give a lower bound on the regret of the GD algorithm for the m -set problem. This lower bound is expressed as a function of the loss budget.

Theorem 4.1 *Consider the $m = n - k$ set problem with $k \leq n/2$ and unit bit vectors as loss vectors. Then for any fixed learning rate $\eta \geq 0$, the GD algorithm (4.1) can be forced to have regret $\Omega(\max\{\min\{B_L, k\sqrt{B_L}\}, k\})$.*

We prove this theorem in Appendix C. From the fact that m -set problem is a special case of PCA problem, we get the following corollary, which shows that the GD algorithm is suboptimal (see Table 4.1 for an overview):

Corollary 4.2 *Consider the PCA problem with $k \leq n/2$ and L_1 -bounded instance matrices. Then for any fixed learning rate $\eta \geq 0$, the GD algorithm (2.5) can be forced to have regret $\Omega(\max\{\min\{B_L, k\sqrt{B_L}\}, k\})$.*

4.2 Lower Bound on the Regret of the Follow the Regularized Leader GD Algorithm (FRL-GD)

In the previous section, we showed that for online PCA with L_1 -bounded instance matrices and $k \leq \frac{n}{2}$, the GD algorithm is suboptimal for loss budget dependent regret bounds. However, our lower bounds are only for the Mirror Descent version of GD given in (2.5). This algorithm is prone to “forgetting” lots of information about the past losses when projections with respect to inequality constraints are involved. Recall that at the end of each trial t , the mirror descent algorithm uses the last parameter \mathbf{W}_t as a summary of the knowledge attained so far, and minimizes a trade-off between a divergence to the \mathbf{W}_t and the loss on the last data point \mathbf{x}_t to determine the next parameter \mathbf{W}_{t+1} . When the parameter resulting from the trade-off lies outside the parameter set, then it is projected back into the parameter set (see update (2.5)). In the case when the projection enforces inequality constraints on the parameters, information about the past losses may be lost. This issue was first discussed in Section 5.5 of Helmbold and Warmuth (2009). Curiously enough, Bregman projections with respect to only equality constraints do not lose information.

We now demonstrate in more detail the “forgetting” issue for the Mirror Descent GD algorithm when applied to online PCA. First recall that the batch PCA solution consists of the subspace spanned by the k eigenvectors belonging to the k largest values of the covariance matrix $\mathbf{C} = \sum_{i=1}^T \mathbf{x}_i \mathbf{x}_i^\top$. The complementary space is the $m = n - k$ dimensional subspace formed by the m eigenvectors of m largest eigenvalues of $-\mathbf{C}$. Hence, the final parameter \mathbf{W}_{T+1} of the on-line algorithm should have the same eigenvectors as $-\mathbf{C}$, as well as the order of their corresponding eigenvalues. The descent step of (2.5) accumulates the scaled negated instance matrices $\mathbf{X}_t = \mathbf{x}_t \mathbf{x}_t^\top$, i.e. $\widehat{\mathbf{W}}_{t+1} = \mathbf{W}_t - \eta \mathbf{X}_t$. In the projection step of (2.5), the parameter matrix $\widehat{\mathbf{W}}_{t+1}$ is projected back to the parameter set \mathcal{W}_m by enforcing an equality constraint $\text{tr}(\mathbf{W}_{t+1}) = m$ and inequality constraints that keep all the eigenvalues of \mathbf{W}_{t+1} are in the range $[0, 1]$. The equality constraint on $\widehat{\mathbf{W}}_{t+1}$ results in adding to $\widehat{\mathbf{W}}_{t+1}$ a scaled version of the identity matrix \mathbf{I} (See Appendix C). These iterated shifts do not affect either the eigenvectors or the order of their corresponding eigenvalues. However, when the inequality constraints are enforced, then at trial t the eigenvalues of $\widehat{\mathbf{W}}_{t+1}$ that are larger than 1 or less than 0 are capped at 1 and 0, respectively. Performing such a non-uniform capping of $\widehat{\mathbf{W}}_{t+1}$ ’s eigenvalues in each trial will result in a final parameter \mathbf{W}_{T+1} with an eigensystem that is typically different from $-\mathbf{C}$. Therefore the PCA solution extracted from \mathbf{W}_{T+1} and the covariance matrix \mathbf{C} will not be the same.

There is another version of the GD algorithm that does not “forget”: The Follow the Regularized Leader GD (FRL-GD) algorithm (see, e.g., Shalev-Schwartz and Singer (2007)?)

2. This algorithm is also called as the Incremental Off-line Algorithm in (Azoury and Warmuth, 2001).

trades off the total loss on all data points against the Frobenius norm of the parameter matrix:

$$\widehat{\mathbf{W}}_{t+1} = \operatorname{argmin} \left(\|\mathbf{W}\|_F^2 + \eta \sum_{q=1}^t \operatorname{tr}(\mathbf{W}\mathbf{X}_q) \right) = -\eta \sum_{q=1}^t \mathbf{X}_q, \quad (4.2)$$

Projection step:

$$\mathbf{W}_{t+1} = \operatorname{argmin}_{\mathbf{W} \in \mathbf{W}_m} \|\mathbf{W} - \widehat{\mathbf{W}}_{t+1}\|_F^2 = \operatorname{argmin}_{\substack{\text{Eigenvalues of } \mathbf{W} \text{ in} \\ [0, 1] \text{ and } \operatorname{tr}(\mathbf{W}) = m}} \|\mathbf{W} - \widehat{\mathbf{W}}_{t+1}\|_F^2.$$

Note that in each trial, the update (4.2) projects a parameter $\widehat{\mathbf{W}}_{t+1}$ that accumulates all the past scaled negated instance matrices $(-\eta\mathbf{X}_t)$ back to trial one. In contrast, the Mirror Descent update in (2.5) performs projection iteratively, i.e. it projects parameter matrices of previous trials that are projections themselves. Therefore, the FRL-GD algorithm circumvents the forgetting issue introduced by iterative projections with respect to inequality constraints. In fact the final parameter \mathbf{W}_{T+1} of the FRL-GD is the projection of the scaled negated covariance matrix $\widehat{\mathbf{W}}_{T+1} = -\eta \sum_{t=1}^T \mathbf{x}_t \mathbf{x}_t^\top = -\eta \mathbf{C}$. We will show essentially in Appendix E that a single projection operation does not change the set of eigenvectors belonging to the m largest eigenvalues. This means that the eigenvectors belonging to the k smallest eigenvalues of \mathbf{W}_{T+1} agree with the eigenvectors of \mathbf{C} belonging to the k largest eigenvalues of \mathbf{C} .

Encouraged by this observation, we initially conjectured that the FRL-GD is strictly better than the commonly studied Mirror Descent version. More concretely, we conjectured that the FRL-GD has the optimal loss budget dependent regret bound for vanilla online PCA (as Mirror Descent MEG does which enforces the non-negativity constraints with its divergence). Unfortunately, we are able to show the opposite: The $\Omega(\max\{\min\{B_L, k\sqrt{B_L}\}, k\})$ lower bound we showed for (Mirror Descent) GD in Theorem 4.1 also holds for FRL-GD. To be precise, we have the following theorem and corollary:

Theorem 4.3 *Consider the $m = n - k$ set problem with $k \leq n/2$ and unit bit vectors as loss vectors. Then for any fixed learning rate $\eta \geq 0$, the vector version of the FRL-GD algorithm (4.2) can be forced to have regret $\Omega(\max\{\min\{B_L, k\sqrt{B_L}\}, k\})$.*

The proof is given in Appendix D. Theorem 4.3 immediately gives the lower bound on the regret of FRL-GD algorithm for the online PCA:

Corollary 4.4 *Consider the PCA problem with $k \leq n/2$ and L_1 -bounded instance matrices. Then for any fixed learning rate $\eta \geq 0$, the FRL-GD algorithm (4.2) can be forced to have regret $\Omega(\max\{\min\{B_L, k\sqrt{B_L}\}, k\})$.*

This shows that the worst case regret of the FRL-GD algorithm is the same as that of (Mirror Descent) GD, and hence suboptimal.

5. General Lower Bounds and Optimal Algorithms

In the previous section, we presented lower bounds on the regret of the GD algorithms. In this section we present lower bounds on the regret of *any* algorithm that solves the online PCA problem with L_1 and L_∞ -bounded instance matrices. More importantly, these lower bounds match all our upper bounds on the regret of the MEG algorithms within a constant factor (See bold entries in Table 3.2 and Table 4.1). To be precise, we will prove in this section a series of regret lower bounds that match our loss budget dependent upper bound (3.3) on the regret of Loss MEG, and our time dependent upper bounds (Theorem 3.1) on the regret of Loss MEG and Gain MEG, respectively. For the time dependent bounds, our lower bounds will match the lower of the two MEG bounds in each of the four sub-cases of the problem, i.e. L_1 and L_∞ -bounded instance matrices versus $k \leq \frac{n}{2}$ or $k \geq \frac{n}{2}$ (See Table 3.2 for a summary). Note that in one case the GD algorithm is also optimal: time dependent regret bounds for PCA with L_1 -bound instances when $k \leq \frac{n}{2}$.

We begin with an overview of our proof techniques for proving lower bounds that hold for any algorithm. When proving *upper bounds* on the regret (in Section 3), we first proved upper bounds as a function of the loss budget B_L and then converted them into time dependent upper bounds. For *lower* bounds on the regret, the order is reversed: we first will show time dependent lower bounds and then convert them into loss budget dependent lower bounds. As discussed in Section 4, it suffices to prove lower bounds for the m -set problem, which is the hard special case when all instances are diagonal.

Let \mathcal{A} be the set of all online algorithms for the m -set problem. Such algorithms maintain a weight vector in \mathcal{S}_m (consisting of all vectors in $[0, 1]^m$ of total weight m). For an algorithm $A \in \mathcal{A}$, we denote its regret by $\mathcal{R}(A, \ell_1, \dots, \ell_T)$ where ℓ_1, \dots, ℓ_T is a sequence of T loss vectors. The loss vectors ℓ_t lie in a constraint set \mathcal{L} . The constraint set \mathcal{L} either consists of all n dimensional unit bit vectors (the restriction of the L_1 -bounded case we use in the lower bounds), or $\mathcal{L} = \{0, 1\}^n$ (the restriction used for the L_∞ -bounded case). We use the standard method of lower bounding the regret for worst case loss sequences from \mathcal{L} by the expected regret when the loss vectors are generated i.i.d. with respect to a distribution \mathcal{P} on \mathcal{L} :

$$\min_{\text{alg. } A \in \mathcal{A}} \left\{ \max_{\text{over loss vectors } \ell_1, \dots, \ell_T \in \mathcal{L}} \mathcal{R}(A, \ell_1, \dots, \ell_T) \right\} \geq \min_{\text{over any alg. } A \in \mathcal{A}} \left\{ \mathbb{E}_{\ell_1, \dots, \ell_T \sim \mathcal{P}^T} [\mathcal{R}(A, \ell_1, \dots, \ell_T)] \right\}.$$

Each lower bound is proved as follows: Choose a distribution \mathcal{P} on \mathcal{L} , and then show a lower bound on the expected regret of any algorithm $A \in \mathcal{A}$. Note that this expectation becomes the expected loss of A minus the expected loss of the best comparator (i.e. the best m -set). We first prove time dependent regret lower bounds with L_1 and L_∞ -bounded instance vectors in sections 5.1 and 5.2, respectively. Finally we convert these lower bounds into loss budget dependent lower bounds (in Section 5.3).

5.1 Time Dependent Lower Bounds for Online PCA

Recall that $m = n - k$. First, we give a lower bound on the regret of any algorithm for the m -set problem, when $k \leq \frac{n}{2}$:

Theorem 5.1 *Consider the m -set problem with unit bit vectors as loss vectors. Then for $k \leq \frac{n}{2}$ and $T \geq k$, any online algorithm suffers worst case regret at least $\Omega(\sqrt{Tk})$.*

The proof is given in Appendix F. We lower bound the expected loss w.r.t. the distribution \mathcal{P} which is uniform on the first $2k$ unit bit vectors. Note that Theorem 5.1 requires the condition $T \geq k$. For the case $T < k$, there is a lower bounds of $\Omega(T)$ (See Theorem G.1 in Appendix G). When the loss vectors are bit vectors, then any algorithm has loss (and regret) $O(T)$. Therefore when $T < k$, any algorithm achieves the minimax regret up to a constant factor.

We now consider the uncommon case when $k \geq \frac{n}{2}$:

Theorem 5.2 *Consider the m -set problem with unit bit vectors as loss vectors. Then for $k \geq \frac{n}{2}$ and $T \geq n \log_2(n/m)$, any online algorithm suffers worst case regret of at least $\Omega(n\sqrt{\frac{T}{n} \ln \frac{n}{m}})$.*

We now set \mathcal{P} to the uniform distribution on all n unit bit vectors (See Appendix F). The small T case (here $T < n \log_2(n/m)$) is slightly more involved. There is a lower bound of $\Omega(\frac{m}{n}T)$ regret for any algorithm (see Theorem G.3 in Appendix G). Also the algorithm which predicts with the uniform weight $\frac{n}{m}$ on all experts achieves the matching regret of $O(\frac{m}{n}T)$.

Recall that the m -set problem with unit bit vectors as loss vectors is a special case of the online PCA problem with L_1 -bounded instance matrices. Combining the above two lower bounds for different ranges of k with our upper bound (Theorem 3.1) on the regret of Loss MEG for online PCA with L_1 -bounded instances gives the following corollary:

Corollary 5.3 *Consider the problem of online PCA with L_1 -bounded instance matrices.*

Then for $T \geq n \log_2(n/m)$, the $\Theta(m\sqrt{\frac{T}{n} \ln \frac{n}{m}})$ regret of Loss MEG is within a constant factor of the minimax regret.

Note that we do not use the condition $T \geq k$ of Theorem 5.1, since when $k \leq \frac{n}{2}$, $k = \Theta(n \log_2(n/m))$.

5.2 Time Dependent Lower Bound for the Generalization with L_∞ -Bounded Instance Matrices

We first give the time dependent lower bound for the m -set problem with bit vectors.

Theorem 5.4 *Consider the m -set problem with bit vectors as loss vectors. Then for $T \geq \log_2 \frac{n}{\min\{k,m\}}$, any online algorithm suffers worst case regret of at least*

$$\Omega(k\sqrt{T \ln \frac{n}{k}}) \text{ when } k \leq \frac{n}{2} \quad \text{or} \quad \Omega(m\sqrt{T \ln \frac{n}{m}}) \text{ when } k \geq \frac{n}{2}.$$

The proof is given in Appendix F. The distribution \mathcal{P} is such that each expert incurs a unit of loss with probability $1/2$ independently from the other experts. For the small T case ($T < \log_2 \frac{n}{\min\{k,m\}}$), there is a lower bound of $\Omega(\min\{Tm, Tk\})$ (See Theorem G.4 and Theorem G.5 in Appendix G). A matching upper bound of $O(\min\{Tm, Tk\})$ on the

regret of any algorithm can be reasoned as follows: At each trial, the algorithm plays with $\mathbf{W}_t \in \mathcal{W}_m$ and suffers loss $\text{tr}(\mathbf{W}_t \mathbf{X}_t)$. Since $\text{tr}(\mathbf{W}_t) = m$, the algorithm suffers loss at most m per trial and for T trials, and the cumulative loss (and thus regret) is at most Tm . The Tk upper bound can be showed similarly by considering the “gain” of the best rank k projector \mathbf{P}^* , which is $\sum_{j=1}^T \text{tr}(\mathbf{P}^* \mathbf{X}_j) \leq Tk$. Combining the lower bounds of Theorem 5.4 with the upper bounds on the regret of Loss MEG and Gain MEG when the instance matrices are L_∞ -bounded (Inequality (3.8)), results in the following corollary, which states that the Gain MEG is optimal for $k \leq \frac{n}{2}$ while the Loss MEG is optimal for $k \geq \frac{n}{2}$.

Corollary 5.5 *Consider the generalization of online PCA where the instance matrices are L_∞ -bounded.*

- When $k \leq \frac{n}{2}$ and $T \geq \log_2 \frac{n}{k}$, then the regret $\Theta(k\sqrt{T \log \frac{n}{k}})$ of Gain MEG is within a constant factor of the minimax regret.
- When $k \geq \frac{n}{2}$ and $T \geq \log_2 \frac{n}{m}$, then the regret $\Theta(m\sqrt{T \log \frac{n}{m}})$ of Loss MEG is within a constant factor of the minimax regret.

5.3 Loss Budget Dependent Lower Bounds

In this subsection, we give regret lower bounds that are functions of the loss budget B_t (defined in (3.1)). Similar to our loss budget dependent upper bound (3.3) on the regret of Loss MEG, the loss dependent lower bounds are the same for both unit and arbitrary bit vectors:

Theorem 5.6 *For the m -set problem with either unit or arbitrary bit vectors as loss vectors, any online algorithm suffers worst case regret at least $\Omega(\sqrt{B_t m \ln \frac{n}{m}}) + m \ln \frac{n}{m}$.*

The proof of the theorem is given in Appendix H. We convert the time dependent lower bounds given in Theorem 5.1 and Theorem 5.2 into loss budget dependent ones. Note that unlike our time dependent lower bounds, Theorem 5.6 is stated for the full range of the loss budget parameter B_t . The proof also distinguishes between a small and a large budget case depending on whether $B_t \leq m \ln \frac{n}{m}$. The lower bound of $\Theta(m \ln \frac{n}{m})$ follows from a conversion. However the upper bound of $O(m \ln \frac{n}{m})$ for the small budget case is non-trivial. Incidentally, this upper bound is achieved by Loss MEG.

Finally, combining this lower bound with the upper bounds (3.3) on the regret of Loss MEG, gives the following corollary, which establishes the optimality of Loss MEG no matter if the instance matrices are L_1 or L_∞ -bounded.

Corollary 5.7 *Consider the problem of online PCA with L_1 or L_∞ -bounded instance matrices. Then the regret $\Theta(\sqrt{B_t m \ln \frac{n}{m}} + m \ln \frac{n}{m})$ of Loss MEG is within a constant factor of the minimax regret.*

6. Conclusion

In this paper, we carefully studied two popular online algorithms for PCA: the Gradient Descent (GD) and Matrix Exponentiated Gradient (MEG) algorithms. For the case when the instance matrices are L_1 -bounded, we showed that both algorithms are optimal to within

a constant factor when the worst-case regret is expressed as a function of the number of trials. Furthermore, when considering regret bounds as a function of a loss budget, then MEG remains optimal and strictly outperforms GD for L_1 -bounded instances. We also studied the case when the instance matrices are L_∞ -bounded. Again we show MEG to be optimal and strictly better than GD in this case. It follows that MEG is the algorithm of choice for both cases. Note that that vanilla PCA (where the instances are outer products of vectors of length at most one) is subsumed by the case of L_1 -bounded instance matrices.

In this paper we focused on obtaining online algorithms with optimal regret and we ignored efficiency concerns. Straightforward implementations of both the GD and MEG online PCA updates required $O(n^3)$ computation per trial (because they require an eigen-decomposition of the parameter matrices). This leads to a major open problem for online PCA (Hazan et al., 2010): Is there any algorithm that can achieve optimal regret with $O(n^2)$ computation per trial. To this end, Arora et al. (2013) considers the Gain version of GD (Equation (2.3)), with the squared Euclidean distance as the divergence) where the projection enforces the additional constraint that the parameter matrix \mathbf{W}_t has rank \hat{k} . Encouraging experimental results are provided for the choice $\hat{k} = k + 1$. However, as we shall see immediately, in the most basic case when the instance matrices are outer products of unit length vectors \mathbf{x}_t that are chosen by an adversary, then any algorithm that uses parameter matrices of rank \hat{k} less than n can be forced to suffer worst case regret linear in T . Recall that the parameter matrix \mathbf{W}_t at trial t is simply the expected projection matrix of rank k chosen by the algorithm and this matrix is defined for any (deterministic or randomized) algorithm. We give an adversary argument for any algorithm for which the rank of the parameter matrix \mathbf{W}_t at any trial t is at most \hat{k} . The parameter matrices are known to the adversary. Also the initial parameter matrix \mathbf{W}_1 must have rank \hat{k} and be known to the adversary. For any algorithm following this setup the adversary argument proceeds as follows: At the beginning of the game the adversary fixes any subspace \mathcal{Q} of dimension $\hat{k} + 1$. In each trial, the adversary picks a unit length vector $\mathbf{x}_t \in \mathcal{Q}$, which is in the null space of the parameter matrix \mathbf{W}_t of the algorithm (This is always possible, because the dimension of \mathcal{Q} is larger than the rank of \mathbf{W}_t). After T trials, the algorithm has zero gain, while the total gain T is accumulated within subspace \mathcal{Q} . This means that there are k orthogonal directions within \mathcal{Q} with the total gain at least $\frac{k}{k+1}T$ and therefore, the algorithm suffers regret at least $\frac{k}{k+1}T$.

Besides restricting the rank of the parameter matrix, a second approach is to add perturbations to the current covariance matrix and then find the eigenvectors of the k -largest eigenvalues (Hazan et al., 2010). So far this approach has not led to algorithms with optimal regret bounds and $O(n^2)$ update time. Some partial results recently appeared in Garber et al. (2015) and Kotowski and Warmuth (2015).

Appendix A. Proof of Upper Bound (3.5) on the Regret of Gain MEG

Proof The proof is based on the by now standard proof techniques of Tsuda et al. (2005). Let $\mathbf{W}_t \in \mathcal{W}_k$ be the parameter of the Gain MEG algorithm at trial t and \mathbf{X}_t be the instance matrix at this trial. Now plugging the (un-normalized) relative entropy $\Delta(\mathbf{W}, \mathbf{W}_t) = \text{tr}(\mathbf{W}(\log \mathbf{W} - \log \mathbf{W}_t) + \mathbf{W}_t - \mathbf{W})$ into the descent step of the Gain MEG algorithm (2.7) gives:

$$\widehat{\mathbf{W}}_{t+1} = \exp(\log \mathbf{W}_t + \eta \mathbf{X}_t) \quad \text{where } \eta \geq 0 \text{ is the learning rate.}$$

Take any projection matrix $\mathbf{W} \in \mathcal{W}_k$ as a comparator and use $\Delta(\mathbf{W}, \mathbf{W}_t) - \Delta(\mathbf{W}, \mathbf{W}_{t+1})$ as a measure of progress towards \mathbf{W} :

$$\begin{aligned} \Delta(\mathbf{W}, \mathbf{W}_t) - \Delta(\mathbf{W}, \mathbf{W}_{t+1}) &\geq \Delta(\mathbf{W}, \mathbf{W}_t) - \Delta(\mathbf{W}, \widehat{\mathbf{W}}_{t+1}) \\ &= \text{tr}(\mathbf{W}(\log \widehat{\mathbf{W}}_{t+1} - \log \mathbf{W}_t) + \mathbf{W}_t - \widehat{\mathbf{W}}_{t+1}) \\ &= \text{tr}(\eta \mathbf{W} \mathbf{X}_t) + \text{tr}(\mathbf{W}_t - \exp(\log \mathbf{W}_t + \eta \mathbf{X}_t)) \\ &\geq \text{tr}(\eta \mathbf{W} \mathbf{X}_t) + \text{tr}(\mathbf{W}_t - \mathbf{W}_t \exp(\eta \mathbf{X}_t)) \\ &= \text{tr}(\eta \mathbf{W} \mathbf{X}_t) + \text{tr}(\mathbf{W}_t(\mathbf{I} - \exp(\eta \mathbf{X}_t))), \end{aligned} \quad (\text{A.1})$$

where the first inequality follows from the Pythagorean Theorem and the second from the Golden-Thompson inequality: $\text{tr}(\exp(\log \mathbf{W}_t + \eta \mathbf{X}_t)) \leq \text{tr}(\mathbf{W}_t \exp(\eta \mathbf{X}_t))$. By Lemma 2.1 of Tsuda et al. (2005),

$$\text{tr}(\mathbf{W}_t(\mathbf{I} - \exp(\eta \mathbf{X}_t))) \geq (1 - e^\eta) \text{tr}(\mathbf{W}_t \mathbf{X}_t),$$

and therefore

$$\Delta(\mathbf{W}, \mathbf{W}_t) - \Delta(\mathbf{W}, \mathbf{W}_{t+1}) \geq \underbrace{\text{tr}(\mathbf{W} \mathbf{X}_t)}_{\text{gain of the comparator}} + (1 - e^\eta) \underbrace{\text{tr}(\mathbf{W}_t \mathbf{X}_t)}_{\text{gain of the algorithm}}.$$

Summing over trials gives:

$$\eta \underbrace{\sum_{t=1}^T \text{tr}(\mathbf{W} \mathbf{X}_t)}_{\text{total gain } G_{\mathbf{W}} \text{ of the comparator } \mathbf{W}} + (1 - e^\eta) \underbrace{\sum_{t=1}^T \text{tr}(\mathbf{W}_t \mathbf{X}_t)}_{\text{total gain } G_A \text{ of Gain MEG}} \leq \underbrace{\Delta(\mathbf{W}, \mathbf{W}_1)}_{\substack{\leq k \log \frac{n}{k} \\ \text{with initialization} \\ \mathbf{W}_1 = \frac{\mathbf{I}}{n}}} - \underbrace{\Delta(\mathbf{W}, \mathbf{W}_{T+1})}_{\geq 0}.$$

We now rearrange the terms to bound the regret of Gain MEG:

$$G_{\mathbf{W}} - G_A \leq \frac{1}{e^\eta - 1} k \log \frac{n}{k} + \left(1 - \frac{\eta}{e^\eta - 1}\right) G_{\mathbf{W}}. \quad (\text{A.2})$$

Since $e^\eta \geq 1 + \eta$, the coefficient $\frac{1}{e^\eta - 1}$ of the first term on the RHS is upper bounded by $\frac{1}{\eta}$. Next we upper bound the coefficient of the second term by η :

$$1 - \frac{\eta}{e^\eta - 1} = 1 - \frac{\eta e^{-\eta}}{1 - e^{-\eta}} \leq 1 - \frac{\eta e^{-\eta}}{1 - e^{-\eta}} = 1 - e^{-\eta} \leq \eta.$$

The inequality (3.5) on the regret of Gain MEG now follows from these two upper bounds, the budget inequality $G_{\mathcal{W}} \leq B_G$ and from tuning the learning rate as a function of B_G :

$$\mathcal{R}_{\text{Gain EG}} \leq \frac{k \log \frac{k}{\eta}}{\eta} + \eta B_G \stackrel{\eta = \sqrt{\frac{\log \frac{k}{B_G}}{B_G}}}{=} \sqrt{2B_G k \log \frac{k}{\eta}} \frac{n}{n}.$$

Appendix B. Proof of Upper Bound (3.6) on the Regret of GD

Proof This proof is also standard (Herbster and Warmuth, 2001). Minor alterations are needed because we have matrix parameters. Let $\mathbf{W}_t \in \mathcal{W}_m$ be the parameter of the GD algorithm at trial t and \mathbf{X}_t be the instance matrix at this trial. Then for the best comparator $\mathbf{W} \in \mathcal{W}_m$ and any learning rate $\eta \geq 0$, the following holds

$$\|\mathbf{W}_{t+1} - \mathbf{W}\|_F^2 \leq \|\widehat{\mathbf{W}}_{t+1} - \mathbf{W}\|_F^2 = \|\mathbf{W}_t - \mathbf{W}\|_F^2 - 2\eta \text{tr}((\mathbf{W}_t - \mathbf{W})\mathbf{X}_t^\top) + \eta^2 \|\mathbf{X}_t\|_F^2,$$

where the inequality follows from the Pythagorean Theorem (Herbster and Warmuth, 2001) and the equality follows from the descent step of the GD algorithm (see (2.5)). By rearranging terms, we have

$$\text{tr}(\mathbf{W}_t \mathbf{X}_t^\top) - \text{tr}(\mathbf{W} \mathbf{X}_t^\top) \leq \frac{\|\mathbf{W}_t - \mathbf{W}\|_F^2 - \|\mathbf{W}_{t+1} - \mathbf{W}\|_F^2}{2\eta} + \frac{\eta \|\mathbf{X}_t\|_F^2}{2}.$$

Note that the LHS is the regret in trial t w.r.t. \mathbf{W} . By summing all trials, we have that the (total) regret $\mathcal{R}_{GD} = \sum_{t=1}^T \text{tr}(\mathbf{W}_t \mathbf{X}_t^\top)$ is upper bounded by

$$\frac{\|\mathbf{W}_1 - \mathbf{W}\|_F^2 - \|\mathbf{W}_{T+1} - \mathbf{W}\|_F^2}{2\eta} + \frac{\eta \sum_{t=1}^T \|\mathbf{X}_t\|_F^2}{2} \leq \frac{k(n-k)}{2n\eta} + \frac{\eta \sum_{t=1}^T \|\mathbf{X}_t\|_F^2}{2}, \quad (\text{B.1})$$

where we used $\|\mathbf{W}_1 - \mathbf{W}\|_F^2 \leq \frac{k(n-k)}{n}$ since $\mathbf{W} \in \mathcal{W}_m$ and $\mathbf{W}_1 = \frac{n-k}{n} \mathbf{I}$. In the L_1 -bounded instance matrix case (when $\|\mathbf{X}_t\|_F^2 \leq 1$), (B.1) can be further simplified as

$$\mathcal{R}_{GD} \leq \frac{k(n-k)}{2n\eta} + \frac{\eta T}{2}.$$

By setting $\eta = \frac{k(n-k)}{n\sqrt{T}}$, we obtain the $\sqrt{\frac{k(n-k)}{n}T}$ regret bound for the L_1 -bounded instance case. When the instance matrices are L_∞ -bounded, then $\|\mathbf{X}_t\|_F^2 \leq n$ and hence, $\mathcal{R}_{GD} \leq \sqrt{k(n-k)T}$ with $\eta = \frac{k(n-k)}{\sqrt{T}}$. \blacksquare

Appendix C. Proof of Theorem 4.1

Theorem 4.1 gives a lower bound on the regret of the GD algorithm for the m -set problem with unit bit vectors as loss vectors. At each trial of the m -set problem, the online algorithm

first predicts with a weight vector $\mathbf{w}_t \in [0, 1]^n$, the coordinates of which sum to m . Then the algorithm receives a unit bit vector ℓ_t and suffers loss $\mathbf{w}_t \cdot \ell_t$. The GD algorithm for online PCA (2.5) specializes to the following updates of the parameter vector for learning m -sets:

$$\begin{aligned} \text{Descent step:} \quad & \hat{\mathbf{w}}_{t+1} = \mathbf{w}_t - \eta \ell_t, \\ \text{Projection step:} \quad & \mathbf{w}_{t+1} = \text{argmin}_{\mathbf{w} \in \mathcal{S}_m} \|\mathbf{w} - \hat{\mathbf{w}}_{t+1}\|^2, \end{aligned} \quad (\text{C.1})$$

where $\eta > 0$ is the learning rate and $\mathcal{S}_m = \{\mathbf{w} \in [0, 1]^n : \sum_{i=1}^n w_i = m\}$.

Since our lower bound for GD must hold no matter what the *fixed* learning rate η is, we construct two adversarial loss sequences: The first causes the GD algorithm to suffer large regret when η is small and the second causes large regret when η is large. Specifically, we will show that the GD algorithm suffers regret at least $\Omega(k/\eta)$ on the first sequence, and at least $\Omega(\min\{B_T, kB_T\eta\})$ on the second sequence. We will then show that the lower bound of the theorem follows by taking the maximum of these two bounds and by solving for the learning rate that minimizes this maximum. The first sequence consists of unit losses assigned to the first k experts. At each trial, the adversary gives a unit of loss to the expert (out of the first k) with the largest current weight. If the learning rate η is small, then the weights assigned to the first k experts decrease too slowly (Lemma C.2). This causes the algorithm to suffer a substantial amount of loss on the first sequence, while the loss of the remaining m experts remains zero. The second sequence consists of unit losses assigned to the first $k+1$ experts. As before, the adversary always gives the expert with the largest weight (now out of the first $k+1$) a unit of loss. Intuitively, the GD algorithm will give high weight to the $m-1 = n-(k+1)$ loss free experts and the best out of the first $k+1$ experts. As the η gets larger, the algorithm puts more and more weight on the *current* best out of the $k+1$ experts instead of hedging its bets over all $k+1$ experts. So the algorithm becomes more and more deterministic and the adversary strategy of hitting the expert with the largest weight (out of the first $k+1$) causes the algorithm to suffer a substantial loss (Lemma C.3). Formalizing these findings is not simple as the projection step of the GD algorithm does not have a closed form. Hence, we need to resort to the Karush-Kuhn-Tucker optimality conditions and prove a sequence of lemmas before assembling all the pieces for proving Theorem 4.1.

Let α_i be a dual variable for the constraint $w_{t+1,i} \geq 0$ ($i = 1, \dots, n$), β_i be a dual variable for the constraint $w_{t+1,i} \leq 1$ ($i = 1, \dots, n$), and γ be a dual variable for the constraint $\sum_{i=1}^n w_{t+1,i} = m$. Then the KKT conditions on the projection step of (C.1) have the following form: For $i = 1, \dots, n$,

$$\begin{aligned} \text{Stationarity:} \quad & w_{t+1,i} = -w_{t,i} - \eta \ell_{t,i} + \gamma + \alpha_i - \beta_i, \\ \text{Complementary slackness:} \quad & w_{t+1,i} \alpha_i = 0, \quad (w_{t+1,i} - 1) \beta_i = 0, \\ \text{Primal feasibility:} \quad & \sum_{i=1}^n w_{t+1,i} = m, \quad 0 \leq w_{t+1,i} \leq 1, \\ \text{Dual feasibility:} \quad & \alpha_i \geq 0, \quad \beta_i \geq 0. \end{aligned} \quad (\text{C.2})$$

Note that since the projection step of (C.1) is a convex optimization problem, these conditions are necessary and sufficient for the optimality of a solution. Hence, for any intermediate weight vector $\hat{\mathbf{w}}_{t+1} = \mathbf{w}_t - \eta \ell_t$, if a set of primal and dual variables $\mathbf{w}_{t+1}, \boldsymbol{\alpha} = (\alpha_1, \dots, \alpha_n), \boldsymbol{\beta} = (\beta_1, \dots, \beta_n), \gamma$ satisfy all the conditions (C.2), then they are the unique primal and dual solutions of the projection step.

We start with a special case where the GD update (C.1) actually has a closed form solution:

Lemma C.1 *Consider a trial of the m -set problem with n experts, when only one expert incurs a unit of loss. If this expert has weight w and all remaining experts have weight at most $1 - \min\{\frac{\eta}{n}, \frac{w}{n-1}\}$, then the GD algorithm with learning rate $\eta > 0$ will decrease w by $\min\{\frac{(n-1)\eta}{n}, w\}$ and increase all the other weights by $\min\{\frac{\eta}{n}, \frac{w}{n-1}\}$.*

Proof W.l.o.g., the first expert incurs a unit of loss in trial t , i.e. $w_{t,1} = w$ and $\ell_t = \mathbf{e}_1$, where \mathbf{e}_1 is the unit bit vector with first coordinate equal to 1 (and all other coordinates equal to 0). To solve the projection step of the GD update (C.1), we distinguish two cases based on the value of $w_{t,1}$. In each case we propose a solution to the projection step and show that it is a valid solution by verifying the KKT conditions (C.2).

Case $w_{t,1} = w \geq \frac{n-1}{n}\eta$: The proposed solution is $\gamma = \frac{\eta}{n}$ and for $1 \leq i \leq n$, $\alpha_i = \beta_i = 0$,

$$w_{t+1,i} = \begin{cases} w_{t,1} - \frac{n-1}{n}\eta & \text{for } i = 1 \\ w_{t,i} + \frac{\eta}{n} & \text{for } i \geq 2 \end{cases}.$$

All KKT conditions are easy to check, except for the primal feasibility condition: $w_{t+1,i} \leq 1$, for $i \geq 2$. By the assumption of the lemma, $w_{t,i} \leq 1 - \min\{\frac{\eta}{n}, \frac{w_{t,1}}{n-1}\}$. Since we are in the case $w_{t,1} \geq \frac{n-1}{n}\eta$, we have $w_{t,i} \leq 1 - \frac{\eta}{n}$ and therefore

$$w_{t+1,i} = w_{t,i} + \frac{\eta}{n} \leq 1 - \frac{\eta}{n} + \frac{\eta}{n} = 1.$$

We conclude that in this case, the first weight decreases by $\frac{n-1}{n}\eta$ and all the other weights increase by $\frac{\eta}{n}$.

Case $w_{t,1} = w < \frac{n-1}{n}\eta$: The proposed solution is $\gamma = \frac{w_{t,1}}{n-1}$ and for $1 \leq i \leq n$, $\beta_i = 0$,

$$\alpha_i = \begin{cases} \eta - \frac{\eta}{n-1}w_{t,1} & \text{for } i = 1 \\ 0 & \text{for } i \geq 2 \end{cases}, \quad w_{t+1,i} = \begin{cases} 0 & \text{for } i = 1 \\ w_{t,i} + \frac{w_{t,1}}{n-1} & \text{for } i \geq 2 \end{cases}.$$

Again, all KKT conditions are easy to check, except for the primal feasibility condition $w_{t+1,i} \leq 1$ for $i \geq 2$. By the assumption of the lemma $w_{t,i} \leq 1 - \min\{\frac{\eta}{n}, \frac{w_{t,1}}{n-1}\}$. Since we are in the case $w_{t,1} < \frac{n-1}{n}\eta$, we have $w_{t,i} \leq 1 - \frac{w_{t,1}}{n-1}$ and therefore

$$w_{t+1,i} = w_{t,i} + \frac{w_{t,1}}{n-1} \leq 1 - \frac{w_{t,1}}{n-1} + \frac{w_{t,1}}{n-1} = 1.$$

We conclude that in this case, the first weight decreases by $w_{t,1}$ and all the other weights increase by $\frac{w_{t,1}}{n-1}$. Combining the above two cases proves the lemma. \blacksquare

Our next lemma considers the general case when the weight vector before the update does not necessarily satisfy the assumption in Lemma C.1, i.e. the weights of the experts not incurring loss may be larger than $1 - \min\{\frac{\eta}{n}, \frac{w}{n-1}\}$ (where w is the weight of the only expert incurring loss).

Lemma C.2 *Consider a trial of the m -set problem with n experts, when only one expert incurs a unit of loss. If this expert has weight w , then the GD algorithm with learning rate $\eta > 0$ will decrease w by at most η and will not decrease the weights of any other experts. Furthermore, if any expert not incurring loss has weight at least $1 - \min\{\frac{\eta}{n}, \frac{w}{n-1}\}$, then its weight will be set to 1 by the capping constraint.*

Proof Let w_t be the weight vector at the beginning of the trial and assume w.l.o.g. that the first expert incurs one unit of loss, i.e. $\ell_t = \mathbf{e}_1$. Let w_{t+1} , α , β and γ denote the variables satisfying the KKT conditions (C.2). The lemma now states that:

$$w_{t+1,1} \geq w_{t,1} - \eta \quad \text{and} \quad w_{t+1,i} \geq w_{t,i}, \quad \text{for } 2 \leq i \leq n, \quad (\text{C.3})$$

and furthermore

$$w_{t+1,i} = 1, \quad \text{for any } 2 \leq i \leq n \text{ such that } w_{t,i} \geq 1 - \min\left\{\frac{\eta}{n}, \frac{w_{t,1}}{n-1}\right\}. \quad (\text{C.4})$$

We first prove (C.3). By the stationarity condition of (C.2) and the assumption $\ell_t = \mathbf{e}_1$, we have that

$$w_{t+1,1} - w_{t,1} = \cancel{w_{t,1}} - \eta + \alpha_1 - \beta_1 + \gamma - \cancel{w_{t,1}} = -\eta + \alpha_1 - \beta_1 + \gamma,$$

$$\text{and for } 2 \leq i \leq n: \quad w_{t+1,i} - w_{t,i} = \cancel{w_{t,i}} + \alpha_i - \beta_i + \gamma - \cancel{w_{t,i}} = \alpha_i - \beta_i + \gamma.$$

Therefore, to prove (C.3), it suffices to show $\alpha_i - \beta_i + \gamma \geq 0$ for $1 \leq i \leq n$. By the dual feasibility condition of (C.2), $\alpha_i \geq 0$ but $-\beta_i \leq 0$. However, when $-\beta_i < 0$, we have $w_{t+1,i} = 1$ by the complementary slackness condition, and therefore (C.3) holds trivially in this case (noting that $w_{t,i} \leq 1$). Now we only need to show $\gamma \geq 0$. We do this by summing $w_{t,i} - \eta\ell_{t,i} + \gamma$ over indices i such that $w_{t+1,i} > 0$:

$$\begin{aligned} \sum_{i:1 \leq i \leq n, w_{t+1,i} > 0} (w_{t,i} - \eta\ell_{t,i} + \gamma) & \stackrel{\alpha_i = 0 \text{ since } w_{t+1,i} > 0}{=} \sum_{i:1 \leq i \leq n, w_{t+1,i} > 0} (w_{t,i} - \eta\ell_{t,i} + \gamma + \alpha_i) \\ & \geq \sum_{i:1 \leq i \leq n, w_{t+1,i} > 0} (w_{t,i} - \eta\ell_{t,i} + \gamma + \alpha_i - \beta_i) \\ & \geq \sum_{i:1 \leq i \leq n, w_{t+1,i} > 0} (w_{t,i}) = m. \end{aligned} \quad (\text{C.5})$$

Furthermore, since both the learning rate η and the loss vector ℓ_t are non-negative, we have that for all $1 \leq i \leq n$,

$$\sum_{i:1 \leq i \leq n, w_{t+1,i} > 0} (w_{t,i} - \eta\ell_{t,i}) \leq \sum_{i:1 \leq i \leq n, w_{t+1,i} > 0} (w_{t,i}) \leq m.$$

Combining the above inequality with (C.5) implies that $\gamma \geq 0$, which completes our proof of (C.3).

Next we prove (C.4). By the stationarity condition of (C.2) and the assumption $\ell_t = \mathbf{e}_1$, we have that for $2 \leq i \leq n$,

$$w_{t+1,i} = w_{t,i} - \eta\ell_{t,i} + \alpha_i - \beta_i + \gamma = w_{t,i} + \alpha_i - \beta_i + \gamma. \quad (\text{C.6})$$

Now if we further assume that $w_{t,i} \geq 1 - \min\{\frac{\eta}{n}, \frac{w_{t,1}}{n-1}\}$, then (C.6) is lower bounded by

$$w_{t+1,i} = w_{t,i} + \alpha_i - \beta_i + \gamma \geq 1 - \min\left\{\frac{\eta}{n}, \frac{w_{t,1}}{n-1}\right\} + \alpha_i - \beta_i + \gamma.$$

Thus to prove (C.4), it suffices to show that $-\min\{\frac{\eta}{n}, \frac{w_{t,1}}{n-1}\} + \alpha_i - \beta_i + \gamma \geq 0$. By the dual feasibility condition of (C.2), $\alpha_i \geq 0$ but $-\beta_i \leq 0$. However, when $-\beta_i < 0$, then $w_{t+1,i} = 1$ follows directly from the complementary slackness condition. Therefore w.l.o.g., we assume $\beta_i = 0$. Now all that remains is to show $\gamma \geq \min\{\frac{\eta}{n}, \frac{w_{t,1}}{n-1}\}$, for which we distinguish the following 2 cases.

Case $w_{t+1,1} > 0$: We will show $\gamma \geq \frac{\eta}{n}$ for this case. First note that

$$m \stackrel{(C.5)}{\leq} \sum_{i:1 \leq i \leq n, w_{t+1,i} > 0} (w_{t,i} - \eta \ell_{t,i} + \gamma) \stackrel{\gamma \geq 0}{\leq} \sum_{i:1 \leq i \leq n, w_{t+1,i} > 0} (w_{t,i} - \eta \ell_{t,i}) + n\gamma. \quad (C.7)$$

Now since we assume $w_{t+1,1} > 0$ and $\ell_t = e_1$, the first term on RHS of (C.7) is upper bounded by:

$$\sum_{i:1 \leq i \leq n, w_{t+1,i} > 0} (w_{t,i} - \eta \ell_{t,i}) = \sum_{i:1 \leq i \leq n, w_{t+1,i} > 0} (w_{t,i}) - \eta \leq m - \eta.$$

Together, we get $m \leq n\gamma - \eta + m$, and this gives $\gamma \geq \frac{\eta}{n}$.

Case $w_{t+1,1} = 0$: We will show $\gamma \geq \frac{w_{t,1}}{n-1}$ for this case. Since $w_{t+1,1} = 0$, the summation

$$\sum_{i:1 \leq i \leq n, w_{t+1,i} > 0} (w_{t,i} - \eta \ell_{t,i} + \gamma) \text{ does not include the case } i = 1, \text{ i.e.}$$

$$\sum_{i:1 \leq i \leq n, w_{t+1,i} > 0} (\hat{w}_{t,i} - \eta \ell_{t,i} + \gamma) = \sum_{i:2 \leq i \leq n, w_{t+1,i} > 0} (\hat{w}_{t,i} - \eta \ell_{t,i} + \gamma).$$

Therefore, (C.7) can be tightened as follows:

$$m \stackrel{(C.5)}{\leq} \sum_{i:2 \leq i \leq n, w_{t+1,i} > 0} (w_{t,i} - \eta \ell_{t,i} + \gamma) \stackrel{\gamma \geq 0}{\leq} \sum_{i:1 \leq i \leq n, w_{t+1,i} > 0} (w_{t,i} - \eta \ell_{t,i}) + (n-1)\gamma.$$

Again, by the assumption $\ell_t = e_1$, we have

$$\sum_{i:2 \leq i \leq n, w_{t+1,i} > 0} (w_{t,i} - \eta \ell_{t,i}) = \sum_{i:2 \leq i \leq n, w_{t+1,i} > 0} (w_{t,i}) \leq m - w_{t,1}.$$

Together, we get $m \leq (n-1)\gamma + m - w_{t,1}$, which gives $\gamma \geq \frac{w_{t,1}}{n-1}$ and completes the proof. ■

Our third lemma lower bounds the loss of the GD algorithm with respect to a particular adversarial loss sequence of n trials (instead of the above lower bounds for single trials). We argue this lower bound for the special case of the m -set problem when $m = 1$, i.e. the vanilla expert setting. As we shall see shortly in the main proof of Theorem 4.1, the lower bound of the general m -set problem degenerates into this special case for a certain loss sequence. Note that the assumptions of Lemma C.1 are always met when $m = 1$, because in this case any expert not incurring loss has weight at most $1 - w$, where w is the weight of the expert incurring loss.

Lemma C.3 *Consider the m -set problem with n experts, and $m = 1$. If at each trial, only the expert with the largest weight incurs a unit of loss, then after n consecutive such trials, the GD algorithm with learning rate $\eta > 0$ suffers loss at least $1 + \frac{1}{32} \min\{\eta, 1\}$.*

Proof First notice that when $m = 1$, the largest of the n expert weights at each trial is at least $\frac{1}{n}$. Therefore, any algorithm suffers total loss at least 1 in n trials. To show the extra loss of $\frac{1}{32} \min\{\eta, 1\}$, we claim that in at least $\frac{n}{4}$ of these n trials, the largest expert weight assigned by the GD algorithm is at least $\frac{1}{n} + \frac{1}{8} \min\{\eta, \frac{1}{n}\}$. This claim is proved as follows.

Let $\eta' = \min\{\eta, \frac{1}{n}\}$ and t_0 be the first trial that the largest expert weight of the trial is less than $\frac{1}{n} + \frac{1}{8}\eta'$. If $t_0 > \frac{n}{4}$, the claim holds trivially. Hence, we assume $t_0 \leq \frac{n}{4}$. Now call any expert with weight at least $\frac{1}{n} - \frac{1}{8}\eta'$ at trial t_0 a *candidate*. We will show that the number of candidates s is at least $\frac{n}{4}$. To show this we first upper bound the expert weights at trial t_0 as follows:

$$\begin{aligned} \text{sum of non-candidates' weights} &\leq (n-s) \left(\frac{1}{n} - \frac{1}{8}\eta'\right), \\ \text{sum of candidates' weights} &\leq s \left(\frac{1}{n} + \frac{1}{8}\eta'\right). \end{aligned}$$

The first inequality follows from the fact that non-candidates have weight at most $\frac{1}{n} - \frac{1}{8}\eta'$ and the second inequality follows from the definition of t_0 , i.e. the maximum weight at that trial is less than $\frac{1}{n} + \frac{1}{8}\eta'$. Now, since all the expert weights at a trial sum to 1, we have

$$1 \leq s \left(\frac{1}{n} + \frac{1}{8}\eta'\right) + (n-s) \left(\frac{1}{n} - \frac{1}{8}\eta'\right) = 1 + \frac{s}{4} \eta' - \frac{n}{8} \eta',$$

which gives $s \geq \frac{n}{2}$ since $\eta' \geq \eta > 0$.

Next, we show that at trial $t_0 + \frac{n}{4}$, there will be a subset of at least $\frac{n}{4}$ candidates whose weight will be at least $\frac{1}{n} + \frac{1}{8}\eta'$. First recall that at each trial, only one expert incurs a unit of loss. Therefore, in the $\frac{n}{4}$ trials from t_0 to $t_0 + \frac{n}{4} - 1$, there will be at least $\frac{n}{2} - \frac{n}{4} = \frac{n}{4}$ candidates that do not incur any loss. By Lemma C.1, the weight of an expert not incurring loss is increased at each trial by $\min\{\frac{\eta}{n}, \frac{w_{t,i}}{n-1}\}$, where w is the weight of the expert not incurring loss at that trial. Note that $w \geq \frac{1}{n}$ always hold since the expert incurring loss has the largest weight among the n experts. Therefore, at trial $t_0 + \frac{n}{4}$, each of the $\frac{n}{4}$ candidates that do not incur any loss from trial t_0 to trial $t_0 + \frac{n}{4} - 1$ has weight at least:

$$\underbrace{\frac{1}{n} - \frac{1}{8}\eta'}_{\text{lower bound on the weight at trial } t_0} + \underbrace{\frac{n}{4} \min\left\{\frac{\eta}{n}, \frac{w_t}{n-1}\right\}}_{\text{lower bound on the increase from trial } t_0 \text{ to trial } t_0 + \frac{n}{4} - 1} \stackrel{w_t \geq \frac{1}{n}}{\geq} \frac{1}{n} - \frac{1}{8}\eta' + \frac{n}{4} \min\left\{\frac{\eta}{n}, \frac{1}{n^2}\right\} = \frac{1}{n} + \frac{\eta'}{8}.$$

Finally, consider the next $\frac{n}{4}$ trials from $t_0 + \frac{n}{4}$ to $t_0 + \frac{n}{2} - 1$. (The game must have more than $t_0 + \frac{n}{2}$ trials, since we assume $t_0 \leq \frac{n}{4}$.) The maximum weights at these trials are always at least $\frac{1}{n} + \frac{1}{8}\eta'$, because only one expert incurs loss at a time, and the weights of the remaining experts are never decreased. This completes the proof of the claim and the lemma. ■

Now we are ready to give the lower bound on the regret of the GD algorithm for the m -set problem. For the sake of readability, we repeat the statement of Theorem 4.1 below:

Theorem 4.1 *Consider the m -set problem with $k \leq n/2$ and unit bit vectors as loss vectors. Then for any fixed learning rate η , the GD algorithm (C.1) can be forced to have regret at least $\Omega(\max\{\min\{B_L, k\sqrt{B_L}\}, k\})$.*

Proof The lower bound $\Omega(k)$ directly follows from Lemma G.2 proven later: If we set the variable i in the statement of the lemma to k , then this results in a lower bound of $\Omega(m \log \frac{m}{k})$ for any algorithm. Now, $m \log \frac{m}{k} = m \log(\frac{k}{m} + 1) \geq k$. Hence to prove this theorem, we only need to show a lower bound of $\Omega(\min\{B_L, k\sqrt{B_L}\})$, where B_L is the loss budget (defined in (3.1)). Also, w.l.o.g., assume $B_L \geq 4k$ since when $B_L \leq 4k$, the claimed bound is in fact $\Omega(k)$, which always holds as we just argued.

The hard part (deferred to later) in proving the $\Omega(\min\{B_L, k\sqrt{B_L}\})$ lower bound for GD is to show that the algorithm suffers regret at least $\Omega(k/\eta)$ and $\Omega(\min\{B_L, kB_L\eta\})$ on two different loss sequences, respectively. Clearly, it follows that the regret of GD is then at least the maximum of these two bounds. By a case analysis, one can show that $\max\{a, \min\{b, c\}\} \geq \min\{b, c\}$ for any $a, b, c \in \mathbb{R}$. (We prove this as Lemma I.1 in Appendix I.) Therefore we get the lower bound of $\Omega(\min\{B_L, \max\{k/\eta, kB_L\eta\}\})$. The lower bound for GD with any fixed learning rate now follows from fact that $\max\{k/\eta, kB_L\eta\}$ is minimized at $\eta = \Theta(1/\sqrt{B_L})$. The value of the lower bound with this choice of η is the target lower bound of $\Omega(k\sqrt{B_L})$.

We still need to describe the two loss sequences and prove the claimed lower bounds on the regret. The first loss sequence forces GD to suffer regret $\Omega(k/\eta)$. It consists of $\lfloor \frac{km}{m\eta} \rfloor + 1$ trials in which only the first k experts incur losses. More precisely, at each trial, the expert with the largest weight (within the first k experts) incurs one unit of loss (In the case of tied weights, only the expert with the smallest index incurs loss). The last m experts have loss 0. Therefore the regret is simply the total loss of the GD algorithm. The loss of the algorithm at each trial is equal to the largest weight of the first k experts. Therefore the loss is lower bounded by the average of the first k weights. With a uniform initial weight vector, this average is $\frac{m}{n}$ at the beginning of the first trial, and by Lemma C.2, it is decreased by at most $\frac{\eta}{k}$ after each of the following $\lfloor \frac{km}{m\eta} \rfloor + 1$ trials. Therefore, at the beginning of trial t , the average is at least $\frac{m}{n} - (t-1)\frac{\eta}{k}$. Summing up the arithmetic series from trial 1 to trial $\lfloor \frac{km}{m\eta} \rfloor + 1$ gives the following lower bound on the total loss of GD:

$$\frac{1}{2} \left(\left\lfloor \frac{km}{m\eta} \right\rfloor + 1 \right) \left(\frac{m}{n} - \left(\left\lfloor \frac{km}{m\eta} \right\rfloor + 1 - 1 \right) \frac{\eta}{k} \right) \stackrel{\frac{m}{n} \geq \frac{1}{2}}{\geq} \frac{1}{4} \left(\left\lfloor \frac{k}{2\eta} \right\rfloor + 1 \right) = \Omega\left(\frac{k}{\eta}\right).$$

Now we describe the second loss sequence which forces the GD algorithm to suffer regret $\Omega(\min\{B_L, kB_L\eta\})$. For the sake of clarity, we assume that B_L is integer (otherwise replace B_L by $\lfloor B_L \rfloor$ in the proof). The sequence consists of $(k+1)B_L$ trials, where the expert with the largest weight among first $k+1$ experts incurs a unit of loss. The best comparator of this sequence consists of the last $m-1$ experts that have 0 total loss and the best of the first $k+1$ experts which has total loss at most B_L .

Next we lower bound the loss of GD with respect to this loss sequence. First observe, that the last $m-1$ experts do not incur any loss in the $(k+1)B_L$ trials. Therefore their weight may increase (from their initial value of $\frac{m}{n}$), but at any trial the weights of these

experts always have the same value. The value of this block of equal weights is always the maximum weight of any expert, since the weight value of the block is never decreased by the algorithm. More precisely, at each trial the block's value is increased as given in Lemma C.1, until it becomes 1 at trial t_{cap} and stay at 1 till the end of the game. If no such trial t_{cap} exists (i.e. the value of the block remains less than 1 at the end of the game), then let $t_{cap} = \infty$. In the degenerate case when $m = 1$ (i.e. the block has size $m-1 = 0$), we simply set $t_{cap} = 1$ from the beginning.

Depending on the value of t_{cap} , we distinguish two cases in which GD suffers loss at least $B_L + \Omega(B_L)$ and $B_L + \Omega(\min\{B_L, kB_L\eta\})$, respectively.

Case $t_{cap} > (k+1)B_L/2$: We will show that GD suffers loss at least $B_L + \Omega(B_L)$ in this case. First recall that at the beginning of the proof we assumed $B_L \geq 4k$. Therefore in the case $t_{cap} > (k+1)B_L/2$ we have $t_{cap} > 4$. From our definition of t_{cap} this means that $m \geq 2$. Next we argue that since $t_{cap} > (k+1)B_L/2$, we have $\eta \leq \frac{1}{k+1}$. Let W_t denote the sum of the first $k+1$ weights at trial t and let w_t be their maximum. By Lemma C.1, we know that in each trial prior to t_{cap} , the weight w_t of the expert incurring loss is decreased by $\min\{\frac{(n-1)\eta}{n}, w_t\}$ and all other weights are increased by $\min\{\frac{\eta}{n}, \frac{w_t}{n-1}\}$. Since the expert incurring loss is always one of the first $k+1$ experts, we have that in each trial prior to t_{cap} , the total weight W_t is decreased by at least

$$\min \left\{ \frac{(n-1)\eta}{n}, w_t \right\} - k \min \left\{ \frac{\eta}{n}, \frac{w_t}{n-1} \right\} \geq \frac{m-1}{n} \min\{\eta, w_t\} \geq \frac{m-1}{n} \min \left\{ \eta, \frac{1}{k+1} \right\}.$$

The second inequality follows from the fact that since w_t is the largest of the first $k+1$ expert weights, it must be at least $\frac{1}{k+1}$. Together with the fact that $W_1 = \frac{(k+1)m}{n}$, we have

$$W_{(k+1)B_L/2} \leq \frac{(k+1)m}{n} - \frac{(k+1)B_L m - 1}{2n} \min \left\{ \eta, \frac{1}{k+1} \right\}. \quad (\text{C.8})$$

Now if $\eta \geq \frac{1}{k+1}$, the upper bound (C.8) becomes $\frac{(k+1)m}{n} - \frac{(m-1)B_L}{2n}$, which can be further upper bounded by $\frac{m}{n}$ using the fact $m \geq 2$ and the assumption $B_L \geq 4k$. However, the upper bound of $W_{(k+1)B_L/2} \leq \frac{m}{n}$ is less than 1 and all W_t are at least 1 since $m - W_t$ is the total weight of the last $m-1$ experts which is at most $m-1$. Therefore we have $\eta < \frac{1}{k+1}$ in this case.

Now we lower bound the loss of GD by lower bounding the average weight $W_t/(k+1)$. We have $\eta < \frac{1}{k+1}$ and $t_{cap} > (k+1)B_L/2$. Also by Lemma C.1, W_t decreases by exactly $\frac{(m-1)\eta}{n}$ at each trial for $1 \leq t \leq (k+1)B_L/2$. Therefore the total average weight in trials 1 through $(k+1)B_L/2$ is at least

$$\frac{1}{2k+1} \left(\frac{(k+1)m}{n} + 1 \right) \frac{(k+1)B_L}{2} = \left(\frac{(k+1)m}{n} + 1 \right) \frac{B_L}{4}. \quad (\text{C.9})$$

Now with $m \geq 2$, $k \geq 1$ and $n = m+k$, it is easy to verify that $\frac{(k+1)m}{n}$ is at least $1 + \Omega(1)$, which along with (C.9) results in a $\frac{B_L}{4} + \Omega(B_L)$ lower bound on the loss of GD for $1 \leq t \leq (k+1)B_L/2$. In trials $(k+1)B_L/2 < t \leq (k+1)B_L$, GD suffers loss at least $\frac{(k+1)B_L}{2} = \frac{B_L}{2}$ since the weight of the expert incurring loss is at least $\frac{1}{k+1}$. Thus in trial

1 through $(k+1)B_L$ the loss of GD is at least $B_L + \Omega(B_L)$ which concludes the proof of the case $t_{\text{cap}} \geq (k+1)B_L/2$.

Case $t_{\text{cap}} \leq (k+1)B_L/2$: We will show that GD suffers total loss at least $B_L + \Omega(\min\{B_L, kB_L\eta\})$ in this case. First note that GD suffers loss at least $B_L/2$ in the first $(k+1)B_L/2$ trials. This follows from the fact that in each trial, the expert with the largest weight among first $k+1$ experts incurs a unit of loss. Since the sum of all weights is equal to m , and none of the remaining $m-1$ weights can exceed 1, the sum of weights of the first $k+1$ experts must be at least 1, and hence the largest weight among the first $k+1$ experts is at least $\frac{1}{k+1}$. This means that in a sequence of $(k+1)B_L/2$ trials, the loss of the GD algorithm is at least $B_L/2$.

Thus, it suffices to show that GD suffers loss at least $B_L/2 + \Omega(\min\{B_L, kB_L\eta\})$ in trials $(k+1)B_L/2 + 1$ through $(k+1)B_L$. First note that since $t_{\text{cap}} \leq (k+1)B_L/2$, in each of these trials the weights of the $m-1$ loss free experts have reached the cap 1. This means that GD updates the weights of the first $k+1$ experts as in the vanilla expert setting (i.e. $m=1$). Therefore by Lemma C.3, the loss of GD in the second $(k+1)B_L/2$ trials is at least $\frac{B_L}{2}(1 + \frac{1}{32} \min\{(k+1)\eta, 1\}) = \frac{B_L}{2} + \Omega(\min\{B_L, kB_L\eta\})$.

We conclude that for the second loss sequence, the loss of the best comparator is at most B_L and the loss of GD is at least $B_L + \Omega(\min\{B_L, kB_L\eta\})$. Therefore, the regret of GD is at least $\Omega(\min\{B_L, kB_L\eta\})$ for the second loss sequence and this completes our proof of the theorem. \blacksquare

Appendix D. Proof of Theorem 4.3

Theorem 4.3 gives a lower bound on the regret of the FRL-GD algorithm for the m -set problem with unit bit vectors as loss vectors. In this case, the FRL-GD algorithm (4.2) specializes to the following:

$$\begin{aligned} \text{Follow the regularized leader: } \hat{\mathbf{w}}_{t+1} &= -\eta \sum_{g=1}^t \ell_{g_t} \\ \text{Projection step: } \mathbf{w}_{t+1} &= \underset{\mathbf{w} \in \mathcal{S}_m}{\text{argmin}} \|\mathbf{w} - \hat{\mathbf{w}}_{t+1}\|^2. \end{aligned} \quad (\text{D.1})$$

The proof has the same structure as the lower bound for the GD algorithm (Appendix C). Again we use two adversarial loss sequences (one for low and high learning rates) and give three technical lemmas that reason with the KKT conditions. The details are different because the intermediate weight vector \mathbf{w}_{t+1} has a different form than for vanilla GD. The KKT conditions are the same as the KKT condition for GD (C.1) except for a slight change in the stationarity condition. For $i=1, \dots, n$,

$$\begin{aligned} \text{Stationarity:} & \quad w_{t+1,i} = -\eta \ell_{\leq t,i} + \gamma + \alpha_i - \beta_i, \\ \text{Complementary slackness: } & \quad w_{t+1,i} \alpha_i = 0, \quad (w_{t+1,i} - 1) \beta_i = 0, \\ \text{Primal feasibility:} & \quad \sum_{i=1}^n w_{t+1,i} = m, \quad 0 \leq w_{t+1,i} \leq 1, \\ \text{Dual feasibility:} & \quad \alpha_i \geq 0, \quad \beta_i \geq 0, \end{aligned} \quad (\text{D.2})$$

where $\ell_{\leq t,i} = \sum_{g=1}^t \ell_{g_t,i}$ is the cumulative loss of expert i up to trial t . Again we prove three technical lemmas before assembling them into the main proof.

Lemma D.1 Consider the m -set problem with n experts, where at the beginning of trial $t+1$, each of the first $k+1$ experts (where $k = n-m$) have incurred the same cumulative loss ℓ , and all the remaining experts are loss free, i.e.

$$\ell_{\leq t,i} = \begin{cases} \ell & \text{for } i \leq k+1 \\ 0 & \text{for } i > k+1 \end{cases}.$$

Now the FRL-GD algorithm predicts at trial $t+1$ with the weight vector \mathbf{w}_{t+1} given by:

$$w_{t+1,i} = \begin{cases} \begin{cases} \text{if } \eta \ell < \frac{k}{k+1} \text{ then } \begin{cases} \frac{m-\eta \ell(m-1)}{n} & \text{for } i \leq k+1 \\ \frac{m+\eta \ell(k+1)}{n} & \text{for } i > k+1 \end{cases} \\ \text{if } \eta \ell \geq \frac{k}{k+1} \text{ then } \begin{cases} \frac{1}{k+1} & \text{for } i \leq k+1 \\ 1 & \text{for } i > k+1 \end{cases} \end{cases} \end{cases}.$$

Proof We prove this lemma by verifying the KKT conditions (D.2). If $\eta \ell < \frac{k}{k+1}$, we have:

$$1 > \frac{m - \eta \ell(m-1)}{n} > 0, \quad \text{and} \quad 0 < \frac{m + \eta \ell(k+1)}{n} < 1.$$

Therefore $0 < w_{t+1,i} < 1$, for all i . By taking $\boldsymbol{\alpha} = \boldsymbol{\beta} = \mathbf{0}$, and $\gamma = \frac{m+\eta \ell(k+1)}{n}$, the KKT conditions can easily be verified to hold. If $\eta \ell \geq \frac{k}{k+1}$, the KKT conditions are satisfied by taking $\alpha_i = 0$ for $i \leq k+1$ and $\alpha_i = \frac{k}{k+1} - \eta \ell$ for $i > k+1$, $\boldsymbol{\beta} = \mathbf{0}$ and $\gamma = \frac{1}{k+1} + \eta \ell$. \blacksquare

Lemma D.2 Consider a trial of the m -set problem with n experts, when only one expert incurs a unit of loss. Then the FRL-GD algorithm with learning rate $\eta > 0$ decreases the weight of this expert by at most η and none of the other weights are decreased in this trial.

Proof Let $\ell_{\leq t-1}$ be the cumulative loss vector at the beginning of the trial, and let $\mathbf{w}_t, \boldsymbol{\alpha}_t, \boldsymbol{\beta}_t$ and γ_t be the corresponding primal and dual variables satisfying KKT conditions (D.2) with respect to $\ell_{\leq t-1}$. W.l.o.g., we assume the first expert incurs a unit of loss, i.e. $\ell_{\leq t} = \ell_{\leq t-1} + \mathbf{e}_1$. Let $\mathbf{w}_{t+1}, \boldsymbol{\alpha}_{t+1}, \boldsymbol{\beta}_{t+1}$ and γ_{t+1} denote the variables satisfying the KKT conditions with respect to the updated loss vector $\ell_{\leq t}$. The lemma now states that $w_{t+1,1} - w_{t,1} \geq -\eta$.

The lemma holds trivially when $\mathbf{w}_{t+1} = \mathbf{w}_t$. When $\mathbf{w}_{t+1} \neq \mathbf{w}_t$, we first show that $\gamma_{t+1} \geq \gamma_t$. Since both \mathbf{w}_t and \mathbf{w}_{t+1} sum to m , there must be an expert j , such that $w_{t+1,j} < w_{t,j}$. By the stationarity condition of (D.2), we have:

$$\begin{aligned} 0 < w_{t+1,j} - w_{t,j} &= (-\eta \ell_{\leq t,j} + \alpha_{t+1,j} - \beta_{t+1,j} + \gamma_{t+1}) - (-\eta \ell_{\leq t-1,j} + \alpha_{t,j} - \beta_{t,j} + \gamma_t), \\ \text{or, equivalently,} & \quad \gamma_{t+1} - \gamma_t > \eta(\ell_{\leq t,j} - \ell_{\leq t-1,j}) + (\alpha_{t,j} - \alpha_{t+1,j}) + (\beta_{t+1,j} - \beta_{t,j}). \end{aligned} \quad (\text{D.3})$$

Since $w_{t+1,j} > w_{t,j}$, and the weights must be non-negative, we have $w_{t+1,j} > 0$, and thus $\alpha_{t+1,j} = 0$ due to the complementary slackness condition of (D.2). Since $\alpha_{t,j}$ must be

non-negative due to the dual feasibility condition of (D.2), we have $\alpha_{t,j} \geq \alpha_{t+1,j}$. A similar argument gives $\beta_{t+1,j} \geq \beta_{t,j}$. Moreover, since $\ell_{\leq t,j} - \ell_{\leq t-1,j} \geq 0$ (due to $\ell_{\leq t} = \ell_{\leq t-1} + \mathbf{e}_t$), the RHS of (D.3) is non-negative, and thus $\gamma_{t+1} \geq \gamma_t$.

By the stationary condition of (D.2), we have:

$$\begin{aligned} w_{t+1,1} - w_{t,1} &= (-\eta \ell_{\leq t,1} + \alpha_{t+1,1} - \beta_{t+1,1} + \gamma_{t+1}) - (-\eta \ell_{\leq t-1,1} + \alpha_{t,1} - \beta_{t,1} + \gamma_t) \\ &= -\eta + (\gamma_{t+1} - \gamma_t) + (\alpha_{t+1,1} - \alpha_{t,1}) + (\beta_{t,1} - \beta_{t+1,1}), \end{aligned} \quad (\text{D.4})$$

where we used $\ell_{\leq t,1} = \ell_{\leq t-1,1} + 1$. If $\alpha_{t,1} \neq 0$, then $w_{t,1} = 0$ due to complementary slackness, and the lemma trivially holds. Similarly if $\beta_{t+1,1} \neq 0$, then $w_{t+1,1} = 1$, and again the lemma holds trivially. Thus, we may assume that $\alpha_{t,1} = \beta_{t+1,1} = 0$. However then (D.4) becomes

$$w_{t+1,1} - w_{t,1} = -\eta + (\gamma_{t+1} - \gamma_t) + \alpha_{t+1,1} + \beta_{t,1} \geq -\eta.$$

We now show the second statement of the lemma, that $w_{t+1,i} \geq w_{t,i}$ for all $i > 1$. First note that if $\alpha_{t,i} > 0$, then by the complementary slackness condition of (D.2), $w_{t,i} = 0$, and the statement trivially holds. Similarly, if $\beta_{t+1,i} > 0$, then by the complementary slackness condition, $w_{t+1,i} = 1$, and, again the statement trivially holds. Therefore we prove the statement assuming that $\alpha_{t,i} = 0$ and $\beta_{t+1,i} = 0$. Since $\ell_{\leq t,i} = \ell_{\leq t-1,i}$, the complementary slackness condition of (D.2) implies:

$$\begin{aligned} w_{t+1,i} - w_{t,i} &= (-\eta \ell_{\leq t,i} + \alpha_{t+1,i} - \beta_{t+1,i} + \gamma_{t+1}) - (-\eta \ell_{\leq t-1,i} + \alpha_{t,i} - \beta_{t,i} + \gamma_t) \\ &= (\underbrace{\alpha_{t+1,i} - \alpha_{t,i}}_{=0}) + (\underbrace{\beta_{t,i} - \beta_{t+1,i}}_{=0}) + \underbrace{(\gamma_{t+1} - \gamma_t)}_{\geq 0} \\ &\geq \alpha_{t+1,i} + \beta_{t,i} \geq 0, \end{aligned}$$

where the last inequality is by the dual feasibility condition of (D.2). This finishes the proof. \blacksquare

Lemma D.3 Consider the m -set problem with n experts, and $m = 1$. Assume at the end of trial t , the cumulative losses of all experts are the same. Assume further that the loss sequence in trials $t+1, \dots, n$ is $\ell_{t+1} = \mathbf{e}_1, \ell_{t+2} = \mathbf{e}_2, \dots, \ell_{t+n} = \mathbf{e}_n$, i.e. each expert subsequently incurs a unit of loss. Then the cumulative loss incurred by the FRL-GD algorithm in iterations $t+1, \dots, n$ is at least $1 + \frac{1}{4} \min\{\eta\eta, 1\}$.

Proof The proof goes by providing primal and dual variables satisfying the KKT conditions (D.2). Since the solution w_{t+1} to (D.2) does not change if we shift all cumulative losses $\ell_{\leq t,i}$ by a constant we can assume w.l.o.g. that the cumulative loss of all experts at the end of trial t is 0.

Take trial $t+j+1$ ($j \geq 0$), at the beginning of which each of the first j experts have already incurred a unit of loss and the remaining $n-j$ experts are loss free. If $\eta \leq \frac{1}{n-j}$, then the KKT conditions (D.2) are satisfied by taking $\alpha_i = \beta_i = 0$ for all $i = 1, \dots, n$, $\gamma = \frac{j}{n}\eta + \frac{1}{n}$, and

$$w_{t+j+1,i} = \begin{cases} \frac{1}{n} - \frac{n-j}{n}\eta & \text{for } i \leq j \\ \frac{1}{n} + \frac{j}{n}\eta & \text{for } i > j \end{cases}.$$

In this trial, expert $j+1$ incurs a unit of loss, and hence the algorithm's loss is $\frac{1}{n} + \frac{j}{n}\eta$. If $\eta > \frac{1}{n-j}$, then the KKT conditions (D.2) are satisfied by taking $\gamma = \frac{1}{n-j}$ and for $1 \leq i \leq n$, $\beta_i = 0$,

$$w_{t+j+1,i} = \begin{cases} 0 & \text{for } i \leq j \\ \frac{1}{n-j} & \text{for } i > j \end{cases}, \quad \alpha_i = \begin{cases} \eta - \frac{1}{n-j} & \text{for } i \leq j \\ 0 & \text{for } i > j \end{cases}.$$

The loss of the algorithm in such a case is $\frac{1}{n-j}$.

Thus depending on η , the algorithm's loss at trial $t+j+1$ is equal to

$$\begin{cases} \frac{1}{n} + \frac{j}{n}\eta & \text{if } \eta \leq \frac{1}{n-j} \\ \frac{1}{n-j} + \frac{1}{n} + \frac{j}{n} \frac{1}{n-k} & \text{if } \eta > \frac{1}{n-j} \end{cases},$$

which can be concisely written as: $\frac{1}{n} + \frac{j}{n} \min\left\{\eta, \frac{1}{n-j}\right\}$. Summing the above over $j = 0, \dots, n$ gives the cumulative loss of the algorithm incurred at trials $t+1, \dots, t+n$:

$$\begin{aligned} \sum_{j=0}^{n-1} \frac{1}{n} + \frac{j}{n} \min\left\{\eta, \frac{1}{n-j}\right\} &\geq \sum_{j=0}^{n-1} \frac{1}{n} + \frac{j}{n} \min\left\{\eta, \frac{1}{n}\right\} \\ &= 1 + \frac{n-1}{2} \min\left\{\eta, \frac{1}{n}\right\} \\ &\geq 1 + \frac{1}{4} \min\{\eta\eta, 1\}, \end{aligned}$$

where the last inequality is due to $n-1 > \frac{n}{2}$ for $n \geq 2$. \blacksquare

We are now ready to give the proof of Theorem 4.3:

Theorem 4.3 Consider the m -set problem with $k \leq n/2$ and unit bit vectors as loss vectors. Then for any fixed learning rate η , the FRL-GD algorithm (D.1) can be forced to have regret at least $\Omega(\max\{\min\{B_L, k\sqrt{B_L}\}, k\})$.

Proof Theorem 5.6 gives a lower bound of $\Omega(\sqrt{B_L m \log \frac{n}{m}} + m \log \frac{n}{m})$ that holds for any algorithm. This lower bound is at least $\Omega(k)$ since $m \log \frac{n}{m} = m \log(\frac{n}{m} + 1) \geq k$. Hence to prove this theorem, we only need to show a lower bound of $\Omega(\{\min\{B_L, k\sqrt{B_L}\}\})$. Similarly as in the proof of Theorem 4.1, we show this in two steps: First, we give two loss sequences that force FRL-GD to have regret at least $\Omega(k/\eta)$ and $\Omega(\min\{B_L, kB_L\eta\})$, respectively. Then, the lower bound follows by taking the maximum between the two lower bounds.

The first loss sequence is exactly the same as in the proof of Theorem 4.1, i.e. the sequence consists of $\lfloor \frac{k\eta}{m} \rfloor + 1$ trials and in each trial, the expert with the largest weight (within the first k experts) incurs one unit of loss. With Lemma D.2 in place of Lemma C.2, one can easily show an $\Omega(k/\eta)$ regret lower bound for FRL-GD by repeating the argument from the proof of Theorem 4.1.

Now we describe the second loss sequence which forces the FRL-GD algorithm to suffer regret $\Omega(\min\{B_L, kB_L\eta\})$. For the sake of clarity, we assume that B_L is integer (otherwise

replace B_L by $[B_L]$ in the proof). The sequence consists of B_L “rounds”, and each round consist of $k + 1$ trials (so that there are $(k + 1)B_L$ trials in total). In each round, one unit of loss is given alternately to each of the first $k + 1$ experts, one at a time. In other words, in trial t , the loss vector ℓ_t equals to e_r where $r = t \bmod (k + 1)$. The best comparator of this sequence consists of the last $m - 1$ loss free experts and any of the first $k + 1$ experts, which incurs cumulative loss B_L .

To lower bound the loss of the algorithm, first notice that in each round, each of the first $k + 1$ experts incurs exactly one unit of loss. The sum of weights of these experts at the beginning of a round lower bounds the algorithm’s loss in this round. This is because the weight of a given expert cannot decrease if the expert does not incur any loss (Lemma D.2); hence, the weight of a given expert at a trial, in which that expert receives a unit of loss, will be at least as large as the weight of that expert at the beginning of a round. Since the weights are initialized uniformly, this sum is $m(k + 1)/n$ before round 1, and by Lemma D.1, each of the following rounds decreases it by $(m - 1)(k + 1)/n$ until it is lower capped at 1 (Since the total sum of the weights is m , and none of the remaining $m - 1$ weights can exceed 1, the sum of weights of the first $k + 1$ experts must be at least 1).

We first assume that after $B_L/2$ rounds, this sum is strictly larger than 1 which means the sum decreases as an arithmetic series for all the first $B_L/2$ rounds and the algorithm’s loss can be lower bounded by

$$\frac{1}{2}(m(k + 1)/n + 1) \frac{B_L}{2} \stackrel{\text{Use the same argument as in (C.9)}}{=} B_L/2 + \Omega(B_L).$$

Since the sum of the first $k + 1$ weights at the beginning of any trial is at least 1, the algorithm incurs loss at least $B_L/2$ in the remaining $B_L/2$ rounds. Summing up the algorithm’s loss on both halves of the sequence, we get a regret lower bound of $\Omega(B_L)$.

Now consider the case, when after the first $B_L/2$ rounds, the sum of the first $k + 1$ weights is 1. This implies that the weights of $m - 1$ remaining experts are all equal to 1, and will stay at this value, since only the first $k + 1$ experts incur any loss (and, by Lemma D.2, the weight of an expert cannot decrease if that expert does not incur any loss). Thus, we can disregard the loss free $m - 1$ experts, and in the remaining $B_L/2$ rounds, the first $k + 1$ expert weights are updated as in the m -set problem with $m = 1$. Notice that the algorithm suffers loss at least $B_L/2$ in the first $B_L/2$ rounds and by Lemma D.3, suffers loss at least $B_L/2 + B_L \min\{(k + 1)/n, 1\}/8$ in the second $B_L/2$ rounds. Summing up the algorithm’s loss on both halves of the sequence, we get a regret lower bound of $\Omega(\min\{B_L, kB_L/n\})$. ■

Appendix E. A Discussion on the Final Parameter of FRL-GD

In this appendix, we show that the final parameter matrix of the FRL-GD algorithm essentially contains the solution to the batch PCA problem. First recall that given n dimensional data points $\mathbf{x}_1, \dots, \mathbf{x}_T$, the batch version of the k -PCA problem is solved by the eigenvectors of the k largest eigenvalues of the covariance matrix $C = \sum_{T=1}^T \mathbf{x}_T \mathbf{x}_T^\top$. Let \mathbf{W}_{T+1} be the final parameter matrix of the FRL-GD algorithm when the instance matrices are $\mathbf{X}_1 = \mathbf{x}_1 \mathbf{x}_1^\top, \dots, \mathbf{X}_T = \mathbf{x}_T \mathbf{x}_T^\top$. We will show that the eigenvectors of the $m = n - k$ largest eigenvalues of \mathbf{W}_{T+1} are the same as the eigenvectors of the m largest eigenvalues of the

negated covariance matrix $-C$. Thus, by computing the complementary subspace of rank k , one finds the solution of the batch PCA problem with respect to data points $\mathbf{x}_1, \dots, \mathbf{x}_T$.

Recall that the final parameter \mathbf{W}_{T+1} of FRL-GD is the projection of the $-C$ into the parameter set \mathcal{W}_m :

$$\mathbf{W}_{T+1} = \operatorname{argmin}_{\mathbf{W} \in \mathcal{W}_m} \|\mathbf{W} - \mathbf{W}_{T+1}^*\|_F^2.$$

Let $-C$ have eigendecomposition $-C = U \operatorname{diag}(\boldsymbol{\lambda}) U^\top$, where $\boldsymbol{\lambda}$ is the vector of the eigenvalues of $-C$. Agra et al. (2013, Lemma 3.2) shows that the projection of $-C$ is solved by projecting the eigenvalues $\boldsymbol{\lambda}$ into \mathcal{S}_m while keeping its eigensystem unchanged:

$$\mathbf{W}_{T+1} = U \operatorname{diag}(\boldsymbol{\lambda}') U^\top \quad \text{and} \quad \boldsymbol{\lambda}' = \operatorname{argmin}_{\boldsymbol{\lambda}' \in \mathcal{S}_m} \|\boldsymbol{\lambda} - \boldsymbol{\lambda}'\|_2^2.$$

W.l.o.g., assume the elements of $\boldsymbol{\lambda}$ are in descending order, i.e. $\lambda_1 \geq \lambda_2 \geq \dots \geq \lambda_m$. To prove that the eigenvectors of the m largest eigenvalues are the same in \mathbf{W}_{T+1} and $-C$, we only need to show the following: for any integers pair i and j such that $1 \leq i \leq m < j \leq n$, if $\lambda_i > \lambda_j$, then $\lambda'_i > \lambda'_j$. First note that by the KKT analysis of the problem of projecting into \mathcal{S}_m (see (D.2)), it is easy to see that if $\lambda_i > \lambda_j$, then exactly one of the following three cases holds.

$$\lambda'_i > \lambda'_j \quad \text{or} \quad \lambda'_i = \lambda'_j = 0 \quad \text{or} \quad \lambda'_i = \lambda'_j = 1.$$

Now we show that when i and j further satisfy $i \leq m < j$, the latter two cases can never happen. Suppose $\lambda'_i = \lambda'_j = 1$ for some $i \leq m < j$. In this case for any $i' \leq m$, $\lambda'_{i'} = \lambda'_j = 1$ also holds. Therefore, the sum of all the coordinates of $\boldsymbol{\lambda}'$ will be at least $m + 1$ which contradicts $\boldsymbol{\lambda}' \in \mathcal{S}_m$. Now assume $\lambda'_i = \lambda'_j = 0$ for some $i \leq m < j$. In this case for any $m < j'$, $\lambda'_{j'} = \lambda'_j = 0$ also holds. This implies that the sum of all the coordinates of $\boldsymbol{\lambda}'$ will be at most $m - 1$ which again contradicts $\boldsymbol{\lambda}' \in \mathcal{S}_m$.

Appendix F. Regret Lower Bounds When the Number of Trials Is Large

This appendix proves lower bounds on the regret of any online algorithm for the m -set problem: Theorem 5.1 and Theorem 5.2 prove lower bounds for unit bit vectors as loss vectors and Theorem 5.4 proves lower bounds for arbitrary bit vectors as loss vectors. In all of these lower bounds, we assume that the number of the trials T is larger than either the number of experts n or some function of n , m and k (see details of the assumptions in individual theorems). The regret lower bounds for small number of trials are given in the next Appendix G.

All the lower bounds given in this appendix are proved with the probabilistic bounding technique described in Section 5, i.e. in each case, we first choose a probability distribution \mathcal{P} and then show a lower bound on the expected regret of any algorithm when the loss vectors are generated i.i.d. from \mathcal{P} . Our lower bounds on the expected regret make use of the following lemma which gives an upper bound on the expected loss of the best comparator in a two expert game.

Lemma F.1 Consider a two expert game in which the random loss pairs of both experts are i.i.d. between trials, and at each trial the random pair follows the distribution:

$$\begin{array}{c|ccc} \text{value of the loss pair} & (0, 1) & (1, 0) & (1, 1) & (0, 0) \\ \hline \text{probability} & p & p & q & 1 - 2p - q \end{array} \quad (\text{F.1})$$

where non-negative parameters p and q satisfy $2p+q \leq 1$. Let M be the minimum total loss of the two experts in T such trials. If T and p satisfy $Tp \geq 1/2$, then

$$\mathbb{E}[M] \leq T(p+q) - c\sqrt{Tp}$$

for some constant $c > 0$ independent of T , p and q .

Later we will use the case $q = 0$ of the two expert distribution (F.1) as a submodule for building distributions over the n unit bit vectors and $p = q = 1/4$ for building distributions over $\{0, 1\}^n$. To prove Lemma F.1, we need the following lemma from (Koolen, 2011, Theorem 2.5.3):

Lemma F.2 Let a_t and b_t be two binary random variables following the distribution

$$\frac{\text{value of } (a_t, b_t)}{\text{probability}} \mid \begin{array}{l} (0, 1) \\ 0.5 \end{array} \mid \begin{array}{l} (1, 0) \\ 0.5 \end{array}.$$

For T independent such pairs, we have

$$\frac{T}{2} - \sqrt{\frac{T-1}{2\pi}} \leq \mathbb{E} \left[\min \left\{ \sum_{t=1}^T a_t, \sum_{t=1}^T b_t \right\} \right] \leq \frac{T}{2} - \sqrt{\frac{T+1}{2\pi}}.$$

Proof of Lemma F.1 Denote the experts' losses at trials $1 \leq t \leq T$ by \tilde{a}_t and \tilde{b}_t . In this notation, the statement of Lemma F.1 is equivalent to:

$$\mathbb{E} \left[\min \left\{ \sum_t \tilde{a}_t, \sum_t \tilde{b}_t \right\} \right] \leq T(p+q) - c\sqrt{Tp}.$$

At each trial, the random variable pair $(\tilde{a}_t, \tilde{b}_t)$ has four possible values: $(1, 0)$, $(0, 1)$, $(1, 1)$ or $(0, 0)$. If $\tilde{a}_t \neq \tilde{b}_t$, then this trial is "covered by" Lemma F.2. If $\tilde{a}_t = \tilde{b}_t$, then this trial affects $\sum_t \tilde{a}_t$ and $\sum_t \tilde{b}_t$ the same way and therefore can be excluded from the minimization. We formalize this observation as follows:

$$\begin{aligned} \mathbb{E} \left[\min \left\{ \sum_t \tilde{a}_t, \sum_t \tilde{b}_t \right\} \right] &= \mathbb{E} \left[\min \left\{ \sum_{t: \tilde{a}_t \neq \tilde{b}_t} \tilde{a}_t, \sum_{t: \tilde{a}_t \neq \tilde{b}_t} \tilde{b}_t \right\} \right] + \mathbb{E} \left[\sum_{t: \tilde{a}_t = \tilde{b}_t} \tilde{a}_t \right] \\ &\stackrel{\text{Lemma F.2}}{\leq} \mathbb{E} \left[\frac{R-1}{2} - \sqrt{\frac{R-1}{2\pi}} \right] + Tq, \end{aligned}$$

where R is a binomial random variable with T draws and success probability $2p$. Clearly $\mathbb{E}[R] = 2Tp$ and therefore $\mathbb{E}[\frac{R-1}{2}] = Tp$. Moreover under the assumption that $Tp \geq 1/2$, we will show in Lemma I.2 of Appendix I (using an application of the Chernoff bound) that $\mathbb{E} \left[\sqrt{\frac{R-1}{2\pi}} \right] \geq c\sqrt{Tp}$ for some constant c that does not depend on T , p and q . ■

We now use Lemma F.1 to prove the following theorem which addresses the m -set problem with unit bit vectors for the case $k \leq \frac{n}{2}$.

Theorem 5.1 Consider the m -set problem with unit bit vectors as loss vectors, where $m = n - k$. Then for $k \leq \frac{n}{2}$ and $T \geq k$, any online algorithm suffers worst case regret at least $\Omega(\sqrt{Tk})$.

Proof In this proof, each loss vector is uniformly sampled from the first $2k$ unit bit vectors, i.e. at each trial, one of the first $2k$ experts is uniformly chosen to incur a unit of loss. To show an upper bound on the loss of the comparator, we group these $2k$ experts into k pairs and note that the loss of each expert pair follows the joint distribution described Lemma F.1 with $p = \frac{1}{2k}$ and $q = 0$. Furthermore, the condition $Tp \geq 1/2$ of Lemma F.1 is also satisfied because of the assumption $T \geq k$. Hence, by applying Lemma F.1 we know that the expected loss of the winner in each pair is at most $T/2k - c\sqrt{T/2k}$, and the total expected loss for k winners from all k pairs is upper bounded by $T/2 - c\sqrt{kT/2}$. Now recalling that the comparator consists of the $m = n - k$ best experts, its total expected loss is upper bounded by the expected loss of the k winners, which is at most $T/2 - c\sqrt{kT/2}$, plus the expected loss of the remaining $n - 2k$ experts, which is zero. Therefore, we have an upper bound of $T/2 - c\sqrt{kT/2}$ on the expected loss of the comparator. On the other hand, since losses are generated independently between trials, any online algorithm suffers loss at least $T/2$. The difference between the lower bound on the expected loss of the algorithm and the upper bound on the expected loss of the best m -set gives the regret lower bound of the theorem. ■

The case $k \geq \frac{n}{2}$ is more complicated. Recall that $k = n - 1$ reproduces the vanilla single expert case. Therefore additional $\log n$ factor must appear in the square root of the lower bound. We need the following lemma, which is a generalization of Lemma F.1 to n experts. In the proof, we upper bound the minimum loss of the experts by the loss of the winner of a tournament among the n experts. The tournament winner does not necessarily have the lowest loss. However as we shall see, its expected loss is close enough to the expected loss of the best expert so that this bounding technique is still useful for obtaining lower bounds on the regret.

Lemma F.3 Choose any n, S and T , such that $n = 2^S$ and S divides T . If the loss sequence of length T is generated from a distribution \mathcal{P} , such that:

- at each trial t , the distribution of losses on n experts is exchangeable, i.e. for any permutation π on a set $\{1, \dots, n\}$, and for any t , $\ell_t = (\ell_{t,1}, \ell_{t,2}, \dots, \ell_{t,n})$ and $\ell_t^\pi = (\ell_{t,\pi(1)}, \ell_{t,\pi(2)}, \dots, \ell_{t,\pi(n)})$ have the same distribution,
- and the distribution of losses is i.i.d. between trials,

then,

$$\mathbb{E}[\text{minimum loss among } n \text{ experts in } T \text{ trials}] \leq S \mathbb{E}[\text{minimum loss among experts } 1 \text{ and } 2 \text{ in } T/S \text{ trials}].$$

Proof The key idea is to upper bound the minimum loss of any expert by the loss of the expert that wins an S round tournament. In the first round, we start with n experts and pair each expert with a random partner. The round lasts for T/S trials. For each pair, the expert with the smaller loss wins in this round (tie always broken randomly). The

	first round			second round		
$t = 1$	$t = 2$	$t = 3$	$t = 4$	$t = 5$	$t = 6$	
[expert 1	1	0	1	0	0	
expert 4	0	1	0	1	1	
[expert 2	0	0	1	1	0	
expert 3	1	1	0	1	1	

Table F.1: A tournament with $T = 6$ trials, $S = 2$ rounds, and $n = 4$ experts. The bits in the table are the binary losses of the experts in each trial. The brackets show the pairing in each round. The losses of the winners are in bold

$n/2$ winners continue to the second round. At round s , the remaining $n/2^{s-1}$ experts are randomly paired and the winners are determined based on the losses in another set of T/S trials. After S rounds and $T = ST/S$ trials we are left with 1 overall winner.

