But we have seen earlier that the maximum additional payoff increase that one can obtain from future periods as a result of showing the ad with uncertain eCPM in the first period is no greater than $\frac{\delta \bar{f}}{2(1-\delta)} \frac{\gamma^4 \omega^4}{1-\omega}$. Thus we know that $\Delta V \leq \frac{\delta \bar{f}}{2(1-\delta)} \frac{\gamma^4 \omega^4}{1-\omega}$. By combining this with the result in the previous paragraph, we see that the difference between the maximum possible payoff the auctioneer could obtain under the theoretically optimal strategy and the auctioneer's payoff from the greedy strategy is no greater than $\frac{\delta^2 \gamma^4 \omega^4 \bar{f}^3}{8(1-\delta)^3 (1-\omega)^2}$. ■

Abstract

In this paper we introduce, in the setting of machine learning, a generalization of wavelet analysis which is a popular approach to low dimensional structured signal analysis. The wavelet decomposition of a Random Forest provides a sparse approximation of any regression or classification high dimensional function at various levels of detail, with a concrete ordering of the Random Forest nodes: from ‘significant’ elements to nodes capturing only ‘insignificant’ noise. Motivated by function space theory, we use the wavelet decomposition to compute numerically a ‘weak-type’ smoothness index that captures the complexity of the underlying function. As we show through extensive experimentation, this sparse representation facilitates a variety of applications such as improved regression for difficult datasets, a novel approach to feature importance, resilience to noisy or irrelevant features, compression of ensembles, etc.

Keywords: Random Forest, Wavelets, Besov spaces, adaptive approximation, feature importance.

1. Introduction

Our work brings together Function Space theory, Harmonic Analysis and Machine Learning for the analysis of high dimensional big data. In the field of (low-dimensional) signal processing, there is a complete theory that models structured datasets (e.g. audio, images, video) as functions in certain Besov spaces (DeVore 1998), (DeVore et al. 1992). When representing the signal using time-frequency localized dictionaries, this theory characterizes

the performance of adaptive approximation and is used in a variety of applications, such as denoising, compression, feature extraction, etc. using very simple algorithms.

The first contribution of this work is a construction of wavelet decomposition of Random Forests (Breiman 2001), (Biau and Scornet 2016), (Denil et al. 2014). Wavelets (Daubechies 1992), (Mallat 2009) and geometric wavelets (Dekel and Leviatan 2005), (Alani et al. 2007), (Dekel and Gershtansky 2012), are a powerful yet simple tool for constructing sparse representations of ‘complex’ functions. The Random Forest (RF) (Biau and Scornet 2016), (Criminisi et al. 2011), (Hastie et al. 2009) introduced by Breiman (Breiman 2001), (Breiman 1996), is a very effective machine learning method that can be considered as a way to overcome the ‘greedy’ nature and high variance of a single decision tree. When combined, the wavelet decomposition of the RF unravels the sparsity of the underlying function and establishes an order of the RF nodes from ‘important’ components to ‘negligible’ noise. Therefore, the method provides a better understanding of any constructed RF. This helps to avoid over-fitting in certain scenarios (e.g. small number of trees), to remove noise or provide compression. Our approach could also be considered as an alternative method for pruning of ensembles (Chen et al. 2009), (Kulkarni and Sinha 2012), (Yang et al. 2012), (Joly et al. 2012) where the most important decision nodes of a huge and complex ensemble of models can be quickly and efficiently extracted. Thus, instead of controlling complexity by restricting trees’ depth or node size, one controls complexity through adaptive wavelet approximation.

Our second contribution is to generalize the function space characterization of adaptive algorithms (DeVore 1998), (DeVore and Lorentz 1993), to a typical machine learning setup. Using the wavelet decomposition of a RF, we can actually numerically compute a ‘weak-type’ smoothness index of the underlying regression or classification function overcoming noise. We prove the first part of the characterization and demonstrate, using several examples, the correspondence between the smoothness of the underlying function and properties such as compression.

Applying a ‘wavelet-type’ machinery for learning tasks, using ‘Treelets’, was introduced by (Lee et al. 2008). Treelets provide a decomposition of the domain into localized basis functions that enable a sparse representation of smooth signals. This method performs a bottom-up construction in the feature space, where at each step, a local PCA among two correlated variables generates a new node in a tree. Our method is different, since for supervised learning tasks, the response variable should be used during the construction of the adaptive representation. Also, our work significantly improves upon the ‘wavelet-type’ construction of (Gavish et al. 2010). First, since our wavelet decomposition is built on the solid foundations of RFs, it leverages on the well-known fact that over-complete representations/ensembles outperform the critical sampled representations/single decision trees

in problems such as regression, estimation, etc. Secondly, from the theoretical perspective, the Lipschitz space analysis of (Gavish et. al. 2010) is generalized by our Besov space analysis, which is the right mathematical setup for adaptive approximation using wavelets.

The paper is organized as follows: In Section 2 we review Random Forests. In Section 3 we present our main wavelet construction and list some of its key properties. In section 4 we present some theoretical aspects of function space theory and its connection to sparsity. This characterization quantifies the sparsity of the data with respect to the response variable. In Section 5 we review how a novel form of Variable Importance (VI) is computed using our approach. Section 6 provides extensive experimental results that demonstrate the applicative added value of our method in terms of regression, classification, compression and variable importance quantification.

2. Overview of Random Forests

We begin with an overview of single trees. In statistics and machine learning (Breiman et. al. 1984), (Alpaydm 2004), (Bian and Scornet 2016), (Denil et. al. 2014), (Hastie et. al. 2009) the construction is called a Decision Tree or the Classification and Regression Tree (CART) while in image processing and computer graphics (Radha et. al. 1996), (Salembier and Garrido 2000) it is coined as the Binary Space Partition (BSP) tree. We are given a real-valued function $f \in L_2(\Omega_0)$ or a discrete dataset $\{x_i \in \Omega_0, f(x_i)\}_{i \in I}$ in some convex bounded domain $\Omega_0 \subset \mathbb{R}^n$. The goal is to find an efficient representation of the underlying function, overcoming the complexity, geometry and possibly non-smooth nature of the function values. To this end, we subdivide the initial domain Ω_0 into two subdomains, e.g. by intersecting it with a hyper-plane. The subdivision is performed to minimize a given cost function. This subdivision process then continues recursively on the subdomains until some stopping criterion is met, which in turn, determines the leaves of the tree. We now describe one instance of the cost function which is related to minimizing variance. At each stage of the subdivision process, at a certain node of the tree, the algorithm finds, for the convex domain $\Omega \subset \mathbb{R}^n$ associated with the node:

- (i) A partition by a hyper-plane into two convex subdomains Ω', Ω'' (see Figure 1),
- (ii) Two multivariate polynomials $Q_{\Omega'}, Q_{\Omega''} \in \Pi_{r-1}(\mathbb{R}^n)$, of fixed (typically low) total degree $r - 1$.

The subdomains and the polynomials are chosen to minimize the following quantity

$$\|f - Q_{\Omega'}\|_{L_p(\Omega')}^p + \|f - Q_{\Omega''}\|_{L_p(\Omega'')}^p, \quad \Omega' \cup \Omega'' = \Omega. \quad (1)$$

Here, for $1 \leq p < \infty$, we used the definition

$$\|g\|_{L_p(\Omega)} := \left(\int_{\Omega} |g(x)|^p dx \right)^{1/p},$$

If the dataset is discrete, consisting of feature vectors $x_i \in \mathbb{R}^n, i \in I$, with response values $f(x_i)$, then a discrete functional is minimized

$$\sum_{x_i \in \Omega'} |f(x_i) - Q_{\Omega'}(x_i)|^p + \sum_{x_i \in \Omega''} |f(x_i) - Q_{\Omega''}(x_i)|^p, \quad \Omega' \cup \Omega'' = \Omega. \quad (2)$$

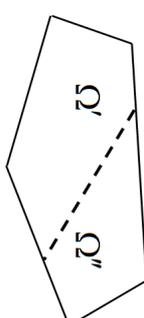

Figure 1: Illustration of a subdivision by an hyperplane of a parent domain Ω into two children Ω', Ω'' .

Observe that for any given subdividing hyperplane, the approximating polynomials in (2) can be uniquely determined for $p = 2$ by least square minimization (see (Avery)) for a survey of local polynomial regression). For the order $r = 1$, the approximating polynomials are nothing but the mean of the function values over each of the subdomains

$$Q_{\Omega'}(x) = C_{\Omega'} = \frac{1}{\#\{x_i \in \Omega'\}} \sum_{x_i \in \Omega'} f(x_i), \quad Q_{\Omega''}(x) = C_{\Omega''} = \frac{1}{\#\{x_i \in \Omega''\}} \sum_{x_i \in \Omega''} f(x_i). \quad (3)$$

In many applications of decision trees, the high-dimensionality of the data does not allow to search through all possible subdivisions. As in our experimental results, one may restrict the subdivisions to the class of hyperplanes aligned with the main axes. In contrast, there are cases where one would like to consider more advanced form of subdivisions, where they take certain hyper-surface form, such as conic-sections. Our paradigm of wavelet decompositions can support in principle all of these forms.

Random Forest (RF) is a popular machine learning tool that collects decision trees into an ensemble model (Breiman 2001), (Bernard et. al 2012), (Bian 2012), (Bian and Scornet 2016). The trees are constructed independently in a diverse fashion and prediction is done by a voting mechanism among all trees. A key element (Breiman 2001), is that large diversity between the trees reduces the ensemble's variance. There are many RFs variations

that differ in the way randomness is injected into the model, e.g bagging, random feature subset selection and the partition criterion (Boulesteix et. al. 2012), (Criminisi et. al. 2011), (Hastie et. al. 2009). Our wavelet decomposition paradigm is applicable to most of the RF versions known from the literature.

Bagging (Breiman 1996) is a method that produces partial replicates of the training data for each tree. A typical approach is to randomly select for each tree a certain percentage of the training set (e.g. 80%) or to randomly select samples with repetitions (Hastie et. al. 2009). From an approximation theoretical perspective, this form of RF allows to create an over-complete representation (Christensen 2002) of the underlying function that overcomes the ‘greedy’ nature of a single tree .

Additional methods to inject randomness can be achieved at the node partitioning level. For each node, we may restrict the partition criteria to a small random subset of the parameter values (hyper-parameter). A typical selection is to search for a partition from a random subset of \sqrt{n} features (Breiman 2001). This technique is also useful for reducing the amount of computations when searching the appropriate partition for each node. Bagging and random feature selections are not mutually exclusive and could be used together.

For $j = 1, \dots, J$, one creates a decision tree \mathcal{T}_j , based on a subset of the data, X^j . One then provides a weight (score) w_j to the tree \mathcal{T}_j , based on the estimated performance of the tree. In the supervised learning, one typically uses the remaining data points $x_i \notin X^j$ to evaluate the performance of \mathcal{T}_j . We note that for any point $x \in \Omega_0$, the approximation associated with the j^{th} tree, denoted by $\tilde{f}_j(x)$, is computed by finding the leaf $\Omega \in \mathcal{T}_j$ in which x is contained and then evaluating $\tilde{f}_j(x_i) := Q_\Omega(x)$, where Q_Ω is the corresponding polynomial associated with the decision node Ω . One then assigns a weight $w_j > 0$ to each tree \mathcal{T}_j , such that $\sum_{j=1}^J w_j = 1$. For simplicity, we will mostly consider in this paper the choice of uniform weights $w_j = 1/J$. One then assigns a value to any point $x \in \Omega_0$ by

$$\tilde{f}(x) = \sum_{j=1}^J w_j \tilde{f}_j(x).$$

Typically, in classification problems, the response variables does not have a numeric value, but rather are labeled by one of L classes. In this scenario, each input training point $x_i \in \mathbb{R}^n$ is assigned with a class $Cl(x_i)$. To convert the problem to the ‘functional’ setting described above one assigns to each class Cl the value of a node on the regular simplex consisting of L vertices in \mathbb{R}^{L-1} (all with equal pairwise distances). Thus, we may assume that the input data is in the form

$$\{x_i, Cl(x_i)\}_{i \in I} \in (\mathbb{R}^n, \mathbb{R}^{L-1}).$$

In this case, if we choose approximation using constants ($r = 1$), then the calculated mean over any subdomain Ω is in fact a point $\tilde{E}_\Omega \in \mathbb{R}^{L-1}$, inside the simplex. Obviously, any value inside the multidimensional simplex, can be mapped back to a class, along with an estimated certainty level, by calculating the closest vertex of the simplex to it. As will become obvious, these mappings can be applied to any wavelet approximation of functions receiving multidimensional values in the simplex.

3. Wavelet decomposition of a random forest

In some applications, there is a need to understand which nodes of a forest encapsulate more information than the others. Furthermore, in the presence of noise, one popular approach is to limit the levels of the tree, so as not to over-fit and contaminate the decisions by noise. Following the classic paradigm of nonlinear approximation using wavelets (Daubechies 1992), (DeVore 1998), (Mallat 2009) and the geometric function space theory presented in (Dekel and Leviatan 2005), (Karaivanov and Petrushev 2003), we present a construction of a wavelet decomposition of a forest. Some aspects of the theoretical justification for the construction are covered in the next section. Let Ω' be a child of Ω in a tree \mathcal{T} , i.e. $\Omega' \subset \Omega$ and Ω' was created by a partition of Ω as in Figure 1. Denote by $\mathbf{1}_{\Omega'}$, the indicator function over the child domain Ω' , i.e. $\mathbf{1}_{\Omega'}(x) = 1$, if $x \in \Omega'$ and $\mathbf{1}_{\Omega'}(x) = 0$, if $x \notin \Omega'$. We use the polynomial approximations $Q_{\Omega'}, Q_\Omega \in \Pi_{r-1}(\mathbb{R}^n)$, computed by the local minimization (1) and define

$$\psi_{\Omega'} := \psi_{\Omega'}(f) := \mathbf{1}_{\Omega'}(Q_{\Omega'} - Q_\Omega), \quad (4)$$

as the **geometric wavelet** associated with the subdomain Ω' and the function f , or the given discrete dataset $\{x_i, f(x_i)\}_{i \in I}$. Each wavelet $\psi_{\Omega'}$, is a ‘local difference’ component that belongs to the detail space between two levels in the tree, a ‘low resolution’ level associated with Ω and a ‘high resolution’ level associated with Ω' . Also, the wavelets (4) have the ‘zero moments’ property, i.e., if the response variable is sampled from a polynomial of degree $r-1$ over Ω , then our local scheme will compute $Q_{\Omega'}(x) = Q_\Omega(x) = f(x)$, $\forall x \in \Omega$, and therefore $\psi_{\Omega'} = 0$.

Under certain mild conditions on the tree \mathcal{T} and the function f , we have by the nature of the wavelets, the ‘telescopic’ sum of differences

$$f = \sum_{\Omega \in \mathcal{T}} \psi_\Omega, \quad \psi_{\Omega_0} := Q_{\Omega_0}. \quad (5)$$

For example, (5) holds in L_p -sense, $1 \leq p < \infty$, if $f \in L_p(\Omega_0)$ and for any $x \in \Omega_0$ and series of domains $\Omega_l \in \mathcal{T}$, each on a level l with $x \in \Omega_l$, we have that $\lim_{l \rightarrow \infty} \text{diam}(\Omega_l) = 0$.

In the setting of a real-valued function, the norm of a wavelet is computed by

$$\|\psi_{\Omega'}\|_2^2 = \int_{\Omega'} (Q_{\Omega'}(x) - Q_{\Omega}(x))^2 dx,$$

and in the discrete case by,

$$\|\psi_{\Omega'}\|_2^2 = \sum_{x_i \in \Omega'} |Q_{\Omega'}(x_i) - Q_{\Omega}(x_i)|^2, \quad (6)$$

where Ω' is a child of Ω .

Observe that for $r = 1$, the subdivision process for partitioning a node by minimizing (1) is equivalent to maximizing the sum of squared norms of the wavelets that are formed in that partition

Lemma 1 For any partition $\Omega = \Omega' \cup \Omega''$ denote

$$V_{\Omega} := \sum_{x_i \in \Omega'} |f(x_i) - C_{\Omega'}|^2 + \sum_{x_i \in \Omega''} |f(x_i) - C_{\Omega''}|^2,$$

where $C_{\Omega'}$, $C_{\Omega''}$ are defined in (3) and

$$W_{\Omega} := \|\psi_{\Omega'}\|_2^2 + \|\psi_{\Omega''}\|_2^2.$$

Then, the minimization (2) of V_{Ω} is equivalent to maximization of W_{Ω} over all choices of subdomains Ω' , Ω'' , $\Omega = \Omega' \cup \Omega''$ and constants $C_{\Omega'}$, $C_{\Omega''}$.

Proof See Appendix.

Recall that our approach is to convert classification problems into a ‘functional’ setting by assigning the L class labels to vertices of a simplex in \mathbb{R}^{L-1} . In such cases of multi-valued functions, choosing $r = 1$, the wavelet $\psi_{\Omega'}$: $\mathbb{R}^n \rightarrow \mathbb{R}^{L-1}$ is

$$\psi_{\Omega'} = \mathbf{1}_{\Omega'} (\bar{E}_{\Omega'} - \bar{E}_{\Omega}),$$

and its norm is given by

$$\|\psi_{\Omega'}\|_2^2 = \sum_{x_i \in \Omega'} \|\bar{E}_{\Omega'} - \bar{E}_{\Omega}\|_{l_2}^2 = \|\bar{E}_{\Omega'} - \bar{E}_{\Omega}\|_{l_2}^2 \# \{x_i \in \Omega'\}, \quad (7)$$

where for $\vec{v} \in \mathbb{R}^{L-1}$, $\|\vec{v}\|_{l_2} := \sqrt{\sum_{i=1}^{L-1} v_i^2}$.

Using any given weights assigned to the trees, we obtain a wavelet representation of the entire RF

$$\tilde{f}(x) = \sum_{j=1}^J \sum_{\Omega \in \mathcal{T}_j} w_j \psi_{\Omega}(x). \quad (8)$$

The theory (see Theorem 4 below) tells us that sparse approximation is achieved by ordering the wavelet components based on their norm

$$w_{f(\Omega_{k_1})} \|\psi_{\Omega_{k_1}}\|_2 \geq w_{f(\Omega_{k_2})} \|\psi_{\Omega_{k_2}}\|_2 \geq w_{f(\Omega_{k_3})} \|\psi_{\Omega_{k_3}}\|_2 \dots \quad (9)$$

with the notation $\Omega \in \mathcal{T}_j \Rightarrow j(\Omega) = j$. Thus, the adaptive M-term approximation of a RF is

$$f_M(x) := \sum_{m=1}^M w_{f(\Omega_{k_m})} \psi_{\Omega_{k_m}}(x). \quad (10)$$

Observe that, contrary to existing tree pruning techniques, where each tree is pruned separately, the above approximation process applies a ‘global’ pruning strategy where the significant components can come from any node of any of the trees at any level. For simplicity, one could choose $w_j = 1/j$, and obtain

$$f_M(x) = \frac{1}{J} \sum_{m=1}^M \psi_{\Omega_{k_m}}(x). \quad (11)$$

Figure 2 below depicts an M-term (11) selected from an RF ensemble. The red colored nodes illustrate the selection of the M wavelets with the highest norm values from the entire forest. Observe that they can be selected from any tree at any level, with no connectivity restrictions.

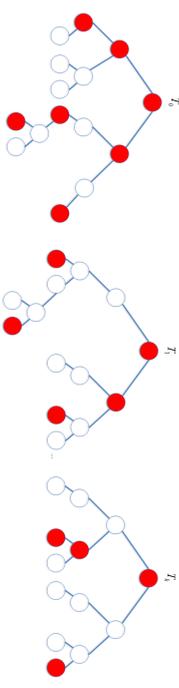

Figure 2: Selection of an M-term approximation from the entire forest.

Figure 3 depicts how the parameter M is selected for the challenging ‘Red Wine Quality’ dataset from the UCI repository (UCI repository). The generation of 10 decision trees on the training set creates approximately 3500 wavelets. The parameter M is then selected by minimization of the approximation error on a validation set. In contrast with other pruning

methods (Loh 2011), using (9), the wavelet approximation method may select significant components from any tree and any level in the forest. By this method, one does not need to predetermine the maximal depth of the trees and over-fitting is controlled by the selection of significant wavelet components.

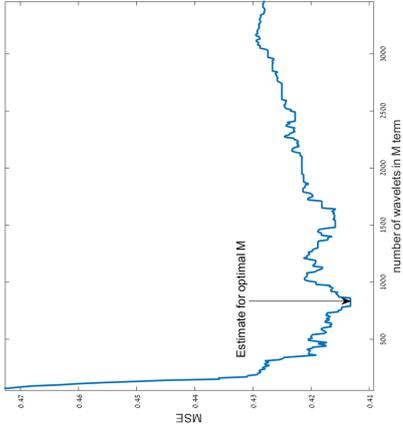

Figure 3: “Red Wine Quality” dataset - Numeric computation of M for optimal regression.

In a similar manner to certain successful applications in signal processing (e.g. coefficient quantization in the image compression standard JPEG), one may replace the selection of the parameter M in (11), with a threshold parameter $\varepsilon > 0$, chosen suitably for the problem (see for example Section 6.2). One then creates a wavelet approximation using all wavelet terms with norm (6) greater than ε .

In some cases, as presented in (Strobl et. al. 2006) explanatory attributes may be non-descriptive and even noisy, leading to the creation of problematic nodes in the decision trees. Nevertheless, in these cases, the corresponding wavelet norms are controlled and these nodes can be pruned out of the sparse representation (11). The following example demonstrates exactly this, that with high probability, the wavelets associated with the correct variables have relatively higher norms than wavelets associated with non-descriptive variables. Hence the wavelet based criterion will choose, with high probability the correct variable.

Example 1 Let $\{y_i\}_{i=1}^m$, where $y_i \sim \text{Ber}(1/2)$ i.i.d. and $\{x_i\}_{i=1}^m \subset [0, 1]^n$, $x_i = (x_{i1}, \dots, x_{ik}, \dots, x_{in}) \in \mathbb{R}^n$ with $x_{ik} = y_i$ and x_{ij} , $j \neq k$, uniformly distributed in $[0, 1]$. Then, for a subdivision along the j th axis, $[0, 1]^n = \Omega' \cup \Omega''$, and given $\delta \in (0, 1)$, w.p. $\geq 1 - \delta$,

1. If $j \neq k$, then $\|\psi_{\Omega'}\|_2^2, \|\psi_{\Omega''}\|_2^2 \leq 2 \log(2/\delta)$,
2. If $j = k$ and the subdivision minimizes (1), then

$$\|\psi_{\Omega'}\|_2^2, \|\psi_{\Omega''}\|_2^2 \geq \left(\frac{m}{2} - \sqrt{\frac{\log(2/\delta)}{2m}} \right)^3 / m^2.$$

Proof See Appendix.

4. ‘Weak-Type’ Smoothness and Sparse Representations of the response variable

In this section, we generalize to unstructured and possibly high dimensional datasets, a theoretical framework that has been applied in the context of signal processing, where the data is well structured and of low dimension (DeVore 1998), (DeVore et. al. 1992). The ‘sparsity’ of a function in some representation is an important property that provides a robust computational framework (Elad 2010(©)). Approximation Theory relates the sparsity of a function to its Besov smoothness index and supports cases where the function is not even continuous. Our motivation is to provide additional tools that can be used in the context of machine learning to associate a Besov-index, which is roughly a ‘complexity’ score, to the underlying function of a dataset. As the theory below and the experimental results show, this index correlates well with the performance of RFs and wavelet decompositions of RFs.

For a function $f \in L_r(\Omega)$, $0 < r \leq \infty$, $h \in \mathbb{R}^n$ and $r \in \mathbb{N}$, we recall the r -th order difference operator

$$\Delta_h^r(f, x) := \Delta_h^r(f, \Omega, x) := \begin{cases} \sum_{k=0}^r (-1)^{r+k} \binom{r}{k} f(x + kh) & [x, x + rh] \subset \Omega, \\ 0 & \text{otherwise,} \end{cases}$$

where $[x, y]$ denotes the line segment connecting any two points $x, y \in \mathbb{R}^n$. The **modulus of smoothness of order r** over Ω is defined by

$$\omega_r(f, t)_\tau := \sup_{|h| \leq t} \|\Delta_h^r(f, \Omega, \cdot)\|_{L_r(\Omega)}, \quad t > 0,$$

where for $h \in \mathbb{R}^n$, $\|h\|$ denotes the norm of h . We also denote

$$\omega_r(f, \Omega)_\tau := \omega_r\left(f, \frac{\text{diam}(\Omega)}{\tau}\right)_\tau.$$

Definition 2 For $0 < p < \infty$ and $\alpha > 0$, we set $\tau = \tau(\alpha, p)$, to be $1/\tau := \alpha + 1/p$. For a given function $f \in L_p(\Omega_0)$, $\Omega_0 \subset \mathbb{R}^n$, and tree \mathcal{T} , we define the associated B -space smoothness in $B_p^{\alpha, \tau}(\mathcal{T})$, $r \in \mathbb{N}$, by

$$|f|_{B_p^{\alpha, \tau}(\mathcal{T})} := \left(\sum_{\Omega \in \mathcal{T}} (|\Omega|^{-\alpha} \omega_r(f, \Omega)_r)^\tau \right)^{1/\tau}, \quad (12)$$

where, $|\Omega|$ denotes the volume of Ω .

We now show that a ‘well clustered’ function is in fact infinitely smooth in the right adaptively chosen Besov space.

Lemma 3 Let $f(x) = \sum_{k=1}^K P_k(x) \mathbf{1}_{B_k}(x)$, where each $B_k \subset \Omega_0$ is a box with sides parallel to the main axes and $P_k \in \Pi_{r-1}$. We further assume that $B_k \cap B_j = \emptyset$, whenever $j \neq k$. Then, there exists an adaptive tree partition \mathcal{T} , such that $f \in B_p^{\alpha, \tau}(\mathcal{T})$, for any $\alpha > 0$.

Proof See Appendix.

For a given forest $\mathcal{F} = \{\mathcal{T}_j\}_{j=1}^J$ and weights $w_j = 1/J$, the α Besov semi-norm associated with the forest is

$$|f|_{B_p^{\alpha, \tau}(\mathcal{F})} := \frac{1}{J} \left(\sum_{j=1}^J |f|_{B_p^{\alpha, \tau}(\mathcal{T}_j)}^\tau \right)^{1/\tau}. \quad (13)$$

The Besov index of f is determined by the maximal index α for which (13) is finite. The above definition generalizes the classical function space theory of Besov spaces, where the tree partitions are non-adaptive. That is, classical Besov spaces may be defined by the special case of partitioning into dyadic cubes, each time using n levels of the tree.

Remark An active research area of approximation theory is the characterization of more geometrically adaptive approximation algorithms by generalizations of the classic ‘isotropic’ Besov space to more ‘geometric’ Besov-type spaces (Dahmen et. al 2001), (Dekel and Leviatan 2005), (Karaivanov and Petrushev 2003). It is known that different geometric approximation schemes are characterized by different flavors of Besov-type smoothness. In this work, for example, we assume all trees are created using partitions along the main n axes. This restriction may lead in general to potentially lower Besov smoothness of the underlying function and the sparsity of the wavelet representation. Yet, the theoretical definitions and results of this paper can also apply to more generalized schemes where for example the tree partitions are by arbitrary hyper-planes. In such a case, the smoothness index of a given function may increase.

Next, for a given tree \mathcal{T} and parameter $0 < \tau < p$ we denote the τ -strength of the tree by

$$N_\tau(f, \mathcal{T}) = \left(\sum_{\Omega \in \mathcal{T}} \|\psi_\Omega\|_p^\tau \right)^{1/\tau}. \quad (14)$$

Observe that

$$\lim_{\tau \rightarrow 0} N_\tau(f, \mathcal{T})^\tau = \#\{\Omega \in \mathcal{T} : \psi_\Omega \neq 0\}.$$

Let us further denote the τ -strength of a forest \mathcal{F} , by

$$\begin{aligned} N_\tau(f, \mathcal{F}) &:= \frac{1}{J} \left(\sum_{j=1}^J \sum_{\Omega \in \mathcal{T}_j} \|\psi_\Omega\|_p^\tau \right)^{1/\tau} \\ &= \frac{1}{J} \left(\sum_{j=1}^J N_\tau(f, \mathcal{T}_j)^\tau \right)^{1/\tau}. \end{aligned}$$

In the setting of a single tree constructed to represent a real-valued function, under mild conditions on the partitions (see remark after (5) and condition (17)), the theory of (Dekel and Leviatan 2005) proves the equivalence

$$|f|_{B_p^{\alpha, \tau}(\mathcal{T})} \sim N_\tau(f, \mathcal{T}). \quad (15)$$

This implies that there are constants $0 < C_1 < C_2 < \infty$, that depend on parameters such as α, p, n, r and ρ in condition (17) below, such that

$$C_1 |f|_{B_p^{\alpha, \tau}(\mathcal{T})} \leq N_\tau(f, \mathcal{T}) \leq C_2 |f|_{B_p^{\alpha, \tau}(\mathcal{T})}.$$

Therefore, we also have for the forest model

$$|f|_{B_p^{\alpha, \tau}(\mathcal{F})} \sim N_\tau(f, \mathcal{F}). \quad (16)$$

We now present a ‘Jackson-type estimate’ for the degree of the adaptive wavelet forest approximation. Its proof is in the Appendix.

Theorem 4 Let $\mathcal{F} = \{\mathcal{T}_j\}_{j=1}^J$ be a forest. Assume there exists a constant $0 < p < 1$, such that for any domain $\Omega \in \mathcal{F}$ on a level l and any domain $\Omega' \in \mathcal{F}$, on the level $l+1$, with $\Omega \cap \Omega' \neq \emptyset$, we have

$$|\Omega'| \leq \rho |\Omega|, \quad (17)$$

where $|E|$ denotes the volume of $E \subset \mathbb{R}^n$. Denote formally $f = \sum_{\Omega \in \mathcal{F}} w_j(\Omega) \psi_\Omega$, and assume that $|f|_{B_T^{\alpha,r}(\mathcal{F})} < \infty$, where

$$\frac{1}{\tau} = \alpha + \frac{1}{p}.$$

Then, for the M -term approximation (10) we have

$$\sigma_M(f) := \|f - f_M\|_p \leq C(p, \alpha, \rho) JM^{-\alpha} |f|_{B_T^{\alpha,r}(\mathcal{F})}. \quad (18)$$

One important contribution of this work is the attempt to generalize to the setting of machine learning, the function space theoretical perspective. There are several candidate numeric methods to estimate the critical ‘weak-type’ Besov smoothness index α from the given data. That is, the maximal α for which the Besov norm is finite. Our goal is to estimate the true smoothness of the underlying function, removing influences of noise and outliers if exist within the given dataset. One potential method is to use the equivalence (16) and then search for a transient value of τ for which $N_\tau(f, \mathcal{F})$ becomes ‘infinite’. However, we choose to generalize the numeric algorithm of (DeVore et. al. 1992) and estimate the critical index α using a numeric exponential fit of the error σ_M in (18). We found that it is somewhat more robust to fit each decision tree in the forest with an estimated smoothness index α_j and then average to obtain the estimated forest smoothness α . Thus, based on (18), we model the error function by $\sigma_{j,m} \sim c_j m^{-\alpha_j}$ for unknown c_j, α_j , where $\sigma_{j,m}$ is the approximation error when using the m most significant wavelets of the j th tree. First, notice that we can estimate $c_j \sim \sigma_{j,1}$. Then, using $\int_1^M m^{-\alpha} dm = (M^{1-\alpha} - 1)/(1 - \alpha)$, we estimate α_j by

$$\min_{\alpha_j} \left| \frac{M^{1-\alpha_j} - 1}{1 - \alpha_j} \sigma_{j,1} - \sum_{m=1}^{M-1} \sigma_{j,m} \right|. \quad (19)$$

Similarly to (DeVore et. al. 1992), we select only M significant terms, to avoid fitting the tail of the exponential expression. This is done by discarding wavelets that are overfitting the error on the Out Of Bag (OOB) samples (see Figure 3). Let us see some examples of how this works in practice. As can be seen in Figure 4, the estimate of the Besov index of two target functions using (19) stabilizes after a relatively small number of trees are added.

Next, we show that when an underlying function is not ‘well clustered’ and has a sharp transition of values across the boundary of two domains, then the Besov index is limited in the general case and suffers from the curse of dimensionality. Again, it should make sense to the practitioners, that such a function can be learnt but with more effort, e.g. trees with higher depth.

Lemma 5 Let $f(x) = \mathbf{1}_{\tilde{\Omega}}(x)$, where $\tilde{\Omega} \subset [0, 1]^n$ is a compact domain with a smooth boundary. Then, $f \in B_T^{\alpha,r}(\mathcal{T})$, for $\alpha < 1/p(n-1)$, $\tau^{-1} = \alpha + 1/p$, and any $r \geq 1$, where \mathcal{T}

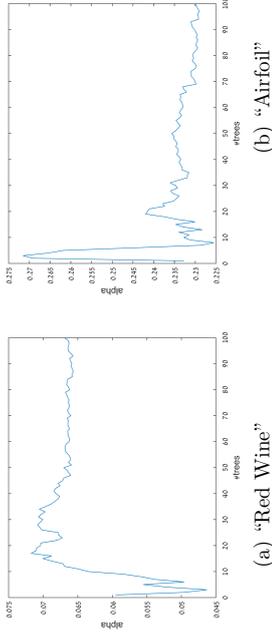

Figure 4: Estimation of the Besov critical smoothness index

is the tree with isotropic dyadic partitions, creating dyadic cubes of side lengths 2^{-k} on the level nk .

Proof See Appendix.

We note that in the general case, when subdivisions along main axes are used, the non-adaptive tree of the above lemma is almost best possible. That is, one cannot hope for significantly higher smoothness index using an adaptive tree with subdivisions along main axes. In Figure 5(a) we see 5000 random points and in (b) 250 random points, sampled from a uniform distribution taking a response value of $f(x) = \mathbf{1}_{\tilde{\Omega}}(x)$, where $\tilde{\Omega} \subset \mathbb{R}^2$, is the unit sphere.

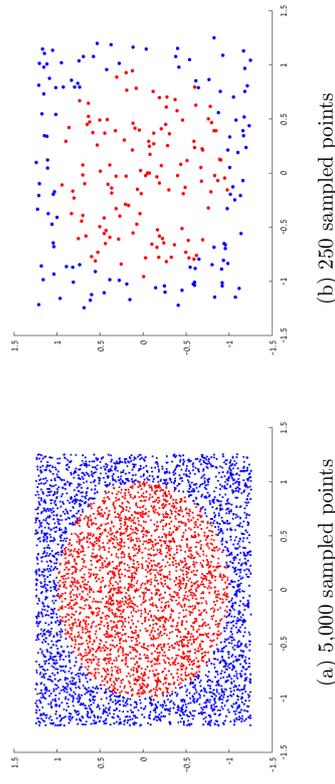

Figure 5: Dataset created by random sampling points of the indicator function of a unit sphere

By Lemma 4.3, the lower bound for the critical Besov exponent of f is $\alpha = 0.5$, for $p = 2$. This should correlate with the intuition of machine learning practitioners: the dataset does have two well defined clusters, but the boundary between the clusters (boundary of the sphere) is a non-trivial curve and any classification algorithm will need to learn the geometry of the curve.

In Figure 6 we see a plot of the numeric calculation of the α Besov index for given number of sampling points of f . We see relatively fast convergence to $\alpha = 0.51$. As discussed, our method attempts to capture the geometric properties of the ‘true’ underlying function that is potentially buried in the noisy input data. To show this, we constructed from a dataset of 10k samples of f , a ten dimensional dataset, by adding additional eight noisy features, with uniform distribution in $[0, 1]$ and no bearing on the response variable. The numeric computation in this example was again, $\alpha = 0.51$, which demonstrates that the method is stable under this noisy embedding in \mathbb{R}^n as well.

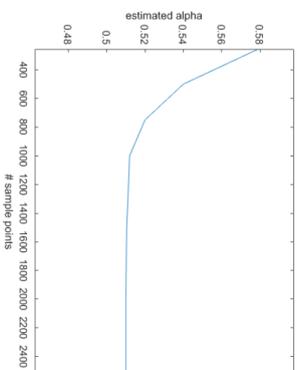

Figure 6: Numeric calculation of the α Besov index for given number of sampling points of the indicator function of a unit sphere.

5. Wavelet-based variable importance

In many cases, there is a need to understand in greater detail in what way the different variables influence the response variable (Guyon and Elisseeff 2003). Which of the possibly hundreds of parameters is more critical? What are the interactions between the significant variables? Also, the property of obtaining fewer features that provide equivalent prediction could be used for feature engineering and for ‘feature budget algorithms’ such as in (Feng et. al. 2015), (Vens and Costa 2011). As described in (Genner et. al. 2010), the use of RF for variable importance detection has several advantages.

There are several existing Variable Importance (VI) quantification methods that use RF. A popular approach for measuring the importance of a variable is summing the total decrease in node impurities when splitting on the variable, averaged over all trees (RF in R), (Hastie et. al. 2009). As suggested in the RF package documentation of the R language (RF in R): “For classification, the node impurity is measured by the Gini Index. For regression; it is measured by the residual sum of squares”. Although not stated specifically in (RF in R), it is common practice to multiply the information gain of each node by its size (Raibman and Stoffel 2004), (Du and Zhan 2002), (Rokach and Maimon 2005). Additional methods for variable importance measure are the ‘Permutation Importance’ measure (Genner et. al. 2010), or similarly ‘OOB randomization’ (Hastie et. al. 2009). With these latter two methods, sequential predictions of RF are done, when each time one feature is being permuted as the rest of the features remain. Then, the measure for variable importance is the difference in prediction accuracy before and after a feature is permuted in MSE terms.

However, both ‘Impurity gain’ and ‘Permutation’ have some pitfalls that should be considered, when used for variable importance. As shown by (Strobl et. al. 2006), the ‘Impurity gain’ tends to be in favor of variables with more varying values. As shown in (Strobl et. al. 2008), ‘Permutation’ tends to overestimate the variable importance of highly correlated variables.

The wavelet-based VI is derived by imposing a restriction on the adaptive re-ordering of the wavelet components (11), such that they must appear in ‘feature related blocks’. To make this precise, let $\{x \in \mathbb{R}^n, f(x)\}$ be a dataset and let \tilde{f} represent the RF decomposition, as in (8). We evaluate the importance of the i -th feature by

$$S_i^\tau := \frac{1}{J} \sum_{j=1}^J \sum_{\Omega \in T_j^{\cap V_i}} \|\psi_{i\Omega}\|_2^\tau, \quad i = 1, \dots, n, \quad (20)$$

where, $\tau > 0$ and V_i is the set of child domains formed by partitioning their parent domain along the i th variable. This allows us to score the variables, using the ordering $S_i^\tau \geq S_{i_2}^\tau \geq \dots$. Recall that our wavelet-based approach transforms classification problems into the functional setting (see section 2) by mapping each label l_k to a vertex $\vec{l}_k \in \mathbb{R}^{L-1}$ of a regular simplex. Therefore, in classification problems, the wavelet norms in (20) are given by (7) which implies that we provide a unified approach to VI.

It is crucial to observe that from an approximation theoretical perspective, the more suitable choice in (20) is $\tau = 1$, since with this choice, the ordering is related to ordering

the variables by the approximation error of their corresponding wavelet subset

$$\begin{aligned}
 & \left\| \bar{f} - \frac{1}{J} \sum_{j=1}^J \sum_{\Omega \in \mathcal{T}_j \cap V_i} \psi_\Omega \right\|_2 \\
 &= \min_{1 \leq i \leq n} \left\| \frac{1}{J} \sum_{k \neq i} \sum_{j=1}^J \sum_{\Omega \in \mathcal{T}_j \cap V_k} \psi_\Omega \right\|_2 \\
 &\leq \min_{1 \leq i \leq n} \frac{1}{J} \sum_{k \neq i} \sum_{j=1}^J \sum_{\Omega \in \mathcal{T}_j \cap V_k} \|\psi_\Omega\|_2 \\
 &= \min_{1 \leq i \leq n} \sum_{k \neq i} S_k^1 \\
 &= \sum_{1 \leq k \leq n} S_k^1 - \max_{1 \leq i \leq n} S_i^1.
 \end{aligned}$$

What is interesting is that, in regression problems, when using piecewise constant approximation in (1),(4), the VI score (20) with $\tau = 2$, is in fact exactly as in (Louppe et. al. 2013) when variance is used as the impurity measure. To see this, for any dataset $\{x \in \mathbb{R}^n, f(x)\}$ and domain $\tilde{\Omega}$ of an RF, denote briefly

$$K_{\tilde{\Omega}} := \#\{x_i \in \tilde{\Omega}\}, \quad \text{Var}(\tilde{\Omega}) = \frac{1}{\#\{x_i \in \tilde{\Omega}\}} \sum_{x_i \in \tilde{\Omega}} (f(x_i) - C_{\tilde{\Omega}})^2.$$

For any domain Ω of a RF, with children Ω', Ω'' , the variance impurity measure is

$$\Delta(\Omega) := \text{Var}(\Omega) - \frac{K_{\Omega'} \text{Var}(\Omega')}{K_\Omega} - \frac{K_{\Omega''} \text{Var}(\Omega'')}{K_\Omega}.$$

The importance of the variable i (up to normalization by the size of the dataset) is defined in (Louppe et. al. 2013) by

$$\frac{1}{J} \sum_{j=1}^J \sum_{\text{children of } \Omega \text{ in } \mathcal{T}_j \cap V_i} K_{\Omega} \Delta(\Omega). \quad (21)$$

Theorem 6 *The variable importance methods of (20) and (21) are identical for $\tau = 2$.*

Proof For any domain Ω and its two children Ω', Ω'' ,

$$\begin{aligned}
 K_\Omega \Delta(\Omega) &= K_\Omega \left(\text{Var}(\Omega) - \frac{K_{\Omega'} \text{Var}(\Omega')}{K_\Omega} - \frac{K_{\Omega''} \text{Var}(\Omega'')}{K_\Omega} \right) \\
 &= \sum_{x_i \in \tilde{\Omega}} (f(x_i) - C_\Omega)^2 - \sum_{x_i \in \Omega'} (f(x_i) - C_{\Omega'})^2 - \sum_{x_i \in \Omega''} (f(x_i) - C_{\Omega''})^2 \\
 &= \|\psi_{\Omega'}\|_2^2 + \|\psi_{\Omega''}\|_2^2.
 \end{aligned}$$

Therefore,

$$\frac{1}{J} \sum_{j=1}^J \sum_{\text{children of } \Omega \text{ in } \mathcal{T}_j \cap V_i} K_\Omega \Delta(\Omega) = S_i^1. \quad \diamond$$

Further to the choice of $\tau = 1$ over $\tau = 2$ in (20), the novelty of the wavelet-based VI approach is targeted at difficult noisy datasets. In these cases, one should compute VI at various degrees of approximation, using only subsets of ‘significant’ nodes, by thresholding out wavelet components with norm below some $\epsilon > 0$

$$S_i^1(\epsilon) := \sum_{j=1}^J \sum_{\Omega \in \mathcal{T}_j \cap V_i, \|\psi_\Omega\|_2 \geq \epsilon} \|\psi_\Omega\|_2. \quad (22)$$

As pointed out, a popular RF approach for identifying important variables is summing the total decrease in node impurities when splitting on the variable, averaged over all trees (RF in R), (Hastie et. al. 2009). However, this method may not be reliable in situations where potential predictor variables vary in their scale of measurement or their number of categories (Strobl et. al. 2006). This restriction is very limiting in practice, as in many cases binary variables such as ‘Gender’ are very descriptive where less descriptive variables (or noise) may vary with many values.

To demonstrate this problem, we follow the experiment suggested in (Strobl et. al. 2006). We set a number of samples to $m = 120$, where each sample has two explanatory independent variables: $x_1 \sim N(0, 1)$ and $x_2 \sim \text{Ber}(0.5)$. A correlation between $y = f(x_1, x_2)$ and x_2 is established by:

$$y \sim \begin{cases} \text{Ber}(0.7), & x_2 = 0, \\ \text{Ber}(0.3), & x_2 = 1. \end{cases} \quad (23)$$

In accordance with the point made in (Strobl et. al. 2006), when applying the VI of (RF in R), (Hastie et. al. 2009) we observe that the important variable is the ‘noisy’ uncorrelated feature x_1 . As shown in Example 1, while we may obtain many false partitions along the noise, with high probability their wavelet norm is controlled, and relatively small. In Figure 7 we see a histogram of the wavelet norms (taken from one of the RF trees) for the example (23). We see that the wavelet norms of the important variable x_2 are larger, but that there exists a long tail of wavelet norms relating to x_1 . Therefore, applying the thresholding strategy (22) as part of the feature importance estimation could be advantageous in such a case.

We now address the choice of ϵ in (22). So as to remove the noisy wavelet components from the VI scoring process, we choose the threshold as norm of the M -th wavelet, where

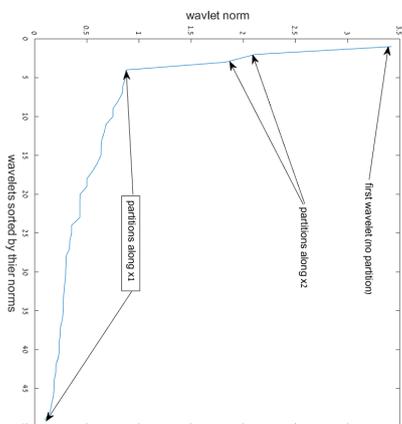

Figure 7: wavelets norms taken from one of the RF trees constructed for the example (23)

M is the selected using the M -term wavelet that minimizes the approximation error on the validation set $\{x_i, f(x_i)\}_{i=1\dots k}$ by

$$\epsilon = \|\psi_M\|_2, \quad s.t. \min_M \left\{ \sum_{i=1}^k \left(f(x_i) - \frac{1}{J} \sum_{m=1}^M \psi_{\gamma_{k_m}}(x_i) \right)^2 \right\}. \quad (24)$$

The calculation of ϵ for the ‘‘Pima diabetes’’ dataset using a validation set is depicted in Figure 8. In Section 6.2 we demonstrate the advantage of the wavelet-based thresholding technique in VI on several datasets.

6. Applications and Experimental Results

For our experimental results, we implemented C# code that supports RF construction, Besov index analysis, wavelet decompositions of RF and applications such as wavelet-based VI, etc. (source code is available, see link in (Wavelet RF code)). The algorithms are executed on the Amazon Web Services cloud, using up to 120 CPUs. Most datasets are taken from the UCI repository (UCI repository), which allows us to compare our results to previous work.

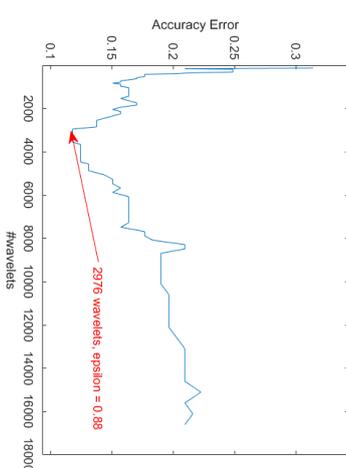

Figure 8: ‘‘Pima diabetes’’ - Choice of ϵ in (22) using the validation set

6.1 Ensemble Compression

In applications, constructed predictive models, such as RF, need to be stored, transmitted and applied to new data. In such cases the size of the model becomes a consideration, especially when using many trees to predict large amounts of incoming new data over distributed architectures. Furthermore, as presented in (Geurts and Gilles 2011), the number of total nodes of the RF and the average tree depth impact the memory requirements and evaluation performance of the ensemble.

In order to demonstrate the correlation between the Besov index of the underlying function and the ‘complexity’ of these datasets we need to compare on the same scale different datasets of different sizes and dimensions. Therefore, we replaced the commonly used metrics in machine learning such as MSE (Mean Square Error) by the normalized PSNR (Peak Signal To Noise Ratio) metric which is commonly used in the context of signal processing. For a given dataset $\{x_i, f(x_i)\}$ and an approximation $\{x_i, f_A(x_i)\}$ PSNR is defined by

$$\text{PSNR} := 10 \cdot \log_{10} \frac{\max_{i,j} \left\{ |f(x_i) - f(x_j)|^2 \right\}}{\frac{1}{\#\{x_i\}} \sum_i (f(x_i) - f_A(x_i))^2}.$$

Observe that higher PSNR implies smaller error. In Figure 9 we observe the rate-distortion performance measured on validation points in a fivefold cross validation of M -term wavelet approximation and standard RF, as trees are added. It can be seen that for functions that are smoother in ‘weak-type’ sense (e.g. higher α), wavelet approximation outperforms the standard RF. Table 1 below shows an extensive list of more datasets.

We now compare wavelet-based compression with existing RF pruning strategies. As stated by (Kulkarni and Sinha 2012), most of the current efforts in pruning RF are based on ‘Over-produce-and-Choose’ strategy, where the forest is grown to a fixed number of trees, and then only a subset of these trees are chosen by a ‘leave one out strategy’ as in (Martinez-Muoz et. al. 2009), (Yang et. al. 2012). For each dataset we first computed a point at which the graph of wavelet approximation error begins to ‘flatten out’ on the validation set. We then used this target error pre-saturation point for both wavelet shrinkage and the pruning methods that aim for a minimal number of nodes to achieve it on a validation set of fivefold cross validation. To this end, we have generated RF with 100 decision trees with 80% bagging and \sqrt{n} hyper-parameter. The two pruning strategies are based on a ‘leave one out’ strategy as presented in (Yang et. al. 2012). In this approach trees are recursively omitted according to their correspondence with the rest of the ensemble (based on the correspondence of the margins in classification and MSE in regression). We have collected the results of the experiment described above applied to 12 UCI datasets in Table 1. The datasets for classification are marked (C) and regression (R). One may observe from Table 1 that the wavelet-based method performs better than conventional pruning. Also, as expected, there is significant correlation between the performance of compression and the function smoothness. That is, the compression is more effective for smoother functions.

Note that when computing an M -term wavelet approximation, some components may be unconnected as depicted in Figure 2. Obviously, any compression of the wavelet approximation would need to encode the nodal data associated with these unconnected components. Therefore, we enforce connectivity on any wavelet approximation we compute, by adding all wavelet components along the tree paths leading to the selected significant wavelet components. Thus, the wavelet compression appearing in Table 1 is in the form of a collection of J connected subtrees.

6.2 Variable Importance

We first demonstrate how the wavelet-based method (20) with $\tau = 1$, succeeds in identifying the features with the highest impact on the prediction. In Figure 10 (a), we show an histogram of VI scores for the ‘Red Wine’ dataset using the wavelet-based approach (20). As can be seen, the top three features in the histogram are ‘Alcohol’, ‘Volatile acidity’ and ‘Sulphates’. We then constructed RFs for all the possible triple combinations of features of the UCI repository ‘Wine Quality’ dataset (165 simulations) using 100 trees and 80% bagging. In Figure 10(b), we can see the MSE of each of these RFs. One can verify that the triple ‘Alcohol’, ‘Volatile acidity’ and ‘Sulphates’ (index 81) has the smallest error, as identified by our wavelet-based method.

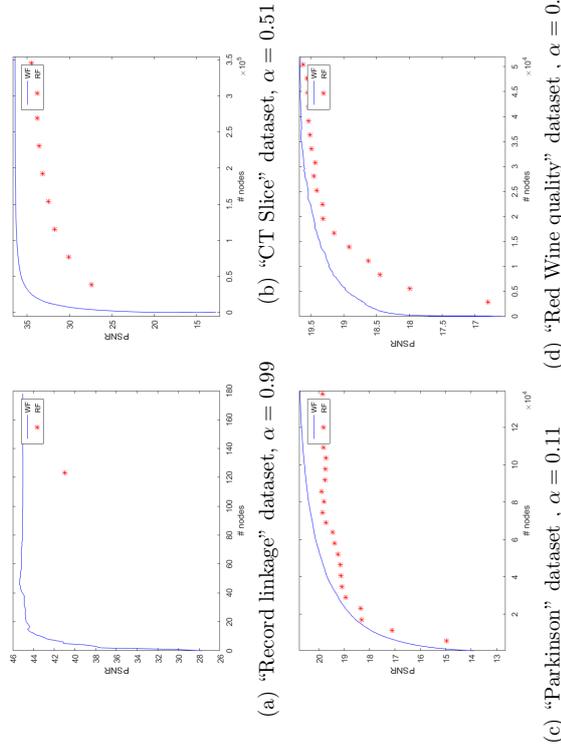

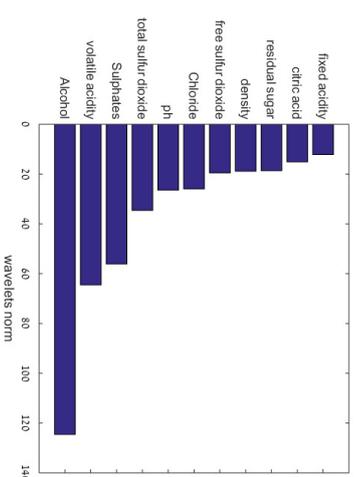

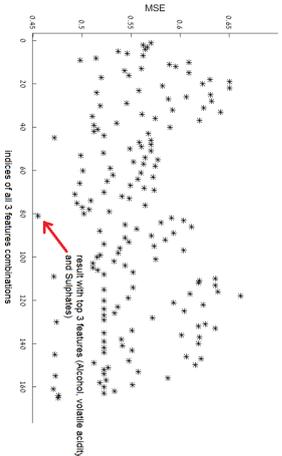

Figure 9: PSNR of four UCI data sets.

Table 1: Compression - number of nodes required to reach the error pre-saturation point

Dataset	error	Pruning Min-D (Yang et. al. 2012)		Pruning Mean-D (Yang et. al. 2012)		Wavelet subtrees		α
		#trees	#nodes	#trees	#nodes	#trees	#nodes

(a) Wavelet-based feature importance histogram

(b) Error of RFs constructed over all possible 3 feature subsets

Figure 10: Wavelet-based variable importance of the UCI Red wine data set

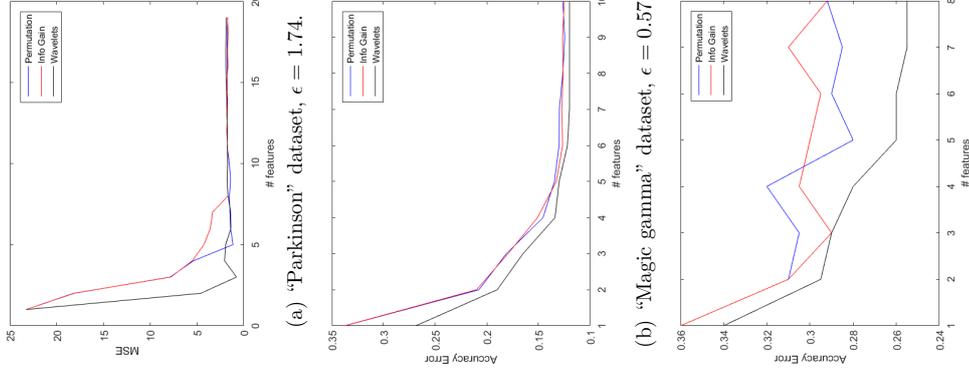

Next, we show that the wavelet-based VI approach, in particular, the noise-removal variant using (22) with $\epsilon > 0$, can provide a better estimation of VI than the existing methods in R (RF in R). Note that we apply the wavelet-based VI method in classification problems as well, competing with, for example, the standard Gini-based algorithm of R. To this end we employ a test methodology used in (Feng et. al. 2015). Using each VI method we first calculate a corresponding VI score of the features. Each method uses an RF with 100 trees and 80% bagging. However, the wavelet-based method was computed using our implementation, based on (22) while the Permutation and Information Gain based methods were applied using R. After each method ‘decides’ on the order of the features by importance, we iterate by adding features one-by-one, where at the k -th iteration, only the selected first k features are used for prediction. Here also, we used wavelet-based choice of k most important features to construct a wavelet-based best prediction, while for the other methods, we used their choice of k most important features as the input for an R based RF. The results of fivefold cross validation are presented in Figure 11. For example, in Figure 11(a), we see that on the “Parkinson” dataset, the wavelet-based method reaches better prediction using the first three features it selected. This is due to fact that the wavelet-based method selected different features (‘Age’, ‘Time’ and ‘Gender’) than the other methods.

6.3 Classification and regression tasks

In this Section we focus on difficult datasets, such as small sets or with high bias, bad features, mis-labeling and outliers (see for example “Pima Diabetes” dataset with only 768 samples with 8 attributes in Figure 11(c)) and show that in such cases the wavelet-based approach provides smaller predictive errors.

We begin with a demonstration of a case of ‘false labeling’ using the R machine learning benchmark “Spirals” (Spiral dataset). From the given dataset we create a dataset with mis-labeling by randomly replacing 20% of the values of the response variable. The original and noisy datasets are rendered in Figure 12. We then compare the predictive performance of the standard RF and the M -term wavelet approximation (11), where optimal M values are computed automatically as depicted in Figure 3. We also compare the M -term performance to a minimal node size restriction as in (Biau and Scornet 2016), setting this value to 5, as in (Denil et. al. 2014). We perform RF construction with 1000 trees and 5 fold cross validation.

When the training dataset contains ‘false labeling’, the correspondence with the testing set is reduced. Trying to restrict the tree depth, can potentially miss the geometry of the underlying function, while too many levels can lead to overfitting. As seen in Table 2, the wavelet approach selects the right significant components from any tree and any level and thus outperforms the standard RF method. Observe that the added value of the wavelet

(c) “Pima Diabetes” dataset, $\epsilon = 0.93$.

Figure 11: Comparisons of performance of standard VI methods used in R, with the wavelet-based method (22)

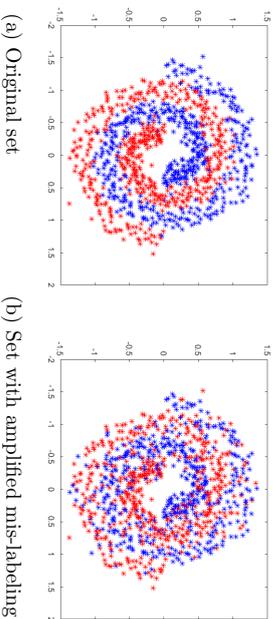

Figure 12: ‘Spirals’ dataset (Spiral dataset)

approach is more significant in the second case with more ‘false labeling’ in the training set.

Table 2: ‘Spirals’ dataset - Classification results.

	Wavelet error	RF error	Pruned RF error
Original spiral set	$12.2 \pm 0.9\%$	$14.4 \pm 1.1\%$	$15.9 \pm 0.8\%$
Set with amplified mis-labeling	$13.9 \pm 1.2\%$	$17.8 \pm 1.3\%$	$22.7 \pm 1.6\%$

Next, we compare the performance of wavelet-based regression with state-of-the-art method on a challenging problem. The authors of (Denil et. al. 2014) provide comparative results of different pruning strategies for the difficult “Wine Quality” dataset. Learning this dataset is challenging since the data is very biased and depends on the personal taste of the wine experts. In Table 3 below, we collect the results of (Biau 2012), (Biau et. al. 2008), (Breiman 2001) and (Denil et. al. 2014) (as listed in (Denil et. al. 2014)). The RFs are all constructed of 1000 trees and fivefold cross validation is applied. We follow the notation presented in (Denil et. al. 2014) and use the abbreviation that was provided for each method variation (‘+’, ‘F’, ‘S’, ‘NB’, ‘T’). In our RF implementation, we used bootstrapping with 80% and randomized \sqrt{n} features at each node. M was selected automatically using 10 percent of the training set.

Another form of a challenging dataset is when some of the features are extremely noisy or uncorrelated with the response variable. As shown in (Strobl et. al. 2006) (see the discussion in Section 5), in such cases, RF partitions sometimes are influenced by these variables and the constructed ensemble is of lower quality. To explore the impact of our approach on such datasets, we used the “Poker Hand” dataset from the UCI repository (UCI repository) in two modes: with and without a very non-descriptive feature “instance

Table 3: Performance comparison on the “Wine Quality”

Algorithm	MSE
Biau08	0.53
Biau12	0.59
Biau12+T	0.57

Appendix

Proof of Lemma 1

Denoting briefly for any domain $\tilde{\Omega}$, $K_{\tilde{\Omega}} := \#\{x_i \in \tilde{\Omega}\}$ we have

$$\begin{aligned}
 \sum_{x_i \in \Omega} (f(x_i) - C_{\Omega})^2 - V_{\Omega} &= \sum_{x_i \in \Omega} (f(x_i) - C_{\Omega})^2 - \sum_{x_i \in \Omega'} (f(x_i) - C_{\Omega'})^2 - \sum_{x_i \in \Omega''} (f(x_i) - C_{\Omega''})^2 \\
 &= \sum_{x_i \in \Omega'} [(f(x_i) - C_{\Omega})^2 - (f(x_i) - C_{\Omega'})^2] + \\
 &\quad \sum_{x_i \in \Omega''} [(f(x_i) - C_{\Omega})^2 - (f(x_i) - C_{\Omega''})^2] \\
 &= 2(C_{\Omega'} - C_{\Omega}) \sum_{x_i \in \Omega'} f(x_i) + K_{\Omega'} (C_{\Omega}^2 - C_{\Omega'}^2) \\
 &\quad + 2(C_{\Omega''} - C_{\Omega}) \sum_{x_i \in \Omega''} f(x_i) + K_{\Omega''} (C_{\Omega}^2 - C_{\Omega''}^2) \\
 &= 2(C_{\Omega'} - C_{\Omega}) K_{\Omega'} C_{\Omega'} + K_{\Omega'} (C_{\Omega}^2 - C_{\Omega'}^2) \\
 &\quad + 2(C_{\Omega''} - C_{\Omega}) K_{\Omega''} C_{\Omega''} + K_{\Omega''} (C_{\Omega}^2 - C_{\Omega''}^2) \\
 &= K_{\Omega'} (C_{\Omega'} - C_{\Omega})^2 + K_{\Omega''} (C_{\Omega''} - C_{\Omega})^2 \\
 &= \|\psi_{\Omega'}\|_2^2 + \|\psi_{\Omega''}\|_2^2 = W_{\Omega}.
 \end{aligned}$$

Now, since $\sum_{x_i \in \Omega} (f(x_i) - C_{\Omega})^2$ is independent of the selection of the partition of Ω and since W_{Ω} is always positive, the search for minimizing V_{Ω} is equivalent to maximizing W_{Ω} .

◇

Proof of Example 1

1. For any attribute $j \neq k$ we denote $m_1 := \#\{x_i \in \Omega'\}$ and $m_2 := m - m_1$. Hence, for any $\delta \in (0, 1)$, applying the Hoeffding bound gives w.p. $\geq 1 - \delta$

$$\left| C_{\Omega'} - \frac{1}{2} \right| \leq \sqrt{\frac{\log(2/\delta)}{2m_1}}, \quad \left| C_{\Omega''} - \frac{1}{2} \right| \leq \sqrt{\frac{\log(2/\delta)}{2m_2}}. \quad (25)$$

Note, that we can write $C_{\Omega} = \frac{m_1}{m} C_{\Omega'} + \frac{m_2}{m} C_{\Omega''}$. Thus, using (25) we get w.p. $\geq 1 - \delta$,

$$\begin{aligned}
 (C_{\Omega} - C_{\Omega'})^2 &= \frac{m_2^2}{m^2} (C_{\Omega''} - C_{\Omega'})^2 \\
 &\leq \frac{m_2^2}{m^2} \left(\frac{1}{m_1} + \frac{1}{m_2} \right) \log(2/\delta).
 \end{aligned}$$

Therefore, w.p. $\geq 1 - \delta$,

$$\begin{aligned}
 \|\psi_{\Omega'}\|_2^2 &= m_1 (C_{\Omega} - C_{\Omega'})^2 \\
 &\leq \frac{m_1 m_2^2}{m^2} \left(\frac{1}{m_1} + \frac{1}{m_2} \right) \log(2/\delta) \\
 &= \left(\frac{m_2^2}{m^2} + \frac{m_1 m_2}{m^2} \right) \log(2/\delta) \\
 &\leq 2 \log(2/\delta).
 \end{aligned}$$

2. Observe that for the case $j = k$, a subdivision that minimizes (1) is $x_k = 1/2$. Denote $m_1 = \#\{x_i \in \Omega : y_i = 1\}$. Applying the Hoeffding bound with $\delta \in (0, 1)$ yields w.p. $\geq 1 - \delta$

$$\left| m_1 - \frac{m}{2} \right| \leq \sqrt{\frac{\log(2/\delta)}{2m}}.$$

If Ω' is the subset of $[0, 1]^m$ where $x_k > 1/2$, then $C_{\Omega'} = 1$ and $\|\psi_{\Omega'}\|_2^2 = m_1 (1 - \frac{m_1}{m})^2$. Plugging into the bound above we conclude that w.p. $\geq 1 - \delta$,

$$\begin{aligned}
 \|\psi_{\Omega'}\|_2^2 &\geq \left(\frac{m}{2} - \sqrt{\frac{\log(2/\delta)}{2m}} \right) \left(1 - \frac{\frac{m}{2} + \sqrt{\frac{\log(2/\delta)}{2m}}}{m} \right)^2 \\
 &= \left(\frac{m}{2} - \sqrt{\frac{\log(2/\delta)}{2m}} \right)^3 / m^2.
 \end{aligned}$$

◇

Proof of Theorem 4 We prove the case $1 < p < \infty$ (the case $0 < p \leq 1$ is easier). We need to show two essential properties. First, for any $\Omega' \in \mathcal{F}$ and any $x \in \Omega'$, denoting $\Lambda := \{\Omega \in \mathcal{F} : x \in \Omega, |\Omega| \geq |\Omega'|\}$, we have

$$\sum_{\Omega \in \Lambda} \left(\frac{|\Omega'|}{|\Omega|} \right)^{1/p} \leq C(\rho, p) J. \quad (26)$$

Indeed, using (17), recursively for all domains on lower levels intersecting with Ω' we have

$$\begin{aligned}
 \sum_{\Omega \in \Lambda} \left(\frac{|\Omega'|}{|\Omega|} \right)^{1/p} &\leq \sum_{k=0}^{\infty} J \rho^{k/p} \\
 &\leq \frac{J}{1 - \rho^{1/p}}.
 \end{aligned}$$

Secondly, we need the property that

$$\|\psi_\Omega\|_\infty \leq c|\Omega|^{-1/p} \|\psi_\Omega\|_p, \quad \forall \Omega \in \mathcal{F}. \quad (27)$$

It is easy to see property (27) for the case $r = 1$, where $\psi_\Omega = \mathbf{1}_\Omega C_\Omega$, but it is also known for the general case of $r \geq 1$ and convex domains (see e.g. (Dekel and Leviatan 2005)). This allows us to prove the following Lemma

Lemma 7 For $1 < p < \infty$, let $F(x) = \sum_{i=1}^I w_{j_i(\Omega_i)} \psi_{\Omega_i}(x)$, $\Omega_i \in \mathcal{F}$, where $\|w_{j_i(\Omega_i)} \psi_{\Omega_i}\|_p \leq L$. Then

$$\|F\|_p \leq cJLL^{1/p}. \quad (28)$$

Proof Applying property (27) gives

$$\begin{aligned} \|F\|_p &\leq \left\| \sum_{i=1}^I w_{j_i(\Omega_i)} \psi_{\Omega_i} \right\|_\infty \left\| \mathbf{1}_{\Omega_i}(\cdot) \right\|_p \\ &\leq L \left\| \sum_{i=1}^I |\Omega_i|^{-1/p} \mathbf{1}_{\Omega_i}(\cdot) \right\|_p. \end{aligned}$$

We define

$$\Gamma(x) := \begin{cases} \min_{1 \leq i \leq I} \{|\Omega_i| : x \in \Omega_i\}, & x \in \bigcup_{i=1}^I \Omega_i, \\ 0, & \text{else.} \end{cases}$$

Then, (26) yields

$$\sum_{i=1}^I |\Omega_i|^{-1/p} \mathbf{1}_{\Omega_i}(x) \leq cJ\Gamma(x)^{-1/p}, \quad \forall x \in \Omega_0.$$

Thus,

$$\begin{aligned} \|F\|_p &\leq cL \left\| \Gamma(\cdot)^{-1/p} \right\|_p \\ &= cJL \left(\int_{\bigcup \Omega_i} \Gamma(x)^{-1} dx \right)^{1/p} \\ &\leq cJL \left(\sum_{i=1}^I |\Omega_i|^{-1} \int_{\Omega_i} dx \right)^{1/p} = cJLL^{1/p}. \end{aligned}$$

◇

We now proceed with the proof of the Theorem. Observe that we may use (16), that is, $|f|_{B_{2^{\nu}}(\mathcal{F})} \sim N_\tau(f, \mathcal{F})$. For $\nu = 1, 2, \dots$, denote

$$\Xi_\nu := \left\{ \Omega \in \mathcal{F} : 2^{-\nu} N_\tau(f, \mathcal{F}) \leq w_{j(\Omega)} \|\psi_\Omega\|_p < 2^{-\nu+1} N_\tau(f, \mathcal{F}) \right\}.$$

Recall that for any non-negative discrete sequence $\beta = \{\beta_k\}_{k=1}^\infty$, the weak- l_r norm $\|\beta\|_{w_{l_r}}$ is defined as the infimum (if exists) over all $A > 0$, for which

$$\#\{\beta_k : \beta_k > \varepsilon\} \varepsilon^\tau \leq A^\tau, \quad \forall \varepsilon > 0.$$

Since $\|\beta\|_{w_{l_r}} \leq \|\beta\|_r$, this implies that

$$\#\Xi_m \leq \sum_{\nu \leq m} \#\Xi_\nu = \# \bigcup_{\nu \leq m} \Xi_\nu \leq 2^m \tau.$$

Let $F_\nu(x) := \sum_{\Omega \in \Xi_\nu} w_{j(\Omega)} \psi_\Omega(x)$. For the special case $M := \sum_{\nu \leq m} \#\Xi_\nu$, we have by (28)

$$\begin{aligned} \|f - f_M\|_p &\leq \left\| \sum_{\nu=m+1}^\infty F_\nu \right\|_p \\ &\leq \sum_{\nu=m+1}^\infty \|F_\nu\|_p \\ &\leq cJ \sum_{\nu=m+1}^\infty 2^{-\nu} N_\tau(f, \mathcal{F}) (\#\Xi_\nu)^{1/p} \\ &\leq cJ N_\tau(f, \mathcal{F}) \sum_{\nu=m+1}^\infty 2^{-\nu(1-\tau/p)} \\ &\leq cJ N_\tau(f, \mathcal{F}) M^{-(1/\tau-1/p)} = cJ N_\tau(f, \mathcal{F}) M^{-\alpha}. \end{aligned}$$

Extending this result for any $M \geq 1$ is standard (using a larger leading constant). This completes the proof.

◇

Proof of Lemma 3 Since there are a finite number of boxes, there exists a, possibly unbalanced, binary tree that after at most $K2^n$ partitions, has also the boxes $\{B_k\}$ as nodes of the tree. Since the modulus of smoothness of order r of polynomials of degree $r-1$ is zero (DeVore 1998), (Devore and Lorentz 1993), for any of these box nodes we have that

$$\omega_r(f, B_k)_\tau = \omega_r(P_k, B_k)_\tau = 0.$$

Similarly, for any descendant node $\Omega' \subset B_k$, for some $1 \leq k \leq K$,

$$\omega_r(f, \Omega')_\tau = \omega_r(P_k, \Omega')_\tau = 0.$$

For any node Ω such that $\Omega \cap B_k = \emptyset$, $1 \leq k \leq K$, we have

$$\omega_r(f, \Omega)_\tau = \omega_r(0, \Omega)_\tau = 0.$$

We may then conclude that $\omega_r(f, \Omega)_\tau \neq 0$, for only a finite low-level subset Λ of the tree nodes, each strictly containing at least one B_k . Therefore, for any $\alpha > 0$,

$$\begin{aligned} |f|_{B_k^{\alpha, r}} &= \left(\sum_{\Omega \in \mathcal{T}} (|\Omega|^{-\alpha} \omega_r(f, \Omega))^\tau \right)^{1/\tau} \\ &= \left(\sum_{\Omega \in \Lambda} (|\Omega|^{-\alpha} \omega_r(f, \Omega)_\tau)^\tau \right)^{1/\tau} \\ &\leq 2^r \|f\|_\tau \left(\min_k |B_k| \right)^{-\alpha} (K2^n)^{1/\tau}, \end{aligned}$$

where we have used the inequality

$$\omega_r(f, \Omega)_\tau \leq 2^r \|f\|_{L_r(\Omega)} \leq 2^r \|f\|_{L_r(\Omega_0)}.$$

◇

Proof of Lemma 5 As stated, the tree \mathcal{T}_l with isotropic dyadic partitions, creates dyadic cubes of side lengths 2^{-k} at the level nk . Let us denote by $D := \{D_k\}_{k=0}^\infty$, the collection of dyadic cubes of $[0, 1]^n$, where D_k is the collection of cubes with side lengths 2^{-k} . Observe that any domain $\Omega' \in \mathcal{T}_l$, at a level $nk < l < n(k+1)$, is contained in some dyadic cube $\Omega \in \mathcal{T} \cap D_k$ at the level nk . Also, from the properties of the modulus of smoothness, $\Omega' \subset \Omega \Rightarrow \omega_r(f, \Omega')_\tau \leq \omega_r(f, \Omega)_\tau$. Combining these two observations gives

$$|\Omega'|^{-\alpha} \omega_r(f, \Omega')_\tau \leq 2^{n\alpha} |\Omega|^{-\alpha} \omega_r(f, \Omega)_\tau.$$

Next, observe that for any $\Omega \in D_k$

$$\omega_r(f, \Omega)_\tau \begin{cases} = 0, & \Omega \cap \partial\tilde{\Omega} = \emptyset, \\ \leq 2^{-kn/\tau}, & \Omega \cap \partial\tilde{\Omega} \neq \emptyset, \end{cases}$$

where $\partial\tilde{\Omega}$ is the boundary of $\tilde{\Omega}$. Therefore,

$$\begin{aligned} |f|_{B_k^{\alpha, r}(\mathcal{T})} &\leq c(n, \alpha, \tau) \left(\sum_{\Omega \in D} (|\Omega|^{-\alpha} \omega_r(f, \Omega)_\tau)^\tau \right)^{1/\tau} \\ &\leq c(n, \alpha, \tau, r) \left(\sum_{k=0}^\infty 2^{kn(\alpha\tau-1)} \#\left\{ \Omega \in D_k : \Omega \cap \partial\tilde{\Omega} \neq \emptyset \right\} \right)^{1/\tau}. \end{aligned}$$

Thus, it remains to estimate the maximal number of dyadic cubes of side length 2^{-k} that can intersect a smooth boundary of a domain $\tilde{\Omega} \subset [0, 1]^n$. For sufficiently large k , only one connected component of the boundary $\partial\tilde{\Omega}$ intersects a dyadic cube $\Omega \in D_k$, in similar manner to an hyperplane of dimension $n-1$ with surface area $\leq c2^{-k(n-1)}$. Therefore, for sufficiently large k

$$\#\left\{ \Omega \in D_k : \Omega \cap \partial\tilde{\Omega} \neq \emptyset \right\} \leq c2^{k(n-1)}.$$

This gives

$$|f|_{B_k^{\alpha, r}(\mathcal{T})} \leq c \left(n, \alpha, \tau, r, \partial\tilde{\Omega} \right) \left(\sum_{k=0}^\infty 2^{kn(\alpha\tau-1)} 2^{k(n-1)} \right)^{1/\tau}.$$

Therefore, if $\tau^{-1} = \alpha + 1/p$, then

$$\alpha < \frac{1}{p(n-1)} \Rightarrow |f|_{B_k^{\alpha, r}(\mathcal{T})} < \infty.$$

Abstract

This paper presents an information theory-driven matching methodology for making causal inference from observational data. The paper adopts a “potential outcomes framework” view on evaluating the strength of cause-effect relationships: the population-wide average effects of binary treatments are estimated by comparing two groups of units – the treated and untreated (control). To reduce the bias in such treatment effect estimation, one has to compose a control group in such a way that across the compared groups of units, treatment is independent of the units’ covariates. This requirement gives rise to a subset selection / matching problem. This paper presents the models and algorithms that solve the matching problem by minimizing the mutual information (MI) between the covariates and the treatment variable. Such a formulation becomes tractable thanks to the derived optimality conditions that tackle the non-linearity of the sample-based MI function. Computational experiments with mixed integer-programming formulations and four matching algorithms demonstrate the utility of MI based matching for causal inference studies. The algorithmic developments culminate in a matching heuristic that allows for balancing the compared groups in polynomial (close to linear) time, thus allowing for treatment effect estimation with large data sets.

Keywords: Observational Causal Inference, Mutual Information, Matching, Subset Selection, Optimization

1. Introduction

The tools for making inference based on observational data are useful for estimating the effects of binary treatments that are non-randomly assigned to the units of a studied population (Cochran, 1965). Causal investigations are of importance in various domains of science including economics (Abadie and Imbens, 2006), medical research (da Veiga and Wilder, 2008), political science (Ho et al., 2007), sociology (Morgan and Harding, 2006), law (Rubin, 2001), etc. As a conventional recipe, *matching* of treated and untreated units allows one to compare them and distill the effect of the treatment, while blocking the effects of confounding unit covariates.

The most widely adopted conventional matching methods employ various distance metrics (e.g., Mahalanobis distance) and propensity scores (see Section 2 for a detailed review); the success of a matching venture is typically assessed by checking if the compared groups are “well-balanced”, i.e., if the distributions of covariates within them are similar. The methods introduced more recently strive to directly optimize balance (Zubizarreta, 2012). In particular, Nikolaev et al. (2013) re-cast matching as a subset selection problem with the objective to optimize a measure of covariate balance across groups (as opposed to individual unit pairs). The approach was coined Balance Optimization Subset Selection, with its applicability illustrated by employing linear programming models (Nikolaev et al., 2013) and simulated annealing heuristics (Tam Cho et al., 2013).

Note, however, that improving balance, expressed via some metric(s) capturing the difference between the distributions of covariates in the compared groups, is just one approach that defines a matching procedure objective. It is as good as any other approach that would achieve the reduction of the dependence between the covariates and the treatment variable in the matched groups. This observation is exploited in the present paper, as it explores a new form of covariate balance and an alternative approach to doing matching.

This paper frames matching as an optimization problem with a mutual information (MI) based objective. The presented methods are non-parametric, and hence, do not suffer from human bias in model selection. The value of information theory in empirical statistics research and computer science has been emphasized over the past decade (Burnham and Anderson, 2002). However, while this thrust has been successful in facilitating hypothesis testing, optimization problems with information measures have proven to be difficult, mainly due to the inherent non-linearity of entropy and MI functions (Shannon, 1948). This paper presents a way to treat such non-linearity in subset selection problems, which arise in applying information theory logic for making causal inference with observational data.

MI has been used to formulate various problems involving feature selection (Estévez et al., 2009), dependency analysis (Kraskov et al., 2004) and chaotic data identification (Fraser and Swinney, 1986). It measures the level of dependence between random variables; e.g., when evaluated for two variables, it takes a high value when one random variable contains much information about the other, signifying high dependence, while zero MI implies that the variables are independent. We show that the difference between the covariate distributions among the treated and untreated units can be directly evaluated MI, exploiting the fact that randomization in treatment assignment implies zero MI between covariates and the treatment variable. To the best of the authors’ knowledge, no MI based method has yet been employed for grouping observations (units) to achieve a particular group property – most likely due to the non-linearity in the expression defining MI. This paper tackles this challenge and offers the models and algorithms that make theoretical and practical advances in subset selection, or simply, matching for treatment effect estimation.

While some optimization methods have already been employed for the methodological developments in causal inference with observational data (Hansen, 2004), the use of mathematical programming techniques for statistics-oriented applications is still rare. One such notable contribution is due to Bertsimas and Shioda (2007) who re-framed the classification and regression problems using integer programming. Similar to their efforts, this paper motivates the use of non-linear integer programming techniques in causal inference research.

First, this paper identifies pathways for the effective use of information theoretic measures (namely, MI) in optimization problems. The presented theoretical analysis techniques for treating non-linearity are generic, and hence, can be adopted in other applications, where making assumptions on model/data structures is undesirable. More generally, this paper may open up venues for the application of mathematical programming and optimization techniques in information theory itself.

Second, this paper explains how MI can serve as the basis of a new form of covariate balance. The resulting MI-based matching method for selecting control groups for causal inference is flexible in that it can achieve solutions of pre-specified quality, with pre-set control group size, – moreover, it can optimize the latter. The presented algorithmic developments produce a matching heuristic that runs in polynomial (close to linear) time: it thus allows for causal effect estimation with large data sets that are nowadays becoming available through mining social networks, health records, etc. While this work is not the first effort to employ the information theoretic tools for the needs of causal inference Hainmüller (2012), it appears to be the first where mutual information is used as an optimization objective.

The paper is organized as follows. Section 2 explains the problem of causal inference with observational data, and motivates optimization-driven subset selection approaches to attacking it. Section 3 introduces a class of MI-based matching problems with different objectives. Section 4 derives optimality conditions for matched groups using MI, and presents the mixed integer programming-based and sequential selection-based matching algorithms that work to balance the covariate distributions across the treatment and control groups. Section 5 showcases the practical value of the MI-based matching approach by comparing the designed algorithms’ performance against the best previously existing matching methods. Section 6 discusses the MIM limitations and future research directions. Section 7 provides concluding remarks and discusses the promising extensions of this line of work.

2. Causal Inference with Observation Data

Observational studies are often the only source of information about a program, policy, or treatment. For example, people non-randomly choose to participate in economy-boosting programs, political movements, online activities such as post re-tweeting, question answering, service subscription, etc. In estimating any causal effect with such data, the researchers resort to the nonparametric data preprocessing, commonly referred to as matching (Ho et al., 2011).

In a real-world causal inference problem instance, a treatment group (a group of *treated* units) is typically smaller than the size of a pool of available *control* (untreated) units: a control *group* can then be selected by a researcher from this pool. When a matching procedure is performed (Rubin, 2006), a control group is designed to contain the units that are similar in covariate values to those in the treatment group (differing only on the treatment indicators). A rule-of-thumb for evaluating the success of a matching procedure posits that better balance on covariates leads to smaller bias in the treatment effect estimation (Rosenbaum and Rubin, 1985); here, balance is understood as similarity between the empirical covariate distributions in the treatment and control groups. Note that theoretically, if an optimal matching does not exist, no guarantee as to the bias reduction amount can be given.

Among different types of matching recipes, the first proposed and well-used one is the nearest neighbor matching (Rubin, 1973). It prescribes to pair up each observed treatment unit with a control unit so as to minimize a weighted distance between the units’ covariate vectors in each such pair. Mahalanobis distance is widely used for this purpose (Rubin, 1980), however, as a measure of divergence, it relies on elliptical distributions of covariates (Sekhon, 2008). Another widely-used recipe prescribes to match units on propensity score (Rosenbaum and Rubin, 1983) defined as the probability of a unit to receive treatment.

The Mahalanobis distance and propensity score based matching methods can be combined in various ways (Rubin, 2001; Diamond and Sekhon, 2013). However, such methods require assumptions on model and/or data structure. As such, true units’ propensity score values are generally unknown, and must be estimated via regression on covariates, which makes room for the researcher’s bias in data analysis (when one can “thinker with” with an analysis tool to make it output the result that one anticipates, perhaps subconsciously). This weakness has led to controversial exchanges between the authors analyzing the same data and reaching conflicting conclusions (Dehejia and Wahba, 1999, 2002; Smith and Todd, 2005b; Dehejia, 2005; Smith and Todd, 2005a).

Both the Mahalanobis distance and propensity score based matching methods are applied with the objective to minimize the differences between the units in the treatment group and the control group of the same size. In contrast, Iacus et al. (2012) introduce a new class of matching methods, the Monotonic Imbalance Bounding (MIB) matching, which looks to assemble matched control groups consisting of a sufficiently large number of observations with a fixed pre-set level of maximum allowed imbalance. Based on the imbalance level, an algorithm is designed to split the range of each covariate into several coarse categories, so that any exact matching algorithm can be applied to solve this discretized problem.

Methodologies for direct optimization of balance have been proposed by researchers just recently. Rosenbaum et al. (2007) introduce a *fine balance* method, where exact balance is sought on several categorized nominal covariates and approximate matching is conducted on the remaining ones. For the exact matching part, a matrix of Mahalanobis distance values across all pairs of treatment and control units is defined, and then the classic assignment algorithm is used to minimize the total distance. Nikolaev et al. (2013) introduce Balance Optimization Subset Selection (BOSS) approach, optimizing explicit measures of balance and treating several models with exact and heuristic methods. Zubizarreta (2012) builds mixed integer programming models to optimize covariate balance directly by minimizing the total sum of the distances between the treated units and matched control units. The latter two lines of research work to measure the difference between the covariate distributions in the treatment group and control pool by employing chi-square, correlations, quantiles and Kolmogorov-Smirnov statistics, which are fundamentally different from the information theory-driven approach developed in the present paper.

3. Problem Definition

This section begins by presenting several matching problems, using illustrative examples, and explains how mutual information can guide a matching process. Then, relying on the mutual information function, nonlinear integer optimization problems are formally stated.

3.1 Motivating the Use of Matching for Causal Inference: Problem Statements

Given a set of observed units that have been treated, termed a treatment pool, and a set of observed untreated units, termed a control pool \mathcal{C} , the causal inference problem objective is to evaluate the degree of influence of the treatment on the population units, termed treatment effect. For an observable unit u , let Y_u^1 (Y_u^0) denote a treated (untreated) response and t_u a treatment indicator (1 means treated, 0 means not treated). Per Rubin's model of causal inference, these responses are referred to as *potential outcomes*, reflecting the fact that it is impossible to observe both Y_u^1 and Y_u^0 on the same unit u (Holland, 1986). For this reason, in estimating the population-wide effects of a treatment, researchers have to resort to comparing the averages across the treatment and control groups (Holland, 1986). One commonly targeted quantity of interest in causal inference studies, and the one this paper focuses on, is the average treatment effect for the treated (ATT), $E(Y^1|t=1) - E(Y^0|t=1)$, i.e., the average effect of treatment on the units that actually receive it.

Assume that a treatment group, $\mathcal{T} : |\mathcal{T}| < |\mathcal{C}|$, is given (randomly selected from a treatment pool), so $E(Y^1|t=1)$ can be estimated directly. A decision has to be made about selecting a control subset $\mathcal{S} \subset \mathcal{C}$ so that the units in \mathcal{T} and \mathcal{S} can be compared. If the two groups have the same distribution of covariates, one can use the value $E(Y^0|t=0)$ over \mathcal{S} as an estimate of $E(Y^0|t=1)$ over the entire population (refer Rosenbaum and Rubin (1983) for more statistical fundamental work), and then, obtain an estimate of ATT.

The goal of a matching procedure is to ensure that the covariate distributions in the treatment and control groups are as similar as possible. The key insight this paper exploits is that, if a matching procedure is successful, then it should make it impossible to distinguish the treatment units from the control units based on the covariates, or, in other words, learn the treatment status of an observation based on the information captured by its covariate values. For example, randomization guarantees that the treated and control units are indistinguishable by making the covariate distributions in both groups be identical to that in the whole population; in other words, randomization tends to balance covariates on expectation. The information about the treatment captured in the covariates can be quantified as the MI between the covariates and the treatment variable, and more specifically, expressed using either the joint covariate distribution or the marginal covariate distributions. This paper considers both these formulations, separately.

Let K be the set of covariates. For an observed unit, the $|K|$ -dimensional covariate vector is denoted by $\mathbf{X} = \{X_1, X_2, \dots, X_{|K|}\}$. Assume that every covariate is or can be made categorical. The discretization of continuous covariates can be accomplished by applying a binning scheme (Iacus et al., 2012; Nikolaev et al., 2013) to divide the range of values for each such covariate into a fixed set of intervals. These categorical or interval bounds partition the covariate hyperspace into subspaces. Define a marginal bin as the largest subspace associated with an interval from a covariate's range, and a joint bin as a covariate subspace that is not further subdivided into any smaller subspaces. Then, by design, a joint bin is an intersection of $|K|$ marginal bins, and every observed unit is contained in one such bin. Let b denote a joint bin, B denote the set of all joint bins, m denote a marginal bin and M denote the set of all marginal bins. With the binning scheme, units with covariate values falling into the same joint bin can no longer be distinguished from each other.

(a) Treatment group		(b) Matching on joint distribution		(c) Matching on marginal distribution	
10	10	10	10	11	9
15		16		15	
	2		1(*)		11
	10		10		

Figure 1: Different control groups selected when the perfect matching cannot be achieved due to the lack of control units in bin (*).

Note that the matching problem is trivial if there exists a control group that perfectly matches the treatment group (i.e., the empirical covariate distributions in the groups are identical). Consider the treatment group in Figure 1a, where the two-dimensional grid (built for two covariates) contains in its cells, termed bins, the number of units found in each bin. If a perfect matching of the control units to the treated ones does not exist, then the selection of a good control group becomes challenging. When a joint distribution is used to capture the dependence between the treatment variable and the covariates, the joint bins can be viewed as being independent and all equally important for representing the distribution. A good matching method should select some control units to form a group with a minimum loss in the joint distribution (Figure 1b). On the other hand, since the joint bins are formed as the intersections of $|K|$ multiple marginal bins, the assumption of the independence between the bins may not be well justified. Then, one can take an alternative approach and select the control group that achieves the best matching in all the marginal distributions (Figure 1c), albeit sacrificing some information captured in the copula. In summary, the problems of matching on the joint or marginal distributions each have their pros and cons, which is why the ensuing computational studies use and compare them both for treatment effect estimation (see Section 5).

3.2 Nonlinear Integer Optimization Problems

The objective of our matching problem is to select such a subset $S \subseteq C$ that minimizes the MI between the treatment indicator and covariate vector over set $S \cup T$. The MI between t and \mathbf{X} (or all the X_k) is denoted by $I(t; \mathbf{X})$ if the computation is based on the full joint distribution of the covariates, and by $\sum_{k \in K} I(t; X_k)$ if the computation is based on the marginal distributions of individual covariates. Since these expressions have similar mathematical forms, only $I(t, X)$ will be used for notation in the following discussion, with X representing either \mathbf{X} or X_k , depending on the context. Note that $I(t, X)$ is an unambiguous notation for MI in a problem with a single covariate. Meanwhile, for a problem with multiple covariates, the units in the joint or marginal bins can be thought of as being projected

into a one-dimensional range, and hence, can also be treated as a single-covariate problem, albeit possibly with the additional constraints capturing the copula-based dependencies.

In order to express $I(t; X)$ using the empirical covariate distribution for the units in a given problem, denote the covariate value for any unit contained in bin b by the same variable X_b . Let $p(b)$ be the probability that a unit is treated, and $p(X_b)$ be the probability that its covariate value falls into bin b , with $\sum_{b \in B} p(X_b) = 1$. Also, let $p(X_b, t)$ be the probability that the covariate value of a unit with treatment indicator t falls into bin b . Then, the empirical MI between the treatment indicator t and covariate X can be expressed as

$$I(t; X) = \sum_{b \in B} \sum_{t \in \{0,1\}} p(X_b, t) \log \frac{p(X_b, t)}{p(X_b)p(t)}. \quad (1)$$

Let S_b (or T_b , C_b) denote the number of units in group S (or T , C) with covariate values falling into bin b . From the characteristics of the units in $S \cup T$, the probabilities in equation (1) can be estimated. If $t = 0$, $p(X_b, t) = \frac{S_b}{|S|+|T|}$ and $p(t) = \frac{|S|}{|S|+|T|}$; if $t = 1$, $p(X_b, t) = \frac{T_b}{|S|+|T|}$ and $p(t) = \frac{T_b}{|S|+|T|}$; also, $p(X_b) = \frac{T_b + S_b}{|S|+|T|}$.

In general, an MI estimation bias (which is different from the causal estimation bias discussed above) arises when the MI estimation is done based on a fixed limited number of observations (1) (Panzetti and Tereves, 1996; Ronitston, 1999). However, this paper analyzes the *empirical* distributions of the variables defined for the units in the control and treatment groups, which are available in their entirety, and hence, by (1), the MI is exactly given,

$$I(t; X) = \log(|S| + |T|) + \frac{1}{|S| + |T|} \left(\sum_{b \in B} S_b [\log S_b - \log(T_b + S_b)] - \log|S| \right) + \sum_{b \in B} T_b [\log T_b - \log(T_b + S_b)] - \log|T|. \quad (2)$$

Two alternative MI-based objective functions are analyzed in this paper: $I(t; \mathbf{X})$ and $\sum_{k \in K} I(t; X_k)$. Formally, a problem from the class of **Mutual Information based Matching (MIMM)** problems is stated:

Given: $|K|$ covariates; treatment group T ; control pool C with $|C| > |T|$; for each observed unit $u \in T \cup C$, the covariate vectors $\mathbf{X} = \{X_1, X_2, \dots, X_{|K|}\}$; segmented covariate space with joint bins $b \in B$ and marginal bins $m \in M$; a fixed integer N as the target control group size.

Objective: find a subset $S \subseteq C$ such that

- $|S| = N$ and $I(t; \mathbf{X})$ is minimized (MIM-Joint problem), or
- $|S| = N$ and $\sum_{k \in K} I(t; X_k)$ is minimized (MIM-Marginal problem).

A matching problem based on either joint or marginal covariate distribution(s) is designed with the decision variables returning the number of control units to be selected from each joint bin. Complete enumeration of feasible solutions in a problem with any of these two objective types would take an exponentially growing number of computing operations in the size of the control pool. Another challenge lies in the nonlinearity of the objective functions, further analysis of which is required in order to arrive at tractable mathematical programming formulations for MIM.

Theorem 1 *The decision version of the MIM-Marginal problem, $\min_{S \subseteq C} \sum_{k \in K} I(t; X_k)$ subject to $|S| = N$, is NP-complete.*

Proof See Appendix A. ■

4. Solution Approaches

This section investigates the properties of solutions with the minimum MI, with the goal of developing a method for treating the nonlinearity in the objective function of MIM problems. The derivations presented in this section unfold from the problem of minimizing $I(t; X)$ under the assumption that the contents of the bins capturing the distribution of covariate X are independent. The obtained insights are next extended to the MIM-Joint and MIM-Marginal problems. The mixed integer programming models and matching algorithms are then developed for selecting control subsets for MIM-Joint and MIM-Marginal problems.

4.1 Analyses of Optimality Conditions

Consider the expression of MI in (2): observe that since the treatment group is given, and the target control group size is known, $|S| = N$, several terms in equation (2) are constant. Also, $\sum_{b \in B} S_b \log|S| + \sum_{b \in B} T_b \log|T| = |T| \log|T| + |S| \log|S|$. Then, the term $\sum_{b \in B} S_b [\log S_b - \log(T_b + S_b)] + \sum_{b \in B} T_b [\log T_b - \log(T_b + S_b)]$ remains the only one to be considered for MI minimization. For the ease of presentation, this term can now be rewritten based not on the bins' aggregate contents but on the individual units' locations in the bins. Because all the observed units, whose covariate values X^u are contained in the same bin, have the same values of T_b and S_b , the minimization of (2) is equivalent to that of

$$R \equiv \prod_{u \in S, X^u \in b} \frac{S_b}{T_b + S_b} \prod_{u \in T, X^u \in b} \frac{T_b}{T_b + S_b}. \quad (3)$$

Consider the MIM problem instance illustrated by Figure 2, where $N - 1$ control units have been selected from the control pool into a control group (not necessarily optimally). In order to complete the selection of units into the control group, one last unit has to be selected from any of the bins with $S_b < C_b$. All such bins can be partitioned into three subsets: $B^1 = \{b : S_b < T_b\}$, $B^2 = \{b : S_b \geq T_b, T_b \neq 0\}$, $B^3 = \{b : T_b = 0\}$. Given that the last unit added to the control group is contained in bin b , let I_b denote the resulting MI between t and X , and R_b denote the resulting objective function value in (3).

The following two lemmas provide the guidelines for the optimal selection of the last unit to be included into the control group.

Lemma 2 *Consider an instance where an incomplete control group has $N - 1$ units in it, and three candidate units (that could complete it) are contained in bins $b_1 \in B^1$, $b_2 \in B^2$ and $b_3 \in B^3$, respectively. Then, $I_1 < I_2 < I_3$.*

Proof If the candidate unit from bin $b_1 \in B^1$ is selected, then the value of S_b increases by 1, while all the other S_b and T_b values stay unchanged. Thus, the objective function value in (3) becomes $R_1 = \hat{R} \left(\frac{S_{b_1} + 1}{T_{b_1} + S_{b_1} + 1} \right)^{S_{b_1} + 1} \left(\frac{T_{b_1}}{T_{b_1} + S_{b_1} + 1} \right)^{T_{b_1}} \left(\frac{S_{b_2}}{T_{b_2} + S_{b_2}} \right)^{S_{b_2}} \left(\frac{T_{b_2}}{T_{b_2} + S_{b_2}} \right)^{T_{b_2}}$,

$I(t; X)$, with $\frac{S_{b_1-1-\Delta-A}}{T_{b_1}} < \frac{S_{b_1-1-A}}{T_{b_1}} < \frac{S_{b_2-A}}{T_{b_2}} < \frac{S_{b_2+\Delta-A}}{T_{b_2}}$ holding for $\forall \Delta > 0$. Note again that b_1 and b_2 were arbitrarily picked. Such unit shuffling (i.e., removal and addition) operations can repeat until S is modified to become identical to S^* . Since in this process, $I(t; X)$ increases with every shuffle, then S^* could not be optimal, which is a contradiction. If $\frac{S_{b_1-1-A}}{T_{b_1}} = \frac{S_{b_2-A}}{T_{b_2}}$, then as a result of removing a unit from b_1 and adding one into b_2 , $I(t; X)$ will not change. In such a case, if the updated S becomes identical to S^* , then this means that S is an alternative optimal solution with the minimum $I(t; X)$. Otherwise, one can continue shuffling units, with $\frac{S_{b_1-1-\Delta-A}}{T_{b_1}} < \frac{S_{b_1-1-A}}{T_{b_1}} = \frac{S_{b_2-A}}{T_{b_2}} < \frac{S_{b_2+\Delta-A}}{T_{b_2}}$ holding for $\forall \Delta > 0$. Similarly, $I(t; X)$ will continue increasing, leading to S^* not being optimal, i.e., to a contradiction.

Theorem 4 provides the necessary and sufficient optimality conditions for the control groups with the minimum $I(t; X)$. Its value lies in condition (4) being linear in S_{b_i} unlike the minimization problem objective (2). Note, however, that Theorem 4 only works to determine whether a control group is optimal or not; it cannot be used to assess or compare the quality of suboptimal control groups.

In order to effectively apply Theorem 4 in practice, one would like to avoid the exhaustive traversal of bin pairs. Corollaries 5 and 6 allow for tackling this problem and provide a means for efficient optimal control group selection.

Corollary 5 Consider an instance of minimizing $I(t; X)$ where $N > \sum_{b \in \{b: T_b \geq 1\}} C_b$. Then, a control group S is optimal if it includes all the control units in all $b \in \{b : T_b \geq 1\}$.

Proof Follows directly from Lemma 2.

Corollary 6 Consider an instance of minimizing $I(t; X)$, where $N \leq \sum_{b \in \{b: T_b \geq 1\}} C_b$. Then, a control group S is optimal if and only if for every pair of bins b_1 and b_2 such that

$$b_1 \in \operatorname{argmax}_{b \in B} \left\{ \frac{S_b - 1 - A}{T_b} \right\} \quad (5)$$

and

$$b_2 \in \operatorname{argmin}_{b \in B} \left\{ \frac{S_b - A}{T_b} : |C_b - S_b| \geq 1 \right\}, \quad (6)$$

one has $\frac{S_{b_1-1-A}}{T_{b_1}} \leq \frac{S_{b_2-A}}{T_{b_2}}$, where $A \approx -0.47$.

Proof Consider any pair of bins, b_2 and b_1 , with $|C_{b_1} - S_{b_1}| \geq 1$. In order to determine if S is optimal, Theorem 4 prescribes to compare the left-hand and right-hand sides of inequality (4) for bins b_2 and b_1 . By the statement of this corollary, one has $\frac{S_{b_1-1-A}}{T_{b_1}} \geq \frac{S_{b_2-A}}{T_{b_2}}$ and $\frac{S_{b_2-A}}{T_{b_2}} \leq \frac{S_{b_1-1-A}}{T_{b_1}}$. Then, if inequality (4) holds for bins b_1 and b_2 , then it also holds for bins B_3 and B_4 , because $\frac{S_{b_3-1-A}}{T_{b_3}} \leq \frac{S_{b_1-1-A}}{T_{b_1}} \leq \frac{S_{b_2-A}}{T_{b_2}} \leq \frac{S_{b_4-A}}{T_{b_4}}$, and vice versa.

4.2 Mixed Integer Programming-Based Matching Algorithms

The optimality conditions in Theorem 4 and Corollary 6 allow one to construct an alternative formulation for the problem of minimizing $I(t; X)$ with $N \leq \sum_{b \in \{b: T_b \geq 1\}} C_b$, using the expression $\frac{S_b - 1 - A}{T_b}$. Note that this ratio is undefined for bins with $T_b = 0$; however, per Lemma 2, an optimal solution can contain control units from such bins only if all the available control units from other bins have been exhausted. In order to reformulate the objective function of minimizing $I(t; X)$, the expression $\frac{S_b - 1 - A}{T_b}$ should first be revised so that its denominator evaluates to a fixed number, $\alpha \in (0, 1)$, small enough to make the selection of control units from bins with $T_b = 0$ very costly. In order to search for a control group satisfying the condition in Corollary 6, the following optimization problem is formulated:

$$\min \left\{ \max_{b \in B} \frac{S_b - 1 - A}{T_b}, \alpha \right\}, \quad (7)$$

where α is a positive parameter small enough to distinguish $T_b = 0$ from other positive values of T_b , e.g., $\alpha = 0.01$.

By solving (7), one can work to construct an optimal control group through minimizing the maximum value of the function in (5). Having found an optimal solution to (7), one can check if (for this solution) the set in (5) is a singleton. If it is, then the condition in Corollary 6 holds. Otherwise, satisfying (7) may not be sufficient for satisfying Corollary 6, since it requires one to check every pair of bins in both the set in (5) and the set in (6). As an example of this situation, suppose that there exist two bins, b_1 and b_2 , in the set in (5), and a bin b_3 in the set in (6) such that $\frac{S_{b_1-1-A}}{T_{b_1}} = \frac{S_{b_2-1-A}}{T_{b_2}} > \frac{S_{b_3-1-A}}{T_{b_3}}$. If a unit is removed from b_1 while another unit is added into b_2 , the objective value of (7) does not improve because $\frac{S_{b_2-1-A}}{T_{b_2}}$ does not decrease. Thus, the optimization process based purely on solving (7) would terminate early without guaranteeing an optimal matching.

To handle the situation where the set in (5) is not a singleton for a solution of (7), an algorithm is developed to iteratively solve for the optimal number of units to be selected from each bin. In any iteration, if solving (7) returns multiple bins with values of $\frac{S_b - 1 - A}{T_b}$ equal to the maximum (over all the bins), then one of these bins is added to a ‘‘forbidden bin set’’, denoted by B^F and initialized at an empty set before the first iteration. Every time B^F is updated, problem (7) is reformulated, with all the bins that are not in B^F , and solved again in the next iteration. After several such iterations, once the set in (5) is found to be a singleton for a solution to (7), one can be sure that an optimal control group has been found. In order to ensure that the unit picking in a given iteration does not mess up the optimality achieved within any bin in the previous iteration(s), a bin with the smallest number of the treatment units in the non-singleton set (5) is always fixed first. In every iteration, (7) is solved as a mixed integer programming (MIP) model,

$$\min \quad q \quad (8)$$

$$s.t. \quad q \geq \frac{S_b - 1 - A}{\max\{T_b, \alpha\}} \quad \forall b \notin B^F, \quad (9)$$

$$\sum_{b \in B} S_b = N, \quad (10)$$

$$\begin{aligned}
 S_b &\leq C_b \quad \forall b \in B, & (11) \\
 S_b &\geq 0 \quad \forall b \in B, & (12) \\
 S_b &: \text{integer} \quad \forall b \in B, & (13) \\
 B &= \{b : C_b + T_b \geq 1\}. & (14)
 \end{aligned}$$

The decision variables in this MIP are the numbers of the control units, S_b , to be selected from each bin. Since it is only necessary to consider the bins in $\{b : C_b + T_b \geq 1\}$, then despite the fact that the total number of joint bins grows exponentially with the binning partition granularity, the number of the decision variables is bounded by $|T| + |C|$. The contents of the forbidden bin set B^F are updated iteratively in the described algorithm. The minimax optimization problem (7) is formulated with the objective function (8) and the constraint set (9). Constraint (10) ensures that the total number of units in the control group is equal to N . Constraints (11), (12) and (13) restrict the range of S_b to nonnegative integers not exceeding the number of available control units in each respective bin.

Note that for solving any MIM-Joint problem, since the bins' contents can be treated as being independent from each other, the described procedure for minimizing $I(t; X)$ can be exactly followed to minimize $I(t; \mathbf{X})$, with bins b in (8)-(14) being the joint bins.

Algorithm 1 MIP-based matching for MIM-Joint problem

- 1: Initialize the bin set $\{b : C_b + T_b \geq 1\}$ consisting of all the bins occupied by the units in $\mathcal{T} \cup \mathcal{C}$; compute T_b and C_b ; forbidden bin set $B^F = \emptyset$.
 - 2: Update and solve the corresponding instantiation of formulation (8)-(14) to obtain S_b for every bin b .
 - 3: If $\text{argmax}_{b \notin B^F} \{\frac{S_b - 1 - A}{T_b}\}$ is a singleton, go to step 4. Otherwise, add the bin with the smallest number of treatment units in $\text{argmax}_{b \notin B^F} \{\frac{S_b - 1 - A}{T_b}\}$ into set B^F , record and fix the optimal number of control units to be selected in it, and go to step 2.
 - 4: Construct a control group complying with the obtained values of S_b over all the initialized bins b . Stop.
-

However, for solving an MIM-Marginal problem, modifications to the above formulation and the algorithm are necessary due to the fact that the marginal bins cannot be assumed independent. The decision variables of an MIP-Marginal model are the numbers of control units to be selected into \mathcal{S} for every joint bin (b still denotes a joint bin), and constraints (10)-(14) remain a part of the optimization problem. Let m denote a marginal bin, M^F denote the forbidden marginal bin set, and T_m , C_m and S_m denote the number of all the treatment units, number of all the control units and number of the selected control units in m , respectively. Equation (9) is then replaced by (15). Also, an additional constraint (16) is added to the formulation to ensure that the number of units in any marginal bin equals the summed total number of units in all the corresponding joint bins.

$$q \geq \frac{S_m - 1 - A}{\max\{T_m, \alpha\}} \quad \forall m \notin M^F, \quad (15)$$

$$S_m = \sum_{b: X_m \in b} S_b \quad \forall m \in \{m : C_m + T_m \geq 1\} \quad (16)$$

Recall that in every iteration of solving MIM-Joint using Algorithm 1, one checks whether the set of bins with the maximum value of $\frac{S_b - 1 - A}{T_b}$ is a singleton. Because of the dependence between the contents of marginal bins, this condition by itself does not guarantees optimality for MIM-Marginal problem. Specifically, given a feasible solution to an MIM-Marginal problem, if exactly one marginal bin is found to achieve the maximum value of $\frac{S_b - 1 - A}{T_b}$ and this marginal bin is associated with covariate k , then because the bins in the same covariate are independent and according to Corollary 6, $I(t; X_k)$ is minimized. But the MI in other covariates might still be improved without changing $I(t; X_k)$, e.g., by adding and removing the same number of control units to/from the same marginal bin in covariate k . Thus, while solving for the optimal number of units in each marginal bin, and adding the marginal bins one-by-one to a forbidden bin set, one should not stop until the sets of bins with the maximum values of $\frac{S_b - 1 - A}{T_b}$ in all the $|K|$ covariates become singletons.

Algorithm 2 MIP-based matching for MIM-Marginal problem

- 1: Initialize the joint bin set $\{b : C_b + T_b \geq 1\}$ and the marginal bin set $\{m : C_m + T_m \geq 1\}$ consisting of all the bins occupied by the units in $\mathcal{T} \cup \mathcal{C}$; compute T_b , C_b , T_m and C_m ; forbidden bin set $M^F = \emptyset$.
 - 2: Update and solve the corresponding instantiation of formulation (8), (10)-(16) to obtain S_b for every joint bin b .
 - 3: If $\text{argmax}_{m \notin M^F} \{\frac{S_m - 1 - A}{T_m}\}$ is a singleton for every covariate, go to step 4. Otherwise, add the marginal bin with the smallest number of treatment units in $\text{argmax}_{m \notin M^F} \{\frac{S_m - 1 - A}{T_m}\}$ into set M^F , record and fix the optimal number of control units to be selected in it, and go to step 2.
 - 4: Construct a control group complying with the obtained values of S_b over all the initialized bins b . Stop.
-

4.3 Sequential Selection Matching Algorithms

Based on the optimality conditions in Theorem 4, Algorithms 1 and 2 are guaranteed to achieve best matched control groups for MIM-fixed and MIM-marginal problem instances. However, their MIPs may become difficult to solve for problems of large size, which, however, can be avoided by utilizing the result captured in Theorem 7, presented for the problem of minimizing $I(t; X)$.

Theorem 7 *If control group \mathcal{S} has the minimum $I(t; X)$ among all the control groups of size N , then a group with the minimum $I(t; X)$ among all the control groups of size $N + 1$ ($N - 1$) can be obtained from \mathcal{S} by adding to it a single unit from bin $b \in \text{argmin}_{b \in B} \{\frac{S_b - A}{T_b} : |C_b - S_b| \geq 1\}$ (removing from it a single unit from bin $b \in \text{argmax}_{b \in B} \{\frac{S_b - 1 - A}{T_b}\}$).*

Proof Let \mathcal{S}^+ denote a control group obtained from \mathcal{S} by adding to it a single unit from bin $b \in \text{argmin}_{b \in B} \{\frac{S_b - A}{T_b} : |C_b - S_b| \geq 1\}$. According to Lemma 3, the MI between \mathcal{T} and X over set $\mathcal{T} \cup \mathcal{S}^+$ is minimal among all the groups that can be built on \mathcal{S} . The following proof will show \mathcal{S}^+ is also globally optimal.

Let S_b^+ denote the number of control units selected into S^+ in bin b . Let b_1 and b_2 be two bins such that $b_1 \in \operatorname{argmax}_{b \in B} \{\frac{S_b^{+-A}}{T_b}\}$ and $|C_{b_2} - S_{b_2}^+| \geq 1$. If b_1 is the bin where S^+ has one more unit than S , then $S_{b_1}^+ - 1 = S_{b_1}$ and $S_{b_2}^+ = S_{b_2}$, and then $\frac{S_{b_1}^{+-A}}{T_{b_1}} = \frac{S_{b_1}^+ - A}{T_{b_1}} \leq \frac{S_{b_2}^+ - A}{T_{b_2}} = \frac{S_{b_2}^+ - A}{T_{b_2}}$. Note that by Theorem 4, because S is optimal, one has $\frac{S_{b_1}^+ - A}{T_{b_1}} \leq \frac{S_{b_2}^+ - A}{T_{b_2}}$. If b_2 is the bin where S^+ has one more unit than S , then $S_{b_2}^+ - 1 = S_{b_2}$ and $S_{b_1}^+ = S_{b_1}$, and then $\frac{S_{b_1}^{+-A}}{T_{b_1}} = \frac{S_{b_1}^+ - A}{T_{b_1}} \leq \frac{S_{b_2}^+ - A}{T_{b_2}} < \frac{S_{b_2}^+ - A}{T_{b_2}}$. If S and S^+ have the same numbers of units in both b_1 and b_2 , then $\frac{S_{b_1}^+ - A}{T_{b_1}} = \frac{S_{b_1}^+ - A}{T_{b_1}} = \frac{S_{b_1}^+ - A}{T_{b_1}} \leq \frac{S_{b_2}^+ - A}{T_{b_2}} = \frac{S_{b_2}^+ - A}{T_{b_2}}$. Therefore, by Corollary 6, S^+ is a group with the minimum $I(t; X)$ among all the control groups of size $N + 1$.

Let S^- denote a control group obtained from S by removing a single unit from bin $b \in \operatorname{argmax}_{b \in B} \{\frac{S_b^{-A}}{T_b}\}$. Let S_b^- denote the number of control units selected into S^- in bin b . Let b_1 and b_2 be two bins such that $b_1 \in \operatorname{argmax}_{b \in B} \{\frac{S_b^{-A}}{T_b}\}$ and $|C_{b_2} - S_{b_2}^-| \geq 1$. If b_2 is the bin where S has one more unit than S^- , then $S_{b_2}^- - 1 = S_{b_2}$ and $S_{b_1}^- = S_{b_1}$, and then $\frac{S_{b_1}^{-A}}{T_{b_1}} = \frac{S_{b_1}^- - A}{T_{b_1}} \leq \frac{S_{b_2}^- - A}{T_{b_2}} = \frac{S_{b_2}^- - A}{T_{b_2}}$. Note that due to the optimality of S , $\frac{S_{b_1}^{-A}}{T_{b_1}} \leq \frac{S_{b_2}^- - A}{T_{b_2}}$. If b_1 is the bin where S has one more unit than S^- , then $S_{b_1}^- - 1 = S_{b_1}$ and $S_{b_2}^- = S_{b_2}$, and then $\frac{S_{b_1}^{-A}}{T_{b_1}} = \frac{S_{b_1}^- - A}{T_{b_1}} \leq \frac{S_{b_2}^- - A}{T_{b_2}} < \frac{S_{b_2}^- - A}{T_{b_2}}$. Therefore, by Corollary 6, S^- is a group with the minimum $I(t; X)$ among all the control groups of size $N - 1$. ■

Theorem 7 provides a method for finding optimal control groups for MIM problems, without solving any programming models. One can iteratively build control groups of increasing sizes until an optimal solution of the desired size N is obtained. Each control group in this process results in the minimum value of MI among all the groups of the same size. Also, Theorem 7 provides establishes a relationship between the optimal subsets for problems with different target control group sizes. This result will be important for seeking the minimum MI in the problems with an unrestricted (flexible) control group size.

For the MIM-Joint problem, since its bins are treated as independent from each other, Theorem 7 directly applies, and Algorithm 3 guarantees to return an optimal solution. Note that Algorithm 3 is polynomial. In the worst case, it needs to make comparisons of $\frac{S_b^{+-A}}{T_b}$ for N multiples of the number of bins occupied by treatment units.

With the MIM-Marginal problem, a challenge arises due to the dependence between the marginal bins' contents. By comparing the terms $\frac{S_{b_m}^{+-A}}{T_{b_m}}$, one can identify the marginal bin to which a control unit should be added, but one still needs to pick some joint bin. Even further, since the marginal bins on the same covariate are independent from each other, the comparison of $\frac{S_{b_m}^{+-A}}{T_{b_m}}$ can reveal the most favorable marginal bin for each covariate, but the bin that lies at the intersection of those $|K|$ marginal bins may not contain any control unit that could be added to the control group. Algorithm 4 offers an organized way

Algorithm 3 Sequential selection matching for MIM-Joint problem

- 1: Initialize the joint bin set $\{b : C_b + T_b \geq 1\}$ consisting of all the bins occupied by the units in $T \cup C$; compute T_b and C_b ; set $S_b = 0$ for all b .
- 2: Select a bin $b \in \operatorname{argmin}_{b \in B} \{\frac{S_b^{+-A}}{T_b} : |C_b - S_b| \geq 1\}$, update S_b by adding 1.
- 3: If N units are selected, go to step 4. Otherwise, go to step 2.
- 4: Construct a control group complying with the obtained values of S_b over all the initialized bins b . Stop.

to achieve good (but not necessarily optimal) solutions to MIM-Marginal instances in the following manner. For each joint unit, $|K|$ ratios of the form $\frac{S_{b_m}^{+-A}}{T_{b_m}}$ are evaluated (one per covariate); these $|K|$ ratios are organized in a descending order; then, the joint bin with the lexicographically minimal ratio gets one more unit added to it. Again, the resulting Algorithm 4 is an approximate method, but it is polynomial, and in practice, is found to return solutions of high quality for diverse matching problem instances (see Section 5).

Algorithm 4 Sequential selection matching for MIM-Marginal problem

- 1: Initialize the joint bin set $\{b : C_b + T_b \geq 1\}$ consisting of all the bins occupied by the units in $T \cup C$; compute T_b and C_b ; set $S_b = 0$ for all b .
 - 2: Update $\frac{S_{b_m}^{+-A}}{T_{b_m}}$ for each marginal bin, and order all associated $\frac{S_{b_m}^{+-A}}{T_{b_m}}$ by values in descend sequence for each joint bin.
 - 3: Find a bin b in set $\{b : |C_b - S_b| \geq 1\}$ such that its ordered set of $\frac{S_{b_m}^{+-A}}{T_{b_m}}$ is lexicographically minimal; increase the value of the decision variable, S_b , corresponding to this bin, by 1.
 - 4: If N units are selected, go to step 5. Otherwise, go to step 2.
 - 5: Construct a control group complying with the obtained values of S_b over all the initialized bins b . Stop.
-

The complexity of Algorithm 4 depends on the number of covariates $|K|$, the number of marginal bins $|M|$, treatment group size $|T|$, control pool size $|C|$ and target control group size N . In the worst case, every unit (treated or control) occupies one unique joint bin, with each joint bin contributing to $|K|$ marginal bins. The storage of these data requires a space of size $\mathcal{O}(|K|(|T| + |C|))$. In the binning step, both the treatment group and control pool are traversed, with each unit being assigned to the appropriate marginal and joint bins; this operation takes $\mathcal{O}(|M|(|T| + |C|))$ time. In the matching step, all the occupied joint bins are traversed for the lexicographic comparison, which takes $\mathcal{O}(N(|T| + |C|)|K|^2)$ time.

5. Computational Analyses

This section presents the results of the computational experiments with synthetic and real-world (Lalonde, 1986) data sets, evaluating the performance of the MIM method in estimating causal effects, and comparing it to the BOSS method (Nikolaev et al., 2013) and the widely used propensity score based matching method (Rosenbaum and Rubin, 1983).

5.1 Algorithm Performance Assessment

In order to evaluate the performance of the MIM algorithms, a series of tests is first conducted with the data set designed by Sauppe et al. (2014), which was found challenging for the existing matching methods¹. This synthetic data set with 25 covariates contains 100 treatment units and 10,000 control units. All the covariate values are drawn from normal distributions with mean 0. All the treatment and control units have the same, highly nonlinear response function. Thus, by design, the average treatment effect for the treated (ATT) for the created population is zero.

The experiments were conducted with the number of the considered covariates varied in the range from 1 to 25. In optimizing the covariate balance, Sauppe et al. (2014) uniformly partitioned the range of the observed unit values in each covariate into 20 bins, and used Balance Optimization Subset Selection (BOSS) for control group selection. In order to limit the instances resulting in large MIP formulations, Sauppe et al. (2014) adopted a time limit heuristic. They achieved quite well balanced control groups; however, the limited computational efficiency remains the key challenge for the existing BOSS methods, especially when the data sets to make inference from are very large.

With the same settings as in Sauppe et al. (2014), this section compares the performance of the following matching methods: the Mahalanobis distance-based one, the propensity score-based one, the BOSS methods from Sauppe et al. (2014), and three MIM methods – MIM-Joint, MIM-Marginal MIP, and MIM-Marginal sequential selection. Note that the first two of these methods are widely used and included in several existing matching packages, e.g., MatchIt (Ho et al., 2011) and optmatch (Hansen and Klopfer, 2012). We also used Coarsened Exact Matching (CEM) in MatchIt (Ho et al., 2011) and fullmatch method in optmatch (Hansen and Klopfer, 2012). However, CEM excluded many treatment units from the matched treatment group in the experiments with five or more covariates, and thus, was not found suitable for ATT estimation. Also, under the pre-set control group size, the results of fullmatch were no different from those of the standard Mahalanobis distance or propensity score matching (depending on the selected parameter settings).

The MIP models for MIM were solved using CPLEX. To reduce the runtime in solving some large-size problems, a heuristic was applied that utilized the solution of sequential selection to convert MIP to an integer program. Generally, MIP-based methods (be it for BOSS or MIM) are time-consuming. However, the sequential selection algorithm always runs very quickly: it took about 7 seconds on average to find solutions for the instances with 25 covariates on a desktop with an Intel Xeon E5-2420 1.9GHz CPU and 16G RAM.

Table 1 presents the ATT estimates obtained with the considered methods for the instances with the varied number of covariates; Figure 3 provides a graphical illustration of the results. Recall that by design, the ATT is zero, so the closer an estimate is to zero, the better. Table 2, Figure 4a and Figure 4b report the Kolmogorov-Smirnov (KS) test statistic scores and associated p -values for checking whether the underlying covariate distributions differ in the treated and control groups. In Table 2, column ‘‘Avg’’ reports the average

1. The data set, named 25c10k, features a highly nonlinear response function and is available in full in the online supplement of Sauppe et al. (2014). The response function in it is $y = 0.8x_1(1.0 - x_1) + 0.5x_2(0.7 + x_1) + 0.27x_3x_2 - 0.9x_4^2 + 0.7x_5(0.5 + x_5)x_2 - 0.6x_6x_1 + 0.4x_7 - 0.8x_8 + 0.6x_9(0.9 - x_9) + 0.2x_{10}^2(0.3 - x_7) + 0.5x_{11}^2 - 1.4x_{12} - 0.8x_{13} - 0.9x_{14}^2 + 0.5x_{15}^2(0.1 + x_{15}) + 0.8x_{16} - 0.9x_{17}(0.2 - x_{13}) + 1.5x_{18} - 1.2x_{19}(1.0 + x_{11}) + 0.7x_{20}(0.8 - x_{20}) - 0.5x_{21} - 1.3x_{22}(1.0 + x_{22}) + 1.1x_{23} - 1.2x_{24}(1.0 + x_{23}) + 0.4x_{25}^2(0.6 - x_{25}) + N(0, 1)$.

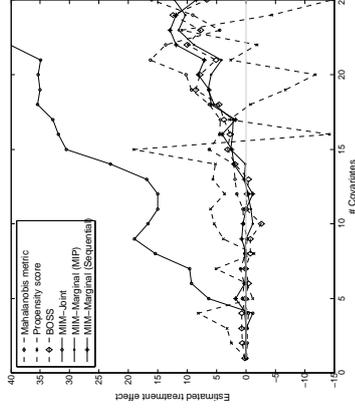

Figure 3: Trends for estimated treatment effects with different matching methods.

KS distance or p -value over all the covariates, and columns ‘‘Max’’ and ‘‘Min’’ report the maximum KS test statistic and minimum p -values, respectively. The smaller the KS score and the larger the p -value, the better balance is achieved.

In general, the MIM-Joint does not output accurate treatment effect estimates in the multi-covariate cases. If an exact or almost-exact matching solution exists, the MIM-Joint performs well, e.g., as in the one-covariate case. However, it is too sensitive to imbalance. As the number of the covariates grows, there remain fewer and fewer bins in which exact matching is possible, making the MIM-Joint formulation not-so-useful for most practical cases. At the same time, the marginal bin-based matching methods succeed in obtaining rather accurate ATT estimates.

Because of the high non-linearity of the response function, propensity score matching does not produce good ATT estimates, and there is no clear trend in its performance as it degrades. Mahalanobis metric matching, BOSS and two MIM-Marginal methods all produce similar estimates, with the MIM-Marginal MIP performing slightly better than the other methods. For the instances with fewer than 15 covariates, the estimates produced by these four methods are close zero (the true ATT value 0), but MIM-Marginal methods achieve much better balance in covariates judging by the KS test scores and p -values. For the

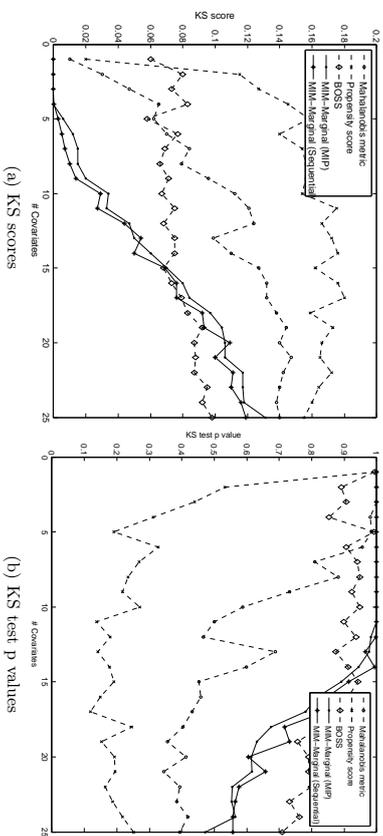

Figure 4: Trends for marginal balance quality for matching solutions.

instances with more than 15 covariates, the large number of bins makes for a large variance in the ATT estimates; comparing only the 100 treatment units and the 100 matched control units, one observes significant divergence between the ATT and its estimates obtained with all the methods, even though BOSS achieves the smallest KS scores. Considering both the matching quality and runtime performance, the MIM-Marginal with sequential selection algorithm comes out as the most efficient matching method for practical purposes.

5.2 The Experiences with Using Mutual Information as a Measure of Balance

The next set of experiments reveals that the MI function, employed as the objective in MIM, can be viewed as a surrogate measure of covariate balance. In order to trace the dependence between the MI values, obtained with different control groups, and the corresponding ATT estimates, an additional set of results is reported with the data set of Section 5.1 with 10 covariates. This set is also used to help us assess the impact of the MIM algorithm parameter settings on the matching quality.

For a large number of randomly generated control groups, the MI values were recorded together with the resulting treatment effect estimates (see Figure 5). Among these, four groups were found to have the MI less than 0.002 and at least 100 groups fell in each of the other intervals, into which the MI range was divided. Observe that, as the MI grows, the average of the ATT estimates tends to increase, and the standard deviation of the estimate values over the intervals grows as well. This confirms the premise that minimizing MI is a valid approach to guiding the matching process.

Another benefit of using MI lies in the ability to directly compare the matching problem solutions (control groups) of different sizes. Indeed, with the empirical covariate distribution in a given treatment group being fixed, the decision-maker has the freedom of selecting the target control group size. With the same binning scheme, the MI values obtained with

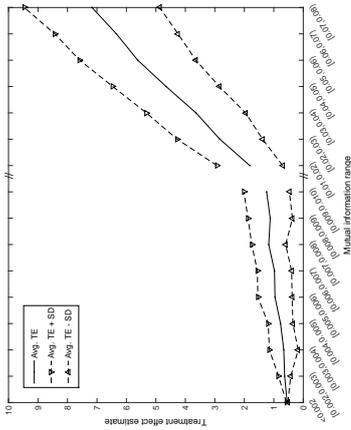

Figure 5: Trends for estimated treatment effects with different mutual information ranges.

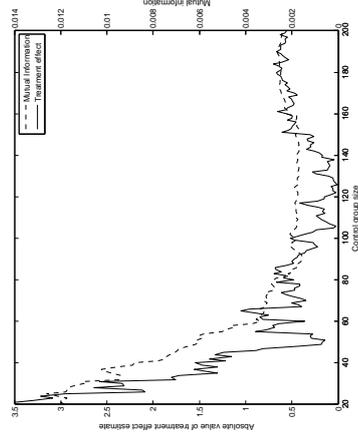

Figure 6: Trends for estimated treatment effects with different control group sizes.

the control groups of different sizes can be compared on the same scale, and hence, the optimization of the control group size becomes possible.

Figure 6 shows the MI values and MIM-based ATT estimates as functions of the control group size in the range from 20 to 200 (of control units). Despite the noise, it is clear that for some control group sizes, the MIM method achieves lower MI values, and simultaneously, higher quality estimates. Most importantly, the group size range, over which the MI is consistently low, coincides with the range, for which the estimates are closest to the truth. As such, in the considered example, the MI gets closer to zero with the lowest noise for the control group of sizes of about 130; a control group of this size returns the ATT estimate value of 0.099.

5.3 Experiences with Large Data Sets

In order to test the performance of the presented MIM methods with large data sets, three suitable real-world data sets were identified. The first one contains weighted census data extracted from the 1994 and 1995 Current Population Surveys conducted by the U.S. Census Bureau (Lichman, 2013): it contains 199,523 records with 41 demographic and employment related variables. The second one was extracted from the 1994 Census database (Lichman, 2013): it contains 32,561 records with 14 variables. The third one was collected in a study focusing on the National Supported Work Demonstration Program (NSW) (LaLonde, 1986), where the randomized job training experiment benchmark was obtained for the treatment effect: it contains 16,177 records with 8 variables. Of the three data sets, only the third one was originally created for a matching purpose. The aim of its creator was to examine how well the statistical methods would perform in trying to replicate the result of a randomized experiment (LaLonde, 1986). To design the test instances with the different number of covariates and varied control pool and treatment group sizes, the first data set was split into a treatment group and a control pool by “US citizenship” and “Business ownership” indicators, respectively; and the second data set was split by “US native” and “Doctorate degree” indicators, respectively. To apply the MIM-Marginal method, each continuous covariate’s range was partitioned into 20 bins, while all the categorical covariates kept their original categories. The target control group size was set equal to the treatment group size. Table 3 gives an aggregate view of the data sets’ specifics, and MIM results and runtimes.

Overall, the MIM-marginal method achieves very good balance across all the covariates. The average KS scores in all the tests are below 0.01 and the average p -values are all greater than 0.05. Note that since the treated and control data sets in every test are distinct, the results cannot be meaningfully compared across the test instances. For example, the best balance metric values were achieved in the experiment the “Business ownership” data set, even though it had more units and covariates than some other data sets. In the experiment with the “US citizenship” data set, the matching algorithm performed the worst. Indeed, this was a challenging test instance with the target control group size of 13,401, amounting to about 7.2% of the control pool: in such a case, the method is forced to pick non-optimal units to reach the target size, and hence, increases the imbalance. Note, however, that selecting such a large size control group might not be a good idea in practice anyway.

Excellent computational efficiency of the MIM-Marginal method is unparalleled by any other matching method, making it highly practical for data mining: its runtime requirement grows polynomially with the problem size. For example, the “US citizenship” test instance features a very large data set: compared to the training data set, it has 11.6 times more control units, 72.4 times more treated units, significantly larger target control group size, and 5 times more covariates. Yet, the MIM-Marginal runtime with the “US citizenship” is only 38,040 times larger.

The NSW data set is the most famous one in the matching literature, because an ATT benchmark of 1,794 has been separately obtained for the problem that it addresses (LaLonde, 1986). Deleija and Walha (1999) reported the estimate based on propensity score method was 1,691. Tam Cho et al. (2013) used BOSS and obtained the best individual matched solution resulting in the estimate of 1,741, as well as a set of alternative solutions, with mean 1,595 and standard deviation 281.

Table 3: Performance of the MIM-Marginal method on practical data sets.

	Census 94-95 (US Citizenship)	Census 94-95 (Business Ownership)	Extracted 94 (US Native)	Extracted 94 (Doctorate)	NSW 86 (Training)
Data	# Control Units	186,122	196,825	29,170	32,148
	# Treated Units	13,401	2,698	3,391	413
	# Continuous Covariates	8	8	6	6
	# Categorical Covariates	32	32	7	7
	# Marginal Bins	645	647	180	206
Balance	Avg KS	0.064	0.001	0.020	0.095
	Max KS	0.412	0.002	0.133	0.200
	Avg p-value	0.524	1.000	0.769	0.746
	Min p-value	0.109	1.000	0.518	0.459
	Avg MI	0.020	0.001	0.004	0.085
Time	Binning (seconds)	4,410.84	4,319.71	46.23	47.62
	Matching (seconds)	66,950.58	14,235.49	399.70	49.83

The runs of MIM-Marginal with the NSW data set produce a solution set with mean 1,851.5 and standard deviation 92.1. The average MI over this set is 0.002383; see the achieved balance metrics in Table 3. Importantly, if one removes the target control group size restriction and allows the MIM-Marginal to optimize over it, then a solution with 169 control units is obtained, with the MI of 0.001824 and ATT estimate set with mean 1,818.2 and standard deviation 91.2.

6. MIM Limitations and Future Research Directions

While the presented computational investigations demonstrate the utility of the MIM methodology, this work has its limitations and desirable directions for further improvement.

First, this paper does not offer an approach to the calculated selection of a binning scheme. The discretization of the covariate space affects the MI-based estimation outputs, however, the present MIM algorithms take the binning scheme as an input and do not work to perturb it to account for the differences in the shapes of the distributions of different covariates or the distances between bins. Intuitively, if the binning is coarse then the MIM cannot be expected to produce high quality solutions. While binning has been a point of research in multiple branches of optimization-based matching literature, the design of binning structures is still an open question. Another point, relevant to the MI based methods specifically, is that mutual information could be employed in its continuous form, in which case the accuracy of matching might be improved without the use of bins.

Second, in its current form as a non-parametric matching methodology, MIM does not differentiate the covariates by relative importance. Moreover, if there is any indispensable information of the form of the response function, covariate relationships, or covariate distributions that is not captured via binning, MIM may underperform. There may even exist circumstances where MIM would be consistently unsuccessful in producing accurate treatment effect estimates: such circumstances, as those exposed by Sauppe et al. (2014) with propensity score-based matching, are yet to be explored with MIM. In any case, prior to using MIM, the researcher must be careful about selecting the covariates to work with. Indeed, data preprocessing has been a topic of research worth much attention. Distance-based matching methods employ weights to emphasize the importance of balancing certain some covariates over others. The developments in propensity score-based methods led to the introduction of the concept of “fine balance”. Expanding the MIM research in a similar direction would add to its value.

Finally, by relaxing the integrality constraints of the MIM problems’ decision variables, one could produce linear (non necessarily integer) solutions allowing for insightful interpretations. The research in this direction might remedy the MIM dependence on binning.

7. Conclusion

The problem of causal inference based on observational data lies in selecting control units from a large unit pool to achieve control groups that are similar in covariate distributions to a given treatment group. To address this problem, this paper presents a set of methods with the objective of minimizing the mutual information between the treatment and covariates over the merged set of selected control and treatment units. Optimal conditions are derived

for matching on a single covariate and on the joint distribution of multiple covariates, allowing one to remove non-linear terms from the original mutual information formula and leading to a mixed integer programming formulation of the problem. A sequential selection algorithm is presented that runs in polynomial time and obtains optimal solutions for the problems of matching on a single covariate and matching on a joint distribution of multiple covariates.

Matching problems formulated in this paper for both joint distribution and marginal covariate distributions are analyzed theoretically, and the resulting solution methods tested computationally. The problem of group matching with marginal covariate distributions is proven to be NP-complete, and a fast sub-optimal algorithm is presented. The reported computational study shows that the matching problem formulation with marginal covariate distributions is more valuable than that based on the joint covariate distribution for obtaining accurate causal effect estimates in practice.

Appendix A. Proof of Theorem 1

The decision version of the matching problem on marginal covariate distributions with a fixed target control group size (MIM-Marginal) can be stated as follows. Given a treatment group \mathcal{T} , a control pool \mathcal{C} and a set of covariates X_k , $k \in K$. Let m be a marginal bin. (In this proof, it is not necessary to indicate which covariate this marginal bin partitions.) Given parameters γ and N , do there exist subsets $\mathcal{S} \subset \mathcal{C}$ such that $\sum_{k \in K} I(\mathcal{T}; X_k) \leq \gamma$ and $|\mathcal{S}| = N$?

First, it has to be proven that MIM-Marginal belongs to the NP class. For any given subset, one can check that the subset contains exactly N units, and then, calculate the mutual information value as in 2 to check if it is smaller or equal to γ . This can be completed in polynomial time, thus MIM-Marginal belongs to NP.

Second, it has to be proven that MIM-Marginal is NP-hard. Let δ_{um} be a binary variable, with $\delta_{um} = 1$ if unit u belongs to m , and 0 otherwise; let η_u be another binary variable, with $\eta_u = 1$ if unit u is selected into \mathcal{S} , and 0 otherwise. Let T_m denote the number of units in group \mathcal{T} with the values of covariates falling into bin m . If let $\gamma = 0$ and $N = |\mathcal{T}|$, then problem's objective is to check whether a perfect matching exists, i.e., whether the following constraints can be simultaneously satisfied:

$$\sum_{u=1}^{|\mathcal{C}|} \delta_{um} \eta_u = T_m \quad \forall m, \quad (17)$$

$$\sum_{u=1}^{|\mathcal{C}|} \eta_u = N, \quad (18)$$

$$\eta_u \in \{0, 1\} \quad \forall u,$$

where η_u is the decision variable. Constraint (17) ensures that a perfect matching is achieved in each covariate. Constraint (18) limits the size of a control group that can be selected. Note that, since $N = |\mathcal{T}|$ and each unit belongs to exactly $|K|$ marginal bins, then converting the constraints (17) and (18) into inequalities does not affect the optimal set of the problem, which can now be stated as

$$\sum_{u=1}^{|\mathcal{C}|} \delta_{um} \eta_u \geq T_m \quad \forall m,$$

$$\sum_{u=1}^{|\mathcal{C}|} \eta_u \leq N,$$

$$\eta_u \in \{0, 1\} \quad \forall u.$$

Now, the set cover (SC) problem can be reduced to MIM-Marginal problem. The SC problem is known to be NP-Hard (Garey and Johnson, 1979), and can be stated as follows. Given: an element set J , a collection I of finite subsets of J , and a fixed number n . Question: does I contain a subcollection of sets such that the total number of sets in this subcollection is at most n , and each element of J is included in at least one of the selected sets?

Let δ_{ij}^I be a binary variable, with $\delta_{ij}^I = 1$ if element j is included in set $I_i \in I$, and 0 otherwise; let η_i^I be another binary variable, with $\eta_i^I = 1$ if set I_i is selected, and 0 otherwise. The objective of the SC problem is to find η^I such that

$$\begin{aligned} \prod_{i=1}^{|I|} \delta_{ij}^I \eta_i^I &\geq 1 \quad \forall j \in J, \\ \sum_{i=1}^{|I|} \eta_i^I &\leq n, \end{aligned}$$

$$\eta_i^I \in \{0, 1\} \quad \forall i.$$

Define the following mapping: $T_m = 1$, $N = n$, $u = i$, $m = j$, $\delta_{um} = \delta_{ij}^I$ and $\eta_u = \eta_j^I$. Thus, the SC problem has a feasible solution if and only if the corresponding MIM-Marginal has a solution. The transformation required to execute the described mapping can be completed in polynomial time in the size of problem inputs. This completes the proof.

Appendix B. Properties of the Ratio Function $f(x, y)$ in Lemma 3

This Appendix analyzes how the values of function $f(x, y) = \frac{(1+\frac{1}{x})^x}{(1+\frac{1}{x+y})^x(1+\frac{1}{x+1})^x}$ can be compared for arbitrary inputs (x, y) , with $x > 0$ and $y > 0$.

Define function $g(x, y) \equiv \log f(x, y) = x \log(1 + \frac{1}{x}) - (x+y) \log(1 + \frac{1}{x+y}) - \log(1 + \frac{x}{1+x}) = x(\log(1+x) - \log(x)) - (x+y)(\log(1+x+y) - \log(x+y)) - (\log(1+x+y) - \log(1+x)) = (1+x) \log(1+x) - x \log(x) - (1+x+y) \log(1+x+y) + (x+y) \log(x+y)$.

Then, $\frac{\partial g}{\partial x} = \log(1+x) - \log(x) + \log(x+y) - \log(1+x+y)$ and $\frac{\partial g}{\partial y} = \log(x+y) - \log(1+x+y)$. Also, $\frac{\partial g}{\partial x} = \frac{1}{x} \frac{\partial f}{f}$ and $\frac{\partial g}{\partial y} = \frac{1}{y} \frac{\partial f}{f}$.

Because $x > 0$ and $y > 0$, one has $1+x+y > 1+x > 0$. Also, the logarithm is a monotonically increasing function with the monotonically decreasing slope, and hence, one has $\log(1+x) - \log(x) > \log(1+x+y) - \log(x+y) > 0$, which implies that $\frac{\partial g}{\partial x} > 0$ and $\frac{\partial g}{\partial y} < 0$. Moreover, since $f > 0$, then $\frac{\partial f}{\partial x} > 0$ and $\frac{\partial f}{\partial y} < 0$.

To sum up, the function of interest is monotonic along both x and y directions. This prompts one to study its contour lines over the feasible range of inputs (x, y) (Figure 7). Unfortunately, even though the contours look linear, it does not seem possible to produce a closed-form expression for them, of the form $f(x, y) = C$, with constant C .

Since $f(x, y) = C$ is approximately a straight line for every specific C , then the values of $f(x, y)$ under different inputs can be compared by evaluating the slopes of the corresponding contour lines: $\frac{\partial f}{\partial x} = -\frac{\frac{\partial f}{\partial y}}{\frac{\partial f}{\partial x}} = -\frac{\log(1+x) - \log(x)}{\log(1+x+y) - \log(x+y)} - 1$. Let $h(x, y) \equiv \frac{\partial f}{\partial x}$. For arbitrary

(x_0, y_0) and (x_1, y_1) such that $f(x_0, y_0) = f(x_1, y_1)$, one has $h(x_0, y_0) = h(x_1, y_1) = \frac{y_1 - y_0}{x_1 - x_0}$; thus, one can study the linearization $h(x, y)$ of $f(x, y)$. Since these contour lines are straight and do not intersect in the first quadrant, they must have a unique, common intersection point. Thus, one can write $h(x, y) = \frac{y - A_1}{x - A_2}$, where (A_1, A_2) are the coordinates of that unknown intersection point. By numerical approximation, one can derive that $(A_1, A_2) \approx (-0.47, 0)$.

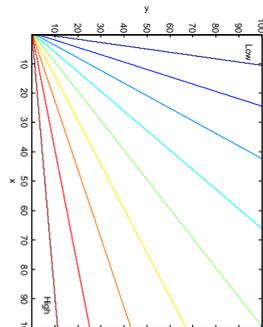

Figure 7: A sketch of the contour lines of $f(x, y)$ on (x, y) plane.

Due to the monotonicity of $f(x, y)$, the greater the slope of a contour line that the point (x, y) lies on, the smaller its corresponding function value. In other words, the smaller $h^{-1}(x, y) = \frac{y - A_1}{x - A_2}$, the smaller $f(x, y)$, and vice versa.

Appendix C. A Complete List of Notations Used

- T : Treatment group.
- C : Control pool.
- S : Control group.
- N : A given integer as the target control group size, i.e. $|S| = N$ for an eligible matched control group.
- u : An observable unit, $u \in \mathcal{T} \cup C$.
- t : Treatment indicator (1 means treated; 0 means not treated).
- Y_u^1 (or Y_u^0): Treated (or untreated) response of unit u .
- b : Joint bin. b_1, b_2 and b_3 are different bins used in proofs.
- B : Set of joint bins. B^1, B^2 and B^3 are different bin sets used in proofs. B^F is particular bin set in the MIP-based algorithm.
- m : Marginal bin.
- M^F : Set of marginal bins. M^F is particular bin set in the MIP-based algorithm.
- k : A covariate.
- K : Set of covariates.
- X_k : Value of covariate k .
- \mathbf{X} : Covariate vector $\{X_1, X_2, \dots, X_{|K|}\}$.
- X : A generalized covariate value to represent \mathbf{X} and X_k for writing convenience.
- X_k^u : Covariate value of unit u .
- X_k^m : Covariate value for any unit contained in bin b .
- X_m : Covariate value for any unit contained in marginal bin m .
- $p(t)$: Probability that a unit is treated.
- $p(X_k|t)$: Probability that a unit's covariate value falls into bin b .
- $p(X_k, t)$: Probability that the covariate value of a unit with treatment indicator t falls into

bin b .
 S_b (or T_b, C_b): Number of units in group \mathcal{S} (or \mathcal{T}, \mathcal{C}) with covariate values falling into bin b . $S_{b_1}, S_{b_2}, S_{b_3}, T_{b_1}, T_{b_2}, T_{b_3}$ and C_{b_2} are the number of units in different groups used in proofs.
 S_m (or T_m, C_m): Number of units in group \mathcal{S} (or \mathcal{T}, \mathcal{C}) with covariate values falling into marginal bin m .
 $I(t; X)$ (or $I(t; \mathbf{X}), I(t; X_k)$): Mutual information between treatment indicator and covariate value X (or covariate vector \mathbf{X} , covariate value X_k).
 I_b : Mutual information treatment indicator and covariate value if a unit in bin b is added to the control group, e.g. I_1, I_2 and I_3 .
 A and α : Constant numbers.
 q : Objective value of MIP models.

Abstract

The proliferation of online communities has attracted much attention to modelling user behaviour in terms of social interaction, language adoption and contribution activity. Nevertheless, when applied to large-scale and cross-platform behavioural data, existing approaches generally suffer from expressiveness, scalability and generality issues. This paper proposes trans-dimensional von Mises-Fisher (TvMF) mixture models for L_2 normalised behavioural data, which encapsulate: (1) a Bayesian framework for vMF mixtures that enables prior knowledge and information sharing among clusters, (2) an extended version of reversible jump MCMC algorithm that allows adaptive changes in the number of clusters for vMF mixtures when the model parameters are updated, and (3) an online TvMF mixture model that accommodates the dynamics of clusters for time-varying user behavioural data. We develop efficient collapsed Gibbs sampling techniques for posterior inference, which facilitates parallelism for parameter updates. Empirical results on simulated and real-world data show that the proposed TvMF mixture models can discover more interpretable and intuitive clusters than other widely-used models, such as k-means, non-negative matrix factorization (NMF), Dirichlet process Gaussian mixture models (DP-GMM), and dynamic topic models (DTM). We further evaluate the performance of proposed models in real-world applications, such as the churn prediction task, that shows the usefulness of the features generated.

Keywords: Mixture Models, von Mises-Fisher, Bayesian Nonparametric, Temporal Evolution, User Modelling

1. Introduction

Recent years have witnessed an increasing population of online peer production communities, such as *Wikipedia*, *Stack Overflow* and *OpenStreetMap*, which rely on contributions from volunteers to build knowledge, software artifacts and navigational tools, respectively. The growing popularity and importance of these communities requires a better understanding and characterisation of user behaviour so that the communities can be better managed, new services delivered, challenges and opportunities detected. For instance, by understanding the general lifecycles that users go through and the key features that distinguish different user groups and different life stages, we can develop

techniques for the following applications (Qin et al., 2014): (i) predict whether a user is likely to abandon the community; (ii) develop intelligent software to recommend tasks for users within the same life-stage. Moreover, social interaction and contribution behaviour of contributors plays a significant role in shaping the health and sustainability of online communities.

Different from text documents, which are commonly represented as term-frequency vectors, user behavioural data derived from online communities are generally represented as unit vectors. For instance, the level of linguistic change for online users in beer rating websites is denoted as a numeric feature (Danescu-Niculescu-Mizil et al., 2013). The measures used to quantify the centrality of members' positions in social networks are naturally numeric measurements (Rowe, 2013; Chan et al., 2010). The quality of questions, answers, and comments posted by users on Q&A sites are also numeric measures (Furtado et al., 2013). Existing approaches to identify patterns of user behaviour include principle component analysis, clustering analysis and entropy-based methods. However, these studies tend to be application-specific and suffer from scalability and generality issues due to the constrained feature set and the inherent limitations of the approaches employed. Additionally, the existing approaches fail to capture a mixture of user interests over time.

On the other hand, over the last decade, there have been significant advances in topic models which develop automatic text analysis techniques to discover latent structures from time-varying document collections (e.g. Blei and Lafferty (2006); Ahmed and Xing (2010); Gopal and Yang (2014)) and from time-varying user activity data in computational advertising (Ahmed et al., 2011). Topic models generally work well in document collections and user activity data where the data are represented in term-frequency format. However, many traditional topic models are not applicable to scenarios where the data are represented as unit vectors, e.g. the term frequency-inverse document frequency (tf-idf) representation of documents. Based on von Mises-Fisher (vMF) distributions, Gopal and Yang (2014) proposed dynamic clustering models which combine the success of normalised representation and flexibility of graphical models, and found that their proposed models can discover more intuitive clusters than existing approaches. Nevertheless, the vMF clustering models by Gopal and Yang (2014) did not take into consideration the dynamic evolution in the number of clusters and the birth/death of clusters over time. This work makes the following contributions:

- Extend the reversible jump Markov Chain Monte Carlo (RJCMC) algorithm (Richardson and Green, 1997) for directional distribution (i.e. vMF mixtures).
- Enhance the Bayesian and temporal vMF mixture models by Gopal and Yang (2014) by integrating with our extended version of RJCMC algorithm, which empowers both models with the ability to change the number of clusters automatically and to refine an inappropriate initialization of model parameters.
- Apply the model to analyse time-varying user behaviour data in online communities, in particular Wikipedia. Compared with previous works in this direction (Danescu-Niculescu-Mizil et al., 2013; Rowe, 2013; Furtado et al., 2013; Chan et al., 2010), the proposed model is more general and can be applied to model user behaviour in online communities (e.g. *Wikipedia*, *Stack Overflow*, *Twitter*, and *Facebook*) whenever user behavioural data are available.

We develop efficient collapsed Gibbs sampling techniques for the proposed models, which allows parallelism for parameter updates. The empirical comparison on synthetic and real-world data demonstrates that the proposed model can generate a more intuitive and interpretable clustering than other popular tools, such as k-means (Hartigan and Wong, 1979), non-negative matrix factorization

(NMF) (Lee and Seung, 1999), Dirichlet process Gaussian mixture models (DP-GMM) (Chang and Fisher III, 2013), and dynamic topic models (DTM) (Blei and Lafferty, 2006).

The rest of the paper is organised as follows. Section 2 provides an overview of related work, followed by an introduction to the von Mises-Fisher (VMF) distribution in Section 3. In Section 4, we present posterior inference for Bayesian von Mises-Fisher mixture models using collapsed Gibbs sampling techniques, model exploration using our extension of the reversible jump MCMC algorithm, and an online trans-dimensional von Mises-Fisher mixture model for time-varying user behavioural data. We demonstrate the empirical performance of the proposed models using synthetic and real-world data in Section 5. We then present an application of the features generated by the models for user clustering and churn prediction tasks, followed by discussion and concluding remarks in Section 6. The appendix includes detailed derivations for model inference and additional detailed analysis of the models.

2. Related Work

In this section, we provide an overview of the main lines of research underpinning this work, and discuss how our work leverages and advances the state-of-the-art techniques.

2.1 Modelling User Behaviour

Recently, researchers have approached the issue of modelling online user behaviour from different perspectives. They have so far focused on a separate set or combination of user properties, such as information exchange behaviour in discussion forums (Chan et al., 2010), social and/or lexical dynamics in online platforms (Danesescu-Niculescu-Mizil et al., 2013; Rowe, 2013), and diversity of participation behaviour on Q&A sites (Furrado et al., 2013). These studies generally employed either principle component analysis and clustering analysis to identify user profiles (Chan et al., 2010; Furrado et al., 2013) or entropy measures to track social and/or linguistic changes throughout user lifecycles (Danesescu-Niculescu-Mizil et al., 2013; Rowe, 2013). While previous studies provide insights into community composition, user profiles and their dynamics, they have limitations either in their definition of lifecycle periods (e.g. dividing each user’s lifetime using a fixed time-slicing approach (Danesescu-Niculescu-Mizil et al., 2013) or a fixed activity-slicing approach (Rowe, 2013)) or in the expressiveness of user lifecycles in terms of the evolution of expertise and user activity for users and online communities over time. Specifically, previous studies failed to capture a mixture of user interests over time. Different from previous works, Qin et al. (2014) employed topic modelling to study the evolving patterns of editor behaviour in Wikipedia. They found that a number of editor roles (e.g. Technical Experts, Social Networkers) prevail in the temporal Wikipedia editor activity data, and that the features inspired by latent space representation are beneficial for the churn prediction task. However, two major limitations exist in the topic model used by Qin et al. (2014): (1) the inability to deal with numeric behavioural data, and (2) the inability to capture the birth/death of topics over time.

2.2 Parametric and Nonparametric Temporal Models

Parametric models, such as Latent Dirichlet Allocation (LDA) by Blei et al. (2003) and non-negative matrix factorization (NMF) by Lee and Seung (1999), generally assume a fixed pre-specified number of topics a priori. This assumption inevitably involves computationally expensive model com-

parison using model selection criteria such as penalised log-likelihoods (AIC and BIC) in order to choose an appropriate number of topics for a given dataset. While log-likelihood related criteria have shown success in static settings, it is obvious that doing model selection for each time period may lead to a sub-optimal solution as it ignores the role of context in model selection, or alternatively, local optima problems in model selection at each epoch may accumulate and result in a globally suboptimal solution (Wang et al., 2007; Ahmed and Xing, 2008). Nonparametric models have been suggested in order to relax the assumption of a fixed number of topics for stationary and time-varying data.

There are two major lines of research for non-parametric models: (1) hierarchical Dirichlet process (HDP, Teh et al. (2006)), and (2) trans-dimensional (split/merge) approaches. The hierarchical Dirichlet process is a Bayesian nonparametric model that can be used to cluster groups of data with a potentially infinite number of components. In HDP based nonparametric models, each observation within a group is a draw from a Dirichlet process (DP) (or mixture model), the group-specific DPs can be linked together via another DP to ensure the sharing of mixture components between groups; the well-known clustering property of the DP can provide a nonparametric prior for the number of mixture components within each group (Teh et al., 2006). HDP has been widely used to learn recurring patterns (or “topics”) from document collections (e.g. the nonparametric Topics over Time (npTOT) model by Dubey et al. (2013)) and time-varying user activity data in computational advertising (the Time-Varying User Model (TVUM) by Ahmed et al. (2011)). In contrast, trans-dimension nonparametric models adapt the number of components by using a split-merge or birth-death mechanism while preserving certain properties (e.g. the zeroth, first and second moments) of the components. One well-known example of trans-dimensional models in this direction is the reversible jump MCMC algorithm by Richardson and Green (1997). Recently, Chang and Fisher III (2013) proposed a novel parallel restricted Gibbs sampling algorithm for Dirichlet process Gaussian mixture models (DP-GMM) with sub-cluster split/merge moves, and showed that their proposed sampler is orders of magnitude faster than other exact MCMC methods. In addition, based on the small-variance limit of Bayesian nonparametric von-Mises Fisher (VMF) mixture distributions (i.e. the birth-death strategy), Straub et al. (2015a) proposed two novel flexible and efficient k -means-like clustering algorithms for directional data such as surface normals in computer vision applications.

The evolving nature of data in different scenarios, such as scientific publications, news stories, and user query logs for search engines, has motivated research about temporal models to cope with the challenges of learning coherent and interpretable clusters over time (Ahmed and Xing, 2008). A good evolutionary model should be able to accommodate the dynamics of different aspects of the evolving clusters (Ahmed and Xing, 2008; Ahmed and Xing, 2010), specifically:

- Dynamics of cluster parameters. For example, in Gaussian mixture models, the mean and covariance for a mixture of Gaussians should be able to evolve according to a given time series model, such as Kalman filter that is used in the dynamic topic model (DTM) by Blei and Lafferty (2006). One principle for choosing a time series model for cluster parameters is to guarantee the smoothness of cluster parameters over time. One common strategy for this is to draw the cluster parameters at time epoch t from the corresponding distribution at the previous time $t - 1$ by leveraging the smoothness assumption over cluster parameters (Blei and Lafferty, 2006; Ahmed and Xing, 2008; Ahmed and Xing, 2010; Ahmed et al., 2011; Gopal and Yang, 2014).

- Popularity of clusters over time. The popularity of clusters can change over time due to the evolving nature of data. Existing models have relied on the rich gets richer assumption to capture the trends of clusters over time (Ahmed and Xing, 2008; Ahmed and Xing, 2010; Ahmed et al., 2011).
- Automatic change in the number of clusters over time. Non-parametric models allow the clusters to remain, die out or emerge over time (Ahmed and Xing, 2008; Ahmed and Xing, 2010; Ahmed et al., 2011; Dubey et al., 2013).

To the authors' knowledge, while many aforementioned models have focused on categorical data, only the models by Gopal and Yang (2014) are designed for \mathcal{L}_2 normalised data. However, their models are parametric which require using model selection criteria to choose the appropriate number of clusters. In this work, based on the smoothness assumption and the idea of reversible jump MCMC algorithm, we extend their Bayesian vMF mixture model and propose an online trans-dimensional von Mises-Fisher mixture model (OTvMFMM) for time-varying user behavioural data. The proposed model not only allows us to explore the model space for clusters, but more importantly, it can model time-varying clusters that are consistent.

2.3 Models for Directional Data

The existence of directional data in many applications has attracted much attention from researchers to build models for clustering on the hypersphere. There are three lines of research related to clustering directional data: (1) Euclidean geometry based algorithms, which ignore the geometric properties of the data and usually use Euclidean distance to measure similarity or distance between data points (e.g. k-means by Hartigan and Wong (1979), the Dirichlet process Gaussian mixture model (DPGMM) by Rasmussen (2000)); (2) spherical geometry based models, which consider the inherent geometry of the data and use cosine similarity to measure similarity between data points with standardized length (e.g. the von Mises-Fisher mixture model (vMFMM) by Banerjee et al. (2005), the Spherical Topic Model (SAM) for documents by Reisinger et al. (2010), the Dirichlet process vMFMM for radiation therapy data by Bangert et al. (2010), the temporal vMF mixture model (Temporal vMFMM) for time-varying document collections by Gopal and Yang (2014)); and (3) models that consider spherical geometry and anisotropic covariance of directional data, which capture the geometric properties and different variances in each dimension of the data (e.g. the Dirichlet process tangential Gaussian mixture model (DP-TGMM) by Straub et al. (2015b)).

Essentially, the vMF distribution can be considered as a variant of the multivariate Gaussian with spherical covariance on \mathbb{S}^{D-1} , parameterized by cosine distance rather than Euclidean distance (Reisinger et al., 2010). Cosine distance belongs to the normalized correlation coefficient and takes into consideration the directions of the \mathcal{L}_2 -normalized feature vectors when computing the similarity. Empirical studies have suggested the advantages of such type of directional measure over Euclidean distance in high-dimensional data particularly in information retrieval (Banerjee et al., 2005; Zhong and Ghosh, 2005; Reisinger et al., 2010; Gopal and Yang, 2014). The vMF distribution can capture the absence/presence of words, which the Multinomial distribution cannot. For instance, let $\theta = [1/3, 1/3, 1/3]$ be a Multinomial parameter (i.e. topic-word) vector, $d = [n_1, n_2, n_3]$ denote the number of occurrences of word w_1, w_2 and w_3 in document d . Assume we have two documents: $d_1 = [1, 1, 1]$ and $d_2 = [3, 0, 0]$. The two documents are more likely to be clustered together under $\text{Multi}(\cdot|\theta)$, whereas d_1 and d_2 have different densities under a corresponding $\text{vMF}(\cdot|\theta)$. The von Mises-Fisher mixture models have been shown to model sparse data (e.g. text) more accurately

than their Multinomial counterparts (Banerjee et al., 2005; Zhong and Ghosh, 2005; Reisinger et al., 2010; Gopal and Yang, 2014).

In this work, we employ the von Mises-Fisher distribution to deal with \mathcal{L}_2 normalised user behavioural data. Table 1 compares the capabilities of the proposed model and previous approaches. Although, it is possible to make the proposed OTvMFMM aiming for anisotropic covariance using Fisher-Bingham distribution as in (Kent, 1982; Peel et al., 2001), extensions to high-dimensional data are difficult due to the normaliser of the probability density function (Straub et al., 2015b).

Notation. In this work, random variables are denoted by capital letters (e.g. X, Y, Z), the observations of random variables (or vectors) are represented by the corresponding lower-case letters (e.g. x, y, z, μ). The set of N observations corresponding to random variable X is denoted by $\mathcal{X} = \{x_i\}_{i=1}^N$. The probability of a set of events A is denoted by $P(A)$, the probability of A given B (i.e. conditional probability) is written as $P(A|B)$. Probability density functions (for continuous random variables) and probability mass functions (for discrete random variables) are denoted by lower-case letters, e.g. $f(x), f(x|\theta)$, p or q , where θ is the set of parameters for a specific distribution. $p(\cdot)$ and $q(\cdot)$ are frequently used to represent the distributions of random variables. The set of observations or prior parameters is denoted by a calligraphic letter (e.g. $\mathcal{X}, \mathcal{Z}, \mathcal{B}$). The set of real numbers is denoted by \mathbb{R} ; the norm $\|\cdot\|$ denotes the \mathcal{L}_2 norm.

3. Preliminaries

This section provides a brief review of the finite von Mises-Fisher mixture models that facilitates a better understanding of the proposed models.

3.1 Von Mises-Fisher Distribution

A random D -dimensional unit vector x (i.e. $x \in \mathbb{R}^D$ and $\|x\|=1$) is said to follow the D -variate von Mises-Fisher (vMF) distribution if its probability density function is given by

$$f(x|\mu, \kappa) = C_D(\kappa) \exp(\kappa \mu^T x); \quad C_D(\kappa) = \frac{\kappa^{D/2-1}}{(2\pi)^{D/2} I_{D/2-1}(\kappa)} \quad (1)$$

where $\|\mu\| = 1, \kappa \geq 0, D \geq 2$; $C_D(\kappa)$ is the normalising constant, $I_{D/2-1}(\kappa)$ denotes the modified Bessel function of the first kind with order $D/2 - 1$ and argument κ . The concentration parameter,

κ , quantifies how tightly the distribution is concentrated around the mean direction μ . Note that $\mu^T x$ is the cosine similarity between x and μ and that κ plays the role of the inverse of variances (precision). The VMF distribution is used for clustering data on the unit hypersphere, whereas the Gaussian distribution is used for modelling data with a multivariate Normal distribution. A very useful property of the VMF distribution that we will use in this work is the preservation of the functional form under multiplication (Chiusso and Picci, 1998)

$$f(x | \mu_1, \kappa_1) f(x | \mu_2, \kappa_2) = f(x | \mu, \kappa), \quad \text{where } \mu = \frac{\kappa_1 \mu_1 + \kappa_2 \mu_2}{\|\kappa_1 \mu_1 + \kappa_2 \mu_2\|}, \quad \kappa = \|\kappa_1 \mu_1 + \kappa_2 \mu_2\| \quad (2)$$

Following [Mardia and Jupp \(2000\)](#), the sample covariance matrix of directional data, $\hat{\Sigma} = \{x_i\}_{i=1}^N$, about μ is defined by:

$$S = \frac{1}{N-1} \sum_{i=1}^N (x_i - \mu)(x_i - \mu)^T \quad (3)$$

which is an unbiased estimator of the covariance matrix (i.e. $\Sigma = S$).

3.2 Finite von Mises-Fisher Mixture

Let $f(x|\theta_h)$ denote a VMF distribution with parameters $\theta_h = (\mu_h, \kappa_h)$ for $h \in [1, H]$. [Banerjee et al. \(2005\)](#) proposed a simple VMF mixture model with the density of VMF mixtures given by

$$f(x | \{\pi_h, \theta_h\}_{h=1}^H) = \sum_{h=1}^H \pi_h f(x|\theta_h) \quad (4)$$

where $\Theta = \{\pi_h, \theta_h\}_{h=1}^H$ are the set of parameters to be estimated, π_h are the mixing proportions which are non-negative and sum to 1 (i.e. $0 \leq \pi_h \leq 1, \sum_h \pi_h = 1$). To sample a point from this mixture distribution, we randomly choose the h -th component with probability π_h , and then sample a point x following $f(x|\theta_h)$. Let $\mathcal{X} = \{x_i\}_{i=1}^N$ be a set of N data points that are sampled independently following Eq. (4). The mixture model in Eq. (4) can be interpreted as a missing data model if we introduce a set of membership variables (a.k.a. latent/hidden variables), $\mathcal{Z} = \{z_i\}_{i=1}^N$, for the data points [Celeux et al., 2006](#), indicating the specific VMF distribution from which the points are sampled. Each membership variable is a H -dimensional indicator vector, denoted by $z_i = (z_{i1}, \dots, z_{iH})$, $z_{ih} \in \{0, 1\}$, so that $z_{ih} = 1$ if and only if x_i is generated from the VMF distribution $f(\cdot | \{\pi_h, \theta_h\}_{h=1}^H)$, conditioning on z_i . The z_{ih} are assumed to be drawn independently from the following distributions

$$P(z_{ih} = 1) = \pi_h, \quad i \in [1, N], \quad h \in [1, H] \quad (5)$$

where $P(z_i) = \prod_{h=1}^H \pi_h^{z_{ih}}$. The density of the corresponding VMF mixture model with latent variables is given by [Celeux et al., 2006](#))

$$f(x_i, z_i | \{\pi_h, \theta_h\}_{h=1}^H) = P(z_i) f(x_i | z_i, \{\pi_h, \theta_h\}_{h=1}^H) = \prod_{h=1}^H \{\pi_h f(x_i | \theta_h)\}^{z_{ih}} \quad (6)$$

4. Proposed Trans-dimensional VMF Mixture Models

In this section, we first describe the Bayesian von Mises-Fisher mixture model (BvMFEMM) by [Gopal and Yang \(2014\)](#), including inference via efficient collapsed Gibbs sampling. We then present

our extension of the reversible jump MCMC algorithm for model exploration of Bayesian VMF mixtures, and introduce the proposed online trans-dimensional von Mises-Fisher mixture model for temporal user behavioural data.

4.1 Formulation of Bayesian VMF Mixture Model

The Bayesian VMF mixture model views the VMF mixture model parameters as random variables and introduces prior distributions on them. This brings advantages, such as sharing statistical strength among mean directions and flexibility for parameter estimation [\(Gopal and Yang, 2014\)](#). The Bayesian VMF mixture model is very similar to the Spherical Topic Model [\(Raisinger et al., 2010\)](#), the only difference lies in the fact that the former allows learning cluster-specific concentration parameters while the latter keeps the concentration parameters fixed. The generative process of BvMFEMM proceeds as follows:

1. Draw topic proportions, $\pi \sim \text{Dirichlet}(\{\alpha\})$, from a Dirichlet with hyperparameter α .
2. Draw topics, $\mu_h \sim \text{VMF}(\mu_0, C_0)$, on the unit hypersphere for $h \in [1, H]$.
3. Draw concentration parameters, $\kappa_h \sim \log\text{Normal}(\ln, \sigma^2)$, from a log-normal distribution with mean m and variance σ^2 for $h \in [1, H]$.
4. For each \mathcal{L}_2 normalised data point $x_i \in \{x_i\}_{i=1}^N$:
 - (a) Draw topic indicator $z_i \sim \text{Multic}(\cdot; \pi)$.
 - (b) Draw the data point $x_i \sim \text{VMF}(\mu_{z_i}, \kappa_{z_i})$.

where $\text{Multic}(\cdot; \pi)$ denotes a Multinomial distribution. The plate notation¹ of BvMFEMM is given in [Figure 1](#).

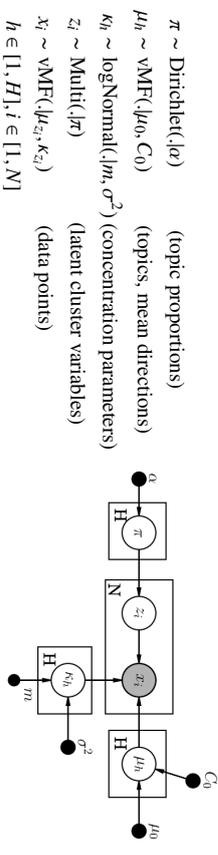

Figure 1: A graphical model representation of BvMFEMM, in which nodes represent random variables, arrows denote dependency among variables, and plates denote replication. Shaded nodes correspond to observed variables, unshaded nodes represent hidden variables, and solid nodes represent the hyperparameters.

For a fully Bayesian VMF mixture model, the number of components H is considered as a random variable for which a posterior distribution should be found. [Nobile \(2005\)](#) suggested that compared with a uniform prior, Poisson(1) prior is strongly biased towards low H and removes

¹ All the plate notations for graphical models used in this work were drawn using the Dact software provided by Dan Foreman-Mackey and David W. Hogg, available at: <http://dact-pgm.org/>

empty clusters. In other words, to some extent, the Poisson(1) prior acts as a penalty term that favors simpler models (i.e., ones with fewer components or factors), which is similar to the idea of AIC or BIC styled model comparison metrics (McLachlan and Peel, 2000; Gershman and Blei, 2012). Therefore, we use Poisson(1) as the prior distribution for H . From the topology of the Bayesian network, the likelihood of the complete-data, i.e., the joint distribution of all known and hidden variables that corresponds to the above generative process and the graphical model of BvMFMM in Figure 1 is given by

$$P(H, X, Z, \{\eta_h, \theta_h\}_{h=1}^H | \mathcal{B}) = P(H) f(\pi(\alpha)) \prod_{h=1}^H f(\mu_h | \mu_0, C_0) f(\kappa_h | m, \sigma^2) \prod_{i=1}^N P(z_i | \pi) f(x_i | \mu_{z_i}, \kappa_{z_i}) \quad (7)$$

where $P(H)$ is the prior probability for H , $f(\pi|\alpha)$ is the prior probability for π , $f(\mu_h | \mu_0, C_0)$ and $f(\kappa_h | m, \sigma^2)$ are the prior probabilities for μ and κ respectively. $P(z_i | \pi)$ are the mixed membership priors for each data point. $f(x_i | \mu_{z_i}, \kappa_{z_i})$ are the pdfs of each observation given its mixed membership and model parameters.

In Eq. (7), the global variables are the topics μ_h , the concentration parameters κ_h and the topic proportions π , while the local variables are the per-data point topic indicators z_i . The user specified prior parameters are $\mathcal{B} = \{\alpha, \mu_0, C_0, m, \sigma^2\}$. We can learn these prior parameters using empirical Bayes and do not rely on the user to set any prior parameters. Alternatively, to avoid potential problems such as overfitting caused by estimating too many parameters, we can specify the values for certain prior parameters with empirical knowledge and update other parameters using empirical Bayes method. The empirical Bayes estimate for prior parameters are given in Appendix B.

Following Heinrich (2009), we can obtain the likelihood of x_i as one of its marginal distributions by integrating out the distributions π , μ and κ and summing over z_i :

$$f(x_i | m, \sigma^2, \mu_0, C_0, \alpha) = \int_{\mu} \int_{\kappa} \text{Mult}(z_i | \pi) f(\pi | \alpha) \times \prod_{j=1}^N f(x_j | \mu_{z_j}, \kappa_{z_j}) f(\mu | \mu_0, C_0) f(\kappa | m, \sigma^2) \quad (8)$$

Finally, the corresponding likelihood of the complete data $\{x_i\}_{i=1}^N$ is given by:

$$f(\{x_i\}_{i=1}^N | m, \sigma^2, \mu_0, C_0, \alpha) = \prod_{i=1}^N f(x_i | m, \sigma^2, \mu_0, C_0, \alpha) \quad (9)$$

4.2 Inference via Collapsed Gibbs Sampling

Because the likelihood of x_i in Eq. (8) is not a closed form distribution, the exact inference of the high dimensional vMF mean parameter μ_h is generally intractable. Following Gopal and Yang (2014), we make use of the fact that the vMF distributions are conjugate and employ this fact to completely integrate out the mean parameters μ and the mixing proportions π . Therefore we need to infer only two sets of parameters $\{Z, \kappa\}$. The conditional distribution for z_i is given by²

$$\begin{aligned} \gamma(z_{ih}) &\equiv P(z_{ih} = i | Z_{-i}, \{x_j\}_{j=1}^N, \kappa, m, \sigma^2, \mu_0, C_0, \alpha) \\ &\propto (\alpha + n_{h,-i}) C_D(\kappa_h) \frac{C_D(\|\kappa_h \sum_{j \neq i} z_{jh} x_j + C_0 \mu_0\|)}{C_D(\|\kappa_h (x_i + \sum_{j \neq i} z_{jh} x_j) + C_0 \mu_0\|)} \end{aligned} \quad (10)$$

² We defer the detailed derivations to Appendix A. The $\gamma(z_{ih})$ can also be seen as the responsibility of component h for explaining the i -th data point, subject to $0 \leq \gamma(z_{ih}) \leq 1$, $\sum_h \gamma(z_{ih}) = 1$.

where Z_{-i} indicates excluding the contribution of the i -th data point. Similarly, the conditional distribution for κ_h is given by²

$$f(\kappa_h | X, Z, \kappa, m, \sigma^2, \mu_0, C_0) \propto \frac{C_D(\kappa_h)^{n_h} C_D(C_0)}{C_D(\|\kappa_h \sum_{j=1}^N z_{jh} x_j + C_0 \mu_0\|)} \log \text{Normal}(\kappa_h | m, \sigma^2) \quad (11)$$

where n_h is the number of observations assigned to the h -th component, $n_h = \sum_i z_{ih}$. Since the conditional distribution for κ_h is not a closed form, we need to use a step of MCMC sampling (with appropriate distribution) to draw κ_h .

Sampling for μ and π . Finally, we need to estimate (π, μ) . According to their usual definitions as directional distributions with vMF priors, applying Bayes' rule on the component $z_{ih} = 1$ in Eq. (9) gives the full conditional posterior density function for μ as follows:

$$\begin{aligned} f(\mu_h | \{x_i\}_{i=1}^N, \{z_i\}_{i=1}^N, \mu_0, C_0) &= \frac{\prod_{z_{ih}=1}^N f(x_i | \mu_h, \kappa_h) P(\mu_h | \mu_0, C_0)}{\int \prod_{z_{ih}=1}^N f(x_i | \mu_h, \kappa_h) P(\mu_h | \mu_0, C_0) d\mu} \\ &= \frac{\prod_{z_{ih}=1}^N C_D(\kappa_h) C_D(C_0) \exp\{\kappa_h^T x_i + C_0 \mu_0^T \mu_h\}}{Z_{\mu}} \propto \exp\left\{\kappa_h \sum_i z_{ih} x_i^T + C_0 \mu_0^T \mu_h\right\} \end{aligned} \quad (12)$$

where the updates for concentration parameter and mean direction of the posterior distribution are given by $\|\kappa_h \sum_i z_{ih} x_i + C_0 \mu_0\|$ and $\frac{\kappa_h \sum_i z_{ih} x_i + C_0 \mu_0}{\|\kappa_h \sum_i z_{ih} x_i + C_0 \mu_0\|}$, respectively. The update for the mean parameter μ_h is drawn from the von Mises-Fisher distribution in Eq. (12). Similarly, according to their usual definitions as Multinomial distributions with Dirichlet³ priors, applying Bayes' rule in Eq. (9) yields the posterior distribution for π :

$$\begin{aligned} f(\pi | \{x_i\}_{i=1}^N, \{z_i\}_{i=1}^N, \vec{\alpha}) &= \frac{\prod_{i=1}^N f(\pi | \vec{\alpha}) P(z_i | \pi)}{\int \prod_{i=1}^N f(\pi | \vec{\alpha}) P(z_i | \pi) d\pi} = \frac{1}{Z_{\pi}} \frac{1}{B(\vec{\alpha})} \prod_{h=1}^{(c_h-1)} \prod_{i=1}^N \pi_h^{z_{ih}} \\ &= \frac{1}{Z_{\pi}} \frac{1}{B(\vec{\alpha})} \prod_{h=1}^H \pi_h^{(\alpha_h + n_h - 1)} = \text{Dir}(\vec{\pi} | \vec{\alpha} + \vec{n}_h) \end{aligned} \quad (13)$$

Empirical Bayes estimate for prior parameters. When the user does not have enough information to specify the prior parameters, a general approach is to estimate them directly from the data. The prior parameters can be estimated by maximising the summation of the marginal likelihood of the data. The details are discussed in Appendix B.

4.3 Reversible Jump MCMC Algorithm

This section presents our extension of the reversible jump MCMC algorithm for directional distribution (i.e. vMF distribution), and then ensembles the new algorithm with the Bayesian vMF mixture model to allow adaptive change in the number of components, leading to trans-dimensional von Mises-Fisher mixture model (TvMFMM). Compared with BvMFMM, the proposed TvMFMM has the ability to explore multiple models simultaneously, which brings additional benefit - refining an inappropriate initialization of model parameters which parametric models are incapable of.

³ The Dirichlet distribution of order $H \geq 2$ with parameters $\alpha_1, \dots, \alpha_H > 0$ is given by: $\text{Dir}(\vec{\pi} | \vec{\alpha}) = \frac{1}{B(\vec{\alpha})} \prod_{h=1}^H \pi_h^{\alpha_h - 1}$, where $B(\vec{\alpha})$ is the multinomial Beta function defined as $B(\vec{\alpha}) = \frac{\prod_{h=1}^H \Gamma(\alpha_h)}{\Gamma(\sum_{h=1}^H \alpha_h)}$.

4.3.1 REVERSIBLE JUMP MOVE TYPES

Richardson and Green (1997) developed a methodology to perform Bayesian inference and model exploration for the univariate Gaussian mixture model by using the reversible jump MCMC algorithm, one sweep of which consists of six types of moves:

1. Updating the weights, π , following Eq. (13);
2. Updating the parameters, (μ, κ) , following Eq. (12) for μ and Eq. (11) for κ using MCMC sampling;
3. Updating the allocation, z , following Eq. (10);
4. Updating the hyperparameters, \mathcal{G} ;
5. Splitting one mixture component into two, or combining two into one;
6. The birth or death of an empty component.

Moves (5) and (6) involve changing H by 1 and making necessary corresponding changes to (μ, κ, π, z) , and are used for model exploration via the Metropolis-Hastings algorithm (**Metropolis et al., 1953; Hastings, 1970**). Assume that a proposed move type t , from $s=(Z, \Theta, H)$ to $\tilde{s}=(\tilde{Z}, \Theta', H+1)=f(s, u)$, where $f(s, u)$ is an invertible deterministic function (**Richardson and Green, 1997**). The reverse of the move (from \tilde{s} to s) can be accomplished by using the inverse transformation, so that the proposal is deterministic. The acceptance probabilities from s to \tilde{s} and from \tilde{s} to s are $\min\{1, A\}$ and $\min\{1, A^{-1}\}$ respectively, where

$$\begin{aligned} A &= \text{likelihood ratio} \times \text{prior ratio} \times \text{proposal ratio} \times \text{Jacobian} \\ &= \frac{f(\tilde{s}|X)}{f(s|X)} \times \frac{r_1(\tilde{s})}{r_1(s)q(u)} \times \left| \frac{\partial \tilde{s}}{\partial(s, u)} \right| \\ &= \frac{f(\tilde{s}|Z, \Theta', \mathcal{G}, H+1)}{f(s|Z, \Theta, \mathcal{G}, H)} \times \frac{P(H+1)P(\tilde{Z}, \Theta'| \mathcal{G}, H+1)}{P(H)P(Z, \Theta| \mathcal{G}, H)} \times \frac{r_1(\tilde{s})}{r_1(s)q(u)} \times \left| \frac{\partial \tilde{s}}{\partial(s, u)} \right| \end{aligned} \quad (14)$$

where $r_t(s)$ is the probability of choosing move type t when in state s , $q(u)$ is the density function of the auxiliary random variables u , the final term is the Jacobian determinant arising from the change of variables from (s, u) to \tilde{s} . The birth-death moves in (6) are supplements to the split-merge moves in (5) in a sense that the former are used for empty components, whereas the latter are used for non-empty components.

4.3.2 SPLIT AND MERGE MOVES

In the split-merge move in (5), the RJMCMC algorithm makes a random choice between splitting or merging existing component(s) with probabilities b_h and $d_h=1-b_h$ respectively, depending on h . Generally, $d_1=0$, $b_{H_{max}}=0$, and $b_h=d_h=0.5$ for $h \in [2, H_{max}-1]$. The merging proposal works by choosing two random components j_1 and j_2 , subject to the following constraint (adjacency condition)

$$\mu_{j_1} < \mu_{j_2}, \quad \text{with no other } \mu_s \in [\mu_{j_1}, \mu_{j_2}], s \neq j_1, j_2 \quad (15)$$

In the univariate setting, **Richardson and Green (1997)** proposed the constraints of preserving the zeroth, first and second moments of components before and after the split-merge move. In the multivariate setting, previous works (**Delaportas and Papageorgiou, 2006; Zhang et al., 2004**)

generally preserved the mean vectors and covariance matrices of components via spectral decomposition of the covariance matrices. The first two moments of vMF distribution are mean direction and concentration parameter. However, a direct extension of the RJMCMC algorithm (i.e. preserving the first two moments) for vMF mixture model would be impractical for the split-merge move. Recall that the concentration parameter controls how tightly the distribution is concentrated around the mean direction, which resembles the idea behind covariance matrices - groups of similar data points would result in high (variance) values in the diagonal of the matrices. In other words, to some extent, preserving the concentration parameter is similar to preserving the statistical properties of the covariance matrices. In this work, we make use of the spectral decomposition of the covariance matrices for the split-merge moves of vMF mixtures.

Let $\Sigma_h = V_h \Lambda_h V_h^T$ be the spectral decomposition of the covariance matrix, Σ_h , of the components in Eq. (6), where Λ_h is a diagonal matrix $\Lambda_h = \text{diag}(\lambda_{h1}, \dots, \lambda_{hD})$ with the eigenvalues of Σ_h in increasing order, and V_h is an orthogonal matrix with the eigenvectors of Σ_h in order corresponding to the eigenvalues in Λ_h . Let λ_{hd} denote the d -th largest eigenvalue of Σ_h . Let j_s be one of the H components to be considered to split, j_1, j_2 be the two proposed components, π_{j_1}, π_{j_2} , the corresponding weights, μ_{j_1}, μ_{j_2} , the corresponding mean vectors, $\kappa_{j_1}, \kappa_{j_2}$, the corresponding concentration parameters, and $\Sigma_{j_1}, \Sigma_{j_2}$, the corresponding variance matrices. Let $u_1, u_2 = (u_{21}, \dots, u_{2D})^T, u_3 = (u_{31}, \dots, u_{3D})^T$ be the $2D+1$ random variables needed to construct weights, means and eigenvalues for the split move. They are generated from beta and uniform distributions

$$\begin{aligned} u_1 &\sim \text{Beta}(2, 2), \quad u_2 \sim \text{Beta}(1, 2D), \quad u_{2d} \sim U(-1, 1) \\ u_{31} &\sim \text{Beta}(1, D), \quad u_{3d} \sim U(0, 1), \quad d \in [2, D] \end{aligned} \quad (16)$$

Let P be $D \times D$ rotation matrix with columns orthonormal unit vectors which has $D(D-1)/2$ free parameters. The elements in the lower triangular are randomly generated from uniform distribution $U(0, 1)$, and the elements in other positions are determined by the fact that P is an orthonormal matrix. Then, the proposed split moves are given by

$$\begin{aligned} \pi_{j_1} &= u_1 \pi_{j_s}, \quad \pi_{j_2} = (1 - u_1) \pi_{j_s} \\ \mu_{j_1} &= \mu_{j_s} - \sqrt{\frac{\pi_{j_1}}{\pi_{j_2}}} \left(\sum_{d=1}^D u_{2d} \sqrt{\lambda_{j_s, d}} V_{j_s, d} \right) \\ \mu_{j_2} &= \mu_{j_s} + \sqrt{\frac{\pi_{j_2}}{\pi_{j_1}}} \left(\sum_{d=1}^D u_{2d} \sqrt{\lambda_{j_s, d}} V_{j_s, d} \right) \\ \lambda_{j_1, d} &= u_{3d} (1 - u_{2d}^2) \lambda_{j_s, d} \frac{\pi_{j_1}}{\pi_{j_s}} \\ \lambda_{j_2, d} &= (1 - u_{3d}) (1 - u_{2d}^2) \lambda_{j_s, d} \frac{\pi_{j_2}}{\pi_{j_s}} \\ V_{j_1} &= P V_{j_s}, \quad V_{j_2} = P^T V_{j_s}, \quad d \in [1, D] \\ \mu_{j_1} &= \frac{\mu_{j_1}}{\|\mu_{j_1}\|}, \quad \mu_{j_2} = \frac{\mu_{j_2}}{\|\mu_{j_2}\|} \quad (\text{Normalized mean directions}) \end{aligned} \quad (17)$$

It can be readily shown that these are indeed valid, with weights positive and covariance matrices positive-definite. Now we need to check whether the adjacency condition in Eq. (15) is satisfied. If the condition is satisfied, we reallocate those with $\arg \max_h \gamma(z_{ih}) = j_s$ to j_1 or j_2 using the formula

$P(z_{ih} = 1 | \dots) \propto \pi_{ih} f(x_i | \pi_{ih}, \theta_{ih})_{h=1}^H$. If the test is not passed, then the move is rejected in order to preserve the reversibility of the split/merge move.

The corresponding merge move is specified by the following expressions

$$\begin{aligned} \pi_{j_1} &= \pi_{j_1} / \pi_{j_2} \\ \pi_{j_2} &= \pi_{j_1} + \pi_{j_2} \\ \pi_{j_1} \mu_{j_1} &= \pi_{j_1} \mu_{j_1} + \pi_{j_2} \mu_{j_2} \\ \pi_{j_1} [(\mu_{j_1}^T V_{j_1,d})^2 + \lambda_{j_1,d}] &= \pi_{j_1} [(\mu_{j_1}^T V_{j_1,d})^2 + \lambda_{j_1,d}] + \pi_{j_2} [(\mu_{j_2}^T V_{j_2,d})^2 + \lambda_{j_2,d}] \end{aligned} \quad (18)$$

$$\mu_{j_1} = \frac{\mu_{j_1}}{\|\mu_{j_1}\|} \quad (\text{Normalized mean directions})$$

The solutions of $u_1, u_2, u_3, \lambda_{j_1,d}, V_{j_1}$ and P are as follows:

$$\begin{aligned} u_1 &= \pi_{j_1} / \pi_{j_2} \\ u_{2,d} &= (\mu_{j_1}^T V_{j_1,d} - \mu_{j_2}^T V_{j_1,d}) / \left(\sqrt{\lambda_{j_1,d} \frac{\pi_{j_1}}{\pi_{j_2}}} \right) \\ u_{3,d} &= \pi_{j_1} \lambda_{j_1,d} / [\pi_{j_1} \lambda_{j_1,d} (1 - u_{2,d}^2)] \\ \lambda_{j_1,d} &= \pi_{j_1}^{-1} \left\{ \pi_{j_1} [(\mu_{j_1}^T V_{j_1,d})^2 + \lambda_{j_1,d}] + \pi_{j_2} [(\mu_{j_2}^T V_{j_2,d})^2 + \lambda_{j_2,d}] - (\mu_{j_2}^T V_{j_1,d})^2 \right\} \\ V_{j_1} &= \frac{1}{2} (P^T V_{j_1} + P V_{j_2}), d \in [1, D] \end{aligned} \quad (19)$$

For successful merge move, we have to reallocate those observations x_i with $\arg \max_h \gamma(z_{ih}) = j_1$ or $\arg \max_h \gamma(z_{ih}) = j_2$ to j_1 . At this point, we calculate the acceptance probabilities of split and merge moves: $\min(1, A)$ and $\min(1, A^{-1})$ according to Eq. (14), where

$$A = \frac{P(H+1, \mathcal{Z}, \Theta, \mathcal{B}) \int d_{H+1}}{P(H, \mathcal{Z}, \Theta, \mathcal{B}) b_H P_{alloc} q(t)} \times \left| \det \left(\frac{\partial \Sigma}{\partial (\lambda, V)} \right) \right| \times | \det(\mathcal{J}) | \quad (20)$$

where P_{alloc} is the probability of making this particular allocation of data to j_1 and j_2 given by (Bouguila and Elguebaly, 2012)

$$P_{alloc} = \frac{\prod_{z_{ij}=1} \pi_{j_1} f(x_i | \mu_{j_1}, \kappa_{j_1}) \prod_{z_{ij}=2} \pi_{j_2} f(x_i | \mu_{j_2}, \kappa_{j_2})}{\prod_{z_{ij}=1} \pi_{j_1} f(x_i | \mu_{j_1}, \kappa_{j_1}) + \prod_{z_{ij}=2} \pi_{j_2} f(x_i | \mu_{j_2}, \kappa_{j_2})} \quad (21)$$

The $\frac{\partial \Sigma}{\partial (\lambda, V)}$ term is the Jacobian of the transformation from the Σ of the components to the eigenvalues and eigenvectors (Dellaportas and Papageorgiou, 2006); \mathcal{J} is the Jacobian of the parameter transformation. The calculation of the Jacobian terms and the factorization of $P(H, \mathcal{Z}, \Theta, \mathcal{B})_{(x_i)_{i=1}^N}$ are given in Appendix C and Appendix D.

It is worth noting that it can be computationally inefficient to calculate the Jacobian term $\left| \det \left(\frac{\partial \Sigma}{\partial (\lambda, V)} \right) \right|$ particularly for high-dimensional data. To solve this issue, Zhang et al. (2004) proposed a simplified multivariate Gaussian mixture model (GMM) with reversible jump MCMC algorithm, which imposed a common eigenvector matrix for the covariance matrices of all components. Their experiments showed that their proposed simplified GMM obtains good estimates on general GMMs, especially on their model exploration. In this work, we follow Zhang et al. (2004) and use a common eigenvector matrix for the covariance matrices of all the vMF components when splitting/merging the components.

Algorithm 1: Collapsed Gibbs sampling for TvMFMM

Input:

Data points: $\mathcal{X} = \{x_i\}_{i=1}^N$ (Unit vectors on the hypersphere)
 Prior parameters: $\mathcal{B} = (\alpha, \mu_0, C_0, m, \sigma^2)$
 Initial number of components: H

Output:

Estimation of model parameters
 1 Initialise parameters: $\pi = \{\pi_h\}_{h=1}^H, \mu = \{\mu_h\}_{h=1}^H, \kappa = \{\kappa_h\}_{h=1}^H$;
 2 Initialise latent variables $\mathcal{Z} = \{(z_{ih})_{h=1}^H\}_{i=1}^N$ arbitrarily;
 3 $n \leftarrow 0$;
 4 **while** *NotConverged* **do**
 5 Sample a random variable u from Uniform(0,1): $u \leftarrow U(0,1)$;
 6 **if** $u \leq b_{birth-death}$ **then**
 7 Create or delete an empty component;
 8 **else if** $u \leq b_{birth-death} + b_{split-merge}$ **then**
 9 Split one nonempty component into two, or merge two into one;
 10 **else**
 11 Sample latent variables, z_{ih} , following the parallel sampling in Algorithm 2;
 12 **end if**
 13 **if** *Accept the birth-death/split-merge move or Update latent variables* **then**
 14 Sample the weights, π_h , following Eq. (13);
 15 Sample the mean directions, μ_h , following Eq. (12);
 16 Sample the concentration parameters, κ_h , using MCMC sampling;
 17 Sample hyperparameters;
 18 **end if**
 19 $n \leftarrow n + 1$;
 20 Check for convergence;
 21 **end while**
 22 Employ the k-means style algorithm by Celeux et al. (2000) to solve label switching problem for RJMCMC chains for mixture model estimation;

4.3.3 BIRTH AND DEATH MOVES

Our birth-death move can be adopted straightforwardly from the one used in (Richardson and Green, 1997; Zhang et al., 2004). We first make a random choice between birth or death of an empty component with the same probabilities b_k and d_k as above. For a birth, a mixing weight and parameters of the proposed component are drawn using the following distributions

$$\pi_{j_1} \sim \text{Beta}(1, H), \mu_{j_1} \sim \text{vMF}(\mu_0, C_0), \kappa_{j_1} \sim \text{logNormal}(\ln, \sigma^2) \quad (22)$$

It is necessary to rescale the existing weights in order to ‘make space’ for the new component using $\pi_j \gamma = \pi_j(1 - \pi_{j_1})$, so that $\sum \pi_h = 1.0$. The acceptance probabilities for birth and death moves are

$\min(1, A)$ and $\min(1, A^{-1})$ respectively, where

$$\begin{aligned} A &= \frac{P(H+1)}{P(H)} \times \frac{P(\alpha^2(H+1, \alpha))}{P(\pi(H, \alpha))} \times \frac{r(\beta)}{r(\beta)} \times \left| \frac{\beta^{\beta}}{[\beta(s, u)]} \right| \\ &= \frac{P(H+1)}{P(H)} \times \frac{\prod_{h=1}^{L(H+1, \alpha)} \pi_{r_h}^{m_h + \alpha - 1}}{\prod_{h=1}^{L(H, \alpha)} \pi_{r_h}^{m_h + \alpha - 1}} \times \frac{d_{H+1}}{(H_0 + 1)^{b_H}} \times \frac{1}{g_{1,H}(\sigma_{r_j})} \times (1 - \pi_j)^{H-1} \\ &= \frac{P(H+1)}{P(H)} \times \frac{1}{\prod_{i=1}^H \pi_{r_i}^{m_i + \alpha - 1}} \times \frac{d_{H+1}}{(H_0 + 1)^{b_H}} \times \frac{1}{g_{1,H}(\sigma_{r_j})} \times (1 - \pi_j)^{H-1} \end{aligned} \quad (23)$$

In Eq. (23), H_0 is the number of empty components, $g_{1,H}(\cdot)$ is the probability density function of $\text{Beta}(1, H)$ distribution.

In our implementation of the reversible jump MCMC algorithm, rather than passing through each of the six moves deterministically, following (Andrieu et al., 2003; Dellaportas and Papageorgiou, 2006), we choose to randomly select one of the three moves (i.e. Moves (3), (5) and (6)) with fixed probabilities in each iteration. We have used (1., 4., 5) as probabilities to choose the three moves respectively. This allows some extra tuning which can potentially speed up the convergence and improve the mixing of the RJMCMC chain. The resulting collapsed Gibbs sampling procedure of TVMFMM is summarised in Algorithm 1. Note that we employ parallel sampling to update the latent variables in Algorithm 2, which is very similar to state synchronization in the parallel topic models proposed by Smola and Narayanaswamy (2010).

Algorithm 2: Parallel sampling for latent variables \mathcal{Z}

```

1 function INFERENCE( $X, \mathcal{Z}, \alpha, \mu_0, C_0, m, \sigma^2$ )
2   Initialise  $\gamma^{old}(z_{ih}) = \gamma(z_{ih})$  for all  $i, h$ ;
3   while Sampling do
4     Read global stats  $\{n_h\}_{h=1}^H$ 
5     for every component  $h \in [1, H]$  do
6       Sample a latent,  $z_{ih}$ , conditioned on all other labels following Eq. (10).
7     end
8     Normalise local latent variables for data point  $x_i$ :
9        $\gamma(z_{ih}) = \frac{\gamma(z_{ih})}{\sum_{h=1}^H \gamma(z_{ih})}$  for every  $h \in [1, H]$ 
10    Lock  $\{n_h\}_{h=1}^H$  globally.
11    Update  $n_h = n_h + [\gamma(z_{ih}) - \gamma^{old}(z_{ih})]$  for every  $h \in [1, H]$ .
12    Release  $\{n_h\}_{h=1}^H$  globally.
13  end
    
```

4.4 Online Trans-dimensional vMF Mixture Model

This section presents the procedures of collapsed Gibbs sampling for the proposed online trans-dimensional von Mises-Fisher mixture model (OTVMFMM). Given data, $X = \{x_i, i=1, \dots, T\}$, where $x_i \in \mathbb{R}^D$, OTVMFMM assumes the generative model for the data given in Figure 2.

The user specified prior parameters are $\mathcal{B} = (\alpha, \mu_{0,0}, C_0, m, \sigma^2)$. To some extent, the prior parameter C_0 acts as a smoothing term to ensure that the parameters of the next time epoch to be similar to the previous one. Following Gopal and Yang (2014), the concentration parameters of the clusters at time t ($k_{t,i}$) are drawn from a log-Normal distribution with mean m and variance σ^2 . The

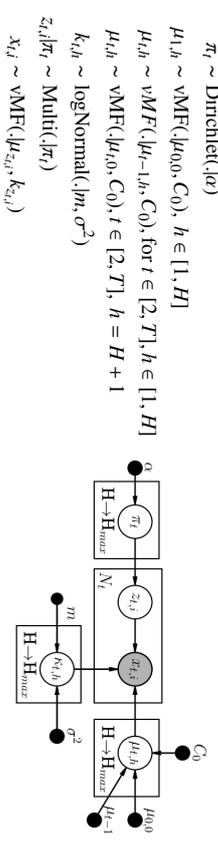

Figure 2: A graphical model representation of OTVMFMM, in which nodes represent random variables, arrows denote dependency among variables, and plates denote replication.

cluster-specific mean parameters at time t ($\mu_{t,h}$) are drawn from a vMF distribution centered around the corresponding clusters at the previous time $t-1$ or centered around $\mu_{0,0}$ with concentration C_0 . This evolutionary change of the cluster parameters introduces flexibility and enables OTVMFMM to accommodate smooth changes in the mean parameter within a given cluster over time.

The inference and reversible jump MCMC algorithm for OTVMFMM can be adapted straightforwardly from those of TVMFMM introduced in Section 4.2, 4.3. The likelihood of the complete data is given by

$$\begin{aligned} &P(H, \{x_i, i=1, \dots, T\}, \{z_i, i=1, \dots, T\}, \{\pi_{t,h}, \theta_{t,h}\}_{h=1}^H | \mathcal{B}) \\ &= P(H) f(\pi | \alpha) P(\{z_i, i=1, \dots, T\} | \pi) f(\mu | \mu_{0,0}, C_0) f(k | m, \sigma^2) f(\{x_i, i=1, \dots, T\} | \{\pi_{t,h}, \theta_{t,h}\}_{h=1}^H) \\ &= P(H) f(\pi | \alpha) \prod_{h=1}^H f(\mu_{t,h} | \mu_{t-1,h}, C_0) f(k_{t,h} | m, \sigma^2) \prod_{i=1}^N P(z_i, i | \pi) f(x_i | \mu_{z_i}, k_{z_i}) \end{aligned} \quad (24)$$

The likelihood of x_i can be defined as one of its marginal distributions by integrating out the distributions $\pi_{t,h}$, $\mu_{t,h}$ and $k_{t,h}$ and summing over $z_{t,i}$:

$$\begin{aligned} &f(x_i | m, \sigma^2, \mu_{t-1,h}, C_0, \alpha) = \\ &= \int_{\pi} \int_{\mu} \int_{k} f(\pi | \alpha) \prod_{h=1}^H P(z_i, i | h) = 1) f(x_i | \mu_{t,h}, k_{t,h}) f(\mu_{t,h} | \mu_{t-1,h}, C_0) f(k_{t,h} | m, \sigma^2) \\ &= \int_{\pi} f(\pi | \alpha) \prod_{h=1}^H P(z_i, i | h) = 1) \int_{\mu} \int_{k} \prod_{h=1}^H f(x_i | \mu_{t,h}, k_{t,h}) f(\mu_{t,h} | \mu_{t-1,h}, C_0) f(k_{t,h} | m, \sigma^2) \end{aligned} \quad (25)$$

Similarly to Section 4.2, we obtain the following updates for the posterior parameters.

$$\begin{aligned}
 \gamma(z_{i,t,h}) &\equiv P(z_{i,t,h} = 1 | \mathbf{Z}_{i,t-h}, \{x_{i,t}\}_{i=1}^{N_t}, \kappa_t, m, \sigma^2, \mu_{t-1,h}, C_0, \alpha) \\
 &\propto (n_{t,h} + \alpha) C_D(\kappa_{t,h}) \frac{C_D(\|\kappa_{t,h} \sum_{j \neq i} z_{i,j,h} x_{i,j} + C_0 \mu_{t-1,h}\|)}{C_D(\|\kappa_{t,h} \sum_{j \neq i} z_{i,j,h} x_{i,j} + C_0 \mu_{t-1,h}\|)} \\
 f(\kappa_{t,h} | X_t, \mathbf{Z}_t, \kappa_t, m, \sigma^2, \mu_{t-1,h}, C_0) &\propto \frac{C_D(\kappa_{t,h})^{n_{t,h}} C_D(C_0)}{C_D(\|\kappa_{t,h} \sum_j z_{i,j,h} x_{i,j} + C_0 \mu_{t-1,h}\|)} \log \text{Normal}(\kappa_{t,h} | m, \sigma^2) \\
 f(\mu_{t,h} | X_t, \mathbf{Z}_t, \mu_{t-1,h}, C_0) &\propto \exp \left\{ \left\{ \kappa_{t,h} \sum_i z_{i,t,h} x_{i,t} + C_0 \mu_{t-1,h} \right\} \mu_{t,h} \right\}
 \end{aligned} \tag{26}$$

$$f(\pi_{t,h} | \{x_{i,t}\}_{i=1}^{N_t}, \{z_{i,t}\}_{i=1}^{N_t}, \alpha) \propto (n_{t,h} + \alpha)$$

where $n_{t,h}$ is the number of observations assigned to the h -th component at time t , $n_{t,h} = \sum_i z_{i,t,h}$. The empirical updates for the prior parameters are given as follows

$$\begin{aligned}
 \mu_{t,0} &= \frac{\sum_{h=1}^H \mu_{t,h}}{\|\sum_{h=1}^H \mu_{t,h}\|}, C_0 = \frac{\bar{r}D - \bar{r}^3}{1 - \bar{r}^2}, \text{ where } \bar{r} = \frac{\|\sum_{h=1}^H \mu_{t,h}\|}{H}, t \in [2, T] \\
 \arg \max_{\alpha > 0} -\log \left(\prod_{h=1}^H \Gamma(\alpha) \right) + (\alpha - 1) \sum_{h=1}^H \pi_{t,h} &\tag{27} \\
 m &= \frac{1}{H} \sum_{h=1}^H \log(\kappa_{t,h}), \sigma^2 = \frac{1}{H} \sum_{h=1}^H \log(\kappa_{t,h}^2) - m^2
 \end{aligned}$$

Similarly, the move (5) and (6) of the RJMCMC algorithm for OTvMFMM can be straightforwardly derived following the strategy for TvMFMM in Section 4.3. The acceptance probabilities of split and merge moves are $\min(1, A)$ and $\min(1, A^{-1})$ respectively, where

$$A = \frac{P(H+1, \mathbf{Z}_t, \{\pi_{t,h}, \theta_{t,h}\}_{h=1}^H, \mathcal{B} | X_t)}{P(H, \mathbf{Z}_t, \{\pi_{t,h}, \theta_{t,h}\}_{h=1}^H, \mathcal{B} | X_t)} \times \frac{d_{H+1}}{b_H P_{\text{alloc}}(u)} \times \left| \frac{\partial \Sigma}{\partial(\lambda, V)} \right| \times | \det(J) | \tag{28}$$

The acceptance probabilities for birth and death moves are $\min(1, A)$ and $\min(1, A^{-1})$ respectively, where

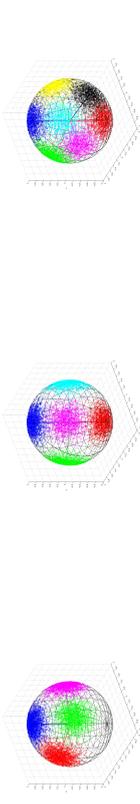

$$\begin{aligned}
 A &= \frac{P(H+1)}{P(H)} \times \frac{1}{B(\alpha, H\alpha)} \times \pi_{i,j}^{\alpha-1} (1 - \pi_{i,j})^{N+H\alpha-M} \times (H+1) \\
 &\times \frac{d_{H+1}}{(H_0+1)b_H} \times \frac{1}{g_{1,H}(\pi_{i,j})} \times (1 - \pi_{i,j})^H
 \end{aligned} \tag{29}$$

In Eq. (29), H_0 is the number of empty components, $g_{1,H}(\cdot)$ is the probability density function of $Beta(1, H)$ distribution.

5. Empirical Evaluation

In this section, we evaluate the proposed models on synthetic and real-world data. We used the movMF software⁴ provided by Banerjee et al. (2005) to generate synthetic data with: a) 4 well-separated components; b) 5 well-separated components; c) 7 not well-separated components. Each of the synthetic datasets has a training size of 10000 and held-out test data size of 2500. The visualisation of synthetic dataset is presented in Figure 3.

4. <http://suwit.de/woztk/soft/movmf/>

(a) 4 well-separated components (b) 5 well-separated components (c) 7 not well-separated components
Figure 3: Visualisation of synthetic data on 3-d unit sphere.

Preprocessing of Wikipedia data. In Wikipedia, pages are subdivided into ‘namespaces’⁵ which represent general categories of pages based on their function. For instance, the article (or main) namespace is the most common namespace and is used to organise encyclopedia articles. In many practical applications, we might be more interested in how the actual interests of editors (in terms of the categories of Wikipedia articles they have edited) change over time. For this reason, rather than using the main namespace as one feature, we further group Wikipedia articles into clusters based on their macro-categories⁶. Because the categories for articles given by Wikipedia are generally not fine-grained, we infer the macro-categories for articles by identifying candidate categories from the DBpedia⁷ category graph. DBpedia is one of the best known multi-domain knowledge bases which extracts structure information from Wikipedia Categorization system and forms a semantic graph of concepts and relations. The association between Wikipedia categories and DBpedia concepts is defined using the **subject** property of the DCIM terms vocabulary (pre-fixed by **dcterms**) (Hulpus et al., 2013). A category’s parent and child categories can be extracted by querying for properties **skos:broad** and **skos:broaderof**, these category-subcategory relationships create connections between DBpedia concepts. We can obtain a DBpedia category graph⁸ by merging all the connections among DBpedia concepts together. With the category graph available, we can identify the macro-categories for Wikipedia articles by searching for the shortest paths from the categories associated with the articles to the macro-categories in the category graph. If multiple shortest paths exist, then the article is assigned to multiple macro-categories with weights proportional to the number of paths leading to a specific macro-category. For other complex methods of labelling topics, we recommend the readers refer to Hulpus et al. (2013).

Users can make edits to any namespace or article based on their interests and expertise. The amount of edits across all the 28 namespaces and 22 macro-categories can be considered as work archetypes. A namespace or macro-category can be considered as a ‘term’ in the vector space for document collections, the number of edits to that namespace/category is analogous to word frequency. A user’s edit activity across different namespaces/categories in a time period can be regarded as a ‘document’. The main motivation of this work is to apply topic models on the evolving user behavioural data in order to identify and characterise the patterns of change in user edit activity

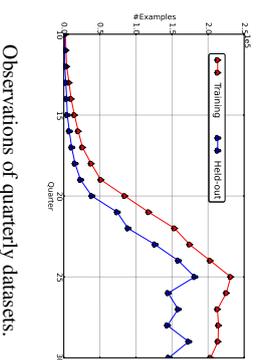

5. <http://en.wikipedia.org/wiki/Wikipedia:Namespace>

6. At the time we collected data for this work, there were 22 macro-categories: http://en.wikipedia.org/wiki/Category:Main_topic_classifications

7. <http://dbpedia.org>

8. The category graph is a directed one due to the nature of category-subcategory structure.

(i.e. common work archetypes) over time in Wikipedia. For this purpose, we parsed the May 2014 dump of English Wikipedia⁹, collected the edit activity of all registered users, then aggregated the edit activity of each user on a quarterly basis. In this way, we obtained a time-varying dataset consisting of the quarterly editing activity of all users from the inception of Wikipedia till May 2nd, 2014. There is an overwhelming number of users who stayed active for only one quarter. To avoid a bias towards behaviours most dominant in dataset with larger user bases, following [Furtado et al. \(2013\)](#), we randomly selected 20% of users who stayed active for only one quarter, included these users and those who were active for at least two quarters as our training dataset; the remaining 80% of short-term users were used as held-out dataset. The statistics and an example of the dataset are given in [Figure 4](#). The size of the quarterly datasets range from several hundreds to about 200,000.

Figure 4: Statistics and an example of Wikipedia dataset.

We implement the models in Python, and parallelize the models wherever possible by using the parallel functionality of Python. Specifically, we make use of the *multiprocessing*¹⁰ package to implement parallelism for parameter updates, and use *Value* and *Array* data structures provided by the package to enable data sharing among multiprocessors.

Experimental settings. All our experiments were run on 32 core AMD Opteron 6134 @ 2.25Ghz with 252GB RAM. The main computational bottleneck in our collapsed Gibbs sampling algorithm is the computation of z and κ . We compared the proposed models with the following algorithms and models that are widely-used in the literature:

- K-means ([Hartigan and Wong, 1979](#)) and MiniBatchKMeans ([Sculley, 2010](#)) algorithms with random and k-means++ ([Arthur and Vassilvitski, 2007](#)) initialization for the centroids. Different initialization of the centroids for k-means can affect its convergence and may lead to a local minimum. The k-means++ initialization scheme selects initial cluster centers in a heuristic way which can speed up convergence and lead to better results than random initialization.
- Non-negative matrix factorization (NMF) model ([Lee and Seung, 1999](#)). We used the Non-negative Double Singular Value Decomposition (NNDSDVD) strategy ([Boutsidis and Gallopoulos, 2008](#)) to choose initial factors for NMF, which can produce deterministic results and avoid a poor local minimum.

- Dynamic topic model (DTM)¹¹ ([Blei and Lafferty, 2006](#)), designed for clustering of temporal document collections represented in term-frequency style format.
- Bayesian von Mises-Fisher mixture model (BvMFMM) ([Gopal and Yang, 2014](#)), designed for clustering of static numeric (and directional) data. The model is initialised with k-means++ ([Arthur and Vassilvitski, 2007](#)) method.
- Dirichlet process Gaussian mixture model (DP-GMM) with sub-cluster split/merge moves¹² ([Chang and Fisher III, 2013](#)).

The generated synthetic data is \mathcal{L}_2 normalised. For Wikipedia datasets, we used the tf-idf normalised representation for NMF, BvMFMM, DP-GMM and OTvMFMM, and feature count representation (without normalisation) for DTM. For k-means, MiniBatchKMeans and NMF, we used the implementation in the scikit-learn package. If not specified, we run the models with their default parameters. If not explained specifically, TvMFMM is initialised with k-means++ strategy, and OTvMFMM is initialised with posterior estimation from the previous time point. To determine the number of clusters for parametric models (i.e. NMF, BvMFMM, and DTM) on real-world data, we experimented with different number of clusters $k \in [5, 45]$ with steps of 5 on the quarterly Wikipedia editor datasets using Non-negative Matrix Factorization (NMF) clustering, and then employed measures such as normalised pairwise mutual information (NPMI) as suggested by [O’Callaghan et al. \(2015\)](#) to assess model coherence for different ks . We found that overall, the run with 10 clusters generates more coherent clusters, so we set $H = 10$ for parametric models. Detailed analysis is given in [Appendix F](#).

Chaining of clusters¹³. Label switching of the components (stemming from the posterior distribution being invariant with respect to the permutation of the component labels) is an issue which needs to be solved when analyzing MCMC samples. Briefly, label switching can be solved by imposing certain ordering constraints on component parameters. [Celeux et al. \(2000\)](#) proposed a k-means style clustering algorithm to deal with label switching problem for MCMC chains, and showed the advantages and justification of k-means clustering over loss functions for label switching problem in terms of avoiding storage of the complete MCMC chain. In this work, we employ their k-means style algorithm for two purposes: (1) to solve label switching problem for RMCMC chains for mixture model estimation, and (2) to chain the clusters in different quarters together in order to visualise the popularity and dynamics of clusters over time.

To evaluate the influence of the two different strategies for split-merge moves, we compared the performance of TvMF mixture model with/without common eigenvectors for split-merge moves on synthetic data. The results suggest that TvMFMM with two different strategies for the split-merge moves show similar performance and mixing properties on synthetic data. Therefore, for the results presented in the following sections, we ran TvMFMM and OTvMFMM with common eigenvectors for split-merge moves. The detailed results are provided in [Appendix E](#).

The prior parameters for all the vMF mixtures are $\{\alpha, \mu_0, C_0, m, \sigma^2\}$. Although we provide an empirical Bayes step to estimate the priors from data, estimating too many parameters is prone to problems such as overfitting. The acceptance rate of the birth-death move in [Eq. \(23, 29\)](#) is sensitive to the value of α , larger value of α tends to result in lower acceptance rate for the move. We set

⁹ <http://dumps.wikimedia.org/enwiki/20140502/>
¹⁰ <https://docs.python.org/2/library/multiprocessing.html>

¹¹ Available at: <https://www.cs.princeton.edu/~blei/topicmodeling.html>
¹² Available at: <http://people.csail.mit.edu/johang7/code.php>
¹³ Throughout the paper, we use the terms topic, component, cluster, mixture, and common user role interchangeably to denote the same concept.

$\alpha = 1.0$ for all models. The prior parameter μ_0 is estimated using empirical Bayes. Gopal and Yang (2014) suggested setting the prior parameter manually with relative low values (typically smaller than 1.0) rather than directly learning it from data. Following the suggestion, we set $C_0 = 2.0$ for all the vMF mixtures. The prior parameters m and σ^2 control the range of the concentration parameters κ , which can affect the mixing property / convergence of the RJMCMC chain. More details about this effect are discussed in Appendix H. In the following analyses (excluding those in Appendix H), we used the trace plot of the number of components and log likelihood over sweeps to assist setting appropriate values for m and σ^2 .

5.1 Clustering Performance on Synthetic Data

This section compares the clustering performance of TvMF mixture model with other models on synthetic data. Following Gopal and Yang (2014), we compared the clustering performance of TvMFMM with other models on synthetic datasets using the following performance metrics:

- Adjusted Rand Index (ARI) ¹⁴.
- Normalised Mutual Information (NMI) ¹⁴.
- Adjusted Mutual Information (AMI) ¹⁴.
- Purity-related metrics ¹⁴: Homogeneity, quantifies the extent to which each cluster contains only members of a single class; Completeness, quantifies the extent to which all members of a given class are assigned to the same cluster.

Table 2 presents the comparison of clustering performance. The results are the average of 10 runs for each method. K-means and MiniBatchKMeans algorithms are run with the true number of components and hard assignments for each dataset but with 2 different strategies to initialise the centroids. BvMFMM is also run with the true number of components. The posterior estimation of the number of components for TvMFmix are 4, 5, and 7 for the three synthetic datasets, respectively, based on the results in Appendix E. To further verify our findings, we conducted two-way significance tests using paired t-tests between TvMFMM and other models for every metric. The null hypothesis is that there is no significant difference between the performance of TvMFMM and other models.

The results show that TvMFMM performs statistically significantly better than BvMFMM on synthetic datasets with 7 not well-separated components, but both models have similar performance on datasets with 4 and 5 well-separated components; TvMFMM performs statistically significantly better than DP-GMM on all the three synthetic datasets; TvMFMM has similar Homogeneity scores as k-means and MiniBatchKMeans, but performs statistically significantly better than k-means and MiniBatchKMeans on the other four performance metrics. Note that the clustering performance of BvMFMM relies on setting the optimal number of clusters and reasonable initialisation of cluster centres, while TvMFMM solves the two issues via the use of RJMCMC algorithm. For BvMFMM, even if the number of clusters could be tuned carefully to be the optimal number for a specific dataset, a reasonable initialisation of the cluster parameters (i.e. mean directions) would still be difficult particularly for not well-separated datasets. This explains why TvMFMM performs better than BvMFMM on the synthetic dataset with 7 components. Overall, the results suggest that the proposed TvMF mixture model performs significantly better than other widely-used models such as, k-means, BvMFMM, and DP-GMM on synthetic data, i.e. points on the unit sphere.

Table 2: Comparison of clustering performance for different models on synthetic data. Bold face numbers indicate best performing method for the corresponding metric. The results of the paired t-test against TvMFMM are denoted by: * for significance at 5% level, ** for significance at 1% level.

5.2 Performance on Real-world Data

In this section, we evaluate the performance of the proposed online trans-dimensional von Mises-Fishes mixture model (OTvMFMM) on Wikipedia editor activity data over 21 quarters. Because the first 9 quarters had a small number of user activity records (generally less than 1000), we choose to analyse the editor activity from the 10-th quarter to the 30-th quarter.

14. <http://scikit-learn.org/stable/modules/clustering.html#clustering-performance-evaluation>

5.2.1 CONVERGENCE DIAGNOSTICS OF OTVMFMM

Before proceeding to model exploration, we diagnose the convergence of the OTVMFMMs. We follow the methodology of [Brooks and Giudici \(2000\)](#) which monitors particular functions of parameters (e.g. log likelihood). The method requires running I independent chains with $2T$ iterations, and then divides the I sequences into batches of length b , which gives a series of sequences of chains with length $2kb$ (where $k \in [1, T/b]$). With sequences of chains ready, we then calculate the total variations of log likelihood both between chains and between models to diagnose the convergence of the RJMCMC chain. Following [Brooks and Giudici \(2000\)](#), six quantities are computed:

- The total variation \hat{V} and the within-chain variance W_c . Essentially, the ratio \hat{V}/W_c is analogous to the potential scale reduction factor (PSRF, denoted by \hat{R}) of [Gelman and Rubin \(1992\)](#).
- The within-model variance W_m , the variance within both chains and models $W_m W_c$. The comparison of W_m and $W_m W_c$ which should well approximate the true mean of within-model variance, tells us how well the chains are mixing within models.
- The between-model variance B_m , and the within-chain variation split between and averaged over models $B_m W_c$. The comparison of B_m and $B_m W_c$, which should well approximate the true between-model variance, tells us how well the chains are mixing between models.

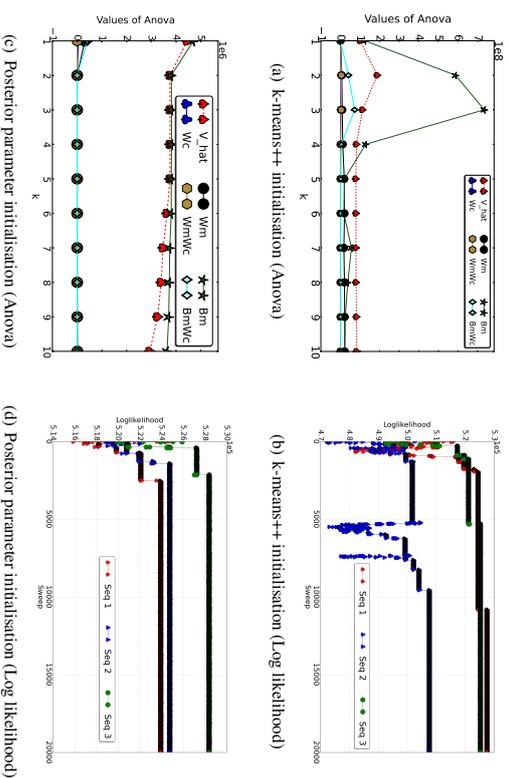

Figure 5: Diagnostic plots for convergence analysis and trace of the log likelihood on Wikipedia data: (a)-(b) models started with k-means++ initial means; (c)-(d) models started with the posterior mean of the previous quarter.

For details of the quantities readers can refer to [Brooks and Giudici \(2000\)](#). Three independent chains (each chain running 20000 iterations) were used to diagnose the convergence of OTVMFMMs started with k-means++ initial mean parameters (the initial number of components was set to 10) and started with the posterior mean of the previous quarter, respectively. We use log likelihood as the scalar parameter for convergence diagnostics which has also been used by ([Brooks and Giudici, 2000](#); [Zhong and Girolami, 2009](#)). Figure 5 gives the diagnostic plots of convergence analysis on the 15th quarter of Wikipedia editor activity data.

The results showed that in general, OTVMFMMs started with k-means++ initial mean parameters have higher level of variations in log likelihood than those started with posterior parameter initialisation. OTVMFMMs started with k-means++ initial mean parameters became convergent after $k=4$, as evidenced in the corresponding trace plot for log likelihood: the overall variations of log likelihood for OTVMFMMs started with posterior mean initialisation were relatively stable throughout the range of k s, the chains were mixing very well after 3000 iterations. The results suggested that OTVMFMM started with posterior mean initialisation converges faster than that started with k-means++ initial mean parameters. When analysing the massive temporal Wikipedia data, we notice that OTVMFMMs started with posterior mean initialisation tend to converge within 3000 iterations; we generally determine the convergence of OTVMFMM by checking the trace of the log likelihood.

5.2.2 QUALITATIVE ANALYSIS

To show how the OTVMFMM can generate more coherent, interpretable and intuitive clusters (or common user roles) than existing models for time-varying user behavioural data, we compare the popularity of clusters over time and the evolution of top terms for selected similar clusters identified by different models. Figure 6 presents the trends of clusters over time for different models¹⁵. We hand-labelled the clusters generated by DTM and OTVMFMM evolve relatively smoothly in their trends over time: NMF tends to generate many clusters that appear in less than 4 quarters, indicating smoothness issues in the clusters; DTM fails to capture the birth/death of clusters over time, while OTVMFMM can capture the birth/time of clusters over time; BvMFMM generates the least smooth clusters in terms of popularity over time. Comparing the cluster labels for DP-GMM and OTVMFMM in Figure 6, we notice that DP-GMM tends to generate fewer clusters that are relatively general, whereas OTVMFMM tends to generate a larger number of clusters that are specific, interpretable and intuitive.

Figure 7 visualises the evolution of top terms for selected common user roles identified by different models. We observe that user roles generated by DTM and OTVMFMM generally contain a few most dominant terms, indicating interpretable and intuitive clusters; NMF also generates a few interpretable clusters, BvMFMM and DP-GMM tends to generate clusters with many dominant terms, indicating general and less interpretable clusters. The visualisation of more common user roles are provided in Figure 18 of [Appendix 1](#). Overall, the results suggest that DTM and OTVMFMM tend to generate interpretable and intuitive clusters, NMF tends to generate many clusters that appear in less than 4 quarters, BvMFMM and DP-GMM tend to generate general clusters that lack of most dominant terms.

[Appendix G](#) presents a discriminative analysis of the topical representations by different models on the 18th quarter of Wikipedia Editor dataset.

¹⁵. To improve readability, we only visualise the trends for clusters that appear at least 4 quarters.

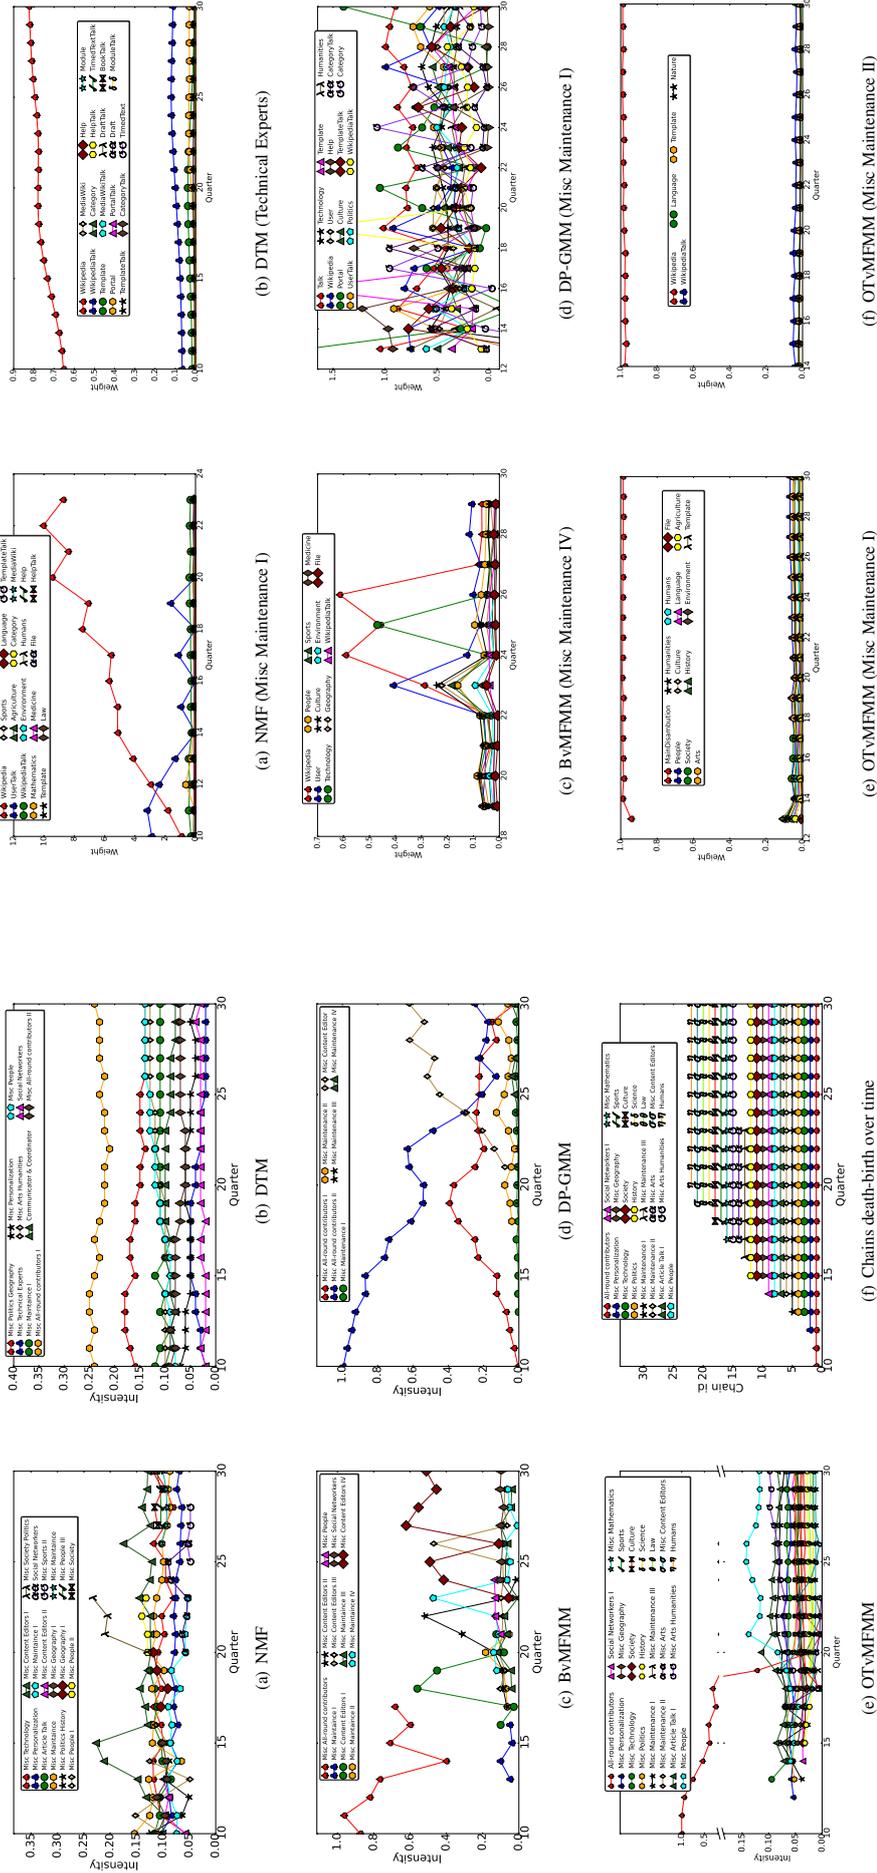

Figure 6: Popularity of common user roles over time for different models and birth-death of user roles over time for OTvMFMM. Quarter corresponds to the index of quarter. Intensity indicates the weight of user roles in each quarter, and is calculated as the percentage of user profiles assigned to that user role in a quarter. Each curve represents the trend of one user role over time. Chain id indicates the corresponding user role for OTvMFMM. NB: in (e), we make use of a discontinuity in the y-axis to better visualise the detail in the bottom of the plot.

Figure 7: Evolution of top terms for similar common user roles (*Misc Maintenance*) identified by different models. Weight indicates the weight of features for the user roles, and is available from the model parameters.

5.2.3 QUANTITATIVE ANALYSIS

We evaluate the performance of OTvMFMM and its counterparts quantitatively from two aspects: the coherence of the clusters generated, and the perplexity (equivalently, held-out log likelihood) of the models. Traditional predictive metrics, such as perplexity, are commonly used in the literature to evaluate topic models; these metrics capture the model’s predictive ability over a test set of un-

seen documents based on the parameters learned from a training set (Chang et al., 2009). Following these authors, the predictive likelihood of data point x can be approximated using $P(x | \chi_{train}) = \int_0^1 P(x, \Theta | \chi_{train}) \approx P(x | \Theta) P(\Theta | \chi_{train})$, where Θ are the posterior estimation of model parameters learned from the training set. Chang et al. (2009) showed that perplexity was often negatively correlated with human judgements of topic quality, and suggested alternative measures such as topic coherence or focusing upon real-world task performance that includes human knowledge to evaluate topic quality. Topic coherence can capture the semantic interpretability of discovered topics based on their corresponding descriptor terms using measures such as normalised Pointwise Mutual Information (NPMI) (Chang et al., 2009; O’Callaghan et al., 2015). Higher coherence scores indicate better semantic interpretability, thus more coherent and interpretable topics. Figure 8 compares the coherence of clusters, and held-out log likelihood for different models¹⁶.

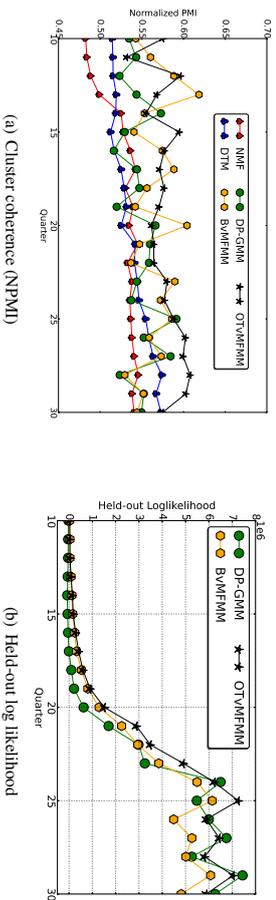

Figure 8: Mean normalised PMI and held-out log likelihood.

We observe that the NPMI values of OTvMFMM are constantly higher than those of NMF and DTM in the range of quarters considered; the NPMI values of OTvMFMM are higher than those of BvMFMM and DP-GMM in most quarters. The NPMI values of BvMFMM and DP-GMM experience certain level of fluctuation compared with those of the other three models. The held-out log likelihood of OTvMFMM is constantly higher than that of BvMFMM in all the quarters considered; the held-out log likelihood of OTvMFMM is higher than that of DP-GMM from quarter 10 to 23, after which the measures of the two models are approximately at the same level. To summarise, the results suggest that OTvMFMM presents better predictive ability on unseen data than BvMFMM and DP-GMM, and that OTvMFMM generates more interpretable and coherent clusters than other models.

5.2.4 TIME ANALYSIS

Table 3 compares the learning time of different models on the 13th to 16th quarter of Wikipedia datasets. For DTM, the time reported was the total learning time on the 4 datasets. It is obvious from the table that NMF took the least time to learn the model; DTM took the second least time to learn the model; DP-GMM and BvMFMM took about the same amount of time to train the

¹⁶ We did not compare with the perplexity of DTM because DTM inferred model parameters using variational Bayes, and gave a lower bound of held-out log likelihood.

model. Comparing with the other four models, OTvMFMM took the maximum amount of time to learn the model on all the datasets considered. This is due to two reasons: (i) it generally takes a substantial amount of time for reversible jump MCMC styled algorithms (e.g. Richardson and Green (1997); Zhang et al. (2004); Delaportas and Papageorgiou (2006); Zhong and Giridhari (2009)) to generate convergent MCMC chains; (ii) compared with other models, updating the latent variables in OTvMFMM involves calculating the normalising constants of von Mises-Fisher distributions, which is computationally expensive, particularly for large datasets.

Table 3: Learning time in seconds for number of iterations (#iterations) after which the algorithms converged for different models.

	NMF	DTM	DP-GMM	BvMFMM	OTvMFMM	#Obs
#iterations	–	200	5000	40	10000	–
Quarter 13	12.65		867.95	735.66	53333.33	7344
Quarter 14	15.83		1170.56	1503.28	69504.62	10217
Quarter 15	32.34	6217.0	1722.03	1742.40	119349.18	14829
Quarter 16	27.92		2215.67	2032.45	108577.73	20129

6. Applications of User Profiles

In this section, we explore: (1) how discriminative are the generated features in distinguishing different groups of users, and (2) how useful are the features generated from patterns of change in editor activities by different models for the churn prediction task. Identifying the key features that distinguish different user groups and different life stages makes it possible to develop techniques for important applications, such as churn prediction and task recommendation. Churners present a great challenge for community management and maintenance as the turnover of established members can have a detrimental effect on the community in terms of creating communication gaps, knowledge gaps or other gaps. Qin et al. (2014) presented similar applications of user profiles. This work replicates their application scenarios in order to provide insights into the usefulness of the features generated by the proposed models in real-world applications.

6.1 Group Level Change in User Profiles

Different users are more likely to follow slightly or totally different trajectories in their lifecycle. In this analysis, we examine how different groups of users evolve throughout their lifecycle periods by comparing how each user’s profile in one period is different from that in the previous periods. The historical comparison of the distribution of user profiles toward user roles is a useful indicator of how the user changes edit activity relative to past behaviour. Cross-period entropy can be used to gauge the cross-period variation in user’s edit activity throughout lifecycle periods. The cross-entropy of one probability distribution P (from a given lifecycle period) with respect to another distribution Q from an earlier period (e.g. the previous quarter) is defined as follows (Rowe, 2013):

$$C(P, Q) = - \sum_x p(x) \log q(x) \quad (30)$$

prediction. Specifically, we make predictions based on features generated from editor profile distributions in a sliding window with $w=4$ quarters. An editor is in the ‘departed’ class if she leaved the community before being active for less than $m=1$ quarter after the sliding window, denote the interval $[w, w+m]$ as the departed range. Similarly, an editor is in the ‘staying’ class if she was active in the community long enough for a relatively large $n \geq 3$ quarters after the sliding-window, term the interval $[w+n, +\infty]$ as the staying range.

6.2.1 FEATURES FOR THE TASK

Our features are generated based on the findings reported in the previous section. For simplicity, we assume the w quarters included in the t -th sliding-window being $t = [j, \dots, j+w-1]$ ($j \in [1, 0, 30]$), and denote the Probability Of Activity Profile of an editor in quarter j assigned to the k -th user role as $POAP_{t,j,k}$. We use the following features to characterise the patterns of change in editor profile distributions:

- *First active quarter*: the quarter in which an editor began edits in Wikipedia. The timestamp a user joined the community may affect her decision about whether to stay for longer.
- *Cumulative active quarters*: the total number of quarters an editor had been active in the community till the last quarter in the sliding window.
- *Fraction of active quarters in lifespan*: the proportion of quarters a user was active till the sliding window.
- *Fraction of active quarters in sliding window*: the fraction of quarters a user was active in current sliding window.
- *Similarity of profile distribution in sliding window*: quantifies the similarity of user profile distributions in any two successive quarters using cosine similarity.
- *Diversity of edit activity*: denotes the entropy of $POAP_{t,j,k}$ for each quarter j in window t . This measure captures the extent to which an editor diversified her edits toward multiple namespaces and categories of articles.
- *Cross-entropy of edit activity*: denotes the historical variation in $POAP_{t,j,k}$ compared to the same measure in previous quarters, calculated using Eq. (30). This measure captures the extent to which an editor changed her edit activity compared to her past behaviour.
- *mean POAP_{t,j,k}*: denotes the average of $POAP_{t,j,k}$ for each user role k in window t , and captures whether an editor focused her edits on certain namespaces and categories of articles in window t .
- $\Delta POAP_{t,j,k}$: denotes the change in $POAP_{t,j,k}$ between the quarter $j-1$ and j , measured by $-\Delta POAP_{t,j,k} = (POAP_{t,j,k} - POAP_{t,j-1,k} + \delta) / (POAP_{t,j-1,k} + \delta)$, where δ is a small positive real number (i.e. 0.001) to avoid the case when $POAP_{t,j-1,k}$ is 0. This measure also captures the fluctuation of $POAP_{t,j,k}$ for each user role k in window t .

For each editor, the first three features are global-level features which may be updated with the sliding window, the remaining features are window-level features and are recalculated within each sliding window. The intuition behind the last four features is to approximate the evolution of editor lifecycle we sought to characterise in the previous section. The dataset is of the following form: $D = (x_i, y_i)$, where y_i denotes the churn status of the editor, $y_i \in \{\text{Churner, Non-churner}\}$; x_i denotes the feature vector for the editor.

6.2.2 TASK PERFORMANCE

Table 5: Performance of sliding-window based churn prediction using features generated from different models. The measures are averaged over all sliding windows for each model.

Models	FP Rate	Precision	Recall	F-Measure	ROC Area
DTM	0.40±0.02	0.72±0.01	0.73±0.01	0.72±0.01	0.77±0.01
OTV-MFMM	0.47±0.03	0.69±0.01	0.71±0.01	0.69±0.01	0.72±0.02
NMF	0.45±0.02	0.70±0.01	0.71±0.01	0.69±0.01	0.73±0.02
BvMFMM	0.48±0.03	0.69±0.01	0.71±0.01	0.68±0.01	0.70±0.03
DP-GMM	0.45±0.04	0.70±0.01	0.71±0.01	0.69±0.02	0.72±0.04

Table 5 gives the averaged performance of sliding-window based churn prediction using features generated from different models. We observe that the best performance is obtained using features generated from DTM; churn prediction using features generated from the other four models presents similar performance. Notice that DTM and NMF generally generate a mixture of topics for user profiles, while the other three models tend to generate unique topics for user profiles. This suggests that different models may be applied to applications with different requirements. Alternatively, models such as DTM and NMF may be better at capturing change in user behaviour for churn prediction, while discriminative models such as DP-GMM and OTV-MFMM may be better at identifying user expertise for task recommendation. Our results suggest that sudden changes in user behaviour can be a signal that the user is likely to abandon the community, and that features inspired by topic models are useful for churn prediction.

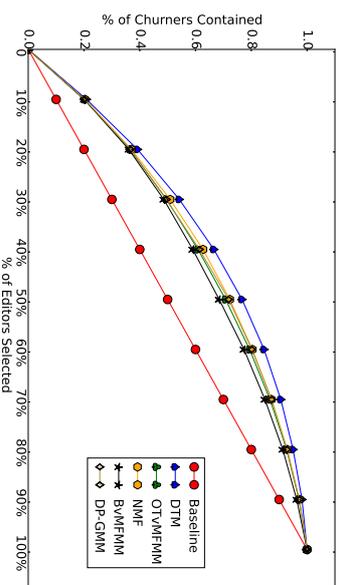

Figure 11: Lift chart of churn prediction using features generated from different models. The measures are averaged over all sliding windows.

Lift factors have been widely used by researchers to evaluate the performance of churn-prediction models (Weia and Chub, 2002). The lift factors achieved by different models are shown in Figure 11. In a lift chart, the diagonal line represents a baseline which randomly selects a subset of editors as potential churners, i.e., it selects $s\%$ of the editors that will contain $s\%$ of the true churners, resulting in a lift factor of 1. For instance, in Figure 11, on average, all models (except Baseline) was capable of identifying 10% of editors that contained at least 20% of true churners (i.e. a lift factor of 2.0). DTM was capable of identifying 20% of editors that contained 39.3% of true churners (i.e. a lift factor of 1.966), and 30% of editors that contained 53.9% of true churners (i.e. a lift factor of 1.799). Evidently, DTM achieved slightly higher lift factors than the other four models, all models achieved higher lift factors than the baseline. Thus if the objective of the lift analysis is to identify a small subset of likely churners for an intervention that might persuade them not to churn, then this analysis suggests that all models can identify a set of 10% of users where the probability of churning is more than twice the baseline figure.

7. Conclusion

This work proposed an online trans-dimensional von Mises-Fisher mixture model (OTvMFMM) for temporal user behavioural data, which (a) enables information sharing among clusters via a Bayesian framework, (b) allows adaptive change in the number of clusters by using our extended version of the reversible jump MCMC algorithm, and (c) accommodates the dynamics of clusters for time-varying user behavioural data based on the smoothness assumption. Our efficient collapsed Gibbs sampling algorithms make the models applicable to large-scale real-world data such as Wikipedia dataset. Empirical results on synthetic and real-world data show that the proposed models can discover more interpretable and intuitive clusters than other widely-used models, such as k-means, Non-negative Matrix Factorization (NMF), Dirichlet process Gaussian mixture models (DP-GMM), and dynamic topic models (DTM). We further evaluated the performance of proposed models in real-world applications, such as churn prediction task, that shows the usefulness of the features generated.

The results show that the proposed OTvMFMM can discover more interpretable and intuitive clusters for evolving user behavioural data than DP-GMM with sub-cluster split/merge moves by Chang and Fisher III (2013), whereas the latter is found to converge much faster than the former. An interesting and promising future direction is to replace the reversible jump MCMC algorithm (Richardson and Green, 1997) with the subcluster split-merge strategy (Chang and Fisher III, 2013) in order to allow adaptive change in the number of clusters for the Bayesian von Mises-Fisher mixture models. The new integration would lead to more efficient and interpretable non-parametric models for L_2 normalised data that combine the advantages of both OTvMFMM and DP-GMM. In addition, heterogeneous user behavioural data are ubiquitous in the sense of multiplicity of features and multiple data sources available. We would like to handle heterogeneous data and apply the models to analyse user behavioural data in other online communities.

Appendices

Appendix A Detailed Inference for Collapsed Gibbs Sampling

Updates for z_i . The conditional distribution for z_i is given by

$$\begin{aligned} \gamma(z_{ih}) &\equiv P(z_{ih} = i | \mathcal{Z}_{-i}, \{x_j\}_{j=1}^N, \kappa, m, \sigma^2, \mu_0, C_0, \alpha) \propto \\ &\int_{\pi} \int_{\mu} f(x_i | \mu_{z_i}, \kappa_{z_i}) P(z_i | \pi) \prod_{j \neq i} P(z_j | \pi) f(x_j | \mu_{z_j}, \kappa_{z_j}) \prod_{h=1}^H f(\mu_h | \mu_0, C_0) f(\kappa_h | m, \sigma^2) \\ &\propto \int_{\pi} P(z_i | \pi) f(\pi | \alpha) \prod_{j \neq i} P(z_j | \pi) \times \\ &\quad \prod_{h=1}^H \int_{\mu_h} f(x_i | \mu_{z_i}, \kappa_{z_i}) \prod_{j \neq i, z_j \neq h} f(x_j | \mu_h, \kappa_h) f(\mu_h | \mu_0, C_0) f(\kappa_h | m, \sigma^2) \\ &\propto \int_{\pi} P(z_i | \pi) f(\pi | \alpha) \prod_{j \neq i} P(z_j | \pi) \times \prod_{h=1}^H \int_{\mu_h} f(x_i | \mu_{z_i}, \kappa_{z_i}) \prod_{j \neq i, z_j \neq h} f(x_j | \mu_h, \kappa_h) f(\mu_h | \mu_0, C_0) \end{aligned} \quad (\text{A-1})$$

where the description of each term in Eq. (A-1) can be referred to Eq. (7). Expanding out the Dirichlet priors and the discrete distributions according to their usual definitions, i.e., $P(\pi | \alpha) \sim \text{Dirichlet}(H, \alpha)$, $P(z_i | \pi) \sim \text{Multi}(\cdot | \pi)$, yields¹⁸:

$$\begin{aligned} \int_{\pi} P(z_{ih} = 1 | \pi) f(\pi | \alpha) \prod_{j \neq i} P(z_j | \pi) &= \int_{\pi} \prod_{h=1}^H \pi_h^{z_{ih}} \prod_{h=1}^H \frac{\Gamma(H\alpha)}{\Gamma(\alpha)} \prod_{h=1}^H \prod_{j \neq i} \pi_h^{\alpha-1} \prod_{j \neq i, h=1}^H \pi_h^{z_{jh}} \\ &= \frac{\Gamma(H\alpha)}{\prod_{h=1}^H \Gamma(\alpha)} \int_{\pi} \pi_h^{\alpha + n_{h,-i} + z_{ih} - 1} \\ &= \frac{\Gamma(H\alpha)}{\prod_{h=1}^H \Gamma(\alpha)} \prod_{h=1}^H \frac{\Gamma(\alpha + n_{h,-i} + z_{ih})}{\Gamma(H\alpha + N)} \\ &\propto \Gamma(\alpha + n_{h,-i} + 1) \propto (\alpha + n_{h,-i}) \Gamma(\alpha + n_{h,-i}) \propto (\alpha + n_{h,-i}) \end{aligned} \quad (\text{A-2})$$

Similarly, expanding out the probabilities $f(x_i | \mu_{z_i}, \kappa_{z_i})$, $f(x_j | \mu_h, \kappa_h)$ and $f(\mu_h | \mu_0, C_0)$ according to their usual definitions, $f(x_i | \mu_{z_i}, \kappa_{z_i}) = C_D(\kappa_{z_i}) \exp(\kappa_{z_i} \mu_{z_i}^T x_i)$ and $f(\mu_h | \mu_0, C_0) = C_D(C_0) \exp(C_0 \mu_h^T \mu_h)$

¹⁸ In the calculation, following [Heinrich \(2009\)](#), the Dirichlet integral of the first kind for summation function, $\sum_{\pi, \pi_0=1} \frac{\Gamma(\alpha)^H}{\Gamma(H\alpha)} = \int_{\pi} \prod_{h=1}^H \pi_h^{\alpha-1}$ is used, analogous to the identity of the beta integral: $B(\alpha_1, \alpha_2) = \int_0^1 x^{\alpha_1-1} (1-x)^{\alpha_2-1} dx$. The identity $\Gamma(x+1) = x\Gamma(x)$ is used in the last line.

yields ¹⁹:

$$\begin{aligned}
 & \prod_{h=1}^H \int_{\mu_h} \left(f(x_i | \mu_{z_i}, \kappa_{z_i}) \prod_{j \neq i, z_j=h} f(x_j | \mu_h, \kappa_h) \right) f(\mu_h | \mu_0, C_0) = \\
 & = \prod_{h=1}^H \int_{\nu_{\mu_h}} C_D(\kappa_h)^{n_h + z_{2h}} C_D(C_0) \exp \left\{ C_0 \mu_0^T \mu_h + \kappa_h \mu_h^T \left(x_i + \sum_{j \neq i} z_{jh} x_j^T \right) \right\} \\
 & = \prod_{h=1}^H C_D(\kappa_h)^{n_h + z_{2h}} C_D(C_0) \int_{\mu_h} \exp \left\{ C_0 \mu_0^T + \kappa_h x_i^T + \kappa_h \sum_{j \neq i} z_{jh} x_j^T \right\} \mu_h \\
 & = \prod_{h=1}^H \frac{C_D(\kappa_h)^{n_h + z_{2h}} C_D(C_0)}{C_D(\|\kappa_h (x_i + \sum_{j \neq i} z_{jh} x_j^T) + C_0 \mu_0\|)}
 \end{aligned} \tag{A-3}$$

Substituting Eq. (A-2)-(A-3) in Eq. (A-1) yields the following:

$$\begin{aligned}
 P(z_{2h} = 1 | z_{-i}, \{x_j\}_{j=1}^N, \kappa, m, \sigma^2, \mu_0, C_0, \alpha) \\
 & \propto \int_{\pi} P(z_{2h} | \pi) f(\pi | \alpha) \prod_{j \neq i} P(z_j | \pi) \prod_{h=1}^H \int_{\mu_h} \left(f(x_i | \mu_{z_i}, \kappa_{z_i}) \prod_{j \neq i, z_j=h} f(x_j | \mu_h, \kappa_h) \right) f(\mu_h | \mu_0, C_0) \\
 & \propto (\alpha + n_{h,-}) \prod_{h=1}^H \frac{C_D(\kappa_h)^{n_{h,-} + z_{2h}} C_D(C_0)}{C_D(\|\kappa_h (x_i + \sum_{j \neq i} z_{jh} x_j^T) + C_0 \mu_0\|)} + C_0 \mu_0 \| \\
 & \propto (\alpha + n_{h,-}) C_D(\kappa_h) \frac{C_D(\|\kappa_h \sum_{j \neq i} z_{jh} x_j^T + C_0 \mu_0\|)}{C_D(\|\kappa_h (x_i + \sum_{j \neq i} z_{jh} x_j^T) + C_0 \mu_0\|)}
 \end{aligned} \tag{A-4}$$

Updates for κ . Similarly, the conditional distribution for κ_h is given by

$$\begin{aligned}
 f(\kappa_h | Z, \{x_j\}_{j=1}^N, \kappa, m, \sigma^2, \mu_0, C_0) & \propto \prod_{z_{2h}=1} \prod_{\mu_h} f(x_i | \mu_h, \kappa_h) f(\mu_h | \mu_0, C_0) f(\kappa_h | m, \sigma^2) \\
 & \propto \prod_{z_{2h}=1} \prod_{\mu_h} C_D(\kappa_h) C_D(C_0) \exp \left\{ \kappa_h \mu_h^T x_i + C_0 \mu_0^T \mu_h \right\} \log \text{Normal}(\kappa_h | m, \sigma^2) \\
 & \propto \int_{\mu_h} C_D(\kappa_h)^{n_h} C_D(C_0) \exp \left\{ \kappa_h \mu_h^T \sum_{z_{2h}=1} x_i + C_0 \mu_0^T \mu_h \right\} \log \text{Normal}(\kappa_h | m, \sigma^2) \\
 & \propto C_D(\kappa_h)^{n_h} C_D(C_0) \log \text{Normal}(\kappa_h | m, \sigma^2) \int_{\mu_h} \exp \left\{ \kappa_h \mu_h^T \sum_{z_{2h}=1} x_i + C_0 \mu_0^T \mu_h \right\} \\
 & \propto \frac{C_D(\kappa_h)^{n_h} C_D(C_0)}{C_D(\|\kappa_h \sum_{j: z_{jh}=1} z_{jh} x_j^T + C_0 \mu_0\|)} \log \text{Normal}(\kappa_h | m, \sigma^2)
 \end{aligned} \tag{A-5}$$

where n_h is the number of observations assigned to the h -th component.

¹⁹ In this calculation, the identity of the von Mises-Fisher integral (Mardia and Jupp (2000), page 168; Chiu and Pici (1998)) is used. $\int_{S^{k-1}} \exp \left\{ \kappa \mu^T x \right\} dx = (2\pi)^{\frac{k}{2}} \left(\frac{\kappa}{2}\right)^{1-D/2} I_{D/2-1}(\kappa) = \frac{\Gamma(D/2)}{\Gamma(D/2)}$, where $\kappa = \|\kappa\|$.

Appendix B Empirical Bayes Estimates for Prior Parameters

The joint likelihood function of the prior parameters $(\mu_0, C_0, m, \sigma^2, \alpha)$ is given by:

$$\begin{aligned}
 \mathcal{L}(\mu_0, C_0, m, \sigma^2, \alpha | \{x_i\}_{i=1}^N, \mu, \kappa, \pi) & = f(\{x_i\}_{i=1}^N | \mu, \kappa, \pi) f(\mu | \mu_0, C_0) f(\kappa | m, \sigma^2) f(\pi | \alpha) \\
 & \propto \prod_{h=1}^H C_D(C_0) \exp \left\{ C_0 \mu_0^T \mu_h \right\} \prod_{h=1}^H \frac{1}{\kappa_h \sigma \sqrt{2\pi}} \exp \left\{ -\frac{(\log \kappa_h - m)^2}{2\sigma^2} \right\} \frac{\Gamma(H\alpha)}{\prod_{h=1}^H \Gamma(\alpha)} \prod_{h=1}^H \pi_h^{\alpha-1}
 \end{aligned} \tag{B-1}$$

Since the prior parameters are assumed to be independent, we have the following log-likelihood functions according to Eq. (B-1)

$$\begin{aligned}
 \log \mathcal{L}(C_0, \mu_0 | \{x_i\}_{i=1}^N, \mu) & = H \log C_D(C_0) + C_0 \mu_0^T \left(\sum_{h=1}^H \mu_h \right) \\
 \log \mathcal{L}(m, \sigma^2 | \{x_i\}_{i=1}^N, \kappa) & = -\frac{H}{2} \log(\sigma^2) - \frac{1}{2\sigma^2} \sum_{h=1}^H (\log(\kappa_h)^2 - 2m \log(\kappa_h) + m^2) \\
 \log \mathcal{L}(\alpha | \{x_i\}_{i=1}^N, \pi) & = -\log \left(\frac{\Gamma(H\alpha)}{\prod_{h=1}^H \Gamma(\alpha)} \right) + (\alpha - 1) \prod_{h=1}^H \pi_h
 \end{aligned} \tag{B-2}$$

Following Gopal and Yang (2014), the empirical Bayes estimate for C_0, μ_0 is given by:

$$\arg \max_{\mu_0, C_0} H \log C_D(C_0) + C_0 \mu_0^T \left(\sum_{h=1}^H \mu_h \right) \tag{B-3}$$

which suggests the following updates (Gopal and Yang, 2014)

$$\mu_0 = \frac{\sum_{h=1}^H \mu_h}{\|\sum_{h=1}^H \mu_h\|}, \quad C_0 = \frac{\bar{r}D - \bar{r}^3}{1 - \bar{r}^2}, \quad \text{where, } \bar{r} = \frac{\|\sum_{h=1}^H \mu_h\|}{H} \tag{B-4}$$

Similarly, the empirical Bayes estimate for α is given by Gopal and Yang (2014):

$$\arg \max_{\alpha > 0} -\log \left(\frac{\Gamma(H\alpha)}{\prod_{h=1}^H \Gamma(\alpha)} \right) + (\alpha - 1) \sum_{h=1}^H \pi_h \tag{B-5}$$

Since there exists no closed-form solution for Eq. (B-5), we rely on numerical optimization such as gradient descent to find the Maximum Likelihood Estimate for α .

The empirical Bayes estimate for m, σ^2 can be obtained in a similar way by taking the partial derivative on Eq. (B-2) w. r. t. m and σ^2 , respectively, which gives:

$$\begin{aligned}
 \frac{\partial \log \mathcal{L}(m, \sigma^2 | X, \kappa)}{\partial m} & = -\frac{1}{2\sigma^2} \sum_{h=1}^H [-2 \log(\kappa_h) + 2m] = 0 \\
 \frac{\partial \log \mathcal{L}(m, \sigma^2 | X, \kappa)}{\partial \sigma^2} & = -\frac{H}{2\sigma^2} + \frac{1}{2\sigma^4} \sum_{h=1}^H (\log(\kappa_h)^2 - 2m \log(\kappa_h) + m^2) = 0 \quad (\text{Let } x = \sigma^2) \\
 \Rightarrow m & = \frac{1}{H} \sum_{h=1}^H \log(\kappa_h), \quad x = \sigma^2 = \frac{1}{H} \sum_{h=1}^H \log(\kappa_h)^2 - m^2
 \end{aligned} \tag{B-6}$$

Alternatively, we can use the Monte Carlo Expectation-Maximum (MCEM) algorithm (Wei and Tanner, 1990) to estimate the prior parameters m and σ^2 .

- E-step: Randomly sample L times the value for κ_i , $(\kappa_h^{(i)})_{h=1}^L, i \in [1, L]$. Note that previously, we use MCMC sampling to estimate κ_{iS} . Here, we can reuse the set of generated κ_{iS} in the MCMC step.

- M-step: Estimate m and σ^2 by maximising the log-likelihood:

$$m = \frac{1}{LH} \sum_{i=1}^L \sum_{h=1}^H \log(\kappa_h^{(i)}), \quad \sigma^2 = \frac{1}{LH} \sum_{i=1}^L \sum_{h=1}^H \log(\kappa_h^{(i)})^2 - m^2 \quad (\text{B-7})$$

Appendix C Factorization of Acceptance Probability

We can factorize $P(H, \mathcal{Z}, \{\pi_h, \theta_h\}_{h=1}^H, \mathcal{B}(\{x_i\}_{i=1}^N))$ below:

$$\begin{aligned} P(H, \mathcal{Z}, \{\pi_h, \theta_h\}_{h=1}^H, \mathcal{B}(\{x_i\}_{i=1}^N)) &= \frac{P(H, \mathcal{Z}, \pi, \mu, \kappa, m, \sigma^2, \mu_0, C_0, \alpha, \{x_i\}_{i=1}^N)}{P(\{x_i\}_{i=1}^N)} \\ &= \frac{P(H) f(\pi(\alpha)) P(\mathcal{Z}|\pi) f(\mu|C_0, \mu_0) f(\kappa|m, \sigma^2) f(\{x_i\}_{i=1}^N | \mathcal{Z}, \mu, \kappa)}{P(\{x_i\}_{i=1}^N)} \end{aligned} \quad (\text{C-1})$$

where each term in Eq. (C-2) can be specified as follows:

$$\begin{aligned} \frac{P(H+1, \mathcal{Z}', \Theta', \mathcal{B}(\{x_i\}_{i=1}^N))}{P(H, \mathcal{Z}, \Theta, \mathcal{B}(\{x_i\}_{i=1}^N))} &= \frac{P(H+1)}{P(H)} \times \frac{f(\pi'|\alpha)}{f(\pi|\alpha)} \times \frac{P(\mathcal{Z}'|\pi')}{P(\mathcal{Z}|\pi)} \times \frac{f(\mu'|\mu_0, C_0)}{f(\mu|\mu_0, C_0)} \\ &= \frac{f(\kappa'|m, \sigma^2)}{f(\kappa|m, \sigma^2)} \times \frac{f(\{x_i\}_{i=1}^N | \mathcal{Z}', \mu', \kappa')}{f(\{x_i\}_{i=1}^N | \mathcal{Z}, \mu, \kappa)} \end{aligned} \quad (\text{C-2})$$

$$\begin{aligned} \frac{P(H+1)}{P(H)} &= \frac{f(H+1; 1)}{f(H; 1)}, \quad \frac{P(\{z_i'\}_{i=1}^N | \pi')}{P(\{z_i\}_{i=1}^N | \pi)} = \frac{\pi_{j_1}^{n_{j_1}} \pi_{j_2}^{n_{j_2}}}{\pi_{j_1}^{n_{j_1}} \pi_{j_2}^{n_{j_2}}} \\ \frac{f(\pi'|\alpha)}{f(\pi|\alpha)} &= \frac{\Gamma((H+1)\alpha)}{\Gamma(\alpha)^{H+1}} \prod_{h=1}^{H+1} \pi_h^{\alpha-1} = \frac{1}{\pi_h^{\alpha-1}} \frac{\pi_h^{\alpha-1}}{\pi_{j_1}^{\alpha-1}} \\ \frac{f(\mu'|C_0, \mu_0)}{f(\mu|C_0, \mu_0)} &= (H+1) \frac{f(\mu_{j_1}|C_0, \mu_0)}{f(\mu_{j_1}|C_0, \mu_0)} \\ \frac{f(\kappa'|m, \sigma^2)}{f(\kappa|m, \sigma^2)} &= \frac{f(\kappa_{j_1}|m, \sigma^2) f(\kappa_{j_2}|m, \sigma^2)}{f(\kappa_{j_1}|m, \sigma^2)} \\ \frac{f(\{x_i\}_{i=1}^N | \{z_i'\}_{i=1}^N, \mu', \kappa')}{f(\{x_i\}_{i=1}^N | \{z_i\}_{i=1}^N, \mu, \kappa)} &= (\text{likelihood ratio}) = \frac{\prod_{i=1}^N f(x_i | \mu_{z_i}', \kappa_{z_i}')}{\prod_{i=1}^N f(x_i | \mu_{z_i}, \kappa_{z_i})} \end{aligned} \quad (\text{C-3})$$

$$\text{where } n_{j_1} = \sum_{i=1}^N z_{ij_1}, n_{j_2} = \sum_{i=1}^N z_{ij_2}, n_{j_3} = n_{j_1} + n_{j_2}$$

where $B(\cdot, \cdot)$ is the Beta function, the $(H+1)$ -factor in the third line being the ratio $(H+1)!/H!$ from the order statistics densities for the parameters (π, μ, κ) (i.e. label switching for the parameters). The calculation of the Jacobian matrix J and its determinant is similar to that in Zhang et al. (2004) and given in Appendix D.

Following Dellaportas and Papageorgiou (2006), the Jacobian term $\left| \frac{\partial \Sigma}{\partial(\lambda, V)} \right|$ can be computed by using the following formulae

$$\partial \lambda = V_d' (\partial \Sigma) V_d, \quad \partial V = (\lambda_d I_D - \Sigma)^+ (\partial \Sigma) V_d \quad (\text{C-4})$$

where λ_d and V_d , $d=1, \dots, D$, are the specific eigenvalue-eigenvector pairs of Σ ; $(A)^+$ denotes the Moore-Penrose pseudo-inverse matrix of A (See Magnus and Neudecker (1988) p.179). For symmetric perturbations, Magnus and Neudecker (1988) (p.181) suggested that applying the properties of vec operator (i.e. $\text{vec } ABC = (C \otimes A) \text{vec } B$) and the chain rule, Eq. (C-4) can be rewritten as follows

$$\partial \lambda = (V_d' \otimes V_d') \mathbf{D} \partial \text{vec}(\Sigma), \quad \partial V = (V_d' \otimes (\lambda_d I_D - \Sigma)^+) \mathbf{D} \partial \text{vec}(\Sigma) \quad (\text{C-5})$$

where \mathbf{D} is the duplication matrix (see Magnus and Neudecker (1988) Chapter 3). From Eq. (C-5), we obtain the derivatives

$$\begin{aligned} \frac{\partial \lambda}{\partial(\text{vec } \Sigma)} &= V_d' \otimes V_d' \\ \frac{\partial V}{\partial(\text{vec } \Sigma)} &= V_d' \otimes (\lambda_d I_D - \Sigma)^+ \end{aligned} \quad (\text{C-6})$$

According to the inverse function theorem (Spivak, 1965), the inverse of the Jacobian matrix of an invertible function is equivalent to the Jacobian matrix of the inverse function. Specifically, if the Jacobian of the function $F: \mathbb{R}^n \rightarrow \mathbb{R}^n$ is continuous and non-singular at the point $p \in \mathbb{R}^n$, then F is invertible in some neighbourhood of p and we have

$$J_{F^{-1}}(F(p)) = (J_F(p))^{-1} \quad (\text{C-7})$$

Thus, if $\left| \frac{\partial(\lambda, V)}{\partial(\text{vec } \Sigma)} \right|$ is non-zero, then we can have

$$\left| \frac{\partial \Sigma}{\partial(\lambda, V)} \right| = \left| \frac{\partial(\lambda, V)}{\partial(\text{vec } \Sigma)} \right|^{-1} \quad (\text{C-8})$$

Appendix D Calculation of Jacobian Matrix

Let $s = \{\pi_{j_1}, \mu_{j_1}, g_{j_1}\}$ and $s' = \{\pi_{j_2}, \mu_{j_2}, g_{j_2}\}$ denote the state of Markov chain before and after the split move, respectively, where $g_{j_1} = (\lambda_{j_1}, \dots, \lambda_{j_1 D})^T$, $g_{j_2} = (\lambda_{j_2}, \dots, \lambda_{j_2 D})^T$, $g_{j_3} = (\lambda_{j_3}, \dots, \lambda_{j_3 D})^T$. Denote the set of continuous random variables needed for the split move as $u = \{u_1, u_2, u_3\}$, where $u_2 = (u_{21}, \dots, u_{2D})^T$, $u_3 = (u_{31}, \dots, u_{3D})^T$. Thus, from the transformation defined by Eq. (17), we can obtain the Jacobian matrix J for the split move (from (s, u) to (s') as follows (Zhang et al., 2004)

$$J = \frac{\partial s'}{\partial(s, u)} = \begin{bmatrix} \frac{\partial \pi_{j_1}}{\partial \pi_{j_1}} & \frac{\partial \pi_{j_1}}{\partial \pi_{j_2}} & \frac{\partial \pi_{j_1}}{\partial \pi_{j_3}} & \frac{\partial \pi_{j_1}}{\partial \mu_{j_1}} & \frac{\partial \pi_{j_1}}{\partial \mu_{j_2}} & \frac{\partial \pi_{j_1}}{\partial \mu_{j_3}} & \frac{\partial \pi_{j_1}}{\partial g_{j_1}} & \frac{\partial \pi_{j_1}}{\partial g_{j_2}} & \frac{\partial \pi_{j_1}}{\partial g_{j_3}} \\ \frac{\partial \pi_{j_2}}{\partial \pi_{j_1}} & \frac{\partial \pi_{j_2}}{\partial \pi_{j_2}} & \frac{\partial \pi_{j_2}}{\partial \pi_{j_3}} & \frac{\partial \pi_{j_2}}{\partial \mu_{j_1}} & \frac{\partial \pi_{j_2}}{\partial \mu_{j_2}} & \frac{\partial \pi_{j_2}}{\partial \mu_{j_3}} & \frac{\partial \pi_{j_2}}{\partial g_{j_1}} & \frac{\partial \pi_{j_2}}{\partial g_{j_2}} & \frac{\partial \pi_{j_2}}{\partial g_{j_3}} \\ \frac{\partial \pi_{j_3}}{\partial \pi_{j_1}} & \frac{\partial \pi_{j_3}}{\partial \pi_{j_2}} & \frac{\partial \pi_{j_3}}{\partial \pi_{j_3}} & \frac{\partial \pi_{j_3}}{\partial \mu_{j_1}} & \frac{\partial \pi_{j_3}}{\partial \mu_{j_2}} & \frac{\partial \pi_{j_3}}{\partial \mu_{j_3}} & \frac{\partial \pi_{j_3}}{\partial g_{j_1}} & \frac{\partial \pi_{j_3}}{\partial g_{j_2}} & \frac{\partial \pi_{j_3}}{\partial g_{j_3}} \\ \frac{\partial \mu_{j_1}}{\partial \pi_{j_1}} & \frac{\partial \mu_{j_1}}{\partial \pi_{j_2}} & \frac{\partial \mu_{j_1}}{\partial \pi_{j_3}} & \frac{\partial \mu_{j_1}}{\partial \mu_{j_1}} & \frac{\partial \mu_{j_1}}{\partial \mu_{j_2}} & \frac{\partial \mu_{j_1}}{\partial \mu_{j_3}} & \frac{\partial \mu_{j_1}}{\partial g_{j_1}} & \frac{\partial \mu_{j_1}}{\partial g_{j_2}} & \frac{\partial \mu_{j_1}}{\partial g_{j_3}} \\ \frac{\partial \mu_{j_2}}{\partial \pi_{j_1}} & \frac{\partial \mu_{j_2}}{\partial \pi_{j_2}} & \frac{\partial \mu_{j_2}}{\partial \pi_{j_3}} & \frac{\partial \mu_{j_2}}{\partial \mu_{j_1}} & \frac{\partial \mu_{j_2}}{\partial \mu_{j_2}} & \frac{\partial \mu_{j_2}}{\partial \mu_{j_3}} & \frac{\partial \mu_{j_2}}{\partial g_{j_1}} & \frac{\partial \mu_{j_2}}{\partial g_{j_2}} & \frac{\partial \mu_{j_2}}{\partial g_{j_3}} \\ \frac{\partial \mu_{j_3}}{\partial \pi_{j_1}} & \frac{\partial \mu_{j_3}}{\partial \pi_{j_2}} & \frac{\partial \mu_{j_3}}{\partial \pi_{j_3}} & \frac{\partial \mu_{j_3}}{\partial \mu_{j_1}} & \frac{\partial \mu_{j_3}}{\partial \mu_{j_2}} & \frac{\partial \mu_{j_3}}{\partial \mu_{j_3}} & \frac{\partial \mu_{j_3}}{\partial g_{j_1}} & \frac{\partial \mu_{j_3}}{\partial g_{j_2}} & \frac{\partial \mu_{j_3}}{\partial g_{j_3}} \\ \frac{\partial g_{j_1}}{\partial \pi_{j_1}} & \frac{\partial g_{j_1}}{\partial \pi_{j_2}} & \frac{\partial g_{j_1}}{\partial \pi_{j_3}} & \frac{\partial g_{j_1}}{\partial \mu_{j_1}} & \frac{\partial g_{j_1}}{\partial \mu_{j_2}} & \frac{\partial g_{j_1}}{\partial \mu_{j_3}} & \frac{\partial g_{j_1}}{\partial g_{j_1}} & \frac{\partial g_{j_1}}{\partial g_{j_2}} & \frac{\partial g_{j_1}}{\partial g_{j_3}} \\ \frac{\partial g_{j_2}}{\partial \pi_{j_1}} & \frac{\partial g_{j_2}}{\partial \pi_{j_2}} & \frac{\partial g_{j_2}}{\partial \pi_{j_3}} & \frac{\partial g_{j_2}}{\partial \mu_{j_1}} & \frac{\partial g_{j_2}}{\partial \mu_{j_2}} & \frac{\partial g_{j_2}}{\partial \mu_{j_3}} & \frac{\partial g_{j_2}}{\partial g_{j_1}} & \frac{\partial g_{j_2}}{\partial g_{j_2}} & \frac{\partial g_{j_2}}{\partial g_{j_3}} \\ \frac{\partial g_{j_3}}{\partial \pi_{j_1}} & \frac{\partial g_{j_3}}{\partial \pi_{j_2}} & \frac{\partial g_{j_3}}{\partial \pi_{j_3}} & \frac{\partial g_{j_3}}{\partial \mu_{j_1}} & \frac{\partial g_{j_3}}{\partial \mu_{j_2}} & \frac{\partial g_{j_3}}{\partial \mu_{j_3}} & \frac{\partial g_{j_3}}{\partial g_{j_1}} & \frac{\partial g_{j_3}}{\partial g_{j_2}} & \frac{\partial g_{j_3}}{\partial g_{j_3}} \end{bmatrix} \quad (\text{D-1})$$

From the transformation in Eq. (17), we calculate the partial derivatives:

$$\begin{aligned}
 \frac{\partial \pi_{1i}}{\partial \pi_{1j}} &= u_1, & \frac{\partial \pi_{1i}}{\partial u_1} &= \pi_{1j}, & \frac{\partial \pi_{1i}}{\partial \pi_{1j}} &= 0_{1 \times D}, & \frac{\partial \pi_{1i}}{\partial u_2} &= 0_{1 \times D} \\
 \frac{\partial \pi_{1i}}{\partial \pi_{1j}} &= 0_{1 \times D}, & \frac{\partial \pi_{1i}}{\partial u_2} &= 0_{1 \times D} \\
 \frac{\partial \pi_{2i}}{\partial \pi_{1j}} &= 1 - u_1, & \frac{\partial \pi_{2i}}{\partial u_1} &= -\pi_{1j}, & \frac{\partial \pi_{2i}}{\partial \pi_{1j}} &= 0_{1 \times D}, & \frac{\partial \pi_{2i}}{\partial u_2} &= 0_{1 \times D} \\
 \frac{\partial \pi_{2i}}{\partial \pi_{1j}} &= 0_{1 \times D}, & \frac{\partial \pi_{2i}}{\partial u_1} &= 0_{1 \times D} \\
 \frac{\partial \pi_{3i}}{\partial \pi_{1j}} &= 0_{D \times 1}, & \frac{\partial \pi_{3i}}{\partial u_1} &= 0_{D \times 1}, & \frac{\partial \pi_{3i}}{\partial \pi_{1j}} &= I, & \frac{\partial \pi_{3i}}{\partial u_2} &= 0_{D \times D} \\
 \frac{\partial \pi_{3i}}{\partial \pi_{1j}} &= 0_{D \times 1}, & \frac{\partial \pi_{3i}}{\partial u_1} &= 0_{D \times 1}, & \frac{\partial \pi_{3i}}{\partial \pi_{1j}} &= I, & \frac{\partial \pi_{3i}}{\partial u_2} &= 0_{D \times D} \\
 \frac{\partial \pi_{3i}}{\partial \pi_{1j}} &= 0_{D \times 1}, & \frac{\partial \pi_{3i}}{\partial u_1} &= 0_{D \times 1}, & \frac{\partial \pi_{3i}}{\partial \pi_{1j}} &= 0_{D \times D}, & \frac{\partial \pi_{3i}}{\partial u_2} &= 0_{D \times D} \\
 \frac{\partial \pi_{3i}}{\partial \pi_{1j}} &= 0_{D \times 1}, & \frac{\partial \pi_{3i}}{\partial u_1} &= 0_{D \times 1}, & \frac{\partial \pi_{3i}}{\partial \pi_{1j}} &= 0_{D \times D}, & \frac{\partial \pi_{3i}}{\partial u_2} &= 0_{D \times D}
 \end{aligned} \tag{D-2}$$

The other partial derivatives can be calculated as:

$$\begin{aligned}
 \frac{\partial \mu_{1i}}{\partial u_{2d}} &= -\sqrt{\frac{\pi_{1i}}{\pi_{1j}}} \lambda^{\frac{1}{2}} V_{j,d} \\
 \frac{\partial \mu_{1i}}{\partial u_{2d}} &= \sqrt{\frac{\pi_{1i}}{\pi_{1j}}} \lambda^{\frac{1}{2}} V_{j,d} \\
 \frac{\partial \lambda_{j,d}}{\partial u_{2i}} &= \begin{cases} -2u_{3d}u_{2d}\lambda_{j,d}\frac{\pi_{1i}}{\pi_{1j}} & l = d, \\ 0 & l \neq d \end{cases} \\
 \frac{\partial \lambda_{j,d}}{\partial u_{2i}} &= \begin{cases} -2(1 - u_{3d})u_{2d}\lambda_{j,d}\frac{\pi_{1i}}{\pi_{1j}} & l = d, \\ 0 & l \neq d \end{cases} \\
 \frac{\partial \lambda_{j,d}}{\partial u_{3i}} &= \begin{cases} u_{3d}(1 - u_{2d})\frac{\pi_{1i}}{\pi_{1j}} & l = d, \\ 0 & l \neq d \end{cases} \\
 \frac{\partial \lambda_{j,d}}{\partial \lambda_{j,i}} &= \begin{cases} (1 - u_{3d})(1 - u_{2d})\frac{\pi_{1i}}{\pi_{1j}} & l = d, \\ 0 & l \neq d \end{cases} \\
 \frac{\partial \lambda_{j,d}}{\partial \lambda_{j,i}} &= \begin{cases} \lambda_{j,d}(1 - u_{2d})\frac{\pi_{1i}}{\pi_{1j}} & l = d, \\ 0 & l \neq d \end{cases} \\
 \frac{\partial \lambda_{j,d}}{\partial u_{3i}} &= \begin{cases} -\lambda_{j,d}(1 - u_{2d})\frac{\pi_{1i}}{\pi_{1j}} & l = d, \\ 0 & l \neq d, \quad d \in [1, D] \end{cases}
 \end{aligned} \tag{D-3}$$

Therefore, we have the following expressions

$$\begin{aligned}
 \frac{\partial \mu_{1i}}{\partial u_2} &= -\sqrt{\frac{\pi_{1i}}{\pi_{1j}}} V_{j,i} \Lambda_{j,i}^{-\frac{1}{2}} \\
 \frac{\partial \mu_{1i}}{\partial u_2} &= \sqrt{\frac{\pi_{1i}}{\pi_{1j}}} V_{j,i} \Lambda_{j,i}^{-\frac{1}{2}} \\
 \frac{\partial \mu_{1i}}{\partial u_2} &= -2\frac{\pi_{1i}}{\pi_{1j}} \Lambda_{j,i} U_3 U_2 \\
 \frac{\partial \mu_{1i}}{\partial u_2} &= 2\frac{\pi_{1i}}{\pi_{1j}} \Lambda_{j,i} (U_3 - I) U_2 \\
 \frac{\partial \mu_{1i}}{\partial \pi_{1j}} &= -\frac{1}{2} \sqrt{\frac{\pi_{1i}}{\pi_{1j}}} V_{j,i} \Lambda_{j,i}^{-\frac{1}{2}} U_2 \\
 \frac{\partial \mu_{1i}}{\partial \pi_{1j}} &= \frac{1}{2} \sqrt{\frac{\pi_{1i}}{\pi_{1j}}} V_{j,i} \Lambda_{j,i}^{-\frac{1}{2}} U_2 \\
 \frac{\partial \mu_{1i}}{\partial \pi_{1j}} &= \frac{\pi_{1i}}{\pi_{1j}} U_3 (1 - U_2^2) \\
 \frac{\partial \mu_{1i}}{\partial \pi_{1j}} &= \frac{\pi_{1i}}{\pi_{1j}} (I - U_3)(I - U_2^2) \\
 \frac{\partial \mu_{1i}}{\partial \pi_{1j}} &= \frac{\pi_{1i}}{\pi_{1j}} \Lambda_{j,i} (I - U_2^2) \\
 \frac{\partial \mu_{1i}}{\partial \pi_{1j}} &= \frac{\pi_{1i}}{\pi_{1j}} \Lambda_{j,i} (U_2^2 - I)
 \end{aligned} \tag{D-4}$$

where $U_2 = \text{diag}(u_{21}, \dots, u_{2D})$ and $U_3 = \text{diag}(u_{31}, \dots, u_{3D})$ are diagonal matrices. Substituting Eq. (D-2) and (D-4) into Eq. (D-1) yields the Jacobian matrix, J , as follows:

$$J = \begin{bmatrix} u_1 & \pi_{1i} & \mathbf{0}_{1 \times D} & \mathbf{0}_{1 \times D} & \mathbf{0}_{1 \times D} & \mathbf{0}_{1 \times D} \\ 1 - u_1 & -\pi_{1i} & \mathbf{0}_{1 \times D} & \mathbf{0}_{1 \times D} & \mathbf{0}_{1 \times D} & \mathbf{0}_{1 \times D} \\ \mathbf{0}_{D \times 1} & \mathbf{0}_{D \times 1} & \mathbf{I} & -\sqrt{\frac{\pi_{1i}}{\pi_{1j}}} V_{j,i} \Lambda_{j,i}^{-\frac{1}{2}} & -\frac{1}{2} \sqrt{\frac{\pi_{1i}}{\pi_{1j}}} V_{j,i} \Lambda_{j,i}^{-\frac{1}{2}} U_2 & \mathbf{0}_{D \times D} \\ \mathbf{0}_{D \times 1} & \mathbf{0}_{D \times 1} & \mathbf{I} & \sqrt{\frac{\pi_{1i}}{\pi_{1j}}} V_{j,i} \Lambda_{j,i}^{-\frac{1}{2}} & \frac{1}{2} \sqrt{\frac{\pi_{1i}}{\pi_{1j}}} V_{j,i} \Lambda_{j,i}^{-\frac{1}{2}} U_2 & \mathbf{0}_{D \times D} \\ \mathbf{0}_{D \times 1} & \mathbf{0}_{D \times 1} & \mathbf{0}_{D \times D} & -2\frac{\pi_{1i}}{\pi_{1j}} \Lambda_{j,i} U_3 U_2 & \frac{\pi_{1i}}{\pi_{1j}} U_3 (I - U_2^2) & \frac{\pi_{1i}}{\pi_{1j}} \Lambda_{j,i} (I - U_2^2) \\ \mathbf{0}_{D \times 1} & \mathbf{0}_{D \times 1} & \mathbf{0}_{D \times D} & 2\frac{\pi_{1i}}{\pi_{1j}} \Lambda_{j,i} (U_3 - I) U_2 & \frac{\pi_{1i}}{\pi_{1j}} (I - U_3)(I - U_2^2) & \frac{\pi_{1i}}{\pi_{1j}} \Lambda_{j,i} (U_2^2 - I) \end{bmatrix} \tag{D-5}$$

where $\mathbf{0}_{D \times 1}$ is the $D \times 1$ zero vector, $\mathbf{0}_{1 \times D}$ is the $1 \times D$ zero vector, $\mathbf{0}_{D \times D}$ the $D \times D$ zero matrix, $U_2 = \text{diag}(u_{21}, u_{22}, \dots, u_{2D})$ and $U_3 = \text{diag}(u_{31}, u_{32}, \dots, u_{3D})$ are diagonal matrices.

