Theorem 2 is new, but its special case $\Theta = \mathcal{A} = \{1, \dots, N\}$, $L(\theta, a) := \mathbb{I}(\theta \neq a)$ and the uniform prior w is known (see Gushchin (2003) and Guntuboyina (2011b)). In such a discrete setting, $w(B(a)) = 1/N$ for any $a \in \mathcal{A}$ and thus $R_0 = 1 - 1/N$. The proof of Theorem 2 heavily relies on the following lemma, which is a consequence of the data processing inequality for f -divergences (see (10) in Section 2).

Lemma 3 *Suppose that the loss function L is zero-one valued. For every $f \in \mathcal{C}$, every probability measure Q on \mathcal{X} and every decision rule \mathfrak{d} , we have*

$$\int_{\Theta} D_f(P_\theta \| Q) w(d\theta) \geq \phi_f(R^\theta, R_Q^{\mathfrak{d}}) \quad (20)$$

where

$$R^\theta := \int_{\Theta} \mathbb{E}_\theta L(\theta, \mathfrak{d}(X)) w(d\theta), \quad R_Q^{\mathfrak{d}} := \int_{\mathcal{X}} \int_{\Theta} L(\theta, \mathfrak{d}(x)) w(d\theta) Q(dx). \quad (21)$$

We note that Lemma 3 is of independent interest, which can be applied to establish minimax lower bound as shown in the following remark.

Proof [Proof of Lemma 3]

Let \mathbb{P} denote the joint distribution of θ and X under the prior w i.e., $\theta \sim w$ and $X|\theta \sim P_\theta$. For any decision rule \mathfrak{d} , R^θ in (21) can be written as $R^\theta = \mathbb{E}_{\mathbb{P}} L(\theta, \mathfrak{d}(X))$. Let \mathbb{Q} denote the joint distribution of θ and X under which they are independently distributed according to $\theta \sim w$ and $X \sim Q$ respectively. The quantity $R_Q^{\mathfrak{d}}$ in (21) can then be written as $R_Q^{\mathfrak{d}} = \mathbb{E}_{\mathbb{Q}} L(\theta, \mathfrak{d}(X))$.

Because the loss function is zero-one valued, the function $\Gamma(\theta, x) := L(\theta, \mathfrak{d}(x))$ maps $\Theta \times \mathcal{X}$ into $\{0, 1\}$. Our strategy is to fix $f \in \mathcal{C}$ and apply the data processing inequality (10) to the probability measures \mathbb{P} , \mathbb{Q} and the mapping Γ . This gives

$$D_f(\mathbb{P} \| \mathbb{Q}) \geq D_f(\mathbb{P}^{-1} \| \mathbb{Q}^{-1}), \quad (22)$$

where \mathbb{P}^{-1} and \mathbb{Q}^{-1} are induced measures on the space $\{0, 1\}$ of Γ . In other words, since L is zero-one valued, both \mathbb{P}^{-1} and \mathbb{Q}^{-1} are two-point distributions on $\{0, 1\}$ with

$$\mathbb{P}^{-1}\{1\} = \int_{\Gamma} d\mathbb{P} = \mathbb{E}_{\mathbb{P}} L(\theta, \mathfrak{d}(X)) = R^\theta, \quad \mathbb{Q}^{-1}\{1\} = \int_{\Gamma} d\mathbb{Q} = R_Q^{\mathfrak{d}}.$$

By the definition of the function $\phi_f(\cdot, \cdot)$, it follows that $D_f(\mathbb{P}^{-1} \| \mathbb{Q}^{-1}) = \phi_f(R^\theta, R_Q^{\mathfrak{d}})$. It is also easy to see $D_f(\mathbb{P} \| \mathbb{Q}) = \int_{\Theta} D_f(P_\theta \| Q) w(d\theta)$. Combining this equation with inequality (22) establishes inequality (20). ■

With Lemma 3 in place, we are ready to prove Theorem 2.

Proof [Proof of Theorem 2]

We write R as a shorthand notation of $R_{\text{Bayes}}(w)$. By the definition (11) of $I_f(w, \mathcal{P})$, it suffices to prove that

$$\int D_f(P_\theta \| Q) w(d\theta) \geq \phi_f(R, R_0) \quad (23)$$

for every probability measure Q .

Notice that $R \leq R_0$. If $R = R_0$, then the right hand side of (17) is zero and hence the inequality immediately holds. Assume that $R < R_0$. Let $\epsilon > 0$ be small enough so that $R + \epsilon < R_0$. Let \mathfrak{d} denote any decision rule for which $R \leq R^\theta < R + \epsilon$ and note that such a rule exists since $R = \inf_{\theta \in \mathcal{A}} R^\theta$. It is easy to see that

$$R_Q^{\mathfrak{d}} = \int_{\mathcal{X}} \int_{\Theta} L(\theta, \mathfrak{d}(x)) w(d\theta) Q(dx) \geq \int_{\mathcal{X}} \left(\inf_{a \in \mathcal{A}} \int_{\Theta} L(\theta, a) w(d\theta) \right) Q(dx) = R_0.$$

We thus have $R \leq R^\theta < R + \epsilon < R_0 \leq R_Q^{\mathfrak{d}}$. By Lemma 3, we have

$$\int_{\Theta} D_f(P_\theta \| Q) w(d\theta) \geq \phi_f(R^\theta, R_Q^{\mathfrak{d}}).$$

Because $x \mapsto \phi_f(x, R_Q^{\mathfrak{d}})$ is non-increasing on $x \in [0, R_Q^{\mathfrak{d}}]$, we have

$$\phi_f(R^\theta, R_Q^{\mathfrak{d}}) \geq \phi_f(R + \epsilon, R_Q^{\mathfrak{d}}).$$

Because $x \mapsto \phi_f(R + \epsilon, x)$ is non-decreasing on $x \in [R + \epsilon, 1]$, we have

$$\phi_f(R + \epsilon, R_Q^{\mathfrak{d}}) \geq \phi_f(R + \epsilon, R_0).$$

Combining the above three inequalities, we have

$$\int_{\Theta} D_f(P_\theta \| Q) w(d\theta) \geq \phi_f(R^\theta, R_Q^{\mathfrak{d}}) \geq \phi_f(R + \epsilon, R_Q^{\mathfrak{d}}) \geq \phi_f(R + \epsilon, R_0).$$

The proof of (23) completes by letting $\epsilon \downarrow 0$ and using the continuity of $\phi_f(\cdot, R_0)$ (continuity was noted in Lemma 1). This completes the proof of Theorem 2. ■

Remark 4 *Lemma 3 can also be used to derive minimax lower bounds in a different way. For example, when the minimax decision rule \mathfrak{d} exists (e.g., for finite space Θ and \mathcal{A} (Ferguson, 1967)), we have $R^\theta \leq R_{\text{minimax}}$. If the probability measure Q is chosen so that $R_{\text{minimax}} \leq R_Q^{\mathfrak{d}}$, then, by Lemma 1, the right hand side of (17) can be lower bounded by replacing R^θ with R_{minimax} which yields*

$$\int_{\Theta} D_f(P_\theta \| Q) w(d\theta) \geq \phi_f(R_{\text{minimax}}, R_Q^{\mathfrak{d}}). \quad (24)$$

Similarly, this inequality can be converted to an explicit lower bound on minimax risk. We will show an application of this inequality in deriving Brygé-Gushchin inequality (Gushchin, 2003; Brygé, 2005) in Section 3.3.

3.1 Generalized Fano's Inequality

In the next result, we derive the generalized Fano's inequality (5) using Theorem 2. The inequality proved here is in fact slightly stronger than (5); see Remark 6 for the clarification.

Corollary 5 (Generalized Fano's inequality) For any given prior w and zero-one loss L , we have

$$R_{\text{Bayes}}(w, L; \Theta) \geq 1 + \frac{I(w, \mathcal{P}) + \log(1 + R_0)}{\log(\sup_{a \in \mathcal{A}} w(B(a)))}, \quad (25)$$

where $B(a)$ is defined in (16).