For example for $S = 2$ rounds, $n = 2^2 = 4$ experts and $T = 6$ trials, consider the sequence of losses shown in Table F. Each of the two tournament consists of $6/2 = 3$ trials. In the first round, expert 1 is paired with expert 4 and expert 2 with expert 3. The cumulative losses of experts 1, 2, 3, 4 in this round are 2, 1, 2, 1, respectively. So expert 4 is the winner of the first pair and expert 2 is the winner of the second pair. In the second round, the two winners (experts 2 and 4) are paired, and they incur cumulative loss 2 and 3, respectively. Hence, expert 2 wins the tournament. The total loss of the tournament winner in all 6 trials is 3. Note that this is larger than the minimum total loss of the 4 experts since expert 1 incurred total loss 2. Nevertheless we shall see that for our probabilistic lower bound proof, the total loss of the tournament winner is close enough to the total loss of the best expert.

To complete the proof it suffices to show that

$$\begin{aligned} & \mathbb{E} [\text{total loss of tournament winner in } T \text{ trials}] \\ &= S \mathbb{E} [\text{minimum loss among experts 1 and 2 in } T/S \text{ trials}]. \end{aligned}$$

Due to linearity of expectation:

$$\begin{aligned} & \mathbb{E} [\text{total loss of tournament winner in } T \text{ trials}] \\ &= \sum_{i=1}^S \mathbb{E} [\text{total loss of tournament winner in } i\text{-th round}]. \end{aligned}$$

The exchangeability of the losses and the symmetry of the tournament guarantees that each expert is equally likely to be the overall winner. Therefore w.l.o.g., expert 1 is the overall winner. Consider i -th round of the tournament ($1 \leq i \leq S$), and let (w.l.o.g.) expert 2 be

the partner of expert 1 in this round. We have:

$$\begin{aligned} & \mathbb{E} [\text{total loss of tournament winner in } i\text{-th round}] \\ &= \mathbb{E} \left[\begin{array}{c} \text{total loss of exp. 1 in } i\text{-th round} \\ \text{total loss of exp. 2 won all past competitions} \\ \text{at rounds } 1, \dots, i-1. \end{array} \right] \\ &= \mathbb{E} [\text{total loss of exp. 1 in } i\text{-th round} \mid \text{exp. 1 wins over exp. 2 in } i\text{-th round}]. \end{aligned}$$

The second equality is due to the fact that the distribution of losses is i.i.d. between trials, and therefore the future and past rounds are independent of the current round. Since the last expression is the same for each of the S rounds we have:

$$\begin{aligned} & \mathbb{E} [\text{total loss of tournament winner in } T \text{ trials}] \\ &= S \mathbb{E} [\text{expected loss of expert 1 in } T/S \text{ trials} \mid \text{expert 1 wins over expert 2}]. \end{aligned}$$

Remains to be shown that the latter expectation is simple the expectation of the minimum of the two experts losses in a single round. Let L_1 and L_2 be the total losses of both experts in the T/S trials and let " $L_1 > L_2$ " denote the event that 1 wins over 2 (ties broken uniformly; so that, e.g., $\Pr(L_1 > L_2) + \Pr(L_2 > L_1) = 1$). Then

$$\begin{aligned} \mathbb{E} [L_1 | L_2 > L_1] &= \left(\Pr(L_2 > L_1) + \Pr(L_1 > L_2) \right) \mathbb{E} [L_1 | L_2 > L_1], \\ &= \Pr(L_2 > L_1) \mathbb{E} [L_1 | L_2 > L_1] + \Pr(L_1 > L_2) \mathbb{E} [L_1 | L_2 > L_1] \\ \text{(exchangeability)} &= \Pr(L_2 > L_1) \mathbb{E} [L_1 | L_2 > L_1] + \Pr(L_1 > L_2) \mathbb{E} [L_2 | L_1 > L_2] \\ &= \Pr(L_2 > L_1) \mathbb{E} [\min\{L_1, L_2\} | L_2 > L_1] \\ &\quad + \Pr(L_1 > L_2) \mathbb{E} [\min\{L_1, L_2\} | L_1 > L_2] \\ &= \mathbb{E} [\min\{L_1, L_2\}]. \quad \blacksquare \end{aligned}$$

Now, we use this lemma to prove a lower bound for the m -set problem with $k \geq \frac{n}{2}$:

Theorem 5.2 *Consider the m -set problem with unit bit vectors as loss vectors, where $m = n - k$. Then for $k \geq \frac{n}{2}$ and $T \geq n \log_2(n/m)$, any online algorithm suffers worst case regret at least $\Omega(m \sqrt{T \ln(n/m)/n})$.*

Proof Let us first assume that $n = 2^j m$ for some integer $j > 0$, i.e. $\log_2(n/m)$ is a positive integer, and that $\frac{T}{\log_2(n/m)}$ is an integer value as well.

At each trial, a randomly chosen expert out of n experts incurs a unit of loss. To show an upper bound on the loss of the comparator, we partition the n experts into m groups (n divides m from the assumption), and notice that the losses of the n/m experts in each group are exchangeable. Applying Lemma F.3 to each group of n/m experts with $S = \log_2(n/m)$ rounds and T/S trials per round, we obtain:

$$\begin{aligned} & \mathbb{E} [\text{Loss of the winner in a given group in } T \text{ trials}] \\ &\leq \log_2 \binom{n}{m} \mathbb{E} \left[\text{Loss of the winner of two experts in } \frac{T}{\log_2(n/m)} \text{ trials} \right]. \quad (\text{F.2}) \end{aligned}$$

The expectation on the RHS is the two expert game considered in Lemma F.1 with parameters $p = 1/n$ and $q = 0$. Note that $q = 0$ because only one expert suffers loss in each trial. Applying this lemma bounds the expectation on the RHS as

$$\frac{T}{\log_2(n/m)n} - c\sqrt{\frac{T}{\log_2(n/m)n}}.$$

Plugging this into (F.2) gives $T/n - c\sqrt{T \log_2(n/m)/n}$ upper bound on the expected loss of the winner in a given group. We upper bound the expected loss of the comparator by the total loss of m winners from the m groups, which in expectation is at most $Tm/n - cm\sqrt{T \log_2(n/m)/n}$.

Finally the loss of the algorithm is lower bounded as follows: Every expert incurs loss $1/n$ in expectation at each trial and losses are i.i.d. between trials. Therefore any online algorithm suffers loss at least mT/n , and the expected regret is lower bounded by $cm\sqrt{T \log_2(n/m)/n}$. This concludes the proof when $n = 2^j m$ and $\log_2(n/m)$ divides T .

If n is not of this form, we take the largest $n_0 < n$, such that $n_0 = 2^j m$ for some integer j , i.e. $n_0 = \max_{j \in \mathbb{N}} \{2^j m : 2^j m \leq n\}$. We then apply the reasoning above to n_0 experts, while the remaining $n - n_0$ will incur loss 1 all the time, which can only increase the loss of the algorithm, but this will not affect the loss of the comparator (comparator will never pick these experts). Since $n_0 \geq n/2$ (otherwise n_0 would not be the largest integer of the form $2^j n$, smaller than n), this does not change the rate under $\Omega(\cdot)$ for the lower bound in the statement of the theorem. Finally, if $\frac{T}{\log_2(n/m)}$ is not an integer value, we can choose the largest $T_0 < T$, such $\frac{T_0}{\log_2(n/m)}$ is integer, and use the proof with T_0 rounds, while in the remaining $T - T_0$ rounds all losses are zero. Since $T_0 \geq T/2$, this, again, does not change the rate under $\Omega(\cdot)$. ■

Finally, we consider the m -set problems with L_∞ -bounded loss vectors. The following theorem proves lower bounds for such problems when $k \leq \frac{n}{2}$ and when $k \geq \frac{n}{2}$.

Theorem 5.4 Consider the m -set problem with loss vectors in $\{0, 1\}^n$, where $m = n - k$. Then for $T \geq \log_2 \frac{n}{\min\{k, m\}}$, any online algorithm suffers worst case regret of at least

$$\Omega\left(k\sqrt{T \ln \frac{n}{k}}\right) \text{ when } k \leq \frac{n}{2} \quad \text{or} \quad \Omega\left(m\sqrt{T \ln \frac{n}{m}}\right) \text{ when } k \geq \frac{n}{2}.$$

Proof The proof is similar to the proof of Theorem 5.2, except that at each trial, the losses of all n experts are i.i.d. Bernoulli random variable with probability $p = 1/2$. For such a distribution over losses, any algorithm suffers expected cumulative loss at least $mT/2$ for the m -set problem.

For the sake of simplicity, we make some assumptions about n , k and T that avoid rounding issues. When $k \leq n/2$, we assume that $n = 2^j k$ for some integer $j \geq 1$ and that $\frac{T}{\log_2(n/k)}$ is an integer. When $k \geq n/2$, i.e. $m = n - k \leq n/2$, we assume that $n = 2^j m$ for some integer $j \geq 1$ and that $\frac{T}{\log_2(n/m)}$ is an integer. As in the proof of Theorem 5.2, it is easy to generalize the theorem to arbitrary n , k and T satisfying $T \geq \log_2 \frac{n}{\min\{k, m\}}$.

Now, we prove our regret lower bounds for each of the two cases: When $m \leq n/2$, we group the experts into m groups of size n/m and upper bound the loss of the comparator using the m group winners. As before, the loss of each winner can be upper bounded by the lemmas F.1 (with $p = q = 1/4$) and F.3:

$$\begin{aligned} \mathbb{E}[\text{Loss of the winner in a given group in } T \text{ trials}] & \\ \stackrel{\text{Lemma F.3}}{\leq} \log_2 \frac{n}{m} & \mathbb{E}\left[\text{Loss of two experts in } \frac{T}{\log_2(n/m)} \text{ trials}\right] \\ \stackrel{\text{Lemma F.1}}{\leq} \frac{T}{2} - c\sqrt{\frac{T}{4} \log_2 \frac{n}{m}}. & \end{aligned}$$

Note that since the experts here incur i.i.d. *Bernoulli*($\frac{1}{2}$) losses, the above application of Lemma F.1 requires $p = q = 1/4$. Next, summing up m winners, we have the expected loss of the comparator upper bounded by $Tm/2 - cm\sqrt{T \log_2(n/m)/4}$. Taking the difference between this upper bound and the $Tm/2$ lower bound on loss of any algorithm results in the claimed $\Omega(m\sqrt{T \ln(n/m)})$ lower bound on the regret.

When $k \leq n/2$, we group the experts into k groups and consider a *loser* out of each group which is the expert which incurs the *largest* loss in each group. One can flip around the content of Lemma F.1 and F.3 to show that the loser in a group of n/k experts incurs loss in expectation at least $T/2 + c\sqrt{T \log_2(n/k)/4}$. Therefore, the expected loss of all k losers is lower bounded by $Tk/2 + ck\sqrt{T \log_2(n/k)/4}$. Now note that the expected loss of the comparator is upper bounded by the expected total loss of all the experts, which is $Tn/2$, minus the expected loss of the k losers, and hence upper bounded by

$$\frac{Tn}{2} - \left(\frac{Tk}{2} + ck\sqrt{\frac{T}{4} \log_2 \frac{n}{k}}\right) = \frac{Tm}{2} - ck\sqrt{\frac{T}{4} \log_2 \frac{n}{k}}.$$

Finally, the claimed regret bound follows from taking the difference between this upper bound and the $Tm/2$ lower bound on the loss of any online algorithm. ■

Appendix G. Regret Lower Bounds When the Number of Trials Is Small

This appendix gives general regret lower bounds for the m -set problem when the number of trials T is small: Theorem G.1 and Theorem G.3 show lower bounds when the loss vectors are unit bit vectors; Theorem G.4 and Theorem G.5 show lower bounds when the loss vectors are bit vectors. Unlike the lower bounds for large T that are proved with probabilistic arguments (see previous Appendix F) all of the lower bounds in this appendix are proved by showing explicit adversary strategies that force large regret to any online algorithm. The matching upper bounds for small T are trivial and can be found in Section 5.

Theorem G.1 Consider the m -set problem with unit bit vectors as loss vectors, where $m = n - k$. Then for $k \leq \frac{n}{2}$ and $T \leq k$, any online algorithm suffers worst case regret at least $\Omega(T)$.

Proof Consider an adversary that at each trial gives a unit of loss to the expert with the largest weight assigned by the algorithm. Recall that $m = n - k$ and $k \leq \frac{n}{2}$. Therefore

all the weights assigned by the algorithm sum to $m \geq \frac{n}{2}$ and the largest weight out of n experts is at least $\frac{n}{2}$. Hence, after T trials, any algorithm suffers total loss at least $\frac{n}{2}$. On the other hand, since there are at least $n - T \geq m$ (because $T \leq k$) experts that are loss free, the loss of the best m -set of experts is zero. Therefore, the regret of any algorithm is at least $\frac{n}{2}$. ■

Now we consider the case when $k \geq \frac{n}{2}$. We start with a lemma which is parameterized by an integer $1 \leq i \leq k$ instead of the number of the trials T .

Lemma G.2 *Consider the m -set problem with unit bit vectors as loss vectors, where $m = n - k$. For any integer $1 \leq i \leq k$, an adversary can force any algorithm to suffer loss $\Omega(m \log_2 \frac{n}{n-i})$ in $O(n \log_2 \frac{n}{n-i})$ trials, and at the same time, keep a set of m experts with loss zero.*

Proof The adversary's strategy has i rounds, where the j -th round ($1 \leq j \leq i$) has at most $\lceil \frac{n}{n-j+1} \rceil$ trials and after it finishes, there will be at least $n - j$ experts that still have loss zero. The first round has only one trial, in which a unit of loss is given to the expert with the largest weight. Since all the weights assigned by the algorithm sum to m , the algorithm suffers loss at least $\frac{m}{n}$ in the first round.

Each of the following rounds may contain multiple trials and at the end of round $j - 1$ ($2 \leq j \leq i$), there are still at least $n - j + 1$ loss free experts. In round j , the adversary uses a strategy with two subcases as follows: The adversary first considers the experts that are still loss free. If any of the first $n - j + 1$ of them has weight at least $\frac{2m}{2(n-j+1)}$, then we are in case 1, where a unit of loss is given to this expert. Otherwise, we are in case 2, in which the adversary considers the remaining $j - 1$ experts (which may or may not be loss free) and gives a unit of loss to the one with the largest weight among them. The j -th round ends when the algorithm has suffered total loss at least $\frac{m}{2(n-j+1)}$ in that round. Note that whenever case 1 is reached, a round ends immediately. Our strategy guarantees that after round j , there are at least $n - j$ experts that are loss free. Next we upper bound the number of case 2 trials in a round by showing a lower bound on the loss of the algorithm in case 2 trials. Recall that in case 2, $n - j + 1$ experts have weight no more than $\frac{2m}{2(n-j+1)}$ each, and the expert that has the largest weight in the remaining $j - 1$ experts incurs a unit of loss. Using these facts as well as the fact that all the weights sum to m , we can lower bound the weight of the expert that incurs loss (which is also the loss of the algorithm) as follows:

$$\frac{\left(m - \frac{m}{2(n-j+1)}(n-j+1)\right)}{j-1} \geq \frac{m}{2(j-1)} \geq \frac{m}{2n}.$$

Recalling that the j -th round ends when the algorithm suffers total loss $\frac{m}{2(n-j+1)}$ in that round, we conclude that the j -th round can have at most $\lceil \frac{n}{n-j+1} \rceil$ trials.

Summing up over i rounds, the algorithm suffers total loss at least $\sum_{j=1}^i \frac{m}{2(n-j+1)} = \Omega(m \log_2 \frac{n}{n-i})$ in at most $\sum_{j=1}^i \lceil \frac{n}{2(n-j+1)} \rceil = O(n \log_2 \frac{n}{n-i})$ trials. On the other hand, the loss of the best m -set of experts is zero due to assumption $i \leq k$ and the fact that after $j = i$ rounds, there are at least $n - i$ loss free experts. Hence the lemma follows. ■

Theorem G.3 *Consider the m -set problem with unit bit vectors as loss vectors, where $m = n - k$. Then for $k \geq \frac{n}{2}$ and $T \leq n \log_2 \frac{n}{m}$, any algorithm suffers worst case regret at least $\Omega(\frac{n}{m}T)$.*

Proof Lemma G.2 states that there exist two positive constants c_1 and c_2 , such that for any integer $1 \leq i \leq k$, the adversary can force any algorithm to suffer regret at least $c_1 m \log_2 \frac{n}{n-i}$ in at most $c_2 n \log_2 \frac{n}{n-i}$ trials. The proof splits into two cases, depending on the number of the trials T :

- When $T < c_2 n \log_2 \frac{n}{n-1}$, T is upper bounded by a constant as follows:

$$T < c_2 n \log_2 \frac{n}{n-1} = \frac{c_2 n}{\log 2} \log \left(1 + \frac{1}{n-1}\right) \leq \frac{c_2 n}{(n-1) \log 2} \stackrel{n \geq 2}{\leq} \frac{2c_2}{\log 2}.$$

Since the adversary can always force any algorithm to suffer constant regret, the theorem holds trivially.

- When $T \geq c_2 n \log_2 \frac{n}{n-1}$, we set $i = \min\{\lceil i' \rceil, k\}$, where $i' = n(1 - 2^{-T/c_2 n})$ is the solution of $c_2 n \log_2 \frac{n}{n-i'} = T$. We note that the function $c_2 n \log_2 \frac{n}{n-i'}$ is monotonically increasing in i' , which results in two facts: first, $i' \geq 1$, since we assumed $T \geq c_2 n \log_2 \frac{n}{n-1}$; second, $c_2 n \log_2 \frac{n}{n-i'} \leq T$, since $i \leq \lceil i' \rceil$. We further show that $c_2 n \log_2 \frac{n}{n-i'} \geq \min\{c_2, \frac{1}{3}\}T$ as follows:

$$\begin{aligned} & \text{— When } i = \lceil i' \rceil, \text{ first note that } \left(\frac{n}{n-i'}\right)^3 \geq \frac{n}{n-T}, \text{ since:} \\ & (n-i')n^2 - (n-i')^3 \geq (n-i-1)n^2 - (n-i)^3 = 2ni^2 + 3ni^2 - i^3 - n^2 \stackrel{1 \leq i < n}{\geq} 0. \end{aligned}$$

$$\text{Plugging } c_2 n \log_2 \frac{n}{n-i'} = T, \text{ we have } c_2 n \log_2 \frac{n}{n-i'} \geq \frac{1}{3}T.$$

- When $i = k$, $c_2 n \log_2 \frac{n}{n-i} = c_2 n \log_2 \frac{n}{n-i} \geq c_2 T$, since $T \leq n \log_2 \frac{n}{m}$ is assumed in the theorem.

Now, using Lemma G.2 with i set as $i = \min\{\lceil i' \rceil, k\}$, results in an adversary that forces the algorithm to suffer regret at least $c_1 m \log_2 \frac{n}{n-i} \geq \frac{m \log 2}{n c_2} \min\{c_2, \frac{1}{3}\}T = \Omega(\frac{n}{m}T)$ in at most T trials. When the adversary uses less than T trials, then the game can be extended to last exactly T trials by playing zero loss vectors for the remaining trials. ■

Theorem G.4 *Consider the m -set problem with loss vectors in $\{0, 1\}^n$, where $m = n - k$. Then for $k \geq \frac{n}{2}$ and $T \leq \log_2 \frac{n}{m}$, the worst case regret of any algorithm is at least $\Omega(Tm)$.*

Proof The proof uses an adversary which forces any algorithm to suffer loss $\Omega(Tm)$, and still keeps the best m -set of experts to be loss free. Note that at each trial, the adversary decides on the loss vector after the algorithm makes its prediction w_t , where $w_t \in \{0, 1\}^n$ with $\sum_i w_{t,i} = m$.

At trial one, the adversary first sorts the n experts by their weights assigned by the algorithm, and then gives a unit of loss to each of the experts in the first half, i.e. the experts with larger weights. Since the weights sum to m , the total weight assigned to the experts in the first half is at least $\frac{m}{2}$. Hence in the first trial, the algorithm suffers loss at least $\frac{m}{2}$.

At each of the following trials, the adversary only sorts those experts that have not incur any loss so far and gives unit losses to the first half (the half with larger weights) of these experts, as well as all the experts that have already incurred losses before this trial. It is easy to see that in this way the algorithm suffers loss at least $\frac{m}{2}$ at each trial.

Since the number of the experts that are loss free halves at each trial, after $T \leq \log_2 \frac{m}{2}$ trials, there will still be at least m loss free experts. Now since the algorithm suffers loss at least $\frac{mT}{2}$ in T trials, the theorem follows. ■

Theorem G.5 Consider the m -set problem with loss vectors in $\{0, 1\}^n$, where $m = n - k$. Then for $k \leq \frac{n}{2}$ and $T \leq \log_2 \frac{n}{k}$, any algorithm suffers worst case regret at least $\Omega(Tk)$.

Proof The proof becomes conceptually simpler if we use the notion of gain defined as the follows: if \mathbf{w}_t is the parameter of the algorithm, we define its complement $\bar{\mathbf{w}}_t$ as $\bar{w}_{t,i} = 1 - w_{t,i}$. The gain of the algorithm at trial t is the inner product between the “gain” vector $\boldsymbol{\ell}_t$ and the complement $\bar{\mathbf{w}}_t$, i.e. $\bar{\mathbf{w}}_t \cdot \boldsymbol{\ell}_t$. Similarly, for any comparator $\mathbf{w} \in \mathcal{S}_m$, we define its gain as $\bar{\mathbf{w}} \cdot \boldsymbol{\ell}_t = \sum_{i=1}^n (1 - w_i) \ell_{t,i}$. It is easy to verify that the regret of the algorithm can be written as the difference between the largest gain of any subset of k experts and the gain of the algorithm:

$$\mathcal{R} = \max_{\mathbf{w} \in \mathcal{S}_k} \sum_{t=1}^T \bar{\mathbf{w}} \cdot \boldsymbol{\ell}_t - \sum_{t=1}^T \bar{\mathbf{w}}_t \cdot \boldsymbol{\ell}_t,$$

where $\mathcal{S}_k = \{\mathbf{w} \in [0, 1]^n : \sum_i w_i = k\}$. At trial one, the adversary first sorts the n experts by their complementary weights and then gives a unit of gain to each of the experts in the second half, i.e. the experts with smaller complementary weights. Since the complementary weights sum to k , the gain of the algorithm is at most $\frac{k}{2}$ in the first trial.

At each of the following trials, the adversary only sorts the experts that received gains in all of the previous trials by their complementary weights. It then gives unit gains to the second half (the half with smaller complementary weights) of these experts. It is easy to see that in this way the gain of the algorithm is at most $\frac{k}{2}$ at each trial.

Note that half of the experts that always receive gain prior to a trial t will receive gain again in trial t . Hence, after $T \leq \log_2 \frac{k}{2}$ trials, there will be at least k experts that received gains in all of the T trials, which means that the total gain of the best k experts is Tk . Now, since the algorithm receives total gain at most $\frac{kT}{2}$ in T trials, the theorem follows. ■

Appendix H. Proof of Theorem 5.6

The following theorem gives a regret lower bound that is expressed as a function of the loss budget B_L . This lower bound holds for any online algorithm that solves the m -set problem

with either unit bit vectors or arbitrary bit vectors as loss vectors. The proof is based on the time dependent regret lower bounds proven in the previous appendices.

Theorem 5.6 For the m set problem with either unit bit vectors or arbitrary bit vectors, any online algorithm suffers worst case regret of at least $\Omega(\max\{\sqrt{B_L m \ln(n/m)}, m \ln(n/m)\})$.

Proof It suffices to prove the lemma for unit bit vectors. The lower bound $\Omega(m \ln(n/m))$ follows directly from Lemma G.2 by setting the variable i of the lemma to k .

What is left to show is the lower bound $\Omega(\sqrt{B_L m \ln(n/m)})$ when it dominates the bound $\Omega(m \ln(n/m))$, i.e. when $B_L = \Omega(m \ln \frac{n}{m})$. Thus, we assume $B_L \geq m \log_2 \frac{n}{m} + 1$ and we construct an instance sequence of loss budget B_L incurring regret at least $\Omega(\sqrt{B_L m \ln(n/m)})$ to any algorithm. This instance sequence is constructed via Theorem 5.1 and Theorem 5.2: For any algorithm, these theorems provide a sequence of T unit bit vectors that incurs regret at least $\Omega(m \sqrt{\frac{T \ln(n/m)}{n}})$. We apply these theorems with $T = \lfloor \frac{n}{m} B_L \rfloor \geq n \log_2 \frac{n}{m}$. Since the produced sequence consists of unit bit vectors and has length $\lfloor \frac{n}{m} B_L \rfloor$, the total loss of the m best experts is at most B_L . Finally plugging $T = \lfloor \frac{n}{m} B_L \rfloor$ into the regret bounds guaranteed by the theorems results in the regret $\Omega(\sqrt{B_L m \ln(n/m)})$. ■

Appendix I. Auxiliary Lemmas

Lemma I.1 Inequality $\max\{\min\{a, b\}, c\} \geq \min\{\max\{a, c\}, b\}$ holds for any real number a, b and c .

Proof If $c \geq \max\{a, b\}$, LHS is c and RHS is b . Hence, the inequality holds. If $a \geq c \geq b$ or $b \geq c \geq a$, LHS is c while RHS is at most c . If $c \leq a$ and $c \leq b$, both sides are $\min\{a, b\}$. ■

Lemma I.2 Let $X \sim \text{Binomial}(T, p)$. If $Tp \geq 8c$ for any positive constant c , then $\mathbb{E}[\sqrt{X}] \geq \frac{\sqrt{c}}{\sqrt{2(1+c)}} \sqrt{Tp}$.

Proof We use the following form of the Chernoff bound (DeGroot and Schervish, 2002):

$$\Pr(X \leq Tp - \delta) \leq e^{-\frac{\delta^2}{2Tp}}.$$

Setting $\delta = \frac{1}{2}Tp$, we have $\Pr(X \leq \frac{1}{2}Tp) \leq e^{-Tp/8} \leq e^{-c}$. Since for $c > 0$, $\log(c) \leq c - 1$, this implies $e^{-c} \leq \frac{1}{1+c}$, so that we further have $\Pr(X \leq \frac{1}{2}Tp) \leq \frac{1}{1+c} = 1 - \frac{c}{1+c}$. Now we

calculate $\mathbb{E}[\sqrt{X}]$ from its definition,

$$\begin{aligned} \mathbb{E}[\sqrt{X}] &= \sum_{x=0}^T \Pr(X=x)\sqrt{x} \geq \sum_{x=\lfloor \frac{Tp}{2} \rfloor+1}^T \Pr(X=x)\sqrt{x} \\ &\geq \sum_{x=\lfloor \frac{Tp}{2} \rfloor+1}^T \Pr(X=x)\sqrt{\left\lfloor \frac{Tp}{2} \right\rfloor+1} \\ &= \Pr(X > \tfrac{1}{2}Tp) \sqrt{\left\lfloor \frac{Tp}{2} \right\rfloor+1} \\ &\geq \frac{c}{\sqrt{2(1+c)}} \sqrt{Tp}. \end{aligned}$$

Abstract

This paper develops an efficient computational method for solving a Gaussian process (GP) regression for large spatial data sets using a collection of suitably defined local GP regressions. The conventional local GP approach first partitions a domain into multiple non-overlapping local regions, and then fits an independent GP regression for each local region using the training data belonging to the region. Two key issues with the local GP are (1) the prediction around the boundary of a local region is not as accurate as the prediction at interior of the local region, and (2) two local GP regressions for two neighboring local regions produce different predictions at the boundary of the two regions, creating undesirable discontinuity in the prediction. We address these issues by constraining the predictions of local GP regressions sharing a common boundary to satisfy the same boundary constraints, which in turn are estimated by the data. The boundary constrained local GP regressions are solved by a finite element method. Our approach shows competitive performance when compared with several state-of-the-art methods using two synthetic data sets and three real data sets.

Keywords: constrained Gaussian process regression, kriging, local regression, boundary value problem, spatial prediction, variational problem

1. Introduction

Within its origin in geostatistics and known as kriging, the Gaussian process regression (hereafter abbreviated as GP regression) has been developed to be a useful tool in machine learning (Rasmussen and Williams, 2005). It provides the best linear unbiased prediction computable by a simple closed-form expression, which also has a nice probabilistic interpretation (MacKay, 1998). However, computing the exact solution of a GP regression requires $O(N^3)$ operations when the number of data points is N , which is more than 10,000 or 100,000 in a typical geospatial data set. Such a computational complexity is prohibitively

high for data sets of large size. The purpose of this paper is to develop a new computational method to expedite the computation of GP regression for large data sets.

The computation issue for GP regression has received much attention in machine learning and spatial statistics. Since a major computation bottleneck for a GP regression is the inversion of a big sample covariance matrix of size $N \times N$, many approaches proposed to approximate the sample covariance matrix with a more easily invertible one. Covariance tapering (Furrer et al., 2006; Kaufman et al., 2008) tapers the original covariance function to make a sample covariance matrix sparser and applies the sparse matrix computation algorithms for faster inversion of the matrix. Low-rank approximation (Seeger et al., 2003; Snelson and Ghahramani, 2006; Cressie and Johannesson, 2008; Banerjee et al., 2008; Sang and Huang, 2012) introduces M latent variables and assumes a certain conditional independence given the latent variables, which reduces the rank of the resulting sample covariance matrix to M . The approximation of a Gaussian random field by a Gaussian Markov random field has also been proposed (Lindgren et al., 2011). When a covariance matrix of the approximated Gaussian random field is a Matérn covariance function, the sparse precision matrix for the Gaussian Markov random field can be explicitly constructed, and the approximation can be efficiently computed.

On the other hand, local GP regression partitions a regression domain into local regions, and an independent GP regression model is learned for each local region. Since the number of observations belonging to a local region is much smaller than the total number of observations, the resulting sample covariance matrix for the local GP regression becomes much smaller. However, because of the independence of the local GP regressions, two local GP regressions for two neighboring local regions produce different predictions at the boundary of the two regions. This discontinuity in prediction is not acceptable in applications. Many proposed methods have combined local GP regressions into a global model. A popular approach is to take a mixture of local GP regressions through a Dirichlet mixture (Rasmussen and Ghahramani, 2002), a tree mixture (Gramacy and Lee, 2008), Bayesian model averaging (Tresp, 2000; Chen and Ren, 2009; Deisenroth and Ng, 2015), or a locally weighted projection (Nguyen-Tuong et al., 2009). Another approach is to use multiple additive covariance functions of a global covariance and a local covariance (Snelson and Ghahramani, 2007; Vanhatalo and Vehtari, 2008), to simply construct a new local model for each testing location (Gramacy and Apley, 2015).

Domain decomposition method (DDM, Park et al., 2011) is a specific local GP regression method that attempts to constrain the prediction of local GP regressions to be equal at their shared domain boundaries. DDM was shown in the original paper to numerically outperform several existing local GP methods in terms of computational cost and prediction accuracy. Our proposed approach in this paper follows and advances DDM in several aspects. In particular, we improve the way of constraining the prediction at boundaries of local regions. In the original DDM paper, the predictions of two local GP regressions for two neighboring local regions were constrained to be equal only at a finite number of locations on the boundary of the two regions, so there is no guarantee that the predictions are the same at other boundary locations. Our new approach considers a variational formulation for a collection of boundary constrained local GP regressions to ensure that the predictions of the two local GP regressions for neighboring regions are the same for all points on the shared boundary. The variational formulation allows us to solve the boundary

constrained local GP regressions using the finite element method. This is mathematically more elegant and conceptually simpler than the previously somewhat ad hoc treatment. In addition, we significantly improve the DDM by proposing two approaches for estimating the boundary constraints (i.e., boundary values of local regions). The improved accuracy of estimating these constraints leads to better prediction accuracy of our constrained local GP regressions. Last, our new approach has better numerical stability than the DDM. It was previously reported that the predictive variance estimate of the DDM can be negative for some numerical examples (Ponhahitb et al., 2014). Since the expression of the DDM’s predictive variance estimate cannot be theoretically negative, the negative estimate is due to numerical issues. Our new approach provides positive predictive variances for all the examples. The computation speed of the new approach is comparable to the DDM. When the domain in \mathbb{R}^d is partitioned into S local regions and each local region has N_S training data points, the computational cost of the proposed method is $O(NN_S^2 + dS)$, where $N_S \ll N$. Since our method can be viewed as “patching” a collection of local GP regressions, we refer to our method as *patched Gaussian Process regression* or *patched GP* for short.

The proposed patched GP method is theoretically applicable for an arbitrary input dimension d , but the implementation of the approach may be practically difficult for $d > 2$ mainly due to hardness in generating finite element meshes for high dimensions. Therefore, the practical application of the proposed approach would be a GP regression with a spatial data set of large volume (i.e., the data fall in a domain in \mathbb{R}^2), which finds broad applications in spatial statistics and remote sensing (Stein, 2012; Curran and Atkinson, 1998). We will still describe and derive our approach for a general dimension to ease a possible future extension of the approach to high dimensional problems. As a byproduct of this work, we develop a finite element method for the boundary constrained GP regression problem, which may have potential applications in GP solutions for partial differential equations (Graepel, 2003) or for linear stochastic differential equations having boundary conditions (Steinke and Schölkopf, 2008).

The rest of the paper is organized as follows. Section 2 reformulates the GP regression as an optimization problem and also provides an equivalent variational formulation. Section 3 considers the boundary constrained GP regression problem through optimization and develops a finite element method for solving the equivalent variational problem. Section 4 presents the core methodology of the proposed patched GP method for efficient computation of GP regressions, including a finite element method for solving a boundary constrained local GP regression, estimation of the boundary constraints, and estimation of the parameters of the Gaussian process. Section 5 shows the numerical performance of the patched GP method for different tuning parameters, and compares it to the full GP regression (i.e., full implementation of GP regression without approximation) and its precursor, the DDM, using both synthetic and real data sets. Section 6 provides additional numerical comparisons of the patched GP with several state-of-the-art approaches using real data sets. Finally Section 7 concludes the paper.

2. Reformulation of Gaussian Process Regression as An Optimization Problem

A GP regression is formulated as follows: given a training set $\mathcal{D} = \{(x_n, y_n), n = 1, \dots, N\}$ of N pairs of inputs x_n and noisy outputs y_n of a latent function f , obtain the predictive distribution of f at a test location x_* , denoted by $f_* = f(x_*)$. We assume that the latent function comes from a zero-mean Gaussian process with a covariance function $k(\cdot, \cdot)$ and the noisy observations y_i are given by

$$y_i = f(x_i) + \epsilon_i, \quad i = 1, \dots, N,$$

where $\epsilon_i \sim \mathcal{N}(0, \sigma^2)$ are white noises independent of $f(x_i)$. Denote $\mathbf{x} = [x_1, x_2, \dots, x_N]^T$ and $\mathbf{y} = [y_1, y_2, \dots, y_N]^T$. The joint distribution of (f_*, \mathbf{y}) is

$$P(f_*, \mathbf{y}) = \mathcal{N} \left(\mathbf{0}, \begin{bmatrix} k_{**} & \mathbf{k}'_{**} \\ \mathbf{k}_{**} & \sigma^2 \mathbf{I} + \mathbf{K}_{\mathbf{xx}} \end{bmatrix} \right),$$

where $k_{**} = k(x_*, x_*)$, $\mathbf{k}_{**} = (k(x_1, x_*), \dots, k(x_N, x_*))'$ and $\mathbf{K}_{\mathbf{xx}}$ is an $N \times N$ matrix with $(i, j)^{th}$ entry $k(x_i, x_j)$. The subscripts of k_{**} , \mathbf{k}_{**} , and $\mathbf{K}_{\mathbf{xx}}$ represent two sets of locations between which the covariance is computed, and x_* is abbreviated as $*$. The predictive distribution of f_* given \mathbf{y} is

$$P(f_* | \mathbf{y}) = \mathcal{N}(\mathbf{k}'_{**}(\sigma^2 \mathbf{I} + \mathbf{K}_{\mathbf{xx}})^{-1} \mathbf{y}, k_{**} - \mathbf{k}'_{**}(\sigma^2 \mathbf{I} + \mathbf{K}_{\mathbf{xx}})^{-1} \mathbf{k}_{**}). \quad (1)$$

The predictive mean $\mathbf{k}'_{**}(\sigma^2 \mathbf{I} + \mathbf{K}_{\mathbf{xx}})^{-1} \mathbf{y}$ gives the point prediction of $f(x)$ at location x_* , whose uncertainty is measured by the predictive variance $k_{**} - \mathbf{k}'_{**}(\sigma^2 \mathbf{I} + \mathbf{K}_{\mathbf{xx}})^{-1} \mathbf{k}_{**}$. Efficient calculation of the predictive mean and variance has been the focus of much research.

The predictive mean and variance can be derived using the viewpoint of the best linear unbiased predictor (BLUP) as follows. Consider all linear predictors

$$\mu(x_*) = \mathbf{u}(x_*)' \mathbf{y}, \quad (2)$$

which automatically satisfy the unbiasedness requirement $E[\mu(x_*)] = 0$ since all random variables y_i have zero mean. We seek an N -dimensional vector $\mathbf{u}(x_*)$ such that the mean squared prediction error $E[\mu(x_*) - f(x_*)]^2$ is minimized. Since $E[\mu(x_*)] = 0$ and $E[f(x_*)] = 0$, the mean squared prediction error equals the error variance $\text{var}[\mu(x_*) - f(x_*)]$ and can be expressed as

$$\begin{aligned} \sigma(x_*) &= \mathbf{u}(x_*)' E(\mathbf{y} \mathbf{y}') \mathbf{u}(x_*) - 2 \mathbf{u}(x_*)' E(\mathbf{y} f_*) + E(f_*^2) \\ &= \mathbf{u}(x_*)' (\sigma^2 \mathbf{I} + \mathbf{K}_{\mathbf{xx}}) \mathbf{u}(x_*) - 2 \mathbf{u}(x_*)' \mathbf{k}_{**} + k_{**}, \end{aligned} \quad (3)$$

which is a quadratic form in $\mathbf{u}(x_*)$. It is easy to see $\sigma(x_*)$ is minimized if and only if $\mathbf{u}(x_*)$ is chosen to be $(\sigma^2 \mathbf{I} + \mathbf{K}_{\mathbf{xx}})^{-1} \mathbf{k}_{**}$; moreover, the minimal value of $\sigma(x_*)$ equals the predictive variance given in (1).

The BLUP view of GP regression suggests a reformulation of GP regression as the following optimization problem:

$$\begin{aligned} \text{Minimize}_{\mathbf{u}(x_*) \in \mathbb{R}^N} \quad & z[\mathbf{u}(x_*)] = \frac{1}{2} \mathbf{u}(x_*)' \mathbf{A} \mathbf{u}(x_*) - \mathbf{f}(x_*)' \mathbf{u}(x_*), \end{aligned} \quad (4)$$

where $\mathbf{A} = (\sigma^2 \mathbf{I} + \mathbf{K}_{\mathbf{xx}})$ is an $N \times N$ positive definite matrix, and $\mathbf{f}(x_*) = \mathbf{k}_{\mathbf{x}*}$ is a $N \times 1$ vectorial function. Note that the objective function in (4) equals half of the error variance of a linear predictor given in (3) subtracting the constant term $k_{**}/2$. The one half factor is introduced here to make subsequent formulas neat. The solution of (4) is $\mathbf{u}^l(x_*) = \mathbf{A}^{-1} \mathbf{k}_{\mathbf{x}*} = (\sigma^2 \mathbf{I} + \mathbf{K}_{\mathbf{xx}})^{-1} \mathbf{k}_{\mathbf{x}*}$. Back to the GP regression problem, the predictive mean is given by $\mathbf{u}^l(x_*)^T \mathbf{y}$ and the predictive variance is $2z[\mathbf{u}^l(x_*) + k_{**}] + k_{**}$, twice the optimal objective value plus the variance of f_* at the location x_* .

Usually we are interested in obtaining the predictive mean and variance at multiple locations in a domain $\Omega \subset \mathbb{R}^N$, where all training locations x_i 's also belong to. To consider the prediction at all locations in Ω , we consider the following optimization problem:

$$\underset{\mathbf{u}(\cdot) \in [L^2(\Omega)]^N}{\text{Minimize}} \quad J(\mathbf{u}) = \int_{\Omega} \left\{ \frac{1}{2} \mathbf{u}(x)^T \mathbf{A} \mathbf{u}(x) - \mathbf{f}(x)^T \mathbf{u}(x) \right\} dx, \quad (5)$$

where $[L^2(\Omega)]^N$ is the Cartesian product of N Hilbert spaces $L^2(\Omega)$. The objective function here is simply the integration of the objective function in the single location problem (4). Since the optimal solution $\mathbf{u}^l(x_*)$ obtains the minimum objective value of (4) at every location $x_* \in \Omega$, $\mathbf{u}^l(x_*)$ as a function of x_* also solves the global problem (5).

According to a standard result from functional analysis (Ern and Guermond, 2004), the problem (5) has an equivalent variational formulation, as follows.

Proposition 1 *The vector $\mathbf{u} \in [L^2(\Omega)]^N$ minimizes $J(\mathbf{u})$ if and only if it solves the integral equation*

$$\int_{\Omega} \mathbf{u}(x)^T \mathbf{A} \mathbf{v}(x) dx = \int_{\Omega} \mathbf{f}(x)^T \mathbf{v}(x) dx \quad \text{for each } \mathbf{v} \in [L^2(\Omega)]^N. \quad (6)$$

The proof is given in Appendix A.

Throughout the rest of the paper, whenever no confusion may arise and to alleviate the notation, we omit the Lebesgue measure under the integral sign. For example, we shall write $\int_{\Omega} \mathbf{u}^T \mathbf{A} \mathbf{v}$ and $\int_{\Omega} \mathbf{f}^T \mathbf{v}$ instead of $\int_{\Omega} \mathbf{u}(x)^T \mathbf{A} \mathbf{v}(x) dx$ and $\int_{\Omega} \mathbf{f}(x)^T \mathbf{v}(x) dx$.

3. Gaussian Process Regression with Boundary Constraints

The optimization problem (5) was introduced in previous section as a reformulation of the GP regression. Now we introduce boundary constraints to the GP regression through this optimization problem and develop a finite element solution for the corresponding variational formulation. This finite element solution will serve as a building block in the next section for the patched GP regression, which consists of a collection of boundary constrained GP regressions.

3.1 Constrained Optimization Problem and Its Variational Formulation

We require that the domain Ω is a Lipschitz bounded open set. Let $\partial\Omega$ denote the boundary of the domain Ω . We need to restrict our attention to smooth functions and specifically consider only solution vectors in the Sobolev space $[H^1(\Omega)]^N$ instead of $[L^2(\Omega)]^N$, where $H^1(\Omega) := \{u \in L^2(\Omega); \partial_i u \in L^2(\Omega), 1 \leq i \leq d\}$ with $\partial_i u$ denoting the partial derivative of u with respect to the i th dimension of input. We cannot use the bigger $L^2(\Omega)$ space because

the value of a function in this space can be unbounded on $\partial\Omega$ and so not well-defined. For example, take $\Omega = (0, 1)$ and $u(x) = x^{-1/3}$. It is clear that $u(x) \in L^2(\Omega)$ but $u(0) = \infty$. On the other hand, the values of a function in $H^1(\Omega)$ are bounded at its domain boundary. In fact, if $u \in H^1(\Omega)$, then u restricted on $\partial\Omega$, which we denote by $u|_{\partial\Omega}$, is a member of $H^{1/2}(\partial\Omega) := \{u \in L^2(\Omega) : \frac{u(x) - u(y)}{\|x - y\|^{(d+1)/2}} \in L^2(\Omega \times \Omega)\}$ (Ern and Guermond, 2004, Theorem B.52).

Consider the boundary constraints of the form $\mathbf{y}^T \mathbf{u}(x) = b(x)$ for some known function $b \in H^{1/2}(\partial\Omega)$. Since $\mathbf{y}^T \mathbf{u}(x)$ can be interpreted as a linear predictor at location x , the constraints simply require the predictions at the domain boundary to have certain specified functional form. Denote

$$H_b = \left\{ \mathbf{u} \in [H^1(\Omega)]^N : \int_{\partial\Omega} \mathbf{y}^T \mathbf{u}|_{\partial\Omega} v = \int_{\partial\Omega} b v \quad \text{for each } v \in H^{1/2}(\partial\Omega) \right\}.$$

A constrained version of the optimization problem (5) can be written as

$$\underset{\mathbf{u} \in H_b}{\text{Minimize}} \quad J(\mathbf{u}) = \int_{\Omega} \left\{ \frac{1}{2} \mathbf{u}(x)^T \mathbf{A} \mathbf{u}(x) - \mathbf{f}(x)^T \mathbf{u}(x) \right\} dx. \quad (7)$$

Here, for mathematical convenience, we have replaced the strict boundary constraints $\mathbf{y}^T \mathbf{u}(x) = b(x)$ by a weaker form for $\mathbf{u} \in H_b$.

Similar to Proposition 1, we can show that the optimization problem (7) is equivalent to a variational formulation:

Proposition 2 *The vector $\mathbf{u} \in H_b$ minimizes $J(\mathbf{u})$ if and only if it solves the integral equation*

$$\int_{\Omega} \mathbf{u}(x)^T \mathbf{A} \mathbf{v}(x) dx = \int_{\Omega} \mathbf{f}(x)^T \mathbf{v}(x) dx \quad \text{for each } \mathbf{v} \in H_b. \quad (8)$$

The proof is given in Appendix B.

3.2 Finite Element Approximation

A finite element method approximates the space H_b of vector-valued functions on a domain Ω by a finite dimensional vector space. With the approximation, the integral equation (8) is converted to a finite-dimensional linear system of equations.

The finite dimensional approximation scheme requires a mesh and a set of finite elements. A mesh $\mathcal{K}_h = \{K_1, \dots, K_M\}$ is a set of a finite number of compact, connected and Lipschitz subsets of Ω with non-empty interior which partitions Ω , where each K_m is called a mesh cell, and h parameterizes the size of K_m ; e.g. if K_m is a polygon, h is the length of the polygon's side. For each $K_m \in \mathcal{K}_h$, a finite element is defined as a triplet $\{K_m, P_m, \mathcal{A}_m\}$, where P_m is a vector space of functions $q : K_m \rightarrow \mathbb{R}$ with $\dim(P_m) = p$, and \mathcal{A}_m is a set of p linear forms $\alpha_{mj} : P_m \rightarrow \mathbb{R}^N$ spanning the dual vector space of P_m , which is called the local degrees of freedom. There exists a basis $\{\phi_{m1}, \dots, \phi_{mp}\}$ of the vector space P_m satisfying $\alpha_{mj}(\phi_{mk}) = \mathbf{I}_N \delta_{jk}$, where \mathbf{I}_N is a N -vector of 1's. In our implementation, we use the Lagrange finite element for $\{K_m, P_m, \mathcal{A}_m\}$, where K_m is a simplex in \mathbb{R}^d , P_m is the polynomial of order k and $\alpha_{mj} = \mathbf{u}(x_{mj})$ with $x_{mj} \in K_m$; more details can be found in Ern and Guermond (2004, Section 1.2.3).

For any vector-valued function $\mathbf{u} \in [H^1(\Omega)]^N$, let $\mathbf{u}|_{K_m}$ denote its restriction to K_m , i.e., $\mathbf{u}|_{K_m}(x) = \mathbf{1}_{K_m}(x)\mathbf{u}(x)$. The finite element approximation of \mathbf{u} on K_m is given by

$$\mathbf{u}|_{K_m} \approx \mathbf{u}_{mh} := \sum_{j=1}^p \beta_{mj} \phi_{mj},$$

where β_{mj} is an N -vector of coefficients in the basis expansion. The combination of \mathbf{u}_{mh} 's over K_m , $m \in \mathcal{M}$, provides a global approximation of \mathbf{u} over the whole domain Ω , i.e.,

$$\mathbf{u}_h = \sum_{m=1}^M \mathbf{u}_{mh} = \sum_{m=1}^M \sum_{j=1}^p \beta_{mj} \phi_{mj}, \quad (9)$$

which has a matrix-vector representation

$$\mathbf{u}_h = \mathbf{U}^T \phi, \quad (10)$$

where \mathbf{U} is the $(Mp) \times N$ matrix formed by concatenating row vectors β_{mj} in row-wise and ϕ is the (Mp) -dimensional column vector of ϕ_{mj} 's. In (9) and (10) we explicitly extended ϕ_{mj} to be zero outside K_m . The collection of vector-valued functions with expression (10) is a finite-dimensional linear space. We call this space the finite element space and denote it as G_h , where the subscript denotes the mesh size h .

The finite element method for solving the unconstrained integral equation (6) seeks $\mathbf{u}_h \in G_h$ such that

$$a(\mathbf{u}_h, \mathbf{v}_h) = c(\mathbf{v}_h) \quad \text{for each } \mathbf{v}_h \in G_h, \quad (11)$$

where $a(\mathbf{u}, \mathbf{v}) = \int \mathbf{u}' \mathbf{A} \mathbf{v}$ and $c(\mathbf{v}) = \int \mathbf{f}' \mathbf{v}$. Following (10), we can write $\mathbf{u}_h = \mathbf{U}^T \phi$ and similarly $\mathbf{v}_h = \mathbf{V}^T \phi$. Both of the lhs and rhs of (11) can be simply represented as algebraic forms as follows. First, since

$$\mathbf{u}_h' \mathbf{A} \mathbf{v}_h = \text{trace}(\phi' \mathbf{U} \mathbf{A} \mathbf{V}^T \phi) = \text{trace}(\phi \phi' \mathbf{U} \mathbf{A} \mathbf{V}^T),$$

we have

$$a(\mathbf{u}_h, \mathbf{v}_h) = \int_{\Omega} \mathbf{u}_h' \mathbf{A} \mathbf{v}_h = \text{trace} \left(\int_{\Omega} \phi \phi' \mathbf{U} \mathbf{A} \mathbf{V}^T \right) = \text{trace}(\Phi \mathbf{U} \mathbf{A} \mathbf{V}^T),$$

where $\Phi = \int_{\Omega} \phi \phi'$. Second, since

$$\mathbf{f}' \mathbf{v}_h = \text{trace}(\mathbf{f}' \mathbf{V}^T \phi) = \text{trace}(\phi \mathbf{f}' \mathbf{V}^T),$$

we have that

$$c(\mathbf{v}_h) = \int_{\Omega} \mathbf{f}' \mathbf{v}_h = \text{trace} \left(\int_{\Omega} \phi \mathbf{f}' \mathbf{V}^T \right) = \text{trace}(\mathbf{F} \mathbf{V}^T),$$

where $\mathbf{F} = \int_{\Omega} \phi \mathbf{f}'$. Therefore, the integral equation (11) is equivalent to the following linear system

$$\text{trace}((\Phi \mathbf{U} \mathbf{A} - \mathbf{F}) \mathbf{V}^T) = 0 \quad \text{for each } \mathbf{V} \in \mathbb{R}^{N \times (Mp)},$$

which is equivalent to

$$\Phi \mathbf{U} = \mathbf{F} \mathbf{A}^{-1}. \quad (12)$$

We now introduce the boundary constraints. We partition (after reordering the elements) the basis function vector ϕ used in $\mathbf{u}_h = \mathbf{U}^T \phi$ into two vectors ϕ_0 and ϕ_b in column-wise such that, ϕ_0 is a column vector of the $\phi_{mj}(x)$'s satisfying $\phi_{mj}|_{\partial\Omega} = 0$ and ϕ_b is a column vector of the $\phi_{mj}(x)$'s satisfying $\phi_{mj}|_{\partial\Omega} \neq 0$. Suppose that ϕ_0 has Q elements and ϕ_b has R elements. Since the number of columns of ϕ is Mp , $Q + R = Mp$. With the partition, we have that

$$\mathbf{u}_h = \mathbf{U}'_0 \phi_0 + \mathbf{U}'_b \phi_b, \quad (13)$$

where \mathbf{U}'_0 and \mathbf{U}'_b are submatrices consisting of \mathbf{U} 's rows corresponding to ϕ_0 and ϕ_b respectively. Substituting (13) into equation (12), we have that

$$\Phi'_0 \mathbf{U}'_0 + \Phi'_b \mathbf{U}'_b = \mathbf{F}' \mathbf{A}^{-1}, \quad (14)$$

where $\Phi'_0 = \int_{\Omega} \phi'_0 \phi'_0$ and $\Phi'_b = \int_{\Omega} \phi'_b \phi'_b$.

The boundary constraints restricted to G_h can be written as

$$\int_{\partial\Omega} \mathbf{y}' \mathbf{u}_h|_{\partial\Omega} v = \int_{\partial\Omega} b v \quad \text{for each } v \in G_h.$$

Using (14) and dropping the basis functions whose values are zero at the boundary, we obtain

$$\int_{\partial\Omega} \mathbf{y}' \mathbf{U}'_b \phi_b|_{\partial\Omega} \phi_{mj}|_{\partial\Omega} = \int_{\partial\Omega} b \phi_{mj}|_{\partial\Omega} \quad \text{for each } \phi_{mj}|_{\partial\Omega} \neq 0,$$

which implies

$$\int_{\partial\Omega} \mathbf{y}' \mathbf{U}'_b \phi_b|_{\partial\Omega} \phi'_b|_{\partial\Omega} = \int_{\partial\Omega} b \phi'_b|_{\partial\Omega}.$$

Letting $\mathbf{B} = \int_{\partial\Omega} \phi_b|_{\partial\Omega} \phi'_b|_{\partial\Omega}$ and $\mathbf{b} = \int_{\partial\Omega} b \phi'_b|_{\partial\Omega}$, we have

$$\mathbf{y}' \mathbf{U}'_b \mathbf{B} = \mathbf{b}', \quad (15)$$

We decompose \mathbf{U}'_b into two components: one orthogonal to \mathbf{y} and the residual. Let \mathbf{O}_g be $N \times (N-1)$ matrix of $N-1$ column vectors orthogonal to \mathbf{y} , which can be obtained by the Gram-Schmidt process. There exist $\mathbf{Z} \in \mathbb{R}^{R \times (N-1)}$ and $\mathbf{z} \in \mathbb{R}^{R \times 1}$ satisfying

$$\mathbf{U}'_b = \mathbf{Z} \mathbf{O}'_g + \mathbf{z} \mathbf{y}'. \quad (16)$$

Therefore, (14) becomes

$$\Phi'_0 \mathbf{U}'_0 + \Phi'_b \mathbf{Z} \mathbf{O}'_g + \Phi'_b \mathbf{z} \mathbf{y}' = \mathbf{F}' \mathbf{A}^{-1} \quad (17)$$

Since

$$\mathbf{y}' \mathbf{U}'_b = \mathbf{y}' (\mathbf{O}_g \mathbf{Z}' + \mathbf{y} \mathbf{z}') = \mathbf{y}' \mathbf{y} \mathbf{z}',$$

equation (15) gives us

$$\mathbf{y}' \mathbf{y} \mathbf{z}' \mathbf{B} = \mathbf{b}',$$

therefore,

$$(\mathbf{y}' \mathbf{y}) \mathbf{z} = \mathbf{B}^{-1} \mathbf{b}'. \quad (18)$$

In summary, we first solve (18) for \mathbf{z} , then solve (17) for \mathbf{U}'_0 and \mathbf{Z} , and then calculate \mathbf{U}'_b using (16). The finite element solution of the variational problem (8) is given by $\mathbf{u}_h = \mathbf{U}'_0 \phi_0 + \mathbf{U}'_b \phi_b$. By the theory of finite element method (Ern and Guermond, 2004), the approximate solution \mathbf{u}_h converges to the solution of the original problem as the mesh size h tends to zero.

4. Patching Constrained Local GPs for Efficient Computation of Global GP regression

This section presents our patched GP regression method. We start from some notations. We partition the domain Ω of the data into small local regions $\{\Omega_s, s = 1, \dots, S\}$ and partition the training data set $\mathcal{D} = \{(x_n, y_n) : n = 1, \dots, N\}$ accordingly into S data sets $\mathcal{D}_s := \{(x_n, y_n) \in \mathcal{D} : x_n \in \Omega_s\}$. We then calculate the local prediction function f_s for the local region Ω_s using the data set \mathcal{D}_s . There are some issues with this localized solution. First, the prediction at around $\partial\Omega_s$ is not as accurate as the prediction at the interior of Ω_s , mainly because of the less number of observations available around $\partial\Omega_s$. In particular, when S becomes large, the boundary regions also increase. Therefore, the inaccuracy at the boundaries $\partial\Omega_s$ can have significant negative effects on the overall prediction accuracy. Second, two local GP regressions from two neighboring local regions Ω_s and Ω_t produce different predictions f_s and f_t at the shared boundary, making the prediction discontinuous on the boundary. This discontinuity is unacceptable since continuity of the prediction is often desired. We propose to impose boundary constraints such that the two neighboring local GP regressions give the same predictions on the shared boundary.

Section 4.1 applies the finite element method of Section 3 to solve a boundary constrained local GP problem for each local region when the boundary constraints are given. Section 4.2 gives two methods for estimating the boundary constraints. Section 4.3 discusses some implementation details, including calculation of the integrations involving the finite elements, and learning parameters of the covariance function of the GP regression.

4.1 Boundary-constrained Local GP

For two neighboring local regions Ω_s and Ω_t , let $\Gamma_{st} = \bar{\Omega}_s \cap \bar{\Omega}_t$ denote the shared boundary, where $\bar{\Omega}_s$ is the closure of Ω_s . The prediction function f specialized on Γ_{st} is denoted by a boundary function $b_{st}(x)$ for $x \in \Gamma_{st}$. For the time being, we assume that $b_{st}(x)$ is known and shall discuss in next section how to estimate $b_{st}(x)$. Fix a domain Ω_s , suppose all its boundary functions $\{b_{st} : \forall t, \Gamma_{st} \neq \emptyset\}$ are known. Consider the following local GP problem on Ω_s

$$\begin{aligned} \text{Minimize}_{\mathbf{u}_s} \quad & J(\mathbf{u}_s) = \int_{\Omega_s} \left\{ \frac{1}{2} \mathbf{u}_s(x)' \mathbf{A}_s \mathbf{u}_s(x) - \mathbf{f}_s(x)' \mathbf{u}_s(x) \right\} dx \\ \text{subject to} \quad & \mathbf{y}'_s \mathbf{u}_s(x) = b_{st}(x) \text{ on } x \in \Gamma_{st}, \quad \forall t, \Gamma_{st} \neq \emptyset \end{aligned} \quad (19)$$

where \mathbf{A}_s , $\mathbf{f}_s(x)$ and \mathbf{y}_s are the localized versions of \mathbf{A} , $\mathbf{f}(x)$ and \mathbf{y} , which are all computed using the data in Ω_s . The constraints used in (19) restrict two local GP prediction functions f_s and f_t to have the same prediction b_{st} on the shared boundary Γ_{st} .

As in Section 3, we replace the boundary constraints by the weak form, approximate \mathbf{u}_s by its finite element approximation $\mathbf{u}_{s,h} = \mathbf{U}'_{s,0} \phi_{s,0} + \mathbf{U}'_{s,b} \phi_{s,b}$, where $\phi_{s,0}$ is a vector of local basis functions ϕ_{mj} 's satisfying $\phi_{mj}(x)|_{\Gamma_{st}} = 0$ for all t 's, and $\phi_{s,b}$ is a vector of local basis functions ϕ_{mj} 's satisfying $\phi_{mj}(x)|_{\Gamma_{st}} \neq 0$ for all t 's, and $\phi_s = (\phi'_{s,0}, \phi'_{s,b})'$. Let N_s be the length of \mathbf{y}_s and \mathbf{O}_{y_s} be $N_s \times (N_s - 1)$ matrix of $N_s - 1$ column vectors orthogonal to \mathbf{y}_s . We can decompose $\mathbf{U}_{s,b}$ into $\mathbf{U}_{s,b} = \mathbf{Z}_s \mathbf{O}'_{y_s} + \mathbf{z}_s \mathbf{y}'_s$. As we derived in Section 3, the finite element solution of the local problem (19) is obtained by solving the following linear

$$\begin{aligned} \text{system of equations for } \mathbf{U}_{s,0}, \mathbf{Z}_s \text{ and } \mathbf{z}_s, \\ \Phi_{s,0} \mathbf{U}_{s,0} + \Phi_{s,b} \mathbf{Z}_s \mathbf{O}'_{y_s} + \Phi_{s,b} \mathbf{z}_s \mathbf{y}'_s = \mathbf{F}_s \mathbf{A}_s^{-1}, \end{aligned} \quad (20)$$

$$\text{where } \Phi_{s,0} = \int_{\Omega_s} \phi_s \phi'_{s,0}, \quad \Phi_{s,b} = \int_{\Omega_s} \phi_s \phi'_{s,b}, \quad \mathbf{F}_s = \int_{\Omega_s} \phi_s \mathbf{f}'_s, \text{ and}$$

$$\mathbf{B}_s = \sum_{t: \Gamma_{st} \neq \emptyset} \int_{\Gamma_{st}} \phi_{s,b} |_{\Gamma_{st}} \phi_{s,b} |_{\Gamma_{st}},$$

$$\mathbf{b}_s = \sum_{t: \Gamma_{st} \neq \emptyset} \int_{\Gamma_{st}} b_{st} |_{\Gamma_{st}} \phi_{s,b} |_{\Gamma_{st}}.$$

Since $b_{st}(x)$ is unknown, we need to estimate \mathbf{b}_s using the procedure to be described in Section 4.2. Using the second equation of (20), we obtain $\mathbf{z}_s = \mathbf{B}_s^{-1} \mathbf{b}_s / \mathbf{y}'_s \mathbf{y}_s$. Substituting this expression of \mathbf{z}_s in the first equation of (20), we obtain

$$\begin{aligned} \Phi_{s,0} \mathbf{U}_{s,0} + \Phi_{s,b} \mathbf{Z}_s \mathbf{O}'_{y_s} &= \mathbf{F}_s \mathbf{A}_s^{-1} - \Phi_{s,b} \mathbf{z}_s \mathbf{y}'_s, \\ &= \mathbf{F}_s \mathbf{A}_s^{-1} - \Phi_{s,b} \frac{\mathbf{B}_s^{-1} \mathbf{b}_s \mathbf{y}'_s}{\mathbf{y}'_s \mathbf{y}_s}. \end{aligned} \quad (21)$$

We then solve this equation for $\mathbf{U}_{s,0}$ and \mathbf{Z}_s , and compute $\mathbf{U}_{s,b} = \mathbf{Z}_s \mathbf{O}'_{y_s} + \mathbf{z}_s \mathbf{y}'_s$. Finally the finite element solution of the constrained local GP problem (19) is $\mathbf{u}_{s,h} = \mathbf{U}'_{s,0} \phi_{s,0} + \mathbf{U}'_{s,b} \phi_{s,b}$.

When the number of mesh cells in each local region is M on average and the number of training data in each domain is N_s , the computation complexity of solving the constrained local GP regression (21) for one local region is $O(N_s^3 + M^2)$. The first part N_s^3 is for inverting \mathbf{A}_j , and the second part is for inverting $\Phi_{s,0}$ and $\Phi_{s,b}$, which is proportional to M^2 because $\Phi_{s,0}$ and $\Phi_{s,b}$ are sparse banded matrices; note that the complexity of solving a linear system with a banded coefficient matrix is proportional to the square of the size of the linear system (Mahmood et al., 1991). The cost per local region is mostly bounded by the cubic term $O(N_s^3)$. The total computational cost for S local regions is thus $O(SN_s^3)$, which also equals to $O(NN_s^2)$.

4.1.1 ILLUSTRATIVE OUTPUT OF THE CONSTRAINED GP FORMULATION

Our constrained local GP regression provides a good approximate to a full GP regression when the value of boundary function b_{st} is close to the mean prediction of the full GP regression at Γ . To show this, we performed a simple simulation study. In the study, we generated a data set of 6,000 noisy observations from a zero-mean Gaussian process with an exponential covariance function,

$$y_i = f(x_i) + \epsilon_i \quad \text{for } i = 1, \dots, 6000,$$

where $x_i \sim \text{Uniform}(0, 10)$ and $\epsilon_i \sim \mathcal{N}(0, 1)$ are independently sampled, and $f(x_i)$ is simulated by the R package `RandomField`. Three hundreds of the observations were randomly sampled to learn a Gaussian process regression (full GP) and the covariance hyperparameters, while the remaining 5,700 were kept for test data. The domain $[0, 10]$ was partitioned into ten local regions of size 1 delineated by boundary points $\{0.0, 0.1, 0.2, 0.3, \dots, 1.0\}$,

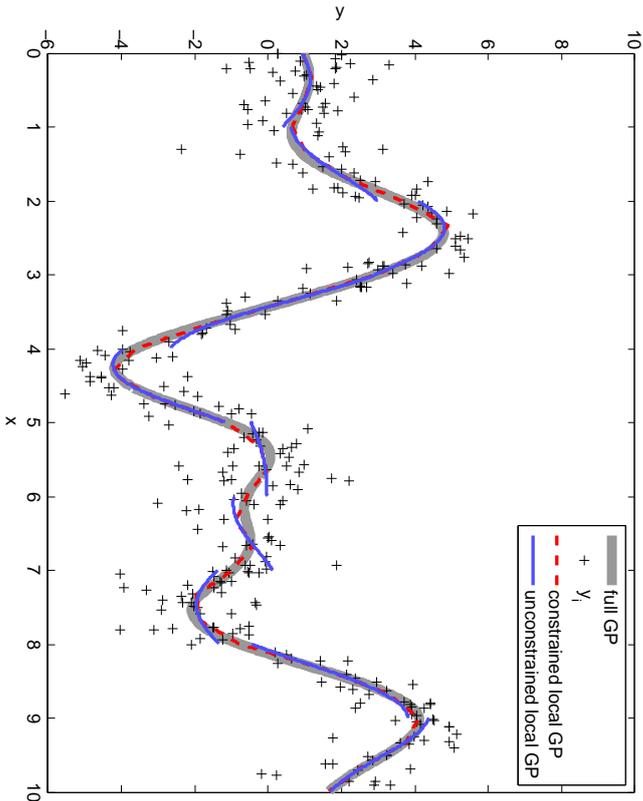

Figure 1: Effect of the boundary constraint on Gaussian process regression.

and the 300 observations were distributed into the local regions accordingly. For each domain, an unconstrained GP regression (unconstrained local GP) and a constrained GP regression (constrained local GP) were learned. When the constrained local GP was learned, the values of the regression outcome at the boundary points were constrained to be equal to the mean prediction of a full GP regression at the points. Note this is not a fair comparison since the full GP prediction was used. This example was just used to show the room for improvement if constraints are used.

Figure 1 shows the comparison of the mean predictions from a full GP, the constrained local GP and the unconstrained local GP regressions. Compared to the unconstrained local GP regression, the constrained model is much closer to a full GP regression especially at the boundary points. The maximum difference in the mean predictions of the constrained model and a full GP over the test data was 0.2803, while that of the unconstrained version was 0.6411. The advantage of placing the boundary constraints on the local GP in improving the prediction accuracy is clear. However, placing the boundary constraints requires knowing the value of the ground truth f at boundary points, i.e., boundary function b_{st} . Estimating the values of f at boundary points is the subject of the next section.

4.2 Estimation of Boundary Values

The prediction function f at Γ_{st} , i.e., the boundary function b_{st} is unknown and needs to be estimated before the constrained local GP regression is solved. We propose two approaches for the estimation boundary values for the local GP regressions. The first approach is to train a separate local GP regression using a subset of training data located around the boundary Γ_{st} —this together with the constrained local GP regressions, leads to a two-step procedure. The second approach is to iteratively solve the boundary value estimation and the constrained local GP problems.

4.2.1 LOCALIZED ESTIMATION

This approach is motivated by our observation that a GP regression for a local domain gives accurate prediction at the center of the domain. We propose to estimate the prediction function f at Γ_{st} by learning a local GP regression with a subset of the training data that belong to a neighborhood of Γ_{st} . When $x \in \mathcal{R}$, Γ_{st} is a point coordinate in \mathcal{R} , and its neighborhood is defined by an interval $[\Gamma_{st}-r, \Gamma_{st}+r]$ around it with half width $r > 0$. When $x \in \mathcal{R}^d$ in general, Γ_{st} is a $d-1$ dimensional hyperplane within \mathcal{R}^d , and its neighborhood is defined by $Nh_r(\Gamma_{st})$,

$$Nh_r(\Gamma_{st}) = \{x' \in \mathcal{R}^d; \min_{x \in \Gamma_{st}} \|x' - x\|_2 \leq r\}.$$

The value of the prediction function f at $x \in \Gamma_{st}$, i.e. $b_{st}(x)$, is estimated by the mean prediction of the local GP regression built from a subset of training data, $\mathbf{x}_{st} = \{x_n \in \mathcal{D}; x_n \in Nh_r(\Gamma_{st})\}$ and the corresponding observed outputs \mathbf{y}_{st} ,

$$\hat{b}_{st}(x) = \mathbf{K}_{\mathbf{x}_{st}, x}^*(\sigma^2 \mathbf{I} + \mathbf{K}_{\mathbf{x}_{st}, \mathbf{x}_{st}})^{-1} \mathbf{y}_{st}. \quad (22)$$

When the average number of observations in the local neighborhood $Nh_r(\Gamma_{st})$ is N_B , the complexity of this boundary estimation per boundary is $O(N_B^3)$. When the dimension of the domain Ω is d and the domain is decomposed into S local regions of d -simplices, the total number of the boundaries in between the local regions is proportional to dS . So, the complexity of this boundary estimation procedure is $O(dSN_B^3)$.

4.2.2 BLOCK GAUSS-SEIDEL ITERATION

The system of equations for the constrained local GP regression given by (20) is converted into the following equation for three unknown variables $\mathbf{U}_{s,0}$, \mathbf{Z}_s and \mathbf{b}_{s1} ,

$$\Phi_{s,0} \mathbf{U}_{s,0} + \Phi_{s,\delta} \mathbf{Z}_s \mathbf{O}'_s + \Phi_{s,\delta} \mathbf{B}_s^{-1} \mathbf{b}_{s1} \mathbf{g}'_s / (\mathbf{g}'_s \mathbf{g}_s) = \mathbf{F}_s \mathbf{A}_s^{-1}, \quad (23)$$

where we used $(\mathbf{g}'_s \mathbf{g}_s) \mathbf{z}_s = \mathbf{B}_s^{-1} \mathbf{b}_s$ to replace the \mathbf{z}_s in the first line of (20) with $\mathbf{B}_s^{-1} \mathbf{b}_s / (\mathbf{g}'_s \mathbf{g}_s)$. Note that the above equation depends on an unknown boundary function b_{st} only through \mathbf{b}_{s1} . We will estimate the vector quantity \mathbf{b}_{s1} instead of estimating the boundary function b_{st} directly. The equation for $\mathbf{U}_{s,0}$, \mathbf{Z}_s and \mathbf{b}_{s1} can be solved iteratively by the block Gauss-Seidel method (Saad, 2003). The block Gauss-Seidel method is an iterative solver for a linear system that partitions a number of unknowns into multiple blocks and solves the linear system for one block at a time while keeping the other blocks fixed. In our problem,

we have two block of unknowns, one block for $\mathbf{U}_{s,0}$ and \mathbf{Z}_s and the other block for \mathbf{b}_s . The corresponding block Gauss-Seidel iteration is as follows. Start with an initial guess $\mathbf{b}_s^{(0)}$. We used a zero vector for the initial guess. At iteration k , we perform the following two steps sequentially:

Step 1. With $\mathbf{b}_s^{(k-1)}$ fixed from the previous iteration, obtain $\mathbf{U}_{s,0}^{(k)}$ and $\mathbf{Z}_s^{(k)}$ by solving

$$\Phi_{s,0} \mathbf{U}_{s,0}^{(k)} + \Phi_{s,b} \mathbf{Z}_s^{(k)} \mathbf{O}'_{y_s} = \mathbf{F}_s \mathbf{A}_s^{-1} - \Phi_{s,b} \mathbf{B}_s^{-1} \mathbf{b}_s^{(k-1)} \mathbf{y}'_s / (\mathbf{y}'_s \mathbf{y}_s), \quad s = 1, \dots, S. \quad (24)$$

Step 2. Obtain $\mathbf{b}_s^{(k)}$ by solving

$$\Phi_{s,b} \mathbf{B}_s^{-1} \mathbf{b}_s^{(k)} \mathbf{y}'_s / (\mathbf{y}'_s \mathbf{y}_s) = \mathbf{F}_s \mathbf{A}_s^{-1} - \Phi_{s,0} \mathbf{U}_{s,0}^{(k)} - \Phi_{s,b} \mathbf{Z}_s^{(k)} \mathbf{O}'_{y_s}, \quad s = 1, \dots, S. \quad (25)$$

Note that the equations in the system (24) appeared in Step 1 can be solved in parallel for $s = 1, \dots, S$. But the equations in the system (25) appeared in Step 2 should be solved collectively for all $s = 1, \dots, S$, since \mathbf{b}_s is shared by multiple local regions and thus appears in multiple equations. The block Gauss-Seidel method converges very fast. When the dimension of the domain Ω is d and the domain is decomposed into S local regions of d -simplices, the total number of boundaries in between the local regions is proportional to dS . On the other hand, the size of the linear system to be solved in Step 2 is proportional to the number of boundaries. Since the coefficient matrix of the linear system is a banded matrix, the complexity of solving such a linear system is proportional to the square of the size of the linear system (Mahmood et al., 1991), that is, $O(d^2 S^2)$.

4.2.3 NUMERICAL COMPARISON

This section numerically compares the two aforementioned solutions for boundary value estimation. We used the same data set used in Section 4.1.1 and applied the same partitioning scheme for splitting the entire domain into 10 local regions, in between which there are nine boundary locations. We applied the localized estimation method and the iterative block Gauss-Seidel approach for estimating $f(x)$ at the nine locations, and compared them with the estimated values from a full GP regression. Figure 2-(a) shows the comparison results. The root mean squared difference of the localized estimation to a full GP regression was 0.0775, while that of the iterative approach was 0.1369. Both of the errors are far below the noise parameter $\sigma = 1$. The computation time for the estimation was comparable, 0.041328 seconds for the localized method and 0.038071 seconds for the iterative approach.

For another comparison, we generated a synthetic data set in 2-d of 8,000 noisy observations from a zero-mean Gaussian process with an exponential covariance function of scale one and variance 10,

$$y_i = f(x_i) + \epsilon_i \quad \text{for } i = 1, \dots, 8000,$$

where $x_i \sim \text{Uniform}([0, 6] \times [0, 6])$ and $\epsilon_i \sim \mathcal{N}(0, 1)$ were independently sampled, and the Gaussian process realization $f(x_i)$ was simulated by the R package `RandomField`. We split the input domain $[0, 6] \times [0, 6]$ into sixteen local regions of equal size, and 1,881 test locations were chosen uniformly surrounding the local region boundaries. For each test location, we obtained the prediction based on a full GP regression and computed the differences of the

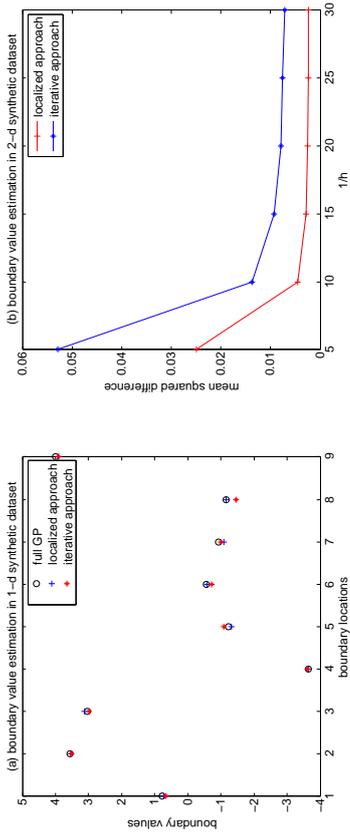

Figure 2: Comparison of the two proposed methods of boundary value estimation with a full GP regression.

boundary estimation by the localized approach or the iterative approach and the full GP regression prediction. The mean squared differences versus mesh size h are plotted in Figure 2-(b). Again, the localized approach works better.

4.3 Computation Complexity and Implementation Details

The total computation complexity of our proposed approach is the summation of two complexities, one for the constrained GP regressions and the other for the boundary value estimation. It is $O(SN_S^3 + dSN_B^2)$ when the localized estimation approach is used for boundary value estimation, and it is $O(SN_S^3 + d^2 S^2)$ when the block Gauss-Seidel iteration is used. Since $SN_S = N$ and N_B is a constant, the complexity is $O(NN_S^2 + dS)$ or $O(NN_S^2 + d^2 S^2)$ respectively.

4.3.1 EVALUATION OF INTEGRALS FOR QUANTITIES IN EQUATION (20)

The integrals for defining several quantities in equation (20) can be computed effectively using well-established finite element computations. Suppose that $\Omega \subset \mathbb{R}^d$ and we use the Lagrange finite elements of polynomial degree k , where the s th local region Ω_s is partitioned into M mesh cells $\{\mathcal{K}_m; m = 1, \dots, M\}$ for the finite element approximation. The ϕ_s is a column vector of the Lagrange basis functions for the mesh cells,

$$\{\phi_{m,j}; m = 1, \dots, M, j = 0, 1, \dots, J\}, \quad \text{and } J = \binom{d+k}{k}.$$

It is well known that each $\phi_{m,j}$ is a polynomial function of barycentric coordinates λ_j 's with respect to the d -simplex \mathcal{K}_m (Ern and Guermond, 2004, pages 22-23). One can use the integral formula for barycentric coordinates (Voitovich and Vandewalle, 2008) to compute

$\Phi_{s,0}$ and $\Phi_{s,b}$. For example, when $d = 2$,

$$\int_{\mathcal{K}_m} \lambda_{j_1}^a \lambda_{j_2}^b \lambda_{j_3}^c = 2! |\mathcal{K}_m| \frac{a!b!c!}{(2+a+b+c)!},$$

and when $d = 3$,

$$\int_{\mathcal{K}_m} \lambda_{j_1}^a \lambda_{j_2}^b \lambda_{j_3}^c \lambda_{j_4}^d = 6! |\mathcal{K}_m| \frac{a!b!c!d!}{(3+a+b+c+d)!},$$

where $|\mathcal{K}_m|$ is the volume of \mathcal{K}_m . Since $\phi_{m,j_1} \phi_{m,j_2}$ is also a polynomial functions of λ_j 's, one can use the previous integration formulas to evaluate $\int_{\mathcal{K}_m} \phi_{m,j_1} \phi_{m,j_2}$ and

$$\int_{\Omega_s} \phi_{m,j_1} \phi_{m,j_2} = \sum_m \int_{\mathcal{K}_m} \phi_{m,j_1} \phi_{m,j_2}. \quad (26)$$

For the values of $\mathbf{F}_{s,i}$, one can take the finite element approximation of $\mathbf{f}_{s,i}$ where each function f_i in \mathbf{f}_s is approximated by

$$\sum_j \alpha_{m,j}^{(i)} \phi_{m,j} \text{ on } \mathcal{K}_m.$$

With this approximation, \mathbf{F}_s becomes

$$\begin{aligned} \int_{\Omega_s} \phi_s f_i &= \sum_m \int_{\mathcal{K}_m} \phi_s \sum_j \alpha_{m,j}^{(i)} \phi_{m,j} \\ &= \sum_m \sum_j \alpha_{m,j}^{(i)} \int_{\mathcal{K}_m} \phi_s \phi_{m,j}. \end{aligned}$$

The last integral can be computed using (26).

Since $\phi_{m,j} \Gamma_{st}$ is a polynomial function of barycentric coordinates with respect to Γ_{st} ,

$$\int_{\Gamma_{st}} \phi_{m,j_1} \Gamma_{st} \phi_{m,j_2} \Gamma_{st}$$

can be computed using the integral formulas in barycentric coordinates, facilitating the evaluation of \mathbf{B}_s and \mathbf{b}_s .

4.3.2 LEARNING COVARIANCE PARAMETERS

By far, our discussions have been made when using fixed parameters (often referred to as hyperparameters in the literature) for the covariance function $k(\cdot, \cdot)$. In this subsection, we discuss how to choose the hyperparameters. Basically, we follow the approach in Park et al. (2011), which has two options, namely choosing different hyperparameters for each local region or choosing the same hyperparameters for all local regions. When different hyperparameters are chosen for each local region, the hyperparameters are estimated by maximizing the local marginal likelihood functions. Specifically, the local hyperparameters, denoted by θ_s associated with each Ω_s , are selected such that they minimize the negative log marginal likelihood:

$$ML_s(\theta_s) := -\log p(\mathbf{y}_{s,i}; \theta_s) = \frac{n_s}{2} \log(2\pi) + \frac{1}{2} \log |\mathbf{A}_s| + \frac{1}{2} \mathbf{y}_{s,i}^T \mathbf{A}_s^{-1} \mathbf{y}_{s,i}. \quad (27)$$

where \mathbf{A}_s depends on θ_s . Note that (27) is the marginal likelihood of the standard local kriging model typically seen in geostatistics.

When we want to choose the same hyperparameters applied for all local regions, we choose the hyperparameter θ such that it minimizes

$$ML(\theta) = \sum_{s=1}^S ML_s(\theta), \quad (28)$$

where the summation of the negative log local marginal likelihoods is over all local regions. The above treatment implicitly assumes that the data from each local region are mutually independent. We used the criterion (28) for all numerical comparisons presented below.

5. Numerical Study of Patched GP and Comparison with DDM

In this section, we present the numerical performance of our patched GP method for different tuning parameters, compared to the full GP regression. We also compare our patched GP method with its precursor, the DDM (Park et al., 2011).

5.1 Data Sets and Evaluation Criteria

We considered four data sets: one synthetic data set in 1-d, one synthetic data set in 2-d, and three real spatial data sets both in 2-d. The two synthetic data sets were generated by the R package `RandomField`. The first data set in 1-d (hereafter denoted by `synthetic-1d`) consists of 6,000 noisy observations from a zero-mean Gaussian process with an exponential covariance function of scale one and variance 10,

$$y_i = f(x_i) + \epsilon_i \quad \text{for } i = 1, \dots, 6000,$$

where $x_i \sim \text{Uniform}(0, 10)$ and $\epsilon_i \sim \mathcal{N}(0, 1)$ were independently sampled, and the Gaussian process realization $f(x_i)$ was simulated by the R package `RandomField`. The two (hereafter denoted by `synthetic-2d`) consists of 8,000 noisy observations from a zero-mean Gaussian process with an exponential covariance function of scale one and variance 10,

$$y_i = f(x_i) + \epsilon_i \quad \text{for } i = 1, \dots, 8000,$$

where $x_i \sim \text{Uniform}([0, 6] \times [0, 6])$ and $\epsilon_i \sim \mathcal{N}(0, 1)$ were independently sampled, and the Gaussian process realization $f(x_i)$ was simulated by the R package `RandomField`. The two synthetic data sets were used to show how our proposed method performs, compared to the full GP regression.

The first real data set, TCO, contains data collected by NIMBUS-7/TOMS satellite to measure the total column of ozone over the globe on Oct 1 1988. This set consists of 48,331 measurements. The second real data set, TCO-L2, also contains the total column of ozone measured by the same satellite on the same date at much more locations (182,591 locations). The third real data set, ICETHICK, is the ice thickness profile for a portion of the western Antarctic ice sheet, which is available at <http://nsidc.org/>. The data set has 32,481 measurements. As shown in Figure 3, the ICETHICK data set has some sparse regions with very few training points, while the TCO data set has a very dense distribution of the training points; TCO-L2 data set has even denser distribution.

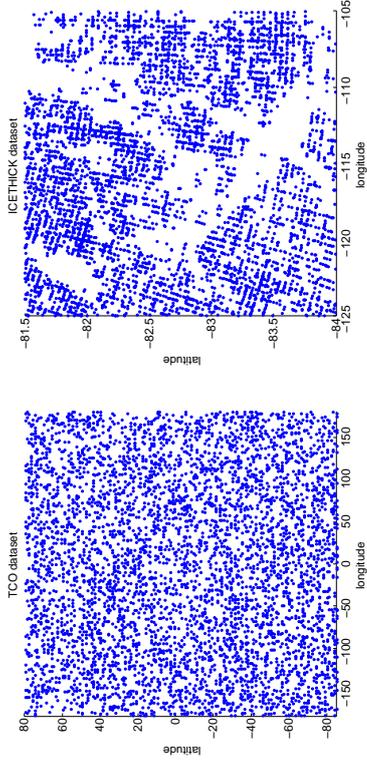

Figure 3: Spatial distribution of the measurements for two real data sets. A dot represent one measurement.

Using the three real spatial data sets, we can compare the computation time and prediction accuracy of the patched GP with other methods. We randomly split each data set into a training set containing 90% of the total observations and a test set containing the remaining 10% of the observations. To compare the computational efficiency of methods, we measure two computation times, the training time (including the time for hyperparameter learning) and the prediction (or test) time. For comparison of accuracy, we use two measures on the set of the test data, denoted as $\{(x_t, y_t); t = 1, \dots, T\}$, where T is the size of the test set. The first measure is the mean squared error (MSE)

$$\text{MSE} = \frac{1}{T} \sum_{t=1}^T (y_t - \mu_t)^2, \quad (29)$$

which measures the accuracy of the mean prediction μ_t at location x_t . The second one is the negative log predictive density (NLPD)

$$\text{NLPD} = \frac{1}{T} \sum_{t=1}^T \left[\frac{(y_t - \mu_t)^2}{2\sigma_t^2} + \frac{1}{2} \log(2\pi\sigma_t^2) \right], \quad (30)$$

which considers the accuracy of the predictive variance σ_t as well as the mean prediction μ_t . These two criteria were used broadly in the GP regression literature. A smaller value of MSE or NLPD indicates a better performance.

When applying the patched GP, one issue is how to partition the whole domain into local regions, also known as *meshing* in the finite element analysis literature (Ern and Guermond, 2004). The patched GP works with any shapes of meshing. For this paper, we used a uniform triangular mesh, where each local region is a triangular shaped region of the same size. The implementation of the meshing was performed using the `DistMesh` MATLAB

software (Persson and Strang, 2004). We used the localized estimation presented in Section 4.2.1 for boundary value estimation, and the hyperparameters of a covariance function was obtained by minimizing (28) and was applied for all local regions. All numerical studies were performed on a computer with Intel Xeon Processor W3520 and 6GB memory.

5.2 Performance of Patched GP with Different Tuning Parameters

The patched GP has two tuning parameters, number of local regions S and mesh size h in finite element approximation. If the number of local regions (S) is one (i.e. there is no split to local regions), the patched GP should converge to a full GP as the mesh size of the patched GP's finite element approximation goes to zero. In this section we illustrate how the patched GP works for $S > 1$ and different mesh sizes using the data sets described in the previous section.

For `synthetic-1d`, we uniformly partitioned the domain $[0, 10]$ into S local regions of equal size where S varies over $\{2, 4, 6, 8, 10\}$. The number of meshes per local region is denoted by M , and it is related to mesh size h , which is the length of an interval mesh. We randomly split 6,000 observations in `synthetic-1d` into a training data set of 4,500 observations and a test data set of 1,500 observations. For each S and h , we used the training data set to learn the patched GP and a full GP, and compared the mean squared difference of the patched GP and a full GP over the test data set. Figure 4-(a) shows the mean squared difference versus S and h . Regardless of S , the difference converges to almost zero (about e^{-6}) as h goes to zero, which implies that the mean prediction of the patched GP becomes very close to that of a full GP even with a large S ; this can be qualitatively seen in Figure 4-(b), -(c) and -(d). In other words, the performance of the patched GP does not vary much with the choice of S although the method with a larger S typically converges faster.

For `synthetic-2d`, we uniformly partitioned the domain into S local regions of equal size where S varies over $\{8, 47, 32, 17, 10, 4\}$. The number of meshes per local region is denoted by M , and it is related to mesh size h , which is the side length of a triangular mesh for `synthetic-2d`. We randomly split 8,000 observations in `synthetic-2d` into a training data set of size 6,500 and a test data set of size 1,500. For each S and h , we used the training data set to learn the patched GP and a full GP, and compared the mean squared difference between the patched GP and the full GP over the test data set. Figure 5 shows the mean squared difference versus S and h . Similar to the 1-d case, the performance of patched GP does not vary much with different S values for the two synthetic data sets.

We also evaluated the performance of the patched GP on the real data sets `TCO` and `ICETHICK` for different values of S and M . As described in Section 5.1, 90% of each data set was randomly chosen and used as a training data set, and the remaining 10% was used for computing the MSE. Figure 6 summarizes the results. The performance of the patched GP did not vary much for different S . If S is large, the overall computation complexity decreases significantly as M decreases. Therefore, in general, a larger S is preferred.

5.3 Comparison with DDM

Our proposed patched GP method is the direct enhancement of DDM. In this section, we compare the numerical performance of DDM and patched GP.

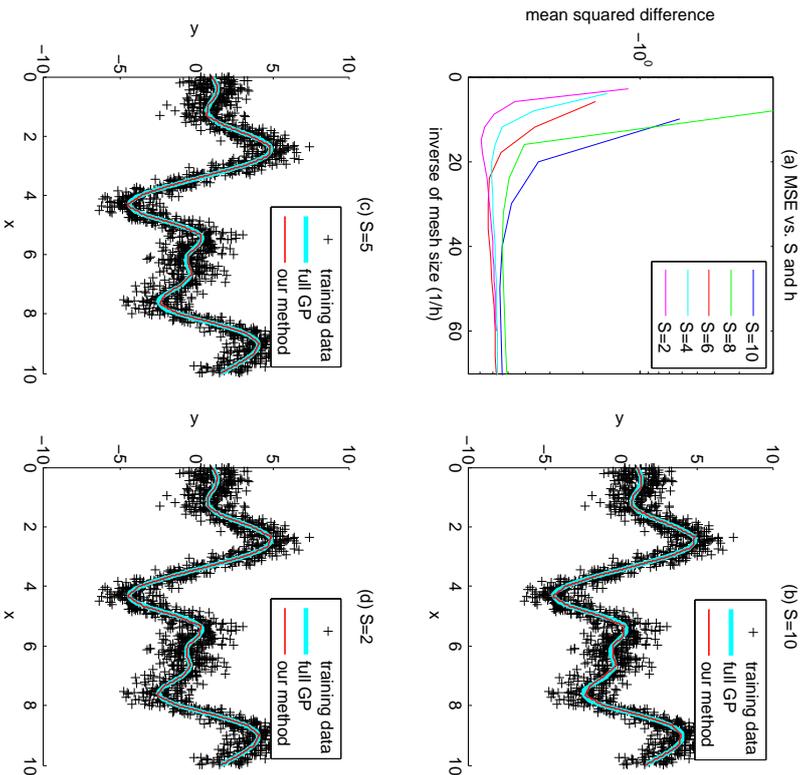

Figure 4: Mean squared difference of the patched GP and a full GP over the test data set for `synthetic-1d`: (a) shows the mean squared differences for different S and h parameter values, and (b)-(d) illustrate the mean predictions of the patched GP and a full GP for different S 's with fixed $1/h = 3$.

5.3.1 OVERALL PERFORMANCE

We used three real data sets in 2-d to compare the MSEs and NLPDs of patched GP and DDM versus the total computation time (training and test time), which includes the time for hyperparameter learning, model learning, and prediction.