By blocking the Jacobian matrix J defined by Eq. (D-5), we have

$$|\det(J)| = \pi_{1i} \cdot |\det(J_1)| \tag{D-6}$$

where

$$J_1 = \begin{bmatrix} \mathbf{I} & -\sqrt{\frac{\pi_{1i}}{\pi_{1j}}} V_{j,i} \Lambda_{j,i}^{-\frac{1}{2}} & \mathbf{0}_{D \times D} \\ \mathbf{I} & \sqrt{\frac{\pi_{1i}}{\pi_{1j}}} V_{j,i} \Lambda_{j,i}^{-\frac{1}{2}} & \mathbf{0}_{D \times D} \\ \mathbf{0}_{D \times D} & -2\frac{\pi_{1i}}{\pi_{1j}} \Lambda_{j,i} U_3 U_2 & \frac{\pi_{1i}}{\pi_{1j}} U_3 (I - U_2^2) \\ \mathbf{0}_{D \times D} & 2\frac{\pi_{1i}}{\pi_{1j}} \Lambda_{j,i} (U_3 - I) U_2 & \frac{\pi_{1i}}{\pi_{1j}} (I - U_3)(I - U_2^2) \\ & & \frac{\pi_{1i}}{\pi_{1j}} \Lambda_{j,i} (U_2^2 - I) \end{bmatrix} \tag{D-7}$$

We partitioned J_1 into $J_1 = \begin{bmatrix} J_{11} & J_{12} \\ J_{21} & J_{22} \end{bmatrix}$ as indicated by the vertical and horizontal lines in Eq. (D-7). When J_{11} is invertible, according to Theorem by [Brunaldi and Schneider \(1983\)](#), we have

$$|\det(J_1)| = |\det(J_{11})| \cdot |\det(J_{22} - J_{21} J_{11}^{-1} J_{12})| \tag{D-8}$$

Calculating each determinant in Eq. (D-8) and substituting them into Eq. (D-6) yields the absolute of determinant of J , $\det(J)$, as follows

$$|\det(J)| = \frac{\pi_{1i}^{3D+1}}{(\pi_{1j} \pi_{1i})^{\frac{3D}{2}}} \prod_{d=1}^D \lambda_{j,d}^{1/2} (1 - u_{2d}^2) \tag{D-9}$$

Appendix E: Comparison of Different Split-Merge Moves

In this appendix, we compared the performance of TvMF mixture model with common eigenvectors (i.e. simplified RIMCMC move) and without common eigenvectors (i.e. original RIMCMC move) for split-merge moves on synthetic data from three aspects: (1) clustering performance, (2) acceptance rate for the moves and posterior estimation for the number of components H , and (3) the trace plot of the log likelihood and number of components over sweeps (in Figure 12). Table 6 compares the clustering performance and posterior estimation of H for TvMFMM with two different strategies for split-merge moves.

Table 6: Clustering performance and posterior estimation of H for TvMFMM with/without common eigenvectors for split-merge moves on synthetic data.

True H	ARI	AMI	NMI	Homogeneity	Completeness
TvMFMM with common eigenvectors for split-merge move					
4	0.925	0.898	0.899	0.898	0.899
5	0.947	0.941	0.945	0.947	0.944
7	0.809	0.821	0.829	0.827	0.832
TvMFMM without common eigenvectors for split-merge move					
4	0.931	0.904	0.904	0.904	0.904
5	0.936	0.931	0.935	0.936	0.934
7	0.792	0.812	0.82	0.814	0.826

True H	Portion of moves accepted (%)		Posterior estimation for H	
	Split-merge	Birth-death	Split-merge	Birth-death
TvMFMM with common eigenvectors for split-merge move				
4	0.89	0.15	$P(4)=0.997$, $P(5)=0.002$, $P(6)=0.001$	
5	0.25	0.16	$P(5)=0.999$, $P(6)=0.001$	
7	0.69	0.3	$P(7)=0.977$, $P(8)=0.020$, $P(9)=0.002$, $P(10)=0.001$	
TvMFMM without common eigenvectors for split-merge move				
4	0.08	0.05	$P(4)=1.000$	
5	0.02	0.1	$P(5)=0.999$, $P(6)=0.001$	
7	0.42	0.11	$P(7)=0.855$, $P(8)=0.143$, $P(9)=0.001$	

We observe from Table 6 that TvMFMM with and without common eigenvectors for split-merge moves present very similar clustering performance on the three datasets; TvMFMM with common eigenvectors for split-merge move achieves relatively better clustering performance. Both versions of TvMFMM give an accurate estimation of the number of components with the highest posterior probability for the true value of H . In addition, TvMFMM with both settings show very low acceptance rate for the split-merge and birth-death moves. This is one of the characteristics of the RJMCMC algorithm, which generally has very low acceptance rate for the moves, as observed by other researchers (Richardson and Green, 1997; Zhang et al., 2004; Dellaportas and Papageorgiou, 2006).

Figure 12 shows that TvMFMM with/without common eigenvectors for split-merge moves present similar mixing properties for the RJMCMC chains in terms of the smoothness of the log likelihood and number of components over sweeps. It is obvious that the RJMCMC chain becomes stable gradually in terms of the number of components and log likelihood after 5000 sweeps. We actually choose to use a burn-in period of 10000 sweeps for comparison of clustering performance on synthetic data. Overall, the results suggest that TvMFMM with/without common eigenvectors for the split-merge moves show similar performance and mixing rates on synthetic data. Therefore, for the results presented in the empirical evaluation, we ran TvMFMM and OTvMFMM with common eigenvectors for split-merge moves.

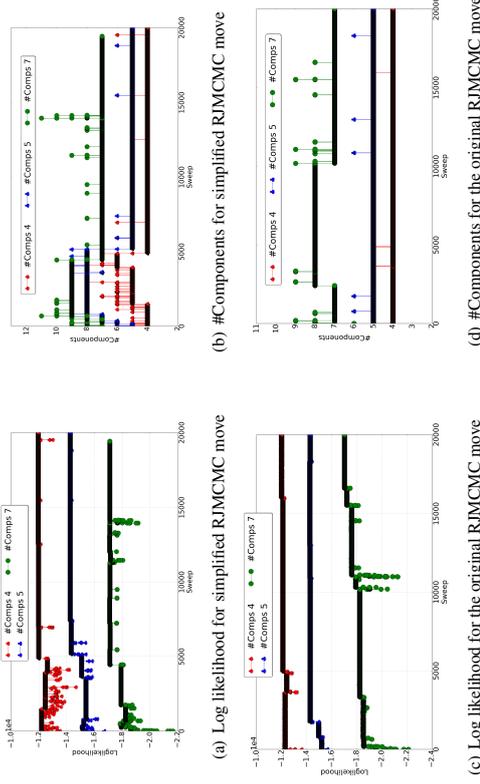

Figure 12: Trace plot of the log likelihood and estimated number of components for TvMFMM with simplified RJMCMC move and with original RJMCMC move on synthetic data.

Appendix F. Model Parameter Analysis

To choose the optimal number of clusters for parametric models, we used NMF model with different number of clusters to analyse Wikipedia quarterly datasets, and measured cluster coherence using normalised pairwise mutual information (NPMI). The results are presented in Figure 13. Recall that the NPMI metric captures the semantic interpretability of discovered clusters based on the corresponding descriptor terms. Higher coherence scores indicate better semantic interpretability, thus more coherent and interpretable topics. One obvious trend in Figure 13 is that NMF models running with larger number of clusters result in lower values of NPMI scores, indicating less coherent and interpretable clusters; whereas models running with smaller number of clusters have higher values of NPMI scores, suggesting more coherent and interpretable clusters. Moreover, NMF models running with 5, 10 and 15 clusters generate very close NPMI scores on all the quarterly datasets, of which models with 10 clusters output the best overall NPMI scores. Therefore, we choose $H = 10$ for parametric models.

We perform further analysis of the log likelihood and cluster coherence of Bayesian vMF mixture model on selected Wikipedia quarterly datasets for varying number of clusters, which are given in Figure 14. As the number of clusters increase from 5 to 20, the log likelihood of the model on the training and held-out datasets also increases, after which the log likelihood becomes relatively stable for any increase in #clusters. On the other hand, as #clusters increases from 5 to 10, the NPMI scores also go up, after which the NPMI scores reduce slightly and become relatively stable. This suggests that larger numbers of clusters does not indicate improved cluster coherence

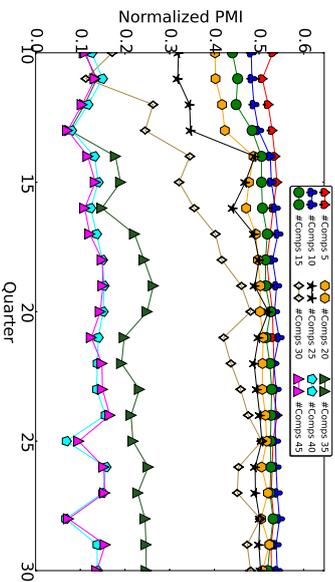

Figure 13: Cluster coherence (NPMI) of NMF model for varied number of clusters ($k \in [5, 45]$) on Wikipedia quarterly training datasets.

/ interpretability. The analysis provides further support for our choice of $H = 10$ for parametric models.

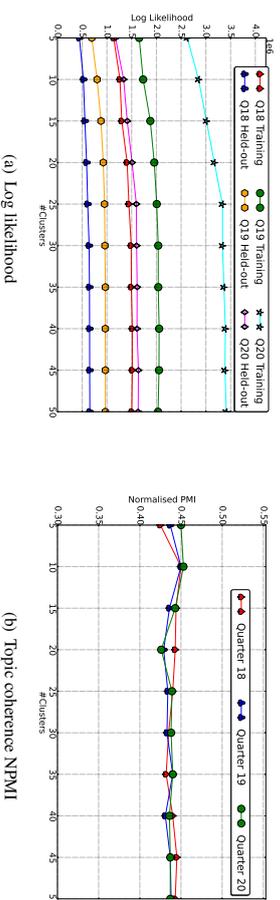

Figure 14: Log likelihood and cluster coherence for Bayesian vMFMM with varied number of clusters ($k \in [5, 50]$) on the 18th (Q18), 19th (Q19) and 20th (Q20) quarter of Wikipedia editor dataset.

One main advantage of the reversible jump MCMC algorithm is the ability to explore multiple models simultaneously, which brings side-benefit that can refine the inappropriate initialization of model parameters. To explore this point, we present a plot of log likelihood and estimated number of components of TVMFMM on selected Wikipedia and synthetic datasets after every 100 iterations. The results are presented in Figure 15, from which we observe that: the log likelihood of the model increases in the beginning, but then becomes relatively stable as more iterations proceed; there are some fluctuations in the log likelihood corresponding to synthetic training dataset with 7

components. The number of components increases with the iterations in the beginning, and then experiences some fluctuations with more iterations. By checking the output of model statistics at these points, we notice that the fluctuation points correspond to the accepted split-merge / birth-death moves where the model explores alternative models. In addition, the statistics of TVMFMM on Wikipedia data and synthetic data with 5 components shows better mixing property (i.e. less fluctuations) than those on synthetic data with 7 components. The results are consistent with our statement about the advantage of RMCMC.

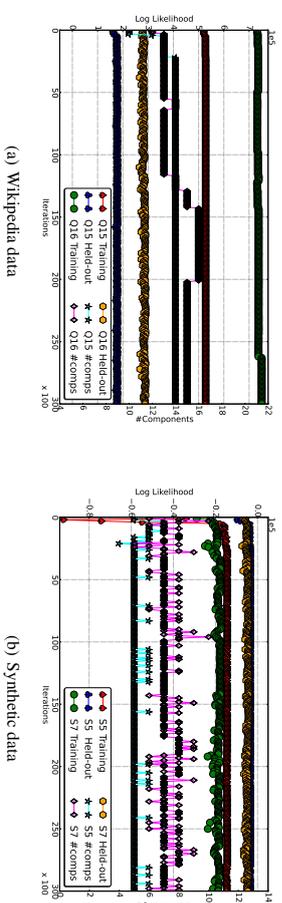

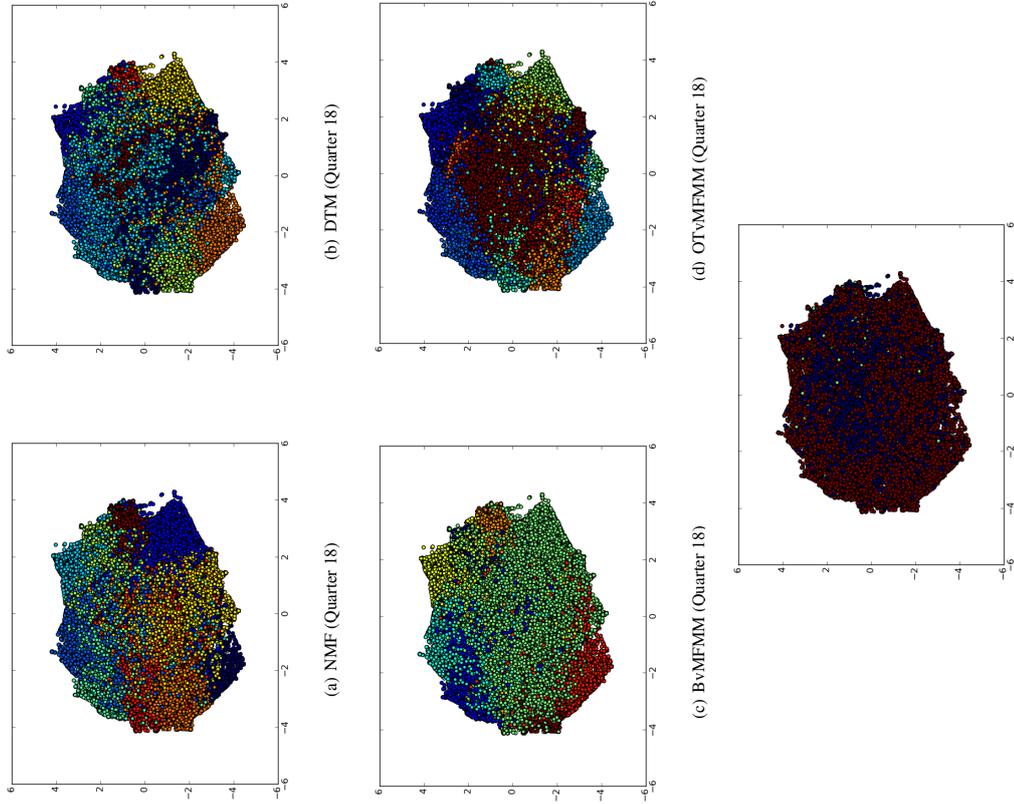

Figure 15: Trace plot of log likelihood and estimated number of components for TVMFMM after each 100 iterations on the 15th (Q15) and 16th (Q16) quarter of Wikipedia editor datasets, and synthetic datasets with 5 (S5) and 7 (S7) components. Where the left yaxis corresponds to log likelihood and the right yaxis represents #components.

Appendix G: Discriminative Analysis for Different Models

Embedding methods, such as t-distributed stochastic neighbourhood embedding (t-SNE; van der Maaten and Hinton (2008)) can be used to visualise high-dimensional data in a two or three-dimensional map. This visualisation provides a unique insight into the discriminative ability of mixture models in terms of separating data points in low-dimensional representation.

Figure 16 presents a 2D embedding of the inferred topic estimation by five models, using the t-SNE method, where each dot represents an entry of user behavioural data and each color-shape represents a topic. Visually, the proposed OTvMFMM produces a relatively better separation of data points than NMF, DTM and BvMFMM, while DP-GMM does not produce a well-separated embedding, and data points assigned to different clusters tend to mix together. This is consistent with our qualitative analysis in Section 5.2.2 that OTvMFMM can produce more interpretable and intuitive topics than other models. Intuitively, a well-separated representation is more discriminative for data separation.

(c) DP-GMM (Quarter 18)

Figure 16: t-SNE 2D embedding of the topical representations by different models on the 18th quarter of Wikipedia Editor dataset.

Appendix H Effects of Prior Parameters

The prior parameters m and σ^2 control the range of the concentration parameters κ , where the value of κ affects the mixing property / convergence of the RJMCMC chain. Figure 17 presents the trace plot of the number of components and log likelihood for TvMFMM with different values for m and σ^2 on synthetic data with 5 and 7 components. The values of m and σ^2 are chosen so that the corresponding ranges of κ are able to illustrate the effects of appropriate and inappropriate priors on the convergence of the chain. If the priors m and σ^2 are appropriately set, the convergence of RJMCMC algorithm can be sped up, leading to well mixing chain, as observed in Figure 17 (a-b) that the chains begin converging from around the 5000th sweep onwards. On the other hand, when the priors m and σ^2 are inappropriately set, the convergence of RJMCMC algorithm can be slowed down, resulting in poor mixing chain, as obvious in Figure 17 (c-d) that the chains experience more fluctuations in the number of components and log likelihood over sweeps. The observations suggest that the trace plot can be used to diagnose whether the priors are appropriately set.

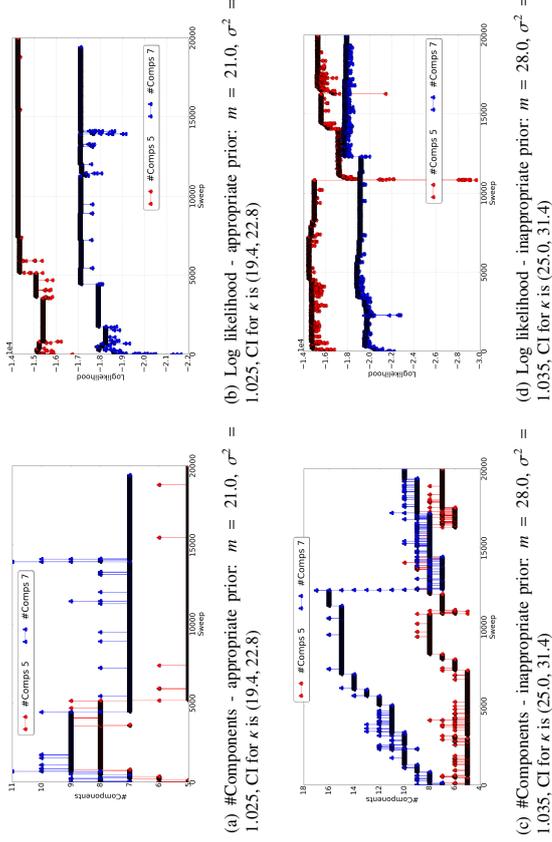

Figure 17: Trace plot of log likelihood and the number of components over iterations for TvMFMM with appropriate/inappropriate values for the prior parameters m and σ^2 on synthetic data, including 99.9% confidence interval (CI) for κ .

Editor: Jie Peng

Abstract

We study the problem of rank aggregation: given a set of ranked lists, we want to form a consensus ranking. Furthermore, we consider the case of extreme lists: i.e., only the rank of the best or worst elements are known. We impute missing ranks and generalise Spearman's ρ to extreme ranks. Our main contribution is the derivation of a non-parametric estimator for rank aggregation based on multivariate extensions of Spearman's ρ , which measures correlation between a set of ranked lists. Multivariate Spearman's ρ is defined using copulas, and we show that the geometric mean of normalised ranks maximises multivariate correlation. Motivated by this, we propose a weighted geometric mean approach for learning to rank which has a closed form least squares solution. When only the best (top-k) or worst (bottom-k) elements of a ranked list are known, we impute the missing ranks by the average value, allowing us to apply Spearman's ρ . We discuss an optimistic and pessimistic imputation of missing values, which respectively maximise and minimise correlation, and show its effect on aggregating university rankings. Finally, we demonstrate good performance on the rank aggregation benchmarks MQ2007 and MQ2008.

1. Introduction

Ranking is a central task in many applications such as information retrieval, recommender systems and bioinformatics. It may also be a subtask of other learning problems such as feature selection, where features are scored according to their predictiveness, and then the most significant ones are selected. One major advantage of ranks over scores is that the resulting predicted ranks are automatically normalised and hence can be used to combine diverse sources of information. However, unlike many other supervised learning problems, the problem of learning to rank (Lebanon and Mao, 2008; Liu, 2011) does not have the simple one example one label paradigm. This has led to many formulations of learning tasks, depending on what label information is available, including pairwise ranking, listwise ranking and rank aggregation.

This paper considers a novel formulation of rank aggregation based on multivariate extensions to Spearman's ρ . For a set of n objects from the domain Ω , we are given a set of d experts that rank these objects providing rankings R_1, \dots, R_d . Each rank is a permutation of the n objects, and can be represented as a vector of unique integers from 1 to n . The problem of rank aggregation is to construct a new vector R that is most similar to the set of d ranks provided by the experts. In this paper we use Spearman's correlation ρ , a widely used correlation measure for ranks Spearman (1904). Instead of decomposing the association into a combination of pairwise similarities, $\rho(R, R_1), \rho(R, R_2), \dots, \rho(R, R_d)$, we directly maximise the multivariate correlation

$$R^* = \arg \max_R \rho(R, R_1, R_2, \dots, R_d).$$

Measures of association such as Spearman's ρ capture the concordance between random variables (Nelsen, 2006). Informally, random variables are concordant if large values of one tend to be associated with large values of the other. Let (x_i, y_i) and (x_j, y_j) be two observations of a pair of continuous random variables. We say that (x_i, y_i) and (x_j, y_j) are *concordant* if $x_i < x_j$ and $y_i < y_j$ or $x_i > x_j$ and $y_i > y_j$. If the inequalities disagree, we say that the samples are *discordant*. The concept of concordance captures only the order of the random variables, and is invariant to their values, and therefore is ideal for analysing ranks. As will be described in section 3.3, Spearman's ρ is based on the difference between the concordance and discordance of the samples.

In short, Spearman's correlation can be defined as the concordance Q between the copula C corresponding to the data and the independent copula π

$$\rho \propto Q(C, \pi).$$

We review the concept of copulas in section 2 and derive our generalisation of concordance in section 3. While the mathematical machinery to derive our proposed algorithm relies on constructions that may not be familiar to some machine learners, the resulting algorithm for rank aggregation is straightforward. We solve a least squares problem for n items,

$$\min_{\omega} \sum_{x=1}^n \left(l(x) - \sum_{j=1}^d \omega_j r_d(x) \right)^2,$$

where we minimise the weights $\omega_1, \dots, \omega_d$ corresponding to the d experts. It turns out that the appropriate transformation to learn weights between experts is to use logarithmic scaled ranks. In the above equation, $l(x)$ and $r(x)$ denote the logarithm of the labels and individual expert ranks respectively, with all ranks normalised uniformly to the interval $(0, 1)$. Since it is a least squares problem, there is a closed form solution for the optimal weights. This is in contrast to previous approaches to rank aggregation that involve complex optimisation methods or sampling.

1.1 Our Contributions

We theoretically justify why the above least squares problem provides a meaningful way to weight experts. We show that the geometric mean of a set of normalised ranks maximises

multivariate Spearman's ρ . This motivates our method which finds a setting of weights that maximise multivariate Spearman's ρ for a specific target (supervised rank aggregation).

As previously mentioned, in many applications of rank aggregation, only extreme ranks are available, whereas the standard definitions of Spearman's ρ require full ranks. For practical problems, the expert may only rank the most liked (top- k) or most disliked (bottom- k) objects where k can be different for each expert. We propose a method for estimating Spearman's ρ for extreme ranks by inputting the remaining ranks. We describe this method and show that it is an unbiased estimator in section 4.

This results in a non-parametric approach for rank aggregation that learns the weights of experts by solving a least squares problem. The weights in this case model dependencies between the rankings, i.e., the rankings are not independent. This is different to much prior work (see section 1.3) in that we explicitly learn the dependencies between experts simultaneously and not in a pairwise fashion. Our method thus offers significant computational benefits, modelling flexibility in the presence of dependencies between experts, and also interpretability due to the simplicity of the model. In section 6 we describe our empirical results for rank aggregation and show that our simple algorithm performs better than current state of the art results.

1.2 Multiple Representations of Ranks

There are a wide range of applications which benefit from rank analysis, resulting in various equivalent ways to represent ranks and orderings. The basic representation often used in introductory texts is to provide the list of objects, for example $[a, b, c, d, e, f]$, denoting the fact that a is the most highly ranked object and f is the lowest ranked. It is often more convenient to numerically represent the rank for computational purposes, that is to keep a list of integers $1, \dots, n$ corresponding to the rank of a particular object. For the example above, by maintaining the set of objects as is, the ranks are then $[1, 2, 3, 4, 5, 6]$. It turns out for empirical copula modeling, it is important that the numerical values are in the interval $(0, 1)$, and therefore we normalise the numerical representation by $n + 1$, that is $[\frac{1}{n+1}, \frac{2}{n+1}, \dots, \frac{n}{n+1}]$. However, note that the numerical representation is actually dependent on the fact that we have maintained the set of objects in a particular fashion. In fact, by the above numerical list, we are saying that object a has rank $\frac{1}{n+1}$, and object f has rank $\frac{n}{n+1}$. In other words, we are defining a permutation mapping $R : \Omega \rightarrow (0, 1)$ from the space of objects Ω to the interval $(0, 1)$.

1.3 Related Work

There are two related rank aggregation tasks: score based rank aggregation and order based rank aggregation. For score based rank aggregation objects are associated with scores, while for order based rank aggregation only the relative order of objects are available. There has been recent work on combining both scores and ranks (Scutley, 2010; Iyer and Bilmes, 2013). We consider the learning task referred to as the listwise approach in Lin (2011), where the input is a set of ranked lists of documents from multiple experts, and the learner has to predict the final ranks. Numerous proposals for solving the problem of combining multiple lists into a single list are surveyed in Lin (2011). Nin et al. (2012) has focused on learning a

good ranking from given features. A good review of probability and statistics applied to permutations is Diaconis (1988).

Spearman's ρ is a natural measure of similarity for distributions of permutations (Mallows, 1957; Eligner and Verducci, 1986). Interestingly, there has not been much work using Spearman's ρ for dealing with ranked data, but instead the focus has been on Kendall's τ . One difficulty of inference with the Mallows model (Mallows, 1957) for Spearman's ρ is that it involves estimating the permanent of a matrix. Our model is derived from the copula form of Spearman's ρ and allows a simple formulation for aggregation that does not require any computationally complex operations, thus providing a significant computational advantage.

Other previous approaches (Klementiev et al., 2008; Iyer and Bilmes, 2012) to rank aggregation considers pairwise comparisons between ranked lists. In contrast, our approach does not consider pairwise combinations and operates over all lists. We prove a result saying that the geometric mean of normalised ranks maximise Spearman's ρ (theorem 17), which is similar in spirit to the result in Iyer and Bilmes (2012) that shows that for Lovász-Bregman divergences the best aggregator is the arithmetic mean. This provides a computational advantage over pairwise methods as the number of lists grows.

Our work builds heavily on copula theory, and we use results from Nelsen (2006). Brief introductions to copulas can be found in Trivedi and Zimmer (2005), Genest and Favre (2007), and Elidan (2013). Further details on copula modeling are available in a recent book (Joe, 2014). Many of these results are presented for bivariate copulas only. There are fewer results on multivariate copulas (Joe, 1990; Nelsen, 1996) and their relation to Spearman's ρ (Ubeda Flores, 2005; Schmid et al., 2010), which we shall discuss later in this paper.

Finally, other well known measures of bivariate dependence have forms under the copula framework and have multivariate extensions. In particular, multivariate extensions of Kendall's τ have been proposed (Joe, 2014). It is possible investigations into these copula formulations results in other efficient aggregation methods with different tradeoffs, however in this work we focus on Spearman's ρ .

The work on partial ranks goes back to at least Critchlow (1985), who describes the rank aggregation task in terms of distances between rankings. We have applied the results of this paper to rank aggregation (Macintyre et al., 2014) and stability estimation (Bedő et al., 2014) in the domain of life sciences.

2. Copulas

Copulas are functions from the unit hypercube to the unit interval (Elidan, 2013). In this section we briefly review the bivariate setting, in preparation for the multivariate setting in the next section. The expert reader may skip directly to section 3 to see the definition of multivariate Spearman's ρ in terms of the multivariate copula.

2.1 Definition of Copulas

Intuitively, for continuous random variables copulas model the dependence component of a multivariate distribution after discounting for univariate marginal effects. We let \mathbb{R} denote the ordinary real line $(-\infty, \infty)$, and \mathbb{R} denote the extended real line $[-\infty, \infty]$. The following algebraic definition of bivariate copulas is generalised to the multivariate setting in section 3.

It essentially constrains copulas to be functions that are *monotonically increasing* along each dimension as well as towards the diagonal of the volume.

Definition 1 Let A_1 and A_2 be nonempty subsets of \mathbb{R} , and let $H(\cdot, \cdot)$ be a real function such that the domain of $H = A_1 \times A_2$. Let $B = [x_1, x_2] \times [y_1, y_2]$ be a rectangle all of whose vertices are in the domain of H . Then the H -volume of B is given by:

$$V_H(B) = H(x_1, y_1) + H(x_2, y_2) - H(x_1, y_2) - H(x_2, y_1).$$

Definition 2 A real function $H(\cdot, \cdot)$ is 2-increasing if its H -volume is non-negative, that is $V_H(B) \geq 0$ for all rectangles B whose vertices lie in the domain of H .

Definition 3 A copula is a function $C: [0, 1]^2 \rightarrow [0, 1]$ with the following properties:

1. For every $u, v \in [0, 1]$,

$$C(u, 0) = 0 = C(0, v)$$

$$C(u, 1) = u \quad \text{and} \quad C(1, v) = v$$

2. C is 2-increasing.

2.2 Relation Between Bivariate Cumulative Density Functions and Copulas

Sklar's theorem is central to the theory of copulas and is the foundation of many applications in statistics. Indeed, Sklar's theorem can be defined for general distribution functions outside of probabilistic settings. However, since we are interested in statistical applications we will consider cumulative distribution functions.

Theorem 4 (Sklar's theorem) Let $H(\cdot, \cdot)$ be a cumulative distribution function with marginals $F(\cdot)$ and $G(\cdot)$. Then there exists a copula $C: [0, 1]^2 \rightarrow [0, 1]$ such that for all x, y in \mathbb{R} ,

$$H(x, y) = C(F(x), G(y)).$$

If $F(\cdot)$ and $G(\cdot)$ are continuous then $C(\cdot, \cdot)$ is unique; otherwise $C(\cdot, \cdot)$ is uniquely determined on the ranges of $F(\cdot)$ and $G(\cdot)$.

Conversely, if $C(\cdot, \cdot)$ is a copula and $F(\cdot)$ and $G(\cdot)$ are cumulative distribution functions then the function $H(\cdot, \cdot)$ is a bivariate cumulative distribution function with marginals $F(\cdot)$ and $G(\cdot)$.

3. Spearman's ρ

We briefly review the bivariate model to lay out the approach for estimating the copula using data, the so-called empirical copula.

3.1 Empirical bivariate Spearman's ρ

Let R and S be ranking functions, which are bijections mapping elements x in the domain U to $[1, 2, \dots, n]$. The domain U represents the space of objects that we are interested in ranking, such as documents retrieved in response to a query or the biomarkers most

associated with a disease. Since we consider only the ranks of the object $R(x)$ and $S(x)$, the actual domain U does not affect the analysis. The sums below are over the n objects x . Similar to the approach of Pearson's correlation for the measure of dependence, Spearman's ρ is a measure of correlation between ranks, empirically given by:

$$\rho_n = \frac{\sum_x (R(x) - \bar{R})(S(x) - \bar{S})}{\sqrt{\sum_x (R(x) - \bar{R})^2 \sum_x (S(x) - \bar{S})^2}}, \tag{1}$$

where $\bar{R} := \frac{1}{n} \sum_x R(x)$ and $\bar{S} := \frac{1}{n} \sum_x S(x)$ are the empirical means of the respective random variables. This is equivalent to applying Pearson's correlation to the ranks instead of the values of the score function itself. There is no direct way to generalise this expression to more than two ranking functions, but as we shall see in section 3.3 we can obtain an expression via the copula.

By substituting the definitions of the empirical means and rearranging the terms, we obtain

$$\rho_n = \left(\frac{n+1}{n-1} \right) \left[\frac{12}{n} \sum_x \frac{R(x) S(x)}{n+1} - 3 \right].$$

The constants 12 and 3 seem strange, but are a natural consequence of the mean and variance of a list of ranks. As we will see later, these constants are dependent only on the dimension of the copula. Similar to the definition of an empirical CDF, we define an empirical copula as:

$$C_n(u, v) = \frac{1}{n} \sum_x \mathbf{1} \left(\frac{R(x)}{n+1} \leq u, \frac{S(x)}{n+1} \leq v \right),$$

where $\mathbf{1}$ is the indicator function. This allows us to re-express the form of ρ_n above in terms of an integral over the unit square,

$$\rho_n = \left(\frac{n+1}{n-1} \right) \left[\frac{12}{n} \sum_x \frac{R(x) S(x)}{n+1} - 3 \right] = \left(\frac{n+1}{n-1} \right) \left[12 \int_{[0,1]^2} uv C_n(u, v) - 3 \right].$$

It can be shown (Nelsen, 2006; Genest and Favre, 2007) that ρ_n is an asymptotically unbiased estimator of

$$\rho = 12 \int_{[0,1]^2} C(u, v) du dv - 3,$$

where C is the population version of C_n .

3.2 Multivariate Copulas

We now generalise the definitions in section 2.1 to the multivariate case. The concepts are essentially the same, constraining the copula to be "monotonically increasing" in the interval $[0, 1]$ and also towards the center of the volume (Durante and Sempi, 2010).

Definition 5 Let A_j be nonempty subsets of \mathbb{R} for $j = 1, \dots, d$, and let $H_d: A_1 \times \dots \times A_d \rightarrow \mathbb{R}$. Let $B = [a_1, b_1] \times \dots \times [a_d, b_d]$ be the d -box where all vertices are contained in $\text{Dom } H_d$. Then the H_d -volume of B is the d^{th} order difference:

$$V_{H_d}(B) = \Delta_{a_d}^{b_d} \dots \Delta_{a_1}^{b_1} H_d(\vec{v}),$$

where

$$\Delta_{a_i}^b H(\vec{t}) = H_d(t_1, \dots, t_{i-1}, b_i, t_{i+1}, \dots, t_d) - H_d(t_1, \dots, t_{i-1}, a_i, t_{i+1}, \dots, t_d).$$

Definition 6 A real function H_d is grounded if $H_d(\vec{t}) = 0$ for all $t \in \text{Dom } H_d$ such that $t_j = a_j$ for at least one $j \in \{1, \dots, d\}$.

Definition 7 A real function H_d is d -increasing if $V_{H_d}(B) \geq 0$ for all n -boxes B whose vertices lie in the domain of H .

Definition 8 A multivariate copula has the following properties:

1. $\text{Dom } C = [0, 1]^d$
2. C has margins $C_j(u) = C(1, \dots, 1, u, 1, \dots, 1) = u$ for all j and $u \in I$
3. C is grounded
4. C is d -increasing.

There is an alternative probabilistic definition that may be more familiar to readers with a statistical background.

Definition 9 Let U_1, \dots, U_d be real uniformly distributed random variables on the unit interval $\sim U([0, 1])$. A copula function $C: [0, 1]^d \rightarrow [0, 1]$ is a joint distribution

$$C(u_1, \dots, u_d) = P(U_1 \leq u_1, \dots, U_d \leq u_d).$$

Let $X \sim F$ be a continuous random variable such that the inverse of the CDF F^{-1} exists. What is the distribution of $F(x) = P(X \leq x)$?

$$\begin{aligned} P(F(X) \leq u) &= P(F^{-1}(F(X)) \leq F^{-1}(u)) \\ &= P(X \leq F^{-1}(u)) \\ &= F(F^{-1}(u)) = u \end{aligned}$$

The above calculation shows that the distribution is uniform, i.e. $F(x) \sim U([0, 1])$. This can be considered to be the *copula trick*, as the user has the freedom to choose the copula independently of the marginal distributions.

3.3 Multivariate Extension of Spearman's ρ

We generalise the concept of concordance to the multivariate setting such that we can define multivariate Spearman's ρ in an analogous way to the bivariate ρ as defined in Nelsen (2006).

Recall that two random variables are concordant if they tend to be in the same order, that is (x_i, y_i) and (x_j, y_j) are concordant if $(x_i - x_j)(y_i - y_j) > 0$, and are discordant if $(x_i - x_j)(y_i - y_j) < 0$. The concordance function Q denotes the difference between the probabilities of concordance and discordance, and as the following theorem shows, can be expressed in terms of the copulas. The proof is in Nelsen (2006).

Theorem 10 (Concordance function) Let (X_1, Y_1) and (X_2, Y_2) be two independent vectors with joint distributions $H_1(x, y) = C_1(F(x), G(y))$ and $H_2(x, y) = C_2(F(x), G(y))$ respectively. Then the concordance function Q is given by

$$\begin{aligned} Q(C_1, C_2) &:= P[(X_1 - X_2)(Y_1 - Y_2) > 0] - P[(X_1 - X_2)(Y_1 - Y_2) < 0] \\ &= 4 \int_{[0, 1]^2} C_2(u, v) dC_1(u, v) - 1 \end{aligned}$$

We now state the generalisation of concordance to the multivariate case (Nelsen, 1996; Joe, 1990). Further details of multivariate concordance can be found in Taylor (2007) and Schmid et al. (2010).

Definition 11 (Multivariate concordance) Let (X_1, \dots, X_d) and (Y_1, \dots, Y_d) be two independent d -vectors with joint distributions $C_X(F(x))$ and $C_Y(F(y))$ where $F(x) = F_1(x_1), \dots, F_d(x_d)$ and $F(y) = F_1(y_1), \dots, F_d(y_d)$ are the marginal distributions, and C_X, C_Y are the respective d copulas. Then the concordance function Q is given by

$$Q(C_X, C_Y) := 2^d \int_{[0, 1]^d} C_X(u) dC_Y(u) - 1.$$

Note that although the integral is a straight forward generalisation of theorem 10, it is no-longer equal to the difference between the probability of concordance and discordance. Consequently, the properties possessed by Q are different for $d > 2$.

There are three copulas that are of particular interest: the independent copula $\pi(u) := \prod_i u_i$, and the upper and lower Fréchet-Hoeffding bounds, $M(u) = \min\{u_1, u_2, \dots, u_d\}$ and $W(u) = \max\{u_1 + u_2 + \dots + u_d - (d-1), 0\}$ respectively (Joe, 2014, pg. 48). Note that that while W is point-wise sharp, this lower bound is not itself a copula, and hence the lower bound is not tight (Ubeda Flores, 2005).

Theorem 12 Let C, C' , and Q be given as in definition 11, M and W be the upper and lower Fréchet-Hoeffding bounds respectively, and assume $d > 2$. Then

1. Q is symmetric in its arguments if $C = C'$.
2. Q is non-decreasing in the first argument, and both arguments if $C = C'$.
3. $-1 \leq Q(W, W) \leq Q(C, C) \leq Q(M, M) = 2^{d-1} - 1$.
4. $Q(\pi, \pi) = 0$.

Proof

Property 1 The first property is clear from the definition of $Q(C, C')$ and the properties of integration.

Property 2 Q is non-decreasing in the first argument by properties of integration. For the second part, notice that

$$\begin{aligned} \int C(u) dC(u) &= C^2(u) - \int C(u) dC(u) \\ &\Rightarrow \int C(u) dC(u) = \frac{1}{2} C^2(u) \end{aligned}$$

by applying integration by parts. The property now follows.

Property 3 It follows that

$$\begin{aligned} Q(M, M) &= 2^d \int_{[0,1]^d} M(u) \, dM(u) - 1 \\ &= 2^d \int_0^1 u \, du - 1 \\ &= 2^{d-1} - 1, \end{aligned}$$

and

$$\begin{aligned} Q(W, W) &= 2^d \int_{[0,1]^d} W(u) \, dW(u) - 1 \\ &\geq 2^d \int_0^1 0 \, du - 1 \\ &= -1. \end{aligned}$$

Property 3 now follows from the first two properties.

Property 4

$$\begin{aligned} Q(\pi, \pi) &= 2^d \int_{[0,1]^d} \pi(u) \, d\pi(u) - 1 \\ &= 2^d \int_{[0,1]^d} u \, du - 1 \\ &= \frac{2^d}{2^d} - 1 \\ &= 0 \end{aligned}$$

■

It is clear from this theorem that Q is well calibrated at $Q(W, W)$ and $Q(\pi, \pi)$, however not for $Q(M, M)$. Consequently, with this multidimensional extension it becomes increasingly difficult to estimate discordance as d increases.

Proposition 13 Let Q be given as in definition 11, and M and π be the upper Fréchet–Hoeffding bound and the independent copula respectively, then

$$Q(M, \pi) = Q(\pi, M) = \frac{2^d - (d + 1)}{d + 1}. \tag{2}$$

Proof To show the symmetry,

$$\begin{aligned} Q(M, \pi) &= 2^d \int_{[0,1]^d} M(u) \, d\pi(u) - 1 \\ &= 2^d \int_{[0,1]^d} u_1 u_2 \cdots u_d \, du - 1 \end{aligned}$$

and

$$\begin{aligned} Q(\pi, M) &= 2^d \int_{[0,1]^d} \pi(u) \, dM(u) - 1 \\ &= 2^d \int_{[0,1]^d} u_1 u_2 \cdots u_d \, du - 1. \end{aligned}$$

To obtain the second equality, we observe that

$$\begin{aligned} \int_{[0,1]^d} u_1 u_2 \cdots u_d \, du &= \int_0^1 u^d \, du \\ &= \frac{1}{d+1} u^{d+1} \Big|_0^1 \\ &= \frac{1}{d+1}, \end{aligned}$$

and therefore the expression for $Q(M, \pi)$ follows. ■

In terms of the concordance function, Spearman's ρ is given by the concordance between the copula C and the independent copula $\pi(u) := \prod_i u_i$. However, unlike the symmetry in proposition 13, the concordance function is in general not symmetric with respect to its arguments. This gives us two possible ways of defining multivariate Spearman's ρ , corresponding to $Q(C, \pi)$ and $Q(\pi, C)$. Both generalisations are equivalent in the bivariate case, and has been called ρ_d^- and ρ_d^+ by Nelsen (1996) and ρ_1 and ρ_2 by Schmid and Schmidt (2007) respectively. Naturally, there is a third symmetric generalisation which is the average of them.

Definition 14 (Multivariate Spearman's ρ)

$$\rho_d^- = h(d)Q(\pi, C) = h(d) \left[2^d \int_{[0,1]^d} C(u) \, du - 1 \right] \tag{3}$$

and

$$\rho_d^+ = h(d)Q(C, \pi) = h(d) \left[2^d \int_{[0,1]^d} \pi(u) \, dC(u) - 1 \right], \tag{4}$$

where $h(d) = \frac{d+1}{2^d - (d+1)}$ is the normalisation factor.

The scaling factor $h(d)$ is derived such that the maximum correlation is 1. Thus, for Spearman's ρ , this is the concordance between the maximum copula M and the independent copula π , which we obtain by proposition 13:

$$h(d) = 1/Q(M, \pi) = \frac{d+1}{2^d - (d+1)}. \tag{5}$$

Spearman's correlation can equivalently be seen as measuring average orthant dependence, and the two versions ρ_d^+ and ρ_d^- correspond to whether we look at the upper or lower orthant (Nelsen, 1996). Positive upper orthant dependence is defined as

$$P(X > x) \geq \prod_{i=1}^d P(X_i > x_i),$$

and positive lower orthant dependence is defined as

$$P(X \leq x) \geq \prod_{i=1}^d P(X_i \leq x_i).$$

When $d = 2$, the two definitions are the same and are called positive quadrant dependence (Lehmann, 1966), as we have already observed for the concordance function:

$$\begin{aligned} P(X_1 > x_1, X_2 > x_2) &\geq P(X_1 > x_1)P(X_2 > x_2) \\ &\geq [1 - P(X_1 \leq x_1)][1 - P(X_2 \leq x_2)] \\ &\geq 1 - P(X_1 \leq x_1) - P(X_2 \leq x_2) + P(X_1 \leq x_1)P(X_2 \leq x_2). \end{aligned}$$

Rearranging gives

$$P(X_1 > x_1, X_2 > x_2) + P(X_1 \leq x_1) + P(X_2 \leq x_2) - 1 \geq P(X_1 \leq x_1)P(X_2 \leq x_2).$$

The left hand side is $P(X_1 \leq x_1, X_2 \leq x_2)$.

Observe that the scaling factor $h(d)$ is the same for both ρ_d^- and ρ_d^+ due to proposition 13. Furthermore, since $P(X_i > x_i) = 1 - P(X_i \leq x_i)$ for each random variable, the two versions of Spearman's ρ correspond to looking at whether we interpret the ranks as top down or bottom up. Converting from one version to the other can be done by reinterpreting the data. For a particular application, the choice of which version to use depends on the ranks that are available. We will focus on ρ_d^+ henceforth.

Recall that for a set of n objects from the domain Ω , we are given a set of d experts that rank these objects providing ranks R_1, \dots, R_d , where each R_j is a bijection to $(0, 1)$. Putting (4) and (5) together, we obtain the following expression for multivariate Spearman's correlation:

$$\rho(R_1, \dots, R_d) = h(d)Q(C; \pi) = \frac{d+1}{2^d - (d+1)} \left[2^d \int_{[0,1]^d} \pi(u) dC(u) - 1 \right]. \quad (6)$$

In practice, we do not have access to the population version of the copula $C(u)$ but have the empirical copula $C_n(u)$. We discuss this further in section 5.

Unlike the bivariate case, as the number of dimensions increases, the lower bound of Spearman's ρ tends to zero. This counterintuitive fact can be understood by considering the three dimensional case. Consider three rankings R_1, R_2 , and R_3 . If R_1 and R_2 are anti-correlated ($\rho = -1$), and at the same time R_1 and R_3 are also anti-correlated, this implies that R_2 and R_3 must be perfectly correlated ($\rho = 1$). Hence, the overall 3 dimensional

correlation is no longer -1. This can be made precise by considering the inclusion-exclusion principle, which results in the following relation from Nelsen (1996):

$$\frac{1}{2}(\rho_d^-(R_1, R_2, R_3) + \rho_d^+(R_1, R_2, R_3)) = \frac{1}{3}(\rho(R_1, R_2) + \rho(R_1, R_3) + \rho(R_2, R_3)).$$

The following corollary defines the lower bound as the number of dimensions increases.

Corollary 15 Under the minimum Fréchet-Hoeffding bound W , $Q(W, \pi) \geq -1$ and

$$\lim_{d \rightarrow \infty} \rho(R_1, \dots, R_d) \geq h(d)Q(W, \pi) = 0.$$

In particular, for dimension d ,

$$\rho(R_1, \dots, R_d) \geq \frac{2^n - (n+1)!}{n!(2^n - (n+1))}.$$

Proof This follows immediately from the bound $-1 \leq Q(W, \pi) \leq 0$ (from theorem 12) since $h(d)$ goes to zero as $d \rightarrow \infty$. The lower bound has also been observed in Nelsen (1996) and Schmid et al. (2010). ■

In summary, the multivariate extension of Spearman's correlation is still calibrated under maximum correlation as it achieves a value of 1, but it becomes increasingly difficult to observe anti-correlated sets of ranks as the number of lists to be aggregated increases. In the next section, we investigate an aggregation algorithm that maximises correlation. The effect of the lower bound is discussed with respect to imputing missing values in section 5.

4. Optimal Aggregation with Spearman's ρ

The empirical copula requires R and S to comprise of ranks for the same set of elements, that is $\text{Dom } R = \text{Dom } S$. Recall from section 3.1 that ranks map to the range $\{1, \dots, n\}$, but the empirical copula is expressed in terms of fractional ranks (divided by $n+1$). In the following it is convenient to work with normalised ranks, that is to consider R and S as bijections to $(0, 1)$. The expression for the empirical copula then simplifies to

$$C_n(u, v) = \frac{1}{|\Omega|} \sum_{x \in \Omega} \mathbf{1}(R(x) \leq u, S(x) \leq v), \quad (7)$$

where Ω is the domain of the objects we are interested in ranking. Correspondingly, the d dimensional empirical copula for n objects given by

$$C_n(u) = \frac{1}{n} \sum_x \prod_{j=1}^d \mathbf{1}(R_j(x) \leq u_j), \quad (8)$$

where $R_1(x), \dots, R_d(x)$ is the rankings of the d experts. Plugging the empirical copula (8) expression into Spearman's ρ (6), and observing that integrating the product over the copula is the product of the ranks Schmid and Schmidt (2007), we obtain an empirical expression for multivariate Spearman's correlation:

$$\rho_n(R_1, \dots, R_d) = h(d) \left[\frac{2^d}{n} \sum_x \prod_{j=1}^d R_j(x) - 1 \right]. \quad (9)$$

4.1 Geometric Mean is Optimal

We are now in a position to derive the deceptively simple result: the ranking R that maximises correlation with a given set of rankings $\{R_1, \dots, R_d\}$ is given by the geometric mean of R_1, \dots, R_d . The following definition is needed to capture the notion that ranks only depend on the order.

Definition 16 (Rank generator) $\sigma: \mathbb{R}^{[d]} \rightarrow [0, 1]^{[d]}$ is a rank generator if:

- for all $x, y \in \Omega$ and R with domain Ω , $R(x) < R(y) \iff \sigma \circ R(x) < \sigma \circ R(y)$;
- for any rankings R, R' with domain Ω there exists a permutation ξ such that $\sigma \circ R' = \sigma \circ \xi \circ R$;
- for any permutation ξ , $\xi \circ \sigma = \sigma \circ \xi$.

A rank generator formalises the idea of generating a rank: the ranks it generates must be invariant to scale and only dependent on the ordering of elements. The standard ranking functions from statistics such as fractional ranking and dense ranking fit into this framework.

Theorem 17 Let $\{R_1, R_2, \dots, R_d\}$ be a set of rankings with common domain Ω and σ be a rank generator. Then

$$\arg \max_{R \in \text{codom } \sigma} \rho_n(R, R_1, R_2, \dots, R_d) = \sigma \left(\prod_{j=1}^d R_j \right).$$

Proof Consider the expression for Spearman's ρ_n (9):

$$\rho_n(R, R_1, R_2, \dots, R_d) = h(d+1) \left[\frac{2^{d+1}}{n} \sum_x \left(R(x) \prod_{j=1}^d R_j(x) \right) - 1 \right].$$

Focusing on the terms in the sum, showing that the best possible $R(x)$ is $\prod_{j=1}^d R_j(x)$ reduces to showing

$$\sum_{x \in U} \sigma \circ P(x) P(x)$$

is maximal, where $P := \prod_j R_j$. Suppose there exists an P' such that

$$\sum_{x \in U} \sigma \circ P'(x) P(x) > \sum_{x \in U} \sigma \circ P(x) P(x).$$

By definition of σ , there exists a permutation ξ such that

$$\begin{aligned} \sum_{x \in U} \sigma \circ P'(x) P(x) &= \sum_{x \in U} \sigma \circ \xi \circ P(x) P(x) \\ &= \sum_{x \in U} \xi \circ \sigma \circ P(x) P(x) \\ &> \sum_{x \in U} \sigma \circ P(x) P(x). \end{aligned}$$

This is a contradiction for any permutation ξ as σ is order preserving. ■

Corollary 18 The converse applies, that is:

$$\arg \min_{R \in \text{codom } \sigma} \rho_n(R, R_1, R_2, \dots, R_d) = \sigma \left(\prod_{j=1}^d (1 - R_j) \right).$$

Proof Proof follows from a similar argument. ■

5. Empirical Copulas with Partial Lists

In many applications it is prohibitive to obtain complete annotations of the object ranks. For example, in the document retrieval setting, this amounts to providing ranks for all documents. The empirical copula requires the set of rankings $\{R_1, \dots, R_d\}$ to comprise of ranks for the same set of elements, that is $\text{Dom } R_1 = \dots = \text{Dom } R_d$. Hence, a key challenge in applying Spearman's ρ to rank aggregation is to estimate the statistic on incompletely labelled lists.

Recall the definition of the empirical copula (7). We now consider the case where $\text{Dom } R \neq \text{Dom } S$, but R and S are generated from two *top ranked* lists. We define extended rankings R', S' with codomain $[0, 1]$ such that $\text{Dom } R' = \text{Dom } R \cup \text{Dom } S = \text{Dom } S'$. One way to impute the missing values is to set them to a constant value for all the ranks below the top- k ranks. This value is chosen to be the mid point between the start and end of the missing section. The values in the top- k are retained to be the original values in the extension. The definition below formally defines this notion. Note that we have to renormalise the values.

Definition 19 (non-informative extension) Let R be a ranking operator and R' be its extension to domain $\text{Dom } R'$. Then,

$$R'(x) = \begin{cases} \frac{|\text{Dom } R|}{|\text{Dom } R'|} R(x) & x \in \text{Dom } R \\ \frac{|\text{Dom } R| + |\text{Dom } R'|}{2|\text{Dom } R'|} & \text{otherwise} \end{cases} \quad (10)$$

$\forall x \in \text{Dom } R'$.

We call this the non-informative extension since it assumes that all items that are not ranked have the same rank (the mean of the missing ranks). Note that the two experts R_i and R_j may have ranked different numbers of objects. An advantage of this extension is that it can easily deal with the case of more than two experts. Consider d experts R_1, \dots, R_d , each of which may have ranked a different subset of the objects. Hence the extension has to impute values on the union of items from all experts. Denote $\text{Dom } R' := \text{Dom } R_1 \cup \dots \cup \text{Dom } R_d$, then we can apply definition 19 to complete each ranking operator R_j . An additional advantage to the non-informative extension is that it results in a consistent ranking.

Definition 20 An extended ranking R' of R is called consistent if the following axioms hold:

1. $R'(x) < R'(y) \forall x, y \in \text{Dom } R$ with $R(x) < R(y)$
2. $R'(x) = R'(y) \forall x, y \in \text{Dom } R$ with $R(x) = R(y)$
3. $R'(y) > R'(x) \forall x \in \text{Dom } R, y \in \text{Dom } R'$

If $E[R] = E[R']$ also holds, then R' is called strictly consistent.

Lemma 21 Definition 19 produces a consistent ranking. If $E[R] = \frac{1}{2}$ then (10) produces a strictly consistent ranking.

Proof The notation $|\text{Dom } R|$ can become unwieldy in following proof. We therefore adopt the shorthand notations $r := |\text{Dom } R|$ and $r' := |\text{Dom } R'|$ for the size of the respective sets. Axioms 1 and 2 are satisfied by definition as the map $x \mapsto \frac{x}{r}$ is monotonic. For all $x \in \text{Dom } R' \setminus \text{Dom } R$,

$$R'(x) = \frac{r+r'}{2r'} \leq 2R(y) \frac{r+r'}{2r'} \leq \frac{2R(y)r}{2r'} = \frac{r}{r'} R(y) = R'(y)$$

for any $y \in \text{Dom } R$, satisfying axiom 3. Furthermore, as

$$\begin{aligned} E[R'] &= \frac{1}{r'} \left(\sum_{x \in \text{Dom } R} R'(x) + \sum_{x \in \text{Dom } R' \setminus \text{Dom } R} R'(x) \right) \\ &= \frac{1}{r'} \left(\frac{r}{r'} \sum_{x \in \text{Dom } R} R(x) + (r' - r) \frac{r+r'}{2r'} \right) \\ &= \frac{1}{r'} \left(\frac{r^2}{r'} E[R] + (r' - r) \frac{r+r'}{2r'} \right) \\ &= \frac{r^2(2E[R] - 1) + r'}{2r'^2}, \end{aligned}$$

R' is strictly consistent if $E[R] = \frac{1}{2}$. ■

Definition 19 is called a *non-informative* extension as it uses no additional information and does not bias the inputted elements in anyway: imputed values are all considered tied and mapped to the same value. Furthermore, the strictly consistent property that definition 19 satisfied is important when using fractional ranking as it guarantees no introduction of bias.

Note also that there is a dual imputation whereby missing values are assigned to the top of the list rather than the bottom. This is equivalent to the above imputation applied to reverse rankings. The choice of top or bottom imputation is application dependent.

5.1 Empirical Upper and Lower Bounds

Proposition 22 For top- k lists where k of n items are ranked by all d experts with codomain $\{1, \dots, n\}$ (i.e., unnormalised ranks), the Spearman's ρ is bounded by

$$\rho_n(R_1, R_2, \dots, R_d) = \rho_k(R_1, R_2, \dots, R_d) + C,$$

where

$$\begin{aligned} 2^d h(d) & \left(\frac{k(k+1)^d - n(n+1)^d}{\sum_{i=1}^k \prod_{j=1}^d \frac{R_{ij}(i)}{k+1}} + k \frac{\sum_{i=k+1}^n i^{\frac{d}{2}} (k-i+n+1)^{\frac{d}{2}}}{n(n+1)^d k} \right) \\ & \leq C \leq \\ & 2^d h(d) \left(\frac{k(k+1)^d - n(n+1)^d}{\sum_{i=1}^k \prod_{j=1}^d \frac{R_{ij}(i)}{k+1}} + \frac{\sum_{i=k+1}^n i^d}{\sum_{i=k+1}^n i^d} k \right) \\ & \frac{2^d h(d)}{n(n+1)^d k}. \end{aligned}$$

Proof Proof sketch: the definition of ρ for unnormalised rankings is

$$\rho_n(R_1, R_2, \dots, R_d) = h(d+1) \left[\frac{2^{d+1}}{n} \sum_{i=1}^n \left(\prod_{j=1}^d \frac{R_{ij}(i)}{n+1} \right) - 1 \right]$$

By considering the difference $\rho_n(R_1, R_2, \dots, R_d) - \rho_k(R_1, R_2, \dots, R_d)$ and factorising out the common terms, we obtain

$$C = \frac{(d+1) 2^d \left(k \left(\sum_{i=1}^n \prod_{j=1}^d \frac{R_{ij}(i)}{n+1} \right) - \left(\sum_{i=1}^k \prod_{j=1}^d \frac{R_{ij}(i)}{k+1} \right) n \right)}{(2^d - d - 1) k n}.$$

The term $\sum_{i=1}^n \prod_{j=1}^d \frac{R_{ij}(i)}{n+1}$ can be bounded above by

$$\sum_{i=1}^n \prod_{j=1}^d \frac{R_{ij}(i)}{n+1} = \sum_{i=1}^k \prod_{j=1}^d \frac{R_{ij}(i)}{n+1} + \sum_{i=1+k}^n \prod_{j=1}^d \frac{R_{ij}(i)}{n+1} \leq \sum_{i=1}^k \prod_{j=1}^d \frac{R_{ij}(i)}{n+1} + \sum_{i=1+k}^n \left(\frac{i}{n+1} \right)^d,$$

and below by

$$\begin{aligned} \sum_{i=1}^n \prod_{j=1}^d \frac{R_{ij}(i)}{n+1} &= \sum_{i=1}^k \prod_{j=1}^d \frac{R_{ij}(i)}{n+1} + \sum_{i=1+k}^n \prod_{j=1}^d \frac{R_{ij}(i)}{n+1} \\ &\geq \sum_{i=1}^k \prod_{j=1}^d \frac{R_{ij}(i)}{n+1} + \sum_{i=k+1}^n \left(\prod_{j=i}^{\lfloor \frac{i}{2} \rfloor} \frac{i}{n+1} \right) \prod_{j=\lceil \frac{i}{2} \rceil}^d \frac{n-i+1+k}{n+1}, \end{aligned}$$

giving us the bounds in the proposition. ■

5.2 Optimal Imputation

An alternative to the previously presented imputation method is to impute such that ρ is maximised or minimised. In general this is a NP-hard problem as it involves searching all permutations. In this section, we formulate this as an optimisation problem.

Let $\mathbb{I} = \{1, \dots, n\} \times \{1, \dots, d\}$ be indices over n items and d experts. Let $\mathbb{O} \subset \mathbb{I}$ be the observed indices (for which we have a rank) and define $\mathbb{U} := \mathbb{I} \setminus \mathbb{O}$. We then have a rank function $R: \mathbb{O} \rightarrow \{1, \dots, n\}$. Recall that Spearman's ρ is determined by a sum of the products over ranks. By introducing a log transformation, we convert the product into a sum using the logarithm rule:

$$\sum_{i=1}^n \left(\prod_{j=1}^d \frac{R_j(i)}{n+1} \right) = \sum_{i=1}^n \left(\exp \log \prod_{j=1}^d \frac{R_j(i)}{n+1} \right) = \sum_{i=1}^n \left(\exp \sum_{j=1}^d \log \frac{R_j(i)}{n+1} \right).$$

5.2.1 IMPUTING TO MAXIMISE CORRELATION

We can maximise Spearman's ρ by introducing binary indicators $x_{i,j,k}$ indexed over $\mathbb{I} \times \{1, \dots, n\}$ to denote a rank of k for item i in list j .

$$\max_{x_{i,j,k}} \sum_{i=1}^n \exp \left[\sum_{j=1}^d \sum_{k=1}^n x_{i,j,k} \log \left(\frac{k}{n+1} \right) \right]$$

such that

$$\sum_k x_{i,j,k} = 1 \quad \forall i, j \quad (11)$$

$$\sum_i x_{i,j,k} = 1 \quad \forall k, j \quad (12)$$

$$\sum_k x_{i,j,k} k = R(i, j) \quad \forall (i, j) \in \mathbb{O} \quad (13)$$

$$x_{i,j,k} \in \{0, 1\} \quad \forall i, j, k \quad (14)$$

Constraint (11) ensures an item is only assigned one rank per expert, and constraint (12) ensures a rank is only assigned once per expert. Finally, the third constraint (13) ensures known ranks are assigned.

5.2.2 IMPUTING TO MINIMISE CORRELATION

Analogously, we can consider the problem of minimising Spearman's ρ .

$$\min_{x_{i,j,k}} \sum_{i=1}^n \exp \left[\sum_{j=1}^d \sum_{k=1}^n x_{i,j,k} \log \left(\frac{k}{n+1} \right) \right] \quad (15)$$

such that

$$\sum_k x_{i,j,k} = 1 \quad \forall i, j$$

$$\sum_i x_{i,j,k} = 1 \quad \forall k, j$$

$$\sum_k x_{i,j,k} k = R(i, j) \quad \forall (i, j) \in \mathbb{O}$$

$$x_{i,j,k} \in \{0, 1\} \quad \forall i, j, k$$

By considering the relaxation of $x_{i,j,k} \in \{0, 1\}$ to $x_{i,j,k} \in [0, 1]$, we obtain a convex optimisation problem.

Proposition 23 *The relaxation of optimisation problem (15) such that $x_{i,j,k}$ is in the interval $[0, 1]$ is a convex optimisation problem.*

Proof The objective has the form $\sum_i \exp((x_i, \omega))$ with $\omega \in [\log(\frac{1}{n+1}), \dots, \log(\frac{n}{n+1})]^{nd}$. Thus, as each term in the sum is convex, and as the sum of convex functions is convex, the objective is convex. The constraints are all linear, hence this is a convex optimisation problem. ■

However, as a consequence of corollary 15, as $d \rightarrow \infty$ we know that $\rho \geq 0$, hence the minimum ρ will approach the ρ when using the non-informative extension (the non-informative extension has $\rho = 0$), thus there is little need to solve the optimisation problem after a sufficient number of dimensions is reached.

5.3 Experiments on University Ranking

The optimal imputation algorithm presented in section 5.2 is difficult to solve due to the integer constraints. We evaluated the performance of a relaxed version of the program, whereby the constraints are relaxed such that the variables may take a value in the range $[0, 1]$. To solve the relaxed problem, we used a BFGS based optimiser by shifting the equality constraints into the objective function with high penalties. Final ranks were determined by ranking item i in list j based on the score $\sum_k x_{i,j,k}$.

We evaluated this relaxed solution on imputing rankings for universities. To this end, the top-200 universities ranked by QS in 2014, Shanghai in 2014, and Times in 2015 were obtained. In aggregating these three lists, there are a total of 266 ranks that need to be imputed.

Measuring multivariate Spearman's ρ on all three lists imputing the missing elements using the non-informative extension gives $\rho = 0.632$. In comparison, the relaxed optimal imputation found a solution that obtained $\rho = 0.683$, a modest increase in the correlation. We also developed an interactive website¹ showing the detailed results for all universities, which also allows the user to alter the weights of each of the original experts. The top 36 aggregate rankings for the universities are given in appendix B.

1. <http://uni.cua0.org>

6. Supervised Learning to Rank

We now consider the task of learning rank aggregation from extreme ranks. Theorem 17 and definition 19 provide the core of our algorithm. Using theorem 17, we can find an average rank that aggregates a set of ranks, and by extending top- k and bottom- k ranks to a common domain, we can apply it to partially labelled data.

6.1 Weighted Mixture of Experts

As a result of theorem 17 we have a way of finding the ranking (according to some rank generator) that is closest to a set of ranks. Consider the learning problem where we have a ranking L which comprise our labels, and a set of d experts $\{R_j\}$. During training, we would like to find a weighting of the input rankings such that it gives the label. Given a target ranking L , we would like to optimise the weights ω ,

$$\max_{\omega} \rho_n(L, R_1^{\omega_1}, R_2^{\omega_2}, \dots, R_n^{\omega_n}).$$

Here we have introduced weights ω over each rank to control the influence of each rank over the final consensus rank; the intuition here is that ranks with $\omega_i > 1$ are replicated with more influence, which is easy to see when ω_i are natural numbers. For example, a weight of 2 would mean the ranked list has appeared twice in the calculation of the consensus rank. While it is convenient to have integer weights for interpretability, the weights ω could be any real number in general. In the following, we consider $\omega \in \mathbb{R}^n$. Instead of performing this high-dimensional optimisation, we decompose it into a pairwise (bivariate) comparison between the label L and the weighted geometric mean, where we now explicitly show the fact that the ranks are a function of the n objects x

$$\max_{\omega} \sum_x \rho_n(L(x), \sigma(R_1^{\omega_1} \otimes R_2^{\omega_2} \otimes \dots \otimes R_n^{\omega_n})(x)),$$

where the notation \otimes indicates the product operator. Observe that we have used theorem 17 to convert the d dimensional problem into the product of ranks R_j and the Spearman's correlation above is only two dimensional. For bivariate Spearman's ρ , this can be expressed in terms of the squared difference (1). We further assume that σ is the identity mapping to simplify the problem, giving us:

$$\min_{\omega} \sum_x (L(x) - R_1^{\omega_1}(x) R_2^{\omega_2}(x) \dots R_n^{\omega_n}(x))^2. \quad (16)$$

The objective (16) minimises the distance between the label ranks and the weighted expert ranks.

6.2 Least Squares Method on Logarithm of Ranks

Recall that we consider normalised ranks (divided by $n+1$). By using the logarithm identity, we convert the power scaling in (16) into a multiplicative scaling. Our algorithm is:

1. Extend incomplete ranks $\{R_i\}$ to $\{R_i^l\}$ by imputing the average missing value such that $\text{Dom } R_i^l = \text{Dom } L$;

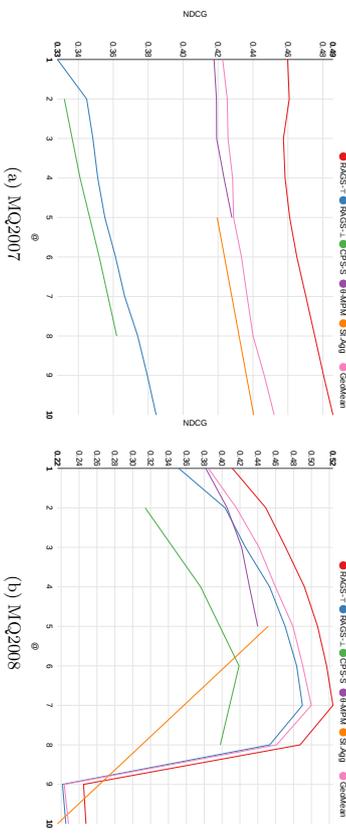

Figure 1: Results on MQ2007-aggr (a, left) and MQ2008-aggr (b, right): NDCG@k. Our method is labelled RAGS- and RAGS- corresponding to top and bottom non-informative imputation respectively. The results for CPS-S was the best reported in Qin et al. (2010a). The results of θ -MPM was the best among the reported results in Volkovs and Zennel (2012) from BordatCount, CPS, SVP, Bradley-Terry model, and Plackett-Luce model. The results of St-Agg was the best among the reported results in Nin et al. (2013) and was the best among MCLK, SVP, Plackett-Luce model, θ -MPM, BordatCount and RRF.

2. Convert to log-ranks $r_i^l = \log \circ R_i^l$ and $l = \log \circ L$;
3. Learn weights ω by minimising

$$\sum_x \left(l(x) - \sum_{j=1}^d \omega_j r_j^l(x) \right)^2, \quad \text{where the outer sum is over the } n \text{ examples } x.$$

A log transformation of the ranks is used as it naturally encodes the weights as a power scaling in the framework of theorem 17, i.e., the weighted consensus rank is given by $\prod_j r_j^l(x)^{\omega_j}$. Note that this is still solving (16) as we are optimising Spearman's ρ , which is sensitive only to ordering, and therefore though the final weights are different ρ is maximised via (1).

In the following experiments we also included a bias/offset term in the least squares problem, which can be interpreted as adding a ranking that is constant (gives all objects the same rank). It is interesting to note that the final step in this procedure is closely related to Borda Count, except our consensus rank is the geometric mean instead of the arithmetic mean. Since this is a least squares estimation problem, we directly use the closed form solution.

6.3 Benchmarking on LETOR 4.0

We tested our method on the MQ2007-aggr and MQ2008-aggr list aggregation benchmarks Qin et al. (2010b). The goal in these challenges is to aggregate 21 and 25 different rankers respec-

tively over a set of query-document pairs. Each data set has 5 pre-defined cross-validation folds with each fold providing a training, testing and validation data set (60%/20%/20%). We trained our model on the training set and tested on the testing set, leaving the validation set unused since we have no hyperparameters.

In the following we consider two types of experts: either experts $\{R_i\}$ are top- k experts, that is they only rank the best k samples from Ω , or experts are bottom- k experts, that is they identify the worst k samples from Ω . We call our proposed method RAGS- and RAGS- respectively. We assume that the ranked documents in the benchmark data sets are either top- k or bottom- k respectively, with potentially different numbers of documents k labelled by each expert. Ties are given the average rank of tied documents.

To evaluate the agreement, we use the standard evaluation tool from the LETOR website², which implements the Normalised Discounted Cumulative Gain (NDCG). In fig. 1a, we see that our approach RAGS- performs better than all other methods at any selection size on the MQ2007-agg data set. Indeed, we also perform better than Qin et al. (2010a) where the best result uses a coset-permutation distance based stagewise (CPS) model with Spearman's ρ in a probabilistic model. Recall that our approach considers the multivariate Spearman's ρ whereas Qin et al. (2010a) uses bivariate Spearman's ρ in a pairwise fashion. For MQ2008-agg (fig. 1b), again our approach performs better than all other methods.

To tease apart the effect of inputting missing ranks and the effect of weighting the experts, we compared our proposed method with and without training (uniform weights). GeoMean denotes the results for the geometric mean (uniform weights on the experts) after performing imputation assuming top- k ranking by the experts. First we observe that our proposed approach outperforms the geometric mean, which is a good sanity check. It is surprising that the geometric mean performs quite well in MQ2007. The major difference is that we are inputting the missing ranks, and the other methods suffer from assigning them to an arbitrary value. This demonstrates the importance of imputation.

6.4 Strictly Ordered Labels

One issue with the benchmark aggregation data set is that the labels are only $\{0,1,2\}$ relevance scores, and hence it is unclear exactly what the rankings are within the relevance classes. We create a new data set which is formed by taking the intersection between the documents retrieved by a particular query between MQ2007-agg and MQ2007-list. This new data set contains the strictly ordered labels from MQ2007-list, but uses the aggregation data from MQ2007-agg. The same procedure is used to create the corresponding data set for MQ2008-agg and MQ2008-list. These data sets are available for download at the LETOR website. We maintain exactly the same 5-fold cross validation splits and report our results in table 3.

Considering the results for Spearman's ρ , we observe that our learning method performs well. Note that the geometric mean outperforms Borda count on both data sets, which confirms that our theoretically justified model performs better than the heuristic model. It is interesting to observe that optimising for Spearman's ρ could result in a decrease in Kendall's τ . This demonstrates the importance of choosing the appropriate objective function for learning.

7. Discussion and Conclusion

We propose an approach for learning weights between experts for the task of rank aggregation. By generalising the derivation of concordance functions, we obtain an expression for multivariate Spearman's ρ . Furthermore, we show that the geometric mean of the expert ranks is the optimal aggregator under Spearman's correlation. Motivated by this, our method solves a least squares estimation problem for logarithmic normalised ranks to find optimal weights.

One possible extension of our work is to compute the correlation for all possible subsets of rankings. While corollary 15 shows that the overall correlation cannot be negative as the number of rankings increase, there may be subgroups which are positively correlated within groups but negatively correlated between groups. By computing the correlation on the power set, we could use a clustering method to find such subgroups.

Though we have focused on ρ_d^+ , our results are equally applicable to ρ_d^- ; indeed it is a simple reversal of ranks that give ρ_d^- . The choice between ρ_d^+ and ρ_d^- is thus problem dependent: for tasks where being ranked highly is more informative ρ_d^+ is a better choice; conversely ρ_d^- is more suitable for tasks where being ranked lowly is more informative.

In contrast to other rank aggregation approaches, our method is very computationally efficient. However, the core of our method requires a complete set of rankings and hence does not handle missing variables. To resolve this, we propose three imputation methods (unbiased, optimistic, pessimistic) for completing top- k ranked lists that allows us to apply Spearman's ρ to aggregate ranks from partial lists. Our method is thus applicable for large scale applications with top- k rankings that arise in areas such as text mining and bioinformatics. One subtlety is that imputation from top- k should not be confused with the choice of using ρ_d^+ , which is an separate design choice.

Surprisingly, our weighted geometric mean shows state of the art results on benchmark data sets, without the need for tuning hyperparameters or expensive computation. The simplicity of our model makes it easier to interpret, and the weights give a direct estimate of the influence of each expert. This problem has wide applications to ensemble learning, voting, text mining, recommender systems and bioinformatics.

Appendix A. Bivariate Spearman's ρ and Squared Distance

This well known result³ shows that Spearman's ρ can be expressed in terms of the squared distance between ranks.

In the following derivation, we use the expressions for the sum of integers and the sum of squares of integers:

$$\sum_{k=1}^n k_i = \frac{n(n+1)}{2} \quad \sum_{k=1}^n k_i^2 = \frac{n(n+1)(2n+1)}{6}.$$

Recall that Spearman's ρ is defined (1) as:

$$\rho_n = \frac{\sum_x (R(x) - \bar{R})(S(x) - \bar{S})}{\sqrt{\sum_x (R(x) - \bar{R})^2 \sum_x (S(x) - \bar{S})^2}}.$$

Since there are no ties, both $R(x)$ and $S(x)$ consist of integers from 1 to n inclusive, and the two squared sums in the denominator are the same. Recall that the mean rank is

$$\bar{R} = \bar{S} = \frac{n+1}{2}, \quad \text{and} \quad \sum_x R(x) = \frac{n(n+1)}{2} = n\bar{R}.$$

Therefore, the denominator can be expressed as a function of n :

$$\begin{aligned} \sqrt{\sum_x (R(x) - \bar{R})^2 \sum_x (S(x) - \bar{S})^2} &= \sum_x (R(x) - \bar{R})^2 \\ &= \sum_x (R(x)^2 - 2R(x)\bar{R} + \bar{R}^2) \\ &= \sum_x R(x)^2 - 2\bar{R} \sum_x R(x) + n\bar{R}^2 \\ &= \sum_x R(x)^2 - n\bar{R}^2 \\ &= \frac{n(n+1)(2n+1)}{6} - n \left(\frac{n+1}{2} \right)^2 \\ &= n(n+1) \left(\frac{2n+1}{6} - \frac{n+1}{4} \right) \\ &= n(n+1) \left(\frac{n-1}{12} \right) \\ &= \frac{n(n^2-1)}{12}. \end{aligned}$$

3. http://en.wikipedia.org/wiki/Spearman's_rank_correlation_coefficient accessed on 20 May 2014

Since both $R(x)$ and $S(x)$ consists of the same integers, we can express the squared difference in terms of the product.

$$\begin{aligned} \sum_x \frac{1}{2}(R(x) - S(x))^2 &= \sum_x \frac{1}{2}(R(x)^2 - 2R(x)S(x) + S(x)^2) \\ &= \sum_x \frac{1}{2}(R(x)^2 + S(x)^2) - \sum_x R(x)S(x) \\ &= \sum_x R(x)^2 - \sum_x R(x)S(x), \end{aligned}$$

where the first term is a function of n .

We express the product of the means, which appears in the numerator later, to match the denominator:

$$\begin{aligned} n \binom{n+1}{2}^2 &= \frac{n(n+1)}{12} 3(n+1) \\ &= -\frac{n(n+1)}{12} [(n-1) - (4n+2)] \\ &= -\frac{n(n+1)(n-1)}{12} + \frac{n(n+1)(2n+1)}{6} \\ &= -\frac{n(n^2-1)}{12} + \sum_x R(x)^2, \end{aligned}$$

where the last term in the sum is the expression for the sum of squares. We can now derive the expression for the numerator:

$$\begin{aligned} \sum_x (R(x) - \bar{R})(S(x) - \bar{S}) &= \sum_x R(x)S(x) - \bar{R} \sum_x S(x) - \bar{S} \sum_x R(x) + n\bar{R}\bar{S} \\ &= \sum_x R(x)S(x) - n\bar{R}\bar{S} \\ &= \sum_x R(x)S(x) - n \binom{n+1}{2}^2 \\ &= \sum_x R(x)S(x) + \frac{n(n^2-1)}{12} - \sum_x R(x)^2 \\ &= \frac{n(n^2-1)}{12} - \sum_x \frac{1}{2}(R(x) - S(x))^2, \end{aligned}$$

where the last line uses the expression of the sum of squared differences above. Putting together the expressions for the numerator and denominator together gives the desired result:

$$\rho_n = 1 - \frac{6 \sum_x (R(x) - S(x))^2}{n(n^2 - 1)}.$$

Abstract

Many data sets can be represented as a sequence of interactions between entities—for example communications between individuals in a social network, protein-protein interactions or DNA-protein interactions in a biological context, or vehicles' journeys between cities. In these contexts, there is often interest in making predictions about future interactions, such as who will message whom.

A popular approach to network modeling in a Bayesian context is to assume that the observed interactions can be explained in terms of some latent structure. For example, traffic patterns might be explained by the size and importance of cities, and social network interactions might be explained by the social groups and interests of individuals. Unfortunately, while elucidating this structure can be useful, it often does not directly translate into an effective predictive tool. Further, many existing approaches are not appropriate for sparse networks, a class that includes many interesting real-world situations.

In this paper, we develop models for sparse networks that combine structure elucidation with predictive performance. We use a Bayesian nonparametric approach, which allows us to predict interactions with entities outside our training set, and allows the both the latent dimensionality of the model and the number of nodes in the network to grow in expectation as we see more data. We demonstrate that we can capture latent structure while maintaining predictive power, and discuss possible extensions.

Keywords: Dirichlet process, networks, Bayesian nonparametrics, Gibbs sampling, hierarchical modeling

1. Introduction

We are often interested in characterizing and predicting the interactions between objects, be they individuals within an organization, proteins within a cell, or transportation hubs within a region. We can represent these objects as nodes in a network, with the non-zero edges of the network describing the interactions between nodes. For example, we can represent a social network as a binary network, where each node corresponds to an individual, and an edge between nodes corresponds to a friendship between individuals. Patterns of email communication can be modeled using an integer-valued network, with integer-valued edges representing the number of emails sent from one individual to another. Interactions between proteins can be represented using a real-valued network, where the nodes correspond to proteins and the edges correspond to interaction strength.

A number of statistical models for such networks have been proposed. Many of these models fall under the *stochastic blockmodel* (SB) framework (Holland et al., 1983; Wang

and Wong, 1987; Suijders and Nowicki, 1997), where each node is assumed to belong to one of K latent groups, and the interaction between two nodes depends only on their group assignments. This basic model can be extended by allowing the number of latent groups to be unbounded, as in the infinite relational model (IRM, Kemp et al., 2006), or by allowing each node to exhibit membership in multiple latent groups, as in the mixed membership stochastic blockmodel (MMSB, Airolidi et al., 2008). One thing that these models have in common is that they treat nodes as exchangeable, and assume that there exists a fixed, stationary network between these nodes. Each node is represented by the totality of its interactions with other nodes, and we use this information to cluster (or, in the case of the MMSB, co-cluster) the data into distinct groups.

In this paper we follow a different approach: we treat the interactions, rather than the nodes, as data points, and construct an exchangeable sequence of directed binary links. Each link corresponds to a single interaction—such as “friending” or “liking” in a social network, or sending a single email—and is characterized in terms of an ordered pair of nodes. We may observe multiple links between two nodes; this corresponds to repeated interactions (for example, sending multiple emails).

This approach has a number of advantages. Unlike the stochastic blockmodel family, the approach described in this paper allows us to model sparse graphs, where the number of non-zero entries grows as $O(M)$, where M is the number of nodes. Sparsity is a property of many real-life networks, which tend to exhibit small-world behavior (Caron and Fox, 2015; Orbanz and Roy, 2014).

Another advantage is that our model is explicitly designed for the prediction task. In many scenarios, we might be interested in what the next interaction will be: who will email whom, for example. Stochastic blockmodels aim to model a fully observed network, where the absence of an observed edge is interpreted as an explicitly observed zero. In this setting, any predictions must directly contradict these observed zeros. While it is possible to explicitly mark edges as “missing”, we can only do this for a small subset of unobserved edges—if we assume all zero edges in a stochastic blockmodel are in fact unobserved, the maximum likelihood network will have all the edges equal to one. Conversely, by constructing an integer-valued network via an exchangeable sequence of links, we frame our problem in a manner that directly provides a predictive distribution over the location of the next link, and allows us to continuously update our posterior predictive distribution in the face of new data. Further, by choosing to place a nonparametric distribution over the sequence of links, we can easily incorporate previously unseen nodes, without any prior knowledge of the number of such nodes.

A further advantage is seen in the computational complexity of the model. Under a stochastic blockmodel with M nodes and K clusters, the computational cost of evaluating the likelihood of the i th node belonging to the k th cluster grows as $O(M)$, meaning that the overall computational cost of inferring the cluster allocations, without resorting to approximations, scales as $O(M^2K)$. Conversely, under the proposed model, the cluster likelihood for a link involves only the two nodes associated with the interaction, yielding $O(N)$ computational complexity where N is the number of links. If N grows significantly slower than M^2 —as is the case if we assume sparsity—this will lead to computational savings as our data set grows.

This paper begins by examining existing Bayesian network models in Section 2, before going on to present our model in Section 3. We begin by introducing the Dirichlet network distribution in Section 3.1, before proceeding to describe how a mixture of such distributions can create a flexible network model with interesting latent structure in Section 3.2. While the focus of this paper is on integer-valued networks, we also consider extensions to the binary case in Section 3.3. While the primary method we consider does not exhibit exchangeable links, we can sample an auxiliary integer-value network and leverage its exchangeability to obtain predictive distributions. In Section 4, we describe an MCMC sampler for the mixture of Dirichlet network distributions, before presenting experimental results in Section 5.

1.1 Notation

We will use the notation Z to represent an $M \times M$ network, with elements $z_{sr} \in \mathbb{N}$ indicating the relationship between nodes s and r . If $z_{sr} \in \{0, 1\}$, then a non-zero value indicates the presence of a relationship. If z_{sr} is allowed to take on arbitrary non-negative integer values, we take this to indicate the number of interactions (for example, emails in a social network, packages in a computer network) between nodes s and r . Unless otherwise specified, we will assume Z to be a directed network, where $Z \neq Z^T$.

It will sometimes be more convenient to represent the matrix Z as a sequence of interactions $Y = y_1, y_2, \dots$ where each interaction y_i consists of an ordered pair of nodes. We can reconstruct the matrix Z by setting $z_{sr} = \sum_i \mathbb{I}(y_i = (s, r))$, where $\mathbb{I}(\cdot)$ represents an indicator function, that returns one iff the statement it refers to is true.

2. Related Work

A number of models have been proposed for modeling interactions within a network. In a Bayesian context, most of these models fall under the general category of stochastic blockmodels (SBs), a class of clustering-based models that generate dense networks. We discuss stochastic blockmodels in Section 2.1.

Recently, there has been growing interest in models for sparse networks, where the number of edges grows linearly (rather than quadratically) with the number of nodes. We discuss relevant work in this area in Section 2.2.

2.1 Stochastic Blockmodels and Related Models

The basic stochastic blockmodel (Holland et al., 1983; Wang and Wong, 1987) posits that each node belongs to one of K latent clusters. For each pair (i, j) of clusters there is a cluster-specific distribution over interactions governed by some parameter $\theta_{i,j}$; conditioned on their cluster allocations c_s and c_r , interactions between nodes s and r are i.i.d. samples from the distribution parametrized by θ_{c_s, c_r} . Typically, this is a Bernoulli distribution, giving rise to a binary matrix; however Maradjasson et al. (2010) show that the basic idea can be extended to real- or integer-valued networks by using different choices of distribution (for example, Gaussian or Poisson).

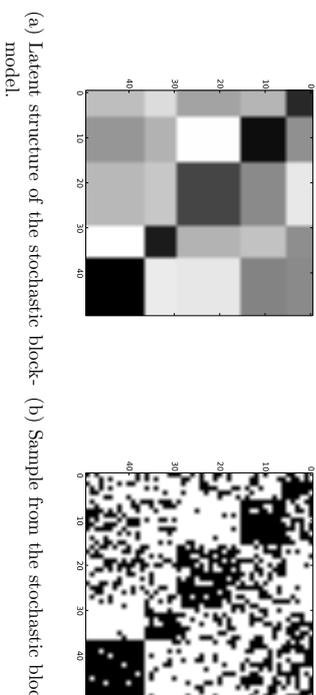

Figure 1: A stochastic blockmodel with 5 clusters.

To position SBs in a Bayesian context (Snijders and Nowicki, 1997), we can place appropriate conjugate priors on the cluster parameters $\theta_{i,j}$ and the cluster proportions. For example, a Bayesian version of the standard Bernoulli stochastic blockmodel takes the form

$$\begin{aligned} \pi &\sim \text{Dirichlet}(\phi) \\ \theta_{i,j} &\sim \text{Beta}(\alpha, \beta), \quad i, j \in \{1, \dots, K\} \\ c_s &\sim \text{Discrete}(\pi), \quad s \in \{1, \dots, M\} \\ z_{sr} &\sim \text{Bernoulli}(\theta_{c_s, c_r}). \end{aligned}$$

Figure 1a shows the underlying partitioning of the nodes, with the color of each partition indicating the corresponding value of θ_{c_s, c_r} in a binary SB. Figure 1b shows an instantiation of a network generated from this structure.

The basic stochastic blockmodel can be extended in a number of ways. The infinite relational model (IRM; Kemp et al., 2006) allows an unbounded number of latent clusters by placing a Dirichlet process prior over the cluster probabilities; this removes the need to pre-specify a latent dimensionality and allows the number of clusters to grow (in expectation) with the number of nodes. A more general class of models is obtained if we associate each pair of nodes with a location in some metric space, and place a continuous or piecewise-continuous parameter function over this space (Lloyd et al., 2012); this class of model includes the SB and the IRM.

The SB and the IRM both assume that each node belongs to a single cluster. The mixed-membership stochastic blockmodel (MMSB, Airoldi et al., 2008) relaxes this assumption by associating each node with a *distribution* over latent clusters. To generate the interaction between nodes s and r , each node selects a cluster from their individual distributions over clusters; the interaction is then generated according to the distribution associated with this pair. This extension allows the model to capture the fact that individuals may perform multiple “roles” leading to different patterns of interaction: Ian may be friends with Janelle because they both play tennis, and friends with Keira because they both study computer science.

While SBs are well-suited to community detection, they are less appropriate for the task of predicting unseen interactions, i.e., asking questions such as “who will Ian interact with next?”. Stochastic blockmodels, and related models, explicitly model the entire network, with the likelihood for a data point’s cluster allocation(s) depending on its interactions with all M nodes in the network. Unless explicitly marked as missing, zeros in the network indicate the observed absence of a relationship, and affect the likelihood. As a result, predictions about the locations of unseen interactions must directly contradict the zeros present in the training set. This cannot be avoided by marking all zeros as unobserved, since in this case the maximum likelihood network is maximally connected.

Further, if we explicitly model the absence of interactions, the model likelihood is changed if we discover the existence of an $(M + 1)$ st node who hasn’t yet interacted with anyone—since we must explicitly cluster this node and include its interactions in other nodes’ likelihood terms. Therefore, if we want to allow prediction of links to or from individuals not included in our training set, we must know in advance the number of such individuals. This is not realistic in many settings: we do not know how many people will join a social network in the future.

Another consequence of modeling both non-zero- and zero-valued edges is that the computational cost of evaluating the conditional probability that node i belongs to cluster k scales linearly with the number of nodes, since

$$P(c_s = k | c_{-s}, Z, \pi, \{\theta_{i,j}\}) \propto \pi_k \prod_{r=1}^M P(z_{rs} | \theta_{k,c_r}) P(z_{rs} | \theta_{c_r,k}).$$

Therefore, resampling the cluster allocations of all M cluster allocations scales quadratically with M (and linearly with K). As M grows, Gibbs sampling (Suijders and Nowicki, 1997) quickly becomes computationally infeasible. Variational methods (Mariadassou et al., 2010; Airoldi et al., 2008) generally give faster inference (albeit at the cost of lower estimate quality); however they still scale quadratically in the number of nodes. A number of approximate methods have been proposed that reduce the computational cost by approximating the full likelihood (Amini et al., 2013; Ho et al., 2012); however as with variational methods these approaches are no longer asymptotically guaranteed to sample from the true model.

2.2 Statistical Models for Sparse Networks

A limitation of stochastic blockmodel-type approaches—and indeed the more general class of models discussed in Lloyd et al. (2012)—is that they yield dense models almost surely (Orbanz and Roy, 2014). In other words, the number of non-zero entries in the resulting network grows as $O(M^2)$. This follows from the structure shown in Figure 1a: each partition is a simple Erdős-Rényi $G(n, p)$ model, with all possible relationships being equally likely, and the number of non-zero relationships growing in expectation with the number of pairs of nodes in that partition.

This contrasts with the sparse nature of many real-life social networks, where the number of non-zero entries grows as $O(M)$, since the number of interactions a person makes does not grow proportionately with the size of the network. In general, an individual will only interact with a small subset of the total population. Caron and Fox (2015) have shown that

several real-world networks, including the ENRON data set explored in this paper, have a very high probability of exhibiting this form of sparsity.

Caron and Fox (2015) presented a construction for sparse networks based on a Poisson process. An integer-valued network is represented as a discrete measure $Z = \sum_{n=1}^{\infty} z_n \delta_{s_n, r_n}$ on \mathbb{R}^2 , where each atom’s size z_n indicates the edge value, and the location (s_n, r_n) specifies a pair of nodes. The atoms are distributed according to a Poisson process, with base measure given by the outer product of two generalized gamma process (GGP)-distributed random measures (Brix, 1999), i.e.

$$\begin{aligned} W &\sim \text{GGP}(\rho, \lambda) \\ Z &\sim \text{PP}(W \times W). \end{aligned} \tag{1}$$

This construction can also be used to generate a binary network, by thresholding the integer-valued network N . Caron and Fox (2015) demonstrate that the construction in Equation 1 can be used to generate networks that are sparse in terms of the number of edges, and exhibit power-law degree distribution. These are both properties that are commonly found in real world networks.

A link between the sparse binary models of Caron and Fox (2015) and the stochastic blockmodel family has recently been made explicit by Veitch and Roy (2015). Under their “graphex” construction for random binary networks, a candidate set of nodes, and associated node-specific parameters, is selected via a Poisson process on \mathbb{R}^2 . As with the SB, the probability of a link between two nodes is governed by the nodes’ parameter values via an appropriate link function, meaning that the SB is a member of this graphex-based class of models. However, different choices of link models can yield sparse graphs including the binary model of Caron and Fox (2015).

3. Nonparametric Models for Networks

As we saw in Section 2, stochastic blockmodels assume a fixed, fully observed network, where zero-valued entries are taken to represent the observed absence of an interaction, and model the network by clustering these nodes. We take a different approach: We model a network as a sequence of observed interactions, and aim to predict the locations of future interactions by explicitly clustering the interactions, rather than the nodes.

To do so, we consider distributions over a sequence of links connecting a set of nodes. Each link, therefore, is associated with an (ordered) pair of nodes sampled from some distribution over such pairs; we may have multiple links associated with a given pair. To allow the network to expand over time, and to facilitate out-of-sample prediction, we let this set of nodes be countably infinite and use a Bayesian nonparametric distribution to assign probabilities to potential pairs.

The main focus of this paper is on integer-valued networks—we will use the running example of an email network—where there can be multiple links between the same pair of nodes. While not explored in as much depth, we also suggest modifications that allow us to model binary networks in Section 3.3.

3.1 Dirichlet Network Distributions

A simple way of constructing an integer-valued network with an unbounded number of nodes is to place a probability distribution G over a countably infinite number of actors. We can represent such a network as a sequence of (sender, receiver) pairs; each pair might, for example, correspond to a single email from a sender to a receiver, or a single journey between two cities. The value of a (directed) edge from a “sender” s to a “receiver” r is the number of times we have seen the pair (s, r) . We call each individual pair in the sequence a link; the value of an edge between two nodes is the number of links between them.

To generate such a pair, we simply sample a sender and a receiver according to G . Let N be the total number of links in our network—that is, the total sum of the edge values. An appropriate prior over G might be the Dirichlet process, so that

$$\begin{aligned} G &\sim \text{DP}(\tau, \Theta) \\ s_n, r_n &\stackrel{i.i.d.}{\sim} G, \quad n = 1, \dots, N \\ z_{ij}^{(N)} &= \sum_{n=1}^N \mathbb{I}(s_n = i, r_n = j). \end{aligned} \quad (2)$$

In other words, we generate a sequence of links by sampling with replacement from the distribution implied by the product measure $G \times G$. We will refer to this construction as a symmetric Dirichlet network distribution (DND). Figure 2a shows a network constructed in this manner.

This model is related to the sparse network model proposed by Caron and Fox (2015) and described in Section 2.2. As we described in Equation 1, Caron and Fox generate a directed, integer-valued graph Z by sampling interactions according to a Poisson process, with rate given by the product measure $W \times W$ where $W \sim \text{GGP}$. If W has finite total mass $W(\Omega)$, then this can equivalently be described as:

$$\begin{aligned} W &\sim \text{GGP}(\rho, \lambda) \\ N &\sim \text{Poisson}(W(\Omega)^2) \\ s_n, r_n &\stackrel{i.i.d.}{\sim} \frac{W}{W(\Omega)}, \quad n = 1, \dots, N \\ Z &= \sum_{n=1}^N \delta_{(s_n, r_n)}. \end{aligned} \quad (3)$$

If we choose a standard gamma process as the random measure W in Equation 3 then, conditioned on the total number of links N , we recover the symmetric nonparametric model described in Equation 2. In this paper, we focus on the gamma process/Dirichlet process case in order to achieve simple inference strategies; however the models proposed in this section can easily be extended to use a normalized generalized gamma process (Lijoi et al., 2008), or some other random probability measure such as a Pitman-Yor process (Pitman and Yor, 1997), in place of the Dirichlet process.

This basic model assumes that the probability of a node being the “sender” of a link is the same as the probability of being a “receiver”. In practice, this is often not a reasonable

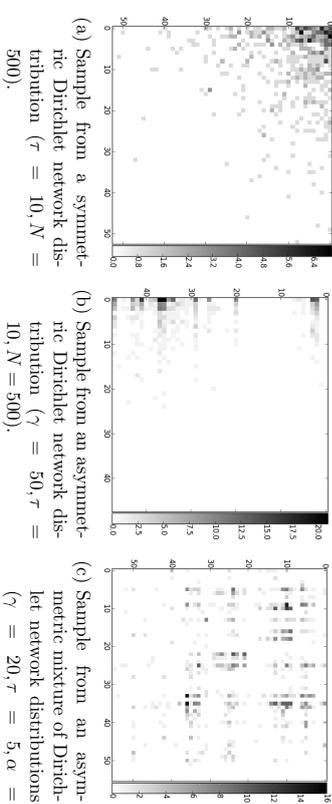

Figure 2: Samples from Dirichlet network distributions and mixtures of Dirichlet network distributions.

assumption. For example, in a university’s email network, administrators may send out a large number of group emails—that is, they often operate in the “sender” role—but receive a relatively small number of emails. When modeling human migration patterns, the United States had over 13 times as many immigrants as emigrants in 2015, whereas Micronesia had around twice as many emigrants as immigrants (United Nations, Department of Economic and Social Affairs, Population Division, 2015). We can capture this form of asymmetry by replacing the single distribution G over nodes (Equation 2) with a pair of distributions, A and B . To ensure the two distributions have the same support (meaning that any node can have both incoming and outgoing links), we couple these two distributions via a shared, discrete base measure H . The generalized process becomes

$$\begin{aligned} H &:= \sum_{i=1}^{\infty} h_i \delta_{\theta_i} \sim \text{DP}(\gamma, \Theta) \\ A &:= \sum_{i=1}^{\infty} a_i \delta_{\theta_i} \sim \text{DP}(\tau, H) \\ B &:= \sum_{i=1}^{\infty} b_i \delta_{\theta_i} \sim \text{DP}(\tau, H) \\ s_n &\sim A, \quad n = 1, \dots, N \\ r_n &\sim B, \quad n = 1, \dots, N \\ z_{ij}^{(N)} &= \sum_{n=1}^N \mathbb{I}(s_n = i, r_n = j). \end{aligned} \quad (4)$$

Figure 2b shows a network constructed in this manner; note the nodes that “send” a large number of links are not necessarily those that “receive” a large number of links. The concentration parameter τ governs how similar the two distributions are to the base measure, and hence to each other.

On their own, like the sparse models explored by Caron and Fox (2015), the symmetric and asymmetric Dirichlet network distributions allow very little internal structure. While we do see some preferential attachment due to the discrete nature of the underlying random measures, there is no clustering structure—if we know that an email was sent by a given

sender, this tells us nothing about the receiver. This makes it a poor model for real-world networks, where we observe cliques of users who are strongly interconnected, or groups that interact with other groups in characterizable manners. While we cannot capture such behavior with the basic symmetric or asymmetric Dirichlet network distributions described above, we can use them as a component of more complex and flexible models.

3.2 Mixtures of Dirichlet Network Distributions

Rather than use a single Dirichlet network distribution over integer-valued networks, as described by Equations 2 and 4, we can use a *mixture* of such distributions, which we will refer to as a mixture of Dirichlet network distributions, or MDND. By ensuring both sender and receiver belong to a common mixture component, we break the independence between sender and receiver, allowing us to identify communication patterns that cannot be captured using the DND or the related Caron and Fox (2015) model. To allow links between the subgraphs associated with each mixture component, we couple the networks using a shared, discrete base measure H . Concretely, in the asymmetric case, let

$$\begin{aligned} D &:= (d_k, k \in \mathbb{N}) \sim \text{GEM}(\alpha) \\ H &:= \sum_{i=1}^{\infty} h_i \delta_{\theta_i} \sim \text{DP}(\gamma, \Theta) \\ A_k &:= \sum_{i=1}^{\infty} a_{k,i} \delta_{\theta_i} \sim \text{DP}(\tau, H), \quad k = 1, 2, \dots \\ B_k &:= \sum_{i=1}^{\infty} b_{k,i} \delta_{\theta_i} \sim \text{DP}(\tau, H) \end{aligned} \quad (5)$$

where $\text{GEM}(\alpha)$ is the distribution over the size-biased atom sizes of a Dirichlet process with concentration parameter α . Figure 2c shows a network constructed in this manner. A symmetric version of the MDND is recovered if we replace the sender- and receiver-specific distributions A_k and B_k with a shared distribution $G_k \sim \text{DP}(\tau, H)$, and is appropriate when we believe the distribution over edges originating from a given node is similar to the distribution over edges ending at that node. For the remainder of this paper, we will focus on the asymmetric setting.

We can verbalize the generative process of the asymmetric MDND as follows. To generate the n th link, we first select a cluster c_n . We then select a “sender” s_n and a “receiver” r_n —identifying a link (s_n, r_n) —according to the cluster-specific distributions A_{c_n} and B_{c_n} . The concentration parameters α , τ and γ can be manipulated to obtain differing network properties. The parameter α controls the number of clusters, with the total number of clusters used to model N links growing approximately as $O(\gamma \log N)$. The parameter τ controls the degree of similarity between the clusters: As τ decreases, the overlap between clusters will tend to decrease. Increasing γ increases the overall number of nodes represented in the network.

Since the pairs are sampled i.i.d. given the random measures, the resulting sequence is exchangeable, meaning the construction is appropriate for sequences of links where there

is no specific ordering of the links, or where the order is believed to be irrelevant. This has useful implications for inference: It means we can easily construct a Gibbs sampler, as described in Section 4. However, in many networks the order in which links are formed does carry information. In Section 3.3, we discuss an extension for explicitly ordered binary links, and in Section 6, we will discuss possible extensions of the integer-valued network model to explicitly ordered links.

3.3 Extension: Binary-valued Networks

Many real-world networks exhibit binary, rather than real-valued, edges. One way of capturing this behavior is to threshold the integer-valued edges generated by the DND or the MDND. The most straightforward version of this is simply to sample a network $Z = (z_{ij})$ according to the DND or the MDND, and then generate a binary network $Y = (y_{ij})$ by letting $y_{ij} = 1$ iff $z_{ij} > 0$. If we place a negative binomial distribution over $N = \sum_{i,j} z_{ij}$, so that $N \sim \text{NB}(\alpha, 1/(1+\beta))$ for some $\beta > 0$, we can represent this thresholded model as

$$\begin{aligned} \Gamma &:= \sum_{k=1}^{\infty} \mu_k \delta_{\theta_k} \sim \text{GP}(\alpha D_0, \beta) & s_n^{(k)} &\sim G_k, \quad n = 1, \dots, N_k \\ & & r_n^{(k)} &\sim G_k \\ G_0 &\sim \text{DP}(\gamma, H_0) & z_j^{(N)} &= \sum_{k=1}^{\infty} \sum_{n=1}^{N_k} \mathbb{I}(s_n^{(k)} = j, r_n^{(k)} = j) \\ G_k &\sim \text{DP}(\tau, G_0), \quad k = 1, 2, \dots & N &:= \sum_k N_k \\ N_k &\sim \text{Poisson}(\mu_k) & y_{ij}^{(N)} &= \mathbb{I}(z_{ij}^{(N)} > 0), \end{aligned} \quad (6)$$

where GP indicates a gamma process. This approach is a form of *restricted exchangeable distribution*, as described by Williamson et al. (2013). As in the unrestricted, integer-valued network, the distribution over edge events is exchangeable. We note that this truncation technique is the same as that used by Caron and Fox (2015) to generate binary networks, and indeed if Z is the symmetric version of the DND given by Equation 3, and if we obtain a symmetric network by mirroring the link counts, then this construction corresponds to the binary network described in Caron and Fox (2015), itself a special case of the class of binary network models described by Veitch and Roy (2015).

If our observations are explicitly ordered, and we believe that ordering to be important, we can modify the DND or the MDND to sample *without* replacement from the set of possible links, giving a non-exchangeable model. This form of non-exchangeability mimics behavior found in many naturally-occurring networks. For example, in a social network, a user will add their close friends first, and then over time add more distant acquaintances. In integer-valued networks exchangeability can represent the fact that close friends will communicate both early and often, but in an exchangeable binary setting all relationships appear identical.

The resulting binary network model is mathematically equivalent to a *censored* DND or MDND, where we only observe the first instance of a link between nodes i and j :

$$\begin{aligned}
D &:= (d_k, k \in \mathbb{N}) \sim \text{GEM}(\alpha) \\
H &:= \sum_{i=1}^{\infty} h_i \delta_{\theta_i} \sim \text{DP}(\gamma_i, \Theta) \\
A_k &:= \sum_{i=1}^{\infty} a_{k,i} \delta_{\theta_i} \sim \text{DP}(\tau, H), \quad k = 1, 2, \dots \\
B_k &:= \sum_{i=1}^{\infty} b_{k,i} \delta_{\theta_i} \sim \text{DP}(\tau, H)
\end{aligned}$$

$$\begin{aligned}
c_t &\sim D, \quad t = 1, 2, \dots \\
s_t &\sim A_{c_t} \\
r_t &\sim B_{c_t} \\
y_{ij}^{(t)} &= \mathbb{I}\left(\sum_{t'=1}^t \mathbb{I}(s_{t'} = i, r_{t'} = j) > 0\right).
\end{aligned}$$

Due to the finite probability of sampling an existing (s, r) pair, $Y^{(t+1)}$ may be the same as $Y^{(t)}$; instead we would likely work with the corresponding non-repeating sequence $(Z^{(n)}, n \in \mathbb{N})$, where $Z^{(n)} = \min_{t'} \left(Y^{(t')} : \sum_{t'=1}^{t'} \mathbb{I}(Y^{(t')} \neq Y^{(t-1)}) = n \right)$. While this censored model is no longer exchangeable, we can make use of the underlying exchangeable sequence of interactions to make predictions.

3.4 Relationship to Other Models

As we described in Section 3.1, the Dirichlet network distribution is strongly related to the sparse network models of Caron and Fox (2015)—in fact, conditioned on the total number of links, the integer-valued model of Caron and Fox (2015) is a special case of the symmetric DND, and the truncated model of Equation 6 describes the binary model of Caron and Fox (2015) as a special case. However, the DND on its own lacks the flexibility to model structured networks, where nodes tend to belong to locally connected sub-networks, and where knowing who sent a message tells us something about the intended recipient. The mixture of Dirichlet network distributions allows us to capture multiple sub-networks, while allowing interaction between sub-networks via a common Dirichlet process-distributed base measure H .

A related integer-valued network model is described by Grane and Dempsey (2016). This model is explicitly designed for multi-way interactions, such as collaborations or actors co-starring in movies, but can be modified to give two-way interactions. The number of “roles” in an interaction is sampled from an appropriate distribution, and for each role, nodes are sampled from a (single) Pitman–Yor process. The two-way interaction setting corresponds to a Pitman–Yor variant of the symmetric Dirichlet network distribution obtained by replacing the Dirichlet process in Equation 2 with a Pitman–Yor process; as such it is unable to capture the clustering behavior obtained using the mixture of Dirichlet network distributions.

The models described in this paper also bear some similarity to stochastic blockmodels, which were described in Section 2. The main difference between the stochastic blockmodel family and the models proposed in this paper is that, under the blockmodel paradigm, nodes are clustered into a (potentially) infinite, in the case of the IRM) number of clusters. Conversely, the MDND directly clusters links, rather than nodes, and represents a network as a (potentially) infinite sequence of pairs of nodes. This creates a natural framework for questions of prediction. For the basic symmetric DND described in Section 3.1, the predictive distribution over the next pair of nodes is available in analytic form via an urn

representation. For the mixture models proposed in Sections 3.2 and 3.3, the predictive distribution depends on the values of latent variables, but we can easily sample from this distribution, as we will see in Section 4.

While the MDND does not explicitly cluster the nodes, we can obtain a similar mixed-membership interpretation to that found in the MMSB. We can think of each cluster of links representing a latent topic of conversation between nodes. Each topic of conversation is described by distributions over the nodes likely to take part in such a conversation. If we condition on the fact that the s th node is sending an email, we can use these distributions to infer the probability of that email belonging to a given discussion. Since the hierarchical construction of Equation 5 ensures that the topics of conversation have overlapping participants, the node will be associated with a conditional distribution over an unbounded number of conversations.

In Section 2.2, we discussed how the graphex construction for binary exchangeable networks by Veitch and Roy (2015) allows us to represent the stochastic blockmodel and the sparse binary model of Caron and Fox (2015) using a common framework. While the integer-valued MDND, and the non-exchangeable binary network described in Section 3.3, do not fall under the graphex framework, it suggests an alternative way to describe the exchangeable binary network obtained by thresholding a MDND (as described in Equation 6).

4. Fully Nonparametric Inference via an Urn Scheme

In the simple symmetric network model of Equation 2, we can directly evaluate the predictive distribution over the n th link, given the previous $n - 1$ links, via a straightforward extension of the Polya urn sampler for the Chinese restaurant process Neal (1998), where the probability of seeing a link between two nodes is proportional to the product of those nodes’ degrees (excluding the link in question):

$$P(y_n = (s, r) | y_1, \dots, y_{n-1}) = \begin{cases} \frac{m_{s, (m_s + \mathbb{I}(s=j))}}{(2n-2+\tau)(2n-1+\tau)} & \text{if } m_i \neq 0, m_j \neq 0 \\ \frac{m_i m_j}{(2n-2+\tau)(2n-1+\tau)} & \text{if } m_i \neq 0, m_j = 0 \\ \frac{m_i \tau}{(2n-2+\tau)(2n-1+\tau)} & \text{if } m_i = 0, m_j \neq 0 \\ \frac{\tau + \mathbb{I}(s=r)}{(2n-2+\tau)(2n-1+\tau)} & \text{if } m_i = 0, m_j = 0, \end{cases}$$

where $m_i = \sum_{n=1}^{n-1} \mathbb{I}(s_n = i) + \mathbb{I}(r_n = i)$ is the sum of the links to or from node i .

The MDND is based on a mixture of coupled hierarchical Dirichlet processes, allowing us to construct a collapsed Gibbs sampler by modifying the direct assignment sampler for the hierarchical Dirichlet process introduced by Teh et al. (2006). Recall that associated with each cluster k we have a sender-specific distribution A_k and a receiver-specific distribution B_k .¹ Let $\eta_k = \sum_{i=1}^N I_{c_i=k}$ be the number of links associated with cluster k ; let $m_{k,i}^{(1)}$ be the number of edges associated with cluster k that originate from node i (that is, edges where node i is the “sender”); and let $m_{k,i}^{(2)}$ be the number of edges associated with cluster k that end at node i (that is, edges where node i is the “receiver”). We also introduce auxiliary

1. In this section, we focus on the asymmetric MDND, where there are separate distributions over senders and receivers; extension to the symmetric case is straightforward.

count variables $\rho_{k,i}^{(1)}$ and $\rho_{k,i}^{(2)}$ and a probability vector $(\beta_1, \dots, \beta_J, \beta_u) \sim \text{Dir}(\rho_1^{(1)}, \dots, \rho_J^{(1)}, \gamma)$, where $\rho_i = \sum_k \rho_{k,i}^{(1)} + \rho_{k,i}^{(2)}$; here β_1, \dots, β_J correspond to the atoms of H that are associated with represented nodes, and $\beta_u = \sum_{j=J+1}^{\infty} h_j$.

The distribution over the cluster assignment of the n th link, given β and all other $N-1$ links, is given by:

$$P(c_n = k | s_n, r_n, c^{-n}, \beta) \propto \begin{cases} \eta_k^{-n} (m_{k,s_n}^{(1)-n} + \tau \beta_{s_n}) (m_{k,r_n}^{(2)-n} + \tau \beta_{r_n}) & \text{if } \eta_k^{-n} > 0 \\ \alpha \tau^2 \beta_{s_n} \beta_{r_n} & \text{if } \eta_k^{-n} = 0. \end{cases} \quad (7)$$

where we use c^{-n} to indicate the sequence $(c_{n'} : n' \neq n)$ and $m_{k,i}^{(1)-n} = \sum_{c_{n'} \neq n} I_{c_{n'}=k, s_{n'}=i}$, i.e., the $-n$ notation is used to exclude the value associated with the current observation.

Following Fox et al. (2007) we can sample the ‘‘dish counts’’ $\rho_{k,i}^{(1)}$ ($\rho_{k,i}^{(2)}$) by simulating the partitioning of $m_{k,i}^{(1)}$ ($m_{k,i}^{(2)}$) according to a Chinese restaurant process with parameter $\tau \beta_k$.

Conditioned on the cluster assignments for the first N links, and the probability vector $(\beta_1, \dots, \beta_J, \beta_u)$, we can evaluate the predictive distribution over the $N+1$ st link as:

$$P(y_{N+1} = (s, r) | c_{1:N}, y_{1:N}, \beta) = \begin{cases} \sum_{k=1}^{K+} \frac{\eta_k}{N+\alpha} \frac{m_{k,s}^{(1)+\tau\beta_s} m_{k,r}^{(2)+\tau\beta_r}}{\eta_k + \tau} + \frac{\alpha}{N+\alpha} \beta_s \beta_r & \text{if } s, r \leq J \\ \sum_{k=1}^{K+} \frac{\eta_k}{N+\alpha} \frac{m_{k,s}^{(1)+\tau\beta_s} \beta_r}{\eta_k + \tau} + \frac{\alpha}{N+\alpha} \beta_s \beta_u & \text{if } s \leq J, r > J \\ \sum_{k=1}^{K+} \frac{\eta_k}{N+\alpha} \beta_u \frac{m_{k,r}^{(2)+\tau\beta_r}}{\eta_k + \tau} + \frac{\alpha}{N+\alpha} \beta_u \beta_r & \text{if } r \leq J, s > J \\ \beta_u^2 & \text{if } r, s > J. \end{cases}$$

To improve mixing, we augmented the sampler with split/merge moves, proposed using the Restricted Gibbs method of Jain and Neal (2004).

5. Experimental Evaluation

We begin by demonstrating the ability of the MDND to recover latent network structure in a two synthetically-generated data sets, before performing a quantitative analysis on three real-world networks.

5.1 Synthetic Data

In Figure 3, we show the performance of the MDND evaluated on a 60-node network generated according to a stochastic blockmodel. A distribution over cluster memberships was drawn from a Dirichlet(5, 5, 5, 5, 5) distribution. Intra-cluster link parameters $\theta_{i,i}$ were distributed according to $\theta_{i,i} \sim \text{Gamma}(5, 1)$, and inter-cluster link parameters $\theta_{i,j}$ were distributed according to $\theta_{i,j} \sim \text{Gamma}(0.5, 1)$. Link counts z_{sr} for each pair (s, r) were Poisson-distributed given the appropriate parameter θ_{c_s, c_r} , where c_s is the cluster of

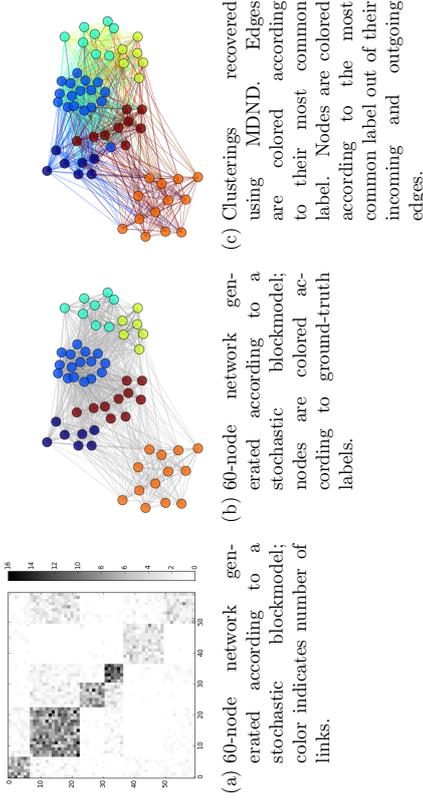

Figure 3: Structure recovery: stochastic blockmodel.

node s . The raw matrix of link counts is shown in Figure 3a, and a visualization of the matrix is shown in Figure 3b, where the edge color indicates the number of nodes and the node color indicates the ground-truth cluster labels.³

Figure 3c shows the structure recovered by the MDND. Each edge in the MDND representation has multiple cluster labels, one per link; the edges are colored according to their most common cluster label. The nodes are colored according to the most common cluster label amongst their incoming and outgoing edges. As we can see from Figure 3c, all but one node is most commonly associated with its ground-truth label.

Figure 4 evaluates the MDND on a 50-node with manually constructed overlapping blocks. The network shown in Figure 4a was generated from 5 equiprobable clusters; each cluster puts 95% of its probability mass on one of five overlapping blocks, and the remaining mass is uniformly distributed over the entire population. Figure 4b shows a visualization of this matrix, where the edge color indicates the number of nodes and the node color indicates most common ground-truth label amongst the incoming and outgoing edges, as in Figure 3b. Figure 4c shows the structure recovered by the MDND; as before, the edges are colored according to their most common cluster label, and the nodes are colored according to the most common cluster label amongst their incoming and outgoing edges. Again, we have very high agreement between the ground-truth labels and the recovered clustering.

5.2 Real Network Data

We compared the mixture of Dirichlet network distributions to the infinite relational model, the mixed membership stochastic blockmodel, and several baselines, in three real-world scenarios: A small network representing character interactions in Shakespeare’s ‘Macbeth’;

3. The visualization layouts in this section (Figures 3b, 3c, 4b and 4c) were generated using the Python package NetworkX with a Fruchterman-Reingold force-directed algorithm.

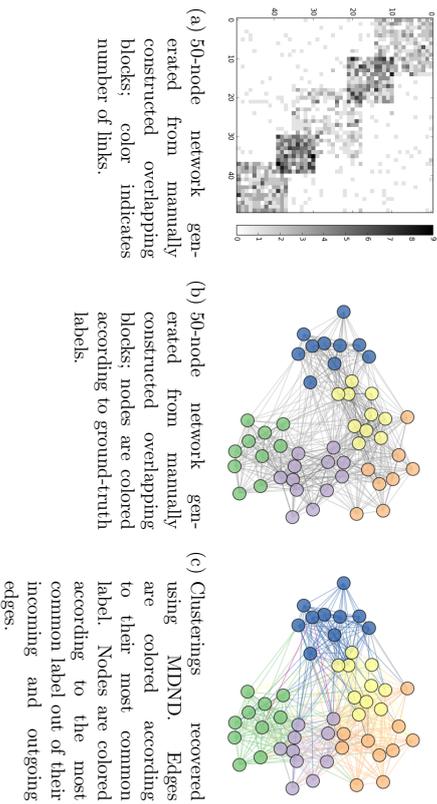

Figure 4: Structure recovery: Overlapping blocks.

a medium-sized network representing political interactions; and a large network representing email interactions. In Section 5.2.1 we describe the comparison methods, and in Section 5.2.2 we describe the three networks and present our results.

5.2.1 COMPARISON METHODS

We compare the mixture of Dirichlet network distributions to a single symmetric Dirichlet network distribution; to integer-valued variants of the mixed-membership stochastic block-model (MMSB, Airoldi et al., 2008) and the infinite relational model (IRM, Kemp et al., 2006); and to two baseline methods.

1. **Symmetric Dirichlet network distribution.** We modeled the data using a single symmetric DND as described in Section 3.1, with Dirichlet process concentration parameter $\tau = 1$.

2. **Infinite relational model.** Kemp et al. (2006) describe a variant of the IRM appropriate for integer-valued data. Each pair of clusters (i, j) is associated with a positive real-valued parameter θ_{ij} , and the N links are assigned to clusters according to a multinomial distribution parameterized by the θ_{ij} . Inference in this model is performed using existing C code released by the authors of Kemp et al. (2006). This code was not able to handle the number of nodes present in the Enron data sets.

3. **Mixed-membership stochastic blockmodel.** While the MMSB is designed for binary-valued networks, it can trivially be extended to integer-valued networks by replacing the Bernoulli distributions with Poisson distributions, and placing gamma priors on the Poisson parameters. While, to the best of our knowledge, this extension has not yet been explored in the literature, it is a natural, and easily implementable,

extension. We perform inference in this model, with $K = 50$ clusters, using Gibbs sampling, via an existing R package (Chang, 2012) that was modified to replace the beta/Bernoulli pairs with gamma/Poisson pairs. Since inference in this model was significantly slower than inference in the IRM and the DNM, we only compared with the gamma/Poisson MMSB on our smallest data set.

4. **Baseline 1: equiprobable links.** Our first baseline assumed that all (sender, receiver) pairs are equally likely, provided the sender and receiver are different—so if we have M nodes, the probability of a given link is $1/M(M-1)$.

5. **Baseline 2: Dirichlet-multinomial distribution over links.** Here we assumed an $M(M-1)$ -dimensional Dirichlet prior over the potential links, and looked at the conditional distribution given the N observed links,

$$P((s_{N+1}, r_{N+1}) = (i, j)) = \frac{\sum_{m=1}^N \mathbb{I}(s_m = i, r_m = j) + \alpha_{ij}}{M(M-1) + N}.$$

We note that this corresponds to an IRM where each pair of nodes is in its own cluster.

5.2.2 EVALUATION ON THREE REAL NETWORKS

We compared the mixture of Dirichlet network distributions to the comparison methods described above, on three real data sets. We describe the data sets below; Table 1 summarizes the networks' statistics.

1. **Macbeth.** This data set represents the implied social network in Shakespeare's 'Macbeth'. We constructed a directed network where each link indicates an uninterrupted block of speech from the speaker to all other characters presently on stage. To evaluate predictive performance, we split the play into 5 contiguous subsets, each containing (approximately) $N/5$ consecutive edges. We used these subsets to generate a 5-fold split into training data (4 of the 5 subsets) and a test set (the remaining one subset), and evaluated the joint predictive likelihood on the test set.

2. **Militarized disputes.** Next, we evaluated our model on a network representing militarized disputes between 188 countries (Maoz, 2005). The data set contains 8650 disputes between 1816 and 1976. We split this data set into 10 subsets, and used these subsets to generate 10 train/test splits, where 9 subsets were used for training and 1 for evaluation.

3. **ENRON email network.** Finally, we looked at subsets of the ENRON email data set (Klimmt and Yang, 2004). We looked at five training sets, corresponding to the total set of emails sent and received in each of the first 5 months of 2000. For each data set, we evaluated predictive performance on the first 1000 emails sent in the subsequent month.

Table 2 shows the log predictive likelihoods obtained on the above data sets. In each case, we condition on the latent structure obtained on the training set, and consider the joint conditional distribution over the test set. For the MMSB and the IRM, our training

Network	Number of links (N)	Number of nodes (M)	N/M^2
Macbeth	2153	39	1.42
Military Disputes	8650	188	0.245
Enron (average)	13994	3883.8	$9.14e-4$
Enron (range)	8692–20464	3006–4652	$7.55e-4$ – $1.03e-3$

Table 1: Network statistics. Note that the Macbeth and Military Disputes data sets were split into equally sized subsets, while the Enron data set was split according to month. We therefore report both the average and the range of the Enron monthly statistics.

	Macbeth	Military Disputes	ENRON
Symmetric DND	-2900.56 ± 193.06	-5019.35 ± 38.70	-15030.77 ± 208.71
MDND	-1769.74 ± 71.60	-5000.74 ± 54.64	-9053.68 ± 235.02
IRM	-1941.50 ± 102.69	-6984.25 ± 16.49	-
MMSB	-3077.22 ± 65.42	-	-
Baseline 1	-2723.33 ± 0	-5748.78 ± 40.59	-16509.75 ± 125.47
Baseline 2	-2462.94 ± 70.05	-5433.24 ± 38.76	-15800.01 ± 138.84

Table 2: Test set log likelihood (mean \pm standard error).

set explicitly included those nodes with interactions present in the test set but not in the training set. We note that this is an unrealistic setting that gives an advantage to the MMSB and the IRM: In most situations, the number of new nodes is unknown. However, without including at least the correct number of unseen nodes, we would be unable to obtain an estimate for the predictive performance on the data sets used.

For the IRM and the MMSB, we already have cluster assignments for each pair of nodes, and can use the cluster parameters to directly obtain a probability distribution over pairs of nodes. We use this probability distribution to directly calculate the joint predictive log likelihood. For the MDND, we do not yet have cluster assignments for the test set links. It is analytically intractable to sum over all possible test set cluster assignments. Instead, we estimate the predictive log likelihood using our Gibbs sampler to generate 100 samples of the test cluster assignments, conditioned on the training set assignments and the test set links. We then use the harmonic mean of the likelihoods given these cluster assignments as an estimator for the overall joint predictive likelihoods.

The MMSB code was unable to run on the Disputes and ENRON data sets, and the IRM code was unable to run on the ENRON data set. By looking at the ratio M/N^2 in Table 1, we see that the Disputes data set is much sparser than Macbeth, and the ENRON data set is much sparser than Macbeth. This means that the blockmodel-based approaches, which scale quadratically with the number of nodes, are unable to run. We note that our experiments were based on of existing implementations of the MMSB and IRM; while different implementations may be able to process the entire data set, it is likely to be much slower than the MDND, due to the density of the network.

We see that, in each case, the MDND out-performs the comparison methods—even though we have included more information in the MMSB and the IRM by making use of the number of unseen nodes.

6. Discussion and Future Work

We have presented a new Bayesian nonparametric model, the mixture of Dirichlet network distributions, for integer-valued networks where the number of nodes is unbounded and grows in expectation with the number of binary links. This model allows us to capture sparse networks with latent structure. Existing network models focus either on latent structure—capturing the fact that each node will have a different pattern over which nodes it connects with—or on capturing sparsity; this is, to our knowledge, the first model that combines these two goals. Further, unlike most existing Bayesian network models, this model is explicitly designed for prediction. We can use the mixture of Dirichlet network distributions to obtain an explicit predictive distribution over the nodes associated with an as-yet unseen observation, even if we have not observed these nodes in our training set; we have shown good predictive and qualitative performance on a variety of data sets.

The mixture of Dirichlet network distributions is based on a simpler network model that we refer to as a Dirichlet network distribution. In the symmetric setting—where a common distribution is used for both senders and receivers—this corresponds to a special case of the integer-valued network models of Caron and Fox (2015) and Crane and Dempsey (2016). While these models can be used to obtain desirable properties such as network sparsity and power law degree distribution, they are unable to capture community-type structure in the network. By using a mixture of these networks, we can capture multiple modalities of interaction between nodes; by using a nonparametric hierarchical framework we ensure that both the number of nodes is unbounded, and that nodes can interact as part of multiple clusters. The MDND therefore increases the modeling flexibility of this class of models, while retaining desirable sparsity properties.

The mixture of Dirichlet network distributions is an exchangeable model: It is invariant to permutations of the order in which we observe links. While this is computationally appealing and leads to a straightforward predictive distribution, it does not allow us to capture network dynamics in integer-valued networks. In practice, such dynamics may be important: an individual’s level of activity within a topic may vary over time, and the overall popularity of topics may change. A number of authors have found that adding temporal dynamics to network models improves performance (Ishiguro et al., 2010; King et al., 2010; Xu and Hero III, 2013). In the case of Dirichlet network distributions, similar temporal dynamics could be incorporated by replacing some or all of the component Dirichlet processes with *dependent* Dirichlet processes (MacEachern, 2000; Lin et al., 2010; Ren et al., 2008); we intend to explore this in a future work.

In addition to the base model for integer-valued networks, we also discussed extensions to binary networks. The methods considered involve truncating the exchangeable integer-valued network; while it is possible to obtain exchangeable binary networks related to those considered by Caron and Fox (2015) and Veitch and Roy (2015), we argued that a dynamic truncation, yielding a non-exchangeable model, is more appropriate for a temporally expanding binary network. Unfortunately, inference in such truncated models is trickier

than the integer-valued case. While we can analytically sample the censored observations as auxiliary variables and recover the integer network, the number of censored observations grows according to a coupon-collector problem with the number of observed links, making this approach infeasible for large data sets. An interesting avenue for future research is to develop scalable inference methods for this setting.

Abstract

Many data mining and statistical machine learning algorithms have been developed to select a subset of covariates to associate with a response variable. Spurious discoveries can easily arise in high-dimensional data analysis due to enormous possibilities of such selections. How can we know statistically our discoveries better than those by chance? In this paper, we define a measure of goodness of spurious fit, which shows how good a response variable can be fitted by an optimally selected subset of covariates under the null model, and propose a simple and effective LAMM algorithm to compute it. It coincides with the maximum spurious correlation for linear models and can be regarded as a generalized maximum spurious correlation. We derive the asymptotic distribution of such goodness of spurious fit for generalized linear models and L_1 regression. Such an asymptotic distribution depends on the sample size, ambient dimension, the number of variables used in the fit, and the covariance information. It can be consistently estimated by multiplier bootstrapping and used as a benchmark to guard against spurious discoveries. It can also be applied to model selection, which considers only candidate models with goodness of fits better than those by spurious fits. The theory and method are convincingly illustrated by simulated examples and an application to the binary outcomes from German Neuroblastoma Trials.

Keywords: Bootstrap, Gaussian approximation, generalized linear models, L_1 regression, model selection, sparsity, spurious correlation, spurious fit

1. Introduction

Technological developments in science and engineering lead to collections of massive amounts of high-dimensional data. Scientific advances have become more and more data-driven, and researchers have been making efforts to understand the contemporary large-scale and complex data. Among these efforts, variable selection plays a pivotal role in high-dimensional statistical modeling, where the goal is to extract a small set of explanatory variables that are associated with given responses such as biological, clinical, and societal outcomes. Toward this end, in the past two decades, statisticians have developed many data learning methods and algorithms, and have applied them to solve problems arising from diverse fields of sciences, engineering and humanities, ranging from genomics, neurosciences and health

sciences to economics, finance and machine learning. For an overview, see Bühlmann and van de Geer (2011) and Hastie, Tibshirani and Wainwright (2015).

Linear regression is often used to investigate the relationship between a response variable Y and explanatory variables $\mathbf{X} = (X_1, \dots, X_p)^T$. In the high-dimensional linear model $Y = \mathbf{X}^T \boldsymbol{\beta}^* + \varepsilon$, the coefficient $\boldsymbol{\beta}^*$ is assumed to be sparse with support $S_0 = \text{supp}(\boldsymbol{\beta}^*)$. Variable selection techniques such as the forward stepwise regression, the Lasso (Tibshirani, 1996) and folded concave penalized least squares (Fan and Li, 2001; Zou and Li, 2008) are frequently used. However, it has been recently noted in Fan, Guo and Hao (2012) that high dimensionality introduces large spurious correlations between response and unrelated covariates, which may lead to wrong statistical inference and false scientific discoveries. As an illustration, Fan, Shao and Zhou (2015) considered a real data example using the gene expression data from the international ‘HapMap’ project (Thorisson et al., 2005). There, the sample correlation between the observed and post-Lasso fitted responses is as large as 0.92. While conventionally it is a common belief that a correlation of 0.92 between the response and a fit is noteworthy, in high-dimensional scenarios, this intuition may no longer be true. In fact, even if the response and all the covariates are scientifically independent in the sense that $\boldsymbol{\beta}^* = \mathbf{0}$, simply by chance, some covariates will appear to be highly correlated with the response. As a result, the findings obtained via any variable selection techniques are hardly impressive unless they are proven to be better than by chance. To simplify terminology, in this paper we say that the discovery (by a variable selection method) is spurious if it is no better than by chance.

To guard against spurious discoveries, one naturally asks how good a response can be fitted by optimally selected subsets of covariates, even when the response variable and the covariates are not causally related to each other, that is, when they are independent. Such a measure of the goodness of spurious fit (GOSF) is a random variable whose distribution can provide a benchmark to gauge whether the discoveries by statistical machine learning methods any better than a spurious fit (chance). Measuring such a goodness of spurious fit and estimating its theoretical distributions are the aims of this paper. This problem arises from not only high-dimensional linear models and generalized linear models, but also robust regression and other statistical model fitting. To formally measure the degree of spurious fit, Fan, Shao and Zhou (2015) derived the distributions of maximum spurious correlations, which provide a benchmark to assess the strength of the spurious associations (between response and independent covariates) and to judge whether discoveries by a certain variable selection technique are any better than by chance.

The response, however, is not always a quantitative value. Instead, it is often binary; for example, positive or negative, presence or absence and success or failure. In this regard, generalized linear models (GLIM) serve as a flexible parametric approach to modeling the relationship between explanatory and response variables (McCullagh and Nelder, 1989). Prototypical examples include linear, logistic and Poisson regression models which are frequently encountered in practice.

In GLIM, the relationship between the response and covariates is more complicated and cannot be effectively measured via Pearson correlation coefficient, which is essentially a measure of the linear correlation between two variables. We need to extend the concept of spurious correlation or the measure of goodness of spurious fit to more general models and study its null distribution. A natural measure of goodness of fit is the likelihood

ratio statistic, denoted by $\mathcal{LR}_n(s, p)$, where n is the sample size and s is size of optimally fitted model. It measures the goodness of spurious fit when \mathbf{X} and Y are independent. This generalization is consistent with the spurious correlation studied in Fan, Shao and Zhou (2015), that is, applying $\mathcal{LR}_n(s, p)$ to linear regression yields the maximum spurious correlation. We plan to study the limiting null distribution of $2\mathcal{LR}_n(s, p)$ under various scenarios. This reference distribution then serves as a benchmark to determine whether the discoveries are spurious.

To gain further insights, let us illustrate the issue by using the gene expression profiles for 10,707 genes from 251 patients in the German Neuroblastoma Trials NB90-NB2004 (Oberthuer et al., 2006). The response labeled as “3-year event-free survival” (3-year EFS) is a binary outcome indicating whether each patient survived 3 years after the diagnosis of neuroblastoma. Excluding five outlier arrays, there are 246 subjects (101 females and 145 males) with 3-year EFS information available. Among them, 56 are positives and 190 are negatives. We apply Lasso using the logistic regression model with tuning parameter selected via ten-fold cross validation (40 genes are selected). The fitted likelihood ratio $2\mathcal{LR} = 211.96$. To judge the credibility of the finding of these 40 genes, we should compare the value 211.96 with the distribution of the Goodness Of Spurious Fit (GOSF) $2\mathcal{LR}_n(s, p)$ when \mathbf{X} and Y are indeed independent, where $n = 246$, $p = 10,707$ and $s = 40$. This requires some new methodology and technical work. Figure 1 shows the distribution of the GOSF estimated by our proposed method below and indicates how abnormal the value 211.96 is. It can be concluded that the goodness of fit to the binary outcome is not statistically significantly better than GOSF.

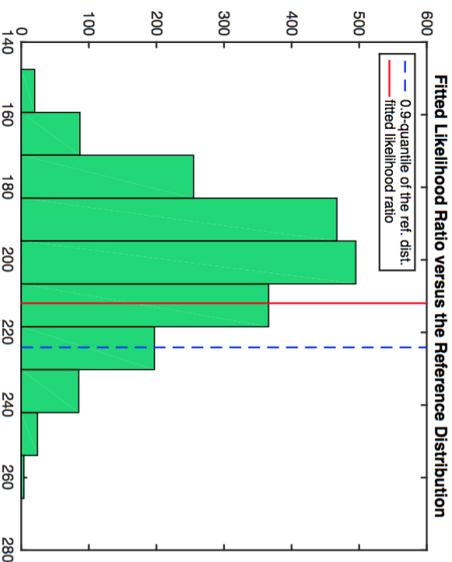

Figure 1: Lasso fitted likelihood ratio $2\mathcal{LR}$ in comparison to the distribution of GOSF $2\mathcal{LR}_n(s, p)$ with $n = 246$, $p = 10,707$ and $s = 40$.

The above result shows that the 10-fold cross-validation chooses a too large model with 40 variables. This prompts us to reduce the model sizes along the Lasso path such that their fits are better than GOSF. The results are reported in Table 2. The largest model along the LASSO path that fits better than GOSF has model size 17. We can use the cross-validation to select a model with model size no more than 17 or to select a best model among all models that fit better than GOSF. This is another important application of our method.

1.1 Structure of the paper

In Section 2, we introduce a general measure of spurious fit via generalized likelihood ratios, which extends the concept of spurious correlation in the linear model to more general models, including generalized linear models and robust linear regression. We also introduce a local adaptive majorization-minimization (LAMM) algorithm to compute the GOSF. Section 3 presents the main results on the limiting laws of goodness of spurious fit and their bootstrap approximations. For conducting inference, we use the proposed LAMM algorithm to compute the bootstrap statistic. In Section 4, we discuss an application of our theoretical findings to high-dimensional statistical inference and model selection. Section 5 presents numerical studies. Proofs of the main results, Theorems 2 and 6, are provided in Section 6; in each case, we break down the key steps in a series of lemmas with proofs deferred to the appendix.

1.2 Notations

We collect standard pieces of notation here for readers’ convenience. For two sequences $\{a_n\}$ and $\{b_n\}$ of positive numbers, we write $a_n = O(b_n)$ or $a_n \lesssim b_n$ if there exists a constant $C > 0$ such that $a_n/b_n \leq C$ for all sufficiently large n ; we write $a_n \asymp b_n$ if there exist constants $C_1, C_2 > 0$ such that, for all n large enough, $C_1 \leq a_n/b_n \leq C_2$; and we write $a_n = o(b_n)$ if $\lim_{n \rightarrow \infty} a_n/b_n = 0$, respectively. For $a, b \in \mathbb{R}$, we write $a \vee b = \max(a, b)$.

For every positive integer ℓ , we write $[\ell] = \{1, 2, \dots, \ell\}$, and for any set S , we use S^c to denote its complement and $|S|$ for its cardinality. For any real-valued random variable X , its sub-Gaussian norm is defined by $\|X\|_{\psi_2} = \sup_{\ell \geq 1} \ell^{-1/2} (\mathbb{E}|X|^\ell)^{1/\ell}$. We say that a random variable X is sub-Gaussian if $\|X\|_{\psi_2} < \infty$.

Let p, q be two positive integers. For every p -vector $\mathbf{u} = (u_1, \dots, u_p)^T$, we define its ℓ_q -norm to be $\|\mathbf{u}\|_q = (\sum_{i=1}^p |u_i|^q)^{1/q}$, and set $\|\mathbf{u}\|_0 = \sum_{i=1}^p I\{u_i \neq 0\}$. Let $S^{p-1} = \{\mathbf{u} \in \mathbb{R}^p : \|\mathbf{u}\|_2 = 1\}$ be the unit sphere in \mathbb{R}^p . Moreover, for each subset $S \subseteq [p]$ with $|S| = s \in [p]$, we denote by \mathbf{u}_S the s -variate sub-vector of \mathbf{u} containing only the coordinates indexed by S . We use $\|\mathbf{M}\|$ to denote the spectral norm of a matrix \mathbf{M} .

2. Goodness of spurious fit

Let Y, Y_1, \dots, Y_n be independent and identically distributed (i.i.d.) random variables with mean zero and variance $\sigma^2 > 0$, and $\mathbf{X}, \mathbf{X}_1, \dots, \mathbf{X}_n$ be i.i.d. p -dimensional random vectors. We write

$$\mathbf{X} = (X_1, \dots, X_p)^T, \mathbb{X} = (\mathbf{X}_1, \dots, \mathbf{X}_n)^T \in \mathbb{R}^{n \times p} \text{ and } \mathbf{X}_i = (X_{i1}, \dots, X_{ip})^T, \quad i = 1, \dots, n.$$

For $s \in [p]$, the maximum s -multiple correlation between Y and \mathbf{X} is given by

$$\widehat{R}_n(s, p) = \max_{\alpha \in \mathbb{R}^p: \|\alpha\|_0 \leq s} \widehat{\text{corr}}_n(Y, \alpha^\top \mathbf{X}), \quad (1)$$

where $\widehat{\text{corr}}_n(\cdot, \cdot)$ denotes the sample Pearson correlation coefficient. When Y and \mathbf{X} are independent, we regard $\widehat{R}_n(s, p)$ as the maximum spurious (multiple) correlation. The limiting distribution of $\widehat{R}_n(s, p)$ is studied in Cai and Jiang (2012) and Fan, Guo and Hao (2012) when $s = 1$ and $X \sim N(\mathbf{0}, \mathbf{I}_p)$ (the standard normal distribution in \mathbb{R}^p), and later in Fan, Shao and Zhou (2015) under a general setting where $s \geq 1$ and \mathbf{X} is sub-Gaussian with an arbitrary covariance matrix.

For binary data, the sample Pearson correlation is not effective for measuring the regression effect. We need a new metric. In classical regression analysis, the multiple correlation coefficient, also known as the R^2 , is the proportion of variance explained by the regression model. For each submodel $S \subseteq [p]$, its R^2 statistic can be computed as

$$R_S^2 = \max_{\theta \in \mathbb{R}^S} \widehat{\text{corr}}_n^2(Y, \mathbf{X}_S^\top \theta). \quad (2)$$

Then, the maximum s -multiple correlation $\widehat{R}_n(s, p)$ can be expressed as the maximum R^2 statistic:

$$\widehat{R}_n^2(s, p) = \max_{S \subseteq [p]: |S| = s} R_S^2. \quad (3)$$

The concept of R^2 can be extended to more general models. For binary response models, Maddala (1983) suggested the following generalization: $-\log(1 - R^2) = \frac{2}{n} \{\ell(\widehat{\beta}) - \ell(\mathbf{0})\}$, where $\ell(\widehat{\beta}) = \log L(\widehat{\beta})$ and $\ell(\mathbf{0}) = \log L(\mathbf{0})$ denote the log-likelihoods of the fitted and the null model, respectively. This motivates us to use the likelihood ratio as a generalization of the goodness of fit beyond the linear model.

Let $L_n(\beta)$, $\beta \in \mathbb{R}^p$ be the negative logarithm of a quasi-likelihood process of the sample $\{(Y_i, \mathbf{X}_i)\}_{i=1}^n$. For a given model size $s \in [p]$, the best subset fit is $\widehat{\beta}(s) := \underset{\beta \in \mathbb{R}^p: \|\beta\|_0 \leq s}{\text{argmin}} L_n(\beta)$. The goodness of such a fit, in comparison with the baseline fit $L_n(\mathbf{0})$, can be measured by

$$\mathcal{LR}_n(s, p) := L_n(\mathbf{0}) - L_n(\widehat{\beta}(s)) = L_n(\mathbf{0}) - \min_{\beta \in \mathbb{R}^p: \|\beta\|_0 \leq s} L_n(\beta). \quad (4)$$

When \mathbf{X} and Y are independent, it becomes the Goodness Of Spurious Fit (GOSF). According to (2) and (3), this definition is consistent with the maximum spurious correlation when it is applied to the linear model with Gaussian quasi-likelihood, where $L_n(\beta; \beta_0, \sigma) = \frac{1}{2} \log(2\pi\sigma^2) + \frac{1}{2} \|\mathbf{Y} - \beta_0 - \mathbb{X}\beta\|_2^2/\sigma^2$ and $\mathbf{Y} = (Y_1, \dots, Y_n)^\top$.

Throughout, we refer to $L_n(\cdot)$ as the loss function which is assumed to be convex. This setup encompasses the generalized linear models (McCullagh and Nelder, 1989) with $L_n(\beta) = \sum_{i=1}^n \{b(\mathbf{X}_i^\top \beta) - Y_i \mathbf{X}_i^\top \beta\}$ under the canonical link where $b(\cdot)$ is a model-dependent convex function (we take the dispersion parameter as one, as we don't consider the dispersion issue), robust regression with $L_n(\beta) = \sum_{i=1}^n |Y_i - \mathbf{X}_i^\top \beta|$, the hinge loss $L_n(\beta) = \sum_{i=1}^n (1 - Y_i \mathbf{X}_i^\top \beta)_+$ in the support vector machine (Vapnik, 1995) and exponential loss $L_n(\beta) =$

$\sum_{i=1}^n \exp(-Y_i \mathbf{X}_i^\top \beta)$ in AdaBoost (Freund and Schapire, 1997) in classification with Y taking values ± 1 .

The prime goal of this paper is to derive the limiting laws of GOSF $\mathcal{LR}_n(s, p)$ in the setting where the response Y and the explanatory variables \mathbf{X} are independent. Here, both s and p can depend on n , as we shall use double-array asymptotics. We will mainly focus on the GLIM and robust linear regression that are of particular interest in statistics.

2.1 Generalized linear models

Recall that $(Y_1, \mathbf{X}_1), \dots, (Y_n, \mathbf{X}_n)$ are i.i.d. copies of (Y, \mathbf{X}) . Assume that the conditional distribution of Y given $\mathbf{X} = \mathbf{x} \in \mathbb{R}^p$ belongs to the canonical exponential family with the probability density function taking the form (McCullagh and Nelder, 1989)

$$f(y; \mathbf{x}, \beta^*) = \exp \{ [y \mathbf{x}^\top \beta^* - b(\mathbf{x}^\top \beta^*)] / \phi + c(y, \phi) \}, \quad (5)$$

where $\beta^* = (\beta_1^*, \dots, \beta_p^*)^\top$ is the unknown p -dimensional vector of regression coefficients, and $\phi > 0$ is the dispersion parameter. The log-likelihood function with respect to the given data $\{(Y_i, \mathbf{X}_i)\}_{i=1}^n$ is $\sum_{i=1}^n c(Y_i, \phi) + \phi^{-1} \sum_{i=1}^n \{Y_i \mathbf{X}_i^\top \beta - b(\mathbf{X}_i^\top \beta)\}$. For simplicity, we take $\phi = 1$ with the exception that in the linear model with Gaussian noise, $\phi = \sigma^2$ is the variance. Two other showcases are

1. Logistic regression: $b(u) = \log(1 + e^u)$, $u \in \mathbb{R}$ and $\phi = 1$.

2. Poisson regression: $b(u) = e^u$, $u \in \mathbb{R}$ and $\phi = 1$.

In GLIM, the loss function is $L_n(\beta) = \sum_{i=1}^n \{b(\mathbf{X}_i^\top \beta) - Y_i \mathbf{X}_i^\top \beta\}$. By (4), the generalized measure of goodness of fit for GLIM is

$$\mathcal{LR}_n(s, p) = nb(0) - \min_{\beta \in \mathbb{R}^p: \|\beta\|_0 \leq s} L_n(\beta). \quad (6)$$

In Section 3, we derive under mild regularity conditions the limiting distribution of GOSF $\mathcal{LR}_n(s, p)$ in the null model. This extends the classical Wilks theorem (Wilks, 1938). Here, we interpret $\mathcal{LR}_n(s, p)$ as the degree of spuriousness caused by the high-dimensionality.

2.2 L_1 regression

In this section, we revisit the high-dimensional linear model

$$\mathbf{Y} = \mathbb{X}\beta^* + \varepsilon \quad \text{or} \quad Y_i = \mathbf{X}_i^\top \beta^* + \varepsilon_i, \quad i = 1, \dots, n, \quad (7)$$

where $\mathbf{Y} = (Y_1, \dots, Y_n)^\top$ is the response vector and $\varepsilon = (\varepsilon_1, \dots, \varepsilon_n)^\top$ is the n -vector of measurement errors. Robustness considerations lead to least absolute deviation (LAD) regression and more generally quantile regression (Koenker, 2005). For simplicity, we consider the ℓ_1 -loss $L_n(\beta) = \sum_{i=1}^n |Y_i - \mathbf{X}_i^\top \beta|$, $\beta \in \mathbb{R}^p$. The generalized measure of goodness of fit (4) now becomes

$$\mathcal{LR}_n(s, p) = \|\mathbf{Y}\|_1 - \min_{\beta \in \mathbb{R}^p: \|\beta\|_0 \leq s} L_n(\beta). \quad (8)$$

The limiting distribution of GOSF $\mathcal{LR}_n(s, p)$ is studied in Section 3.4.

In particular, if $\varepsilon_1, \dots, \varepsilon_n$ in (7) are i.i.d. from the double exponential distribution with density $f_\varepsilon(u) = \frac{1}{2}e^{-|u|}$, $u \in \mathbb{R}$, the ℓ_1 -loss $L_n(\cdot)$ corresponds to the negative log-likelihood function. In general, we assume that the regression error ε_i has median zero, that is, $\mathbb{P}(\varepsilon_i \leq 0) = \frac{1}{2}$. Hence, the conditional median of Y_i given \mathbf{X}_i is $\mathbf{X}_i^T \boldsymbol{\beta}^*$ for $i \in [n]$, and $\boldsymbol{\beta}^* = \operatorname{argmin}_{\boldsymbol{\beta} \in \mathbb{R}^p} \mathbb{E} \mathbf{X}^T L_n(\boldsymbol{\beta})$, where $\mathbb{E} \mathbf{X}(\cdot) = \mathbb{E}[\mathbf{X}_1, \dots, \mathbf{X}_n]$ denotes the conditional expectation given $\{\mathbf{X}_i\}_{i=1}^n$.

2.3 An LAMM algorithm

The computation of the best subset regression coefficient $\hat{\boldsymbol{\beta}}(s)$ in (4) requires solving a combinatorial optimization problem with a cardinality constraint, and therefore is NP-hard. In the following, we suggest a fast and easily implementable method, which combines the forward selection (stepwise addition) algorithm and a local adaptive majorization-minimization (LAMM) algorithm (Lange, Hunter and Yang, 2000; Fan et al., 2015) to provide an approximate solution.

Our optimization problem is $\min_{\boldsymbol{\beta} \in \mathbb{R}^p: \|\boldsymbol{\beta}\|_0 \leq s} f(\boldsymbol{\beta})$, where $f(\boldsymbol{\beta}) = L_n(\boldsymbol{\beta})$. We say that a function $g(\boldsymbol{\beta}) | \boldsymbol{\beta}^{(k)}$ majorizes $f(\boldsymbol{\beta})$ at the point $\boldsymbol{\beta}^{(k)}$ if $f(\boldsymbol{\beta}^{(k)}) = g(\boldsymbol{\beta}^{(k)} | \boldsymbol{\beta}^{(k)})$ and $f(\boldsymbol{\beta}) \leq g(\boldsymbol{\beta} | \boldsymbol{\beta}^{(k)})$ for all $\boldsymbol{\beta} \in \mathbb{R}^p$. An majorization-minimization (MM) algorithm initializes at $\boldsymbol{\beta}^{(0)}$ and then iteratively computes $\boldsymbol{\beta}^{(k+1)} = \operatorname{argmin}_{\boldsymbol{\beta} \in \mathbb{R}^p: \|\boldsymbol{\beta}\|_0 \leq s} g(\boldsymbol{\beta} | \boldsymbol{\beta}^{(k)})$. The target value of such an algorithm is non-increasing since

$$f(\boldsymbol{\beta}^{(k+1)}) \stackrel{\text{majorization}}{\leq} g(\boldsymbol{\beta}^{(k+1)} | \boldsymbol{\beta}^{(k)}) \stackrel{\text{minimization}}{\leq} g(\boldsymbol{\beta}^{(k)} | \boldsymbol{\beta}^{(k)}) \stackrel{\text{initialization}}{=} f(\boldsymbol{\beta}^{(k)}). \quad (9)$$

We now majorize $f(\boldsymbol{\beta})$ at $\hat{\boldsymbol{\beta}}^{(k)}$ by an isotropic quadratic function

$$g_\lambda(\boldsymbol{\beta} | \hat{\boldsymbol{\beta}}^{(k)}) = f(\boldsymbol{\beta}) + \langle \nabla f(\hat{\boldsymbol{\beta}}^{(k)}), \boldsymbol{\beta} - \hat{\boldsymbol{\beta}}^{(k)} \rangle + \frac{\lambda}{2} \|\boldsymbol{\beta} - \hat{\boldsymbol{\beta}}^{(k)}\|_2^2, \quad \boldsymbol{\beta} \in \mathbb{R}^p. \quad (10)$$

This is a valid majorization as long as $\lambda \geq \max_{\boldsymbol{\beta}} \|\nabla^2 f(\boldsymbol{\beta})\|$ (this will be relaxed below).

The isotropic form on the right-hand side of (10) allows a simple analytic solution given by

$$\hat{\boldsymbol{\beta}}_\lambda^{(k+1)} = \operatorname{argmin}_{\boldsymbol{\beta} \in \mathbb{R}^p: \|\boldsymbol{\beta}\|_0 \leq s} g(\boldsymbol{\beta} | \boldsymbol{\beta}^{(k)}) = \{\hat{\boldsymbol{\beta}}^{(k)} - \lambda^{-1} \nabla f(\hat{\boldsymbol{\beta}}^{(k)})\}_{[1:s]}.$$

Here, we used the notation that for any $\boldsymbol{\beta} \in \mathbb{R}^p$, $\boldsymbol{\beta}_{[1:s]} \in \mathbb{R}^p$ retains the s largest (in magnitude) entries of $\boldsymbol{\beta}$ and assigns the rest to zero.

Remark 1 To implement the MM algorithm, we need to compute the gradient of the objective function of interest. In the L_1 regression, the loss function $L_n(\boldsymbol{\beta}) = \sum_{i=1}^n |Y_i - \mathbf{X}_i^T \boldsymbol{\beta}|$, $\boldsymbol{\beta} \in \mathbb{R}^p$ is not differentiable everywhere. Recall that the subdifferential of the absolute function $h(x) = |x|$, $x \in \mathbb{R}$ is given by

$$\partial h(x) = \begin{cases} \{1\}, & \text{if } x > 0, \\ [-1, 1], & \text{if } x = 0, \\ \{-1\}, & \text{if } x < 0. \end{cases}$$

With slight abuse of notation, we suggest a randomized algorithm using the stochastic subgradient $\nabla L_n(\boldsymbol{\beta}) = \sum_{i=1}^n I(Y_i - \mathbf{X}_i^T \boldsymbol{\beta} > 0) - I(Y_i - \mathbf{X}_i^T \boldsymbol{\beta} < 0) + U_i I(Y_i - \mathbf{X}_i^T \boldsymbol{\beta} = 0)$, where U_1, \dots, U_n are i.i.d. random variables uniformly distributed on $[-1, 1]$.

We propose to use the stepwise forward selection algorithm to compute an initial estimator $\hat{\boldsymbol{\beta}}^{(0)}$. As the MM algorithm decreases the target value as shown in (9), the resulting target value is no larger than that produced by the stepwise forward selection algorithm.

To properly choose the isotropic parameter $\lambda > 0$ without computing the maximum eigenvalue, we use the local adaptive procedure as in Fan et al. (2015). Note that, in order to have a non-increasing target value, the majorization is not actually required. As long as $f(\boldsymbol{\beta}^{(k+1)}) \leq g(\boldsymbol{\beta}^{(k+1)} | \boldsymbol{\beta}^{(k)})$, arguments in (9) hold. Starting from a prespecified value $\lambda = \lambda_0$, we successively inflate λ by a factor $\rho > 1$. After the k th iteration, $\lambda = \lambda_k = \rho^{k-1} \lambda_0$. We take the first ℓ such that $f(\hat{\boldsymbol{\beta}}_{\lambda_k}^{(k+1)}) \leq g_{\lambda_k}(\hat{\boldsymbol{\beta}}_{\lambda_k}^{(k+1)} | \hat{\boldsymbol{\beta}}^{(k)})$ and set $\hat{\boldsymbol{\beta}}^{(k+1)} = \hat{\boldsymbol{\beta}}_{\lambda_k}^{(k+1)}$. Such an ℓ always exists as a large ℓ will major the function f . We then continue with the iteration in the MM part. A simple criteria for stopping the iteration is that $|f(\hat{\boldsymbol{\beta}}^{(k+1)}) - f(\hat{\boldsymbol{\beta}}^{(k)})| \leq \epsilon$ for a sufficiently small ϵ , say 10^{-5} . We refer to Fan et al. (2015) for a detailed computational complexity analysis of the LAMM algorithm.

While the LAMM algorithm can be applied to compute $\hat{\boldsymbol{\beta}}(s)$ in a general setting, in our application, the algorithm is mainly applied to compute GOSF under the null model (see Figure 1 and Section 3.5). From our simulation experiences, our algorithm delivers a good enough solution under the null model. It always provides an upper certificate $f(\hat{\boldsymbol{\beta}}_0)$ to the problem $\min_{\|\boldsymbol{\beta}\|_0 \leq s} f(\boldsymbol{\beta})$, where $\hat{\boldsymbol{\beta}}_0$ is the output of the LAMM algorithm. As in Bertsimas, King and Mazumder (2016), if needed to verify the accuracy of our method, a lower certificate is $f(\hat{\boldsymbol{\beta}}_1)$, where $\hat{\boldsymbol{\beta}}_1$ is the solution to the convex problem $\min_{\|\boldsymbol{\beta}\|_0 \leq B_s} f(\boldsymbol{\beta})$, and B_s is a sufficient large constant so that the L_∞ -solution satisfies $\|\hat{\boldsymbol{\beta}}(s)\|_\infty \leq B_s$. For example, under the null model, it is well known that $\|\hat{\boldsymbol{\beta}}(s)\|_\infty = O_{\mathbb{P}}\{s \sqrt{(\log p)/n}\}$. Therefore, we can take $B_s = C_s s \sqrt{(\log p)/n}$ for a sufficiently large constant C_s . A data-driven heuristic approach is to take $B_s = 2\|\hat{\boldsymbol{\beta}}_1(s)\|_\infty$ along the Lasso path such that $\|\hat{\boldsymbol{\beta}}_1(s)\|_0 = s$.

Note that the minimum target value falls in the interval $[f(\hat{\boldsymbol{\beta}}_1), f(\hat{\boldsymbol{\beta}}_0)]$. If this interval is very tight, we have certified that $\hat{\boldsymbol{\beta}}_0$ is an accurate solution.

3. Asymptotic distribution of goodness of spurious fit

3.1 Preliminaries

Define $p \times p$ covariance matrices

$$\boldsymbol{\Sigma} = \mathbb{E}(\mathbf{X} \mathbf{X}^T) \quad \text{and} \quad \hat{\boldsymbol{\Sigma}} = n^{-1} \sum_{i=1}^n \mathbf{X}_i \mathbf{X}_i^T. \quad (11)$$

For $s \in [p]$, we say that $S \subseteq [p]$ is an s -subset if $|S| = s$. For every s -subset $S \subseteq [p]$, let $\boldsymbol{\Sigma}_{SS}$ and $\hat{\boldsymbol{\Sigma}}_{SS}$ be the $s \times s$ sub-matrices of $\boldsymbol{\Sigma}$ and $\hat{\boldsymbol{\Sigma}}$ containing the entries indexed by $S \times S$, that is,

$$\boldsymbol{\Sigma}_{SS} = \mathbb{E}(\mathbf{X}_S \mathbf{X}_S^T), \quad \hat{\boldsymbol{\Sigma}}_{SS} = n^{-1} \sum_{i=1}^n \mathbf{X}_{iS} \mathbf{X}_{iS}^T. \quad (12)$$

Condition 3.1 The covariates are standardized to have unit second moment, that is, $\mathbb{E}(\mathbf{X}_j^2) = 1$ for $j = 1, \dots, p$. There exists a random vector $\mathbf{U} \in \mathbb{R}^p$ satisfying $\mathbb{E}(\mathbf{U} \mathbf{U}^T) = \mathbf{I}_p$, such that $\mathbf{X} = \boldsymbol{\Sigma}^{1/2} \mathbf{U}$ and $A_0 := \sup_{\rho \in \mathcal{S}^{p-1}} \|\rho^T \mathbf{U}\|_{q_2} < \infty$.

For $1 \leq s \leq p$, the s -sparse condition number of Σ is given by

$$\gamma_s = \gamma_s(\Sigma) = \sqrt{\lambda_{\max}(s)/\lambda_{\min}(s)}, \quad (13)$$

where $\lambda_{\max}(s) = \max_{\mathbf{u} \in \mathbb{S}^{p-1}, \|\mathbf{u}\|_0 \leq s} \mathbf{u}^\top \Sigma \mathbf{u}$ and $\lambda_{\min}(s) = \min_{\mathbf{u} \in \mathbb{S}^{p-1}, \|\mathbf{u}\|_0 \leq s} \mathbf{u}^\top \Sigma \mathbf{u}$ denote the s -sparse largest and smallest eigenvalues of Σ , respectively.

Let $\mathbf{G} = (G_1, \dots, G_p)^\top \sim N(\mathbf{0}, \Sigma)$ be a centered Gaussian random vector with covariance matrix Σ . For any s -subset $S \subseteq [p]$, $\mathbf{G}_S \sim N(\mathbf{0}, \Sigma_{SS})$. Define the random variable

$$R_0(s, p) = \max_{S \subseteq [p], |S|=s} \|\Sigma_{SS}^{-1/2} \mathbf{G}_S\|_2, \quad (14)$$

which is the maximum of the ℓ_2 -norms of a sequence of dependent chi-squared random variables with s degrees of freedom. The distribution of $R_0(s, p)$ depends on the unknown Σ and can be estimated by the multiplier bootstrap in Section 3.5. It will be shown that this distribution is the asymptotic distribution of GOSF. In particular, for the isotropic case where $\Sigma = \mathbf{I}_p$, $R_0(s, p) = G_{(1)}^2 + \dots + G_{(s)}^2$, the sum of the largest s order statistics of p independent χ_1^2 random variables.

3.2 Generalized linear models

For i.i.d. observations $\{(Y_i, \mathbf{X}_i)\}_{i=1}^n$ from the distribution in (5), define individual residuals $\varepsilon_i = Y_i - \mathbb{E}\mathbf{X}^\top(Y_i) = Y_i - b(\mathbf{X}_i^\top \boldsymbol{\beta}^*)$ with conditional variance $\text{Var}_{\mathbf{X}}(\varepsilon_i) = \phi b''(\mathbf{X}_i^\top \boldsymbol{\beta}^*)$, where $\text{Var}_{\mathbf{X}}(\cdot) = \mathbb{E}\mathbf{X}^\top \{\cdot - \mathbb{E}\mathbf{X}^\top(\cdot)\}^2$. In particular, under the null model, Y is independent of \mathbf{X} with mean $\mu_Y := \mathbb{E}(Y) = b'(0)$ and variance $\sigma_Y^2 := \text{Var}(Y) = \phi b''(0)$.

Condition 3.2 There exists $a_0 > 0$ such that $\mathbb{E} \exp\{u \sigma_Y^{-1}(Y - \mu_Y)\} \leq \exp(a_0 u^2/2)$ holds for all $u \in \mathbb{R}$. The function $b(\cdot)$ in (5) satisfies

$$\min_{u: |u| \leq 1} b''(u) \geq a_1 \quad \text{and} \quad \max_{u: |u| \leq 1} |b'''(u)| \leq A_1 \quad (15)$$

for some constants $a_1, A_1 > 0$.

Condition 3.2 is satisfied by a wide class of GLIMs, including the logistic and Poisson regression models. The following theorem shows that, under certain moment and regularity conditions, the distribution of the generalized likelihood ratio statistic $2\mathcal{LR}_n(s, p)$ can be consistently approximated by that of $R_0^2(s, p)$ given in (14).

Theorem 2 Let Conditions 3.1 and 3.2 be satisfied. Assume that $\phi = 1$ in (5), $p, n \geq 3$ and $1 \leq s \leq \min(p, n)$. Then, under the null model (7) with $\boldsymbol{\beta}^* = \mathbf{0}$,

$$\sup_{t \geq 0} \mathbb{P}\{2\mathcal{LR}_n(s, p) \leq t\} - \mathbb{P}\{R_0^2(s, p) \leq t\} \leq C \left[\{s \log(\gamma_s p m)\}^{7/8} n^{-1/8} + \sigma_Y^{1/2} \{s \log(\gamma_s p m)\}^2 n^{-1/2} \right], \quad (16)$$

where $C > 0$ is a constant depending only on a_0, a_1, A_0, A_1 in Conditions 3.1 and 3.2.

Remark 3 We regard Theorem 2 as a nonasymptotic, high-dimensional version of the celebrated Wilks theorem. In the low-dimensional setting where $s = p$ is fixed, Theorem 2 reduces to the conventional Wilks theorem, which asserts that the generalized likelihood ratio statistic converges in distribution to χ_p^2 . In addition, we also provide a Berry-Esseen bound in (16).

3.3 Linear least squares regression

As a specific case of GLIM, we consider the linear regression model (7) with the loss function $L_n(\boldsymbol{\beta}) = \frac{1}{2} \|\mathbf{Y} - \mathbb{X}\boldsymbol{\beta}\|_2^2$. The corresponding likelihood ratio statistic

$$\mathcal{LR}_n(s, p) = \frac{1}{2} \|\mathbf{Y}\|_2^2 - \min_{\boldsymbol{\beta} \in \mathbb{R}^p: \|\boldsymbol{\beta}\|_0 \leq s} L_n(\boldsymbol{\beta}) \quad (17)$$

then coincides with that in (6) with $b(u) = \frac{1}{2} u^2$. We state the null limiting distribution of $\mathcal{LR}_n(s, p)$ in a general case, where $\varepsilon_1, \dots, \varepsilon_n$ are i.i.d. copies of a sub-Gaussian random variable ε . Specifically, we assume that

Condition 3.3 ε is a centered, sub-Gaussian random variable with $\text{Var}(\varepsilon) = \sigma^2 > 0$ and $K_0 := \|\varepsilon\|_{\psi_2} < \infty$. Moreover, write $v_\ell = \mathbb{E}(|\varepsilon|^\ell)$ for $\ell \geq 3$.

The following corollary is a particular case of the general result Theorem 2 with $b(u) = \frac{1}{2} u^2$, $u \in \mathbb{R}$ and $\phi = \sigma^2$. By examining the proof of Theorem 2 and noting that $b'' \equiv 0$, it can be easily shown that the second term on the right-side of (16) vanishes. Hence, the proof is omitted.

Corollary 4 Let Conditions 3.1 and 3.3 hold. Assume that $p, n \geq 3$ and $1 \leq s \leq \min(p, n)$. Then, under the null model (7) with $\boldsymbol{\beta}^* = \mathbf{0}$,

$$\sup_{t \geq 0} \mathbb{P}\{2\mathcal{LR}_n(s, p) \leq t\} - \mathbb{P}\{\sigma^2 R_0^2(s, p) \leq t\} \leq C \{s \log(\gamma_s p m)\}^{7/8} n^{-1/8},$$

where $C > 0$ is a constant depending only on A_0 and K_0 in Conditions 3.1 and 3.3.

Remark 5 Under the null model, the variance σ^2 can be consistently estimated by $\hat{\sigma}_0^2 = n^{-1} \sum_{i=1}^n (Y_i - \bar{Y})^2$, where $\bar{Y} = n^{-1} \sum_{i=1}^n Y_i$. Under the same conditions of Corollary 4, it can be proved that

$$\sup_{t \geq 0} \mathbb{P}\{2\mathcal{LR}_n(s, p) \leq t\} - \mathbb{P}\{\hat{\sigma}_0^2 R_0^2(s, p) \leq t\} \lesssim \{s \log(\gamma_s p m)\}^{7/8} n^{-1/8},$$

which is in line with Theorem 3.1 in Fan, Shao and Zhou (2015). To see this, note that

$$\begin{aligned} 2\mathcal{LR}_n(s, p) &= \|\mathbf{Y}\|_2^2 - \min_{S \subseteq [p], |S|=s} \min_{\boldsymbol{\theta} \in \mathbb{R}^S} \|\mathbf{Y} - \mathbb{X}_S \boldsymbol{\theta}\|_2^2 \\ &= \max_{S \subseteq [p], |S|=s} \mathbf{Y}^\top \mathbb{X}_S (\mathbb{X}_S^\top \mathbb{X}_S)^{-1} \mathbb{X}_S^\top \mathbf{Y} = \max_{\boldsymbol{\alpha} \in \mathbb{R}^p: \|\boldsymbol{\alpha}\|_0 \leq s} (\mathbf{Y}^\top \mathbb{X} \boldsymbol{\alpha})^2 / \|\mathbb{X} \boldsymbol{\alpha}\|_2^2. \end{aligned}$$

The estimator $\hat{\sigma}_0^2$, used in computing the maximum spurious correlation, can be seriously biased beyond the null model and hence adversely affect the power. Thus, we suggest using either the refitted cross-validation procedure (Fan, Guo and Hao, 2012) or the scaled Lasso estimator (Sun and Zhang, 2012) to estimate σ^2 .

3.4 Linear median regression

We now state an analogous result to Theorem 2 regarding the ℓ_1 -loss considered in Section 2.2.

Condition 3.4 The noise $\varepsilon_1, \dots, \varepsilon_n$ in (7) are i.i.d. copies of a random variable ε satisfying $\mathbb{E}|\varepsilon|^\kappa < \infty$ for some $1 < \kappa \leq 2$. There exist positive constants $a_2 < (\mathbb{E}|\varepsilon|)^{-1}$, A_2 and A_3 such that the distribution function $F_\varepsilon(\cdot)$ and the density function $f_\varepsilon(\cdot)$ of ε satisfy

$$2 \max\{1 - F_\varepsilon(u), F_\varepsilon(-u)\} \leq (1 + a_2 u)^{-1} \quad \text{for all } u \geq 0, \quad (18)$$

$$\max_{u \in \mathbb{R}} f_\varepsilon(u) \leq A_2 \quad \text{and} \quad \max_{|u| \leq 1} \max_{|v| \leq 1} \{ |f_\varepsilon(u+v)|, |f_\varepsilon(u-v)| \} \leq A_3. \quad (19)$$

Theorem 6 If $p, n \geq 3$ and $1 \leq s \leq \min(p, n)$, then under the null model (7) with $\beta^* = \mathbf{0}$ and Conditions 3.1 and 3.4, we have

$$\begin{aligned} \sup_{t \geq 0} \mathbb{P}\{2\mathcal{LR}_n(s, p) \leq t\} &= \mathbb{P}\{R_0^2(s, p)/\{2f_\varepsilon(0)\} \leq t\} \\ &\leq C_1 n^{1-\kappa} + C_2 \{s \log(\gamma_s p n)\}^{7/8} n^{-1/8} + \gamma_s^{1/4} \{s \log(\gamma_s p n)\}^{3/2} n^{-1/4}, \end{aligned} \quad (20)$$

where $\mathcal{LR}_n(s, p)$ is given by (8), $C_1 > 0$ is a constant depending on $a_2, \kappa, \mathbb{E}|\varepsilon|, \mathbb{E}|\varepsilon|^\kappa$ and $C_2 > 0$ is a constant depending on a_2, A_0, A_2 and A_3 in Conditions 3.1 and 3.4.

Remark 7 Under the null model, the unknown parameter $f_\varepsilon(0)$ can be consistently estimated by the kernel density estimator $\widehat{f}_\varepsilon(0) = (nh)^{-1} \sum_{i=1}^n K(Y_i/h)$, where $K(\cdot)$ is a kernel function and $h = h_n > 0$ is the bandwidth. For simplicity, we may use the Epanechnikov kernel function $K_{\text{Epa}}(u) = \frac{3}{4}(1 - u^2)I(|u| \leq 1)$ along with the rule-of-thumb bandwidth $h_{\text{EOT}} = 2.34 \widehat{\sigma}_0 n^{-1/5}$, where $\widehat{\sigma}_0^2 = n^{-1} \sum_{i=1}^n (Y_i - \bar{Y})^2$.

3.5 Multiplier bootstrap procedure

The distribution of the random variable $R_0(s, p)$ given by (14) depends on the unknown covariance matrix Σ . In practice, it is natural to replace Σ by $\widehat{\Sigma} = n^{-1} \sum_{i=1}^n \mathbf{X}_i \mathbf{X}_i^T$ and $\mathbf{G} \sim N(0, \Sigma)$ by $\widehat{\mathbf{G}} \sim N(0, \widehat{\Sigma})$ in the definition of $R_0(s, p)$. With this substitution, the distribution of $R_0(s, p)$ can be simulated. In particular, $\widehat{\mathbf{G}}$ can be simulated as $n^{-1/2} \sum_{i=1}^n \varepsilon_i \mathbf{X}_i$, where $\varepsilon_1, \dots, \varepsilon_n$ are i.i.d. standard normal random variables that are independent of $\{\mathbf{X}_i\}_{i=1}^n$. The resulting estimator is

$$R_n(s, p) = \max_{S \subseteq [p]: |S|=s} \|\widehat{\Sigma}_{SS}^{-1/2} \widehat{\mathbf{G}}_S\|_2, \quad (21)$$

which is a multiplier bootstrap version of $R_0(s, p)$. The following proposition follows directly from Theorem 3.2 in Fan, Shao and Zhou (2015).

Proposition 8 Assume that Condition (3.1) holds, $1 \leq s \leq \min(p, n)$ and $s \log(\gamma_s p n) = o(n^{1/5})$ as $n \rightarrow \infty$. Then $\sup_{p \geq 20} \mathbb{P}\{R_0(s, p) \leq t\} - \mathbb{P}\{R_n(s, p) \leq t | \mathbf{X}_1, \dots, \mathbf{X}_n\} \rightarrow 0$ in probability.

The computation of $R_n(s, p)$ requires solving a combinatorial optimization. This can be alleviated by using the LAMM algorithm in Section 2.3. To begin with, by Remark 5, we write $R_n(s, p)$ in (21) as

$$R_n^2(s, p) = \max_{S \subseteq [p]: |S|=s} \mathbf{e}^T \mathbb{X}_S (\mathbb{X}_S^T \mathbb{X}_S)^{-1} \mathbb{X}_S^T \mathbf{e} = \|\mathbf{e}\|_2^2 - \min_{\beta \in \mathbb{R}^p: \|\beta\|_0 \leq s} \|\mathbf{e} - \mathbb{X} \beta\|_2^2,$$

where $\mathbf{e} = (\varepsilon_1, \dots, \varepsilon_n)^T$ and $\mathbb{X}_S = (\mathbf{X}_{1S}, \dots, \mathbf{X}_{nS})^T$ for every subset $S \subseteq [p]$. This can be computed approximately by the LAMM algorithm in Section 2.3, resulting in the solution $\widehat{\beta}(s)$. Finally, we set $R_n^2(s, p) = \|\mathbf{e}\|_2^2 - \|\mathbf{e} - \mathbb{X} \widehat{\beta}(s)\|_2^2$.

The numerical performance may be improved by employing mixed integer optimization formulations (Bertsimas, King and Mazumdar, 2016). Such an attempt, however, is beyond the scope of the paper and we leave it for future research.

4. Spurious discoveries and model selection

Based on the theoretical developments in Section 3, here we address the question whether discoveries by machine learning and data mining techniques for GLIM are any better than by chance. For simplicity, we focus on the Lasso. Let $q_\alpha(s, p)$ be the upper α -quantile of the random variable $R_0(s, p)$ defined by (14). Assume that the dispersion parameter ϕ in (5) equals 1. By Theorem 2, we see that for any prespecified $\alpha \in (0, 1)$,

$$\mathbb{P}\{2\mathcal{LR}_n(s, p) \leq q_\alpha^2(s, p)\} \rightarrow 1 - \alpha, \quad (22)$$

where $\mathcal{LR}_n(s, p)$ is as in (6).

Let $\widehat{\beta}_\lambda = \arg \min_{\beta} \{L_n(\beta) + \lambda \|\beta\|_1\}$ be the ℓ_1 -penalized maximum likelihood estimator with $\widehat{s}_\lambda = \|\widehat{\beta}_\lambda\|_0 = \lceil \text{supp}(\widehat{\beta}_\lambda) \rceil$, where $\lambda > 0$ is the regularization parameter. The goodness of fit is likelihood ratio $L_n(\mathbf{0}) - L_n(\widehat{\beta}_\lambda)$. Since \widehat{s}_λ covariates are selected, it should be compared with the distribution of GOSF $\mathcal{LR}_n(s, p)$ by taking $s = \widehat{s}_\lambda$. In view of (22), if

$$L_n(\widehat{\beta}_\lambda) \geq L_n(\mathbf{0}) - q_\alpha^2(\widehat{s}_\lambda, p)/2 = nb(0) - q_\alpha^2(\widehat{s}_\lambda, p)/2,$$

then we may regard the discovery of variables \widehat{s}_λ as unimpressive, no better than fitting by chance, or simply spurious.

In practice, the unknown quantile $q_\alpha(s, p)$ should be replaced by its bootstrap version $q_{n,\alpha}(s, p)$, the upper α -quantile of $R_n(s, p)$ defined by (21). This leads to the following data-driven criteria for judging where the discovery $\widehat{S}(\lambda)$ is spurious:

$$L_n(\widehat{\beta}_\lambda) \geq nb(0) - q_{n,\alpha}^2(\widehat{s}_\lambda, p)/2. \quad (23)$$

The theoretical justification is given by Theorem 2 and Proposition 8. In particular, when the loss is quadratic, this reduces to the case studied by Fan, Shao and Zhou (2015).

The concept of GOSF and its theoretical quantile provide important guidelines for model selection. Let $\widehat{\beta}_{cv}$ be a cross-validated Lasso estimator, which selects $\widehat{s}_{cv} = \|\widehat{\beta}_{cv}\|_0$ important variables. Due to the bias of the ℓ_1 penalty, the Lasso typically selects far larger model size since the visible bias in Lasso forces the cross-validation procedure to choose a smaller value of λ . This phenomenon is documented in the simulations studies. See Table 1 in

Section 5.2. With an over-selected model, both the goodness of fit $\widehat{\mathcal{LR}}_\lambda = L_n(\mathbf{0}) - L_n(\widehat{\beta}_\lambda)$ and the spurious fit can be very large, and so is the finite sample Wilks approximation error. To avoid over-selecting, we suggest an alternative procedure that uses the quantity $q_{n,\alpha}(s, p)$ as a guidance to choose the tuning parameter, which guards us from spurious discoveries. More specifically, for each λ in the Lasso solution path, we compute $\widehat{\mathcal{LR}}_\lambda$ and $q_{n,\alpha}(s, p)_{s=\widehat{s}_\lambda}$ with a prespecified α . Starting from the largest λ , we stop the Lasso path the first time that the sign of $2\widehat{\mathcal{LR}}_\lambda - q_{n,\alpha}(\widehat{s}_\lambda, p)$ is changed from positive to negative, and let $\widehat{\lambda}_{\text{fit}}$ be the smallest λ satisfying $2\widehat{\mathcal{LR}}_\lambda \geq q_{n,\alpha}(\widehat{s}_\lambda, p)$. Denote by \widehat{n}_{fit} the corresponding selected model size. This value can be regarded as the maximum model size for Lasso (or any other variable selection technique such as SCAD) to choose from. Another viable alternative is to only select the best cross-validated model among those whose fit are better than GOSF. We will show in Section 5.2 by simulation studies that this procedure selects much smaller model size which is closer to the truth.

5. Numerical studies

5.1 Accuracy of the Gaussian approximation

First we ran a simulation study to examine how accurate the Gaussian approximation $R_0^2(s, p)$ is to the generalized likelihood ratio statistic $2\mathcal{LR}_n(s, p)$ in the null model. To illustrate the method, we focus on the logistic regression model: $\mathbb{P}(Y = 1 | \mathbf{X}) = \exp(\mathbf{X}^T \boldsymbol{\beta}^*) / (1 + \exp(\mathbf{X}^T \boldsymbol{\beta}^*))$. Under the null model $\boldsymbol{\beta}^* = 0$, Y_1, \dots, Y_n are i.i.d. Bernoulli random variables with success probability 1/2. Independent of Y_i 's, we generate $\mathbf{X}_i \sim N(0, \boldsymbol{\Sigma})$ with two different covariance matrices: $\boldsymbol{\Sigma}_1 = (\rho^{|j-k|})_{1 \leq j, k \leq p}$ and $\boldsymbol{\Sigma}_2 = (\sigma_{2,jk})_{1 \leq j, k \leq p}$, where

$$\sigma_{2,jk} = (| |j - k| + 1 |^{2\rho} + | |j - k| - 1 |^{2\rho} - 2 |j - k| - 1 |^{2\rho}) / 2, \quad 1 \leq j, k \leq p.$$

The first design has an AR(1) correlation structure (a short-memory process), whereas the second design reflects strong long memory dependence. We take $\rho = 0.8$ in both cases.

Figure 2 reports the distributions of generalized likelihood ratios (GLRs) and their Gaussian approximations (GARs) when $n = 400$, $p = 1000$ and $s \in \{1, 2, 5, 10\}$. The results show that the accuracy of Gaussian approximation is fairly reasonable and is affected by the size of s as well as the dependence between the coordinates of \mathbf{X} .

5.2 Detection of spurious discoveries

In this section, we conduct a moderate scale simulation study to examine how effective the multiplier bootstrap quantile $q_{n,\alpha}(s, p)$ serves as a benchmark for judging whether the discovery is spurious. To illustrate the main idea, again we restrict our attention to the logistic regression model and the Lasso procedure.

The results reported here are based on 200 simulations with the ambient dimension $p = 400$ and the sample size n taken values in $\{120, 160, 200\}$. The true regression coefficient vector $\boldsymbol{\beta}^* \in \mathbb{R}^p$ is $(3, -1, 3, -1, 3, 0, \dots, 0)^T$. We consider two random designs: $\boldsymbol{\Sigma} = \mathbf{I}_p$ (independent) and $\boldsymbol{\Sigma} = (\sigma_{2,j-k})_{1 \leq j, k \leq p}$ (dependent).

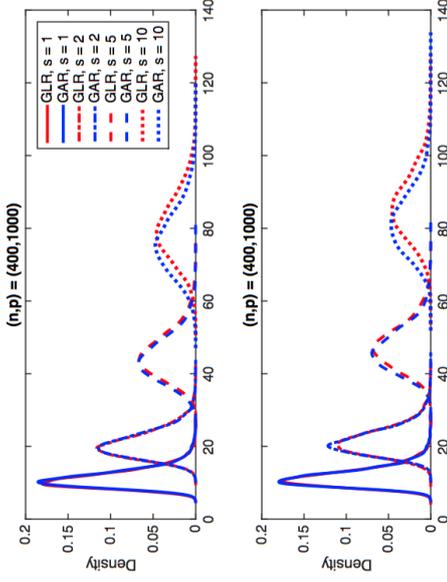

Figure 2: Distributions of generalized likelihood ratios (red) and Gaussian approximations (blue) based on 5000 simulations for $n = 400$, $p = 1000$ and $s = 1, 2, 5, 10$ when $\boldsymbol{\Sigma}$ is equal to $\boldsymbol{\Sigma}_1$ (upper panel) or $\boldsymbol{\Sigma}_2$ (lower panel).

Let $\widehat{\beta}_{\text{cv}}$ be the five-fold cross-validated Lasso estimator, which selects a model of size $\widehat{s}_{\text{cv}} = \|\widehat{\beta}_{\text{cv}}\|_0$. For a given $\alpha \in (0, 1)$, consider the spurious discovery probability (SDP)

$$\mathbb{P}\{n \log(2) - L_n(\widehat{\beta}_{\text{cv}}) \leq q_{n,\alpha}^2(\widehat{s}_{\text{cv}}, p) / 2\},$$

which is basically the probability of the type II error since the simulated model is not null. We take $\alpha = 0.1$ and compute the empirical SDP based on 200 simulations. For each simulated data set, $q_{n,\alpha}(s, p)|_{s=\widehat{s}_{\text{cv}}}$ is computed based on 1000 bootstrap replications. The results are depicted in Table 1 below.

Table 1: The empirical power and the median size of the selected models with its robust standard deviation (RSD) in the parenthesis based on 200 simulations when $p = 400$ and $\alpha = 10\%$. RSD is the interquantile range divided by 1.34.

	$n = 120$			$n = 160$			$n = 200$		
	Ind.	Dep.	Dep.	Ind.	Dep.	Dep.	Ind.	Dep.	Dep.
Power	0.595	0.750	0.925	0.980	0.980	1.000	1.000	1.000	1.000
\widehat{s}_{cv}	32.0 (13.43)	24.5 (11.94)	40.0 (13.81)	25.5 (12.69)	42.0 (14.18)	29.0 (14.18)	42.0 (14.18)	42.0 (14.18)	42.0 (14.18)

As reflected by Table 1, the empirical power, which is one minus the empirical SDP, increases rapidly as the sample size n grows. This is in line with our intuition that the more data we have, the less likely that the discovery by a variable selection method is spurious. When the sample size is small, the SDP can be high and hence the discovery

$\hat{S}_{cv} = \text{supp}(\hat{\beta}_{\alpha})$ should be interpreted with caution. We need either more samples or more powerful variable selection methods.

We see from Table 1 that the Lasso with cross-validation selects far larger model size than the true one, which is 5. This is because the intrinsic bias in Lasso forces the cross-validation procedure to choose a smaller value of λ . We now use our procedure in Section 4 to choose the tuning parameter from the Lasso solution path. As before, we take $\alpha = 0.1$ in $q_{n,\alpha}(s, p)$ to provide an upper bound on the model size from perspective of guarding against spurious discoveries. The empirical median of \hat{m}_n and its robust standard deviation are 9 and 1.87 over 200 simulations when $(n, p) = (200, 400)$ and $\Sigma = (0.5^{j-k})_{1 \leq j, k \leq p}$. The feature over-selection phenomenon is considerably alleviated.

5.3 Neuroblastoma data

In this section, we apply the idea of detecting spurious discoveries to the neuroblastoma data reported in Oberthner et al. (2006). This data set consists of 251 patients of the German Neuroblastoma Trials NB90-NB2004, diagnosed between 1989 and 2004. The complete data set, obtained via the MicroArray Quality Control phase-II (MAQC-II) project (Shi et al., 2010), includes gene expression over 10,707 probe sites. There are 246 subjects with 3-year event-free survival information available (56 positive and 190 negative). See Oberthner et al. (2006) for more details about the data sets.

For each $\lambda > 0$, we apply Lasso using the logistic regression model to select $\hat{\Sigma}_\lambda$ genes. In particular, ten-fold cross-validated Lasso selects $\hat{S}_{cv} = 40$ genes. Then we calculate the goodness of fit $\widehat{\mathcal{LR}}_\lambda := L_n(\mathbf{0}) - L_n(\hat{\beta}_\lambda) = n \log(2) - L_n(\hat{\beta}_\lambda)$. Along the Lasso path, we record in Table 2 the number of selected probes, the corresponding square-root the goodness of fit $(2\widehat{\mathcal{LR}}_\lambda)^{1/2}$ and upper α -quantiles of the multiplier bootstrap approximations $R_n(s, p)_{s=\hat{S}_\alpha, p=10,707}$ with $\alpha = 10\%$ and 5% based on 2000 bootstrap replications. For illustrative purposes, we only display partial Lasso solutions with selected model size $\hat{\Sigma}_\lambda$ lying between 20 and 40. From Table 2, we observe that only the discovery of 17 probes has a generalized measure of the goodness of fit better than GOSF at $\alpha = 5\%$, whereas the finding (of the 40 probes) via the cross-validation procedure is likely to over-select.

6. Proofs

We now turn to the proofs of Theorems 2 and 6. In each proof, we provide the primary steps, with more technical details stated as lemmas and proved in the appendix.

6.1 Proof of Theorem 2

Throughout, we work with the quasi-likelihood $\mathcal{L}_n(\beta) = -L_n(\beta) = \sum_{i=1}^n \{Y_i \mathbf{X}_i^T \beta - b(\mathbf{X}_i^T \beta)\}$ and consider the general case where the dispersion parameter ϕ in (5) is specified (not necessarily equals 1 to facilitate the derivations for the normal case). For a given $s \in [p]$, define

$$Q_n(s, p) = \max_{\beta \in \mathbb{R}^p: \|\beta\|_0 \leq s} \mathcal{L}_n(\beta) \quad \text{and} \quad Q_n^* = \mathcal{L}_n(\mathbf{0}).$$

We divide the proof into three steps. First, for each s -subset $S \subseteq [p]$, we prove Wilks's result for the S -restricted model where only a subset of the covariates indexed by S are

Table 2: Lasso fitted square-root likelihood ratio statistic, the mean cross-validated error, and upper 0.1- and 0.05-quantiles of the multiplier bootstrap approximation based on 2000 bootstrap samples.

included. Specifically, we show that the square root deviation of the S -restricted maximum log-likelihood from its baseline value under the null model can be well approximated by the ℓ_2 -norm of the normalized score vector. Second, based on a high-dimensional invariance principle, we prove the Gaussian/chi-squared approximation for the maximum of the ℓ_2 -norms of normalized score vectors. Finally, we apply an anti-concentration argument to construct non-asymptotic Wilks approximation for $2\{Q_n(s, p) - Q_n^*\}$.

Step 1: Wilks approximation. In the null model where Y and \mathbf{X} are independent, the true parameter β^* in (5) is zero, and thus the density function of Y has the form $f(y) = \exp\{-\phi^{-1}b(0) + c(y, \phi)\}$. Moreover, we have

$$\arg \max_{\beta \in \mathbb{R}^p} \mathbb{E}_{\mathbf{X}} \{ \mathcal{L}_n(\beta) \} = \arg \max_{\beta \in \mathbb{R}^p} \sum_{i=1}^n \mathbb{E}_{\mathbf{X}} \{ Y_i \mathbf{X}_i^T \beta - b(\mathbf{X}_i^T \beta) \} = \mathbf{0}.$$

To this see, note that in model (5) with $\beta^* = \mathbf{0}$, $\mathbb{E}(Y) = b'(0)$ and $\text{Var}(Y) = \phi b''(0)$. This implies that $\mathbb{E}_{\mathbf{X}} \{ \mathcal{L}_n(\beta) \} = \sum_{i=1}^n \{ b'(0) \mathbf{X}_i^T \beta - b(\mathbf{X}_i^T \beta) \}$. This function is strictly concave with respect to β and $\beta = \mathbf{0}$ satisfies its first order condition, and hence is its maximizer.

For each s -subset $S \subseteq [p]$, define the S -restricted log-likelihood $\mathcal{L}_n^S(\theta) = \sum_{i=1}^n \{ Y_i \mathbf{X}_{iS}^T \theta - b(\mathbf{X}_{iS}^T \theta) \}$ and the score function $\nabla \mathcal{L}_n^S(\theta) = \sum_{i=1}^n \{ Y_i - b'(\mathbf{X}_{iS}^T \theta) \} \mathbf{X}_{iS}$, $\theta \in \mathbb{R}^s$. In this

notation, it can be seen from (6) that

$$Q_n(s, p) = \max_{S \subseteq [p]: |S|=s} \max_{\boldsymbol{\theta} \in \mathbb{R}^s} \mathcal{L}_n^S(\boldsymbol{\theta}) = \max_{S \subseteq [p]: |S|=s} \mathcal{L}_n^S(\hat{\boldsymbol{\theta}}_S), \quad (24)$$

where

$$\hat{\boldsymbol{\theta}}_S = (\hat{\theta}_{S1}, \dots, \hat{\theta}_{Ss})^\top = \arg \max_{\boldsymbol{\theta} \in \mathbb{R}^s} \mathcal{L}_n^S(\boldsymbol{\theta}) \quad (25)$$

denotes the maximum likelihood estimate of the target parameter for the S -restricted model, which is given by $\boldsymbol{\theta}_S^* := \arg \max_{\boldsymbol{\theta} \in \mathbb{R}^s} \mathbb{E} \mathbf{X} \{ \mathcal{L}_n^S(\boldsymbol{\theta}) \} = \mathbf{0}$.

Given the i.i.d. observations $\{(Y_i, \mathbf{X}_i)\}_{i=1}^n$, $\nabla \mathbb{E} \mathbf{X} \{ \mathcal{L}_n^S(\boldsymbol{\theta}) \} = \sum_{i=1}^n \{ b'(0) - b(\mathbf{X}_{iS}^\top \boldsymbol{\theta}) \} \mathbf{X}_{iS}$ and $\mathbf{H}_S(\boldsymbol{\theta}) := -\nabla^2 \mathbb{E} \mathbf{X} \{ \mathcal{L}_n^S(\boldsymbol{\theta}) \} = \sum_{i=1}^n b''(\mathbf{X}_{iS}^\top \boldsymbol{\theta}) \mathbf{X}_{iS} \mathbf{X}_{iS}^\top$ for $\boldsymbol{\theta} \in \mathbb{R}^s$. In particular, write

$$\mathbf{H}_S^* := \mathbf{H}_S(\mathbf{0}) = n b''(0) \widehat{\boldsymbol{\Sigma}}_{SS} \quad (26)$$

for $\boldsymbol{\Sigma}_{SS}$ as in (12). Further, define the S -restricted normalized score

$$\hat{\boldsymbol{\xi}}_S = \mathbf{H}_S^{*-1/2} \nabla \mathcal{L}_n^S(\mathbf{0}) = \{ n b''(0) \}^{-1/2} \widehat{\boldsymbol{\Sigma}}_{SS}^{-1/2} \sum_{i=1}^n \varepsilon_i \mathbf{X}_{iS}, \quad \varepsilon_i = Y_i - b(0). \quad (27)$$

The following result is a conditional analogue of Corollary 1.12 in the supplement of Spokoiny (2012), which provides an exponential inequality for the ℓ_2 -norm of $\hat{\boldsymbol{\xi}}_S$ given $\{\mathbf{X}_i\}_{i=1}^n$. The proofs of this Lemma and other lemmas can be found in the appendix.

Lemma 9 *Assume that Conditions 3.1 and 3.2 hold. Then, for every $t \geq 0$,*

$$\mathbb{P} \mathbf{x} \{ \|\hat{\boldsymbol{\xi}}_S\|_2^2 \geq a_0 \phi \Delta(s, t) \} \leq 2e^{-t} \quad (28)$$

holds almost surely on the event $\{\widehat{\boldsymbol{\Sigma}}_{SS} \succ \mathbf{0}\}$, where

$$\Delta(s, t) := \begin{cases} s + (8ts)^{1/2}, & \text{if } 0 \leq t \leq \frac{1}{18}(2s)^{1/2}, \\ s + 6t, & \text{if } t > \frac{1}{18}(2s)^{1/2}. \end{cases} \quad (29)$$

The following lemma characterizes the Wilks phenomenon from a non-asymptotic perspective. Recall that $\hat{\boldsymbol{\theta}}_S$ at (25) is the S -restricted maximum likelihood estimator, and in the null model, $\mathcal{L}_n^S(\mathbf{0}) = \mathcal{L}_n(\mathbf{0}) = -nb(0)$, $\sigma_Y^2 = \text{Var}(Y) = \phi b''(0)$. For every $\tau > 0$, define the event

$$\mathcal{E}_0(\tau) = \bigcap_{S \subseteq [p]: |S|=s} \left\{ \widehat{\boldsymbol{\Sigma}}_{SS} \succ \mathbf{0}, \max_{1 \leq i \leq n} \mathbf{X}_{iS}^\top \widehat{\boldsymbol{\Sigma}}_{SS}^{-1} \mathbf{X}_{iS} \leq \tau \right\}. \quad (30)$$

Lemma 10 *Assume that Conditions 3.1 and 3.2 hold. Then, on the event $\mathcal{E}_0(\tau)$, for any $\tau > 0$,*

$$\mathbb{P} \mathbf{x} \left(\max_{S \subseteq [p]: |S|=s} \left| 2\{\mathcal{L}_n^S(\hat{\boldsymbol{\theta}}_S) - \mathcal{L}_n(\mathbf{0})\} \right|^{1/2} - \|\hat{\boldsymbol{\xi}}_S\|_2 \leq C_1 \phi \tau^{1/2} s \log(pm) \sqrt{\frac{s}{n}} \right) \leq 5n^{-1} \quad (31)$$

whenever $n \geq C_2 \phi \tau s \log(pm)$, where C_1 and C_2 are positive constants depending only on a_0, σ_1, A_1 and $b''(0)$.

To apply Lemma 10, we need to show first that for properly chosen τ , the event $\mathcal{E}_0(\tau)$ occurs with high probability. First, applying Theorem 5.39 in Vershynin (2012) to the random vectors $\boldsymbol{\Sigma}_{SS}^{-1/2} \mathbf{X}_{1S}, \dots, \boldsymbol{\Sigma}_{SS}^{-1/2} \mathbf{X}_{nS}$ yields that, for every $t \geq 0$,

$$\left\| \boldsymbol{\Sigma}_{SS}^{-1/2} \widehat{\boldsymbol{\Sigma}}_{SS} \boldsymbol{\Sigma}_{SS}^{-1/2} - \mathbf{I}_s \right\| = \left\| n^{-1} \boldsymbol{\Sigma}_{SS}^{-1/2} \mathbf{X}_S^\top \mathbf{X}_S \boldsymbol{\Sigma}_{SS}^{-1/2} - \mathbf{I}_s \right\| \leq \max(\delta, \delta^2) \quad (32)$$

holds with probability at least $1 - 2e^{-t}$, where $\delta = C_3(s \vee t)^{1/2} n^{-1/2}$, and $C_3 > 0$ is a constant depending only on A_0 . This, together with Boole's inequality implies by taking $t = s \log \frac{ep}{s} + \log n$ that, with probability at least $1 - 2n^{-1}$,

$$\max_{S \subseteq [p]: |S|=s} \left\| \boldsymbol{\Sigma}_{SS}^{-1/2} \widehat{\boldsymbol{\Sigma}}_{SS} \boldsymbol{\Sigma}_{SS}^{-1/2} - \mathbf{I}_s \right\| \leq C_3 \left(\frac{s \log \frac{ep}{s} + \log n}{n} \right) \leq \frac{1}{2} \quad (33)$$

whenever $n \geq 4C_3^2(s \log \frac{ep}{s} + \log n)$. Providing (33) holds, the smallest eigenvalue of $\boldsymbol{\Sigma}_{SS}^{-1/2} \widehat{\boldsymbol{\Sigma}}_{SS} \boldsymbol{\Sigma}_{SS}^{-1/2}$ is bounded from below by $\frac{1}{2}$ so that $\lambda_{\min}(\widehat{\boldsymbol{\Sigma}}_{SS}) \geq \frac{1}{2} \lambda_{\min}(\boldsymbol{\Sigma}_{SS})$. Moreover,

$$\mathbf{X}_{iS}^\top \widehat{\boldsymbol{\Sigma}}_{SS}^{-1} \mathbf{X}_{iS} \leq 2\lambda_{\min}^{-1}(\boldsymbol{\Sigma}_{SS}) \|\mathbf{X}_{iS}\|_2^2 \leq 2s\lambda_{\min}^{-1}(\boldsymbol{\Sigma}_{SS}) \max_{j \in S} X_{ij}^2. \quad (34)$$

For the last term on the right-hand side of (34), let $\mathbf{e}_j = (0, \dots, 0, 1, 0, \dots, 0)^\top$ be the unit vector in \mathbb{R}^p with 1 at the j th position and note that $\mathbf{X}_{ij} = \mathbf{e}_j^\top \mathbf{X}_i = \mathbf{e}_j^\top \boldsymbol{\Sigma}_{SS}^{1/2} \mathbf{U}_i$ with $\|\mathbf{e}_j^\top \boldsymbol{\Sigma}_{SS}^{1/2}\|_2 = 1$, where $\mathbf{U}_1, \dots, \mathbf{U}_n$ are i.i.d. p -dimensional random vectors with covariance matrix \mathbf{I}_p . By Condition 3.1, $\|\mathbf{X}_{ij}\|_{\psi_2} = \|\mathbf{e}_j^\top \boldsymbol{\Sigma}_{SS}^{1/2} \mathbf{U}_i\|_{\psi_2} \leq A_0$ and hence for every $t \geq 0$,

$$\mathbb{P} \left(\max_{1 \leq i \leq n} \max_{1 \leq j \leq p} X_{ij}^2 \geq t \right) \leq 2 \sum_{i=1}^n \sum_{j=1}^p \exp(-C_4^{-1}t) \leq 2 \exp\{\log(pm) - C_4^{-1}t\},$$

where $C_4 > 0$ is a constant depending only on A_0 . This, together with (34) implies by taking $t = 2C_4 \log(pm)$ that, with probability at least $1 - 3n^{-1}$,

$$\max_{1 \leq i \leq n} \max_{S \subseteq [p]: |S|=s} \mathbf{X}_{iS}^\top \widehat{\boldsymbol{\Sigma}}_{SS}^{-1} \mathbf{X}_{iS} \leq 2\lambda_{\min}^{-1}(s) \{1 + 2C_4 s \log(pm)\}. \quad (35)$$

Now, by (30) and (35), we take $\tau_0 = 2\lambda_{\min}^{-1}(s) \{1 + 2C_4 s \log(pm)\}$ such that the event $\mathcal{E}_0(\tau_0)$ occurs with probability greater than $1 - 3n^{-1}$ as long as $n \geq 4C_3^2(s \log \frac{ep}{s} + \log n)$. This, together with Lemma 10 yields that with probability at least $1 - 8n^{-1}$,

$$\max_{S \subseteq [p]: |S|=s} \left| 2\{\mathcal{L}_n^S(\hat{\boldsymbol{\theta}}_S) - \mathcal{L}_n(\mathbf{0})\} \right|^{1/2} - \|\hat{\boldsymbol{\xi}}_S\|_2 \leq C_5 \phi \lambda_{\min}^{-1/2}(s) \{s \log(pm)\}^{3/2} n^{-1/2} \quad (36)$$

whenever $n \geq C_6(1 \vee \phi) \lambda_{\min}^{-1}(s) \{s \log(pm)\}^2$, where $C_5, C_6 > 0$ are constants depending only on a_0, σ_1, A_0, A_1 and $b''(0)$.

Step 2: Gaussian approximation. For any $i = 1, \dots, n$ and $S \subseteq [p]$, define $\mathbf{Z}_i = \{b''(0)\}^{-1/2} \varepsilon_i \mathbf{X}_i$ and $\mathbf{Z}_{iS} = \{b''(0)\}^{-1/2} \varepsilon_i \mathbf{X}_{iS}$ such that $\hat{\boldsymbol{\xi}}_S = n^{-1/2} \sum_{i=1}^n \widehat{\boldsymbol{\Sigma}}_{SS}^{-1/2} \mathbf{Z}_{iS}$. Moreover, define

$$\boldsymbol{\xi} = n^{-1/2} \sum_{i=1}^n \mathbf{Z}_i \quad \text{and} \quad \boldsymbol{\xi}_S = n^{-1/2} \sum_{i=1}^n \boldsymbol{\Sigma}_{SS}^{-1/2} \mathbf{Z}_{iS}. \quad (37)$$

The following result shows that for each s -subset $S \subseteq [p]$, the ℓ_2 -norm of the S -restricted normalized score $\hat{\boldsymbol{\xi}}_S$ is close to that of $\boldsymbol{\xi}_S$ with overwhelmingly high probability.

Lemma 11 *Assume that Condition 3.1 holds. Then, for every s -subset $S \subseteq [p]$ and for every $0 \leq t \leq \frac{3}{4}(n - 2s)$,*

$$\mathbb{P}\left[\|\hat{\boldsymbol{\xi}}_S\|_2 - \|\boldsymbol{\xi}_S\|_2 > C_7\{s + t\}\phi\Delta(s, t)\}^{1/2}n^{-1/2}\right] \leq 12.4e^{-t}, \quad (38)$$

provided that $n \geq C_8(s + t)$, where $\Delta(s, t)$ is as in (29) and $C_7, C_8 > 0$ are constants depending only on a_0 and A_0 .

Using the union bound and taking $t = s \log \frac{e^2}{s} + \log n$ in Lemma 11, we see that with probability at least $1 - 12.4n^{-1}$,

$$\max_{S \subseteq [p]: |S|=s} \|\hat{\boldsymbol{\xi}}_S\|_2 - \|\boldsymbol{\xi}_S\|_2 \leq C_7\phi^{1/2}(s \log \frac{e^2}{s} + \log n)n^{-1/2} \quad (39)$$

whenever $n \geq C_9(s \log \frac{e^2}{s} + \log n)$.

Note that, the random vectors $\boldsymbol{\xi}$ and $\boldsymbol{\xi}_S$, $S \subseteq [p]$ defined in (37) satisfy $\mathbb{E}(\boldsymbol{\xi}) = \mathbf{0}$, $\mathbb{E}(\boldsymbol{\xi}_S^T) = \phi \boldsymbol{\Sigma}$, $\mathbb{E}(\boldsymbol{\xi}_S) = \mathbf{0}$ and $\mathbb{E}(\boldsymbol{\xi}_S \boldsymbol{\xi}_S^T) = \phi \mathbf{I}_s$. The following lemma provides a coupling inequality, showing that the random variable $\max_{S \subseteq [p]: |S|=s} \|\phi^{-1/2} \boldsymbol{\xi}_S\|_2$ can be well approximated, with high probability, by some random variable which is distributed as the maximum of the ℓ_2 -norms of a sequence of normalized Gaussian random vectors, that is, $\{\|\boldsymbol{\Sigma}_S^{-1/2} \mathbf{G}_S\|_2 : S \subseteq [p], |S|=s\}$.

Lemma 12 *Assume that Condition 3.1 holds. Then, there exists a random variable $T_0 \stackrel{d}{=} R_0(s, p)$ such that for any $\delta \in (0, 1]$,*

$$\left| \max_{S \subseteq [p]: |S|=s} \|\phi^{-1/2} \boldsymbol{\xi}_S\|_2 - T_0 \right| \leq C_{10}[\delta + \{s \log(\gamma_s p n)\}^{1/2}n^{-1/2} + \{s \log(\gamma_s p n)\}^2 n^{-3/2}] \quad (40)$$

holds with probability greater than $1 - C_{11}[\delta^{-3}n^{-1/2}\{s \log(\gamma_s p n)\}^2 \vee \delta^{-4}n^{-1}\{s \log(\gamma_s p n)\}^5]$, where $C_{10}, C_{11} > 0$ are constants depending only on a_0 and A_0

Step 3: Completion of the proof. We now apply an anti-concentration argument to construct the Berry-Esseen bound for the square root of the excess $2\phi^{-1}\{Q_n(s, p) - Q_n^*\}$. To this end, taking $\delta = \{s \log(\gamma_s p n)\}^{3/8}n^{-1/8}$ in Lemma 12 leads to that, with probability at least $1 - C_{11}\{s \log(\gamma_s p n)\}^{7/8}n^{-1/8}$,

$$\left| \max_{S \subseteq [p]: |S|=s} \|\phi^{-1/2} \boldsymbol{\xi}_S\|_2 - T_0 \right| \leq C_{12}\{s \log(\gamma_s p n)\}^{3/8}n^{-1/8} \quad (41)$$

whenever $n \geq \{s \log(\gamma_s p n)\}^3$. Further, for $R_0(s, p)$ in (14), note that

$$R_0^2(s, p) = \max_{S \subseteq [p]: |S|=s} \max_{\mathbf{u} \in \mathbb{S}^{s-1}} \frac{(\mathbf{u}^T \mathbf{G}_S)^2}{\mathbf{u}^T \boldsymbol{\Sigma}_S \mathbf{u}} = \max_{\mathbf{u} \in \mathcal{F}(s, p)} \frac{(\mathbf{u}^T \mathbf{G})^2}{\mathbf{u}^T \boldsymbol{\Sigma} \mathbf{u}},$$

where $\mathbf{G} \sim N(\mathbf{0}, \boldsymbol{\Sigma})$ and $\mathcal{F}(s, p) := \{\mathbf{x} \mapsto \mathbf{u}^T \mathbf{x} : \mathbf{u} \in \mathbb{S}^{p-1}, \|\mathbf{u}\|_0 \leq s\}$ is a class of linear functions $\mathbb{R}^p \mapsto \mathbb{R}$. Hence, it follows from Lemma 7.3 in Fan, Shao and Zhou (2015) with slight modification and Lemma A.1 in the supplement of Chernozhukov, Chetverikov and Kato (2014) that, for every $t > 0$,

$$\sup_{u \geq 0} \mathbb{P}\{|T_0 - u| \leq t\} = \sup_{u \geq 0} \mathbb{P}\{|R_0(s, p) - u| \leq t\} \leq C_{13}(s \log \frac{2se^2}{s})^{1/2}t, \quad (42)$$

where $C_{13} > 0$ is an absolute constant. Combining (42) with the preceding results (36), (39) and (41) proves (16). \blacksquare

6.2 Proof of Theorem 6

The main strategy of the proof is similar to that of Theorem 2 but technical details are substantially different. As before, we define the quasi-likelihood $\mathcal{L}_n(\boldsymbol{\beta}) = -\sum_{i=1}^n |Y_i - \mathbf{X}_i^T \boldsymbol{\beta}|$, $\boldsymbol{\beta} \in \mathbb{R}^p$, and observe that $\max_{\boldsymbol{\beta} \in \mathbb{R}^p: \|\boldsymbol{\beta}\|_0 \leq s} \mathcal{L}_n(\boldsymbol{\beta}) = \max_{S \subseteq [p]: |S|=s} \max_{\boldsymbol{\theta} \in \mathbb{R}^S} \mathcal{L}_n^S(\boldsymbol{\theta})$, where $\mathcal{L}_n^S(\boldsymbol{\theta}) = -\sum_{i=1}^n |Y_i - \mathbf{X}_{iS}^T \boldsymbol{\theta}|$. In the null model (7) with $\boldsymbol{\beta}^* = \mathbf{0}$, we have for each s -subset $S \subseteq [p]$, $\arg \max_{\boldsymbol{\theta}} \mathbb{E}_{\mathbf{X}} \{\mathcal{L}_n^S(\boldsymbol{\theta})\} = \mathbf{0}$ by the first order condition and concavity, and the S -restricted least absolute deviation estimator can be written as

$$\hat{\boldsymbol{\theta}}_S = \arg \max_{\boldsymbol{\theta} \in \mathbb{R}^S} \mathcal{L}_n^S(\boldsymbol{\theta}). \quad (43)$$

We first establish in Lemma 13 an upper bound for the maximum ℓ_2 -risks of $\hat{\boldsymbol{\theta}}_S$.

Lemma 13 *Assume that (18) holds and that $\mathbb{E}|\varepsilon|^\kappa < \infty$ for some $1 < \kappa \leq 2$. Then, on the event $\mathcal{E}_0(\tau)$ for $\tau > 0$, the sequence of LAD estimators $\{\hat{\boldsymbol{\theta}}_S : S \subseteq [p], |S|=s\}$ satisfies*

$$\max_{S \subseteq [p]: |S|=s} \|\hat{\boldsymbol{\Sigma}}_{SS}^{1/2} \hat{\boldsymbol{\theta}}_S\|_2 \leq C_1 a_2^{-1} \{s \log(pn)\}^{1/2} n^{-1/2} \quad (44)$$

with conditional probability (over the randomness of $\{\varepsilon_i\}_{i=1}^n$) greater than $1 - c_1 n^{-1} - c_2 n^{1-\kappa}$, where $C_1, c_1 > 0$ are absolute constants and $c_2 > 0$ is a constant depending only on $a_2, \kappa, \mathbb{E}|\varepsilon|$ and $\mathbb{E}|\varepsilon|^\kappa$.

Based on Lemma 13, we further study the concentration property of the Wilks expansion for the excess $\mathcal{L}_n^S(\hat{\boldsymbol{\theta}}_S) - \mathcal{L}_n^S(\mathbf{0})$. Since the function $\mathcal{L}_n^S(\cdot)$ is concave, we use $\nabla \mathcal{L}_n^S(\cdot)$ to denote its subgradient. For $\boldsymbol{\theta} \in \mathbb{R}^s$, let $\zeta^S(\boldsymbol{\theta}) = \mathcal{L}_n^S(\boldsymbol{\theta}) - \mathbb{E}_{\mathbf{X}} \mathcal{L}_n^S(\boldsymbol{\theta})$ be the stochastic component of $\mathcal{L}_n^S(\boldsymbol{\theta})$. Then, it is easy to see that

$$\nabla \zeta^S(\boldsymbol{\theta}) = -2 \sum_{i=1}^n w_i^S(\boldsymbol{\theta}) \mathbf{X}_{iS}, \quad \nabla \mathbb{E}_{\mathbf{X}} \mathcal{L}_n^S(\boldsymbol{\theta}) = - \sum_{i=1}^n \{2\mathbb{P}_{\mathbf{X}}(Y_i \leq \mathbf{X}_{iS}^T \boldsymbol{\theta}) - 1\} \mathbf{X}_{iS}, \quad (45)$$

where $w_i^S(\boldsymbol{\theta}) := I(Y_i \leq \mathbf{X}_{iS}^T \boldsymbol{\theta}) - \mathbb{P}_{\mathbf{X}}(Y_i \leq \mathbf{X}_{iS}^T \boldsymbol{\theta})$. In particular, we have $\nabla \zeta^S(\mathbf{0}) = -\sum_{i=1}^n \{2I(\varepsilon_i \leq 0) - 1\} \mathbf{X}_{iS}$. Recall that f_ε and F_ε denote, respectively, the density function and the cumulative distribution function of ε . By the second expression in (45), $\nabla \mathbb{E}_{\mathbf{X}} \mathcal{L}_n^S(\boldsymbol{\theta}) = -\sum_{i=1}^n \{2F_\varepsilon(\mathbf{X}_{iS}^T \boldsymbol{\theta}) - 1\} \mathbf{X}_{iS}$ and

$$\mathbf{H}_S(\boldsymbol{\theta}) := -\nabla^2 \mathbb{E}_{\mathbf{X}} \mathcal{L}_n^S(\boldsymbol{\theta}) = 2 \sum_{i=1}^n f_\varepsilon(\mathbf{X}_{iS}^T \boldsymbol{\theta}) \mathbf{X}_{iS} \mathbf{X}_{iS}^T. \quad (46)$$

In line with (26), we have $\mathbf{H}_S^* = \mathbf{H}_S(\mathbf{0}) = 2nf_\varepsilon(\mathbf{0})\widehat{\Sigma}_{SS}$, which is the negative Hessian of $\mathbb{E}_X \mathcal{L}_n^S(\mathbf{0})$. As in (27), define the normalized score

$$\widehat{\xi}_S = \mathbf{H}_S^{*-1/2} \nabla \mathcal{L}_n^S(\mathbf{0}) = \{2nf_\varepsilon(\mathbf{0})\}^{-1/2} \widehat{\Sigma}_{SS}^{-1/2} \sum_{i=1}^n \{2I(\varepsilon_i \leq 0) - 1\} \mathbf{X}_{iS}. \quad (47)$$

The following result is a non-asymptotic, conditional version of the Wilks theorem, saying that with high probability, the square root of the excess $\max_{\boldsymbol{\theta}} \mathcal{L}_n^S(\boldsymbol{\theta}) - \mathcal{L}_n^S(\mathbf{0})$ and the ℓ_2 -norm of the normalized score $\widehat{\xi}_S$ are sufficiently close uniformly over all s -subsets $S \subseteq [p]$.

Lemma 14 *Assume that Conditions 3.1 and 3.4 are satisfied. Then*

$$\begin{aligned} \max_{S \subseteq [p]; |S|=s} \left| 2\{\mathcal{L}_n^S(\widehat{\boldsymbol{\theta}}_S) - \mathcal{L}_n^S(\mathbf{0})\}^{1/2} - \|\widehat{\xi}_S\|_2 \right| \\ \leq C_2 \{f_\varepsilon(\mathbf{0})\}^{-1/2} [\lambda_{\min}^{-1/2}(s) \{s \log(pm)\}^{3/2} n^{-1/2} + \lambda_{\min}^{-1/4}(s) s \log(pm) n^{-1/4}] \end{aligned} \quad (48)$$

holds with probability greater than $1 - c_2 n^{1-\kappa} - c_3 n^{-1}$ whenever $n \geq C_3 \lambda_{\min}^{-1}(s) \{s \log(pm)\}^2$, where $C_2 > 0$ is a constant depending only on a_2, A_2 and A_3 , c_2 is as in Lemma 13, $c_3 > 0$ is an absolute constant and $C_3 > 0$ is a constant depending only on a_2 and A_2 .

Further, write $\tilde{\varepsilon}_i = 2I(\varepsilon_i \leq 0) - 1$ and $\widetilde{\mathbf{X}}_i = \tilde{\varepsilon}_i \mathbf{X}_i$. Note that $\tilde{\varepsilon}_1, \dots, \tilde{\varepsilon}_n$ are i.i.d. Rademacher random variables and thus $\widetilde{\mathbf{X}}_1, \dots, \widetilde{\mathbf{X}}_n$ are sub-exponential random vectors. In this notation, we have $\widehat{\xi}_S = \{2nf_\varepsilon(\mathbf{0})\}^{-1/2} \sum_{i=1}^n \widehat{\Sigma}_{SS}^{-1/2} \widetilde{\mathbf{X}}_{iS}$. For each $S \subseteq [p]$, define

$$\xi_S = \{2nf_\varepsilon(\mathbf{0})\}^{-1/2} \sum_{i=1}^n \widehat{\Sigma}_{SS}^{-1/2} \mathbf{X}_{iS}.$$

Then, applying Lemma 11 with slight modification and the union bound we obtain that, with probability at least $1 - c_4 n^{-1}$,

$$\max_{S \subseteq [p]; |S|=s} \left| \|\widehat{\xi}_S\|_2 - \|\xi_S\|_2 \right| \leq C_4 \{f_\varepsilon(\mathbf{0})\}^{-1/2} s \log(pm) n^{-1/2} \quad (49)$$

for all $n \geq C_5 s \log(pm)$, where $c_4 > 0$ is an absolute constant and $C_4, C_5 > 0$ are constants depending only on A_0 .

Observe that $\mathbb{E}(\widetilde{\mathbf{X}}_i) = \mathbb{E}[\mathbf{X}_i \{2\mathbb{P}(\varepsilon_i \leq 0) \mathbf{X}_i - 1\}] = 0$ and $\mathbb{E}(\widetilde{\mathbf{X}}_i \widetilde{\mathbf{X}}_i^\top) = \mathbb{E}(\mathbf{X}_i \mathbf{X}_i^\top) = \boldsymbol{\Sigma}$. Hence, it follows from Lemma 12 that there exists a random variable $T_0 \stackrel{d}{=} R_0(s, p)$ such that for any $\delta \in (0, 1]$,

$$\left| \sqrt{2f_\varepsilon(\mathbf{0})} \max_{S \subseteq [p]; |S|=s} \|\xi_S\|_2 - T_0 \right| \leq C_6 [\delta + \{s \log(\gamma_s pm)\}^{1/2} n^{-1/2} + \{s \log(\gamma_s pm)\}^2 n^{-3/2}] \quad (50)$$

holds with probability at least $1 - C_7 [\delta^{-3} n^{-1/2} \{s \log(\gamma_s pm)\}^2 \vee \delta^{-4} n^{-1} \{s \log(\gamma_s pm)\}^5]$, where $C_6, C_7 > 0$ are constants depending only on A_0 .

Finally, combining (48), (49), (50) and (42) proves (20). \blacksquare

Appendix A. Appendix A.

In this appendix we prove the technical lemmas appeared in Section 6.

A.1 Proof of Lemma 9

Define the loss function $\ell(y, z) = yz - b(z)$ for $y, z \in \mathbb{R}$. For each s -subset $S \subseteq [p]$ and $\theta \in \mathbb{R}^s$, define $\zeta^S(\theta) = L_n^S(\theta) - \mathbb{E} \mathbf{X} \mathcal{L}_n^S(\theta) = \sum_{i=1}^n \zeta_i^S(\theta)$, where $\zeta_i^S(\theta) = \ell(Y_i, \mathbf{X}_{iS}^T \theta) - \mathbb{E} \mathbf{X} \ell(Y_i, \mathbf{X}_{iS}^T \theta)$. Note that $\nabla \zeta_i^S(\theta)|_{\theta=0} = \varepsilon_i \mathbf{X}_{iS}$ with $\varepsilon_i = Y_i - b(0)$. Thus, we have $\mathbf{V}_0^S := \text{Var} \mathbf{X} \{\nabla \zeta^S(\mathbf{0})\} = n\phi^{S'}(0) \widehat{\Sigma}_{SS}$.

For every $\mathbf{u} \in \mathbb{R}^s \setminus \{\mathbf{0}\}$ and $u \in \mathbb{R}$,

$$\begin{aligned} \mathbb{E} \mathbf{X} \exp \left\{ u \frac{\mathbf{u}^T \nabla \zeta^S(\mathbf{0})}{\|\mathbf{V}_0 \mathbf{u}\|_2} \right\} &= \prod_{i=1}^n \mathbb{E} \mathbf{X} \exp \left(u \frac{\mathbf{u}^T \mathbf{X}_{iS} \varepsilon_i}{\|\mathbf{V}_0 \mathbf{u}\|_2} \right) \\ &= \prod_{i=1}^n \mathbb{E} \mathbf{X} \exp \left\{ \frac{u}{\sqrt{n}} \times \frac{\mathbf{u}^T \mathbf{X}_{iS}}{(\mathbf{u}^T \widehat{\Sigma}_{SS} \mathbf{u})^{1/2}} \times \frac{\varepsilon_i}{(\text{Var } \varepsilon_i)^{1/2}} \right\} \\ &\leq \exp \left\{ \frac{1}{2} a_0 u^2 \times \frac{1}{n} \sum_{i=1}^n \frac{(\mathbf{u}^T \mathbf{X}_{iS})^2}{\mathbf{u}^T \widehat{\Sigma}_{SS} \mathbf{u}} \right\} = \exp(a_0 u^2 / 2). \end{aligned}$$

This verifies condition (ED_0) with $\eta_0^S = a_0$ in Theorem B.3 from the supplement of Spokoiny and Zhilova (2015). Consequently, taking $\mathbb{B}^2 = \mathbf{H}_S^{-1/2} \mathbf{V}_0^2 \mathbf{H}_S^{*-1/2} = \phi \mathbf{I}_s$ and $\mathbf{g} = \{C \text{tr}(\mathbb{B}^2)\}^{1/2}$ for some $C \geq 2$ there, we have $\lambda_{\max}(\mathbb{B}^2) = \phi$, $\text{tr}(\mathbb{B}^2) = \phi s$, $\text{tr}(\mathbb{B}^4) = \phi^2 s^2$ and $\mathbf{x}_c = \frac{1}{2}(\frac{2}{3}C - 1 - \log 3)s \geq \frac{3}{4}(C - 2)s$. This implies that almost surely on the event $\{\widehat{\Sigma}_{SS} \succ \mathbf{0}\}$, with conditional probability at least $1 - 2e^{-t} - 8.4 e^{-x_c}$,

$$\|\widehat{\xi}_s\|_2^2 \leq a_0 \phi \times \begin{cases} s + (8ts)^{1/2}, & \text{if } 0 \leq t \leq \frac{1}{18}(2s)^{1/2}, \\ s + 6t, & \text{if } \frac{1}{18}(2s)^{1/2} < t \leq x_c. \end{cases}$$

Finally, letting $C \rightarrow \infty$ proves (28). ■

A.2 Proof of Lemma 10

We prove this lemma by applying the conditional version of Theorem 2.3 in Spokoiny (2013). To this end, we need to verify conditions (ED_0) , (ED_2) , (\mathcal{L}_0) , (\mathcal{I}) and (\mathcal{L}) . In line with the notation used therein, we fix $S \subseteq [p]$ and write

$$\mathbf{D}^2(\theta) = -\nabla^2 \mathbb{E} \mathbf{X} \{\mathcal{L}_n^S(\theta)\} = \sum_{i=1}^n \theta^{i'} (\mathbf{X}_{iS}^T \theta) \mathbf{X}_{iS} \mathbf{X}_{iS}^T, \quad \mathbf{D}_0^2 = \mathbf{D}^2(\mathbf{0}) = n\theta^{i'}(0) \widehat{\Sigma}_{SS}.$$

The validity of (ED_0) is guaranteed from the proof of Lemma 9, and (ED_2) is automatically satisfied with $\omega \equiv 0$ since $\nabla^2 \zeta^S(\theta)$ vanishes for all $\theta \in \mathbb{R}^s$. Turning to (\mathcal{L}_0) , observe

that

$$\begin{aligned}
& \|\mathbf{D}_0^{-1} \mathbf{D}^2(\boldsymbol{\theta}) \mathbf{D}_0^{-1} - \mathbf{I}_s\| \\
&= \left\| \mathbf{D}_0^{-1} \sum_{i=1}^n \{b''(\mathbf{X}_{iS}^T \boldsymbol{\theta}) - b''(0)\} \mathbf{X}_{iS} \mathbf{X}_{iS}^T \mathbf{D}_0^{-1} \right\| \\
&= \left\| \mathbf{D}_0^{-1} \sum_{i=1}^n b'''(\eta_i) \mathbf{X}_{iS}^T \boldsymbol{\theta} \mathbf{X}_{iS} \mathbf{X}_{iS}^T \mathbf{D}_0^{-1} \right\|, \tag{51}
\end{aligned}$$

where η_i lies between 0 and $\mathbf{X}_{iS}^T \boldsymbol{\theta}$. For $r > 0$, define $\Theta_0(r) = \{\boldsymbol{\theta} \in \mathbb{R}^s : \|\mathbf{D}_0 \boldsymbol{\theta}\|_2 \leq r\}$. On the event $\mathcal{E}_0(\tau)$ for some $\tau > 0$ and for $\boldsymbol{\theta} \in \Theta_0(r)$,

$$\|\mathbf{X}_{iS}^T \boldsymbol{\theta}\| = |\boldsymbol{\theta}^T \mathbf{D}_0 \mathbf{D}_0^{-1} \mathbf{X}_{iS}| \leq \|\mathbf{D}_0^{-1} \mathbf{X}_{iS}\|_2 \leq \{nb''(0)\}^{-1/2} \tau^{1/2} r. \tag{52}$$

This together with (51) implies that

$$\|\mathbf{D}_0^{-1} \mathbf{D}^2(\boldsymbol{\theta}) \mathbf{D}_0^{-1} - \mathbf{I}_s\| \leq \frac{\max_{|\mu| \leq \{nb''(0)\}^{-1/2} \tau^{1/2} r} |b'''(\mu)|}{\{b''(0)\}^{3/2}} \tau^{1/2} r := \delta(\tau, r). \tag{53}$$

Recalling that $\mathbf{V}_2^S = \text{Var} \mathbf{x}\{\mathcal{L}_n^S(\mathbf{0})\} = \phi \mathbf{D}_0^S$, (\mathcal{L}) is satisfied with $a = \phi^{1/2}$.

To verify $(\mathcal{L}v)$, define $g(t) = b'(0)t - b(t)$ so that $g'(t) = b'(0) - b'(t)$ and $g''(t) = -b''(t)$. Then, for any $\boldsymbol{\theta} \in \mathbb{R}^s$ satisfying $\|\mathbf{D}_0 \boldsymbol{\theta}\|_2 = r > 0$, it follows from the second-order Taylor expansion that

$$\begin{aligned}
& -2\{\mathbb{E} \mathbf{x} \mathcal{L}_n^S(\boldsymbol{\theta}) - \mathbb{E} \mathbf{x} \mathcal{L}_n^S(\mathbf{0})\} = -2 \sum_{i=1}^n \{g(\mathbf{X}_{iS}^T \boldsymbol{\theta}) - g(0)\} \\
&= -2 \sum_{i=1}^n \{g'(0) \mathbf{X}_{iS}^T \boldsymbol{\theta} + \frac{1}{2} g''(\eta_i) (\mathbf{X}_{iS}^T \boldsymbol{\theta})^2\} = \sum_{i=1}^n b''(\eta_i) (\mathbf{X}_{iS}^T \boldsymbol{\theta})^2, \tag{54}
\end{aligned}$$

where η_i is a point lying between 0 and $\mathbf{X}_{iS}^T \boldsymbol{\theta}$. On the event $\mathcal{E}_0(\tau)$, the right-hand side of (54) is further bounded from below by

$$r^2 \{b''(0)\}^{-1} \min_{|\mu| \leq \{nb''(0)\}^{-1/2} \tau^{1/2} r} b''(\mu).$$

When $\|\mathbf{D}_0 \boldsymbol{\theta}\|_2 = r \leq \{nb''(0)/\tau\}^{1/2}$, $-2\{\mathbb{E} \mathbf{x} \mathcal{L}_n^S(\boldsymbol{\theta}) - \mathbb{E} \mathbf{x} \mathcal{L}_n^S(\mathbf{0})\}$ is bounded from below by $a_1 r^2$ for a_1 as in (15). Further, from the convexity of the function $\boldsymbol{\theta} \mapsto -\mathbb{E} \mathbf{x}\{\mathcal{L}_n^S(\boldsymbol{\theta}) - \mathcal{L}_n^S(\mathbf{0})\}$, we see that $-\mathbb{E} \mathbf{x}\{\mathcal{L}_n^S(\boldsymbol{\theta}) - \mathcal{L}_n^S(\mathbf{0})\} \geq a_1 r \{nb''(0)/\tau\}^{1/2}$, for all $\boldsymbol{\theta}$ satisfying $\|\mathbf{D}_0 \boldsymbol{\theta}\|_2 = r \geq \{nb''(0)/\tau\}^{1/2}$. Define the function $r \mapsto b(r)$ as

$$b(r) = \begin{cases} a_1 & \text{if } 0 \leq r \leq \{nb''(0)/\tau\}^{1/2}, \\ a_1 r^{-1} \{nb''(0)/\tau\}^{1/2} & \text{if } r > \{nb''(0)/\tau\}^{1/2}. \end{cases} \tag{55}$$

By definition, $r\dot{b}(r)$ is non-decreasing in $r \geq 0$ and for $\boldsymbol{\theta} \in \mathbb{R}^s$ satisfying $\|\mathbf{D}_0 \boldsymbol{\theta}\|_2 = r$,

$$-\frac{2\mathbb{E} \mathbf{x}\{\mathcal{L}_n^S(\boldsymbol{\theta}) - \mathcal{L}_n^S(\mathbf{0})\}}{\|\mathbf{D}_0 \boldsymbol{\theta}\|_2^2} \geq b(r). \tag{56}$$

With the above preparations, we apply Theorem 2.3 in Spokoiny (2013) with slight modification on the constant. In view of (29) and (55), set

$$r_0 = 2(\phi a_0)^{1/2} a_1^{-1} [s + 6(s \log \frac{\phi}{s} + \log n)]^{1/2}, \tag{57}$$

such that Condition 2.3 there is satisfied on $\mathcal{E}_0(\tau)$ whenever $n \geq \{b''(0)\}^{-1} r_0^2 \tau$. Hence, it follows from Theorem 2.3 in Spokoiny (2013) and the union bound that, conditional on the event $\mathcal{E}_0(\tau)$,

$$\mathbb{P} \mathbf{x} \left(\max_{S \subseteq [p]: |S|=s} |2\{\mathcal{L}_n^S(\widehat{\boldsymbol{\theta}}_S) - \mathcal{L}_n^S(\mathbf{0})\}|^{1/2} - \|\widehat{\boldsymbol{\xi}}_S\|_2 \leq 5\delta(\tau, r_0) r_0 \right) \leq 5n^{-1}, \tag{58}$$

where $\delta(\tau, r)$ and r_0 are as in (53) and (57), respectively. This proves (31) by properly choosing C_1 and C_2 . \blacksquare

A.3 Proof of Lemma 11

To begin with, note that for each s -subset $S \subseteq [p]$, $\mathbf{Z}_{iS}, \dots, \mathbf{Z}_{nS}$ are i.i.d. s -dimensional random vectors with mean zero and covariance matrix $\phi \boldsymbol{\Sigma}_{SS}$. By (27) and (37),

$$\|\widehat{\boldsymbol{\xi}}_S\|_2^2 - \|\boldsymbol{\xi}_S\|_2^2 = \boldsymbol{\xi}_S^T (\boldsymbol{\Sigma}_{SS}^{1/2} \widehat{\boldsymbol{\Sigma}}_{SS}^{-1} \boldsymbol{\Sigma}_{SS}^{1/2} - \mathbf{I}_s) \boldsymbol{\xi}_S.$$

Write $\mathbb{X}_S = (\mathbf{X}_{1S}, \dots, \mathbf{X}_{nS})^T \in \mathbb{R}^{n \times s}$, then $\mathbb{X}_S \boldsymbol{\Sigma}_{SS}^{-1/2}$ is an $n \times s$ matrix whose rows are independent sub-Gaussian random vectors in \mathbb{R}^s . Further, observe that $\mathbf{X}_{iS} = \mathbf{P}_S \mathbf{X}_i$ and $\boldsymbol{\Sigma}_{SS} = \mathbf{P}_S \boldsymbol{\Sigma} \mathbf{P}_S^T$, where $\mathbf{P}_S \in \mathbb{R}^{s \times p}$ is a projection matrix. Under Condition 3.1, $\|\mathbf{u}^T \boldsymbol{\Sigma}_{SS}^{-1/2} \mathbf{X}_{iS}\|_{\psi_2} = \|\mathbf{u}^T \boldsymbol{\Sigma}_{SS}^{-1/2} \mathbf{P}_S \boldsymbol{\Sigma}_{SS}^{1/2} \mathbf{U}\|_{\psi_2} \leq A_0 \|\boldsymbol{\Sigma}_{SS}^{1/2} \mathbf{P}_S^T \boldsymbol{\Sigma}_{SS}^{-1/2} \mathbf{u}\|_2 = A_0$ for $\mathbf{u} \in \mathbb{S}^{s-1}$. Then, it follows from (32) that for all sufficient large n so that $\delta \leq \frac{1}{2}$, $\|\boldsymbol{\Sigma}_{SS}^{1/2} \widehat{\boldsymbol{\Sigma}}_{SS}^{-1} \boldsymbol{\Sigma}_{SS}^{1/2} - \mathbf{I}_s\| \leq 2\delta$ and hence,

$$\begin{aligned}
\|\widehat{\boldsymbol{\xi}}_S\|_2 - \|\boldsymbol{\xi}_S\|_2 &= \frac{\|\widehat{\boldsymbol{\xi}}_S\|_2^2 - \|\boldsymbol{\xi}_S\|_2^2}{\|\widehat{\boldsymbol{\xi}}_S\|_2 + \|\boldsymbol{\xi}_S\|_2} \\
&\leq \|\boldsymbol{\xi}_S\|_2^{-1} \times \|\widehat{\boldsymbol{\xi}}_S\|_2^2 - \|\boldsymbol{\xi}_S\|_2^2 \leq 2C_3 (s \vee t)^{1/2} n^{-1/2} \times \|\boldsymbol{\xi}_S\|_2. \tag{59}
\end{aligned}$$

Next we upper bound the quadratic term $\|\boldsymbol{\xi}_S\|_2$. First we show that $\boldsymbol{\Sigma}_{SS}^{-1/2} \mathbf{Z}_{iS} = \phi^{1/2} \boldsymbol{\Sigma}_{SS}^{-1/2} \widetilde{\boldsymbol{\varepsilon}}_i \mathbf{X}_i$ are sub-exponential random vectors, where $\widetilde{\boldsymbol{\varepsilon}}_i := \boldsymbol{\varepsilon}_i / (\text{Var } \boldsymbol{\varepsilon}_i)^{1/2}$. In fact, for every $\mathbf{u} \in \mathbb{S}^{s-1}$, $\|\mathbf{u}^T \boldsymbol{\Sigma}_{SS}^{-1/2} \mathbf{Z}_{iS}\|_{\psi_1} \leq 2\|\widetilde{\boldsymbol{\varepsilon}}_i\|_{\psi_2} \|\mathbf{u}^T \boldsymbol{\Sigma}_{SS}^{-1/2} \mathbf{X}_i\|_{\psi_2} \leq 2A_0 A_0$, where $A_0 > 0$ is a constant depending only on a_0 in Condition 3.1. Following the proof of Lemma 5.15 in Vershynin (2012), we derive that for every $\mathbf{u} \in \mathbb{R}^s$ satisfying $\|\mathbf{u}\|_2 \leq \phi^{-1/2} (4eA_0' A_0)^{-1} \sqrt{n}$,

$$\begin{aligned}
\log \mathbb{E} \exp(\mathbf{u}^T \boldsymbol{\xi}_S) &= \sum_{i=1}^n \log \mathbb{E} \exp(n^{-1/2} \mathbf{u}^T \boldsymbol{\Sigma}_{SS}^{-1/2} \mathbf{Z}_{iS}) \\
&\leq 2e^2 \|\mathbf{u}\|_2^2 n^{-1} \sum_{i=1}^n \|\mathbf{u} / \|\mathbf{u}\|_2\|_2^T \boldsymbol{\Sigma}_{SS}^{-1/2} \mathbf{Z}_{iS}\|_{\psi_1}^2 \\
&\leq (4eA_0' A_0)^2 \phi \frac{\|\mathbf{u}\|_2^2}{2}.
\end{aligned}$$

Consequently, applying Corollary 1.12 in the supplement of Spokoiny (2012) with $\mathbf{g} = \sqrt{n}$, $\mathbb{B} = \mathbf{I}_s$ and $\mathbf{x}_c = \frac{3}{4}n - \frac{1}{2}(1 + \log 3)s \geq \frac{3}{4}n - \frac{3}{2}s$ to the random vector $(4eA_0^*A_0)^{-1}\phi^{-1/2}\boldsymbol{\xi}_S$ yields that, for every $0 \leq t \leq \mathbf{x}_c$,

$$\mathbb{P}\{\|\boldsymbol{\xi}_S\|_2 \geq 4eA_0^*A_0\{\phi\Delta(s,t)\}^{1/2}\} \leq 2e^{-t} + 8.4e^{-\mathbf{x}_c}. \quad (60)$$

Finally, combining (59) and (60) completes the proof of (38). ■

A.4 Proof of Lemma 12

First, observe that

$$\max_{S \subseteq [p]: |S|=s} \|\boldsymbol{\xi}_S\|_2 = \max_{\mathbf{u} \in \mathcal{F}(s,p)} n^{-1/2} \sum_{i=1}^n \frac{\mathbf{u}^T \mathbf{Z}_i}{(\mathbf{u}^T \boldsymbol{\Sigma} \mathbf{u})^{1/2}},$$

where $\mathcal{F}(s,p) = \{\mathbf{x} \mapsto \mathbf{u}^T \mathbf{x} : \mathbf{u} \in \mathbb{S}^{p-1}, \|\mathbf{u}\|_0 \leq s\}$. Recall that $\mathbf{Z}_1, \dots, \mathbf{Z}_n$ are i.i.d. p -dimensional centered random vectors with covariance matrix $\mathbb{E}[\mathbf{Z}_i \mathbf{Z}_i^T] = \phi \boldsymbol{\Sigma}$. As in the proof of Lemma 11, we have for any $\mathbf{u} \in \mathbb{S}^{p-1}$,

$$\|\phi^{-1/2} \mathbf{u}^T \mathbf{Z}_i\|_{\psi_1} \leq 2\|\varepsilon_i / (\text{Var } \varepsilon_i)^{1/2}\|_{\psi_2} \|\mathbf{u}^T \boldsymbol{\Sigma}^{1/2} \mathbf{T}_i\|_{\psi_2} \leq 2A_0^*A_0(\mathbf{u}^T \boldsymbol{\Sigma} \mathbf{u})^{1/2}.$$

Consequently, it follows from Lemma 7.5 in Fan, Shao and Zhou (2015) that there exists a random variable $T_0 \stackrel{d}{=} R_0(s,p) = \max_{\mathbf{u} \in \mathcal{F}(s,p)} \frac{\mathbf{u}^T \mathbf{G}}{(\mathbf{u}^T \boldsymbol{\Sigma} \mathbf{u})^{1/2}}$ for $\mathbf{G} \sim \mathcal{N}(\mathbf{0}, \boldsymbol{\Sigma})$ such that, for any $\delta \in (0, 1]$,

$$\begin{aligned} \mathbb{P}\left\{ \max_{S \subseteq [p]: |S|=s} \|\phi^{-1/2} \boldsymbol{\xi}_S\|_2 - T_0 \geq C_1 A_0^* A_0 \left(\delta + \frac{\gamma_{s,p}^{1/2}}{\sqrt{n}} + \frac{\gamma_{s,p}^2}{n^{3/2}} \right) \right\} \\ \leq C_2 \left[\frac{\{s \log(\gamma_{s,p})\}^2}{\delta^3 \sqrt{n}} + \frac{\{s \log(\gamma_{s,p})\}^5}{\delta^4 n} \right], \end{aligned}$$

where $\gamma_{s,p} = s \log \frac{\gamma_{s,p}}{s} + \log n$ and $C_1, C_2 > 0$ are absolute constants. This proves (40). ■

A.5 Proof of Lemma 13

The proof employs techniques from empirical process theory which modify the arguments used in Wang (2013). To begin with, note that

$$\hat{\boldsymbol{\theta}}_S = \arg \min_{\boldsymbol{\theta} \in \mathbb{R}^s} f(\boldsymbol{\theta}) := \arg \min_{\boldsymbol{\theta} \in \mathbb{R}^s} \|\mathbf{Y} - \mathbb{X}_S \boldsymbol{\theta}\|_1.$$

Under the null model, $\mathbf{Y} = \mathbb{X}_S \boldsymbol{\theta}^* + \boldsymbol{\varepsilon}$ with $\boldsymbol{\theta}^* = \mathbf{0}$. Then the sub-differential of $f(\boldsymbol{\theta})$ at $\boldsymbol{\theta} = \mathbf{0}$ can be written as $\nabla f(\mathbf{0}) = -\mathbb{X}_S^T \text{sgn}(\boldsymbol{\varepsilon})$, where $\text{sgn}(\boldsymbol{\varepsilon}) = (\text{sgn}(\varepsilon_1), \dots, \text{sgn}(\varepsilon_n))^T$ with $\text{sgn}(u) := I(u > 0) - I(u < 0)$. Define $\mathbf{z} = (z_1, \dots, z_n)^T = \text{sgn}(\boldsymbol{\varepsilon})$, and note that z_1, \dots, z_n are i.i.d. random variables satisfying $\mathbb{P}(z_i = 1) = \mathbb{P}(z_i = -1) = 1/2$. Since $\hat{\boldsymbol{\theta}}_S$ minimizes $\|\mathbf{Y} - \mathbb{X}_S \boldsymbol{\theta}\|_1$ over \mathbb{R}^s , we have the following basic inequality

$$\|\mathbf{Y} - \mathbb{X}_S \hat{\boldsymbol{\theta}}_S\|_1 = \|\mathbb{X}_S \hat{\boldsymbol{\theta}}_S - \boldsymbol{\varepsilon}\|_1 \leq \|\boldsymbol{\varepsilon}\|_1. \quad (61)$$

Further, define a random process $\{Q(\boldsymbol{\theta})\}$ indexed by $\boldsymbol{\theta} \in \mathbb{R}^s$:

$$Q(\boldsymbol{\theta}) = n^{-1/2} \sum_{i=1}^n (\mathbf{X}_{iS}^T \boldsymbol{\theta} - \varepsilon_i) - |\varepsilon_i|. \quad (62)$$

In what follows, we prove that with overwhelmingly high probability, $Q(\boldsymbol{\theta})$ is concentrated around its expectation $Q_{\mathbb{X}}(\boldsymbol{\theta}) := \mathbb{E}_{\mathbf{X}}\{Q(\boldsymbol{\theta})\}$ uniformly over $\boldsymbol{\theta} \in \mathbb{R}^s$ via a straightforward adaptation of the peeling argument.

For $\delta_1 > 0$ and $\ell = 1, 2, \dots$, consider the following sequence of events

$$\mathcal{G}(\delta_1) = \{\boldsymbol{\theta} \in \mathbb{R}^s : \|\widehat{\boldsymbol{\Sigma}}_{SS}^{1/2} \boldsymbol{\theta}\|_2 \geq \delta_1\}, \quad \mathcal{G}_\ell(\delta_1) = \{\boldsymbol{\theta} \in \mathbb{R}^s : \alpha^{\ell-1} \delta_1 \leq \|\widehat{\boldsymbol{\Sigma}}_{SS}^{1/2} \boldsymbol{\theta}\|_2 \leq \alpha^\ell \delta_1\}, \quad (63)$$

where $\alpha = \sqrt{2}$. Here, δ_1 can be regarded as a tolerance parameter, and it is easy to see that $\mathcal{G}(\delta_1) = \cup_{\ell=1}^{\infty} \mathcal{G}_\ell(\delta_1)$. For $R > 0$, set $\mathcal{V}(R) = \{\boldsymbol{\theta} \in \mathcal{G}(\delta_1) : \|\widehat{\boldsymbol{\Sigma}}_{SS}^{1/2} \boldsymbol{\theta}\|_2 \leq R\}$ and let $\Delta(R)$ be the maximum deviation over the elliptic vicinity $\mathcal{V}(R)$:

$$\Delta(R) = \max_{\boldsymbol{\theta} \in \mathcal{V}(R)} |Q(\boldsymbol{\theta}) - Q_{\mathbb{X}}(\boldsymbol{\theta})|. \quad (64)$$

For every $\boldsymbol{\theta} \in \mathbb{R}^s$, define the rescaled vector $\tilde{\boldsymbol{\theta}} = \widehat{\boldsymbol{\Sigma}}_{SS}^{1/2} \boldsymbol{\theta}$ such that

$$\Delta(R) = \max_{\delta_1 \leq \|\tilde{\boldsymbol{\theta}}\|_2 \leq R} |Q(\widehat{\boldsymbol{\Sigma}}_{SS}^{-1/2} \tilde{\boldsymbol{\theta}}) - Q_{\mathbb{X}}(\widehat{\boldsymbol{\Sigma}}_{SS}^{-1/2} \tilde{\boldsymbol{\theta}})|.$$

For every $0 < \epsilon \leq R$, there exists an ϵ -net \mathcal{N}_ϵ of the Euclidean ball $\mathbb{B}_{\mathbb{R}^s}(R)$ with cardinality bounded by $(1 + \frac{2R}{\epsilon})^s$. For $\boldsymbol{\theta}_1, \boldsymbol{\theta}_2 \in \mathbb{B}_{\mathbb{R}^s}(R)$ satisfying $\|\boldsymbol{\theta}_1 - \boldsymbol{\theta}_2\|_2 \leq \epsilon$, observe that

$$\begin{aligned} \left| Q(\widehat{\boldsymbol{\Sigma}}_{SS}^{-1/2} \tilde{\boldsymbol{\theta}}_1) - Q(\widehat{\boldsymbol{\Sigma}}_{SS}^{-1/2} \tilde{\boldsymbol{\theta}}_2) \right| &\leq n^{-1/2} \sum_{i=1}^n \left| \mathbf{X}_{iS}^T \widehat{\boldsymbol{\Sigma}}_{SS}^{-1/2} (\tilde{\boldsymbol{\theta}}_1 - \tilde{\boldsymbol{\theta}}_2) \right| \\ &\leq \|\mathbb{X}_S \widehat{\boldsymbol{\Sigma}}_{SS}^{-1/2} (\tilde{\boldsymbol{\theta}}_1 - \tilde{\boldsymbol{\theta}}_2)\|_2 \leq \epsilon n^{1/2}. \end{aligned}$$

Then, it is easy to see that

$$\Delta(R) \leq \max_{\tilde{\boldsymbol{\theta}} \in \mathcal{N}_\epsilon} |Q(\widehat{\boldsymbol{\Sigma}}_{SS}^{-1/2} \tilde{\boldsymbol{\theta}}) - Q_{\mathbb{X}}(\widehat{\boldsymbol{\Sigma}}_{SS}^{-1/2} \tilde{\boldsymbol{\theta}})| + 2\epsilon n^{1/2}. \quad (65)$$

For each $\tilde{\boldsymbol{\theta}} \in \mathbb{B}_{\mathbb{R}^s}(R)$ fixed, $Q(\widehat{\boldsymbol{\Sigma}}_{SS}^{-1/2} \tilde{\boldsymbol{\theta}}) - Q_{\mathbb{X}}(\widehat{\boldsymbol{\Sigma}}_{SS}^{-1/2} \tilde{\boldsymbol{\theta}})$ is a sum of independent random variables with zero means and for $i = 1, \dots, n$, $\|\mathbf{X}_{iS}^T \widehat{\boldsymbol{\Sigma}}_{SS}^{-1/2} \tilde{\boldsymbol{\theta}} - \varepsilon_i\| \leq \|\mathbf{X}_{iS}^T \widehat{\boldsymbol{\Sigma}}_{SS}^{-1/2} \tilde{\boldsymbol{\theta}}\|$. Therefore, it follows from Hoeffding's inequality that for every $t > 0$,

$$\begin{aligned} \mathbb{P}_{\mathbf{X}} \left\{ \left| Q(\widehat{\boldsymbol{\Sigma}}_{SS}^{-1/2} \tilde{\boldsymbol{\theta}}) - Q_{\mathbb{X}}(\widehat{\boldsymbol{\Sigma}}_{SS}^{-1/2} \tilde{\boldsymbol{\theta}}) \right| \geq t \right\} \\ \leq 2 \exp \left\{ - \frac{nt^2}{2 \sum_{i=1}^n (\mathbf{X}_{iS}^T \widehat{\boldsymbol{\Sigma}}_{SS}^{-1/2} \tilde{\boldsymbol{\theta}})^2} \right\} = 2 \exp \left(- \frac{t^2}{2\|\tilde{\boldsymbol{\theta}}\|_2^2} \right). \end{aligned}$$

In other words, for every $\tilde{\boldsymbol{\theta}} \in \mathbb{B}_2^s(R)$ and $\delta > 0$,

$$\left| Q(\widehat{\Sigma}_{SS}^{-1/2} \tilde{\boldsymbol{\theta}}) - Q_{\mathbf{X}}(\widehat{\Sigma}_{SS}^{-1/2} \tilde{\boldsymbol{\theta}}) \right| \leq (2\delta)^{1/2} \|\tilde{\boldsymbol{\theta}}\|_2 \leq (2\delta)^{1/2} R$$

holds with probability at least $1 - 2e^{-\delta}$. This, together with the union bound yields

$$\mathbb{P}_{\mathbf{X}} \left\{ \max_{\tilde{\boldsymbol{\theta}} \in \mathcal{V}} \left| Q(\widehat{\Sigma}_{SS}^{-1/2} \tilde{\boldsymbol{\theta}}) - Q_{\mathbf{X}}(\widehat{\Sigma}_{SS}^{-1/2} \tilde{\boldsymbol{\theta}}) \right| \geq (2\delta)^{1/2} R \right\} \leq \exp \left\{ s \log \left(1 + \frac{2R}{\epsilon} \right) - \delta \right\}. \quad (66)$$

In particular, by taking $\epsilon = Rn^{-1}$ in (65) and $\delta = s \log(1 + \frac{2R}{\epsilon}) + t \leq 2s \log n + t$ in (66) we conclude that

$$\mathbb{P}_{\mathbf{X}} \left\{ \Delta(R) \geq R(2t)^{1/2} + 2R(s \log n)^{1/2} + 2Rn^{-1/2} \right\} \leq 2e^{-t} \quad (67)$$

holds almost surely on the event $\mathcal{E}_0(\tau)$ for any $\tau > 0$.

In particular, by taking $t = cnR^2$ in (67) for some $c > 0$ to be specified below (72) and the union bound, we have

$$\begin{aligned} & \mathbb{P}_{\mathbf{X}} \left[\exists \boldsymbol{\theta} \in \mathcal{G}(\delta_1), \text{ s.t. } |Q(\boldsymbol{\theta}) - Q_{\mathbf{X}}(\boldsymbol{\theta})| \geq 2^{3/2} \|\tilde{\boldsymbol{\theta}}\|_2 \{ \|\tilde{\boldsymbol{\theta}}\|_2 (cn)^{1/2} + (s \log n)^{1/2} + n^{-1/2} \} \right] \\ & \leq \sum_{\ell=1}^{\infty} \mathbb{P}_{\mathbf{X}} \left[\exists \boldsymbol{\theta} \in \mathcal{G}_{\ell}(\delta_1), \text{ s.t. } |Q(\boldsymbol{\theta}) - Q_{\mathbf{X}}(\boldsymbol{\theta})| \geq (\alpha^{\ell} \delta_1)^2 (2cn)^{1/2} + 2\alpha^{\ell} \delta_1 \{ (s \log n)^{1/2} + n^{-1/2} \} \right] \\ & \leq \sum_{\ell=1}^{\infty} \mathbb{P}_{\mathbf{X}} \left[\Delta(\alpha^{\ell} \delta_1) \geq (\alpha^{\ell} \delta_1)^2 (2cn)^{1/2} + 2\alpha^{\ell} \delta_1 \{ (s \log n)^{1/2} + n^{-1/2} \} \right] \\ & \leq 2 \sum_{\ell=1}^{\infty} \exp \{ -cn(\alpha^{\ell} \delta_1)^2 \} \leq 2 \sum_{\ell=1}^{\infty} \exp \{ -2c\ell \log(\alpha) n \delta_1^2 \} \leq \frac{2 \exp(-c_0 n \delta_1^2)}{1 - \exp(-c_0 n \delta_1^2)}, \end{aligned}$$

where $c_0 = c \log 2$. This implies that with probability at least $1 - 4 \exp(-c_0 n \delta_1^2)$,

$$|Q(\boldsymbol{\theta}) - Q_{\mathbf{X}}(\boldsymbol{\theta})| \leq 2^{3/2} \sqrt{c} \|\widehat{\Sigma}_{SS}^{-1/2} \boldsymbol{\theta}\|_2 + 2^{3/2} \|\widehat{\Sigma}_{SS}^{-1/2} \boldsymbol{\theta}\|_2 \{ (s \log n)^{1/2} + n^{-1/2} \} \quad (68)$$

holds for all $\boldsymbol{\theta} \in \mathcal{G}(\delta_1)$ whenever $n \geq c^{-1} \delta_1^{-2}$.

For the (conditional) expectation

$$Q_{\mathbf{X}}(\boldsymbol{\theta}) = n^{-1/2} \sum_{i=1}^n \mathbb{E}_{\mathbf{X}} (\mathbf{X}_{iS}^{\top} \boldsymbol{\theta} - \epsilon_i - |\epsilon_i|) = n^{-1/2} (\mathbb{E}_{\mathbf{X}} \|\mathbf{X}_S \boldsymbol{\theta} - \boldsymbol{\epsilon}\|_1 - \mathbb{E} \|\boldsymbol{\epsilon}\|_1),$$

applying Lemmas 5 and 6 in Wang (2013) with slight modifications gives

$$Q_{\mathbf{X}}(\boldsymbol{\theta}) \geq \begin{cases} \frac{1}{4\sqrt{n}} \|\mathbf{X}_S \boldsymbol{\theta}\|_1 = \frac{\sqrt{n}}{4} \|n^{-1} \mathbf{X}_S \boldsymbol{\theta}\|_1 & \text{if } \|\mathbf{X}_S \boldsymbol{\theta}\|_1 \geq \frac{2n}{a_2}, \\ \frac{a_2}{8\sqrt{n}} \|\mathbf{X}_S \boldsymbol{\theta}\|_2^2 = \frac{a_2 \sqrt{n}}{8} \|\widehat{\Sigma}_{SS}^{-1/2} \boldsymbol{\theta}\|_2^2 & \text{if } \|\mathbf{X}_S \boldsymbol{\theta}\|_1 < \frac{2n}{a_2}, \end{cases} \quad (69)$$

where a_2 is as in Condition 3.4. For the sequence of LAD estimators $\{\widehat{\boldsymbol{\theta}}_S : S \subseteq [p], |S| = s\}$, from (61) it can be seen that $\|\mathbf{X}_S \widehat{\boldsymbol{\theta}}_S\|_1 \leq \|\mathbf{X}_S \widehat{\boldsymbol{\theta}}_S - \boldsymbol{\epsilon}\|_1 + \|\boldsymbol{\epsilon}\|_1 \leq 2\|\boldsymbol{\epsilon}\|_1$, and hence

$$\max_{S \subseteq [p]: |S|=s} \|n^{-1} \mathbf{X}_S \widehat{\boldsymbol{\theta}}_S\|_1 \leq 2 \left\{ \mathbb{E} \|\boldsymbol{\epsilon}\|_1 + n^{-1} \sum_{i=1}^n (\|\epsilon_i\|_1 - \mathbb{E} \|\epsilon_i\|_1) \right\}.$$

For every $t > 0$ and $1 < \kappa \leq 2$, by Markov's inequality we have

$$\mathbb{P} \left\{ \sum_{i=1}^n (\|\epsilon_i\|_1 - \mathbb{E} \|\epsilon_i\|_1) \geq t \right\} \leq t^{-\kappa} \mathbb{E} \left| \sum_{i=1}^n (\|\epsilon_i\|_1 - \mathbb{E} \|\epsilon_i\|_1) \right|^{\kappa} \leq 4^{2-\kappa} t^{-\kappa} n \mathbb{E} \|\epsilon\|^{\kappa},$$

where we used the inequality $|1 + x|^{\kappa} \leq 1 + \kappa x + 2^{2-\kappa} |x|^{\kappa}$ for $1 < \kappa \leq 2$ and $x \in \mathbb{R}$. The last two displays together imply that, with probability at least $1 - \delta_2$,

$$\max_{S \subseteq [p]: |S|=s} \|n^{-1} \mathbf{X}_S \widehat{\boldsymbol{\theta}}_S\|_1 \leq 2\mathbb{E} \|\epsilon\|_1 \left\{ 1 + 4^{(2-\kappa)/\kappa} (\mathbb{E} \|\epsilon\|_1)^{-1/\kappa} \delta_2^{-1/\kappa} n^{-1+1/\kappa} \right\}.$$

By Condition 3.4, we have $a_2 \mathbb{E} \|\epsilon\|_1 < 1$. Therefore, as long as the sample size n satisfies

$$n \geq \left\{ \frac{4^{2-q} a_2^q \mathbb{E} \|\epsilon\|^{\kappa}}{(1 - a_2 \mathbb{E} \|\epsilon\|_1)^{\kappa}} \right\}^{1/(\kappa-1)} \delta_2^{-1/(\kappa-1)}, \quad (70)$$

the event

$$\mathcal{E}_1 := \left\{ \max_{S \subseteq [p]: |S|=s} \|n^{-1} \mathbf{X}_S \widehat{\boldsymbol{\theta}}_S\|_1 \leq 2a_2^{-1} \right\} \quad (71)$$

occurs with probability at least $1 - \delta_2$.

Now, by (61), we have $Q(\widehat{\boldsymbol{\theta}}_S) \leq 0$ and thus $-Q(\widehat{\boldsymbol{\theta}}_S) - Q_{\mathbf{X}}(\widehat{\boldsymbol{\theta}}_S) \geq Q_{\mathbf{X}}(\widehat{\boldsymbol{\theta}}_S)$ holds for every s -subset $S \subseteq [p]$. Together with (68)–(71) and the union bound, this implies that on the event $\mathcal{E}_0(\tau) \cap \mathcal{E}_1$ for any $\tau > 0$,

$$\max_{S \subseteq [p]: |S|=s} \|\widehat{\Sigma}_{SS}^{-1/2} \widehat{\boldsymbol{\theta}}_S\|_2 \leq \min \left[\delta_1, 32\sqrt{2} a_2^{-1} \left\{ \left(\frac{s \log n}{n} \right)^{1/2} + \frac{1}{n} \right\} \right] \quad (72)$$

holds with (conditional) probability $1 - 4 \binom{p}{s} \exp(-c_0 n \delta_1^2) - \delta_2$, provided that the sample size n satisfies $n \geq 2 \cdot 32^2 (a_2 \delta_1)^{-2}$ and (70).

Finally, taking

$$\delta_1 = \frac{32}{a_2} \sqrt{\frac{2}{\log(2)}} \left(\frac{s \log \frac{ep}{s} + \log n}{n} \right)^{1/2} \quad \text{and} \quad \delta_2 = \frac{4^{2-q} a_2^q \mathbb{E} \|\epsilon\|^{\kappa}}{(1 - a_2 \mathbb{E} \|\epsilon\|_1)^{\kappa} n^{\kappa-1}}$$

in (72) proves (44). \blacksquare

A.6 Proof of Lemma 14

We prove this lemma by employing the arguments similar to those used in Spokoiny (2013), where the likelihood function $\mathcal{L}(\boldsymbol{\theta})$ is assumed to be twice differentiable with respect to $\boldsymbol{\theta}$. It is worth noticing that both Conditions (L) and (ED₂) in Spokoiny (2013) are not satisfied in the current situation. We provide here a self-contained proof in which Lemma 13 also plays an important role.