Proof [Proof of Corollary 5]

We simply apply (19) to $f(x) = x \log x$ and $r = R_0/(1 + R_0)$, it can then be checked that

$$\phi_f(r; R_0) = -\log(1 + R_0) - \frac{1}{1 + R_0} \log(1 - R_0), \quad \phi_f'(r-, R_0) = \log(1 - R_0),$$

Inequality (19) then gives

$$R \geq 1 + \frac{I(w, \mathcal{P}) + \log(1 + R_0)}{\log(1 - R_0)}$$

which proves (25). ■

Remark 6 This inequality is slightly stronger than (5) because $R_0 \leq 1$ (thus $\log(1 + R_0) \leq \log 2$). For example, when $\Theta = \mathcal{A} = \{0, 1\}$, $L(\theta, a) := \mathbb{I}\{\theta \neq a\}$ and $w\{0\} = w\{1\} = 1/2$, the inequality (5) leads to a trivial bound since the right hand side of (5) is negative. However, since $R_0 = 1/2$, the inequality (25) still provides a useful lower bound when $I(w, \mathcal{P})$ is strictly smaller than $\log 2 - \log(3/2)$.

As mentioned in the introduction, the classical Fano inequality (3) and the recent continuum Fano inequality (4) are both special cases (restricted to uniform priors) of Corollary 5. The proof of (4) given in Duchi and Wainwright (2013) is rather complicated with a stronger assumption and a discretization-approximation argument. Our proof based on Theorem 2 is much simpler. Lemma 3 also has its independent interest. Using Lemma 3, we are able to recover another recently proposed variant of Fano's inequality in Braun and Pokutta (2014, Proposition 2.2). Details of this argument are provided in Appendix A.2.

3.2 Specialization of Theorem 2 to Different f -Divergences and Their Applications

In addition to the generalized Fano's inequality, Theorem 2 allows us to derive a class of lower bounds on Bayes risk for zero-one losses by plugging other f -divergences. In the next corollary, we consider some widely used f -divergences and provide the corresponding Bayes risk lower bounds by inverting (17) in Theorem 2.

Corollary 7 Let L be zero-one valued, w be any prior on Θ and $R = R_{\text{Bayes}}(w, L, \Theta)$. We then have the following inequalities

(i) *Chi-squared divergence:*

$$R \geq R_0 - \sqrt{R_0(1 - R_0)I_{\chi^2}(w, \mathcal{P})}. \quad (26)$$

(ii) *Total variation distance:*

$$R \geq R_0 - I_{\text{TV}}(w, \mathcal{P}). \quad (27)$$

(iii) *Hellinger distance:*

$$R \geq R_0 - (2R_0 - 1) \frac{h^2}{2} - \sqrt{R_0(1 - R_0)h^2(2 - h^2)}. \quad (28)$$

provided $h^2 \leq 2R_0$. Here $h^2 = \int_{\Theta} \int_{\Theta} H^2(P_{\theta} \| P_{\theta'}) w(d\theta) w(d\theta')$.

See Appendix A.3 for the proof of the corollary. The special case of Corollary 7 for $\Theta = \mathcal{A} = \{1, \dots, N\}$, $L(\theta, a) = \mathbb{I}\{\theta \neq a\}$ and w being the uniform prior has been discovered previously in Guntuboyina (2011b). It is clear from Corollary 7 that the choice of f -divergence will affect the tightness of the lower bound for R . In Appendix A.5, we provide a qualitative comparison of the lower bounds (25), (26) and (28). In particular, we show that in the discrete setting with $\Theta = \mathcal{A} = \{1, \dots, N\}$, the lower bounds induced by the KL divergence and the chi-squared divergence are much stronger than the bounds given by the Hellinger distance. Therefore, in most applications in this paper, we shall only use the bounds involving the KL divergence and the chi-squared divergence.

Corollary 7 can be used to recover classical inequalities of Le Cam (for two point hypotheses) and Assouad (Theorem 2.12 in Tsybakov (2010) with both total variation distance and Hellinger distance) and Theorem 2.15 in Tsybakov (2010) that involves fuzzy hypotheses. The details are presented in Appendix A.4.

3.3 Birgé-Gushchin's Inequality

In this section, we expand (24) to obtain a minimax risk lower bound due to Gushchin (2003) and Birgé (2005), which presents an improvement of the classical Fano's inequality when specializing to KL divergence.

Proposition 8 (Gushchin, 2003; Birgé, 2005) Consider the finite parameter and action space $\Theta = \mathcal{A} = \{\theta_0, \theta_1, \dots, \theta_N\}$ and the zero-one valued indicator loss $L(\theta, a) = \mathbb{I}\{\theta \neq a\}$, for any f -divergence,

$$\phi_f(R_{\text{minimax}}, 1 - R_{\text{minimax}}/N) \leq \min_{0 \leq j \leq N} \frac{1}{N} \sum_{i \neq j} D_f(P_{\theta_i} \| P_{\theta_j}). \quad (29)$$

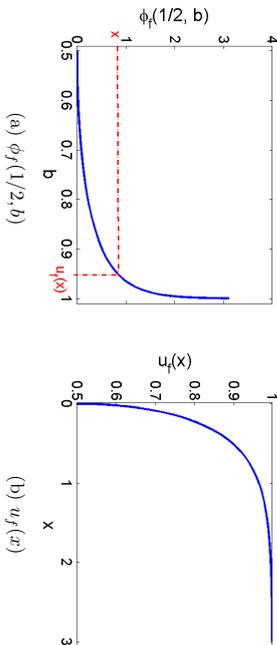

Proof [Proof of Proposition 8]

To prove Proposition 8, it is enough to prove that $\frac{1}{N} \sum_{i \neq j} D_f(P_{\theta_i} \| P_{\theta_j}) \geq \phi_f(R_{\text{minimax}}, 1 - R_{\text{minimax}}/N)$ for every $j \in \{0, \dots, N\}$. Without loss of generality, we assume that $j = 0$. We apply (20) with the uniform distribution on $\Theta \setminus \{\theta_0\} = \{\theta_1, \dots, \theta_N\}$ as w , $Q = P_{\theta_0}$ and the minimax rule for the problem as \mathfrak{d} . Because \mathfrak{d} is the minimax rule, $R^{\mathfrak{d}} \leq R_{\text{minimax}}$. Also

$$R_Q^{\mathfrak{d}} = \frac{1}{N} \sum_{i=1}^N \mathbb{E}_{\theta_0} L(\theta_i, \mathfrak{d}(X)) = \frac{1}{N} \mathbb{E}_{\theta_0} \sum_{i=1}^N \mathbb{I}\{\theta_i \neq \mathfrak{d}(X)\}.$$

It is easy to verify that $\sum_{i=1}^N \mathbb{I}\{\theta_i \neq \mathfrak{d}(X)\} = N - \mathbb{I}\{\theta_0 \neq \mathfrak{d}(X)\}$. We thus have $R_Q^{\mathfrak{d}} = 1 - \mathbb{E}_{\theta_0} L(\theta_0, \mathfrak{d}(X))/N$. Because \mathfrak{d} is minimax, $\mathbb{E}_{\theta_0} L(\theta_0, \mathfrak{d}(X)) \leq R_{\text{minimax}}$ and thus

$$R_Q^{\mathfrak{d}} \geq 1 - R_{\text{minimax}}/N. \quad (30)$$

Figure 2: Illustration of $\phi_f(1/2, b)$ and $u_f(x)$ for $f(x) = x \log x$.