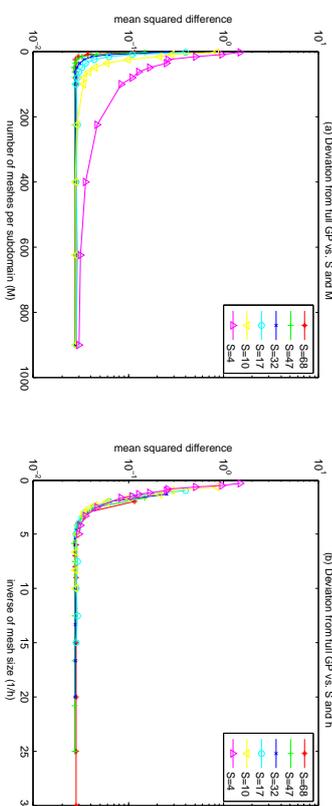

Figure 5: Mean squared difference of the patched GP and a full GP versus S and h for `synthetic-2d`

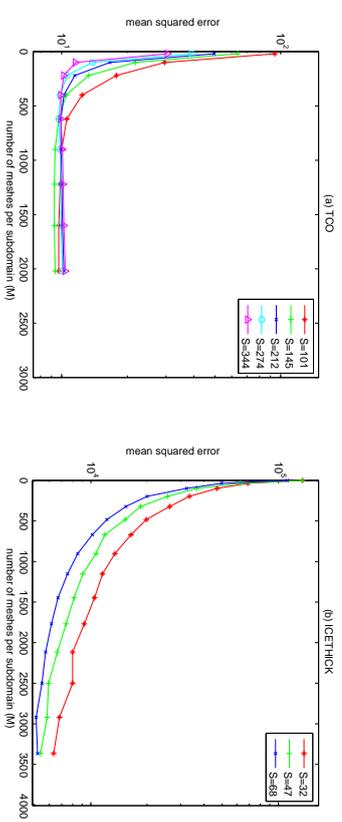

Figure 6: MSE of the patched GP versus S and h for TCO and ICETHICK.

For both methods, we fixed S , $S = 145$ for TCO, $S = 623$ for TCO.L2, and $S = 47$ for ICETHICK, because the performance did not vary much with the choice of S . We applied the squared exponential covariance function and the same covariance hyperparameter learning method for both DDM and patched GP, which is described in Park et al. (2011, Section 5). In the hyperparameter learning, we used a subset of the training data. The fractions of the training data set used for the hyperparameter learning varied over $\{0.3, 0.5, 0.8, 1.0\}$. As the fraction increases, we expect the training time increases, and the accuracy of the hyperparameter estimation and the final prediction improves. For patched GP, the number of meshes per local region for the finite element approximation (h) varied from 5 to 30 with step size 5. As seen in Section 5.2, the increase of h implies the increase of the

overall prediction accuracy and the total computation time. For DDM, we varied the number of degree of freedoms on a local region boundary from 5 to 30 with step size 5. For each experimental setting, we performed 20 replicated experiments with new random splits of training and test data sets. We randomly split each data set into a training set containing 90% of the total observations and a test set containing the remaining 10% of the observations. The MSEs, NLPDs and the total computation times were averaged to reduce the variation caused by random splits.

Figure 7 shows the MSE and NLPD versus the total computation time for both DDM and patched GP. For shorter computation time, DDM performed better in terms of MSE but patched GP obtained lower MSEs with longer computation time. In terms of NLPD, the DDM was better for TCO and TCO.L2. The NLPD is roughly the squared bias of the predictive mean divided by the predictive variance. Since the patched GP is better than the DDM in MSE, the better NLPD performance of the DDM can be attributed to difference in variance estimation. For TCO and TCO.L2, the DDM's variance estimation is sufficiently large to cover most observations. However, the DDM's variance estimation is sometimes too small, being negative. For example, the DDM produced the negative predictive variances for ICETHICK, so the resulting NLPDs are imaginary numbers. The issue with DDM regarding possible negative predictive variances has been reported in Pourhabib et al. (2014). The same problem occurred in this numerical example.

5.3.2 COMPARISON IN BOUNDARY VALUE ESTIMATION

We compared DDM and patched GP for boundary value estimation. For this comparison, we used the localized estimation approach described in Section 4.2.1 with $N_B = 50$. The comparison was primarily focused on (1) how the boundary estimation of each method on a boundary location is close to the mean prediction of a full GP regression on the same location, and (2) how the boundary estimations of two neighboring local regions on a boundary point are close to each other. We fixed $S = 16$ and tried different mesh sizes h for patched GP and different numbers of the control points placed on each boundary (p) for DDM, which are directly relevant to the performance of boundary estimation. The h varied over one fifth of a local region size through one thirtieth of a local region size, while p comparably varied over five through thirty.

We used the whole `synthetic-2d` data set as a training data set to train both of the methods, and 1,881 test locations were chosen uniformly from local region boundaries. For each test location, we obtained the mean prediction of a full GP regression. The squared differences of the mean prediction of DDM or patched GP to that of a full GP at the test locations are averaged to obtain the mean squared difference. This difference versus h or p is plotted in Figure 8-(a). As h decreases, the boundary estimation of patched GP at the test locations converges to the mean prediction of a full GP regression at the same locations, while the boundary estimation of DDM keeps deviating from a full GP result.

We also compared how consistent the mean predictions from two neighboring local regions at their shared boundary are. We simply took the two mean predictions from two neighboring local regions at some of the 1,881 test locations on their shared boundary. The squared differences were taken and averaged over all shared boundaries. The mean squared differences versus h or p are plotted in Figure 8-(b). The mean squared differences for

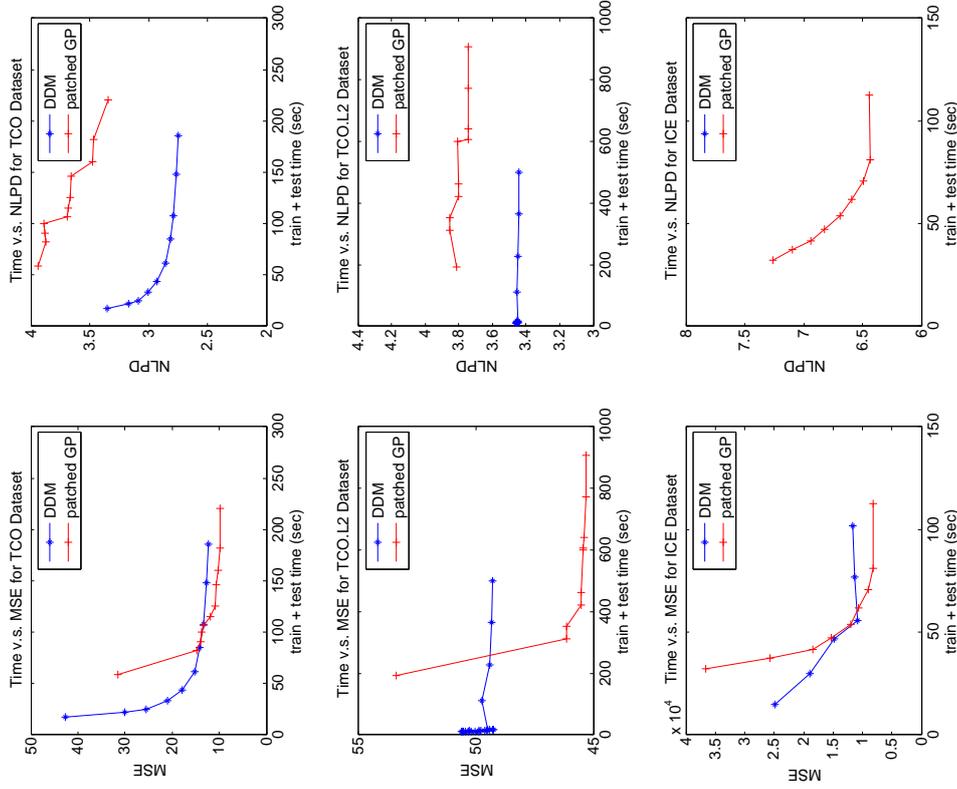

Figure 7: Prediction accuracy versus total computation time. For ICETHICK (ICE) data set, the NLPDs of DDM are imaginary numbers since the predictive variance estimates were all negative.

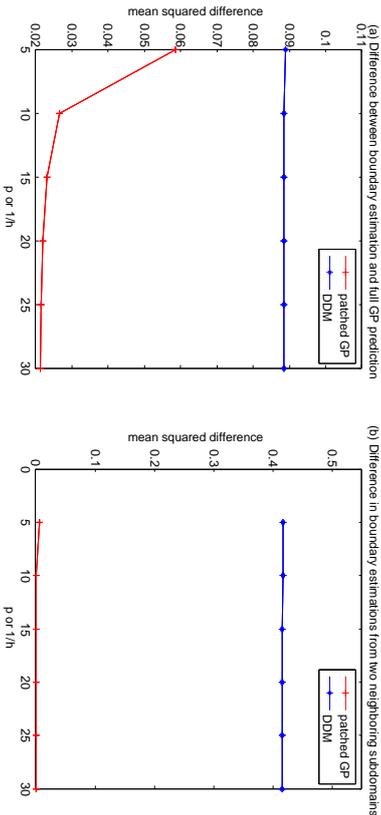

Figure 8: Accuracy of Boundary Estimation.

patched GP are almost zero, while those for DDM are significantly non-zero relative to those of patched GP.

6. Numerical Comparison with Other State-of-The-Art methods

This section compares patched GP with other state-of-the-art methods. Section 6.1 contains the comparison to several localized approaches for GP regression, while Section 6.2 contains the comparison to the Gaussian Markov random field approach to the GP regression (Lindgren et al., 2011).

6.1 Comparison with Other Local GP Methods

In this section, we compare patched GP with other localized approaches for GP regression, including BCM (Tresp, 2000), PIC (Snelson and Ghahramani, 2007), and RBCM (Deisenroth and Ng, 2015); we used the author’s implementation of BCM and implemented RBCM and PIC with matlab by ourselves. We used three real data sets TCO, TCO_L2 and ICETHICK to compare the MSEs and NLPDs of the approaches versus the total computation time, which includes the time for hyperparameter learning, model learning and prediction. We used the squared exponential covariance function and used the whole training data set to choose hyperparameters for all of the compared methods. For patched GP, we fixed $S = 145$ for TCO, $S = 623$ for TCO_L2, and $S = 47$ for ICETHICK, and the number of meshes per local region was varied from 5 to 40 with step size 5. For BCM and RBCM, we varied the number of local experts $M \in \{100, 150, 200, 250, 300, 600\}$ for TCO, $M \in \{50, 100, 150, 200, 250, 300\}$ for TCO_L2, and $M \in \{50, 100, 150, 200, 250, 300\}$ for ICETHICK. For PIC, we varied the total number of local regions $m \in \{100, 150, 200, 250, 350\}$ for TCO, $m \in \{100, 200, 300, 400, 600\}$ for TCO_L2, and $m \in \{50, 100, 150, 200\}$ for ICETHICK, and also varied the number of in-

cluding inputs ($M \in \{100, 150, 200, 250, 300, 400, 500, 600, 700\}$) for all of the data sets. We used the k-means clustering for splitting training data for both of BCM, RBCM, and PIC.

Figure 9 shows the logarithms of MSEs and NLPDs versus total computation times for the three data sets. For TCO data set, the BCM, RBCM, and patched GP obtained more accurate prediction than the PIC, and the patched GP was computationally more efficient than the BCM and RBCM. For TCO_L2 data set, the patched GP uniformly outperformed other competing methods; scaling better than BCM and achieving better MSE than the PIC. It is interesting to see that BCM is almost identically performing as the RBCM when N is so large like in TCO_L2 data set. For ICETHICK data set, the PIC and patched GP obtained more accurate prediction than the BCM and the RBCM. Please note that the training data are quite densely spread over the whole domain for TCO while the training data are sparse for some local regions in ICETHICK. The patched GP worked well for both of the cases, while the PIC worked better for the sparse case and the BCM worked better for the dense case. The RBCM has shown much better results than the BCM for the sparse case but it is not better than the patched GP and PIC. The PIC combines a global model with local models, which may help to improve the performance for the sparse case.

6.2 Comparison with GMRF

In this section, we compare patched GP with the Gaussian Markov random field approach to the GP regression (Lindgren et al., 2011, GMRF), which was reported to scale great with massive data set; we implemented the GMRF with matlab. The major checkpoints of this comparison are the scalability and prediction accuracy. We used three real data sets of different sizes, ICETHICK ($N = 32, 813$), TCO ($N = 48, 311$) and TCO_L2 ($N = 182, 591$) to compare the MSEs, NLPDs, and computation time of the approaches. In this comparison, we used the exponential covariance function, since the GMRF does not work with the squared exponential covariance function used for the other comparissons; at least, the construction of the precision matrix for Gaussian Markov random field is not straightforward. The GMRF does not have any tuning parameters, and the hyperparameter learning of the GMRF was performed using 5% of the training data; the MSE performance did not change much as the percentage increases, so we chose the smallest percentage to obtain the smallest computation time. For patched GP, we presented the results with the combinations of tuning parameters that obtain the best RMSE and the worst RMSE. To be specific, we fixed $S = 145$ for TCO, $S = 47$ for ICETHICK, and $S = 623$ for TCO_L2, while the number of meshes per local region was varied from 5 to 40 with step size 5.

Table 1 summarizes the comparison results. The computation time of patched GP increases linearly in data size N , while the GMRF’s computation time increases in $O(N^2)$. This is not surprising because the GMRF’s computation depends on n_z , the number of nonzero elements in the precision matrix, proportionally in n_z^2 or $n_z^{3/2}$ and the n_z increases at least linearly in N . For prediction performance, the best RMSE of the patched GP was at least comparable or better than that of GMRF. The patched GP uniformly outperformed the GMRF in terms of NLPD, which means that the posterior distribution of the patched GP was better fitted to test data sets.

Datasets	patched GP (best, worst)			GMRF		
	Time	RMSE	NLPD	Time	RMSE	NLPD
TCO	(250.4, 48.4)	(2.85, 5.75)	(3.20, 3.91)	651.4	2.78	5.01
TCO.L2	(807.4, 192.2)	(6.74, 7.31)	(3.70, 3.82)	5702.7	9.24	5.26
ICETHICK	(212.1, 31.2)	(89.30, 199.33)	(6.12, 6.80)	385.0	89.80	7.08

Table 1: Performance comparison of the patched GP with GMRF: the time unit used is second.

7. Conclusion

We developed a method for solving a Gaussian process regression with constraints on a domain boundary and also developed a solution approach based on a finite element method. The method is then applied to local GP regressions as a building block to develop the patched GP method as a computationally efficient solver of a large-scale Gaussian process regression or spatial kriging problem. The patched GP solves two issues of the simple local GP approaches, namely the inaccuracy and inconsistency of prediction on the boundaries of neighboring local regions. Comparing with its precursor DDM, the patched GP has an improved way of considering the constraints related to the boundary regions. Both methods reformulate the GP regression as an optimization problem, the patched GP method improves DDM by rewriting the optimization problem in a function space and using the finite element methods to solve the required integrals arising from the solution of the minimization problem. The patched GP method is mathematically more elegant and its competitiveness to existing methods is demonstrated through numerical studies.

Huang was supported by grants from the National Science Foundation (DMS-1208952) and the Air Force Office of Scientific Research (FA9550-13-1-0075).

Appendix A. Proof of Proposition 1

Note that $[L^2(\Omega)]^N$ is a Hilbert space with the following inner product

$$(\mathbf{u}, \mathbf{v}) = \int_{\Omega} \mathbf{u}' \mathbf{v}.$$

We define a bi-linear form on $[L^2(\Omega)]^N$ by $a : [L^2(\Omega)]^N \times [L^2(\Omega)]^N \rightarrow \mathbb{R}$,

$$a(\mathbf{u}, \mathbf{v}) = (\mathbf{A}\mathbf{u}, \mathbf{v}) = \int_{\Omega} \mathbf{u}' \mathbf{A} \mathbf{v} \quad \text{for } \mathbf{u}, \mathbf{v} \in [L^2(\Omega)]^N,$$

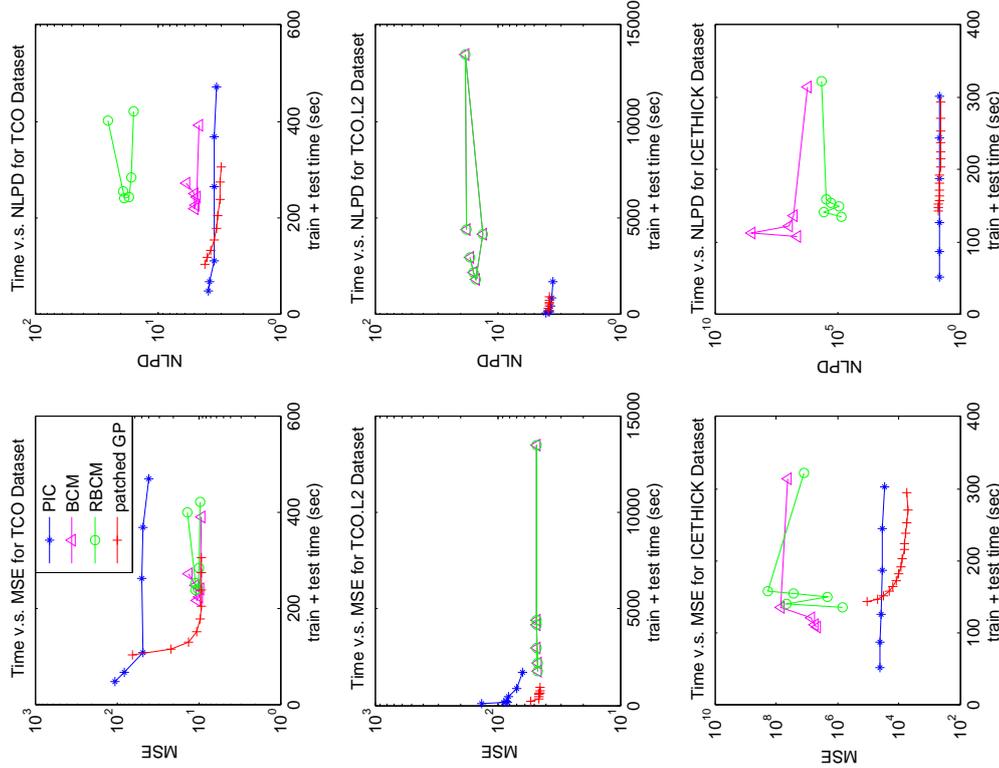

Figure 9: Prediction accuracy versus total computation time. The legend in the upper left panel applies to all other panels.

a linear functional $c : [L^2(\Omega)]^N \rightarrow \mathbb{R}$ as

$$c(\mathbf{u}) = \int_{\Omega} \mathbf{f}^T \mathbf{u},$$

and define $J(\mathbf{u}) = \frac{1}{2}a(\mathbf{u}, \mathbf{u}) - c(\mathbf{u})$. Since \mathbf{A} is a $N \times N$ (real) positive definite matrix, the bilinear form $a(\mathbf{u}, \mathbf{v})$ is symmetric and positive. Let α be the smallest eigenvalue of \mathbf{A} . We have that

$$a(\mathbf{u}, \mathbf{u}) \geq \alpha \|\mathbf{u}\|^2, \quad \forall \mathbf{u} \in [L^2(\Omega)]^N.$$

Therefore, the bilinear form a is coercive. It follows from Ern and Guermond (2004, Proposition 2.4) that, \mathbf{u} satisfies $a(\mathbf{u}, \mathbf{v}) - c(\mathbf{v}) = 0$ for every $\mathbf{v} \in [L^2(\Omega)]^N$ if and only if it minimizes $J(\mathbf{u})$ over $\mathbf{u} \in [L^2(\Omega)]^N$. Note that the coercivity of the bilinear form a can be interpreted as a strong convexity property of the functional $J(\mathbf{u})$, which makes the problem have a unique optimal solution (Ern and Guermond, 2004, Lemma 2.2). ■

Appendix B. Proof of Proposition 2

We have already proven that $a(\mathbf{u}, \mathbf{v}) = \int_{\Omega} \mathbf{u}^T \mathbf{A} \mathbf{v}$ is coercive, symmetric and positive for $\mathbf{u}, \mathbf{v} \in [L^2(\Omega)]^N$ in the proof of Proposition 1. The same result holds for $\mathbf{u}, \mathbf{v} \in H_0$ because $H_0 \subset [L^2(\Omega)]^N$. Since H_0 is a Hilbert space, solving the minimization problem is equivalent to solving the integral equation (8) by Ern and Guermond (2004, Proposition 2.4). ■

Abstract

bandicoot is an open-source Python toolbox to extract more than 1442 features from standard mobile phone metadata. bandicoot makes it easy for machine learning researchers and practitioners to load mobile phone data, to analyze and visualize them, and to extract robust features which can be used for various classification and clustering tasks. Emphasis is put on ease of use, consistency, and documentation. bandicoot has no dependencies and is distributed under MIT license.

Keywords: Python, feature engineering, mobile phone metadata, CDR, visualization

1. Introduction

The metadata generated at large-scale by mobile phones and collected by every carrier around the world have the potential to fundamentally transform the way we fight diseases and design transportation systems. Scientists have compared the recent availability of these large-scale behavioral data sets to the invention of the microscope (Giles, 2012) and their business value is considerable (Kaye, 2015). In machine learning, mobile phone metadata have been used to predict people’s gender (Sarraute et al., 2014), age (Sarraute et al., 2014), personality (de Montjoye et al., 2013), literacy rates (Sundsoy, 2016); as well as their likelihood to repay loans (Bjorktegren and Grissen, 2015), subscribe to services (Sundsoy et al., 2014), and commit crimes (Bogomolov et al., 2014). In disaster relief operations for instance, knowing the demographics of a person along with his or her mobility data is extremely valuable (Wilson et al., 2016). As most phones in low and middle income countries are prepaid (ITU, 2013), we often lack these information about the users. Being able to predict million of people’s demographic information with a small training set is therefore tremendously valuable and cost-efficient.

Despite a great potential for impact and close to 10 years of academic and industry research in using mobile phone metadata (Blondel et al., 2015), there were so far no open-source software to process and extract robust features from them. All prediction works were consequently based on a limited number of custom indicators. This has prevented research from progressing: features had to be redeveloped every time and numerous implementation

choices (e.g. reconciling data, choices of thresholds and time periods, edge cases) were lost from one paper to another. This made it hard to replicate results, quantify the impact of new methods, and transfer learnings.

bandicoot solves this problem by providing researchers and practitioners with an efficient open-source Python feature extractor for mobile phone metadata. bandicoot is a complete, easy-to-use and extensible environment: with a few lines of code, a user can load mobile phone data, extract features, and export them. bandicoot’s modular structure makes it easy for users to add new features and leverage existing pre- and post-processing functions.

2. Usage and features

bandicoot provides users with more than 1442 individual, spatial, and social network features:

Individual features (e.g. percent of nocturnal interactions, time it takes someone to answer text message, inter-event time between two phones calls) describe an individual’s phone usage and interactions with his or her contacts.

Spatial features (e.g. entropy of visited antennas, radius of gyration) describe an individual’s mobility patterns. Note that to avoid sampling biases, bandicoot groups location data per 30 min slots.

Social network (e.g. clustering coefficient, assortativity) describe an individual’s social network and compare his or her behavior with the one of their contacts.

bandicoot computes these indicators or, when they are a distribution their mean and standard deviation, on a weekly basis. It then returns the weekly mean and standard deviation to the user (see Fig. 1 (a)). The user can also compute indicators only on call/texts, weekdays/weekends, or days/nights and an extended set of weekly summary statistics (median, min, max, kurtosis, and skewness).

bandicoot also standardizes from the mobile phone research literature (Blondel et al., 2015) the definition of conversations between individuals, the conversion of directed to undirected matrices, the assortativity of attributes within ego-networks, as well as a the binning scheme to avoid sampling biases in location data.

3. Project focus

Code quality Correctness and consistency is absolutely crucial for us. The metrics implemented need to be correct and the values returned stable over time. To ensure this, we implemented functions to generate synthetic mobile phone data, regression tests, and more than 50 function-level unit tests covering 88% of the source code.

Community-driven development The choice of the Python language, as well as a specific focus on readability, helps contributors understand and modify bandicoot. We are actively building a community of users around bandicoot to foster changes and improvements in the source code, develop new features, and to report and help correct faulty behaviors. bandicoot is hosted on GitHub and has already been developed by 9 contributors over

the last three years with many others helping with bug reports, features requests, and discussions.

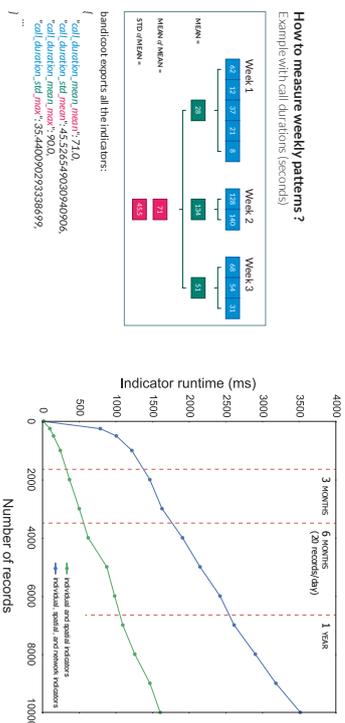

Figure 1: (a) Weekly aggregation of bandicoot's behavioral indicators. (b) bandicoot's run-time as a function of the number of records (single core) with and without network indicators

Documentation An extensive documentation has been written and is maintained. This includes an exhaustive description of the input and output of functions, a quick start guide, and a demonstration notebook. A specific part of the documentation is written to help users test and contribute new features.

Easy-to-install and without dependencies bandicoot runs on Python 2 and 3; we support (and test bandicoot with) GNU/Linux, Mac OS, and Windows. bandicoot is meant to (and already is) used in highly secured and heterogeneous telco environments where packages have to be approved and verified. To make its use (incl. in Hadoop environments) and installation easier, we developed bandicoot to be free of any dependencies such as pandas or compilers.

Detecting data issues Numerous data issues can happen in mobile phone data sets: incorrect locations, missing incoming records, duplicates, etc. We have built 38 reporting variables that are automatically added when exporting features. These include details about the underlying data (start and end date, number of records, percentage of antenna missing location information, etc.) and about the data processing (bandicoot version number, type of aggregation used, records that have been removed and why, whether a home location has been detected, etc.).

4. Visualization

bandicoot includes an interactive tool to visualize the data of a specific user. The visualization allows researchers to inspect the data, detect issues, and spot potentially important patterns. Fig. 2 shows the visualization tool, with options to display only specific weeks

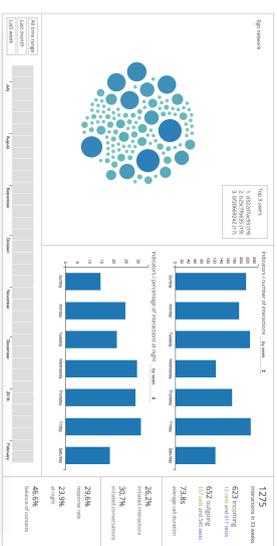

Figure 2: bandicoot visualization tool for an individual's data

and to plot indicators (or their weekly mean/sum) over the time period considered. It can be generated and served on-the-fly over HTTP, or exported to disk and shared.

5. Performances

While our priority developing bandicoot is to produce correct and verifiable code that can be easily extended, a certain number of implementation choices and optimizations were made to ensure that a standard large-scale dataset can be processed overnight. For instance, bandicoot caches groups of records by week, weekend, call or text to limit both the computing time and the memory footprint. All together these optimizations have sped up computation by a factor 3 compared to a naive implementation.

We tested bandicoot on a computer with an Intel i7 CPU (2.6GHz) and 8GB of memory for users with an average of 20 records per days over 3 months. It takes on average 250ms to compute all 1442 behavioral and mobility indicators using the standard Python Interpreter, CPython, and 160ms using pypy, a fast just-in-time compiler. For all indicators, including network features, the total time is 1.11s using CPython (740ms with pypy). Network indicators take significantly more time as data for all the neighbors of one node have to be loaded and their behavioral indicators computed. All indicators run in linear time with the number of records (Fig. 1(b)) and a standard large-scale data set of one million mobile phone users is processed in less than 9 hours (resp. 39h for the network indicators) using the multiprocessing code we provide.

6. Conclusion

The application of machine learning algorithms to mobile phone metadata has a great potential for good and businesses. Until now, there were no toolbox to efficiently process and extract robust features from them. This was a major issue for both researchers and practitioners. bandicoot implements a full data pipeline for mobile phone data including more than 1442 features. It has been used in research papers as well as by carriers (e.g. Orange, Telenor) and international organizations (e.g. WFP).

Abstract

In this paper, we introduce a novel approach, called Input Output Kernel Regression (IOKR), for learning mappings between structured inputs and structured outputs. The approach belongs to the family of Output Kernel Regression methods devoted to regression in feature space endowed with some output kernel. In order to take into account structure in input data and benefit from kernels in the input space as well, we use the Reproducing Kernel Hilbert Space theory for vector-valued functions. We first recall the ridge solution for supervised learning and then study the regularized hinge loss-based solution used in Maximum Margin Regression. Both models are also developed in the context of semi-supervised setting. In addition we derive an extension of Generalized Cross Validation for model selection in the case of the least-square model. Finally we show the versatility of the IOKR framework on two different problems: link prediction seen as a structured output problem and multi-task regression seen as a multiple and interdependent output problem. Eventually, we present a set of detailed numerical results that shows the relevance of the method on these two tasks.

Keywords: structured output prediction, output kernel regression, vector-valued RKHS, operator-valued kernel, semi-supervised learning

1. Introduction

Many real world applications involve objects with an explicit or implicit discrete structure. Texts, images and videos in document processing and retrieval as well as genes and proteins in computational biology are all examples of implicit structured data that we may want to use as inputs or outputs in a prediction system. Besides these structured objects, structured output prediction can also concern multiple outputs linked by some relationship that is relevant to take into account. Surprisingly, although a lot of attention has been paid to learning from structured inputs for now two decades, this problem, often referred as *structured output learning*, has emerged relatively recently as a field of interest in statistical learning. In the literature, structured output prediction has been addressed from two main angles. A first angle consists in *discriminative learning algorithms* that provide predictions by maximizing a scoring function over the output space. Conditional Random Fields (Lafferty et al., 2001) and their extension to kernels (Lafferty et al., 2004) were first proposed for discriminative modeling of graph-structured data and sequence labeling. Other discriminative learning algorithms based on maximum margin such as structured SVM (Tsochantaridis et al., 2004, 2005), Maximum Margin Markov Networks (M^3N) (Taskar et al., 2004) or Maximum Margin Regression (Szedmak et al., 2005) have then been developed and thoroughly studied. A common approach to those methods consists in defining a linear scoring function based on the image of an input-output pair by a joint feature map. Both methods, either based on Conditional Random Fields or maximum-margin techniques, are costly to train and generally assume that the output set \mathcal{Y} is discrete. Keeping the idea of a joint feature map over inputs and outputs, a generative method called Joint Kernel Support Estimation has been recently proposed (Lampert and Blaschko, 2009). In this approach, a one-class SVM is used to learn the support of the joint-probability density $p(x, y)$. More recently, another angle to structured output prediction, that we called *Output Kernel Regression (OKR)*, has emerged around the idea of using the kernel trick in the output space and making predictions in a feature space associated to the output kernel. As a first example, the seminal work of Kernel Dependency Estimation (KDE) was based on the definition of an input kernel as well as an output kernel. After a first version using kernel PCA to define a finite-dimensional output feature space (Weston et al., 2003), a more general KDE framework consisting in learning a linear function from the input feature space to the output feature space was proposed by Cortes et al. (2005). In this setting, predictions in the original output space are retrieved by solving a pre-image problem. Interestingly, the idea of Output Kernel Regression can be implemented without defining an input kernel as it is shown with Output Kernel Tree-based methods (Geurts et al., 2006, 2007a,b). In these approaches, a regression tree whose outputs are linear combinations of the training outputs in the output feature space is built using the kernel trick in the output space: the loss function which is locally minimized during the construction only involves inner products between training outputs. These methods are not limited to discrete output sets and they do not require expensive computations to make a prediction nor to train the model. Combined in ensembles such as random forests and boosting, they exhibit excellent performances. However these tree-based approaches suffer from two drawbacks: trees do not take into account structured input data except by using a flat description of them and the associated (greedy) building algorithm cannot be easily extended to semi-supervised learning.

In this work, we therefore propose to extend the methodology of Output Kernel Regression to another large family of nonparametric regression tools that allows to tackle structured data in the input space as well as in the output space. Moreover we will show that this new family of tools is useful in a semi-supervised context. Called Input Output Kernel Regression, this novel family for structured output prediction from structured inputs relies on Reproducing Kernel Hilbert Spaces (RKHS) for vector-valued functions with the following specification: the output vector belongs to some output feature space associated to a chosen output kernel, as introduced in the works of Brouard et al. (2011) and Brouard (2013). Let us recall that in the case of scalar-valued functions, the RKHS theory offers a flexible framework for penalized regression as witnessed by the abundant literature on the subject (Wahba, 1990; Pearce and Wand, 2006). A penalized regression problem is seen as a minimization problem in a functional space built on an input scalar-valued kernel. Depending the nature of the prediction problem, appropriate penalties can be defined and representer theorem can be proven, facilitating the minimization problem to be further solved. In the RKHS theory, regularization constraint on the geometry of the probability distribution of labeled and unlabeled data can also be added to perform semi-supervised regression (Belkin et al., 2006). When functions are vector-valued, the adequate RKHS theory makes use of operator-valued kernels (Pedrick, 1957; Senkane and Tempelman, 1973; Mitchell and Pontil, 2005). Operator-valued kernels have already been proposed to solve problems of multi-task regression (Evgeniou et al., 2005; Baldassarre et al., 2012), structured classification (Dinuzzo et al., 2011), vector autoregression (Lim et al., 2013) as well as functional regression (Kadri et al., 2010). The originality of this work is to consider that the output space is a feature space associated to a chosen output kernel. This new approach not only enhances setting of pattern recognition tasks by requiring to pay attention on both input and output sets but also opens new perspectives in machine learning. It encompasses in a unique framework kernel-based regression tools devoted to structured inputs as well as structured outputs.

1.1 Related Works

In Brouard et al. (2011), the vector-valued RKHS theory was used to address the output kernel regression problem in the semi-supervised setting. This approach was applied to the link prediction problem. By working in the framework of RKHS theory for vector-valued functions, we extended the manifold regularization framework introduced by Belkin et al. (2006) to functions with values in a Hilbert space. We have also shown that the first step of KDE (Cortes et al., 2005) is a special case of IOKR using a particular operator-valued kernel.

Kadri et al. (2013) studied a formulation of KDE using operator-valued kernels. The first step of this approach is identical to the IOKR framework developed in Brouard et al. (2011) and Brouard (2013). The second step consists in extending the pre-image step of KDE using the vector-valued RKHS theory. They also proposed two covariance-based operator-valued kernels and showed that using these operator-valued kernels allow to express the pre-image problem using only input and output Gram matrices.

In parallel of Brouard et al. (2011), Minh and Shindhwani (2011) generalized the manifold regularization framework proposed by Belkin et al. (2006) for semi-supervised learning to vector-valued functions.

1.2 Contributions

We introduce Input Output Kernel Regression (IOKR), a novel class of penalized regression problems based on the definition of an output scalar-valued kernel and an input operator-valued kernel. This article is an extended version of Brouard et al. (2011), that addresses more generally the problem of structured output prediction. In this work, we present several novel contributions regarding the RKHS theory for functions with values in a Hilbert space. We present the representer theorem for vector-valued functions in the semi-supervised setting. Based on this representer theorem, we study two particular models obtained using two different loss functions: the *IOKR-ridge* model introduced in Brouard et al. (2011) and a new model called *IOKR-margin*. This model extends the Maximum Margin Regression (MMR) framework introduced by Seidman et al. (2005) to operator-valued kernels and to the semi-supervised setting. In this paper, we also put the reformulation of Kernel Dependency Estimation proposed by Cortes et al. (2005) into perspective in the Output Kernel Regression framework. We present the solutions corresponding to decomposable kernels. In the case of the least-squared loss function, we describe a new tool for model selection, which was first introduced in Brouard (2013). The selection of the hyperparameters is done by estimating the averaged error obtained with leave-one-out cross-validation as a closed-form solution. We show the versatility of the IOKR framework on two different problems: link prediction and multi-task regression. Finally, we present numerical results obtained with IOKR on these two tasks.

1.3 Organization of the Paper

This paper is organized as follows. In Section 2, we introduce the Input Output Kernel Regression approach and show how it can be used to solve structured output prediction problems. In Section 3 we describe the RKHS theory devoted to vector-valued function and present our contributions to this theory in the supervised and semi-supervised settings. We also present in this section models based on decomposable operator-valued kernels. We then show in Section 4 that, in the case of the least-squares loss function, the leave-one-out criterion can be estimated by a closed-form solution. In Section 5, we describe how Input Output Kernel Regression (IOKR) can be used to solve two structured prediction problems, which are link prediction and multi-task learning. In Section 6, we present the results obtained with IOKR on these two problems.

The notations used in this paper are summarized in Table 1.

2. From Output Kernel Regression to Input Output Kernel Regression

We consider the general regression task consisting in learning a mapping between an input set \mathcal{X} and an output set \mathcal{Y} . We assume that both \mathcal{X} and \mathcal{Y} are sample spaces and that $S_n = \{(x_i, y_i), i = 1 \dots n\}$ is an i.i.d. sample drawn from the joint probability law \mathcal{P} defined on $\mathcal{X} \times \mathcal{Y}$. Outputs are supposed to be structured, for example objects such as sequences,

Meaning	Symbol
number of labeled examples	ℓ
number of unlabeled examples	n
input set	\mathcal{X}
set of labeled examples	\mathcal{X}_ℓ
union of the labeled and unlabeled sets	$\mathcal{X}_{\ell+n}$
output set	\mathcal{Y}
input scalar kernel	$\kappa_x : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R}$
output scalar kernel	$\kappa_y : \mathcal{Y} \times \mathcal{Y} \rightarrow \mathbb{R}$
input feature space	\mathcal{F}_x
output feature space	\mathcal{F}_y
input feature map	$\varphi_x : \mathcal{X} \rightarrow \mathcal{F}_x$
output feature map	$\varphi_y : \mathcal{Y} \rightarrow \mathcal{F}_y$
set of bounded operators from an Hilbert space \mathcal{F} to itself	$\mathcal{B}(\mathcal{F})$
set of bounded operators from \mathcal{F} to an Hilbert space \mathcal{G}	$\mathcal{B}(\mathcal{F}, \mathcal{G})$
operator-valued kernel	$\mathcal{K}_x : \mathcal{X} \times \mathcal{X} \rightarrow \mathcal{B}(\mathcal{F}_y)$
reproducing kernel Hilbert space of \mathcal{K}_x	$\mathcal{H}, \mathcal{HK}_x$
canonical feature map of \mathcal{K}_x	$\phi_x : \mathcal{X} \rightarrow \mathcal{B}(\mathcal{F}_y, \mathcal{H})$
gram matrix of \mathcal{K}_x on \mathcal{X}_ℓ and $\mathcal{X}_{\ell+n}$	$\mathbf{K}_{\mathcal{X}_\ell}, \mathbf{K}_{\mathcal{X}_{\ell+n}}$
gram matrix of κ_x on \mathcal{X}_ℓ and $\mathcal{X}_{\ell+n}$	$K_{\mathcal{X}_\ell}, K_{\mathcal{X}_{\ell+n}}$
gram matrix of κ_y on \mathcal{Y}_ℓ	$K_{\mathcal{Y}_\ell}$

Kronecker product	\otimes
Hadamard product (element-wise product)	\circ

Table 1: Notations used in this paper

graphs, nodes in a graph, or simply vectors of interdependent variables. It is realistic to assume that one can build a similarity $\kappa_y : \mathcal{Y} \times \mathcal{Y} \rightarrow \mathbb{R}$ between the elements of the output set \mathcal{Y} , such that κ_y takes into account the inherent structure of the elements of \mathcal{Y} and has the properties of a positive definite kernel. Then, due to the Moore-Aronszajn theorem (Aronszajn, 1950), there exists a Hilbert space \mathcal{F}_y , called a *feature space*, and a corresponding function $\varphi_y : \mathcal{Y} \rightarrow \mathcal{F}_y$, called a *feature map* such that:

$$\forall (y, y') \in \mathcal{Y} \times \mathcal{Y}, \kappa_y(y, y') = \langle \varphi_y(y), \varphi_y(y') \rangle_{\mathcal{F}_y}.$$

The regression problem between \mathcal{X} and \mathcal{Y} can be decomposed into two tasks (see Figure 1):

- the first task is to learn a function h from the set \mathcal{X} to the Hilbert space \mathcal{F}_y
- the second one is to define or learn a function f from \mathcal{F}_y to \mathcal{Y} to provide an output in the set \mathcal{Y} .

We call the first task, *Output Kernel Regression* (OKR), referring to previous works based on Output Kernel Trees (OK3) (Geurts et al., 2006, 2007a) and the second task, a

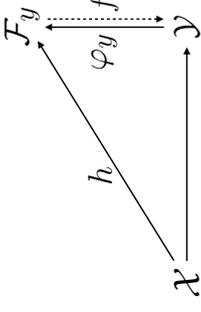

Figure 1: Schema of the Output Kernel Regression approach.

pre-image problem. In this paper, we develop a general theoretical and practical framework for the OKR task, allowing to deal with structured inputs as well as structured outputs. To illustrate our approach, we have chosen two structured output learning tasks which do not require to solve a pre-image problem. One is *multi-task regression* for which the dimension of the output feature space is finite, and the other one is *link prediction* for which prediction in the original set \mathcal{Y} is not required. However, the approach we propose can be combined with pre-image solvers now available on the shelves. The interested reader may want to refer to Honeine and Richard (2011) or Kadri et al. (2013) to benefit from existing pre-image algorithms to solve structured output learning tasks.

In this work, we propose to build a family of models and learning algorithms devoted to *Output Kernel Regression* that present two additional properties compared to OK3-based methods: namely, models are able to take into account structure in input data and can be learned within the framework of penalized regression, enjoying various penalties including smoothness penalties for semi-supervised learning. To achieve this goal, we choose to use kernels both in the input and output spaces. As the models have values in a feature space and not in \mathbb{R} , we turn to the vector-valued reproducing kernel Hilbert spaces theory (Pedrick, 1957; Senkane and Tempelman, 1973; Burbea and Masani, 1984) to provide a general framework for penalized regression of nonparametric vector-valued functions. In that theory, the values of kernels are operators on the output vectors which belong to some Hilbert space. Introduced in machine learning by the seminal work of Micchelli and Pontil (2005) to solve multi-task regression problems, operator-valued kernels (OVK) have then been studied under the angle of their universality (Caponnetto et al. (2008); Carmeli et al. (2010)) and developed in different contexts such as structured classification (Dinuazzo et al., 2011), functional regression (Kadri et al., 2010), link prediction (Brouard et al., 2011) or semi-supervised learning (Minh and Sindhvani, 2011; Brouard et al., 2011). With operator-valued kernels, models of the following form can be constructed:

$$\forall x \in \mathcal{X}, h(x) = \sum_{i=1}^n \mathcal{K}_x(x, x_i) \mathbf{c}_i, \mathbf{c}_i \in \mathcal{F}_y, x_i \in \mathcal{X}, \quad (1)$$

extending nicely the usual kernel-based models devoted to real-valued functions.

In the case of IOKR, the output Hilbert space \mathcal{F}_y is defined as a feature space related to a given output kernel. Note that there exists different pairs (feature space, feature map) associated with a given kernel κ_y . Let us take for instance the polynomial kernel

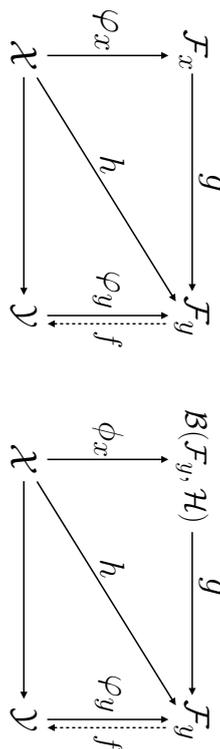

Figure 2: Diagrams describing Kernel Dependency Estimation (KDE) on the left and Input Output Kernel Regression (IOKR) on the right.

$\kappa_{y_g}(y, y') = (y^T y' + c)^p$: we can choose the finite feature space defined by the different monomies of the coordinates of a vector \mathbf{y} or we can choose the RKHS associated with the polynomial kernel. This choice will open doors to different output feature spaces \mathcal{F}_{y_g} , leading to different definitions of the input operator-valued kernel \mathcal{K}_x and thus to different learning problems. Omitting the choice of the feature map associated to \mathcal{F}_{y_g} , we therefore need to define a triplet $(\kappa_{y_g}, \mathcal{F}_{y_g}, \mathcal{K}_x)$ as a pre-requisite to solve the structured output learning task. By explicitly requiring to define an output kernel we emphasize the fact that an input operator-valued kernel cannot be defined without calling into question the output space, \mathcal{F}_{y_g} , and therefore, the output kernel κ_{y_g} . We will show in Section 6 that the same structured output prediction problem can be solved in different ways using different values for the triplet $(\kappa_{y_g}, \mathcal{F}_{y_g}, \mathcal{K}_x)$.

Interestingly, IOKR generalizes Kernel Dependency Estimation (KDE), a problem that was introduced in Weston et al. (2003) and was reformulated in a more general way by Cortes et al. (2005). If we call \mathcal{F}_x a feature space associated to a scalar input kernel $\kappa_x : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R}$ and $\varphi_x : \mathcal{X} \rightarrow \mathcal{F}_x$ a corresponding feature map, KDE uses Kernel Ridge regression to learn a function h from \mathcal{X} to \mathcal{F}_{y_g} by building a function g from \mathcal{F}_x to \mathcal{F}_{y_g} and composing it with the feature map φ_x (see Figure 2). The function h is modeled as a linear function: $h(x) = W\varphi_x(x)$, where W is a linear operator from \mathcal{F}_x to \mathcal{F}_{y_g} . The second phase consists in computing the pre-image of the obtained prediction.

In the case of IOKR, we build models of the general form introduced in Equation (1). Denoting ϕ_x the canonical feature map associated to the OVK \mathcal{K}_x , which is defined as: $\phi_x(x) = \mathcal{K}_x(\cdot, x)$, we can draw the chart depicted in Figure 2 on the right. The function ϕ_x maps inputs from \mathcal{X} to $\mathcal{B}(\mathcal{F}_{y_g}, \mathcal{H})$. Indeed the value $\phi_x(x)y = \mathcal{K}_x(\cdot, x)y$ is a function of the RKHS \mathcal{H} for all y in \mathcal{F}_{y_g} . The model h is seen as the composition of a function g from $\mathcal{B}(\mathcal{F}_{y_g}, \mathcal{H})$ to the output feature space \mathcal{F}_{y_g} with the input feature map ϕ_x .

We can therefore see on Figure 2 how IOKR extends KDE. In Brouard et al. (2011), we have shown that we retrieve the model used in KDE when considering the following operator-valued kernel:

$$\mathcal{K}_x(x, x') = \kappa_x(x, x')I, \quad (2)$$

where I is the identity operator from \mathcal{F}_{y_g} to \mathcal{F}_{y_g} . Unlike KDE, that learns independently each component of the vectors $\varphi_y(y)$, IOKR takes into account the structure existing between these components.

The next section is devoted to the RKHS theory for vector-valued functions and to our contributions to this theory in the supervised and semi-supervised settings.

3. Operator-Valued Kernel Regression

In the following, we briefly recall the main elements of the RKHS theory devoted to vector-valued functions (Senkane and Tempelman, 1973; Mitchell and Pontil, 2005) and then present our contributions to this theory.

Let \mathcal{X} be a set and \mathcal{F}_{y_g} a Hilbert space. In this section, no assumption is needed about the existence of an output kernel κ_{y_g} . We note $\tilde{\mathbf{y}}$ the vectors in \mathcal{F}_{y_g} . Given two Hilbert spaces \mathcal{F} and \mathcal{G} , we note $\mathcal{B}(\mathcal{F}, \mathcal{G})$ the set of bounded operators from \mathcal{F} to \mathcal{G} and $\mathcal{B}(\mathcal{F})$ the set of bounded operators from \mathcal{F} to itself. Given an operator A , A^* denotes the adjoint of A .

Definition 1 *An operator-valued kernel on $\mathcal{X} \times \mathcal{X}$ is a function $\mathcal{K}_x : \mathcal{X} \times \mathcal{X} \rightarrow \mathcal{B}(\mathcal{F}_{y_g})$ that verifies the two following conditions:*

- $\forall (x, x') \in \mathcal{X} \times \mathcal{X}, \mathcal{K}_x(x, x') = \mathcal{K}_x(x', x)^*$,
- $\forall m \in \mathbb{N}, \forall \mathcal{S}_m = \{(x_i, \tilde{\mathbf{y}}_i)\}_{i=1}^m \subseteq \mathcal{X} \times \mathcal{F}_{y_g}, \sum_{i,j=1}^m \langle \tilde{\mathbf{y}}_i, \mathcal{K}_x(x_i, x_j)\tilde{\mathbf{y}}_j \rangle_{\mathcal{F}_{y_g}} \geq 0$.

The following theorem shows that given any operator-valued kernel, it is possible to build a reproducing kernel Hilbert space associated to this kernel.

Theorem 2 (Senkane and Tempelman (1973); Micchelli and Pontil (2005))

Given an operator-valued kernel $\mathcal{K}_x : \mathcal{X} \times \mathcal{X} \rightarrow \mathcal{B}(\mathcal{F}_{y_g})$, there is a unique Hilbert space $\mathcal{H}_{\mathcal{K}_x}$ of functions $h : \mathcal{X} \rightarrow \mathcal{F}_{y_g}$ which satisfies the following reproducing property:

$$\forall h \in \mathcal{H}_{\mathcal{K}_x}, \forall x \in \mathcal{X}, h(x) = \mathcal{K}_x(x, \cdot)h,$$

where $\mathcal{K}_x(x, \cdot)$ is an operator in $\mathcal{B}(\mathcal{H}_{\mathcal{K}_x}, \mathcal{F}_{y_g})$.

As a consequence, $\forall x \in \mathcal{X}, \forall \tilde{\mathbf{y}} \in \mathcal{F}_{y_g}, \forall h \in \mathcal{H}_{\mathcal{K}_x}, \langle \mathcal{K}_x(\cdot, x)\tilde{\mathbf{y}}, h \rangle_{\mathcal{H}_{\mathcal{K}_x}} = \langle \tilde{\mathbf{y}}, h(x) \rangle_{\mathcal{F}_{y_g}}$.

The Hilbert space $\mathcal{H}_{\mathcal{K}_x}$ is called the reproducing kernel Hilbert space associated to the kernel \mathcal{K}_x . This RKHS can be built by taking the closure of $\text{span}\{\mathcal{K}_x(\cdot, x)\alpha \mid x \in \mathcal{X}, \alpha \in \mathcal{F}_{y_g}\}$. The scalar product on $\mathcal{H}_{\mathcal{K}_x}$ between two functions $f = \sum_{i=1}^n \mathcal{K}_x(\cdot, x_i)\alpha_i$ and $g = \sum_{j=1}^m \mathcal{K}_x(\cdot, t_j)\beta_j, x_i, t_j \in \mathcal{X}, \alpha_i, \beta_j \in \mathcal{F}_{y_g}$, is defined as:

$$\langle f, g \rangle_{\mathcal{H}_{\mathcal{K}_x}} = \sum_{i=1}^n \sum_{j=1}^m \langle \alpha_i, \mathcal{K}_x(x_i, t_j)\beta_j \rangle_{\mathcal{F}_{y_g}}.$$

The corresponding norm $\|\cdot\|_{\mathcal{H}_{\mathcal{K}_x}}$ is defined by $\|f\|_{\mathcal{H}_{\mathcal{K}_x}}^2 = \langle f, f \rangle_{\mathcal{H}_{\mathcal{K}_x}}$. For sake of simplicity we replace the notation $\mathcal{H}_{\mathcal{K}_x}$ by \mathcal{H} in the rest of the paper.

As for scalar-valued functions, one of the most appealing feature of RKHS is to provide a theoretical framework for regularization with the representer theorems.

3.1 Regularization in Vector-Valued RKHS

Based on the RKHS theory for vector-valued functions, Micchelli and Pontil (2005) have proved a representer theorem for convex loss functions in the supervised case.

We note $S_\ell = \{(x_i, \tilde{\mathbf{y}}_i)\}_{i=1}^\ell \subseteq \mathcal{X} \times \mathcal{F}_y$ the set of labeled examples and \mathcal{H} the RKHS with reproducing kernel $\mathcal{K}_x : \mathcal{X} \times \mathcal{X} \rightarrow \mathcal{B}(\mathcal{F}_y)$.

Theorem 3 (Micchelli and Pontil (2005)) *Let \mathcal{L} be a convex loss function, and $\lambda_1 > 0$ a regularization parameter. The minimizer of the following optimization problem:*

$$\operatorname{argmin}_{h \in \mathcal{H}} \mathcal{J}(h) = \sum_{i=1}^{\ell} \mathcal{L}(h(x_i), \tilde{\mathbf{y}}_i) + \lambda_1 \|h\|_{\mathcal{H}}^2,$$

admits an expansion:

$$\hat{h}(\cdot) = \sum_{j=1}^{\ell} \mathcal{K}_x(\cdot, x_j) \mathbf{c}_j,$$

where the coefficients $\mathbf{c}_j, j = 1, \dots, \ell$ are vectors in the Hilbert space \mathcal{F}_y .

In the following, we plug the expansion form of the minimizer into the optimization problem and consider the problem of finding the coefficients \mathbf{c}_j for two different loss functions: the least-squares loss and the hinge loss.

3.1.1 PENALIZED LEAST SQUARES

Considering the least-squares loss function for regularization of vector-valued functions, the minimization problem becomes:

$$\operatorname{argmin}_{h \in \mathcal{H}} \mathcal{J}(h) = \sum_{i=1}^{\ell} \|h(x_i) - \tilde{\mathbf{y}}_i\|_{\mathcal{F}_y}^2 + \lambda_1 \|h\|_{\mathcal{H}}^2. \quad (3)$$

Theorem 4 (Micchelli and Pontil (2005)) *Let $\mathbf{c}_j \in \mathcal{F}_y, j = 1, \dots, \ell$, be the coefficients of the expansion admitted by the minimizer \hat{h} of the optimization problem in Equation (3). The vectors $\mathbf{c}_j \in \mathcal{F}_y$ satisfy the equations:*

$$\sum_{i=1}^{\ell} (\mathcal{K}_x(x_j, x_i) + \lambda_1 \delta_{ij}) \mathbf{c}_i = \tilde{\mathbf{y}}_j,$$

where δ is the Kronecker symbol: $\delta_{ii} = 1$ and $\forall j \neq i, \delta_{ij} = 0$.

Let $\mathbf{c} = (\mathbf{c}_j)_{j=1}^{\ell} \in \mathcal{F}_y^{\ell}$ and $\tilde{\mathbf{y}} = (\tilde{\mathbf{y}}_j)_{j=1}^{\ell} \in \mathcal{F}_y^{\ell}$. This system of equations can be equivalently written (Micchelli and Pontil, 2005):

$$(S_{X_\ell} S_{X_\ell}^* + \lambda_1 I) \mathbf{c} = \tilde{\mathbf{y}},$$

where I denotes the identity operator from \mathcal{F}_y^{ℓ} to \mathcal{F}_y^{ℓ} and $S_{X_\ell} : \mathcal{H} \rightarrow \mathcal{F}_y^{\ell}$ is the sampling operator defined for every $h \in \mathcal{H}$ by: $S_{X_\ell} h = (h(x_i))_{i=1}^{\ell}$. The expression of its adjoint $S_{X_\ell}^* : \mathcal{F}_y^{\ell} \rightarrow \mathcal{H}$ of S_{X_ℓ} for every $\mathbf{c} \in \mathcal{F}_y^{\ell}$ is given by: $S_{X_\ell}^* \mathbf{c} = \sum_{i=1}^{\ell} \mathcal{K}_x(\cdot, x_i) \mathbf{c}_i$. Therefore the solution of the optimization problem in Equation (3) writes as:

$$h_{\text{ridge}}(x) = \mathcal{K}_x(x, \cdot) S_{X_\ell}^* (S_{X_\ell} S_{X_\ell}^* + \lambda_1 I)^{-1} \tilde{\mathbf{y}}.$$

3.1.2 MAXIMUM MARGIN REGRESSION

Szedmak et al. (2005) formulated a Support Vector Machine algorithm with vector output, called Maximum Margin Regression (MMR). The optimization problem of MMR in the supervised setting is the following:

$$\operatorname{argmin}_h \mathcal{J}(h) = \sum_{i=1}^{\ell} \max(0, 1 - \langle \tilde{\mathbf{y}}_i, h(x_i) \rangle_{\mathcal{F}_y}) + \lambda_1 \|h\|_{\mathcal{H}}^2. \quad (4)$$

In Szedmak et al. (2005), the function h was modeled as: $h(x) = W \varphi_x(x) + b$, where φ_x is a feature map associated to a scalar-valued kernel. In this subsection, we extend this maximum margin based regression framework to the context of the vector-valued RKHS theory by searching h in the RKHS \mathcal{H} associated to \mathcal{K}_x .

Similarly to SVM, the MMR problem (4) can be expressed according to a primal formulation that involves the optimization of $h \in \mathcal{H}$ and slack variables $\xi_i \in \mathbb{R}, i = 1, \dots, \ell$, as well as its dual formulation which is expressed according to the Lagrangian parameters $\boldsymbol{\alpha} = [\alpha_1, \dots, \alpha_\ell]^T \in \mathbb{R}^\ell$. The latter leads to solve a quadratic program, for which efficient solvers exist. Both formulations are given below.

The primal form of the MMR optimization problem can be written as:

$$\begin{aligned} \min_{h \in \mathcal{H}, \{\xi_i \in \mathbb{R}\}_{i=1}^{\ell}} \quad & \lambda_1 \|h\|_{\mathcal{H}}^2 + \sum_{i=1}^{\ell} \xi_i \\ \text{s.t.} \quad & \langle \tilde{\mathbf{y}}_i, h(x_i) \rangle_{\mathcal{F}_y} \geq 1 - \xi_i, i = 1, \dots, \ell \\ & \xi_i \geq 0, i = 1, \dots, \ell. \end{aligned}$$

The Lagrangian of the above problem is given by:

$$\mathcal{L}_\alpha(h, \boldsymbol{\xi}, \boldsymbol{\alpha}, \boldsymbol{\eta}) = \lambda_1 \|h\|_{\mathcal{H}}^2 + \sum_{i=1}^{\ell} \xi_i - \sum_{i=1}^{\ell} \alpha_i (\langle \mathcal{K}_x(\cdot, x_i) \tilde{\mathbf{y}}_i, h \rangle_{\mathcal{H}} - 1 + \xi_i) - \sum_{i=1}^{\ell} \eta_i \xi_i,$$

with α_i and η_i being Lagrange multipliers. By differentiating the Lagrangian with respect to ξ_i and h and setting the derivatives to zero, the dual form of the optimization problem can be expressed as:

$$\begin{aligned} \min_{\boldsymbol{\alpha} \in \mathbb{R}^\ell} \quad & \frac{1}{4\lambda_1} \sum_{i,j=1}^{\ell} \alpha_i \alpha_j \langle \tilde{\mathbf{y}}_i, \mathcal{K}_x(x_i, x_j) \tilde{\mathbf{y}}_j \rangle_{\mathcal{F}_y} - \sum_{i=1}^{\ell} \alpha_i \\ \text{s.t.} \quad & 0 \leq \alpha_i \leq 1, i = 1, \dots, \ell \end{aligned} \quad (5)$$

and the solution \hat{h} can be written as: $\hat{h}(\cdot) = \frac{1}{2\lambda_1} \sum_{j=1}^{\ell} \alpha_j \mathcal{K}_x(\cdot, x_j) \tilde{\mathbf{y}}_j$. Note that, similarly to KDE, we retrieve the original MMR solution when using the following operator-valued kernel: $\mathcal{K}_x(x, x') = \kappa_x(x, x') I$.

In Appendix B, we derive the dual optimization problem for a general convex loss function using the Fenchel duality.

3.2 Extension to Semi-Supervised Learning

In the case of real-valued functions, Belkin et al. (2006) have introduced a novel framework, called *manifold regularization*. This approach is based on the assumption that the data lie in a low-dimensional manifold. Belkin et al. (2006) have proved a representer theorem devoted to semi-supervised learning by adding a new regularization term which exploits the information of the geometric structure. This regularization term forces the target function h to be smooth with respect to the underlying manifold. In general, the geometry of this manifold is not known but it can be approximated by a graph. In this graph, nodes correspond to labeled and unlabeled data and edges reflect the local similarities between data in the input space. For example, this graph can be built using k -nearest neighbors. The representer theorem of Belkin et al. (2006) has been extended to the case of vector-valued functions in Brouard et al. (2011) and Minh and Sindhwani (2011). In the following, we present this theorem and derive the solutions for the least-squares loss function and maximum margin regression.

Let \mathcal{L} be a convex loss function. Given a set of ℓ labeled examples $\{(x_i, \tilde{y}_i)\}_{i=1}^{\ell} \subseteq \mathcal{X} \times \mathcal{F}_y$ and an additional set of n unlabeled examples $\{x_j\}_{j=\ell+1}^{\ell+n} \subseteq \mathcal{X}$, we consider the following optimization problem:

$$\operatorname{argmin}_{h \in \mathcal{H}} \mathcal{J}(h) = \sum_{i=1}^{\ell} \mathcal{L}(h(x_i), \tilde{y}_i) + \lambda_1 \|h\|_{\mathcal{H}}^2 + \lambda_2 \sum_{i,j=1}^{\ell+n} W_{ij} \|h(x_i) - h(x_j)\|_{\mathcal{F}_y}^2, \quad (6)$$

where $\lambda_1, \lambda_2 > 0$ are two regularization hyperparameters and W is the adjacency matrix of a graph built from labeled and unlabeled data. This matrix measures the similarity between objects in the input space. We assume that the values of W are non-negative. This optimization problem can be rewritten as:

$$\operatorname{argmin}_{h \in \mathcal{H}} \mathcal{J}(h) = \sum_{i=1}^{\ell} \mathcal{L}(h(x_i), \tilde{y}_i) + \lambda_1 \|h\|_{\mathcal{H}}^2 + 2\lambda_2 \sum_{i,j=1}^{\ell+n} L_{ij} \langle h(x_i), h(x_j) \rangle_{\mathcal{F}_y},$$

where L is the graph Laplacian given by $L = D - W$ and D is the diagonal matrix of general term $D_{ii} = \sum_{j=1}^{\ell+n} W_{ij}$. Instead of the graph Laplacian, other matrices, such as iterated Laplacians or diffusion kernels (Kondor and Lafferty, 2002), can also be used.

Theorem 5 (Brouard et al. (2011); Minh and Sindhwani (2011)) *The minimizer of the optimization problem in Equation (6) admits an expansion:*

$$\hat{h}(\cdot) = \sum_{j=1}^{\ell+n} \mathcal{K}_x(\cdot, x_j) \mathbf{c}_j,$$

for some vectors $\mathbf{c}_j \in \mathcal{F}_y$, $j = 1, \dots, \ell + n$.

This theorem extends the representer theorem proposed by Belkin et al. (2006) to vector-valued functions. Besides, it also extends Theorem 3 to the semi-supervised framework.

3.2.1 SEMI-SUPERVISED PENALIZED LEAST-SQUARES

Considering the least-squares cost, the optimization problem becomes:

$$\operatorname{argmin}_{h \in \mathcal{H}} \mathcal{J}(h) = \sum_{i=1}^{\ell} \|h(x_i) - \tilde{y}_i\|_{\mathcal{F}_y}^2 + \lambda_1 \|h\|_{\mathcal{H}}^2 + 2\lambda_2 \sum_{i,j=1}^{\ell+n} L_{ij} \langle h(x_i), h(x_j) \rangle_{\mathcal{F}_y}. \quad (7)$$

Theorem 6 (Brouard et al. (2011); Minh and Sindhwani (2011)) *The coefficients $\mathbf{c}_j \in \mathcal{F}_y$, $j = 1, \dots, \ell + n$ of the expansion admitted by the minimizer \hat{h} of the optimization problem (7) satisfy this equation:*

$$J_j \sum_{i=1}^{\ell+n} \mathcal{K}_x(x_j, x_i) \mathbf{c}_i + \lambda_1 \mathbf{c}_j + 2\lambda_2 \sum_{i=1}^{\ell+n} L_{ij} \sum_{m=1}^{\ell+n} \mathcal{K}_x(x_i, x_m) \mathbf{c}_m = J_j \tilde{y}_j,$$

where $J_j \in \mathcal{B}(\mathcal{F}_y)$ is the identity operator if $j \leq \ell$ and the null operator if $\ell < j \leq (\ell + n)$.

For the proofs of Theorems 5 and 6, the reader can refer to the proofs given in the supplementary materials of Brouard et al. (2011) or Minh and Sindhwani (2011).

As in the supervised setting, the solution of the optimization problem (7) can be expressed using the sampling operator:

$$h_{\text{ridge}}(x) = \mathcal{K}_x(x, \cdot) S_{X_{\ell+n}}^* (J J^* S_{X_{\ell+n}} S_{X_{\ell+n}}^* + \lambda_1 I + 2\lambda_2 M S_{X_{\ell+n}} S_{X_{\ell+n}}^*)^{-1} J \tilde{y},$$

where the operator $J \in \mathcal{B}(\mathcal{F}_y^{\ell}, \mathcal{F}^{\ell+n})$ is defined for every $\mathbf{c} = (\mathbf{c}_j)_{j=1}^{\ell} \in \mathcal{F}_y^{\ell}$ as: $J\mathbf{c} = (\mathbf{c}_1, \dots, \mathbf{c}_{\ell}, \mathbf{0}, \dots, \mathbf{0})$. Its adjoint is defined as: $J^*(\mathbf{c}_j)_{j=1}^{\ell+n} = (\mathbf{c}_j)_{j=1}^{\ell}$. M is an operator in $\mathcal{B}(\mathcal{F}^{\ell+n})$ and each M_{ij} , $i, j \in \mathbb{N}^{\ell+n}$ is an operator in $\mathcal{B}(\mathcal{F}_y)$ equal to $L_{ij}I$.

3.2.2 SEMI-SUPERVISED MAXIMUM MARGIN REGRESSION

The optimization problem in the semi-supervised case using the hinge loss is the following:

$$\operatorname{argmin}_{h \in \mathcal{H}} \mathcal{J}(h) = \sum_{i=1}^{\ell} \max(0, 1 - \langle \tilde{y}_i, h(x_i) \rangle_{\mathcal{F}_y}) + \lambda_1 \|h\|_{\mathcal{H}}^2 + 2\lambda_2 \sum_{i,j=1}^{\ell+n} L_{ij} \langle h(x_i), h(x_j) \rangle_{\mathcal{F}_y}. \quad (8)$$

Theorem 7 *The solution of the optimization problem (8) is given by*

$$h(\cdot) = \frac{1}{2} B^{-1} \left(\sum_{i=1}^{\ell} \alpha_i \mathcal{K}_x(\cdot, x_i) \tilde{y}_i \right),$$

where $B = \lambda_1 I + 2\lambda_2 \sum_{i,j=1}^{\ell+n} L_{ij} \mathcal{K}_x(\cdot, x_i) \mathcal{K}_x(x_j, \cdot)$ is an operator from \mathcal{H} to \mathcal{H} , and α is the solution of

$$\begin{aligned} \min_{\alpha \in \mathbb{R}^{\ell}} \quad & \frac{1}{4} \sum_{i,j=1}^{\ell} \alpha_i \alpha_j \langle \mathcal{K}_x(\cdot, x_i) \tilde{y}_i, B^{-1} \mathcal{K}_x(\cdot, x_j) \tilde{y}_j \rangle_{\mathcal{H}} - \sum_{i=1}^{\ell} \alpha_i \\ \text{s.t.} \quad & 0 \leq \alpha_i \leq 1, i = 1, \dots, \ell. \end{aligned} \quad (9)$$

The proof of this theorem is detailed in Appendix A.

3.3 Solutions when $\mathcal{F}_y = \mathbb{R}^d$

In this subsection we consider that the dimension of \mathcal{F}_y is finite and equal to d . We first introduce the following notations:

- $\tilde{Y}_\ell = (\tilde{y}_1, \dots, \tilde{y}_\ell)$ is a matrix of size $d \times \ell$,
- $C_\ell = (\mathbf{c}_1, \dots, \mathbf{c}_\ell)$, $C_{\ell+n} = (\mathbf{c}_1, \dots, \mathbf{c}_{\ell+n})$,
- $\mathcal{K}_{X_\ell}^x = (\mathcal{K}_x(x_1, x), \dots, \mathcal{K}_x(x_\ell, x))^T$, $\mathcal{K}_{X_{\ell+n}}^x = (\mathcal{K}_x(x_1, x), \dots, \mathcal{K}_x(x_{\ell+n}, x))^T$,
- \mathbf{K}_{X_ℓ} is a $\ell \times \ell$ block matrix, where each block is a $d \times d$ matrix. The (j, k) -th block of \mathbf{K}_{X_ℓ} is equal to $\mathcal{K}_x(x_j, x_k)$,
- $\mathbf{K}_{X_{\ell+n}}$ is a $(\ell + n) \times (\ell + n)$ block matrix such that the (j, k) -th block of $\mathbf{K}_{X_{\ell+n}}$ is equal to $\mathcal{K}_x(x_j, x_k)$,
- $I_{\ell d}$ and $I_{(\ell+n)d}$ are identity matrices of size $(\ell d) \times (\ell d)$ and $(\ell + n)d \times (\ell + n)d$,
- $J = (I_\ell, 0)$ is a $\ell \times (\ell + n)$ matrix that contains an identity matrix of size $\ell \times \ell$ on the left hand side and a zero matrix of size $\ell \times n$ on the right hand side,
- \otimes denotes the Kronecker product and $\text{vec}(A)$ denotes the vectorization of a matrix A , formed by stacking the columns of A into a single column vector.

In the supervised setting, the solutions for the least-squares loss and MMR can be rewritten as $h(x) = (\mathcal{K}_{X_\ell}^x)^T C_\ell$, where C_ℓ is given by:

$$\begin{aligned} C_{\ell, \text{lsqr}} &= (\lambda_1 I_{\ell d} + \mathbf{K}_{X_\ell})^{-1} \text{vec}(\tilde{Y}_\ell), \\ C_{\ell, \text{mmr}} &= \frac{1}{2\lambda_1} \text{vec}(\tilde{Y}_\ell \text{diag}(\boldsymbol{\alpha})). \end{aligned}$$

In the semi-supervised setting, these solutions can be written as $h(x) = (\mathcal{K}_{X_{\ell+n}}^x)^T C_{\ell+n}$ where:

$$\begin{aligned} C_{\ell+n, \text{lsqr}} &= (\lambda_1 I_{(\ell+n)d} + ((J^T J + 2\lambda_2 L) \otimes I_d) \mathbf{K}_{X_{\ell+n}})^{-1} \text{vec}(\tilde{Y}_\ell J), \\ C_{\ell+n, \text{mmr}} &= (2\lambda_1 I_{(\ell+n)d} + 4\lambda_2 (L \otimes I_d) \mathbf{K}_{X_{\ell+n}})^{-1} \text{vec}(\tilde{Y}_\ell \text{diag}(\boldsymbol{\alpha}) J). \end{aligned}$$

For MMR, the vector $\boldsymbol{\alpha}$ is obtained by solving the following optimization problem:

$$\begin{aligned} \min_{\boldsymbol{\alpha} \in \mathbb{R}^\ell} & \frac{1}{4} \text{vec}(\tilde{Y}_\ell \text{diag}(\boldsymbol{\alpha}) J)^T \\ & (\lambda_1 I_{(\ell+n)d} + 2\lambda_2 \mathbf{K}_{X_{\ell+n}} (L \otimes I_d))^{-1} \mathbf{K}_{X_{\ell+n}} \text{vec}(\tilde{Y}_\ell \text{diag}(\boldsymbol{\alpha}) J) - \boldsymbol{\alpha}^T \mathbf{1} \end{aligned} \quad (10)$$

s.t. $0 \leq \alpha_i \leq 1, i = 1, \dots, \ell$.

In the case of IOKR, \mathcal{F}_y is the feature space of some output kernel. Its dimension may therefore be infinite depending of which kernel is used. In this case, explicit feature vectors can be defined using the eigendecomposition of the output kernel matrix on the labeled data.

3.4 Models for General Decomposable Kernels

In the remainder of this section we propose to derive models based on a simple but powerful family of operator-valued kernels (OVK) based on scalar-valued kernels, called *decomposable kernels* or *separable kernels* (Alvarez et al., 2012; Baldassarre et al., 2012). They correspond to the simplest generalization of scalar kernels to operator-valued kernels. Decomposable kernels were first defined to deal with multi-task regression (Evgeniou et al., 2005; Michelli and Pontil, 2005) and later, with structured multi-class classification (Dinuzzo et al., 2011). Other kernels (Caponnetto et al., 2008; Álvarez et al., 2012) have also been proposed: for instance, Lim et al. (2013) introduced a Hadamard kernel based on the Hadamard product of decomposable kernels and transformable kernels to deal with nonlinear vector autoregressive models. Caponnetto et al. (2008) proved that they are universal, meaning that an operator-valued regressor built on them is a universal approximator in \mathcal{F}_y .

Proposition 8 *The class of decomposable operator-valued kernels is composed of kernels of the form:*

$$\mathcal{K}_x : \mathcal{X} \times \mathcal{X} \rightarrow \mathcal{B}(\mathcal{F}_y)$$

$$(x, x') \mapsto \kappa_x(x, x') A$$

where $\kappa_x : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R}$ is a scalar-valued input kernel and $A \in \mathcal{B}(\mathcal{F}_y)$ is a positive semidefinite operator.

In the multi-task learning framework, $\mathcal{F}_y = \mathbb{R}^d$ is a finite dimensional output space and the matrix A encodes the existing relations among the d different tasks. This matrix can be estimated from labeled data or being learned simultaneously with the matrix C (Dinuzzo et al., 2011).

In the following we assume that the dimension of \mathcal{F}_y is finite and equal to d : $\mathcal{F}_y = \mathbb{R}^d$.

3.4.1 PENALIZED LEAST-SQUARES REGRESSION

In this section, we will use the following notations: \mathcal{F}_x and the function $\varphi_x : \mathcal{X} \rightarrow \mathcal{F}_x$ correspond respectively to the feature space and the feature map associated to the input scalar kernel κ_x . We note $\kappa_{X_\ell}^x = (\kappa_x(x_1, x), \dots, \kappa_x(x_\ell, x))^T$ the vector of length ℓ containing the kernel values between the labeled examples and x and $\kappa_{X_{\ell+n}}^x = (\kappa_x(x_1, x), \dots, \kappa_x(x_{\ell+n}, x))^T$. Let K_{X_ℓ} and $K_{X_{\ell+n}}$ be respectively the Gram matrices of κ_x over the sets X_ℓ and $X_{\ell+n}$. I_ℓ denotes the identity matrix of size ℓ .

The minimizer h of the optimization problem for the penalized least-squares cost in the supervised setting (3) using a decomposable OVK can be expressed as:

$$\begin{aligned} \forall x \in \mathcal{X}, h(x) &= A \sum_{i=1}^{\ell} \kappa_x(x, x_i) \mathbf{c}_i = AC_\ell \kappa_{X_\ell}^x = ((\kappa_{X_\ell}^x)^T \otimes A) \text{vec}(C_\ell) \\ &= ((\kappa_{X_\ell}^x)^T \otimes A) (\lambda_1 I_{\ell d} + K_{X_\ell} \otimes A)^{-1} \text{vec}(\tilde{Y}_\ell). \end{aligned} \quad (11)$$

Therefore, the computation of the solution h requires to compute the inverse of a matrix of size $\ell d \times \ell d$. A being a real symmetric matrix, we can write the eigendecomposition of A :

$$A = E \Gamma E^T = \sum_{i=1}^d \gamma_i \mathbf{e}_i \mathbf{e}_i^T,$$

where $E = (\mathbf{e}_1, \dots, \mathbf{e}_d)$ is a $d \times d$ matrix and Γ is a diagonal matrix containing the eigenvalues of A : $\Gamma = \text{diag}(\gamma_1, \dots, \gamma_d)$. Using the eigendecomposition of A , we can prove that the solution $\hat{h}(x)$ can be obtained by solving d independent problems.

Proposition 9 *The minimizer of the optimization problem for the supervised penalized least squares cost (3) in the case of a decomposable operator-valued kernel can be expressed as:*

$$\forall x \in \mathcal{X}, h_{\text{ridge}}(x) = \sum_{j=1}^d \gamma_j \mathbf{e}_j \mathbf{e}_j^T \tilde{Y}_\ell (\lambda_1 I + \gamma_j K_{X_j})^{-1} \kappa_{X_{\ell+1}}^x \quad (12)$$

and in the semi-supervised setting (7), it writes as

$$\forall x \in \mathcal{X}, h_{\text{ridge}}(x) = \sum_{j=1}^d \gamma_j \mathbf{e}_j \mathbf{e}_j^T \tilde{Y}_\ell J (\lambda_1 I_{\ell+n} + \gamma_j K_{X_{\ell+n}} (J^T J + 2\lambda_2 L))^{-1} \kappa_{X_{\ell+n}}^x.$$

We observe that, in the supervised setting, the complexity to solve Equation (11) is equal to $O((d\ell)^3)$, while the complexity for solving Equation (12) is $O(d^3 + \ell^3)$.

3.4.2 MAXIMUM MARGIN REGRESSION

Proposition 10 *Given $K_x(x, x') = \kappa_x(x, x')$, A , the dual formulation of the MMR optimization problem (4) in the supervised setting becomes:*

$$\begin{aligned} \min_{\alpha \in \mathbb{R}^\ell} \quad & \frac{1}{4\lambda_1} \alpha^T (\tilde{Y}_\ell^T A \tilde{Y}_\ell \circ K_{X_\ell}) \alpha - \alpha^T \mathbf{1} \\ \text{s.t.} \quad & 0 \leq \alpha_i \leq 1, i = 1, \dots, \ell \end{aligned}$$

where \circ denotes the Hadamard product, and the solution is given by:

$$h_{\text{mmr}}(x) = \frac{1}{2\lambda_1} A \tilde{Y}_\ell \text{diag}(\alpha) \kappa_{X_\ell}^x.$$

In the semi-supervised MMR minimization problem (8), it writes as:

$$\begin{aligned} \min_{\alpha \in \mathbb{R}^\ell} \quad & \frac{1}{2} \alpha^T \left(\sum_{i=1}^d \gamma_i \tilde{Y}_\ell^T \mathbf{e}_i \mathbf{e}_i^T \tilde{Y}_\ell \circ J (2\lambda_1 I_{\ell+n} + 4\lambda_2 \gamma_i K_{X_{\ell+n}} L)^{-1} K_{X_{\ell+n}} J^T \right) \alpha - \alpha^T \mathbf{1} \\ \text{s.t.} \quad & 0 \leq \alpha_i \leq 1, i = 1, \dots, \ell. \end{aligned}$$

The corresponding solution is:

$$h_{\text{mmr}}(x) = \frac{1}{2} \sum_{j=1}^d \gamma_j \mathbf{e}_j \mathbf{e}_j^T \tilde{Y}_\ell \text{diag}(\alpha) J (\lambda_1 I_{\ell+n} + 2\gamma_j \lambda_2 K_{X_{\ell+n}} L)^{-1} \kappa_{X_{\ell+n}}^x.$$

Proofs of Propositions 9 and 10 are given in Appendix A.

4. Model Selection

Real-valued kernel-based models enjoy a closed-form solution for the estimate of the leave-one-out criterion in the case of kernel ridge regression (Golub et al., 1979; Rifkin and Lippert, 2007). In order to select the hyperparameters of OVK-based models with a least-squares loss presented below, we develop a closed-form solution for the leave-one-out estimate of the sum of square errors. This solution extends Allen's predicted residual sum of squares (PRESS) statistics (Allen, 1974) to vector-valued functions. This result was first presented in french in the PhD thesis of Brouard (2013) in the case of decomposable kernels. In the following, we will use the notations used by Rifkin and Lippert (2007). We assume in this section that the dimension of \mathcal{F}_y is finite.

Let $\mathcal{S} = \{(x_1, \tilde{\mathbf{y}}_1), \dots, (x_\ell, \tilde{\mathbf{y}}_\ell)\}$ be the training set composed of ℓ labeled points. We define \mathcal{S}^i , $1 \leq i \leq \ell$, as the labeled data set with the i^{th} point removed:

$$\mathcal{S}^i = \{(x_1, \tilde{\mathbf{y}}_1), \dots, (x_{i-1}, \tilde{\mathbf{y}}_{i-1}), (x_{i+1}, \tilde{\mathbf{y}}_{i+1}), \dots, (x_\ell, \tilde{\mathbf{y}}_\ell)\}.$$

In this section, h_S denotes the function obtained when the regression problem is trained on the entire training set \mathcal{S} and we note $h_{\mathcal{S}^i}(x_i)$ the i^{th} leave-one-out value, that is the value at the point x_i of the function obtained when the training set is \mathcal{S}^i . The PRESS criterion corresponds to the sum of the ℓ leave-one-out square errors:

$$\text{PRESS} = \sum_{i=1}^{\ell} \|\tilde{\mathbf{y}}_i - h_{\mathcal{S}^i}(x_i)\|_{\mathcal{F}_y}^2.$$

As for scalar-valued functions, we show that it is possible to compute this criterion without evaluating explicitly $h_{\mathcal{S}^i}(x_i)$ for $i = 1, \dots, \ell$ and for each value of the grid of parameters.

Assuming we know $h_{\mathcal{S}^i}$, we define the matrix $\tilde{Y}_\ell^i = (\tilde{\mathbf{y}}_1^i, \dots, \tilde{\mathbf{y}}_\ell^i)$, where the vector $\tilde{\mathbf{y}}_j^i$ is given by:

$$\tilde{\mathbf{y}}_j^i = \begin{cases} \tilde{\mathbf{y}}_j & \text{if } j \neq i, \\ h_{\mathcal{S}^i}(x_i) & \text{if } j = i. \end{cases}$$

In the following, we show that when using \tilde{Y}_ℓ^i instead of \tilde{Y}_ℓ , the optimal solution corresponds to $h_{\mathcal{S}^i}$:

$$\begin{aligned} & \sum_{j=1}^{\ell} \|\tilde{\mathbf{y}}_j^i - h_{\mathcal{S}}(x_j)\|_{\mathcal{F}_y}^2 + \lambda_1 \|h_{\mathcal{S}}\|_{\mathcal{H}}^2 + \lambda_2 \sum_{j,k=1}^{\ell+n} W_{j,k} \|h_{\mathcal{S}}(x_j) - h_{\mathcal{S}}(x_k)\|_{\mathcal{F}_y}^2 \\ & \geq \sum_{j \neq i} \|\tilde{\mathbf{y}}_j^i - h_{\mathcal{S}}(x_j)\|_{\mathcal{F}_y}^2 + \lambda_1 \|h_{\mathcal{S}}\|_{\mathcal{H}}^2 + \lambda_2 \sum_{j,k=1}^{\ell+n} W_{j,k} \|h_{\mathcal{S}}(x_j) - h_{\mathcal{S}}(x_k)\|_{\mathcal{F}_y}^2 \\ & \geq \sum_{j \neq i} \|\tilde{\mathbf{y}}_j^i - h_{\mathcal{S}^i}(x_j)\|_{\mathcal{F}_y}^2 + \lambda_1 \|h_{\mathcal{S}^i}\|_{\mathcal{H}}^2 + \lambda_2 \sum_{j,k=1}^{\ell+n} W_{j,k} \|h_{\mathcal{S}^i}(x_j) - h_{\mathcal{S}^i}(x_k)\|_{\mathcal{F}_y}^2 \\ & \geq \sum_{j=1}^{\ell} \|\tilde{\mathbf{y}}_j^i - h_{\mathcal{S}^i}(x_j)\|_{\mathcal{F}_y}^2 + \lambda_1 \|h_{\mathcal{S}^i}\|_{\mathcal{H}}^2 + \lambda_2 \sum_{j,k=1}^{\ell+n} W_{j,k} \|h_{\mathcal{S}^i}(x_j) - h_{\mathcal{S}^i}(x_k)\|_{\mathcal{F}_y}^2. \end{aligned}$$

The second inequality comes from the fact that h_{S^i} is defined as the minimizer of the optimization problem when the i^{th} point is removed from the training set. As h_{S^i} is the optimal solution when \tilde{Y}_ℓ is replaced with \tilde{Y}_ℓ^i , it can be written as:

$$\forall i = 1, \dots, \ell, \quad h_{S^i}(x_i) = (\mathbf{K}_{X_{\ell+n}}^{x_i})^T B \text{vec}(\tilde{Y}_\ell^i) = (KB)_i \cdot \text{vec}(\tilde{Y}_\ell^i),$$

where $K = \mathbf{K}_{X_{\ell+n}(\ell+n)}$ is the input gram matrix between the sets X_ℓ and $X_{\ell+n}$ and $B = (\lambda_1 I_{(\ell+n)d} + ((J^T J + 2\lambda_2 L) \otimes I_d) \mathbf{K}_{X_{\ell+n}})^{-1} (J^T \otimes I_d)$. $(KB)_i$ corresponds to the i^{th} row of the matrix KB and $(KB)_{i,j}$ is the value of the matrix corresponding to the row i and the column j .

We can then derive an expression of h_{S^i} by computing the difference between $h_{S^i}(x_i)$ and $h_S(x_i)$:

$$\begin{aligned} h_S(x_i) - h_{S^i}(x_i) &= (KB)_i \cdot \text{vec}(\tilde{Y}_\ell^i - \tilde{Y}_\ell) \\ &= \sum_{k=1}^{\ell} (KB)_{i,k} (\tilde{Y}_k^i - \tilde{Y}_k) \\ &= (KB)_{i,i} (h_{S^i}(x_i) - \tilde{y}_i), \end{aligned}$$

which leads to

$$\begin{aligned} (I_d - (KB)_{i,i}) h_{S^i}(x_i) &= h_S(x_i) - (KB)_{i,i} \tilde{y}_i \\ \Rightarrow (I_d - (KB)_{i,i}) h_{S^i}(x_i) &= (KB)_i \cdot \text{vec}(\tilde{Y}_\ell) - (KB)_{i,i} \tilde{y}_i \\ \Rightarrow h_{S^i}(x_i) &= (I_d - (KB)_{i,i})^{-1} \left((KB)_i \cdot \text{vec}(\tilde{Y}_\ell) - (KB)_{i,i} \tilde{y}_i \right). \end{aligned}$$

Let $L_{oo} = (h_{S^1}(x_1), \dots, h_{S^i}(x_\ell))$ be the matrix containing the leave-one-out vector values over the training set. The equation above can be rewritten as:

$$\text{vec}(L_{oo}) = (I_d - \text{diag}_b(KB))^{-1} (KB - \text{diag}_b(KB)) \text{vec}(\tilde{Y}_\ell),$$

where diag_b corresponds to the block diagonal of a matrix.

The Allen's PRESS statistic can be expressed as:

$$\begin{aligned} \text{PRESS} &= \|\text{vec}(\tilde{Y}_\ell) - \text{vec}(L_{oo})\|^2 \\ &= \|(I_d - \text{diag}_b(KB))^{-1} (I_d - \text{diag}_b(KB) - KB + \text{diag}_b(KB)) \text{vec}(\tilde{Y}_\ell)\|^2 \\ &= \|(I_d - \text{diag}_b(KB))^{-1} (I_d - KB) \text{vec}(\tilde{Y}_\ell)\|^2. \end{aligned}$$

This closed-form expression allows to evaluate the PRESS criterion without having to solve ℓ problems involving the inversion of a matrix of size $(\ell + n - 1)d$.

5. Input Output Kernel Regression

We now have all the needed tools to approximate vector-valued functions. In this section, we go back to IOKR and consider that \mathcal{F}_y is the feature space associated to some output kernel $\kappa_y : \mathcal{Y} \times \mathcal{Y} \rightarrow \mathbb{R}$, and that vectors \tilde{y}_i now correspond to output feature vectors $\varphi_y(y_i)$. Several feature spaces can be defined, including the unique RKHS associated to the kernel

κ_y . This choice has direct consequences on the choice of the input operator-valued kernel \mathcal{K}_x . Depending on the application, we might be interested for instance on choosing \mathcal{F}_y as a functional space to get integral operators or as the finite-dimensional Euclidean space \mathbb{R}^d to get matrices. It is important to notice that this reflects a radically new approach in machine learning where we usually focus on the choice of the input feature space and do not discuss a lot the output space. Moreover, the choice of a given triplet $(\kappa_y, \mathcal{F}_y, \mathcal{K}_x)$ has a great impact of the learning task both in terms of complexity in time and potentially of performance. In the following, we explain how Input Output Kernel Regression can be used to solve link prediction and multi-task problems.

5.1 Link Prediction

Link prediction is a challenging machine learning problem that has been defined recently in social networks as well as biological networks. Let us formulate this problem using the previous notations: $\mathcal{X} = \mathcal{Y} = \mathcal{U}$ is the set of candidate nodes we are interested in. We want to estimate some relation between these nodes, for example a social relationship between persons or some physical interaction between molecules. During the training phase we are given $\mathcal{G}_\ell = (\mathcal{U}_\ell, A_\ell)$, a non oriented graph defined by the subset $\mathcal{U}_\ell \subseteq \mathcal{U}$ and the adjacency matrix A_ℓ of size $\ell \times \ell$. Supervised link prediction is usually addressed by learning a binary pairwise classifier $f : \mathcal{U} \times \mathcal{U} \rightarrow \{0, 1\}$ that predicts if there exists a link between two objects or not, from the training information \mathcal{G}_ℓ . One way to solve this learning task is to build a pairwise classifier. However, the link prediction problem can also be formalized as an output kernel regression task (Geurts et al., 2007a; Brouard et al., 2011).

The OKR framework for link prediction is based on the assumption that an approximation of the output kernel κ_y will provide valuable information about the proximity of the objects of \mathcal{U} as nodes in the unknown graph defined on \mathcal{U} . Given that assumption, a classifier f_θ is defined from the approximation $\widehat{\kappa}_y$ by thresholding its output values:

$$f_\theta(u, u') = \text{sgn}(\widehat{\kappa}_y(u, u') - \theta).$$

An approximation of the target output kernel κ_y is built from the scalar product between the outputs of a single variable function $h : \mathcal{U} \rightarrow \mathcal{F}_y$: $\widehat{\kappa}_y(u, u') = \langle h(u), h(u') \rangle_{\mathcal{F}_y}$. Using the kernel trick in the output space therefore allows to reduce the problem of learning a pairwise classifier to the problem of learning a single variable function with output values in a Hilbert space (the output feature space \mathcal{F}_y).

In the case of IOKR, the function h is learnt in an appropriate RKHS by using the operator-valued kernel regression approach presented in Section 3. In the following, we describe the output kernel and the input operator-valued kernel that we propose to use for solving the link prediction problem with IOKR.

Regarding the output kernel, we do not have a kernel κ_y defined on $\mathcal{U} \times \mathcal{U}$ in the link prediction problem but we can define a Gram matrix K_{Y_ℓ} on the training set \mathcal{U}_ℓ . Here, we define K_{Y_ℓ} from the known adjacency matrix A_ℓ of the training graph such that it encodes the proximities in the graph between the labeled nodes. For instance, we can choose the diffusion kernel matrix (Kondor and Lafferty, 2002), which is defined as:

$$K_{Y_\ell} = \exp(-\beta L_{y_\ell}),$$

$B =$	Supervised learning	Semi-supervised learning
Ridge	$(\lambda I_\ell + K_X)^{-1}$	$J(\lambda I_{\ell+n} + K_{X_{\ell+n}})^{-1}$
MMR	$\frac{1}{2\lambda} \text{diag}(\alpha)$	$\frac{1}{2} \text{diag}(\alpha) J(\lambda I_{\ell+n} + 2\lambda_2 K_{X_{\ell+n}} L)^{-1}$

Table 2: Matrix B of the models obtained using the identity decomposable kernel in the case of different settings and loss functions.

where $L_{y_\ell} = D_\ell - A_\ell$ is the graph Laplacian, with D_ℓ the diagonal matrix of degrees. The kernel trick allows to work as if we have chosen the subspace spanned by $\{\mathbf{e}_1, \dots, \mathbf{e}_\ell\}$, the eigenvectors of the matrix K_Y as a feature space with an associated feature map that verifies:

$$\forall i \in \{1, \dots, \ell\}, \varphi_{y_\ell}(u_i) = [\sqrt{\gamma_1} \mathbf{e}_1^i, \dots, \sqrt{\gamma_\ell} \mathbf{e}_\ell^i]^T.$$

The kernel $\kappa_{y_\ell} : \mathcal{U} \times \mathcal{U} \rightarrow \mathbb{R}$, also verifies:

$$\forall i, j \in \{1, \dots, \ell\}, \kappa_{y_\ell}(u_i, u_j) = (K_Y)_{i,j}.$$

In practise, we only need to know K_Y . Regarding the operator-valued kernel, we consider here the identity decomposable kernel:

$$\forall (u, u') \in \mathcal{U} \times \mathcal{U}, \mathcal{K}_x(u, u') = \kappa_x(u, u') I.$$

We underline that even if this kernel may seem simple, we must be aware that in this task, we do not have the explicit expressions of outputs $\varphi_y(u)$ and prediction in \mathcal{F}_y is not the final target. Therefore this operator-valued kernel allows us to work properly with output Gram matrix values.