Step 1: Local linear approximation of $\nabla \mathcal{L}_n^S(\boldsymbol{\theta})$. Let $\chi_1^S(\boldsymbol{\theta})$ be the normalized residual of the local linear approximation of $\nabla \mathcal{L}_n^S(\boldsymbol{\theta})$ given by

$$\begin{aligned} \chi_1^S(\boldsymbol{\theta}) &= \mathbf{D}_0^{-1} \{ \nabla \mathcal{L}_n^S(\boldsymbol{\theta}) - \nabla \mathcal{L}_n^S(\mathbf{0}) + \mathbf{D}_0^{\top} \boldsymbol{\theta} \} \\ &= \mathbf{D}_0^{-1} \{ \mathbf{U}(\boldsymbol{\theta}) + \nabla \mathbb{E}_{\mathbf{X}} \mathcal{L}_n^S(\boldsymbol{\theta}) - \nabla \mathbb{E}_{\mathbf{X}} \mathcal{L}_n^S(\mathbf{0}) + \mathbf{D}_0^{\top} \boldsymbol{\theta} \}, \end{aligned} \quad (73)$$

where $\mathbf{U}(\boldsymbol{\theta}) = \nabla \zeta^S(\boldsymbol{\theta}) - \nabla \zeta^S(\mathbf{0})$ and $\mathbf{D}_0^2 = -\nabla^2 \mathbb{E} \mathbf{X} \{ \mathcal{L}_n^S(\mathbf{0}) \} = 2f_\varepsilon(0) \sum_{i=1}^n \mathbf{X}_{iS} \mathbf{X}_{iS}^T$. Then it follows from the mean value theorem that

$$\mathbb{E} \mathbf{X} \{ \chi_1^S(\boldsymbol{\theta}) \} = \{ \mathbf{I}_s - \mathbf{D}_0^{-1} \mathbf{D}^2(\tilde{\boldsymbol{\theta}}) \mathbf{D}_0^{-1} \} \mathbf{D}_0 \boldsymbol{\theta}, \quad (74)$$

where $\mathbf{D}^2(\boldsymbol{\theta}) = -\nabla^2 \mathbb{E} \mathbf{X} \{ \mathcal{L}_n^S(\boldsymbol{\theta}) \} = 2 \sum_{i=1}^n f_\varepsilon(\mathbf{X}_{iS}^T \boldsymbol{\theta}) \mathbf{X}_{iS} \mathbf{X}_{iS}^T$ and $\tilde{\boldsymbol{\theta}} = \lambda \boldsymbol{\theta}$ for some $0 \leq \lambda \leq 1$. As before, for every $r \geq 0$, define the local elliptic neighborhood of $\mathbf{0}$ as

$$\Theta_0(r) = \{ \boldsymbol{\theta} \in \mathbb{R}^s : \|\mathbf{D}_0 \boldsymbol{\theta}\|_2 \leq r \}.$$

On the event $\mathcal{E}_0(r)$ for some $r > 0$,

$$\|\mathbf{X}_{iS}^T \boldsymbol{\theta}\| \leq \|\mathbf{D}_0 \boldsymbol{\theta}\|_2 \|\mathbf{D}_0^{-1} \mathbf{X}_{iS}\|_2 \leq \{2n f_\varepsilon(0)\}^{-1/2} r^{1/2} r^{1/2} \quad (75)$$

for all $\boldsymbol{\theta} \in \Theta_0(r)$. Thus it follows from the Taylor expansion that for $r \leq \{2n f_\varepsilon(0)/\tau\}^{1/2}$,

$$\begin{aligned} & \|\mathbf{I}_s - \mathbf{D}_0^{-1} \mathbf{D}^2(\tilde{\boldsymbol{\theta}}) \mathbf{D}_0^{-1}\| \\ &= 2 \left\| \mathbf{D}_0^{-1} \sum_{i=1}^n \{ f_\varepsilon(\mathbf{X}_{iS}^T \tilde{\boldsymbol{\theta}}) - f_\varepsilon(0) \} \mathbf{X}_{iS} \mathbf{X}_{iS}^T \mathbf{D}_0^{-1} \right\| \leq \frac{A_3}{\sqrt{2} f_\varepsilon^3(0)} \frac{\tau^{1/2} r}{n^{1/2}} := \delta(\tau, r). \end{aligned} \quad (76)$$

Together, (74) and (76) imply that under the same constraint for (76),

$$\|\mathbb{E} \mathbf{X} \{ \chi_1^S(\boldsymbol{\theta}) \}\|_2 \leq \delta(\tau, r)r. \quad (77)$$

Turning to the stochastic component $\mathbf{D}_0^{-1} \mathbf{U}(\boldsymbol{\theta}) = \chi_1^S(\boldsymbol{\theta}) - \mathbb{E} \mathbf{X} \{ \chi_1^S(\boldsymbol{\theta}) \}$, we aim to bound $\max_{\boldsymbol{\theta} \in \Theta_0(r)} \|\mathbf{D}_0^{-1} \mathbf{U}(\boldsymbol{\theta})\|_2$, which can be written as

$$\max_{\boldsymbol{\theta} \in \Theta_0(r)} \max_{\|\mathbf{u}\|_2 \leq 1} \mathbf{u}^T \mathbf{D}_0^{-1} \mathbf{U}(\boldsymbol{\theta}) = r^{-1} \max_{\mathbf{u}, \boldsymbol{\theta} \in \Theta_0(r)} \mathbf{v}^T \mathbf{U}(\boldsymbol{\theta}). \quad (78)$$

Note that $\{\mathbf{v}^T \mathbf{U}(\boldsymbol{\theta}) : \mathbf{v}, \boldsymbol{\theta} \in \mathbb{R}^{2s}\}$ is a bivariate process indexed by $(\mathbf{v}^T, \boldsymbol{\theta}^T)^T \in \mathbb{R}^{2s}$. Define

$$\begin{aligned} \bar{\boldsymbol{\theta}} &= (\mathbf{v}^T, \boldsymbol{\theta}^T)^T \in \mathbb{R}^{2s}, \quad \bar{\mathbf{D}}_0 = \begin{pmatrix} \mathbf{D}_0 & \mathbf{0} \\ \mathbf{0} & \mathbf{D}_0 \end{pmatrix} \in \mathbb{R}^{(2s) \times (2s)}, \\ \bar{\mathbf{U}}(\bar{\boldsymbol{\theta}}) &= \mathbf{v}^T \mathbf{U}(\boldsymbol{\theta}), \quad \bar{\Theta}_0(r) = \{ \bar{\boldsymbol{\theta}} \in \mathbb{R}^{2s} : \|\bar{\mathbf{D}}_0 \bar{\boldsymbol{\theta}}\|_2 \leq r \}. \end{aligned}$$

In this notation, from (78) and the identity $\bar{\mathbf{D}}_0 \bar{\boldsymbol{\theta}} = \mathbf{D}_0 \mathbf{v} + \mathbf{D}_0 \boldsymbol{\theta}$, it is easy to see that

$$\max_{\boldsymbol{\theta} \in \Theta_0(r)} \|\mathbf{D}_0^{-1} \mathbf{U}(\boldsymbol{\theta})\|_2 \leq r^{-1} \max_{\bar{\boldsymbol{\theta}} \in \bar{\Theta}_0(2r)} \bar{\mathbf{U}}(\bar{\boldsymbol{\theta}}). \quad (79)$$

Recall that $\nabla \zeta^S(\boldsymbol{\theta}) - \nabla \zeta^S(\mathbf{0}) = -2 \sum_{i=1}^n \{ I(Y_i \leq \mathbf{X}_{iS}^T \boldsymbol{\theta}) - I(Y_i \leq 0) + 1/2 - F_\varepsilon(\mathbf{X}_{iS}^T \boldsymbol{\theta}) \} \mathbf{X}_{iS}$, where for $i = 1, \dots, n$, $I(Y_i \leq \mathbf{X}_{iS}^T \boldsymbol{\theta}) - I(Y_i \leq 0) + 1/2 - F_\varepsilon(\mathbf{X}_{iS}^T \boldsymbol{\theta})$ is equal to

$$\begin{cases} I(0 < Y_i \leq \mathbf{X}_{iS}^T \boldsymbol{\theta}) - \mathbb{P} \mathbf{X}(0 < Y_i \leq \mathbf{X}_{iS}^T \boldsymbol{\theta}) & \text{if } \mathbf{X}_{iS}^T \boldsymbol{\theta} \geq 0, \\ -I(\mathbf{X}_{iS}^T \boldsymbol{\theta} < Y_i \leq 0) + \mathbb{P} \mathbf{X}(\mathbf{X}_{iS}^T \boldsymbol{\theta} < Y_i \leq 0) & \text{if } \mathbf{X}_{iS}^T \boldsymbol{\theta} < 0. \end{cases}$$

For $\boldsymbol{\theta} \in \mathbb{R}^s$, define random variables $\varepsilon_{i\boldsymbol{\theta}} = I(0 < Y_i \leq \mathbf{X}_{iS}^T \boldsymbol{\theta}) - I(\mathbf{X}_{iS}^T \boldsymbol{\theta} < Y_i \leq 0)$ satisfying

(i) conditional on $\mathbf{X}_{iS}^T \boldsymbol{\theta} \geq 0$, $\varepsilon_{i\boldsymbol{\theta}} = 1$ with probability $P_{i\boldsymbol{\theta}} - 1/2$ and $\varepsilon_{i\boldsymbol{\theta}} = 0$ with probability $3/2 - P_{i\boldsymbol{\theta}}$;

(ii) conditional on $\mathbf{X}_{iS}^T \boldsymbol{\theta} < 0$, $\varepsilon_{i\boldsymbol{\theta}} = -1$ with probability $1/2 - P_{i\boldsymbol{\theta}}$ and $\varepsilon_{i\boldsymbol{\theta}} = 0$ with probability $1/2 + P_{i\boldsymbol{\theta}}$,

where $P_{i\boldsymbol{\theta}} = F_\varepsilon(\mathbf{X}_{iS}^T \boldsymbol{\theta})$. In this notation, $\nabla \zeta^S(\boldsymbol{\theta}) - \nabla \zeta^S(\mathbf{0}) = -2 \sum_{i=1}^n (\text{Id} - \mathbb{E} \mathbf{X}) \varepsilon_{i\boldsymbol{\theta}} \mathbf{X}_{iS}$. For every $\lambda \in \mathbb{R}$ and $\mathbf{u} \in \mathbb{R}^s$, we have

$$\begin{aligned} & \mathbb{E} \mathbf{X} \exp \{ \lambda \mathbf{u}^T \{ \nabla \zeta^S(\boldsymbol{\theta}) - \nabla \zeta^S(\mathbf{0}) \} \} \\ &= \prod_{i=1}^n \left[\mathbb{E} \mathbf{X} \{ e^{-2\lambda \mathbf{u}^T \mathbf{X}_{iS} (I - \mathbb{E} \mathbf{X}) \varepsilon_{i\boldsymbol{\theta}}} \} I(\mathbf{X}_{iS}^T \boldsymbol{\theta} \geq 0) + \mathbb{E} \mathbf{X} \{ e^{-2\lambda \mathbf{u}^T \mathbf{X}_{iS} (I - \mathbb{E} \mathbf{X}) \varepsilon_{i\boldsymbol{\theta}}} \} I(\mathbf{X}_{iS}^T \boldsymbol{\theta} < 0) \right] \\ &= \prod_{i=1}^n \left\{ e^{-2\lambda \mathbf{u}^T \mathbf{X}_{iS} (3/2 - P_{i\boldsymbol{\theta}})} (P_{i\boldsymbol{\theta}} - 1/2) + e^{2\lambda \mathbf{u}^T \mathbf{X}_{iS} (P_{i\boldsymbol{\theta}} - 1/2)} (3/2 - P_{i\boldsymbol{\theta}}) \right\} I(\mathbf{X}_{iS}^T \boldsymbol{\theta} \geq 0) \\ &\quad + \left\{ e^{2\lambda \mathbf{u}^T \mathbf{X}_{iS} (1/2 + P_{i\boldsymbol{\theta}})} (1/2 - P_{i\boldsymbol{\theta}}) + e^{2\lambda \mathbf{u}^T \mathbf{X}_{iS} (P_{i\boldsymbol{\theta}} - 1/2)} (1/2 + P_{i\boldsymbol{\theta}}) \right\} I(\mathbf{X}_{iS}^T \boldsymbol{\theta} < 0). \end{aligned}$$

Further, using the inequalities $|e^u - 1 - u| \leq \frac{1}{2} u^2 e^{|u|}$ and $1 + u \leq e^u$ which hold for all $u \in \mathbb{R}$, the last term above can be bounded by

$$\begin{aligned} & \prod_{i=1}^n \left[\left\{ 1 + 2\lambda^2 (\mathbf{u}^T \mathbf{X}_{iS})^2 (P_{i\boldsymbol{\theta}} - 1/2) (3/2 - P_{i\boldsymbol{\theta}}) e^{2\lambda |\mathbf{u}^T \mathbf{X}_{iS}|} \right\} I(\mathbf{X}_{iS}^T \boldsymbol{\theta} \geq 0) \right. \\ & \quad \left. + \left\{ 1 + 2\lambda^2 (\mathbf{u}^T \mathbf{X}_{iS})^2 (1/2 - P_{i\boldsymbol{\theta}}) (1/2 + P_{i\boldsymbol{\theta}}) e^{2\lambda |\mathbf{u}^T \mathbf{X}_{iS}|} \right\} I(\mathbf{X}_{iS}^T \boldsymbol{\theta} < 0) \right] \\ & \leq \prod_{i=1}^n \left\{ 1 + 2\lambda^2 (\mathbf{u}^T \mathbf{X}_{iS})^2 |P_{i\boldsymbol{\theta}} - 1/2| e^{2\lambda |\mathbf{u}^T \mathbf{X}_{iS}|} \right\} \\ & \leq \prod_{i=1}^n \exp \{ 2\lambda^2 (\mathbf{u}^T \mathbf{X}_{iS})^2 |P_{i\boldsymbol{\theta}} - 1/2| e^{2\lambda |\mathbf{u}^T \mathbf{X}_{iS}|} \}. \end{aligned}$$

Consequently, for every $\bar{\boldsymbol{\theta}} = (\mathbf{v}^T, \boldsymbol{\theta}^T)^T \in \bar{\Theta}_0(2r)$,

$$\begin{aligned} & \log \mathbb{E} \mathbf{X} \exp \left\{ \lambda \frac{\bar{\mathbf{U}}(\bar{\boldsymbol{\theta}}) - \bar{\mathbf{U}}(\mathbf{0})}{\|\mathbf{D}_0 \bar{\boldsymbol{\theta}}\|_2} \right\} = \log \mathbb{E} \mathbf{X} \exp \left\{ \lambda \frac{\mathbf{v}^T \{ \zeta^S(\boldsymbol{\theta}) - \zeta^S(\mathbf{0}) \}}{\|\mathbf{D}_0 \bar{\boldsymbol{\theta}}\|_2} \right\} \\ & \leq \frac{2\lambda^2}{\|\mathbf{D}_0 \mathbf{v}\|_2^2 + \|\mathbf{D}_0 \boldsymbol{\theta}\|_2^2} \sum_{i=1}^n (\mathbf{v}^T \mathbf{X}_{iS})^2 |P_{i\boldsymbol{\theta}} - 1/2| \exp \left(\frac{2\lambda |\mathbf{v}^T \mathbf{X}_{iS}|}{\|\mathbf{D}_0 \bar{\boldsymbol{\theta}}\|_2} \right). \end{aligned} \quad (80)$$

On the event $\mathcal{E}_0(\tau)$ for some $\tau > 0$, we have $|P_{i\boldsymbol{\theta}} - 1/2| \leq 2A_2 \{2n f_\varepsilon(0)\}^{-1/2} \tau^{1/2} r$ and $|\mathbf{v}^T \mathbf{X}_{iS}| \leq \|\mathbf{D}_0 \mathbf{v}\|_2 \|\mathbf{D}_0^{-1} \mathbf{X}_{iS}\|_2 \leq \|\mathbf{D}_0 \mathbf{v}\|_2 \{2n f_\varepsilon(0)\}^{-1/2} \tau^{1/2}$. Together with (80), this yields that for all $|\lambda| \leq \{2n f_\varepsilon(0)/\tau\}^{1/2}$,

$$\log \mathbb{E} \mathbf{X} \exp \left\{ \lambda \frac{\bar{\mathbf{U}}(\bar{\boldsymbol{\theta}}) - \bar{\mathbf{U}}(\mathbf{0})}{\|\mathbf{D}_0 \bar{\boldsymbol{\theta}}\|_2} \right\} \leq \frac{\lambda^2 4e^2 A_2 r}{2 f_\varepsilon(0)} \sqrt{\frac{\tau}{2n f_\varepsilon(0)}}. \quad (81)$$

In view of (81), define

$$w_0(\tau) = 2e\sqrt{\frac{A_2 r_0}{f_\varepsilon(0)} \left\{ \frac{\tau}{2nf_\varepsilon(0)} \right\}^{1/4}} \quad (82)$$

for some $r_0 > 0$ to be specified (see (88) below), such that for any $\hat{\boldsymbol{\theta}} = (\boldsymbol{v}^\top, \boldsymbol{\theta}^\top)^\top \in \widehat{\Theta}_0(2r)$ with $0 \leq r \leq r_0$,

$$\mathbb{E} \mathbf{X} \exp \left\{ \frac{\lambda}{w_0(\tau)} \frac{\bar{\mathbf{U}}(\hat{\boldsymbol{\theta}}) - \bar{\mathbf{U}}(\mathbf{0})}{\|\mathbf{D}_0 \hat{\boldsymbol{\theta}}\|_2} \right\} \leq \exp(\lambda^2/2) \quad (83)$$

holds almost surely on $\mathcal{E}_0(\tau)$ for all

$$|\lambda| \leq 2e\sqrt{\frac{A_2 r_0}{f_\varepsilon(0)} \left\{ \frac{2nf_\varepsilon(0)}{\tau} \right\}^{1/4}} := g_0(\tau). \quad (84)$$

By (83), it follows from Corollary 2.2 in the supplement of Spokoiny (2012) and (79) that, for any $\tau > 0$, $0 \leq r \leq r_0$ and $0 < t \leq \frac{1}{2}g_0^2(\tau) - 2s$,

$$\mathbb{P} \mathbf{X} \left\{ \max_{\boldsymbol{\theta} \in \Theta_0(\tau)} \|\mathbf{D}_0^{-1} \mathbf{U}(\boldsymbol{\theta})\|_2 \geq 6w_0(\tau)(2t + 4s)^{1/2} \right\} \leq e^{-t} \quad (85)$$

holds almost surely on $\mathcal{E}_0(\tau)$, where g_0 is given at (84).

Combining (74) and (85) we obtain that for any $\tau > 0$, $0 \leq r \leq r_0 \leq \{2nf_\varepsilon(0)/\tau\}^{1/2}$ and $0 < t \leq \frac{1}{2}g_0^2(\tau) - 2s$,

$$\mathbb{P} \mathbf{X} \left\{ \max_{\boldsymbol{\theta} \in \Theta_0(\tau)} \|\chi_1^S(\boldsymbol{\theta})\|_2 \geq \delta(\tau, r)r + 6w_0(\tau)(2t + 4s)^{1/2} \right\} \leq e^{-t} \quad (86)$$

almost surely on $\mathcal{E}_0(\tau)$. For a given triplet (τ, r, t) , define the event

$$\Omega_0^S(\tau, r, t) = \left\{ \max_{\boldsymbol{\theta} \in \Theta_0(\tau)} \|\chi_1^S(\boldsymbol{\theta})\|_2 \leq \delta(\tau, r)r + 6w_0(\tau)(2t + 4s)^{1/2} \right\}. \quad (87)$$

Step 2: Fisher approximation. By Lemma 13,

$$\begin{aligned} & \max_{s \leq |\hat{p}|: |\hat{S}|=s} \|\mathbf{D}_0 \hat{\boldsymbol{\theta}}_S\|_2 \\ &= \{2nf_\varepsilon(0)\}^{1/2} \max_{s \leq |\hat{p}|: |\hat{S}|=s} \|\widehat{\Sigma}_{SS}^{1/2} \hat{\boldsymbol{\theta}}_S\|_2 \leq C_1 \sigma_2^{-1} \{2f_\varepsilon(0)s \log(pn)\}^{1/2} := r_0 \end{aligned} \quad (88)$$

holds with probability at least $1 - c_1 n^{-1} - c_2 n^{1-\kappa}$. Moreover, since $\hat{\boldsymbol{\theta}}_S$ maximizes $\mathcal{L}_n^S(\boldsymbol{\theta})$ over $\boldsymbol{\theta} \in \mathbb{R}^s$ for each s -subset $S \subseteq [p]$, we have $\nabla \mathcal{L}_n^S(\hat{\boldsymbol{\theta}}_S) = \mathbf{0}$ and $\chi_1^S(\hat{\boldsymbol{\theta}}) = \mathbf{D}_0 \hat{\boldsymbol{\theta}}_S - \widehat{\boldsymbol{\xi}}_S$. Thus, together with (87) implies that on the event $\{\hat{\boldsymbol{\theta}}_S \in \Theta_0(r_0) \cap \Omega_0^S(\tau, r_0, t)\}$,

$$\|\mathbf{D}_0 \hat{\boldsymbol{\theta}}_S - \widehat{\boldsymbol{\xi}}_S\|_2 \leq \delta(\tau, r_0)r_0 + 6w_0(\tau)(2t + 4s)^{1/2} \quad (89)$$

whenever $n \geq \{2f_\varepsilon(0)\}^{-1}\tau r_0^2$.

Step 3: Wilks approximation. For $\boldsymbol{\theta}_1, \boldsymbol{\theta}_2 \in \Theta_0(r)$, define

$$\chi_2^S(\boldsymbol{\theta}_1, \boldsymbol{\theta}_2) = \mathcal{L}_n^S(\boldsymbol{\theta}) - \mathcal{L}_n^S(\boldsymbol{\theta}_2) - (\boldsymbol{\theta}_1 - \boldsymbol{\theta}_2)^\top \nabla \mathcal{L}_n^S(\boldsymbol{\theta}_2) + \frac{1}{2} \|\mathbf{D}_0(\boldsymbol{\theta}_1 - \boldsymbol{\theta}_2)\|_2^2. \quad (90)$$

Noting that $\nabla_{\boldsymbol{\theta}_1} \chi_2^S(\boldsymbol{\theta}_1, \boldsymbol{\theta}_2) = \nabla \mathcal{L}_n^S(\boldsymbol{\theta}_1) - \nabla \mathcal{L}_n^S(\boldsymbol{\theta}_2) + \mathbf{D}_0^2(\boldsymbol{\theta}_1 - \boldsymbol{\theta}_2) = \mathbf{D}_0 \{\chi_1^S(\boldsymbol{\theta}_1) - \chi_1^S(\boldsymbol{\theta}_2)\}$, we have

$$|\chi_2^S(\boldsymbol{\theta}_1, \boldsymbol{\theta}_2)| = |\chi_2^S(\boldsymbol{\theta}_1, \boldsymbol{\theta}_2) - \chi_2^S(\boldsymbol{\theta}_2, \boldsymbol{\theta}_2)| \leq 2 \|\mathbf{D}_0(\boldsymbol{\theta}_1 - \boldsymbol{\theta}_2)\|_2 \max_{\boldsymbol{u} \in \Theta_0(r)} \|\chi_1^S(\boldsymbol{u})\|_2, \quad (91)$$

where $\tilde{\boldsymbol{\theta}} = \lambda \boldsymbol{\theta}$ for some $0 \leq \lambda \leq 1$. Let $r_0 > 0$ be as in (88). Then, it follows from (91) that on $\Omega_0^S(\tau, r_0, t)$ with $n \geq \{2f_\varepsilon(0)\}^{-1}\tau r_0^2$,

$$\max_{\boldsymbol{\theta}_1, \boldsymbol{\theta}_2 \in \Theta_0(r_0)} \frac{|\chi_2^S(\boldsymbol{\theta}_1, \boldsymbol{\theta}_2)|}{\|\mathbf{D}_0(\boldsymbol{\theta}_1 - \boldsymbol{\theta}_2)\|_2} \leq 2\delta(\tau, r_0)r_0 + 12w_0(\tau)(2t + 4s)^{1/2}.$$

In view of (90), $\mathcal{L}_n^S(\hat{\boldsymbol{\theta}}_S) - \mathcal{L}_n^S(\mathbf{0}) - \frac{1}{2} \|\mathbf{D}_0 \hat{\boldsymbol{\theta}}_S\|_2^2 = -\chi_2^S(\mathbf{0}, \hat{\boldsymbol{\theta}}_S)$. Therefore, on the event $\{\hat{\boldsymbol{\theta}}_S \in \Theta_0(r_0) \cap \Omega_0^S(\tau, r_0, t)\}$ we have

$$\begin{aligned} & \left| 2\{\mathcal{L}_n^S(\hat{\boldsymbol{\theta}}_S) - \mathcal{L}_n^S(\mathbf{0})\}^{1/2} - \|\mathbf{D}_0 \hat{\boldsymbol{\theta}}_S\|_2 \right| \\ & \leq \frac{2\{\mathcal{L}_n^S(\hat{\boldsymbol{\theta}}_S) - \mathcal{L}_n^S(\mathbf{0})\} - \|\mathbf{D}_0 \hat{\boldsymbol{\theta}}_S\|_2^2}{\|\mathbf{D}_0 \hat{\boldsymbol{\theta}}_S\|_2} \leq \frac{2|\chi_2^S(\mathbf{0}, \hat{\boldsymbol{\theta}}_S)|}{\|\mathbf{D}_0 \hat{\boldsymbol{\theta}}_S\|_2} \leq 4\{\delta(\tau, r_0)r_0 + 6w_0(\tau)(2t + 4s)^{1/2}\}, \end{aligned}$$

provided that $n \geq \{2f_\varepsilon(0)\}^{-1}\tau r_0^2$. Together with (89), this implies that conditional on the event $\cap_{s \leq |\hat{p}|: |\hat{S}|=s} \{\hat{\boldsymbol{\theta}}_S \in \Theta_0(r_0) \cap \Omega_0^S(\tau, r_0, t)\}$,

$$\max_{s \leq |\hat{p}|: |\hat{S}|=s} \left| 2\{\mathcal{L}_n^S(\hat{\boldsymbol{\theta}}_S) - \mathcal{L}_n^S(\mathbf{0})\}^{1/2} - \|\widehat{\boldsymbol{\xi}}_S\|_2 \right| \leq 5\{\delta(\tau, r_0)r_0 + 6w_0(\tau)(2t + 4s)^{1/2}\} \quad (92)$$

whenever $n \geq \{2f_\varepsilon(0)\}^{-1}\tau r_0^2$, where $\delta(\tau, r)$, r_0 and $w_0(\tau)$ are as in (76), (88) and (82).

Finally, taking $\tau = \tau_0 \asymp \lambda_{\min}^{-1}(s)s \log(pn)$ as in (36) and setting $t = s \log \frac{pn}{s} + \log n$ in the concentration bound (86) prove (48) using Boole's inequality. \blacksquare

Bayesian Graphical Models for Multivariate Functional Data

Abstract

Graphical models express conditional independence relationships among variables. Although methods for vector-valued data are well established, functional data graphical models remain underdeveloped. By functional data, we refer to data that are realizations of random functions varying over a continuum (e.g., images, signals). We introduce a notion of conditional independence between random functions, and construct a framework for Bayesian inference of undirected, decomposable graphs in the multivariate functional data context. This framework is based on extending Markov distributions and hyper Markov laws from random variables to random processes, providing a principled alternative to naive application of multivariate methods to discretized functional data. Markov properties facilitate the composition of likelihoods and priors according to the decomposition of a graph. Our focus is on Gaussian process graphical models using orthogonal basis expansions. We propose a hyper-inverse-Wishart-process prior for the covariance kernels of the infinite coefficient sequences of the basis expansion, and establish its existence and uniqueness. We also prove the strong hyper Markov property and the conjugacy of this prior under a finite rank condition of the prior kernel parameter. Stochastic search Markov chain Monte Carlo algorithms are developed for posterior inference, assessed through simulations, and applied to a study of brain activity and alcoholism.

Keywords: graphical model, functional data analysis, gaussian process, model uncertainty, stochastic search

1. Introduction

Graphical models provide a powerful tool for describing conditional independence structures between random variables. In the multivariate data case, Dawid and Lauritzen (1993) defined Markov distributions (distributions with Markov property over a graph) of random vectors which can be factorized according to the structure of a graph. They also introduced

hyper-Markov laws serving as prior distributions in Bayesian analysis. The special case of Gaussian graphical models, in which a multivariate Gaussian distribution is assumed and the graph structure corresponds to the zero pattern of the precision matrix (Dempster, 1972; Lauritzen, 1996), is well studied. Computational algorithms, such as Markov chain Monte Carlo (MCMC) and stochastic search, are developed to estimate the graph based on the conjugate hyper-inverse-Wishart prior and its extensions (Giudici and Green, 1999; Roverato, 2002; Jones et al., 2005; Scott and Carvalho, 2008; Carvalho and Scott, 2009).

In the frequentist literature, notable works on graphical models include the graphical LASSO (Yuan and Lin, 2007; Friedman et al., 2008; Mazumder and Hastie, 2012a,b) and the neighborhood selection approach (Meinshausen and Bühlmann, 2006; Ravikumar et al., 2010). The graphical LASSO induces sparse estimation of the precision matrix of the Gaussian likelihood through l_1 regularization. The neighborhood selection approach relies on estimating the neighborhood of each node separately by regressing each variable on all the remaining variables, sparsifying with l_1 regularization, and then stitching the neighborhoods together to form the global graph estimate. Various extensions, computational methods, and theoretical properties have been developed in these frameworks (Lam and Fan, 2009; Höfling and Tibshirani, 2009; Cai et al., 2011; Witten et al., 2011; Yang et al., 2012; Mazumder and Hastie, 2012a,b; Anandkumar et al., 2012; Loh and Wainwright, 2013).

The graphical modeling literature focuses primarily on vector-valued data with each node corresponding to one variable. Many applications, however, involve *functional data*—data that are realizations of random functions varying over a continuum such as a time interval or a spatial domain. Common types of functional data include signals, images, and many emerging high-throughput digital measurements. The dependence structure of functional data is of interest in a wide range of applications. For example, in neuroimaging, we are often interested in the dependence network across brain regions, where data from each region are of functional form (e.g. EEG/ERP signals, MRI/fMRI regions). In bioinformatics, we often need to model gene networks based on time-course gene expression data (Ma et al., 2006), treating each time-course as a continuous process. In epigenetics, it is of interest to study how cells are differentiated into organs (cell lineage and differentiation) by exploring the dependence structure of genome-wide methylation levels across different cell types, and for each cell type, the methylation level can be considered as a function of the genomic locations.

Although there is increasingly rich literature on generalizations to accommodate matrix-variate graphical models (Wang and West, 2009), time varying graphical models (Zhou et al., 2010; Kolar and Xing, 2011), and dynamic linear models (Carvalho and West, 2007), the generalization to functional data has not received much attention in the literature. In recent work, Qiao et al. (2015) extended the graphical LASSO of Yuan and Lin (2007) to the functional data case. They estimate the graph by maximizing a penalized log-Gaussian likelihood constructed through truncated basis expansion, and prove the consistency of the estimated edges. In this paper, we propose Bayesian graphical models for functional data following a fundamentally different approach. In particular, we construct the graphical model directly in the space of infinite dimensional random functions through establishing the Markov distributions and hyper Markov laws for random processes, and propose a Bayesian framework that generally holds for all random processes. We then demonstrate the special case of a multivariate Gaussian process in the space of square integrable func-

tions. Through representing the random functions with orthogonal basis expansions, we transform functional data from the function space to the isometrically isomorphic space of basis coefficients, where Markov distributions and hyper Markov laws can be conveniently constructed. We further propose a hyper-inverse-Wishart-process prior for the covariance kernels of the coefficient sequences, and study theoretical properties of the proposed prior such as existence and uniqueness. We also establish the strong hyper Markov property and conjugacy of this prior under a finite rank condition for the prior kernel parameter, which implies that the covariance kernel of the coefficient sequences is a priori finite dimensional. To perform posterior inference, we introduce a regularity condition which allows us to write the likelihood and prior density and design stochastic search MCMC algorithms for posterior sampling. Performance of the proposed approach is demonstrated through simulation studies and analysis of brain activity and alcoholism data.

To our knowledge, the proposed approach is the first considering functional data graphical models from a Bayesian perspective. It extends the theory of Dawid and Lauritzen (1993) from multivariate data to multivariate functional data. Most existing graphical model approaches often naively apply multivariate methods to functional data after performing discretization or feature extraction. Such approaches may not take full advantage of the fact that data arise from a function and can lack reasonable limiting behavior. Our graphical model framework guarantees proper theoretical behavior as well as computational convenience.

2. Graphical Models for Multivariate Functional Data

In this section, we first review graphical models for multivariate data in Section 2.1, then introduce graphical models for multivariate functional data in Section 2.2, and finally present the specific case of Gaussian process graphical models in Section 2.3.

2.1 Review of Graph Theory and Gaussian Graphical Models

We follow Dawid and Lauritzen (1993), Lauritzen (1996), and Jones et al. (2005). Let $G = (V, E)$ denote an undirected graph with a vertex set V and a set of edge pairs $E = \{(i, j)\}$. Each vertex corresponds to one variable. Two variables a and b are conditionally independent if and only if $(a, b) \notin E$. A graph or a subgraph is *complete* if all possible pairs of vertices are joined by edges. A complete subgraph is *maximal* if it is not contained within another complete subgraph. A maximal subgraph is called a *clique*. If A, B, C are subsets of V with $V = A \cup B$, $C = A \cap B$, then C is said to separate A from B if every path from a vertex in A to a vertex in B goes through C . C is called a *separator* and the pair (A, B) forms a decomposition of G . The separator is *minimal* if it does not contain a proper subgraph which also separates A from B . While keeping the separators minimal, we can iteratively decompose a graph into a sequence of *prime components* – a sequentially defined collection of subgraphs that cannot be further decomposed (Jones et al., 2005). If all the prime components of a connected graph are complete, the graph is called *decomposable*. All the prime components of a decomposable graph are cliques. Iteratively decomposing a decomposable graph G produces a *perfectly ordered* sequence of cliques and separators $(C_1, S_2, C_3, \dots, S_m, C_m)$ such that $S_i = H_{i-1} \cap C_i$ and $H_{i-1} = C_1 \cup \dots \cup C_{i-1}$. Let $\mathcal{C} = \{C_1, \dots, C_m\}$ denote the set of cliques and $\mathcal{S} = \{S_2, \dots, S_m\}$ denote the set of

separators. The perfect ordering means that for every $i = 2, \dots, m$, there is a $j < i$ with $S_i \subset C_j$ (Lauritzen, 1996, page 15).

If the components of a random vector $\mathbf{X} = (X_1, \dots, X_p)^T$ obey conditional independence according to a decomposable graph G , the joint density can be factorized as

$$p(\mathbf{X} | G) = \frac{\prod_{C \in \mathcal{C}} p(\mathbf{X}_C)}{\prod_{S \in \mathcal{S}} p(\mathbf{X}_S)},$$

where $\mathbf{X}_A = \{X_i, i \in A\}$. If \mathbf{X} is Gaussian with zero mean and precision matrix $\mathbf{\Omega} = \mathbf{\Sigma}^{-1}$, then X_i is conditionally independent of X_j given $\mathbf{X}_{V \setminus \{i, j\}}$, denoted by $X_i \perp\!\!\!\perp X_j | \mathbf{X}_{V \setminus \{i, j\}}$, if and only if the (i, j) th element of $\mathbf{\Omega}$ is zero. In this case $p(\mathbf{X} | G)$ is uniquely determined by marginal covariances $\{\mathbf{\Sigma}_C, \mathbf{\Sigma}_S, C \in \mathcal{C}, S \in \mathcal{S}\}$, which are sub-diagonal blocks of $\mathbf{\Sigma}$ according to the clique and separator sets. For a given G , a convenient conjugate prior for $\mathbf{\Sigma}$ is hyper-inverse-Wishart (HIW) with density

$$p(\mathbf{\Sigma} | G, \delta, \mathbf{U}) = \frac{\prod_{C \in \mathcal{C}} p(\mathbf{\Sigma}_C | \delta, \mathbf{U}_C)}{\prod_{S \in \mathcal{S}} p(\mathbf{\Sigma}_S | \delta, \mathbf{U}_S)},$$

where $p(\mathbf{\Sigma}_C | \delta, \mathbf{U}_C)$ and $p(\mathbf{\Sigma}_S | \delta, \mathbf{U}_S)$ are densities of inverse-Wishart (IW) distributions. In this paper, the inverse-Wishart follows the parameterization of Dawid (1981), i.e., $\mathbf{\Sigma} \sim \text{IW}(\delta, \mathbf{U})$ if and only if $\mathbf{\Sigma}^{-1}$ has a Wishart distribution $W(\delta + p - 1, \mathbf{U}^{-1})$, where $\delta > 0$ and $\mathbf{\Sigma}$ is a p by p matrix.

2.2 Graphical Models for Multivariate Functional Data

Let $\mathbf{f} = \{f_j\}_{j=1}^p$ denote a collection of random processes where each component f_j is in $L^2(T_j)$ and each T_j is a closed subset of the real line. The domain of \mathbf{f} is denoted by $T = \bigcup_{j=1}^p T_j$, where \bigcup denotes the disjoint union defined by $\bigcup_{j=1}^p T_j = \bigcup_{j=1}^p \{(t, j) : t \in T_j\}$. For each j , let $\{\phi_{j,k}\}_{k=1}^{\infty}$ denote an orthonormal basis of $L^2(T_j)$. The extended basis functions $\psi_{j,k} = (0, \dots, 0, \phi_{j,k}, 0, \dots, 0)$, with $\phi_{j,k}$ in the j th component and 0 functions elsewhere for $j = 1, \dots, p$ and $k = 1, \dots, \infty$, form an orthonormal basis of $L^2(T)$. Let $(L^2(T), \mathcal{B}(L^2(T)), P)$ be a probability space, where $\mathcal{B}(L^2(T))$ is the Borel σ -algebra on $L^2(T)$. For $V = \{1, 2, \dots, p\}$ and $A \subset V$, denote by \mathbf{f}_A the subset of \mathbf{f} with domain $T_A = \bigcup_{i \in A} T_i$. We define the conditional independence relationships for components of \mathbf{f} in Definition 1.

Definition 1 Let A, B , and C be subsets of V . Then \mathbf{f}_A is *conditionally independent of* \mathbf{f}_B given \mathbf{f}_C under P , written as $\mathbf{f}_A \perp\!\!\!\perp \mathbf{f}_B | \mathbf{f}_C [P]$, if for any $\mathbf{f}_A \in D_A$, where D_A is a measurable set in $L^2(T_A)$, there exists a version of the conditional probability $P(\mathbf{f}_A \in D_A | \mathbf{f}_B, \mathbf{f}_C) = P(\mathbf{f}_A \in D_A | \mathbf{f}_C)$ which is $\mathcal{B}(L^2(T_C))$ measurable, and hence one may write $P(\mathbf{f}_A \in D_A | \mathbf{f}_B, \mathbf{f}_C) = P(\mathbf{f}_A \in D_A | \mathbf{f}_C)$. Here, $\mathcal{B}(L^2(T_C))$ denotes the Borel σ -algebra on $L^2(T_C)$. Note that this implies $P(\mathbf{f}_A \in D_A, \mathbf{f}_B \in D_B | \mathbf{f}_C) = P(\mathbf{f}_A \in D_A | \mathbf{f}_C) P(\mathbf{f}_B \in D_B | \mathbf{f}_C)$.

We would like to use a decomposable graph $G = (V, E)$ to describe the conditional independence relationships of components in \mathbf{f} , whereby a Bayesian framework can be constructed and G can be inferred through posterior inference. To this end, we link the probability measure P of \mathbf{f} with G by assuming that P is Markov over G , as defined in Definition 2.

Definition 2 Let $G = (V, E)$ denote a decomposable graph. A probability measure P of \mathbf{f} is called Markov over G if for any decomposition (A, B) of G , $\mathbf{f}_A \perp\!\!\!\perp \mathbf{f}_B \mid \mathbf{f}_{A \cap B}[P]$.

Given a decomposable graph G , a probability measure of \mathbf{f} with Markov property may be constructed. To enable the construction, we first state Lemma 1, which generalizes Lemma 2.5 of Dawid and Lauritzen (1993) from the random variable to the random process case.

Lemma 1 Let $\mathbf{f} = (f_1, \dots, f_p)$ be a collection of random processes in $L^2(T)$. For subsets $A, B \subset V = \{1, \dots, p\}$ with $A \cap B \neq \emptyset$, suppose that P_1 and P_2 are probability measures of \mathbf{f}_A and \mathbf{f}_B , respectively. If P_1 and P_2 are consistent, meaning that they induce the same measure for $\mathbf{f}_{A \cap B}$, then there exists a unique probability measure P for $\mathbf{f}_{A \cup B}$ such that (i) $P_A = P_1$, (ii) $P_B = P_2$, and (iii) $\mathbf{f}_A \perp\!\!\!\perp \mathbf{f}_B \mid \mathbf{f}_{A \cap B}[P]$. The measure P is called a Markov combination of P_1 and P_2 , denoted as $P = P_1 \star P_2$.

We provide a proof of Lemma 1 through construction in Appendix B. The main idea is to first construct the conditional probability $P_1 \{ \cdot \mid \pi_{A \cap B}(\mathbf{f}_A) \}$ from P_1 , where $\pi_{A \cap B} : L^2(T_A) \rightarrow L^2(T_{A \cap B})$ is a projection map and $T_A = \bigsqcup_{j \in A} T_j$. We then define $P \{ \cdot \mid \pi_B(\mathbf{f}) \}$ based upon $P_1 \{ \cdot \mid \pi_{A \cap B}(\mathbf{f}_A) \}$ using disintegration theory (Chang and Pollard, 1997), and finally construct the joint measure P that satisfies conditions (i)–(iii). With Lemma 1, we can construct a joint probability measure for \mathbf{f} that is Markov over G . The construction is based on the perfectly ordered decomposition $(C_1, S_2, C_2, \dots, S_m, C_m)$ of G with $S_i = H_{i-1} \cap C_i$ and $H_{i-1} = C_1 \cup \dots \cup C_{i-1}$. Let $\{M_{C_i}, i = 1, \dots, m\}$ be a sequence of pairwise consistent probability measures for $\{\mathbf{f}_{C_i}, i = 1, \dots, m\}$. We construct a Markov probability measure P over G through the following recursive procedure

$$\begin{aligned} P_{C_1} &= M_{C_1}, & (1) \\ P_{H_{i+1}} &= P_{H_i} \star M_{C_{i+1}}, \quad i = 1, \dots, m-1. & (2) \end{aligned}$$

One can show that the probability measure constructed this way is the unique Markov probability measure over G with marginals $\{M_{C_i}\}$, and the proof follows that of Theorem 2.6 in Dawid and Lauritzen (1993). We call the probability distribution induced by the probability measure constructed above the *Markov distribution* of \mathbf{f} over G .

Denote the Markov distributions of \mathbf{f} constructed in (1)–(2) by P_G , and denote the space of all Markov distributions over G by $\mathcal{M}(G)$. A prior law for P_G is then supported on $\mathcal{M}(G)$. We follow Dawid and Lauritzen (1993) to define hyper Markov laws and use them as prior laws for P_G . A prior law \mathcal{L} of P_G is called *hyper Markov* over G if for any decomposition (A, B) of G , $(P_G)_A \perp\!\!\!\perp (P_G)_B \mid (P_G)_{A \cap B}[\mathcal{L}]$, where $(P_G)_A$ takes values in $\mathcal{M}(G_A)$ which is the space of all Markov distributions over subgraph G_A . Here, we have assumed that G is collapsible onto A , therefore $\phi \in \mathcal{M}(G_A)$ if and only if $\phi = (P_G)_A$ for some $(P_G) \in \mathcal{M}(G)$. The following Proposition 1 states that the theory of hyper Markov laws of Dawid and Lauritzen (1993) applies to our random process setup.

Proposition 1 The theory of hyper Markov laws over undirected decomposable graphs, as described in Section 3 of Dawid and Lauritzen (1993), holds for random processes.

According to the theory of hyper Markov laws, one can construct a prior law for P_G using a sequence of consistent marginal laws $\{\mathcal{L}_C, C \in \mathcal{C}\}$ in a similar fashion as (1)–(2).

Denote by \mathcal{L}_G the constructed hyper Markov prior for P_G and by Π a prior distribution for the graph G . A Bayesian graphical model for the collection of random processes \mathbf{f} can be described as

$$\mathbf{f} \sim P_G; \quad P_G \sim \mathcal{L}_G; \quad G \sim \Pi. \quad (3)$$

As we have yet to specify a concrete example for the probability measure P_G , the above Bayesian framework remains abstract at the moment. In Section 2.3, we construct P_G using Gaussian processes and propose a hyper-inverse-Wishart-process law as the prior for P_G . The prior distribution Π is supported on the finite dimensional space of decomposable graphs with p nodes.

2.3 Gaussian Process Graphical Models for Multivariate Functional Data

Let $\mathbf{f}_0 = (f_{01}, \dots, f_{0p})$ be an element in $L^2(T)$. Denote by $\mathcal{K} = \{k_{ij} : T_i \times T_j \rightarrow \mathbb{R}\}$ a collection of covariance kernels such that $\text{cov}\{f_i(s), f_j(t)\} = k_{ij}(s, t), s \in T_i, t \in T_j$. We assume that \mathcal{K} is positive semidefinite and trace class. Positive semidefinite means that

$$\sum_{i,j=1}^p \sum_{k,l=1}^p c_{ik} c_{jl} \int_{T_j} \int_{T_i} k_{ij}(s, t) \phi_{ik}(s) \phi_{jl}(t) ds dt \geq 0$$

for any square summable sequence $\{c_{ik}, i = 1, \dots, p, k = 1, \dots, \infty\}$; trace class means that

$$\sum_{j=1}^p \sum_{l=1}^p \int_{T_j} \int_{T_l} k_{jl}(s, t) \phi_{jl}(s) \phi_{jl}(t) ds dt < \infty.$$

Then \mathbf{f}_0 and \mathcal{K} uniquely determine a Gaussian process on $L^2(T)$ (Prato, 2006), which we call a multivariate Gaussian process, and write $\text{MGP}(\mathbf{f}_0, \mathcal{K})$. The definition of multivariate Gaussian process implies that for $A \subset V$, $\mathbf{f}_A \sim \text{MGP}(\mathbf{f}_{0,A}, \mathcal{K}_A)$ where $\mathcal{K}_A = \{k_{ij}, i, j \in A\}$. Furthermore, on a sequence of cliques $\mathcal{C} = \{C_1, \dots, C_m\}$, the marginal Gaussian process measures for $\{\mathbf{f}_C, C \in \mathcal{C}\}$ are automatically consistent because they are induced from the same joint distribution. Therefore, we can construct a Markov distribution for \mathbf{f} over G through procedure (1)–(2). We denote the resulting distribution of \mathbf{f} by $\text{MGP}_G(\mathbf{f}_0, \mathcal{K}_G)$, where $\mathcal{K}_G = \{k_{ij} : i, j \in C, C \in \mathcal{C}\}$. It is clear from this construction that the distribution MGP_G is Markov over G whereas MGP is not.

For the convenience of both theoretical analysis and computation, we represent elements in $L^2(T)$ using orthonormal basis expansions and construct a Bayesian graphical model in the dual space of basis coefficients. Let $\{\phi_{jk}\}_{k=1}^{\infty}$ denote an orthonormal basis of $L^2(T_j)$. For example, $\{\phi_{jk}\}_{k=1}^{\infty}$ could be a wavelet basis. We have the representation $f_j(t) = \sum_{k=1}^{\infty} c_{jk} \phi_{jk}(t)$ where $c_{jk} = \langle f_j, \phi_{jk} \rangle = \int_{T_j} f_j(t) \phi_{jk}(t) dt$. The coefficient sequence $c_j = \{c_{jk}, k = 1, \dots, \infty\}$ lies in the space of square-summable sequences, denoted by $\ell_j^2 = \{c_jk : \sum_{k=1}^{\infty} c_jk^2 < \infty\}$. Denote $\ell^2 = \prod_{j=1}^p \ell_j^2$. Since ℓ_j^2 and $L^2(T_j)$ are isometrically isomorphic for each j , once an orthonormal basis of $L^2(T)$ has been chosen, we have an identification between the Borel probability measures defined on ℓ^2 and $L^2(T)$; therefore we can construct statistical models on ℓ^2 without loss of generality. Let $\mathbf{c} = (c_1, \dots, c_p)$ denote

the coefficient sequence of \mathbf{f} . Then $\mathbf{f} \sim \text{MGP}(\mathbf{f}_0, \mathcal{K})$ corresponds to $\mathbf{c} \sim \text{dMGP}(\mathbf{c}_0, \mathcal{Q})$, where dMGP denotes the infinite dimensional discrete multivariate Gaussian processes, \mathbf{c}_0 is the coefficient sequence of \mathbf{f}_0 and $\mathcal{Q} = \{q_{ij}(\cdot, \cdot), i, j \in V\}$. Here, q_{ij} is the covariance kernel so that $\text{cov}(c_{k_h}, c_{l_j}) = q_{ij}(k, l)$ for $k, l \in \{1, 2, 3, \dots\}$. Similarly, $\mathbf{f} \sim \text{MGP}_G(\mathbf{f}_0, \mathcal{K}_G)$ corresponds to $\mathbf{c} \sim \text{dMGP}_G(\mathbf{c}_0, \mathcal{Q}_G)$ where $\mathcal{Q}_G = \{q_{ij}(\cdot, \cdot), i, j \in C, C \in \mathcal{C}\}$. The collection \mathcal{Q} is also positive semidefinite and trace class, so that $\sum_{i,j=1}^p \sum_{k,l=1}^{\infty} c_{k_h} c_{l_j} q_{ij}(k, l) \geq 0$ for any square summable sequence $\{c_{k_h}, i = 1, \dots, p, k = 1, \dots, \infty\}$, and $\sum_{j=1}^p \sum_{k=1}^{\infty} q_{ij}(k, k) < \infty$. Furthermore, \mathcal{K} relates to \mathcal{Q} through equation $k_{ij}(s, t) = \sum_{k_h=1}^p \sum_{l_j=1}^p q_{ij}(k_h, l_j) \phi_{k_h}(s) \phi_{l_j}(t)$. Denote by \mathbf{p}^C and \mathbf{p}^f the probability measures of \mathbf{c} and \mathbf{f} respectively, then $\mathbf{f}_A \perp \mathbf{f}_B \mid \mathbf{f}_C [\mathbf{p}^f]$ implies $\mathbf{c}_A \perp \mathbf{c}_B \mid \mathbf{c}_C [\mathbf{p}^c]$ and vice versa. Thus, the distribution $\text{dMGP}_G(\mathbf{c}_0, \mathcal{Q}_G)$ of \mathbf{c} is again Markov.

Assume that $\mathbf{c} \sim \text{dMGP}_G(\mathbf{c}_0, \mathcal{Q}_G)$. The parameters involved in this distribution include \mathbf{c}_0 and \mathcal{Q}_G . In this study, we assume that \mathbf{c}_0 is fixed (e.g., a zero sequence) so that the distribution of \mathbf{c} is uniquely determined by \mathcal{Q}_G . As indicated in Section 2.2, we would like to construct a hyper Markov law for the dMGP $_G$ distribution. Since dMGP $_G$ is uniquely determined by \mathcal{Q}_G , it is equivalent to construct a hyper Markov law for \mathcal{Q}_G . Given a positive integer δ and a collection $\mathcal{U} = \{u_{ij} : \mathbb{N} \times \mathbb{N} \rightarrow \mathbb{R}, i, j \in V\}$ which is symmetric, positive semidefinite, and trace class, we construct a hyper-inverse-Wishart-process (HIWP) prior for \mathcal{Q}_G following Theorem 1.

Theorem 1 Assume that $\mathbf{c} \sim \text{dMGP}_G(\mathbf{c}_0, \mathcal{Q}_G)$. Suppose that δ is a positive integer, and \mathcal{U} is a collection of kernels that is symmetric, positive semidefinite and trace class. Then there exists a sequence of pairwise consistent inverse-Wishart processes determined by δ and $\mathcal{U}_C = \{u_{ij}, i, j \in C\}$, $C \in \mathcal{C}$, based on which one can construct a unique hyper Markov law for \mathcal{Q}_G , which we call a hyper-inverse-Wishart-process, and write $\mathcal{Q}_G \sim \text{HIWP}_G(\delta, \mathcal{U}_C)$, where $\mathcal{U}_C = \{u_{ij}, i, j \in C, C \in \mathcal{C}\}$.

Based on Theorem 1, a Bayesian Gaussian process graphical model can be written as

$$\mathbf{c} \sim \text{dMGP}_G(\mathbf{c}_0, \mathcal{Q}_G), \quad \mathcal{Q}_G \sim \text{HIWP}_G(\delta, \mathcal{U}_C), \quad G \sim \Pi. \quad (4)$$

It is of interest to investigate the properties of the HIWP prior and the corresponding posterior distribution. As shown in Dawid and Lauritzen (1993), one nice property of the HIW law is the strong hyper Markov property, which leads to conjugacy as well as convenient posterior computation at each clique. In case of the HIWP prior, the strong hyper Markov property is defined such that for any decomposition (A, B) of G in model (4), $\mathcal{Q}_{B|A} \perp \mathcal{Q}_A$, where $\mathcal{Q}_{B|A}$ denotes the conditional distribution (i.e., conditional covariance) of \mathbf{c}_B given \mathbf{c}_A . In the following proposition, we show that the HIWP $_G$ prior constructed in Theorem 1 is strong hyper Markov when $\text{rank}(u_{ij}) < \infty$ for $i, j \in V$.

Proposition 2 Suppose that the collection of kernels \mathcal{U} satisfies that $\text{rank}(u_{ij}) < \infty$ for $i, j \in V$, then the hyper-inverse-Wishart-process prior constructed in Theorem 1 satisfies the strong hyper Markov property. That is, if $\mathcal{Q}_G \sim \text{HIWP}_G(\delta, \mathcal{U}_C)$, then for any decomposition (A, B) of G , $\mathcal{Q}_{B|A} \perp \mathcal{Q}_A$, where $\mathcal{Q}_{B|A}$ denotes the conditional distribution (e.g., conditional covariance) of \mathbf{c}_B given \mathbf{c}_A .

The finite rank condition for the prior parameters $\{u_{ij}\}$ in Proposition 2 is a relatively strong condition under which the HIWP $_G$ satisfies the strong hyper Markov property. It

implies that the covariance kernel \mathcal{Q}_G , thus the sequence \mathbf{c} , is a priori finite dimensional. Whether the strong hyper Markov property still holds without this condition remains a challenging open problem. In the online appendix, we have included several interesting results made through our preliminary study, which may provide useful insights into further investigations of this problem. The strong hyper Markov property of HIWP $_G$ ensures that the joint posterior of \mathcal{Q}_G (conditional on G) can be constructed from the marginal posterior of \mathcal{Q}_G (conditional on G) at each clique C , as stated in Theorem 2. Therefore one essentially transforms the Bayesian analysis to a sequence of sub-analyses at the cliques, which substantially reduces the size of the problem.

Theorem 2 Suppose that $\mathbf{c}_i \sim \text{dMGP}_G(\mathbf{c}_0, \mathcal{Q}_G)$, $i = 1, \dots, n$ are independent and identically distributed. Further assume that the prior of \mathcal{Q}_G is $\text{HIWP}_G(\delta, \mathcal{U}_C)$ where the collection of kernels \mathcal{U} satisfies that $\text{rank}(u_{ij}) < \infty$ for $i, j \in V$. Then the conditional posterior of \mathcal{Q}_G given $\{\mathbf{c}_i\}$ and G is $\text{HIWP}_G(\tilde{\delta}, \tilde{\mathcal{U}}_C)$, where $\tilde{\delta} = \delta + n$, $\tilde{\mathcal{U}}_C = \{\tilde{u}_{ij}, i, j \in C, C \in \mathcal{C}\}$ and $\tilde{u}_{ij} = u_{ij} + \sum_{r=1}^n (\mathbf{c}_r - \mathbf{c}_0) \otimes (\mathbf{c}_r - \mathbf{c}_0)$. Here \otimes denotes the outer product. Furthermore, the marginal distribution of $\{\mathbf{c}_i\}$ given $\{G, \mathbf{c}_0, \delta, \tilde{\mathcal{U}}_C\}$ is again Markov over G .

Theorem 2 implies that when $\text{rank}(u_{ij}) < \infty$ for $i, j \in V$, the HIWP $_G(\delta, \mathcal{U}_C)$ prior is a conjugate prior for \mathcal{Q}_G in the dMGP $_G(\mathbf{c}_0, \mathcal{Q}_G)$ likelihood. Note that here the likelihood, the prior, and the posterior are all conditional on G , which makes Bayesian inference of G tractable. Model (4) and results in Theorem 2 provide the theoretical foundation for practical Bayesian inference under a reasonable regularity condition, as discussed in Section 3.

3. Bayesian Posterior Inference

Despite the fact that functional data are realizations of inherently infinite-dimensional random processes, data can only be collected at a finite number of measurement points. Essentially, estimating the conditional independence structure of infinite-dimensional random processes based on a finite number of measurement points is an inverse problem and therefore requires regularization. Müller and Yao (2008) reviewed two main approaches for regularization in functional data analysis—finite approximation through, e.g., suitably truncating the basis expansion representation and penalized likelihood. In this paper, we suggest performing posterior inference based on approximating the underlying random processes with orthogonal basis functions. In particular, we assume the following regularity condition:

Condition 1 The functional data \mathbf{f} are observed discretely on a dense grid $\mathbf{t} = \bigsqcup_{j=1}^m \mathbf{t}_j$ with $\mathbf{t}_j = (t_{j1}, \dots, t_{jn_j(n)})$ and $n_j(n) \rightarrow \infty$ as $n \rightarrow \infty$. One can find $N_j(n)$ so that the underlying random process f_j can be approximated with an N_j -term orthogonal basis expansion $\tilde{f}_j = \sum_{l=1}^{N_j} c_{jl} \phi_{jl}$, with approximation error $\|f_j - \tilde{f}_j\|_2 = O_p(n^{-\beta})$ with $\beta \geq 1/2$ for all $j \in V$.

Essentially, Condition 1 requires that the discretely-measured functional data capture sufficient information about the underlying random processes, so that we can approximate each f_j with a negligible approximation error. This condition provides the consistency of the basis representation, i.e., the approximation error converges to zero with order $O_p(n^{-\beta})$

when M_j increases with the sample size n . We need such a condition in order to guarantee that the behavior of $\{f_j\}$ is not too outrageous. Certain assumptions, such as the decay rate of the eigenvalues of f_j , the smoothness property of f_j , or the characteristics of the basis functions, will determine the specific rate β (De Boor, 2001; Jansen and Oonincx, 2015). However, under our generic setup, since we prefer not to specify particular assumptions, we only require a mild range for the convergence rate. Condition 1 is a basic assumption in the functional setting, and a similar regularity condition has been adopted by Qiao et al. (2015) in a functional graphical model based on the group LASSO penalty.

3.1 Bayesian Posterior Inference under the Regularization Condition

The regularity from Condition 1 enables us to write the density functions of the Markov distributions and hyper Markov laws so that posterior inference can be practically implemented. Denoting $M = (M_1, \dots, M_p)$, we can explicitly write the density function for the truncated process $\mathbf{c}^M = (c_1^M, \dots, c_p^M)$, and an MCMC algorithm can then be designed for the posterior inference of the underlying graph G . The density function of \mathbf{c}^M is

$$p(\mathbf{c}^M | \mathbf{c}_0^M, \mathbf{Q}_C, G) = \frac{\prod_{C \in \mathcal{C}} p(\mathbf{c}_C^M | \mathbf{c}_{0_C}^M, \mathbf{Q}_C)}{\prod_{S \in \mathcal{S}} p(\mathbf{c}_S^M | \mathbf{c}_{0_S}^M, \mathbf{Q}_S)}, \quad (5)$$

where \mathbf{Q}_C is a block-wise covariance matrix with the (i, j) th block formed by $\{q_{ij}(k, l), k = 1, \dots, M_i, l = 1, \dots, M_j\}$, and $\mathbf{Q}_C, \mathbf{Q}_S$ are submatrices of \mathbf{Q}_C corresponding to clique C and separator S , respectively. The HIWPC prior of \mathbf{Q}_C induces a hyper inverse-Wishart prior with density

$$p(\mathbf{Q}_C | G) = \frac{\prod_{C \in \mathcal{C}} p(\mathbf{Q}_C | \delta, \mathbf{U}_C)}{\prod_{S \in \mathcal{S}} p(\mathbf{Q}_S | \delta, \mathbf{U}_S)}, \quad (6)$$

where $p(\mathbf{Q}_C | \delta, \mathbf{U}_C)$ is the density of inverse-Wishart defined in Dawid (1981), \mathbf{U}_C is a submatrix of \mathbf{U}_C corresponding to clique C , and \mathbf{U}_C is a block-wise matrix formed by $\{u_{ij}\}$ in the same way as \mathbf{Q}_C is formed by $\{q_{ij}\}$. The $p(\mathbf{Q}_S | \delta, \mathbf{U}_S)$ component in the denominator is defined similarly. Based on (5) and (6), and assuming that $\{c_i, i = 1, \dots, n\}$ is a random sample of \mathbf{c} , one can further integrate out \mathbf{Q}_C to get the marginal density

$$p(\{\mathbf{c}_i^M\} | \mathbf{c}_0^M, G) = (2\pi)^{-\frac{d}{2}(\sum_i M_i)} \frac{h(\delta, \mathbf{U}_C)}{h(\delta, \mathbf{U}_C)}, \quad (7)$$

where

$$h(\delta, \mathbf{U}_C) = \frac{\prod_{C \in \mathcal{C}} \frac{1}{2} |\mathbf{U}_C| \left(\frac{d+d_C-1}{2}\right) \Gamma_{d_C}^{-1} \left\{ \frac{1}{2}(\delta + d_C - 1) \right\}}{\prod_{S \in \mathcal{S}} \frac{1}{2} |\mathbf{U}_S| \left(\frac{d+d_S-1}{2}\right) \Gamma_{d_S}^{-1} \left\{ \frac{1}{2}(\delta + d_S - 1) \right\}},$$

and d_C and d_S are the dimensions of \mathbf{U}_C and \mathbf{U}_S respectively, and $\Gamma_b(a) = \pi^{b(b-1)/4} \prod_{l=0}^{b-1} \Gamma(a - l/2)$. The denominator $h(\delta, \mathbf{U}_C)$ in (7) is defined in the same way. Based on these results, posterior inference can be done through sampling from the posterior density

$$p(G | \{\mathbf{c}_i^M\}, \mathbf{c}_0^M) \propto p(\{\mathbf{c}_i^M\} | \mathbf{c}_0^M, G) p(G), \quad (8)$$

where $p(G)$ is the density function corresponding to the prior distribution $G \sim \Pi$, which is a discrete distribution supported on all decomposable graphs with p nodes. Giudici and Green (1999) used the discrete uniform prior $\Pr(G = G_0) = 1/d$ for any fixed p -node decomposable graph G_0 , where d is the total number of such graphs; Jones et al. (2005) used the independent Bernoulli prior with probability $2/(p-1)$ for each edge, which favors sparser graphs (Giudici, 1996). The following MCMC algorithm describes the steps to generate posterior samples based on (8).

Algorithm 1

Step 0. Set an initial decomposable graph G and set the prior parameters $\mathbf{c}_0, \delta,$ and \mathbf{U}_C .

Step 1. With probability $1 - q$, propose \tilde{G} by randomly adding or deleting an edge from G (each with probability 0.5) within the space of decomposable graphs; with probability q , propose \tilde{G} from a discrete uniform distribution supported on the set of all decomposable graphs. Accept the new \tilde{G} with probability

$$\alpha = \min \left\{ 1, \frac{p(\tilde{G} | \{\mathbf{c}_i^M\}, \mathbf{c}_0^M) p(G | \tilde{G})}{p(G | \{\mathbf{c}_i^M\}, \mathbf{c}_0^M) p(\tilde{G} | G)} \right\}.$$

Repeat Step 1 for a large number of iterations until convergence is achieved.

Detailed derivations are available in the online appendix. The above algorithm is a Metropolis-Hastings sampler with a mixture of local and heavier-tailed proposals, also called a *small-world sampler*. The ‘‘local’’ move involves randomly adding or deleting one edge based on the current graph, and the ‘‘global’’ move is achieved through the discrete uniform proposal. Guan et al. (2006) and Guan and Krone (2007) have shown that the small-world sampler leads to much faster convergence especially when the posterior distribution is either multi-modal or spiky.

3.2 Bayesian Posterior Inference for Noisy Functional Data

The theory in Section 2 and the posterior inference in Section 3.1 relies on the assumption that the distribution of \mathbf{f} (and \mathbf{c}) is Markov over G . In many situations, it is more desirable to make such an assumption in a hierarchical model. For example, when functional data are subject to measurement error, one might wish to incorporate an additive error term and consider the following model

$$y_{ijt} = f_{ij}(t) + \varepsilon_{ijt}, \quad i = 1, \dots, n, \quad j = 1, \dots, p, \quad t \in \mathbf{t}_j, \quad (9)$$

where $\{y_{ijt}, t \in \mathbf{t}_j\}$ are noisy observations measured on a dense grid $\mathbf{t}_j = (t_{j1}, \dots, t_{jm_j})$, $\{f_{ij}\}$ are the underlying true functions, and $\{\varepsilon_{ijt}, t \in \mathbf{t}_j\}$ are measurement errors. We assume that $\{f_{ij}\}$ and $\{\varepsilon_{ijt}, t \in \mathbf{t}_j\}$ are mutually independent of each other. The inference of model (9) involves both smoothing (i.e., estimating f_{ij}) and estimation of the underlying graph G . We achieve these goals simultaneously through fitting a Bayesian hierarchical model.

In particular, we assume that $\{f_{ij}\}$ are Gaussian processes in $L^2(\mathcal{T}_j)$, and denote $\{c_{ijk}\}$ their basis coefficients corresponding an orthonormal basis $\{\phi_{jk}\}_{k=1}^\infty$. With this representation, model (9) has the form $y_{ijt} = \sum_{k=1}^\infty c_{ijk} \phi_{jk}(t) + \varepsilon_{ijt}$, and $\{c_{ijk}\}$ is a discrete Gaussian

process. We further assume that the measurement error $\epsilon_{tj} = \{\epsilon_{tjh}, t \in \mathbf{t}_j\}$ is Gaussian while noise with variance σ_j^2 , i.e., $\epsilon_{tjh} \sim N(0, \sigma_j^2)$ independently across all t for $t \in \mathbf{t}_j$. Truncating at the M_j th basis element, we can reparameterize the model as

$$y_{jt} = \sum_{k=1}^{M_j} c_{tjk} \phi_{jk}(t) + \tilde{\epsilon}_{tjh}, \quad t \in \mathbf{t}_j \quad (10)$$

where $\tilde{\epsilon}_{tjh}$ is a new residual term that consists of the approximation error of the truncated series $(\epsilon_{tG}, \sum_{k=M_j+1}^{\infty} c_{tjk} \phi_{jk}(t))$ and the measurement error. If we concatenate the noisy observations to form a vector

$$\mathbf{y}_i = (y_{i1t_1}, \dots, y_{iM_1t_1}, \dots, y_{iM_p t_p}, \dots, y_{iM_p t_p})^T$$

and denote \mathbf{c}_i^M the vector formed by the basis coefficients $\{c_{tjk}, j = 1, \dots, p, k = 1, \dots, M_j\}$, then model (10) can be written as $\mathbf{y}_i = \Phi \mathbf{c}_i^M + \tilde{\epsilon}_i$, where $\Phi = \text{diag}\{\phi_{11}, \dots, \phi_{p1}\}$ is a $\sum_j M_j$ by $\sum_j M_j$ block-diagonal matrix with the j th diagonal block containing $\phi_j = [\phi_{j1}(\mathbf{t}_j), \dots, \phi_{jM_j}(\mathbf{t}_j)]$, and $\tilde{\epsilon}_i$ denote the concatenated vector of the new residual terms. We assume that $\tilde{\epsilon}_i \sim N(0, \Lambda)$ where $\Lambda = \text{diag}(s_{1m_1}^2, \dots, s_{pM_p}^2)$. Notice that if $\mathbf{Q}_C = \text{cov}(\mathbf{c}_i^M)$, then $\text{cov}(\mathbf{y}_i^M) = \Phi \mathbf{Q}_C \Phi^T + \Lambda$. The diagonals of $\Phi \mathbf{Q}_C \Phi^T$ and Λ can not be separately identifiable. Therefore, we treat Λ as a fixed model parameter, whose quantity can be pre-determined by the approximation $s_j^2 \approx \hat{\sigma}_j^2$, where $\hat{\sigma}_j^2$ is the estimation of σ_j^2 using local smoothing on $\{\tilde{\epsilon}_{tjh}\}$.

Applying a prior for \mathbf{c}_i^M in the form of (5) (conditional on G) and the HMWP prior for the covariance matrix \mathbf{Q}_C in the form of (6), we obtain the density function for the joint posterior

$$p(\{\mathbf{c}_i^M\}, \mathbf{Q}_C, G | \{\mathbf{y}_i\}) \propto \prod_{i=1}^n p(\mathbf{y}_i | \mathbf{c}_i^M, \Lambda) p(\mathbf{c}_i^M | \mathbf{c}_0^M, \mathbf{Q}_C, G) p(\mathbf{Q}_C | G) p(G). \quad (11)$$

From (11), we can integrate out \mathbf{Q}_C to obtain the marginal posterior distribution of $\{\mathbf{c}_i^M\}$ and G . The MCMC algorithm for generating posterior samples based on (11) is listed in Algorithm 2.

Algorithm 2

Step 0 Set initial values for $\{\mathbf{c}_i^M\}$, G and set the model parameters δ , \mathbf{c}_0^M , \mathbf{U} and Λ .

Step 1 Conditional on $\{\mathbf{c}_i^M\}$, update $G \sim p(G | \{\mathbf{c}_i^M\}, \mathbf{c}_0^M)$ using the small-world sampler as described in Step 1 of Algorithm 1, where $p(G | \{\mathbf{c}_i^M\}, \mathbf{c}_0^M)$ is computed based on (11).

Step 2 Given G , update $\mathbf{Q}_C \sim p(\mathbf{Q}_C | \{\mathbf{c}_i^M\}, G)$, which takes the same form as (6) except that δ and \mathbf{U} are replaced by δ and $\tilde{\mathbf{U}}$ respectively using the formulae in Theorem 2.

Step 3 Conditional on G and \mathbf{Q}_C , update $\mathbf{c}_i^M \sim N(\boldsymbol{\mu}_i, \mathbf{V})$, where $\mathbf{V} = (\Phi^T \Lambda^{-1} \Phi + \mathbf{Q}_C^{-1})^{-1}$ and $\boldsymbol{\mu}_i = \mathbf{V}(\Phi^T \Lambda^{-1} \mathbf{y}_i + \mathbf{Q}_C^{-1} \mathbf{c}_0^M)$.

Repeat Step 1 \sim 3 for a large number of iterations until convergence is achieved.

3.3 Other Practical Computational Issues

Calculating the coefficient sequences $\{c_j\}$ from the functional observations $\{\mathbf{f}_j\}$ requires the selection of an orthonormal basis $\{\phi_{jk}, j = 1, \dots, p, k = 1, \dots, \infty\}$. If a known basis is chosen (e.g., Fourier), the coefficient sequences can be estimated by $c_{tjk} = \langle \mathbf{f}_{tj}, \phi_{jk} \rangle$ using numerical integration. Another convenient choice is the eigenbasis of the autocovariance operators of $\{\mathbf{f}_j\}$, in which case the coefficient sequences are called functional principal component (FPC) scores. The corresponding basis representation is called Karhunen-Loève expansion. The eigenbasis can be estimated using the method of Ramsay and Silverman (2005) or the Principal Analysis by Conditional Expectation (PACE) algorithm of Yao et al. (2005). Owing to the rapid decay of the eigenvalues, the eigenbasis provides a more parsimonious and efficient representation compared with other bases. Furthermore, the FPC scores within a curve are mutually uncorrelated, so one may set the prior parameter \mathbf{U}_C to be a matrix with blocks of diagonal sub-matrices, or simply a diagonal matrix.

In addition to the estimation of coefficient sequences, a suitable truncation of the infinite sequences $\{c_j\}$ is needed to facilitate practical posterior inference. We suggest to pre-determine the truncation parameters using approximation criteria, following Rice and Silverman (1991) or Yao et al. (2005). This includes cross-validation (Rice and Silverman, 1991), applying the pseudo Akaike information criterion (Yao et al., 2005), or controlling the fraction-of-variance-explained (FVE) in the FPC analysis (Lei et al., 2014).

4. Simulation Study

Three simulation studies were conducted to assess the performance of posterior inference using the Gaussian process graphical models outlined in Section 2.3 and Section 3. Simulation 1 corresponds to the smooth functional data case (without measurement error), and Simulation 2 corresponds to the noisy data case when measurement error is considered. Both simulations are based on a true underlying graph with 6 nodes, demonstrated in Figure 1 (a). In simulation 3, we show the performance of the proposed Bayesian inference in a $p > n$ case, with the number of nodes $p = 60$ and the sample size $n = 50$.

4.1 Simulation 1: Graph Estimation for Smooth Functional Data

Multivariate functional data are generated on the domain $[0, 1]$ using Fourier basis with the number of basis functions $\{M_j\}_{j=1}^p$ varying from 3 to 7. The true eigenvalues are generated from Gamma distributions and are subject to exponential decay. The conditional independence structure is determined by a $p \times p$ correlation matrix \mathbf{R}_0 , with the inverse \mathbf{R}_0^{-1} containing a zero pattern corresponding to the graph in Figure 1 (a). We then generate principal component scores from a multivariate normal distribution with zero mean and a block-wise covariance matrix $\mathbf{Q} = \mathbf{Z}\mathbf{R}\mathbf{Z}$, which has dimension $\sum_{j=1}^p M_j$. Here \mathbf{R} is a block-wise correlation matrix that has a diagonal form in each block. In particular, the (i, j) th block of \mathbf{R} , denoted by \mathbf{R}_{ij} , satisfies that $\mathbf{R}_{ij} = (\mathbf{R}_0)_{ij} \mathbf{I}$ where \mathbf{I} is a rectangular identity matrix with size $M_i \times M_j$. An image plot of \mathbf{R} is shown in Figure 1(d), with its data-domain counterpart (the correlation of \mathbf{f} evaluated on a grid \mathbf{t}) shown in Figure 1(c). The multivariate functional data are finally generated through linearly combining the eigenbasis using the principal component scores. A common mean function is added to each curve.

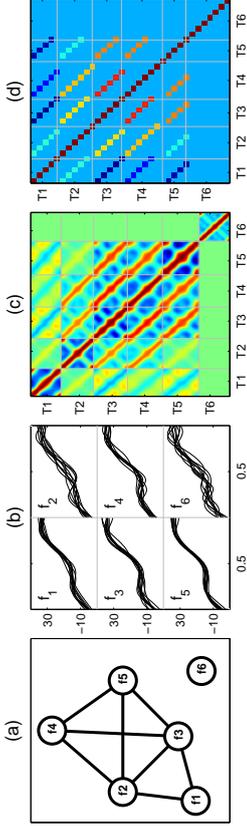

Figure 1: Plots of Simulation 1. (a) The true underlying graph; (b) The first 10 samples of $\{f_{ij}, j = 1, \dots, 6\}$; (c) The image plot of the underlying data-domain correlation matrix; (d) The image plot of the underlying correlation matrix \mathbf{R} .

The generated data contain $n = 200$ independent samples, and each sample contains six curves measured on six different grids. We display the first 10 samples in Figure 1(b).

Based on the data generated above, we estimate the principal component scores $\{c_j\}$ using the PACE algorithm of Yao et al. (2005) and determine the truncation parameter $\{M_j\}$ using the FVE criterion with a 90% threshold, resulting in $\{M_j\}$ values around 5. We apply Algorithm 1 and set $\delta = 5$ and $\mathbf{U} = \widehat{\mathbf{R}}\widehat{\mathbf{R}}^T$, where $\widehat{\mathbf{R}} = \text{diag}\{\widehat{\lambda}_{jk}^{1/2}, k = 1, \dots, M_j, j = 1, \dots, p\}$, $\{\widehat{\lambda}_{jk}\}$ are the estimated eigenvalues and $\widehat{\mathbf{R}}$ is set to be the identity matrix. A total of 5,000 MCMC iterations are performed. Starting from the empty graph, the chain reaches the true underlying graph in around 500 iterations. We have also tried implementing Algorithm 1 with different initial graphs; all implementations resulted in the same posterior mode at the true underlying graph.

We compare the performance of our approach with three other related methods: the Gaussian graphical model of Jones et al. (2005) based on Metropolis-Hastings (GGM-MH), the graphical LASSO (GLASSO) of Friedman et al. (2008), and the matrix-normal graphical model (MNGM) of Wang and West (2009). As both GGM-MH and GLASSO assume that each node is associated with one variable, we reduce the dimension of the functional data by retaining only the first principal component score. The MNGM method assumes matrix data, so we take the first five principal component scores and stack them up to form a 6×5 matrix for each sample. In the MNGM method, graph estimates across the rows and columns are obtained simultaneously, and only that across the rows is of interest to us.

The simulation results are demonstrated in the top panel of Table 1. Summary statistics, such as running-time, mis-estimation rate, sensitivity and specificity are calculated for each method. The running-time was obtained using a laptop with Intel(R) Core(TM) i5 CPU, M430 with 2.27 GHz processor and 4GB RAM. The comparison of running-time shows that the GLASSO method is the fastest. This is because GLASSO does not require posterior sampling. However, GLASSO relies on a penalized optimization approach which requires determination of the tuning parameter. In this simulation, we have selected the tuning parameter that results in the lowest mis-estimation rate with respect to the underlying true

graph. When the true graph is unknown, the tuning procedure can be time-consuming. The MNGM is much slower to implement, perhaps due to the numerical approximation of the marginal density in the MCMC algorithm.

Data	Method	nFPC	Time	nEdge	nUnique	MisR	Sen	Spec
Smooth	FDGM-S	3 - 5	38	7.66	3	0.02	0.96	1.0

Table 1: Summary statistics of simulation 1 and 2. nFPC: number of FPCs used to approximate each curve; Time: running time (in seconds) based on 5000 MCMC iterations; nEdge: total number of edges of the graph averaged across all posterior samples; nUnique: number of unique graphs visited after the burnin period; MisR: mean mis-estimation rate with respect to the true graph; Sen: sensitivity; Spec: specificity; FDGM-S: the proposed functional data graphical model for smooth data, based on Algorithm 1; FDGM-N: the proposed functional data graphical model for noisy data, based on Algorithm 2; GGM-MH: Gaussian graphical model; GLASSO: graphical LASSO; MNGM: matrix-normal graphical model.

In Table 1, the mis-estimation rate is defined as the proportion of mis-estimated edges, obtained by averaging across all posterior samples. The sensitivity is the proportion of missed edges among the true edges, and the specificity is the proportion of over-estimated edges among the true non-edge pairs. The top panel of Table 1 shows that the proposed functional data graphical model provides the smallest mis-estimation rate as well as the highest sensitivity and specificity. We also observe that, although relying on excessive dimension reduction, the Gaussian graphical model and the GLASSO still provide reasonably good estimates. This suggests that for problems involving more nodes (>50), we can use these methods to obtain an initial estimate before applying our approach.

4.2 Simulation 2: Graph Estimation for Noisy Functional Data

We add Gaussian white noise to the functional data generated in Simulation 1 to demonstrate the performance of posterior inference for noisy data. The variances of the additive Gaussian white noise $\{\varepsilon_{ij}, t \in \mathbf{t}_j\}$ are generated from a gamma distribution with mean 2.5 and variance 0.25, resulting in a signal-to-noise ratio around 9, where the signal-to-noise ratio is defined by $f_{ij}(t)/\text{var}\{\varepsilon_{ij}\}$ and is averaged across the grid points and the samples. We apply model (11) and generate posterior samples using Algorithm 2. The eigenbasis and the variance of the noise are estimated simultaneously using the PACE algorithm. The parameter \mathbf{A} is determined using the estimated variance of the Gaussian white noise, and the other model parameters are set to be the same as in Simulation 1. The posterior infer-

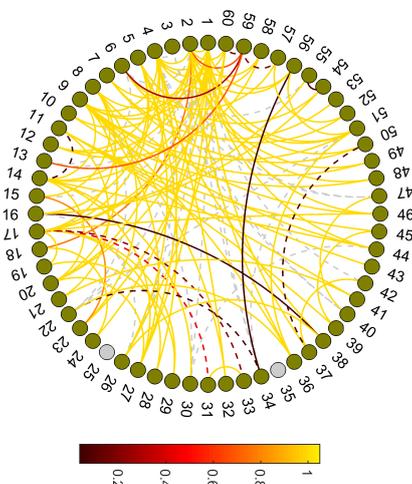

Figure 2: Plot of Simulation 3. The estimated graph based on the marginal inclusion probability for each edge.

ence results are compared with the other three methods in the bottom panel of Table 1. Similar patterns are observed as in Simulation 1. In particular, the proposed functional data graphical model shows a clear advantage in accurately estimating the graph. Estimates of the functions $\{f_j\}$ and their time-domain correlations are provided in the online appendix.

4.3 Simulation 3: Graph Estimation When p is Greater than n

To further investigate the performance of the proposed approach when the number of nodes p is greater than the sample size n , we design another simulation study with $p = 60$ and $n = 55$. The true graph contains 60 nodes, among which 2 are singletons and 58 are connected with edges. The total number of edges in the true graph is 121. Smooth functional data are simulated following the procedure described in Section 4.1. With the simulated data, we apply the PACE algorithm to estimate $\{c_j\}$ and determine the truncation parameters using the FVE criterion with a 95% threshold. We then apply Algorithm 1 and set prior parameters δ and \mathbf{U} following Simulation 1. Posterior samples of the graph are obtained for 30,000 MCMC iterations after removing 10,000 burn-in samples.

The posterior inference results are summarized in a circular graph plot in Figure 2, where we show an estimated graph by thresholding the marginal inclusion probability for each edge—the proportion that each edge is included in the posterior samples—to be greater than 0.03. In Figure 2, the colors indicate the levels of the marginal inclusion probabilities, the colored dashed lines indicate edges that are mistakenly estimated, and the gray dashed lines indicate edges that are missed. This gives 105 estimated edges, among which 98 are correctly estimated, and 7 are mistakenly estimated. Additionally, 23 edges in the true graph are missed. We have also calculated the summary statistics similarly as in previous

simulations, resulting in mean mis-estimation rate 0.02, sensitivity 0.77, and specificity 0.99. Extra simulation runs show that the sensitivity level is improved when we increase the sample size n .

5. Analysis of Event-related Potential Data in an Alcoholism Study

We apply the proposed method to event-related potential data from an alcoholism study. Data were initially obtained from 64 electrodes placed on subjects' scalps that captured EEG signals at 256 Hz during a one-second period. The measurements were taken from 122 subjects, of which 77 belonged to the alcoholism group and 45 to the control group. Each subject completed 120 trials. During each trial, the subject was exposed to either a single stimulus (a single picture) or two stimuli (a pair of pictures) shown on a computer monitor. We band-pass filtered the EEG signals to extract the α frequency band in the range of 8–12.5 Hz. The filtering was performed by applying the `egfilt` function in the EEGLAB toolbox of Matlab. The α -band signal is known to be associated with inhibitory control (Knyazev, 2007). Research has shown that, relative to control subjects, alcoholic subjects demonstrate unstable or poor rhythm and lower signal power in the α -band signal (Porjesz et al., 2005; Finn and Justus, 1999), indicating decreased inhibitory control (Sher et al., 2005). Moreover, regional asymmetric patterns have been found in alcoholics—alcoholics exhibit lower left α -band activities in anterior regions relative to right (Hayden et al., 2006). In this study, we aim to estimate the conditional independence relationships of α -band signals from different locations of the scalp, and expect to find evidence that reflects differences in brain connectivity and asymmetric pattern between the two groups.

Since multiple trials were measured over time for each subject, the EEG measurements may not be treated as independent due to the time dependence of the trials. Furthermore, since the measurements were taken under different stimuli, the signals could be influenced by different stimulus effects. To remove the potential dependence between the measurements and the influence of different stimulus types, for each subject, we averaged the band-filtered EEG signals across all trials under the single stimulus, resulting in one *Event-related potential* (ERP) curve per electrode per subject. ERP is a type of electrophysiological signal generated by averaging EEG segments recorded under repeated applications of a stimulus, with the averaging serving to reduce biological noise levels and enhance the stimulus evoked neurological signal (Brandeis and Lehmann, 1986; Bressler, 2002). Based on the preprocessed ERP curves, we further removed subjects with missing nodes, and balanced the sample size across the two groups, producing multivariate functional data with $n = 44$ and $p = 64$ for both the alcoholic and the control group. We applied model (4) using coefficients of the eigenbasis expansion. The number of eigenbasis $\{M_j\}$ was determined through retaining 90% of the total variation; this resulted in 4–7 coefficients per f_j . We collected 30,000 posterior samples using Algorithm 1, in which the first 10,000 were treated as the burn-in period. The model was fitted for both the alcoholic and the control group, and convergence of the MCMC was justified by running multiple chains starting with various initial values.

The posterior results are summarized in Figure 3. The plots in (a) and (b) show the marginal inclusion probabilities for edges in the alcoholic and the control group respectively, where the edge color indicates the proportion that each edge is included in the posterior

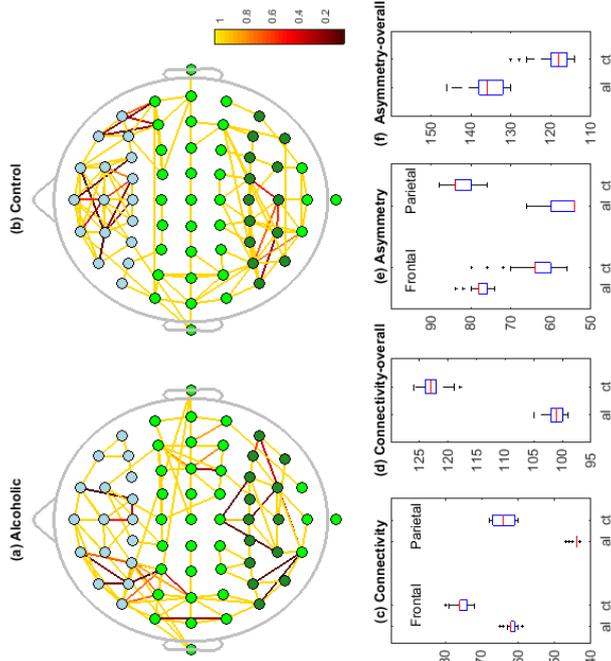

Figure 3: Summary of posterior inference: the marginal inclusion probabilities for edges in the alcoholic group (a) and the control group (b); the boxplots of connectivity measures: the number of edges connecting with nodes in the frontal and parietal regions (c), and the overall total number of edges (d); the boxplots of asymmetry measures: the number of asymmetric edges for nodes in the frontal and the parietal regions (e), and the overall total number of asymmetric edges (f). In (a) and (b), the edge color indicates the magnitude of the posterior inclusion probability. In (c)–(f), the alcoholic group is abbreviated as “al”, and the control group is abbreviated as “ct”.

samples. To distinguish different regions, we used light blue to highlight nodes in the frontal region, used dark green to highlight nodes in the parietal region, and used green to indicate nodes in the central and occipital regions. Comparing (a) with (b), we see that the alcoholic group contains more edges connecting the left frontal-central, right central, and right parietal regions than the control group. The control group, on the other hand, contains more edges connecting the middle and right frontal regions, as well as the left parietal region than the alcoholic group.

To further compare with established results, we calculated two summary statistics for connectivity: the number of edges connected with nodes in a specific region, and the overall total number of edges. We also calculated two additional summary statistics for asymmetry: the number of asymmetric edges for all nodes in a specific region, and the overall total number of asymmetric edges. We summarized these summary statistics across the two groups using boxplots in Figure 3 (c)–(f), and calculated the posterior probability that the alcoholic group is greater than, equal to, or less than the control group for each statistic. Results show that, with probability ≈ 1 , the alcoholic group has fewer edges than the control group in the frontal and the parietal region, and has fewer overall total number of edges; with probability 0.95, the alcoholic group has more asymmetric edges than the control group in the frontal region; and with probability ≈ 1 , the alcoholic group has higher overall total number of asymmetric edges than the control group. These results indicate that the alcoholic group exhibits decreased regional and overall connectivity, increased asymmetry in the frontal region, and increased overall asymmetry. These observations are consistent with the findings of Hayden et al. (2006), who studied the asymmetric patterns at two frontal electrodes (F3, F4) and two parietal electrodes (P3, P4) using the analysis of variance method based on the resting-state α -band power. In comparison, our analysis provides connectivity and asymmetric pattern of all 64 electrodes simultaneously whereas Hayden et al. (2006) only focuses on the four representative electrodes.

6. Discussion

We have constructed a theoretical framework for graphical models of multivariate functional data and proposed a HIWP prior for the special case of Gaussian process graphical models. For practical implementation, we have suggested a posterior inference approach based on a regularization condition, which enables posterior sampling through MCMC algorithms.

One concern is whether it is possible to perform exact posterior inference without the regularity condition on approximation, i.e., inferring the graph directly from the joint posterior $p(G|\{\mathbf{c}_i\}) \propto p(\{\mathbf{c}_i\}|G)p(G)$ based on model (4), where $p(\{\mathbf{c}_i\}|G)$ is the marginal likelihood (with the covariance kernel \mathcal{Q}_C integrated out) and $p(G)$ is the prior distribution for G . Although the above joint posterior is theoretically well-defined according to Theorem 2, exact posterior sampling is difficult due to the fact that the density function for the marginal likelihood can only be calculated on a finite dimensional projection of $\{\mathbf{c}_i\}$.

In posterior inference, the influence of the approximation error on the posterior distribution can be quantified empirically. Assuming that the functional data are pre-smoothed, the approximation error can be quantified by calculating the difference of the ℓ^2 norms between the full sequence and the truncated sequence. The influence on the posterior distribution can be quantified by measuring the sensitivity of the posterior distribution to the change of truncation (Saltelli et al., 2000). For example, based on model (4) one may calculate the Kullback-Leibler divergence for two different truncation parameters M and M' . An alternative method for pre-determining the truncation parameter is to choose a prior for M in a Bayesian hierarchical model, in which case hybrid MCMC algorithms are needed for fitting both models (4) and (11). The posterior sampling in these models would become

more complicated because the dimension of the truncated sequences and the size of the covariance matrix \mathbf{Q}_P would change whenever M is updated.

We have demonstrated the application of the proposed approach through an ERP data set. By treating ERPs as functional data, we are estimating the systematic brain connectivity that is common across a group of subjects and a time interval. For other modeling purposes, such as estimating the individual level or dynamic brain connectivity, one could use multivariate graphical models described in Carralho and West (2007) or Bihnes (2010).

We have focused on decomposable graphs. In case of non-decomposable graphs, the proposed HiWP prior may still apply if we replace the inverse-Wishart process prior for each clique with that for a prime component of the graph. For a non-complete prime component P , the inverse-Wishart processes prior for \mathbf{Q}_P is subject to extra constraint induced by missing edges.

We have applied the proposed method to graphs of small to moderate size, with number of nodes as large as 60. To deal with larger scale problems (e.g. multivariate functional data with hundreds or thousands of functional components), more efficient large-scale computational techniques such as the fast Cholesky factorization (Li et al., 2012) can be readily combined with our MCMC algorithms. Furthermore, non-MCMC algorithms may be more computationally efficient in case of large graphs. For example, based on the posterior distribution of G in (8), a fast search algorithm may be developed to search for the maximum a posteriori (MAP) solution following ideas similar to Dauriné III (2007) and Jalali et al. (2011).

Appendix A. Definitions

Definitions used in the lemmas, theorems and their proofs are listed as follows: (I) *Projection map*. Let \mathbb{R} be the real line and T be an index set. Consider the Cartesian product space $\mathbb{R}^{T \times T} = \prod_{(\alpha, \beta) \in T \times T} \mathbb{R}^{(\alpha, \beta)}$. For a fixed point $(\alpha, \beta) \in T \times T$, we define the projection map $\pi_{(\alpha, \beta)} : \mathbb{R}^{T \times T} \rightarrow \mathbb{R}^{(\alpha, \beta)}$ as $\pi_{(\alpha, \beta)}(\{x_{(l,m)} : (l, m) \in T \times T\}) = x_{(\alpha, \beta)}$. For a subset $B \subset T \times T$, we define the partial projection $\pi_B : \mathbb{R}^{T \times T} \rightarrow \mathbb{R}^B$ as $\pi_B(\{x_{(l,m)} : (l, m) \in T \times T\}) = \{x_{(s,t)} : (s, t) \in B\}$. More generally, for subsets B_1, B_2 , such that $B_2 \subset B_1 \subset T \times T$, we define the partial sub-projections $\pi_{B_2 \leftarrow B_1} : \mathbb{R}^{B_1} \rightarrow \mathbb{R}^{B_2}$, by $\pi_{B_2 \leftarrow B_1}(\{x_{(l,m)} : (l, m) \in B_1\}) = \{x_{(s,t)} : (s, t) \in B_2\}$. (II) *The pullback of a σ -algebra*. Let $\mathcal{B}_{(\alpha, \beta)}$ be a σ -algebra on $\mathbb{R}^{(\alpha, \beta)}$. We can create a σ -algebra on $\mathbb{R}^{T \times T}$ by pulling back the $\mathcal{B}_{(\alpha, \beta)}$ using the inverse of the projection map and define $\pi_{(\alpha, \beta)}^*(\mathcal{B}_{(\alpha, \beta)}) = \{\pi_{(\alpha, \beta)}^{-1}(A) : A \in \mathcal{B}_{(\alpha, \beta)}\}$. One can verify that $\pi_{(\alpha, \beta)}^*(\mathcal{B}_{(\alpha, \beta)})$ is a σ -algebra. (III) *Product σ -algebra*. We define the product σ -algebra as $\mathcal{B}(\mathbb{R}^{T \times T}) = \prod_{(\alpha, \beta) \in T \times T} \mathcal{B}_{(\alpha, \beta)}$, where $\prod_{(\alpha, \beta) \in T \times T} \mathcal{B}_{(\alpha, \beta)} = \sigma\left(\bigcup_{(\alpha, \beta) \in T \times T} \pi_{(\alpha, \beta)}^*(\mathcal{B}_{(\alpha, \beta)})\right)$. (IV) *Pushforward measure*. Given a measure $\mu_{T \times T}$ on the product σ -algebra, and a subset B of $T \times T$, we define the pushforward measure $\mu_B = (\pi_B)_* \mu_{T \times T}$ on \mathbb{R}^B as $\mu_B(A) = \mu_{T \times T}(\pi_B^{-1}(A))$ for all $A \in \mathcal{B}_B$, where $\mathcal{B}_B = \prod_{(\alpha, \beta) \in B} \mathcal{B}_{(\alpha, \beta)}$. (V) *Compatibility*. Given subsets B_1, B_2 of $T \times T$ such that $B_2 \subset B_1 \subset T \times T$, the pushforward measures μ_{B_1} and μ_{B_2} are said to obey compatibility relation if $(\pi_{B_2 \leftarrow B_1})_* \mu_{B_1} = \mu_{B_2}$.

Appendix B. Proof of Lemma 1

This proof involves some measure-theoretic arguments. The essential idea is to use disintegration theory Chang and Pollard (1997) to first construct the conditional probability measure $P_1\{\cdot | \pi_{A \cap B}(\mathbf{f}_A)\}$ on $\mathcal{B}(L^2(T_A))$, extend this to $P\{\cdot | \pi_B(\mathbf{f})\}$ on $\mathcal{B}(L^2(T_{A \cup B}))$, and finally construct the joint measure P which satisfies conditions (i)–(iii).

Denote $T_A = \bigcup_{j \in A} T_j$. Since P_1 is a finite Radon measure and the projection $\pi_{A \cap B} : L^2(T_A) \rightarrow L^2(T_{A \cap B})$ is measurable, we invoke the disintegration theorem to obtain measures $P_1\{\cdot | \pi_{A \cap B}(\mathbf{f}_A)\}$ on $\mathcal{B}(L^2(T_A))$ satisfying:

$$(a.1) \quad P_1(\mathcal{X} | \mathbf{f}_{A \cap B}) = P_1\{\mathcal{X} \cap [L^2(T_{A \cap B}) \times \{\pi_{A \cap B}(\mathbf{f}_A)\}] | \pi_{A \cap B}(\mathbf{f}_A)\},$$

$$(b.1) \quad \text{the map } \mathbf{f}_{A \cap B} \mapsto (P_1)_{\mathbf{f}_{A \cap B}} H : = \int H(\mathbf{f}_A) dP_1(\mathbf{f}_A | \mathbf{f}_{A \cap B}) \text{ is measurable for all non-negative measurable } H : L^2(T_A) \rightarrow \mathbb{R},$$

$$(c.1) \quad P_1 H = ((\pi_{A \cap B})_* P_1)(P_1)_{\mathbf{f}_{A \cap B}} H \text{ for all nonnegative measurable } H : L^2(T_A) \rightarrow \mathbb{R},$$

where $(\pi_{A \cap B})_* P_1$ is the push-forward measure of P_1 .

Now, we define the measure $P\{\cdot | \pi_B(\mathbf{f})\}$ by setting $P\{\mathcal{A} | \pi_B(\mathbf{f})\} = P_1\{\pi_A(A \cap [L^2(T_{A \setminus B}) \times \{\pi_B(\mathbf{f})\}]) | \pi_{A \cap B}(\mathbf{f})\}$. Note that this is well defined for all measurable $A \in \mathcal{B}(L^2(T_{A \cup B}))$ since the sections $\pi_A(A \cap [L^2(T_{A \setminus B}) \times \{\pi_B(\mathbf{f})\}])$ are always measurable, and also that (a) $P\{\mathcal{A} | \pi_B(\mathbf{f})\} = P\{\mathcal{A} \cap [L^2(T_{A \setminus B}) \times \{\pi_B(\mathbf{f})\}] | \pi_B(\mathbf{f})\}$ holds by construction. Now, let \mathcal{M} denote the set of measurable functions from $L^2(T_{A \cup B})$ to \mathbb{R} satisfying (b) $\mathbf{f}_B \mapsto P_B H$ is a measurable function on $L^2(T_B)$. We shall argue that \mathcal{M} is a monotone class. First,

suppose H_n is a sequence of positive measurable functions in \mathcal{M} increasing pointwise to a bounded measurable function H . For each fixed \mathbf{f}_B in $L^2(T_B)$, we then have that H_n is a sequence of positive measurable functions increasing pointwise to H , and hence the monotone convergence theorem implies $P_{T_B} H_n \rightarrow P_{T_B} H$ in an increasing manner. Since this holds for each \mathbf{f}_B , we conclude that $P_{T_B} H$ is the point-wise increasing limit of measurable functions on $L^2(T_B)$, and hence it is measurable. Moreover, it is simple to see that $P_{T_B} \mathbf{1}_{\mathcal{X} \times \mathcal{Y}} = P_1(\mathcal{X} | \mathbf{f}_{A \cap B}) \mathbf{1}_{\mathcal{Y}}(\mathbf{f}_{B \setminus A})$ is a measurable function on $L^2(T_B)$ for all $\mathcal{X} \in \mathcal{B}(L^2(T_A))$ and $\mathcal{Y} \in \mathcal{B}(L^2(T_{B \setminus A}))$, and hence $\mathbf{1}_{\mathcal{X} \times \mathcal{Y}} \in \mathcal{M}$. By the Monotone Class Theorem, we then have that all bounded measurable functions on $L^2(T_{A \cup B})$ satisfy (b), and hence it will hold for all positive measurable functions on $L^2(T_{A \cup B})$. Since (b) is satisfied for all positive measurable functions, we may define the measure $PH = P_2 P_{T_B} H$. By construction, we have that $P_1 L^2(T_{A \setminus B}) \times \{\mathbf{f}_{A \cap B}\} = P_2 P_1(L^2(T_{A \setminus B}) | \mathbf{f}_{A \cap B}) \mathbf{1}_{\mathcal{Y}}(\mathbf{f}_B) = P_2(\mathcal{Y})$ and $P_1 \mathbf{1}_{\mathcal{X} \times L^2(T_{B \setminus A})} = P_2 P_1(\mathcal{X} | \mathbf{f}_{A \cap B}) = ((\pi_{A \cap B})_* P_2) P_1(\mathcal{X} | \mathbf{f}_{A \cap B}) = ((\pi_{A \cap B})_* P_1) P_1(\mathcal{X} | \mathbf{f}_{A \cap B}) = P_1(\mathcal{X})$. Thus, we also have that $PH = P_2 P_{T_B} H = ((\pi_B)_* P) P_{\pi_B(\mathcal{G})} H$ for all measurable H , and this is the final property establishing that $P(\cdot | \mathbf{f}_B)$ is a disintegration of P with respect to the map π_B . By the disintegration theorem, this disintegration is a version of the regular conditional probability of \mathbf{f}_A given \mathbf{f}_B . Since this version only depends upon $\mathbf{f}_{A \cap B}$, we conclude that (iii) holds. Finally, we note that any other measure satisfying these properties must agree with the measure we have constructed on π -system, and therefore the uniqueness of P immediately follows. ■

Appendix C. Proof of Proposition 1

Proof. The Properties 1 - 4 in Dawid and Lauritzen (1993) are treated as axioms; they are universal properties thus also hold when X, Y, Z are random processes. Since the graph G is undirected and decomposable, the results on graphical theory in Appendix A of Dawid and Lauritzen (1993) continue to hold. Properties 1 - 4 and results in Appendix A imply that results in B1- B7 of Dawid and Lauritzen (1993) continue to hold when P is a Markov distribution constructed in Lemma 1. Theorem 2.6 and Corollary 2.7 of Dawid and Lauritzen (1993) are also implied. These results, combined with the definition of marginal distribution defined by pushforward measure and the definition of conditional probability measure based on disintegration theory, prove that Lemmas 3.1, 3.3, Theorems 3.9 - 3.10 as well as Propositions 3.11, 3.13, 3.15, 3.16, 3.18 from Dawid and Lauritzen (1993) hold. ■

Appendix D. Lemma 2 and Proof

Lemma 2 Let \mathbb{N} be the set of positive integers and I an arbitrary finite subset of it. Suppose that $\delta > 4$ is a positive integer and that $u : \mathbb{N} \times \mathbb{N} \rightarrow \mathbb{R}$ is a symmetric positive semidefinite and trace class kernel so that the matrix $\mathbf{U}_{I \times I}$ formed by $\{u(i, j), i, j \in I\}$ is symmetric positive semidefinite. Then there exists a unique probability measure μ on $(\mathbb{R}^{\mathbb{N} \times \mathbb{N}}, \mathcal{B}(\mathbb{R}^{\mathbb{N} \times \mathbb{N}}))$ satisfying

- i. $(\pi_{I \times I})_* \mu = \mu_{I \times I}$, where $\mu_{I \times I}$ is the law of $\text{IW}(\delta, \mathbf{U}_{I \times I})$ defined in Dawid (1981);
- ii. if $B = \{(\alpha_i, \beta_i)\}_{i=1}^n \subset \mathbb{N} \times \mathbb{N}$ and $\mathbf{g} = \{\alpha_i\}_{i=1}^n \cup \{\beta_i\}_{i=1}^n$, then $(\pi_B)_* \mu = \mu_B$, where $\mu_B = (\pi_{B \times \mathbb{R} \times \mathbb{R}})_* \mu_{\mathbb{R} \times \mathbb{R}}$.

Setting $\mu = \text{IWP}(\delta, \mathbf{U})$ so that $(\mathbf{U})_{ij} = u(i, j)$, we further have that if $\mathbf{Q} \sim \text{IWP}(\delta, \mathbf{U})$ and $\delta > 4$, the countably infinite array \mathbf{Q} is a positive semidefinite trace class operator on $\ell^2(\mathbb{N})$ almost surely.

Proof. Let $\mathbf{U}_{I \times I}$ be a matrix with the law $\mu_{I \times I}$. We will prove following Tao (2011, Theorem 2.4.3) as follows: (1) we verify the compatibility of μ_B for all finite $B \subset \mathbb{N} \times \mathbb{N}$. There are two successive cases we shall consider. Case 1: Suppose $I_2 \subset I_1$ are two finite subsets of \mathbb{N} , then $\mathbf{Q}_{I_2 \times I_2}$ is the sub-matrix of $\mathbf{Q}_{I_1 \times I_1}$ obtained by deleting the rows and columns with indices in $I_1 \setminus I_2$. If $\mathbf{Q}_{I_1 \times I_1}$ has law $\mu_{I_1 \times I_1} = \text{IW}(\delta, \mathbf{U}_{I_1 \times I_1})$, then $\mathbf{Q}_{I_2 \times I_2}$ has law $\text{IW}(\delta, \mathbf{U}_{I_2 \times I_2})$ due to the consistency property of the inverse-Wishart distribution (Dawid and Lauritzen, 1993, Lemma 7.4). Consequently, $(\pi_{I_2 \times I_2 \leftarrow I_1 \times I_1})_* \mu_{I_1 \times I_1} = \mu_{I_2 \times I_2}$. Case 2: Let $B_1 = \{(\alpha_i, \beta_i)\}_{i=1}^n \subset \mathbb{N} \times \mathbb{N}$ and suppose $B_2 = \{(\tilde{\alpha}_i, \tilde{\beta}_i)\}_{i=1}^m \subset B_1$. Set $\mathbf{g}_1 = \{\alpha_i\}_{i=1}^n \cup \{\beta_i\}_{i=1}^n$ and $\mathbf{g}_2 = \{\tilde{\alpha}_i\}_{i=1}^m \cup \{\tilde{\beta}_i\}_{i=1}^m$ so that $\mathbf{g}_2 \times \mathbf{g}_2 \subset \mathbf{g}_1 \times \mathbf{g}_1$. It is clear that $\pi_{B_2 \leftarrow B_1} \circ \pi_{B_1 \leftarrow \mathbf{g}_1} = \pi_{B_2 \leftarrow \mathbf{g}_1} = \pi_{B_2 \leftarrow \mathbf{g}_2 \times \mathbf{g}_2} \circ \pi_{\mathbf{g}_2 \times \mathbf{g}_2 \leftarrow \mathbf{g}_1 \times \mathbf{g}_1}$. Thus,

$$\begin{aligned} (\pi_{B_2 \leftarrow B_1})_* \mu_{B_1} &= (\pi_{B_2 \leftarrow B_1})_* (\pi_{B_1 \leftarrow \mathbf{g}_1})_* \mu_{\mathbf{g}_1 \times \mathbf{g}_1} = (\pi_{B_2 \leftarrow B_1} \circ \pi_{B_1 \leftarrow \mathbf{g}_1})_* \mu_{\mathbf{g}_1 \times \mathbf{g}_1} \\ &= (\pi_{B_2 \leftarrow \mathbf{g}_2 \times \mathbf{g}_2} \circ \pi_{\mathbf{g}_2 \times \mathbf{g}_2 \leftarrow \mathbf{g}_1 \times \mathbf{g}_1})_* \mu_{\mathbf{g}_1 \times \mathbf{g}_1} = (\pi_{B_2 \leftarrow \mathbf{g}_2 \times \mathbf{g}_2})_* (\pi_{\mathbf{g}_2 \times \mathbf{g}_2 \leftarrow \mathbf{g}_1 \times \mathbf{g}_1})_* \mu_{\mathbf{g}_1 \times \mathbf{g}_1} \\ &= (\pi_{B_2 \leftarrow \mathbf{g}_2 \times \mathbf{g}_2})_* \mu_{\mathbf{g}_2 \times \mathbf{g}_2} = \mu_{B_2}, \end{aligned}$$

where the second to last equality holds because of our demonstration in Case 1. (2) Second, we claim that the finite dimensional measure $\mu_{I \times I} = \text{IW}(\delta, \mathbf{U}_{I \times I})$ is an inner regular probability measure on the product σ -algebra $\mathcal{B}_{I \times I}$. We will show that $\mu_{I \times I}$ is a finite Borel measure on a Polish space, which then implies that $\mu_{I \times I}$ is regular, hence inner regular by Bauer (2001, Lemma 26.2). This is done through (a)-(c) as follows: (a) For finite I , $\mathbf{Q}_{I \times I}$ takes values in the space of symmetric and positive semidefinite matrices, denoted by $\Psi_{|I|}$ where $|I|$ denotes the number of elements in I . Since the subset of symmetric matrices is closed in $\mathbb{R}^{I \times I}$, it is Polish. Furthermore, the space of symmetric positive semidefinite matrices is an open convex cone in the space of symmetric matrices, hence it is Polish as well. Therefore the space $\Psi_{|I|}$ is Polish. (b) Since $\mu_{I \times I}$, the law of $\mathbf{Q}_{I \times I} \sim \text{IW}(\delta, \mathbf{U}_{I \times I})$, has an almost everywhere continuous density function, $\mu_{I \times I}$ is a measure defined by Lebesgue integration against an almost everywhere continuous function. Therefore $\mu_{I \times I}$ is Borel on $\Psi_{|I|}$. As $\Psi_{|I|} \subset \mathbb{R}^{I \times I}$, we may extend the measure $\mu_{I \times I}$ from $\Psi_{|I|}$ to $\mathbb{R}^{I \times I}$ via the Carathéodory theorem (Tao, 2011, Theorem 1.7.3). In particular, define $\mu_{I \times I}(A) = \mu_{I \times I}(A \cap \Psi_{|I|})$ for $A \in \mathcal{B}(\mathbb{R}^{I \times I})$. With extension, $\mu_{I \times I}$ is Borel on $\mathbb{R}^{I \times I}$, and the σ -algebra associated is $\mathcal{B}(\mathbb{R}^{I \times I}) = \mathcal{B}_{I \times I} = \prod_{(\alpha, \beta) \in I \times I} \mathcal{B}_{(\alpha, \beta)}$. (c) The measure $\mu_{I \times I}$ is certainly finite since it is a probability measure.

The compatibility and regularity conditions in (1) and (2) ensure that the Kolmogorov extension theorem holds. Therefore there exists a unique probability measure μ on the product σ -algebra $\mathcal{B}(\mathbb{R}^{\mathbb{N} \times \mathbb{N}})$ that satisfies (i) and (ii).

We now prove that if $\mathbf{Q} \sim \text{IWP}(\delta, \mathbf{U})$, then the countably infinite array \mathbf{Q} is a well-defined positive semidefinite trace class operator on $\ell^2(\mathbb{N})$ almost surely. First, we note that the spectral theorem ensures the existence of an orthonormal basis of $\ell^2(\mathbb{N})$ that diagonalizes \mathbf{U} . Thus, without loss of generality, we may assume that \mathbf{Q} is drawn from $\text{IWP}(\delta, \mathbf{U})$ where \mathbf{U} is a diagonal positive semidefinite trace class operator on $\ell^2(\mathbb{N})$.

First, we show each row of $\mathbf{Q}\mathbf{x}$ is finite almost surely hence is well-defined for all $\mathbf{x} \in \ell^2(\mathbb{N})$. It is sufficient to show that $E[|(\mathbf{Q}\mathbf{x})_i|] < \infty$. We note that for arbitrary $i \neq j$,

$\begin{pmatrix} q_{ii} & q_{ij} \\ q_{ij} & q_{jj} \end{pmatrix} \sim \text{IW}\left(\delta, \begin{pmatrix} u_{ii} & 0 \\ 0 & u_{jj} \end{pmatrix}\right)$ and hence using the moments of finite dimensional inverse-Wishart, $E(q_{ii}^2) = u_{ii}^2(\delta - 2)^{-1}(\delta - 4)^{-1}$, $E(q_{ij}^2) = u_{ii}u_{jj}(\delta - 1)^{-1}(\delta - 2)^{-1}(\delta - 4)^{-1}$, for $\delta > 4$. By Tonelli's theorem, we have that $E\sum_j q_{ij}^2 = \sum_j E q_{ij}^2 \leq C\sum_j u_{ii}u_{jj} = C u_{ii} \sum_j u_{jj}$, where C is the maximum of the above constants. Thus

$$E[|\langle \mathbf{Q}\mathbf{x}, \mathbf{x} \rangle|] \leq \|\mathbf{x}\| \sqrt{E\sum_j q_{ij}^2} < \infty.$$

Because there are only countably many rows, we have that $\mathbf{Q}\mathbf{x}$ is finite almost surely for all rows simultaneously. Consequently, we have that $\mathbf{Q}\mathbf{x}$ is well-defined for all $\mathbf{x} \in \ell^2(\mathbb{N})$. Now we show that $\mathbf{Q}\mathbf{x} \in \ell^2(\mathbb{N})$ almost surely. By similar considerations, let $\mathbf{q}_i = (\mathbf{Q}\mathbf{x})_i$, then $E\|\sum_i \mathbf{q}_i\|^2 \leq C\sum_i u_{ii}^2 < \infty$ and $\|\mathbf{Q}\mathbf{x}\|^2 \leq C\|\mathbf{x}\|^2 \sum_i \|q_i\|^2$; this implies that $\|\mathbf{Q}\mathbf{x}\| < \infty$ almost surely hence $\mathbf{Q}\mathbf{x} \in \ell^2(\mathbb{N})$ almost surely, and it also implies that the operator norm $\|\mathbf{Q}\|_{\text{op}}$ is finite almost surely.

By construction, we must have that \mathbf{Q} is positive semidefinite almost surely since $\langle \mathbf{Q}\mathbf{x}, \mathbf{x} \rangle = \lim_{\eta \rightarrow \infty} \langle \mathbf{Q}_\eta \mathbf{x}, \mathbf{x} \rangle \geq 0$, where \mathbf{Q}_η is the restriction of \mathbf{Q} to its n by n leading principal minor. Finally, \mathbf{Q} is trace class almost surely since $E[|\text{tr}(\mathbf{Q})|] = \sum_i E(q_{ii}) = (\delta - 2)^{-1} \sum_i u_{ii} < \infty$. ■

Appendix E. Proof of Theorem 1

Proof. Based on Lemma 2, we can define a sequence of inverse-Wishart process prior for \mathcal{Q}_C , denoted by $\mathcal{Q}_C \sim \text{IWP}(\delta, \mathcal{U}_C)$, $C \in \mathcal{C}$. These sequences are pairwise consistent due to the consistency of inverse-Wishart processes and the fact that \mathcal{U}_C is a common collection of kernels. Therefore, we can construct a unique hyper Markov law for \mathcal{Q}_C following procedure (12) - (13) of Dawid and Lauritzen (1993). And Theorem 3.9 of Dawid and Lauritzen (1993) guarantees that the constructed hyper Markov law is unique. ■

Appendix F. Proof of Proposition 2

Proof. Note that an operator drawn from a hyper-inverse-Wishart process with the parameter \mathcal{U} satisfies $\text{rank}(u_{ij}) < \infty$ for $i, j \in V$ will have finite-rank almost surely. This follows by noting that if $\mathcal{Q} \sim \text{HIWP}(\delta, \mathcal{U})$ and \mathcal{W} is a fixed unitary transformation on ℓ^2 , then $\mathcal{W}^T \mathcal{Q} \mathcal{W} \sim \text{HIWP}(\delta, \mathcal{W}^T \mathcal{U} \mathcal{W})$. Thus, choosing \mathcal{W} so that the block representation $\mathcal{W}^T \mathcal{U} \mathcal{W} = \begin{pmatrix} U & 0 \\ 0 & 0 \end{pmatrix}$ holds (here, U is a finite matrix and 0's represent infinite arrays of zeros), we see that the block representation $\mathcal{W}^T \mathcal{Q} \mathcal{W} = \begin{pmatrix} Q & 0 \\ 0 & 0 \end{pmatrix}$ holds almost surely, and that $Q \sim \text{IW}(\delta, U)$. Consequently, we have reduced to the finite-dimensional setting where the result is well-known. ■

Appendix G. Proof of Theorem 2

Proof. By the result of Proposition 1, the HIWPG prior is a strong hyper Markov law. So by Corollary 5.5 of Dawid and Lauritzen (1993), the posterior law of \mathcal{Q}_C is the unique

hyper Markov law specified by the marginal posterior laws at each clique. In other words, we just need to find the posterior law for the model: $\mathbf{c}_{i,C} \sim \text{DMGP}(\mathbf{c}_{0,C}; \mathcal{Q}_C)$ with prior $\mathcal{Q}_C \sim \text{IWP}(\delta, \mathcal{U}_C)$ for each \mathcal{Q}_C , and use them to construct the posterior law of \mathcal{Q}_C following (12) - (13) of Dawid and Lauritzen (1993). As in the last proof, choosing an appropriate transformation reduces this to the finite-dimensional case which is well-known. Finally, by Proposition 5.6 of Dawid and Lauritzen (1993), the marginal distribution of $\{c_j\}$ given $C, \mathbf{c}_0, \delta, \mathcal{U}_C$ is again Markov over G . ■

Abstract

We present Neural Autoregressive Distribution Estimation (NADE) models, which are neural network architectures applied to the problem of unsupervised distribution and density estimation. They leverage the probability product rule and a weight sharing scheme inspired from restricted Boltzmann machines, to yield an estimator that is both tractable and has good generalization performance. We discuss how they achieve competitive performance in modeling both binary and real-valued observations. We also present how deep NADE models can be trained to be agnostic to the ordering of input dimensions used by the autoregressive product rule decomposition. Finally, we also show how to exploit the topological structure of pixels in images using a deep convolutional architecture for NADE.

Keywords: deep learning, neural networks, density modeling, unsupervised learning

1. Introduction

Distribution estimation is one of the most general problems addressed by machine learning. From a good and flexible distribution estimator, in principle it is possible to solve a variety of types of inference problem, such as classification, regression, missing value imputation, and many other predictive tasks.

Currently, one of the most common forms of distribution estimation is based on directed graphical models. In general these models describe the data generation process as sampling

a latent state \mathbf{h} from some prior $p(\mathbf{h})$, followed by sampling the observed data \mathbf{x} from some conditional $p(\mathbf{x} | \mathbf{h})$. Unfortunately, this approach quickly becomes intractable and requires approximations when the latent state \mathbf{h} increases in complexity. Specifically, computing the marginal probability of the data, $p(\mathbf{x}) = \sum_{\mathbf{h}} p(\mathbf{x} | \mathbf{h}) p(\mathbf{h})$, is only tractable under fairly constraining assumptions on $p(\mathbf{x} | \mathbf{h})$ and $p(\mathbf{h})$.

Another popular approach, based on undirected graphical models, gives probabilities of the form $p(\mathbf{x}) = \exp\{\phi(\mathbf{x})\} / Z$, where ϕ is a tractable function and Z is a normalizing constant. A popular choice for such a model is the restricted Boltzmann machine (RBM), which substantially out-performs mixture models on a variety of binary data sets (Salakhutdinov and Murray, 2008). Unfortunately, we often cannot compute probabilities $p(\mathbf{x})$ exactly in undirected models either, due to the normalizing constant Z .

In this paper, we advocate a third approach to distribution estimation, based on autoregressive models and feed-forward neural networks. We refer to our particular approach as Neural Autoregressive Distribution Estimation (NADE). Its main distinguishing property is that computing $p(\mathbf{x})$ under a NADE model is tractable and can be computed efficiently, given an arbitrary ordering of the dimensions of \mathbf{x} .

The NADE framework was first introduced for binary variables by Larochelle and Murray (2011), and concurrent work by Gregor and LeCun (2011). The framework was then generalized to real-valued observations (Urias et al., 2013), and to versions based on deep neural networks that can model the observations in any order (Urias et al., 2014). This paper pulls together an extended treatment of these papers, with more experimental results, including some by Urias (2015). We also report new work on modeling 2D images by incorporating convolutional neural networks into the NADE framework. For each type of data, we're able to reach competitive results, compared to popular directed and undirected graphical model alternatives.

2. NADE

We consider the problem of modeling the distribution $p(\mathbf{x})$ of input vector observations \mathbf{x} . For now, we will assume that the dimensions of \mathbf{x} are binary, that is $x_d \in \{0, 1\} \forall d$. The model generalizes to other data types, which is explored later (Section 3) and in other work (Section 8).

NADE begins with the observation that any D -dimensional distribution $p(\mathbf{x})$ can be factored into a product of one-dimensional distributions, in any order o (a permutation of the integers $1, \dots, D$):

$$p(\mathbf{x}) = \prod_{d=1}^D p(x_{o_d} | \mathbf{x}_{o_{<d}}). \quad (1)$$

Here $o_{<d}$ contains the first $d - 1$ dimensions in ordering o and $\mathbf{x}_{o_{<d}}$ is the corresponding subvector for these dimensions. Thus, one can define an 'autoregressive' generative model of the data simply by specifying a parameterization of all D conditionals $p(x_{o_d} | \mathbf{x}_{o_{<d}})$.

Frey et al. (1996) followed this approach and proposed using simple (log-)linear logistic regression models for these conditionals. This choice yields surprisingly competitive results, but are not competitive with non-linear models such as an RBM. Bengio and Bengio (2000) proposed a more flexible approach, with a single-layer feed-forward neural network for each

conditional. Moreover, they allowed connections between the output of each network and the hidden layer of networks for the conditionals appearing earlier in the autoregressive ordering. Using neural networks led to some improvements in modeling performance, though at the cost of a really large model for very high-dimensional data.

In NADE, we also model each conditional using a feed-forward neural network. Specifically, each conditional $p(x_{o_d} | \mathbf{x}_{<d})$ is parameterized as follows:

$$p(x_{o_d} = 1 | \mathbf{x}_{o_{<d}}) = \text{sigm}(\mathbf{V}_{o_d} \mathbf{h}_{o_d} + b_{o_d}) \quad (2)$$

$$\mathbf{h}_d = \text{sigm}(\mathbf{W}_{\cdot, o_{<d}} \mathbf{x}_{o_{<d}} + \mathbf{c}), \quad (3)$$

where $\text{sigm}(a) = 1/(1 + e^{-a})$ is the logistic sigmoid, and with H as the number of hidden units, $\mathbf{V} \in \mathbb{R}^{D \times H}$, $\mathbf{b} \in \mathbb{R}^D$, $\mathbf{W} \in \mathbb{R}^{H \times D}$, $\mathbf{c} \in \mathbb{R}^H$ are the parameters of the NADE model.

The hidden layer matrix \mathbf{W} and bias \mathbf{c} are shared by each hidden layer \mathbf{h}_d (which are all of the same size). This parameter sharing scheme (illustrated in Figure 1) means that NADE has $O(HD)$ parameters, rather than $O(HD^2)$ required if the neural networks were separate. Limiting the number of parameters can reduce the risk of over-fitting. Another advantage is that all D hidden layers \mathbf{h}_d can be computed in $O(HD)$ time instead of $O(HD^2)$. Denoting the pre-activation of the d^{th} hidden layer as $\mathbf{a}_d = \mathbf{W}_{\cdot, o_{<d}} \mathbf{x}_{o_{<d}} + \mathbf{c}$, this complexity is achieved by using the recurrence

$$\mathbf{h}_1 = \text{sigm}(\mathbf{a}_1), \quad \text{where } \mathbf{a}_1 = \mathbf{c} \quad (4)$$

$$\mathbf{h}_d = \text{sigm}(\mathbf{a}_d), \quad \text{where } \mathbf{a}_d = \mathbf{W}_{\cdot, o_{<d}} \mathbf{x}_{o_{<d}} + \mathbf{c} = \mathbf{W}_{\cdot, o_{d-1}} \mathbf{x}_{o_{d-1}} + \mathbf{a}_{d-1} \quad (5)$$

for $d \in \{2, \dots, D\}$,

where Equation 5 given vector \mathbf{a}_{d-1} can be computed in $O(H)$. Moreover, the computation of Equation 2 given \mathbf{h} is also $O(H)$. Thus, computing $p(\mathbf{x})$ from D conditional distributions (Equation 1) costs $O(HD)$ for NADE. This complexity is comparable to that of regular feed-forward neural network models.

NADE can be trained by maximum likelihood, or equivalently by minimizing the average negative log-likelihood,

$$\frac{1}{N} \sum_{n=1}^N -\log p(\mathbf{x}^{(n)}) = \frac{1}{N} \sum_{n=1}^N \sum_{d=1}^D -\log p(x_{o_d}^{(n)} | \mathbf{x}_{o_{<d}}^{(n)}), \quad (6)$$

usually by stochastic (minibatch) gradient descent. As probabilities $p(\mathbf{x})$ cost $O(HD)$, gradients of the negative log-probability of training examples can also be computed in $O(HD)$. Algorithm 1 describes the computation of both $p(\mathbf{x})$ and the gradients of $-\log p(\mathbf{x})$ with respect to NADE's parameters.

2.1 Relationship with the RBM

The proposed weight-tying for NADE isn't simply motivated by computational reasons. It also reflects the computations of approximation inference in the RBM.

Denoting the energy function and distribution under an RBM as

$$E(\mathbf{x}, \mathbf{h}) = -\mathbf{h}^T \mathbf{W} \mathbf{x} - \mathbf{b}^T \mathbf{x} - \mathbf{c}^T \mathbf{h} \quad (7)$$

$$p(\mathbf{x}, \mathbf{h}) = \exp\{-E(\mathbf{x}, \mathbf{h})\} / Z, \quad (8)$$

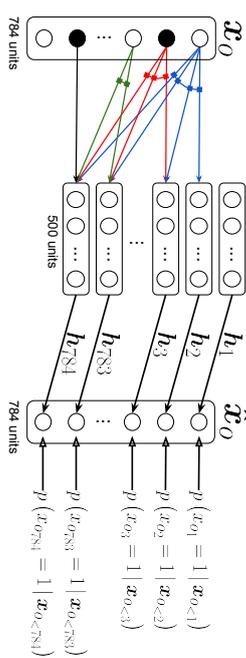

Figure 1: Illustration of a NADE model. In this example, in the input layer, units with value 0 are shown in black while units with value 1 are shown in white. The dashed border represents a layer pre-activation. The outputs $\hat{\mathbf{x}}_0$ give predictive probabilities for each dimension of a vector \mathbf{x}_0 , given elements earlier in some ordering. There is no path of connections between an output and the value being predicted, or elements of \mathbf{x}_0 later in the ordering. Arrows connected together correspond to connections with shared (tied) parameters.

computing all conditionals

$$p(\mathbf{x}_{o_d} | \mathbf{x}_{o_{<d}}) = \sum_{\mathbf{x}_{o_{>d}} \in \{0,1\}^{D-d}} \sum_{\mathbf{h} \in \{0,1\}^H} \exp\{-E(\mathbf{x}, \mathbf{h})\} / Z(\mathbf{x}_{o_{<d}}) \quad (9)$$

$$Z(\mathbf{x}_{o_{<d}}) = \sum_{\mathbf{x}_{o_{>d}} \in \{0,1\}^{D-d+1}} \sum_{\mathbf{h} \in \{0,1\}^H} \exp\{-E(\mathbf{x}, \mathbf{h})\} \quad (10)$$

is intractable. However, these could be approximated using mean-field variational inference. Specifically, consider the conditional over x_{o_d} , $\mathbf{x}_{o_{>d}}$ and \mathbf{h} instead:

$$p(x_{o_d}, \mathbf{x}_{o_{>d}}, \mathbf{h} | \mathbf{x}_{o_{<d}}) = \exp\{-E(\mathbf{x}, \mathbf{h})\} / Z(\mathbf{x}_{o_{<d}}). \quad (11)$$

A mean-field approach could first approximate this conditional with a factorized distribution

$$q(x_{o_d}, \mathbf{x}_{o_{>d}}, \mathbf{h} | \mathbf{x}_{o_{<d}}) = \mu_d^i(d)^{x_{o_d}} (1 - \mu_d^i(d))^{1-x_{o_d}} \prod_{j>d} \mu_j(d)^{x_{o_j}} (1 - \mu_j(d))^{1-x_{o_j}} \prod_k \tau_k(d)^{h_k} (1 - \tau_k(d))^{1-h_k}, \quad (12)$$

where $\mu_j(d)$ is the marginal probability of x_{o_j} being equal to 1, given $\mathbf{x}_{o_{<d}}$. Similarly, $\tau_k(d)$ is the marginal for hidden variable h_k . The dependence on d comes from conditioning on $\mathbf{x}_{o_{<d}}$, that is on the first $d-1$ dimensions of \mathbf{x} in ordering o .

For some d , a mean-field approximation is obtained by finding the parameters $\mu_j(d)$ for $j \in \{d, \dots, D\}$ and $\tau_k(d)$ for $k \in \{1, \dots, H\}$ which minimize the KL divergence between $q(x_{o_d}, \mathbf{x}_{o_{>d}}, \mathbf{h} | \mathbf{x}_{o_{<d}})$ and $p(x_{o_d}, \mathbf{x}_{o_{>d}}, \mathbf{h} | \mathbf{x}_{o_{<d}})$. This is usually done by finding message

Algorithm 1 Computation of $p(\mathbf{x})$ and learning gradients for NADE.

Input: training observation vector \mathbf{x} and ordering o of the input dimensions.

Output: $p(\mathbf{x})$ and gradients of $-\log p(\mathbf{x})$ on parameters.

```

# Computing  $p(\mathbf{x})$ 
 $\mathbf{a}_1 \leftarrow \mathbf{c}$ 
 $p(\mathbf{x}) \leftarrow 1$ 
for  $d$  from 1 to  $D$  do
   $\mathbf{h}_d \leftarrow \text{sigm}(\mathbf{a}_d)$ 
   $p(x_{o_d} = 1 | \mathbf{x}_{o_{<d}}) \leftarrow \text{sigm}(\mathbf{V}_{o_d} \mathbf{h}_d + b_{o_d})$ 
   $p(\mathbf{x}) \leftarrow p(\mathbf{x}) (p(x_{o_d} = 1 | \mathbf{x}_{o_{<d}}))^{x_{o_d}} + (1 - p(x_{o_d} = 1 | \mathbf{x}_{o_{<d}}))^{1-x_{o_d}}$ 
   $\mathbf{a}_{d+1} \leftarrow \mathbf{a}_d + \mathbf{W}_{\cdot, o_d} x_{o_d}$ 
end for

```

   $\delta \mathbf{W}_{\cdot, o_d} \leftarrow \delta \mathbf{a}_d x_{o_d}$ 
   $\delta \mathbf{a}_{d-1} \leftarrow \delta \mathbf{a}_d + \delta \mathbf{h}_d \odot \mathbf{h}_d \odot (1 - \mathbf{h}_d)$ 
end for
return  $p(\mathbf{x})$ ,  $\delta \mathbf{b}$ ,  $\delta \mathbf{V}$ ,  $\delta \mathbf{c}$ ,  $\delta \mathbf{W}$ 

```

passing updates that each set the derivatives of the KL divergence to 0 for some of the parameters of $q(x_{o_d}, \mathbf{x}_{o_{>d}}, \mathbf{h} | \mathbf{x}_{o_{<d}})$ given others.

For some d , let us fix $\mu_j(d) = x_{o_d}$ for $j < d$, leaving only $\mu_j(d)$ for $j > d$ to be found. The KL-divergence develops as follows:

$$\begin{aligned}
& \text{KL}(q(x_{o_d}, \mathbf{x}_{o_{>d}}, \mathbf{h} | \mathbf{x}_{o_{<d}}) \| p(x_{o_d}, \mathbf{x}_{o_{>d}}, \mathbf{h} | \mathbf{x}_{o_{<d}})) \\
&= - \sum_{x_{o_d}, \mathbf{x}_{o_{>d}}, \mathbf{h}} q(x_{o_d}, \mathbf{x}_{o_{>d}}, \mathbf{h} | \mathbf{x}_{o_{<d}}) \log p(x_{o_d}, \mathbf{x}_{o_{>d}}, \mathbf{h} | \mathbf{x}_{o_{<d}}) \\
&+ \sum_{x_{o_d}, \mathbf{x}_{o_{>d}}, \mathbf{h}} q(x_{o_d}, \mathbf{x}_{o_{>d}}, \mathbf{h} | \mathbf{x}_{o_{<d}}) \log q(x_{o_d}, \mathbf{x}_{o_{>d}}, \mathbf{h} | \mathbf{x}_{o_{<d}}) \\
&= \log Z(\mathbf{x}_{o_{<d}}) - \sum_j \sum_k \tau_k(d) W_{k, o_j} \mu_j(d) - \sum_j b_{o_j} \mu_j(d) - \sum_k c_k \tau_k(d) \\
&+ \sum_{j \geq d} (\mu_j(d) \log \mu_j(d) + (1 - \mu_j(d)) \log(1 - \mu_j(d))) \\
&+ \sum_k (\tau_k(d) \log \tau_k(d) + (1 - \tau_k(d)) \log(1 - \tau_k(d))).
\end{aligned}$$

Then, we can take the derivative with respect to $\tau_k(d)$ and set it to 0, to obtain:

$$\begin{aligned}
0 &= \frac{\partial \text{KL}(q(x_{o_d}, \mathbf{x}_{o_{>d}}, \mathbf{h} | \mathbf{x}_{o_{<d}}) \| p(x_{o_d}, \mathbf{x}_{o_{>d}}, \mathbf{h} | \mathbf{x}_{o_{<d}}))}{\partial \tau_k(d)} \\
0 &= -c_k - \sum_j W_{k, o_j} \mu_j(d) + \log \left(\frac{\tau_k(d)}{1 - \tau_k(d)} \right) \\
\frac{\tau_k(d)}{1 - \tau_k(d)} &= \exp \left\{ c_k + \sum_j W_{k, o_j} \mu_j(d) \right\} \\
\tau_k(d) &= \frac{\exp \left\{ c_k + \sum_j W_{k, o_j} \mu_j(d) \right\}}{1 + \exp \left\{ c_k + \sum_j W_{k, o_j} \mu_j(d) \right\}} \\
\tau_k(d) &= \text{sigm} \left(c_k + \sum_{j \geq d} W_{k, o_j} \mu_j(d) + \sum_{j < d} W_{k, o_j} x_{o_j} \right).
\end{aligned} \tag{13}$$

where in the last step we have used the fact that $\mu_j(d) = x_{o_j}$ for $j < d$. Equation 14 would correspond to the message passing updates of the hidden unit marginals $\tau_k(d)$ given the marginals of input $\mu_j(d)$.

Similarly, we can set the derivative with respect to $\mu_j(d)$ for $j \geq d$ to 0 and obtain:

$$\begin{aligned}
0 &= \frac{\partial \text{KL}(q(x_{o_d}, \mathbf{x}_{o_{>d}}, \mathbf{h} | \mathbf{x}_{o_{<d}}) \| p(x_{o_d}, \mathbf{x}_{o_{>d}}, \mathbf{h} | \mathbf{x}_{o_{<d}}))}{\partial \mu_j(d)} \\
0 &= -b_{o_j} - \sum_k \tau_k(d) W_{k, o_j} + \log \left(\frac{\mu_j(d)}{1 - \mu_j(d)} \right) \\
\frac{\mu_j(d)}{1 - \mu_j(d)} &= \exp \left\{ b_{o_j} + \sum_k \tau_k(d) W_{k, o_j} \right\} \\
\mu_j(d) &= \frac{\exp \left\{ b_{o_j} + \sum_k \tau_k(d) W_{k, o_j} \right\}}{1 + \exp \left\{ b_{o_j} + \sum_k \tau_k(d) W_{k, o_j} \right\}} \\
\mu_j(d) &= \text{sigm} \left(b_{o_j} + \sum_k \tau_k(d) W_{k, o_j} \right).
\end{aligned} \tag{15}$$

Equation 15 would correspond to the message passing updates of the input marginals $\mu_j(d)$ given the hidden layer marginals $\tau_k(d)$. The complete mean-field algorithm would thus alternate between applying the updates of Equations 14 and 15, right to left.

We now notice that Equation 14 corresponds to NADE's hidden layer computation (Equation 3) where $\mu_j(d) = 0 \forall j \geq d$. Also, Equation 15 corresponds to NADE's output layer computation (Equation 2) where $j = d$, $\tau_k(d) = h_{d,k}$ and $\mathbf{W}^\top = \mathbf{V}$. Thus, in short, NADE's forward pass is equivalent to applying a single pass of mean-field inference to approximate all the conditionals $p(\mathbf{x}_{o_d} | \mathbf{x}_{o_{<d}})$ of an RBM, where initially $\mu_j(d) = 0$ and where a separate matrix \mathbf{V} is used for the hidden-to-input messages. A generalization of NADE based on this connection to mean field inference has been further explored by Raiko et al. (2014).

3. NADE for Non-Binary Observations

So far we have only considered the case of binary observations x_i . However, the framework of NADE naturally extends to distributions over other types of observations.

In the next section, we discuss the case of real-valued observations, which is one of the most general cases of non-binary observations and provides an illustrative example of the technical considerations one faces when extending NADE to new observations.

3.1 RNADE: Real-Valued NADE

A NADE model for real-valued data could be obtained by applying the derivations shown in Section 2.1 to the Gaussian-RBM (Welling et al., 2005). The resulting neural network would output the mean of a Gaussian with fixed variance for each of the conditionals in Equation 1. Such a model is not competitive with mixture models, for example on perceptual data sets (Uria, 2015). However, we can explore alternative models by making the neural network for each conditional distribution output the parameters of a distribution that’s not a fixed-variance Gaussian.

In particular, a mixture of one-dimensional Gaussians for each autoregressive conditional provides a flexible model. Given enough components, a mixture of Gaussians can model any continuous distribution to arbitrary precision. The resulting model can be interpreted as a sequence of mixture density networks (Bishop, 1994) with shared parameters. We call this model RNADE-MoG. In RNADE-MoG, each of the conditionals is modeled by a mixture of Gaussians:

$$p(\pi_{o_d} | \mathbf{x}_{o_{<d}}) = \sum_{c=1}^C \pi_{o_d,c} \mathcal{N}(\pi_{o_d}; \mu_{o_d,c}, \sigma_{o_d,c}^2), \quad (16)$$

where the parameters are set by the outputs of a neural network:

$$\pi_{o_d,c} = \frac{\exp \left\{ z_{o_d,c}^{(\pi)} \right\}}{\sum_{c=1}^C \exp \left\{ z_{o_d,c}^{(\pi)} \right\}} \quad (17)$$

$$\mu_{o_d,c} = z_{o_d,c}^{(\mu)} \quad (18)$$

$$\sigma_{o_d,c} = \exp \left\{ z_{o_d,c}^{(\sigma)} \right\} \quad (19)$$

$$z_{o_d,c}^{(\pi)} = b_{o_d,c}^{(\pi)} + \sum_{k=1}^H V_{o_d,k,c}^{(\pi)} h_{d,k} \quad (20)$$

$$z_{o_d,c}^{(\mu)} = b_{o_d,c}^{(\mu)} + \sum_{k=1}^H V_{o_d,k,c}^{(\mu)} h_{d,k} \quad (21)$$

$$z_{o_d,c}^{(\sigma)} = b_{o_d,c}^{(\sigma)} + \sum_{k=1}^H V_{o_d,k,c}^{(\sigma)} h_{d,k} \quad (22)$$

Parameter sharing conveys the same computational and statistical advantages as it does in the binary NADE.

Different one dimensional conditional forms may be preferred, for example due to limited data set size or domain knowledge about the form of the conditional distributions. Other choices, like single variable-variance Gaussians, sinh-arcsinh distributions, and mixtures of Laplace distributions, have been examined by Uria (2015).

Training an RNADE can still be done by stochastic gradient descent on the parameters of the model with respect to the negative log-density of the training set. It was found empirically (Uria et al., 2013) that stochastic gradient descent leads to better parameter configurations when the gradient of the mean $\left(\frac{\partial \mu}{\partial \pi_{o_d,c}} \right)$ was multiplied by the standard deviation $(\sigma_{o_d,c})$.

4. Orderless and Deep NADE

The fixed ordering of the variables in a NADE model makes the exact calculation of arbitrary conditional probabilities computationally intractable. Only a small subset of conditional distributions, those where the conditioned variables are at the beginning of the ordering and marginalized variables at the end, are computationally tractable.

Another limitation of NADE is that a naive extension to a deep version, with multiple layers of hidden units, is computationally expensive. Deep neural networks (Bengio, 2009; LeCun et al., 2015) are at the core of state-of-the-art models for supervised tasks like image recognition (Krizhevsky et al., 2012) and speech recognition (Dahl et al., 2013). The same inductive bias should also provide better unsupervised models. However, extending the NADE framework to network architectures with several hidden layers, by introducing extra non-linear calculations between Equations 3 and 2, increases its complexity to cubic in the number of units per layer. Specifically, the cost becomes $O(DH^2L)$, where L stands for the number of hidden layers and can be assumed to be a small constant, D is the number of variables modeled, and H is the number of hidden units, which we assumed to be of the same order as D . This increase in complexity is caused by no longer being able to share hidden layer computations across the conditionals in Equation 1, after the non-linearity in the first layer.

In this section we describe an order-agnostic training procedure, DeepNADE (Uria et al., 2014), which will address both of the issues above. This procedure trains a single deep neural network that can assign a conditional distribution to any variable given any subset of the others. This network can then provide the conditionals in Equation 1 for any ordering of the input observations. Therefore, the network defines a factorial number of different models with shared parameters, one for each of the $D!$ orderings of the inputs. At test time, given an inference task, the most convenient ordering of variables can be used. The models for different orderings will not be consistent with each other: they will assign different probabilities to a given test vector. However, we can use the models’ differences to our advantage by creating ensembles of NADE models (Section 4.1), which results in better estimators than any single NADE. Moreover, the training complexity of our procedure increases linearly with the number of hidden layers $O(H^2L)$, while remaining quadratic in the size of the network’s layers.

We first describe the model for an L -layer neural network modeling binary variables. A conditional distribution is obtained directly from a hidden unit in the final layer:

$$p(x_{o_d} = 1 \mid \mathbf{x}_{o_{<d}}, \boldsymbol{\theta}, o_{<d}, o_d) = \mathbf{h}_{o_d}^{(L)}. \quad (23)$$

This hidden unit is computed from previous layers, all of which can only depend on the $\mathbf{x}_{o_{<d}}$ variables that are currently being conditioned on. We remove the other variables from the computation using a binary mask,

$$\mathbf{m}_{o_{<d}} = [1_{1 \in o_{<d}}, 1_{2 \in o_{<d}}, \dots, 1_{D \in o_{<d}}], \quad (24)$$

which is element-wise multiplied with the inputs before computing the remaining layers as in a standard neural network:

$$\mathbf{h}^{(0)} = \mathbf{x} \odot \mathbf{m}_{o_{<d}} \quad (25)$$

$$\mathbf{a}^{(\ell)} = \mathbf{W}^{(\ell)} \mathbf{h}^{(\ell-1)} + \mathbf{b}^{(\ell)} \quad (26)$$

$$\mathbf{h}^{(\ell)} = \sigma(\mathbf{a}^{(\ell)}) \quad (27)$$

$$\mathbf{h}^{(L)} = \text{sigm}(\mathbf{a}^{(L)}). \quad (28)$$

The network is specified by a free choice of the activation function $\sigma(\cdot)$, and learnable parameters $\mathbf{W}^{(\ell)} \in \mathbb{R}^{H^{(\ell)} \times H^{(\ell-1)}}$ and $\mathbf{b}^{(\ell)} \in \mathbb{R}^{H^{(\ell)}}$, where $H^{(\ell)}$ is the number of units in the ℓ -th layer. As layer zero is the masked input, $H^{(0)} = D$. The final L -th layer needs to be able to provide predictions for any element (Equation 23) and so also has D units.

To train a DeepNADE, the ordering of the variables is treated as a stochastic variable with a uniform distribution. Moreover, since we wish DeepNADE to provide good predictions for any ordering, we optimize the expected likelihood over the ordering of variables:

$$\mathcal{J}(\boldsymbol{\theta}) = \mathbb{E}_{o \in D!} [-\log p(\mathbf{X} \mid \boldsymbol{\theta}, o)] \propto \mathbb{E}_{o \in D!} \mathbb{E}_{\mathbf{x} \in \mathcal{X}} [-\log p(\mathbf{x} \mid \boldsymbol{\theta}, o)], \quad (29)$$

where we've made the dependence on the ordering o and the network's parameters $\boldsymbol{\theta}$ explicit, $D!$ stands for the set of all orderings (the permutations of D elements) and \mathbf{x} is a uniformly sampled data point from the training set \mathcal{X} . Using NADE's expression for the density of a data point in Equation 1 we have

$$\mathcal{J}(\boldsymbol{\theta}) = \mathbb{E}_{o \in D!} \mathbb{E}_{\mathbf{x} \in \mathcal{X}} \sum_{d=1}^D -\log p(x_{o_d} \mid \mathbf{x}_{o_{<d}}, \boldsymbol{\theta}, o), \quad (30)$$

where d indexes the elements in the ordering, o , of the variables. By moving the expectation over orderings inside the sum over the elements of the ordering, the ordering can be split in three parts: $o_{<d}$ (the indices of the $d-1$ first dimensions in the ordering), o_d (the index of the d -th variable) and $o_{>d}$ (the indices of the remaining dimensions). Therefore, the loss function can be rewritten as:

$$\mathcal{J}(\boldsymbol{\theta}) = \mathbb{E}_{\mathbf{x} \in \mathcal{X}} \sum_{d=1}^D \mathbb{E}_{o_{<d}} \mathbb{E}_{o_d} \mathbb{E}_{o_{>d}} [-\log p(x_{o_d} \mid \mathbf{x}_{o_{<d}}, \boldsymbol{\theta}, o_{<d}, o_d, o_{>d})]. \quad (31)$$

The value of each of these terms does not depend on $o_{>d}$. Therefore, it can be simplified as:

$$\mathcal{J}(\boldsymbol{\theta}) = \mathbb{E}_{\mathbf{x} \in \mathcal{X}} \sum_{d=1}^D \mathbb{E}_{o_{<d}} \mathbb{E}_{o_d} [-\log p(x_{o_d} \mid \mathbf{x}_{o_{<d}}, \boldsymbol{\theta}, o_{<d}, o_d)]. \quad (32)$$

In practice, this loss function will have a very high number of terms and will have to be approximated by sampling \mathbf{x} , d and $o_{<d}$. The innermost expectation over values of o_d can be calculated cheaply, because all of the neural network computations depend only on the masked input $\mathbf{x}_{o_{<d}}$, and can be reused for each possible o_d . Assuming all orderings are equally probable, we will estimate $\mathcal{J}(\boldsymbol{\theta})$ by:

$$\hat{\mathcal{J}}(\boldsymbol{\theta}) = \frac{D}{D-d+1} \sum_{o_d} -\log p(x_{o_d} \mid \mathbf{x}_{o_{<d}}, \boldsymbol{\theta}, o_{<d}, o_d), \quad (33)$$

which is an unbiased estimator of Equation 29. Therefore, training can be done by descent on the gradient of $\hat{\mathcal{J}}(\boldsymbol{\theta})$.

For binary observations, we use the cross-entropy scaled by a factor of $\frac{D}{D-d+1}$ as the training loss which corresponds to minimizing $\hat{\mathcal{J}}$:

$$\mathcal{J}(\mathbf{x}) = \frac{D}{D-d+1} \mathbf{m}_{o_{>d}}^\top (\mathbf{x} \odot \log(\mathbf{h}^{(L)}) + (1-\mathbf{x}) \odot \log(1-\mathbf{h}^{(L)})). \quad (34)$$

Differentiating this cost involves backpropagating the gradients of the cross-entropy only from the outputs in $o_{>d}$ and rescaling them by $\frac{D}{D-d+1}$.

The resulting training procedure resembles that of a denoising autoencoder (Vincent et al., 2008). Like the autoencoder, D outputs are used to predict D inputs corrupted by a random masking process ($\mathbf{m}_{o_{<d}}$ in Equation 25). A single forward pass can compute $\mathbf{h}_{o_{>d}}^{(L)}$, which provides a prediction $p(x_{o_d} = 1 \mid \mathbf{x}_{o_{<d}}, \boldsymbol{\theta}, o_{<d}, o_d)$ for every masked variable, which could be used next in an ordering starting with $o_{<d}$. Unlike the autoencoder, the outputs for variables corresponding to those provided in the input (not masked out) are ignored.

In this order-agnostic framework, missing variables and zero-valued observations are indistinguishable by the network. This shortcoming can be alleviated by concatenating the inputs to the network (masked variables $\mathbf{x} \odot \mathbf{m}_{o_{<d}}$) with the mask $\mathbf{m}_{o_{<d}}$. Therefore we advise substituting the input described in Equation 25 with

$$\mathbf{h}^{(0)} = \text{concat}(\mathbf{x} \odot \mathbf{m}_{o_{<d}}, \mathbf{m}_{o_{<d}}). \quad (35)$$

We found this modification to be important in order to obtain competitive statistical performance (see Table 3). The resulting neural network is illustrated in Figure 2.

4.1 Ensembles of NADE Models

As mentioned, the DeepNADE parameter fitting procedure effectively produces a factorial number of different NADE models, one for each ordering of the variables. These models will not, in general, assign the same probability to any particular data point. This disagreement is undesirable if we require consistent inferences for different inference problems, as it will preclude the use of the most convenient ordering of variables for each inference task.

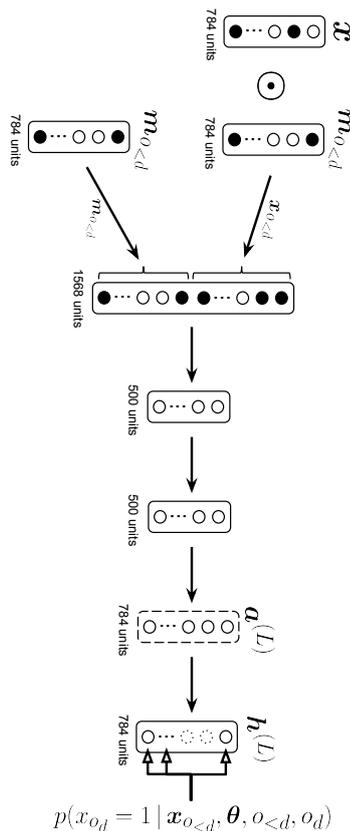

Figure 2: Illustration of a DeepNADe model with two hidden layers. The dashed border represents a layer pre-activation. Units with value 0 are shown in black while units with value 1 are shown in white. A mask $m_{o_{<d}}$ specifies a subset of variables to condition on. A conditional or predictive probability of the remaining variables is given in the final layer. The output units with a corresponding input mask of value 1 (shown with dotted contour) are not involved in DeepNADe’s training loss (Equation 34).

However, it is possible to use this variability across the different orderings to our advantage by combining several models. A usual approach to improve on a particular estimator is to construct an ensemble of multiple, strong but different estimators, e.g. using bagging (Breiman and Cutler, 1994) or stacking (Smyth and Wolpert, 1999). The DeepNADe training procedure suggests a way of generating ensembles of NADe models: take a set of uniformly distributed orderings $\{o^{(k)}\}_{k=1}^K$ over the input variables and use the average probability $\frac{1}{K} \sum_{k=1}^K p(\mathbf{x} | \theta, o^{(k)})$ as an estimator.

The use of an ensemble increases the test-time cost of density estimation linearly with the number of orderings used. The complexity of sampling does not change however: after one of the K orderings is chosen at random, the single corresponding NADe is sampled. Importantly, the cost of training also remains the same, unlike other ensemble methods such as bagging. Furthermore, the number of components can be chosen after training and even adapted to a computational budget on the fly.

5. ConvNADe: Convolutional NADe

One drawback of NADe (and its variants so far) is the lack of a mechanism for truly exploiting the high-dimensional structure of the data. For example, when using NADe on binarized MNIST, we first need to flatten the 2D images before providing them to the model as a vector. As the spatial topology is not provided to the network, it can’t use this information to share parameters and may learn less quickly.

Recently, convolutional neural networks (CNN) have achieved state-of-the-art performance on many supervised tasks related to images (Krizhevsky et al. (2012)). Briefly, CNNs are composed of convolutional layers, each one having multiple learnable filters. The outputs of a convolutional layer are feature maps and are obtained by the convolution on the input image (or previous feature maps) of a linear filter, followed by the addition of a bias and the application of a non-linear activation function. Thanks to the convolution, spatial structure in the input is preserved and can be exploited. Moreover, as per the definition of a convolution the same filter is reused across all sub-regions of the entire image (or previous feature maps), yielding a parameter sharing that is natural and sensible for images.

The success of CNNs raises the question: can we exploit the spatial topology of the inputs while keeping NADe’s autoregressive property? It turns out we can, simply by replacing the fully connected hidden layers of a DeepNADe model with convolutional layers. We thus refer to this variant as Convolutional NADe (ConvNADe).

First we establish some notation that we will use throughout this section. Without loss of generality, let the input $\mathbf{X} \in \{0, 1\}^{N \times N \times N}$ be a square binary image of size $N \times N$ and every convolution filter $\mathbf{W}_{ij}^{(\ell)} \in \mathbb{R}^{N_W^{(\ell)} \times N_W^{(\ell)}}$ connecting two feature maps $\mathbf{H}_i^{(\ell-1)}$ and $\mathbf{H}_j^{(\ell)}$ also be square with their size $N_W^{(\ell)}$ varying for each layer ℓ . We also define the following mask $\mathbf{M}_{o_{<d}} \in \{0, 1\}^{N \times N \times N}$, which is 1 for the locations of the first $d - 1$ pixels in the ordering o . Formally, Equation 26 is modified to use convolutions instead of dot products. Specifically for an L -layer convolutional neural network that preserves the input shape (explained below) we have

$$p(x_{o_d} = 1 | \mathbf{x}_{o_{<d}}, \theta, o_{>d}, o_d) = \text{vec} \left(\mathbf{H}_1^{(L)} \right)_{o_d}, \quad (36)$$

with

$$\mathbf{H}_1^{(0)} = \mathbf{X} \odot \mathbf{M}_{o_{<d}} \quad (37)$$

$$\mathbf{A}_j^{(\ell)} = h_j^{(\ell)} + \sum_{i=1}^{H^{(\ell-1)}} \mathbf{H}_i^{(\ell-1)} \otimes \mathbf{W}_{ij}^{(\ell)} \quad (38)$$

$$\mathbf{H}_j^{(\ell)} = \sigma \left(\mathbf{A}_j^{(\ell)} \right) \quad (39)$$

$$\mathbf{H}_j^{(L)} = \text{sigm} \left(\mathbf{A}_j^{(L)} \right), \quad (40)$$

where $H^{(\ell)}$ is the number of feature maps output by the ℓ -th layer and $\mathbf{h}^{(\ell)} \in \mathbb{R}^{H^{(\ell)}}$, $\mathbf{W}^{(\ell)} \in \mathbb{R}^{H^{(\ell-1)} \times H^{(\ell)} \times N_W^{(\ell)} \times N_W^{(\ell)}}$, with \odot denoting the element-wise multiplication, $\sigma(\cdot)$ being any activation function and $\text{vec}(\mathbf{X}) \rightarrow \mathbf{x}$ is the concatenation of every row in \mathbf{X} . Note that $H^{(0)}$ corresponds to the number of channels the input images have.

For notational convenience, we use \otimes to denote both “valid” convolutions and “full” convolutions, instead of introducing bulky notations to differentiate these cases. The “valid” convolutions only apply a filter to complete patches of the image, resulting in a smaller image (its shape is decreased to $N \times N - N_W^{(\ell)} + 1$). Alternatively, “full” convolutions zero-pad the contour of the image before applying the convolution, thus expanding the image (its shape is increased to $N \times N + N_W^{(\ell)} - 1$). Which one is used should be self-explanatory depending on the context. Note that we only use convolutions with a stride of 1.

Moreover, in order for ConvNADE to output conditional probabilities as shown in Equation 36, the output layer must have only one feature map $\mathbf{H}_1^{(L)}$, whose dimension matches the dimension of the input \mathbf{X} . This can be achieved by carefully combining layers that use either “valid” or “full” convolutions.

To explore different model architectures respecting that constraint, we opted for the following strategy. Given a network, we ensured the first half of its layers was using “valid” convolutions while the other half would use “full” convolutions. In addition to that, we made sure the network was symmetric with respect to its filter shapes (i.e. the filter shape used in layer ℓ matched the one used in layer $L - \ell$).

For completeness, we wish to mention that ConvNADE can also include pooling and upsampling layers, but we did not see much improvement when using them. In fact, recent research suggests that these types of layers are not essential to obtain state-of-the-art results (Springenberg et al., 2015).

The flexibility of DeepNADE allows us to easily combine both convolutional and fully connected layers. To create such hybrid models, we used the simple strategy of having two separate networks, with their last layer fused together at the end. The ‘convnet’ part is only composed of convolutional layers whereas the ‘fullnet’ part is only composed of fully connected layers. The forward pass of both networks follows respectively Equations 37–39 and Equations 25–27. Note that in the ‘fullnet’ network case, \mathbf{x} corresponds to the input image having been flattened.

In the end, the output layer \mathbf{g} of the hybrid model corresponds to the aggregation of the last layer pre-activation of both ‘convnet’ and ‘fullnet’ networks. The conditionals are slightly modified as follows:

$$p(\alpha_{o_d} = 1 | \mathbf{x}_{o_{<d}}, \boldsymbol{\theta}, o_{<d}, o_d) = \mathbf{g}_{o_d} \quad (41)$$

$$\mathbf{g} = \mathbf{sigm} \left(\mathbf{vec} \left(\mathbf{A}_1^{(L)} \right) + \mathbf{a}^{(L)} \right). \quad (42)$$

The same training procedure as for DeepNADE model can also be used for ConvNADE. For binary observations, the training loss is similar to Equation 34, with $\mathbf{h}^{(L)}$ being substituted for \mathbf{g} as defined in Equation 42.

As for the DeepNADE model, we found that providing the mask $\mathbf{M}_{o_{<d}}$ as an input to the model improves performance (see Table 4). For the ‘convnet’ part, the mask was provided as an additional channel to the input layer. For the ‘fullnet’ part, the inputs were concatenated with the mask as shown in Equation 35.

The final architecture is shown in Figure 3. In our experiments, we found that this type of hybrid model works better than only using convolutional layers (see Table 4). Certainly, more complex architectures could be employed but this is a topic left for future work.

6. Related Work

As we mentioned earlier, the development of NADE and its extensions was motivated by the question of whether a tractable distribution estimator could be designed to match a powerful but intractable model such as the restricted Boltzmann machine.

The original inspiration came from the autoregressive approach taken by fully visible sigmoid belief networks (FVSBN), which were shown by Frey et al. (1996) to be surprisingly

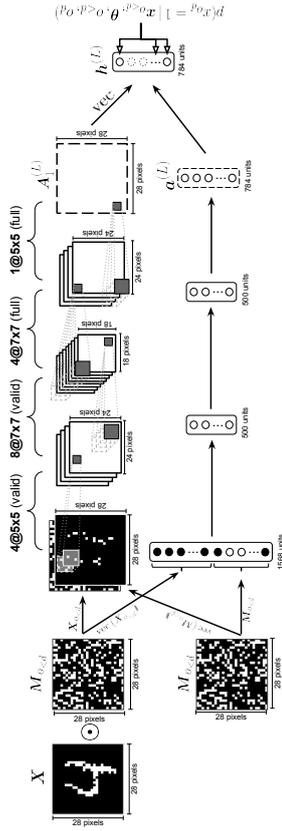

Figure 3: Illustration of a ConvNADE that combines a convolutional neural network with three hidden layers and a fully connected feed-forward neural network with two hidden layers. The dashed border represents a layer pre-activation. Units with a dotted contour are not valid conditionals since they depend on themselves i.e. they were given in the input.

competitive, despite the simplicity of the distribution family for its conditionals. Bengio and Bengio (2000) later proposed using more powerful conditionals, modeled as single layer neural networks. Moreover, they proposed connecting the output of each d^{th} conditional to all of the hidden layers of the $d - 1$ neural networks for the preceding conditionals. More recently, Germain et al. (2015) generalized this model by deriving a simple procedure for making it deep and orderless (akin to DeepNADE, in Section 4). We compare with all of these approaches in Section 7.1.

There exists, of course, more classical and non-autoregressive approaches to tractable distribution estimation, such as mixture models and Chow-Liu trees (Chow and Liu, 1968). We compare with these as well in Section 7.1.

This work also relates directly to the recently growing literature on generative neural networks. In addition to the autoregressive approach described in this paper, there exists three other types of such models: directed generative networks, undirected generative networks and hybrid networks.

Work on directed generative networks dates back to the original work on sigmoid belief networks (Neal, 1992) and the Helmholtz machine (Hinton et al., 1995; Dayan et al., 1995). Helmholtz machines are equivalent to a multilayer sigmoid belief network, with each using binary stochastic units. Originally they were trained using Gibbs sampling and gradient descent (Neal, 1992), or with the so-called wake sleep algorithm (Hinton et al., 1995). More recently, many alternative directed models and training procedures have been proposed. Kingma and Welling (2014); Rezende et al. (2014) proposed the variational autoencoder (VAE), where the model is the same as the Helmholtz machine, but with real-valued (usually Gaussian) stochastic units. Importantly, Kingma and Welling (2014) identified a reparameterization trick making it possible to train the VAE in a way that resembles the training of an autoencoder. This approach falls in the family of stochastic variational inference methods, where the encoder network corresponds to the approximate variational

posterior. The VAE optimizes a bound on the likelihood which is estimated using a single sample from the variational posterior, though recent work has shown that a better bound can be obtained using an importance sampling approach (Burda et al., 2016). Gregor et al. (2015) later exploited the VAE approach to develop DRAM, a directed generative model for images based on a read-write attentional mechanism. Goodfellow et al. (2014) proposed an adversarial approach to training directed generative networks, that relies on a discriminator network simultaneously trained to distinguish between data and model samples. Generative networks trained this way are referred to as Generative Adversarial Networks (GAN). While the VAE optimizes a bound of the likelihood (which is the KL divergence between the empirical and model distributions), it can be shown that the earliest versions of GANs optimize the Jensen–Shannon (JS) divergence between the empirical and model distributions. Li et al. (2015) instead propose a training objective derived from Maximum Mean Discrepancy (MMD; Gretton et al., 2007). Recently, the directed generative model approach has been very successfully applied to model images (Denton et al., 2015; Sohl-Dickstein et al., 2011).

The undirected paradigm has also been explored extensively for developing powerful generative networks. These include the restricted Boltzmann machine (Smolensky, 1986; Freund and Haussler, 1992) and its multilayer extension, the deep Boltzmann machine (Salakhutdinov and Hinton, 2009), which dominate the literature on undirected neural networks. Salakhutdinov and Murray (2008) provided one of the first quantitative evidence of the generative modeling power of RBMs, which motivated the original parameterization for NADE (Larochelle and Murray, 2011). Efforts to train better undirected models can vary in nature. One has been to develop alternative objectives to maximum likelihood. The proposal of Contrastive Divergence (CD; Hinton, 2002) was instrumental in the popularization of the RBM. Other proposals include pseudo-likelihood (Besag, 1975; Marlin et al., 2010), score matching (Hyvärinen, 2005; Hyvärinen, 2007a,b), noise contrastive estimation (Gutmann and Hyvärinen, 2010) and probability flow minimization (Sohl-Dickstein et al., 2011). Another line of development has been to optimize likelihood using Robbins–Morro stochastic approximation (Younes, 1989), also known as Persistent CD (Telesman, 2008), and develop good MCMC samplers for deep undirected models (Salakhutdinov, 2009, 2010; Desjardins et al., 2010; Cho et al., 2010). Work has also been directed towards proposing improved update rules or parameterization of the model’s energy function (Telesman and Hinton, 2009; Cho et al., 2013; Montavon and Müller, 2012) as well as improved approximate inference of the hidden layers (Salakhutdinov and Larochelle, 2010). The work of Ngiem et al. (2011) also proposed an undirected model that distinguishes itself from deep Boltzmann machines by having deterministic hidden units, instead of stochastic.

Finally, hybrids of directed and undirected networks are also possible, though much less common. The most notable case is the Deep Belief Network (DBN; Hinton et al., 2006), which corresponds to a sigmoid belief network for which the prior over its top hidden layer is an RBM (whose hidden layer counts as an additional hidden layer). The DBN revived interest in RBMs, as they were required to successfully initialize the DBN.

NADE thus substantially differs from this literature focusing on directed and undirected models, benefiting from a few properties that these approaches lack. Mainly, NADE does not rely on latent stochastic hidden units, making it possible to tractably compute its associated data likelihood for some given ordering. This in turn makes it possible to efficiently produce

Name	# Inputs	Train	Valid.	Test

exact samples from the model (unlike in undirected models) and get an unbiased gradient for maximum likelihood training (unlike in directed graphical models).

7. Results

In this section, we evaluate the performance of our different NADE models on a variety of data sets. The code to reproduce the experiments of the paper is available on GitHub¹. Our implementation is done using Theano (Team et al., 2016).

7.1. Binary Vectors Data Sets

We start by evaluating the performance of NADE models on a set of benchmark data sets where the observations correspond to binary vectors. These data sets were mostly taken from the LIBSVM data sets web site², except for OCR-letters³ and NIPS-0-12⁴. Code to download these data sets is available here: <http://info.usherbrooke.ca/hlarochelle/code/nae.tar.gz>. Table 1 summarizes the main statistics for these data sets.

For these experiments, we only consider tractable distribution estimators, where we can evaluate $p(\mathbf{x})$ on test items exactly. We consider the following baselines:

- **MoB**: A mixture of multivariate Bernoullis, trained using the EM algorithm. The number of mixture components was chosen from {32, 64, 128, 256, 512, 1024} based on validation set performance, and early stopping was used to determine the number of EM iterations.
- **RBM**: A restricted Boltzmann machine made tractable by using only 23 hidden units, trained by contrastive divergence with up to 25 steps of Gibbs sampling. The validation set performance was used to select the learning rate from {0.005, 0.0005, 0.00005}, and the number of iterations over the training set from {100, 500, 1000}.

2. <http://www.csie.ntu.edu.tw/~cjlin/libsvmtools/datasets/>

3. <http://ai.stanford.edu/~btaskar/ocr/>

4. <http://www.cs.nyu.edu/~trovets/data.html>

- **FVSBN**: Fully visible sigmoid belief network, that models each conditional $p(x_{o_d} | \mathbf{x}_{\rho_{<d}})$ with logistic regression. The ordering of inputs was selected randomly. Training was by stochastic gradient descent. The validation set was used for early stopping, as well as for choosing the base learning rate $\eta \in \{0.05, 0.005, 0.0005\}$, and a decreasing schedule constant γ from $\{0, 0.001, 0.000001\}$ for the learning rate schedule $\eta/(1 + \gamma t)$ for the t^{th} update.

- **Chow-Liu**: A Chow-Liu tree is a graph over the observed variables, where the distribution of each variable, except the root, depends on a single parent node. There is an $O(D^2)$ fitting algorithm to find the maximum likelihood tree and conditional distributions (Chow and Liu, 1968). We adapted an implementation provided by Harmeling and Williams (2011), who found Chow-Liu to be a strong baseline.

The maximum likelihood parameters are not defined when conditioning on events that haven't occurred in the training set. Moreover, conditional probabilities of zero are possible, which could give infinitely bad test set performance. We re-estimated the conditional probabilities on the Chow-Liu tree using Lidstone or "add- α " smoothing:

$$p(x_d = 1 | x_{\text{parent}} = z) = \frac{\text{count}(x_d = 1 | x_{\text{parent}} = z) + \alpha}{\text{count}(x_{\text{parent}} = z) + 2\alpha}, \quad (43)$$

selecting α for each data set from $\{10^{-20}, 0.001, 0.01, 0.1\}$ based on performance on the validation set.

- **MADE** (Germain et al., 2015): Generalization of the neural network approach of Bengio and Bengio (2000), to multiple layers. We consider a version using a single (fixed) input ordering and another trained on multiple orderings from which an ensemble was constructed (which was inspired from the order-agnostic approach of Section 4) that we refer to as MADE-E. See Germain et al. (2015) for more details.

We compare these baselines with the two following NADE variants:

- **NADE (fixed order)**: Single layer NADE model, trained on a single (fixed) randomly generated order, as described in Section 2. The sigmoid activation function was used for the hidden layer, of size 500. Much like for FVSBN, training relied on stochastic gradient descent and the validation set was used for early stopping, as well as for choosing the learning rate from $\{0.05, 0.005, 0.0005\}$, and the decreasing schedule constant γ from $\{0, 0.001, 0.000001\}$.

- **NADE-E**: Single layer NADE trained according to the order-agnostic procedure described in Section 4. The rectified linear activation function was used for the hidden layer, also of size 500. Minibatch gradient descent was used for training, with minibatches of size 100. The initial learning rate, chosen among $\{0.016, 0.004, 0.001, 0.00025, 0.0000675\}$, was linearly decayed to zero over the course of 100,000 parameter updates. Early stopping was used, using Equation 34 to get a stochastic estimate of the validation set average log-likelihood. An ensemble using 16 orderings was used to compute the test-time log-likelihood.

Model	Adult	Connect4	DNA	Mushrooms	NIPS-0-12	OCR-letters	RCV1	Web

Table 2: Average log-likelihood performance of tractable distribution baselines and NADE models, on binary vector data sets. The best result is shown in bold, along with any other result with an overlapping confidence interval.

Table 2 presents the results. We observe that NADE restricted to a fixed ordering of the inputs achieves very competitive performance compared to the baselines. However, the order-agnostic version of NADE is overall the best method, being among the top performing model for 5 data sets out of 8.

The performance of fixed-order NADE is surprisingly robust to variations of the chosen input ordering. The standard deviation on the average log-likelihood when varying the ordering was small: on Mushrooms, DNA and NIPS-0-12, we observed standard deviations of 0.045, 0.05 and 0.15, respectively. However, models with different orders can do well on different test examples, which explains why ensembling can still help.

7.2 Binary Image Data Set

We now consider the case of an image data set, constructed by binarizing the MNIST digit data set. Each image has been stochastically binarized according to their pixel intensity as generated by Salakhutdinov and Murray (2008). This benchmark has been a popular choice for the evaluation of generative neural network models. Here, we investigate two questions:

1. How does NADE compare to intractable generative models?
2. Does the use of a convolutional architecture improve the performance of NADE?

For these experiments, in addition to the baselines already described in Section 7.1, we consider the following:

- **DARN** (Gregor et al., 2014): This deep generative autoencoder has two hidden layers, one deterministic and one with binary stochastic units. Both layers have 500 units (denoted as $n_h = 500$). Adaptive weight noise (adaNoise) was either used or not to avoid the need for early stopping (Graves, 2011). Evaluation of exact test probabilities is intractable for large latent representations. Hence, Monte Carlo was used to approximate the expected description length, which corresponds to an upper bound on the negative log-likelihood.

Model	$-\log p$	\approx
MoBertoullis K=10	168.95	
MoBertoullis K=500	137.64	
Chow-Lin tree	134.99	
MADDE 2hl (32 masks)	86.64	
RBM (500 h, 25 CD steps)		86.34
DBN 2hl		84.55
DARN $n_h = 500$		84.71
DARN $n_h = 500$ (adaNoise)		84.13
NADE (fixed order)	88.33	
DeepNADE 1hl (no input masks)	99.37	
DeepNADE 2hl (no input masks)	95.33

DeepNADE 2hl	89.17	
DeepNADE 3hl	89.38	
DeepNADE 4hl	89.60	
EoNADE 1hl (2 orderings)	90.69	
EoNADE 1hl (128 orderings)	87.71	
EoNADE 2hl (2 orderings)	87.96	
EoNADE 2hl (128 orderings)	85.10	

Table 3: Negative log-likelihood test results of models ignorant of the 2D topology on the binarized MNIST data set.

- **DRAW** (Gregor et al., 2015): Similar to a variational autoencoder where both the encoder and the decoder are LSTMs, guided (or not) by an attention mechanism. In this model, both LSTMs (encoder and decoder) are composed of 256 recurrent hidden units and always perform 64 timesteps. When the attention mechanism is enabled, patches (2×2 pixels) are provided as inputs to the encoder instead of the whole image and the decoder also produces patches (5×5 pixels) instead of a whole image.
- **Pixel RNN** (Oord et al., 2016): NADE-like model for natural images that is based on convolutional and LSTM hidden units. This model has 7 hidden layers, each composed of 16 units. Oord et al. (2016) proposed a novel two-dimensional LSTM, named Diagonal BiLSTM, which is used in this model. Unlike our ConvNADE, the ordering is fixed before training and at test time, and corresponds to a scan of the image in a diagonal fashion starting from a corner at the top and reaching the opposite corner at the bottom.

We compare these baselines with some NADE variants. The performance of a basic (fixed-order, single hidden layer) NADE model is provided in Table 3 and samples are illustrated in Figure 4. More importantly, we will focus on whether the following variants achieve better test set performance:

- **DeepNADE**: Multiple layers (1hl, 2hl, 3hl or 4hl) trained according to the order-agnostic procedure described in Section 4. Information about which inputs are masked

was either provided or not (no input masks) to the model. The rectified linear activation function was used for all hidden layers. Minibatch gradient descent was used for training, with minibatches of size 1000. Training consisted of 200 iterations of 1000 parameter updates. Each hidden layer was pre-trained according to Algorithm 2. We report an average of the average test log-likelihoods over ten different random orderings.

- **EoNADE**: This variant is similar to DeepNADE except for the log-likelihood on the test set, which is instead computed from an ensemble that averages predictive probabilities over 2 or 128 orderings. To clarify, the DeepNADE results report the typical performance of one ordering, by averaging results after taking the log, and so do not combine the predictions of the models like EoNADE does.

- **ConvNADE**: Multiple convolutional layers trained according to the order-agnostic procedure described in Section 4. The exact architecture is shown in Figure 5(a). Information about which inputs are masked was either provided or not (no input masks). The rectified linear activation function was used for all hidden layers. The Adam optimizer (Kingma and Ba, 2015) was used with a learning rate of 10^{-4} . Early stopping was used with a look ahead of 10 epochs, using Equation 34 to get a stochastic estimate of the validation set average log-likelihood. An ensemble using 128 orderings was used to compute the log-likelihood on the test set.

- **ConvNADE + DeepNADE**: This variant is similar to ConvNADE except for the aggregation of a separate DeepNADE model at the end of the network. The exact architecture is shown in Figure 5(b). The training procedure is the same as with ConvNADE.

Algorithm 2 Pre-training of a NADE with n hidden layers on data set X .