On the other hand, we have $R_{\min\max} \leq N/(N+1)$. To see this, note that the minimax risk is upper bounded by the maximum risk of a random decision rule, which chooses among the $N+1$ hypotheses uniformly at random. For this random decision rule, its risk is $\frac{N}{N+1}$ no matter what the true hypothesis is. Thus, $\frac{N}{N+1}$ is an upper bound on the minimax risk. We thus have, from (30), that $R_0^2 \geq 1 - R_{\min\max}/N \geq R_{\min\max}$. We can thus apply (24) to obtain

$$\frac{1}{N} \sum_{i=1}^N D_f(P_{\theta_i} \| P_{\theta_0}) \geq \phi_f(R_{\min\max}, 1 - R_{\min\max}/N),$$

which completes the proof Proposition 8. \blacksquare

4. Bayes Risk Lower Bounds for Nonnegative Loss Functions

In the previous section, we discussed Bayes risk lower bounds for zero-one valued loss functions. We deal with general nonnegative loss functions in this section. The main result of this section, Theorem 9, provides lower bounds for $R_{\text{Bayes}}(w, L; \Theta)$ for any given loss L and prior w . To state this result, we need the following notion. Fix $f \in \mathcal{C}$ and recall the definition of ϕ_f in (13). We define $u_f : [0, \infty) \rightarrow [1/2, 1]$ by

$$u_f(x) := \inf \{1/2 \leq b \leq 1 : \phi_f(1/2, b) > x\} \quad (31)$$

and if $\phi_f(1/2, b) \leq x$ for every $b \in [1/2, 1]$, then we take $u_f(x)$ to be 1. By Lemma 1, it is easy to see that $u_f(x)$ is a non-decreasing function of x . For example, for KL-divergence with $f(x) = x \log x$, we have $\phi_f(1/2, b) = \frac{1}{2} \log \frac{1-b}{1-b}$ and $u_f(x) = \frac{1}{2} + \frac{1}{2} \sqrt{1 - e^{-2x}}$ (see Figure 2). We are now ready to state the main theorem of this paper.

Theorem 9 For every $\Theta, \mathcal{A}, L, w$ and $f \in \mathcal{C}$, we have

$$R_{\text{Bayes}}(w, L; \Theta) \geq \frac{1}{2} \sup \left\{ t > 0 : \sup_{a \in \mathcal{A}} w(B_t(a, L)) < 1 - u_f(I_f(w, \mathcal{P})) \right\}, \quad (32)$$

where

$$B_t(a, L) := \{\theta \in \Theta : L(\theta, a) < t\} \quad \text{for } a \in \mathcal{A} \text{ and } t > 0. \quad (33)$$

Proof [Proof of Theorem 9]

Fix $\Theta, \mathcal{A}, L, w$ and f . Let $I := I_f(w, \mathcal{P})$ be a shorthand notation. Suppose $t > 0$ is such that

$$\sup_{a \in \mathcal{A}} w(B_t(a, L)) < 1 - u_f(I). \quad (34)$$

We prove below that $R_{\text{Bayes}}(w, L; \Theta) \geq t/2$ and this would complete the proof. Let L_t denote the zero-one valued loss function $L_t(\theta, a) := \mathbb{1}\{L(\theta, a) \geq t\}$. It is obvious that $L \geq tL_t$ and hence the proof will be complete if we establish that $R_{\text{Bayes}}(w, L_t; \Theta) \geq 1/2$. Let $R := R_{\text{Bayes}}(w, L_t; \Theta)$ for a shorthand notation.

Because L_t is a zero-one valued loss function, Theorem 2 gives

$$I \geq \phi_f(R, R_0) \quad \text{where } R_0 = 1 - \sup_{a \in \mathcal{A}} w(B_t(a, L)). \quad (35)$$

By (34), it then follows that $R_0 > u_f(I)$. By definition of $u_f(\cdot)$, it is clear that there exists $b^* \in [1/2, R_0)$ such that $\phi(1/2, b^*) > I$ (this in particular implies that $R_0 \geq 1/2$). Lemma 1 implies that $b \mapsto \phi_f(1/2, b)$ is non-decreasing for $b \in [1/2, 1]$, which yields $\phi_f(1/2, b^*) \leq \phi_f(1/2, R_0)$. The above two inequalities imply $I < \phi_f(1/2, R_0)$. Combining this inequality with (35), we have

$$\phi_f(1/2, R_0) > I \geq \phi_f(I, R_0).$$

Lemma 1 shows that $a \mapsto \phi_f(a, R_0)$ is non-increasing for $a \in [0, R_0]$. Thus, we have $R \geq 1/2$. \blacksquare

We further note that because $u_f(x)$ is non-decreasing in x , one can replace $I_f(w, \mathcal{P})$ in (32) by any upper bound I_f^{ub} i.e., for any $I_f^{\text{ub}} \geq I_f(w, \mathcal{P})$, we have

$$R_{\text{Bayes}}(w, L; \Theta) \geq \frac{1}{2} \sup \left\{ t > 0 : \sup_{a \in \mathcal{A}} w(B_t(a, L)) < 1 - u_f(I_f^{\text{ub}}) \right\}. \quad (36)$$

This is useful since $I_f(w, \mathcal{P})$ is often difficult to calculate exactly. When $f(x) = x \log x$, Hausler and Oppet (1997) provided a useful upper bound on the mutual information $I(w, \mathcal{P})$. We describe this result in Section 5 where we also extend it to power divergences f_a for $a \notin [0, 1]$ (which covers the case of chi-squared divergence).

Remark 10 From the proof of Theorem 9, it can be observed that the constant $1/2$ in the right hand side of (32) and in the definition of $u_f(\cdot)$ can be replaced by any $c \in (0, 1]$. This gives the sharper lower bound:

$$R_{\text{Bayes}}(w, L; \Theta) \geq \sup_{c \in (0, 1]} \left(c \sup \left\{ t > 0 : \sup_{a \in \mathcal{A}} w(B_t(a, L)) < 1 - u_{f,c}(I_f(w, \mathcal{P})) \right\} \right),$$

where $u_{f,c}(x) = \inf\{c \leq b \leq 1 : \phi_f(c, b) \geq x\}$. Since obtaining exact constants is not our main concern, the inequality (32) is usually sufficient to provide Bayes risk lower bounds with correct dependence on the model and prior.

Remark 11 We note that the lower bound presented in Theorem 9 might not be tight for some spectral priors, e.g., when the prior w has extremely large density in some small region of the parameter space. We call such regions with unbounded density as spikes in the prior distribution. As a concrete example, let $\Theta = \mathcal{A}$ be a subset of a finite dimensional Euclidean space containing the origin with L being the Euclidean distance and let w denote the mixture of the uniform priors over the balls $B_1(0, L)$ and $B_\epsilon(0, L)$ for some very small $0 < \epsilon \ll 1$. In this case, the mixture component $B_\epsilon(0, L)$ is a spike. If ϵ is very small, then the term $\sup_{a \in \mathcal{A}} w(B_\epsilon(a, L))$ might be too big for Theorem 9 to establish a tight lower bound.

Even in such extreme cases, the tight lower bound can be salvaged by partitioning the parameter space Θ into finite or countably many disjoint subsets $\Theta_i, i \geq 0$ and to apply Theorem 9 to w restricted to each Θ_i . To illustrate this technique, suppose that w has a Lebesgue density φ that is bounded from above. Let φ_{\max} denote the supremum of φ . We partition the parameter space Θ into disjoint subsets $\Theta_0, \Theta_1, \dots$ with

$$\Theta_i := \{\theta \in \Theta : 2^{-(i+1)}\varphi_{\max} < \varphi(\theta) \leq 2^{-i}\varphi_{\max}\}. \quad (37)$$

Then, we apply Theorem 9 to w restricted to each Θ_i . More specifically, let w_i denote the probability measure w restricted to Θ_i i.e., $w_i(S) := w(S \cap \Theta_i)/w(\Theta_i)$ for any measurable set $S \subseteq \Theta_i$. we have

$$R_{\text{Bayes}}(w, L; \Theta) \geq \sum_i w(\Theta_i) R_{\text{Bayes}}(w_i, L; \Theta_i), \quad (38)$$

where $R_{\text{Bayes}}(w_i, L; \Theta_i) = \inf_{\delta} \int_{\Theta_i} \mathbb{E}_{\theta} L(\theta, \delta(X)) w_i(d\theta)$. To see this, for any decision rule δ , we have $\mathbb{R}^{\delta}(w, L; \Theta) = \sum_{i=1}^{\infty} w(\Theta_i) \mathbb{R}^{\delta}(w_i, L; \Theta_i)$; then take infimum over all possible δ on both sides,

$$\begin{aligned} R_{\text{Bayes}}(w, L; \Theta) &= \inf_{\delta} \mathbb{R}^{\delta}(w, L; \Theta) \\ &\geq \sum_{i=1}^{\infty} w(\Theta_i) \inf_{\delta} \mathbb{R}^{\delta}(w_i, L; \Theta_i) = \sum_{i=1}^{\infty} w(\Theta_i) R_{\text{Bayes}}(w_i, L; \Theta_i) \end{aligned}$$

One can lower bound each Bayes risk $R_{\text{Bayes}}(w_i, L; \Theta_i)$ for all i using Theorem 9. Since the density of w_i differs by a factor at most 2, the spiking prior problem will no longer exist while applying Theorem 9 for w_i . We also note that another useful application of such a partitioning technique is presented in Corollary 17.