Of particular interest for us is the expression of the scalar product which is the only one we need for link prediction. When using the identity decomposable kernel, the approximation of the output kernel can be written as follows:

$$\widehat{\kappa}_{y_\ell}(u, u') = \langle \hat{h}(u), \hat{h}(u') \rangle_{\mathcal{F}_y} = (\kappa_{x_\ell}^u)^T B^T K_Y B \kappa_{x_\ell}^{u'} \quad (13)$$

where B is a matrix of size $\ell \times \ell$ that depends of the loss function used (see Table 2). In the semi-supervised setting, the approximated output kernel has a similar expression, where $\kappa_{x_\ell}^u, \kappa_{x_\ell}^{u'}$ are replaced by $\kappa_{x_\ell}^u, \kappa_{x_\ell}^{u'}$ and B is a matrix of size $(\ell + n) \times \ell$. We can notice that we do not need to know the explicit expressions of outputs $\varphi_y(u)$ to compute this scalar product. Besides, the approximation of the scalar product $\langle \varphi_y(u), \varphi_y(u') \rangle_{\mathcal{F}_y}$ can be interpreted as a modified scalar product between the inputs $\varphi_x(u)$ and $\varphi_x(u')$.

5.2 Multi-Task Learning

Multi-task learning has been developed based on the observation that it may happen that several learning tasks are not disjoint and are characterized by a relationship such as inclusion or similarity. Learning simultaneously such related tasks has been shown to improve the performance comparing to learning the different tasks independently from each other

(Carrara, 1997; Eygenion et al., 2005). Examples of multi-task learning problems can be found in document categorization as well as in protein functional annotation prediction. Dependencies among target variables can also be encountered in the case of multiple regression.

We consider here the case of learning d tasks having the same input and output domains. Eygenion et al. (2005) have shown that this problem is equivalent to learning a vector-valued function $h : \mathcal{X} \rightarrow \mathcal{Y}$ with d components $h^i : \mathcal{X} \rightarrow \mathcal{Y}_i$ using the vector-valued RKHS theory. A natural way to integrate the task relatedness with operator-valued kernels is to use the decomposable kernels introduced in Subsection 3.4: $\mathcal{K}_x(x, x') = \kappa_x(x, x') A$. Several values for the matrix A have been proposed (Eygenion et al., 2005; Sheldon, 2008; Balassare et al., 2012) based on the fact that the regularization term in the RKHS associated to a decomposable OVK can be expressed in function of A :

$$\|h\|_{\mathcal{H}}^2 = \sum_{i,j=1}^d A_{i,j}^1 \langle h^i, h^j \rangle_{\mathcal{H}_{\kappa_x}},$$

where \dagger denotes the pseudoinverse and \mathcal{H}_{κ_x} the RKHS associated to the scalar kernel κ_x .

In the IOKR framework, the task structure can be encoded in two different ways. We can use a decomposable OVK in input as described previously and define a regularization term that will penalize the d components of the function h according to the task structure. Another way is to modify the output representation by defining an output kernel that will integrate the task structure. We propose to compare the three following models to solve multi-task learning with our framework:

- Model 0: $\kappa_y(\mathbf{y}, \mathbf{y}') = \mathbf{y}^T \mathbf{y}'$, with the identity kernel $\mathcal{K}_x(x, x') = \kappa_x(x, x') I$,
- Model 1: $\kappa_y(\mathbf{y}, \mathbf{y}') = \mathbf{y}^T A_1 \mathbf{y}'$, with the identity kernel $\mathcal{K}_x(x, x') = \kappa_x(x, x') I$,
- Model 2: $\kappa_y(\mathbf{y}, \mathbf{y}') = \mathbf{y}^T \mathbf{y}'$, with the decomposable kernel $\mathcal{K}_x(x, x') = \kappa_x(x, x') A_2$.

In the first case, the different tasks are learned independently :

$$\forall x \in \mathcal{X}, \hat{h}_0(x) = Y_\ell J (\lambda_1 I_{\ell+n} + K_{X_{\ell+n}})^{-1} \kappa_{X_{\ell+n}}^x,$$

while in the other cases, the tasks relatedness is taken into account :

$$\begin{aligned} \forall x \in \mathcal{X}, \hat{h}_1(x) &= \sqrt{\lambda_1} Y_\ell J (\lambda_1 I_{\ell+n} + K_{X_{\ell+n}})^{-1} \kappa_{X_{\ell+n}}^x, \\ \forall x \in \mathcal{X}, \hat{h}_2(x) &= \sum_{j=1}^d \gamma_j \mathbf{e}_j \mathbf{e}_j^T Y_\ell J (\lambda_1 I_{\ell+n} + \gamma_j K_{X_{\ell+n}})^{-1} \kappa_{X_{\ell+n}}^x, \end{aligned}$$

where γ_j and \mathbf{e}_j are the eigenvalues and eigenvectors of A_2 .

We consider a matrix M of size $d \times d$ that encodes the relations existing between the different tasks. This matrix can be considered as the adjacency matrix of a graph between tasks. We note L_M the graph Laplacian associated to this matrix. The matrices A_1 and A_2 are defined as follow:

$$\begin{aligned} A_1 &= \mu M + (1 - \mu) I_d, \\ A_2 &= (\mu L_M + (1 - \mu) I_d)^{-1}, \end{aligned}$$

where μ is a parameter in $[0, 1]$.

The matrix A_2 was proposed by Evgeniou et al. (2005) and Sheldon (2008) for multi-task learning from the following regularizer:

$$\|h_2\|_{\mathcal{H}}^2 = \frac{\mu}{2} \sum_{i,j=1}^d M_{ij} \|h_2^i - h_2^j\|^2 + (1 - \mu) \sum_{i=1}^d \|h_2^i\|^2.$$

This regularization term forces two tasks h_2^i and h_2^j to be close to each other when the similarity value M_{ij} is high and conversely.

6. Numerical Experiments

In this section, we present the performances obtained with the IOKR approach on two different problems: link prediction and multi-task regression. In these experiments, we examine the effect of the smoothness constraint through the variation of its related hyperparameter λ_2 , using supervised method as a baseline. We evaluate the method in the transductive setting, in which the goal is to predict the correct outputs for the unlabeled examples, as well as in the semi-supervised setting.

6.1 Link Prediction

For the link prediction problem, we considered experiments on three datasets: a collection of synthetic networks, a co-authorship network and a protein-protein interaction (PPI) network.

6.1.1 PROTOCOL

For different percentages of labeled nodes, we randomly selected a subsample of nodes as labeled nodes. We split the remaining nodes in two subsets: one containing the unlabeled nodes and another containing the test nodes. Labeled interactions correspond to interactions between two labeled nodes. This means that when 10% of labeled nodes are selected, it corresponds to only 1% of labeled interactions. The performances were evaluated by averaging the areas under the ROC curve and the precision-recall curve (denoted AUC-ROC and AUC-PR) over ten random choices of the labeled set. A Gaussian kernel was used for the scalar input kernel κ_x . Its corresponding bandwidth σ was selected by a leave-one-out cross-validation procedure on the training set to maximize the AUC-ROC, jointly with the hyperparameter λ_1 . In the case of the least-squares loss function, we used the leave-one-out estimates approach introduced in Section 4. The output kernel used is a diffusion kernel of parameter β . Another diffusion kernel of parameter β_2 was also used for the smoothing penalty: $\exp(-\beta_2 L) = \sum_{i=0}^{\infty} \frac{(-\beta_2 L)^i}{i!}$, where L is the Laplacian of W . Preliminary runs have shown that the values of β and β_2 have a limited influence on the performances, we then have set both parameters to 1. Finally we set W to $K_{X_{t+n}}$.

6.1.2 SYNTHETIC NETWORKS

We first illustrate our method on synthetic networks where the input kernel was chosen as a very good approximation of the output kernel. In these experiments we wanted to measure

the improvement brought by the semi-supervised method in extreme cases, i.e. when the percentage of labeled nodes is very low.

The output networks were obtained by sampling random graphs containing 700 nodes from an Erdős-Rényi law with different graph densities. The graph density corresponds to the probability of presence of edges in the graph. In this experiment we chose three densities that are representative of real network densities: 0.007, 0.01 and 0.02. For each network, we used the diffusion kernel on the full graph as output kernel and chose the diffusion parameter such that it maximizes an information criterion. To built an input kernel corresponding to a good approximation of the output kernel, we applied kernel PCA on the output kernel and derived input vectors from the truncated basis of the first components. We can control the quality of the input representation by varying the relative inertia captured by the first components. We then build a Gaussian kernel based on these inputs.

Figures 3 and 4 report respectively the averaged values and standard deviations for the AUC-ROC and AUC-PR obtained for different network densities and different percentages of labeled nodes in the transductive setting. IOKR-ridge corresponds to IOKR with a least-square loss and IOKR-margin to the hinge loss used in MMR. For these results, we used the components capturing 95% of the variance for defining the input vectors. We observe that IOKR-ridge outperforms IOKR-margin in the supervised and in the semi-supervised cases. This improvement is particularly significant for AUC-PR, especially when the network density is strong and the percentage of labeled data is high. It is thus very significant for 10% and 20% of labeled data. In the supervised case, this observation can be explained by the difference between the complexities of the models. As shown in Equation (13), the solution obtained in the supervised case writes as: $\kappa_{\tilde{y}}(u, u') = (\kappa_{x, U_{\ell}}^u)^T B^T K_Y B \kappa_{x, U_{\ell}}^{u'}$. In Table 2, we can see that the matrix B is only a diagonal matrix in the case of IOKR-margin while B is a full matrix for IOKR-ridge. This can also be seen in the dual optimization problem for a general loss function (see Appendix B), where we observe that the dual variables α_i are simply collinear to the vector \tilde{y}_i for IOKR-margin. The synthetic networks may therefore require a more complex predictor.

We observe an improvement of the performances in terms of AUC-ROC and AUC-PR for both approaches in the semi-supervised setting compared to the supervised setting. This improvement is more significant for IOKR-margin. This can be explained by the fact that the IOKR-margin models obtained in the supervised and in the semi-supervised cases do not have the same complexity. As shown in Table 2, the matrix B of the IOKR-margin model is a much richer matrix in the semi-supervised setting than in the supervised setting where it corresponds to a diagonal matrix. For IOKR-ridge, the improvement of the performance is only observed for low percentages of labeled data. We can therefore make the assumption that for this model, using unlabeled data increases the AUCs for low percentages of labeled data. But when enough information can be found in the labeled data, semi-supervised learning does not improve the performance. Based on these results, we can also formulate the assumption that link prediction is harder in the case of dense networks.

In Appendix C we experimented how the method behaves with perfect to noisy input features. We chose different levels of inertia (75%, 85%, 95% and 100%) for defining the input features. The results obtained with IOKR-ridge and IOKR-margin are shown in Table 8. We also include results on synthetic networks generated using mixtures of Erdős-Rényi random graphs in Table 9.

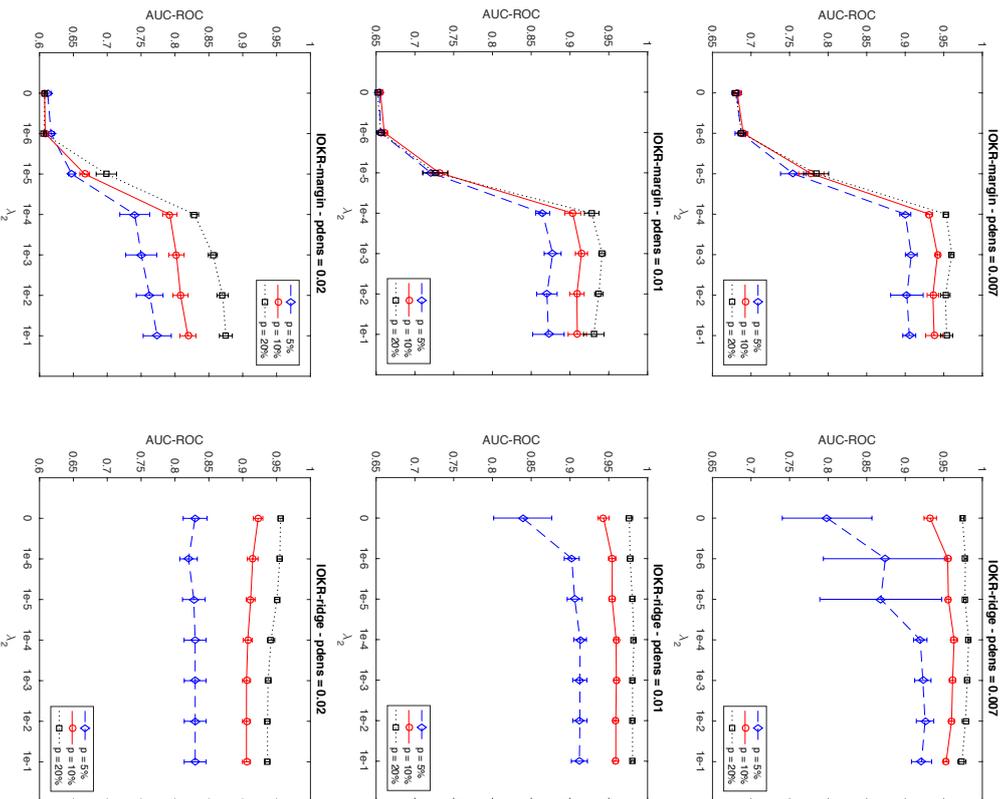

Figure 3: Averaged AUC-ROC for the reconstruction of three synthetic networks with IOKR-margin (left) and IOKR-ridge (right) in the transductive setting. The rows correspond to different graph densities (denoted pdens), which are 0.007, 0.01 and 0.02 respectively.

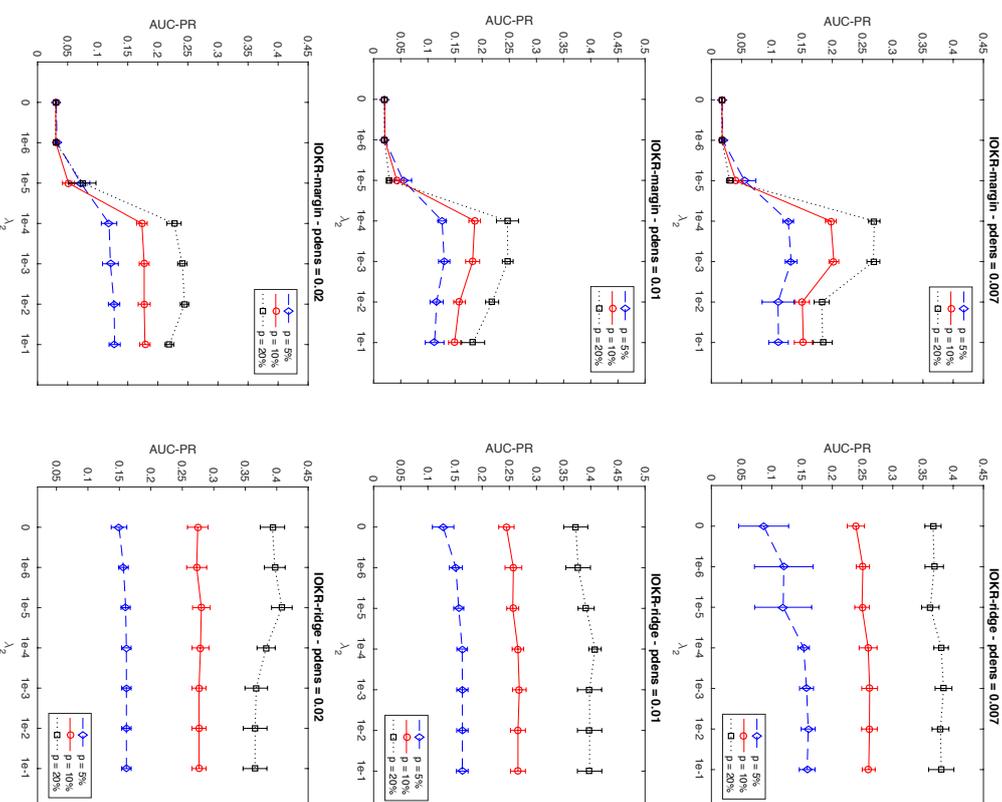

Figure 4: Averaged AUC-PR for the reconstruction of three synthetic networks with IOKR-margin (left) and IOKR-ridge (right) in the transductive setting. The rows correspond to different graph densities (denoted pdens), which are 0.007, 0.01 and 0.02 respectively.

6.1.3 NIPS CO-AUTHORSHIP NETWORK

We applied our method on a co-authorship network containing information on publications of the NIPS conferences between 1988 to 2003 (Globerson et al., 2007). In this network, vertices represent authors and an edge connects two authors if they have at least one NIPS publication in common. Among the 2865 authors, we considered the ones with at least two links in the co-authorship network in order to have a significant density and try to keep close to the original data. We therefore focused on a network containing 2026 authors with an empirical link density of 0.002. Each author was described by a vector of 14036 values, corresponding to the frequency with which he uses each given word in his papers.

Figure 5 reports the averaged AUC-ROC and AUC-PR obtained on the NIPS co-authorship network in the transductive setting for different values of λ_2 and different percentages of labeled nodes. As previously, we observe that the semi-supervised approach

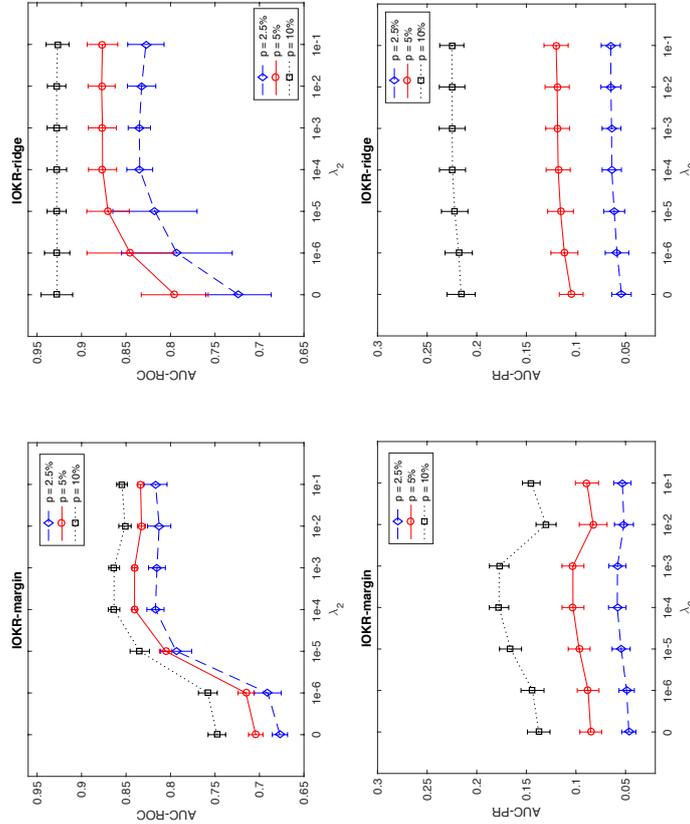

Figure 5: AUC-ROC and AUC-PR obtained for the NIPS co-authorship network inference with IOKR-margin (left) and IOKR-ridge (right) in the transductive setting.

p	AUC-ROC		AUC-PR			
	5%	20%	5%	20%		
Transductive setting						
EM	87.3 ± 2.4	92.9 ± 1.7	96.4 ± 0.8	13.8 ± 4.5	22.5 ± 6.6	41.1 ± 2.5
PKMR	85.7 ± 4.1	92.4 ± 1.6	96.4 ± 0.4	9.7 ± 2.8	20.0 ± 4.8	38.8 ± 2.0
IOKR	83.6 ± 5.9	93.6 ± 1.0	96.5 ± 0.4	12.0 ± 3.0	24.5 ± 2.9	43.7 ± 1.9
Semi-supervised setting						
IOKR	86.0 ± 2.7	93.3 ± 0.7	95.7 ± 1.4	7.6 ± 2.3	13.8 ± 1.7	25.3 ± 3.0

Table 3: AUC-ROC and AUC-PR obtained for the NIPS co-authorship network inference with EM, PKMR, IOKR in the transductive setting, and with IOKR in the semi-supervised setting. p indicates the percentage of labeled examples.

improves the performances compared to the supervised one for both models. For AUC-ROC values, this improvement is especially important when the percentage of labeled nodes is low. Indeed, with 2.5% of labeled nodes, the improvement can reach in average up to 0.14 points of AUC-ROC for IOKR-margin and up to 0.11 points for IOKR-ridge. As for the synthetic networks, the IOKR-ridge model outperforms IOKR-margin model in terms of AUC-ROC and AUC-PR, especially when the proportion of labeled examples is large. The explanation provided for the synthetic networks regarding the complexity of the solutions for IOKR-margin and IOKR-ridge holds here also. In the following, we will focus on IOKR-ridge only.

We compared IOKR-ridge with two transductive approaches: the EM-based approach (Tsuda et al., 2003; Kato et al., 2005) and Penalized Kernel Matrix Regression (PKMR) (Yamanishi and Vert, 2007). These two methods regard the link prediction problem as a kernel matrix completion problem. The EM method fills the missing entries of the output Gram matrix K_Y by minimizing the information geometry, as measured by the Kullback-Leibler divergence, with the input Gram matrix K_X . The PKMR approach considers the kernel matrix completion problem as a regression problem between the labeled input Gram matrix K_{Y_L} and the labeled output Gram matrix K_{Y_U} . We did not compare our method with the *Link Propagation* framework (Kashima et al., 2009) because this framework assumes that arbitrary interactions may be considered as labeled while IOKR requires a known subgraph. 500 examples were used for the test set and the remaining 1526 examples for the training set, which corresponds to the union of the labeled and unlabeled sets. For the labeled set we used 5%, 10% and 20% of the training examples and the left examples for the unlabeled set. We averaged the AUC over ten random partitions of the examples in labeled/unlabeled/test sets. The hyperparameters were selected by a 5-CV experiment on the labeled set for the three methods. The hyperparameters were selected separately for the AUC-ROC and the AUC-PR. For IOKR, we selected also the λ_2 parameter in this experiment, and we sparsified the matrix W in the semi-supervised constraint using 10% of the k -nearest-neighbors.

The results obtained for the comparison in the transductive and semi-supervised setting are reported in Table 3. Only the results for IOKR-ridge are reported in the semi-supervised

setting as the other methods are transductive. We observe that IOKR obtains better AUC-ROC and AUC-PR than EMI and PKMR when the percentage of labeled data is greater or equal than 10%. For 5% the best performing method is the EMI approach. Regarding the results of IOKR in the semi-supervised setting, we observe that the AUC-ROC results stay relatively similar compared to the transductive setting. However the AUC-PR values decrease significantly between the transductive and the semi-supervised settings. Considering the proteins for which we want to predict the interactions in the continuity constraint seems to help a lot the performances in term of AUC-PR.

6.1.4 PROTEIN-PROTEIN INTERACTION NETWORK

We also performed experiments on a protein-protein interaction (PPI) network of the yeast *Saccharomyces Cerevisiae*. This network was built using the DIP database (Salwinski et al., 2004), which contains protein-protein interactions that have been experimentally determined and manually curated. We used more specifically the high confidence DIP core subset of interactions (Deane et al., 2002). For the input kernels, we used the annotations provided by Gene Ontology (GO) (Ashburner et al., 2000) in terms of biological processes, cellular components and molecular functions. These annotations are organized in three different ontologies. Each ontology is represented by a directed acyclic graph, where each node is a GO annotation and edges correspond to relationships between the annotations, like sub-class relationships for example. A protein can be annotated to several terms in an ontology. We chose to represent each protein u_i by a vector s_i , whose dimension is equal to the total number of terms in the considered ontology. If a protein u_i is annotated by the term t , then :

$$s_i^{(t)} = -\ln \left(\frac{\text{number of proteins annotated by } t}{\text{total number of proteins}} \right).$$

This encoding allows to take into account the specificity of a term in the ontology. We then used these representations to build a Gaussian kernel for each GO ontology. By considering the set of proteins being annotated for each input kernel and being involved in at least one physical interaction, we obtained a PPI network containing 1242 proteins.

Based on the previous numerical results, we chose to consider only IOKR-ridge in the following experiments. We compared our approach to several supervised methods proposed for biological network inference:

- *Naive* (Yamanishi et al., 2004): this approach predicts an interaction between two proteins u and u' if $\kappa_{x_i}(u, u')$ is greater than a threshold θ .
- *kCCA* (Yamanishi et al., 2004): kernel CCA is used to detect correlations existing between the input kernel and a diffusion kernel derived from the adjacency matrix of the labeled PPI network.
- *kML* (Vert and Yamanishi, 2005): kernel Metric Learning consists in learning a new metric such that interacting proteins are close to each other, and conversely for non interacting proteins.
- *Local* (Bleakley et al., 2007): a local model is built for each protein in order to learn the subnetwork associated to each protein and these models are then combined together.

- *OK3+ET* (Gauts et al., 2006, 2007a): Output Kernel Tree with extra-trees is a tree-based method where the output is kernelized and is combined with ensemble methods.

The pairwise kernel method (Ben-Hur and Noble, 2005) was not considered here because this method requires to define a Gram matrix between pairs of nodes, which raises some practical issues in terms of computation time and storage. However we could have used an online implementation of the pairwise kernel method like the one used in Kashima et al. (2009) and thus avoid to store the large Gram matrix.

Each method was evaluated through a 5-fold cross-validation (5-CV) experiment and the hyperparameters were tuned on the training fold using a 4-CV experiment. As the local method can not be used for predicting interactions between two proteins of the test set, AUC-ROC and AUC-PR were only computed for the prediction of interactions between proteins in the test set and proteins in the training set. Input kernel matrices were defined for GO ontology and an integrated kernel, which was obtained by averaging the three input kernels, was also considered. Table 4 reports the results obtained for the comparison of the different methods in the supervised setting. We can see that output kernel regression based methods work better on this dataset than the other methods. In terms of AUC-ROC, the IOKR-ridge method obtains the best results for the four different input kernels, while for AUC-PR, OK3 with extra-trees presents better performances. We also compared the aver-

a) AUC-ROC:

Method	GO-BP	GO-CC	GO-MF	int
Naive	60.8 ± 0.8	64.4 ± 2.5	64.2 ± 0.8	67.7 ± 1.5
kCCA	82.4 ± 3.6	77.0 ± 1.7	75.0 ± 0.6	85.7 ± 1.6
kML	83.2 ± 2.4	77.8 ± 1.1	76.6 ± 1.9	84.5 ± 1.5
Local	79.5 ± 1.6	73.1 ± 1.3	66.8 ± 1.2	83.0 ± 0.5
OK3+ET	84.3 ± 2.4	81.5 ± 1.6	79.3 ± 1.8	86.9 ± 1.6
IOKR-ridge	88.8 ± 1.9	87.1 ± 1.3	84.0 ± 0.6	91.2 ± 1.2

b) AUC-PR:

Method	GO-BP	GO-CC	GO-MF	int
Naive	4.8 ± 1.0	2.1 ± 0.6	2.4 ± 0.4	8.0 ± 1.7
kCCA	7.1 ± 1.5	7.7 ± 1.4	4.2 ± 0.5	9.9 ± 0.4
kML	7.1 ± 1.3	3.1 ± 0.6	3.5 ± 0.4	7.8 ± 1.6
Local	6.0 ± 1.1	1.1 ± 0.3	0.7 ± 0.0	22.6 ± 6.6
OK3+ET	19.0 ± 1.8	21.8 ± 2.5	10.5 ± 2.0	26.8 ± 2.4
IOKR-ridge	15.3 ± 1.2	20.9 ± 2.1	8.6 ± 0.3	22.2 ± 1.6

Table 4: AUC-ROC and AUC-PR estimated by 5-CV for the yeast PPI network reconstruction in the supervised setting with different input kernels (*GO-BP*: GO biological processes; *GO-CC*: GO cellular components; *GO-MF*: GO molecular functions; *int*: average of the different kernels).

Method	Running time (s)
Naive	0.05 ± 0.01
kCCA	144.60 ± 70.70
kML	18.28 ± 0.78
Local	141.64 ± 14.91
OK3+ET	638.53 ± 69.09
IOKR-ridge	0.49 ± 0.02

Table 5: Averaged running time in seconds for one fold of the 5-CV for the yeast PPI network reconstruction in the supervised setting.

aged running time for one fold of the 5-CV for the different methods. These running times are shown in Table 5 and correspond to the times needed to perform both the training and the prediction steps. All the algorithms were implemented in Matlab and run on a MacBook Pro 2.4 GHz dual-core. For this computation, we fixed the values of the parameters and we did not take into account the computation of the input kernel. In Table 5 we observe that the running time of IOKR-ridge is relatively small compared to the other methods. The fastest method is the naive method. It can be explained by the fact that this method does not have a training step like the other methods. Interactions between two proteins are simply predicted if the proteins are similar according to the input kernel function.

As for the NIPS co-authorship network, we compared IOKR-ridge with the EM and PKMR approaches in the transductive setting. For this network, we used 300 examples for the test set and the remaining 942 examples for the training set. We used as input kernel the integrated kernel introduced in the supervised experiments. The results obtained for this comparison as well as the results for IOKR-ridge in the semi-supervised setting are reported in Table 6. Regarding the AUC-ROC, the EM approach obtains better results when the percentage of labeled data is equal to 5%. For 10% and 20% of labeled data, the difference between EM and IOKR-ridge is not significant. In terms of AUC-PR, EM achieves rather good performances compared to the others, especially for 5% and 10% of labeled data.

p	AUC-ROC			AUC-PR		
	5%	10%	20%	5%	10%	20%
Transductive setting						
EM	82.2 ± 0.6	82.9 ± 0.6	84.6 ± 0.6	15.7 ± 1.4	16.5 ± 2.7	19.7 ± 0.7
PKMR	77.5 ± 2.3	80.8 ± 1.1	83.9 ± 1.2	6.1 ± 1.5	9.8 ± 1.8	13.8 ± 1.2
IOKR	80.6 ± 0.7	83.1 ± 0.5	83.9 ± 0.5	7.1 ± 1.1	11.7 ± 1.1	17.8 ± 1.5
Semi-supervised setting						
IOKR	81.0 ± 1.1	82.9 ± 1.2	83.8 ± 1.0	6.6 ± 1.6	10.5 ± 1.3	16.0 ± 2.3

Table 6: AUC-ROC and AUC-PR obtained for the PPI network inference with EM, PKMR, IOKR in the transductive setting, and with IOKR in the semi-supervised setting.

p	5%	10%	20%
EM	0.19 ± 0.01	0.19 ± 0.00	0.22 ± 0.04
PKMR	0.16 ± 0.01	0.18 ± 0.00	0.19 ± 0.01
IOKR	1.61 ± 0.01	1.63 ± 0.01	1.76 ± 0.22

Table 7: Averaged running time in seconds of one repetition for the yeast PPI network reconstruction in the transductive setting.

However we can notice that the EM-based approach is purely transductive while IOKR-ridge learns a function and can therefore be used in the semi-supervised learning, which is more general. Regarding the IOKR-ridge results in the semi-supervised setting, we observe that the performances are very similar to the ones obtained in the transductive setting. We also compared in Table 7 the averaged running time for different percentages of labeled data. We can first observe that the three methods have a small running time (less than 2 seconds). EM and PKMR are a bit faster than IOKR-ridge as these methods require to inverse a matrix of size $\ell \times \ell$ while IOKR-ridge needs to inverse a matrix of size $(\ell+n) \times (\ell+n)$.

6.2 Application to Multi-Task Regression

In the following, we compare the behavior of the three models proposed for multi-task learning with IOKR in Section 5 on a drug activity prediction problem. The goal of this problem is to predict the activities of molecules in different cancer cell lines (cancer types). This problem has potential applications in cancer drug discovery. In this application, \mathcal{X} corresponds to the set of molecules and $\mathcal{Y} = \mathcal{F}_y = \mathbb{R}^d$, where d is the number of cell lines.

6.2.1 DATASET

We used the dataset of Su et al. (2010) that contains the biological activities of molecules against a set of 59 human cancer cell lines. These data have been extracted from the NCI-Cancer dataset. We used the "No-Zero-Active" version of the dataset which contains the 2303 molecules that are all active against at least one cell line. Each molecule is represented by a graph, where nodes correspond to atoms and edges to bonds between atoms. The Tanimoto kernel (Ralaivola et al., 2005) is used for the scalar input kernel:

$$\kappa_x(x, x') = \frac{k_m(x, x')}{k_m(x, x) + k_m(x', x') - k_m(x, x')}.$$

In this application, k_m is chosen as a linear path kernel. The corresponding input feature vectors $\varphi_{x_m}(x)$ are binary vectors that indicate the presences and absences in the molecules of all existing paths containing a maximum of m bonds. In this experiment, the value of m was set to 6.

6.2.2 PROTOCOL

We evaluated the behavior of the IOKR-ridge model in the transductive setting. The performances were measured by computing the mean squared error (MSE) on the unlabeled

set:

$$MSE = \frac{1}{n} \sum_{i=\ell+1}^{\ell+n} \|h(x_i) - \varphi_j(\mathbf{Y}^i)\|_2^2.$$

We estimated the task structure between the cancer types by comparing the molecular activities associated to each cancer type on the training set:

$$M_{ij} = \exp\left(-\gamma \|Y_\ell^i - Y_\ell^j\|^2\right), \quad i, j = 1, \dots, d,$$

where $Y_\ell^i = (\mathbf{Y}_1^i, \mathbf{Y}_2^i, \dots, \mathbf{Y}_\ell^i)$.

The parameter γ of the matrix M was chosen to maximize an information criterion and the regularization parameter λ_1 was set to 1. Regarding the matrix W used in the semi-supervised term, we sparsified the Gram matrix $K_{\ell+\ell+n}$ of the scalar input kernel κ_x using a k -nearest neighbors procedure with $k = 50$. We then computed the graph Laplacian of the obtained graph and considered the Laplacian iterated to degree 5.

6.2.3. RESULTS

The results presented in Figure 6 were obtained from ten random choices of the training set. The performances obtained with model 1 and model 2 for different percentages of labeled data are represented as a function of the parameters μ and λ_2 .

We observe on this figure that for both models, using unlabeled data helps to improve the performances. We also observe that when μ is increased from 0 to 0.8 or 1, the mean squared errors are decreased. The obtained results therefore show the benefit of taking into account the relationships existing between the outputs for both models and both settings (supervised and semi-supervised).

We reported on Figure 7 the MSE obtained with models 1 and 2 for the best parameter μ and added the results obtained with the model 0, which corresponds to the case where $A = I$. We observe on this figure that the model 2 obtains better results than the model 1 when the percentage of labeled data is small ($p = 5\%$). For $p = 10\%$, the two models behave similarly, while for 20% of labeled data, the model 1 improves significantly the performances, compared to model 2. Therefore, we observe that using the output structure information either in the input operator-valued kernel or in the output kernel leads to different results. And depending on the amount of labeled data, one of the two models can be more interesting to use.

7. Conclusion and Perspectives

Operator-valued kernels and the associated RKHS theory provide a general framework to address approximation of functions with values in some Hilbert space. When characterizing the output Hilbert space as a feature space related to some real-valued scalar kernel, we get an original framework to deal with structured outputs. Extending our previous work (Brouard et al., 2011) which introduced a new representer theorem for semi-supervised learning with vector-valued functions, we presented solutions of semi-supervised penalized regression developed for two empirical loss functions, the square loss and the hinge loss in the general case and in the special case of decomposable kernels using tensors. We also showed

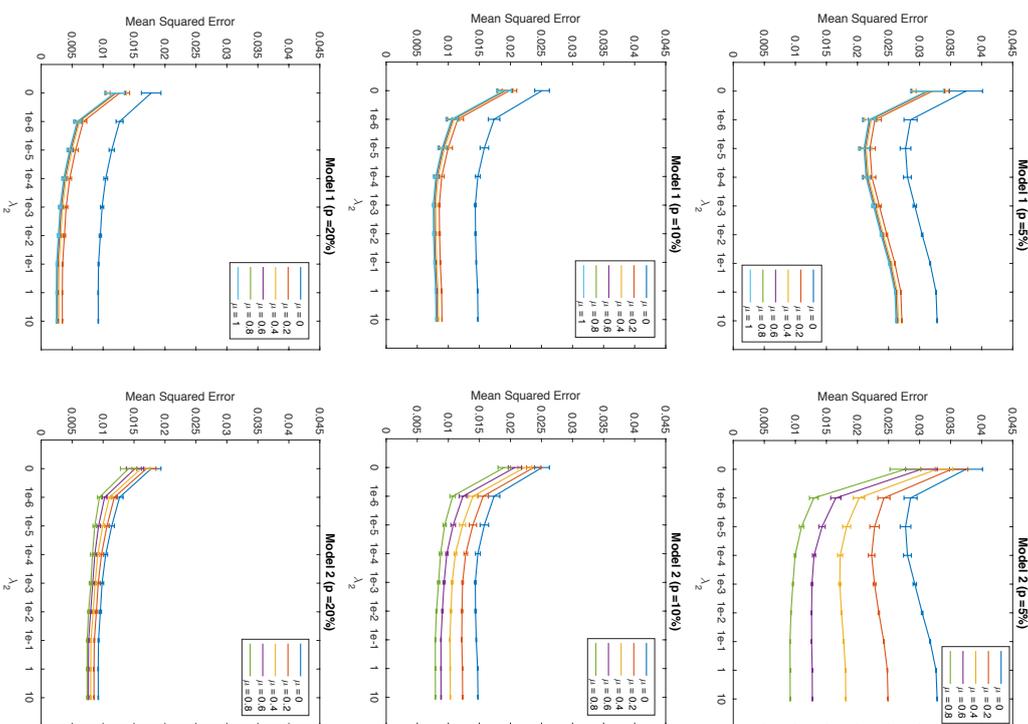

Figure 6: Mean squared errors obtained with the two models for the prediction of molecular activities. The results are averaged over ten random choices of the training set and are given for different percentages of labeled data (5%, 10% and 20%).

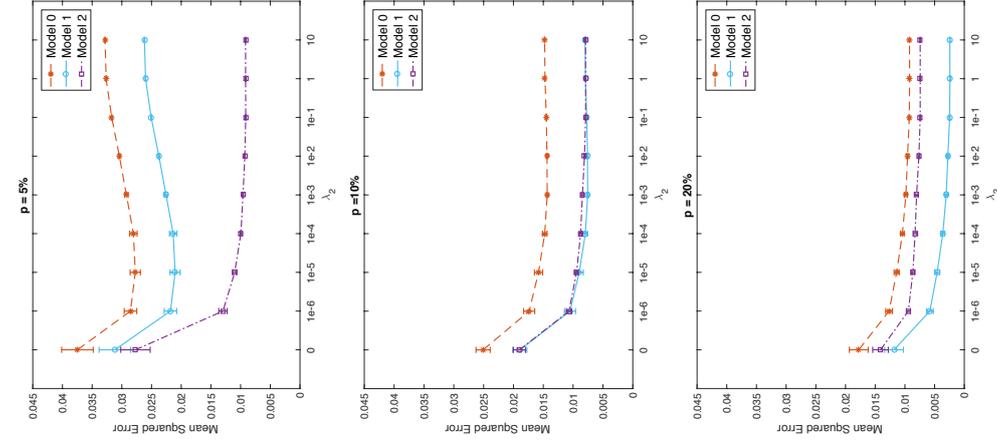

Figure 7: Mean squared errors obtained for the prediction of molecular activities for the model 0 (corresponding to $A = I$), model 1 ($\mu = 1$) and model 2 ($\mu = 0.8$). The results are averaged over ten random training sets and are given for different percentages of labeled data (5%, 10% and 20%).

that Generalized Cross-Validation extends in the case of the closed-form solution of IOKR-ridge, providing an efficient tool for model selection. Perspectives to this work concern the construction of new models by minimizing loss functions with different penalties, for instance, penalties that enforce the parsimony of the model. For these non-smooth penalties, proximal gradient descent methods can be applied such as in Lim et al. (2013). A more general research direction is related to the design of new kernels and appropriate kernel learning algorithms. Finally, although the pre-image problem has received a lot of attention in the literature, there is still room for improvement in order to apply IOKR in other tasks than link prediction or multiple output structured regression.

Acknowledgments

We thank the reviewers for their valuable comments. We are also grateful to Maxime Sangnier for his relevant comments about the paper. We would like to acknowledge support for this project from ANR (grant ANR-009-SYSC-009-02) and University of Evry (PhD grant).

Appendix A. Technical Proofs

In this appendix section, we provide the proofs for some theorems and propositions presented in the paper.

A.1 Proof of Theorem 7

We derive here the solution obtained for the Maximum Margin Regression optimization problem in the semi-supervised setting (Equation 8). We begin by writing the primal formulation of this optimization problem:

$$\begin{aligned} \min_{h \in \mathcal{H}, \xi \in \mathbb{R}^\ell} \quad & \lambda_1 \|h\|_{\mathcal{H}}^2 + 2\lambda_2 \sum_{i,j=1}^{\ell+n} L_{ij} \langle h(x_i), h(x_j) \rangle_{\mathcal{F}_y} + \sum_{i=1}^{\ell} \xi_i \\ \text{s.t.} \quad & \langle \tilde{y}_i, h(x_i) \rangle_{\mathcal{F}_y} \geq 1 - \xi_i, i = 1, \dots, \ell \\ & \xi_i \geq 0, i = 1, \dots, \ell. \end{aligned}$$

We write the corresponding Lagrangian:

$$\begin{aligned} \mathcal{L}_a(h, \xi, \alpha, \eta) = & \lambda_1 \|h\|_{\mathcal{H}}^2 + 2\lambda_2 \sum_{i,j=1}^{\ell+n} L_{ij} \langle h(x_i), h(x_j) \rangle_{\mathcal{F}_y} + \sum_{i=1}^{\ell} \xi_i \\ & - \sum_{i=1}^{\ell} \alpha_i (\langle \tilde{y}_i, h(x_i) \rangle_{\mathcal{F}_y} - 1 + \xi_i) - \sum_{i=1}^{\ell} \eta_i \xi_i. \end{aligned}$$

In the following we note $K_x = K_x(\cdot, \cdot)$ and $K_x^* = K_x(x, \cdot)$. By using the reproducing property the expression of the Lagrangian becomes:

$$\begin{aligned}
 \mathcal{L}_\alpha &= \lambda_1 \|h\|_{\mathcal{H}}^2 + 2\lambda_2 \sum_{i,j=1}^{\ell+n} L_{ij} \langle K_{x_i}^* h, K_{x_j}^* h \rangle_{\mathcal{H}} - \sum_{i=1}^{\ell} \alpha_i \langle \tilde{y}_i, K_{x_i}^* h \rangle_{\mathcal{H}} - 1 + \sum_{i=1}^{\ell} (1 - \alpha_i - \eta_i) \xi_i \\
 &= \langle (\lambda_1 I + 2\lambda_2) \sum_{i,j=1}^{\ell+n} L_{ij} K_{x_j} K_{x_i}^* \rangle h, h \rangle_{\mathcal{H}} - \sum_{i=1}^{\ell} \alpha_i \langle K_{x_i} \tilde{y}_i, h \rangle_{\mathcal{H}} + \sum_{i=1}^{\ell} \alpha_i + \sum_{i=1}^{\ell} (1 - \alpha_i - \eta_i) \xi_i \\
 &= \langle Bh, h \rangle_{\mathcal{H}} - \sum_{i=1}^{\ell} \alpha_i \langle K_{x_i} \tilde{y}_i, h \rangle_{\mathcal{H}} + \sum_{i=1}^{\ell} \alpha_i + \sum_{i=1}^{\ell} (1 - \alpha_i - \eta_i) \xi_i,
 \end{aligned}$$

where $B \in \mathcal{B}(h)$ is the operator defined as: $B = \lambda_1 I + 2\lambda_2 \sum_{i,j=1}^{\ell+n} L_{ij} K_{x_j} K_{x_i}^*$. Due to the symmetry of the Laplacian L , this operator is self-adjoint:

$$B^* = \lambda_1 I + 2\lambda_2 \sum_{i,j=1}^{\ell+n} L_{ij} K_{x_j} K_{x_i}^* = \lambda_1 I + 2\lambda_2 \sum_{i,j=1}^{\ell+n} L_{ij} K_{x_i} K_{x_j}^* = B.$$

Differentiating the Lagrangian with respect to ξ_i and h gives:

$$\begin{aligned}
 \frac{\partial \mathcal{L}_\alpha}{\partial \xi_i} &= 0 \Rightarrow 1 - \alpha_i - \eta_i = 0 \\
 \frac{\partial \mathcal{L}_\alpha}{\partial h} &= 0 \Rightarrow 2Bh - \sum_{i=1}^{\ell} \alpha_i K_{x_i} \tilde{y}_i = 0 \Rightarrow h = \frac{1}{2} B^{-1} \left(\sum_{i=1}^{\ell} \alpha_i K_{x_i} \tilde{y}_i \right).
 \end{aligned}$$

B is invertible as it is a positive definite operator:

$$\begin{aligned}
 \forall h \in \mathcal{H}, \langle h, Bh \rangle_{\mathcal{H}} &= \lambda_1 \|h\|_{\mathcal{H}}^2 + 2\lambda_2 \sum_{i,j=1}^{\ell+n} L_{ij} \langle h, K_{x_j} K_{x_i}^* h \rangle_{\mathcal{H}} \\
 &= \lambda_1 \|h\|_{\mathcal{H}}^2 + 2\lambda_2 \sum_{i,j=1}^{\ell+n} L_{ij} \langle h(x_j), h(x_i) \rangle_{\mathcal{F}_n} \\
 &= \lambda_1 \|h\|_{\mathcal{H}}^2 + \lambda_2 \sum_{i,j=1}^{\ell+n} W_{ij} \|h(x_j) - h(x_i)\|_{\mathcal{F}_n}^2 \\
 &> 0 \text{ for all non-zero function } h.
 \end{aligned}$$

The last inequality is deduced from the assumption that the values of W are non-negative. We formulate a reduced Lagrangian :

$$\begin{aligned}
 \mathcal{L}_\alpha(\alpha) &= \frac{1}{4} \sum_{i,j=1}^{\ell} \alpha_i \alpha_j \langle BB^{-1} K_{x_i} \tilde{y}_i, B^{-1} K_{x_j} \tilde{y}_j \rangle_{\mathcal{H}} - \frac{1}{2} \sum_{i,j=1}^{\ell} \alpha_i \alpha_j \langle K_{x_i} \tilde{y}_i, B^{-1} K_{x_j} \tilde{y}_j \rangle_{\mathcal{H}} + \sum_{i=1}^{\ell} \alpha_i \\
 &= -\frac{1}{4} \sum_{i,j=1}^{\ell} \alpha_i \alpha_j \langle K_{x_i} \tilde{y}_i, B^{-1} K_{x_j} \tilde{y}_j \rangle_{\mathcal{H}} + \sum_{i=1}^{\ell} \alpha_i.
 \end{aligned}$$

The dual formulation of the optimization problem (8) can thus be expressed as:

$$\begin{aligned}
 \min_{\alpha \in \mathbb{R}^{\ell}} \quad & \frac{1}{4} \sum_{i,j=1}^{\ell} \alpha_i \alpha_j \langle K_{x_i} \tilde{y}_i, B^{-1} K_{x_j} \tilde{y}_j \rangle_{\mathcal{H}} - \sum_{i=1}^{\ell} \alpha_i \\
 \text{s.t.} \quad & 0 \leq \alpha_i \leq 1, i = 1, \dots, \ell.
 \end{aligned}$$

This concludes the proof.

A.2 Proof of Proposition 9

We start from the expression of $\text{vec}(C_{\ell+n})$ given in Section 3.3 for the least-squares loss and replace A by its eigendecomposition:

$$\text{vec}(C_{\ell+n}) = (\lambda_1 I_{(\ell+n)d} + M \otimes A)^{-1} \text{vec}(\tilde{Y} \tilde{Y}^T),$$

where $M = (J^T J + 2\lambda_2 L) K X_{\ell+n}$.

We introduce the vec-permutation matrices P_{nm} and P_{mn} defined as:

$$\forall A \in \mathbb{R}^{m \times n}, \text{vec}(A^T) = P_{nm} \text{vec}(A) \text{ and } \text{vec}(A) = P_{mn} \text{vec}(A^T).$$

For any $m \times n$ matrix A and $p \times q$ matrix B ,

$$B \otimes A = P_{pm} (A \otimes B) P_{nq}.$$

Using these properties, we can write:

$$\begin{aligned}
 \text{vec}(C_{\ell+n}^T) &= P_{d(\ell+n)} \text{vec}(C_{\ell+n}) \\
 &= P_{d(\ell+n)} (\lambda_1 I_{(\ell+n)d} + P_{(\ell+n)d} (A \otimes M) P_{d(\ell+n)})^{-1} \text{vec}(\tilde{Y} \tilde{Y}^T) \\
 &= (\lambda_1 I_{(\ell+n)d} + P_{d(\ell+n)} P_{(\ell+n)d} (A \otimes M))^{-1} P_{d(\ell+n)} \text{vec}(\tilde{Y} \tilde{Y}^T) \\
 &= (\lambda_1 I_{(\ell+n)d} + A \otimes M)^{-1} \text{vec}(J^T \tilde{Y}^T) \\
 &= (\lambda_1 I_{(\ell+n)d} + ETE^T \otimes M)^{-1} \text{vec}(J^T \tilde{Y}^T).
 \end{aligned}$$

We multiply each side by $(E^T \otimes I_{\ell+n})$

$$\begin{aligned}
 (E^T \otimes I_{\ell+n}) \text{vec}(C_{\ell+n}^T) &= \\
 (E^T \otimes I_{\ell+n}) (\lambda_1 I_{(\ell+n)d} + (E \otimes I_{\ell+n})(\Gamma \otimes M)(E^T \otimes I_{\ell+n}))^{-1} \text{vec}(J^T \tilde{Y}^T).
 \end{aligned}$$

We use the facts that $\text{vec}(AXB) = (B^T \otimes I) \text{vec}(X)$ and that $E^T E = I_d$ to obtain the following equation:

$$\text{vec}(C_{\ell+n}^T E) = (\lambda_1 I_{(\ell+n)d} + \Gamma \otimes M)^{-1} \text{vec}(J^T \tilde{Y}^T E).$$

The matrix $(\lambda_1 I_{(\ell+n)d} + \Gamma \otimes M)$ being block-diagonal, we have

$$C_{\ell+n}^T \mathbf{e}_i = (\lambda_1 I_{\ell+n} + \gamma_i M)^{-1} J^T \tilde{Y}^T \mathbf{e}_i, \text{ for } i = 1, \dots, \ell + n.$$

Then, we can express the model h as:

$$\begin{aligned} \forall x \in \mathcal{X}, h(x) &= AC_{\ell+n} \mathbf{K}_{x_{\ell+n}}^{\mathbf{w}} = \sum_{j=1}^d \gamma_j \mathbf{e}_j \mathbf{e}_j^T C_{\ell+n} \mathbf{K}_{x_{\ell+n}}^{\mathbf{w}} \\ &= \sum_{j=1}^d \gamma_j \mathbf{e}_j \mathbf{e}_j^T \tilde{Y}_\ell J (\lambda_1 I_{\ell+n} + \gamma_j K_{X_{\ell+n}} (J^T J + 2\lambda_2 L))^{-1} \mathbf{K}_{X_{\ell+n}}^{\mathbf{w}}. \end{aligned}$$

In the supervised setting ($\lambda_2 = 0$), the model h writes as:

$$\forall x \in \mathcal{X}, h(x) = \sum_{j=1}^d \gamma_j \mathbf{e}_j \mathbf{e}_j^T \tilde{Y}_\ell (\lambda_1 I_\ell + \gamma_j K_{X_\ell})^{-1} \mathbf{K}_{X_\ell}^{\mathbf{w}}.$$

This completes the proof.

A.3 Proof of Proposition 10

Let $Z_\ell = \tilde{Y}_\ell \text{diag}(\boldsymbol{\alpha}) J$. We start from the expression of the Lagrangian in the case of a general operator-valued kernel (Equation 10) and replace A by its eigendecomposition:

$$\begin{aligned} \mathcal{L}_\alpha(\boldsymbol{\alpha}) &= -\frac{1}{4} \text{vec}(Z_\ell)^T (\lambda_1 I_{(\ell+n)d} + 2\lambda_2 K_{X_{\ell+n}} L \otimes A)^{-1} (K_{X_{\ell+n}} \otimes A) \text{vec}(Z_\ell) + \boldsymbol{\alpha}^T \mathbf{1} \\ &= -\frac{1}{4} \text{vec}(Z_\ell)^T (\lambda_1 I_{(\ell+n)d} + 2\lambda_2 (I_{\ell+n} \otimes E)(K_{X_{\ell+n}} L \otimes \Gamma)(I_{\ell+n} \otimes E^T))^{-1} \\ &\quad (I_{\ell+n} \otimes E)(K_{X_{\ell+n}} \otimes \Gamma)(I_{\ell+n} \otimes E^T) \text{vec}(Z_\ell) + \boldsymbol{\alpha}^T \mathbf{1}. \\ &= -\frac{1}{4} \text{vec}(E^T Z_\ell)^T (\lambda_1 I_{(\ell+n)d} + 2\lambda_2 K_{X_{\ell+n}} L \otimes \Gamma)^{-1} (K_{X_{\ell+n}} \otimes \Gamma) \text{vec}(E^T Z_\ell) + \boldsymbol{\alpha}^T \mathbf{1}. \end{aligned}$$

Using the vec-permutation matrices, we can show that:

$$\mathcal{L}_\alpha(\boldsymbol{\alpha}) = -\frac{1}{4} \text{vec}(Z_\ell^T E)^T (\lambda_1 I_{(\ell+n)d} + 2\lambda_2 \Gamma \otimes K_{X_{\ell+n}} L)^{-1} (\Gamma \otimes K_{X_{\ell+n}}) \text{vec}(Z_\ell^T E) + \boldsymbol{\alpha}^T \mathbf{1}.$$

As $(\lambda_1 I_{(\ell+n)d} + 2\lambda_2 \Gamma \otimes K_{X_{\ell+n}} L)$ is a block diagonal matrix, we can write:

$$\begin{aligned} \mathcal{L}_\alpha(\boldsymbol{\alpha}) &= -\frac{1}{4} \sum_{i=1}^d \mathbf{e}_i^T Z_\ell (\lambda_1 I_{\ell+n} + 2\lambda_2 \gamma_i K_{X_{\ell+n}} L)^{-1} \gamma_i K_{X_{\ell+n}} Z_\ell^T \mathbf{e}_i + \boldsymbol{\alpha}^T \mathbf{1} \\ &= -\frac{1}{4} \sum_{i=1}^d \gamma_i \text{trace}(\tilde{Y}_\ell \mathbf{e}_i \mathbf{e}_i^T \tilde{Y}_\ell \text{diag}(\boldsymbol{\alpha}) J (\lambda_1 I_{\ell+n} + 2\lambda_2 \gamma_i K_{X_{\ell+n}} L)^{-1} K_{X_{\ell+n}} J^T \text{diag}(\boldsymbol{\alpha})) \\ &\quad + \boldsymbol{\alpha}^T \mathbf{1}. \end{aligned}$$

Using the fact that $\mathbf{y}^T (A \circ B) \mathbf{x} = \text{trace}(\text{diag}(\mathbf{y})^T A \text{diag}(\mathbf{x}) B^T)$, the Lagrangian can be written as:

$$\mathcal{L}_\alpha(\boldsymbol{\alpha}) = -\frac{1}{4} \sum_{i=1}^d \gamma_i \boldsymbol{\alpha}^T (\tilde{Y}_\ell^T \mathbf{e}_i \mathbf{e}_i^T \tilde{Y}_\ell \circ J (\lambda_1 I_{\ell+n} + 2\lambda_2 \gamma_i K_{X_{\ell+n}} L)^{-1} K_{X_{\ell+n}} J^T) \boldsymbol{\alpha} + \boldsymbol{\alpha}^T \mathbf{1}.$$

In the supervised setting ($\lambda_2 = 0$), the Lagrangian becomes:

$$\begin{aligned} \mathcal{L}_\alpha(\boldsymbol{\alpha}) &= -\frac{1}{4\lambda_1} \sum_{i=1}^d \gamma_i \boldsymbol{\alpha}^T (\tilde{Y}_\ell^T \mathbf{e}_i \mathbf{e}_i^T \tilde{Y}_\ell \circ K_{X_\ell}) \boldsymbol{\alpha} + \boldsymbol{\alpha}^T \mathbf{1} \\ &= -\frac{1}{4\lambda_1} \boldsymbol{\alpha}^T (\tilde{Y}_\ell^T A \tilde{Y}_\ell \circ K_{X_\ell}) \boldsymbol{\alpha} + \boldsymbol{\alpha}^T \mathbf{1}, \end{aligned}$$

which concludes the proof.

Appendix B. Dual Optimization Problem for a General Convex Loss Function

In this appendix we derive the dual optimization problem for a general convex loss function in the supervised and semi-supervised settings using the Fenchel duality.

B.1 Supervised Setting

We consider the following optimization problem where the cost function $\mathcal{L} : \mathcal{F}_y \times \mathcal{F}_y \rightarrow \mathbb{R}$ is convex in its first variable:

$$\min_{h \in \mathcal{H}} \sum_{i=1}^{\ell} \mathcal{L}(h(x_i), \tilde{\mathbf{y}}_i) + \lambda \|h\|_{\mathcal{H}}^2.$$

It can be rewritten by introducing the constraint $\mathbf{u}_i = h(x_i)$ and the function $\mathcal{L}_i : \mathcal{F}_y \rightarrow \mathbb{R}$ defined as $\mathcal{L}_i(\mathbf{u}_i) = \mathcal{L}(\mathbf{u}_i, \tilde{\mathbf{y}}_i)$ for $i \in [1, \ell]$:

$$\begin{aligned} \min_{h \in \mathcal{H}, \{\mathbf{u}_i \in \mathcal{F}_y\}_{i=1}^{\ell}} \quad & \sum_{i=1}^{\ell} \mathcal{L}_i(\mathbf{u}_i) + \lambda \|h\|_{\mathcal{H}}^2 \\ \text{s.t.} \quad & \mathbf{u}_i = h(x_i), \quad i = 1, \dots, \ell. \end{aligned}$$

We write the expression of the Lagrangian:

$$\begin{aligned} \mathcal{L}_\alpha(h, \mathbf{u}_i, \boldsymbol{\alpha}_i) &= \sum_{i=1}^{\ell} \mathcal{L}_i(\mathbf{u}_i) + \lambda \|h\|_{\mathcal{H}}^2 + \sum_{i=1}^{\ell} \langle \boldsymbol{\alpha}_i, \mathbf{u}_i - h(x_i) \rangle_{\mathcal{F}_y} \\ &= \sum_{i=1}^{\ell} \mathcal{L}_i(\mathbf{u}_i) + \lambda \|h\|_{\mathcal{H}}^2 + \sum_{i=1}^{\ell} \langle \boldsymbol{\alpha}_i, \mathbf{u}_i \rangle_{\mathcal{F}_y} - \sum_{i=1}^{\ell} \langle \mathcal{K}_x(\cdot, x_i) \boldsymbol{\alpha}_i, h \rangle_{\mathcal{H}}. \end{aligned}$$

The dual function can be written:

$$\begin{aligned} g(\alpha) &= \inf_{h \in \mathcal{H}, \{\mathbf{u}_i \in \mathcal{F}_y\}_{i=1}^{\ell}} \left(\sum_{i=1}^{\ell} \mathcal{L}_i(\mathbf{u}_i) + \lambda \|h\|_{\mathcal{H}}^2 + \sum_{i=1}^{\ell} \langle \alpha_i, \mathbf{u}_i \rangle_{\mathcal{F}_y} - \sum_{i=1}^{\ell} \langle \mathcal{K}_x(\cdot, x_i) \alpha_i, h \rangle_{\mathcal{H}} \right) \\ &= \sum_{i=1}^{\ell} \inf_{\mathbf{u}_i \in \mathcal{F}_y} \left(\mathcal{L}_i(\mathbf{u}_i) + \langle \alpha_i, \mathbf{u}_i \rangle_{\mathcal{F}_y} \right) + \inf_h \left(\lambda \|h\|_{\mathcal{H}}^2 - \sum_{i=1}^{\ell} \langle \mathcal{K}_x(\cdot, x_i) \alpha_i, h \rangle_{\mathcal{H}} \right) \\ &= - \sum_{i=1}^{\ell} \sup_{\mathbf{u}_i \in \mathcal{F}_y} \left(-\mathcal{L}_i(\mathbf{u}_i) + \langle -\alpha_i, \mathbf{u}_i \rangle_{\mathcal{F}_y} \right) + \inf_h \left(\lambda \|h\|_{\mathcal{H}}^2 - \sum_{i=1}^{\ell} \langle \mathcal{K}_x(\cdot, x_i) \alpha_i, h \rangle_{\mathcal{H}} \right) \\ g(\alpha) &= - \sum_{i=1}^{\ell} \mathcal{L}_i^*(-\alpha_i) - \frac{1}{4\lambda} \sum_{i,j=1}^{\ell} \langle \alpha_i, \mathcal{K}_x(x_i, x_j) \alpha_j \rangle_{\mathcal{F}_y}, \end{aligned}$$

where \mathcal{L}_i^* denotes the convex conjugate, also called Fenchel conjugate, of the function \mathcal{L}_i :

$$\mathcal{L}_i^*(\alpha_i) = \sup_{\mathbf{u}_i \in \mathcal{F}_y} \langle \alpha_i, \mathbf{u}_i \rangle_{\mathcal{F}_y} - \mathcal{L}_i(\mathbf{u}_i)$$

and $h = \frac{1}{2\lambda} \sum_{i=1}^{\ell} \mathcal{K}_x(\cdot, x_i) \alpha_i$.

The dual optimization problem for a general convex loss function writes as follows:

$$\max_{\{\alpha_i \in \mathcal{F}_y\}_{i=1}^{\ell}} - \sum_{i=1}^{\ell} \mathcal{L}_i^*(-\alpha_i) - \frac{1}{4\lambda} \sum_{i,j=1}^{\ell} \langle \alpha_i, \mathcal{K}_x(x_i, x_j) \alpha_j \rangle_{\mathcal{F}_y}. \quad (14)$$

In the following, we derive it for the least-squares and the MMR loss functions.

B.1.1 LEAST-SQUARES LOSS

We compute the convex conjugate of the least-squares loss:

$$\mathcal{L}_i^*(-\alpha_i) = \sup_{\mathbf{u}_i \in \mathcal{F}_y} -\langle \alpha_i, \mathbf{u}_i \rangle_{\mathcal{F}_y} - \|\mathbf{u}_i - \tilde{\mathbf{y}}_i\|_{\mathcal{F}_y}^2.$$

By setting the derivative $\frac{\partial \mathcal{L}_i^*}{\partial \mathbf{u}_i}$ to 0 we find that $\mathbf{u}_i = \tilde{\mathbf{y}}_i - \frac{1}{2} \alpha_i$. By substituting we see that:

$$\mathcal{L}_i^*(-\alpha_i) = \frac{1}{4} \|\alpha_i\|_{\mathcal{F}_y}^2 - \langle \alpha_i, \tilde{\mathbf{y}}_i \rangle_{\mathcal{F}_y}.$$

We replace the expression of $\mathcal{L}_i^*(-\alpha_i)$ in the dual problem:

$$\max_{\{\alpha_i \in \mathcal{F}_y\}_{i=1}^{\ell}} - \frac{1}{4} \sum_{i=1}^{\ell} \|\alpha_i\|_{\mathcal{F}_y}^2 + \sum_{i=1}^{\ell} \langle \alpha_i, \tilde{\mathbf{y}}_i \rangle_{\mathcal{F}_y} - \frac{1}{4\lambda} \sum_{i,j=1}^{\ell} \langle \alpha_i, \mathcal{K}_x(x_i, x_j) \alpha_j \rangle_{\mathcal{F}_y}.$$

We derive with respect to α_i , $i = 1, \dots, \ell$ and find that the solution of the dual optimization problem satisfy the following equations:

$$\sum_{j=1}^{\ell} (\mathcal{K}_x(x_i, x_j) + \lambda \delta_{ij}) \alpha_j = 2\lambda \tilde{\mathbf{y}}_i, \quad i = 1, \dots, \ell.$$

B.1.2 MAXIMUM MARGIN REGRESSION

We compute the convex conjugate function of the MMR loss using the Lagrange technique:

$$\begin{aligned} -\mathcal{L}_i^*(-\alpha_i) &= - \sup_{\mathbf{u}_i \in \mathcal{F}_y} \{ -\langle \alpha_i, \mathbf{u}_i \rangle_{\mathcal{F}_y} - \max(0, 1 - \langle \tilde{\mathbf{y}}_i, \mathbf{u}_i \rangle_{\mathcal{F}_y}) \} \\ &= \inf_{\mathbf{u}_i \in \mathcal{F}_y, \xi_i \in \mathbb{R}} \{ \langle \alpha_i, \mathbf{u}_i \rangle_{\mathcal{F}_y} + \xi_i \} \\ &= \inf_{\xi_i \geq 0, \xi_i \geq 1 - \langle \tilde{\mathbf{y}}_i, \mathbf{u}_i \rangle_{\mathcal{F}_y}} \{ \langle \alpha_i, \mathbf{u}_i \rangle_{\mathcal{F}_y} + \xi_i \} \\ &= \sup_{\beta_i, \eta_i \geq 0} \left\{ \inf_{\mathbf{u}_i \in \mathcal{F}_y, \xi_i \in \mathbb{R}} \{ \langle \alpha_i, \mathbf{u}_i \rangle_{\mathcal{F}_y} + \xi_i + \beta_i (1 - \langle \tilde{\mathbf{y}}_i, \mathbf{u}_i \rangle_{\mathcal{F}_y} - \xi_i) - \eta_i \xi_i \} \right\} \\ &= \sup_{\beta_i, \eta_i \geq 0} \left\{ \inf_{\mathbf{u}_i \in \mathcal{F}_y} \{ \langle \alpha_i, \mathbf{u}_i \rangle_{\mathcal{F}_y} - \beta_i \langle \tilde{\mathbf{y}}_i, \mathbf{u}_i \rangle_{\mathcal{F}_y} \} + \inf_{\xi_i \in \mathbb{R}} \{ \xi_i - \beta_i \xi_i - \eta_i \xi_i \} + \beta_i \right\} \\ &= \sup_{\substack{0 \leq \beta_i \leq 1 \\ \alpha_i = \beta_i \tilde{\mathbf{y}}_i}} \beta_i. \end{aligned}$$

This means that $-\mathcal{L}_i^*(-\alpha_i) = \beta_i$ at the condition that $\alpha_i = \beta_i \tilde{\mathbf{y}}_i$ and $0 \leq \beta_i \leq 1$. Otherwise it is unbounded. We replace in the dual problem in Equation (14):

$$\max_{\beta_i \in \mathbb{R}^{\ell}} \sum_{i=1}^{\ell} \beta_i - \frac{1}{4\lambda} \sum_{i,j=1}^{\ell} \beta_i \beta_j \langle \tilde{\mathbf{y}}_i, \mathcal{K}_x(x_i, x_j) \tilde{\mathbf{y}}_j \rangle_{\mathcal{F}_y} \quad \text{s.t.} \quad 0 \leq \beta_i \leq 1, \quad i = 1, \dots, \ell.$$

B.2 Semi-supervised Setting

In the semi-supervised setting, the optimization problem can be written as:

$$\min_{h \in \mathcal{H}, \{\mathbf{u}_i \in \mathcal{F}_y\}_{i=1}^{\ell}} \sum_{i=1}^{\ell} \mathcal{L}(\mathbf{u}_i, \tilde{\mathbf{y}}_i) + \lambda_1 \|h\|_{\mathcal{H}}^2 + 2\lambda_2 \sum_{i,j=1}^{\ell+n} L_{ij} \langle h(x_i), h(x_j) \rangle_{\mathcal{H}} \quad \text{s.t.} \quad \mathbf{u}_i = h(x_i), \quad i = 1, \dots, \ell.$$

We write the expression of the dual function:

$$\begin{aligned} g(\alpha) &= \inf_{h \in \mathcal{H}} \sum_{i=1}^{\ell} \mathcal{L}(\mathbf{u}_i, \tilde{\mathbf{y}}_i) + \lambda_1 \|h\|_{\mathcal{H}}^2 + 2\lambda_2 \sum_{i,j=1}^{\ell+n} L_{ij} \langle h(x_i), h(x_j) \rangle_{\mathcal{H}} + \sum_{i=1}^{\ell} \langle \alpha_i, \mathbf{u}_i - h(x_i) \rangle_{\mathcal{F}_y} \\ &= - \sum_{i=1}^{\ell} \mathcal{L}_i^*(-\alpha_i) + \inf_{h \in \mathcal{H}} \left(\langle B \mathbf{1}_\ell, h \rangle_{\mathcal{H}} - \sum_{i=1}^{\ell} \langle \mathcal{K}_x \alpha_i, h \rangle_{\mathcal{H}} \right), \end{aligned}$$

where $B \in \mathcal{B}(h)$ is the operator defined as: $B = \lambda_1 I + 2\lambda_2 \sum_{i,j=1}^{\ell+n} L_{ij} \mathcal{K}_x(\cdot, x_j) \mathcal{K}_x(x_i, \cdot)$.

By setting the derivative of the second term with respect to h to zero we find that: $h = \frac{1}{2} B^{-1} \left(\sum_{i=1}^{\ell} \mathcal{K}_x(\cdot, x_i) \alpha_i \right)$. The proof that B can be inverted was already given in Appendix A.1.

We replace in the dual function and obtain the following dual optimization problem:

$$\max_{\{\alpha_i \in \mathcal{F}_i\}_{i=1}^{\ell}} - \sum_{i=1}^{\ell} \mathcal{L}_i^*(-\alpha_i) - \frac{1}{4} \sum_{i,j=1}^{\ell} \langle K_{x_i} \alpha_i, B^{-1} K_{x_j} \alpha_j \rangle_{\mathcal{H}}.$$

Appendix C. Additional Results on Synthetic Networks

This appendix contains additional results on synthetic networks.

C.1 Influence of the Level of Inertia

We experimented how IOKR behaves with perfect to noisy input features on the synthetic networks. We modified the quality of the input representation by varying the relative inertia captured by the first components. We chose four different levels of inertia: 75%, 85%, 95% and 100%. The results obtained with IOKR-ridge and IOKR-margin are shown in Table 8.

For both methods we observe small differences in term of AUC-ROC when the inertia varies between 75% and 100%. On the other hand, there is more variation in the AUC-PR results, especially for a low graph density. The difference between the AUC-PRs for 75% and 100% of inertia increases when the percentage of labeled nodes is increased. Overall IOKR is robust to the noise level of the input data in all the cases for the AUC-ROC, and in the networks of density 0.01 and 0.02 for the AUC-PR.

C.2 Mixture of Erdős-Renyi Random Graphs

We generated synthetic networks using mixtures of Erdős-Renyi random graphs. The 700 nodes of the graphs were divided equally in three classes. We considered that the connection probability between a node belonging to the class i and a node in the class j can take two values:

$$\forall i, j \in \{1, \dots, 3\}, p_{i,j} = \begin{cases} p_{intra} & \text{if } i = j, \\ p_{inter} & \text{if } i \neq j. \end{cases}$$

We evaluated the performances of IOKR-ridge and IOKR-margin on these random networks for $p_{intra} \in \{0.02, 0.03\}$ and $p_{inter} \in \{5 * 10^{-4}, 10^{-3}\}$. The input vectors were derived from the diffusion kernel applied on the network as described in Section 6.1.2. These results are reported in Table 9. For IOKR-margin, we observe that the AUC values stay relatively similar for the different networks and also for the different percentage of labeled data. On the opposite, IOKR-ridge presents better performances when the inter-class connection probability is higher. As in Section 6.1.2, in which we noted that denser networks are more difficult to predict, we observe here that the AUC values decrease when the intra-class connection probability increases.

In Figure 8, we illustrate the fact that IOKR is able to recover the clusters present in a synthetic network ($p_{intra} = 0.02$, $p_{inter}=5e-4$). The true network is shown on the left and the network predicted with IOKR-ridge is shown on the right. The predicted network was obtained by thresholding the values in the predicted output kernel. The value of the threshold was selected with the other parameters on the training set such that it maximizes the F1-score value.

a) IOKR-ridge:

pdens	var %	nc	AUC-ROC			AUC-PR

Abstract

We consider the problem of recovering an invertible $n \times n$ matrix A and a sparse $n \times p$ random matrix X based on the observation of $Y = AX$ (up to a scaling and permutation of columns of A and rows of X). Using only elementary tools from the theory of empirical processes we show that a version of the Er-SpUD algorithm by Spielman, Wang and Wright with high probability recovers A and X exactly, provided that $p \geq Cn \log n$, which is optimal up to the constant C .

Keywords: sparse dictionaries, Er-SpUD algorithm, ℓ_1 minimization, exact recovery, sample complexity

1. Introduction

Recovery of sparsely-used dictionaries has recently attracted considerable attention in connection to applications in machine learning, signal processing or computational neuroscience. In particular, two important fields of applications are *dictionary learning* (Olshausen and Field, 1996; Kreutz-Delgado et al., 2003; Bruckstein et al., 2009; Rubinfeld et al., 2010; Yang et al., 2010) and *blind source separation* (Zibulevsky and Pearlmutter, 2001; Georgiev et al., 2005). We do not discuss these applications and refer the Reader to the aforesaid articles for details.

Among many approaches to this problem a particularly successful one has been presented by Spielman, Wang, and Wright (2012a,b), who considered the noiseless-invertible case:

The main problem:

Consider an invertible $n \times n$ matrix A and a random $n \times p$ sparse matrix X . Denote $Y = AX$. The objective is to reconstruct A and X (up to scaling and permutation of columns of A and rows of X) based on the observable data Y .

Spielman, Wang, and Wright (2012a,b) provide an algorithm which with high probability successfully recovers the matrices A and X up to rescaling and permutation of the columns

of A and rows of X , provided that X is a sparse random matrix satisfying the following probabilistic assumptions.

Probabilistic model specification

$$X = [X_{ij}]_{1 \leq i \leq n, 1 \leq j \leq p},$$

where

$$X_{ij} = \chi_{ij} R_{ij}$$

and

- χ_{ij}, R_{ij} are independent random variables,
- χ_{ij} are Bernoulli distributed: $\mathbb{P}(\chi_{ij} = 1) = 1 - \mathbb{P}(\chi_{ij} = 0) = \theta$,
- R_{ij} are i.i.d., with mean zero and satisfy

$$\mu := \mathbb{E}|R_{ij}| \geq 1/10,$$

$$\forall t > 0 \quad \mathbb{P}(|R_{ij}| \geq t) \leq 2e^{-t^2/2}.$$

Following Spielman, Wang, and Wright (2012a) we will say that matrices satisfying the above assumptions follow the Bernoulli-Subgaussian model with parameter θ .

We remark that the constant $1/10$ above is of no importance and has been chosen following Spielman, Wang, and Wright (2012a) and Luh and Vu (2016).

The approach of Spielman, Wang and Wright consists of two steps. At the first step (given by the Er-SpUD algorithm we describe below) one gathers $p/2$ candidates for the rows of X . The second, greedy step (Greedy algorithm, also described below) selects from the candidates the set of n sparse vectors, which form a matrix of rank n .

The algorithms work as follows:

ER-SpUD(DC): Exact Recovery of Sparsely-Used Dictionaries using the sum of two columns of Y as constraint vectors.

1. Randomly pair the columns of Y into $p/2$ groups $g_j = \{Y_{e_{j_1}}, Y_{e_{j_2}}\}$.
2. For $j = 1, \dots, p/2$
 Let $r_j = Y_{e_{j_1}} + Y_{e_{j_2}}$, where $g_j = \{Y_{e_{j_1}}, Y_{e_{j_2}}\}$.
 Solve $\min_w \|w^T Y\|_1$ subject to $r_j^T w = 1$, and set $s_j = w^T Y$.

Above we use the convention that if $r_j = 0$ (which happens with nonzero probability), and as a consequence the minimization problem has no solution, then we skip the corresponding step of the algorithm.

The second stage, described below, is run on the set S of vectors s_i returned at the first stage (for notational simplicity we relabel them if $r_j = 0$ for some j). We use the standard notation that $\|x\|_0$ denotes the number of nonzero coordinates of a vector x .

Greedy: A Greedy Algorithm to Reconstruct X and A .

1. **REQUIRE:** $S = \{s_1, \dots, s_T\} \subseteq \mathbb{R}^p$.
2. **For** $i = 1, \dots, n$
REPEAT
 $l \leftarrow \operatorname{argmin}_{s_i \in S} \|s_i\|_0$, **breaking ties arbitrarily**
 $x_i = s_l$, $S = S \setminus \{s_l\}$
UNTIL $\operatorname{rank}([x_1, \dots, x_i]) = i$
3. **Set** $X = [x_1, \dots, x_n]^T$ and $A = YY^T(XY^T)^{-1}$.

Spielman, Wang, and Wright (2012a) have proved that there exist positive constants C, α , such that if

$$\frac{2}{n} \leq \theta \leq \frac{\alpha}{\sqrt{n}}$$

and $p \geq Cn^2 \log^2 n$, then the ER-SpUD algorithm successfully recovers the matrices A, X with probability at least $1 - \frac{1}{Cnp}$. Note that the equation $Y = AX'$ still holds if we set $A' = A\Pi A$ and $X' = A^{-1}\Pi^T X$ for some permutation matrix Π and a nonsingular diagonal matrix A . Therefore, by recovery we mean that nonzero multiples of all the rows of X are among the set $\{s_1, \dots, s_{n/2}\}$ produced by the ER-SpUD(DC) algorithm. In (Spielman, Wang, and Wright, 2012a) it is also proved that if $\mathbb{P}(R_{ij} = 0) = 0$, then for $p > Cn \log n$, with probability $1 - C'n \exp(-c\theta p)$ for any matrices A', X' such that $Y = A'X'$ and $\max_i \|e_i^T X'\|_0 \leq \max_i \|e_i^T X\|_0$ there exists a permutation matrix Π and a nonsingular diagonal matrix A such that $A' = A\Pi A$, $X' = A^{-1}\Pi^T X$. In fact, Spielman, Wang, and Wright (2012a) prove that with the above probability any row of X is nonzero and has at most $(10/9)\theta p$ nonzero entries, whereas any linear combination of two or more rows of X has at least $(11/9)\theta p$ nonzero entries.

In particular it follows that the Greedy algorithm will extract from the set $\{s_1, \dots, s_T\}$ multiples of all n rows of X (note that all s_j 's are in the row space of Y and thus also in the row space of X). Since X is with high probability of rank n , one easily shows that one can recover A by the formula used in the 3rd step of the algorithm. We remark that Luh and Vu (2016) obtained the same results concerning sparsity of linear combinations of rows of X without the assumptions about the symmetry of the variables R_{ij} .

Note also that for θ of the order n^{-1} , $p = Cn \log n$ is necessary for uniqueness of the solution in the sense described above, otherwise with significant probability some of the rows of X may be zero, which means that some columns of A do not influence the matrix Y .

In (Spielman, Wang, and Wright, 2012a) it is also proved that if $p > Cn \log n$, $\theta > C\sqrt{\frac{\log n}{n}}$, then with high probability the ER-SpUD algorithm does not recover any of the rows of X .

Spielman, Wang and Wright have conjectured that their algorithm works with high probability provided that $p > Cn \log n$ (which, as mentioned above is required for well-posedness of the problem).

In this note we will consider a modified version of the algorithm with a slightly different first stage. Namely, instead of using only $p/2$ pairs of columns of Y , we will use all $\binom{p}{2}$ pairs. For fixed p it clearly increases the time complexity of the algorithm (which however remains polynomial), but the advantage of this modification is the possibility of proving that it requires only $p = Cn \log n$ to recover X and A with high probability, which as explained above is optimal. More specifically, we will consider the following algorithm.

Modified ER-SpUD(DC): Exact Recovery of Sparsely-Used Dictionaries using the sum of two columns of Y as constraint vectors.

- For** $i = 1, \dots, p - 1$
For $j = i + 1, \dots, p$
 Let $r_{ij} = Y e_j + Y e_i$
 Solve $\min_w \|w^T Y\|_1$ subject to $r_{ij}^T w = 1$, and set $s_{ij} = w^T Y$.

The final step of the recovery algorithm is again a greedy selection of the sparsest vectors among the candidates collected at the first step. As before, under the assumption $\mathbb{P}(R_{ij} = 0) = 0$, the greedy procedure successfully recovers X and A , provided that multiples of all the rows of X are present among the input set S .

The main result of this note is

Theorem 1 *There exist absolute constants $C, \alpha \in (0, \infty)$ such that if*

$$\frac{2}{n} \leq \theta \leq \frac{\alpha}{\sqrt{n}}$$

and X follows the Bernoulli-Subgaussian model with parameter θ , then for $p \geq Cn \log n$, with probability at least $1 - 1/p$ the modified ER-SpUD(DC) algorithm successfully recovers all the rows of X , i.e., multiples of all the rows of X are present among the vectors s_{ij} returned by the algorithm.

Remark on the single column algorithm. Spielman, Wang, and Wright (2012a,b) proposed also a version of the ER-SpUD algorithm, which instead of sums of two columns of Y as the vectors r_j in the constraints $r_j^T w = 1$ of the optimization problem, chooses simply consecutive columns of Y . They prove that such a version of the algorithm performs well under the assumption that the random variables X_{ij} are i.i.d. standard Gaussian variables, $2/n \leq \theta \leq \alpha/\sqrt{n \log n}$ and $p > Cn^2 \log^2 n$ (α, C are again universal constants). We remark that by using our approach in combination with the original arguments of Spielman, Wang, and Wright (2012a) one can prove that this algorithm works for $p > Cn \log^3 n$. To this end

one needs to prove a counterpart of our Lemma 3 (see below) with the vectors b_{ij} replaced just by the columns of the matrix X and combine it with Lemma 12 of Spielman, Wang, and Wright (2012a) (Lemma 6 below) in exactly the same way as in Section B.3. of (Spielman, Wang, and Wright, 2012a) (with $\gamma \simeq 1/\log n$). The needed counterpart of Lemma 3 can be obtained just by formal changes from the proof we present below. The factor $\log^3 n$ (instead of $\log n$) is related to the use of Lemma 12 and is a consequence of the fact that one takes γ depending on n).

Remarks on recent developments Very recently Sun, Qing, and Wright (2015) proposed an algorithm with polynomial sample complexity, which recovers well conditioned dictionaries under the assumption that the variables R_{ij} are i.i.d. standard Gaussian and $\theta \leq 1/2$, thus allowing for the first time for a linear number of nonzero entries per column of the matrix X . Their novel approach is based on non-convex optimization. The sample complexity of the algorithms in (Sun, Qing, and Wright, 2015) is however higher than for the Er-SpUD algorithm; as mentioned by the Authors, numerical simulations suggest that it is at least $p = \Omega(n^2 \log n)$ even in the case of orthogonal matrix A . Sun, Qing, and Wright (2015) conjecture that algorithms with sample complexity $p = O(n \log n)$ should be possible also for large θ .

As for the complexity of the Er-SpUD algorithm (in its original version), the recent article (Luh and Vu, 2016) contains a claim that it works for $p > Cn \log^4 n$, which differs from the number of samples conjectured by Spielman, Wang, and Wright (2012a) just by a polylogarithmic factor. However, as pointed out very recently (after the submission of the first version of this article) by Blasiok and Nelson (2016), the argument of Luh and Vu (2016) contains certain inaccuracies. Moreover, Blasiok and Nelson have proved that if the variables R_{ij} are Rademachers, than for the original version of the Er-SpUD algorithm to work one needs $p \geq n^{1.99}$, which shows that the result of Luh and Vu (2016) and in fact the original conjecture do not hold. Blasiok and Nelson also propose a modified version of the algorithm (in the same spirit as in this article) and prove that it works with probability $1 - \varepsilon$ for $p > Cn \log(Cn/\varepsilon)$, thus obtaining an independent proof of our main result. We remark that while certain aspects of the analysis are common for (Blasiok and Nelson, 2016) and the present article, the main technical ingredient (i.e., bounding the empirical process involved in the estimates) is approached differently. While Proposition 2 below is based on the contraction principle, Blasiok and Nelson (2016) rely on the generic chaining (majorizing measure) method, see (Talagrand, 2014). Let us also remark that it seems that by combining the inequality for empirical processes obtained by Luh and Vu (2016) with the approach of this paper or of (Blasiok and Nelson, 2016) one can prove a weaker result, namely that the modified version of the algorithm works for $p > Cn \log^4 n$.

2. Proof of Theorem 1

We will follow the general approach proposed by Spielman, Wang, and Wright (2012a). The main new part of the argument is an improved bound on the sample complexity for empirical approximation of first moments of arbitrary marginals of the columns of the matrix X , given in Proposition 2 below. So as not to reproduce technical and lengthy parts of the original proof, we organize this section as follows. First, we present the crucial Proposition 2 and provide a brief discussion of its mathematical content. Next, we present an overview of the

main steps in the proof scheme of Spielman, Wang, and Wright (2012a). For parts of the proof not related to Proposition 2 or to the modification of the algorithm considered here, we only indicate the relevant statements from (Spielman, Wang, and Wright, 2012a), while for parts involving the use of Proposition 2 and for the conclusion of the proof we provide the full argument. Proposition 2 is proved in Section 3.

Below by $\epsilon_1, \dots, \epsilon_N$ we will denote the standard basis in \mathbb{R}^N for various choices of N (in particular for $N = n$ and $N = p$). The value of N will be clear from the context and so this should not lead to ambiguity.

By B_1^n we will denote the unit ball in the space ℓ_1^n , i.e., $B_1^n = \{x \in \mathbb{R}^n : \|x\|_1 \leq 1\}$, where for $x = (x(1), \dots, x(n))$, $\|x\|_1 = \sum_{i=1}^n |x(i)|$. The coordinates of a vector x will be denoted by $x(i)$ or if it does not interfere with other notation (e.g. for indexed families of vectors) simply by x_i . Again, the meaning of the notation will be clear from the context. If Y is a random variable and $q > 0$, we denote $\|Y\|_q = (\mathbb{E}|Y|^q)^{1/q}$.

Proposition 2 *Let $U_1, U_2, \dots, U_p, \chi_1, \dots, \chi_p$ be independent random vectors in \mathbb{R}^n . Assume that for some constant M and all $1 \leq i \leq p, 1 \leq j \leq n$,*

$$\mathbb{E}e^{U_i(j)/M} \leq 2 \tag{1}$$

and

$$\mathbb{P}(\chi_i(j) = 1) = 1 - \mathbb{P}(\chi_i(j) = 0) = \theta.$$

Define the random vectors Z_1, \dots, Z_p with the equality $Z_i(j) = U_i(j)\chi_i(j)$ for $1 \leq i \leq p, 1 \leq j \leq n$ and consider the random variable

$$W := \sup_{x \in B_1^p} \left| \frac{1}{p} \sum_{i=1}^p (|x^T Z_i| - \mathbb{E}|x^T Z_i|) \right|. \tag{2}$$

Then, for some universal constant C and every $q \geq \max(2, \log n)$,

$$\|W\|_q \leq \frac{C}{p} (\sqrt{p\theta q} + q)M \tag{3}$$

and as a consequence

$$\mathbb{P}\left(W \geq \frac{C}{p} (\sqrt{p\theta q} + q)M\right) \leq e^{-q}. \tag{4}$$

The above proposition can be considered a quantitative version of the uniform law of large numbers for linear functionals $x^T Z$ indexed by the unit sphere in the space ℓ_1^p . As such it is a classical object of study in the theory of empirical processes. The proof we give uses only Bernstein's inequality, see e.g., (van der Vaart and Wellner, 1996), and Talagrand's contraction principle (Ledoux and Talagrand, 1991), which in a somewhat similar context was applied e.g., by Mendelson (2008); Adamczak et al. (2010).

Let us also remark that in the above proposition we do not require independence between components of the random vectors U_i or χ_i for fixed i , but just independence between the random vectors $U_i, \chi_i, i = 1, \dots, p$.

2.1 Main Steps of the Proof of Theorem 1

As announced, we will now present an outline of the proof of Theorem 1, indicating which steps differ from the original argument in (Spielman, Wang, and Wright, 2012a).

Step 1. A change of variables.

Recall that r_{ij} are sums of two columns of the matrix Y . At the first step of the proof, instead of looking at the original optimization problem

$$\text{minimize } \|w^T Y\|_1 \text{ subject to } r_{ij}^T w = 1 \quad (5)$$

one performs a change of variables $z = A^T w$, $b_{ij} = A^{-1} r_{ij}$, arriving at the optimization problem

$$\text{minimize } \|z^T X\|_1 \text{ subject to } b_{ij}^T z = 1. \quad (6)$$

Note that one cannot solve (6) since it involves the unknown matrices X and A . The goal of the subsequent steps is to prove that with probability sufficiently separated from zero the solution z_* of (6) is a multiple of one of the basis vectors e_1, \dots, e_n , say $z_* = \lambda e_k$. This means that $w_*^T Y = z_*^T X = \lambda e_k^T X$, i.e., (5) recovers the k -th row of X up to scaling. In combination with a coupon collector phenomenon this will allow to conclude that if p is sufficiently large, then all the rows will be recovered (this is the content of Step 4).

Step 2. If $0 < |(\text{supp } X_{e_j}) \cup (\text{supp } X_{e_j})| < 1/(8\theta)$, then $\text{supp } (z_*) \subseteq (\text{supp } X_{e_j}) \cup (\text{supp } X_{e_j})$.

At this step we prove the following lemma, which is a counterpart of Lemma 11 in (Spielman et al., 2012a). It is weaker in that we do not consider arbitrary vectors b_{ij} , but only sums of two distinct columns of X (which is enough for the application in the proof of Theorem 1). On the other hand it works already for $p > Cn \log n$ and not for $p > Cr^2 \log n$ as the original lemma from (Spielman, Wang, and Wright, 2012a).

Lemma 3 For $1 \leq i < j \leq p$, define $b_{ij} = X_{e_i} + X_{e_j}$, $I_{ij} = (\text{supp } X_{e_i}) \cup (\text{supp } X_{e_j})$.

There exist numerical constants $C, \alpha > 0$ such that if $2/n \leq \theta \leq \alpha/\sqrt{n}$ and $p > Cn \log n$, then with probability at least $1 - p^{-2}$ the random matrix X has the following property:

(P1) For every $1 \leq i < j \leq p$, if $0 < |I_{ij}| \leq 1/(8\theta)$ then every solution z_* to the optimization problem (6) satisfies $\text{supp } z_* \subseteq I_{ij}$.

Before we pass to the presentation of auxiliary facts needed in the proof of the above lemma, let us indicate briefly the two main observations behind the lemma, not present in (Spielman, Wang, and Wright, 2012a). The first one is Proposition 2, which allows to prove the technical Lemma 5 below. The second one is the fact that due to independence of the entries of the matrix we do not need to use the union bound over all possible locations of nonzero coefficients of X_{e_i} and X_{e_j} , instead we can condition on the disjoint events that $(\text{supp } X_{e_i}) \cup (\text{supp } X_{e_j}) = I$ (where I ranges over nonempty subsets of $[n]$ with $|I| \leq 1/(8\theta)$), estimate appropriate conditional probabilities and integrate the result over I .