```

procedure PRETRAIN( $n, X$ )
  if  $n = 1$  then
    return RANDOM-ONE-HIDDEN-LAYER-NADE
  else
     $\text{nade} \leftarrow$  PRETRAIN( $n - 1, X$ )
     $\text{nade} \leftarrow$  REMOVE-OUTPUT-LAYER( $\text{nade}$ )
     $\text{nade} \leftarrow$  ADD-A-NEW-HIDDEN-LAYER( $\text{nade}$ )
     $\text{nade} \leftarrow$  ADD-A-NEW-OUTPUT-LAYER( $\text{nade}$ )
     $\text{nade} \leftarrow$  TRAIN-ALL( $\text{nade}, X, \text{iters}=20$ )
    return  $\text{nade}$ 
   $\triangleright$  Train for 20 iterations.
  end if
end procedure

```

Table 3 presents the results obtained by models ignorant of the 2D topology, such as the basic NADE model. Addressing the first question, we observe that the order-agnostic version of NADE with two hidden layers is competitive with intractable generative models. Moreover, examples of the ability of DeepNADE to solve inference tasks by marginalization and conditional sampling are shown in Figure 6.

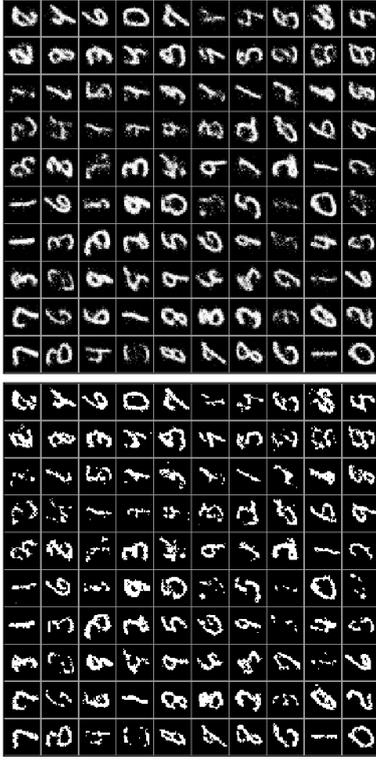

Figure 4: **Left:** samples from NADE trained on binarized MNIST. **Right:** probabilities from which each pixel was sampled. Ancestral sampling was used with the same fixed ordering used during training.

Model	$-\log p$	\leq
DRAW (without attention)	87.40	
DRAW	80.97	
Pixel RNN	79.20	
ConvNADE+DeepNADE (no input masks)	85.25	
ConvNADE	81.30	
ConvNADE+DeepNADE	80.82	

Table 4: Negative log-likelihood test results of models exploiting 2D topology on the binarized MNIST data set.

Now, addressing the second question, we can see from Table 4 that convolutions do improve the performance of NADE. Moreover, we observe that providing information about which inputs are masked is essential to obtaining good results. We can also see that combining convolutional and fully-connected layers helps. Even though ConvNADE+DeepNADE performs slightly worse than Pixel RNN, we note that our proposed approach is order-agnostic, whereas Pixel RNN requires a fixed ordering. Figure 7 shows samples obtained from the ConvNADE+DeepNADE model using ancestral sampling on a random ordering.

7.3 Real-Valued Observations Data Sets

In this section, we compare the statistical performance of RNADE to mixtures of Gaussians (MoG) and factor analyzers (MFA), which are surprisingly strong baselines in some tasks (Tang et al., 2012; Zoran and Weiss, 2012).

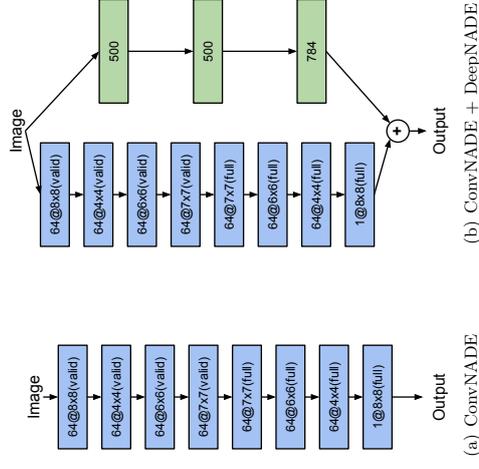

Figure 5: Network architectures for binarized MNIST. (a) ConvNADE with 8 convolutional layers (depicted in blue). The number of feature maps for a given layer is given by the number before the “@” symbol followed by the filter size and the type of convolution is specified in parentheses. (b) The same ConvNADE combined with a DeepNADE consisting of three fully-connected layers of respectively 500, 500 and 784 units.

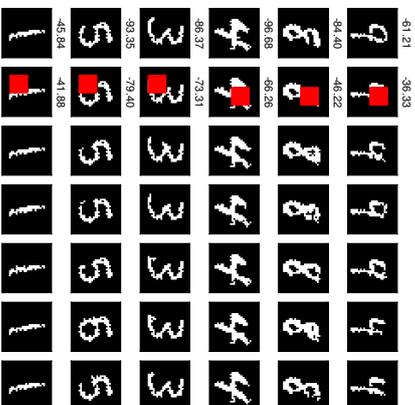

Figure 6: Example of marginalization and sampling. The first column shows five examples from the test set of the MNIST data set. The second column shows the density of these examples when a random 10×10 pixel region is marginalized. The right-most five columns show samples for the hollowed region. Both tasks can be done easily with a NADE where the pixels to marginalize are at the end of the ordering.

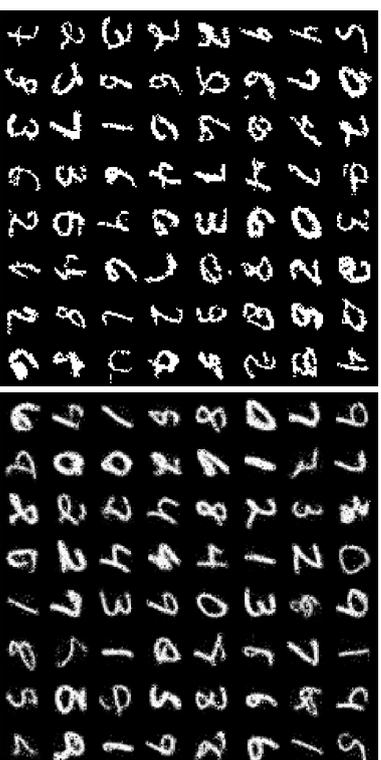

Figure 7: **Left:** samples from ConvNADE+DeepNADE trained on binarized MNIST. **Right:** probabilities from which each pixel was sampled. Ancestral sampling was used with a different random ordering for each sample.

7.3.1 LOW-DIMENSIONAL DATA

We start by considering three UCI data sets (Bache and Lichman, 2013), previously used to study the performance of other density estimators (Sliva et al., 2011; Tang et al., 2012), namely: *red wine*, *white wine* and *parkinsons*. These are low dimensional data sets (see Table 5) with hard thresholds and non-linear dependencies that make it difficult to fit mixtures of Gaussians or factor analyzers.

Following Tang et al. (2012), we eliminated discrete-valued attributes and an attribute from every pair with a Pearson correlation coefficient greater than 0.98. We normalized each dimension of the data by subtracting its training-subset sample mean and dividing by its standard deviation. All results are reported on the normalized data.

We use full-covariance Gaussians and mixtures of factor analyzers as baselines. Models were compared on their log-likelihood on held-out test data. Due to the small size of the data sets (see Table 5), we used 10-folds, using 90% of the data for training, and 10% for testing.

We chose the hyperparameter values for each model by doing per-fold cross-validation, using a ninth of the training data as validation data. Once the hyperparameter values have been chosen, we train each model using all the training data (including the validation data) and measure its performance on the 10% of held-out testing data. In order to avoid overfitting, we stopped the training after reaching a training likelihood higher than the one obtained on the best validation-wise iteration of the best validation run. Early stopping was important to avoid overfitting the RNADe models. It also improved the results of the MFAs, but to a lesser degree.

The MFA models were trained using the EM algorithm (Chahramani and Hinton, 1996; Verbeek, 2005). We cross-validated the number of components and factors. We also selected the number of factors from $2, 4, \dots, D$, where choosing D results in a mixture of Gaussians, and the number of components was chosen among $2, 4, \dots, 50$. Cross-validation selected fewer than 50 components in every case.

We report the performance of several RNADe models using different parametric forms for the one-dimensional conditionals: Gaussian with fixed variance (RNADe-FV), Gaussian with variable variance (RNADe-Gaussian), *sinh-arcsinh* distribution (RNADe-SAS), mixture of Gaussians (RNADe-MoG), and mixture of Laplace distributions (RNADe-MoL). All RNADe models were trained by stochastic gradient descent, using minibatches of size 100, for 500 epochs, each epoch comprising 10 minibatches. We fixed the number of hidden units to 50, and the non-linear activation function of the hidden units to ReLU. Three hyperparameters were cross-validated using grid-search: the number of components on each one-dimensional conditional (only applicable to the RNADe-MoG and RNADe-MoL models) was chosen from $\{2, 5, 10, 20\}$, the weight-decay (used only to regularize the input to hidden weights) from $\{2.0, 1.0, 0.1, 0.01, 0.001, 0\}$, and the learning rate from $\{0.1, 0.05, 0.025, 0.0125\}$. Learning rates were decreased linearly to reach 0 after the last epoch.

The results are shown in Table 6. RNADe with mixture of Gaussian conditionals was among the statistically significant group of best models on all data sets. As shown in Figure 8, RNADe-SAS and RNADe-MoG models are able to capture hard thresholds and heteroscedasticity.

Table 6: Average test set log-likelihoods per data point for seven models on three UCI data sets. Performances not in bold can be shown to be significantly worse than at least one of the results in bold as per a paired t -test on the ten mean-likelihoods (obtained from each data fold), with significance level 0.05.

7.3.2 NATURAL IMAGE PATCHES

We also measured the ability of RNADE to model small patches of natural images. Following the work of Zoran and Weiss (2011), we use 8-by-8-pixel patches of monochrome natural images, obtained from the BSDS300 data set (Martin et al., 2001; Figure 9 gives examples).

Pixels in this data set can take a finite number of brightness values ranging from 0 to 255. We added uniformly distributed noise between 0 and 1 to the brightness of each pixel. We then divided by 256, making the pixels take continuous values in the range $[0, 1]$. Adding noise prevents deceptively high-likelihood solutions that assign narrow high-density spikes around some of the possible discrete values.

We subtracted the mean pixel value from each patch. Effectively reducing the dimensionality of the data. Therefore we discarded the 64th (bottom-right) pixel, which would be perfectly predictable and models could fit arbitrarily high densities to it. All of the results in this section were obtained by fitting the pixels in a raster-scan order.

Experimental details follow. We trained our models by using patches randomly drawn from 180 images in the training subset of BSDS300. We used the remaining 20 images in the training subset as validation data. We used 1000 random patches from the validation subset to early-stop training of RNADE. We measured the performance of each model by their log-likelihood on one million patches drawn randomly from the test subset of 100 images not present in the training data. Given the larger scale of this data set, hyperparameters of the RNADE and MoG models were chosen manually using the performance of preliminary runs on the validation data, rather than by grid search.

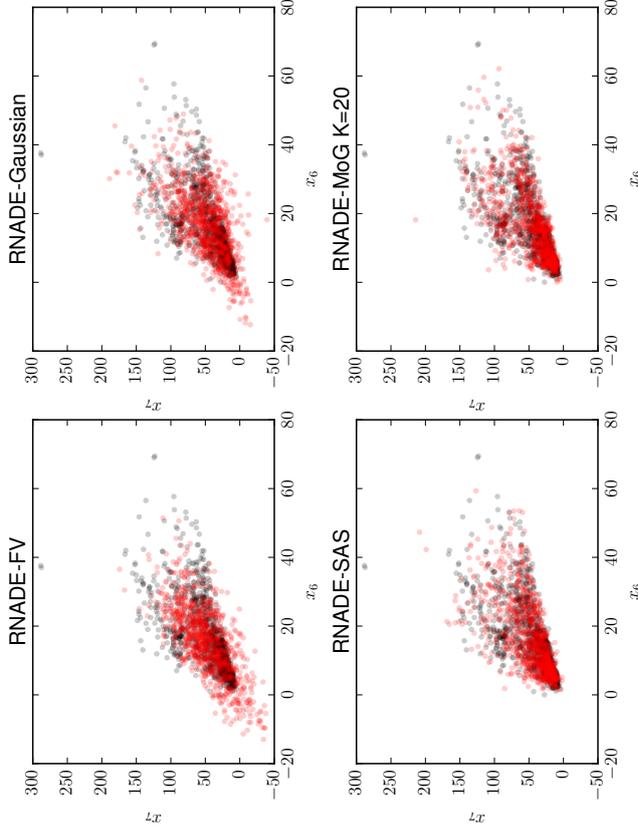

Figure 8: Scatter plot of dimensions x_7 vs x_6 of the *red wine* data set. A thousand data points from the data set are shown in black in all subfigures. As can be observed, this conditional distribution $p(x_7 | x_6)$ is heteroscedastic, skewed and has hard thresholds. In red, a thousand samples from four RNADE models with different one-dimensional conditional forms are shown. **Top-left:** In red, one thousand samples from a RNADE-FV model. **Top-right:** In red, one thousand samples from a RNADE-Gaussian model. **Bottom-left:** In red, one thousand samples from a RNADE-SAS (sinh-arcsinh distribution) model. **Bottom-right:** In red, one thousand samples from a RNADE-MoG model with 20 components per one-dimensional conditional. The RNADE-SAS and RNADE-MoG models successfully capture all the characteristics of the data.

All RNADe models reported use ReLU activations for the hidden units. The RNADe models were trained by stochastic gradient descent, using 25 data points per minibatch, for a total of 1,000 epochs, each comprising 1,000 minibatches. The learning rate was initialized to 0.001, and linearly decreased to reach 0 after the last epoch. Gradient momentum with factor 0.9 was used, but initiated after the first epoch. A weight decay rate of 0.001 was applied to the input-to-hidden weight matrix only. We found that multiplying the gradient of the mean output parameters by the standard deviation improves results of the models with mixture outputs⁵. RNADe training was early stopped but didn't show signs of overfitting. Even larger models might perform better.

The MoG models were trained using 1,000 iterations of minibatch EM. At each iteration 20,000 randomly sampled data points were used in an EM update. A step was taken from the previous parameters' value towards the parameters resulting from the M-step: $\theta_t = (1 - \eta)\theta_{t-1} + \eta\theta_{EM}$. The step size, η , was scheduled to start at 0.1 and linearly decreased to reach 0 after the last update. The training of the MoG was early-stopped and also showed no signs of overfitting.

The results are shown in Table 7. We report the average log-likelihood of each model for a million image patches from the test set. The ranking of RNADe models is maintained when ordered by validation likelihood: the model with best test-likelihood would have been chosen using cross-validation across all the RNADe models shown in the table. We also compared RNADe with a MoG trained by Zoran and Weiss (downloaded from Daniel Zoran's website) from which we removed the 64th row and column of each covariance matrix. There are two differences in the set-up of our experiments and those of Zoran and Weiss. First, we learned the means of the MoG components, while Zoran and Weiss (2011) fixed them to zero. Second, we held-out 20 images from the training set to do early-stopping and hyperparameter optimisation, while they used the 200 images for training.

The RNADe-FV model with fixed conditional variances obtained very low statistical performance. Adding an output parameter per dimension to have variable standard deviations made our models competitive with MoG with 100 full-covariance components. However, in order to obtain results superior to the mixture of Gaussians model trained by Zoran and Weiss, we had to use richer conditional distributions: one-dimensional mixtures of Gaussians (RNADe-MoG). On average, the best RNADe model obtained 3.3 nats per patch higher log-density than a MoG fitted with the same training data.

In Figure 9, we show one hundred examples from the test set, one hundred examples from Zoran and Weiss' mixture of Gaussians, and a hundred samples from our best RNADe-MoG model. Similar patterns can be observed in the three cases: uniform patches, edges, and locally smooth noisy patches.

7.3.3 SPEECH ACOUSTICS

We also measured the ability of RNADe to model small patches of speech spectrograms, extracted from the TIMIT data set (Garofolo et al., 1993). The patches contained 11 frames of 20 filter-banks plus energy; totalling 231 dimensions per data point. A good generative model of speech acoustics could be used, for example, in denoising, or speech detection tasks.

⁵ Empirically, we found this to work better than regular gradients and also better than multiplying by the variances, which would provide a step with the right units.

Model	Test log-likelihood
MoG $K=200$ (Zoran and Weiss, 2012) ^a	152.8
MoG $K=100$	144.7
MoG $K=200$	150.4
MoG $K=300$	150.4
RNADe-FV $h=512$	100.3
RNADe-Gaussian $h=512$	143.9
RNADe-Laplace $h=512$	145.9
RNADe-SAS ^b $h=512$	148.5
RNADe-MoG $K=2$ $h=512$	149.5
RNADe-MoG $K=2$ $h=1024$	150.3
RNADe-MoG $K=5$ $h=512$	152.4
RNADe-MoG $K=5$ $h=1024$	152.7
RNADe-MoG $K=10$ $h=512$	153.5
RNADe-MoG $K=10$ $h=1024$	153.7
RNADe-MoL $K=2$ $h=512$	149.3
RNADe-MoL $K=2$ $h=1024$	150.1
RNADe-MoL $K=5$ $h=512$	151.5
RNADe-MoL $K=5$ $h=1024$	151.4
RNADe-MoL $K=10$ $h=512$	152.3
RNADe-MoL $K=10$ $h=1024$	152.5

Table 7: Average per-example log-likelihood of several mixture of Gaussian and RNADe models on 8×8 pixel patches of natural images. These results are reported in nats and were calculated using one million patches. Standard errors due to the finite test sample size are lower than 0.1 nats in every case. h indicates the number of hidden units in the RNADe models, and K the number of one-dimensional components for each conditional in RNADe or the number of full-covariance components for MoG.

^a This model was trained using the full 200 images in the BSDS training data set, the rest of the models were trained using 180, reserving 20 for hyperparameter cross-validation and early-stopping.

^b Training an RNADe with sinh-arcsinh conditionals required the use of a starting learning rate 20 times smaller to avoid divergence during training. For this reason, this model was trained for 2000 epochs.

Model	Test LogL
MoG $N=50$	110.4
MoG $N=100$	112.0
MoG $N=200$	112.5
MoG $N=300$	112.5
RNADE-Gaussian	110.6
RNADE-Laplace	108.6
RNADE-SAS	119.2
RNADE-MoG $K=2$	121.1
RNADE-MoG $K=5$	124.3
RNADE-MoG $K=10$	127.8
RNADE-MoL $K=2$	116.3
RNADE-MoL $K=5$	120.5
RNADE-MoL $K=10$	123.3

Table 8: Log-likelihood of several MoG and RNADE models on the core-test set of TIMIT measured in nats. Standard errors due to the finite test sample size are lower than 0.4 nats in every case. RNADE obtained a higher (better) log-likelihood.

We fitted the models using the standard TIMIT training subset, which includes recordings from 605 speakers of American English. We compare RNADE with a mixture of Gaussians by measuring their log-likelihood on the complete TIMIT core-test data set: a held-out set of 25 speakers.

The RNADE models have 512 hidden units, ReLU activations, and a mixture of 20 one-dimensional Gaussian components per output. Given the large scale of this data set, hyperparameter choices were again made manually using validation data. The same training procedures for RNADE and mixture of Gaussians were used as for natural image patches.

The RNADE models were trained by stochastic gradient descent, with 25 data points per minibatch, for a total of 200 epochs, each comprising 1,000 minibatches. The learning rate was initialized to 0.001 and linearly decreased to reach 0 after the last epoch. Gradient momentum with momentum factor 0.9 was used, but initiated after the first epoch. A weight decay rate of 0.001 was applied to the input-to-hidden weight matrix only. Again, we found that multiplying the gradient of the mean output parameters by the standard deviation improved results. RNADE training was early stopped but didn't show signs of overfitting. As for the MoG model, it was trained exactly as in Section 7.3.2.

The results are shown in Table 8. The best RNADE (which would have been selected based on validation results) has 15 nats higher likelihood per test example than the best mixture of Gaussians. Examples from the test set, and samples from the MoG and RNADE-MoG models are shown in Figure 10. In contrast with the log-likelihood measure, there are no marked differences between the samples from each model. Both sets of samples look like blurred spectrograms, but RNADE seems to capture sharper formant structures (peaks of energy at the lower frequency bands characteristic of vowel sounds).

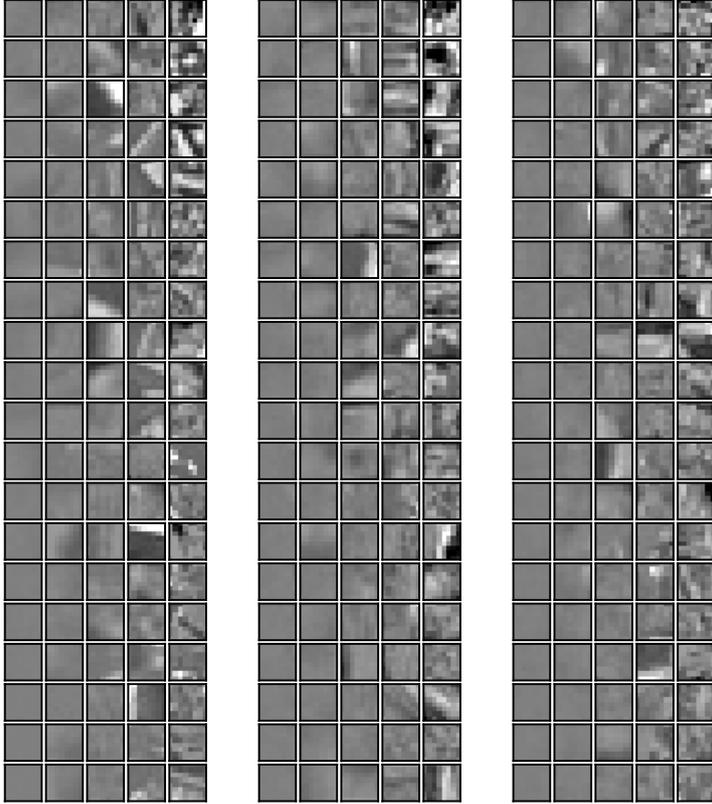

Figure 9: **Top:** 100 8×8 patches from the BSDS test set. **Center:** 100 samples from a mixture of Gaussians with 200 full-covariance components. **Bottom:** 100 samples from an RNADE with 1024 hidden units and 10 Gaussian components per conditional. All data and samples were drawn randomly and sorted by their density under the RNADE.

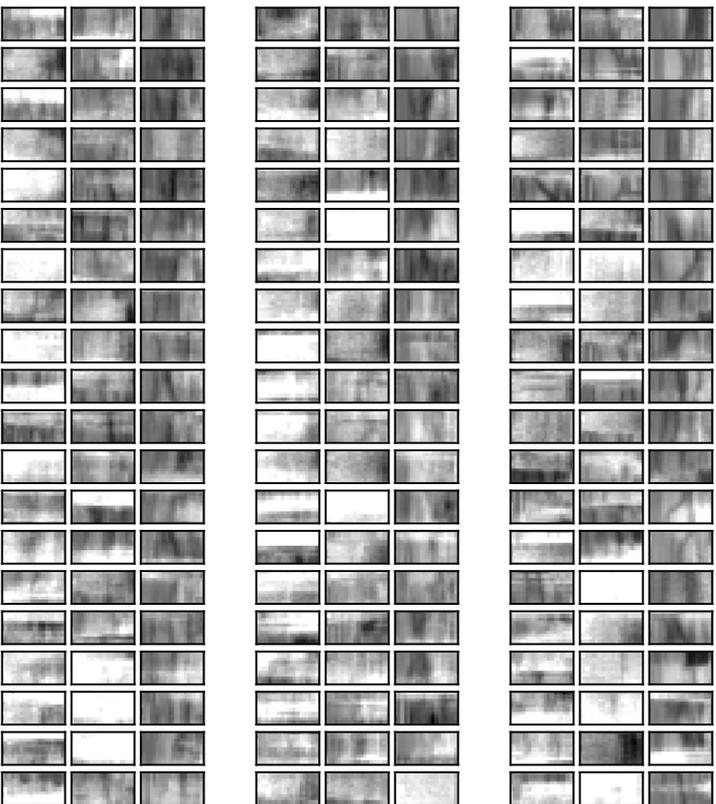

Figure 10: **Top:** 60 data points from the TIMT core-test set. **Center:** 60 samples from a MoG model with 200 components. **Bottom:** 60 samples from an RNADe with 10 Gaussian output components per dimension. For each data point displayed, time is shown on the horizontal axis, the bottom row displays the energy feature, while the others display the Mel filter bank features (in ascending frequency order from the bottom). All data and samples were drawn randomly and sorted by density under the RNADe model.

We’ve described the Neural Autoregressive Distribution Estimator, a tractable, flexible and competitive alternative to directed and undirected graphical models for unsupervised distribution estimation.

Since the publication of the first formulation of NADE (Larochelle and Murray, 2011), it has been extended to many more settings, other than those described in this paper. Larochelle and Lairly (2012); Zheng et al. (2015b) adapted NADE for topic modeling of documents and images, while Boulanger-Lewandowski et al. (2012) used NADE for modeling music sequential data. Theis and Bethge (2015) and Oord et al. (2016) proposed different NADE models for images than the one we presented, applied to natural images and based on convolutional and LSTM hidden units. Zheng et al. (2015a) used a NADE model to integrate an attention mechanism into an image classifier. Bornschein and Bengio (2015) showed that NADE could serve as a powerful prior over the latent state of directed graphical model. These are just a few examples of many possible ways one can leverage the flexibility and effectiveness of NADE models.

Our recent work (Arias-Castro et al., 2016) established the convergence of the mean shift algorithm under relatively general conditions. After the publication of this article, Prof. Jose E. Chacón — who has worked on the topic (Chacón and Monfort, 2013; Chacón and Duong, 2013) — alerted us of a mistake in the proof of the first part of our Theorem 1. The mistake is in the display following Eq. (32), where we applied the triangle inequality to the *squared* Euclidean distance, which of course is incorrect in general.

It turns out that the mistake has a simple and short fix, which we detail below. This relatively minor mistake would not warrant an errata, except that the same mistake has been made before by others also working on the convergence of the mean shift algorithm, including Comaniciu and Meer (2002), as revealed in (Li et al., 2007; Ghassabel, 2015). (Prof. Chacón also provided these last two references.)

Below is a slightly modified statement of our Theorem 1 with the additional assumption that the end point x^* of the flow line is an isolated local maximum, meaning that for all $\epsilon > 0$ small enough $B(x^*, \epsilon)$ contains no local maximum other than x^* . Since f is also assumed of class C^3 , this is equivalent to assuming that for all $\epsilon > 0$ small enough, $B(x^*, \epsilon)$ contains only one critical point of f , namely x^* , and $f(x^*) > f(x)$ for all $x \in B(x^*, \epsilon)$ such that $x \neq x^*$.

The equations numbered (xx) refers to the original paper, while equations numbered (R.xx) are new to this note.

Theorem 1 *Let f be a function of class C^3 . Let $(x(t) : t \geq 0)$ denote the flow line of f starting at x_0 and ending at an isolated local maximum x^* of f . Let (x_ℓ) be the sequence defined in (6) starting at x_0 . Then there exists $A = A(x_0, f) > 0$ such that, whenever*

$0 < a < A$,

$$\lim_{\ell \rightarrow +\infty} x_\ell = x^*.$$

Denote by $x_a(t)$ the following polygonal line

$$x_a(t) = x_{\ell-1} + (t/a - \ell + 1)(x_\ell - x_{\ell-1}), \quad \forall t \in [(\ell - 1)a, \ell a).$$

Assume $H_f(x^*)$ has all eigenvalues in $(-\underline{\nu}, -\underline{\nu})$ for some $0 < \underline{\nu} < \bar{\nu}$. Then, there exists a $C = C(x_0, f, \underline{\nu}, \bar{\nu}) > 0$ such that, for any $0 < a < A$,

$$\sup_{t \geq 0} \|x_a(t) - x(t)\| \leq C a^\delta, \quad \delta := \frac{\underline{\nu}}{\underline{\nu} + \bar{\nu}}.$$

The rest of this note is dedicated to a corrected proof of the first part of this theorem. Claims 1 and 2 refer to the first two claims in the original published proof of Theorem 1. (Note that in the proof of Claim 1, we can assume without loss of generality that $f(x) > 0$ over $B(x_0, 3r_0)$.) Also notice that x_0 is not a global minimum of f since x_0 is not a critical point of f and f is C^3 . In the published proof of Theorem 1, the second claim on page 15 should be removed.

Now replace the claim on page 16 by the following definition, observation and Claims A, B and C:

For any $\eta > 0$, denote by $\mathcal{C}(\eta)$ the connected component of $\mathcal{L}_f(f(x^*) - \eta)$ that contains x^* . Notice that since x^* is a local maximum, for all $\eta > 0$ small enough

$$\mathcal{C}(\eta) = \mathcal{C}(x^*, \eta), \tag{R.1}$$

where $\mathcal{C}(x^*, \eta)$ be the connected component of

$$\{y : f(x^*) - \eta \leq f(y) \leq f(x^*)\}$$

that contains x^* .

Claim A. *Let y^* be such that $f(y^*) = f(x^*)$, but $y^* \neq x^*$. For all $\eta > 0$ small enough $y^* \notin \mathcal{C}(x^*, \eta)$. Choose such a y^* . Since x^* is an isolated local maximum, for all $\epsilon > 0$ small enough, $y^* \notin \bar{B}(x^*, \epsilon)$ and for some $\eta_\epsilon > 0$, $f(y) < f(x^*) - \eta_\epsilon$ for all $y \in \bar{B}(x^*, \epsilon) - B(x^*, \epsilon/2)$. Note that $\eta_\epsilon > 0$ can be chosen as small as desired by choosing $\epsilon > 0$ small enough. Suppose $y^* \in \mathcal{C}(x^*, \eta_\epsilon)$, then since $\mathcal{C}(x^*, \eta_\epsilon)$ is connected and $x^* \in \mathcal{C}(x^*, \eta_\epsilon)$ there is a continuous path lying inside $\mathcal{C}(x^*, \eta_\epsilon)$ joining x^* and y^* . Such a path would have to pass through a point $y \in \mathcal{C}(x^*, \eta_\epsilon) \cap (\bar{B}(x^*, \epsilon) - B(x^*, \epsilon/2))$ for which $f(y) < f(x^*) - \eta_\epsilon$. This cannot happen, since $y \in \mathcal{C}(x^*, \eta_\epsilon)$ forces $f(x^*) - \eta_\epsilon \leq f(y)$. Hence for all for all $\eta > 0$ small enough $y^* \notin \mathcal{C}(x^*, \eta)$.*

Claim B. *For all $\eta > 0$ small enough $\mathcal{C}(x^*, \eta)$ contains only one critical point of f . Towards proving this we shall first show that for all $\epsilon > 0$ there exists an $\eta > 0$ such that*

$$\mathcal{C}(x^*, \eta) \subset \bar{B}(x^*, \epsilon). \tag{R.2}$$

To see this, for any $\eta > 0$ small, denote the contour set

$$c(\eta) = \{y : f(y) = f(x^*) - \eta, y \in \mathcal{C}(x^*, \eta)\}.$$

Note that each contour set $c(\eta)$ is closed and hence is compact. (To see this, by Claim 1, we may assume that $\mathcal{L}(f(x_0))$ is bounded and thus compact. Therefore, since $c(\eta) \subset \mathcal{C}(x^*, \eta) \subset \mathcal{L}(f(x_0))$, $c(\eta)$ is compact.) Since $c(2^{-k})$ is compact, for each $k \geq 1$ large enough there exists a $x_k \in c(2^{-k})$ such that

$$r_k := \sup \left\{ \|y - x^*\| : y \in c(2^{-k}) \right\} = \|x_k - x^*\|.$$

Observe that since $f(x_k) \rightarrow f(x^*)$ and x^* is isolated, necessarily by a compactness argument, $x_k \rightarrow x^*$. To see this, suppose that for some subsequence y_j of x_k we have $y_j \rightarrow y^*$. Necessarily $f(y^*) = f(x^*)$ and $y^* \in \mathcal{C}(x^*, \eta)$ for all $\eta > 0$. However by Claim A, necessarily $y^* = x^*$. Thus $x_k \rightarrow x^*$, which implies $r_k \rightarrow 0$. Noting that for all large k

$$\mathcal{C}(x^*, 2^{-k}) \subset \overline{B}(x^*, r_k),$$

we see that for all $\epsilon > 0$ there exists an $\eta > 0$ such that (R.2) holds. Therefore, since for all small enough $\epsilon > 0$, $\overline{B}(x^*, \epsilon)$ contains only one critical point of f , we get that for all $\eta > 0$ small enough $\mathcal{C}(x^*, \eta)$ contains only one critical point of f .

Claim C. (x_ℓ) converges to x^* . By Claim B and (R.1), there exists $\eta_0 > 0$ small enough such that $\mathcal{C}(\eta_0)$ contains no critical point of f other than x^* . Moreover since f is C^3 , there exists $\epsilon > 0$ such that $\overline{B}(x^*, \epsilon) \subset \mathcal{C}(\eta_0)$. Let ℓ_ϵ be such that $\|x(t_{\ell_\epsilon}) - x^*\| \leq \epsilon/2$ and let a_ϵ be such that

$$\left[e^{\ell_\epsilon a_\epsilon \kappa_2 \sqrt{a}} - 1 \right] \kappa_1 a_\epsilon = \epsilon/2.$$

Assume now that $a \leq A_1 \wedge a_\epsilon$, where A_1 is defined in (31). Then, by (33) and the triangle inequality,

$$\|x_{t_\ell} - x^*\| \leq \|x_{t_\ell} - x(t_{t_\ell})\| + \|x(t_{t_\ell}) - x^*\| \leq \epsilon.$$

Thus, x_{t_ℓ} belongs to $\overline{B}(x^*, \epsilon)$, and so to $\mathcal{C}(\eta_0)$. By Claim 2 the values of f are increasing along the polygonal curve x_{t_ℓ} , so x_{t_ℓ} belongs to $\mathcal{C}(\eta_0)$ for all $\ell \geq \ell_\epsilon$.

Since the sequence $(f(x_\ell)) : \ell \geq 0$ is increasing and bounded, it is convergent and since

$$f(x_{t+1}) - f(x_t) \geq \frac{\theta}{2} \|\nabla f(x_\ell)\|^2,$$

we deduce that

$$\lim_{\ell \rightarrow \infty} \|\nabla f(x_\ell)\| = 0.$$

Recall that by Claim 1 we can assume that $\mathcal{L}(f(x_0))$ is bounded in which case $\mathcal{C}(\eta_0)$ is compact. Then we conclude that (x_ℓ) is convergent with $x_\ell \rightarrow x^*$ by continuity of the gradient of f and the fact that x^* is the only critical point of f in $\mathcal{C}(\eta_0)$.

Acknowledgments

We are grateful to Jose E. Chacón for alerting us of the mistake and for referring us to the articles (Li et al., 2007; Ghassabeh, 2015).

Modelling Interactions in High-dimensional Data with Backtracking

Abstract

We study the problem of high-dimensional regression when there may be interacting variables. Approaches using sparsity-inducing penalty functions such as the Lasso can be useful for producing interpretable models. However, when the number of variables runs into the thousands, and so even two-way interactions number in the millions, these methods may become computationally infeasible. Typically variable screening based on model fits using only main effects must be performed first. One problem with screening is that important variables may be missed if they are only useful for prediction when certain interaction terms are also present in the model.

To tackle this issue, we introduce a new method we call Backtracking. It can be incorporated into many existing high-dimensional methods based on penalty functions, and works by building increasing sets of candidate interactions iteratively. Models fitted on the main effects and interactions selected early on in this process guide the selection of future interactions. By also making use of previous fits for computation, as well as performing calculations in parallel, the overall run-time of the algorithm can be greatly reduced.

The effectiveness of our method when applied to regression and classification problems is demonstrated on simulated and real data sets. In the case of using Backtracking with the Lasso, we also give some theoretical support for our procedure.

Keywords: high-dimensional data, interactions, Lasso, path algorithm

1. Introduction

In recent years, there has been a lot of progress in the field of high-dimensional regression. Much of the development has centred around the Lasso (Tibshirani, 1996), which given a vector of responses $\mathbf{Y} \in \mathbb{R}^n$ and design matrix $\mathbf{X} \in \mathbb{R}^{n \times p}$, solves

$$(\hat{\mu}, \hat{\beta}) := \arg \min_{(\mu, \beta) \in \mathbb{R} \times \mathbb{R}^p} \left\{ \frac{1}{2n} \|\mathbf{Y} - \mu \mathbf{1} - \mathbf{X}\beta\|_2^2 + \lambda \|\beta\|_1 \right\}, \quad (1)$$

where $\mathbf{1}$ is an n -vector of ones and the regularisation parameter λ controls the relative contribution of the penalty term to the objective. The many extensions of the Lasso allow most familiar models from classical (low-dimensional) statistics to now be fitted in situations where the number of variables p may be tens of thousands and even greatly exceed the number of observations n (see the monograph Bühlmann and van de Geer (2011b) and references therein).

However, despite the advances, fitting models with interactions remains a challenge. Two issues that arise are:

- (i) Since there are $p(p-1)/2$ possible first-order interactions, the main effects can be swamped by the vastly more numerous interaction terms and without proper regularisation, stand little chance of being selected in the final model (see Figure 1b).
- (ii) Monitoring the coefficients of all the interaction terms quickly becomes infeasible as p runs into the thousands.

1.1 Related Work

For situations where $p < 1000$ or thereabouts and the case of two-way interactions, a lot of work has been done in recent years to address this need. To tackle (i), many of the proposals use penalty functions and constraints designed to enforce that if an interaction term is in the fitted model, one or both main effects are also present (Lin and Zhang, 2006; Zhao et al., 2009; Yuan et al., 2009; Radchenko and James, 2010; Jenatton et al., 2011; Bach et al., 2012a,b; Bien et al., 2013; Lim and Hastie, 2015; Haris et al., 2015). See also Turlach (2004) and Yuan et al. (2007), which consider modifications of the LAR algorithm Efron et al. (2004) that impose this type of condition.

In the moderate-dimensional setting that these methods are designed for, the computational issue (ii) is just about manageable. However, when p is larger—the situation of interest in this paper—it typically becomes necessary to narrow the search for interactions. Comparatively little work has been done on fitting models with interactions to data of this sort of dimension. An exception is the method of Random Intersection Trees (Shah and Meinshausen, 2014), which does not explicitly restrict the search space of interactions. However this is designed for a classification setting with a binary predictor matrix and does not fit a model but rather tries to find interactions that are marginally informative.

One option is to screen for important variables and only consider interactions involving the selected set. Wu et al. (2010) and others take this approach: the Lasso is first used to select main effects; then interactions between the selected main effects are added to the design matrix, and the Lasso is run once more to give the final model.

The success of this method relies on all main effects involved in interactions being selected in the initial screening stage. However, this may well not happen. Certain interactions may need to be included in the model before some main effects can be selected. To address this issue, Bickel et al. (2010) propose a procedure involving sequential Lasso fits which, for some predefined number K , selects K variables from each fit and then adds all interactions between those variables as candidate variables for the following fit. The process continues until all interactions to be added are already present. However, it is not clear how one should choose K : a large K may result in a large number of spurious interactions being added at each stage, whereas a small K could cause the procedure to terminate before it has had a chance to include important interactions.

Rather than adding interactions in one or more distinct stages, when variables are selected in a greedy fashion, the set of candidate interactions can be updated after each selection. This dynamic updating of interactions available for selection is present in the popular MARS procedure of Friedman (1991). One potential problem with this approach

is that particularly in high-dimensional situations, overly greedy selection can sometimes produce unstable final models and predictive performance can suffer as a consequence.

The iFORT method of Hao and Zhang (2014) applies forward selection to a dynamically updated set of candidate interactions and main effects, for the purposes of variable screening. In this work, we propose a new method we call Backtracking, for incorporating a similar model building strategy to that of MARS and iFORT into methods based on sparsity-inducing penalty functions. Though greedy forward selection methods often work well, penalty function-based methods such as the Lasso can be more stable (see Efron et al. (2004)) and offer a useful alternative.

1.2 Outline of the Idea

When used with the Lasso, Backtracking begins by computing the Lasso solution path, decreasing λ from ∞ . A second solution path, P_2 , is then produced, where the design matrix contains all main effects, and also the interaction between the first two active variables in the initial path. Continuing iteratively, subsequent solution paths P_3, \dots, P_T are computed where the set of main effects and interactions in the design matrix for the k th path is determined based on the previous path P_{k-1} . Thus if in the third path, a key interaction was included and so variable selection was then more accurate, the selection of interactions for all future paths would benefit. In this way information is used as soon as it is available, rather than at discrete stages as with the method of Bickel et al. (2010). In addition, if all important interactions have already been included by P_3 , we have a solution path unhindered by the addition of further spurious interactions.

It may seem that a drawback of our proposed approach is that the computational cost of producing all T solution paths will usually be unacceptably large. However, computation of the full collection of solution paths is typically very fast. This is because rather than computing each of the solution paths from scratch, for each new solution path P_{k+1} , we first track along the previous path P_k to find where P_{k+1} departs from P_k . This is the origin of the name Backtracking. Typically, checking whether a given trial solution is on a solution path requires much less computation than calculating the solution path itself, and so this Backtracking step is rather quick. Furthermore, when the solution paths do separate, the tail portions of the paths can be computed in parallel.

An R (R Development Core Team, 2005) package for the method is available on the author's website.

1.3 Organisation of the Paper

The rest of the paper is organised as follows. In Section 2 we describe an example which provides some motivation for our Backtracking method. In Section 3 we develop our method in the context of the Lasso for the linear model. In Section 4, we describe how our method can be extended beyond the case of the Lasso for the linear model. In Section 5 we report the results of some simulation experiments and real data analyses that demonstrate the effectiveness of Backtracking. Finally, in Section 6, we present some theoretical results which aim to give a deeper understanding of the way in which Backtracking works. Proofs are collected in the appendix.

2. Motivation

In this section we introduce a toy example where approaches that select candidate interactions based on selected main effects will tend to perform poorly. We consider a linear model with interactions involving a design matrix $\mathbf{X} \in \mathbb{R}^{n \times p}$ with $n = 200$, $p = 500$ and where

$$Y_i = \sum_{j=1}^6 \beta_j X_{ij} + \beta_7 X_{i1} X_{i2} + \beta_8 X_{i3} X_{i4} + \beta_9 X_{i5} X_{i6} + \varepsilon_i, \quad \varepsilon_i \sim N(0, \sigma^2), \quad i = 1, \dots, n. \quad (2)$$

We take \mathbf{X} with i.i.d. rows having a distribution such that X_{i5} is uncorrelated with $\{X_{ij} : j \neq 5\}$. We then choose β_1, \dots, β_9 in such a way that X_{i5} is also uncorrelated with the response yet $\beta_5 \neq 0$. The precise construction is detailed in the appendix.

In order to select variable 5 using that Lasso, we would need to have already selected some important interactions. Thus if we first select important main effects using the Lasso, for example, it is very unlikely that variable 5 will be selected. Then if we add all two-way interactions between the selected variables and fit the Lasso once more, the interaction between variables 5 and 6 will not be included. Of course, one can again add interactions between selected variables and compute another Lasso fit, and then there is a chance the interaction will be selected. Thus it is very likely that at least three Lasso fits will be needed in order to select the right variables.

Figure 1a shows the result of applying the Lasso to data generated according to (2), σ chosen to give a signal-to-noise ratio (SNR) of 4, and

$$\boldsymbol{\beta} = (-1.25, -0.75, 0.75, -0.5, -2, 1.5, 2, 2, 1)^T.$$

As expected, we see variable 5 is nowhere to be seen and instead many unwanted variables are selected as λ is decreased. Figure 1b illustrates the effect of including all $p(p-1)/2$ possible interactions in the design matrix. Even in our rather moderate-dimensional situation, we are not able to recover the true signal. Though all the true interaction terms are selected, now neither variable 4 nor variable 5 are present in the solution paths and many false interactions are selected.

Although this example is rather contrived, it illustrates how sometimes the right interactions need to be augmented to the design matrix in order for certain variables to be selected. Even when interactions are only present if the corresponding main effects are too, main effects can be missed by a procedure that does not consider interactions. In fact, we can see the same phenomenon occurring when the design matrix has i.i.d. Gaussian entries (see Section 5.1). Thus multiple Lasso fits might be needed to have any chance of selecting the right model.

This raises the question of which tuning parameters to use in the multiple Lasso fits. One option, which we shall refer to as the iterated Lasso, is to select tuning parameters by cross-validation each time. A drawback of this approach, though, is that the number of interactions to add can be quite large if cross-validation chooses a large active set. This is often the case when the presence of interactions makes some important main effects hard to distinguish from noise variables in the initial Lasso fit. Then cross-validation may choose a low λ in order to try to select those variables, but this would result in many noise variables also being included in the active set.

We take an alternative approach here and include suspected interactions in the design matrix as soon as possible. That is, if we progress along the solution path from $\lambda = \infty$, and two variables enter the model, we immediately add their interaction to the design matrix and start computing the Lasso again. We could now disregard the original path, but there is little to lose, and possibly much to gain, in continuing the original path in parallel with the new one. We can then repeat this process, adding new interactions when necessary, and restarting the Lasso, whilst still continuing all previous paths in parallel. We show in the next section how computation can be made very fast since many of these solution paths will share the same initial portions.

3. Backtracking with the Lasso

In this section we introduce a version of the Backtracking algorithm applied to the Lasso (1). First, we present a naive version of the algorithm, which is easy to understand. Later in Section 3.2, we show that this algorithm performs a large number of unnecessary calculations, and we give a far more efficient version.

3.1 A Naive Algorithm

As well as a base regression procedure, the other key ingredient that Backtracking requires is a way of suggesting candidate interactions based on selected main effects, or more generally a way of suggesting higher-order interactions based on lower-order interactions. In order to discuss this and present our algorithm, we first introduce some notation concerning interactions.

Let \mathbf{X} be the original $n \times p$ design matrix, with no interactions. In order to consider interactions in our models, rather than indexing variables by a single number j , we use subsets of $\{1, \dots, p\}$. Thus by variable $\{1, 2\}$, we mean the interaction between variables 1 and 2, or in our new notation, variables $\{1\}$ and $\{2\}$. When referring to main effects $\{j\}$ however, we will often omit the braces. As we are using the Lasso as the base regression procedure here, interaction $\{1, 2\}$ will be the componentwise product of the first two columns of \mathbf{X} . We will write $\mathbf{X}_v \in \mathbb{R}^n$ for variable v .

The choice of whether and how to scale and centre interactions and main effects can be a rather delicate one, where domain knowledge may play a key role. In this work, we will centre all main effects, and scale them to have ℓ_2 -norm \sqrt{n} . The interactions will be created using these centred and scaled main effects, and they themselves will also be centred and scaled to have ℓ_2 -norm \sqrt{n} .

For C a set of subsets of $\{1, \dots, p\}$ we can form a modified design matrix \mathbf{X}_C , where the columns of \mathbf{X}_C are given by the variables in C , centred and scaled as described above. Thus C is the set of candidate variables available for selection when design matrix \mathbf{X}_C is used. This subsetting operation will always be taken to have been performed before any further operations on the matrix, so in particular \mathbf{X}_C^T means $(\mathbf{X}_C)^T$.

We will consider all associated vectors and matrices as indexed by variables, so we may speak of component $\{1, 2\}$ of β , denoted $\beta_{\{1,2\}}$, if β were multiplying a design matrix which included $\{1, 2\}$. Further, for any collection of variables A , we will write β_A for the subvector whose components are those indexed by A . To represent an arbitrary variable which may be an interaction, we shall often use v or u and reserve j to index main effects.

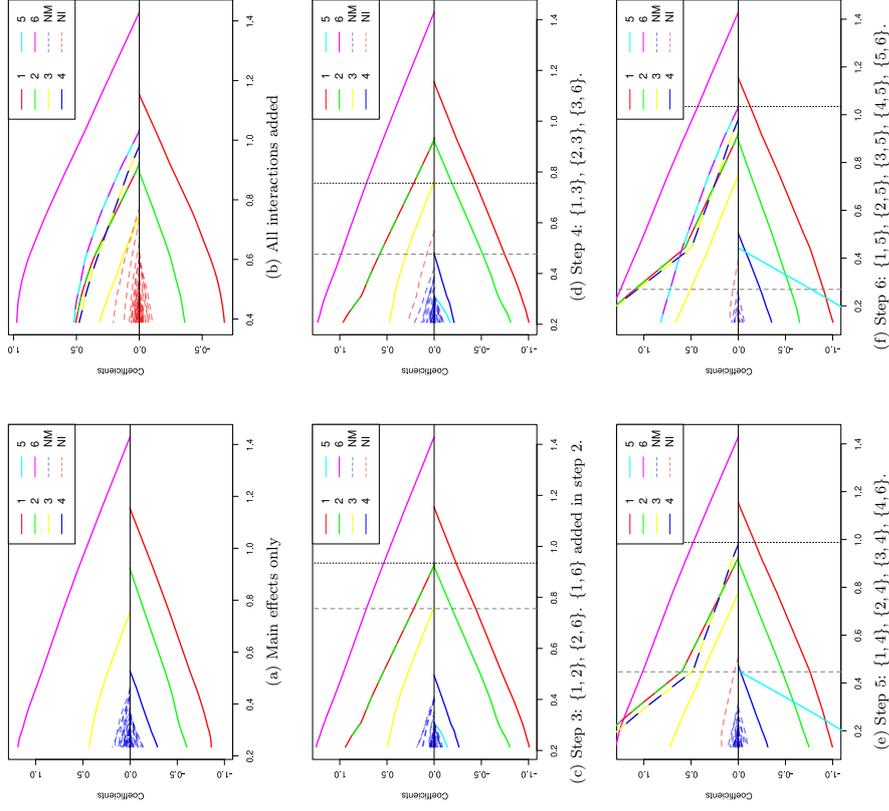

Figure 1: For data generated as described in Section 2, the coefficient paths against λ of the Lasso with main effects only, (a); the Lasso with all interactions added, (b); and Backtracking with $k = 3, \dots, 6$, ((c)-(d)); when applied to the example in Section 2. Below the Backtracking solution paths we give $C_k \setminus C_{k-1}$: the interactions which have been added in the current step. The solid red, green, yellow, blue, cyan and magenta lines trace the coefficients of variables 1, ..., 6 respectively, with the alternately coloured lines representing the corresponding interactions. The dotted blue and red coefficient paths indicate noise main effect ('NM') and interaction ('NI') terms respectively. Vertical dotted black and dashed grey lines give the values of λ_k^{start} and λ_k^{add} respectively.

We will often need to express the dependence of the Lasso solution $\hat{\beta}(1)$ on the tuning parameter λ and the design matrix used. We shall write $\hat{\beta}(\lambda, C)$ when \mathbf{X}_C is the design matrix. We will denote the set of active components of a solution β by $\mathcal{A}(\beta) = \{v : \hat{\beta}_v \neq 0\}$.

We now introduce a function \mathcal{I} that given a set of variables A , suggests a set of interactions to add to the design matrix. The choice of \mathcal{I} we use here is as follows:

$$\mathcal{I}(A) = \{v \subseteq \{1, \dots, p\} : \text{for all } u \subseteq v, u \neq \emptyset, u \in A\}.$$

In other words, $\mathcal{I}(A)$ is the set of variables not in A , all of whose corresponding lower order interactions are present in A . To ease notation, when A contains only main effects j_1, \dots, j_s , we will write $\mathcal{I}(j_1, \dots, j_s) = \mathcal{I}(A)$. For example, $\mathcal{I}(1, 2) = \{\{1, 2\}\}$, and $\mathcal{I}(1, 2, 3) = \{\{1, 2\}, \{2, 3\}, \{1, 3\}\}$. Note $\{1, 2, 3\} \notin \mathcal{I}(1, 2, 3)$ as the lower order interaction $\{1, 2\}$ of $\{1, 2, 3\}$ is not in $\{\{1\}, \{2\}, \{3\}\}$; for example. Other choices for \mathcal{I} can be made, and we discuss some further possibilities in Section 4.

Backtracking relies on a path algorithm for computing the Lasso on a grid of λ values $\lambda_1 > \dots > \lambda_T$. Several algorithms are available and coordinate descent methods (Friedman et al., 2010) appears to work well in practice.

We are now in a position to introduce a naive version of our Backtracking algorithm applied to the Lasso (Algorithm 1). We will assume that the response \mathbf{Y} is centred in addition to the design matrix; so no intercept term is necessary.

Algorithm 1 A naive version of Backtracking with the Lasso

Set T to be the (given) maximum number of candidate interaction sets to generate. Let the initial candidate set consist of just main effects: $C_1 = \{\{1\}, \dots, \{p\}\}$. Set the index for the candidate sets $k = 1$. Let $\lambda_1^{\text{start}} = \lambda_1$, the largest λ value on the grid. In the steps which follow, we maintain a record of the set of variables which have been non-zero at any point in the algorithm up to the current point (an ‘‘ever active set’’, A).

1. Compute the solution path of the Lasso with candidate set C_k from λ_k^{start} onwards until the ever active set A has $\mathcal{I}(A) \not\subseteq C_k$ (if the smallest λ value on the grid is reached then go to 5). Let the λ value where this occurs be λ_k^{add} . We will refer to this solution path as P_k .
2. Set $C_{k+1} = C_k \cup \mathcal{I}(A)$ so the next candidate set contains all interactions between variables in the ever active set.
3. Set $\lambda_{k+1}^{\text{start}} = \lambda_1$.
4. Increment k . If $k > T$ go to 5, otherwise go back to 1.
5. For each k complete the solution path P_k by continuing it until $\lambda = \lambda_T$. Computing these final pieces of the solution paths can be done in parallel.

The algorithm computes Lasso solution paths whose corresponding design matrices include interactions chosen based on previous paths. The quantity λ_k^{add} records the value of λ at which interaction terms were added to the set of candidates C_k . Here λ_k^{start} is a redundant quantity and can be replaced everywhere with λ_1 to give the same algorithm.

We include it at this stage though to aid with the presentation of an improved version of the algorithm where λ_k^{start} in general takes values other than λ_1 . We note that the final step of completing the solution paths can be carried out as the initial paths are being created, rather than once all initial paths have been created. Though here the algorithm can include three-way or even higher order interactions; it is straightforward to restrict the possible interactions to be added to first-order interactions, for example.

3.2 An Improved Algorithm

The process of performing multiple Lasso fits is computationally cumbersome, and an immediate gain in efficiency can be realised by noticing that the final collection of solution paths is in fact a tree of solutions: many of the solution paths computed will share the same initial portions.

To discuss this, we first recall the KKT conditions for the Lasso dictate that $\hat{\beta}$ is a solution to (1) when the design matrix is \mathbf{X}_C if and only if

$$\frac{1}{n} \mathbf{X}_C^T (\mathbf{Y} - \mathbf{X}_C \hat{\beta}) = \lambda \text{sgn}(\hat{\beta}_v) \quad \text{for } \hat{\beta}_v \neq 0 \tag{3}$$

$$\frac{1}{n} |\mathbf{X}_C^T (\mathbf{Y} - \mathbf{X}_C \hat{\beta})| \leq \lambda \quad \text{for } \hat{\beta}_v = 0. \tag{4}$$

Note the $\beta \mathbf{X}_C^T \mathbf{1}$ term vanishes as the columns of \mathbf{X}_C are centred.

We see that if for some λ

$$\frac{1}{n} \|\mathbf{X}_{C_{k+1} \setminus C_k}^T (\mathbf{Y} - \mathbf{X}_{C_k} \hat{\beta}(\lambda, C_k))\|_\infty \leq \lambda, \tag{5}$$

then

$$\hat{\beta}_{C_{k+1} \setminus C_k}(\lambda, C_{k+1}) = 0, \quad \hat{\beta}_{C_k}(\lambda, C_{k+1}) = \hat{\beta}(\lambda, C_k).$$

Thus given solution path P_k , we can attempt to find the smallest λ such that (5) holds. Up to that point then, path P_{k+1} will coincide with P_k and so those Lasso solutions need not be re-computed. Note that verifying (5) is a computationally simple task requiring only $O(|C_{k+1} \setminus C_k|n)$ operations.

Our final Backtracking algorithm therefore replaces step 3 of Algorithm 1 with the following:

- 3a. Find the smallest $\lambda \geq \lambda_T \geq \lambda_k^{\text{add}}$ such that (5) holds with $\lambda = \lambda$ and set this to be $\lambda_{k+1}^{\text{start}}$. If no such λ exists, set $\lambda_{k+1}^{\text{start}}$ to be λ_1 .

Figures 1c–1f show steps 3–6 (i.e. $k = 3, \dots, 6$) of Backtracking applied to the example described in Section 2. Note that Figure 1a is in fact step 1. Step 2 is not shown as the plot looks identical to that in Figure 1a. We see that when $k = 6$, we have a solution path where all the true variable and interaction terms are active before any noise variables enter the coefficient plots.

We can further speed up the algorithm by first checking if P_k coincides with P_{k+1} at λ_k^{add} . If not, we can perform a bisection search to find any point where P_k and P_{k+1} agree, but after which they disagree. This avoids checking (5) for every λ up to λ_k^{add} . We will work with the simpler version of Backtracking here using step 3a, but use this faster version in our implementation.

4. Further Applications of Backtracking

Our Backtracking algorithm has been presented in the context of the Lasso for the linear model. However, the real power of the idea is that it can be incorporated into any method that produces a path of increasingly complex sparse solutions by solving a family of convex optimisation problems parametrised by a tuning parameter. For the Backtracking step, the KKT conditions for these optimisation problems provide a way of checking whether a given trial solution is an optimum. As in the case of the Lasso, checking whether the KKT conditions are satisfied typically requires much less computational effort than computing a solution from scratch. Below we briefly sketch some applications of Backtracking to a few of the many possible methods with which it can be used.

4.1 Multinomial Regression

An example, which we apply to real data in Section 5.2, is multinomial regression with a group Lasso (Yuan and Lin, 2006) penalty. Consider m observations of a categorical response that takes J levels, and p associated covariates. Let \mathbf{Y} be the indicator response matrix, with ij th entry equal to 1 if the i th observation takes the j th level, and 0 otherwise. We model

$$\mathbb{P}(Y_{ij} = 1) := \Pi_{ij}(\boldsymbol{\mu}^*, \boldsymbol{\beta}^*; \mathbf{X}_{S^*}) := \frac{\exp(\mu_j^* + (\mathbf{X}_{S^*} \boldsymbol{\beta}_j^*)_i)}{\sum_{j'=1}^J \exp(\mu_{j'}^* + (\mathbf{X}_{S^*} \boldsymbol{\beta}_{j'}^*)_i)}.$$

Here $\boldsymbol{\mu}^*$ is a vector of intercept terms and $\boldsymbol{\beta}^*$ is a $|S^*| \times J$ matrix of coefficients; $\boldsymbol{\beta}_j^*$ denotes the j th column of $\boldsymbol{\beta}^*$. This model is over-parametrised, but regularisation still allows us to produce estimates of $\boldsymbol{\mu}^*$ and $\boldsymbol{\beta}^*$ and hence also of $\boldsymbol{\Pi}$ (see Friedman et al. (2010)). When our design matrix is \mathbf{X}_C , these estimates are given by $(\hat{\boldsymbol{\mu}}, \hat{\boldsymbol{\beta}}) := \arg \min_{\boldsymbol{\mu}, \boldsymbol{\beta}} Q(\boldsymbol{\mu}, \boldsymbol{\beta}; \lambda)$ where

$$Q(\boldsymbol{\mu}, \boldsymbol{\beta}; \lambda) := \frac{1}{n} \sum_{j=1}^J \mathbf{Y}_j^T (\boldsymbol{\mu}_j \mathbf{1} + \mathbf{X}_C \boldsymbol{\beta}_j) - \frac{1}{n} \mathbf{1}^T \log \left(\sum_{j=1}^J \exp(\boldsymbol{\mu}_j \mathbf{1} + \mathbf{X}_C \boldsymbol{\beta}_j) \right) + \lambda \sum_{v \in C} \|(\boldsymbol{\beta}^T)_v\|_2.$$

The functions log and exp are to be understood as applied componentwise and the rows of $\boldsymbol{\beta}$ are indexed by elements of C . To derive the Backtracking step for this situation, we turn to the KKT conditions which characterise the minima of Q :

$$\begin{aligned} \frac{1}{n} (\mathbf{Y}^T - \boldsymbol{\Pi}^T(\hat{\boldsymbol{\mu}}, \hat{\boldsymbol{\beta}}; \mathbf{X}_C)) \mathbf{1} &= \mathbf{0}, \\ \frac{1}{n} \{ \mathbf{Y}^T - \boldsymbol{\Pi}^T(\hat{\boldsymbol{\mu}}, \hat{\boldsymbol{\beta}}; \mathbf{X}_C) \} \mathbf{X}_v &= -\lambda \frac{(\hat{\boldsymbol{\beta}}^T)_v}{\|(\hat{\boldsymbol{\beta}}^T)_v\|_2} \quad \text{for } (\hat{\boldsymbol{\beta}}^T)_v \neq \mathbf{0}, \\ \frac{1}{n} \| \{ \mathbf{Y}^T - \boldsymbol{\Pi}^T(\hat{\boldsymbol{\mu}}, \hat{\boldsymbol{\beta}}; \mathbf{X}_C) \} \mathbf{X}_v \|_2 &\leq \lambda \quad \text{for } (\hat{\boldsymbol{\beta}}^T)_v = \mathbf{0}. \end{aligned}$$

Thus, analogously to (5), for $D \supseteq C$, $(\hat{\boldsymbol{\beta}}^T(\lambda, D))_{D \setminus C} = \mathbf{0}$ and $(\hat{\boldsymbol{\beta}}^T(\lambda, D))_C = \hat{\boldsymbol{\beta}}^T(\lambda, C)$ if and only if

$$\max_{v \in D \setminus C} \frac{1}{n} \| \{ \mathbf{Y}^T - \boldsymbol{\Pi}^T(\hat{\boldsymbol{\mu}}(\lambda, C), \hat{\boldsymbol{\beta}}(\lambda, C); \mathbf{X}_C) \} \mathbf{X}_v \|_2 \leq \lambda.$$

4.2 Structural Sparsity

Although in our Backtracking algorithm, interaction terms are only added as candidates for selection when all their lower order interactions and main effects are active, this hierarchy in the selection of candidates does not necessarily follow through to the final model: one can have first-order interactions present in the final model without one or more of their main effects, for example. One way to enforce the hierarchy constraint in the final model is to use a base procedure which obeys the constraint itself. Examples of such base procedures are provided by the Composite Absolute Penalties (CAP) family (Zhao et al., 2009).

Consider the linear regression setup with interactions. For simplicity we only describe Backtracking with first-order interactions. Let C be the candidate set and let $I = C \setminus C_1$ be the (first-order) interaction terms in C . In order to present the penalty, we borrow some notation from Combinatorics. Let $C_1^{(r)}$ denote the set of r -subsets of C_1 . For $A \subseteq C_1^{(r)}$ and $r \geq 1$, define

$$\begin{aligned} \partial_l(A) &= \{v \in C_1^{(r-1)} : v \subset u \text{ for some } u \in A\} \\ \partial_u(A) &= \{v \in C_1^{(r+1)} : v \subset u \text{ for some } u \in A\} \end{aligned}$$

These are known as the *lower shadow* and *upper shadow* respectively (Bollobás, 1986).

Our objective function Q is given by

$$Q(\boldsymbol{\mu}, \boldsymbol{\beta}) = \frac{1}{2n} \|\mathbf{Y} - \boldsymbol{\mu} \mathbf{1} - \mathbf{X}_C \boldsymbol{\beta}\|_2^2 + \lambda \|\boldsymbol{\beta}_{C_1 \setminus \partial_l(I)}\|_1 + \lambda \sum_{v \in \partial_l(I)} \|\boldsymbol{\beta}_{\{v\} \cup \partial_u(\{v\} \cap I)}\|_\gamma + \lambda \|\boldsymbol{\beta}_I\|_1,$$

where $\gamma > 1$. For example, if $C = \{\{1\}, \dots, \{4\}, \{1, 2\}, \{2, 3\}\}$, then omitting the factor of λ , the penalty terms in Q are

$$|\beta_4| + \|(\beta_1, \beta_{\{1,2\}})^T\|_\gamma + \|(\beta_2, \beta_{\{1,2\}}, \beta_{\{2,3\}})^T\|_\gamma + \|(\beta_3, \beta_{\{2,3\}})^T\|_\gamma + |\beta_{\{1,2\}}| + |\beta_{\{2,3\}}|.$$

The form of this penalty forces interactions to enter the active set only after or with their corresponding main effects.

The KKT conditions for this optimisation take a more complicated form than those for the Lasso. Nevertheless, checking they hold for a trial solution is an easier task than computing a solution.

4.3 Nonlinear Models

If a high-dimensional additive modelling method (Ravikumar et al., 2009; Meier et al., 2009) is used as the base procedure, it is possible to fit nonlinear models with interactions. Here each variable is a collection of basis functions, and to add an interaction between variables, one adds the tensor product of the two collections of basis functions, penalizing the new interaction basis functions appropriately. Structural sparsity approaches can also be used here. The VANISH method of Radchenko and James (2010) uses a CAP-type penalty in nonlinear regression, and this can be used as a base procedure in a similar way to that sketched above.

4.4 Introducing more Candidates

In our description of the Backtracking algorithm, we only introduce an interaction term when *all* of its lower order interactions and main effects are active. Another possibility, in the spirit of MARS (Friedman, 1991), is to add interaction terms when *any* of their lower order interactions or main effects are active. As at the k th step of Backtracking, there will be roughly kp extra candidates, an approach that can enforce the hierarchical constraint may be necessary to allow main effects to be selected from amongst the more numerous interaction candidates. The key point to note is that if the algorithm is terminated after T steps, we are having to deal with roughly at most Tp variables rather than $O(p^2)$, the latter coming from including all first-order interactions.

Another option proposed by a referee is to augment the initial set of candidates with interactions selected through a simple marginal screening step. If only pairwise interactions are considered here, then this would require $O(p^2\pi)$ operations. Though this would be infeasible for very large p , for moderate p this would allow important interactions whose corresponding main effects are not strong to be selected.

5. Numerical Results

In this section we evaluate the performance of Backtracking on both simulated and real data sets.

5.1 Simulations

Here we consider five numerical studies designed to demonstrate the effectiveness of Backtracking with the Lasso and also highlight some of the drawbacks of using the Lasso with main effects only, when interactions are present. In each of the five scenarios, we generated 200 design matrices with $n = 250$ observations and $p = 1000$ covariates. The rows of the design matrices were sampled independently from $N_p(\mathbf{0}, \Sigma)$ distributions. The covariance matrix Σ was chosen to be the identity in all scenarios except scenario 2, where

$$\Sigma_{ij} = 0.75^{-|i-j|-p/2+p/2}.$$

Thus in this case, the correlation between the components decays exponentially with the distance between them in $\mathbb{Z}/p\mathbb{Z}$.

We created the responses according to the linear model with interactions and set the intercept to 0:

$$\mathbf{Y} = \mathbf{X}_S^* \beta_S^* + \epsilon, \quad \epsilon_i \stackrel{\text{i.i.d.}}{\sim} N(0, \sigma^2). \quad (6)$$

The error variance σ^2 was chosen to achieve a signal-to-noise ratio (SNR) of either 2 or 3. The set of main effects in S^* , S_1^* , was $1, \dots, 10$. The subset of variables involved in interactions was $1, \dots, 6$. The set of first-order interactions in S^* chosen in the different scenarios, S_2^* , is displayed in Table 1, and we took $S^* = S_1^* \cup S_2^*$ so S^* contained no higher order interactions. In each simulation run, $\beta_{S_1^*}^*$ was fixed and given by

$$(2, -1.5, 1.25, -1, 1, -1, 1, 1, 1, 1)^T.$$

Scenario	S_2^*
1	\emptyset
2	\emptyset
3	$\{\{1, 2\}, \{3, 4\}, \{5, 6\}\}$
4	$\{\{1, 2\}, \{1, 3\}, \dots, \{1, 6\}\}$
5	$\mathcal{I}(1, 2, 3) \cup \mathcal{I}(4, 5, 6)$

Table 1: Simulation settings.

Each component of $\beta_{S_2^*}^*$ was chosen to be $\sqrt{\|\beta_{S_1^*}^*\|_2^2 / |S_1^*|}$. Thus the squared magnitude of the interactions was equal to average of the squared magnitudes of the main effects.

In all of the scenarios, we applied four methods: the Lasso using only the main effects; iterated Lasso fits; marginal screening for interactions followed by the Lasso; and the Lasso with Backtracking. Note that due to the size of p in these examples, most of the methods for finding interactions in lower-dimensional data discussed in Section 1, are computationally impractical here.

For the iterated Lasso fits, we repeated the following process. Given a design matrix, first fit the Lasso. Then apply 5-fold cross-validation to give a λ value and associated active set. Finally add all interactions between variables in this active set to the design matrix, ready for the next iteration. For computational feasibility, the procedure was terminated when the number of variables in the design matrix exceeded $p + 250 \times 249/2$.

With the marginal screening approach, we selected the $2p$ interactions with the largest marginal correlation with the response and added them to the design matrix. Then a regular Lasso was performed on the augmented matrix of predictors.

Additionally, in scenarios 3-5, we applied the Lasso with all main effects and only the true interactions. This theoretical Oracle approach provided a gold standard against which to test the performance of Backtracking.

We used the procedures mentioned to yield active sets on which we applied OLS to give a final estimator. To select the tuning parameters of the methods we used cross-validation randomly selection 5 folds but repeating this a total of 5 times to reduce the variance of the cross-validation scores. Thus for each λ value we obtained an estimate of the expected prediction error that was an average over the observed prediction errors on 25 (overlapping) validation sets of size $n/5 = 50$. Note that for both Backtracking and the iterated Lasso, this form of cross-validation chose not just a λ value but also a path rank. When using Backtracking, the size of the active set was restricted to 50 and the size of C_λ to $p + 50 \times 49/2 = 1225$, so T was at most 50.

In scenarios 1 and 2, the results of the methods were almost indistinguishable except that the screening approach performed far worse in scenario 1 where it tended to select several false interactions which in turn hampered the selection of main effects and resulted in a much larger prediction error.

The results of scenarios 3-5, where the signal contains interactions, are more interesting and given in Table 2. For each scenario, method and SNR level, we report 5 statistics. L_2 -sq² is the expected squared distance of the signal \mathbf{f}^* and our prediction functions $\hat{\mathbf{f}}$ based

on training data $(\mathbf{Y}_{\text{train}}, \mathbf{X}_{\text{train}})$, evaluated at a random independent test observation \mathbf{x}_{new} :

$$\mathbb{E}_{\mathbf{x}_{\text{new}}, \mathbf{Y}_{\text{train}}, \mathbf{X}_{\text{train}}} \|\mathbf{f}^*(\mathbf{x}_{\text{new}}) - \hat{\mathbf{f}}(\mathbf{x}_{\text{new}}; \mathbf{Y}_{\text{train}}, \mathbf{X}_{\text{train}})\|^2.$$

‘FP Main’ and ‘FP Inter’ are the numbers of noise main effects and noise interaction terms respectively, incorrectly included in the final active set. ‘FN Main’ and ‘FN Inter’ are the numbers of true main effects and interaction terms respectively, incorrectly excluded from the final active set.

For all the statistics presented, lower numbers are to be preferred. However, the higher number of false selections incurred by both Backtracking and the Oracle procedure compared to using the main effects only or iterated Lasso fits, is due to the model selection criterion being the expected prediction error. It should not be taken as an indication that the latter procedures are performing better in these cases.

Backtracking performs best out of the four methods compared here. Note that under all of the settings, iterated Lasso fits incorrectly selects more interaction terms than Backtracking. We see that the more careful way in which Backtracking adds candidate interactions, helps here. Unsurprisingly, fitting the Lasso on just the main effects performs rather poorly in terms of predictive performance. However, it also fails to select important main effects; Backtracking and Iterates have much lower main effect false negatives. The screening approach appears to perform worst here. This is partly because it is not making use of the fact that in all of the examples considered, the main effects involved in interactions are also informative. However, its poor performance is also due to the fact that too many false interactions are added to the design matrix after the screening stage. Reducing the number added may help to improve results, but choosing the number of interactions to include via cross-validation, for example, would be computationally costly, unless a Backtracking-type strategy of the sort introduced in this paper were used. We also note that for very large p , marginal screening of interactions would be infeasible due to the quadratic scaling in complexity with p .

5.2 Data Analyses

In this section, we look at the performance of Backtracking using two base procedures, the Lasso for the linear model and the Lasso for multinomial regression, on a regression and a classification data set. As competing methods, we consider simply using the base procedures (‘Main’), iterated Lasso fits (‘Iterated’), Lasso following marginal screening for interactions (‘Screening’), Random Forests (Breiman, 2001), hierNet (Bien et al., 2013) and MARS (Friedman, 1991) (implemented using Hastie et al. (2013)). Note that we do not view the latter two methods as competitors of Backtracking, as they are designed for use on lower dimensional data sets than Backtracking is capable of handling. However, it is still interesting to see how the methods perform on data of dimension that is perhaps approaching the upper end of what is easily manageable for methods such as hierNet and MARS, but at the lower end of what one might use Backtracking on.

Below we describe the data sets used which are both from the UCI machine learning repository (Asuncion and Newman, 2007).

Scenario	Statistic	SNR = 2			SNR = 3		
		Main	Iter-ate	Back-tracking	Main	Iter-ate	Back-tracking

Table 2: Simulation results.

5.2.1 COMMUNITIES AND CRIME

This data set available at <http://archive.ics.uci.edu/ml/datasets/Communities+and+Crime> contains crime statistics for the year 1995 obtained from FBI data, and national census data from 1990, for various towns and communities around the USA. We took violent crimes per capita as our response: violent crime being defined as murder, rape, robbery, or assault. The data set contains two different estimates of the populations of the communities: those from the 1990 census and those from the FBI database in 1995. The latter was used to calculate our desired response using the number of cases of violent crimes. However, in several cases, the FBI population data seemed suspect and we discarded all observations where the maximum of the ratios of the two available population estimates differed by more than 1.25. In addition, we removed all observations that were missing a response and several variables for which the majority of values were missing. This resulted in a data set with $n = 1903$ observations and $p = 101$ covariates. The response was scaled to have empirical variance 1.

5.2.2 ISOLET

This data set consists of $p = 617$ features based on the speech waveforms generated from utterances of each letter of the English alphabet. The task is to learn a classifier which can determine the letter spoken based on these features. The data set is available from <http://archive.ics.uci.edu/ml/datasets/ISOLET>; see Fänty and Cole (1991) for more background on the data. We consider classification on the notoriously challenging E-set consisting of the letters ‘B’, ‘C’, ‘D’, ‘E’, ‘G’, ‘P’, ‘T’, ‘V’ and ‘Z’ (pronounced ‘zee’). As there were 150 subjects and each spoke each letter twice, we have $n = 2700$ observations spread equally among 9 classes. The dimension of this data is such that MARS and hierNet could not be applied.

5.3 Methods and Results

For the Communities and crime data set, we used the Lasso for the linear model as the base regression procedure for Backtracking and Iterates. Since the per capita violent crime response was always non-negative, the positive part of the fitted values was taken. For Main, Backtracking, Iterates, Screening and hierNet, we employed 5-fold cross-validation with squared error loss to select tuning parameters. For MARS we used the default settings for pruning the final fits using generalised cross-validation. With Random Forests, we used the default settings on both data sets. For the classification example, penalised multinomial regression was used (see Section 4.1) as the base procedure for Backtracking and Iterates, and the deviance was used as the loss function for 5-fold cross-validation. In all of the methods except Random Forests, we only included first-order interactions. When using Backtracking, we also restricted the size of C_k to $p + 50 \times 49/2 = p + 1225$.

To evaluate the procedures, we randomly selected 2/3 for training and the remaining 1/3 was used for testing. This was repeated 200 times for each of the data sets. Note that we have specifically chosen data sets with n large as well as p large. This is to ensure that comparisons between the performances of the methods can be made with more accuracy. For the regression example, out-of-sample squared prediction error was used as a measure of error; for the classification example, we used out-of-sample misclassification error with 0–1 loss. The results are given in Table 3.

Random Forests has the lowest prediction error on the regression data set, with Backtracking not far behind, whilst Backtracking wins in the classification task, and in fact achieves strictly lower misclassification error than all the other methods on 90% of all test samples. Note that a direct comparison with Random Forests is perhaps unfair, as the latter is a black-box procedure whereas Backtracking is aiming for a more interpretable model.

MARS performs very poorly indeed on the regression data set. The enormous prediction error is caused by the fact that whenever observations corresponding to either New York or Los Angeles were in the test set, MARS predicted their responses to be far larger than they were. However, even with these observations removed, the instability of MARS meant that it was unable to give much better predictions than an intercept-only model.

HierNet performs well on this data set, though it is worth noting that we had to scale the interactions to have the same ℓ_2 -norm as the main effects to get such good results (the default scaling produced error rates worse than that of an intercept-only model). Backtracking does better here. One reason for this is that because the main effects are reasonably strong in this case, a low amount of penalisation works well. However, because with hierNet, the penalty on the interactions is coupled with the penalty on the main effects, the final model tended to include close to two hundred interaction terms. The Screening approach similarly suffers from including too many interactions and performs only a little better than a main effects only fit.

The way that Backtracking creates several solution paths with varying numbers of interaction terms means that it is possible to fit main effects and a few interactions using a low penalty without this low penalisation opening the door to many other interaction terms. The iterated Lasso approach also has this advantage, but as the number of interactions are increased in discrete stages, it can miss a candidate set with the right number of interactions that may be picked up by the more continuous model building process used

Method	Error	
	Communities and crime	ISOLET
Main	0.414 (6.5×10^{-3})	0.0641 (4.7×10^{-4})
Iterate	0.384 (5.9×10^{-3})	0.0641 (4.7×10^{-4})
Screening	0.390 (7.8×10^{-3})	-
Backtracking	0.365 (3.7×10^{-3})	0.0563 (4.5×10^{-4})
Random Forest	0.356 (2.4×10^{-3})	0.0837 (6.0×10^{-4})
hierNet	0.373 (4.7×10^{-3})	-
MARS	5580.586 (3.1×10^3)	-

Table 3. Real data analyses results. Average error rates over 200 training–testing splits are given, with standard deviations of the results divided by $\sqrt{200}$ in parentheses.

by Backtracking. This occurs in a rather extreme way with the ISOLET data set where, since in the first stage of the iterated Lasso, cross-validation selected far too many variables (> 250), the second and subsequent steps could not be performed. This is why the results are identical to using the main effects alone.

6. Theoretical Properties

Our goal in this section is to understand under what circumstances Backtracking with the Lasso can arrive at a set of candidates, C^* , that contains all of the true interactions, and only a few false interactions. On the event on which this occurs, we can then apply many of the existing results on the Lasso, to show that the solution path $\hat{\beta}(\lambda, C^*)$ has certain properties. As an example, in Section 6.2 we give sufficient conditions for the existence of a λ^* such that $\{v : \hat{\beta}_v(\lambda^*, C^*) \neq 0\}$ equals the true set of variables.

We work with the normal linear model with interactions,

$$Y = \mu^* \mathbf{1} + \mathbf{X}_S^* \beta_S^* + \epsilon, \tag{7}$$

where $\epsilon_l \stackrel{i.i.d.}{\sim} N(0, \sigma^2)$, and to ensure identifiability, \mathbf{X}_S^* has full column rank. We will assume that $S^* = S_1^* \cup S_2^*$, where S_1^* and S_2^* are main effects and two-way interactions respectively. Let the interacting main effects be I^* ; formally, I^* is the smallest set of main effects such that $I \setminus I^* \supseteq S_2^*$. Assume $I^* \subseteq S_1^*$ so interactions only involve important main effects. Let $s_l = |S_l^*|$, $l = 1, 2$ and set $s = s_1 + s_2$. Define $C^* = C_1 \cup I(S_1^*)$. Note that C^* contains S^* but not additional interactions from any variables from $C_1 \setminus S_1^*$.

Although the Backtracking algorithm was presented for a base path algorithm that computed solutions at only discrete values, for the following results, we need to imagine an idealised algorithm which computes the entire path of solutions. In addition, we will assume that we only allow first-order interactions in the Backtracking algorithm, and that $T \geq s_1$.

We first consider the special case where the design matrix is derived from a random matrix with i.i.d. multivariate normal rows, before describing a result for fixed design.

6.1 Random Normal Design

Let the random matrix \mathbf{Z} have independent rows distributed as $N_p(\mathbf{0}, \Sigma)$. Suppose that \mathbf{X}_{C_1} , the matrix of main effects, is formed by scaling and centring \mathbf{Z} . We consider an asymptotic regime where \mathbf{X} , \mathbf{f}^* , S^* , σ^2 and p can all change as $n \rightarrow \infty$, though we will suppress their dependence on n in the notation. Furthermore, for sets of indices $S, M \subseteq \{1, \dots, p\}$, let $\Sigma_{S,M} \in \mathbb{R}^{|S| \times |M|}$ denote the submatrix of Σ formed from those rows and columns of Σ indexed by S and M respectively. For any positive semi-definite matrix \mathbf{A} , we will let $c_{\min}(\mathbf{A})$ and $c_{\max}(\mathbf{A})$ denote its minimal and maximal eigenvalues respectively. For sequences a_n, b_n , by $a_n \succ b_n$ we mean $b_n = o(a_n)$. We make the following assumptions.

- A1. $c_{\min}(\Sigma_{S_1^*, S_1^*}) \geq c_* > 0$.
- A2. $\sup_{\tau \in \mathbb{R}^{S_1^*}, \|\tau\|_\infty \leq 1} \|\Sigma_{N, S_1^*}^{-1} \Sigma_{S_1^*, S_1^*}^{-1} \tau\|_\infty \leq \delta < 1$.
- A3. $s_1^4 \log(p)/n \rightarrow 0$ and $s_1^8 \log(s_1)^2/n \rightarrow 0$.
- A4. $\min_{j \in S^*} |\beta_j^*| \succ \frac{s_1(\sigma \sqrt{\log p} + \sqrt{s_1 + \log p})}{\sqrt{n}} + \frac{\sqrt{s_1^3 \log(s_1)}}{n^{1/3}}$.
- A5. $\|\beta_{S_2^*}^*\|_2$ is bounded as $n \rightarrow \infty$ and $c_{\max}(\Sigma_{S_1^*, S_1^*}) \leq c^* < \infty$.

A1 is a standard assumption in high-dimensional regression and is, for example, implied by the compatibility constant of Bühlmann and van de Geer (2011a) being bounded away from zero. A2 is closely related to irrepresentable conditions (see Meinshausen and Bühlmann (2006), Zhao and Yu (2006), Zou (2006), Bühlmann and van de Geer (2011a), Wainwright (2009)), which are used for proving variable selection consistency of the Lasso. Note that although here the signal may contain interactions, our irrepresentable-type condition only involves main effects.

A3 places restrictions on the rates at which s_1 and p can increase with n . The first condition involving $\log(p)$ is somewhat natural as $s_1^2 \log(p)/n \rightarrow 0$ would typically be required in order to show ℓ_1 estimation consistency of β where only s_1 main effects are present; here our effective number of variables is $s_1 \leq s \leq s_1^2$. The second condition restricts the size of s_1 more stringently but is nevertheless weaker than equivalent conditions in Hao and Zhang (2014).

A4 is a minimal signal strength condition. The term involving σ is the usual bound on the signal strength required in results on variable selection consistency with the Lasso when there are s_1^2 non-zero variables. Due to the presence of interactions, the terms not involving σ place additional restrictions on the sizes of non-zero components of β^* even when $\sigma = 0$. A5 ensures that the model is not too heavily misspecified in the initial stages of the algorithm, where we are regressing on only main effects.

The following theorem states that given the assumptions above, with probability tending to 1 we are guaranteed a candidate set will be produced by our algorithm which contains all true interactions and no interactions involving a noise variable.

Theorem 1 *Assuming A1–A5, the probability that there exists a k^* such that $C^* \supseteq C_{k^*} \supseteq S^*$ tends to 1 as $n \rightarrow \infty$.*

6.2 Fixed Design

The result for a random normal design above is based on a corresponding result for fixed design which we present here. In order for Backtracking not to add any interactions involving noise variables, to begin with, one pair of interacting signal variables must enter the solution path before any noise variables. Other interacting signal variables need only become active after the interaction between this first pair has become active. Thus we need that there is some ordering of the interacting variables where each variable only requires interactions between those variables earlier in the order to be present before it can become active. Variables early on in the order must have the ability to be selected when there is serious model misspecification as few interaction terms will be available for selection. Variables later in the order only need to have the ability to be selected when the model is approximately correct.

Note that a signal variable having a coefficient large in absolute value does not necessarily ensure that it becomes active before any noise variable. Indeed, in our example in Section 2, variable 5 did not enter the solution path at all when only main effects were present, but had the largest coefficient. Write \mathbf{f}^* for $\mathbf{X}_{S^*} \beta_{S^*}^*$, and for a set S such that \mathbf{X}_S has full column rank, define

$$\beta^S := (\mathbf{X}_S^T \mathbf{X}_S)^{-1} \mathbf{X}_S^T \mathbf{f}^*.$$

Intuitively what should matter are the sizes of the appropriate coefficients of β^S for suitable choices of S . In the next section, we give a sufficient condition based on β^S for a variable $v \in S$ to enter the solution path before any variable outside S .

6.2.1 THE ENTRY CONDITION

Let $\mathbf{P}^S = \mathbf{X}_S (\mathbf{X}_S^T \mathbf{X}_S)^{-1} \mathbf{X}_S^T$ denote orthogonal projection on to the space spanned by the columns of \mathbf{X}_S . Further, for any two candidate sets S, M that are sets of subsets of $\{1, \dots, p\}$, define

$$\hat{\Sigma}_{S,M} = \frac{1}{n} \mathbf{X}_{S,M}^T \mathbf{X}_{S,M}.$$

Now given a set of candidates, C , let $v \in S \subset C$ and write $M = C \setminus S$. For $\eta > 0$, we shall say that the $\text{Ent}(v, S, C; \eta)$ condition holds if, \mathbf{X}_S has full column rank, and the following holds,

$$\sup_{\tau_S \in \mathbb{R}^{|S|}, \|\tau_S\|_\infty \leq 1} \|\hat{\Sigma}_{M,S} \hat{\Sigma}_{S,S}^{-1} \tau_S\|_\infty < 1, \quad (8)$$

$$|\beta_v^S| > \max_{w \in M} \left\{ \frac{1}{n} |\mathbf{X}_w^T (\mathbf{I} - \mathbf{P}^S) \mathbf{f}^*| + 2\eta + \eta \right\} \|\hat{\Sigma}_{S,S}^{-1}\|_1. \quad (9)$$

In Lemma 4 given in the appendix, we show that this condition is sufficient for variable v to enter the active set before any variable in M , when the set of candidates is C and $\|\mathbf{X}_C^T \epsilon\|_\infty \leq \eta$. In addition, we show that v will remain in the active set at least until some variable from M enters the active set.

The second part of the entry condition (9) asserts that coefficient v of the regression of \mathbf{f}^* on \mathbf{X}_S must exceed a certain quantity that we now examine in more detail. The

$\frac{1}{n} \mathbf{X}_u^T (\mathbf{I} - \mathbf{P}_S) \mathbf{f}^*$ term is the sample covariance between \mathbf{X}_u , which is one of the columns of \mathbf{X}_M , and the residual from regressing \mathbf{f}^* on \mathbf{X}_S . Note that the more of S^* that S contains, the closer this will be to 0.

To understand the $\|(\hat{\Sigma}_{S,S}^{-1})_v\|_1$ term, without loss of generality take v as $\{1\}$ and write $\mathbf{b} = \hat{\Sigma}_{S^* \setminus \{v\}, \{v\}}$ and $\mathbf{D} = \hat{\Sigma}_{S^* \setminus \{v\}, S^* \setminus \{v\}}$. For any square matrix $\hat{\Sigma}$, let $c_{\min}(\hat{\Sigma})$ denote its minimal eigenvalue. Using the formula for the inverse of a block matrix and writing s for $|S|$, we have

$$\begin{aligned} \|(\hat{\Sigma}_{S,S}^{-1})_v\|_1 &= \left\| \begin{pmatrix} 1 + \mathbf{b}^T (\mathbf{D} - \mathbf{b} \mathbf{b}^T)^{-1} \mathbf{b} \\ -(\mathbf{D} - \mathbf{b} \mathbf{b}^T)^{-1} \mathbf{b} \end{pmatrix} \right\|_1 \\ &\leq 1 + \frac{\|\mathbf{b}\|_2^2 + \sqrt{s-1} \|\mathbf{b}\|_2}{c_{\min}(\hat{\Sigma}_{S,S})}. \end{aligned}$$

In the final line we have used the Cauchy-Schwarz inequality and the fact that if \mathbf{w}^* is a unit eigenvector of $\mathbf{D} - \mathbf{b} \mathbf{b}^T$ with minimal eigenvalue, then

$$c_{\min}(\mathbf{D} - \mathbf{b} \mathbf{b}^T) = \left\| \hat{\Sigma}_{S,S} \begin{pmatrix} -\mathbf{b}^T \mathbf{w}^* \\ \mathbf{w}^* \end{pmatrix} \right\|_2 \geq c_{\min}(\hat{\Sigma}_{S,S}) \sqrt{1 + \|\mathbf{b}^T \mathbf{w}^*\|^2} \geq c_{\min}(\hat{\Sigma}_{S,S}).$$

Thus when variable v is not too correlated with the other variables in S , and so $\|\mathbf{b}\|_2$ is small, $\|(\hat{\Sigma}_{S,S}^{-1})_v\|_1$ will not be too large. Even when this is not the case, we still have the bound

$$\|(\hat{\Sigma}_{S,S}^{-1})_v\|_1 \leq \frac{\sqrt{|S|}}{c_{\min}(\hat{\Sigma}_{S,S})}.$$

Turning now to the denominator, $\|\hat{\Sigma}_{S,S}^{-1} \hat{\Sigma}_{S^* \setminus \{v\}}\|_1$ is the ℓ_1 -norm of the coefficient of regression of \mathbf{X}_u on \mathbf{X}_S , and the maximum of this quantity over $u \in M$ gives the left-hand side of (8). Thus when u is highly correlated with many of the variables in S , $\|\hat{\Sigma}_{S,S}^{-1} \hat{\Sigma}_{S^* \setminus \{v\}}\|_1$ will be large. On the other hand, in this case one would expect $\|(\mathbf{I} - \mathbf{P}_S) \mathbf{X}_u\|_2$ to be small, and so to some extent the numerator and denominator compensate for each other.

6.2.2 STATEMENT OF RESULTS

Without loss of generality assume $I^* = \{1, \dots, |I^*|\}$. Also let $\mathcal{J} = \{\mathcal{I}(A) : A \subseteq S_1^*\}$. Our formal assumption corresponding to the discussion at the beginning of Section 6 is the following.

The entry order condition. There is some ordering of the variables in I^* , which without loss of generality we take to simply be $1, \dots, |I^*|$, such that for each $j \in I^*$, we have,

For all $A \in \mathcal{J}$ with $\mathcal{I}(1, \dots, j-1) \subseteq A \subseteq \mathcal{I}(S_1^*)$
 $\text{Ent}(j, S_1^* \cup B, C_1 \cup A; \eta)$ holds for some $A \cap S_2^* \subseteq B \subseteq A$.

Here

$$\eta = \eta(t; n, p, s_1, \sigma) = \sigma \sqrt{\frac{t^2 + 2 \log(p + s_1^2)}{n}}.$$

First we discuss the implications for variable 1. The condition ensures that whenever the candidate set is enlarged from C_1 to also include any set of interactions built from S_1 , variable 1 enters the active set before any variable outside $\mathcal{I}(S_1^*)$, and moreover, it remains in the active set at least until a variable outside $\mathcal{I}(S_1^*)$ enters.

For $j > 2$, we see that the enlarged candidate sets for which we require the entry conditions to hold, are fewer in number. Variable $|I^*|$ only requires the entry condition to hold for candidate sets that at least include $\mathcal{I}(1, \dots, |I^*| - 1)$ and thus include almost all of S^* . What this means is that we require some ‘strong’ interacting variables, for which when \mathbf{f}^* is regressed onto a variety of sets of variables containing them (some of which contain only a few of the true interaction variables), always have large coefficients. Given the existence of such strong variables, other interacting variables need only have large coefficients when \mathbf{f}^* is regressed onto sets containing them that also include many true interaction terms. Note that the equivalent result for the success of the strategy that simply adds interactions between selected main effects would essentially require all main effect involved in interactions to satisfy the conditions imposed on the variables 1 and 2 here. Going back to the example in Section 2, variable 5 has $|\beta_5^S| \approx 0$ for all $S \subseteq \{1, \dots, 6\}$, but $|\beta_5^S| > 0$ once $\{1, 2\} \in S$ or $\{3, 4\} \in S$.

Theorem 2 Assume the entry order condition holds. With probability at least $1 - \exp(-t^2/2)$, there exists a k^* such that $C^* \supseteq C_{k^*} \supseteq S^*$.

The following corollary establishes variable selection consistency under some additional conditions.

Corollary 3 Assume the entry order condition holds. Writing $N = C^* \setminus S^*$, further assume

$$\|\hat{\Sigma}_{N,S^*} \hat{\Sigma}_{S^*,S^*}^{-1} \text{sgn}(\beta_{S^*}^*)\|_\infty < 1;$$

and that for all $v \in S^*$,

$$|\beta_v^*| > \frac{\eta \left| \text{sgn}(\beta_{S^*}^*)^T (\hat{\Sigma}_{S^*,S^*}^{-1})_v \right|}{1 - \|\hat{\Sigma}_{N,S^*} \hat{\Sigma}_{S^*,S^*}^{-1} \text{sgn}(\beta_{S^*}^*)\|_\infty} + \xi,$$

where

$$\xi = \xi(t; n, s, \sigma, c_{\min}(\hat{\Sigma}_{S^*,S^*})) = \sigma \sqrt{\frac{t^2 + 2 \log(s)}{n c_{\min}(\hat{\Sigma}_{S^*,S^*})}}.$$

Then with probability at least $1 - 3 \exp(-t^2/2)$, there exist k^* and λ^* such that

$$\mathcal{A}(\hat{\beta}(\lambda^*, C_{k^*})) = S^*.$$

Note that if we were to simply apply the Lasso to the set of candidates $C^{\text{all}} := C_1 \cup \mathcal{I}(C_1)$ (i.e. all possible main effects and their first-order interactions), we would require an irreparable condition of the form

$$\|\hat{\Sigma}_{N^{\text{all}}, S^*} \hat{\Sigma}_{S^*, S^*}^{-1} \text{sgn}(\beta_{S^*}^*)\|_\infty < 1,$$

where $N^{\text{all}} = C^{\text{all}} \setminus S^*$. Thus we would need $O(p^2)$ inequalities to hold, rather than our $O(p)$. Of course, we had to introduce many additional assumptions to reach this stage and no set of assumptions is uniformly stronger or weaker than the other. However, our proposed method is computationally feasible.

7. Discussion

While several methods now exist for fitting interactions in moderate-dimensional situations where p is in the order of hundreds, the problem of fitting interactions when the data is of truly high dimension has received less attention.

Typically, the search for interactions must be restricted by first fitting a model using only main effects, and then including interactions between those selected main effects, as well as the original main effects, as candidates in a final fit. This approach has the drawbacks that important main effects may not be selected in the initial stage as they require certain interactions to be present in order for them to be useful for prediction. In addition, the initial model may contain too many main effects when, without the relevant interactions, the model selection procedure cannot find a good sparse approximation to the true model.

The Backtracking method proposed in this paper allows interactions to be added in a more natural gradual fashion, so there is a better chance of having a model which contains the right interactions. The method is computationally efficient, and our numerical results demonstrate its effectiveness for both variable selection and prediction.

From a theoretical point of view we have shown that when used with the Lasso, rather than requiring all main effects involved in interactions to be highly correlated with the signal, Backtracking only needs there to exist some ordering of these variables where those early on in the order are important for predicting the response by themselves. Variables later in the order only need to be helpful for predicting the response when interactions between variables early on in the order are present.

Though in this paper, we have largely focussed on Backtracking used with the Lasso, the method is very general and can be used with many procedures that involve sparsity-inducing penalty functions. These methods tend to be some of the most useful for dealing with high-dimensional data, as they can produce stable, interpretable models. Combined with Backtracking, the methods become much more flexible, and it would be very interesting to explore to what extent using non-linear base procedures could yield interpretable models with predictive power comparable to black-box procedures such as Random Forests (Breiman, 2001). In addition, we believe integrating Backtracking with some of the penalty-based methods for fitting interactions to moderate-dimensional data, will prove to be a fruitful direction for future research.

Acknowledgments

I am very grateful to Richard Samworth, for many helpful comments and suggestions.

Appendix A. Construction of \mathbf{X} in Section 2

First, consider (Z_{i1}, Z_{i2}, Z_{i3}) generated from a mean zero multivariate normal distribution with $\text{Var}(Z_{ij}) = 1$, $j = 1, 2, 3$, $\text{Cov}(Z_{i1}, Z_{i2}) = 0$ and $\text{Cov}(Z_{i1}, Z_{i3}) = \text{Cov}(Z_{i2}, Z_{i3}) = 1/2$. Independently generate R_{i1} and R_{i2} each of which takes only the values $\{-1, 1\}$, each with

probability $1/2$. We form the i th row of the design matrix as follows:

$$\begin{aligned} X_{i1} &= R_{i1} \text{sgn}(Z_{i1}) |Z_{i1}|^{1/4}, \\ X_{i2} &= R_{i1} |Z_{i1}|^{3/4}, \\ X_{i3} &= R_{i2} \text{sgn}(Z_{i2}) |Z_{i2}|^{1/4}, \\ X_{i4} &= R_{i2} |Z_{i2}|^{3/4}, \\ X_{i5} &= Z_{i3}. \end{aligned}$$

The remaining X_{ij} , $j = 6, \dots, p$ are independently generated from a standard normal distribution. Note that the random signs R_{i1} and R_{i2} ensure that X_{i5} is uncorrelated with each of X_{i1}, \dots, X_{i4} . Furthermore, the fact that $X_{i1} X_{i2} = Z_{i1}$ and $X_{i3} X_{i4} = Z_{i2}$, means that when $\beta_5 = -\frac{1}{2}(\beta_7 + \beta_8)$, X_{i5} is uncorrelated with the response.

Appendix B. Proofs of Theorem 2 and Corollary 3

In this subsection we use many ideas from Section B of Wainwright (2009) and Section 6 of Bühlmann and van de Geer (2011a).

Lemma 4 *Let $S \subseteq C$ be such that X_S has full column rank and let $M = C \setminus S$. On the event*

$$\Omega_{C,\eta} := \left\{ \frac{1}{n} \|\mathbf{X}_C^T \boldsymbol{\varepsilon}\|_\infty \leq \eta \right\},$$

the following hold:

(i) *If*

$$\lambda > \max_{u \in M} \left\{ \frac{\frac{1}{n} \|\mathbf{X}_u^T (\mathbf{I} - \mathbf{P}^S) \mathbf{f}^*\| + 2\eta}{1 - \|\tilde{\boldsymbol{\Sigma}}_{S,S}^{-1} \tilde{\boldsymbol{\Sigma}}_{S,\{u\}}\|_1} \right\}, \tag{10}$$

then the Lasso solution is unique and $\hat{\boldsymbol{\beta}}_M(\lambda, C) = \mathbf{0}$.

(ii) *If λ is such that for some Lasso solution $\hat{\boldsymbol{\beta}}_M(\lambda, C) = \mathbf{0}$, and for $v \in S$,*

$$|\beta_v^S| > \|(\tilde{\boldsymbol{\Sigma}}_{S,S}^{-1})_{v\cdot}\|_1 (\lambda + \eta),$$

then for all Lasso solutions, $\hat{\beta}_v(\lambda, C) \neq 0$.

(iii) *Let*

$$\lambda^{\text{ent}} = \sup\{\lambda : \lambda \geq 0 \text{ and for some Lasso solution } \hat{\boldsymbol{\beta}}_M(\lambda, C) \neq \mathbf{0}\},$$

where we take $\sup \emptyset = 0$. If for $v \in S$,

$$|\beta_v^S| > \max_{u \in M} \left\{ \frac{\frac{1}{n} \|\mathbf{X}_u^T (\mathbf{I} - \mathbf{P}^S) \mathbf{f}^*\| + 2\eta}{1 - \|\tilde{\boldsymbol{\Sigma}}_{S,S}^{-1} \tilde{\boldsymbol{\Sigma}}_{S,\{u\}}\|_1} + \eta \right\} \|(\tilde{\boldsymbol{\Sigma}}_{S,S}^{-1})_{v\cdot}\|_1,$$

there exists a $\lambda > \lambda^{\text{ent}}$ such that the solution $\hat{\boldsymbol{\beta}}(\lambda, C)$ is unique, and for all $v \in (\lambda^{\text{ent}}, \lambda]$ and all Lasso solutions $\hat{\boldsymbol{\beta}}(\lambda, C)$, we have $\hat{\beta}_v(\lambda, C) \neq 0$.

Proof We begin by proving (i). Suppressing the dependence of $\hat{\beta}$ on λ and C , we can write the KKT conditions ((3), (4)) as

$$\frac{1}{n} \mathbf{X}_C^T (\mathbf{Y} - \mathbf{X}_C \hat{\beta}) = \lambda \hat{\tau},$$

where $\hat{\tau}$ is an element of the subdifferential $\partial \|\hat{\beta}\|_1$ and thus satisfies

$$\|\hat{\tau}\|_\infty \leq 1, \quad (11)$$

$$\hat{\beta}_0 \neq 0 \Rightarrow \hat{\tau}_0 = \text{sgn}(\hat{\beta}_0). \quad (12)$$

By decomposing \mathbf{Y} as $\mathbf{P}^S \mathbf{f}^* + (\mathbf{I} - \mathbf{P}^S) \mathbf{f}^* + \epsilon$, \mathbf{X}_C as $(\mathbf{X}_S \mathbf{X}_M)$, and noting that $\mathbf{X}_S^T (\mathbf{I} - \mathbf{P}^S) = \mathbf{0}$, we can rewrite the KKT conditions in the following way:

$$\frac{1}{n} \mathbf{X}_S^T (\mathbf{P}^S \mathbf{f}^* - \mathbf{X}_S \hat{\beta}_S) + \frac{1}{n} \mathbf{X}_S^T \epsilon - \hat{\Sigma}_{S,M} \hat{\beta}_M = \lambda \hat{\tau}_S, \quad (13)$$

$$\frac{1}{n} \mathbf{X}_M^T (\mathbf{P}^S \mathbf{f}^* - \mathbf{X}_S \hat{\beta}_S) + \frac{1}{n} \mathbf{X}_M^T \{(\mathbf{I} - \mathbf{P}^S) \mathbf{f}^* + \epsilon\} - \hat{\Sigma}_{M,M} \hat{\beta}_M = \lambda \hat{\tau}_M. \quad (14)$$

Now let $\hat{\beta}_S$ be a solution to the restricted Lasso problem.

$$(\hat{\mu}, \hat{\beta}_S) = \arg \min_{\mu, \beta_S} \left\{ \frac{1}{2n} \|\mathbf{Y} - \mu \mathbf{I} - \mathbf{X}_S \beta_S\|^2 + \lambda \|\beta_S\|_1 \right\}.$$

The KKT conditions give that $\hat{\beta}_S$ satisfies

$$\frac{1}{n} \mathbf{X}_S^T (\mathbf{Y} - \mathbf{X}_S \hat{\beta}_S) = \lambda \hat{\tau}_S, \quad (15)$$

where $\hat{\tau}_S \in \partial \|\hat{\beta}_S\|_1$. We now claim that

$$(\hat{\beta}_S, \hat{\beta}_M) = (\hat{\beta}_S, \mathbf{0}) \quad (16)$$

$$(\hat{\tau}_S, \hat{\tau}_M) = \left(\hat{\tau}_S, \hat{\Sigma}_{M,S} \hat{\Sigma}_{S,S}^{-1} (\hat{\tau}_S - \frac{1}{n} \lambda^{-1} \mathbf{X}_S^T \epsilon) + \frac{1}{n} \lambda^{-1} \mathbf{X}_M^T \{(\mathbf{I} - \mathbf{P}^S) \mathbf{f}^* + \epsilon\} \right) \quad (17)$$

is the unique solution to (13), (14), (11) and (12). Indeed, as $\hat{\beta}_S$ solves the reduced Lasso problem, we must have that (13) and (12) are satisfied. Multiplying (13) by $\mathbf{X}_S \hat{\Sigma}_{S,S}^{-1}$, setting $\hat{\beta}_M = \mathbf{0}$ and rearranging gives us that

$$\mathbf{P}^S \mathbf{f}^* - \mathbf{X}_S \hat{\beta}_S = \mathbf{X}_S \hat{\Sigma}_{S,S}^{-1} (\lambda \hat{\tau}_S - \frac{1}{n} \mathbf{X}_S^T \epsilon), \quad (18)$$

and substituting this into (14) shows that our choice of $\hat{\tau}_M$ satisfies (14). It remains to check that we have $\|\hat{\tau}_M\|_\infty \leq 1$. In fact, we shall show that $\|\hat{\tau}_M\|_\infty < 1$. Since we are on Ω_{C_T} and $\|\hat{\tau}_S\|_\infty \leq 1$, for $u \in M$ we have

$$\begin{aligned} \lambda |\hat{\tau}_u| &\leq \|\hat{\Sigma}_{S,S}^{-1} \hat{\Sigma}_{S,\{u\}}\|_1 (\lambda \|\hat{\tau}_S\|_\infty + \|\frac{1}{n} \mathbf{X}_S^T \epsilon\|_\infty) + \frac{1}{n} |\mathbf{X}_M^T (\mathbf{I} - \mathbf{P}^S) \mathbf{f}^*| + \frac{1}{n} |\mathbf{X}_M^T \epsilon| \\ &< \lambda \|\hat{\Sigma}_{S,S}^{-1} \hat{\Sigma}_{S,\{u\}}\|_1 + \frac{1}{n} |\mathbf{X}_M^T (\mathbf{I} - \mathbf{P}^S) \mathbf{f}^*| + 2\eta \\ &< \lambda, \end{aligned}$$

where the final inequality follows from (10). We have shown that there exists a solution, $\hat{\beta}$, to the Lasso optimisation problem with $\hat{\beta}_M = \mathbf{0}$. The uniqueness of this solution follows from noting that $\|\hat{\tau}_M\|_\infty < 1$, \mathbf{X}_S has full column rank and appealing to Lemma 1 of Wainwright (2009).

For (ii), note that from (13), provided $\hat{\beta}_M = \mathbf{0}$, we have that

$$\hat{\beta}_S = \mathbf{g}^S - \hat{\Sigma}_{S,S}^{-1} (\lambda \hat{\tau}_S - \frac{1}{n} \mathbf{X}_S^T \epsilon).$$

But by assumption

$$|\beta_u^S| > \|\hat{\Sigma}_{S,S}^{-1}\|_1 (\lambda + \eta) \geq \left| \hat{\Sigma}_{S,S}^{-1} \right|_v (\lambda \hat{\tau}_S - \frac{1}{n} \mathbf{X}_S^T \epsilon),$$

whence $\hat{\beta}_u \neq 0$.

(iii) follows easily from (i) and (ii). ■

Proof of Theorem 2. In all that follows, we work on the event $\Omega_{C^* \cap T}$ defined in Lemma 4. Using standard bounds for the tails of Gaussian random variables and the union bound, it is easy to show that $\mathbb{P}(\Omega_1 \cap \Omega_{C^* \cap T}) \geq 1 - \exp(-t^2/2)$. Let $N = \{1, \dots, p\} \setminus S_1^*$.

Let T be the number of steps taken by the algorithm: this would typically be T , but may be smaller if a perfect fit is reached or if $p < T$ for example. Let C_k be the largest member of $\{C_1, \dots, C_T\}$ satisfying $C_k \subseteq C^*$. Such a C_k exists since $C_1 \subseteq C^*$.

Now suppose for a contradiction that $C_k \not\subseteq S^*$. Let j be such that

$$\mathcal{I}(1, \dots, j-1) \subseteq C_k,$$

with j maximal. Since $\mathcal{I}(1) = \emptyset$, such a j exists. Let $A = C_k \setminus C_1$. Note that $A \in \mathcal{J}$ and

$$\mathcal{I}(1, \dots, j-1) \subseteq A \subseteq C^* \setminus C_1 = \mathcal{I}(S_1^*).$$

By the entry order condition, we know that j will enter the active set before any variable in N , and before a perfect fit is reached. Thus $k+1 \leq \bar{T}$ and C_{k+1} contains only additional interactions not involving any variables from N , so $C_{k+1} \subseteq C^*$. ■

Proof of Corollary 3. Let $\Omega_{C^* \cap T}$ be defined as in Lemma 4. Also define the events

$$\begin{aligned} \Omega_1 &= \left\{ \frac{1}{n} \|\mathbf{X}_N^T (\mathbf{I} - \mathbf{P}^{S^*}) \epsilon\|_\infty \leq \eta \right\}, \\ \Omega_2 &= \left\{ \frac{1}{n} \|\hat{\Sigma}_{S^*, S^*}^{-1} \mathbf{X}_N^T \epsilon\|_\infty \leq \xi \right\} \end{aligned}$$

In all that follows, we work on the event $\Omega_1 \cap \Omega_2 \cap \Omega_{C^* \cap T}$. As $\mathbf{I} - \mathbf{P}^{S^*}$ is a projection,

$$\mathbb{P}\left(\frac{1}{n} \|\mathbf{X}_N^T (\mathbf{I} - \mathbf{P}^{S^*}) \epsilon\| \leq \eta\right) \geq \mathbb{P}\left(\frac{1}{n} \|\mathbf{X}_N^T \epsilon\| \leq \eta\right).$$

Further, $\frac{1}{n} \hat{\Sigma}_{S^*, S^*}^{-1} \mathbf{X}_N^T \epsilon \sim N^{|\mathcal{S}^*|}(\mathbf{0}, \frac{1}{n} \sigma^2 \hat{\Sigma}_{S^*, S^*}^{-1})$. Thus

$$\mathbb{P}(\Omega_2) \geq |\mathcal{S}^*| \mathbb{P}(|Z| \leq \xi)$$

where $Z \sim N(0, \sigma^2 / (nc_{\min}(\hat{\Sigma}_{S^*, S^*})))$. Note that

$$\mathbb{P}(\Omega_1 \cap \Omega_2 \cap \Omega_{C^*, \eta}) \geq 1 - \mathbb{P}(\Omega_{C^*, \eta}^c) - \mathbb{P}(\Omega_1^c) - \mathbb{P}(\Omega_2^c).$$

Using this, it is straightforward to show that $\mathbb{P}(\Omega_1 \cap \Omega_2 \cap \Omega_{C^*, \eta}) \geq 1 - 3 \exp(-t^2/2)$.

Since we are on $\Omega_{C^*, \eta}$, we can assume the existence of a k^* from Theorem 2. We now follow the proof of Lemma 4 taking $S = S^*$ and $M = C_{k^*} \setminus S^* \subseteq N$. The KKT conditions become

$$\hat{\Sigma}_{S^*, S^*}(\beta_{S^*}^* - \hat{\beta}_{S^*}^*) + \frac{1}{n} \mathbf{X}_{S^*}^T \boldsymbol{\epsilon} - \hat{\Sigma}_{S^*, M} \hat{\beta}_M = \lambda \hat{\tau}_{S^*}, \quad (19)$$

$$\hat{\Sigma}_{M, S^*}(\beta_{S^*}^* - \hat{\beta}_{S^*}^*) + \frac{1}{n} \mathbf{X}_M^T \boldsymbol{\epsilon} - \hat{\Sigma}_{M, M} \hat{\beta}_M = \lambda \hat{\tau}_M, \quad (20)$$

with $\hat{\tau}$ also satisfying (11) and (12) as before. Now let λ be such that

$$\frac{\eta}{1 - \|\hat{\Sigma}_{M, S^*} \hat{\Sigma}_{S^*, S^*}^{-1} \text{sgn}(\beta_{S^*}^*)\|_\infty} < \lambda < \min_{v \in S^*} \left\{ \left| \text{sgn}(\beta_{S^*}^*)^T (\hat{\Sigma}_{S^*, S^*}^{-1})^{-1} (\beta_{S^*}^* - \xi) \right| \right\}.$$

It is straightforward to check that

$$(\hat{\beta}_{S^*}^*, \hat{\beta}_M) = (\beta_{S^*}^* - \lambda \hat{\Sigma}_{S^*, S^*}^{-1} \text{sgn}(\beta_{S^*}^*) + \frac{1}{n} \hat{\Sigma}_{S^*, S^*}^{-1} \mathbf{X}_{S^*}^T \boldsymbol{\epsilon}, \mathbf{0})$$

$$(\hat{\tau}_{S^*}, \hat{\tau}_M) = \left(\text{sgn}(\beta_{S^*}^*), \hat{\Sigma}_{M, S^*} \hat{\Sigma}_{S^*, S^*}^{-1} \text{sgn}(\beta_{S^*}^*) + \frac{1}{n} \lambda^{-1} \mathbf{X}_M^T (\mathbf{I} - \mathbf{P}^{S^*}) \boldsymbol{\epsilon} \right)$$

is the unique solution to (19), (20), (11) and (12). \blacksquare

Appendix C. Proof of Theorem 1

In the following, we make use of notation defined in Section 6.2. In addition, for convenience we write $S = S_1^*$, $M = S \cup J^*$. Also, we will write main effects variables $\{j\}$ as simply j . For any matrix \mathbf{M} , $\|\mathbf{M}\|_\infty$ will denote $\max_{j,k} |M_{j,k}|$. First we collect together various results concerning $\hat{\Sigma}_{C^*, C^*}$.

Lemma 5 Consider the setup of Theorem 1. Let \mathbb{E}_n and Var_n denote empirical expectation and variance with respect to \mathbf{Z} so that, for example $\mathbb{E}_n z_j = \sum_{i=1}^n Z_{ij}/n$.

(i) Let \mathbf{D} be the diagonal matrix indexed by C^* used to scale transformations of \mathbf{Z} in order to create \mathbf{X}_{C^*} i.e. with entries such that $D_{jj}^2 = \text{Var}_n(z_j)$ and $D_{vv}^2 = \text{Var}_n(z_j - \mathbb{E}_n z_j)(z_k - \mathbb{E}_n z_k)$ when $v = \{j, k\}$. Then

$$\max_{j \in C_1} |D_{jj}^2 - 1| = O_P(\sqrt{\log(p)/n}) \quad (21)$$

$$\max_{\{j,k\} \in M} |D_{\{j,k\}}^2 - 1 - \Sigma_{jk}^2| = O_P(\sqrt{\log(s_1)n^{-1/4}}) \quad (22)$$

$$(ii) \quad \frac{1}{n} \|\mathbf{X}_{J^*}^T \mathbf{X}_S\|_\infty = O_P(\sqrt{\log(s_1)n^{-1/3}}) \quad (23)$$

$$c_{\min}(\hat{\Sigma}_{S,S}) \geq c_* - s_1 O_P(\sqrt{\log(s_1)/n}) \quad (24)$$

$$c_{\min}(\hat{\Sigma}_{M,M}) \geq c_*^2 + s_1^2 O_P(\sqrt{\log(s_1)n^{-1/4}}) \quad (25)$$

$$c_{\max}(\hat{\Sigma}_{J^*, J^*}) \leq 2c_*^2 + s_1^2 O_P(\sqrt{\log(s_1)n^{-1/4}}). \quad (26)$$

Proof We use bounds on the tails of products of normal random variables from Hao and Zhang (2014) (equation B.9). We have

$$\begin{aligned} \max_{j,k} |\text{Cov}_n(z_j, z_k) - \Sigma_{jk}| &= \max_{j,k} |\mathbb{E}_n(z_j z_k) - \mathbb{E}_n z_j \mathbb{E}_n z_k - \Sigma_{jk}| \\ &= O_P(\sqrt{\log(p)/n}). \end{aligned}$$

Also,

$$\begin{aligned} \max_{j,k,l,m \in S} |\text{Cov}_n(z_j - \mathbb{E}_n z_j)(z_k - \mathbb{E}_n z_k), (z_l - \mathbb{E}_n z_l)(z_m - \mathbb{E}_n z_m)) - \Sigma_{jl} \Sigma_{km} - \Sigma_{jm} \Sigma_{kl}| \\ = \max_{j,k,l,m \in S} |\mathbb{E}_n(z_j z_k z_l z_m) - \mathbb{E}_n(z_j z_k) \mathbb{E}_n(z_l z_m) - \Sigma_{jl} \Sigma_{km} - \Sigma_{jm} \Sigma_{kl}| + O_P(\sqrt{\log(s_1)/n}) \\ = O_P(\sqrt{\log(s_1)n^{-1/4}}). \end{aligned}$$

Now we consider (ii). We have

$$\begin{aligned} \frac{1}{n} \|\mathbf{X}_{J^*}^T \mathbf{X}_S\|_\infty &\leq \max_{v \in J^*} D_{kk}^{-1} \max_{k \in S} |\text{Cov}_n(z_j - \mathbb{E}_n z_j)(z_k - \mathbb{E}_n z_k), z_l| \\ &\leq O_P(\sqrt{\log(s_1)n^{-1/3}}), \end{aligned}$$

the rate being driven by the size of $\mathbb{E}_n(z_j z_k z_l)$. Also

$$\begin{aligned} c_{\min}(\hat{\Sigma}_{S,S}) &= \min_{\tau \in \mathbb{R}^{s_1}: \|\tau\|_2=1} \tau \{ \Sigma_{S,S} - (\Sigma_{S,S} - \hat{\Sigma}_{S,S}) \} \tau \\ &\geq c_{\min}(\Sigma_{S,S}) - \max_{\tau \in \mathbb{R}^{s_1}: \|\tau\|_2=1} \|\tau\|_2^2 \|\Sigma_{S,S} - \hat{\Sigma}_{S,S}\|_\infty \\ &= c_* - s_1 O_P(\sqrt{\log(s_1)/n}). \end{aligned}$$

Now let $\hat{\Sigma}$ be a matrix with entries indexed by M with

$$\hat{\Sigma}_{uv} = \Sigma_{jl} \Sigma_{km} + \Sigma_{jm} \Sigma_{kl}$$

when $u = \{j, k\}$ and $v = \{l, m\}$. Lemma A.4 of Hao and Zhang (2014) shows that $c_{\min}(\hat{\Sigma}) \geq 2c_{\min}(\Sigma_{S,S})^2$ and $c_{\max}(\hat{\Sigma}) \leq 2c_{\max}(\Sigma_{S,S})^2$. Thus we have

$$\begin{aligned} c_{\min}(\hat{\Sigma}_{M,M}) &= \min_{\tau \in \mathbb{R}^{|M|}: \|\mathbf{D}_{M,M} \tau\|_2=1} \tau \mathbf{D}_{M,M} \hat{\Sigma}_{M,M} \mathbf{D}_{M,M} \tau \\ &\geq \|\mathbf{D}_{M,M}\|_\infty^{-1} c_{\min}(\mathbf{D}_{M,M} \hat{\Sigma}_{M,M} \mathbf{D}_{M,M}) \\ &\geq \{1 + O_P(\sqrt{\log(s_1)n^{-1/4}})\} \{c_*^2 - s_1^2\} \|\hat{\Sigma} - \mathbf{D}_{M,M} \hat{\Sigma}_{M,M} \mathbf{D}_{M,M}\|_\infty + O_P(\sqrt{\log(s_1)n^{-1/3}}) \\ &\geq c_*^2 + s_1^2 O_P(\sqrt{\log(s_1)n^{-1/4}}). \end{aligned}$$

Similarly

$$\begin{aligned} c_{\max}(\hat{\Sigma}_{J^*, J^*}) &= \max_{\tau \in \mathbb{R}^{|J^*|}: \|\mathbf{D}_{J^*, J^*} \tau\|_2=1} \tau \mathbf{D}_{J^*, J^*} \hat{\Sigma}_{J^*, J^*} \mathbf{D}_{J^*, J^*} \tau \\ &\leq \{1 - O_P(\sqrt{\log(s_1)n^{-1/4}})\} c_{\max}(\mathbf{D}_{J^*, J^*} \hat{\Sigma}_{J^*, J^*} \mathbf{D}_{J^*, J^*}) \\ &\leq \{1 - O_P(\sqrt{\log(s_1)n^{-1/4}})\} \{2c_*^2 + s_1^2\} \|\hat{\Sigma} - \mathbf{D}_{J^*, J^*} \hat{\Sigma}_{J^*, J^*} \mathbf{D}_{J^*, J^*}\|_\infty \\ &\leq 2c_*^2 + s_1^2 O_P(\sqrt{\log(s_1)n^{-1/4}}). \end{aligned}$$

Lemma 6 Working with the assumptions of Theorem 1, we have

$$\max_{A \in \mathcal{J}} \|\beta_{S^A}^{S_{U^A}} - \beta_{S^A}^*\|_{\infty} \leq O_P(\sqrt{s_1^3 \log(s_1)} n^{-1/3}).$$

Proof For $A \in \mathcal{J}$ let $\Delta^A \in \mathbb{R}^{|\mathcal{S}_{U^A}|}$ with $\Delta_{S^A}^A = \beta_{S^A}^{S_{U^A}} - \beta_{S^A}^*$ and $\Delta_{A^c}^A = \beta_{S^A}^{S_{U^A}}$. Define $\mathbf{g}^* = \mathbf{X}_{S^A} \beta_{S^A}^*$. Note that

$$\mathbf{r}^* = \mathbf{X}_{S^A} \beta_{S^A}^* + \mathbf{g}^*,$$

so

$$\Delta^A = (\mathbf{X}_{S_{U^A}}^T \mathbf{X}_{S_{U^A}})^{-1} \mathbf{X}_{S_{U^A}} \mathbf{g}^*.$$

First we bound $\|\Delta_{A^c}^A\|_2$ in terms of $\|\mathbf{g}^*\|_2$. We have that

$$\|\mathbf{X}_{S_{U^A}} \Delta^A\|_2^2 = \|\mathbf{X}_{S^A} \Delta_{S^A}^A\|_2^2 + 2 \Delta_{S^A}^A{}^T \mathbf{X}_{S^A}^T \mathbf{X}_{A^c} \Delta_{A^c}^A + \|\mathbf{X}_{A^c} \Delta_{A^c}^A\|_2^2 \leq \|\mathbf{g}^*\|_2^2.$$

Thus

$$c_{\min}(\frac{1}{n} \mathbf{X}_{S^A}^T \mathbf{X}_{S^A}) \|\Delta_{S^A}^A\|_2^2 - 2\sqrt{|A|} \|S\| \frac{1}{n} \mathbf{X}_{S^A}^T \mathbf{X}_{A^c} \|\Delta_{A^c}^A\|_2 + c_{\min}(\frac{1}{n} \mathbf{X}_{A^c}^T \mathbf{X}_{A^c}) \|\Delta_{A^c}^A\|_2^2 - \frac{1}{n} \|\mathbf{g}^*\|_2^2 \leq 0.$$

Thinking of this as a quadratic in $\|\Delta_{A^c}^A\|_2$ and considering the discriminant yields

$$\|\Delta_{A^c}^A\|_2^2 \leq \frac{\frac{1}{n} c_{\min}(\frac{1}{n} \mathbf{X}_{S^A}^T \mathbf{X}_{S^A}) \|\mathbf{g}^*\|_2^2}{c_{\min}(\frac{1}{n} \mathbf{X}_{S^A}^T \mathbf{X}_{S^A}) c_{\min}(\frac{1}{n} \mathbf{X}_{A^c}^T \mathbf{X}_{A^c}) - \|\frac{1}{n} \mathbf{X}_{S^A}^T \mathbf{X}_{A^c}\|_{\infty}^2 |A| |S|}.$$

Thus by Lemma 5 (ii) and condition A2, $\max_{A \in \mathcal{J}} \|\Delta_{A^c}^A\|_2 = \frac{1}{\sqrt{n}} \|\mathbf{g}^*\|_2 O_P(1)$.

But

$$\frac{1}{\sqrt{n}} \|\mathbf{g}^*\|_2 \leq \sqrt{c_{\max}(\hat{\Sigma}_{J^*, J^*})} \|\beta_{S_{S^A}^*}\|_2 = O_P(1)$$

by Lemma 5 (ii) and A5, so $\max_{A \in \mathcal{J}} \|\Delta_{A^c}^A\|_2 = O_P(1)$.

Next observe that

$$\|\mathbf{X}_{S_{U^A}} \Delta^A - \mathbf{g}^*\|_2^2 \leq \|\mathbf{X}_{A^c} \Delta_{A^c}^A - \mathbf{g}^*\|_2^2,$$

so

$$\begin{aligned} \|\Delta_{S^A}^A\|_2^2 c_{\min}(\frac{1}{n} \mathbf{X}_{S^A}^T \mathbf{X}_{S^A}) &\leq \frac{1}{n} \|\mathbf{X}_{S^A} \Delta_{S^A}^A\|_2^2 \\ &\leq 2 \frac{1}{n} \Delta_{S^A}^A{}^T \mathbf{X}_{S^A}^T (\mathbf{X}_{A^c} \Delta_{A^c}^A - \mathbf{g}^*) \\ &\leq 2\sqrt{|A|} \|S\| \|\Delta_{S^A}^A\|_2 \|\frac{1}{n} \mathbf{X}_{S^A}^T \mathbf{X}_{A^c}\|_{\infty} \|\Delta_{A^c}^A\|_2 + 2 \|\Delta_{S^A}^A\|_2 \|\frac{1}{n} \mathbf{X}_{S^A}^T \mathbf{g}^*\|_2. \end{aligned}$$

Therefore

$$\|\Delta_{S^A}^A\|_{\infty} \leq 2\{c_{\min}(\frac{1}{n} \mathbf{X}_{S^A}^T \mathbf{X}_{S^A})\}^{-1} (\sqrt{|A|} \|S\| \|\frac{1}{n} \mathbf{X}_{S^A}^T \mathbf{X}_{A^c}\|_{\infty} \|\Delta_{A^c}^A\|_2 + \|\frac{1}{n} \mathbf{X}_{S^A}^T \mathbf{g}^*\|_2),$$

so

$$\max_{A \in \mathcal{J}} \|\Delta_{S^A}^A\|_{\infty} \leq 2\{c_{\min}(\frac{1}{n} \mathbf{X}_{S^A}^T \mathbf{X}_{S^A})\}^{-1} (\sqrt{|S|} \|J^*\| \|\frac{1}{n} \mathbf{X}_{S^A}^T \mathbf{X}_{J^*}\|_{\infty} O_P(1) + \|\frac{1}{n} \mathbf{X}_{S^A}^T \mathbf{g}^*\|_2).$$

Now

$$\begin{aligned} \|\frac{1}{n} \mathbf{X}_{S^A}^T \mathbf{g}^*\|_2 &\leq \sqrt{|S|} \|\frac{1}{n} \mathbf{X}_{S^A}^T \mathbf{X}_{S^A}\|_{\infty} \|\beta_{S_{S^A}^*}\|_1 \\ &\leq O_P(s_1 \sqrt{\log(s_1)} n^{-1/3}). \end{aligned}$$

Thus

$$\max_{A \in \mathcal{J}} \|\Delta_{S^A}^A\|_{\infty} \leq O_P(\sqrt{s_1^3 \log(s_1)} n^{-1/3}).$$

Proof of Theorem 1. In view of Theorem 2 and its proof, it is enough to show that with probability tending to 1, we have

$$\max_{A \in \mathcal{J}} \sup_{\tau \in \mathbb{R}^{p_1}} \|\hat{\Sigma}_{N, S_{U^A}} \hat{\Sigma}_{S_{U^A}, S_{U^A}}^{-1} \tau\|_{\infty} < 1, \quad (27)$$

$$\min_{j \in \mathcal{J}} \min_{A \in \mathcal{J}} |\beta_j^{S_{U^A}}| > \max_{A \in \mathcal{J}} \max_{j \in \mathcal{N}} \left\{ \frac{\frac{1}{n} \mathbf{X}_j^T (\mathbf{I} - \mathbf{P}^{S_{U^A}}) \mathbf{r}^*}{1 - \|\hat{\Sigma}_{S_{U^A}, S_{U^A}}^{-1} \hat{\Sigma}_{S_{U^A}, S_{U^A}}\|} + \frac{2 \frac{1}{n} \|\mathbf{X}_{C^*}^T \mathbf{e}\|_{\infty}}{n} + \frac{1}{n} \|\mathbf{X}_{C^*}^T \mathbf{e}\|_{\infty} \right\} \frac{\sqrt{|M|}}{c_{\min}(\hat{\Sigma}_{M, M})}. \quad (28)$$

First note that for $j \in N$, $\mathbf{Z}_j = \mathbf{Z}_S \Sigma_{S, S}^{-1} \Sigma_{S, j} + \mathbf{E}_j$ where \mathbf{E}_j is independent of \mathbf{Z}_S and $\mathbf{E}_j \sim N_n(\mathbf{0}, (1 - \Sigma_{j, S} \Sigma_{S, S}^{-1} \Sigma_{S, j}) \mathbf{I})$. Thus

$$\mathbf{X}_j D_j = \mathbf{X}_j \mathbf{D}_{S, S} \Sigma_{S, S}^{-1} \Sigma_{S, j} + \mathbf{E}_j - \mathbf{1} \bar{E}_j,$$

and

$$\max_{A \in \mathcal{J}} \|(\mathbf{X}_{S_{U^A}}^T \mathbf{X}_{S_{U^A}})^{-1} \mathbf{X}_{S_{U^A}}^T \mathbf{X}_j\|_1 \leq D_{kk}^{-1} \|\mathbf{D}_{S, S} \Sigma_{S, S}^{-1} \Sigma_{S, j}\|_1 + \max_{A \in \mathcal{J}} \|\hat{\Sigma}_{S_{U^A}, S_{U^A}}^{-1} \frac{1}{n} \mathbf{X}_{S_{U^A}}^T \mathbf{E}_j\|_1.$$

Now the second term above is at most

$$\max_{A \in \mathcal{J}} \max_{\tau \in \mathbb{R}^{|\mathcal{S}_{U^A}|}: \|\tau\|_2 \leq 1} \|\hat{\Sigma}_{S_{U^A}, S_{U^A}}^{-1} \frac{1}{n} \mathbf{X}_{S_{U^A}}^T \mathbf{E}_j\|_2.$$

But

$$\begin{aligned} \max_{A \in \mathcal{J}} \max_{\tau \in \mathbb{R}^{|\mathcal{S}_{U^A}|}: \|\tau\|_{\infty} \leq 1} \|\hat{\Sigma}_{S_{U^A}, S_{U^A}}^{-1} \tau\|_1 &\leq \frac{\sqrt{|M|}}{c_{\min}(\hat{\Sigma}_{M, M})} \\ &\leq \frac{c_2^2 + s_1^2 O_P(\sqrt{\log(s_1)} n^{-1/4})}{\sqrt{|M|}}. \end{aligned}$$

Also since for $v \in M$ and $j \in N$, $\mathbf{X}_v^T \mathbf{E}_j / n \sim N(0, 1)$ we have

$$\max_{j \in N} \|\frac{1}{n} \mathbf{X}_M^T \mathbf{E}_j\|_2^2 \leq |M| O_P(\log(p)/n).$$

Therefore

$$\max_{A \in \mathcal{J}} \sup_{\tau \in \mathbb{R}^{p_1}} \|\hat{\Sigma}_{N, S_{U^A}} \hat{\Sigma}_{S_{U^A}, S_{U^A}}^{-1} \tau\|_{\infty} \leq (1 + o_P(1)) \delta + \frac{s_1^2 o_P(1)}{c_2^2 + o_P(1)}.$$

This shows that (27) is satisfied with probability tending to 1.
Next

$$\max_{j \in N} \max_{A \in \mathcal{U}} \frac{1}{n} |\mathbf{X}_j^T (\mathbf{I} - \mathbf{P}^{S_{UA}}) \mathbf{f}^*| = \max_{j \in N} \max_{A \in \mathcal{U}} \frac{D_{-1}^{-1}}{n} |\mathbf{E}_j^T (\mathbf{I} - \mathbf{P}^{S_{UA}}) \mathbf{X}_A \beta_A^*|.$$

Since $\mathbf{E}_j^T (\mathbf{I} - \mathbf{P}^{S_{UA}}) \mathbf{X}_A \beta_A^* / n \sim N(0, \|(\mathbf{I} - \mathbf{P}^{S_{UA}}) \mathbf{X}_A \beta_A^*\|_2^2 / n^2)$ we have

$$\max_{j \in N} \max_{A \in \mathcal{U}} \frac{1}{n} |\mathbf{X}_j^T (\mathbf{I} - \mathbf{P}^{S_{UA}}) \mathbf{f}^*| \leq \sqrt{\frac{\log(2^{s_1} p)}{n}} \frac{1}{\sqrt{n}} \|\mathbf{X}_{S_2^*} \beta_{S_2^*}^*\|_2 O_P(1).$$

By (26) we have

$$\frac{1}{\sqrt{n}} \|\mathbf{X}_{S_2^*} \beta_{S_2^*}^*\|_2 \leq \{2c^* + s_1^* \sqrt{\log(s_1)} n^{-1/4} O_P(1)\} \|\beta_{S_2^*}\|_2.$$

Now using Lemma 6 we see that the difference between the LHS and RHS of (28) is at least

$$\min_{j \in \mathcal{P}} |\beta_j^*| - O_P \left(\sqrt{s_1^* \log(s_1)} n^{-1/3} \right) - \left(\frac{\sqrt{s_1 + \log p} + \sigma \sqrt{\log p} / \sqrt{n}}{1 - \delta + o_P(1)} + \sigma \sqrt{\frac{\log(p)}{n}} \right) s_1 O_P(1).$$

Thus A4 ensures that (28) holds with probability tending to 1. ■

Abstract

This paper studies V -fold cross-validation for model selection in least-squares density estimation. The goal is to provide theoretical grounds for choosing V in order to minimize the least-squares loss of the selected estimator. We first prove a non-asymptotic oracle inequality for V -fold cross-validation and its bias-corrected version (V -fold penalization). In particular, this result implies that V -fold penalization is asymptotically optimal in the nonparametric case. Then, we compute the variance of V -fold cross-validation and related criteria, as well as the variance of key quantities for model selection performance. We show that these variances depend on V like $1 + 4/(V - 1)$, at least in some particular cases, suggesting that the performance increases much from $V = 2$ to $V = 5$ or 10 , and then is almost constant. Overall, this can explain the common advice to take $V = 5$ —at least in our setting and when the computational power is limited—, as supported by some simulation experiments. An oracle inequality and exact formulas for the variance are also proved for Monte-Carlo cross-validation, also known as repeated cross-validation, where the parameter V is replaced by the number B of random splits of the data.

Keywords: V -fold cross-validation, Monte-Carlo cross-validation, leave-one-out, leave- p -out, resampling penalties, density estimation, model selection, penalization

1. Introduction

Cross-validation methods are widely used in machine learning and statistics, for estimating the risk of a given statistical estimator (Stone, 1974; Allen, 1974; Geisser, 1975) and for selecting among a family of estimators. For instance, cross-validation can be used for model selection, where a collection of linear spaces is given (the models) and the problem is to choose the best least-squares estimator over one of these models. Cross-validation is also often used for choosing hyperparameters of a given learning algorithm. We refer to Arlot and Celisse (2010) for more references about cross-validation for model selection.

Model selection can target two different goals: (i) *estimation*, that is, minimizing the risk of the final estimator, which is the goal of AIC and related methods, or (ii) *identification*, that is, identifying the smallest true model in the family considered, assuming it exists and

it is unique, which is the goal of BIC for instance; see the survey by Arlot and Celisse (2010) for more details about this distinction. These two goals cannot be attained simultaneously in general (Yang, 2005).

We assume throughout the paper that the goal of model selection is estimation. We refer to Yang (2006, 2007) and Celisse (2014) for some results and references on cross-validation methods with an identification goal.

Then, a natural question arises: which cross-validation method should be used for minimizing the risk of the final estimator? For instance, a popular family of cross-validation methods is V -fold cross-validation (Geisser, 1975, often called k -fold cross-validation), which depends on an integer parameter V , and enjoys a smaller computational cost than other classical cross-validation methods. The question becomes (1) which V is optimal, and (2) can we do almost as well as the optimal V with a small computational cost, that is, a small V ? Answering the second question is particularly useful for practical applications where the computational power is limited.

Surprisingly, few theoretical results exist for answering these two questions, especially with a non-asymptotic point of view (Arlot and Celisse, 2010). In short, it is proved in least-squares regression that at first order, V -fold cross-validation is suboptimal for model selection (with an estimation goal) if V stays bounded, because V -fold cross-validation is biased (Arlot, 2008). When correcting for the bias (Burman, 1989; Arlot, 2008), we recover asymptotic optimality whatever V , but without any theoretical result distinguishing among values of V in second order terms in the risk bounds (Arlot, 2008).

Intuitively, if there is no bias, increasing V should reduce the variance of the V -fold cross-validation estimator of the risk, hence reduce the risk of the final estimator, as supported by some simulation experiments (Arlot, 2008, for instance). But variance computations for unbiased V -fold methods have only been made in the asymptotic framework for a fixed estimator, and they focus on risk estimation instead of model selection (Burman, 1989).

This paper aims at providing theoretical grounds for the choice of V by two means: a non-asymptotic oracle inequality valid for any V (Section 3) and exact variance computations shedding light on the influence of V on the variance (Section 5). In particular, we would like to understand why the common advice in the literature is to take $V = 5$ or 10 , based on simulation experiments (Breiman and Spector, 1992; Hastie et al., 2009, for instance).

The results of the paper are proved in the least-squares density estimation framework, because we can then benefit from explicit closed-form formulas and simplifications for the V -fold criteria. In particular, we show that V -fold cross-validation and all leave- p -out methods are particular cases of V -fold penalties in least-squares density estimation (Lemma 1).

The first main contribution of the paper (Theorem 5) is an oracle inequality with leading constant $1 + \varepsilon_n$, with $\varepsilon_n \rightarrow 0$ as $n \rightarrow \infty$ for unbiased V -fold methods, which holds for any value of V . To the best of our knowledge, Theorem 5 is the first non-asymptotic oracle inequality for V -fold methods enjoying such properties: the leading constant $1 + \varepsilon_n$ is new in density estimation, and the fact that it holds whatever the value of V had never been obtained in any framework. Theorem 5 relies on a new concentration inequality for the V -fold penalty (Proposition 4). Note that Theorem 5 implicitly assumes that the oracle loss is of order $n^{-\alpha}$ for some $\alpha \in (0, 1)$, that is, the setting is nonparametric; otherwise,

Theorem 5 may not imply the asymptotic optimality of V -fold penalization. Let us also emphasize that the leading constant is $1 + \varepsilon_n$ whatever V for unbiased V -fold methods, with ε_n independent from V in Theorem 5. So, second-order terms must be taken into account for understanding how the model selection performance depends on V . Section 4 proposes a heuristic for comparing these second order terms thanks to variance comparisons. This motivates our next result.

The second main contribution of the paper (Theorem 6) is the first non-asymptotic variance computation for V -fold criteria that allows to understand precisely how the *model selection performance* of V -fold cross-validation or penalization depends on V . Previous results only focused on the variance of the V -fold criterion (Bunman, 1989; Bengio and Grandvalet, 2005; Celisse, 2008, 2014; Celisse and Robin, 2008), which is not sufficient for our purpose, as explained in Section 4. In our setting, we can explain, partly from theoretical results, partly from a heuristic argument, why taking, say, $V > 10$ is not necessary for getting a performance close to the optimum, as supported by experiments on synthetic data in Section 6.

An oracle inequality and exact formulas for the variance are also proved for other cross-validation methods: Monte-Carlo cross-validation, also known as repeated cross-validation, where the parameter V is replaced by the number B of random splits of the data (Section 8.1), and hold-out penalization (Section 8.2).

Notation. For any integer $k \geq 1$, $[k]$ denotes $\{1, \dots, k\}$.

For any vector $\xi_{[n]} := (\xi_1, \dots, \xi_n)$ and any $B \subset [n]$, ξ_B denotes $(\xi_i)_{i \in B}$, $|B|$ denotes the cardinality of B and $B^c = [n] \setminus B$.

For any real numbers t, u , we define $t \vee u := \max\{t, u\}$, $u_+ := u \vee 0$ and $u_- := (-u) \vee 0$. All asymptotic results and notation $o(\cdot)$ or $\mathcal{O}(\cdot)$ are for the regime when the number n of observations tends to infinity.

2. Least-Squares Density Estimation and Definition of V -Fold Procedures

This section introduces the framework of the paper, the main procedures studied, and some useful notation.

2.1 General Statistical Framework

Let ξ_1, \dots, ξ_n be independent random variables taking value in a Polish space \mathcal{X} , with common distribution P and density s with respect to some known measure μ . Suppose that $s \in L^\infty(\mu)$, which implies that $s \in L^2(\mu)$. The goal is to estimate s from $\xi_{[n]} = (\xi_1, \dots, \xi_n)$, that is, to build an estimator $\widehat{s} = \widehat{s}(\xi_{[n]}) \in L^2(\mu)$ such that its loss $\|\widehat{s} - s\|^2$ is as small as possible, where for any $t \in L^2(\mu)$, $\|t\|^2 := \int_{\mathcal{X}} t^2 d\mu$.

Projection estimators are among the most classical estimators in this framework (see, for example, DeVore and Lorentz, 1993 and Massart, 2007). Given a separable linear subspace S_m of $L^2(\mu)$ (called a model), the projection estimator of s onto S_m is defined by

$$\widehat{s}_m := \operatorname{argmin}_{t \in S_m} \{\|t\|^2 - 2P_n(t)\}, \quad (1)$$

where P_n is the empirical measure; for any $t \in L^2(\mu)$, $P_n(t) = \int t dP_n = \frac{1}{n} \sum_{i=1}^n t(\xi_i)$. The quantity minimized in the definition of \widehat{s}_m is often called the empirical risk, and can be

denoted by

$$P_n \gamma(t) = \|t\|^2 - 2P_n(t) \quad \text{where } \forall x \in \mathcal{X}, \forall t \in L^2(\mu), \quad \gamma(t; x) = \|t\|^2 - 2t(x).$$

The function γ is called the least-squares contrast. Note that $S_m \subset L^1(P)$ since $s \in L^2(\mu)$.

2.2 Model Selection

When a finite collection of models $(S_m)_{m \in \mathcal{M}_n}$ is given, following Massart (2007), we want to choose from data one among the corresponding projection estimators $(\widehat{s}_m)_{m \in \mathcal{M}_n}$. The goal is to design a model selection procedure $\widehat{m} : \mathcal{X}^n \rightarrow \mathcal{M}_n$ so that the final estimator $\widehat{s} := \widehat{s}_{\widehat{m}}$ has a quadratic loss as small as possible, that is, comparable to the oracle loss $\inf_{m \in \mathcal{M}_n} \|\widehat{s}_m - s\|^2$. This goal is what is called the estimation goal in the Introduction. More precisely, we aim at proving that an oracle inequality of the form

$$\|\widehat{s}_{\widehat{m}} - s\|^2 \leq C_n \inf_{m \in \mathcal{M}_n} \{\|\widehat{s}_m - s\|^2\} + R_n$$

holds with a large probability. The procedure \widehat{m} is called asymptotically optimal when R_n is much smaller than the oracle loss and $C_n \rightarrow 1$, as $n \rightarrow +\infty$. In order to avoid trivial cases, we will always assume that $|\mathcal{M}_n| \geq 2$.

In this paper, we focus on model selection procedures of the form

$$\widehat{m} := \operatorname{argmin}_{m \in \mathcal{M}_n} \{\operatorname{crit}(m)\},$$

where $\operatorname{crit} : \mathcal{M}_n \rightarrow \mathbb{R}$ is some data-driven criterion. Since our goal is to satisfy an oracle inequality, an ideal criterion is

$$\operatorname{crit}_{\text{ideal}}(m) = \|\widehat{s}_m - s\|^2 - \|s\|^2 = -2P(\widehat{s}_m) + \|\widehat{s}_m\|^2 = P\gamma(\widehat{s}_m).$$

Penalization is a popular way of designing a model selection criterion (Barron et al., 1999; Massart, 2007)

$$\operatorname{crit}(m) = P_n \gamma(\widehat{s}_m) + \operatorname{pen}(m)$$

for some penalty function $\operatorname{pen} : \mathcal{M}_n \rightarrow \mathbb{R}$, possibly data-driven. From the ideal criterion $\operatorname{crit}_{\text{ideal}}$, we get the ideal penalty

$$\operatorname{pen}_{\text{ideal}}(m) := \operatorname{crit}_{\text{ideal}}(m) - P_n \gamma(\widehat{s}_m) = (P - P_n) \gamma(\widehat{s}_m) = 2(P_n - P)(\widehat{s}_m) \quad (2)$$

$$= 2(P_n - P)(\widehat{s}_m - s_m) + 2(P_n - P)(s_m) = 2\|\widehat{s}_m - s_m\|^2 + 2(P_n - P)(s_m),$$

$$\text{where } s_m := \operatorname{argmin}_{t \in S_m} \{\|t - s\|^2\}$$

is the orthogonal projection of s onto S_m in $L^2(\mu)$. Let us finally recall some useful and classical reformulations of the main term in the ideal penalty (2), that proves in particular the last equality in Eq. (2): If $\mathbb{B}_m = \{t \in S_m \text{ s.t. } \|t\| \leq 1\}$ and $(\psi_\lambda)_{\lambda \in \Lambda_m}$ denotes an orthonormal basis of S_m in $L^2(\mu)$, then

$$\begin{aligned} (P_n - P)(\widehat{s}_m - s_m) &= \sum_{\lambda \in \Lambda_m} [(P_n - P)(\psi_\lambda)]^2 \\ &= \|\widehat{s}_m - s_m\|^2 = \sup_{t \in \mathbb{B}_m} [(P_n - P)(t)]^2, \end{aligned} \quad (3)$$

where the last equality follows from Eq. (30) in Appendix A.

2.3 V -Fold Cross-Validation

A standard approach for model selection is cross-validation. We refer the reader to Arlot and Celisse (2010) for references and a complete survey on cross-validation for model selection. This section only provides the minimal definitions and notation necessary for the remainder of the paper.

For any subset $A \subset \llbracket n \rrbracket$, let

$$P_n^{(A)} := \frac{1}{|A|} \sum_{t \in A} \delta_t \quad \text{and} \quad \hat{s}_m^{(A)} := \operatorname{argmin}_{t \in S_m} \left\{ \|t\|^2 - 2P_n^{(A)}(t) \right\}.$$

The main idea of cross-validation is data splitting: some $T \subset \llbracket n \rrbracket$ is chosen, one first trains $\hat{s}_m(\cdot)$ with ξ_T , then test the trained estimator on the remaining data ξ_{T^c} . The hold-out criterion is the estimator of $\operatorname{crit}_{\text{id}}(m)$ obtained with this principle, that is,

$$\operatorname{crit}_{\text{HO}}(m, T) := P_n^{(T^c)} \gamma \left(\hat{s}_m^{(T)} \right) = -2P_n^{(T^c)} \left(\hat{s}_m^{(T)} \right) + \|\hat{s}_m^{(T)}\|^2, \quad (4)$$

and all cross-validation criteria are defined as averages of hold-out criteria with various subsets T .

Let $V \in \{2, \dots, n\}$ be a positive integer and let $\mathcal{B} = \mathcal{B}_{\llbracket V \rrbracket} = (\mathcal{B}_1, \dots, \mathcal{B}_V)$ be some partition of $\llbracket n \rrbracket$. The V -fold cross-validation criterion is defined by

$$\operatorname{crit}_{\text{VFCV}}(m, \mathcal{B}) := \frac{1}{V} \sum_{K=1}^V \operatorname{crit}_{\text{HO}}(m, \mathcal{B}_K^c).$$

Compared to the hold-out, one expects cross-validation to be less variable thanks to the averaging over V splits of the sample into $\xi_{\mathcal{B}_K}$ and $\xi_{\mathcal{B}_K^c}$.

Since $\operatorname{crit}_{\text{VFCV}}(m, \mathcal{B})$ is known to be a biased estimator of $\mathbb{E}[\operatorname{crit}_{\text{id}}(m)]$, Burman (1989) proposed the bias-corrected V -fold cross-validation criterion

$$\operatorname{crit}_{\text{corr,VFCV}}(m, \mathcal{B}) := \operatorname{crit}_{\text{VFCV}}(m, \mathcal{B}) + P_n \gamma \left(\hat{s}_m \right) - \frac{1}{V} \sum_{K=1}^V P_n \gamma \left(\hat{s}_m^{\mathcal{B}_K^c} \right).$$

In the particular case where $V = n$, this criterion is studied by Massart (2007, Section 7.2.1, p. 204–205) under the name cross-validation estimator.

2.4 Resampling-Based and V -Fold Penalties

Another approach for building general data-driven model selection criteria is penalization with a resampling-based estimator of the expectation of the ideal penalty, as proposed by Efron (1983) with the bootstrap and later generalized to all resampling schemes (Arlot, 2009). Let $W \sim \mathcal{W}$ be some random vector of \mathbb{R}^n independent from $\xi_{\llbracket n \rrbracket}$ with

$$\frac{1}{n} \sum_{i=1}^n W_i = 1,$$

and denote by $P_n^W = n^{-1} \sum_{i=1}^n W_i \delta_{\xi_i}$ the weighted empirical distribution of the sample. Then, the resampling-based penalty associated with \mathcal{W} is defined as

$$\operatorname{pen}_{\mathcal{W}}(m) := C_{\mathcal{W}} \mathbb{E}_{\mathcal{W}} \left[\left(P_n - P_n^W \right) \gamma \left(\hat{s}_m^W \right) \right], \quad (5)$$

where $\hat{s}_m^W \in \operatorname{argmin}_{\xi \in S_m} \{ P_n^W \gamma(t) \}$, $\mathbb{E}_{\mathcal{W}}[\cdot]$ denotes the expectation with respect to W only (that is, conditionally to the sample $\xi_{\llbracket n \rrbracket}$), and $C_{\mathcal{W}}$ is some positive constant. Resampling-based penalties have been studied recently in the least-squares density estimation framework (Lerasle, 2012), assuming that W is exchangeable, that is, its distribution is invariant by any permutation of its coordinates.

Since computing exactly $\operatorname{pen}_{\mathcal{W}}(m)$ has a large computational cost in general for exchangeable W , some non-exchangeable resampling schemes were introduced by Arlot (2008), inspired by V -fold cross-validation: given some partition $\mathcal{B} = \mathcal{B}_{\llbracket V \rrbracket}$ of $\llbracket n \rrbracket$, the weight vector W is defined by $W_i = (1 - \operatorname{Card}(\mathcal{B}_J)/n)^{-1} \mathbb{1}_{i \notin \mathcal{B}_J}$ for some random variable J with uniform distribution over $\llbracket V \rrbracket$. Then, $P_n^W = P_n^{\mathcal{B}_J^c}$ so that the associated resampling penalty, called V -fold penalty, is defined by

$$\begin{aligned} \operatorname{pen}_{\text{VF}}(m, \mathcal{B}, x) &:= \frac{x}{V} \sum_{K=1}^V \left[\left(P_n - P_n^{\mathcal{B}_K^c} \right) \gamma \left(\hat{s}_m^{\mathcal{B}_K^c} \right) \right] \\ &= \frac{2x}{V} \sum_{K=1}^V \left(P_n^{\mathcal{B}_K^c} - P_n \right) \left(\hat{s}_m^{\mathcal{B}_K^c} \right) \end{aligned} \quad (6)$$

where $x > 0$ is left free for flexibility, which is quite useful according to Lemma 1 below.

2.5 Links Between V -Fold Penalties, Resampling Penalties and (Corrected) V -Fold Cross-Validation

In this paper, we focus our study on V -fold penalties because Lemma 1 below shows that formula (6) covers all V -fold and resampling-based procedures mentioned in Sections 2.3 and 2.4.

First, when $V = n$, the only possible partition is $\mathcal{B}_{\text{LOO}} = \{\{1\}, \dots, \{n\}\}$, and the V -fold penalty is called the leave-one-out penalty $\operatorname{pen}_{\text{LOO}}(m, x) := \operatorname{pen}_{\text{VF}}(m, \mathcal{B}_{\text{LOO}}, x)$. The associated weight vector W is exchangeable, hence Eq. (6) leads to all exchangeable resampling penalties since they are all equal up to a deterministic multiplicative factor in the least-squares density estimation framework when $\sum_{i=1}^n W_i = n$, as proved by Lerasle (2012).

For V -fold methods, let us assume \mathcal{B} is a regular partition of $\llbracket n \rrbracket$, that is,

$$V = |\mathcal{B}| \geq 2 \text{ divides } n \quad \text{and} \quad \forall K \in \llbracket V \rrbracket, |\mathcal{B}_K| = \frac{n}{V}. \quad (\text{Reg})$$

Then, we get the following connection between V -fold penalization and cross-validation methods.

Lemma 1 *For least-squares density estimation with projection estimators, under assumption (Reg),*

$$\operatorname{crit}_{\text{corr,VFCV}}(m, \mathcal{B}) = P_n \gamma \left(\hat{s}_m \right) + \operatorname{pen}_{\text{VF}}(m, \mathcal{B}, V - 1) \quad (7)$$

$$\text{critVRCV}(m, \mathcal{B}) = P_n \gamma(\widehat{s}_m) + \text{pen}_{\text{VF}} \left(m, \mathcal{B}, V - \frac{1}{2} \right) \quad (8)$$

$$\text{critLPO}(m, p) = P_n \gamma(\widehat{s}_m) + \text{pen}_{\text{LPO}} \left(m, p, \frac{n}{p} - \frac{1}{2} \right) \quad (9)$$

$$\begin{aligned} &= P_n \gamma(\widehat{s}_m) + \text{pen}_{\text{LOO}} \left(m, (n-1) \frac{n/p-1/2}{n/p-1} \right) \\ &= P_n \gamma(\widehat{s}_m) + \text{pen}_{\text{VF}} \left(m, \mathcal{B}_{\text{LOO}}, (n-1) \frac{n/p-1/2}{n/p-1} \right) \end{aligned} \quad (10)$$

where for any $p \in \llbracket n-1 \rrbracket$, the leave- p -out cross-validation criterion is defined by

$$\text{critLPO}(m, p) := \frac{1}{|\mathcal{E}_p|} \sum_{A \in \mathcal{E}_p} P_n^{(A)} \gamma(\widehat{s}_m^{(A)}) \quad \text{with} \quad \mathcal{E}_p := \{A \subset \llbracket n \rrbracket \text{ s.t. } |A| = p\}$$

and the leave- p -out penalty is defined by

$$\forall x > 0, \quad \text{pen}_{\text{LPO}}(m, p, x) := \frac{x}{|\mathcal{E}_p|} \sum_{A \in \mathcal{E}_p} \left(P_n - P_n^{(A)} \right) \gamma(\widehat{s}_m^{(A)}) .$$

Lemma 1 is proved in Section A.1.

Remark 2 Eq. (7) was first proved by Arlot (2008) in a general framework that includes least-squares density estimation, assuming only **(Reg)**. Eq. (10) follows from Lemsle (2012, Lemma A.11) since pen_{LPO} belongs to the family of exchangeable resampling penalties, with weights $W_i := (1-p/n)^{-1} \mathbb{1}_{i \notin A}$ and A is randomly chosen uniformly over \mathcal{E}_p ; note that $\sum_{i=1}^n W_i = n$ for these weights. It can also be deduced from Proposition 3.1 by Celisse (2014), see Section A.1.

Remark 3 It is worth mentioning here the cross-validation estimators studied by Massart (2007, Chapter 7). First, the unbiased cross-validation criterion defined by Rademio (1982) is exactly $\text{crit}_{\text{corr,VRCV}}(m, \mathcal{B}_{\text{LOO}}$) (see also Massart, 2007, Section 7.2.1). Second, the penalized estimator of Massart (2007, Theorem 7.6) is the estimator selected by the penalty

$$\text{pen}_{\text{LOO}} \left(m, \frac{(1+\epsilon)^6(n-1)^2}{2[n-(1+\epsilon)^6]} \right)$$

for some $\epsilon > 0$ such that $(1+\epsilon)^6 < n$ (see Section A.1 for details).

So, in the least-squares density estimation framework and assuming only **(Reg)**, Lemma 1 shows that it is sufficient to study V -fold penalization with a free multiplicative factor x in front of the penalty for studying also V -fold cross-validation ($x = V-1/2$), corrected V -fold cross-validation ($x = V-1$), the leave- p -out ($V = n$ and $x = (n-1)(n/p-1/2)/(n/p-1)$) and all exchangeable resampling penalties. For any $C > 0$ and \mathcal{B} some partition of $\llbracket n \rrbracket$ into V pieces, taking $x = C(V-1)$, the V -fold penalization criterion is denoted by

$$C_{(C,\mathcal{B})}(m) := P_n \gamma(\widehat{s}_m) + \text{pen}_{\text{VF}}(m, \mathcal{B}, C(V-1)) . \quad (11)$$

A key quantity in our results is the bias $\mathbb{E}[C_{(C,\mathcal{B})}(m)] - \text{crit}_{\text{id}}(m)$. From Lemma 13 in Section A.2, we have

$$\mathbb{E}[\text{pen}_{\text{VF}}(m, \mathcal{B}, V-1)] = \mathbb{E}[\text{pen}_{\text{id}}(m)] = 2\mathbb{E}[\|\widehat{s}_m - s_m\|^2] , \quad (12)$$

so that for any $C > 0$,

$$\mathbb{E}[C_{(C,\mathcal{B})}(m)] - \text{crit}_{\text{id}}(m) = 2(C-1)\mathbb{E}[\|\widehat{s}_m - s_m\|^2] . \quad (13)$$

In Sections 3-7, we focus our study on V -fold methods, that is, we study the performance of the V -fold penalized estimators \widehat{s}_m , defined by

$$\widehat{m} = \widehat{m}(C_{(C,\mathcal{B})}) = \underset{m \in \mathcal{M}_n}{\text{argmin}} \{C_{(C,\mathcal{B})}(m)\} , \quad (14)$$

for all values of V and $C > 1/2$. Additional results on hold-out (penalization) are given in Section 8.2 to complete the picture.

3. Oracle Inequalities

In this section, we state our first main result, that is, a non-asymptotic oracle inequality satisfied by V -fold procedures. This result holds for any divisor $V \geq 2$ of n , any constant $x = C(V-1)$ in front of the penalty with $C > 1/2$, and provides an asymptotically optimal oracle inequality for the selected estimator when $C \rightarrow 1$ (assuming the setting is non parametric). In addition, as proved by Section 2.5, it implies oracle inequalities satisfied by leave- p -out procedures for all p .

3.1 Concentration of V -Fold Penalties

Concentration is the key property to establish oracle inequalities. Let us start with some new concentration results for V -fold penalties.

Proposition 4 Let $\xi_{\llbracket n \rrbracket}$ be i.i.d. real-valued random variables with density $s \in L^\infty(\mu)$, \mathcal{B} some partition of $\llbracket n \rrbracket$ into V pieces satisfying **(Reg)**, S_m a separable linear space of measurable functions and $(\psi_\lambda)_{\lambda \in \Lambda_m}$ an orthonormal basis of S_m . Define

$$\begin{aligned} \mathbb{B}_m &= \{t \in S_m \text{ s.t. } \|t\| \leq 1\} & \Psi_m &= \sum_{\lambda \in \Lambda_m} \psi_\lambda^2 = \sup_{t \in \mathbb{B}_m} t^2 & b_m &:= \|\sqrt{\Psi_m}\|_\infty \\ \mathcal{D}_m &:= P(\Psi_m) - \|s_m\|^2 = n\mathbb{E}[\|s_m - \widehat{s}_m\|^2] , \end{aligned}$$

where \widehat{s}_m is defined by Eq. (1), and for any $x, \epsilon > 0$,

$$\rho_1(m, \epsilon, s, x, n) := \frac{\|s\|_\infty x}{\epsilon n} + \frac{(b_m^2 + \|s\|^2)x^2}{\epsilon^3 n^2} .$$

Then, an absolute constant κ exists such that for any $x \geq 0$, with probability at least $1 - 8e^{-x}$, for any $\epsilon \in (0, 1]$, the following two inequalities hold true

$$\left| \text{pen}_{\text{VF}}(m, \mathcal{B}, V-1) - \frac{2\mathcal{D}_m}{n} \right| \leq \frac{\mathcal{D}_m}{n} + \kappa \rho_1(m, \epsilon, s, x, n) \quad (15)$$

$$\left| \text{pen}_{\text{VF}}(m, \mathcal{B}, V-1) - 2\|s_m - \widehat{s}_m\|^2 \right| \leq \frac{\mathcal{D}_m}{n} + \kappa \rho_1(m, \epsilon, s, x, n) . \quad (16)$$

Proposition 4 is proved in Section A.2. Eq. (15) gives the concentration of the V -fold penalty around its expectation $2\mathcal{D}_m/n = \mathbb{E}[\text{pen}_{\text{id}}(m)]$, see Eq. (12). Eq. (16) gives the concentration of the V -fold penalty around the ideal penalty, see Eq. (2). Optimizing over ϵ , the first order of the deviations of $\text{pen}_{\text{VF}}(m, \mathcal{B}, V-1)$ around $\text{pen}_{\text{id}}(m)$ is driven by $\sqrt{\mathcal{D}_m/n}$. The deviation term in Proposition 4 does not depend on V and cannot therefore help to discriminate between different values of this parameter.

3.2 Example: Histogram Models

Histograms on \mathbb{R} provide some classical examples of collections of models. Let \mathcal{X} be a measurable subset of \mathbb{R} , μ denote the Lebesgue measure on \mathcal{X} and m be some countable partition of \mathcal{X} such that $\mu(\lambda) > 0$ for any $\lambda \in m$. The histogram space S_m based on m is the linear span of the functions $(\psi_\lambda)_{\lambda \in \Lambda_m}$ where $\Lambda_m = m$ and for every $\lambda \in m$, $\psi_\lambda = \mu(\lambda)^{-1/2} \mathbb{1}_\lambda$. More precisely, we illustrate our results with the following examples.

Example 1 (Regular histograms on $\mathcal{X} = \mathbb{R}$)

$$\mathcal{M}_n = \{m_h, h \in \llbracket n \rrbracket\} \quad \text{where} \quad \forall h \in \llbracket n \rrbracket, \quad m_h = \left\{ \left[\frac{\lambda}{h}, \frac{\lambda+1}{h} \right], \lambda \in \mathbb{Z} \right\}.$$

In Example 1, defining $d_{m_h} = h$ for every $h \in \llbracket n \rrbracket$, for every $m \in \mathcal{M}_n$, $\mathcal{D}_m = d_m - \|s_m\|^2$ since Ψ_m is constant and equal to d_m . Therefore, Proposition 4 shows that $\text{pen}_{\text{VF}}(m, \mathcal{B}, V-1)$ is asymptotically equivalent to $\text{pen}_{\text{dim}}(m) := 2d_m/n$ when $d_m \rightarrow \infty$. Penalties of the form of pen_{dim} are classical and have been studied for instance by Barron et al. (1999).

Example 2 (k -rupture points on $\mathcal{X} = [0, 1]$)

$$\mathcal{M}_n = \left\{ m_{h_{\llbracket k+1 \rrbracket}, x_{\llbracket k+1 \rrbracket}} \text{ s.t. } x_1 < \dots < x_k \in \llbracket n-1 \rrbracket \text{ and } \forall i \in \llbracket k+1 \rrbracket, h_i \in \llbracket x_i - x_{i-1} \rrbracket \right\},$$

where $x_0 = 0$, $x_{k+1} = n$ and for any $x_1, \dots, x_k \in \llbracket n-1 \rrbracket$ such that $x_1 < \dots < x_k$ and any $h_{\llbracket k+1 \rrbracket} \in \mathbb{N}^{k+1}$, $m_{h_{\llbracket k+1 \rrbracket}, x_{\llbracket k+1 \rrbracket}}$ is defined as the union

$$\bigcup_{i \in \llbracket k+1 \rrbracket} \left\{ \left[\frac{x_{i-1}}{n} + \frac{(x_i - x_{i-1})(\lambda-1)}{nh_i}, \frac{x_{i-1}}{n} + \frac{(x_i - x_{i-1})\lambda}{nh_i} \right], \lambda \in \llbracket h_i \rrbracket \right\}.$$

In other words, $m_{h_{\llbracket k+1 \rrbracket}, x_{\llbracket k+1 \rrbracket}}$ splits $[0, 1]$ into $k+1$ pieces (at the x_i), and then splits the i -th piece into h_i pieces of equal size.

In Example 2, the function Ψ_m is constant on each interval $[x_{i-1}, x_i]$, equal to h_i , therefore,

$$\mathcal{D}_m = \sum_{i=1}^{k+1} h_i \mathbb{P}(\xi \in [x_{i-1}, x_i]) - \|s_m\|^2.$$

3.3 Oracle Inequality for V -Fold Procedures

In order to state the main result, we introduce the following hypotheses:

- A uniform bound on the L^∞ norm of the L^2 ball of the models

$$\forall m \in \mathcal{M}_n, \quad b_m \leq \sqrt{n} \quad (\text{H1})$$

where we recall that $b_m := \sup_{t \in \mathbb{B}_m} \|t\|_\infty$ and $\mathbb{B}_m := \{t \in S_m, \|t\| \leq 1\}$.

- The family of the projections of s is uniformly bounded.

$$\exists a > 0, \quad \forall m \in \mathcal{M}_n, \quad \|s_m\|_\infty \leq a, \quad (\text{H2})$$

- The collection of models is nested.

$$\forall (m, m') \in \mathcal{M}_n^2, \quad S_m \cup S_{m'} \in \{S_m, S_{m'}\} \quad (\text{H2}')$$

Hereafter, we define $A := a \vee \|s\|_\infty$ when (H2) holds and $A := \|s\|_\infty$ when (H2') holds. On histogram spaces, (H1) holds if and only if $\inf_{m \in \mathcal{M}_n} \inf_{\lambda \in m} \mu(\lambda) \geq n^{-1}$, and (H2) holds with $a = \|s\|_\infty$.

Theorem 5 Let $\xi_{\llbracket n \rrbracket}$ be i.i.d. real-valued random variables with common density $s \in L^\infty(\mu)$, \mathcal{B} some partition of $\llbracket n \rrbracket$ into V pieces satisfying (Reg) and $(S_m)_{m \in \mathcal{M}_n}$ be a collection of separable linear spaces satisfying (H1). Assume that either (H2) or (H2') holds true. Let $C \in (1/2, 2]$, $\delta := 2(C-1)$ and, for any $x, \epsilon > 0$,

$$\rho_2(\epsilon, s, x, n) := \frac{Ax}{\epsilon n} + \left(1 + \frac{\|s\|^2}{n}\right) \frac{x^2}{\epsilon^3 n} \quad \text{and} \quad x_n = x + \log |\mathcal{M}_n|.$$

For every $m \in \mathcal{M}_n$, let \hat{s}_m be the estimator defined by Eq. (1) and $\tilde{s} = \hat{s}_{\hat{m}}$ where

$$\hat{m} = \hat{m}(C, \mathcal{B})$$

is defined by Eq. (14). Then, an absolute constant κ exists such that, for any $x > 0$, with probability at least $1 - e^{-x}$, for any $\epsilon \in (0, 1]$,

$$\frac{1 - \delta - \epsilon}{1 + \delta + \epsilon} \|\tilde{s} - s\|^2 \leq \inf_{m \in \mathcal{M}_n} \|\hat{s}_m - s\|^2 + \kappa \rho_2(\epsilon, s, x_n, n). \quad (17)$$

Theorem 5 is proved in Section A.3.

Taking $\epsilon > 0$ small enough in Eq. (17), Theorem 5 proves that V -fold model selection procedures satisfy an oracle inequality with large probability. The remainder term can be bounded under the following classical hypothesis

$$\exists a' > 0, \quad \forall n \in \mathbb{N}^*, \quad |\mathcal{M}_n| \leq n^{a'}. \quad (\text{H3})$$

For instance, (H3) holds in Example 1 with $a' = 1$ and in Example 2 with $a' = k$. Under (H3), the remainder term in Eq. (17) is bounded by $L(\log n)^2 / (\epsilon^3 n)$ for some $L > 0$, which is much smaller than the oracle loss in the nonparametric case.

The leading constant in the oracle inequality (17) is $(1 + \delta_+)/ (1 - \delta_-) + o(1)$ by choosing $\epsilon = o(1)$, so the first-order behaviour of the upper bound on the loss is driven by δ . An asymptotic optimality result can be derived from Eq. (17) only if $\delta = o(1)$. The meaning of

$\delta = 2(C-1)$ is the amount of bias of the V -fold penalization criterion, as shown by Eq. (13). Given this interpretation of δ , the model selection literature suggests that no asymptotic optimality result can be obtained in general when $\delta \neq o(1)$ in the nonparametric case (see, for instance, Shao, 1997). Therefore, even if the leading constant $(1 + \delta_+)/ (1 - \delta_-)$ is only an upper bound, we conjecture that it cannot be taken as small as $1 + o(1)$ unless $\delta = o(1)$; such a result can be proved in our setting using similar arguments and assumptions as the ones of Arlot (2008) for instance.

For bias-corrected V -fold cross-validation, that is, $C = 1$ hence $\delta = 0$, Theorem 5 shows a first-order optimal non-asymptotic oracle inequality, since the leading constant $(1 + \epsilon)/(1 - \epsilon)$ can be taken equal to $1 + o(1)$, and the remainder term is small enough in the nonparametric case, under assumption (H3), for instance. Such a result valid with no upper bound on V had never been obtained before in any setting.

V -fold cross-validation is also analyzed by Theorem 5, since by Lemma 1 it corresponds to $C = 1 + 1/(2(V-1))$, hence $\delta = 1/(V-1)$. When V is fixed, the oracle inequality is asymptotically sub-optimal, which is consistent with the result proved in regression by Arlot (2008). On the contrary, if $\mathcal{B} = \mathcal{B}_n$ has V_n blocs, with $V_n \rightarrow \infty$, Theorem 5 implies under assumption (H3) the asymptotic optimality of V_n -fold cross-validation in the nonparametric case.

The bound obtained in Theorem 5 can be integrated and we get

$$\frac{1 - \delta_- - \epsilon}{1 + \delta_+ + \epsilon} \mathbb{E} \left[\|\tilde{s} - s\|^2 \right] \leq \mathbb{E} \left[\inf_{m \in \mathcal{M}_n} \|\hat{s}_m - s\|^2 \right] + \kappa' \rho_2 \left(\epsilon, s, \log(\mathcal{M}_n) \right)$$

for some absolute constant $\kappa' > 0$.

Assuming $C > 1/2$ is necessary, according to minimal penalty results proved by Lerasle (2012). Assuming $C \leq 2$ only simplifies the presentation; if $C > 2$, the same proof shows that Theorem 5 holds with κ replaced by $C\kappa$.

An oracle inequality similar to Theorem 5 holds in a more general setting, as proved in a previous version of this paper (Arlot and Lerasle, 2012, Theorem 1); we state a less general result here for simplifying the exposition, since it does not change the message of the paper. First, assumption (Reg) can be relaxed into assuming the partition \mathcal{B} is close to regular, that is,

$$\mathcal{B} \text{ is a partition of } \llbracket n \rrbracket \text{ of size } V \text{ and } \sup_{k \in \llbracket V \rrbracket} \left| \text{Card}(\mathcal{B}_k) - \frac{n}{V} \right| \leq 1, \quad (\text{Reg})$$

which can hold for any $V \in \llbracket n \rrbracket$. Second, data ξ_1, \dots, ξ_n can belong to a general Polish space \mathcal{X} , at the price of some additional technical assumption.

3.4 Comparison with Previous Works on V -Fold Procedures

Few non-asymptotic oracle inequalities have been proved for V -fold penalization or cross-validation procedures.

Concerning cross-validation, previous oracle inequalities are listed in the survey by Arlot and Celisse (2010). In the least-squares density estimation framework, oracle inequalities were proved by van der Laan et al. (2004) in the V -fold case, but compared the risk of the selected estimator with the risk of an oracle trained with $n(V-1)/V$ data. In comparison,

Theorem 5 considers the strongest possible oracle, that is, trained with n data. Optimal oracle inequalities were proved by Celisse (2014) for leave- p -out estimators with $p \ll n$, a case also treated in Theorem 5 by taking $V = n$ and $C = (n/p - 1/2)/(n/p - 1)$ as shown by Lemma 1. If $p \ll n$, $C \sim 1$, hence $\delta = o(1)$ and we recover the result of Celisse (2014).

Concerning V -fold penalization, previous results were either valid for $V = n$ only—by Massart (2007, Theorem 7.6) and Lerasle (2012) for least-squares density estimation, by Arlot (2009) for regression estimators—, or for V bounded when n tends to infinity—by Arlot (2008) for regression estimators. In comparison, Theorem 5 provides a result valid for all V , except for the assumption that V divides n , which can be removed (Arlot and Lerasle, 2012). In particular, the loss bound by Arlot (2008) deteriorates when V grows, while it remains stable in our result. Our result is therefore much closer to the typical behavior of the loss ratio $\|\tilde{s} - s\|^2 / \inf_{m \in \mathcal{M}_n} \|\hat{s}_m - s\|^2$ of V -fold penalization, which usually decreases as a function of V in simulation experiments, see Section 6 and the experiments by Arlot (2008), for instance.

Theorem 5 may not satisfactorily address the parametric setting, that is, when the collection $(\mathcal{S}_m)_{m \in \mathcal{M}_n}$ contains some fixed true model. In such a case, the usual way to obtain asymptotic optimality is to use a model selection procedure targeting identification, that is, taking $C \rightarrow +\infty$ when $n \rightarrow +\infty$. For instance, Celisse (2014, Theorem 3.3) shows that $\log(n) \ll C \ll n$ is a sufficient condition for such a result.

4. How to Compare Theoretically the Performances of Model Selection Procedures for Estimation?

The main goal of the paper is to compare the model selection performances of several (V -fold) cross-validation methods, when the goal is estimation, that is, minimizing the loss $\|\hat{s}_m - s\|^2$ of the final estimator. In this section, we discuss how such a comparison can be made on theoretical grounds, in a general setting.

For some data-driven function $\mathcal{C} : \mathcal{M}_n \rightarrow \mathbb{R}$, the goal is to understand how $\|\hat{s}_{\hat{m}(\mathcal{C})} - s\|^2$ depends on \mathcal{C} when the selected model is

$$\hat{m}(\mathcal{C}) \in \underset{m \in \mathcal{M}_n}{\text{argmin}} \{ \mathcal{C}(m) \}. \quad (18)$$

From now on, in this section, \mathcal{C} is assumed to be a cross-validation estimator of the risk, but the heuristic developed here applies to the general case.

Ideal comparison. Ideally, for proving that \mathcal{C}_1 is a better method than \mathcal{C}_2 in some setting, we would like to prove that

$$\|\hat{s}_{\hat{m}(\mathcal{C}_1)} - s\|^2 < (1 - \epsilon_n) \|\hat{s}_{\hat{m}(\mathcal{C}_2)} - s\|^2 \quad (19)$$

with a large probability, for some $\epsilon_n \geq 0$.

Previous works and their limits. When the goal is estimation, the classical way to analyze the performance of a model selection procedure is to prove an oracle inequality, that is, to *upper bound* (with a large probability or in expectation)

$$\|\hat{s}_{\hat{m}(\mathcal{C})} - s\|^2 - \inf_{m \in \mathcal{M}_n} \left\{ \|\hat{s}_m - s\|^2 \right\} \quad \text{or} \quad \mathfrak{R}_n(\mathcal{C}) := \frac{\|\hat{s}_{\hat{m}(\mathcal{C})} - s\|^2}{\inf_{m \in \mathcal{M}_n} \left\{ \|\hat{s}_m - s\|^2 \right\}}.$$

Alternatively, asymptotic results show that when n tends to infinity, $\mathfrak{R}_n(\mathcal{C}) \rightarrow 1$ (asymptotic optimality of \mathcal{C}) or $\mathfrak{R}_n(\mathcal{C}_1) \sim \mathfrak{R}_n(\mathcal{C}_2)$ (asymptotic equivalence of \mathcal{C}_1 and \mathcal{C}_2); see Arlot and Celisse (2010, Section 6) for a review of such results. Nevertheless, proving Eq. (19) requires a lower bound on $\mathfrak{R}_n(\mathcal{C})$ (asymptotic or not), which has been done only once for some cross-validation method, to the best of our knowledge. In some least-squares regression setting, V -fold cross-validation (\mathcal{C}^{VF}) performs (asymptotically) worse than all asymptotically optimal model selection procedures since $\mathfrak{R}_n(\mathcal{C}^{VF}) \geq \kappa(V) > 1$ with a large probability (Arlot, 2008).

The major limitation of all these previous results is that they can only compare \mathcal{C}_1 to \mathcal{C}_2 at first order, that is, according to $\lim_{n \rightarrow \infty} \mathfrak{R}_n(\mathcal{C}_1)/\mathfrak{R}_n(\mathcal{C}_2)$, which only depends on the bias of $\mathcal{C}_i(m)$ ($i = 1, 2$) as an estimator of $\mathbb{E}[\|\hat{s}_m - s\|^2]$; hence, on the asymptotic ratio between the training set size and the sample size (Arlot and Celisse, 2010, Section 6). For instance, the leave- p -out and the hold-out with a training set of size $(n - p)$ cannot be distinguished at first order, while the leave- p -out performs much better in practice, certainly because its “variance” is much smaller.

Beyond first-order. So, we must go beyond the first-order of $\mathfrak{R}_n(\mathcal{C})$ and take into account the variance of $\mathcal{C}(m)$. Nevertheless, proving a lower bound on $\mathfrak{R}_n(\mathcal{C})$ is already challenging at first order—probably the reason why only one has been proved up to now, in a specific setting only—so the challenge of computing a precise lower bound on the second order term of $\mathfrak{R}_n(\mathcal{C})$ seems too high for the present paper. We propose instead a heuristic showing that the variances of some quantities—depending on $(\mathcal{C}_i)_{i=1,2}$ and on \mathcal{M}_n —can be used as a proxy to a proper comparison of $\mathfrak{R}_n(\mathcal{C}_1)$ and $\mathfrak{R}_n(\mathcal{C}_2)$ at second order. Since we focus on second-order terms, from now on, we assume that \mathcal{C}_1 and \mathcal{C}_2 have the same bias, that is,

$$\forall m \in \mathcal{M}_n, \quad \mathbb{E}[\mathcal{C}_1(m)] = \mathbb{E}[\mathcal{C}_2(m)]. \quad (\text{SameBias})$$

In least-squares density estimation, given Lemma 1, this means that for $i \in \{1, 2\}$,

$$\mathcal{C}_i = \mathcal{C}_{(C, \mathcal{B}_i)}$$

as defined by Eq. (11), with different partitions \mathcal{B}_i satisfying **(Reg)** with different $V = V_i$, but the same constant $C > 0$; $C = 1$ corresponds to the unbiased case.

The variance of the cross-validation criteria is not the correct quantity to look at. If we were only comparing cross-validation methods $\mathcal{C}_1, \mathcal{C}_2$ as estimators of $\mathbb{E}[\|\hat{s}_m - s\|^2]$ for every single $m \in \mathcal{M}_n$, we could naturally compare them through their mean squared errors. Under assumption **(SameBias)**, this would mean to compare their variances. This can be done from Eq. (23) below, but it is not sufficient to solve our problem, since it is known that the best cross-validation estimator of the risk does not necessarily yield the best model selection procedure (Breiman and Spector, 1992). More precisely, the selected model $\hat{m}(\mathcal{C})$ defined by Eq. (18) is unchanged when $\mathcal{C}(m)$ is translated by any random quantity, but such a translation does change $\text{Var}(\mathcal{C}(m))$ and can make it as large as desired. For model selection, what really matters is that

$$\text{sign}(\mathcal{C}(m_1) - \mathcal{C}(m_2)) = \text{sign}(\|\hat{s}_{m_1} - s\|^2 - \|\hat{s}_{m_2} - s\|^2)$$

as often as possible for every $(m_1, m_2) \in \mathcal{M}_n^2$, and that most mistakes in the ranking of models occur when $\|\hat{s}_{m_1} - s\|^2 - \|\hat{s}_{m_2} - s\|^2$ is small, so that $\|\hat{s}_{\hat{m}(\mathcal{C})} - s\|^2$ cannot be much larger than $\inf_{m \in \mathcal{M}_n} \{\|\hat{s}_m - s\|^2\}$.

Heuristic. The heuristic we propose goes as follows. For simplicity, we assume that $m^* = \arg\min_{m \in \mathcal{M}_n} \mathbb{E}[\|\hat{s}_m - s\|^2]$ is uniquely defined. If the goal was identification, we could directly state that for any \mathcal{C} , the smaller is $\mathbb{P}(m = \hat{m}(\mathcal{C}))$ for all $m \neq m^*$, the better should be the performance of $\hat{m}(\mathcal{C})$. In this paper, our goal is estimation, but a similar claim can be conjectured by considering “all $m \in \mathcal{M}_n$ sufficiently far from m^* in terms of risk”, that is, all $m \in \mathcal{M}_n$ such that $\mathbb{E}[\|\hat{s}_m - s\|^2]$ is significantly worse than $\mathbb{E}[\|\hat{s}_{m^*} - s\|^2]$. Indeed, for any m “close to m^* ” in terms of risk, selecting m instead of m^* does not significantly change the performance of $\hat{m}(\mathcal{C})$; on the contrary, for any m “far from m^* ” in terms of risk, selecting m instead of m^* does increase significantly the risk $\mathbb{E}[\|\hat{s}_{\hat{m}(\mathcal{C})} - s\|^2]$.

Then, our idea is to find a proxy for $\mathbb{P}(m = \hat{m}(\mathcal{C}))$, that is, a quantity that should behave similarly as a function of \mathcal{C} and its “variance” properties. For all $m, m' \in \mathcal{M}_n$, let $\Delta_{\mathcal{C}}(m, m') := \mathcal{C}(m) - \mathcal{C}(m')$. \mathcal{N} some standard Gaussian random variable and, for all $t \in \mathbb{R}$, $\Phi(t) = \mathbb{P}(\mathcal{N} > t)$. Then, for every $m \in \mathcal{M}_n$

$$\begin{aligned} \mathbb{P}(\hat{m}(\mathcal{C}) = m) &= \mathbb{P}(\forall m' \neq m, \Delta_{\mathcal{C}}(m, m') < 0) \\ &\asymp \min_{m' \neq m} \mathbb{P}(\Delta_{\mathcal{C}}(m, m') < 0) \end{aligned} \quad (20)$$

$$\begin{aligned} &\approx \min_{m' \neq m} \mathbb{P}(\mathbb{E}[\Delta_{\mathcal{C}}(m, m')] + \mathcal{N}\sqrt{\text{Var}(\Delta_{\mathcal{C}}(m, m'))} < 0) \\ &= \overline{\Phi}(\text{SNR}_{\mathcal{C}}(m)) \quad \text{where} \quad \text{SNR}_{\mathcal{C}}(m) := \max_{m' \neq m} \frac{\mathbb{E}[\Delta_{\mathcal{C}}(m, m')]}{\sqrt{\text{Var}(\Delta_{\mathcal{C}}(m, m'))}}. \end{aligned} \quad (21)$$

So, if $\text{SNR}_{\mathcal{C}_1}(m) > \text{SNR}_{\mathcal{C}_2}(m)$ for all m “sufficiently far from m^* ”, \mathcal{C}_1 should be better than \mathcal{C}_2 . Assuming **(SameBias)** holds true and that

$$\{m^*\} = \arg\min_{m \in \mathcal{M}_n} \mathbb{E}[\mathcal{C}_1(m)] = \arg\min_{m \in \mathcal{M}_n} \mathbb{E}[\mathcal{C}_2(m)], \quad (\text{SameMin})$$

this leads to the following heuristic

$$\forall m \neq m', \quad \text{Var}(\Delta_{\mathcal{C}_1}(m, m')) < \text{Var}(\Delta_{\mathcal{C}_2}(m, m')) \Rightarrow \mathcal{C}_1 \text{ better than } \mathcal{C}_2. \quad (22)$$

Indeed, for every $m \neq m'$, assumption **(SameMin)** implies that $\text{SNR}_{\mathcal{C}_1}(m) > 0$ for $i = 1, 2$, hence we can restrict the max in the definition of $\text{SNR}_{\mathcal{C}_i}$ to all m' such that $\mathbb{E}[\Delta_{\mathcal{C}_i}(m, m')] > 0$. By assumption **(SameBias)**, the numerator in the definition of $\text{SNR}_{\mathcal{C}_i}$ does not depend on i , hence the ratio is maximal when the denominator is minimal, which leads to Eq. (22). Let us make some remarks.

- The quantity $\Delta_{\mathcal{C}}(m, m')$ appears in relative bounds (Catoni, 2007, Section 1.4) which can be used as a tool for model selection (Audibert, 2004).
- Assumptions **(SameBias)** and **(SameMin)** hold true in particular in the unbiased case, that is, when $\mathbb{E}[\mathcal{C}_i(m)] = \mathbb{E}[\|\hat{s}_m - s\|^2]$ for all $m \in \mathcal{M}_n$ and $i \in \{1, 2\}$.

- Assumption (**SameMin**) is necessary: Figure 3 shows an example where a larger variance corresponds to better performance under assumption (**SameBias**) alone.
- As noticed above, the heuristic (22) should apply when the goal is estimation *and* when the goal is identification, provided that (**SameBias**) and (**SameMin**) hold true. What should depend on the goal is the suitable amount of bias for $C_\alpha(m)$ as an estimator of the risk $\mathbb{E}\|\widehat{s}_m - s\|^2$.
- Approximation (20) is the strongest one. Clearly, inequality \leq holds true. The equality case occurs is for a very particular dependence setting; that is, when one among the events $(\{\Delta_C(m, m') < 0\})$, $m' \in \mathcal{M}_n$, is included into all the others. In general, the left-hand side is significantly smaller than the right-hand side; we conjecture that they vary similarly as a function of C .
- The Gaussian approximation (21) for $\Delta_C(m, m')$ does not hold exactly, but it seems reasonable to make it, at first order at least.
- The validity of approximations (20) and (21) is supported by the numerical experiments of Section 6.

In the heuristic (22), all (m, m') do not matter equally for explaining a quantitative difference in the performances of C . First, we can fix $m' = m^*$ since intuitively, the strongest candidate against any $m \neq m^*$ is m^* , which clearly holds in all our experiments, see Figures 18 and 24 in Section G of the Online Appendix. Second, as mentioned above, if m and m^* are very close, that is, $\|\widehat{s}_m - s\|^2 / \|\widehat{s}_{m^*} - s\|^2$ is smaller than the minimal order of magnitude we can expect for $\mathfrak{R}_n(C)$ with a data-driven C , taking m instead of m^* does not decrease the performance significantly. Third, if $\Phi(\text{SNR}_C(m))$ is very small, increasing it even by an order of magnitude will not affect the performance of $\widehat{m}(C)$ significantly; hence, all m such that, say, $\text{SNR}_C(m) \gg (\log(n))^\alpha$ for all $\alpha > 0$, can also be discarded. Overall, pairs (m, m') that really matter in (22) are pairs (m, m^*) that are at a “moderate distance”, in terms of $\mathbb{E}\|\widehat{s}_m - s\|^2 - \|\widehat{s}_{m^*} - s\|^2$.

5. Dependence on V of V -Fold Penalization and Cross-Validation

Let us now come back to the least-squares density estimation setting. Our goal is to compare the performance of cross-validation methods having the same bias, that is, according to Section 2.5, $\widehat{m}(C_{(C, \mathcal{B})})$ with the same constant C but different partitions \mathcal{B} , where $\widehat{m}(C_{(C, \mathcal{B})})$ is defined by Eq. (14).

Theorem 6 *Let $\xi_{[n]}$ be i.i.d. random variables with common density $s \in L^\infty(\mu)$, \mathcal{B} some partition of $[n]$ into V pieces satisfying (**Reg**), and $(\psi_\lambda)_{\lambda \in \Delta_{m_1}}$, $(\psi_\lambda)_{\lambda \in \Delta_{m_2}}$ two orthonormal families in $L^2(\mu)$. For any $m, m' \in \{m_1, m_2\}$, we define S_m the linear span of $(\psi_\lambda)_{\lambda \in \Delta_{m^*}}$, s_m the orthogonal projection of s onto S_m in $L^2(\mu)$, $\Psi_m := \sup_{t \in S_m} \text{s.t. } \|t\| \leq 1$, t^2 ,*

$$\beta(m, m') := \sum_{\lambda \in \Delta_m} \sum_{\lambda' \in \Delta_{m'}} \left(\mathbb{E} \left[(\psi_\lambda(\xi_1) - P_{\psi_\lambda})(\psi_{\lambda'}(\xi_1) - P_{\psi_{\lambda'}}) \right] \right)^2$$

and $\mathbf{B}(m_1, m_2) := \beta(m_1, m_1) + \beta(m_2, m_2) - 2\beta(m_1, m_2)$.

Then, for every $C > 0$,

$$\begin{aligned} \text{Var}(C_{(C, \mathcal{B})}(m_1)) &= \frac{2}{n^2} \left(1 + \frac{4C^2}{V-1} - \frac{2C-1}{n} \right) \beta(m_1, m_1) \\ &+ \frac{4}{n} \text{Var} \left(\left(1 + \frac{2C-1}{n} \right) s_{m_1}(\xi_1) - \frac{2C-1}{2n} \Psi_{m_1}(\xi_1) \right) \end{aligned} \quad (23)$$

$$\begin{aligned} \text{and } \text{Var}(C_{(C, \mathcal{B})}(m_1) - C_{(C, \mathcal{B})}(m_2)) &= \frac{2}{n^2} \left(1 + \frac{4C^2}{V-1} - \frac{2C-1}{n} \right) \mathbf{B}(m_1, m_2) \\ &+ \frac{4}{n} \text{Var} \left(\left(1 + \frac{2C-1}{n} \right) (s_{m_1} - s_{m_2})(\xi_1) - \frac{2C-1}{2n} (\Psi_{m_1} - \Psi_{m_2})(\xi_1) \right) \end{aligned} \quad (24)$$

where $C_{(C, \mathcal{B})}$ is defined by Eq. (11).

Theorem 6 is proved in Section A.4.

Unbiased case. When $C = 1$, Theorem 6 shows that

$$\text{Var}(C_{(1, \mathcal{B})}(m_1) - C_{(1, \mathcal{B})}(m_2)) = a + \left(1 + \frac{4}{V-1} - \frac{1}{n} \right) b$$

for some $a, b \geq 0$ depending on n, m_1, m_2 but not on V . If we admit that the heuristic (22) holds true, this implies that the model selection performance of bias-corrected V -fold cross-validation improves when V increases, but the improvement is at most in a second order term as soon as V is large. In particular, even if $a \ll b$, the improvement from $V = 2$ to 5 or 10 is much larger than from $V = 10$ to $V = n$, which can justify the commonly used principle that taking $V = 5$ or $V = 10$ is large enough.

Assuming in addition that S_{m_1} and S_{m_2} are regular histogram models (Example 1 in Section 3.2) with d_{m_1} that divides d_{m_2} , then, by Lemma 19 in Section B.2 of the Online Appendix,

$$\begin{aligned} a &= \frac{4}{n} \left(1 + \frac{1}{n} \right)^2 \text{Var}(s_{m_1}(\xi_1) - s_{m_2}(\xi_1)) \approx \mathcal{O} \left(\frac{1}{n} \|s_{m_1} - s_{m_2}\|^2 \right) \\ \text{and } b &= \frac{2}{n^2} \mathbf{B}(m_1, m_2) \asymp \|s_{m_2}\|^2 \frac{d_{m_2}}{n^2}. \end{aligned}$$

When d_{m_2}/n is at least as large as $\|s_{m_1} - s_{m_2}\|^2$, we obtain that the first-order term in the variance is of the form $\alpha + \beta/(V-1)$ where $\alpha, \beta > 0$ do not depend on V and are of the same order of magnitude, as supported by the numerical experiments of Section 6. Then, increasing V from 2 to n does reduce significantly the variance, by a constant multiplicative factor.

Let $C_{\text{id}}(m) := P_\gamma(\widehat{s}_m) + \mathbb{E}[\text{pen}_{\text{id}}(m)]$ be the criterion we could use if we knew the expectation of the ideal penalty. From Proposition 17 in Section B of the Online Appendix,

$$\begin{aligned} \text{Var}(C_{\text{id}}(m_1) - C_{\text{id}}(m_2)) &= \frac{2}{n^2} \left(1 - \frac{1}{n} \right) \mathbf{B}(m_1, m_2) \\ &+ \frac{4}{n} \text{Var} \left(\left(1 - \frac{1}{n} \right) (s_{m_1} - s_{m_2})(\xi_1) + \frac{1}{2n} (\Psi_{m_1} - \Psi_{m_2})(\xi_1) \right) \end{aligned}$$

which easily compares to formula (24) obtained for the V -fold criterion when $C = 1$. Up to smaller order terms, the difference lies in the first term, where $(1 + 4/(V - 1) - 1/n)$ is replaced by $(1 - 1/n)$ when using the expectation of the ideal penalty instead of a V -fold penalty. In other words, the leave-one-out penalty—that is, taking $V = n$ —behaves like the expectation of the ideal penalty.

We can also compare Eq. (23) with the asymptotic results obtained by Burman (1989), which imply that for any fixed model m_1

$$\text{Var}(\mathcal{C}_{(1,\mathcal{B})}(m_1) - P\gamma(\widehat{s}_{m_1})) = \frac{\gamma_0}{n} + \left(\frac{V}{V-1}\gamma_1 + \gamma_2\right) \frac{1}{n^2} + o\left(\frac{1}{n^2}\right)$$

with $\gamma_0, \gamma_1, \gamma_2$ that depend on m_1 and $\gamma_1 > 0$. Here, putting $C = 1$ in Eq. (23) yields a result with a similar flavour, valid for all $n \geq 1$, even if Eq. (23) computes the variance of a slightly different quantity.

Cross-validation criteria. V -fold cross-validation and the leave- p -out are also covered by Theorem 6, according to Lemma 1, respectively with $C = 1 + 1/(2(V - 1))$ and with $V = n$ and $C = 1 + 1/(2(n/p - 1))$. As in the unbiased case, increasing V decreases the variance, and if we admit that the heuristic (22) holds true, V -fold cross-validation performs almost as well as the leave- (n/V) -out as soon as V is larger than 5 or 10.

Similarly, the variances of the V -fold cross-validation and leave- p -out criteria, for instance, can be derived from Eq. (23). In the leave- p -out case, we recover formulas obtained by Celisse (2014) and Celisse and Robin (2008), with a different grouping of the variance components; Eq. (23) clearly emphasizes the influence of the bias—through $(C - 1)$ —on the variance. For V -fold cross-validation, we believe that Eq. (23) shows in a simpler way how the variance depends on V , compared to the result of Celisse and Robin (2008) which was focusing on the difference between V -fold cross-validation and the leave- (n/V) -out; here the difference can be written

$$\frac{8}{n^2} \left(\frac{1}{V-1} - \frac{1}{n-1} \right) \left(1 + \frac{1}{2(V-1)} \right)^2 \beta(m_1, m_1) .$$

A major novelty in Eq. (23) is also to cover a larger set of criteria, such as bias-corrected V -fold cross-validation. Note that $\text{Var}(\mathcal{C}_{(C,\mathcal{B})}(m_1))$ is generally much larger than

$$\text{Var}(\mathcal{C}_{(C,\mathcal{B})}(m_1) - \mathcal{C}_{(C,\mathcal{B})}(m_2)) ,$$

which illustrates again why computing the former quantity might not help for understanding the model selection properties of $\mathcal{C}_{(C,\mathcal{B})}$, as explained in Section 4. For instance, comparing Eq. (23) and (24), changing s_{m_1} into $s_{m_1} - s_{m_2}$ in the second term can reduce dramatically the variance when s_{m_1} and s_{m_2} are close, which happens for the pairs (m_1, m_2) that matter for model selection according to Section 4.

The variance of other criteria and their increments are computed in subsequent sections of the paper and in the Online Appendix: Monte-Carlo cross-validation (Theorem 10 in Section 8.1 and Theorem 24 in Section C.4) and hold-out penalization (Proposition 28 in Section D.2).

Remark 7 The term $\mathbf{B}(m_1, m_2)$ does not depend on the choice of particular bases of S_{m_1} and S_{m_2} ; as proved by Proposition 18 in Section B of the Online Appendix

$$\mathbf{B}(m_1, m_2) = n \text{Var}((\widehat{s}_{m_1} - \widehat{s}_{m_2})(\xi)) - (n+1) \text{Var}((s_{m_1} - s_{m_2})(\xi)) .$$

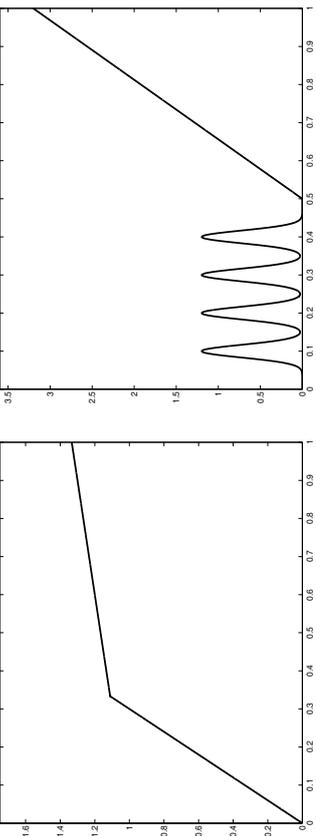

Figure 1: The two densities considered. Left: setting L. Right: setting S.

6. Simulation Study

This section illustrates the main theoretical results of the paper with some experiments on synthetic data.

6.1 Setting

In this section, we take $\mathcal{X} = [0, 1]$ and μ is the Lebesgue measure on \mathcal{X} . Two examples are considered for the target density s and for the collection of models $(S_m)_{m \in \mathcal{M}_n}$.

Two density functions s are considered, see Figure 1:

- Setting L: $s(x) = \frac{10x}{3} \mathbb{1}_{0 \leq x < 1/3} + (1 + \frac{x}{3}) \mathbb{1}_{1/3 \leq x < 1/2}$.
- Setting S: s is the mixture of the piecewise linear density $x \mapsto (8x - 4) \mathbb{1}_{1/2 \leq x < 1/2}$ (with weight 0.8) and four truncated Gaussian densities with means $(k/10)_{k=1, \dots, 4}$ and standard deviation $1/60$ (each with weight 0.05).

Two collections of models are considered, both leading to histogram estimators: for every $m \in \mathcal{M}_n$, S_m is the set of piecewise constant functions on some partition Λ_m of \mathcal{X} .

- “Regu” for regular histograms: $\mathcal{M}_n = \{1, \dots, n\}$ where for every $m \in \mathcal{M}_n$, Λ_m is the regular partition of $[0, 1]$ into m bins.

- “Dya2” for dyadic regular histograms with two bin sizes and a variable change-point:
$$\mathcal{M}_n = \bigcup_{k \in \{1, \dots, \tilde{n}\}} \{k\} \times \left\{ 0, \dots, \lfloor \log_2(k) \rfloor \right\} \times \left\{ 0, \dots, \lfloor \log_2(\tilde{n} - k) \rfloor \right\}$$

where $\tilde{n} = \lfloor n / \log(n) \rfloor$ and for every $(k, i, j) \in \mathcal{M}_n$, $\Lambda_{(k,i,j)}$ is the union of the regular partition of $[0, k/\tilde{n}]$ into 2^i pieces and the regular partition of $[k/\tilde{n}, 1]$ into 2^j pieces.

The difference between “Regu” and “Dya2” can be visualized on Figure 2, on which the corresponding oracle estimators \widehat{s}_{m^*} have been plotted for one sample in setting S, where

$$\widehat{m}^* \in \underset{m \in \mathcal{M}_n}{\text{argmin}} \|\widehat{s}_m - s\|^2 .$$

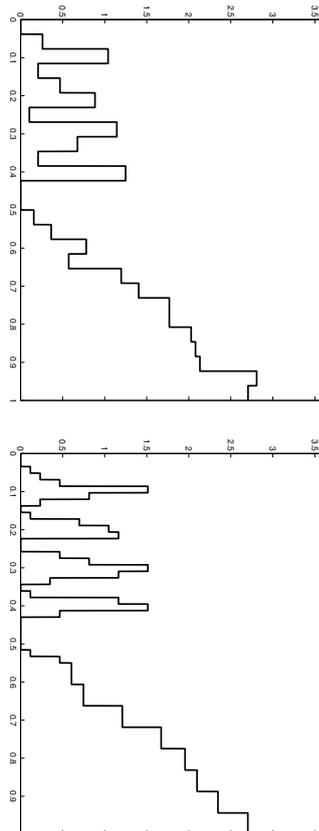

Figure 2: Oracle estimator for one sample of size $n = 500$, in setting S. Left: Regu. Right: Dya2.

Setting	Oracle(Regu)	Oracle(Dya2)	Best(Regu)	Best(Dya2)
L	13.4 ± 0.1	5.46 ± 0.02	25.8 ± 0.1	19.4 ± 0.1
S	62.4 ± 0.1	43.9 ± 0.1	100.9 ± 0.2	83.4 ± 0.2

Table 1: Comparison of Regu and Dya2: quadratic risks $\mathbb{E}[\|\hat{s}_m - s\|^2]$ of “Oracle” and “Best” estimators (multiplied by 10^3) with the two collections of models. “Best” means that \hat{m} is the data-driven procedure minimizing $\mathbb{E}[\|\hat{s}_m - s\|^2]$ among all the data-driven procedures we considered in our experiments (see Section 6.2). “Oracle” means that $\hat{m} \in \arg\min_{m \in \mathcal{M}_n} \|\hat{s}_m - s\|^2$ is the oracle model for each sample.

While “Regu” is one of the simplest and most classical collections for density estimation, the flexibility of “Dya2” allows to adapt to the variability of the smoothness of s . Intuitively, in settings L and S, the optimal bin size is smaller on $[0, 1/2]$ (where s is varying fastly) than on $[1/2, 1]$ (where $|s'|$ is much smaller).

Another point of comparison of Regu and Dya2 is given by Table 1, that reports values of the quadratic risks obtained depending on the collection of models considered. Table 1 shows that in settings L and S, the collection Dya2 helps reducing the quadratic risk by approximately 20% (when comparing the best data-driven procedures of our experiment), and even more when comparing oracle estimators (30% in setting S, 59% in setting L). Therefore, in settings L and S, it is worth considering more complex collections of models (such as Dya2) than regular histograms.

Let us finally remark that Dya2 does not reduce the quadratic risk in all settings as significantly as in settings L and S. We performed similar experiments with a few other density functions, sometimes leading to less important differences between Regu and Dya2 in terms of risk (results not shown). The oracle model was always better with Dya2, but in

two cases, the risk of the best data-driven procedure with Dya2 was larger than with Regu by 6 to 8%.

6.2 Procedures Compared

In each setting, we consider the following model selection procedures:

- pen_{dm} (Barron et al., 1999): penalization with $\text{pen}(m) = 2 \text{Card}(\Lambda_m)/n$.
- V -fold cross-validation with $V \in \{2, 5, 10, n\}$, see Section 2.3.
- V -fold penalties (with leading constant $x = V - 1$, that is, bias-corrected V -fold cross-validation), for $V \in \{2, 5, 10, n\}$, see Section 2.4.
- for comparison, penalization with $\mathbb{E}[\text{pen}_d(m)]$, that is, $\hat{m}(C_{1d})$.

Since it is often suggested to multiply the usual penalties by some factor larger than one (Arlot, 2008), we consider all penalties above multiplied by a factor $C \in [0, 10]$. Complete results can be found in Section G of the Online Appendix.

6.3 Model Selection Performances

In each setting, all procedures are compared on $N = 10000$ independent synthetic data sets of size $n = 500$. For measuring their respective model selection performances, for each procedure $\hat{m}(C)$ we estimate

$$C_{\text{or}}(C) := \mathbb{E}[\mathfrak{R}_n(C)] = \mathbb{E} \left[\frac{\|\hat{s}_{\hat{m}(C)} - s\|^2}{\inf_{m \in \mathcal{M}_n} \|\hat{s}_m - s\|^2} \right]$$

by the corresponding average over the N simulated data sets; $C_{\text{or}}(C)$ represents the constant that would appear in front of an oracle inequality. The uncertainty of estimation of $C_{\text{or}}(C)$ is measured by the empirical standard deviation of $\mathfrak{R}_n(C)$ divided by \sqrt{N} . The results are reported in Table 2 for settings L and S, with the collection Dya2.

Results for Regu are not reported here since dimensionality-based penalties are already known to work well with Regu (Lerasle, 2012), so V -fold methods cannot improve significantly their performance, with a larger computational cost. Complete results (including Regu, with $n = 100$ and $n = 500$) are given in Tables 3 and 4 in Section G of the Online Appendix, showing that the performances of pen_{dm} and V -fold methods indeed are very close.

Performance as a function of V . Let us first consider V -fold penalization. In both settings L and S, as suggested by our theoretical results, C_{or} decreases when V increases. The improvement is large when V goes from 2 to 5 (27% for L, 10% for S) and small when V goes from 5 to 10 and when V goes from 10 to $n = 500$ (each time, 8% for L, 2% for S). Since the main influence of V is on the variance of the V -fold penalty, these experiments support our interpretation of Theorem 6 in Section 5: increasing V helps much more from 2 to 5 or 10 than from 10 to n .

The picture is less clear for V -fold cross-validation, for which almost no difference is observed among $V \in \{2, 5, 10, n\}$ —less than 2%—, and C_{or} is minimized for $V \in \{5, 10\}$.

Procedure	L-Dya2	S-Dya2
pen _{dim}	8.27 ± 0.07	3.21 ± 0.01
pen2F	10.21 ± 0.08	2.39 ± 0.01
pen5F	7.47 ± 0.06	2.16 ± 0.01
pen10F	6.89 ± 0.06	2.11 ± 0.01
penLOO	6.35 ± 0.05	2.06 ± 0.01
2FCV	6.41 ± 0.05	2.05 ± 0.01
5FCV	6.27 ± 0.05	2.05 ± 0.01
10FCV	6.24 ± 0.05	2.05 ± 0.01
LOO	6.34 ± 0.05	2.06 ± 0.01
$\mathbb{E}[\text{pen}_{\text{id}}]$	6.52 ± 0.05	2.07 ± 0.01

Table 2: Estimated model selection performances, see text. ‘LOO’ is a shortcut for ‘leave-one-out’, that is, V -fold with $V = n = 500$.

Indeed, increasing V simultaneously decreases the bias and the variance of the V -fold cross-validation criterion, leading to various possible behaviours of C_{or} as a function of V , depending on the setting. The same phenomenon has been observed in regression (Arlot, 2008).

Overpenalization. In all settings considered in this paper, V -fold penalization performs much better when multiplying the penalty by $C > 1$, as illustrated by Figure 3. In particular, the best overpenalization factor for pen_{LOO} is $C_n^* \approx 2.5$ for L-Dya2 and $C_n^* \approx 1.4$ for S-Dya2, when $n = 500$. Such a phenomenon, which can also be observed in regression (Arlot, 2008), is related to the fact that some nonparametric model selection problems are “practically parametric”, using the terminology of Liu and Yang (2011), that is, BIC beats AIC and the optimal C is closer to $\log(n)/2$ than to 1. For instance, Figure 3 shows that L-Dya2 is practically parametric, while S-Dya2 is practically nonparametric since AIC beats BIC and the optimal C is close to 1.

Given an overpenalization factor C close to its optimal value C_n^* , V -fold penalization performs significantly better than V -fold cross-validation in settings S-Dya2 and L-Dya2 (Figure 3). Since V -fold cross-validation corresponds to taking

$$C = C^{\text{VF}}(V) := 1 + \frac{1}{2(V-1)}$$

according to Lemma 1, this mostly means that $C^{\text{VF}}(V)$ is not close to C_n^* in these settings. In addition, when $C \approx C_n^*$ is fixed, increasing V always improves the performance of V -fold penalization, as predicted by the heuristic of Section 4 and the theoretical results of Section 5. Let us emphasize that this fact does not depend on the parametricness of the setting: although the value of C_n^* is quite different for S-Dya2 and L-Dya2, in both cases, we observe qualitatively the same relationship between V and the performance of the procedure.

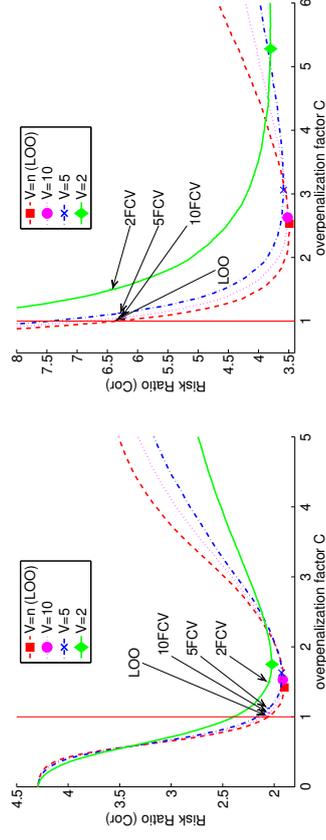

Figure 3: Overpenalization in settings S-Dya2 (left) and L-Dya2 (right), with $n = 500$ in both cases. Each plot represents the estimated model selection performance $C_{\text{or}}(\mathcal{C}(C, \mathcal{E}))$ of several penalization procedures, as a function of the overpenalization constant C ; unbiased risk estimation ($C = 1$) is materialized by a vertical red line. For each value of V , the estimated optimal value of C is shown on the graph; some arrows also show the performance of V -fold cross-validation, that is, $C = 1 + 1/2(V-1)$. Error bars are not shown for clarity; Table 2 shows their order of magnitude, which is smaller than visible differences in the above graph. The performance obtained with the penalty $\mathbb{E}[\text{pen}_{\text{id}}(m)]$ (not shown on the graph) is almost the same as with the leave-one-out penalty.

The results reported in Section G of the Online Appendix lead to similar conclusions in several other settings, as well as unshown results in a truly parametric setting, with a true model of dimension 2. Although a wider simulation study would be necessary to get general conclusions, this suggests at least that the heuristic of Section 4 and the theoretical results of Section 5 can be applied to both parametric and nonparametric settings.

Figure 3 also helps understanding how the performance of V -fold cross-validation depends on V in Table 2. Indeed, the performance of V -fold cross-validation for each value of V can be visualized on Figure 3 by taking the point of abscissa $C = C^{VF}(V)$ on the curve associated with V -fold penalization. Two phenomena are coupled when $C \leq C_n^*$, which always holds in our simulations for V -fold cross-validation since $\max_V C^{VF}(V) = 1.5$ and the estimated value of C_n^* is always larger. (i) The performance improves when V is fixed and C gets closer to C_n^* . (ii) The performance improves when C is fixed and V increases. Even if both phenomena (i) and (ii) seem quite universal, their coupling can result in various behaviours for V -fold cross-validation as a function of V , as shown by Table 3 in Section G of the Online Appendix for instance.

Other comments.

- `pendim` performs much worse than V -fold penalization (except $V = 2$ in setting L) with the collection `Dya2`. On the contrary, `pendim` does well with `Regu` (see Table 3 in Section G of the Online Appendix), but V -fold penalization then performs as well.
- In other settings considered in a preliminary phase of our experiments, for V -fold penalization, differences between $V = 2$ and $V = 5$ were sometimes smaller or not significant, but always with the same ordering (that is, the worse performance for $V = 2$ when C is fixed). In a few settings, for which the “change-point” in the smoothness of s was close to the median of sq_{L_s} , we found `pendim` among the best procedures with collection `Dya2`; then, V -fold penalization and cross-validation always had a performance very close to `pendim`. Both phenomena lead us to discard all settings for which there were no significant difference to comment.

6.4 Variance as a Function of V

We now illustrate the results of Section 5 about the variance of V -fold penalization and the heuristic of Section 4 about its influence on model selection. We focus on the unbiased case, that is, criteria $C_{(1,\mathcal{B})}$ with partitions \mathcal{B} satisfying **(Reg)**. Since the distribution of $(C_{(1,\mathcal{B})}(m))_{m \in \mathcal{M}_n}$ then only depends on $V = |\mathcal{B}|$, we write C_V instead of $C_{(1,\mathcal{B})}$ by abuse of notation. All results presented in this subsection have been obtained from $N = 10\,000$ independent samples in setting S with a sample size $n = 100$ and the collection `Regu`—for which models are naturally indexed by their dimension.

First, Figure 4 shows the variance of $\Delta_{C_V}(m, m^*) = C_V(m) - C_V(m^*)$ as a function of the dimension m of S_m , illustrating the conclusions of Theorem 6: the variance decreases when V increases. More precisely, the variance decrease is significant between $V = 2$ and $V = 5$, an order of magnitude smaller between $V = 5$ and $V = 10$ and between $V = 10$ and $V = n$, while the leave-one-out C_n is hard to distinguish from the ideal penalized criterion

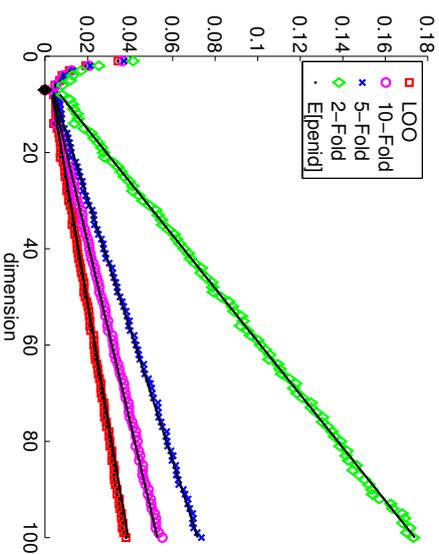

Figure 4: Illustration of the variance heuristic: $\text{Var}(\Delta c(m, m^*))$ as a function of m for five different C . Setting S-Regu, $n = 100$. The black diamond shows $m^* = 7$. The black lines show the linear approximation $n^{-2} [29(1 + \frac{0.81}{V-1}) + 3 \cdot 7(1 + \frac{3.8}{V-1})(m - m^*)]$ for $m > m^*$.

\mathcal{C}_{id} . On Figure 4, we can remark that for $m > m^*$

$$\text{Var}(\Delta_{C_V}(m, m^*)) \approx \frac{1}{m^2} \left[K_1 \left(1 + \frac{K_2}{V-1} \right) + K_3 \left(1 + \frac{K_4}{V-1} \right) (m - m^*) \right]$$

with $K_1 \approx 29$, $K_2 \approx 0.81$, $K_3 \approx 3.7$ and $K_4 \approx 3.8$. The shape of the dependence on V already appears in Theorem 6, the above formula clarifies the relative importance of the terms called a and b in Section 5, and their dependence on the dimension m of S_m . Remark that the same behaviour holds when $n = 500$ with very close values for K_3 and K_4 (see Figure 25 in Section G of the Online Appendix), as well as in setting L with $m = 100$ or $n = 500$ with $K_3 \approx 2.1$ and $K_4 \approx 4.2$ (see Figures 19 and 30 in Section G of the Online Appendix). The fact that K_4 is close to 4 in both settings supports that the term $1 + 4/(V-1)$ appearing Theorem 6 indeed drives how $\text{Var}(\Delta_{C_V}(m, m^*))$ depends on V .

Figures 5 and 6 respectively show $\mathbb{P}(\hat{m}(\mathcal{C}) = m)$ and its proxy $\bar{\Phi}(\text{SNR}_{\mathcal{C}}(m))$ as a function of m for $\mathcal{C} = C_V$ with $V \in \{2, 5, 10, n\}$ and for $\mathcal{C} = C_{\text{id}}$. First, we remark that both quantities behave similarly as a function of m and \mathcal{C} —see also Figure 16 in Section G of the Online Appendix—supporting empirically the heuristic of Section 4. The decrease of the variance observed on Figure 4 when V increases here translates into a better concentration of the distribution of $\hat{m}(C_V)$ around m^* , which can explain the performance improvement observed in Section 6.3. Figures 5–6 actually show how the decrease of the variance quantitatively influences the distribution of $\hat{m}(C_V)$: $\hat{m}(C_5)$ is significantly more concentrated than $\hat{m}(C_2)$, while the difference between $V = 10$ and $V = 5$ is much smaller and comparable to the difference between $V = n$ and $V = 10$; C_n is hard to distinguish from C_{id} . Similar experiments with $n = 500$ and in setting L are reported in Section G of the Online Appendix, leading to similar conclusions.

7. Fast Algorithm for Computing V -Fold Penalties for Least-Squares Density Estimation

Since the use of V -fold algorithms is motivated by computational reasons, it is important to discuss the actual computational cost of V -fold penalization and cross-validation as a function of V . In the least-squares density estimation framework, two approaches are possible: a naive one—valid for all other frameworks—, and a faster one—specific to least-squares density estimation. For clarifying the exposition, we assume in this section that **(Reg)** holds true—so, V divides n . The general algorithm for computing the V -fold penalized criterion and/or the V -fold cross-validation criterion consists in training the estimator with data sets $(\xi_i)_{i \notin B_j}$ for $j = 1, \dots, V$ and then testing each trained estimator on the data sets $(\xi_i)_{i \in B_j}$ and/or $(\xi_i)_{i \notin B_j}$. In the least-squares density estimation framework, for any model S_m given through an orthonormal family $(\psi_\lambda)_{\lambda \in \Lambda_m}$ of elements of $L^2(\mu)$, we get the “naive” algorithm described and analysed more precisely in Section E.1 of the Online Appendix, whose complexity is of order $nV \text{Card}(\Lambda_m)$.

Several simplifications occur in the least-squares density estimation framework, that allow to avoid a significant part of the computations made in the naive algorithm.

Algorithm 1

Input: \mathcal{B} some partition of $\{1, \dots, n\}$ satisfying **(Reg)**, $\xi_1, \dots, \xi_n \in \mathcal{X}$ and $(\psi_\lambda)_{\lambda \in \Lambda_m}$ a finite orthonormal family of $L^2(\mu)$.

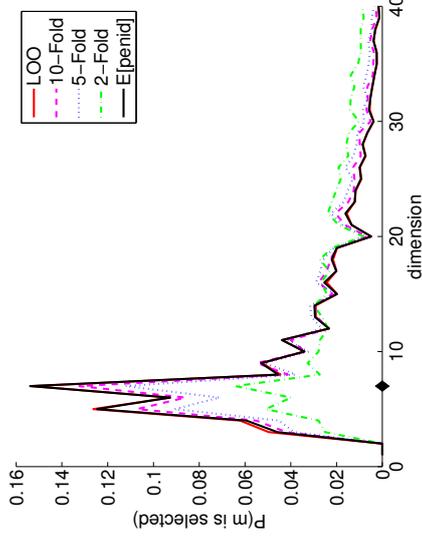

Figure 5: $\mathbb{P}(\hat{m}(\mathcal{C}) = m)$ as a function of m for five different \mathcal{C} . Setting S-Regu, $n = 100$. The black diamond shows $m^* = 7$.

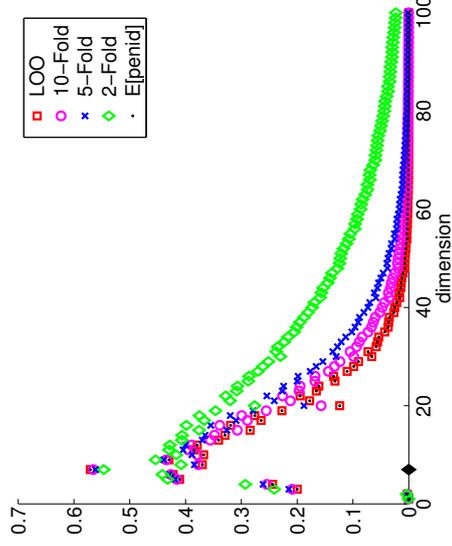

Figure 6: Illustration of the variance heuristic: $\bar{\Phi}(\text{SNR}_{\mathcal{C}}(m))$ as a function of m for five different \mathcal{C} . Setting S-Regu, $n = 100$. The black diamond shows $m^* = 7$.

1. For $i \in \{1, \dots, V\}$ and $\lambda \in \Delta_m$, compute $A_{i,\lambda} := \frac{1}{n} \sum_{j \in B_i} \psi_\lambda(\xi_j)$.
2. For $i, j \in \{1, \dots, V\}$, compute $C_{i,j} := \sum_{\lambda \in \Delta_m} A_{i,\lambda} A_{j,\lambda}$.
3. Compute $S := \sum_{1 \leq i, j \leq V} C_{i,j}$ and $\mathcal{T} := \text{tr}(C)$.

Output:

Empirical risk: $P_n \gamma(\widehat{s}_m) = \frac{-S}{V^2}$;

V -fold cross-validation criterion: $\text{crit}_{V\text{FCV}}(m) = \frac{\mathcal{T}}{V(V-1)} - \frac{S-\mathcal{T}}{(V-1)^2}$;

V -fold penalty: $\text{pen}_{V\text{F}}(m) = (\text{crit}_{V\text{FCV}}(m) - P_n \gamma(\widehat{s}_m)) \frac{V-1/2}{V-1}$.

To the best of our knowledge, Algorithm 1 is new, even for computing the V -fold cross-validation criterion. Its correctness and complexity are analyzed with the following proposition.

Proposition 8 *Algorithm 1 is correct and has a computational complexity of order*

$$(n + V^2) \text{Card}(\Delta_m) .$$

In the histogram case, that is, when Δ_m is a partition of \mathcal{X} and $\forall \lambda \in \Delta_m$, $\psi_\lambda = \mu(\lambda)^{-1/2} \mathbb{1}_\lambda$, the computational complexity of Algorithm 1 can be reduced to the order of $n + V^2 \text{Card}(\Delta_m)$.

Proposition 8 is proved in Section E.2 of the Online Appendix. It shows that Algorithm 1 is significantly faster than the “naive” algorithm, by a factor of order

$$\frac{nV}{n + V^2} = \left(\frac{1}{V} + \frac{V}{n} \right)^{-1} \ll 1 \quad \text{if} \quad 1 \ll V \ll n .$$

Note that closed-form formulas are available for the leave- p -out criterion in least-squares density estimation (Celisse, 2014), allowing to compute it with a complexity of order $n \text{Card}(\Delta_m)$ in general, and smaller in some particular cases—for instance, n for histograms.

8. Discussion

Before discussing how to choose V when using V -fold methods for model selection—our more generally for choosing among a given family of estimators—, we state some additional results and we discuss the model selection literature in least-squares density estimation.

8.1 Monte-Carlo Cross-Validation

Our analysis of V -fold procedures for model selection can be extended to some other cross-validation procedures. We here present results for Monte-Carlo cross-validation (MCCV, Picard and Cook, 1984), also known as repeated cross-validation, where B training samples of the same size $n - p$ are chosen independently and uniformly (see also Ahtol and Celisse, 2010, Section 4.3.2). Formally, we consider the criterion

$$\text{crit}_{\text{CV}}(m, (TK)_{1 \leq K \leq B}) := \frac{1}{B} \sum_{K=1}^B \text{crit}_{\text{HO}}(m, TK) , \quad (25)$$

where T_1, \dots, T_B are subsets of $[n]$ and we recall that the hold-out criterion is defined by Eq. (4). We make the following three assumptions throughout this subsection

$$\begin{aligned} \exists p \in [n-1], \quad \forall j \in [B], \quad |T_j| = n - p = n\tau_n, & \quad (\text{SameSize}) \\ (TK)_{1 \leq K \leq B} \text{ is independent from } D_n, & \quad (\text{Ind}) \\ T_1, \dots, T_B \text{ are independent with uniform distribution over } \mathcal{E}_{n-p}, & \quad (\text{MCCV}) \end{aligned}$$

where we recall that $\mathcal{E}_{n-p} = \{A \subset [n] \text{ s.t. } |A| = n - p\}$. Under these assumptions, we write $\text{crit}_{\text{MCCV}}(m)$ as a shortcut for $\text{crit}_{\text{CV}}(m, (TK)_{1 \leq K \leq B})$.

Similarly to Theorem 5, we prove in Section C.3 of the Online Appendix the following oracle inequality for MCCV.

Theorem 9 *Let $\xi_{[n]}$ be i.i.d. real-valued random variables with common density $s \in L^\infty(\mu)$, $(TK)_{1 \leq K \leq B}$ some sequence of subsets of $[n]$ satisfying (SameSize), (Ind) and (MCCV) and $(S_m)_{m \in \mathcal{M}_n}$ be a collection of separable linear spaces satisfying (H1). Assume that either (H2) or (H2') holds true. For every $m \in \mathcal{M}_n$, let \widehat{s}_m be the estimator defined by Eq. (1), and $\widehat{s} = \widehat{s}_{\widehat{m}}$ where*

$$\widehat{m} \in \underset{m \in \mathcal{M}_n}{\text{argmin}} \left\{ \text{crit}_{\text{CV}}(m, (TK)_{1 \leq K \leq B}) \right\}$$

and crit_{CV} is defined by Eq. (25). Let us define, for any $x, y, \epsilon > 0$, $x_n = x + \log |\mathcal{M}_n|$ and

$$\rho_3(\epsilon, x, y, n, \tau_n, B, A) := \frac{1}{n\tau_n^2} \left(1 + \frac{B \wedge (\log n + y)}{B(1 - \tau_n)} \right)^\alpha \left(\frac{Ax}{\tau_n \epsilon} + \frac{(A \vee 1)x^2}{\epsilon^3} \right)$$

with $\alpha = 1$ under assumption (H2) and $\alpha = 2$ under assumption (H2'). Then, an absolute constant $\kappa > 0$ exists such that, for any $x, y \geq 0$, with probability at least $1 - e^{-x} - e^{-y}$, for any $\epsilon \in (0, \kappa^{-1})$,

$$\left(1 - \frac{\epsilon}{\tau_n} \right) \|\widehat{s} - s\|^2 \leq \frac{1 + \epsilon}{\tau_n} \inf_{m \in \mathcal{M}_n} \left\{ \|\widehat{s}_m - s\|^2 \right\} + \kappa \rho_3(\epsilon, x_n, y, n, \tau_n, B, A) . \quad (26)$$

Theorem 9 actually is a corollary of a more general result (Theorem 23 in Section C.3 of the Online Appendix), which is valid without assumption (MCCV) and extends therefore our previous results on V -fold cross-validation).

Very few results exist in the literature about the model selection performance of MCCV with an estimation goal. Some asymptotic optimality result has been obtained by Burman (1990) for spline regression, and some oracle inequalities comparing the risk of the selected estimator with the risk of an oracle trained with $\tau_n n < n$ data have been proved by van der Laan and Dudoit (2003) in a general framework and by van der Laan et al. (2004) for density estimation with the Kullback-Leibler loss. In comparison, Theorem 9 provides a precise non-asymptotic comparison to an oracle trained with n data.

As in Theorem 5, the leading constant of the oracle inequality (26) is directly related to the bias, which is here quantified by $\tau_n^{-1} - 1 \geq 0$ instead of δ . The remainder term ρ_3 is also comparable to ρ_2 in Theorem 5: they differ by a factor between τ_n^{-2} (when B is large enough) and $\tau_n^{-2}(1 - \tau_n)^{-\alpha}$ (when B is small). In particular, let $V \geq 2$ and assume that

$p = n/V$ in Theorem 9, hence $\tau_n = 1 - V^{-1} \in [1/2, 1)$. Then, for the hold-out ($B = 1$), ρ_3 is larger than ρ_2 by a factor V^α with $\alpha \in \{1, 2\}$. For $B = V$, MCCV with $\tau_n = 1 - V^{-1}$ can be called ‘‘Monte-Carlo V -fold’’ (MCVF); then, with $y \approx \log n$, we loose a factor at most $\log n$ for MCVF compared to V -fold cross-validation. Finally, when B is large enough, that is, larger than $V \log n$, ρ_3 and ρ_2 are of the same order.

The above comparison of remainder terms suggests a hierarchy between several cross-validation methods with a common training sample size $n-p = n\tau_n$: from the (presumably) worse to the (presumably) best procedure, the hold-out, Monte-Carlo CV with $B = V$, V -fold CV, Monte-Carlo CV with B large and the leave- p -out. Nevertheless, upper bounds comparison can be misleading, so, following the heuristics (22) presented in Section 4, we compute below the variance of $\Delta\mathcal{L}(m, m')$ when C is a Monte-Carlo CV criterion.

Theorem 10 *We consider the setting and notation of Theorem 6, and we assume that (SameSize), (MCCV) and (Ind) hold true. We recall that $C^{\text{MCCV}}(m)$ is defined above at the beginning of Section 8.1. Then, for regular histogram models m_1, m_2 (Example 1 in Section 3.2), we have*

$$\begin{aligned} \text{Var}(C^{\text{MCCV}}(m_1) - C^{\text{MCCV}}(m_2)) &= C_1^{\text{MC}}(B, n, \tau_n) \frac{2}{n^2} \mathbf{B}(m_1, m_2) \\ &\quad + C_2^{\text{MC}}(B, n, \tau_n) \frac{4}{n} \text{Var}(s_{m_1}(\xi_1) - s_{m_2}(\xi_1)) \end{aligned} \quad (27)$$

where

$$\begin{aligned} C_1^{\text{MC}}(B, n, \tau_n) &= \frac{1}{B} \left(\frac{1}{\tau_n^2} + \frac{2}{\tau_n(1-\tau_n)} - \frac{1}{n\tau_n^3} \right) + \left(1 - \frac{1}{B} \right) \left[1 + \frac{1}{n-1} \left(\frac{1}{\tau_n} + 1 \right) - \frac{1}{n\tau_n^2} \right] \\ C_2^{\text{MC}}(B, n, \tau_n) &= \frac{1}{B} \left(\frac{1}{n^2\tau_n^3} + \frac{1}{1-\tau_n} \right) + \left(1 - \frac{1}{B} \right) \left(1 + \frac{1}{n\tau_n} \right) \end{aligned}$$

and we recall that $\tau_n = \lfloor T_K \rfloor / n = 1 - (p/n)$.

Theorem 10 is proved in Section C.4 of the Online Appendix, as a corollary of a more general result, called Theorem 24, which holds for all models m_1, m_2 —not only regular histograms—and provides a formula for the variance of the criterion itself—not its increments. Let us make a few comments.

Eq. (27) is similar to the formula obtained for bias-corrected V -fold and V -fold penalization, see Eq. (24) in Theorem 6. In the particular case of regular histogram models, Eq. (24) even fits the general form of Eq. (27), with constants $C_i^{\text{penVF}}(V, n, C)$ instead of $C_i^{\text{MC}}(B, n, \tau_n)$.

Assuming the heuristics of Section 4 is valid, for m_1, m_2 which matter for model selection, the two terms $2n^{-2}\mathbf{B}(m_1, m_2)$ and $4n^{-1}\text{Var}(s_{m_1}(\xi_1) - s_{m_2}(\xi_1))$ are of the same order of magnitude (see Section 5). Then, we can compare model selection performance of several cross-validation methods by comparing the values of the constants C_i only.

In order to get a variance of the same order of magnitude as the one of bias-corrected V -fold CV—that is, constants C_i of order 1—, MCCV requires to take τ_n far enough from 0 and 1, hence training and sample sets of comparable sizes, unless B is large enough.

Eq. (27) allows to compare the hold-out ($B = 1$) with the leave- p -out ($B \rightarrow +\infty$), for a given value $n\tau_n = n - p$ of the training sample size. Let us assume for simplicity that $n \rightarrow +\infty$ and $\tau_n \gg n^{-1/2}$. Then,

$$\begin{aligned} C_1^{\text{MC}}(1, n, \tau_n) &\sim \frac{1}{\tau_n^2} + \frac{2}{\tau_n(1-\tau_n)} > 11 \quad \text{and} \quad C_2^{\text{MC}}(1, n, \tau_n) \sim \frac{1}{1-\tau_n} \geq 1 \\ \text{whereas} \quad C_1^{\text{MC}}(\infty, n, \tau_n) &\rightarrow 1 \quad \text{and} \quad C_2^{\text{MC}}(\infty, n, \tau_n) \rightarrow 1 \end{aligned}$$

which shows an improvement at least by a constant factor in general. When τ_n tends to zero—leave-most-out—or 1—such as for the leave-one-out—, the improvement is by an order of magnitude. The fact that the leave- p -out has a smaller variance than the hold-out is not surprising at all—it holds in full generality, as a consequence of Jensen’s inequality—, but the exact quantification of the improvement given by Theorem 10 is new and can be useful in practice for choosing the number of splits B when using Monte-Carlo cross-validation.

Eq. (27) also allows to compare V -fold cross-validation, given by Theorem 6 with

$$C = 1 + \frac{1}{2(V-1)},$$

with MCCV with $B = V$ and $\tau_n = (V-1)/V$, which can be named ‘‘Monte-Carlo V -fold’’ cross-validation. The only difference between the two methods is that the V splits are chosen independently for ‘‘Monte-Carlo V -fold’’, whereas the usual V -fold makes a balanced use of each observation—putting it exactly $(V-1)$ times in the training set. Let us assume for simplicity that $n \rightarrow +\infty$ while $V = V_n$ can vary with n . Then, we have

$$\begin{aligned} C_1^{\text{MCCV}}(V_n, n) &:= C_1^{\text{MC}}\left(V_n, n, \frac{V_n-1}{V_n}\right) \sim 3 + \frac{2V_n+1}{V_n(V_n-1)} + \frac{1}{(V_n-1)^2} \\ C_1^{\text{VF}}(V_n, n) &:= C_1^{\text{penVF}}\left(V_n, n, 1 + \frac{1}{2(V_n-1)}\right) \sim 1 + \frac{4}{V_n-1} + \frac{4}{(V_n-1)^2} + \frac{1}{(V_n-1)^3} \end{aligned}$$

$$\text{hence} \quad \frac{C^{\text{MCCV}}(V_n, \infty)}{C_1^{\text{VF}}(V_n, \infty)} > 1 \text{ if } V_n \geq 3, \quad \frac{C_1^{\text{MCCV}}(V_n, n)}{C_1^{\text{VF}}(V_n, n)} \xrightarrow{n, V_n \rightarrow +\infty} 3,$$

$$C_2^{\text{MCCV}}(V_n, n) := C_2^{\text{MC}}\left(V_n, n, \frac{V_n-1}{V_n}\right) \sim 2 - \frac{1}{V_n} \in \left[\frac{3}{2}, 2\right]$$

$$\text{and} \quad C_2^{\text{VF}}(V_n, n) := C_2^{\text{penVF}}\left(V_n, n, 1 + \frac{1}{2(V_n-1)}\right) \rightarrow 1.$$

Overall, we get that V -fold cross-validation has a smaller variance than ‘‘Monte-Carlo V -fold’’ for $V \geq 3$, at least for n large enough, and that the improvement is by a constant factor between 3/2 and 3. Since increasing V cannot decrease the variance of (bias-corrected) VFVCV by more than a small constant factor, the above difference between two methods with the same computational complexity is quite important. This supports strongly the use of V -fold CV methods instead of ‘‘Monte-Carlo V -fold’’. Such an improvement was previously noticed in the asymptotic computations of Burman (1989); here we show that it holds in a non-asymptotic framework, where the models m_1, m_2 can depend on n .

8.2 Hold-Out Criteria

Our analysis of cross-validation procedures for model selection can also be extended to hold-out criteria. First, let us emphasize that the hold-out criterion defined by Eq. (4) corresponds to taking $B = 1$ in the results of Section 8.1, since choosing T uniformly over \mathcal{E}_{n-p} independently from D_n is equivalent to choosing some arbitrary T of size $n-p$ before seeing the data D_n .

Second, similarly to the definition of the hold-out criterion in Eq. (4), we can define the hold-out penalty by

$$\forall x \geq 0, \quad \text{pen}_{\text{HO}}(m, T, x) := 2x \left(P_n^{(T)} - P_n \right) \left(\widehat{s}_m^{(T)} - \widehat{s}_m \right), \quad (28)$$

that is, the hold-out estimator of $\mathbb{E}[2(P_n - P)(\widehat{s}_m - s_m)]$ which is equal to the expectation of the ideal penalty, see Eq. (2). We do not define pen_{HO} by Eq. (6) with $V = 1$ and $T = \mathcal{B}_1^c$ —that is, the hold-out estimator of $\mathbb{E}[(P - P_n)\gamma(\widehat{s}_m)]$, which amounts to removing the centering term $-\widehat{s}_m$ in Eq. (28)—because this would dramatically increase its variability. Note that adding such a term $-\widehat{s}_m$ in Eq. (6) does not change the value of the V -fold penalty under **(Reg)** since $\sum_{K=1}^V (P_n^{(\mathcal{B}_K^c)} - P_n) = 0$.

Denoting by $\tau_n = |T|/n$ as in Section 8.1, it comes from Lemma 26 in Section D.1 of the Online Appendix that

$$\mathbb{E}[\text{pen}_{\text{HO}}(m, T, x)] = x \frac{1 - \tau_n}{\tau_n} \mathbb{E}[\text{pen}_{\text{d}}(m)].$$

In the following, we choose $x = C\tau_n/(1 - \tau_n)$ so that $C = 1$ corresponds to the unbiased case, as in the previous sections for the V -fold penalty.

Remark 11 Since $P_n = \tau_n P_n^{(T)} + (1 - \tau_n) P_n^{(T^c)}$, by linearity of the estimator \widehat{s}_m ,

$$\text{pen}_{\text{HO}}(m, T, x) := 2x(1 - \tau_n)^2 \left(P_n^{(T)} - P_n^{(T^c)} \right) \left(\widehat{s}_m^{(T)} - \widehat{s}_m^{(T^c)} \right)$$

which is symmetric in T and T^c , hence $\text{pen}_{\text{HO}}(m, T^c, x) = \text{pen}_{\text{HO}}(m, T, x)$. In particular, if $|T| = n/2$, the 2-fold penalty computed on the partition $\mathcal{B} = \{T, T^c\}$ and the hold-out penalty coincide

$$\forall x > 0, \quad \text{pen}_{\text{VF}}(m, \{T, T^c\}, x) = \text{pen}_{\text{HO}}(m, T, x).$$

Theorem 12 Let $\xi_{[n]}$ be i.i.d. real-valued random variables, $s \in L^\infty(\mu)$ their common density, $T \subset [n]$ with $\tau_n = |T|/n \in (0, 1)$ and $(S_m)_{m \in \mathcal{M}_n}$ be a collection of separable linear spaces satisfying **(H1)**. Assume that either **(H2)** or **(H2')** holds true. Let $C \in (1/2, 2]$ and $\delta := 2(C - 1)$. For every $m \in \mathcal{M}_n$, let \widehat{s}_m be the projection estimator onto S_m defined by Eq. (1), and $\widehat{s}_{\text{HO}} = \widehat{s}_{\text{HO}}$ where

$$\widehat{m}_{\text{HO}} = \underset{m \in \mathcal{M}_n}{\text{argmin}} \left\{ P_n \gamma(\widehat{s}_m) + \text{pen}_{\text{HO}} \left(m, T, \frac{C\tau_n}{1 - \tau_n} \right) \right\}.$$

Then, an absolute constant κ exists such that, for any $x > 0$, defining $x_n = x + \log |\mathcal{M}_n|$, with probability at least $1 - e^{-x}$, for any $\epsilon \in (0, 1]$,

$$\frac{1 - \delta - \epsilon}{1 + \delta_+ + \epsilon} \|\widehat{s}_{\text{HO}} - s\|^2 \leq \inf_{m \in \mathcal{M}_n} \|\widehat{s}_m - s\|^2 + \kappa \left(\frac{Ax_n}{cn} + \frac{\tau_n^2 + (1 - \tau_n)^2 x_n^2}{\tau_n(1 - \tau_n)} \frac{x_n^2}{c^2 \tau_n} \right). \quad (29)$$

Theorem 12 is proved in Section D.1 of the Online Appendix.

Theorem 12 extends Theorem 5 to hold-out penalties, under similar assumptions. As in Theorem 5, δ quantifies the bias of the hold-out penalized criterion, and plays the same role in the leading constant of the oracle inequality (29).

We can compare the results obtained for hold-out and V -fold penalization in Theorems 5 and 12. For this comparison, let V be some divisor of n , $T \subset [n]$ such that $|T| = n - n/V$ and choose the same C so that both criteria have the same bias δ . Then, the only difference lies in the remainder term, the one in Eq. (29) is larger than the one of Eq. (17) in Theorem 5 by a factor of order V when V is large. These only are upper bounds, but at least they are consistent with the common intuition about the stabilizing effect of averaging over V folds. We can also compare the results obtained for hold-out penalization in Theorem 12 and for the hold-out criterion in Theorem 9. First, hold-out penalization gives a flexibility to choose an unbiased criterion and therefore to obtain asymptotically optimal oracle inequalities while hold-out criteria are always biased for fixed τ_n , hence a leading constant $\tau_n^{-1} > 1$ in the oracle inequality. The loss in the remainder term is also smaller in Eq. (29) than in Eq. (26) by a factor of order $\tau_n^{-1}(1 - \tau_n)^{-1}$ under assumption **(H2')**.

Similarly to Theorems 6 and 10, the variance terms can be computed for the hold-out penalty in order to understand separately the roles of the training sample size and of averaging over the V splits, in the V -fold criteria. Detailed results are given by Proposition 28 in Section D.2 of the Online Appendix.

8.3 Other Oracle Inequalities for Least-Squares Density Estimation

Although the primary topic of the paper is the study of V -fold procedures, let us compare briefly our results to other oracle inequalities that have been proved in the least-squares density estimation setting. For projection estimators, Massart (2007, Section 7.2) proves an oracle inequality for some penalization procedures, which are suboptimal since the leading constant C_n does not tend to 1 as n goes to $+\infty$. Oracle inequalities have also been proved for other estimators: blockwise Stein estimators (Rigollet, 2006), linear estimators (Goldenshluger and Lepski, 2011) and some T -estimators (Birgé, 2013). The models considered by Birgé (2013) are more general than ours, but the corresponding estimators are not computable in practice, and the oracle inequality by Birgé (2013) also has a suboptimal constant C_n . Some aggregation procedures also satisfy oracle inequalities (Rigollet and Tsybakov, 2007; Bunea et al., 2010). Overall, under our assumptions, none of these results imply strictly better bounds than ours.

Let us finally mention that Birgé and Rozenholc (2006) propose a precise evaluation of the penalty term in the case of regular histogram models and the log-likelihood contrast. Their final penalty is a function of the dimension, only slightly modified compared to $\text{pen}_{\text{d}}^{\text{lim}}$ performing very well on regular histograms. These performances are likely to become much worse on the collection Dyad2 presented in Section 6. This can be seen, for example, in Table 3 in Section G of the Online Appendix, where we present the performances of $\text{pen}_{\text{d}}^{\text{lim}}$ with different over-penalizing constants.

8.4 Conclusion on the Choice of V

This section summarizes the results of the paper in order to address the main question we would like to answer: How to choose a V -fold procedure for model selection?

Generality of the results. The results of the paper only hold for projection estimators in least-squares density estimation, but we conjecture that most of the statements below are valid much more generally. At least, they have been observed experimentally for projection estimators in least-squares regression (Arlot, 2008) and they are supported by theoretical results for kernel density estimators (Magalhães, 2015, Chapters 3–4). Nevertheless, it is reported in the literature that V -fold cross-validation can behave differently in other settings (Arlot and Celisse, 2010), so we must keep in mind that the statements below may not be universal.

Let us also recall that we focus here on model selection with an estimation goal, that is, minimizing the risk of the final estimator; see Yang (2006, 2007) and Celisse (2014) for results when the goal is identification.

Choice of a model selection procedure. Choosing among procedures of the form $\widehat{m}(\mathcal{C})$, as defined by Eq. (18), requires to take into account three quantities:

- *the bias of $\mathcal{C}(m)$* as an estimator of the risk of \widehat{s}_m for every $m \in \mathcal{M}_n$, or equivalently, the *overpenalization factor C* , which usually drives the performance at first order when $n \rightarrow +\infty$, as in Theorem 5. The simulation experiments of Section 6 also show that varying C can strongly change the performance of the procedure. In all settings considered in the paper, some C_n^* exists (the optimal overpenalization constant) such that the performance decreases for $C \in [0, C_n^*]$ and increases for $C > C_n^*$ (Figure 3). Note that C_n^* strongly depends on the setting, and can also vary with V when using V -fold penalization (in particular from $V = 2$ to $V \geq 5$). In the nonparametric case, when $n \rightarrow +\infty$, Theorem 5 shows that $C_n^* \sim 1$. On the contrary, in the parametric case, when $n \rightarrow +\infty$, it is known that a BIC-type penalty performs better, hence $C_n^* \rightarrow +\infty$. For a finite sample size, Section 6 and Liu and Yang (2011) show that some nonparametric settings can be “practically parametric”, that is, C_n^* can be much larger than 1.
- *the variance of increments $\mathcal{C}(m) - \mathcal{C}(m')$* drives the performance $\widehat{m}(\mathcal{C})$ at second order, according to the heuristic of Section 4, which suggests that this variance should be minimized, at least for a given “good enough” value of the overpenalization factor C .
- *the computational complexity of the procedure $\widehat{m}(\mathcal{C})$* , that we want to minimize—for a given statistical performance—or on which some upper bound is given—fixed budget.

V -fold cross-validation. The paper analyzes how the above three terms depend on V when $\mathcal{C} = C_{VFCV}^V$ is a V -fold cross-validation procedure, under assumption **(Reg)**. First, by Lemma 1, its overpenalization factor is $C^{VF}(V) = 1 + 1/[2(V - 1)] \in [1, 3/2]$, which decreases to 1 as V increases to $+\infty$. Second, by Theorem 6, its variance decreases as V increases. Theoretical and empirical arguments in Sections 5 and 6 show that the variance almost reaches its minimal value by taking, say, $V = 5$ or $V = 10$. Third, by Section 7,

its computational complexity is proportional to V in general; in the least-squares density estimation setting, it can be reduced to $(n + V^2) \text{Card}(\Lambda_m)$.

These three results can explain why the most common advices for choosing V in the literature (for instance Breiman and Spector, 1992; Hastie et al., 2009, Section 7.10.1) are between $V = 5$ and $V = 10$. Indeed, taking V larger does not reduce the variance significantly—with almost no impact on the risk of the final estimator—and it reduces the overpenalization factor although C_n^* is often larger than $C^{VF}(10) = 19/18$ or $C^{VF}(5) = 9/8$. So, if C_n^* is not much larger than $1 + 1/8$, which is likely to occur in many nonparametric settings, taking $V = 5$ or 10 can be close to be optimal.