Now take the concrete example of the mixture of the uniform priors over $B_1 := B_1(0, L)$ and $B_\epsilon := B_\epsilon(0, L)$. It is clear from (37) that $\Theta_0 = B_\epsilon$ and $\Theta_k = B_1 \setminus B_\epsilon$ for some $k > 0$ and the rest of Θ_i 's are empty sets. Applying (38), we have

$$\begin{aligned} R_{\text{Bayes}}(w, L; \Theta) &\geq w(B_\epsilon) R_{\text{Bayes}}(w_1, L; B_\epsilon) + w(B_1 \setminus B_\epsilon) R_{\text{Bayes}}(w_2, L; B_1 \setminus B_\epsilon) \\ &\geq w(B_1 \setminus B_\epsilon) R_{\text{Bayes}}(w_2, L; B_1 \setminus B_\epsilon) \end{aligned}$$

Note that $w(B_1 \setminus B_\epsilon)$ is lower bounded by a universal constant. Then we can lower bound $R_{\text{Bayes}}(w_2, L; B_1 \setminus B_\epsilon)$ using Theorem 9 and obtain a tight lower bound up to a constant factor that is independent of ϵ (see an example of deriving Bayes risk lower bound for estimating the mean of a Gaussian model with uniform prior on a ball in Section 5).

For specific $f \in \mathcal{C}$, the right hand side of (36) can be explicitly evaluated as shown in the next corollary.

Corollary 12 Fix $\Theta, \mathcal{A}, L, w$ and \mathcal{P} . The Bayes risk $R_{\text{Bayes}}(w, L; \Theta)$ satisfies each of the following inequalities (the quantity I_f^{up} represents an upper bound on the corresponding f -informativity):

(i) KL divergence:

$$R_{\text{Bayes}}(w, L; \Theta) \geq \frac{1}{2} \sup_{a \in \mathcal{A}} \left\{ t > 0 : \sup_{a \in \mathcal{A}} w(B_t(a, L)) < \frac{1}{4} e^{-2I_f^{\text{up}}} \right\}. \quad (39)$$

(ii) Chi-squared divergence:

$$R_{\text{Bayes}}(w, L; \Theta) \geq \frac{1}{2} \sup_{a \in \mathcal{A}} \left\{ t > 0 : \sup_{a \in \mathcal{A}} w(B_t(a, L)) < \frac{1}{4(1+I_f^{\text{up}})} \right\}. \quad (40)$$

(iii) Total variation distance:

$$R_{\text{Bayes}}(w, L; \Theta) \geq \frac{1}{2} \sup_{a \in \mathcal{A}} \left\{ t > 0 : \sup_{a \in \mathcal{A}} w(B_t(a, L)) < \frac{1}{2} - I_f^{\text{up}} \right\}. \quad (41)$$

(iv) Hellinger distance: If $I_f^{\text{up}} < 1 - 1/\sqrt{2}$, then we have

$$R_{\text{Bayes}}(w, L; \Theta) \geq \frac{1}{2} \sup_{a \in \mathcal{A}} \left\{ t > 0 : \sup_{a \in \mathcal{A}} w(B_t(a, L)) < \frac{1}{2} - (1 - I_f^{\text{up}}) \sqrt{I_f^{\text{up}}(2 - I_f^{\text{up}})} \right\}. \quad (42)$$

Proof [Proof of Corollary 12]

Inequality (39) involving KL divergence: Suppose $f(x) = x \log x$ so that $D_f(P||Q) = D(P||Q)$ equals the KL divergence. Then the function $u_f(x)$ in (31) has the expression for all $x > 0$,

$$u_f(x) = \inf \left\{ 1/2 \leq b \leq 1 : b(1-b) < e^{-2x}/4 \right\} = \frac{1}{2} + \frac{1}{2} \sqrt{1 - e^{-2x}}.$$

The elementary inequality $\sqrt{1-a} \leq 1 - a/2$ gives for all $x > 0$,

$$u_f(x) \leq 1 - \frac{1}{4} e^{-2x}.$$

Inequality (32) reduces to the desired inequality (39):

$$R_{\text{Bayes}}(w, L; \Theta) \geq \frac{1}{2} \sup_{a \in \mathcal{A}} \left\{ t > 0 : \sup_{a \in \mathcal{A}} w(B_t(a, L)) < \frac{1}{4} e^{-2I_f^{\text{up}}} \right\}.$$

The proof of the Bayes risk lower bounds for the other three f -divergences are similar and thus we only present the form of $u_f(x)$. Inequality (40) involves chi-squared divergence with $f(x) = x^2 - 1$. Therefore, we have for all $x > 0$,

$$u_f(x) = \inf \left\{ 1/2 \leq b \leq 1 : \frac{(1-2b)^2}{4b(1-b)} > x \right\} = \frac{1}{2} + \frac{1}{2} \sqrt{\frac{x}{1+x}} \leq 1 - \frac{1}{4(1+x)}.$$

Inequality (41) involves total variation distance with $f(x) = |x - 1|/2$. Then

$$u_f(x) = \inf \{1/2 \leq b \leq 1 : |1 - 2b| > 2x\} = \frac{1}{2} + x.$$

Inequality (42) involves Hellinger divergence with $f(x) = 1 - \sqrt{x}$ and thus

$$\begin{aligned} u_f(x) &= \inf \left\{ 1/2 \leq b \leq 1 : 1 - \sqrt{b/2} - \sqrt{(1-b)/2} > x \right\} \\ &= \begin{cases} 1 & \text{if } x \geq 1 - 1/\sqrt{2} \\ \frac{1}{2} + (1-x)\sqrt{x(2-x)} & \text{if } x < 1 - 1/\sqrt{2}. \end{cases} \end{aligned}$$

■

Remark 13 A special case of Corollary 12(i) appeared as Zhang (2006, Theorem 6.1). To see that Zhang (2006, Theorem 6.1) is indeed a special case of (39), note first that (39) is equivalent to

$$R_{\text{Bayes}}(w, L; \Theta) \geq \frac{1}{2} \sup \left\{ t > 0 : \inf_{a \in \mathcal{A}} \frac{1}{w(B_t(a, L))} > 2I^w + \log 4 \right\}. \quad (43)$$

Here I^w is any upper bound on the mutual information. One such upper bound on the mutual information is

$$I^w = \int_{\Theta} \int_{\Theta} D(P_{\theta} \| P_{\xi}) w(d\xi) w(d\theta) \quad (44)$$

That I^w is an upper bound on the mutual information can be seen for example by using concavity of the logarithm (46) when the family $\{Q_{\xi}, \xi \in \Xi\}$ is chosen to be the same as $\{P_{\theta}, \theta \in \Theta\}$. Using (44) in (43), we obtain

$$R_{\text{Bayes}}(w, L; \Theta) \geq \frac{1}{2} \sup \left\{ t > 0 : \inf_{a \in \mathcal{A}} \frac{1}{w(B_t(a, L))} > 2 \int_{\Theta} \int_{\Theta} D(P_{\theta} \| P_{\xi}) w(d\xi) w(d\theta) + \log 4 \right\}.$$

If we now specialize to the setting when the probability measures $\{P_{\theta}, \theta \in \Theta\}$ are all n -fold product measures i.e., when each P_{θ} is of the form $\mathfrak{P}_{\theta}^{\otimes n}$ for some class of probabilities $\{\mathfrak{P}_{\theta}, \theta \in \Theta\}$, then the inequality becomes

$$R_{\text{Bayes}}(w, L; \Theta) \geq \frac{1}{2} \sup \left\{ t > 0 : \inf_{a \in \mathcal{A}} \frac{1}{w(B_t(a, L))} > 2n \int_{\Theta} \int_{\Theta} D(\mathfrak{P}_{\theta} \| \mathfrak{P}_{\xi}) w(d\xi) w(d\theta) + \log 4 \right\}.$$

This inequality is precisely Zhang (2006, Theorem 6.1).