To prove Lemma 3, one first shows a counterpart of Lemma 16 in (Spielman, Wang, and Wright, 2012a).

Lemma 4 For any $1 \leq j \leq p$, if $Z = (X_{1j} R_{1j}, \dots, X_{nj} R_{nj})$, then for all $v \in \mathbb{R}^n$,

$$\mathbb{E} \|v^T Z\| \geq \frac{\mu}{8} \sqrt{\frac{\theta}{n}} \|v\|_1.$$

Proof Let $\varepsilon_1, \dots, \varepsilon_n$ be a sequence of i.i.d. Rademacher variables, independent of $\{X_{ij}, R_{ij}\}$. By standard symmetrization inequalities, see e.g., Lemma 6.3. in (Ledoux and Talagrand, 1991),

$$\mathbb{E} \|v^T R\| = \mathbb{E} \left| \sum_{i=1}^n v_i X_{ij} R_{ij} \right| \geq \frac{1}{2} \mathbb{E} \left| \sum_{i=1}^n v_i \varepsilon_i X_{ij} R_{ij} \right|.$$

The random variables $\varepsilon_i R_{ij}$ are symmetric and $\mathbb{E} |\varepsilon_i R_{ij}| = \mu$, so by Lemma 16 from (Spielman, Wang, and Wright, 2012a), the right-hand side above is bounded from below by $\frac{\mu}{8} \sqrt{\frac{\theta}{n}} \|v\|_1$. ■

The next lemma is an improvement of Lemma 17 in (Spielman, Wang, and Wright, 2012a), which is crucial for obtaining Lemma 3.

Lemma 5 There exists an absolute constant C , such that the following holds for $p > Cn \log n$. Let $J \subseteq \{1, \dots, p\}$ be a fixed subset of size $|J| \leq \frac{p}{4}$. Let X_J be the submatrix of X , obtained by a restriction of X to the columns indexed by J . With probability at least $1 - p^{-8}$, for any $v \in \mathbb{R}^n$,

$$\|v^T X\|_1 - 2\|v^T X_J\|_1 > \frac{p\mu}{32} \sqrt{\frac{\theta}{n}} \|v\|_1.$$

Proof Note first that by increasing the set J , we increase $\|v^T X_J\|_1$, so without loss of generality we can assume that $|J| = \lfloor p/4 \rfloor$. Apply Proposition 2 with the vectors $U_j = (R_{1j}, \dots, R_{nj})$ and $X_j = (X_{1j}, \dots, X_{nj})$ and $q = 8 \log p$. Note that our integrability assumptions on R_{ij} imply (1) with M being a universal constant. Therefore, for some absolute constant C and $p \geq Cn \log n$, with probability at least $1 - p^{-8}$ we have

$$\begin{aligned} \sup_{v \in B_1^n} \left| \|v^T X\|_1 - \mathbb{E} \|v^T X\|_1 \right| &\leq C \sqrt{p\theta \log p} + \log p \leq 2C \sqrt{p\theta \log p}, \\ \sup_{v \in B_1^n} \left| \|v^T X_J\|_1 - \mathbb{E} \|v^T X_J\|_1 \right| &\leq 2C \sqrt{p\theta \log p}, \end{aligned}$$

where we used that for C sufficiently large, $p/\log p \geq n \geq 1/\theta$.

Thus, by homogeneity, with probability at least $1 - p^{-8}$, for all $v \in \mathbb{R}^n$,

$$\begin{aligned} \left| \|v^T X\|_1 - \mathbb{E} \|v^T X\|_1 \right| &\leq 2C \sqrt{p\theta \log p} \|v\|_1, \\ \left| \|v^T X_J\|_1 - \mathbb{E} \|v^T X_J\|_1 \right| &\leq 2C \sqrt{p\theta \log p} \|v\|_1. \end{aligned}$$

In particular this means that (using the notation of Proposition 2)

$$\begin{aligned} \|v^T X\|_1 &\geq \mathbb{E} \|v^T X\|_1 - 2C \sqrt{p\theta \log p} \|v\|_1 = p \mathbb{E} \|v^T Z\|_1 - 2C \sqrt{p\theta \log p} \|v\|_1, \\ 2\|v^T X_J\|_1 &\leq 2\mathbb{E} \|v^T X_J\|_1 + 4C \sqrt{p\theta \log p} \|v\|_1 = 2|J| \mathbb{E} \|v^T Z\|_1 + 4C \sqrt{p\theta \log p} \|v\|_1, \end{aligned}$$

and so

$$\begin{aligned} \|v^T X\|_1 - 2\|v^T X_J\|_1 &\geq (p-2|J|)\mathbb{E}\|v^T Z_1\| - 6C\sqrt{\theta p \log p}\|v\|_1. \\ \|v^T X\|_1 - 2\|v^T X_J\|_1 &\geq \left(\frac{p\mu}{16}\sqrt{\frac{\theta}{n}} - 6C\sqrt{\theta p \log p}\right)\|v\|_1 > \frac{p\mu}{32}\sqrt{\frac{\theta}{n}}\|v\|_1 \end{aligned}$$

Now, by Lemma 4 and the assumed bound on the cardinality of J , we get

■

for $p > C'n \log n$, where C' is another absolute constant.

We are now in position to prove Lemma 3.

Proof of Lemma 3 We will show that for each $1 \leq i < j \leq p$ the probability that $0 < |I_{ij}| \leq 1/(8\theta)$ and there exists a solution to (6) not supported on I_{ij} is bounded from above by $1/p^4$. This will imply the lemma, since by the union bound over all $i < j$,

$$\begin{aligned} \mathbb{P}(\text{Property P1 does not hold}) & \quad (7) \\ \leq \sum_{1 \leq i < j \leq p} \mathbb{P}(0 < |I_{ij}| \leq 1/(8\theta) \ \& \ \text{there exists a solution } z_* \text{ to (6) not supported on } I_{ij}). \end{aligned}$$

Let us thus fix i, j and let

$$S = \{I \in [p] : \exists_{k \in I_{ij}} X_{ki} \neq 0\}.$$

Moreover, for any set $I \subseteq [n]$, define the event

$$\mathcal{A}_I = \{I_{ij} = I\}.$$

By independence of the random variables R_{ij}, χ_{ij} , for each $k \notin \{i, j\}$, if $0 < |I| \leq 1/(8\theta)$, then

$$\mathbb{P}(k \in S | \mathcal{A}_I) \leq 1 - (1 - \theta)^{|I|} \leq 1 - e^{-2\theta|I|} \leq 1 - e^{-\frac{1}{4}} < \frac{1}{4},$$

where the second inequality holds if α is sufficiently small.

Thus, by independence of columns of X and Hoeffding's inequality, if $0 < |I| \leq 1/(8\theta)$, then

$$\mathbb{P}\left(|S \setminus \{i, j\}| \leq \frac{p-2}{4} \mid \mathcal{A}_I\right) \geq 1 - 2e^{-c\theta} \quad (8)$$

for some universal constant $c > 0$.

Let z_* be any solution of (6) and denote by z_0 its orthogonal projection on $\mathbb{R}^{I_{ij}} = \{x \in \mathbb{R}^n : x_k = 0 \text{ for } k \notin I_{ij}\}$. Set also $z_1 = z_* - z_0$ and let X_S, X_{S^c} be the matrices obtained from X by selecting the columns labeled by S and $S^c = [p] \setminus S$ respectively. By the triangle inequality, and the fact that $z_0^T X_{S^c} = 0$, we get

$$\begin{aligned} \|z_*^T X\|_1 &= \|(z_0^T + z_1^T)X_S\|_1 + \|(z_0^T + z_1^T)X_{S^c}\|_1 \\ &\geq \|z_0^T X_S\|_1 - \|z_1^T X_S\|_1 + \|z_1^T X\|_1 - \|z_1^T X_{S^c}\|_1 \\ &= \|z_0^T X\|_1 + (\|z_1^T X\|_1 - 2\|z_1^T X_S\|_1). \end{aligned} \quad (9)$$

For $J \subseteq [p] \setminus \{i, j\}$ define the events

$$\mathcal{S}_J = \{S \setminus \{i, j\} = J\}.$$

For the moment let us restrict our attention to the event $\mathcal{A}_I \cap \mathcal{S}_J$, for a fixed (but arbitrary) $I \subseteq [n]$, satisfying $0 < |I| \leq 1/(8\theta)$ and $J \subseteq [p] \setminus \{i, j\}$, satisfying $|J| \leq (p-2)/4$.

Denote by X' the $|I^c| \times (p-2)$ matrix obtained by restricting X to the rows from I^c and columns from $[p] \setminus \{i, j\}$. If, slightly abusing the notation, we identify z_1 with a vector from $\mathbb{R}^{|I^c|}$, on the event $\mathcal{A}_I \cap \mathcal{S}_J$ we have

$$\|z_1^T X\|_1 - 2\|z_1^T X_S\|_1 = \|z_1^T X'\|_1 - 2\|z_1^T X'_S\|_1 = \|z_1^T X'\|_1 - 2\|z_1^T X'_J\|_1, \quad (10)$$

where in the first equality we used the fact that $z_1^T X e_i = z_1^T X e_j = 0$ and the second one follows from the definition of the event \mathcal{S}_J .

Due to independence and identical distribution of the entries of X , conditionally on the event $\mathcal{A}_I \cap \mathcal{S}_J$ the matrix X' still follows the Bernoulli-Subgaussian model with parameter θ . This matrix is of size $|I^c| \times (p-2)$, therefore if the constant C' is large enough and $p > C'n \log n$, it satisfies the assumptions of Lemma 5 (with $p-2$ instead of p and $|I^c|$ instead of n). Since $|J| \leq (p-2)/4$, a conditional application of Lemma 5 gives

$$\begin{aligned} \mathbb{P}\left(\text{for all } v \in \mathbb{R}^{|I^c|} : \|v^T X'\|_1 - 2\|v^T X'_J\|_1 \geq \frac{(p-2)\mu}{32} \sqrt{\frac{\theta}{|I^c|}} \|v\|_1 \mid \mathcal{A}_I \cap \mathcal{S}_J\right) & \quad (11) \\ \geq 1 - (p-2)^{-8} \geq 1 - 2p^{-8}, \end{aligned}$$

where the last inequality holds for $p > C'$ and C' sufficiently large.

Note that by the definition of z_0 , we have $b_{ij}^T z_0 = b_{ij}^T z_* = 1$, therefore z_0 is a feasible candidate for the solution of the optimization problem (6). Thus, by (9) and (10), we have $\|z_1^T X'\|_1 - 2\|z_1^T X'_J\|_1 \leq 0$ and as a consequence, if $z_1 \neq 0$ then the event of inequality (11) does not hold. Thus, for $0 < |I| \leq 1/(8\theta)$ and $|J| \leq (p-2)/4$, we get

$$\mathbb{P}(\text{for some solution } z_* \text{ to (6), } z_1 \neq 0 \mid \mathcal{A}_I \cap \mathcal{S}_J) \leq 2p^{-8}. \quad (12)$$

We are now ready to finish the proof. To shorten the notation, let us denote

$$\mathcal{B} = \{\text{for some solution } z_* \text{ to (6), } z_1 \neq 0 \text{ and } 0 < |I_{ij}| \leq 1/(8\theta)\}.$$

By (8) we get

$$\begin{aligned} \mathbb{P}\left(\mathcal{B} \cap \{|S \setminus \{i, j\}| > (p-2)/4\}\right) &= \sum_{I \subseteq [n] : 0 < |I| \leq 1/(8\theta)} \mathbb{P}(\mathcal{B} \cap \mathcal{A}_I \cap \{|S'| > (p-2)/4\}) \\ &\leq \sum_{I \subseteq [n] : 0 < |I| \leq 1/(8\theta)} \mathbb{P}(\mathcal{A}_I \cap \{|S'| > (p-2)/4\}) \\ &= \sum_{I \subseteq [n] : 0 < |I| \leq 1/(8\theta)} \mathbb{P}(|S'| > (p-2)/4 \mid \mathcal{A}_I) \\ &\leq 2e^{-c\theta} \sum_{I \subseteq [n] : 0 < |I| \leq 1/(8\theta)} \mathbb{P}(\mathcal{A}_I) \leq 2e^{-c\theta}, \end{aligned}$$

where the second to last inequality follows from (8) and the last one from the pairwise disjointness of the events \mathcal{A}_I .

Similarly,

$$\begin{aligned} \mathbb{P}(\mathcal{B} \cap \{S \setminus \{i, j\}\}) &\leq (p-2)/4) = \sum_{\substack{J \subseteq [n]: \\ 0 < |J| \leq 1/(8\theta)}} \sum_{\substack{J \subseteq [p] \setminus \{i, j\}: \\ |J| \leq (p-2)/4}} \mathbb{P}(\mathcal{B} \cap \mathcal{A}_I \cap S_J) \\ &\leq \sum_{\substack{J \subseteq [n]: \\ 0 < |J| \leq 1/(8\theta)}} \sum_{\substack{J \subseteq [p] \setminus \{i, j\}: \\ |J| \leq (p-2)/4}} \mathbb{P}(\mathcal{B}_I \mathcal{A}_I \cap S_J) \mathbb{P}(\mathcal{A}_I \cap S_J) \\ &\leq 2p^{-8} \sum_{\substack{J \subseteq [n]: \\ 0 < |J| \leq 1/(8\theta)}} \sum_{\substack{J \subseteq [p] \setminus \{i, j\}: \\ |J| \leq (p-2)/4}} \mathbb{P}(\mathcal{A}_I \cap S_J) \leq 2p^{-8}, \end{aligned}$$

where we used (12) and disjointness of the events $\mathcal{A}_I \cap S_J$. Combining the two last inequalities, we get

$$\mathbb{P}(\mathcal{B}) \leq 2e^{-cp} + 2p^{-8} \leq p^{-4}$$

for $p > Cn \log n$ with a sufficiently large absolute constant C . By (7) this ends the proof of the lemma. \blacksquare

Step 3. If $(\text{supp } X_{e_j}) \cup (\text{supp } X_{e_j})$ is small, then $z_k = \lambda e_k$ where $k = \text{argmax}_{1 \leq i \leq n} |b_{ij}(t)|$.

At this step one proves the following lemma (Lemma 12 in Spielman, Wang, and Wright 2012a). Since no changes with respect to the original argument are required (we do not use Proposition 2 here), we do not reproduce the proof and refer the Reader to (Spielman, Wang, and Wright, 2012a) for details. We remark that although the lemma is formulated therein for symmetric variables, the symmetry assumption is not used in its proof.

Below, by $|b_1^\dagger| \geq |b_2^\dagger| \geq \dots \geq |b_n^\dagger|$ we denote the nonincreasing rearrangement of the sequence $|b_1|, \dots, |b_n|$, while for $J \subseteq [n]$, X^J denotes the matrix obtained from X by selecting the rows indexed by the set J .

Lemma 6 *There exist two positive constants c_1, c_2 such that the following holds. For any $\gamma > 0$ and $s \in \mathbb{Z}_+$, such that $\theta s < \gamma/8$ and p such that*

$$p \geq \max \left\{ \frac{c_1 s \log n}{\theta \gamma^2}, n \right\}, \quad \text{and} \quad \frac{p}{\log p} \geq \frac{c_2}{\theta \gamma^2},$$

with probability at least $1 - 4p^{-10}$, the random matrix X has the following property:

(P2) For every $J \subseteq [n]$ with $|J| = s$ and every $b \in \mathbb{R}^s$, satisfying $\frac{|b_i^\dagger|}{|b_i|} \leq 1 - \gamma$, the solution to the restricted problem

$$\text{minimize } \|z^T X^J\|_1 \text{ subject to } b^T z = 1, \quad (13)$$

is unique, 1-sparse, and is supported on the index of the largest entry of b .

Step 4. Conclusion of the proof.

Set $s = 12\theta n + 1$. Our first goal is to prove that with probability at least $1 - 1/p^2$, for all $k \in [n]$, there exist $i, j \in [p]$, $i \neq j$ such that the vector $b = X_{e_i} + X_{e_j}$ satisfies the assumptions of Lemma 6, $|b_1^\dagger| = |b_k|$ and $I_{ij} := (\text{supp } X_{e_i}) \cup (\text{supp } X_{e_j})$ satisfies $0 < |I_{ij}| \leq 1/(8\theta)$, which will allow us to take advantage of Lemma 3. This will already imply that the solution to the problem (6) for such i, j produces a multiple of the k -th row of X .

Note that we have

$$\mathbb{E} R_{ij}^2 \leq 4 \int_0^\infty t e^{-t^2/2} dt = 4.$$

Since $\mathbb{E}|R_{ij}| = \mu \geq \frac{1}{10}$, by the Paley-Zygmund inequality, see e.g., Corollary 3.3.2. in (de la Peña and Giné, 1999), we have

$$\mathbb{P}(|R_{ij}| \geq \frac{1}{20}) \geq \frac{3}{4} \frac{(\mathbb{E}|R_{ij}|)^2}{\mathbb{E} R_{ij}^2} \geq c_0$$

for some universal constant $c_0 > 0$. In particular $\mathbb{P}(|R_{ij}| = 0) < 1 - \frac{c_0}{2}$. Let q be any $(1 - c_0/(2s))$ -quantile of $|R_{ij}|$, i.e., $\mathbb{P}(|R_{ij}| \leq q) \geq (1 - c_0/(2s))$ and $\mathbb{P}(|R_{ij}| \geq q) \geq c_0/(2s)$. In particular, since $s \geq 1$, we get $q > 0$. We have $\mathbb{P}(R_{ij} \geq q) \geq c_0/(4s)$ or $\mathbb{P}(R_{ij} \leq -q) \geq c_0/(4s)$. Let us assume that $\mathbb{P}(R_{ij} \geq q) \geq c_0/(4s)$, the other case is analogous.

Before we proceed with the formal proof, which due to many events under consideration may appear technical, let us provide its informal description. Let us focus on a single value of k (at the end of the argument we will take a union bound over all $k \leq n$). We will first prove that among the first $p/2$ columns of the matrix X there is one (say X_{e_i}) which has few nonzero entries, the k -th entry exceeds the quantile q and all the other entries are smaller than q in the absolute value. This corresponds to the events \mathcal{E}_{ki} and \mathcal{A}_k considered below. Once we establish that this holds with high probability (equation (14)), we will fix a single column with this property (say with the smallest index) and will prove that conditionally on this event among the $p/2$ last columns of X we can find a column (say X_{e_j}) with the same properties and such that the only entry which is nonzero in both X_{e_i} and X_{e_j} is the k -th one (which corresponds to the event \mathcal{B}_k below and is the content of equation (17)). This will imply that

- the set I_{ij} satisfies the premises of Lemma 3 (it is nonempty and not too large),
- the k -th entry of $b_{ij} = X_{e_i} + X_{e_j}$ exceeds $2q$ while all the other entries are smaller than q in absolute value, which allows to use Lemma 6 with $\gamma = 1/2$.

Combining the two lemmas will allow us to conclude that the solution to (6) produces a nonzero multiple of e_k , i.e., the solution to (5) produces a nonzero multiple of the k -th row of X .

Establishing the aforesaid properties is not difficult and relies just on the independence of entries. In essence it can be reduced to saying that in a sequence of Bernoulli trials with probability of success equal to ρ , it is highly unlikely that we will have to wait much longer than $1/\rho$ for the first success. Specifically, if $\rho > c/n$, then under our assumptions on p , the probability that no success occurs in $p/2$ steps is smaller than $1/p^4$ (see e.g.,

equation (16) below). In the proof the trials correspond to columns of X and success to the conjunction of the properties stated above. Both parts of the proof rely on estimating the probability of success from below (in the second part it is the conditional probability, since the event in question depends on the first part). The main reason behind technical (notational) difficulties is that one needs to explore independence of the variables χ_{ij} and R_{ij} in the right order to be able to take advantage of the already established bounds in consecutive steps.

Define thus the event \mathcal{E}_{ki} as

$$\mathcal{E}_{ki} = \left\{ \chi_{ki} = 1, |\{r \in [n] \setminus \{k\} : \chi_{ri} = 1\}| \leq (s-1)/2, R_{ki} \geq q, \forall_{r \neq k} \chi_{ri} = 1 \implies |R_{ri}| \leq q \right\}$$

(see the description above for the motivation of this and subsequent definitions).

We will assume that $p \geq 2Cn \log n$ for some numerical constant C to be fixed later on. For $k \in [n]$, consider the events

$$\mathcal{A}_k = \bigcup_{1 \leq i \leq \lfloor p/2 \rfloor} \mathcal{E}_{ki}$$

and

$$\mathcal{B}_k = \bigcup_{1 \leq i \leq \lfloor p/2 \rfloor} \bigcup_{\lfloor p/2 \rfloor < j \leq p} (\mathcal{E}_{ki} \cap \mathcal{E}_{kj} \cap \{l \in [n] : \chi_{li} = \chi_{lj} = 1\} = \{k\}).$$

We will first show that for all $k \in [n]$,

$$\mathbb{P}(\mathcal{A}_k) \geq 1 - \frac{1}{p^4}, \tag{14}$$

which we will use to prove that

$$\mathbb{P}(\mathcal{B}_k) \geq 1 - \frac{1}{p^3}. \tag{15}$$

Let us start with the proof of (14). Set $\mathcal{B}_{ki} = \{|\{r \in [n] \setminus \{k\} : \chi_{rk} = 1\}| \leq (s-1)/2\}$. By independence we have

$$\begin{aligned} \mathbb{P}(\mathcal{E}_{ki}) &= \mathbb{P}(\chi_{ki} = 1) \mathbb{P}(R_{ki} \geq q) \mathbb{P}(\mathcal{B}_{ki}) \mathbb{P}(\forall_{r \neq k} \chi_{ri} = 1 \implies |R_{ri}| \leq q | \mathcal{B}_{ki}) \\ &\geq \theta \frac{c_0}{4s} \left(1 - \frac{c_0}{2s}\right) \left(\frac{c_0}{4s}\right)^{(s-1)/2}, \end{aligned}$$

where to estimate $\mathbb{P}(\mathcal{B}_{ki})$ we used Markov's inequality. The last factor comes from the definition of q as the $(1 - c_0/(2s))$ -quantile of R_{ij} . The right hand side above is bounded from below by c_1/n for some universal constant c_1 . Therefore if the constant C is large enough, we obtain

$$\mathbb{P}\left(\bigcap_{1 \leq i \leq \lfloor p/2 \rfloor} \mathcal{E}_{ki}^c\right) \leq \left(1 - \frac{c_1}{n}\right)^{\lfloor p/2 \rfloor} \leq \exp(-c_1 p / (4n)) \leq \exp(-4 \log p) = \frac{1}{p^4}, \tag{16}$$

where we used the inequality $p / \log p \geq 16c_1^{-1}n$ for $p \geq Cn \log n$. We have thus established (14).

Let us now pass to (15). Denote by \mathcal{F}_1 the σ -field generated by $\chi_{ki}, R_{ki}, k \in [n], 1 \leq i \leq \lfloor p/2 \rfloor$. Note that $\mathcal{A}_k \in \mathcal{F}_1$.

For $\omega \in \mathcal{A}_k$ define $i_{\min}(\omega) = \min\{1 \leq i \leq \lfloor p/2 \rfloor : \omega \in \mathcal{E}_{ki}\}$. Note that on \mathcal{A}_k ,

$$\mathbb{P}(\mathcal{B}_k | \mathcal{F}_1) \geq \mathbb{P}\left(\bigcup_{\lfloor p/2 \rfloor < j \leq p} (\mathcal{E}_{kj} \cap \{l \in [n] : \chi_{li_{\min}} = \chi_{lj} = 1\} = \{k\}) \mid \mathcal{F}_1\right)$$

Define

$$\mathcal{C}_{kj} = \{|\{r \in [n] \setminus \{k\} : \chi_{rj} = 1\}| \leq (s-1)/2\} \cap \{l \in [n] : \chi_{li_{\min}} = \chi_{lj} = 1\} = \{k\}.$$

Similarly as in the argument leading to (14), for fixed j , using the independence of the variables χ_{lm}, R_{lm} and properties of the conditional probability, we obtain on the event \mathcal{A}_k ,

$$\begin{aligned} \mathbb{P}(\mathcal{E}_{kj} \cap \{l \in [n] : \chi_{li_{\min}} = \chi_{lj} = 1\} = \{k\} \mid \mathcal{F}_1) &= \mathbb{P}(R_{kj} \geq q) \mathbb{E}\left(\mathbf{1}_{\mathcal{C}_{kj}} \mathbb{P}(\forall_{r \neq k} \chi_{rj} = 1 \implies |R_{rj}| \leq q | \mathcal{C}_{kj}, \mathcal{F}_1) \mid \mathcal{F}_1\right) \\ &\geq \mathbb{P}(R_{kj} \geq q) \mathbb{E}\left(\mathbf{1}_{\mathcal{C}_{kj}} \left(1 - \frac{c_0}{2s}\right)^{\frac{s-1}{2}} \mid \mathcal{F}_1\right) \\ &= \mathbb{P}(R_{kj} \geq q) \left(1 - \frac{c_0}{2s}\right)^{\frac{s-1}{2}} \mathbb{P}(\mathcal{C}_{kj} | \mathcal{F}_1) \\ &\geq \frac{c_0}{4s} \left(1 - \frac{c_0}{2s}\right)^{\frac{s-1}{2}} \times \\ &\quad \left(\mathbb{P}\left(\{l \in [n] : \chi_{li_{\min}} = \chi_{lj} = 1\} = \{k\} \mid \mathcal{F}_1\right) - \mathbb{P}\left(\chi_{kj} = 1, |\{r \in [n] \setminus \{k\} : \chi_{rj} = 1\}| > \frac{s-1}{2} \mid \mathcal{F}_1\right)\right) \\ &\geq \frac{c_0}{4s} \left(1 - \frac{c_0}{4s}\right)^{\frac{s-1}{2}} \left(\theta(1-\theta)^{(s-1)/2} - \theta \frac{2\theta(n-1)}{s-1}\right), \end{aligned}$$

where in the last line we again used Markov's inequality.

Now recall that $\theta \leq \frac{\alpha}{\sqrt{n}}$ for some universal constant α . If α is small enough then $1 - \theta \geq e^{-2\theta}$ and

$$(1 - \theta)^{(s-1)/2} \geq e^{-\theta(s-1)} = e^{-12\theta^2 n} \geq e^{-12\alpha^2} \geq \frac{1}{3}.$$

Since $\frac{2\theta(n-1)}{s-1} \leq \frac{1}{6}$, this implies that

$$\mathbb{P}(\mathcal{E}_{kj} \cap \{l \in [n] : \chi_{li_{\min}} = \chi_{lj} = 1\} = \{k\} \mid \mathcal{F}_1) \geq \frac{c_2}{n}$$

for some positive universal constant c_2 . Since the events $\mathcal{E}_{kj} \cap \{l \in [n] : \chi_{li_{\min}} = \chi_{lk} = 1\} = \{k\}$, $\lfloor p/2 \rfloor < k \leq p$ are conditionally independent, given \mathcal{F}_1 , we obtain that on \mathcal{A}_k ,

$$\mathbb{P}(\mathcal{B}_k^c | \mathcal{F}_1) \leq \left(1 - \frac{c_2}{n}\right)^{\lfloor p/2 \rfloor} \leq \frac{1}{p^4}, \tag{17}$$

provided C is a sufficiently large universal constant. Now, using (14), we get

$$\mathbb{P}(\mathcal{B}_k) \geq \mathbb{E} \mathbf{1}_{\mathcal{A}_k} \mathbb{P}(\mathcal{B}_k | \mathcal{A}_k) \geq \mathbb{P}(\mathcal{A}_k) \left(1 - \frac{1}{p}\right) \geq \left(1 - \frac{1}{p}\right)^2 \geq 1 - \frac{1}{p^3},$$

proving (15).

Taking the union bound over $k \in [n]$, we get

$$\mathbb{P}\left(\bigcap_{1 \leq k \leq n} \mathcal{B}_k\right) \geq 1 - \frac{1}{p^2}.$$

Set $\gamma = 1/2$ and observe that if C is large enough and α small enough, then the assumptions of Lemma 3 and Lemma 6 are satisfied. In particular $s = 12\theta n + 1 \leq \frac{\gamma}{s\theta} \leq \frac{1}{s\theta}$. Recall the properties P1 and P2 considered in the said lemmas. Consider the event $\mathcal{A} = \bigcap_{1 \leq k \leq n} \mathcal{B}_k \cap \{\text{properties P1 and P2 hold}\}$ and note that $\mathbb{P}(\mathcal{A}) \geq 1 - \frac{1}{p}$. On the event \mathcal{A} , for every k , there exist $1 \leq i < j \leq p$, such that

- $1 \leq |I_{ij}| \leq s \leq \frac{\gamma}{s\theta} \leq \frac{1}{s\theta}$,
- the largest entry of b_{ij} (in absolute value) equals $b_{ij}(k) \geq 2q > 0$ whereas the remaining entries do not exceed q ,

In particular, by property P1 we obtain that any solution z_* to the problem (6) satisfies $\text{supp } z_* \subseteq I_{ij}$. Therefore for some (any) $J \supseteq I_{ij}$ with $|J| = |s|$, we obtain (identifying vectors supported on J with their restrictions to J), that z_* is in fact a solution to the restricted problem (13) with $b = b_{ij}$, which by property P2 implies that $z_* = \lambda e_k$ for some $\lambda \neq 0$.

According to the discussion at the beginning of Step 1, this means that the solution w_* to (5) satisfies $w_*^T Y = \lambda e_k^T X$, i.e., the algorithm, when analyzing the vector b_{ij} , will add a multiple of the k -th row of X to the collection S .

This ends the proof of Theorem 1. \blacksquare

3. Proof of Proposition 2

The first tool we will need is the classical Bernstein's inequality, see e.g., Lemma 2.2.11 in (van der Vaart and Wellner, 1996).

Lemma 7 (Bernstein's inequality) *Let Y_1, \dots, Y_p be independent mean zero random variables such that for some constants M, v and every integer $k \geq 2$, $\mathbb{E}|Y_i|^k \leq k!M^{k-2}v/2$. Then, for every $t > 0$,*

$$\mathbb{P}\left(\left|\sum_{i=1}^p Y_i\right| \geq t\right) \leq 2 \exp\left(-\frac{t^2}{2(pv + Mt)}\right).$$

As a consequence, for every $q \geq 2$,

$$\left\|\sum_{i=1}^p Y_i\right\|_q \leq C(\sqrt{qp} + qM), \quad (18)$$

where C is a universal constant.

Another (also quite standard) tool we will rely on is the contraction principle for empirical processes due to Talagrand, see Theorem 4.12. in (Ledoux and Talagrand, 1991).

Lemma 8 (Talagrand's contraction principle) *Let $F: \mathbb{R}_+ \rightarrow \mathbb{R}_+$ be convex and increasing. Let further $\varphi: \mathbb{R} \rightarrow \mathbb{R}$ be a 1-Lipschitz function such that $\varphi(0) = 0$. For every bounded subset T of \mathbb{R}^n , if $\varepsilon_1, \dots, \varepsilon_n$ are i.i.d. Rademacher variables, then*

$$\mathbb{E}F\left(\sup_{t \in T} \frac{1}{2} \left|\sum_{i=1}^n \varphi(t_i) \varepsilon_i\right|\right) \leq \mathbb{E}F\left(\sup_{t \in T} \left|\sum_{i=1}^n t_i \varepsilon_i\right|\right)$$

We can now present the proof of Proposition 2.

Proof of Proposition 2 Let $\varepsilon_1, \dots, \varepsilon_p$ be i.i.d. Rademacher variables, independent of the sequences (U_i) , (X_i) . By the symmetrization inequality, see e.g., (Ledoux and Talagrand, 1991, Lemma 6.3.) or (van der Vaart and Wellner, 1996, Lemma 2.31), we have

$$\mathbb{E}W^q \leq 2^q \mathbb{E} \sup_{x \in \mathcal{B}_1^p} \left| \sum_{i=1}^p \varepsilon_i x^T Z_i \right|^q.$$

Now, since the function $t \mapsto |t|$ is a contraction, an application of Lemma 8 with $F(x) = |x|^q$, conditionally on Z_i , gives

$$\begin{aligned} \mathbb{E}W^q &\leq 2^{2q} \mathbb{E} \sup_{x \in \mathcal{B}_1^p} \left| \sum_{i=1}^p \varepsilon_i x^T Z_i \right|^q = \frac{2^{2q}}{p^q} \mathbb{E} \sup_{x \in \mathcal{B}_1^p} \left| x^T \sum_{i=1}^p \varepsilon_i Z_i \right|^q \\ &= \frac{2^{2q}}{p^q} \mathbb{E} \left\| \sum_{i=1}^p \varepsilon_i Z_i \right\|_\infty^q = \frac{2^{2q}}{p^q} \mathbb{E} \max_{1 \leq j \leq n} \left| \sum_{i=1}^p \varepsilon_i Z_i(j) \right|^q \\ &\leq \frac{2^{2q}}{p^q} \sum_{j=1}^n \mathbb{E} \left| \sum_{i=1}^p \varepsilon_i Z_i(j) \right|^q. \end{aligned} \quad (19)$$

Now, for every i, j and every integer $k \geq 2$ we have

$$\mathbb{E}|Z_i(j)|^k = \theta \mathbb{E}|U_i(j)|^k \leq \theta M^k k! \mathbb{E}e^{|U_i(j)|/M} \leq 2k! \theta M^k = k! v M^{k-2} / 2$$

with $v = 4\theta M^2$. Thus by the moment version (18) of Bernstein's inequality for some universal constant C we get

$$\mathbb{E} \left| \sum_{i=1}^p \varepsilon_i X_i(j) \right|^q \leq C^q \left(\sqrt{qp\theta} M + qM \right)^q,$$

which, when combined with (19), yields for $q \geq \log n$,

$$\|W\|_q \leq \frac{4C^q}{p} (\sqrt{p\theta}q + q)M.$$

The first part of the proposition follows by adjusting the constant C . The tail bound is a direct consequence of the Chebyshev inequality for the q -th moment. \blacksquare

Abstract

In this article, a study of the mean-square error (MSE) performance of linear echo-state neural networks is performed, both for training and testing tasks. Considering the realistic setting of noise present at the network nodes, we derive deterministic equivalents for the aforementioned MSE in the limit where the number of input data T and network size n both grow large. Specializing then the network connectivity matrix to specific random settings, we further obtain simple formulas that provide new insights on the performance of such networks.

Keywords: recurrent neural networks; echo state networks; random matrix theory; mean square error; linear networks

1. Introduction

Echo State Networks (ESN) are a class of recurrent neural networks (RNN) designed for performing supervised learning tasks, such as time-series prediction (Jaeger, 2001; Jaeger and Haas, 2004) or more generally any supervised learning task involving sequences. The ESN architecture is a special case of the general framework of reservoir computing (Lukoševičius and Jaeger, 2009). The ESN reservoir is a fixed (generally randomly designed) recurrent neural network, driven by a (usually time dependent) input. Since the internal connectivity matrix is not modified during learning, the number of parameters to learn is much smaller than in a classical RNN setting and the system is as such less prone to overfitting. However, the prediction performance of ESN often depends significantly on several hyper-parameters controlling the law of the internal connectivity matrix.

It has in particular been understood that the spectral radius and spectral norm of the connectivity matrix play a key role on the stability of the network (Jaeger, 2001) and that the structure of the connectivity matrix may be adapted to trade memory capacities versus task complexity (Verstraeten et al., 2010; Rodan and Tino, 2011; Strauss et al., 2012; Ozturk et al., 2007). Nonetheless, to date, and to the best of the authors' knowledge, the understanding of echo-state networks has progressed mostly through extensive empirical studies and lacks solid theoretical foundations.

In the present article, we consider linear ESN's with a general connectivity matrix and internal network noise. By leveraging tools from the field of random matrix theory, we shall attempt to provide a first *theoretical* study of the performance of ESN's. Beyond the obvious advantage of exploiting theoretical formulas to select the optimal hyper-parameters, this mathematical study reveals key quantities that intimately relate the internal network memory to the input-target relationship, therefore contributing to a better understanding of short-term memory properties of RNNs.

More specifically, we shall consider an n -node ESN trained with an input of size T and shall show that, assuming the internal noise variance η^2 remains large compared to $1/\sqrt{n}$, the training and testing performances of the network can be well approximated by a deterministic quantity which is a function of the training and test data as well as the connectivity matrix. Under the further assumption that the connectivity matrix is random, we shall then obtain closed-form formulas of the aforementioned performances for a large class of connectivity structures. The reach of our study so far only addresses ESN's with linear activation functions, a limitation which we anticipate to work around with more elaborate methods in the future, as discussed in Section 4.

At this point, we wish to highlight the specificity of our approach regarding (i) the introduction of noise perturbing the internal dynamics of the reservoir and (ii) the restriction to linear networks.

The introduction of additive noise in the reservoir is inspired on the one hand by it being a natural assumption in modelling biological neural networks (Ganguli et al., 2008; Toyozumi and Abbott, 2011) and on the other hand by the observation in (Jaeger, 2001) that ESN's are very sensitive to low variance noise and thus likely unstable in this regime, a problem successfully cured by internal noise addition (Jaeger, 2005).¹ From the neuro-computational perspective, we shall observe tight connections between the ESN performance and the reservoir information processing capacities discussed in (Ganguli et al., 2008). As for the artificial neural network viewpoint, it shall be noticed that the internal noise regularizes the network in a way sharing interesting similarities with the well-known connection between noise at the network output and Tikhonov regularization (Bishop, 1995). It is, as a matter of fact, already mentioned in (Lukoševičius and Jaeger, 2009, Section 8.2) that internal noise behaves as a natural regularization option (similar to what input or output noise would) although this aspect was not deeply investigated. More importantly, while internal noise necessarily leads to random outputs (a not necessarily desirable feature on the onset), we shall show that all these outputs (almost surely) asymptotically have the same performance, thus inducing random but equally useful innovation; this we believe is a more desirable feature than deterministic arbitrary biases in the innovation (see the comments around Remark 12 in Section 2.2).

As for the choice of studying linear activation functions, rarely considered in the practical side of RNNs, it obviously follows first from a mathematical tractability of the problem under study. Nonetheless, while being clearly a strong limitation of our study (recall that the non-linearity is the main driver for the network to perform complex tasks), we believe it brings sufficient insights (at least as far as memory capabilities and minimal performance are concerned) and exploitable results when it comes to parametrizing non-linear network counterparts.

Among other results, the main findings of our study are as follows:

1. According to Jaeger in (Jaeger, 2005) (specifically in the context of reservoirs with output feedback): "When you are training an ESN with output feedback from accurate (mathematical, noise-free) training data, stability of the trained network is often difficult to achieve. A method that works wonders is to inject noise into the dynamical reservoir update during sampling [...]. It is not clearly understood why this works."⁹

1. we retrieve a deterministic implicit expression for the mean-square error (MSE) performance of training and testing for any fixed connectivity matrix $W \in \mathbb{R}^{n \times n}$ which, for every given internal noise variance $\eta^2 > 0$, is all the more accurate that the network size n is large
2. the aforementioned expression reveals fundamental quantities which generalize several known qualitative notions of ESN's, such as the *memory capacity* and the *Fisher memory curve* (Jaeger, 2001; Ganguli et al., 2008);
3. we obtain more tractable closed-form expressions for the same quantities for simple classes of random normal and non-normal matrices: these two classes exhibit a strikingly different asymptotic performance behavior;
4. from the previous analysis, we shall also introduce a novel multi-modal connectivity matrix that adapts to a wider scope of memory ranges and that is reminiscent to the long short-term memory ESNs designed in (Xue et al., 2007);
5. an important interplay between memory and internal noise will be shed light on, by which the questions of noise-induced stability are better understood.

The remainder of the article is organized as follows. In Section 2, we introduce the ESN model and the associated supervised learning problem and we give our main theoretical results in Theorems 2 and 9 (technical proofs are deferred to the Appendix). Then, in Section 3, we apply our theoretical results for various choices of specific connectivity matrices and discuss their consequences in terms of prediction performance. Finally, in Section 4, we discuss our findings and their limitations.

Notations: In the remainder of the article, uppercase characters will stand for matrices, lowercase for scalars or vectors. The transpose operation will be denoted $(\cdot)^T$. The multivariate Gaussian distribution of mean μ and covariance C will be denoted $\mathcal{N}(\mu, C)$. The notation $V = \{V_{ij}\}_{i,j=1}^T$ denotes the matrix with (i, j) -entry V_{ij} (scalar or matrix), $1 \leq i \leq n$, $1 \leq j \leq T$, while $\{V_{ij}\}_{i=1}^n$ is the row-wise concatenation of the V_i 's and $\{V_{ij}\}_{j=1}^T$ the column-wise concatenation of the V_j 's. We further introduce the notation $(x)^+ \equiv \max(x, 0)$. For random or deterministic matrices X_n and $Y_n \in \mathbb{R}^{n \times n}$, the notation $X_n \leftrightarrow Y_n$ stands for $\frac{1}{n} \text{tr} A_n(X_n - Y_n) \rightarrow 0$ and $a_n(X_n - Y_n) b_n \rightarrow 0$, almost surely, for every deterministic matrix A_n and vectors a_n, b_n having bounded norm (spectral norm for matrices and Euclidean norm for vectors); for $X_n, Y_n \in \mathbb{R}$ scalar, the notation will simply mean that $X_n - Y_n \rightarrow 0$ almost surely. The notation $\rho(X)$ will denote the spectral radius of matrix X , while $\|X\|$ will denote its operator norm (and for vectors, $\|x\|$ is the Euclidean norm). The symbol δ_x shall stand for Kronecker's delta function, i.e., $\delta_x(y) = 1$ if $y = x$ (or x is true) and zero otherwise.

2. Main Results

We consider here an echo-state neural network constituted of n nodes, with state $x_t \in \mathbb{R}^n$ at time instant t , connectivity matrix $W \neq 0$, and input source sequence $\dots, u_{-1}, u_0, u_1, \dots \in \mathbb{R}$. The state evolution is given by the linear recurrent equation

$$x_{t+1} = Wx_t + mu_{t+1} + \eta \epsilon_{t+1}$$

for all $t \in \mathbb{Z}$, in which $\eta > 0$ and $\epsilon_t \sim \mathcal{N}(0, I_n)$, while $m \in \mathbb{R}^n$ is the input-to-network connectivity.

Our first objective is to understand the training performance of such a network. To this end, we shall focus on a (training) time window $\{0, \dots, T-1\}$ and will denote $X =$

$\{x_j\}_{j=0}^{T-1} \in \mathbb{R}^{n \times T}$ as well as $A = MU$, $M \in \mathbb{R}^{n \times T}$, $U \in \mathbb{R}^{T \times T}$, where

$$\begin{aligned} M &\equiv \{W^j m\}_{j=0}^{T-1} \\ U &\equiv \frac{1}{\sqrt{T}} \{u_j - \bar{u}\}_{i,j=1}^T. \end{aligned}$$

With these notations, we especially have $X = \sqrt{T}(A+Z)$, where $Z = \frac{1}{\sqrt{T}} \{\sum_{k=0}^{\infty} W^k \epsilon_{j-k}\}_{j=0}^{T-1}$. The matrix A can be seen here as the matrix carrying the information about the input vector u while Z serves the purpose of regularization noise.

For X to be properly defined (at least almost surely so), we shall impose the following hypothesis.

Assumption 1 (Spectral Norm) *The spectral norm $\|W\|$ of W satisfies $\|W\| < 1$.*

Note that this constraint is in general quite strong and it is believed (following the insights of previous works (Jaeger, 2001)) that for many model choices of W , it can be lightened to merely requiring that the spectral radius $\rho(W)$ be smaller than one. Nonetheless, in the course of the article, we shall often take W to be such that both its spectral norm and spectral radius coincide.

2.1. Training Performance

The training step consists in teaching the network to obtain a specific output sequence $r = \{r_j\}_{j=0}^{T-1}$ out of the network, when fed by a corresponding input vector $u = \{u_j\}_{j=0}^{T-1}$ over the time window. To this end, unlike conventional neural networks, where W is adapted to u and r , ESN's adopt the strategy to solely enforce an output link from the network to a sink (or readout). Letting $\omega = \{\omega_i\}_{i=1}^n$ be the network-to-sink connectivity vector, we shall consider here that ω is obtained as the (least-square) minimizer of $\|X^T \omega - r\|^2$. When $T > n$, we have

$$\omega \equiv (X X^T)^{-1} X r \quad (1)$$

which is almost surely well-defined (since $\eta > 0$) or, when $T \leq n$,

$$\omega \equiv X (X^T X)^{-1} r. \quad (2)$$

The per-input mean-square error in training associated with the couple (u, r) for the ESN under study is then defined as

$$E_\eta(u, r) \equiv \frac{1}{T} \|r - X^T \omega\|^2 \quad (3)$$

which is identically zero when $T \leq n$.

Our first objective is to study precisely the random quantity $E_\eta(u, r)$ for every given W and noise variance η^2 in the limit where $n \rightarrow \infty$. Our scaling hypotheses are as follows.

Assumption 2 (Random Matrix Regime) *The following conditions hold:*

1. $\limsup_n \eta/T < \infty$
2. $\limsup_n \|AA^T\| < \infty$.

That is, according to Item 1, we allow n to grow with T . Also, from Item 2, we essentially allow u_t to be of order $O(1)$ (unless u is sparse and then u_t may be as large as $O(\sqrt{T})$) when m remains of bounded Euclidean norm. Under this setting, and along with Assumption 1, we shall thus essentially require all neural connections to be of order $O(n^{-\frac{1}{2}})$ while all input and output data (constituents of u and r) shall be in general of order $O(1)$.

For every square symmetric matrix $B \in \mathbb{R}^{n \times n}$, a central quantity in random matrix theory is the resolvent $(B - zI_n)^{-1}$ defined for every $z \in \mathbb{C} \setminus \mathcal{S}_B$, with $\mathcal{S}_B \subset \mathbb{R}$ the support of the eigenvalues of B . Here, letting $z = -\gamma$ for some $\gamma > 0$, it is particularly convenient to make the following observation.

Lemma 1 (Training MSE and resolvent) For $\gamma > 0$, let $\bar{Q}_\gamma \equiv (\frac{1}{T}X^T X + \gamma I_T)^{-1}$. Then we have, for $E_\gamma(u, r)$ defined as in (3),

$$E_\gamma(u, r) = \lim_{\gamma \downarrow 0} \frac{1}{T} r^T \bar{Q}_\gamma r.$$

Our first technical result provides an asymptotically tight approximation for \bar{Q}_γ for every $\gamma > 0$. Recall that, for $X_n, Y_n \in \mathbb{R}^{n \times n}$, the notation $X_n \leftrightarrow Y_n$ means that, for every deterministic and bounded norm matrix A_n or vector $a_n, b_n, \frac{1}{n} \text{tr} A_n(X_n - Y_n) \rightarrow 0$ and $a_n^T(X_n - Y_n)b_n \rightarrow 0$, almost surely.

Theorem 2 (Deterministic Equivalent) Let Assumptions 1–2 hold. For $\gamma > 0$, let also $Q_\gamma \equiv (\frac{1}{T}X X^T + \gamma I_n)^{-1}$ and $\hat{Q}_\gamma \equiv (\frac{1}{T}X^T X + \gamma I_T)^{-1}$. Then, as $n \rightarrow \infty$, the following approximations hold:

$$\begin{aligned} Q_\gamma \leftrightarrow \hat{Q}_\gamma &\equiv \frac{1}{\gamma} \left(I_n + \eta^2 \bar{R}_\gamma + \frac{1}{\gamma} A (I_T + \eta^2 R_\gamma)^{-1} A^T \right)^{-1} \\ \hat{Q}_\gamma \leftrightarrow \bar{Q}_\gamma &\equiv \frac{1}{\gamma} \left(I_T + \eta^2 R_\gamma + \frac{1}{\gamma} A^T (I_n + \eta^2 \bar{R}_\gamma)^{-1} A \right)^{-1} \end{aligned}$$

where $R_\gamma \in \mathbb{R}^{T \times T}$ and $\bar{R}_\gamma \in \mathbb{R}^{n \times n}$ are solutions to the system of equations

$$\begin{aligned} R_\gamma &= \left\{ \frac{1}{T} \text{tr} (S_{t-j} \bar{Q}_\gamma) \right\}_{i,j=1}^T \\ \bar{R}_\gamma &= \sum_{q=-\infty}^{\infty} \frac{1}{T} \text{tr} (J^q \bar{Q}_\gamma) S_q \end{aligned}$$

with $[J^q]_{ij} \equiv \delta_{i+q,j}$ and $S_q \equiv \sum_{k \geq 0} W^{k+(-q)^+} (W^{k+q^+})^T$.

Remark 3 (On Theorem 2) Theorem 2 is in fact valid under more general assumptions than in the present setting. In particular, A may be any deterministic matrix satisfying Assumption 2. However, when $A = MU$, an important phenomenon arises, which is that A behaves similar to a low-rank matrix, since, by Assumption 1, only $o(n)$ columns of M have non-vanishing norm. As such, by a low-rank perturbation argument, it can be shown that the term \bar{Q}_γ in the expression of R_γ and the term \hat{Q}_γ in the expression of \bar{R}_γ can be replaced by $\gamma^{-1} (I_n + \eta^2 \bar{R}_\gamma)^{-1}$ and $\gamma^{-1} (I_T + \eta^2 R_\gamma)^{-1}$, respectively. As such, R_γ and \bar{R}_γ only depend on the matrix W and the parameter η^2 , and are thus asymptotically independent of the input data matrix U . Note also in passing that, while \bar{R}_γ is defined with a sum over $q = -\infty$ to ∞ , this summation is empty for all $|q| \geq T$.

2. Note that $\text{tr}(J^q B)$ is merely $\text{tr}(J^q B) = \sum_{i=1+q^+}^{T-q^+} [B]_{i+i|q}$.

In order to evaluate the training mean-square error $E_\gamma(u, r)$ from Lemma 1, one must extend Theorem 2 uniformly over γ approaching zero. This can be guaranteed under the following additional assumption.

Assumption 3 (Network size versus training time) As $n \rightarrow \infty$, $n/T \rightarrow c \in [0, 1) \cup (1, \infty)$.

Under Assumption 3, two scenarios must be considered. Either $c < 1$ or $c > 1$. In the former case, we can show that, as $\gamma \downarrow 0$, R_γ and $\gamma \bar{R}_\gamma$ have well defined limits. Besides, it appears that the limit of $\eta^2 R_\gamma$ does not depend on η^2 , so that we shall denote \mathcal{R} and $\bar{\mathcal{R}}$ the limits of $\eta^2 R_\gamma$ and $\gamma \bar{R}_\gamma$, as $\gamma \downarrow 0$, respectively. Similarly, $\eta^2 \bar{Q}_\gamma$ and $\gamma \bar{Q}_\gamma$ converge to well defined limits, denoted respectively \mathcal{Q} and $\bar{\mathcal{Q}}$. Symmetrically, for $c > 1$, as $\gamma \downarrow 0$, γR_γ and $\eta^2 \bar{R}_\gamma$ have well-behaved limits which we shall also refer to as \mathcal{R} and $\bar{\mathcal{R}}$; similarly, γQ_γ and $\eta^2 \bar{Q}_\gamma$ converge to non trivial limits again denoted \mathcal{Q} and $\bar{\mathcal{Q}}$. These results are gathered in the following proposition.

Proposition 4 (Small γ limit of Theorem 2) Let Assumptions 1–3 hold. For all large n , define \mathcal{R} and $\bar{\mathcal{R}}$ a pair of solutions of the system

$$\begin{aligned} \mathcal{R} &= c \left\{ \frac{1}{n} \text{tr} \left(S_{t-j} \left(\delta_{c>1} I_n + \bar{\mathcal{R}} \right)^{-1} \right) \right\}_{i,j=1}^T \\ \bar{\mathcal{R}} &= \sum_{q=-\infty}^{\infty} \frac{1}{T} \text{tr} (J^q (\delta_{c<1} I_T + \mathcal{R})^{-1}) S_q. \end{aligned}$$

Subsequently define

$$\begin{aligned} \bar{\mathcal{Q}} &\equiv \left(\delta_{c<1} I_T + \mathcal{R} + \frac{1}{\eta^2} A^T \left(\delta_{c>1} I_n + \bar{\mathcal{R}} \right)^{-1} A \right)^{-1} \\ \mathcal{Q} &\equiv \left(\delta_{c>1} I_n + \bar{\mathcal{R}} + \frac{1}{\eta^2} A \left(\delta_{c<1} I_T + \mathcal{R} \right)^{-1} A^T \right)^{-1}. \end{aligned}$$

Then, with the definitions of Theorem 2, we have the following results.

1. If $c < 1$, then in the limit $\gamma \downarrow 0$, $\eta^2 R_\gamma \rightarrow \mathcal{R}$, $\gamma \bar{R}_\gamma \rightarrow \bar{\mathcal{R}}$, $\eta^2 \bar{Q}_\gamma \rightarrow \bar{\mathcal{Q}}$, and $\gamma \bar{Q}_\gamma \rightarrow \bar{\mathcal{Q}}$.
2. If $c > 1$, then in the limit $\gamma \downarrow 0$, $\gamma R_\gamma \rightarrow \mathcal{R}$, $\eta^2 \bar{R}_\gamma \rightarrow \bar{\mathcal{R}}$, $\gamma \bar{Q}_\gamma \rightarrow \bar{\mathcal{Q}}$, and $\eta^2 \bar{Q}_\gamma \rightarrow \bar{\mathcal{Q}}$.

With these notations, we now have the following result.

Corollary 5 (Training MSE for $n < T$) Let Assumptions 1–3 hold and let $r \in \mathbb{R}^T$ be of $O(\sqrt{T})$ Euclidean norm. Then, with $E_\gamma(u, r)$ defined in (3), as $n \rightarrow \infty$,

$$E_\gamma(u, r) \leftrightarrow \begin{cases} (1/T)^T \bar{\mathcal{Q}}^r & , c < 1 \\ 0 & , c > 1. \end{cases}$$

It is interesting at this point to discuss the a priori involved expression of Proposition 4 and Corollary 5. Let us concentrate on the interesting $c < 1$ case. To start with, observe that \mathcal{R} and $\bar{\mathcal{R}}$ are deterministic matrices which only depend on W through the S_q matrices so that the only dependence of $E_\gamma(u, r)$ on the noise variance η^2 lies explicitly in the expression of $\bar{\mathcal{Q}}$. Now, making $A^T \bar{\mathcal{R}}^{-1} A$ explicit, we have the following telling limiting expression for $E_\gamma(u, r)$

$$E_\gamma(u, r) \leftrightarrow \frac{1}{T} r^T \left(I_T + \mathcal{R} + \frac{1}{\eta^2} U^T \left\{ m^T (W^t)^T \bar{\mathcal{R}}^{-1} W^t m \right\}_{i,j=0}^{T-1} U \right)^{-1} r. \quad (4)$$

Recalling that $\tilde{\mathcal{R}}$ is a linear combination of the matrices $S_q = W^{(-q)} S_0 W^{(q)}$, with $S_0 = \sum_{k \geq 0} W^k (W^k)^T$, the expression $\frac{1}{\eta} m^T (W^i)^T \tilde{\mathcal{R}}^{-1} W^i m$ is strongly reminiscent of the Fisher memory curve $f : \mathbb{N} \rightarrow \mathbb{R}$ of the ESN, introduced in (Ganguli et al., 2008) and defined by $f(k) = \frac{1}{\eta} m^T (W^k)^T S_0^{-1} W^k m$. The Fisher memory curve $f(k)$ qualifies the ability of a k -step behind past input to influence the ESN at present time. Correspondingly, it appears here that the ability of the ESN to retrieve the desired expression of r from input u is importantly related to the matrix $\{\frac{1}{\eta} m^T (W^i)^T \tilde{\mathcal{R}}^{-1} W^i m\}_{i,j=0}^{T-1}$. As a matter of fact, for $c = 0$ (thus for a long training period), note that $\mathcal{R} = 0$ while $\tilde{\mathcal{R}} = S_0$ and we then find in particular

$$E_{\eta}(u, r) \leftrightarrow \frac{1}{\tau} r^T \left(I_T + \frac{1}{\eta^2} U^T \{m^T (W^i)^T S_0^{-1} W^i m\}_{i,j=0}^{T-1} U \right)^{-1} r.$$

Pushing further our discussion on \mathcal{R} and $\tilde{\mathcal{R}}$, it is interesting to intuit their respective structures. Observe in particular that \mathcal{R}_{ij} depends only on $i - j$ and thus \mathcal{R} is a Toeplitz matrix. Besides, since $\text{tr } B = \text{tr } B^T$ for square matrices B , from $S_{i-j}^T = S_{j-i}$ it comes that $\mathcal{R}_{ij} = \mathcal{R}_{ji}$. Also note that, since $\rho(W^q) = \rho(W)^q$ decays exponentially as $q \rightarrow \infty$, it is expected that $\mathcal{R}_{i,i+q}$ decays exponentially fast for large q . As a consequence, \mathcal{R} is merely defined by $o(n)$ first entries of its first row.

From the results of (Gray, 2006) on Toeplitz versus circulant matrices, it then appears that, for every deterministic matrix B , $\frac{1}{\tau} \text{tr } B \mathcal{R}^{-1}$ is well approximated by $\frac{1}{\tau} \text{tr } B \mathcal{R}_c^{-1}$ for \mathcal{R}_c a circulant matrix approximation of \mathcal{R} . Since circulant matrices are diagonalizable in a Fourier basis, so are their inverses and then, as far as normalized traces are concerned, $(I_T + \mathcal{R})^{-1}$ can be seen as approximately Toeplitz with again decaying behavior away from the main diagonals. Although slightly ambiguous, this approximation still makes it that the trace $\frac{1}{\tau} \text{tr } \eta^2 (I_T + \mathcal{R})^{-1}$ appearing in the expression of $\tilde{\mathcal{R}}$, is well approximated by any value $\lfloor (I_T + \mathcal{R})^{-1} \rfloor_{i,i+q}$ for i sufficiently far from 1 and T , and decays to zero as q grows large. This, and the fact that S_q also decays exponentially fast in norm allows us to conclude that \mathcal{R} can be seen as a decaying weighted sum of $o(n)$ matrices S_{q_r} .

As shall be shown in Section 3, for W taken random with sufficient invariance properties, fundamental differences appear in the structure of \mathcal{R} and $\tilde{\mathcal{R}}$ depending on whether W is taken normal or not. In particular, for W non-normal with left and right independent isotropic eigenvectors and m deterministic or random independent of W , \mathcal{R} is well approximated by a scaled identity matrix and $\{m^T (W^i)^T \tilde{\mathcal{R}}^{-1} W^i m\}_{i,j=0}^{T-1}$ well approximated by a diagonal matrix with exponential decay along the diagonal.

Having a clearer understanding of Corollary 5, a few key remarks are in order.

Remark 6 (On the ESN stability to low noise levels) It is easily seen by differentiation along η^2 that $r^T \mathcal{Q} r$ is an increasing function of η^2 , thus having a minimum as $\eta^2 \downarrow 0$. It is thus tempting to suppose that $E_{\eta}(u, r)$ converges to this limit in the noiseless case (*i.e.*, for $\eta^2 = 0$). Such a reasoning is however hazardous and incorrect in most cases. Indeed, Corollary 5 only ensures an appropriate approximation of $E_{\eta}(u, r)$ for given $\eta > 0$ in the limit where $n \rightarrow \infty$. Classical random matrix considerations allow one to assert slightly stronger results. In particular, for the approximation of $E_{\eta}(u, r)$ to hold, one may allow η^2 to depend on n in such a way that $\eta^2 \gg n^{-\frac{1}{2}}$. This indicates that n must be quite large for the ESN behavior at moderate noise levels to be understood through the random matrix method. What seems like a defect of the tool on the onset in fact sheds some light on a deeper feature of ESN's. When η^2 is of the same order of magnitude or smaller than $n^{-\frac{1}{2}}$, Corollary 5 may become invalid due to the resurgence of randomness from $\dots, \epsilon_{-1}, \epsilon_0, \epsilon_1, \dots$. Precisely, when η^2 gets small and thus the training MSE variance should decay, an opposite effect makes

the MSE more random and thus possibly no longer tractable; this means in particular that, for any two independent runs of the ESN (with different noise realizations), all other parameters being fixed, the resulting MSE's might be strikingly different, making the network quite unstable. In practice, the opposition of the reduced noise variance η^2 and the resurgence of noise effects lead to various behaviors depending on the task and input data under considerations, ranging from largely increased MSE fluctuations at low η^2 to reduced fluctuations, through stabilisation of the fluctuations. In some specific cases discussed later, it might nonetheless be accepted to let $\eta^2 \rightarrow 0$ irrespective of n while keeping the random matrix approximation valid.

Remark 7 (Memory capacity revisited) For $c < 1$, letting $u_k = \sqrt{T} \delta_k$ and $r_k = \sqrt{T} \delta_{k-\tau}$ (that is, all input energy is gathered in a single entry), for some $t, \tau \in \mathbb{N}$, makes the ESN fill a pure delay task of τ time-steps. In this case, we find that

$$E_{\eta}(u, r) \leftrightarrow \left[\left(I_T + \mathcal{R} + \frac{1}{\eta^2} \{m^T (W^i)^T \tilde{\mathcal{R}}^{-1} W^i m\}_{i,j=0}^{T-1} \right)^{-1} \right]_{t+\tau, t+\tau}^{-1}.$$

In the particular case where, for all $i \neq j$, $\mathcal{R}_{ij} = o(1)$ and $m^T (W^i)^T \tilde{\mathcal{R}}^{-1} W^i m = o(1)$ (see Section 3.1 for a practical application with random non-normal W), by a uniform control argument due to the fast decaying for off-diagonal elements of \mathcal{R} and $\{m^T (W^i)^T \tilde{\mathcal{R}}^{-1} W^i m\}$, the training MSE is further (almost surely) well approximated as

$$E_{\eta}(u, r) \leftrightarrow \frac{\eta^2}{\eta^2(1 + \mathcal{R}_{11}) + m^T (W^t)^T \tilde{\mathcal{R}}^{-1} W^t m}.$$

If the quantity $m^T (W^t)^T \tilde{\mathcal{R}}^{-1} W^t m$ remains away from zero as $n \rightarrow \infty$, then it is allowed here to say (as opposed to the general case discussed in Remark 6) that $E_{\eta}(u, r) \rightarrow 0$ as $\eta \rightarrow 0$ and that $\eta^2/E_{\eta}(u, r) \sim m^T (W^t)^T \tilde{\mathcal{R}}^{-1} W^t m$, where we recover again a generalized form of the Fisher information curve at delay τ . From this discussion and Remark 6, we propose to define a novel network memory capacity metric $\text{MC}(\tau)$, representing the inverse slope of decay of $E_{\eta}(\sqrt{T} \delta_t, \sqrt{T} \delta_{t-\tau})$ for small η^2 :

$$\text{MC}(\tau) \equiv \lim_{\eta \downarrow 0} \liminf_{\tau} \left[\left(\eta^2 (I_T + \mathcal{R}) + \{m^T (W^i)^T \tilde{\mathcal{R}}^{-1} W^i m\}_{i,j=0}^{T-1} \right)^{-1} \right]_{\tau+1, \tau+1}^{-1}.$$

Remark 7 follows up on recent works, here from an MSE performance perspective, that establish links between memory capacity metrics and the Fisher memory curve, as in e.g., (Tño and Rodan, 2013). Practical applications of Corollary 5 to specific matrix models for W shall be derived in Section 3. Beforehand, we will study the more involved question of the test MSE performance.

2.2 Test Performance

In this section, we assume $\omega \equiv \omega(X; u, r)$ has been obtained as per (1) or (2), depending on whether $c < 1$ or $c > 1$. We now consider the test performance of the ESN that corresponds to its ability to map an input vector $\hat{u} \in \mathbb{R}^T$ to an expected output vector $\hat{r} \in \mathbb{R}^T$ of duration T in such a way to fulfill the same task that links u to r . For notational convenience, all test data will be denoted with a hat mark on top.

As opposed to the training mean square error, the testing MSE, defined as

$$\hat{E}_{\eta}(u, r; \hat{u}, \hat{r}) \equiv \frac{1}{T} \|\hat{r} - \hat{X}^T \omega\|^2 \quad (5)$$

where $\hat{X} = \{\hat{x}_t\}_{t=0}^{T-1} \in \mathbb{R}^{n \times T}$ is defined by the recurrent equation $\hat{x}_{t+1} = W\hat{x}_t + m\hat{u}_{t+1} + \eta\hat{\varepsilon}_{t+1}$, with $\hat{\varepsilon}_t \sim \mathcal{N}(0, I_n)$ independent of the ε_t 's, does not assume a similar simple form as the training MSE. We importantly assume here that a sufficiently long washout period between training and testing is present in the sense that \hat{x}_0 is assumed independent of the x_t described in the previous section (see Remark 22 in Appendix A for a discussion on the results generalization when no washout period is assumed). Under these assumptions, we merely have the following result.

Lemma 8 (Testing MSE) For $\gamma > 0$, $Q_\gamma = (\frac{1}{T}XX^T + \gamma I_n)^{-1}$, and $\hat{Q}_\gamma = (\frac{1}{T}X^T X + \gamma I_T)^{-1}$, we have

$$\begin{aligned} \hat{E}_\eta(u, r; \hat{u}, \hat{r}) &= \lim_{T \rightarrow \infty} \frac{1}{T} \|\hat{r}\|^2 + \frac{1}{T^2 T} r^T X^T Q_\gamma \hat{X} \hat{X}^T Q_\gamma X r - \frac{2}{T T} r^T \hat{X}^T Q_\gamma X r \\ &= \lim_{T \rightarrow \infty} \frac{1}{T} \|\hat{r}\|^2 + \frac{1}{T^2 T} r^T \hat{Q}_\gamma X^T \hat{X} \hat{X}^T X \hat{Q}_\gamma r - \frac{2}{T T} r^T \hat{X}^T X \hat{Q}_\gamma r \end{aligned}$$

with $\hat{E}_\eta(u, r; \hat{u}, \hat{r})$ defined in (5).

If $n < T$, Q_γ is well-defined in the limit $\gamma \downarrow 0$, while if instead $n \geq T$, then one may observe that $X^T Q_\gamma = \hat{Q}_\gamma X^T$ with \hat{Q}_γ having well defined limit as $\gamma \downarrow 0$.

Technically, estimating \hat{E} requires to retrieve, in a similar fashion as for Theorem 2, a deterministic approximation of quantities of the type $Q_\gamma X$ and $X^T Q_\gamma B Q_\gamma X = \hat{Q}_\gamma X^T B X \hat{Q}_\gamma$ for B a matrix independent of X . We precisely obtain the following result.

Theorem 9 (Second order deterministic equivalent) Let Assumptions 1–2 hold and let $B \in \mathbb{R}^{n \times n}$ be a deterministic symmetric matrix of bounded spectral norm. Then, recalling the notations of Theorem 2, for every $\gamma > 0$,

$$\begin{aligned} Q_\gamma \frac{1}{\sqrt{T}} X \leftrightarrow Q_\gamma A (I_n + \eta^2 R_\gamma)^{-1} \\ \frac{1}{T} X^T Q_\gamma B Q_\gamma X \leftrightarrow \eta^2 \gamma^2 \hat{Q}_\gamma C^{[B]} \hat{Q}_\gamma + (I_n + \eta^2 R_\gamma)^{-1} A^T \hat{Q}_\gamma [B + \hat{G}_\gamma^{[B]}] \hat{Q}_\gamma A (I_n + \eta^2 R_\gamma)^{-1} \end{aligned}$$

where $G_\gamma^{[B]} \in \mathbb{R}^{T \times T}$ and $\hat{G}_\gamma^{[B]} \in \mathbb{R}^{n \times n}$ are solutions to the system of equations

$$\begin{aligned} G_\gamma^{[B]} &= \left\{ \frac{1}{T} \text{tr} \left(S_{i-j} \hat{Q}_\gamma [B + \hat{G}_\gamma^{[B]}] \hat{Q}_\gamma \right) \right\}_{i,j=1}^T \\ \hat{G}_\gamma^{[B]} &= \sum_{q=-\infty}^{\infty} \eta \gamma^2 \frac{1}{T} \text{tr} \left(J^q \hat{Q}_\gamma C_\gamma^{[B]} \hat{Q}_\gamma \right) S_q. \end{aligned}$$

With these results at hand, we may then determine limiting approximations of the test mean-square error under both $n < T$ and $n > T$ regimes. As in Section 2.1, one may observe here that, under Assumption 3 with, say $c < 1$, $\eta^4 G_\gamma^{[B]}$ and $\hat{G}_\gamma^{[B]}$ both have well defined limits as $\gamma \downarrow 0$ which we shall subsequently refer to as $\mathcal{G}^{[B]}$ and $\hat{\mathcal{G}}^{[B]}$, respectively, and the symmetrical result holds for $c > 1$. Precisely, we have the following result.

Proposition 10 (Small γ limit of Theorem 9) Let Assumptions 1–3 hold and let $B \in \mathbb{R}^{n \times n}$ be a deterministic symmetric matrix of bounded spectral norm. For all large n , define $\mathcal{G}^{[B]}$ and $\hat{\mathcal{G}}^{[B]}$ a pair of solutions of the system

$$\begin{aligned} \mathcal{G}^{[B]} &= c \left\{ \frac{1}{n} \text{tr} \left(S_{i-j} (\delta_{>1} I_n + \hat{\mathcal{R}})^{-1} [B + \hat{\mathcal{G}}^{[B]}] (\delta_{>1} I_n + \hat{\mathcal{R}})^{-1} \right) \right\}_{i,j=1}^T \\ \hat{\mathcal{G}}^{[B]} &= \sum_{q=-\infty}^{\infty} \frac{1}{T} \text{tr} \left(J^q (\delta_{<1} I_T + \mathcal{R})^{-1} \mathcal{G}^{[B]} (\delta_{<1} I_T + \mathcal{R})^{-1} \right) S_q. \end{aligned}$$

Then, with the definitions of Theorem 9, we have the following results.

1. If $c < 1$, then in the limit $\gamma \downarrow 0$, $\eta^4 G_\gamma^{[B]} \rightarrow \mathcal{G}^{[B]}$ and $\hat{G}_\gamma^{[B]} \rightarrow \hat{\mathcal{G}}^{[B]}$.
2. If $c > 1$, then in the limit $\gamma \downarrow 0$, $\gamma^2 G_\gamma^{[B]} \rightarrow \mathcal{G}^{[B]}$ and $\hat{G}_\gamma^{[B]} \rightarrow \hat{\mathcal{G}}^{[B]}$.

Proposition 10 will be exploited on the deterministic matrix $\frac{1}{T} E[\hat{X} \hat{X}^T] = \eta^2 S_0 + \hat{A} \hat{A}^T$. Rather than taking $B = \eta^2 S_0 + \hat{A} \hat{A}^T$, which would induce an implicit dependence of $\mathcal{G}^{[B]}$ and $\hat{\mathcal{G}}^{[B]}$ on η^2 , we shall instead split $\eta^2 S_0 + \hat{A} \hat{A}^T$ into η^2 times S_0 and $\hat{A} \hat{A}^T$. Noticing then that $\mathcal{G}^{[A \hat{A}^T]}$ is asymptotically the same as $\mathcal{G}^{[0]}$, with 0 the all zero matrix, we may then obtain an approximation for the test mean square error. Prior to this, we need the following growth control assumptions.

Assumption 4 (Random Matrix Regime for Test Data) The following conditions hold:

1. $\limsup_n n/T < \infty$
2. $\limsup_n \|\hat{A} \hat{A}^T\| < \infty$.

Note in passing here that the $\min(T, \hat{T})$ first columns of $\hat{M} \in \mathbb{R}^{n \times \hat{T}}$ in the definition of \hat{A} and $M \in \mathbb{R}^{n \times T}$ in the definition of A are identical. As such, only \hat{U} actually particularizes the data matrix \hat{A} .

With this condition, we have the following corollary of Theorem 9.

Corollary 11 (Test MSE) Let Assumptions 1–4 hold and let $\hat{r} \in \mathbb{R}^{\hat{T}}$ be a vector of Euclidean norm $O(\sqrt{\hat{T}})$. Then, as $n \rightarrow \infty$, both for $c < 1$ and $c > 1$, we have, with the notations of Propositions 4–10,

$$\begin{aligned} \hat{E}_\eta(u, r; \hat{u}, \hat{r}) \leftrightarrow & \left\| \frac{1}{\eta^2 \sqrt{T}} A^T Q_A (\delta_{<1} I_T + \mathcal{R})^{-1} r - \frac{1}{\sqrt{T}} \hat{r} \right\|^2 + \frac{1}{T} r^T \hat{\mathcal{G}} \hat{\mathcal{G}} \hat{Q} r \\ & + \frac{1}{\eta^2 T} r^T (\delta_{<1} I_T + \mathcal{R})^{-1} A^T \mathcal{Q} [S_0 + \hat{\mathcal{G}}] Q_A (\delta_{<1} I_T + \mathcal{R})^{-1} r \end{aligned} \quad (6)$$

where $\mathcal{G} \equiv \mathcal{G}^{[S_0]}$ and $\hat{\mathcal{G}} \equiv \hat{\mathcal{G}}^{[S_0]}$.

The form of Corollary 11 is more involved than that of Corollary 5 but is nonetheless quite interpretable. To start with, observe that \mathcal{G} and $\hat{\mathcal{G}}$ are again only function of W and therefore quantify the network connectivity only. Then, note that only the first right-hand side term of the approximation of $E_\eta(u, r; \hat{u}, \hat{r})$ depends on \hat{u} and \hat{r} . As such, the quality of the learned task relies mostly on this term.

If $c = 0$, for all B , $\mathcal{G}^{[B]} = 0$ and $\hat{\mathcal{G}}^{[B]} = 0$, so we have here the simplified expression

$$\hat{E}_\eta(u, r; \hat{u}, \hat{r}) \leftrightarrow \left\| \frac{1}{\sqrt{T}} A^T (\eta^2 S_0 + A A^T)^{-1} A r - \frac{1}{\sqrt{T}} r \right\|^2 + \frac{1}{T} r^T A^T (\eta^2 S_0 + A A^T)^{-2} A r.$$

Some remarks are in order to appreciate these results.

Remark 12 (Noiseless case) As a follow-up on Remark 6, note that some alternative approaches to ESN normalization assume instead that $\eta = 0$ but that ω is taken to be the regularized least-square (or ridge-regression) estimator $\omega = X(X^T X + \gamma I_T)^{-1} r$ with $\gamma > 0$. In this case, it is easily seen that the corresponding mean-square error performance in training is given by $E^T(u, r) \equiv \gamma \frac{1}{T} r^T \hat{Q}_\gamma^T r$, which is precisely

$$E^T(u, r) = \frac{1}{T} r^T \left(I_T + \frac{1}{\gamma} U^T \{ m^T (W^T W^T m) \}_{i,j=0}^{T-1} U \right)^{-2} r.$$

It is interesting to parallel this (exact) expression to the approximation (4) in which the noise variance η^2 plays the role of the regularization γ , but (i) where the two additional quantities \mathcal{R} and \mathcal{R} are present, and (ii) where the power factor of the matrix inverse is 1 in place of 2. As for the testing performance, we are here comparing Corollary 11 to the noiseless regularized MSE

$$E^r(u, r; \hat{u}, \hat{r}) = \left\| \frac{1}{\sqrt{T}} \hat{A}^T (\gamma I_n + A A^T)^{-1} A r - \frac{1}{\sqrt{T}} \hat{r} \right\|^2.$$

This is again easily paralleled with the first right-hand side term in (6) which, for say $c < 1$, reads

$$\left\| \frac{1}{\sqrt{T}} \hat{A}^T \left(\eta^2 \tilde{\mathcal{R}} + A(I_T + \mathcal{R})^{-1} A^T \right)^{-1} A(I_T + \mathcal{R})^{-1} r - \frac{1}{\sqrt{T}} \hat{r} \right\|^2.$$

Again, it is clear that η^2 plays a similar role as that of γ , and that the matrices \mathcal{R} and $\tilde{\mathcal{R}}$ capture the behavior of the in-network noise.

Remark 12 suggests that internal noise plays a similar role to ridge normalization and that both lead to similar MSE performances. This being said, both regularizations behave strikingly differently in practice. While ridge-regularization provides a deterministic network output for given input vector u , internal noise instead induces random independent outputs for any two feeds of the network by the same vector u . Since all such random outputs have similar MSE performance (for sufficiently large network sizes), this may be a preferable choice in practice to avoid deterministic arbitrary mappings.

3. Applications

In this section, we shall further estimate the results of Corollary 5 and Corollary 11 in specific settings for the network connectivity matrix W and the input weights m . By leveraging specific properties of certain stochastic models for W (such as invariance by orthogonal matrix product or by normality), the results of Section 2 will be greatly simplified, by then providing further insights on the network performance.

3.1 Bi-orthogonally invariant W

We first consider the scenario where W is random with distribution invariant to left- and right-multiplication by orthogonal matrices, which we refer to as *bi-orthogonal invariance*. Precisely, in singular-value decomposition form, we shall write $W = UGV^T$, where U , V , and Ω are independent and U , V are real Haar distributed (that is, orthogonal with bi-orthogonally invariant distribution) and shall impose that the eigenvalues of W remain bounded by $\sigma < 1$ for all large n . Two classical examples of such a scenario are (i) W is itself a scaled Haar matrix, in which case $\Omega = \sqrt{\sigma} I_n$, and the eigenvalues of W all have modulus σ , or (ii) W has independent $\mathcal{N}(0, \sigma^2)$ entries, in which case, according to standard random matrix results, for any $\varepsilon > 0$, the eigenvalues of W have modulus less than $\sigma + \varepsilon$ for all large n almost surely and W is clearly orthogonally invariant by orthogonal invariance of the real multivariate Gaussian distribution.

In this scenario, one can exploit the fact (arising for instance from free probability considerations (Biane, 2003)) that, for all $i \neq j$ fixed, the moments $\frac{1}{n} \text{tr}(W^i (W^j)^T)$ vanish as $n \rightarrow \infty$. In our setting, i and j may however be growing with n , but then in all, in the large n setting, only the first few moments $\frac{1}{n} \text{tr}(W^i (W^j)^T)$, $i = 1, 2, \dots$, do not vanish. Although the implication is not immediate, this remark leads naturally to the intuition that

the Toeplitz matrix \mathcal{R} defined in Proposition 4 should be diagonal and thus proportional to the identity matrix.

At this point, we need to differentiate the cases where $c < 1$ and $c > 1$.

3.1.1 CASE $c < 1$

Based on the remarks above, we may explicitly solve for \mathcal{R} and $\tilde{\mathcal{R}}$ to find that, in the large n limit

$$\begin{aligned} \mathcal{R} &\leftrightarrow \frac{c}{1-c} I_r \\ \tilde{\mathcal{R}} &\leftrightarrow (1-c) S_0 \\ \hat{g}^{[B]} &\leftrightarrow \frac{c}{(1-c)^3} \frac{1}{n} \text{tr}(S_0^{-1} B) I_r \\ \hat{g}^{[B]} &\leftrightarrow \frac{c}{1-c} \frac{1}{n} \text{tr}(S_0^{-1} B) S_0. \end{aligned}$$

Replacing in the expressions of both Corollaries 5–11, we obtain the further corollary

Corollary 13 (Orthogonally invariant case, $c < 1$) *Let W be random and left and right independently orthogonally invariant. Then, under Assumptions 1–4 and with $c < 1$, the following hold*

$$\begin{aligned} E_\eta(u, r; \hat{u}, \hat{r}) &\leftrightarrow (1-c) \frac{1}{T} r^T \left(I_T + \frac{1}{\eta^2} U^T D U \right)^{-1} r \\ E_\eta(u, r; \hat{u}, \hat{r}) &\leftrightarrow \left\| \frac{1}{\eta^2 \sqrt{T}} \hat{U}^T D U \left(I_T + \frac{1}{\eta^2} U^T D U \right)^{-1} r - \frac{1}{\sqrt{T}} \hat{r} \right\|^2 \\ &\quad + \frac{1}{1-c} \frac{1}{T} r^T \left(I_T + \frac{1}{\eta^2} U^T D U \right)^{-1} r - \frac{1}{T} r^T \left(I_T + \frac{1}{\eta^2} U^T D U \right)^{-2} r \end{aligned}$$

where we defined $D \equiv \{m^T (W^i)^T S_0^{-1} W^j m\}_{i,j=0}^{T-1}$ and $\hat{D} \equiv \{m^T (W^i)^T S_0^{-1} W^j m\}_{i,j=0}^{\hat{T}-1, T-1}$.

We see here that the matrix D plays a crucial role in the ESN performance. First, from its Gram structure and the positive definiteness of S_0 , D is symmetric and nonnegative definite. This matrix has an exponential decaying profile down its rows and columns. As such, the dominating coefficients of the matrix $U^T D U$ lie in its upper-left corner. Recalling that the j -th column of $\sqrt{T} U^T$ is $\{u_{i-j}\}_{i=1}^T$, $U^T D U$ is essentially a linear combination of the outer products $\{u_{i-j}\}_{i=1}^T \{u_{i-j}\}_{i=1}^T$ for small j ,³ that is of combinations of (outer-products of) short-time delayed versions of the input vector u .

Note that, although we do not provide a rigorous proof of this fact, by the standard universality property of random matrix results, Corollary 13 is equally valid if W is chosen to be a matrix with i.i.d. zero mean and variance σ^2 non-necessarily Gaussian entries. In particular, it extends to the case of (properly recentered) matrices W with Bernoulli entries of Bernoulli parameter not scaling with n . In the regime under consideration, the asymptotic performance equivalence suggests that (here non sparse) Bernoulli random matrices have no particular advantage when compared to Gaussian random matrices, which is somewhat opposed to what is sometimes suggested in the ESN literature.³

Now, it is interesting to particularize the vector m and study its impact on D . It may be thought that taking m to be one of the dominant eigenvectors of W could drive the

3. However, sparse connectivity matrices prevail over non sparse ones in the literature, in which case our claim no longer holds.

inputs towards interesting memory-capacity levels of W ; this aspect is discussed in (Ganguli et al., 2008) where it is found that such an m maximizes the integrated Fisher-memory curve. If such a real eigenvector having eigenvalue close to σ exists, then we would find that $D_{ij} \simeq \sigma^{i+j} m^{-1} S_0^{-1} m$ and thus D would essentially be a rank-one matrix. As we shall discuss below, this would lead to extremely bad MSE performance in general.

If instead m is chosen deterministic or random independent of W with say $\|m\| = 1$ (or tending to one) for simplicity, then by the trace lemma (Bai and Silverman, 2009, Lemma B.26), one can show that $m^T (W^T)^T S_0^{-1} W^j m \leftrightarrow \frac{1}{n} \text{tr} W^j (W^T)^T S_0^{-1}$. According to our earlier discussion, this quantity vanishes for all $i \neq j$ as $n \rightarrow \infty$, and thus D would now essentially be diagonal. Besides, it is clear that $\text{tr} D \leftrightarrow 1$ and thus D here plays the role of affecting a short-term memorization ability, that can be seen as a total load 1, to the successive delayed versions of u . In particular, from our definition in Remark 7, we have precisely here

$$\text{MC}(\tau) = \frac{1}{1-c} \liminf_n \frac{1}{n} \text{tr} (W^T (W^T)^T S_0^{-1})$$

which, for the chosen m , is precisely the Fisher memory curve (Ganguli et al., 2008), up to the factor $1-c$.

Remark 14 (Haar W and independent m) For $W = \sigma Z$ with Z Haar distributed (orthogonal and orthogonally invariant) and m independent of Z and of unit norm, D is asymptotically diagonal and we find precisely

$$D_{ii} \leftrightarrow (1 - \sigma^2) \sigma^{2(i-1)}$$

and in particular

$$\text{MC}(\tau) = \frac{1 - \sigma^2}{1 - c} \sigma^{2r}.$$

Remark 14 can be extended to design an interesting multiple memory-mode network as follows.

Remark 15 (Multiple memory modes) Take W to be the block diagonal matrix $W = \text{diag}(W_1, \dots, W_k)$ where, for $j = 1, \dots, k$, $W_j = \sigma_j Z_j$, $\sigma_j > 0$, and $Z_j \in \mathbb{R}^{n_j \times n_j}$ is Haar distributed, independent across j . Take then m independent of W with unit norm. Also assume that $n_j/n \rightarrow c_j > 0$ as $n \rightarrow \infty$ and $\sum_j n_j = n$. Then we find that

$$D_{ii} \leftrightarrow \sum_{j=1}^k c_j \sigma_j^{2(i-1)} \frac{1}{\sum_{j=1}^k c_j (1 - \sigma_j^2)^{-1}}$$

and in particular, with $\text{MC}(\tau)$ defined in Remark 7,

$$\text{MC}(\tau) = \frac{1}{1-c} \frac{\sum_{j=1}^k c_j \sigma_j^{2r}}{\sum_{j=1}^k c_j (1 - \sigma_j^2)^{-1}}.$$

A graph of $\text{MC}(\tau)$ for $k=3$ is depicted in Figure 1, where it clearly appears that the memory curve follows successively each one of the three modes, giving in particular more weight to short-term past inputs at first, and then smoothly providing increasingly more importance to longer-term past inputs. This is reminiscent of the long short-term memory framework devised in (Xue et al., 2007).

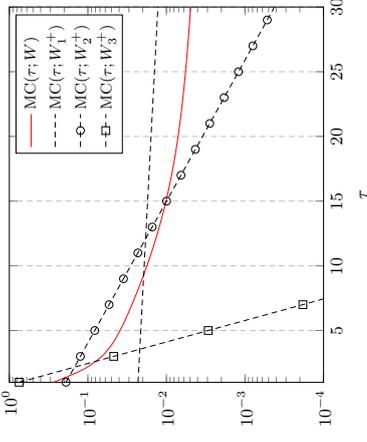

Figure 1: Memory curve for $W = \text{diag}(W_1, W_2, W_3)$, $W_j = \sigma_j Z_j$, $Z_j \in \mathbb{R}^{n_j \times n_j}$ Haar distributed, $\sigma_1 = .99$, $n_1/n = .01$, $\sigma_2 = .9$, $n_2/n = .1$, and $\sigma_3 = .5$, $n_3/n = .89$. The matrices W_i^+ are defined by $W_i^+ = \sigma_i Z_i^+$, with $Z_i^+ \in \mathbb{R}^{n_i \times n_i}$ Haar distributed.

It is next interesting to study Corollary 13 more deeply. Let us first assume that the task to be performed, both in training and testing, consists in retrieving a mere linear combination of latest past inputs $u_k, u_{k-1}, \dots, u_{k-(k-1)}$ for k fixed. Then we may write $r = \sqrt{T} U^T b$ for some vector $b \in \mathbb{R}^T$ with $b_j = 0$ for all $j \geq k$. We then have

$$E_\eta(u, r) \leftrightarrow (1-c)b^T U \left(I_T + \frac{1}{\eta^2} U^T D U \right)^{-1} U^T b.$$

For D positive diagonal with exponential decaying profile, D^{-1} is extremely ill-conditioned and may only be used with extreme care. However, for k fixed, $D^{-\frac{1}{2}} b$ is well behaved as its norm is bounded by $\|b\| D_{k-1, k-1}^{-\frac{1}{2}}$. We may thus write $b = D^{\frac{1}{2}} (D^{-\frac{1}{2}} b)$ to obtain, after basic algebraic manipulations

$$E_\eta(u, r) \leftrightarrow \eta^2 (1-c) (D^{-\frac{1}{2}} b)^T \frac{1}{\eta^2} D^{\frac{1}{2}} U U^T D^{\frac{1}{2}} \left(I_T + \frac{1}{\eta^2} D^{\frac{1}{2}} U U^T D^{\frac{1}{2}} \right)^{-1} (D^{-\frac{1}{2}} b).$$

Since $\|A(I+A)^{-1}\| \leq 1$ for any symmetric nonnegative definite matrix A , we thus conclude that, for every $\eta, \varepsilon > 0$, $E_\eta(u, r) \leq (1-c)\eta^2 b^T D^{-1} b + \varepsilon$ for all large n almost surely. Thus, for sufficiently large n , $E_\eta(u, r)$ can be made arbitrarily small in the limit where $\eta \rightarrow 0$ and thus the task can be performed accurately. As for E_η , note that, since D and D are essentially zero away from the upper left corner and otherwise equal, if $\hat{r} = \sqrt{T} \hat{U} \hat{b}$, for $\hat{b} \in \mathbb{R}^T$ having the same first k entries as b and zeroes next, then we find

$$\begin{aligned} \hat{E}_\eta(u, r; \hat{u}, \hat{r}) &\leftrightarrow \frac{\eta^2}{1-c} (D^{-\frac{1}{2}} b)^T \frac{1}{\eta^2} D^{\frac{1}{2}} U U^T D^{\frac{1}{2}} \left(I_T + \frac{1}{\eta^2} D^{\frac{1}{2}} U U^T D^{\frac{1}{2}} \right)^{-1} (D^{-\frac{1}{2}} b) \\ &\quad + (D^{-\frac{1}{2}} b)^T \left(I_T + \frac{1}{\eta^2} D^{\frac{1}{2}} U U^T D^{\frac{1}{2}} \right)^{-1} D^{\frac{1}{2}} \Delta D^{\frac{1}{2}} \left(I_T + \frac{1}{\eta^2} D^{\frac{1}{2}} U U^T D^{\frac{1}{2}} \right)^{-1} (D^{-\frac{1}{2}} b) \end{aligned} \quad (7)$$

where $\Delta \equiv [\hat{U}^T I_{r \times r} - U U^T]$, with the operator $[X]_{I_{r \times r}}$ extending (or reducing) X to a $T \times T$ matrix by filling it with zeroes (or discarding fast rows and columns). Note here that, for $U = \hat{U}$, $\Delta = 0$ and we find that

$$\hat{E}_\eta(u, r; u, r) \leftrightarrow \frac{1}{(1-c)^2} E_\eta(u, r). \quad (8)$$

When $\Delta \neq 0$, observe first that $\|(I_r + \eta^{-2} D^{\frac{1}{2}} U U^T D^{\frac{1}{2}})^{-1}\| \leq 1$ and thus $\hat{E}_\eta(u, r; \hat{u}, \hat{r})$ remains bounded. Now, with a more subtle analysis, note that, since the product $B D^{-\frac{1}{2}} b$ for any matrix B only concerns the first k columns of B , the behavior of E_η as $\eta \rightarrow 0$ merely depends on the behavior of the top-left $k \times k$ submatrix of $(I_r + \eta^{-2} D^{\frac{1}{2}} U U^T D^{\frac{1}{2}})^{-1}$. A block matrix inverse then reveals that the second right-hand side term of (7) goes to zero as $\eta \rightarrow 0$ provided that the k -th largest eigenvalue of $D^{\frac{1}{2}} U U^T D^{\frac{1}{2}}$ remains away from zero as $T \rightarrow \infty$. From the structure of U , we thus conclude that, for E_η to vanish as $\eta \rightarrow 0$, it is sufficient for the vector u to be sufficiently ‘‘diverse’’ in its constituents (that is, so that the first columns of U remain linearly independent). An obvious counter-example is when the sequence $\dots, u_{-1}, u_0, u_1, \dots \in \mathbb{R}$ is periodic of period less than k . Note that the specific choice of \hat{u} does not alter this behavior.

The discussion above leads to interesting practical considerations that may help improve the design of an ESN.

Remark 16 (Selecting W based on delayed correlations) Note that, in the aforementioned formulas, the quantity $b^T D^{-1} b$ with b defined by $r = U^T b$ appears as a fundamental quantity bounding the training and testing MSE. In practical settings where r is not a pure linear combination of delayed versions of u , it may nonetheless be useful to obtain an estimate \hat{b} of the closest approximation of r by delays of u , in such a way that $b^T D^{-1} b$ be small. One may for instance let

$$\hat{b} = (U U^T + \gamma I_r)^{-1} U r$$

for some regularization parameter $\gamma \geq 0$ (if needed), and parameterize W so that $b^T D^{-1} \hat{b}$ is minimal. For instance, if $b_i = \alpha^{i-1}$ for some $\alpha \in (-1, 1)$, it is easily shown that an optimal choice for $W = \sigma Z$ with Z Haar is to take $\sigma^2 = |\alpha|$. This scenario is illustrated in Figure 2, where the theoretical approximations for the testing and training normalized MSE are depicted for various choices of σ^2 . For less obvious values of \hat{b} , a more elaborate multi-memory matrix W , as introduced in Remark 15, can be used, with proper setting of the parameters n_i and σ_i .