Nevertheless, other situations can occur, for instance in (practically) parametric settings where C_n^* is much larger, possibly leading to the failure of the heuristic “ $5 \leq V \leq 10$ is almost optimal”. More generally, understanding precisely how C_{VFCV}^{VF} performs as a function of V seems to be a difficult question: V influences the performance in two opposite directions simultaneously, through the bias and the variance, so that various behaviours can result from this coupling of bias and variance, as shown in the simulation experiments.

V -fold penalization. Lemma 1 shows that a natural way to solve this difficulty is to consider instead a V -fold penalization procedure $\mathcal{C}_{(C,V)}^{\text{penVF}}$, with overpenalization factor $C > 0$. The value $C = C^{VF}(V)$ corresponds to V -fold cross-validation, but any other value of C can also be considered, making it easier to understand. Indeed, the overpenalization factor is directly given by C , while the variance and computational complexity of $\mathcal{C}_{(C,V)}^{\text{penVF}}$ vary with V —independently from C —exactly as for V -fold cross-validation. So, V should be taken as large as possible—depending on the maximal computational budget available—, while C should be taken as close as possible to C_n^* .

Compared to V -fold cross-validation, another interest of V -fold penalization is the improvement of the performance for a given computational cost, that is, a given value of V , because it is then possible to take C closer to C_n^* than $C^{VF}(V)$. This is especially true in (practically) parametric settings for which $C_n^* > 3/2 \geq C^{VF}(V)$ for all $V \geq 2$.

Data-driven overpenalization factor C . Although the paper shows that choosing well C is a key practical problem, making an optimal data-driven choice of C remains an open question which deserves to be studied, even independently from the analysis of cross-validation procedures. We postpone such a study to future works, but we can already make two suggestions. First, an external cross-validation loop can be used for choosing C , if the computational power is not a limitation. Second, a procedure built for choosing between AIC and BIC can be used in order to detect whether C should be close to 1 or significantly larger (see, for instance, Liu and Yang, 2011 and references therein).

Acknowledgments

The authors thank the two referees for their comments that allowed us to improve the paper. The authors thank gratefully Yannick Baraud and Guillaume Obozinski for precious comments on an earlier version of the paper, and Nelo Magalhães for his careful reading and helpful remarks on this earlier version. Let us also emphasize that this paper has changed a lot since its first version (Arlot and Lerasle, 2012), and that the most recent

results (Section 8.1, Section C of the Online Appendix) and some aspects of the proofs (for instance, the systematic use of $U_m(x; y)$ and $K_m(x; y)$) have been strongly influenced by our ongoing collaboration with Nello Magalhães (Chapters 3–4 Magalhães, 2015).

This work was done while the first author was financed by CNRS and member of the Sierra team in the Département d'Informatique de l'École normale supérieure (CNRS/ENS/INRIA UMR 8548), 45 rue d'Ulm, F-75230 Paris Cedex 05, France. The authors acknowledge the support of the French Agence Nationale de la Recherche (ANR) under reference ANR-09-JCJC-0027-01 (DETRECT project) and ANR 2011 BSO1 010 01 (projet Calibration). The first author also acknowledges the support of the GARGANTUA project funded by the Mastodon program of CNRS. The first author was partly supported by Institut des Hautes Études Scientifiques (IHES), Le Bois-Marie, 35, route de Chartres, 91440 Bures-Sur-Yvette, France) during the last days of writing of this paper.

Appendix A. Proofs

Before proving the main results stated in the paper, let us recall two simple results that we use repeatedly in the paper. First, if $(b_\lambda)_{\lambda \in \Lambda_m}$ is a family of real numbers such that $\sum_{\lambda \in \Lambda_m} b_\lambda^2 < \infty$, then

$$\sup_{\sum_{\lambda \in \Lambda_m} a_\lambda^2 \leq 1} \left(\sum_{\lambda \in \Lambda_m} a_\lambda b_\lambda \right)^2 = \sum_{\lambda \in \Lambda_m} b_\lambda^2. \quad (30)$$

The left-hand side is smaller than the right-hand side by Cauchy-Schwarz inequality, and considering $a_\lambda = b_\lambda / (\sum_{\lambda \in \Lambda_m} b_\lambda^2)^{1/2}$ shows that the converse inequality holds true. Second, for any probability distribution Q on \mathcal{X} ,

$$\sum_{\lambda \in \Lambda_m} (Q\psi_\lambda) \psi_\lambda \in \operatorname{argmin}_{t \in S_m} \{Q\gamma(t)\}, \quad (31)$$

a result which provides in particular a formula for \widehat{s}_m and for s_m , by taking $Q = P_n$ and $Q = P$, respectively.

A.1 Proof of Lemma 1

Let us first recall here the proof of Eq. (7)—coming from Arlot (2008)—for the sake of completeness. By **(Reg)**,

$$P_n - P_n^{(\beta_K)} = \frac{1}{V} (P_n^{(\beta_K)} - P_n^{(\beta_K)}) \quad \text{and} \quad P_n^{(\beta_K)} - P_n = \frac{V-1}{V} (P_n^{(\beta_K)} - P_n^{(\beta_K)}),$$

so that

$$\begin{aligned} G_{1,\beta}(m) &:= P_n \gamma(\widehat{s}_m) + \operatorname{pen}_{V,F}(m, \beta, V-1) \\ &= P_n \gamma(\widehat{s}_m) + \frac{V-1}{V^2} \sum_{k=1}^V [(P_n^{(\beta_K)} - P_n^{(\beta_K)}) \gamma(\widehat{s}_m^{(\beta_K)})] \\ &= P_n \gamma(\widehat{s}_m) + \frac{1}{V} \sum_{k=1}^V [(P_n^{(\beta_K)} - P_n) \gamma(\widehat{s}_m^{(\beta_K)})] \end{aligned}$$

Eq. (8) and (9) follow simultaneously from Eq. (35) below. Let \mathcal{E} be a set of subsets of $[n]$ such that

$$\forall A \in \mathcal{E}, \quad |A| = p \quad \text{and} \quad \frac{1}{|\mathcal{E}|} \sum_{A \in \mathcal{E}} P_n^{(A)} = P_n. \quad (32)$$

Let us consider the associated penalty

$$\operatorname{pen}_{\mathcal{E}}(m, C) = \frac{C}{|\mathcal{E}|} \sum_{A \in \mathcal{E}} (P_n - P_n^{(A)}) \gamma(\widehat{s}_m^{(A)}) = \frac{2C}{|\mathcal{E}|} \sum_{A \in \mathcal{E}} (P_n^{(A)} - P_n) (\widehat{s}_m^{(A)})$$

and the associated cross-validation criterion

$$\operatorname{crit}_{\mathcal{E}}(m) = \frac{1}{|\mathcal{E}|} \sum_{A \in \mathcal{E}} P_n^{(A)} \gamma(\widehat{s}_m^{(A)}).$$

When $\mathcal{E} = \mathcal{B}$, we get the V -fold penalty $\operatorname{pen}_V = \operatorname{pen}_{\mathcal{E}}$ and the V -fold cross-validation criterion $\operatorname{crit}_{V,F} = \operatorname{crit}_{\mathcal{E}}$, and Eq. (32) holds true with $p = n/V$ under assumption **(Reg)**. When $\mathcal{E} = \mathcal{E}_p := \{A \subset [n] \text{ s.t. } |A| = p\}$, Eq. (32) always holds true and we get the leave- p -out penalty $\operatorname{pen}_{LPO} = \operatorname{pen}_{\mathcal{E}}$ and the leave- p -out cross-validation criterion $\operatorname{crit}_{LPO} = \operatorname{crit}_{\mathcal{E}}$.

Let $(\psi_\lambda)_{\lambda \in \Lambda_m}$ be some orthonormal basis of S_m in $L^2(\mu)$. On the one hand, using Eq. (32), we get

$$\begin{aligned} \operatorname{pen}_{\mathcal{E}}(m, C) &= \frac{2C}{|\mathcal{E}|} \sum_{A \in \mathcal{E}} (P_n^{(A)} - P_n) (\widehat{s}_m^{(A)}) \\ &= \frac{2C}{|\mathcal{E}|} \sum_{A \in \mathcal{E}} \sum_{\lambda \in \Lambda_m} [(P_n^{(A)}(\psi_\lambda) - P_n(\psi_\lambda)) P_n^{(A)}(\psi_\lambda)] \\ &= \frac{2C}{|\mathcal{E}|} \sum_{\lambda \in \Lambda_m} \left[\sum_{A \in \mathcal{E}} (P_n^{(A)}(\psi_\lambda))^2 - P_n(\psi_\lambda) \sum_{A \in \mathcal{E}} P_n^{(A)}(\psi_\lambda) \right] \\ &= \frac{2C}{|\mathcal{E}|} \sum_{\lambda \in \Lambda_m, A \in \mathcal{E}} \left[(P_n^{(A)}(\psi_\lambda))^2 - (P_n(\psi_\lambda))^2 \right]. \end{aligned} \quad (33)$$

On the other hand, using that $P_n^{(A)} = \frac{n}{p} P_n - \frac{n-p}{p} P_n^{(A^c)}$ by Eq. (32),

$$\begin{aligned} \operatorname{crit}_{\mathcal{E}}(m) - P_n \gamma(\widehat{s}_m) &= \frac{1}{|\mathcal{E}|} \sum_{A \in \mathcal{E}} [P_n^{(A)} \gamma(\widehat{s}_m^{(A)}) - P_n \gamma(\widehat{s}_m)] \\ &= \frac{1}{|\mathcal{E}|} \sum_{A \in \mathcal{E}} [\|\widehat{s}_m^{(A^c)}\|^2 - 2P_n^{(A)}(\widehat{s}_m^{(A^c)}) - \|\widehat{s}_m\|^2 + 2P_n(\widehat{s}_m)] \\ &= \frac{1}{|\mathcal{E}|} \sum_{A \in \mathcal{E}} \sum_{\lambda \in \Lambda_m} \left[(P_n^{(A^c)}(\psi_\lambda))^2 - 2P_n^{(A)}(\psi_\lambda) P_n^{(A^c)}(\psi_\lambda) + (P_n(\psi_\lambda))^2 \right] \\ &= \frac{1}{|\mathcal{E}|} \sum_{\lambda \in \Lambda_m, A \in \mathcal{E}} \left[\left(\frac{2n}{p} - 1 \right) (P_n^{(A^c)}(\psi_\lambda))^2 - \frac{2n}{p} P_n(\psi_\lambda) P_n^{(A^c)}(\psi_\lambda) + (P_n(\psi_\lambda))^2 \right] \end{aligned}$$

$$= \binom{2n-1}{p} \frac{1}{|\mathcal{E}|} \sum_{\lambda \in \Lambda_m} \sum_{A \in \mathcal{E}} \left[\left(P_n^{(A^c)}(\psi_\lambda) \right)^2 - \left(P_n(\psi_\lambda) \right)^2 \right], \quad (34)$$

where we used again Eq. (32). Comparing Eq. (33) and (34) gives

$$\text{crit}_\mathcal{E}(m) = P_n\gamma(\widehat{s}_m) + \text{pen}_\mathcal{E}\left(m, \frac{n}{p} - \frac{1}{2}\right) \quad (35)$$

which implies Eq. (8) and (9). Eq. (10) follows by Lemma A.11 of Lerasle (2012). ■

We now prove the statements made in Remarks 2-3 below Lemma 1.

Proof of Remark 2 We first note that Eq. (10) can also be deduced from Celisse (2014, Proposition 2.1), which proves

$$\text{crit}_{\text{LPO}}(m, p) = \frac{1}{n(n-p)} \sum_{\lambda \in \Lambda_m} \left(\sum_{i=1}^n \psi_\lambda(\xi_i) \right)^2 - \frac{n-p+1}{n-1} \sum_{1 \leq i \neq j \leq n} \psi_\lambda(\xi_i) \psi_\lambda(\xi_j).$$

Elementary algebraic computations then show that

$$\begin{aligned} \text{crit}_{\text{LPO}}(m, p) - P_n\gamma(\widehat{s}_m) &= \frac{2n-p}{n^2(n-p)} \sum_{\lambda \in \Lambda_m} \left(\sum_{i=1}^n \psi_\lambda(\xi_i) \right)^2 - \frac{1}{n-1} \sum_{1 \leq i \neq j \leq n} \psi_\lambda(\xi_i) \psi_\lambda(\xi_j) \end{aligned} \quad (36)$$

hence for any $p, p' \in \llbracket n \rrbracket$,

$$\frac{n/p-1}{n/p-1/2} (\text{crit}_{\text{LPO}}(m, p) - P_n\gamma(\widehat{s}_m)) = \frac{n/p'-1}{n/p'-1/2} (\text{crit}_{\text{LPO}}(m, p') - P_n\gamma(\widehat{s}_m)).$$

In particular, when $p' = 1$, from Eq. (9), since $\text{pen}_{\text{LPO}}(m, 1, C) = \text{pen}_{\text{LOO}}(m, C)$,

$$\begin{aligned} \text{pen}_{\text{LPO}}\left(m, p, \frac{n}{p} - \frac{1}{2}\right) &= \frac{n/p-1/2}{n/p-1} \frac{n-1}{n-1/2} \text{pen}_{\text{LPO}}\left(m, 1, n - \frac{1}{2}\right) \\ &= \text{pen}_{\text{LOO}}\left(m, (n-1) \frac{n/p-1/2}{n/p-1}\right). \end{aligned}$$

■

Proof of Remark 3 Note first that the CV estimator of Massart (2007, Sec. 7.2.1, p. 204-205) is defined as the minimizer of

$$\begin{aligned} \|\widehat{s}_m\|^2 - \frac{2}{n(n-1)} \sum_{1 \leq i \neq j \leq n} \psi_\lambda(\xi_i) \psi_\lambda(\xi_j) \\ = P_n\gamma(\widehat{s}_m) + \frac{2}{n^2} \sum_{\lambda \in \Lambda_m} \left(\sum_{i=1}^n \psi_\lambda(\xi_i) \right)^2 - \frac{1}{n-1} \sum_{1 \leq i \neq j \leq n} \psi_\lambda(\xi_i) \psi_\lambda(\xi_j) \end{aligned} \quad (37)$$

On the other hand, from Eq. (36) and (9) with $p = 1$, we have

$$\text{pen}_{\text{LOO}}(m, n-1) = \frac{2}{n^2} \sum_{\lambda \in \Lambda_m} \left(\sum_{i=1}^n \psi_\lambda(\xi_i) \right)^2 - \frac{1}{n-1} \sum_{1 \leq i \neq j \leq n} \psi_\lambda(\xi_i) \psi_\lambda(\xi_j).$$

Hence, from Eq. (37), the CV estimator is the minimizer of $\text{crit}_{\text{cor, VFCV}}(m, \mathcal{B}_{\text{LOO}})$. Massart (2007, Theorem 7.6) studies the minimizers of the criterion

$$P_n\gamma(\widehat{s}_m) + \frac{C}{n^2} \sum_{i=1}^n \sum_{\lambda \in \Lambda_m} \psi_\lambda(\xi_i)^2, \quad (38)$$

where $C = (1 + \epsilon)^6$ for any $\epsilon > 0$. Let $\alpha = C/n$, so that $\alpha = (C - \alpha)/(n - 1)$. Then, the criterion (38) is equal to

$$\begin{aligned} (1-\alpha)P_n\gamma(\widehat{s}_m) + \frac{C-\alpha}{n^2} \sum_{\lambda \in \Lambda_m} \sum_{i=1}^n \psi_\lambda(\xi_i)^2 - \frac{\alpha}{n^2} \sum_{\lambda \in \Lambda_m} \sum_{1 \leq i \neq j \leq n} \psi_\lambda(\xi_i) \psi_\lambda(\xi_j) \\ = (1-\alpha)P_n\gamma(\widehat{s}_m) + \frac{C-\alpha}{n^2} \sum_{\lambda \in \Lambda_m} \left(\sum_{i=1}^n \psi_\lambda(\xi_i) \right)^2 - \frac{1}{n-1} \sum_{\lambda \in \Lambda_m} \sum_{1 \leq i \neq j \leq n} \psi_\lambda(\xi_i) \psi_\lambda(\xi_j) \\ = (1-\alpha) \left[P_n\gamma(\widehat{s}_m) + \frac{C-\alpha}{2(1-\alpha)} \text{pen}_{\text{LOO}}(m, n-1) \right] \\ = (1-\alpha) \left[P_n\gamma(\widehat{s}_m) + \text{pen}_{\text{LOO}}\left(m, \frac{C(n-1)^2}{2(n-C)}\right) \right]. \end{aligned}$$

■

A.2 Proof of Proposition 4

Note that the two formulas given for Ψ_m in the statement of Proposition 4 coincide by Eq. (30). The proof is decomposed into 3 lemmas.

Lemma 13 Let $\xi_{[n]}$ denote i.i.d. random variables taking value in a Polish space \mathcal{X} , $\mathcal{B}_{[V]}$ some partition of $\llbracket n \rrbracket$ satisfying **(Reg)**, S_m some separable linear subspace of $L^2(\mu)$ with orthonormal basis $(\psi_\lambda)_{\lambda \in \Lambda_m}$ and

$$U(m) := \frac{1}{n^2} \sum_{1 \leq k \neq k' \leq V} \sum_{i \in \mathcal{B}_k, j \in \mathcal{B}_{k'}} \sum_{\lambda \in \Lambda_m} (\psi_\lambda(\xi_i) - P\psi_\lambda)(\psi_\lambda(\xi_j) - P\psi_\lambda). \quad (39)$$

Then, the V -fold penalty is equal to

$$\text{pen}_{\text{VF}}(m, \mathcal{B}, C) = \frac{2C}{V-1} \|s_m - \widehat{s}_m\|^2 - \frac{2VC}{(V-1)^2} U(m) \quad (40)$$

$$\text{and } \mathbb{E} \left[\text{pen}_{\text{VF}}\left(m, \mathcal{B}, \frac{V-1}{2}\right) \right] = \mathbb{E}[\|s_m - \widehat{s}_m\|^2] = \frac{D_m}{2n}. \quad (41)$$

Proof Let $W_i = \frac{V}{V-1} \mathbb{1}_{i \notin \mathcal{B}_j}$, and use the formulation (5) of the V -fold penalty as a resampling penalty. Then,

$$\begin{aligned} \text{pen}_{V,F}(m, \mathcal{B}, C) &= C \mathbb{E}_W \left[(P_n - P_n^W) \left(\gamma(\hat{s}_m^W) \right) \right] \\ &= 2C \mathbb{E}_W \left[(P_n^W - P_n) (\hat{s}_m^W) \right] \\ &= 2C \mathbb{E}_W \left[(P_n^W - P_n) (\hat{s}_m^W - \hat{s}_m) \right] \quad \text{by (Reg)} \\ &= 2C \sum_{\lambda \in \Delta_m} \mathbb{E}_W \left[\left((P_n^W - P_n) (\psi_\lambda) \right)^2 \right] \\ &= 2C \sum_{\lambda \in \Delta_m} \mathbb{E}_W \left[\left((P_n^W - P_n) (\psi_\lambda - P\psi_\lambda) \right)^2 \right] \\ &= 2C \sum_{\lambda \in \Delta_m} \sum_{1 \leq i, j \leq n} e_{i,j}^{(V,F)} (\psi_\lambda(\xi_i) - P\psi_\lambda)(\psi_\lambda(\xi_j) - P\psi_\lambda) \end{aligned} \quad (42)$$

where $e_{i,j}^{(V,F)} := \mathbb{E}[(W_i - 1)(W_j - 1)]$. Since $\mathbb{E}[W_i] = 1$ by (Reg) and

$$W_i W_j = \left(\frac{V}{V-1} \right)^2 \mathbb{1}_{j \notin \{i_0, j_1\}} \quad \text{if } i \in \mathcal{B}_{i_0} \text{ and } j \in \mathcal{B}_{j_1},$$

we get that $e_{i,j}^{(V,F)} = (V-1)^{-1}$ if i and j belong to the same block and $e_{i,j}^{(V,F)} = -(V-1)^{-2}$ otherwise. So,

$$\begin{aligned} \text{pen}_{V,F}(m, \mathcal{B}, C) &= \frac{2C}{n^2(V-1)} \sum_{\lambda \in \Delta_m} \sum_{k=1}^V \sum_{(i,j) \in \mathcal{B}_k} (\psi_\lambda(\xi_i) - P\psi_\lambda)(\psi_\lambda(\xi_j) - P\psi_\lambda) - \frac{2C}{(V-1)^2} U(m) \\ &= \frac{2C}{V-1} \sum_{\lambda \in \Delta_m} \left((P_n - P)\psi_\lambda \right)^2 - \frac{2CV}{(V-1)^2} U(m) \end{aligned}$$

and Eq. (40) follows by Eq. (3). Eq. (41) directly follows from Eq. (40). \blacksquare

Lemma 14 Let $\xi_{[n]}$ be i.i.d. random variables taking values in a Polish space \mathcal{X} with common density $s \in L^\infty(\mu)$, S_m a separable linear subspace of $L^2(\mu)$ and denote by $(\psi_\lambda)_{\lambda \in \Delta_m}$ an orthonormal basis of S_m . Let $\mathcal{B}_m = \{t \in S_m \text{ s.t. } \|t\| \leq 1\}$, $\mathcal{D}_m = \sum_{\lambda \in \Delta_m} P(\psi_\lambda^2) - \|s_m\|^2$ and assume that $b_m = \sup_{t \in \mathcal{B}_m} \|t\|_\infty < \infty$. An absolute constant κ exists such that, for any $x > 0$, with probability larger than $1 - 2e^{-x}$, we have for every $\epsilon > 0$,

$$\left| \|s_m - \hat{s}_m\|^2 - \frac{\mathcal{D}_m}{n} \right| \leq \epsilon \frac{\mathcal{D}_m}{n} + \kappa \left(\frac{\|s\|_\infty x}{(\epsilon \wedge 1)n} + \frac{b_m^2 x^2}{(\epsilon \wedge 1)^3 n^2} \right).$$

Proof By Eq. (3), $\|s_m - \hat{s}_m\|^2 = \sup_{t \in \mathcal{B}_m} [(P_n - P)(t)]^2$ has expectation \mathcal{D}_m/n . In addition, for any $t \in \mathcal{B}_m$,

$$\text{Var}(t(\xi_1)) \leq \int_{\mathbb{R}} t^2 s \, d\mu \leq \|s\|_\infty \|t\|^2 \leq \|s\|_\infty, \quad (43)$$

which gives the conclusion thanks to a result by Lerasle (2011, Theorem 4.1 of the supplementary material), which is recalled in the Online Appendix (Proposition 29 in Section F). \blacksquare

Lemma 15 Assume that $\xi_{[n]}$ is a sequence of i.i.d. real-valued random variables with common density $s \in L^\infty(\mu)$ and $\mathcal{B}_{[n]}$ is some partition of $[n]$ satisfying (Reg). Let S_m denote a separable subspace of $L^2(\mu)$ with orthonormal basis $(\psi_\lambda)_{\lambda \in \Delta_m}$ such that

$$b_m := \sup_{t \in S_m, \|t\| \leq 1} \|t\|_\infty < +\infty.$$

Let $U(m)$ be the U -statistics defined by Eq. (39). Using the notations of Lemma 14, an absolute constant κ exists such that, with probability larger than $1 - 6e^{-x}$,

$$|U(m)| \leq \frac{3\sqrt{(V-1)}\|s\|_\infty \mathcal{D}_m x}{\sqrt{V}n} + \kappa \left(\frac{\|s\|_\infty x}{n} + \frac{(b_m^2 + \|s\|^2)x^2}{n^2} \right).$$

Hence, an absolute constant κ' exists such that, for any $x > 0$, with probability larger than $1 - 6e^{-x}$, for any $\theta \in (0, 1]$,

$$|U(m)| \leq \theta \frac{\mathcal{D}_m}{n} + \kappa' \left(\frac{\|s\|_\infty x}{\theta n} + \frac{(b_m^2 + \|s\|^2)x^2}{n^2} \right).$$

Proof For any $x, y \in \mathbb{R}$ and $i, j \in [n]$, let us define

$$U_m(x, y) = \sum_{\lambda \in \Delta_m} (\psi_\lambda(x) - P\psi_\lambda)(\psi_\lambda(y) - P\psi_\lambda)$$

and $g_{i,j}(x, y) = U_m(x, y) \mathbb{1}_{\{k, k' \in [V] \text{ s.t. } k \neq k', i \in \mathcal{B}_k, j \in \mathcal{B}_{k'}\}}$

so that $U(m) = \frac{2}{n^2} \sum_{i=2}^n \sum_{j=1}^{i-1} g_{i,j}(\xi_i, \xi_j) = \frac{2}{n^2} \sum_{k=2}^V \sum_{k'=1}^{k-1} \sum_{i \in \mathcal{B}_k, j \in \mathcal{B}_{k'}} U_m(\xi_i, \xi_j)$.

From Houdré and Reynaud-Bouret (2003, Theorem 3.4), an absolute constant κ exists such that, for any $x > 0$ and $\epsilon \in (0, 1]$,

$$\mathbb{P} \left(|U(m)| \geq \frac{1}{n^2} \left[(4 + \epsilon) \bar{A} \sqrt{x} + \kappa \left(\frac{\bar{B}x}{\epsilon} + \frac{C \bar{x}^{3/2}}{\epsilon^3} + \frac{\bar{D}x^2}{\epsilon^3} \right) \right] \right) \leq 6e^{-x}. \quad (44)$$

$$\bar{A}^2 = \sum_{i=2}^n \sum_{j=1}^{i-1} \mathbb{E}[g_{i,j}(\xi_i, \xi_j)^2],$$

$$\bar{B} = \sup \left\{ \mathbb{E} \left[\sum_{i=2}^n \sum_{j=1}^{i-1} a_i(\xi_i) b_j(\xi_j) g_{i,j}(\xi_i, \xi_j) \right] \right.$$

$$\left. \text{such that } \mathbb{E} \left[\sum_{i=1}^n a_i^2(\xi_i) \right] \leq 1 \text{ and } \mathbb{E} \left[\sum_{i=1}^n b_i^2(\xi_i) \right] \leq 1 \right\},$$

$$\overline{\mathcal{C}}^2 = \sup_{x \in \mathbb{R}} \left\{ \sum_{i=2}^n \mathbb{E}[g_{i,1}(\xi_i, x)^2] \right\} \quad \text{and} \quad \overline{D} = \sup_{x, y} |g_{i,j}(x, y)|.$$

It remains to upper bound these different terms for proving the first inequality, and the second inequality follows. First,

$$\begin{aligned} \mathbb{E}[U_m(\xi_1, \xi_2)^2] &= \sum_{\lambda \in \Lambda_m, \lambda' \in \Lambda_m} \mathbb{E} \left[(\psi_\lambda(\xi_1) - P\psi_\lambda)(\psi_{\lambda'}(\xi_1) - P\psi_{\lambda'}) \right]^2 \\ &= \sum_{\lambda \in \Lambda_m} \left(\sup_{\sum_{\lambda' \in \Lambda_m} a_{\lambda'}^2 \leq 1} \mathbb{E} \left[(\psi_\lambda(\xi_1) - P\psi_\lambda) \sum_{\lambda' \in \Lambda_m} a_{\lambda'} (\psi_{\lambda'}(\xi_1) - P\psi_{\lambda'}) \right) \right]^2 \\ &= \sum_{\lambda \in \Lambda_m} \left(\sup_{t \in \mathbb{B}_m} \mathbb{E} \left[(\psi_\lambda(\xi_1) - P\psi_\lambda)(t(\xi_1) - P(t)) \right] \right)^2 \\ &\leq \mathcal{D}_m \sup_{t \in \mathbb{B}_m} \mathbb{E} \left[(t(\xi_1) - P(t))^2 \right] \\ &\leq \|s\|_\infty \mathcal{D}_m \quad \text{by Eq. (43)} \end{aligned} \quad (45)$$

so that

$$\overline{A}^2 = \sum_{k=2}^V \sum_{k'=1}^{k-1} \sum_{t \in \mathbb{B}_{k,j} \in \mathcal{B}_{k'}} \mathbb{E} \left[U_m(\xi_i, \xi_j)^2 \right] \leq \frac{\eta^2(V-1)}{2V} \times \|s\|_\infty \mathcal{D}_m.$$

Second, let $a_1, \dots, a_n, b_1, \dots, b_n$ be functions in $L^2(\mu)$ such that

$$\mathbb{E} \left[\sum_{i=1}^n a_i^2(\xi_i) \right] \leq 1 \quad \text{and} \quad \mathbb{E} \left[\sum_{i=1}^n b_i^2(\xi_i) \right] \leq 1.$$

Using successively the independence of the ξ_i and that $\alpha\beta \leq (\alpha^2 + \beta^2)/2$ for every $\alpha, \beta \in \mathbb{R}$, for every $i \neq j$,

$$\begin{aligned} & \left| \mathbb{E} [a_i(\xi_i) b_j(\xi_j) U_m(\xi_i, \xi_j)] \right| \\ &= \left| \sum_{\lambda \in \Lambda_m} \mathbb{E} [a_i(\xi_i) (\psi_\lambda(\xi_i) - P\psi_\lambda)] \mathbb{E} [b_j(\xi_j) (\psi_\lambda(\xi_j) - P\psi_\lambda)] \right| \\ &\leq \frac{1}{2} \sum_{\lambda \in \Lambda_m} \left(\mathbb{E} [a_i(\xi_i) (\psi_\lambda(\xi_i) - P\psi_\lambda)]^2 + \mathbb{E} [b_j(\xi_j) (\psi_\lambda(\xi_j) - P\psi_\lambda)]^2 \right). \end{aligned} \quad (46)$$

Now, we have, for every $i \in \llbracket n \rrbracket$, using Eq. (30), Cauchy-Schwarz inequality and the fact that for every $t \in L^2(\mu)$, $\text{Var}(t(\xi_1)) \leq \|s\|_\infty \|t\|^2$,

$$\sum_{\lambda \in \Lambda_m} \mathbb{E} [a_i(\xi_i) (\psi_\lambda(\xi_i) - P\psi_\lambda)]^2 = \sup_{\sum_{\lambda \in \Lambda_m} t_\lambda^2 \leq 1} \left(\mathbb{E} \left[a_i(\xi_i) \sum_{\lambda \in \Lambda_m} t_\lambda \psi_\lambda(\xi_i) - P(t_\lambda \psi_\lambda) \right] \right)^2$$

$$\begin{aligned} &= \sup_{t \in \mathbb{B}_m} \left(\mathbb{E} [a_i(\xi_i) (t(\xi_i) - P(t))] \right)^2 \\ &\leq \mathbb{E} [a_i(\xi_i)^2] \sup_{t \in \mathbb{B}_m} \text{Var}(t(\xi_1)) \leq \mathbb{E} [a_i(\xi_i)^2] \|s\|_\infty. \end{aligned}$$

Plugging this bound in (46) yields

$$\left| \mathbb{E} [a_i(\xi_i) b_j(\xi_j) U_m(\xi_i, \xi_j)] \right| \leq \frac{\|s\|_\infty}{2} \left(\mathbb{E} [a_i(\xi_i)^2] + \mathbb{E} [b_j(\xi_j)^2] \right) \quad (47)$$

hence

$$\overline{B} \leq n \|s\|_\infty.$$

Third, for every $x, y \in \mathbb{R}$, let $g_x(y) = \sum_{\lambda \in \Lambda_m} (\psi_\lambda(x) - P\psi_\lambda) \psi_\lambda(y)$ so that

$$\begin{aligned} \|g_x\|^2 &= \sum_{\lambda \in \Lambda_m} (\psi_\lambda(x) - P\psi_\lambda)^2 \leq 2 \sum_{\lambda \in \Lambda_m} (\psi_\lambda(x))^2 + 2 \sum_{\lambda \in \Lambda_m} (P\psi_\lambda)^2 \\ &= 2\Psi_m(x)^2 + 2\|s_m\|^2 \leq 2(b_m^2 + \|s_m\|^2). \end{aligned}$$

Then,

$$\mathbb{E}[U_m(\xi_i, x)^2] = \text{Var}(g_x(\xi_1)) \leq \|g_x\|^2 \|s\|_\infty \leq 2(b_m^2 + \|s_m\|^2) \|s\|_\infty \quad (48)$$

and, using **(Reg)**, we get that

$$\overline{\mathcal{C}}^2 \leq \frac{2n(V-1)}{V} (b_m^2 + \|s_m\|^2) \|s\|_\infty.$$

Fourth, from Cauchy-Schwarz inequality, for every $x, y \in \mathcal{X}$,

$$U_m(x, y) \leq \sup_{x \in \mathbb{R}, \lambda \in \Lambda_m} (\psi_\lambda(x) - P\psi_\lambda)^2 \leq 2(b_m^2 + \|s_m\|^2). \quad (49)$$

Hence,

$$\overline{D} \leq 2(b_m^2 + \|s_m\|^2)$$

and we get the desired result. \blacksquare

Let us conclude the proof of Proposition 4. From Lemmas 13 and 15, an absolute constant κ exists such that, with probability larger than $1 - 6e^{-x}$, for every $\epsilon \in (0, 1]$,

$$\begin{aligned} & \left| \text{pen}_{\text{VF}}(m, V, V-1) - 2\|s_m - \widehat{s}_m\|^2 \right| \\ &= \frac{2V}{V-1} |U(m)| \leq \epsilon \frac{\mathcal{D}_m}{n} + \kappa \left(\frac{\|s\|_\infty x}{\epsilon n} + \frac{(b_m^2 + \|s\|^2) x^2}{n^2} \right). \end{aligned} \quad (50)$$

Using in addition Lemma 14, we get that an absolute constant κ' exists such that with probability larger than $1 - 8e^{-x}$, for every $\epsilon \in (0, 1]$, Eq. (50) holds true and

$$\left| \text{pen}_{\text{VF}}(m, V, V-1) - \frac{2\mathcal{D}_m}{n} \right| \leq \epsilon \frac{\mathcal{D}_m}{n} + \kappa \left(\frac{\|s\|_\infty x}{\epsilon n} + \frac{(b_m^2 \epsilon^{-3} + \|s\|^2) x^2}{n^2} \right),$$

which implies Eq. (15) and (16). \blacksquare

A.3 Proof of Theorem 5

By construction, the penalized estimator satisfies, for any $m \in \mathcal{M}_n$,

$$\begin{aligned} & \|\widehat{s}_{\widehat{m}} - s\|^2 - \left(\text{pen}_{\text{rd}}(\widehat{m}) - \text{pen}_{\text{VF}}(\widehat{m}, V, C(V-1)) \right) \\ & \leq \|\widehat{s}_{\widehat{m}} - s\|^2 + \left(\text{pen}_{\text{VF}}(m, V, C(V-1)) - \text{pen}_{\text{rd}}(m) \right). \end{aligned}$$

Now, by Eq. (2) and (3), $\text{pen}_{\text{rd}}(m) = 2\|\widehat{s}_m - s_{m'}\|^2 + 2(P_n - P)(s_m)$, hence

$$\begin{aligned} \|\widehat{s}_{\widehat{m}} - s\|^2 & \leq \|\widehat{s}_{\widehat{m}} - s\|^2 + \left[\text{pen}_{\text{VF}}(m, V, C(V-1)) - 2\|s_m - \widehat{s}_{\widehat{m}}\|^2 \right] \\ & \quad - \left[\text{pen}_{\text{VF}}(\widehat{m}, V, C(V-1)) - 2\|s_{\widehat{m}} - \widehat{s}_{\widehat{m}}\|^2 \right] + 2(P_n - P)(s_m - s_{\widehat{m}}) \\ & = \|\widehat{s}_{\widehat{m}} - s\|^2 + \left[\text{pen}_{\text{VF}}(m, V, C(V-1)) - 2C\|s_m - \widehat{s}_{\widehat{m}}\|^2 \right] \\ & \quad - \left[\text{pen}_{\text{VF}}(\widehat{m}, V, C(V-1)) - 2C\|s_{\widehat{m}} - \widehat{s}_{\widehat{m}}\|^2 \right] + 2(P_n - P)(s_m - s_{\widehat{m}}) \\ & \quad + 2(C-1) \left(\|\widehat{s}_{\widehat{m}} - s_m\|^2 - \|\widehat{s}_{\widehat{m}} - s_{\widehat{m}}\|^2 \right). \end{aligned} \quad (51)$$

Let $x > 0$ and $x_n = \log(|\mathcal{M}_n|) + x$. A union bound in Proposition 4 gives

$$\begin{aligned} \mathbb{P} \left(\exists m \in \mathcal{M}_n, \epsilon \in (0, 1] \text{ s.t. } \left| \text{pen}_{\text{VF}}(m, V, V-1) - 2\|s_m - \widehat{s}_m\|^2 \right| \right. \\ \left. > \epsilon \frac{D_m}{n} + \kappa \rho_1(m, \epsilon, s, x_n, n) \right) \leq 8 \sum_{m \in \mathcal{M}_n} e^{-x_n} = 8e^{-x} \sum_{m \in \mathcal{M}_n} \frac{1}{|\mathcal{M}_n|} = 8e^{-x} \end{aligned} \quad (52)$$

and a union bound in Lemma 14 gives

$$\mathbb{P} \left(\exists m \in \mathcal{M}_n, \epsilon \in (0, 1] \text{ s.t. } \left| \|\widehat{s}_m - s_m\|^2 - \frac{D_m}{n} \right| > \epsilon \frac{D_m}{n} + \kappa \rho_1(m, \epsilon, s, x_n, n) \right) \\ \leq 2 \sum_{m \in \mathcal{M}_n} e^{-x_n} = 2e^{-x}. \quad (53)$$

It remains to bound $2(P_n - P)(s_m - s_{m'})$ uniformly over m and m' in \mathcal{M}_n . In order to apply Bernstein's inequality, we first bound the variance and the sup norm of $s_m - s_{m'}$ for some $m, m' \in \mathcal{M}_n$. Since $s \in L^\infty(\mu)$,

$$\text{Var}((s_m - s_{m'})(\xi_1)) \leq \|s\|_\infty \|s_m - s_{m'}\|^2.$$

Under assumption (H2)

$$\|s_m - s_{m'}\|_\infty \leq \|s_m\|_\infty + \|s_{m'}\|_\infty \leq 2a.$$

Under assumption (H2), $s_m - s_{m'} \in \mathcal{S}_{m, m'}$ for some $m'' \in \{m, m'\}$, hence by (H1) we have

$$\|s_m - s_{m'}\|_\infty \leq b_{m''} \|s_m - s_{m'}\| \leq \sqrt{n} \|s_m - s_{m'}\|.$$

Therefore, by Bernstein's inequality, for any $x > 0$, for any m, m' , with probability larger than $1 - e^{-x}$, for any $\epsilon \in (0, 1]$,

$$\begin{aligned} (P_n - P)(s_m - s_{m'}) & \leq \sqrt{\frac{2x \text{Var}((s_m - s_{m'})(\xi_1))}{n}} + \frac{\|s_m - s_{m'}\|_\infty x}{3n} \\ & \leq \epsilon \|s_m - s_{m'}\|^2 + \frac{\kappa(Ax + x^2)}{\epsilon n}. \end{aligned}$$

for some absolute constant κ , where the last inequality is obtained by considering separately the cases (H2) and (H2'), and by using that for every $\alpha, \beta, \epsilon > 0$, $\alpha\beta \leq \epsilon\alpha^2 + (\beta^2)/4\epsilon$. A union bound gives that for any $x > 0$, with probability at least $1 - |\mathcal{M}_n|^2 e^{-x}$, for every $m, m' \in \mathcal{M}_n$ and every $\epsilon \in (0, 1]$,

$$(P_n - P)(s_m - s_{m'}) \leq \epsilon \|s_m - s_{m'}\|^2 + \frac{\kappa(Ax + x^2)}{\epsilon n} \quad (54)$$

for some absolute constant κ . Plugging Eq. (52), (53) and (54) into Eq. (51) and using that $C \in (1/2, 2]$ yields that, with probability $1 - (|\mathcal{M}_n|^2 + 10)e^{-x}$, for any $\epsilon \in (0, 1/2]$,

$$\begin{aligned} (1-4\epsilon)\|\widehat{s}_{\widehat{m}} - s\|^2 & \leq (1+4\epsilon)\|\widehat{s}_m - s\|^2 + (\delta_+ + 4\epsilon) \frac{D_m}{n} + (\delta_- + 3\epsilon) \frac{D_{\widehat{m}}}{n} \\ & \quad + \kappa \left(\rho_1(m, \epsilon, s, x, n) + \rho_1(\widehat{m}, \epsilon, s, x, n) + \frac{Ax + x^2}{\epsilon n} \right) \\ & \leq (1 + \delta_+ + 16\epsilon) \|\widehat{s}_m - s\|^2 + (\delta_- + 8\epsilon) \|\widehat{s}_{\widehat{m}} - s_{\widehat{m}}\|^2 \\ & \quad + \kappa' \left(\rho_1(m, \epsilon, s, x, n) + \rho_1(\widehat{m}, \epsilon, s, x, n) + \frac{Ax + x^2}{\epsilon n} \right) \end{aligned}$$

for some absolute constants $\kappa, \kappa' > 0$. Since $b_m \leq \sqrt{n}$ for all $m \in \mathcal{M}_n$, we get

$$2 \sup_{m \in \mathcal{M}_n} \rho_1(m, \epsilon, s, x, n) + \frac{Ax + x^2}{\epsilon n} \leq \frac{(2\|s\|_\infty + A)x}{\epsilon n} + \left(3 + \frac{2\|s\|^2}{n} \right) \frac{x^2}{\epsilon^3 n}$$

for every $\epsilon \in (0, 1]$. Hence, with probability larger than $1 - (|\mathcal{M}_n|^2 + 10)e^{-x}$, for any $\epsilon \in (0, 1]$,

$$\frac{1 - \delta_- - \epsilon}{1 + \delta_+ + \epsilon} \|\widehat{s}_{\widehat{m}} - s\|^2 \leq \|\widehat{s}_m - s\|^2 + \kappa \left[\frac{(\|s\|_\infty + A)x}{\epsilon n} + \left(1 + \frac{\|s\|^2}{n} \right) \frac{x^2}{\epsilon^3 n} \right] \quad (55)$$

for some absolute constant $\kappa > 0$. To conclude, we remark that Eq. (17) clearly holds true when $|\mathcal{M}_n| = 1$, so we can assume that $|\mathcal{M}_n| \geq 2$. Therefore, for every $x > 0$, Eq. (55) holds true with probability at least

$$1 - \left(|\mathcal{M}_n|^2 + 10 \right) e^{-x} \geq 1 - |\mathcal{M}_n|^4 e^{-x} \geq 1 - e^{-x+4 \log |\mathcal{M}_n|}.$$

So, if we replace x by $4x_n \geq x + 4 \log |\mathcal{M}_n|$ in Eq. (55), we get that Eq. (17) holds true with probability at least $1 - e^{-x}$ for some absolute constant $\kappa > 0$, slightly larger than the one appearing in Eq. (55). \blacksquare

A.4 Proof of Theorem 6

For every $x, y \in \mathcal{X}$ and $m \in \{m_1, m_2\}$, let $K_m(x, y) := \sum_{\lambda \in \Lambda_m} \psi_\lambda(x) \psi_\lambda(y)$ and remark that

$$\begin{aligned} U_m(x, y) &= \sum_{\lambda \in \Lambda_m} (\psi_\lambda(x) - P\psi_\lambda)(\psi_\lambda(y) - P\psi_\lambda) \\ &= K_m(x, y) - s_m(x) - s_m(y) + \|s_m\|^2. \end{aligned} \quad (56)$$

For every $x \in \mathcal{X}$, $K_m(x, x) = \Psi_m(x, x)$ by Eq. (30), $U_m(x, x) = \Psi_m(x, x) - 2s_m(x) + \|s_m\|^2$ and, by independence, for every $m, m' \in \{m_1, m_2\}$

$$\begin{aligned} \text{Cov}(U_m(\xi_1, \xi_2), U_{m'}(\xi_1, \xi_2)) &= \sum_{\lambda \in \Lambda_m, \lambda' \in \Lambda_{m'}} \mathbb{E} \left[(\psi_\lambda(\xi_1) - P\psi_\lambda)(\psi_{\lambda'}(\xi_2) - P\psi_{\lambda'}) (\psi_\lambda(\xi_1) - P\psi_\lambda)(\psi_{\lambda'}(\xi_2) - P\psi_{\lambda'}) \right] \\ &= \sum_{\lambda \in \Lambda_m, \lambda' \in \Lambda_{m'}} \mathbb{E} \left[(\psi_\lambda(\xi_1) - P\psi_\lambda)(\psi_{\lambda'}(\xi_1) - P\psi_{\lambda'}) \right]^2 = \beta(m, m'), \end{aligned}$$

hence, $\text{Var}(U_{m_1}(\xi_1, \xi_2) - U_{m_2}(\xi_1, \xi_2)) = \mathbf{B}(m_1, m_2)$. For every $m \in \{m_1, m_2\}$, by Eq. (56),

$$\begin{aligned} P_n \gamma(\widehat{s}_m) &= - \sum_{\lambda \in \Lambda_m} (P_n \psi_\lambda)^2 = - \frac{1}{n^2} \sum_{1 \leq i, j \leq n} K_m(\xi_i, \xi_j) \\ &= - \frac{1}{n^2} \sum_{1 \leq i, j \leq n} U_m(\xi_i, \xi_j) - \frac{2}{n} \sum_{i=1}^n s_m(\xi_i) + \|s_m\|^2. \end{aligned} \quad (57)$$

Moreover, by Eq. (42) in the proof of Lemma 13,

$$\text{pen}_{\text{VF}}(m, \mathbf{B}, C(V-1)) = \frac{2C}{n^2} \sum_{1 \leq i, j \leq n} E_{i,j}^{(\text{VF})} U_m(\xi_i, \xi_j)$$

where $\forall I, J \in \{1, \dots, V\}$, $\forall i \in B_I, \forall j \in B_J$, $E_{i,j}^{(\text{VF})} = 1 - \frac{V \mathbb{1}_{I \neq J}}{V-1} = (V-1)e_{i,j}^{(\text{VF})}$.

It follows that

$$C_{C, \mathbf{B}}(m) = \sum_{1 \leq i, j \leq n} \frac{2C E_{i,j}^{(\text{VF})} - 1}{n^2} U_m(\xi_i, \xi_j) + \sum_{i=1}^n \frac{-2s_m(\xi_i)}{n} + \|s_m\|^2. \quad (58)$$

Hence, up to the deterministic term $\|s_m\|^2$, $C_{C, \mathbf{B}}(m)$ has the form of a function \mathcal{C}_m defined in Lemma 16 below with

$$\bar{\omega}_{i,j} = \frac{2C E_{i,j}^{(\text{VF})} - 1}{n^2}, \quad f_m = \frac{-2s_m}{n} \quad \text{and} \quad \bar{\sigma}_i = 1.$$

It remains to evaluate the quantities appearing in Lemma 16 for these weights and function. First,

$$\sum_{i=1}^n E_{i,i}^{(\text{VF})} = n \quad \text{and} \quad \sum_{i=1}^n (E_{i,i}^{(\text{VF})})^2 = n.$$

Second, by **(Reg)**,

$$\begin{aligned} \sum_{1 \leq i \neq j \leq n} (E_{i,j}^{(\text{VF})}) &= n \left(\frac{n}{V} - 1 \right) + \frac{-1}{(V-1)} \times \frac{n^2(V-1)}{V} = -n \\ \text{and} \quad \sum_{1 \leq i \neq j \leq n} (E_{i,j}^{(\text{VF})})^2 &= n \left[\left(\frac{n}{V} - 1 \right) + \frac{n}{V(V-1)} \right] = \frac{n^2}{V-1} - n. \end{aligned}$$

It follows that

$$\begin{aligned} \sum_{1 \leq i \leq n} \bar{\omega}_{i,i}^2 &= \frac{(2C-1)^2}{n^3}, \quad \sum_{i=1}^n \bar{\omega}_{i,i} \bar{\sigma}_i = \frac{2C-1}{n} \\ \text{and} \quad \sum_{1 \leq i \neq j \leq n} \bar{\omega}_{i,j} \bar{\omega}_{j,i} &= \sum_{1 \leq i \neq j \leq n} \bar{\omega}_{i,j}^2 = \frac{1}{n^2} \left(1 + \frac{4C^2}{V-1} - \frac{(2C-1)^2}{n} \right). \end{aligned}$$

Hence, from Lemma 16, for every $m, m' \in \{m_1, m_2\}$,

$$\begin{aligned} \text{Cov}(C_{C, \mathbf{B}}(m), C_{C, \mathbf{B}}(m')) &= \frac{2}{n^2} \left(1 + \frac{4C^2}{V-1} - \frac{(2C-1)^2}{n} \right) \beta(m, m') \\ &\quad + \frac{(2C-1)^2}{n^3} \text{Cov}(U_m(\xi, \xi), U_{m'}(\xi, \xi)) + \frac{4}{n} \text{Cov}(s_m(\xi), s_{m'}(\xi)) \\ &\quad - \frac{2(2C-1)}{n^2} \left[\text{Cov}(U_m(\xi, \xi), s_{m'}(\xi)) + \text{Cov}(U_{m'}(\xi, \xi), s_m(\xi)) \right] \\ &= \frac{2}{n^2} \left(1 + \frac{4C^2}{V-1} - \frac{(2C-1)^2}{n} \right) \beta(m, m') \\ &\quad + \frac{1}{n} \text{Cov} \left(\frac{2C-1}{n} U_m(\xi, \xi) - 2s_m(\xi), \frac{2C-1}{n} U_{m'}(\xi, \xi) - 2s_{m'}(\xi) \right). \end{aligned}$$

Therefore,

$$\begin{aligned} \text{Var}(C_{C, \mathbf{B}}(m_1)) &= \frac{2}{n^2} \left(1 + \frac{4C^2}{V-1} - \frac{(2C-1)^2}{n} \right) \beta(m_1, m_1) \\ &\quad + \frac{1}{n} \text{Var} \left(\frac{2C-1}{n} U_{m_1}(\xi, \xi) - 2s_{m_1}(\xi) \right) \\ \text{and} \quad \text{Var}(C_{C, \mathbf{B}}(m_1) - C_{C, \mathbf{B}}(m_2)) &= \frac{2}{n^2} \left(1 + \frac{4C^2}{V-1} - \frac{(2C-1)^2}{n} \right) \mathbf{B}(m_1, m_2) \\ &\quad + \frac{1}{n} \text{Var} \left(2(s_{m_1} - s_{m_2})(\xi) - \frac{2C-1}{n} (U_{m_1}(\xi, \xi) - U_{m_2}(\xi, \xi)) \right) \\ &= \frac{2}{n^2} \left(1 + \frac{4C^2}{V-1} - \frac{(2C-1)^2}{n} \right) \text{Var}(U_{m_1}(\xi, \xi) - U_{m_2}(\xi, \xi_2)) \\ &\quad + \frac{4}{n} \text{Var} \left(\left(1 + \frac{2C-1}{n} \right) (s_{m_1} - s_{m_2})(\xi) - \frac{2C-1}{2n} (\Psi_{m_1}(\xi) - \Psi_{m_2}(\xi)) \right), \end{aligned}$$

which concludes the proof. \blacksquare

Lemma 16 Let $C_m = \sum_{1 \leq i, j \leq n} \bar{w}_{ij} U_m(\xi_i, \xi_j) + \sum_{i=1}^n \bar{\sigma}_i f_m(\xi_i)$, where U_m is defined by Eq. (56) and $f_m \in L^2(\mu)$. For every m, m' , we have

$$\begin{aligned} \text{Cov}(C_m, C_{m'}) &= \left(\sum_{1 \leq i \neq j \leq n} \bar{w}_{ij}^2 + \bar{w}_{ij} \bar{w}_{ji} \right) \text{Cov}(U_m(\xi_1, \xi_2), U_{m'}(\xi_1, \xi_2)) \\ &+ \left(\sum_{i=1}^n \bar{w}_{ii}^2 \right) \text{Cov}(U_m(\xi_1, \xi_1), U_{m'}(\xi_1, \xi_1)) \\ &+ \left(\sum_{i=1}^n \bar{w}_{ii} \bar{\sigma}_i \right) \left[\text{Cov}(U_m(\xi_1, \xi_1), f_{m'}(\xi_1)) + \text{Cov}(U_{m'}(\xi_1, \xi_1), f_m(\xi_1)) \right] \\ &+ \left(\sum_{i=1}^n \bar{\sigma}_i^2 \right) \text{Cov}(f_m(\xi_1), f_{m'}(\xi_1)). \end{aligned}$$

Proof We develop the covariance to get

$$\begin{aligned} \text{Cov}(C_m, C_{m'}) &= \sum_{1 \leq i, j, k, \ell \leq n} \bar{w}_{ij} \bar{w}_{k\ell} \text{Cov}(U_m(\xi_i, \xi_j), U_{m'}(\xi_k, \xi_\ell)) \\ &+ \sum_{1 \leq i, j, k \leq n} \bar{w}_{ij} \bar{\sigma}_k \text{Cov}(U_m(\xi_i, \xi_j), f_{m'}(\xi_k)) \\ &+ \sum_{1 \leq i, j, k \leq n} \bar{w}_{ij} \bar{\sigma}_k \text{Cov}(U_{m'}(\xi_i, \xi_j), f_m(\xi_k)) \\ &+ \sum_{1 \leq i, j \leq n} \bar{\sigma}_i \bar{\sigma}_j \text{Cov}(f_m(\xi_i), f_{m'}(\xi_j)). \end{aligned}$$

The proof is then concluded with the following remarks, which rely on the fact that the random variables $\xi_{[n]}$ are independent and identically distributed.

1. $\text{Cov}(f_m(\xi_j), f_{m'}(\xi_j)) = 0$ unless $i \neq j$, therefore

$$\sum_{1 \leq i, j \leq n} \bar{\sigma}_i \bar{\sigma}_j \text{Cov}(f_m(\xi_i), f_{m'}(\xi_j)) = \left(\sum_{i=1}^n \bar{\sigma}_i^2 \right) \text{Cov}(f_m(\xi_1), f_{m'}(\xi_1)).$$
2. By definition (56) of U_m , $\text{Cov}(U_m(\xi_i, \xi_j), f_{m'}(\xi_k)) = 0$ unless $i = j = k$, hence

$$\sum_{1 \leq i, j, k \leq n} \bar{w}_{ij} \bar{\sigma}_k \text{Cov}(U_m(\xi_i, \xi_j), f_{m'}(\xi_k)) = \left(\sum_{i=1}^n \bar{w}_{ii} \bar{\sigma}_i \right) \text{Cov}(U_m(\xi_1, \xi_1), f_{m'}(\xi_1)).$$
3. By definition (56) of U_m , $\text{Cov}(U_m(\xi_i, \xi_j), U_m(\xi_k, \xi_\ell)) = 0$ unless $i = j = k = \ell$ or $i = k \neq j = \ell$ or $i = \ell \neq j = k$. It follows that

$$\sum_{1 \leq i, j, k, \ell \leq n} \bar{w}_{ij} \bar{w}_{k\ell} \text{Cov}(U_m(\xi_i, \xi_j), U_{m'}(\xi_k, \xi_\ell))$$

$$\begin{aligned} &= \left(\sum_{1 \leq i \neq j \leq n} \bar{w}_{ij}^2 + \bar{w}_{ij} \bar{w}_{ji} \right) \text{Cov}(U_m(\xi_1, \xi_2), U_{m'}(\xi_1, \xi_2)) \\ &+ \left(\sum_{i=1}^n \bar{w}_{ii}^2 \right) \text{Cov}(U_m(\xi_1, \xi_1), U_{m'}(\xi_1, \xi_1)). \end{aligned}$$

Abstract

Symmetric positive semi-definite (SPSPD) matrix approximation methods have been extensively used to speed up large-scale eigenvalue computation and kernel learning methods. The standard sketch based method, which we call the prototype model, produces relatively accurate approximations, but is inefficient on large square matrices. The Nyström method is highly efficient, but can only achieve low accuracy. In this paper we propose a novel model that we call the *fast SPSPD matrix approximation model*. The fast model is nearly as efficient as the Nyström method and as accurate as the prototype model. We show that the fast model can potentially solve eigenvalue problems and kernel learning problems in linear time with respect to the matrix size n to achieve $1 + \epsilon$ relative-error, whereas both the prototype model and the Nyström method cost at least quadratic time to attain comparable error bound. Empirical comparisons among the prototype model, the Nyström method, and our fast model demonstrate the superiority of the fast model. We also contribute new understandings of the Nyström method. The Nyström method is a special instance of our fast model and is approximation to the prototype model. Our technique can be straightforwardly applied to make the CUR matrix decomposition more efficiently computed without much affecting the accuracy.

Keywords: Kernel approximation, matrix factorization, the Nyström method, CUR matrix decomposition

1. Introduction

With limited computational and storage resource, machine-precision inversion and decompositions of large and dense matrix are prohibitive. In the past decade matrix approximation techniques have been extensively studied by the theoretical computer science community

(Woodruff, 2014), the machine learning community (Mahoney, 2011), and the numerical linear algebra community (Halko et al., 2011).

In machine learning, many graph analysis techniques and kernel methods require expensive matrix computations on symmetric matrices. The truncated eigenvalue decomposition (that is to find a few eigenvectors corresponding to the greatest eigenvalues) is widely used in graph analysis such as spectral clustering, link prediction in social networks (Shin et al., 2012), graph matching (Patro and Kingsford, 2012), etc. Kernel methods (Schölkopf and Smola, 2002) such as kernel PCA and manifold learning require the truncated eigenvalue decomposition. Some other kernel methods such as Gaussian process regression/classification require solving $n \times n$ matrix inversion, where n is the number of training samples. The rank k ($k \ll n$) truncated eigenvalue decomposition (k -eigenvalue decomposition for short) of an $n \times n$ matrix costs time $\tilde{O}(n^2k)^1$; the matrix inversion costs time $\mathcal{O}(n^3)$. Thus, the standard matrix computation approaches are infeasible when n is large.

For kernel methods, we are typically given n data samples of dimension d , while the $n \times n$ kernel matrix \mathbf{K} is unknown beforehand and should be computed. This adds to the additional $\mathcal{O}(n^2d)$ time cost. When n and d are both large, computing the kernel matrix is prohibitively expensive. Thus, a good kernel approximation method should avoid the computation of the entire kernel matrix.

Typical SPSPD matrix approximation methods speed up matrix computation by efficiently forming a low-rank decomposition $\mathbf{K} \approx \mathbf{CUC}^T$ where $\mathbf{C} \in \mathbb{R}^{n \times c}$ is a sketch of \mathbf{K} (e.g., randomly sampled c columns of \mathbf{K}) and $\mathbf{U} \in \mathbb{R}^{c \times c}$ can be computed in different ways. With such a low-rank approximation at hand, it takes only $\mathcal{O}(nc^2)$ additional time to approximately compute the rank k ($k \leq c$) eigenvalue decomposition or the matrix inversion. Therefore, if \mathbf{C} and \mathbf{U} are obtained in linear time (w.r.t. n) and c is independent of n , then the aforementioned eigenvalue decomposition and matrix inversion can be approximately solved in linear time.

The Nyström method is perhaps the most widely used kernel approximation method. Let \mathbf{P} be an $n \times c$ sketching matrix such as uniform sampling (Williams and Seeger, 2001; Gittens, 2011), adaptive sampling (Kumar et al., 2012), leverage score sampling (Gittens and Mahoney, 2016), etc. The Nyström method computes \mathbf{C} by $\mathbf{C} = \mathbf{KP} \in \mathbb{R}^{n \times c}$ and $\mathbf{U} = (\mathbf{P}^T \mathbf{C})^\dagger \in \mathbb{R}^{c \times c}$. This way of computing \mathbf{U} is very efficient, but it incurs relatively large approximation error even if \mathbf{C} is a good sketch of \mathbf{K} . As a result, the Nyström method is reported to have low approximation accuracy in real-world applications (Dai et al., 2014; Hsieh et al., 2014; Si et al., 2014b). In fact, the Nyström is impossible to attain $1 + \epsilon$ bound relative to $\|\mathbf{K} - \mathbf{K}_k\|_F^2$ unless $c \geq \Omega(\sqrt{nk}/\epsilon)$ (Wang and Zhang, 2013). Here \mathbf{K}_k denotes the best rank- k approximation of \mathbf{K} . The requirement that c grows at least linearly with \sqrt{n} is a very pessimistic result. It implies that in order to attain $1 + \epsilon$ relative-error bound, the time cost of the Nyström method is of order $nc^2 = \Omega(n^2k/\epsilon)$ for solving the k -eigenvalue decomposition or matrix inversion, which is quadratic in n . Therefore, under the $1 + \epsilon$ relative-error requirement, the Nyström method is not a linear time method.

The main reason for the low accuracy of the Nyström method is due to the way that the \mathbf{U} matrix is calculated. In fact, much higher accuracy can be obtained if \mathbf{U} is calculated

1. The \tilde{O} notation hides the logarithm factors.

by solving the minimization problem $\min_{\mathbf{U}} \|\mathbf{K} - \mathbf{C}\mathbf{U}\mathbf{C}^T\|_F^2$, which is a standard way to approximate symmetric matrices (Halcko et al., 2011; Gittens and Mahoney, 2016; Wang and Zhang, 2013; Wang et al., 2016). This is the randomized SVD for symmetric matrices (Halcko et al., 2011). Wang et al. (2016) called this approxized the prototype model and provided an algorithm that samples $c = \mathcal{O}(k/\epsilon)$ columns of \mathbf{K} to form \mathbf{C} such that $\min_{\mathbf{U}} \|\mathbf{K} - \mathbf{C}\mathbf{U}\mathbf{C}^T\|_F^2 \leq (1+\epsilon)\|\mathbf{K} - \mathbf{K}_k\|_F^2$. Unlike the Nystrom method, the prototype model does not require c to grow with n . The downside of the prototype model is the high computational cost. It requires the full observation of \mathbf{K} and $\mathcal{O}(n^2c)$ time to compute \mathbf{U} . Therefore when applied to kernel approximation, the time cost cannot be less than $\mathcal{O}(n^2d + n^2c)$. To reduce the computational cost, this paper considers the problem of efficient calculation of \mathbf{U} with fixed \mathbf{C} while achieving an accuracy comparable to the prototype model.

More specifically, the key question we try to answer in this paper can be described as follows.

Question 1 For any fixed $n \times n$ symmetric matrix \mathbf{K} , target rank k , and parameter γ , assume that

A1 We are given a sketch matrix $\mathbf{C} \in \mathbb{R}^{n \times c}$ of \mathbf{K} , which is obtained in time $\text{Time}(\mathbf{C})$;

A2 The matrix \mathbf{C} is a good sketch of \mathbf{K} in that $\min_{\mathbf{U}} \|\mathbf{K} - \mathbf{C}\mathbf{U}\mathbf{C}^T\|_F^2 \leq (1+\gamma)\|\mathbf{K} - \mathbf{K}_k\|_F^2$.

Then we would like to know whether for an arbitrary ϵ , it is possible to compute \mathbf{C} and \mathbf{U} such that the following two requirements are satisfied:

R1 The matrix \mathbf{U} has the following error bound:

$$\|\mathbf{K} - \mathbf{C}\mathbf{U}\mathbf{C}^T\|_F^2 \leq (1+\epsilon)(1+\gamma)\|\mathbf{K} - \mathbf{K}_k\|_F^2.$$

R2 The procedure of computing \mathbf{C} and \mathbf{U} and approximately solving the aforementioned k -eigenvalue decomposition or the matrix inversion run in time $\mathcal{O}(n \cdot \text{poly}(k, \gamma^{-1}, \epsilon^{-1})) + \text{Time}(\mathbf{C})$.

Unfortunately, the following theorem shows that neither the Nystrom method nor the prototype model enjoys such desirable properties. We prove the theorem in Appendix B.

Theorem 1 Neither the Nystrom method nor the prototype model satisfies the two requirements in Question 1. To make requirement R1 hold, both the Nystrom method and the prototype model cost time no less than $\mathcal{O}(n^2 \cdot \text{poly}(k, \gamma^{-1}, \epsilon^{-1})) + \text{Time}(\mathbf{C})$ which is at least quadratic in n .

In this paper we give an affirmative answer to the above question. In particular, it has the following consequences. First, the overall approximation has high accuracy in the sense that $\|\mathbf{K} - \mathbf{C}\mathbf{U}\mathbf{C}^T\|_F^2$ is comparable to $\min_{\mathbf{U}} \|\mathbf{K} - \mathbf{C}\mathbf{U}\mathbf{C}^T\|_F^2$, and is thereby comparable to the best rank k approximation. Second, with \mathbf{C} at hand, the matrix \mathbf{U} is obtained efficiently (linear in n). Third, with \mathbf{C} and \mathbf{U} at hand, it takes extra time which is also linear in n to compute the aforementioned eigenvalue decomposition or linear system. Therefore, with a good \mathbf{C} , we can use linear time to obtain desired \mathbf{U} matrix such that the accuracy is comparable to the best possible low-rank approximation.

The CUR matrix decomposition (Mahoney and Drineas, 2009) is closely related to the prototype model and troubled by the same computational problem. The CUR matrix decomposition is an extension of the prototype model from symmetric matrices to general

matrices. Given any $m \times n$ fixed matrix \mathbf{A} , the CUR matrix decomposition selects c columns of \mathbf{A} to form $\mathbf{C} \in \mathbb{R}^{m \times c}$ and r rows of \mathbf{A} to form $\mathbf{R} \in \mathbb{R}^{r \times n}$, and computes matrix $\mathbf{U} \in \mathbb{R}^{c \times r}$ such that $\|\mathbf{A} - \mathbf{C}\mathbf{U}\mathbf{R}\|_F^2$ is small. Traditionally, it costs time

$$\mathcal{O}(mn \cdot \min\{c, r\})$$

to compute the optimal $\mathbf{U}^* = \mathbf{C}^\dagger \mathbf{A} \mathbf{R}^\dagger$ (Stewart, 1999; Wang and Zhang, 2013; Boutsidis and Woodruff, 2014). How to efficiently compute a high-quality \mathbf{U} matrix for CUR is unsolved.

1.1 Main Results

This work is motivated by an intrinsic connection between the Nystrom method and the prototype model. Based on a generalization of this observation, we propose the *fast SPSPD matrix approximation model* for approximating any symmetric matrix. We show that the fast model satisfies the requirements in Question 1. Given n data points of dimension d , the fast model computes \mathbf{C} and \mathbf{U}^{fast} and approximately solves the truncated eigenvalue decomposition or matrix inversion in time

$$\mathcal{O}(nc^3/\epsilon + nc^2d/\epsilon) + \text{Time}(\mathbf{C}).$$

Here $\text{Time}(\mathbf{C})$ is defined in Question 1.

The fast SPSPD matrix approximation model achieves the desired properties in Question 1 by solving $\min_{\mathbf{U}} \|\mathbf{K} - \mathbf{C}\mathbf{U}\mathbf{C}^T\|_F$ approximately rather than exactly while ensuring

$$\|\mathbf{K} - \mathbf{C}\mathbf{U}^{\text{fast}}\mathbf{C}^T\|_F^2 \leq (1+\epsilon) \min_{\mathbf{U}} \|\mathbf{K} - \mathbf{C}\mathbf{U}\mathbf{C}^T\|_F^2.$$

The time complexity for computing \mathbf{U}^{fast} is linear in n , which is far less than the time complexity $\mathcal{O}(n^2c)$ of the prototype model. Our method also avoids computing the entire kernel matrix \mathbf{K} ; instead, it computes a block of \mathbf{K} of size $\frac{\sqrt{nc}}{\epsilon} \times \frac{\sqrt{nc}}{\epsilon}$, which is substantially smaller than $n \times n$. The lower bound in Theorem 7 indicates that the \sqrt{n} factor here is optimal, but the dependence on c and ϵ are suboptimal and can be potentially improved.

This paper provides a new perspective on the Nystrom method. We show that, as well as our fast model, the Nystrom method is approximate solution to the problem $\min_{\mathbf{U}} \|\mathbf{C}\mathbf{U}\mathbf{C}^T - \mathbf{K}\|_F^2$. Unfortunately, the approximation is so rough that the quality of the Nystrom method is low.

Our method can also be applied to improve the CUR matrix decomposition of the general matrices which are not necessarily square. Given any matrices $\mathbf{A} \in \mathbb{R}^{m \times n}$, $\mathbf{C} \in \mathbb{R}^{m \times c}$, and $\mathbf{R} \in \mathbb{R}^{r \times n}$, it costs time $\mathcal{O}(mn \cdot \min\{c, r\})$ to compute the matrix $\mathbf{U} = \mathbf{C}^\dagger \mathbf{A} \mathbf{R}^\dagger$. Applying our technique, the time cost drops to only

$$\mathcal{O}(c^2r\epsilon^{-1} \cdot \min\{m, n\} \cdot \min\{c, r\}),$$

while the approximation quality is nearly the same.

1.2 Paper Organization

The remainder of this paper is organized as follows. Section 2 defines the notation used in this paper. Section 3 introduces the related work of matrix sketching and SPSPD matrix

Table 1: A summary of the notation.

Notation	Description
n	number of data points
d	dimension of the data point
\mathbf{K}	$n \times n$ kernel matrix
\mathbf{P}, \mathbf{S}	sketching matrices
\mathbf{C}	$n \times c$ sketch computed by $\mathbf{C} = \mathbf{K}\mathbf{P}$
\mathbf{U}^*	$\mathbf{C}^T(\mathbf{C}^T)^T \in \mathbb{R}^{c \times c}$ —the \mathbf{U} matrix of the prototype model
\mathbf{U}^{NYS}	$(\mathbf{P}^T \mathbf{K})^\dagger \in \mathbb{R}^{c \times c}$ —the \mathbf{U} matrix of the Nyström method
\mathbf{U}^{fast}	$(\mathbf{S}^T \mathbf{C})^\dagger (\mathbf{S}^T \mathbf{K} \mathbf{S})(\mathbf{C}^T \mathbf{S})^\dagger \in \mathbb{R}^{c \times c}$ —the \mathbf{U} matrix of the fast model

approximation. Section 4 describes our fast model and analyze the time complexity and error bound. Section 5 applies the technique of the fast model to compute the CUR matrix decomposition more efficiently. Section 6 conducts empirical comparisons to show the effect of the \mathbf{U} matrix. The proofs of the theorems are in the appendix.

2. Notation

The notation used in this paper are defined as follows. Let $[n] = \{1, \dots, n\}$, \mathbf{I}_n be the $n \times n$ identity matrix, and $\mathbf{1}_n$ be the $n \times 1$ vector of all ones. We let $x \in y \pm z$ denote $y - z \leq x \leq y + z$. For an $m \times n$ matrix $\mathbf{A} = [A_{ij}]$, we let \mathbf{a}_i be its i -th row, $\mathbf{a}_{:j}$ be its j -th column, $\text{nnz}(\mathbf{A})$ be the number of nonzero entries of \mathbf{A} , $\|\mathbf{A}\|_F = (\sum_{i,j} A_{ij}^2)^{1/2}$ be its Frobenius norm, and $\|\mathbf{A}\|_2 = \max_{\mathbf{x} \neq 0} \|\mathbf{A}\mathbf{x}\|_2 / \|\mathbf{x}\|_2$ be its spectral norm.

Let $\rho = \text{rank}(\mathbf{A})$. The condensed singular value decomposition (SVD) of \mathbf{A} is defined

as

$$\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^T = \sum_{i=1}^{\rho} \sigma_i \mathbf{u}_i \mathbf{v}_i^T$$

where $\sigma_1, \dots, \sigma_r$ are the positive singular values in the descending order. We also use $\sigma_i(\mathbf{A})$ to denote the i -th largest singular value of \mathbf{A} . Unless otherwise specified, in this paper “SVD” means the condensed SVD. Let $\mathbf{A}_k = \sum_{i=1}^k \sigma_i \mathbf{u}_i \mathbf{v}_i^T$ be the top k principal components of \mathbf{A} for any positive integer k less than ρ . In fact, \mathbf{A}_k is the closest to \mathbf{A} among all the rank k matrices. Let $\mathbf{A}^\dagger = \mathbf{V}\mathbf{\Sigma}^{-1}\mathbf{U}^T$ be the Moore-Penrose inverse of \mathbf{A} .

Assume that $\rho = \text{rank}(\mathbf{A}) < n$. The column leverage scores of \mathbf{A} are $l_i = \|\mathbf{v}_i\|_2^2$ for $i = 1$ to n . Obviously, $l_1 + \dots + l_n = \rho$. The row leverage scores and coherence are similarly $\frac{l_i}{\rho} \max_{j \in [n]} \|\mathbf{v}_j\|_2^2$. If $\rho = \text{rank}(\mathbf{A}) < m$, the row leverage scores and coherence are similarly defined. The row leverage scores are $\|\mathbf{u}_1\|_2^2, \dots, \|\mathbf{u}_m\|_2^2$ and the row coherence is $\mu(\mathbf{A}) = \frac{l_i}{\rho} \max_{i \in [m]} \|\mathbf{u}_i\|_2^2$.

We also list some frequently used notation in Table 1. Given the decomposition $\tilde{\mathbf{K}} = \mathbf{C}\mathbf{U}^T \approx \mathbf{K}$ which has rank at most c , it takes $\mathcal{O}(nc^2)$ time to compute the eigenvalue decomposition of $\tilde{\mathbf{K}}$ and $\mathcal{O}(nc^2)$ time to solve the linear system $(\tilde{\mathbf{K}} + \alpha \mathbf{I}_n)\mathbf{w} = \mathbf{y}$ to obtain \mathbf{w} (see Appendix A for more discussions). The truncated eigenvalue decomposition and linear system are the bottleneck of many kernel methods, and thus an accurate and efficient low-rank approximation can help to accelerate the computation of kernel learning.

3. Related Work

In Section 3.1 we introduce matrix sketching. In Section 3.2 we describe two SPSPD matrix approximation methods.

3.1 Matrix Sketching

Popular matrix sketching methods include uniform sampling, leverage score sampling (Drineas et al., 2006, 2008; Woodruff, 2014), Gaussian projection (Johnson and Lindenstrauss, 1984), subsampled randomized Hadamard transform (SRHT) (Drineas et al., 2011; Lu et al., 2013; Tropp, 2011), count sketch (Charikar et al., 2004; Clarkson and Woodruff, 2013; Meng and Mahoney, 2013; Nelson and Nguyen, 2013; Pham and Pagh, 2013; Thorup and Zhang, 2012; Weinberger et al., 2009), etc.

3.1.1 COLUMN SAMPLING

Let $p_1, \dots, p_n \in (0, 1)$ with $\sum_{i=1}^n p_i = 1$ be the sampling probabilities. Let each integer in $[n]$ be independently sampled with probabilities sp_1, \dots, sp_n , where $s \in [n]$ is integer. Assume that \tilde{s} integers are sampled from $[n]$. Let $i_1, \dots, i_{\tilde{s}}$ denote the selected integers, and let $\mathbb{E}[\tilde{s}] = s$. We scale each selected column by $\frac{1}{\sqrt{sp_{i_1}}}, \dots, \frac{1}{\sqrt{sp_{i_{\tilde{s}}}}}$, respectively. Uniform sampling means that the sampling probabilities are $p_1 = \dots = p_n = \frac{1}{n}$. Leverage score sampling means that the sampling probabilities are proportional to the leverage scores l_1, \dots, l_n of a certain matrix.

We can equivalently characterize column selection by the matrix $\mathbf{S} \in \mathbb{R}^{n \times \tilde{s}}$. Each column of \mathbf{S} has exactly one nonzero entry; let (i_j, j) be the position of the nonzero entry in the j -th column for $j \in [\tilde{s}]$. For $j = 1$ to \tilde{s} , we set

$$S_{i_j, j} = \frac{1}{\sqrt{sp_{i_j}}}. \quad (1)$$

The expectation $\mathbb{E}[\tilde{s}]$ equals to s , and $\tilde{s} = \Theta(s)$ with high probability. For the sake of simplicity and clarity, in the rest of this paper we will not distinguish \tilde{s} and s .

3.1.2 RANDOM PROJECTION

Let $\mathbf{G} \in \mathbb{R}^{n \times s}$ be a standard Gaussian matrix, namely each entry is sampled independently from $\mathcal{N}(0, 1)$. The matrix $\mathbf{S} = \frac{1}{\sqrt{s}}\mathbf{G}$ is a Gaussian projection matrix. Gaussian projection is also well known as the Johnson-Lindenstrauss (JL) transform (Johnson and Lindenstrauss, 1984); its theoretical property is well established. It takes $\mathcal{O}(mns)$ time to apply $\mathbf{S} \in \mathbb{R}^{n \times s}$ to any $m \times n$ dense matrix, which makes Gaussian projection inefficient.

The subsampled randomized Hadamard transform (SRHT) is usually a more efficient alternative of Gaussian projection. Let $\mathbf{H}_n \in \mathbb{R}^{n \times n}$ be the Walsh-Hadamard matrix with $+1$ and -1 entries, $\mathbf{D} \in \mathbb{R}^{n \times n}$ be a diagonal matrix with diagonal entries sampled uniformly from $\{+1, -1\}$, and $\mathbf{P} \in \mathbb{R}^{n \times s}$ be the uniform sampling matrix defined above. The matrix $\mathbf{S} = \frac{1}{\sqrt{n}}\mathbf{D}\mathbf{H}_n\mathbf{P} \in \mathbb{R}^{n \times s}$ is an SRHT matrix, and it can be applied to any $m \times n$ matrix in $\mathcal{O}(mn \log s)$ time.

Count sketch stems from the data stream literature (Charikar et al., 2004; Thorup and Zhang, 2012) and has been applied to speedup matrix computation. The count sketch

matrix $\mathbf{S} \in \mathbb{R}^{n \times s}$ can be applied to any matrix \mathbf{A} in $\mathcal{O}(\text{nnz}(\mathbf{A}))$ time where nnz denotes the number of non-zero entries. The readers can refer to (Woodruff, 2014) for detailed descriptions of count sketch.

3.1.3 THEORIES

The following lemma shows important properties of the matrix sketching methods. In the lemma, leverage score sampling means that the sampling probabilities are proportional to the row leverage scores of the column orthogonal matrix $\mathbf{U} \in \mathbb{R}^{n \times k}$. (Here \mathbf{U} is different from the notation elsewhere in the paper.) We prove the lemma in Appendix C.

Lemma 2 *Let $\mathbf{U} \in \mathbb{R}^{n \times k}$ be any fixed matrix with orthonormal columns and $\mathbf{B} \in \mathbb{R}^{n \times d}$ be any fixed matrix. Let $\mathbf{S} \in \mathbb{R}^{n \times s}$ be any sketching matrix considered in this section; the order of s (with the \mathcal{O} -notation omitted) is listed in Table 2. Then*

$$\begin{aligned} \mathbb{P}\left\{\|\mathbf{U}^T \mathbf{S} \mathbf{S}^T \mathbf{U} - \mathbf{I}_k\|_2 \geq \eta\right\} &\leq \delta_1 && \text{(Property 1),} \\ \mathbb{P}\left\{\|\mathbf{U}^T \mathbf{B} - \mathbf{U}^T \mathbf{S} \mathbf{S}^T \mathbf{B}\|_F^2 \geq \epsilon \|\mathbf{B}\|_F^2\right\} &\leq \delta_2 && \text{(Property 2),} \\ \mathbb{P}\left\{\|\mathbf{U}^T \mathbf{B} - \mathbf{U}^T \mathbf{S} \mathbf{S}^T \mathbf{B}\|_2^2 \geq \epsilon' \|\mathbf{B}\|_2^2 + \frac{\epsilon'}{k} \|\mathbf{B}\|_F^2\right\} &\leq \delta_3 && \text{(Property 3).} \end{aligned}$$

Table 2: The leverage score sampling is w.r.t. the row leverage scores of \mathbf{U} . For uniform sampling, the notation $\mu(\mathbf{U}) \in [1, \eta]$ is the row coherence of \mathbf{U} .

Sketching	Property 1	Property 2	Property 3
Leverage Sampling	$\frac{k}{\eta} \log \frac{k}{\delta_1}$	$\frac{k}{\delta_2}$	—
Uniform Sampling	$\frac{\mu(\mathbf{U})k}{\eta^2} \log \frac{k}{\delta_1}$	$\frac{\mu(\mathbf{U})}{\delta_2}$	—
Gaussian Projection	$\frac{k + \log(1/\delta_1)}{k \log(1/\delta_1)}$	$\frac{k}{\delta_2}$	—
SRHT	$\frac{k + \log(1/\delta_1)}{\eta^2} \log \frac{k}{\delta_1}$	$\frac{k + \log(1/\delta_1)}{\delta_2}$	$\frac{1}{\epsilon'} (k + \log \frac{d}{\delta_3})$
Count Sketch	$\frac{k}{\delta_1^2}$	$\frac{k}{\delta_2}$	$\frac{1}{\epsilon'} (k + \log \frac{nd}{k \delta_1}) \log \frac{d}{\delta_3}$

Property 1 is known as the subspace embedding property (Woodruff, 2014). It shows that all the singular values of $\mathbf{S}^T \mathbf{U}$ are close to one. Properties 2 and 3 show that sketching preserves the multiplication of a row orthogonal matrix and an arbitrary matrix.

For the SPSPD/CUR matrix approximation problems, the three properties are all we need to capture the randomness in the sketching methods. Leverage score sampling, uniform sampling, and count sketch do not enjoy Property 3, but it is fine—Frobenius norm (Property 2) will be used as a loose upper bound on the spectral norm (Property 3). Gaussian projection and SRHT satisfy all the three properties; when applied to the SPSPD/CUR problems, their error bounds are stronger than the leverage score sampling, uniform sampling, and count sketch.

3.2 SPSPD Matrix Approximation Models

We first describe the prototype model and the Nystrom method, which are most relevant to this work. We then introduce several other SPSPD matrix approximation methods.

3.2.1 MOST RELEVANT WORK

Given an $n \times n$ matrix \mathbf{K} and an $n \times c$ sketching matrix \mathbf{P} , we let $\mathbf{C} = \mathbf{K}\mathbf{P}$ and $\mathbf{W} = \mathbf{P}^T \mathbf{C} = \mathbf{P}^T \mathbf{K}\mathbf{P}$. The *prototype model* (Wang and Zhang, 2013) is defined by

$$\tilde{\mathbf{K}}_c^{\text{proto}} \triangleq \mathbf{C}\mathbf{U}^T \mathbf{C}^T = \mathbf{C}\mathbf{C}^t \mathbf{K}(\mathbf{C}^t)^T \mathbf{C}^T, \quad (2)$$

and the *Nystrom method* is defined by

$$\begin{aligned} \tilde{\mathbf{K}}_c^{\text{nys}} &\triangleq \mathbf{C}\mathbf{U}^{\text{nys}} \mathbf{C}^T = \mathbf{C}\mathbf{W}^t \mathbf{C}^T \\ &= \mathbf{C}(\mathbf{P}^T \mathbf{C})^t (\mathbf{P}^T \mathbf{K}\mathbf{P})(\mathbf{C}^T \mathbf{P})^t \mathbf{C}^T. \end{aligned} \quad (3)$$

The only difference between the two models is their \mathbf{U} matrices, and the difference leads to big difference in their approximation accuracies. Wang and Zhang (2013) provided a lower error bound of the Nystrom method, which shows that no algorithm can select less than $\Omega(\sqrt{nk/\epsilon})$ columns of \mathbf{K} to form \mathbf{C} such that

$$\|\mathbf{K} - \mathbf{C}\mathbf{U}^{\text{nys}} \mathbf{C}^T\|_F^2 \leq (1 + \epsilon) \|\mathbf{K} - \mathbf{K}_k\|_F^2.$$

In contrast, the prototype model can attain the $1 + \epsilon$ relative-error bound with $c = \mathcal{O}(k/\epsilon)$ (Wang et al., 2016), which is optimal up to a constant factor.

While we have mainly discussed the time complexity of kernel approximation in the previous sections, the memory cost is often a more important issue in large scale problems due to the limitation of computer memory. The Nystrom method and the prototype model require $\mathcal{O}(nc)$ memory to hold \mathbf{C} and \mathbf{U} to approximately solve the aforementioned eigenvalue decomposition or the linear system.² Therefore, we hope to make c as small as possible while achieving a low approximation error. There are two elements: (1) a good sketch $\mathbf{C} = \mathbf{K}\mathbf{P}$, and (2) a high-quality \mathbf{U} matrix. We focus on the latter in this paper.

3.2.2 LESS RELEVANT WORK

We note that there are many other kernel approximation approaches in the literature. However, these approaches do not directly address the issue we consider here, so they are complementary to our work. These studies are either less effective or inherently rely on the Nystrom method.

The Nystrom-like models such as MEKA (Si et al., 2014a) and the ensemble Nystrom method (Kumar et al., 2012) are reported to significantly outperform the Nystrom method in terms of approximation accuracy, but their key components are still the Nystrom method and the component can be replaced by any other methods such as the method studied in this work. The spectral shifting Nystrom method (Wang et al., 2014) also outperforms the

² The memory costs of the prototype model is $\mathcal{O}(nc + nd)$ rather than $\mathcal{O}(n^2)$. This is because we can hold the $n \times d$ data matrix and the $c \times n$ matrix \mathbf{C}^t in memory; compute a small block of \mathbf{K} each time; and then compute $\mathbf{C}^t \mathbf{K}$ block by block.

Nyström method in certain situations, but the spectral shifting strategy can be used for any other kernel approximation models beyond the prototype model. We do not compare with these methods in this paper because MEKA, the ensemble Nyström method, and the spectral shifting Nyström method can all be improved if we replace the underlying Nyström method or the prototype model by the new method developed here.

The column-based low-rank approximation model (Kumar et al., 2009) is another SPSPD matrix approximation approach different from the Nyström-like methods. Let $\mathbf{P} \in \mathbb{R}^{n \times c}$ be any sketching matrix and $\mathbf{C} = \mathbf{K}\mathbf{P}$. The column-based model approximates \mathbf{K} by $\mathbf{C}(\mathbf{C}^T\mathbf{C})^{-1/2}\mathbf{C}^T = (\mathbf{C}\mathbf{C}^T)^{1/2}$. Equivalently, it approximates \mathbf{K}^2 by

$$\mathbf{K}^T\mathbf{K} \approx \mathbf{C}\mathbf{C}^T = \mathbf{K}^T\mathbf{P}\mathbf{P}^T\mathbf{K}.$$

From Lemma 2 we can see that it is a typical sketch based approximation to the matrix multiplication. Unfortunately, the approximate matrix multiplication is effective only when \mathbf{K} has much more rows than columns, which is not true for the kernel matrix. The column-based model does not have good error bound and is not empirically as good as the Nyström method (Kumar et al., 2009).

The random feature mapping (Rahimi and Recht, 2007) is a family of kernel approximation methods. Each random feature mapping method is applicable to certain kernel rather than arbitrary SPSPD matrix. Furthermore, they are known to be noticeably less effective than the Nyström method (Yang et al., 2012).

4. The Fast SPSPD Matrix Approximation Model

In Section 4.1 we present the motivation behind the fast model. In Section 4.2 we provide an alternative perspective on our fast model and the Nyström method by formulating them as approximate solutions to an optimization problem. In Section 4.3 we analyze the error bound of the fast model. Theorem 3 is the main theorem, which shows that in terms of the Frobenius norm approximation, the fast model is almost as good as the prototype model. In Section 4.4 we describe the implementation of the fast model and analyze the time complexity. In Section 4.5 we give some implementation details that help to improve the approximation quality. In Section 4.6 we show that our fast model exactly recovers \mathbf{K} under certain conditions, and we provide a lower error bound of the fast model.

4.1 Motivation

Let $\mathbf{P} \in \mathbb{R}^{n \times c}$ be sketching matrix and $\mathbf{C} = \mathbf{K}\mathbf{P} \in \mathbb{R}^{n \times c}$. The fast SPSPD matrix approximation model is defined by

$$\tilde{\mathbf{K}}_{c,s}^{\text{fast}} \triangleq \mathbf{C}(\mathbf{S}^T\mathbf{C})^\dagger(\mathbf{S}^T\mathbf{K}\mathbf{S})(\mathbf{C}^T\mathbf{S})^\dagger\mathbf{C}^T,$$

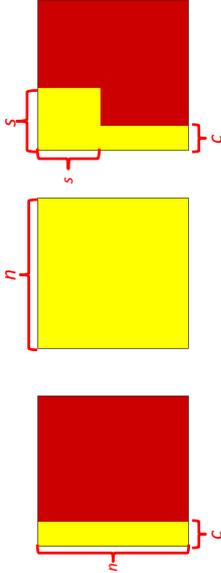

where \mathbf{S} is $n \times s$ sketching matrix.

From (2) and (3) we can see that the Nyström method is a special case of the fast model where \mathbf{S} is defined as \mathbf{P} and that the prototype model is a special case where \mathbf{S} is defined as \mathbf{I}_n .

The fast model allows us to trade off the accuracy and the computational cost—larger s leads to higher accuracy and higher time cost, and vice versa. Setting s as small as c

Table 3: Summary of the time cost of the models for computing the \mathbf{U} matrices and the number of entries of \mathbf{K} required to be observed in order to compute the \mathbf{U} matrices. As for the fast model, assume that \mathbf{S} is column selection matrix. The notation is defined previously in Table 1.

	Time	#Entries
Nyström	$\mathcal{O}(c^3)$	nc
Prototype	$\mathcal{O}(\min(\mathbf{K})c + nc^2)$	n^2
Fast	$\mathcal{O}(nc^2 + s^2c)$	$nc + (s-c)^2$

Nyström Prototype Fast

Figure 1: The yellow blocks denote the submatrices of \mathbf{K} that must be seen by the kernel approximation models. The Nyström method computes an $n \times c$ block of \mathbf{K} , provided that \mathbf{P} is column selection matrix; the prototype model computes the entire $n \times n$ matrix \mathbf{K} ; the fast model computes an $n \times c$ block and an $(s-c) \times (s-c)$ block of \mathbf{K} (due to the symmetry of \mathbf{K}), provided that \mathbf{P} and \mathbf{S} are column selection matrices.

sacrifices too much accuracy, whereas setting s as large as n is unnecessarily expensive. Later on, we will show that $s = \mathcal{O}(c\sqrt{n/\epsilon}) \ll n$ is a good choice. The setting $s \ll n$ makes the fast model much cheaper to compute than the prototype model. When applied to kernel methods, the fast model avoids computing the entire kernel matrix. We summarize the time complexities of the three matrix approximation methods in Table 3; the middle column lists the time cost for computing the \mathbf{U} matrices given \mathbf{C} and \mathbf{K} ; the right column lists the number of entry of \mathbf{K} which must be observed. We show a very intuitive comparison in Figure 1.

4.2 Optimization Perspective

With the sketch $\mathbf{C} = \mathbf{K}\mathbf{P} \in \mathbb{R}^{n \times c}$ at hand, we want to find the \mathbf{U} matrix such that $\mathbf{C}\mathbf{U}\mathbf{C}^T \approx \mathbf{K}$. It is very intuitive to solve the following problem to make the approximation

tight:

$$\mathbf{U}^* = \underset{\mathbf{U}}{\operatorname{argmin}} \|\mathbf{C}\mathbf{U}\mathbf{C}^T - \mathbf{K}\|_F^2 = \mathbf{C}^\dagger \mathbf{K} (\mathbf{C}^\dagger)^T. \quad (4)$$

This is the prototype model. Since solving this system is time expensive, we propose to draw a sketching matrix $\mathbf{S} \in \mathbb{R}^{n \times s}$ and solve the following problem instead:

$$\begin{aligned} \mathbf{U}^{\text{fast}} &= \underset{\mathbf{U}}{\operatorname{argmin}} \|\mathbf{S}^T (\mathbf{C}\mathbf{U}\mathbf{C}^T - \mathbf{K}) \mathbf{S}\|_F^2 \\ &= \underset{\mathbf{U}}{\operatorname{argmin}} \|(\mathbf{S}^T \mathbf{C}) \mathbf{U} (\mathbf{S}^T \mathbf{C})^T - \mathbf{S}^T \mathbf{K} \mathbf{S}\|_F^2 \\ &= (\mathbf{S}^T \mathbf{C})^\dagger (\mathbf{S}^T \mathbf{K} \mathbf{S}) (\mathbf{C}^T \mathbf{S})^\dagger, \end{aligned} \quad (5)$$

which results in the fast model. Similar ideas have been exploited to efficiently solve the least squares regression problem (Drineas et al., 2006, 2011; Clarkson and Woodruff, 2013), but their analysis can not be directly applied to the more complicated system (5).

This approximate linear system interpretation offers a new perspective on the Nystrom method. The \mathbf{U} matrix of the Nystrom method is in fact an approximate solution to the problem $\min_{\mathbf{U}} \|\mathbf{C}\mathbf{U}\mathbf{C}^T - \mathbf{K}\|_F^2$. The Nystrom method uses $\mathbf{S} = \mathbf{P}$ as the sketching matrix, which leads to the solution

$$\mathbf{U}^{\text{NYS}} = \underset{\mathbf{U}}{\operatorname{argmin}} \|\mathbf{P}^T (\mathbf{C}\mathbf{U}\mathbf{C}^T - \mathbf{K}) \mathbf{P}\|_F^2 = (\mathbf{P}^T \mathbf{K} \mathbf{P})^\dagger = \mathbf{W}^\dagger.$$

4.3 Error Analysis

Let \mathbf{U}^{fast} correspond to the fast model (5). Any of the five sketching methods in Lemma 2 can be used to compute \mathbf{U}^{fast} , although column selection is more useful than random projection in this application. In the following we show that \mathbf{U}^{fast} is nearly as good as \mathbf{U}^* in terms of the objective function value. The proof is in Appendix D.

Theorem 3 (Main Result) *Let \mathbf{K} be any $n \times n$ fixed symmetric matrix, \mathbf{C} be any $n \times c$ fixed matrix, $k_c = \operatorname{rank}(\mathbf{C})$, and \mathbf{U}^{fast} be the $c \times c$ matrix defined in (5). Let $\mathbf{S} \in \mathbb{R}^{n \times s}$ be any of the five sketching matrices defined in Table 4. Assume that $\epsilon^{-1} = o(n)$ or $\epsilon^{-1} = o(n/c)$. The inequality*

$$\|\mathbf{K} - \mathbf{C}\mathbf{U}^{\text{fast}}\mathbf{C}^T\|_F^2 \leq (1 + \epsilon) \min \|\mathbf{K} - \mathbf{C}\mathbf{U}\mathbf{C}^T\|_F^2 \quad (6)$$

holds with probability at least 0.8.

In the theorem, Gaussian projection and SRHT require smaller sketch size than the other three methods. It is because Gaussian projection and SRHT enjoys all of Properties 1, 2, 3 in Lemma 2, whereas leverage score sampling, uniform sampling, and count sketch does not enjoy Property 3.

Remark 4 Wang et al. (2016) showed that there exists an algorithm (though not linear-time algorithm) attaining the error bound

$$\|\mathbf{K} - \mathbf{C}\mathbf{C}^\dagger \mathbf{K} (\mathbf{C}^\dagger)^T \mathbf{C}^T\|_F^2 \leq (1 + \epsilon) \|\mathbf{K} - \mathbf{K}_k\|_F^2$$

Table 4: Leverage score sampling means sampling according to the row leverage scores of \mathbf{C} . For uniform sampling, the parameter $\mu(\mathbf{C}) \in [1, n]$ is the row coherence of \mathbf{C} .

Sketching	Order of s	Assumption	T_{sketch}	#Entries
Leverage Score Sampling	$c\sqrt{n}/\epsilon$	$\epsilon = o(n)$	$\mathcal{O}(nc^2 + s^2)$	$nc + (s - c)^2$
Uniform Sampling	$\mu(\mathbf{C})c\sqrt{n}/\epsilon$	$\epsilon = o(n)$	$\mathcal{O}(s^2)$	n^2
Gaussian Projection	$\sqrt{\frac{nc}{\epsilon}}(c + \log \frac{n}{\epsilon})$	$\epsilon = o(n/c)$	$\mathcal{O}(\operatorname{mnz}(\mathbf{K})s)$	n^2
SRHT	$\sqrt{\frac{nc}{\epsilon}}(c + \log n) \log(n)$	$\epsilon = o(n/c)$	$\mathcal{O}(n^2 \log s)$	n^2
Count Sketch	$c\sqrt{n}/\epsilon$	$\epsilon = o(n)$	$\mathcal{O}(\operatorname{mnz}(\mathbf{K}))$	n^2

Algorithm 1 The Fast SPSPD Matrix Approximation Model.

- 1: **Input:** an $n \times n$ symmetric matrix \mathbf{K} and the number of selected columns or target dimension of projection $c (< n)$.
- 2: Sketching: $\mathbf{C} = \mathbf{K}\mathbf{P}$ using an arbitrary $n \times c$ sketching matrix \mathbf{P} (not studied in this work);
- 3: Optional: replace \mathbf{C} by any orthonormal bases of the columns of \mathbf{C} ;
- 4: Compute another $n \times s$ sketching matrix \mathbf{S} , e.g. the leverage score sampling in Algorithm 2;
- 5: Compute the sketches $\mathbf{S}^T \mathbf{C} \in \mathbb{R}^{s \times c}$ and $\mathbf{S}^T \mathbf{K} \mathbf{S} \in \mathbb{R}^{s \times s}$;
- 6: Compute $\mathbf{U}^{\text{fast}} = (\mathbf{S}^T \mathbf{C})^\dagger (\mathbf{S}^T \mathbf{K} \mathbf{S}) (\mathbf{C}^T \mathbf{S})^\dagger \in \mathbb{R}^{c \times c}$;
- 7: **Output:** \mathbf{C} and \mathbf{U}^{fast} such that $\mathbf{K} \approx \mathbf{C}\mathbf{U}^{\text{fast}}\mathbf{C}^T$.

with high probability by sampling $c = \mathcal{O}(k/\epsilon)$ columns of \mathbf{K} to form \mathbf{C} . Let $\mathbf{C} \in \mathbb{R}^{n \times c}$ be formed by this algorithm and $\mathbf{S} \in \mathbb{R}^{n \times s}$ be the leverage score sampling matrix. With $c = \mathcal{O}(k/\epsilon)$ and $s = \mathcal{O}(n^{1/2} k \epsilon^{-3/2})$, the fast model satisfies

$$\|\mathbf{K} - \mathbf{C}\mathbf{U}^{\text{fast}}\mathbf{C}^T\|_F^2 \leq (1 + \epsilon) \|\mathbf{K} - \mathbf{K}_k\|_F^2$$

with high probability.

4.4 Algorithm and Time Complexity

We describe the whole procedure of the fast model in Algorithm 1, where $\mathbf{S} \in \mathbb{R}^{n \times s}$ can be one of the five sketching matrices described in Table 4. Given \mathbf{C} and (the whole or a part of) \mathbf{K} , it takes time

$$\mathcal{O}(s^2 c) + T_{\text{sketch}}$$

to compute \mathbf{U}^{fast} , where T_{sketch} is the time cost of forming the sketches $\mathbf{S}^T \mathbf{C}$ and $\mathbf{S}^T \mathbf{K} \mathbf{S}$ and is described in Table 4. In Table 4 we also show the number of entries of \mathbf{K} that must be observed. From Table 4 we can see that column selection is much more efficient than random projection, and column selection does not require the full observation of \mathbf{K} .

We are particularly interested in the column selection matrix \mathbf{S} corresponding to the row leverage scores of \mathbf{C} . The leverage score sampling described in Algorithm 2 can be efficiently performed. Using the leverage score sampling, it takes time $\mathcal{O}(nc^2/\epsilon)$ (excluding the time of computing $\mathbf{C} = \mathbf{K}\mathbf{P}$) to compute \mathbf{U}^{fast} . For the kernel approximation problem, suppose that we are given n data points of dimension d and that the kernel matrix \mathbf{K} is unknown beforehand. Then it takes $\mathcal{O}(nc^2 d/\epsilon)$ additional time to evaluate the kernel function values.

Algorithm 2 The Leverage Score Sampling Algorithm.

- 1: **Input:** an $n \times c$ matrix \mathbf{C} , an integer s .
- 2: Compute the condensed SVD of \mathbf{C} (by discarding the zero singular values) to obtain the orthonormal bases $\mathbf{U}_G \in \mathbb{R}^{n \times \rho}$, where $\rho = \text{rank}(\mathbf{C}) \leq c$;
- 3: Compute the sampling probabilities $p_i = s\ell_i/\rho$, where $\ell_i = \|\mathbf{e}_i^T \mathbf{U}_G\|_2^2$ is the i -th leverage score;
- 4: Initialize \mathbf{S} to be an matrices of size $n \times 0$;
- 5: **for** $i = 1$ to n **do**
- 6: With probability p_i , add $\sqrt{\frac{c}{s_i}} \mathbf{e}_i$ to be a new column of \mathbf{S} , where \mathbf{e}_i is the i -th standard basis;
- 7: **end for**
- 8: **Output:** \mathbf{S} , whose expected number of columns is s .

4.5 Implementation Details

In practice, the approximation accuracy and numerical stability can be significantly improved by the following techniques and tricks.

If \mathbf{P} and \mathbf{S} are both random sampling matrices, then empirically speaking, enforcing $\mathcal{P} \subset \mathcal{S}$ significantly improves the approximation accuracy. Here \mathcal{P} and \mathcal{S} are the subsets of $[n]$ selected by \mathbf{P} and \mathbf{S} , respectively. Instead of directly sampling s indices from $[n]$ by Algorithm 2, it is better to sample s indices from $[n] \setminus \mathcal{P}$ to form \mathcal{S}' and let $\mathcal{S} = \mathcal{S}' \cup \mathcal{P}$. In this way, $s + c$ columns are sampled. Whether the requirement $\mathcal{P} \subset \mathcal{S}$ improves the accuracy is unknown to us.

Corollary 5 *Theorem 3 still holds when we restrict $\mathcal{P} \subset \mathcal{S}$.*

Proof Let p_1, \dots, p_n be the original sampling probabilities without the restriction $\mathcal{P} \subset \mathcal{S}$. We define the modified sampling probabilities by

$$\tilde{p}_i = \begin{cases} 1 & \text{if } i \in \mathcal{P}; \\ p_i & \text{otherwise.} \end{cases}$$

The column sampling with restriction $\mathcal{P} \subset \mathcal{S}$ amounts to sampling columns according to $\tilde{p}_1, \dots, \tilde{p}_n$. Since $\tilde{p}_i \geq p_i$ for all $i \in [n]$, it follows from Remark 14 that the error bound will not get worse if p_i is replaced by \tilde{p}_i . ■

If \mathbf{S} is the leverage score sampling matrix, we find it better not to scale the entries of \mathbf{S} , although the scaling is necessary for theoretical analysis. According to our observation, the scaling sometimes makes the approximation numerically unstable.

4.6 Additional Properties

When \mathbf{K} is a low-rank matrix, the Nyström method and the prototype model are guaranteed to exactly recover \mathbf{K} (Kumar et al., 2009; Talwalkar and Rostamizadeh, 2010; Wang et al., 2016). We show in the following theorem that the fast model has the same property. We prove the theorem in Appendix E.

Theorem 6 (Exact Recovery) *Let \mathbf{K} be any $n \times n$ symmetric matrix, $\mathbf{P} \in \mathbb{R}^{n \times c}$ and $\mathbf{S} \in \mathbb{R}^{n \times s}$ be any sketching matrices, $\mathbf{C} = \mathbf{K}\mathbf{P}$, and $\mathbf{W} = \mathbf{P}^T \mathbf{C}$. Assume that $\text{rank}(\mathbf{S}^T \mathbf{C}) \geq \text{rank}(\mathbf{W})$. Then $\mathbf{K} = \mathbf{C}(\mathbf{S}^T \mathbf{C})^\dagger (\mathbf{S}^T \mathbf{K}\mathbf{S})(\mathbf{C}^T \mathbf{S})^\dagger \mathbf{C}^T$ if and only if $\text{rank}(\mathbf{K}) = \text{rank}(\mathbf{C})$.*

In the following we establish a lower error bound of the fast model, which implies that to attain the $1 + \epsilon$ Frobenius norm bound relative to the best rank k approximation, the fast model must satisfy

$$c \geq \Omega(k/\epsilon) \quad \text{and} \quad s \geq \Omega(\sqrt{nk/\epsilon}).$$

Notice that the theorem only holds for column selection matrices \mathbf{P} and \mathbf{S} . We prove the theorem in Appendix F.

Theorem 7 (Lower Bound) *Let $\mathbf{P} \in \mathbb{R}^{n \times c}$ and $\mathbf{S} \in \mathbb{R}^{n \times s}$ be any two column selection matrices such that $\mathcal{P} \subset \mathcal{S} \subset [n]$, where \mathcal{P} and \mathcal{S} are the index sets formed by \mathbf{P} and \mathbf{S} , respectively. There exists an $n \times n$ symmetric matrix \mathbf{K} such that*

$$\frac{\|\mathbf{K} - \tilde{\mathbf{K}}_{c,cs}^{\text{fast}}\|_F^2}{\|\mathbf{K} - \mathbf{K}_k\|_F^2} \geq \frac{n-c}{n-k} \left(1 + \frac{2k}{c}\right) + \frac{n-s}{n-k} \frac{k(n-s)}{s^2}, \quad (7)$$

where k is arbitrary positive integer smaller than n , $\mathbf{C} = \mathbf{K}\mathbf{P} \in \mathbb{R}^{n \times c}$, and

$$\tilde{\mathbf{K}}_{c,cs}^{\text{fast}} = \mathbf{C}(\mathbf{S}^T \mathbf{C})^\dagger (\mathbf{S}^T \mathbf{K}\mathbf{S})(\mathbf{C}^T \mathbf{S})^\dagger \mathbf{C}^T$$

is the fast model.

Interestingly, Theorem 7 matches the lower bounds of the Nyström method and the prototype model. When $s = c$, the right-hand side of (7) becomes $\Omega(1 + kn/c^2)$, which is the lower error bound of the Nyström method given by Wang and Zhang (2013). When $s = n$, the right-hand side of (7) becomes $\Omega(1 + k/c)$, which is the lower error bound of the prototype model given by Wang et al. (2016).

5. Extension to CUR Matrix Decomposition

In Section 5.1 we describe the CUR matrix decomposition and establish an improved error bound of CUR in Theorem 8. In Section 5.2 we use sketching to more efficiently compute the \mathbf{U} matrix of CUR. Theorem 8 and Theorem 9 together show that our fast CUR method satisfies $1 + \epsilon$ error bound relative to the best rank k approximation. In Section 5.3 we provide empirical results to intuitively illustrate the effectiveness of our fast CUR. In Section 5.4 we discuss the application of our results beyond the CUR decomposition.

5.1 The CUR Matrix Decomposition

Given any $m \times n$ matrix \mathbf{A} , the CUR matrix decomposition is computed by selecting c columns of \mathbf{A} to form $\mathbf{C} \in \mathbb{R}^{m \times c}$ and r rows of \mathbf{A} to form $\mathbf{R} \in \mathbb{R}^{r \times n}$ and computing the \mathbf{U} matrix such that $\|\mathbf{A} - \mathbf{CUR}\|_F^2$ is small. CUR preserves the sparsity and non-negativity properties of \mathbf{A} ; it is thus more attractive than SVD in certain applications (Mahoney and Drineas, 2009). In addition, with the CUR of \mathbf{A} at hand, the truncated SVD of \mathbf{A} can be very efficiently computed.

A standard way to finding the \mathbf{U} matrix is by minimizing $\|\mathbf{A} - \mathbf{CUR}\|_F^2$ to obtain the optimal \mathbf{U} matrix

$$\mathbf{U}^* = \underset{\mathbf{U}}{\text{argmin}} \|\mathbf{A} - \mathbf{CUR}\|_F^2 = \mathbf{C}^\dagger \mathbf{A} \mathbf{R}^\dagger, \quad (8)$$

which has been used by Stewart (1999); Wang and Zhang (2013); Boutsidis and Woodruff (2014). This approach costs time $\mathcal{O}(mc^2 + nr^2)$ to compute the Moore-Penrose inverse and $\mathcal{O}(m \cdot \min\{c, r\})$ to compute the matrix product. Therefore, even if \mathbf{C} and \mathbf{R} are uniformly sampled from \mathbf{A} , the time cost of CUR is $\mathcal{O}(m \cdot \min\{c, r\})$.

At present the strongest theoretical guarantee is by Boutsidis and Woodruff (2014). They use the adaptive sampling algorithm to select $c = \mathcal{O}(k/\epsilon)$ column and $r = \mathcal{O}(k/\epsilon)$ rows to form \mathbf{C} and \mathbf{R} , respectively, and form $\mathbf{U}^* = \mathbf{C}^\dagger \mathbf{A} \mathbf{R}^\dagger$. The approximation error is bounded by

$$\|\mathbf{A} - \mathbf{C}\mathbf{U}^*\mathbf{R}\|_F^2 \leq (1 + \epsilon)\|\mathbf{A} - \mathbf{A}_k\|_F^2.$$

This result matches the theoretical lower bound up to a constant factor. Therefore this CUR algorithm is near optimal. We establish in Theorem 8 an improved error bound of the adaptive sampling based CUR algorithm, and the constants in the theorem are better than the those in (Boutsidis and Woodruff, 2014). Theorem 8 is obtained by following the idea of Boutsidis and Woodruff (2014) and slightly changing the proof of Wang and Zhang (2013). The proof is in Appendix G.

Theorem 8 *Let \mathbf{A} be any given $m \times n$ matrix, k be any positive integer less than m and n , and $\epsilon \in (0, 1)$ be an arbitrary error parameter. Let $\mathbf{C} \in \mathbb{R}^{m \times c}$ and $\mathbf{R} \in \mathbb{R}^{r \times n}$ be columns and rows of \mathbf{A} selected by the near-optimal column selection algorithm of Boutsidis et al. (2014). When c and r are both greater than $4ke^{-1}(1 + o(1))$, the following inequality holds:*

$$\|\mathbf{A} - \mathbf{C}\mathbf{C}^\dagger \mathbf{A} \mathbf{R}^\dagger \mathbf{R}\|_F^2 \leq (1 + \epsilon)\|\mathbf{A} - \mathbf{A}_k\|_F^2,$$

where the expectation is taken w.r.t. the random column and row selection.

5.2 Fast CUR Decomposition

Analogous to the fast SPSPD matrix approximation model, the CUR decomposition can be sped up while preserving its accuracy. Let $\mathbf{S}_C \in \mathbb{R}^{m \times s_c}$ and $\mathbf{S}_R \in \mathbb{R}^{n \times s_r}$ be any sketching matrices satisfying the approximate matrix multiplication properties. We propose to compute \mathbf{U} more efficiently by

$$\begin{aligned} \tilde{\mathbf{U}} &= \underset{\mathbf{U}}{\operatorname{argmin}} \|\mathbf{S}_C^T \mathbf{A} \mathbf{S}_R - (\mathbf{S}_C^T \mathbf{C}) \mathbf{U} (\mathbf{R} \mathbf{S}_R)\|_F^2 \\ &= \underbrace{(\mathbf{S}_C^T \mathbf{C})^\dagger (\mathbf{S}_C^T \mathbf{A} \mathbf{S}_R)}_{c \times s_c} \underbrace{(\mathbf{R} \mathbf{S}_R)}_{s_r \times s_r}^\dagger, \end{aligned} \quad (9)$$

which costs time

$$\mathcal{O}(s_r r^2 + s_c c^2 + s_c s_r \cdot \min\{c, r\}) + T_{\text{sketch}},$$

where T_{sketch} denotes the time for forming the sketches $\mathbf{S}_C^T \mathbf{A} \mathbf{S}_R$, $\mathbf{S}_C^T \mathbf{C}$, and $\mathbf{R} \mathbf{S}_R$. As for Gaussian projection, SRHT, and count sketch, T_{sketch} are respectively $\mathcal{O}(\min\{s_c, s_r\})$, $\mathcal{O}(m \log(\min\{s_c, s_r\}))$, and $\mathcal{O}(\min\{\mathbf{A}\})$. As for leverage score sampling and uniform sampling, T_{sketch} are respectively $\mathcal{O}(m c^2 + nr^2 + s_c s_r)$ and $\mathcal{O}(s_c s_r)$. Forming the sketches by column selection is more efficient than by random projection.

The following theorem shows that when s_c and s_r are sufficiently large, $\tilde{\mathbf{U}}$ is nearly as good as the best possible \mathbf{U} matrix. In the theorem, leverage score sampling means that \mathbf{S}_C and \mathbf{S}_R sample columns according to the row leverage scores of \mathbf{C} and \mathbf{R}^T , respectively. The proof is in Appendix H.

Theorem 9 *Let $\mathbf{A} \in \mathbb{R}^{m \times n}$, $\mathbf{C} \in \mathbb{R}^{m \times c}$, $\mathbf{R} \in \mathbb{R}^{r \times n}$ be any fixed matrices with $c \ll n$ and $r \ll m$. Let $q = \min\{m, n\}$ and $\hat{q} = \min\{m/c, n/r\}$. The sketching matrices $\mathbf{S}_C \in \mathbb{R}^{m \times s_c}$ and $\mathbf{S}_R \in \mathbb{R}^{n \times s_r}$ are described in Table 5. Assume that $\epsilon^{-1} = o(q)$ or $\epsilon^{-1} = o(\hat{q})$, as shown in the table. The matrix $\tilde{\mathbf{U}}$ is defined in (9). Then the inequality*

$$\|\mathbf{A} - \mathbf{C}\tilde{\mathbf{U}}\mathbf{R}\|_F^2 \leq (1 + \epsilon) \min\|\mathbf{A} - \mathbf{C}\mathbf{U}\mathbf{R}\|_F^2$$

holds with probability at least 0.7.

Table 5: Leverage score sampling means sampling according to the row leverage scores of \mathbf{C} and the column leverage scores of \mathbf{R} , respectively. For uniform sampling, the parameter $\mu(\mathbf{C})$ is the row coherence of \mathbf{C} and $\nu(\mathbf{R})$ is the column coherence of \mathbf{R} .

Sketching	Order of s_c	Order of s_r	Assumption
Leverage Score Sampling	$c\sqrt{q/\epsilon}$	$r\sqrt{q/\epsilon}$	$\epsilon^{-1} = o(q)$
Uniform Sampling	$\frac{\mu(\mathbf{C})c\sqrt{q/\epsilon}}{\epsilon}$	$\frac{\nu(\mathbf{R})r\sqrt{q/\epsilon}}{\epsilon}$	$\epsilon^{-1} = o(\hat{q})$
Gaussian Projection	$\sqrt{\frac{m}{\epsilon}}(c + \log \frac{m}{\epsilon})$	$\sqrt{\frac{n}{\epsilon}}(r + \log \frac{n}{\epsilon})$	$\epsilon^{-1} = o(q)$
SRHT	$\sqrt{\frac{m}{\epsilon}}(c + \log \frac{m}{\epsilon}) \log(m)$	$\sqrt{\frac{n}{\epsilon}}(r + \log \frac{n}{\epsilon}) \log(n)$	$\epsilon^{-1} = o(\hat{q})$
Count Sketch	$c\sqrt{q/\epsilon}$	$r\sqrt{q/\epsilon}$	$\epsilon^{-1} = o(q)$

As for leverage score sampling, uniform sampling, and count sketch, the sketch sizes $s_c = \mathcal{O}(c\sqrt{q/\epsilon})$ and $s_r = \mathcal{O}(r\sqrt{q/\epsilon})$ suffice, where $q = \min\{m, n\}$. As for Gaussian projection and SRHT, much smaller sketch sizes are required: $s_c = \tilde{\mathcal{O}}(\sqrt{mc/\epsilon})$ and $s_r = \tilde{\mathcal{O}}(\sqrt{nr/\epsilon})$ suffice. However, these random projection methods are inefficient choices in this application and only have theoretical interest. Only column sampling methods have linear time complexities. If \mathbf{S}_C and \mathbf{S}_R are leverage score sampling matrices (according to the row leverage scores of \mathbf{C} and \mathbf{R}^T , respectively), it follows from Theorem 9 that $\tilde{\mathbf{U}}$ with $1 + \epsilon$ bound can be computed in time

$$\mathcal{O}(s_r r^2 + s_c c^2 + s_c s_r \cdot \min\{c, r\}) + T_{\text{sketch}} = \mathcal{O}(\epsilon r \epsilon^{-1} \cdot \min\{m, n\} \cdot \min\{c, r\}),$$

which is linear in $\mathcal{O}(\min\{m, n\})$.

5.3 Empirical Comparisons

To intuitively demonstrate the effectiveness of our method, we conduct a simple experiment on a 1920 \times 1168 natural image obtained from the internet. We first uniformly sample $c = 100$ columns to form \mathbf{C} and $r = 100$ rows to form \mathbf{R} , and then compute the \mathbf{U} matrix by varying s_c and s_r . We show the image $\mathbf{A} = \mathbf{C}\mathbf{U}\mathbf{R}$ in Figure 2.

Figure 2(b) is obtained by computing the \mathbf{U} matrix according to (8), which is the best possible result when \mathbf{C} and \mathbf{R} are fixed. The \mathbf{U} matrix of Figure 2(c) is computed according to Drines et al. (2008):

$$\mathbf{U} = (\mathbf{P}_R^T \mathbf{A} \mathbf{P}_C)^\dagger,$$

where \mathbf{P}_C and \mathbf{P}_R are column selection matrices such that $\mathbf{C} = \mathbf{A}\mathbf{P}_C$ and $\mathbf{R} = \mathbf{P}_R^T\mathbf{A}$. This is equivalently to (9) by setting $\mathbf{S}_C = \mathbf{P}_R$ and $\mathbf{S}_R = \mathbf{P}_C$. Obviously, this setting leads to very poor quality. In Figures 2(c) and (d) the sketching matrices \mathbf{S}_C and \mathbf{S}_R are uniform sampling matrices. The figures show that when s_c and s_r are moderately greater than r and c , respectively, the approximation quality is significantly improved. Especially, when $s_c = 4r$ and $s_r = 4c$, the approximation quality is nearly as good as using the optimal \mathbf{U} matrix defined in (8).

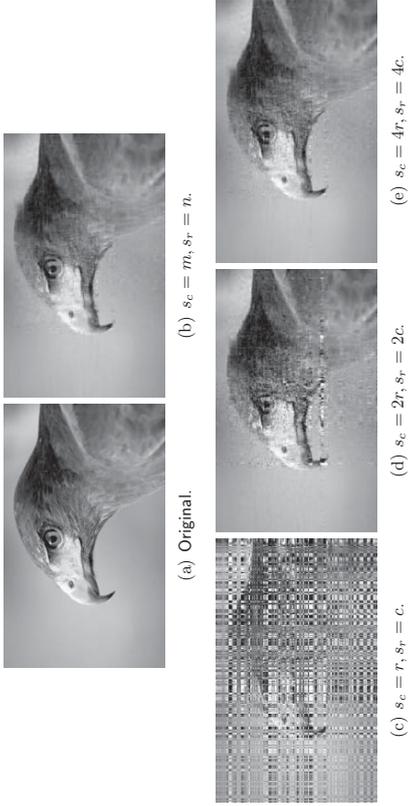

Figure 2: (a): the original 1920×1168 image. (b) to (e): CUR decomposition with $c = r = 100$ and different settings of s_c and s_r .

5.4 Discussions

We note that we are not the first to use row and column sampling to solve the CUR problem more efficiently, though we are the first to provide rigorous error analysis. Previous work has exploited similar ideas as heuristics to speed up computation and to avoid visiting every entry of \mathbf{A} . For example, the MEKA method (Si et al., 2014a) partitions the kernel matrix \mathbf{K} into b^2 blocks $\mathbf{K}^{(i,j)}$ ($i = 1, \dots, b$ and $j = 1, \dots, b$), and requires solving

$$\mathbf{L}^{(i,j)} = \operatorname{argmin}_{\mathbf{L}} \|\mathbf{W}^{(i)}\mathbf{L}\mathbf{W}^{(j)T} - \mathbf{K}^{(i,j)}\|_F^2$$

for all $i \in [b]$, $j \in [b]$, and $i \neq j$. Since $\mathbf{W}^{(i)}$ and $\mathbf{W}^{(j)}$ have much more rows than columns, Si et al. (2014a) proposed to approximately solve the linear system by uniformly sampling rows from $\mathbf{W}^{(i)}$ and $\mathbf{K}^{(i,i)}$ and columns from $(\mathbf{W}^{(j)})^T$ and $\mathbf{K}^{(i,j)}$, and they noted that this heuristic works pretty well. The basic ideas of our fast CUR and their MEKA are the same; their experiments demonstrate the effectiveness and efficiency of this approach, and

Table 6: A summary of the datasets for kernel approximation.

Dataset	Letters	PenDigit	Cpustall	Mushrooms	WineQuality
#Instance	15,000	10,992	8,192	8,124	4,898
#Attribute	16	16	12	112	12
σ (when $\eta = 0.90$)	0.400	0.101	0.075	1.141	0.314
σ (when $\eta = 0.99$)	0.590	0.178	0.180	1.960	0.486

our analysis answers why this approach is correct. This also implies that our algorithms and analysis may have broad applications and impacts beyond the CUR decomposition and SPSPD matrix approximation.

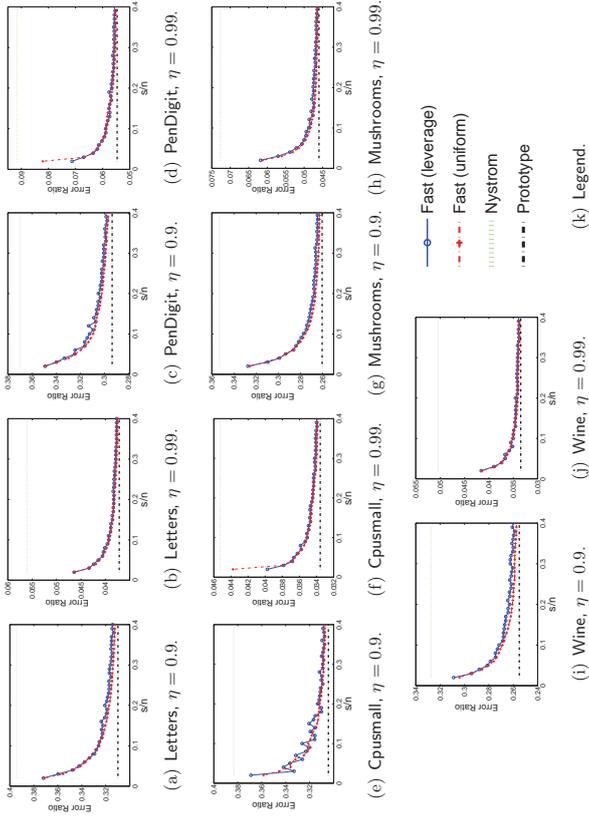

Figure 3: The plot of $\frac{\|\mathbf{K} - \mathbf{CUC}^T\|_F^2}{\|\mathbf{K}\|_F^2}$ against the approximation error $\|\mathbf{K} - \mathbf{CUC}^T\|_F^2 / \|\mathbf{K}\|_F^2$, where \mathbf{C} contains $c = \lfloor n/100 \rfloor$ column of $\mathbf{K} \in \mathbb{R}^{n \times n}$ selected by uniform sampling.

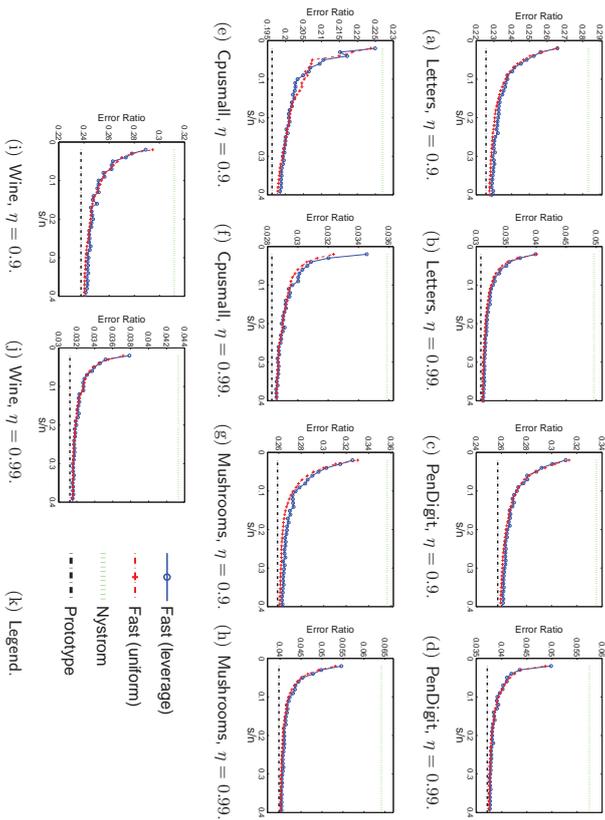

Figure 4: The plot of $\frac{\sigma}{n}$ against the approximation error $\|\mathbf{K} - \mathbf{C}\mathbf{U}\mathbf{C}^T\|_F^2 / \|\mathbf{K}\|_F^2$, where \mathbf{C} contains $c = \lceil n/100 \rceil$ column of $\mathbf{K} \in \mathbb{R}^{n \times n}$ selected by the uniform+adaptive² sampling algorithm (Wang et al., 2016).

6. Experiments

In this section we conduct several sets of illustrative experiments to show the effect of the \mathbf{U} matrix. We compare the three methods with different settings of c and s . We do not compare with other kernel approximation methods for the reasons stated in Section 3.2.2.

6.1 Setup

Let $\mathbf{X} = [\mathbf{x}_1, \dots, \mathbf{x}_n]$ be the $d \times n$ data matrix, and \mathbf{K} be the RBF kernel matrix with each entry computed by $K_{ij} = \exp(-\frac{\|\mathbf{x}_i - \mathbf{x}_j\|_2^2}{2\sigma^2})$ where σ is the scaling parameter.

When comparing the kernel approximation error $\|\mathbf{K} - \mathbf{C}\mathbf{U}\mathbf{C}^T\|_F^2$, we set the scaling parameter σ in the following way. We let $k = \lceil n/100 \rceil$ and define

$$\eta = \frac{\|\mathbf{K}_k\|_F^2}{\|\mathbf{K}\|_F^2} = \frac{\sum_{i=1}^k \sigma^2(\mathbf{K})}{\sum_{i=1}^n \sigma^2(\mathbf{K})},$$

which indicate the importance of the top one percent singular values of \mathbf{K} . In general η grows with σ . We set σ such that $\eta = 0.9$ or 0.99 .

All the methods are implemented in MATLAB and run on a laptop with Intel i5 2.5GHz CPU and 8GB RAM. To compare the running time, we set MATLAB in the single thread mode.

6.2 Kernel Approximation Accuracy

We conduct experiments on several datasets available at the LIBSVM site. The datasets are summarized in Table 6. In this set of experiments, we study the effect of the \mathbf{U} matrices. We use two methods to form $\mathbf{C} \in \mathbb{R}^{n \times c}$: uniform sampling and the uniform+adaptive² sampling (Wang et al., 2016); we fix $c = \lceil n/100 \rceil$. For our fast model, we use two kinds of sketching matrices $\mathbf{S} \in \mathbb{R}^{n \times s}$: uniform sampling and leverage score sampling; we vary s from $2c$ to $40c$. We plot $\frac{\sigma}{n}$ against the approximation error $\|\mathbf{K} - \mathbf{C}\mathbf{U}\mathbf{C}^T\|_F^2 / \|\mathbf{K}\|_F^2$ in Figures 3 and 4. The Nystrom method and the prototype model are included for comparison.

Figures 3 and 4 show that the fast SPSSD matrix approximation model is significantly better than the Nystrom method when s is slightly larger than c , e.g., $s = 2c$. Recall that the prototype model is a special case of the fast model where $s = n$. We can see that the fast model is nearly as accurate as the prototype model when s is far smaller than n , e.g., $s = 0.2n$.

The results also show that using uniform sampling and leverage score sampling to generate \mathbf{S} does not make much difference. Thus, in practice, one can simply compute \mathbf{S} by uniform sampling.

By comparing the results in Figures 3 and 4, we can see that computing \mathbf{C} by uniform+adaptive² sampling is substantially better than uniform sampling. However, adaptive sampling requires the full observation of \mathbf{K} ; thus with uniform+adaptive² sampling, our fast model does not have much advantage over the prototype model in terms of time efficiency. Our main focus of this work is the \mathbf{U} matrix, so in the rest of the experiments we simply use uniform sampling to compute \mathbf{C} .

6.3 Approximate Kernel Principal Component Analysis

We apply the three methods to approximately compute kernel principal component analysis (KPCA), and contrast with the exact solution. The experiment setting follows Zhang and Kwok (2010). We fix k and vary c . For our fast model, we set $s = 2c$, $4c$, or $8c$. Since computing \mathbf{S} by uniform sampling or leverage score sampling yields the same empirical performance, we use only uniform sampling. Let $\mathbf{C}\mathbf{U}\mathbf{C}^T$ be the low-rank approximation formed by the three methods. Let $\tilde{\mathbf{V}}\tilde{\mathbf{A}}\tilde{\mathbf{V}}^T$ be the k -eigenvalue decomposition of $\mathbf{C}\mathbf{U}\mathbf{C}^T$.

6.3.1 QUALITY OF THE APPROXIMATE EIGENVECTORS

Let $\mathbf{U}_{k,k} \in \mathbb{R}^{n \times k}$ contain the top k eigenvectors of \mathbf{K} . In the first set of experiments, we measure the distance between $\mathbf{U}_{k,k}$ and the approximate eigenvectors $\tilde{\mathbf{V}}$ by

$$\text{Misalignment} = \frac{1}{k} \|\mathbf{U}_{k,k} - \tilde{\mathbf{V}}\tilde{\mathbf{V}}^T \mathbf{U}_{k,k}\|_F^2 \in [0, 1]. \quad (10)$$

Small misalignment indicates high approximation quality. We fix $k = 3$.

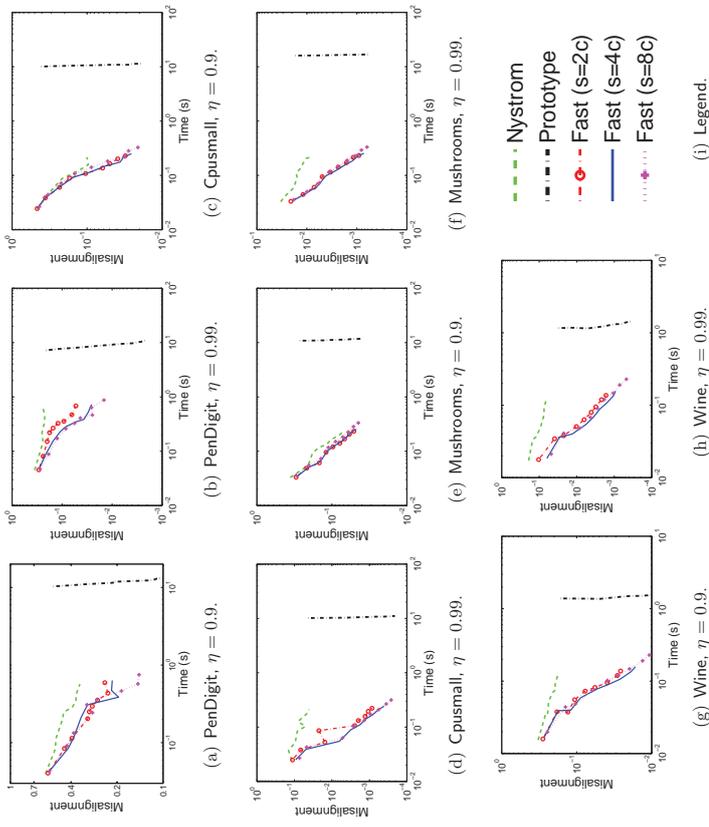

Figure 5: The plot of (log-scale) elapsed time against the (log-scale) misalignment defined in (10).

We conduct experiments on the datasets summarized in Table 6. We record the elapsed time of the entire procedure—computing (part of) the kernel matrix, computing \mathbf{C} and \mathbf{U} by the kernel approximation methods, computing the k -eigenvalue decomposition of \mathbf{CUC}^T . We plot the elapsed time against the misalignment defined in Figure 5. Results on the Letters dataset are not reported because the exact k -eigenvalue decomposition on MATLAB ran out of memory, making it impossible to calculate the misalignment.

At the end of Section 3.2.1 we have mentioned the importance of memory cost of the kernel approximation methods and that all three compared methods cost $\mathcal{O}(nc + nd)$ memory. Since n and d are fixed, we plot c against the misalignment in Figure 6 to show the memory efficiency.

The results show that using the same amount of time or memory, the misalignment incurred by the Nystrom method is usually tens of times higher than our fast model. The

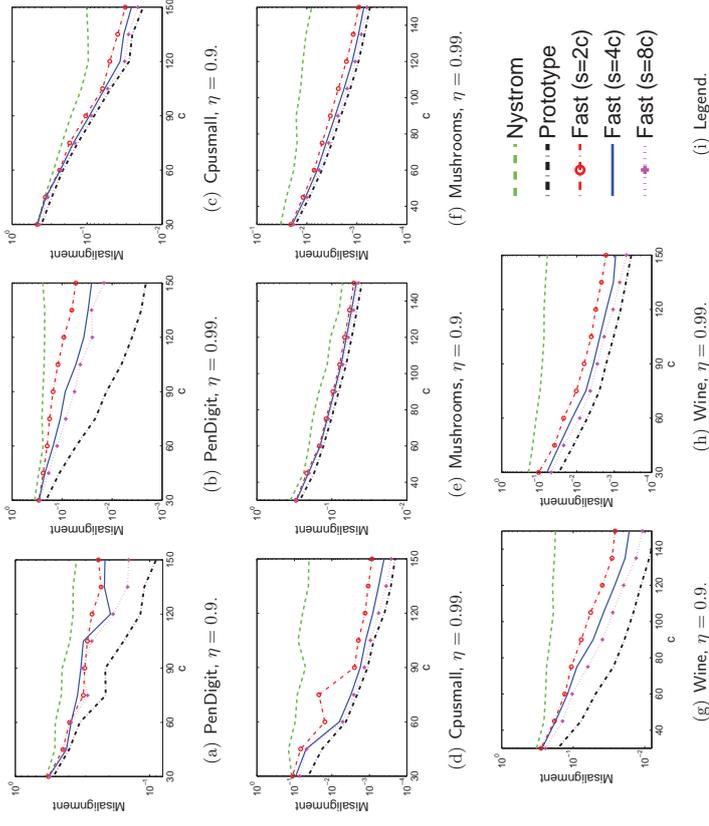

Figure 6: The plot of c against the (log-scale) misalignment defined in (10).

Table 7: A summary of the datasets for clustering and classification.

Dataset	MNIST	PenDigit	USPS	Mushrooms	Gisette	DNA
#Instance	60,000	10,992	9,298	8,124	7,000	2,000
#Attribute	780	16	256	112	5,000	180
#Class	10	10	10	2	2	3
Scaling Parameter σ	10	0.7	15	3	50	4

experiment also shows that with fixed c , the fast model is nearly as accurate as the prototype model when $s = 8c \ll n$.

6.3.2 QUALITY OF THE GENERALIZATION

In the second set of experiments, we test the generalization performance of the kernel approximation methods on classification tasks. The classification datasets are described in

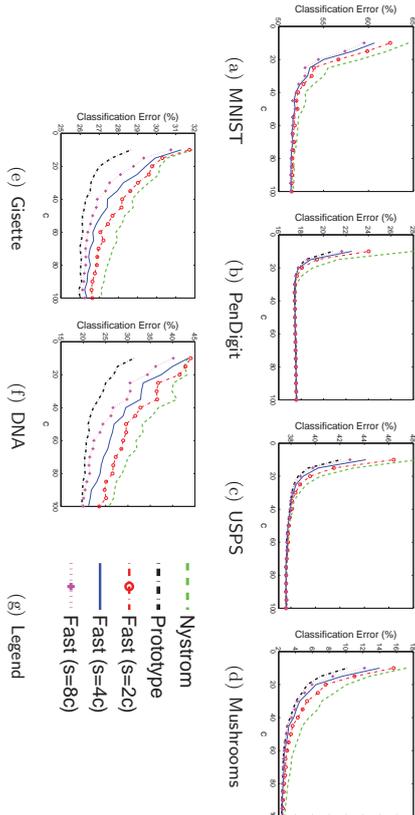

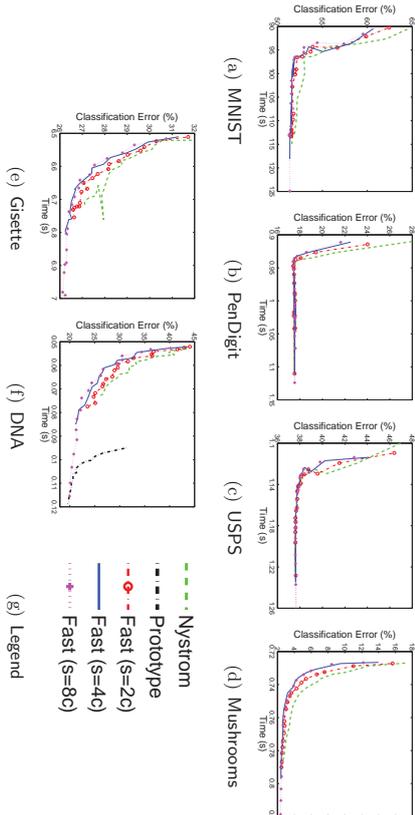

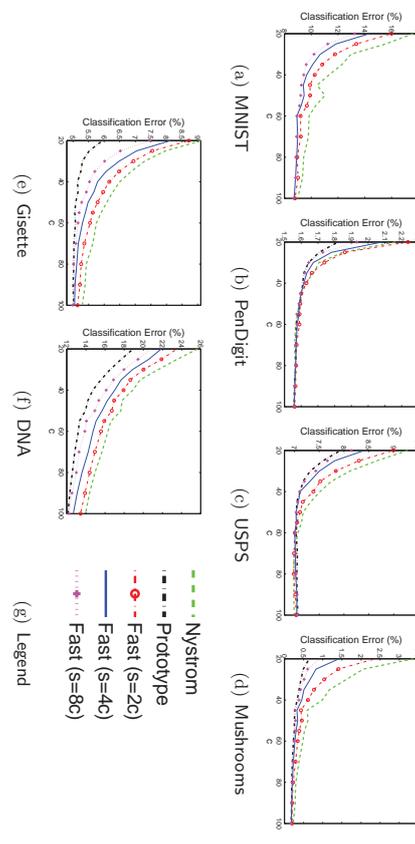

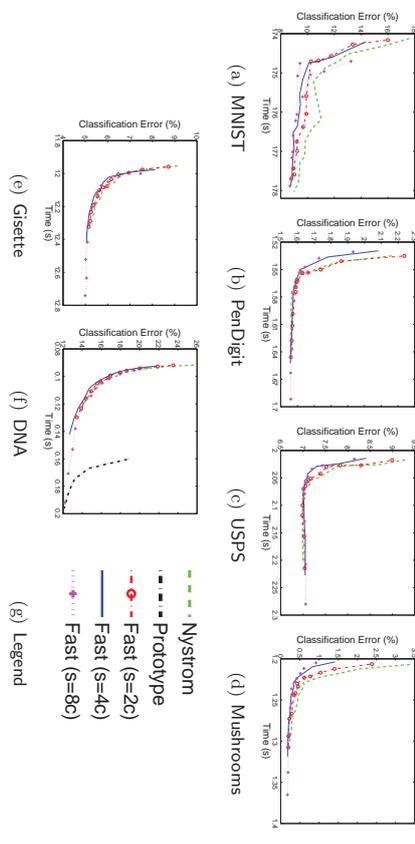

Figure 7: The plot of c against the classification error. Here $k = 3$.Figure 8: The plot of elapsed time against the classification error. Here $k = 3$.

Table 7. For each dataset, we randomly sample $n_1 = 50\%$ data points for training and the rest 50% for test. In this set of experiments, we set $k = 3$ and $k = 10$.

We let $\mathbf{K} \in \mathbb{R}^{n_1 \times n_1}$ be the RBF kernel matrix of the training data and $\mathbf{k}(\mathbf{x}) \in \mathbb{R}^{n_1}$ be defined by $[\mathbf{k}(\mathbf{x})]_i = \exp(-\frac{\|\mathbf{x} - \mathbf{x}_i\|^2}{2\sigma^2})$, where \mathbf{x}_i is the i -th training data point. In the training step, we approximately compute the top k eigenvalues and eigenvectors, and denote

Figure 9: The plot of c against the classification error. Here $k = 10$.Figure 10: The plot of elapsed time against the classification error. Here $k = 10$.

$\tilde{\mathbf{A}} \in \mathbb{R}^{k \times k}$ and $\tilde{\mathbf{V}} \in \mathbb{R}^{n_1 \times k}$. The feature vector (extracted by KPCA) of the i -th training data point is the i -th column of $\tilde{\mathbf{A}}^{0.5} \tilde{\mathbf{V}}^T$. In the test step, the feature vector of test data \mathbf{x} is $\tilde{\mathbf{A}}^{-0.5} \tilde{\mathbf{V}}^T \mathbf{k}(\mathbf{x})$. Then we put the training labels and training and test features into the MATLAB K-nearest-neighbor classifier `knnclassify` to classify the test data. We fix the number of nearest neighbors to be 10. The scaling parameters of each dataset are listed in

Table 7. Since the kernel approximation methods are randomized, we repeat the training and test procedure 20 times and record the average elapsed time and average classification error.

We plot c against the classification error in Figures 7 and 9, and plot the elapsed time (excluding the time cost of KNN) against the classification error in Figures 8 and 10. Using the same amount of memory, the fast model is significantly better than the Nyström method, especially when c is small. Using the same amount of time, the fast model outperforms the Nyström method by one to two percent of classification error in many cases, and it is at least as good as the Nyström method in the rest cases. This set of experiments also indicate that the fast model with $s = 4c$ or $8c$ has the best empirical performance.

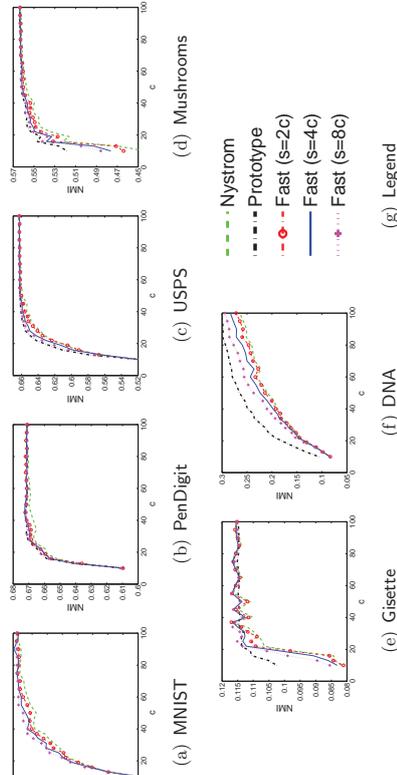

Figure 11: The plot of c against NMI.

6.4 Approximate Spectral Clustering

Following the work of Fowlkes et al. (2004), we evaluate the performance of the kernel approximation methods on the spectral clustering task. We conduct experiments on the datasets summarized in Table 7.

We describe the approximate spectral clustering in the following. The target is to cluster n data points into k classes. We use the RBF kernel matrix \mathbf{K} as the weigh matrix and let $\mathbf{CUC}^T \approx \mathbf{K}$ be the low-rank approximation. The degree matrix $\mathbf{D} = \text{diag}(\mathbf{d})$ is a diagonal matrix with $\mathbf{d} = \mathbf{CUC}^T \mathbf{1}_n$, and the normalized graph Laplacian is $\mathbf{L} = \mathbf{I}_n - \mathbf{D}^{-1/2}(\mathbf{CUC}^T)\mathbf{D}^{-1/2}$. The bottom k eigenvectors of \mathbf{L} are the top k eigenvectors of

$$\underbrace{(\mathbf{D}^{-1/2}\mathbf{C})}_{n \times c} \underbrace{\mathbf{U}}_{c \times c} \underbrace{(\mathbf{D}^{-1/2}\mathbf{C}^T)}_{c \times n},$$

which can be efficiently computed according to Appendix A. We denote the top k eigenvectors by $\tilde{\mathbf{V}} \in \mathbb{R}^{n \times k}$. We normalize the rows of $\tilde{\mathbf{V}}$ and take the normalized rows

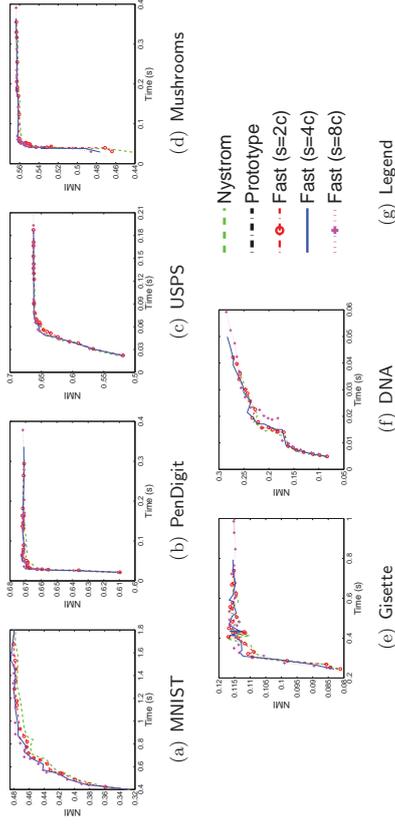

Figure 12: The plot of elapsed time against NMI.

of $\tilde{\mathbf{V}}$ as the input of the k -means clustering. Since the matrix approximation methods are randomized, we repeat this procedure 20 times and record the average elapsed time and the average normalized mutual information (NMI)³ of clustering.

We plot c against NMI in Figure 11 and the elapsed time (excluding the time cost of k -means) against NMI in Figure 12. Figure 11 shows that using the same amount of memory, the performance of the fast model is better than the Nyström method. Using the same amount of time, the fast model and the Nyström method have almost the same performance, and they are both better than the prototype model.

7. Concluding Remarks

In this paper we have studied the fast SPSPD matrix approximation model for approximating large-scale SPSPD matrix. We have shown that our fast model potentially costs time linear in n , while it is nearly as accurate as the best possible approximation. The fast model is theoretically better than the Nyström method and the prototype model because the latter two methods cost time quadratic in n to attain the same theoretical guarantee. Experiments show that our fast model is nearly as accurate as the prototype model and nearly as efficient as the Nyström method.

The technique of the fast model can be straightforwardly applied to speed up the CUR matrix decomposition, and theoretical analysis shows that the accuracy is almost unaffected. In this way, for any $m \times n$ large-scale matrix, the time cost of computing the \mathbf{U} matrix drops from $\mathcal{O}(mn)$ to $\mathcal{O}(\min\{m, n\})$.

3. NMI is a standard metric of clustering. NMI is between 0 and 1. Big NMI indicates good clustering performance.

Appendix A. Approximately Solving the Eigenvalue Decomposition and Matrix Inversion

In this section we show how to use the SPSPD matrix approximation methods to speed up eigenvalue decomposition and linear system. The two lemmas are well known results. We show them here for the sake of self-containing.

Lemma 10 (Approximate Eigenvalue Decomposition) *Given $\mathbf{C} \in \mathbb{R}^{n \times c}$ and $\mathbf{U} \in \mathbb{R}^{c \times c}$. Then the eigenvalue decomposition of $\tilde{\mathbf{K}} = \mathbf{C}\mathbf{U}\mathbf{C}^T$ can be computed in time $\mathcal{O}(nc^2)$.*

Proof It cost $\mathcal{O}(nc^2)$ time to compute the SVD

$$\mathbf{C} = \underbrace{\mathbf{U}_c}_{n \times c} \underbrace{\Sigma_c}_{c \times c} \underbrace{\mathbf{V}_c^T}_{c \times c}$$

and $\mathcal{O}(c^3)$ time to compute $\mathbf{Z} = (\Sigma_c \mathbf{V}_c^T) \mathbf{U} (\Sigma_c \mathbf{V}_c^T)^T \in \mathbb{R}^{c \times c}$. It costs $\mathcal{O}(c^3)$ time to compute the eigenvalue decomposition $\mathbf{Z} = \mathbf{V}_z \mathbf{A}_z \mathbf{V}_z^T$. Combining the results above, we obtain

$$\begin{aligned} \mathbf{C}\mathbf{U}\mathbf{C}^T &= (\mathbf{U}_c \Sigma_c \mathbf{V}_c^T) \mathbf{U} (\mathbf{U}_c \Sigma_c \mathbf{V}_c^T)^T \\ &= \mathbf{U}_c \mathbf{Z} \mathbf{U}_c^T = (\mathbf{U}_c \mathbf{V}_z \mathbf{V}_z^T) \mathbf{A}_z (\mathbf{U}_c \mathbf{V}_z)^T. \end{aligned}$$

It then cost time $\mathcal{O}(nc^2)$ to compute the matrix product $\mathbf{U}_c \mathbf{V}_z$. Since $(\mathbf{U}_c \mathbf{V}_z)$ has orthonormal columns and \mathbf{A}_z is diagonal matrix, the eigenvalue decomposition of $\mathbf{C}\mathbf{U}\mathbf{C}^T$ is solved. The total time cost is $\mathcal{O}(nc^2) + \mathcal{O}(c^3) = \mathcal{O}(nc^2)$. \blacksquare

Lemma 11 (Approximately Solving Matrix Inversion) *Given $\mathbf{C} \in \mathbb{R}^{n \times c}$, SPSPD matrix $\mathbf{U} \in \mathbb{R}^{c \times c}$, vector $\mathbf{y} \in \mathbb{R}^n$, and arbitrary positive real number α . Then it costs time $\mathcal{O}(nc^2)$ to solve the $n \times n$ linear system $(\mathbf{C}\mathbf{U}\mathbf{C}^T + \alpha \mathbf{I}_n) \mathbf{w} = \mathbf{y}$ to obtain $\mathbf{w} \in \mathbb{R}^n$.*

In addition, if the SVD of \mathbf{C} is given, then it takes only $\mathcal{O}(c^3 + nc)$ time to solve the linear system.

Proof Since the matrix $(\mathbf{C}\mathbf{U}\mathbf{C}^T + \alpha \mathbf{I}_n)$ is nonsingular when $\alpha > 0$ and \mathbf{U} is SPSPD, the solution is $\mathbf{w}^* = (\mathbf{C}\mathbf{U}\mathbf{C}^T + \alpha \mathbf{I}_n)^{-1} \mathbf{y}$. Instead of directly computing the matrix inversion, we can expand the matrix inversion by the Sherman-Morrison-Woodbury matrix identity and obtain

$$(\mathbf{C}\mathbf{U}\mathbf{C}^T + \alpha \mathbf{I}_n)^{-1} = \alpha^{-1} \mathbf{I}_n - \alpha^{-1} \mathbf{C} (\alpha \mathbf{U}^{-1} + \mathbf{C}^T \mathbf{C})^{-1} \mathbf{C}^T.$$

Thus the solution to the linear system is

$$\mathbf{w}^* = \alpha^{-1} \mathbf{y} - \underbrace{\alpha^{-1} \mathbf{C}}_{n \times c} \underbrace{(\alpha \mathbf{U}^{-1} + \mathbf{C}^T \mathbf{C})^{-1}}_{c \times c} \underbrace{\mathbf{C}^T}_{c \times n} \mathbf{y}.$$

Suppose we are given only \mathbf{C} and \mathbf{U} . The matrix multiplication $\mathbf{C}^T \mathbf{C}$ costs time $\mathcal{O}(nc^2)$, the matrix inversions cost time $\mathcal{O}(c^3)$, and multiplying matrix with vector costs time $\mathcal{O}(nc)$. Thus the total time cost is $\mathcal{O}(nc^2) + \mathcal{O}(c^3) + \mathcal{O}(nc) = \mathcal{O}(nc^2)$.

Suppose we are given \mathbf{U} and the SVD $\mathbf{C} = \mathbf{U}_c \Sigma_c \mathbf{V}_c^T$. The matrix product

$$\mathbf{C}^T \mathbf{C} = \mathbf{V}_c \Sigma_c \mathbf{U}_c^T \mathbf{U}_c \Sigma_c \mathbf{V}_c = \mathbf{V}_c \Sigma_c^2 \mathbf{V}_c$$

can be computed in time $\mathcal{O}(c^3)$. Thus the total time cost is merely $\mathcal{O}(c^3 + nc)$. \blacksquare

Appendix B. Proof of Theorem 1

The prototype model trivially satisfies requirement R1 with $\epsilon = 0$. However, it violates requirement R2 because computing the \mathbf{U} matrix by solving $\min_{\mathbf{U}} \|\mathbf{K} - \mathbf{C}\mathbf{U}\mathbf{C}^T\|_F^2$ costs time $\mathcal{O}(n^2c)$.

For the Nystrom method, we provide such an adversarial case that assumptions A1 and A2 can both be satisfied and that requirements R1 and R2 cannot hold simultaneously. The adversarial case is the block diagonal matrix

$$\mathbf{K} = \text{diag}(\underbrace{\mathbf{B}, \dots, \mathbf{B}}_{k \text{ blocks}}),$$

where

$$\mathbf{B} = (1-a) \mathbf{I}_p + \alpha \mathbf{1}_p \mathbf{1}_p^T, \quad a < 1, \quad \text{and } p = \frac{n}{k},$$

and let $a \rightarrow 1$. Wang et al. (2016) showed that sampling $c = 3k\gamma^{-1}(1 + o(1))$ columns of \mathbf{K} to form \mathbf{C} makes assumptions A1 and A2 in Question 1 be satisfied. This indicates that \mathbf{C} is a good sketch of \mathbf{K} . The problem is caused by the way the \mathbf{U}^{NYS} matrix is computed. Wang and Zhang (2013, Theorem 12) showed that to make requirement R1 in Question 1 satisfied, c must be greater than $\Omega(\sqrt{nk}/(\epsilon + \gamma))$. Thus it takes time $\mathcal{O}(nc^2) = \Omega(n^2k/(\epsilon + \gamma))$ to compute the rank- k eigenvalue decomposition of $\mathbf{C}\mathbf{U}^{\text{NYS}}\mathbf{C}^T$ or the linear system $(\mathbf{C}\mathbf{U}^{\text{NYS}}\mathbf{C}^T + \alpha \mathbf{I}_n) \mathbf{w} = \mathbf{y}$. Thus, requirement R2 is violated.

Appendix C. Proof of Lemma 2

Lemma 2 is a simplified version of Lemma 12. We prove Lemma 12 in the subsequent subsections. In the lemma, leverage score sampling means that the sampling probabilities are proportional to the row leverage scores of $\mathbf{U} \in \mathbb{R}^{n \times k}$. For uniform sampling, $\mu(\mathbf{U})$ is the row coherence of \mathbf{U} .

Lemma 12 Let $\mathbf{U} \in \mathbb{R}^{n \times k}$ be any fixed matrix with orthonormal columns and $\mathbf{B} \in \mathbb{R}^{n \times d}$ be any fixed matrix. Let $\mathbf{S} \in \mathbb{R}^{n \times s}$ be any sketching matrix described in Table 8. Then

$$\begin{aligned} \mathbb{P}\left\{\|\mathbf{U}^T \mathbf{S} \mathbf{S}^T \mathbf{U} - \mathbf{I}_k\|_2 \geq \eta\right\} &\leq \delta_1 && \text{(Property 1),} \\ \mathbb{P}\left\{\|\mathbf{U}^T \mathbf{B} - \mathbf{U}^T \mathbf{S} \mathbf{S}^T \mathbf{B}\|_F^2 \geq \epsilon \|\mathbf{B}\|_F^2\right\} &\leq \delta_2 && \text{(Property 2),} \\ \mathbb{P}\left\{\|\mathbf{U}^T \mathbf{B} - \mathbf{U}^T \mathbf{S} \mathbf{S}^T \mathbf{B}\|_2^2 \geq \epsilon' \|\mathbf{B}\|_2^2 + \frac{\epsilon'}{k} \|\mathbf{B}\|_F^2\right\} &\leq \delta_3 && \text{(Property 3).} \end{aligned}$$

Table 8: The sketch size s for satisfying the three properties. For SRHT, we define $\lambda = (1 + \sqrt{8k-1} \log(100n))^2$ and $\lambda' = (1 + \sqrt{4k-1} \log \frac{nd}{k\delta_1})^2$.

C.1 Column Selection

In this subsection we prove Property 1 and Property 2 of leverage score sampling and uniform sampling. We cite the following lemma from (Wang et al., 2016); the lemma was firstly proved by the work Drineas et al. (2008); Gittens (2011); Woodruff (2014).

Lemma 13 Let $\mathbf{U} \in \mathbb{R}^{n \times k}$ be any fixed matrix with orthonormal columns. The column selection matrix $\mathbf{S} \in \mathbb{R}^{n \times s}$ samples s columns according to arbitrary probabilities p_1, p_2, \dots, p_n . Assume $\alpha \geq k$ and

$$\max_{i \in [n]} \frac{\|\mathbf{u}_i\|_2^2}{p_i} \leq \alpha.$$

If $s \geq \alpha \frac{6+2\eta}{3\eta^2} \log(k/\delta_1)$, it holds that

$$\mathbb{P}\left\{\|\mathbf{I}_k - \mathbf{U}^T \mathbf{S} \mathbf{S}^T \mathbf{U}\|_2 \geq \eta\right\} \leq \delta_1.$$

If $s \geq \frac{\alpha}{\epsilon \delta_2}$, it holds that

$$\mathbb{P}\left\{\|\mathbf{U} \mathbf{B} - \mathbf{U}^T \mathbf{S} \mathbf{S}^T \mathbf{B}\|_F^2 \geq \epsilon \|\mathbf{B}\|_F^2\right\} \leq \delta_2.$$

Leverage score sampling satisfies $\max_{i \in [n]} \frac{\|\mathbf{u}_i\|_2^2}{p_i} \leq k$. Uniform sampling satisfies $\max_{i \in [n]} \frac{\|\mathbf{u}_i\|_2^2}{p_i} \leq \mu(\mathbf{U})k$, where $\mu(\mathbf{U})$ is the row coherence of \mathbf{U} . Then Property 1 and Property 2 of the two column sampling methods follow from Lemma 13.

Remark 14 Let p_1, \dots, p_n be the sampling probabilities corresponding to the leverage score sampling or uniform sampling, and let $\tilde{p}_i \in [p_i, 1]$ for all $i \in [n]$ be arbitrary. For all $i \in [n]$, if the i -th column is sampled with probability \tilde{p}_i and scaled by $\frac{1}{\sqrt{\tilde{p}_i}}$ if it gets sampled, then Lemma 2 still holds. This can be easily seen from the proof of the above lemma (in (Wang et al., 2016)). Intuitively, it indicates that if we increase the sampling probabilities, the resulting error bound will not get worse.

C.2 Count Sketch

Count sketch stems from the data stream literature (Charikar et al., 2004; Thorup and Zhang, 2012). Theoretical guarantees were first shown by Weinberger et al. (2009); Pham and Pagh (2013); Clarkson and Woodruff (2013). Meng and Mahoney (2013); Nelson and Nguyen (2013) strengthened and simplified the proofs. Because the proof is involved, we will not show the proof here. The readers can refer to (Meng and Mahoney, 2013; Nelson and Nguyen, 2013; Woodruff, 2014) for the proof.

C.3 Property 1 and Property 2 of SRHT

The properties of SRHT were established in the previous work (Drineas et al., 2011; Lu et al., 2013; Tropp, 2011). Following (Tropp, 2011), we show a simple proof of the properties of SRHT. Our analysis is based on the following two key observations.

- The scaled Walsh-Hadamard matrix $\frac{1}{\sqrt{n}} \mathbf{H}_n$ and the diagonal matrix \mathbf{D} are both orthogonal, so $\frac{1}{\sqrt{n}} \mathbf{D} \mathbf{H}_n$ is also orthogonal. If \mathbf{U} has orthonormal columns, the matrix $\frac{1}{\sqrt{n}} (\mathbf{D} \mathbf{H}_n)^T \mathbf{U}$ has orthonormal columns.
- For any fixed matrix $\mathbf{U} \in \mathbb{R}^{n \times k}$ ($k \ll n$) with orthonormal columns, the matrix $\frac{1}{\sqrt{n}} (\mathbf{D} \mathbf{H}_n)^T \mathbf{U} \in \mathbb{R}^{n \times k}$ has low row coherence with high probability. Tropp (2011) showed that the row coherence of $\frac{1}{\sqrt{n}} (\mathbf{D} \mathbf{H}_n)^T \mathbf{U}$ satisfies

$$\mu \triangleq \frac{n}{k} \max_{i \in [n]} \left\| \left(\frac{1}{\sqrt{n}} (\mathbf{D} \mathbf{H}_n)^T \mathbf{U} \right)_i \right\|_2^2 \leq \left(1 + \sqrt{\frac{8 \log(n/\delta)}{k}} \right)^2$$

with probability at least $1 - \delta$. In other words, the randomized Hadamard transform flats out the leverage scores. Consequently uniform sampling can be safely applied to form a sketch.

In the following, we use the properties of uniform sampling and the bound on the coherence μ to analyze SRHT. Let $\mathbf{V} \triangleq \frac{1}{\sqrt{n}} (\mathbf{D} \mathbf{H}_n)^T \mathbf{U} \in \mathbb{R}^{n \times k}$, $\mathbf{B} \triangleq \frac{1}{\sqrt{n}} (\mathbf{D} \mathbf{H}_n)^T \mathbf{B} \in \mathbb{R}^{n \times d}$, and μ be the row coherence of \mathbf{V} . It holds that

$$\begin{aligned} \mathbf{V}^T \mathbf{V} &= \mathbf{U}^T \mathbf{U} = \mathbf{I}_k, & \mathbf{V}^T \mathbf{P} \mathbf{P}^T \mathbf{V} &= \mathbf{U}^T \mathbf{S} \mathbf{S}^T \mathbf{U}, \\ \mathbf{V}^T \mathbf{B} &= \mathbf{U}^T \mathbf{B}, & \mathbf{V}^T \mathbf{P} \mathbf{P}^T \mathbf{B} &= \mathbf{U}^T \mathbf{S} \mathbf{S}^T \mathbf{B}, & \|\mathbf{B}\|_F &= \|\mathbf{B}\|_F, \\ \mathbb{P}\left\{\mu > (1 + \sqrt{8k-1} \log(100n))\right\} &\leq 0.01. \end{aligned}$$

Therefore it suffices to prove that

$$\begin{aligned} & \mathbb{P}\left\{\|\mathbf{I}_k - \mathbf{V}^T \mathbf{P} \mathbf{P}^T \mathbf{V}\|_2 \geq \eta\right\} \leq \delta_1 - 0.01, \\ & \mathbb{P}\left\{\|\mathbf{V} \bar{\mathbf{B}} - \mathbf{V}^T \mathbf{P} \mathbf{P}^T \bar{\mathbf{B}}\|_F \geq \epsilon \|\bar{\mathbf{B}}\|_F\right\} \leq \delta_2 - 0.01. \end{aligned}$$

The above inequalities follows from the two properties of uniform sampling.

C.4 Property 1 and Property 2 of Gaussian Projection

The two properties of Gaussian projection can be found in (Woodruff, 2014). In the following we prove Property 1 in a much simpler way than (Woodruff, 2014).

The concentration of the singular values of standard Gaussian matrix is very well known. Let \mathbf{G} be an $n \times s$ ($n > s$) standard Gaussian matrix. For any fixed matrix $\mathbf{U} \in \mathbb{R}^{n \times k}$ with orthonormal columns, the matrix $\mathbf{N} = \mathbf{G}^T \mathbf{U} \in \mathbb{R}^{s \times k}$ is also standard Gaussian matrix. Vershynin (2010) showed that for every $t \geq 0$, the following holds with probability at least $1 - 2e^{-t^2/2}$:

$$\sqrt{s} - \sqrt{k} - t \leq \sigma_k(\mathbf{N}) \leq \sigma_1(\mathbf{N}) \leq \sqrt{s} + \sqrt{k} + t.$$

Therefore, for any $\eta \in (0, 1)$, if $s = 9\eta^{-2}(\sqrt{k} + \sqrt{2 \log(2/\delta_1)})^2$, then

$$\sigma_i(\mathbf{U}^T \mathbf{S} \mathbf{S}^T \mathbf{U}) = \sigma_i^2(\mathbf{S}^T \mathbf{U}) \in [1 \pm \eta] \quad \text{for all } i \in [n]$$

hold simultaneously with probability at least $1 - \delta_1$. Hence

$$\mathbb{P}\left\{\|\mathbf{I}_k - \mathbf{U}^T \mathbf{S} \mathbf{S}^T \mathbf{U}\|_2 \geq \eta\right\} \leq \delta_1.$$

This concludes Property 1 of Gaussian projection.

C.5 Property 3 of SRHT and Gaussian Projection

The following lemma is the main result of (Cohen et al., 2015). If a sketching method satisfies Property 1 for arbitrary column orthogonal matrix \mathbf{U} , then it satisfies Property 3 due to the following lemma. Notice that the lemma does not apply to the leverage score and uniform sampling because they depends on the leverage scores or matrix coherence of specific column orthogonal matrix \mathbf{U} . The lemma is inappropriate for count sketch because Property 1 of count sketch holds with constant probability rather than arbitrary high probability.

Lemma 15 *Let $\mathbf{A} \in \mathbb{R}^{n \times k}$ and $\mathbf{B} \in \mathbb{R}^{n \times d}$ be any fixed matrices and r be any fixed integer. Let $k \geq k$ and $d \geq d$ be the least integer divisible by r . Let $\mathbf{S} \in \mathbb{R}^{n \times s}$ be a certain data-independent sketching matrix satisfying*

$$\mathbb{P}\left\{\|\mathbf{U}^T \mathbf{S} \mathbf{S}^T \mathbf{U} - \mathbf{I}\|_2 \geq \eta\right\} \leq \frac{r^2 \delta_3}{kd}$$

for any fixed matrix $\mathbf{U} \in \mathbb{R}^{n \times 2r}$ with orthonormal columns. Then

$$\|\mathbf{A}^T \mathbf{S} \mathbf{S}^T \mathbf{B} - \mathbf{A}^T \mathbf{B}\|_2 \leq \eta \left(\|\mathbf{A}\|_2^2 + \frac{\|\mathbf{A}\|_F^2 - \|\mathbf{A}\|_2^2}{r} \right) \left(\|\mathbf{B}\|_2^2 + \frac{\|\mathbf{B}\|_F^2 - \|\mathbf{B}\|_2^2}{r} \right)$$

holds with probability at least $1 - \delta_3$.

SRHT and Gaussian projection enjoys Property 1 with high probability for arbitrary column orthogonal matrix \mathbf{U} . Thus Property 3 can be immediately obtained by applying the above lemma with the setting $r = k$.

Appendix D. Proof of Theorem 3

Let $\mathbf{K} \in \mathbb{R}^{n \times n}$ be any fixed SPSPD matrix, $\mathbf{C} \in \mathbb{R}^{n \times c}$ be any fixed matrix, $\mathbf{S} \in \mathbb{R}^{n \times s}$ be a sketching matrix, and

$$\begin{aligned} \mathbf{U}^* &= \underset{\mathbf{U}}{\operatorname{argmin}} \|\mathbf{K} - \mathbf{C} \mathbf{U} \mathbf{C}^T\|_F^2 = \mathbf{C}^\dagger \mathbf{K} (\mathbf{C}^T)^\dagger, \\ \tilde{\mathbf{U}} &= \underset{\mathbf{U}}{\operatorname{argmin}} \|\mathbf{S}^T (\mathbf{K} - \mathbf{C} \mathbf{U} \mathbf{C}^T) \mathbf{S}\|_F^2 = (\mathbf{S}^T \mathbf{C})^\dagger (\mathbf{S}^T \mathbf{K} \mathbf{S}) (\mathbf{C}^T \mathbf{S})^\dagger. \end{aligned}$$

Lemma 16 is a direct consequence of Lemma 24.

Lemma 16 *Let $\mathbf{K} \in \mathbb{R}^{n \times n}$ be any fixed SPSPD matrix, $\mathbf{C} \in \mathbb{R}^{n \times c}$ be any fixed matrix, and $\mathbf{C} = \mathbf{U} \mathbf{C} \mathbf{\Sigma} \mathbf{C}^T \mathbf{V}_C^T$ be the SVD. Assume that $\mathbf{S}^T \mathbf{U} \mathbf{C}$ has full column rank. Let \mathbf{U}^* and $\tilde{\mathbf{U}}$ be defined in the above. Then the following inequality holds:*

$$\|\mathbf{K} - \mathbf{C} \tilde{\mathbf{U}} \mathbf{C}^T\|_F^2 \leq \|\mathbf{A} - \mathbf{C} \mathbf{U}^* \mathbf{C}^T\|_F^2 + \left(2f\sqrt{h} + f^2\sqrt{g_2 g_F} \right)^2,$$

where $\alpha \in [0, 1]$ is arbitrary and

$$\begin{aligned} f &= \sigma_{\min}^{-1}(\mathbf{U}_C^T \mathbf{S} \mathbf{S}^T \mathbf{U}_C), \quad h = \|\mathbf{U}_C^T \mathbf{S} \mathbf{S}^T (\mathbf{K} - \mathbf{U}_C \mathbf{U}_C^T \mathbf{K})\|_F^2 \\ g_2 &= \|\mathbf{U}_C^T \mathbf{S} \mathbf{S}^T (\mathbf{I}_n - \mathbf{U}_C \mathbf{U}_C^T) \mathbf{K}^\alpha\|_2^2, \quad g_F = \|\mathbf{U}_C^T \mathbf{S} \mathbf{S}^T (\mathbf{I}_n - \mathbf{U}_C \mathbf{U}_C^T) \mathbf{K}^{1-\alpha}\|_F^2. \end{aligned}$$

The following lemma shows that $\tilde{\mathbf{X}}$ is nearly as good as \mathbf{X}^* in terms of objective function value if \mathbf{S} satisfies Assumption 1.

Assumption 1 *Let \mathbf{B} be any fixed matrix. Let $\mathbf{C} \in \mathbb{R}^{m \times c}$ and $\mathbf{G} = \mathbf{U}_C \mathbf{\Sigma}_C \mathbf{V}_C^T$ be the SVD.*

Assume that the sketching matrix $\mathbf{S} \in \mathbb{R}^{m \times s}$ satisfies

$$\begin{aligned} & \mathbb{P}\left\{\|\mathbf{U}_C \mathbf{S} \mathbf{S}^T \mathbf{U}_C - \mathbf{I}\|_2 \geq \frac{1}{10}\right\} \leq \delta_1 \\ & \mathbb{P}\left\{\|\mathbf{U}_C^T \mathbf{S} \mathbf{S}^T \mathbf{B} - \mathbf{U}_C^T \mathbf{B}\|_F \geq \epsilon \|\mathbf{B}\|_F\right\} \leq \delta_2 \end{aligned}$$

for any $\delta_1, \delta_2 \in (0, 1/3)$.

Lemma 17 *Let $\mathbf{K} \in \mathbb{R}^{n \times n}$ be any fixed SPSPD matrix, $\mathbf{C} \in \mathbb{R}^{n \times c}$ be any fixed matrix, and $\mathbf{C} = \mathbf{U}_C \mathbf{\Sigma}_C \mathbf{V}_C^T$ be the SVD. Let \mathbf{U}^* and $\tilde{\mathbf{U}}$ be defined in the above, respectively. Let $\mathbf{S} \in \mathbb{R}^{n \times s}$ be certain sketching matrix satisfying Assumption 1. Assume that $\epsilon^{-1} = o(n)$. Then*

$$\begin{aligned} & \|\mathbf{K} - \mathbf{C} \tilde{\mathbf{U}} \mathbf{C}^T\|_F^2 - \|\mathbf{K} - \mathbf{C} \mathbf{U}^* \mathbf{C}^T\|_F^2 \\ & \leq \left(\frac{20\sqrt{\epsilon}}{9} \|\mathbf{A} - \mathbf{C} \mathbf{U}^* \mathbf{C}^T\|_F + \frac{100\epsilon}{81} \|\mathbf{I}_n - \mathbf{U}_C \mathbf{U}_C^T\|_2 \|\mathbf{K}\|_* \right)^2 \\ & \leq 4\epsilon^2 \eta \|\mathbf{A} - \mathbf{C} \mathbf{U}^* \mathbf{C}^T\|_F^2. \end{aligned}$$

holds with probability at least $1 - \delta_1 - 2\delta_2$.

Proof Let f, h, g_2, g_F, α be defined in Lemma 16 and fix $\alpha = 1/2$. Under Assumption 1 it holds simultaneously with probability at least $1 - \delta_1 - 2\delta_2$ that

$$f \leq \frac{10}{9}, \quad h \leq \epsilon \|(\mathbf{I}_n - \mathbf{U}_C \mathbf{U}_C^T) \mathbf{K}\|_F, \quad g_2 \leq g_F \leq \epsilon \|(\mathbf{I}_n - \mathbf{U}_C \mathbf{U}_C^T) \mathbf{K}^{1/2}\|_F^2.$$

It follows that

$$\begin{aligned} g_2 \leq g_F &\leq \epsilon \cdot \text{tr} \left((\mathbf{I}_n - \mathbf{U}_C \mathbf{U}_C^T) \mathbf{K}^{1/2} (\mathbf{I}_n - \mathbf{U}_C \mathbf{U}_C^T) \right) \\ &\leq \epsilon \cdot \text{tr} \left((\mathbf{I}_n - \mathbf{U}_C \mathbf{U}_C^T) \mathbf{K} (\mathbf{I}_n - \mathbf{U}_C \mathbf{U}_C^T) \right) \\ &= \epsilon \|(\mathbf{I}_n - \mathbf{U}_C \mathbf{U}_C^T) \mathbf{K} (\mathbf{I}_n - \mathbf{U}_C \mathbf{U}_C^T)\|_* \\ &\leq \epsilon \|(\mathbf{I}_n - \mathbf{U}_C \mathbf{U}_C^T) \mathbf{K}\|_*. \end{aligned}$$

It follows from Lemma 16 and the assumption $\epsilon^{-1} = o(n)$ that

$$\begin{aligned} &\|\mathbf{K} - \mathbf{C}\tilde{\mathbf{U}}\mathbf{C}^T\|_F^2 - \|\mathbf{A} - \mathbf{C}\mathbf{U}^*\mathbf{C}^T\|_F^2 \\ &\leq \left(\frac{20\sqrt{\epsilon}}{9} \|\mathbf{A} - \mathbf{C}\mathbf{U}^*\mathbf{C}^T\|_F + \frac{10^2\epsilon}{g^2} \|(\mathbf{I}_n - \mathbf{U}_C \mathbf{U}_C^T) \mathbf{K}\|_* \right)^2 \\ &\leq \left(\frac{20\sqrt{\epsilon}}{9} \|\mathbf{A} - \mathbf{C}\mathbf{U}^*\mathbf{C}^T\|_F + \frac{10^2\epsilon\sqrt{n}}{g^2} \|(\mathbf{I}_n - \mathbf{U}_C \mathbf{U}_C^T) \mathbf{K}\|_F \right)^2 \\ &= \frac{10^4\epsilon^2 n}{9^4} (1 + o(1)) \|\mathbf{A} - \mathbf{C}\mathbf{U}^*\mathbf{C}^T\|_F^2, \end{aligned}$$

by which the lemma follows. \blacksquare

Under both Assumption 1 and Assumption 2, the error bound can be further improved. We show the improved bound in Lemma 18.

Assumption 2 Let \mathbf{B} be any fixed matrix. Let $\mathbf{C} \in \mathbb{R}^{n \times c}$, $k_c = \text{rank}(\mathbf{C})$, and $\mathbf{C} = \mathbf{U}_C \mathbf{\Sigma}_C \mathbf{V}_C^T$ be the SVD. Assume that the sketching matrix $\mathbf{S} \in \mathbb{R}^{m \times s}$ satisfies

$$\mathbb{P} \left\{ \|\mathbf{U}_C^T \mathbf{S} \mathbf{S}^T \mathbf{B} - \mathbf{U}_C^T \mathbf{B}\|_2 \geq \epsilon \|\mathbf{B}\|_2^2 + \frac{\epsilon}{k_c} \|\mathbf{B}\|_F^2 \right\} \leq \delta_3$$

for any $\delta_3 \in (0, 1/3)$.

Lemma 18 Let $\mathbf{K} \in \mathbb{R}^{n \times n}$ be any fixed SPSPD matrix, $\mathbf{C} \in \mathbb{R}^{n \times c}$ be any fixed matrix, $k_c = \text{rank}(\mathbf{C})$, and $\mathbf{C} = \mathbf{U}_C \mathbf{\Sigma}_C \mathbf{V}_C^T$ be the SVD. Let \mathbf{U}^* and $\tilde{\mathbf{U}}$ be defined in the beginning of this section. Let $\mathbf{S} \in \mathbb{R}^{n \times s}$ be certain sketching matrix satisfying both Assumption 1 and Assumption 2. Assume that $\epsilon = o(n/k_c)$. Then

$$\|\mathbf{K} - \mathbf{C}\tilde{\mathbf{U}}\mathbf{C}^T\|_F^2 \leq \|\mathbf{A} - \mathbf{C}\mathbf{U}^*\mathbf{C}^T\|_F^2 + 4\epsilon^2 n/k_c \|\mathbf{A} - \mathbf{C}\mathbf{U}^*\mathbf{C}^T\|_F^2$$

holds with probability at least $1 - \delta_1 - \delta_2 - \delta_3$.

Proof Let f, h, g_2, g_F, α be defined in Lemma 16 and fix $\alpha = 0$. Under Assumption 1 it holds simultaneously with probability at least $1 - \delta_1 - \delta_2$ that

$$f \leq \frac{10}{9}, \quad h = g_F \leq \epsilon \|(\mathbf{I}_n - \mathbf{U}_C \mathbf{U}_C^T) \mathbf{K}\|_F^2.$$

Under Assumption 2, it holds with probability at least $1 - \delta_3$ that

$$\begin{aligned} g_2 &= \|\mathbf{U}_C^T \mathbf{S} \mathbf{S}^T (\mathbf{I}_n - \mathbf{U}_C \mathbf{U}_C^T) + \underbrace{\mathbf{U}_C^T (\mathbf{I}_n - \mathbf{U}_C \mathbf{U}_C^T)}_{=0}\|_2^2 \\ &\leq \epsilon \|\mathbf{I}_n - \mathbf{U}_C \mathbf{U}_C^T\|_2^2 + \frac{\epsilon}{k_c} \|\mathbf{I}_n - \mathbf{U}_C \mathbf{U}_C^T\|_F^2 \leq \epsilon + \frac{\epsilon}{k_c} (n - k_c) = \frac{\epsilon n}{k_c}. \end{aligned}$$

It follows from Lemma 16 and the assumption $\epsilon^{-1} = o(n/k_c)$ that

$$\begin{aligned} &\|\mathbf{K} - \mathbf{C}\tilde{\mathbf{U}}\mathbf{C}^T\|_F^2 - \|\mathbf{A} - \mathbf{C}\mathbf{U}^*\mathbf{C}^T\|_F^2 \\ &\leq \left(\frac{20\sqrt{\epsilon}}{9} \|\mathbf{A} - \mathbf{C}\mathbf{U}^*\mathbf{C}^T\|_F + \frac{10^2\epsilon}{g^2} \sqrt{n/k_c} \|\mathbf{A} - \mathbf{C}\mathbf{U}^*\mathbf{C}^T\|_F \right)^2 \\ &\leq 4\epsilon^2 n/k_c \|\mathbf{A} - \mathbf{C}\mathbf{U}^*\mathbf{C}^T\|_F^2, \end{aligned}$$

by which the lemma follows. \blacksquare

Finally, we prove Theorem 3 using Lemma 17 and Lemma 18. Leverage score sampling, uniform sampling, and count sketch satisfy Assumption 1, and the bounds follow by setting $\epsilon = 0.5\sqrt{\epsilon'/n}$ and applying Lemma 17. For the three sketching methods, we set $\delta_1 = 0.01$ and $\delta_2 = 0.095$.

Gaussian projection and SRHT satisfy Assumption 1 and Assumption 2, and their bounds follow by setting $\epsilon = 0.5\sqrt{\epsilon'/k_c n}$ and applying Lemma 18. For Gaussian projection, we set $\delta_1 = 0.01$, $\delta_2 = 0.09$, and $\delta_3 = 0.1$. For SRHT, we set $\delta_1 = 0.02$, $\delta_2 = 0.08$, and $\delta_3 = 0.1$.

Appendix E. Proof of Theorem 6

Since $\mathbf{C} = \mathbf{K}\mathbf{P} \in \mathbb{R}^{n \times c}$, $\mathbf{W} = \mathbf{P}^T \mathbf{C} \in \mathbb{R}^{c \times c}$, and $\text{rank}(\mathbf{S}^T \mathbf{C}) \geq \text{rank}(\mathbf{W})$, we have that

$$\text{rank}(\mathbf{K}) \geq \text{rank}(\mathbf{C}) \geq \text{rank}(\mathbf{S}^T \mathbf{C}) \geq \text{rank}(\mathbf{W}). \quad (11)$$

If $\text{rank}(\mathbf{C}) = \text{rank}(\mathbf{K})$, there exists a matrix \mathbf{X} such that $\mathbf{K} = \mathbf{C}\mathbf{X}$. By left multiplying both sides by \mathbf{P}^T , it follows that

$$\mathbf{C}^T = \mathbf{P}^T \mathbf{K} = \mathbf{P}^T \mathbf{C}\mathbf{X} = \mathbf{W}\mathbf{X},$$

and thus $\text{rank}(\mathbf{W}) = \text{rank}(\mathbf{S}^T \mathbf{C}) = \text{rank}(\mathbf{C}) = \text{rank}(\mathbf{K})$. It follows from $\mathbf{K} = \mathbf{C}\mathbf{X}$ and $\mathbf{C} = \mathbf{X}^T \mathbf{W}$ that

$$\mathbf{K} = \mathbf{X}^T \mathbf{W}\mathbf{X}.$$

We let $\Phi = \mathbf{X}\mathbf{S}$, and it holds that

$$\begin{aligned}\tilde{\mathbf{K}}_{c,s}^{\text{fast}} &= \mathbf{C}(\mathbf{S}^T \mathbf{C})^\dagger (\mathbf{S}^T \mathbf{K} \mathbf{S}) (\mathbf{C}^T \mathbf{S})^\dagger \mathbf{C}^T \\ &= \mathbf{X}^T \mathbf{W} (\mathbf{S}^T \mathbf{X}^T \mathbf{W})^\dagger (\mathbf{S}^T \mathbf{X}^T \mathbf{W} \mathbf{X} \mathbf{S}) (\mathbf{W} \mathbf{X} \mathbf{S})^\dagger \mathbf{W} \mathbf{X} \\ &= \mathbf{X}^T \mathbf{W} (\Phi^T \mathbf{W})^\dagger (\Phi^T \mathbf{W} \Phi) (\mathbf{W} \Phi)^\dagger \mathbf{W} \mathbf{X}.\end{aligned}$$

Let $\text{rank}(\mathbf{W}) = \text{rank}(\mathbf{C}) = \text{rank}(\mathbf{S}^T \mathbf{C}) = \text{rank}(\mathbf{K}) = \rho$. Since \mathbf{W} is symmetric, we denote the rank- ρ eigenvalue decomposition of \mathbf{W} by

$$\mathbf{W} = \underbrace{\mathbf{U}}_{c \times \rho} \underbrace{\mathbf{A} \mathbf{W}}_{\rho \times \rho} \underbrace{\mathbf{U}_W^T}_{\rho \times c}.$$

Since $\mathbf{S}^T \mathbf{C} = \Phi^T \mathbf{W}$ and $\text{rank}(\mathbf{S}^T \mathbf{C}) = \text{rank}(\mathbf{W}) = \rho$, we have that $\text{rank}(\Phi^T \mathbf{W}) = \text{rank}(\mathbf{W}) = \rho$. The $n \times \rho$ matrix $\Phi^T \mathbf{U}_W$ must have full column rank, otherwise $\text{rank}(\Phi^T \mathbf{W}) < \rho$. Thus we have

$$(\Phi^T \mathbf{W})^\dagger = (\Phi^T \mathbf{U}_W \mathbf{A} \mathbf{W} \mathbf{U}_W^T)^\dagger = (\mathbf{A} \mathbf{W} \mathbf{U}_W^T)^\dagger (\Phi^T \mathbf{U}_W)^\dagger.$$

It follows that

$$\begin{aligned}\tilde{\mathbf{K}}_{c,s}^{\text{fast}} &= \mathbf{X}^T \mathbf{W} \underbrace{(\mathbf{A} \mathbf{W} \mathbf{U}_W^T)^\dagger}_{c \times \rho} \underbrace{(\Phi^T \mathbf{U}_W)^\dagger}_{\rho \times n} \underbrace{(\Phi^T \mathbf{U}_W)^\dagger}_{n \times \rho} \mathbf{A} \mathbf{W} (\mathbf{U}_W^T \Phi) (\mathbf{U}_W^T \Phi)^\dagger (\mathbf{U}_W \mathbf{A} \mathbf{W})^\dagger \mathbf{W} \mathbf{X} \\ &= \mathbf{X}^T \mathbf{U}_W \mathbf{A} \mathbf{W} \mathbf{U}_W \mathbf{X} = \mathbf{X}^T \mathbf{W} \mathbf{X} = \mathbf{K}.\end{aligned}$$

This shows that the fast model is exact. To this end, we have shown that if $\text{rank}(\mathbf{C}) = \text{rank}(\mathbf{K})$, then the fast model is exact.

Conversely, if the fast model is exact, that is, $\mathbf{K} = \mathbf{C}(\mathbf{S}^T \mathbf{C})^\dagger (\mathbf{S}^T \mathbf{K} \mathbf{S}) (\mathbf{C}^T \mathbf{S})^\dagger \mathbf{C}^T$, we have that $\text{rank}(\mathbf{K}) \leq \text{rank}(\mathbf{C})$. It follows from (11) that $\text{rank}(\mathbf{K}) = \text{rank}(\mathbf{C})$.

Appendix F. Proof of Theorem 7

We prove Theorem 7 by constructing an adversarial case. Theorem 7 is a direct consequence of the following theorem.

Theorem 19 *Let \mathbf{A} be the $n \times n$ symmetric matrix defined in Lemma 21 with $\alpha \rightarrow 1$ and k be any positive integer smaller than n . Let \mathcal{P} be any subset of $[n]$ with cardinality c and $\mathbf{C} \in \mathbb{R}^{n \times c}$ contain c columns of \mathbf{A} indexed by \mathcal{P} . Let \mathbf{S} be any $n \times s$ column selection matrix satisfying $\mathcal{P} \subset S$, where $S \subset [n]$ is the index set formed by \mathbf{S} . Then the following inequality holds:*

$$\frac{\|\mathbf{A} - \mathbf{C}(\mathbf{S}^T \mathbf{C})^\dagger (\mathbf{S}^T \mathbf{A} \mathbf{S}) (\mathbf{C}^T \mathbf{S})^\dagger \mathbf{C}^T\|_F^2}{\|\mathbf{A} - \mathbf{A}_k\|_F^2} \geq \frac{n-c}{n-k} \left(1 + \frac{2k}{c}\right) + \frac{n-s}{n-k} \frac{k(n-s)}{s^2}.$$

Proof Let \mathbf{A} and \mathbf{B} be defined in Lemma 21. We prove the theorem using Lemma 21 and Lemma 23. Let $n = pk$. Let \mathbf{C} consist of c column sampled from \mathbf{A} and $\tilde{\mathbf{C}}_i$ consist of c_i columns sampled from the i -th diagonal block of \mathbf{A} . Thus $\mathbf{C} = \text{diag}(\tilde{\mathbf{C}}_1, \dots, \tilde{\mathbf{C}}_k)$. Without loss of generality, we assume $\tilde{\mathbf{C}}_i$ consists of the first c_i columns of \mathbf{B} . Let $\tilde{\mathbf{S}} =$

$\text{diag}(\tilde{\mathbf{S}}_1, \dots, \tilde{\mathbf{S}}_k)$ be an $n \times s$ column selection matrix, where $\tilde{\mathbf{S}}_i$ is a $p \times s_i$ column selection matrix and $s_1 + \dots + s_k = s$. Then the \mathbf{U} matrix is computed by

$$\begin{aligned}\mathbf{U} &= (\mathbf{S}^T \mathbf{C})^\dagger (\mathbf{S}^T \mathbf{A} \mathbf{S}) (\mathbf{C}^T \mathbf{S})^\dagger \\ &= [\text{diag}(\tilde{\mathbf{S}}_1^T \tilde{\mathbf{C}}_1, \dots, \tilde{\mathbf{S}}_k^T \tilde{\mathbf{C}}_k)]^\dagger \text{diag}(\tilde{\mathbf{S}}_1^T \mathbf{B} \tilde{\mathbf{S}}_1, \dots, \tilde{\mathbf{S}}_k^T \mathbf{B} \tilde{\mathbf{S}}_k) [\text{diag}(\tilde{\mathbf{C}}_1^T \tilde{\mathbf{S}}_1, \dots, \tilde{\mathbf{C}}_k^T \tilde{\mathbf{S}}_k)]^\dagger \\ &= \text{diag}\left((\tilde{\mathbf{S}}_1^T \tilde{\mathbf{C}}_1)^\dagger (\tilde{\mathbf{S}}_1^T \mathbf{B} \tilde{\mathbf{S}}_1) (\tilde{\mathbf{C}}_1^T \tilde{\mathbf{S}}_1)^\dagger, \dots, (\tilde{\mathbf{S}}_k^T \tilde{\mathbf{C}}_k)^\dagger (\tilde{\mathbf{S}}_k^T \mathbf{B} \tilde{\mathbf{S}}_k) (\tilde{\mathbf{C}}_k^T \tilde{\mathbf{S}}_k)^\dagger\right).\end{aligned}$$

The approximation formed by the fast model is the block-diagonal matrix whose the i -th ($i \in [k]$) diagonal block is the $p \times p$ matrix

$$[\tilde{\mathbf{A}}_{c,s}^{\text{fast}}]_{ii} = \tilde{\mathbf{C}}_i (\tilde{\mathbf{S}}_i^T \tilde{\mathbf{C}}_i)^\dagger (\tilde{\mathbf{S}}_i^T \mathbf{B} \tilde{\mathbf{S}}_i) (\tilde{\mathbf{C}}_i^T \tilde{\mathbf{S}}_i)^\dagger \mathbf{C}_i^T.$$

It follows from Lemma 23 that for any $i \in [k]$,

$$\lim_{\alpha \rightarrow 1} \frac{\|\mathbf{B} - [\tilde{\mathbf{A}}_{c,s}^{\text{fast}}]_{ii}\|_F^2}{(1-\alpha)^2} = (p-c_i) \left(1 + \frac{2}{c_i}\right) + \frac{(p-s_i)^2}{s_i^2}.$$

Thus

$$\begin{aligned}\lim_{\alpha \rightarrow 1} \frac{\|\mathbf{A} - \tilde{\mathbf{A}}_{c,s}^{\text{fast}}\|_F^2}{(1-\alpha)^2} &= \lim_{\alpha \rightarrow 1} \sum_{i=1}^k \frac{\|\mathbf{B} - [\tilde{\mathbf{A}}_{c,s}^{\text{fast}}]_{ii}\|_F^2}{(1-\alpha)^2} \\ &= \sum_{i=1}^k (p-c_i) \left(1 + \frac{2}{c_i}\right) + \frac{(p-s_i)^2}{s_i^2} \\ &= \left(\sum_{i=1}^k p - c_i - 2\right) + \left(2p \sum_{i=1}^k \frac{1}{c_i}\right) + \left(p^2 \sum_{i=1}^k \frac{1}{s_i^2}\right) - \left(2p \sum_{i=1}^k \frac{1}{s_i}\right) + k \\ &\geq n-c-2k + \frac{2nk}{c} + \frac{kn^2}{s^2} - 2nk + k \\ &= (n-c) \left(1 + \frac{2k}{c}\right) + \frac{k(n-s)^2}{s^2}.\end{aligned}$$

Here the inequality follows by minimizing over c_1, \dots, c_k and s_1, \dots, s_k with constraints $\sum_i c_i = c$ and $\sum_i s_i = s$. Finally, it follows from Lemma 21 that

$$\lim_{\alpha \rightarrow 1} \frac{\|\mathbf{A} - \tilde{\mathbf{A}}_{c,s}^{\text{fast}}\|_F^2}{\|\mathbf{A} - \mathbf{A}_k\|_F^2} \geq \frac{n-c}{n-k} \left(1 + \frac{2k}{c}\right) + \frac{n-s}{n-k} \frac{k(n-s)}{s^2}.$$

■

F.1 Key Lemmas

Lemma 20 provides a useful tool for expanding the Moore-Penrose inverse of partitioned matrices.

Lemma 20 (Page 179 of Ben-Israel and Greville (2003)) Given a matrix $\mathbf{X} \in \mathbb{R}^{m \times n}$ of rank c which has a nonsingular $c \times c$ submatrix \mathbf{X}_{11} . By rearrangement of columns and rows by permutation matrices \mathbf{P} and \mathbf{Q} , the submatrix \mathbf{X}_{11} can be brought to the top left corner of \mathbf{X} , that is,

$$\mathbf{P}\mathbf{X}\mathbf{Q} = \begin{bmatrix} \mathbf{X}_{11} & \mathbf{X}_{12} \\ \mathbf{X}_{21} & \mathbf{X}_{22} \end{bmatrix}.$$

Then the Moore-Penrose inverse of \mathbf{X} is

$$\mathbf{X}^\dagger = \mathbf{Q} \begin{bmatrix} \mathbf{I}_c & \\ \mathbf{T}^T & \end{bmatrix} (\mathbf{I}_c + \mathbf{T}\mathbf{T}^T)^{-1} \mathbf{X}_{11}^{-1} (\mathbf{I}_c + \mathbf{H}^T\mathbf{H})^{-1} \begin{bmatrix} \mathbf{I}_c & \mathbf{H}^T \end{bmatrix} \mathbf{P},$$

where $\mathbf{T} = \mathbf{X}_{11}^{-1}\mathbf{X}_{12}$ and $\mathbf{H} = \mathbf{X}_{21}\mathbf{X}_{11}^{-1}$.

Lemmas 21 and 23 will be used to prove Theorem 19.

Lemma 21 (Lemma 19 of Wang and Zhang (2013)) Given n and k , we let \mathbf{B} be an $\frac{n}{k} \times \frac{n}{k}$ matrix whose diagonal entries equal to one and off-diagonal entries equal to $\alpha \in [0, 1)$. We let \mathbf{A} be an $n \times n$ block-diagonal matrix

$$\mathbf{A} = \text{diag}(\underbrace{\mathbf{B}, \dots, \mathbf{B}}_{k \text{ blocks}}). \quad (12)$$

Let \mathbf{A}_k be the best rank- k approximation to the matrix \mathbf{A} , then we have that

$$\|\mathbf{A} - \mathbf{A}_k\|_F^2 = (1 - \alpha)^2(n - k).$$

Lemma 22 The following equality holds for any nonzero real number a :

$$(a\mathbf{I}_c + b\mathbf{I}_c\mathbf{I}_c^T)^{-1} = a^{-1}\mathbf{I}_c - \frac{b}{a(a + bc)}\mathbf{I}_c\mathbf{I}_c^T.$$

Proof The lemma directly follows from the Sherman-Morrison-Woodbury matrix identity

$$(\mathbf{X} + \mathbf{Y}\mathbf{Z}\mathbf{R})^{-1} = \mathbf{X}^{-1} - \mathbf{X}^{-1}\mathbf{Y}(\mathbf{Z}^{-1} + \mathbf{R}\mathbf{X}^{-1}\mathbf{Y})^{-1}\mathbf{R}\mathbf{X}^{-1}.$$

■

Lemma 23 Let \mathbf{B} be any $n \times n$ matrix with diagonal entries equal to one and off-diagonal entries equal to α . Let $\mathbf{C} = \mathbf{B}\mathbf{P} \in \mathbb{R}^{n \times c}$; let $\tilde{\mathbf{B}} = \mathbf{C}(\mathbf{S}^T\mathbf{C})^\dagger(\mathbf{S}^T\mathbf{K}\mathbf{S})(\mathbf{C}^T\mathbf{S})^\dagger\mathbf{C}^T$ be the fast SPSD matrix approximation model of \mathbf{B} . Let \mathcal{P} and \mathcal{S} be the index sets formed by \mathbf{P} and \mathbf{S} , respectively. If $\mathcal{P} \subset \mathcal{S}$, the error incurred by the fast model satisfies

$$\lim_{\alpha \rightarrow 1} \frac{\|\mathbf{B} - \tilde{\mathbf{B}}\|_F^2}{(1 - \alpha)^2} \geq (n - c) \left(1 + \frac{2}{c}\right) + \frac{(n - s)^2}{s^2}.$$

Proof Let $\mathbf{B}_1 = \mathbf{S}^T\mathbf{B}\mathbf{S} \in \mathbb{R}^{s \times s}$ and $\mathbf{C}_1 = \mathbf{S}^T\mathbf{C} = \mathbf{S}^T\mathbf{B}\mathbf{P} \in \mathbb{R}^{s \times c}$. Without loss of generality, we assume that \mathbf{P} selects the first c columns and \mathbf{S} selects the first s columns. We partition \mathbf{B} and \mathbf{C} by:

$$\mathbf{B} = \begin{bmatrix} \mathbf{B}_1 & \mathbf{B}_3^T \\ \mathbf{B}_3 & \mathbf{B}_2 \end{bmatrix} \quad \text{and} \quad \mathbf{C} = \begin{bmatrix} \mathbf{C}_1 \\ \mathbf{C}_2 \end{bmatrix} = \begin{bmatrix} \mathbf{W} \\ \mathbf{C}_2 \end{bmatrix}.$$

We further partition $\mathbf{B}_1 \in \mathbb{R}^{s \times s}$ by

$$\mathbf{B}_1 = \begin{bmatrix} \mathbf{W} & \mathbf{C}_{12}^T \\ \mathbf{C}_{12} & \mathbf{B}_{12} \end{bmatrix},$$

where

$$\mathbf{C}_{12} = \alpha \mathbf{1}_{s-c}\mathbf{1}_c^T \quad \text{and} \quad \mathbf{B}_{12} = (1 - \alpha)\mathbf{I}_{s-c} + \alpha \mathbf{1}_{s-c}\mathbf{1}_{s-c}^T.$$

The \mathbf{U} matrix is computed by

$$\mathbf{U} = (\mathbf{S}^T\mathbf{C})^\dagger(\mathbf{S}^T\mathbf{B}\mathbf{S})(\mathbf{C}^T\mathbf{S})^\dagger = \mathbf{C}_1^\dagger\mathbf{B}_1(\mathbf{C}_1^\dagger)^T.$$

It is not hard to see that \mathbf{C}_1 contains the first c rows of \mathbf{B}_1 .

We expand the Moore-Penrose inverse of \mathbf{C}_1 by Lemma 20 and obtain

$$\mathbf{C}_1^\dagger = \mathbf{W}^{-1}(\mathbf{I}_c + \mathbf{H}^T\mathbf{H})^{-1} \begin{bmatrix} \mathbf{I}_c & \mathbf{H}^T \end{bmatrix},$$

where

$$\mathbf{W}^{-1} = \left((1 - \alpha)\mathbf{I}_c + \alpha \mathbf{1}_c\mathbf{1}_c^T \right)^{-1} = \frac{1}{1 - \alpha}\mathbf{I}_c - \frac{\alpha}{(1 - \alpha)(1 - \alpha + c\alpha)}\mathbf{1}_c\mathbf{1}_c^T$$

and

$$\mathbf{H} = \mathbf{C}_{12}\mathbf{W}^{-1} = \frac{\alpha}{1 - \alpha + c\alpha}\mathbf{1}_{s-c}\mathbf{1}_c^T.$$

It is easily verified that $\mathbf{H}^T\mathbf{H} = \left(\frac{\alpha}{1 - \alpha + c\alpha}\right)^2(s - c)\mathbf{1}_c\mathbf{1}_c^T$. It follows from Lemma 22 that

$$(\mathbf{I}_c + \mathbf{H}^T\mathbf{H})^{-1} = \mathbf{I}_c - \frac{(s - c)\alpha^2}{c(s - c)\alpha^2 + (1 - \alpha + c\alpha)^2}\mathbf{1}_c\mathbf{1}_c^T.$$

Then we obtain

$$\begin{aligned} \mathbf{C}_1^\dagger &= \mathbf{W}^{-1}(\mathbf{I}_c + \mathbf{H}^T\mathbf{H})^{-1} \begin{bmatrix} \mathbf{I}_c & \mathbf{H}^T \end{bmatrix} \\ &= \left(\frac{1}{1 - \alpha}\mathbf{I}_c + \gamma_1\mathbf{1}_c\mathbf{1}_c^T \right) \begin{bmatrix} \mathbf{I}_c & \mathbf{H}^T \end{bmatrix}, \end{aligned} \quad (13)$$

where

$$\begin{aligned} \gamma_1 &= c\gamma_2\gamma_3 - \gamma_2 - \frac{\gamma_3}{1 - \alpha}, \\ \gamma_2 &= \frac{\alpha}{(1 - \alpha)(1 - \alpha + c\alpha)}, \\ \gamma_3 &= \frac{(s - c)\alpha^2}{c(s - c)\alpha^2 + (1 - \alpha + c\alpha)^2}. \end{aligned}$$

Then

$$\begin{aligned} [\mathbf{I}_c; \mathbf{H}^T] \mathbf{B}_1 [\mathbf{I}_c; \mathbf{H}^T]^T &= \mathbf{W} + \mathbf{B}_{13}^T \mathbf{H} + \mathbf{H}^T \mathbf{B}_{13} + \mathbf{H}^T \mathbf{B}_{12} \mathbf{H} \\ &= (1-\alpha) \mathbf{I}_c + \gamma_4 \mathbf{1}_c \mathbf{1}_c^T, \end{aligned} \quad (14)$$

where

$$\gamma_4 = \frac{\alpha(3\alpha s - \alpha c - 2\alpha + \alpha^2 c - 3\alpha c^2 s + \alpha^2 + \alpha^2 s^2 + 1)}{(\alpha c - \alpha + 1)^2}.$$

It follows from (13) (14) that

$$\begin{aligned} \mathbf{U} &= \mathbf{C}_1^T \mathbf{B}_1 (\mathbf{C}_1^T)^T = \left(\frac{1}{1-\alpha} \mathbf{I}_c + \gamma_1 \mathbf{1}_c \mathbf{1}_c^T \right) \left((1-\alpha) \mathbf{I}_c + \gamma_4 \mathbf{1}_c \mathbf{1}_c^T \right) \left(\frac{1}{1-\alpha} \mathbf{I}_c + \gamma_1 \mathbf{1}_c \mathbf{1}_c^T \right) \\ &= \frac{1}{1-\alpha} \mathbf{I}_c + \gamma_5 \mathbf{1}_c \mathbf{1}_c^T, \end{aligned}$$

where

$$\gamma_5 = \gamma_1 + \left(c\gamma_1 + \frac{1}{1-\alpha} \right) \left(c\gamma_1 \gamma_4 + \gamma_1(1-\alpha) + \frac{\gamma_4}{1-\alpha} \right).$$

Then we have

$$\begin{aligned} \mathbf{W}\mathbf{U} &= \mathbf{I}_c + \gamma_6 \mathbf{1}_c \mathbf{1}_c^T, \\ \gamma_6 &= (1-\alpha + \alpha c) \gamma_5 + \frac{\alpha}{1-\alpha}. \end{aligned}$$

We partition the fast SPSPD matrix approximation model by

$$\tilde{\mathbf{B}} = \begin{bmatrix} \tilde{\mathbf{W}} & \tilde{\mathbf{B}}_{21}^T \\ \tilde{\mathbf{B}}_{21} & \tilde{\mathbf{B}}_{22} \end{bmatrix},$$

where

$$\begin{aligned} \mathbf{B}_{11} &= \mathbf{W}\mathbf{U}\mathbf{W} = (1-\alpha) \mathbf{I}_c + (\alpha + (1-\alpha + \alpha c) \gamma_6) \mathbf{1}_c \mathbf{1}_c^T, \\ \tilde{\mathbf{B}}_{21} &= \mathbf{W}\mathbf{U}(\alpha \mathbf{1}_c \mathbf{1}_{n-c}^T) = \alpha(1 + c\gamma_6) \mathbf{1}_c \mathbf{1}_{n-c}^T, \\ \tilde{\mathbf{B}}_{22} &= (\alpha \mathbf{1}_{n-c} \mathbf{1}_c^T) \mathbf{U}(\alpha \mathbf{1}_c \mathbf{1}_{n-c}^T) = \alpha^2 c \left(\frac{1}{1-\alpha} + \gamma_5 c \right) \mathbf{1}_c \mathbf{1}_{n-c}^T \end{aligned}$$

The approximate error is

$$\|\mathbf{B} - \tilde{\mathbf{B}}\|_F^2 = \|\mathbf{W} - \tilde{\mathbf{W}}\|_F^2 + 2\|\mathbf{B}_{21} - \tilde{\mathbf{B}}_{21}\|_F^2 + \|\mathbf{B}_{22} - \tilde{\mathbf{B}}_{22}\|_F^2,$$

where

$$\begin{aligned} \|\mathbf{W} - \tilde{\mathbf{W}}\|_F^2 &= \|(1-\alpha + \alpha c) \gamma_6 \mathbf{1}_c \mathbf{1}_c^T\|_F^2 = c^2(1-\alpha + \alpha c) \gamma_6^2, \\ \|\mathbf{B}_{21} - \tilde{\mathbf{B}}_{21}\|_F^2 &= \|\alpha c \gamma_6 \mathbf{1}_c \mathbf{1}_{n-c}^T\|_F^2 = \alpha^2 c^3 (n-c) \gamma_6^2, \\ \|\mathbf{B}_{22} - \tilde{\mathbf{B}}_{22}\|_F^2 &= \underbrace{(n-c)(n-c-1)\alpha^2 \left(\frac{\alpha c}{1-\alpha} + \alpha c^2 \gamma_5 - 1 \right)^2}_{\text{off-diagonal}} + \underbrace{(n-c) \left(\frac{\alpha^2 c}{1-\alpha} + \alpha^2 c^2 \gamma_5 - 1 \right)^2}_{\text{diagonal}}. \end{aligned}$$

We let

$$\eta \triangleq \frac{\|\mathbf{B} - \tilde{\mathbf{B}}\|_F^2}{(1-\alpha)^2},$$

which is a symbolic expression of α , n , s , and c . We then simplify the expression using MATLAB and substitute the α in η by 1, and we obtain

$$\lim_{\alpha \rightarrow 1} \eta = (n-c)(1+2/c) + (n-s)^2/s^2,$$

by which the lemma follows. \blacksquare

Appendix G. Proof of Theorem 8

We define the projection operation $\mathcal{P}_{C,k}(\mathbf{A}) = \mathbf{C}\mathbf{X}$ where \mathbf{X} is defined by

$$\mathbf{X} = \underset{\text{rank}(\mathbf{X}) \leq k}{\text{argmin}} \|\mathbf{A} - \mathbf{C}\mathbf{X}\|_F^2.$$

By sampling $c = 2k\epsilon^{-1}(1 + o(1))$ columns of \mathbf{A} by the near-optimal algorithm of Boutsidis et al. (2014) to form $\mathbf{C} \in \mathbb{R}^{m \times c}$, we have that

$$\|\mathbf{A} - \mathcal{P}_{C,k}(\mathbf{A})\|_F^2 \leq (1+\epsilon) \|\mathbf{A} - \mathbf{A}_k\|_F^2.$$

Applying Lemma 3.11 of Boutsidis and Woodruff (2014), there exists a much smaller column orthogonal matrix $\mathbf{Z} \in \mathbb{R}^{m \times k}$ such that $\text{range}(\mathbf{Z}) \subset \text{range}(\mathbf{C})$ and

$$\|\mathbf{A} - \mathbf{C}\mathbf{C}^T \mathbf{A}\|_F^2 \leq \|\mathbf{A} - \mathbf{Z}\mathbf{Z}^T \mathbf{A}\|_F^2 \leq \|\mathbf{A} - \mathcal{P}_{C,k}(\mathbf{A})\|_F^2.$$

Notice that the algorithm does not compute \mathbf{Z} .

Let $\mathbf{R}_1^T \in \mathbb{R}^{n \times r_1}$ be columns of \mathbf{A}^T selected by the randomized dual-set sparsification algorithm of Boutsidis et al. (2014). When $r_1 = \mathcal{O}(k)$, it holds that

$$\|\mathbf{A} - \mathbf{R}_1 \mathbf{R}_1^T \mathbf{A}\|_F^2 \leq 2(1 + o(1)) \|\mathbf{A} - \mathbf{A}_k\|_F^2.$$

Let $\mathbf{R}_2^T \in \mathbb{R}^{n \times r_2}$ be columns of \mathbf{A}^T selected by adaptive sampling according to the residual $\mathbf{A}^T - \mathbf{R}_1^T (\mathbf{R}_1^T)^T \mathbf{A}^T$. Set $r_2 = 2k\epsilon^{-1}(1 + o(1))$. Let $\mathbf{R}^T = [\mathbf{R}_1^T, \mathbf{R}_2^T]$. By the adaptive sampling theorem of Wang and Zhang (2013), we obtain

$$\begin{aligned} \|\mathbf{A} - \mathbf{Z}\mathbf{Z}^T \mathbf{A}\mathbf{R}\mathbf{R}^T \mathbf{A}\|_F^2 &\leq \|\mathbf{A} - \mathbf{Z}\mathbf{Z}^T \mathbf{A}\|_F^2 + \frac{k}{r_2} \mathbb{E} \|\mathbf{A} - \mathbf{A}\mathbf{R}\mathbf{R}^T \mathbf{A}\|_F^2 \\ &\leq (1+\epsilon) \|\mathbf{K} - \mathbf{K}_k\|_F^2 + \epsilon \|\mathbf{K} - \mathbf{K}_k\|_F^2 \\ &\leq (1+2\epsilon) \|\mathbf{K} - \mathbf{K}_k\|_F^2. \end{aligned} \quad (15)$$

Obviously \mathbf{R}^T contains

$$r = r_1 + r_2 = 2k\epsilon^{-1}(1 + o(1))$$

columns of \mathbf{A}^T .

It remains to show $\|\mathbf{A} - \mathbf{C}\mathbf{C}^\dagger\mathbf{A}\mathbf{R}^\dagger\mathbf{R}\|_F^2 \leq \|\mathbf{A} - \mathbf{Z}\mathbf{Z}^T\mathbf{A}\mathbf{R}^\dagger\mathbf{R}\|_F^2$. Since the columns of \mathbf{Z} are contained in the column space of \mathbf{C} , for any matrix \mathbf{Y} the inequality $\|(\mathbf{I}_m - \mathbf{C}\mathbf{C}^\dagger)\mathbf{Y}\|_F^2 \leq \|(\mathbf{I}_m - \mathbf{Z}\mathbf{Z}^T)\mathbf{Y}\|_F^2$ holds. Then we obtain

$$\begin{aligned} \|\mathbf{A} - \mathbf{C}\mathbf{C}^\dagger\mathbf{A}\mathbf{R}^\dagger\mathbf{R}\|_F^2 &= \|\mathbf{A} - \mathbf{A}\mathbf{R}^\dagger\mathbf{R} + \mathbf{A}\mathbf{R}^\dagger\mathbf{R} - \mathbf{C}\mathbf{C}^\dagger\mathbf{A}\mathbf{R}^\dagger\mathbf{R}\|_F^2 \\ &= \|\mathbf{A}(\mathbf{I}_n - \mathbf{R}^\dagger\mathbf{R})\|_F^2 + \|(\mathbf{I}_m - \mathbf{C}\mathbf{C}^\dagger)\mathbf{A}\mathbf{R}^\dagger\mathbf{R}\|_F^2 \\ &\leq \|\mathbf{A}(\mathbf{I}_n - \mathbf{R}^\dagger\mathbf{R})\|_F^2 + \|(\mathbf{I}_m - \mathbf{Z}\mathbf{Z}^T)\mathbf{A}\mathbf{R}^\dagger\mathbf{R}\|_F^2 \\ &= \|\mathbf{A}(\mathbf{I}_n - \mathbf{R}^\dagger\mathbf{R}) + (\mathbf{I}_m - \mathbf{Z}\mathbf{Z}^T)\mathbf{A}\mathbf{R}^\dagger\mathbf{R}\|_F^2 \\ &= \|\mathbf{A} - \mathbf{Z}\mathbf{Z}^T\mathbf{A}\mathbf{R}^\dagger\mathbf{R}\|_F^2. \end{aligned} \quad (16)$$

The theorem follows from (15) and (16) and by setting $\epsilon' = 2\epsilon$.

Appendix H. Proof of Theorem 9

In Section H.1 we establish a key lemma to decompose the error incurred by the approximation. In Section H.2 we prove Theorem 9 using the key lemma.

H.1 Key Lemma

We establish the following lemma for decomposing the error of the approximate solution.

Lemma 24 *Let $\mathbf{A} \in \mathbb{R}^{m \times n}$, $\mathbf{C} \in \mathbb{R}^{m \times c}$, and $\mathbf{R} \in \mathbb{R}^{r \times n}$ be any fixed matrices, and $\mathbf{A} = \mathbf{U}_A \Sigma_A \mathbf{V}_A^T$, $\mathbf{C} = \mathbf{U}_C \Sigma_C \mathbf{V}_C^T$, $\mathbf{R} = \mathbf{U}_R \Sigma_R \mathbf{V}_R^T$ be the SVD. Assume that $\mathbf{S}_C^T \mathbf{U}_C$ and $\mathbf{S}_R^T \mathbf{V}_R$ have full column rank. Let \mathbf{U}^* and \mathbf{V} be defined in (8) and (9), respectively. Then the following inequalities hold:*

$$\begin{aligned} \|\mathbf{A} - \mathbf{C}\mathbf{U}\mathbf{R}\|_F^2 &\leq \|\mathbf{A} - \mathbf{C}\mathbf{U}^*\mathbf{R}\|_F^2 + \left(f_R \sqrt{h_R} + f_C \sqrt{h_C} + f_C f_R \sqrt{g_C g_R} \right)^2, \\ \|\mathbf{A} - \mathbf{C}\mathbf{U}\mathbf{R}\|_F^2 &\leq \|\mathbf{A} - \mathbf{C}\mathbf{U}^*\mathbf{R}\|_F^2 + \left(f_R \sqrt{h_R} + f_C \sqrt{h_C} + f_C f_R \sqrt{g_C g_R} \right)^2, \end{aligned}$$

where $\alpha \in [0, 1]$ is arbitrary, and

$$\begin{aligned} f_C &= \sigma_{\min}^{-1}(\mathbf{U}_C^T \mathbf{S}_C \mathbf{S}_C^T \mathbf{U}_C), & f_R &= \sigma_{\min}^{-1}(\mathbf{V}_R^T \mathbf{S}_R \mathbf{S}_R^T \mathbf{V}_R), \\ h_C &= \|\mathbf{U}_C^T \mathbf{S}_C \mathbf{S}_C^T (\mathbf{A} - \mathbf{U}_C \mathbf{U}_C^T \mathbf{A})\|_F^2, & h_R &= \|(\mathbf{A} - \mathbf{A}\mathbf{V}_R \mathbf{V}_R^T) \mathbf{S}_C \mathbf{S}_C^T \mathbf{V}_R\|_F^2, \\ g_C &= \|\mathbf{U}_C^T \mathbf{S}_C \mathbf{S}_C^T (\mathbf{I}_m - \mathbf{U}_C \mathbf{U}_C^T) \mathbf{U}_A \Sigma_A\|_F^2, & g_R &= \|\Sigma_A^{1-\alpha} \mathbf{V}_A (\mathbf{I}_n - \mathbf{V}_R \mathbf{V}_R^T) \mathbf{S}_R \mathbf{S}_R^T \mathbf{V}_R\|_F^2, \\ g'_C &= \|\mathbf{U}_C^T \mathbf{S}_C \mathbf{S}_C^T (\mathbf{I}_m - \mathbf{U}_C \mathbf{U}_C^T) \mathbf{U}_A \Sigma_A^\alpha\|_2^2, & g'_R &= \|\Sigma_A^{1-\alpha} \mathbf{V}_A (\mathbf{I}_n - \mathbf{V}_R \mathbf{V}_R^T) \mathbf{S}_R \mathbf{S}_R^T \mathbf{V}_R\|_2^2. \end{aligned}$$

Proof Let $k_C = \text{rank}(\mathbf{C}) \leq c$ and $k_R = \text{rank}(\mathbf{R}) \leq r$. Let $\mathbf{U}_C \in \mathbb{R}^{m \times k_C}$ be the left singular vectors of \mathbf{C} and $\mathbf{V}_R \in \mathbb{R}^{n \times k_R}$ be the right singular vectors of \mathbf{R} . Define \mathbf{Z}^* , $\tilde{\mathbf{Z}} \in \mathbb{R}^{k_C \times k_R}$ by

$$\mathbf{Z}^* = \mathbf{U}_C^T \mathbf{A} \mathbf{V}_R, \quad \tilde{\mathbf{Z}} = (\mathbf{S}_C^T \mathbf{U}_C)^\dagger (\mathbf{S}_C^T \mathbf{A} \mathbf{S}_R) (\mathbf{V}_R^T \mathbf{S}_R)^\dagger.$$

We have that $\mathbf{C}\mathbf{U}^*\mathbf{R} = \mathbf{C}\mathbf{C}^\dagger\mathbf{A}\mathbf{R}^\dagger\mathbf{R} = \mathbf{U}_C \mathbf{U}_C^T \mathbf{A} \mathbf{V}_R \mathbf{V}_R^T = \mathbf{U}_C \mathbf{Z}^* \mathbf{V}_R^T$. By definition, it holds that that

$$\begin{aligned} \tilde{\mathbf{U}} &= (\mathbf{S}_C^T \mathbf{C})^\dagger (\mathbf{S}_C^T \mathbf{A} \mathbf{S}_R) (\mathbf{R} \mathbf{S}_R)^\dagger \\ &= (\mathbf{S}_C^T \mathbf{U}_C \Sigma_C \mathbf{V}_C^T)^\dagger (\mathbf{S}_C^T \mathbf{A} \mathbf{S}_R) (\mathbf{U}_R \Sigma_R \mathbf{V}_R^T \mathbf{S}_R)^\dagger \\ &= (\Sigma_C \mathbf{V}_C^T)^\dagger (\mathbf{S}_C^T \mathbf{U}_C)^\dagger (\mathbf{S}_C^T \mathbf{A} \mathbf{S}_R) (\mathbf{V}_R^T \mathbf{S}_R)^\dagger (\mathbf{U}_R \Sigma_R)^\dagger \\ &= (\Sigma_C \mathbf{V}_C^T)^\dagger \tilde{\mathbf{Z}} (\mathbf{U}_R \Sigma_R)^\dagger, \end{aligned}$$

where the third equality follows from that $\mathbf{S}_C^T \mathbf{U}_C$ and $\mathbf{S}_R^T \mathbf{V}_R$ have full column rank and that $\Sigma_C \mathbf{V}_C^T$ and $\mathbf{V}_R^T \mathbf{S}_R$ have full row rank. It follows that

$$\mathbf{C}\tilde{\mathbf{U}}\mathbf{R} = \mathbf{U}_C \Sigma_C \mathbf{V}_C^T (\Sigma_C \mathbf{V}_C^T)^\dagger \tilde{\mathbf{Z}} (\mathbf{U}_R \Sigma_R)^\dagger \mathbf{U}_R \Sigma_R \mathbf{V}_R^T = \mathbf{U}_C \tilde{\mathbf{Z}} \mathbf{V}_R^T.$$

Since $\mathbf{C}\mathbf{U}^*\mathbf{R} = \mathbf{U}_C \mathbf{Z}^* \mathbf{V}_R^T$ and $\mathbf{C}\tilde{\mathbf{U}}\mathbf{R} = \mathbf{U}_C \tilde{\mathbf{Z}} \mathbf{V}_R^T$, it suffices to prove the two inequalities:

$$\begin{aligned} \|\mathbf{A} - \mathbf{U}_C \tilde{\mathbf{Z}} \mathbf{V}_R^T\|_F^2 &\leq \|\mathbf{A} - \mathbf{U}_C \mathbf{Z}^* \mathbf{V}_R^T\|_F^2 + \left(f_R \sqrt{h_R} + f_C \sqrt{h_C} + f_C f_R \sqrt{g_C g_R} \right)^2, \\ \|\mathbf{A} - \mathbf{U}_C \tilde{\mathbf{Z}} \mathbf{V}_R^T\|_F^2 &\leq \|\mathbf{A} - \mathbf{U}_C \mathbf{Z}^* \mathbf{V}_R^T\|_F^2 + \left(f_R \sqrt{h_R} + f_C \sqrt{h_C} + f_C f_R \sqrt{g_C g_R} \right)^2. \end{aligned} \quad (17)$$

The left-hand side can be expressed as

$$\begin{aligned} \|\mathbf{A} - \mathbf{U}_C \tilde{\mathbf{Z}} \mathbf{V}_R^T\|_F^2 &= \|(\mathbf{A} - \mathbf{U}_C \mathbf{Z}^* \mathbf{V}_R^T) + \mathbf{U}_C (\mathbf{Z}^* - \tilde{\mathbf{Z}}) \mathbf{V}_R^T\|_F^2 \\ &= \|(\mathbf{I}_m - \mathbf{U}_C \mathbf{U}_C^T) \mathbf{A} + \mathbf{U}_C \mathbf{U}_C^T (\mathbf{A} (\mathbf{I}_n - \mathbf{V}_R \mathbf{V}_R^T) + \mathbf{U}_C (\mathbf{Z}^* - \tilde{\mathbf{Z}}) \mathbf{V}_R^T)\|_F^2 \\ &= \|(\mathbf{I}_m - \mathbf{U}_C \mathbf{U}_C^T) \mathbf{A}\|_F^2 + \|\mathbf{U}_C \mathbf{U}_C^T \mathbf{A} (\mathbf{I}_n - \mathbf{V}_R \mathbf{V}_R^T) + \mathbf{U}_C (\mathbf{Z}^* - \tilde{\mathbf{Z}}) \mathbf{V}_R^T\|_F^2 \\ &= \|(\mathbf{I}_m - \mathbf{U}_C \mathbf{U}_C^T) \mathbf{A}\|_F^2 + \|\mathbf{U}_C \mathbf{U}_C^T \mathbf{A} (\mathbf{I}_n - \mathbf{V}_R \mathbf{V}_R^T)\|_F^2 + \|\mathbf{U}_C (\mathbf{Z}^* - \tilde{\mathbf{Z}}) \mathbf{V}_R^T\|_F^2 \\ &= \|(\mathbf{I}_m - \mathbf{U}_C \mathbf{U}_C^T) \mathbf{A} + \mathbf{U}_C \mathbf{U}_C^T \mathbf{A} (\mathbf{I}_n - \mathbf{V}_R \mathbf{V}_R^T)\|_F^2 + \|\mathbf{U}_C (\mathbf{Z}^* - \tilde{\mathbf{Z}}) \mathbf{V}_R^T\|_F^2 \\ &= \|\mathbf{A} - \mathbf{U}_C \mathbf{U}_C^T \mathbf{A} \mathbf{V}_R \mathbf{V}_R^T\|_F^2 + \|\mathbf{U}_C (\mathbf{Z}^* - \tilde{\mathbf{Z}}) \mathbf{V}_R^T\|_F^2. \end{aligned}$$

From (17) we can see that it suffices to prove the two inequalities:

$$\begin{aligned} \|\mathbf{Z}^* - \tilde{\mathbf{Z}}\|_F &\leq f_R \sqrt{h_R} + f_C \sqrt{h_C} + f_C f_R \sqrt{g_C g_R}, \\ \|\mathbf{Z}^* - \tilde{\mathbf{Z}}\|_F &\leq f_R \sqrt{h_R} + f_C \sqrt{h_C} + f_C f_R \sqrt{g_C g_R}. \end{aligned} \quad (18)$$

We left multiply both sides of $\tilde{\mathbf{Z}} = (\mathbf{S}_C^T \mathbf{U}_C)^\dagger (\mathbf{S}_C^T \mathbf{A} \mathbf{S}_R) (\mathbf{V}_R^T \mathbf{S}_R)^\dagger$ by $(\mathbf{S}_C^T \mathbf{U}_C)^T (\mathbf{S}_C^T \mathbf{U}_C)$ and right multiply by $(\mathbf{V}_R^T \mathbf{S}_R) (\mathbf{V}_R^T \mathbf{S}_R)^T$. We obtain

$$\begin{aligned} &(\mathbf{U}_C^T \mathbf{S}_C \mathbf{S}_C^T \mathbf{U}_C) \tilde{\mathbf{Z}} (\mathbf{V}_R^T \mathbf{S}_R \mathbf{S}_R^T \mathbf{V}_R) \\ &= (\mathbf{S}_C^T \mathbf{U}_C)^T (\mathbf{S}_C^T \mathbf{U}_C) (\mathbf{S}_C^T \mathbf{U}_C)^\dagger (\mathbf{S}_C^T \mathbf{A} \mathbf{S}_R) (\mathbf{V}_R^T \mathbf{S}_R) (\mathbf{V}_R^T \mathbf{S}_R) (\mathbf{V}_R^T \mathbf{S}_R)^T \\ &= (\mathbf{S}_C^T \mathbf{U}_C)^T (\mathbf{S}_C^T \mathbf{A} \mathbf{S}_R) (\mathbf{V}_R^T \mathbf{S}_R)^T \\ &= \mathbf{U}_C^T \mathbf{S}_C \mathbf{S}_C^T (\mathbf{A} - \mathbf{U}_C \mathbf{Z}^* \mathbf{V}_R^T) \mathbf{S}_R \mathbf{S}_R^T \mathbf{V}_R. \end{aligned}$$

Here the second equality follows from that $\mathbf{Y}^T \mathbf{Y} \mathbf{Y}^\dagger = \mathbf{Y}^T$ and $\mathbf{Y}^\dagger \mathbf{Y} \mathbf{Y}^T = \mathbf{Y}^\dagger$ for any \mathbf{Y} , and the last equality follows by defining $\mathbf{A}^\perp = \mathbf{A} - \mathbf{U}_C \mathbf{Z}^* \mathbf{V}_R^T$. It follows that

$$(\mathbf{U}_C^T \mathbf{S}_C \mathbf{S}_C^T \mathbf{U}_C) (\tilde{\mathbf{Z}} - \mathbf{Z}^*) (\mathbf{V}_R^T \mathbf{S}_R \mathbf{S}_R^T \mathbf{V}_R) = \mathbf{U}_C^T \mathbf{S}_C \mathbf{S}_C^T \mathbf{A}^\perp \mathbf{S}_R \mathbf{S}_R^T \mathbf{V}_R.$$

We decompose \mathbf{A}^\perp by

$$\begin{aligned}\mathbf{A}^\perp &= \mathbf{A} - \mathbf{U}_C \mathbf{U}_C^T \mathbf{A} + \mathbf{U}_C \mathbf{U}_C^T \mathbf{A} - \mathbf{U}_C \mathbf{U}_C^T \mathbf{A} \mathbf{V}_R \mathbf{V}_R^T \\ &= \mathbf{U}_C \mathbf{U}_C^T \mathbf{A} (\mathbf{I}_n - \mathbf{V}_R \mathbf{V}_R^T) + (\mathbf{I}_m - \mathbf{U}_C \mathbf{U}_C^T) \mathbf{A} \mathbf{V}_R \mathbf{V}_R^T + (\mathbf{I}_m - \mathbf{U}_C \mathbf{U}_C^T) \mathbf{A} (\mathbf{I}_n - \mathbf{V}_R \mathbf{V}_R^T).\end{aligned}$$

It follows that

$$\begin{aligned}(\mathbf{U}_C^T \mathbf{S}_C \mathbf{S}_C^T \mathbf{U}_C) (\tilde{\mathbf{Z}} - \mathbf{Z}^*) (\mathbf{V}_R^T \mathbf{S}_R \mathbf{S}_R^T \mathbf{V}_R) \\ = \mathbf{U}_C^T \mathbf{S}_C \mathbf{S}_C^T \mathbf{U}_C \mathbf{U}_C^T \mathbf{A} (\mathbf{I}_n - \mathbf{V}_R \mathbf{V}_R^T) \mathbf{S}_R \mathbf{S}_R^T \mathbf{V}_R \\ + \mathbf{U}_C^T \mathbf{S}_C \mathbf{S}_C^T (\mathbf{I}_m - \mathbf{U}_C \mathbf{U}_C^T) \mathbf{A} \mathbf{V}_R \mathbf{V}_R^T \mathbf{S}_R \mathbf{S}_R^T \mathbf{V}_R \\ + \mathbf{U}_C^T \mathbf{S}_C \mathbf{S}_C^T (\mathbf{I}_m - \mathbf{U}_C \mathbf{U}_C^T) \mathbf{A} (\mathbf{I}_n - \mathbf{V}_R \mathbf{V}_R^T) \mathbf{S}_R \mathbf{S}_R^T \mathbf{V}_R.\end{aligned}$$

and thus

$$\begin{aligned}\tilde{\mathbf{Z}} - \mathbf{Z}^* &= \mathbf{U}_C^T \mathbf{A} (\mathbf{I}_n - \mathbf{V}_R \mathbf{V}_R^T) \mathbf{S}_R \mathbf{S}_R^T \mathbf{V}_R (\mathbf{V}_R^T \mathbf{S}_R \mathbf{S}_R^T \mathbf{V}_R)^{-1} \\ &+ (\mathbf{U}_C^T \mathbf{S}_C \mathbf{S}_C^T \mathbf{U}_C)^{-1} \mathbf{U}_C^T \mathbf{S}_C \mathbf{S}_C^T (\mathbf{I}_m - \mathbf{U}_C \mathbf{U}_C^T) \mathbf{A} \mathbf{V}_R \\ &+ (\mathbf{U}_C^T \mathbf{S}_C \mathbf{S}_C^T \mathbf{U}_C)^{-1} \mathbf{U}_C^T \mathbf{S}_C \mathbf{S}_C^T (\mathbf{I}_m - \mathbf{U}_C \mathbf{U}_C^T) \mathbf{A} (\mathbf{I}_n - \mathbf{V}_R \mathbf{V}_R^T) \mathbf{S}_R \mathbf{S}_R^T \mathbf{V}_R (\mathbf{V}_R^T \mathbf{S}_R \mathbf{S}_R^T \mathbf{V}_R)^{-1}.\end{aligned}$$

It follows that

$$\begin{aligned}\|\tilde{\mathbf{Z}} - \mathbf{Z}^*\|_F &\leq \sigma_{\min}^{-1} (\mathbf{V}_R^T \mathbf{S}_R \mathbf{S}_R^T \mathbf{V}_R) \|\mathbf{A} (\mathbf{I}_n - \mathbf{V}_R \mathbf{V}_R^T) \mathbf{S}_R \mathbf{S}_R^T \mathbf{V}_R\|_F \\ &+ \sigma_{\min}^{-1} (\mathbf{U}_C^T \mathbf{S}_C \mathbf{S}_C^T \mathbf{U}_C) \|\mathbf{U}_C^T \mathbf{S}_C \mathbf{S}_C^T (\mathbf{I}_m - \mathbf{U}_C \mathbf{U}_C^T) \mathbf{A} \mathbf{V}_R\|_F \\ &+ \sigma_{\min}^{-1} (\mathbf{U}_C^T \mathbf{S}_C \mathbf{S}_C^T \mathbf{U}_C) \sigma_{\min}^{-1} (\mathbf{V}_R^T \mathbf{S}_R \mathbf{S}_R^T \mathbf{V}_R) \|\mathbf{U}_C^T \mathbf{S}_C \mathbf{S}_C^T (\mathbf{I}_m - \mathbf{U}_C \mathbf{U}_C^T) \mathbf{A} (\mathbf{I}_n - \mathbf{V}_R \mathbf{V}_R^T) \mathbf{S}_R \mathbf{S}_R^T \mathbf{V}_R\|_F.\end{aligned}$$

This proves (18) and thereby concludes the proof. \blacksquare

H.2 Proof of the Theorem

Assumption 3 assumes that the sketching matrices \mathbf{S}_C and \mathbf{S}_R satisfy the first two approximate matrix multiplication properties. Under the assumption, we obtain Lemma 25, which shows that $\tilde{\mathbf{U}}$ is nearly as good as \mathbf{U}^* in terms of objective function value.

Assumption 3 Let \mathbf{B} be any fixed matrix. Let $\mathbf{C} \in \mathbb{R}^{m \times c}$ and $\mathbf{C} = \mathbf{U}_C \mathbf{\Sigma}_C \mathbf{V}_C^T$ be the SVD.

Assume that a certain sketching matrix $\mathbf{S}_C \in \mathbb{R}^{m \times s_c}$ satisfies

$$\begin{aligned}\mathbb{P}\left\{\|\mathbf{U}_C \mathbf{S}_C \mathbf{S}_C^T \mathbf{U}_C - \mathbf{I}\|_2 \geq \frac{1}{10}\right\} &\leq \delta_1 \\ \mathbb{P}\left\{\|\mathbf{U}_C^T \mathbf{S}_C \mathbf{S}_C^T \mathbf{B} - \mathbf{U}_C^T \mathbf{B}\|_F^2 \geq \epsilon \|\mathbf{B}\|_F^2\right\} &\leq \delta_2\end{aligned}$$

for any $\delta_1, \delta_2 \in (0, 0.2)$. Let $\mathbf{R} \in \mathbb{R}^{r \times n}$ and $\mathbf{R} = \mathbf{U}_R \mathbf{\Sigma}_R \mathbf{V}_R^T$ be the SVD. Similarly, assume $\mathbf{S}_R \in \mathbb{R}^{n \times s_r}$ satisfies

$$\begin{aligned}\mathbb{P}\left\{\|\mathbf{V}_R^T \mathbf{S}_R \mathbf{S}_R^T \mathbf{V}_R - \mathbf{I}\|_2 \geq \frac{1}{10}\right\} &\leq \delta_1 \\ \mathbb{P}\left\{\|\mathbf{V}_R^T \mathbf{S}_R \mathbf{S}_R^T \mathbf{B} - \mathbf{V}_R^T \mathbf{B}\|_F^2 \geq \epsilon \|\mathbf{B}\|_F^2\right\} &\leq \delta_2.\end{aligned}$$

Lemma 25 Let $\mathbf{A} \in \mathbb{R}^{m \times n}$, $\mathbf{C} \in \mathbb{R}^{m \times c}$, and $\mathbf{R} \in \mathbb{R}^{r \times n}$ be any fixed matrices. Let \mathbf{U}^* and $\tilde{\mathbf{U}}$ be defined in (8) and (9), respectively. Let $k_c = \text{rank}(\mathbf{C})$, $k_r = \text{rank}(\mathbf{R})$, $q = \min\{m, n\}$, and $\epsilon \in (0, 1)$ be the error parameter. Assume that the sketching matrices \mathbf{S}_C and \mathbf{S}_R satisfy Assumption 3 and that $\epsilon^{-1} = o(q)$. Then

$$\|\mathbf{A} - \mathbf{C} \tilde{\mathbf{U}} \mathbf{R}\|_F^2 \leq (1 + 4\epsilon^2 q) \|\mathbf{A} - \mathbf{C} \mathbf{U}^* \mathbf{R}\|_F^2$$

holds with probability at least $1 - 2\delta_1 - 3\delta_2$.

Proof Let $f_C, f_R, h_C, h_R, g_C, g_R, g'_C, g'_R$ be defined Lemma 24. Under Assumption 3, we have that

$$\begin{aligned}f_C &\leq \frac{10}{9}, & h_C &\leq \epsilon \|\mathbf{A} - \mathbf{U}_C \mathbf{U}_C^T \mathbf{A}\|_F^2 \leq \epsilon \|\mathbf{A} - \mathbf{C} \mathbf{U}^* \mathbf{R}^T\|_F^2, \\ f_R &\leq \frac{10}{9}, & h_R &\leq \epsilon \|\mathbf{A} - \mathbf{A} \mathbf{V}_R \mathbf{V}_R^T\|_F^2 \leq \epsilon \|\mathbf{A} - \mathbf{C} \mathbf{U}^* \mathbf{R}^T\|_F^2,\end{aligned}$$

hold simultaneously with probability at least $1 - 2\delta_1 - 2\delta_2$.

We fix $\alpha = 1$, then $g_C = h_C$, and $g'_R \leq \|(\mathbf{I}_n - \mathbf{V}_R \mathbf{V}_R^T) \mathbf{S}_R \mathbf{S}_R^T \mathbf{V}_R\|_2^2$. Under Assumption 3, we have that

$$\begin{aligned}\sqrt{g'_R} &\leq \|(\mathbf{I}_n - \mathbf{V}_R \mathbf{V}_R^T) \mathbf{S}_R \mathbf{S}_R^T \mathbf{V}_R - (\mathbf{I}_n - \mathbf{V}_R \mathbf{V}_R^T) \mathbf{V}_R\|_F \\ &\leq \sqrt{\epsilon} \|(\mathbf{I}_n - \mathbf{V}_R \mathbf{V}_R^T)\|_F \leq \sqrt{\epsilon n}\end{aligned}$$

holds with probability at least $1 - \delta_2$. It follows from Lemma 24 that

$$\begin{aligned}\|\mathbf{A} - \mathbf{C} \tilde{\mathbf{U}} \mathbf{R}\|_F^2 - \|\mathbf{A} - \mathbf{C} \mathbf{U}^* \mathbf{R}\|_F^2 \\ \leq \left(f_R \sqrt{h_R} + f_C \sqrt{h_C} + f_C f_R \sqrt{g_C g'_R} \right)^2 \\ \leq \left(\frac{20}{9} \sqrt{\epsilon} \|\mathbf{A} - \mathbf{C} \mathbf{U}^* \mathbf{R}^T\|_F + \frac{10^2}{9^2} \epsilon \sqrt{n} \|\mathbf{A} - \mathbf{C} \mathbf{U}^* \mathbf{R}^T\|_F \right)^2 \\ = \frac{10^4}{9^4} \epsilon^2 n (1 + o(1)) \|\mathbf{A} - \mathbf{C} \mathbf{U}^* \mathbf{R}^T\|_F^2 \leq 4\epsilon^2 n \|\mathbf{A} - \mathbf{C} \mathbf{U}^* \mathbf{R}^T\|_F^2\end{aligned}$$

holds with probability at least $1 - 2\delta_1 - 3\delta_2$. Here the equality follows from that $\epsilon^{-1} = o(n)$.

Alternatively, if we fix $\alpha = 0$, we will obtain that

$$\|\mathbf{A} - \mathbf{C} \tilde{\mathbf{U}} \mathbf{R}\|_F^2 \leq \|\mathbf{A} - \mathbf{C} \mathbf{U}^* \mathbf{R}\|_F^2 + 4\epsilon^2 n \|\mathbf{A} - \mathbf{C} \mathbf{U}^* \mathbf{R}^T\|_F^2$$

with probability $1 - 2\delta_1 - 3\delta_2$. Therefore, if $n \leq m$, we fix $\alpha = 1$; otherwise we fix $\alpha = 0$. This concludes the proof. \blacksquare

In the following we further assume that the sketching matrices \mathbf{S}_C and \mathbf{S}_R satisfy the third approximate matrix multiplication property. Under Assumption 3 and Assumption 4, we obtain Lemma 26 which is stronger than Lemma 25.

Assumption 4 Let \mathbf{B} be any fixed matrix. Let $\mathbf{C} \in \mathbb{R}^{n \times c}$, $k_c = \text{rank}(\mathbf{C})$, and $\mathbf{C} = \mathbf{U}_C \mathbf{\Sigma}_C \mathbf{V}_C^T$ be the SVD. Assume that a certain sketching matrix $\mathbf{S}_C \in \mathbb{R}^{n \times s_c}$ satisfies

$$\mathbb{P}^f \left\{ \left\| \mathbf{U}_C^T \mathbf{S}_C \mathbf{S}_C^T \mathbf{B} - \mathbf{U}_C^T \mathbf{B} \right\|_2 \geq \epsilon \|\mathbf{B}\|_2 + \frac{\epsilon}{k_c} \|\mathbf{B}\|_F^2 \right\} \leq \delta_3$$

for any $\epsilon \in (0, 1)$ and $\delta_3 \in (0, 0.2)$. Let $\mathbf{R} \in \mathbb{R}^{r \times n}$, $k_r = \text{rank}(\mathbf{R})$, and $\mathbf{R} = \mathbf{U}_R \mathbf{\Sigma}_R \mathbf{V}_R^T$ be the SVD. Similarly, assume that $\mathbf{S}_R \in \mathbb{R}^{n \times s_r}$ satisfies

$$\mathbb{P}^f \left\{ \left\| \mathbf{V}_R^T \mathbf{S}_R \mathbf{S}_R^T \mathbf{B} - \mathbf{V}_R^T \mathbf{B} \right\|_2 \geq \epsilon \|\mathbf{B}\|_2 + \frac{\epsilon}{k_r} \|\mathbf{B}\|_F^2 \right\} \leq \delta_3.$$

Lemma 26 Let $\mathbf{A} \in \mathbb{R}^{m \times n}$, $\mathbf{C}, \mathbf{R}, \mathbf{U}^*, \tilde{\mathbf{U}}, k_c, k_r$ be defined in Lemma 25. Let $q = \min\{n, n\}$ and $\tilde{q} = \min\{m/k_c, n/k_r\}$. Assume that the sketching matrices \mathbf{S}_C and \mathbf{S}_R satisfy Assumption 3 and Assumption 4 and that $\epsilon^{-1} = o(\tilde{q})$. Then

$$\|\mathbf{A} - \mathbf{C}\tilde{\mathbf{X}}\mathbf{R}\|_F^2 \leq (1 + 4\epsilon^2 \tilde{q}) \|\mathbf{A} - \mathbf{C}\mathbf{X}^*\mathbf{R}\|_F^2$$

holds with probability at least $1 - 2\delta_1 - 2\delta_2 - \delta_3$.

Proof Let $f_C, f_R, h_C, h_R, g_C, g_R, g'_C, g'_R$ be defined Lemma 24. Under Assumption 3, we have shown in the proof of Lemma 25 that

$$\begin{aligned} f_C &\leq \frac{10}{9}, & h_C &\leq \epsilon \|\mathbf{A} - \mathbf{C}\mathbf{U}^*\mathbf{R}\|_F^2, \\ f_R &\leq \frac{10}{9}, & h_R &\leq \epsilon \|\mathbf{A} - \mathbf{C}\mathbf{U}^*\mathbf{R}\|_F^2, \end{aligned}$$

hold simultaneously with probability at least $1 - 2\delta_1 - 2\delta_2$.

We fix $\alpha = 1$, then $g_C = h_C$, and $g'_R \leq \|(\mathbf{I}_n - \mathbf{V}_R \mathbf{V}_R^T) \mathbf{S}_R \mathbf{S}_R^T \mathbf{V}_R\|_2^2$. Under Assumption 4, we have that

$$\begin{aligned} g'_R &\leq \|(\mathbf{I}_n - \mathbf{V}_R \mathbf{V}_R^T) \mathbf{S}_R \mathbf{S}_R^T \mathbf{V}_R - \underbrace{(\mathbf{I}_n - \mathbf{V}_R \mathbf{V}_R^T) \mathbf{V}_R}_= \|_2^2 \\ &\leq \|\mathbf{I}_n - \mathbf{V}_R \mathbf{V}_R^T\|_2^2 + \frac{\epsilon}{k_r} \|\mathbf{I}_n - \mathbf{V}_R \mathbf{V}_R^T\|_F^2 \leq \epsilon + \frac{\epsilon(n - k_r)}{k_r} = \frac{\epsilon n}{k_r} \end{aligned}$$

holds with probability at least $1 - \delta_3$. It follows from Lemma 24 that

$$\begin{aligned} \|\mathbf{A} - \mathbf{C}\tilde{\mathbf{U}}\mathbf{R}\|_F^2 - \|\mathbf{A} - \mathbf{C}\mathbf{U}^*\mathbf{R}\|_F^2 &\leq \left(f_R \sqrt{h_R} + f_C \sqrt{h_C} + f_C f_R \sqrt{g_C g_R} \right)^2 \\ &\leq \left(\frac{20}{9} \sqrt{\epsilon} \|\mathbf{A} - \mathbf{C}\mathbf{U}^*\mathbf{R}\|_F + \frac{10^2}{9^2} \epsilon \sqrt{n/k_r} \|\mathbf{A} - \mathbf{C}\mathbf{U}^*\mathbf{R}\|_F \right)^2 \\ &= \frac{10^4}{9^4} \epsilon^2 n k_r^{-1} (1 + o(1)) \|\mathbf{A} - \mathbf{C}\mathbf{U}^*\mathbf{R}\|_F^2 \leq 4\epsilon^2 n k_r^{-1} \|\mathbf{A} - \mathbf{C}\mathbf{U}^*\mathbf{R}\|_F^2 \end{aligned}$$

holds with probability at least $1 - 2\delta_1 - 2\delta_2 - \delta_3$. Here the equality follows from that $\epsilon^{-1} = o(n/k_r)$.

Analogously, by fixing $\alpha = 0$ and assuming $\epsilon^{-1} = o(m/k_c)$, we can show that

$$\|\mathbf{A} - \mathbf{C}\tilde{\mathbf{U}}\mathbf{R}\|_F^2 - \|\mathbf{A} - \mathbf{C}\mathbf{U}^*\mathbf{R}\|_F^2 \leq 4\epsilon^2 m k_c^{-1} \|\mathbf{A} - \mathbf{C}\mathbf{U}^*\mathbf{R}\|_F^2$$

holds with probability at least $1 - 2\delta_1 - 2\delta_2 - \delta_3$. This concludes the proof. \blacksquare

Finally, we prove Theorem 9 using Lemma 25 and Lemma 26.

For leverage score sampling, uniform sampling, and count sketch, Assumption 3 is satisfied. Then the bound follows by setting $\epsilon = 0.5\sqrt{\epsilon'}/\tilde{q}$ and applying Lemma 25. Here $q = \min\{m, n\}$. For the three sketching methods, we set $\delta_1 = 0.01$ and $\delta_2 = 0.093$.

For Gaussian projection and SRHT, Assumption 3 and Assumption 4 are satisfied. Then the bound follows by setting $\epsilon = 0.5\sqrt{\epsilon'}/\tilde{q}$ and applying Lemma 26. Here $\tilde{q} = \min\{m/k_c, n/k_r\}$. For Gaussian projection, we set $\delta_1 = 0.01$, $\delta_2 = 0.09$, and $\delta_3 = 0.1$. For SRHT, we set $\delta_1 = 0.02$, $\delta_2 = 0.08$, and $\delta_3 = 0.1$.

Abstract

We present new methodology based on Multi-Objective Markov Decision Processes for developing sequential decision support systems from data. Our approach uses sequential decision-making data to provide support that is useful to many different decision-makers, each with different, potentially time-varying preference. To accomplish this, we develop an extension of fitted- Q iteration for multiple objectives that computes policies for all scalarization functions, i.e. preference functions, simultaneously from continuous-state, finite-horizon data. We identify and address several conceptual and computational challenges along the way, and we introduce a new solution concept that is appropriate when different actions have similar expected outcomes. Finally, we demonstrate an application of our method using data from the Clinical Antipsychotic Trials of Intervention Effectiveness and show that our approach offers decision-makers increased choice by a larger class of optimal policies.

Keywords: multi-objective optimization, reinforcement learning, Markov decision processes, clinical decision support, evidence-based medicine

1. Introduction

Markov Decision Processes (MDPs) (Bertsekas and Tsitsiklis, 1996) provide a framework for reasoning about the actions of an autonomous decision-making agent in an environment as it strives to achieve long-term success. Operating within this framework, reinforcement learning (RL) methods for finding optimal actions in MDPs hold great promise for using vast amounts of accumulating longitudinal data to help humans make better-informed decisions. Batch reinforcement learning methods, including fitted Q -learning (Ernst et al., 2005), A -learning (Blatt et al., 2004), and regret regression (Henderson et al., 2010), are already being used to aid decision-making in diverse areas including medicine (Alagoz et al., 2010; Shortreed et al., 2011; Burnside et al., 2012), ecology (Păduraru et al., 2012), intelligent

tutoring systems (Brunskill and Russell, 2011), and water reservoir control (Castelletti et al., 2010). Although headway has been made in these application areas, progress is hampered by the fact that many sequential decision *support* problems are not modelled well by MDPs.

One reason for this is that in most cases, human action selection is driven by multiple competing objectives; for example, a medical decision will be based not only on the effectiveness of a treatment, but also on its potential side-effects, cost, and other considerations. Because the relative importance of these objectives varies from user to user, the quality of a policy is not well captured by a universal single scalar “reward” or “value.” Multi-Objective Markov Decision Processes (MOMDPs) accommodate this by allowing vector-valued rewards (Rojers et al., 2013) and proposing an application-dependent *solution concept*. A solution concept is essentially a partial order on policies; the set of policies that are maximal according to the partial order are considered “optimal” and are indistinguishable under that solution concept. Depending on the application, a single policy may be selected from among these, or a set of policies may be presented in some way. Computing and presenting a set of policies is termed the *decision support* setting by Roijers et al. and is the setting we consider here.

2. Existing Methods and Our Contributions

Rojers et al. (2013) note that, “...there are currently no methods for learning multiple policies with non-linear [preferences] using a value-function approach.” We present a method that fills this gap, and that additionally uses value function approximation to accommodate continuous state features, thus allowing us to use the MOMDP framework to analyze continuous-valued sequential data. Previous work (Lizotte et al., 2012) on this problem computes a set of policies based on the assumptions that i) end-users have a “true reward function” that is linear in the objectives and ii) all future actions will be chosen optimally with respect to the same “true reward function” over time. Our new method relaxes both of these assumptions as it allows the decision-maker to revisit action selection at each decision point in light of new information, both about state and about their own preferences and priorities over different outcomes of interest. Therefore, the proposed method can accommodate changes in preference over time while still making optimal decisions according to our new solution concepts by introducing the *non-deterministic multi-objective fitted- Q* algorithm, which computes policies for all scalarization functions, i.e., preference functions, simultaneously from continuous-state, finite-horizon data. This allows us to present a greater variety of action choices by acknowledging that preference functions may be non-linear. We then present the vector-valued expected returns associated with the different policies in order to provide decision support without having to refer to any particular scalarization function. Showing the expected returns in the original reward space allows us to more easily understand the qualitative differences between action choices. Although decision support is important in many application areas, we are motivated by clinical decision-making; therefore we demonstrate the use of our algorithm using data from the Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE).

Simplified versions of some of our ideas were presented in a shorter paper by Laber et al. (2014a), but we treat the problem in its full generality here. In particular, our work goes beyond “Set-Valued Dynamic Treatment Regimes” in four significant ways:

- We introduce a complete *non-deterministic fitted-Q* algorithm that is applicable to arbitrary numbers of actions and arbitrary time horizons. (Previous work was limited to binary actions and maximum two decision points.) This allows us to perform fitted-Q backups in general settings using multiple reward functions over continuous-valued state features.
- We prove that our algorithm finds all policies that are optimal for some scalarization function by considering a collection of policies at the next time step that is only polynomial in the data set size.
- We formalize a solution concept, *practical domination*, that is more flexible than Pareto domination for identifying whether an action is not desirable. A similar concept was introduced in previous work (Laber et al., 2014a), but we show that using practical domination, while useful, is problematic for more than two decision points because it does not induce a partial order on actions. However, we show that a modification of practical domination leads to a partial ordering for any number of actions or time points.
- We demonstrate the use of our algorithm on the Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) and we compare our approach quantitatively and qualitatively with a competing approach derived from previous work of Lizotte et al. (2010, 2012).

3. Motivation

Our work is motivated by a clear opportunity for reinforcement learning methods to provide novel ways of analyzing data to produce high-quality, evidence-based decision support. We briefly review some specific applications here where we believe our approach could be particularly relevant.

3.1 Intelligent Tutorial Systems

Brunskill and Russell (2011), and Rafferty et al. (2011) study the automatic construction of adaptive pedagogical strategies for intelligent tutoring systems. They employ POMDP models to capture the partially observable and sequential aspect of this problem, using hidden state to represent a student’s knowledge. Their approach uses time taken to learn all skills as a cost, i.e., negative reward, that drives teaching action selection. Chi et al. (2011) use an MDP formulation and use “Normalized Learning Gain,” a quantification of skill acquisition, as a reward; however, they do not explicitly consider time spent. The ability to consider both of these rewards simultaneously would empower the learner or the teacher to emphasize one or the other over the course of their interaction with the system. The method we present could offer a selection of teaching actions that are all optimal for different preferences over these rewards, and possibly others as well.

3.2 Computational Sustainability

Paduraru et al. (2012) identify an application within the domain of sustainable wildlife management where the MDP framework is particularly appropriate. They investigate the

efficacy of several off-policy methods for developing control policies for mallard duck populations. Their output, rather than providing autonomous control, is intended to provide decision support for public environmental policy-makers. They use “number of birds harvested per year” as the reward. However, in practical management plans, several outcomes may be of interest including minimum population size, program cost, and so on. Because formulating a (e.g. linear) trade-off among these rewards would be difficult, our method is relevant to this problem.

3.3 Treating Chronic Disease

Reinforcement learning has also been used as a means of analyzing sequential medical data to inform clinical decision-makers of the comparative effectiveness of different treatments (Shortreed et al., 2011). RL methods are suited to decision support for treating chronic illness where a good *policy* for choosing treatments over time is crucial for success. Indeed, optimal policies—known as “Dynamic Treatment Regimes” in statistics and the behavioral sciences—have been learned for the management of chronic conditions including attention deficit hyperactivity disorder (Laber et al., 2014b), HIV infection (Moodie et al., 2007), and smoking addiction (Strecher et al., 2006). They have also been applied to sequences of diagnostics as well, for example in breast cancer (Burnside et al., 2012). We present a case study in this domain in Section 7.

4. Background

We introduce a new approach for solving Multi-Objective Markov Decision Processes with the goal of providing data-driven decision support. Our approach uses non-deterministic policies to encode the set of all non-dominated policies. In this section, we review the most relevant existing literature on MOMDPs and NDPs.

4.1 Multi-objective Optimization and MOMDPs

The most basic definition of a Markov Decision Process is as a 4-tuple $\langle S, \mathcal{A}, P, R \rangle$ where S is a set of states, \mathcal{A} is a set of actions, $P(s, a, s') = \Pr(s'|s, a)$ gives the probability of a state transition given action and current state, and $R(s, a)$ is the immediate scalar reward obtained in state s when taking action a . One common goal of “solving” an MDP, if we assume a finite time horizon of T steps, is to find a policy $\pi : S \rightarrow \mathcal{A}$ that maximizes

$$V^\pi(s) = \mathbb{E}^\pi \left[\sum_{t=1}^T R(s_t, a_t) \mid s_1 = s \right]$$

pointwise for all states. In the preceding, \mathbb{E}^π indicates that the expectation is taken assuming the state-action trajectories are obtained by following policy π . Because in the finite-horizon setting that the optimal π is in general non-stationary (Bertsekas, 2007), we define π to be a sequence of functions π_t for $t \in \{1, \dots, T\}$, where $\pi_t : S_t \rightarrow \mathcal{A}_t$.

Like previous work by Lizotte et al. (2010, 2012) and by many others (Roijfers et al., 2013), we focus on the setting where the definition of an MDP is augmented by assuming a D -dimensional reward vector $\mathbf{R}(s_t, a_t)$ is observed at each time step. We define a finite-horizon MOMDP with finite time horizon T as a tuple of state spaces S_t , action spaces \mathcal{A}_t ,

state transition functions $P_t : \mathcal{S}_t \times \mathcal{A}_t \rightarrow \mathbb{P}(\mathcal{S}_{t+1})$ where $\mathbb{P}(\mathcal{S}_{t+1})$ is the space of probability measures on \mathcal{S}_{t+1} , and reward functions $\mathbf{R}_t : \mathcal{S}_t \times \mathcal{A}_t \rightarrow \mathbb{R}^D$ for $t \in \{1, \dots, T\}$. In keeping with the Markov assumption, both \mathbf{R}_t and P_t depend only on the current state and action. In this work we assume finite action sets, but we do *not* assume that state spaces are finite. The *value* of a policy π is then given by

$$\mathbf{V}^\pi(s) = \mathbb{E}^\pi \left[\sum_{t=1}^T \mathbf{R}^t(s_t, a_t) \mid s_1 = s \right] \quad (1)$$

which is the expected sum of (vector-valued) rewards we achieve by following policy π .

Just as “solving” an MDP is an optimization problem (i.e. we want the optimal value function or policy), “solving” a MOMDP is a *multi-objective optimization* (MOO) problem. Whereas in typical scalar optimization problems having a unique solution is viewed as typical or at least desirable, in the MOO setting, the most common goal is to produce a *set* of solutions that are *non-dominated*.

Definition 1 (Non-dominated a.k.a. Pareto optimal solutions) *Let \mathcal{X} be the set of all feasible inputs to a multi-objective optimization problem with objective $\mathbf{f}(x)$. Let \mathcal{Y} be the range of \mathbf{f} on \mathcal{X} . (In the RL context, one can think of \mathcal{X} as the set of all possible policies starting from a given state, and \mathcal{Y} as their corresponding values, which are vectors in this case.) A solution vector $\mathbf{y} \in \mathcal{Y}$ is non-dominated if $\nexists \mathbf{y}' \in \mathcal{Y}$ s.t. $\forall i, y'_i \geq y_i$ and $\exists j, y'_j > y_j$. A preimage $\mathbf{x} \in \mathcal{X}$ of such a \mathbf{y} is sometimes called an efficient solution, but we will also refer to such inputs as non-dominated.*

A common goal in MOO is to find *all* of the non-dominated solutions (Miettinen, 1999; Ehrgott, 2005). Some work on MOMDPs has this same goal (Perry and Weng, 2010). One approach to finding non-dominated solutions of a MOO problem is to solve a set of optimization problems that are *scalarized* versions of the MOO. A *scalarization function* ρ is chosen which maps vector-valued outcomes scalars and then one solves

$$\max_{x \in \mathcal{X}} \rho(\mathbf{f}(x)),$$

the scalar optimization defined by composing the vector-valued outcome function with the scalarization function. If a specific “correct” scalarization function is fixed and known, we can simply apply it to all outcome vectors and reduce our MOO problem to a scalar optimization problem (and arguably we never had a MOO problem to begin with.) Otherwise, we may seek solutions to scalarized problems for all ρ belonging to some function class. We assume that any ρ of interest is non-decreasing along each dimension, that is, it is always preferable to increase a reward dimension, all else being equal. It is well-known (Miettinen, 1999) that the set of Pareto-optimal solutions corresponds to the set of all solutions that are optimal for some scalarization function; we will use these two views of optimality as we construct our algorithm.

Previous work by Lizotte et al. (2012) uses dynamic programming to compute policies for all possible scalar rewards that are a convex combination of the basis rewards, using Q -functions learned by linear regression. Thus the output produces the optimal policies for all ρ such that $\rho(\mathbf{r}) = \mathbf{r}^\top \mathbf{w}$, $w_d > 0$, $\sum_d w_d = 1$. Each convex combination is interpreted

as a preference describing the relative importance of the the different basis rewards, and the method is used to show how preference relates to optimal action choice. This gives a new and potentially useful way of visualizing the connection between preference and action choice, but there are drawbacks to the approach. First, one must assume that the convex combination is fixed for all time points—that is, preferences do not change over time. This assumption enables dynamic programming to work, but is not reasonable for some applications, particularly in clinical decision-making where a patient’s first-hand experience with a treatment may influence subsequent preferences for symptom versus side-effect reduction. Second, the method is overly eager to eliminate actions. Consider two actions a_1 and a_2 that are extreme, e.g. a_1 has excellent efficacy but terrible side-effects and a_2 has no side-effects but poor efficacy. These could eliminate a third action a_3 that is moderately good according to both rewards. An example of this situation is illustrated in Figure 1 (a), which shows that the actions chosen by this method are restricted to the convex hull of the Pareto frontier, rather than the entire frontier. In this circumstance where a_3 is qualitatively very different from both a_1 and a_2 , we argue that a decision support system should suggest *all three* treatments and thereby allow the decision-maker to make the final choice based on her expertise. The third drawback of using this approach is that it is limited to ordinary least squares regression, which may not work well for data with non-Gaussian errors, e.g., a binary terminal reward.

Rather than use the method of Lizotte et al., we will instead base our method on assessing actions and policies using a *partial order* on their vector of Q -values. Perhaps the most common partial order on vectors comes from the notion of *Pareto-optimality* (Vamplew et al., 2011). For example, an action a is *Pareto-optimal* at a state st if $\forall (d, d') Q_{T|d}(st, a) \geq Q_{T|d'}(st, a')$. We will show in Section 5 that for $t < T$, the problem of deciding which actions are optimal is more complex, but we will still leverage the idea of a partial order. The problem of identifying Pareto-optimal policies is of significant interest in RL (Perry and Weng, 2010; Vamplew et al., 2009) and is closely related to what we wish to accomplish. Basing our work on the Pareto-optimal approach rather than on the previous work of Lizotte et al. avoids assuming that preferences are fixed over time, and it avoids the problem of “extreme” actions eliminating “moderate” ones. Furthermore, our approach works with a larger class of regression models, including ordinary least squares, the lasso, support vector regression, and logistic regression. While our Pareto-based approach makes these three improvements, using Pareto-optimality can *still* result in actions being eliminated unnecessarily; this is illustrated in Figure 1(b). We address this problem by introducing an alternative notion of domination in Section 6. Each of these contributions leads to increased action choice for the decision-maker by considering a larger class of preferences over reward vectors.

4.2 Non-Deterministic Policies

Milani Fard and Pineau (2011) describe non-deterministic policies for Markov Decision Processes (MDPs) with a finite state space and a single reward function. The term *non-deterministic* is used as in the study of *non-deterministic finite automata* and indicates that there are choices made as the system evolves about which we assume we have no

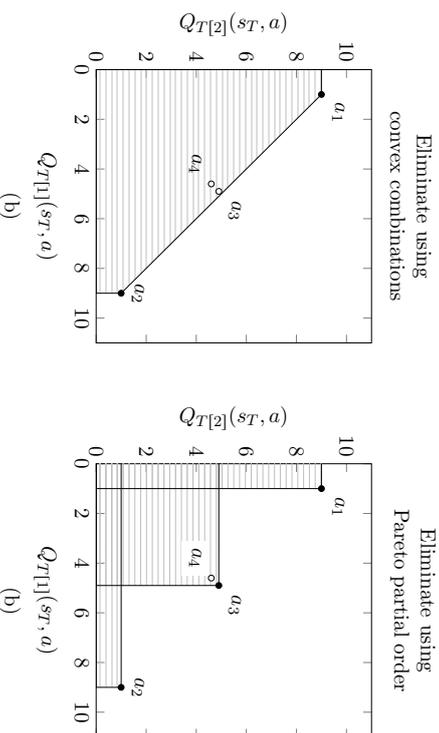

Figure 1: Comparison of existing approaches to eliminating actions at time T . The problems illustrated here have analogs for $t < T$ where the picture is more complicated. In this simple example, we suppose the vector-valued expected rewards ($Q_{T[1]}(s_T, a), Q_{T[2]}(s_T, a)$) are (1, 9), (9, 1), (4, 9, 4, 9), (4, 6, 4, 6) for actions a_1, a_2, a_3, a_4 , respectively. **Figure 1(a)**: Using the method of Lizotte et al. (2010, 2012) based on convex combinations of rewards, actions a_3 and a_4 would be eliminated, and we would have $\Pi_T(s_t) = \{a_1, a_2\}$. (Any action whose expected rewards fall in the shaded region would be eliminated.) However, we would prefer to at least include a_3 since it offers a more “moderate” outcome that may be important to some decision-makers. **Figure 1(b)**: Using the Pareto partial order, only action a_4 is eliminated, and we have $\Pi_T(s_T) = \{a_1, a_2, a_3\}$. However, we may prefer to include a_4 since its performance is very close to that of a_3 , and may be preferable for reasons we cannot infer from our data—e.g. cost, or allergy to a_3 .

information.¹ Given an MDP with *state space* S and an *action set* A , an NDP Π is a map from the state space to the set $2^A \setminus \{\emptyset\}$. Milani Fard and Pineau assume that a *user* operating the MDP will, at each timestep, choose an action from the set $\Pi(s)$. They are motivated by the same considerations that we are in the sense that they wish to provide choice to the user while still achieving good performance; thus, they only eliminate actions that are clearly sub-optimal. Because they consider only a single reward function, they can measure performance using the expected discounted infinite sum of future (scalar) rewards in the usual way, and they can produce an NDP Π that has near-optimal performance even if the user chooses the “worst” actions from $\Pi(s)$ in each state.

One can view the NDP as a compact way of expressing a set of policies that might be executed. Suppose that $\#A = |\Pi(s)|$, the number of actions provided by the NDP Π , is the same at all states. Then the number of policies that are *consistent* with Π , that is, the policies for which $\pi(s) \in \Pi(s)$, is $\#A^{|\mathcal{S}|}$. So the NDP Π is a compact encoding of an exponential number of policies. We will make use of this property to encode our policies. The two most important differences between our work and that of Milani Fard and Pineau are that our motivation for learning non-deterministic policies is driven explicitly by having more than one basis reward of interest, and that we use more general value function models rather than a tabular representation. Having multiple basis rewards combined with value function approximation leads us to a different, novel algorithm for learning NDPs.

5. Fitted- Q for MOMDPs

Our non-deterministic fitted- Q algorithm for multiple objectives uses finite-horizon, batch data. We present a version that uses linear value function approximation because this model is commonly used by statisticians working in clinical decision support (Strecher et al., 2006; Lizotte et al., 2010, 2012; Laber et al., 2014b), and because available data often contain continuous-valued features, e.g., symptom and side-effect levels, laboratory values, etc., and outcomes, e.g., symptom scores, body mass index. It is a flexible model because we will not restrict the state features one might use. For learning, we assume a batch of n data trajectories of the form

$$s^i_1, a^i_1, r^i_1[1], \dots, r^i_1[D]; s^i_2, a^i_2, r^i_2[1], \dots, r^i_2[D]; \dots; s^i_T, a^i_T, r^i_T[1], \dots, r^i_T[D] \text{ for } i = 1, \dots, n.$$

In the following exposition, we begin by specifying how the algorithm works for the last time point $t = T$. This would be the only step needed in a “non-sequential” decision problem. We then describe the steps analogous to the fitted- Q “backup” operation for earlier timepoints $t < T$, which are more complex.

5.1. Final time point, $t = T$

At time T , we define the approximate Q -function for reward dimension d as the linear least squares fit

$$\hat{Q}_{T[d]}(s_T, a_T) = \phi_T(s_T, a_T)^\top \hat{w}_{T[d]}, \quad \hat{w}_{T[d]} = \arg \min_w \sum_i \left(\phi_T(s^i_T, a^i_T)^\top w - r^i_T[a] \right)^2 \quad (2)$$

1. Note that *non-deterministic* does not mean “stochastic”; i.e., we do not suppose a known stationary random policy will be followed.

giving the estimated vector-valued expected reward function

$$\hat{\mathbf{Q}}_T(s_T, a_T) = (\hat{Q}_{T[1]}(s_T, a_T), \dots, \hat{Q}_{T[D]}(s_T, a_T))^T. \quad (3)$$

Here, $\phi_T(s_T, a_T)$ is a feature vector of state and action. As discussed by Lizotte et al. (2012), $\phi_T(s_T, a_T)$ would typically include: a constant component for the intercept, features describing s_T , dummy variables encoding the discrete action a_T , and the product of the dummy variables with the features describing s_T (Cook and Weisberg, 1999). One could also include other non-linear functions of s_T and a_T as features if desired. We present our method assuming that $\tilde{\mathbf{w}}_{T[d]}$ are found by least squares regression, but one could for example add an L_1 penalty, or use support vector regression (Hastie et al., 2001). Furthermore, unlike previous work by Lizotte et al. (2012), any Generalized Linear Model (GLM) with a monotonic increasing link function (e.g. logistic regression, Poisson regression, and so on) can also be used (Cook and Weisberg, 1999). Note that we can recover a ‘‘tabular’’ representation if the states are discrete and we assign mutually orthogonal feature vectors to each one.

Having obtained the $\hat{\mathbf{Q}}_T$ from (2), we construct an NDP Π_T that will give, for each state, the actions one might take at the last time point. For each state s_T at the last time point, each action a_T is associated with a *unique* vector-valued estimated expected reward given by $\mathbf{Q}_T(s_T, a_T)$. Thus, we decide which among these vectors is a desirable outcome, and include their associated actions in $\Pi_T(s_T)$. Our main focus will be to construct $\Pi_T(s_T)$ for each state based on the multi-objective criterion of Pareto optimality; however, an important advantage of our algorithm is that it can use other definitions of Π_T as well; we discuss an extension in Section 6. For example, different definitions of Π_T allow us to recover other varieties of Q -learning:

Scalar Fitted-Q: Defining

$$\Pi_T(s_T) = \{\arg \max_a \hat{Q}_{T[0]}(s_T, a)\}$$

gives standard fitted- Q applied to reward dimension 0.

Convex Pareto-optimal Fitted-Q: Defining

$$\Pi_T(s) = \{a : \exists \theta (\theta \geq \mathbf{0} \wedge \theta^T \mathbf{1} = 1 \wedge \forall a' \hat{\mathbf{Q}}_T(s_T, a)^T \theta \geq \hat{\mathbf{Q}}_T(s_T, a')^T \theta)\}$$

includes those actions whose expected reward is on the convex hull of the Pareto frontier; these are the actions that would be included by the previous method of Lizotte et al. (2012).

Pareto-optimal Fitted-Q: Defining

$$\Pi_T(s) = \{a : \nexists a' (\forall d \hat{Q}_{T[d]}(s_T, a) < \hat{Q}_{T[d]}(s_T, a'))\}$$

includes precisely those actions whose expected reward is on the (weak) Pareto frontier; this is a superset of those included by the method of Lizotte et al. (2012). It includes the actions that are optimal for some scalarization function, which is our action set of interest.

5.2 Earlier time points, $t < T$

For $t < T$, it is only possible to define the expected return of taking an action in a given state by also deciding which particular policy will be followed to choose future actions. In standard fitted- Q , for example, one assumes that the future policy is given by $\pi_t(s) = \arg \max_a \hat{Q}_j(s, a)$ for all $j > t$. In the non-deterministic setting, we may know that the future policy belongs to some set of possible policies derived from Π_j for $j > t$, but in general we do not know which among that set will be chosen; therefore, we explicitly include the dependence of $\hat{\mathbf{Q}}_t$ on the choice of future policies π_j , $t < j \leq T$:

$$\hat{\mathbf{Q}}_t(s_t, a_t; \pi_{t+1}, \dots, \pi_T) = \left\{ \hat{Q}_{t[1]}(s_t, a_t; \pi_{t+1}, \dots, \pi_T), \dots, \hat{Q}_{t[D]}(s_t, a_t; \pi_{t+1}, \dots, \pi_T) \right\}^T$$

where

$$\text{for } d = 1, \dots, D, \quad \hat{Q}_{t[d]}(s_t, a_t; \pi_{t+1}, \dots, \pi_T) = \phi_t(s_t, a_t)^T \tilde{\mathbf{w}}_{t[d]|\pi_{t+1}, \dots, \pi_T},$$

and

$$\tilde{\mathbf{w}}_{t[d]|\pi_{t+1}, \dots, \pi_T} = \arg \min_{\mathbf{w}} \sum_{i=1}^n \left[\phi_t(s_t^i, a_t^i)^T \mathbf{w} - \left\{ r_{t[d]}^i + \hat{Q}_{t+1[d]}(s_{t+1}^i, \pi_{t+1}(s_{t+1}^i); \pi_{t+2}, \dots, \pi_T) \right\} \right]^2. \quad (4)$$

We say an expected return is *achievable* if it can be obtained by taking some immediate action in the current state and following it with a fixed sequence of policies until we reach the last time point.

We use \mathcal{Q}_t to denote a set of partially-evaluated Q -functions; each member of \mathcal{Q}_t is a function of s_t and a_t only and assumes a particular fixed sequence π_{t+1}, \dots, π_T of future policies. Precisely which future policies should be considered is the subject of the next section. For the last time point, we define $\mathcal{Q}_T = \{\hat{\mathbf{Q}}_T\}$, the set containing the single (multivariate) Q -function for the last time point. Figure 2 is a visualization of an example \mathcal{Q}_{T-1} where each function in the set is evaluated at the same given state and for each of the five available actions, $\{\blacktriangleright, \blacksquare, \blacktriangleleft, \blacktriangleright\}$. Thus, each element of the example \mathcal{Q}_{T-1} corresponds to a collection of five markers on the plot, one for the expected return for each action, assuming we follow a particular π_T . The question of what collection of π_T we should consider is the subject of the next section.

5.3 Constructing Π_t from Π_{t+1}

We now describe the ‘‘backup’’ step that constructs Π_t and \mathcal{Q}_t from Π_{t+1} and \mathcal{Q}_{t+1} . A member of \mathcal{Q}_t is constructed from data using equation (4) by choosing two components: An element of \mathcal{Q}_{t+1} (with its implicit choice of π_{t+2} through π_T) and a policy π_{t+1} . When considering different possible π_{t+1} , we restrict our attention to policies that i) are *consistent* with Π_{t+1} , and ii) are *representable* using the approximation space chosen for $\hat{\mathbf{Q}}_{t+1}$. In the following, we define these notions of consistency and representability, argue that this subset of policies contains all those we need to consider, and show how the set of consistent and representable policies can be efficiently enumerated using mixed integer linear programming.

To construct \mathcal{Q}_t , we will only consider future policies that are consistent with the NDPs we have already learned for later time points. As described above, each $\Pi(s)$ contains each action for which some scalarization function (i.e. preference) prefers that action.

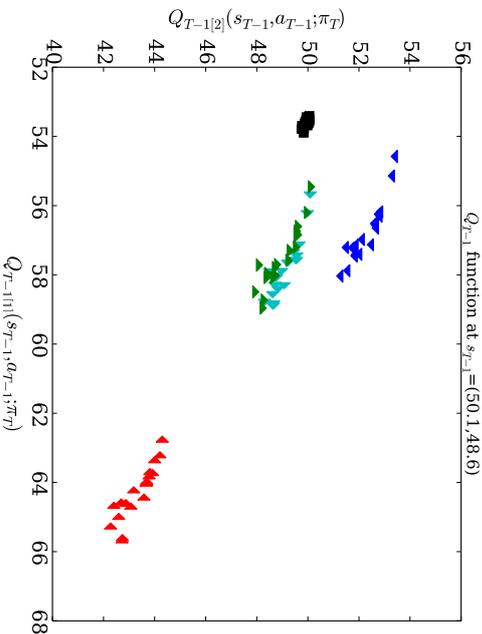

Figure 2: Partial visualization of the members of an example Q_{T-1} . We fix a state $s_{T-1} = (50.1, 48.6)$ in this example, and we plot $\hat{Q}_{T-1}(s_{T-1}, a_{T-1})$ for each $\hat{Q}_{T-1} \in Q_{T-1}$ and for each $a_{T-1} \in \{\blacktriangledown, \blacksquare, \blacktriangle, \blacklozenge, \blacktriangleright, \blacktriangleleft\}$. For example, the \blacktriangledown markers near the top of the plot correspond to expected returns for each $\hat{Q} \in Q_{T-1}$ that is achievable by taking the \blacktriangledown action at the current time point and then following a particular future policy. This example Q_{T-1} contains 20 \hat{Q}_{T-1} functions, each assuming a different π_T .

Definition 2 (Policy consistency) A policy π is consistent with an NDP Π , denoted $\pi \subset \Pi$, if and only if $\pi(s) \in \Pi(s) \forall s \in S$. We denote the set of all policies consistent with Π by $C(\Pi)$.

This restriction is analogous to fitted- Q in the scalar reward setting, where we estimate the current Q function assuming we will follow the greedy policy of the estimated optimal Q function at later time points. In our setting, there are likely to be multiple different policies whose values, pointwise at each state, are considered “optimal,” e.g. that are Pareto non-dominated. Although we cannot pare down the possible future policies to a single unique choice as in scalar fitted- Q , we can still make significant computational savings. Note that in the batch RL setting, two policies are distinguishable only if they differ in action choice on states observed in our data set. In the following, when we talk about the properties of policies, we mean in particular over the observed states in our data set. Where clarification is needed, we write S_t^n to mean the n states observed in our data set at time t . Note that $|C(\Pi_t)| = \sum_{s \in S_t^n} |\Pi_t(s_t)|$; the product of the cardinalities of the sets produced by Π_t over the observed data. Because $|\Pi_t(s_t)| \leq |\mathcal{A}|$, we have $|C(\Pi_t)| \leq |\mathcal{A}|^n$. If Π_t screens out enough actions from enough observed states, restriction to consistent policies can result in a much smaller Q_T . Unfortunately, in the worst case where $\forall s_t, \Pi_t(s_t) = \mathcal{A}_t$, we have $|C(\Pi_t)| = |\mathcal{A}|^n$,

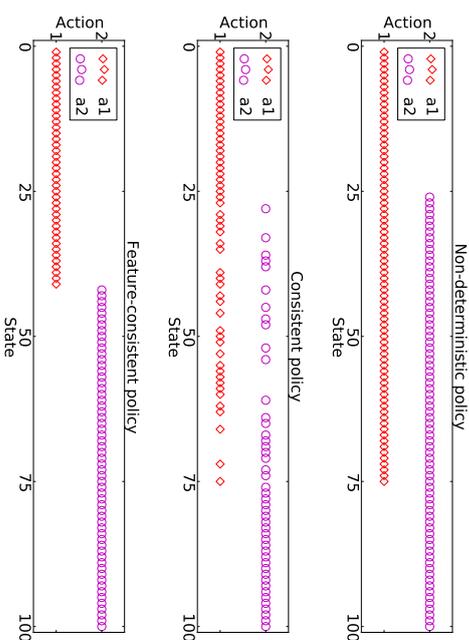

Figure 3: An NDP on a one-dimensional continuous state-space, a consistent policy, and a ϕ -consistent policy.

and if for some fraction η of the n trajectories ($0 < \eta \leq 1$) we have $|\Pi_t(s_t)| \geq 2$, then we have $|C(\Pi_t)| \in \Omega(2^\eta)$. Therefore in many interesting cases, computing a Q_t that includes even just the consistent future policies is computationally intractable.

We therefore impose a further restriction on possible future policies, again only eliminating policies we do not wish to consider. In scalar fitted- Q , the learned optimal policy is given by $\text{argmax}_a Q(s, a)$. If the learned Q -functions are linear in some feature space, then the learned optimal policy can be represented by a collection of linear separators that divide feature space into regions where different actions are chosen. This is true for *any* scalar reward signal. Therefore, in the scalar reward case for a given feature space, any future policy that cannot be represented in this way will never be considered when computing \hat{Q} for earlier timepoints no matter what the observed rewards are.

In NDP settings where $\dim \phi_t(s_t, a_t) \ll n$, most of the policies that are consistent with $\Pi_t(s_t)$ are not representable in the form $\pi(s_t) = \text{argmax}_a Q_t(s_t, a)$, and therefore would never be learned by fitted- Q iteration using *any* scalar reward signal. Figure 3 illustrates this. The top panel shows a non-deterministic policy on a one-dimensional continuous state-space with two possible actions. The middle panel shows a policy that is consistent with the NDP. Though it is consistent, this policy is a complex function of the 1D state and is difficult to justify if the state is a continuous patient measurement and the action is a treatment. Furthermore, there is *no* Q -function linear in the given feature space that produces this consistent policy as its greedy policy. In other words, given the feature space, there is *no scalar reward signal* that would cause us to learn this policy with fitted- Q and

linear regression. We therefore will “prune away” these consistent but un-representable policies in order to reduce the size of \mathcal{Q}_t by introducing the notion of *policy ϕ -consistency*.

Definition 3 (Policy ϕ -consistency) *Given a feature map $\phi : \mathcal{S} \times \mathcal{A} \rightarrow \mathbb{R}^p$, we say a policy π_t is ϕ -consistent with a non-deterministic policy Π_t over a data set with n trajectories, if and only if $\exists \mathbf{w} (\forall i \in 1, \dots, n \pi_t(s_t^i) \wedge \pi_t(s_t^i) = \arg\max_a \phi(s_t^i, a)^\top \mathbf{w})$. We write $\pi_t \sqsubseteq_\phi \Pi_t$, and we denote the set of all policies that are ϕ -consistent with Π_t by $\mathcal{C}_\phi(\Pi_t)$.*

A ϕ -consistent policy is an element of $\mathcal{C}(\Pi_t)$ that is the argmax policy for some (scalar) Q -function over the feature map ϕ . The form of such a policy is much like that of the function learned by a structured-output SVM (Tsochantaridis et al., 2005).

We now show that the number of ϕ -optimal policies for any given time point is polynomial in the data set size n .

Theorem 1 *Given a data set of size n , a feature map ϕ , and an action set \mathcal{A} , there are at most $O(n^{\dim(\phi)} \cdot |\mathcal{A}|^{2 \dim(\phi)})$ feature-consistent policies.*

Proof The space of ϕ -consistent policies is exactly analogous to the space of linear multiclass predictors with ϕ as their feature map. We therefore port two results from learning theory to analyze the number of ϕ -consistent policies in terms of the dimension of ϕ , the size of the data set n , and the size of the action set. The *Natarajan dimension* (Natarajan, 1989; Shalev-Shwartz and Ben-David, 2014) is an extension of VC-dimension to the multiclass setting. For a supervised learning data set of size n , k classes, and a hypothesis class \mathcal{H} with Natarajan dimension $\text{Ndim}(\mathcal{H})$, the number $|\mathcal{H}_n|$ of hypotheses restricted to the n datapoints is subject to the following upper bound due to Natarajan (1989):

$$|\mathcal{H}_n| \leq n^{\text{Ndim}(\mathcal{H})} \cdot k^{2 \cdot \text{Ndim}(\mathcal{H})}. \quad (5)$$

Furthermore, the hypothesis class given by

$$\mathcal{H}_\phi = \{x \mapsto \arg\max_i \phi(x, i)^\top \mathbf{w} : \mathbf{w} \in \mathbb{R}^{\dim \phi}\} \quad (6)$$

has Natarajan dimension $\text{Ndim}(\mathcal{H}_\phi) = \dim(\phi)$ (Shalev-Shwartz and Ben-David, 2014). ■ Combining Equations (5) and (6) and completes our proof.

Theorem 1 shows that for fixed $|\mathcal{A}|$ and $\dim(\phi)$ there are only polynomially many ϕ -consistent future policies, rather than a potentially exponential number of consistent policies as a function of n . Therefore, by considering only ϕ -consistent future policies, we can ensure that the size of \mathcal{Q}_{T-1} is polynomial in n . The restriction to ϕ -consistent policies applies to Q -functions based on Generalized Linear Models with monotonic increasing link functions (such as logistic regression) as well. Such models have output of the form $g(\phi(s_t, a)^\top \mathbf{w})$ for monotonic increasing g . For these models, $\arg\max_a g(\phi(s_t^i, a)^\top \mathbf{w}) = \arg\max_a \phi(s_t, a)^\top \mathbf{w}$, so all of our results and algorithms for ϕ -consistency immediately apply.

We note that even if we prune using ϕ -consistency, the number of policies is exponential in $\dim \phi$, the feature space. Hence, this approach is tractable only for relatively simple Q -models. In this work we demonstrate that it is practical in a proof-of-concept setting (the CATIE study) but we acknowledge this limitation and defer it to future work.

We now express $\mathcal{C}_\phi(\Pi)$ in a way that allows us to enumerate it using a Mixed Integer Program (MIP). To formulate the constraints describing $\mathcal{C}_\phi(\Pi)$, we take advantage of *indicator constraints*, a mathematical programming formalism offered by modern solvers; e.g. the CPLEX optimization software package as of version 10.0, which was released in 2006 (CPLEX). Each indicator constraint is associated with a binary variable, and is only enforced when that variable takes the value 1. To construct the MIP, we introduce $n \times |\mathcal{A}|$ indicator variables $\alpha_{i,j}$ that indicate whether $\pi(s^i) = j$ or not. We then impose the following constraints:

$$\forall i \in 1, \dots, n, j \in 1, \dots, |\mathcal{A}|, \alpha_{i,j} \in \{0, 1\} \quad (7)$$

$$\forall i \in 1, \dots, n, \sum_j \alpha_{i,j} = 1 \quad (8)$$

$$\forall i \in 1, \dots, n, \forall j \in 1, \dots, |\mathcal{A}|, \alpha_{i,j} = 1 \implies \forall k \neq j, (\phi(s^i, j) - \phi(s^i, k))^\top \mathbf{w} \geq 1. \quad (9)$$

Constraints (7) ensure that the indicator variables for the actions are binary. Constraints (8) ensure that, for each example in our data set, exactly one action indicator variable is on. The indicator constraints in (9) ensure that if the indicator for action j is on for the i th example, then weights must satisfy $j = \arg\max_a \phi(s^i, a)^\top \mathbf{w}$. Note that the margin condition (i.e., having the constraint be ≥ 1 rather than ≥ 0) avoids a degenerate solution with $w = \mathbf{0}$.

The above constraints ensure that any feasible $\alpha_{i,j}$ define a policy that can be represented as an argmax of linear functions over the given feature space. Imposing the additional constraint that the policy defined is consistent with a given NDP Π is now trivial:

$$\forall i \in 1, \dots, n, \sum_{j \in \Pi(s^i)} \alpha_{i,j} = 1. \quad (10)$$

Constraints (10) ensure that the indicator that turns on for the i th example in the data must be one that indicates an action that belongs to the set $\Pi(s^i)$.

Note that we have not specified an objective for this MIP; for the problem of generating ϕ -consistent policies, we are only interested in generating feasible solutions and interpreting the label variables as a potential future policy. Software such as CPLEX can enumerate all possible discrete feasible solutions to the constraints we have formulated. To do so, we give the constraints to the solver and ask for solutions given an objective that is identically zero. Note that if we instead minimized the quadratic objective $\|w\|^2$ subject to these constraints, we would recover the consistent policy with the largest margin between action choices in the feature space. The output would be equivalent to exact transductive learning of a hard-margin multiclass SVM using the actions as class labels (Tsochantaridis et al., 2005).

Given \mathcal{Q}_t , our final task is to define $\Pi_t(s_t)$ for all s_t . While \mathcal{Q}_T is a singleton, for $t < T$ this is not the case in general, and we must take this into account when defining $\Pi_t(s_t)$. We present two definitions for $\Pi_t(s_t)$ based on a strict partial order $<$. (For example $<$ may be the Pareto partial order.)

$$\begin{aligned} \Pi_t^>(s_t) &= \{a : \forall \hat{Q} \in \mathcal{Q}_t, (\nexists! a' \neq a, \hat{Q}' \in \mathcal{Q}_t) (\hat{Q}(s_t, a) < \hat{Q}'(s_t, a'))\} \\ \Pi_t^<(s_t) &= \{a : \exists \hat{Q} \in \mathcal{Q}_t (\nexists! a' \neq a, \hat{Q}' \in \mathcal{Q}_t) (\hat{Q}(s_t, a) < \hat{Q}'(s_t, a'))\}. \end{aligned}$$

Algorithm 1 Non-deterministic fitted- Q