5. Upper Bounds on f -informativity and Examples

Application of Theorem 9 requires upper bounds on the f -informativity $I_f(w; \mathcal{P})$. This is the subject of this section. We focus on the power divergence f_{α} for $\alpha \geq 1$ which includes the KL divergence and chi-squared divergence as special cases. Recall that in the comment/paragraph below Corollary 7 (see also Section A.5 in the appendix), we provided

motivation for restricting our attention to such divergences as opposed to e.g., Hellinger distance.

We assume that there is a measure μ on \mathcal{X} that dominates P_{θ} for every $\theta \in \Theta$. None of our results depend on the choice of the dominating measure μ .

When the f -informativity is the mutual information, Haussler and Opper (1997) have proved useful upper bounds which we briefly review here. Let P and $\{Q_{\xi}, \xi \in \Xi\}$ be probability measures on \mathcal{X} having densities p and $\{q_{\xi}, \xi \in \Xi\}$ respectively with respect to μ . Let ν be an arbitrary probability measure on Ξ and \bar{Q} be the probability measure on \mathcal{X} having density $\bar{q} = \int_{\Xi} q_{\xi} \nu(d\xi)$ with respect to μ . Haussler and Opper (1997) proved the following inequality

$$D(P \| \bar{Q}) \leq -\log \left(\int_{\Xi} \exp(-D(P \| Q_{\xi})) \nu(d\xi) \right). \quad (45)$$

Now given a class of probability measures $\{P_{\theta}, \theta \in \Theta\}$, applying the above inequality for each P_{θ} and integrating the resulting inequalities with respect to a probability measure w on Θ , Haussler and Opper (1997, Theorem 2) obtained the following mutual information upper bound:

$$I(w, \mathcal{P}) \leq -\int_{\Theta} \log \left(\int_{\Xi} \exp(-D(P_{\theta} \| Q_{\xi})) \nu(d\xi) \right) w(d\theta). \quad (46)$$

In the special case when $\Xi = \{1, \dots, M\}$ and ν is the uniform probability measure on Ξ , we have $\bar{Q} = (Q_1 + \dots + Q_M)/M$ and inequality (45) then becomes $D(P \| \bar{Q}) \leq -\log \left(\frac{1}{M} \sum_{j=1}^M \exp(-D(P \| Q_j)) \right)$. Because $\sum_{j=1}^M \exp(-D(P \| Q_j)) \geq \exp(-\min_j D(P \| Q_j))$, we obtain

$$D(P \| \bar{Q}) \leq \log M + \min_{1 \leq j \leq M} D(P \| Q_j).$$

Inequality (46) can be further simplified to

$$I(w, \mathcal{P}) \leq \log M + \int_{\Theta} \min_{1 \leq j \leq M} D(P_{\theta} \| Q_j) w(d\theta). \quad (47)$$

This inequality can be used to give an upper bound for f -informativity in terms of the KL covering numbers. Recall the definition of $M_{KL}(\epsilon, \Theta)$ from (12). Applying (47) to any fixed $\epsilon > 0$ and choosing $\{Q_1, \dots, Q_M\}$ to be an ϵ^2 -covering, we have

$$I(w, \mathcal{P}) \leq \inf_{\epsilon > 0} (\log M_{KL}(\epsilon, \Theta) + \epsilon^2). \quad (48)$$

When w is the uniform prior on a finite subset of Θ , the above inequality has been proved by Yang and Barron (1999, Page 1571). If $M_{KL}(\epsilon, \Theta)$ is infinity for all ϵ , then (48) gives ∞ as the upper bound on $I(w, \mathcal{P})$ and thus (39) will lead to a trivial lower bound 0 for R_{Bayes} . In such a case, one may find a subset $\tilde{\Theta} \subset \Theta$ for which $M_{KL}(\epsilon, \tilde{\Theta})$ is bounded and contains most prior mass. If \tilde{w} denotes the prior w restricted in $\tilde{\Theta}$, then it is easy to see that $R_{\text{Bayes}}(w, L; \Theta) \geq w(\tilde{\Theta}) R_{\text{Bayes}}(\tilde{w}, L; \tilde{\Theta})$. Then we can use (39) and (48) to lower bound $R_{\text{Bayes}}(w, L; \Theta)$.

In the next theorem, we extend inequalities (45) and (46) to power divergences corresponding to f_{α} for $\alpha \notin [0, 1]$. We also note that in Appendix B.2, we demonstrate the tightness of the bound (49) in Theorem 14 by a simple example.

Theorem 14 Fix $\alpha \notin [0, 1]$ and let $f_\alpha \in \mathcal{C}$ be as defined in Section 2. Under the setting of inequalities (45) and (46), we have

$$D_{f_\alpha}(P\|\bar{Q}) \leq \left[\int_{\Xi} (D_{f_\alpha}(P\|Q_\xi) + 1)^{1/(1-\alpha)} \nu(d\xi) \right]^{1-\alpha} - 1. \quad (49)$$

and

$$I_{f_\alpha}(w, \mathcal{P}) \leq \int_{\Theta} \left[\int_{\Xi} (D_{f_\alpha}(P_\theta\|Q_\xi) + 1)^{1/(1-\alpha)} \nu(d\xi) \right]^{1-\alpha} w(d\theta) - 1. \quad (50)$$

To prove Theorem 14, the following lemma is critical (the proof of this lemma in given in Appendix B.1).

Lemma 15 Fix $r < 1$. Let μ be a probability measure on the space T and let $S := \{u : T \rightarrow \mathbb{R}_+ : u \in L_r^+(T)\}$. Then the map $f : S \rightarrow \mathbb{R}$ defined by $f(u) := \left(\int_T u(t)^r \mu(dt) \right)^{1/r}$ is concave in u .

Note that the discrete version of Lemma 15 states that $f(u) = \left(\sum_{i=1}^M u_i^r / M \right)^{1/r}$ is a concave function of $u \in \mathbb{R}_+^M$ when $r < 1$.

In fact, since we will apply this lemma to prove Theorem 14 with $r = \frac{1}{1-\alpha}$, the condition $r < 1$ in Lemma 15 translates into $\alpha \notin [0, 1]$ in Theorem 14. We are now ready to prove Theorem 14.

Proof [Proof of Theorem 14]

By the identity that $D_{f_\alpha}(P\|Q) = D_{f_{1-\alpha}}(Q\|P)$, we have

$$\begin{aligned} D_{f_\alpha}(P\|\bar{Q}) &= D_{f_{1-\alpha}}(\bar{Q}\|P) = \int_{\mathcal{X}} p \left(\int_{\Xi} \frac{q\xi}{p} \nu(d\xi) d\mu \right)^{1-\alpha} - 1 \\ &= \int_{\mathcal{X}} p \left(\int_{\Xi} \left[\frac{q\xi}{p} \right]^{1-\alpha} \nu(d\xi) d\mu \right)^{1-\alpha} - 1 \end{aligned}$$

Let $u(\xi, x) = \left(\frac{q\xi}{p} \right)^{1-\alpha}$. Since $\frac{1}{1-\alpha} < 1$ when $\alpha \notin [0, 1]$, Lemma 15 implies that $u(\xi, x) \mapsto \left(\int_{\Xi} u(\xi, x)^{1/(1-\alpha)} \nu(d\xi) \right)^{1-\alpha}$ is concave in u . Applying Jensen's inequality,

$$\begin{aligned} D_{f_\alpha}(P\|\bar{Q}) &\leq \left(\int_{\Xi} \left[\int_{\mathcal{X}} p \left(\frac{q\xi}{p} \right)^{1-\alpha} d\mu \right]^{1/(1-\alpha)} \nu(d\xi) \right)^{1-\alpha} - 1 \\ &= \left(\int_{\Xi} [D_{f_{1-\alpha}}(Q_\xi\|P)]^{1/(1-\alpha)} \nu(d\xi) \right)^{1-\alpha} - 1. \end{aligned}$$

This completes the proof of (49) because $D_{f_{1-\alpha}}(Q_\xi\|P) = D_{f_\alpha}(P\|Q_\xi)$. The proof of (50) follows by applying (49) for $P = P_\theta$ and then integrating the resulting bound with respect to $w(d\theta)$. \blacksquare

For $\alpha > 1$, one can deduce an upper bound analogous to (48) for the f_α -informativity which is described in the next corollary. Recall the notion of the covering numbers $M_\alpha(\epsilon, \Theta)$ from Section 2.