Remark 17 (Memory Capacity for Stationary Inputs) Let W be orthogonally invariant and m random, so that D is diagonal in the limit. Further assume the sequence u is an anti-regressive Gaussian process, so that we may write $u = C^{\frac{1}{2}} \tilde{u}$ with \tilde{u} having independent zero mean unit variance Gaussian entries and C a Toeplitz covariance matrix with $C_{ab} = q^{|b-a|}$ for some $q \in [0, 1)$. Then, for the r -delay memory task, i.e., $r_i = u_{i-r}$ with τ fixed, we find that

$$E_\eta(u, r) \leftrightarrow \eta^2 \frac{1-c}{D_{\tau+1, \tau+1}} \left[1 - \left[\left(I_r + \frac{1}{\eta^2} \left\{ \sqrt{D_{i_i q}^{|i-j|}} \sqrt{D_{j_j}} \right\}_{i,j=0}^{T-1} \right)^{-1} \right]_{\tau+1, \tau+1} \right].$$

Since $q < 1$, the matrix $\{q^{|i-j|}\}_{i,j}$ has its smallest eigenvalue asymptotically far from zero (see e.g., (Gruy, 2006) for arguments) so that the right-hand side inner bracket vanishes as $\eta^2 \rightarrow 0$ and we thus have, for small η^2

$$\eta^{-2} E_\eta(u, r) \leftrightarrow \frac{1-c}{D_{\tau+1, \tau+1}} + o(\eta^2).$$

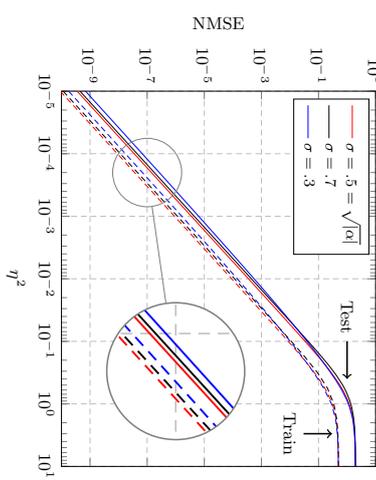

Figure 2: Optimal σ choice for $r_i = \sum_{i \geq 0} u_{-i} b_i$, $b_i = \alpha^{i-1}$ with $\alpha = -0.25$, u i.i.d. zero mean Gaussian, W Haar distributed, $n = 200$, $T = \hat{T} = 400$.

As a consequence, the memory task is performed irrespectively of the smoothness of u , so that u can be assumed composed of i.i.d. elements (i.e., $q = 0$). Observe that this leads to the same performance as the memory task considering $u = \sqrt{T} \delta_0$, defining the memory capacity in Remark 7. Of course, if instead $q = 1$, then the matrix in curly brackets would have unit rank and the previous conclusions would fail (in this case u is a constant vector).

Expression (8) also provides us an opportunity to open a short parenthesis on the effect of c on the training and testing MSE. From Corollary 13, it appears that, while E_η is minimal for $c = 1$, \hat{E}_η is minimal for $c = 0$. The former observation is clear from the fact that ω is a least-square regressor, but the latter observation is less trivial. As a matter of fact, note that, even if $U = I$ and $\hat{r} = r$, in the limit of $\eta > 0$ fixed and $c \rightarrow 1$, E_η becomes arbitrarily large. The reason for this seemingly counter-intuitive effect (after all, we merely ask the ESN to reproduce the exact learned sequence) lies in the fact that ω is built upon the network noise realization during training, while during testing a new noise realization is produced. As such, training an ESN of size almost equal to T produces dramatic effects on testing. However, this has the positive effect of strongly reducing over fitting. Of course, in practical settings, there exists an interplay between η^2 that drives both MSEs to zero as $\eta \rightarrow 0$ and c that reduces overfitting as it tends to 1.

Coming back to the approximations of E_η and \hat{E}_η , note now that if D is a rank-one matrix, then we may write $D = d d^T$ for some vector $d \in \mathbb{R}^T$ having exponentially vanishing entries. In this case, we find, again after standard algebraic calculus, that

$$E_\eta(u, r) \leftrightarrow (1-c) \left(\frac{1}{T} \|r\|^2 - \frac{1}{\eta^2} \frac{d^T U r r^2}{|d^T U r|^2} \right).$$

Taking as above $r = \sqrt{T} U b$, this is $E_\eta(u, r) \leftrightarrow (1-c) \left(b^T U U^T b - \frac{|d^T U U^T b|^2}{\eta^2 + d^T U U^T d} \right)$. By Cauchy-Schwarz inequality, this quantity, even in the limit $\eta^2 \rightarrow 0$, cannot vanish unless $b = d$.

As such, the ESN will only adequately fulfill a single task, which depends on the network configuration itself through d . A similar reasoning can be made on E_η , revealing the same shortcomings.

As a practical example, we provide in Figure 3 Monte Carlo simulations versus theory curves of the training and testing performances of networks of $n = 200$ and $n = 400$ nodes, for training and testing times $T = T = 2n$, on the Mackey Glass one-step ahead anticipation task (Glass and Mackey, 1979). The network is chosen to be the multi-memory model introduced in Remark 15 and following the description of Figure 1. The NMSE is defined here as the ratio between the MSE and the output vector squared norm $\|r\|^2/T$ or $\|s\|^2/\hat{T}$. Simulations are run for a single W but different noise realizations and comparison is made against theory for either this W or its approximated asymptotic limit. Observe the extremely accurate match between theory and practice, with increasing precision as n, T grow large.

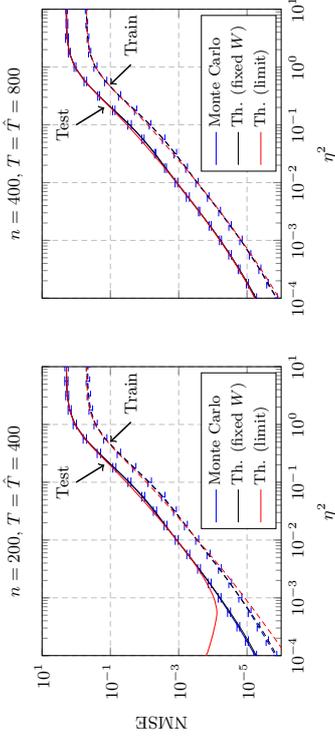

Figure 3: Training and testing (normalized) MSE for the Mackey Glass one-step ahead task, W fixed and defined as in Figure 1, $n = 200$, $T = \hat{T} = 400$ (left) and $n = 400$, $T = \hat{T} = 800$ (right). Comparison between Monte Carlo simulations (Monte Carlo), deterministic approximation assuming W fixed (Th. (fixed W)) as per Corollaries 5 and 11, and assuming W random in the large n limit (Th. (limit)) as per Corollary 13. Error bars indicate one standard deviation of the Monte Carlo simulations.

3.1.2 CASE $c > 1$

The case $c > 1$ is slightly more involved as it does not lend itself to a purely explicit expression. Precisely, following the same steps as for $c < 1$, we find that in the large n

limit

$$\begin{aligned} \tilde{R} &\leftrightarrow \alpha I_T \\ \tilde{R} &\leftrightarrow \frac{1}{\alpha} S_0 \\ \hat{G}^{[B]} &\leftrightarrow \alpha \alpha^{\frac{1}{n}} \frac{\frac{1}{n} \text{tr} S_0 (\alpha I_n + S_0)^{-1} B (\alpha I_n + S_0)^{-1} I_T}{1 - c \frac{1}{n} \text{tr} S_0^2 (\alpha I_n + S_0)^{-2}} \\ \hat{G}^{[B]} &\leftrightarrow c \frac{1}{n} \frac{\frac{1}{n} \text{tr} S_0 (\alpha I_n + S_0)^{-1} B (\alpha I_n + S_0)^{-1} S_0}{1 - c \frac{1}{n} \text{tr} S_0^2 (\alpha I_n + S_0)^{-2}} \end{aligned}$$

where $\alpha > 0$ is the unique solution to the equation

$$1 = c \frac{1}{n} \text{tr} S_0 (\alpha I_n + S_0)^{-1}.$$

With these notations, we have the following counterpart to Corollary 13.

Corollary 18 (Orthogonally invariant case, $c > 1$) *Let W be random and left and right independently orthogonally invariant and let $\alpha > 0$ be the unique solution to $1 = c \frac{1}{n} \text{tr} S_0 (\alpha I_n + S_0)^{-1}$. Then, under Assumptions 1–4 and with $c > 1$, the following holds*

$$\begin{aligned} \hat{E}_\eta(u, r; \hat{u}, \hat{r}) &\leftrightarrow \left\| \frac{\eta^{-2} \hat{U}^T \hat{D} U (I_T + \eta^{-2} U^T D U)^{-1} \frac{r}{\sqrt{T}} - \frac{1}{\sqrt{T}} r^T (I_T + \eta^{-2} U^T D U)^{-1} r}{\frac{1}{T} r^T (I_T + \eta^{-2} U^T D U)^{-1} [I_T + \eta^{-2} U^T D_2 U] (I_T + \eta^{-2} U^T D U)^{-1} r} \right\|^2 \\ &\quad + \frac{\frac{1}{T} r^T (I_T + \eta^{-2} U^T D U)^{-1} [I_T + \eta^{-2} U^T D_2 U] (I_T + \eta^{-2} U^T D U)^{-1} r}{1 - c \frac{1}{n} \text{tr} S_0^2 (\alpha I_T + S_0)^{-2}} \end{aligned}$$

where $D \equiv \{m^T (W^i)^T (\alpha I_n + S_0)^{-1} W^j m\}_{i,j=0}^{T-1}$, $\hat{D} \equiv \{m^T (W^i)^T (\alpha I_n + S_0)^{-1} W^j m\}_{i,j=0}^{T-1, T-1}$, and $D_2 \equiv \{m^T (W^i)^T (\alpha I_n + S_0)^{-1} S_0 (\alpha I_n + S_0)^{-1} W^j m\}_{i,j=0}^{T-1}$.

Of course here $E_\eta(u, r) = 0$.

Remark 19 (Haar W , random m for $c > 1$) *Although seemingly less tractable, for W following a Haar model, Corollary 18 takes a much simpler form. Indeed, for W and m as defined in Remark 14, we find that $\alpha = (c-1)(1-\sigma^2)^{-1}$ and $S_0 = (1-\sigma^2)^{-1} I_n$ which then leads to*

$$\begin{aligned} \hat{E}_\eta(u, r; \hat{u}, \hat{r}) &\leftrightarrow \left\| (c\eta^2)^{-1} \hat{U}^T \hat{D} U (I_T + (c\eta^2)^{-1} U^T D U)^{-1} \frac{r}{\sqrt{T}} - \frac{1}{\sqrt{T}} r^T \right\|^2 \\ &\quad + \frac{1}{c-1} \frac{1}{T} r^T (I_T + (c\eta^2)^{-1} U^T D U)^{-1} r \end{aligned}$$

where D is diagonal with $D_{ii} \equiv (1-\sigma^2)\sigma^{2(i-1)}$.

Aside from obtaining a shorter form expression for D and D_2 , the multi-memory model of Remark 15 does not lead to an explicit formulation as in Remark 19, but it is nonetheless instructive to observe the performance achieved on the Mackey Glass model from Figure 3, now in the setting where $c > 1$. This is depicted here in Figure 4.

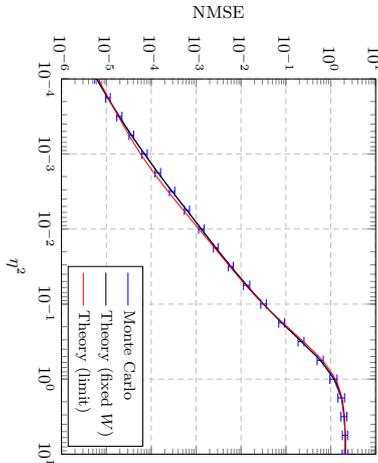

Figure 4: Testing (normalized) MSE for the Mackey Glass one-step ahead task. W fixed and defined as in Figure 1, $n = 400$, $T = \tilde{T} = 200$. Error bars indicate one standard deviation of the Monte Carlo simulations.

3.2 Normal W

We now turn to the case of normal matrices. Let then W be normal (i.e., diagonalizable in orthogonal basis) and having an eigenvalue decomposition of the type $W = V\Lambda V^T$ with V orthogonal and Λ diagonal with largest absolute entry less than one. For simplicity, we shall further assume that, as $n \rightarrow \infty$, the normalized counting measure of the diagonal elements of Λ ($n^{-1}\sum_i \delta_{\Lambda_i}$) converges in law to a probability measure μ . We do not make any assumption here on V .

For instance, real Gaussian Wigner matrices W , that is with i.i.d. zero mean variance $\frac{1}{4}\sigma^2$ Gaussian entries on and above the diagonal, and symmetrized below the diagonal, is an example of such a matrix. In this case, μ corresponds (almost surely) to the well-known semi-circular distribution, with density $\mu(d\lambda) = 2(\pi\sigma^2)^{-1}\sqrt{(\sigma^2 - \lambda^2)^+}d\lambda$. Another example is when $\mu(d\lambda) = \frac{1}{2}[\delta_c + \delta_{-c}]d\lambda$, so that W is the sum of two (σ^2 -scaled) projection matrices on orthogonal subspaces. In particular here, $W^2 = \sigma^2 I_n$, so that $W^{2k} = \sigma^{2k} I_n$ and $W^{2k+1} = \sigma^{2k} W$, for all $k \geq 0$.

Because of the symmetry property, it is no longer true that $\frac{1}{n} \text{tr } W^t (W^j)^T = \frac{1}{n} \text{tr } W^{t+j}$ vanished for $t \neq j$, and we then obtain more involved results. To keep this discussion short and since the results take here more involved forms, we shall only deal here with the case $c < 1$ and focus on the training performance. In this case, solving Proposition 4 for \mathcal{R} and \mathcal{R} , we have the following result. As $n \rightarrow \infty$, \mathcal{R} has a limit (which for simplicity we keep calling \mathcal{R}) which is solution to

$$\mathcal{R}_{ab} = c \int \frac{t^{a-b} \mu(dt)}{\sum_{q=-\infty}^{\infty} \frac{1}{t^q} \text{tr}(J^q (I_T + \mathcal{R})^{-1}) |t|^q} \quad (9)$$

for all $a, b \in \{1, \dots, T\}$. Remember that \mathcal{R} is Toeplitz with fast decaying values off the diagonal, so that (9) is computationally easy to solve. Similar conclusions can be drawn on the matrices $\mathcal{G}^{|\beta|}$ and $\tilde{\mathcal{G}}^{|\beta|}$, that however do not lead to simple expressions.

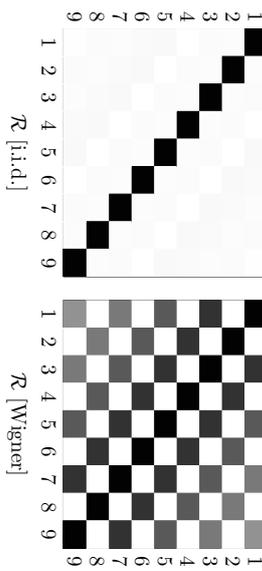

Figure 5: Upper 9×9 part of \mathcal{R} for $c = 1/2$ and $\sigma = 0.9$ for W with i.i.d. zero mean Gaussian entries (left) and W Gaussian Wigner (right). Linear grayscale representation with black being 1 and white being 0.

Remark 20 (Symmetric μ) An interesting scenario is when μ is symmetric, i.e., $\mu(-t) = \mu(t)$, which is the case of both aforementioned (Wigner and projection matrix) examples. From (9), we find in this case that $[\mathcal{R}]_{ab}$ is zero if $a - b$ is odd and positive if $a - b$ is even. As such, \mathcal{R} takes the form of a checkerboard matrix. Figure 5 provides a representation of \mathcal{R} in both normal and non-normal Gaussian W cases.

Remark 21 (Projection W) Let $W = V\Lambda V^T$ with the normalized counting measure of Λ converging to $\mu(d\lambda) = \frac{1}{2}[\delta_c + \delta_{-c}]d\lambda$ and $c < 1$. Then, $\mathcal{R}_{ab} \leftrightarrow \sigma^{|b-a|} r_0 \delta_{|b-a| \in 2\mathbb{N}}$ and $\mathcal{R} \leftrightarrow -(1-\sigma^2)^{-1} \sigma r_0^{-1} I_n$ where

$$r_0 = c \left(\sum_{j=-\infty}^{\infty} \frac{1}{T^j} \text{tr } J^j (I_T + \mathcal{R})^{-1} \right)^{-1}.$$

As a consequence, letting m be random, we find that

$$E_{r_0}(u, r) \leftrightarrow \frac{1}{T} \text{tr} \left(I_T + r_0 \left\{ \sigma^{|j-i|} \delta_{|j-i| \in 2\mathbb{N}} \right\}^{T-1} + r_0 (1-\sigma^2) U^T \left\{ \sigma^{j+i} \delta_{|j-i| \in 2\mathbb{N}} \right\}^{T-1} U \right)^{-1} r.$$

Note in particular that the matrix $\{\sigma^{|j+i|} \delta_{|j-i| \in 2\mathbb{N}}\}_{i,j=0}^{T-1}$ can be decomposed as the sum of two matrices: (i) the rank-one matrix $v v^T$ with $v = (1, 0, \sigma^2, 0, \sigma^4, \dots)^T$ and the diagonal matrix $\text{diag}(0, \sigma^2, 0, \sigma^4, \dots)$. Recalling that rank-one matrices in this position do not allow for efficient training (see the final discussions in Section 3.1, $c < 1$ case), only the diagonal component $\text{diag}(0, \sigma^2, 0, \sigma^4, \dots)$ really matters here. This diagonal misses half its entries and thus intuitively does not allow for efficient retrieval of odd past steps. This remark generally prefigures a weaker performance of normal matrices with symmetric spectrum than their non-normal counterparts.

The final discussion in Remark 21 motivates a deeper comparative study of the performance of non-normal versus normal connectivity matrices. From (9), we may in particular evaluate the memory curve (as defined here in Remark 7) for W a Wigner random matrix. The performance figures are displayed in Table 1, which show a dramatic decay of the memory curve for the Wigner connectivity matrix as compared to an i.i.d. Gaussian non-normal

matrix. In Figure 6, a practical scenario of a τ -delay task is depicted comparatively for Haar versus Wigner matrices (the input data being extracted from Mackey-Glass processes but the general results hold for any non-trivial input dataset); there we confirm that, for increasing values of the delay τ , the ESN performance strongly decays for Wigner matrices as compared to Haar matrices, as predicted by the theoretical results of Table 1.

τ	i.i.d.	Wigner
0	$5.2 \cdot 10^{-1}$	$4.8 \cdot 10^{-1}$
1	$2.0 \cdot 10^{-1}$	$1.6 \cdot 10^{-2}$
2	$1.0 \cdot 10^{-1}$	$1.3 \cdot 10^{-3}$
3	$6.0 \cdot 10^{-2}$	$2.0 \cdot 10^{-4}$
4	$3.9 \cdot 10^{-2}$	$5.7 \cdot 10^{-5}$

Table 1: Memory curve $MC(\tau)$ for i.i.d. versus Wigner matrices, $c = .5$.

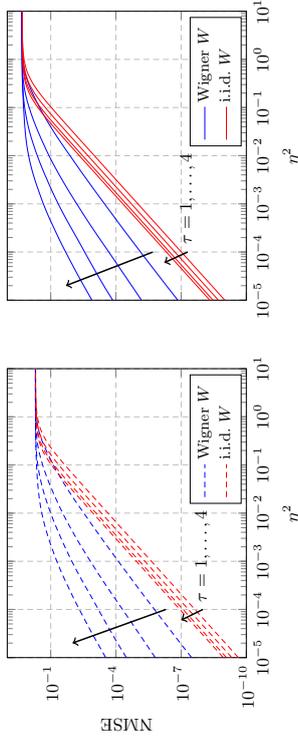

Figure 6: Training (left) and testing (right) performance of a τ -delay task for $\tau \in \{1, \dots, 4\}$ compared for i.i.d. W versus Wigner W , $\sigma = .9$ and $n = 200$, $T = \hat{T} = 400$ in both cases (here on the Mackey-Glass dataset).

An application example in a less artificial context is devised in Figure 7, where, on a real dataset of daily pollution (PM10) records, we provide the one-day ahead interpolation performance of neural networks assuming m random i.i.d. and either (i) W with i.i.d. Gaussian entries or (ii) W Gaussian Wigner. We observe again a better performance achieved by the ESN with non-normal matrix W which, accordingly with the fact that ESN's rely heavily on past input retrieval, is coherent with the previous remark.

3.3 Further Experiments

In this section, we provide further noticeable results of interest to neural network optimization.

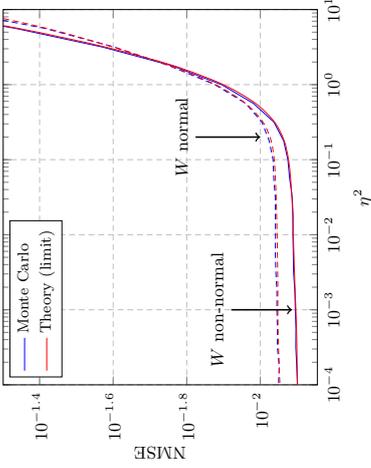

Figure 7: Testing (normalized) MSE for the PM10 one-step ahead task, W i.i.d. Gaussian or Gaussian Wigner ($\sigma = .9$), $n = 200$, $T = \hat{T} = 400$.

To start with, we consider a scenario where the testing dataset is polluted by an additional impulsive white Gaussian noise arising independently with probability p . This is depicted in Figure 8 for the Mackey-Glass one-step ahead task. It is observed here that the in-network noise is valuable in bringing the normalized MSE down to acceptable values. It is in particular seen that the more the noise impulsion probability the larger the variance η^2 should be chosen. A particular realization of the noisy Mackey-Glass output is provided in Figure 9, where it is observed that a visually small noise impulsion in the input vector drives a large fluctuation of the output for a too small- η^2 ESN.

This phenomenon can be theoretically anticipated in simple settings. Let us consider the scenario of Section 3.1 with W orthogonally invariant, where $r = U^T b$ for a vector $b \in \mathbb{R}^T$ having only its last $T - k$ entries identically zero for some fixed k ; let us now assume that $\hat{u} = \hat{u}_0 + \hat{\epsilon}$ for some noise vector $\hat{\epsilon}$ made of i.i.d. zero mean and variance s^2 entries, and suppose that $\hat{r} = \hat{U}_0$ for $\{\hat{U}_0\}_{ij} = [\hat{u}_0]_{i=j}$. Then, an application of Corollary 13 leads to $\hat{E}_\eta(u, r; \hat{u}, \hat{r})$ asymptotically equal to (7) plus an additional term given by (after calculus)

$$s^2 \left\| \left(\eta^2 I_T + D^{\frac{1}{2}} U U^T D^{\frac{1}{2}} \right)^{-1} D^{\frac{1}{2}} U U^T D^{\frac{1}{2}} (D^{-\frac{1}{2}} b) \right\|^2. \quad (10)$$

From the inequality $\|(\eta^2 I_T + D^{\frac{1}{2}} U U^T D^{\frac{1}{2}})^{-1}\| \leq \eta^{-2}$ and the fact that $\|D^{-\frac{1}{2}} b\|$ remains bounded, we get that the term (10) can be made arbitrarily small by letting $\eta^2 \rightarrow \infty$. Therefore, η^2 induces robustness in this scenario. Since $\eta^2 \rightarrow 0$ was shown to be optimal in the scenario where $s^2 = 0$, there must exist an MSE minimizing choice of $\eta^2 \in (0, \infty)$.

In a second experiment, we shall illustrate the ‘‘noise resurgence’’ effect discussed earlier in Remark 6. In Figure 10, we specifically draw the curves of the testing MSE variances for various experiments conducted earlier in the article. It is observed, as discussed in Remark 6 that, somewhat counter-intuitively, smaller η^2 values may lead to increased variances solely due to the in-network noise realization itself (recall that in all our experiments,

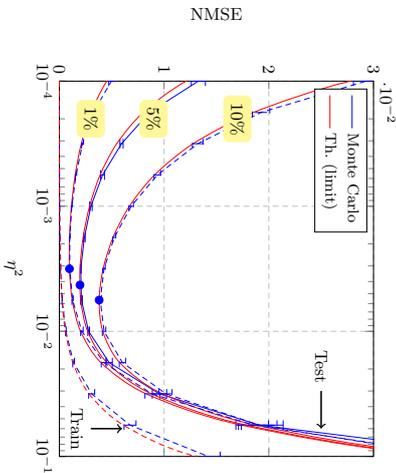

Figure 8: Testing (normalized) MSE for the Mackey-Glass one-step ahead task with 1% or 10% impulsive $\mathcal{N}(0, .01)$ noise pollution in test data inputs, W Haar with $\sigma = .9$, $n = 400$, $T = \hat{T} = 1000$. Circles indicate the NMSE theoretical minima. Error bars indicate one standard deviation of the Monte Carlo simulations.

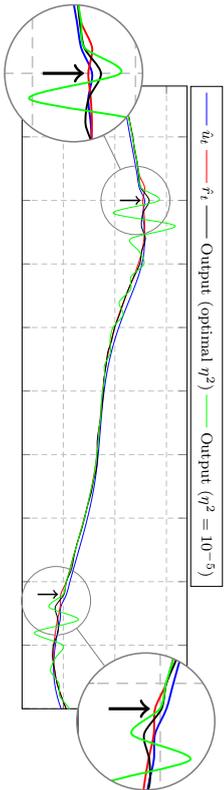

Figure 9: Realization of a 1% $\mathcal{N}(0, .01)$ -noisy Mackey-Glass sequence versus network output, W Haar with $\sigma = .9$, $n = 400$, $T = \hat{T} = 1000$. In magnifying lenses, points of added impulsive noise.

the connectivity matrix W and the input-output pairs (u_i, r_i) and (\hat{u}_i, \hat{r}_i) are fixed across all Monte Carlo realizations). It is even more interesting to observe here each of the three possible behaviors: a “natural” MSE variance decay as $\gamma^2 \rightarrow 0$, a surprising MSE increase, and even an MSE stabilization. Further theoretical analysis to understand those strikingly different behaviors would be appreciable, which would demand more advanced technical considerations.

We complete this section by a last comparative experiment of the performance of the multi-memory matrix W defined in Remark 15 specialized to the setting of Figure 1 (that is, with three rates $\sigma_1 = .99$, $\sigma_2 = .9$, and $\sigma_3 = .5$) versus Haar matrices for the different σ_i

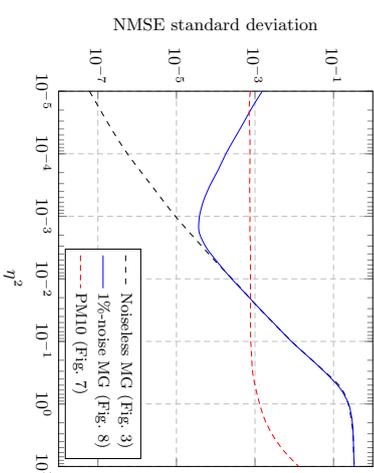

Figure 10: Standard deviation of testing NMSE for different testbeds (exemplifying the resurgence of noise effect). MG in legend stands for Mackey-Glass. In all scenarios, $n = 200$, $T = \hat{T} = 400$.

values, for the Mackey-Glass model. This is depicted in Figure 11, which shows a valuable performance gain versus ill-chosen individual hypotheses of σ and a rather fair match to the best individual σ value.

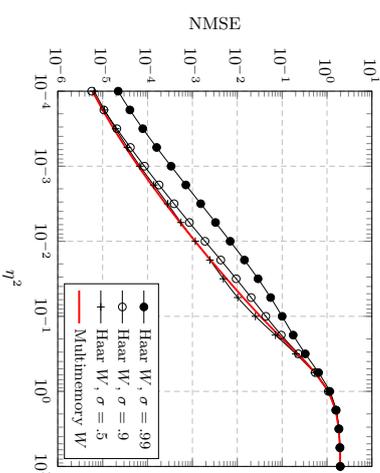

Figure 11: Testing (normalized) MSE for the Mackey-Glass one-step ahead task, W (multi-memory) versus $W_1^+ = .99Z_1^+$, $W_2^+ = .9Z_2^+$, $W_3^+ = .5Z_3^+$ (with Z_i^+ Haar distributed) all defined as in Figure 1, $n = 400$, $T = \hat{T} = 800$.

4. Concluding Remarks

One of the main outcomes of the present study is a better understanding of the ESN instability to low internal noise variance described by Jaeger in (Jaeger, 2001). We made it clear here that, when the noise variance is sufficiently large compared to the inverse square root of the network size, the ESN tends to have a deterministic behavior (that is, independent of the noise realization) as both time and network size grow large. This deterministic behavior was characterized here through new results from random matrix theory, with the main consequences to ESN's being encapsulated in Corollary 5 and Corollary 11. When the noise variance is however too small, random matrix theory cannot guarantee in general the aforementioned deterministic network behavior in the large system asymptotic. Although difficult to read, the asymptotic performances revolve around a critical matrix that contains the exponential memory decay information and may be used to generalize Ganguli's notion of memory curve (see Remark 7). This generalized memory curve draws improved conclusions on the ESN performance (with sometimes opposite outcomes as compared to the conclusions drawn upon the former memory curve notion).

In the particular case of some standard random matrix models for the neural connectivity matrix, we further simplified the rather involved generic expressions from Corollary 5 and Corollary 11. Of particular interest is the case of bi-orthogonally invariant random connectivity matrices for which the mean square error performances of learning and testing take on the explicit expressions of Corollary 13 or Corollary 18 from which much can be inferred. Among other results, we understood the importance of random input weights for the network performance as compared to input weights that match the leading eigenvectors of the connectivity matrix and we made it clear that the ESN testing performance is asymptotically optimal for arbitrary low noise variances *when* the task to fulfill is a mere linear combination of the last few past inputs. In additional experiments, we also understood the role of a non-trivial noise level as a robustness-to-outliers enhancer.

Beyond their theoretical value, note also that the results of this article may be used in practice to anticipate the behavior of ESN's on real-life datasets, thereby saving one from the painstaking task of running long Monte Carlo simulations. For instance, one may consider retrieving the theoretical MSE outputs corresponding to successive sequences of training and testing inputs so to better tune the ESN parameters. This is all the more precious that the network size and time windows are large since then the formulas of, say Corollary 13, can be retrieved extremely fast. In practice, for random networks, results such as Corollary 13 can be evaluated at a computational cost of $O(T^2)$ operations with minimal optimization (one may exploit the Toeplitz structure in U to further improve computations), when each run of a Monte Carlo simulation requires a prior evaluation of the successive products Wx_t , $t = 1, \dots, T-1$, to evaluate X , prior to evaluating $(XX^T)^{-1}X$; the latter amounts to a total minimum cost of $O(RTn^2)$ with R the number of Monte Carlo iterations.

One frustrating aspect of the work nonetheless remains that, for low noise variances (typically of practical interest), our analysis leads to large mismatches when the network size is kept moderate. This is observed in Figure 3 in particular. There is as such no theoretical control of this regime. This being said, in some scenarios where the limiting singularity at zero noise can be avoided, we showed an accurate fit of our theoretical findings at all noise levels. But the main limitation of the analysis so far lies in its dealing with linear activation functions only. In a currently on-going study, using more advanced notions of random matrix theory, the authors have managed to overcome the non-linearity limitation in retrieving deterministic approximations for the mean-square error performance of a single-layer feedforward neural network with random input layer (sometimes referred

to as extreme learning machines (Huang et al., 2006)). Since the key to this result lies in the independence of the random connectivity matrix entries when seen from each neuron, the extension to multi-layer networks and eventually to recurrent network is naturally envisioned in a future investigation.

Appendix A. Proof of Theorem 2

The present and next sections are dedicated to the proofs of the main results Theorems 2-9 of the article. The proofs rely on now well-established tools from random matrix theory, with an additional specificity due to the "infinitely long" time dependence between the columns of the random matrices involved; however, as the time dependence is *effectively* short (of order $o(T^\alpha)$ for any $\alpha > 0$), these matrices can be handled as if dependence was among only a few next and previous columns. We shall not deeply elaborate on all technical arguments for the sake of readability and concision. The reader more interested in the proof techniques and in more advanced time dependence considerations may refer to (Pastur and Šerbina, 2011; Hachem et al., 2008) on the Gaussian methods and (Baum and Merlevède, 2013) for stationary processes in random matrix theory.

Before delving into the proof of Theorem 2, let us first prove Lemma 1 which provides the expression of interest for $E_\eta(u, r)$ exploited in Theorem 2. The result is clearly valid when $n/T > 1$ as $X^T X$ is almost surely non singular. Thus, only the scenario where $n/T < 1$ is of interest. Expanding the expression of ω , first observe that $E_\eta(u, r) = \frac{1}{2} \|r - X^T \omega\|^2 = \frac{1}{2} r^T (I_T - X^T (X X^T)^{-1} X) r$ and that $(I_T - X^T (X X^T)^{-1} X)^2 = I_T - \frac{1}{2} r^T (X X^T)^{-1} X$. Introducing $\gamma > 0$, $E_\eta(u, r) = \lim_{\gamma \rightarrow 0} \frac{1}{2} r^T (I_T - X^T (X X^T + \gamma I_n)^{-1} X) r$. Now, using the identities $(AB+I)^{-1} A = A(BA+I)^{-1}$ and $A(A+bI)^{-1} = I - b(A+bI)^{-1}$ for matrices A, B and scalar b , this is $E_\eta(u, r) = \lim_{\gamma \rightarrow 0} \frac{1}{2} r^T (I_T - X^T X (X^T X + \gamma T I_T)^{-1}) r = \lim_{\gamma \rightarrow 0} \frac{1}{2} \gamma T r^T (X^T X + \gamma T I_T)^{-1} r$, from which Lemma 1 follows.

With the result at hand, we are ready to tackle the proof of Theorem 2. In the present section, W is considered a deterministic matrix with operator norm less than unity. We recall that $X = \{x_j\}_{j=0}^{T-1} \in \mathbb{R}^{n \times T}$, for the infinite time series $\dots, x_{-1}, x_0, x_1, \dots \in \mathbb{R}^n$, defined recursively through

$$x_{t+1} = Wx_t + mu_{t+1} + \eta \varepsilon_{t+1}$$

with m of bounded norm and $\dots, u_{-1}, u_0, u_1, \dots \in \mathbb{R}$ some time series. We additionally denote $A = MU$ where $M = \{W^k/m\}_{k=0}^{T-1}$ and $U = T^{-\frac{1}{2}} \{u_j\}_{j=0}^{T-1}$. Also, let $Z = \eta T^{-\frac{1}{2}} \{\sum_{k \geq 0} W^k \varepsilon_{j-k}\}_{j=0}^{T-1}$ the concatenated noise vectors, with $\varepsilon_t \sim \mathcal{M}(0, I_n)$. With these notations and normalization, we have $X = \sqrt{T}(A+Z)$, where A and Z are expected to have operator norm of order $O(1)$ with respect to $n, T \rightarrow \infty$ as per Assumption 3 and thus should $\frac{1}{2} X X^T$.

For $\gamma > 0$, denoting $Q_\gamma = (\frac{1}{2} X X^T + \gamma I_n)^{-1}$, our objective is to obtain an approximation of Q_γ in the sense of the equivalence \Leftrightarrow using the so-called *Gaussian method* introduced by Pastur in (Pastur and Šerbina, 2011). This method consists in two ingredients: (i) an integration by parts formula for Gaussian random variables (also called Stein's lemma) that stipulates that, for $x \sim \mathcal{N}(0, 1)$ and a polynomially bounded differentiable f , $E[xf(x)] =$

$E[f'(x)]$, and (ii) concentration inequalities or moment based bounds (such as the Nash-Poincaré inequality) to control small terms. The idea here is to expand terms of the type $E[|\varepsilon_{it}|_k |Q_{it}|_k]$ using the Gaussian integration by parts formula in order to retrieve an implicit *but deterministic* expression for Q_{it} , up to small random terms. Then, thanks to concentration or moment bounds, the aforementioned small terms are shown to vanish at a sufficient speed to ensure almost sure convergence of Q_{it} to the deterministic solution of the implicit equation in the sense of the equivalence \leftrightarrow .

We start by noticing that $Q_{it} = \frac{1}{\gamma} I_n - \frac{1}{\gamma} X^T X^T Q_{it}$, a relation often referred to as the *resolvent identity*. This allows one to write $E[Q_{it}]$ as a function of $E[XX^T Q_{it}]$ which lends itself to the integration by parts approach since X is a linear function of the Gaussian variables $\{\varepsilon_{it}\}$.

In what follows, for readability, we shall denote $Q = Q_{it}$ (and thus $Q_{it} = [Q_{it}]_{ij}$) and $\varepsilon_{it} = \{\varepsilon_{it}\}$. Then we have

$$E[Q_{it}] = \frac{1}{\gamma} \delta_{ij} - \frac{1}{\gamma} \underbrace{\left(E[[ZZ^T Q]_{ij}] \right)}_{(I)} + \underbrace{E[[ZA^T Q]_{ij}]}_{(II)} + \underbrace{E[[AZ^T Q]_{ij}]}_{(III)} + \underbrace{E[[AA^T Q]_{ij}]}_{(IV)}. \quad (11)$$

Each of the four bracketed terms needs be treated independently. Note first that term (IV) is simply $\sum_k [AA^T]_{kk} E[Q_{it}]$ and is thus treated similar to $E[Q_{it}]$ itself. It then remains to handle terms (I)–(III). Before handling each term, let us first introduce a few elementary results of constant use in what follows. First, by a mere development, we have

$$Z_{ab} = \frac{\eta}{\sqrt{T}} \sum_{k \geq 0} \sum_{p=1}^n [W^k]_{\sigma^p \varepsilon_{i,b-k}}$$

from which

$$\frac{\partial Z_{ab}}{\partial \varepsilon_{it}} = \frac{\eta}{\sqrt{T}} \sum_{k \geq 0} \sum_{p=1}^n \delta_{\sigma^p \varepsilon_{i,b-k}} [W^k]_{\sigma^p}. \quad (12)$$

Expanding X in the expression of Q and using $\partial Q = -Q(\partial Q^{-1})Q$, we then find

$$\frac{\partial Q_{mi}}{\partial \varepsilon_{it}} = -\frac{\eta}{\sqrt{T}} \sum_{p=1}^n \delta_{i \leq p} \left([Q(Z+A)]_{mp} [W^{p-1}]^T Q \right]_{ij} + \left[(Z+A)^T Q \right]_{ji} [QW^{p-1}]_{mi}. \quad (13)$$

It is important at this point to bring some insight from random matrix theory. If ε_{it} were a *complex* rather than real standard Gaussian random variable, the second term in the right-hand side parenthesis would not have appeared. Since first order deterministic equivalents (which is what we are proceeding to here) are usually valid irrespective of the i.i.d. distribution (real or complex) of the ε_{it} 's, it is expected that this second term will lead to vanishing terms in what follows.

With these preliminary results and this remark in mind, we can tackle the calculus of terms (I)–(III) from (11). Let us first focus on term (I). Developing $E[[ZZ^T Q]_{ij}]$ as a function of the ε_{it} 's and applying the Gaussian integration-by-parts formula, we find

$$\begin{aligned} E[[ZZ^T Q]_{ij}] &= \eta \sum_{l=1}^T \sum_{m=1}^n \sum_{o=1}^n \sum_{k \geq 0} E[\varepsilon_{o,l-k} Z_{m,l} Q_{mj}] [W^k]_{io} \\ &= \eta \sum_{l=1}^T \sum_{m=1}^n \sum_{o=1}^n \sum_{k \geq 0} \left(E \left[\frac{\partial Z_{m,k}}{\partial \varepsilon_{o,l-k}} Q_{mj} \right] + E \left[\frac{\partial Q_{mj}}{\partial \varepsilon_{o,l-k}} Z_{ml} \right] \right) [W^k]_{io}. \end{aligned}$$

Substituting the derivatives by the forms (12) and (13), we obtain after full development and simplifications

$$\begin{aligned} E[[ZZ^T Q]_{ij}] &= \eta^2 \sum_{k \geq 0} E \left[[W^k (W^k)^T Q]_{ij} \right] \\ &\quad - \eta^2 \sum_{k \geq 0} \sum_{q=-k}^{T-1} E \left[[W^k (W^{k+q})^T Q]_{ij} \frac{1}{T} [Z^T (Z+A) \tilde{Q}]_{i,q+1} \right] + E[\zeta_{ij}^{[1]}] \end{aligned}$$

where we defined $\tilde{Q} = \tilde{Q}_{it} = (\frac{1}{T} X^T X + \gamma I_n)^{-1}$ and where the term $\zeta_{ij}^{[1]}$ arises from the development of the aforementioned second term in the parentheses of (13) and can be shown to satisfy $\zeta^{[1]} \leftrightarrow 0$. Similarly, addressing the term (II) in (11), we find

$$E[[ZA^T Q]_{ij}] = -\eta^2 \sum_{k \geq 0} \sum_{q=-k}^{T-1} E \left[\frac{1}{T} [A^T (Z+A) \tilde{Q}]_{i,q+1} [W^k (W^{k+q})^T Q]_{ij} \right] + E[\zeta_{ij}^{[2]}]$$

where again we can show that $\zeta^{[2]} \leftrightarrow 0$. Summing the approximations for (I) and (II), from the resolvent identity $(Z+A)^T (Z+A) \tilde{Q} = I_n - \gamma \tilde{Q}$, we find

$$\begin{aligned} E[[Z(Z+A)^T Q]_{ij}] &= \eta^2 \sum_{k \geq 0} E \left[[W^k (W^k)^T Q]_{ij} \right] \\ &\quad - \eta^2 \sum_{k \geq 0} \sum_{q=-k}^{T-1} E \left[[W^k (W^{k+q})^T Q]_{ij} \frac{1}{T} [I_n - \gamma \tilde{Q}]_{i,q+1} \right] + E[\zeta_{ij}^{[1]}] + \zeta_{ij}^{[2]}. \end{aligned}$$

Since $[I_n]_{i,q+1} = \delta_{q=0}$, the first right-hand side term cancels with the part of the second term involved with matrix $\frac{1}{T} I_n$, and we find

$$E[[Z(Z+A)^T Q]_{ij}] = \eta^2 \sum_{k \geq 0} \sum_{q=-k}^{T-1} \sum_{l=1}^n E \left[[W^k (W^{k+q})^T Q]_{ij} \frac{1}{T} \tilde{Q}_{l,q+1} \right] + E[\zeta_{ij}^{[1]}] + \zeta_{ij}^{[2]}. \quad (14)$$

Moving to term (III) in (11), since A is deterministic, we first find the interesting expression

$$E[[AZ^T Q]_{ij}] = -\eta^2 \sum_{k \geq 0} \sum_{q=-k}^{T-1} \sum_{l=1}^n E \left[\frac{1}{T} \text{tr}(W^k (W^{k+q})^T Q) (Z+A)^T Q]_{l,i+1} \right] + E[\zeta_{ij}^{[3]}] \quad (15)$$

with $\zeta^{[3]} \leftrightarrow 0$ from which immediately we get

$$E[[AZ^T Q]_{ij}] = -\eta^2 \sum_{k \geq 0} \sum_{q=-k}^{T-1} \sum_{l=1}^n E \left[\frac{1}{T} \text{tr}(W^k (W^{k+q})^T Q) A_{il} ((Z+A)^T Q]_{l,i+1} \right] + E[A \zeta_{ij}^{[3]}]$$

and we of course still have $A \zeta^{[3]} \leftrightarrow 0$.

We must discuss at this point the next key idea of the Gaussian method. In term (III), the right-hand side expectation is taken over the product of the trace $\frac{1}{T} \text{tr}(W^k (W^{k+q})^T Q)$ and of the quantity $A_{il} ((Z+A)^T Q]_{l,i+1}$. Writing $\frac{1}{T} \text{tr}(W^k (W^{k+q})^T Q) = E[\frac{1}{T} \text{tr}(W^k (W^{k+q})^T Q)] + (\frac{1}{T} \text{tr}(W^k (W^{k+q})^T Q) - E[\frac{1}{T} \text{tr}(W^k (W^{k+q})^T Q)])$, it can be shown, using Cauchy-Schwarz and the Nash-Poincaré inequalities (Pastur and Seppälä, 2011), along with the Borel-Cantelli lemma (Billingsley, 1995), that

$$\sum_{k \geq 0} \sum_{q=-k}^{T-1} \sum_{l=1}^n \left(\frac{1}{T} \text{tr}(W^k (W^{k+q})^T Q) - E \left[\frac{1}{T} \text{tr}(W^k (W^{k+q})^T Q) \right] \right) A_{il} ((Z+A)^T Q]_{l,i+1} \leftrightarrow 0$$

which unfolds from $\frac{1}{T} \text{tr}(W^k(W^{k+q})^\top Q)$ concentrating around its mean in the large n, T regime, a standard result of random matrix theory. The main non-classical difficulty in showing this result lies here in the fact that the summation over up to T values of the dummy variable q involves both terms in and outside the bracket. Nonetheless, since $\rho(W) < 1$, $\|W^q\|$ vanishes at exponential speed and thus only $O(\log(T))$ values of q are effectively playing a role. The aforementioned Nash–Poincaré inequality ensures a control of the residual terms with a $O(1/T^2)$ variance for each q -summand which can then be summed over the non-trivial values of q to bring a total variance bounded by $O(\log(T)/T^2)$, which is summable, and then allows for Borel–Cantelli to be applied.

The same reasoning applies to the main expectation in the expression of $(I) + (II)$, where here the term that concentrates around its mean is $\frac{1}{T} \sum_{j=1}^{T-\eta} \bar{Q}_{i, q+\eta}$, which is more easily seen as $\frac{1}{T} \text{tr}(J^\eta \bar{Q})$.

The relation (15) in itself is quite instructive. Indeed, with the previous remark on the concentration of $\frac{1}{T} \text{tr}(W^k(W^{k+q})^\top Q)$, we may break the right-hand expectation as well as the term $(Z+A)^\top Q$ into $Z^\top Q + A^\top Q$ to retrieve a connection between left- and right-hand sides. Precisely, we find that

$$\begin{aligned} & \left[\left(I_T + \eta^2 \sum_{k \geq 0} \sum_{q=-k}^{T-1} \mathbb{E} \left[\frac{1}{T} \text{tr}(W^k W^{k+q})^\top Q \right] \right) \mathbb{E}[X^\top Q] \right]_{ij} \\ &= -\eta^2 \sum_{k \geq 0} \sum_{q=-k}^{T-1} \mathbb{E} \left[\frac{1}{T} \text{tr}(W^k(W^{k+q})^\top Q) \right] \mathbb{E}[J^\eta A^\top Q]_{i,j} + o(1) \end{aligned}$$

where we used $[B]_{|q|+i,j} = [J^\eta B]_{i,j}$. Remark now that

$$\begin{aligned} \sum_{k \geq 0} \sum_{q=-k}^{T-1} \frac{1}{T} \text{tr}(W^k(W^{k+q})^\top Q) J^q &= \sum_{k \geq 0} \left\{ \frac{1}{T} \text{tr}(W^{k+(b-a)^+} (W^{k+(a-b)^+})^\top Q) \right\}_{a,b=1}^T \\ &= \left\{ \frac{1}{T} \text{tr}(S_{a-b} Q) \right\}_{a,b=1}^T. \end{aligned}$$

Denoting $\bar{R} = \mathbb{E}[\{\frac{1}{T} \text{tr}(S_{a-b} Q)\}_{a,b=1}^T]$ and using concentration arguments (Nash–Poincaré inequality in particular) entails

$$Z^\top Q \leftrightarrow -\eta^2 (I_T + \eta^2 \bar{R})^{-1} \bar{R} A^\top Q. \quad (16)$$

From the definition of the equivalence relation \leftrightarrow , this entails

$$AZ^\top Q \leftrightarrow -\eta^2 A (I_T + \eta^2 \bar{R})^{-1} \bar{R} A^\top Q. \quad (17)$$

Similarly, recalling (14), we have

$$\begin{aligned} Z(Z+A)^\top Q &\leftrightarrow \eta^2 \gamma \sum_{k \geq 0} \sum_{q=-k}^{T-1} \text{tr}(J^\eta \bar{Q}) W^k (W^{k+q})^\top Q \\ &= \eta^2 \gamma \sum_{q=-\infty}^{\infty} \frac{1}{T} \text{tr}(J^\eta \bar{Q}) S_q Q. \end{aligned}$$

We may then define $\bar{R} = \sum_{q=-\infty}^{\infty} \mathbb{E}[\frac{1}{T} \text{tr}(J^\eta \bar{Q}) S_q]$. Added to (17) and $AA^\top Q$, this is

$$(Z+A)(Z+A)^\top Q \leftrightarrow -\eta^2 \gamma \bar{R} - \eta^2 A (I_T + \eta^2 \bar{R})^{-1} \bar{R} A^\top Q + AA^\top Q.$$

With $AA^\top = A(I_T + \eta^2 \bar{R})^{-1} (I_T + \eta \bar{R}) A^\top$ and $(Z+A)(Z+A)^\top Q = I_n - \gamma Q$, this further reads

$$Q \leftrightarrow \frac{1}{\gamma} I_n - \eta^2 \bar{R} Q - \frac{1}{\gamma} A (I_T + \eta^2 \bar{R})^{-1} A^\top Q.$$

which, after gathering the factors of Q together, finally gives the first identity

$$Q \leftrightarrow \frac{1}{\gamma} \left(I_n + \eta^2 \bar{R} + \frac{1}{\gamma} A (I_T + \eta^2 \bar{R})^{-1} A^\top \right)^{-1}. \quad (18)$$

To pursue our investigation, we need to proceed to the same development for the matrix \bar{Q} which appears in the definition of \bar{R} . The idea is to express \bar{Q} under a form involving Q itself, then closing the loop. The analysis is extremely similar to that of Q and it is not surprising (from the symmetry between Q and \bar{Q}) to finally obtain

$$\bar{Q} \leftrightarrow \frac{1}{\gamma} \left(I_T + \eta^2 \bar{R} + \frac{1}{\gamma} A^\top (I_n + \eta^2 \bar{R})^{-1} A \right)^{-1}. \quad (19)$$

At this point, however, both \bar{R} and \bar{Q} are non explicit quantities that depend on the statistics of Q and \bar{Q} . From (18), we get that, for each a, b ,

$$\frac{1}{T} \text{tr}(S_{a-b} Q) \leftrightarrow \frac{1}{\gamma} \frac{1}{T} \text{tr} S_{a-b} \left(I_n + \eta^2 \bar{R} + \frac{1}{\gamma} A (I_T + \eta^2 \bar{R})^{-1} A^\top \right)^{-1}$$

and this relation is shown to be uniform across a, b , as it involves only $O(\log(T))$ non-trivial coefficients. To freely identify \bar{R} with $\{\frac{1}{\gamma} \text{tr} S_{a-b} (I_n + \eta^2 \bar{R} + \frac{1}{\gamma} A (I_T + \eta^2 \bar{R})^{-1} A^\top)^{-1}\}_{a,b=1}^n$, one may ensure that the difference between both matrices vanishes in spectral norm almost surely (here the relation \leftrightarrow may not be enough).⁴ Here the result holds true because both $\{\frac{1}{T} \text{tr}(S_{a-b} Q)\}_{a,b=1}^n$ and \bar{R} are Toeplitz matrices with exponentially decaying coefficients away from the main diagonal. Hence, we may essentially see each matrix as the sum of a circulant matrix and of a matrix with $O(\log(T))$ non-vanishing upper-right and lower-left entries (see (Gray, 2006) for such a construction). Circulant matrices being diagonalizable in the Fourier basis with eigenvalues equal to the Fourier transform of the concatenated first column and row, that the difference in spectral norm vanishes boils down to the convergence of the difference between these Fourier transforms, which is easily obtained through the joint entry convergence and exponential decrease. As for the remaining corner entries, being of $\log(T)$ number, we deal here with the difference in spectral norm of small rank matrices, which is obtained by direct uniform convergence. As such, generally speaking, if the entries of a Toeplitz matrix with exponentially vanishing profile converge jointly to given limits, then the limiting Toeplitz matrix is equivalent in the spectral norm sense.

Similarly, to identify \bar{R} with $\sum_{q \neq 0} \frac{1}{\gamma} \text{tr}(J^q (I_T + \eta^2 \bar{R} + \frac{1}{\gamma} A^\top (I_n + \eta^2 \bar{R})^{-1} A)^{-1}) S_q$, we need to show the spectral norm difference of these matrices vanishes almost surely. This is here obtained from the uniform convergence across the $O(\log(T))$ first trace coefficients (say for all $|q| \leq C \log(T)$) and from the corresponding exponentially vanishing spectral norm of S_q .

All said, we may then define $\bar{R}_\gamma, \bar{R}_{\bar{\gamma}}, \bar{Q}_\gamma,$ and $\bar{Q}_{\bar{\gamma}}$ as in Theorem 2 and the results above ensure that $Q_\gamma \leftrightarrow \bar{Q}_\gamma$ and $\bar{Q}_{\bar{\gamma}} \leftrightarrow \bar{Q}_{\bar{\gamma}}$.

4. A typical counter-example is the case of $Z \in \mathbb{R}^{n \times T}$ with i.i.d. zero mean and unit variance entries for which $\{\frac{1}{T} Z Z^\top\}_{ab} \rightarrow \delta_{a-b}$ uniformly over a, b while clearly $(\frac{1}{T} Z Z^\top + \gamma I_n)^{-1} \not\rightarrow (1 + \gamma)^{-1} I_T$.

Remark 22 (Result without washout period) *Theorem 2 assumes an infinite noise time series $(\dots, \varepsilon_{-1}, \varepsilon_0, \varepsilon_1, \dots)$. One might have alternatively considered a scenario without washout period, that is, with $x_{-1} = 0$ and first time instant being $t = 0$. In this case, Theorem 2 remains valid but for the following updated expressions of R_γ and \bar{R}_γ*

$$R_\gamma = \left\{ \sum_{k=0}^{\max(i,j)-1} \frac{1}{T} \text{tr } W^{k+(j-i)^+} (W^{k+(i-j)^+})^T Q_\gamma \right\}_{i,j=1}^T$$

$$\bar{R}_\gamma = \sum_{q=-(T-1)}^{T-1} \frac{1}{T} \text{tr} \left(J^q \bar{Q}_\gamma \right) \sum_{k=0}^{T-1-|q|} W^{k+(-q)^+} (W^{k+q^+})^T.$$

In particular, R_γ is no longer Toeplitz. Nonetheless the non-Toeplitz behavior is essentially concentrated in the top-left corner of size $O(\log(T))$ since the remainder of the matrix behaves essentially as Toeplitz (for $i, j \geq C \log(T)$ for some large enough constant C). This modification may alter the behavior of the associated train and test MSE, especially if r and \hat{r} concentrate their energy in their first entries.

Appendix B. Proof of Theorem 9

The first part of Theorem 9 is directly obtained from (16) along with $Q_\gamma \leftrightarrow \bar{Q}_\gamma$. Indeed, from these relations, we have

$$Q_\gamma \frac{1}{\sqrt{T}} X = Q_\gamma Z + Q_\gamma A \leftrightarrow -\eta^2 Q_\gamma A \bar{R}_\gamma (I_T + \eta^2 R_\gamma)^{-1} + Q_\gamma A$$

$$= \bar{Q}_\gamma A (I_T + \eta^2 R_\gamma)^{-1}.$$

The proof of the second part of Theorem 9 is not as straightforward as it involves twice the matrix Q_γ and thus results from Theorem 2 cannot be immediately applied. To handle this term, first write

$$\frac{1}{T} X^T Q_\gamma B Q_\gamma X = \underbrace{Z^T Q_\gamma B Q_\gamma Z}_{(I)} + \underbrace{Z^T Q_\gamma B Q_\gamma A}_{(II)} + \underbrace{A^T Q_\gamma B Q_\gamma Z}_{(III)} + \underbrace{A^T Q_\gamma B Q_\gamma A}_{(IV)}. \quad (20)$$

Since B is assumed symmetric, (III) is the transposed version of (II), so that only one of the two needs be studied.

Similar to Appendix A, we shall from now on simply write Q_γ as \bar{Q}_γ , \bar{Q}_γ as \bar{Q} , etc. We start by addressing term (I). We use again the Gaussian tools centered around the Gaussian integration by parts formula. We shall also benefit from the results of Theorem 2. Since B is deterministic, it needs not be included early in calculations so we merely start by evaluating, for given indices i, j, k, l ,

$$\begin{aligned} \mathbb{E} \left[Z^T Q_{ij} [QZ]_{kl} \right] &= \sum_{m, m', p, p' = 1}^n \sum_{q, q' \geq 0} \eta^2 \mathbb{E} \left[\varepsilon_{p,i} \varepsilon_{p',l} \varepsilon_{q,j} Q_{km} Q_{km'} \right] [W^q]_{mp} [W^{q'}]_{m'p'} \\ &= \sum_{m, m', p, p' = 1}^n \sum_{q, q' \geq 0} \eta^2 \mathbb{E} \left[\frac{\partial (\varepsilon_{p,i} \varepsilon_{p',l} Q_{km} Q_{km'})}{\partial \varepsilon_{p',l} \varepsilon_{q'}} \right] [W^q]_{mp} [W^{q'}]_{m'p'} \end{aligned}$$

where the second line follows from the Gaussian integration-by-parts formula. Developing the derivative based on (13) and on the fact that $\partial \varepsilon_{ab} / \partial \varepsilon_{cd} = \delta_{ac} \delta_{bd}$, we get after

$$\begin{aligned} \mathbb{E} \left[Z^T Q_{ij} [QZ]_{kl} \right] &= \eta^2 \sum_{q, q' \geq 0} \mathbb{E} \left[\frac{1}{T} Q W^q (W^{q'})^T Q_{ij} \delta_{i-q,l-q'} \right] \\ &= \eta^3 \sum_{q, q' \geq 0} \sum_{s=1}^T \mathbb{E} \left[\frac{1}{\sqrt{T}} \varepsilon^T (W^q)^T Q (Z + A)_{i-q,s} \frac{1}{T} [Q W^{q'} (W^{q'+s-1})^T Q]_{kj} \right] \\ &\quad - \eta^3 \sum_{q, q' \geq 0} \sum_{s=1}^T \mathbb{E} \left[\frac{1}{\sqrt{T}} \varepsilon^T (W^q)^T Q_{i-q,j} [Q (Z + A)]_{k,s} \frac{1}{T} \text{tr} (W^{q'} (W^{q'+s-1})^T Q) \right] \\ &\quad + \mathbb{E} [\zeta_{ij,kl}^{(1)}] \end{aligned}$$

simplification

$$\begin{aligned} &= \eta^2 \bar{G}_{ij} - \eta^2 \mathbb{E} \left[Z^T Q (Z + A) \bar{G} (I_T + \eta^2 \bar{R})^{-1} - \eta^2 Z^T Q B Q A \bar{R} (I_T + \eta^2 \bar{R})^{-1} \right] \\ &= \eta^2 \bar{G}_{ij} - \eta^2 \mathbb{E} \left[\frac{1}{T} \text{tr} \left(B Q W^{k+(j-i)^+} (W^{k+(i-j)^+})^T Q \right) \right]. \end{aligned} \quad (21)$$

for some $\zeta_{ij,kl}^{(1)} \leftrightarrow 0$ (arising from terms consistent with the remark following (13) in Appendix A) and where $\varepsilon = \{\varepsilon_{ij}\}_{j=1}^{n \times T}$. Inserting $B_{j,k}$, summing over j and k , we obtain after simplifications

$$\mathbb{E} \left[Z^T Q B Q Z_{ij} \right] = \eta^2 \bar{G}_{ii} - \eta^2 \mathbb{E} \left[Z^T Q (Z + A) \bar{G} [i] \right] - \eta^2 \mathbb{E} \left[Z^T Q B Q (Z + A) \bar{R} [i] \right] + o(1)$$

where \bar{R} was introduced in Appendix A and we defined \bar{G} the matrix with

$$\bar{G}_{ij} = \sum_{k \geq 0} \mathbb{E} \left[\frac{1}{T} \text{tr} \left(B Q W^{k+(j-i)^+} (W^{k+(i-j)^+})^T Q \right) \right].$$

Gathering the terms in $Z^T Q B Q Z$ together along with concentration arguments, we finally obtain

$$Z^T Q B Q Z \leftrightarrow \eta^2 \bar{G} (I_T + \eta^2 \bar{R})^{-1} - \eta^2 Z^T Q (Z + A) \bar{G} (I_T + \eta^2 \bar{R})^{-1} - \eta^2 Z^T Q B Q A \bar{R} (I_T + \eta^2 \bar{R})^{-1}.$$

In the right-hand side formulation, the second term can be approximated from the results of Theorem 2 as well as the first part of Theorem 9; indeed, note from $(Z + A)^T Q (Z + A) = Q (Z + A)^T (Z + A) = I_T - \gamma \bar{Q}$ that $Z^T Q (Z + A) = I_T - \gamma \bar{Q} - A^T Q (Z + A)$, so that

$$\begin{aligned} Z^T Q B Q Z &\leftrightarrow \eta^2 \gamma \bar{Q} \bar{G} (I_T + \eta^2 \bar{R})^{-1} + \eta^2 A^T \bar{Q} A (I_T + \eta^2 \bar{R})^{-1} \bar{G} (I_T + \eta^2 \bar{R})^{-1} \\ &\quad - \eta^2 Z^T Q B Q A \bar{R} (I_T + \eta^2 \bar{R})^{-1}. \end{aligned} \quad (22)$$

In this expression, the last right-hand side term still involves $Z^T Q B Q A$, yet to be characterized. This is the objective of the next step, which coincides with the study of the term (II) in (20).

Following the derivation of term (I), terms (II) and (III) are easily obtained (indeed, they somewhat boil down to (21) without the first right-hand side term and without the components $\varepsilon^T (W^q)^T$ in the subsequent terms). Precisely, all calculus made, we find that

$$Q B Q Z \leftrightarrow -\eta^2 Q (Z + A) \bar{G} - \eta^2 Q B Q (Z + A) \bar{R}$$

from which

$$Q B Q Z \leftrightarrow -\eta^2 Q (Z + A) \bar{G} (I_T + \eta^2 \bar{R})^{-1} - \eta^2 Q B Q A \bar{R} (I_T + \eta^2 \bar{R})^{-1}.$$

Again, the first right-hand side term is easily expressed by Theorem 2 and the first result of Theorem 9, from which

$$Q B Q Z \leftrightarrow -\eta^2 \bar{Q} A (I_T + \eta^2 \bar{R})^{-1} \bar{G} (I_T + \eta^2 \bar{R})^{-1} - \eta^2 Q B Q A \bar{R} (I_T + \eta^2 \bar{R})^{-1}. \quad (23)$$

but the second term now involves the quantity QBQ which is our next target. Since studying QBQ entails studying A^TQBQA , this shall provide us with the term (IV) in (20). To address QBQ , it suffices to estimate $E[Q_{ij}Q_{kl}]$; from the resolvent identity $Q_{ij} = \frac{1}{\gamma}\delta_{ij} - \frac{1}{\gamma}[\frac{1}{\gamma}XX^TQ]_{ij}$, this is developed as

$$E[Q_{ij}Q_{kl}] = -\frac{1}{\gamma} \left(E[[Z^T Z]Q_{ij}Q_{kl}] + E[[ZA^T Q]_{ij}Q_{kl}] + E[[AZ^T Q]_{ij}Q_{kl}] + E[[AA^T Q]_{ij}Q_{kl}] \right) + \frac{1}{\gamma}\delta_{ij}E[Q_{kl}].$$

The deterministic equivalent for $E[Q_{kl}]$ is already known, and we are then left to evaluate the first four terms, some of which can be retrieved from previous calculus. Developing each term, integrating the previously developed equivalents, while introducing the matrix B and summing, after some tedious calculus, we finally obtain

$$QBQ \leftrightarrow \frac{1}{\gamma}B\bar{Q} + \frac{\eta^2}{\gamma}A(I_T + \eta^2\bar{R})^{-1}\bar{G}(I_T + \eta^2\bar{R})^{-1}A^T\bar{Q} - \eta^2\bar{R}QBQ + \frac{1}{\gamma}\bar{G}\bar{Q} - \frac{1}{\gamma}A(I_T + \eta^2\bar{R})^{-1}A^TQBQ$$

where we introduced the notation

$$\bar{G} = \sum_{q=-\infty}^{\infty} \eta^2 E \left[\frac{1}{T} \text{tr} \left(J^q(A+Z)^T QBQ(Z+A) \right) \sum_{k \geq 0} W^{k+(-q)^+} (W^{k+q^+})^T \right].$$

Gathering all terms proportional to QBQ , we finally obtain

$$QBQ \leftrightarrow \bar{Q}(B + \bar{G})\bar{Q} + \eta^2\bar{Q}A(I_T + \eta^2\bar{R})^{-1}\bar{G}(I_T + \eta^2\bar{R})^{-1}A^T\bar{Q}. \quad (24)$$

Substituting (24) in (23), then substituting the result in (22), we may now completely characterize $\frac{1}{T}X^TQBQX$ (after simplification) as

$$\frac{1}{T}X^TQBQX \leftrightarrow \eta^2\gamma^2\bar{Q}\bar{G}\bar{Q} + (I_T + \eta^2\bar{R})^{-1}A^T\bar{Q}[\bar{Q}(B + \bar{G})\bar{Q}A(I_T + \eta^2\bar{R})^{-1}].$$

It remains to evaluate $E[\frac{1}{T} \text{tr}(J^q(A+Z)^T QBQ(Z+A))]$ in the expression of \bar{G} . For this, we shall exploit the fact that $A = MU$ which, since M has columns of exponentially decreasing norm, can be considered as a matrix of rank “essentially of order $O(\log(T))$ ”; that is, while being full rank, A can be well approximated in spectral norm by the product $\bar{M}\bar{U}$ of the first $O(\log(T))$ columns \bar{M} of M and first $O(\log(T))$ rows \bar{U} of U . This entails that, in the deterministic approximation for $(A+Z)^TQBQ(Z+A)$, only the terms not involving a product with A or A^T will remain after taking the normalized trace. And thus we get, after development and simplification

$$\left\| \bar{G} - \sum_{q=-\infty}^{\infty} \gamma^2 \eta^2 \frac{1}{T} \text{tr} \left(J^q \bar{Q} \bar{G} \bar{Q} \right) \sum_{k \geq 0} W^{k+(-q)^+} (W^{k+q^+})^T \right\| \rightarrow 0.$$

It then suffices to use concentration identities and the results of Appendix A to finally substitute \bar{R} with \bar{R} , \bar{R} with \bar{R} , and \bar{G} , \bar{G} with G and \bar{G} , respectively. This concludes the proof of Theorem 9.

Remark 23 (On the speed of convergence) To better appreciate the interplay between η^2 and n, T , note that all convergences discussed in Appendices A–B involve either quadratic forms of the type $a^T Q a$ for $Q \in \mathbb{R}^{n \times n}$ a random matrix based on some $\varepsilon \in \mathbb{R}^{n \times T}$, matrix with independent entries, or normalized traces $\frac{1}{n} \text{tr} Q$. It is a standard central limit result in random matrix theory that the former quadratic form $a^T Q a$ fluctuates at speed $O(n^{-\frac{1}{2}})$, that is, $\text{var}(a^T Q a) = O(n^{-1})$, and that normalized traces fluctuate at the faster speed $O(n^{-1})$. As such, the results of Theorems 2–9 and Proposition 4–10 can be trusted with high probability within a $O(n^{-\frac{1}{2}})$ error bound.

With respect to η^2 , the bounds between random quantities and deterministic equivalents, say Q and \bar{Q} , are proportional to $1/\eta^2$. This is why η^2 is assumed fixed and not decaying in our results. Nonetheless, as both bounds in n and η^2 multiply, it is expected that convergence is maintained in general so long that $n^{-\frac{1}{2}}/\eta^2 \rightarrow 0$, i.e., when $\eta^2 \gg n^{-\frac{1}{2}}$.

Abstract

Given a graph in which a few vertices are deemed interesting a priori, the vertex nomination task is to order the remaining vertices into a nomination list such that there is a concentration of interesting vertices at the top of the list. Previous work has yielded several approaches to this problem, with theoretical results in the setting where the graph is drawn from a stochastic block model (SBM), including a vertex nomination analogue of the Bayes optimal classifier. In this paper, we prove that maximum likelihood (ML)-based vertex nomination is consistent, in the sense that the performance of the ML-based scheme asymptotically matches that of the Bayes optimal scheme. We prove theorems of this form both when model parameters are known and unknown. Additionally, we introduce and prove consistency of a related, more scalable restricted-focus ML vertex nomination scheme. Finally, we incorporate vertex and edge features into ML-based vertex nomination and briefly explore the empirical effectiveness of this approach.

Keywords: vertex nomination, graph matching, graph inference, stochastic block model, graph mining

1. Introduction and Background

Graphs are a common data modality, useful for modeling complex relationships between objects, with applications spanning fields as varied as biology (Jeong et al., 2001; Bullmore and Sporns, 2009), sociology (Wasserman and Faust, 1994), and computer vision (Foggia et al., 2014; Kandel et al., 2007), to name a few. For example, in neuroscience, vertices may be neurons and edges adjoin pairs of neurons that share a synapse (Bullmore and Sporns, 2009);

in social networks, vertices may correspond to people and edges to friendships between them (Carrington et al., 2005; Yang and Leskovec, 2015); in computer vision, vertices may represent pixels in an image and edges may represent spatial proximity or multi-resolution mappings (Kandel et al., 2007). In many useful networks, vertices with similar attributes form densely-connected communities compared to vertices with highly disparate attributes, and uncovering these communities is an important step in understanding the structure of the network. There is an extensive literature devoted to uncovering this community structure in network data, including methods based on maximum modularity (Newman and Girvan, 2004; Newman, 2006b), spectral partitioning algorithms (Luxburg, 2007; Rohe et al., 2011; Sussman et al., 2012; Lyzinski et al., 2014b), and likelihood-based methods (Bickel and Chen, 2009), among others.

In the setting of *vertex nomination*, one community in the network is of particular interest, and the inference task is to order the vertices into a nomination list with those vertices from the community of interest concentrating at the top of the list. See Marchette et al. (2011); Coppersmith and Priebe (2012); Coppersmith (2014); Fishkind et al. (2015) and the references contained therein for a review of the relevant vertex nomination literature. Vertex nomination is a semi-supervised inference task, with example vertices from the community of interest—and, ideally, also examples not from the community of interest—being leveraged in order to create a nomination list. In this way, the vertex nomination problem is similar to the problem faced by personalized recommender systems (see, for example, Resnick and Varian, 1997; Ricci et al., 2011), where, given a training list of objects of interest, the goal is to arrange the remaining objects into a recommendation list with “interesting” objects concentrated at the top of the list. The main difference between the two inference tasks is that in vertex nomination the features of the data are encoded into the topology of a network, rather than being observed directly as features (though see Section 5 for the case where vertices are annotated with additional information in the form of features).

In this paper, we develop the notion of a consistent vertex nomination scheme (Definition 2). We then proceed to prove that the maximum-likelihood vertex nomination scheme of Fishkind et al. (2015) is consistent under mild model assumptions on the underlying stochastic block model (Theorem 6). In the process, we propose a new, efficiently executable solvable likelihood-based nomination scheme, the restricted-focus maximum-likelihood vertex-nomination scheme, $\mathcal{L}_R^{\text{ML}}$, and prove the analogous consistency result (Theorem 8). In addition, under mild model assumptions, we prove that both schemes maintain their consistency when the stochastic block model parameters are unknown and are estimated using the seed vertices (Theorems 9 and 10). In both cases, we show that consistency is possible even when the seeds are an asymptotically vanishing portion of the graph. Lastly, we show how both schemes can be easily modified to incorporate edge weights and vertex features (Section 5), before demonstrating the practical effect of our theoretical results on real and synthetic data (Section 6) and closing with a brief discussion (Section 7).

1.1 Notation

We say that a sequence of random variables $(X_n)_{n=1}^\infty$ converges almost surely to random variable X , written $X_n \rightarrow X$ a.s., if $\mathbb{P}[\lim_{n \rightarrow \infty} X_n = X] = 1$. We say a sequence of events $(A_n)_{n=1}^\infty$ occurs almost always almost surely (abbreviated a.a.s.) if with probability 1,

A_n^c occurs for at most finitely many n . By the Borel-Cantelli lemma, $\sum_{n=1}^{\infty} \mathbb{P}[A_n^c] < \infty$ implies $(A_n)_{n=1}^{\infty}$ a.a.s. We write G_n to denote the set of all (possibly weighted) graphs on n vertices. Throughout, without loss of generality, we will assume that the vertex set is given by $V = \{1, 2, \dots, n\}$. For a positive integer K , we will often use $[K]$ to denote the set $\{1, 2, \dots, K\}$. For a set V , we will use $\binom{V}{2}$ to denote the set of all pairs of distinct elements of V . That is, $\binom{V}{2} = \{u, v\} : u, v \in V, u \neq v\}$. For a function f with domain V , we write $f|_U$ to denote the restriction of f to the set $U \subset V$.

1.2 Background

Stochastic block model random graphs offer a theoretically tractable model for graphs with latent community structure (Rohle et al., 2011; Sussman et al., 2012; Bickel and Chen, 2009), and have been widely used in the literature to model community structure in real networks (Airoldi et al., 2008; Karrer and Newman, 2011). While stochastic block models can be too simplistic to capture the eccentricities of many real graphs, they have proven to be a useful tractable surrogate for more complicated networks (Airoldi et al., 2013; Olhede and Wolfe, 2014).

Definition 1 Let K and n be positive integers and let $\vec{n} = (n_1, n_2, \dots, n_K)^T \in \mathbb{R}^K$ be a vector of positive integers with $\sum_k n_k = n$. Let $b : [n] \rightarrow [K]$ and let $\Lambda \in [0, 1]^{K \times K}$ be symmetric. A G_n -valued random graph G is an instantiation of a (K, \vec{n}, b, Λ) conditional Stochastic Block Model, written $G \sim \text{SBM}(K, \vec{n}, b, \Lambda)$, if

- i. The vertex set V is partitioned into K blocks, V_1, V_2, \dots, V_K of cardinalities $|V_k| = n_k$ for $k = 1, 2, \dots, K$;
- ii. The block membership function $b : V \rightarrow [K]$ is such that for each $v \in V$, $v \in V_{b(v)}$;
- iii. The symmetric block communication matrix $\Lambda \in [0, 1]^{K \times K}$ is such that for each $\{v, u\} \in \binom{V}{2}$, there is an edge between vertices u and v with probability $\Lambda_{b(u), b(v)}$, independently of all other edges.

Without loss of generality, let V_1 be the block of interest for vertex nomination. For each $k \in [K]$, we further decompose V_k into $V_k = S_k \cup U_k$ (with $|S_k| = m_k$), where the vertices in $S := \cup_k S_k$ have their block membership observed *a priori*. We call the vertices in S *seed vertices*, and let $m = |S|$. We will denote the set of nonseed vertices by $U = \cup_k U_k$, and for all $k \in [K]$, let $u_k := n_k - m_k = |U_k|$ and $n - m = u = |U|$. Throughout this paper, we assume that the seed vertices S are chosen uniformly at random from all possible subsets of V of size m . The task in vertex nomination is to leverage the information contained in the seed vertices to produce a *nomination list* $\mathcal{L} : U \rightarrow [u]$ (i.e., an ordering of the vertices in U) such that the vertices in U_1 concentrate at the top of the list. We note that, strictly speaking, a nomination list \mathcal{L} is also a function of the observed graph G , a fact that we suppress for ease of notation. We measure the efficacy of a nomination scheme via *average precision*

$$\text{AP}(\mathcal{L}) = \frac{1}{u_1} \sum_{i=1}^u \frac{\sum_{j=1}^i \mathbb{1}\{\mathcal{L}^{-1}(j) \in U_1\}}{i}. \quad (1)$$

AP ranges from 0 to 1, with a higher value indicating a more effective nomination scheme: indeed, $\text{AP}(\mathcal{L}) = 1$ indicates that the first u_1 vertices in the nomination list are all from the block of interest, and $\text{AP}(\mathcal{L}) = 0$ indicates that none of the u_1 top-ranked vertices are from the block of interest. Letting $H_k = \sum_{j=1}^k 1/j$ denote the k -th harmonic number, with the convention that $H_0 = 0$, we can rearrange (1) as

$$\text{AP}(\mathcal{L}) = \sum_{i=1}^{u_1} \frac{H_{u_1} - H_{i-1}}{u_1} \mathbb{1}\{\mathcal{L}^{-1}(i) \in U_1\},$$

from which we see that the average precision is simply a convex combination of the indicators of correctness in the rank list, in which correctly placing an interesting vertex higher in the nomination list (i.e., with rank close to 1) is rewarded more than correctly placing an interesting vertex lower in the nomination list.

In Fishkind et al. (2015), three vertex nomination schemes are presented in the context of stochastic block model random graphs: the canonical vertex nomination scheme, \mathcal{L}^C , which is suitable for small graphs (tens of vertices); the maximum-likelihood vertex-nomination scheme, \mathcal{L}^{ML} , which is suitable for small to medium graphs (up to thousands of vertices); and the spectral partitioning vertex nomination scheme, \mathcal{L}^{SP} , which is suitable for medium to very large graphs (up to tens of millions of vertices). In the stochastic block model setting, the canonical vertex nomination scheme is provably optimal: under mild model assumptions, $\mathbb{E} \text{AP}(\mathcal{L}^C) \geq \mathbb{E} \text{AP}(\mathcal{L})$ for any vertex nomination scheme \mathcal{L} (Fishkind et al., 2015), where the expectation is with respect to a G_{n+n} -valued random graph G and the selection of the seed vertices. Thus, the canonical method is the vertex nomination analogue of the Bayes classifier, and this motivates the following definition:

Definition 2 Let $G \sim \text{SBM}(K, \vec{n}, b, \Lambda)$. With notation as above, a vertex nomination scheme \mathcal{L} is consistent if

$$\lim_{n \rightarrow \infty} |\mathbb{E} \text{AP}(\mathcal{L}^C) - \mathbb{E} \text{AP}(\mathcal{L})| = 0.$$

In our proofs below, where we establish the consistency of two nomination schemes, we prove a stronger fact, namely that $\text{AP}(\mathcal{L}) = 1$ a.a.s. We prefer the definition of consistency given in Definition 2 since it allows us to speak about the best possible nomination scheme even when the model is such that $\lim_{n \rightarrow \infty} \mathbb{E} \text{AP}(\mathcal{L}^C) < 1$.

In Fishkind et al. (2015), it was proven that under mild assumptions on the stochastic block model underlying G , we have

$$\lim_{n \rightarrow \infty} \mathbb{E} \text{AP}(\mathcal{L}^{\text{SP}}) = 1,$$

from which the consistency of \mathcal{L}^{SP} follows immediately. The spectral nomination scheme \mathcal{L}^{SP} proceeds by first K -means clustering the adjacency spectral embedding (Sussman et al., 2012) of G , and then nominating vertices based on their distance to the cluster of interest. Consistency of \mathcal{L}^{SP} is an immediate consequence of the fact that, under mild model assumptions on the underlying stochastic block model, K -means clustering of the adjacency spectral embedding of G perfectly clusters the vertices of G a.a.s. (Lyzinski et al., 2014b). Bickel and Chen (2009) proved that maximum-likelihood estimation provides consistent estimates of the model parameters in a more common variant of the conditional stochastic

is equivalent to finding

$$\hat{P} = \arg \min_{P \in \Pi_u} -\frac{1}{2} \operatorname{tr} \left(A^{(2,2)} P (B^{(2,2)})^T P^T \right) - \operatorname{tr} \left((A^{(1,2)})^T B^{(1,2)} P^T \right), \quad (5)$$

as we shall explain below.

With B defined as in (4), we define

$$\mathcal{Q} = \left\{ Q \in \Pi_u \text{ s.t. } (I_m \oplus Q) B (I_m \oplus Q)^T = B \right\}.$$

Define an equivalence relation \sim on Π_u via $P_1 \sim P_2$ iff there exists a $Q \in \mathcal{Q}$ such that $P_1 = P_2 Q$; i.e.,

$$(I_m \oplus P_1) B (I_m \oplus P_1)^T = (I_m \oplus P_2 Q) B (I_m \oplus P_2 Q)^T = (I_m \oplus P_2) B (I_m \oplus P_2)^T.$$

Let \hat{P}/\sim denote the set of equivalence classes of \hat{P} under equivalence relation \sim . Solving (2) is equivalent to solving (5) in that there is a one-to-one correspondence between \hat{b} and \hat{P}/\sim : for each $\phi \in \hat{b}$ there is a unique $P \in \hat{P}/\sim$ (with associated permutation σ) such that $\phi|_U = b|_U \circ \sigma$; and for each $P \in \hat{P}/\sim$ (with the permutation associated with $I_m \oplus P$ given by σ), it holds that $b \circ \sigma \in \hat{b}$.

2.1 The \mathcal{L}^{ML} Vertex Nomination Scheme

The maximum-likelihood vertex-nomination scheme proceeds as follows. First, the SGM algorithm (Fishkind et al., 2012; Lyzinski et al., 2014a) is used to approximately find an element of \hat{P} , which we shall denote by P . Let the corresponding element of \hat{b} be denoted by ϕ . For any $i, j \in V$ such that $\phi(i) \neq \phi(j)$, define $\phi_{i \leftrightarrow j} \in \mathcal{B}$ as

$$\phi_{i \leftrightarrow j}(v) = \begin{cases} \phi(i) & \text{if } v = j, \\ \phi(j) & \text{if } v = i, \\ \phi(v) & \text{if } v \neq i, j; \end{cases}$$

i.e., $\phi_{i \leftrightarrow j}$ agrees with ϕ except that i and j have their block memberships from ϕ switched in $\phi_{i \leftrightarrow j}$. For $i \in U$ such that $\phi(i) = 1$, define

$$\eta(i) := \left(\prod_{\substack{j \in U \text{ s.t.} \\ \phi(j) \neq 1}} \frac{\ell(\phi_{i \leftrightarrow j}, G)}{\ell(\phi, G)} \right)^{\frac{1}{n-1}},$$

where, for each $\psi \in \mathcal{B}$, the likelihood ℓ is given by

$$\ell(\psi, G) = \prod_{\{i,j\} \in \binom{V}{2}} A_{\psi(i), \psi(j)}^{A_{i,j}} (1 - A_{\phi(i), \phi(j)})^{1-A_{i,j}} \prod_{(i,j) \in S \times U} A_{\psi(i), \psi(j)}^{A_{i,j}} (1 - A_{b(i), b(j)})^{1-A_{i,j}}.$$

A low/high value of $\eta(i)$ is a measure of our confidence that i is/is not in the block of interest. For $i \in U$ such that $\phi(i) \neq 1$, define

$$\xi(i) := \left(\prod_{\substack{j \in U \text{ s.t.} \\ \phi(j)=1}} \frac{\ell(\phi_{i \leftrightarrow j}, G)}{\ell(\phi, G)} \right)^{\frac{1}{n-1}}.$$

A low/high value of $\xi(i)$ is a measure of our confidence that i is/is not in the block of interest. We are now ready to define the maximum-likelihood nomination scheme \mathcal{L}^{ML} :

$$\begin{aligned} (\mathcal{L}^{\text{ML}})^{-1}(1) &\in \arg \min \{ \eta(v) : \phi(v) = 1 \} \\ (\mathcal{L}^{\text{ML}})^{-1}(2) &\in \arg \min \{ \eta(v) : v \in U \setminus \{ (\mathcal{L}^{\text{ML}})^{-1}(1) \}, \phi(v) = 1 \} \\ &\vdots \\ (\mathcal{L}^{\text{ML}})^{-1}(u_1) &\in \arg \min \{ \eta(v) : v \in U \setminus \{ (\mathcal{L}^{\text{ML}})^{-1}(i) \}_{i=1}^{u_1-1}, \phi(v) = 1 \} \\ (\mathcal{L}^{\text{ML}})^{-1}(u_1+1) &\in \arg \max \{ \xi(v) : \phi(v) \neq 1 \} \\ (\mathcal{L}^{\text{ML}})^{-1}(u_1+2) &\in \arg \max \{ \xi(v) : v \in U \setminus \{ (\mathcal{L}^{\text{ML}})^{-1}(u_1+1) \}, \phi(v) \neq 1 \} \\ &\vdots \\ (\mathcal{L}^{\text{ML}})^{-1}(u) &\in \arg \max \{ \xi(v) : v \in U \setminus \{ (\mathcal{L}^{\text{ML}})^{-1}(i) \}_{i=u_1+1}^{u-1}, \phi(v) \neq 1 \} \end{aligned}$$

Note that in the event that an argmin (or argmax) above contains more than one element, the order in which these elements is nominated should be taken to be uniformly random.

Remark 5 In the event that Λ is unknown *a priori*, we can use the block memberships of the seeds S (assumed to be chosen uniformly at random from V) to estimate the edge probability matrix Λ as

$$\hat{\Lambda}_{k,\ell} = \frac{|\{i,j\} \in E \text{ s.t. } i \in S_k, j \in S_\ell\}|}{m_k m_\ell} \quad \text{for } k \neq \ell,$$

and

$$\hat{\Lambda}_{k,k} = \frac{|\{i,j\} \in E \text{ s.t. } i \in S_k, j \in S_k\}|}{\binom{m_k}{2}}.$$

The plug-in estimate \hat{B} of B , given by

$$\hat{B}_{i,j} := \log \left(\frac{\hat{\Lambda}_{b(i), b(j)}}{1 - \hat{\Lambda}_{b(i), b(j)}} \right),$$

can then be used in place of B in Eq. (5). If, in addition, \bar{n} is unknown, we can estimate the block sizes n_k as

$$\hat{n}_k = \frac{m_k \bar{n}}{m},$$

for each $k \in [K]$, and these estimates can be used to determine the block sizes in \hat{B} .

2.2 The $\mathcal{L}_R^{\text{ML}}$ Vertex Nomination Scheme

Graph matching is a computationally difficult problem, and there are no known polynomial time algorithms for solving the general graph matching problem for simple graphs. Furthermore, if the graphs are allowed to be weighted, directed, and loopy, then graph matching is equivalent to the NP-hard quadratic assignment problem. While there are numerous

efficient, approximate graph matching algorithms (see, for example, Vogelstein et al., 2014; Fishkind et al., 2012; Zaslavskiy et al., 2009; Fiori et al., 2013, and the references therein), these algorithms often lack performance guarantees.

Inspired by the restricted-focus seeded graph matching problem considered in Lyzinski et al. (2014a), we now define the computationally tractable restricted-focus maximum-likelihood nomination scheme $\mathcal{L}_R^{\text{ML}}$. Rather than attempting to quickly approximate a solution to the full graph matching problem as in Vogelstein et al. (2014); Fishkind et al. (2012); Zaslavskiy et al. (2009); Fiori et al. (2013), this approach simplifies the problem by ignoring the edges between unseeded vertices. An analogous restriction for matching simple graphs was introduced in Lyzinski et al. (2014a). We begin by considering the graph matching problem in Eq. (5). The objective function

$$-\frac{1}{2} \text{tr} \left(A^{(2,2)} P (B^{(2,2)})^\top P^\top \right) - \text{tr} \left((A^{(1,2)})^\top B^{(1,2)} P^\top \right)$$

consists of two terms: $-\frac{1}{2} \text{tr} (A^{(2,2)} P (B^{(2,2)})^\top P^\top)$, which seeks to align the induced sub-graphs of the nonseed vertices; and $-\text{tr} (A^{(1,2)} B^{(1,2)} P^\top)$, which seeks to align the induced bipartite subgraphs between the seed and nonseed vertices. While the graph matching objective function, Eq. (5), is quadratic in P , restricting our focus to the second term in Eq. (5) yields the following *linear assignment problem*

$$\tilde{P} = \arg \min_{P \in \Pi_u} - \text{tr} \left((A^{(1,2)})^\top B^{(1,2)} P^\top \right), \quad (6)$$

which can be efficiently and exactly solved in $O(u^3)$ time with the Hungarian algorithm (Kuhn, 1955; Jonker and Volgenant, 1987). We note that, exactly as was the case of \tilde{P} and \tilde{b} , finding \tilde{P} is equivalent to finding

$$\tilde{b} = \arg \max_{\phi \in \mathcal{B}} \sum_{(i,j) \in \mathcal{S} \times \mathcal{U}} A_{i,j} \log \left(\frac{\Lambda_{b(i),\phi(j)}}{1 - \Lambda_{b(i),\phi(j)}} \right),$$

in that there is a one-to-one correspondence between \tilde{b} and \tilde{P} / \sim .

The $\mathcal{L}_R^{\text{ML}}$ scheme proceeds as follows. First, the linear assignment problem, Eq. (6), is exactly solved using, for example, the Hungarian algorithm (Kuhn, 1955) or the path augmenting algorithm of Jonker and Volgenant (1987), yielding $P \in \tilde{P}$. Let the corresponding element of \tilde{b} be denoted by ϕ . For $i \in U$ such that $\phi(i) = 1$, define

$$\tilde{\eta}(i) := \left(\prod_{\substack{j \in U \text{ s.t.} \\ \phi(j) \neq 1}} \frac{\ell_R(\phi_{k+i,j}, G)}{\ell_R(\phi, G)} \right)^{\frac{1}{u-1}},$$

where, for each $\psi \in \mathcal{B}$, the *restricted likelihood* ℓ_R is defined via

$$\ell_R(\psi, G) = \prod_{(i,j) \in \mathcal{S} \times \mathcal{U}} \Lambda_{b(i),\psi(j)}^{A_{i,j}} (1 - \Lambda_{b(i),\psi(j)})^{1-A_{i,j}}.$$

As with \mathcal{L}^{ML} , a low/high value of $\tilde{\eta}(i)$ is a measure of our confidence that i is/is not in the block of interest. For $i \in U$ such that $\phi(i) \neq 1$, define

$$\tilde{\xi}(i) := \left(\prod_{\substack{j \in U \text{ s.t.} \\ \phi(j) = 1}} \frac{\ell_R(\phi_{k+i,j}, G)}{\ell_R(\phi, G)} \right)^{\frac{1}{u-1}}.$$

As before, a low/high value of $\tilde{\xi}(i)$ is a measure of our confidence that i is/is not in the block of interest. We are now ready to define $\mathcal{L}_R^{\text{ML}}$:

$$\begin{aligned} (\mathcal{L}_R^{\text{ML}})^{-1}(1) &\in \arg \min \{ \tilde{\eta}(v) : \phi(v) = 1 \} \\ (\mathcal{L}_R^{\text{ML}})^{-1}(2) &\in \arg \min \{ \tilde{\eta}(v) : v \in U \setminus \{ (\mathcal{L}_R^{\text{ML}})^{-1}(1) \}, \phi(v) = 1 \} \\ &\vdots \\ (\mathcal{L}_R^{\text{ML}})^{-1}(u_1) &\in \arg \min \{ \tilde{\eta}(v) : v \in U \setminus \{ (\mathcal{L}_R^{\text{ML}})^{-1}(i) \}_{i=1}^{u_1-1}, \phi(v) = 1 \} \\ (\mathcal{L}_R^{\text{ML}})^{-1}(u_1 + 1) &\in \arg \max \{ \tilde{\xi}(v) : \phi(v) \neq 1 \} \\ (\mathcal{L}_R^{\text{ML}})^{-1}(u_1 + 2) &\in \arg \max \{ \tilde{\xi}(v) : v \in U \setminus \{ (\mathcal{L}_R^{\text{ML}})^{-1}(u_1 + 1) \}, \phi(v) \neq 1 \} \\ &\vdots \\ (\mathcal{L}_R^{\text{ML}})^{-1}(u) &\in \arg \max \{ \tilde{\xi}(v) : v \in U \setminus \{ (\mathcal{L}_R^{\text{ML}})^{-1}(i) \}_{i=u_1+1}^{u-1}, \phi(v) \neq 1 \} \end{aligned}$$

Note that, as before, in the event that the argmin (or argmax) in the definition of $\mathcal{L}_R^{\text{ML}}$ contains more than one element above, the order in which these elements are nominated should be taken to be uniformly random.