```

Learn  $\hat{Q}_T = (\hat{Q}_{T[1]}, \dots, \hat{Q}_{T[D]})$ , set  $\mathcal{Q}_T = \{\hat{Q}_T\}$ 
for  $t = T-1, T-2, \dots, 1$  do
  for all  $s_t^i$  in the data do
    Generate  $\Pi_{\leq}^{\pm}(s_t^i)$  using  $\mathcal{Q}_{t+1}$ 
   $\mathcal{Q}_t \leftarrow \emptyset$ 
  for all  $\pi_t \in \mathcal{C}_\phi(\Pi_{\leq}^{\pm})$  do
    for all  $\hat{Q}_{t+1} \in \mathcal{Q}_{t+1}$  do
      Learn  $(\hat{Q}_{t[1]}(\cdot, \cdot, \pi_t, \dots), \dots, \hat{Q}_{t[D]}(\cdot, \cdot, \pi_t, \dots))$  using  $\hat{Q}_{t+1}$ , add to  $\mathcal{Q}_t$ 

```

Under Π_{\leq}^{\vee} , action a is included if for *all* fixed sequences of policies we might follow after choosing a , no other choice of current action and future policy is preferable according to \prec . Π_{\leq}^{\vee} is appealing in cases where we wish to guard against a naive decision maker choosing poor sequences of future actions. For the \mathcal{Q}_{T-1} shown in Figure 2, we would have $\Pi_{\leq}^{\vee}(s_{T-1}) = \{\blacktriangleright, \blacktriangleleft\}$. The \blacksquare action is obviously eliminated because any \blacktriangleright point dominates every single \blacksquare point. The \blacktriangleleft and \blacktriangleright actions eliminate each other: There are \blacktriangleleft points that are dominated by \blacktriangleright points, and \blacktriangleright points that are dominated by \blacktriangleleft points. Note that this illustrates how $\Pi_{\leq}^{\vee}(s_t)$ could be empty: if our example only contained the \blacktriangleright and \blacktriangleleft actions, we would have $\Pi_{\leq}^{\vee}(s_{T-1}) = \emptyset$. In practice we find that Π_{\leq}^{\vee} can be very restrictive; we therefore present Π_{\leq}^{\pm} as an alternative. Under Π_{\leq}^{\pm} , action a is included if there is *at least one* fixed future policy for which a is not dominated by a value achievable by another (a', \hat{Q}) pair. Note that $\Pi_{\leq}^{\pm} \supseteq \Pi_{\leq}^{\vee}$, and that because the relation $\mathbf{Q} < \mathbf{Q}'$ is a partial order on a finite set, there must exist at least one maximal element; therefore $\Pi_{\leq}^{\pm}(s_t) \neq \emptyset$. In the Figure 2 example, we have $\Pi_{\leq}^{\pm}(s_{T-1}) = \{\blacktriangleright, \blacktriangleleft, \blacktriangle, \blacklozenge\}$; note that \blacksquare is not included because there is always another action that can dominate it if we choose an appropriate future policy. In order to provide increased choice and to ensure we do not generate NDRs with empty action sets, we will use Π_{\leq}^{\pm} in our complete non-deterministic multiple-reward fitted- Q algorithm, but in our examples we will investigate the effect of choosing Π_{\leq}^{\vee} instead.

5.4 Time Complexity

Pseudocode is given in Algorithm 1. The time cost of Algorithm 1 is dominated by the construction of \mathcal{Q}_t , whose size may increase by a factor of $O(n^{\text{dim } \phi})$ at each timestep; therefore in the worst case $|\mathcal{Q}_1|$ is exponential in T . This can be mitigated somewhat by pruning \mathcal{Q}_t at each step, essentially removing from consideration future policy sequences that are dominated no matter what current action is chosen. Again, this pruning has no impact on solution quality because we are only eliminating future policy sequences that will never be executed. Despite the exponential dependence on T , we will show that our method can be successfully applied to real data in Section 7, and we defer the development of approximations to future work.

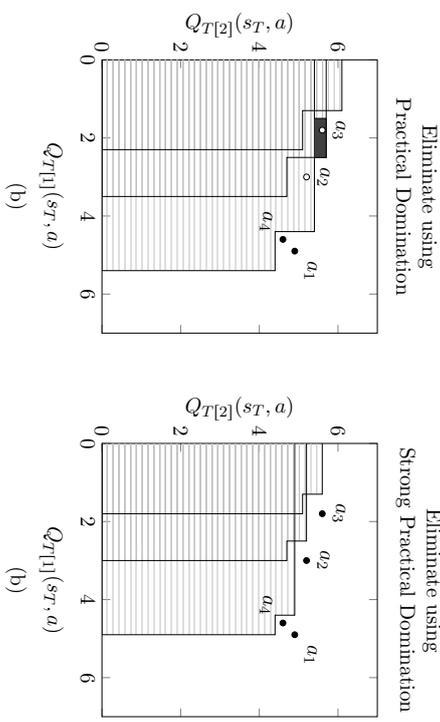

Figure 4: Comparison of rules for eliminating actions. In this simple example, we suppose the Q -vectors $(Q_{T[1]}(s_T, a), Q_{T[2]}(s_T, a))$ are $(4.9, 4.9)$, $(3, 5.2)$, $(1.8, 5.6)$, $(4.6, 4.6)$ for a_1, a_2, a_3, a_4 , respectively, and suppose $\Delta_1 = \Delta_2 = 0.5$. **Figure 4(a)**: Using the Practical Domination rule, action a_4 is not eliminated by a_3 because it is not much worse according to either basis reward, as judged by Δ_1 and Δ_2 . Action a_2 is eliminated because although it is slightly better than a_1 according to basis reward 2, it is much worse according to basis reward 1. Similarly, a_3 is eliminated by a_2 . Note the small solid rectangle to the left of a_2 : points in this region (including a_3) are dominated by a_2 , but not by a_1 . This illustrates the non-transitivity of the Practical Domination relation, and in turn shows that it is not a partial order. **Figure 4(b)**: Using Strong Practical Domination, which is a partial order, no actions are eliminated, and there are no regions of non-transitivity.

6. Practical domination

So far we have presented our algorithm assuming we will use Pareto dominance to define \prec . However, there are two ways in which Pareto dominance does not reflect the reasoning of a physician when she determines whether one action is superior to another. First, an action that has a *slightly* lower value along a single dimension, but is otherwise equivalent, will be Pareto-dominated (and eliminated) even if this difference is clinically meaningless. A physician with this knowledge would consider both actions in light of other “tie-breaking” factors not known to the RL policy, e.g., cost, allergies, etc. Second, an action that is slightly better for one reward but *much* worse for another would *not* be dominated, even though it may realistically be a very poor choice, and perhaps even unethical. Chatterjee et al. (2006) introduced ε -dominance which would partially address the first issue, but not the second. We wish to eliminate only actions that are “obviously” inferior while maintaining as much freedom of choice as possible. To accomplish this, we use the idea of *practical significance* (Kirk, 1996) to develop a definition of domination based on the idea that in real-world applications, small enough differences in expected reward simply do not matter. Differences that fall below a threshold of importance are termed “practically insignificant.”

We introduce two notions of domination that are modifications of Pareto domination. The first, *Practical Domination*, most accurately describes our intuition about the set of actions that should be recommended. However, we show that it has an undesirable non-transitivity property. We then describe an alternative strategy based on what we call *Strong Practical Domination*.

Definition 4 (Practical Domination) *We say that an action a_2 is practically dominated by a_1 at state s_T , and we write $a_2 \prec_p a_1$, if both of the following hold*

$$\forall d \in 1, \dots, D \quad Q_{T[d]}(s_T, a_2) \leq Q_{T[d]}(s_T, a_1) + \Delta_d, \quad (11)$$

$$\exists d \in 1, \dots, D \quad Q_{T[d]}(s_T, a_2) < Q_{T[d]}(s_T, a_1) - \Delta_d. \quad (12)$$

If either of the above do not hold, we write $a_2 \not\prec_p a_1$.

Intuitively, an action a_1 practically dominates a_2 if a_2 is “not practically better” than a_1 for any basis reward (property 11), and if a_2 is “practically worse” than a_1 for *some* basis reward (property 12). “Practically better” and “practically worse” are determined by the elicited differences $\Delta_d \geq 0$. Note that we could have Δ_d depend on the current state if that were appropriate for the application at hand; for simplicity we assume a uniform Δ_d . We might consider using the relation \prec_p as the ordering that produces our NDP according to one of the mappings from Section 5. Unfortunately, \prec_p is not transitive. Suppose that the Q -vectors $(Q_{T[1]}(s_T, a), Q_{T[2]}(s_T, a))$ are $(4.9, 4.9)$, $(3, 5.2)$, $(1.8, 5.6)$, $(4.6, 4.6)$ for a_1, a_2, a_3, a_4 , respectively, and suppose $\Delta_1 = \Delta_2 = 0.5$. Then $a_2 \prec_p a_1$ and $a_3 \prec_p a_2$ but $a_3 \not\prec_p a_1$. This non-transitivity causes undesirable behavior: if we consider only actions a_1 and a_3 , we get $\Pi_{\prec}^+(s_T) = \{a_1, a_3\}$. However, if we consider a_1, a_2 and a_3 , we get $\Pi_{\prec}^+(s_T) = \{a_1\}$! Thus by considering *more* actions, we get a *smaller* $\Pi_{\prec}^+(s_T)$. This is unacceptable in our domain, so we introduce an alternative.²

² Note that for binary actions, the non-transitivity is not an issue and that this is common in some medical applications (e.g. treatment vs. watchful waiting, high-intensity vs. low-intensity treatment, etc.)

Definition 5 (Strong Practical Domination) *We say an action a_2 is strongly practically dominated by a_1 at state s_T , and we write $a_2 \prec_{sp} a_1$, if both of the following hold.*

$$\forall d \in 1, \dots, D \quad Q_{T[d]}(s_T, a_2) \leq Q_{T[d]}(s_T, a_1) \quad (13)$$

$$\exists d \in 1, \dots, D \quad Q_{T[d]}(s_T, a_2) < Q_{T[d]}(s_T, a_1) - \Delta_d \quad (14)$$

If either of the above do not hold, we write $a_2 \not\prec_{sp} a_1$.

The relation \prec_{sp} is transitive, and will not cause the unintuitive results of \prec_p . However, it does not eliminate actions that are slightly better for one basis reward but much worse for another. (Note that $\exists d \in 1..D, Q_{T[d]}(s_T, a_2) > Q_{T[d]}(s_T, a_1) \implies a_2 \not\prec_{sp} a_1$.) We propose a compromise: we will use \prec_{sp} as our partial order for producing NDPs as in Section 5. However, if an action a would have been eliminated according to \prec_p but not according to \prec_{sp} , we may “warn” that it may be a bad choice. This has no impact on computation of Π and Q at earlier time points, but can warn the user that choosing a entails taking a practically significant loss on one basis reward to achieve a practically insignificant gain on another.

7. Empirical Example: CATIE

We illustrate the output of non-deterministic fitted- Q using data from the Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) study. The CATIE study was designed to compare sequences of antipsychotic drug treatments for the care of schizophrenia patients. The full study design is quite complex (Stroup and al, 2003; Swartz et al., 2003); we use a simplified subset of the CATIE data in order to more clearly illustrate the proposed methodology. CATIE was an 18-month study of $n = 1460$ patients that was divided into two main phases of treatment. Upon entry, most patients began “Phase 1,” and were randomized to one of five treatments³ with equal probability: olanzapine \blacklozenge , risperidone \blacklozenge , quetiapine \blacklozenge , ziprasidone \blacklozenge , or perphenazine \blacksquare . As time passed, patients were given the opportunity to discontinue their Phase 1 treatment and begin “Phase 2” on a new treatment. The possible Phase 2 treatments depended on the reason for discontinuing Phase 1 treatment. If the Phase 1 treatment was ineffective at reducing symptoms, then patients entered the “Efficacy” arm of Phase 2, and their Phase 2 treatment was chosen randomly as: {clozapine \blacklozenge } with probability 1/2, or uniformly randomly from the set {olanzapine \blacklozenge , risperidone \blacklozenge , quetiapine \blacklozenge } with probability 1/2. Because relatively few patients entered this arm, and because of the uneven action probabilities, it is reasonable to combine {olanzapine \blacklozenge , risperidone \blacklozenge , quetiapine \blacklozenge } into one “not-clozapine” action, and we will do so here. If the Phase 1 treatment produced unacceptable side-effects, they entered the “Tolerability” arm of Phase 2, and their Phase 2 treatment was chosen uniformly randomly from {olanzapine \blacklozenge , risperidone \blacklozenge , quetiapine \blacklozenge , ziprasidone \blacklozenge }.

The goal of analyzing CATIE is to develop a two-time point policy ($T = 2$), choosing the initial treatment at $t = 1$ and possibly a follow-up treatment at $t = 2$. From a methodological perspective, the $t = 1$ policy is most interesting as it requires the computation of Q_1 using Algorithm 1. Previous authors have used batch RL to analyze data from this study using

³ Throughout the text we will suffix each treatment name with its corresponding plot-marker.

a single basis reward (Shortreed et al., 2011) and examining convex combinations of basis rewards (Lizotte et al., 2012). In the following, we present the treatment recommendations of a non-deterministic fitted- Q analysis that considers both symptom relief and side-effects, and we compare with the output of a method by Lizotte et al. (2010, 2012). We begin by describing our basis rewards and our state spaces for $t = 2$ and $t = 1$, and we then present our results, paying particular attention to how much action choice is available using the different methods.

7.1 Basis Rewards

We will use ordinary least squares to learn Q functions for two basis rewards. For our first basis reward, we use the Positive and Negative Syndrome Scale (PANSS) which is a numerical representation of the severity of psychotic symptoms experienced by a patient (Kay et al., 1987). PANSS has been used in previous work on the CATIE study (Shortreed et al., 2011; Lizotte et al., 2012; Swartz et al., 2003), and is measured for each patient at the beginning of the study and at several times over the course of the study. Larger PANSS scores are worse, so for our first basis reward $r_{[1]}$ we use 100 minus the percentile of a patient’s PANSS at their exit from the study. We use the distribution of PANSS at intake as the reference distribution for the percentile.

For our second basis reward, we use Body Mass Index (BMI), a measure of obesity. Weight gain is an important and problematic side-effect of many antipsychotic drugs (Allison et al., 1999), and has been studied in the multiple-reward context (Lizotte et al., 2012). Because having a larger BMI is worse, for our second basis reward, $r_{[2]}$, we use 100 minus the percentile of a patient’s BMI at the end of the study, using the distribution of BMI at intake as the reference distribution.

7.2 State Space

For our state space, we use the patient’s most recently recorded PANSS score, which experts consider for decision making (Shortreed et al., 2011). We also include their most recent BMI, and several baseline characteristics.

Because the patients who entered Phase 2 had different possible action sets based on whether they entered the Tolerability or Efficacy arm, we learn separate Q -functions for these two cases. The feature vectors we use for Stage 2 Efficacy patients are given by

$$\phi^{\text{EFF}}(s_2, a_2) = [1, \text{1TD}, \text{1EX}, \text{1ST1}, \text{1ST2}, \text{1ST3}, \text{1ST4}, s_{2:P}, s_{2:B}, \\ \mathbf{1}_{a_2=\bullet}, s_{2:P} \cdot \mathbf{1}_{a_2=\bullet}, s_{2:B} \cdot \mathbf{1}_{a_2=\bullet}]^T.$$

Here, $s_{2:P}$ and $s_{2:B}$ are the PANSS and BMI percentiles at entry to Phase 2, respectively. Feature $\mathbf{1}_{a_2=\bullet}$ indicates that the action at the second stage was clozapine \bullet and not one of the other treatments. We also have other features that do not influence the optimal action choice but that are chosen by experts to reduce variance in the value estimates. 1TD indicates whether the patient has had tardive dyskinesia (a motor-control side-effect), 1EX indicates whether the patient has been recently hospitalized, and 1ST1 through 1ST4

indicate the “site type,” which is the type of facility at which the patient is being treated (e.g. hospital, specialist clinic, etc.)

For Phase 2 patients in the Tolerability arm, the possible actions are $\mathcal{A}_2^{\text{TOI}} = \{\blacktriangleleft, \blacktriangle, \blacktriangleright, \blacktriangleright\}$, and the feature vectors we use are given by

$$\phi^{\text{TOI}}(s_2, a_2) = [1, \text{1TD}, \text{1EX}, \text{1ST1}, \text{1ST2}, \text{1ST3}, \text{1ST4}, s_{2:P}, s_{2:B}, \\ \mathbf{1}_{a_2=\blacktriangleleft}, s_{2:P} \cdot \mathbf{1}_{a_2=\blacktriangleleft}, s_{2:B} \cdot \mathbf{1}_{a_2=\blacktriangleleft}, \mathbf{1}_{a_2=\blacktriangle}, s_{2:P} \cdot \mathbf{1}_{a_2=\blacktriangle}, s_{2:B} \cdot \mathbf{1}_{a_2=\blacktriangle}, \\ \mathbf{1}_{a_2=\blacktriangleright}, s_{2:P} \cdot \mathbf{1}_{a_2=\blacktriangleright}, s_{2:B} \cdot \mathbf{1}_{a_2=\blacktriangleright}, \mathbf{1}_{a_2=\blacktriangleright}, s_{2:P} \cdot \mathbf{1}_{a_2=\blacktriangleright}, s_{2:B} \cdot \mathbf{1}_{a_2=\blacktriangleright}]^T.$$

Here we have three indicator features for different treatments at Phase 2, $\mathbf{1}_{a_2=\blacktriangleleft}$, $\mathbf{1}_{a_2=\blacktriangle}$, with ziprasidone represented by turning all of these indicators off. Again we include the product of each of these indicators with the PANSS percentile s_2 . The remainder of the features are the same as for the Phase 2 Efficacy patients.

For Phase 1 patients, the possible actions are $\mathcal{A}_1 = \{\blacktriangleleft, \blacksquare, \blacktriangle, \blacktriangleright, \blacktriangleright\}$, and the feature vectors we use are given by

$$\phi^{\text{EFF}}(s_2, a_2) = [1, \text{1TD}, \text{1EX}, \text{1ST1}, \text{1ST2}, \text{1ST3}, \text{1ST4}, s_{1:P}, s_{1:B}, \\ \mathbf{1}_{a_2=\blacktriangleleft}, s_{1:P} \cdot \mathbf{1}_{a_2=\blacktriangleleft}, s_{1:B} \cdot \mathbf{1}_{a_2=\blacktriangleleft}, \mathbf{1}_{a_2=\blacksquare}, s_{1:P} \cdot \mathbf{1}_{a_2=\blacksquare}, s_{1:B} \cdot \mathbf{1}_{a_2=\blacksquare}, \\ \mathbf{1}_{a_2=\blacktriangle}, s_{1:P} \cdot \mathbf{1}_{a_2=\blacktriangle}, s_{1:B} \cdot \mathbf{1}_{a_2=\blacktriangle}, \mathbf{1}_{a_2=\blacktriangleright}, s_{1:P} \cdot \mathbf{1}_{a_2=\blacktriangleright}, s_{1:B} \cdot \mathbf{1}_{a_2=\blacktriangleright}, \\ \mathbf{1}_{a_2=\blacktriangleright}, s_{1:P} \cdot \mathbf{1}_{a_2=\blacktriangleright}, s_{1:B} \cdot \mathbf{1}_{a_2=\blacktriangleright}]^T.$$

We have four indicator features for different treatments at Phase 2, $\mathbf{1}_{a_1=\blacktriangleleft}$, $\mathbf{1}_{a_1=\blacksquare}$, and $\mathbf{1}_{a_1=\blacktriangle}$, with ziprasidone represented by turning all of these indicators off. We include the product of each of these indicators with the PANSS percentile s_1 at entry to the study, and the remainder of the features are the same as for the Phase 2 feature vectors. (These are collected before the study begins and are therefore available at Phase 1 as well.)

7.3 Results

The purpose of our empirical study is to demonstrate that our non-deterministic fitted- Q algorithm is feasible to use on real clinical trial data, and that it can offer increased choice over other approaches in a real-world setting. We will discuss several plots of different NDPs. Each point on a plot represents one value of s_1 in our data set, and at each point is placed a marker for each action recommended by an NDP⁵. To use the plots to make a decision for Phase 1, one would find the point on the plot corresponding to a current patient’s state, and see what actions are recommended for that state. One would then decide among them using expert knowledge, knowing that according to the data and the chosen solution concept, any of those actions would be optimal. Then the process would be repeated should the patient move on to Phase 2, using the corresponding plots for $T = 2$ (not shown.) It is important to note that the axes in Figures 5 through 8 represent *state*, even though the same features (measured after treatment) are also used as reward values.

One can think of all of the learned NDPs that we present in the following experiments as transformations of the raw trajectory data into recommended actions, made under different solution concepts. The choice of solution concept is subjective and tied an application at

4. See Section 4.2 of the paper by Shortreed et al. (2011) for an explanation of these kinds of features.

5. Note that Figure 2 is in fact a plot of the Q -function for Phase 1 at a state where (PANSS, BMI) = (50.1, 48.6), limited to a Q_t of size of 20 for clarity.

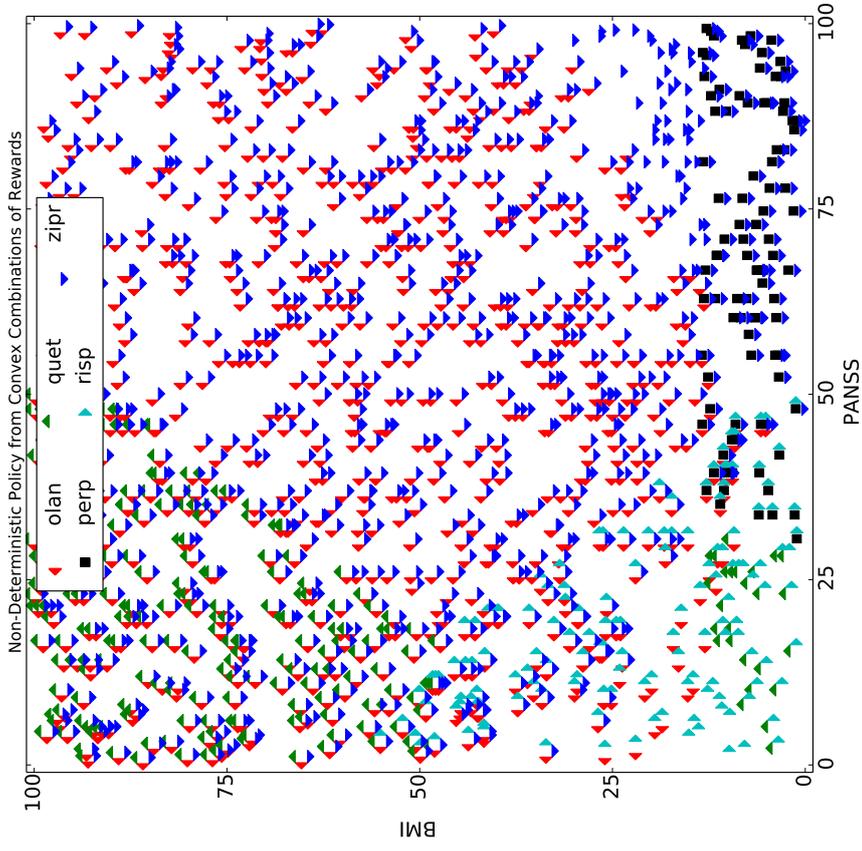

Figure 5: NDP produced by taking the union over actions recommended by Lizotte et al. (2010, 2012)

hand; hence we will not argue that one result is necessarily “better” than another, but rather illustrate some of the differences between them. Indeed, the ability to accommodate different solution concepts is a strength of our approach. That said, we argue that if two solution concepts are both acceptable for a given application, we should prefer the one that offers more action choice to the decision-maker. Therefore, as we discuss the appropriateness of different solution concepts for the CATIE data, and we will examine how the amount of action choice varies for different solution concepts.

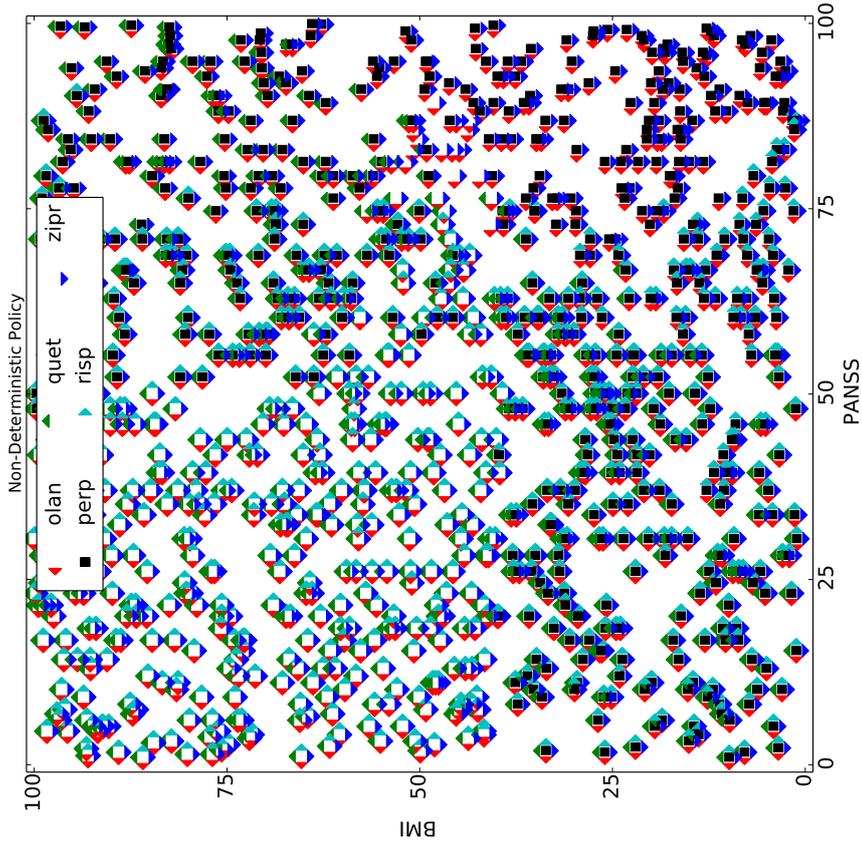

Figure 6: NDP produced by Π_{\leq}^3 with Pareto Domination.

Figure 5 serves as our baseline. It shows the NDP at Phase 1 produced using the convex combination technique of Lizotte et al. (2012), which assumes a linear scalarization function (equivalent to the convex Pareto partial order) and assumes that preferences are fixed over time. One can see that for a large part of the state space, only ziprasidone and olanzapine are recommended. This occurs because for much of the state space, ziprasidone and olanzapine have Q values similar to those in Figure 2: olanzapine performs better on PANSS than on BMI, and ziprasidone has the opposite effect. These two treatments tend to eliminate the more “moderate” actions by the mechanism we described in Figure 1. In

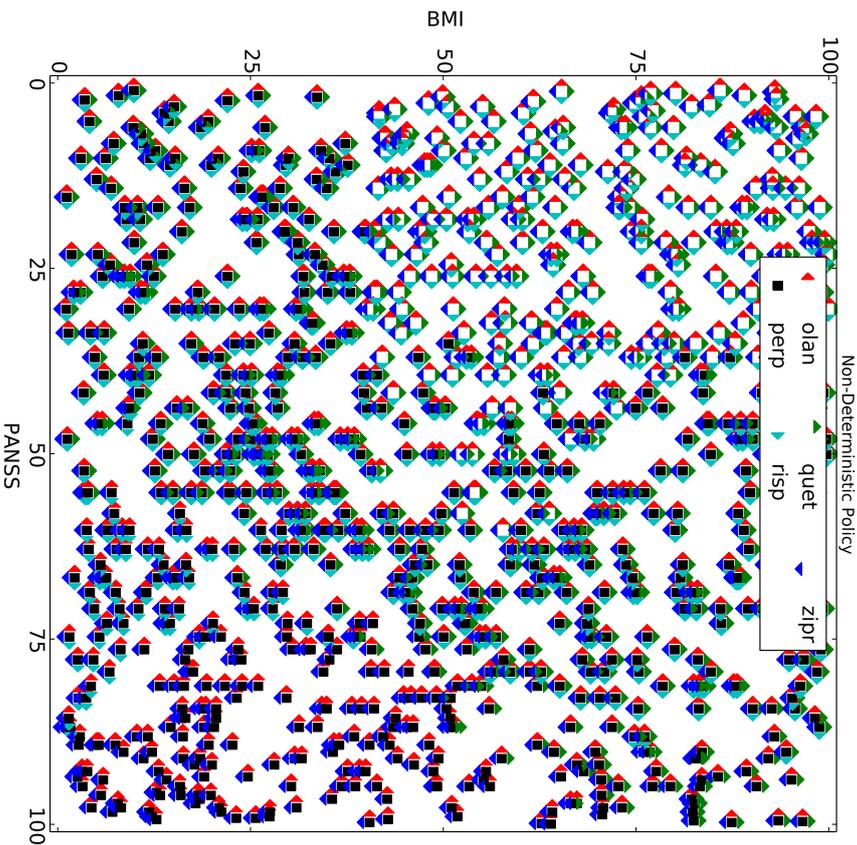

Figure 7: CATIE NDP for Phase 1 made using Π_{\leq}^E ; “warning” actions that would have been eliminated by Practical Domination but not by Strong Practical Domination have been removed.

this NDP, the mean number of choices per state is 2.26, and 100% of states have had one or more actions eliminated.

In our opinion, the convex Pareto domination solution criterion is overly eager to eliminate actions in this context, and the assumption of a fixed scalarization function is unrealistic. Figure 6 shows the NDP learned for Phase 1 using Algorithm 1 with Pareto domination and Π_{\leq}^E , which relaxes these two assumptions. As expected, the recommended action sets

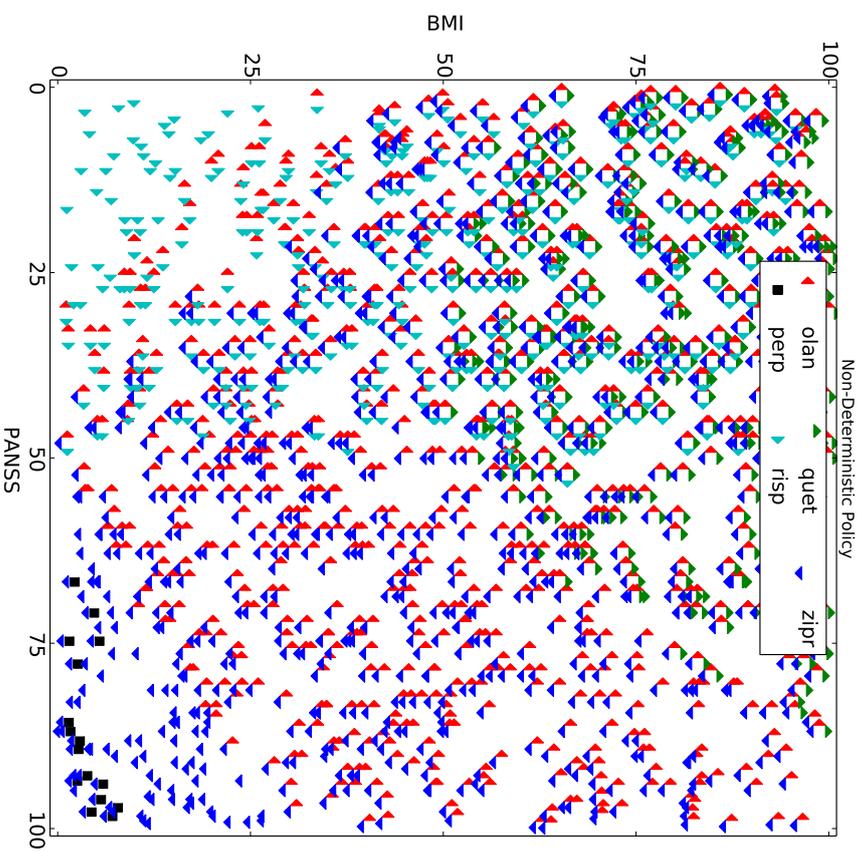

Figure 8: NDP produced by Π_{\leq}^V with Strong Practical Domination.

are larger. Despite the increased choice available, a user following these recommendations can still achieve a value on the Pareto frontier even if their preferences change in Phase 2. In this NDP, the mean number of choices per state is 4.14, and 68% of states have had at least one eliminated.

We now examine the actions that would be recommended if the decision-maker used the Strong Practical Domination solution concept. Figure 7 shows the NDP learned for Phase 1 using our algorithm with Strong Practical Domination ($\Delta_1 = \Delta_2 = 2.5$) and Π_{\leq}^E , and actions that receive a “warning” according to Practical Domination have been removed. In this example, choice is further increased by requiring an action to be practically better

than another action in order to dominate it, and although we have removed actions that were warned to have a bad trade-off—those that were slightly better for one reward but practically worse for another—we still provide increased choice over using the Pareto frontier alone. In this NDP, the mean number of choices per state is 4.30, and 55% of states have had one or more actions eliminated.

We now consider using the same solution concept but the more strict Π_{\leq}^V definition for constructing the NDP. Figure 8 shows the NDP learned for Phase 1 using our algorithm with Strong Practical Domination ($\Delta_1 = \Delta_2 = 2.5$) and Π_{\leq}^V . Again, an action must be practically better than another action in order to dominate it, which tends to increase action choices. However, recall that for Π_{\leq}^V we only recommend actions that are not dominated by another action for any future policy. Hence, these actions are extremely “safe” in the sense that they achieve an expected value on the \leq_{sp} -frontier as long as the user selects from our recommended actions in the future. In this NDP, the mean number of choices per state is 2.56, and 100% of states have had one or more actions eliminated. Hence, we have a trade-off here: Relative to Π_{\leq}^E , this approach reduces choice, yet increases safety; whether or not this is preferable will depend on the application at hand. That said, using Π_{\leq}^V in this way provides more choice than recommending actions based on convex Pareto optimality and a fixed future policy, while at the same time providing a guarantee that the recommended actions are safe choices even if preferences change.

Using ϕ -consistency to reduce the size of Q_t was critical for all of our analyses. In the Phase 2 Tolerability NDP there are over 10^{124} consistent policies but only 1213 ϕ -consistent policies, and in the Phase 2 Efficacy NDP there are 1048576 consistent policies but only 98 ϕ -consistent policies. Finding the ϕ -consistent policies took less than one minute on an Intel Core i7 at 3.4 GHz using Python and CPLEX.

8. Discussion

Our overarching goal is to expand the toolbox of data analysts by developing new, useful methods for producing decision support systems in very challenging settings. To have maximum impact, decision support must appropriately take into account the sequential aspects of the problem at hand and at the same time acknowledge the fact that different decision makers have different preferences. Working toward this goal, we have presented a suite of novel ideas for learning non-deterministic policies for MDPs with multiple objectives. We gave a formulation of fitted- Q iteration for multiple basis rewards, we discussed ways of producing an NDP from a set Q_t of Q -functions that depend on different future policies, we introduced the idea of ϕ -consistent policies to control computational complexity, and we introduced “practical domination” to help users express their preference over actions without explicitly eliciting a preference over basis rewards. Finally, we showed using clinical trial data how our method could be used, and we showed that the NDPs we are able to learn offer more optimal action choice than previous approaches.

One of our next steps will be to augment the definition of practical dominance to incorporate our estimation uncertainty in the Q -values. We will also investigate more aggressive “pruning” of the Q_t to control computational complexity—one could even consider using a single consistent policy per timestep, for example, by adding a margin-based objective to the MIP as described in Section 3.

Rather than restrict ourselves by trying to identify a single “best approach” for all decision support systems, we have developed an algorithm that is modular: One could substitute another notion of domination for the ones we proposed if another notion is more appropriate for a given problem domain. Regardless of this choice, our algorithm will suggest sets of actions that are optimal in the sense we have described. For some applications, Π_{\leq}^E may be appropriate; for other more conservative applications Π_{\leq}^V may be the only responsible choice. Note that we are not dictating how the output from the NDP is used; one could imagine an interface that accepted patient state information and displayed richer information based on Π_{\leq}^E , Π_{\leq}^V , and perhaps plots like Figure 2 to convey to the user what the pros and cons are for the different actions. Our contributions make a wide variety of new decision support systems possible.

Acknowledgments

Abstract

Given a high-dimensional data set, we often wish to find the strongest relationships within it. A common strategy is to evaluate a measure of dependence on every variable pair and retain the highest-scoring pairs for follow-up. This strategy works well if the statistic used (a) has good power to detect non-trivial relationships, and (b) is *equitable*, meaning that for some measure of noise it assigns similar scores to equally noisy relationships regardless of relationship type (e.g. linear, exponential, periodic). In this paper, we define and theoretically characterize two new statistics that together yield an efficient approach for obtaining both power and equitability. To do this, we first introduce a new population measure of dependence and show three equivalent ways that it can be viewed, including as a canonical “smoothing” of mutual information. We then introduce an efficiently computable consistent estimator of our population measure of dependence, and we empirically establish its equitability on a large class of noisy functional relationships. This new statistic has better bias/variance properties and better runtime complexity than a previous heuristic approach. Next, we derive a second, related statistic whose computation is a trivial side-

product of our algorithm and whose goal is powerful independence testing rather than equitability. We prove that this statistic yields a consistent independence test and show in simulations that the test has good power against independence. Taken together, our results suggest that these two statistics are a valuable pair of tools for exploratory data analysis.

Keywords: maximal information coefficient, total information coefficient, equitability, statistical power, mutual information

1. Introduction

The growing dimensionality of today’s data sets has popularized the idea of *hypothesis-generating science*, whereby a data set is used not to test existing hypotheses but rather to help a researcher formulate new ones. A common approach among practitioners is to evaluate some statistic on many candidate variable pairs in a data set, sort the variable pairs from highest-scoring to lowest, and manually examine all the pairs above a threshold score (Storey and Tibshirani, 2003; Emilsson et al., 2008).

A popular class of statistics used for such analyses is *measures of dependence*, i.e., statistics whose population value is zero in cases of statistical independence and non-zero otherwise. Measures of dependence are attractive because they guarantee that asymptotically no non-trivial relationship will erroneously be declared trivial. In the setting of continuous-valued data, which is our focus, there is a long line of fruitful research on such statistics including, e.g., Hoeffding (1948); Rényi (1959); Breiman and Friedman (1985); Painski (2003); Székely et al. (2007); Gretton et al. (2005); Reshef et al. (2011); Gretton et al. (2012); Lopez-Paz et al. (2013); Heller et al. (2013); Jiang et al. (2015); Heller et al. (2016).

One way to measure the utility of a measure of dependence $\hat{\varphi}$ is *power against independence*, i.e., the power of independence testing based on $\hat{\varphi}$ to detect various types of non-trivial relationships. This is an important goal for data sets that have very few non-trivial relationships, or only very weak relationships that are difficult to detect. Often, however, the number of relationships declared statistically significant by a measure of dependence greatly exceeds the number of relationships that can then be explored further. For example, biological data sets often contain many non-trivial relationships, but further corroborating any one of them may take extensive manual lab work or a study on human or animal subjects. In this case, it is tempting to restrict follow-up to a few relationships with the highest values of $\hat{\varphi}$, but this can skew the direction of follow-up work: if $\hat{\varphi}$ systematically assigns higher scores to, say, linear relationships than to non-linear ones, relatively noisy linear relationships might crowd out strong non-linear relationships from the top-scoring set.

Motivated by this problem, we previously introduced a second way of assessing a measure of dependence, called *equitability* (Reshef et al., 2011). Informally, an equitable statistic is one that, for some measure of relationship strength, assigns similar scores to equally strong relationships regardless of relationship type. For instance, we may want our measure of dependence to also have the property that on noisy functional relationships it assigns similar scores to relationships with the same R^2 , i.e., the squared Pearson correlation in question the observed y-values and the x-values passed through the underlying function in question (Reshef et al., 2011). Or, alternatively, we may want the value of our statistic to tell us about the proportion of points coming from the deterministic component of a mixture containing part signal and part uniform noise (Ding and Li, 2013). Defining measures of dependence that achieve good equitability with respect to interesting measures of relationship strength

is a new and challenging problem, with a number of different formalizations. (See, e.g., Reshef et al., 2015b and Ding and Ji, 2013 cited above, as well as Kinney and Atrwal, 2014 along with associated technical comments Reshef et al., 2014 and Murrell et al., 2014.) A companion paper to this work (Reshef et al., 2015b) presents a general formalization that unifies these.

In this paper, we introduce and theoretically characterize two new measures of dependence that we empirically show to have good equitability with respect to R^2 and power against independence, respectively. We begin by introducing a new population measure of dependence called MIC_* . Given a pair of jointly distributed random variables (X, Y) , $MIC_*(X, Y)$ is the supremum, over all finite grids G imposed on the support of (X, Y) , of the mutual information of the discrete distribution induced by (X, Y) on the cells of G , subject to a regularization based on the resolution of G . We prove three results, each of which gives a different way that this population quantity can be viewed.

1. MIC_* is the population value of the maximal information coefficient (MIC), a statistic introduced in Reshef et al. (2011) that is empirically highly equitable with respect to R^2 on a large class of noisy functional relationships. Simple corollaries of this result simplify and strengthen many of the theoretical results proven in Reshef et al. (2011) about MIC.
2. MIC_* is a minimal smoothing of mutual information, in the sense that the regularization in the definition of MIC_* renders it uniformly continuous as a function of random variables with respect to statistical distance, and no “smaller” regularization achieves continuity. This result yields as a corollary that mutual information by itself is not continuous with respect to statistical distance.
3. MIC_* is the supremum of an infinite sequence defined in terms of optimal (one-dimensional) partitions of the marginal distributions of (X, Y) rather than optimal (two-dimensional) grids imposed on the joint distribution. This characterization greatly simplifies computation.

After proving these three results, we leverage them to introduce efficient algorithms both for approximating MIC_* in practice and for estimating it consistently from a finite sample. We first provide an efficient algorithm that in many cases allows for computation to arbitrary precision of the MIC_* of a pair of random variables whose joint density is known. We then introduce a statistic, called MIC_e , that we prove is a consistent estimator of MIC_* . In contrast to the MIC statistic from Reshef et al. (2011), for which no efficient algorithm is known and a heuristic algorithm is used in practice, MIC_e is efficiently computable. It has a better runtime complexity than the heuristic algorithm currently in use for computing the original MIC statistic, and is orders of magnitude faster in practice.

With a consistent and fast estimator for MIC_* in hand, we turn to empirical analysis of its performance. Specifically, we show through simulation that MIC_e has better bias/variance properties than the heuristic algorithm used in Reshef et al. (2011) for computing MIC, which has no theoretical convergence guarantees. Our analysis also reveals that the main parameter of MIC_e can be used to tune statistical performance toward either stronger or weaker relationships in general. After studying the bias/variance properties of MIC_e , we

then demonstrate via simulation that it outperforms currently available methods in terms of equitability with respect to R^2 on a broad set of noisy functional relationships. We show this performance advantage both on the set of functional relationships analyzed in Reshef et al. (2011) as well as on a large set of randomly chosen noisy functional relationships.

We choose in this paper to analyze equitability specifically with respect to R^2 , rather than some other notion of relationship strength, because R^2 on noisy functional relationships is a simple measure with broad familiarity and intuitive interpretation among practitioners. Of course, it is also important to develop measures of dependence that are equitable with respect to notions of relationship strength besides R^2 or on families of relationships besides noisy functional relationships; however, our focus here remains on the “simple” case of R^2 on noisy functional relationships.

Importantly, we note that although there are methods for directly estimating the R^2 of a noisy functional relationship via nonparametric regression (see, e.g., Cleveland and Devlin, 1988; Stone, 1977), those methods are not applicable in the context of equitability because they are not measures of dependence. That is, because non-parametric regression methods assume a functional form for the relationship in question, they can give trivial scores to non-functional relationships, even in the large-sample limit. (A simple example of this is a uniform distribution over a circle, whose regression function is constant.) In contrast, a *measure of dependence* is guaranteed never to make this “mistake”. A measure of dependence that is equitable with respect to R^2 can therefore be viewed either as an “upgraded” measure of dependence that also comes with some of the interpretability properties of non-parametric regression, or as an “upgraded” approximate non-parametric regression method that also has the robustness properties of a measure of dependence.

The main strength of MIC_e is equitability rather than power to reject a null hypothesis of independence. In some settings, though, it may be more important to focus on good power against independence. We therefore introduce here a statistic closely related to MIC_e called the total information coefficient and denoted TIC_e . We prove the consistency of testing for independence using TIC_e , and show via simulations that it achieves excellent power in practice, performing comparably to or better than current methods on an index suite of relationships from Simon and Tibshirani (2012). Because TIC_e arises naturally as a side-product of the computation of MIC_e , it is available “for free” once MIC_e has been computed. This leads us to propose a data analysis strategy consisting of first using TIC_e to filter out non-significant relationships, and then ranking the remaining ones using the simultaneously computed values of MIC_e .

In addition to the companion paper Reshef et al. (2015b), which focuses on the theory behind equitability, this paper is accompanied by a second companion work (Reshef et al., 2015a) that explores in detail the empirical performance of the methods introduced here. That paper compares MIC_e and TIC_e to several leading measures of dependence (Kruskowl et al., 2004; Székely and Rizzo, 2009; Heller et al., 2013, 2016; Gretton et al., 2005; Breiman and Friedman, 1985; Lopez-Paz et al., 2013) on a broad range of relationship types under many different sampling and noise models, finding that the equitability with respect to R^2 of MIC_e and the power of independence testing using TIC_e are both state-of-the-art on the relationships examined. It also shows that these methods can be computed very fast in practice.

Taken together, our results shed significant light on the theory behind the maximal information coefficient, and suggest that TIC_e and MIC_e are a useful pair of methods for data exploration. Specifically, they point to joint use of these two statistics to filter and then rank relationships as a fast, practical way to explore large data sets by measuring dependence both powerfully and equitably.

2. Preliminaries

We work extensively in this paper with grids and discrete distributions over their cells. Given a grid G and a point (x, y) , we define the function $\text{row}_G(y)$ to be the row of G containing y and we define $\text{col}_G(x)$ analogously. For a pair (X, Y) of jointly distributed random variables, we write $(X, Y)|_G$ to denote $(\text{col}_G(X), \text{row}_G(Y))$, and we use $I((X, Y)|_G)$ to denote the discrete mutual information (Cover and Thomas, 2006; Csiszár and Shields, 2004; Csiszár, 2008) between $\text{col}_G(X)$ and $\text{row}_G(Y)$. Given a finite sample D from the distribution of (X, Y) , we sometimes use D to refer both to the set of points in the sample as well as to a point chosen uniformly at random from D . In the latter case, it will then make sense to talk about, e.g., $D|_G$ and $I(D|_G)$.

For natural numbers k and ℓ , we use $G(k, \ell)$ to denote the set of all k -by- ℓ grids (possibly with empty rows/columns). A grid G is an equipartition of (X, Y) if all the rows of $(X, Y)|_G$ have the same probability mass, and all the columns do as well. We also use the term equipartition in the analogous way for one-dimensional partitions into just rows or columns. For a one-dimensional partition P into rows and a one-dimensional partition Q into columns, we write (P, Q) to refer to the grid constructed from these two partitions. When a partition P can be obtained from a partition P' by addition of separators alone, we write $P' \subset P$.

Finally, let us establish some notation for infinite matrices. We use m^∞ to denote the space of infinite matrices equipped with the supremum norm. Given a matrix $A \in m^\infty$, we often examine only the k, ℓ -th entries of A for which $k\ell \leq i$ for some i . Thus, for $i \in \mathbb{Z}^+$, we define the projection $r_i : m^\infty \rightarrow m^\infty$ via

$$r_i(A)_{k,\ell} = \begin{cases} A_{k,\ell} & k\ell \leq i \\ 0 & k\ell > i \end{cases}.$$

Unless noted otherwise, all logarithms are to base 2.

3. The Population Maximal Information Coefficient MIC_{*}

In this section, we define and characterize the population maximal information coefficient MIC_{*}. We begin by defining the population quantity MIC_{*}(X, Y) for a pair of jointly distributed random variables (X, Y) . We then show three different ways to characterize this population quantity: first, as the large-sample limit of the statistic MIC from Reshef et al. (2011); second, as a minimally smoothed version of mutual information; and third, as the supremum of an infinite sequence defined in terms of optimal one-dimensional partitions of the marginal distributions of (X, Y) . We conclude the section by showing how the third characterization leads to an efficient approach for approximating MIC_{*} in practice from the density of (X, Y) .

3.1 Defining MIC_{*}

The population maximal information coefficient can be defined in several equivalent ways, as we will see later. For now, we begin with the simplest definition.

Definition 1 Let (X, Y) be jointly distributed random variables. The population maximal information coefficient (MIC_{*}) of (X, Y) is defined by

$$\text{MIC}_*(X, Y) = \sup_G \frac{I((X, Y)|_G)}{\log \|G\|}$$

where $\|G\|$ denotes the minimum of the number of rows of G and the number of columns of G .

Given that $I(X, Y) = \sup_G I((X, Y)|_G)$ (see, e.g., Chapter 8 of Cover and Thomas 2006), this can be viewed as a regularized version of mutual information that penalizes complicated grids and ensures that the result falls between zero and one.

Before we continue, we state one simple equivalent definition of MIC_{*} that is useful for the results in this section. This definition views MIC_{*} as the supremum of a matrix called the population characteristic matrix, defined below.

Definition 2 Let (X, Y) be jointly distributed random variables. Let

$$I^*((X, Y), k, \ell) = \max_{G \in G(k, \ell)} I((X, Y)|_G).$$

The population characteristic matrix of (X, Y) , denoted by $M(X, Y)$, is defined by

$$M(X, Y)_{k,\ell} = \frac{I^*((X, Y), k, \ell)}{\log \min\{k, \ell\}}$$

for $k, \ell > 1$.

It is easy to see the following:

Proposition 3 Let (X, Y) be jointly distributed random variables. We have

$$\text{MIC}_*(X, Y) = \sup M(X, Y)$$

where $M(X, Y)$ is the population characteristic matrix of (X, Y) .

The population characteristic matrix is so named because just as MIC_{*}, the supremum of this matrix, captures a sense of relationship strength, other properties of this matrix correspond to different properties of relationships. For instance, later in this paper we introduce an additional property of the characteristic matrix, the total information coefficient, that is useful for testing for the presence or absence of a relationship rather than quantifying relationship strength.

3.2 First Alternate Characterization: MIC_* Is the Population Value of MIC

With MIC_* defined, we now state our first alternate characterization of it, as the large-sample limit of the statistic MIC introduced in Reshef et al. (2011). We begin by first reproducing a description of MIC from Reshef et al. (2011), via the two definitions below.

Definition 4 (Reshef et al., 2011) Let $D \subset \mathbb{R}^2$ be a set of ordered pairs. The sample characteristic matrix $\widehat{M}(D)$ of D is defined by

$$\widehat{M}(D)_{k,\ell} = \frac{I^*(D, k, \ell)}{\log \min\{k, \ell\}},$$

Definition 5 (Reshef et al., 2011) Let $D \subset \mathbb{R}^2$ be a set of n ordered pairs, and let $B : \mathbb{Z}^+ \rightarrow \mathbb{Z}^+$. We define

$$MIC_B(D) = \max_{k \leq B(n)} \widehat{M}(D)_{k,\ell}.$$

where the function $B(n)$ is specified by the user. In Reshef et al. (2011), it was suggested that $B(n)$ be chosen to be n^α for some constant α in the range of 0.5 to 0.8. (The statistics we introduce later will have an analogous parameter; see Section 4.4.1.)

We show the following result about convergence of functions of the sample characteristic matrix to their population counterparts, a consequence of which is the convergence of MIC to MIC_* . (In the theorem statement below, recall that m^∞ is the space of infinite matrices equipped with the supremum norm, and given a matrix A the projection τ_i zeros out all the entries $A_{k,\ell}$ for which $k\ell > i$.)

Theorem 6 Let $f : m^\infty \rightarrow \mathbb{R}$ be uniformly continuous, and assume that $f \circ \tau_i \rightarrow f$ pointwise. Then for every random variable (X, Y) , we have

$$(f \circ \tau_{B(n)}) (\widehat{M}(D_n)) \rightarrow f(M(X, Y))$$

in probability where D_n is a sample of size n from the distribution of (X, Y) , provided $\omega(1) < B(n) \leq O(n^{1-\varepsilon})$ for some $\varepsilon > 0$.

Proof See Appendix A. ■

Since the supremum of a matrix is uniformly continuous as a function on m^∞ and can be realized as the limit of maxima of larger and larger segments of the matrix, this theorem yields our claim about MIC_* as a corollary.

Corollary 7 MIC_B is a consistent estimator of MIC_* provided $\omega(1) < B(n) \leq O(n^{1-\varepsilon})$ for some $\varepsilon > 0$.

Though Theorem 6 is proven in Appendix A, we provide here some intuition for why it should hold as well as a description of the obstacles that must be overcome in the proof.

For concreteness, suppose f is the supremum function. To see why the theorem should hold, fix a random variable (X, Y) and let D be a sample of size n from its distribution. It is known that for a fixed grid G $I(D|_G)$ is a consistent estimator of $I(X, Y|_G)$ (Roulston,

1999; Paninski, 2003). We might therefore expect $I^*(D, k, \ell)$ to be a consistent estimator of $I^*(X, Y, k, \ell)$ as well. And if $I^*(D, k, \ell)$ is a consistent estimator of $I^*(X, Y, k, \ell)$, then we might expect the maximum of the sample characteristic matrix (which just consists of normalized I^* terms) to be a consistent estimator of the supremum of the true characteristic matrix.

These intuitions turn out to be true, but there are two reasons they are non-trivial to prove. First, consistency for I^* does not follow from abstract considerations since the supremum of an infinite set of estimators is not necessarily a consistent estimator of the supremum of the estimands.¹ Second, consistency of I^* alone does not suffice to show that the maximum of the sample characteristic matrix converges to MIC_* . In particular, if $B(n)$ grows too quickly, and the convergence of $I^*(D, k, \ell)$ to $I^*(X, Y, k, \ell)$ is slow, inflated values of MIC can result. To see this, notice that if $B(n) = \infty$ then $MIC = 1$ for uniformly generated noise at any finite sample size, even though each individual entry of the sample characteristic matrix converges to its true value eventually.

The technical heart of the proof is overcoming these obstacles by using the dependencies between the quantities $I(D|_G)$ for different grids G to not only show the consistency of $I^*(D, k, \ell)$ but then to quantify how quickly $I^*(D, k, \ell)$ converges to $I^*(X, Y, k, \ell)$.

3.3 Second Alternate Characterization: MIC_* Is a Minimally Smoothed Mutual Information

We now describe a second equivalent view of MIC_* . Recall that for a pair of jointly distributed random variables (X, Y) , we defined $MIC_*(X, Y)$ as

$$MIC_*(X, Y) = \sup_G \frac{I((X, Y)|_G)}{\log \|G\|}$$

where $\|G\|$ denotes the minimum of the number of rows of G and the number of columns of G . As we discussed in Section 3.1, the mutual information $I(X, Y)$ is also a supremum, namely

$$I(X, Y) = \sup_G I((X, Y)|_G).$$

and so MIC_* can be viewed as a regularized version of I . It is natural to ask whether the regularization in the definition of MIC_* has any smoothing effect on I . In this sub-section we show first that it does, in the sense that MIC_* is uniformly continuous as a function of random variables with respect to the metric of statistical distance,² and second that the regularization by $\log \|G\|$ is in some sense the minimal one necessary for achieving any sort of continuity. As a corollary, we obtain that I by itself is not continuous as a function of

1. If $\theta_1, \dots, \theta_k$ is a finite set of estimators, then a union bound shows that the random variable $(\theta_1(D), \dots, \theta_k(D))$ converges in probability to $(\theta_1, \dots, \theta_k)$ with respect to the supremum metric. The continuous mapping theorem then gives the desired result. However, if the set of estimators is infinite, the union bound cannot be employed. And indeed, if we let $\theta_1 = \dots = \theta_k = 0$, and let $\theta_i(D_n) = i/n$ deterministically, then each θ_i is a consistent estimator of θ_i , but since the set $\{\theta_i(D_n), \theta_{i+1}(D_n), \dots\} = \{1/n, 2/n, \dots\}$ is unbounded, $\sup_i \theta_i(D_n) = \infty$ for every n .

2. Recall that the statistical distance between random variables A and B is defined as $\sup_P |\mathbf{P}(A \in T) - \mathbf{P}(B \in T)|$. When A and B have probability density functions or probability mass functions, this equals one-half of the L_1 distance between those functions.

random variables with respect to the metric of statistical distance. This provides a view of MIC_* as a canonical smoothing of I that yields continuity.

Formally, let $\mathcal{P}(\mathbb{R}^2)$ denote the space of random variables supported on \mathbb{R}^2 equipped with the metric of statistical distance. Our first claim is that as a function defined on $\mathcal{P}(\mathbb{R}^2)$, MIC_* is uniformly continuous. We prove this claim by establishing a stronger result: the uniform continuity of the characteristic matrix $M(X, Y)$. Specifically, by showing that the family of maps corresponding to each individual entry of the characteristic matrix is uniformly equicontinuous, we obtain the following result.

Theorem 8 *The map from $\mathcal{P}(\mathbb{R}^2)$ to m^∞ defined by $(X, Y) \mapsto M(X, Y)$ is uniformly continuous.*

Proof See Appendix B. ■

Since the supremum is a uniformly continuous function on m^∞ , Theorem 8 yields the following corollary.

Corollary 9 *The map $(X, Y) \mapsto MIC_*(X, Y)$ is uniformly continuous.*

Similar corollaries exist for any uniformly continuous function of the characteristic matrix.

Interestingly, Theorem 8 relies crucially on the normalization in the definition of the characteristic matrix. This is not a coincidence: as the following proposition shows, any normalization that is meaningfully smaller than the one in the definition of the characteristic matrix will cause the matrix to contain a discontinuity as a function on $\mathcal{P}(\mathbb{R}^2)$.

Proposition 10 *For some function $N(k, \ell)$, let M^N be the characteristic matrix with normalization N , i.e.,*

$$M^N(X, Y)_{k, \ell} = \frac{I^*((X, Y), k, \ell)}{N(k, \ell)}.$$

If $N(k, \ell) = o(\log \min\{k, \ell\})$ along some infinite path in $\mathbb{N} \times \mathbb{N}$, then M^N and $\sup M^N$ are not continuous as functions of $\mathcal{P}([0, 1] \times [0, 1]) \subset \mathcal{P}(\mathbb{R}^2)$.

Proof See Appendix C. ■

The above proposition implies that the “smoothing” that MIC_* applies to mutual information is necessary in some sense. In particular, one corollary of the proposition is that mutual information with no smoothing will contain a discontinuity.

Corollary 11 *Mutual information is not continuous on $\mathcal{P}([0, 1] \times [0, 1]) \subset \mathcal{P}(\mathbb{R}^2)$.*

Proof Mutual information is the supremum of M^N with $N \equiv 1$. ■

The same result can also be shown for the squared Linfoot correlation (Speed, 2011; Linfoot, 1957), which equals $1 - 2^{-2I}$ where I represents mutual information. Thus, though the Linfoot correlation smooths the mutual information enough to cause it to lie in the unit interval, it does not smooth the mutual information sufficiently to cause it to be continuous.

As we remarked previously, these results, when contrasted with the uniform continuity of MIC_* , allow us to view the latter as a canonical “minimally smoothed” version of mutual information that is uniformly continuous. This view gives a meaningful interpretation to the normalization used in MIC_* . Understanding MIC_* as having smoothness properties not shared by mutual information also suggests that estimators of MIC_* may have better statistical properties than estimators of ordinary mutual information. This is consistent with a recent hardness-of-estimation result for mutual information in Ding and Li (2013) and is also borne out empirically in Reshef et al. (2015a).

3.4 Third Alternate Characterization: MIC_* Is the Supremum of the Boundary of the Characteristic Matrix

We now show the third alternate view of MIC_* : that it can be equivalently defined as the supremum over a boundary of the characteristic matrix rather than as a supremum over all of the entries of the matrix. This characterization of MIC_* will serve as the foundation both for our approach to approximating $MIC_*(X, Y)$ as well as the new estimator of MIC_* that we introduce later in this paper.

We begin by defining what we mean by the boundary of the characteristic matrix. Our definition rests on the following observation.

Proposition 12 *Let M be a population characteristic matrix. Then for $\ell \geq k$, $M_{k, \ell} \leq M_{k, \ell+1}$.*

Proof Let (X, Y) be the random variable in question. Since we can always let a row/column be empty, we know that $I^*((X, Y), k, \ell) \leq I^*((X, Y), k, \ell + 1)$. And since $\ell, \ell + 1 \geq k$, we know that $M_{k, \ell} = I^*((X, Y), k, \ell) / \log k \leq I^*((X, Y), k, \ell + 1) / \log k = M_{k, \ell+1}$. ■

Since the entries of the characteristic matrix are bounded, the monotone convergence theorem then gives the following corollary. In the corollary and henceforth, we let $M_{k, \uparrow} = \lim_{\ell \rightarrow \infty} M_{k, \ell}$ and define $M_{\uparrow, \ell}$ similarly.

Corollary 13 *Let M be a population characteristic matrix. Then $M_{k, \uparrow}$ exists, is finite, and equals $\sup_{\ell \geq k} M_{k, \ell}$. The same is true for $M_{\uparrow, \ell}$.*

The above corollary allows us to define the boundary of the characteristic matrix.

Definition 14 *Let M be a population characteristic matrix. The boundary of M is the set*

$$\partial M = \{M_{k, \uparrow} : 1 < k < \infty\} \cup \{M_{\uparrow, \ell} : 1 < \ell < \infty\}.$$

The theorem below then gives a relationship between the boundary of the characteristic matrix and MIC_* .

Theorem 15 *Let (X, Y) be a random variable. We have*

$$MIC_*(X, Y) = \sup \partial M(X, Y)$$

where $M(X, Y)$ is the population characteristic matrix of (X, Y) .

Proof The following argument shows that every entry of M is at most $\sup \partial M$: fix a pair (k, ℓ) and notice that either $k \leq \ell$, in which case $M_{k,\ell} \leq M_{k,\uparrow}$ or $\ell \leq k$, in which case $M_{k,\ell} \leq M_{\uparrow,\ell}$. Thus, $\text{MIC}_* \leq \sup\{M_{\uparrow,\ell}\} \cup \{M_{k,\uparrow}\} = \sup \partial M$.

On the other hand, Corollary 13 shows that each element of ∂M is a supremum over some elements of M . Therefore, $\sup \partial M$, being a supremum over suprema of elements of M , cannot exceed $\sup M = \text{MIC}_*$. ■

3.5 Approximating MIC_* in Practice

The importance of the characterization in Theorem 15 from the previous sub-section is computational. Specifically, elements of the boundary of the characteristic matrix can be expressed in terms of a maximization over (one-dimensional) partitions rather than (two-dimensional) grids, the former being much quicker to compute exactly. This is stated in the theorem below.

Theorem 16 *Let M be a population characteristic matrix. Then $M_{k,\uparrow}$ equals*

$$\max_{P \in \mathcal{P}(k)} \frac{I(X, Y|P)}{\log k}$$

where $\mathcal{P}(k)$ denotes the set of all partitions of size at most k .

Proof See Appendix D. ■

To formally state how this will help us from an algorithmic standpoint, we note that Theorems 15 and 16 above together give the following corollary.

Corollary 17 *Let (X, Y) be a random variable, and let \mathbb{P} be the set of finite-size partitions. Then*

$$\text{MIC}_*(X, Y) = \sup \left\{ \frac{I(X, Y|P)}{\log |P|} : P \in \mathbb{P} \right\} \bigcup \left\{ \frac{I(X|P, Y)}{\log |P|} : P \in \mathbb{P} \right\}$$

where $|P|$ is the number of bins in the partition P .

We can exploit the fact that the expressions in the above corollary involve maximization only over one-dimensional partitions rather than two-dimensional grids to give an algorithm for computing elements of the boundary of the characteristic matrix to arbitrary precision, and by extension an approach to approximating MIC_* in practice. To do so, we utilize as a subroutine a dynamic programming algorithm from Reshef et al. (2011) called OPTIMIZE-X-AXIS. Before continuing, we therefore give a brief overview of that algorithm.

Overview of OPTIMIZE-X-AXIS algorithm from Reshef et al. (2011). The OPTIMIZE-X-AXIS algorithm takes as input a set D of n data points, a fixed partition into columns³ \mathcal{Q} of size ℓ , a “master” partition into rows Π , and a number k . The algorithm returns, for

3. Despite its name, the OPTIMIZE-X-AXIS algorithm can be used to optimize a partition of either axis. In our description of the algorithm here, we choose to describe the algorithm as it would work for optimizing a partition of the y -axis rather than the x -axis. This is for notational coherence of this paper only.

$2 \leq i \leq k$, the partition into rows $P_i \subset \Pi$ that maximizes the mutual information of $D|_{(P_i, \mathcal{Q})}$ among all sub-partitions of Π of size at most i . The algorithm works by exploiting the fact that, conditioned on the location y of the top-most line of P_i , the optimization of the rest of P_i can be formulated as a sub-problem that depends only on the data points below y . The algorithm uses dynamic programming to store and reuse solutions to these subproblems, resulting in a runtime of $O(|\Pi|^2 k \ell)$. If a black-box algorithm is used to compute each required mutual information in time at most T , then the runtime of the algorithm can be shown to be $O(Tk|\Pi|)$.

The following theorem shows that the theory developed about the boundary of the characteristic matrix, together with OPTIMIZE-X-AXIS, yields an efficient algorithm for computing entries of the boundary to arbitrary precision.

Theorem 18 *Given a random variable (X, Y) , $M_{k,\uparrow}$ (resp. $M_{\uparrow,\ell}$) is computable to within an additive error of $O(k\epsilon \log(1/(k\epsilon))) + \epsilon$ (resp. $O(\ell \log(1/(\ell\epsilon))) + \epsilon$) in time $O(kT(E)/\epsilon)$ (resp. $O(\ell T(E)/\epsilon)$), where $T(E)$ is the time required to numerically compute the mutual information of a continuous distribution to within an additive error of ϵ .*

Proof See Appendix E. ■

The algorithm proposed in Theorem 18 gives us a polynomial-time method for computing any finite subset of the boundary ∂M of the population characteristic matrix $M(X, Y)$ of a random variable (X, Y) . Thus, if we have some k_0, ℓ_0 such that the maximum of the finite subset $\{M_{k,\uparrow}, M_{\uparrow,\ell} : k \leq k_0, \ell \leq \ell_0\}$ of ∂M will be ϵ -close to the supremum of the entire set ∂M , we can compute $\text{MIC}_*(X, Y)$ to within an error of ϵ . Though we usually do not have precise knowledge of k_0 and ℓ_0 , for many distributions it is often easy to make very conservative educated guesses for them, in which case this algorithm allows us to approximate $\text{MIC}_*(X, Y)$ very well in practice.

Being able to compute $\text{MIC}_*(X, Y)$ to arbitrary precision in some cases has two main advantages. The first advantage is that it allows us to assess in simulations the large-sample properties of MIC_* , independent of any estimator. This is done in the companion paper (Reshef et al., 2015a), which shows that MIC_* achieves high equitability with respect to R^2 on a set of noisy functional relationships thereby confirming that statistically efficient estimation of MIC_* is a worthwhile goal.

The second advantage is that we can empirically assess the bias, variance, and expected squared error of estimators of MIC_* by taking a distribution, computing MIC_* , and then comparing the result to estimators of it based on finite samples. In the next section, we introduce a new estimator MIC_ϵ of MIC_* and carry out such an analysis to compare its statistical properties to those of the statistic MIC from Reshef et al. (2011).

4. Estimating MIC_* with MIC_ϵ

As we have shown, MIC_* is the population value of the statistic MIC introduced in Reshef et al. (2011). However, though consistent, the statistic MIC is not known to be efficiently computable and in Reshef et al. (2011) a heuristic approximation algorithm called APPROX- MIC was computed instead. In this section, we leverage the theory we have developed here

to introduce a new estimator of MIC_* that is both consistent and efficiently computable. The new estimator, called MIC_e , has better runtime complexity even than the heuristic APPROX-MIC algorithm, and runs orders of magnitude faster in practice.

The estimator MIC_e is based on one of the alternate characterizations of MIC_* proven in the previous section. Namely, if MIC_* can be viewed as the supremum of the *boundary* of the characteristic matrix rather than of the entire matrix, then only the boundary of the matrix must be accurately estimated in order to estimate MIC_* . This has the advantage that, whereas computing individual entries of the sample characteristic matrix involves finding optimal (two-dimensional) grids, estimating entries of the boundary requires us only to find optimal (one-dimensional) partitions. While the former problem is computationally difficult, the latter can be solved using the dynamic programming algorithm from Reshef et al. (2011) that we also employed in Section 3.5 to compute MIC_* to arbitrary precision in the large-sample limit.

We formalize this idea via a new object called the *equicharacteristic matrix*, which we denote by $[M]$. The difference between $[M]$ and the characteristic matrix M is as follows: while the k, ℓ -th entry of M is computed from the maximal achievable mutual information using any k -by- ℓ grid, the k, ℓ -th entry of $[M]$ is computed from the maximal achievable mutual information using any k -by- ℓ grid that equipartitions the dimension with more rows/columns. (See Figure 1.) Despite this difference, as the equipartition in question gets finer and finer it becomes indistinguishable from an optimal partition of the same size. This intuition can be formalized to show that the boundary of $[M]$ equals the boundary of M , and therefore that $\sup[M] = \sup M = \text{MIC}_*$. It will then follow that estimating $[M]$ and taking the supremum—as we did with M in the case of MIC —yields a consistent estimate of MIC_* .

4.1 The Equicharacteristic Matrix

We now define the equicharacteristic matrix and show that its supremum is indeed MIC_* . To do so, we first define a version of I^* that equipartitions the dimension with more rows/columns. Note that in the definition, brackets are used to indicate the presence of an equipartition.

Definition 19 Let (X, Y) be jointly distributed random variables. Define

$$I^*((X, Y), k, [\ell]) = \max_{G \in \mathcal{G}(k, [\ell])} I((X, Y)|_G)$$

where $G(k, [\ell])$ is the set of k -by- ℓ grids whose y -axis partition is an equipartition of size ℓ . Define $I^*((X, Y), [k], \ell)$ analogously.

Define $I^{[*]}((X, Y), k, \ell)$ to equal $I^*((X, Y), k, [\ell])$ if $k < \ell$ and $I^*((X, Y), [k], \ell)$ otherwise.

We now define the equicharacteristic matrix in terms of $I^{[*]}$. In the definition below, we continue our convention of using brackets to denote the presence of equipartitions.

Definition 20 Let (X, Y) be jointly distributed random variables. The population equicharacteristic matrix of (X, Y) , denoted by $[M](X, Y)$, is defined by

$$[M](X, Y)_{k, \ell} = \frac{I^{[*]}((X, Y), k, \ell)}{\log \min\{k, \ell\}}$$

for $k, \ell > 1$.

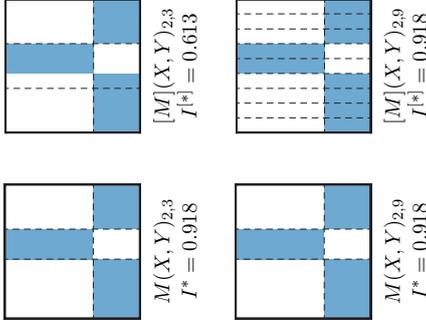

Figure 1: A schematic illustrating the difference between the characteristic matrix M and the equicharacteristic matrix $[M]$. (Top) When restricted to 2 rows and 3 columns, the characteristic matrix M is computed from the optimal 2-by-3 grid. In contrast, the equicharacteristic matrix $[M]$ still optimizes the smaller partition of size 2 but is restricted to have the larger partition be an equipartition of size 3. This results in a lower mutual information of 0.613. (Bottom) When 9 columns are allowed instead of 3, the grid found by the characteristic matrix does not change, since the grid with 3 columns was already optimal. However, now the equicharacteristic matrix uses an equipartition into columns of size 9, whose resolution is able to fully capture the dependence between X and Y .

The boundary of the equicharacteristic matrix can be defined via a limit in the same way as the characteristic matrix. We then have the following theorem.

Theorem 21 Let (X, Y) be jointly distributed random variables. Then $\partial[M] = \partial M$.

Proof See Appendix F. ■

Since every entry of the equicharacteristic matrix is dominated by some entry on its boundary, the equivalence of $\partial[M]$ and ∂M yields the following corollary as a simple consequence.

Corollary 22 Let (X, Y) be jointly distributed random variables. Then $\sup[M](X, Y) = \text{MIC}_*(X, Y)$.

4.2 The Estimator MIC_e

With the equicharacteristic matrix defined, we can now define our new estimator MIC_e in terms of the sample equicharacteristic matrix, analogously to the way we defined MIG in terms of the sample characteristic matrix.

Definition 23 Let $D \subset \mathbb{R}^2$ be a set of ordered pairs. The sample equicharacteristic matrix $[\widehat{M}](D)$ of D is defined by

$$[\widehat{M}](D)_{k,\ell} = \frac{J^*(D, k, \ell)}{\log \min\{k, \ell\}}.$$

Definition 24 Let $D \subset \mathbb{R}^2$ be a set of n ordered pairs, and let $B : \mathbb{Z}^+ \rightarrow \mathbb{Z}^+$. We define

$$MIC_{e,B}(D) = \max_{k,\ell \leq B(n)} [\widehat{M}](D)_{k,\ell}.$$

With the equivalence between the boundary of the characteristic matrix and that of the equicharacteristic matrix established, it is straightforward to show that MIC_e is a consistent estimator of MIC_* via arguments similar to those we applied in the case of MIG . (See Appendix G.) Specifically, we show the following theorem, an analogue of Theorem 6.

Theorem 25 Let $f : m^\infty \rightarrow \mathbb{R}$ be uniformly continuous, and assume that $f \circ r_i \rightarrow f$ pointwise. Then for every random variable (X, Y) , we have

$$(f \circ r_{B(n)})([\widehat{M}](D_n)) \rightarrow f([M](X, Y))$$

in probability where D_n is a sample of size n from the distribution of (X, Y) , provided $\omega(1) < B(n) \leq O(n^{1-\varepsilon})$ for some $\varepsilon > 0$.

By setting $f([M]) = \sup[M]$, we then obtain as a corollary the consistency of MIC_e .

Corollary 26 $MIC_{e,B}$ is a consistent estimator of MIC_* provided $\omega(1) < B(n) \leq O(n^{1-\varepsilon})$ for some $\varepsilon > 0$.

As with the statistic MIG , the statistic MIC_e requires the user to specify a function $B(n)$ to use. While the theory suggests that any function of the form $B(n) = n^\alpha$ suffices provided $0 < \alpha < 1$, different values of α may yield different finite-sample properties. We study the empirical performance of MIC_e for different choices of $B(n)$ in Section 4.4 and point the reader to specific recommendations for practical use in Section 4.4.1.

4.3 Computing MIC_e

Both MIG and MIC_e are consistent estimators of MIC_* . The difference between them is that while MIG can currently be computed efficiently only via a heuristic approximation, MIC_e can be computed exactly, very efficiently, via an approach similar to the one used for approximating MIG_* involving the OPTIMIZEAXIS subroutine. We now describe the details of this approach.

Recall that, given a fixed x -axis partition Q into ℓ columns, a set of n data points, a “master” y -axis partition Π , and a number k , the OPTIMIZEAXIS subroutine finds, for

every $2 \leq i \leq k$, a y -axis partition $P_i \subset \Pi$ of size at most i that maximizes the mutual information induced by the grid (P_i, Q) . The algorithm does this in time $O(|\Pi|^2 k \ell)$. (For more discussion of OPTIMIZEAXIS, see Section 3.5)

In the pair of theorems below, we show two ways that OPTIMIZEAXIS can be used to compute MIC_e efficiently. In the proofs of both theorems, we neglect issues of divisibility, e.g., we often write $B/2$ rather than $\lfloor B/2 \rfloor$. This does not affect the results.

Theorem 27 There exists an algorithm EQUICHAR that, given a sample D of size n and some $B \in \mathbb{Z}^+$, computes the portion $r_{B(n)}([\widehat{M}](D))$ of the sample equicharacteristic matrix in time $O(n^2 B^2)$, which equals $O(n^{4-2\varepsilon})$ for $B(n) = O(n^{1-\varepsilon})$ with $\varepsilon > 0$.

Proof We describe the algorithm and simultaneously bound its runtime. We do so only for the k, ℓ -th entries of $[\widehat{M}](D)$ satisfying $k \leq \ell, k, \ell \leq B$. This suffices, since by symmetry computing the rest of the required entries at most doubles the runtime.

To compute $[\widehat{M}](D)_{k,\ell}$ with $k \leq \ell$, we must fix an equipartition into ℓ columns on the x -axis and then find the optimal partition of the y -axis of size at most k . If we set the master partition Π of the OPTIMIZEAXIS algorithm to be an equipartition into rows of size n , then it performs precisely the required optimization. Moreover, for fixed ℓ it can carry out the optimization simultaneously for all of the pairs $\{(2, \ell), \dots, (B/\ell, \ell)\}$ in time $O(|\Pi|^2 (B/\ell) \ell) = O(n^2 B)$. For fixed ℓ , this set contains all the pairs (k, ℓ) satisfying $k \leq \ell, k \ell \leq B$. Therefore, to compute all the required entries of $[\widehat{M}](D)$ we need only apply this algorithm for each $\ell = 2, \dots, B/2$. Doing so gives a runtime of $O(n^2 B^2)$. ■

The algorithm above, while polynomial-time, is nonetheless not efficient enough for use in practice. However, a simple modification solves this problem without affecting the consistency of the resulting estimates. The modification hinges on the fact that OPTIMIZEAXIS can use master partitions Π besides the equipartition of size n that we used above. Specifically, setting Π in the above algorithm to be an equipartition into ck “chunks”, where k is the size of the largest optimal partition being sought, speeds up the computation significantly. This modification gives a slightly different statistic, but one that has all of the theoretical properties of MIC_e —namely, consistent estimation of MIC_* and efficient exact computation. These properties are formalized in the following theorem.

Theorem 28 Let (X, Y) be a pair of jointly distributed random variables, and let D_n be a sample of size n from the distribution of (X, Y) . For every $c \geq 1$, there exists a matrix $\{\widehat{M}\}^c(D_n)$ such that

1. The function

$$\widetilde{MIC}_{e,B}(\cdot) = \max_{k,\ell \leq B(n)} \{\widehat{M}\}^c(\cdot)_{k,\ell}$$

is a consistent estimator of MIC_* provided $\omega(1) < B(n) \leq O(n^{1-\varepsilon})$ for some $\varepsilon > 0$.

2. There exists an algorithm EQUICHARCLUMP for computing $\text{TR}(\{\widehat{M}\}^c(D_n))$ in time $O(n + B^{5/2})$, which equals $O(n + n^{5(1-\varepsilon)/2})$ when $B(n) = O(n^{1-\varepsilon})$.

Proof See Appendix H. ■

For an analysis of the effect of the parameter c in the above theorem on the results of the EQUICHARCLUMP algorithm, see Appendix H.3.

Setting $\varepsilon = 0.6$ in the above theorem yields the following corollary.

Corollary 29 MIC_* can be estimated consistently in linear time.

Of course, at low sample sizes, setting $\varepsilon = 0.6$ would be undesirable. However, our companion paper (Reshef et al., 2015a) shows empirically that at large sample sizes this strategy works very well on typical relationships.

We remark that the EQUICHARCLUMP algorithm given above is asymptotically faster even than the heuristic APPROX-MIC algorithm used to calculate MIC in practice, which runs in time $O(B(n)^4)$. As demonstrated in our companion paper (Reshef et al., 2015a), this difference translates into a substantial difference in runtimes for similar performance at a range of realistic sample sizes, ranging from a 30-fold speedup at $n = 500$ to over a 350-fold speedup at $n = 10,000$.

For readability, in the rest of this paper we do not distinguish between the two versions of MIC_e computed by the EQUICHAR and EQUICHARCLUMP algorithms described above. Wherever we present simulation data about MIC_e in simulations though, we use the version of the statistic computed by EQUICHARCLUMP.

4.4 Bias/Variance Characterization of MIC_e

The algorithm we presented in Section 3.5 for computing MIC_* to arbitrary precision in some cases allows us to examine the bias/variance properties of estimators of MIC_* . Here, we use it to examine the bias and variance of both MIC as computed by the heuristic APPROX-MIC algorithm from Reshef et al. (2011), and MIC_e as computed by the EQUICHARCLUMP algorithm given above. To do this, we performed a simulation analysis on the following set of relationships

$$\mathcal{Q} = \{(x + \varepsilon_\sigma, f(x) + \varepsilon'_\sigma) : x \in X_f, \varepsilon_\sigma, \varepsilon'_\sigma \sim \mathcal{N}(0, \sigma^2), f \in F, \sigma \in \mathbb{R}_{\geq 0}\}$$

where ε_σ and ε'_σ are i.i.d., F is the set of 16 functions analyzed in Reshef et al. (2011), and X_f is the set of n x-values that result in the points $(x_i, f(x_i))$ being equally spaced along the graph of f .

For each relationship $Z \in \mathcal{Q}$ that we examined, we used the algorithm from Theorem 18 with very conservative values of k_0 and l_0 to compute MIC_* . We then simulated 500 independent samples from Z , each of size $n = 500$, and computed both APPROX-MIC and MIC_e on each one to obtain estimates of the sampling distributions of the two statistics. From each of the two sampling distributions, we estimated the bias and variance of either statistic on Z . We then analyzed the bias, variance, and expected squared error of the two determinations (R^2) with respect to the generating function.

The results, presented in Figure 2, are interesting for two reasons. First, they demonstrate that for a typical usage parameter of $B(n) = n^{0.6}$, MIC_e performs substantially better than APPROX-MIC overall. Specifically, the median of the expected squared error of MIC_e

across the set F of functions is uniformly lower across R^2 values than that of APPROX-MIC. When average expected squared error is used instead of median, MIC_e still performs better on all but the strongest of relationships (R^2 above ~ 0.9). The superior performance of MIC_e is consistent with the fact that we have theoretical guarantees about its statistical properties whereas APPROX-MIC is a heuristic.

Second, the results show that different values of the exponent in $B(n) = n^b$ give good performance in different signal-to-noise regimes due to a bias-variance trade-off represented by this parameter. We expand on this phenomenon and discuss its implications for choosing α in practice below.

4.4.1 CHOOSING $B(n)$

Large values of α lead to increased expected error in lower-signal regimes (low R^2) through both a positive bias in those regimes and a general increase in variance that predominantly affects those regimes. On the other hand, small values of α lead to an increased expected error in higher-signal regimes (high R^2) by leading to a negative bias in those regimes and by shifting the variance of the estimator toward those regimes. In other words, lower values of α are better suited for detecting weaker signals, while higher values of α are better suited for distinguishing among stronger signals. This is consistent with the results seen in our companion paper (Reshef et al., 2015a), which show that low values of α cause MIC_e to yield better powered independence tests while high values of α cause MIC_e to have better equitability.

Reshef et al. (2015a) provides simple, empirical recommendations about appropriate values of α for different settings. Those recommendations are formulated by choosing a set of representative relationships (e.g., a set of noisy functional relationships), as well as a “ground truth” population quantity Φ (e.g., R^2) that can be used to quantify the strength of each of those relationships, and then assessing which values of α maximize the equitability of MIC_e with respect to Φ at a given sample size. This approach is applied to an analysis of real data from the World Health Organization in Reshef et al. (2015a), and the parameters chosen for that analysis are the ones used for all subsequent analyses in this paper.

We remark that if the goal of the user is only detection of non-trivial relationships rather than discovery of the strongest such relationships, α can also be chosen in a more straightforward manner: the user can subsample a small random set of relationships on which to compare the power of MIC_e for different values of α . Those relationships can then be discarded and the rest of the relationships analyzed with the optimal value of α . However, if the user’s primary goal is power against independence, the statistic TIC_e introduced in Section 5 of this paper should be used with this strategy rather than MIC_e .

4.5 Equitability of MIC_e

As mentioned previously, one of the main motivations for the introduction of MIC was equitability, the extent to which a measure of dependence usefully captures some notion of relationship strength on some set of standard relationships. We therefore carried out an empirical analysis of the equitability of MIC_e with respect to R^2 and compared its performance to distance correlation (Székely et al., 2007; Székely and Rizzo, 2009), mutual

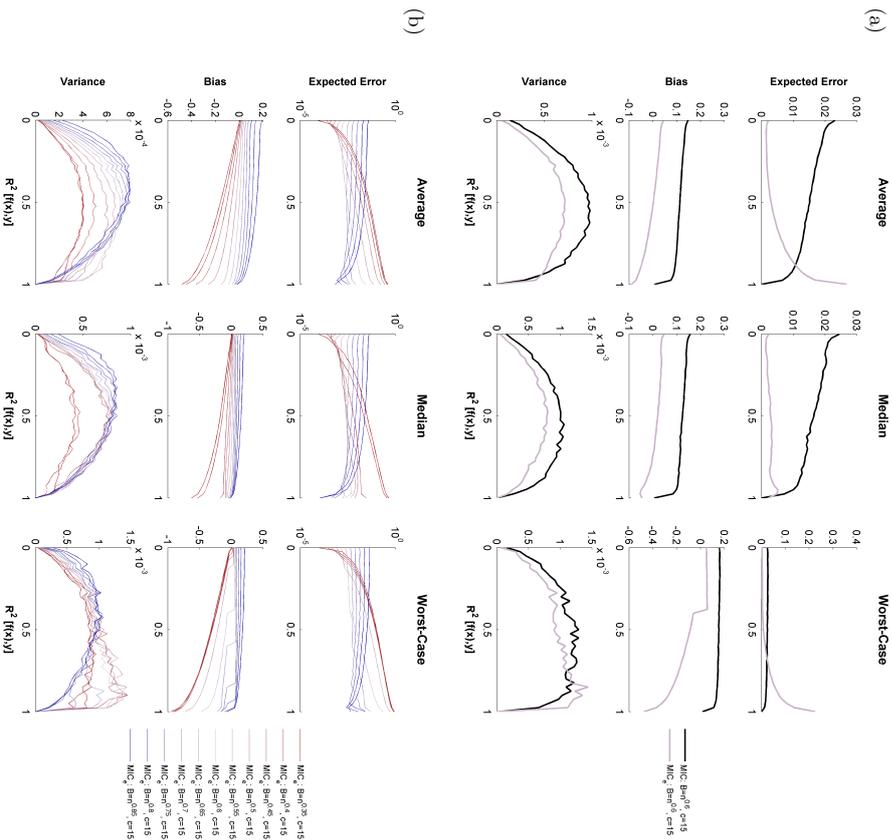

Figure 2: Bias/variance characterization of APPROX-MIC and MIC_C . Each plot shows expected squared error, bias, or variance across the set of noisy functional relationships described in Section 4.4 as a function of the R^2 of the relationships. The results are aggregated across the 16 function types analyzed by either the average, median, or worst result at every value of R^2 . (a) A comparison between MIC_C (light purple) and MIC as computed via the heuristic APPROX-MIC algorithm (black), at a typical usage parameter. (b) Performance of MIC_C with $B(n) = n^\alpha$ for various values of α .

information estimation (Kraskov et al., 2004), and maximal correlation estimation (Breiman and Friedman, 1985).

We began by assessing equitability on the set of relationships \mathcal{Q} defined above, a set that has been analyzed in previous work (Reshef et al., 2011, 2015a; Kinney and Atwal, 2014). The results, shown in Figure 3, confirm the superior equitability of the new estimator MIC_C on this set of relationships.

To assess equitability more objectively without relying on a manually curated set of functions, we then analyzed 160 random functions drawn from a Gaussian process distribution with a radial basis function kernel with one of eight possible bandwidths in the set $\{0.01, 0.025, 0.05, 0.1, 0.2, 0.25, 0.5, 1\}$ to represent a range of possible relationship complexities. The results, shown in Figure 4, show that MIC_C outperforms existing methods in terms of equitability with respect to R^2 on these functions as well. Appendix Figure J1 shows a version of this analysis under a different noise model that yields the same conclusion. We also examined the effect of outlier relationships on our results by repeatedly subsampling random subsets of 20 functions from this large set of relationships and measuring the equitability of each method on average over the subsets: results were similar.

One feature of the performance of MIC_C on these randomly chosen relationships that is demonstrated in Figure 4 is that it appears minimally sensitive to the bandwidth of the Gaussian process from which a given relationship is drawn. This puts it in contrast to, e.g., mutual information estimation, which shows a pronounced sensitivity to this parameter that prevents it from being highly equitable when relationships with different bandwidths are present in the same data set.

In our companion paper (Reshef et al., 2015a), we perform more in-depth analyses of the equitability with respect to R^2 of MIC_C , MIC, and the four measures of dependence described above as well as the Hilbert-Schmidt independence criterion (HSIC) (Gretton et al., 2005, 2007), the Heller-Heller-Gorfine (HHG) test (Heller et al., 2013), the data-derived partitions (DDP) test (Heller et al., 2016), and the randomized dependence coefficient (RDC) (Lopez-Paz et al., 2013). These analyses consider a range of sample sizes, noise models, marginal distributions, and parameter settings. They conclude that, in terms of equitability with respect to R^2 on the sets of noisy functional relationships studied, a) MIC_C uniformly outperforms MIC, and b) MIC_C outperforms all the methods tested in the large majority of settings examined. Appendix Figure II contains a reproduction of a representative equitability analysis from that paper for the reader’s reference.

5. The Total Information Coefficient

So far we have presented results about estimators of the population maximal information coefficient, a quantity for which equitability is the primary motivation. We now introduce and analyze a new measure of dependence coefficient, the *total information coefficient* (TIC). In contrast to the maximal information coefficient, the total information coefficient is designed not for equitability but rather as a test statistic for testing a null hypothesis of independence.

We begin by giving some intuition. Recall that the maximal information coefficient is the supremum of the characteristic matrix. While estimating the supremum of this matrix has many advantages, this estimation involves taking a maximum over many estimates of individual entries of the characteristic matrix. Since maxima of sets of random variables

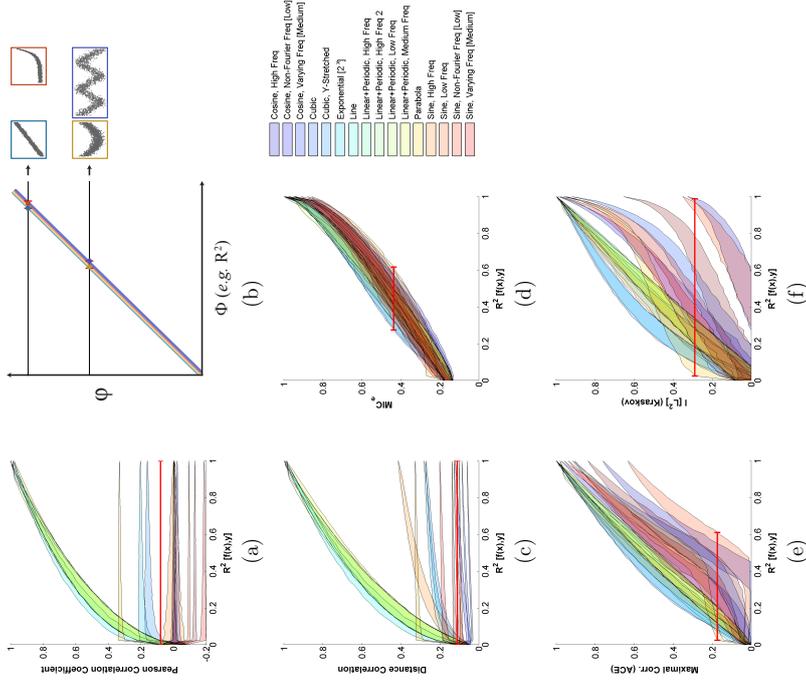

Figure 3: Equitability with respect to R^2 on a set of noisy functional relationships of (a) the Pearson correlation coefficient, (b) a hypothetical measure of dependence φ with perfect equitability, (c) distance correlation, (d) MIC_e , (e) maximal correlation estimation, and (f) mutual information estimation. For each relationship, a shaded region denotes estimated 5th and 95th percentile values of the sampling distribution of the statistic in question on that relationship at every R^2 . The resulting plot shows which values of R^2 correspond to a given value of each statistic. The red interval on each plot indicates the widest range of R^2 values corresponding to any one value of the statistic; the narrower the red interval, the higher the equitability. A red interval with width 0, as in (b), means that the statistic reflects only R^2 with no dependence on relationship type, as demonstrated by the pairs of thumbnails of relationships of different types with identical R^2 values.

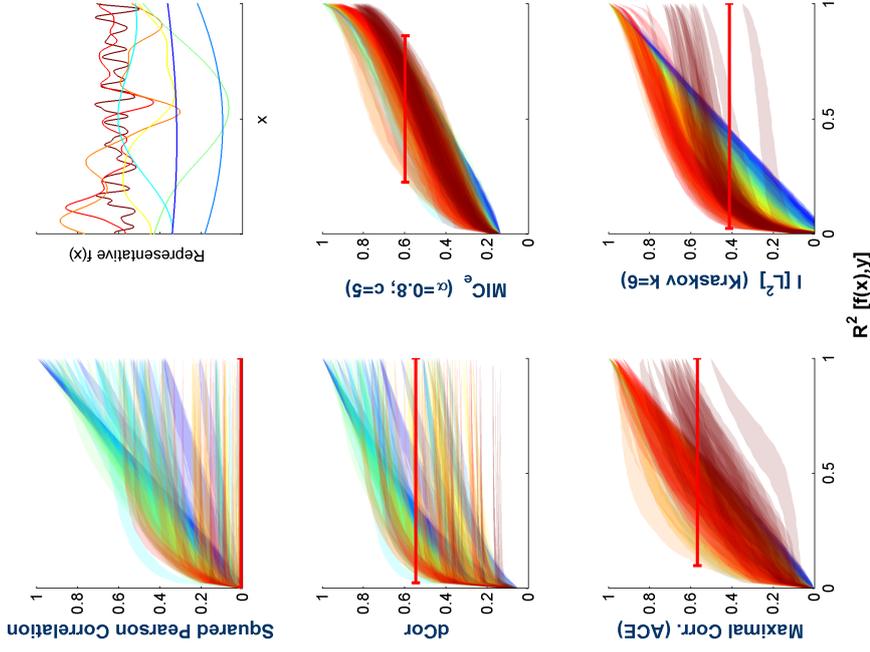

Figure 4: Equitability of methods examined on functions randomly drawn from a Gaussian process distribution. Each method is assessed as in Figure 3, with a red interval indicating the widest range of R^2 values corresponding to any one value of the statistic; the narrower the red interval, the higher the equitability. Each shaded region corresponds to one relationship, and the regions are colored by the bandwidth of the Gaussian process from which they were sampled. Sample relationships for each bandwidth are shown in the top right with matching colors.

tend to become large as the number of variables grows, one can imagine that this procedure may lead to an undesirable positive bias in the case of statistical independence, when the population characteristic matrix equals 0. This might be detrimental for independence testing, when the sampling distribution of a statistic under a null hypothesis of independence is crucial.

The intuition behind the total information coefficient is that if we instead consider a more stable property, such as the sum of the entries in the characteristic matrix, we might expect to obtain a statistic with a smaller bias in the case of independence and therefore better power. Stated differently, if our only goal is to distinguish any dependence at all from complete noise, then disregarding all of the sample characteristic matrix except for its maximal value may throw away useful signal, and the total information coefficient avoids this by summing all the entries.

We remark that in Reshef et al. (2011) it is suggested that other properties of the characteristic matrix may allow us to measure other aspects of a given relationship besides its strength, and several such properties were defined. The total information coefficient fits within this conceptual framework.

In this section we define the total information coefficient in the case of both the characteristic matrix (TIC) and the equicharacteristic matrix (TIC_e). We then prove that both TIC and TIC_e yield independence tests that are consistent against all dependent alternatives. (As in the case of MIC and MIC_e, TIC_e is more easily computable than TIC.) Finally, we present a simulation study of the power of independence testing based on TIC_e on an index set of relationships chosen in Simon and Tibshirani (2012), showing that TIC_e outperforms other common measures of dependence on many of the relationships and closely matches their performance on the rest.

5.1 Definition and Consistency of the Total Information Coefficient

We begin by defining the two versions of the total information coefficient. In the definition below, recall that \widehat{M} denotes a sample characteristic matrix whereas \widehat{M} denotes a sample equicharacteristic matrix.

Definition 30 Let $D \subset \mathbb{R}^2$ be a set of n ordered pairs, and let $B : \mathbb{Z}^+ \rightarrow \mathbb{Z}^+$. We define

$$TIC_B(D) = \sum_{k \leq B(n)} \widehat{M}(D)_{k,\ell}$$

$$TIC_{e,B}(D) = \sum_{k \leq B(n)} \widehat{M}(D)_{k,\ell}$$

and

To show that these two statistics lead to consistent independence tests, we must take a step back and analyze the behavior of the analogous population quantities.

Definition 31 For a matrix A and a positive number B , the B -partial sum of A , denoted by $S_B(A)$, is

$$S_B(A) = \sum_{k \leq B} A_{k,\ell}.$$

When A is an (equi)characteristic matrix, $S_B(A)$ is the sum over all entries corresponding to grids with at most B total cells. Thus, if $M(D)$ is a sample characteristic matrix of a sample D , $S_B(\widehat{M}(D)) = TIC_B(D)$, and the same holds for $S_B(\widehat{M}(D))$ and $TIC_{e,B}(D)$.

It is clear that if X and Y are statistically independent random variables, then both the characteristic matrix $M(X, Y)$ and the equicharacteristic matrix $[M](X, Y)$ are identically 0, so that $S_B(M(X, Y)) = S_B([M](X, Y)) = 0$ for all B . However, we are also interested in how these quantities behave when X and Y are dependent. The following pair of propositions helps us understand this. The first proposition shows a lower bound on the values of entries in both $M(X, Y)$ and $[M](X, Y)$. The second proposition translates this into an asymptotic characterization of how quickly $S_B(M)$ and $S_B([M])$ grow as functions of B . These two propositions are the technical heart of why the total information coefficient yields a consistent independence test.

Proposition 32 Let (X, Y) be a pair of jointly distributed random variables. If X and Y are statistically independent, then $M(X, Y) \equiv [M](X, Y) \equiv 0$. If not, then there exists some $a > 0$ and some integer $\ell_0 \geq 2$ such that

$$M(X, Y)_{k,\ell}, [M](X, Y)_{k,\ell} \geq \frac{a}{\log \min\{k, \ell\}}$$

either for all $k \geq \ell \geq \ell_0$, or for all $\ell \geq k \geq \ell_0$.

Proof See Appendix K.1

Proposition 33 Let (X, Y) be a pair of jointly distributed random variables. If X and Y are statistically independent, then $S_B(M(X, Y)) = S_B([M](X, Y)) = 0$ for all $B > 0$. If not, then $S_B(M(X, Y))$ and $S_B([M](X, Y))$ are both $\Omega(B \log \log B)$.

Proof See Appendix K.2

The propositions above, together with reasoning analogous to the convergence arguments presented earlier, can be used to show the main result of this section, namely that the statistics TIC and TIC_e yield consistent independence tests.

Theorem 34 The statistics TIC_B and $TIC_{e,B}$ yield consistent right-tailed tests of independence, provided $\omega(1) < B(n) \leq O(n^{1-\varepsilon})$ for some $\varepsilon > 0$.

Proof See Appendix K.3. ■

In practice, we often use the EQUICHARGLUMP algorithm (see Section 4.3) to compute the equicharacteristic matrix from which we calculate TIC_e . This algorithm does not compute the sample equicharacteristic matrix exactly. However, as in the case of MIC_e , the use of the algorithm does not affect the theoretical properties of the statistic. This is proven in Appendix H.

5.2 Power of Independence Tests Based on TIC_e

With the consistency of independence tests based on TIC and TIC_e established, we turn now to empirical evaluation of the power of independence testing based on TIC_e as computed using the EQUICHARCLUMP algorithm.

To evaluate the power of TIC_e -based tests, we reproduced the analysis performed in Simon and Tibshirani (2012). Namely, we considered the set of relationships they analyzed, defined by

$$\mathcal{Q} = \{(X, f(X) + \varepsilon) : X \sim \text{Unif}, f \in F, \varepsilon' \sim \mathcal{N}(0, \sigma^2), \sigma \in \mathbb{R}_{>0}\}.$$

where F is a set of functions specified in Simon and Tibshirani (2012). (NB: one of the relationships is a circle, which we treat as a union of two half-circles.)

For each relationship Z in this set that we examined, we simulated a null hypothesis of independence with the same marginal distributions, and generated 1,000 independent samples, each with a sample size of $n = 500$, from both Z and from the null distribution. These were used to estimate the power of the size- α right-tailed independence test based on each statistic being evaluated. Following Simon and Tibshirani, we compared TIC_e to the distance correlation (Székely et al., 2007; Székely and Rizzo, 2009), the original maximal information coefficient (Reshef et al., 2011) as approximated using APPROX-MIC, and to the Pearson correlation. (Though it is not a measure of dependence, the Pearson correlation was presumably included by Simon and Tibshirani as an intuitive benchmark for what is achievable under a linear model.) We also compared to MIC_e using identical parameters to those of TIC_e to examine whether the summation performed by TIC_e is better than maximization when all other things are equal. Note that we do not compare to methods of analyzing contingency tables, such as Pearson’s chi-squared test. This is because our data are real-valued rather than discrete, and so contingency-based methods are not applicable. However, when data are discrete, those methods can be very well powered.

The results of our analysis are presented in Figure 5. First, the figure shows that TIC_e compares quite favorably with distance correlation, a method considered to have state-of-the-art power (Simon and Tibshirani, 2012). Specifically, TIC_e uniformly outperforms distance correlation on 5 of the 8 relationship types examined, and performs comparably to it on the other three relationship types. We remark that distance correlation has many advantages over TIC_e , including the fact that it easily generalizes to higher-dimensional relationships and comes with an elegant and comprehensive theoretical framework.

The analysis also shows that TIC_e outperforms the original maximal information coefficient by a very large margin, and outperforms MIC_e as well, supporting the intuition that the summation performed by the former can indeed lead to substantial gains in power against independence over the maximization performed by the latter. (We note that in both Simon and Tibshirani’s analysis and in this one, the original maximal information coefficient was run with default parameters that were optimized for equitability rather than power against independence. When run with different parameters, its power improves substantially, though it still does not match the power of MIC_e . See Appendix Figure I2 and the discussion in Reshef et al., 2015a.)

Our companion paper (Reshef et al., 2015a) expands on this analysis, conducting an in-depth evaluation of the power against independence of the tests described above as well

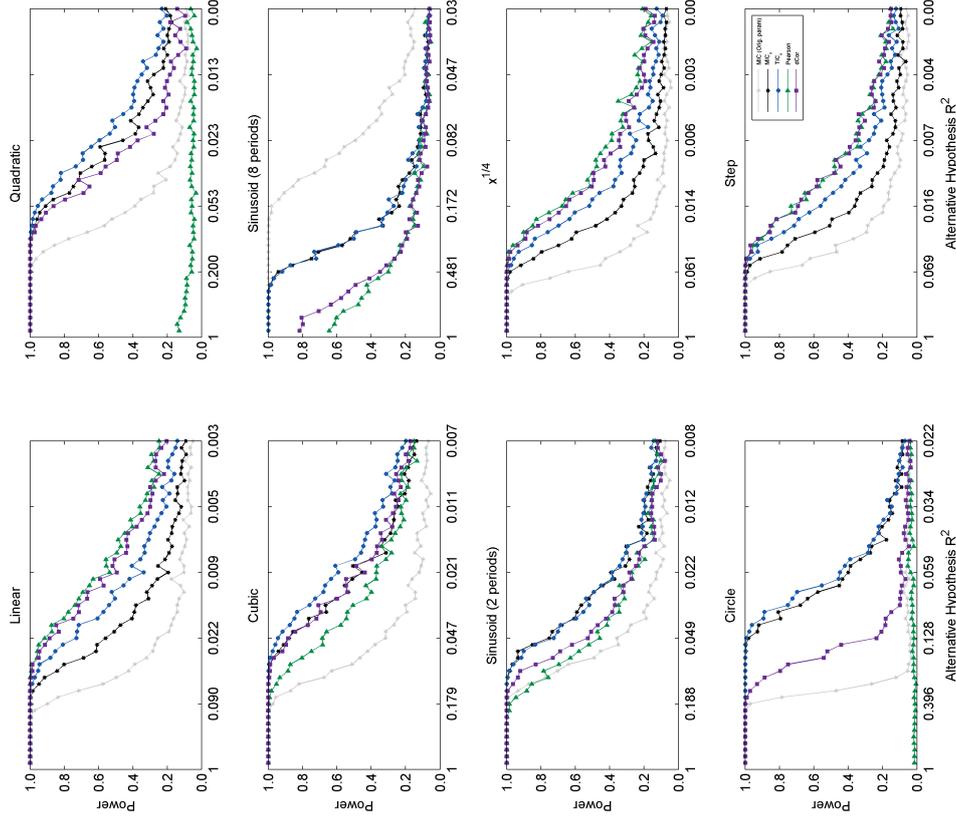

Figure 5: Comparison of power of independence testing based on TIC_e (blue) to MIC with default parameters (gray), MIC_e with the same parameters as TIC_e (black), distance correlation (purple), and the Pearson correlation coefficient (green) across several alternative hypothesis relationship types chosen by Simon and Tibshirani (2012). The relationships analyzed are described in Section 5.2.

as tests based on mutual information estimation (Kraskov et al., 2004), maximal correlation estimation (Breiman and Friedman, 1985), HSIC (Gretton et al., 2005, 2007), HHG (Heller et al., 2013), DDP (Heller et al., 2016), and RDC (Lopez-Paz et al., 2013). These analyses consider a range of sample sizes and parameter settings, as well as a variety of ways of quantifying power across different alternative hypothesis relationship types and noise levels. They conclude that in most settings TIC_e either outperforms all the methods tested or performs comparably to the best ones. Appendix Figure 12 contains a reproduction of one detailed set of power curves from the main analysis in that paper for the reader’s reference.

6. Conclusion

As high-dimensional data sets become increasingly common, data exploration requires not only statistics that can accurately detect a large number of non-trivial relationships in a data set, but also ones that can identify a smaller number of strongest relationships. The former property is achieved by measures of dependence that yield independence tests with high power; the latter is achieved by measures of dependence that are equitable with respect to some measure of relationship strength. In this paper, we introduced two related measures of dependence that achieve these two goals, respectively, through the following theoretical contributions.

- A new population measure of dependence, MIC_* , that we proved can be viewed in three different ways: as the population value of the maximal information coefficient (MIC) from Reshef et al. (2011), as a “minimal smoothing” of mutual information that makes it uniformly continuous, or as the supremum of an infinite sequence defined in terms of optimal partitions of one marginal at a time of a given joint distribution.
- An efficient approach for approximating the MIC_* of a given joint distribution.
- A statistic MIC_e that is a consistent estimator of MIC_* , is efficiently computable, and has good equitability with respect to R^2 both on a manually chosen set of noisy functional relationships as well as on a set of randomly chosen noisy functional relationships.
- The total information coefficient (TIC_e), a statistic that arises as a trivial side-product of the computation of MIC_e and yields a consistent and powerful independence test.

Though we presented here some empirical results for MIC_* , MIC_e , and TIC_e , our focus was on theoretical considerations; the performance of these methods is analyzed in detail in our companion paper (Reshef et al., 2015a). That paper shows that on a large set of noisy functional relationships with varying noise and sampling properties, the asymptotic equitability with respect to R^2 of MIC_* is quite high and the equitability with respect to R^2 of MIC_e is state-of-the-art. It also shows that the power of the independence test based on TIC_e is state-of-the-art across a wide variety of dependent alternative hypotheses. Finally, it demonstrates that the algorithms presented here allow for MIC_e and TIC_e to be computed simultaneously very quickly, enabling analysis of extremely large data sets using both statistics together.

Our contributions are of both theoretical and practical importance for several reasons. First, our characterization of MIC_* as the large-sample limit of MIC sheds light on the latter statistic. For example, while MIC is parametrized, MIC_* is not. Knowing that MIC converges in probability to MIC_* tells us that this parametrization is statistical only: it controls the bias/variance properties of the statistic, but not its asymptotic behavior.

Second, the normalization in the definition of MIC, while empirically seen to yield good performance, had previously not been theoretically understood. Our result that this normalization is the minimal smoothing necessary to make mutual information uniformly continuous provides for the first time a lens through which the normalization is canonical. In doing so, it constitutes an initial step toward understanding the role of the normalization in the performance of MIC_* and MIC. The uniform continuity of MIC_* and the lack of continuity of ordinary mutual information also suggest that estimation of the former may be easier in some sense than estimation of the latter. This is consonant with a recent result concerning difficulty of estimation of mutual information shown in Ding and Li (2013). It is also borne out empirically by the substantial finite-sample bias and variance observed in Reshef et al. (2015a) of the Kraskov mutual information estimator (Kraskov et al., 2004) compared to MIC_e .

Third, our alternate characterization of MIC_* in terms of one-dimensional optimization over partitions rather than two-dimensional optimization over grids enhances our understanding of how to efficiently compute it in the large-sample limit and estimate it from finite samples using MIC_e . This is a significant improvement over the previous state of affairs, in which the statistic MIC could only be approximated heuristically, with even the heuristic approximation being orders of magnitude slower than the results in this paper now allow.

Finally, the introduction of the total information coefficient provides evidence that the basic approach of considering the set of normalized mutual information values achievable by applying different grids to a joint distribution is of fundamental value in characterizing dependence. Interestingly, a statistic introduced in Heller et al. (2016) follows a similar approach by considering the (non-normalized) sum of the mutual information values achieved by all possible finite grids. Consistent with our demonstration here that an aggregative grid-based approach works well, that statistic also achieves excellent power. (TIC_e is compared to the statistic from Heller et al. 2016 in our companion paper, Reshef et al., 2015a.)

Taken together, our results point to joint use of the statistics MIC_e and TIC_e as a theoretically grounded, computationally efficient, and highly practical approach to data exploration. Specifically, since the two statistics can be computed simultaneously with little extra cost beyond that of computing either individually, we propose computing both of them on all variable pairs in a data set, using TIC_e to filter out non-significant associations, and then using MIC_e to rank the remaining variable pairs. Such a strategy would have the advantage of leveraging the state-of-the-art power of TIC_e to substantially reduce the multiple-testing burden on MIC_e , while utilizing the latter statistic’s state-of-the-art equitability to effectively rank relationships for follow-up by the practitioner.

Our results, while useful, nevertheless have limitations that warrant exploration in future work. First, for a sample D from the distribution of some random (X, Y) , all of the sample quantities we define here use the naive estimate $I(D|G)$ of the quantity $I(X, Y|G)$ for various grids G . There is a long and fruitful line of work on more sophisticated estimators of the discrete mutual information Paminski (2003) whose use instead of $I(D|G)$ could improve

the statistics introduced here. Second, our approach to approximating the MIC_* of a given joint density consists of computing a finite subset of an infinite set whose supremum we seek to calculate. However, the choice of how large a finite set we should compute in order to approximate the supremum to a given precision remains heuristic. Finally, though empirical characterization of the equitability of MIC_e on representative sets of relationships is important and promising, we are still missing a theoretical characterization of its equitability in the large-sample limit. A clear theoretical demarcation of the set of relationships on which MIC_* achieves good equitability with respect to R^2 , and an understanding of why that is, would greatly advance our understanding of both MIC_* and equitability.

Appendix A. Proof of Theorem 6

This appendix is devoted to proving Theorem 6, restated below.

Theorem *Let $f : m^\infty \rightarrow \mathbb{R}$ be uniformly continuous, and assume that $f \circ r_i \rightarrow f$ pointwise. Then for every random variable (X, Y) , we have*

$$(f \circ r_{B(n)}) \left(\widetilde{M}(D_n) \right) \rightarrow f(M(X, Y))$$

in probability where D_n is a sample of size n from the distribution of (X, Y) , provided $\omega(1) < B(n) \leq O(n^{1-\varepsilon})$ for some $\varepsilon > 0$.

We prove the theorem by a sequence of lemmas that build on each other to bound the bias of $I^*(D, k, \ell)$. The general strategy is to capture the dependencies between different k -by- ℓ grids G by considering a “master grid” Γ that contains many more than $k\ell$ cells. Given this master grid, we first bound the difference between $I(D|_G)$ and $I((X, Y)|_G)$ only for sub-grids G of Γ . The bound is in terms of the difference between $D|_\Gamma$ and $(X, Y)|_\Gamma$. We then show that this bound can be extended without too much loss to all k -by- ℓ grids. This gives what we seek, because then the difference between $I(D|_G)$ and $I((X, Y)|_G)$ is uniformly bounded for all grids G in terms of the same random variable: $D|_\Gamma$. Once this is done, standard arguments give the consistency we seek. ■

In our argument we occasionally require technical facts about entropy and mutual information that are self-contained and unrelated to the central ideas. These lemmas are consolidated in Appendix L.

We begin by using one of these technical lemmas to prove a bound on the difference between $I(D|_G)$ and $I((X, Y)|_G)$ that is uniform over all grids G that are sub-grids of a much denser grid Γ . The common structure imposed by Γ will allow us to capture the dependence between the quantities $|I(D|_G) - I((X, Y)|_G)|$ for different grids G .

Lemma 35 *Let $\Pi = (\Pi_X, \Pi_Y)$ and $\Psi = (\Psi_X, \Psi_Y)$ be random variables distributed over the cells of a grid Γ , and let $(\pi_{i,j})$ and $(\psi_{i,j})$ be their respective distributions. Define*

$$\varepsilon_{i,j} = \frac{\psi_{i,j} - \pi_{i,j}}{\pi_{i,j}}.$$

Let G be a sub-grid of Γ with B cells. Then for every fixed $0 < a < 1$ we have

$$|I(\Psi|_G) - I(\Pi|_G)| \leq O \left((\log B) \sum_{i,j} |\varepsilon_{i,j}| \right)$$

when $|\varepsilon_{i,j}| \leq 1 - a$ for all i and j .

Proof Let $P = \Pi|_G$ and $Q = \Psi|_G$ be the random variables induced by Π and Ψ respectively on the cells of G . Using the fact that $I(X, Y) = H(X) + H(Y) - H(X, Y)$, we write

$$|I(Q) - I(P)| \leq |H(Q_X) - H(P_X)| + |H(Q_Y) - H(P_Y)| + |H(Q) - H(P)|$$

where Q_X and P_X denote the marginal distributions on the columns of G and Q_Y and P_Y denote the marginal distributions on the rows. We can bound each of the terms on the right-hand side of the equation above using a Taylor expansion argument given in Lemma 51, whose proof is found in Appendix L. Doing so gives

$$|I(Q) - I(P)| \leq (\ln B) \left(\sum_i O(|\varepsilon_{i,*}|) + \sum_j O(|\varepsilon_{*,j}|) + \sum_{i,j} O(|\varepsilon_{i,j}|) \right)$$

where

$$\varepsilon_{i,*} = \frac{\sum_j (\psi_{i,j} - \pi_{i,j})}{\sum_j \pi_{i,j}}$$

and $\varepsilon_{*,j}$ is defined analogously.

To obtain the result, we observe that

$$|\varepsilon_{i,*}| = \left| \frac{\sum_j \pi_{i,j} \varepsilon_{i,j}}{\sum_j \pi_{i,j}} \right| \leq \frac{\sum_j \pi_{i,j} |\varepsilon_{i,j}|}{\sum_j \pi_{i,j}} \leq \sum_j |\varepsilon_{i,j}|$$

since $\pi_{i,j} / \sum_j \pi_{i,j} \leq 1$, and the analogous bound holds for $|\varepsilon_{*,j}|$. ■

We now extend Lemma 35 to all grids with B cells rather than just those that are sub-grids of the master grid Γ . The proof of this lemma relies on an information-theoretic result proven in Appendix B that bounds the difference in mutual information between two distributions that can be obtained from each other by moving a small amount of probability mass.

Lemma 36 Let $\Pi = (\Pi_X, \Pi_Y)$ and $\Psi = (\Psi_X, \Psi_Y)$ be random variables, and let Γ be a grid. Define $\varepsilon_{i,j}$ on Π_Γ and Ψ_Γ as in Lemma 35. Let G be any grid with B cells, and let δ (resp. d) represent the total probability mass of Π_Γ (resp. Ψ_Γ) falling in cells of Γ that are not contained in individual cells of G . We have that

$$|I(\Psi|_G) - I(\Pi|_G)| \leq O\left(\left(\sum_{i,j} |\varepsilon_{i,j}| + \delta + d\right) \log B + \delta \log(1/\delta) + d \log(1/d)\right)$$

provided that the $|\varepsilon_{i,j}|$ are bounded away from 1 and that $d, \delta \leq 1/2$.

Proof In the proof below, we use the convention that for any two grids G and G' and any random variable Z , the expression $\Delta^Z(G, G')$ denotes $|I(Z|_G) - I(Z|_{G'})|$.

Consider the grid G' obtained by replacing every horizontal or vertical line in G that is not in Γ with a closest line in Γ . The grid G' is clearly a sub-grid of Γ . Moreover, $\Pi|_{G'}$ (resp. $\Psi|_{G'}$) can be obtained from $\Pi|_G$ (resp. $\Psi|_G$) by moving at most δ (resp. d) probability mass. This can be shown to imply that

$$\Delta^\Pi(G, G') \leq O(\delta \log(1/\delta) + \delta \log B) \quad \text{and} \quad \Delta^\Psi(G', G) \leq O(d \log(1/d) + d \log B).$$

The proof of this information-theoretic fact is self-contained and so we defer it to Proposition 40 in Appendix B, as it is more central to the arguments presented there.

With $\Delta^\Phi(G, G')$ and $\Delta^\Psi(G', G)$ bounded in terms of δ and d , we can bound $|I(\Psi|_G) - I(\Phi|_G)|$ using the triangle inequality by comparing it with

$$\Delta^\Pi(G, G') + |I(\Pi|_{G'}) - I(\Psi|_G)| + \Delta^\Psi(G', G)$$

and bounding the middle term using Lemma 35, since $G' \subset \Gamma$. ■

We now use the fact that the variables $\varepsilon_{i,j}$ defined in Lemma 35 are small with high probability to give a concrete bound on the bias of $I(D|_G)$ that is uniform over all k -by- ℓ grids G and that holds with high probability. It is useful at this point to recall that, given a distribution (X, Y) , an equipartition of (X, Y) is a grid G such that all the rows of $(X, Y)|_G$ have the same probability mass, and all the columns do as well.

Lemma 37 Let D_n be a sample of size n from the distribution of a pair (X, Y) of jointly distributed random variables. For any $\alpha \geq 0$, any $\varepsilon > 0$, and any integers $k, \ell > 1$, we have that for all n

$$|I(D_n|_G) - I((X, Y)|_G)| \leq O\left(\frac{\log(k\ell)}{C(n)^\alpha} + \frac{\log(k\ell n)}{n^{\varepsilon/4}}\right)$$

for every k -by- ℓ grid G with probability at least $1 - C(n)e^{-\Omega(n/C(n)^{1+2\alpha})}$, where $C(n) = k\ell n^{\varepsilon/2}$.

Proof Fix n , and let Γ be an equipartition of (X, Y) into $k\ell n^{\varepsilon/4}$ rows and $\ell n^{\varepsilon/4}$ columns. $C(n)$ is now the number of cells in Γ . Lemma 36, with $\Pi = (X, Y)$ and $\Psi = D$, shows that $|I(D|_G) - I((X, Y)|_G)|$ is at most

$$O\left(\left(\sum_{i,j} |\varepsilon_{i,j}| + \delta + d\right) \log(k\ell) + \delta \log(1/\delta) + d \log(1/d)\right)$$

provided the $\varepsilon_{i,j}$ have absolute value bounded away from 1, and provided that $d, \delta \leq 1/2$.

The remainder of the proof proceeds as follows. We first show that the $\varepsilon_{i,j}$ are small with high probability. This will both show that the lemma's requirement on the $\varepsilon_{i,j}$ holds and allow us to bound the sum in the inequality above. We will then use our bound on the $\varepsilon_{i,j}$ to bound d in terms of δ . Finally, we will bound δ using the fact that the number of rows and columns in Γ increases with n . This will give us that $d, \delta \leq 1/2$ and allow us to bound the rest of the terms in the expression above.

Bounding the $\varepsilon_{i,j}$: We bound the $\varepsilon_{i,j}$ using a multiplicative Chernoff bound. Let $\pi_{i,j}$ and $\psi_{i,j}$ represent the probability mass functions of $(X, Y)|_\Gamma$ and $D|_\Gamma$ respectively. We write

$$\begin{aligned} \mathbf{P}(|\varepsilon_{i,j}| \geq \delta) &= \mathbf{P}(\pi_{i,j}(1 - \delta) \leq \psi_{i,j} \leq \pi_{i,j}(1 + \delta)) \\ &\leq e^{-\Omega(n\pi_{i,j}\delta^2)} \end{aligned}$$

since $\psi_{i,j}$ is a sum of n i.i.d. Bernoulli random variables and $\mathbf{E}(\psi_{i,j}) = n\pi_{i,j}$. (See, e.g., Mitzenmacher and Upfal 2005.) Setting $\delta = \sqrt{\pi_{i,j}/C(n)^{1/2+\alpha}}$ yields

$$\mathbf{P}\left(|\varepsilon_{i,j}| \geq \frac{\sqrt{\pi_{i,j}}}{C(n)^{1/2+\alpha}}\right) \leq e^{-\Omega(n/C(n)^{1+2\alpha})}.$$

A union bound over the pairs (i, j) then gives that, with the desired probability, the above bound on $|\varepsilon_{i,j}|$ holds for all i, j .

Bounding $\sum |\varepsilon_{i,j}|$: The bound on the $\varepsilon_{i,j}$ implies that

$$\begin{aligned} \sum_i |\varepsilon_{i,j}| &\leq \frac{1}{C(n)^{1/2+\alpha}} \sum_{i,j} \sqrt{\pi_{i,j}} \\ &\leq \frac{1}{C(n)^{1/2+\alpha}} \sqrt{C(n)} \\ &\leq \frac{1}{C(n)^\alpha} \end{aligned}$$

where the second line follows from the fact that the function $\sum \sqrt{\pi_{i,j}}$ is symmetric and concave and therefore, when restricted to the hyperplane $\sum \pi_{i,j} = 1$, must achieve its maximum when $\pi_{i,j} = 1/C(n)$ for all i, j .

Bounding d in terms of δ : We use our bound on the $\varepsilon_{i,j}$ to bound d . We do so by observing that it implies

$$\psi_{i,j} \leq \pi_{i,j} \left(1 + \frac{\sqrt{\pi_{i,j}}}{C(n)^{1/2+\alpha}}\right) = \pi_{i,j} + \frac{\pi_{i,j}^{3/2}}{C(n)^{1/2+\alpha}} \leq \pi_{i,j} + \frac{\pi_{i,j}}{C(n)^{1/2+\alpha}} \leq 2\pi_{i,j}$$

since $\pi_{i,j} \leq 1$ and $C(n) \geq 1$.

The connection to d comes from the fact that for any column j of Γ , this means that

$$\psi_{i,*} = \sum_i \psi_{i,j} \leq 2 \sum_i \pi_{i,j} = 2\pi_{*,j}.$$

This also applies to the sums across rows. Since d is a sum of terms of the form $\psi_{i,*}$ and $\psi_{i,*}$ for j in some index set J and i in an index set I , and δ is a sum of terms of the form $\pi_{*,j}$ and $\pi_{i,*}$ with the same index sets, we therefore get that $d \leq 2\delta$.

Bounding δ and obtaining the result: To bound δ , we observe that because G has at most $\ell - 1$ vertical lines and $k - 1$ horizontal lines, we have

$$\delta \leq \frac{\ell}{\ell n^{\varepsilon/4}} + \frac{k}{k n^{\varepsilon/4}} \leq \frac{2}{n^{\varepsilon/4}}.$$

This bound on δ allows us to bound the terms involving d and δ by

$$\delta + d \leq O\left(\frac{1}{n^{\varepsilon/4}}\right), \quad \delta \log\left(\frac{1}{\delta}\right) + d \log\left(\frac{1}{d}\right) \leq O\left(\frac{\log n}{n^{\varepsilon/4}}\right).$$

Combining all of the bounds gives the desired result. \blacksquare

Our final lemma shows that as long as $B(n)$ doesn't grow too fast, the bound from the previous lemma yields a uniform bound on the entire sample characteristic matrix. This is done by specifying an error threshold for which Lemma 37 yields a bound that holds with high probability, and then invoking a union bound.

Lemma 38 *Let D_n be a sample of size n from the distribution of a pair (X, Y) of jointly distributed random variables. For every $B(n) = O(n^{1-\varepsilon})$, there exists an $a > 0$ such that for sufficiently large n ,*

$$\left| \widehat{M}(D_n)_{k,\ell} - M(X, Y)_{k,\ell} \right| \leq O\left(\frac{1}{n^a}\right)$$

holds for all $k\ell \leq B(n)$ with probability $P(n) = 1 - o(1)$, where $\widehat{M}(D_n)_{k,\ell}$ is the k, ℓ -th entry of the sample characteristic matrix and $M(X, Y)_{k,\ell}$ is the k, ℓ -th entry of the population characteristic matrix of (X, Y) .

Proof Fix k, ℓ , and any α satisfying $0 < \alpha < \varepsilon/(4 - 2\varepsilon)$. Lemma 37 implies that with high probability the difference $|\widehat{M}(D_n)_{k,\ell} - M_{k,\ell}|$ is at most

$$\begin{aligned} O\left(\frac{\log(k\ell)}{C(n)^\alpha} + \frac{\log(k\ell n)}{n^{\varepsilon/4}}\right) &\leq O\left(\frac{\log n}{C(n)^\alpha} + \frac{\log n}{n^{\varepsilon/4}}\right) \\ &\leq O\left(\frac{\log n}{n^{\alpha\varepsilon/2}} + \frac{\log n}{n^{\varepsilon/4}}\right) \end{aligned}$$

where the first inequality comes from $k\ell \leq B(n)$ and second is because $C(n) = k\ell n^{\varepsilon/2} \geq n^{\varepsilon/2}$. This bound is at most $O(1/n^a)$ for every $a < \min\{\alpha\varepsilon/2, \varepsilon/4\}$, as desired. It remains only to show that the bound holds with high probability across all $k\ell \leq B(n)$.

Lemma 37 states that the probability our bound holds for one fixed pair (k, ℓ) is at least

$$1 - C(n)e^{-\Omega(n/C(n)^{1+2\alpha})} \geq 1 - O(n)e^{-\Omega(n^u)}$$

for some positive u . This is because $C(n) \leq B(n)n^{\varepsilon/2} \leq O(n^{1-\varepsilon/2})$ for large n , and so our choice of α ensures that $C(n)^{1+2\alpha} = O(n^{1-u})$ for some $u > 0$.

We can then perform a union bound over all pairs $k\ell \leq B(n)$: since the number of such pairs can be bounded by a polynomial in n , we have that the desired condition is satisfied for all $k\ell \leq B(n)$ with probability approaching 1. \blacksquare

We are now ready to prove the main result.

Theorem *Let $f : m^\infty \rightarrow \mathbb{R}$ be uniformly continuous, and assume that $f \circ r_i \rightarrow f$ pointwise. Then for every random variable (X, Y) , we have*

$$(f \circ r_{B(n)})\left(\widehat{M}(D_n)\right) \rightarrow f(M(X, Y))$$

in probability where D_n is a sample of size n from the distribution of (X, Y) , provided $\omega(1) < B(n) \leq O(n^{1-\varepsilon})$ for some $\varepsilon > 0$.

Proof Let N denote $B(n)$, let $M_N = r_N(M)$, and let $\widehat{M}_N(D_n) = r_N(\widehat{M}(D_n))$. We begin by writing

$$\begin{aligned} \left| f\left(\widehat{M}_N(D_n)\right) - f(M) \right| &\leq \left| f\left(\widehat{M}_N(D_n)\right) - f(M_N) \right| + \left| f(M_N) - f(M) \right| \\ &= \left| f\left(\widehat{M}_N(D_n)\right) - f(M_N) \right| + \left| (f \circ r_N)(M) - f(M) \right| \end{aligned}$$

and observing that as $n \rightarrow \infty$, the second term vanishes by the pointwise convergence of $f \circ r_i$ and the fact that $B(n) > \omega(1)$. It therefore suffices to show that the first term converges to zero in probability. Since f is uniformly continuous, we can establish this via a simple adaptation of the continuous mapping theorem, which says that if the sequence of random variables $R_n \rightarrow R$ in probability, and g is continuous, then $g(R_n) \rightarrow g(R)$ in probability. We replace R with a second sequence, and replace continuity with uniform continuity.

Let $\|\cdot\|$ denote the supremum norm on m^∞ , and fix any $z > 0$. Then, for any $\delta > 0$, define

$$C_\delta = \{A \in m^\infty : \exists A' \in m^\infty \text{ s.t. } \|A - A'\| < \delta, \|f(A) - f(A')\| > z\}.$$

This is the set of matrices $A \in m^\infty$ for which it is possible to find, within a δ -neighborhood of A , a second matrix that f maps to more than z away from $f(A)$. Because f is uniformly continuous, there exists a δ^* sufficiently small so that $C_{\delta^*} = \emptyset$.

Suppose that $|f(\widehat{M}_N(D_n)) - f(M_N)| > z$. This means that either $\|\widehat{M}_N(D_n) - M_N\| > \delta^*$, or $M_N \in C_{\delta^*}$. The latter option is impossible since $C_{\delta^*} = \emptyset$, and Lemma 38 tells us that $\mathbf{P}\left(\|\widehat{M}_N(D_n) - M_N\| > \delta^*\right) \rightarrow 0$ as n grows. We therefore have that

$$\left| f\left(\widehat{M}_N(D_n)\right) - f(M_N) \right| \rightarrow 0$$

in probability, as desired. \blacksquare

Appendix B. Proof of Theorem 8

In this appendix we prove Theorem 8, reproduced below.

Theorem Let $\mathcal{P}(\mathbb{R}^2)$ denote the space of random variables supported on \mathbb{R}^2 equipped with the metric of statistical distance. The map from $\mathcal{P}(\mathbb{R}^2)$ to m^∞ defined by $(X, Y) \mapsto M(X, Y)$ is uniformly continuous.

The proposition below begins our argument with the simple observation that the family of maps consisting of applying any finite grid to some $(X, Y) \in \mathcal{P}(\mathbb{R}^2)$ is uniformly equicontinuous. The reason this holds is that $(X, Y)|_G$ is a deterministic function of (X, Y) , and deterministic functions cannot increase statistical distance.

Proposition 39 Let \mathbb{G} be the set of all finite grids. The family $\{(X, Y) \mapsto (X, Y)|_G : G \in \mathbb{G}\}$ is uniformly equicontinuous on $\mathcal{P}(\mathbb{R}^2)$.

Proof To establish uniform equicontinuity, we need to show that, given some $(X, Y) \in \mathcal{P}(\mathbb{R}^2)$ and some $\varepsilon > 0$, we can choose δ to satisfy the continuity condition in a way that does not depend on G or on (X, Y) . But because deterministic functions cannot increase statistical distance, we have that if $(X, Y), (X', Y') \in \mathcal{P}$ are at most ε apart then

$$\Delta((X, Y)|_G, (X', Y')|_G) \leq \Delta((X, Y), (X', Y')) = \varepsilon$$

where Δ denotes statistical distance. Choosing $\delta = \varepsilon$ therefore gives the result. \blacksquare

At this point it is tempting to try to use continuity properties of discrete mutual information to obtain uniform continuity of the characteristic matrix. And indeed, this strategy does yield that each *individual* entry of the characteristic matrix is a uniformly continuous function. However, to obtain continuity of the entire (infinite) characteristic matrix we need to make a statement about all grid resolutions simultaneously. This is not straightforward because mutual information is only uniformly continuous for a fixed grid resolution, and the family $\{(X, Y) \mapsto I((X, Y)|_G) : G \in \mathbb{G}\}$ is in fact not even equicontinuous.

The normalization in the definition of MIC_* is what allows us to establish the uniform continuity of the characteristic matrix despite this problem. To see why, suppose we have a distribution over a k -by- ℓ grid and we are allowed to move at most δ away in statistical distance for some small δ . The largest change in discrete mutual information that this can cause indeed increases as we increase k and ℓ . However, it turns out that we can bound the extent of this ‘‘non-uniformity’’: the proposition below shows that as we move away from a distribution, the discrete mutual information can change only proportionally to the amount of mass we move, with the proportionality constant bounded by $\log \min\{k, \ell\}$. Because $\log \min\{k, \ell\}$ is the quantity by which we regularize the entries of the characteristic matrix, this is exactly enough to make the normalized matrix continuous. This proposition is the technical heart of our continuity result. And as we show in Corollary 11 when we demonstrate the non-continuity of the non-normalized characteristic matrix mutual information, our bound is tight.

Proposition 40 Let $I_{k,\ell} : \mathcal{P}(\{1, \dots, k\} \times \{1, \dots, \ell\}) \rightarrow \mathbb{R}$ denote the discrete mutual information function on k -by- ℓ grids. For $0 < \delta \leq 1/4$, the maximal change in $I_{k,\ell}$ over any subset of $\mathcal{P}(\{1, \dots, k\} \times \{1, \dots, \ell\})$ of diameter δ (in statistical distance) is

$$O\left(\delta \log\left(\frac{1}{\delta}\right) + \delta \log \min\{k, \ell\}\right).$$

Proof Without loss of generality, assume $k \leq \ell$, so that $\log \min\{k, \ell\} = \log k$. Let (X, Y) and (X', Y') be two random variables distributed over $\{1, \dots, k\} \times \{1, \dots, \ell\}$ that are at most δ apart in statistical distance. Using $I(X, Y) = H(Y) - H(Y|X)$, we can express the difference between the mutual information of these two pairs of random variables as

$$|I(X, Y) - I(X', Y')| \leq |H(Y) - H(Y')| + |H(Y|X) - H(Y'|X')|.$$

We now use Lemma 55, which relates movement of probability mass to changes in entropy and is proven in Appendix L, to separately bound each of the terms on the right hand side. Straightforward application of the lemma to $|H(Y) - H(Y')|$ shows that it is at most $2H_b(2\delta) + 3\delta \log k$, where $H_b(\cdot)$ is the binary entropy function. Since $H_b(x) \leq O(x \log(1/x))$ for x small, this is $O(\delta \log(1/\delta) + \delta \log k)$.

Bounding the term with the conditional entropies is more involved. Let $p_x = \mathbf{P}(X = x)$, and let $p'_x = \mathbf{P}(X' = x)$. We have

$$\begin{aligned} |H(Y|X) - H(Y'|X')| &= \sum_x |p_x H(Y|X = x) - p'_x H(Y'|X' = x)| \\ &\leq \sum_x (p_x |H(Y|X = x) - H(Y'|X' = x)| + \\ &\quad |p'_x - p_x| H(Y'|X' = x)) \\ &= \sum_x p_x |H(Y|X = x) - H(Y'|X' = x)| + \sum_x |p'_x - p_x| \log k \\ &\leq \sum_x p_x |H(Y|X = x) - H(Y'|X' = x)| + \delta \log k \end{aligned} \tag{2}$$

where the last line is because $\sum_x |p_x - p'_x| \leq \delta$ and $H(Y'|X' = x) \leq \log k$.

Now let $\delta_{x,+}$ be the magnitude of all the probability mass entering any cell in column x , let $\delta_{x,-}$ be the magnitude of all the probability mass leaving any cell in column x , and let $\delta_x = \delta_{x,+} + \delta_{x,-}$. Using this notation, we can again apply Lemma 55 to obtain

$$\begin{aligned} \sum_x p_x |H(Y|X = x) - H(Y'|X' = x)| &\leq \sum_x p_x \left(2H_b\left(\frac{2\delta_x}{p_x}\right) + 3\delta_x \log k \right) \\ &= 2 \sum_x p_x H_b\left(\frac{2\delta_x}{p_x}\right) + 3 \sum_x \delta_x \log k \\ &\leq 2 \sum_x p_x H_b\left(\frac{2\delta_x}{p_x}\right) + 3\delta \log k \\ &\leq 2H_b(2\delta) + 3\delta \log k \end{aligned}$$

where the last line is by application of Lemma 52 from the appendix, which bounds weighted sums of binary entropies.

Combining this with Line (2) gives that

$$|H(Y|X) - H(Y'|X')| \leq 2H_\delta(2\delta) + 4\delta \log k$$

which, together with the bound on $|H(Y) - H(Y')|$ and the fact that $H_\delta(X) \leq O(x \log(1/x))$ for x small, gives the result. \blacksquare

Having bounded the extent to which variation in mutual information depends on grid resolution, we are now ready to show the uniform continuity of the characteristic matrix.

Theorem Let $\mathcal{P}(\mathbb{R}^2)$ denote the space of random variables supported on \mathbb{R}^2 equipped with the metric of statistical distance. The map from $\mathcal{P}(\mathbb{R}^2)$ to m^∞ defined by $(X, Y) \mapsto M(X, Y)$ is uniformly continuous.

Proof We complete the proof in three steps. First, we show that a certain family of functions F is uniformly equicontinuous. Second, we use this to show that a different family F' consisting of functions of the form $\sup_{g \in A} g$ with $A \subset F$ is uniformly equicontinuous. Finally, we argue that since the entries of $M(X, Y)$ consist of the functions in F' , this is sufficient to establish the result.

Define

$$F = \left\{ (X, Y) \mapsto \frac{I_{k,\ell}((X, Y)|_G)}{\log \min\{k, \ell\}} : k, \ell \in \mathbb{Z}_{>1}, G \in \mathcal{G}(k, \ell) \right\}.$$

F is uniformly equicontinuous by the following argument. Given some $\varepsilon > 0$, we know (Proposition 39) that for any (X', Y') in an ε -ball around (X, Y) , $(X', Y')|_G$ will remain within ε of $(X, Y)|_G$ for any G . Proposition 40 then tells us that if ε is sufficiently small then the distance between $I_{k,\ell}((X', Y')|_G)$ and $I_{k,\ell}((X, Y)|_G)$ will be at most

$$O(\varepsilon \log(1/\varepsilon) + \varepsilon \log \min\{k, \ell\}).$$

After the normalization, this becomes at most $O(\varepsilon(\log(1/\varepsilon) + 1))$, which goes to zero (uniformly with respect to (X, Y)) as ε approaches zero, as desired.

Next, define

$$F' = \{(X, Y) \mapsto M(X, Y)_{k,\ell} : k, \ell \in \mathbb{Z}_{>1}\}.$$

Each map in F' is of the form $\sup_{g \in A} g$ for some $A \subset F$. Therefore, for a given $\varepsilon > 0$, whatever δ establishes the uniform equicontinuity for F can be used to establish continuity of all the functions in F' . (To see this: $\sup_{g \in A} g$ can't increase by more than ε if no g increases by more than ε , and $\sup_{g \in A} g$ is also lower bounded by any of the g 's, so it can't decrease by more than ε either.) Since we can use the same δ for all of the maps in F' , they therefore form a uniformly equicontinuous family.

Finally, the δ provided by the uniform equicontinuity of F' also ensures that $M(X', Y')$ is within ε of $M(X, Y)$ in the supremum norm, thus giving the uniform continuity of $(X, Y) \mapsto M(X, Y)$. \blacksquare

Appendix C. Proof of Proposition 10

Theorem For some function $N(k, \ell)$, let M^N be the characteristic matrix with normalization N , i.e.,

$$M^N(X, Y) = \frac{I^*((X, Y), k, \ell)}{N(k, \ell)}.$$

If $N(k, \ell) = o(\log \min\{k, \ell\})$ along some infinite path in $\mathbb{N} \times \mathbb{N}$, then M^N and $\sup M^N$ are not continuous as functions of $\mathcal{P}([0, 1] \times [0, 1]) \subset \mathcal{P}(\mathbb{R}^2)$.

Proof Consider a random variable Z uniformly distributed on $[0, 1/2]^2$. Because Z exhibits statistical independence, $I^*(Z, k, \ell)$ is zero for all k, ℓ . Now define Z_ε to be uniformly distributed on $[0, 1/2]^2$ with probability $1 - \varepsilon$ and uniformly distributed on the line from $(1/2, 1/2)$ to $(1, 1)$ with probability ε .

We lower-bound $I^*(Z_\varepsilon, k, \ell)$. Without loss of generality suppose that $k \leq \ell$, and consider a grid that places all of $[0, 1/2]^2$ into one cell and uniformly partitions the set $[1/2, 1]^2$ into $k - 1$ rows and $k - 1$ columns. By considering just the rows/columns in the set $[1/2, 1]^2$ we see that this grid gives a mutual information of at least $\varepsilon \log(k - 1)$. Thus, we have that for all k, ℓ ,

$$I^*(Z_\varepsilon, k, \ell) \geq \varepsilon \log \min\{k - 1, \ell - 1\}.$$

This implies that the limit of $M^N(Z_\varepsilon)$ along P is ∞ , and so the distance between $M^N(Z)$ and $M^N(Z_\varepsilon)$ in the supremum norm is infinite. \blacksquare

Appendix D. Proof of Theorem 16

Theorem Let M be a population characteristic matrix. Then $M_{k,\uparrow}$ equals

$$\max_{P \in \mathcal{P}(k)} \frac{I(X, Y|_P)}{\log k}$$

where $\mathcal{P}(k)$ denotes the set of all partitions of size at most k .

Proof Define

$$M_{k,\uparrow}^* = \max_{P \in \mathcal{P}(k)} \frac{I(X, Y|_P)}{\log k}.$$

We wish to show that $M_{k,\uparrow}^*$ is in fact equal to $M_{k,\uparrow}$. To show that $M_{k,\uparrow} \leq M_{k,\uparrow}^*$ we observe that for every k -by- ℓ grid $G = (P, Q)$, where P is a partition into rows and Q is a partition into columns, the data processing inequality gives $I((X, Y)|_G) \leq I(X, Y|_P)$. Thus $M_{k,\ell} \leq M_{k,\uparrow}^*$ for $\ell \geq k$, implying that

$$M_{k,\uparrow} = \lim_{\ell \rightarrow \infty} M_{k,\ell} \leq M_{k,\uparrow}^*.$$

It remains to show that $M_{k,\uparrow}^* \leq M_{k,\uparrow}$. To do this, we let P be any partition into k rows, and we define Q_ℓ to be an equipartition into ℓ columns. We let

$$M_{k,\ell,P}^* = \frac{I(X|_{Q_\ell}, Y|_P)}{\log k}.$$

Since $M_{k,\ell}^* \leq M_{k,\ell}$ when $\ell \geq k$, we have that for all P

$$\frac{I(X, Y|P)}{\log k} = \lim_{\ell \rightarrow \infty} M_{k,\ell}^* \leq \lim_{\ell \rightarrow \infty} M_{k,\ell} = M_{k,\uparrow}$$

which gives that

$$M_{k,\uparrow}^* = \sup_P \frac{I(X, Y|P)}{\log k} \leq M_{k,\uparrow}$$

as desired. \blacksquare

Appendix E. Proof of Theorem 18

Theorem *Given a random variable (X, Y) , $M_{k,\uparrow}$ (resp. $M_{\uparrow,\ell}$) is computable to within an additive error of $O(k\varepsilon \log(1/(k\varepsilon))) + E$ (resp. $O(\ell\varepsilon \log(1/(\ell\varepsilon))) + E$) in time $O(kT(E)/\varepsilon)$ (resp. $O(\ell T(E)/\varepsilon)$), where $T(E)$ is the time required to numerically compute the mutual information of a continuous distribution to within an additive error of E .*

Proof Without loss of generality we prove the claim only for $M_{k,\uparrow}$. Given $0 < \varepsilon < 1$, we would like a partition into rows P of size at most k such that $I(X, Y|P)$ is maximized. We would like to use OPTIMIZEXAXIS for this purpose, but while our search problem is continuous, OPTIMIZEXAXIS can only perform a discrete search over sub-partitions of some master partition Π . We therefore set Π to be an equipartition into $1/\varepsilon$ rows and show that this gets us close enough to achieve the desired result.

With Π as described, the OPTIMIZEXAXIS provides in time $O(kT(E)/\varepsilon)$ a partition P_0 into at most k rows such that $I(X, Y|P_0)$ is maximized, subject to $P_0 \subset \Pi$, to within an additive error of E . To prove the claim then, we must show that the loss we incur by restricting to sub-partitions of Π costs us at most $O(k\varepsilon \log(1/(k\varepsilon)))$. In other words, we must show that

$$I(X, Y|P) - I(X, Y|P_0) \leq O(k\varepsilon)$$

where P is an optimal partition into rows. Note that we have omitted the absolute value above, since by the optimality of P , $I(X, Y|P) \geq I(X, Y|P_0)$ always.

We prove the desired bound by showing that there exists some $P' \subset \Pi$ such that the mutual information of $(X, Y|P')$ is $O(k\varepsilon \log(1/(k\varepsilon)))$ -close to that achieved with $(X, Y|P)$. Since $P' \subset \Pi$ gives us that $I(X, Y|P_0) \geq I(X, Y|P')$, we may then conclude that $I(X, Y|P) - I(X, Y|P_0)$ is at most $O(k\varepsilon \log(1/(k\varepsilon)))$.

We construct P' by simply replacing every horizontal line in P with a horizontal line in Π closest to it. Since there are at most $k - 1$ horizontal lines in P , and each such line is contained in a row of Π containing $1/\varepsilon$ probability mass, performing this operation moves at most $(k - 1)\varepsilon$ probability mass. In other words, the statistical distance between $(X, Y|P)$ and $(X, Y|P')$ is at most $(k - 1)\varepsilon \leq k\varepsilon$. Thus, for sufficiently small ε , Proposition 40, proven in Appendix B, can be used to show that

$$|I(X, Y|P) - I(X, Y|P')| \leq O\left(k\varepsilon \log\left(\frac{1}{k\varepsilon}\right) + k\varepsilon \log\left(\frac{1}{\varepsilon}\right)\right)$$

which yields the desired result. \blacksquare

Remark 41 *We do not explore here the details of the numerical integration associated with the above theorem, since the error introduced by the numerical integration is independent of the algorithm being proposed. However, standard numerical integration methods can be used to make this error arbitrarily small with an understood complexity tradeoff (see, e.g., Stoer and Bittenschi 1980).*

Appendix F. Proof of Theorem 21

Theorem *Let (X, Y) be jointly distributed random variables. Then $\partial[M] = \partial M$.*

Proof Without loss of generality, we show that $[M]_{k,\uparrow} = M_{k,\uparrow}$. Fix any partition into rows P . If Q_ℓ is an equipartition into ℓ columns then

$$\lim_{\ell \rightarrow \infty} I(X|_{Q_\ell}, Y|P) = I(X, Y|P),$$

because the continuous mutual information equals the limit of the discrete mutual information with increasingly fine partitions. (See, e.g., Chapter 8 of Cover and Thomas 2006 for a proof of this.) This means that, letting $P(k)$ denote the set of all partitions of size at most k , we have

$$[M]_{k,\uparrow} = \max_{P \in P(k)} \frac{I(X, Y|P)}{\log k} = M_{k,\uparrow}$$

where the second equality follows from Proposition 16. \blacksquare

Appendix G. Consistency of MIC_ε in Estimating MIC_{*}

The consistency of MIC_ε for estimating MIC_{*} can be established using the same technical lemmas that we used to show that MIC_ε \rightarrow MIC_{*}. Specifically, we can use Lemma 37, which bounds the difference, for all k -by- ℓ grids G , between the sample quantity $I(D_n|G)$ and the population quantity $I((X, Y)|G)$ with high probability, where D_n is a sample of size n from (X, Y) . That lemma yields the following fact about the sample equicharacteristic matrix, whose proof is similar to that of Lemma 38.

Lemma 42 *Let D_n be a sample of size n from the distribution of a pair (X, Y) of jointly distributed random variables. For every $B(n) = O(n^{1-\varepsilon})$, there exists an $a > 0$ such that for sufficiently large n ,*

$$\left| \widehat{[M]}(D_n)_{k,\ell} - [M](X, Y)_{k,\ell} \right| \leq O\left(\frac{1}{n^a}\right)$$

holds for all $k\ell \leq B(n)$ with probability $P(n) = 1 - o(1)$, where $\widehat{[M]}(D_n)_{k,\ell}$ is the k, ℓ -th entry of the sample equicharacteristic matrix and $[M](X, Y)_{k,\ell}$ is the k, ℓ -th entry of the population equicharacteristic matrix of (X, Y) .

In the case of MIC, we proceeded to apply abstract continuity considerations to obtain our consistency theorem (Theorem 6) from a result analogous to the above lemma. A similar argument shows us that, in the case of the equicharacteristic matrix as well, we can estimate a large class of functions of the matrix in the same way. This is stated formally in the theorem below. As before, we let m^∞ be the space of infinite matrices equipped with the supremum norm, and given a matrix A the projection r_i zeros out all the entries $A_{k,\ell}$ for which $k\ell > i$.

Theorem *Let $f : m^\infty \rightarrow \mathbb{R}$ be uniformly continuous, and assume that $f \circ r_i \rightarrow f$ pointwise. Then for every random variable (X, Y) , we have*

$$(f \circ r_{B(n)}) \left(\widehat{M}(D_n) \right) \rightarrow f(M(X, Y))$$

in probability where D_n is a sample of size n from the distribution of (X, Y) , provided $\omega(1) < B(n) \leq O(n^{1-\varepsilon})$ for some $\varepsilon > 0$.

Appendix H. The EQUICHARCLUMP Algorithm

In Theorem 28, we sketched an algorithm called EQUICHARCLUMP for approximating the sample equicharacteristic matrix that is more efficient than the naive computation. In this appendix, we describe the algorithm in detail, bound its runtime, and show that it indeed yields a consistent estimator of MIC_* from finite samples as well as a consistent independence test when used to compute the total information coefficient. We then present some empirical results characterizing the sensitivity of the algorithm to its speed-versus-optimality parameter c .

The results in this section can be summarized as follows: let (X, Y) be a pair of jointly distributed random variables, and let D_n be a sample of size n from the distribution of (X, Y) . For every $c \geq 1$, there exists a matrix $\{\widehat{M}\}^c(D_n)$ such that

1. There exists an algorithm EQUICHARCLUMP for computing $r_B(\{\widehat{M}\}^c(D_n))$ in time $O(n + B^{5/2})$, which equals $O(n + n^{5(1-\varepsilon)/2})$ when $B(n) = O(n^{1-\varepsilon})$.

2. The function

$$\widehat{\text{MIC}}_{e,B}(\cdot) = \max_{k\ell \leq B(n)} \{\widehat{M}\}^c(\cdot)_{k,\ell}$$

is a consistent estimator of MIC_* provided $\omega(1) < B(n) \leq O(n^{1-\varepsilon})$ for some $\varepsilon > 0$.

3. The function

$$\widehat{\text{TIC}}_{e,B}(\cdot) = \sum_{k\ell \leq B(n)} \{\widehat{M}\}^c(\cdot)_{k,\ell}$$

yields a consistent right-tailed test of independence provided $\omega(1) < B(n) \leq O(n^{1-\varepsilon})$ for some $\varepsilon > 0$

We will prove these results in order.

H.1 Algorithm Description and Analysis of Runtime

We begin by describing the algorithm and bounding its runtime simultaneously. As in the proof of Theorem 27, we bound the runtime required to approximately compute only the k, ℓ -th entries of $\{\widehat{M}\}^c(D_n)$ satisfying $k \leq \ell, k\ell \leq B$. To do this, we analyze two portions of $\{\widehat{M}\}^c(D_n)$ separately: we first consider the case $\ell \geq \sqrt{B}$, in which we must compute the entries corresponding to all the pairs $\{(2, \ell), \dots, (B/\ell, \ell)\}$. We then consider $\ell < \sqrt{B}$, in which case we need only compute the entries $\{(2, \ell), \dots, (\ell, \ell)\}$ since the additional pairs would all have $k > \ell$.

For the case of $\ell \geq \sqrt{B}$, as in the previous theorem we can simultaneously compute using OPTIMIZEXAXIS the entries corresponding to all the pairs $\{(2, \ell), \dots, (B/\ell, \ell)\}$ in time $O(|\Pi|^2 B/\ell) = O(|\Pi|^2 B)$, which equals $O(c^2 B^3/\ell^2)$ when we set Π to be an equipartition of size cB/ℓ . Doing this for $\ell = \sqrt{B}, \dots, B/2$ gives a contribution of the following order to the runtime.

$$\begin{aligned} O(c^2 B^3) \sum_{\ell=\sqrt{B}}^{B/2} \frac{1}{\ell^2} &= O(c^2 B^3) O\left(\frac{1}{\sqrt{B}}\right) \\ &= O(c^2 B^{5/2}) \end{aligned}$$

For the case of $\ell < \sqrt{B}$, we can simultaneously compute using OPTIMIZEXAXIS the entries corresponding to all the pairs $\{(2, \ell), \dots, (\ell, \ell)\}$ in time $O(|\Pi|^2 \ell^2)$ which equals $O(c^2 \ell^4) \leq O(c^2 B^2)$ when we set Π to be an equipartition of size $c\ell$. Summing over the $O(\sqrt{B})$ possible values of ℓ with $\ell < \sqrt{B}$ gives an upper bound of $O(c^2 B^{5/2})$.

H.2 Consistency

Let (X, Y) be a pair of jointly distributed random variables. For a sample D_n of size n from the distribution of (X, Y) and a speed-versus-optimality parameter $c \geq 1$, let $\{\widehat{M}\}^c(D_n)$ denote the matrix computed by EQUICHARCLUMP. (Notice the use of curly braces to differentiate this from the sample equicharacteristic matrix $[M]$.) We show here that $\max_{k\ell \leq B(n)} \{\widehat{M}\}^c(D_n)_{k,\ell}$ is a consistent estimator of $\text{MIC}_*(X, Y)$, and correspondingly that $\sum_{k\ell \leq B(n)} \{\widehat{M}\}^c(D_n)_{k,\ell}$ yields a consistent independence test.

The key to both consistency results is that, though in calculating the k, ℓ -th entry of $\{\widehat{M}\}^c(D_n)$ the algorithm only searches for optimal partitions that are sub-partitions of some equipartition, the size of the equipartition used always grows as n, k , and ℓ grow large. Therefore, in the limit this additional restriction does not hinder the optimization. We present this argument by introducing a population object called the *clumped equicharacteristic matrix*. We observe that this matrix is the limit of the EQUICHARCLUMP procedure as sample size grows, and then show that the supremum and partial sums of this matrix have the necessary properties.

Definition 43 *Let (X, Y) be jointly distributed random variables and fix some $c \geq 1$. Let*

$$I^{(c*)}((X, Y), k, \ell) = \max_G I((X, Y)|_G)$$

where the maximum is over k -by- ℓ grids whose larger partition is an equipartition and whose smaller partition must be contained in an equipartition of size $c \cdot \max\{k, \ell\}$. The clumped equicharacteristic matrix of (X, Y) , denoted by $\{M\}^c(X, Y)$, is defined by

$$\{M\}^c(X, Y)_{k, \ell} = \frac{I^{c(\ast)}((X, Y), k, \ell)}{\log \min\{k, \ell\}}$$

Notice that curly braces differentiate the quantities $I^{c(\ast)}$ and $\{M\}^c$ defined above from the corresponding equicharacteristic matrix quantities $I^{(\ast)}$ and $[M]$.

The following two results, which we state without proof, characterize the convergence of the output of EQUICHARCLUMP to the clumped equicharacteristic matrix. These lemmas can be shown using Lemma 37, which simultaneously bounds the difference, for all k -by- ℓ grids G , between the sample quantity $I(D_n|G)$ and the population quantity $I((X, Y)|G)$ with high probability over the sample D_n of size n from (X, Y) .

Lemma 44 *Let D_n be a sample of size n from the distribution of a pair (X, Y) of jointly distributed random variables. For every $B(n) = O(n^{1-\varepsilon})$, there exists an $a > 0$ such that for sufficiently large n ,*

$$\left| \widehat{[M]}^c(D_n)_{k, \ell} - \{M\}^c(X, Y)_{k, \ell} \right| \leq O\left(\frac{1}{n^a}\right)$$

holds for all $k, \ell \leq \sqrt{B(n)}$ with probability $P(n) = 1 - o(1)$, where $\widehat{[M]}^c(D_n)$ denotes the matrix computed by the EQUICHARCLUMP algorithm with parameter c on the sample D_n .

Notice that the error bound provided by the above lemma holds not for $k\ell \leq B(n)$ as in the analogous Lemma 38 and Lemma 42, but rather for the smaller region defined by $k, \ell \leq \sqrt{B(n)}$. However, though we do not have uniform convergence outside the region $k, \ell \leq \sqrt{B(n)}$, we do nevertheless have pointwise convergence there, as stated below.

Lemma 45 *Fix $k, \ell \geq 2$. Let D_n be a sample of size n from the distribution of a pair (X, Y) of jointly distributed random variables. For every $B(n) > \omega(1)$, we have that*

$$\widehat{[M]}^c(D_n)_{k, \ell} \rightarrow \{M\}^c(X, Y)_{k, \ell}$$

in probability as n grows, where $\widehat{[M]}^c(D_n)$ denotes the matrix computed by the EQUICHARCLUMP algorithm with parameter c on the sample D_n .

H.2.1 CONSISTENCY FOR ESTIMATING MIC_*

The consistency of $\widehat{[M]}^c(D_n)$ for estimating MIC_* follows from the following property of the clumped equicharacteristic matrix $\{M\}^c$, for which we state a proof sketch.

Proposition 46 *Let (X, Y) be a pair of jointly distributed random variables. Then we have $\sup\{[M]^c(X, Y) = \text{MIC}_*(X, Y)$.*

Proof (Sketch) Let $\{M\}^c = \{M\}^c(X, Y)$, and let $M = M(X, Y)$ be the characteristic matrix. Fix k , and consider the limit $\{M\}_{k, \ell}^c$ as ℓ grows. The grid chosen for the k, ℓ -th entry when $\ell > k$ will contain an equipartition P_ℓ of size ℓ on the x -axis, and a partition Q_ℓ of size k on the y -axis that is optimal subject to the restriction that Q_ℓ be contained in an equipartition of size $c\ell$. As ℓ grows large, the equipartition P_ℓ on the first axis will become finer and finer until in the limit $X|_{P_\ell} \rightarrow X$. And the partition Q_ℓ will be chosen from a finer and finer equipartition, so that in the limit it approaches an unconditionally optimal partition Q of size k . The convergence of Q_ℓ to the optimal partition Q of size k can be shown to be uniform using Proposition 40. This implies that

$$\{M\}_{k, \uparrow}^c = \lim_{\ell \rightarrow \infty} \{M\}_{k, \ell}^c = \max_{P \in \mathcal{P}(k)} \frac{I(X, Y|P)}{\log k}$$

where $\mathcal{P}(k)$ denotes the set of all partitions of size at most k . Therefore, the boundary $\partial\{M\}^c$ of $\{M\}^c$ equals the boundary ∂M of M . Since $\text{MIC}_*(X, Y) = \sup \partial M$ (Theorem 15), this implies that

$$\sup\{M\}^c \geq \sup \partial\{M\}^c = \sup \partial M = \text{MIC}_*(X, Y).$$

On the other hand, $\{M\}^c \leq M$ element-wise since the optimization for the k, ℓ -th entry of $\{M\}^c$ is performed over a subset of the grids searched for the k, ℓ -th entry of M . This means that $\sup\{M\}^c \leq \sup M = \text{MIC}_*(X, Y)$. ■

This fact, together with the pointwise convergence of $\widehat{[M]}^c(D_n)$ to $\{M\}^c$, suffices to establish the consistency we seek via standard continuity arguments, which we give in the abstract lemma below. The lemma applies to a double-indexed sequence indexed by i and j : in our argument, the index i corresponds to position in the equicharacteristic matrix, and the index j corresponds to sample size. The sequence A corresponds to the output of the EQUICHARCLUMP algorithm, the sequence a corresponds to the clumped equicharacteristic matrix, and the sequence B corresponds to the sample equicharacteristic matrix.

Lemma 47 *Let $\{A_{ij}\}_{i,j=1}^\infty$ and $\{B_{ij}\}_{i,j=1}^\infty$ be sequences of random variables, and let $\{a_j\}_{j=1}^\infty$ be a non-stochastic sequence. Assume that the following conditions hold*

1. $A_{ij} \leq B_{ij}$ almost surely
2. For every i , $A_{ij} \rightarrow a_i$ in probability
3. $B_j^i = \max_{s \leq j} B_{is}$ satisfies $B_j^i \rightarrow \sup\{a_i\}$ in probability

Then $A_j^i = \max_{s \leq j} A_{is}$ converges in probability to $\sup\{a_i\}$ as well.

Proof Let $a = \sup\{a_j\}$. We give the proof for the case that $a < \infty$. However, it is easily adapted to the infinite case. We must show that for every $\varepsilon > 0$ and every $0 < p \leq 1$, there exists some N such that $\mathbf{P}(|A_j^i - a| < \varepsilon) > p$ for all $j \geq N$. By the definition of a , we know that there exists some k such that $|a_k - a| < \varepsilon/2$. Also, by the convergence of A_{ij} to a_i , there exists some m such that $\mathbf{P}(|A_{kj} - a_k| < \varepsilon/2) > 1 - p$ for all $j \geq m$. Thus, with probability at least $1 - p$, we have

$$\begin{aligned} |A_{kj} - a| &\leq |A_{kj} - a_k| + |a_k - a| \\ &\leq \varepsilon \end{aligned}$$

for all $j \geq m$.

Next, we observe that since $A'_j \geq A_{k_j}$ for $j \geq k$, the above inequality implies that for $j \geq \max\{m, k\}$ we have $\mathbf{P}(A'_j > a - \varepsilon) > 1 - p$. It remains only to show that A'_j doesn't get too large, but this follows from the fact that $A'_j \leq B'_j$ and $B'_j \rightarrow a$ in probability. Specifically, we are guaranteed some $N \geq \max\{m, k\}$ such that $\mathbf{P}(B'_j < a + \varepsilon) > 1 - p$ for $j \geq N$. Since $B'_j < a + \varepsilon$ implies $A'_j < a + \varepsilon$, we have that $\mathbf{P}(|A'_j - a| < \varepsilon) > 1 - p$ for $j \geq N$, as desired. ■

Proposition 48 *The function*

$$\widetilde{\text{MIC}}_{e,B}(\cdot) = \max_{k\ell \leq B(n)} \{\widehat{M}\}^c(\cdot)_{k,\ell}$$

is a consistent estimator of MIC_* provided $\omega(1) < B(n) \leq O(n^{1-\varepsilon})$ for some $\varepsilon > 0$, where $\{\widehat{M}\}^c(\cdot)$ is the output of the `EQUICHARCLUMP` algorithm.

Proof Let (X, Y) be a pair of jointly distributed random variables, and let D_n be a sample of size n from the distribution of (X, Y) . Let $\{(k_i, \ell_i)\}_{i=1}^\infty \subset \mathbb{Z}^+ \times \mathbb{Z}^+$ be a sequence of coordinates with the property that for every number B there exists an index $q(B)$ such that $\{(k_i, \ell_i) : i \leq q(B)\} = \{(k, \ell) : k\ell \leq B\}$.

We define $B_{ij} = [\widehat{M}(D_j)_{k_i, \ell_i}]$, i.e., B_{ij} is the k_i, ℓ_i -th entry of the sample characteristic matrix evaluated on a sample of size j . We analogously define $A_{ij} = \{\widehat{M}\}^c(D_j)_{k_i, \ell_i}$, and we define $a_i = \{M\}^c(X, Y)_{k_i, \ell_i}$. We observe that by Proposition 46, $\sup a_i = \sup\{M\}^c(X, Y) = \text{MIC}_*$.

It is straightforward to see that $A_{ij} \leq B_{ij}$. Additionally, Lemma 45 shows that $A_{ij} \rightarrow a_i$ in probability, and Corollary 26, which states that MIC_e is a consistent estimator of MIC_* , shows that $B'_j = \max_{i \leq j} B_{ij} \rightarrow \text{MIC}_*(X, Y)$. In the notation of the lemma, it therefore follows that $A'_j = \max_{i \leq j} A_{ij}$ converges in probability to $\text{MIC}_*(X, Y)$ as well. But this means that the sub-sequence

$$A'_{q(B(n))} = \max_{i \leq q(B(n))} \{\widehat{M}\}^c(D_{q(B(n))})_{k_i, \ell_i} = \max_{k\ell \leq B(n)} \{\widehat{M}\}^c(D_{q(B(n))})_{k,\ell}$$

converges in probability to $\text{MIC}_*(X, Y)$, which implies the result since the sequence A'_j is monotone. ■

H.2.2. CONSISTENCY FOR TOTAL INFORMATION COEFFICIENT

Similarly to the consistency argument for MIC_* , we begin by exhibiting the relevant property of the population clumped equicharacteristic matrix.

Proposition 49 *Let (X, Y) be a pair of jointly distributed random variables. If X and Y are statistically independent, then $\{M\}^c(X, Y) \equiv 0$. If not, then there exists some $a > 0$ and some integer $\ell_0 \geq 2$ such that*

$$\{M\}^c(X, Y)_{k,\ell} \geq \frac{a}{\log \min\{k, \ell\}}$$

either for all $k \geq \ell \geq \ell_0$, or for all $\ell \geq k \geq \ell_0$.

Proof (Sketch) Let $\{M\}^c = \{\widehat{M}\}^c(X, Y)$. Under independence, every entry of $\{M\}^c$ is zero since $I((X, Y)|_G) = 0$ for any grid G . For the case of dependence, the argument is identical to that given in the proof of Proposition 32. Specifically, it can be shown that there exists some index ℓ_0 , taken without loss of generality to be a column index, and some $r > 0$ such that all but finitely many of the entries in the ℓ_0 -column are at least r . It can then be shown that for large k , the entries $(k, \ell_0), (k, \ell_0 + 1), \dots, (k, k)$ have non-decreasing values of $I^{(a)}$. This establishes the claim for $a = r \log \ell_0$. ■

We now show that the above result, together with the uniform convergence of $\{\widehat{M}\}^c(D_n)$ to $\{M\}^c(X, Y)$, implies the consistency we seek.

Proposition 50 *The function*

$$\widetilde{\text{TIC}}_{e,B}(\cdot) = \sum_{k\ell \leq B(n)} \{\widehat{M}\}^c(\cdot)_{k,\ell}$$

yields a consistent right-tailed test of independence provided $\omega(1) < B(n) \leq O(n^{1-\varepsilon})$ for some $\varepsilon > 0$, where $\{\widehat{M}\}^c(\cdot)$ is the output of the `EQUICHARCLUMP` algorithm.

Proof Let (X, Y) a pair of jointly distributed random variables, and let D_n be a sample of size n from the distribution of (X, Y) . It suffices to show consistency for any deterministic monotonic function of the statistic in question. We therefore choose to analyze $\widetilde{\text{TIC}}_{e,B}(D_n) \log(B(n))/B(n)$.

For the null hypothesis in which X and Y are independent, we observe that since $\{\widehat{M}\}^c(D_n) \leq [\widehat{M}(D_n)]$ element-wise, $0 \leq \widetilde{\text{TIC}}_{e,B}(D_n) \leq \text{TIC}_{e,B}(D_n)$ as well. Moreover, the argument given in Appendix K, which shows that $\text{TIC}_{e,B}(D_n)/B(n)$ converges to 0 in probability under the null hypothesis, can be adapted to show that $\widetilde{\text{TIC}}_{e,B}(D_n) \log(B(n))/B(n) \rightarrow 0$ as well. Thus, $\widetilde{\text{TIC}}_{e,B}(D_n) \log(B(n))/B(n)$ converges to zero in probability, as required.

For the case that X and Y are dependent, the proof is analogous to the argument given in Appendix K for TIC_e . The only difference is that Lemma 44, which guarantees the uniform convergence of $\{\widehat{M}\}^c(D_n)$ to $\{M\}^c(X, Y)$, applies only to the k, ℓ -th entries for which $k, \ell \leq \sqrt{B(n)}$, rather than the entries over which we are summing, which are those for which $k\ell \leq B(n)$. However, since we require only a lower bound on $\widetilde{\text{TIC}}_{e,B}(D_n)$, we may neglect these entries because

$$\widetilde{\text{TIC}}_{e,B}(D_n) = \sum_{k\ell \leq B(n)} \{\widehat{M}\}^c(D_n)_{k,\ell} \geq \sum_{k,\ell \leq \sqrt{B(n)}} \{\widehat{M}\}^c(D_n)_{k,\ell}.$$

It can then be shown, following the argument from Appendix K, that there exists some $a > 0$ depending only on B such that, with probability $1 - o(1)$,

$$\frac{\log B(n)}{B(n)} \left(\sum_{k,\ell \leq \sqrt{B(n)}} \{\widehat{M}\}^c(X, Y)_{k,\ell} - \widetilde{\text{TIC}}_{e,B}(D_n) \right) \leq O\left(\frac{\#_n \log B(n)}{B(n)n^a}\right) = O\left(\frac{\log B(n)}{n^a}\right)$$

where $\#_n = B(n)$ represents the number of pairs (k, ℓ) such that $k, \ell \leq \sqrt{B(n)}$. To obtain the result, we note that this means that

$$\frac{\log B(n)}{B(n)} \widehat{\text{TTC}}_{\epsilon, B}(D_n) \geq \frac{\log B(n)}{B(n)} \sum_{k, \ell \leq \sqrt{B(n)}} \{\widehat{M}^{\epsilon}(X, Y)_{k, \ell} - O\left(\frac{\log B(n)}{n^{\alpha}}\right)\}$$

and then invoke Proposition 49, which implies that for large n

$$\sum_{k, \ell \leq \sqrt{B(n)}} \{M\}^{\epsilon}(X, Y) \geq \Omega\left(\frac{B(n)}{\log B(n)}\right).$$

■

H.3 Empirical Characterization of the Performance of EQUICHARCLUMP

The EQUICHARCLUMP algorithm has a parameter c that controls the fineness of the equipartition whose sub-partitions are searched over by the algorithm. To gain an empirical understanding of the effect of c on performance, we computed MIC_{ϵ} on the set of relationships described in Section 4.4 using EQUICHARCLUMP with different values of c . For each relationship, we compared the average MIC_{ϵ} across all 500 independent samples from that relationship with different values of c . We performed this analysis at sample sizes of $n = 250$ (Figure H1), $n = 500$ (Figure H2), and 5,000 (Figure H3).

We summarize our findings as follows.

- At low ($n = 250$) and medium ($n = 500$) sample sizes, using $c = 1$ introduces a downward bias for more complex relationships when $B(n) = n^{0.6}$ is used but not when $B(n) = n^{0.8}$ is used. This makes sense since the low sample size and low setting of $B(n)$ mean that the algorithm is searching over grids with relatively few cells, and so setting $c = 1$ hinders its ability to find good grids in this limited search space. This bias is almost entirely alleviated by setting $c \geq 2$.
- At high sample size ($n = 5,000$), this effect is still observable but much reduced. This makes sense since when n is large, $B(n)$ is large as well, and so the number of cells allowed in the grids being searched over is already large regardless of the exponent α used in $B(n) = n^{\alpha}$. Thus, there is less need for the robustness provided by searching for an optimal grid.

Appendix I. Equitability and Power Analyses from Reshef et al. (2015a)

Figure I1 contains a representative equitability analysis from Reshef et al. (2015a). Figure I2 contains power curves from Reshef et al. (2015a) for a large set of leading methods.

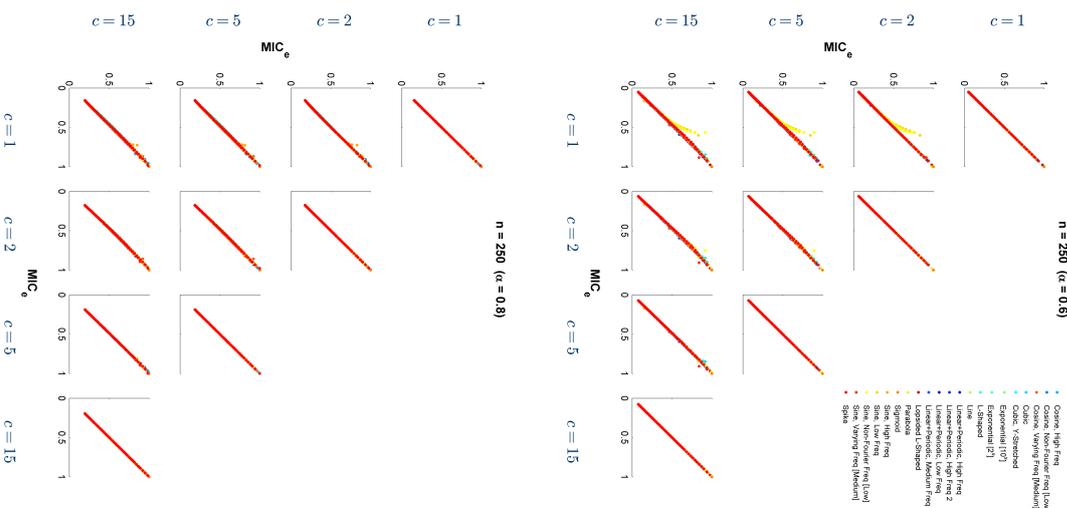

Figure H1: The effect of the parameter c on the performance of EQUICHARCLUMP, at $n = 250$. See Section H.3 for details.

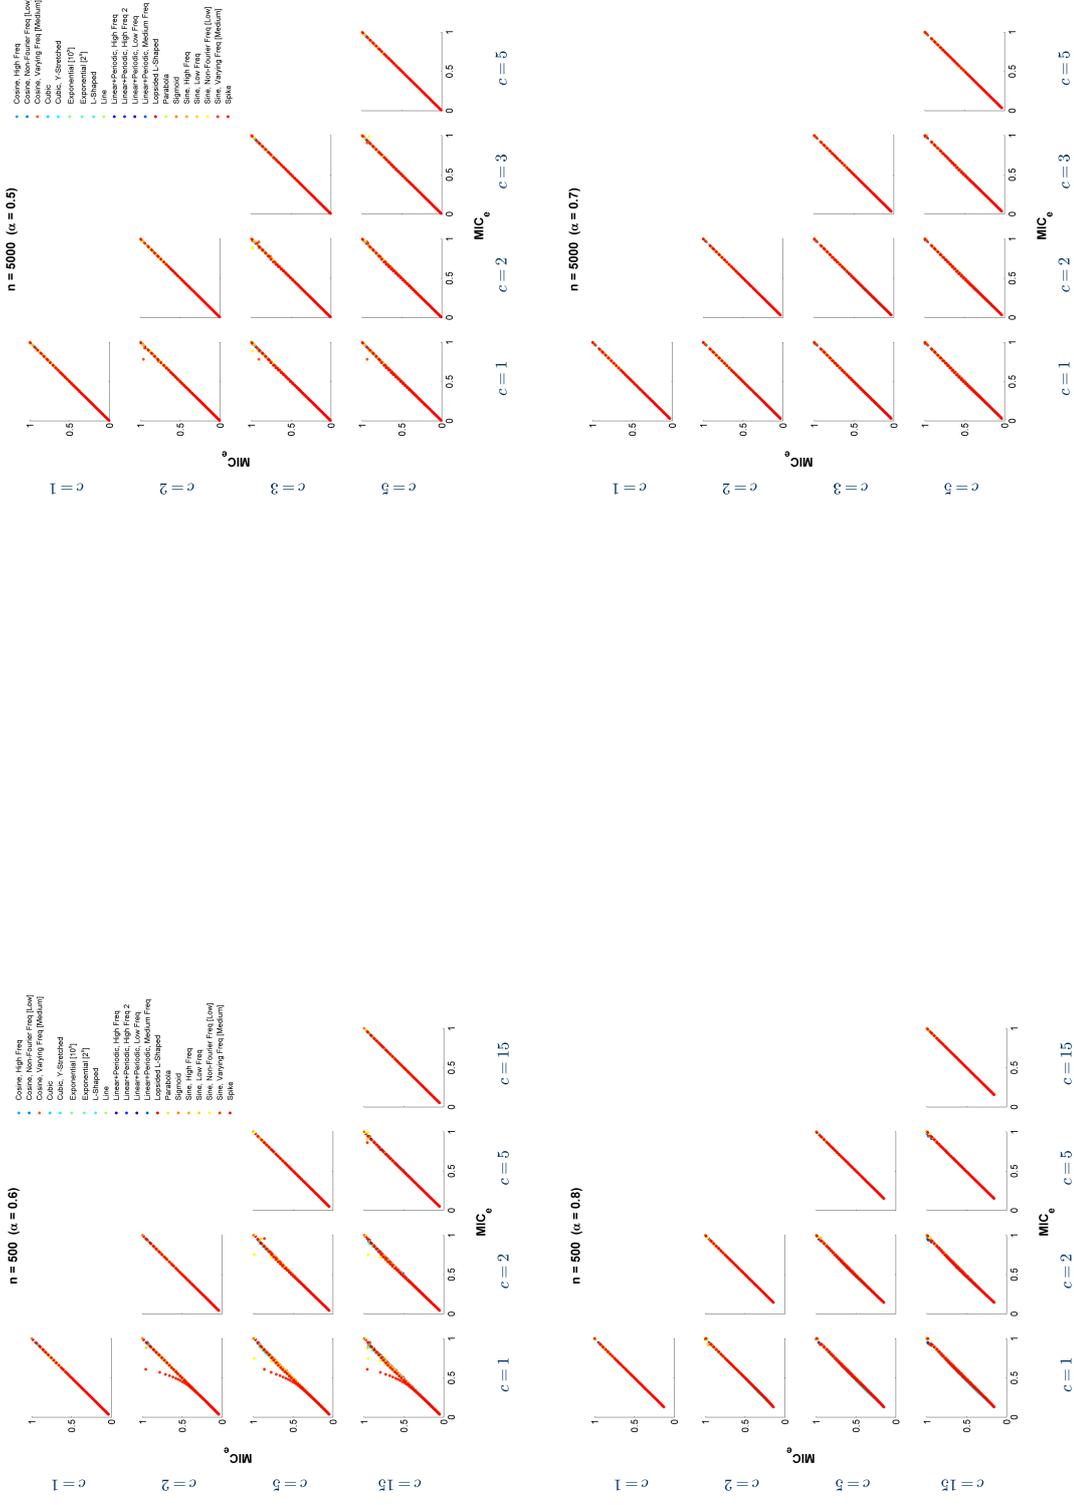

Figure H2: The effect of the parameter c on the performance of EQUICHARCLUMP, at $n = 500$. See Section H.3 for details.

Figure H3: The effect of the parameter c on the performance of EQUICHARCLUMP, at $n = 5,000$. See Section H.3 for details.

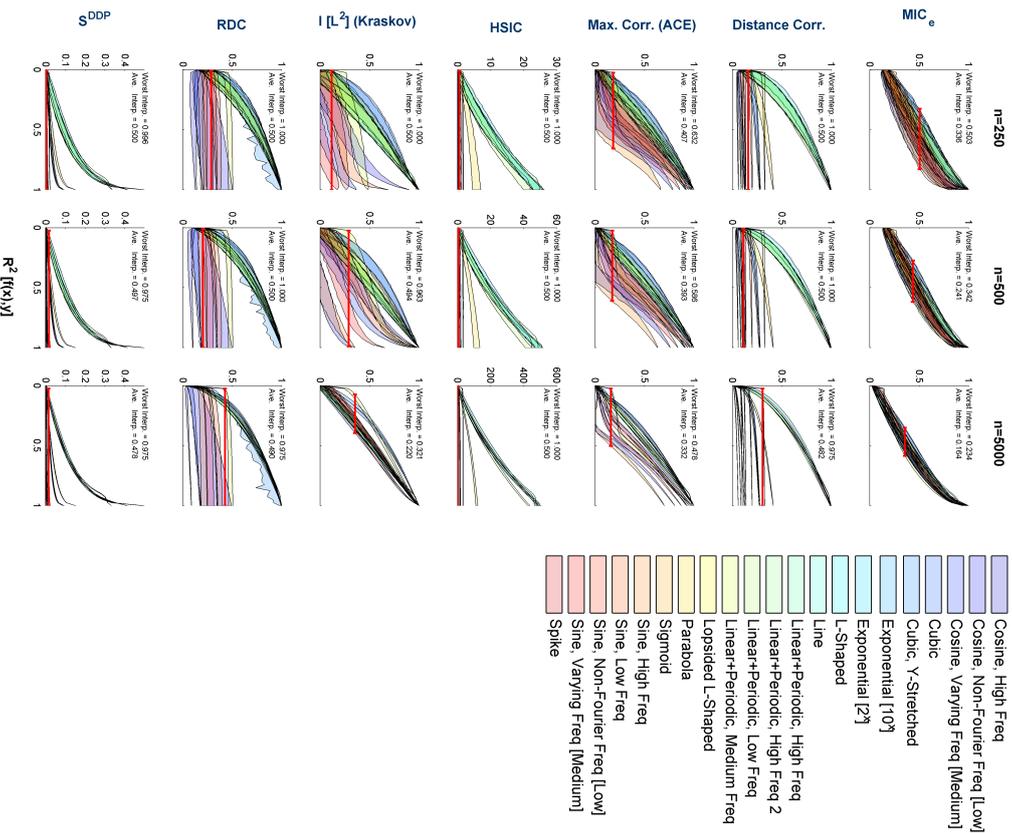

Figure 11: (Reproduced from Reshef et al., 2015a.) The equitability of measures of dependence on a set of noisy functional relationships, reproduced from Reshef et al. (2015a). *Narrower is more equitable.* The plots were constructed as in Figure 3. Mutual information, estimated using the Kraskov estimator, is represented using the squared Linf-foot correlation.

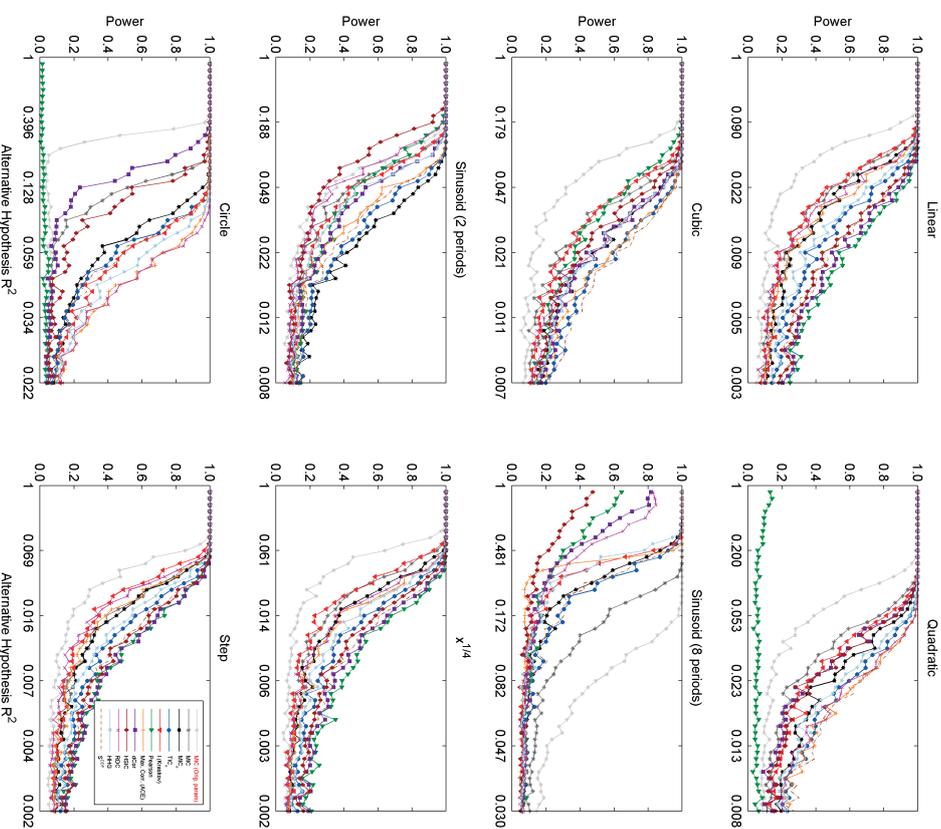

Figure 12: (Reproduced from Reshef et al., 2015a.) Power of independence testing using several leading measures of dependence, on the relationships chosen by Simon and Tibshirani (2012), at 50 noise levels with linearly increasing magnitude for each relationship and $n = 500$. To enable comparison of power regimes across relationships, the x-axis of each plot lists R^2 rather than noise magnitude.

Appendix J. Equitability Analysis of Randomly Chosen Functions with Additional Noise Model

Figure J1 contains a version of the main text Figure 4, but where noise has been added only to the dependent variable in each functional relationship, rather than to both the independent and dependent variables.

Appendix K. Consistency of Independence Testing Based on TIC_e

Here we prove Propositions 32 and 33 and then use those propositions to prove Theorem 34, which shows that TIC_e can be used for independence testing.

K.1 Proof of Proposition 32

Proposition *Let (X, Y) be a pair of jointly distributed random variables. If X and Y are statistically independent, then $M(X, Y) \equiv [M](X, Y) \equiv 0$. If not, then there exists some $a > 0$ and some integer $\ell_0 \geq 2$ such that*

$$M(X, Y)_{k,\ell}, [M](X, Y)_{k,\ell} \geq \frac{a}{\log \min\{k, \ell\}}$$

either for all $k \geq \ell \geq \ell_0$, or for all $\ell \geq k \geq \ell_0$.

Proof We give the proof only for $[M] = [M](X, Y)$, with the understanding that all parts of the argument are either identical or similar for $M(X, Y)$. When X and Y are independent, then for any grid $G, (X, Y)|_G$ exhibits independence as well. Therefore $I((X, Y)|_G) = 0$ for all grids G , and so every entry of $[M]$, being a supremum over such quantities, is 0.

For the case that X and Y are dependent, our strategy is to first find, without loss of generality, a column of $[M]$ almost all of whose values are bounded away from zero, and then argue that this suffices.

The dependence of X and Y implies that $\text{MIC}_*(X, Y) > 0$. By Corollary 22, which states that $\sup \partial[M] = \text{MIC}_*(X, Y)$, we therefore know that there is at least one non-zero element of the boundary of $[M]$, as defined in Definition 14. Without loss of generality, suppose that this element is $[M]_{r,\ell_0} = \lim_{k \rightarrow \infty} [M]_{k,\ell_0}$. The fact that this limit is strictly positive implies that there exists some $k_0 \geq \ell_0$ and some $r > 0$ such that $[M]_{k,\ell_0} \geq r$ for all $k \geq k_0$. That is, all but finitely many of the entries in the ℓ_0 -th column of $[M]$ are at least r .

We now show that the existence of such a column suffices to prove the claim. Fix some $k > k_0$ and note that this implies that $k > \ell_0$. We argue that for all ℓ in $\{\ell_0, \dots, k\}$, the desired condition holds. Since $k > \ell_0$, the term $I^{[\bullet]}((X, Y), k, \ell_0)$ in the definition of $[M]_{k,\ell_0}$ is a maximization over grids that have an equipartition of size k on one axis and an optimal partition of size ℓ_0 on the other. Since we allow empty rows/columns in the maximization, substituting any ℓ satisfying $\ell_0 \leq \ell \leq k$ therefore does not constrain the maximization in any way and so it cannot decrease $I^{[\bullet]}$. In other words, for ℓ satisfying $\ell_0 \leq \ell \leq k$, we have

$$I^{[\bullet]}((X, Y), k, \ell) \geq I^{[\bullet]}((X, Y), k, \ell_0).$$

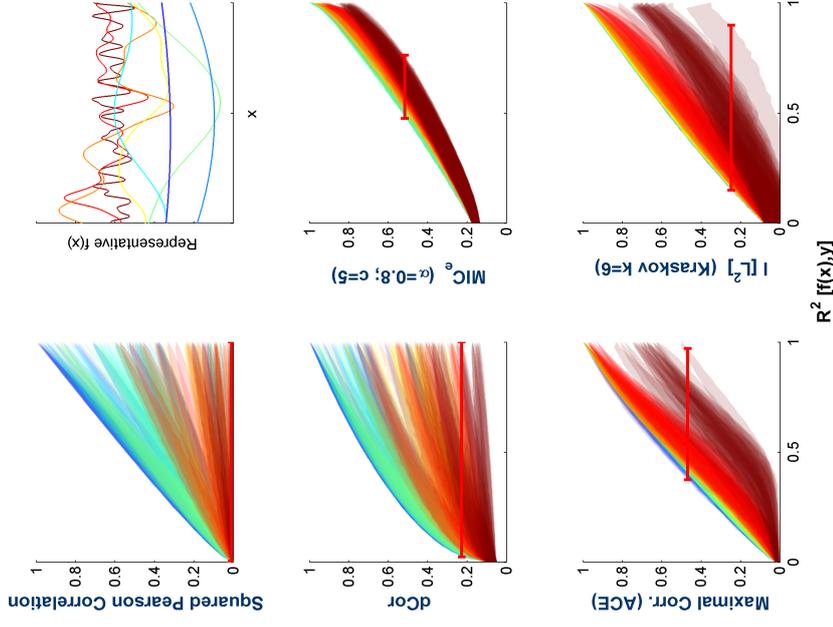

Figure J1: Equitability of methods examined on functions randomly drawn from a Gaussian process distribution, using a different noise model. This figure is identical to Figure 4, but with noise added only to the dependent variable in each relationship. Each method is assessed as in Figure 4, with a red interval indicating the widest range of R^2 values corresponding to any one value of the statistic; the narrower the red interval, the higher the equitability. Sample relationships for each Gaussian process bandwidth are shown in the top right with matching colors.

Since $k \geq \ell$, ℓ_0 , the normalizations in the definition of $[M]_{k,\ell}$ and $[M]_{k,\ell_0}$ are $\log \ell$ and $\log \ell_0$ respectively. Therefore, we have that

$$[M]_{k,\ell} \geq [M]_{k,\ell_0} \frac{\log \ell_0}{\log \ell} \geq \frac{r \log \ell_0}{\log \ell}$$

where the last inequality is because $k > k_0$. Setting $a = r \log \ell_0$ then gives the result. \blacksquare

K.2 Proof of Proposition 33

Proposition *Let (X, Y) be a pair of jointly distributed random variables. If X and Y are statistically independent, then $S_B(M(X, Y)) = S_B([M](X, Y)) = 0$ for all $B > 0$. If not, then $S_B(M(X, Y))$ and $S_B([M](X, Y))$ are both $\Omega(B \log \log B)$.*

Proof We give the argument for $M = M(X, Y)$ only, but the argument holds as stated for $[M](X, Y)$ as well.

The result follows from the guarantee given by the Proposition 32 above. In the case of independence, the proposition tells us that $M \equiv 0$, which immediately gives that $S_B(M) = 0$ for all $B > 0$. For the case of dependence, the proposition implies that there is some $a > 0$ and some integer $\ell_0 \geq 2$ such that, without loss of generality, $M_{k,\ell} \geq a/\log \ell$ for all $k \geq \ell \geq \ell_0$. We convert this into a lower bound on $S_B(M)$.

The key is to write the sum one column at a time, counting how many entries in each column both satisfy $k \geq \ell \geq \ell_0$ and $k\ell \leq B$. For any ℓ satisfying $\ell_0 \leq \ell \leq \sqrt{B}$, the entries $(\ell, \ell), \dots, (B/\ell, \ell)$ meet this criterion, and there are $B/\ell_0 - (\ell_0 - 1)$ of them. Moreover, since the guarantee of Proposition 32 tells us that all of these entries are at least $a/\log \ell$, we can lower-bound $S_B(M)$ as follows.

$$\begin{aligned} S_B(A) &\geq \sum_{\ell=\ell_0}^{\sqrt{B}} \frac{a}{\log \ell} \left(\frac{B}{\ell} - (\ell - 1) \right) \\ &= aB \sum_{\ell=\ell_0}^{\sqrt{B}} \frac{1}{\ell \log \ell} - a \sum_{\ell=\ell_0}^{\sqrt{B}} \frac{\ell - 1}{\log \ell} \\ &= a \left(B \sum_{\ell=\ell_0}^{\sqrt{B}} \frac{1}{\ell \log \ell} - O(B) \right) \\ &= \Omega(B \log \log B) \end{aligned}$$

where the second-to-last equality is because $(\ell - 1)/\log \ell \leq \ell$, and the last equality is because $\sum_{\ell=\ell_0}^{\sqrt{B}} 1/(\ell \log \ell)$ grows like $\log \log n$. \blacksquare

K.3 Proof of Theorem 34

Theorem *The statistics TTC_B and $\text{TTC}_{\alpha,B}$ yield consistent right-tailed tests of independence, provided $\omega(1) < B(n) \leq O(n^{1-\varepsilon})$ for some $\varepsilon > 0$.*

Proof We give the proof for TTC only; however, the argument holds as stated for TTC_ε as well.

Let (X, Y) be jointly distributed random variables, and let D_n be a sample of size n from the distribution of (X, Y) . Let $M = M(X, Y)$ be the characteristic matrix of (X, Y) and let $\widehat{M}(D_n)$ be the sample characteristic matrix. It suffices to establish the result for a deterministic monotonic function of $\text{TTC}_B(D_n)$. We therefore show convergence of $\text{TTC}_B(D_n)/B(n)$ to zero under the null hypothesis of independence and to ∞ under any alternative. Our general strategy for doing so is to translate known bounds on our error at estimating entries of M into bounds on the difference between $\text{TTC}_B(D_n)/B(n) = S_{B(n)}(\widehat{M}(D_n))/B(n)$ and $S_B(M)/B(n)$. We then obtain the result by invoking Proposition 33, which implies that $S_B(M)/B(n)$ is zero under the null hypothesis but grows without bound under the alternative.

We know from Lemma 38 (Lemma 42 for the equicharacteristic matrix) that there exists some $a > 0$ depending only on B such that

$$\left| \widehat{M}(D_n)_{k,\ell} - M_{k,\ell} \right| \leq O\left(\frac{1}{n^a}\right)$$

for all $k\ell \leq B(n)$ with probability $1 - o(1)$. This means that with probability $1 - o(1)$ we have

$$\frac{1}{B(n)} \left| \text{TTC}_B(D_n) - S_{B(n)}(M) \right| \leq O\left(\frac{\#_n}{B(n)n^a}\right)$$

where $\#_n$ is the number of pairs (k, ℓ) such that $k\ell \leq B(n)$. It can be shown by taking the integral of B/x with respect to x that $\#_n = O(B(n) \log B(n))$. Therefore, the error in the above bound is at most $O(\log B(n)/n^a) = O(1/\text{poly}(n))$ for our choice of $B(n)$.

We now use Proposition 33 to show that this bound gives the desired result. Under the null hypothesis of independence, the proposition says that $S_{B(n)}(M) = 0$ always, and so since B is a growing function the bound implies that $\text{TTC}_B(D_n)/B(n) \rightarrow 0$ in probability. Under the alternative hypothesis in which (X, Y) exhibit a dependence, the proposition implies that $S_{B(n)}(M)/B(n) > \omega(1)$. Since B is a growing function of n , this means that for any $\tau > 0$, the probability that $S_{B(n)}(M)/B(n) > \tau$ goes to 1 as n grows. In other words, $\text{TTC}_B(D_n)/B(n) \rightarrow \infty$ in probability. \blacksquare

Appendix L. Information-Theoretic Lemmas

Lemma 51 *Let Π and Ψ be random variables distributed over a discrete set of states Γ , and let (π_i) and (ψ_i) be their respective distributions. Let $P = f(\Pi)$ and $Q = f(\Psi)$ for some function f whose image is of size B . Define*

$$\varepsilon_i = \frac{\psi_i - \pi_i}{\pi_i}.$$

Then for every $0 < a < 1$ there exists some $A > 0$ such that

$$|H(Q) - H(P)| \leq (\log B) A \sum_i |\varepsilon_i|$$

when $|\varepsilon_i| \leq 1 - a$ for all i .

Proof We prove the claim with entropy measured in nats. A rescaling then gives the general result.

Let (p_i) and (q_i) be the distributions of P and Q respectively, and define

$$e_i = \frac{q_i - p_i}{p_i}$$

analogously to ε_i . Before proceeding, we observe that

$$e_i = \sum_{j \in f^{-1}(i)} \frac{\pi_j \varepsilon_j}{p_i}.$$

We now proceed with the argument. We have from [Roulston \(1999\)](#) that

$$|H(Q) - H(P)| \leq \left| \sum_i \left(e_i p_i (1 + \ln p_i) + \frac{1}{2} e_i^2 p_i + O(e_i^3) \right) \right| \quad (3)$$

$$\leq \sum_i |e_i p_i| + \sum_i |e_i p_i \ln p_i| + \frac{1}{2} \sum_i |e_i^2 p_i| + \left| \sum_i O(e_i^3) \right| \quad (4)$$

$$= \sum_i |e_i p_i \ln p_i| + \frac{1}{2} \sum_i |e_i^2 p_i| + \left| \sum_i O(e_i^3) \right| \quad (5)$$

where the final equality is because $\sum_i e_i p_i = \sum_i q_i - \sum_i p_i = 0$. We proceed by bounding each of the terms in Equation 5 separately.

To bound the first term, we write

$$\left| \sum_i e_i p_i \ln p_i \right| \leq - \sum_i |e_i| p_i \ln p_i.$$

We then note that $-\sum_i p_i \ln p_i \leq \ln B$, and since each of the summands has the same sign this means that $-p_i \ln p_i \leq \ln B$. We also observe that

$$|e_i| \leq \left| \sum_{j \in f^{-1}(i)} \frac{\pi_j \varepsilon_j}{p_i} \right| \leq \sum_j \frac{\pi_j}{p_i} |\varepsilon_j| \leq \sum_j |\varepsilon_j|$$

since $\pi_j/p_i \leq 1$. Together, these two facts give

$$\begin{aligned} - \sum_i |e_i| p_i \ln p_i &\leq (\ln B) \sum_i |e_i| \\ &\leq (\ln B) \sum_i |\varepsilon_i| \end{aligned}$$

The second inequality is because each e_i is a weighted average of a set of ε_i and each ε_i enters into the expression of exactly one e_i .

To bound the second term, we use the fact that $p_i \leq 1$ for all i , and so

$$\sum_i e_i^2 p_i \leq \sum_i e_i^2.$$

We then write

$$\begin{aligned} \sum_i e_i^2 &= \sum_i \left(\sum_{j \in f^{-1}(i)} \frac{\pi_j \varepsilon_j}{p_i} \right)^2 \\ &\leq \sum_i \sum_{j \in f^{-1}(i)} \frac{\pi_j \varepsilon_j^2}{p_i} \\ &\leq \sum_j \varepsilon_j^2 \\ &= \sum_j O(|\varepsilon_j|) \end{aligned}$$

where the second line is a consequence of the convexity of $f(x) = x^2$ and the third line is because the sets $f^{-1}(i)$ partition Γ .

To bound the third term, we write

$$\left| \sum_i O(e_i^3) \right| \leq \sum_i O(|e_i|^3)$$

and then proceed as we did with the second term, using the fact that $f(x) = x^3$ is convex for $x \geq 0$. This gives

$$\sum_i O(|e_i|^3) \leq \sum_i O(|\varepsilon_i|^3) = \sum_i O(|\varepsilon_i|)$$

completing the proof. \blacksquare

Lemma 52 Let $\{w_i\} \subset [0, 1]$ be a set of size n with $\sum_i w_i \leq 1$, and let $\{u_i\}$ be a set of n non-negative numbers satisfying $\sum_i u_i = a$ and $u_i \leq w_i$. Then

$$\sum_{i=1}^n u_i H_b \left(\frac{u_i}{w_i} \right) \leq H_b(a)$$

where H_b is the binary entropy function.

Proof Consider the random variable X taking values in $\{0, \dots, n\}$ that equals zero with probability $1 - \sum_j w_j$ and equals i with probability w_i for $0 < i \leq n$. Define the random variable Y taking values in $\{0, 1\}$ by

$$\mathbf{P}(Y = 0 | X = i) = \begin{cases} 0 & i = 0 \\ u_i/w_i & 0 < i \leq n \end{cases}.$$

The function we wish to bound equals $H(Y|X) \leq H(Y)$. We therefore observe that

$$\sum_{i=1}^n u_i H_b \left(\frac{u_i}{w_i} \right) \leq H(Y).$$

The result follows from the observation that

$$\mathbf{P}(Y=0) = \sum_i \mathbf{P}(X=i) \frac{u_i}{w_i} = \sum_i u_i \leq a.$$

■

Lemma 53 *Let X be a random variable distributed over k states, with $\mathbf{P}(X=x) = p_x$. Let $\alpha_x \geq 0$ be such that $\sum \alpha_x = \delta$, and define the random variable X' by $\mathbf{P}(X'=x) = (p_x + \alpha_x)/(1 + \delta)$. We have*

$$|H(X') - H(X)| \leq H_b(\delta) + \delta \log k$$

where H_b is the binary entropy function.

Proof Define a new random variable Z by

$$\mathbf{P}(Z=0|X'=x) = \frac{p_x}{p_x + \alpha_x}, \quad \mathbf{P}(Z=1|X'=x) = \frac{\alpha_x}{p_x + \alpha_x}.$$

We will use the fact that $H(X'|Z=0) = H(X)$ to obtain the required bound.

To upper bound $H(X') - H(X)$, we write

$$\begin{aligned} H(X') - H(X) &\leq H(X', Z) - H(X) \\ &= H(Z) + \mathbf{P}(Z=0)H(X'|Z=0) + \mathbf{P}(Z=1)H(X'|Z=1) - H(X) \\ &\leq H_b(\delta) + (1-\delta)H(X) + \delta H(X'|Z=1) - H(X) \\ &= H_b(\delta) - \delta H(X) + \delta \log k \\ &\leq H_b(\delta) + \delta \log k \end{aligned}$$

where in the fourth line we have used that $H(X'|Z=1) \leq \log k$.

To upper bound $H(X) - H(X')$, we write

$$\begin{aligned} H(X') + H(Z) &\geq H(X', Z) \\ &\geq \mathbf{P}(Z=0)H(X'|Z=0) \\ &= (1-\delta)H(X) \end{aligned}$$

which yields

$$H(X') \geq (1-\delta)H(X) - H_b(\delta)$$

since $H(Z) = H_b(\delta)$. Thus, we have

$$H(X) - H(X') \leq \delta H(X) + H_b(\delta) \leq \delta \log k + H_b(\delta). \quad \blacksquare$$

Lemma 54 *Let X be a random variable distributed over k states, with $\mathbf{P}(X=x) = p_x$. Let $\alpha_x \leq 0$ be such that $\sum |\alpha_x| = \delta$, and define the random variable X' by $\mathbf{P}(X'=x) = (p_x + \alpha_x)/(1 - \delta)$. We have*

$$|H(X') - H(X)| \leq H_b\left(\frac{\delta}{1-\delta}\right) + \frac{\delta}{1-\delta} \log k$$

where H_b is the binary entropy function. In particular, when $\delta \leq 1/3$ we have

$$|H(X') - H(X)| \leq H_b(2\delta) + 2\delta \log k.$$

Proof We observe that we can get from X' to X by adding $\delta/(1-\delta)$ probability mass and rescaling. The previous lemma then gives the result. ■

Lemma 55 *Let X be a random variable distributed over k states, with $\mathbf{P}(X=x) = p_x$. Let α_x be such that $\sum |\alpha_x| = \delta$, and define the random variable X' by $\mathbf{P}(X'=x) = (p_x + \alpha_x)/(1 - \sum \alpha_x)$. That is, X' is the result of changing the probability of state x by α_x and then re-normalizing to obtain a valid distribution. If $\delta \leq 1/4$, we have*

$$|H(X') - H(X)| \leq 2H_b(2\delta) + 3\delta \log k$$

where H_b is the binary entropy function.

Proof Let δ_+ be the total magnitude of all the positive α_x , and let δ_- be the total magnitude of all the negative α_x . We first add all the mass we're going to add, and apply the first of the previous two lemmas. Then we remove all the mass we are going to remove, and apply the second of the two previous lemmas. This yields a bound of

$$\begin{aligned} &H_b(\delta_+) + \delta_+ \log k + H_b\left(\frac{2\delta_-}{1+\delta_+}\right) + 2\frac{\delta_-}{1+\delta_+} \log k \\ &\leq H_b(\delta_+) + \delta_+ \log k + H_b(2\delta_-) + 2\delta_- \log k \\ &\leq H_b(2\delta) + \delta \log k + H_b(2\delta) + 2\delta \log k \\ &\leq 2H_b(2\delta) + 3\delta \log k \end{aligned}$$

where the first inequality is because $1 + \delta_+ \leq 1 + \delta < 2$ and $2\delta_- \leq 2\delta \leq 1/2$, and the second inequality is because $\delta_+ \leq \delta < 2\delta \leq 1/2$. ■

Abstract

Most existing binary classification methods target on the optimization of the overall classification risk and may fail to serve some real-world applications such as cancer diagnosis, where users are more concerned with the risk of misclassifying one specific class than the other. Neyman-Pearson (NP) paradigm was introduced in this context as a novel statistical framework for handling asymmetric type I/II error priorities. It seeks classifiers with a minimal type II error and a constrained type I error under a user specified level. This article is the first attempt to construct classifiers with guaranteed theoretical performance under the NP paradigm in high-dimensional settings. Based on the fundamental Neyman-Pearson Lemma, we used a plug-in approach to construct NP-type classifiers for Naive Bayes models. The proposed classifiers satisfy the NP oracle inequalities, which are natural NP paradigm counterparts of the oracle inequalities in classical binary classification. Besides their desirable theoretical properties, we also demonstrated their numerical advantages in prioritized error control via both simulation and real data studies.

Keywords: classification, high-dimension, Naive Bayes, Neyman-Pearson (NP) paradigm, NP oracle inequality, plug-in approach, screening

1. Introduction

Classification plays an important role in many aspects of our society. In medical research, identifying pathogenically distinct tumor types is central to advances in cancer treatments (Golub et al., 1999; Alderton, 2014). In cyber security, spam messages and virus make automatic categorical decisions a necessity. Binary classification is arguably the simplest and most important form of classification problems, and can serve as a building block for more complicated applications. We focus our attention on binary classification in this work.

A few common notations are introduced to facilitate our discussion. Let (X, Y) be a random pair where $X \in \mathcal{X} \subset \mathbb{R}^d$ is a vector of features and $Y \in \{0, 1\}$ indicates X 's class label. A classifier $\phi: \mathcal{X} \rightarrow \{0, 1\}$ is a mapping from \mathcal{X} to $\{0, 1\}$ that assigns X to one of the classes. A classification loss function is defined to assign a “cost” to each misclassified instance $\phi(X) \neq Y$, and the classification error is defined as the expectation of this loss function with respect to the joint distribution of (X, Y) . We will focus our discussion on the 0-1 loss function $\mathbb{I}\{\phi(X) \neq Y\}$ throughout the paper, where $\mathbb{I}(\cdot)$ denotes the indicator function. Denote by \mathbb{P} and \mathbb{E} the generic probability distribution and expectation, whose meaning depends on specific contexts. The classification error is $R(\phi) = \mathbb{E}\mathbb{I}\{\phi(X) \neq Y\} = \mathbb{P}\{\phi(X) \neq Y\}$. The law of total probability allows us to decompose it into a weighted average of type I error $R_0(\phi) = \mathbb{P}\{\phi(X) \neq Y | Y = 0\}$ and type II error $R_1(\phi) = \mathbb{P}\{\phi(X) \neq Y | Y = 1\}$ as

$$R(\phi) = \mathbb{P}(Y = 0)R_0(\phi) + \mathbb{P}(Y = 1)R_1(\phi). \quad (1.1)$$

With the advent of high-throughput technologies, classification tasks have experienced an exponential growth in the feature dimensions throughout the past decade. The fundamental challenge of “high dimension, low sample size” has motivated the development of a plethora of classification algorithms for various applications. While dependencies among features are usually considered a crucial characteristic of the data (Ackermann and Strimmer, 2009), and can effectively reduce classification errors under suitable models and relative data abundance (Shao et al., 2011; Cai and Liu, 2011; Fan et al., 2012; Mai et al., 2012; Witten and Tibshirani, 2012), independence rules, with their superb scalability, become a rule of thumb when the feature dimension grows faster than the sample size (Hastie et al., 2009; James et al., 2013). Despite Naive Bayes models’ reputation of being “simplistic” by ignoring all dependency structure among features, they lead to simple classifiers that have proven worthy on high-dimensional data with remarkably good performances in numerous real-life applications. Taking the classical model setting of two-class Gaussian with a common covariance matrix, Bickel and Levina (2004) showed the superior performance of Naive Bayes models over (naive implementation of) the Fisher linear discriminant rule under broad conditions in high-dimensional settings. Fan and Fan (2008) further established the necessity of feature selection for high-dimensional classification problems by showing that even independence rules can be as poor as random guessing due to noise accumulation. Featuring both independence rule and feature selection, the (sparse) Naive Bayes model remains a good choice for classification when the sample size is *fairly limited*.

1.1 Asymmetrical priorities on errors

Most existing binary classification methods target on the optimization of the overall risk (1.1) and may fail to serve the purpose when users’ relative priorities over type I/II errors differ significantly from those implied by the marginal probabilities of the two classes. A representative example of such scenario is the diagnosis of serious disease. Let 1 code the healthy class and 0 code the diseased class. Given that usually

$$\mathbb{P}(Y = 1) \gg \mathbb{P}(Y = 0),$$

minimizing the overall risk (1.1) might yield classifiers with small overall risk R (as a result of small R_1) yet large R_0 — a situation quite undesirable in practice given flagging a healthy

case incurs only extra cost of additional tests while failing to detect the disease endangers a life.

The neuroblastoma dataset introduced by Oberthner et al. (2006) provides a perfect illustration of such intuition. The dataset contains gene expression profiles on $d = 10707$ genes from 246 patients in a German neuroblastoma trial, among which 56 are high-risk (labeled as 0) and 190 are low-risk (labeled as 1). We randomly selected 41 '0's and 123 '1's as our training sample (such that the proportion of '0's is about the same as that in the entire dataset), and tested the resulting classifiers on the rest 15 '0's and 67 '1's. The average error rates of PSN² (to be proposed; implemented here at significance level 0.05), Gaussian Naive Bayes (nb), penalized logistic regression (pen-log), and Support Vector Machine (svm) over 1000 random splits are summarized in Table 1. All procedures except

Table 1: Average error rates over 1000 random splits for neuroblastoma dataset.

Error Type	PSN ²	nb	pen-log	svm
type I (0 as 1)	<u>.038</u>	.304	.529	.375
type II (1 as 0)	.761	.162	.103	.092

PSN² led to high type I errors, and are thus considered unsatisfactory given the more severe consequences of missing a diseased instance than vice versa.

One existing solution to asymmetric error control is *cost-sensitive learning*, which assigns two different costs as weights of the type I/II errors (Elkan, 2001; Lin et al., 2002; Zadrozny et al., 2003). Despite many merits and practical values of this framework, limitations arise in applications when there is no consensus over how much costs to be assigned to each class, or more fundamentally, whether it is morally acceptable to assign costs in the first place. Also, when users have a specific target for type I/II error control, cost-sensitive learning does not fit. Other methods aiming for small type I error include the Asymmetric Support Vector Machine (Wu et al., 2008), and the p -value for classification (Dünngeen et al., 2008). However, the former has no theoretical guarantee on errors, while the latter treats all classes as of equal importance.

1.2 Neyman-Pearson (NP) paradigm and NP oracle inequalities

Neyman-Pearson (NP) paradigm was introduced as a novel statistical framework for targeted type I/II error control. Assume type I error R_0 as the prioritized error type, this paradigm seeks to control R_0 under a user specified level α with R_1 as small as possible. The *oracle* is thus

$$\phi^* \in \operatorname{argmin}_{R_0(\phi) \leq \alpha} R_1(\phi), \quad (1.2)$$

where the *significance level* α reflects the level of conservativeness towards type I error. Given ϕ^* is unattainable in the learning paradigm, the best within our capability is to construct a data dependant classifier $\hat{\phi}$ that mimics it.

Despite its practical importance, NP classification has not received much attention in the statistics and machine learning communities. Cannon et al. (2002) initiated the theoretical treatment of NP classification. Under the same framework, Scott (2005) and Scott and

Nowak (2005) derived several results for traditional statistical learning such as PAC bounds or oracle inequalities. By combining type I and type II errors in sensible ways, Scott (2007) proposed a performance measure for NP classification. More recently, Blanchard et al. (2010) developed a general solution to semi-supervised novelty detection by reducing it to NP classification. Other related works include Cassesant and Chen (2003) and Han et al. (2008). A common issue with methods in this line of literature is that they all follow an empirical risk minimization (ERM) approach, and use some forms of relaxed empirical type I error constraint in the optimization program. As a result, all type I errors can only be proven to satisfy some relaxed upper bound. Take the framework set up by Cannon et al. (2002) for example. Given $\epsilon_0 > 0$, they proposed the program

$$\min_{\phi \in \mathcal{H}, R_0(\phi) \leq \alpha + \epsilon_0/2} \hat{R}_1(\phi),$$

where \mathcal{H} is a set of classifiers with finite Vapnik-Chervonenkis dimension, and \hat{R}_0, \hat{R}_1 are the empirical type I and type II errors respectively. It is shown that with high probability, the solution $\hat{\phi}$ to the above program satisfies simultaneously: i) the type I error $R_0(\hat{\phi})$ is bounded from above by $\alpha + \epsilon_0$, and ii) the type II error $R_1(\hat{\phi})$ is bounded from above by $R_1(\phi^*) + \epsilon_1$ for some $\epsilon_1 > 0$.

Rigollet and Tong (2011) is a significant departure from the previous NP classification literature. This paper argues that a good classifier $\hat{\phi}$ under the NP paradigm should respect the chosen significance level α , rather than some relaxation of it. More precisely, two **NP oracle inequalities** should be satisfied simultaneously with high probability:

- (I) the type I error constraint is respected, i.e., $R_0(\hat{\phi}) \leq \alpha$.
- (II) the excess type II error $R_1(\hat{\phi}) - R_1(\phi^*)$ diminishes with explicit rates (w.r.t. sample size).

Recall that, for a classifier \hat{h} , the classical oracle inequality insists that with high probability

$$\text{the excess risk } R(\hat{h}) - R(h^*) \text{ diminishes with explicit rates,} \quad (1.3)$$

where $h^*(x) = \mathbb{I}(g(x) \geq 1/2)$ is the Bayes classifier, in which $\eta(x) = \mathbb{E}[Y|X = x] = \mathbb{P}(Y = 1|X = x)$ is the regression function of Y on X (see Koltchinskii (2008) and references within). The two NP oracle inequalities defined above can be thought of as a generalization of (1.3) that provides a novel characterization of classifiers' theoretical performances under the NP paradigm.

Using a more stringent empirical type I error constraint (than the level α), Rigollet and Tong (2011) established NP oracle inequalities for its proposed classifiers under convex loss functions (as opposed to the indicator loss). They also proved an interesting negative result: under the binary loss, ERM approaches (convexification or not) cannot guarantee diminishing excess type II error as long as one insists type I error of the proposed classifier be bounded from above by α with high probability. This negative result motivated a plug-in approach to NP classification in Tong (2013).

1.3 Plug-in approaches

Plug-in methods in classical binary classification have been well studied in the literature, where the usual plug-in target is the Bayes classifier $\mathbb{I}(\eta(x) \geq 1/2)$. Earlier works gave rise to pessimism of the plug-in approach to classification. For example, under certain assumptions, Yang (1999) showed plug-in estimators cannot achieve excess risk with rates faster than $O(1/\sqrt{n})$, while direct methods can achieve rates up to $O(1/n)$ under *margin assumption* (Mammen and Tsybakov, 1999; Tsybakov, 2004; Tsybakov and van de Geer, 2005; Tarigan and van de Geer, 2006). However, it was shown in Audibert and Tsybakov (2007) that plug-in classifiers $\mathbb{I}(\hat{\eta}_n \geq 1/2)$ based on local polynomial estimators can achieve rates faster than $O(1/n)$, with a smoothness condition on η and the margin assumption.

The oracle classifier under the NP paradigm arises from its close connection to the Neyman-Pearson Lemma in statistical hypothesis testing. Hypothesis testing bears strong resemblance to binary classification if we assume the following model. Let P_1 and P_0 be two known probability distributions on $\mathcal{X} \subset \mathbb{R}^d$. Assume that $Y \sim \text{Bern}(\zeta)$ for some $\zeta \in (0, 1)$, and the conditional distribution of X given Y is P_Y . Given such a model, the goal of statistical hypothesis testing is to determine if we should reject the null hypothesis that X was generated from P_0 . To this end, we construct a randomized test $\phi : \mathcal{X} \rightarrow [0, 1]$ that rejects the null with probability $\phi(X)$. Two types of errors arise: type I error occurs when P_0 is rejected yet $X \sim P_0$, and type II error occurs when P_0 is not rejected yet $X \sim P_1$. The Neyman-Pearson paradigm in hypothesis testing amounts to choosing ϕ that solves the following constrained optimization problem

$$\text{maximize } \mathbb{E}[\phi(X)|Y = 1], \text{ subject to } \mathbb{E}[\phi(X)|Y = 0] \leq \alpha,$$

where $\alpha \in (0, 1)$ is the significance level of the test. A solution to this constrained optimization problem is called a *most powerful test* of level α . The Neyman-Pearson Lemma gives mild sufficient conditions for the existence of such a test.

Lemma 1.1 (Neyman-Pearson Lemma). *Let P_1 and P_0 be two probability measures with densities p and q respectively, and denote the density ratio as $r(x) = p(x)/q(x)$. For a given significance level α , let C_α be such that $P_0\{r(X) > C_\alpha\} \leq \alpha$ and $P_0\{r(X) \geq C_\alpha\} \geq \alpha$. Then, the most powerful test of level α is*

$$\phi^*(X) = \begin{cases} 1 & \text{if } r(X) > C_\alpha, \\ 0 & \text{if } r(X) < C_\alpha, \\ \frac{\alpha - P_0\{r(X) > C_\alpha\}}{P_0\{r(X) = C_\alpha\}} & \text{if } r(X) = C_\alpha. \end{cases}$$

Under mild continuity assumption, we take the NP oracle

$$\phi^*(x) = \phi_\alpha^*(x) = \mathbb{I}\{p(x)/q(x) \geq C_\alpha\} = \mathbb{I}\{r(x) \geq C_\alpha\}. \quad (1.4)$$

as our plug-in target for NP classification. With kernel density estimates \hat{p} , \hat{q} , and a proper estimate of the threshold level \hat{C}_α , Tong (2013) constructed a plug-in classifier $\mathbb{I}\{\hat{p}(x)/\hat{q}(x) \geq \hat{C}_\alpha\}$ that satisfies both NP oracle inequalities with high probability when the dimensionality is small, leaving the high-dimensional case an uncharted territory.

1.4 Contribution

In the big data era, NP classification framework faces the same curse of dimensionality as its classical counterpart. Despite its wide potential applications, this paper is the *first attempt* to construct performance-guaranteed classifiers under the NP paradigm in high-dimensional settings. Based on the Neyman-Pearson Lemma, we employ Naive Bayes models and propose a computationally feasible plug-in approach to construct classifiers that satisfy the NP oracle inequalities. We also improve the *detection condition*, a critical theoretical assumption first introduced in Tong (2013), for effective threshold level estimation that grounds the good NP properties of these classifiers. Necessity of the new detection condition is also discussed. Note that classifiers proposed in this work are not straightforward extensions of Tong (2013): kernel density estimation is now applied in combination with feature selection, and the threshold level is estimated in a more precise way by order statistics that require only moderate sample size — while Tong (2013) resorted to the Vapnik-Chervonenkis theory and required sample size much bigger than what is available in most high-dimensional applications.

The rest of the paper is organized as follows. Two screening based plug-in NP-type classifiers are presented in Section 2, where theoretical properties are also discussed. Performance of the proposed classifiers is demonstrated in Section 3 by both simulation studies and real data analysis. We conclude in Section 4 with a short discussion. The technical proofs are relegated to the Appendix.

2. Methods

In this section, we first introduce several notations and definitions, with a focus on the *detection condition*. Then we present the plug-in procedure, together with its theoretical properties.

2.1 Notations and definitions

We introduce here several notations adapted from Audibert and Tsybakov (2007). For $\beta > 0$, denote by $|\beta|$ the largest integer strictly less than β . For any $x, x' \in \mathbb{R}$ and any $|\beta|$ times continuously differentiable real-valued function $g(\cdot)$ on \mathbb{R} , we denote by g_x its Taylor polynomial of degree $|\beta|$ at point x . For $L > 0$, the $(\beta, L, [-1, 1])$ -Hölder class of functions, denoted by $\Sigma(\beta, L, [-1, 1])$, is the set of functions $g : [-1, 1] \rightarrow \mathbb{R}$ that are $|\beta|$ times continuously differentiable and satisfy, for any $x, x' \in [-1, 1]$, the inequality $|g(x') - g_x(x')| \leq L|x - x'|^\beta$. The $(\beta, L, [-1, 1])$ -Hölder class of density is defined as

$$\mathcal{P}_{\Sigma}(\beta, L, [-1, 1]) = \left\{ f : f \geq 0, \int f = 1, f \in \Sigma(\beta, L, [-1, 1]) \right\}.$$

We will use β -valid kernels (kernels of order β , Tsybakov (2009)) for all the kernel estimation throughout the theoretical discussion, the definition of which is as follows.

Definition 2.1. *Let $K(\cdot)$ be a real-valued function on \mathbb{R} with support $[-1, 1]$. The function $K(\cdot)$ is a β -valid kernel if it satisfies $\int K = 1$, $\int |K|^v < \infty$ for any $v \geq 1$, $\int |t|^\beta |K(t)| dt < \infty$, and in the case $|\beta| \geq 1$, it satisfies $\int t^l K(t) dt = 0$ for any $l \in \mathbb{N}$ such that $1 \leq l \leq \lfloor \beta \rfloor$.*

We assume that all the β -valid kernels considered in the theoretical part of this paper are constructed from Legendre polynomials, and are thus Lipschitz and bounded, satisfying the kernel conditions for the important technical Lemma A.6.

Definition 2.2 (margin assumption). *A function $f(\cdot)$ is said to satisfy margin assumption of order $\bar{\gamma}$ with respect to probability distribution P at the level C^* if there exists a positive constant M_0 , such that for any $\delta \geq 0$,*

$$P\{|f(X) - C^*| \leq \delta\} \leq M_0 \delta^{\bar{\gamma}}.$$

This assumption was first introduced in Polonik (1995). In the classical binary classification framework, Mannen and Tsybakov (1999) proposed a similar condition named “margin condition” by requiring most data to be away from the optimal decision boundary. In the classical classification paradigm, definition 2.2 reduces to the “margin condition” by taking $f = \eta$ and $C^* = 1/2$, with $\{x : |f(x) - C^*| = 0\} = \{x : \eta(x) = 1/2\}$ giving the decision boundary of the Bayes classifier. On the other hand, unlike the classical paradigm where the optimal threshold level is known and does not need an estimate, the optimal threshold level C_α in the NP paradigm is unknown and needs to be estimated, suggesting the necessity of having sufficient data around the decision boundary to detect it well. This concern motivated the following condition improved from Tong (2013).

Definition 2.3 (detection condition). *A function $f(\cdot)$ is said to satisfy detection condition of order $\bar{\gamma}$ with respect to P (i.e., $X \sim P$) at level (C^*, δ^*) if there exists a positive constant M_1 , such that for any $\delta \in (0, \delta^*)$,*

$$P\{C^* \leq f(X) \leq C^* + \delta\} \geq M_1 \delta^{\bar{\gamma}}.$$

A detection condition works as an opposite force to the margin assumption, and is basically an assumption on the lower bound of probability. Through we take here a power function of δ as the lower bound, so that it is simple and aesthetically similar to the margin assumption, any increasing function $u(\cdot)$ of δ on R^+ with $\lim_{\delta \rightarrow 0^+} u(\delta) = 0$ should be able to serve the purpose. The version of detection condition we would use to establish the NP inequalities for the (to be) proposed classifiers takes $f = r$, $C^* = C_\alpha$, and $P = P_0$ (recall that P_0 is the conditional distribution of X given $Y = 0$).

Now we argue why such a condition is *necessary* to achieve the NP oracle inequalities. Consider the simpler case where the density ratio r is known, and we only need a proper estimate of the threshold level \hat{C}_α . If there is nothing like the detection condition (Definition 2.3 involves a power function, but the idea is just to have any kind of lower bound), we would have, for some $\delta > 0$,

$$P_0\{C_\alpha \leq r(X) \leq C_\alpha + \delta\} = 0. \quad (2.1)$$

In getting the threshold estimate \hat{C}_α of $\hat{\phi}(x) = \mathbb{1}\{r(x) \geq \hat{C}_\alpha\}$, we can not distinguish any threshold level between C_α and $C_\alpha + \delta$. In particular, it is possible that

$$\hat{C}_\alpha > C_\alpha + \delta/2.$$

But then the excess type II error is bounded from below as follows

$$R_1(\hat{\phi}) - R_1(\phi^*) = P\{C_\alpha < r(X) < \hat{C}_\alpha\} > P\{C_\alpha < r(X) < C_\alpha + \delta/2\},$$

where the last quantity can be positive. Therefore, the second NP oracle inequality (diminishing excess type II error) does not hold for $\hat{\phi}$. Since some detection condition is necessary in this simpler case, it is certainly necessary in our real setup.

Note that Definition 2.3 is a significant improvement of the detection condition formulated in Tong (2013), which requires

$$P\{C^* - \delta \leq f(X) \leq C^*\} \wedge P\{C^* \leq f(X) \leq C^* + \delta\} \geq M_1 \delta^{\bar{\gamma}}.$$

We are able to drop the lower bound for the first piece due to an improved layout of the proofs. Intuitively, our new detection condition ensures an upper bound on \hat{C}_α . But we do not need an extra condition to get a lower bound of \hat{C}_α , because of the type I error bound requirement (see the proof of Proposition 2.4 for details). One example that satisfies the current condition but violate that in Tong (2013) is cited in the Appendix.

2.2 Neyman-Pearson plug-in procedure

Suppose the sampling scheme is fixed as follows.

Assumption 1. *Assume the training sample contains n i.i.d. observations $\mathbf{S}^1 = \{U_1, \dots, U_n\}$ from class 1 with density p , and m i.i.d. observations $\mathbf{S}^0 = \{V_1, \dots, V_m\}$ from class 0 with density q . Given fixed n_1, n_2, m_1, m_2 and m_3 such that $n_1 + n_2 = n$, $m_1 + m_2 + m_3 = m$, we further decompose \mathbf{S}^1 and \mathbf{S}^0 into independent subsamples as: $\mathbf{S}^1 = \mathbf{S}_1^1 \cup \mathbf{S}_2^1$, and $\mathbf{S}^0 = \mathbf{S}_1^0 \cup \mathbf{S}_2^0 \cup \mathbf{S}_3^0$, where $|\mathbf{S}_1^1| = n_1$, $|\mathbf{S}_2^1| = n_2$, $|\mathbf{S}_1^0| = m_1$, $|\mathbf{S}_2^0| = m_2$, $|\mathbf{S}_3^0| = m_3$.*

The sample splitting idea has been considered in the literature, such as in Meinshausen and Bühlmann (2010) and Robins et al. (2006). Given these samples, we introduce the following plug-in procedure.

Definition 2.4. Neyman-Pearson plug-in procedure

Step 1 Use \mathbf{S}_1^1 , \mathbf{S}_2^1 , \mathbf{S}_1^0 , and \mathbf{S}_2^0 to construct a density ratio estimate \hat{r} . The specific use of each subsample will be introduced in Section 2.4.

Step 2 Given \hat{r} , choose a threshold estimate \hat{C}_α from the set $\hat{r}(\mathbf{S}_3^0) = \{\hat{r}(V_{i+m_1+m_2})\}_{i=1}^{m_3}$.

Denote by $\hat{r}_{(k)}(\mathbf{S}_3^0)$ the k -th order statistic of $\hat{r}(\mathbf{S}_3^0)$, $k \in \{1, \dots, m_3\}$. The corresponding plug-in classifier by setting $\hat{C}_\alpha = \hat{r}_{(k)}(\mathbf{S}_3^0)$ is

$$\hat{\phi}_k(x) = \mathbb{1}\{\hat{r}(x) \geq \hat{r}_{(k)}(\mathbf{S}_3^0)\}. \quad (2.2)$$

A generic procedure for choosing the optimal k will be given in Section 2.3.

2.3 Threshold estimate \hat{C}_α

For any arbitrary density ratio estimate \hat{r} , we employ a proper order statistic $\hat{r}_{(k)}(\mathbf{S}_3^0)$ to estimate the threshold C_α and establish a probabilistic upper bound for the type I error of $\hat{\phi}_k$ for each $k \in \{1, \dots, m_3\}$.

Proposition 2.1. For any arbitrary density ratio estimate \hat{r} , let $\hat{\phi}_k(x) = \mathbb{I}\{\hat{r}(x) \geq \hat{r}_{(k)}(\mathcal{S}_3^0)\}$. It holds for any $\delta \in (0, 1)$ and $k \in \{1, \dots, m_3\}$ that

$$\mathbb{P}\{R_0(\hat{\phi}_k) > \delta\} \leq \text{Beta.cdf}_{k, m_3+1-k}(1 - \delta), \quad (2.3)$$

where $\text{Beta.cdf}_{k, m_3+1-k}(\cdot)$ is the CDF of $\text{Beta}(k, m_3+1-k)$. The inequality becomes equality when $F_{0,\hat{r}}(t) = F_0\{\hat{r}(X) \leq t\}$ is continuous almost surely.

In view of the above proposition, a sufficient condition for the classifier $\hat{\phi}_k$ to satisfy NP Oracle Inequality (I) at tolerance level $\delta_3 \in (0, 1)$ is thus

$$\text{Beta.cdf}_{k, m_3+1-k}(1 - \alpha) \leq \delta_3. \quad (2.4)$$

Despite the potential tightness of (2.3), we are not able to derive an explicit formula for the minimum k that satisfies (2.4). To get an explicit choice for k , we resort to concentration inequalities for an alternative.

Proposition 2.2. For any arbitrary density ratio estimate \hat{r} , let $\hat{\phi}_k(x) = \mathbb{I}\{\hat{r}(x) \geq \hat{r}_{(k)}(\mathcal{S}_3^0)\}$. It holds for any $\delta_3 \in (0, 1)$ and $k \in \{1, \dots, m_3\}$ that

$$\mathbb{P}\{R_0(\hat{\phi}_k) > g(\delta_3, m_3, k)\} \leq \delta_3, \quad (2.5)$$

where

$$g(\delta_3, m_3, k) = \frac{m_3 + 1 - k}{m_3 + 1} + \sqrt{\frac{k(m_3 + 1 - k)}{\delta_3(m_3 + 2)(m_3 + 1)^2}}. \quad (2.6)$$

Let $\mathcal{K} = \mathcal{K}(\alpha, \delta_3, m_3) = \{k \in \{1, \dots, m_3\} : g(\delta_3, m_3, k) \leq \alpha\}$. Proposition 2.2 implies that $k \in \mathcal{K}(\alpha, \delta_3, m_3)$ is a sufficient condition for the classifier $\hat{\phi}_k$ to satisfy NP Oracle Inequality (I). The next step is to characterize \mathcal{K} and choose some $k \in \mathcal{K}$, so that $\hat{\phi}_k$ has small excess type II error. Clearly, we would like to find the smallest element in \mathcal{K} .

Proposition 2.3. The minimum $k \in \{1, \dots, m_3 + 1\}$ that satisfies $g(\delta_3, m_3, k) \leq \alpha$ is

$$k_{\min}(\alpha, \delta_3, m_3) = \lceil (m_3 + 1)A_{\alpha, \delta_3}(m_3) \rceil, \quad (2.7)$$

where $\lceil z \rceil$ denotes the smallest integer larger than or equal to z , and

$$A_{\alpha, \delta_3}(m_3) = \frac{1 + 2\delta_3(m_3 + 2)(1 - \alpha) + \sqrt{1 + 4\delta_3(1 - \alpha)\alpha(m_3 + 2)}}{2\{\delta_3(m_3 + 2) + 1\}}.$$

Moreover,

1. $A_{\alpha, \delta_3}(m_3) \in (1 - \alpha, 1)$.
2. $\hat{r}_{(k_{\min}(\alpha, \delta_3, m_3))}(\mathcal{S}_3^0)$ is asymptotically the empirical $(1 - \alpha)$ -th quantile of $F_{0,\hat{r}}$ in the sense that

$$\lim_{m_3 \rightarrow \infty} \frac{k_{\min}(\alpha, \delta_3, m_3)}{m_3} = \lim_{m_3 \rightarrow \infty} A_{\alpha, \delta_3}(m_3) = 1 - \alpha.$$

3. For any $m_3 \geq 4/(\alpha\delta_3)$, we have $k_{\min}(\alpha, \delta_3, m_3) \leq m_3$, and thus

$$\mathcal{K}(\alpha, \delta_3, m_3) = \{k_{\min}(\alpha, \delta_3, m_3), k_{\min}(\alpha, \delta_3, m_3) + 1, \dots, m_3\}.$$

Introduce shorthand notations $k_{\min} = k_{\min}(\alpha, \delta_3, m_3)$, $\hat{r}_{(k)} = \hat{r}_{(k)}(\mathcal{S}_3^0)$, and $\hat{C}_\alpha = \hat{r}_{(\min\{k_{\min}, m_3\})}$. We will take

$$\hat{\phi}(x) = \mathbb{I}\{\hat{r}(x) \geq \hat{C}_\alpha\} = \begin{cases} \mathbb{I}\{\hat{r}(x) \geq \hat{r}_{(k_{\min})}\}, & \text{if } k_{\min} \leq m_3, \\ \mathbb{I}\{\hat{r}(x) \geq \hat{r}_{(m_3)}\}, & \text{if } k_{\min} = m_3 + 1 \end{cases} \quad (2.8)$$

as the default NP plug-in classifier for any arbitrary \hat{r} . An alternative threshold estimate that also guarantees type I error bound is derived in the Appendix C. Assume $m_3 \geq 4/(\alpha\delta_3)$ for the rest of the theoretical discussion. It follows from Proposition 2.3 that $k_{\min} \leq m_3$, and thus $\hat{C}_\alpha = \hat{r}_{(k_{\min})}$, $\hat{\phi} = \hat{\phi}_{(k_{\min})}$ with guaranteed type I error control.

Remark 2.1. Note that $\lim_{m_3 \rightarrow \infty} k_{\min}/\lceil m_3(1 - \alpha) \rceil = 1$. Thus, choosing the k_{\min} -th order statistic of $\hat{r}(\mathcal{S}_3^0)$ as the threshold can be viewed as a modification to the classical approach of estimating the $1 - \alpha$ quantile of $F_{0,\hat{r}}$ by the $\lceil m_3(1 - \alpha) \rceil$ -th order statistic of $\hat{r}(\mathcal{S}_3^0)$. Recall that the oracle C_α is actually the $1 - \alpha$ quantile of distribution $F_{0,r}$, so the intuition is that \hat{C}_α is asymptotically (when $m_3 \rightarrow \infty$) equivalent to the $1 - \alpha$ quantile of $F_{0,\hat{r}}$, which in turn converges (when $n_1, n_2, m_1, m_2 \rightarrow \infty$) to C_α as the $1 - \alpha$ quantile of $F_{0,r}$ under moderate conditions.

Lemma 2.1. Let $\alpha, \delta_3 \in (0, 1)$. In addition to Assumption 1, suppose \hat{r} be such that $F_{0,\hat{r}}$ is continuous almost surely. Then for any $\delta_4 \in (0, 1)$ and $m_3 \geq 4/(\alpha\delta_3)$, the distance between $R_0(\hat{\phi})$ ($\hat{\phi}$ as defined in (2.8)) and $R_0(\phi^*)$ can be bounded as

$$\mathbb{P}\{|R_0(\hat{\phi}) - R_0(\phi^*)| > \xi_{\alpha, \delta_3, m_3}(\delta_4)\} \leq \delta_4,$$

where

$$\xi_{\alpha, \delta_3, m_3}(\delta_4) = \sqrt{\frac{k_{\min}(m_3 + 1 - k_{\min})}{(m_3 + 2)(m_3 + 1)^2\delta_4}} + A_{\alpha, \delta_3}(m_3) - (1 - \alpha) + \frac{1}{m_3 + 1}. \quad (2.9)$$

If $m_3 \geq \max\{\delta_3^{-2}, \delta_4^{-2}\}$, we have $\xi_{\alpha, \delta_3, m_3}(\delta_4) \leq (5/2)m_3^{-1/4}$.

Proposition 2.4. Let $\alpha, \delta_3, \delta_4 \in (0, 1)$. In addition to assumptions of Lemma 2.1, assume that the density ratio r satisfies the margin assumption of order $\bar{\gamma}$ at level C_α (with constant M_0) and detection condition of order $\underline{\gamma}$ at level (C_α, δ^*) (with constant M_1), both with respect to distribution P_0 . If $m_3 \geq \max\{4/(\alpha\delta_3), \delta_3^{-2}, \delta_4^{-2}, (\frac{2}{5}M_1\delta^{*\bar{\gamma}})^{-4}\}$, the excess type II error of the classifier $\hat{\phi}$ defined in (2.8) satisfies with probability at least $1 - \delta_3 - \delta_4$,

$$\begin{aligned} & R_1(\hat{\phi}) - R_1(\phi^*) \\ & \leq 2M_0 \left[\left\{ \frac{|R_0(\hat{\phi}) - R_0(\phi^*)|}{M_1} \right\}^{1/2} + 2\|\hat{r} - r\|_\infty \right]^{1+\bar{\gamma}} + C_\alpha |R_0(\hat{\phi}) - R_0(\phi^*)| \\ & \leq 2M_0 \left[\left(\frac{2}{5}M_3^{1/4}M_1 \right)^{-1/2} + 2\|\hat{r} - r\|_\infty \right]^{1+\bar{\gamma}} + C_\alpha \left(\frac{2}{5}M_3^{1/4} \right)^{-1}. \end{aligned}$$

Given the above proposition, we can control the excess (type II error as long as the uniform deviation of density ratio estimate $\|\hat{r} - r\|_\infty$ is controlled. In the following subsection, we will introduce estimates \hat{r} and provide bounds for $\|\hat{r} - r\|_\infty$.

2.4 Density ratio estimate \hat{r}

Denote the marginal densities of class 1 and 0 as p_j and q_j ($j = 1, \dots, d$) respectively, Naive Bayes models for the density ratio take the form

$$r(x) = \prod_{j=1}^d \frac{p_j(x_j)}{q_j(x_j)}, \quad \text{where } x_j \text{ is the } j\text{-th component of } x.$$

The subsamples $S_1^j = \{U_{i_j}^{n_1}\}_{i_j=1}^{n_1}$, $S_2^j = \{U_{i_j+n_1}^{n_2}\}_{i_j=1}^{n_2}$, $S_0^j = \{V_i\}_{i=1}^{m_1}$ and $S_0^j = \{V_i+m_1\}_{i=1}^{m_2}$ are used to construct (nonparametric/parametric) estimators of p_j and q_j for $j = 1, \dots, d$.

Nonparametric estimate of the density ratio. For marginal densities p_j and q_j , we apply kernel estimates $\hat{p}_j(x_j) = \{(n_1 + m_2)h_1\}^{-1} \sum_{i=1}^{n_1+m_2} K\left(\frac{U_{i_j}-x_j}{h_1}\right)$, and $\hat{q}_j(x_j) = \{(m_1 + m_2)h_0\}^{-1} \sum_{i=1}^{m_1+m_2} K\left(\frac{V_{i_j}-x_j}{h_0}\right)$, where $K(\cdot)$ is the kernel function, h_1, h_0 are the bandwidths, and V_{i_j} and U_{i_j} denote the j -th component of V_i and U_i respectively. The resulting nonparametric estimate is

$$\hat{r}_N(x) = \prod_{j=1}^d \frac{\hat{p}_j(x_j)}{\hat{q}_j(x_j)}. \quad (2.10)$$

Parametric estimate of the density ratio. Assume the two-class Gaussian model $XY = 0 \sim \mathcal{N}(\mu^0, \Sigma)$ and $XY = 1 \sim \mathcal{N}(\mu^1, \Sigma)$, where $\Sigma = \text{diag}(\sigma_1^2, \dots, \sigma_d^2)$. We estimate μ^0, μ^1 and Σ using their sample versions $\hat{\mu}^0, \hat{\mu}^1$ and $\hat{\Sigma}$. Under this model, the density ratio function is given by

$$r_P(x) = \exp \left\{ (\mu^1 - \mu^0)' \Sigma^{-1} x + \frac{1}{2} (\mu^0)' \Sigma^{-1} \mu^0 - \frac{1}{2} (\mu^1)' \Sigma^{-1} \mu^1 \right\},$$

and the corresponding parametric estimate is

$$\hat{r}_P(x) = \exp \left\{ (\hat{\mu}^1 - \hat{\mu}^0)' \hat{\Sigma}^{-1} x + \frac{1}{2} (\hat{\mu}^0)' \hat{\Sigma}^{-1} \hat{\mu}^0 - \frac{1}{2} (\hat{\mu}^1)' \hat{\Sigma}^{-1} \hat{\mu}^1 \right\}. \quad (2.11)$$

2.5 Screening-based density ratio estimate and plug-in procedures

For ‘‘high dimension, low sample size’’ applications, complex models that take into account all features usually fail: even Naive Bayes models that ignore feature dependency might lead to poor performance due to noise accumulation (Fan and Fan, 2008). A common solution in these scenarios is to first study marginal relations between the response and each of the features (Fan and Lv, 2008; Li et al., 2012). By selecting the most important individual features, we greatly reduce the model size, and other models can be applied after this screening step. We now introduce screening based variants of \hat{r}_N and \hat{r}_P . Let F_j^0 and F_j^1 denote the CDFs of q_j and p_j respectively, for $j = 1, \dots, d$. Step 1 of Procedure 2.4

introduced in Section 2.1 is now decomposed into a screening substep and an estimation substep.

Nonparametric Screening-based NP Naive Bayes (NSN²) classifier

Step 1.1 Select features using S_0^j and S_1^j as follows:

$$\hat{\mathcal{A}}_\tau = \left\{ 1 \leq j \leq d : \|F_j^0 - F_j^1\|_\infty \geq \tau \right\}, \quad (2.12)$$

where $\tau > 0$ is some threshold level, and

$$\hat{F}_j^0(x_j) = \frac{1}{m_1} \sum_{i=1}^{m_1} \mathbb{I}(V_{i_j} \leq x_j), \quad \hat{F}_j^1(x_j) = \frac{1}{n_1} \sum_{i=1}^{n_1} \mathbb{I}(U_{i_j} \leq x_j) \quad (2.13)$$

are the empirical CDFs.

Step 1.2 Use S_0^j and S_1^j to construct kernel estimates of q_j and p_j for $j \in \hat{\mathcal{A}}_\tau$. The density ratio estimate is given by

$$\hat{r}_N^S(x) = \prod_{j \in \hat{\mathcal{A}}_\tau} \frac{\hat{p}_j(x_j)}{\hat{q}_j(x_j)}.$$

Step 2 Given \hat{r}_N^S , use S_0^j to get a threshold estimate $(\hat{r}_N^S)_{(k_{\min})}$ as in (2.8).

The resulting NSN² classifier is

$$\hat{\phi}_{\text{NSN}^2}^S(x) = \mathbb{I} \left\{ \hat{r}_N^S(x) \geq (\hat{r}_N^S)_{(k_{\min})} \right\}. \quad (2.14)$$

Parametric Screening-based NP Naive Bayes (PSN²) classifier

The PSN² procedure is similar to NSN², except the following two differences. In Step 1.1, features are now selected based on t -statistics (\mathcal{A}_τ represent the index set of the selected features). In Step 1.2, p_j, q_j for $j \in \hat{\mathcal{A}}_\tau$ follow two-class Gaussian model, and the resulting parametric screening-based density ratio estimate is

$$\hat{r}_P^S(x) = \prod_{j \in \hat{\mathcal{A}}_\tau} \frac{\hat{p}_j(x_j)}{\hat{q}_j(x_j)}.$$

The corresponding PSN² classifier is thus given by

$$\hat{\phi}_{\text{PSN}^2}^S(x) = \mathbb{I} \left\{ \hat{r}_P^S(x) \geq (\hat{r}_P^S)_{(k_{\min})} \right\}. \quad (2.15)$$

We assume the domains of all p_j and q_j to be $[-1, 1]$ for all the following theoretical discussion. We will prove NP oracle inequalities for $\hat{\phi}_{\text{NSN}^2}^S$, and those for $\hat{\phi}_{\text{PSN}^2}^S$ can be developed similarly. Recall that by Proposition 2.4, we need an upper bound for $\|\hat{r}_N^S - r\|_\infty$. Necessarily, performance of the screening step should be studied. To this end, we assume that only a small fraction of the d features have marginal differentiating power.

Assumption 2. *There exists a signal set $\mathcal{A} \subset \{1, \dots, d\}$ with size $|\mathcal{A}| = s \ll d$ such that $\inf_{j \in \mathcal{A}} \|F_j^0 - F_j^1\|_\infty \geq D$ for some positive constant D , and $F_j^0 = F_j^1$ for $j \notin \mathcal{A}$.*

The following proposition shows that Step 1.1 achieves exact recovery ($\hat{\mathcal{A}}_\tau = \mathcal{A}$) with high probability for some properly chosen τ .

Proposition 2.5 (exact recovery). *Let $\delta_1 \in (0, 1)$. In addition to Assumptions 1 and 2, suppose $n_1 \wedge m_1 \geq 8D^{-2} \log(4d/\delta_1)$. Then for any $\tau \in [\Delta_0, D - \Delta_0]$, where $\Delta_0 = \sqrt{\frac{\log(4d/\delta_1)}{2n_1}} + \sqrt{\frac{\log(4d/\delta_1)}{2m_1}}$, the screening substep Step 1.1 (2.12) satisfies*

$$\mathbb{P}(\hat{\mathcal{A}}_\tau = \mathcal{A}) \geq 1 - \delta_1.$$

Now we are ready to control the uniform deviation of density ratio estimate given in Step 1.2.

Assumption 3. *The marginal densities $p_j, q_j \in \mathcal{P}_{\Sigma}(\beta, L, [-1, 1])$ for all $j = 1, \dots, d$, and there exists $\underline{\mu} > 0$ such that $p_j, q_j \geq \underline{\mu}$ for all $j \in \mathcal{A}$. There exists some constant $\bar{C} > 0$, such that $\|r\|_\infty \leq \bar{C}$, and there is a uniform absolute upper bound for $\|p_j^{(l)}\|_\infty$ and $\|q_j^{(l)}\|_\infty$ for $j \in \mathcal{A}$ and $l \in [0, \lfloor \beta \rfloor]$. Moreover, the kernel K in the nonparametric density estimates is β -valid and L -Lipschitz.*

Smoothness conditions (Assumption 3) and the margin assumption were used together in the classical classification literature. However, it is not entirely obvious why Assumption 3 does not render the detection condition redundant. We refer interested readers to Appendix B for more detailed discussion.

Let C_j^1 and C_j^0 be the constants C in Lemma A.6 when applied to p_j and q_j respectively. Assumption 3 ensures the existence of absolute constants $C^1 \geq \sup_{j \in \mathcal{A}} C_j^1$ and $C^0 \geq \sup_{j \in \mathcal{A}} C_j^0$.

Proposition 2.6 (uniform deviation of density ratio estimate). *Under Assumptions 1 - 3, for any $\delta_1, \delta_2 \in (0, 1)$, if $n_1 \wedge m_1 \geq 8D^{-2} \log(4d/\delta_1)$, $\sqrt{\frac{\log(2m_2s/\delta_2)}{n_2h_0}} \leq \min(1, \underline{\mu}/C^1)$, $\sqrt{\frac{\log(2m_2s/\delta_2)}{m_2h_0}} \leq \min(1, \underline{\mu}/C^0)$, and the screening threshold τ is specified as in Proposition 2.5, we have*

$$\mathbb{P}(\|\hat{r}_N^S - r\|_\infty \leq T) \geq 1 - \delta_1 - \delta_2, \quad (2.16)$$

where $T = Be^B \|r\|_\infty$ with

$$B = s \left\{ \frac{C^1 \sqrt{\frac{\log(2m_2s/\delta_2)}{n_2h_1}}}{\underline{\mu} - C^1 \sqrt{\frac{\log(2m_2s/\delta_2)}{n_2h_1}}} + \frac{C^0 \sqrt{\frac{\log(2m_2s/\delta_2)}{m_2h_0}}}{\underline{\mu} - C^0 \sqrt{\frac{\log(2m_2s/\delta_2)}{m_2h_0}}} \right\}.$$

Moreover, assume that $n_2 \wedge m_2 \geq 1/\delta_2$, $|\mathcal{A}| = s \leq (n_2 \wedge m_2)^{\frac{\beta}{2(\beta+1)}}$, and the bandwidths $h_1 = (\log n_2/n_2)^{\frac{\beta}{2\beta+1}}$ and $h_0 = (\log m_2/m_2)^{\frac{1}{2\beta+1}}$, then there exists an absolute constant $C_2 > 0$ such that

$$\mathbb{P} \left[\|\hat{r}_N^S - r\|_\infty \leq C_2 s \left\{ \left(\frac{\log n_2}{n_2} \right)^{\frac{\beta}{2\beta+1}} + \left(\frac{\log m_2}{m_2} \right)^{\frac{\beta}{2\beta+1}} \right\} \geq 1 - \delta_1 - \delta_2 \right]$$

The condition $|\mathcal{A}| = s \leq (n_2 \wedge m_2)^{\frac{\beta}{2(\beta+1)}}$ in the above proposition ensures that the upper bound of the uniform deviation diminishes as sample sizes n_2, m_2 go to infinity. Now we are in a position to present the theorem finale of NSN².

Theorem 2.1 (NP Oracle Inequalities for $\hat{\phi}_{\text{NSN}^2}$). *In addition to Assumptions 1 - 3, assume the density ratio r satisfies the margin assumption of order $\bar{\gamma}$ at level C_α and detection condition of order $\underline{\gamma}$ at level (C_α, δ^*) , both with respect to P_0 . For any given $\delta_1, \delta_2, \delta_3, \delta_4 \in$*

(0, 1), let the NSN² classifier $\hat{\phi}_{\text{NSN}^2}$ be defined as in (2.14), with the screening threshold τ specified as in Proposition 2.5 and kernel bandwidths $h_1 = (\log n_2/n_2)^{\frac{\beta}{2\beta+1}}$ and $h_0 = (\log m_2/m_2)^{\frac{\beta}{2\beta+1}}$, and \hat{r}_N^S be such that $F_{0, \hat{r}_N^S} = F_0\{\hat{r}_N^S \leq t\}$ is continuous almost surely.

*For subsample sizes that satisfy $n_1 \wedge m_1 \geq 8D^{-2} \log(4d/\delta_1)$, $n_2 \wedge m_2 \geq \max\{\delta_2^{-1}, s^{\frac{2(\beta+1)}{\beta}}\}$, $\sqrt{\frac{\log(2m_2s/\delta_2)}{n_2h_1}} \leq \min(1, \underline{\mu}/C^1)$, $\sqrt{\frac{\log(2m_2s/\delta_2)}{m_2h_0}} \leq \min(1, \underline{\mu}/C^0)$, and $m_3 \geq \max\{4/(\alpha\delta_3), \delta_3^{-2}, \delta_4^{-2}, (\frac{2}{5}M_1\delta^{*2})^{-4}\}$, there exists an absolute constant $\tilde{C} > 0$ such that with probability at least $1 - \delta_1 - \delta_2 - \delta_3 - \delta_4$,*

$$(I) \quad R_0(\hat{\phi}_{\text{NSN}^2}) \leq \alpha, \\ (II) \quad R_1(\hat{\phi}_{\text{NSN}^2}) - R_1(\phi^*) \leq \tilde{C} \left\{ m_3^{-\left(\frac{1}{4} \wedge \frac{1-\beta}{2}\right)} + s^{1+\bar{\gamma}} \left(\frac{\log n_2}{n_2} \right)^{\frac{\beta(1+\beta)}{2\beta+1}} + s^{1+\bar{\gamma}} \left(\frac{\log m_2}{m_2} \right)^{\frac{\beta(1+\beta)}{2\beta+1}} \right\}.$$

Theorem 2.1 establishes the NP oracle inequalities for $\hat{\phi}_{\text{NSN}^2}$. To help understand the conditions of this theorem, recall that Assumption 1 is about sample splitting, Assumption 2 is on minimal signal strength for active feature set, Assumption 3 is on marginal densities and kernels in nonparametric estimates, and the margin assumption and detection condition describe the neighbourhood of the oracle decision boundary. Note that the subsample sizes n_1 and m_1 do not enter the upper bound for the excess type II error explicitly. Instead, we have size requirements on them so that the important features are kept with high probability $1 - \delta_1$ in the screening substep. The tolerance parameter δ_2 arises from the nonparametric estimation of densities, the parameter δ_3 is for the tolerance on violation of type I error bound, and δ_4 arises from controlling $|R_0(\hat{\phi}_{\text{NSN}^2}) - R_0(\phi^*)|$.

3. Numerical investigation

In this section, we analyze two simulated examples and two real datasets to demonstrate the performance of our newly proposed NSN² and PSN² classifiers, in comparison with their corresponding non-screening counterparts (denoted as NN² and PN² respectively) as well as three popular methods under the classical framework: Gaussian Naive Bayes (nb), penalized logistic regression (pen-log), and Support Vector Machine (svm). We use R package ‘‘e1071’’ for nb and svm, and the R package ‘‘glmnet’’ for pen-log. Note that for fair comparison, we also include a pre-screening step for nb and svm under the high-dimensional settings. To facilitate the presentation, we summarize the four Neyman-Pearson Naive Bayes classifiers in Table 2.

To train the classifiers in Table 2, we set $\alpha = 0.05$, $\delta_1 = 0.05$, and $\delta_3 = 0.05$ throughout this section unless specified otherwise. In Assumption 1, motivated by Proposition 2.5, we

Table 2: A summary of the four Neyman-Pearson Naive Bayes classifiers.

	Screening-based	Non-screening
Non-parametric	$\hat{\phi}_{\text{NSN}^2}^{\text{NS}}(x) = \mathbb{I}\left\{\hat{r}_{\text{N}}^{\text{NS}}(x) \geq (\hat{r}_{\text{N}}^{\text{NS}})_{(k_{\text{min}})}\right\}$	$\hat{\phi}_{\text{NN}^2}^{\text{NS}}(x) = \mathbb{I}\left\{\hat{r}_{\text{N}}^{\text{NS}}(x) \geq (\hat{r}_{\text{N}}^{\text{NS}})_{(k_{\text{min}})}\right\}$
Parametric	$\hat{\phi}_{\text{PSN}^2}^{\text{NS}}(x) = \mathbb{I}\left\{\hat{r}_{\text{P}}^{\text{NS}}(x) \geq (\hat{r}_{\text{P}}^{\text{NS}})_{(k_{\text{min}})}\right\}$	$\hat{\phi}_{\text{PN}^2}^{\text{NS}}(x) = \mathbb{I}\left\{\hat{r}_{\text{P}}^{\text{NS}}(x) \geq (\hat{r}_{\text{P}}^{\text{NS}})_{(k_{\text{min}})}\right\}$

take $m_1 = \min\{10 \log(4d/\delta_1), m/4\} \mathbb{I}(\text{screening})$, $n_1 = \min\{10 \log(4d/\delta_1), n/2\} \mathbb{I}(\text{screening})$, $m_2 = \lfloor m/2 \rfloor - m_1$, $n_2 = n - n_1$, and $m_3 = m - \lfloor m/2 \rfloor$.

Due to the absence of information with respect to the true p and q , the theoretical screening cutoff that achieves exact recovery is not feasible in practice. We resort to an empirical permutation-based approach (Fan et al., 2011) as a substitute. Specifically, the screening substep in NSN² is executed as follows:

1. Combine S_0^0 and S_1^1 into $\{(X_i, Y_i)\}_{i=1}^{m_1+n_1}$, where $X_i \in S_0^0 \cup S_1^1$, and Y_i is X_i 's class label.
2. Calculate the marginal D -statistic for each feature:

$$D_j = \|\hat{F}_j^0 - \hat{F}_j^1\|_{\infty}, \quad j = 1, 2, \dots, d,$$

where $\hat{F}_j^0(x) = \sum_{i:Y_i=0} \mathbb{I}(X_{i,j} \leq x_j)$ and $\hat{F}_j^1(x) = \sum_{i:Y_i=1} \mathbb{I}(X_{i,j} \leq x_j)$.

3. Let $\pi = \{\pi(1), \dots, \pi(m_1 + n_1)\}$ be a random permutation of $\{1, \dots, (m_1 + n_1)\}$. For $j = 1, \dots, d$, compute $D_j^{\text{null}} = \|\hat{F}_j^{0,\text{null}} - \hat{F}_j^{1,\text{null}}\|_{\infty}$, where $\hat{F}_j^{0,\text{null}}(x_j) = \sum_{i:\pi(i)=0} \mathbb{I}(X_{i,j} \leq x_j)$, $\hat{F}_j^{1,\text{null}}(x_j) = \sum_{i:\pi(i)=1} \mathbb{I}(X_{i,j} \leq x_j)$.

4. For some pre-specified $Q \in [0, 1]$, let $\omega(Q)$ be the Q -th quantile of $\{D_j^{\text{null}} : j = 1, \dots, d\}$ and select $\hat{\mathcal{A}} = \{j : D_j \geq \omega(Q)\}$. Here, Q is a tuning parameter that keeps the percentage of noise features that pass the screening around $1 - Q$.

The same permutation idea is applied to the screening substep of PSN². Q is set at 0.95 throughout this section.

3.1 Simulation

Samples in both simulated examples are generated from the model

$$p(x) = \prod_{j=1}^d p_j(x_j), \quad q(x) = \prod_{j=1}^d q_j(x_j)$$

at 3 different dimensions: $d \in \{10, 100, 1000\}$. Sparsity for $d = 100$ and 1000 is imposed by setting $p_j = q_j$ for all $j > 10$. Seven different training sample sizes: $m = n \in \{200, 400, 800, 1600, 3200, 6400, 12800\}$ are considered. The number of replications for each scenario is 1000. Test errors are estimated using the average of 1000 independent observations from each class for each replication.

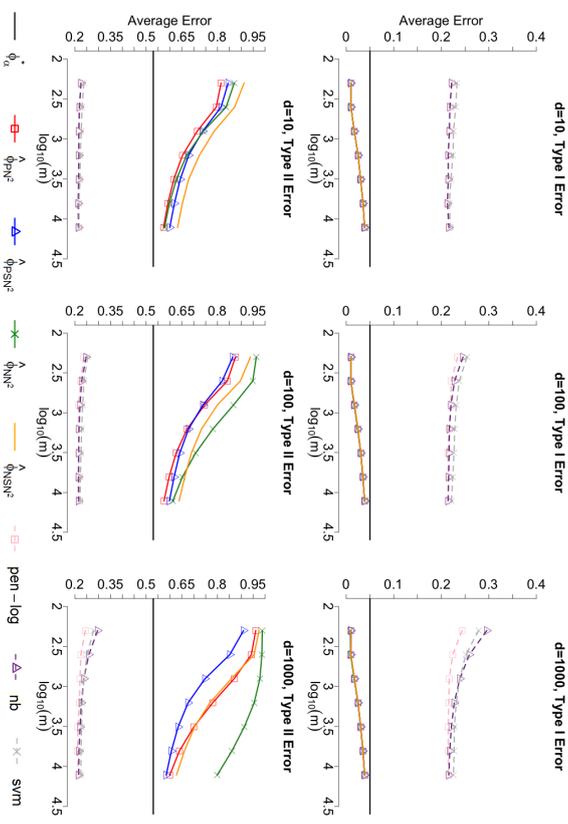

3.1.1 EXAMPLE 1: NORMALS WITH DIFFERENT MEANS

Assume the two-class conditional densities $p \sim \mathcal{N}(0.5(1_{10}^T, 0_{d-10}^T)^T, I_d)$ and $q \sim \mathcal{N}(0_d, I_d)$ where I_d is the identity matrix. At significance level $\alpha = 0.05$, the oracle type I/II risks are $R_0(\phi_{\alpha}^*) = 0.05$ and $R_1(\phi_{\alpha}^*) = 0.53$ respectively.

We first evaluate the screening performance of PSN² and NSN² with results presented in Table 3. Both t -statistic (in PSN²) and D -statistic (in NSN²) are able to pick up most of the true signals while keeping the false positive rates at around $1 - Q$.

 Table 3: Average screening performance summarized over 1000 independent replications at sample sizes $m = n = 400$ and $Q = 0.95$ with standard errors in parentheses.

d	# of selected features		# of missed signals		# of false positive	
	t -stat	D -stat	t -stat	D -stat	t -stat	D -stat
10	9.11 (1.14)	8.11 (1.63)	0.89 (1.14)	1.89 (1.63)	0 (0)	0 (0)
100	14.64 (3.46)	12.43 (3.38)	0.78 (0.90)	2.00 (1.39)	5.43 (3.17)	4.43 (2.77)
1000	59.99 (9.77)	58.82 (9.87)	0.48 (0.66)	1.14 (1.05)	50.47 (9.71)	49.96 (9.78)

 Figure 1: Average errors of $\hat{\phi}$'s over 1000 independent replications for each combination of (d, m, n) .

We then move on to evaluate the trend of type I and type II errors as the sample size increases in Figure 1. All the Neyman-Pearson based classifiers have type I error approaching α from below as sample size increases and they have similar type I errors at each sample size. However, nb, pen-log and svm all lead to a type I error larger than α .

By enlarging the second row of Figure 1, one would observe the differences in type II errors among PN^2 , PSN^2 , NN^2 , NSN^2 . In the case of $d = 10$ when all features are signals, PN^2 performs the best throughout all sample sizes since it assumes the correct model without the unnecessary screening substep. When sample size is small, PSN^2 outperforms NN^2 , but NN^2 gradually catches up on larger samples. In the case of $d = 100$, screening helps PSN^2 to take the lead at low sample sizes. The advantage of screening fades off as the sample size increases. In the case of $d = 1000$, PSN^2 dominates all other three classifiers throughout the sample size range we investigate.

Overall, the advantage of PSN^2 over NSN^2 , and PN^2 over NN^2 are uniform across all dimensions and sample sizes. This is consistent with the intuition that when the data are from a two-class Gaussian model, the parametric methods lead to more efficient estimators than nonparametric counterparts.

3.1.2 EXAMPLE 2: NORMAL VS. MIXTURE NORMAL

Normality assumption is violated in the second example. Assume $p \sim 0.5\mathcal{N}(a, \Sigma) + 0.5\mathcal{N}(-a, \Sigma)$ and $q \sim \mathcal{N}(0_d, I_d)$, where $a = \begin{pmatrix} 3 \\ -10 \\ 0 \end{pmatrix}$, $\Sigma = \begin{pmatrix} 10^{-1}I_{10} & 0 \\ 0 & I_{d-10} \end{pmatrix}$. At significance level $\alpha = 0.05$, the oracle type I/II risks are $R_0(\phi_\alpha^*) = 0.05$ and $R_1(\phi_\alpha^*) = 0.027$ respectively.

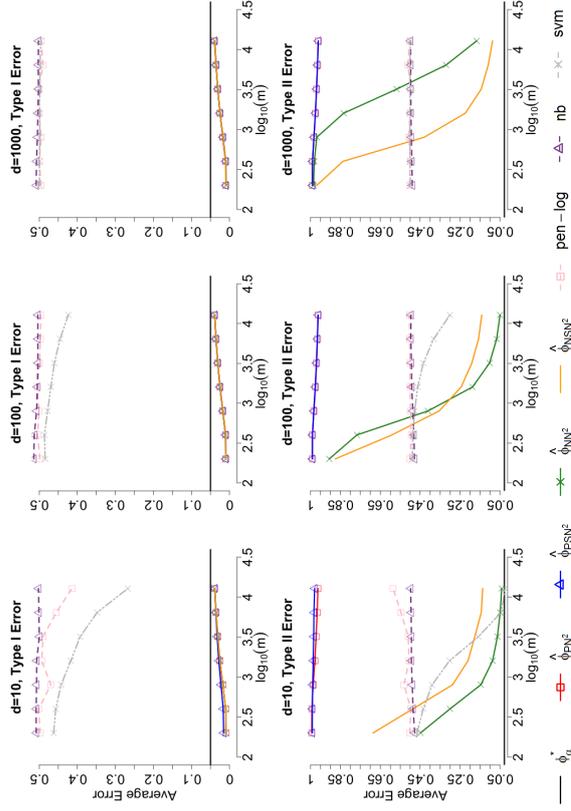

The performance of the screening substep of PSN^2 and NSN^2 is shown in Table 4. While both screening methods keep the false positive rates at around $1 - Q$, the parametric screening method (PSN^2) with t -statistic misses almost all signals. This is not surprising since t -statistics rank features by differences in means and the two groups have exactly the same marginal mean and variance across all dimensions.

Table 4: Average screening performance summarized over 1000 independent replications at sample sizes $m = n = 400$ and $Q = 0.95$ with standard errors in parentheses.

d	# of selected features		# of missed signals		# of false positive	
	t -stat	D -stat	t -stat	D -stat	t -stat	D -stat
10	1.76 (1.53)	8.13 (1.83)	8.24 (1.53)	1.87 (1.83)	0 (0)	0 (0)
100	5.93 (3.44)	11.96 (3.57)	9.38 (0.80)	2.34 (1.59)	5.31 (3.17)	4.29 (2.68)
1000	50.69 (9.60)	58.78 (9.87)	9.50 (0.69)	1.26 (1.04)	50.19 (9.51)	50.04 (9.62)

Figure 2 presents the average error rates. The same reason that causes the above fiasco of t -statistic screening reduces PSN^2 and PN^2 to nothing more than, if not less than, two unfair random coins with probability 0.05 of landing 1, while the behaviors of nb and pen-log bear more resemblance to that of fair random coins. This fundamental difference is due to that the classical framework aims to minimize the overall risk, and therefore tends to distribute errors evenly when the sample size for the two classes are about the same. The NSN^2 and NN^2 based on nonparametric assumptions, on the other hand, perform very

Figure 2: Average error rates of $\hat{\phi}^*$'s over 1000 independent replications for each combination of (d, m, n) . Error rates are computed as the average of 1000 independent testing data points from each class in each replication, and then average over replications.

well on non-normal data. Their difference in type II error performances are similar as in Example 1.

From the two simulation examples, it is clear that the screening-based NSN^2 and PSN^2 exhibit advantages over their non-screening counterparts under high-dimensional settings. When the normality assumption is violated, and the sample sizes are reasonably large for efficient kernel estimates, NSN^2 prevails over PSN^2 . As a rule of thumb, for high-dimensional classification problems that emphasize type I error control, we recommend NSN^2 if the sample size is relatively large and PSN^2 otherwise.

3.2 Real data analysis

In addition to the neuroblastoma dataset analyzed in the introduction, we now demonstrate the performance of PSN^2 and NSN^2 for targeted asymmetric error control on two additional real datasets.

3.2.1 P53 MUTANTS DATASET

The p53 mutants dataset (Danziger et al., 2006) contains $d = 5407$ attributes extracted from biophysical experiments for 16772 mutant p53 proteins, among which 143 are determined as “active” and the rest as “inactive” via in vivo assays.

All 143 active samples and the first 1500 inactive samples are included in our analysis. We treat the active class as class 0 and aimed to control the error of missing an active under $\alpha = 0.05$. This dataset is split into a training set with 100 observations from the active class and 1000 observations from the inactive class, and a testing set with the remaining observations. PSN² is used as the representative of our proposed methods, as the class 0 sample size is small for nonparametric methods. The average type I and type II errors over 1000 random splits are shown in Table 5. Compared with pen-log, nb and svm, PSN² performs much better in controlling the type I error.

Table 5: Average errors over 1000 random splits with standard errors in parentheses. $\alpha = 0.05$, $\delta_1 = 0.05$, $Q = 0.95$, and $\delta_3 = 0.1$.

	PSN ²	pen-log	nb	svm
type I	<u>.019 (.028)</u>	.162 (.060)	.054 (.035)	.275 (.189)
type II	.461 (.291)	.010 (.004)	.384 (.427)	.344 (.457)

3.2.2 EMAIL SPAM DATASET

Now, we consider an e-mail spam dataset available at <https://archive.ics.uci.edu/ml/datasets/Spambase>, which contains 4601 observations with 57 features, among which 2788 are class 0 (non-spam) and 1813 are class 1 (spam). We first standardize each feature and add 5000 synthetic features consisting of independent $\mathcal{N}(0, 1)$ variables to make the problem more challenging. The augmented data has $n = 4601$ observations with $d = 5057$ features. This augmented dataset is split into a training set with 1000 observations from each class and a testing set with the remaining observations. We use NSN² since the sample size is relatively large. The average type I and type II errors over 1000 random splits are shown in Table 6.

To evaluate the flexibility of NSN² in terms of prioritized error control, we also report the performance when the priority is switched to control the type II error below $\alpha = 0.05$. The results in Table 6 demonstrate that NSN² is able to control either type I or type II error depending on the specific need of the practitioner.

4. Discussion

The Neyman-Pearson classification framework is an important and interesting paradigm to explore beyond the Naive Bayes models considered in this work. For example, we can relax the independence assumption on PSN², and consider a general covariance matrix. Also, we can consider NP-type classifiers with decision boundaries involving feature interactions.

Table 6: Average errors over 1000 random splits with standard errors in parentheses. $\alpha = 0.05$, $\delta_1 = 0.05$, $Q = 0.95$, and $\delta_3 = 0.05$. The suffix after NSN² indicates the type of error it targets to control under α .

	NSN ² - R_0	NSN ² - R_1	pen-log	nb	svm
type I	<u>.019 (.007)</u>	.488 (.078)	.064 (.007)	.423 (.024)	.099 (.012)
type II	.439 (.057)	<u>.020 (.009)</u>	.133 (.015)	.058 (.010)	.174 (.016)

It is also worthwhile to study the non-probabilistic approaches under high-dimensional NP paradigm. Methods of potential interest include the k nearest neighbor (Weiss et al., 2010) and the centroid based classifiers (Tibshirani et al., 2002; Hall et al., 2010). However, the NP oracle inequalities are likely to be replaced by a new theoretical formulation for these methods.

A benefit of the present approach is that, for any given estimator \hat{r} , we have a uniform method to determine the proper threshold level in the plug-in classifiers. However, it would be interesting to develop new ways to estimate the threshold level C_α that is adaptive to the particular method used to approximate the density ratio r . Another future work is to study the theoretical properties of the permutation based choice of the threshold for the screening step.

Appendix A. Technical Lemmas and Proofs

Let $\text{Bin.cdf}_{n,p}(\cdot)$ denote the CDF of $\text{Bin}(n, p)$, and $\text{Beta.cdf}_{a,b}(\cdot)$ denote the CDF of $\text{Beta}(a, b)$. The following lemma proves a duality between the beta and binomial distributions.

Lemma A.1 (Beta-binomial duality). *For any $p \in [0, 1]$ and $k \in \{1, \dots, n\}$, it holds that*

$$1 - \text{Bin.cdf}_{n,p}(k-1) = \text{Beta.cdf}_{k,n+1-k}(p).$$

Proof of Lemma A.1. Let U_1, \dots, U_n be n i.i.d. $\text{Uniform}[0, 1]$. For any $p \in [0, 1]$, let $N_p = \sum_{i=1}^n \mathbb{1}\{U_i \leq p\}$ denote the number of U_i 's that are less or equal to p . Given

$$\mathbb{P}(\mathbb{1}\{U_i \leq p\} = 1) = \mathbb{P}(U_i \leq p) = p, \quad \mathbb{1}\{U_i \leq p\} \sim \text{Bern}(p) \quad \forall i,$$

we have $N_p \sim \text{Bin}(n, p)$, and therefore

$$\mathbb{P}(N_p \geq k) = 1 - \mathbb{P}(N_p \leq k-1) = 1 - \text{Bin.cdf}_{n,p}(k-1). \quad (\text{A.1})$$

On the other hand, let $U_{(k)}$ denote the k -th order statistic of $\{U_i\}_{i=1}^n$. It follows from the definition of order statistics that

$$\{N_p \geq k\} = \{\text{at least } k \text{ of } U_1, \dots, U_n \text{ are less or equal to } p\} = \{U_{(k)} \leq p\}. \quad (\text{A.2})$$

Combining (A.1) with (A.2) yields

$$1 - \text{Bin.cdf}_{n,p}(k-1) = \mathbb{P}(N_p \geq k) = \mathbb{P}(U_{(k)} \leq p) = \text{Beta.cdf}_{k,n+1-k}(p),$$

where the last equality follows from $U_{(k)} \sim \text{Beta}(k, n+1-k)$ ($k = 1, \dots, n$) as a direct implication of Rényi's representation. This completes the proof. \square

Lemma A.2. *Let Z be a random variable from CDF F . We have*

$$P_F\{F(Z) < \delta\} \leq \delta, \quad P_F\{F(Z) > \delta\} \geq 1 - \delta \quad \forall \delta \in [0, 1]. \quad (\text{A.3})$$

For continuous F , the inequality becomes equality as

$$P_F\{F(Z) < \delta\} = \delta, \quad P_F\{F(Z) > \delta\} = 1 - \delta \quad \forall \delta \in [0, 1]. \quad (\text{A.4})$$

Proof. Let $t_1 = \min\{t : F(t) \geq \delta\}$. Given the right continuity of F , it can be easily proved by contradiction that i) $F(t_1-) = F(t_1) = \delta$ if F is continuous at t_1 , and ii) $F(t_1-) < \delta \leq F(t_1)$ if F is discontinuous at t_1 . Thus,

$$P_F\{F(Z) < \delta\} = P_F(Z < t_1) = F(t_1-) \leq \delta.$$

Likewise, let $t_2 = \inf\{t : F(t) > \delta\}$. We have i) $F(t_2-) = F(t_2) = \delta$ if F is continuous at t_2 , and ii) $F(t_2-) < \delta \leq F(t_2)$ if F is discontinuous at t_2 . As a result,

$$P_F\{F(Z) > \delta\} = P_F\{Z \geq t_2\} = 1 - P_F\{Z < t_2\} \geq 1 - \delta.$$

This completes the proof. \square

Lemma A.3. *Let $S = \{Z_i\}_{i=1}^n$ be a set n i.i.d. random variables from distribution F , and let $Z_{(k)}$ denote its k -th order statistic ($k = 1, \dots, n$). For any $\delta \in (0, 1)$, the probability of a new, independent realization Z from F to be greater than $Z_{(k)}$ satisfies*

$$\begin{aligned} \mathbb{P}\{P_F(Z > Z_{(k)} | S) > \delta\} &\leq 1 - \text{Bin.cdf}_{n,1-\delta}(k-1), \\ \mathbb{P}\{P_F(Z > Z_{(k)} | S) < \delta\} &\geq 1 - \text{Bin.cdf}_{n,\delta}(n-k) = \text{Bin.cdf}_{n,1-\delta}(k-1). \end{aligned} \quad (\text{A.5}) \quad (\text{A.6})$$

The inequalities become equalities if F is continuous.

Proof of Lemma A.3. Rewrite the left-hand side of (A.5) as

$$\begin{aligned} \mathbb{P}\{P_F(Z > Z_{(k)} | S) > \delta\} &= \mathbb{P}\{1 - P_F(Z \leq Z_{(k)} | S) > \delta\} \\ &= \mathbb{P}\{1 - F(Z_{(k)}) > \delta\} = \mathbb{P}\{F(Z_{(k)}) < 1 - \delta\}. \end{aligned} \quad (\text{A.7})$$

To bound the probability of $\{F(Z_{(k)}) < 1 - \delta\}$, let $N_{1-\delta} = \sum_{i=1}^n \mathbb{1}_{\{F(Z_i) < 1-\delta\}}$ denote the number of $F(Z_i)$'s that are less than $1 - \delta$. It follows from $F(Z_{(1)}) \leq F(Z_{(2)}) \leq \dots \leq F(Z_{(n)})$ that

$$\begin{aligned} \{F(Z_{(k)}) < 1 - \delta\} &= \{F(Z_{(i)}) < 1 - \delta, i = 1, \dots, k\} = \{N_{1-\delta} \geq k\}, \\ \mathbb{P}\{F(Z_{(k)}) < 1 - \delta\} &= \mathbb{P}(N_{1-\delta} \geq k). \end{aligned} \quad (\text{A.8})$$

Let $\tau = P_F\{F(Z_1) < 1 - \delta\}$ denote the success probability of $N_{1-\delta}$ as a binomial. It follows from (A.3) that $\tau \leq 1 - \delta$. Given $\text{Bin.cdf}_{n,p}(k-1)$ being decreasing in p for any fixed n and k , we have

$$\mathbb{P}(N_{1-\delta} \geq k) = 1 - \text{Bin.cdf}_{n,\tau}(k-1) \leq 1 - \text{Bin.cdf}_{n,1-\delta}(k-1) \quad (\text{A.9})$$

as a result of The equalities hold for continuous F . Connecting (A.7), (A.8), and (A.9) together yields

$$\begin{aligned} \mathbb{P}\{P_F(Z > Z_{(k)} | S) > \delta\} &= \mathbb{P}\{F(Z_{(k)}) < 1 - \delta\} = \mathbb{P}(N_{1-\delta} \geq k) \\ &\leq 1 - \text{Bin.cdf}_{n,1-\delta}(k-1). \end{aligned}$$

Likewise, let $M_{1-\delta} = \sum_{i=1}^n \mathbb{1}_{\{F(Z_i) > 1-\delta\}}$ be a binomial random variable with size n and success rate $\tau' = P_F\{F(Z_i) > 1 - \delta\} \geq \delta$ that represents the number of $F(Z_i)$'s that are greater than $1 - \delta$. The left-hand side of (A.6) can be rewritten as

$$\begin{aligned} \mathbb{P}\{P_F(Z > Z_{(k)} | S) < \delta\} &= \mathbb{P}\{F(Z_{(k)}) > 1 - \delta\} \\ &= \mathbb{P}\{F(Z_{(i)}) > 1 - \delta, i = k, \dots, n\} = \mathbb{P}\{M_{1-\delta} \geq n + 1 - k\} \\ &= 1 - \mathbb{P}\{M_{1-\delta} \leq n - k\} = 1 - \text{Bin.cdf}_{n,\tau'}(n-k) \\ &\geq 1 - \text{Bin.cdf}_{n,\delta}(n-k). \end{aligned} \quad (\text{A.10})$$

This completes the proof. \square

Proof of Proposition 2.1. Letting $Z_i = \hat{r}_i$, $n = m_3$ in Lemma (A.3) yields

$$\mathbb{P}\{R_{t_0}(\hat{\phi}_k) > \delta\} \leq 1 - \text{Bin.cdf}_{m_3,1-\delta}(k-1).$$

This, together with Lemma A.1, completes the proof. \square

Lemma A.4. *For random variable $Z \sim \text{Beta}(a, b)$, and any $\epsilon > 0$, we have*

$$\mathbb{P}\{Z > (1 + \epsilon)\mathbb{E}Z\} < \mathbb{P}(|Z - \mathbb{E}Z| > \epsilon\mathbb{E}Z) < \frac{b\epsilon^{-2}}{(a+b+1)a}. \quad (\text{A.11})$$

Proof of Lemma A.4. By Chebyshev inequality,

$$\mathbb{P}(|Z - \mathbb{E}Z| > \epsilon\mathbb{E}Z) \leq \frac{\text{var}(Z)}{(\epsilon\mathbb{E}Z)^2} = \frac{ab}{(a+b)^2(a+b+1)} \left(\frac{\epsilon a}{a+b}\right)^{-2} = \frac{b\epsilon^{-2}}{(a+b+1)a}.$$

\square

Proof of Proposition 2.2. Let B be a realization from $\text{Beta}(k, m_3 + 1 - k)$. It follows from Proposition 2.1 that

$$\begin{aligned} \mathbb{P}\{R_0(\hat{\phi}_k) > g(\delta_3, m_3, k)\} &\leq \text{Beta.cdf}_{k, m_3+1-k}\{1 - g(\delta_3, m_3, k)\} \\ &= \mathbb{P}\{B \leq 1 - g(\delta_3, m_3, k)\} = \mathbb{P}\{1 - B \geq g(\delta_3, m_3, k)\} \end{aligned}$$

for any $k \in \{1, \dots, m_3\}$ and \hat{r} , with $1 - B \sim \text{Beta}(m_3 + 1 - k, k)$. Letting $a = m_3 + 1 - k$, $b = k$, and $\epsilon = k^{1/2}\{\delta_3(m_3 + 2)(m_3 + 1 - k)\}^{-1/2}$ in Lemma A.4 yields

$$\mathbb{P}\{R_0(\hat{\phi}_k) > g(\delta_3, m_3, k)\} \leq \delta_3,$$

where

$$g(\delta_3, m_3, k) = (1 + \epsilon) \left(\frac{m_3 + 1 - k}{m_3 + 1} \right) + \sqrt{\frac{k(m_3 + 1 - k)}{\delta_3(m_3 + 2)(m_3 + 1)^2}}.$$

This completes the proof. \square

Proof of Proposition 2.3. By some basic algebra we have

$$\begin{aligned} A_{\alpha, \delta_3}(m_3) - (1 - \alpha) &= \frac{-1 + 2\alpha + \sqrt{1 + 4\delta_3(1 - \alpha)\alpha(m_3 + 2)}}{2\{\delta_3(m_3 + 2) + 1\}} > 0, \\ A_{\alpha, \delta_3}(m_3) - 1 &= \frac{-1 - 2\delta_3(m_3 + 2)\alpha + \sqrt{1 + 4\delta_3(1 - \alpha)\alpha(m_3 + 2)}}{2\{\delta_3(m_3 + 2) + 1\}} < 0, \end{aligned}$$

and

$$\begin{aligned} g(\delta_3, m_3, k) &= \frac{m_3 + 1 - k}{m_3 + 1} + \sqrt{\frac{k(m_3 + 1 - k)}{\delta_3(m_3 + 2)(m_3 + 1)^2}} \leq \alpha \\ &\Leftrightarrow k - (1 - \alpha)(m_3 + 1) \geq 0, \\ &\Leftrightarrow \begin{cases} \{\delta_3(m_3 + 2) + 1\} \left(\frac{k}{m_3 + 1}\right)^2 - \{1 + 2\delta_3(m_3 + 2)(1 - \alpha)\} \left(\frac{k}{m_3 + 1}\right) \\ + \delta_3(m_3 + 2)(1 - \alpha)^2 \geq 0 \end{cases} \\ &\Leftrightarrow k \geq (m_3 + 1) \max\{1 - \alpha, A_{\alpha, \delta_3}(m_3)\} \\ &\Leftrightarrow k \geq (m_3 + 1) A_{\alpha, \delta_3}(m_3). \end{aligned}$$

Thus,

$$\begin{aligned} k_{\min}(\alpha, \delta_3, m_3) &= \lceil (m_3 + 1) A_{\alpha, \delta_3}(m_3) \rceil \\ &\in \lceil (m_3 + 1) A_{\alpha, \delta_3}(m_3), (m_3 + 1) A_{\alpha, \delta_3}(m_3) + 1 \rceil. \end{aligned}$$

Since $A_{\alpha, \delta_3}(m_3) \rightarrow 1 - \alpha$, as $m_3 \rightarrow \infty$, it follows from sandwich rule that

$$\lim_{m_3 \rightarrow \infty} \frac{k_{\min}(\alpha, \delta_3, m_3)}{m_3} = \lim_{m_3 \rightarrow \infty} A_{\alpha, \delta_3}(m_3) = 1 - \alpha.$$

We have $k_{\min}(\alpha, \delta_3, m_3) \in \mathcal{K}(\alpha, \delta_3, m_3)$ ($\Leftrightarrow k_{\min}(\alpha, \delta_3, m_3) \leq m_3$) as long as

$$(m_3 + 1) A_{\alpha, \delta_3}(m_3) + 1 \leq m_3 \quad \Leftrightarrow \quad (1 - \alpha \leq) \quad A_{\alpha, \delta_3}(m_3) \leq \frac{m_3 - 1}{m_3 + 1}. \quad (\text{A.12})$$

For any $\Delta \in (0, \alpha)$, a sufficient condition for (A.12) is

$$\frac{m_3 - 1}{m_3 + 1} \geq 1 - \Delta, \quad A_{\alpha, \delta_3}(m_3) \leq 1 - \Delta,$$

which can be further simplified as

$$m_3 \geq \frac{2}{\Delta} - 1, \quad m_3 \geq x^* - 2,$$

where

$$x^* = \frac{-2\Delta^2 - \alpha^2 + 2\alpha\Delta + \Delta + (1 - 2\alpha)\Delta + \alpha^2}{2(\alpha - \Delta)^2\delta_3} = \frac{\Delta(1 - \Delta)}{(\alpha - \Delta)^2\delta_3}$$

is the positive root of the quadratic equation

$$(\alpha - \Delta)^2\delta_3^2x^2 + \delta_3(2\Delta^2 + \alpha^2 - 2\alpha\Delta - \Delta)x - \Delta(1 - \Delta) = 0.$$

Thus, a sufficient condition for (A.12) is

$$m_3 \geq \max \left\{ \frac{\Delta(1 - \Delta)}{(\alpha - \Delta)^2\delta_3} - 2, \frac{2}{\Delta} - 1 \right\}.$$

Setting $\Delta = \alpha/2$ yields

$$\max \left\{ \frac{\Delta(1 - \Delta)}{(\alpha - \Delta)^2} - 2, \frac{2}{\Delta} - 1 \right\} = \max \left\{ \frac{2 - \alpha}{\alpha\delta_3} - 2, \frac{4}{\alpha} - 1 \right\} \leq \frac{4}{\alpha\delta_3}.$$

Therefore, $m_3 \geq 4/(\alpha\delta_3)$ guarantees (A.12) and $k_{\min}(\alpha, \delta_3, m_3) \in \mathcal{K}(\alpha, \delta_3, m_3)$. This completes the proof. \square

Proof of Lemma 2.1. Introduce shorthand notation let $A = A_{\alpha, \delta_3}(m_3)$ (defined in Proposition 2.3) and $\alpha_1 = (m_3 + 1 - k_{\min})/(m_3 + 1)$ for simplicity of exposition. For any $B_1, B_2 \in \mathbb{R}^+$, we have

$$\{|R_0(\hat{\phi}) - \alpha| > B_1 + B_2\} \subset \{|R_0(\hat{\phi}) - \alpha_1| > B_1\} \cup \{|\alpha_1 - \alpha| > B_2\},$$

and thus

$$\begin{aligned} &\mathbb{P}\{|R_0(\hat{\phi}) - \alpha| > B_1 + B_2 \mid \hat{r}\} \\ &\leq \mathbb{P}\{|R_0(\hat{\phi}) - \alpha_1| > B_1 \mid \hat{r}\} + \mathbb{P}\{|\alpha_1 - \alpha| > B_2 \mid \hat{r}\} \\ &\leq \frac{k_{\min}(m_3 + 1 - k_{\min})}{(m_3 + 2)(m_3 + 1)^2} B_1^{-2} + \mathbb{I}\{|\alpha_1 - \alpha| > B_2\}, \end{aligned} \quad (\text{A.13})$$

where the last inequality follows from applying Lemma A.4 to $R_0(\hat{\phi})$ which follows Beta($m_3 + 1 - k_{\min}, k_{\min}$) for $m_3 \geq 4/(\alpha\delta_3)$ and continuous $F_{\hat{r}}$ due to Lemma A.3. It follows from Proposition 2.3 that

$$|\alpha - \alpha_1| \leq A - (1 - \alpha) + \frac{1}{m_3 + 1}. \quad (\text{A.14})$$

Letting $B_1 = \sqrt{\frac{k_{\min}(m_3+1-k_{\min})}{(m_3+2)(m_3+1)^2\delta_4}}$ and $B_2 = A - (1 - \alpha) + \frac{1}{m_3+1}$ in (A.13) yields

$$\begin{aligned} & \mathbb{P}\{|R_0(\hat{\phi}) - \alpha| > \xi_{\alpha, \delta_3, m_3}(\delta_4) \mid \hat{r}\} \\ & \leq \delta_4 + \mathbb{P}\{|\alpha_1 - \alpha| > A - (1 - \alpha) + \frac{1}{m_3 + 1}\} \\ & = \delta_4 \end{aligned}$$

for any arbitrary \hat{r} . This, together with the independence between \mathcal{S}_3^0 and \hat{r} (as a function of $(\mathcal{S}_1^0, \mathcal{S}_1^1, \mathcal{S}_2^0, \mathcal{S}_2^1)$) yields

$$\mathbb{P}\{|R_0(\hat{\phi}) - \alpha| > \xi_{\alpha, \delta_3, m_3}(\delta_4)\} \leq \delta_4.$$

To establish an upper bound for $\xi_{\alpha, \delta_3, m_3}(\delta_4)$, note that

$$\begin{aligned} & \xi_{\alpha, \delta_3, m_3}(\delta_4) \\ & = \sqrt{\frac{k_{\min}(m_3+1-k_{\min})}{(m_3+2)(m_3+1)^2\delta_4}} + \frac{-1+2\alpha+\sqrt{1+4\delta_3(1-\alpha)\alpha(m_3+2)}}{2\{\delta_3(m_3+2)+1\}} + \frac{1}{m_3+1} \\ & \leq \sqrt{\frac{(m_3+1)^2/4}{(m_3+2)(m_3+1)^2\delta_4}} + \frac{1}{2\{\delta_3(m_3+2)+1\}} + \frac{\sqrt{1+\delta_3(m_3+2)}}{2\{\delta_3(m_3+2)+1\}} + \frac{1}{m_3+1} \\ & < \frac{1}{2\sqrt{m_3\delta_4}} + \frac{1}{2m_3\delta_3} + \frac{1}{2\sqrt{m_3\delta_3}} + \frac{1}{m_3}. \end{aligned}$$

When $m_3 \geq \max(\delta_3^{-2}, \delta_4^{-2})$, we have

$$\begin{aligned} \xi_{\alpha, \delta_3, m_3}(\delta_4) & < \frac{1}{2m_3^{1/4}} + \frac{1}{2m_3^{1/2}} + \frac{1}{2m_3^{3/4}} + \frac{1}{m_3} \\ & = \frac{1}{m_3^{1/4}} \left(1 + \frac{1}{2m_3^{1/4}} + \frac{1}{m_3^{3/4}} \right) < \frac{5/2}{m_3^{1/4}} = \left(\frac{2}{5} m_3^{1/4} \right)^{-1}. \end{aligned}$$

This completes the proof. \square

Proof of Proposition 2.4. Let $G^* = \{r < C_\alpha\}$ and $\widehat{G} = \{\hat{r} < \widehat{C}_\alpha\}$, the excess type II error can be decomposed as:

$$\begin{aligned} & P_1(\widehat{G}) - P_1(G^*) \\ & = \int_{\widehat{G}} dP_1 - \int_{G^*} dP_1 = \int_{\widehat{G}} \frac{p}{q} dP_0 - \int_{G^*} \frac{p}{q} dP_0 \\ & = \int_{\widehat{G}} (r - C_\alpha) dP_0 + C_\alpha P_0(\widehat{G}) - \int_{G^*} (r - C_\alpha) dP_0 - C_\alpha P_0(G^*) \\ & = \int_{\widehat{G} \setminus G^*} (r - C_\alpha) dP_0 - \int_{G^* \setminus \widehat{G}} (r - C_\alpha) dP_0 + C_\alpha \{P_0(\widehat{G}) - P_0(G^*)\} \\ & = \int_{\widehat{G} \setminus G^*} |r - C_\alpha| dP_0 + \int_{G^* \setminus \widehat{G}} |r - C_\alpha| dP_0 + C_\alpha \{R_0(\hat{\phi}^*) - R_0(\hat{\phi})\}. \end{aligned} \quad (\text{A.15})$$

It follows from Lemma 2.1 that when $m_3 \geq \max\{\frac{1}{\alpha\delta_3}, \delta_3^{-2}, \delta_4^{-2}, (\frac{2}{5}M_1\delta^{*2})^{-4}\}$,

$$\xi_{\alpha, \delta_3, m_3}(\delta_4) \leq \frac{5}{2} m_3^{-1/4} \leq M_1(\delta^*)^{2/3}, \quad \left\{ \frac{\xi_{\alpha, \delta_3, m_3}(\delta_4)}{M_1} \right\}^{1/2} \leq \delta^*.$$

Introduce shorthand notations $\Delta R_0 = |R_0(\hat{\phi}^*) - R_0(\hat{\phi})|$, $\mathcal{E}_0 = \{\Delta R_0 < \xi_{\alpha, \delta_3, m_3}(\delta_4)\}$, and $T = \|\hat{r} - r\|_\infty$. On the event \mathcal{E}_0 ,

$$\left(\frac{\Delta R_0}{M_1} \right)^{1/2} \leq \left\{ \frac{\xi_{\alpha, \delta_3, m_3}(\delta_4)}{M_1} \right\}^{1/2} \leq \delta^*.$$

By the detection condition, we have

$$\Delta R_0 \leq P_0\{C_\alpha < r(X) < C_\alpha + (\Delta R_0/M_1)^{1/2}\}.$$

Note that

$$\begin{aligned} & P_0\{r(X) \geq C_\alpha + (\Delta R_0/M_1)^{1/2}\} = R_0(\hat{\phi}^*) - P_0\{C_\alpha < r(X) < C_\alpha + (\Delta R_0/M_1)^{1/2}\} \\ & \leq R_0(\hat{\phi}^*) - \Delta R_0 \\ & \leq R_0(\hat{\phi}) = P_0\{\hat{r}(X) > \widehat{C}_\alpha\} \\ & \leq P_0\{r(X) + T \geq \widehat{C}_\alpha\} = P_0\{r(X) \geq \widehat{C}_\alpha - T\}. \end{aligned}$$

Thus, we have $\widehat{C}_\alpha \leq C_\alpha + (\Delta R_0/M_1)^{1/2} + T$, and

$$\begin{aligned} \widehat{G} \setminus G^* & = \{r \geq C_\alpha, \hat{r} < \widehat{C}_\alpha\} = \{r \geq C_\alpha, \hat{r} < C_\alpha + (\Delta R_0/M_1)^{1/2} + T\} \cap \{\hat{r} < \widehat{C}_\alpha\} \\ & = \{C_\alpha + (\Delta R_0/M_1)^{1/2} + 2T \geq r \geq C_\alpha, \hat{r} < C_\alpha + (\Delta R_0/M_1)^{1/2} + T\} \cap \{\hat{r} < \widehat{C}_\alpha\} \\ & \subset \{C_\alpha + (\Delta R_0/M_1)^{1/2} + 2T \geq r \geq C_\alpha\}. \end{aligned}$$

Therefore, the margin assumption implies

$$\begin{aligned} P_0(\widehat{G} \setminus G^*) & \leq P_0\{C_\alpha + (\Delta R_0/M_1)^{1/2} + 2T \geq r \geq C_\alpha\} \\ & \leq M_0\{(\Delta R_0/M_1)^{1/2} + 2T\}^{\bar{\gamma}}. \end{aligned}$$

Hence on the event \mathcal{E}_0 ,

$$\begin{aligned} \int_{\widehat{\mathcal{A}} \setminus G^*} |r - C_\alpha| dP_0 &\leq \{(\Delta R_0/M_1)^{1/2} + 2T\} P_0(\widehat{G} \setminus G^*) \\ &\leq M_0 \{(\Delta R_0/M_1)^{1/2} + 2T\}^{1+\bar{\gamma}}. \end{aligned}$$

We will bound $\int_{G^* \setminus \widehat{G}} |r - C_\alpha| dP_0$ on the event $\mathcal{E}_1 = \{R_0(\widehat{\phi}) \leq \alpha\}$. Note that

$$P_0(r \geq C_\alpha) = \alpha \geq R_0(\widehat{\phi}) = R_0(\hat{r} \geq \widehat{C}_\alpha) \geq P_0(r \geq \widehat{C}_\alpha + \|r - r\|_\infty) = P_0(r \geq \widehat{C}_\alpha + T).$$

The above chain implies that $\widehat{C}_\alpha \geq C_\alpha - T$. Therefore,

$$\begin{aligned} G^* \setminus \widehat{G} &= \{r < C_\alpha, \hat{r} \geq \widehat{C}_\alpha\} \\ &= \{r < C_\alpha, r \geq r - \hat{r} + \widehat{C}_\alpha\} \\ &\subset \{r < C_\alpha, r \geq \widehat{C}_\alpha - T\} \\ &\subset \{C_\alpha - 2T \leq r \leq C_\alpha\}. \end{aligned}$$

Hence on the event \mathcal{E}_1 ,

$$\int_{G^* \setminus \widehat{G}} |r - C_\alpha| dP_0 \leq 2T \cdot P_0(C_\alpha - 2T \leq r \leq C_\alpha) \leq M_0(2T)^{1+\bar{\gamma}},$$

where the last inequality follows from the margin assumption. Then it follows from (A.15) that on the event $\mathcal{E}_0 \cap \mathcal{E}_1$,

$$\begin{aligned} R_1(\widehat{\phi}) - R_1(\phi^*) &\leq M_0 \left[\left\{ \frac{|\Delta R|}{M_1} \right\}^{1/2} + 2T \right]^{1+\bar{\gamma}} + M_0(2T)^{1+\bar{\gamma}} + C_\alpha |R_0(\widehat{\phi}) - R_0(\phi^*)| \\ &\leq 2M_0 \left[\left\{ \frac{\xi_{\alpha, \delta_3, m_3}(\delta_4)}{M_1} \right\}^{1/2} + 2T \right]^{1+\bar{\gamma}} + C_\alpha \cdot \xi_{\alpha, \delta_3, m_3}(\delta_4). \end{aligned}$$

From Lemma 2.1, we know that the event \mathcal{E}_0 occurs with probability at least $1 - \delta_4$. By Proposition 2.2 and Proposition 2.3 we know event \mathcal{E}_1 occurs with probability at least $1 - \delta_3$, so $\mathcal{E}_0 \cap \mathcal{E}_1$ occurs with probability at least $1 - \delta_3 - \delta_4$. This completes the proof. \square

Proof of Proposition 2.5. Define event

$$\mathcal{E}_{\delta_1} = \bigcap_{j=1}^d \{ \|\widehat{F}_j^1 - F_j^1\|_\infty < \delta_1^1 \} \cap \{ \|\widehat{F}_j^0 - F_j^0\|_\infty < \delta_1^0 \},$$

where $\delta_1^1 = \sqrt{\frac{\log(4d/\delta_1)}{2m_1}}$ and $\delta_1^0 = \sqrt{\frac{\log(4d/\delta_1)}{2m_0}}$. On the event \mathcal{E}_{δ_1} , for any $j \in \mathcal{A}$,

$$\begin{aligned} \|\widehat{F}_j^0 - \widehat{F}_j^1\|_\infty &\geq \|\widehat{F}_j^0 - F_j^0\|_\infty - \|F_j^0 - \widehat{F}_j^0\|_\infty - \|F_j^1 - \widehat{F}_j^1\|_\infty \\ &\geq D - \|\widehat{F}_j^0 - F_j^0\|_\infty - \|F_j^1 - \widehat{F}_j^1\|_\infty \\ &> D - \delta_1^0 - \delta_1^1. \end{aligned}$$

For any $j \notin \mathcal{A}$,

$$\begin{aligned} \|\widehat{F}_j^0 - \widehat{F}_j^1\|_\infty &\leq \|\widehat{F}_j^0 - \widehat{F}_j^0\|_\infty + \|\widehat{F}_j^0 - F_j^0\|_\infty + \|F_j^1 - \widehat{F}_j^1\|_\infty \\ &= \|\widehat{F}_j^0 - F_j^0\|_\infty + \|F_j^1 - \widehat{F}_j^1\|_\infty \\ &< \delta_1^0 + \delta_1^1. \end{aligned}$$

Since $n_1 \geq 8D^{-2} \log(4d/\delta_1)$ and $m_1 \geq 8D^{-2} \log(4d/\delta_1)$, $\delta_1^0 + \delta_1^1 \leq D - \delta_1^0 - \delta_1^1$. As a result, on the event \mathcal{E}_{δ_1} , any $\tau \in [\delta_1^0 + \delta_1^1, D - \delta_1^0 - \delta_1^1]$ would lead to $\widehat{\mathcal{A}}_\tau = \mathcal{A}$. Therefore,

$$\begin{aligned} \mathbb{P}(\widehat{\mathcal{A}}_\tau = \mathcal{A}) &\geq \mathbb{P}(\mathcal{E}_{\delta_1}) \\ &\geq 1 - \sum_{j=1}^d \left\{ \mathbb{P}(\|\widehat{F}_j^1 - F_j^1\|_\infty \geq \delta_1^1) + \mathbb{P}(\|\widehat{F}_j^0 - F_j^0\|_\infty \geq \delta_1^0) \right\} \\ &\geq 1 - \delta_1, \end{aligned}$$

where the last inequality follows from applying Lemma A.5 to F_j^0 and F_j^1 for $j = 1, \dots, d$. This completes the proof. \square

Proof of Proposition 2.6. Define event

$$\mathcal{E} = \bigcap_{j \in \mathcal{A}} \{ \|\log \hat{r}_j - \log P_j\|_\infty < B_j^1 \} \cap \{ \|\log \hat{q}_j - \log Q_j\|_\infty < B_j^0 \},$$

where

$$B_j^1 = \frac{C_j^1 \sqrt{\frac{\log(2m_2s/\delta_2)}{n_2 \hat{n}_1}}}{n_2 \hat{n}_1}, \quad B_j^0 = \frac{C_j^0 \sqrt{\frac{\log(2m_2s/\delta_2)}{m_2 \hat{m}_0}}}{m_2 \hat{m}_0}.$$

Let $B^1 = \sup_{j \in \mathcal{A}} B_j^1$ and $B^0 = \sup_{j \in \mathcal{A}} B_j^0$, we have $B \geq s(B^0 + B^1)$. On the event $\{\widehat{\mathcal{A}}_\tau = \mathcal{A}\} \cap \mathcal{E}$, we have

$$\log \hat{r}_N^S(x) = \sum_{j \in \widehat{\mathcal{A}}} \log \frac{\hat{r}_j(x_j)}{\hat{q}_j(x_j)} = \sum_{j \in \mathcal{A}} \log \hat{r}_j(x_j) - \sum_{j \in \mathcal{A}} \log \hat{q}_j(x_j).$$

Therefore,

$$\begin{aligned} \|\log \hat{r}_N^S - \log r\|_\infty &= \left\| \sum_{j \in \mathcal{A}} \log \hat{r}_j - \sum_{j \in \mathcal{A}} \log \hat{q}_j - \sum_{j \in \mathcal{A}} \log P_j + \sum_{j \in \mathcal{A}} \log Q_j \right\|_\infty \\ &\leq \sum_{j \in \mathcal{A}} (\|\log \hat{r}_j - \log P_j\|_\infty + \|\log \hat{q}_j - \log Q_j\|_\infty) \\ &\leq \sum_{j \in \mathcal{A}} (B^1 + B^0) \leq B. \end{aligned}$$

On the event $\{\widehat{\mathcal{A}}_\tau = \mathcal{A}\} \cap \mathcal{E}$, it follows from Lagrange's mean value theorem that for any x , there exists some w_x between $\log \hat{r}_N^S(x)$ and $\log r(x)$ such that

$$\begin{aligned} |\hat{r}_N^S(x) - r(x)| &= |e^{\log \hat{r}_N^S(x)} - e^{\log r(x)}| = e^{w_x} |\log \hat{r}_N^S(x) - \log r(x)| \\ &\leq e^{\|\log r\|_\infty + B} B = B e^B \|r\|_\infty = T, \end{aligned}$$

where the last inequality follows from the fact that

$$w_x \leq \max(\log r(x), \log \hat{r}_N^S(x)) \leq \max(\|\log r\|_\infty, \|\log \hat{r}_N^S\|_\infty) \leq \|\log r\|_\infty + B.$$

Thus, $\|\hat{r}_N^S - r\|_\infty \leq T$, and we have

$$\begin{aligned} \mathbb{P}(\|\hat{r}_N^S - r\|_\infty \leq T) &\geq \mathbb{P}(\{\hat{\mathcal{A}}_T = \mathcal{A}\} \cap \mathcal{E}) \geq \mathbb{P}(\hat{\mathcal{A}}_T = \mathcal{A}) + \mathbb{P}(\mathcal{E}) - 1 \\ &= \mathbb{P}(\hat{\mathcal{A}}_T = \mathcal{A}) - \mathbb{P}(\mathcal{E}^c). \end{aligned} \quad (\text{A.16})$$

By Proposition 2.5, we have

$$\mathbb{P}(\hat{\mathcal{A}}_T = \mathcal{A}) \geq 1 - \delta_1. \quad (\text{A.17})$$

Also, it follows from Lemma A.6 that

$$\mathbb{P}(\|\log \hat{p}_j - \log p_j\|_\infty > B_j^1) \vee \mathbb{P}(\|\log \hat{q}_j - \log q_j\|_\infty > B_j^0) \leq \delta_2/(2s).$$

Therefore,

$$\mathbb{P}(\mathcal{E}^c) \leq (2s)\delta_2/(2s) = \delta_2. \quad (\text{A.18})$$

Plugging (A.17) and (A.18) back to (A.16) yields (2.16). Moreover, because $s \leq n_2 \wedge m_2$, it follows from Lemma A.6 that there exists some $C_2 > 0$, such that

$$B \leq C_2 s \left\{ \left(\frac{\log n_2}{n_2} \right)^{\frac{\beta}{2\beta+1}} + \left(\frac{\log m_2}{m_2} \right)^{\frac{\beta}{2\beta+1}} \right\}.$$

Moreover, since $s \leq (n_2 \wedge m_2)^{\frac{\beta}{2\beta+1}}$, the above bound implies that B is bounded from above by some absolute constant. Also note that $\|r\|_\infty$ is bounded from above, so there exists an absolute constant $C_2 > 0$, such that

$$T = Be^B \|r\|_\infty \leq C_2 s \left\{ \left(\frac{\log n_2}{n_2} \right)^{\frac{\beta}{2\beta+1}} + \left(\frac{\log m_2}{m_2} \right)^{\frac{\beta}{2\beta+1}} \right\}.$$

This completes the proof. \square

Proof of Theorem 2.1. Combining Propositions 2.2, 2.3, 2.4 and 2.6,

$$\mathbb{P}\left(R_0(\hat{\phi}_{\text{NSN}^2}) \leq \alpha, R_1(\hat{\phi}_{\text{NSN}^2}) \leq R_1(\phi^*) + W\right) \geq 1 - \delta_1 - \delta_2 - \delta_3 - \delta_4,$$

where

$$\begin{aligned} W = & 2M_0 \left[\left(\frac{2}{5} m_3^{1/4} M_1 \right)^{-1/2} + 2C_2 s \left\{ \left(\frac{\log n_2}{n_2} \right)^{\frac{\beta}{2\beta+1}} + \left(\frac{\log m_2}{m_2} \right)^{\frac{\beta}{2\beta+1}} \right\} \right]^{1+\gamma} \\ & + C_\alpha \left(\frac{2}{5} m_3^{1/4} \right)^{-1}. \end{aligned}$$

This completes the proof. \square

Lemma A.5 (Dvoretzky-Kiefer-Wolfowitz inequality (Dvoretzky et al., 1956)). Let X_1, X_2, \dots, X_n be real-valued i.i.d. random variables with cdf $F(\cdot)$, and let $\hat{F}_n(x) = n^{-1} \sum_{i=1}^n \mathbb{1}(X_i \leq x)$. For any $t > 0$, it holds that

$$\mathbb{P}(\|\hat{F}_n - F\|_\infty \geq t) \leq 2e^{-2nt^2}.$$

Or, for any given $\delta \in (0, 1)$,

$$\mathbb{P}(\|\hat{F}_n - F\|_\infty \geq \sqrt{\frac{\log(2/\delta)}{2n}}) \leq \delta. \quad (\text{A.19})$$

Lemma A.6. Given a density function $p \in \mathcal{P}_\Sigma(\beta, L, [-1, 1])$, construct its kernel estimate $\hat{p}(x) = (nh)^{-1} \sum_{i=1}^n K\left(\frac{X_i - x}{h}\right)$ from i.i.d. sample $\{X_i\}_{i=1}^n$, where the kernel K is β -valid and L -Lipschitz, and the bandwidth $h = (\log n/n)^{\frac{1}{2\beta+1}}$. For any $\delta \in (0, 1)$, as long as the sample size n is such that $\sqrt{\frac{\log(n/\delta)}{nh}} < \min(1, \underline{\mu}/C)$, where $C = \sqrt{48c_1} + 32c_2 + 2Lc_3 + L + L + \tilde{C} \sum_{1 \leq |\beta| \leq \frac{1}{h}} \frac{1}{h}$, in which $c_1 = \|p\|_\infty \|K\|_2^2$, $c_2 = \|K\|_\infty + \|p\|_\infty + \int |K| |t|^\beta dt$, $c_3 = \int |K| |t|^\beta dt$, and \tilde{C} is such that $\tilde{C} \geq \sup_{1 \leq |\beta| \leq \frac{1}{h}} \sup_{x \in [-1, 1]} |p^{(\beta)}(x)|$, and $\underline{\mu}(> 0)$ is a lower bound of p , we have

$$\mathbb{P}(\|\log \hat{p} - \log p\|_\infty \geq U) \leq \delta, \quad (\text{A.20})$$

where $U = \frac{C\sqrt{\frac{\log(n/\delta)}{nh}}}{\underline{\mu} - C\sqrt{\frac{\log(n/\delta)}{nh}}}$. When $n \geq 1/\delta$, we have $U \leq C_1 (\log n/n)^{\frac{\beta}{2\beta+1}}$ for some absolute constant C_1 .

Proof. Let $\mathcal{E}_1 = \{\|\hat{p} - p\|_\infty \leq C\sqrt{\frac{\log(n/\delta)}{nh}}\}$. On the event \mathcal{E}_1 , since $\sqrt{\frac{\log(n/\delta)}{nh}} < \min(1, \underline{\mu}/C)$, we have

$$\min(p(x_0), \hat{p}(x_0)) \geq \min(p(x_0), p(x_0) - \|\hat{p} - p\|_\infty) \geq \underline{\mu} - \|\hat{p} - p\|_\infty > 0.$$

It then follows from Lagrange's mean value theorem that for any fixed x_0 , there exists some w_{x_0} between $\hat{p}(x_0)$ and $p(x_0)$,

$$\begin{aligned} |\log \hat{p}(x_0) - \log p(x_0)| &= w_{x_0}^{-1} |\hat{p}(x_0) - p(x_0)| \\ &\leq [\min\{\hat{p}(x_0), p(x_0)\}]^{-1} |\hat{p}(x_0) - p(x_0)| \leq \frac{\|\hat{p} - p\|_\infty}{\underline{\mu} - \|\hat{p} - p\|_\infty}. \end{aligned}$$

As a result, it holds on event \mathcal{E}_1 that

$$\|\log \hat{p} - \log p\|_\infty \leq \frac{C\sqrt{\frac{\log(n/\delta)}{nh}}}{\underline{\mu} - C\sqrt{\frac{\log(n/\delta)}{nh}}} = U,$$

and

$$\mathbb{P}(\|\log \hat{p} - \log p\|_\infty \leq U) \geq \mathbb{P}(\|\hat{p} - p\|_\infty \leq C\sqrt{\frac{\log(n/\delta)}{nh}}) \geq 1 - \delta,$$

where the last inequality follows from Lemma A.1 in Tong (2013) (the special case of $d = 1$). Finally when $n \geq 1/\delta$, we have $U = \frac{C\sqrt{\frac{\log(n/\delta)}{nh}}}{\underline{\mu} - C\sqrt{\frac{\log(n/\delta)}{nh}}} \leq C_1 (\log n/n)^{\frac{\beta}{2\beta+1}}$ for some absolute constant C_1 . This completes the proof. \square

Appendix B. About detection condition and Assumption 3

We show that it is possible for densities satisfying Assumption 3 to violate a generalized version of the detection condition defined in Definition 2.3. While the generalized detection condition applies to general (P, f, C^*) as the original one, we narrow its definition to (P_0, r, C_α) which we actually use in the main text.

Definition B.1 (Generalized detection condition). *Let $u(\cdot)$ be a strictly increasing differentiable function on \mathbb{R}^+ with $\lim_{x \rightarrow 0+} u(x) = 0$, a function $r(\cdot)$ is said to satisfy the generalized detection condition with respect to P_0 and $u(\cdot)$ at level (C_α, δ^*) if for any $\delta \in (0, \delta^*)$,*

$$P_0\{C_\alpha \leq r(X) \leq C_\alpha + \delta\} \geq u(\delta). \quad (\text{B.1})$$

The following conditions suffice to make (B.1) fail

$$P_0\{C_\alpha \leq r(X) \leq C_\alpha + k^{-1}\} < u(k^{-1}), \quad k = 1, 2, \dots \quad (\text{B.2})$$

A 1-dimensional toy example that satisfies Assumption 3 and (B.2) (thus violating the generalized detection condition) is given as follows. Assume P_0 and P_1 have the same support $[-1, 1]$. Given $u(\cdot)$ as a strictly increasing differentiable function on \mathbb{R}^+ with $\lim_{x \rightarrow 0+} u(x) = 0$, let $q(x) = \alpha$ for all $x \in [0, 1]$, and set $p(x)$ accordingly such that

$$r(x) = \frac{p(x)}{q(x)} = \begin{cases} 2u^{-1}(1) + 2u^{-1}(\alpha x), & x \in (0, 1], \\ 2u^{-1}(1), & x = 0, \\ 2u^{-1}(1) - v(x), & x \in [-1, 0), \end{cases} \quad (\text{B.3})$$

where $v(\cdot)$ is some positive differentiable function that makes $r(\cdot)$ differentiable at $x = 0$. It follows from (B.3) that $\{x \in [-1, 1] : r(x) \geq 2u^{-1}(1)\} = [0, 1]$, and identity

$$P_0\{r(X) \geq 2u^{-1}(1)\} = \int_{\{x \in [-1, 1] : r(x) \geq 2u^{-1}(1)\}} q(x) dx = \int_{[0, 1]} q(x) dx = \alpha$$

implies $C_\alpha = 2u^{-1}(1)$. As a result, for any $k \in \{1, 2, \dots\}$ we have

$$\{C_\alpha \leq r(X) \leq C_\alpha + k^{-1}\} = \{X \in [0, 1], 2u^{-1}(\alpha X) \leq k^{-1}\} = \{X \in [0, \alpha^{-1}u(0.5k^{-1})]\},$$

and

$$\begin{aligned} P_0\{C_\alpha \leq r(X) \leq C_\alpha + k^{-1}\} &= P_0\{X \in [0, \alpha^{-1}u(0.5k^{-1})]\} = \int_0^{\alpha^{-1}u(0.5k^{-1})} q(x) dx \\ &= \alpha \cdot \alpha^{-1}u(0.5k^{-1}) = u(0.5k^{-1}) < u(k^{-1}) \end{aligned}$$

satisfies (B.2). Note that the above construction makes no assumption about the behavior of $q(\cdot)$ and $p(\cdot)$ on $[-1, 0)$ except the normalization constraints $\int_{[-1, 1]} p dx = \int_{[-1, 1]} q dx = 1$ and $r(\cdot)$ being differentiable on $[-1, 1]$. Thus, there exist p, q , and r that satisfy Assumption 3.

Appendix C. An alternative threshold estimate

This part contains an alternative estimate of threshold C_α that guarantees type I error bound. Based on Chernoff inequality, the following Proposition gives an alternative version of Proposition 2.2. First, we introduce two technical lemmas.

Lemma C.1. *If $G_k \sim \text{Gamma}(k, 1)$, $k > 0$, then for any $\tau \in (0, k)$, we have*

$$\mathbf{P}\{G_k \geq k + \tau\} \leq e^{-\tau^2/(4k)}, \quad \mathbf{P}\{G_k \leq k - \tau\} \leq e^{-\tau^2/(2k)} \leq e^{-\tau^2/(4k)}.$$

Proof of Lemma C.1. For any $\epsilon \in (0, 1)$ and $t \in (0, 1)$, it follows from Chernoff inequality that

$$\mathbf{P}\{G_k \geq (1 + \epsilon)k\} = \mathbf{P}\{e^{G_k} \geq e^{t(1+\epsilon)k}\} \leq \frac{\mathbf{E}(e^{tG_k})}{e^{t(1+\epsilon)k}} = (1 - t)^{-k} e^{-t(1+\epsilon)k}. \quad (\text{C.1})$$

Letting $t = \arg \min_{x \in (0, 1)} (1 - x)^{-k} e^{-x(1+\epsilon)k} = \epsilon/(1 + \epsilon)$ in (C.1) yields

$$\mathbf{P}\{G_k \geq (1 + \epsilon)k\} \leq (1 + \epsilon)^k e^{-\epsilon k} = e^{k(\log(1+\epsilon) - \epsilon)} \leq e^{-k\epsilon^2/4},$$

Likewise, for any $\epsilon \in (0, 1)$ and $s < 0$,

$$\mathbf{P}\{G_k \leq (1 - \epsilon)k\} = \mathbf{P}\{e^{sG_k} \geq e^{s(1-\epsilon)k}\} = (1 - s)^{-k} e^{-s(1-\epsilon)k}. \quad (\text{C.2})$$

Letting $s = \arg \min_{x < 0} (1 - x)^{-k} e^{-x(1-\epsilon)k} = -\epsilon/(1 - \epsilon)$ in (C.2) yields

$$\mathbf{P}\{G_k \leq (1 - \epsilon)k\} \leq (1 - \epsilon)^k e^{\epsilon k} = e^{k(\log(1-\epsilon) + \epsilon)} \leq e^{-k\epsilon^2/2},$$

where the last inequality follows from Taylor expansion

$$\log(1 - \epsilon) + \epsilon = \sum_{i=1}^{\infty} \frac{\epsilon^i}{i} - \epsilon = \sum_{i=2}^{\infty} \frac{\epsilon^i}{i} > \frac{\epsilon^2}{2}, \quad \forall 0 < \epsilon < 1.$$

Take $\epsilon = \tau/k$, the conclusion of the lemma follows. \square

Lemma C.2. *Let $B \sim \text{Beta}(a, b)$, and $\mu = \mathbf{E}(B) = a/(a + b)$. For any $t \in (0, 1 - \mu)$,*

$$\mathbf{P}\{B > \mu + t\} \leq 2 \exp \left[-4^{-1} \left\{ \frac{(a + b)t}{\sqrt{b(\mu + t) + \sqrt{a(1 - \mu - t)}}} \right\}^2 \right].$$

Proof of Lemma C.2. By properties of beta distribution, we can represent B as

$$B = \frac{G_a}{G_a + G_b}, \quad \text{where } G_a \sim \Gamma(a, 1), G_b \sim \Gamma(b, 1) \text{ are independent.}$$

For any $t > 0$ and constant C such that $a(1 - \mu - t) < C < b(\mu + t)$, we have

$$\begin{aligned} \mathbb{P}(B \leq \mu + t) &= \mathbb{P}\{(1 - \mu - t)G_a \leq (\mu + t)G_b\} \geq \mathbb{P}\{(1 - \mu - t)G_a \leq C \leq (\mu + t)G_b\} \\ &= \mathbb{P}\{(1 - \mu - t)G_a \leq C\} \mathbb{P}\{C \leq (\mu + t)G_b\} \\ &= \mathbb{P}\left(G_a \leq \frac{C}{1 - \mu - t}\right) \mathbb{P}\left(G_b \geq \frac{C}{\mu + t}\right) \\ &= \left\{1 - \mathbb{P}\left(G_a > \frac{C}{1 - \mu - t}\right)\right\} \left\{1 - \mathbb{P}\left(G_b > \frac{C}{\mu + t}\right)\right\} \\ &\geq 1 - \mathbb{P}\left(G_a > \frac{C}{1 - \mu - t}\right) - \mathbb{P}\left(G_b > \frac{C}{\mu + t}\right), \end{aligned} \quad (\text{C.3})$$

where by Lemma C.1

$$\begin{aligned} \mathbb{P}\left(G_a > \frac{C}{1 - \mu - t}\right) &\leq \mathbb{P}\left\{G_a > a + \left(\frac{C}{1 - \mu - t} - a\right)\right\} \leq e^{-\left(\frac{C}{1 - \mu - t} - a\right)^2 (4a)^{-1}}, \\ \mathbb{P}\left(G_b < \frac{C}{\mu + t}\right) &\leq \mathbb{P}\left\{G_b < b - \left(b - \frac{C}{\mu + t}\right)\right\} \leq e^{-\left(b - \frac{C}{\mu + t}\right)^2 (4b)^{-1}}. \end{aligned} \quad (\text{C.4})$$

Letting

$$C = \frac{(1 - \mu - t)(\mu + t)(a\sqrt{b} + \sqrt{ab})}{\sqrt{b}(\mu + t) + \sqrt{a}(1 - \mu - t)}$$

in (C.3) such that the two exponents in (C.4) equal

$$\left(\frac{C}{1 - \mu - t} - a\right)^2 (4a)^{-1} = \left(b - \frac{C}{\mu + t}\right)^2 (4b)^{-1} = 4^{-1} \left\{ \frac{(a + b)t}{\sqrt{b}(\mu + t) + \sqrt{a}(1 - \mu - t)} \right\}^2$$

yields

$$\begin{aligned} \mathbb{P}(B > \mu + t) &= 1 - \mathbb{P}(B \leq \mu + t) \leq \mathbb{P}\left(G_a > \frac{C}{1 - \mu - t}\right) + \mathbb{P}\left(G_b > \frac{C}{\mu + t}\right) \\ &\leq e^{-\left(\frac{C}{1 - \mu - t} - a\right)^2 (4a)^{-1}} + e^{-\left(b - \frac{C}{\mu + t}\right)^2 (4b)^{-1}} \\ &= 2 \exp \left[-4^{-1} \left\{ \frac{(a + b)t}{\sqrt{b}(\mu + t) + \sqrt{a}(1 - \mu - t)} \right\}^2 \right]. \end{aligned}$$

This completes the proof. \square

Proposition C.1. Let $\hat{r}(\cdot)$ be any estimate of the density ratio function. For any $\delta_3 \in (0, 1)$ and $k \in \{1, \dots, m_3\}$, the type I error of classifier $\hat{\phi}_k$ defined in (2.1) satisfies

$$\mathbb{P}\left\{R_0(\hat{\phi}_k) > h(\delta_3, m_3, k)\right\} \leq \delta_3,$$

where

$$h(\delta_3, m_3, k) = \frac{m_3 + 1 - k + 2\sqrt{\log(2/\delta_3)}\sqrt{m_3 - k + 1}}{m_3 + 1 + 2\sqrt{\log(2/\delta_3)}\left(\sqrt{m_3 - k + 1} - \sqrt{k}\right)}.$$

Proof. Let B be a realization from $\text{Beta}(k, m_3 + 1 - k)$. It follows from Proposition 2.1 that

$$\begin{aligned} \mathbb{P}\{R_0(\hat{\phi}_k) > h(\delta_3, m_3, k)\} &\leq \text{Beta.cdf}_{k, m_3 + 1 - k}\{1 - h(\delta_3, m_3, k)\} \\ &= \mathbb{P}\{B \leq 1 - h(\delta_3, m_3, k)\} = \mathbb{P}\{1 - B \geq h(\delta_3, m_3, k)\} \end{aligned}$$

for any $k \in \{1, \dots, m_3\}$ and \hat{r} , with $1 - B \sim \text{Beta}(m_3 + 1 - k, k)$. Letting $a = m_3 + 1 - k$, $b = k$, and

$$t = \frac{2\sqrt{\log(2/\delta_3)}\left\{(m_3 + 1 - k)\sqrt{k} + k\sqrt{m_3 + 1 - k}\right\}}{(m_3 + 1)\left\{m_3 + 1 + 2\sqrt{\log(2/\delta_3)}\left(\sqrt{m_3 + 1 - k} - \sqrt{k}\right)\right\}}.$$

in Lemma C.2 yields

$$\mathbb{P}\left\{R_0(\hat{\phi}_k) > h(\delta_3, m_3, k)\right\} \leq \delta_3.$$

This completes the proof. \square

Proposition C.1 implies that $h(\delta_3, m_3, k) \leq \alpha$ is a sufficient condition for the classifier $\hat{\phi}_k$ (defined in (2.2)) to satisfy NP Oracle Inequality (1) ($k = 1, \dots, m_3$). Let $\mathcal{K}_{\text{chem}} = \{k \in \{1, \dots, m_3\} : h(\delta_3, m_3, k) \leq \alpha\}$. Similar to Proposition 2.3 we can prove $\mathcal{K}_{\text{chem}}$ to be non-empty as long as m_3 is greater than some threshold.

Numerical investigation shows that for most combinations of (α, δ_3, m_3) with non-empty \mathcal{K} and $\mathcal{K}_{\text{chem}}$, $k_{\min} = \min_k \mathcal{K}$ as defined in (2.7) is better than $k_{\text{chem}} = \min_k \mathcal{K}_{\text{chem}}$ in the sense that $\hat{\phi}_{k_{\min}}$ has a lower type II error than $\hat{\phi}_{k_{\text{chem}}}$ as a result of $k_{\min} < k_{\text{chem}}$. Specifically, for each $\delta_3 \in \{0.01 \cdot \iota\}_{\iota=1}^{10}$, the number of $\{k_{\text{chem}} < k_{\min}\}$ out of 100 combinations of $(\alpha, m_3) \in \{0.01 \cdot \iota\}_{\iota=1}^{10} \times \{100 \cdot \iota\}_{\iota=1}^{10}$ is reported as follows. Only when δ_3 gets very close to 0 is k_{chem} preferred to k_{\min} .

δ_3	0.01	0.02	0.03	0.04	0.05	0.06	0.07	0.08	0.09	0.10
$\#\{k_{\text{chem}} < k_{\min}\}$	83	70	49	4	0	0	0	0	0	0

Appendix D. An example violating detection condition in Tong (2013)

Definition D.1. A function $f(\cdot)$ is said to satisfy 'detection condition Tong (2013)' of order γ with respect to P (i.e., $X \sim P$) at level (C^*, δ^*) if there exists a positive constant M , such that for any $\delta \in (0, \delta^*)$,

$$P\{C^* \leq f(X) \leq C^* + \delta\} \geq M\delta^\gamma, \quad P\{C^* - \delta \leq f(X) \leq C^*\} \geq M\delta^\gamma.$$

Our target is to construct an $f(\cdot) = p(\cdot)/q(\cdot)$ function, such that

1. there exists some positive constant M_1 such that

$$P_0\{C^* \leq f(X) \leq C^* + \delta\} \geq M_1\delta^\gamma$$

for any $\delta \in (0, \delta^*)$;

2. there exists no M_2 such that

$$P_0\{C^* - \delta \leq f(X) \leq C^*\} \geq M_2 \delta^2$$

for any $\delta \in (0, \delta^*)$.

Let

$$q(x) = \begin{cases} \frac{5}{8}, & x \in [-1, 0), \\ \frac{5}{8} - \frac{x}{2}, & x \in [0, 1], \end{cases}$$

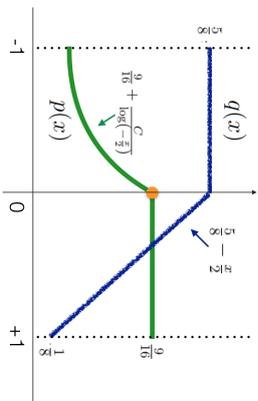

$$p(x) = \begin{cases} \frac{9}{16} + \frac{C}{\log(-\frac{x}{2})}, & x \in [-1, 0), \\ \frac{9}{16}, & x \in [0, 1]. \end{cases}$$

where

$$C = -\frac{1}{8} \left(\int_{-1}^0 \frac{1}{\log(-\frac{x}{2})} dx \right)^{-1} \approx 0.165.$$

such that

$$\int_{-1}^1 p(x) dx = \int_{-1}^1 \left[\frac{9}{16} + I_{(x \in [-1, 0])} \cdot \frac{C}{\log(-\frac{x}{2})} \right] dx = 1.$$

$$f(x) = \frac{p(x)}{q(x)} = \begin{cases} \frac{9}{10} + \frac{8C}{5 \log(-\frac{x}{2})}, & x \in [-1, 0) \\ \frac{9}{10 - 8x}, & x \in [0, 1] \end{cases}, \tag{D.1}$$

We have

Let $C^* = \frac{9}{10}$ and we have $\{x : f(x) \leq C^*\} \subset [-1, 0]$ and thus

$$P_0(C^* - \delta \leq f(X) \leq C^*) = P_0(-2e^{-\frac{8C}{5\delta}} \leq X \leq 0) = \frac{5}{8} \cdot 2e^{-\frac{8C}{5\delta}} = \frac{5e^{-\frac{8C}{5\delta}}}{4}.$$

For any constant γ , we have

$$\lim_{\delta \rightarrow 0^+} \frac{e^{-\frac{8C}{5\delta}}}{\delta^\gamma} = \lim_{\kappa = \delta^{-1} \rightarrow \infty} e^{-\frac{8C}{5} \kappa} \kappa^\gamma = 0.$$

Therefore, no such M_2 could possibly satisfy (b).

On the other hand, assume $\delta < 1$ without loss of generality. It follows from $\{x : f(x) \geq C^*\} \subset [0, 1]$ and $\frac{25\delta}{18+20\delta} \geq \frac{\delta}{2}$ that

$$\begin{aligned} P_0(C^* \leq f(X) \leq C^* + \delta) &= P_0\left(C^* \leq \frac{9}{10 - 8X} \leq C^* + \delta\right) \\ &= P_0\left(0 \leq X \leq \frac{25\delta}{18 + 20\delta}\right) \geq P_0\left(0 \leq X \leq \frac{\delta}{2}\right) = \int_0^{\delta/2} \left(\frac{5-x}{8} - \frac{x}{2}\right) dx \\ &= \left(\frac{5x}{8} - \frac{x^2}{4}\right) \Big|_0^{\delta/2} = \frac{5\delta}{16} - \frac{\delta^2}{16} \geq \frac{5\delta}{16} - \frac{\delta}{16} = \frac{\delta}{4}, \end{aligned}$$

satisfying (a) for constant $M = 1/4$ and $\bar{\gamma} = 1$.

This completes the construction of the density functions p and q such that the current detection condition is met but that in Tong (2013) is violated.

Abstract

We consider statistical as well as algorithmic aspects of solving large-scale least-squares (LS) problems using randomized sketching algorithms. For a LS problem with input data $(X, Y) \in \mathbb{R}^{n \times p} \times \mathbb{R}^n$, sketching algorithms use a “sketching matrix,” $S \in \mathbb{R}^{r \times n}$, where $r \ll n$. Then, rather than solving the LS problem using the full data (X, Y) , sketching algorithms solve the LS problem using only the “sketched data” (SX, SY) . Prior work has typically adopted an *algorithmic perspective*, in that it has made no statistical assumptions on the input X and Y , and instead it has been assumed that the data (X, Y) are fixed and worst-case (WC). Prior results show that, when using sketching matrices such as random projections and leverage-score sampling algorithms, with $p \lesssim r \ll n$, the WC error is the same as solving the original problem, up to a small constant. From a *statistical perspective*, we typically consider the mean-squared error performance of randomized sketching algorithms, when data (X, Y) are generated according to a statistical linear model $Y = X\beta + \epsilon$, where ϵ is a noise process. In this paper, we provide a rigorous comparison of both perspectives leading to insights on how they differ. To do this, we first develop a framework for assessing, in a unified manner, algorithmic and statistical aspects of randomized sketching methods. We then consider the statistical prediction efficiency (PE) and the statistical residual efficiency (RE) of the sketched LS estimator; and we use our framework to provide upper bounds for several types of random projection and random sampling sketching algorithms. Among other results, we show that the RE can be upper bounded when $p \lesssim r \ll n$ while the PE typically requires the sample size r to be substantially larger. Lower bounds developed in subsequent results show that our upper bounds on PE can not be improved.¹

Keywords: algorithmic leveraging, randomized linear algebra, sketching, random projection, statistical leverage, statistical efficiency

1. Introduction

Recent work in large-scale data analysis has focused on developing so-called sketching algorithms: given a data set and an objective function of interest, construct a small “sketch”

1. A preliminary version of this paper appeared as Raskutti and Mahoney (2014, 2015).

of the full data set, e.g., by using random sampling or random projection methods, and use that sketch as a surrogate to perform computations of interest for the full data set (see Mahoney (2011) for a review). Most effort in this area has adopted an *algorithmic perspective*, whereby one shows that, when the sketches are constructed appropriately, one can obtain answers that are approximately as good as the exact answer for the input data at hand, in less time than would be required to compute an exact answer for the data at hand. In statistics, however, one is often more interested in how well a procedure performs relative to an hypothesized model than how well it performs on the particular data set at hand. Thus an important question to consider is whether the insights from the algorithmic perspective of sketching carry over to the statistical setting.

Thus, in this paper, we develop a unified approach that considers both the *statistical perspective* as well as *algorithmic perspective* on recently-developed randomized sketching algorithms, and we provide bounds on two statistical objectives for several types of random projection and random sampling sketching algorithms.

1.1 Overview of the Problem

The problem we consider in this paper is the ordinary least-squares (LS or OLS) problem: given as input a matrix $X \in \mathbb{R}^{n \times p}$ of observed features or covariates and a vector $Y \in \mathbb{R}^n$ of observed responses, return as output a vector β_{OLS} that solves the following optimization problem:

$$\beta_{OLS} = \arg \min_{\beta \in \mathbb{R}^p} \|Y - X\beta\|_2^2. \quad (1)$$

We will assume that n and p are both very large, with $n \gg p$, and for simplicity we will assume $\text{rank}(X) = p$, e.g., to ensure a unique full-dimensional solution. The OLS solution, $\beta_{OLS} = (X^T X)^{-1} X^T Y$, has a number of well-known desirable statistical properties (Chatterjee and Hadi, 1988); and it is also well-known that the running time or computational complexity for this problem is $O(np^2)$ (Golub and Loan, 1996).² For many modern applications, however, n may be on the order of $10^6 - 10^9$ and p may be on the order of $10^3 - 10^4$, and thus computing the exact LS solution with traditional $O(np^2)$ methods can be computationally challenging. This, coupled with the observation that approximate answers often suffice for downstream applications, has led to a large body of work on developing fast approximation algorithms to the LS problem (Mahoney, 2011).

One very popular approach to reducing computation is to perform LS on a carefully-constructed “sketch” of the full data set. That is, rather than computing a LS estimator from Problem (1) from the full data (X, Y) , generate “sketched data” (SX, SY) where $S \in \mathbb{R}^{r \times n}$, with $r \ll n$, is a “sketching matrix,” and then compute a LS estimator from the following sketched problem:

$$\beta_S \in \arg \min_{\beta \in \mathbb{R}^p} \|SY - SX\beta\|_2^2. \quad (2)$$

2. That is, $O(np^2)$ time suffices to compute the LS solution from Problem (1) for arbitrary or worst-case input, with, e.g., the Cholesky Decomposition on the normal equations, with a QR decomposition, or with the Singular Value Decomposition (Golub and Loan, 1996).

Once the sketching operation has been performed, the additional computational complexity of β_S is $O(nr^2)$, i.e., simply call a traditional LS solver on the sketched problem. Thus, when using a sketching algorithm, two criteria are important: first, ensure the accuracy of the sketched LS estimator is comparable to, e.g., not much worse, than the performance of the original LS estimator; and second, ensure that computing and applying the sketching matrix S is not too computationally intensive, e.g., that is faster than solving the original problem exactly.

1.2 Prior Results

Random sampling and random projections provide two approaches to construct sketching matrices S that satisfy both of these criteria and that have received attention recently in the computer science community. Very loosely speaking, a random projection matrix S is a dense matrix,³ where each entry is a mean-zero bounded-variance Gaussian or Rademacher random variable, although other constructions based on randomized Hadamard transformations are also of interest; and a random sampling matrix S is a very sparse matrix that has exactly 1 non-zero entry (which typically equals one multiplied by a rescaling factor) in each row, where that one non-zero can be chosen uniformly, non-uniformly based on hypotheses about the data, or non-uniformly based on empirical statistics of the data such as the leverage scores of the matrix X . In particular, note that a sketch constructed from an $r \times n$ random projection matrix S consists of r linear combinations of most or all of the rows of (X, Y) , and a sketch constructed from a random sampling matrix S consists of r typically-rescaled rows of (X, Y) . Random projection algorithms have received a great deal of attention more generally, largely due to their connections with the Johnson-Lindenstrauss lemma (Johnson and Lindenstrauss, 1984) and its extensions; and random sampling algorithms have received a great deal of attention, largely due to their applications in large-scale data analysis applications (Mahoney and Drineas, 2009). A detailed overview of random projection and random sampling algorithms for matrix problems may be found in the recent monograph of Mahoney (2011). Here, we briefly summarize the most relevant aspects of the theory.

In terms of running time guarantees, the running time bottleneck for random projection algorithms for the LS problem is the application of the projection to the input data, i.e., actually performing the matrix-matrix multiplication to implement the projection and compute the sketch. By using fast Hadamard-based random projections, however, Drineas et al. (2011) developed a random projection algorithm that runs on arbitrary or worst-case input in $o(nr^2)$ time. (See Drineas et al. (2011) for a precise statement of the running time.) As for random sampling, it is trivial to implement uniform random sampling, but it is very easy to show examples of input data on which uniform sampling performs very poorly. On the other hand, Drineas et al. (2006b, 2012) have shown that if the random sampling is performed with respect to nonuniform importance sampling probabilities that depend on the *empirical statistical leverage scores* of the input matrix X , i.e., the diagonal entries of the *hat matrix* $H = X(X^T X)^{-1} X^T$, then one obtains a random sampling algorithm that achieves much better results for arbitrary or worst-case input.

3. The reader should, however, be aware of recently-developed input-sparsity time random projection methods (Clarkson and Woodruff, 2013; Meng and Mahoney, 2013; Nelson and Hry, 2013).

Leverage scores have a long history in robust statistics and experimental design. In

the robust statistics community, samples with high leverage scores are typically flagged as potential outliers (see, e.g., Chatterjee and Hadi (2006, 1988); Hampel et al. (1986); Hoaglin and Weisich (1978); Huber and Ronchetti (1981)). In the experimental design community, samples with high leverage have been shown to improve overall efficiency, provided that the underlying statistical model is accurate (see, e.g., Royall (1970); Zaslavsky et al. (2008)). This should be contrasted with their use in theoretical computer science. From the algorithmic perspective of worst-case analysis, that was adopted by Drineas et al. (2011) and Drineas et al. (2012), samples with high leverage tend to contain the most important information for subsampling/sketching, and thus it is beneficial for worst-case analysis to bias the random sample to include samples with large statistical leverage scores or to rotate to a random basis where the leverage scores are approximately uniformized.

The running-time bottleneck for this leverage-based random sampling algorithm is the computation of the leverage scores of the input data; and the obvious well-known algorithm for this involves $O(nr^2)$ time to perform a QR decomposition to compute an orthogonal basis for X (Golub and Loan, 1996). By using fast Hadamard-based random projections, however, Drineas et al. (2012) showed that one can compute approximate QR decompositions and thus approximate leverage scores in $o(nr^2)$ time, and (based on previous work (Drineas et al., 2006b)) this immediately implies a leverage-based random sampling algorithm that runs on arbitrary or worst-case input in $o(nr^2)$ time (Drineas et al., 2012). Readers interested in the practical performance of these randomized algorithms should consult BENDENPIK (Avron et al., 2010) or ISRN (Meng et al., 2014).

In terms of accuracy guarantees, both Drineas et al. (2011) and Drineas et al. (2012) prove that their respective random projection and leverage-based random sampling LS sketching algorithms each achieve the following worst-case (WC) error guarantee: for any arbitrary (X, Y) ,

$$\|Y - X\beta_S\|_2^2 \leq (1 + \kappa) \|Y - X\beta_{OLS}\|_2^2, \quad (3)$$

with high probability for some pre-specified error parameter $\kappa \in (0, 1)$.⁴ This $1 + \kappa$ relative-error guarantee⁵ is extremely strong, and it is applicable to arbitrary or worst-case input. That is, whereas in statistics one typically assumes a model, e.g., a standard linear model on Y ,

$$Y = X\beta + \epsilon, \quad (4)$$

where $\beta \in \mathbb{R}^p$ is the true parameter and $\epsilon \in \mathbb{R}^n$ is a standardized noise vector, with $\mathbb{E}[\epsilon] = 0$ and $\mathbb{E}[\epsilon\epsilon^T] = I_{n \times n}$, in Drineas et al. (2011) and Drineas et al. (2012) no statistical model is assumed on X and Y , and thus the running time and quality-of-approximation bounds apply to any arbitrary (X, Y) input data.

1.3 Our Approach and Main Results

In this paper, we adopt a statistical perspective on these randomized sketching algorithms, and we address the following fundamental questions. First, under a standard linear model, e.g., as given in Eqn. (4), what properties of a sketching matrix S are sufficient to ensure

4. The quantity $\|\beta_S - \beta_{OLS}\|_2^2$ is also bounded by Drineas et al. (2011) and Drineas et al. (2012).

5. The nonstandard parameter κ is used here for the error parameter since ϵ is used below to refer to the noise or error process.

low statistical error, e.g., mean-squared, error? Second, how do existing random projection algorithms and leverage-based random sampling algorithms perform by this statistical measure? Third, how does this relate to the properties of a sketching matrix S that are sufficient to ensure low worst-case error, e.g., of the form of Eqn. (3), as has been established previously in Drineas et al. (2011, 2012); Mahoney (2011)? We address these related questions in a number of steps.

In Section 2, we will present a framework for evaluating the algorithmic and statistical properties of randomized sketching methods in a unified manner; and we will show that providing worst-case error bounds of the form of Eqn. (3) and providing bounds on two related statistical objectives boil down to controlling different structural properties of how the sketching matrix S interacts with the left singular subspace of the design matrix. In particular, we will consider the oblique projection matrix, $\Pi_S^U = U(SU)^\dagger S$, where $(\cdot)^\dagger$ denotes the Moore-Penrose pseudo-inverse of a matrix and U is the left singular matrix of X . This framework will allow us to draw a comparison between the worst-case error and two related statistical efficiency criteria, the statistical prediction efficiency (PE) (which is based on the prediction error $\mathbb{E}\|X(\hat{\beta} - \beta)\|_2^2$) and which is given in Eqn. (7) below) and the statistical residual efficiency (RE) (which is based on residual error $\mathbb{E}\|Y - X\hat{\beta}\|_2^2$) and which is given in Eqn. (8) below); and it will allow us to provide sufficient conditions that any sketching matrix S must satisfy in order to achieve performance guarantees for these two statistical objectives.

In Section 3, we will present our main theoretical results, which consist of bounds for these two statistical quantities for variants of random sampling and random projection sketching algorithms. In particular, we provide upper bounds on the PE and RE (as well as the worst-case WC) for four sketching schemes: (1) an approximate leverage-based random sampling algorithm, as is analyzed by Drineas et al. (2012); (2) a variant of leverage-based random sampling, where the random samples are *not* re-scaled prior to their inclusion in the sketch, as is considered by Ma et al. (2014, 2015); (3) a vanilla random projection algorithm, where S is a random matrix containing i.i.d. Gaussian or Rademacher random variables, as is popular in statistics and scientific computing; and (4) a random projection algorithm, where S is a random Hadamard-based random projection, as analyzed in Boutsidis and Gittens (2013). For sketching schemes (1), (3), and (4), our upper bounds for each of the two measures of statistical efficiency are identical up to constants; and they show that the RE scales as $1 + \frac{p}{r}$, while the PE scales as $\frac{p}{r}$. In particular, this means that it is possible to obtain good bounds for the RE when $p \lesssim r \ll n$ (in a manner similar to the sampling complexity of the WC bounds); but in order to obtain even near-constant bounds for PE, r must be at least of constant order compared to n . We then present a lower bound developed in subsequent work by Pilanci and Wainwright (2014) which shows that under general conditions on S , our upper bound of $\frac{p}{r}$ for PE can not be improved. For the sketching scheme (2), we show, on the other hand, that under the strong assumption that there are k “large” leverage scores and the remaining $n - k$ are “small,” then the WC scales as $1 + \frac{p}{r}$, the RE scales as $1 + \frac{2pk}{r}$, and the PE scales as $\frac{k}{r}$. That is, sharper bounds are possible for leverage-score sampling without re-scaling in the statistical setting, but much stronger assumptions are needed on the input data.

In Section 4, we will supplement our theoretical results by presenting our main empirical results, which consist of an evaluation of the complementary properties of random sampling

versus random projection methods. Our empirical results support our theoretical results, and they also show that for r larger than p but much closer to p than n , projection-based methods tend to out-perform sampling-based methods, while for r significantly larger than p , our leverage-based sampling methods perform slightly better. In Section 5, we will provide a brief discussion and conclusion and we provide proofs of our main results in the Appendix.

1.4 Additional Related Work

Very recently Ma et al. (2014) considered statistical aspects of leverage-based sampling algorithms (called *algorithmic leveraging* in Ma et al. (2014)). Assuming a standard linear model on Y of the form of Eqn. (4), the authors developed first-order Taylor approximations to the statistical relative efficiency of different estimators computed with leverage-based sampling algorithms, and they verified the quality of those approximations with computations on real and synthetic data. Taken as a whole, their results suggest that, if one is interested in the statistical performance of these randomized sketching algorithms, then there are nontrivial trade-offs that are not taken into account by standard worst-case analysis. Their approach, however, does not immediately apply to random projections or other more general sketching matrices. Further, the realm of applicability of the first-order Taylor approximation was not precisely quantified, and they left open the question of structural characterizations of random sketching matrices that were sufficient to ensure good statistical properties on the sketched data. We address these issues in this paper.

After the appearance of the original technical report version of this paper (Raskutti and Mahoney, 2014), we were made aware of subsequent work by Pilanci and Wainwright (2014), who also consider a statistical perspective on sketching. Amongst other results, they develop a lower bound which confirms that using a single randomized sketching matrix S can not achieve a PE better than $\frac{p}{r}$. This lower bound complements our upper bounds developed in this paper. Their main focus is to use this insight to develop an iterative sketching scheme which yields bounds on the PE when an $r \times n$ sketch is applied repeatedly.

2. General Framework and Structural Results

In this section, we develop a framework that allows us to view the algorithmic and statistical perspectives on LS problems from a common perspective. We then use this framework to show that existing worst-case bounds as well as our novel statistical bounds for the mean-squared errors can be expressed in terms of different structural conditions on how the sketching matrix S interacts with the data (X, Y) .

2.1 A Statistical-Algorithmic Framework

Recall that we are given as input a data set, $(X, Y) \in \mathbb{R}^{n \times p} \times \mathbb{R}^n$, and the objective function of interest is the standard LS objective, as given in Eqn. (1). Since we are assuming, without loss of generality, that $\text{rank}(X) = p$, we have that

$$\beta_{OLS} = X^\dagger Y = (X^T X)^{-1} X^T Y, \quad (5)$$

where $(\cdot)^{\dagger}$ denotes the Moore-Penrose pseudo-inverse of a matrix, and where the second equality follows since $\text{rank}(X) = p$.

To present our framework and objectives, let $S \in \mathbb{R}^{r \times n}$ denote an *arbitrary* sketching matrix. That is, although we will be most interested in sketches constructed from random sampling or random projection operations, for now we let S be *any* $r \times n$ matrix. Then, we are interested in analyzing the performance of objectives characterizing the quality of a “sketched” LS objective, as given in Eqn (2), where again we are interested in solutions of the form

$$\beta_S = (SX)^{\dagger}SY. \quad (6)$$

(We emphasize that this does *not* in general equal $((SX)^T SX)^{-1}(SX)^T SY$, since the inverse will *not* exist if the sketching process does not preserve rank.) Our goal here is to compare the performance of β_S to β_{OLS} . We will do so by considering three related performance criteria, two of a statistical flavor, and one of a more algorithmic or worst-case flavor.

From a statistical perspective, it is common to assume a standard linear model on Y ,

$$Y = X\beta + \epsilon,$$

where we remind the reader that $\beta \in \mathbb{R}^p$ is the true parameter and $\epsilon \in \mathbb{R}^n$ is a standardized noise vector, with $\mathbb{E}[\epsilon] = 0$ and $\mathbb{E}[\epsilon\epsilon^T] = I_{n \times n}$. From this statistical perspective, we will consider the following two criteria.

- The first statistical criterion we consider is the *prediction efficiency* (PE), defined as follows:

$$C_{PE}(S) = \frac{\mathbb{E}[\|X(\beta - \beta_S)\|_2^2]}{\mathbb{E}[\|X(\beta - \beta_{OLS})\|_2^2]}, \quad (7)$$

where the expectation $\mathbb{E}[\cdot]$ is taken over the random noise ϵ .

- The second statistical criterion we consider is the *residual efficiency* (RE), defined as follows:

$$C_{RE}(S) = \frac{\mathbb{E}[\|Y - X\beta_S\|_2^2]}{\mathbb{E}[\|Y - X\beta_{OLS}\|_2^2]}, \quad (8)$$

where, again, the expectation $\mathbb{E}[\cdot]$ is taken over the random noise ϵ .

Recall that the standard relative statistical efficiency for two estimators β_1 and β_2 is defined as $\text{eff}(\beta_1, \beta_2) = \frac{\text{Var}(\beta_2)}{\text{Var}(\beta_1)}$, where $\text{Var}(\cdot)$ denotes the variance of the estimator (see e.g., Lehmann (1998)). For the PE, we have replaced the variance of each estimator by the mean-squared prediction error. For the RE, we use the term residual since for any estimator $\hat{\beta}$, $Y - X\hat{\beta}$ are the residuals for estimating Y .

From an algorithmic perspective, there is no noise process ϵ . Instead, X and Y are arbitrary, and β is simply computed from Eqn (5). To draw a parallel with the usual statistical generative process, however, and to understand better the relationship between various objectives, consider “defining” Y in terms of X by the following “linear model”:

$$Y = X\beta + \epsilon,$$

where $\beta \in \mathbb{R}^p$ and $\epsilon \in \mathbb{R}^n$. Importantly, β and ϵ here represent different quantities than in the usual statistical setting. Rather than ϵ representing a noise process and β representing

a “true parameter” that is observed through a noisy Y , here in the algorithmic setting, we will take advantage of the rank-nullity theorem in linear algebra to relate X and Y .⁶ To define a “worst case model” $Y = X\beta + \epsilon$ for the algorithmic setting, one can view the “noise” process ϵ to consist of any vector that lies in the null-space of X^T . Then, since the choice of $\beta \in \mathbb{R}^p$ is arbitrary, one can construct any arbitrary or worst-case input data Y . From this algorithmic case, we will consider the following criterion.

- The algorithmic criterion we consider is the *worst-case* (WC) error, defined as follows:

$$C_{WC}(S) = \sup_Y \frac{\|Y - X\beta_S\|_2^2}{\|Y - X\beta_{OLS}\|_2^2}. \quad (9)$$

This criterion is worst-case since we take a supremum Y , and it is the performance criterion that is analyzed in Drineas et al. (2011) and Drineas et al. (2012), as bounded in Eqn. (3).

Writing Y as $X\beta + \epsilon$, where $X^T\epsilon = 0$, the WC error can be re-expressed as:

$$C_{WC}(S) = \sup_{Y=X\beta+\epsilon, X^T\epsilon=0} \frac{\|Y - X\beta_S\|_2^2}{\|Y - X\beta_{OLS}\|_2^2}.$$

Hence, in the worst-case algorithmic setup, we take a supremum over ϵ , where $X^T\epsilon = 0$, whereas in the statistical setup, we take an expectation over ϵ where $\mathbb{E}[\epsilon] = 0$.

Before proceeding, several other comments about this algorithmic-statistical framework and our objectives are worth mentioning.

- The most important distinction between the algorithmic approach and the statistical approach is how the data is assumed to be generated. For the statistical approach, (X, Y) are assumed to be generated by a standard Gaussian linear model and the goal is to estimate a true parameter β while for the algorithmic approach (X, Y) are not assumed to follow any statistical model and the goal is to do prediction on Y rather than estimate a true parameter β . Since ordinary least-squares is often run in the context of solving a statistical inference problem, we believe this distinction is important and focus in this article more on the implications for the statistical perspective.
- From the perspective of our two linear models, we have that $\beta_{OLS} = \beta + (X^T X)^{-1} X^T \epsilon$. In the statistical setting, since $\mathbb{E}[\epsilon\epsilon^T] = I_{n \times n}$, it follows that β_{OLS} is a random variable with $\mathbb{E}[\beta_{OLS}] = \beta$ and $\mathbb{E}[(\beta - \beta_{OLS})(\beta - \beta_{OLS})^T] = (X^T X)^{-1}$. In the algorithmic setting, on the other hand, since $X^T\epsilon = 0$, it follows that $\beta_{OLS} = \beta$.
- $C_{RE}(S)$ is a statistical analogue of the worst-case algorithmic objective $C_{WC}(S)$, since both consider the ratio of the metrics $\frac{\|Y - X\beta_S\|_2^2}{\|Y - X\beta_{OLS}\|_2^2}$. The difference is that a sup over Y in the algorithmic setting is replaced by an expectation over noise ϵ in the statistical

⁶ The rank-nullity theorem asserts that given any matrix $X \in \mathbb{R}^{n \times p}$ and vector $Y \in \mathbb{R}^n$, there exists a unique decomposition $Y = X\beta + \epsilon$, where β is the projection of Y on to the range space of X^T and $\epsilon = Y - X\beta$ lies in the null-space of X^T (Meyer, 2000).

setting. A natural question is whether there is an algorithmic analogue of $C_{PE}(S)$. Such a performance metric would be:

$$\sup_Y \frac{\|X(\beta - \beta_S)\|_2^2}{\|X(\beta - \beta_{OLS})\|_2^2}, \quad (10)$$

where β is the projection of Y on to the range space of X^T . However, since $\beta_{OLS} = \beta + (X^T X)^{-1} X^T \epsilon$ and since $X^T \epsilon = 0$, $\beta_{OLS} = \beta$ in the algorithmic setting, the denominator of Eqn. (10) equals zero, and thus the objective in Eqn. (10) is not well-defined. The ‘‘difficulty’’ of computing or approximating this objective parallels our results below that show that approximating $C_{PE}(S)$ is much more challenging (in terms of the number of samples needed) than approximating $C_{RE}(S)$.

- In the algorithmic setting, the sketching matrix S and the objective $C_{WC}(S)$ can depend on X and Y in any arbitrary way, but in the following we consider only sketching matrices that are either independent of both X and Y or depend only on X (e.g., via the statistical leverage scores of X). In the statistical setting, S is allowed to depend on X , but not on Y , as any dependence of S on Y might introduce correlation between the sketching matrix and the noise variable ϵ . Removing this restriction is of interest, especially since one can obtain WC bounds of the form Eqn. (3) by constructing S by randomly sampling according to an importance sampling distribution that depends on the *influence scores*—essentially the leverage scores of the matrix X augmented with $-Y$ as an additional column—of the (X, Y) pair.

- Both $C_{PE}(S)$ and $C_{RE}(S)$ are qualitatively related to quantities analyzed by Ma et al. (2014, 2015). In addition, $C_{WC}(S)$ is qualitatively similar to $\text{Cov}(\hat{\beta})Y$ in Ma et al. (2014, 2015), since in the algorithmic setting Y is treated as fixed; and $C_{RE}(S)$ is qualitatively similar to $\text{Cov}(\hat{\beta})$ in Ma et al. (2014, 2015), since in the statistical setting Y is treated as random and coming from a linear model. That being said, the metrics and results we present in this paper are not directly comparable to those of Ma et al. (2014, 2015) since, e.g., they had a slightly different setup than we have here, and since they used a first-order Taylor approximation while we do not.

2.2 Structural Results on Sketching Matrices

We are now ready to develop structural conditions characterizing how the sketching matrix S interacts with the data matrix X that will allow us to provide upper bounds for the quantities $C_{WC}(S)$, $C_{PE}(S)$, and $C_{RE}(S)$. To do so, recall that given the data matrix X , we can express the singular value decomposition of X as $X = U\Sigma V^T$, where $U \in \mathbb{R}^{n \times p}$ is an orthogonal matrix, i.e., $U^T U = I_{p \times p}$. In addition, we can define the *oblique projection* matrix

$$\Pi_S^U := U(SU)^\dagger S. \quad (11)$$

Note that if $\text{rank}(SX) = p$, then Π_S^U can be expressed as $\Pi_S^U = U(U^T S^T S U)^{-1} U^T S^T S$, since $U^T S^T S U$ is invertible. Importantly however, depending on the properties of X and how S is constructed, it can easily happen that $\text{rank}(SX) < p$, even if $\text{rank}(X) = p$.

Given this setup, we can now state the following lemma, the proof of which may be found in Section A.1. This lemma characterizes how $C_{WC}(S)$, $C_{PE}(S)$, and $C_{RE}(S)$ depend on different structural properties of Π_S^U and SU .

Lemma 1 *For the algorithmic setting,*

$$C_{WC}(S) = 1 + \sup_{\delta \in \mathbb{R}^p, U^T \epsilon = 0} \left[\frac{\|(I_{p \times p} - (SU)^\dagger (SU) \delta)\|_2^2}{\|\epsilon\|_2^2} + \frac{\|\Pi_S^U \epsilon\|_2^2}{\|\epsilon\|_2^2} \right].$$

For the statistical setting,

$$C_{PE}(S) = \frac{p}{\|(I_{p \times p} - (SU)^\dagger (SU) \Sigma V^T \beta)\|_2^2} + \frac{\|\Pi_S^U \beta\|_2^2}{p},$$

and

$$C_{RE}(S) = 1 + \frac{\|(I_{p \times p} - (SU)^\dagger (SU) \Sigma V^T \beta)\|_2^2}{n - p} + \frac{\|\Pi_S^U \beta\|_2^2}{n - p} = 1 + \frac{C_{PE}(S) - 1}{n/p - 1}.$$

Several points are worth making about Lemma 1.

- For all 3 criteria, the term which involves $(SU)^\dagger SU$ is a ‘‘bias’’ term that is non-zero in the case that $\text{rank}(SU) < p$. For $C_{PE}(S)$ and $C_{RE}(S)$, the term corresponds exactly to the statistical bias; and if $\text{rank}(SU) = p$, meaning that S is a *rank-preserving* sketching matrix, then the bias term equals 0, since $(SU)^\dagger SU = I_{p \times p}$. In practice, if r is chosen smaller than p or larger than but very close to p , it may happen that $\text{rank}(SU) < p$, in which case this bias is incurred.
- The final equality $C_{RE}(S) = 1 + \frac{C_{PE}(S) - 1}{n/p - 1}$ shows that in general it is much more difficult (in terms of the number of samples needed) to obtain bounds on $C_{PE}(S)$ than $C_{RE}(S)$ —since $C_{RE}(S)$ re-scales $C_{PE}(S)$ by p/n , which is much less than 1. This will be reflected in the main results below, where the scaling of $C_{RE}(S)$ will be a factor of p/n smaller than $C_{PE}(S)$. In general, it is significantly more difficult to bound $C_{PE}(S)$, since $\|X(\beta - \beta_{OLS})\|_2^2$ is p , whereas $\|Y - X\beta_{OLS}\|_2^2$ is $n - p$, and so there is much less margin for error in approximating $C_{PE}(S)$.
- In the algorithmic or worst-case setting, $\sup_{\epsilon \in \mathbb{R}^p, \langle \epsilon, 0 \rangle} \frac{\|\Pi_S^U \epsilon\|_2^2}{\|\epsilon\|_2^2}$ is the relevant quantity, whereas in the statistical setting $\|\Pi_S^U\|_F^2$ is the relevant quantity. The Frobenius norm enters in the statistical setting because we are taking an average over homoscedastic noise, and so the ℓ_2 norm of the eigenvalues of Π_S^U need to be controlled. On the other hand, in the algorithmic or worst-case setting, the worst direction in the null-space of U^T needs to be controlled, and thus the spectral norm enters.

3. Main Theoretical Results

In this section, we provide upper bounds for $C_{WC}(S)$, $C_{PE}(S)$, and $C_{RE}(S)$, where S correspond to random sampling and random projection matrices. In particular, we provide upper bounds for 4 sketching matrices: (1) a vanilla leverage-based random sampling algorithm

from Drineas et al. (2012): (2) a variant of leverage-based random sampling, where the random samples are *not* re-scaled prior to their inclusion in the sketch; (3) a vanilla random projection algorithm, where S is a random matrix containing i.i.d. sub-Gaussian random variables; and (4) a random projection algorithm, where S is a random Hadamard-based random projection, as analyzed in Boutsidis and Gittens (2013).

3.1 Random Sampling Methods

Here, we consider random sampling algorithms. To do so, first define a random sampling matrix $\tilde{S} \in \mathbb{R}^n$ as follows: $\tilde{S}_{ij} \in \{0, 1\}$ for all (i, j) and $\sum_{j=1}^n \tilde{S}_{ij} = 1$, where each row has an independent multinomial distribution with probabilities $(p_i)_{i=1}^n$. The matrix of cross-leverage scores is defined as $L = UU^T \in \mathbb{R}^{n \times n}$, and $\ell_i = L_{ii}$ denotes the leverage score corresponding to the i^{th} sample. Note that the leverage scores satisfy $\sum_{i=1}^n \ell_i = \text{trace}(L) = p$ and $0 \leq \ell_i \leq 1$.

The sampling probability distribution we consider $(p_i)_{i=1}^n$ is of the form $p_i = (1 - \theta)\frac{\ell_i}{p} + \theta q_i$, where $\{q_i\}_{i=1}^n$ satisfies $0 \leq q_i \leq 1$ and $\sum_{i=1}^n q_i = 1$ is an arbitrary probability distribution, and $0 \leq \theta < 1$. In other words, it is a convex combination of a leverage-based distribution and another arbitrary distribution. Note that for $\theta = 0$, the probabilities are proportional to the leverage scores, whereas for $\theta = 1$, the probabilities follow $\{\ell_i\}_{i=1}^n$.

We consider two sampling matrices, one where the random sampling matrix is re-scaled, as in Drineas et al. (2011), and one in which no re-scaling takes place. In particular, let $S_{NR} = \tilde{S}$ denote the random sampling matrix (where the subscript NR denotes the fact that no re-scaling takes place). The re-scaled sampling matrix is $SR \in \mathbb{R}^{n \times n} = \tilde{S}W$, where $W \in \mathbb{R}^{n \times n}$ is a diagonal re-scaling matrix, where $[W]_{jj} = \sqrt{\frac{1}{\tau p_j}}$ and $W_{ji} = 0$ for $j \neq i$. The quantity $\frac{1}{p_j}$ is the re-scaling factor. In this case, we have the following result, the proof of which may be found in Section B.1.

Theorem 1 For $S = S_R$, there exists constants C and C' such that if $\tau \geq \frac{Cp}{1-\theta} \log\left(\frac{C'p}{1-\theta}\right)$, $\text{rank}(S_R U) = p$ and:

$$\begin{aligned} C_{WC}(S_R) &\leq 1 + 12\frac{p}{r} \\ C_{PE}(S_R) &\leq 44\frac{p}{r} \\ C_{RE}(S_R) &\leq 1 + 44\frac{p}{r}, \end{aligned}$$

with probability at least 0.7 .

Several things are worth noting about this result. First, note that both $C_{WC}(S_R) - 1$ and $C_{RE}(S_R) - 1$ scale as $\frac{p}{r}$; thus, it is possible to obtain high-quality performance guarantees for ordinary least squares, as long as $\frac{p}{r} \rightarrow 0$, e.g., if r is only slightly larger than p . On the other hand, $C_{PE}(S_R)$ scales as $\frac{p}{r}$, meaning r needs to be close to n to provide similar performance guarantees. Next, note that all of the upper bounds apply to any data matrix X , without assuming any additional structure on X . Finally, note that when $\theta = 1$, which corresponds to sampling the rows based on $\{\ell_i\}_{i=1}^n$, all the upper bounds are ∞ . Our simulations also reveal that uniform sampling generally performs more poorly than leverage-score based approaches under the linear models we consider.

An important practical point is the following: the distribution $\{q_i\}_{i=1}^n$ does *not* enter the results. This allows us to consider different distributions. An obvious choice is uniform, i.e., $q_i = \frac{1}{n}$ (see e.g., Ma et al. (2014, 2015)). Another important example is that of *approximate* leverage-score sampling, as developed in Drineas et al. (2012). (The running time of the main algorithm of Drineas et al. (2012) is $o(np^2)$, and thus this reduces computation compared with the use of exact leverage scores, which take $O(np^2)$ time to compute). Let $(\ell_i)_{i=1}^n$ denote the approximate leverage scores developed by the procedure in Drineas et al. (2012). Based on Theorem 2 in Drineas et al. (2012), $|\ell_i - \tilde{\ell}_i| \leq \epsilon$ where $0 < \epsilon < 1$ for r appropriately chosen. Now, using $p_i = \frac{\tilde{\ell}_i}{p}$, p_i can be re-expressed as $p_i = (1 - \epsilon)\frac{\ell_i}{p} + \epsilon q_i$ where $(q_i)_{i=1}^n$ is a distribution (unknown since we only have a bound on the approximate leverage scores). Hence, the performance bounds achieved by approximate leveraging are analogous to those achieved by adding ϵ multiplied by a uniform or other arbitrary distribution.

Next, we consider the leverage-score estimator without re-scaling S_{NR} . In order to develop nontrivial bounds on $C_{WC}(S_{NR})$, $C_{PE}(S_{NR})$, and $C_{RE}(S_{NR})$, we need to make a strong assumption on the leverage-score distribution on X . To do so, we define the following.

Definition 1 (k-heavy hitter leverage distribution) A sequence of leverage scores $(\ell_i)_{i=1}^n$ is a k -heavy hitter leverage score distribution if there exist constants $c, C > 0$ such that for $1 \leq i \leq k$, $\frac{c}{p} \leq \ell_i \leq \frac{Cp}{k}$ and for the remaining $n - k$ leverage scores, $\sum_{i=k+1}^n \ell_i \leq \frac{3}{4}$.

The interpretation of a k -heavy hitter leverage distribution is one in which only k samples in X contain the majority of the leverage score mass. In the simulations below, we provide examples of synthetic matrices X where the majority of the mass is in the largest leverage scores. The parameter k acts as a measure of non-uniformity, in that the smaller the k , the more non-uniform are the leverage scores. The k -heavy hitter leverage distribution allows us to model highly non-uniform leverage scores. In this case, we have the following result, the proof of which may be found in Section B.2.

Theorem 2 For $S = S_{NR}$, with $\theta = 0$ and assuming a k -heavy hitter leverage distribution and, there exist constants c_1 and $r \geq c_1 p \log(c_2 p)$, such that $\text{rank}(S_{NR}) = p$ and:

$$\begin{aligned} C_{WC}(S_{NR}) &\leq 1 + \frac{44C^2 p}{c^2 r} \\ C_{PE}(S_{NR}) &\leq \frac{44C^4 k}{c^2 r} \\ C_{RE}(S_{NR}) &\leq 1 + \frac{44C^4 pk}{c^2 mp}, \end{aligned}$$

with probability at least 0.6 .

Notice that when $k \ll n$, bounds in Theorem 2 on $C_{PE}(S_{NR})$ and $C_{RE}(S_{NR})$ are significantly sharper than bounds in Theorem 1 on $C_{PE}(S_R)$ and $C_{RE}(S_R)$. Hence not re-scaling has the potential to provide sharper bound in the statistical setting. However a stronger assumption on X is needed for this result.

3.2 Random Projection Methods

Here, we consider two random projection algorithms, one based on a sub-Gaussian projection matrix and the other based on a Hadamard projection matrix. To do so, define $[S_{SGP}]_{ij} = \frac{1}{\sqrt{p}} X_{ij}$, where $(X_{ij})_{1 \leq i \leq r, 1 \leq j \leq n}$ are i.i.d. sub-Gaussian random variables with $\mathbb{E}[X_{ij}] = 0$, variance $\mathbb{E}[X_{ij}^2] = \sigma^2$ and sub-Gaussian parameter 1. In this case, we have the following result, the proof of which may be found in Section B.3.

Theorem 3 *For any matrix X , there exists a constant c such that if $r \geq c \log n$, then with probability greater than 0.7, it holds that $\text{rank}(S_{SGP}) = p$ and that:*

$$\begin{aligned} C_{WC}(S_{SGP}) &\leq 1 + 11 \frac{p}{r} \\ C_{PE}(S_{SGP}) &\leq 44 \left(1 + \frac{n}{r}\right) \\ C_{RE}(S_{SGP}) &\leq 1 + 44 \frac{p}{r}. \end{aligned}$$

Notice that the bounds in Theorem 3 for S_{SGP} are equivalent to the bounds in Theorem 1 for S_R , except that r is required only to be larger than $O(\log n)$ rather than $O(p \log p)$. Hence for smaller values of p , random sub-Gaussian projections are more stable than leverage-score sampling based approaches. This reflects the fact that to a first-order approximation, leverage-score sampling performs as well as performing a smooth projection.

Next, we consider the randomized Hadamard projection matrix. In particular, $S_{Had} = S_{ni,f} H D$, where $H \in \mathbb{R}^{n \times n}$ is the standard Hadamard matrix (see e.g., Hedayat and Wallis (1978)), $S_{ni,f} \in \mathbb{R}^{r \times n}$ is an $r \times n$ uniform sampling matrix, and $D \in \mathbb{R}^{n \times n}$ is a diagonal matrix with random equiprobable ± 1 entries. In this case, we have the following result, the proof of which may be found in Section B.4.

Theorem 4 *For any matrix X , there exists a constant c such that if $r \geq cp \log n (\log p + \log \log n)$, then with probability greater than 0.8, it holds that $\text{rank}(S_{Had}) = p$ and that:*

$$\begin{aligned} C_{WC}(S_{Had}) &\leq 1 + 40 \log(np) \frac{p}{r} \\ C_{RE}(S_{Had}) &\leq 40 \log(np) \left(1 + \frac{n}{r}\right) \\ C_{PE}(S_{Had}) &\leq 1 + 40 \log(np) \left(1 + \frac{p}{r}\right). \end{aligned}$$

Notice that the bounds in Theorem 4 for S_{Had} are equivalent to the bounds in Theorem 1 for S_R , up to a constant and $\log(np)$ factor. As discussed in Drineas et al. (2011), the Hadamard transformation makes the leverage scores of X approximately uniform (up to a $\log(np)$ factor), which is why the performance is similar to the sub-Gaussian projection (which also tends to make the leverage scores of X approximately uniform). We suspect that the additional $\log(np)$ factor is an artifact of the analysis since we use an entry-wise concentration bound; using more sophisticated techniques, we believe that the $\log(np)$ can be removed. The probabilities of 0.6, 0.7, and 0.8 for which the upper bounds hold in the four Theorems above is an artifact of the concentration bounds used in the proof and can be improved at the expense of weaker constants (e.g. 40) in front of the efficiency bounds. As

we show in the next section, the upper bound of $\frac{n}{r}$ on $C_{PE}(S)$ for $S = S_R, S_{SGP}$ and S_{Had} can not be improved up to constant while for $S = S_{NR}$ the upper bound of $\frac{k}{r}$ can not be improved.

3.3 Lower Bounds

Subject to the dissemination of the original version of this paper (Raskutti and Mahoney, 2014), Pilanci and Wainwright (2014) amongst other results develop lower bounds on the numerator in $C_{PE}(S)$. This proves that our upper bounds on $C_{PE}(S)$ can not be improved. We re-state Theorem 1 (Example 1) in Pilanci and Wainwright (2014) in a way that makes it most comparable to our results.

Theorem 5 (Theorem 1 in Pilanci and Wainwright (2014)) *For any sketching matrix satisfying $\|\mathbb{E}[S^T(SS^T)^{-1}S]\|_{op} \leq \eta \frac{n}{r}$, any estimator based on (SX, SY) satisfies the lower bound with probability greater than 1/2:*

$$C_{PE}(S) \geq \frac{n}{128\eta r}.$$

Pilanci and Wainwright (2014) show that for $S = S_R, S_{SGP}$ and S_{Had} , $\|\mathbb{E}[S^T(SS^T)^{-1}S]\|_{op} \leq c \frac{n}{r}$ where c is a constant and hence $\eta = c$ and the lower bound matches our upper bounds up to constant. On the other hand, for $S = S_{NR}$, it is straightforward to show that $\|\mathbb{E}[S^T(SS^T)^{-1}S]\|_{op} \leq c \frac{k}{r}$ for some constant c and hence $\eta = c \frac{k}{r}$ and the lower bound scales as $\frac{k}{r}$, to match the upper bound on $C_{PE}(S_{NR})$ from Theorem 2. This is why we are able to prove a tighter upper bound when the matrix X has highly non-uniform leverage scores.

Importantly, this proves that $C_{PE}(S)$ is a quantity that is more challenging to control than $C_{RE}(S)$ and $C_{WC}(S)$ when only a single sketch is used. Using this insight, Pilanci and Wainwright (2014) show that by using a particular iterative Hessian sketch, $C_{PE}(S)$ can be controlled up to constant. In addition to providing a lower bound on the PE using a sketching matrix just once, Pilanci and Wainwright (2014) also develop a new iterative sketching scheme where sketching matrices are used repeatedly can reduce the PE significantly. Once again the probability of 0.5 can be improved by making the constant of $\frac{1}{128}$ less tight.

Finally in prior related work, Lu and Foster (2014); Lu et al. (2013) show that the rate $1 + \frac{p}{r}$ may be achieved for the PE using the estimator $\hat{\beta} = ((SX)^T(SX))^{-1}X^TY$. This estimator is related to the ridge regression estimator since sketches or random projections are applied only in the computation of the X^TX matrix and not X^TY . Since both X^TY and $(SX)^T(SX)$ have small dimension, this estimator has significant computational benefits. However this estimator does not violate the lower bound in Pilanci and Wainwright (2014) since it is not based on the sketches (SX, SY) but instead uses (SX, X^TY) .

4. Empirical Results

In this section, we present the results of an empirical evaluation, illustrating the results of our theory. We will compare the following 6 sketching matrices.

- (1) $S = S_R$ - random leverage-score sampling with re-scaling.

- (2) $S = S_{NVR}$ - random leverage-score sampling without re-scaling.
- (3) $S = S_{Unif}$ - random uniform sampling (each sample drawn independently with probability $1/n$).
- (4) $S = S_{SIR}$ - random leverage-score sampling with re-scaling and with $\theta = 0.1$.
- (5) $S = S_{GCP}$ - Gaussian projection matrices.
- (6) $S = S_{Had}$ - Hadamard projections.

To compare the methods and see how they perform on inputs with different leverage scores, we generate test matrices using a method outlined in Ma et al. (2014, 2015). Set $n = 1024$ (to ensure, for simplicity, an integer power of 2 for the Hadamard transform) and $p = 50$, and let the number of samples drawn with replacement, r , be varied. X is then generated based on a t -distribution with different choices of ν to reflect different uniformity of leverage scores. Each row of X is selected independently with distribution $X_i \sim t_p(\Sigma)$, where Σ corresponds to an auto-regressive model with ν the degrees of freedom. The 3 values of ν presented here are $\nu = 1$ (highly non-uniform), $\nu = 2$ (moderately non-uniform), and $\nu = 10$ (very uniform). See Figure 1 for a plot to see how ν influences the uniformity of the leverage scores. For each setting, the simulation is repeated 100 times in order to average

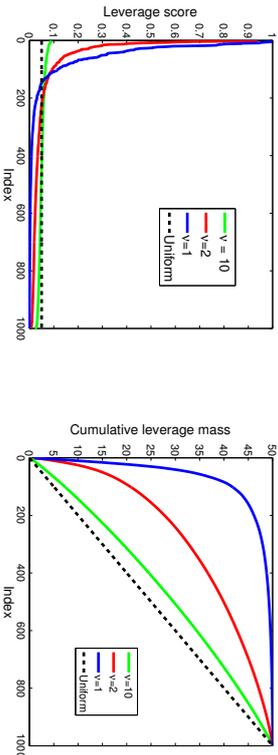

Figure 1: Ordered leverage scores for different values of ν (a) and cumulative sum of ordered leverage scores for different values of ν (b).

over both the randomness in the sampling, and in the statistical setting, the randomness over y .

Note that a natural comparison can be drawn between the parameter ν and the parameter k in the k -heavy hitter definition. If we want to find the value k such that 90% of the leverage mass is captured, for $\nu = 1$, $k \approx 100$, for $\nu = 2$, $k \approx 700$ and for $\nu = 10$, $k \approx 900$, according to Figure 1 (b). Hence the smaller ν , the smaller k since the leverage-scores are more non-uniform.

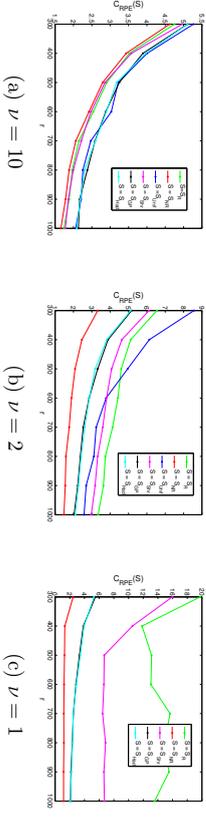

Figure 2: Relative prediction efficiency $CPE(S)$ for large r .

r	S_R	S_{NR}	S_{Unif}	S_{SIR}	S_{GCP}	S_{Had}
80	39.8	38.7	37.3	39.8	35.5	40.0
90	27.8	27.2	27.2	27.2	26.1	27.4
100	22.4	22.1	22.7	22.2	21.3	23.1
200	8.33	7.88	8.51	7.62	8.20	8.14

(a) $\nu = 10$

r	S_R	S_{NR}	S_{Unif}	S_{SIR}	S_{GCP}	S_{Had}
80	70.7	60.1	1.05×10^2	73.3	36.5	39.8
90	45.6	34.6	66.2	44.7	26.7	28.2
100	35.1	25.9	52.8	33.8	22.1	22.5
200	9.82	5.54	15.3	9.17	7.59	7.81

(b) $\nu = 2$

r	S_R	S_{NR}	S_{Unif}	S_{SIR}	S_{GCP}	S_{Had}
80	4.4×10^4	3.1×10^4	7.0×10^3	1.4×10^4	34.2	40.0
90	1.5×10^4	7.0×10^3	5.2×10^3	1.0×10^4	26.0	28.7
100	1.8×10^4	3.6×10^3	3.9×10^3	3.4×10^3	22.7	24.8
200	2.0×10^2	34.0	5.2×10^2	3.6×10^2	7.94	7.84

(c) $\nu = 1$

Figure 3: Relative prediction efficiency $CPE(S)$ for small r .

Overall, S_{NR} , S_R , and S_{SIR} compare very favorably to S_{Unif} , which is consistent with Theorem 2, since samples with higher leverage scores tend to reduce the mean-squared

error. Furthermore, S_R (which recall involves re-scaling) only increases the mean-squared error, which is again consistent with the theoretical results. The effects are more apparent as the leverage score distribution is more non-uniform (i.e., for $\nu = 1$).

The theoretical upper bound in Theorems 1-4 suggests that $C_{PE}(S)$ is of the order $\frac{n}{r}$, independent of the leverage scores of X , for $S = S_R$ as well as $S = S_{Had}$ and S_{GP} . On the other hand, the simulations suggest that for highly non-uniform leverage scores, $C_{PE}(S_R)$ is higher than when the leverage scores are uniform, whereas for $S = S_{Had}$ and S_{GP} , the non-uniformity of the leverage scores does not significantly affect the bounds. The reason that S_{Had} and S_{GP} are not significantly affected by the leverage-score distribution is that the Hadamard and Gaussian projection has the effect of making the leverage scores of any matrix uniform Drineas et al. (2011). The reason for the apparent disparity when $S = S_R$ is that the theoretical bounds use Markov's inequality which is a crude concentration bound. We suspect that a more refined analysis involving the bounded difference inequality would reflect that non-uniform leverage scores result in a larger $C_{PE}(S_R)$.

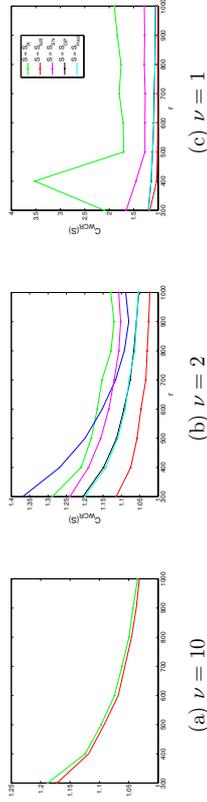

Figure 4: Worst-case relative error $C_{WC}(S)$ for large r .

Finally, Figures 4 and 5 provide a comparison of the worst-case relative error $C_{WCE}(S)$ for large and small ($r > 200$ and $r \leq 200$, respectively) values of r . Observe that, in general, $C_{WC}(S)$ are much closer to 1 than $C_{PE}(S)$ for all choices of S . This reflects the scaling of $\frac{2}{n}$ difference between the bounds. Interestingly, Figures 4 and 5 indicates that S_{NR} still tends to out-perform S_R in general, however the difference is not as significant as in the statistical setting.

5. Discussion and Conclusion

In this paper, we developed a framework for analyzing algorithmic and statistical criteria for general sketching matrices $S \in \mathbb{R}^{r \times n}$ applied to the least-squares objective. As our analysis makes clear, our framework reveals that the algorithmic and statistical criteria depend on different properties of the oblique projection matrix $\Pi_S^U = U(SU)^\dagger U$, where U is the left singular matrix for X . In particular, the algorithmic criteria (WC) depends on the quantity $\sup_{U^T \epsilon=0} \frac{\|\Pi_S^U \epsilon\|_2}{\|\epsilon\|_2}$, since in that case the data may be arbitrary and worst-case, whereas the two statistical criteria (RE and PE) depends on $\|\Pi_S^U\|_F$, since in that case the data follow a linear model with homogenous noise variance.

Figure 5: Worst-case relative error $C_{WC}(S)$ for large r .

Using our framework, we develop upper bounds for 3 performance criteria applied to 4 sketching schemes. Our upper bounds reveal that in the regime where $p < r \ll n$, our sketching schemes achieve optimal performance up to constants, in terms of WC and RE. On the other hand, the PE scales as $\frac{n}{r}$ meaning r needs to be close to (or greater than) n for good performance. Subsequent lower bounds in Pilanci and Wainwright (2014) show that this upper bound can not be improved, but subsequent work by Pilanci and Wainwright (2014) as well as Lu and Foster (2014); Lu et al. (2013) provide alternate more sophisticated sketching approaches to deal with these challenges. Our simulation results reveal that for when r is very close to p , projection-based approaches tend to out-perform sampling-based approaches since projection-based approaches tend to be more stable in that regime.

There are numerous ways in which the framework and results from this paper can be extended. Firstly, there is a large literature that presents a number of different approaches to sketching. Since our framework provides general conditions to assess the statistical and algorithmic performance for sketching matrices, a natural and straightforward extension would be to use our framework to compare other sketching matrices. Another natural extension is to determine whether aspects of the framework can be adapted to other statistical models and problems of interest (e.g., generalized linear models, covariance estimation, PCA, etc.). Finally, another important direction is to compare the stability and robustness properties of different sketching matrices. Our current analysis assumes a known linear model, and it is unclear how the sketching matrices behave under model mis-specification.

Acknowledgement. We would like to thank the Statistical and Applied Mathematical Sciences Institute and the members of its various working groups for helpful discussions.

Appendix A. Auxiliary Results

In this section, we provide proofs of Lemma 1 and an intermediate result we will later use to prove the main theorems.

A.1. Proof of Lemma 1

Recall that $X = U\Sigma V^T$, where $U \in \mathbb{R}^{n \times p}$, $\Sigma \in \mathbb{R}^{p \times p}$ and $V \in \mathbb{R}^{p \times p}$ denote the left singular matrix, diagonal singular value matrix and right singular matrix respectively.

First we show that $\|Y - X\beta_{OLS}\|_2^2 = \|\epsilon\|_2^2$. To do so, observe that

$$\|Y - X\beta_{OLS}\|_2^2 = \|Y - U\Sigma V^T\beta_{OLS}\|_2^2$$

and set $\delta_{OLS} = \Sigma V^T\beta_{OLS}$. It follows that $\delta_{OLS} = U^T Y$. Hence

$$\|Y - X\beta_{OLS}\|_2^2 = \|Y - \Pi_U Y\|_2^2$$

where $\Pi_U = UU^T$. For every $Y \in \mathbb{R}^n$, there exists a unique $\delta \in \mathbb{R}^p$ and $\epsilon \in \mathbb{R}^n$ such that $U^T \epsilon = 0$ and $Y = U\delta + \epsilon$. Hence

$$\|Y - X\beta_{OLS}\|_2^2 = \|(I_{n \times n} - \Pi_U)\epsilon\|_2^2 = \|\epsilon\|_2^2,$$

where the final equality holds since $\Pi_U \epsilon = 0$.

Now we analyze $\|Y - X\beta_S\|_2^2$. Observe that

$$\|Y - X\beta_S\|_2^2 = \|Y - \Pi_U^S Y\|_2^2,$$

where $\Pi_U^S = U(SU)^T S$. Since $Y = U\delta + \epsilon$, it follows that

$$\begin{aligned} \|Y - X\beta_S\|_2^2 &= \|U(I_{p \times p} - (SU)^T(SU)\delta + (I_{n \times n} - \Pi_U^S)\epsilon)\|_2^2 \\ &= \|(I_{p \times p} - (SU)^T(SU)\delta)\|_2^2 + \|(I_{n \times n} - \Pi_U^S)\epsilon\|_2^2 \\ &= \|(I_{p \times p} - (SU)^T(SU)\delta)\|_2^2 + \|\epsilon\|_2^2 + \|\Pi_U^S \epsilon\|_2^2. \end{aligned}$$

Therefore for all Y :

$$C_{WC}(S) = \frac{\|Y - X\beta_S\|_2^2}{\|Y - X\beta_{OLS}\|_2^2} = 1 + \frac{\|(I_{p \times p} - (SU)^T(SU)\delta)\|_2^2 + \|\Pi_U^S \epsilon\|_2^2}{\|\epsilon\|_2^2},$$

where $U^T \epsilon = 0$. Taking a supremum over Y and consequently over ϵ and δ completes the proof for $C_{WC}(S)$.

Now we turn to the proof for $C_{PE}(S)$. First note that

$$\mathbb{E}\|X(\beta_{OLS} - \beta)\|_2^2 = \mathbb{E}\|UU^T Y - U\Sigma V^T \beta\|_2^2.$$

Under the linear model $Y = U\Sigma V^T \beta + \epsilon$,

$$\mathbb{E}\|X(\beta_{OLS} - \beta)\|_2^2 = \mathbb{E}\|\Pi_U \epsilon\|_2^2.$$

Since $\mathbb{E}[\epsilon^T] = I_{n \times n}$, it follows that

$$\mathbb{E}\|X(\beta_{OLS} - \beta)\|_2^2 = \mathbb{E}\|\Pi_U \epsilon\|_2^2 = \|\Pi_U\|_F^2 = p.$$

For β_S , we have that

$$\begin{aligned} \mathbb{E}\|X(\beta_S - \beta)\|_2^2 &= \mathbb{E}\|\Pi_U^S Y - U\Sigma V^T \beta\|_2^2 = \mathbb{E}\|(U(I - (SU)^T(SU)\Sigma V^T \beta + \Pi_U^S \epsilon)\|_2^2 \\ &= \mathbb{E}\|(I_{p \times p} - (SU)^T(SU)\Sigma V^T \beta)\|_2^2 + \mathbb{E}\|\Pi_U^S \epsilon\|_2^2 \\ &= \mathbb{E}\|(I_{p \times p} - (SU)^T(SU)\Sigma V^T \beta)\|_2^2 + \|\Pi_U^S\|_F^2. \end{aligned}$$

Hence $C_{PE}(S) = 1/p(\|(I_{p \times p} - (SU)^T(SU)\Sigma V^T \beta)\|_2^2 + \|\Pi_U^S\|_F^2)$ as stated.

For $C_{RE}(S)$, the mean-squared error for δ_{OLS} and δ_S are

$$\begin{aligned} \mathbb{E}\|Y - X\beta_{OLS}\|_2^2 &= \mathbb{E}\|(I - \Pi_U^T)\epsilon\|_2^2 \\ &= \|I - \Pi_U^T\|_F^2 = n - p, \end{aligned}$$

and

$$\begin{aligned} \mathbb{E}\|Y - X\beta_S\|_2^2 &= \mathbb{E}\|(I_{p \times p} - (SU)^T(SU)\Sigma V^T \beta)\|_2^2 + \mathbb{E}\|(I - \Pi_U^S)\epsilon\|_2^2 \\ &= \mathbb{E}\|(I_{p \times p} - (SU)^T(SU)\Sigma V^T \beta)\|_2^2 + \text{trace}((I - \Pi_S)^T(I - \Pi_S)) \\ &= \mathbb{E}\|(I_{p \times p} - (SU)^T(SU)\Sigma V^T \beta)\|_2^2 + \text{trace}(I) - 2\text{trace}(\Pi_S) + \|\Pi_S\|_F^2 \\ &= \mathbb{E}\|(I_{p \times p} - (SU)^T(SU)\Sigma V^T \beta)\|_2^2 + n - 2p + \|\Pi_S\|_F^2 \\ &= \mathbb{E}\|(I_{p \times p} - (SU)^T(SU)\Sigma V^T \beta)\|_2^2 + n - p + \|\Pi_S\|_F^2 - p. \end{aligned}$$

Hence,

$$\begin{aligned} C_{RE}(S) &= \frac{n - p + \|(I_{p \times p} - (SU)^T(SU)\Sigma V^T \beta)\|_2^2 + \|\Pi_S\|_F^2 - p}{n - p} \\ &= 1 + \frac{\|(I_{p \times p} - (SU)^T(SU)\Sigma V^T \beta)\|_2^2 + \|\Pi_S\|_F^2 - p}{n - p} \\ &= 1 + \frac{C_{PE}(S) - 1}{n/p - 1}. \end{aligned}$$

A.2. Intermediate Result

In order to provide a convenient way to parameterize our upper bounds for $C_{WC}(S)$, $C_{PE}(S)$, and $C_{RE}(S)$, we introduce the following three structural conditions on S . Let $\hat{\sigma}_{\min}(A)$ denote the minimum *non-zero* singular value of a matrix A .

- The first condition is that there exists an $\alpha(S) > 0$ such that

$$\hat{\sigma}_{\min}(SU) \geq \alpha(S). \quad (12)$$

- The second condition is that there exists a $\beta(S)$ such that

$$\sup_{\epsilon, U^T \epsilon = 0} \frac{\|U^T S^T S \epsilon\|_2}{\|\epsilon\|_2} \leq \beta(S). \quad (13)$$

- The third condition is that there exists a $\gamma(S)$ such that

$$\|U^T S^T S\|_F \leq \gamma(S). \quad (14)$$

Note that the structural conditions defined by $\alpha(S)$ and $\beta(S)$ have been defined previously as Eqn. (8) and Eqn. (9) in Drineas et al. (2011).

Given these quantities, we can state the following lemma, the proof of which may be found in Section A.2. This lemma provides upper bounds for $C_{WC}(S)$, $C_{PE}(S)$, and $C_{RE}(S)$ in terms of the parameters $\alpha(S)$, $\beta(S)$, and $\gamma(S)$.

Lemma 2 For $\alpha(S)$ and $\beta(S)$, as defined in Eqn. (12) and (13),

$$C_{WC}(S) \leq 1 + \sup_{\delta \in \mathbb{R}^p, U^T \epsilon = 0} \frac{\|(I_{p \times p} - (SU)^\dagger(SU))\delta\|_2}{\|\epsilon\|_2} + \frac{\beta^2(S)}{\alpha^4(S)}.$$

For $\alpha(S)$ and $\gamma(S)$, as defined in Eqn. (12) and (14),

$$C_{PE}(S) \leq \frac{\|(I_{p \times p} - (SU)^\dagger(SU))\Sigma V^T \beta\|_2}{p} + \frac{\gamma^2(S)}{\alpha^4(S)}.$$

Furthermore,

$$C_{RE}(S) \leq 1 + \frac{p}{n} \left[\frac{\|(I_{p \times p} - (SU)^\dagger(SU))\Sigma V^T \beta\|_2}{p} + \frac{\gamma^2(S)}{\alpha^4(S)} \right].$$

Again, the terms involving $(SU)^\dagger S U$ are a ‘‘bias’’ that equal zero for rank-preserving sketching matrices. In addition, we emphasize that the results of Lemma 1 and Lemma 2 hold for arbitrary sketching matrices S . In Appendix A.3, we bound $\alpha(S)$, $\beta(S)$ and $\gamma(S)$ for several different randomized sketching matrices, and this will permit us to obtain bounds on $C_{WC}(S)$, $C_{PE}(S)$, and $C_{RE}(S)$. For the sketching matrices we analyze, we prove that the bias term is 0 with high probability.

A.3 Proof of Lemma 2

Note that $\Pi_S^U = U(SU)^\dagger S$. Let $\text{rank}(SU) = k < p$, and the singular value decomposition is $SU = \tilde{U}\tilde{\Sigma}\tilde{V}^T$, where $\tilde{\Sigma} \in \mathbb{R}^{k \times k}$ is a diagonal matrix with non-zero singular values of SU . Then,

$$\begin{aligned} \frac{\|\Pi_S^U \epsilon\|_2}{\|\epsilon\|_2} &= \frac{\|U(SU)^\dagger S \epsilon\|_2}{\|\epsilon\|_2} = \frac{\|(SU)^\dagger S \epsilon\|_2}{\|\epsilon\|_2} \\ &= \frac{\|\tilde{V}\tilde{\Sigma}^{-1}\tilde{U}^T S \epsilon\|_2}{\|\epsilon\|_2} \\ &= \frac{\|\tilde{V}\tilde{\Sigma}^{-2}\tilde{V}^T \tilde{V}\tilde{\Sigma}\tilde{U}^T S \epsilon\|_2}{\|\epsilon\|_2}, \end{aligned}$$

where we have ignored the bias term which remains unchanged. Note that $\tilde{V}\tilde{\Sigma}^{-2}\tilde{V}^T \succeq \alpha^{-2}(S)I_{p \times p}$ and $\tilde{V}\tilde{\Sigma}\tilde{U}^T = (SU)^T = U^T S^T$. Hence,

$$\begin{aligned} \frac{\|\Pi_S^U \epsilon\|_2}{\|\epsilon\|_2} &= \frac{\|\tilde{V}\tilde{\Sigma}^{-2}\tilde{V}^T \tilde{V}\tilde{\Sigma}\tilde{U}^T S \epsilon\|_2}{\|\epsilon\|_2} \\ &\leq \frac{\|U^T S^T S \epsilon\|_2}{\alpha^4(S)\|\epsilon\|_2} \\ &= \frac{\beta^2(S)}{\alpha^4(S)\|\epsilon\|_2}, \end{aligned}$$

and the upper bound on $C_{WC}(S)$ follows.

Similarly,

$$\|\Pi_S^U\|_F^2 = \|U(SU)^\dagger S\|_F^2 = \|(SU)^\dagger S\|_F^2 = \|\tilde{V}\tilde{\Sigma}^{-2}\tilde{V}^T \tilde{V}\tilde{\Sigma}\tilde{U}^T S\|_F^2 \leq \alpha^{-4}(S)\|U^T S^T S\|_F^2$$

and the upper bound on $C_{PE}(S)$ follows.

Appendix B. Proof of Main Theorems

The proof techniques for all of four theorems are similar, in that we use the intermediate result Lemma 2 and bound the expectations of $\alpha(S)$, $\beta(S)$, and $\gamma(S)$ for each S , then apply Markov’s inequality to develop high probability bounds.

B.1 Proof of Theorem 1

First we bound $\alpha^2(S_R)$ by using existing results in Drineas et al. (2011). In particular applying Theorem 4 in Drineas et al. (2011) with $\beta = 1 - \theta$, $A = U^T$, $\epsilon = \frac{1}{\sqrt{2}}$ and $\delta = 0.1$ provides the desired lower bound on $\alpha(S_R)$ and ensures that the ‘‘bias’’ term in Lemma 2 is 0 since $\text{rank}(S_R U) = p$.

To upper bound $\beta(S_R)$, we first upper bound its expectation, then apply Markov’s inequality. Using the result of Table 1 (second row) of Drineas et al. (2006a) with $\beta = 1 - \theta$:

$$\mathbb{E}[\|U^T S_R^T S_R \epsilon\|_2^2] \leq \frac{1}{(1-\theta)^r} \|U^T\|_F^2 \|\epsilon\|_2^2 = \frac{p}{(1-\theta)^r} \|\epsilon\|_2^2.$$

Applying Markov’s inequality,

$$\|U^T S_R^T S_R \epsilon\|_2^2 \leq \frac{11p}{(1-\theta)^r} \|\epsilon\|_2^2,$$

with probability at least 0.9.

Finally we bound $\gamma(S_R)$:

$$\begin{aligned} \frac{1}{p} \mathbb{E}[\|U^T S_R^T S_R\|_F^2] &= \frac{1}{p} [\text{trace}(U^T (S_R^T S_R)^2 U)] \\ &= \frac{1}{p} \sum_{j=1}^p \sum_{i=1}^n \sum_{k=1}^n U_{ij} U_{kj} [(S_R^T S_R)^2]_{ki} \\ &= \frac{1}{p} \sum_{j=1}^p \sum_{i=1}^n U_{ij}^2 [S_R^T S_R]_{ii}^2 \\ &= \frac{1}{p} \sum_{i=1}^n \ell_i |S_R^T S_R|_{ii}^2, \end{aligned}$$

where the second last equality follows since $[S_R^T S_R]_{ki}^2 = 0$ for $k \neq i$ and the final equality follows since $\ell_i = \sum_{j=1}^p U_{ij}^2$. First we upper bound $\mathbb{E}[\gamma(S_R)]$ and then apply Markov's inequality. Recall that $|S_R|_{ki} = \frac{1}{\sqrt{r}} \sigma_{ki}$ where $\mathbb{P}(\sigma_{ki} = \pm 1) = p_i$. Then,

$$\begin{aligned} \frac{1}{p} \sum_{i=1}^n \ell_i \mathbb{E}[(S_R^T S_R)_{ii}^2] &= \frac{1}{r^2 p} \sum_{i=1}^n \ell_i \sum_{m=1}^r \sum_{t=1}^r \mathbb{E}[\sigma_{mi}^2 \sigma_{ti}^2] \\ &= \frac{1}{r^2 p} \sum_{i=1}^n \ell_i \sum_{m=1}^r \sum_{t=1}^r \mathbb{E}[\sigma_{mi} \sigma_{ti}] \\ &= \frac{1}{r^2 p} \sum_{i=1}^n \ell_i \sum_{m=1}^r [(r^2 - r)p_i^2 + r p_i] \\ &= \frac{1}{r^2 p} \sum_{i=1}^n (\ell_i (r^2 - r) + r \frac{\ell_i}{p_i}) \\ &= 1 - \frac{1}{r} + \frac{1}{r p} \sum_{i=1}^n \frac{\ell_i}{p_i}. \end{aligned}$$

Substituting $p_i = (1 - \theta) \frac{\ell_i}{p} + \theta q_i$ completes the upper bound on $\mathbb{E}[\gamma(S_R)]$:

$$\begin{aligned} 1 - \frac{1}{r} + \frac{1}{r p} \sum_{i=1}^n \frac{\ell_i}{p_i} &= 1 - \frac{1}{r} + \frac{1}{r p} \sum_{i=1}^n \frac{\ell_i}{(1 - \theta) \frac{\ell_i}{p} + \theta q_i} \\ &\leq 1 - \frac{1}{r} + \frac{1}{r} \sum_{i=1}^n \frac{1}{1 - \theta} \\ &\leq 1 - \frac{1}{r} + \frac{1}{r} \frac{n}{(1 - \theta)^r} \\ &\leq 1 + \frac{1}{(1 - \theta)^r}. \end{aligned}$$

Using Markov's inequality,

$$\mathbb{P}(|\gamma(S_R) - \mathbb{E}[\gamma(S_R)]| \geq 10 \mathbb{E}[\gamma(S_R)]) \leq 0.1,$$

and consequently $\gamma(S_R) \leq 11(1 + \frac{n}{(1 - \theta)^r})$ with probability greater than 0.9. The final probability of 0.7 arises since we simultaneously require all three bounds to hold which hold with probability $0.9^3 > 0.7$. Applying Lemma 2 in combination with our high probability bounds for $\alpha(S_R)$, $\beta(S_R)$ and $\gamma(S_R)$ completes the proof for Theorem 1.

B.2 Proof of Theorem 2

Define $\bar{S} = \sqrt{\frac{k}{n}} S_{NR}$ where S_{NR} is the sampling matrix without re-scaling. Recall the k -heavy litter leverage-score assumption. Since $\sum_{i=k+1}^n \ell_i \leq \frac{p}{10r}$, $\sum_{i=k+1}^n p_i \leq \frac{1}{10r}$ (recall $p_i = \frac{\ell_i}{p}$). Hence the probability that a sample only contains the k samples with high leverage score is:

$$\left(1 - \frac{1}{10r}\right)^r \geq 1 - \frac{1}{10} = 0.9.$$

For the remainder of the proof, we condition on the event \mathcal{A} that only the rows with the k largest leverage scores are selected. Let $\tilde{U} \in \mathbb{R}^{k \times p}$ be the sub-matrix of U corresponding to the top k leverage scores.

Let $W = \mathbb{E}[\tilde{S}^T \tilde{S}] \in \mathbb{R}^{k \times k}$. Since $\frac{k}{n} \leq p_i \leq \frac{c}{k}$ for all $1 \leq i \leq k$, $c I_{k \times k} \preceq W \preceq C I_{k \times k}$. Furthermore since $\sum_{i=k+1}^n \ell_i \leq \frac{p}{10r}$, $0.9 I_{p \times p} \preceq U^T U \preceq I_{p \times p}$.

First we lower bound $\alpha^2(S_{NR})$. Applying Theorem 4 in Drineas et al. (2011) with $\beta = C$, $A = \tilde{U}^T W^{1/2}$, $\epsilon = \frac{c}{2}$ and $\delta = 0.1$ ensures that as long as $r \geq c' p \log(p)$ for sufficiently large c' ,

$$\|\tilde{U}^T W \tilde{U} - \tilde{U}^T \tilde{S}^T \tilde{S} \tilde{U}\|_{op} \leq \frac{c}{2C},$$

with probability at least 0.9. Since $\tilde{U}^T W \tilde{U} \succeq \frac{3c}{4}$, $\tilde{U}^T \tilde{S}^T \tilde{S} \tilde{U} \succeq \frac{c}{4}$. Therefore with probability at least 0.9,

$$\alpha^2(S_{NR}) \geq \frac{c^r}{4C^r}.$$

Next we bound $\beta(S_{NR})$. Since $\bar{S} = \sqrt{\frac{k}{n}} S_{NR}$, if we condition on \mathcal{A} , only the leading k leverage scores are selected and let $\tilde{U} \in \mathbb{R}^{k \times p}$ be the sub-matrix of U corresponding to the top k leverage scores. Using the result of Table 1 (second row) of Drineas et al. (2006a) with $\beta = 1$:

$$\mathbb{E}[\|U^T S_{NR}^T S_{NR} \epsilon\|_2^2] = \frac{r^2}{k^2} \mathbb{E}[\|U^T \tilde{S}^T \tilde{S} \epsilon\|_2^2] = \frac{r^2}{k^2} \mathbb{E}[\|\tilde{U}^T \tilde{S}^T \tilde{S} \epsilon\|_2^2] \leq \frac{r^2}{k^2} \|\tilde{U}^T\|_2 \|\epsilon\|_2 \leq \frac{p r^2}{k^2} \|\epsilon\|_2^2.$$

Applying Markov's inequality,

$$\|U^T S_{NR}^T S_{NR} \epsilon\|_2^2 \leq \frac{11 p r^2}{k^2} \|\epsilon\|_2^2.$$

with probability at least 0.9 which completes the upper bound for $\beta(S_{NR})$.

Finally we bound $\gamma(S_{NR})$:

$$\begin{aligned} \text{trace}(\bar{U}^T (\bar{S}^T \bar{S})^2 \bar{U})/p &= \frac{1}{p} \sum_{i=1}^n [\bar{S}^T \bar{S}]_{ii}^2 \sum_{j=1}^r \bar{U}_{ij}^2 \\ &= \frac{1}{p} \sum_{i=1}^k \ell_i [\bar{S}^T \bar{S}]_{ii}^2 \\ &\leq \frac{Ck}{r} \sum_{i=1}^k \frac{1}{r} \left(\sum_{m=1}^r \sigma_{mi}^2 \right), \end{aligned}$$

where the last step follows since $\ell_i \leq \frac{Cp}{k}$ for $1 \leq i \leq k$ and 0 otherwise. Now taking expectations:

$$\begin{aligned} \frac{1}{r} \mathbb{E} \left[\sum_{i=1}^k \left(\sum_{m=1}^r \sigma_{mi}^2 \right)^2 \right] &= \frac{1}{r} \sum_{i=1}^k \sum_{\ell=1}^r \sum_{m=1}^r \mathbb{E}[\sigma_{\ell i} \sigma_{m i}] \\ &\leq \frac{C^2}{r} \sum_{i=1}^k \left(\frac{r^2}{k^2} - \frac{r}{k} + \frac{r}{k} \right) \\ &= C^2 \left(\frac{r-1}{k} + 1 \right) \\ &\leq C^2 \left(\frac{r}{k} + 1 \right). \end{aligned}$$

Since $S_{NR} = \sqrt{\frac{k}{r}} \bar{S}$, $\mathbb{E}[\text{trace}(U^T (S_{NR}^T S_{NR})^2 U)/p] \leq C^2(1 + \frac{k}{r})$. Applying Markov's inequality,

$$\text{trace}(U^T (S_{NR}^T S_{NR})^2 U)/p \leq 11C^2(1 + \frac{k}{r}),$$

with probability at least 0.9. The probability of 0.6 arises since $0.9^4 > 0.6$. Again, using Lemma 2 completes the proof for Theorem 2.

B.3 Proof of Theorem 3

First we bound the smallest singular value of $S_{SGP}(U)$. Using standard results for bounds on the eigenvalues of sub-Gaussian matrices (see Proposition 2.4 in Rudelson and Vershynin (2009)), each entry of $A \in \mathbb{R}^{r \times n}$ is an i.i.d. zero-mean sub-Gaussian matrix:

$$\mathbb{P} \left(\inf_{\|x\|_2=1} \frac{1}{\sqrt{r}} \|Ax\|_2 \leq \frac{1}{\sqrt{2}} \right) \leq n \exp(-cr).$$

Hence, provided $cr \geq 2 \log n$,

$$\alpha(S_{SGP}) \geq \frac{1}{\sqrt{2}},$$

with probability greater than $1 - c \exp(-cr)$.

Next we bound $\beta(S_{SGP})$. Since $U^T \epsilon = 0$, $\|U^T S_{SGP}^T S_{SGP} \epsilon\|_2^2 = \|U^T (S_{SGP}^T S_{SGP} - I_{n \times n}) \epsilon\|_2^2$. Therefore

$$\begin{aligned} \|U^T S_{SGP}^T S_{SGP} \epsilon\|_2^2 &= \sum_{j=1}^p \left(\sum_{i=1}^n \sum_{k=1}^n U_{ij} (S_{SGP}^T S_{SGP} - I_{n \times n})_{ik} \epsilon_k \right)^2 \\ &= \sum_{j=1}^p \sum_{i=1}^n \sum_{k=1}^n \sum_{m=1}^n U_{ij} U_{mj} (S_{SGP}^T S_{SGP} - I_{n \times n})_{ik} (S_{SGP}^T S_{SGP} - I_{n \times n})_{m\ell} \epsilon_k \epsilon_\ell. \end{aligned}$$

First we bound $\mathbb{E}[\|U^T S_{SGP}^T S_{SGP} \epsilon\|_2^2]$.

$$\mathbb{E}[\|U^T S_{SGP}^T S_{SGP} \epsilon\|_2^2] = \sum_{j=1}^p \sum_{i=1}^n \sum_{k=1}^n \sum_{m=1}^n U_{ij} U_{mj} \mathbb{E}[(S_{SGP}^T S_{SGP} - I_{n \times n})_{ik} (S_{SGP}^T S_{SGP} - I_{n \times n})_{m\ell}] \epsilon_k \epsilon_\ell.$$

Recall that $S_{SGP} \in \mathbb{R}^{r \times n}$, $[S_{SGP}]_{si} = \frac{\lambda_{si}}{\sqrt{r}}$ where X_{si} are i.i.d. sub-Gaussian random variables with mean 0 and sub-Gaussian parameter 1. Hence

$$\mathbb{E}[(S_{SGP}^T S_{SGP} - I_{n \times n})_{ik} (S_{SGP}^T S_{SGP} - I_{n \times n})_{m\ell}] = \frac{1}{r} (\mathbb{I}(i=k) \mathbb{I}(\ell=m) + \mathbb{E}[X_i X_j X_k X_m]),$$

where X_i, X_k, X_ℓ and X_m are i.i.d. sub-Gaussian random variables. Therefore

$$\mathbb{E}[\|U^T S_{SGP}^T S_{SGP} \epsilon\|_2^2] = \frac{1}{r} \sum_{j=1}^p \sum_{i=1}^n \sum_{k=1}^n \sum_{m=1}^n U_{ij} U_{mj} (\mathbb{I}(i=k) \mathbb{I}(\ell=m) + \mathbb{E}[X_i X_k X_\ell X_m]) \epsilon_k \epsilon_\ell.$$

First note that $\mathbb{I}(i=k) \mathbb{I}(\ell=m) + \mathbb{E}[X_i X_k X_\ell X_m] = 0$ unless $i=k$ and $\ell=m$, or $i=\ell$ and $k=\ell$ or any other combination of two pairs of variables have the same index. When $i=k=\ell=m$, $\mathbb{I}(i=k) \mathbb{I}(\ell=m) + \mathbb{E}[X_i X_k X_\ell X_m] = 1 + \mathbb{E}[X_i^4] \leq 2$, since for sub-Gaussian random variables with parameter 1, $\mathbb{E}[X_i^4] \leq 1$ and

$$\begin{aligned} \frac{1}{r} \sum_{j=1}^p \sum_{i=1}^n \sum_{k=1}^n \sum_{m=1}^n U_{ij} U_{mj} (\mathbb{I}(i=k) \mathbb{I}(\ell=m) + \mathbb{E}[X_i X_k X_\ell X_m]) \epsilon_k \epsilon_\ell &= \frac{1}{r} \sum_{j=1}^p \sum_{i=1}^n U_{ij}^2 \epsilon_i^2 (1 + \mathbb{E}[X_i^4]) \\ &\leq \frac{2}{r} \sum_{j=1}^p \sum_{i=1}^n U_{ij}^2 \epsilon_i^2 \\ &\leq \frac{2}{r} \sum_{j=1}^p U_{ij}^2 \|\epsilon\|_2^2 \\ &= \frac{2p}{r} \|\epsilon\|_2^2. \end{aligned}$$

When $i=k$ and $\ell=m$ but $k \neq \ell$, $\mathbb{I}(i=k) \mathbb{I}(\ell=m) + \mathbb{E}[X_i X_k X_\ell X_m] = 2$ and

$$\sum_{j=1}^p \sum_{i=1}^n \sum_{k=1}^n \sum_{m=1}^n U_{ij} U_{mj} (\mathbb{I}(i=k) \mathbb{I}(\ell=m) + \mathbb{E}[X_i X_k X_\ell X_m]) \epsilon_k \epsilon_\ell = 2 \sum_{j=1}^p \sum_{i=1}^n \sum_{k=1}^n U_{ij} U_{mj} \epsilon_i \epsilon_m = 0,$$

since $U^T \epsilon = 0$. Using similar logic when the two pairs of variables are not identical, the sum is 0, and hence

$$\mathbb{E} \|U^T S_{SGP}^T S_{SGP} \epsilon\|_2^2 \leq \frac{2p}{r} \|\epsilon\|_2^2,$$

for all ϵ such that $U^T \epsilon = 0$. Applying Markov's inequality,

$$\|U^T S_{SGP}^T S_{SGP} \epsilon\|_2^2 \leq \frac{22p}{r} \|\epsilon\|_2^2,$$

with probability greater than 0.9. Therefore $\beta(S_{SGP}) \leq \sqrt{\frac{22p}{r}}$ with probability at least 0.9.

Now we bound $\gamma(S_{SGP}) = \|U^T S_{SGP}^T S_{SGP}\|_F^2 = \text{trace}(U^T (S_{SGP}^T S_{SGP})^2 U)/p$:

$$\begin{aligned} \text{trace}(U^T (S_{SGP}^T S_{SGP})^2 U)/p &= \frac{1}{p} \sum_{j=1}^p \sum_{i=1}^n \sum_{k=1}^n [(S_{SGP}^T S_{SGP})^2]_{ik} U_j U_i U_k \\ &= \frac{1}{pr^2} \sum_{j=1}^p \sum_{i=1}^n \sum_{k=1}^n \sum_{v=1}^r \sum_{m=1}^r U_j U_{ij} U_{kj} \sum_{v=1}^r \sum_{m=1}^r U_{ij} U_{kv} X_{mv} X_{mi} X_{lv} X_{lk} \end{aligned}$$

First we bound the expectation:

$$\begin{aligned} \mathbb{E}[\text{trace}(U^T (S_{SGP}^T S_{SGP})^2 U)/p] &= \frac{1}{pr^2} \sum_{j=1}^p \sum_{i=1}^n \sum_{k=1}^n \sum_{v=1}^r \sum_{m=1}^r \mathbb{E}[X_{mv} X_{mi} X_{lv} X_{lk}] \\ &= \frac{1}{pr^2} \sum_{j=1}^p \sum_{i=1}^n \sum_{k=1}^n \sum_{v=1}^r (\sigma^2 - r) U_{ij} U_{kj} \mathbb{E}[X_{iv} X_{kv}] + r \mathbb{E}[X_v^2 X_i X_k] \\ &= \frac{1}{pr^2} \sum_{j=1}^p \sum_{i=1}^n (\sigma^2 - r) U_{ij}^2 (\mathbb{E}[X_i^2])^2 + \frac{1}{pr^2} \sum_{j=1}^p \sum_{i=1}^n \sum_{v=1}^r r U_{ij}^2 \mathbb{E}[X_v^2 X_i^2] \\ &= \frac{1}{pr^2} \sum_{j=1}^p \sum_{i=1}^n (\sigma^2 - r) U_{ij}^2 \sigma^4 + \frac{1}{pr^2} \sum_{j=1}^p \sum_{i=1}^n \sum_{v=1}^r r U_{ij}^2 \mathbb{E}[X_v^2 X_i^2] \\ &= 1 - \frac{1}{r} + \frac{\mu_4}{4r} + \frac{n-1}{r} \\ &\leq 1 + \frac{3}{r} + \frac{n-2}{r} \\ &= 1 + \frac{(n+1)}{r}. \end{aligned}$$

Applying Markov's inequality,

$$\gamma(S_{SGP}) \leq 11 \left(1 + \frac{(n+1)}{r}\right),$$

with probability at least 0.9. This completes the proof for Theorem 3.

B.4 Proof of Theorem 4

For $S = S_{Had}$ we use existing results in Drineas et al. (2011) to lower bound $\alpha^2(S_{Had})$ and $\beta(S_{Had})$ and then upper bound $\gamma(S_{Had})$. Using Lemma 4 in Drineas et al. (2011) provides the desired lower bound on $\alpha^2(S_{Had})$.

To upper bound $\beta(S_{Had})$, we use Lemma 5 in Drineas et al. (2011) which states that:

$$\|U^T S_{Had}^T S_{Had} \epsilon\|_2^2 \leq \frac{20d \log(40nd) \|\epsilon\|_2^2}{r},$$

with probability at least 0.9.

Finally to bound $\gamma(S_{Had})$ recall that $S_{Had} = S_{Unif} H D$, where S_{Unif} is the uniform sampling matrix, D is a diagonal matrix with ± 1 entries and H is the Hadamard matrix:

$$\begin{aligned} \frac{1}{p} \|U^T S_{Had}^T S_{Had} \epsilon\|_2^2 &= \frac{1}{p} [\text{trace}(U^T (S_{Had}^T S_{Had})^2 U)] \\ &= \frac{1}{p} [\text{trace}(U^T (D^T H^T S_{Unif}^T S_{Unif} H D)^2 U)] \\ &= \frac{1}{p} [\text{trace}(U^T D^T H^T S_{Unif}^T S_{Unif} H D D^T H^T S_{Unif}^T S_{Unif} H D U)] \\ &= \frac{1}{p} [\text{trace}(U^T D^T H^T (S_{Unif}^T S_{Unif})^2 H D U)] \\ &= \frac{1}{p} \sum_{j=1}^p \sum_{i=1}^n \sum_{k=1}^n [H D U]_{ij} [H D U]_{kj} [(S_{Unif}^T S_{Unif})^2]_{ki} \\ &= \frac{1}{p} \sum_{j=1}^p \sum_{i=1}^n [H D U]_{ij}^2 [S_{Unif}^T S_{Unif}]_{ii}^2. \end{aligned}$$

Using Lemma 3 in Drineas et al. (2011), with probability greater than 0.95,

$$\frac{1}{p} \sum_{j=1}^p [H D U]_{ij}^2 \leq \frac{2 \log(40np)}{n}.$$

In addition, we have that

$$\begin{aligned} \frac{1}{p} \|U^T S_{Had}^T S_{Had} \epsilon\|_2^2 &= \frac{1}{p} \sum_{j=1}^p \sum_{i=1}^n [H D U]_{ij}^2 [S_{Unif}^T S_{Unif}]_{ii}^2 \\ &\leq \frac{2 \log(40np)}{n} \sum_{i=1}^n [S_{Unif}^T S_{Unif}]_{ii}^2. \end{aligned}$$

Now we bound $\mathbb{E} \sum_{i=1}^n [S_{Unif}^T S_{Unif}]_{ii}^2$.

$$\begin{aligned}
 \sum_{i=1}^n \mathbb{E}(|S_{\text{Unif}}^T S_{\text{Unif}} f_{\text{ii}}|^2) &= \frac{n^2}{r^2} \sum_{i=1}^n \sum_{m=1}^r \sum_{\ell=1}^r \mathbb{E}[\sigma_m^2 \sigma_\ell^2] \\
 &= \frac{n^2}{r^2} \sum_{i=1}^n \sum_{m=1}^r \sum_{\ell=1}^r \mathbb{E}[\sigma_m \sigma_\ell] \\
 &= \frac{n^2}{r^2} \sum_{i=1}^n \left[\frac{r^2 - r}{n^2} + \frac{r}{n} \right] \\
 &= \frac{n^2}{r^2} \left[\frac{r^2 - r}{n} + r \right] \\
 &= n - \frac{n}{r} + \frac{n^2}{r} \\
 &\leq n + \frac{n^2}{r}.
 \end{aligned}$$

Using Markov's inequality, with probability greater than 0.9,

$$\sum_{i=1}^n |S_{\text{Unif}}^T S_{\text{Unif}} f_{\text{ii}}|^2 \leq 10 \left(n + \frac{n^2}{r} \right),$$

which completes the proof.

Abstract

Inference and learning of graphical models are both well-studied problems in statistics and machine learning that have found many applications in science and engineering. However, exact inference is intractable in general graphical models, which suggests the problem of seeking the best approximation to a collection of random variables within some tractable family of graphical models. In this paper, we focus on the class of planar Ising models, for which exact inference is tractable using techniques of statistical physics. Based on these techniques and recent methods for planarity testing and planar embedding, we propose a greedy algorithm for learning the best planar Ising model to approximate an arbitrary collection of binary random variables (possibly from sample data). Given the set of all pairwise correlations among variables, we select a planar graph and optimal planar Ising model defined on this graph to best approximate that set of correlations. We demonstrate our method in simulations and for two applications: modeling senate voting records and identifying geo-chemical depth trends from Mars rover data.

Keywords: Ising models, graphical models

1. Introduction

Graphical models are widely used to represent the statistical relations among a set of random variables (Lauritzen, 1996; MacKay, 2003). Nodes of the graph correspond to random variables and edges of the graph represent statistical interactions among the variables. The problems of inference and learning on graphical models arise in many practical applications. The problem of inference is to deduce certain statistical properties (such as marginal probabilities, modes etc.) of a given set of random variables whose graphical model is known. Inference has wide applications in areas such as error correcting codes, statistical physics and so on. The problem of learning on the other hand is to deduce the graphical model of a set of random variables given statistics (possibly from samples) of the random variables. Learning is also a widely encountered problem in areas such as biology, neuroscience and so on (Barabasi and Oltvai, 2004; Smith et al., 2011).

The *Ising model*, a class of binary-variable graphical models with pairwise interactions, has been studied by physicists as a simple model of order-disorder transitions in magnetic materials (Onsager, 1944). Remarkably, it was found that in the special case of an Ising model with zero-mean $\{-1, +1\}$ binary random variables and pairwise interactions defined on a planar graph, calculation of the partition function (which is closely tied to inference) is tractable, essentially reducing to calculation of a matrix determinant (Kac and Ward, 1952; Sherman, 1960; Kasteleyn, 1963; Fisher, 1966). Planar graph inference methods have been used in machine learning for efficient inference on planar graphs (Schraudolph and Kamenetsky, 2008; Gómez et al., 2010), in approximating inference for general graphs with planar graph decomposition (Jaakkola and T., 2007); and applied to problems such as computer vision (Batra et al., 2010; Yarkony et al., 2012) and financial forecasting (Pozzi et al., 2013), usually as an approximation method for problems with non-binary data.

We address the problem of approximating a collection of binary random variables (given their pairwise marginal distributions) by a zero-mean planar Ising model. We also consider the related problem of selecting a non-zero mean Ising model defined on an outer-planar graph (these models are also tractable, being essentially equivalent to a zero-field model on a related planar graph).

There has been a great deal of work on learning graphical models. Much of these have focused on learning over the class of thin graphical models (Deshpande et al., 2001; Bach and Jordan, 2001; Karger and Srebro, 2001; Shahaf et al., 2009) for which inference is tractable by converting the model to a junction tree. The simplest case of this is learning tree models (treewidth one graphs) for which it is tractable to find the best tree model by reduction to a max-weight spanning tree problem (Chow and Liu, 1968). However, the problem of finding the best bounded-treewidth model is NP-hard for treewidths greater than two (Karger and Srebro, 2001), and so heuristic methods are used to select the graph structure (Deshpande et al., 2001; Karger and Srebro, 2001). Another popular method is to use convex optimization of the log-likelihood penalized by the ℓ_1 norm of parameters of the graphical model so as to promote sparsity (Banerjee et al., 2008; Lee et al., 2006). To go beyond low-treewidth graphs, such methods either focus on Gaussian graphical models or adopt a tractable approximation of the likelihood. Other methods learn only the graph structure itself (Ravikumar et al., 2010; Abbeel et al., 2006) and are often able to demonstrate asymptotic correctness of this estimate under appropriate conditions.

In contrast to existing approaches, this paper explores planarity as an alternative restriction on the model class, instead of low treewidth, to make learning tractable while maintaining a tractable model for inference, unlike unrestricted regularized approaches, while still providing a solution in which the number of edges learned is linear in the number of variables.

2. Preliminaries

We develop our notation and briefly review the necessary background theory on graph estimation, Ising models and exact inference in planar graphs.

2.1 Divergence and Likelihood

A graph represents a joint probability distribution over a collection of variables. Suppose we want to calculate how well a probability distribution Q approximates another probability distribution P (on the same sample space \mathcal{X}). For any two probability distributions P and Q on some sample space \mathcal{X} , we denote by $D(P, Q)$ the *Kullback-Leibler divergence* (or *relative entropy*) between P and Q as $D(P, Q) = \sum_{x \in \mathcal{X}} P(x) \log \frac{P(x)}{Q(x)}$. The *log-likelihood function* is defined as $LL(P, Q) = \sum_{x \in \mathcal{X}} P(x) \log Q(x)$. The probability distribution in a family \mathcal{F} that maximizes the log-likelihood of a probability distribution P is called the *maximum-likelihood estimate* of P in \mathcal{F} , and this is equivalent to the *minimum-divergence projection* of P to \mathcal{F} , so that $P_{\mathcal{F}} = \arg \max_{Q \in \mathcal{F}} LL(P, Q) = \arg \min_{Q \in \mathcal{F}} D(P, Q)$.

2.2 Graphical Models and The Ising Model

We will be dealing with binary random variables throughout the paper. We write $P(x)$ to denote the probability distribution of a collection of random variables $x = (x_1, \dots, x_n)$. Unless otherwise stated, we work with undirected graphs $G = (V, E)$ with vertex (or node) set V and edges $\{i, j\} \in E \subset \binom{V}{2}$. For vertices $i, j \in V$ we write $G + ij$ to denote the graph $(V, E \cup \{i, j\})$. A *pairwise graphical model* is a probability distribution $P(x) = P(x_1, \dots, x_n)$ that is defined on a graph $G = (V, E)$ with vertices $V = \{1, \dots, n\}$ as

$$P(x) \propto \prod_{i \in V} \psi_i(x_i) \prod_{\{i, j\} \in E} \psi_{ij}(x_i, x_j) \\ \propto \exp \left\{ \sum_{i \in V} f_i(x_i) + \sum_{\{i, j\} \in E} f_{ij}(x_i, x_j) \right\}, \quad (1)$$

where $\psi_i, \psi_{ij} \geq 0$ are non-negative node and edge compatibility functions. For positive ψ 's, we may also represent $P(x)$ as a Gibbs distribution with potentials $f_i = \log \psi_i$ and $f_{ij} = \log \psi_{ij}$.

Definition 1 An Ising model on binary random variables $x = (x_1, \dots, x_n)$ and graph $G = (V, E)$ is the probability distribution defined by

$$P(x) = \frac{1}{Z(\theta)} \exp \left\{ \sum_{i \in V} \theta_i x_i + \sum_{\{i, j\} \in E} \theta_{ij} x_i x_j \right\}, \\ Z(\theta) = \sum_x \exp \left\{ \sum_{i \in V} \theta_i x_i + \sum_{\{i, j\} \in E} \theta_{ij} x_i x_j \right\},$$

where $x_i \in \{-1, 1\}$. The partition function $Z(\theta)$ serves to normalize the probability distribution.

Formally, this defines an *exponential family* $P_\theta(x) = \exp\{\theta^T \phi(x) - \Phi(\theta)\}$ (Barndorff-Nielsen, 1979; Wainwright and Jordan, 2008) based on sufficient statistics $\phi_i(x) = x_i, i \in V$ and $\phi_{ij}(x) = x_i x_j, \{i, j\} \in E$, parameters $\theta_i, i \in V$ and $\theta_{ij}, \{i, j\} \in E$ and moment

parameters $(\mu_i = \mathbb{E}[x_i], i \in V)$ and $(\mu_{ij} = \mathbb{E}[x_i x_j], \{i, j\} \in E)$. The function $\Phi(\theta) = \log Z(\theta)$ is a convex function of θ and has the moment generating properties: $\nabla \Phi(\theta) = \mathbb{E}_\theta[\phi(x)] = \mu$ and $\nabla^2 \Phi(\theta) = \mathbb{E}_\theta[(\phi(x) - \mu)(\phi(x) - \mu)^T]$.

In fact, any pairwise graphical model among binary variables can be represented as an Ising model:

$$\theta_i = \frac{1}{2} \sum_{x_i} x_i f_i(x_i) + \frac{1}{4} \sum_{\{i, j\} \in E} \sum_{x_i, x_j} x_i f_{ij}(x_i, x_j), \\ \theta_{ij} = \frac{1}{4} \sum_{x_i, x_j} x_i x_j f_{ij}(x_i, x_j).$$

The moments can be computed as: $\mu_i = \sum_{x_i} x_i P(x_i)$ and $\mu_{ij} = \sum_{x_i, x_j} x_i x_j P(x_i, x_j)$. Inversely, the marginals are computed by:

$$P(x_i) = \frac{1}{2} (1 + \mu_i x_i), \\ P(x_i, x_j) = \frac{1}{4} (1 + \mu_i x_i + \mu_j x_j + \mu_{ij} x_i x_j).$$

We will be especially concerned with the following sub-family of Ising models:

Definition 2 An Ising model is said to be zero-field if $\theta_i = 0$ for all $i \in V$. It is zero-mean if $\mu_i = 0$ ($P(x_i = \pm 1) = \frac{1}{2}$) for all $i \in V$.

The Ising model is zero-field if and only if it is zero-mean. Although the zero-field assumption appears very restrictive, a general Ising model can be represented as a zero-field model by adding one auxiliary variable node connected to every other node of the graph (Jaakkola and T., 2007). The parameters and moments of the two models are then related as follows:

Proposition 1 Consider the Ising model on $G = (V, E)$ with $V = \{1, \dots, n\}$, parameters $\{\theta_i\}$ and $\{\theta_{ij}\}$, moments $\{\mu_i\}$ and $\{\mu_{ij}\}$ and partition function Z . Let $\widehat{G} = (\widehat{V}, \widehat{E})$ denote the extended graph based on nodes $\widehat{V} = V \cup \{n+1\}$ with edges $\widehat{E} = E \cup \{\{i, n+1\}, i \in V\}$. We define a zero-field Ising model on \widehat{G} with parameters $\{\theta_{ij}\}$, moments $\{\widehat{\mu}_{ij}\}$ and partition function \widehat{Z} . If we set the parameters according to

$$\widehat{\theta}_{ij} = \begin{cases} \theta_i & \text{if } j = n+1 \\ \theta_{ij} & \text{otherwise} \end{cases}, \\ \widehat{\mu}_{ij} = \begin{cases} \mu_i & \text{if } j = n+1 \\ \mu_{ij} & \text{otherwise} \end{cases}.$$

then $\widehat{Z} = 2Z$ and

Thus, inference on the corresponding zero-field Ising model on the extended graph \widehat{G} is equivalent to inference on the (non-zero-field) Ising model defined on G . Proof given in Appendix A.

2.3 Inference for Planar Ising Models

The motivation for our paper is the following result on tractability of inference for the planar zero-field Ising model.

Definition 3 *A graph is planar if it may be embedded in the plane without any edge crossings.*

Moreover, it is known that any planar graph can be embedded such that all edges are drawn as straight lines.

Theorem 1 (Kac and Ward, 1952; Sherman, 1960; Loeb, 2010) *Let G be a planar graph with specified straight-line embedding in the plane and let $\phi_{i,j,k} \in [-\pi, +\pi]$ denote the clockwise rotation between the directed edges (i,j) and (j,k) . We define the matrix $W \in \mathbb{C}^{2|E| \times 2|E|}$ indexed by directed edges of the graph as follows: $W = AD$ where D is the diagonal matrix with $D_{i,j,i} = \tanh \theta_{ij} \triangleq w_{ij}$ and*

$$A_{i,j,kl} = \begin{cases} \exp(\frac{1}{2}\sqrt{-1}\phi_{ijl}), & j = k \text{ and } i \neq l \\ 0, & \text{otherwise.} \end{cases}$$

Then, the partition function of the zero-field planar Ising model is given by the Kac-Ward determinant formula:

$$Z = 2^n \left(\prod_{\{i,j\} \in E} \cosh \theta_{ij} \right) \det(I - W)^{\frac{1}{2}}.$$

Another related method for computing the Ising model partition function is based on counting perfect matchings of planar graphs (Kasteleyn, 1963; Fisher, 1966). Thus, calculating the partition function reduces to calculating the determinant of a matrix; therefore, using the generalized nested dissection algorithm to exploit sparsity of the matrix, the complexity of these calculations is $O(n^{3/2})$ (Lipton et al., 1979; Lipton and Tarjan, 1979; Galluccio et al., 2000). Thus, inference of the zero-field planar Ising model is tractable and scales well with problem size.

The gradient and Hessian of the log-partition function $\Phi(\theta) = \log Z(\theta)$ can also be calculated efficiently from the Kac-Ward determinant formula. Derivatives of $\Phi(\theta)$ recover the moment parameters of the exponential family model as $\nabla \Phi(\theta) = \mathbb{E}_\theta[\phi] = \mu$ (Barndorff-Nielsen, 1979; Wainwright and Jordan, 2008). Thus, inference of moments (and node and edge marginals) is tractable for the zero-field planar Ising model.

Proposition 2 *Let $\mu = \nabla \Phi(\theta)$, $H = \nabla^2 \Phi(\theta)$. Let $S = (I - W)^{-1}A$ and $T = (I + P)(S \circ S^T)(I + P^T)$ where A and W are defined as in Theorem 1, \circ denotes the element-wise product and P is the permutation matrix swapping the indices of the directed edges (i,j) and (j,i) . Then,*

$$\mu_{ij} = w_{ij} - \frac{1}{2}(1 - w_{ij}^2)(S_{ij,ij} + S_{ji,ji}) \quad ij = kl \\ H_{i,j,kl} = \begin{cases} 1 - \mu_{ij}^2, & ij = kl \\ -\frac{1}{2}(1 - w_{ij}^2)T_{i,j,kl}(1 - w_{kl}^2), & \text{otherwise.} \end{cases}$$

Calculating the full matrix S requires $O(n^3)$ calculations. However, to compute just the moments μ only the diagonal elements of S are needed. Then, using the generalized nested dissection method, inference of moments (edge-wise marginals) of the zero-field Ising model can be achieved with complexity $O(n^{3/2})$. Computing the full Hessian is more expensive, requiring $O(n^3)$ calculations.

2.3.1 INFERENCE FOR OUTER-PLANAR GRAPHICAL MODELS

We emphasize that the above calculations require both a planar graph G and a zero-field Ising model. Using the graphical transformation of Proposition 1, the latter zero-field condition may be relaxed but at the expense of adding an auxiliary node connected to all the other nodes. In general planar graphs G , the new graph \widehat{G} may not be planar and hence may not admit tractable inference calculations. However, for the subset of planar graphs where this transformation does preserve planarity inference is still tractable.

Definition 4 *A graph G is said to be outer-planar if there exists an embedding of G in the plane where all the nodes are on the outer face.*

In other words, the graph G is outer-planar if the extended graph \widehat{G} (defined by Proposition 1) is planar. Then, from Proposition 1 and Theorem 1 it follows that:

Proposition 3 (Jaakkola and T., 2007) *The partition function and moments of any outer-planar Ising graphical model (not necessarily zero-field) can be calculated efficiently. Hence, inference is tractable for any binary-variable graphical model with pairwise interactions defined on an outer-planar graph.*

This motivates the problem of learning outer-planar graphical models for a collection of (possibly non-zero mean) binary random variables.

3. Learning Planar Ising Models

This section addresses the main goals of the paper, which are two-fold:

1. Solving for the maximum-likelihood Ising model on a given planar graph to best approximate a collection of zero-mean random variables.
2. Selecting heuristically the planar graph to obtain the best approximation.

We address these problems in the following two subsections. The solution of the first problem is an integral part of our approach to the second. Both solutions are easily adapted to the context of learning outer-planar graphical models of (possibly non-zero mean) binary random variables.

3.1 Maximum-Likelihood Parameter Estimation

Maximum-likelihood estimation over an exponential family is a convex optimization problem based on the log-partition function $\Phi(\theta)$. In the case of the zero-field Ising model defined on a given planar graph it is tractable to compute $\Phi(\theta)$ via a matrix determinant described in

Theorem 1. Thus, we obtain an unconstrained, tractable, convex optimization problem for the maximum-likelihood zero-field Ising model on the planar graph G to best approximate a probability distribution $P(x)$:

$$\max_{\theta} \{\mu^T \theta - \Phi(\theta)\} = \max_{\theta \in \mathbb{R}^{|E|}} \left\{ \sum_{ij} (\mu_{ij} \theta_{ij} - \log \cosh \theta_{ij}) - \frac{1}{2} \log \det(I - W(\theta)) \right\}.$$

Here, $\mu_{ij} = \mathbb{E}_P[x_i x_j]$ for all edges $\{i, j\} \in G$ and the matrix $W(\theta)$ is as defined in Theorem 1. If P represents the empirical distribution of a set of independent identically-distributed (iid) samples $\{x^{(s)}, s = 1, \dots, S\}$, then $\{\mu_{ij}\}$ are the corresponding empirical moments $\mu_{ij} = \frac{1}{S} \sum_s x_i^{(s)} x_j^{(s)}$.

3.1.1 NEWTON'S METHOD

We solve this unconstrained convex optimization problem using Newton's method with step-size chosen by back-tracking line search (Boyd and Vandenberghe, 2004). This produces a sequence of estimates $\theta^{(t)}$ calculated as follows:

$$\theta^{(t+1)} = \theta^{(t)} + \lambda_t H(\theta^{(t)})^{-1} (\mu(\theta^{(t)}) - \mu),$$

where $\mu(\theta^{(t)})$ and $H(\theta^{(t)})$ are calculated using Proposition 2 and $\lambda_t \in (0, 1]$ is a step-size parameter chosen by backtracking line search (see Boyd and Vandenberghe (2004): Chapter 9, Section 2 for details). The per iteration complexity of this optimization is $O(n^3)$ using explicit computation of the Hessian at each iteration. This complexity can be offset somewhat by only re-computing the Hessian a few times (reusing the same Hessian for a number of iterations), to take advantage of the fact that the gradient computation only requires $O(n^{\frac{3}{2}})$ calculations. As Newton's method has quadratic convergence, the number of iterations required to achieve a high-accuracy solution is typically 8-16 iterations (essentially independent of problem size). We estimate the computational complexity of solving this convex optimization problem as roughly $O(n^3)$.

3.2 Greedy Planar Graph Selection

We now consider the problem of selection of the planar graph G to best approximate a probability distribution $P(x)$ with pairwise moments $\mu_{ij} = \mathbb{E}_P[x_i x_j]$ given for all $i, j \in V$. Formally, we seek the planar graph that maximizes the log-likelihood (minimizes the divergence) relative to P :

$$\hat{G} = \arg \max_{G \in \mathcal{P}_V} LL(P, P_G) = \arg \max_{Q \in \mathcal{F}_G} LL(P, Q),$$

where \mathcal{P}_V is the set of planar graphs on the vertex set V , \mathcal{F}_G denotes the family of zero-field Ising models defined on graph G and $P_G = \arg \max_{Q \in \mathcal{F}_G} LL(P, Q)$ is the maximum-likelihood (minimum-divergence) approximation to P over this family.

We obtain a heuristic solution to this graph selection problem using the following greedy edge-selection procedure. The input to the algorithm is a probability distribution P (which could be empirical) on n binary $\{-1, 1\}$ random variables. In fact, it is sufficient to summarize P by its pairwise correlations $\mu_{ij} = \mathbb{E}_P[x_i x_j]$ on all pairs $i, j \in V$. The output is a

maximal planar graph G and the maximum-likelihood approximation θ_G to P in the family of zero-field Ising models defined on this graph. Note that a maximal planar graph is a planar graph for which no new edge can be added that would maintain planarity. Planar graphs are inherently sparse. All maximal planar graphs with $n > 2$ have $3n - 6$ edges¹.

Algorithm 1 GreedyPlanarGraphSelect(P)