Corollary 16 For every $\alpha > 1$, we have

$$I_{f_\alpha}(w, \mathcal{P}) \leq \inf_{\epsilon > 0} (1 + \epsilon^2) M_\alpha(\epsilon, \Theta)^{\alpha-1} - 1. \quad (51)$$

In particular, when D_{f_α} is the chi-square divergence, Corollary 16 implies

$$I_{\chi^2}(w, \mathcal{P}) \leq \inf_{\epsilon > 0} (1 + \epsilon^2) M_{\chi^2}(\epsilon, \Theta) - 1. \quad (52)$$

Note that Corollary 16 gives trivial bound when $M_\alpha(\epsilon, \Theta)$ equals ∞ for all $\epsilon > 0$. This can be handled in a way similar to that outlined in the discussion after (48).

Proof [Proof of Corollary 16]

Let Q_1, \dots, Q_M be probability measures on \mathcal{X} and fix $\theta \in \Theta$. Inequality (49) applied to $P = P_\theta$, $\Xi := \{1, \dots, M\}$ and the uniform probability measure on Ξ as ν gives

$$D_{f_\alpha}(P_\theta\|\bar{Q}) \leq M^{\alpha-1} \left[\sum_{j=1}^M (1 + D_{f_\alpha}(P_\theta\|Q_j))^{1/(1-\alpha)} \right]^{1-\alpha} - 1$$

We now use (note that $\alpha > 1$)

$$\begin{aligned} \sum_{j=1}^M (1 + D_{f_\alpha}(P_\theta\|Q_j))^{1/(1-\alpha)} &\geq \max_{1 \leq j \leq M} (1 + D_{f_\alpha}(P_\theta\|Q_j))^{1/(1-\alpha)} \\ &= (1 + \min_{1 \leq j \leq M} D_{f_\alpha}(P_\theta\|Q_j))^{1/(1-\alpha)}. \end{aligned}$$

This gives

$$D_{f_\alpha}(P_\theta\|\bar{Q}) \leq M^{\alpha-1} \left(1 + \min_{1 \leq j \leq M} D_{f_\alpha}(P_\theta\|Q_j) \right) - 1.$$

We now fix $\epsilon > 0$ and apply the above with $\{Q_1, \dots, Q_M\}$ taken to be an ϵ^2 -cover of Θ under the f_α -divergence. We then obtain

$$D_{f_\alpha}(P_\theta\|\bar{Q}) \leq \inf_{\epsilon > 0} (1 + \epsilon^2) M_\alpha(\epsilon, \Theta)^{\alpha-1} - 1.$$

The proof is complete by integrating the above inequality with respect to $w(d\theta)$. \blacksquare

We now turn to applications of the Bayes risk lower bounds in Corollary 12 and the informativity upper bounds in this section. We present a toy example here and postpone more complicated examples (e.g., generalized linear model, spiked covariance model, Gaussian model with general prior and loss) to Appendix C.

Example 1 (Gaussian model with uniform priors on large balls) Fix $d \geq 1$. Suppose $\Theta = \mathcal{A} \subset \mathbb{R}^d$ and let $L(\theta, a) := \|\theta - a\|_2^2$. For each $\theta \in \mathbb{R}^d$, let P_θ denote the Gaussian distribution with mean θ and covariance matrix $\sigma^2 I_{d \times d}$ ($\sigma^2 > 0$ is a constant). Let w be the uniform distribution on the closed ball of radius Γ centered at the origin. Let $\Gamma \geq \sigma\sqrt{d}$.

We will show below how to obtain the tight Bayes risk lower bound using Corollary 12 along with the f -informativity upper bound in Corollary 16.

We can assume that Θ (and \mathcal{A}) is the closed ball of radius Γ centered at the origin as w puts zero probability outside this ball. We use the inequality (40) induced by the chi-squared divergence. To establish the lower bound, we need to upper bound $\sup_{a \in \mathcal{A}} w(B_1(a, L))$ and the chi-squared informativity. The former can be easily controlled because $\sup_{a \in \mathcal{A}} w(B_1(a, L)) \leq (\sqrt{L}/\Gamma)^d$. For the latter, we use (52), which requires an upper bound on $M_{\chi^2}(\epsilon, \Theta)$. Note that $\chi^2(P_\theta \| P_\theta) = \exp(\|\theta - \theta'\|_2^2 / \sigma^2) - 1$ for $\theta, \theta' \in \Theta$. As a consequence, $\chi^2(P_\theta \| P_\theta) \leq e^2$ if and only if $\|\theta - \theta'\|_2 \leq e' := \sigma \sqrt{\log(1 + e^2)}$. Therefore, by a standard volumetric argument, we have

$$M_{\chi^2}(\epsilon, \Theta) \leq \left(\frac{\Gamma + e'/2}{e'/2} \right)^d \leq \left(\frac{3\Gamma}{e'} \right)^d = \left(\frac{3\Gamma}{\sigma \sqrt{\log(1 + e^2)}} \right)^d$$

provided $e' \leq \Gamma$. In particular, if we take $\epsilon := \sqrt{e^d} - 1$, then $e' = \sigma \sqrt{d} \leq \Gamma$, we will obtain $M_{\chi^2}(\epsilon, \Theta) \leq (3\Gamma/(\sigma \sqrt{d}))^d$. Inequality (52) then gives $I_{\chi^2}(w, \mathcal{P}) \leq \left(\frac{3e\Gamma}{\sigma \sqrt{d}} \right)^d - 1$. Let I_f^{up} be the right hand side. If we choose $t = cd\sigma^2$ for a sufficiently small constant $c > 0$, then we have $\sup_{a \in \mathcal{A}} w(B_1(a, L)) < \frac{1}{4}(1 + I_f^{\text{up}})^{-1}$. Inequality (40) then gives

$$R_{\text{Bayes}}(w, L; \Theta) \geq cd\sigma^2. \quad (53)$$

This lower bound is tight due to the trivial upper bound $R_{\text{Bayes}}(w, L; \Theta) \leq d \min(\sigma^2, \Gamma^2)$ since $R_{\text{Bayes}}(w, L; \Theta)$ is smaller than the risk of the constant estimator 0 as well as the trivial estimator of the observation itself.

This example allows us to compare the bound given by Theorem 9 for different $f \in \mathcal{C}$. We argue below that using KL divergence and applying (39) along with inequality (48) for controlling the mutual information will not yield a tight lower bound for this example. In other words, the same strategy that works for $f(x) = x^2 - 1$ does not work for $f(x) = x \log x$. To see this, notice that $D(P_\theta \| P_\theta) = \|\theta - \theta'\|_2^2 / \sigma^2$ for $\theta, \theta' \in \Theta$. As a result, $D(P_\theta \| P_\theta) \leq e^2$ if and only if $\|\theta - \theta'\|_2 \leq \sqrt{2e}\sigma$. The same volumetric argument again gives $M_{KL}(\epsilon, \Theta) \leq \left(\frac{3\Gamma}{\sqrt{2e}\sigma} \right)^d$ provided $\sqrt{2e}\sigma \leq \Gamma$. The bound (48) implies that the mutual information $I(w, \mathcal{P})$ is bounded by

$$I(w, \mathcal{P}) \leq \int_{0 < \delta \leq \Gamma / (\sqrt{2e}\sigma)} d \log \left(\frac{3\Gamma}{\sqrt{2e}\sigma} \right) + e^2 = d \log \left(\frac{3\Gamma}{\sigma \sqrt{d}} \right) + \frac{d}{2}.$$

Let I_f^{up} be the right hand side above. The maximum $t > 0$ for which $(\sqrt{t}/\Gamma)^d < \frac{1}{4} \exp(-2I_f^{\text{up}})$ is on the order of $d^2 \sigma^4 / \Gamma^2$. This means that inequality (39) implies a weaker lower bound $\Omega(d^2 \sigma^4 / \Gamma^2)$, which is suboptimal when $d\sigma^2$ is small or when Γ is large. This is in contrast with the optimal bound (53).