Unlike \mathcal{L}^{ML} , the restricted focus scheme $\mathcal{L}_R^{\text{ML}}$ is feasible even for comparatively large graphs (up to thousands of nodes, in our experience). However, we will see in Section 6 that the extra information available to $\mathcal{L}_R^{\text{ML}}$ —the adjacency structure among the nonseed vertices—leads to superior precision in the \mathcal{L}^{ML} nomination lists as compared to $\mathcal{L}_R^{\text{ML}}$. We next turn our attention to proving the consistency of the \mathcal{L}^{ML} and $\mathcal{L}_R^{\text{ML}}$ schemes.

3. Consistency of \mathcal{L}^{ML} and $\mathcal{L}_R^{\text{ML}}$

In this section, we state theorems ensuring the consistency of the vertex nomination schemes \mathcal{L}^{ML} (Theorem 6) and $\mathcal{L}_R^{\text{ML}}$ (Theorem 8). For the sake of expository continuity, proofs are given in the Appendix. We note here that in these Theorems, the parameters of the underlying block model are assumed to be known *a priori*. In Section 4, we prove the consistency of \mathcal{L}^{ML} and $\mathcal{L}_R^{\text{ML}}$ in the setting where the model parameters are unknown and must be estimated, as in Remark 5.

Let $G \sim \text{SBM}(K, \tilde{\eta}, b, \Lambda)$ with associated adjacency matrix A , and let \mathcal{B} be defined as in (4). For each $P \in \Pi_u$ (with associated permutation σ) and $k, \ell \in [K]$, define

$$\epsilon_{k,\ell} = \epsilon_{k,\ell}(P) = |\{v \in U_k \text{ s.t. } \sigma(v) \in U_\ell\}|$$

to be the number of vertices in U_k mapped to U_ℓ by $I_m \oplus P$, and for each $k \in [K]$ define

$$\epsilon_{k,\bullet}(P) := \epsilon_{k,\bullet} = \sum_{\ell \neq k} \epsilon_{k,\ell}.$$

Before stating and proving the consistency of \mathcal{L}^{ML} , we first establish some necessary notation. Note that in the definitions and theorems presented next, all values implicitly depend on n , as $\Lambda = \Lambda_n$ is allowed to vary in n . Let L be the set of distinct entries of Λ , and define

$$\begin{aligned} \alpha &= \min_{\{k,\ell\} \text{ s.t. } k \neq \ell} |\Lambda_{k,k} - \Lambda_{k,\ell}| & \beta &= \min_{\{k,\ell\} \text{ s.t. } k \neq \ell} |B_{k,k} - B_{k,\ell}| & c &= \max_{i,j,k,\ell} |B_{i,j} - B_{k,\ell}|, & (7) \\ \gamma &= \min_{x,y \in L} |x - y|, & \kappa &= \min_{x,y \in L} \left| \log \left(\frac{x}{1-x} \right) - \log \left(\frac{y}{1-y} \right) \right|. & & (8) \end{aligned}$$

Theorem 6 *Let $G \sim \text{SBM}(K, \bar{n}, b, \Lambda)$ and assume that*

- i. $K = o(\sqrt{n})$;
- ii. $\Lambda \in [0, 1]^{K \times K}$ is such that for all $k, \ell \in [K]$ with $k \neq \ell$, $\Lambda_{k,k} \neq \Lambda_{k,\ell}$;
- iii. For each $k \in [K]$, $u_k = \omega(\sqrt{n})$, and $m_k = \omega(\log u_k)$;
- iv. $\frac{c^2}{\alpha \beta \kappa \gamma} = \Theta(1)$.

Then it holds that $\lim_{n \rightarrow \infty} \mathbb{E} \text{AP}(\mathcal{L}^{\text{ML}}) = 1$, and \mathcal{L}^{ML} is a consistent nomination scheme.

A proof of Theorem 6 is given in the Appendix.

Remark 7 There are numerous assumptions akin to those in Theorem 6 under which we can show that \mathcal{L}^{ML} is consistent. Essentially, we need to ensure that if we define $\mathcal{P} = \{P \in \Pi_n : \epsilon_{1,\bullet}(P) = \Theta(u_1)\}$, then $\mathbb{P}(\exists P \in \mathcal{P} \text{ s.t. } X_P \leq 0)$ is summably small, from which it follows that $\epsilon_{1,\bullet} = o(u_1)$ with high probability, which is enough to ensure the desired consistency of \mathcal{L}^{ML} .

Consistency of $\mathcal{L}_R^{\text{ML}}$ holds under similar assumptions.

Theorem 8 *Let $G \sim \text{SBM}(K, \bar{n}, b, \Lambda)$. Under the following assumptions*

- i. $K = \Theta(1)$;
- ii. $\Lambda \in [0, 1]^{K \times K}$ is such that for all $k, \ell \in [K]$ with $k \neq \ell$, $\Lambda_{k,k} \neq \Lambda_{k,\ell}$;
- iii. For each $k \in [K]$, $u_k = \omega(\sqrt{n})$, and $m_k = \omega(\log u_k)$;
- iv. $\frac{c^2}{\alpha \beta \kappa \gamma} = \Theta(1)$;

it holds that $\lim_{n \rightarrow \infty} \mathbb{E} \text{AP}(\mathcal{L}^{\text{ML}}) = 1$, and \mathcal{L}^{ML} is a consistent nomination scheme.

A proof of this Theorem can be found in the Appendix.

4. Consistency of \mathcal{L}^{ML} and $\mathcal{L}_R^{\text{ML}}$ When the Model Parameters are Unknown

If Λ is unknown a priori, then the seeds can be used to estimate Λ as $\hat{\Lambda}$, and n_i as \hat{n} for each $i \in [K]$. In this section, we will prove analogues of the consistency Theorems 6 and 8 in the case where Λ and \bar{n} are estimated using seeds. In Theorems 9 and 10 below, we prove that under mild model assumptions, both \mathcal{L}^{ML} and $\mathcal{L}_R^{\text{ML}}$ are consistent vertex nomination schemes, even when the seed vertices form a vanishing fraction of the graph.

We now state the consistency result analogous to Theorem 6, this time for the case where we estimate Λ and \bar{n} . The proof can be found in the Appendix.

Theorem 9 *Let $\Lambda \in \mathbb{R}^{K \times K}$ be a fixed, symmetric, block probability matrix satisfying*

- i. K is fixed in n ;
- ii. $\Lambda \in [0, 1]^{K \times K}$ is such that for all $k, \ell \in [K]$ with $k \neq \ell$, $\Lambda_{k,k} \neq \Lambda_{k,\ell}$;
- iii. For each $k \in [K]$, $n_k = \Theta(n)$ and $m_k = \omega(n^{2/3} \log(n))$;
- iv. α and γ defined as in (7) and (8) are fixed in n .

Suppose that the model parameters of $G \sim (K, \bar{n}, b, \Lambda)$ are estimated as in Remark 5 yielding log-odds matrix estimate B and estimated block sizes $\hat{n} = (\hat{n}_1, \hat{n}_2, \dots, \hat{n}_K)^T$. If \mathcal{L}^{ML} is run on A and \hat{B} using the block sizes given by \hat{n} , then under the above assumptions it holds that $\lim_{n \rightarrow \infty} \mathbb{E} \text{AP}(\mathcal{L}^{\text{ML}}) = 1$, and \mathcal{L}^{ML} is a consistent nomination scheme.

We now state the analogous consistency result to Theorem 8 when we estimate Λ and \bar{n} . The proof is given in the Appendix.

Theorem 10 *Let $\Lambda \in \mathbb{R}^{K \times K}$ be a fixed, symmetric, block probability matrix satisfying*

- i. K is fixed in n ;
- ii. $\Lambda \in [0, 1]^{K \times K}$ is such that for all $k, \ell \in [K]$ with $k \neq \ell$, $\Lambda_{k,k} \neq \Lambda_{k,\ell}$;
- iii. For each $k \in [K]$ s.t. $k \neq 1$, $n_k = \Theta(n)$ and $m_k = \omega(n^{2/3} \log(n))$;
- iv. $n_1 = \Theta(n)$ and $m_1 = \omega(n^{4/5})$;
- v. α and γ defined at (7) and (8) are fixed in n .

Suppose that the model parameters of $G \sim (K, \bar{n}, b, \Lambda)$ are estimated as in Remark 5 yielding B and estimated block sizes $\hat{n} = (\hat{n}_1, \hat{n}_2, \dots, \hat{n}_K)^T$. If \mathcal{L}^{ML} is run on A and \hat{B} using block sizes given by \hat{n} , then under the above assumptions it holds that $\lim_{n \rightarrow \infty} \mathbb{E} \text{AP}(\mathcal{L}^{\text{ML}}) = 1$ and \mathcal{L}^{ML} is a consistent nomination scheme.

The two preceding theorems imply that vertex nomination is possible even when the number of seeds is a vanishing fraction of the vertices in the graph. Indeed, we find that in practice, accurate nomination is possible even with just a handful of seed vertices. See the experiments presented in Section 6.

where, for $k \in [K]$, $\hat{f}_k(\cdot)$ is the estimated density of the k -th block features. Note that here we assume that the feature densities must be estimated, even when the matrix Λ is known. A low/high value of $\eta_P(i)$ is a measure of our confidence that i is/is not in the block of interest. For $i \in U$ such that $\phi(i) \neq 1$, define

$$\xi_P(i) := \left(\prod_{\substack{j \in U \text{ s.t.} \\ \phi(j)=1}} \frac{f_P(\phi_{k+j}, G)}{f_P(\phi, G)} \right)^{\frac{1}{u_1}}$$

A low/high value of $\xi_P(i)$ is a measure of our confidence that i is/is not in the block of interest. The nomination list produced by $\mathcal{L}_P^{\text{ML}}$ is then realized via:

$$\begin{aligned} (\mathcal{L}_P^{\text{ML}})^{-1}(1) &\in \arg \min \{ \eta_P(v) : \phi(v) = 1 \} \\ (\mathcal{L}_P^{\text{ML}})^{-1}(2) &\in \arg \min \{ \eta_P(v) : v \in U \setminus \{ (\mathcal{L}_P^{\text{ML}})^{-1}(1) \}, \phi(v) = 1 \} \\ &\vdots \\ (\mathcal{L}_P^{\text{ML}})^{-1}(u_1) &\in \arg \min \left\{ \eta_P(v) : v \in U \setminus \{ (\mathcal{L}_P^{\text{ML}})^{-1}(i) \}_{i=1}^{u_1-1}, \phi(v) = 1 \right\} \\ (\mathcal{L}_P^{\text{ML}})^{-1}(u_1 + 1) &\in \arg \max \{ \xi_P(v) : \phi(v) \neq 1 \} \\ (\mathcal{L}_P^{\text{ML}})^{-1}(u_1 + 2) &\in \arg \max \{ \xi_P(v) : v \in U \setminus \{ (\mathcal{L}_P^{\text{ML}})^{-1}(u_1 + 1) \}, \phi(v) \neq 1 \} \\ &\vdots \\ (\mathcal{L}_P^{\text{ML}})^{-1}(u) &\in \arg \max \left\{ \xi_P(v) : v \in U \setminus \{ (\mathcal{L}_P^{\text{ML}})^{-1}(i) \}_{i=u_1+1}^{u-1}, \phi(v) \neq 1 \right\} \end{aligned}$$

Note that, once again, in the event that the argmin (or argmax) contains more than one element above, the order in which these elements is nominated should be taken to be uniformly random.

We leave for future work a more thorough investigation of how best to choose the parameter λ . We found that choosing λ approximately equal to the number of nonseed vertices yielded reliably good results, but in general the best choice of λ is likely to be dependent on both the structure of the graph and the available features (e.g., how well the features actually predict block membership). We note also that in the case where the feature densities are not easily estimated or where we would like to relax our distributional assumptions, we might consider other terms to use in lieu of $\text{tr } FP^T$. For example, let $\hat{\mu}_k = \frac{1}{m_k} \sum_{v \in S_k} X_v$ be the empirical estimate of μ_k , the average feature vector for the seeds in block k , and create let Y be defined via

$$Y = \begin{bmatrix} u_1 & \hat{\mu}_1 \otimes \bar{\mathbf{1}} \\ u_2 & \hat{\mu}_2 \otimes \bar{\mathbf{1}} \\ \vdots & \vdots \\ u_k & \hat{\mu}_k \otimes \bar{\mathbf{1}} \end{bmatrix}^d.$$

Incorporating these features into the seeded graph matching problem similarly to (9), we have

$$\hat{P} = \arg \min_{P \in \Pi_u} -\frac{1}{2} \text{tr} \left(A^{(2,2)} P (B^{(2,2)})^T P^T \right) - \text{tr} \left((A^{(1,2)})^T B^{(1,2)} P^T \right) - \lambda \text{tr} (X^{(u)} Y^T P^T). \quad (10)$$

We leave further exploration of this and related approaches, as well as how to deal with categorical data (e.g., as in Newman and Clauset (2016)), for future work.

6. Experiments

To compare the performance of maximum-likelihood vertex nomination against other methods, we performed experiments on five data sets, one synthetic, the others from linguistics, sociology, political science and ecology.

In all our data sets, we consider vertex nomination both when the edge probability matrix Λ is known and when it must be estimated. When model parameters are unknown, $m < n$ seed vertices are selected at random and the edge probability matrix is estimated based on the subgraph induced by the seeds, with entries of the edge probability matrix estimated via add-one smoothing. In the case of synthetic data, the known-parameter case simply corresponds to the algorithm having access to the parameters used to generate the data. In this paper, we consider a 3-block stochastic block model (see below), so the known-parameter case corresponds to the true edge probability matrix being given. In the case of our real-world data sets, the notion of a ‘‘true’’ Λ is more hazy. Here, knowing the model parameters corresponds to using the entire graph, along with the true block memberships, to estimate Λ , again using add-one smoothing. This is, in some sense, the best access we can hope to have to the model parameters, to the extent that such parameters even exist in the first place.

6.1 Simulations

We consider graphs generated from stochastic block models at two different scales. Following the experiments in Fishkind et al. (2015), we consider 3-block models, where block sizes are given by $\bar{n} = q \cdot (4, 3, 3)^T$ for $q = 1, 50$, which we term the small and medium cases, respectively. In Fishkind et al. (2015), a third case, with $q = 1000$, was also considered, but since ML vertex nomination is not practical at this scale, we do not include such experiments here, though we note that $\mathcal{L}_R^{\text{ML}}$ can be run successfully on such a graph. We use an edge probability matrix given by

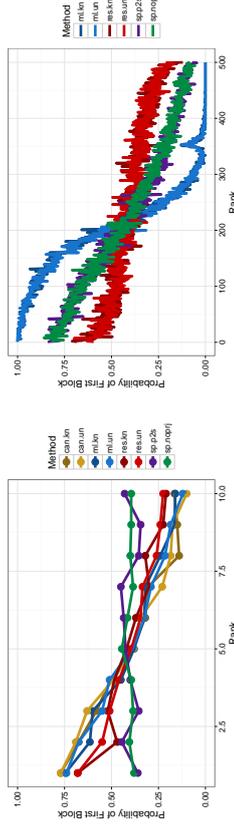

$$\Lambda(t) = t \begin{bmatrix} 0.5 & 0.3 & 0.4 \\ 0.3 & 0.8 & 0.6 \\ 0.4 & 0.6 & 0.3 \end{bmatrix} + (1-t) \begin{bmatrix} 0.5 & 0.5 & 0.5 \\ 0.5 & 0.5 & 0.5 \\ 0.5 & 0.5 & 0.5 \end{bmatrix} \quad (11)$$

for $t = 1, 0.3$ respectively in the small and medium cases, so that the amount of signal present in the graph is smaller as the number of vertices increases. We consider $m = 4, 20$ seeds in the small and medium scales, respectively. For a given choice of \bar{n}, m, t , we generate a single draw of an SBM with edge probability matrix $\Lambda(t)$ and block sizes given by \bar{n} . A set

of m vertices is chosen uniformly at random from the first block to be seeds. Note that this means that the only model parameter that can be estimated is the intra-block probability for the first block. For all model parameter estimation in the ML methods (i.e., for the unknown case of \mathcal{L}^{ML} and $\mathcal{L}_R^{\text{ML}}$), we use add-1 smoothing to prevent inaccurate estimates. We note that in all conditions, the block of interest (the first block) is not the densest block of the graph.

Recall that all of the methods under consideration return a list of the nonseed vertices, which we call a *nomination list*, with the vertices sorted according to how likely they are to be in the block of interest. Thus, vertices appearing early in the nomination list are the best candidates to be vertices of interest. Figure 1 compares the performance of canonical, spectral, maximum-likelihood and restricted-focus ML vertex nomination by looking at (estimates of) their average nomination lists. The plot shows, for each of the methods under consideration, an estimate (each based on 200 Monte Carlo replicates) of the average nomination list. Each curve describes the empirical probability that the k th-ranked vertex was indeed a vertex of interest. A perfect method, which on every input correctly places the n_1 vertices of interest in the first n_1 entries of the nomination list, would produce a curve in Figure 1 resembling a step function, with a step from 1 to 0 at the $(n_1 + 1)$ th rank. Conversely, a method operating purely at random would yield an average nomination list that is constant n_1/n . Canonical vertex nomination is shown in gold, ML in blue, restricted-focus ML in red, and spectral vertex nomination is shown in purple and green. These two colors correspond, respectively, to spectral VN in which vertex embeddings are projected to the unit sphere prior to nomination and in which the embeddings are used as-is. In sparse networks, the adjacency spectral embedding places all vertices near to the origin. In such settings, projection to the sphere often makes cluster structure in the embeddings more easily recoverable. Dark colors correspond to the known-parameter case, and light colors correspond to unknown parameters. Note that spectral VN does not make such a distinction.

Examining the plots, we see that in the small case, maximum-likelihood nomination is quite competitive with the canonical method, and restricted-focus ML nomination is not much worse. Somewhat surprising is that these methods perform well seemingly irrespective of whether or not the model parameters are known, though this phenomenon is accounted for by the fact that the smoothed estimates are automatically close to the truth, since A is approximately equal to the matrix with all entries $1/2$. Meanwhile, the small number of nodes is such that there is little signal available to spectral vertex nomination. We see that spectral vertex nomination performs approximately at-chance regardless of whether or not we project the spectral embeddings to the sphere. 10 nodes are not enough to reveal eigenvalue structure that spectral methods attempt to recover. In the medium case, where there are 500 vertices, enough signal is present that reasonable performance is obtained by spectral vertex nomination, with performance with (purple) and without (green) projection to the sphere again indistinguishable. The comparative density of the SBM in question ensures that projection to the sphere is not necessary, and that doing so does no appreciable harm to nomination. However, in the medium case, ML-based vertex nomination still appears to best spectral methods, with the known and unknown cases being nearly indistinguishable. We note that in both the small and medium cases all of the methods appear to intersect at an empirical probability of 0.4. These intersection points correspond

(a) Small scale simulation results

(b) Medium scale simulation results

Figure 1: The mean nomination lists for the (a) small and (b) medium stochastic block model experiments for the different vertex nomination techniques in both the known (dark colors) and unknown (light colors). Plot (a) shows performance for the canonical (gold), maximum likelihood (blue), restricted-focus maximum likelihood (red) and spectral (green and purple) methods. Spectral VN both with and without projection to the sphere is shown in purple and green, respectively. Plot (b) does not include canonical vertex nomination due to runtime constraints.

to the transition from the block of interest to the non-interesting vertices: these vertices, about which we are least confident, tend to be nominated correctly at or near chance, which is 40% in both the small and large cases.

A more quantitative assessment of the vertex nomination methods is contained in Tables 1 and 2, which compare the performance of the methods as assessed by, respectively, average precision (AP) and adjusted Rand index (ARI). As defined in Equation (1), AP is a value between 0 and 1, where a value of 1 indicates perfect performance. ARI Hubert and Arabie (1985) measures how well a given partition of a set recovers some ground truth partition. Here a value of 1 indicates perfect recovery, while randomly partitioning a data set yields ARI approximately 0 (note that negative ARI is possible). We include ARI as an evaluation to highlight the fact that spectral and maximum-likelihood nomination do not merely classify vertices as interesting or not. Rather, they return a partition of the vertices into clusters. Canonical vertex nomination, on the other hand, makes no attempt to recover the full cluster structure of the graph, instead only attempting to classify vertices according to whether or not they are of interest. As such, we do not include ARI numbers for canonical vertex nomination. Turning first to performance in the small graph condition in Table 1, we see that \mathcal{L}^{C} is the best method, so long as the graph in question is small enough that the canonical method is tractable, but \mathcal{L}^{ML} , regardless of whether or not model parameters are known, nearly matches canonical VN, and, unlike its canonical counterpart, scales to graphs with more than a few nodes. The numbers for \mathcal{L}^{SP} bear out our observation above, that the small graphs contain too little information for spectral VN to act upon, and \mathcal{L}^{SP} performs approximately at chance, as a result. It is worth noting that while $\mathcal{L}_R^{\text{ML}}$ does not match the performance of \mathcal{L}^{ML} , presumably owing to the fact that the restricted-focus algorithm does not use all of the information present in the graph, it still outperforms spectral nomination, and lags \mathcal{L}^{ML} by less than 0.1 AP.

	Known				Unknown			
	ML	RES	SP	CAN	ML	RES	SP	CAN
small	0.670	0.588	0.388	0.700	0.680	0.606	0.415	0.710
medium	0.954	0.545	0.738	—	0.954	0.537	0.735	—

Table 1: Empirical estimates of mean average precision on the two stochastic block model data sets for the four methods under consideration. Each data point is the mean of 200 independent trials.

	Known				Unknown			
	ML	RES	SP	CAN	ML	RES	SP	CAN
small	0.338	0.259	0.011	—	0.338	0.259	0.011	—
medium	0.572	0.039	0.268	—	0.572	0.037	0.271	—

Table 2: ARI on the different sized data sets for the ML, restricted ML, and spectral methods. Each data point is the mean of 200 independent trials. Performance of canonical vertex nomination is knot included, since canonical vertex nomination makes no attempt to recover all three blocks, and thus ARI is not a sensible measure.

Turning our attention to the medium case, we see again that $\mathcal{L}_{ML}^{\text{ML}}$ and $\mathcal{L}_{R}^{\text{ML}}$ remain largely impervious to whether model parameters are known or not, presumably a consequence of the use of smoothing—we’ll see in the sequel that estimation can be the difference between near-perfect performance and near-chance. With more vertices, we see that spectral improves above chance, leaving restricted ML slightly worse, but spectral still fails to match the performance of ML, VN, even when model parameters are unknown.

In sum, these results suggest that different size graphs (and different modeling assumptions) call for different vertex nomination methods. In small graphs, regardless of whether or not model parameters are known, canonical vertex nomination is both tractable and quite effective. In medium graphs, maximum-likelihood vertex nomination remains tractable and achieves impressively good nomination. Of course, for graphs with thousands of vertices, $\mathcal{L}_{ML}^{\text{ML}}$ becomes computationally expensive, leaving only $\mathcal{L}_{R}^{\text{SP}}$ and $\mathcal{L}_{R}^{\text{ML}}$ as options. We have observed that $\mathcal{L}_{R}^{\text{ML}}$ tends to lag $\mathcal{L}_{R}^{\text{SP}}$ in such large graphs, though increasing the number of seeds (and hence the amount of information available to $\mathcal{L}_{R}^{\text{ML}}$) closes this gap considerably. We leave for future work a more thorough exploration of under what circumstances we might expect $\mathcal{L}_{R}^{\text{ML}}$ to be competitive with $\mathcal{L}_{R}^{\text{SP}}$ in graphs on thousands of vertices.

6.2 Word Co-occurrences

We consider a linguistic data set consisting of co-occurrences of 54 nouns and 58 adjectives in Charles Dickens’ novel *David Copperfield* Newman (2006a). We construct a graph in which each node corresponds to a word, and an edge connects two nodes if the two corresponding words occurred adjacent to one another in the text. The adjacency matrix of this graph is shown in Figure 2. Visual inspection reveals a clear block structure, and that this block structure is clearly not assortative (i.e., inter-block edges are more frequent than intra-block

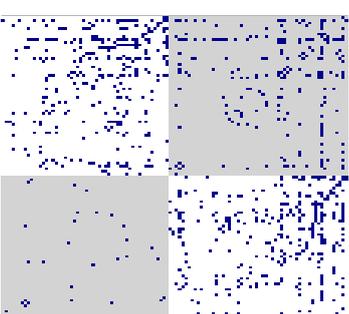

Figure 2: Adjacency matrix of the linguistic data set, arranged to highlight the graph’s structure. The grey shading indicates the two blocks, with adjectives in the upper left and nouns in the lower right. Note the disassortative block structure.

edges). This runs contrary to many commonly-studied data sets and model assumptions. Figure 3 shows the performance of spectral and maximum-likelihood vertex nomination, measured by (a) average precision and adjusted Rand index (ARI) at various numbers of seeds. Each data point is the average over 1000 trials. In each trial, a set of m seeds was chosen uniformly at random from the 112 nodes, with the restriction that at least one noun and one adjective be included in the seed set. Performance was then measured as the mean average precision in identifying the adjective block.

Figure 3 shows the performance of the VN schemes under consideration, as a function of the number of seed vertices, using both known (dark colors) and estimated (light colors) model parameters. Looking first at AP in Figure 3 (a), we see that ML in the known-parameter case (dark blue) does consistently well, even with only a handful of seeds, and attains near-perfect performance for $m \geq 20$. When model parameters must be estimated (light blue), ML is less dominant, though it still performs nearly perfectly for $m \geq 20$. We note the dip in unknown-parameters ML as m increases from 2 to 5 to 10, a phenomenon we attribute to the bias-variance tradeoff. Namely, with more seeds available, variance in the estimated model parameters increases, but for $m < 20$, this increase in variance is not offset by an appreciable improvement in estimation, possibly attributable to our use of add-one smoothing. Somewhat surprisingly, restricted-focus ML performs quite well, consistently improving on spectral VN in the known parameter case for $m > 2$, and in the unknown parameter case once $m > 10$. Finally, we turn our attention to spectral VN, shown in green for the variant in which we project embeddings to the sphere and in purple for the variant in which we do not. In contrast to our simulations, the sparsity of this network makes projection to the sphere a critical requirement for successful retrieval of the first block. Without projection to the sphere, spectral VN fails to rise appreciably above chance performance.

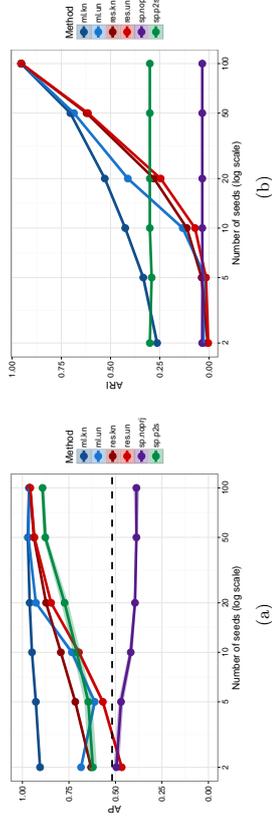

Figure 3: Performance on the linguistic data set as measured by (a) AP and (b) ARI as a function of the number of seeds for the ML vertex nomination (blue), restricted-focus ML (red), and spectral vertex nomination with (green) and without projection to the sphere (violet), when model parameters are known (light colors) and unknown (dark colors). Each data point is the mean of 1000 Monte Carlo trials, and shaded regions indicate two standard deviations of the mean.

6.3 Zachary’s Karate Club

We consider the classic sociological data set, Zachary’s karate club network Zachary (1977). The graph, visualized in Figure 4, consists of 34 nodes, each corresponding to a member of a college karate club, with edges joining pairs of club members according to whether or not those members were observed to interact consistently outside of the club. Over the course of Zachary’s observation of the group, a conflict emerged that led to the formation of two factions, led by the individuals numbered 1 and 34 in Figure 4, and these two factions constitute the two blocks in this experiment. Zachary’s karate data set is particularly well-suited for spectral methods. Indeed, the flow-based model originally proposed by Zachary recovers factions nearly perfectly, and visual inspection of the graph (Figure 4) suggests a natural cut separating the two factions. As such, we expect ML-based vertex nomination to lose out against the spectral-based method. Figure 5 shows performance of the two algorithms as measured by ARI and average precision. We see, as expected, that spectral performance performs nearly perfectly, irrespective of the number of seeds. Surprisingly, maximum-likelihood nomination is largely competitive with spectral VN, but only provided that the model parameters are already known. Interesting to note that here again we see the phenomenon discussed previously in which ML performance with an unknown edge probability matrix degrades when going from $s = 2$ seeds to $s = 5$ before improving again, with AP comparable to the known case for $s \geq 20$.

6.4 Political Blogs

We consider a network of American political blogs in the lead-up to the 2004 election Adamic and Glance (2005), where an edge joins two blogs if one links to the other, with blogs classified according to political leaning (liberal vs conservative). From an initial 1490 vertices, we

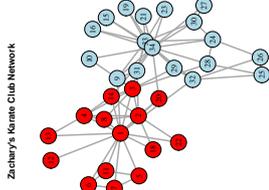

Figure 4: Visualization of the graph corresponding to Zachary’s karate club data set. The vertices are colored according to which of the two clubs each member chose to join after the schism. Our block of interest is in red.

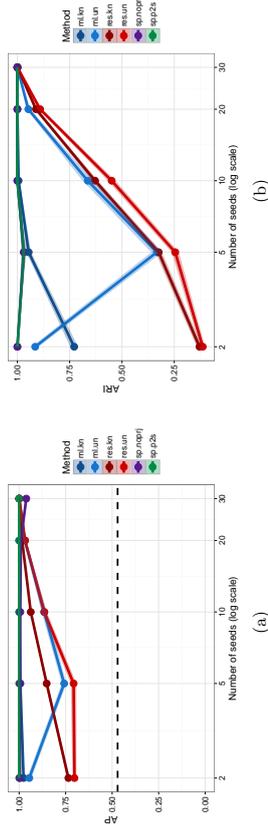

Figure 5: Performance on the karate data set as a function of the number of seeds for the ML vertex nomination (blue), restricted-focus ML nomination (red), and spectral vertex nomination with (green) and without projection to the sphere (violet), when model parameters are known (light colors) and unknown (dark colors) as measured by (a) AP and (b) ARI. The black dashed line indicates chance performance. Each observation is the mean of 1000 independent trials, with the shaded bars indicating two standard errors of the mean in either direction.

removed all isolated vertices to obtain a network of 1224 vertices and 16718 edges. Figure 6 shows the performance of the spectral- and ML-based methods in recovering the liberal block. We observe first and foremost that the sparsity of this network results in exceptionally poor performance in both AP and ARI for spectral VN unless the embeddings are projected to the sphere, but that spectral vertex nomination is otherwise quite effective at recovering the liberal block, with performance nearly perfect for $m > 10$. Unsurprisingly, ML and its restricted counterpart both perform approximately at-chance when $m < 10$. We see that in both the known and unknown cases, ML VN is competitive with spectral VN for

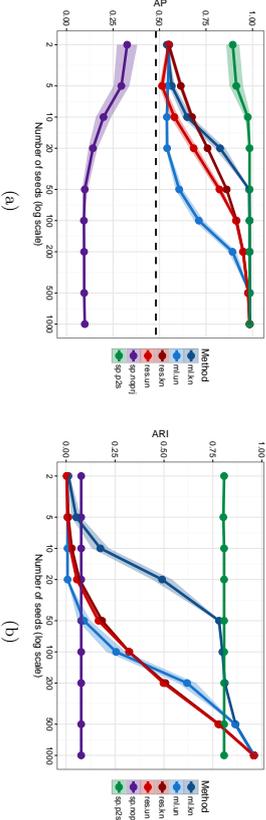

Figure 6: Performance on the political blogs data set as a function of the number of seeds for the ML vertex nomination (blue), restricted-focus ML (red), and spectral vertex nomination with (green) and without projection to the sphere (violet), when model parameters are known (light colors) and unknown (dark colors), as measured by (a) AP and (b) ARI.

suitably large m ($m \geq 50$ for known, $m \geq 500$ for unknown). As expected in such a sparse network, restricted-focus ML lags ML in the known-parameter case, but surprisingly, in the unknown-parameter case, restricted ML achieves remarkably better AP than does ML, a fact we are unable to account for, though it is worth noting that looking at ARI in Figure 6 (b), no such gap appears between ML and its restricted-focus counterpart in the unknown-parameter case.

6.5 Ecological Network

We consider a trophic network, consisting of 125 nodes and 1907 edges, in which nodes correspond to (groups of) organisms in the Florida Bay ecosystem Ulanowicz et al. (1997): Noy et al. (2011), and an edge joins a pair of organisms if one feeds on the other. Our features are the (log) mass of organisms. We take our community of interest to be the 16 different types of birds in the ecosystem. This choice makes for an interesting task for several reasons. Firstly, unlike the other data sets we consider, our community of interest is a comparatively small fraction of the network—it consists of a mere 16 nodes of 125 in total. Further, our block of interest is comparatively heterogeneous in the sense that the roles of the different types of birds in the Florida Bay ecosystem is quite diverse. For example, the block of interest includes both raptors and shorebirds, which feed on quite different collections of organisms. Finally, it stands to reason that the mass of the organisms in question might be a crucial piece of information for disambiguating, say, a raptor from a shark. Thus, we expect that using node features will be crucial for retrieving the block of interest.

The topology of the Florida Bay network is shown in Figure 7 (a). Note that the block of interest, indicated in red, has a strongly disassortative structure. Indeed, all intra-block edges in the red block are incident to the node corresponding to raptors. Figure 7 (b) summarizes vertex nomination performance for several methods. The plot shows performance,

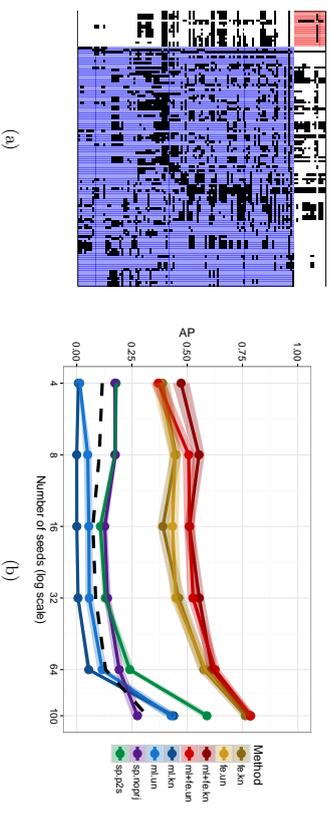

Figure 7: (a) The adjacency matrix of the Florida Bay trophic network. Nodes correspond to classes of plants and animals (e.g., sharks, rays, shorebirds, zooplankton, phytoplankton). An edge joins two nodes if the corresponding organisms are in a predator-prey relation. The sixteen types of birds in the network are highlighted in the red block. Note the disassortative structure of the bird block (the edges within the red block are all incident to the node that corresponds to raptors). (b) Average precision in identifying the bird nodes as a function of the number of seed vertices for ML vertex nomination (blue), restricted-focus ML (red), and spectral vertex nomination with (green) and without projection to the sphere (violet), when model parameters are known (light colors) and unknown (dark colors). The black dashed line indicates chance performance.

as measured by mean average precision (AP), as a function of the number of seeds for several different nomination schemes. As in earlier plots, dark colors correspond to model parameters being known, while light colors correspond to model parameters being estimated using the seed vertices. We see immediately that spectral nomination (green and purple) and ML VN (blue) fail to improve appreciably upon chance performance except when the vast majority of the vertices’ labels are observed. Like in the linguistic data set presented above, the disassortative structure of the data appears to cause problems for spectral nomination. The failure of ML suggests that no useful information is encoded in the graph itself, but turning our attention to the curves corresponding to \mathcal{L}_{PL}^{ML} (red) and using only features (gold), we see that this is not the case. Indeed, we see that while using features alone achieves a marked improvement over both spectral and ML-based nomination, using both features and graph matching in the form of \mathcal{L}_{PL}^{ML} yields an additional improvement of some 0.1 AP in the range of $m = 8, 16, 32$. This result suggests that there may be cases where the only reliable way to retrieve vertices of interest is to leverage both features and graph topology jointly.

7. Discussion and Future Work

Network data has become ubiquitous in the sciences, giving rise to a vast array of computational and statistical problems that are only beginning to be explored. In this paper, we have explored one such problem that arises when working with network data, namely the task of performing vertex nomination. This task, in some sense the graph analogue of the classic information retrieval problem, is fundamental to exploratory data analysis on graphs as well as to machine learning applications. Above, we established the consistency of two methods of vertex nomination: a maximum-likelihood scheme \mathcal{L}^{ML} and its restricted-focus variant $\mathcal{L}_R^{\text{ML}}$, in which we obtain a feasibly exactly-solvable optimization problem at the expense of using less than the full information available in the graph. Additionally, we have introduced a maximum-likelihood nomination scheme for the case where vertices are endowed with features and when (possibly weighted) edges are drawn from a canonical exponential family. The key to all of these methods is the ability to quickly approximate a solution to the seeded graph matching problem.

We have presented experimental comparisons of these methods against each other and against several other benchmark methods, where we see that the best choice of method depends highly on graph size and structure. The major tradeoff appears to be that large graphs (tens of thousands of vertices) are not tractable for \mathcal{L}^{ML} , but in smaller and medium-sized graphs, \mathcal{L}^{ML} can detect signal where spectral methods fail to do so. It is worth noting that \mathcal{L}^{ML} , and, to a lesser extent, $\mathcal{L}_R^{\text{ML}}$, is quite competitive with \mathcal{L}^{SP} , and even manages to best \mathcal{L}^{SP} when the structure of the graph is ill-suited to the typical assumptions of spectral methods, as in the case of our linguistic data set. All told, our experimental results mirror those in Fishkind et al. (2015) and point toward a theory of which methods are best-suited to which graphs, a direction that warrants further exploration.

Appendix A.

Before proving Theorem 6, we first state a useful initial proposition.

Proposition 12 *Let $\vec{x} = (x_1, x_2, \dots, x_k)$ be a vector with distinct entries in \mathbb{R}^k . Let $f(\cdot)$ be a strictly increasing real valued function (with the abuse of notation, $f(\vec{x})$, denoting $f(\cdot)$ applied entrywise to \vec{x}). Let the order statistics of \vec{x} be denoted*

$$x_{(1)} < x_{(2)} < \dots < x_{(k)},$$

and define $\alpha = \min_{i \in \{2, 3, \dots, k\}} |x_{(i)} - x_{(i-1)}|$, and $\beta = \min_{i \in \{2, 3, \dots, k\}} |f(x_{(i)}) - f(x_{(i-1)})|$. If σ is the cyclic permutation

$$\sigma = \begin{pmatrix} 1 & 2 & 3 & \dots & k \\ 2 & 3 & 4 & \dots & 1 \end{pmatrix},$$

then

$$\langle \vec{x}, f(\vec{x}) \rangle - \langle \vec{x}, f(\sigma(\vec{x})) \rangle \geq (k-1)\alpha\beta.$$

Proof We will induct on k . To establish the base case, $k = 2$, let $x_1 = x_{(1)}$ without loss of generality and observe that

$$\begin{aligned} \langle \vec{x}, f(\vec{x}) \rangle - \langle \vec{x}, f(\sigma(\vec{x})) \rangle &= (x_2 - x_1)(f(x_2) - f(x_1)) \\ &= (x_{(2)} - x_{(1)})(f(x_{(2)}) - f(x_{(1)})) \geq \alpha\beta. \end{aligned}$$

For general k , again, without loss of generality let $x_1 = x_{(1)}$, and define the permutation

$$\tau = \begin{pmatrix} 2 & 3 & \dots & k \\ 3 & 4 & \dots & 2 \end{pmatrix}.$$

Then

$$\begin{aligned} \langle \vec{x}, f(\vec{x}) \rangle - \langle \vec{x}, f(\sigma(\vec{x})) \rangle &= \langle \vec{x}, f(\vec{x}) \rangle - \langle \vec{x}, f(\tau(\vec{x})) \rangle + \langle \vec{x}, f(\tau(\vec{x})) \rangle - \langle \vec{x}, f(\sigma(\vec{x})) \rangle \\ &= \langle \vec{x}, f(\vec{x}) \rangle - \langle \vec{x}, f(\tau(\vec{x})) \rangle + (x_k - x_1)(f(x_2) - f(x_1)) \\ &\geq \langle \vec{x}, f(\vec{x}) \rangle - \langle \vec{x}, f(\tau(\vec{x})) \rangle + \alpha\beta, \end{aligned}$$

and the result follows from the inductive hypothesis. \blacksquare

Remark 13 It follows immediately that in Proposition 12, if there exists an index $i \in [k]$ such that $\alpha_i = \min_{j \neq i} |x_{(i)} - x_{(j)}| > 0$, and $\beta_i = \min_{j \neq i} |f(x_{(i)}) - f(x_{(j)})| > 0$, then $\langle \vec{x}, f(\vec{x}) \rangle - \langle \vec{x}, f(\sigma(\vec{x})) \rangle \geq \alpha_i \beta_i$.

We are now ready to prove Theorem 6.

Proof [Proof of Theorem 6] Define

$$X_P := \text{tr}(AB^\top) - \text{tr}(A(I_m \oplus P)B(I_m \oplus P)^\top)$$

and define $\mathcal{P} = \{P \in \Pi_u : \epsilon_{1,\bullet}(P) > 0\}$. We will show that

$$\mathbb{P}(\exists P \in \mathcal{P} \text{ s.t. } X_P \leq 0) = O(1/n^2),$$

from which the desired consistency of \mathcal{L}^{ML} follows by the Borel-Cantelli Lemma, since this probability is summable in n . Fix $P \in \mathcal{P}$, and let $\sigma_P \in S_n$ be the permutation associated with $I_m \oplus P$. The action of shuffling B via $I_m \oplus P$ is equivalent to permuting the $[n^2]$ elements of $\text{vec}(B)$ via a permutation τ_P , in that

$$\text{tr}(A(I_m \oplus P)B(I_m \oplus P)^\top) = \langle \text{vec}(A), \tau_P(\text{vec}(B)) \rangle.$$

Moreover, τ_P can be chosen so that, in the cyclic decomposition of $\tau_P = \tau_P^{(1)} \tau_P^{(2)} \cdots \tau_P^{(l)}$, each (disjoint) cycle is acting on a set of distinct real numbers. Note that Proposition 12 implies that the contribution of each cycle $\tau_P^{(i)}$ to $\mathbb{E}(X_P)$ is nonnegative, and the assumptions of Theorem 6 imply that for each $i, j \in [K]$ such that $i \neq j$, the contribution of each (nontrivial) cycle permuting a $\Lambda_{i,j}$ entry to a $\Lambda_{i,j}$ entry contributes at least $\alpha\beta$ to $\mathbb{E}(X_P)$. It follows immediately that

$$\begin{aligned} \mathbb{E}(X_P) &= \mathbb{E}\left(\operatorname{tr}(AB) - \operatorname{tr}(APBP^\top)\right) \\ &= \mathbb{E}\left(\operatorname{vec}(A), \operatorname{vec}(B)\right) - \left(\operatorname{vec}(A), \tau_P(\operatorname{vec}(B))\right) \\ &\geq 2\alpha\beta \sum_i \left(\frac{1}{2} \sum_{j \neq i} \sum_{k \neq j} \epsilon_{i,j} \epsilon_{i,k} + m_i \epsilon_{i,\bullet}\right) \\ &\geq 2\alpha\beta \sum_i \left(\frac{u_i - \epsilon_{i,\bullet}}{2} \epsilon_{i,\bullet} + m_i \epsilon_{i,\bullet}\right). \end{aligned}$$

Let $\mathfrak{n}(P)$ be the total number of distinct entries of $\operatorname{vec}(B)$ permuted by τ_P , and note that an application of Proposition 12 yields

$$\begin{aligned} \mathbb{E}(X_P) &= \mathbb{E}\left(\operatorname{tr}(AB) - \operatorname{tr}(APBP^\top)\right) \\ &= \mathbb{E}\left(\operatorname{vec}(A), \operatorname{vec}(B)\right) - \left(\operatorname{vec}(A), \tau_P(\operatorname{vec}(B))\right) \\ &\geq \frac{1}{2} \mathfrak{n}(P) \gamma \kappa. \end{aligned}$$

The assumptions in the Theorem also immediately yield that

$$\mathfrak{n}(P) \geq \sum_k \left(\frac{u_k - \epsilon_{k,\bullet}}{2} \epsilon_{k,\bullet} + m_k \epsilon_{k,\bullet}\right).$$

We next note that X_P is a sum of $\mathfrak{n}(P)$ independent random variables, each bounded in $[-c, c]$. An application of Hoeffding's inequality then yields

$$\begin{aligned} \mathbb{P}(X_P \leq 0) &\leq \mathbb{P}\left(|X_P - \mathbb{E}X_P| \geq \mathbb{E}X_P\right) \leq 2 \exp\left\{-\frac{2\mathbb{E}^2 X_P}{4c^2 \mathfrak{n}(P)}\right\} \\ &\leq 2 \exp\left\{-\frac{\mathbb{E}X_P |\kappa \gamma}{2c^2}\right\} \leq 2 \exp\left\{-\frac{\alpha\beta \kappa \gamma}{4c^2} \sum_k \left(\frac{u_k - \epsilon_{k,\bullet}}{2} \epsilon_{k,\bullet} + m_k \epsilon_{k,\bullet}\right)\right\}. \end{aligned}$$

Next, note that

$$|\{P \in \mathcal{P} \text{ s.t. } X_P \leq 0\}| = 0 \text{ iff } |\{P \in \mathcal{P}' \sim \text{s.t. } X_P \leq 0\}| = 0.$$

Given $\{\epsilon_{k,\ell}\}_{k,\ell=1}^K$ satisfying $u_k = \sum_{\ell} \epsilon_{k,\ell} = \sum_{\ell} \epsilon_{\ell,k}$ for all $k \in [K]$, the number of elements $P \in \mathcal{P}' \sim$ with $\epsilon_{k,\ell}(P) = \epsilon_{k,\ell}$ for all $k, \ell \in [K]$ is at most

$$\begin{aligned} &\prod_{\substack{i_1, \ell_1, \ell_2 \\ i_2}} \sum_{\substack{\ell_1, \ell_2 \\ k \neq \ell_1}} \sum_{\substack{\ell_1, \ell_2 \\ k \neq \ell_1}} \epsilon_{k,\ell_1} \epsilon_{k,\ell_2} = u_1^{u_1 - \epsilon_{1,1}} u_2^{u_2 - \epsilon_{2,2}} \cdots u_K^{u_K - \epsilon_{K,K}} \\ &= e^{\sum_k (u_k - \epsilon_{k,k}) \log(u_k)}. \end{aligned} \tag{12}$$

The number of ways to choose such a set (i.e. the $\{\epsilon_{k,\ell}\}_{k,\ell}$) is bounded above by

$$\prod_{k \text{ s.t. } \epsilon_{k,\bullet} \neq 0} (u_k + K)^{K} = e^{\sum_k \text{s.t. } \epsilon_{k,\bullet} \neq 0 K \log(u_k + K)}. \tag{13}$$

Applying the union bound over all $P \in \mathcal{P}' \sim$, we then have

$$\begin{aligned} \mathbb{P}(\exists P \in \mathcal{P} \text{ s.t. } X_P \leq 0) &= \mathbb{P}(\exists P \in \mathcal{P}' \sim \text{ s.t. } X_P \leq 0) \\ &\leq \exp\left\{-\frac{\alpha\beta \kappa \gamma}{2c^2} \sum_k \left(\frac{u_k - \epsilon_{k,\bullet}}{2} \epsilon_{k,\bullet} + m_k \epsilon_{k,\bullet}\right)\right\} \\ &\quad + \sum_k (u_k - \epsilon_{k,k}) \log u_k + \sum_{k \text{ s.t. } \epsilon_{k,\bullet} \neq 0} K \log(u_k + K). \end{aligned} \tag{14}$$

It remains for us to establish that the expression inside the exponent goes to $-\infty$ fast enough to ensure our desired bound. For each k , the contribution to the exponent in (14) is

$$\begin{aligned} &-\frac{\alpha\beta \kappa \gamma}{2c^2} \left(\frac{u_k - \epsilon_{k,\bullet}}{2} \epsilon_{k,\bullet} + m_k \epsilon_{k,\bullet}\right) + (u_k - \epsilon_{k,k}) \log u_k + \mathbb{I}\{\epsilon_{k,\bullet} \neq 0\} K \log(u_k + K) \\ &= -\frac{\alpha\beta \kappa \gamma}{2c^2} \left(\frac{\epsilon_{k,k} \epsilon_{k,\bullet}}{2} + m_k \epsilon_{k,\bullet}\right) + \epsilon_{k,\bullet} \log u_k + \mathbb{I}\{\epsilon_{k,\bullet} \neq 0\} K \log(u_k + K) \end{aligned} \tag{16}$$

If $u_k/2 \leq \epsilon_{k,k} < u_k$, then

$$\epsilon_{k,k} \epsilon_{k,\bullet} \geq \frac{u_k \epsilon_{k,\bullet}}{2} = \omega(\epsilon_{k,\bullet} \log u_k), \text{ and } \epsilon_{k,k} \epsilon_{k,\bullet} \geq \frac{u_k \epsilon_{k,\bullet}}{2} = \omega(K \log(u_k + K)),$$

and the contribution to the exponent in (14) from k , Eq. (16), is clearly bounded above by $-2 \log(n)$ for sufficiently large n . If $\epsilon_{k,k} \leq u_k/2$ then $\epsilon_{k,\bullet} > u_k/2$, and

$$m_k \epsilon_{k,\bullet} = \omega(\epsilon_{k,\bullet} \log u_k), \text{ and } m_k \epsilon_{k,\bullet} \geq \frac{m_k u_k}{2} = \omega(K \log(u_k + K)),$$

and the contribution to the exponent in (14) from k , Eq. (16), is clearly bounded above by $-2 \log(n)$ for sufficiently large n . If $\epsilon_{k,k} = u_k$, then all terms in the exponent (16) are equal to 0. For sufficiently large n , Eq. (14) is then bounded above by

$$\exp\left\{-\sum_{k \text{ s.t. } \epsilon_{k,\bullet} \neq 0} 2 \log(n)\right\} \leq \exp\{-2 \log(n)\},$$

and the result follows. \blacksquare

Consistency of $\mathcal{L}_K^{\text{ML}}$ as claimed in Theorem 8 follows similarly to that of \mathcal{L}^{ML} , and we next briefly sketch the details of the proof.

Proof [Proof of Theorem 8 (Sketch)] Analogously to the proof of Theorem 6, define

$$X_P := \operatorname{tr}\left((A^{(1,2)})^\top B^{(1,2)}\right) - \operatorname{tr}\left((A^{(1,2)})^\top B^{(1,2)} P^\top\right).$$

The proof follows *mutatis mutandis* to the proof of Theorem 6, with the key difference being that in this case,

$$\begin{aligned} \mathbb{E}(X_P) &= \mathbb{E} \left(\operatorname{tr} \left((A^{(1,2)})^\top B^{(1,2)} \right) - \operatorname{tr} \left((A^{(1,2)})^\top B^{(1,2)} P^\top \right) \right) \\ &\geq 2\alpha\beta \sum_k m_k \epsilon_{k,\bullet}. \end{aligned}$$

Details are omitted for brevity. \blacksquare

Before proving Theorem 9 we establish some preliminary concentration results for our estimates $\hat{\Lambda}$, and \hat{n}_k , $k \in [K]$. An application of Hoeffding's inequality yields that for $k, \ell \in [K]$ such that $k \neq \ell$,

$$\mathbb{P} \left(\left| \hat{\Lambda}_{k,\ell} - \Lambda_{k,\ell} \right| \geq \frac{\sqrt{n \log n}}{m_k m_\ell} \right) \leq 2 \exp \{-2n \log n\}, \quad (17)$$

and for $k \in [K]$,

$$\mathbb{P} \left(\left| \hat{\Lambda}_{k,k} - \Lambda_{k,k} \right| \geq \frac{\sqrt{n \log n}}{\binom{m_k}{2}} \right) \leq 2 \exp \{-2n \log n\}, \quad (18)$$

and

$$\mathbb{P} \left(|\hat{n}_k - n_k| \geq t \right) \leq 2 \exp \left\{ -\frac{2nt^2}{n^2} \right\}, \quad (19)$$

With γ defined as in (8), define the events $\mathcal{E}_n^{(1)}$ and $\mathcal{E}_n^{(2)}$ via

$$\mathcal{E}_n^{(1)} = \left\{ \forall \{k, \ell\} \in \binom{[K]}{2}, \text{ s.t. } |\Lambda_{k,k} - \Lambda_{k,\ell}| > \gamma, \text{ it holds that } \left| \hat{\Lambda}_{k,k} - \hat{\Lambda}_{k,\ell} \right| > \frac{\gamma}{2} \right\};$$

$$\mathcal{E}_n^{(2)} = \left\{ \forall k \in [K], |\hat{n}_k - n_k| \leq n_k^{2/3} \right\}.$$

Combining (17)–(19), we see that if for each $k \in [K]$, $n_k = \Theta(n)$, $\min_k m_k = \omega(\sqrt{n_k} \log(n_k))$, then for sufficiently large n ,

$$\mathbb{P} \left((\mathcal{E}_n^{(1)} \cup \mathcal{E}_n^{(2)})^c \right) \leq e^{-2 \log n}. \quad (20)$$

We are now ready to prove Theorem 9, proving the consistency of \mathcal{L}^{ML} when the model parameters are unknown.

Proof [Proof of Theorem 9] Let \tilde{B} be our estimate of B using the seed vertices; i.e., there are \hat{n}_k vertices from block k for each $k \in [K]$, and for each $k, \ell \in [K]$, the entry of \tilde{B} between a block k vertex and a block ℓ vertex is

$$\log \left(\frac{\hat{\Lambda}_{k,\ell}}{1 - \hat{\Lambda}_{k,\ell}} \right).$$

Let \tilde{L} be the set of distinct entries of $\hat{\Lambda}$, and define

$$\hat{\alpha} = \min_{\{k,\ell\} \text{ s.t. } k \neq \ell} \left| \hat{\Lambda}_{k,k} - \hat{\Lambda}_{k,\ell} \right| \quad \hat{\beta} = \min_{\{k,\ell\} \text{ s.t. } k \neq \ell} \left| \hat{B}_{k,k} - B_{k,\ell} \right| \quad \hat{c} = \max_{i,j,k,\ell} \left| \hat{B}_{i,j} - \hat{B}_{k,\ell} \right|, \quad (21)$$

$$\hat{\gamma} = \min_{x,y \in \tilde{L}} |x - y|, \quad \hat{\kappa} = \min_{x,y \in \tilde{L}} \left| \log \left(\frac{x}{1-x} \right) - \log \left(\frac{y}{1-y} \right) \right|. \quad (22)$$

Note that conditioning on $\mathcal{E}_n^{(1)} \cup \mathcal{E}_n^{(2)}$ and assumption *iv*, ensures that each of $\hat{\alpha}$, $\hat{\beta}$, \hat{c} , $\hat{\gamma}$, and $\hat{\kappa}$ is bounded away from 0 by an absolute constant for sufficiently large n . For each $k \in [K]$, define

$$\epsilon_k := |\hat{n}_k - n_k| = |\hat{u}_k - u_k|, \quad \epsilon = \sum_k \epsilon_k, \quad \eta_k := \min(n_k, \hat{n}_k), \quad \eta = \sum_k \eta_k, \quad (23)$$

and note that conditioning on $\mathcal{E}_n^{(1)} \cup \mathcal{E}_n^{(2)}$ ensures that $\epsilon_k = O(n_k^{2/3})$ for all $k \in [K]$. An immediate result of this is that, conditioning on $\mathcal{E}_n^{(1)} \cup \mathcal{E}_n^{(2)}$, we have that $\eta_k = \Theta(n_k) = \Theta(n)$ for all $k \in [K]$.

Define $\mathcal{P} := \{P \in \Pi_u : \epsilon_{1,\bullet}(P) > n^{2/3} \log n\}$, and for $P \in \Pi_u$, define

$$X_P := \operatorname{tr}(A\tilde{B}^\top) - \operatorname{tr}(A(I_m \oplus P)\tilde{B}(I_m \oplus P)^\top).$$

We will show that

$$\mathbb{P}(\exists P \in \mathcal{P} \text{ s.t. } X_P \leq 0) = O(1/n^2),$$

and the desired consistency of \mathcal{L}^{ML} follows immediately. To this end, decompose A and B as

$$A = \begin{bmatrix} \eta & \epsilon \\ A^{(c,c)} & A^{(c,e)} \end{bmatrix} \quad B = \begin{bmatrix} \eta & \epsilon \\ B^{(c,c)} & B^{(c,e)} \end{bmatrix},$$

where $A^{(c,c)}$ (resp., $B^{(c,c)}$) is an $\eta \times \eta$ submatrix of A (resp., B)—which contains the seed vertices in A —with exactly η_k vertices (resp., labels) from block k for each $k \in [K]$. We view $A^{(c,c)}$ as the “core” matrix of A (with $A^{(c,e)}$ and $A^{(e,c)}$ being the “errorful” part of A), as $A^{(c,c)}$ is a submatrix of A that we could potentially cluster perfectly along block assignments. Note that similarly decomposing P as

$$P = \begin{bmatrix} \eta & \epsilon \\ P^{(c,c)} & P^{(c,e)} \end{bmatrix},$$

we see that there exists a principal permutation submatrix of size $(\eta - 2\epsilon) \times (\eta - 2\epsilon)$, which we denote \tilde{P} (with associated permutation $\tilde{\sigma}$). This matrix represents a subgraph of the core vertices of A mapped to a subgraph of the core vertices in B . We can then write $P = \tilde{P} \oplus Q$, where $Q \in \Pi_{3\epsilon}$. For each $k, \ell \in [K]$, let

$$\tilde{\epsilon}_{k,\ell} = \tilde{\epsilon}_{k,\ell}(\tilde{P}) = |\{v \in U_k \text{ s.t. } \tilde{\sigma}(v) \in U_k\}|$$

Consider now

$$X_P = \operatorname{tr}(A(I_{\eta-3\epsilon} \oplus Q)B(I_{\eta-3\epsilon} \oplus Q)^\top) - \operatorname{tr}(A(\tilde{P} \oplus Q)B(\tilde{P} \oplus Q)^\top). \quad (24)$$

Letting \tilde{u}_k denote the number of vertices from the k -th block acted on by \tilde{P} , our assumptions yield

$$\mathbb{E}(X_P) \geq 2\hat{\alpha}\hat{\beta} \sum_k \left(\frac{(\tilde{u}_k - \bar{\epsilon}_{k,\bullet})\bar{\epsilon}_{k,\bullet}}{2} + m_k \bar{\epsilon}_{k,\bullet} \right) - \Theta(n\epsilon) - \Theta(\epsilon^2).$$

Let $\tilde{n}(P)$ be the total number of distinct entries of $\text{vec}(B^{(c,\epsilon)})$ permuted by \tilde{P} , and note that another application of Proposition 12 yields

$$\mathbb{E}(X_P) \geq \frac{1}{2} \tilde{n}(P) \bar{\gamma} \bar{\kappa} - \Theta(n\epsilon) - \Theta(\epsilon^2).$$

The assumptions in the Theorem also immediately yield that

$$\tilde{n}(P) \geq \sum_k \left(\frac{(\tilde{u}_k - \bar{\epsilon}_{k,\bullet})\bar{\epsilon}_{k,\bullet}}{2} + m_k \bar{\epsilon}_{k,\bullet} \right).$$

We then have that there exists a constants $c_1 > 0$ and $c_2 > 0$ such that

$$\begin{aligned} \mathbb{P}(\exists P \in \mathcal{P} \text{ s.t. } X_P \leq 0 \mid \mathcal{E}_n^{(1)} \cup \mathcal{E}_n^{(2)}) &= \mathbb{P}(\exists P \in \mathcal{P} / \sim \text{ s.t. } X_P \leq 0 \mid \mathcal{E}_n^{(1)} \cup \mathcal{E}_n^{(2)}) \\ &\leq \exp \left\{ -\frac{\hat{\alpha}\hat{\beta}\bar{\kappa}\bar{\gamma}}{2c_2^2} \sum_k \left(\frac{(\tilde{u}_k - \bar{\epsilon}_{k,\bullet})\bar{\epsilon}_{k,\bullet}}{2} + m_k \bar{\epsilon}_{k,\bullet} \right) + \Theta(n\epsilon) + \Theta(\epsilon^2) \right\} \\ &\quad + \sum_k (\tilde{u}_k - \bar{\epsilon}_{k,k}) \log \tilde{u}_k + \sum_{k \text{ s.t. } \bar{\epsilon}_{k,\bullet} \neq 0} K \log(\tilde{u}_k + K) + O(\epsilon \log \epsilon) \\ &= \exp \left\{ -c_1 \sum_k \left(\frac{(\tilde{u}_k - \bar{\epsilon}_{k,\bullet})\bar{\epsilon}_{k,\bullet}}{2} + m_k \bar{\epsilon}_{k,\bullet} \right) \right. \\ &\quad \left. + \sum_k \bar{\epsilon}_{k,\bullet} \log \tilde{u}_k + \sum_{k \text{ s.t. } \bar{\epsilon}_{k,\bullet} \neq 0} K \log(\tilde{u}_k + K) + \Theta(n\epsilon) \right\} \\ &\leq \exp\{-c_2 n^{7/4} \log n\}. \end{aligned} \tag{25}$$

Unconditioning Equation (25) combined with Equation (20) yields the desired result. ■

Proof [Proof of Theorem 10 (Sketch)] The proof of Theorem 10 is a straightforward combination of the proofs of Theorems 8 and 9 once we have defined

$$P := \{P \in \Pi_n : \epsilon_{1,\bullet}(P) > n^{8/9} \log n\}.$$

Details are omitted for the sake of brevity. ■

Abstract

We connect shift-invariant characteristic kernels to infinitely divisible distributions on \mathbb{R}^d . Characteristic kernels play an important role in machine learning applications with their kernel means to distinguish any two probability measures. The contribution of this paper is twofold. First, we show, using the Lévy–Khintchine formula, that any shift-invariant kernel given by a bounded, continuous, and symmetric probability density function (pdf) of an infinitely divisible distribution on \mathbb{R}^d is characteristic. We mention some closure properties of such characteristic kernels under addition, pointwise product, and convolution. Second, in developing various kernel mean algorithms, it is fundamental to compute the following values: (i) kernel mean values $m_P(x)$, $x \in \mathcal{X}$, and (ii) kernel mean RKHS inner products $\langle m_P, m_Q \rangle_{\mathcal{H}}$, for probability measures P, Q . If P, Q , and kernel k are Gaussians, then the computation of (i) and (ii) results in Gaussian pdfs that are tractable. We generalize this Gaussian combination to more general cases in the class of infinitely divisible distributions. We then introduce a *conjugate* kernel and a *convolution trick* so that the above (i) and (ii) have the same pdf form, expecting tractable computation at least in some cases. As specific instances, we explore α -stable distributions and a rich class of generalized hyperbolic distributions, where the Laplace, Cauchy, and Student's t distributions are included.

Keywords: Characteristic Kernel, Kernel Mean, Infinitely Divisible Distribution, Conjugate Kernel, Convolution Trick

1. Introduction

Let $(\mathcal{X}, \mathcal{B}(\mathcal{X}))$ be a measurable space and $\mathcal{M}_1(\mathcal{X})$ be the set of probability measures. Let \mathcal{H} be the real-valued reproducing kernel Hilbert space (RKHS) associated with a bounded and measurable positive-definite (p.d.) kernel $k : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R}$. In machine learning, kernel methods provide a technique for developing nonlinear algorithms, by mapping data X_1, \dots, X_n in \mathcal{X} to higher- or infinite-dimensional RKHS functions $k(\cdot, X_1), \dots, k(\cdot, X_n)$ in \mathcal{H} (Schölkopf and Smola, 2002; Steinwart and Christmann, 2008).

Recently, an RKHS representation of a probability measure $P \in \mathcal{M}_1(\mathcal{X})$, called kernel mean, $m_P := \mathbb{E}_{X \sim P}[k(\cdot, X)] \in \mathcal{H}$ (Smola et al., 2007; Fukumizu et al., 2013), or equivalently,

$$m_P(x) = \int k(x, y) dP(y), \quad x \in \mathcal{X} \quad (1)$$

has been used to handle probability measures in RKHSs. The kernel mean enables us to introduce a similarity and distance between two probability measures $P, Q \in \mathcal{M}_1(\mathcal{X})$, via the RKHS inner product $\langle m_P, m_Q \rangle_{\mathcal{H}}$ and the norm $\|m_P - m_Q\|_{\mathcal{H}}$, respectively. Using these quantities, different authors have proposed many algorithms, including density estimations (Smola et al., 2007; Song et al., 2008; McCalman et al., 2013), hypothesis tests (Gretton et al., 2012; Gretton et al., 2008; Fukumizu et al., 2008), kernel Bayesian inference (Song et al., 2009; Song et al., 2010; Song et al., 2011; Fukumizu et al., 2013; Song et al., 2013; Kanagawa et al., 2016; Nishiyama et al., 2016), classification (Muandet et al., 2012), dimension reduction (Fukumizu and Leng, 2012), and reinforcement learning (Grünewälder et al., 2012; Nishiyama et al., 2012, Rawlik et al., 2013, Boots et al., 2013).

In these applications, the characteristic property of a p.d. kernel k is important: a p.d. kernel is said to be *characteristic* if any two probability measures $P, Q \in \mathcal{M}_1(\mathcal{X})$ can be distinguished by their kernel means $m_P, m_Q \in \mathcal{H}$ (Fukumizu et al., 2004; Sriperumbudur et al., 2010, 2011). For a continuous, bounded, and shift-invariant p.d. kernel on \mathbb{R}^d with $k(x, y) = \kappa(x - y)$, a necessary and sufficient condition for the kernel to be characteristic is known via the Bochner theorem (Sriperumbudur et al., 2010, Theorem 9).

As the first contribution of this paper, we show, using the Lévy–Khintchine formula (Sato, 1999; F. W. Steutel, 2004; Applebaum, 2009), that if κ is a continuous, bounded, and symmetric pdf of an infinitely divisible distribution P on \mathbb{R}^d , then k is a characteristic p.d. kernel. We call such kernels *convolutionally infinitely divisible* (CID) kernels. Examples of CID kernels are given in Example 3.4. In addition, we note some closure properties of the CID kernels with respect to addition, pointwise product, and convolution.

To describe the second contribution, we briefly explain what is essentially computed in kernel mean algorithms. In general kernel methods, the following computations are fundamental:

- (i) RKHS function values: $f(x)$ for $f \in \mathcal{H}$, $x \in \mathcal{X}$,
- (ii) RKHS inner products: $\langle f, g \rangle_{\mathcal{H}}$, $f, g \in \mathcal{H}$.

If $f \in \mathcal{H}$ is represented by $f := \sum_{i=1}^n w_i k(\cdot, X_i)$, $w \in \mathbb{R}^n$, then the function value (i) $f(x) = \sum_{i=1}^n w_i k(x, X_i)$ reduces to the evaluation of the kernel $k(x, y)$. Similarly, if two RKHS functions $f, g \in \mathcal{H}$ are both represented by $f := \sum_{i=1}^n w_i k(\cdot, X_i)$ and $g := \sum_{j=1}^l \tilde{w}_j k(\cdot, \tilde{X}_j)$, respectively, then the inner product (ii) $\langle f, g \rangle_{\mathcal{H}} = \sum_{i=1}^n \sum_{j=1}^l w_i \tilde{w}_j k(X_i, \tilde{X}_j)$ reduces to the evaluation of the kernel $k(x, y)$, which is so-called the *kernel trick* $\langle k(\cdot, x), k(\cdot, y) \rangle_{\mathcal{H}} = k(x, y)$.

We consider a more general case in which $f, g \in \mathcal{H}$ are represented by $f := \sum_{i=1}^n w_i m_{P_i}$ and $g := \sum_{j=1}^l \tilde{w}_j m_{Q_j}$, respectively, where $\{m_{P_i}\}, \{m_{Q_j}\} \subset \mathcal{H}$ are kernel means of probability measures $\{P_i\}, \{Q_j\} \subset \mathcal{M}_1(\mathcal{X})$. Kernel algorithms involving kernel means use this type of RKHS functions explicitly or implicitly. If $\{P_i\}, \{Q_j\}$ are delta measures $\{\delta_{x_i}\}, \{\delta_{\tilde{x}_j}\}$, then these functions are specialized to the above kernel trick case, where $m_{\delta_x} = k(\cdot, x)$. The computation of (i) $f(x) = \sum_{i=1}^n w_i m_{P_i}(x)$ and (ii) $\langle f, g \rangle_{\mathcal{H}} = \sum_{i=1}^n \sum_{j=1}^l w_i \tilde{w}_j \langle m_{P_i}, m_{Q_j} \rangle_{\mathcal{H}}$ requires the following kernel mean evaluations:²

1. A probability measure $\delta_x(\cdot)$, $x \in \mathcal{X}$ is a delta measure; if $x \in B$, then $\delta_x(B) = 1$; otherwise, $\delta_x(B) = 0$ for $B \in \mathcal{B}(\mathcal{X})$.
2. If kernel means m_P, m_Q are also both expressed by a weighted sum, $m_P := \sum_{i=1}^n \eta_i k(\cdot, \tilde{X}_i)$ and $m_Q := \sum_{j=1}^l \tilde{\eta}_j k(\cdot, \tilde{X}_j)$, $\{\tilde{X}_i\}, \{\tilde{X}_j\} \subset \mathcal{X}$, then the computation also reduces to the above kernel trick case.

- (iii) kernel mean values: $m_P(x)$ for $P \in \mathcal{M}_1(\mathcal{X})$, $x \in \mathcal{X}$,
- (iv) kernel mean inner products: $\langle m_P, m_Q \rangle_{\mathcal{H}}$, $P, Q \in \mathcal{M}_1(\mathcal{X})$.

Note that the kernel mean value (1) and the kernel mean inner product $\langle m_P, m_Q \rangle_{\mathcal{H}} = \int k(x, y) dP(x) dQ(y)$ involve an integral, and their rigorous computation is not tractable in general.

The second contribution of this paper is to provide some classes of p.d. kernels and parametric models $P, Q \in \mathcal{P}_{\Theta} := \{P_{\theta} | \theta \in \Theta\}$ such that the kernel computation of (iii) and (iv) can be reduced to a kernel evaluation, where tractable computation is considered. For a shift-invariant kernel $k(x, y) = \kappa(x - y)$, $x, y \in \mathbb{R}^d$ on \mathbb{R}^d , as shown in Lemma 2.5, the computation of (iii) and (iv) reduces to the following convolution:

- (iii)' kernel mean values: $m_P(x) = (\kappa * P)(x)$,
- (iv)' kernel mean inner products: $\langle m_P, m_Q \rangle_{\mathcal{H}} = (\kappa * \tilde{P} * \tilde{Q})(0) = (\kappa * P * \tilde{Q})(0)$,

where \tilde{P} and \tilde{Q} are the dual of P and Q , respectively.³ This convolution representation motivates us to explore a set of parametric distributions \mathcal{P}_{Θ} that is closed under convolution, namely, a convolution semigroup $(\mathcal{P}_{\Theta}, *) \subset \mathcal{M}_1(\mathbb{R}^d)$, where κ is a density function in \mathcal{P}_{Θ} .

To illustrate the basic idea, let us consider Gaussian distributions \mathcal{P}_{Θ} as a parametric class, which is closed under convolution, and a Gaussian kernel. For simplicity, we consider the case of scalar variance matrices $\sigma^2 I_d$. Let $N_d(\mu, \sigma^2 I_d)$ and $f_d(x | \mu, \sigma^2 I_d)$ denote the d -dimensional Gaussian distribution with mean μ and variance-covariance matrix $\sigma^2 I_d$, and its pdf, respectively. If P and Q are Gaussian distributions $N_d(\mu_P, \sigma_P^2 I_d)$ and $N_d(\mu_Q, \sigma_Q^2 I_d)$, respectively, and k is given by the pdf $f_d(x - y | 0, \sigma^2 I_d)$, it is easy to see that $m_P(x) = f_d(x | \mu_P, (\sigma_P^2 + \sigma^2) I_d)$ and $\langle m_P, m_Q \rangle_{\mathcal{H}} = f_d(\mu_P - \mu_Q, (\sigma_P^2 + \sigma_Q^2 + \sigma^2) I_d)$. The kernel mean value and inner product are thus reduced to simply evaluating Gaussian pdfs, which are given by a parameter update following a specific rule. This type of computation appears in various applications: to list a few, Muanudet et al. (2012) proposed a support measure classification by considering kernels $k(P, Q)$ between two input probability measures P, Q , including Gaussian models; Song et al. (2008) and McCalmann et al. (2013) considered an approximation of a (target) probability measure P with a Gaussian mixture P_{θ} , via an optimization problem $\theta = \text{argmin}_{\theta} \|m_P - m_{P_{\theta}}\|_{\mathcal{H}}^2$. The parametric expression of (iii) and (iv) is especially useful for the optimization of θ in the class of distributions. Other such applications are given in Section 5.

We generalize this closedness or ‘‘conjugacy’’⁴ of Gaussians with respect to kernel means and explore other cases in CID kernels. We then introduce a *conjugate* kernel k to parametric models \mathcal{P}_{θ} and a *convolution trick*, so that (iii) and (iv) have the same density form, i.e., there is some parameter update in the class. If P, Q are delta measures δ_a, δ_b , then the convolution trick simplifies to the kernel trick. See Proposition 4.2 for a description.

While a general perspective is obtained from the convolution semigroup $(\mathbb{I}(\mathbb{R}^d), *)$ of infinitely divisible distributions, the pdfs of $\mathbb{I}(\mathbb{R}^d)$ are not tractable in general. We then

3. A probability measure $\tilde{P} \in \mathcal{M}_1(\mathbb{R}^d)$ is called a *dual* of $P \in \mathcal{M}_1(\mathbb{R}^d)$ if $\tilde{P}(B) = P(-B)$ for every $B \in \mathcal{B}(\mathbb{R}^d)$, where $-B := \{-x : x \in B\}$ (Sato, 1999, p.8)

4. Here, the term ‘‘conjugacy’’ is an analogy of the conjugate prior in the Bayes’ theorem, where the prior and posterior have the same pdf form in a probabilistic model.

explore smaller convolution sub-semigroups $(\mathcal{P}_{\Theta}, *) \subset (\mathbb{I}(\mathbb{R}^d), *)$ having a small number of parameters. In particular, we focus on the well-known α -stable distributions $S_{\alpha}(\mathbb{R}^d)$ for each $\alpha \in (0, 2]$ and generalized hyperbolic (GH) distributions $\mathbb{G}\mathbb{H}(\mathbb{R}^d)$, which include Laplace, Cauchy, and Student’s t distributions. For each $\alpha \in (0, 2]$, the class $S_{\alpha}(\mathbb{R}^d)$ is closed under convolution. The GH class has various convolutional properties, as given in Proposition 4.5. As in the Gaussian cases, the computation of (iii) and (iv) is realized by the evaluation of pdfs, i.e., evaluation of conjugate kernels, after a parameter update.

Unfortunately, these conjugate kernels are not generally tractable. However, we can find some subclasses of tractable conjugate kernels. See Section 6 for a discussion on the computation of conjugate kernels. Note that α -stable and GH distribution classes have many applications: applications of $S_{\alpha}(\mathbb{R}^d)$ are listed in Nolan (2013a), and the GH distributions have been applied, e.g., to mathematical finance with the Lévy processes (Schoutens, 2003; Cont and Tankov, 2004; Barndorff-Nielsen and Halgreen, 1990; Madan et al., 1998; Barndorff-Nielsen, 1998; Barndorff-Nielsen and Prause, 2001; Carr et al., 2002). Note also that the Matérn kernel (Rasmussen and Williams, 2006, Section 4.2.1), often used in machine learning, is included in this GH class.

The rest of this paper is organized as follows. In Section 2, we review the notions of kernel means, characteristic kernels, and related matters. In Section 3, we show that the CID kernels are characteristic p.d. kernels on \mathbb{R}^d . In addition, we present the closedness property with respect to addition, pointwise product, and convolution. In Section 4, we introduce the absorbing, conjugate kernel and convolution trick for convolution semigroups of infinitely divisible distributions. Section 5 lists some motivating examples of kernel machine algorithms involving kernel means and parametric models. Section 6 notes the computation of the pdfs of conjugate kernels to realize the convolution trick.

2. Preliminaries: Kernel Means and Characteristic Kernels

In this section, we review kernel means and characteristic kernels restricted to \mathbb{R}^d .

Let \mathbb{R}^d be the set of $d \times d$ p.d. matrices. Let $\|x\|_{\Sigma} = \sqrt{x^{\top} \Sigma x}$, $x \in \mathbb{R}^d$, and $\Sigma \in \mathbb{P}_d$. Let $L^1(\mathbb{R}^d)$ be the absolutely integrable function space on \mathbb{R}^d . Let $C_0(\mathbb{R}^d)$ be the continuous and bounded function space on \mathbb{R}^d .

A symmetric function $k : \mathbb{R}^d \times \mathbb{R}^d \rightarrow \mathbb{R}$ is called a *p.d. kernel* on \mathbb{R}^d if, for any $n \in \mathbb{N}$, $x_1, \dots, x_n \in \mathbb{R}^d$, the matrix $G_{ij} = k(x_i, x_j)$, $i, j \in \{1, \dots, n\}$ is positive-semidefinite. Throughout this paper, we assume a p.d. kernel k is on \mathbb{R}^d . It is known (Aronszajn, 1950) that every p.d. kernel k has the unique RKHS \mathcal{H} , which is a Hilbert space of functions $f : \mathbb{R}^d \rightarrow \mathbb{R}$, satisfying the following: (i) $k(\cdot, x) \in \mathcal{H}$, $\forall x \in \mathbb{R}^d$, (ii) $\text{Span}\{k(\cdot, x) | x \in \mathbb{R}^d\}$ is dense in \mathcal{H} ; and (iii) the *reproducing property* holds:

$$f(x) = \langle f, k(\cdot, x) \rangle_{\mathcal{H}}, \quad \forall f \in \mathcal{H}, \quad \forall x \in \mathbb{R}^d,$$

where $\langle \cdot, \cdot \rangle_{\mathcal{H}}$ denotes the inner product of \mathcal{H} . The map $\Phi : \mathbb{R}^d \rightarrow \mathcal{H}; x \mapsto k(\cdot, x)$ is called a *feature map*.

A p.d. kernel k is called *bounded* if $\sup_{x \in \mathbb{R}^d} k(x, x) < \infty$. A p.d. kernel k is bounded if and only if every $f \in \mathcal{H}$ is bounded (Steinwart and Christmann, 2008, Lemma 4.23). A p.d. kernel k is called *separately continuous* if $k(\cdot, x) : \mathbb{R}^d \rightarrow \mathbb{R}$ is continuous for all $x \in \mathbb{R}^d$. A p.d. kernel k is bounded and separately continuous if and only if every $f \in \mathcal{H}$ is a bounded

and continuous function, i.e., $\mathcal{H} \subset C_b(\mathbb{R}^d)$, (Steinwart and Christmann, 2008, Lemma 4.28). A p.d. kernel k is called *continuous* if k is separately continuous and $x \mapsto k(x, x)$, $x \in \mathbb{R}^d$ is continuous (Steinwart and Christmann, 2008, Lemma 4.29). If a p.d. kernel k is continuous, the RKHS \mathcal{H} is separable (Steinwart and Christmann, 2008, Lemma 4.33).

A p.d. kernel k is called *shift-invariant* if there exists a function $\kappa : \mathbb{R}^d \rightarrow \mathbb{R}$ such that $k(x, y) = \kappa(x - y)$, $x, y \in \mathbb{R}^d$. The function κ is called a *p.d. function*. A p.d. function κ on \mathbb{R}^d is characterized by the Bochner theorem:

Theorem 2.1 (Bochner, 1959) (Wendland, 2005, Theorem 6.6) *A continuous function $\kappa : \mathbb{R}^d \rightarrow \mathbb{C}$ is positive definite if and only if it is the Fourier transform $\mathcal{F}(\Lambda)$ of a finite nonnegative Borel measure Λ on \mathbb{R}^d :*

$$\kappa(x) = \int_{\mathbb{R}^d} e^{\sqrt{-1}w^\top x} d\Lambda(w), \quad x \in \mathbb{R}^d.$$

Let $\mathcal{K}_{cb}(\mathbb{R}^d) \subset C_b(\mathbb{R}^d)$ denote the set of continuous bounded p.d. functions.

A p.d. kernel k is called *radial* if there exists a function $\tilde{\kappa} : [0, \infty) \rightarrow \mathbb{R}$ such that $k(x, y) = \tilde{\kappa}(\|x - y\|)$, $x, y \in \mathbb{R}^d$. A radial kernel k is given by

$$k(x, y) = \tilde{\kappa}(\|x - y\|) = \int_{[0, \infty)} e^{-t\|x-y\|} d\nu(t), \quad x, y \in \mathbb{R}^d, \quad (2)$$

where $\nu(t)$ is a finite nonnegative Borel measure on the Borel sets $\mathcal{B}([0, \infty))$. A p.d. kernel k is called *elliptical* if $k(x, y) = \tilde{\kappa}(\|x - y\|_\Sigma)$, $x, y \in \mathbb{R}^d$, $\Sigma \in \mathbb{P}^d$.

Let $\mathcal{M}_1(\mathbb{R}^d)$ be the set of Borel probability measures on $(\mathbb{R}^d, \mathcal{B}(\mathbb{R}^d))$. An RKHS element $m_P \in \mathcal{H}$ with a p.d. kernel k is called a *kernel mean* of a probability measure $P \in \mathcal{M}_1(\mathbb{R}^d)$ if there exists an expectation of the feature map:

$$m_P := \mathbb{E}_{X \sim P}[\Phi(X)] = \mathbb{E}_{X \sim P}[k(\cdot, X)] \in \mathcal{H}, \quad P \in \mathcal{M}_1(\mathbb{R}^d).$$

If k is a bounded and continuous p.d. kernel, then the feature map $\Phi : \mathbb{R}^d \rightarrow \mathcal{H}$ is Bochner P -integrable for all $P \in \mathcal{M}_1(\mathbb{R}^d)$, since $\mathbb{E}_{X \sim P}[\|k(\cdot, X)\|_{\mathcal{H}}] = \mathbb{E}_{X \sim P}[\sqrt{k(X, X)}] < \infty$ for all $P \in \mathcal{M}_1(\mathbb{R}^d)$ (Steinwart and Christmann, 2008, p. 510). Throughout this paper, we assume a bounded and continuous p.d. kernel k . We write $m_P := \{m_P\} \in \mathcal{P} \subset \mathcal{M}_1(\mathbb{R}^d)$.

As mentioned in the Introduction, there are many applications using m_P , since m_P enables us to introduce a similarity and distance between probability measures $P, Q \in \mathcal{M}_1(\mathbb{R}^d)$, via the Hilbert space inner product $\langle m_P, m_Q \rangle_{\mathcal{H}}$ and norm $\|m_P - m_Q\|_{\mathcal{H}}$, respectively, where the reproducing property is also exploited. In these applications, the characteristic kernel is important to distinguish any probability measures $P, Q \in \mathcal{M}_1(\mathbb{R}^d)$ by their kernel means $m_P, m_Q \in \mathcal{H}$. The following is the definition restricted to \mathbb{R}^d :

Definition 2.2 (Fukumizu et al., 2004)(Sriperumbudur et al., 2010, Definition 6) *A bounded and continuous p.d. kernel $k : \mathbb{R}^d \times \mathbb{R}^d \rightarrow \mathbb{R}$ is called characteristic on \mathbb{R}^d if the kernel mean map $\mathcal{M}_1(\mathbb{R}^d) \rightarrow \mathcal{H}; P \mapsto m_P$ is injective, i.e., $m_P = m_Q$ implies $P = Q$ for any $P, Q \in \mathcal{M}_1(\mathbb{R}^d)$.*

Sriperumbudur et al. (2010) showed a necessary and sufficient condition for a shift-invariant p.d. kernel $k(x, y) = \kappa(x - y)$, $x, y \in \mathbb{R}^d$, $\kappa \in \mathcal{K}_{cb}(\mathbb{R}^d)$, to be characteristic via the Bochner theorem:

Theorem 2.3 (Sriperumbudur et al., 2010, Theorem 9) *A shift-invariant p.d. kernel k with $\kappa \in \mathcal{K}_{cb}(\mathbb{R}^d)$ is characteristic if and only if the finite nonnegative measure Λ in Theorem 2.1 has the entire support, $\text{supp}(\Lambda) = \mathbb{R}^d$.*

Let $\mathcal{K}_{cb}^{ch}(\mathbb{R}^d) \subset \mathcal{K}_{cb}(\mathbb{R}^d)$ denote the set of such characteristic p.d. functions on \mathbb{R}^d .

The convolution $f * g$ of two functions f and g is defined by $f * g := \int_{\mathbb{R}^d} f(\cdot - y)g(y)dy$. The convolution $f * Q$ of a function f and a probability measure $Q \in \mathcal{M}_1(\mathbb{R}^d)$ is defined by $f * Q := \int_{\mathbb{R}^d} f(\cdot - y)dQ(y)$. The convolution $P * Q$ of two probability measures $P, Q \in \mathcal{M}_1(\mathbb{R}^d)$ is defined by the probability measure $(P * Q)(B) := \int_{\mathbb{R}^d} P(B - x)dQ(x)$, where $B - x := \{z - x : z \in B\}$, $B \in \mathcal{B}(\mathbb{R}^d)$.

Given a function $f(x)$, $x \in \mathbb{R}^d$, the function \tilde{f} denotes $\tilde{f}(x) = f(-x)$, $x \in \mathbb{R}^d$. Given a probability measure $P \in \mathcal{M}_1(\mathbb{R}^d)$, a probability measure $\tilde{P} \in \mathcal{M}_1(\mathbb{R}^d)$ is called *dual* if $\tilde{P}(B) = P(-B)$, $B \in \mathcal{B}(\mathbb{R}^d)$, where $-B := \{-x : x \in B\}$ (Sato, 1999, p.8). A probability measure P is symmetric if $P = \tilde{P}$.

We have the following simple equalities:

Proposition 2.4 $\widetilde{f * g} = \tilde{f} * \tilde{g}$, $\widetilde{f * P} = \tilde{f} * \tilde{P}$, and $\widetilde{P * Q} = \tilde{P} * \tilde{Q}$.

Kernel mean m_P and RKHS inner product $\langle m_P, m_Q \rangle_{\mathcal{H}}$ have the following convolution representation:

Lemma 2.5 *Let k be a shift-invariant p.d. kernel with $\kappa \in C_b(\mathbb{R}^d)$. Then, we have the following:*

1. Kernel mean m_P is given by the convolution

$$m_P = \kappa * P \in \mathcal{H} \subset C_b(\mathbb{R}^d), \quad P \in \mathcal{M}_1(\mathbb{R}^d).$$
2. The RKHS inner product $\langle m_P, m_Q \rangle_{\mathcal{H}}$ is given by the convolution

$$\langle m_P, m_Q \rangle_{\mathcal{H}} = (\kappa * \tilde{P} * Q)(0) = (\kappa * P * \tilde{Q})(0), \quad P, Q \in \mathcal{M}_1(\mathbb{R}^d),$$
 where \tilde{P} and \tilde{Q} are the dual of P and Q , respectively.

Proof 1. Kernel mean m_P has the following convolution representation:

$$m_P = \int_{\mathbb{R}^d} k(x, \cdot) dP(x) = \int_{\mathbb{R}^d} \kappa(\cdot - x) dP(x) = \kappa * P, \quad P \in \mathcal{M}_1(\mathbb{R}^d).$$

Kernel mean $m_P \in \mathcal{H} \subset C_b(\mathbb{R}^d)$ exists for all $P \in \mathcal{M}_1(\mathbb{R}^d)$ because, for $\kappa \in C_b(\mathbb{R}^d)$, the feature map $\Phi : x \mapsto k(x, \cdot)$ is Bochner P -integrable for all $P \in \mathcal{M}_1(\mathbb{R}^d)$, as given in the definition of m_P .

2. RKHS inner product $\langle m_P, m_Q \rangle_{\mathcal{H}}$ has the following convolution representation:

$$\langle m_P, m_Q \rangle_{\mathcal{H}} = \int_{\mathbb{R}^d} m_P(y)dQ(y) = \int_{\mathbb{R}^d} \tilde{m}_P(-y)dQ(y) = (\tilde{m}_P * Q)(0) = (\kappa * \tilde{P} * Q)(0),$$

where we have used Proposition 2.4 and $\tilde{\kappa} = \kappa$ in the last equality. Since $\langle m_P, m_Q \rangle_{\mathcal{H}}$ is symmetric with respect to P and Q , then $(\kappa * \tilde{P} * Q)(0) = (\kappa * P * \tilde{Q})(0)$. This is also

obtained by $(\kappa * \tilde{P} * \tilde{Q})(0) = (\kappa * \widetilde{\tilde{P} * \tilde{Q}})(0) = (\kappa * P * \tilde{Q})(0)$. ■

In this paper, we simply consider that κ is a pdf of a probability distribution.⁵ Then, Lemma 2.5 motivates us to explore the set of probability distributions $\mathcal{P}_\Theta \subset \mathcal{M}_1(\mathbb{R}^d)$ that is closed under convolution, i.e., convolution semigroup $(\mathcal{P}_\Theta, *)$.

3. Characteristic kernels and infinitely divisible distributions

In this section, we introduce CID kernels, which are defined by infinitely divisible distributions, and show that they are characteristic (Section 3.1). In addition, we examine some closure properties of CID kernels with respect to addition, pointwise product, and convolution (Section 3.2).

3.1 Convolutionally Infinitely Divisible kernels

We review the infinite divisibility of a probability measure (Sato, 1999; F. W. Steutel, 2004; Applebaum, 2009).

Definition 3.1 (Sato, 1999, Definition 7.1, p. 31) *A probability measure $P \in \mathcal{M}_1(\mathbb{R}^d)$ is called infinitely divisible if, for any integer $n \in \mathbb{N}$, there exists a probability measure $P_n \in \mathcal{M}_1(\mathbb{R}^d)$ such that $P = P_n^{*n}$.*

The support of every infinitely divisible distribution P is unbounded except for delta measures $\{\delta_x(\cdot) \mid x \in \mathbb{R}^d\}$ (Sato, 1999, Examples 7.2, p. 31). Let $\mathbb{I}(\mathbb{R}^d)$ denote the set of infinitely divisible distributions on \mathbb{R}^d , $\mathbb{I}(\mathbb{R}^d)$ is closed under convolution. Every infinitely divisible distribution $P \in \mathbb{I}(\mathbb{R}^d)$ has the following unique Lévy–Khintchine representation for the characteristic function. Let $x \wedge y = \min\{x, y\}$; $x, y \in \mathbb{R}$. Let 1_B denote the indicator function on \mathbb{R}^d with $B \subset \mathbb{R}^d$.