```

1:  $G = \emptyset, \theta_G = 0$ 
2: for  $k = 1 : 3n - 6$  do
    $\triangleright$  Add edges until maximal planar graph reached
3:    $\Delta = \{\{i, j\} \subset V \mid \{i, j\} \notin G, G + ij \in \mathcal{P}_V\}$ 
    $\triangleright$  Set of edges that preserve planarity
4:    $\hat{\mu}_\Delta = \{\hat{\mu}_{ij} = \mathbb{E}_{P_G}[x_i x_j], \{i, j\} \in \Delta\}$ 
    $\triangleright$  Compute pairwise correlations
5:    $G \leftarrow G \cup \arg \max_{e \in \Delta} D(P_{e_i}, P_e)$ 
    $\triangleright$  Select edge that maximizes gain in log-likelihood
6:    $\theta_G = \text{PlanarIsing}(G, P)$ 
    $\triangleright$  Compute maximum-likelihood parameters for  $G$ 
7: end for

```

The algorithm starts with an empty graph and then sequentially adds edges to the graph one at a time so as to greedily increase the log-likelihood (decrease the divergence) relative to P as much as possible at each step. Here is a more detailed description of the algorithm along with estimates of the computational complexity of each step:

- *Line 3.* First, we enumerate the set Δ of all edges one might add (individually) to the graph while preserving planarity. This is accomplished by an $O(n^3)$ algorithm in which we iterate over all pairs $\{i, j\} \notin G$ and for each such pair we form the graph $G + ij$ and test planarity of this graph using known $O(n)$ algorithms (Chrobak and Payne, 1995).
- *Line 4.* Next, we perform tractable inference calculations with respect to the Ising model on G to calculate the pairwise correlations $\hat{\mu}_{ij}$ for all pairs $\{i, j\} \in \Delta$. This is accomplished using $O(n^{\frac{3}{2}})$ inference calculations on augmented versions of the graph G . For computational efficiency instead of calculating the addition of each proposed edge individually, moments of proposed edges are calculated in batches as follows. For each inference calculation we add as many edges to G from Δ as possible (setting $\theta = 0$ on these edges) while preserving planarity and then calculate all the edge-wise moments of this graph using Proposition 2 (including the zero-edges). This requires at most $O(n)$ iterations to cover all pairs of Δ , so the worst-case complexity to compute all required pairwise moments is $O(n^{\frac{5}{2}})$.
- *Line 5.* Once we have these moments, which specify the corresponding pairwise marginals of the current Ising model, we compare these moments (pairwise marginals) to those of the input distribution P by evaluating the pairwise KL-divergence between the Ising model and P . As seen by the following proposition, this gives us a lower-

¹ Euler's formula states that for a planar graph, $n - e + f = 2$, where f is the number of faces and e is the number of edges (Ritchson, 2012). The faces of a planar graph are simple polygons, so each face has at least 3 edges and each edge is part of at most 2 faces, $2e \leq 3f$. Combining these two properties, gives $e \leq 3n - 6$ for planar graphs. A maximal planar graph is triangulated, meaning that all faces have three sides, and therefore $e = 3n - 6$ (if any face has more than 3 sides, an edge can be added as a chord of that face polygon without breaking planarity).

bound on the improvement obtained by adding edge $\{i, j\}$ (see Appendix A for proof):

Proposition 4 Let P_G and P_{G+ij} be projections of P on G and $G + ij$ respectively.

Then,

$$D(P, P_G) - D(P, P_{G+ij}) \geq D(P(x_i, x_j), P_G(x_i, x_j)),$$

where $P(x_i, x_j)$ and $P_G(x_i, x_j)$ represent the marginal distributions on x_i, x_j of probabilities P and P_G respectively.

Thus, we greedily select the next edge $\{i, j\}$ to add so as to maximize this lower-bound on the improvement measured by the increase on log-likelihood (this being equal to the decrease in KL-divergence).

- *Line 6.* Finally, we calculate the new maximum-likelihood parameters θ_G on the new graph $G \leftarrow G + ij$. This involves solving the convex optimization problem discussed in the preceding subsection, which requires $O(n^3)$ complexity. This step is necessary in order to subsequently calculate the pairwise moments $\tilde{\mu}$ which guide further edge-selection steps, and also to provide the final estimate.

We continue adding one edge at a time until a maximal planar graph (with $3n - 6$ edges) is obtained. Thus, the total complexity of our greedy algorithm for planar graph selection is $O(n^4)$.

3.2.1 NON-MAXIMAL PLANAR GRAPHS

Since adding an edge always improves the log-likelihood, the greedy algorithm always outputs a maximal planar graph. However, this might lead to over-fitting of the data especially when the input probability distribution is an empirical distribution. Note that at $3n - 6$ edges, the maximal planar graph is sparse and our empirical work indicates that over-fitting is often not an issue. In the case that over-fitting is a concern, we could terminate the algorithm when adding an edge to the graph would only improve the log-likelihood by less than some threshold γ . A data-driven search can be performed for a suitable value of this threshold so as to minimize some estimate of the generalization, such as in cross validation methods (Zhang, 1993). Or, one could use some heuristic value for γ based on the number of samples such as Akaike's information criterion (AIC) or Schwarz's Bayesian information criterion (BIC) (Akaike, 1974; Schwarz, 1978).

3.2.2 OUTER-PLANAR GRAPHS AND NON-ZERO MEANS

The greedy algorithm returns a zero-field Ising model (which has zero mean for all the random variables) defined on a planar graph. If the actual random variables are non-zero mean, this may not be desirable. For this case we may prefer to exactly model the means of each random variable but still retain tractability by restricting the greedy learning algorithm to select outer-planar graphs. This model faithfully represents the marginals of each random variable but at the cost of modeling fewer pairwise interactions among the variables.

This is equivalent to the following procedure. First, given the sample moments $\{\mu_i\}$ and $\{\mu_{ij}\}$ we convert these to an equivalent set of zero-mean moments $\hat{\mu}$ on the extended

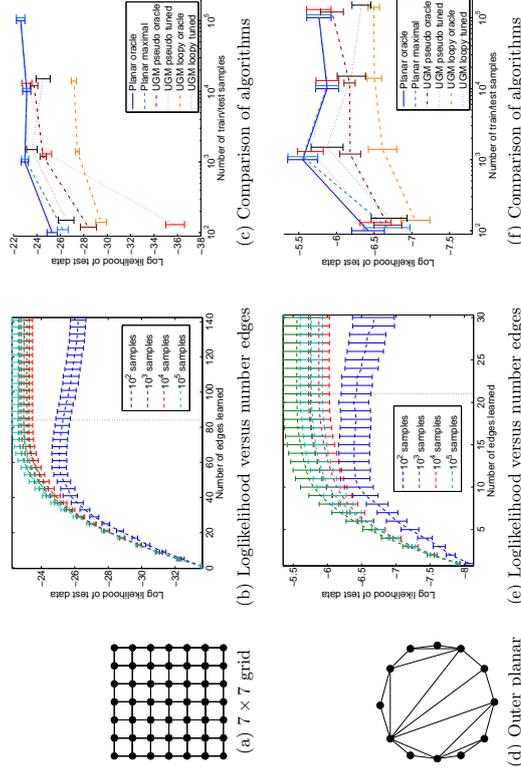

Figure 1: Results on known models, (top row): 7×7 grid; and (bottom row): outer planar. Left column (a,d): true graph. Middle column (b,e): likelihood of learned planar graphs as edges are added; the true number of edges is marked with a vertical dashed line. Right column (c,f): likelihood of test data for various algorithms; x-axis values are perturbed horizontally so that overlapping errorbars are visible.

vertex set $\hat{V} = V \cup \{n + 1\}$ according to Proposition 1. Then, we select a zero-mean planar Ising model for these moments using our greedy algorithm. However, to fit the means of each of the original n variables, we initialize this graph to include all the edges $\{i, n + 1\}$ for all $i \in V$ (requiring that these are present in our final estimate of the graph \hat{G}). After this initialization step, we use the same greedy edge-selection procedure as before. This yields the graph \hat{G} and parameters $\theta_{\hat{G}}$. Lastly, we convert back to a (non-zero field) Ising model on the subgraph of \hat{G} defined on nodes V , as prescribed by Proposition 1. The resulting graph G and parameters θ_G is our heuristic solution for the maximum-likelihood outer-planar Ising model.

We remark that it is not essential to choose between the zero-field planar Ising model and the outer-planar Ising model. The greedy algorithm may instead select something in between—a partial outer-planar Ising model where only nodes of the outer-face are allowed to have non-zero means. This is accomplished simply by omitting the initialization step of adding edges $\{i, n + 1\}$ for all $i \in V$.

4. Experiments

We present the results of experiments evaluating our algorithm on known models with simulated data to evaluate the correctness of the learned models. We generate two styles of known Ising models: a 7×7 grid ($n = 49$) with zero-field; and a 12-node outer planar model where nodes have non-zero mean; shown in Figures 1a and 1d. The edge parameters are chosen uniformly randomly between -1 and 1 with the condition that the absolute value be greater than a threshold (chosen to be 0.05) so as to avoid edges with negligible interactions. We use Gibbs sampling to obtain samples from this model and calculate empirical moments from these samples which are then passed as input to our algorithm. We run 10 trials of randomly generated edge parameters and data samples. Though our algorithm can run on graphs with many more nodes, we choose small examples here to illustrate the result effectively. On the outer planar model, we ensure that the first moments of all the nodes are satisfied by starting our algorithm with the auxiliary node connected to all other nodes.

As the planar learning algorithm adds edges to the model, the likelihood of the training data is guaranteed to increase. We assess how adding edges affects the likelihood of out-of-sample test data. Figures 1b and 1e demonstrate that likelihood on test sets generally increases as edges are added up to the maximal planar graph. The true number of edges in each synthetic graph is marked with a vertical dotted line. On the smallest data sets (100 samples) the out-of-sample performance begins to degrade, a sign of over-fitting the training data; yet the likelihood of the maximal graph is not significantly worse than the best likelihood obtained (with fewer edges).

We also compare against a Markov random field (MRF) learning algorithm for binary data (Schmidt et al., 2008), as implemented in the undirected graphical model learning Matlab package, UGMLearn². UGM is not restricted to learning planar graphs. The objective is optimized via projected gradient descent. We try two versions of the objective function, one using pseudo-likelihood and the other using loopy belief propagation for inference. UGM employs a regularization parameter which we set using two different methods. First, we used the *tuning* method on validation data as detailed in Schmidt et al. (2008). That is, we split the data into two parts, train on half the data using 7 different values for the parameter; measure the data likelihood of the other half of the data and vice-versa, then select the parameter value that maximizes the validation data likelihood across both folds. The learned model is trained on the full training data with the tuned regularization parameter value. The second method for setting the regularization parameter we call the *oracle* method, where we select the learned model at the true number of edges, k , in our known models. For UGM, we set the regularization parameter via linear search until k edges are learned. The likelihood of test data for the learned UGM model is calculated exactly when $n \leq 25$; in this case, the outer planar example. For larger graphs, e.g. the grid example, the likelihood of test data for UGM is approximated via loopy belief propagation, which we observed to converge well therefore providing a reasonable estimate.

We compare the likelihood of test data from the various learned models in Figures 1c and 1f. For comparison, we selected the maximal planar graph that our algorithm learns, **Planar maximal**; as well as the planar graph learned if the algorithm was stopped when the true number of edges are learned, **Planar oracle**. We compare against UGM **pseudo**

tuned and UGM **loopy tuned**, both of which tune the regularization parameter on validation data; but the former uses pseudo-likelihood in learning and the latter uses loopy belief propagation. The tuning method is the most common way of selecting the regularization parameter, but tends to produce relatively dense graphs. For fair comparison, we also show the likelihood of UGM **pseudo oracle** and UGM **loopy oracle**; that is, the model with the known true number of edges.

Figures 1c and 1f show that our greedy planar Ising model learning algorithm is at least as accurate and often better than the UGM learning algorithms on these inputs. As mentioned earlier, we see that **Planar maximal** and **Planar oracle** fit test data nearly equally well. On the outer planar model, UGM **pseudo tuned** performs nearly as well as our planar algorithm, yet on the larger grid model it performs quite poorly at the smaller sample sizes. UGM **loopy tuned** performs more consistently close to our planar algorithm, but it seems that loopy belief propagation performs worse at large sample sizes.

On the largest data set (10^5 samples) of the 7×7 grid model, UGM was aborted after running for 40 hours without reaching convergence on a single run, and so results are not available.

5. Applications

We apply our planar graph learning algorithm to real-world data in which there is no guarantee that the data is generated according to our model assumptions. The first application models voting patterns of the United States senate, while the second application models geological layers in rocks on Mars. We compare our learned planar graphs against the non-planar graph learning algorithm UGM, as described in the previous section. For the UGM learned graphs, the likelihood of test data is approximated via loopy belief propagation, which we observed to converge well therefore providing a reasonable estimate. Quantitative comparisons indicate that the learned planar models better predict held-out test data with sparser graphs than the non-planar graphs. We also discuss qualitative comparisons of the learned graphs.

5.1 Modeling Correlations of Senator Voting

We consider an interesting application of our algorithm to model correlations of senator voting following Banerjee et al. (2008). We use senator voting data from the years 2009 and 2010 to calculate correlations in the voting patterns among senators. A *Yea* vote is treated as $+1$ and a *Nay* vote is treated as -1 . We also treat non-votes as -1 , but only consider senators who voted in at least $\frac{2}{3}$ of the votes per year to limit bias. The data includes $n = 108$ variables and 645 samples. To accommodate the non-zero mean data we add an auxiliary node and allow the algorithm to select the connections between it and other nodes. We run a 10-fold cross-validation, training on 90% of the data and measuring likelihood on the held-out 10% of data. Figure 3 shows that the likelihood of test data increases as edges are added. We also show the likelihood of cross-validation test data for the UGM **pseudo** and UGM **loopy** algorithms for two different methods of choosing the value of the regularization parameter: (1) the value that produces the same number of edges as the maximal planar graph (at 318 edges); and (2) the value selected by tuning with validation data (at a variable number of edges, typically a dense graph). The likelihood of the sparse UGM models are

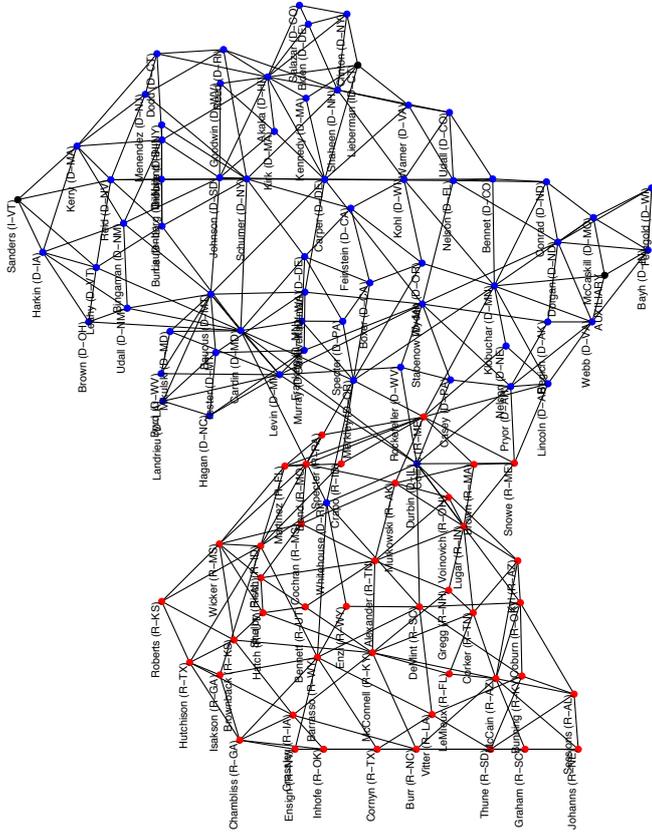

Figure 2: Senator voting results: Learned planar graphical model representing the senator voting pattern. Blue nodes represent Democrats, red nodes represent Republicans and black nodes represents Independents. We use a force-directed graph drawing algorithm (Fruchterman and Reingold, 1991).

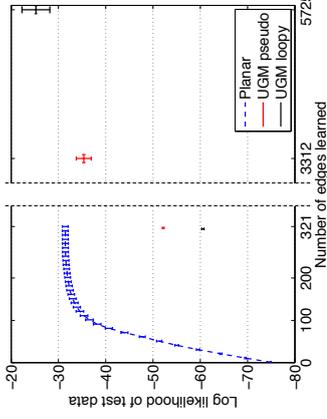

Figure 3: Senator voting results: Comparison of algorithms by likelihood of holdout data versus the number of edges in the learned graph. Note the break in the x-axis, due to tuned UGM learning dense graphs. On the tuned UGM models, we indicate standard error on number of edges learned.

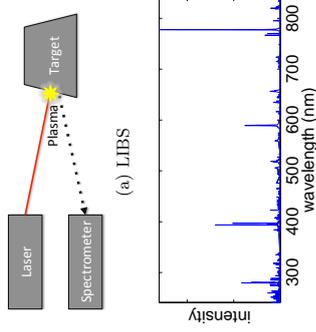

Figure 4: The ChemCam LIBS instrument fires a laser at a target, creating a plasma. Depending on its chemical composition, the plasma gives off different wavelengths of light which are measured by the spectrometer, producing an observed spectrum. Each shot ablates the target surface, leaving a small pit. Typically, sequences of 30 or more shots are fired in several locations on a single target.

5.2 Discovering Depth Trends in Rocks on Mars from Sample Correlations

Our second real-world data set consists of geological observations from the Mars rover *Curiosity*. We are interested in identifying correlations in chemical composition among spatially-related rock samples as taken from the Mars rover *Curiosity*. The ChemCam instrument onboard *Curiosity* collects observations of the chemical composition of rock targets using Laser-Induced Breakdown Spectrometry (LIBS) (Wiens et al., 2012). With each laser

significantly worse than the planar model. Only the UGM 1copy algorithm at a very dense (nearly fully connected) graph has better fit to test data.

The maximal planar graph learned from the full data set, shown in Figure 2, conveys many facts that are already known to us. For instance, the graph shows Sanders with edges only to Democrats which makes sense because he caucuses with Democrats. Same is the case with Lieberman. The graph also shows the senate minority leader McConnell well connected to other Republicans though the same is not true of the senate majority leader Reid. The learned UGM models can be seen in Appendix B, and they show that the non-planar models are qualitatively different, learning one or two densely connected components.

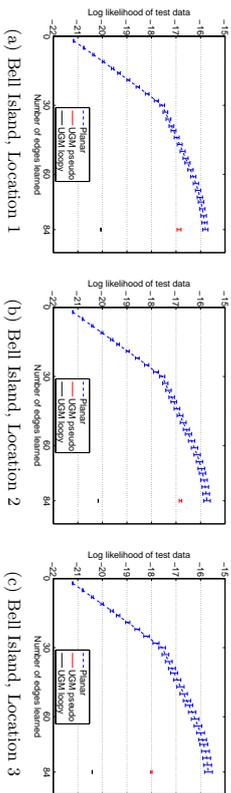

Figure 5: Comparison of algorithms on ChemCam data. Likelihood of holdout data versus the number of edges in the learned graph.

shot, the rock surface is ablated and therefore ChemCam produces a sequence of samples at increasing depth, potentially revealing compositional trends such as coatings, weathering rinds and thin stratigraphic layers that could give clues about the past atmospheric and aqueous conditions of Mars (Lanza et al., 2014).

We expect spatial correlations to exist among observations (samples), yet do not expect that the correlations will necessarily correspond to a fixed (known) grid; therefore, our planar model is a reasonable assumption to make. To test this, we compare against the non-planar UGM algorithm.

As shown in Figure 4, each LIBS shot produces a spectral observation consisting of 5810 wavelength bands between 224nm and 840nm. The spectral response is given as a table of intensity values for each wavelength band for each shot. A typical sequence of shots includes 30 - 150 shots on a fixed location. We model the correlations of rock chemistry among these shots, as measured by the set of wavelength bands that show non-zero response (above a noise threshold) in the observed spectra. More precisely, each spectrum is normalized, then thresholded so that 50% of the values are +1. To investigate shot-to-shot correlations, shots are the nodes in the graph while the 5810 wavelength bands are treated as samples. We add an auxiliary node and allow the algorithm to select the connections between it and other nodes. For comparison, we run a 10-fold cross validation using our planar model, the UGM model with pseudolikelihood and loopy³ belief propagation. Model selection for UGM is done by tuning with validation data and by comparing at the same number of edges learned by the planar algorithm.

We look at 30-shot depth sequences taken at one location at a time to find depth trends of interest. The rock is named Bell Island, and there are three locations that we investigated³. The graphs learned by our planar algorithm are quantitatively better than those learned by UGM, as shown in Figure 5. We compare the log-likelihood of 10-fold cross validation data for Planar, UGM pseudo and UGM loopy. With the number of edges in the graph fixed at $3n - 6$ (the number of edges in a maximal planar graph), we see that Planar achieves a significantly better fit to holdout data than UGM with either objective function. When we use the standard tuning method for UGM, it selects dense graphs that

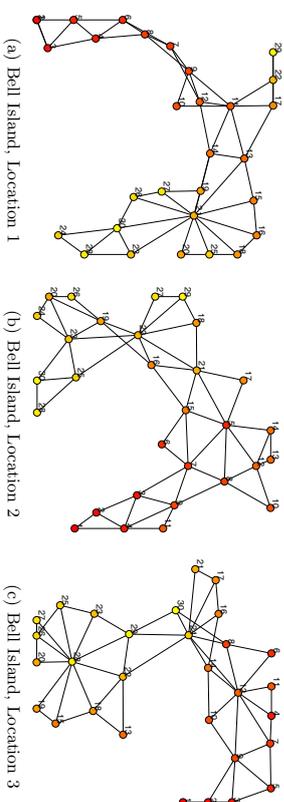

Figure 6: Learned planar graphs from ChemCam data. Nodes are numbered by LIBS laser shot number and color-coded by number starting with dark red at shot 1 and fading to light yellow at shot 30. We use a force-directed graph drawing algorithm (Fruchterman and Reingold, 1991).

are nearly fully-connected. While these tuned graphs learned by UGM do fit the data with higher log-likelihood, they provide no insight into the nature of depth trends.

Figure 6 shows the planar graphs learned from the Bell Island ChemCam data. Bell Island, Location 1 shows an interesting pattern of the first 10 or so shots being related to each other in ascending order, while the last 20 shots are more arbitrarily dependent. This pattern is consistent with the observation that the rock is covered in a layer of dust. As the laser ablates through the dust, each shot is conditionally dependent on the next shot. Once the rock itself is being sampled, the composition is more homogeneous. At Locations 2 and 3, there is less dust cover, and so there is less of a "tail" formed by the first few shots than seen at Location 1. However, in all of these graphs, we see that the graphs generally link earlier shots with early shots and later shots with late shots, despite not being given this ordering information. This indicates that the chemical composition of the rock is changing with depth.

6. Conclusion and Future Work

We provide a greedy heuristic to obtain the maximum-likelihood planar Ising model approximation to a collection of binary random variables with known pairwise marginals. The algorithm is simple to implement with the help of known methods for tractable exact inference in planar Ising models, efficient methods for planarity testing and embedding of planar graphs. While limiting the search to planar graphs, our learning model provides key advantages over arbitrary (non-planar) graph learning. Namely, the planar graph is sparse without necessitating a regularization term or tuning parameter. Also, the learned planar graph can be used for efficient inference of hidden values in future partially observed data. Further validating this approach, our empirical results on synthetic data and on real data indicate that our planar graph learning finds solutions that it are competitive with arbitrary (non-planar) graph learning in terms of fitting the distribution well.

³ NASA data is archived and available at <http://pds-geosciences.wustl.edu/missions/msl/chemcam.htm>.

Directions for further work are suggested by the methods and results of this paper. Firstly, we know that the greedy algorithm is not guaranteed to find the best planar graph. In Appendix C, we provide an enlightening counterexample in which the combination of the planarity restriction and greedy method prevent the correct model from being learned, because a strong indirect correlation exists that masks the correct combination of weaker direct correlations. That counterexample suggests strategies one might consider to further refine the estimate. One strategy would be to allow the greedy algorithm to prune edges which turn out to be less important once later edges are added. It would also be feasible to implement a multi-step greedy look-ahead search technique for selection of which edge to add (or prune) next.

Currently, our framework only allows learning planar graphical models on the set of observed random variables and requires that all variables are observed in each sample. One could imagine extensions of our approach to handle missing samples or to try to identify hidden variables that were not seen in the data. This concept offers another avenue to achieve a better fit to data that is not well-approximated by a planar graph among just the set of observed nodes, but might be well-approximated as the marginal distribution of a planar model with more nodes.

Appendix A. Proofs

Proof [Proposition 1] Let the probability distributions corresponding to G and \widehat{G} be P and \widehat{P} respectively and the corresponding expectations be \mathbb{E} and $\widehat{\mathbb{E}}$ respectively. For the partition function, we have that

$$\begin{aligned} \widehat{Z} &= \sum_{x_{\widehat{V}}} \exp \left(\sum_{\{i,j\} \in \widehat{E}} \widehat{\theta}_{ij} x_i x_j \right) \\ &= \sum_{x_{\widehat{V}}} \exp \left(x_{n+1} \sum_{i \in V} \theta_i x_i + \sum_{\{i,j\} \in E} \theta_{ij} x_i x_j \right) \\ &= \sum_{x_V} \exp \left(\sum_{i \in V} \theta_i x_i + \sum_{\{i,j\} \in E} \theta_{ij} x_i x_j \right) + \sum_{x_V} \exp \left(- \sum_{i \in V} \theta_i x_i + \sum_{\{i,j\} \in E} \theta_{ij} x_i x_j \right) \\ &= 2 \sum_{x_V} \exp \left(\sum_{i \in V} \theta_i x_i + \sum_{\{i,j\} \in E} \theta_{ij} x_i x_j \right) \\ &= 2Z, \end{aligned}$$

where the fourth equality follows from the symmetry between -1 and 1 in an Ising model. For the second part, since \widehat{P} is zero-field, we have that

$$\widehat{\mathbb{E}}[x_i] = 0 \quad \forall i \in \widehat{V}.$$

Now consider any $\{i, j\} \in E$. If x_{n+1} is fixed to a value of 1 , then the model is the same as the original one on V and we have

$$\widehat{\mathbb{E}}[x_i x_j \mid x_{n+1} = 1] = \mathbb{E}[x_i x_j] \quad \forall \{i, j\} \in E.$$

By symmetry (between -1 and 1) in the model, the same is true for $x_{n+1} = -1$ and so

$$\begin{aligned} \widehat{\mathbb{E}}[x_i x_j] &= \widehat{\mathbb{E}}[x_i x_j \mid x_{n+1} = 1] \widehat{P}(x_{n+1} = 1) + \widehat{\mathbb{E}}[x_i x_j \mid x_{n+1} = -1] \widehat{P}(x_{n+1} = -1) \\ &= \mathbb{E}[x_i x_j]. \end{aligned}$$

Fixing x_{n+1} to a value of 1 , we have

$$\widehat{\mathbb{E}}[x_i \mid x_{n+1} = 1] = \mathbb{E}[x_i] \quad \forall i \in V,$$

and by symmetry

$$\widehat{\mathbb{E}}[x_i \mid x_{n+1} = -1] = -\mathbb{E}[x_i] \quad \forall i \in V.$$

Combining the two equations above, we have

$$\begin{aligned} \widehat{\mathbb{E}}[x_i x_{n+1}] &= \widehat{\mathbb{E}}[x_i \mid x_{n+1} = 1] \widehat{P}(x_{n+1} = 1) + \widehat{\mathbb{E}}[-x_i \mid x_{n+1} = -1] \widehat{P}(x_{n+1} = -1) \\ &= \mathbb{E}[x_i]. \end{aligned}$$

■

Proof [Proposition 2] From Theorem 1, we see that the log partition function can be written as

$$\Phi(\theta) = n \log 2 + \sum_{\{i,j\} \in E} \log \cosh \theta_{ij} + \frac{1}{2} \log \det(I - AD),$$

where A and D are as given in Theorem 1. For the derivatives, we have

$$\begin{aligned} \frac{\partial \Phi(\theta)}{\partial \theta_{ij}} &= \tanh \theta_{ij} + \frac{1}{2} \text{Tr} \left((I - AD)^{-1} \frac{\partial (I - AD)}{\partial \theta_{ij}} \right) \\ &= \tanh \theta_{ij} - \frac{1}{2} \text{Tr} \left((I - AD)^{-1} AD'_{ij} \right) \\ &= w_{ij} - \frac{1}{2} (1 - w_{ij})^2 (S_{ij,ij} + S_{j,i,j}), \end{aligned}$$

where D'_{ij} is the derivative of the matrix D with respect to θ_{ij} . The first equality follows from the chain rule and the fact that $\nabla \ln |K| = K^{-1}$ for any matrix K . Please refer to Boyd and Vandenberghe (2004) for details.

For the Hessian, we have

$$\begin{aligned} \frac{\partial^2 \Phi(\theta)}{\partial \theta_{ij}^2} &= \frac{1}{Z(\theta)} \frac{\partial^2 Z(\theta)}{\partial \theta_{ij}^2} - \frac{1}{Z(\theta)^2} \left(\frac{\partial Z(\theta)}{\partial \theta_{ij}} \right)^2 \\ &= 1 - \mu_{ij}^2. \end{aligned}$$

For $\{i, j\} \neq \{k, l\}$, following Boyd and Vandenberghe (2004), we have

$$\begin{aligned} \frac{\partial^2 \Phi(\theta)}{\partial \theta_{ij} \partial \theta_{kl}} &= -\frac{1}{2} \text{Tr} \left(SD'_{ij} SD'_{kl} \right) \\ &= -\frac{1}{2} (1 - w_{ij}^2) (S_{ij,kl} S_{kl,ij} + S_{j,i,kl} S_{kl,ji} + S_{ij,kl} S_{kl,ij} + S_{j,i,kl} S_{kl,ji}) (1 - w_{kl}^2). \end{aligned}$$

On the other hand, we also have

$$\begin{aligned} T_{ijkl} &= e_{ij}^T(I + P)(S \circ S^T)(I + P)e_{kl} \\ &= (e_{ij} + e_{ji})^T(S \circ S^T)(e_{kl} + e_{lk}) \\ &= (S \circ S^T)_{ij,kl} + (S \circ S^T)_{ji,lk} + (S \circ S^T)_{j,i,kl} + (S \circ S^T)_{j,i,lk} \\ &= S_{ijkl}S_{kl,ij} + S_{ji,kl}S_{kl,ji} + S_{j,i,kl}S_{kl,ij} + S_{j,i,lk}S_{lk,ji} \end{aligned}$$

where e_{ij} is the unit vector with 1 in the ij^{th} position and 0 everywhere else. Using the above two equations, we obtain

$$H_{ijkl} = -\frac{1}{2}(1 - u_{ij}^2)T_{ijkl}(1 - u_{kl}^2).$$

Proof [Proposition 4] The proof follows from the following steps of inequalities. The Pythagorean law of information projection (Amari et al., 1992) gives

$$D(P, P_G) = D(P, P_{G+ij}) + D(P_{G+ij}, P_G).$$

The conditional rule of relative entropy (Cover and Thomas, 2006) gives

$$D(P_{G+ij}, P_G) = D(P_{G+ij}(x_i, x_j), P_G(x_i, x_j)) + D(P_{G+ij}(x_{V-ij}|x_i, x_j), P_G(x_{V-ij}|x_i, x_j)),$$

where $P_{G+ij}(x_i, x_j)$ and $P_G(x_i, x_j)$ represent the marginal distributions on x_i, x_j of probabilities P_{G+ij} and P_G respectively. Information inequality (Cover and Thomas, 2006) gives us:

$$D(P_{G+ij}(x_{V-ij}|x_i, x_j), P_G(x_{V-ij}|x_i, x_j)) \geq 0.$$

Plugging the above two properties into the first equation leads to the inequality

$$D(P, P_G) \geq D(P, P_{G+ij}) + D(P_{G+ij}(x_i, x_j), P_G(x_i, x_j)).$$

Finally, the property of information projection to $G + ij$ (Wainwright and Jordan, 2008) gives us $D(P_{G+ij}(x_i, x_j), P_G(x_i, x_j)) \geq D(P(x_i, x_j), P_G(x_i, x_j))$ leading to

$$D(P, P_G) \geq D(P, P_{G+ij}) + D(P(x_i, x_j), P_G(x_i, x_j)).$$

Appendix B. Applications: UGM Learned Models

For comparison to our planar learning algorithm, we provide the results of using the UGM MRF learning algorithm on the senate voting data and the ChemCam data. For all figures, we use a force-directed graph drawing algorithm (Fruchterman and Reingold, 1991). Figure 7 presents the graph learned using pseudolikelihood, UGM pseudo, from the full data set with the regularization parameter set to obtain the same number of edges as learned in the planar case ($3n - 6$ edges).

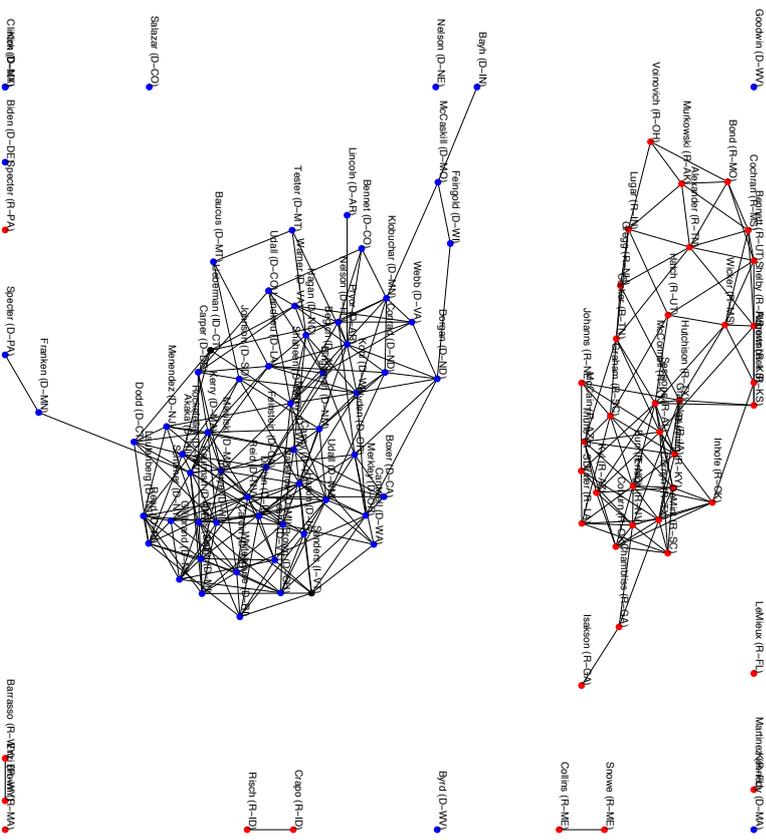

Figure 7: Senate voting graph learned by UGM pseudo with 318 edges. Blue nodes represent Democrats, red nodes represent Republicans and black nodes represent Independents.

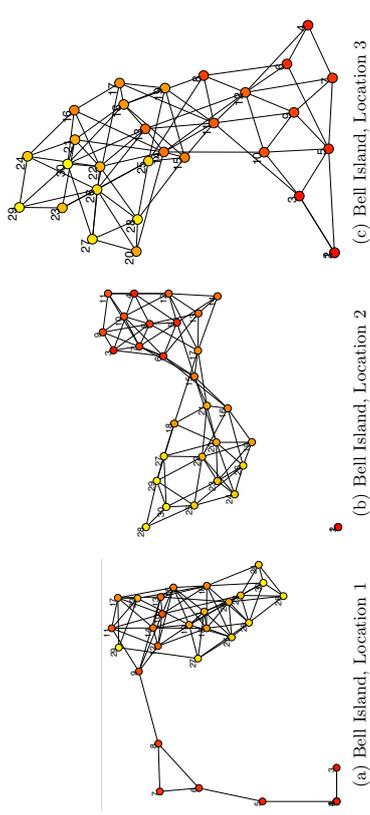

Figure 9: Learned UGM Pseudo graphs from ChemCam data. Nodes are numbered by LIBS laser shot number and color-coded by number starting with dark red at shot 1 and fading to light yellow at shot 30. We use a force-directed graph drawing algorithm (Fruchterman and Reingold, 1991).

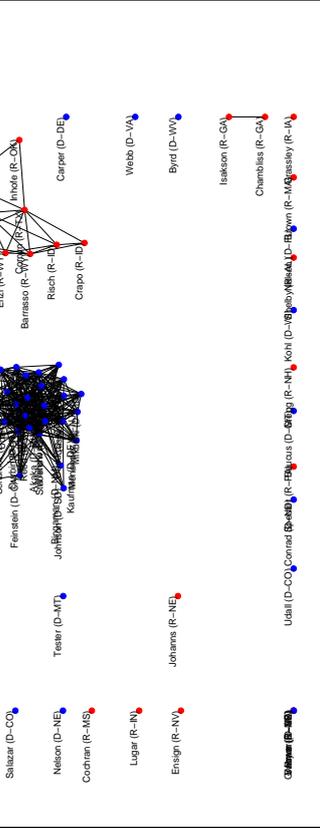

Figure 8: Senate voting graph learned by UGM. Loopy graph with 318 edges. Blue nodes represent Democrats, red nodes represent Republicans and black nodes represent Independents.

UGM graphs learned from the senate voting data are given in Figures 7 – 8. Figure 7 presents the graph learned using pseudolikelihood, UGM pseudo, from the full data set with the regularization parameter set to obtain 318 edges. Figure 8 presents the graph learned using loopy belief propagation, UGM loopy, from the full data set with the regularization parameter set to obtain 318 edges. The graphs learned using the tuning method are not displayed because they are nearly fully-connected graphs providing little visual information.

UGM graphs learned from the ChemCam data from the Bell Island target are given in Figures 9 – 10. Figure 9 presents the graph learned using pseudolikelihood, UGM pseudo, from the full data set with the regularization parameter set to obtain 84 edges. Figure 10 presents the graph learned using loopy belief propagation, UGM loopy, from the full data set with the regularization parameter set to obtain 84 edges. Graphs learned from this data using the tuning method to select the number of edges are nearly fully connected, and therefore provide little visual information.

Appendix C. Discussion: Counter Example

The result presented in Figure 11 illustrates the fact that our algorithm does not always recover the exact structure even when the underlying graph is planar and the algorithm is given exact moments as inputs. This counterexample gives insight into how the greedy algorithm works. The basic idea is that graphical models can have nodes which are not neighbors but are more correlated than some other nodes which are neighbors. If the spurious edges corresponding to these highly correlated nodes are added early on in the algorithm, then the actual edges may have to be left out because of the planarity restriction.

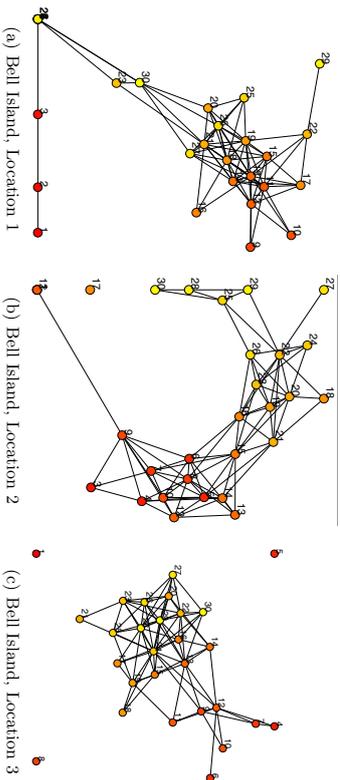

Figure 10: Learned UGM Loopy graphs from ChemCam data. Nodes are numbered by LIBS laser shot number and color-coded by number starting with dark red at shot 1 and fading to light yellow at shot 30. We use a force-directed graph drawing algorithm (Fruchterman and Reingold, 1991).

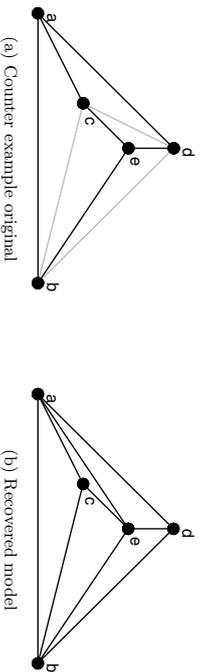

Figure 11: Example graphical models. (a) Counter example. (b) The recovered graphical model has one spurious edge $\{a, e\}$ and one missing edge $\{c, d\}$.

We define a zero-field Ising model on the graph in Figure 11a with the edge parameters as follows: $\theta_{bc} = \theta_{cd} = \theta_{bd} = 0.1$ and $\theta_{ij} = 1$ for all the other edges. Figure 11a shows the edge parameters in the graph pictorially using the intensity of the edges - the higher the intensity of an edge, higher the corresponding edge parameter. With these edge parameters, the correlation between nodes a and e is greater than the correlation between any other pair of nodes. This leads to the edge between a and e to be the first edge added in the algorithm. However, since $K=5$ (the complete graph on 5 nodes) is not planar, one of the actual edges is missed in the output graph as shown in Figure 11b.

Abstract

We consider the problem of efficiently computing the maximum likelihood estimator in *Generalized Linear Models* (GLMs) when the number of observations is much larger than the number of coefficients ($n \gg p \gg 1$). In this regime, optimization algorithms can immensely benefit from approximate second order information. We propose an alternative way of constructing the curvature information by formulating it as an estimation problem and applying a *Stein-type lemma*, which allows further improvements through sub-sampling and eigenvalue thresholding. Our algorithm enjoys fast convergence rates, resembling that of second order methods, with modest per-iteration cost. We provide its convergence analysis for the general case where the rows of the design matrix are samples from a sub-Gaussian distribution. We show that the convergence has two phases, a quadratic phase followed by a linear phase. Finally, we empirically demonstrate that our algorithm achieves the highest performance compared to various optimization algorithms on several data sets.

Keywords: Optimization, Generalized Linear Models, Newton's method, Sub-sampling

1. Introduction

Generalized Linear Models (GLMs) play a crucial role in numerous statistical and machine learning problems. GLMs formulate the natural parameter in exponential families as a linear model and provide a miscellaneous framework for statistical methodology and supervised learning tasks. Celebrated examples include linear, logistic, multinomial regressions and applications to graphical models (Nelder and Baker, 1972; McCullagh and Nelder, 1989; Koller and Friedman, 2009).

In this paper, we focus on how to solve the maximum likelihood problem efficiently in the GLM setting when the number of observations n is much larger than the dimension of the coefficient vector p , i.e., $n \gg p \gg 1$. GLM optimization task is typically expressed as a minimization problem where the objective function is the negative log-likelihood that is denoted by $\ell(\beta)$ where $\beta \in \mathbb{R}^p$ is the coefficient vector. Many optimization algorithms are available for such minimization problems (Bishop, 1995; Boyd and Vandenberghe, 2004; Nesterov, 2004). However, only a few uses the special structure of GLMs. In this paper, we consider updates that are specifically designed for GLMs, which are of the form

$$\beta \leftarrow \beta - \gamma \mathbf{Q} \nabla_{\beta} \ell(\beta), \quad (1)$$

where γ is the step size and \mathbf{Q} is a scaling matrix which provides curvature information.

For the updates of the form Equation 1, the performance of the algorithm is mainly determined by the scaling matrix \mathbf{Q} . Classical *Newton's method* and *natural gradient descent* can be recovered by simply taking \mathbf{Q} to be the inverse Hessian and the inverse Fisher's information at the current iterate, respectively (Amari, 1998; Nesterov, 2004). Second order methods may achieve quadratic convergence rate, yet they suffer from excessive cost of computing the scaling matrix at every iteration. On the other hand, if we take \mathbf{Q} to be the identity matrix, we recover the standard *gradient descent* which has a linear convergence rate. Although the convergence rate of gradient descent is considered slow compared to that of second order methods such as Newton's method, modest per-iteration cost makes it practical for large-scale optimization.

The trade-off between convergence rate and per-iteration cost has been extensively studied (Bishop, 1995; Boyd and Vandenberghe, 2004; Nesterov, 2004). In $n \gg p \gg 1$ regime, the main objective is to construct a scaling matrix \mathbf{Q} that is computationally feasible which also provides sufficient curvature information. For this purpose, several Quasi-Newton methods have been proposed (Bishop, 1995; Nesterov, 2004). Updates given by Quasi-Newton methods satisfy an equation which is often called the *Quasi-Newton relation*. A well-known member of this class of algorithms is the *Broyden-Fletcher-Goldfarb-Shanno* (BFGS) algorithm (Broyden, 1970; Fletcher, 1970; Goldfarb, 1970; Shanno, 1970).

In this paper, we propose a Newton-type algorithm that utilizes the special structure of GLMs by relying on a Stein-type lemma (Stein, 1981). It attains fast convergence rates with low per-iteration cost. We call our algorithm *Newton-Stein* method which we abbreviate as *NewSt*. Our contributions can be summarized as follows:

- We recast the problem of constructing a scaling matrix as an estimation problem and apply a Stein-type lemma along with the sub-sampling technique to form a computationally feasible \mathbf{Q} .
- Newton-Stein method allows further improvements through eigenvalue shrinkage, eigenvalue thresholding, sub-sampling and various other techniques that are available for covariance estimation.
- Excessive per-iteration cost of $\mathcal{O}(np^2 + p^3)$ of Newton's method is replaced by $\mathcal{O}(np + p^2)$ per-iteration cost and a one-time $\mathcal{O}(|S|p^2)$ cost, where $|S|$ is the sub-sample size.
- Assuming that the rows of the design matrix are i.i.d. and have bounded support (or sub-Gaussian), and denoting the iterates of Newton-Stein method by $\{\beta^t\}$, we prove a bound of the form

$$\|\beta^{t+1} - \beta_*\|_2 \leq \tau_1 \|\beta^t - \beta_*\|_2 + \tau_2 \|\beta^t - \beta_*\|_2^2, \quad (2)$$

where β_* is the true minimizer and τ_1, τ_2 are the convergence coefficients. The above bound implies that the local convergence starts with a quadratic phase and transitions into linear as the iterate gets closer to the true minimizer. We further establish a global convergence result of Newton-Stein method coupled with a line search algorithm.

- We demonstrate the performance of Newton-Stein method on real and synthetic data sets by comparing it to commonly used optimization algorithms.

The rest of the paper is organized as follows: Section 1.1 surveys the related work and Section 1.2 introduces the notations we use throughout the paper. Section 2 briefly discusses the GLM framework and its relevant properties. In Section 3, we introduce Newton-Stein method, develop its intuition, and discuss the computational aspects. Section 4 covers the theoretical results and in Section 4.4 we discuss how to choose the algorithm parameters. Section 5 provides the empirical results where we compare the proposed algorithm with several other methods on four data sets. Finally, in Section 6, we conclude with a brief discussion along with a few future research directions.

1.1 Related Work

There are numerous optimization techniques that can be used to find the maximum likelihood estimator in GLMs. For moderate values of n and p , the classical second order methods such as Newton’s method (also referred to as Newton-Raphson) are commonly used. In large-scale problems, data dimensionality is the main factor while determining the optimization method, which typically falls into one of two major categories: online and batch methods. Online methods use a gradient (or sub-gradient) of a single, randomly selected observation to update the current iterate (Robbins and Monro, 1951). Their per-iteration cost is independent of n , but the convergence rate might be extremely slow. There are several extensions of the classical stochastic descent algorithms, providing significant improvement and improved stability (Botton, 2010; Duchi et al., 2011; Schmidt et al., 2013; Kojte et al., 2015).

On the other hand, batch algorithms enjoy faster convergence rates, though their per-iteration cost may be prohibitive. In particular, second order methods enjoy quadratic convergence, but constructing the Hessian matrix generally requires excessive amount of computation. To remedy this issue, recent research is focused on designing an approximate and cost-efficient scaling matrix. This idea lies at the core of Quasi-Newton methods such as BFGS (Bishop, 1995; Nesterov, 2004).

Another approach to construct an approximate Hessian makes use of sub-sampling techniques (Martens, 2010; Byrd et al., 2011; Vinyals and Povey, 2011; Erdogdu and Montanari, 2015; Roosta-Khorasani and Mahoney, 2016a,b). Many contemporary learning methods rely on sub-sampling as it is simple and it provides significant boost over the first order methods. Further improvements through conjugate gradient methods and Krylov sub-spaces are available. Sub-sampling can also be used to obtain an approximate solution, with certain large deviation guarantees (Dhillon et al., 2013).

There are many composite variants of the aforementioned methods, that mostly combine two or more techniques. Well-known composite algorithms are the combinations of sub-sampling and Quasi-Newton (Schraudolph et al., 2007; Byrd et al., 2016), stochastic and deterministic gradient descent (Friedlander and Schmidt, 2012), natural gradient and Newton’s method (Le Roux and Fitzgibbon, 2010), natural gradient and low-rank approximation (Le Roux et al., 2008), sub-sampling and eigenvalue thresholding (Erdogdu and Montanari, 2015).

Lastly, algorithms that specialize on certain types of GLMs include coordinate descent methods for the penalized GLMs (Friedman et al., 2010), trust region Newton-type methods (Lin et al., 2008), and approximation methods (Erdogdu et al., 2016b,a).

1.2 Notation

Let $[n] = \{1, 2, \dots, n\}$ and denote by $|S|$, the size of a set S . The gradient and the Hessian of f with respect to β are denoted by $\nabla_{\beta} f$ and $\nabla_{\beta}^2 f$, respectively. The j -th derivative of a function $f(w)$ is denoted by $f^{(j)}(w)$. For a vector x and a symmetric matrix \mathbf{X} , $\|x\|_2$ and $\|\mathbf{X}\|_2$ denote the ℓ_2 and spectral norms of x and \mathbf{X} , respectively. $\|x\|_{\ell_2}$ denotes the sub-Gaussian norm, which will be defined later. S^{p-1} denotes the p -dimensional sphere. \mathcal{P}_C denotes the projections onto the set C , and $B_p(R) \subset \mathbb{R}^p$ denotes the p -dimensional ball of radius R . For a random variable x and density f , $x \sim f$ means that the distribution of x follows the density f . Multivariate Gaussian density with mean $\mu \in \mathbb{R}^p$ and covariance $\Sigma \in \mathbb{R}^{p \times p}$ is denoted as $N_p(\mu, \Sigma)$. For random variables x, y , $d(x, y)$ and $\mathcal{D}(x, y)$ denote probability metrics (will be explicitly defined) measuring the distance between the distributions of x and y . $\mathcal{N}(\cdot, \cdot)$ and T_{ϵ} denote the bracketing number and ϵ -net.

2. Generalized Linear Models

Distribution of a random variable $y \in \mathbb{R}$ belongs to an exponential family with natural parameter $\eta \in \mathbb{R}$ if its density can be written as

$$f(y|\eta) = e^{\eta y - \phi(\eta)} h(y),$$

where ϕ is the *cumulant generating function* and h is the *carrier density*. Let y_1, y_2, \dots, y_n be independent observations such that $\forall i \in [n], y_i \sim f(y_i|\eta_i)$. Denoting $\eta = (\eta_1, \dots, \eta_n)^T$, the joint likelihood can be written as

$$f(y_1, y_2, \dots, y_n|\eta) = \exp \left\{ \sum_{i=1}^n [y_i \eta_i - \phi(\eta_i)] \right\} \prod_{i=1}^n h(y_i). \quad (3)$$

We consider the problem of learning the maximum likelihood estimator in the above exponential family framework, where the vector $\eta \in \mathbb{R}^n$ is modeled through the linear relation, $\eta = \mathbf{X}\beta$,

for some design matrix $\mathbf{X} \in \mathbb{R}^{n \times p}$ with rows $x_i \in \mathbb{R}^p$, and a coefficient vector $\beta \in \mathbb{R}^p$. This formulation is known as *Generalized Linear Models* (GLMs) with canonical links. The cumulant generating function ϕ determines the class of GLMs, i.e., for ordinary least squares (OLS) $\phi(z) = z^2/2$, for logistic regression (LR) $\phi(z) = \log(1 + e^z)$, and for Poisson regression (PR) $\phi(z) = e^z$.

Finding the maximum likelihood estimator in the above formulation is equivalent to minimizing the negative log-likelihood function $\ell(\beta)$,

$$\ell(\beta) = \frac{1}{n} \sum_{i=1}^n [\phi(x_i, \beta) - y_i \langle x_i, \beta \rangle], \quad (4)$$

where $\langle x, \beta \rangle$ is the inner product between the vectors x and β . The relation to OLS and LR can be seen much easier by plugging in the corresponding $\phi(z)$ in Equation 4. The gradient

and the Hessian of $\ell(\beta)$ can be written as:

$$\nabla_{\beta}^2 \ell(\beta) = \frac{1}{n} \sum_{i=1}^n \begin{bmatrix} \phi^{(1)}(x_i, \beta) x_i - y_i x_i \\ \phi^{(2)}(x_i, \beta) x_i x_i^T \end{bmatrix}, \quad \nabla_{\beta}^2 \ell(\beta) = \frac{1}{n} \sum_{i=1}^n \phi^{(2)}(x_i, \beta) x_i x_i^T. \quad (5)$$

For a sequence of scaling matrices $\{\mathbf{Q}^t\}_{t>0} \in \mathbb{R}^{p \times p}$, we consider iterations of the form

$$\hat{\beta}^{t+1} = \hat{\beta}^t - \gamma_t \mathbf{Q}^t \nabla_{\beta} \ell(\hat{\beta}^t)$$

where γ_t is the step size. The above iteration is our main focus, but with a new approach on how to compute the sequence of matrices $\{\mathbf{Q}^t\}_{t>0}$. We will formulate the problem of finding a scalable \mathbf{Q}^t as an estimation problem and apply a Stein-type lemma that provides us with a computationally efficient update rule.

3. Newton-Stein Method

Classical Newton-Raphson (or simply Newton's) method is the standard approach for training GLMs for moderately large data sets. However, its per-iteration cost makes it impractical for large-scale optimization. The main bottleneck is the computation of the Hessian matrix that requires $\mathcal{O}(np^2)$ flops which is prohibitive when $n \gg p \gg 1$. Numerous methods have been proposed to achieve the fast convergence rate of Newton's method while keeping the per-iteration cost manageable. To this end, a popular approach is to construct a scaling matrix \mathbf{Q}^t , which approximates the inverse Hessian at every iteration t .

The task of constructing an approximate Hessian can be viewed as an estimation problem. Assuming that the rows of \mathbf{X} are i.i.d. random vectors, the Hessian of the negative log-likelihood of GLMs with a cumulant generating function ϕ has the following sample average form

$$[\mathbf{Q}^t]^{-1} = \frac{1}{n} \sum_{i=1}^n x_i x_i^T \phi^{(2)}(x_i, \beta) \approx \mathbb{E}[x x^T \phi^{(2)}(x, \beta)].$$

We observe that $[\mathbf{Q}^t]^{-1}$ is just a sum of i.i.d. matrices. Hence, the true Hessian is nothing but a sample mean estimator to its expectation. Another natural estimator would be the sub-sampled Hessian method which is extensively studied by Martens, 2010; Byrd et al., 2011; Erdogdu and Montanari, 2015; Roosta-Khorasani and Mahoney, 2016a. Therefore, our goal is to propose an estimator for the population level Hessian that is also computationally efficient. Since n is large, the proposed estimator will be close to the true Hessian.

We use the following Stein-type lemma to find a more efficient estimator to the expectation of the Hessian.

Lemma 1 (Stein-type lemma) *Assume that $x \sim \mathbf{N}_p(0, \Sigma)$ and $\beta \in \mathbb{R}^p$ is a constant vector. Then for any function $f: \mathbb{R} \rightarrow \mathbb{R}$ that is twice "weakly" differentiable, we have*

$$\mathbb{E}[x x^T f(x, \beta)] = \mathbb{E}[f(x, \beta)] \Sigma + \mathbb{E}\left[f^{(2)}(x, \beta)\right] \Sigma \beta \beta^T \Sigma. \quad (6)$$

Proof The proof will follow from integration by parts. Let $g(x|\Sigma)$ denote the density of a multivariate normal random variable x with mean 0 and covariance Σ . We recall the basic

Algorithm 1 Newton-Stein Method

Input: $\hat{\beta}^0, |S|, \epsilon, \{\gamma_t\}_{t \geq 0}$.

1. Estimate the covariance using a random sub-sample $S \subset [n]$:

$$\hat{\Sigma}_S = \frac{1}{|S|} \sum_{i \in S} x_i x_i^T.$$

2. **while** $\|\hat{\beta}^{t+1} - \hat{\beta}^t\|_2 > \epsilon$ **do**

$$\hat{\mu}_2(\hat{\beta}^t) = \frac{1}{n} \sum_{i=1}^n \phi^{(2)}(x_i, \hat{\beta}^t), \quad \hat{\mu}_4(\hat{\beta}^t) = \frac{1}{n} \sum_{i=1}^n \phi^{(4)}(x_i, \hat{\beta}^t),$$

$$\mathbf{Q}^t = \frac{1}{\hat{\mu}_2(\hat{\beta}^t)} \left[\hat{\Sigma}_S^{-1} - \frac{\hat{\beta}^t [\hat{\beta}^t]^T}{\hat{\mu}_2(\hat{\beta}^t) / \hat{\mu}_4(\hat{\beta}^t) + \langle \hat{\Sigma}_S \hat{\beta}^t, \hat{\beta}^t \rangle} \right],$$

$$\hat{\beta}^{t+1} = \hat{\beta}^t - \gamma_t \mathbf{Q}^t \nabla_{\beta} \ell(\hat{\beta}^t),$$

$t \leftarrow t + 1$.

3. **end while**

Output: $\hat{\beta}^t$.

identity $xg(x|\Sigma)dx = -\Sigma dg(x|\Sigma)$ and write

$$\begin{aligned} \mathbb{E}[x x^T f(x, \beta)] &= \int x x^T f(x, \beta) g(x) dx, \\ &= \Sigma \left\{ \int f(x, \beta) g(x|\Sigma) dx + \int \beta x^T f^{(1)}(x, \beta) g(x|\Sigma) dx \right\}, \\ &= \Sigma \left\{ \mathbb{E}[f(x, \beta)] + \int \beta \beta^T f^{(2)}(x, \beta) g(x|\Sigma) dx \right\}, \\ &= \mathbb{E}[f(x, \beta)] \Sigma + \mathbb{E}\left[f^{(2)}(x, \beta)\right] \Sigma \beta \beta^T \Sigma. \end{aligned}$$

■

The right hand side of Equation 6 is a rank-1 update to the first term. Hence, its inverse can be computed with $\mathcal{O}(p^2)$ cost. Quantities that change at each iteration are the ones that depend on β , i.e.,

$$\mu_2(\beta) = \mathbb{E}[\phi^{(2)}(x, \beta)], \quad \text{and} \quad \mu_4(\beta) = \mathbb{E}[\phi^{(4)}(x, \beta)].$$

Note that $\mu_2(\beta)$ and $\mu_4(\beta)$ are scalar quantities and they can be estimated by their corresponding sample means $\hat{\mu}_2(\beta)$ and $\hat{\mu}_4(\beta)$ (explicitly defined at Step 2 of Algorithm 1) respectively, with only $\mathcal{O}(np)$ computation.

To complete the estimation task suggested by Equation 6, we need an estimator for the covariance matrix Σ . A natural estimator is the sample mean where, we only use a sub-sample of the indices $S \subset [n]$ so that the cost is reduced to $\mathcal{O}(|S|p^2)$ from $\mathcal{O}(np^2)$. Sub-sampling based sample mean estimator is denoted by $\hat{\Sigma}_S = \frac{1}{|S|} \sum_{i \in S} x_i x_i^T$, which is

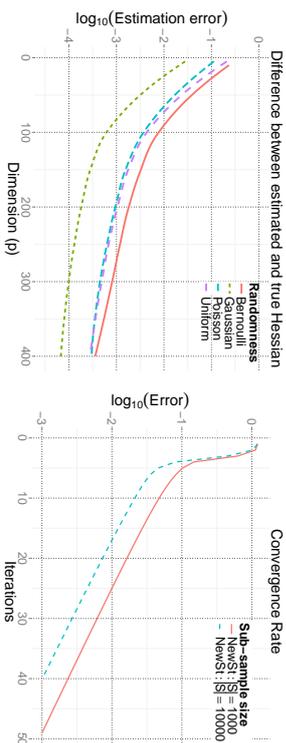

Figure 1: The left plot demonstrates the accuracy of proposed Hessian estimation over different distributions. Number of observations is set to be $n = \mathcal{O}(p \log(p))$. The right plot shows the phase transition in the convergence rate of Newton-Stein method (NewSt). Convergence starts with a quadratic rate and transitions into linear. Plots are obtained using *Covertype* data set.

widely used in large-scale problems (Vershynin, 2010). We highlight the fact that Lemma 1 replaces $\mathcal{O}(np^2)$ per-iteration cost of Newton’s method with a one-time cost of $\mathcal{O}(np^2)$. We further use sub-sampling to reduce this one-time cost to $\mathcal{O}(|S|p^2)$, and obtain the following Hessian estimator at β

$$\left[\mathbf{Q}^q \right]^{-1} = \underbrace{f_{i_2}(\beta)}_{\in \mathbb{R}^{p \times p}} \widehat{\Sigma}_S + \underbrace{f_{i_4}(\beta)}_{\in \mathbb{R}} \underbrace{\widehat{\Sigma}_S \beta \beta^T \widehat{\Sigma}_S}_{\text{rank-1 update}} \underbrace{\widehat{\Sigma}_S}_{\in \mathbb{R}^{p \times p}} \quad (7)$$

We emphasize that any covariance estimation method can be applied in the first step of the algorithm. There are various estimation techniques most of which rely on the concept of *shrinkage* (Cai et al., 2010; Donoho et al., 2013). This is because, important curvature information is generally contained in the largest few spectral features (Erdogdu and Montanari, 2015). In particular, for a given threshold r , we suggest to use the largest r eigenvalues of the sub-sampled covariance estimator $\widehat{\Sigma}_S$, and setting rest of them to $(r+1)$ -th eigenvalue. This operation helps denoising and provides additional computational benefits when inverting the covariance estimator (Erdogdu and Montanari, 2015).

Inverting the constructed Hessian estimator can make use of the low-rank structure. First, notice that the updates in Equation 7 are based on rank-1 matrix additions. Hence, we can simply apply Sherman–Morrison inversion formula to Equation 7 and obtain an explicit equation for the scaling matrix \mathbf{Q}^t (Step 2 of Algorithm 1). This formulation would impose another inverse operation on the covariance estimator. We emphasize that this operation is performed once. Therefore, instead of $\mathcal{O}(p^3)$ per-iteration cost of Newton’s method due to inversion, Newton-Stein method (NewSt) requires $\mathcal{O}(p^2)$ per-iteration and a one-time cost of $\mathcal{O}(p^3)$. Assuming that Newton-Stein and Newton methods converge in T_1 and T_2 iterations respectively, the overall complexity of Newton-Stein is $\mathcal{O}(npT_1 + p^2T_1 + (|S| + p)p^2) \approx$

$\mathcal{O}(npT_1 + p^2T_1 + |S|p^2)$ whereas that of Newton is $\mathcal{O}(np^2T_2 + p^3T_2)$. We show both empirically and theoretically that the quantities T_1 and T_2 are close to each other.

The convergence rate of Newton-Stein method has two phases. Convergence starts quadratically and transitions into linear rate when it gets close to the true minimizer. The phase transition behavior can be observed through the right plot in Figure 1. This is a consequence of the bound provided in Equation 2, which is the main result of our theorems on the local convergence (given in Section 4).

Even though Lemma 1 assumes that the covariates are multivariate Gaussian random vectors, in Section 4, the only assumption we make on the covariates is either bounded support or sub-Gaussianity, both of which cover a wide class of random variables including Bernoulli, elliptical distributions, bounded variables etc. The left plot of Figure 1 shows that the estimation is accurate for many distributions. This is a consequence of the fact that the proposed estimator in Equation 7 relies on the distribution of x only through inner products of the form $\langle x, v \rangle$, which in turn results in an approximate normal distribution due to the central limit theorem. To provide more intuition, we explain this through *zero-biased transformations* which is a general version of Stein’s lemma for arbitrary distributions (Goldstein and Reinert, 1997).

Definition 2 Let z be a random variable with mean 0 and variance σ^2 . Then, there exists a random variable z^* that satisfies $\mathbb{E}[zf(z)] = \sigma^2 \mathbb{E}[f'(z^*)]$, for all differentiable functions f . The distribution of z^* is said to be the *z-zero-bias distribution*.

The normal distribution is the unique distribution whose zero-bias transformation is itself (i.e. the normal distribution is a fixed point of the operation mapping the distribution of z to that of z^*). The distribution of z^* is referred to as *z-zero-bias distribution* and is entirely determined by the distribution of z . Properties such as existence can be found, for example, in Chen et al., 2010.

To provide some intuition behind the usefulness of Lemma 1 even for arbitrary distributions, we use zero-bias transformations. For simplicity, assume that the covariate vector x has i.i.d. entries from an arbitrary distribution with mean 0, and variance 1. Then the zero-bias transformation applied twice to the entry (i, j) of matrix $\mathbb{E}[xx^T f(\langle x, \beta \rangle)]$ yields

$$\mathbb{E}[x_i x_j f(\langle x, \beta \rangle)] = \begin{cases} \mathbb{E}[f(\beta_i x_i^* + \sum_{k \neq i} x_k \beta_k)] + \beta_i^2 \mathbb{E}[f^{(2)}(\beta_i x_i^{**} + \sum_{k \neq i} x_k \beta_k)] & \text{if } i = j, \\ \beta_i \beta_j \mathbb{E}[f^{(2)}(\beta_i x_i^* + \beta_j x_j^* + \sum_{k \neq i, j} x_k \beta_k)] & \text{if } i \neq j, \end{cases}$$

where x_i^* and x_i^{**} have x_i -zero-bias and x_i^* -zero-bias distributions, respectively. For each entry (i, j) at most two summands of $\langle x, \beta \rangle = \sum_k x_k \beta_k$ change their distributions. Therefore, if β is well spread and p is sufficiently large, the sums inside the expectations will behave similar to the inner product $\langle x, \beta \rangle$. Correspondingly, the above equations will be close to their Gaussian counterpart as given in Equation 6.

4. Theoretical Results

We start by introducing the terms that will appear in the theorems. Then we will provide two technical results on bounded and sub-Gaussian covariates. The proofs of the theorems are technical and provided in Appendix.

4.1 Preliminaries

Hessian estimation described in the previous section relies on a Gaussian approximation. For theoretical purposes, we use the following probability metric to quantify the gap between the distribution of x_i 's and that of a normal vector.

Definition 3 Given a family of functions \mathcal{H} , and random vectors $x, y \in \mathbb{R}^p$, for \mathcal{H} and any $h \in \mathcal{H}$, define

$$d_{\mathcal{H}}(x, y) = \sup_{h \in \mathcal{H}} d_h(x, y) \quad \text{where} \quad d_h(x, y) = |\mathbb{E}[h(x)] - \mathbb{E}[h(y)]|.$$

Many probability metrics can be expressed as above by choosing a suitable function class \mathcal{H} . Examples include *Total Variation* (TV), *Kolmogorov* and *Wasserstein* metrics (Gibbs and Su, 2002; Chen et al., 2010). Based on the second and the fourth derivatives of the cumulant generating function, we define the following function classes:

$$\begin{aligned} \mathcal{H}_1 &= \left\{ h(x) = \phi^{(2)}(\langle x, \beta \rangle) : \beta \in \mathcal{C} \right\}, & \mathcal{H}_2 &= \left\{ h(x) = \phi^{(4)}(\langle x, \beta \rangle) : \beta \in \mathcal{C} \right\}, \\ \mathcal{H}_3 &= \left\{ h(x) = \langle v, x \rangle^2 \phi^{(2)}(\langle x, \beta \rangle) : \beta \in \mathcal{C}, \|v\|_2 = 1 \right\}, \end{aligned}$$

where $\mathcal{C} \in \mathbb{R}^p$ is a closed, convex set that is bounded by the radius R . Exact calculation of such probability metrics are often difficult. The general approach is to upper bound the distance by a more intuitive metric. In our case, we observe that $d_{\mathcal{H}_j}(x, y)$ for $j = 1, 2, 3$, can be easily upper bounded by $d_{\text{TV}}(x, y)$ up to a scaling constant, when the covariates have bounded support.

In our theoretical results, we rely on projected updates onto a closed convex set \mathcal{C} , which are of the form

$$\hat{\beta}^{t+1} = \mathcal{P}_{\mathcal{C}}^t \left(\hat{\beta}^t - \gamma \mathbf{Q}^t \nabla_{\beta} \ell(\hat{\beta}^t) \right)$$

where the projection is defined as $\mathcal{P}_{\mathcal{C}}^t(\beta) = \arg \min_{w \in \mathcal{C}} \frac{1}{2} \|w - \beta\|_{\mathbf{Q}^{t-1}}^2$, with \mathcal{C} bounded by R . This is a special case of proximal Newton-type algorithms and further generalization is straightforward (See Lee et al., 2014). We will further assume that the covariance matrix has full rank and its smallest eigenvalue is lower bounded by a positive constant.

4.2 Bounded Covariates

We have the following per-step bound for the iterates generated by the Newton-Stein method, when the covariates are supported on a ball.

Theorem 4 (Local convergence) Assume that the covariates x_1, x_2, \dots, x_n are i.i.d. random vectors supported on a ball of radius \sqrt{K} with

$$\mathbb{E}[x_i] = 0 \quad \text{and} \quad \mathbb{E}[x_i x_i^T] = \Sigma.$$

Further assume that the cumulant generating function ϕ has bounded 2nd-5th derivatives and that the set \mathcal{C} is bounded by R . For $\{\hat{\beta}^t\}_{t>0}$ given by the Newton-Stein method for $\gamma = 1$, define the event

$$\mathcal{E} = \left\{ \inf_{\|u\|_2=1} \left| \mu_2(\hat{\beta}^t)(u, \Sigma u) + \mu_4(\hat{\beta}^t)(u, \Sigma \hat{\beta}^t) \right| > 2\kappa^{-1} \quad \forall t, \quad \beta_* \in \mathcal{C} \right\} \quad (8)$$

for some positive constant κ , and the optimal value β_* . If $n, |S|$ and p are sufficiently large, then there exist constants c, c_1, c_2 depending on the radii K, R , $\mathbb{P}(\mathcal{E})$ and the bounds on $\phi^{(2)}$ and $\phi^{(4)}$ such that conditioned on the event \mathcal{E} , with probability at least $1 - c/p^2$, we have

$$\|\hat{\beta}^{t+1} - \beta_*\|_2 \leq \tau_1 \|\hat{\beta}^t - \beta_*\|_2 + \tau_2 \|\hat{\beta}^t - \beta_*\|_2^2, \quad (9)$$

where the coefficients τ_1 and τ_2 are deterministic constants defined as

$$\tau_1 = \kappa \mathfrak{D}(x, z) + c_1 \kappa \sqrt{\frac{p}{\min\{p/\log(p)|S|, n/\log(n)\}}}, \quad \tau_2 = c_2 \kappa, \quad (10)$$

and $\mathfrak{D}(x, z)$ is defined as

$$\mathfrak{D}(x, z) = \|\Sigma\|_2 d_{\mathcal{H}_1}(x, z) + \|\Sigma\|_2^2 R^2 d_{\mathcal{H}_2}(x, z) + d_{\mathcal{H}_3}(x, z), \quad (11)$$

for a multivariate Gaussian random variable z with the same mean and covariance as x_i 's.

The bound in Equation 9 holds with high probability, and the coefficients τ_1 and τ_2 are deterministic constants which will describe the convergence behavior of the Newton-Stein method. Observe that the coefficient τ_1 is sum of two terms: $\mathfrak{D}(x, z)$ measures how accurate the Hessian estimation is, and the second term depends on the sub-sampling size $|S|$ and the data dimensions n, p .

Theorem 4 shows that the convergence of Newton-Stein method can be upper bounded by a compositely converging sequence, that is, the squared term will dominate at first providing us with a quadratic rate, then the convergence will transition into a linear phase as the iterate gets close to the optimal value. The coefficients τ_1 and τ_2 govern the linear and quadratic terms, respectively. The effect of sub-sampling appears in the coefficient of linear term. In theory, there is a threshold for the sub-sampling size $|S|$, namely $\mathcal{O}(n/\log(n))$, beyond which further sub-sampling has no effect. The transition point between the quadratic and the linear phases is determined by the sub-sampling size and the properties of the data. The phase transition behavior can be observed through the right plot in Figure 1.

Using the above theorem, we state the following corollary.

Corollary 5 Assume that the assumptions of Theorem 4 hold. For a constant $\delta \geq \mathbb{P}(\mathcal{E}^C)$, and a tolerance ϵ satisfying

$$\epsilon \geq 20R \{c/p^2 + \delta\},$$

and for an iterate satisfying $\mathbb{E}[\|\hat{\beta}^t - \beta_*\|_2] > \epsilon$, the following inequality holds for the iterates of Newton-Stein method,

$$\mathbb{E} \left[\|\hat{\beta}^{t+1} - \beta_*\|_2 \right] \leq \bar{\tau}_1 \mathbb{E} \left[\|\hat{\beta}^t - \beta_*\|_2 \right] + \tau_2 \mathbb{E} \left[\|\hat{\beta}^t - \beta_*\|_2^2 \right],$$

where $\bar{\tau}_1 = \tau_1 + 0.1$ and τ_1, τ_2 are as in Theorem 4.

The bound stated in the above corollary is an analogue of composite convergence (given in Equation 9) in expectation. Note that our results make strong assumptions on the derivatives of the cumulant generating function ϕ . We emphasize that these assumptions

are valid for linear and logistic regressions. An example that does not fit in our scheme is *Poisson regression* with $\phi(z) = e^z$. However, we observed empirically that the algorithm still provides significant improvement.

The following theorem characterizes the local convergence behavior of a compositely converging sequence.

Theorem 6 *Assume that the assumptions of Theorem 4 hold with $\tau_1 < 1$ and for $\vartheta = \|\beta^0 - \beta_*\|_2$ define the interval $\Xi = \left(\frac{\tau_1\vartheta}{1-\tau_2\vartheta}, \vartheta\right)$. Conditioned on the event $\mathcal{E} \cap \{\vartheta < (1 - \tau_1)/\tau_2\}$, there exists a constant c such that with probability at least $1 - c/p^2$, the number of iterations to reach a tolerance of ϵ cannot exceed*

$$\inf_{\xi \in \Xi} \mathcal{J}(\xi) := \log_2 \left(\frac{\log(\tau_1 + \tau_2\xi)}{\log((\tau_1/\xi + \tau_2)(1 - \tau_1)/\tau_2)} + \frac{\log(\epsilon/\xi)}{\log(\tau_1 + \tau_2\xi)} \right), \quad (12)$$

where the constants τ_1 and τ_2 are as in Theorem 4.

The expression in Equation 12 has two terms: the first one is due to the quadratic phase whereas the second one is due to the linear phase. To obtain the properties of local convergence, a locality constraint is required. We note that $\tau_1 < 1$ is a necessary assumption, which is satisfied for sufficiently large n and $|S|$.

In the following, we establish the global convergence of the Newton-Stein method coupled with a backtracking line search—which is explicitly given in Section 4.4.

Theorem 7 (Global Convergence) *Assume that the assumptions of Theorem 4 hold and at each step, the step size τ_t of the Newton-Stein method is determined by the backtracking line search with parameters a and b . Then conditioned on the event \mathcal{E} , there exists a constant c such that with probability at least $1 - c/p^2$, the sequence of iterates $\{\beta^t\}_{t>0}$ generated by the Newton-Stein method converges globally.*

4.3 Sub-Gaussian Covariates

In this section, we carry our analysis to the more general case, where the covariates are sub-Gaussian vectors.

Theorem 8 (Local convergence) *Assume that x_1, x_2, \dots, x_n are i.i.d. sub-Gaussian random vectors with sub-Gaussian norm K such that*

$$\mathbb{E}[x_1] = 0, \quad \mathbb{E}[\|x\|_2] = \mu \quad \text{and} \quad \mathbb{E}[xx^T] = \Sigma.$$

Further assume that the cumulant generating function ϕ is uniformly bounded and has bounded 3rd-5th derivatives and that C is bounded by R . For $\{\beta^t\}_{t>0}$ given by the Newton-Stein method and the event \mathcal{E} in Equation 8, if we have $n, |S|$ and p sufficiently large and $n^{0.2}/\log(n) \gtrsim p$,

then there exist constants c_1, c_2, c_3, c_4 depending on the eigenvalues of Σ , the radius R , μ , $\mathbb{P}(\mathcal{E})$ and the bounds on $\phi^{(2)}$ and $|\phi^{(4)}|$ such that conditioned on the event \mathcal{E} , with probability at least $1 - c_1 e^{-c_2 p}$, the bound given in Equation 9 holds for constants

$$\tau_1 = \kappa \mathfrak{D}(x, z) + c_3 \kappa \sqrt{\frac{p}{\min\{|S|, n^{0.2}/\log(n)\}}}, \quad \tau_2 = c_4 \kappa p^{1.5}, \quad (13)$$

where $\mathfrak{D}(x, z)$ defined as in Equation 11.

The above theorem is more restrictive than Theorem 4. We require n to be much larger than the dimension p . Also note that a factor of $p^{1.5}$ appears in the coefficient of the quadratic term. We also notice that the threshold for the sub-sample size reduces to $n^{0.2}/\log(n)$. We have the following analogue of Corollary 5.

Corollary 9 *Assume that the assumptions of Theorem 8 hold. For a constant $\delta \geq \mathbb{P}(\mathcal{E}^c)$, and a tolerance ϵ satisfying*

$$\epsilon \geq 20R\sqrt{c_1 e^{-c_2 p} + \delta},$$

and for an iterate satisfying $\mathbb{E}[\|\beta^t - \beta_*\|_2] > \epsilon$, the iterates of Newton-Stein method will satisfy,

$$\mathbb{E}[\|\beta^{t+1} - \beta_*\|_2] \leq \bar{\tau}_1 \mathbb{E}[\|\beta^t - \beta_*\|_2] + \tau_2 \mathbb{E}[\|\beta^t - \beta_*\|_2^2],$$

where $\bar{\tau}_1 = \tau_1 + 0.1$ and τ_1, τ_2 are as in Theorem 8.

When the covariates are in fact multivariate normal, we have $\mathfrak{D}(x, z) = 0$ which implies that the coefficient τ_1 is smaller. Correspondingly, the quadratic phase lasts longer providing better performance.

We conclude this section by noting that the global convergence properties of the sub-Gaussian case is very similar to the previous section where we had bounded covariates.

4.4 Algorithm Parameters

Newton-Stein method takes two input parameters and for those, we suggest near-optimal choices based on our theoretical results. We further discuss the choice of a covariance estimation method which provides additional improvements to the proposed algorithm.

- *Sub-sample size:* Newton-Stein method uses a subset of indices to approximate the covariance matrix Σ . Corollary 5.50 of Vershynin, 2010 proves that a sample size of $\mathcal{O}(p)$ is sufficient for sub-Gaussian covariates and that of $\mathcal{O}(p \log(p))$ is sufficient for arbitrary distributions supported in some ball to estimate a covariance matrix by its sample mean estimator. In the regime we consider, $n \gg p$, we suggest to use a sample size of $|S| = \mathcal{O}(p \log(p))$ for this task.

- *Covariance estimation method:* Many methods have been suggested to improve the estimation of the covariance matrix and almost all of them rely on the concept of *shrinkage* (Cai et al., 2010; Donoho et al., 2013). Therefore, we suggest to use a thresholding based approach suggested by Erdogdu and Montanari, 2015. For a given threshold r , we take the largest r eigenvalues of the sub-sampled covariance estimator, setting rest of them to $(r + 1)$ -th eigenvalue. Eigenvalue thresholding can be considered as a shrinkage operation which will retain only the important second order information. Choosing the rank threshold r can be simply done on the sample mean estimator of Σ . After obtaining the sub-sampled estimate of the mean, one can either plot the spectrum and choose manually or use an optimal technique from Donoho

et al., 2013. The suggested method requires a single time $\mathcal{O}(np^2)$ computation and reduces the cost of inversion from $\mathcal{O}(p^3)$ to $\mathcal{O}(np^2)$. We highlight that the Newton-Stein method was originally presented with the eigenvalue thresholding in an early version of this paper (Erdogdu, 2015).

- *Step size*: Step size choices for the Newton-Stein method are quite similar to those of Newton-type methods (i.e., see Boyd and Vandenberghe, 2004). In the *damped phase*, one should use a line search algorithm such as *backtracking* with parameters $a \in (0, 0.5)$ and $b \in (0, 1)$. Defining the modified gradient (or composite gradient Lee et al., 2014) $D_\gamma(\hat{\beta}^t) = \frac{1}{\gamma} \{ \hat{\beta}^t - \mathcal{P}_C^t(\hat{\beta}^t - \gamma \mathbf{Q}^t \nabla \ell(\hat{\beta}^t)) \}$, we compute the step size via

$$\gamma = \bar{\gamma}; \quad \text{while: } \ell(\hat{\beta}^t - \gamma D_\gamma(\hat{\beta}^t)) > \ell(\hat{\beta}^t) - a\gamma \langle \nabla \ell(\hat{\beta}^t), D_\gamma(\hat{\beta}^t) \rangle, \quad \gamma \leftarrow \gamma b.$$

The above line search algorithm leads to global convergence with high probability as stated in Theorem 7.

The step choice for the local phase depends on the use of eigenvalue thresholding. If no shrinkage method is applied, line search algorithm should be initialized with $\bar{\gamma} = 1$. If a shrinkage method (e.g. eigenvalue thresholding) is applied, then choosing a larger local step size may provide faster convergence. If the data follows the r -spiked model, the optimal step size will be close to 1 if there is no sub-sampling. However, due to fluctuations resulting from sub-sampling, starting with $\bar{\gamma} = 1.2$ will provide faster local rates. This case has been explicitly studied in a preliminary version of this work (Erdogdu, 2015). A heuristic derivation and a detailed discussion can also be found in Section E in the Appendix.

5. Experiments

In this section, we validate the performance of Newton-Stein method through extensive numerical studies. We experimented on two commonly used GLM optimization problems, namely, *Logistic Regression* (LR) and *Linear Regression* (OLS). LR minimizes Equation 4 for the logistic function $\phi(z) = \log(1 + e^z)$, whereas OLS minimizes the same equation for $\phi(z) = z^2/2$. In the following, we briefly describe the algorithms that are used in the experiments:

- *Newton's Method* (NM) uses the inverse Hessian evaluated at the current iterate, and may achieve local quadratic convergence. NM steps require $\mathcal{O}(np^2 + p^3)$ computation which makes it impractical for large-scale data sets.
- *Broyden-Fletcher-Goldfarb-Shanno* (BFGS) forms a curvature matrix by cultivating the information from the iterates and the gradients at each iteration. Under certain assumptions, the convergence rate is locally super-linear and the per-iteration cost is comparable to that of first order methods.
- *Limited Memory BFGS* (L-BFGS) is similar to BFGS, and uses only the recent few iterates to construct the curvature matrix, gaining significant performance in terms of memory usage.

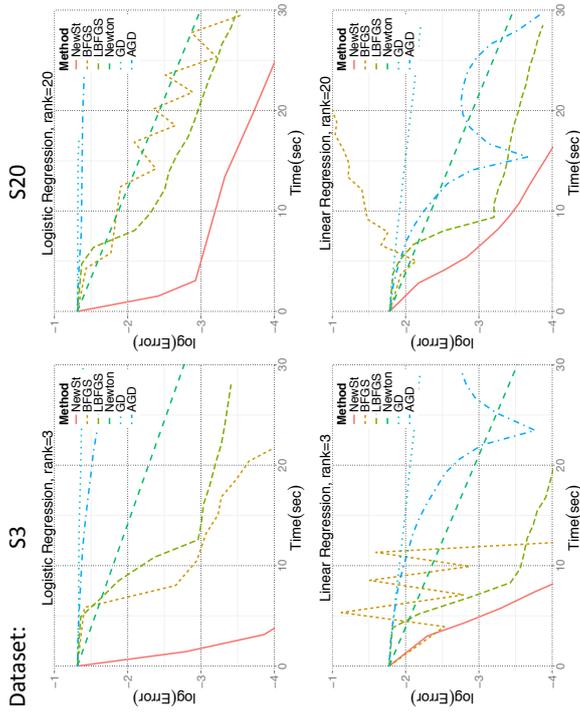

Figure 2: Performance of various optimization methods on two different simulated data sets. Red straight line represents the Newton-Stein method (NewSt). y and x axes denote $\log_{10}(\|\hat{\beta}^t - \beta_*\|_2)$ and time elapsed in seconds, respectively.

- *Gradient Descent* (GD) update is proportional to the negative of the full gradient evaluated at the current iterate. Under smoothness assumptions, GD achieves a locally linear convergence rate, with $\mathcal{O}(np)$ per-iteration cost.
- *Accelerated Gradient Descent* (AGD) is proposed by Nesterov (Nesterov, 1983), which improves over the gradient descent by using a momentum term. Performance of AGD strongly depends of the smoothness of the function.

For all the algorithms, we use a constant step size that provides the fastest convergence. We use the Newton-Stein method with eigenvalue thresholding as described in Section 4.4. The parameters such as sub-sample size $|S|$, and rank r are selected by following the guidelines described in Section 4.4. The rank threshold r (which is an input to the eigenvalue thresholding) is specified at the title of each plot.

5.1 Simulations With Synthetic Data Sets

Synthetic data sets, S3, S10, and S20 are generated through a multivariate Gaussian distribution where the covariance matrix follows r -spiked model, i.e., $r = 3$ for S3 and $r = 20$

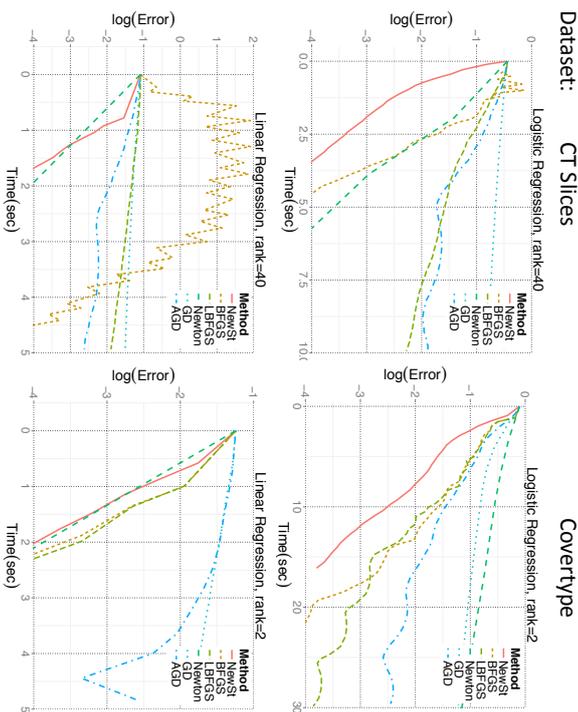

Figure 3: Performance of various optimization methods on two different real data sets obtained from Lichman, 2013. Red straight line represents the Newton-Stein method (NewSt). y and x axes denote $\log_{10}(\|\beta^t - \beta_*\|_2)$ and time elapsed in seconds, respectively.

for S20. To generate the covariance matrix, we first generate a random orthogonal matrix, say M . Next, we generate a diagonal matrix Λ that contains the eigenvalues, i.e., the first r diagonal entries are chosen to be large, and rest of them are equal to 1. Then, we let $\Sigma = M\Lambda M^T$. For dimensions of the data sets, see Table 2. We also emphasize that the data dimensions are chosen so that Newton’s method still does well.

The simulation results are summarized in Figure 2. Further details regarding the experiments can be found in Table 1. We observe that Newton-Stein method (NewSt) provides a significant improvement over the classical techniques.

Observe that the convergence rate of NewSt has a clear phase transition point in the top left plot in Figure 2. As argued earlier, this point depends on various factors including sub-sampling size $|S|$ and data dimensions n, p , the rank threshold r and structure of the covariance matrix. The prediction of the phase transition point is an interesting line of research. However, our convergence guarantees are conservative and we believe that they cannot be used for this purpose.

5.2 Experiments With Real Data Sets

We experimented on two real data sets where the data sets are downloaded from UCI repository (Lichman, 2013). Both data sets satisfy $n \gg p$, but we highlight the difference between the proportions of dimensions n/p . See Table 2 for details.

We observe that Newton-Stein method performs better than classical methods on real data sets as well. More specifically, the methods that come closer to NewSt is Newton’s method for moderate n and p and BFGS when n is large.

The optimal step-size for Newton-Stein method will typically be larger than 1 which is mainly due to eigenvalue thresholding operation. This feature is desirable if one is able to obtain a large step-size that provides convergence. In such cases, the convergence is likely to be faster, yet more unstable compared to the smaller step size choices. We observed that similar to other second order algorithms, Newton-Stein method is also susceptible to the step size selection. If the data is not well-conditioned, and the sub-sample size is not sufficiently large, algorithm might have poor performance. This is mainly because the sub-sampling operation is performed only once at the beginning. Therefore, it might be good in practice to sub-sample once in every few iterations.

5.3 Analysis of Number of Iterations

We provide additional plots to better understand the convergence behavior of the algorithms. Plots in Figure 4 show the decrease in $\log_{10}(\|\hat{\beta}^t - \beta_0\|_2)$ error over iterations (instead of time elapsed).

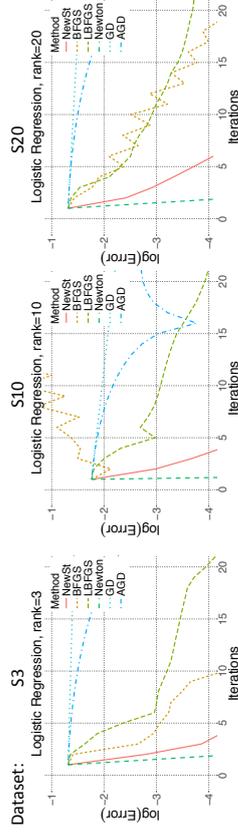

Figure 4: Figure shows the convergence behavior over the number of iterations. y and x axes denote $\log_{10}(\|\hat{\beta}^t - \beta_*\|_2)$ and the number iterations, respectively.

We observe from the plots that Newton’s method enjoys the fastest convergence rate as expected. The one that is closest to Newton’s method is the Newton-Stein method. This is because the Hessian estimator used by Newton-Stein method better approximates the true Hessian as opposed to Quasi-Newton methods. We emphasize that x axes in Figure 4 denote the number of iterations whereas in figures shown previously in this section x axes were the time elapsed.

6. Discussion

In this paper, we proposed an efficient algorithm for training GLMs. We call our algorithm Newton-Stein method (NewSt) as it takes a Newton-type step at each iteration relying on a Stein-type lemma. The algorithm requires a one time $\mathcal{O}(|S|p^2)$ cost to estimate the covariance structure and $\mathcal{O}(np)$ per-iteration cost to form the update equations. We observe that the convergence of Newton-Stein method has a phase transition from quadratic rate to linear rate. This observation is justified theoretically along with several other guarantees for the bounded as well as the sub-Gaussian covariates such as per-step convergence bounds, conditions for local rates and global convergence with line search, etc. Parameter selection guidelines of Newton-Stein method are based on our theoretical results. Our experiments show that Newton-Stein method provides significant improvement over the classical optimization methods.

Relaxing some of the theoretical constraints is an interesting line of research. In particular, strong assumptions on the cumulant generating functions might be loosened. Another interesting direction is to determine when the phase transition point occurs, which would provide a better understanding of the effects of sub-sampling and eigenvalue thresholding.

Appendix A. Preliminary Concentration Inequalities

In this section, we provide several concentration bounds that will be useful throughout the proofs. We start by defining a special class of random variables.

Definition 10 (Sub-Gaussian) A random variable $x \in \mathbb{R}$ is called sub-Gaussian if it satisfies

$$\mathbb{E}[|x|^m]^{1/m} \leq K\sqrt{m}, \quad m \geq 1,$$

for some finite constant K . The smallest such K is the sub-Gaussian norm of x and it is denoted by $\|x\|_{\psi_2}$. Similarly, a random vector $y \in \mathbb{R}^p$ is called sub-Gaussian if there exists a constant $K' > 0$ such that

$$\sup_{v \in S^{p-1}} \|(y, v)\|_{\psi_2} \leq K'.$$

Definition 11 (Sub-exponential) A random variable $x \in \mathbb{R}$ is called sub-exponential if it satisfies

$$\mathbb{E}[|x|^m]^{1/m} \leq Km, \quad m \geq 1,$$

for some finite constant K . The smallest such K is the sub-exponential norm of x and it is denoted by $\|x\|_{\psi_1}$. Similarly, a random vector $y \in \mathbb{R}^p$ is called sub-exponential if there exists a constant $K' > 0$ such that

$$\sup_{v \in S^{p-1}} \|(y, v)\|_{\psi_1} \leq K'.$$

We state the following Lemmas from Vershynin, 2010 for the convenience of the reader (i.e., See Theorem 5.39 and the following remark for sub-Gaussian distributions, and Theorem 5.44 for distributions with arbitrary support):

Lemma 12 (Vershynin, 2010) Let S be an index set and $x_i \in \mathbb{R}^p$ for $i \in S$ be i.i.d. sub-Gaussian random vectors with

$$\mathbb{E}[x_i] = 0, \quad \mathbb{E}[x_i x_i^T] = \Sigma, \quad \|x_i\|_{\psi_2} \leq K.$$

There exists constants c, C depending only on the sub-Gaussian norm K such that with probability $1 - 2e^{-c^2}$,

$$\|\hat{\Sigma}_S - \Sigma\|_2 \leq \max(\delta, \delta^2) \quad \text{where} \quad \delta = C\sqrt{\frac{p}{|S|} + \frac{t}{\sqrt{|S|}}}.$$

Remark 13 We are interested in the case where $\delta < 1$, hence the right hand side becomes $\max(\delta, \delta^2) = \delta$. In most cases, we will simply let $t = \sqrt{p}$ and obtain a bound of order $\sqrt{p}/|S|$ on the right hand side. For this, we need $|S| = \mathcal{O}(C^2 p)$ which is a reasonable assumption in the regime we consider.

The following lemma is an analogue of Lemma 12 for covariates sampled from arbitrary distributions with bounded support.

Lemma 14 (Vershynin, 2010) *Let S be an index set and $x_i \in \mathbb{R}^p$ for $i \in S$ be i.i.d. random vectors with*

$$\mathbb{E}[x_i] = 0, \quad \mathbb{E}[x_i x_i^T] = \Sigma, \quad \|x_i\|_2 \leq \sqrt{K} \text{ a.s.}$$

Then, for some absolute constant c , with probability $1 - pe^{-ct^2}$, we have

$$\|\widehat{\Sigma}_S - \Sigma\|_2 \leq \max\left(\|\Sigma\|_2^{1/2} \delta, \delta^2\right) \quad \text{where} \quad \delta = t \sqrt{\frac{K}{|S|}}.$$

Remark 15 *We will choose $t = \sqrt{3 \log(p)/c}$ which will provide us with a probability of $1 - 1/p^2$. Therefore, if the sample size is sufficiently large, i.e.,*

$$|S| \geq \frac{3K \log(p)}{c \|\Sigma\|_2} = \mathcal{O}(K \log(p) / \|\Sigma\|_2),$$

we can estimate the true covariance matrix quite well for arbitrary distributions with bounded support. In particular, with probability $1 - 1/p^2$, we obtain

$$\|\widehat{\Sigma}_S - \Sigma\|_2 \leq c' \sqrt{\frac{\log(p)}{|S|}}, \tag{14}$$

where $c' = \sqrt{3K \|\Sigma\|_2 / c}$.

In the following, we will focus on empirical processes and obtain uniform bounds for proposed Hessian approximation. To that extent, we provide a few basic definitions which will be useful later in the proofs. For a more detailed discussion on the machinery used throughout the next section, we refer reader to Van der Vaart, 2000.

Definition 16 *On a metric space (X, d) , for $\epsilon > 0$, $T_\epsilon \subset X$ is called an ϵ -net over X if $\forall x \in X, \exists t \in T_\epsilon$ such that $d(x, t) \leq \epsilon$.*

In the following, we will use L_1 distance between two functions f and g , namely $d(f, g) = \int |f - g|$. Note that the same distance definition can be carried to random variables as they are simply real measurable functions. The integral takes the form of expectation.

Definition 17 *Given a function class \mathcal{F} , and any two functions l and u (not necessarily in \mathcal{F}), the bracket $[l, u]$ is the set of all $f \in \mathcal{F}$ such that $l \leq f \leq u$. A bracket satisfying $l \leq u$ and $\int |u - l| \leq \epsilon$ is called an ϵ -bracket in L_1 . The bracketing number $N_{[]}(\epsilon, \mathcal{F}, L_1)$ is the minimum number of different ϵ -brackets needed to cover \mathcal{F} .*

The preliminary tools presented in this section will be utilized to obtain the concentration results in Section B.

Appendix B. Main Lemmas

B.1 Concentration of Covariates With Bounded Support

Lemma 18 *Let $x_i \in \mathbb{R}^p$, for $i = 1, 2, \dots, n$, be i.i.d. random vectors supported on a ball of radius \sqrt{K} , with mean 0, and covariance matrix Σ . Further, let $f : \mathbb{R} \rightarrow \mathbb{R}$ be a uniformly bounded function such that for some $B > 0$, we have $\|f\|_\infty < B$ and f is Lipschitz continuous with constant L . Then, for sufficiently large n , there exist constants c_1, c_2, c_3 such that*

$$\mathbb{P}\left(\sup_{\beta \in B_p(R)} \left| \frac{1}{n} \sum_{i=1}^n f(x_i, \beta) - \mathbb{E}[f(x, \beta)] \right| > c_1 \sqrt{\frac{p \log(n)}{n}}\right) \leq c_2 e^{-c_3 p},$$

where the constants depend only on the bound B .

Proof We start by using the Lipschitz property of the function f , i.e., $\forall \beta, \beta' \in B_p(R)$,

$$\begin{aligned} |f(x, \beta) - f(x, \beta')| &\leq L \|x\|_2 \|\beta - \beta'\|_2, \\ &\leq L \sqrt{K} \|\beta - \beta'\|_2, \end{aligned}$$

where the first inequality follows from Cauchy-Schwartz. Now let T_Δ be a Δ -net over $B_p(R)$. Then $\forall \beta \in B_p(R)$, $\exists \beta' \in T_\Delta$ such that the right hand side of the above inequality is smaller than $\Delta L \sqrt{K}$. Then, we can write

$$\left| \frac{1}{n} \sum_{i=1}^n f(x_i, \beta) - \mathbb{E}[f(x, \beta)] \right| \leq \left| \frac{1}{n} \sum_{i=1}^n f(x_i, \beta') - \mathbb{E}[f(x, \beta')] \right| + 2\Delta L \sqrt{K}. \tag{14}$$

By choosing

$$\Delta = \frac{\epsilon}{4L\sqrt{K}},$$

and taking supremum over the corresponding β sets on both sides, we obtain the following inequality

$$\sup_{\beta \in B_p(R)} \left| \frac{1}{n} \sum_{i=1}^n f(x_i, \beta) - \mathbb{E}[f(x, \beta)] \right| \leq \max_{\beta \in T_\Delta} \left| \frac{1}{n} \sum_{i=1}^n f(x_i, \beta) - \mathbb{E}[f(x, \beta)] \right| + \frac{\epsilon}{2}.$$

Now, since we have $\|f\|_\infty \leq B$ and for a fixed β and $i = 1, 2, \dots, n$, the random variables $f(x_i, \beta)$ are i.i.d., by the Hoeffding's concentration inequality, we have

$$\mathbb{P}\left(\left| \frac{1}{n} \sum_{i=1}^n f(x_i, \beta) - \mathbb{E}[f(x, \beta)] \right| > \epsilon/2\right) \leq 2 \exp\left(-\frac{n\epsilon^2}{8B^2}\right).$$

Combining Equation 14 with the above result and a union bound, we easily obtain

$$\begin{aligned} &\mathbb{P}\left(\sup_{\beta \in B_p(R)} \left| \frac{1}{n} \sum_{i=1}^n f(x_i, \beta) - \mathbb{E}[f(x, \beta)] \right| > \epsilon\right) \\ &\leq \mathbb{P}\left(\max_{\beta \in T_\Delta} \left| \frac{1}{n} \sum_{i=1}^n f(x_i, \beta) - \mathbb{E}[f(x, \beta)] \right| > \epsilon/2\right) \leq 2|T_\Delta| \exp\left(-\frac{n\epsilon^2}{8B^2}\right), \end{aligned}$$

where $\Delta = \epsilon/4L\sqrt{K}$.

Next, we apply Lemma 33 and obtain that

$$|T_\Delta| \leq \left(\frac{R\sqrt{p}}{\Delta} \right)^p = \left(\frac{R\sqrt{p}}{\epsilon/4L\sqrt{K}} \right)^p.$$

We require that the probability of the desired event is bounded by a quantity that attains an exponential decay with rate $\mathcal{O}(p)$. This can be attained if

$$\epsilon^2 \geq \frac{8B^2p}{n} \log(4eLR\sqrt{K}\sqrt{p}/\epsilon).$$

Assuming that n is sufficiently large, and using Lemma 34 with $a = 8B^2p/n$ and $b = 4eLR\sqrt{K}p$, we obtain that ϵ should be

$$\epsilon = \sqrt{\frac{4B^2p}{n} \log\left(\frac{30L^2R^2Kn}{B^2}\right)} = \mathcal{O}\left(\sqrt{\frac{p \log(n)}{n}}\right).$$

When $n > 30L^2R^2K/B^2$, we obtain

$$\mathbb{P}\left(\sup_{\beta \in B_p(R)} \left| \frac{1}{n} \sum_{i=1}^n f(\langle x_i, \beta \rangle) - \mathbb{E}[f(\langle x, \beta \rangle)] \right| > 3B\sqrt{\frac{p \log(n)}{n}}\right) \leq 2e^{-p}.$$

■

In the following, we state similar bounds on functions of the following form

$$x \rightarrow f(\langle x, \beta \rangle) \langle x, v \rangle^2,$$

which appear in the summation that form the Hessian matrix.

Lemma 19 *Let $x_i \in \mathbb{R}^p$, for $i = 1, \dots, n$, be i.i.d. random vectors supported on a ball of radius \sqrt{K} , with mean 0, and covariance matrix Σ . Also let $f : \mathbb{R} \rightarrow \mathbb{R}$ be a uniformly bounded function such that for some $B > 0$, we have $\|f\|_\infty < B$ and f is Lipschitz continuous with constant L . Then, for $v \in S^{p-1}$ and sufficiently large n , there exist constants c_1, c_2, c_3 such that*

$$\mathbb{P}\left(\sup_{\beta \in B_p(R)} \left| \frac{1}{n} \sum_{i=1}^n f(\langle x_i, \beta \rangle) \langle x_i, v \rangle^2 - \mathbb{E}[f(\langle x, \beta \rangle) \langle x, v \rangle^2] \right| > c_1 \sqrt{\frac{p \log(n)}{n}}\right) \leq c_2 e^{-c_3 p},$$

where the constants depend only on the bound B and the radius \sqrt{K} .

Proof As in the proof of Lemma 18, we start by using the Lipschitz property of the function f , i.e., $\forall \beta, \beta' \in B_p(R)$,

$$\begin{aligned} \|f(\langle x, \beta \rangle) \langle x, v \rangle^2 - f(\langle x, \beta' \rangle) \langle x, v \rangle^2\|_2 &\leq L \|x\|_2^2 \|\beta - \beta'\|_2, \\ &\leq LK^{1.5} \|\beta - \beta'\|_2. \end{aligned}$$

For a net T_Δ , $\forall \beta \in B_p(R)$, $\exists \beta' \in T_\Delta$ such that right hand side of the above inequality is smaller than $\Delta LK^{1.5}$. Then, we can write

$$\begin{aligned} \left| \frac{1}{n} \sum_{i=1}^n f(\langle x_i, \beta \rangle) \langle x_i, v \rangle^2 - \mathbb{E}[f(\langle x, \beta \rangle) \langle x, v \rangle^2] \right| &\leq \left| \frac{1}{n} \sum_{i=1}^n f(\langle x_i, \beta' \rangle) \langle x_i, v \rangle^2 - \mathbb{E}[f(\langle x, \beta' \rangle) \langle x, v \rangle^2] \right| \\ &\quad + 2\Delta LK^{1.5}. \end{aligned} \quad (15)$$

This time, we choose

$$\Delta = \frac{\epsilon}{4LK^{1.5}},$$

and take the supremum over the corresponding feasible β -sets on both sides,

$$\begin{aligned} \sup_{\beta \in B_p(R)} \left| \frac{1}{n} \sum_{i=1}^n f(\langle x_i, \beta \rangle) \langle x_i, v \rangle^2 - \mathbb{E}[f(\langle x, \beta \rangle) \langle x, v \rangle^2] \right| \\ \leq \max_{\beta \in T_\Delta} \left| \frac{1}{n} \sum_{i=1}^n f(\langle x_i, \beta \rangle) \langle x_i, v \rangle^2 - \mathbb{E}[f(\langle x, \beta \rangle) \langle x, v \rangle^2] \right| + \frac{\epsilon}{2}. \end{aligned}$$

Now, since we have $\|f\|_\infty \leq B$ and for fixed β and v , $i = 1, 2, \dots, n$, $f(\langle x_i, \beta \rangle) \langle x_i, v \rangle^2$ are i.i.d. random variables. By the Hoeffding's concentration inequality, we write

$$\mathbb{P}\left(\left| \frac{1}{n} \sum_{i=1}^n f(\langle x_i, \beta \rangle) \langle x_i, v \rangle^2 - \mathbb{E}[f(\langle x, \beta \rangle) \langle x, v \rangle^2] \right| > \epsilon/2\right) \leq 2 \exp\left(-\frac{n\epsilon^2}{8B^2K^2}\right).$$

Using Equation 15 and the above result combined with the union bound, we easily obtain

$$\begin{aligned} \mathbb{P}\left(\sup_{\beta \in B_p(R)} \left| \frac{1}{n} \sum_{i=1}^n f(\langle x_i, \beta \rangle) \langle x_i, v \rangle^2 - \mathbb{E}[f(\langle x, \beta \rangle) \langle x, v \rangle^2] \right| > \epsilon\right) \\ \leq \mathbb{P}\left(\max_{\beta \in T_\Delta} \left| \frac{1}{n} \sum_{i=1}^n f(\langle x_i, \beta \rangle) \langle x_i, v \rangle^2 - \mathbb{E}[f(\langle x, \beta \rangle) \langle x, v \rangle^2] \right| > \epsilon/2\right) \\ \leq 2|T_\Delta| \exp\left(-\frac{n\epsilon^2}{8B^2K^2}\right), \end{aligned}$$

where $\Delta = \epsilon/4LK^{1.5}$. Using Lemma 33, we have

$$|T_\Delta| \leq \left(\frac{R\sqrt{p}}{\Delta} \right)^p = \left(\frac{R\sqrt{p}}{\epsilon/4LK^{1.5}} \right)^p.$$

As before, we require that the right hand side of above inequality gets a decay with rate $\mathcal{O}(p)$. Using Lemma 34 with $a = 8B^2K^2p/n$ and $b = 100LRK^{1.5}\sqrt{p}$, we obtain that ϵ should be

$$\epsilon = \sqrt{\frac{4B^2K^2p}{n} \log\left(\frac{50^2L^2R^2Kn}{B^2}\right)} = \mathcal{O}\left(\sqrt{\frac{p \log(n)}{n}}\right).$$

When $n > 50LKR^{1/2}/B$, we obtain

$$\mathbb{P}\left(\sup_{\beta \in B_p(R)} \left| \frac{1}{n} \sum_{i=1}^n f(\langle x_i, \beta \rangle) \langle x_i, v \rangle^2 - \mathbb{E}[f(\langle x, \beta \rangle) \langle x, v \rangle^2] \right| > 4BK \sqrt{\frac{p \log(n)}{n}}\right) \leq 2e^{-32p}.$$

The rate $-3.2p$ will be important later. \blacksquare

B.2 Concentration of Sub-Gaussian Covariates

In this section, we derive the analogues of the Lemmas 18 and 19 for sub-Gaussian covariates. Note that the Lemmas in this section are more general in the sense that they also cover the case where the covariates have bounded support. As a result, the resulting convergence coefficients are worse compared to the previous section.

Lemma 20 *Let $x_i \in \mathbb{R}^p$, for $i = 1, \dots, n$, be i.i.d. sub-Gaussian random vectors with mean 0, covariance matrix Σ and sub-Gaussian norm K . Also let $f : \mathbb{R} \rightarrow \mathbb{R}$ be a uniformly bounded function such that for some $B > 0$, we have $\|f\|_\infty < B$ and f is Lipschitz continuous with constant L . Then, there exists absolute constants c_1, c_2, c_3 such that*

$$\mathbb{P}\left(\sup_{\beta \in B_n(R)} \left| \frac{1}{n} \sum_{i=1}^n f(\langle x_i, \beta \rangle) - \mathbb{E}[f(\langle x, \beta \rangle)] \right| > c_1 \sqrt{\frac{p \log(n)}{n}}\right) \leq c_2 e^{-c_3 p},$$

where the constants depend only on the eigenvalues of Σ , bound B and radius R and sub-Gaussian norm K .

Proof We start by defining the brackets of the form

$$\begin{aligned} l_\beta(x) &= f(\langle x, \beta \rangle) - \frac{\|x\|_2}{4\mathbb{E}\|x\|_2}, \\ u_\beta(x) &= f(\langle x, \beta \rangle) + \frac{\|x\|_2}{4\mathbb{E}\|x\|_2}. \end{aligned}$$

Observe that the size of bracket $[l_\beta, u_\beta]$ is $\epsilon/2$, i.e., $\mathbb{E}[u_\beta - l_\beta] = \epsilon/2$. Now let T_Δ be a Δ -net over $B_p(R)$ where we use $\Delta = \epsilon/(4L\mathbb{E}\|x\|_2)$. Then $\forall \beta \in B_p(R)$, $\exists \beta' \in T_\Delta$ such that $f(\langle \cdot, \beta \rangle)$ falls into the bracket $[l_{\beta'}, u_{\beta'}]$. This can be seen by writing out the Lipschitz property of the function f . That is,

$$\begin{aligned} |f(\langle x, \beta \rangle) - f(\langle x, \beta' \rangle)| &\leq L\|x\|_2 \|\beta - \beta'\|_2, \\ &\leq \Delta L \|x\|_2, \end{aligned}$$

where the first inequality follows from Cauchy-Schwarz. Therefore, we conclude that

$$M_{\lceil \epsilon/2, \mathcal{F}, L, 1 \rceil} \leq |T_\Delta|$$

for the function class $\mathcal{F} = \{f(\langle \cdot, \beta \rangle) : \beta \in B_p(R)\}$. We further have $\forall \beta \in B_p(R)$, $\exists \beta' \in T_\Delta$ such that

$$\begin{aligned} \frac{1}{n} \sum_{i=1}^n f(\langle x_i, \beta \rangle) - \mathbb{E}[f(\langle x, \beta \rangle)] &\leq \frac{1}{n} \sum_{i=1}^n u_{\beta'}(x_i) - \mathbb{E}[u_{\beta'}(x)] + \frac{\epsilon}{2}, \\ \frac{1}{n} \sum_{i=1}^n f(\langle x_i, \beta \rangle) - \mathbb{E}[f(\langle x, \beta \rangle)] &\geq \frac{1}{n} \sum_{i=1}^n l_{\beta'}(x_i) - \mathbb{E}[l_{\beta'}(x)] - \frac{\epsilon}{2}. \end{aligned}$$

Using the above inequalities, we have, $\forall \beta \in B_p(R)$, $\exists \beta' \in T_\Delta$

$$\begin{aligned} &\left\{ \left[\frac{1}{n} \sum_{i=1}^n u_{\beta'}(x_i) - \mathbb{E}[u_{\beta'}(x)] \right] > \epsilon/2 \right\} \cup \left\{ \left[-\frac{1}{n} \sum_{i=1}^n l_{\beta'}(x_i) + \mathbb{E}[l_{\beta'}(x)] \right] > \epsilon/2 \right\} \supset \\ &\left\{ \frac{1}{n} \sum_{i=1}^n f(\langle x_i, \beta \rangle) - \mathbb{E}[f(\langle x, \beta \rangle)] > \epsilon \right\}. \end{aligned}$$

By the union bound, we obtain

$$\begin{aligned} &\mathbb{P}\left(\max_{\beta \in T_\Delta} \left[\frac{1}{n} \sum_{i=1}^n u_{\beta'}(x_i) - \mathbb{E}[u_{\beta'}(x)] \right] > \epsilon/2\right) + \mathbb{P}\left(\max_{\beta \in T_\Delta} \left[-\frac{1}{n} \sum_{i=1}^n l_{\beta'}(x_i) + \mathbb{E}[l_{\beta'}(x)] \right] > \epsilon/2\right) \\ &\geq \mathbb{P}\left(\sup_{\beta \in B_p(R)} \left| \frac{1}{n} \sum_{i=1}^n f(\langle x_i, \beta \rangle) - \mathbb{E}[f(\langle x, \beta \rangle)] \right| > \epsilon\right). \end{aligned} \quad (16)$$

In order to complete the proof, we need concentration inequalities for u_β and l_β . We state the following lemma.

Lemma 21 *There exists a constant C depending on the eigenvalues of Σ and B such that, for each $\beta \in B_p(R)$ and for some $0 < \epsilon < 1$, we have*

$$\begin{aligned} \mathbb{P}\left(\frac{1}{n} \sum_{i=1}^n u_\beta(x_i) - \mathbb{E}[u_\beta(x)] > \epsilon/2\right) &\leq 2e^{-Cn\epsilon^2}, \\ \mathbb{P}\left(\frac{1}{n} \sum_{i=1}^n l_\beta(x_i) - \mathbb{E}[l_\beta(x)] > \epsilon/2\right) &\leq 2e^{-Cn\epsilon^2}, \end{aligned}$$

where

$$C = \frac{c}{\left(B + \frac{\sqrt{2}K}{4\mu/\sqrt{p}}\right)^2}$$

for an absolute constant c .

Remark 22 *Note that $\mu = \mathbb{E}\|x\|_2 = \mathcal{O}(\sqrt{p})$ and hence $\mu/\sqrt{p} = \mathcal{O}(1)$.*

Proof By the relation between sub-Gaussian and sub-exponential norms, we have

$$\begin{aligned} \| |x| \|_2^2 \|_{\psi_2} &\leq \| |x| \|_2^2 \|_{\psi_1} \leq \sum_{i=1}^p \| |x_i| \|_{\psi_1}^2, \\ &\leq 2 \sum_{i=1}^p \| |x_i| \|_{\psi_2}^2, \\ &\leq 2K^2 p. \end{aligned} \quad (17)$$

Therefore $\| |x| \|_2 - \mathbb{E} \| |x| \|_2$ is a centered sub-Gaussian random variable with sub-Gaussian norm bounded above by $2K\sqrt{2p}$. We have,

$$\mathbb{E} \| |x| \|_2 = \mu.$$

Note that μ is actually of order \sqrt{p} . Assuming that the left hand side of the above equality is equal to $\sqrt{p}K'$ for some constant $K' > 0$, we can conclude that the random variable $u_\beta(x) = f(\langle x, \beta \rangle) + \epsilon \frac{\| |x| \|_2}{4\mathbb{E} \| |x| \|_2}$ is also sub-Gaussian with

$$\begin{aligned} \| u_\beta(x) \|_{\psi_2} &\leq B + \frac{\epsilon}{4\mathbb{E} \| |x| \|_2} \| |x| \|_2 \|_{\psi_2} \\ &\leq B + \frac{K\sqrt{2p}}{4\sqrt{p}K'} K\sqrt{2p} \\ &\leq B + C' \end{aligned}$$

where $C' = \sqrt{2}K/4K'$ is a constant and we also assumed $\epsilon < 1$. Now, define the function

$$g_\beta(x) = u_\beta(x) - \mathbb{E}[u_\beta(x)].$$

Note that $g_\beta(x)$ is a centered sub-Gaussian random variable with sub-Gaussian norm

$$\| g_\beta(x) \|_{\psi_2} \leq 2B + 2C'.$$

Then, by the Hoeffding-type inequality for the sub-Gaussian random variables, we obtain

$$\mathbb{P} \left(\left| \frac{1}{n} \sum_{i=1}^n g_\beta(x_i) \right| > \epsilon/2 \right) \leq 2e^{-c\epsilon^2/(B+C')^2}$$

where c is an absolute constant. The same argument also holds for $I_\beta(x)$. \blacksquare

Using the above lemma with the union bound over the set T_Δ , we can write

$$\mathbb{P} \left(\sup_{\beta \in B_n(R)} \left| \frac{1}{n} \sum_{i=1}^n f(\langle x_i, \beta \rangle) - \mathbb{E}[f(\langle x, \beta \rangle)] \right| > \epsilon \right) \leq 4|T_\Delta| e^{-Cn\epsilon^2}.$$

Since we can also write, by Lemma 33

$$\begin{aligned} |T_\Delta| &\leq \left(\frac{R\sqrt{p}}{\Delta} \right)^p \leq \left(\frac{4RL\mathbb{E} \| |x| \|_2 \sqrt{p}}{\epsilon} \right)^p, \\ &\leq \left(\frac{4\sqrt{2}RLKp}{\epsilon} \right)^p, \end{aligned}$$

and we observe that, for the constant $c' = 4\sqrt{2}RLK$,

$$\begin{aligned} \mathbb{P} \left(\sup_{\beta \in B_n(R)} \left| \frac{1}{n} \sum_{i=1}^n f(\langle x_i, \beta \rangle) - \mathbb{E}[f(\langle x, \beta \rangle)] \right| > \epsilon \right) &\leq 4 \left(\frac{4\sqrt{2}RLKp}{\epsilon} \right)^p e^{-Cn\epsilon^2}, \\ &= 4 \exp \{ p \log(c'p/\epsilon) - Cn\epsilon^2 \}. \end{aligned}$$

We will obtain an exponential decay of order p on the right hand side. For some constant h depending on n and p , if we choose $\epsilon = hp$, we need

$$h^2 \geq \frac{1}{Cnp} \log(c'/h).$$

By the Lemma 34, choosing $h^2 = \log(2c^2Cnp)/(2Cnp)$, we satisfy the above requirement. Note that for n large enough, the condition of the lemma is easily satisfied. Hence, for

$$\epsilon^2 = \frac{p \log(2c^2Cnp)}{2Cn} = \mathcal{O} \left(\frac{p \log(n)}{n} \right),$$

we obtain that there exists constants c_1, c_2, c_3 such that

$$\mathbb{P} \left(\sup_{\beta \in B_n(R)} \left| \frac{1}{n} \sum_{i=1}^n f(\langle x_i, \beta \rangle) - \mathbb{E}[f(\langle x, \beta \rangle)] \right| > c_1 \sqrt{\frac{p \log(n)}{n}} \right) \leq c_2 e^{-c_3 p},$$

where

$$\begin{aligned} c_1 &= \frac{3 \left(B + \frac{\sqrt{2}K}{4\sqrt{\text{Tr}(\Sigma)/p-16K^2}} \right)^2}{2c}, \\ c_2 &= 4, \\ c_3 &= \frac{1}{2} \log(7) \leq \frac{1}{2} \log(\log(64R^2L^2K^2C) + 6\log(p)). \end{aligned}$$

when $p > e$ and $64R^2L^2K^2C > e$. \blacksquare

In the following, we state the concentration results on the unbounded functions of the form

$$x \rightarrow f(\langle x, \beta \rangle) \langle x, v \rangle.$$

Functions of this type form the summands of the Hessian matrix in GLMs.

Lemma 23 *Let x_i , for $i = 1, \dots, n$, be i.i.d sub-Gaussian random variables with mean 0, covariance matrix Σ and sub-Gaussian norm K . Also let $f: \mathbb{R} \rightarrow \mathbb{R}$ be a uniformly bounded function such that for some $B > 0$, we have $\|f\|_\infty < B$ and f is Lipschitz continuous with constant L . Further, let $v \in \mathbb{R}^p$ such that $\|v\|_2 = 1$. Then, for n, p sufficiently large satisfying*

$$n^{0.2}/\log(n) \gtrsim p,$$

there exist constants c_1, c_2 depending on L, B, R and the eigenvalues of Σ such that, we have

$$\mathbb{P} \left(\sup_{\beta \in B_p(R)} \left| \frac{1}{n} \sum_{i=1}^n f(\langle x_i, \beta \rangle) \langle x_i, v \rangle^2 - \mathbb{E}[f(\langle x, \beta \rangle) \langle x, v \rangle^2] \right| > c_1 \sqrt{\frac{p}{n^{0.2} \log(n)}} \right) \leq c_2 e^{-p}.$$

Proof We define the brackets of the form

$$\begin{aligned} l_\beta(x) &= f(\langle x, \beta \rangle) \langle x, v \rangle^2 - \epsilon \frac{\|x\|_2^3}{4L\mathbb{E}[\|x\|_2^3]}, \\ u_\beta(x) &= f(\langle x, \beta \rangle) \langle x, v \rangle^2 + \epsilon \frac{\|x\|_2^3}{4\mathbb{E}[\|x\|_2^3]}, \end{aligned} \quad (18)$$

and we observe that the bracket $[l_\beta, u_\beta]$ has size $\epsilon/2$ in L_1 , that is,

$$\mathbb{E}[\|u_\beta(x) - l_\beta(x)\|] = \epsilon/2.$$

Next, for the following constant

$$\Delta = \frac{\epsilon}{4L\mathbb{E}[\|x\|_2^3]},$$

we define a Δ -net over $B_p(R)$ and call it \mathcal{T}_Δ . Then, $\forall \beta \in B_p(R)$, $\exists \beta' \in \mathcal{T}_\Delta$ such that $f(\langle \cdot, \beta \rangle) \langle \cdot, v \rangle^2$ belongs to the bracket $[l_{\beta'}, u_{\beta'}]$. This can be seen by writing the Lipschitz continuity of the function f , i.e.,

$$\begin{aligned} |f(\langle x, \beta \rangle) \langle x, v \rangle^2 - f(\langle x, \beta' \rangle) \langle x, v \rangle^2| &= \langle x, v \rangle^2 \{ |f(\langle x, \beta \rangle) - f(\langle x, \beta' \rangle)| \}, \\ &\leq L \|x\|_2^2 \|v\|_2^2 \langle x, \beta - \beta' \rangle, \\ &\leq L \|x\|_2^3 \|\beta - \beta'\|_2, \\ &\leq \Delta L \|x\|_2^3, \end{aligned}$$

where we used Cauchy-Schwartz to obtain the above inequalities. Hence, we may conclude that for the bracketing functions given in Equation 18, the corresponding bracketing number of the function class

$$\mathcal{F} = \{f(\langle \cdot, \beta \rangle) \langle \cdot, v \rangle^2 : \beta \in B_p(R)\}$$

is bounded above by the covering number of the ball of radius R for the given scale $\Delta = \epsilon/(4L\mathbb{E}[\|x\|_2^3])$, i.e.,

$$N_{[]}(\epsilon/2, \mathcal{F}, L_1) \leq |\mathcal{T}_\Delta|.$$

Next, we will upper bound the target probability using the bracketing functions u_β, l_β . We have $\forall \beta \in B_p(R)$, $\exists \beta' \in \mathcal{T}_\Delta$ such that

$$\begin{aligned} \frac{1}{n} \sum_{i=1}^n f(\langle x_i, \beta \rangle) \langle x_i, v \rangle^2 - \mathbb{E}[f(\langle x, \beta \rangle) \langle x, v \rangle^2] &\leq \frac{1}{n} \sum_{i=1}^n u_{\beta'}(x_i) - \mathbb{E}[u_{\beta'}(x)] + \frac{\epsilon}{2}, \\ \frac{1}{n} \sum_{i=1}^n f(\langle x_i, \beta \rangle) \langle x_i, v \rangle^2 - \mathbb{E}[f(\langle x, \beta \rangle) \langle x, v \rangle^2] &\geq \frac{1}{n} \sum_{i=1}^n l_{\beta'}(x_i) - \mathbb{E}[l_{\beta'}(x)] - \frac{\epsilon}{2}. \end{aligned}$$

Using the above inequalities, $\forall \beta \in B_p(R)$, $\exists \beta' \in \mathcal{T}_\Delta$, we can write

$$\begin{aligned} &\left\{ \left[\frac{1}{n} \sum_{i=1}^n u_{\beta'}(x_i) - \mathbb{E}[u_{\beta'}(x)] \right] > \epsilon/2 \right\} \cup \left\{ \left[-\frac{1}{n} \sum_{i=1}^n l_{\beta'}(x_i) + \mathbb{E}[l_{\beta'}(x)] \right] > \epsilon/2 \right\} \supset \\ &\left\{ \left[\frac{1}{n} \sum_{i=1}^n f(\langle x_i, \beta \rangle) \langle x_i, v \rangle^2 - \mathbb{E}[f(\langle x, \beta \rangle) \langle x, v \rangle^2] \right] > \epsilon \right\}. \end{aligned}$$

Hence, by the union bound, we obtain

$$\begin{aligned} &\mathbb{P} \left(\max_{\beta \in \mathcal{T}_\Delta} \left[\frac{1}{n} \sum_{i=1}^n u_\beta(x_i) - \mathbb{E}[u_\beta(x)] \right] > \epsilon/2 \right) + \mathbb{P} \left(\max_{\beta \in \mathcal{T}_\Delta} \left[-\frac{1}{n} \sum_{i=1}^n l_\beta(x_i) + \mathbb{E}[l_\beta(x)] \right] > \epsilon/2 \right) \\ &\geq \mathbb{P} \left(\sup_{\beta \in B_p(R)} \left[\frac{1}{n} \sum_{i=1}^n f(\langle x_i, \beta \rangle) \langle x_i, v \rangle^2 - \mathbb{E}[f(\langle x, \beta \rangle) \langle x, v \rangle^2] \right] > \epsilon \right). \end{aligned} \quad (19)$$

In order to complete the proof, we need one-sided concentration inequalities for u_β and l_β . Handling these functions is somewhat tedious since $\|x\|_2^3$ terms do not concentrate nicely. We state the following lemma.

Lemma 24 *For given $\alpha, \epsilon > 0$, and n sufficiently large such that, $\nu(n^\alpha, p, \epsilon, B, K, \Sigma) < \epsilon/4$ where*

$$\begin{aligned} \nu(n^\alpha, p, \epsilon, B, K, \Sigma) &= 2 \left(n^\alpha + \frac{6BK^2p}{c} \right) \exp \left(-\frac{n^\alpha}{6BK^2p} \right) + 2 \left\{ n^\alpha + \frac{3K^2p}{c\text{Tr}(\Sigma)} e^{2/3} \right. \\ &\quad \left. + \frac{3K^4p^2}{c^2\text{Tr}(\Sigma)^2} e^{4/3} n^{-\alpha/3} \right\} \exp \left(-\frac{\text{Tr}(\Sigma)(n^\alpha/\epsilon)^{2/3}}{2K^2p} \right). \end{aligned}$$

Then, there exists constants c', c'', c''' depending on the eigenvalues of Σ , B and K such that $\forall \beta$, we have,

$$\begin{aligned} &\mathbb{P} \left(\frac{1}{n} \sum_{i=1}^n u_\beta(x_i) - \mathbb{E}[u_\beta(x)] > \epsilon/2 \right) \leq 2 \exp(-c'n^\alpha/p) \\ &\quad + 2 \exp(-c''n^{2\alpha/3}\epsilon^{-2/3}) + \exp(-c'''n^{1-2\alpha}\epsilon^2), \end{aligned}$$

and

$$\begin{aligned} &\mathbb{P} \left(-\frac{1}{n} \sum_{i=1}^n l_\beta(x_i) + \mathbb{E}[l_\beta(x)] > \epsilon/2 \right) \leq 2 \exp(-c'n^\alpha/p) + \\ &\quad 2 \exp(-c''n^{2\alpha/3}\epsilon^{-2/3}) + \exp(-c'''n^{1-2\alpha}\epsilon^2). \end{aligned}$$

Proof For the sake of simplicity, we define the functions

$$\begin{aligned}\tilde{u}_\beta(w) &= u_\beta(w) - \mathbb{E}[u_\beta(x)], \\ \tilde{l}_\beta(w) &= l_\beta(w) - \mathbb{E}[l_\beta(x)].\end{aligned}$$

We will derive the result for the upper bracket, \tilde{u} , and skip the proof for the lower bracket \tilde{l} as it follows from the same steps. We write,

$$\begin{aligned}\mathbb{P}\left(\frac{1}{n}\sum_{i=1}^n \tilde{u}_\beta(x_i) > \epsilon/2\right) &\leq \mathbb{P}\left(\frac{1}{n}\sum_{i=1}^n \tilde{u}_\beta(x_i) > \epsilon/2, \max_{1 \leq i \leq n} |\tilde{u}_\beta(x_i)| < n^\alpha\right) \\ &\quad + \mathbb{P}\left(\max_{1 \leq i \leq n} |\tilde{u}_\beta(x_i)| \geq n^\alpha\right).\end{aligned}\tag{20}$$

We need to bound the right hand side of the above equation. For the second term, since $\tilde{u}_\beta(x_i)$'s are i.i.d. centered random variables, we have

$$\begin{aligned}\mathbb{P}\left(\max_{1 \leq i \leq n} |\tilde{u}_\beta(x_i)| \geq n^\alpha\right) &= 1 - \mathbb{P}\left(\max_{1 \leq i \leq n} |\tilde{u}_\beta(x_i)| < n^\alpha\right), \\ &= 1 - \mathbb{P}(|\tilde{u}_\beta(x)| < n^\alpha)^n, \\ &= 1 - (1 - \mathbb{P}(\tilde{u}_\beta(x) \geq n^\alpha))^n, \\ &\leq n\mathbb{P}(|\tilde{u}_\beta(x)| \geq n^\alpha).\end{aligned}$$

Also, note that

$$\begin{aligned}|\tilde{u}_\beta(x)| &\leq \mathcal{B}\|x\|_2^2 + \epsilon \frac{\|x\|_3^2}{4\mathbb{E}[\|x\|_2^2]} + \mathbb{E}[u_\beta(x)], \\ &\leq \mathcal{B}\|x\|_2^2 + \epsilon \frac{\|x\|_3^2}{4\mathbb{E}[\|x\|_2^2]} + \mathcal{B}\lambda_{\max}(\Sigma) + \epsilon/4.\end{aligned}$$

Therefore, if $t > 3\mathcal{B}\lambda_{\max}(\Sigma)$ and for ϵ small, we can write

$$\{\tilde{u}_\beta(x) > t\} \subset \{\mathcal{B}\|x\|_2^2 > t/3\} \cup \left\{\epsilon \frac{\|x\|_3^2}{4\mathbb{E}[\|x\|_2^2]} > t/3\right\}.\tag{21}$$

Since x is a sub-Gaussian random variable with $\|x\|_{\psi_2} = K$, we have

$$K = \sup_{w \in S^{p-1}} \langle w, x \rangle \| \psi_2 = \|x\|_{\psi_2}.$$

Using this and the relation between sub-Gaussian and sub-exponential norms as in Equation 17, we have $\|x\|_2^2 \leq 2K^2p$. This provides the following tail bound for $\|x\|_2$,

$$\mathbb{P}(\|x\|_2 > s) \leq 2 \exp\left(-\frac{cs^2}{2pK^2}\right),\tag{22}$$

where c is an absolute constant. Using the above tail bound, we can write,

$$\mathbb{P}\left(\|x\|_2^2 > \frac{1}{3B}t\right) \leq 2 \exp\left(-\frac{t}{6BK^2p}\right).$$

For the next term in Equation 21, we need a lower bound for $\mathbb{E}[\|x\|_2^2]$. We use a modified version of the Hölder's inequality and obtain

$$\mathbb{E}[\|x\|_2^3] \geq \mathbb{E}[\|x\|_2^2]^{3/2} = \text{Tr}(\Sigma)^{3/2}.$$

Using the above inequality, we can write

$$\begin{aligned}\mathbb{P}\left(\frac{\epsilon\|x\|_3^2}{4\mathbb{E}[\|x\|_2^2]} > t/3\right) &\leq \mathbb{P}\left(\|x\|_3^2 > \frac{4}{3\epsilon}\text{Tr}(\Sigma)^{3/2}t\right), \\ &= \mathbb{P}\left(\|x\|_2 > \left(\frac{4t}{3\epsilon}\right)^{1/3}\text{Tr}(\Sigma)^{1/2}\right), \\ &\leq 2 \exp\left(-c\frac{\text{Tr}(\Sigma)(t/\epsilon)^{2/3}}{2K^2p}\right),\end{aligned}$$

where c is the same absolute constant as in Equation 22.

Now for $\alpha > 0$ such that $t = n^\alpha > 3\mathcal{B}\lambda_{\max}(\Sigma)$ (we will justify this assumption for a particular choice of α later), we combine the above results,

$$\mathbb{P}(\tilde{u}_\beta(x) > t) \leq 2 \exp\left(-\frac{t}{6BK^2p}\right) + 2 \exp\left(-c\frac{\text{Tr}(\Sigma)(t/\epsilon)^{2/3}}{2K^2p}\right).\tag{23}$$

Next, we focus on the first term in Equation 20. Let $\mu = \mathbb{E}[\tilde{u}_\beta(x)\mathbb{1}_{\{\tilde{u}_\beta(x) < n^\alpha\}}]$, and write

$$\begin{aligned}\mathbb{P}\left(\frac{1}{n}\sum_{i=1}^n \tilde{u}_\beta(x_i) > \frac{\epsilon}{2}; \max_{1 \leq i \leq n} |\tilde{u}_\beta(x_i)| < n^\alpha\right) &\leq \mathbb{P}\left(\frac{1}{n}\sum_{i=1}^n \tilde{u}_\beta(x_i)\mathbb{1}_{\{\tilde{u}_\beta(x_i) < n^\alpha\}} > \frac{\epsilon}{2}\right), \\ &= \mathbb{P}\left(\frac{1}{n}\sum_{i=1}^n \tilde{u}_\beta(x_i)\mathbb{1}_{\{\tilde{u}_\beta(x_i) < n^\alpha\}} - \mu > \frac{\epsilon}{2} - \mu\right) \\ &\leq \exp\left\{-\frac{n^{1-2\alpha}}{2}\left(\frac{\epsilon}{2} - \mu\right)^2\right\},\end{aligned}$$

where we used the Hoeffding's concentration inequality for the bounded random variables. Further, note that

$$0 = \mathbb{E}[\tilde{u}_\beta(x)] = \mu + \mathbb{E}\left[\tilde{u}_\beta(x)\mathbb{1}_{\{\tilde{u}_\beta(x) > n^\alpha\}}\right].$$

By Lemma 30, we can write

$$|\mu| = \left|\mathbb{E}\left[\tilde{u}_\beta(x)\mathbb{1}_{\{\tilde{u}_\beta(x) > n^\alpha\}}\right]\right| \leq n^\alpha \mathbb{P}(\tilde{u}_\beta(x) > n^\alpha) + \int_{n^\alpha}^{\infty} \mathbb{P}(|\tilde{u}_\beta(x)| > t)dt.$$

The first term on the right hand side can be easily bounded by using Equation 23, i.e.,

$$n^\alpha \mathbb{P}(|\bar{u}_\beta(x)| > n^\gamma) \leq 2n^\alpha \exp\left(-c \frac{n^\alpha}{6BK^2p}\right) + 2n^\alpha \exp\left(-c \frac{\text{Tr}(\Sigma)(n^\alpha/\epsilon^{2/3})}{2K^2p}\right).$$

For the second term, using Equation 23 once again, we obtain

$$\begin{aligned} \int_{n^\alpha}^\infty \mathbb{P}(|\bar{u}_\beta(x)| > t) dt &\leq 2 \int_{n^\alpha}^\infty \exp\left(-c \frac{t}{6BK^2p}\right) dt + 2 \int_{n^\alpha}^\infty \exp\left(-c \frac{\text{Tr}(\Sigma)(t/\epsilon^{2/3})}{2K^2p}\right) dt, \\ &= \frac{12BK^2p}{c} \exp\left(-c \frac{n^\alpha}{6BK^2p}\right) + 2 \int_{n^\alpha}^\infty \exp\left(-c \frac{\text{Tr}(\Sigma)(t/\epsilon^{2/3})}{2K^2p}\right) dt. \end{aligned}$$

Next, we apply Lemma 31 to bound the second term on the right hand side. That is, we have

$$\begin{aligned} &\int_{n^\alpha}^\infty \exp\left(-c \frac{\text{Tr}(\Sigma)(t/\epsilon^{2/3})}{2K^2p}\right) dt \\ &\leq \left\{ \frac{3K^2p}{c \text{Tr}(\Sigma)} n^{\alpha/3} \epsilon^{2/3} + \frac{3K^4p^2}{c^2 \text{Tr}(\Sigma)^2} \epsilon^{4/3} n^{-\alpha/3} \right\} \exp\left(-c \frac{\text{Tr}(\Sigma)(n^\alpha/\epsilon^{2/3})}{2K^2p}\right). \end{aligned}$$

Combining the above results, we can write

$$\begin{aligned} |\mu| &\leq 2 \left(n^\alpha + \frac{6BK^2p}{c} \right) \exp\left(-c \frac{n^\alpha}{6BK^2p}\right) \\ &\quad + 2 \left\{ n^\alpha + \frac{3K^2p}{c \text{Tr}(\Sigma)} n^{\alpha/3} \epsilon^{2/3} + \frac{3K^4p^2}{c^2 \text{Tr}(\Sigma)^2} \epsilon^{4/3} n^{-\alpha/3} \right\} \exp\left(-c \frac{\text{Tr}(\Sigma)(n^\alpha/\epsilon^{2/3})}{2K^2p}\right), \\ &=: \nu(n^\alpha, p, \epsilon, B, K, \Sigma). \end{aligned}$$

Notice that, the upper bound on $|\mu|$, namely $\nu(n^\alpha, p, \epsilon, B, K, \Sigma)$, is close to 0 when n is large. This is because of exponentially decaying functions that dominates the other terms. We assume that n is sufficiently large that the upper bound for $|\mu|$ is less than $\epsilon/4$. For the value of α , we will choose $\alpha = 0.4$ later in the proof.

Applying this bounds in Equation 20, we obtain

$$\begin{aligned} \mathbb{P}\left(\frac{1}{n} \sum_{i=1}^n u_\beta(x_i) > \epsilon/2\right) &\leq 2 \exp\left(-c \frac{n^\alpha}{6BK^2p}\right) \\ &\quad + 2 \exp\left(-c \frac{\text{Tr}(\Sigma)(n^\alpha/\epsilon^{2/3})}{2K^2p}\right) + \exp\left(-\frac{n^{1-2\alpha} \epsilon^2}{32}\right), \\ &= 2 \exp\left(-c' n^\alpha/p\right) + 2 \exp\left(-c'' n^{2\alpha/3} \epsilon^{-2/3}\right) + \exp\left(-c''' n^{1-2\alpha} \epsilon^2\right), \end{aligned}$$

where

$$\begin{aligned} c' &= \frac{c}{6BK^2}, \\ c'' &= \frac{c \text{Tr}(\Sigma)/p}{2K^2} \geq \frac{c \lambda_{\min}(\Sigma)}{2K^2}, \\ c''' &= \frac{1}{32}. \end{aligned}$$

Hence, the proof is completed for the upper bracket.

The proof for the lower brackets $l_\beta(x)$ follows from exactly the same steps and omitted here. \blacksquare

Applying the above lemma on Equation 19, for $\alpha > 0$, we obtain

$$\begin{aligned} &\mathbb{P}\left(\sup_{\beta \in B_n(n)} \left| \frac{1}{n} \sum_{i=1}^n f(x_i, \beta) \langle x_i, v \rangle^2 - \mathbb{E}[f(x, \beta) \langle x, v \rangle^2] \right| > \epsilon\right) \\ &\leq 4|T_\Delta| \exp(-c' n^\alpha/p) + 4|T_\Delta| \exp(-c'' n^{2\alpha/3} \epsilon^{-2/3}) + 2|T_\Delta| \exp(-c''' n^{1-2\alpha} \epsilon^2). \end{aligned} \quad (24)$$

Observe that we can write, by Lemma 33

$$|T_\Delta| \leq \left(\frac{R\sqrt{p}}{\Delta}\right)^p = \left(\frac{4\sqrt{p}RL\mathbb{E}\|x\|_2^3}{\epsilon}\right)^p.$$

Also, recall that $\|x\|_2$ was a sub-Gaussian random variable with $\| \|x\|_2 \|_{\psi_2} \leq K\sqrt{2p}$. Using the definition of sub-Gaussian norm, we have

$$\frac{1}{\sqrt{3}} \mathbb{E}\|x\|_2^{3/2} \leq \| \|x\|_2 \|_{\psi_2} \leq \sqrt{2p}K, \implies \mathbb{E}\|x\|_2^3 \leq 15K^3 p^{3/2}.$$

Therefore, we have $\mathbb{E}\|x\|_2^3 = \mathcal{O}(p^{3/2})$ (recall that we had a lower bound of the same order). We define a constant K' , and as ϵ is small, we have

$$|T_\Delta| \leq \left(\frac{60RLK^3 p^2}{\epsilon}\right)^p = \left(\frac{K' p^2}{\epsilon}\right)^p,$$

where we let $K' = 60RLK^3$. We will show that each term on the right hand side of Equation 24 decays exponentially with a rate of order p . For the first term, for $s > 0$, we write

$$\begin{aligned} |T_\Delta| \exp(-c' n^\alpha/p) &= \exp(-c' n^\alpha/p + p \log(K') + 2p \log(p) + p \log(\epsilon^{-1})), \\ &\leq \exp(-c' n^\alpha/p + 2p \log(K' p/\epsilon)). \end{aligned} \quad (25)$$

Similarly for the second and third terms, we write

$$\begin{aligned} |T_\Delta| \exp(-c'' n^{2\alpha/3} \epsilon^{-2/3}) &\leq \exp(-c'' n^{2\alpha/3} \epsilon^{-2/3} + 2p \log(K' p/\epsilon)), \\ |T_\Delta| \exp(-c''' n^{1-2\alpha} \epsilon^2) &\leq \exp(-c''' n^{1-2\alpha} \epsilon^2 + 2p \log(K' p/\epsilon)). \end{aligned} \quad (26)$$

We will seek values for ϵ and α to obtain an exponential decay with rate p on the right sides of Equations 25 and 26. That is, we need

$$c'n^\alpha/p \geq 2p \log(K''/p/\epsilon), \quad (27)$$

$$c''n^{2\alpha/3} \geq 2p \log(K''/p/\epsilon)e^{2/3},$$

$$c''n^{1-2\alpha}e^2 \geq 2p \log(K''/p/\epsilon),$$

where $K'' = eK'$.

We apply Lemma 34 for the last inequality in Equation 27. That is,

$$\begin{aligned} e^2 &= \frac{p}{c''n^{1-2\alpha}} \log\left(\frac{c''n^{1/2}pn^{1-2\alpha}}{c''n^{1-2\alpha}}\right), \\ &= \mathcal{O}\left(\frac{p}{n^{1-2\alpha}} \log(n)\right). \end{aligned} \quad (28)$$

where we assume that n is sufficiently large. The above statement holds for $\alpha < 1/2$.

In the following, we choose $\alpha = 0.4$ and use the assumption that

$$n^{0.2}/\log(n) \gtrsim p, \quad (29)$$

which provides $\epsilon < 1$. Note that this choice of α also justifies the assumption used to derive Equation 23. One can easily check that $\alpha = 0.4$ implies that the first and the second statements in Equation 27 are satisfied for sufficiently large n .

It remains to check whether $\nu(n^\alpha, p, \epsilon, B, K, \Sigma) < \epsilon/4$ (in Lemma 24) for this particular choice of α and ϵ . It suffices to consider only the dominant terms in the definition of ν . We use the assumption on n, p and write

$$\begin{aligned} \nu(n^{0.4}, p, \epsilon, B, K, \Sigma) &\lesssim n^{0.4} \exp\left(-\frac{cn^{0.4}}{6BK^2p}\right) + n^{0.4} \exp\left(-\frac{c\text{Tr}(\Sigma)/p}{2K^2}n^{0.8/3}\right), \\ &\lesssim n^{0.4} \exp\left(-\frac{c}{6BK^2}n^{0.2}\right) + n^{0.4} \exp\left(-\frac{c\lambda_{\min}(\Sigma)}{2K^2}n^{0.8/3}\right). \end{aligned} \quad (30)$$

For n sufficiently large, due to exponential decay in $n^{0.2}$, the above quantity can be made arbitrarily small. Hence, for some constants c_1, c_2 , we obtain

$$\mathbb{P}\left(\sup_{\beta \in B_p(\hat{\beta})} \left| \frac{1}{n} \sum_{i=1}^n f(x_i, \beta) \langle x_i, v \rangle^2 - \mathbb{E}[f(x, \beta)] \langle x, v \rangle^2 \right| > c_1 \sqrt{\frac{p}{n^{0.2}} \log(n)}\right) \leq c_2 e^{-p}. \quad \blacksquare$$

Appendix C. Proofs of Theorems 4 and 8

We will provide the proofs of Theorems 4 and 8 in parallel as they follow from similar steps. The only difference is the application of the lemmas that are provided in the previous

sections. On the event \mathcal{E} , we write,

$$\begin{aligned} \hat{\beta}^t - \beta_* - \gamma \mathbf{Q}^t \nabla_{\beta} \ell(\hat{\beta}^t) &= \hat{\beta}^t - \beta_* - \gamma \mathbf{Q}^t \int_0^1 \nabla_{\beta}^2 \ell(\beta_* + \xi(\hat{\beta}^t - \beta_*)) d\xi (\hat{\beta}^t - \beta_*), \\ &= \left(I - \gamma \mathbf{Q}^t \int_0^1 \nabla_{\beta}^2 \ell(\beta_* + \xi(\hat{\beta}^t - \beta_*)) d\xi \right) (\hat{\beta}^t - \beta_*). \end{aligned} \quad (31)$$

In the following, we will work on the event that $\hat{\Sigma}_S$ is invertible and that $[\mathbf{Q}^j]^{-1}$ is positive definite. We later show that conditioned on \mathcal{E} , this event holds with very high probability when $|S|$ is sufficiently large.

We use the nonexpensiveness of the projection \mathcal{P}_C^t , i.e., for any $u, u' \in \mathbb{R}^{\mathcal{V}}$ and $v = \mathcal{P}_C^t(u)$, $v' = \mathcal{P}_C^t(u')$ we have $\langle u - u', [\mathbf{Q}^j]^{-1}(u - u') \rangle \geq \langle v - v', [\mathbf{Q}^j]^{-1}(v - v') \rangle$. This simply means that the projection decreases the distance. Therefore, we can write

$$\begin{aligned} \|\hat{\beta}^{t+1} - \beta_*\|_{\mathbf{Q}^{t-1}} &\leq \|\hat{\beta}^t - \beta_* - \gamma \mathbf{Q}^t \nabla_{\beta} \ell(\hat{\beta}^t)\|_{\mathbf{Q}^{t-1}} \\ &\leq \|[\mathbf{Q}^j]^{-1/2} - \gamma [\mathbf{Q}^j]^{1/2} \int_0^1 \nabla_{\beta}^2 \ell(\beta_* + \xi(\hat{\beta}^t - \beta_*)) d\xi\|_2 \|\hat{\beta}^t - \beta_*\|_2. \end{aligned} \quad (32)$$

The coefficient of $\|\hat{\beta}^t - \beta_*\|_2$ in Equation 32 determines the convergence behavior of the algorithm. Switching back to ℓ_2 norm, we obtain an upper bounded of the form

$$\|\hat{\beta}^{t+1} - \beta_*\|_2 \leq \|\mathbf{Q}^j\|_2 \|[\mathbf{Q}^j]^{-1} - \int_0^1 \nabla_{\beta}^2 \ell(\beta_* + \xi(\hat{\beta}^t - \beta_*)) d\xi\|_2 \|\hat{\beta}^t - \beta_*\|_2,$$

where we have set step size $\gamma = 1$. First, we will bound the second term on the right hand side. We define the following,

$$\mathfrak{E}(\beta) = \mathbb{E}\left[\phi^{(2)}(\langle x, \beta \rangle)\right] \Sigma + \mathbb{E}\left[\phi^{(4)}(\langle x, \beta \rangle)\right] \Sigma \beta \beta^T \Sigma.$$

Note that for a function f and fixed β , $\mathbb{E}[f(\langle x, \beta \rangle)] = h(\beta)$ is a function of β . With a slight abuse of notation, we write $\mathbb{E}[f(\langle x, \hat{\beta} \rangle)] = h(\hat{\beta})$ as a random variable. We have

$$\begin{aligned} \|[\mathbf{Q}^j]^{-1} - \int_0^1 \nabla_{\beta}^2 \ell(\beta_* + \xi(\hat{\beta}^t - \beta_*)) d\xi\|_2 &\leq \|[\mathbf{Q}^j]^{-1} - \mathfrak{E}(\hat{\beta}^t)\|_2 \\ &+ \|\mathbb{E}[xx^T \phi^{(2)}(\langle x, \hat{\beta}^t \rangle)] - \mathfrak{E}(\hat{\beta}^t)\|_2 \\ &+ \left\| \int_0^1 \nabla_{\beta}^2 \ell(\beta_* + \xi(\hat{\beta}^t - \beta_*)) d\xi - \mathbb{E}\left[xx^T \int_0^1 \phi^{(2)}(\langle x, \beta_* + \xi(\hat{\beta}^t - \beta_*) \rangle) d\xi\right] \right\|_2 \\ &+ \|\mathbb{E}[xx^T \phi^{(2)}(\langle x, \hat{\beta}^t \rangle)] - \mathbb{E}\left[xx^T \int_0^1 \phi^{(2)}(\langle x, \beta_* + \xi(\hat{\beta}^t - \beta_*) \rangle) d\xi\right] \|_2. \end{aligned} \quad (33)$$

For the first term on the right hand side, we state the following lemma.

Lemma 25 *When the covariates are sub-Gaussian, there exist constants C_1, C_2 such that, with probability at least $1 - C_1/p^2$,*

$$\|\mathbf{Q}^{\dagger-1} - \mathbf{e}(\beta^t)\|_2 \leq C_2 \sqrt{\frac{p}{\min\{|S|p/\log(p), n/\log(n)\}}}.$$

Similarly, when the covariates are sampled from a distribution with bounded support, there exist constants C_1^t, C_2^t, C_3^t such that, with probability $1 - C_1^t e^{-C_2^t p}$,

$$\|\mathbf{Q}^{\dagger-1} - \mathbf{e}(\beta^t)\|_2 \leq C_3^t \sqrt{\frac{p}{\min\{|S|, n/\log(n)\}}},$$

where the constants depend on K, B and the radius R .

Proof In the following, we will only provide the proof for the bounded support case. The proof for the sub-Gaussian covariates follows from the same steps, by only replacing Lemma 14 with Lemma 12, and Lemma 18 with Lemma 20.

Using a uniform bound on the feasible set, we write

$$\begin{aligned} & \|\mathbf{Q}^{\dagger-1} - \mathbf{e}(\beta^t)\|_2 \\ & \leq \sup_{\beta \in \mathcal{C}^t} \|\hat{\mu}_2(\beta) \widehat{\Sigma}_S + \hat{\mu}_4(\beta) \widehat{\Sigma}_S \beta \widehat{\Sigma}_S \beta^T - \mathbb{E}[\phi^{(2)}(\langle x, \beta \rangle)] \Sigma - \mathbb{E}[\phi^{(4)}(\langle x, \beta \rangle)] \Sigma \beta \beta^T \Sigma\|_2. \end{aligned}$$

We will find an upper bound for the quantity inside the supremum. By denoting the expectations of $\hat{\mu}_2(\beta)$ and $\hat{\mu}_4(\beta)$, with $\mu_2(\beta)$ and $\mu_4(\beta)$ respectively, we write

$$\begin{aligned} & \|\hat{\mu}_2(\beta) \widehat{\Sigma}_S + \hat{\mu}_4(\beta) \widehat{\Sigma}_S \beta \widehat{\Sigma}_S \beta^T - \mathbb{E}[\phi^{(2)}(\langle x, \beta \rangle)] \Sigma - \mathbb{E}[\phi^{(4)}(\langle x, \beta \rangle)] \Sigma \beta \beta^T \Sigma\|_2 \\ & \leq \|\hat{\mu}_2(\beta) \widehat{\Sigma}_S - \mu_2(\beta) \Sigma\|_2 + \|\hat{\mu}_4(\beta) \widehat{\Sigma}_S \beta \widehat{\Sigma}_S \beta^T - \mu_4(\beta) \Sigma \beta \beta^T \Sigma\|_2. \end{aligned}$$

For the first term on the right hand side, we have

$$\begin{aligned} & \|\hat{\mu}_2(\beta) \widehat{\Sigma}_S - \mu_2(\beta) \Sigma\|_2 \leq |\hat{\mu}_2(\beta)| \|\widehat{\Sigma}_S - \Sigma\|_2 + \|\Sigma\|_2 |\hat{\mu}_2(\beta) - \mu_2(\beta)|, \\ & \leq B_2 \|\widehat{\Sigma}_S - \Sigma\|_2 + K |\hat{\mu}_2(\beta) - \mu_2(\beta)|. \end{aligned}$$

By the Lemmas 14 and 18, for an absolute constant c , we have with probability $1 - 1/p^2$,

$$\begin{aligned} & \sup_{\beta \in \mathcal{C}^t} \|\hat{\mu}_2(\beta) \zeta_r(\widehat{\Sigma}_S) - \mu_2(\beta) \Sigma\|_2 \leq B_2 c \sqrt{K \|\Sigma\|_2} \sqrt{\frac{\log(p)}{|S|}} + 3B_2 K \sqrt{\frac{p \log(n)}{n}}, \\ & \leq 3cB_2 K \sqrt{\frac{p}{\min\{p/\log(p), |S|, n/\log(n)\}}}, \\ & = \mathcal{O}\left(\sqrt{\frac{p}{\min\{p/\log(p), |S|, n/\log(n)\}}}\right). \end{aligned}$$

For the second term, we have

$$\begin{aligned} & \|\hat{\mu}_4(\beta) \widehat{\Sigma}_S \beta \widehat{\Sigma}_S \beta^T - \mu_4(\beta) \Sigma \beta \beta^T \Sigma\|_2 \\ & \leq |\hat{\mu}_4(\beta)| \|\widehat{\Sigma}_S \beta \beta^T \widehat{\Sigma}_S - \Sigma \beta \beta^T \Sigma\|_2 + |\hat{\mu}_4(\beta) - \mu_4(\beta)| \|\Sigma \beta \beta^T \Sigma\|_2, \\ & \leq B_4 R^2 \left\{ \|\widehat{\Sigma}_S\|_2 + \|\Sigma\|_2 \right\} \|\widehat{\Sigma}_S - \Sigma\|_2 + R^2 \|\Sigma\|_2^2 |\hat{\mu}_4(\beta) - \mu_4(\beta)|, \\ & \leq B_4 R^2 \left\{ \|\widehat{\Sigma}_S\|_2 + K \right\} \|\widehat{\Sigma}_S - \Sigma\|_2 + R^2 K^2 |\hat{\mu}_4(\beta) - \mu_4(\beta)|. \end{aligned}$$

Again, by the Lemmas 14 and 18, for an absolute constant c , we have with probability $1 - 1/p^2$,

$$\begin{aligned} & B_4 R^2 \left\{ \|\widehat{\Sigma}_S\|_2 + K \right\} \|\widehat{\Sigma}_S - \Sigma\|_2 \leq cK B_4 R^2 \left\{ 2K + cK \sqrt{\frac{\log(p)}{|S|}} \right\} \sqrt{\frac{\log(p)}{|S|}}, \\ & \leq 2cK^2 B_4 R^2 \sqrt{\frac{\log(p)}{|S|}} + c^2 K^2 B_4 R^2 \frac{\log(p)}{|S|}, \\ & \leq 2cK^2 B_4 R^2 \left(1 + c_1 \sqrt{\frac{\log(p)}{|S|}} \right) \sqrt{\frac{\log(p)}{|S|}}, \\ & \leq 4cK^2 B_4 R^2 \sqrt{\frac{\log(p)}{|S|}}, \\ & = \mathcal{O}\left(\sqrt{\frac{\log(p)}{|S|}}\right), \end{aligned}$$

for sufficiently large $|S|$, i.e., $|S| \geq c^2 \log(p)$.

Further, by Lemma 18, we have with probability $1 - 2e^{-p}$,

$$\sup_{\beta \in \mathcal{C}^t} |\hat{\mu}_4(\beta) - \mu_4(\beta)| \leq 3B_4 \sqrt{\frac{p \log(n)}{n}} = \mathcal{O}\left(\sqrt{\frac{p \log(n)}{n}}\right).$$

Combining the above results, for sufficiently large $p, |S|$, we have with probability at least $1 - 1/p^2 - 2e^{-p}$,

$$\begin{aligned} & \sup_{\beta \in \mathcal{C}^t} \|\hat{\mu}_2(\beta) \zeta_r(\widehat{\Sigma}_S) - \mu_2(\beta) \Sigma\|_2 + \sup_{\beta \in \mathcal{C}^t} \|\hat{\mu}_4(\beta) \widehat{\Sigma}_S \beta \widehat{\Sigma}_S \beta^T - \mu_4(\beta) \Sigma \beta \beta^T \Sigma\|_2 \\ & \leq 3B_2 K c \sqrt{\frac{p}{\min\{p/\log(p), |S|, n/\log(n)\}}} + 4cK^2 B_4 R^2 \sqrt{\frac{\log(p)}{|S|}} + 3B_4 R^2 K^2 \sqrt{\frac{p \log(n)}{n}}, \end{aligned}$$

$$\begin{aligned}
 &\leq 3B_2Kc\sqrt{\frac{p}{\min\{p/\log(p)|S|, n/\log(n)\}}} + 4cK^2B_4R^2\sqrt{\frac{p}{\min\{p/\log(p)|S|, n/\log(n)\}}}, \\
 &\leq CK\max\{B_2, B_4KR^2\}\sqrt{\frac{p}{\min\{p/\log(p)|S|, n/\log(n)\}}}, \\
 &= \mathcal{O}\left(\sqrt{\frac{p}{\min\{|S|p/\log(p), n/\log(n)\}}}\right).
 \end{aligned}$$

Hence, for some constants C_1, C_2 , with probability $1 - C_1/p^2$, we have

$$\|\mathbf{Q}^{\dagger-1} - \mathbf{e}(\hat{\beta}^t)\|_2 \leq C_2\sqrt{\frac{p}{\min\{|S|p/\log(p), n/\log(n)\}}},$$

where the constants depend on $K, B = \max\{B_2, B_4\}$ and the radius R . \blacksquare

Lemma 26 *The bias term can be upper bounded by*

$$\|\mathbb{E}[xx^T\phi^{(2)}(\langle x, \hat{\beta}^t \rangle)] - \mathbf{e}(\hat{\beta}^t)\|_2 \leq d_{H_3}(x, z) + \|\Sigma\|_2 d_{H_1}(x, z) + \|\Sigma\|_2^2 R^2 d_{H_2}(x, z),$$

for both sub-Gaussian and bounded support cases.

Proof For a random variable $z \sim N_p(0, \Sigma)$, by the triangle inequality, we write

$$\begin{aligned}
 &\|\mathbb{E}[xx^T\phi^{(2)}(\langle x, \hat{\beta}^t \rangle)] - \mathbf{e}(\hat{\beta}^t)\|_2 \\
 &\leq \|\mathbb{E}[xx^T\phi^{(2)}(\langle x, \hat{\beta}^t \rangle)] - \mathbb{E}[zz^T\phi^{(2)}(\langle z, \hat{\beta}^t \rangle)]\|_2 + \|\mathbb{E}[zz^T\phi^{(2)}(\langle z, \hat{\beta}^t \rangle)] - \mathbf{e}(\hat{\beta}^t)\|_2
 \end{aligned}$$

For the first term on the right hand side, we have

$$\begin{aligned}
 &\|\mathbb{E}[xx^T\phi^{(2)}(\langle x, \hat{\beta}^t \rangle)] - \mathbb{E}[zz^T\phi^{(2)}(\langle z, \hat{\beta}^t \rangle)]\|_2 \\
 &\leq \sup_{\beta \in \mathcal{C}} \sup_{\|v\|_2=1} \left| \mathbb{E}\left[\langle v, x \rangle^2 \phi^{(2)}(\langle x, \beta \rangle)\right] - \mathbb{E}\left[\langle v, z \rangle^2 \phi^{(2)}(\langle z, \beta \rangle)\right] \right|, \\
 &\leq d_{H_3}(x, z).
 \end{aligned}$$

For the second term, we write

$$\begin{aligned}
 &\|\mathbb{E}[zz^T\phi^{(2)}(\langle z, \hat{\beta}^t \rangle)] - \mathbf{e}(\hat{\beta}^t)\|_2 \\
 &\leq \sup_{\beta \in \mathcal{C}} \|\mathbb{E}[zz^T\phi^{(2)}(\langle z, \beta \rangle)] - \mathbb{E}[\phi^{(2)}(\langle x, \beta \rangle)]\Sigma + \mathbb{E}\left[\phi^{(4)}(\langle x, \beta \rangle)\right]\Sigma\beta\beta^T\Sigma\|_2, \\
 &\leq \sup_{\beta \in \mathcal{C}} \|\mathbb{E}[\phi^{(2)}(\langle z, \beta \rangle)]\Sigma + \mathbb{E}\left[\phi^{(4)}(\langle z, \beta \rangle)\right]\Sigma\beta\beta^T\Sigma \\
 &\quad - \mathbb{E}[\phi^{(2)}(\langle x, \beta \rangle)]\Sigma - \mathbb{E}\left[\phi^{(4)}(\langle x, \beta \rangle)\right]\Sigma\beta\beta^T\Sigma\|_2, \\
 &\leq \sup_{\beta \in \mathcal{C}} \|\mathbb{E}[\phi^{(2)}(\langle z, \beta \rangle)]\Sigma - \mathbb{E}[\phi^{(2)}(\langle x, \beta \rangle)]\Sigma\|_2, \\
 &\quad + \sup_{\beta \in \mathcal{C}} \|\mathbb{E}\left[\phi^{(4)}(\langle z, \beta \rangle)\right]\Sigma\beta\beta^T\Sigma - \mathbb{E}\left[\phi^{(4)}(\langle x, \beta \rangle)\right]\Sigma\beta\beta^T\Sigma\|_2, \\
 &\leq \|\Sigma\|_2 \sup_{\beta \in \mathcal{C}} \|\mathbb{E}[\phi^{(2)}(\langle z, \beta \rangle)] - \mathbb{E}[\phi^{(2)}(\langle x, \beta \rangle)]\| \\
 &\quad + \|\Sigma\|_2^2 R^2 \sup_{\beta \in \mathcal{C}} \|\mathbb{E}[\phi^{(4)}(\langle z, \beta \rangle)] - \mathbb{E}[\phi^{(4)}(\langle x, \beta \rangle)]\|, \\
 &\leq \|\Sigma\|_2 d_{H_1}(x, z) + \|\Sigma\|_2^2 R^2 d_{H_2}(x, z).
 \end{aligned}$$

Hence, we conclude that

$$\|\mathbb{E}[xx^T\phi^{(2)}(\langle x, \hat{\beta}^t \rangle)] - \mathbf{e}(\hat{\beta}^t)\|_2 \leq d_{H_3}(x, z) + \|\Sigma\|_2 d_{H_1}(x, z) + \|\Sigma\|_2^2 R^2 d_{H_2}(x, z).$$

\blacksquare

Lemma 27 *There exists constants c_1, c_2, c_3 depending on the eigenvalues of Σ, B, L and R such that, with probability at least $1 - c_2e^{-c_3p}$*

$$\left\| \frac{1}{n} \sum_{i=1}^n x_i x_i^T \int_0^1 \phi^{(2)}(\langle x_i, \beta_* + \xi(\hat{\beta}^t - \beta_*) \rangle) d\xi - \mathbb{E}\left[xx^T \int_0^1 \phi^{(2)}(\langle x, \beta_* + \xi(\hat{\beta}^t - \beta_*) \rangle) d\xi\right] \right\|_2 \leq \delta,$$

where $\delta = c_1 \sqrt{\frac{p}{n \log(n)}}$ for sub-Gaussian covariates, and $\delta = c_1 \sqrt{\frac{p}{n} \log(n)}$ for covariates with bounded support.

Proof We provide the proof for bounded support case. The proof for sub-Gaussian case can be carried by replacing Lemma 19 with Lemma 23.

By the Fubini's theorem, we have

$$\begin{aligned}
& \left\| \frac{1}{n} \sum_{i=1}^n x_i x_i^T \int_0^1 \phi^{(2)}(\langle x_i, \beta_* + \xi(\beta^t - \beta_*) \rangle) d\xi - \mathbb{E} \left[x x^T \int_0^1 \phi^{(2)}(\langle x, \beta_* + \xi(\beta^t - \beta_*) \rangle) d\xi \right] \right\|_2, \\
&= \left\| \int_0^1 \left\{ \frac{1}{n} \sum_{i=1}^n x_i x_i^T \phi^{(2)}(\langle x_i, \beta_* + \xi(\beta^t - \beta_*) \rangle) - \mathbb{E} \left[x x^T \phi^{(2)}(\langle x, \beta_* + \xi(\beta^t - \beta_*) \rangle) \right] \right\} d\xi \right\|_2, \\
&\leq \int_0^1 \left\| \left\{ \frac{1}{n} \sum_{i=1}^n x_i x_i^T \phi^{(2)}(\langle x_i, \beta_* + \xi(\beta^t - \beta_*) \rangle) - \mathbb{E} \left[x x^T \phi^{(2)}(\langle x, \beta_* + \xi(\beta^t - \beta_*) \rangle) \right] \right\} \right\|_2 d\xi, \\
&\leq \sup_{\beta \in \mathcal{C}} \left\| \frac{1}{n} \sum_{i=1}^n x_i x_i^T \phi^{(2)}(\langle x_i, \beta \rangle) - \mathbb{E} \left[x x^T \phi^{(2)}(\langle x, \beta \rangle) \right] \right\|_2.
\end{aligned}$$

Using the properties of operator norm, the above bound can be written as

$$\begin{aligned}
& \sup_{\beta \in \mathcal{C}} \left\| \frac{1}{n} \sum_{i=1}^n x_i x_i^T \phi^{(2)}(\langle x_i, \beta \rangle) - \mathbb{E} \left[x x^T \phi^{(2)}(\langle x, \beta \rangle) \right] \right\|_2 \\
&= \sup_{\beta \in \mathcal{C}} \sup_{v \in S^{p-1}} \left\| \frac{1}{n} \sum_{i=1}^n \phi^{(2)}(\langle x_i, \beta \rangle) \langle x_i, v \rangle^2 - \mathbb{E} \left[\phi^{(2)}(\langle x, \beta \rangle) \langle x, v \rangle^2 \right] \right\|,
\end{aligned}$$

where S^{p-1} denotes the p -dimensional unit sphere.

For $\Delta = 0.25$, let T_Δ be an Δ -net over S^{p-1} . Using Lemma 32, we obtain

$$\begin{aligned}
& \mathbb{P} \left(\sup_{\beta \in \mathcal{C}} \sup_{v \in S^{p-1}} \left\| \frac{1}{n} \sum_{i=1}^n \phi^{(2)}(\langle x_i, \beta \rangle) \langle x_i, v \rangle^2 - \mathbb{E} \left[\phi^{(2)}(\langle x, \beta \rangle) \langle x, v \rangle^2 \right] \right\| > \epsilon \right), \\
&\leq \mathbb{P} \left(\sup_{\beta \in \mathcal{C}} \sup_{v \in T_\Delta} \left\| \frac{1}{n} \sum_{i=1}^n \phi^{(2)}(\langle x_i, \beta \rangle) \langle x_i, v \rangle^2 - \mathbb{E} \left[\phi^{(2)}(\langle x, \beta \rangle) \langle x, v \rangle^2 \right] \right\| > \epsilon/2 \right), \\
&\leq |T_\Delta| \mathbb{P} \left(\sup_{\beta \in \mathcal{C}} \left\| \frac{1}{n} \sum_{i=1}^n \phi^{(2)}(\langle x_i, \beta \rangle) \langle x_i, v \rangle^2 - \mathbb{E} \left[\phi^{(2)}(\langle x, \beta \rangle) \langle x, v \rangle^2 \right] \right\| > \epsilon/2 \right), \\
&= 9^p \mathbb{P} \left(\sup_{\beta \in \mathcal{C}} \left\| \frac{1}{n} \sum_{i=1}^n \phi^{(2)}(\langle x_i, \beta \rangle) \langle x_i, v \rangle^2 - \mathbb{E} \left[\phi^{(2)}(\langle x, \beta \rangle) \langle x, v \rangle^2 \right] \right\| > \epsilon/2 \right).
\end{aligned}$$

By applying Lemma 19 to the last line above, we obtain

$$\mathbb{P} \left(\sup_{\beta \in \mathcal{C}} \left\| \frac{1}{n} \sum_{i=1}^n \phi^{(2)}(\langle x_i, \beta \rangle) \langle x_i, v \rangle^2 - \mathbb{E} \left[\phi^{(2)}(\langle x, \beta \rangle) \langle x, v \rangle^2 \right] \right\| > 4B_2 K \sqrt{\frac{p}{n} \log(n)} \right) \leq 2e^{-3.2p}.$$

Notice that $3.2 - \log(9) > 1$. Therefore, by choosing n large enough, on the set \mathcal{E} , we obtain that with probability at least $1 - 2e^{-p}$

$$\sup_{\beta \in \mathcal{C}} \left\| \frac{1}{n} \sum_{i=1}^n x_i x_i^T \phi^{(2)}(\langle x_i, \beta \rangle) - \mathbb{E} \left[x x^T \phi^{(2)}(\langle x, \beta \rangle) \right] \right\|_2 \leq 8B_2 K \sqrt{\frac{p}{n} \log(n)}.$$

■

Lemma 28 *There exists a constant C depending on K and L such that,*

$$\left\| \mathbb{E} \left[x x^T \phi^{(2)}(\langle x, \hat{\beta}^t \rangle) \right] - \mathbb{E} \left[x x^T \int_0^1 \phi^{(2)}(\langle x, \beta_* + \xi(\hat{\beta}^t - \beta_*) \rangle) d\xi \right] \right\|_2 \leq \tilde{C} \|\hat{\beta}^t - \beta_*\|_2,$$

where $\tilde{C} = C$ for the bounded support case and $\tilde{C} = Cp^{1.5}$ for the sub-Gaussian case.

Proof By the Fubini's theorem, we write

$$\begin{aligned}
& \left\| \mathbb{E} \left[x x^T \phi^{(2)}(\langle x, \hat{\beta}^t \rangle) \right] - \mathbb{E} \left[x x^T \int_0^1 \phi^{(2)}(\langle x, \beta_* + \xi(\hat{\beta}^t - \beta_*) \rangle) d\xi \right] \right\|_2, \\
&= \left\| \int_0^1 \mathbb{E} \left[x x^T \left\{ \phi^{(2)}(\langle x, \hat{\beta}^t \rangle) - \phi^{(2)}(\langle x, \beta_* + \xi(\hat{\beta}^t - \beta_*) \rangle) \right\} \right] d\xi \right\|_2.
\end{aligned}$$

Moving the integration out, right hand side of the above equation is smaller than

$$\begin{aligned}
& \int_0^1 \left\| \mathbb{E} \left[x x^T \left\{ \phi^{(2)}(\langle x, \hat{\beta}^t \rangle) - \phi^{(2)}(\langle x, \beta_* + \xi(\hat{\beta}^t - \beta_*) \rangle) \right\} \right] \right\|_2 d\xi, \\
&\leq \int_0^1 \left\| \mathbb{E} \left[x x^T L \langle x, (1 - \xi)(\hat{\beta}^t - \beta_*) \rangle \right] \right\|_2 d\xi, \\
&\leq \mathbb{E} \left[\|x\|_2^2 \|\hat{\beta}^t - \beta_*\|_2 \right] L \int_0^1 (1 - \xi) d\xi, \\
&= \frac{L \mathbb{E} \left[\|x\|_2^3 \right]}{2} \|\hat{\beta}^t - \beta_*\|_2.
\end{aligned}$$

We observe that, when the covariates are supported in the ball of radius \sqrt{K} , we have $\frac{\mathbb{E} \left[\|x\|_2^3 \right]}{\mathbb{E} \left[\|x\|_2^2 \right]} \leq K^{3/2}$. When they are sub-Gaussian random variables with norm K , we have $\frac{\mathbb{E} \left[\|x\|_2^3 \right]}{\mathbb{E} \left[\|x\|_2^2 \right]} \leq K^3 6^{1.5} p^{1.5}$. ■

By combining the above results, for bounded covariates we obtain

$$\begin{aligned}
& \left\| \mathbf{Q}^t \right\|^{-1} - \int_0^1 \frac{\nabla^2 \phi(\beta_* + \xi(\hat{\beta}^t - \beta_*)) d\xi}{\mathbb{E} \left[\phi^{(2)}(\langle x, \hat{\beta}^t \rangle) \right]} \\
&\leq \mathfrak{Q}(x, z) + c_1 \sqrt{\frac{p}{\min\{|S|p/\log(p), n/\log(n)\}}} + c_2 \|\hat{\beta}^t - \beta_*\|_2,
\end{aligned}$$

and for sub-Gaussian covariates, we obtain

$$\begin{aligned} & \left\| [\mathbf{Q}^j]^{-1} - \int_0^1 \nabla_{\beta}^2 \ell(\beta_* + \xi(\hat{\beta}^t - \beta_*)) d\xi \right\|_2 \\ & \leq \mathfrak{D}(x, z) + c_1 \sqrt{\frac{p}{\min\{|S|, n^{0.2}/\log(n)\}}} + c_2 p^{1.5} \|\hat{\beta}^t - \beta_*\|_2, \end{aligned}$$

where

$$\mathfrak{D}(x, z) = d_{H_2}(x, z) + \|\Sigma\|_2 d_{H_4}(x, z) + \|\Sigma\|_2^2 R^2 d_{H_2}(x, z).$$

In the following, we will derive an upper bound for $\|\mathbf{Q}^t\|_2$, which is equivalent to proving the positive definiteness of $[\mathbf{Q}^j]^{-1}$ and finding a lower bound for $\|[\mathbf{Q}^j]^{-1}\|_2$. The sub-Gaussian case is more restrictive than the bounded support case. Therefore we derive the bound for the sub-Gaussian case. We have

$$\begin{aligned} \lambda_{\min}([\mathbf{Q}^j]^{-1}) &= \inf_{\|u\|_2=1} \left\{ \hat{\mu}_2(\hat{\beta}^t) \langle u, \widehat{\Sigma}_S u \rangle + \hat{\mu}_4(\hat{\beta}^t) \langle u, \widehat{\Sigma}_S \hat{\beta}^t \rangle^2 \right\}, \\ &\geq \inf_{\|u\|_2=1} \left\{ \hat{\mu}_2(\hat{\beta}^t) \langle u, \Sigma u \rangle + \hat{\mu}_4(\hat{\beta}^t) \langle u, \Sigma \hat{\beta}^t \rangle^2 \right\} \\ &\quad - B_2 \|\widehat{\Sigma}_S - \Sigma\|_2 - B_4 R^2 \|\widehat{\Sigma}_S - \Sigma\|_2 \|\widehat{\Sigma}_S + \Sigma\|_2. \end{aligned}$$

On the event \mathcal{E} , the first term on the right hand side is lower bounded by κ^{-1} . For the other terms, we use Lemma 12 and write

$$\begin{aligned} \lambda_{\min}([\mathbf{Q}^j]^{-1}) &\leq 2\kappa^{-1} - \|\widehat{\Sigma}_S - \Sigma\|_2 \left\{ B_2 + B_4 R^2 \|\widehat{\Sigma}_S - \Sigma\|_2 + 2B_4 R^2 \|\Sigma\|_2 \right\}, \\ &\leq 2\kappa^{-1} - C \sqrt{\frac{p}{|S|}} \left\{ B_2 + B_4 R^2 C \sqrt{\frac{p}{|S|}} + 2B_4 R^2 \|\Sigma\|_2 \right\} \end{aligned}$$

with probability $1 - 2e^{-cp}$. When $|S| > 4pC^2 \max\{1, 2C(B_2 + 3B_4 R^2 \lambda_{\max}(\Sigma))\kappa\}^2$, with probability $1 - 2e^{-cp}$, we obtain

$$\lambda_{\min}([\mathbf{Q}^j]^{-1}) \geq \kappa^{-1}.$$

This proves that, with high probability, on the event \mathcal{E} , $[\mathbf{Q}^j]^{-1}$ is positive definite and consequently we obtain

$$\|\mathbf{Q}^j\|_2 \leq \kappa.$$

Finally, we take into account the conditioning on the event \mathcal{E} . Since we worked on the event \mathcal{E} , the probability of a desired outcome is at least $\mathbb{P}(\mathcal{E}) - \delta$, where δ is either c/p^2 or ce^{-p} depending on the distribution of the covariates. Hence, conditioned on the event \mathcal{E} , the probability becomes $1 - \delta/\mathbb{P}(\mathcal{E})$, which completes the proof.

C.1 Proof of Corollaries 5 and 9

In the following, we provide the proof for Corollary 5. The proof for Corollary 9 follows from the exact same steps.

The statement of Theorem 4 holds on the probability space with a probability lower bounded by $\mathbb{P}(\mathcal{E}) - c/p^2$ for some constant c (See previous section). Let \mathcal{Q} denote this set, on which the statement of the theorem holds without the conditioning on the event \mathcal{E} . Note that $\mathcal{Q} \subset \mathcal{E}$ and we also have

$$\mathbb{P}(\mathcal{E}) \geq \mathbb{P}(\mathcal{Q}) \geq \mathbb{P}(\mathcal{E}) - c/p^2. \quad (34)$$

This suggests that the difference between \mathcal{Q} and \mathcal{E} is small. By taking expectations on both sides over the set \mathcal{Q} , we obtain,

$$\begin{aligned} \mathbb{E} \left[\|\hat{\beta}^{t+1} - \beta_*\|_2; \mathcal{Q} \right] &\leq \kappa \left\{ \mathfrak{D}(x, z) + c_1 \sqrt{\frac{p}{\min\{p/\log(p)|S|, n/\log(n)\}}} \right\} \mathbb{E} \left[\|\hat{\beta}^t - \beta_*\|_2 \right] \\ &\quad + \kappa c_2 \mathbb{E} \left[\|\hat{\beta}^t - \beta_*\|_2^2 \right] \end{aligned}$$

where we used

$$\mathbb{E} \left[\|\hat{\beta}^t - \beta_*\|_2; \mathcal{Q} \right] \leq \mathbb{E} \left[\|\hat{\beta}^t - \beta_*\|_2^l \right], \quad l = 1, 2.$$

Similarly for the iterate $\hat{\beta}^{t+1}$, we write

$$\begin{aligned} \mathbb{E} \left[\|\hat{\beta}^{t+1} - \beta_*\|_2 \right] &= \mathbb{E} \left[\|\hat{\beta}^{t+1} - \beta_*\|_2; \mathcal{Q} \right] + \mathbb{E} \left[\|\hat{\beta}^{t+1} - \beta_*\|_2; \mathcal{Q}^c \right], \\ &\leq \mathbb{E} \left[\|\hat{\beta}^{t+1} - \beta_*\|_2; \mathcal{Q} \right] + 2R\mathbb{P}(\mathcal{Q}^c), \\ &\leq \mathbb{E} \left[\|\hat{\beta}^{t+1} - \beta_*\|_2; \mathcal{Q} \right] + 2R \left(\mathbb{P}(\mathcal{E}^c) + \frac{c}{p^2} \right), \\ &\leq \mathbb{E} \left[\|\hat{\beta}^{t+1} - \beta_*\|_2; \mathcal{Q} \right] + \frac{\epsilon}{10}, \\ &\leq \mathbb{E} \left[\|\hat{\beta}^{t+1} - \beta_*\|_2; \mathcal{Q} \right] + \frac{\mathbb{E} \left[\|\hat{\beta}^t - \beta_*\|_2 \right]}{10}. \end{aligned}$$

Combining these two inequalities, we obtain

$$\begin{aligned} \mathbb{E} \left[\|\hat{\beta}^{t+1} - \beta_*\|_2 \right] &\leq \left\{ 0.1 + \kappa \mathfrak{D}(x, z) + c_1 \kappa \sqrt{\frac{p}{\min\{p/\log(p)|S|, n/\log(n)\}}} \right\} \mathbb{E} \left[\|\hat{\beta}^t - \beta_*\|_2 \right] \\ &\quad + c_2 \kappa \mathbb{E} \left[\|\hat{\beta}^t - \beta_*\|_2^2 \right]. \end{aligned}$$

Hence the proof follows.

C.2 Proof of Theorem 6

The iterates generated by the Newton-Stein method satisfy the following inequality;

$$\|\beta^{t+1} - \beta_*\|_2 \leq \left(\tau_1 + \tau_2 \|\beta^t - \beta_*\|_2 \right) \|\beta^t - \beta_*\|_2,$$

on the event \mathcal{Q} where \mathcal{Q} is defined in the previous section. We have observed that $\mathbb{P}(\mathcal{Q}) \geq \mathbb{P}(\mathcal{E}) - c/p^2$ in Equation 34. Since the coefficients τ_1 and τ_2 are obtained by uniform bounds on the feasible set, the above inequality holds for every t on \mathcal{Q} . On the event we consider, $\mathcal{Q} \cap \{\theta < (1 - \tau_1)/\tau_2\}$, the starting point satisfies the following

$$\tau_1 + \tau_2 \|\beta^0 - \beta_*\|_2 < 1, \quad (35)$$

which implies that the sequence of iterates converges. Let $\xi \in (c, \theta)$ and t_ξ be the last iteration that $\|\beta^t - \beta_*\|_2 > \xi$. Then, for $t > t_\xi$

$$\begin{aligned} \|\beta^{t+1} - \beta_*\|_2 &\leq \left(\tau_1 + \tau_2 \|\beta^t - \beta_*\|_2 \right) \|\beta^t - \beta_*\|_2, \\ &\leq (\tau_1 + \tau_2 \xi) \|\beta^t - \beta_*\|_2. \end{aligned}$$

This convergence behavior describes a linear rate and requires at most

$$\frac{\log(\epsilon/\xi)}{\log(\tau_1 + \tau_2 \xi)}$$

iterations to reach a tolerance of ϵ . For $t \leq t_\xi$, we have

$$\begin{aligned} \|\beta^{t+1} - \beta_*\|_2 &\leq \left(\tau_1 + \tau_2 \|\beta^t - \beta_*\|_2 \right) \|\beta^t - \beta_*\|_2, \\ &\leq (\tau_1/\xi + \tau_2) \|\beta^t - \beta_*\|_2^2. \end{aligned}$$

This describes a quadratic rate and the number of iterations to reach a tolerance of ξ can be upper bounded by

$$\log_2 \left(\frac{\log(\xi(\tau_1/\xi + \tau_2))}{\log(\tau_1/\xi + \tau_2) \|\beta^0 - \beta_*\|_2} \right) \leq \log_2 \left(\frac{\log(\tau_1 + \tau_2 \xi)}{\log(\tau_1/\xi + \tau_2)(1 - \tau_1)/\tau_2} \right).$$

Therefore, the overall number of iterations to reach a tolerance of ϵ is upper bounded by

$$\log_2 \left(\frac{\log(\tau_1 + \tau_2 \xi)}{\log((\tau_1/\xi + \tau_2)(1 - \tau_1)/\tau_2)} \right) + \frac{\log(\epsilon/\xi)}{\log(\tau_1 + \tau_2 \xi)}$$

which is a function of ξ . Therefore, we take the minimum over the feasible set and conclude that on $\mathcal{E} \cap \{\theta < (1 - \tau_1)/\tau_2\}$, the number of iterations to reach a tolerance of ϵ is upper bounded by $\inf_{\xi} \mathcal{J}(\xi)$ with a bad event probability of c/p^2 . By conditioning on the event $\mathcal{E} \cap \{\theta < (1 - \tau_1)/\tau_2\}$, we conclude that with probability at least $1 - c'/p^2$, the statement of the theorem holds for $c' = c/\mathbb{P}(\mathcal{E} \cap \{\theta < (1 - \tau_1)/\tau_2\})$.

Appendix D. Proof of Theorem 7

We have the following projected updates

$$\beta^{t+1} = \mathcal{P}_{\mathcal{C}} \left(\beta^t - \gamma_t \mathbf{Q}^t \nabla \ell(\beta^t); \mathbf{Q}^t \right) = \beta^t - \gamma_t D_{\eta_t}(\beta^t),$$

where we define

$$D_{\gamma}(\beta^t) = \frac{1}{\gamma} \left(\beta^t - \mathcal{P}_{\mathcal{C}}(\beta^t - \gamma \mathbf{Q}^t \nabla \ell(\beta^t); \mathbf{Q}^t) \right).$$

For simplicity, we only consider the projection onto a convex set, i.e.,

$$\begin{aligned} \mathcal{P}_{\mathcal{C}}^{\ell}(\beta^t) &= \mathcal{P}_{\mathcal{C}}(\beta^t, \mathbf{Q}^t) = \underset{w \in \mathcal{C}}{\operatorname{argmin}} \frac{1}{2} \|w - \beta^t\|_{\mathbf{Q}^{t-1}}^2, \\ &= \underset{w \in \mathbb{R}^p}{\operatorname{argmin}} \frac{1}{2} \|w - \beta^t\|_{\mathbf{Q}^{t-1}}^2 + \mathbb{I}_{\mathcal{C}}(w), \end{aligned} \quad (36)$$

where $\mathbb{I}_{\mathcal{C}}(w)$ is the indicator function for the convex set \mathcal{C} , i.e.

$$\mathbb{I}_{\mathcal{C}}(w) = \begin{cases} 0 & \text{if } w \in \mathcal{C}, \\ \infty & \text{otherwise.} \end{cases}$$

We note that other projection methods (such as proximal mappings) are also applicable to our update rule.

Defining the decrement $\lambda^t = \langle \nabla \ell(\beta^t), D_{\gamma}(\beta^t) \rangle$, we consider the following form of backtracking line search with update parameters $a \in (0, 0.5)$ and $b \in (0, 1)$:

$$\gamma = \bar{\gamma}; \quad \text{while: } \ell(\beta^t - \gamma D_{\gamma}(\beta^t)) > \ell(\beta^t) - a\gamma\lambda^t, \quad \gamma \leftarrow \gamma b.$$

Depending on the projection choice, there are various other search methods that can be applied. Before we move on to the convergence analysis, we first establish some properties of the modified gradient D_{γ} .

For a given point $w \in \mathcal{C}$, the sub-differential of the indicator function is the normal cone. This together with Equation 36 implies that

$$\beta^t - \gamma \mathbf{Q}^t \nabla \ell(\beta^t) - \mathcal{P}_{\mathcal{C}}^{\ell}(\beta^t - \gamma \mathbf{Q}^t \nabla \ell(\beta^t)) \in \mathbf{Q}^t \partial \mathbb{I}_{\mathcal{C}}(\mathcal{P}_{\mathcal{C}}^{\ell}(\beta^t - \gamma \mathbf{Q}^t \nabla \ell(\beta^t))),$$

which in turn implies

$$\gamma [\mathbf{Q}^t]^{-1} \left\{ D_{\gamma}(\beta^t) - \mathbf{Q}^t \nabla \ell(\beta^t), \right\} \in \partial \mathbb{I}_{\mathcal{C}}(\mathcal{P}_{\mathcal{C}}^{\ell}(\beta^t - \gamma \mathbf{Q}^t \nabla \ell(\beta^t))),$$

and correspondingly for any $\beta \in \mathcal{C}$

$$\langle [\mathbf{Q}^t]^{-1} D_{\gamma}(\beta^t) - \nabla \ell(\beta^t), \mathcal{P}_{\mathcal{C}}^{\ell}(\beta^t - \gamma \mathbf{Q}^t \nabla \ell(\beta^t)) - \beta \rangle \geq 0.$$

For $\beta = \beta^t \in \mathcal{C}$, this yields

$$\kappa^{-1} \|D_{\gamma}(\beta^t)\|_2^2 \leq \langle D_{\gamma}(\beta^t), [\mathbf{Q}^t]^{-1} D_{\gamma}(\beta^t) \rangle \leq \langle \nabla \ell(\beta^t), D_{\eta_t}(\beta^t) \rangle, \quad (37)$$

with probability at least $P(\mathcal{E}) - c/p^2$. Also note that the Hessian of the GLM problem can be upper bounded by

$$\left\| \frac{1}{n} \sum_{i=1}^n x_i x_i^T \phi^{(2)}(\langle x_i, \hat{\beta}^t \rangle) \right\|_2 \leq B_2 \left\| \frac{1}{n} \sum_{i=1}^n x_i x_i^T \right\|_2 \leq B_2 K.$$

Now we move to the convergence analysis. For a step size γ , by the convexity of the negative log-likelihood, we can write almost surely

$$\begin{aligned} \ell(\hat{\beta}^t - \gamma D_\gamma(\hat{\beta}^t)) &\leq \ell(\hat{\beta}^t) - \gamma \langle \nabla \ell(\hat{\beta}^t), D_\gamma(\hat{\beta}^t) \rangle + \frac{\gamma^2 B_2 K}{2} \|D_\gamma(\hat{\beta}^t)\|_2^2, \\ &\leq \ell(\hat{\beta}^t) - \gamma \langle \nabla \ell(\hat{\beta}^t), D_\gamma(\hat{\beta}^t) \rangle \left\{ 1 - \frac{\gamma}{2} B_2 K \kappa \right\} \end{aligned}$$

and notice that the exit condition for the backtracking line search algorithm is satisfied when $\gamma \leq (\kappa B_2 K)^{-1}$. Hence, the line search returns a step size satisfying

$$\gamma_t \geq \min\{\bar{\gamma}, b/(\kappa B_2 K)\}.$$

Using the line search condition, we have

$$\ell(\hat{\beta}^t - \gamma_t D_{\gamma_t}(\hat{\beta}^t)) - \ell(\hat{\beta}^t) \leq -a\gamma_t \lambda^t,$$

with probability at least $\mathbb{P}(\mathcal{E}) - c/p^2$ which implies that the sequence $\{\ell(\hat{\beta}^t)\}_t$ is decreasing. We note that this event is independent of the iteration number due to uniform positive definite condition given in \mathcal{E} . Since ℓ is continuous and \mathcal{C} is closed, ℓ is a closed function. Hence, the sequence $\{\ell(\hat{\beta}^t)\}_t$ must converge to a limit. This implies that $a\gamma_t \lambda^t \rightarrow 0$. But we have $a > 0$ and $\gamma_t > \min\{\bar{\gamma}, b/(\kappa B_2 K)\} > 0$. Therefore, we conclude that $\lambda^t \rightarrow 0$. Using the inequality provided in Equation 37, we conclude that $\|D_\gamma(\hat{\beta}^t)\|_2$ converges to 0 which implies that the algorithm converges with probability at least $1 - \frac{c}{\mathbb{P}(\mathcal{E})} p^{-2}$, where in the last step we conditioned on \mathcal{E} .

Appendix E. Local Step Size Selection

This section provides a heuristic calculation for choosing a local step size when eigenvalue thresholding is applied to the Newton-Stein method. We carry our analysis from Equation 32. The optimal local step size would be

$$\gamma_* = \operatorname{argmin}_\gamma \left\| I - \gamma \mathbf{Q}^t \int_0^1 \nabla_\beta^2 \ell(\beta_* + \xi(\hat{\beta}^t - \beta_*)) d\xi \right\|_2.$$

Defining the following matrix,

$$\nabla_\beta^3 \tilde{\ell}(\hat{\beta}^t) = \int_0^1 \nabla_\beta^2 \ell(\beta_* + \xi(\hat{\beta}^t - \beta_*)) d\xi,$$

and we write the governing term as

$$\left\| I - \gamma \mathbf{Q}^t \nabla_\beta^3 \tilde{\ell}(\hat{\beta}^t) \right\|_2.$$

The above function is piecewise linear in γ and it can be minimized by setting

$$\gamma_* = \frac{2}{\lambda_1 \left(\mathbf{Q}^t \nabla_\beta^2 \tilde{\ell}(\hat{\beta}^t) \right) + \lambda_p \left(\mathbf{Q}^t \nabla_\beta^2 \tilde{\ell}(\hat{\beta}^t) \right)}.$$

Since we don't have access to the optimal value β_* , we cannot determine the exact value of $\nabla_\beta^2 \tilde{\ell}(\hat{\beta}^t)$. Hence, we will assume that $\nabla_\beta^2 \tilde{\ell}(\hat{\beta}^t)$ and the current estimate are close.

In the regime $n \gg p$, and by our construction of the scaling matrix \mathbf{Q}^t , we have

$$\mathbf{Q}^t \approx \left[\mathbb{E}[xx^T \phi^{(2)}(\langle x, \hat{\beta}^t \rangle)] \right]^{-1} \quad \text{and} \quad \nabla_\beta^2 \ell(\hat{\beta}^t) \approx \mathbb{E}[xx^T \phi^{(2)}(\langle x, \hat{\beta}^t \rangle)].$$

The crucial observation is that the eigenvalue thresholding suggested in Erdogdu and Montanari, 2015 estimates the smallest eigenvalue with $(r+1)$ -th eigenvalue (say $\hat{\sigma}^2$) which overestimates true value (say σ^2) in general. Even though, the largest eigenvalue of $\mathbf{Q}^t \nabla_\beta^2 \tilde{\ell}(\hat{\beta}^t)$ will be close to 1, the smallest value will be $\sigma^2/\hat{\sigma}^2$. This will make the optimal step size larger than 1. Hence, we suggest

$$\gamma = \frac{2}{1 + \sigma^2/\hat{\sigma}^2},$$

if σ^2 were known. We also have, by the Weyl's inequality,

$$|\sigma^2 - \sigma^2| \leq \left\| \hat{\Sigma} - \Sigma \right\|_2 \leq C \sqrt{\frac{p}{|S|}},$$

with high probability. Whenever r is less than $p/2$, we suggest to use

$$\gamma = \frac{2}{1 + \frac{\sigma^2 - C(\sqrt{p/|S|})}{\hat{\sigma}^2}},$$

if σ^2 is unknown.

Appendix F. Useful Lemmas

Lemma 29 Let Γ denote the Gamma function. Then, for $r \in (0, 1)$, we have

$$z^{1-r} < \frac{\Gamma(z+1)}{\Gamma(z+r)} < (1+z)^{1-r}.$$

Lemma 30 Let Z be a random variable with a density function f and cumulative distribution function F . If $F^C = 1 - F$, then,

$$\mathbb{E}[|Z|_{\{|Z|>t\}}] \leq t \mathbb{P}(|Z| > t) + \int_t^\infty \mathbb{P}(|Z| > z) dz.$$

Proof We write,

$$\mathbb{E}[|Z|_{\{|Z|>t\}}] = \int_{-\infty}^\infty z f(z) dz + \int_{-\infty}^{-t} z f(z) dz.$$

Using integration by parts, we obtain

$$\begin{aligned} \int z f(z) dz &= -z F^C(z) + \int F^C(z) dz, \\ &= z F(z) - \int F(z) dz. \end{aligned}$$

Since $\lim_{z \rightarrow \infty} z F^C(z) = \lim_{z \rightarrow -\infty} z F(z) = 0$, we have

$$\begin{aligned} \int_t^{\infty} z f(z) dz &= t F^C(t) + \int_t^{\infty} F^C(z) dz, \\ \int_{-\infty}^{-t} z f(z) dz &= -t F(-t) - \int_{-\infty}^{-t} F(z) dz, \\ &= -t F(-t) - \int_t^{\infty} F(-z) dz. \end{aligned}$$

Hence, we obtain the following bound,

$$\begin{aligned} |\mathbb{E}[Z \mathbb{1}_{\{|Z|>t\}}]| &= \left| t F^C(t) + \int_t^{\infty} F^C(z) dz - t F(-t) - \int_t^{\infty} F(-z) dz \right|, \\ &\leq t (F^C(t) + F(-t)) + \left(\int_t^{\infty} F^C(z) + F(-z) dz \right), \\ &\leq t \mathbb{P}(|Z| > t) + \int_t^{\infty} \mathbb{P}(|Z| > z) dz. \end{aligned}$$

■

Lemma 31 For positive constants c_1, c_2 , we have

$$\int_{c_1}^{\infty} e^{-c_2 t^{2/3}} dt \leq \left\{ \frac{3c_1^{1/3}}{2c_2} + \frac{3}{4c_2^2 c_1^{1/3}} \right\} e^{-c_2 c_1^{2/3}}$$

Proof By the change of variables $t^{2/3} = x^2$, we get

$$\int_{c_1}^{\infty} e^{-c_2 t^{2/3}} dt = 3 \int_{c_1^{1/3}}^{\infty} x^2 e^{-c_2 x^2} dx.$$

Next, we notice that

$$d e^{-c_2 x^2} = -2c_2 x e^{-c_2 x^2} dx.$$

Hence, using the integration by parts, we have

$$\int_{c_1}^{\infty} e^{-c_2 t^{2/3}} dt = \frac{3}{2c_2} \left\{ c_1^{1/3} e^{-c_2 c_1^{2/3}} + \int_{c_1^{1/3}}^{\infty} e^{-c_2 x^2} dx \right\}.$$

We will find an upper bound on the second term. Using the change of variables, $x = y + c_1^{1/3}$, we obtain

$$\begin{aligned} \int_{c_1^{1/3}}^{\infty} e^{-c_2 x^2} dx &= \int_0^{\infty} e^{-c_2 (y + c_1^{1/3})^2} dy, \\ &\leq e^{-c_2 c_1^{2/3}} \int_0^{\infty} e^{-2c_2 y c_1^{1/3}} dy, \\ &= \frac{e^{-c_2 c_1^{2/3}}}{2c_2 c_1^{1/3}}. \end{aligned}$$

Combining the above results, we complete the proof. ■

Lemma 32 (Vershynin, 2010) Let X be a symmetric $p \times p$ matrix, and let T_ϵ be an ϵ -net over S^{p-1} . Then,

$$\|X\|_2 \leq \frac{1}{1 - 2\epsilon} \sup_{v \in T_\epsilon} |(Xv, v)|.$$

Lemma 33 Let $B_p(R) \subset \mathbb{R}^p$ be the ball of radius R centered at the origin and T_ϵ be an ϵ -net over $B_p(R)$. Then,

$$|T_\epsilon| \leq \left(\frac{R\sqrt{p}}{\epsilon} \right)^p.$$

Proof A similar proof appears in (Van der Vaart, 2000). The set $B_p(R)$ can be contained in a p -dimensional cube of size $2R$. Consider a grid over this cube with mesh width $2\epsilon/\sqrt{p}$. Then $B_p(R)$ can be covered with at most $(2R/(2\epsilon/\sqrt{p}))^p$ many cubes of edge length $2\epsilon/\sqrt{p}$. If one takes the projection of the centers of such cubes onto $B_p(R)$ and considers the circumscribed balls of radius ϵ , we may conclude that $B_p(R)$ can be covered with at most

$$\left(\frac{2R}{2\epsilon/\sqrt{p}} \right)^p$$

many balls of radius ϵ . ■

Lemma 34 For $a, b > 0$, and ϵ satisfying

$$\epsilon = \left\{ \frac{a}{2} \log \left(\frac{2b^2}{a} \right) \right\}^{1/2} \quad \text{and} \quad \frac{2}{a} b^2 > \epsilon,$$

we have $\epsilon^2 \geq a \log(b/\epsilon)$. Moreover, the gap in the inequality can be written as

$$\epsilon^2 - a \log(b/\epsilon) = \frac{a}{2} \log \log \left(\frac{2b^2}{a} \right).$$

Proof Since $a, b > 0$ and $x \rightarrow e^x$ is a monotone increasing function, the above inequality condition is equivalent to

$$\frac{2e^2}{a} e^{\frac{2x^2}{a}} \geq \frac{2b^2}{a}.$$

Now, we use the function $f(w) = we^w$ for $w > 0$ (in fact this function is well-known by the name Lambert W function). f is continuous and invertible on $[0, \infty)$. Note that f^{-1} is also a continuous and increasing function for $w > 0$. Therefore, we have

$$\epsilon^2 \geq \frac{a}{2} f^{-1} \left(\frac{2b^2}{a} \right)$$

Observe that the smallest possible value for ϵ would be simply the square root of $a f^{-1}(2b^2/a)/2$. For simplicity, we will obtain a more interpretable expression for ϵ . By the definition of f^{-1} , we have

$$\log(f^{-1}(y)) + f^{-1}(y) = \log(y).$$

Since the condition on a and b enforces $f^{-1}(y)$ to be larger than 1, we obtain the simple inequality that

$$f^{-1}(y) \leq \log(y).$$

Using the above inequality, if ϵ satisfies

$$\epsilon^2 = \frac{a}{2} \log \left(\frac{2b^2}{a} \right),$$

we obtain the desired inequality. ■

Abstract

Rank aggregation based on pairwise comparisons over a set of items has a wide range of applications. Although considerable research has been devoted to the development of rank aggregation algorithms, one basic question is how to efficiently collect a large amount of high-quality pairwise comparisons for the ranking purpose. Because of the advent of many crowdsourcing services, a crowd of workers are often hired to conduct pairwise comparisons with a small monetary reward for each pair they compare. Since different workers have different levels of reliability and different pairs have different levels of ambiguity, it is desirable to wisely allocate the limited budget for comparisons among the pairs of items and workers so that the global ranking can be accurately inferred from the comparison results. To this end, we model the active sampling problem in *crowdsourced ranking* as a Bayesian Markov decision process, which dynamically selects item pairs and workers to improve the ranking accuracy under a budget constraint. We further develop a computationally efficient sampling policy based on knowledge gradient as well as a moment matching technique for posterior approximation. Experimental evaluations on both synthetic and real data show that the proposed policy achieves high ranking accuracy with a lower labeling cost.

Keywords: crowdsourced ranking, Bayesian, Markov decision process, dynamic programming, knowledge gradient, moment matching

1. Introduction

Inferring the ranking over a set of items, such as documents, images, movies, or URL links, is an important learning problem with many applications in areas like web search, recommendation systems, online games, etc. An interesting problem related to rank inference is estimating a score for each item based on a certain criterion that the items can be ranked,

such as the score of relevance or the score of quality. Typically, both the ranking and the scores of items can be inferred from a collection of high-quality labels on the items. There are mainly two different types of labels. The label of the first type is associated with each individual item in order to characterize the property of the item itself, for example, a binary or an ordinal score (e.g., 5-point grade). The label of the second type is instead associated with a subset of items that reveal their relative properties, for example, a partial ranking that covers only this subset. Labels of both types can be obtained by soliciting the knowledge of human workers, depending on whether the worker is employed to evaluate a single item or to compare a subset of items according to a given criterion. In practice, a binary score usually cannot fully distinguish all items and ordinal scores from different workers are often inconsistent due to the difference in their understandings of the grades in the ordinal scoring scheme. Therefore, the second type of labels has been more widely adopted, which can effectively reduce the impact of misunderstanding among workers and is more appropriate for ranking fine-grained items with a large number of graduations (e.g., in our real data experiment on accessing reading difficulty of an article into one of twelve American grade levels). Moreover, empirical evidences show that the ranking accuracy of a human worker typically decreases when he or she has to compare many items at a time. For this reason, in this paper, we only consider the relative comparisons over *pairs* of items and the label from a human worker indicates which item is preferred to the other.

The traditional approach of conducting pairwise comparisons by a small group of experts is usually time consuming and expensive. It fails to meet the growing need of labeled data for ranking tasks. Because of the advent of online crowdsourcing services (Howe, 2006) such as Amazon Mechanical Turk, a more efficient and more economic approach has emerged: a large amount of unlabeled pairs of items are posted to a crowdsourcing platform, where a crowd of workers are hired to perform pairwise comparisons and provide labels of the assigned pairs. Given the labels from crowd workers, we can infer a global ranking over all items. We refer to the process of collecting pairwise labels and ranking items as *crowdsourced ranking*.

Despite its availability and scalability, challenges remain in crowdsourced ranking. A certain amount of monetary reward is paid to a worker for each pair of items he or she compares while there is usually only a fixed amount of budget available, limiting the total number of pairwise labels we can collect. Hence, there is a need for a budget-efficient decision process for allocating the budget over item pairs and workers. In particular, on crowdsourcing platforms, there are unreliable workers who submit their answers quickly but carelessly in order to obtain more monetary reward with less effort. Hence, the comparison results provided by crowd workers often contain non-negligible noise. As a remedy, multiple workers are hired to compare the same pair of items independently in the hope that the correct ranking can be recovered, and that the unreliable workers can be identified by comparing their answers with the rest of workers. However, each pairwise comparison will incur a pre-specified monetary cost. Without a careful control, such a repetitive labeling strategy often results in too many labels on the same pair by different workers, leading to a high cost. Furthermore, because of the diversity of their backgrounds and expertise, workers do not always agree with each other in the results of pairwise comparisons, especially when the two items in comparison are competitive to each other. We refer to such a competitive pair as an *ambiguous pair* since the ordering of them is more difficult to be determined.

*. The authors are listed in alphabetical order

Presumably, a greater budget should be spent on ambiguous pairs, but identifying ambiguous pairs under the budget constraint itself is a challenging problem, which requires some effective learning scheme. Given the trade-off between the labeling cost and the quality of ranking results, there are two fundamental challenges in crowdsourced ranking:

1. Given the inconsistent pairwise labels from crowd workers with different reliability, how to aggregate these labels into a global ranking over items.
2. With both unreliable workers and ambiguous pairs initially unidentified, how to incorporate a learning scheme with an efficient sampling procedure (over both pairs of items and workers) under the budget constraint to achieve the highest ranking accuracy.

To address these challenges, we need to first model the reliability of workers and the ambiguity of item pairs and analyze how they influence the pairwise label. To this end, we adopt a combination of the Bradley-Terry-Luce ranking model (Bradley and Terry, 1952; Luce, 1959) for modeling the comparison results and the Dawid-Skene model (Dawid and Skene, 1979) for workers' reliability. The reason why we adopt the Bradley-Terry-Luce model is that learning such a model will not only provide a ranking over items but also give a score to each item, which can be useful in many applications (e.g., providing player's rating in chess games). We measure the quality of the ranking inferred from the collected labels using the *Kendall's tau rank correlation coefficient* (Kendall's tau for short) with respect to the underlying true ranking.

Under such a model and a quality measure, we propose a dynamic sampling and ranking procedure which addresses the aforementioned two challenges in a unified framework. In particular, we first introduce the priors' latent true scores and workers' reliability and formulate the crowdsourced ranking problem into a finite-horizon Bayesian *Markov decision problem* (MDP), whose state variables correspond to the posterior distributions given the observed labels. Here, the number of stages is determined by the total budget, i.e., the total number of pairs that can be requested for labeling. As the budget level increases, the size of the state space grows at an exponential rate, which makes the exact solving of such a MDP problem intractable. To address the computational difficulty, we propose an efficient sampling strategy called *approximated knowledge gradient* (AKG) policy based on the popular knowledge gradient policy (Powell, 2010; Frazier, 2009; Frazier et al., 2008; Ryzhov et al., 2012). The proposed policy dynamically chooses the next pair of items and the worker that together lead to a maximum expected improvement in Kendall's tau rank correlation coefficient. Finally, to determine the global ranking that maximizes the expected Kendall's tau, one needs to solve a maximum linear ordering problem (Grötschel et al., 1984) which is a NP-hard problem (and in fact, APX-hard (approximable-hard) (Mishra and Slicker, 2004)). To address this challenge, we propose a moment matching technique to approximate the posteriors in parametric forms so that the linear ordering problem under the approximated posterior can be easily solved by a simple sorting procedure.

The rest of the paper is organized as follows. In Section 2, we review the related literature. In Section 3, we introduce the model and the proposed policy under the simplified case where all workers are homogeneous and perfectly reliable. In Section 4, we extend our policy to the case where the crowd workers have heterogeneous reliability. In Section 5, we

present numerical results on both simulated and real datasets, followed by conclusions in Section 6. The detailed proofs and derivations are provided in the appendix.

2. Related Work

The dataset of partial rankings over items can be generated from a variety of sources including crowdsourcing services (Shah et al., 2016b), online competition games (e.g., Microsoft's TrueSkill system (Herbrich et al., 2007)), and online users' activities such as browsing, clicking and transactions that reveal certain preferences. Learning a global ranking of a large set of items by aggregating a collection of partial rankings/preferences has been an active research area for the past ten years (see, e.g., Gleich and Lin (2011); Negahban et al. (2012); Yi et al. (2013); Shah et al. (2016a,b); Rajkumar and Agarwal (2014); Lu and Boutlier (2014); Volkovs and Zemel (2014)). However, most work on rank aggregation considers a static estimation problem — inferring a global ranking based on a pre-existing dataset. The problem we consider here is related to but significantly different from these works because we model crowdsourced ranking as a dynamic procedure where the inference of ranking and collection of data proceed concurrently and influence each other.

The crowdsourced ranking problem we considered has a close connection with the dynamic sorting problem using noisy pairwise comparisons, which has been studied by several authors (Ailon, 2012; Braverman and Mossel, 2008; Radinsky and Ailon, 2011; Wauthier et al., 2013; Jameson and Nowak, 2011). However, these papers assume the noise of pairwise comparison results has the same distribution for all pairs, which is not reasonable in crowdsourced ranking because workers usually rank significantly different items more correctly than they do for similar items. The approaches proposed by Pfeiffer et al. (2012) and Qian et al. (2015) assume that the labeling noise depends on the latent qualities or features of the items. However, their approaches do not model the reliability of workers in the decision process. In contrast, our approach allows a label's noise to depend not only on the items themselves, but also on the reliability of the worker who provides the label. The ranking model adopted in this paper, which combines the Bradley-Terry-Luce model and the Dawid-Skene model, was originally proposed in (Chen et al., 2013), which also considers a similar problem of Bayesian statistical decision-making for crowdsourced ranking. However, the sampling strategy developed in Chen et al. (2013), which prioritizes the pair of items and the worker with the highest information gain, is a simple heuristic without a well-defined objective function to be optimized. In contrast, our work chooses the expected Kendall's tau as the objective function to maximize, which guides the development of the knowledge gradient policy.

In addition to crowdsourced ranking, the problem of crowdsourced categorical labeling/classification has been extensively studied in the past five years. Most work aims at solving a static problem, which infers the categorical labels and workers' reliability based on a static problem (see, e.g., Dawid and Skene (1979); Raykar et al. (2010); Weinder et al. (2010); Whitehill et al. (2009)); Lin et al. (2012); Gao and Zhou (2013); Zhang et al. (2014)). Recently, some research has been devoted to dynamic sampling in crowdsourced classification (Karger et al., 2013b,a; Bachrach et al., 2012; Ertekin et al., 2012; Kamar et al., 2012; Ho et al., 2013; Chen et al., 2015). In particular, both Kamar et al. (2012) and Chen et al. (2015) utilized the Markov decision process to model the budget allocation (i.e.,

sampling over items and workers) process. Since we also adopt a Bayesian Markov decision process with a variant of knowledge gradient policy, the spirit of our method is similar to that in Chen et al. (2015). However, since the statistical model for a ranking problem is fundamentally different from that of a classification problem, the Markov decision process in this paper is significantly different from the one introduced by Chen et al. (2015) in many aspects such as the objective function, stage-wise rewards, transition probabilities, optimal policy, etc. For example, the policy by Chen et al. (2015) is designed to maximize the expected classification accuracy while our policy aims at maximizing the expected Kendall's tau with respect to the true ranking. In fact, even for a static problem with a given set of collected data, inferring the ranking with the maximum expected Kendall's tau is equivalent to a NP-hard maximum linear ordering problem while classifying items with a maximum expected accuracy can be done in closed-form by Bayesian decision rule. In this paper, we avoid this computational challenge by exploiting the structure of the expected Kendall's tau and approximating the posteriors using moment matching. We also note that, although one can view the problem of ranking K items as a problem of classifying $K(K-1)/2$ pairs (each pair is treated as an item in Chen et al. (2015)), such an approach increases the size of the problem and ignores the dependency between pairwise labels.

In addition, it is worth to note that the problem we consider here is different from the typical tasks in machine-learned ranking or learning to rank (Liu, 2009; Acharya, 2013) where some feature information is available for each item and training data is used to calibrate some statistical models for ranking new items. In contrast to these problems, the feature information is not necessary in our crowdsourced ranking problem. Moreover, besides being applied to ranking items directly, our methods can be utilized to collect training labels for learning to rank problems. According to the type of training data utilized, statistical ranking methods can be classified into three categories (Liu, 2009; Acharya, 2013): pointwise method, pairwise method and listwise method. The pointwise methods (Li et al., 2008; Cooper et al., 1992; Crammer and Singer, 2001) learn a ranking model based on the data of scores or ratings of items. The pairwise methods (Freund et al., 2003; Burges et al., 2005; Zheng et al., 2008; Cao et al., 2006) and the listwise methods (Xu and Li, 2007; Cao et al., 2007; Taylor et al., 2008; Kuo et al., 2009) learn a ranking model using pairwise comparison results or partial rankings over a subset of items. For the pairwise or listwise methods, the crowdsourced ranking technique we proposed can be used as an upstream procedure that provides high-quality pairwise/listwise comparison data which helps increase the accuracy of the models in the aforementioned papers.

3. Crowdsourced Ranking by Homogeneous Workers

In this section, we first consider a simplified setting where workers are homogeneous (we will clarify the meaning of "homogeneous workers" shortly). In Section 4, we further extend the developed method for homogeneous workers to heterogeneous workers with different levels of reliability.

3.1 Model Setup

We assume that there are K items (denoted by $\{1, \dots, K\}$) to be ranked and each item i has an *unknown* latent score $\theta_i > 0$ for $i = 1, 2, \dots, K$. Let $\theta = (\theta_1, \theta_2, \dots, \theta_K)^T$, where each

latent score θ_i models the intensity of preference to item i under some criterion. A *ranking* over K items $\{1, 2, \dots, K\}$ is a permutation/one-to-one mapping $\pi : \{1, 2, \dots, K\} \rightarrow \{1, 2, \dots, K\}$ and $\pi(i)$ is the *rank* of item i under π . We follow the convention that $\theta_i > \theta_j$ means item i is preferred to item j and thus item i should have a higher rank than item j . Therefore, the underlying *true ranking* π^* over K items is determined by the ranking of their latent scores, i.e.,

$$\pi^*(i) > \pi^*(j) \quad \text{if and only if} \quad \theta_i > \theta_j. \quad (1)$$

We note that the latent scores naturally provide a characterization of *ambiguity for a pair of items*: when the values of θ_i and θ_j are closer, the pair of item i and j is more ambiguous in the sense that the true ordering of them is less obvious.

The way we explore the ranking of θ_i 's is through the collection of workers' preferences on different pairs of items. Specifically, we will present only two items at a time to a worker, who will be asked to compare these two items according to the given ranking criterion. Each worker will not be asked to compare the same pair more than once. The results of comparisons will be collected over time and become our historical data, based on which, our task is to infer the true ranking π^* .

In this section, we consider a basic setup where the crowd workers are assumed to be *homogeneous*, meaning that the probabilistic outcomes of their comparisons are only affected by the ambiguities of pairs. More specifically, suppose a worker is randomly selected from the crowd to compare a pair of items i and j with $i < j$ and the comparison result is denoted by a random variable Y_{ij} :

$$Y_{ij} = \begin{cases} 1 & \text{if item } i \text{ is preferred to item } j \text{ by the randomly selected worker} \\ -1 & \text{if item } j \text{ is preferred to item } i \text{ by the randomly selected worker.} \end{cases} \quad (2)$$

The setting of homogeneous workers means the probability distribution of Y_{ij} takes the following form

$$\Pr(Y_{ij} = 1) = \frac{\theta_i}{\theta_i + \theta_j} \quad \text{and} \quad \Pr(Y_{ij} = -1) = \frac{\theta_j}{\theta_i + \theta_j} \quad \text{for } i, j = 1, 2, \dots, K. \quad (3)$$

The probabilistic model we used in (3) is the well-known Bradley-Terry-Luce (BTL) model (Bradley and Terry, 1952; Luce, 1959). We choose this model for the distribution of Y_{ij} because it admits a simple structure and well fits our framework of dynamic sampling. Furthermore, our method developed for the BTL model can be easily extended to the case of heterogeneous workers which will be studied in Section 4.

It is worthwhile to mention that other comparison models can potentially be implemented here. Considering a simplified version of the Thurstone model (Thurstone, 1927) in which each object i has a score following $N(\theta_i, 1)$, then we have

$$\Pr(Y_{ij} = 1) = \Phi\left(\frac{\theta_i - \theta_j}{\sqrt{2}}\right) \quad \text{and} \quad \Pr(Y_{ij} = -1) = \Phi\left(\frac{\theta_j - \theta_i}{\sqrt{2}}\right).$$

The problem can still be formulated using a Bayesian decision process framework. However, there are several reasons why the BTL model is favored in this paper. First of all, moment

matching under the Thurstone model does not have closed-form solutions and hence we must rely on numerical scheme to compute the first and second moments of the posterior. Second, using moment matching approach, because the posterior is an n -dimensional multivariate Gaussian distribution, we need to update $n(n+1)/2$ parameters (the number of mean parameters plus the number of off-diagonal elements of the covariance matrix) during each iteration of the algorithm whereas with Dirichlet posterior there are only n parameters. Last but not least, with Thurstone model the ranking is no longer a simple sorting of parameters, which is a feature of the BTL model as shown in Theorem 2.

Since each worker can compare the same pair at most once, we assume the size of the crowd workers is large enough so that the distribution of Y_{ij} stays the same after sampling workers without replacement. Note that we can assume $\sum_{i=1}^K \theta_i = 1$ without loss of generality since the distribution of Y_{ij} in (3) remains unchanged if we multiply each θ_i by the same positive constant. The probability $\frac{\theta_i}{\theta_i + \theta_j}$ in (3) can also be interpreted as the percentage of workers in the crowd who prefer item i to item j .

Since the probabilistic model (3) does not incorporate or reveal the quality of each worker in the comparison result, in the subsequent study of this section, we only need to focus on how to dynamically select pairs of items to compare. The worker will be selected randomly from the crowd. A dynamic choice over workers will be incorporated into our method in Section 4 where the performance of workers is modeled heterogeneously.

3.2 Bayesian Decision Process

In a typical crowdsourcing marketplace, a monetary cost must be paid to a worker every time this worker completes a task such as comparing a pair of items. We assume the cost for each comparison is one unit and the total budget available is T units so that at most T pairs (repetition allowed) can be compared in total. Since comparing different pairs will generate different historical data and reveal different information about the true ranking, it is critical to dynamically determine the right sequence of pairs to compare in order to maximize the final ranking accuracy, especially when the budget T is small.

In the traditional offline setting, one needs to determine T pairs at a time beforehand and request the comparisons on those pairs in a batch. The potential problem of such a static approach is that the budget T is not spent in an efficient way to discover the true ranking. In fact, the distribution in (3) implies that, when two items have similar latent scores, workers will provide highly inconsistent preferences and it is hard to reach an agreement on such a pair. In this case, the comparison results will be very noisy and one needs to spend more budget on this pair in order to rank them correctly. In contrast, when two items have significantly different latent scores, workers will provide consistent answers so that the additional information we can obtain is little from repeatedly comparing the same two items. In this case, one might want to reduce the budget on such a pair. Unfortunately, without any prior knowledge of the latent scores, it is impossible to decide how much budget should be spent on each pair before observing some comparison results.

In order to efficiently allocate the limited total budget over all pairs, we consider a dynamic crowdsourced ranking policy (Algorithm 1) where only one pair of items is selected and presented to a worker at each time based on historical comparison results. This online

method allows the budget to be adaptively shifted towards the ambiguous pairs so that the final ranking accuracy can be improved.

In particular, given the total budget T , the dynamic decision process consists of T stages and, in stage $t = 0, 1, \dots, T-1$, a pair of items (i_t, j_t) with $i_t < j_t$ is presented to a randomly selected worker and we receive the comparison result $Y_{i_t j_t}$ defined in (2) and (3). The historical comparison results up to stage t can be summarized by a $K \times K$ matrix M^t with its entry¹ M^t_{ij} equal to the number of times item i is preferred to item j up to stage t . For each stage t where the pair (i_t, j_t) is compared, we define Δ^t to be a sparse $K \times K$ matrix with only one non-zero element: $\Delta^t_{i_t j_t} = 1$ if $Y_{i_t j_t} = 1$ and $\Delta^t_{j_t i_t} = 1$ if $Y_{i_t j_t} = -1$. By its definition, M^t can be updated iteratively as follows

$$M^0 = \mathbf{0}, \quad M^{t+1} = M^t + \Delta^t \quad \text{for } t = 0, 1, \dots, T-1, \quad (4)$$

where $\mathbf{0}$ denotes the $K \times K$ all-zero matrix.

We denote an *adaptive dynamic budget allocation/sampling policy* by $\mathcal{A} = \{(i_t, j_t)\}_{t=0,1,\dots,T-1}$ where $(i_t, j_t) = (i_t(M^t), j_t(M^t))$ depends on the previous comparison results through M^t . Our goal is to find the best \mathcal{A} so that the inferred ranking based on all the historical comparisons (represented by M^T) achieves the highest accuracy.

To measure the accuracy of an inferred ranking π , we adopt the popular evaluation criterion — normalized *Kendall's tau rank correlation coefficient* (Kendall, 1938) between π and π^* (Kendall's tau for short):

$$\begin{aligned} \tau(\pi, \pi^*) &\equiv \frac{|\{(i, j) : i < j, (\pi(i) - \pi(j))(\pi^*(i) - \pi^*(j)) > 0\}|}{K(K-1)/2} \\ &= \frac{2}{K(K-1)} \sum_{i \neq j} \mathbf{1}_{\{\pi(i) > \pi(j)\}} \mathbf{1}_{\{\theta_i > \theta_j\}}, \end{aligned} \quad (5)$$

where $\mathbf{1}_{\{\cdot\}}$ denotes the indicator function. Here, the numerator counts the number of pairs that π and π^* agree with each other and the denominator is the total number of pairs over K items. Hence, $\tau(\pi, \pi^*) \in [0, 1]$ and represents the percentage of agreements between π and π^* . The ranking accuracy of π is higher when $\tau(\pi, \pi^*)$ is closer to one and $\pi = \pi^*$ if and only if $\tau(\pi, \pi^*) = 1$.

However, we cannot infer a ranking based on the collected data by directly maximizing $\tau(\pi, \pi^*)$ because π^* and θ are unknown. To address this challenge, we adopt a Bayesian framework by proposing a prior distribution on θ and infer a ranking π that maximizes the posterior expectation of $\tau(\pi, \pi^*)$. Recall that the vector of latent scores θ is assumed to lie in the simplex

$$\Delta \equiv \left\{ \theta \in \mathbb{R}^K \mid \sum_{i=1}^K \theta_i = 1, \theta_i > 0 \right\}. \quad (6)$$

It is natural to assume that θ is drawn from a *Dirichlet prior distribution* parameterized by $\alpha^0 = (\alpha_1^0, \dots, \alpha_K^0)^T$ with $\alpha_i^0 > 0$ for all i (note that Dirichlet distribution of order K is supported on Δ). Namely,

$$\theta \sim \text{Dir}(\alpha^0) = \frac{1}{B(\alpha^0)} \prod_{i=1}^K g_i^{\alpha_i-1},$$

1. In this paper, the notation A_{ij} represents the entry in the i -th row and j -th column of matrix A .

where $B(\boldsymbol{\alpha}) = \frac{\prod_{i=1}^K \Gamma(\alpha_i)}{\Gamma(\sum_{i=1}^K \alpha_i)}$ and $\Gamma(x) \equiv \int_0^\infty \lambda^{x-1} e^{-\lambda} d\lambda$ is the gamma function. Given the comparison data M^t up to stage t and the probability distribution of each comparison result in (3), the density function of the posterior distribution of $\boldsymbol{\theta}$ takes the following form,

$$p(\boldsymbol{\theta}|M^t, \boldsymbol{\alpha}^0) = \frac{1}{H(M^t, \boldsymbol{\alpha}^0)} \prod_{i \neq j} \binom{\theta_i}{\theta_i + \theta_j} \prod_i \theta_i^{\alpha_i^0 - 1} = \frac{1}{H(M^t, \boldsymbol{\alpha}^0)} \prod_{i < j} (\theta_i + \theta_j)^{M_{ij}^t + M_{ji}^t}, \quad (7)$$

where $\boldsymbol{\beta}^t = (\beta_1^t, \beta_2^t, \dots, \beta_K^t)^T$ with $\beta_i^t \equiv \sum_{j \neq i} M_{ij}^t$, i.e., the number of times item i is preferred to another item up to stage t , and

$$H(M^t, \boldsymbol{\alpha}^0) \equiv \int_{\Delta} \frac{\prod_{i=1}^K \theta_i^{\beta_i^t + \alpha_i^0 - 1}}{\prod_{i < j} (\theta_i + \theta_j)^{M_{ij}^t + M_{ji}^t}} d\boldsymbol{\theta},$$

is the normalization constant.

With this posterior distribution in place and with M^t at any stage t , we can infer a ranking $\hat{\pi}_t$ to maximize the posterior expected ranking accuracy measured by its Kendall's tau with respect to π^* , namely, to find

$$\hat{\pi}_t \in \arg \max_{\pi} \mathbb{E} [\tau(\pi, \pi^*) | M^t, \boldsymbol{\alpha}^0], \quad (8)$$

where the expectation is taken with respect to the posterior distribution $p(\boldsymbol{\theta} | M^t, \boldsymbol{\alpha}^0)$ in (7). We denote the corresponding maximum posterior expected accuracy by $h(M^t)$, i.e.,

$$h(M^t) \equiv \max_{\pi} \mathbb{E} [\tau(\pi, \pi^*) | M^t, \boldsymbol{\alpha}^0], \quad (9)$$

where the dependence of h on the prior $\boldsymbol{\alpha}^0$ is suppressed for notational simplicity. We are interested in finding a dynamic budget allocation policy $\mathcal{A} = \{(i_t, j_t)\}_{t=0,1,\dots,T-1}$ that maximizes $h(M^T)$, i.e., the final expected ranking accuracy when the budget is exhausted. This problem can be stated as

$$\max_{\mathcal{A}} \mathbb{E}^{\mathcal{A}} [h(M^T) | \boldsymbol{\alpha}^0], \quad (10)$$

where $\mathbb{E}^{\mathcal{A}}$ represents the expectation over the sample paths (i.e., the sampled pairs and outcomes) generated by the policy \mathcal{A} .

The maximization problem in (10) can be formulated as a T -stage Bayesian Markov decision process (MDP), where the *state variable* is the posterior distribution in (7) or simply the matrix M^t . The *state space* at each stage t denoted by \mathcal{S}^t takes the form of

$$\mathcal{S}^t = \left\{ M^t \in \mathbb{Z}_{\geq 0}^{K \times K} : \sum_{i,j} M_{ij}^t = t \right\}, \quad (11)$$

where $\mathbb{Z}_{>0}$ denotes the set of non-negative integers. The state variable makes a transition according to (4) given the observed comparison result Y_{i_t, j_t} , where the sampled pair (i_t, j_t) is determined by the policy \mathcal{A} . The expected transition probabilities take the form of,

$$\mathbb{E} [\Pr(Y_{ij} = 1) | M^t, \boldsymbol{\alpha}^0] = \mathbb{E} \left[\frac{\theta_i}{\theta_i + \theta_j} | M^t, \boldsymbol{\alpha}^0 \right] \quad (12)$$

$$\mathbb{E} [\Pr(Y_{ij} = -1) | M^t, \boldsymbol{\alpha}^0] = \mathbb{E} \left[\frac{\theta_j}{\theta_i + \theta_j} | M^t, \boldsymbol{\alpha}^0 \right] \quad (13)$$

for $1 \leq i < j \leq K$ and the expectation is taken over the posterior of $\boldsymbol{\theta}$ in (7). To complete the definition of our Bayesian MDP for crowdsourced ranking, we still need to define the *stage-wise reward*. To this end, we rewrite $h(M^T)$ in (10) as a telescopic sum,

$$h(M^T) = \sum_{t=0,1,\dots,T-1} R(M^t, i_t, j_t, Y_{i_t, j_t}); \quad R(M^t, i_t, j_t, Y_{i_t, j_t}) \equiv h(M^{t+1}) - h(M^t), \quad (14)$$

and note that $R(M^t, i_t, j_t, Y_{i_t, j_t}) = h(M^{t+1}) - h(M^t)$ only depends on $M^t, i_t, j_t, Y_{i_t, j_t}$. Given (14), the maximization problem (10) is equivalent to

$$\begin{aligned} \max_{\mathcal{A}} \mathbb{E}^{\mathcal{A}} \left[h(M^0) + \sum_{t=0}^{T-1} R(M^t, i_t, j_t, Y_{i_t, j_t}) | \boldsymbol{\alpha}^0 \right] \\ = h(M^0) + \max_{\mathcal{A}} \mathbb{E}^{\mathcal{A}} \left[\sum_{t=0}^{T-1} \mathbb{E} [R(M^t, i_t, j_t, Y_{i_t, j_t}) | M^t, \boldsymbol{\alpha}^0] | \boldsymbol{\alpha}^0 \right]. \end{aligned} \quad (15)$$

From (15), it is clear that $R(M^t, i_t, j_t, Y_{i_t, j_t})$ is the *stage-wise reward*, which can be interpreted as the improvement of the expected ranking accuracy after receiving the comparison result Y_{i_t, j_t} at stage t for $t = 0, 1, \dots, T-1$.

Given the Bayesian MDP in place, we can apply the dynamic programming (DP) algorithm (a.k.a. backward induction) (Puterman, 2005) to compute the optimal policy. Although DP finds the optimal policy, its computation is intractable because:

1. The sophisticated form of the posterior distribution in (7) makes it difficult to evaluate the posterior expected ranking accuracy $\mathbb{E} [\tau(\pi, \pi^*) | M^t, \boldsymbol{\alpha}^0]$ in (9) and the expected transition probabilities in (12) and (13).
2. The maximization problem (9) for solving the optimal posterior expected ranking accuracy is essentially a linear ordering problem (Grötschel et al., 1984), which is NP-hard in general (see Section 3.3 for more details).
3. The size of the state space \mathcal{S}^t grows exponentially in t according to (11), which is known as the curse of dimensionality that prevents us from solving (15) exactly with the standard techniques such as value iteration, policy iteration and linear programming.

To address these challenges, we propose an approximated knowledge gradient policy (AKG) in the next Section.

3.3 Approximated Knowledge Gradient Policy

In this section, we describe an approximated policy to solve (10), which is computationally efficient and still provides an inferred ranking with high quality. The proposed approximation policy belongs to the family of *knowledge gradient* (KG) policies (Gupta and Miescke, 1996; Frazier et al., 2008; Powell, 2010; Ryzhov et al., 2012), which is essentially a single-step look-ahead policy. In our problem, the KG policy will sample the next pair of items with the highest expected stage-wise reward in each stage, i.e., choosing the pair (i_t, j_t) such that

$$\begin{aligned}
 (i_t, j_t) &\in \arg \max_{i < j} \mathbb{E} [R(M^t, i_t, j_t, Y_{i_t j_t}) | M^t, \alpha^0] \\
 &= \arg \max_{i < j} \mathbb{E} [\Pr(Y_{ij} = 1) | M^t, \alpha^0] R(M^t, i_t, j_t, 1) \\
 &\quad + \mathbb{E} [\Pr(Y_{ij} = -1) | M^t, \alpha^0] R(M^t, i_t, j_t, -1).
 \end{aligned} \tag{16}$$

Despite its simplicity and wide applicability, the implementation of the KG policy for our problem in (16) is still computationally intractable since we have to evaluate the expected stage-wise reward $\mathbb{E}[R(M^t, i_t, j_t, Y_{i_t j_t}) | M^t, \alpha^0]$, where two main challenges will arise.

First, we have to evaluate the transition probabilities (12) and (13) as well as the ranking accuracy (9), which can be written as

$$\begin{aligned}
 h(M^t) &= \max_{\pi} \mathbb{E} [\tau(\pi, \pi^*) | M^t, \alpha^0] \\
 &= \max_{\pi} \frac{2 \sum_{i \neq j} \mathbb{E} [\mathbf{1}_{\{\pi(i) > \pi(j)\}} \mathbf{1}_{\{\theta_i > \theta_j\}} | M^t, \alpha^0]}{K(K-1)} \\
 &= \max_{\pi} \frac{2 \sum_{i \neq j} \mathbf{1}_{\{\pi(i) > \pi(j)\}} \Pr(\theta_i > \theta_j | M^t, \alpha^0)}{K(K-1)}.
 \end{aligned} \tag{17}$$

However, due to the complicated structure of the posterior distribution $p(\theta | M^t, \alpha^0)$ in (7), the expected transition probabilities (12) and (13) and the posterior probability $\Pr(\theta_i > \theta_j | M^t, \alpha^0)$ in (17) do not admit a closed form so that one needs to use multidimensional numerical integral or sampling techniques to compute their values. Note that for each stage t , we need to evaluate (12), (13) and $\Pr(\theta_i > \theta_j | M^t, \alpha^0)$ for all $K(K-1)/2$ pairs. When these quantities cannot be easily computed, the overall computational cost will be extremely expensive.

Second, even if the posterior probabilities $\Pr(\theta_i > \theta_j | M^t, \alpha^0)$ for all pairs are given, the maximization problem (17) with respect to a global ranking π is still very challenging. In fact, this problem is equivalent to the *maximum linear ordering problem (MAX-LOP)* described as follows. Let $G = (V, E, w)$ be a completed directed graph defined on a set V of K nodes, where the edge set E contains the directed arcs between all pairs of nodes and $w(i, j)$ refers to the weight associated with the arc from node i to node j . A tournament D is a sub-graph of G such that, for any pair of nodes i and j , D contains either the arc from i to j or the arc from j to i but not both. The MAX-LOP aims to find an acyclic tournament D with a maximum total weight on its arcs. If we interpret the arc from node i and node j as the preference of node i to node j under a ranking criterion, each acyclic tournament in G corresponds one-to-one to a global ranking of the nodes. Hence, MAX-LOP is equivalent to finding a ranking π such that the total weight $\sum_{\pi(i) > \pi(j)} w(i, j)$ is maximized. In problem (17), the nodes correspond to the K items and the weight $w(i, j) = \Pr(\theta_i > \theta_j | M^t, \alpha^0)$. Unfortunately, the MAX-LOP is known to be a NP-hard problem and in fact, APX (approximable)-complete and thus no PTAS (Polynomial Time Approximation Scheme) under P \neq NP (Mishra and Sikdar, 2004).

Given these two challenges, evaluating $\mathbb{E}[R(M^t, i_t, j_t, Y_{i_t j_t}) | M^t, \alpha^0]$ and solving (16) repeatedly at each stage are computationally intractable. To address this problem, we propose an *approximated knowledge gradient (AKG)* policy, which first replaces the stage-wise reward (14) by an approximated but computable reward and then chooses the pair that

maximizes this approximated reward. Our approximation scheme starts with approximating the posterior distribution $p(\theta | M^t, \alpha^0)$ in (7) recursively using a sequence of Dirichlet distributions $\text{Dir}(\alpha^t)$ for $t = 1, 2, \dots, T$ based on *moment matching*. One key benefit of such an approximation is that, at each stage t , the approximated posterior distribution of θ is still a Dirichlet distribution so that the NP-hard MAX-LOP problem in (17) will admit a simple solution via a sorting procedure (see Theorem 2).