In the above example, a direct application of Theorem 9 with $f(x) = x \log x$ does not produce a tight lower bound. This is mainly because, when the prior is over a large parameter space (e.g., a ball of a constant radius), the upper bound of mutual information over the entire parameter space Θ in (48) could be too loose. This can be corrected by partitioning the

parameter space Θ into small hypercubes, and applying our bounds for the prior restricted to each hypercube separately so that the mutual information inside the partition can be appropriately upper bounded using (48). This is another illustration of the idea described in Remark 11. We first describe this method in a more general setting in the following corollary and then apply it to the setting of Example 1. We use the following notation. For measurable subsets S of a Euclidean space, $\text{Vol}(S)$ denotes the volume (Lebesgue measure) of S .

Corollary 17 *Let $\Theta = \mathcal{A} \subseteq \mathbb{R}^d$. Suppose that the prior w has a Lebesgue density f_w that is positive over Θ . For each $\theta \in \Theta$ and $\delta > 0$, let*

$$r_\delta(\theta) := \sup \left\{ \frac{f_w(\theta_1)}{f_w(\theta_2)} : \theta_i \in \Theta \text{ and } \|\theta_i - \theta\|_2 \leq \sqrt{d}\delta \text{ for } i = 1, 2 \right\}.$$

Suppose also the existence of $A > 0$ such that $D(P_{\theta_1} \| P_{\theta_2}) \leq A \|\theta_1 - \theta_2\|_2^2$ for all $\theta_1, \theta_2 \in \Theta$ and the existence of $V > 0$ (which may depend on d) and $p > 0$ such that $\sup_{a \in \mathcal{A}} \text{Vol}(B_1(a, L)) \leq V\mu^{d/p}$ for every $t > 0$. Then

$$R_{\text{Bayes}}(w, L; \Theta) \geq \frac{1}{2} \sup_{0 < \delta \leq A^{-1/2}} \left[e^{-2p} p^p (8V)^{-p/d} \int_{\Theta} \left(\frac{1}{r_\delta(\theta)} \right)^{p/d} w(d\theta) \right]. \quad (54)$$

The proof of Corollary is quite technically involved and thus is deferred to Appendix B.3.

We demonstrate below that this corollary yields the correct rate in Example 1. More examples (e.g., estimation problem in generalized linear model, spiked covariance model, and Gaussian model with a general loss) are given in Appendix C.

Example 2 (Gaussian model with uniform priors on large balls (continued)) *Consider the same setting as in Example 1. Because $D(P_\theta \| P_\theta) = \|\theta - \theta'\|_2^2 / (2\sigma^2)$, we can take $A = (2\sigma^2)^{-1}$ in Corollary 17. Moreover, because $L(\theta, a) = \|\theta - a\|_2^2$, it is easy to see that $\sup_{a \in \mathcal{A}} \text{Vol}(B_1(a, L)) \leq t^{d/2} \text{Vol}(B)$ which means that we can take $p = 2$ and $V = \text{Vol}(B)$ in Corollary 17 where B is the unit ball in \mathbb{R}^d . Finally, because w is the uniform prior, we have $r_\delta(\theta) = 1$ for all $\theta \in \Theta$. Corollary 17 therefore gives*

$$R_{\text{Bayes}}(w, L; \Theta) \geq \frac{1}{2} \sup_{0 < \delta \leq \sqrt{\delta}\sigma} \left(e^{-4} 8^{-2/d} \delta^2 \text{Vol}(B)^{-2/d} \right).$$

This matches the tight lower bound (53) by noting that $\text{Vol}(B)^{1/d} \asymp d^{-1/2}$.

6. Smoothed Analysis for Spherical Gaussian Mixture Models with Uniform Weights

Smoothed analysis is a useful technique for analyzing algorithms that fail in the worst case but succeed with high probability in the average case. For parameter estimation problems, smoothed analysis assumes that the parameter to be estimated is randomly perturbed

by a small noise, and the data is generated with respect to the perturbed parameter as well. Under this setting, if the set of “bad” parameters that fail the estimator has zero measure, then the estimator will succeed almost surely after the perturbation. Smoothed analysis has been successfully applied to analyze linear programming (Blum and Dumagan, 2002; Duneagan et al., 2011; Hsu and Kakade, 2013; Spielman and Teng, 2003), integer programming (Röglin and Vöcking, 2007), binary search trees (Manthey and Reischuk, 2007), and other combinatorial problems (Banderier et al., 2003). See the paper by Spielman and Teng (2003) for a survey of existing works.

In this section, we use smoothed analysis to study an important problem in statistical estimation: learning mixture of spherical Gaussians. The problem of computing the maximum log-likelihood estimator is NP-hard (Arora and Kannan, 2005). However, if the true parameters are perturbed by a random noise, then we demonstrate that a variant of the polynomial-time algorithm proposed by Hsu and Kakade (2013) succeeds in estimating the Gaussian means. We present an upper bound on the algorithm’s mean-squared error using smoothed analysis, which achieves a better rate than the original algorithm of Hsu and Kakade (2013). Furthermore, we apply the Bayes risk lower bound developed in this paper to show that, the mean squared-error achieved by this algorithm is unimprovable, even under smoothed analysis. To the best of our knowledge, the lower bound cannot be established by traditional information-theoretic techniques for lower bounding minimax risks.

6.1 Learning Mixture of Gaussians

We study estimating the parameter of a Gaussian mixture model (GMM). The parameter of a GMM is a d -by- k matrix $\theta := (\theta_1, \dots, \theta_k)$. Each $\theta_i \in \mathbb{R}^d$ represents the mean of the i -th mixture component. We assume that the number of components k is much less than the dimensionality d . Suppose that n i.i.d. instances $\{x_i\}_{i=1}^n$ are sampled from the GMM with each $x_i \in \mathbb{R}^d$. Equivalently, it is generated by the following procedure: First, an integer z_i is uniformly sampled from $\{1, \dots, k\}$. This integer is called the *membership* of the i -th instance¹. Then, the vector x_i is drawn from the spherical Gaussian distribution $N(\theta_{z_i}; I_{d \times d})$. The goal is to estimate the parameters θ .

Information theoretically, the GMM model is learnable if the Gaussian means are well separated. Let D represent the minimum distance between two distinct component means. Venupala and Wang (2004) show that, as long as $D > C$ for C being a sufficiently large constant, the estimation error on θ scales as $\mathcal{O}(n^{-1/2})$. However, the algorithm achieving this rate has $\mathcal{O}(k^k)$ time complexity. When the mutual distance D is large enough, there are poly(n, d, k)-time algorithms to estimate the model parameters. In particular, Dasgupta (1999) presents an algorithm for $D = \Omega(\sqrt{d})$. Arora and Kannan (2005) and Dasgupta and Schulman (2000) present algorithms for $D = \Omega(d^{1/4})$. Venupala and Wang (2004) reduce this distance lower bound to $\Omega(k^{1/4})$. However, designing poly(n, d, k)-time algorithm for $\Omega(1)$ -separated GMMs is a long-standing open problem.