Theorem 3.2 (Sato, 1999, Theorem 8.1, p. 37) *The characteristic function $\hat{P}(w)$ of an infinitely divisible distribution $P \in \mathbb{I}(\mathbb{R}^d)$ has the following unique representation:*

$$\hat{P}(w) = \exp \left(iw^\top \gamma - \frac{1}{2} w^\top A w + \int_{\mathbb{R}^d} \left(e^{i w^\top x} - 1 - i w^\top x 1_{\{|x| \leq 1\}}(x) \right) \nu(dx) \right), \quad w \in \mathbb{R}^d, \quad (3)$$

where $\gamma \in \mathbb{R}^d$, $A \in \mathbb{R}^{d \times d}$, is a symmetric nonnegative-definite matrix and ν is a measure on \mathbb{R}^d satisfying

$$\nu(\{0\}) = 0 \quad \text{and} \quad \int_{\mathbb{R}^d} (|x|^2 \wedge 1) \nu(dx) < \infty. \quad (4)$$

5. In machine learning, normalized kernels $\bar{k}(x, y) := \frac{k(x, y)}{\sqrt{k(x, x)k(y, y)}}$ are often used (e.g., Gaussian kernels $\bar{k}(x, y) := \exp(-\frac{\|x-y\|_2^2}{2\sigma^2})$) (Steinwart and Christmann, 2008, Lemma 4.55). However, we consider here pdf kernels (e.g., Gaussian kernels $k(x, y) := \frac{1}{\sqrt{(2\pi\sigma^2)^d}} \exp(-\frac{\|x-y\|_2^2}{2\sigma^2})$) for the closedness of the pdfs of P and $m \cdot P$. A scalar multiplication ($c > 0$) changes as follows: $\bar{m} \cdot P := \mathbb{E}^{X \sim P}[\bar{k}(\cdot, X)] = c \mathbb{E}^{X \sim P}[k(\cdot, X)] = cm \cdot P$ and $(\bar{m} \cdot P, \bar{m} \cdot Q)_{\mathcal{H}} = c(m \cdot P, m \cdot Q)_{\mathcal{H}}$, where $(f, g)_{\mathcal{H}} = \int_{\mathcal{X}} f(x)g(x) \nu(x)$ (Berlinet and Thomas-Agnan, 2004, p.37).

Conversely, for any $\gamma \in \mathbb{R}^d$, symmetric nonnegative-definite matrix $A \in \mathbb{R}^{d \times d}$, and measure ν satisfying (4), there exists an infinitely divisible distribution $P \in \mathbb{I}(\mathbb{R}^d)$.

(A, ν, γ) is called the generating triplet of $P \in \mathbb{I}(\mathbb{R}^d)$. A is called the covariance matrix of the Gaussian factor of $P \in \mathbb{I}(\mathbb{R}^d)$, and ν is called the Lévy measure of $P \in \mathbb{I}(\mathbb{R}^d)$. Gaussians correspond to the generating triplet $(A, 0, \gamma)$. α -Stable distributions, including Cauchy distributions, correspond to generating triplet $(0, \nu, \gamma)$, where ν is the corresponding nonzero Lévy measure. The Lévy measure of the α -stable distributions is shown in Appendix A.

An infinitely divisible distribution $P \in \mathbb{I}(\mathbb{R}^d)$ is symmetric if and only if $(A, \nu, \gamma) = (A, \nu_s, 0)$, where ν_s is a symmetric Lévy measure⁶ (Sato, 1999, p.114). Let $\mathbb{IS}(\mathbb{R}^d)$ denote the set of symmetric and infinitely divisible distributions on \mathbb{R}^d . $\mathbb{IS}(\mathbb{R}^d)$ is closed under convolution. Let $\mathcal{K}_{\text{cid}}^{\text{id}}(\mathbb{R}^d) \subset C_b(\mathbb{R}^d) \cap L^1(\mathbb{R}^d)$ denote the set of continuous and bounded pdfs⁷ of symmetric infinitely divisible distributions $\mathbb{IS}(\mathbb{R}^d)$:

$$\mathcal{K}_{\text{cid}}^{\text{id}}(\mathbb{R}^d) := \{\Xi(P_S) \in C_b(\mathbb{R}^d) \mid P_S \in \mathbb{IS}(\mathbb{R}^d)\},$$

where $\Xi : \mathcal{M}_1(\mathbb{R}^d) \rightarrow L^1(\mathbb{R}^d)$ is a function that maps a probability measure P to its pdf f if it exists.

The infinitely divisible pdf $\kappa \in \mathcal{K}_{\text{cid}}^{\text{id}}(\mathbb{R}^d)$ can be used for a characteristic kernel as follows.

Theorem 3.3 *The function $k(x, y) = \kappa(x - y)$, $x, y \in \mathbb{R}^d$, $\kappa \in \mathcal{K}_{\text{cid}}^{\text{id}}(\mathbb{R}^d)$ is a p.d. and characteristic kernel, i.e., $\mathcal{K}_{\text{cid}}^{\text{id}}(\mathbb{R}^d) \subset \mathcal{K}_{\text{cb}}^{\text{id}}(\mathbb{R}^d)$.*

Proof A probability measure P on \mathbb{R}^d is symmetric if and only if the characteristic function $\hat{P}(w)$, $w \in \mathbb{R}^d$ is real valued (Sato, 1999, p.67). If P is symmetric and infinitely divisible, $\hat{P}(w) > 0$ for every $w \in \mathbb{R}^d$ from the Lévy–Khintchine formula (3). Since $\hat{P}(w)$ is positive and has the entire support, $\text{supp}(\hat{P}(w)) = \mathbb{R}^d$, then k is a p.d. and characteristic kernel from Theorem 2.3. ■

We call a p.d. kernel k in Theorem 3.3 a convolutionally infinitely divisible (CID) kernel⁸. CID kernels include the following examples:

Example 3.4 (CID p.d. kernels) *CID kernels include Gaussian kernels, Laplace kernels, Cauchy kernels, α -stable kernels for each $\alpha \in (0, 2]$ ($\alpha = 2$ corresponds to Gaussian kernels (Grosswald, 1976), GH kernels, normalized inverse Gaussian α -stable kernels, Student's t kernels (Grosswald, 1976), GH kernels, normalized inverse Gaussian (NIG) kernels, variance gamma (VG) kernels (Matérn kernel is a special case of this), tempered α -stable (ToS) kernels (Rauchen et al., 2011; Rosinski, 2007; Bianchi et al., 2010), etc.*

6. A symmetric Lévy measure is a Lévy measure such that $\nu_s(B) = \nu_s(-B)$ for $\forall B \in \mathcal{B}(\mathbb{R}^d)$.
7. A necessary and sufficient condition for $P \in \mathbb{IS}(\mathbb{R}^d)$ to have a pdf is not known (Sato, 1999, p.177). If the Gaussian factor $A \in \mathbb{R}^{d \times d}$ is full rank, then $P \in \mathbb{I}(\mathbb{R}^d)$ has the pdf. If $A = 0$, see some sufficient conditions (Sato, 1999, Theorem 27.7, 27.10). Every nondegenerate self-decomposable distribution on \mathbb{R}^d has the pdf (Sato, 1999, Theorem 27.13).
8. The term “infinite divisibility” of a p.d. kernel is used in the pointwise product sense (Berg et al., 1984, Definition 2.6, p. 76), i.e., a p.d. kernel $k : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{C}$ on a nonempty set \mathcal{X} is called infinitely divisible if, for every $n \in \mathbb{N}$, there exists a p.d. kernel $k_n : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{C}$ such that $k = (k_n)^{*n}$. The CID kernel considered here is the convolution sense $\kappa = (\kappa_n)^{*n}$.

3.2 Closure Property

In this subsection, we note some closure properties of CID and characteristic kernels with respect to addition, pointwise product, and convolution. The closure property is used, e.g., to generate a new CID and characteristic kernel. Example 3.8 shows such an example.

It is known that the set of continuous and bounded p.d. kernels $\mathcal{K}_{cb}(\mathbb{R}^d)$ is closed under addition and pointwise product as follows (Steinwart and Christmann, 2008, p. 114):

Proposition 3.5 *If $\kappa_1, \kappa_2 \in \mathcal{K}_{cb}(\mathbb{R}^d)$, then $\kappa_1 + \kappa_2 \in \mathcal{K}_{cb}(\mathbb{R}^d)$ and $\kappa_1 \kappa_2 \in \mathcal{K}_{cb}(\mathbb{R}^d)$.*

Similarly, the set of characteristic kernels $\mathcal{K}_{cb}^{ch}(\mathbb{R}^d)$ is closed under addition and pointwise product as follows (Striperumbudur et al., 2010, Corollary 11):

Proposition 3.6 *If $\kappa \in \mathcal{K}_{cb}^{ch}(\mathbb{R}^d)$, $\kappa_1, \kappa_2 \in \mathcal{K}_{cb}(\mathbb{R}^d)$, and $\kappa_2 \neq 0$, then $\kappa + \kappa_1, \kappa \kappa_2 \in \mathcal{K}_{cb}^{ch}(\mathbb{R}^d)$.*

The set of CID kernels $\mathcal{K}_{cb}^{cid}(\mathbb{R}^d)$ is closed under convolution but not closed under addition or pointwise product.

Proposition 3.7 *Let $\kappa_1, \kappa_2 \in \mathcal{K}_{cb}^{cid}(\mathbb{R}^d)$. Then, we have the following:*

1. *Convolution $\kappa_1 * \kappa_2 \in \mathcal{K}_{cb}^{cid}(\mathbb{R}^d)$.*
2. *Addition $\kappa_1 + \kappa_2$ and product $\kappa_1 \kappa_2$ do not necessarily belong to $\mathcal{K}_{cb}^{cid}(\mathbb{R}^d)$, although they are characteristic, $\kappa_1 + \kappa_2, \kappa_1 \kappa_2 \in \mathcal{K}_{cb}^{ch}(\mathbb{R}^d)$.*

Proof 1. Let $\kappa_1 = \Xi(P_1)$ and $\kappa_2 = \Xi(P_2)$. Then, $\kappa_1 * \kappa_2 = \Xi(P_1 * P_2)$. If $P_1, P_2 \in \mathbb{IS}(\mathbb{R}^d)$ are absolutely continuous and symmetric infinitely divisible measures, so is $P_1 * P_2 \in \mathbb{IS}(\mathbb{R}^d)$.

2. A mixture of two infinitely divisible distributions is not necessarily infinitely divisible. A product of two infinitely divisible distributions is not necessarily infinitely divisible. The counter-examples are as follows. Let $\kappa_1(x) = e^{-|x|}$ and $\kappa_2(x) = e^{-x^2}$, $x \in \mathbb{R}$, be p.d. functions of Laplace and Gaussian kernels, respectively. Then, the product $k(x) \propto e^{-|x|} e^{-x^2}$ is not infinitely divisible (F. W. Steutel, 2004, Example 11.1.3), although it is characteristic (Proposition 3.6). Let $\kappa_1(x) = \frac{1}{4\sqrt{\pi}} e^{-\frac{1}{4}x^2}$ and $\kappa_2(x) = \frac{1}{4\sqrt{2\pi}} e^{-\frac{1}{8}x^2}$, $x \in \mathbb{R}$, be Gaussian kernels; then, the addition $\kappa_1 + \kappa_2$ is not infinitely divisible (F. W. Steutel, 2004, Example 11.15), although it is characteristic (Proposition 3.6). Many examples can be found in F. W. Steutel (2004). ■

As given in Proposition 3.7, the infinite divisibility is not closed under mixing in general, although some special mixing cases preserve it (F. W. Steutel, 2004, Chapter 7). The *normal mean-variance mixture* with an infinitely divisible mixing distribution, given in Lemma 4.4, is one of them.

New CID kernels and characteristic kernels may be generated by using these closure properties. If $\kappa = \mathcal{F}(\tilde{\kappa})$ is an infinitely divisible pdf with the characteristic function $\tilde{\kappa}$, then symmetrization $\kappa^* := \kappa * \tilde{\kappa} = \mathcal{F}(|\tilde{\kappa}|^2)$ and positive powers $(\kappa^*)^{*\lambda} = \mathcal{F}(|\tilde{\kappa}|^{2\lambda})$ ($\lambda > 0$) are also infinitely divisible pdfs. The following example shows that the Laplace and symmetric Gamma kernels are CID kernels generated from an exponential distribution.

Example 3.8 (F. W. Steutel, 2004, Example 2.9) *An exponential distribution P with the pdf $\kappa(x) = \alpha \exp(-\alpha x) 1_{[0, \infty)}(x)$, $\alpha > 0$ is infinitely divisible. The dual is $\tilde{\kappa}(x) = \alpha \exp(\alpha x) 1_{(-\infty, 0)}(x)$.*

1. *The symmetrization $\kappa^* = \kappa * \tilde{\kappa}$ has the characteristic function $\tilde{\kappa}^*(w) = \tilde{\kappa}(w) \tilde{\kappa}(w) = \frac{\alpha}{\alpha^2 + w^2}$. This is a Laplace pdf $\kappa^*(x) = \frac{\alpha}{2} \exp(-\alpha|x|)$.*

2. *Positive powers $(\kappa^*)^{*\lambda}$ ($\lambda > 0$) have the characteristic functions $(\tilde{\kappa}^*)^\lambda(w) = (\frac{\alpha^2}{\alpha^2 + w^2})^\lambda$. If $\lambda = 1$, the pdf is the above Laplace case. If $\lambda = 2$, the pdf is given by $(\kappa^*)^{*2}(x) = \frac{\alpha}{4}(1 + \alpha|x|) \exp(-\alpha|x|)$. For general $\lambda > 0$, the pdf is given by*

$$f(x) = \frac{\alpha^{2\lambda}}{\sqrt{\pi}(2\alpha)^{\lambda - \frac{1}{2}} \Gamma(\lambda)} |x - \mu|^{\lambda - \frac{1}{2}} K_{\lambda - \frac{1}{2}}(\alpha|x - \mu|), \quad x \in \mathbb{R}$$

where $\Gamma(\lambda)$ is the Gamma function and $K_\lambda(x)$ is the modified Bessel function of the third kind with index λ . This is the pdf of the zero-skewed VG distribution $VG_1(\lambda, \alpha, \beta = 0, \mu, 1)$ on \mathbb{R} , as given in Section 4.3.

The additions $(\kappa^*)^{*\lambda} + \tilde{\kappa}$, $\tilde{\kappa} \in \mathcal{K}_{cb}(\mathbb{R}^d)$, and products $(\kappa^*)^{*\lambda} \tilde{\kappa}$, $\tilde{\kappa} \in \mathcal{K}_{cb}^{ch}(\mathbb{R}^d)$, are characteristic kernels based on the closure properties.

4. Kernel Means and Infinitely Divisible Distributions

In this section, we examine the kernel means of a parametric class of distributions $\mathcal{P}_\Theta \subset \mathbb{I}(\mathbb{R}^d)$. As mentioned in the Introduction, we wish to compute (iii) kernel mean values $m_P(x)$, $x \in \mathbb{R}^d$ and (iv) RKHS inner products $\langle m_P, m_Q \rangle_{\mathcal{H}}$ for parametric models $P, Q \in \mathcal{P}_\Theta$. These form a basic computation for establishing kernel machine algorithms combining kernel means and parametric models. In Section 4.1, we introduce absorbing, conjugate kernels, and convolution trick in the set of infinitely divisible distributions $\mathbb{I}(\mathbb{R}^d)$. In Sections 4.2 and 4.3, we focus on well-known subclasses of α -stable distributions and GH distributions, which include Laplace, Cauchy, and Student's t distributions.

4.1 Absorbing, Conjugate Kernels, and Convolution Trick

We begin by introducing the notion of *absorbing* and *conjugate* p.d. kernels to particular sets of parametric models \mathcal{P}_Θ as follows:

Proposition 4.1 (absorbing & conjugate kernel) *Let $\mathcal{P}_\Theta, \mathcal{Q}_{\Theta'} \subset \mathcal{M}_1(\mathbb{R}^d)$ be two sets of parametric models such that $\mathcal{P}_\Theta * \mathcal{Q}_{\Theta'} \subseteq \mathcal{P}_\Theta$, where Θ and Θ' are finite or infinite index p.d. kernel. We have the following statements:*

1. *If $\kappa \in \Xi(\mathcal{P}_\Theta)$, then $m_{\mathcal{Q}_{\Theta'}} \in \Xi(\mathcal{P}_\Theta)$ holds. RKHS inner products $\langle m_P, m_Q \rangle_{\mathcal{H}}$, $P, Q \in \mathcal{P}_\Theta$ are values of pdfs in $\Xi(\mathcal{P}_\Theta)$.*
2. *If $\kappa \in \Xi(\mathcal{Q}_{\Theta'})$, then $m_{\mathcal{P}_\Theta} \in \Xi(\mathcal{P}_\Theta)$ holds. RKHS inner products $\langle m_P, m_Q \rangle_{\mathcal{H}}$, $P, Q \in \mathcal{P}_\Theta$ are not necessarily values of pdfs in $\Xi(\mathcal{P}_\Theta)$.*

Proof These statements are straightforward from Lemma 2.5 and assumptions. ■

Statements 1 and 2 indicate an *absorbing property* of k with respect to parametric models. If $\mathcal{P}_\Theta = \mathcal{Q}_{\Theta'}$ in Proposition 4.1, we call k (and, hence, its RKHS \mathcal{H}) a *conjugate* to \mathcal{P}_Θ . A general perspective may be given by the CID kernels, where these kernels are conjugate to $\mathbb{I}(\mathbb{R}^d)$ as follows:

Proposition 4.2 Let $k_{A,\nu_s}(x, y) = \kappa_{A,\nu_s}(x - y)$, $x, y \in \mathbb{R}^d$ be a CID kernel, where $\kappa_{A,\nu_s} \in \mathcal{K}_{\text{fid}}^d(\mathbb{R}^d)$ has a generating triplet $(A, \nu_s, 0)$, and let \mathcal{H}_{A,ν_s} be the RKHS given by κ_{A,ν_s} . Let $P, Q \in \mathbb{I}(\mathbb{R}^d)$ be infinitely divisible distributions with the generating triplets (A_P, ν_P, γ_P) and (A_Q, ν_Q, γ_Q) , respectively. Then, we have the following:

1. Kernel mean m_P is given by an infinitely divisible pdf:

$$\begin{aligned} m_P(\cdot) &= f(\cdot; A + A_P, \nu_s + \nu_P, \gamma_P), \quad f \in \Xi(\mathbb{I}(\mathbb{R}^d)) \\ &= k_{A+A_P, \nu_s + \nu_P}(\gamma_P, \cdot). \end{aligned}$$

2. The RKHS inner product $\langle m_P, m_Q \rangle_{\mathcal{H}_{A,\nu_s}}$ is given by

$$\begin{aligned} \langle m_P, m_Q \rangle_{\mathcal{H}_{A,\nu_s}} &= f(0; A + A_P + A_Q, \nu_s + \tilde{\nu}_P + \mu_Q, \gamma_Q - \gamma_P) \\ &= f(0; A + A_P + A_Q, \nu_s + \nu_P + \tilde{\nu}_Q, \gamma_P - \gamma_Q), \\ &= k_{A+A_P+A_Q, \nu_s + \nu_P + \tilde{\nu}_Q}(\gamma_P, \gamma_Q), \end{aligned}$$

where $\tilde{\nu}_P$ (respectively, $\tilde{\nu}_Q$) is the dual of the Lévy measure ν_P (respectively, ν_Q).

Proposition 4.2 indicates a general convolution trick. The computation of $\langle m_P, m_Q \rangle_{\mathcal{H}_{A,\nu_s}}$ is reduced to the computation of the same kernel $k_{A+A_P+A_Q, \nu_s + \nu_P + \tilde{\nu}_Q}$ with the updated parameters of the generating triplets. If Q is a delta measure δ_y (i.e., $A_Q = 0$, $\nu_Q = 0$, $\gamma_Q = y$), then statement 2 is specialized to statement 1. If P, Q are both delta measures δ_{x_P} , δ_{y_P} (i.e., $A_P = A_Q = 0$, $\nu_P = \nu_Q = 0$, $\gamma_P = x$, $\gamma_Q = y$), then statement 2 is specialized to the kernel trick $\langle k_{A,\nu_s}(\cdot, x), k_{A,\nu_s}(\cdot, y) \rangle_{\mathcal{H}_{A,\nu_s}} = k_{A,\nu_s}(x, y)$. If P, Q and k are all Gaussians (i.e., $\nu_P = \nu_Q = \nu_s = 0$), then statement 2 results in the computation of the same Gaussian kernel with increased variance $A + A_P + A_Q$, where the computation of Gaussian pdfs is tractable.

Although Proposition 4.2 gives us a theory that kernel means m_P and RKHS inner products $\langle m_P, m_Q \rangle$ are expressed with generating triplets (A, ν, γ) , the computation of the general infinitely divisible pdfs may be intractable. We then systematically examine smaller subsemigroups of parametric models $(\mathcal{P}_{\Theta}, *) \subset (\mathbb{I}(\mathbb{R}^d), *)$ such that the computation of pdfs may be possible. We specifically examine well-known parametric classes of α -stable distributions and GH distributions on \mathbb{R}^d in Sections 4.2 and 4.3, respectively.

4.2 α -stable distributions

α -Stable distributions $S_\alpha(\mathbb{R}^d)$, $\alpha \in (0, 2]$, on \mathbb{R}^d are a well-known convolution subsemigroup of infinitely divisible distributions (Zolotarev, 1986; Samorodnitsky and Taqqu, 1994).

$\alpha = 2$ implies Gaussian distributions $S_2(\mathbb{R}^d) = \mathcal{G}(\mathbb{R}^d)$, which are closed under convolution; if P and Q are $N(\mu_P, R_P)$ and $N(\mu_Q, R_Q)$ with mean vectors μ_P, μ_Q and covariance matrices R_P, R_Q , respectively, then convolution $P * Q$ is $N(\mu_P + \mu_Q, R_P + R_Q)$.

For $\alpha \in (0, 2)$, α -stable distributions are heavy tailed, where there are many applications, as listed in Nolan (2013a). For each $\alpha \in (0, 2)$, a one-dimensional α -stable distribution $S_\alpha(\sigma, \beta, \mu)$ is specified by a scale parameter $\sigma > 0$, a skewness parameter $\beta \in [-1, 1]$, and a location parameter $\mu \in \mathbb{R}$. For each $\alpha \in (0, 2)$, the set $S_\alpha(\mathbb{R})$ is closed under convolution:

if P and Q are two stable laws $S_\alpha(\sigma_P, \beta_P, \mu_P)$ and $S_\alpha(\sigma_Q, \beta_Q, \mu_Q)$, respectively, then $P * Q$ is $S_\alpha(\sigma, \beta, \mu) = S_\alpha((\sigma_P^\alpha + \sigma_Q^\alpha)^{1/\alpha}, \frac{\beta_P \sigma_P^\alpha + \beta_Q \sigma_Q^\alpha}{\sigma_P^\alpha + \sigma_Q^\alpha}, \mu_P + \mu_Q)$ (Samorodnitsky and Taqqu, 1994, Property 1.2.1). See Appendix A.2 for more details.

For each $\alpha \in (0, 2)$, a d -dimensional α -stable distribution $S_\alpha(\mu, \Gamma)$ is specified by a location parameter $\mu \in \mathbb{R}^d$ and a spectral measure Γ on the unit sphere $S_{d-1} := \{s \in \mathbb{R}^d : \|s\| = 1\}$ (Samorodnitsky and Taqqu, 1994, Theorem 2.3.1, p.65). For each $\alpha \in (0, 2)$, the set $S_\alpha(\mathbb{R}^d)$ is closed under convolution; if P and Q are two stable laws $S_\alpha(\mu_P, \Gamma_P)$ and $S_\alpha(\mu_Q, \Gamma_Q)$, respectively, then $P * Q$ is $S_\alpha(\mu_P + \mu_Q, \Gamma_P + \Gamma_Q)$. See Appendix A.1 for more details. α -Stable pdfs on \mathbb{R}^d are intractable in general.

Sub-Gaussian α -stable distributions (equivalently, elliptically contoured α -stable distributions) $\text{SG}_\alpha(\mathbb{R}^d)$ are a well-known subclass of $S_\alpha(\mathbb{R}^d)$ (Samorodnitsky and Taqqu, 1994; Nolan, 2013b). For each $\alpha \in (0, 2)$, a sub-Gaussian α -stable distribution is specified by a location parameter $\mu \in \mathbb{R}^d$ and a p.d. matrix $R \in \mathbb{R}^{d \times d}$ (Samorodnitsky and Taqqu, 1994, Theorem 2.5.2, p.78). See Appendix A.4 for more details. Sub-Gaussian 1-stable distributions imply d -dimensional Cauchy distributions $\text{CAU}(\mathbb{R}^d)$ (Samorodnitsky and Taqqu, 1994, Example 2.5.3, p.79). If $d = 1$, for each $\alpha \in (0, 2)$, sub-Gaussians $\text{SG}_\alpha(\mathbb{R})$ are closed under convolution. If $d > 1$, for each $\alpha \in (0, 2)$, sub-Gaussians $\text{SG}_\alpha(\mathbb{R}^d)$ are not closed under convolution. Let us decompose $\text{SG}_\alpha(\mathbb{R}^d)$ into an equivalent class $\text{SG}_\alpha(\mathbb{R}^d) = \bigcup_R \text{SG}_\alpha(\mathbb{R}^d)[R]$, where

$$\text{SG}_\alpha(\mathbb{R}^d)[R] := \{P \in \text{SG}_\alpha(\mathbb{R}^d) \mid P = \text{SG}_\alpha(\mu, cR), \mu \in \mathbb{R}^d, c > 0\}.$$

For each $\alpha \in (0, 2)$ and a p.d. matrix $R \in \mathbb{P}^d$, the set $\text{SG}_\alpha(\mathbb{R}^d)[R]$ is closed under convolution; if P and Q are $\text{SG}_\alpha(\mu_P, c_P R)$ and $\text{SG}_\alpha(\mu_Q, c_Q R)$, respectively, then $P * Q$ is $\text{SG}_\alpha(\mu_P + \mu_Q, (c_P^2 + c_Q^2)^{\frac{\alpha}{2}} R)$. Note that when $\alpha = 2$, the whole set $\text{SG}_2(\mathbb{R}^d)$ is closed.

These convolution properties of α -stable distributions lead to the following conjugate pairs of α -stable kernels k and α -stable distributions \mathcal{P}_Θ .

Example 4.3 Conjugate pairs of α -stable kernels k and α -stable distributions on \mathbb{R}^d .

1. For $\alpha = 2$, let $k_R(x, y) = \frac{1}{\sqrt{(2\pi)^d |R|}} \exp(-\frac{1}{2}(x - y)^T R^{-1}(x - y))$ be a Gaussian kernel and \mathcal{H}_R be its RKHS. Let P, Q be two Gaussians $N(\mu_P, R_P)$ and $N(\mu_Q, R_Q)$, respectively. Then, the kernel mean is given by the Gaussian pdf $m_P = f_\alpha(\cdot; \mu_P, R + R_P)$ and the RKHS inner product is given by the Gaussian pdf $\langle m_P, m_Q \rangle_{\mathcal{H}_R} = f(\mu_P | \mu_Q, R + R_P + R_Q)$.
2. For each $\alpha \in (0, 2)$, let $k_{\alpha, \sigma}(x, y) = \kappa_{\alpha, \sigma}(x - y)$, $x, y \in \mathbb{R}$, be an α -stable kernel on \mathbb{R} and $\mathcal{H}_{\alpha, \sigma}$ be its RKHS. Let P, Q be two α -stable laws $S_\alpha(\sigma_P, \beta_P, \mu_P)$ and $S_\alpha(\sigma_Q, \beta_Q, \mu_Q)$, respectively, on \mathbb{R} . Then, the kernel mean is given by the stable pdf $m_P = f_\alpha(\cdot; (\sigma_P^\alpha + \sigma^\alpha)^{1/\alpha}, \frac{\beta_P \sigma_P^\alpha}{\sigma_P^\alpha + \sigma^\alpha}, \mu_P)$ and the RKHS inner product is given by the stable pdf $\langle m_P, m_Q \rangle_{\mathcal{H}_{\alpha, \sigma}} = f_\alpha(\mu_P | (\sigma_P^\alpha + \sigma^\alpha)^{1/\alpha}, \frac{\beta_Q \sigma_Q^\alpha - \beta_P \sigma_P^\alpha}{\sigma_Q^\alpha + \sigma_P^\alpha + \sigma^\alpha}, \mu_Q)$. If $\alpha = 1$ and $\beta = 0$, then $S_1(\sigma, 0, \mu)$ corresponds to the Cauchy distribution.
3. For each $\alpha \in (0, 2)$, let $k_{\alpha, \Gamma}(x, y) = \kappa_{\alpha, \Gamma}(x - y)$, $x, y \in \mathbb{R}^d$, be an α -stable kernel on \mathbb{R}^d , where Γ is a symmetric spectral measure, and let $\mathcal{H}_{\alpha, \Gamma}$ be its RKHS. Let P, Q be

two α -stable laws $S_\alpha(\mu_P, \Gamma_P)$ and $S_\alpha(\mu_Q, \Gamma_Q)$, respectively, on \mathbb{R}^d . Then, the kernel mean is given by the stable pdf $m_P = f_\alpha(\cdot | \mu_P, \Gamma_P + \Gamma_s)$ and the RKHS inner product is given by the stable pdf $\langle m_P, m_Q \rangle_{\mathcal{H}_{\alpha, \sigma}} = f_\alpha(\mu_P | \mu_Q, \Gamma_Q + \tilde{\Gamma}_P + \Gamma_s)$.

4. For each $\alpha \in (0, 2)$, let $k_{\alpha, R}(x, y) = k_{\alpha, R}(x - y)$, $x, y \in \mathbb{R}^d$ be a sub-Gaussian α -stable kernel on \mathbb{R}^d and let $\mathcal{H}_{\alpha, R}$ be its RKHS. Let $P, Q \in \text{SG}_\alpha(\mathbb{R}^d)[R]$ be two sub-Gaussian α -stable laws $S_\alpha(\mu_P, c_P R)$ and $S_\alpha(\mu_Q, c_Q R)$, respectively, on \mathbb{R}^d . Then, the kernel mean is given by the sub-Gaussian pdf $m_P = f_\alpha(\cdot | \mu_P, (c_P^{\frac{\alpha}{2}} + 1)^{\frac{\alpha}{2}} R)$ and the RKHS inner product is given by the sub-Gaussian pdf $\langle m_P, m_Q \rangle_{\mathcal{H}_{\alpha, R}} = f_\alpha(\mu_P | \mu_Q, (c_P^{\frac{\alpha}{2}} + c_Q^{\frac{\alpha}{2}} + 1)^{\frac{\alpha}{2}} R)$. If $\alpha = 1$, then $S_1(\mu, R)$ corresponds to multivariate Cauchy distributions with pdf $f(x) \propto (1 + \|x - \mu\|_{R^{-1}}^2)^{-\frac{d+1}{2}}$.

5. Tempered stable distributions can also be considered as examples (Rachev et al., 2011, Table 3.2, p. 77).

4.3 Generalized Hyperbolic Distributions

GH distributions on \mathbb{R}^d are a rich model class that includes, e.g., NIGs, hyperbolic distributions, VG distributions, Laplace distributions, Cauchy distributions, and Student's t distributions, as special cases and limiting cases (Barndorff-Nielsen and Halgreen, 1977; Prause, 1999; v. Hammerstein, 2010). A list of parametric models is found in, e.g., Prause (1999, Table 1.1 p.4). The GH and related models are applied, e.g., to mathematical finance (Schoutens, 2003; Cont and Tankov, 2004; Barndorff-Nielsen and Halgreen, 1990; Madan et al., 1998; Barndorff-Nielsen, 1998; Barndorff-Nielsen and Prause, 2001; Carr et al., 2002). The Matérn kernel, often used in machine learning, is a special case of the VG distributions. A GH distribution is obtained by a *normal mean-variance mixture* of a generalized inverse Gaussian (GIG) distribution, which is a special case of the normal mean-variance mixture of the generalized Γ -convolution (Thorin, 1978). The pdfs of GIG, GH, NIG, and VG distributions are presented in Appendix B.

We start by introducing a normal mean-variance mixture distribution. Let $N_d(\mu, \Delta)$ be a Gaussian distribution with mean vector $\mu \in \mathbb{R}^d$ and covariance matrix $\Delta \in \mathbb{P}^d$. A *normal mean-variance mixture* distribution P on \mathbb{R}^d is given by

$$P(dx) = \int_{\mathbb{R}^+} N_d(\mu + y\beta, y\Delta)(dx)G(dy), \quad \beta \in \mathbb{R}^d,$$

where G is a mixing probability measure on \mathbb{R}^+ (v. Hammerstein, 2010, Definition 2.4, p. 78). $P = N_d(\mu + y\beta, y\Delta) \circ G$ denotes a simple notation. The closure properties of the convolution and the infinite divisibility of G are preserved as follows:

Lemma 4.4 (v. Hammerstein, 2010, Lemma 2.5, p. 68) *Let \mathcal{G} be a class of probability distributions on $(\mathbb{R}^+, \mathcal{B}^+)$ and $G, G_1, G_2 \in \mathcal{G}$.*

1. If $G = G_1 * G_2 \in \mathcal{G}$, then

$$(N_d(\mu_1 + y\beta, y\Delta) \circ G_1) * (N_d(\mu_2 + y\beta, y\Delta) \circ G_2) = N_d(\mu_1 + \mu_2 + y\beta, y\Delta) \circ G.$$
2. If G is infinitely divisible, then so is $N_d(\mu + y\beta, y\Delta) \circ G$.

A GH distribution on \mathbb{R}^d is given by a normal mean-variance mixture with the GIG distribution:

$$GH_d(\lambda, \alpha, \beta, \delta, \mu, \Delta) := N_d(\mu + y\Delta\beta, y\Delta) \circ GIG(\lambda, \delta, \sqrt{\alpha^2 - \|\beta\|_\Delta^2}),$$

where the parameters imply $\lambda \in \mathbb{R}$, shape parameter $\alpha > 0$, skewness parameter β , scaling parameter δ , location parameter μ , and p.d. matrix $\Delta \in \mathbb{P}^d$ (see Appendices B.1 and B.2 for more details). A univariate GH distribution on \mathbb{R} is given by letting $d = 1$ and $\Delta = 1$.

The GH distribution contains the following subclasses and limiting cases. Their pdfs are found in Appendices B.3, B.4, and v. Hammerstein (2010):

1. If $\lambda = -\frac{1}{2}$, then $GH_d(-\frac{1}{2}, \alpha, \beta, \delta, \mu, \Delta)$ corresponds to the NIG distribution:

$$NIG_d(\alpha, \beta, \delta, \mu, \Delta) := N_d(\mu + y\Delta\beta, y\Delta) \circ GIG(-\frac{1}{2}, \delta, \sqrt{\alpha^2 - \|\beta\|_\Delta^2}).$$

2. If $\lambda = \frac{d+1}{2}$, then $GH_d(\frac{d+1}{2}, \alpha, \beta, \delta, \mu, \Delta)$ corresponds to the hyperbolic distribution $HYPd(\alpha, \beta, \delta, \mu, \Delta)$.

3. If $\lambda > 0$ and $\delta \rightarrow 0$, then $GH_d(\lambda > 0, \alpha, \beta, 0, \mu, \Delta)$ corresponds to the VG distribution

$$VG_d(\lambda, \alpha, \beta, \mu, \Delta) := N_d(\mu + y\Delta\beta, y\Delta) \circ \text{Gamma}(\lambda, \frac{\alpha^2 - \|\beta\|_\Delta^2}{2}),$$

where $\text{Gamma}(\lambda, \gamma)$ is the Gamma distribution with the pdf $f(x) = \frac{\gamma^\lambda}{\Gamma(\lambda)} x^{\lambda-1} e^{-\gamma x}$. Furthermore, if $\lambda = \frac{d+1}{2}$ (i.e., the above hyperbolic case), then $VG_d(\frac{d+1}{2}, \alpha, \beta, \mu, \Delta)$ corresponds to the skewed Laplace distribution

$$LAP_d(\alpha, \beta, \mu, \Delta) := N_d(\mu + y\Delta\beta, y\Delta) \circ \text{Gamma}(\frac{d+1}{2}, \frac{\alpha^2 - \|\beta\|_\Delta^2}{2}),$$

with the pdf $f(x) \propto e^{-\alpha\|x-\mu\|_{\Delta^{-1}} + (\beta, x-\mu)}$. We have seen the case of $d = 1$ in Example 3.8.

4. If $\lambda < 0$, $\alpha \rightarrow 0$, and $\beta \rightarrow 0$, then $GH_d(\lambda < 0, 0, \delta, \mu, \Delta)$ corresponds to the scaled and shifted t distribution with $f = -2\lambda$ degrees of freedom:

$$t_d(\lambda, \delta, \mu, \Delta) := N_d(\mu, y\Delta) \circ i\text{Gamma}(\lambda, \frac{\delta^2}{2}),$$

where $i\text{Gamma}(\lambda, \delta)$ is the inverse Gamma distribution with the pdf $f(x) = \frac{\delta^{\lambda-1}}{\delta\Gamma(-\lambda)} e^{-\frac{\delta}{x}}$. Furthermore, if $\lambda = -\frac{1}{2}$ (i.e., the above NIG case), then $t_d(-\frac{1}{2}, \delta, \mu, \Delta)$ corresponds to the multivariate Cauchy distribution

$$CAU(\delta, \mu, \Delta) := N_d(\mu, y\Delta) \circ i\text{Gamma}(-\frac{1}{2}, \frac{\delta^2}{2}),$$

with the pdf $f(x) \propto (1 + \frac{\|x-\mu\|_\Delta^2}{\delta^2})^{-\frac{d+1}{2}}$, which is also shown in Example 4.3.

These classes have the following convolution properties, by using Lemma 4.4 and Proposition B.1, which are the multivariate extensions of the univariate case (v. Hammerstein, 2010, eq. (1.9), p. 14).

Proposition 4.5 For each $d \geq 1$, there are the following convolution properties in the d -dimensional GH distributions:

1. $NIG_d(\alpha, \beta, \delta_1, \mu_1, \Delta) * NIG_d(\alpha, \beta, \delta_2, \mu_2, \Delta) = NIG_d(\alpha, \beta, \delta_1 + \delta_2, \mu_1 + \mu_2, \Delta)$,
2. $VG_d(\lambda_1, \alpha, \beta, \mu_1, \Delta) * VG_d(\lambda_2, \alpha, \beta, \mu_2, \Delta) = VG_d(\lambda_1 + \lambda_2, \alpha, \beta, \mu_1 + \mu_2, \Delta)$,
3. $NIG_d(\alpha, \beta, \delta_1, \mu_1, \Delta) * GH_d(1/2, \alpha, \beta, \delta_2, \mu_2, \Delta) = GH_d(1/2, \alpha, \beta, \delta_1 + \delta_2, \mu_1 + \mu_2, \Delta)$,
4. $GH_d(-\lambda, \alpha, \beta, \delta, \mu_1, \Delta) * GH_d(\lambda, \alpha, \beta, 0, \mu_2, \Delta) = GH_d(\lambda, \alpha, \beta, \delta, \mu_1 + \mu_2, \Delta)$,

where $\lambda, \lambda_1, \lambda_2 > 0$.

These convolution properties can also be obtained by looking up their characteristic functions and Lévy measures in v. Hammerstein (2010, Section 1.6.4, p. 46, Section 2.3, p. 79). Properties 1 and 2 imply a convolution semigroup. Property 3 implies an absorbing property. Property 4 implies another convolution property. By observing Proposition 4.5, we obtain the following conjugate, absorbing, and related pairs in GH kernels and GH distributions. The parametric models in Proposition 4.5 contain p.d. kernels κ if and only if $\beta = \mathbf{0}$. Each example (1–4) in the following corresponds to each property (1–4) in Proposition 4.5.

Example 4.6 Conjugate, absorbing, and related pairs in the GH class.

1. Let $k_{\alpha, \delta, \Delta}(x, y)$ be a shift invariant NIG p.d. kernel and $\mathcal{H}_{\alpha, \delta, \Delta}$ be the RKHS. Let P, Q be two NIG distributions $NIG(\alpha, \mathbf{0}, \delta_P, \mu_P, \Delta)$ and $NIG(\alpha, \mathbf{0}, \delta_Q, \mu_Q, \Delta)$, respectively. Then, the kernel mean is the NIG pdf $m_P = f(\cdot | \alpha, \mathbf{0}, \delta_P + \delta, \mu_P, \Delta)$ and the RKHS inner product is the NIG pdf $\langle m_P, m_Q \rangle_{\mathcal{H}_{\alpha, \delta, \Delta}} = f(\mu_P | \alpha, \mathbf{0}, \delta_P + \delta_Q + \delta, \mu_Q, \Delta)$. If $\alpha \rightarrow 0$, then these correspond to the Cauchy case.
2. Let $k_{\lambda, \alpha, \Delta}(x, y)$ be a shift invariant VG p.d. kernel⁸ and $\mathcal{H}_{\lambda, \alpha, \Delta}$ be the RKHS. Let P, Q be two VG distributions $VG(\lambda_P, \alpha, \mathbf{0}, \mu_P, \Delta)$ and $VG(\lambda_Q, \alpha, \mathbf{0}, \mu_Q, \Delta)$, respectively. Then, the kernel mean is the VG pdf $m_P = f(\cdot | \lambda_P + \lambda, \alpha, \mathbf{0}, \mu_P, \Delta)$ and the RKHS inner product is the VG pdf $\langle m_P, m_Q \rangle_{\mathcal{H}_{\lambda, \alpha, \Delta}} = f(\mu_P | \lambda_P + \lambda_Q + \lambda, \alpha, \mathbf{0}, \mu_Q, \Delta)$. If $\lambda = \frac{d+1}{2}$, $\lambda_P = \frac{d+1}{2}$, or $\lambda_Q = \frac{d+1}{2}$, then these correspond to the Laplace case.
3. Let $k_{\alpha, \delta, \Delta}(x, y)$ be a NIG kernel and $\mathcal{H}_{\alpha, \delta, \Delta}$ be the RKHS. Let P be a GH distribution $GH(1/2, \alpha, \mathbf{0}, \delta_P, \mu_P, \Delta)$. Then, the kernel mean is the GH pdf $m_P = f(\cdot | 1/2, \alpha, \mathbf{0}, \delta_P + \delta, \mu_P, \Delta)$. If $\alpha \rightarrow 0$, then the NIG kernel $k_{\alpha, \delta, \Delta}(x, y)$ corresponds to the Cauchy kernel.

Let $k_{1, 2, \alpha, \delta, \Delta}(x, y)$ be a GH kernel and $\mathcal{H}_{1, 2, \alpha, \delta, \Delta}$ be the RKHS. Let P, Q be two NIG distributions $NIG(\alpha, 0, \delta_P, \mu_P, \Delta)$ and $NIG(\alpha, \mathbf{0}, \delta_Q, \mu_Q, \Delta)$, respectively. Then, the

9. The Matérn kernel corresponds to $\Delta = I$, and $\alpha = \frac{\sqrt{2\nu}}{\sigma}$ (Rasmussen and Williams, 2006, Section 4.2.1) (Sriperumbudur et al., 2010, p. 1533)

kernel mean is the GH pdf $m_P = f(\cdot | 1/2, \alpha, \mathbf{0}, \delta_P + \delta, \mu_P, \Delta)$ and the RKHS inner product is the GH pdf $\langle m_P, m_Q \rangle_{\mathcal{H}_{1, 2, \alpha, \delta, \Delta}} = f(\mu_P | 1/2, \alpha, \mathbf{0}, \delta_P + \delta_Q + \delta, \mu_Q, \Delta)$. If $\alpha \rightarrow 0$, then the NIG distributions, P and Q , correspond to the Cauchy distributions.

4. For $\lambda > 0$, let $k_{-\lambda, \alpha, \delta, \Delta}(x, y)$ be a GH kernel and $\mathcal{H}_{-\lambda, \alpha, \delta, \Delta}$ be the RKHS. Let P be a GH distribution $GH(\lambda, \alpha, \mathbf{0}, 0, \mu_P, \Delta)$. Then, the kernel mean is the GH pdf $m_P = f(\cdot | \lambda, \alpha, \delta, \mu_P, \Delta)$. If $\alpha \rightarrow 0$, then $k_{-\lambda, \alpha, \delta, \Delta}(x, y)$ corresponds to the Student's t kernel. Furthermore, if $\lambda = \frac{1}{2}$, then $k_{-\frac{1}{2}, \alpha, \delta, \Delta}(x, y)$ corresponds to the Cauchy kernel. For $\lambda > 0$, let $k_{\lambda, \alpha, \Delta}(x, y)$ be a GH kernel and $\mathcal{H}_{\lambda, \alpha, \Delta}$ be the RKHS. Let P be a GH distribution $GH(-\lambda, \alpha, \mathbf{0}, \delta_P, \mu_P, \Delta)$. Then, the kernel mean is the GH pdf $m_P = f(\cdot | \lambda, \alpha, \mathbf{0}, \delta_P, \mu_P, \Delta)$. If $\alpha \rightarrow 0$, then P is the Student's t distribution. Furthermore, if $\lambda = -\frac{1}{2}$, then P is the Cauchy distribution.

5. Connection to Machine Learning

As mentioned in the Introduction, absorbing and conjugate kernels (Examples 4.3 and 4.6) provide a way to compute the RKHS values (i) $f(x)$, $x \in \mathbb{R}^d$, and the RKHS inner products (ii) $\langle f, g \rangle_{\mathcal{H}}$ when $f, g \in \mathcal{H}$ are expressed by the weighted sums of parametric kernel means, $f = \sum_{i=1}^n w_i m_{P_i}$ and $g = \sum_{j=1}^n \tilde{w}_j m_{Q_j}$ for $\{P_i\}, \{Q_j\} \subset \mathcal{P}_{\Theta}$. Many algorithms aim to use the convolution trick. Examples include as follows:

- The difference between a probability measure $P \in \mathcal{M}_1(\mathbb{R}^d)$ and a model $P_{\theta} \in \mathcal{P}_{\Theta}$ in the RKHS norm $\|m_P - m_{P_{\theta}}\|_{\mathcal{H}}$ needs to be computed, e.g., for the purpose of a goodness-of-fit test and model criticism (Lloyd and Ghaltrayami, 2015), based on the maximum mean discrepancy (MMD) (Gretton et al., 2012).
- Various kernels $k(P, P_{\theta})$ between a probabilistic measure P and a model P_{θ} , e.g., $k(P, P_{\theta}) = \exp(-\frac{\|m_P - m_{P_{\theta}}\|_{\mathcal{H}}^2}{2\sigma^2})$ need to be computed, as in the support measure machine (Mhandet et al., 2012).
- Song et al. (2008) and McCauman et al. (2013) studied an approximation of a target probability measure $P \in \mathcal{M}_1(\mathbb{R}^d)$ with a Gaussian mixture model $P_{\theta} = \sum_{i=1}^n \theta_i P_i$ via solving the following optimization problem:

$$\hat{\theta} = \operatorname{argmin}_{\theta} \|m_P - m_{P_{\theta}}\|_{\mathcal{H}}^2 + \Omega(\theta) = \operatorname{argmin}_{\theta} \|m_P - \sum_{i=1}^n \theta_i m_{P_i}\|_{\mathcal{H}}^2 + \Omega(\theta),$$

where $\Omega(\theta)$ is a regularization term, $\frac{\lambda}{2} \|\theta\|^2$ ($\lambda > 0$). This optimization is solved by a constrained quadratic program: $\min_{\theta} \frac{1}{2} \theta^T (A + \lambda I_n) \theta - b^T \theta$ subject to $\sum_{i=1}^n \theta_i = 1$ and $\theta \geq 0$, where we then need the computation of matrix $A \in \mathbb{R}^{n \times n}$ and vector $b \in \mathbb{R}^n$:

$$A_{ij} = \langle m_{P_i}, m_{P_j} \rangle_{\mathcal{H}}, \quad b_j = \langle \hat{m}_P, m_{P_j} \rangle_{\mathcal{H}}, \quad 1 \leq i, j \leq n,$$

for parametric kernel means $\{m_{P_i}\}$.

- As mentioned in the Introduction, the kernel Bayesian inference (KBI), which employs Bayesian inference in kernel mean form, has been proposed (Fukumizu et al. 2013,

Song et al. 2013). KBI is applied to, e.g., filtering and smoothing algorithms on state space models (Fukumizu et al. 2013 Kanagawa et al. 2016, Nishiyama et al. 2016) and policy learning in reinforcement learning (Grünewälder et al. 2012, Nishiyama et al. 2012, Rawlik et al. 2013, Boots et al. 2013). When we extend it to *semiparametric* KBI, which combines nonparametric inference and parametric inference, we may want to use the RKHS functions $f = \sum_{i=1}^n w_i m_{P_{\theta_i}} \in \mathcal{H}$ expressed by parametric kernel means $\{P_{\theta_i}\} \in \mathcal{P}_{\Theta}$, as is used in the model-based kernel sum rule (Mb-KSR) (Nishiyama et al., 2014).

- Preimage algorithms (Mika et al., 1999; Fukumizu et al., 2013) and kernel herding algorithms (Chen et al., 2010) can also be extended to estimators $f = \sum_{i=1}^n w_i m_{P_{\theta_i}}$ with parametric kernel means $\{P_{\theta_i}\}$.

6. Computation of Conjugate Kernels (Convolution Trick)

In Section 4, we mathematically investigated that several convolution tricks hold within a general convolution trick (Proposition 4.2): the computation of kernel mean values and RKHS inner products is the same as the computation of p.d. kernels having different parameters, if conjugate kernels are used. However, conjugate kernels do not provide a tractable computation in general. We then discuss the computation of the conjugate kernels: α -stable kernels and GH kernels.

- It is known that α -stable pdfs do not generally have a closed-form expression except for some special cases, Gaussians ($\alpha = 2$) and Cauchy ($\alpha = 1$), as given in Appendix A.3. Gaussian and Cauchy kernels may be used as tractable conjugate kernels. For other α -stable kernels ($\alpha \neq 2$ and $\alpha \neq 1$), some numerical elaborations or approximations may be needed for the computation of the pdfs. The STABLE 5.1¹⁰ software allows the computation of α -stable pdfs when they are independent, isotropic, elliptical, or have discrete spectral measures Γ_d under some settings. More information can be found in the STABLE 5.1 software manual. For elliptically contoured α -stable sub-Gaussian kernels on any dimension \mathbb{R}^d , the computation of pdfs is sufficient only to compute a one-dimensional amplitude function $\tilde{\kappa}(r)$ in equation (2), which can be computed by, e.g., a one-dimensional numerical integration. The STABLE 5.1 software supports the computation of sub-Gaussian pdfs in dimension $d < 100$.

- GH kernels and their subclasses are also elliptical pdfs, and the computation of the kernels is sufficient only to compute a one-dimensional amplitude function $\tilde{\kappa}(r)$. VG kernels or Matérn kernels, which are a generalization of Laplace kernels, are used for covariance kernels in Gaussian processes. GH and NIG kernels are variants of Matérn kernels, all of which are expressed by the Bessel function of the third kind. For example, there is an R package software called ‘ghyp’ on the GH distributions (Breyer and Lüthi, 2013).

In addition, random Fourier features (Rahimi and Recht, 2007) may be an approach to approximately compute conjugate kernels. From Proposition 4.2, we have an equality

$$\langle m_P, m_Q \rangle_{\mathcal{H}_{A, \nu_s}} = k_{A+A_P+A_Q, \nu_s + \nu_P + \nu_Q}(\gamma_P, \gamma_Q) = \mathbb{E}_{\omega}[\zeta_{\omega}(\gamma_P)\zeta_{\omega}(\gamma_Q)^*].$$

An RKHS inner product (l.h.s.) may be computed by approximating the expectation of $\zeta_{\omega}(\gamma_P)\zeta_{\omega}(\gamma_Q)^*$ (r.h.s.) with sampling ω from the characteristic function having the generating triplet $(A + A_P + A_Q, \nu_s + \nu_P + \nu_Q)$.

7. Conclusion

In this paper, we introduced a class of CID kernels that constitutes a large subclass in the set of shift-invariant characteristic kernels on \mathbb{R}^d , where CID kernels are closed under convolution but not closed under addition and pointwise product. We introduced absorbing, conjugate kernels, and convolution trick with respect to parametric models, where the basic computation of kernel mean values and RKHS inner products results in the computation of the same p.d. kernels with different parameters, which is an extension of kernel trick. Although the convolution trick may offer a mathematical view, the computation of conjugate kernels is not tractable in general. We then restrict convolution trick only to tractable cases or approximately compute intractable conjugate kernels. Future works include investigating the effectiveness of convolution trick in practice and developing approximation algorithms to efficiently compute intractable conjugate kernels.

Appendix A. α -Stable Distributions

We briefly review the α -stable distributions on \mathbb{R}^d .

A.1 α -Stable Distributions on \mathbb{R}^d

The α -stable distribution on \mathbb{R}^d has the following characteristic function:

Theorem A.1 (Samorodnitsky and Taqqu, 1994, Theorem 2.3.1, p. 65) *Let $\alpha \in (0, 2)$. Then, $X = (X_1, \dots, X_d)$ is an α -stable random vector in \mathbb{R}^d if and only if there exists a finite measure Γ on the unit sphere $S_{d-1} = \{s \in \mathbb{R}^d : \|s\| = 1\}$ and a vector $\mu^0 \in \mathbb{R}^d$ such that*

$$\hat{P}(\theta) = \begin{cases} \exp\left(-\int_{S_{d-1}} |\theta^\top s|^\alpha (1 - i \operatorname{sgn}(\theta^\top s) \tan \frac{\pi\alpha}{2}) \Gamma(ds) + i\theta^\top \mu^0\right), & (\alpha \neq 1), \\ \exp\left(-\int_{S_{d-1}} |\theta^\top s|^\alpha (1 + i \frac{2}{\pi} \operatorname{sgn}(\theta^\top s) \ln |\theta^\top s|) \Gamma(ds) + i\theta^\top \mu^0\right), & (\alpha = 1). \end{cases}$$

10. John Nolan’s Page. <http://academic2.american.edu/~jpnolan/stable/stable.html>

The pair (Γ, μ^0) is unique.

The measure Γ is called the *spectral measure*. See Samorodnitsky and Taqqu (1994, Section 2.3) for some examples of spectral measures. The radial sub-Gaussian distribution has a uniform spectral measure. An α -stable random vector $X = (X_1, \dots, X_d)$ has independent components if and only if its spectral measure Γ is discrete and concentrated on the intersection of the axes with the sphere S_{d-1} . It is known that any nondegenerate stable distribution on \mathbb{R}^d has the C^∞ pdf (Sato, 1999, Example 28.2, p. 190). An α -stable distribution on \mathbb{R}^d is symmetric if and only if $\mu^0 = 0$ and Γ is a symmetric measure on S_{d-1} (i.e., it satisfies $\Gamma(A) = \Gamma(-A)$ for any $A \in \mathcal{B}(S_{d-1})$) (Samorodnitsky and Taqqu, 1994, p.73). For each $\alpha \in (0, 2)$, α -stable distributions on \mathbb{R}^d have the generating triplet $(0, \nu, \gamma)$ with

$$\nu(B) = \int_{S_{d-1}} \Gamma(ds) \int_0^\infty 1_B(rs) \frac{dr}{r^{1+\alpha}}, \quad B \in \mathcal{B}(\mathbb{R}^d), \quad (5)$$

where Γ is the spectral measure on S_{d-1} (Sato, 1999, Theorem 14.3, p. 77). The sum of Lévy measures $\nu_1 + \nu_2$ implies the sum of spectral measures $\Gamma_1 + \Gamma_2$.

A.2 α -Stable Distributions on \mathbb{R}

As a special case, an α -stable distribution on \mathbb{R} has the following characteristic function:

Theorem A.2 (Samorodnitsky and Taqqu, 1994, Definition 1.1.6, p. 5) *A random variable X is α -stable ($\alpha \in (0, 2]$) in \mathbb{R} if and only if the parameters satisfy the conditions $\sigma \geq 0$, $\beta \in [-1, 1]$, and $\mu \in \mathbb{R}$ such that its characteristic function has the form*

$$\hat{F}(\theta) = \begin{cases} \exp(-\sigma^\alpha |\theta|^\alpha (1 - i\beta(\operatorname{sgn}\theta) \tan(\frac{\pi}{2}) + i\mu\theta)) & (\alpha \neq 1), \\ \exp(-\sigma |\theta| (1 + i\beta \frac{\pi}{2} (\operatorname{sgn}\theta) \ln|\theta| + i\mu\theta)) & (\alpha = 1), \end{cases}$$

where $\operatorname{sgn}\theta$ is a sign function

$$\operatorname{sgn}\theta = \begin{cases} 1 & \theta > 0, \\ 0 & \theta = 0, \\ -1 & \theta < 0. \end{cases}$$

When $\alpha \in (0, 2)$, the parameters σ , β , and μ are unique. When $\alpha = 2$, β is irrelevant, and σ and μ are unique.

An α -stable distribution on \mathbb{R} is specified by the parameters (α, β, μ) , where σ is a scale parameter, β is a skewness parameter, and μ is a location parameter. $\sigma = 0$ implies a delta measure. For $\alpha \in (0, 2)$, an α -stable distribution is symmetric if and only if $\beta = \mu = 0$ (Samorodnitsky and Taqqu, 1994, Property 1.2.5, p. 11). A 2-stable distribution is symmetric if and only if $\mu = 0$. An α -stable density does not generally have a closed-form expression, except for some special cases. However, it is known that every nondegenerate stable distribution has the C^∞ pdf (Sato, 1999, Example 28.2, p. 190). Some known univariate α -stable pdfs, expressed by elementary functions and special functions, are given in Appendix A.3.

The Lévy measure ν of a univariate stable distribution is obtained by letting $d = 1$ in the Lévy measure (5). If $d = 1$, then $S_0 = \{-1, 1\}$ and $\Gamma = \Gamma(\{-1\})\delta_{-1} + \Gamma(\{1\})\delta_1$, where

$\Gamma(\{-1\}), \Gamma(\{1\}) \geq 0$ and $\Gamma(\{-1\}) + \Gamma(\{1\}) > 0$ (Samorodnitsky and Taqqu, 1994, Example 2.3.3, p. 67). By substituting this into equation (5), we can obtain the Lévy measure ν of a univariate stable distribution as

$$\nu(dx) = \Gamma(\{1\}) \frac{1}{x^{1+\alpha}} 1_{(0,\infty)}(x) dx + \Gamma(\{-1\}) \frac{1}{|x|^{1+\alpha}} 1_{(-\infty,0)}(x) dx.$$

A stable distribution $S_\alpha(\alpha, \beta, \mu)$ is given with the spectral measure as

$$\sigma = (\Gamma(\{1\}) + \Gamma(\{-1\}))^{\frac{1}{\alpha}} > 0, \quad \beta = \frac{(\Gamma(\{1\}) - \Gamma(\{-1\}))}{\Gamma(\{1\}) + \Gamma(\{-1\})} \in [-1, 1].$$

The sum of Lévy measures $\nu_1 + \nu_2$ implies the sum of mass functions $\Gamma_1(\{-1\}) + \Gamma_2(\{-1\})$ and $\Gamma_1(\{1\}) + \Gamma_2(\{1\})$. We can see the convolution property $S_\alpha(\alpha_1, \beta_1, \mu_1) * S_\alpha(\alpha_2, \beta_2, \mu_2) = S_\alpha((\sigma_1^\alpha + \sigma_2^\alpha)^{\frac{1}{\alpha}}, \frac{\sigma_1^\alpha \beta_1 + \sigma_2^\alpha \beta_2}{\sigma_1^\alpha + \sigma_2^\alpha}, \mu_1 + \mu_2)$ of the univariate stable distribution from the viewpoint of the spectral measure.

A.3 Closed-Form and Special Function Form of α -Stable PDFs on \mathbb{R}

There are three cases where the α -stable pdf on \mathbb{R} is expressed by elementary functions:

1. The 2-stable distribution $S_2(\alpha, \beta, \mu)$ is the Gaussian $N(\mu, 2\sigma^2)$, where β has no effect, with the pdf

$$f_{\text{Gauss}}(x) = \frac{1}{2\sigma\sqrt{\pi}} e^{-\frac{(x-\mu)^2}{2\sigma^2}}, \quad x \in \mathbb{R}.$$

2. The 1-stable distribution $S_1(\alpha, \beta = 0, \mu)$ is the Cauchy distribution with the pdf

$$f_{\text{Cauchy}}(x) = \frac{\sigma}{\pi((x-\mu)^2 + \sigma^2)}, \quad x \in \mathbb{R}.$$

3. The 1/2-stable distribution $S_{1/2}(\alpha, \beta = \pm 1, \mu)$ is the Lévy distribution with the pdf

$$f_{\text{Lévy}}(x) = \frac{\sqrt{\sigma}}{\sqrt{2\pi}(x-\mu)^{3/2}} e^{-\frac{\sigma(x-\mu)}{2(x-\mu)^2}}, \quad \mu < x < \infty.$$

There are some cases where the α -stable pdf is expressed by special functions. The following expression is found in Lee (2010). Note that kernel means m_P and RKHS inner products also take these expressions. For simplicity, we only show standardized stable pdfs $d_{\text{stable}}(x; \alpha, \sigma = 1, \beta, \mu = 0)$.

Fresnel integrals:

If $(\alpha, \sigma, \beta, \mu) = (1/2, 1, 0, 0)$,

$$\begin{aligned} d_{\text{stable}}(x; 1/2, 1, 0, 0) \\ = \frac{|x|^{-\frac{3}{2}}}{\sqrt{2\pi}} \left(\sin\left(\frac{1}{4|x|}\right) \left(\frac{1}{2} - S\left(\sqrt{\frac{1}{2\pi|x|}}\right) \right) + \cos\left(\frac{1}{4|x|}\right) \left(\frac{1}{2} - C\left(\sqrt{\frac{1}{2\pi|x|}}\right) \right) \right), \end{aligned}$$

where $C(z)$ and $S(z)$ are the Fresnel integrals

$$C(z) = \int_0^z \cos\left(\frac{\pi t^2}{2}\right) dt, \quad S(z) = \int_0^z \sin\left(\frac{\pi t^2}{2}\right) dt.$$

This is a symmetric stable pdf. $k(x, y) = d_{stable}(x - y; 1/2, 1, 0, 0)$, $x, y \in \mathbb{R}$, gives a characteristic p.d. kernel.

Modified Bessel function:

If $(\alpha, \sigma, \beta, \mu) = (1/3, 1, 1, 0)$, the one-sided continuous density is

$$d_{stable}(x; 1/3, 1, 1, 0) = \frac{1}{\pi} \frac{2^{3/2}}{3^{7/4}} x^{-3/2} K_{1/3}\left(\frac{2^{5/2}}{3^{9/4}} x^{-1/2}\right), \quad x \geq 0,$$

where $K_\nu(x)$ is a modified Bessel function of the third kind.

Hypergeometric function:

If $(\alpha, \sigma, \beta, \mu) = (4/3, 1, 0, 0)$,

$$d_{stable}(x; \frac{4}{3}, 1, 0, 0) = \frac{3^{5/4} \Gamma(7/12) \Gamma(11/12)}{2^{5/2} \sqrt{\pi} \Gamma(6/12) \Gamma(8/12)} {}_2F_2\left(\frac{7}{12}, \frac{11}{12}; \frac{1}{2}, \frac{1}{2}; -\frac{3^3 x^4}{2^8}\right) - \frac{3^{11/4} |x|^3 \Gamma(13/12) \Gamma(17/12)}{2^{13/2} \sqrt{\pi} \Gamma(18/12) \Gamma(15/12)} {}_2F_2\left(\frac{13}{12}, \frac{17}{12}; \frac{1}{2}, \frac{1}{2}; -\frac{3^3 x^4}{2^8}\right), \quad x \in \mathbb{R},$$

where ${}_pF_q$ is the (generalized) hypergeometric function

$${}_pF_q(a_1, \dots, a_p; b_1, \dots, b_q; z) = \sum_{n=0}^{\infty} \frac{(a_1)_n \cdots (a_p)_n z^n}{(b_1)_n \cdots (b_q)_n n!}$$

with the Pochhammer symbol $(a)_0 = 1$, $(a)_n = a(a+1)\cdots(a+n-1)$ for $n \in \mathbb{N}^+$. This is a symmetric stable pdf. $k(x, y) = d_{stable}(x - y; \frac{4}{3}, 1, 0, 0)$, $x, y \in \mathbb{R}$, gives a characteristic p.d. kernel.

If $(\alpha, \sigma, \beta, \mu) = (3/2, 1, 0, 0)$ (the Holtsmark distribution),

$$d_{stable}(x; \frac{3}{2}, 1, 0, 0) = \frac{1}{\pi} \Gamma(5/3) {}_2F_3\left(\frac{5}{12}, \frac{11}{12}; \frac{1}{3}, \frac{2}{6}; -\frac{2^2 x^6}{3^6}\right) - \frac{x^2}{3\pi} {}_3F_4\left(\frac{3}{4}, 1, \frac{5}{4}; \frac{3}{6}, \frac{5}{6}, \frac{7}{6}; -\frac{2^2 x^6}{3^6}\right) + \frac{7x^4}{3^4 \pi} \Gamma(4/3) {}_2F_3\left(\frac{13}{12}, \frac{19}{12}; \frac{7}{6}, \frac{5}{2}; -\frac{2^2 x^6}{3^6}\right), \quad x \in \mathbb{R}.$$

This is a symmetric stable pdf. The Holtsmark kernel $k(x, y) = d_{stable}(x - y; 3/2, 1, 0, 0)$, $x, y \in \mathbb{R}$, gives a characteristic p.d. kernel.

Whittaker function:

If $(\alpha, \sigma, \beta, \mu) = (2/3, 1, 0, 0)$,

$$d_{stable}(x; 2/3, 1, 0, 0) = \frac{1}{2\sqrt{3\pi} |x|} \exp\left(\frac{2}{27x^2}\right) W_{-1/2, 1/6}\left(\frac{4}{27x^2}\right), \quad x \in \mathbb{R},$$

where $W_{\lambda, \mu}(z)$ is the Whittaker function defined as

$$W_{\lambda, \mu}(z) = \frac{z^\lambda e^{-z/2}}{\Gamma(\mu - \lambda + 1/2)} \int_0^\infty e^{-t} t^{\mu - \lambda - 1/2} \left(1 + \frac{t}{z}\right)^{\mu - \lambda - 1/2} dt,$$

$$\operatorname{Re}(\mu - \lambda) > -\frac{1}{2}, |\arg(z)| < \pi.$$

This is a symmetric stable pdf. $k(x, y) = d_{stable}(x - y; 2/3, 1, 0, 0)$, $x, y \in \mathbb{R}$, gives a characteristic p.d. kernel.

If $(\alpha, \sigma, \beta, \mu) = (2/3, 1, 1, 0)$, the one-sided density is

$$d_{stable}(x; 2/3, 1, 1, 0) = \sqrt{\frac{3}{\pi}} \frac{1}{|x|} \exp\left(-\frac{16}{27|x|^2}\right) W_{1/2, 1/6}\left(\frac{32}{27|x|^2}\right), \quad x \geq 0.$$

If $(\alpha, \sigma, \beta, \mu) = (3/2, 1, 1, 0)$, the α -stable density is

$$d_{stable}(x; 2/3, 1, 1, 0) = \begin{cases} \sqrt{\frac{3}{\pi}} \frac{1}{|x|} \exp\left(\frac{x^3}{27}\right) W_{1/2, 1/6}\left(-\frac{2}{27}x^3\right), & x < 0 \\ \frac{1}{2\sqrt{3\pi}|x|} \exp\left(\frac{x^3}{27}\right) W_{-1/2, 1/6}\left(\frac{2}{27}x^3\right), & x > 0 \end{cases}$$

Lommel function:

If $(\alpha, \sigma, \beta, \mu) = (1/3, 1, 0, 0)$,

$$d_{stable}(x; 1/3, 1, 0, 0) = \operatorname{Re}\left(\frac{2 \exp(-i\pi/4)}{3\sqrt{3\pi}|x|^{3/2}} S_{0,1/3}\left(\frac{2 \exp(i\pi/4)}{3\sqrt{3}|x|^{1/2}}\right)\right).$$

Here, the Lommel functions $s_{\mu, \nu}(z)$ and $S_{\mu, \nu}(z)$ are defined by

$$s_{\mu, \nu}(z) = \frac{\pi}{2} \left(Y_\nu(z) \int_0^z z^\mu J_\nu(z) dz - J_\nu(z) \int_0^z z^\mu Y_\nu(z) dz \right),$$

$$S_{\mu, \nu}(z) = s_{\mu, \nu}(z) - \frac{2^{\mu-1} \Gamma((1+\mu+\nu)/2)}{\pi \Gamma((\nu-\mu)/2)} \left(J_\nu(z) - \cos\left(\frac{\mu-\nu}{2}\pi\right) Y_\nu(z) \right),$$

where $J_\nu(z)$ and $Y_\nu(z)$ are Bessel functions of the first and second kind, respectively. This is a symmetric stable pdf. $k(x, y) = d_{stable}(x - y; 1/3, 1, 0, 0)$, $x, y \in \mathbb{R}$, gives a characteristic p.d. kernel.

Landau distribution:

If $(\alpha, \sigma, \beta, \mu) = (1, 1, 1, 0)$ (the Landau distribution),

$$d_{stable}(x; 1, 1, 1, 0) = \frac{1}{\pi} \int_0^\infty e^{-t \log t - xt} \sin(\pi t) dt.$$

A.4 Sub-Gaussian (Elliptically Contoured) α -Stable Distributions on \mathbb{R}^d

The sub-Gaussian α -stable distribution has the following characteristic function:

Proposition A.3 (Samorodnitsky and Taqqu, 1994, Proposition 2.5.2, p. 78) *Let $\alpha \in (0, 2)$. The sub-Gaussian α -stable random vector X in \mathbb{R}^d has the characteristic function*

$$E \exp \left[i \sum_{k=1}^d \theta_k X_k \right] = \exp \left(- \left| \frac{1}{2} \sum_{i,j=1}^d \theta_i \theta_j R_{ij} \right|^{\frac{\alpha}{2}} + i(\theta, \mu^0) \right),$$

where R is a p.d. matrix and $\mu^0 \in \mathbb{R}^d$ is a shift vector.

$\alpha = 2$ and $\alpha = 1$ imply the multivariate Gaussian and Cauchy distribution, respectively.

For $\alpha \in (0, 2)$, the radial sub-Gaussian $\text{SG}_\alpha(\mathbb{R}^d)[I]$ (with identity matrix $R = I$) has the uniform spectral measure $\Gamma(B) = c|B|$, $\forall B \in \mathcal{B}(S_{d-1})$ in the Lévy measure (5) (Samorodnitsky and Taqqu, 1994, Proposition 2.5.5, p. 79), Sub-Gaussian $\text{SG}_\alpha(\mathbb{R}^d)[R]$ with a p.d. matrix R is the elliptical version of the radial sub-Gaussians. Its spectral measure is given in Samorodnitsky and Taqqu (1994, Proposition 2.5.8, p. 82).

Appendix B. GH Classes on \mathbb{R}^d

A GH distribution on \mathbb{R}^d is given by the normal mean-variance mixture with the GIG mixing distribution. See, e.g., v. Hammerstein (2010) for more information. We here reproduce some of them.

B.1 GIG Distributions on \mathbb{R}^+

A generalized inverse Gaussian (GIG) distribution $GIG(\lambda, \delta, \gamma)$ on \mathbb{R}^+ is given by the following pdf:

$$d_{GIG(\lambda, \delta, \gamma)}(x) = \left(\frac{\gamma}{\delta}\right)^\lambda \frac{1}{2K_\lambda(\delta\gamma)} x^{\lambda-1} \exp\left(-\frac{1}{2}\left(\frac{\delta^2}{x} + \gamma^2 x\right)\right) 1_{(0, \infty)}(x),$$

where $K_\lambda(x)$ is the modified Bessel function of the third kind with index λ . The parameters $(\lambda, \delta, \gamma)$ take the following values:

$$\begin{cases} \delta \geq 0, \gamma > 0, & \text{if } \lambda > 0, \\ \delta > 0, \gamma > 0, & \text{if } \lambda = 0, \\ \delta > 0, \gamma \geq 0, & \text{if } \lambda < 0, \end{cases}$$

where $\delta = 0$ and $\gamma = 0$ correspond to limiting cases,¹¹ which are the Gamma distribution and the inverse Gamma distribution, respectively. The GIG distributions have the following convolution properties:

Proposition B.1 (v. Hammerstein, 2010, Proposition 1.11, p. 11) *Within the class of GIG distributions, the following convolution properties hold:*

- $GIG(-\frac{1}{2}, \delta_1, \gamma) * GIG(-\frac{1}{2}, \delta_2, \gamma) = GIG(-\frac{1}{2}, \delta_1 + \delta_2, \gamma)$,
 - $GIG(-\frac{1}{2}, \delta_1, \gamma) * GIG(\frac{1}{2}, \delta_2, \gamma) = GIG(\frac{1}{2}, \delta_1 + \delta_2, \gamma)$,
 - $GIG(-\lambda, \delta, \gamma) * GIG(\lambda, 0, \gamma) = GIG(\lambda, \delta, \gamma)$, $\lambda > 0$,
 - $GIG(\lambda_1, 0, \gamma) * GIG(\lambda_2, 0, \gamma) = GIG(\lambda_1 + \lambda_2, 0, \gamma)$, $\lambda_1, \lambda_2 > 0$.
11. If $\lambda \neq 0$, then $K_\lambda(x) \sim \frac{1}{2}\Gamma(\lambda)(\frac{x}{2})^{-\lambda}$ ($x \downarrow 0$).

B.2 GH Distributions on \mathbb{R}^d

A GH distribution has the following pdf:

$$d_{GH_d(\lambda, \alpha, \beta, \delta, \mu, \Delta)}(x) = a(\lambda, \alpha, \beta, \delta, \mu, \Delta) \left(\sqrt{\delta^2 + \|x - \mu\|_{\Delta}^2} \right)^{\lambda - \frac{d}{2}} K_{\lambda - \frac{d}{2}} \left(\alpha \sqrt{\delta^2 + \|x - \mu\|_{\Delta}^2} \right) e^{(\beta, x - \mu)},$$

where $a(\lambda, \alpha, \beta, \delta, \mu, \Delta)$ is the normalization constant:

$$a(\lambda, \alpha, \beta, \delta, \mu, \Delta) = \frac{(\alpha^2 - \|\beta\|_{\Delta}^2)^{\lambda \nu/2}}{(2\pi)^{d/2} |\Delta|^{\frac{1}{2}} \alpha^{\lambda - d/2} \delta^{\lambda} K_{\lambda}(\delta \sqrt{\alpha^2 - \|\beta\|_{\Delta}^2})}.$$

The GH parameters $(\lambda, \alpha, \beta, \delta, \mu, \Delta)$ take the following values:

$$\begin{aligned} \lambda &\in \mathbb{R}, \quad \alpha, \delta \in \mathbb{R}_+, \quad \beta, \mu \in \mathbb{R}^d, \quad \Delta \in \mathbb{P}_d, \\ \delta &\geq 0, 0 \leq \|\beta\|_{\Delta} < \alpha, & \text{if } \lambda > 0, \\ \delta &> 0, 0 \leq \|\beta\|_{\Delta} < \alpha, & \text{if } \lambda = 0, \\ \delta &> 0, 0 \leq \|\beta\|_{\Delta} \leq \alpha, & \text{if } \lambda < 0, \end{aligned}$$

where $\delta = 0$ or $\alpha = \|\beta\|_{\Delta}$ is a limiting case. The GH distribution is symmetric if and only if $\beta = \mathbf{0}$ and $\mu = 0$. The symmetric GH has the following elliptical pdf:

$$d_{SGH_d(\lambda, \alpha, \delta, \Delta)}(x) = \frac{\alpha^{\frac{d}{2}}}{(2\pi)^{\frac{d}{2}} |\Delta|^{\frac{1}{2}} \delta^{\lambda} K_{\lambda}(\delta \alpha)} \left(\sqrt{\delta^2 + \|x\|_{\Delta}^2} \right)^{\lambda - \frac{d}{2}} K_{\lambda - \frac{d}{2}} \left(\alpha \sqrt{\delta^2 + \|x\|_{\Delta}^2} \right),$$

where $\nu(t)$ in equation (2) is given by a GIG distribution.

B.3 NIG Distributions on \mathbb{R}^d

The NIG distribution $NIG_d(\alpha, \beta, \delta, \mu, \Delta)$ has the following pdf (v. Hammerstein, 2010, p.74):

$$d_{NIG_d(\alpha, \beta, \delta, \mu, \Delta)}(x) \propto \left(\sqrt{\delta^2 + \|x - \mu\|_{\Delta}^2} \right)^{-\frac{d+1}{2}} K_{\frac{d+1}{2}} \left(\alpha \sqrt{\delta^2 + \|x - \mu\|_{\Delta}^2} \right) e^{(\beta, x - \mu)}.$$

B.4 VG Distributions on \mathbb{R}^d

The VG distribution $VG_d(\lambda, \alpha, \beta, \mu, \Delta)$ has the following pdf (v. Hammerstein, 2010, p.74):¹²

$$d_{VG_d(\lambda, \alpha, \beta, \mu, \Delta)}(x) \propto \|x - \mu\|_{\Delta}^{-\lambda} \lambda^{-\frac{\lambda}{2}} K_{\lambda - \frac{\lambda}{2}}(\alpha \|x - \mu\|_{\Delta}^{-1}) e^{(\beta, x - \mu)}.$$

Abstract

This paper establishes the consistency of a family of graph-cut-based algorithms for clustering of data clouds. We consider point clouds obtained as samples of a ground-truth measure. We investigate approaches to clustering based on minimizing objective functionals defined on proximity graphs of the given sample. Our focus is on functionals based on graph cuts like the Cheeger and ratio cuts. We show that minimizers of these cuts converge as the sample size increases to a minimizer of a corresponding continuum cut (which partitions the ground truth measure). Moreover, we obtain sharp conditions on how the connectivity radius can be scaled with respect to the number of sample points for the consistency to hold. We provide results for two-way and for multiway cuts. Furthermore we provide numerical experiments that illustrate the results and explore the optimality of scaling in dimension two.

Keywords: data clustering, balanced cut, consistency, graph partitioning

1. Introduction

Partitioning data clouds in meaningful clusters is one of the fundamental tasks in data analysis and machine learning. A large class of the approaches, relevant to high-dimensional data, relies on creating a graph out of the data cloud by connecting nearby points. This allows one to leverage the geometry of the data set and obtain high quality clustering. Many of the graph-clustering approaches are based on optimizing an objective function

which measures the quality of the partition. The basic desire to obtain clusters which are well separated leads to the introduction of objective functionals which penalize the size of cuts between clusters. The desire to have clusters of meaningful size and for the approaches to be robust to outliers lead to the introduction of "balance" terms and objective functionals such as Cheeger cut and closely related edge expansion (Arora et al., 2009; Bresson and Laurent, 2012; Bresson et al., 2012; Kannan et al., 2004; Szlam and Bresson, 2010), ratio cut (Hagen and Kahng, 1992; Hein and Setzer, 2011; von Luxburg, 2007; Wei and Cheng, 1989), normalized cut (Arias-Castro et al., 2012; Shi and Malik, 2000; von Luxburg, 2007), and conductance (sparsest cut) (Arora et al., 2009; Kannan et al., 2004; Spielman and Teng, 2004). Such functionals have been extended by Bresson et al. (2013); Yu and Shi (2003) to treat multiclass partitioning. The balanced cuts above have been widely studied theoretically and used computationally. The algorithms of Andersen et al. (2006); Spielman and Teng (2004, 2013) use local clustering algorithms to compute balanced cuts of large graphs. Total variation based algorithms (Bresson et al., 2012, 2013; Hein and Bühler, 2010; Hein and Setzer, 2011; Szlam and Bresson, 2010) are also used to optimize either the conductance or the edge expansion of a graph. Closely related are the spectral approaches to clustering (Shi and Malik, 2000; von Luxburg, 2007) which can be seen as a relaxation of the normalized cuts.

In this paper we consider data clouds, $X_n = \{\mathbf{x}_1, \dots, \mathbf{x}_n\}$, which have been obtained as i.i.d. samples of a measure ν with density ρ on a bounded domain D . The measure ν represents the ground truth that X_n is a sample of. In the large sample limit, $n \rightarrow \infty$, clustering methods should exhibit *consistency*. That is, the clustering of the data X_n should converge as $n \rightarrow \infty$ towards a specific clustering of the underlying ground-truth domain. In this paper we characterize in a precise manner when and how the minimizers of a ratio, Cheeger, sparsest, and normalized graph cuts, converge towards a suitable partition of the domain. We define the discrete and continuum objective functionals considered in Subsections 1.1 and 1.2 respectively, and informally state our result in Subsection 1.3.

An important consideration when investigating consistency of algorithms is how graphs on X_n are constructed. In simple terms, when building a graph on X_n , one sets a length scale ε_n such that edges between vertices in X_n are given significant weights if the distance of points they connect is ε_n or less. In some way this sets the length scale over which the geometric information is averaged when setting up the graph. Taking smaller ε_n is desirable because it is computationally less expensive and gives better resolution, but there is a price. Taking ε_n small increases the error due to randomness and in fact, if ε_n is too small, the resulting graph may not represent the geometry of D well, and consequently the discrete graph cut may be very far from the desired one. In our work we determine precisely how small ε_n can be taken for the consistency to hold. We obtain consistency results both for two-way and multi-way cuts.

To prove our results we use the variational notion of convergence known as the Γ -convergence. It is one of the standard tools of modern applied analysis that allows one to consider a limit of a family of variational problems (Braides, 2002; Dal Maso, 1993). In the recent work of García Trillos and Slepčev (2016), this notion was developed in the random discrete setting designed for the study of consistency of minimization problems on random point clouds. In particular the proof of Γ -convergence of total variation on graphs proved there, provides the technical backbone of this paper. The approach we take is general and

flexible and we believe suitable for the study of many problems involving large sample limits of minimization problems on graphs.

Background on consistency of clustering algorithms and related problems.

Consistency of clustering algorithms has been considered for a number of approaches. Pol-land (1981) has proved the consistency of k -means clustering.

Consistency of k -means clustering for paths with regularization was recently studied by Thorpe et al. (2015), using a similar viewpoint to those of this paper. Consistency for a class of single linkage clustering algorithms was shown by Hartigan (1981). Arias-Castro and Pelletier (2013) have proved the consistency of low-dimensional embeddings via the maximum variance unfolding. Consistency of spectral clustering was rigorously considered by von Luxburg, Belkin, and Bousquet (2004, 2008). These works show the convergence of all eigenfunctions of the graph Laplacian for fixed length scale $\epsilon_n = \epsilon$ which results in the limiting (as $n \rightarrow \infty$) continuum problem being a nonlocal one. Belkin and Niyogi (2006) consider the spectral problem (Laplacian eigenmaps) and show that there exists a sequence $\epsilon_n \rightarrow 0$ such that in the limit the (manifold) Laplacian is recovered, however no rate at which ϵ_n can go to zero is provided. Consistency of normalized cuts was considered by Arias-Castro, Pelletier, and Pudlo (2012) who provide a rate on $\epsilon_n \rightarrow 0$ under which the minimizers of the discrete cut functionals minimized over a specific family of subsets of X_n converge to the continuum Cheeger set. Our work improves on (Arias-Castro et al., 2012) in several ways. We minimize the discrete functionals over all discrete partitions on X_n as it is considered in practice and prove the result for the optimal, in terms of scaling, range of rates at which ϵ_n can go to zero as $n \rightarrow \infty$ for consistency to hold.

There are also a number of works which investigate how well the discrete functionals approximate the continuum ones for a particular function. Among them are works by Belkin and Niyogi (2008), Giné and Koltchinskii (2006), Hein, Audibert, and Von Luxburg (2005), Narayanan, Belkin, and Niyogi (2006), Singer (2006) and Ting, Huang, and Jordan (2010). Maier, von Luxburg, and Hein (2013) considered pointwise convergence for Cheeger and normalized cuts, both for the geometric and kNN graphs and obtained a range of scalings of graph construction on n for the convergence to hold. While these results are quite valuable, we point out that they do not imply that the minimizers of discrete objective functionals are close to minimizers of continuum functionals.

A notion of convergence suitable for showing the convergence of minimizers of approximating objective functionals converge towards a minimizer of the limit functional is the notion of Γ -convergence, which was introduced by De Giorgi in the 70's and represents a standard notion of variational convergence. For detailed exposition of the properties of Γ -convergence see the books by Braides (2002) and Dal Maso (1993). Particularly relevant to our investigation are works considering nonlocal functionals converging to the perimeter or to total variation which include works by Alberti and Bellotti (1998), Savin and Valdinoci (2012), and Esedoğlu and Otto (2015). Also related are works of Ponce (2004), who showed the Γ -convergence of nonlocal functionals related to characterization of Sobolev spaces and of Gobbino (1998) and Gobbino and Mora (2001) who investigated nonlocal approximations of the Mumford-Shah functional. In the discrete deterministic setting, works related to the Γ -convergence of functionals to continuous functionals involving perimeter include works of

Braides and Yip (2012), Chambolle, Giacomini, and Lussardi (2010), and van Gennip and Bertozzi (2012).

1.1 Graph partitioning

The balanced cut objective functionals we consider are relevant to general graphs (not just the ones obtained from point clouds). We introduce them here.

Given a weighted graph $G = (X, W)$ with vertex set $X = \{x_1, \dots, x_n\}$ and weight matrix $W = \{w_{ij}\}_{1 \leq i, j \leq n}$, the balanced graph cut problems we consider take the form

$$\text{Minimize } \frac{\text{Cut}(Y, Y^c)}{\text{Bal}(Y, Y^c)} := \frac{\sum_{x \in Y} \sum_{x' \in Y^c} w_{ij}}{\text{Bal}(Y, Y^c)} \quad \text{over all nonempty } Y \subsetneq X. \quad (1.1)$$

That is, we consider the class of problems with $\text{Cut}(Y, Y^c)$ as the numerator together with different balance terms. For $Y \subset X$ let $|Y|$ be the ratio between the number of vertices in Y and the number of vertices in X , that is $|Y| = \frac{|X|}{n}$. Well-known balance terms include

$$\text{Bal}_R(Y, Y^c) = 2|Y||Y^c| \quad \text{and} \quad \text{Bal}_C(Y, Y^c) = \min(|Y|, |Y^c|), \quad (1.2)$$

which correspond to ratio cut (Hagen and Kalmg, 1992; Hein and Setzer, 2011; von Luxburg, 2007; Wei and Cheng, 1989) and Cheeger cut (Arya et al., 2009; Cheeger, 1970; Chung, 1997; Kannan et al., 2004) respectively¹, as well as

$$\text{Bal}_S(Y, Y^c) = 2 \frac{\deg(Y) \deg(Y^c)}{\deg(X)^2} \quad \text{and} \quad \text{Bal}_N(Y, Y^c) = \frac{\min(\deg(Y), \deg(Y^c))}{\deg(X)}, \quad (1.3)$$

where $\deg(Y) = \sum_{i=1}^n \sum_{j \neq i} w_{ij}$ is the sum of weighted degrees of all vertices in Y , which correspond to sparsest cut (Arya et al., 2009; Kannan et al., 2004; Spielman and Teng, 2004) and normalized cut (Arias-Castro et al., 2012; Shi and Malik, 2000; von Luxburg, 2007) respectively. We refer to a pair $\{Y, Y^c\}$ that solves (1.1) as an *optimal balanced cut of the graph*. Note that a given graph $G = (X, W)$ may have several optimal balanced cuts (although one expects that generically the optimal cut is unique, since a small perturbation of the weights of a graph with a non-unique minimal balanced cut, is almost sure to lead to only one of them having the least energy).

We are also interested in multi-class balanced cuts. Specifically, in order to partition the set X into $R \geq 3$ clusters, we consider the following ratio cut functional:

$$\text{Minimize } \sum_{r=1}^R \frac{\text{Cut}(Y_r, Y_r^c)}{|Y_r|}, \quad Y_r \cap Y_s = \emptyset \quad \text{if } r \neq s, \quad \bigcup_{r=1}^R Y_r = X. \quad (1.4)$$

1.2 Continuum partitioning

Given a bounded and connected open domain $D \subset \mathbb{R}^d$ and a probability measure ν on D , with positive density $\rho > 0$, we define the class of balanced domain cut problems in an analogous way. A balanced domain-cut problem takes the form

$$\text{Minimize } \frac{\text{Cut}_\rho(A, A^c)}{\text{Bal}_\rho(A, A^c)}, \quad A \subset D \quad \text{with } 0 < \nu(A) < 1. \quad (1.5)$$

¹ The factor of 2 in the definition of $\text{Bal}_R(Y, Y^c)$ is introduced to simplify the computations in the remainder. We remark that when using Bal_R problem (1.1) is equivalent to the usual ratio cut problem.

where $A^c = D \setminus A$. Just as the graph cut term $\text{Cut}(Y, Y^c)$ in (1.1) provides a weighted (by W) measure of the boundary between Y and Y^c , the cut term $\text{Cut}_\rho(A, A^c)$ for a domain denotes a ρ^2 -weighted area of the boundary between the sets A and A^c . Assuming that $\partial_D A := \partial A \cap D$ (the boundary between A and A^c) is a smooth curve (in 2d), surface (in 3d) or manifold (in 4d+), we can define

$$\text{Cut}_\rho(A, A^c) := \int_{\partial_D A} \rho^2(x) \, dS(x). \quad (1.6)$$

We only consider cuts with weight ρ^2 , since they appear as the limit of the discrete cuts we consider in this paper, as indicated in subsection 1.3.

For our results and analysis we need the notion of continuum cut which is defined for sets with less regular boundary. We present the required notions of geometric measure theory and the rigorous and mathematically precise formulation of problem (1.5) in Subsection 3.1.

If $\rho(x) = 1$ then $\text{Cut}_\rho(A, A^c)$ simply corresponds to arc-length (in 2d) or surface area (in 3d). In the general case, the presence of $\rho^2(x)$ in (1.6) indicates that the regions of low density are easier to cut, so $\partial_D A$ has a tendency to pass through regions in D of low density. As in the graph case, we consider balance terms

$$\text{Bal}_\rho(A, A^c) = 2|A| |A^c| \quad \text{and} \quad \text{Bal}_\rho(A, A^c) = \min(|A|, |A^c|), \quad (1.7)$$

which correspond to weighted continuous equivalents of the ratio cut and the Cheeger cut. In the continuum setting $|A|$ stands for the total ν -content of the set A , that is,

$$|A| = \nu(A) = \int_A \rho(x) \, dx. \quad (1.8)$$

We also consider balance terms

$$\text{Bal}_\rho(A, A^c) = 2|A|_{\rho^2} |A^c|_{\rho^2} \quad \text{and} \quad \text{Bal}_\rho(A, A^c) = \min(|A|_{\rho^2}, |A^c|_{\rho^2}), \quad (1.9)$$

which correspond to weighted continuous equivalents of the sparsest cut and the normalized cut. Here $|A|_{\rho^2}$ stands for

$$|A|_{\rho^2} = \frac{1}{\int_D \rho^2(x) \, dx} \int_A \rho^2(x) \, dx. \quad (1.10)$$

We refer to a pair $\{A, A^c\}$ that solves (1.5) as an *optimal balanced cut of the domain*.

The continuum equivalent of the multiway cut problem (1.4) reads

$$\underset{(A_1, \dots, A_R)}{\text{Minimize}} \sum_{r=1}^R \frac{\text{Cut}_\rho(A_r, A_r^c)}{|A_r|}, \quad (1.11)$$

where (A_1, \dots, A_R) is an R -tuple of measurable subsets of D such that $\nu(A_r \cap A_s) = 0$ if $r \neq s$, and $\nu\left(D \setminus \bigcup_{r=1}^R A_r\right) = 0$.

1.3 Consistency of partitioning of data clouds

Let $\mathbf{x}_1, \dots, \mathbf{x}_n, \dots$ be a sequence of i.i.d random points drawn from an underlying ground-truth measure ν . Throughout the paper ν is a probability measure supported on a bounded, open set with Lipschitz boundary D . Furthermore we assume that ν has continuous density $\rho : D \rightarrow \mathbb{R}$ and that $0 < \lambda \leq \rho \leq \Lambda$ on D ; in other words, ρ is bounded below and above by positive constants. We denote by $X_n = \{\mathbf{x}_1, \dots, \mathbf{x}_n\}$, the set consisting of the first n data points.