Although there exist other methods for posterior approximation, these methods cannot be implemented as efficiently as moment matching in our application. For example, some methods such as variational inference (e.g., Beal, 2003; Paisley et al., 2012) minimize the KL-divergence between the exact posterior and the variational posterior, which requires an iterative optimization algorithm as a subroutine. Other methods like Gibbs sampler are computationally expensive in our case because the full conditional distribution does not have a closed form to allow easy sampling. In contrast, the proposed (algorithmic) moment matching admits a closed-form solution for approximating the posterior, which is computationally very efficient, and further provides a Dirichlet distribution as the approximated posterior, which facilitates solving the MAX-LOP. We note that the close-form update is critical for online crowdsourcing applications to reduce the computation time between two stages. In practice, since the crowd workers want to maximize their return in a short period of time, they may quit the current task if we let them wait for too long before we determine the next pair. Finally, we note that, although providing the theoretical guarantee for such an iterative approximation is hard in the Bayesian setup, we empirically show that the resulting AKG policy will generate a final ranking of a high accuracy with the limited budget.

Now we formally introduce the posterior approximation and AKG policy. Suppose $\theta \sim \text{Dir}(\alpha)$ for some parameters $\alpha \in \mathbb{R}^K$. We consider a basic case where only one comparison result Y_{ij} for a pair (i, j) with $i < j$ has been observed. In this case, we approximate the posterior $p(\theta | Y_{ij}, \alpha)$ by another Dirichlet distribution $\text{Dir}(\alpha')$ such that

$$\mathbb{E} [\theta_k | \theta \sim \text{Dir}(\alpha')] = \mathbb{E} [\theta_k | Y_{ij}, \alpha] \text{ for } k = 1, 2, \dots, K \tag{18}$$

$$\mathbb{E} \left[\sum_{k=1}^K \theta_k^2 \theta \sim \text{Dir}(\alpha') \right] = \mathbb{E} \left[\sum_{k=1}^K \theta_k^2 | Y_{ij}, \alpha \right]. \tag{19}$$

This system of equations has the following explicit characterization.

Proposition 1 *Suppose $\theta \sim \text{Dir}(\alpha)$ and Y_{ij} is the only comparison result for $i < j$. Let $\alpha_0 = \sum_{k=1}^K \alpha_k$ and $\alpha'_0 = \sum_{k=1}^K \alpha'_k$. The equations (18) and (19) can be represented as*

$$\begin{cases} \frac{\alpha'_i}{\alpha'_0} = \frac{(\alpha_i + \frac{1+Y_{ij}}{2})(\alpha_i + \alpha_j)}{\alpha_0(\alpha_i + \alpha_j + 1)} \\ \frac{\alpha'_j}{\alpha'_0} = \frac{(\alpha_j + \frac{1-Y_{ij}}{2})(\alpha_i + \alpha_j)}{\alpha_0(\alpha_i + \alpha_j + 1)} \\ \frac{\alpha'_k}{\alpha'_0} = \frac{\alpha_k}{\alpha_0} \text{ for } k \neq i, j \\ \sum_{k=1}^K \frac{\alpha'_k(\alpha'_k + 1)}{\alpha'_0(\alpha'_0 + 1)} = \frac{(\alpha_i + \frac{1+Y_{ij}}{2})(\alpha_i + \frac{3+Y_{ij}}{2})(\alpha_i + \alpha_j)}{\alpha_0(\alpha_0 + 1)(\alpha_i + \alpha_j + 2)} + \sum_{k \neq i, j} \frac{\alpha_k(\alpha_k + 1)}{\alpha_0(\alpha_0 + 1)}. \end{cases} \tag{20}$$

The proof of Proposition 1 is provided in the Appendix. We denote any α' that satisfies (18) and (19), and thus (20), by

$$\alpha' = \mathbf{MM}(\alpha, i, j, Y_{ij}). \quad (21)$$

Note that, given α, i, j and Y_{ij} , the right-hand sides of (20) are all constants so that we can solve $\alpha' = \mathbf{MM}(\alpha, i, j, Y_{ij})$ in a closed form. In fact, we denote the constants on the right hand sides of (20) as C_i, C_j, C_k (for $k \neq i, j$) and D , respectively. It is easy to show that $\sum_{k=1}^K C_k = 1$. The first three equalities in (20) imply that $\alpha'_k = C_k \alpha'_0$ for $k = 1, 2, \dots, K$ so that the fourth equality in (20) can be represented as $\sum_{k=1}^K C_k (\alpha'_k \alpha'_0 + 1) = D(\alpha'_0 + 1)$. Solving α'_0 from this equation leads to a closed-form for $\alpha' = \mathbf{MM}(\alpha, i, j, Y_{ij})$ as follows

$$\alpha'_0 = \frac{D-1}{\sum_{k=1}^K C_k^2 - D} \quad \text{and} \quad \alpha'_k = C_k \alpha'_0 \quad \text{for } k = 1, 2, \dots, K. \quad (22)$$

Although the above approximation scheme is established for only one comparison result, it produces a Dirichlet distribution $\text{Dir}(\alpha')$ which has the same type as the prior distribution $\text{Dir}(\alpha)$. Therefore, as more comparison results are generated sequentially, we can apply this approximation scheme iteratively after each comparison result. In particular, given a policy $\mathcal{A} = \{(i, j_t)\}_{t=0,1,\dots,T-1}$ with $i_t < j_t$ and the comparison results $\{Y_{i_t j_t}\}_{t=0,1,\dots,T-1}$, we define α^t recursively as

$$\alpha^{t+1} = \mathbf{MM}(\alpha^t, i_t, j_t, Y_{i_t j_t}) \quad (23)$$

for $t = 1, 2, \dots, T$. By doing so, we approximate the posterior distribution $p(\theta|M^t, \alpha^0)$ by the Dirichlet distribution $\text{Dir}(\alpha^t)$ for $t = 1, 2, \dots, T$.

With $p(\theta|M^t, \alpha^0)$ approximated by $\text{Dir}(\alpha^t)$, we can mitigate the two challenges mentioned at the beginning of this subsection. First, we can approximate (12) and (13) as

$$\mathbb{E}[\text{Pr}(Y_{ij} = 1)|M^t, \alpha^0] \approx \mathbb{E}\left[\frac{\theta_i}{\theta_i + \theta_j} | \theta \sim \text{Dir}(\alpha^t)\right] = \frac{\alpha_i^t}{\alpha_i^t + \alpha_j^t} \quad (24)$$

$$\mathbb{E}[\text{Pr}(Y_{ij} = -1)|M^t, \alpha^0] \approx \mathbb{E}\left[\frac{\theta_i}{\theta_i + \theta_j} | \theta \sim \text{Dir}(\alpha^t)\right] = \frac{\alpha_i^t}{\alpha_i^t + \alpha_j^t} \quad (25)$$

and approximate $\text{Pr}(\theta_i > \theta_j | M^t, \alpha^0)$ in (7) as

$$\text{Pr}(\theta_i > \theta_j | M^t, \alpha^0) \approx \text{Pr}(\theta_i > \theta_j | \theta \sim \text{Dir}(\alpha^t)) = \int_{\frac{1}{2}}^1 t^{\alpha_i^t - 1} (1-t)^{\alpha_j^t - 1} dt = I_{\frac{1}{2}}(\alpha_i^t, \alpha_j^t), \quad (26)$$

where $I_x(a, b) = \frac{B(x; a, b)}{B(a, b)}$ is known as the *regularized incomplete beta function* with $B(x; a, b) = \int_0^x \lambda^{a-1} (1-\lambda)^{b-1} d\lambda$ and $B(a, b) = \int_0^1 \lambda^{a-1} (1-\lambda)^{b-1} d\lambda$. Note that the approximated quantities in (24), (25) and (26) are much easier to compute than the original ones.

More importantly, the approximation (26) simplifies the NP-hard MAX-LOP in (17):

$$\max_{\pi} \mathbb{E}[\tau(\pi, \pi^*) | M^t, \alpha^0] \approx \max_{\pi} \mathbb{E}[\tau(\pi, \pi^*) | \theta \sim \text{Dir}(\alpha^t)].$$

The right-hand side is still a MAX-LOP but has a special structure so that it can be solved easily by a simple sorting procedure. In particular, the following theorem shows that when $\theta \sim \text{Dir}(\alpha)$, the optimal ranking in (16) can be obtained by sorting the components of α .

Theorem 2 Suppose $\theta \sim \text{Dir}(\alpha)$. We have

$$\begin{aligned} \Pi_{\alpha} &\equiv \{\pi | \pi \text{ is a ranking of } \{1, 2, \dots, K\} \text{ such that } \pi(i) > \pi(j) \text{ only if } \alpha_i \geq \alpha_j \text{ for all } i, j\} \\ &= \arg \max_{\pi} \mathbb{E}[\tau(\pi, \pi^*) | \theta \sim \text{Dir}(\alpha)] \end{aligned} \quad (27)$$

Proof We first show that $\arg \max_{\pi} \mathbb{E}[\tau(\pi, \pi^*) | \theta \sim \text{Dir}(\alpha)] \subset \Pi_{\alpha}$. Suppose $\hat{\pi}$ is the optimal solution of (27) where $\hat{\pi}(j) > \hat{\pi}(i)$ for a pair i and j with $\alpha_i > \alpha_j$. We put all items in a row with their ranks given by $\hat{\pi}$ decreasing from the left to the right and obtain a pattern like

$$X \cdots X_j \underbrace{X \cdots X}_S i X \cdots X,$$

where X represents some item different from i and j and S represents the set of items ranked between i and j . We will show that the objective value of (27) can be increased by switching the ranks of i and j .

Recall that the expected accuracy of $\hat{\pi}$ can be represented as

$$\begin{aligned} \mathbb{E}[\tau(\hat{\pi}, \pi^*) | \theta \sim \text{Dir}(\alpha)] &= \frac{2}{K(K-1)} \sum_{i' \neq j'} \mathbf{1}_{\hat{\pi}(i') > \hat{\pi}(j')} \text{Pr}(\theta_{i'} > \theta_{j'} | \theta \sim \text{Dir}(\alpha)) \quad (28) \\ &= \frac{2}{K(K-1)} \left[I_{\frac{1}{2}}(\alpha_i, \alpha_j) + \sum_{s \in S} I_{\frac{1}{2}}(\alpha_s, \alpha_j) + \sum_{s \in S} I_{\frac{1}{2}}(\alpha_i, \alpha_s) + C \right], \end{aligned}$$

where C is the summation of the remaining terms like $I_{\frac{1}{2}}(\alpha_{i'}, \alpha_{j'})$ which have either at least one of i' and j' not in $S \cup \{i, j\}$ or both i' and j' in S .

Note that switching the ranks of i and j does not change the values of the terms in C . In fact, after such a switch, we obtain a new ranking $\hat{\pi}'$ whose objective value in (27) is

$$\mathbb{E}[\tau(\hat{\pi}', \pi^*) | \theta \sim \text{Dir}(\alpha)] = \frac{2}{K(K-1)} \left[I_{\frac{1}{2}}(\alpha_j, \alpha_i) + \sum_{s \in S} I_{\frac{1}{2}}(\alpha_j, \alpha_s) + \sum_{s \in S} I_{\frac{1}{2}}(\alpha_s, \alpha_i) + C \right].$$

Using the fact that $I_{\frac{1}{2}}(a, b)$ is monotonically decreasing in a and monotonically increasing in b and noticing that $\alpha_i > \alpha_j$, we have

$$I_{\frac{1}{2}}(\alpha_j, \alpha_i) + \sum_{s \in S} I_{\frac{1}{2}}(\alpha_j, \alpha_s) + \sum_{s \in S} I_{\frac{1}{2}}(\alpha_s, \alpha_i) > I_{\frac{1}{2}}(\alpha_i, \alpha_j) + \sum_{s \in S} I_{\frac{1}{2}}(\alpha_s, \alpha_j) + \sum_{s \in S} I_{\frac{1}{2}}(\alpha_s, \alpha_s),$$

which implies $\mathbb{E}[\tau(\hat{\pi}', \pi^*) | \theta \sim \text{Dir}(\alpha)] > \mathbb{E}[\tau(\hat{\pi}, \pi^*) | \theta \sim \text{Dir}(\alpha)]$, contradicting with the optimality of $\hat{\pi}$. Hence, we can have $\hat{\pi}(i) > \hat{\pi}(j)$ only if $\alpha_i \geq \alpha_j$, meaning that $\hat{\pi} \in \Pi_{\alpha}$.

We then show $\arg \max_{\pi} \mathbb{E}[\tau(\pi, \pi^*) | \theta \sim \text{Dir}(\alpha)] = \Pi_{\alpha}$ by showing that $\mathbb{E}[\tau(\pi, \pi^*) | \theta \sim \text{Dir}(\alpha)]$ has the same value for any $\pi \in \Pi_{\alpha}$. Suppose $\hat{\pi}$ and $\hat{\pi}'$ both belong to Π_{α} and there exists a pair i and j with $i \neq j$ such that $\hat{\pi}(i) > \hat{\pi}(j)$ and $\hat{\pi}'(j) > \hat{\pi}'(i)$. By the definition of Π_{α} , we have $\alpha_i = \alpha_j$ so that

$$\text{Pr}(\theta_i > \theta_j | \theta \sim \text{Dir}(\alpha)) = I_{\frac{1}{2}}(\alpha_j, \alpha_i) = \frac{1}{2} = I_{\frac{1}{2}}(\alpha_i, \alpha_j) = \text{Pr}(\theta_j > \theta_i | \theta \sim \text{Dir}(\alpha)).$$

This means

$$\begin{aligned} & \mathbf{1}_{\hat{\pi}(i) > \hat{\pi}(j)} \Pr(\theta_i > \theta_j | \boldsymbol{\theta} \sim \text{Dir}(\boldsymbol{\alpha})) + \mathbf{1}_{\hat{\pi}(j) > \hat{\pi}(i)} \Pr(\theta_j > \theta_i | \boldsymbol{\theta} \sim \text{Dir}(\boldsymbol{\alpha})) \\ &= \mathbf{1}_{\hat{\pi}(i) > \hat{\pi}(j)} \Pr(\theta_i > \theta_j | \boldsymbol{\theta} \sim \text{Dir}(\boldsymbol{\alpha})) + \mathbf{1}_{\hat{\pi}(j) > \hat{\pi}(i)} \Pr(\theta_j > \theta_i | \boldsymbol{\theta} \sim \text{Dir}(\boldsymbol{\alpha})) \end{aligned}$$

for any pair i and j so that $\mathbb{E}[\tau(\hat{\pi}, \pi^*) | \boldsymbol{\theta} \sim \text{Dir}(\boldsymbol{\alpha})] = \mathbb{E}[\tau(\hat{\pi}', \pi^*) | \boldsymbol{\theta} \sim \text{Dir}(\boldsymbol{\alpha})]$ by the formulation (28), which completes the proof. \blacksquare

Given a parameter vector $\boldsymbol{\alpha}$, we denote any ranking in $\Pi_{\boldsymbol{\alpha}}$ by $\pi_{\boldsymbol{\alpha}}$. Using moment matching and Theorem 2, we can approximate the stage-wise reward $R(M^t, i, j, Y_{ij}^t)$ by

$$\begin{aligned} R(M^t, i, j, Y_{ij}^t) &= h(M^{t+1}) - h(M^t) \\ &= \max_{\pi} \mathbb{E}[\tau(\pi, \pi^*) | M^{t+1}, \boldsymbol{\alpha}^0] - \max_{\pi} \mathbb{E}[\tau(\pi, \pi^*) | M^t, \boldsymbol{\alpha}^0] \\ &\approx \max_{\pi} \mathbb{E}[\tau(\pi, \pi^*) | \boldsymbol{\theta} \sim \text{Dir}(\hat{\boldsymbol{\alpha}})] - \max_{\pi} \mathbb{E}[\tau(\pi, \pi^*) | \boldsymbol{\theta} \sim \text{Dir}(\boldsymbol{\alpha}^j)] \\ &= \mathbb{E}[\tau(\pi_{\hat{\boldsymbol{\alpha}}}, \pi^*) | \boldsymbol{\theta} \sim \text{Dir}(\hat{\boldsymbol{\alpha}})] - \mathbb{E}[\tau(\pi_{\boldsymbol{\alpha}}, \pi^*) | \boldsymbol{\theta} \sim \text{Dir}(\boldsymbol{\alpha}^j)] \\ &= \frac{2}{K(K-1)} \left(\sum_{i', j': \pi_{\hat{\boldsymbol{\alpha}}}(\hat{i}) > \pi_{\hat{\boldsymbol{\alpha}}}(\hat{j})} I_{\frac{1}{2}}(\hat{\alpha}_{i'}, \hat{\alpha}_{j'}) - \sum_{i', j': \pi_{\boldsymbol{\alpha}^j}(\hat{i}) > \pi_{\boldsymbol{\alpha}^j}(\hat{j})} I_{\frac{1}{2}}(\alpha_{i'}^j, \alpha_{j'}^j) \right) \\ &\equiv \tilde{R}(\boldsymbol{\alpha}^t, i, j, Y_{ij}^t) \end{aligned} \quad (29)$$

where $\hat{\boldsymbol{\alpha}} = \text{MM}(\boldsymbol{\alpha}^t, i, j, Y_{ij}^t)$, the third equality is from Theorem 2 and the fourth equality is due to (26). Putting (16), (24), (25), and (29) together, we can approximate the expected stage-wise reward $\mathbb{E}[R(M^t, i, j, Y_{ij}^t) | M^t, \boldsymbol{\alpha}^0]$ as

$$\begin{aligned} & \mathbb{E}[R(M^t, i, j, Y_{ij}^t) | M^t, \boldsymbol{\alpha}^0] \\ &= \mathbb{E}[\Pr(Y_{ij}^t = 1) | M^t, \boldsymbol{\alpha}^0] R(\boldsymbol{\alpha}^t, i, j, 1) + \mathbb{E}[\Pr(Y_{ij}^t = -1) | M^t, \boldsymbol{\alpha}^0] R(M^t, i, j, -1) \\ &\approx \frac{\alpha_i^t}{\alpha_i^t + \alpha_j^t} \tilde{R}(\boldsymbol{\alpha}^t, i, j, 1) + \frac{\alpha_j^t}{\alpha_i^t + \alpha_j^t} \tilde{R}(\boldsymbol{\alpha}^t, i, j, -1). \end{aligned} \quad (30)$$

The proposed AKG policy will choose the pair (i_t, j_t) that maximizes the approximated expected stage-wise reward in (30). As a summary, we describe the AKG policy as Algorithm 1.

It is noteworthy that it is easy to implement a *batch version* of Algorithm 1. In fact, the AKG policy in Algorithm 1 is known as an *index policy* where the right-hand side of (31), which calculates the marginal improvement on the ranking accuracy, can be treated as the index for each pair of items. The AKG policy selects the pair with the highest index at each stage. In the batch version, instead of selecting only one pair, one heuristics is to select the top B pairs and distribute to workers simultaneously, where B is a pre-defined batch size. Such a batch implementation can reduce the waiting time of crowd workers and thus accelerate the ranking procedure. Moreover, the AKG policy can be combined with some other batch optimization techniques (Wu and Prazler, 2016) to determine the optimal set of pairs to evaluate next.

Algorithm 1 Approximated Knowledge Gradient Policy with Homogeneous Workers

Initialization: Choose $\boldsymbol{\alpha}^0$ for the prior distribution. Let M^0 be a $K \times K$ all-zero matrix. For $t = 0, \dots, T - 1$ do

- 1: For each pair (i, j) with $i < j$, compute $\tilde{R}(\boldsymbol{\alpha}^t, i, j, 1)$ and $\tilde{R}(\boldsymbol{\alpha}^t, i, j, -1)$ according to (29).
- 2: Select (i_t, j_t) such that

$$(i_t, j_t) \in \arg \max_{i < j} \left[\frac{\alpha_i^t}{\alpha_i^t + \alpha_j^t} \tilde{R}(\boldsymbol{\alpha}^t, i, j, 1) + \frac{\alpha_j^t}{\alpha_i^t + \alpha_j^t} \tilde{R}(\boldsymbol{\alpha}^t, i, j, -1) \right] \quad (31)$$

and present item i_t and item j_t to a randomly selected worker and receive the comparison result $Y_{i_t j_t}^t$.

- 3: According to (21) and (22), compute

$$\boldsymbol{\alpha}^{t+1} = \text{MM}(\boldsymbol{\alpha}^t, i_t, j_t, Y_{i_t j_t}^t) \quad (32)$$

End For

Return: The aggregated ranking $\pi_{\boldsymbol{\alpha}^T}$ obtained by sorting the components of $\boldsymbol{\alpha}^T$.

4. Crowdsourced Ranking by Heterogeneous Workers

In the previous section, we considered the setting of homogeneous workers, where the comparison results are determined only by the intrinsic latent scores of items but not by the characteristics of workers. However, on crowdsourcing platforms, the quality of the workers varies a lot. Some workers are less reliable or lack of the domain knowledge; some workers are spammers, who either do not actually take a look at the assigned pairs or are robots pretending to be human workers, and thus provide random comparison results in order to quickly receive payment; some workers may be poorly informed (or even malicious), misunderstand the ranking criteria and thus always flip the comparison results. To identify the reliability of a worker, one can assign the same pair of items to multiple workers and hope to identify the unreliable ones whose labels are often different from the majority. However, the abuse of this strategy will result in hiring too many workers and lead to a quick growth of the monetary cost. In order to maximize the accuracy of the final ranking under the limited amount of budget, it is critical to balance the budget spent on estimating the reliability of the workers and learning the true ranking of the items. To formalize such trade-off, we incorporate the reliability of each worker to our previous Bayesian MDP and generalize the AKG policy to the heterogeneity of workers.

4.1 Model Setup

Similar to the previous setting, we assume that each item i has an unknown latent score $\theta_i > 0$ for $i = 1, 2, \dots, K$ which determines its true ranking π^* (see (1)) and $\boldsymbol{\theta} \sim \text{Dir}(\boldsymbol{\alpha}^0)$. In the setting of heterogeneous workers, we assume that there are M crowd workers in total, denoted by $w = 1, 2, \dots, M$. If a pair of items i and j with $i < j$ is presented to the worker

w , we denote the returned comparison result by a random variable Y_{ij}^w such that

$$Y_{ij}^w = \begin{cases} 1 & \text{if item } i \text{ is preferred to item } j \text{ by worker } w \\ -1 & \text{if item } j \text{ is preferred to item } i \text{ by worker } w. \end{cases} \quad (33)$$

To model the reliability for workers, we introduce M latent parameters $\boldsymbol{\rho} = (\rho_1, \rho_2, \dots, \rho_M)^T$ of reliability with $\rho_w \in [0, 1]$ for worker w and assume Y_{ij}^w has the following distribution

$$\Pr(Y_{ij}^w = 1) = \rho_w \frac{\theta_i}{\theta_i + \theta_j} + (1 - \rho_w) \frac{\theta_j}{\theta_i + \theta_j} \quad (34)$$

$$\Pr(Y_{ij}^w = -1) = \rho_w \frac{\theta_j}{\theta_i + \theta_j} + (1 - \rho_w) \frac{\theta_i}{\theta_i + \theta_j} \quad (35)$$

for $1 \leq i < j \leq K$ and $w = 1, 2, \dots, M$. This model can be viewed as a combination of David-Skene model for categorical labeling tasks (David and Skene, 1979; Raykar et al., 2010; Karger et al., 2013a) and Bradley-Terry-Luce (BTL) model, which was first introduced in Chen et al. (2013). Such a mixture of BTL model is flexible and capable of modeling various types of workers. When $\rho_w = 1$, the distribution in (34) and (35) reduces to (3), and we refer to worker w with $\rho_w = 1$ as a ‘‘fully reliable’’ worker². Therefore, the reliability parameter ρ_w can be interpreted as the probability that worker w behaves as a random fully reliable workers in the previous section, namely, the one whose preference over a pair i and j follows a distribution in accordance with the BTL model (3). The worker with ρ_w closer to 1 is considered to be more reliable while a worker with ρ_w closer to 0 tends to be a poorly informed (or malicious) one who intentionally gives answers opposite to the majority (truth). Also, a worker is known as a spammer if the associated ρ_w is near 0.5 since this worker prefers i or j in any pair i and j with an equal probability regardless of their latent scores.

The reliability of each worker is unknown for the ranking task, which needs to be gradually identified during the comparison process. In the Bayesian framework, since the reliability parameter ρ_w is supported on $[0, 1]$, it can be naturally modeled to follow a Beta prior distribution, i.e., $\rho_w \sim \text{Beta}(\mu_w^0, \nu_w^0)$, for $w = 1, 2, \dots, M$, where $\boldsymbol{\mu}^0 = (\mu_1^0, \mu_2^0, \dots, \mu_M^0)$ and $\boldsymbol{\nu}^0 = (\nu_1^0, \nu_2^0, \dots, \nu_M^0)$ are positive parameters.

4.2 Bayesian Decision Process

In this section, we model the sequential decision problem with a finite budget of T in the setting of heterogeneous workers. Since the workers now have different levels of reliability, we can no longer randomly select a worker from the crowd in each stage. Instead, we need to adaptively determine not only which pair of items to be compared but also who should perform this comparison task according to the historical results so that the budget can be gradually shifted towards more reliable workers.

2. We note that the full reliability does not imply that the worker is capable of identifying the latent scores of items and always give the correct comparison result, i.e., preferring the item with a higher latent score. Instead, being fully reliable only means the worker tries her best to provide the preference after a careful consideration, and the inconsistency of comparisons among workers is mainly because the intrinsic ambiguity of the pair of items.

Suppose a pair of items (i_t, j_t) with $i_t < j_t$ is compared by a worker w_t in stage t and the comparison result is $Y_{i_t j_t}^{w_t}$ defined in (33). The historical comparison results up to stage t can be summarized by a $K \times K \times M$ tensor \mathbf{M}^t , which is updated iteratively as follows. In particular, at each stage t , we define $\boldsymbol{\Delta}^t$ to be a sparse $K \times K \times M$ tensor with only non-zero element: if $Y_{i_t j_t}^{w_t} = 1$, $\boldsymbol{\Delta}_{i_t j_t}^{w_t} = 1$ and if $Y_{i_t j_t}^{w_t} = -1$, $\boldsymbol{\Delta}_{j_t i_t}^{w_t} = 1$. Let

$$\mathbf{M}^0 = \mathbf{0}, \quad \mathbf{M}^{t+1} = \mathbf{M}^t + \boldsymbol{\Delta}^t \quad \text{for } t = 0, 1, \dots, T - 1, \quad (36)$$

where $\mathbf{0}$ is a $K \times K \times M$ all-zero tensor. In contrast to the matrix M^t in (4), each element in the tensor \mathbf{M}^t takes the value either zero or one because each worker is not allowed to compare the same pair more than once. The dynamic budget allocation policy is denoted by $\mathcal{A} = \{(i_t, j_t, w_t)\}_{t=0,1,\dots,T-1}$ where $(i_t, j_t, w_t) = (i_t(\mathbf{M}^t), j_t(\mathbf{M}^t), w_t(\mathbf{M}^t))$ depends on the previous comparison results through \mathbf{M}^t . The posterior distributions of $\boldsymbol{\theta}$ and $\boldsymbol{\rho}$ in stage t are denoted by $p(\boldsymbol{\theta}|\mathbf{M}^t, \boldsymbol{\alpha}^0, \boldsymbol{\mu}^0, \boldsymbol{\nu}^0)$ and $p(\boldsymbol{\rho}|\mathbf{M}^t, \boldsymbol{\alpha}^0, \boldsymbol{\mu}^0, \boldsymbol{\nu}^0)$, respectively.

Similar to the homogeneous worker setup, we adopt the Kendall’s tau (5) to measure the ranking accuracy. At each stage t , we denote the maximum posterior expected ranking accuracy by (with a slight abuse of notation)

$$\begin{aligned} h(\mathbf{M}^t) &\equiv \max_{\pi} \mathbb{E}[\tau(\pi, \pi^*)|\mathbf{M}^t, \boldsymbol{\alpha}^0, \boldsymbol{\mu}^0, \boldsymbol{\nu}^0] \\ &= \max_{\pi} \frac{2 \sum_{i \neq j} \mathbf{1}_{\pi(i) > \pi(j)} \Pr(\theta_i > \theta_j | \mathbf{M}^t, \boldsymbol{\alpha}^0, \boldsymbol{\mu}^0, \boldsymbol{\nu}^0)}{K(K-1)}. \end{aligned} \quad (37)$$

The maximizer in (37) is the optimal ranking inferred from the historical comparison results up to the stage t . Our goal is to search for the optimal policy \mathcal{A} that maximizes the final expected ranking accuracy $h(\mathbf{M}^T)$, i.e.,

$$\max_{\mathcal{A}} \mathbb{E}^{\mathcal{A}} [h(\mathbf{M}^T) | \boldsymbol{\alpha}^0, \boldsymbol{\mu}^0, \boldsymbol{\nu}^0]. \quad (38)$$

This maximization problem can be further reformulated in a telescopic sum

$$h(\mathbf{M}^0) + \max_{\mathcal{A}} \mathbb{E} \left[\sum_{t=0}^{T-1} \mathbb{E} \left[R(\mathbf{M}^t, i_t, j_t, w_t, Y_{i_t j_t}^{w_t}) | \mathbf{M}^t, \boldsymbol{\alpha}^0, \boldsymbol{\mu}^0, \boldsymbol{\nu}^0 \right] \middle| \boldsymbol{\alpha}^0, \boldsymbol{\mu}^0, \boldsymbol{\nu}^0 \right], \quad (39)$$

where

$$R(\mathbf{M}^t, i_t, j_t, w_t, Y_{i_t j_t}^{w_t}) \equiv h(\mathbf{M}^{t+1}) - h(\mathbf{M}^t), \quad (40)$$

is the *stage-wise reward* depending on $\mathbf{M}^t, i_t, j_t, w_t$ and $Y_{i_t j_t}^{w_t}$. It can be interpreted as the improvement of the expected ranking accuracy after receiving the comparison result at stage t . The *state variable* of the MDP (38) or (39) is the tensor \mathbf{M}^t which evolves according to (36) and the state space at each t is

$$\mathcal{S}^t = \left\{ \mathbf{M} \in \{0, 1\}^{K \times K \times M} : \sum_{i,j,w} \mathbf{M}_{jw} = t \right\}.$$

The expected transition probabilities of MDP (38) are

$$\mathbb{E} [\Pr(Y_{ij}^w = 1) | \mathbf{M}^t, \boldsymbol{\alpha}^0, \boldsymbol{\mu}^0, \boldsymbol{\nu}^0] = \mathbb{E} \left[\rho_w \frac{\theta_i}{\theta_i + \theta_j} + (1 - \rho_w) \frac{\theta_j}{\theta_i + \theta_j} | \mathbf{M}^t, \boldsymbol{\alpha}^0, \boldsymbol{\mu}^0, \boldsymbol{\nu}^0 \right] \quad (41)$$

$$\mathbb{E} [\Pr(Y_{ij}^w = -1) | \mathbf{M}^t, \boldsymbol{\alpha}^0, \boldsymbol{\mu}^0, \boldsymbol{\nu}^0] = \mathbb{E} \left[\rho_w \frac{\theta_j}{\theta_i + \theta_j} + (1 - \rho_w) \frac{\theta_i}{\theta_i + \theta_j} | \mathbf{M}^t, \boldsymbol{\alpha}^0, \boldsymbol{\mu}^0, \boldsymbol{\nu}^0 \right] \quad (42)$$

for $i, j = 1, 2, \dots, K$ and $w = 1, 2, \dots, M$. So far, we have modeled the sequential budget allocation in the heterogeneous worker setting as a Bayesian MDP. Due to the similar reasons that have been explained in Section 3.2, although the dynamic programming can be directly applied to solve the Bayesian MDP and obtain the optimal policy, it is computationally intractable. In fact, the Bayesian MDP (39) is even more challenging to solve than that for the homogeneous worker setting due to a much larger state space after introducing the reliability of workers. In the next subsection, we will propose a computationally efficient approximated knowledge gradient policy for (39).

4.3 Approximated Knowledge Gradient Policy

To solve the Bayesian MDP (39), we still consider the family of knowledge gradient (KG) policies. In our problem, the KG policy will select the pair of items and the worker that together give the highest expected stage-wise reward. In particular, at the t -stage, the KG policy for (39) will choose the pair (i_t, j_t) and the worker w_t such that

$$\begin{aligned} (i_t, j_t, w_t) &\in \arg \max_{i < j, w} \mathbb{E} [R(\mathbf{M}^t, i, j, w, Y_{ij}^w) | \mathbf{M}^t, \boldsymbol{\alpha}^0, \boldsymbol{\mu}^0, \boldsymbol{\nu}^0] \\ &= \arg \max_{i < j, w} \left\{ \mathbb{E} [\Pr(Y_{ij}^w = 1) | \mathbf{M}^t, \boldsymbol{\alpha}^0, \boldsymbol{\mu}^0, \boldsymbol{\nu}^0] R(\mathbf{M}^t, i, j, w, 1) \right. \\ &\quad \left. + \mathbb{E} [\Pr(Y_{ij}^w = -1) | \mathbf{M}^t, \boldsymbol{\alpha}^0, \boldsymbol{\mu}^0, \boldsymbol{\nu}^0] R(\mathbf{M}^t, i, j, w, -1) \right\}. \end{aligned} \quad (43)$$

To implement the KG policy (43), we encounter the same difficulties as when we implemented (16). Specifically, since the posterior distributions $p(\boldsymbol{\theta} | \mathbf{M}^t, \boldsymbol{\alpha}^0, \boldsymbol{\mu}^0, \boldsymbol{\nu}^0)$ and $p(\boldsymbol{\rho} | \mathbf{M}^t, \boldsymbol{\alpha}^0, \boldsymbol{\mu}^0, \boldsymbol{\nu}^0)$ are sophisticated and the MAX-LOP problem (37) is NP-hard, we cannot efficiently evaluate the stage-wise reward (40) and the transition probabilities (41) and (42). To obtain a computationally efficient policy, we follow the techniques in Section 3.3 to approximate the posterior distributions $p(\boldsymbol{\theta} | \mathbf{M}^t, \boldsymbol{\alpha}^0, \boldsymbol{\mu}^0, \boldsymbol{\nu}^0)$ and $p(\boldsymbol{\rho} | \mathbf{M}^t, \boldsymbol{\alpha}^0, \boldsymbol{\mu}^0, \boldsymbol{\nu}^0)$ recursively using a sequence of Dirichlet distributions $\text{Dir}(\boldsymbol{\alpha}^t)$ and a sequence of beta distributions $\text{Beta}(\mu_w^t, \nu_w^t)$, respectively, for $w = 1, 2, \dots, M$ and $t = 1, 2, \dots, T$. The parameters $\boldsymbol{\alpha}^t(\alpha_1^t, \alpha_2^t, \dots, \alpha_K^t)$, $\boldsymbol{\mu}^t = (\mu_1^t, \mu_2^t, \dots, \mu_M^t)$ and $\boldsymbol{\nu}^t = (\nu_1^t, \nu_2^t, \dots, \nu_M^t)$ will be chosen recursively based on a moment matching.

Suppose $\boldsymbol{\theta} \sim \text{Dir}(\boldsymbol{\alpha})$ for some parameter vector $\boldsymbol{\alpha} \in \mathbb{R}^K$ and $\rho_w \sim \text{Beta}(\mu_w, \nu_w)$ for each w with $\boldsymbol{\mu} = (\mu_1, \mu_2, \dots, \mu_M)$ and $\boldsymbol{\nu} = (\nu_1, \nu_2, \dots, \nu_M)$. We consider a basic scenario where only one comparison result Y_{ij}^w from worker w for a pair (i, j) has been observed. We can approximate $p(\boldsymbol{\theta} | Y_{ij}^w, \boldsymbol{\alpha}, \boldsymbol{\mu}, \boldsymbol{\nu})$ by a Dirichlet distribution $\text{Dir}(\boldsymbol{\alpha}')$ and $p(\rho_w | Y_{ij}^w, \boldsymbol{\alpha}, \boldsymbol{\mu}, \boldsymbol{\nu})$ by

$$\mathbb{E} [\theta_k | \boldsymbol{\theta} \sim \text{Dir}(\boldsymbol{\alpha}')] = \mathbb{E} [\theta_k | Y_{ij}^w, \boldsymbol{\alpha}, \boldsymbol{\mu}, \boldsymbol{\nu}] \text{ for } k = 1, 2, \dots, K \quad (44)$$

$$\mathbb{E} \left[\sum_{k=1}^K \theta_k^2 | \boldsymbol{\theta} \sim \text{Dir}(\boldsymbol{\alpha}') \right] = \mathbb{E} \left[\sum_{k=1}^K \theta_k^2 | Y_{ij}^w, \boldsymbol{\alpha}, \boldsymbol{\mu}, \boldsymbol{\nu} \right] \quad (45)$$

$$\mathbb{E} [\rho_w | \rho_w \sim \text{Beta}(\mu_w', \nu_w')] = \mathbb{E} [\rho_w | Y_{ij}^w, \boldsymbol{\alpha}, \boldsymbol{\mu}, \boldsymbol{\nu}] \quad (46)$$

$$\mathbb{E} [\rho_w^2 + (1 - \rho_w)^2 | \rho_w \sim \text{Beta}(\mu_w', \nu_w')] = \mathbb{E} [\rho_w^2 + (1 - \rho_w)^2 | Y_{ij}^w, \boldsymbol{\alpha}, \boldsymbol{\mu}, \boldsymbol{\nu}]. \quad (47)$$

Note that we do not need to approximate $p(\rho_w | Y_{ij}^w, \boldsymbol{\alpha}, \boldsymbol{\mu}, \boldsymbol{\nu})$ for $w' \neq w$ since the worker w' has not performed any comparison so that $p(\rho_w | Y_{ij}^w, \boldsymbol{\alpha}, \boldsymbol{\mu}, \boldsymbol{\nu})$ is still the prior distribution $\text{Beta}(\mu_w, \nu_w)$. This system of equations has the following explicit characterization.

Proposition 3 Suppose $\boldsymbol{\theta} \sim \text{Dir}(\boldsymbol{\alpha})$ and $\rho_w \sim \text{Beta}(\mu_w, \nu_w)$ for worker w and Y_{ij}^w is the only comparison result. Let $\alpha_0 = \sum_{k=1}^K \alpha_k$ and $\alpha'_k = \sum_{k=1}^K \alpha'_k$. The equations (44), (45), (46) and (47) can be represented as

$$\begin{cases} \frac{\alpha'_k}{\alpha_0} = \eta_{ij} w \frac{(\alpha_0+1)(\alpha_i+\alpha_j)}{\alpha_0(\alpha_i+\alpha_j+1)} + (1 - \eta_{ij} w) \frac{\alpha_0(\alpha_i+\alpha_j)}{\alpha_0(\alpha_i+\alpha_j+1)} \\ \frac{\alpha'_j}{\alpha_0} = \eta_{ij} w \frac{\alpha_0(\alpha_i+\alpha_j)}{\alpha_0(\alpha_i+\alpha_j+1)} + (1 - \eta_{ij} w) \frac{\alpha_0(\alpha_i+\alpha_j)}{\alpha_0(\alpha_i+\alpha_j+1)} \\ \frac{\alpha'_k}{\alpha_0} = \frac{\alpha_k}{\alpha_0} \text{ for } k \neq i, j \\ \frac{\alpha'_k}{\alpha_0} = \frac{(\alpha_0+1)(\alpha_i+2)(\alpha_i+\alpha_j)}{\alpha_0(\alpha_0+1)(\alpha_i+\alpha_j+2)} + (1 - \eta_{ij} w) \frac{\alpha_0(\alpha_0+1)(\alpha_i+\alpha_j)}{\alpha_0(\alpha_0+1)(\alpha_i+2)(\alpha_i+\alpha_j)} \\ \quad + \eta_{ij} w \frac{\alpha_0(\alpha_0+1)(\alpha_i+\alpha_j)}{\alpha_0(\alpha_0+1)(\alpha_i+\alpha_j+2)} + (1 - \eta_{ij} w) \frac{\alpha_0(\alpha_0+1)(\alpha_i+\alpha_j)}{\alpha_0(\alpha_0+1)(\alpha_i+2)(\alpha_i+\alpha_j)} \\ \quad + \sum_{k \neq i, j} \frac{\alpha_k(\alpha_k+1)}{\alpha_0(\alpha_k+1)} \\ \frac{\mu_w + \nu_w}{(\mu_w + \nu_w + 1)} = \eta_{ij} w \frac{\mu_w + (1 - Y_{ij}^w)/2}{(\mu_w + \nu_w + 1)(\mu_w + \nu_w + 2)} + (1 - \eta_{ij} w) \frac{\mu_w + (1 - Y_{ij}^w)/2}{(\mu_w + \nu_w + 1)(\mu_w + \nu_w + 2)} \\ \frac{\mu_w + \nu_w}{(\mu_w + \nu_w + 1)} = \eta_{ij} w \frac{\mu_w + \nu_w + 1}{(\mu_w + \nu_w + 1)(\mu_w + \nu_w + 2)} + (1 - \eta_{ij} w) \frac{\mu_w + \nu_w + 1}{(\mu_w + \nu_w + 1)(\mu_w + \nu_w + 2)} \\ \frac{\mu_w + \nu_w}{(\mu_w + \nu_w + 1)} = \eta_{ij} w \frac{\mu_w + \nu_w + 1}{(\mu_w + \nu_w + 1)(\mu_w + \nu_w + 2)} + (1 - \eta_{ij} w) \frac{\mu_w + \nu_w + 1}{(\mu_w + \nu_w + 1)(\mu_w + \nu_w + 2)} \\ \quad + \eta_{ij} w \frac{(\nu_w + 1 - Y_{ij}^w)/2}{(\nu_w + 1 + Y_{ij}^w)/2} + (1 - \eta_{ij} w) \frac{(\nu_w + 1 - Y_{ij}^w)/2}{(\nu_w + 1 + Y_{ij}^w)/2} \\ \quad + \eta_{ij} w \frac{(\nu_w + 1 - Y_{ij}^w)/2}{(\nu_w + 1 + Y_{ij}^w)/2} + (1 - \eta_{ij} w) \frac{(\nu_w + 1 - Y_{ij}^w)/2}{(\nu_w + 1 + Y_{ij}^w)/2} \\ \quad + (1 - \eta_{ij} w) \frac{(\nu_w + 1 + Y_{ij}^w)/2}{(\nu_w + 1 + Y_{ij}^w)/2}. \end{cases} \quad (48)$$

where $\eta_{ij} w = \frac{[(1+Y_{ij}^w)\mu_w + (1-Y_{ij}^w)\nu_w]\alpha_0}{[(1+Y_{ij}^w)\mu_w + (1-Y_{ij}^w)\nu_w]\alpha_0 + [(1+Y_{ij}^w)\mu_w + (1-Y_{ij}^w)\nu_w]\alpha_0}$.

The proof of Proposition 3 is given in Appendix. We denote any $\boldsymbol{\alpha}'$, μ_w' and ν_w' that satisfy (44), (45), (46) and (47), and thus (48), by

$$\boldsymbol{\alpha}' = \text{MM}_{\boldsymbol{\alpha}}(\boldsymbol{\alpha}, i, j, w, Y_{ij}^w) \quad \text{and} \quad (\mu_w', \nu_w') = \text{MM}_{\mu\nu}(\boldsymbol{\alpha}, i, j, w, Y_{ij}^w). \quad (49)$$

Although the equations in Proposition 3 are more complicated than those in Proposition 1, the right-hand sides of (48) are still constants for any given $i, j, w, Y_{ij}^w, \boldsymbol{\alpha}, \mu_w$ and ν_w so that both $\boldsymbol{\alpha}' = \text{MM}_{\boldsymbol{\alpha}}(\boldsymbol{\alpha}, i, j, w, Y_{ij}^w)$ and $(\mu_w', \nu_w') = \text{MM}_{\mu\nu}(\boldsymbol{\alpha}, i, j, w, Y_{ij}^w)$ can be solved in a closed form. In fact, we denote the constants on the right-hand sides of (20) as C_i, C_j, C_k (for $k \neq i, j$), D , E and F , respectively. It is easy to see that $\sum_{k=1}^K C_k = 1$. By the

same derivation for (22), we obtain the following closed form for $\alpha^l = \mathbf{MM}_\alpha(\alpha, i, j, w, Y_{ij}^w)$

$$\alpha_0^l = \frac{D-1}{\sum_{k=1}^K C_k^2 - D} \quad \text{and} \quad \alpha_k^l = C_k \alpha_0^l \quad \text{for } k = 1, 2, \dots, K, \quad (50)$$

which takes the same form as (22) but with the constants C_k for $k = 1, 2, \dots, K$ defined differently (which involve the information of worker w , i.e., μ_w and ν_w). Similarly, solving μ_w^l and ν_w^l from the last two equations in (48), we obtain the following closed form for $(\mu_w^l, \nu_w^l) = \mathbf{MM}_{\mu\nu}(\alpha, i, j, w, Y_{ij}^w)$

$$\mu_w^l = \frac{(F-1)E}{E^2 + (1-E)^2 - F} \quad \text{and} \quad \nu_w^l = \frac{(F-1)(1-E)}{E^2 + (1-E)^2 - F}. \quad (51)$$

Although the approximate scheme above is derived when there is only one comparison result, it generates a Dirichlet distribution $\text{Dir}(\alpha^l)$ for θ and a Beta distribution $\text{Beta}(\mu_w^l, \nu_w^l)$ for ρ_w and does not change the Beta distribution $\text{Beta}(\mu_{w'}^l, \nu_{w'}^l)$ for $w' \neq w$. The fact that the approximated posteriors take the same form as the priors suggests that we can apply this approximation scheme iteratively to approximate $p(\theta|\mathbf{M}^t, \alpha^0, \mu^0, \nu^0)$ and $p(\rho|\mathbf{M}^t, \alpha^0, \mu^0, \nu^0)$ for any given policy $\mathcal{A} = \{(i_t, j_t, w_t)\}_{t=0,1,\dots,T-1}$. In particular, let α^t, μ^t and ν^t be the sequences of parameters generated recursively as follows

$$\alpha^{t+1} = \mathbf{MM}_\alpha(\alpha^t, i_t, j_t, w_t, Y_{i_t j_t}^{w_t}) \quad (52)$$

$$(\mu_w^{t+1}, \nu_w^{t+1}) = \begin{cases} \mathbf{MM}_{\mu\nu}(\alpha^t, i_t, j_t, w_t, Y_{i_t j_t}^{w_t}) & \text{if } w = w_t \\ (\mu_w^t, \nu_w^t) & \text{if } w \neq w_t \end{cases} \quad (53)$$

for $t = 1, 2, \dots, T$. The posterior distributions $p(\theta|\mathbf{M}^t, \alpha^0, \mu^0, \nu^0)$ and $p(\rho|\mathbf{M}^t, \alpha^0, \mu^0, \nu^0)$ can be approximated by $\text{Dir}(\alpha^t)$ and $\Pi_{w=1,\dots,M} \text{Beta}(\mu_w^t, \nu_w^t)$, respectively.

Following the same strategy as in (24) and (25), we can approximate (41) and (42) as

$$\begin{aligned} & \mathbb{E} [\text{Pr}(Y_{ij}^w = 1) | \mathbf{M}^t, \alpha^0, \mu^0, \nu^0] \\ & \approx \mathbb{E} \left[\frac{\rho_w}{\theta_i + \theta_j} + (1 - \rho_w) \frac{\theta_j}{\theta_i + \theta_j} \middle| \theta \sim \text{Dir}(\alpha^t), \rho_w \sim \text{Beta}(\mu_w^t, \nu_w^t) \right] \\ & = \frac{\mu_w^t}{\mu_w^t + \nu_w^t} \frac{\alpha_i^t}{\alpha_i^t + \alpha_j^t} + \frac{\nu_w^t}{\mu_w^t + \nu_w^t} \frac{\alpha_j^t}{\alpha_i^t + \alpha_j^t} \end{aligned} \quad (54)$$

and

$$\begin{aligned} & \mathbb{E} [\text{Pr}(Y_{ij}^w = -1) | \mathbf{M}^t, \alpha^0, \mu^0, \nu^0] \\ & \approx \mathbb{E} \left[\frac{\rho_w}{\theta_i + \theta_j} + (1 - \rho_w) \frac{\theta_i}{\theta_i + \theta_j} \middle| \theta \sim \text{Dir}(\alpha^t), \rho_w \sim \text{Beta}(\mu_w^t, \nu_w^t) \right] \\ & = \frac{\mu_w^t}{\mu_w^t + \nu_w^t} \frac{\alpha_j^t}{\alpha_i^t + \alpha_j^t} + \frac{\nu_w^t}{\mu_w^t + \nu_w^t} \frac{\alpha_i^t}{\alpha_i^t + \alpha_j^t} \end{aligned} \quad (55)$$

and approximate $\text{Pr}(\theta_i > \theta_j | \mathbf{M}^t, \alpha^0, \mu^0, \nu^0)$ in (37) as

$$\text{Pr}(\theta_i > \theta_j | \mathbf{M}^t, \alpha^0, \mu^0, \nu^0) \approx \text{Pr}(\theta_i > \theta_j | \theta \sim \text{Dir}(\alpha^t)) = I_{\frac{1}{2}}(\alpha_j^t, \alpha_i^t). \quad (56)$$

The approximation (56) helps to simplify the NP-hard MAX-LOP in (37) as

$$\max_{\pi} \mathbb{E} [\tau(\pi, \pi^*) | \mathbf{M}^t, \alpha^0, \mu^0, \nu^0] \approx \max_{\pi} \mathbb{E} [\tau(\pi, \pi^*) | \theta \sim \text{Dir}(\alpha^t)],$$

where the right-hand side can be solved easily by sorting of the components of α^t according to Theorem 2.

Similar to (29), the stage-wise reward is approximated as

$$\begin{aligned} R(\mathbf{M}^t, i, j, w, Y_{ij}^w) &= \max_{\pi} \mathbb{E} [\tau(\pi, \pi^*) | \mathbf{M}^{t+1}, \alpha^0, \mu^0, \nu^0] - \max_{\pi} \mathbb{E} [\tau(\pi, \pi^*) | \mathbf{M}^t, \alpha^0, \mu^0, \nu^0] \\ &\approx \max_{\pi} \mathbb{E} [\tau(\pi, \pi^*) | \theta \sim \text{Dir}(\hat{\alpha})] - \max_{\pi} \mathbb{E} [\tau(\pi, \pi^*) | \theta \sim \text{Dir}(\alpha^t)] \\ &= \frac{2}{K(K-1)} \left(\sum_{\pi_{\alpha}(i') > \pi_{\alpha}(j')} I_{\frac{1}{2}}(\hat{\alpha}_{j'}, \hat{\alpha}_{i'}) - \sum_{\pi_{\alpha}(i') > \pi_{\alpha}(j')} I_{\frac{1}{2}}(\alpha_{j'}^t, \alpha_{i'}^t) \right) \\ &\equiv \tilde{R}(\alpha^t, i, j, w, Y_{ij}^w) \end{aligned} \quad (57)$$

where $\hat{\alpha} = \mathbf{MM}_\alpha(\alpha^t, i, j, w, Y_{ij}^w)$. Putting (54), (55), (56) and (57) together, we can approximate the expected stage-wise reward $\mathbb{E} [\tilde{R}(\mathbf{M}^t, i, j, w, Y_{ij}^w) | \mathbf{M}^t, \alpha^0, \mu^0, \nu^0]$ as

$$\begin{aligned} & \mathbb{E} [R(\mathbf{M}^t, i, j, w, Y_{ij}^w) | \mathbf{M}^t, \alpha^0, \mu^0, \nu^0] \\ &= \mathbb{E} [\text{Pr}(Y_{ij}^w = 1) | \mathbf{M}^t, \alpha^0, \mu^0, \nu^0] R(\alpha^t, i, j, w, 1) \\ &+ \mathbb{E} [\text{Pr}(Y_{ij}^w = -1) | \mathbf{M}^t, \alpha^0, \mu^0, \nu^0] R(\alpha^t, i, j, w, -1) \\ &\approx \left(\frac{\mu_w^t}{\mu_w^t + \nu_w^t} \frac{\alpha_i^t}{\alpha_i^t + \alpha_j^t} + \frac{\nu_w^t}{\mu_w^t + \nu_w^t} \frac{\alpha_j^t}{\alpha_i^t + \alpha_j^t} \right) \tilde{R}(\alpha^t, i, j, w, 1) \\ &+ \left(\frac{\mu_w^t}{\mu_w^t + \nu_w^t} \frac{\alpha_j^t}{\alpha_i^t + \alpha_j^t} + \frac{\nu_w^t}{\mu_w^t + \nu_w^t} \frac{\alpha_i^t}{\alpha_i^t + \alpha_j^t} \right) \tilde{R}(\alpha^t, i, j, w, -1). \end{aligned} \quad (58)$$

When the workers have various levels of reliability, our AKG policy will choose the pair (i_t, j_t) and present it to worker w_t so that (58) is maximized. The AKG policy for the setting of heterogeneous workers is formally presented as Algorithm 2. Note that when $\rho_w = 1$ for all w , we do not need to solve (46) and (47) anymore and thus the rest of the problem reduces to the homogeneous setting.

5. Experiment

In this section, we conduct empirical studies using both simulated and real data. We compare the proposed AKG algorithms to some existing methods in terms of ranking accuracy versus different levels of budget as well as computation time. We also show some interesting properties of the proposed AKG policies, e.g., how budget will be allocated over pairs of items with different levels of ambiguity and workers with different levels of reliability. The ranking accuracy is evaluated using the Kendall's tau as defined in (5).

Algorithm 2 Approximated Knowledge Gradient Policy with Heterogeneous Workers

Initialization: Choose α^0 , μ^0 and ν^0 for the prior distributions.

For $t = 0, \dots, T - 1$ **do**

- 1: For each pair (i, j) with $i < j$, compute $\tilde{R}(\alpha^t, i, j, w, 1)$ and $\tilde{R}(\alpha^t, i, j, w, -1)$ according to (57).
- 2: Select (i_t, j_t, w_t) such that

$$(i_t, j_t) \in \underset{i < j, w}{\operatorname{argmax}} \left[\left(\frac{\mu_w^t}{\mu_w^t + \nu_w^t} \frac{\alpha_i^t}{\alpha_i^t + \alpha_j^t} + \frac{\nu_w^t}{\mu_w^t + \nu_w^t} \frac{\alpha_j^t}{\alpha_i^t + \alpha_j^t} \right) \tilde{R}(\alpha^t, i, j, w, 1) \right. \\ \left. + \left(\frac{\mu_w^t}{\mu_w^t + \nu_w^t} \frac{\alpha_j^t}{\alpha_i^t + \alpha_j^t} + \frac{\nu_w^t}{\mu_w^t + \nu_w^t} \frac{\alpha_i^t}{\alpha_i^t + \alpha_j^t} \right) \tilde{R}(\alpha^t, i, j, w, -1) \right] \quad (59)$$

and present item i_t and item j_t to worker w_t and receive the comparison result $Y_{i_t, j_t}^{w_t}$.

- 3: According to (49), (50) and (51), compute

$$\alpha^{t+1} = \operatorname{MM}_\alpha(\alpha^t, i_t, j_t, w_t, Y_{i_t, j_t}^{w_t}) \quad (60)$$

$$\begin{pmatrix} \mu_w^{t+1} \\ \nu_w^{t+1} \end{pmatrix} = \begin{cases} \operatorname{MM}_{\mu\nu}(\alpha^t, i_t, j_t, w_t, Y_{i_t, j_t}^{w_t}) & \text{if } w = w_t \\ \begin{pmatrix} \mu_w^t \\ \nu_w^t \end{pmatrix} & \text{if } w \neq w_t \end{cases} \quad (61)$$

End For

Return: The aggregated ranking π_{α^T} obtained by sorting the components of α^T .

5.1 Simulated Study under the Homogeneous Workers Setting

In this section, we assume that all workers are fully reliable and investigate the performance of the AKG policy (Algorithm 1). Two scenarios are designed: 10 items with a total budget of 100, and 100 items with a total budget of 1000. Each scenario consists of 100 independent trials and the average ranking accuracy is reported. For each trial, the latent item scores θ is sampled uniformly from the simplex in (6), which determines the true ranking π^* . Given θ , the comparison results are generated according to the Bradley-Terry-Luce model (3). We compare several different methods, including the proposed AKG, random sampling (uniformly random sampling), distance-based sampling, adaptive polling (Peiffer et al., 2012) and rank centrality with uniform sampling or knowledge gradient sampling (Negahban et al., 2012). The details of the methods are provided as follows.

1. **AKG** (see Algorithm 1): We set the prior of θ to be the uniform distribution on the simplex (i.e., α^0 is set to be an all-one vector).

2. **Random Sampling:** The random sampling algorithm is similar to Algorithm 1 in terms of the posterior approximation (by moment matching) and rank inference (by sorting the approximated posterior parameters α^t) after receiving each label. The only difference is that this algorithm replaces Step 2 of Algorithm 1 by a random sampling policy, which selects (i_t, j_t) randomly at each stage. We also choose the uniform distribution on the simplex as the prior.

3. **Distance-Based Sampling:** This algorithm is also the same as Algorithm 1 in terms of the posterior approximation. However, in the sampling phase, this algorithm simply selects the pair of items (i_t, j_t) with the closest posterior parameters α_i^t and α_j^t . We choose the uniform distribution on the simplex as the prior.

4. **Adaptive Polling:** This is a greedy policy proposed by Peiffer et al. (2012), which chooses the pair of items to maximize the KL-divergence between the posterior and prior. The initial $K \times K$ matrix M used in adaptive polling is set to 0 on the diagonal and 0.15 everywhere else.

5. **Rank Centrality:** This is a static rank aggregation algorithm recently proposed by Negahban et al. (2012). We combine it with both the random sampling policy and the knowledge gradient policy. Specifically, for **Centrality + RS**, we randomly select a pair of items at each stage and infer the true ranking using rank centrality. For **Centrality + KG**, we select the next pair of items using AKG policy, but estimate the ranking using rank centrality.

It is worthwhile to point out that we are able to compute the optimal policy exactly only up to the 4-item case, which is not interesting from the ranking perspective and thus is left out from the experiment.

As we can see from Figure 1, the AKG policy has higher accuracy than other methods at all budget levels. Note that the average accuracy of AKG surpasses the level of 70% with only 20 pairs in the case of 10 items. In general, random sampling has similar performance as AKG at the beginning, but eventually AKG will outperform random sampling as it will spend more budget on the ambiguous pairs. This will be verified in the next experiment. Meanwhile, if we combine rank centrality with knowledge gradient sampling, the performance of the algorithm can be boosted significantly. Furthermore, the curves of ranking accuracy of AKG are in general monotonically increasing and have fewer ‘‘bumps’’ than other algorithms. This implies that the sequence of posterior parameters α^t is quite stable when the budget level becomes larger. We also note that due to the high computational cost of adaptive polling, it takes extremely long time when the number of items is 100 and thus we omit its performance in Figure 1b.

It is worthwhile to note that AKG runs significantly faster than the adaptive polling method. It enjoys the advantage of closed-form updating rule during each iteration/stage without using a numerical algorithm as a subroutine, which is a good feature for online applications. In contrast, adaptive polling is much slower because it requires inverting a $K \times K$ matrix for all $O(K^2)$ possible pairs and all possible comparison results in each iteration. Table 1 gives the computation time of a *single iteration* for both AKG and adaptive polling. Note that in the 25-item case, the computation time for adaptive polling of a single iteration has already exceeded 40 minutes. Therefore, we omit to present the computation time of adaptive polling when the number of items is 100 in Table 1 since each iteration/stage would take hours to run.

Next, we study the allocation of labeling budget over pairs of items with different levels of ambiguity when using the AKG policy. Again, we consider two scenarios: $K = 10, T = 100$ and $K = 100, T = 1000$, each with 100 independent trials. We report the averaged labeling frequency of each pair. The results are presented in Figure 2 in the form of heat maps.

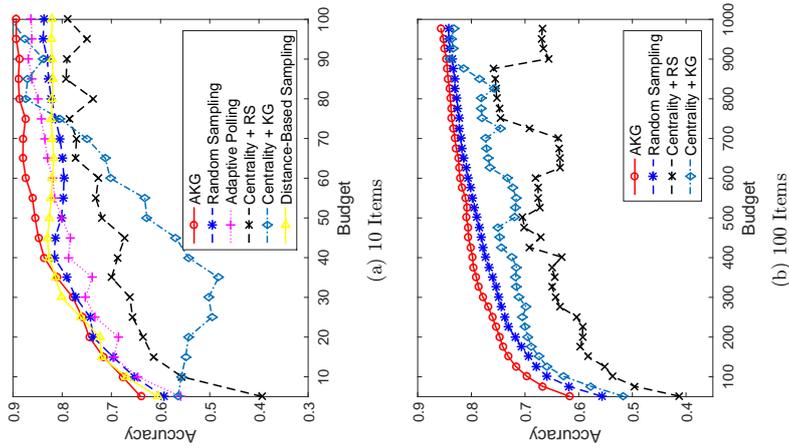

Figure 1: Performance comparison under the homogeneous workers setting. The x -axis is the budget level and y -axis is the averaged ranking accuracy.

Table 1: Comparison in computation time under the homogeneous workers setting.

No. of Items	AKG	Adaptive Polling
10	0.023 sec	20 sec
25	0.75 sec	42 min
100	22 sec	-

In Figure 2, each small block represents a pair of items. Items are sorted based on their true latent scores, from lowest to highest along both y -axis and x -axis, so that the item pairs along the back-diagonal are more ambiguous than those around the corner. Figure

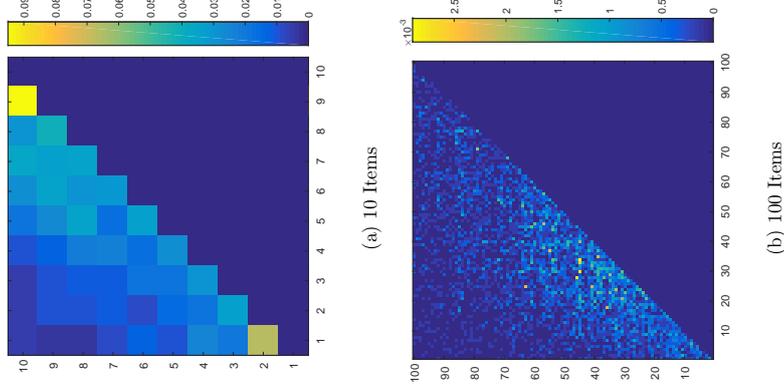

Figure 2: Heat map of labeling frequency for item pairs with different levels of ambiguity

2 presents the normalized number of comparisons over different pairs in total T stages. It can be seen from Figure 2 that the back-diagonal pairs in general have higher labeling frequency than other pairs. Some adjacent pairs are labeled 10 times more frequently than the distant pairs. To further demonstrate this property, we design a scenario in which out of 10 items, the two best items and the two worst items have very close true scores respectively. Although the main goal of the algorithm is to achieve higher ranking accuracy, we are still curious to see whether our policy can spend the budget on these two pairs. As we can see from Figure 3, it is clear that the algorithm concentrates on the 1-2 pair and the 9-10 pair. This implies that our policy can identify and explore more ambiguous pairs to improve the learning of the true ranks.

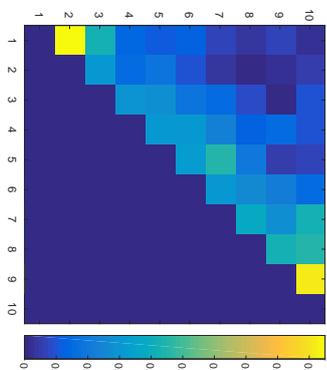

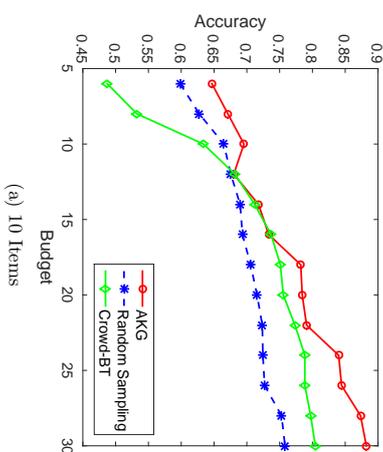

Figure 3: Heat map of labeling frequency for pairs with very close scores

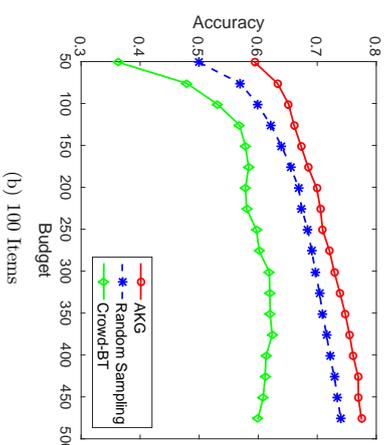

5.2 Simulated Study under the Heterogeneous Workers Setting

In this section we bring worker quality ρ_w into consideration, which is assumed to be drawn from the Beta(4,1) distribution. We choose the Beta(4,1) to generate ρ_w since the average reliability measure of workers in this case is $4/5 = 80\%$. This assumption is in line with the practice in that there are usually more reliable workers than unreliable ones. Similar to the homogeneous worker setting, we consider two scenarios: 10 items with 10 heterogeneous workers ($K = 10, M = 10$); 100 items with 50 heterogeneous workers ($K = 100, M = 50$) and we note that each worker is allowed to label any pair at most once. We compare the following three methods.

1. **AKG** (see Algorithm 2): We set the prior of θ to be the uniform distribution on the simplex (i.e., α^0 is set to be an all-one vector) and choose $\mu_w^0 = 4, \nu_w^0 = 1$ for each worker $w = 1, 2, \dots, M$.
2. **Random Sampling**: It is implemented simply by replacing Step 2 of Algorithm 2 by a random sampling policy, which selects a triplet $\{item\ i, item\ j, worker\ w\}$ uniformly randomly at each stage. The choices of priors are the same as in AKG. Like the AKG method, the random sampling algorithm also maintains a Dirichlet distribution for the scores of items and a beta distribution for the reliability parameter of each worker using moment matching.
3. **Crowd-BT**: This is an adaptive algorithm recently proposed by Chen et al. (2013), which chooses the triplet $\{item\ i, item\ j, worker\ w\}$ at each iteration to maximize the information gain. This can be viewed as an extension of the adaptive polling (Peiffer et al., 2012) by incorporating the workers' reliability. Unlike adaptive polling which computes the relative entropy for each pair exactly, Crowd-BT uses moment matching to approximate the posterior and hence runs significantly faster than adaptive polling. The parameter γ , which balances the exploitation-exploration trade-off in Chen et al. (2013), is set to 1 in this experiment.

(a) 10 Items

(b) 100 Items

Figure 4: Performance comparison under the heterogeneous workers setting. The x -axis is the budget level and y -axis is the averaged ranking accuracy.

The comparison results are presented in Figure 4, where AKG outperforms the other two methods, especially when the budget level is low. The performance of random sampling is comparable to AKG at the beginning. As we gather more information, AKG can learn the reliability of workers so that the budget will be gradually shifted towards those reliable workers (as shown later in Figure 7). In fact, it can be seen from Figure 4 that the ranking accuracy of AKG increases more quickly than that of other methods. In this experiment, even if there is a small amount of budget (e.g. $T = K$), the AKG policy is still able to achieve reasonably good performance. We notice that in the 100-item case Crowd-BT is beaten by random sampling. The main reason is that when the reliability of workers varies and the pool is large, it is difficult to balance exploration and exploitation for Crowd-BT,

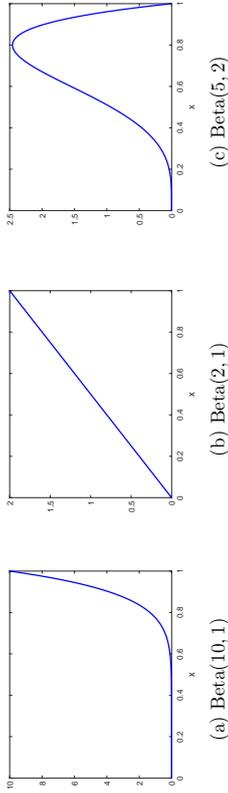

Figure 5: Density plots of different Beta distributions for generating ρ_w

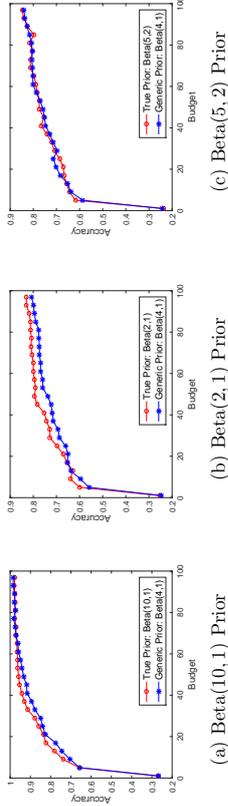

Figure 6: Comparisons between AKG using Beta(4,1) prior and AKG using the true generating distribution as prior.

Table 2: Computation time under the heterogeneous workers setting.

No. of Items	No. of Workers	AKG
10	10	0.038 sec
25	20	0.82 sec
100	50	41 sec

which has already been acknowledged in Chen et al. (2013). Similar to the previous setting, we also give the table of the computation time of a *single iteration* for AKG in Table 2. As we can see from the table, even with another dimension of uncertainty — the reliability of workers, AKG is still quite fast, and thus is suitable for online implementation.

In order to investigate how sensitive the prior for workers' reliability ρ_w is, we generate the workers' true reliability parameters from three different distributions, Beta(10, 1), Beta(2, 1), and Beta(5, 2), and compare the performances of AKG between using the true generating distribution as the prior and using the generic Beta(4, 1) as the prior. The results are plotted in Figure 6. As one can see from Figure 6, using the true generating distribution and generic Beta(4, 1) prior lead to very similar performance in all three cases. Although there are some small differences between the two groups of curves, they are not significant as to the overall performance of the algorithm. This result shows that when there is no

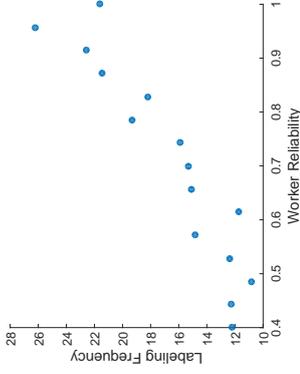

Figure 7: Averaged number of comparisons (a.k.a., labeling frequency) made by workers with different levels of reliability ρ_w .

exact information on the quality of all workers, Beta(4, 1) is a reasonable prior for workers' reliability and the proposed AKG policy is quite robust to the prior distribution in use.

Finally, we investigate whether good workers are indeed assigned more comparison tasks by our AKG policy in the setting of heterogeneous workers. In particular, we consider $k = 10$ items and $M = 15$ workers with the workers' true reliability parameters $\rho_w, w = 1, 2, \dots, M$ ranging from 0.4 to 1 with an equal space in between. This crowd of workers is fixed and the total budget in each trial $T = 250$. We report the averaged number of pairs assigned to workers with different levels of reliability in Figure 7. As one can see from Figure 7, there is a clear trend that more reliable workers receive more pairs on average.

5.3 Real Data Study

We now apply the proposed AKG policy (Algorithm 2) to a real dataset on reading difficulty levels (Collins-Thompson and Callan, 2004). The dataset comprises $K = 491$ different paragraphs, each assigned an integer-valued true reading difficulty score ranging from 1, 2, ..., 12. Here, a higher score means the paragraph is more difficult to read. A total number of $M = 217$ different workers from Canada and the United States performed the comparison tasks on an online crowdsourcing platform called CrowdFlower³. Each worker was presented a pair of paragraphs every time and the worker identified which paragraph is more difficult to read. To overcome the issue of an imbalanced judgemental pool, each worker was allowed to compare at most 40 different pairs. There are 7,898 pairwise comparison results available in this dataset. Using these pairwise labels, we apply the AKG policy to recover the ranking by difficulty of these 491 paragraphs. We note that since the underlying truth is given as a difficulty level (1–12) for each paragraph (denoted by s_i for $i = 1, \dots, K$) instead of a global ranking, we measure the accuracy of a ranking π as

$$\frac{2}{K(K-1)} \sum_{i \neq j} \mathbf{1}_{(\pi(i) > \pi(j))} \mathbf{1}_{(s_i \geq s_j)}.$$

3. <http://www.crowdflower.com/>

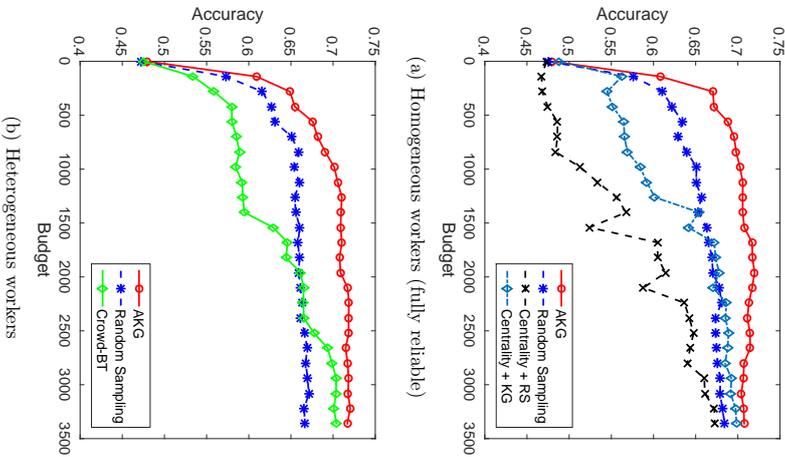

Figure 8: Performance comparison on the real dataset

In the above definition of ranking accuracy, when two paragraphs have the same reading difficulty level, any ranking between this pair will be treated as correct. It is also worth noting that, in the knowledge gradient step in (59), it is possible that the selected triplet (i_t, j_t, w_t) does not exist in the dataset (i.e., the worker w_t did not compare i_t and j_t in this data). Hence, in our implementation of AKG, we select the triplet in the dataset that maximizes the right-hand side of (59). We set the prior of θ to be the uniform distribution on the simplex. This dataset also comes with a rating for each worker which measures the long-run performance of this worker on CrowdFlower. A higher rating implies a higher reliability of the worker. This dataset shows the averaged workers' rating is above 0.75. Thus, we still use Beta(4,1) as the prior on workers' reliability.

We run experiments in two different settings. The first one assumes that all workers are homogeneous and fully reliable. In this setting, we only need to select the next pair of paragraphs to compare but can randomly choose a worker to perform the comparison task. In this case, four algorithms are implemented (AKG policy (Algorithm 1), random sampling, rank centrality with the random sampling policy, and rank centrality with the knowledge gradient policy) and we report the averaged accuracy over 100 independent trials in Figure 8a to minimize the sampling effect of randomly selecting the next worker. The second experiment incorporates the heterogeneous reliability of workers so that the algorithms have to select both the pair to compare and the worker to perform the comparison task. In this case, three algorithms, AKG policy (Algorithm 2), random sampling and Crowd-BT, are implemented and the result is shown in Figure 8b. As one can see from these two plots, AKG outperforms the other methods in both settings, especially when the amount of budget is relatively low. As the budget level increases, the performance of Crowd-BT and rank centrality will eventually improve and achieve a similar accuracy as AKG.

6. Conclusion

In this paper, we address the dynamic budget allocation problem in crowdsourced ranking. Using the Kendall's tau with respect to the true ranking as the measure of ranking accuracy, we formulate the problem of maximizing expected Kendall's tau by sequential comparisons into a Bayesian Markov decision process. To further address the computational challenges (especially, solving the NP-hard MAX-TOP) involved in the decision process, we propose an approximated knowledge gradient policy, which is not only computationally efficient but also achieves good performance as shown in the experimental sections.

We note that although this paper focuses on the Bradley-Terry-Luce model (Bradley and Terry, 1952; Luce, 1959), it will be interesting to study the dynamic sampling in crowdsourced ranking for other ranking models such as permutation-based models (e.g., Mallows (Mallows, 1957) and CPS (Qin et al., 2010) models) or stochastically transitive models (Fishburn, 1973; Shah et al., 2016b)). Meanwhile, theoretical bounds on posterior approximation errors are difficult to obtain and error propagation does exist during each iteration of the algorithm. In our future analysis we would like to quantify this error. Another interesting future direction is to incorporate the feature information of each item into the probabilistic model of the pairwise comparison results and develop a dynamic sampling policy that can further improve the ranking accuracy via modeling the feature information.

Appendix

In this section, we provide detailed proofs of some propositions in the paper.

Proof (of Proposition 1)

We will only show that (18) and (19) can be represented as (20) when $Y_{ij} = 1$. The proof for $Y_{ij} = -1$ is similar.

It is known that $\mathbb{E}[\theta_k|\boldsymbol{\theta} \sim \text{Dir}(\boldsymbol{\alpha}')] = \frac{\alpha'_k}{\alpha'_0}$ and $\mathbb{E}[\theta_k^2|\boldsymbol{\theta} \sim \text{Dir}(\boldsymbol{\alpha}')] = \frac{\alpha'_k(\alpha'_k+1)}{\alpha'_0(\alpha'_0+1)}$ for $k = 1, 2, \dots, K$, which characterize the left-hand sides of (18) and (19).

With elementary calculus, we can show

$$\Pr(Y_{ij} = 1|\boldsymbol{\alpha}) = \int_{\Delta} \frac{\theta_i}{\theta_i + \theta_j} \frac{1}{\text{B}(\boldsymbol{\alpha})} \prod_{k=1}^K \theta_k^{\alpha_k-1} d\boldsymbol{\theta} = \frac{\alpha_i}{\alpha_i + \alpha_j} \quad (62)$$

so that

$$p(\boldsymbol{\theta}|Y_{ij} = 1, \boldsymbol{\alpha}) = \frac{p(\boldsymbol{\theta}, Y_{ij} = 1|\boldsymbol{\alpha})}{\Pr(Y_{ij} = 1|\boldsymbol{\alpha})} = \frac{\alpha_i + \alpha_j}{\alpha_i} \frac{\theta_i}{\theta_i + \theta_j} \frac{1}{\text{B}(\boldsymbol{\alpha})} \prod_{k=1}^K \theta_k^{\alpha_k-1}. \quad (63)$$

Let $\boldsymbol{\beta} = (\beta_1, \dots, \beta_K)$ with $\beta_i = \alpha_i + 1$ and $\beta_k = \alpha_k$ for $k \neq i$. Then, we can show that

$$\begin{aligned} \mathbb{E}[\theta_i|Y_{ij} = 1, \boldsymbol{\alpha}] &= \frac{\alpha_i + \alpha_j}{\alpha_i} \left[\int_{\Delta} \frac{\theta_i^2}{\theta_i + \theta_j} \frac{1}{\text{B}(\boldsymbol{\alpha})} \prod_{k=1}^K \theta_k^{\alpha_k-1} d\boldsymbol{\theta} \right] \\ &= \frac{\alpha_i + \alpha_j}{\alpha_0} \left[\int_{\Delta} \frac{\theta_i}{\theta_i + \theta_j} \frac{1}{\text{B}(\boldsymbol{\beta})} \prod_{k=1}^K \theta_k^{\beta_k-1} d\boldsymbol{\theta} \right] \\ &= \frac{\alpha_i + 1}{\alpha_0} \frac{\alpha_i + \alpha_j}{\alpha_i + \alpha_j + 1}, \end{aligned} \quad (64)$$

where the first and the third equalities are due to (62) and (63) and the second equality is by the definition of $\boldsymbol{\beta}$ and the property $\Gamma(x+1) = x\Gamma(x)$ of Gamma function. Using a similar argument, we can show that

$$\mathbb{E}[\theta_j|Y_{ij} = 1, \boldsymbol{\alpha}] = \frac{\alpha_j}{\alpha_0} \frac{\alpha_i + \alpha_j}{\alpha_i + \alpha_j + 1} \quad (65)$$

$$\mathbb{E}[\theta_k|Y_{ij} = 1, \boldsymbol{\alpha}] = \frac{\alpha_k}{\alpha_0} \quad \text{for } k \neq i, j \quad (66)$$

$$\mathbb{E}[\theta_i^2|Y_{ij} = 1, \boldsymbol{\alpha}] = \frac{\alpha_i + 1}{\alpha_0} \frac{\alpha_i + 2}{\alpha_0 + 1} \frac{\alpha_i + \alpha_j}{\alpha_i + \alpha_j + 2} \quad (67)$$

$$\mathbb{E}[\theta_j^2|Y_{ij} = 1, \boldsymbol{\alpha}] = \frac{\alpha_j}{\alpha_0} \frac{\alpha_j + 1}{\alpha_0 + 1} \frac{\alpha_i + \alpha_j}{\alpha_i + \alpha_j + 2} \quad (68)$$

$$\mathbb{E}[\theta_k^2|Y_{ij} = 1, \boldsymbol{\alpha}] = \frac{\alpha_k}{\alpha_0} \frac{\alpha_k + 1}{\alpha_0 + 1} \quad \text{for } k \neq i, j. \quad (69)$$

Note that, when $Y_{ij} = 1$, the right-hand sides of (18) and (19) can be represented as the right-hand side of (20) using (64)~(69) \blacksquare

Proof (of Proposition 3)

We will only show the conclusion when $Y_{ij}^w = 1$. The proof for $Y_{ij}^w = -1$ is similar.

When $Y_{ij}^w = 1$, we have $\eta_{ijw} = \frac{\mu_w \alpha_i}{\mu_w \alpha_i + \nu_w \alpha_j}$. We will first show (44) and (45) can be represented as the first four equations in (48). Since $\mathbb{E}[\theta_k|\boldsymbol{\theta} \sim \text{Dir}(\boldsymbol{\alpha}')] = \frac{\alpha'_k}{\alpha'_0}$ and $\mathbb{E}[\theta_k^2|\boldsymbol{\theta} \sim \text{Dir}(\boldsymbol{\alpha}')] = \frac{\alpha'_k(\alpha'_k+1)}{\alpha'_0(\alpha'_0+1)}$ for $k = 1, 2, \dots, K$, the left-hand sides of the first four equations in (48) and those of (44) and (45) are identical.

With (62) and some basic properties of the Beta distribution, we can show

$$\begin{aligned} \Pr(Y_{ij}^w = 1|\boldsymbol{\alpha}, \mu_w, \nu_w) &= \mathbb{E} \left[\frac{\rho_w}{\theta_i + \theta_j} + (1 - \rho_w) \frac{\theta_j}{\theta_i + \theta_j} \middle| \boldsymbol{\theta} \sim \text{Dir}(\boldsymbol{\alpha}), \rho_w \sim \text{Beta}(\mu_w, \nu_w) \right] \\ &= \frac{\mu_w}{\mu_w + \nu_w} \frac{\alpha_i}{\alpha_i + \alpha_j} + \frac{\nu_w}{\mu_w + \nu_w} \frac{\alpha_j}{\alpha_i + \alpha_j} \end{aligned} \quad (70)$$

so that

$$\begin{aligned} p(\boldsymbol{\theta}, \rho_w|Y_{ij}^w = 1, \boldsymbol{\alpha}, \mu_w, \nu_w) &= \frac{\theta_i}{\left(\frac{\rho_w}{\theta_i + \theta_j} + (1 - \rho_w) \frac{\theta_j}{\theta_i + \theta_j} \right)} \frac{1}{\text{B}(\boldsymbol{\alpha}) \text{B}(\mu_w, \nu_w)} \prod_{k=1}^K \theta_k^{\alpha_k-1} \rho_w^{\mu_w-1} (1 - \rho_w)^{\nu_w-1} \\ &= \frac{\frac{\mu_w}{\mu_w + \nu_w} \frac{\alpha_i}{\alpha_i + \alpha_j} + \frac{\nu_w}{\mu_w + \nu_w} \frac{\alpha_j}{\alpha_i + \alpha_j}}{\frac{\mu_w}{\mu_w + \nu_w} \frac{\alpha_i}{\alpha_i + \alpha_j} + (1 - \rho_w) \frac{\theta_j}{\theta_i + \theta_j}} \frac{1}{\text{B}(\boldsymbol{\alpha}) \text{B}(\mu_w, \nu_w)} \prod_{k=1}^K \theta_k^{\alpha_k-1} \rho_w^{\mu_w-1} (1 - \rho_w)^{\nu_w-1}. \end{aligned} \quad (71)$$

The equations (70) and (71), together with (64), imply

$$\begin{aligned} \mathbb{E}[\theta_i|Y_{ij}^w = 1, \boldsymbol{\alpha}, \mu_w, \nu_w] &= \frac{\int_0^1 \int_{\Delta} \frac{\theta_i^2}{\left(\frac{\rho_w}{\theta_i + \theta_j} + (1 - \rho_w) \frac{\theta_j}{\theta_i + \theta_j} \right)} \frac{1}{\text{B}(\boldsymbol{\alpha}) \text{B}(\mu_w, \nu_w)} \prod_{k=1}^K \theta_k^{\alpha_k-1} \rho_w^{\mu_w-1} (1 - \rho_w)^{\nu_w-1} d\boldsymbol{\theta} d\rho_w}{\int_{\Delta} \left(\frac{\mu_w}{\mu_w + \nu_w} \frac{\theta_i^2}{\theta_i + \theta_j} + \frac{\nu_w}{\mu_w + \nu_w} \frac{\theta_j}{\theta_i + \theta_j} \right) \frac{1}{\text{B}(\boldsymbol{\alpha})} \prod_{k=1}^K \theta_k^{\alpha_k-1} d\boldsymbol{\theta}} \\ &= \frac{\frac{\mu_w}{\mu_w + \nu_w} \frac{\alpha_i}{\alpha_i + \alpha_j} + \frac{\nu_w}{\mu_w + \nu_w} \frac{\alpha_j}{\alpha_i + \alpha_j}}{\frac{\mu_w}{\mu_w + \nu_w} \frac{\alpha_i}{\alpha_i + \alpha_j} + \frac{\nu_w}{\mu_w + \nu_w} \frac{\alpha_j}{\alpha_i + \alpha_j}} \frac{\frac{\mu_w}{\mu_w + \nu_w} \frac{\alpha_i}{\alpha_i + \alpha_j}}{\frac{\mu_w}{\mu_w + \nu_w} \frac{\alpha_i}{\alpha_i + \alpha_j} + \frac{\nu_w}{\mu_w + \nu_w} \frac{\alpha_j}{\alpha_i + \alpha_j}} \\ &= \frac{\frac{\mu_w}{\mu_w + \nu_w} \frac{\alpha_i}{\alpha_i + \alpha_j} + \frac{\nu_w}{\mu_w + \nu_w} \frac{\alpha_j}{\alpha_i + \alpha_j}}{\frac{\mu_w}{\mu_w + \nu_w} \frac{\alpha_i}{\alpha_i + \alpha_j} + \frac{\nu_w}{\mu_w + \nu_w} \frac{\alpha_j}{\alpha_i + \alpha_j}} \frac{\frac{\mu_w}{\mu_w + \nu_w} \frac{\alpha_i}{\alpha_i + \alpha_j}}{\frac{\mu_w}{\mu_w + \nu_w} \frac{\alpha_i}{\alpha_i + \alpha_j} + \frac{\nu_w}{\mu_w + \nu_w} \frac{\alpha_j}{\alpha_i + \alpha_j}} \\ &= \eta_{ijw} \frac{\alpha_0(\alpha_i + \alpha_j + 1)}{\alpha_0(\alpha_i + \alpha_j) + 1} + (1 - \eta_{ijw}) \frac{\alpha_i(\alpha_i + \alpha_j)}{\alpha_0(\alpha_i + \alpha_j) + 1}. \end{aligned} \quad (72)$$

Using a similar argument, we can show that

$$\mathbb{E}[\theta_j^w | Y_{ij}^{vw} = 1, \alpha, \mu_w, \nu_w] = \eta_{ij}^{vw} \frac{\alpha_j(\alpha_i + \alpha_j)}{\alpha_0(\alpha_i + \alpha_j + 1)} + (1 - \eta_{ij}^{vw}) \frac{(\alpha_j + 1)(\alpha_i + \alpha_j)}{\alpha_0(\alpha_i + \alpha_j + 1)} \quad (73)$$

$$\mathbb{E}[\theta_k | Y_{ij}^{vw} = 1, \alpha, \mu_w, \nu_w] = \frac{\alpha_k}{\alpha_0} \quad \text{for } k \neq i, j \quad (74)$$

$$\mathbb{E}[\theta_i^w | Y_{ij}^{vw} = 1, \alpha, \mu_w, \nu_w] = \frac{\eta_{ij}^{vw}(\alpha_i + 1)(\alpha_i + \alpha_j)}{\alpha_0(\alpha_0 + 1)(\alpha_i + \alpha_j + 2)} + \frac{(1 - \eta_{ij}^{vw})\alpha_i(\alpha_i + 1)(\alpha_i + \alpha_j)}{\alpha_0(\alpha_0 + 1)(\alpha_i + \alpha_j + 2)} \quad (75)$$

$$\mathbb{E}[\theta_j^w | Y_{ij}^{vw} = 1, \alpha, \mu_w, \nu_w] = \frac{\eta_{ij}^{vw}\alpha_j(\alpha_j + 1)(\alpha_i + \alpha_j)}{\alpha_0(\alpha_0 + 1)(\alpha_i + \alpha_j + 2)} + \frac{(1 - \eta_{ij}^{vw})(\alpha_j + 1)(\alpha_i + \alpha_j + 2)(\alpha_i + \alpha_j)}{\alpha_0(\alpha_0 + 1)(\alpha_i + \alpha_j + 2)} \quad (76)$$

$$\mathbb{E}[\theta_k^w | Y_{ij}^{vw} = 1, \alpha, \mu_w, \nu_w] = \frac{\alpha_k}{\alpha_0} \frac{\alpha_k + 1}{\alpha_0 + 1} \quad \text{for } k \neq i, j. \quad (77)$$

In the next, we will show (46) and (47) can be represented as the last two equations in (48). When $Y_{ij}^{vw} = 1$, the last two equations in (48) become

$$\begin{cases} \frac{\mu_w}{\eta_{ij}^{vw} \mu_w + \nu_w + 1} + (1 - \eta_{ij}^{vw}) \frac{\mu_w}{\mu_w + \nu_w + 1} = \eta_{ij}^{vw} k \frac{(\mu_w + 1)(\mu_w + 2)}{(\mu_w + \nu_w + 1)(\mu_w + \nu_w + 2)} + (1 - \eta_{ij}^{vw}) \frac{(\mu_w)(\mu_w + 1)}{(\nu_w + 1)(\nu_w + 2)} \\ \frac{\mu_w}{(\mu_w + \nu_w + 1)(\nu_w + 1)} + (1 - \eta_{ij}^{vw}) \frac{\mu_w}{(\mu_w + \nu_w + 1)(\nu_w + 2)} = \eta_{ij}^{vw} k \frac{(\mu_w + 1)(\mu_w + 2)}{(\mu_w + \nu_w + 1)(\mu_w + \nu_w + 2)} + (1 - \eta_{ij}^{vw}) \frac{(\mu_w + 1)(\nu_w + 2)}{(\nu_w + 1)(\nu_w + 2)}. \end{cases} \quad (78)$$

It is known that $\mathbb{E}[\rho_w | \rho_w \sim \text{Beta}(\mu_w', \nu_w')] = \frac{\mu_w'}{\mu_w' + \nu_w'}$, $\mathbb{E}[\rho_w^2 | \rho_w \sim \text{Beta}(\mu_w', \nu_w')] = \frac{\mu_w'(\mu_w' + 1)}{(\mu_w' + \nu_w')(\mu_w' + \nu_w' + 1)}$ and $\mathbb{E}[(1 - \rho_w)^2 | \rho_w \sim \text{Beta}(\mu_w', \nu_w')] = \frac{\nu_w'(\nu_w' + 1)}{(\mu_w' + \nu_w')(\mu_w' + \nu_w' + 1)}$, indicating that the left-hand sides of (46) and (47) match those of (78).

To characterize the right-hand sides of (46) and (47), we first derive from (71) that

$$\begin{aligned} & \mathbb{E}[\rho_w | Y_{ij}^{vw}, \alpha, \mu, \nu] \\ &= \int_0^1 \int \Delta \left(\frac{\theta_i}{\theta_i + \theta_j} + \rho_w(1 - \rho_w) \frac{\theta_j}{\theta_i + \theta_j} \right) \frac{1}{\text{B}(\alpha)\text{B}(\mu_w, \nu_w)} \prod_{k=1}^K \theta_k^{\alpha_k - 1} \rho_w^{\alpha_w - 1} (1 - \rho_w)^{\nu_w - 1} d\theta d\rho_w \\ &= \frac{\int_0^1 \frac{\mu_w}{\mu_w + \nu_w} \frac{\alpha_i}{\alpha_i + \alpha_j} + \frac{\nu_w}{\mu_w + \nu_w} \frac{\alpha_j}{\alpha_i + \alpha_j}}{\frac{\mu_w}{\mu_w + \nu_w} \frac{\alpha_i}{\alpha_i + \alpha_j} + \frac{\nu_w}{\mu_w + \nu_w} \frac{\alpha_j}{\alpha_i + \alpha_j}} \\ &= \frac{\int_0^1 \left(\frac{\alpha_i}{\alpha_i + \alpha_j} \rho_w^2 + \frac{\alpha_j}{\alpha_i + \alpha_j} \rho_w(1 - \rho_w) \right) \frac{1}{\text{B}(\mu_w, \nu_w)} \rho_w^{\mu_w - 1} (1 - \rho_w)^{\nu_w - 1} d\rho_w}{\frac{\mu_w}{\mu_w + \nu_w} \frac{\alpha_i}{\alpha_i + \alpha_j} + \frac{\nu_w}{\mu_w + \nu_w} \frac{\alpha_j}{\alpha_i + \alpha_j}} \\ &= \frac{\frac{\mu_w}{\mu_w + \nu_w} \frac{\mu_w + 1}{\mu_w + \nu_w + 1} \frac{\alpha_i}{\alpha_i + \alpha_j}}{\frac{\mu_w}{\mu_w + \nu_w} \frac{\alpha_i}{\alpha_i + \alpha_j} + \frac{\nu_w}{\mu_w + \nu_w} \frac{\alpha_j}{\alpha_i + \alpha_j}} + \frac{\frac{\mu_w}{\mu_w + \nu_w} \frac{\nu_w}{\mu_w + \nu_w + 1} \frac{\alpha_j}{\alpha_i + \alpha_j}}{\frac{\mu_w}{\mu_w + \nu_w} \frac{\alpha_i}{\alpha_i + \alpha_j} + \frac{\nu_w}{\mu_w + \nu_w} \frac{\alpha_j}{\alpha_i + \alpha_j}} \\ &= \frac{\eta_{ij}^{vw}}{\mu_w + \nu_w + 1} + (1 - \eta_{ij}^{vw}) \frac{\mu_w}{\mu_w + \nu_w + 1}. \end{aligned} \quad (79)$$

Following a similar procedure, we can show

$$\begin{aligned} & \mathbb{E}[\rho_w^2 + (1 - \rho_w)^2 | \alpha_i \succ_w \alpha_j, \theta \sim \text{Dir}(\alpha), \rho_w \sim \text{Beta}(\mu_w, \nu_w)] \\ &= \frac{\frac{\mu_w}{\mu_w + \nu_w} \frac{\mu_w + 1}{\mu_w + \nu_w + 1} \frac{\mu_w + 2}{\mu_w + \nu_w + 2} \frac{\alpha_i}{\alpha_i + \alpha_j} + \frac{\frac{\nu_w}{\mu_w + \nu_w} \frac{\nu_w + 1}{\mu_w + \nu_w + 1} \frac{\nu_w}{\mu_w + \nu_w + 2} \frac{\alpha_i + \alpha_j}{\alpha_i}}{\frac{\mu_w}{\mu_w + \nu_w} \frac{\alpha_i}{\alpha_i + \alpha_j} + \frac{\nu_w}{\mu_w + \nu_w} \frac{\alpha_j}{\alpha_i + \alpha_j}} + \frac{\frac{\mu_w}{\mu_w + \nu_w} \frac{\mu_w + 1}{\mu_w + \nu_w + 1} \frac{\nu_w}{\mu_w + \nu_w + 2} \frac{\alpha_i + \alpha_j}{\alpha_i}}{\frac{\mu_w}{\mu_w + \nu_w} \frac{\alpha_i}{\alpha_i + \alpha_j} + \frac{\nu_w}{\mu_w + \nu_w} \frac{\alpha_j}{\alpha_i + \alpha_j}} \\ &+ \frac{\frac{\nu_w}{\mu_w + \nu_w} \frac{\nu_w + 1}{\mu_w + \nu_w + 1} \frac{\mu_w}{\mu_w + \nu_w + 2} \frac{\alpha_i + \alpha_j}{\alpha_i}}{\frac{\mu_w}{\mu_w + \nu_w} \frac{\alpha_i}{\alpha_i + \alpha_j} + \frac{\nu_w}{\mu_w + \nu_w} \frac{\alpha_j}{\alpha_i + \alpha_j}} + \frac{\frac{\mu_w}{\mu_w + \nu_w} \frac{\mu_w + 1}{\mu_w + \nu_w + 1} \frac{\mu_w + \nu_w + 2}{\mu_w + \nu_w + 2} \frac{\alpha_i + \alpha_j}{\alpha_i}}{\frac{\mu_w}{\mu_w + \nu_w} \frac{\alpha_i}{\alpha_i + \alpha_j} + \frac{\nu_w}{\mu_w + \nu_w} \frac{\alpha_j}{\alpha_i + \alpha_j}} \\ &= \frac{\eta_{ij}^{vw}}{(\mu_w + 1)(\mu_w + 2)} + (1 - \eta_{ij}^{vw}) \frac{(\mu_w)(\mu_w + 1)}{(\mu_w + 1)(\nu_w + 2)} \\ &+ \eta_{ij}^{vw} \frac{(\mu_w + \nu_w + 1)(\mu_w + \nu_w + 2)}{(\nu_w)(\nu_w + 1)} + (1 - \eta_{ij}^{vw}) \frac{(\mu_w + \nu_w + 1)(\mu_w + \nu_w + 2)}{(\nu_w + 1)(\nu_w + 2)}. \end{aligned} \quad (80)$$

Putting (79) and (80) together, we have shown that the right-hand sides of (78) are exactly the right-hand sides of (70) and (71), which completes the proof. ■

Abstract

In this article, we develop and investigate a new classifier based on features extracted using spatial depth. Our construction is based on fitting a generalized additive model to posterior probabilities of different competing classes. To cope with possible multi-modal as well as non-elliptic nature of the population distribution, we also develop a localized version of spatial depth and use that with varying degrees of localization to build the classifier. Final classification is done by aggregating several posterior probability estimates, each of which is obtained using this localized spatial depth with a fixed scale of localization. The proposed classifier can be conveniently used even when the dimension of the data is larger than the sample size, and its good discriminatory power for such data has been established using theoretical as well as numerical results.

Keywords: Bayes classifier, elliptic distributions, generalized additive models, HDLSS asymptotics, uniform strong consistency, weighted aggregation of posteriors.

1. Introduction

In a supervised classification problem with J competing classes, we have n_j labeled observations $\mathbf{x}_{j1}, \dots, \mathbf{x}_{jn_j}$ from the j -th class ($1 \leq j \leq J$). We use this training sample consisting of $n = \sum_{j=1}^J n_j$ observations to construct a decision rule for classifying an unlabeled observation \mathbf{x} to one of these J classes. If π_j , f_j and $p(j|\cdot)$ denote the prior probability, the probability density function and the posterior probability of the j -th class, respectively, then the *Bayes classifier* assigns \mathbf{x} to the class j_0 , where $j_0 = \operatorname{argmax}_{1 \leq j \leq J} p(j|\mathbf{x}) = \operatorname{argmax}_{1 \leq j \leq J} \pi_j f_j(\mathbf{x})$. However, the f_j 's or the $p(j|\cdot)$'s are usually unknown in practice, and one needs to estimate them from the training sample. Popular parametric classifiers like linear discriminant analysis (LDA) and quadratic discriminant analysis (QDA) (see, e.g., Hastie et al., 2009) are motivated by parametric model assumptions on the f_j 's. So, they may lead to poor classification when these assumptions fail to hold, and the class boundaries of the Bayes classifier have complex geometry. On the other hand, nonparametric classifiers like those based on k -nearest neighbors (k -NN) (see, e.g., Cover and Hart, 1967) and kernel

density estimates (KDE) (see, e.g., Scott, 2015) are more flexible and free from such model assumptions. But, they suffer from the curse of dimensionality and are often not suitable for high-dimensional data.

To demonstrate this, let us consider two examples denoted by **E1** and **E2**. **E1** involves a classification problem with two classes in \mathbb{R}^d , where the distribution of the first class is an equal mixture of $N_d(\mathbf{0}_d, \mathbf{I}_d)$ and $N_d(\mathbf{0}_d, 10\mathbf{I}_d)$, and that of the second class is $N_d(\mathbf{0}_d, 5\mathbf{I}_d)$. Here N_d denotes the d -variate normal distribution, $\mathbf{0}_d = (0, \dots, 0)^T \in \mathbb{R}^d$ and \mathbf{I}_d is the $d \times d$ identity matrix. In **E2**, each class distribution is an equal mixture of two uniform distributions. For the first (respectively, the second) class, it is a mixture of $U_d(0, 1)$ and $U_d(2, 3)$ (respectively, $U_d(1, 2)$ and $U_d(3, 4)$), where $U_d(r_1, r_2)$ denotes the uniform distribution over the region $\{\mathbf{x} \in \mathbb{R}^d : r_1 \leq \|\mathbf{x}\| \leq r_2\}$ with $0 \leq r_1 < r_2 < \infty$ and $\|\cdot\|$ being the Euclidean norm. Figure 1 shows the class boundaries of the Bayes classifier for these two examples when $d = 2$ and $\pi_1 = \pi_2 = 1/2$. The regions colored grey (respectively, black) correspond to observations classified to the first (respectively, the second) class by the Bayes classifier. It is clear that classifiers like LDA and QDA, or any other classifier with linear or quadratic class boundaries will deviate significantly from the Bayes classifier in both examples. A natural question then is how standard nonparametric classifiers like those based on k -NN and KDE perform in such examples.

Figure 2 shows the average misclassification rates of these two classifiers along with the Bayes risks for different values of d . These classifiers were trained on a sample of size 100 from each class, and the misclassification rates were computed based on 250 independent observations from each class. This procedure was repeated 500 times to calculate the average misclassification rates. Smoothing parameters associated with k -NN and KDE (i.e., the number of neighbors k in k -NN and the bandwidth in KDE) were chosen by minimizing leave-one-out cross-validation estimates of misclassification rates (see, e.g., Hastie et al., 2009). Figure 2 shows that in **E1**, the Bayes risk decreases to zero as d grows. Since the class distributions in **E2** have disjoint supports, the Bayes risk is zero for all values of d . But in both examples, the misclassification rates of these two nonparametric classifiers increased to almost 50% as d increased.

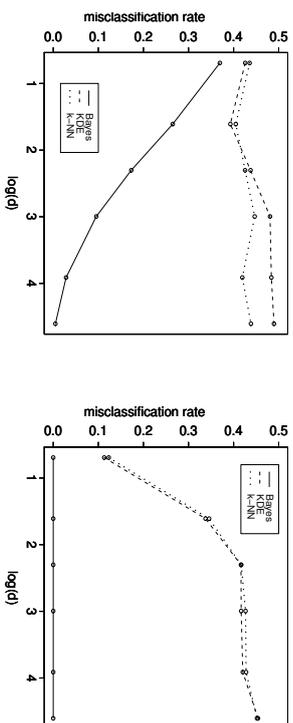

Figure 2: Average misclassification rates of nonparametric classifiers and the Bayes classifier for $d = 2, 5, 10, 20, 50$ and 100 .

These two examples clearly show the necessity to develop new classifiers to cope with such situations. We use the idea of data depth for this purpose. Over the last three decades, data depth (see, e.g., Liu et al., 1999; Zuo and Serfling, 2000) has emerged as a powerful tool for multivariate data analysis with applications in many areas including supervised and unsupervised classification (see, e.g., Jornsten, 2004; Ghosh and Chaudhuri, 2005a,b; Hoberg and Mosler, 2006; Xia et al., 2008; Dutta and Ghosh, 2012; Li et al., 2012; Lange et al., 2014; Paillardaveine and Van Bever, 2015). Spatial depth (also known as the L_1 depth) is a popular notion of data depth that was introduced and studied by Vardi and Zhang (2000) and Serfling (2002). The *spatial depth* (SPD) of an observation $\mathbf{x} \in \mathbb{R}^d$ with respect to (w.r.t.) a distribution function F on \mathbb{R}^d is defined as $\text{SPD}(\mathbf{x}, F) = 1 - \frac{\|E_F[u(\mathbf{x} - \mathbf{X})]\|}{\|\mathbf{x}\|}$, where $\mathbf{X} \sim F$, and $u(\cdot)$ is the multivariate sign function given by $u(\mathbf{x}) = \|\mathbf{x}\|^{-1}\mathbf{x}$ if $\mathbf{x} \neq \mathbf{0}_d \in \mathbb{R}^d$, and $u(\mathbf{0}_d) = \mathbf{0}_d$. This version of SPD is invariant w.r.t. location shift, orthogonal, and homogeneous scale transformations. SPD is often computed on the standardized version of \mathbf{X} as well. In that case, it is defined as

$$\text{SPD}(\mathbf{x}, F) = 1 - \frac{\|E_F[u(\Sigma^{-1/2}(\mathbf{x} - \mathbf{X}))]\|}{\|\mathbf{x}\|},$$

where Σ is a scatter matrix associated with F . One can check that if Σ has the affine equivariance property (see, e.g., Zuo and Serfling, 2000), this version of SPD is affine invariant. To differentiate between these two versions of SPD, we will denote them by SPD° and SPD^* , respectively. If $\Sigma = \lambda \mathbf{I}_d$ for some $\lambda > 0$ (e.g., if F is spherically symmetric, see Pang et al., 1990), then SPD° and SPD^* coincide. Throughout this article, the term SPD will be used in a generic sense.

Like other depth functions, SPD provides a center-outward ordering of multivariate data. An observation has higher (respectively, lower) depth if it lies close to (respectively, away from) the center of the distribution. In other words, given an observation \mathbf{x} and a

pair of probability distributions F_1 and F_2 , if $\text{SPD}(\mathbf{x}, F_1)$ is larger than $\text{SPD}(\mathbf{x}, F_2)$, one would expect \mathbf{x} to come from F_1 instead of F_2 . Based on this simple idea, the *maximum depth classifier* was developed by Jornsten (2004); Ghosh and Chaudhuri (2005b). For a J class problem involving distributions F_1, \dots, F_J , the maximum depth classifier based on SPD assigns an observation \mathbf{x} to the j_0 -th class, where $j_0 = \text{argmax}_{1 \leq j \leq J} \text{SPD}(\mathbf{x}, F_j)$.

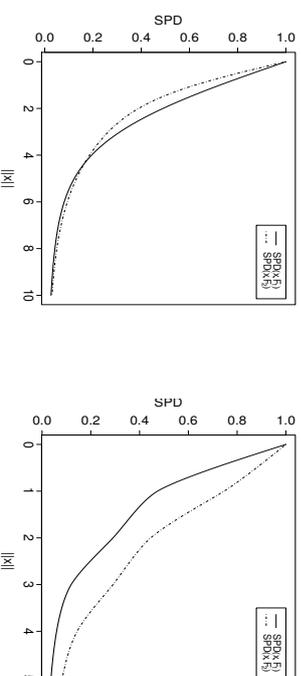

Figure 3: $\text{SPD}(\mathbf{x}, F_1)$ and $\text{SPD}(\mathbf{x}, F_2)$ for different values of $\|\mathbf{x}\|$ when $\mathbf{x} \in \mathbb{R}^2$.

In **E1** and **E2**, since the class distributions are spherically symmetric, SPD^* coincides with SPD° , and they become a monotonically decreasing function of the Euclidean norm of \mathbf{x} (see Lemma 7). In Figure 3, we have plotted $\text{SPD}(\mathbf{x}, F_1)$ and $\text{SPD}(\mathbf{x}, F_2)$ for different values of $\|\mathbf{x}\|$ in **E1** and **E2**, where F_1 and F_2 are the distributions of the two classes and $\mathbf{x} \in \mathbb{R}^2$. It is transparent from Figure 3 that the maximum depth classifier based on SPD will fail in both examples. In **E1**, for all values of $\|\mathbf{x}\|$ smaller (respectively, greater) than a constant close to 4, the observations will be classified to the first (respectively, the second) class by the maximum SPD classifier. On the other hand, this classifier will classify all observations to the second class in **E2**. Most of the popular depth functions turn out to be monotonically decreasing functions of the Euclidean norm in the case of a spherically symmetric distribution. So, the maximum depth classifiers based on those depth functions will have similar problems as well.

In Section 2, we develop a modified classifier based on SPD to overcome this limitation of maximum depth classifiers. In the literature, most of the modified depth based classifiers are developed mainly for two class problems (see, e.g., Ghosh and Chaudhuri, 2005b; Dutta and Ghosh, 2012; Li et al., 2012; Lange et al., 2014). For classification problems involving $J (> 2)$ classes, one usually solves $\binom{J}{2}$ binary classification problems taking one pair of classes at a time and then uses either majority voting (see, e.g., Friedman, 1996) or pairwise coupling (see, e.g., Hastie and Tibshirani, 1998) to make the final classification. Unlike those existing methods, our proposed classifier directly addresses the J class problem.

Almost all existing depth based classifiers require ellipticity of class distributions to achieve Bayes optimality. To cope with possible multi-modal as well as non-elliptic population distributions, we construct a localized version of spatial depth (LSPD) in Section 3. In Section 4, we develop a multi-scale classifier based on LSPD. Relevant theoretical results on SPD, LSPD and the resulting classifiers are studied in these sections. In Sections 5 and 6, some simulated and benchmark data sets are analyzed to demonstrate the usefulness of these proposed classifiers. An advantage of SPD over other depth functions is its computational simplicity. Classifiers based on SPD and LSPD can be constructed even when the dimension exceeds the sample size. We deal with such high dimension, low sample size (HDLSS) cases in Section 7, and show that both classifiers turn out to be optimal under a fairly general framework. Several high-dimensional data sets are also analyzed to evaluate their empirical performance. All proofs and mathematical details are given in Appendix A.

2. Bayes Optimality of a Classifier Based on Spatial Depth

Let us assume that f_1, \dots, f_J are density functions of J elliptically symmetric distributions (Fang et al., 1990) on \mathbb{R}^d , where $f_j(\mathbf{x}) = |\Sigma_j|^{-1/2} g_j(|\Sigma_j^{-1/2}(\mathbf{x} - \boldsymbol{\mu}_j)|)$ for $1 \leq j \leq J$. Here $\boldsymbol{\mu}_j \in \mathbb{R}^d$, Σ_j is a $d \times d$ symmetric and positive definite matrix, and $g_j(|\mathbf{t}|)$ is a probability density function of a spherically symmetric distribution on \mathbb{R}^d for $1 \leq j \leq J$. For such classification problems involving general elliptic populations with equal or unequal priors, the next theorem establishes the Bayes optimality of a classifier, which is based on $\mathbf{z}^*(\mathbf{x}) = (z_1^*(\mathbf{x}), \dots, z_J^*(\mathbf{x}))^T = (\text{SPD}^*(\mathbf{x}, F_1), \dots, \text{SPD}^*(\mathbf{x}, F_J))^T$.

Theorem 1 *If the densities of J competing classes are elliptically symmetric, the posterior probabilities of these classes satisfy the logistic regression model given by*

$$p(j|\mathbf{x}) = \tilde{p}(j|\mathbf{z}^*(\mathbf{x})) = \frac{\exp(\Phi_j(\mathbf{z}^*(\mathbf{x})))}{[1 + \sum_{k=1}^{(J-1)} \exp(\Phi_k(\mathbf{z}^*(\mathbf{x})))]} \text{ for } 1 \leq j \leq (J-1) \quad (1)$$

$$\text{and } p(J|\mathbf{x}) = \tilde{p}(J|\mathbf{z}^*(\mathbf{x})) = \frac{1}{[1 + \sum_{k=1}^{(J-1)} \exp(\Phi_k(\mathbf{z}^*(\mathbf{x})))]} \quad (2)$$

Here $\Phi_j(\mathbf{z}^*(\mathbf{x})) = \varphi_{j1}(z_1^*(\mathbf{x})) + \dots + \varphi_{jJ}(z_J^*(\mathbf{x}))$, and $\varphi_{j\cdot}$ s are appropriate real-valued functions of π_j and f_j for $1 \leq j \leq J$. Consequently, the Bayes rule assigns an observation \mathbf{x} to the class j_0 , where $j_0 = \arg\max_{1 \leq j \leq J} \tilde{p}(j|\mathbf{z}^*(\mathbf{x}))$.

Theorem 1 shows that the Bayes classifier is based on a nonparametric multinomial additive logistic regression model for the posterior probabilities, which is a special case of generalized additive models (GAM) (Hastie and Tibshirani, 1990). If the prior probabilities of J classes are equal, and f_1, \dots, f_J are all elliptic and unimodal differing only in their locations, this Bayes classifier reduces to the maximum depth classifier (Ghosh and Chaudhuri, 2005b) (see Remark 8 after the proof of Theorem 1 in Appendix A). A special case of Theorem 1 with $\Sigma_j = \lambda_j \mathbf{I}_d$, where $\lambda_j > 0$ for $1 \leq j \leq J$ is stated below.

Corollary 2 *If the densities of J competing classes are spherically symmetric (i.e., $f_j(\mathbf{x}) = g_j(\|\mathbf{x} - \boldsymbol{\mu}_j\|)$ for $1 \leq j \leq J$), then the posterior probabilities of these classes satisfy the logistic regression model given in Theorem 1 with $\mathbf{z}^*(\mathbf{x})$ replaced by $\mathbf{z}^\circ(\mathbf{x}) = (\text{SPD}^\circ(\mathbf{x}, F_1), \dots, \text{SPD}^\circ(\mathbf{x}, F_J))^T$.*

For any fixed i and j , one can calculate the J -dimensional vector $\mathbf{z}^\circ(\mathbf{x}_{ji})$ (or, $\mathbf{z}^*(\mathbf{x}_{ji})$), where \mathbf{x}_{ji} is the i -th labeled observation from the j -th class for $1 \leq i \leq n_j$ and $1 \leq j \leq J$. These $\mathbf{z}^\circ(\mathbf{x}_{ji})$ s (or, $\mathbf{z}^*(\mathbf{x}_{ji})$ s) can be viewed as realizations of the vector of covariates in a non-parametric multinomial additive logistic regression model, where the response corresponds to the class label that belongs to $\{1, \dots, J\}$. Now, a classifier based on SPD can be constructed by fitting a GAM with the logistic link function. This procedure can be viewed as a multinomial logistic regression in the J -dimensional depth plot. Lange et al. (2014); Li et al. (2012); Mozharovskiy et al. (2015) used such plots for nonparametric classification. Recently, Cuesta-Albertos et al. also considered GAM to construct a depth based classifier for functional data. In practice, we use a random sample $\mathbf{x}_1, \dots, \mathbf{x}_n$ generated from F to compute the empirical versions of SPD° and SPD^* , which are given by

$$\text{SPD}^\circ(\mathbf{x}, F_n) = 1 - \left\| \frac{1}{n} \sum_{i=1}^n u(\mathbf{x} - \mathbf{x}_i) \right\| \quad \text{and} \quad \text{SPD}^*(\mathbf{x}, F_n) = 1 - \left\| \frac{1}{n} \sum_{i=1}^n u(\widehat{\Sigma}^{-1/2}(\mathbf{x} - \mathbf{x}_i)) \right\|,$$

respectively, where $\widehat{\Sigma}$ is an estimate of Σ , and F_n is the empirical distribution of the data $\mathbf{x}_1, \dots, \mathbf{x}_n$. Clearly, SPD^* is affine invariant if $\widehat{\Sigma}$ has the affine equivariance property. The resulting classifier worked quite well in examples E1 and E2, and we shall see the numerical results later in Section 5.1.

3. Extraction of Small Scale Distributional Features by Localization of Spatial Depth

Under elliptic symmetry, the density function of a class can be expressed as a function of SPD^* , and hence the depth contours coincide with the density contours. This is the main mathematical argument used in the proof of Theorem 1. For non-elliptic distributions, where the density function cannot be expressed as a function of SPD, such mathematical arguments are no longer valid. Consider an equal mixture of $N_d(\mathbf{0}_d, 0.25\mathbf{I}_d)$, $N_d(2\mathbf{1}_d, 0.25\mathbf{I}_d)$ and $N_d(4\mathbf{1}_d, 0.25\mathbf{I}_d)$, where $\mathbf{1}_d = (1, \dots, 1)^T$ denotes a d -dimensional vector with all elements equal to 1. We have plotted the density contours in Figure 4(a) and SPD° contours in Figure 4(b) when $d = 2$. In this trimodal distribution, the SPD° contours failed to match the density contours. As a second example, we consider a d -dimensional distribution with independent components, where the i -th component is exponential with the scale parameter $d/(d-i+1)$ for $1 \leq i \leq d$. Figures 5(a) and 5(b) show the density contours and the SPD° contours, respectively, when $d = 2$. Even in this example, SPD° and density contours differed significantly. We observed a similar picture for contours based on SPD^* as well.

To cope with this issue, we suggest a *localization* of SPD. Note that $\text{SPD}^\circ(\mathbf{x}, F) = 1 - \|E_F[u(\mathbf{x} - \mathbf{X})]\|$ is constructed by assigning the same weight to each unit vector $u(\mathbf{x} - \mathbf{X})$ and ignoring the significance of the distance between \mathbf{x} and \mathbf{X} . By introducing a weight function, which takes account of this distance, one can extract important features related to the local geometry of the data. To capture these local features, we use a kernel function $K(\cdot)$ and define

$$\Gamma_h^\circ(\mathbf{x}, F) = E_F[K_h(\mathbf{t})] - \|E_F[K_h(\mathbf{t})u(\mathbf{t})]\|,$$

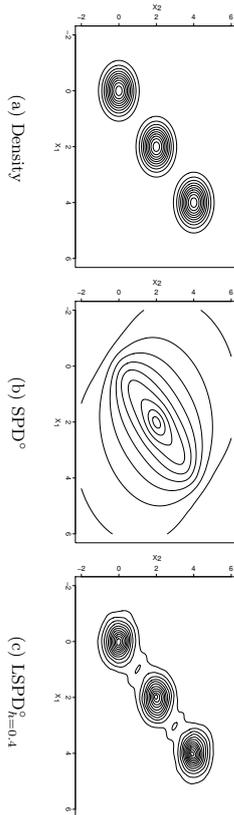

Figure 4: Contours of density; SPD $^\circ$ and LSPD $^\circ_h$ (with $h = 0.4$) functions for a symmetric, trimodal density function.

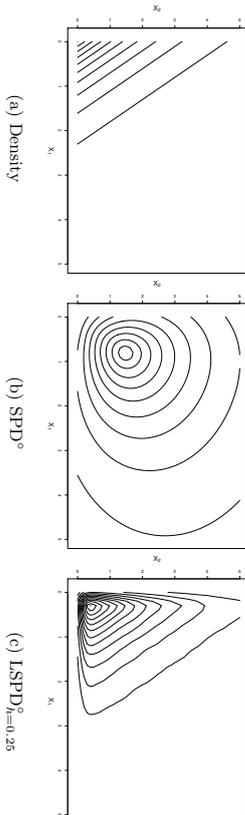

Figure 5: Contours of density; SPD $^\circ$ and LSPD $^\circ_h$ (with $h = 0.25$) functions for the density function $f(x_1, x_2) = 0.5 \exp\{-(x_1 + 0.5x_2)\} I\{x_1 > 0, x_2 > 0\}$.

where $\mathbf{t} = (\mathbf{x} - \mathbf{X})$ and $K_h(\mathbf{t}) = h^{-d}K(\mathbf{t}/h)$. For our theoretical investigation, we will assume K to be a continuous probability density function on \mathbb{R}^d that satisfies the following properties:

- (K1) $K(\mathbf{t}) = g_0(\|\mathbf{t}\|)$, where g_0 is a decreasing function with $g_0(0) < \infty$ and $g_0(\|\mathbf{t}\|) \rightarrow 0$ as $\|\mathbf{t}\| \rightarrow \infty$,
- (K2) $K(\mathbf{t})$ has bounded first derivatives, and
- (K3) $\int_{\mathbb{R}^d} \|t\|K(\mathbf{t})d\mathbf{t} < \infty$.

The Gaussian kernel $K(\mathbf{t}) = (\sqrt{2\pi})^{-d} \exp(-\|\mathbf{t}\|^2/2)$ is a possible choice. It is desirable that localized spatial depth (LSPD) approximates the class density, or a monotone function of it for small values of h . This will ensure that the class densities and hence the class posterior probabilities become functions of LSPD as $h \rightarrow 0$. On the other hand, one should expect that as $h \rightarrow \infty$, LSPD should tend to SPD, or a monotone function of it. However,

$\Gamma_h^\circ(\mathbf{x}, F) \rightarrow 0$ as $h \rightarrow \infty$. So, we re-scale $\Gamma_h^\circ(\mathbf{x}, F)$ by an appropriate factor of h to define LSPD $^\circ$ as follows:

$$\text{LSPD}_h^\circ(\mathbf{x}, F) = \begin{cases} \Gamma_h^\circ(\mathbf{x}, F) & \text{if } h \leq 1, \\ h^d \Gamma_h^\circ(\mathbf{x}, F) & \text{if } h > 1. \end{cases} \quad (3)$$

LSPD $^\circ_h$ defined in this way is a continuous function of h . For $d = 2$, Figures 4(c) and 5(c) show that unlike SPD $^\circ$ contours, LSPD $^\circ_h$ contours matched the density contours in both examples. Using $\mathbf{t} = \Sigma^{-1/2}(\mathbf{x} - \mathbf{X})$ in the definition of $\Gamma_h^\circ(\mathbf{x}, F)$, one gets $\Gamma_h^*(\mathbf{x}, F)$, and LSPD $^\circ_h$ is defined using $\Gamma_h^*(\mathbf{x}, F)$ in the same way. Clearly, LSPD $^\circ_h$ is affine invariant if Σ is affine equivariant. When $\Sigma = \lambda \mathbf{I}_d$, we obtain $\Gamma_h^*(\mathbf{x}, F) = \lambda^{d/2} \Gamma_h^\circ(\mathbf{x}, F)$ with $h' = h\sqrt{\lambda}$, and using this expression, one can derive the relation between LSPD $^\circ_h$ and LSPD $^\circ_{h'}$. The vector $\mathbf{z}_h^*(\mathbf{x}) = (\text{LSPD}_h^*(\mathbf{x}, F_1), \dots, \text{LSPD}_h^*(\mathbf{x}, F_J))^T$ has the desired behavior as shown in Theorem 3.

Theorem 3 *If f_1, \dots, f_J are continuous density functions with bounded first derivatives, and Σ_j is the scatter matrix corresponding to the j -th class ($1 \leq j \leq J$), then*

- (a) $\mathbf{z}_h^*(\mathbf{x}) \rightarrow (\sum_{j=1}^J |f_j(\mathbf{x})|, \dots, \sum_{j=1}^J |f_j(\mathbf{x})|^{1/2} f_j(\mathbf{x}))^T$ as $h \rightarrow 0$, and
- (b) $\mathbf{z}_h^*(\mathbf{x}) \rightarrow (K(\mathbf{0})\text{SPD}^*(\mathbf{x}, F_1), \dots, K(\mathbf{0})\text{SPD}^*(\mathbf{x}, F_J))^T$ as $h \rightarrow \infty$.

Now, we construct a classifier by plugging in LSPD $^\circ_h$ instead of SPD in the GAM framework discussed in equations (1) and (2) of Section 2. Consider the following model for the posterior probabilities:

$$p(j|\mathbf{x}) = \frac{\exp(\Phi_j(\mathbf{z}_h^*(\mathbf{x})))}{[1 + \sum_{k=1}^{(J-1)} \exp(\Phi_k(\mathbf{z}_h^*(\mathbf{x})))]}, \quad \text{for } 1 \leq j \leq (J-1), \quad (4)$$

$$\text{and } p(J|\mathbf{x}) = \frac{1}{[1 + \sum_{k=1}^{(J-1)} \exp(\Phi_k(\mathbf{z}_h^*(\mathbf{x})))]}. \quad (5)$$

The main implication of part (a) of Theorem 3 is that the classifier constructed using GAM and $\mathbf{z}_h^*(\mathbf{x})$ as the covariate tends to the Bayes classifier in a general nonparametric setup as $h \rightarrow 0$. On the other hand, part (b) of Theorem 3 implies that for elliptic class distributions, the same classifier tends to the Bayes classifier when $h \rightarrow \infty$. When we fit a GAM, the unknown functions Φ_j s are estimated nonparametrically. Flexibility of such nonparametric estimates also takes care of the unknown constants $|\Sigma_j|^{1/2}$ for $1 \leq j \leq J$ and $K(\mathbf{0})$ in the expressions of the limiting values of $\mathbf{z}_h^*(\mathbf{x})$ in parts (a) and (b) of Theorem 3, respectively. A special case of Theorem 3 follows by taking $\Sigma_j = \lambda_j \mathbf{I}_d$ with $\lambda_j > 0$ for all $1 \leq j \leq J$.

Corollary 4 *If f_1, \dots, f_J are continuous density functions with bounded first derivatives, then*

- (a) $\mathbf{z}_h^*(\mathbf{x}) = (\text{LSPD}_h^\circ(\mathbf{x}, F_1), \dots, \text{LSPD}_h^\circ(\mathbf{x}, F_J))^T \rightarrow (f_1(\mathbf{x}), \dots, f_J(\mathbf{x}))^T$ as $h \rightarrow 0$, and
- (b) $\mathbf{z}_h^*(\mathbf{x}) \rightarrow (K(\mathbf{0})\text{SPD}^\circ(\mathbf{x}, F_1), \dots, K(\mathbf{0})\text{SPD}^\circ(\mathbf{x}, F_J))^T$ as $h \rightarrow \infty$.

If $\mathbf{x}_1, \dots, \mathbf{x}_n$ is a random sample of size n from F , the empirical version of $\Gamma_h^\circ(\mathbf{x}, F)$ is given by

$$\Gamma_h^\circ(\mathbf{x}, F_n) = \frac{1}{n} \sum_{i=1}^n K_h(\mathbf{t}_i) - \left\| \frac{1}{n} \sum_{i=1}^n K_h(\mathbf{t}_i) u(\mathbf{t}_i) \right\|,$$

where $\mathbf{t}_i = (\mathbf{x} - \mathbf{x}_i)$ for $1 \leq i \leq n$. Then $\text{LSPD}_h^o(\mathbf{x}, F_n)$ is defined using (3) with $\Gamma_h^o(\mathbf{x}, F)$ replaced by $\Gamma_h^o(\mathbf{x}, F_n)$. Similarly, we obtain $\Gamma_h^*(\mathbf{x}, F_n)$ and $\text{LSPD}_h^*(\mathbf{x}, F_n)$ by using $\mathbf{t}_i = \widehat{\Sigma}^{-1/2}(\mathbf{x} - \mathbf{x}_i)$ in the expression stated above. Here $\widehat{\Sigma}$ is an estimate of Σ , and F_n is the empirical distribution of the data $\mathbf{x}_1, \dots, \mathbf{x}_n$.

We know that $\sup_{\mathbf{x} \in \mathbb{R}^d} |\text{LSPD}_h^o(\mathbf{x}, F_n) - \text{LSPD}_h^o(\mathbf{x}, F)|$ goes to 0 almost surely (a.s.) as n goes to infinity (see Gao, 2003). Theorem 5 establishes a similar a.s. uniform convergence of $\text{LSPD}_h^o(\mathbf{x}, F_n)$ to its population counterpart $\text{LSPD}_h^o(\mathbf{x}, F)$ for a fixed value of h .

Theorem 5 *Assume the density corresponding to the distribution function F to be bounded. Then, for any fixed $h > 0$, $\sup_{\mathbf{x} \in \mathbb{R}^d} |\text{LSPD}_h^o(\mathbf{x}, F_n) - \text{LSPD}_h^o(\mathbf{x}, F)| \xrightarrow{a.s.} 0$ as $n \rightarrow \infty$.*

From the proof of Theorem 5 (see Appendix A), it is easy to check that this a.s. uniform convergence also holds when $h \rightarrow \infty$. Under additional moment conditions on F , we obtain this convergence when $h \rightarrow 0$ in such a way that $nh^{2d}/\log n \rightarrow \infty$ as $n \rightarrow \infty$ (see Remarks 9 and 10 after the proof of Theorem 5 in Appendix A).

The fact that LSPD tends to a constant multiple of the probability density function as $h \rightarrow 0$ is a crucial requirement for limiting Bayes optimality of classifiers based on this local depth function. Agostinelli and Romanazzi (2010) proposed localized versions of simplicial depth and half-space depth, but the relationship between the local depth and the probability density function was established only for $d = 1$. A depth function based on inter-point distances was developed by Lok and Lee (2011) to capture multi-modality in a data set. Chen et al. (2009) defined kernelized spatial depth using a reproducing kernel Hilbert space. Hu et al. (2011) also considered a generalized notion of Mahalanobis depth in reproducing kernel Hilbert spaces. However, there is no result connecting them to the probability density function. In fact, the kernelized spatial depth function becomes degenerate at the value $(1 - 1/\sqrt{2})$ as the tuning parameter goes to zero. Consequently, it becomes non-informative for small values of the tuning parameter. It will be appropriate to note here that none of the preceding authors used their proposed depth functions for constructing classifiers.

Recently, Paindaveine and Van Bever (2013, 2015) proposed a notion of local depth and used it for supervised classification along with other applications. Their version of local depth does not relate to the underlying density function either. At this point, one should note that convergence of local depth function to the underlying density function is an advantageous property for classification. However, this may not always be a desirable property for other applications of data depth (see Paindaveine and Van Bever, 2013, for a detailed discussion).

4. Multi-scale Classification using Localized Spatial Depth

When the class distributions are elliptic, part (b) of Theorem 3 implies that LSPD_h with large values of h will lead to good classifiers. These large values may not be appropriate for non-elliptic class distributions, but part (a) of Theorem 3 implies that LSPD_h with small values of h will lead to good classifiers for general nonparametric models for class densities. However, the empirical version of LSPD_h with small h and the resulting classifier may have their statistical limitations for high-dimensional data.

We now consider two examples to demonstrate the above points. The first example (we call it **E3**) involves two multivariate normal distributions $N_d(\mathbf{0}_d, \mathbf{I}_d)$ and $N_d(\mathbf{1}_d, 4\mathbf{I}_d)$. In the second example (we call it **E4**), both the competing classes have trimodal distributions. The first class has the same density as in Figure 4(a) (i.e., an equal mixture of $N_d(\mathbf{0}_d, 0.25\mathbf{I}_d)$, $N_d(2\mathbf{1}_d, 0.25\mathbf{I}_d)$ and $N_d(4\mathbf{1}_d, 0.25\mathbf{I}_d)$), while the second class is an equal mixture of $N_d(\mathbf{1}_d, 0.25\mathbf{I}_d)$, $N_d(3\mathbf{1}_d, 0.25\mathbf{I}_d)$ and $N_d(5\mathbf{1}_d, 0.25\mathbf{I}_d)$. In each of these examples, we considered $d = 5$ and generated a training sample of size 100 from each class. The misclassification rate for the classifier based on LSPD_h^o was computed based on a test sample of size 500 (250 observations from each class). This procedure was repeated 100 times to calculate the average misclassification rates for different values of h . Small values of h extracted local distributional features and yielded low misclassification rates in **E4** (see Figure 6(b)). However, those small values of h led to relatively higher misclassification rates in **E3**, while the underlying global elliptic structure was captured well by the proposed classifier for larger values of h (see Figure 6(a)). This provides a strong motivation for adapting a multi-scale approach in constructing the final classifier so that one can harness the strength of different classifiers corresponding to different scales of localization. One would expect that when aggregated judiciously, the multi-scale classifier will lead to an improved misclassification rate. Usefulness of the multi-scale approach in combining different classifiers has been discussed in the classification literature (see, e.g., Kittler et al., 1998; Dzeroski and Zenko, 2004; Ghosh et al., 2005, 2006).

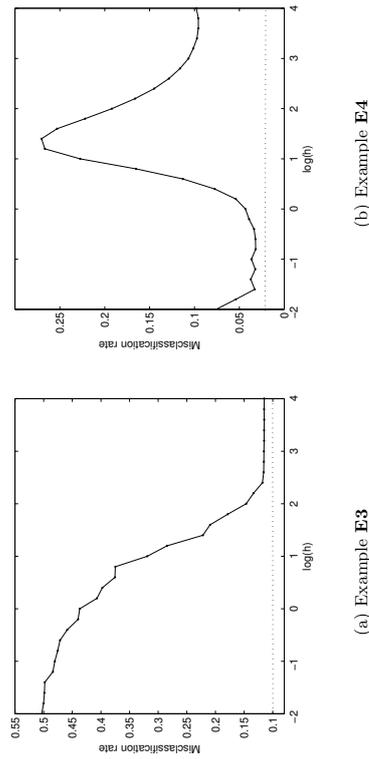

Figure 6: Misclassification rates of the Bayes classifier (indicated by dotted lines) and the classifier based on LSPD_h^o (indicated by solid curves) in examples **E3** and **E4** for varying choices of h .

A popular way of aggregation is to consider a weighted average of the estimated posterior probabilities computed for different values of h . There are various proposals for the choice of the weight function in the literature. Following Ghosh et al. (2005, 2006), we compute $\widehat{\Delta}_h$, a cross-validation estimate of the misclassification rate of the classifier based on LSPD_h^o .

(or, LSPD_h^*) and use

$$W(h) \propto \exp \left[\frac{1}{2} \frac{(\hat{\Delta}_h - \hat{\Delta}_0)^2}{\hat{\Delta}_0(1 - \hat{\Delta}_0)/n} \right]$$

as the weight function, where $\hat{\Delta}_0 = \min_h \hat{\Delta}_h$. The exponential function helps to appropriately weigh up (respectively, weigh down) the promising (respectively, the unsatisfactory) classifier resulting from different choices of the smoothing parameter h . We compute $\int W(h) \bar{g}(h) \bar{p}(j) \mathbf{z}_h^*(\mathbf{x}) dh$ for the j -th class ($1 \leq j \leq J$), where a probability density function \bar{g} is used to make the integral finite. Here $\bar{p}(j) \mathbf{z}_h^*(\mathbf{x})$ is as defined in equations (4) and (5) of Section 3. If we use very small values of h to classify a test case, then the kernel function used in LSPD_h will put almost zero weights on all observations. Clearly, those small values of h will not be useful for classification. On the other hand, LSPD_h behaves like SPD for large values of h . So, after a certain threshold value, increasing the value of h will not provide any additional information about the distributional features. Therefore, one needs to find suitable lower and upper limits of h to compute the weighted posterior probabilities of different classes. Following Ghosh et al. (2006), we compute the pairwise distances (standardized pairwise distances in the case of LSPD_h^*) among the observations in a class and compute the quantiles of these distances. Let $\lambda_{j,\alpha}$ denote the α -th quantile ($0 < \alpha < 1$) of the pairwise distances for the j -th class with $1 \leq j \leq J$. We use $h_L = \min_j \{\lambda_{j,0.05}\} / 3$ as the lower limit of h , and $h_U = 2^r h_L$ as the upper limit of h . Here r is the smallest integer for which we have $\|\mathbf{z}_h^*(\mathbf{x}_{j_1}) - \mathbf{z}^*(\mathbf{x}_{j_1})\| / \|\mathbf{z}^*(\mathbf{x}_{j_1})\| < 0.05$ (or, $\|\mathbf{z}_h^*(\mathbf{x}_{j_1}) - \mathbf{z}^*(\mathbf{x}_{j_1})\| / \|\mathbf{z}^*(\mathbf{x}_{j_1})\| < 0.05$ in case of LSPD_h^*) for $1 \leq i \leq n_j$ and $1 \leq j \leq J$. Our final classifier, which we call the LSPD classifier, assigns an observation \mathbf{x} to the class j_0 , where

$$j_0 = \operatorname{argmax}_{1 \leq j \leq J} \int_{h_L}^{h_U} W(h) \bar{g}(h) \bar{p}(j) \mathbf{z}_h^*(\mathbf{x}) dh.$$

One can choose \bar{g} to be the uniform distribution on the interval $[h_L, h_U]$. Since we are dealing with a scale parameter h , we take the uniform distribution in the logarithmic scale. In practice, we generate M independent observations h_1, \dots, h_M from the distribution \bar{g} . For any given $1 \leq j \leq J$ and \mathbf{x} , $\int_{h_L}^{h_U} W(h) \bar{g}(h) \bar{p}(j) \mathbf{z}_h^*(\mathbf{x}) dh$ is approximated by the average $\sum_{i=1}^M W(h_i) \bar{p}(j) \mathbf{z}_{h_i}^*(\mathbf{x}) / M$.

5. Analysis of Simulated Data Sets

We have analyzed several data sets simulated from elliptic as well as non-elliptic distributions in \mathbb{R}^5 . In each example, taking an equal number of observations from each of the two competing classes, we generated training and test sets of sizes 200 and 500, respectively. This procedure was repeated 500 times, and the average test set misclassification rates of different classifiers are reported in Tables 1 and 2 along with their corresponding standard errors. To facilitate comparison, the corresponding Bayes risks are reported as well. In all the tables in this article, the best misclassification rate in a data set is indicated by ‘*’. The other figures in bold (if any) are the misclassification rates whose differences from the best misclassification rate were found to be statistically insignificant at the 5% level when the usual large sample test for equality of proportions was used.

For the classifiers based on SPD and LSPD , we wrote our own R codes and they are available at the link goo.gl/E5fmld6. Throughout this article, we have used 50 different values of h for multi-scale classification based on LSPD , and the weight function is computed using 5-fold cross-validation method. In this section and in Section 6, we have used SPD^* and LSPD_h^* for classification with the usual sample covariance matrix of the j -th class as $\hat{\Sigma}_j$ for $1 \leq j \leq J$. Any other choice of $\hat{\Sigma}_j$ has been mentioned at appropriate places.

We compared our proposed classifiers with a pool of classifiers that include parametric classifiers like LDA and QDA, and nonparametric classifiers like those based on k -NN (with the Euclidean metric as the distance function) and KDE (with the Gaussian kernel). For k -NN and KDE, we have used the pooled sample covariance matrix for standardization. Tables 1 and 2 show misclassification rates for the multi-scale versions of k -NN (Ghosh et al., 2005) and KDE (Ghosh et al., 2006) based on the same weight function described in Section 4. For the multi-scale method based on KDE, we have considered 50 equi-spaced values of the bandwidth in the range suggested by Ghosh et al. (2006). For the multi-scale version of k -NN, we considered all possible values of k (see Ghosh et al., 2005, for more details). These multi-scale versions usually had better performance than their single scale analogs with the smoothing parameters chosen by the method of cross-validation.

We also considered support vector machines (SVM) (Hastie et al., 2009) based on the linear kernel (i.e., $K(\mathbf{x}, \mathbf{y}) = \langle \mathbf{x}, \mathbf{y} \rangle$) and the radial basis function (RBF) kernel (i.e., $K_r(\mathbf{x}, \mathbf{y}) = \exp(-\gamma \|\mathbf{x} - \mathbf{y}\|^2)$) to facilitate comparison. We used the codes available at the R library `e1071` (Dimitriadou et al., 2011). For the RBF kernel, it has been suggested in the literature to use $\gamma = 1/d$ (see <http://www.csie.ntu.edu.tw/~cjlin1/libsvm/>). However, for our numerical work, we considered $\gamma = i/10d$ for $1 \leq i \leq 50$. We also used 25 different values for the box constraint in the interval $[0.1, 100]$, which were equi-spaced in the logarithmic scale. Misclassification rates were computed for these different choices of the tuning parameters, and the best result is reported in the tables for both classifiers.

Misclassification rates are also reported for classification tree (TREE), and a boosted version of TREE known as random forest (RF) (see, e.g., Hastie et al., 2009). For the implementation of TREE and RF, we used the R codes available in the libraries `tree` (Ripley, 2011) and `randomForest` (Liaw and Wiener, 2002), respectively. For classification tree, the deviance function was used as a measure of impurity, and the maximum height of the tree was restricted to 31. Nodes with less than 5 observations were never considered for splitting. We have combined the results of 500 trees in RF, where each tree was generated based on 63.2% randomly chosen observations from the training sample. At any stage, only a random subset of $\lfloor \sqrt{d} \rfloor$ out of d variables were considered for splitting. Here $\lfloor t \rfloor$ denotes the largest integer less than, or equal to t .

In addition, we also compared the performance of our classifiers with two depth based classification methods: the classifier based on depth-depth (DD) plot (Li et al., 2012) and the maximum depth classifier based on local depth (LD) (Paindaveine and Van Bever, 2013). The DD classifier fits a polynomial on the depth values corresponding to the two competing classes to construct a separating surface. Three notions of depth were used: Mahalanobis depth, half-space depth and projection depth, where the last two depths were computed based on 500 random projections. For each of these depth functions, we used polynomials of degrees 1, 2 and 3. The best result obtained among all these nine possibilities is reported in Tables 1 and 2. For the maximum LD classifier, we used the R library `DepthProc`

(Kosiorowski and Zawadzki, 2016) and considered the best result obtained for different choices of depth and a range of values for the localization parameter. The misclassification rates of the maximum LD classifier was higher than those of the DD classifier in almost all cases, and we do not report those results in this article.

5.1 Examples Involving Elliptic Distributions

Recall examples **E1** and **E2** in Section 2, and example **E3** in Section 4 involving elliptic class distributions. In **E1**, the DD classifier led to the lowest misclassification rate closely followed by SPD and LSPD classifiers (see Table 1), but it did not perform well in **E2**. In this example, SPD and LSPD classifiers significantly outperformed all their competitors. Since the class distributions were elliptic, the SPD classifier had a slight edge over the LSPD classifier in these examples. In view of normality of the class distributions, QDA was expected to have the best performance in **E3**. The DD classifier ranked second here, while SPD and LSPD classifiers performed satisfactorily. In all these examples, the Bayes classifier had non-linear class boundaries. So, LDA and SVM with the linear kernel did not perform well. The performance of SVM with the RBF kernel was relatively better, and it had competitive misclassification rates in **E3**. In all these examples, nonparametric classifiers based on k -NN and KDE yielded much higher misclassification rates compared to SPD and LSPD classifiers.

Table 1: Misclassification rates (in %) of different classifiers in elliptic data sets.

Ex	Bayes risk	LDA	QDA	SVM (linear)	SVM (RBF)	k -NN	KDE	TREE	RF	DD	SPD	LSPD
E1	26.50	50.22 (0.11)	51.58 (0.19)	45.46 (0.12)	33.03 (0.13)	39.99 (0.12)	39.16 (0.12)	36.90 (0.13)	31.32 (0.11)	27.92 * (0.12)	28.32 (0.10)	28.54 (0.11)
E2	0.00	47.43 (0.11)	42.08 (0.12)	43.92 (0.11)	34.06 (0.12)	36.98 (0.13)	34.29 (0.15)	39.10 (0.13)	34.26 (0.11)	26.68 (0.13)	8.23 * (0.11)	8.26 (0.10)
E3	10.14	21.56 (0.09)	11.09 * (0.07)	22.09 (0.09)	11.74 (0.07)	17.86 (0.09)	16.95 (0.08)	19.18 (0.13)	13.77 (0.08)	11.37 (0.08)	11.49 (0.07)	11.64 (0.07)

5.2 Examples Involving Non-elliptic Distributions

We now consider some examples involving non-elliptic class distributions. Recall the trimodal example **E4** discussed in Section 4. In this example, when the classifiers based on k -NN and KDE were used after standardizing the data set by the pooled sample covariance matrix, they yielded misclassification rates higher than 40%. For KDE, we used a common bandwidth in all directions after standardization. This led to the use of a large bandwidth in the principal component direction $\frac{1}{\sqrt{d}}\mathbf{1}_d$ (this can be observed from Figure 4(a)). Since the difference between the posterior probabilities of the two classes changes its sign frequently along this direction, use of this large bandwidth makes it difficult to discriminate between the two competing classes. In the k -NN classifier, this standardization leads to the use of a neighborhood which was also elongated along the direction $\frac{1}{\sqrt{d}}\mathbf{1}_d$, and this affected the performance of this classifier. So, we did not standardize the data for these two classifiers, and they outperformed all other classifiers considered here (see Table 2). Classifiers based on SPD* and LSPD* also had poor performance because of this issue with standard-

ization. So we used classifiers based on SPD° and LSPD° in this example. The LSPD° classifier had the third best performance. SVM with the RBF kernel also performed well. All other classifiers had relatively higher misclassification rates. The DD classifier, LDA, QDA and SVM with the linear kernel all misclassified more than 25% of the observations.

The next example (we call it **E5**) is with exponential distributions, where the component variables are independently distributed in both classes. The i -th variable in the first (respectively, the second) class is exponential with scale parameter $d/(d-i+1)$ (respectively, $d/2i$) for $1 \leq i \leq d$. Further, the second class has a location shift, such that the difference between the mean vectors of the two classes is $\frac{1}{d}\mathbf{1}_d$. Recall that Figure 5(a) shows the density contours of the first class when $d=2$. In this example, the RF classifier had the best performance followed by TREE. Here all the measurement variables were independent, and there was significant separation between the two classes in some of the co-ordinate directions. This is one of the main reasons behind the superior performance of both TREE and RF. Classifiers based on DD, SPD* and LSPD* also performed quite well, and their misclassification rates were significantly lower than all other classifiers. The two linear classifiers performed poorly, but QDA had a reasonably good performance in this example. Good performance of QDA was not surprising as the two competing classes are unimodal, while they differ widely in their dispersion structures.

Table 2: Misclassification rates (in %) of different classifiers in non-elliptic data sets.

Ex	Bayes risk	LDA	QDA	SVM (linear)	SVM (RBF)	k -NN	KDE	TREE	RF	DD	SPD	LSPD
E4	2.10	40.45 (0.12)	42.41 (0.11)	36.16 (0.12)	3.28 (0.04)	2.70 * (0.03)	2.75 (0.03)	15.52 (0.10)	4.98 (0.07)	30.14 (0.12)	10.07 (0.10)	3.25 (0.04)
E5	2.04	41.17 (0.15)	5.97 (0.05)	32.14 (0.34)	7.12 (0.07)	9.55 (0.08)	9.32 (0.07)	4.82 (0.08)	2.04 * (0.03)	5.92 (0.05)	5.53 (0.06)	5.42 (0.06)
E6	13.16	49.67 (0.12)	25.77 (0.12)	47.77 (0.15)	29.33 (0.11)	27.44 (0.11)	27.59 (0.14)	38.39 (0.14)	29.73 (0.11)	28.86 (0.14)	24.15 (0.10)	24.09 * (0.10)
E7	19.96	50.78 (0.23)	50.48 (0.22)	49.77 (0.07)	46.01 (0.23)	35.29 (0.22)	38.88 (0.24)	34.45 (0.13)	27.62 (0.11)	26.48 * (0.12)	38.39 (0.20)	40.64 (0.28)

In example **E6**, each class is an equal mixture of four elliptic distributions. The first class constitutes of $N_d(\mathbf{1}_d, S_{0.6}), t_{3,d}(\beta_d, S_{0.7}), N_d(-\mathbf{1}_d, S_{0.8})$ and $t_{3,d}(-\beta_d, S_{0.9})$, while the second class is an equal mixture of $t_{3,d}(\mathbf{1}_d, S_{-0.9}), N_d(\beta_d, 3S_{-0.8}), t_{3,d}(-\mathbf{1}_d, S_{-0.7})$ and $N_d(-\beta_d, 3S_{-0.6})$. Here $t_{3,d}(\mu, \Sigma)$ denotes the d -variate t distribution with 3 degrees of freedom (df), location parameter μ and scatter matrix Σ . The vector β_d is a d -dimensional vector with the i -th element equal to $(-1)^{i+1}$ for $1 \leq i \leq d$ and the matrix $S_\alpha = ((\alpha^{|i-j|}))_{d \times d}$ for $\alpha \in (-1, 1)$ and $1 \leq i, j \leq d$. This example has a complex structure for the class distributions, and both SPD and LSPD classifiers significantly outperformed all their competitors. As the Bayes classifier was far from being linear, LDA and linear SVM did not have satisfactory performance.

Finally, we consider a classification problem between a Cauchy distribution and a skewed Cauchy distribution (Azzalini, 2014) (we call it **E7**). The Cauchy distribution had location parameter $\mathbf{1}_d$ and scatter matrix $0.5\mathbf{I}_d + 0.5\mathbf{1}_d\mathbf{1}_d^T$; while the skewed Cauchy distribution had location parameter $\mathbf{0}_d$, scatter matrix \mathbf{I}_d and asymmetry vector $\mathbf{1}_d$. The DD classifier and RF performed better than other classifiers, but SPD* and LSPD* classifiers yielded

relatively higher misclassification rates. Both half-space depth and projection depth used in the DD classifier are robust against outliers generated from heavy-tailed distributions, while the moment based estimates used in both SPD* and LSPD* are non-robust. So, it is better to use robust estimates of Σ_j s here. When we used MCD estimates based on 75% of the observations (Rousseeuw and Van Driessen, 1999), the misclassification rates of SPD* and LSPD* classifiers dropped to 31.90% and 32.05%, respectively, with corresponding standard errors of 0.18% and 0.20%.

All these examples clearly demonstrate that the LSPD classifier performs as good as (if not better) popular nonparametric classifiers for non-elliptic, or multi-modal data. This adjustment of the LSPD classifier is automatic in view of the multi-scale approach developed in Section 4.

5.3 Computing Time for SPD and LSPD Classifiers

For a training sample of size n , computation of $\mathbf{z}(\mathbf{x};x_i)$ for $1 \leq i \leq n_j$ and $1 \leq j \leq J$ requires $O(n^2)$ calculations. Fitting a GAM involves an iterative algorithm, and it is quite difficult to calculate its exact computational complexity. Each iteration requires computations of the order $O(n^2)$ (Wood, 2006). So, the algorithm takes no more than $O(n^2)$ computations to fit a GAM for a finite number of iterations. For the multi-scale classifier based on LSPD, we need to repeat this procedure for M different values of h and then compute the weight function $W(h)$ based on V -fold cross-validation. The overall order of computation remains $O(n^2)$ although the associated constant increases linearly with d , J , M and V . However, one should note that these are offline calculations. Both SPD and LSPD classifiers require $O(n)$ calculations to classify a test case.

Throughout this article, we have used $M = 50$ and $V = 5$ and the R library VGAM (Yee, 2008) was used to fit GAM. In a single iteration, the average CPU time to determine the weight function $W(h)$ based on cross-validation for the LSPD classifier was 21.83 seconds, while 0.55 seconds were required to fit a GAM using the full training data. The average CPU time to classify the 500 test observations was about 0.01 seconds. All the calculations were done on a desktop computer with an Intel i7 (2.2 GHz) processor having 8 GB RAM.

6. Analysis of Benchmark Data Sets

We have analyzed seven benchmark data sets for further evaluation of our proposed classifiers. The biomedical data set is taken from the CMU data archive (<http://lib.stat.cmu.edu/datasets/>). In this data set, we ignored the observations with missing values. The diabetes data set is available in the R library mlc1st (also analyzed in Reaven and Miller, 1979). All other data are taken from the UCI machine learning repository (<http://archive.ics.uci.edu/ml/>). Descriptions of these data sets are available at these sources. Satellite image (satimage) data set has specific training and test samples. For this data set, we report misclassification rates of different classifiers based on this fixed test set. If a classifier had misclassification rate ϵ , its standard error was computed as $\sqrt{\epsilon(1-\epsilon)/(\text{size of the test set})}$. For all other data sets, we formed the training and the test sets by randomly partitioning the data, and this random partitioning was repeated 500 times. Average test set misclassification rates of different classifiers were computed over these 500 partitions, and they are reported in Table 3 along with their corresponding stan-

dard errors. Sizes of training and test sets in each partition are also reported in this table. For all classifiers, we used the same tuning procedures as described in Section 5. Codes for the DD classifier are available only for two class problems. In biomedical and Parkinson's data sets, the DD classifier yielded misclassification rates of 12.54% and 14.48%, respectively, with corresponding standard errors of 0.18% and 0.15%. We also used the maximum LD classifier on these real data sets. However, its performance was not satisfactory for most data sets and we do not report those misclassification rates in Table 3.

In biomedical and vehicle data, covariance matrices of the competing classes were different. So, QDA led to significant improvement over LDA, and its misclassification rates were close to the best rate. In both these data sets, the competing classes were nearly elliptic (this can be verified using the diagnostic plots suggested by Li et al., 1997). The SPD classifier utilized this ellipticity of the class distributions to outperform the nonparametric classifiers. The LSPD classifier competed well with the SPD classifier in biomedical data. But, the evidence of ellipticity was much stronger in vehicle data and LSPD had a slightly higher misclassification rate. In diabetes data also, the three competing classes had widely varying covariance structures. As expected, QDA performed better than LDA. Since the class distributions were not elliptic, the SPD classifier yielded a higher misclassification rate than the LSPD classifier, while both TREE and RF outperformed all other classifiers in this data set.

Table 3: Descriptions of the real data sets, and misclassification rates (in %) of different classifiers.

xxxx: QDA could not be used because of singularity of the estimated class dispersion matrices.

In Parkinson's data, we could not use QDA because of singularity of the estimated class dispersion matrices. So, we used the pooled sample covariance matrix for computation

of SPD* and LSPD*. In this data set, all the nonparametric classifiers had significantly lower misclassification rates than LDA, and the classifier based on KDE had the lowest misclassification rate. The performance of the LSPD classifier was also competitive. Since the underlying distributions were non-elliptic, LSPD outperformed the SPD classifier. We observed a similar phenomena in wine data as well. The sample covariance matrices of different classes were nearly singular, and we used the pooled sample covariance matrix for computing SPD* and LSPD*. The classifier based on KDE yielded the lowest misclassification rate, while the LSPD classifier had the second best performance. Although the data dimension was quite high in both data sets, all the competing classes had low intrinsic dimensions (can be estimated using the method described by Levina and Bickel, 2004). So, nonparametric methods like KDE were not affected much by the curse of dimensionality. TREE was the only classifier with a somewhat higher misclassification rate.

In waveform data, the competing class distributions were nearly elliptic and the SPD classifier was expected to perform well. The LSPD classifier is quite flexible, and it yielded a competitive misclassification rate. The class distributions were not normal (can be checked using the method proposed in Royston, 1983) for this data, and did not have low intrinsic dimensions. As a result, LDA, QDA and the nonparametric classifiers had relatively higher misclassification rates.

In satimage data, recall that the results are based on a single training and a single test set. So, the standard errors of the misclassification rates were high for all classifiers, and it is quite difficult to compare the performance of different classifiers. Both RF and SVM with the RBF kernel had lower misclassification rates than other classifiers, while the classifiers based on SPD and LSPD had the next best performance.

7. Classification of High-dimensional Data

A serious practical limitation of many existing depth based classifiers is their computational complexity in high dimensions, and this makes such classifiers impossible to use even for moderately large dimensional data. Besides, depth functions that are based on random simplices formed by the data points (see, e.g., Liu et al., 1999; Zuo and Serfling, 2000) cannot be defined in a meaningful way if the dimension of the data exceeds the sample size. Tukey's half-space depth and projection depth both become degenerate at zero for such high-dimensional data (see, e.g., Dutta et al., 2011). Classification of high-dimensional data presents a substantial challenge to many nonparametric classification tools as well. We have seen in examples **E1** and **E2** (recall Figure 2) that nonparametric classifiers like those based on k -NN and KDE can yield poor performance when the data dimension is large. Some limitations of SVM for classification of high-dimensional data has been noted by Marron et al. (2007); Dutta and Ghosh (2016).

One of our primary motivations behind using SPD is its computational tractability (especially when the dimension is large). If the dimension exceeds the sample size, then the sample covariance matrices become singular, and we cannot use these estimates to define the empirical versions of SPD* and LSPD*. So, we use classifiers based on SPD $^\circ$ and LSPD $^\circ$. We now assume the following regularity conditions to investigate the behavior of these classifiers for such high-dimensional data.

(C) Consider two independent random vectors $\mathbf{X}_1 = (X_1^{(1)}, \dots, X_1^{(d)})^T \sim F_j$ and $\mathbf{X}_2 = (X_2^{(1)}, \dots, X_2^{(d)})^T \sim F_i$ for $1 \leq j, i \leq J$.

Further, assume that

(C1) $a_j = \lim_{d \rightarrow \infty} d^{-1} \sum_{k=1}^d E(X_1^{(k)})^2$ exists, and $d^{-1} \sum_{k=1}^d (X_1^{(k)})^2 \xrightarrow{a.s.} a_j$ as $d \rightarrow \infty$,

(C2) $b_{ji} = \lim_{d \rightarrow \infty} d^{-1} \sum_{k=1}^d E(X_1^{(k)} X_2^{(k)})$ exists, and $d^{-1} \sum_{k=1}^d X_1^{(k)} X_2^{(k)} \xrightarrow{a.s.} b_{ji}$ as $d \rightarrow \infty$.

It is not difficult to verify that for $\mathbf{X}_1 \sim F_j$ ($1 \leq j \leq J$), if we assume that the sequence of variables $\{X_1^{(k)} - E(X_1^{(k)}) : k = 1, 2, \dots\}$ centered at their means are independent with uniformly bounded eighth moments (see Theorem 1 (2) in Jung and Marron, 2009, p. 4110), or they are m -dependent processes with some appropriate conditions (see Theorem 2 in de Jong, 1995, p. 350), then the convergence results in (C1) and (C2) hold. Also, if the observations are generated from discrete time ARMA processes, all these conditions are satisfied. Stationarity of such time series is not required here. These assumptions continue to hold if the sequences $\{(X_1^{(k)})^2 - E(X_1^{(k)})^2 : k = 1, 2, \dots\}$ and $\{X_1^{(k)} X_2^{(k)} - E(X_1^{(k)} X_2^{(k)}) : k = 1, 2, \dots\}$, where $\mathbf{X}_1 \sim F_j$ and $\mathbf{X}_2 \sim F_i$ for all $1 \leq j, i \leq J$, are *mixingales* satisfying some appropriate conditions (see, e.g., Theorem 2 in de Jong, 1995, p. 350).

Define $\sigma_j^2 = a_j - b_{jj}$ and $\nu_{ji} = b_{jj} - 2b_{ji} + b_{ii}$. For the random vector $\mathbf{X}_1 \sim F_j$, σ_j^2 is the limit of $d^{-1} \sum_{k=1}^d \text{Var}(X_1^{(k)})$ as $d \rightarrow \infty$. If we consider a second independent random vector $\mathbf{X}_2 \sim F_i$ with $i \neq j$, then ν_{ji} is the limit of $d^{-1} \sum_{k=1}^d \{E(X_1^{(k)}) - E(X_2^{(k)})\}^2$ as $d \rightarrow \infty$. Hall et al. (2005) assumed a similar set of conditions to study the performance of support vector machines (SVM) with the linear kernel and the 1-NN classifier as the data dimension grows to infinity. Similar conditions on observation vectors were also considered by Jung and Marron (2009) to study consistency of principal components of the empirical covariance matrix for high-dimensional data. Under (C1) and (C2), the following theorem describes the behavior of $\mathbf{z}^\circ(\mathbf{x}) = (\text{SPD}^\circ(\mathbf{x}, F_1), \dots, \text{SPD}^\circ(\mathbf{x}, F_J))^T$ and $\mathbf{z}_h^\circ(\mathbf{x}) = (\text{LSPD}_h^\circ(\mathbf{x}, F_1), \dots, \text{LSPD}_h^\circ(\mathbf{x}, F_J))^T$ as d grows to infinity.

Theorem 6 Suppose that the conditions (C1)-(C2) hold, and $\mathbf{X} \sim F_j$ for $1 \leq j \leq J$.

(a) $\mathbf{z}^\circ(\mathbf{X}) \xrightarrow{a.s.} (c_{j1}, \dots, c_{jJ})^T = \mathbf{c}_j$ as $d \rightarrow \infty$, where $c_{jj} = 1 - \sqrt{\frac{1}{2}}$ and $c_{ji} = 1 - \sqrt{\frac{\sigma_j^2 + \nu_{ji}}{\sigma_j^2 + \sigma_i^2 + \nu_{ji}}}$ for $1 \leq j \neq i \leq J$.

(b) Assume that $h \rightarrow \infty$ and $d \rightarrow \infty$ in such a way that $\sqrt{d}/h \rightarrow 0$ or $A_0(> 0)$. Then, $\mathbf{z}_h^\circ(\mathbf{X}) \xrightarrow{a.s.} g_0(\mathbf{0}; \mathbf{c}_j)$ or $\mathbf{c}_j' = (g_0(\epsilon_{j1}, A_0), c_{j1}, \dots, g_0(\epsilon_{jJ}, A_0), c_{jJ})^T$ depending on whether $\sqrt{d}/h \rightarrow 0$ or A_0 , respectively. Here $K(\mathbf{t}) = g_0(\|\mathbf{t}\|)$, $\epsilon_{jj} = \sqrt{2}\sigma_j$ and $\epsilon_{ji} = \sqrt{\sigma_j^2 + \sigma_i^2 + \nu_{ji}}$ for $j \neq i$.

(c) Assume that $h > 1$, and $\sqrt{d}/h \rightarrow \infty$ as $d \rightarrow \infty$. Then, $\mathbf{z}_h^\circ(\mathbf{X}) \xrightarrow{a.s.} \mathbf{0}_J$.

The \mathbf{c}_j 's as well as the \mathbf{c}_j 's in the statement of Theorem 6 are *distinct* for all $1 \leq j \leq J$ whenever either $\sigma_j^2 \neq \sigma_i^2$ or $\nu_{ji} \neq 0$ for all $1 \leq j \neq i \leq J$ (see Lemma 11 in Appendix A). In such a case, part (a) of Theorem 6 implies that for large d , $\mathbf{z}^\circ(\mathbf{x})$ becomes degenerate at points depending on the class distributions. So, $\mathbf{z}^\circ(\mathbf{x})$ has good discriminatory power, and our classifier based on SPD $^\circ$ can discriminate well among the J populations. Further, it follows from part (b) that when both d and h grow to infinity in such a way that $\sqrt{d}/h \rightarrow 0$ or to a positive constant, $\mathbf{z}_h^\circ(\mathbf{x})$ has good discriminatory power and the classifier based on LSPD $^\circ$ can yield low misclassification probability. However, part (c) shows that if \sqrt{d} grows

at a rate faster than h_n , $\mathbf{z}_n^*(\mathbf{x})$ converges to the same value $\mathbf{0}_J$ and it becomes non-informative. Consequently, the classifier based on $\text{LSPD}_{h_n}^*$ will lead to a high misclassification probability in this case.

To evaluate the performance of our depth based classifiers for high-dimensional data, we considered examples **E1-E7** with $d = 200$. In each example, we generated 20 observations from each class to constitute the training sample, while 250 observations from each class were used to form the test set. We generated 500 training and test sets, and the average test set misclassification rates of the different classifiers along with their corresponding standard errors are reported in Table 4. The Bayes risks were *almost zero* in all these examples, and we have not stated them in Table 4. We did not standardize the data for KDE and k -NN. QDA could not be used in these examples, and we used \mathbf{I}_d instead of the pooled sample covariance matrix for LDA. When the competing classes have equal priors (which is the case in simulated examples), this leads to the Euclidean distance based classifier which classifies an observation to the class having the nearest centroid.

As we have mentioned before, we use SPD° and LSPD° for classification of these high-dimensional data sets. For a single iteration, the LSPD classifier required an average CPU time of 8.82 seconds to compute the weight function $W(h)$, 0.39 seconds for fitting GAM using the full training data, and 0.06 seconds for classification of 500 test cases.

Table 4: Misclassification rates (in %) of different classifiers in simulated data sets.

Example	LDA [†]	SVM (linear)	SVM (RBF)	k -NN	KDE	TREE	RF	SPD [°]	LSPD [°]

[†] \mathbf{I}_d was used instead of the pooled sample covariance matrix.

In the first five examples, the two competing classes had separation between either in their locations and/or scales. So, good performance of the SPD° and LSPD° classifiers was expected in view of Theorem 6 and Lemma 11 (see Appendix A). In **E1** and **E2**, recall that the component distributions of the two classes differed only in scales. The SPD° and LSPD° classifiers performed well in these examples, and the former had an edge due to ellipticity of the class distributions. Surprisingly, all other classifiers failed to extract this separability information properly, and had misclassification rates higher than 25%. Since the Bayes class boundaries were highly nonlinear in these two examples, poor performance of linear SVM and LDA was quite expected. Dutta and Ghosh (2016) showed that when one component

distribution from the first class and one from the second class differ only in their scales, the k -NN classifier gives a decision in favor of the distribution with a smaller spread (also see Hall et al., 2005). This was the main reason behind the poor performance of the k -NN classifier. Similar arguments can be given for the poor performance of the classifier based on KDE. In these two examples, splitting based on a single variable failed to yield significant reduction in the impurity function (one can see this in Figure 1). So, TREE and RF had relatively higher misclassification rates. In **E3**, the two Gaussian distributions differed in their locations and scales. Barring TREE, k -NN and the classifier based on KDE, all other classifiers yielded misclassification rates close to zero. Since the scale difference between the two classes dominates the location difference, such a poor performance of the classifier based on KDE and k -NN was expected (see the results in Hall et al., 2005; Dutta and Ghosh, 2016). The same explanation holds for **E5** as well. These nonparametric classifiers yielded excellent performance in **E4**, where the component distribution differ only in their locations. However, TREE and RF failed to have satisfactory performance here. Splitting based on linear combinations of the variables may be helpful in **E4** (see Figure 4).

Examples **E6** and **E7** were difficult to deal with. Unlike **E1-E5**, none of the classifiers could achieve misclassification rates close to zero in these two examples. Conditions (C1) and (C2) do not hold here, and Theorem 6 is not applicable. The LSPD classifier had the best performance in **E6** (just like the case with $d = 5$ in Section 5). SVM with the RBF kernel and the SPD classifier also led to competitive misclassification rates. Their performance was much better than all other classifiers. In **E7**, the linear classifiers and SVM with the RBF kernel could not perform well. This is also consistent with what we observed in Section 5. Barring TREE, all other classifiers yielded competitive performances in this example. Among them the k -NN classifier led to the lowest misclassification rate.

We also analyzed two high-dimensional benchmark data sets, namely, lightning-2 data and colon data (Alon et al., 1999). The first data set is from the UCR time series classification archive (http://www.cs.ucr.edu/~eamonn/time_series_data/), while the other one is taken from the R library rda. In each case, we formed 500 training and test sets by randomly partitioning each data into two almost equal parts. The average test set misclassification rates of different classifiers are reported in Table 5.

Table 5: Misclassification rates (in %) of different classifiers in real data sets.

Data set	d	J	Sample size [†]	LDA [†]	SVM (linear)	SVM (RBF)	k -NN	KDE	TREE	RF	SPD	LSPD
Lightning-2	637	2	Train	60	31.86	35.64	28.73	29.89	28.11	33.69	22.08 *	27.70
			Test	61	(0.25)	(0.35)	(0.32)	(0.20)	(0.30)	(0.34)	(0.30)	(0.30)
Colon	2000	2	Train	31	14.47	16.38	21.48	22.47	23.20	28.78	19.28	19.66
			Test	31	(0.21)	(0.23)	(0.25)	(0.27)	(0.28)	(0.35)	(0.24)	(0.31)

[†] \mathbf{I}_d was used instead of the pooled sample covariance matrix.

Lightning-2 data consist of observations that are realizations of a time series. In this data set, RF had the best performance followed by the LSPD classifier. The SPD classifier also worked well and yielded the third best performance. The class distributions for this data set turn out to be non-elliptic (can be verified using the method proposed by Li et al., 1997) with low intrinsic dimensions (Levina and Bickel, 2004). As a consequence, the classifier based on KDE and k -NN yielded reasonably good performances.

Colon data contain micro-array expression levels of 2000 genes for ‘normal’ and ‘colon cancer’ tissues. There was a good linear separation among the observations from the two competing classes, and the linear classifiers lead to low misclassification rates. Among the other classifiers, the LSPD classifier yielded the minimum misclassification rate closely followed by RF and the SPD classifier. These three classifiers were less affected by the curse of dimensionality.

In these high-dimensional benchmark data sets, the data had low intrinsic dimensions due to high correlation among the measurement variables (Levina and Bickel, 2004). Moreover, data from the competing classes differed mainly in their locations. As a consequence, though the proposed LSPD classifier had a good overall performance, its superiority over the nonparametric methods was not as prominent as it was in the simulated examples.

Acknowledgments

The authors are grateful to Prof. Probal Chaudhuri for his valuable contributions to this manuscript. They are also thankful to the Action Editor and two anonymous reviewers for providing them with several helpful comments. The first author would like to thank Prof. Thomas W. Yee for his help with VGAM, and Prof. Jun Li for sharing R codes of the DD classifier.

Appendix A. Proofs and Mathematical Details

Lemma 7 *If F has a spherically symmetric density $f(\mathbf{x}) = g(\|\mathbf{x}\|)$ on \mathbb{R}^d with $d > 1$, then $\|E_F[u(\mathbf{x} - \mathbf{X})]\|$ is a non-negative monotonically increasing function of $\|\mathbf{x}\|$.*

Proof of Lemma 7 : In view of spherical symmetry of $f(\mathbf{x})$, $S(\mathbf{x}) = \|E_F[u(\mathbf{x} - \mathbf{X})]\|$ is invariant under orthogonal transformations of \mathbf{x} . Consequently, $S(\mathbf{x}) = \eta(\|\mathbf{x}\|)$ for some non-negative function η . Consider now \mathbf{x}_1 and \mathbf{x}_2 such that $\|\mathbf{x}_1\| < \|\mathbf{x}_2\|$. Using spherical symmetry of $f(\mathbf{x})$, without loss of generality, we can assume $\mathbf{x}_i = (t_i, 0, \dots, 0)^T$ for $i = 1, 2$ such that $|t_1| < |t_2|$. For any $\mathbf{x} = (t, 0, \dots, 0)^T$, we have

$$S(\mathbf{x}) = \left| E_F \left[\frac{(t - X_1)}{\sqrt{(t - X_1)^2 + X_2^2 + \dots + X_d^2}} \right] \right|,$$

due to spherical symmetry of $f(\mathbf{x})$. For any $\mathbf{x} \in \mathbb{R}^d$ with $d > 1$, $E_F[\|\mathbf{x} - \mathbf{X}\|]$ is a strictly convex function of \mathbf{x} in this case. Consequently, it is a strictly convex function of t . Observe now that $S(\mathbf{x})$ with this choice of \mathbf{x} is the absolute value of the derivative of $E_F[\|\mathbf{x} - \mathbf{X}\|]$ w.r.t. t . This derivative is a symmetric function of t that vanishes at $t = 0$. Hence, $S(\mathbf{x})$ is an increasing function of $|t|$, and this proves that $\eta(\|\mathbf{x}_1\|) < \eta(\|\mathbf{x}_2\|)$. ■

Proof of Theorem 1 : If the population distribution $f_j(\mathbf{x})$ is elliptically symmetric, we have $f_j(\mathbf{x}) = |\Sigma_j|^{-1/2} g_j(\delta(\mathbf{x}, F_j))$, where $\delta(\mathbf{x}, F_j) = \|\Sigma_j^{-1/2}(\mathbf{x} - \mu_j)\|$ is the Mahalanobis distance for $1 \leq j \leq J$. Since $\text{SPD}^*(\mathbf{x}, F_j) = 1 - \|E[u(\Sigma_j^{-1/2}(\mathbf{x} - \mu_j))]\|$ is affine invariant, it is a function of $\delta(\mathbf{x}, F_j)$. Again, as $\Sigma_j^{-1/2}(\mathbf{X} - \mu_j)$ has a spherically symmetric distribution

with its center at the origin, from Lemma 7 it follows that $\text{SPD}^*(\mathbf{x}, F_j)$ is a monotonically decreasing function of $\delta(\mathbf{x}, F_j)$. Therefore, $\delta(\mathbf{x}, F_j)$ is also a function of $\text{SPD}^*(\mathbf{x}, F_j)$ and using this fact $f_j(\mathbf{x})$ can also be expressed as

$$f_j(\mathbf{x}) = \psi_j(\text{SPD}^*(\mathbf{x}, F_j)) \text{ for all } 1 \leq j \leq J,$$

where ψ_j is an appropriate real-valued function that depends on g_j . Now, one can check that

$$\log \left[\frac{p(j|\mathbf{x})}{p(J|\mathbf{x})} \right] = \log(\pi_j/\pi_J) + \log \psi_j(\text{SPD}^*(\mathbf{x}, F_j)) - \log \psi_J(\text{SPD}^*(\mathbf{x}, F_J)).$$

for $1 \leq j \leq (J-1)$. Now, if we define $\varphi_{jj}(z) = \log \pi_j + \log \psi_j(z)$ and $\varphi_{jJ}(z) = 0$ for $1 \leq j \neq i \leq (J-1)$; and $\varphi_{1J}(z) = \dots = \varphi_{(J-1)J}(z) = -\log \pi_J - \log \psi_J(z)$, then the proof is complete. ■

Remark 8 *If $f_j(\mathbf{x})$ is unimodal, $\psi_j(z)$ is monotonically increasing for $1 \leq j \leq J$. Moreover, if the distributions differ only in their locations, then the ψ_j s are same for all classes. In that case, $f_j(\mathbf{x}) > f_i(\mathbf{x}) \Leftrightarrow \delta(\mathbf{x}, F_j) < \delta(\mathbf{x}, F_i) \Leftrightarrow \text{SPD}^*(\mathbf{x}, F_j) > \text{SPD}^*(\mathbf{x}, F_i)$ for $1 \leq i \neq j \leq J$, and hence the classifier turns out to be the maximum SPD classifier.*

Proof of Theorem 3(a) : Let $h < 1$. For any fixed $\mathbf{x} \in \mathbb{R}^d$ and the distribution function F_j , we have $\text{LSPD}_h^*(\mathbf{x}, F_j) = E_{F_j}[K_h(\mathbf{t}u(\mathbf{t}))]$, where $\mathbf{t} = \Sigma_j^{-1/2}(\mathbf{x} - \mathbf{X})$ for $1 \leq j \leq J$. For the first term in the expression of $\text{LSPD}_h^*(\mathbf{x}, F_j)$ above, we have

$$E_{F_j}[K_h(\mathbf{t})] = \int_{\mathbb{R}^d} \frac{1}{h^d} K_h(\Sigma_j^{-1/2}(\mathbf{x} - \mathbf{v})) f_j(\mathbf{v}) d\mathbf{v} = |\Sigma_j|^{1/2} \int_{\mathbb{R}^d} K(\mathbf{y}) f_j(\mathbf{x} - h\Sigma_j^{1/2}\mathbf{y}) d\mathbf{y},$$

where $\mathbf{y} = h^{-1}\Sigma_j^{-1/2}(\mathbf{x} - \mathbf{v})$. So, using Taylor’s expansion of $f_j(\mathbf{x})$, we get

$$E_{F_j}[K_h(\mathbf{t})] = |\Sigma_j|^{1/2} f_j(\mathbf{x}) - h|\Sigma_j|^{1/2} \int_{\mathbb{R}^d} K(\mathbf{y}) (\Sigma_j^{1/2}\mathbf{y})^T \nabla f_j(\xi) d\mathbf{y},$$

where ξ lies on the line joining \mathbf{x} and $(\mathbf{x} - h\Sigma_j^{1/2}\mathbf{v})$. Using the Cauchy-Schwarz inequality, one gets $|E_{F_j}[K_h(\mathbf{t})] - |\Sigma_j|^{1/2} f_j(\mathbf{x})| \leq h|\Sigma_j|^{1/2} \lambda_j^{1/2} M_j^c M_K$, where $M_j^c = \sup_{\mathbf{x} \in \mathbb{R}^d} \|\nabla f_j(\mathbf{x})\|$, $M_K = \int \|\mathbf{y}\| K(\mathbf{y}) d\mathbf{y}$, and λ_j is the largest eigenvalue of Σ_j . This implies $|E_{F_j}[K_h(\mathbf{t})] - |\Sigma_j|^{1/2} f_j(\mathbf{x})| \rightarrow 0$ as $h \rightarrow 0$ for $1 \leq j \leq J$.

For the second term in the expression of $\text{LSPD}_h^*(\mathbf{x}, F_j)$, a similar argument yields

$$\begin{aligned} E_{F_j}[K_h(\mathbf{t})u(\mathbf{t})] &= |\Sigma_j|^{1/2} \int_{\mathbb{R}^d} K(\mathbf{y}) u(\mathbf{y}) f_j(\mathbf{x} - h\Sigma_j^{1/2}\mathbf{y}) d\mathbf{y} \\ &= -h|\Sigma_j|^{1/2} \int_{\mathbb{R}^d} K(\mathbf{y}) u(\mathbf{y}) (\Sigma_j^{1/2}\mathbf{y})^T \nabla f_j(\xi) d\mathbf{y} \text{ (as } \int_{\mathbb{R}^d} K(\mathbf{y}) u(\mathbf{y}) d\mathbf{y} = \mathbf{0}). \end{aligned}$$

Now, $\|E_{F_j}[K_h(\mathbf{t})u(\mathbf{t})]\| \leq h|\Sigma_j|^{1/2} \lambda_j^{1/2} M_j^c M_K \rightarrow 0$ and this implies that $\text{LSPD}_h^*(\mathbf{x}, F_j) \rightarrow |\Sigma_j|^{1/2} f_j(\mathbf{x})$, as $h \rightarrow 0$. Consequently, we have $\mathbf{z}_h^*(\mathbf{x}) \rightarrow (|\Sigma_1|^{1/2} f_1(\mathbf{x}), \dots, |\Sigma_J|^{1/2} f_J(\mathbf{x}))^T$ as $h \rightarrow 0$. ■

Proof of Theorem 3(b) : Here we consider the case $h > 1$. Take any fixed $\mathbf{x} \in \mathbb{R}^d$ and a j with $1 \leq j \leq J$. For any fixed \mathbf{t} , since $K(\mathbf{t}/h) \rightarrow K(\mathbf{0})$ as $h \rightarrow \infty$ and K is bounded, using Dominated Convergence Theorem (DCT), one can show that $\text{LSPD}_h^*(\mathbf{x}, F_j) \rightarrow K(\mathbf{0})\text{SPD}^*(\mathbf{x}, F_j)$ as $h \rightarrow \infty$. So, $\mathbf{z}_h^*(\mathbf{x}) \rightarrow (K(\mathbf{0})\text{SPD}^*(\mathbf{x}, F_1), \dots, K(\mathbf{0})\text{SPD}^*(\mathbf{x}, F_J))^T$ as $h \rightarrow \infty$. ■

Proof of Theorem 5 : Define the sets $B_n = \{\mathbf{x} = (x_1, \dots, x_d) : \|\mathbf{x}\| \leq \sqrt{dn}\}$, and $A_n = \{\mathbf{x} : n^2x_i$ is an integer and $|x_i| \leq n$ for all $1 \leq i \leq d\}$. Clearly $A_n \subset B_n \subset \mathbb{R}^d$, the set B_n is a closed ball and the set A_n has cardinality $(2n^2 + 1)^d$. We will prove almost sure (a.s.) uniform convergence on three disjoint sets: (i) A_n , (ii) $B_n \setminus A_n$ and (iii) B_n^c . Consider any fixed $h \in (0, 1]$. Recall that for this choice of h , $\text{LSPD}_h^\circ(\mathbf{x}, F)$ (see equation (3)) and $\text{LSPD}_h^\circ(\mathbf{x}, F_n)$ are defined as follows:

$$\begin{aligned} \text{LSPD}_h^\circ(\mathbf{x}, F_n) &= \frac{1}{nh^d} \sum_{i=1}^n K\left(\frac{\mathbf{x} - \mathbf{X}_i}{h}\right) - \left\| \frac{1}{nh^d} \sum_{i=1}^n K\left(\frac{\mathbf{x} - \mathbf{X}_i}{h}\right) u(\mathbf{x} - \mathbf{X}_i) \right\|, \text{ and} \\ \text{LSPD}_h^\circ(\mathbf{x}, F) &= \frac{1}{h^d} E\left[K\left(\frac{\mathbf{x} - \mathbf{X}}{h}\right)\right] - \frac{1}{h^d} \|E\left[K\left(\frac{\mathbf{x} - \mathbf{X}}{h}\right) u(\mathbf{x} - \mathbf{X})\right]\|. \end{aligned}$$

(i) Define $\mathbf{Z}_i = K(h^{-1}(\mathbf{x} - \mathbf{X}_i))u(\mathbf{x} - \mathbf{X}_i) - E[K(h^{-1}(\mathbf{x} - \mathbf{X}))u(\mathbf{x} - \mathbf{X})]$ for $1 \leq i \leq n$. Note that \mathbf{Z}_i 's are independent and identically distributed (i.i.d.) with $E(\mathbf{Z}_i) = \mathbf{0}$ and $\|\mathbf{Z}_i\| \leq 2K(\mathbf{0})$. Fix an $\epsilon > 0$. Using the exponential inequality for sums of i.i.d. random vectors (see Yurinskii, 1976, p. 491), we obtain $P\left(\|n^{-1} \sum_{i=1}^n \mathbf{Z}_i\| \geq \epsilon\right) \leq 2e^{-C_0 n \epsilon^2}$. Here C_0 is a positive constant that depends on $K(\mathbf{0})$ and ϵ . This now implies that

$$\begin{aligned} P\left(\left\| \frac{1}{nh^d} \sum_{i=1}^n K\left(\frac{\mathbf{x} - \mathbf{X}_i}{h}\right) u(\mathbf{x} - \mathbf{X}_i) \right\| - \left\| \frac{1}{h^d} E\left[K\left(\frac{\mathbf{x} - \mathbf{X}}{h}\right) u(\mathbf{x} - \mathbf{X})\right] \right\| \geq \epsilon\right) \\ \leq P\left(\left\| \frac{1}{nh^d} \sum_{i=1}^n K\left(\frac{\mathbf{x} - \mathbf{X}_i}{h}\right) u(\mathbf{x} - \mathbf{X}_i) - \frac{1}{h^d} E\left[K\left(\frac{\mathbf{x} - \mathbf{X}}{h}\right) u(\mathbf{x} - \mathbf{X})\right] \right\| \geq \epsilon\right) \\ = P\left(\left\| \frac{1}{n} \sum_{i=1}^n \mathbf{Z}_i \right\| \geq h^d \epsilon\right) \leq 2e^{-C_0 n h^{2d} \epsilon^2}. \end{aligned} \quad (6)$$

For a fixed value of h , $\sum_{i=1}^n K(h^{-1}(\mathbf{x} - \mathbf{X}_i))$ is a sum of i.i.d. bounded random variables. Using Bernstein's inequality, we obtain

$$\begin{aligned} P\left(\left| \frac{1}{n} \sum_{i=1}^n K\left(\frac{\mathbf{x} - \mathbf{X}_i}{h}\right) - E\left[K\left(\frac{\mathbf{x} - \mathbf{X}}{h}\right)\right] \right| \geq \epsilon\right) &\leq 2e^{-C_1 n \epsilon^2}, \\ P\left(\left| \frac{1}{nh^d} \sum_{i=1}^n K\left(\frac{\mathbf{x} - \mathbf{X}_i}{h}\right) - \frac{1}{h^d} E\left[K\left(\frac{\mathbf{x} - \mathbf{X}}{h}\right)\right] \right| \geq \epsilon\right) &\leq 2e^{-C_1 n h^{2d} \epsilon^2}. \end{aligned} \quad (7)$$

for some suitable positive constant C_1 . This implies

$$\begin{aligned} \text{Combining (6) and (7), we get } P(|\text{LSPD}^\circ(\mathbf{x}, F_n) - \text{LSPD}^\circ(\mathbf{x}, F)| \geq \epsilon) &\leq C_3 e^{-C_4 n h^{2d} \epsilon^2} \text{ for} \\ \text{some suitable constants } C_3 \text{ and } C_4. \text{ Since the cardinality of } A_n \text{ is } (2n^2 + 1)^d, \text{ we have} \\ P\left(\sup_{\mathbf{x} \in A_n} |\text{LSPD}^\circ(\mathbf{x}, F_n) - \text{LSPD}^\circ(\mathbf{x}, F)| \geq \epsilon\right) &\leq C_3 (2n^2 + 1)^d e^{-C_4 n h^{2d} \epsilon^2}. \end{aligned} \quad (8)$$

Now, $\sum_{n \geq 1} (2n^2 + 1)^d e^{-C_4 n h^{2d} \epsilon^2} < \infty$. So, an application of Borel-Cantelli lemma implies that $\sup_{\mathbf{x} \in A_n} |\text{LSPD}_h^\circ(\mathbf{x}, F_n) - \text{LSPD}_h^\circ(\mathbf{x}, F)| \xrightarrow{\text{a.s.}} 0$ as $n \rightarrow \infty$.

(ii) Consider the set $B_n \setminus A_n$. Given any \mathbf{x} in $B_n \setminus A_n$, there exists $\mathbf{y} \in A_n$ such that $\|\mathbf{x} - \mathbf{y}\| \leq \sqrt{2}/n^2$. First we will show that $|\text{LSPD}^\circ(\mathbf{y}, F_n) - \text{LSPD}^\circ(\mathbf{x}, F_n)| \xrightarrow{\text{a.s.}} 0$ as $n \rightarrow \infty$. Using the mean-value theorem, one obtains

$$\left| \frac{1}{nh^d} \sum_{i=1}^n K\left(\frac{\mathbf{x} - \mathbf{X}_i}{h}\right) - \frac{1}{nh^d} \sum_{i=1}^n K\left(\frac{\mathbf{y} - \mathbf{X}_i}{h}\right) \right| \leq \frac{1}{nh^{d+1}} \sum_{i=1}^n \left| (\mathbf{x} - \mathbf{y})^T \nabla K\left(\frac{\boldsymbol{\xi} - \mathbf{X}_i}{h}\right) \right|,$$

where $\boldsymbol{\xi}$ lies on the line joining \mathbf{x} and \mathbf{y} . Note that the right hand side is less than $\frac{M'_K \sqrt{2}}{h^{d+1} n^2}$, and $M'_K = \sup_{\mathbf{t}} \|\nabla K(\mathbf{t})\|$. This upper bound is free of \mathbf{x} , and goes to 0 as $n \rightarrow \infty$. Now,

$$\begin{aligned} &\left\| \frac{1}{nh^d} \sum_{i=1}^n K\left(\frac{\mathbf{x} - \mathbf{X}_i}{h}\right) u(\mathbf{x} - \mathbf{X}_i) \right\| - \left\| \frac{1}{nh^d} \sum_{i=1}^n K\left(\frac{\mathbf{y} - \mathbf{X}_i}{h}\right) u(\mathbf{y} - \mathbf{X}_i) \right\| \\ &\leq \left\| \frac{1}{nh^d} \sum_{i=1}^n \left[K\left(\frac{\mathbf{x} - \mathbf{X}_i}{h}\right) u(\mathbf{x} - \mathbf{X}_i) - K\left(\frac{\mathbf{y} - \mathbf{X}_i}{h}\right) u(\mathbf{y} - \mathbf{X}_i) \right] \right\| \\ &\leq \frac{1}{nh^d} \sum_{i=1}^n \left[K\left(\frac{\mathbf{x} - \mathbf{X}_i}{h}\right) - K\left(\frac{\mathbf{y} - \mathbf{X}_i}{h}\right) \right] + K(\mathbf{0}) \left\| \frac{1}{nh^d} \sum_{i=1}^n [u(\mathbf{x} - \mathbf{X}_i) - u(\mathbf{y} - \mathbf{X}_i)] \right\|. \end{aligned} \quad (9)$$

We have proved above that the first part converges to 0 in a.s. sense.

For the second part, consider a ball of radius $1/n$ around \mathbf{x} (say, $B(\mathbf{x}, 1/n)$). Now,

$$\begin{aligned} \left\| \frac{1}{nh^d} \sum_{i=1}^n [u(\mathbf{x} - \mathbf{X}_i) - u(\mathbf{y} - \mathbf{X}_i)] \right\| &\leq \left\| \frac{2}{nh^d} \sum_{i=1}^n I[\mathbf{X}_i \in B(\mathbf{x}, 1/n)] \right\| + \frac{2n}{h^d} \|\mathbf{x} - \mathbf{y}\| \\ &\leq \frac{2}{h^d} \left\| \frac{1}{n} \sum_{i=1}^n I[\mathbf{X}_i \in B(\mathbf{x}, 1/n)] - P[\mathbf{X}_1 \in B(\mathbf{x}, 1/n)] \right\| \\ &\quad + \frac{2}{h^d} P[\mathbf{X}_1 \in B(\mathbf{x}, 1/n)] + \frac{2n\sqrt{2}}{n^2 h^d}. \end{aligned}$$

Note that $I[\mathbf{X}_i \in B(\mathbf{x}, 1/n)]$'s are i.i.d. bounded random variables with expectation $P[\mathbf{X} \in B(\mathbf{x}, 1/n)]$. Therefore, a.s. convergence of the first term follows from Bernstein's inequality. Since $P[\mathbf{X} \in B(\mathbf{x}, 1/n)] \leq M_f n^{-d}$ (where $M_f = \sup_{\mathbf{x}} f(\mathbf{x}) < \infty$), the second term converges to 0. For any fixed h , the third term also converges to 0 as $n \rightarrow \infty$. So, we have $|\text{LSPD}_h^\circ(\mathbf{x}, F_n) - \text{LSPD}_h^\circ(\mathbf{y}, F_n)| \xrightarrow{\text{a.s.}} 0$ as $n \rightarrow \infty$.

Similarly, one can prove that $|\text{LSPD}_h^\circ(\mathbf{x}, F) - \text{LSPD}_h^\circ(\mathbf{y}, F)| \xrightarrow{\text{a.s.}} 0$ as $n \rightarrow \infty$. In the arguments above, all the bounds are free from \mathbf{x} and \mathbf{y} . We have also proved that $\sup_{\mathbf{y} \in A_n} |\text{LSPD}_h^\circ(\mathbf{y}, F_n) - \text{LSPD}_h^\circ(\mathbf{y}, F)| \xrightarrow{\text{a.s.}} 0$ as $n \rightarrow \infty$. Combining all these results, we have $\sup_{\mathbf{x} \in B_n \setminus A_n} |\text{LSPD}_h^\circ(\mathbf{x}, F_n) - \text{LSPD}_h^\circ(\mathbf{x}, F)| \xrightarrow{\text{a.s.}} 0$ as $n \rightarrow \infty$.

(iii) Now, consider the region outside B_n (i.e., the set B_n^c). First note that

$$\sup_{\mathbf{x} \in B_n^c} |\text{LSPD}_h^\circ(\mathbf{x}, F_n) - \text{LSPD}_h^\circ(\mathbf{x}, F)| \leq \sup_{\mathbf{x} \in B_n^c} \frac{1}{nh^d} \sum_{i=1}^n K\left(\frac{\mathbf{x} - \mathbf{X}_i}{h}\right) + \sup_{\mathbf{x} \in B_n^c} \frac{1}{h^d} E\left[K\left(\frac{\mathbf{x} - \mathbf{X}}{h}\right)\right].$$

We will show that both of these terms become sufficiently small as $n \rightarrow \infty$.

Fix an $\epsilon > 0$. We can choose two constants M_1 and M_2 such that $P(\|\mathbf{X}\| \geq M_1) \leq h^d \epsilon / 2K(\mathbf{0})$ and $K(\mathbf{t}) \leq h^d \epsilon / 2$ when $\|\mathbf{t}\| \geq M_2$. Now, one can check that

$$\frac{1}{h^d} E \left[K \left(\frac{\mathbf{x} - \mathbf{X}}{h} \right) \right] \leq \frac{1}{h^d} E \left[K \left(\frac{\mathbf{x} - \mathbf{X}}{h} \right) I(\|\mathbf{X}\| \leq M_1) \right] + \frac{1}{h^d} K(\mathbf{0}) P(\|\mathbf{X}\| > M_1).$$

If $\mathbf{x} \in B_n^c$ and $\|\mathbf{X}\| \leq M_1$, then $h^{-1} \|\mathbf{x} - \mathbf{X}\| \geq h^{-1} |\sqrt{dn} - M_1|$. Choose n large enough so that $|\sqrt{dn} - M_1| \geq M_2 h$, and this implies $K(h^{-1}(\mathbf{x} - \mathbf{X})) \leq h^d \epsilon / 2$. So, we obtain

$$\begin{aligned} \frac{1}{h^d} E \left[K \left(\frac{\mathbf{x} - \mathbf{X}}{h} \right) \right] &\leq \frac{\epsilon}{2} + \frac{1}{h^d} K(\mathbf{0}) P(\|\mathbf{X}\| > M_1) \leq \epsilon, \text{ and} \\ \frac{1}{nh^d} \sum_{i=1}^n K \left(\frac{\mathbf{x} - \mathbf{X}_i}{h} \right) &\leq \frac{\epsilon}{2} + \frac{1}{h^d} K(\mathbf{0}) \frac{1}{n} \sum_{i=1}^n I(\|\mathbf{X}_i\| > M_1) \end{aligned}$$

$$\leq \epsilon + \frac{1}{h^d} K(\mathbf{0}) \left| \frac{1}{n} \sum_{i=1}^n I(\|\mathbf{X}_i\| > M_1) - P(\|\mathbf{X}\| > M_1) \right|.$$

The Glivenko-Cantelli theorem implies that the last term on the right hand side converges to 0 as $n \rightarrow \infty$. So, we have $\sup_{\mathbf{x} \in B_n^c} |\text{LSPD}_h^{\circ}(\mathbf{x}, F_n) - \text{LSPD}_h^{\circ}(\mathbf{x}, F)| \xrightarrow{a.s.} 0$ as $n \rightarrow \infty$.

Combining the arguments in parts (i), (ii) and (iii) and for a fixed $h \in (0, 1]$, we get $\sup_{\mathbf{x}} |\text{LSPD}_h^{\circ}(\mathbf{x}, F_n) - \text{LSPD}_h^{\circ}(\mathbf{x}, F)| \xrightarrow{a.s.} 0$ as $n \rightarrow \infty$. If we have $h > 1$, then this convergence result can be proved in a similar way. For this case, recall that the definition of $\text{LSPD}^{\circ}(\mathbf{x}, F)$ does not involve the h^d term in the denominator (see equation (3)). ■

Remark 9 Following the proof of Theorem 5, it is easy to check that a.s. convergence holds when h diverges to infinity with n .

Remark 10 The result continues to hold when $h \rightarrow 0$ as well. However, for a.s. convergence in part (i) (to use the Borel-Cantelli lemma) we require $nh^{2d} / \log n \rightarrow \infty$ as $n \rightarrow \infty$. In part (iii), we need M_1 and M_2 to vary with n . Assume the first moment of the density corresponding to F to be finite, and $\int \|\mathbf{t}\| K(\mathbf{t}) dt < \infty$ (which implies that $\|\mathbf{t}\| K(\mathbf{t}) \rightarrow 0$ as $\|\mathbf{t}\| \rightarrow \infty$). Also, assume that $nh^{2d} / \log n \rightarrow \infty$ as $n \rightarrow \infty$. We can now choose $M_1 = M_2 = \sqrt{n}$ to ensure that both $P(\|\mathbf{X}\| \geq M_1) \leq h^d \epsilon / 2K(\mathbf{0})$ and $K(\mathbf{t}) \leq h^d \epsilon / 2$ for $\|\mathbf{t}\| \geq M_2$ hold for a sufficiently large n .

Proof of Theorem 6(a) : Consider two independent random vectors $\mathbf{X} = (X^{(1)}, \dots, X^{(d)})^T \sim F_j$ and $\mathbf{X}_1 = (X_1^{(1)}, \dots, X_1^{(d)})^T \sim F_j$, where $1 \leq j \leq J$. It follows from (C1) and (C2) that $\|\mathbf{X} - \mathbf{X}_1\| / \sqrt{d} \xrightarrow{a.s.} \sqrt{2\sigma_j^2}$ as $d \rightarrow \infty$. So, for almost every realization \mathbf{x} of $\mathbf{X} \sim F_j$,

$$\|\mathbf{x} - \mathbf{X}_1\| / \sqrt{d} \xrightarrow{a.s.} \sqrt{2\sigma_j^2} \text{ as } d \rightarrow \infty. \quad (10)$$

Next, consider two independent random vectors $\mathbf{X} \sim F_j$ and $\mathbf{X}_1 \sim F_i$ for $1 \leq i \neq j \leq J$. Using (C1) and (C2), we get $\|\mathbf{X} - \mathbf{X}_1\| / \sqrt{d} \xrightarrow{a.s.} \sqrt{\sigma_j^2 + \sigma_i^2 + \nu_{ji}}$ as $d \rightarrow \infty$. Consequently, for almost every realization \mathbf{x} of $\mathbf{X} \sim F_j$

$$\|\mathbf{x} - \mathbf{X}_1\| / \sqrt{d} \xrightarrow{a.s.} \sqrt{\sigma_j^2 + \sigma_i^2 + \nu_{ji}} \text{ as } d \rightarrow \infty. \quad (11)$$

Let us next consider $\langle \mathbf{x} - \mathbf{X}_1, \mathbf{x} - \mathbf{X}_2 \rangle$, where $\mathbf{X} \sim F_j$, $\mathbf{X}_1, \mathbf{X}_2 \sim F_i$ are independent random vectors, and $\langle \cdot, \cdot \rangle$ denotes the inner product in \mathbb{R}^d . Therefore, for almost every realization \mathbf{x} of \mathbf{X} , arguments similar to those used in (10) and (11) yield

$$\frac{\langle \mathbf{x} - \mathbf{X}_1, \mathbf{x} - \mathbf{X}_2 \rangle}{d} \xrightarrow{a.s.} \sigma_j^2 \text{ as } d \rightarrow \infty \text{ if } 1 \leq i = j \leq J, \text{ and} \quad (12)$$

$$\frac{\langle \mathbf{x} - \mathbf{X}_1, \mathbf{x} - \mathbf{X}_2 \rangle}{d} \xrightarrow{a.s.} \sigma_j^2 + \nu_{ji} \text{ as } d \rightarrow \infty \text{ if } 1 \leq i \neq j \leq J. \quad (13)$$

Observe now that $\|E_{F_j}[u(\mathbf{x} - \mathbf{X})]\|^2 = \langle E_{F_j}[u(\mathbf{x} - \mathbf{X}_1)], E_{F_j}[u(\mathbf{x} - \mathbf{X}_2)] \rangle = E_{F_j}[u(\mathbf{x} - \mathbf{X}_1), u(\mathbf{x} - \mathbf{X}_2)]$, where $\mathbf{X}_1, \mathbf{X}_2 \sim F_j$ are independent random vectors for $1 \leq j \leq J$.

Since we are dealing with expectations of random vectors with bounded norm, a simple application of DCT implies that for almost every realization \mathbf{x} of $\mathbf{X} \sim F_j$ ($1 \leq j \leq J$), as $d \rightarrow \infty$,

$$\text{SPD}^{\circ}(\mathbf{x}, F_j) \xrightarrow{a.s.} 1 - \sqrt{\frac{1}{2}} \text{ and } \text{SPD}^{\circ}(\mathbf{x}, F_i) \xrightarrow{a.s.} 1 - \sqrt{\frac{\sigma_j^2 + \nu_{ji}}{\sigma_j^2 + \sigma_i^2 + \nu_{ji}}} \text{ for } i \neq j. \quad (14)$$

Thus, for $\mathbf{X} \sim F_j$, we get $z^{\circ}(\mathbf{X}) = (\text{SPD}^{\circ}(\mathbf{X}, F_1), \dots, \text{SPD}^{\circ}(\mathbf{X}, F_J))^T \xrightarrow{a.s.} \mathbf{c}_j$ as $d \rightarrow \infty$. ■

Proof of Theorem 6(b) : Recall that for $h > 1$, $\text{LSPD}_h^{\circ}(\mathbf{x}, F) = E_{F_j}[h^d K_h(\mathbf{t})] - \|E_{F_j}[h^d K_h(\mathbf{t})u(\mathbf{t})]\|$. Since we have assumed \mathbf{X} s to be standardized, here we get $h^d K_h(\mathbf{t}) = K(\mathbf{x} - \mathbf{X})/h = g_0(\|\mathbf{x} - \mathbf{X}\|/h)$. Let $\mathbf{X} \sim F_j$ and $\mathbf{X}_i \sim F_i$ with $1 \leq i, j \leq J$. Using (10) and (11) above, and the continuity of g_0 , for almost every realization \mathbf{x} of $\mathbf{X} \sim F_j$, one obtains the following

$$g_0 \left(\frac{\|\mathbf{x} - \mathbf{X}_i\| \sqrt{d}}{h} \right) \xrightarrow{a.s.} g_0(0) \text{ or } g_0(\epsilon_{ji} A_0),$$

depending on whether $\sqrt{d}/h \rightarrow 0$ or A_0 . The proof follows from an application of DCT, and the arguments used in the proof of Theorem 6(a). ■

Proof of Theorem 6(c) : Since $g_0(s) \rightarrow 0$ as $s \rightarrow \infty$, using the same argument as used in the proof of Theorem 6(b), for $\mathbf{X}_i \sim F_i$ and almost every realization \mathbf{x} of $\mathbf{X} \sim F_j$, we have

$$g_0 \left(\frac{\|\mathbf{x} - \mathbf{X}_i\| \sqrt{d}}{h} \right) \xrightarrow{a.s.} 0 \text{ as } \sqrt{d}/h \rightarrow \infty.$$

The proof now follows from a simple application of DCT. ■

Lemma 11 Recall \mathbf{c}_j and \mathbf{c}'_j for $1 \leq j \leq J$ defined in Theorem 6(a) and (b), respectively. For any $1 \leq j \neq i \leq J$, $\mathbf{c}_j = \mathbf{c}_i$ if and only if $\sigma_j = \sigma_i$ and $\nu_{ji} = \nu_{ij} = 0$. Similarly, $\mathbf{c}'_j = \mathbf{c}'_i$ if and only if $\sigma_j = \sigma_i$ and $\nu_{ji} = \nu_{ij} = 0$.

Proof of Lemma 11 : The 'if' part is easy to check in both cases. So, it is enough to prove the 'only if' part and that too for the case of $J = 2$. If $\mathbf{c}_1 = (c_{11}, c_{12})^T$ and $\mathbf{c}_2 = (c_{21}, c_{22})^T$ are equal, then we have

$$\frac{\sigma_1^2 + \nu_{12}}{\sigma_1^2 + \sigma_2^2 + \nu_{12}} = 1/2 \text{ and } \frac{\sigma_2^2 + \nu_{12}}{\sigma_1^2 + \sigma_2^2 + \nu_{12}} = 1/2.$$

These two equations hold simultaneously only if $\sigma_1^2 = \sigma_2^2$ and $\nu_12 = \nu_21 = 0$.

Consider the case $c_1^1 = c_2^2$. Recall that $c_{11}^1 = g_0(A_0\sqrt{2\sigma_1})/c_{11}$, $c_{22}^2 = g_0(A_0\sqrt{2\sigma_2})/c_{22}$, $c_{12}^2 = g_0(A_0\sqrt{\sigma_1^2 + \sigma_2^2 + \nu_{12}})/c_{12}$ and $c_{21}^1 = g_0(A_0\sqrt{\sigma_2^2 + \sigma_1^2 + \nu_{21}})/c_{21}$. If possible, assume that $\sigma_1 > \sigma_2$. This implies that $A_0\sqrt{\sigma_1^2 + \sigma_2^2 + \nu_{12}} > A_0\sqrt{2\sigma_1}$ and hence we obtain

$$g_0(A_0\sqrt{2\sigma_1}) > g_0(A_0\sqrt{\sigma_1^2 + \sigma_2^2 + \nu_{12}}) \quad (\text{since } g_0 \text{ is monotonically decreasing}). \quad (15)$$

Also, if $\sigma_1 > \sigma_2$, we must have

$$1/2 < \frac{\sigma_1^2}{\sigma_1^2 + \sigma_2^2} < \frac{\sigma_1^2 + \nu_{12}}{\sigma_1^2 + \sigma_2^2 + \nu_{12}} < 1 \Leftrightarrow 1 - \sqrt{1/2} > 1 - \sqrt{\frac{\sigma_1^2 + \nu_{12}}{\sigma_1^2 + \sigma_2^2 + \nu_{12}}}. \quad (16)$$

Combining (15) and (16), we have $c_{11}^1 > c_{21}^1$, and this implies $c_1^1 \neq c_2^2$. Similarly, if $\sigma_1 < \sigma_2$, we get $c_{12}^2 > c_{22}^2$ and hence $c_1^1 \neq c_2^2$. Again, if $\sigma_1 = \sigma_2$ but $\nu_{12} = \nu_{21} > 0$, similar arguments lead to $c_1^1 \neq c_2^2$. This completes the proof. ■

Abstract

This paper provides a general technique for lower bounding the Bayes risk of statistical estimation, applicable to arbitrary loss functions and arbitrary prior distributions. A lower bound on the Bayes risk not only serves as a lower bound on the minimax risk, but also characterizes the fundamental limit of any estimator given the prior knowledge. Our bounds are based on the notion of f -informativity (Csiszár, 1972), which is a function of the underlying class of probability measures and the prior. Application of our bounds requires upper bounds on the f -informativity, thus we derive new upper bounds on f -informativity which often lead to tight Bayes risk lower bounds. Our technique leads to generalizations of a variety of classical minimax bounds (e.g., generalized Fano's inequality). Our Bayes risk lower bounds can be directly applied to several concrete estimation problems, including Gaussian location models, generalized linear models, and principal component analysis for spiked covariance models. To further demonstrate the applications of our Bayes risk lower bounds to machine learning problems, we present two new theoretical results: (1) a precise characterization of the minimax risk of learning spherical Gaussian mixture models under the smoothed analysis framework, and (2) lower bounds for the Bayes risk under a natural prior for both the prediction and estimation errors for high-dimensional sparse linear regression under an improper learning setting.

Keywords: Bayes risk, Minimax risk, f -divergence, f -informativity, Fano's inequality, Smoothed analysis

1. Introduction

Consider a standard setting where we observe data points X taking values in a sample space \mathcal{X} . The distribution of X depends on an unknown parameter $\theta \in \Theta$ and is denoted by P_θ . The goal is to compute an estimate of θ based on the observed samples. Formally, we denote the estimator by $\mathfrak{d}(X)$, where $\mathfrak{d} : \mathcal{X} \rightarrow \Theta$ is a mapping from the sample space to the parameter space. The risk of the estimator is defined by $\mathbb{E}_\theta L(\theta, \mathfrak{d}(X))$ where $L :$

$\Theta \times \mathcal{A} \mapsto [0, \infty)$ is a non-negative loss function. This framework applies to a broad scope of machine learning problems. Taking sparse linear regression as a concrete example, the data X represents the design matrix and the response vector; the parameter space is the set of sparse vectors; the loss function can be chosen as a squared loss.

Given an estimation problem, we are interested in the lowest possible risk achievable by any estimator, which will be useful in justifying the potential of improving existing algorithms. The classical notion of optimality is formalized by the so-called *minimax risk*. More specifically, we assume that the statistician chooses an optimal estimator \mathfrak{d} , then the adversary chooses the worst parameter θ by knowing the choice of \mathfrak{d} . The minimax risk is defined as:

$$R_{\text{minimax}}(L; \Theta) := \inf_{\mathfrak{d}} \sup_{\theta \in \Theta} \mathbb{E}_\theta L(\theta, \mathfrak{d}(X)). \quad (1)$$

The minimax risk has been determined up to multiplicative constants for many important problems. Examples include sparse linear regression (Raskutti et al., 2011), classification (Yang, 1999), additive models over kernel classes (Raskutti et al., 2012), and crowdsourcing (Zhang et al., 2016).

The assumption that the adversary is capable of choosing a worst-case parameter is sometimes over-pessimistic. In practice, the parameter that incurs a worst-case risk may appear with very small probability. To capture the hardness of the problem with this prior knowledge, it is reasonable to assume that the true parameter is sampled from an underlying prior distribution w . In this case, we are interested in the *Bayes risk* of the problem. That is, the lowest possible risk when the true parameter is sampled from the prior distribution:

$$R_{\text{Bayes}}(w, L; \Theta) := \inf_{\mathfrak{d}} \int_{\Theta} \mathbb{E}_\theta L(\theta, \mathfrak{d}(X)) w(d\theta). \quad (2)$$

If the prior distribution w is known to the learner, then the Bayes estimator attains the Bayes risk (Berger, 2013). But in general, the Bayes estimator is computationally hard to evaluate, and the Bayes risk has no closed-form expression. It is thus unclear what is the fundamental limit of estimators when the prior knowledge is available.

In this paper, we present a technique for establishing lower bounds on the Bayes risk for a general prior distribution w . When the lower bound matches the risk of any existing algorithm, it captures the convergence rate of the Bayes risk. The Bayes risk lower bounds are useful for three main reasons:

1. They provide an idea of the difficulty of the problem under a specific prior w .
2. They automatically provide lower bounds for the minimax risk and, because the minimax regret is always larger than or equal to the minimax risk (see, for example, Rakhlin et al. (2013)), they also yield lower bounds for the minimax regret.
3. As we will show, they have an important application in establishing the minimax lower bound under the *smoothed analysis framework*.

Throughout this paper, when the loss function L and the parameter space Θ are clear from the context, we simply denote the Bayes risk by $R_{\text{Bayes}}(w)$. When the prior w is also clear, the notation is further simplified to R .

1.1 Our Main Results

In order to give the reader a flavor of the kind of results proved in this paper, let us consider Fano’s classical inequality (Han and Verdú, 1994; Cover and Thomas, 2006; Yu, 1997) which is one of the most widely used Bayes risk lower bounds in statistics and information theory. The standard version of Fano’s inequality applies to the case when $\Theta = \mathcal{A} = \{1, \dots, N\}$ for some positive integer N with the indicator loss $L(\theta, a) := \mathbb{I}\{\theta \neq a\}$ (\mathbb{I} stands for the zero-one valued indicator function) and the prior w being the discrete uniform distribution on Θ . In this setting, Fano’s inequality states that

$$R_{\text{Bayes}}(w) \geq 1 - \frac{I(w; \mathcal{P}) + \log 2}{\log N} \quad (3)$$

where $I(w; \mathcal{P})$ is the mutual information between the random variables $\theta \sim w$ and X with $X|\theta \sim P_\theta$ (note that this mutual information only depends on w and $\mathcal{P} = \{P_\theta : \theta \in \Theta\}$ which is why we denote it by $I(w; \mathcal{P})$). Fano’s inequality implies that when $I(w; \mathcal{P})$ is large i.e., when the information that X has about θ is large, then the risk of estimation is small.

A natural question regarding Fano’s inequality, which does not seem to have been asked until very recently, is the following: does there exist an analogue of (3) when w is not necessarily the uniform prior and/or when Θ and \mathcal{A} are arbitrary sets, and/or when the loss function is not necessarily $\mathbb{I}\{\theta \neq a\}$? An interesting result in this direction is the following inequality which has been recently proved by Duchi and Wainwright (2013) who termed it the continuum Fano inequality. This inequality applies to the case when $\Theta = \mathcal{A}$ is a subset of Euclidean space with finite strictly positive Lebesgue measure, $L(\theta, a) = \mathbb{I}\{\|\theta - a\|_2 \geq \epsilon\}$ for a fixed $\epsilon > 0$ ($\|\cdot\|_2$ is the usual Euclidean metric) and the prior w being the uniform probability measure (i.e., normalized Lebesgue measure) on Θ . In this setting, Duchi and Wainwright (2013) proved that

$$R_{\text{Bayes}}(w) \geq 1 + \frac{I(w; \mathcal{P}) + \log 2}{\log(\sup_{a \in \mathcal{A}} w\{\theta \in \Theta : \|\theta - a\|_2 < \epsilon\})}. \quad (4)$$

It turns out that there is a very clean connection between inequalities (3) and (4). Indeed, both these inequalities are special instances of the following inequality:

$$R_{\text{Bayes}}(w) \geq 1 + \frac{I(w; \mathcal{P}) + \log 2}{\log(\sup_{a \in \mathcal{A}} w\{\theta \in \Theta : L(\theta, a) = 0\})} \quad (5)$$

Indeed, the term $w\{\theta \in \Theta : L(\theta, a) = 0\}$ equal to $1/N$ in the setting of (3) and it is equal to $w\{\theta \in \Theta : \|\theta - a\|_2 < \epsilon\}$ in the setting of (4).

Since both (3) and (4) are special instances of (5), one might reasonably conjecture that proving that inequality (5) might hold more generally. In Section 3, we give an affirmative answer by proving that inequality (5) holds for any zero-one valued loss function L and any prior w . No assumptions on Θ , \mathcal{A} and w are needed. We refer to this result as *generalized Fano’s inequality*. Our proof of (5) is quite succinct and is based on the data processing inequality (Cover and Thomas, 2006; Liese, 2012) for Kullback-Leibler (KL) divergence. The use of the data processing inequality for proving Fano-type inequalities was introduced by Gushchin (2003).

The data processing inequality is not only available for the KL divergence. It can be generalized to any divergence belonging to a general family known as f -divergences (Csiszár, 1963; Ali and Silvey, 1966). This family includes the KL divergence, chi-squared divergence, squared Hellinger distance, total variation distance and power divergences as special cases. The usefulness of f -divergences in machine learning has been illustrated in Reid and Williamson (2011); Garcia-Garcia and Williamson (2012); Reid and Williamson (2009).

For every f -divergence, one can define a quantity called f -informativity (Csiszár, 1972) which plays the same role as the mutual information for KL divergence. The precise definitions of f -divergences and f -informativities are given in Section 2. Utilizing the data processing inequality for f -divergence, we prove general Bayes risk lower bounds which hold for every zero-one valued loss L and for arbitrary Θ , \mathcal{A} and w (Theorem 2). The generalized Fano’s inequality (5) is a special case by choosing the f -divergence to be KL. The proposed Bayes risk lower bounds can also be specialized to other f -divergences and have a variety of interesting connections to existing lower bounds in the literature such as Le Cam’s inequality, Assouad’s lemma (see Theorem 2.12 in Tsybakov (2010)), Birgé-Gushchin inequality (Gushchin, 2003; Birgé, 2005). These results are provided in Section 3.

In Section 4, we deal with nonnegative valued loss functions L which are not necessarily zero-one valued. Basically, we use the standard method of lower bounding the general loss function L by a zero-one valued function and then use our results from Section 3 for lower bounding the Bayes risk. This technique, in conjunction with the generalized Fano’s inequality, gives the following lower bound (proved in Corollary 12)

$$R_{\text{Bayes}}(w, L; \Theta) \geq \frac{1}{2} \sup_{a \in \mathcal{A}} \left\{ t > 0 : \sup_{a \in \mathcal{A}} w\{\theta : L(\theta, a) < t\} \leq \frac{1}{4} e^{-2I(w; \mathcal{P})} \right\}. \quad (6)$$

A special case of the above inequality has appeared previously in Zhang (2006, Theorem 6.1) (please refer to Remark 13 for a detailed explanation of the connection between inequality (6) and (Zhang, 2006, Theorem 6.1)).

We also prove analogues of the above inequality for different f divergences. Specifically, using our f -divergence inequalities from Section 3, we prove, in Theorem 9, the following inequality which holds for every f divergence:

$$R_{\text{Bayes}}(w, L; \Theta) \geq \frac{1}{2} \sup_{a \in \mathcal{A}} \left\{ t > 0 : \sup_{a \in \mathcal{A}} w\{\theta : L(\theta, a) < t\} < 1 - u_f(I(w; \mathcal{P})) \right\} \quad (7)$$

where $I_f(w; \mathcal{P})$ represents the f -informativity and $u_f(\cdot)$ is a non-decreasing $[0, 1]$ -valued function that depends only on f . This function $u_f(\cdot)$ (see its definition from (31)) can be explicitly computed for many f -divergences of interest, which gives useful lower bounds in terms of f -informativity. For example, for the case of KL divergence and chi-squared divergence, inequality (7) gives the lower bound in (6) and the following inequality respectively,

$$R_{\text{Bayes}}(w, L; \Theta) \geq \frac{1}{2} \sup_{a \in \mathcal{A}} \left\{ t > 0 : \sup_{a \in \mathcal{A}} w\{\theta : L(\theta, a) < t\} \leq \frac{1}{4(1 + I_{\chi^2}(w; \mathcal{P}))} \right\}. \quad (8)$$

where $I_{\chi^2}(w; \mathcal{P})$ is the chi-squared informativity.

Intuitively, inequality (7) shows that the Bayes risk is lower bounded by half of the largest possible t such that the maximum prior mass of any t -radius “ball” ($w\{\theta : L(\theta, a) < t\}$) is

less than some function of f -informativity. To apply (7), one needs to obtain upper bounds on the following two quantities:

1. The “small ball probability” $\sup_{\theta \in \mathcal{A}} w\{\theta : L(\theta, a) < t\}$, which does not depend of the family of probability measures \mathcal{P} .
2. The f -informativity $I_f(w, \mathcal{P})$, which does not depend on the loss function L .

We note that a nice feature of (7) is that L and \mathcal{P} play separately roles. One may first obtain an upper bound I_f^{up} for the f -informativity $I_f(w, \mathcal{P})$, then choose t so that the small ball probability $w\{\theta : L(\theta, a) < t\}$ can be bounded from above by $1 - u_f(I_f^{\text{up}})$. The Bayes risk will be bounded from below by $t/2$. It is noteworthy that the terminology “small ball probability” was used by Xu and Raginsky (2014) (this paper proved information-theoretic lower bounds on the minimum time in a distributed function computation problem).

We do not have a general guideline for bounding the small ball probability. It needs to be dealt with case by case based on the prior and the loss function. But for upper bounding the f -informativity, we offer a general recipe in Section 5 for a subclass of divergences of interest (power divergences for $\alpha \notin [0, 1)$), which covers the chi-squared divergence as one of the most important divergences in our applications. These bounds generalize results of Hausser and Opper (1997) and Yang and Barron (1999) for mutual information to f -informativities involving power divergences. As an illustration of our techniques (inequality (7) combined with the f -informativity upper bounds), we apply them to a concrete estimation problem in Section 5. We further apply our results to several popular machine learning and statistics problems (e.g., generalized linear model, spiked covariance model, and Gaussian model with general loss) in Appendix C.

In Section 6 and Section 7, we present non-trivial applications of our Bayes risk lower bounds to two learning problems: the first one is a unsupervised learning problem, while the second one is a supervised learning problem. Section 6 studies smoothed analysis for learning mixtures of spherical Gaussians with uniform weights. Although learning mixtures of Gaussians is a computationally hard problem, it has been shown recently by Hsu and Kakade (2013) that under the assumptions that the Gaussian means are linearly independent, it can be learnt in polynomial time by a spectral method. We perform a smoothed analysis on a variant of the algorithm (Hsu and Kakade, 2013), showing that the linear independence assumption can be replaced by perturbing the true parameters by a small random noise. The method described in Section 6 achieves a better convergence rate than the original algorithm of Hsu and Kakade (2013). Furthermore, we apply the Bayes risk lower bound techniques to show that the algorithm’s convergence rate is unimprovable, even under smoothed analysis (i.e. when the true parameters are randomly perturbed). Section 6 highlights the usefulness of our techniques in proving lower bounds for smoothed analysis, which appears to be challenging using traditional techniques of the minimax theory.

In Section 7, we consider the high-dimensional sparse linear regression problem and we provide Bayes risk lower bounds for both prediction error and estimation error under a natural prior on the regression parameter belonging to the set of k -sparse vectors. Although lower bounds for sparse linear regression have been well-studied (see, e.g., Raskutti et al. (2011); Zhang et al. (2014) and references therein), these bounds only focus on the minimax or the worst-case scenario and thus are too pessimistic in practice. Indeed, the parameters

that usually attain these minimax lower bounds have zero probability under any continuous prior, so that their average effects might be negligible. The fundamental limits of sparse linear regression under a realistic prior is, to the best of the our knowledge, unknown. The developed tool of lower bounding Bayes risks can be directly applied to characterize these limits. Moreover, our Bayes risk lower bound is flexible in the sense that by tuning the variance of the prior of non-zero elements of θ , it provides a wide spectrum of lower bounds. For one particular choice of the variance, our Bayes risk lower bounds match the minimax risk lower bounds. This gives a natural *least favorable prior* for sparse linear regression, while the known least favorable prior in Raskutti et al. (2011) is a non-constructive discrete prior over a packing set of the parameter space that cannot be sampled from. We also work under the *improper learning* setting where we allow non-sparse estimators for the true regression vector (even though the true regression vector is assumed to be sparse).

1.2 Related Works

Before finishing this introduction section, we briefly describe related work on Bayes risk lower bounds. There are a few results dealing with special cases of finite dimensional estimation problems under (weighted/truncated) quadratic losses. The first results of this kind were established by Van Trees (1968), and Borovkov and Sakhanienko (1980) with extensions by Brown and Gajek (1990); Brown (1993); Gill and Levit (1995); Sato and Akahira (1996); Takada (1999). A few additional papers dealt with even more specialized problems e.g., Gaussian white noise model (Brown and Liu, 1993), scale models (Gajek and Kaluszka, 1994) and estimating Gaussian variance (Vidakovi and DasGupta, 1995). Most of these results are based on the van Trees inequality (see Gill and Levit (1995) and Theorem 2.13 in Tsybakov (2010)). Although the van Trees inequality usually leads to sharp constant in the Bayes risk lower bounds, it only applies to weighted quadratic loss functions (as its proof relies on Cauchy-Schwarz inequality) and requires the underlying Fisher information to be easily computable, which limits its applicability. There is also a vast body of literature on minimax lower bounds (see, e.g., Tsybakov (2010)) which can be viewed as Bayes risk lower bounds for certain priors. These priors are usually discrete and specially constructed so that the lower bounds do not apply to more general (continuous) priors. Another related area of work involves finding lower bounds on posterior contraction rates (see, e.g., Castillo (2008)).

1.3 Outline of the Paper

The rest of the paper is organized in the following way. In Section 2, we describe notations and review preliminaries such as f -divergences, f -informativity, data processing inequality, etc. Section 3 deals with inequalities for zero-one valued loss functions. These inequalities have many connections to existing lower bound techniques. Section 4 deals with nonnegative loss functions and we provide inequality (7) and its special cases. Section 5 presents upper bounds on the f -informativity for power divergences for $\alpha \notin [0, 1)$. Some examples are given in this section. Section 6 studies smoothed analysis for learning mixtures of spherical Gaussians with uniform weights using our technique. We conclude the paper in Section 1.3. Due to space constraints, we have relegated some proofs and additional examples and results to the appendix.

2. Preliminaries and Notations

We first review the notions of f -divergence (Csiszár, 1963; Ali and Silvey, 1966) and f -informativity (Csiszár, 1972). Let \mathcal{C} denote the class of all convex functions $f : (0, \infty) \rightarrow \mathbb{R}$ which satisfy $f(1) = 0$. Because of convexity, the limits $f(0) := \lim_{x \downarrow 0} f(x)$ and $f'(\infty) := \lim_{x \uparrow \infty} f(x)/x$ exist (even though they may be $+\infty$) for each $f \in \mathcal{C}$. Each function $f \in \mathcal{C}$ defines a divergence between probability measures which is referred to as f -divergence. For two probability measures P and Q on a sample space having densities p and q with respect to a common measure μ , the f -divergence $D_f(P\|Q)$ between P and Q is defined as follows:

$$D_f(P\|Q) := \int f\left(\frac{p}{q}\right) q d\mu + f'(\infty)P\{q=0\}. \quad (9)$$

We note that the convention $0 \cdot \infty = 0$ is adopted here so that $f'(\infty)P\{q=0\} = 0$ when $f'(\infty) = \infty$ and $P\{q=0\} = 0$. Note that $D_f(P\|Q) = +\infty$ when $f'(\infty) = +\infty$ and $P\{q=0\} > 0$. Also note that $f(1) = 0$ implies that $D_f(P\|Q) = 0$ when $P = Q$.

Certain divergences are commonly used because they can be easily computed or bounded when P and Q are product measures. These divergences are the power divergences corresponding to the functions f_α defined by

$$f_\alpha(x) = \begin{cases} x^\alpha - 1 & \text{for } \alpha \notin [0, 1]; \\ 1 - x^\alpha & \text{for } \alpha \in (0, 1); \\ x \log x & \text{for } \alpha = 1; \\ -\log x & \text{for } \alpha = 0. \end{cases}$$

Popular examples of power divergences include:

1) Kullback-Leibler (KL) divergence: $\alpha = 1$, $D_H(P\|Q) = \int p \log(p/q) d\mu$ if P is absolutely continuous with respect to Q (and it is infinite if P is not absolutely continuous with respect to Q). Following the conventional notation, we denote the KL divergence by $D(P\|Q)$ (instead of $D_H(P\|Q)$).

2) Chi-squared divergence: $\alpha = 2$, $D_H(P\|Q) = \int (p^2/q) d\mu - 1$ if P is absolutely continuous with respect to Q (and it is infinite if P is not absolutely continuous with respect to Q). We denote the chi-squared divergence by $\chi^2(P\|Q)$ following the conventional notation.

3) When $\alpha = 1/2$, one has $D_{H_{1/2}}(P\|Q) = 1 - \int \sqrt{pq} d\mu$ which is a half of the squared Hellinger distance. That is, $D_{H_{1/2}}(P\|Q) = H^2(P\|Q)/2$, where $H^2(P\|Q) = \int (\sqrt{p} - \sqrt{q})^2 d\mu$ is the squared Hellinger distance between P and Q .

The total variation distance $\|P - Q\|_{TV}$ is another f -divergence (with $f(x) = |x - 1|/2$) but not a power divergence.

One of the most important properties of f -divergences is the ‘‘data processing inequality’’ (Csiszár (1972) and Liese (2012, Theorem 3.1)) which states the following: let \mathcal{X} and \mathcal{Y} be two measurable spaces and let $\Gamma : \mathcal{X} \rightarrow \mathcal{Y}$ be a measurable function. For every $f \in \mathcal{C}$ and every pair of probability measures P and Q on \mathcal{X} , we have

$$D_f(P\Gamma^{-1}\|Q\Gamma^{-1}) \leq D_f(P\|Q), \quad (10)$$

where $P\Gamma^{-1}$ and $Q\Gamma^{-1}$ denote the *induced measures* of Γ on \mathcal{Y} , i.e., for any measurable set B on the space \mathcal{Y} , $P\Gamma^{-1}(B) := P(\Gamma^{-1}(B))$, $Q\Gamma^{-1}(B) := Q(\Gamma^{-1}(B))$ (see the definition of induced measure from Definition 2.2.1. in Athreya and Lahiri (2006)).

Next, we introduce the notion of f -informativity (Csiszár, 1972). Let $\mathcal{P} = \{P_\theta : \theta \in \Theta\}$ be a family of probability measures on a space \mathcal{X} and w be a probability measure on Θ . For each $f \in \mathcal{C}$, the f -informativity, $I_f(w; \mathcal{P})$, is defined as

$$I_f(w; \mathcal{P}) = \inf_Q \int D_f(P_\theta\|Q) w(d\theta), \quad (11)$$

where the infimum is taken over all possible probability measures Q on \mathcal{X} . When $f(x) = x \log x$ (so that the corresponding f -divergence is the KL divergence^(e)), the f -informativity is equal to the mutual information and is denoted by $I(w; \mathcal{P})$. We denote the informativity corresponding to the power divergence D_{f_α} by $I_{f_\alpha}(w; \mathcal{P})$. For the special case $\alpha = 2$, we use the more suggestive notation $I_{\chi^2}(w; \mathcal{P})$. The informativity corresponding to the total variation distance will be denoted by $I_{TV}(w; \mathcal{P})$.

Additional notations and definitions are described as follows. Recall the Bayes risk (2) and the minimax risk (1). When the loss function L and parameter space Θ are clear from the context, we drop the dependence on L and Θ . When the prior w is also clear from the context, we denote the Bayes risk by R and the minimax risk by $R_{\min\max}$. We need certain notation for covering numbers. For a given f -divergence and a subset $S \subset \Theta$, let $M_f(\epsilon; S)$ denote any upper bound on the smallest number M for which there exist probability measures Q_1, \dots, Q_M that form an ϵ^2 -cover of $\{P_\theta, \theta \in S\}$ under the f -divergence i.e.,

$$\sup_{\theta \in S} \min_{1 \leq j \leq M} D_f(P_\theta\|Q_j) \leq \epsilon^2. \quad (12)$$

We write the covering number as $M_{KL}(\epsilon; S)$ when $f(x) = x \log x$ and $M_{\chi^2}(\epsilon; S)$ when $f(x) = x^2 - 1$. We write $M_A(\epsilon; S)$ when $f = f_\alpha$ for other $\alpha \in \mathbb{R}$. We note that $\log M_f(\epsilon; S)$ is an upper bound on the metric entropy. The quantity $M_f(\epsilon; S)$ can be infinite if S is arbitrary. For a vector $x = (x_1, \dots, x_d)$ and a real number $p \geq 1$, denote by $\|x\|_p$ the l_p -norm of x . In particular, $\|x\|_2$ denotes the Euclidean norm of x . $\mathbb{I}(A)$ denotes the indicator function which takes value 1 when A is true and 0 otherwise. We use C, c , etc. to denote generic constants whose values might change from place to place.

3. Bayes Risk Lower Bounds for Zero-one Valued Loss Functions and Their Applications

In this section, we consider zero-one loss functions L and present a principled approach to derive Bayes risk lower bounds involving f -informativity for every $f \in \mathcal{C}$. Our results hold for any given prior w and zero-one loss L . By specializing the f -divergence to KL divergence, we obtain the generalized Fano’s inequality (5). When specializing to other f -divergences, our bounds lead to some classical minimax bounds of Le Cam and Assouad (Assouad, 1983), more recent minimax results of Gushchin (2003); Birgé (2005) and also results in Tsybakov (2010, Chapter 2). Bayes risk lower bounds for general nonnegative loss functions will be presented in the next section.

We need additional notations to state the main results of this section. For each $f \in \mathcal{C}$, let $\phi_f : [0, 1]^2 \rightarrow \mathbb{R}$ be the function defined in the following way: for $a, b \in [0, 1]^2$, $\phi_f(a, b)$ is the

f -divergence between the two probability measures P and Q on $\{0, 1\}$ given by $P\{1\} = a$ and $Q\{1\} = b$. By the definition (9), it is easy to see that $\phi_f(a, b)$ has the following expression (recall that $f'(\infty) := \lim_{x \rightarrow \infty} f(x)/x$):

$$\phi_f(a, b) = \begin{cases} bf\left(\frac{a}{b}\right) + (1-b)f\left(\frac{1-a}{1-b}\right) & \text{for } 0 < b < 1; \\ f(1-a) + af'(\infty) & \text{for } b = 0; \\ f(a) + (1-a)f'(\infty) & \text{for } b = 1. \end{cases} \quad (13)$$

The convexity of f implies monotonicity and convexity properties of ϕ_f , which is stated in the following lemma.

Lemma 1 *For each $f \in \mathcal{C}$, for every fixed b , the map $g(a) : a \mapsto \phi_f(a, b)$ is non-increasing for $a \in [0, b]$ and $g(a)$ is convex and continuous in a . Further, for every fixed a , the map $h(b) : b \mapsto \phi_f(a, b)$ is non-decreasing for $b \in [a, 1]$.*

We also define the quantity

$$R_0 := \inf_{a \in \mathcal{A}} \int_{\Theta} L(\theta, a) w(d\theta), \quad (14)$$

where the decision a does not depend on data X . Note that R_0 represents the Bayes risk with respect to w in the “no data” problem i.e., when one only has information on Θ , \mathcal{A} , L and the prior w but not the data X . For simplicity, our notation for R_0 suppresses its dependence on w . Because the loss function is zero-one valued so that $L(\theta, a) = 1 - \mathbb{I}(L(\theta, a) = 0)$, the quantity R_0 has the following alternative expression:

$$R_0 = 1 - \sup_{a \in \mathcal{A}} w(B(a)), \quad (15)$$

where

$$B(a) := \{\theta \in \Theta : L(\theta, a) = 0\}, \quad (16)$$

and $w(B(a))$ is the prior mass of the “ball” $B(a)$. It will be important in the sequel to observe that the Bayes risk, $R_{\text{Bayes}}(w)$ is bounded from above by R_0 . This is obvious because the risk with some data cannot be greater than the risk in the no data problem (which can be viewed as an application of the data processing inequality). Formally, if $\mathcal{D} = \{\emptyset : \exists a \in \mathcal{A} \text{ such that } \mathfrak{d}(x) = a \forall x \in \mathcal{X}\}$ is the class of the constant decision rules, then $R_0 = \inf_{\mathfrak{d} \in \mathcal{D}} \int_{\Theta} \mathbb{E}_{\theta} L(\theta, \mathfrak{d}(X)) w(d\theta) \geq R_{\text{Bayes}}(w)$. Because $0 \leq R_{\text{Bayes}}(w) \leq R_0$, we have $R_{\text{Bayes}}(w) = 0$ when $R_0 = 0$. We shall therefore assume throughout this section that $R_0 > 0$.

The main result of this section is presented next. It provides an implicit lower bound for the Bayes risk in terms of R_0 and the f -informativity $I_f(w, \mathcal{P})$ for every $f \in \mathcal{C}$. The only assumption is that L is zero-one valued and we do not assume the existence of the Bayes decision rule.

Theorem 2 *Suppose that the loss function L is zero-one valued. For any $f \in \mathcal{C}$, we have*

$$I_f(w, \mathcal{P}) \geq \phi_f(R_{\text{Bayes}}(w), R_0) \quad (17)$$

where ϕ_f and R_0 are defined (13) and (14) respectively.

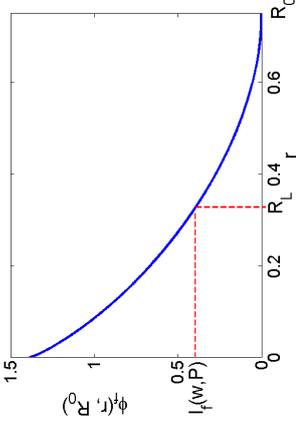

Figure 1: Illustration on why (17) leads to a lower bound on $R_{\text{Bayes}}(w)$. Recall that $R \leq R_0$ and $r \mapsto \phi_f(r, R_0)$ is non-increasing in r for $r \in [0, R_0]$. Given $I_f(w, \mathcal{P})$ as an upper bound of $\phi_f(R_{\text{Bayes}}(w), R_0)$, we have $R_{\text{Bayes}}(w) \geq R_L = g^{-1}(I_f(w, \mathcal{P}))$ and thus R_L serves as a Bayes risk lower bound.

Before we prove Theorem 2, we first show that the inequality (17) indeed provides an implicit lower bound for the Bayes risk $R := R_{\text{Bayes}}(w)$ since $R \leq R_0$ and $r \mapsto \phi_f(r, R_0)$ is non-increasing in r for $r \in [0, R_0]$ (Lemma 1). Therefore, let $g(r) := \phi_f(r, R_0)$. We have

$$R_{\text{Bayes}}(w) \geq g^{-1}(I_f(w, \mathcal{P})), \quad (18)$$

where $g^{-1}(x) := \inf\{0 \leq r \leq R_0, g(r) \leq x\}$ is the generalized inverse function of the non-increasing $g(r)$. As an illustration, we plot $\phi_f(r, R_0)$ for $f(x) = x \log x$ and the corresponding Bayes risk lower bound $g^{-1}(I_f(w, \mathcal{P}))$ in Figure 1. The lower bound (18) can be immediately applied to obtain Bayes risk lower bounds when the f -divergence in (17) is chi-squared divergence, total variation distance, or Hellinger distance (see Corollary 7). However, for the KL divergence, there is no simple form of $g^{-1}(x)$. To obtain the corresponding Bayes risk lower bound, we can invert (17) by utilizing the convexity of $g(r)$, which will give a generalized Fano’s inequality (see Corollary 5). In particular, since $r \mapsto \phi_f(r, R_0)$ is convex (see Lemma 1),

$$\phi_f(R, R_0) \geq \phi_f(r, R_0) + \phi_f'(r-, R_0)(R - r) \quad \text{for every } 0 < r \leq R_0$$

where $\phi_f'(r-, R_0)$ denotes the left derivative of $x \mapsto \phi_f(x, R_0)$ at $x = r$. The monotonicity of $\phi_f(r, R_0)$ in r (Lemma 1) gives $\phi_f'(r-, R_0) \leq 0$ and we thus have,

$$R \geq r + \frac{\phi_f(R, R_0) - \phi_f(r, R_0)}{\phi_f'(r-, R_0)} \quad \text{for every } 0 < r \leq R_0.$$

Inequality (17) $I_f(w, \mathcal{P}) \geq \phi_f(R, R_0)$ can now be used to deduce that (note that $\phi_f'(r-, R_0) \leq 0$)

$$R \geq r + \frac{I_f(w, \mathcal{P}) - \phi_f(r, R_0)}{\phi_f'(r-, R_0)} \quad \text{for every } 0 < r \leq R_0. \quad (19)$$

The inequalities (18) and (19) provide general approaches to convert (17) to an explicit lower bound on R .