Hsu and Kakade (2013) proposed a method that does not need the well-separation condition. The only assumption is that $\{\theta_1, \dots, \theta_k\}$ are linearly independent. Let $\sigma_{\min} > 0$ be the smallest singular value of the matrix θ . Their algorithm runs in poly(n, d, k)-time

1. For simplicity, we focus on the case when all mixture components have equal weights, but our argument can be easily generalized to the case of non-uniform weights.

and achieves the following bound for estimator $\hat{\theta}$:

$$\|\hat{\theta} - \theta\|_F^2 = \mathcal{O}\left(\frac{\text{poly}(d, k, 1/\sigma_{\min}) \log(1/\delta)}{n}\right) \quad \text{with probability at least } 1 - \delta. \quad (55)$$

Here, $\|\cdot\|_F$ denotes the matrix Frobenius norm. In general, we cannot guarantee that $\sigma_{\min} > 0$. However, if we add a small perturbation on the true component means, then the assumption is satisfied almost surely. More precisely, we assume that there is a matrix $\theta^* \in \mathbb{R}^{d \times k}$ so that each entry of matrix θ is sampled from $\theta_{ij} \sim N(\theta_{ij}^*; \rho^2)$. The following lemma lower bounds the smallest singular value.

Lemma 18 (Ge et al. (2015), Lemma G.16) *Let $\theta^* \in \mathbb{R}^{d \times k}$ and suppose that $d \geq 3k$. If all entries of θ^* are independently perturbed by $N(0, \rho^2)$ to yield matrix θ . For any $\epsilon > 0$, with probability at least $1 - c_1(c_2\epsilon)^d$, the smallest singular value of matrix θ is lower bounded by:*

$$\sigma_{\min} > \epsilon\rho\sqrt{d}.$$

Here, c_1, c_2 are universal constants.

We choose $\epsilon, \rho \sim n^{-c}$ for a sufficiently small $c > 0$, then the perturbation diminishes to zero, and if $\sigma_{\min} > \epsilon\rho\sqrt{d}$ holds, then the right-hand side of equation (55) converges to zero at a polynomial rate as $n \rightarrow \infty$. Lemma 18 implies that the probability of this event is at least $1 - \mathcal{O}(n^{-cd})$. Thus, with high probability, the estimator $\hat{\theta}$ is consistent under the smoothed analysis.

The convergence rate of the estimator $\hat{\theta}$ can be improved if we add a mild assumption that $D = \tilde{O}(\sqrt{\log(nk)})$. Although the main focus of the paper is on lower bounds, the upper bound result on the estimation of $\hat{\theta}$ in learning mixture of Gaussians is of its independent interest. To obtain the upper bound on $\mathbb{E}\|\hat{\theta} - \theta\|_F^2$, we first establish the following lemma:

Lemma 19 *Let the mutual distance satisfy $D \geq c_1\sqrt{\log(nk/\delta)} \geq 3$ for a sufficiently large constant c_1 . With probability at least $1 - \delta$, the inequality $\|x_i - \theta_j\|_2 - \|x_i - \theta_{z_i}\|_2 \geq c_2(d \log(nk/\delta))^{-1/2}$ holds for a constant $c_2 > 0$, for any $i \in [n]$ and any $j \in [k] \setminus \{z_i\}$.*

The proof of this technical lemma is relegated to Appendix D. Lemma 19 shows that with high probability, the distance of a random sample to its true component mean is significantly less than the distance to any other means. Let $\hat{\theta}_j$ represent the j -th column of $\hat{\theta}$. When the sample size n is sufficiently large, the method of Hsu and Kakade (2013) guarantees that $\|\hat{\theta}_j - \theta_j\|_2 < o(d \log(nk/\delta))^{-1/2}$ for any $j \in [k]$. Thus, Lemma 19 implies that the distance of x_i to $\hat{\theta}_{z_i}$ is smaller than the distance to any other estimated centers. As a consequence, we may recover the membership of instances by computing the center that is the closest to them.

$$\hat{z}_i = \arg \min_{j \in [k]} \|x_i - \hat{\theta}_j\|_2.$$

According to Lemma 19, with high probability we have $\hat{z}_i = z_i$ for any $i \in [n]$. Given the membership, we refine the mean estimates by:

$$\hat{\theta}_j \leftarrow \frac{\sum_{i: \hat{z}_i=j} x_i}{|\{i: \hat{z}_i=j\}|}.$$

Since the membership is uniformly assigned, with high probability the sample size of the j -th Gaussian component is lower bounded by $\frac{2n}{k}$. Thus, with high probability the squared error of $\hat{\theta}_j$ will be upper bounded by $\mathcal{O}(dk/n)$. Since there are k components, the overall squared error is bounded by $\mathcal{O}(dk^2/n)$. Putting pieces together, we have an upper bound on the mean-squared error of parameter estimation.

Proposition 20 *Suppose that $d \geq 3k$ and n is greater than a fixed polynomial function of $(d, k, 1/\rho)$. Let the true parameter θ be ρ -perturbed from an arbitrary matrix $\theta^* \in \mathbb{R}^{d \times k}$. In addition, assume that the distances between the columns of θ^* are at least $D = c\sqrt{\log(nk)}$ for some universal constant c . Then there is a universal constant C such that the estimator $\hat{\theta}$ described above achieves mean-square error:*

$$\mathbb{E}[\|\hat{\theta} - \theta\|_F^2] \leq \frac{Cdk^2}{n}.$$

6.2 Minimax Risk of Smoothed Analysis

In this section, we formalize the notion of minimax risk under smoothed analysis. Similar to the classical statistical setting, the *minimax risk under smoothed analysis* can be defined in a game theoretic way. The learner first chooses an estimator $\hat{\theta}$, then the adversary chooses a parameter θ^* from the parameter space Θ , which is randomly perturbed to form the true parameter θ . The data X is generated with respect to θ . Under this random perturbation framework, the minimax risk is defined as:

$$R_{\text{minimax}} := \inf_{\hat{\theta}} \sup_{\theta^* \in \Theta} \mathbb{E}_{\theta} [L(\hat{\theta}(X), \theta)] \quad (56)$$

where $L(\cdot, \cdot)$ is the loss function. In our GMM application, the parameters are the means of mixture components. The parameter space is the set of means whose mutual distances are lower bounded by D . The true parameter is generated by a random Gaussian perturbation with variance ρ^2 . The loss is the Frobenius norm of the difference of matrices.

We note that the minimax risk (56) differs from the classical notion of minimax risk in that the adversary is not able to explicitly choose the true parameter θ . Instead, the true parameter is sampled from a prior distribution parameterized by θ^* . This Bayes nature makes it hard to lower bound the minimax risk (56) using the traditional Le Cam's or the Fano's method. In particular, both the Le Cam's method and the Fano's method lower bound the minimax risk by assuming a uniform prior over a carefully constructed discrete set. However, in our GMM setting, the prior distribution of parameter θ is always continuous.

Our Bayes risk lower bound naturally fits into the setting of smoothed analysis. Let w^* be an arbitrary prior distribution over θ^* . Since θ is perturbed from θ^* , the prior w^* induces a prior w over θ . It is sufficient to see that the Bayes risk with respect to w is a lower bound on the minimax risk (56). Thus, it suffices to lower bound the Bayes risk:

$$R_{\text{Bayes}}(w, L; \Theta) := \inf_{\hat{\theta}} \mathbb{E}_{\theta \sim w} [L(\hat{\theta}(X), \theta)].$$

For the GMM example, we construct the prior distribution w^* as follow: the j -th column of θ^* , namely the vector $\theta_j^* \in \mathbb{R}^d$, is sampled from the normal distribution $\mathcal{N}(D_{e_j}, I_{d \times d})$,

where e_j is the unit vector of the j -th coordinate. As a consequence, the prior distribution w samples the j -th column of θ from the normal distribution $\mathcal{N}(D_{e_j}; (1 + \rho^2)I_{d \times d})$.

In the GMM setting, the membership variables z_i are unknown to the estimator. If we assume that the memberships are given to the estimator, it makes the problem easier so that the associated Bayes risk is a smaller than or equal to the original Bayes risk. Since we want to derive a lower bound, we make the assumption that the memberships are given, then partition the instances into k disjoint subsets according to their memberships. Let the j -th subset S_j be defined as $S_j := \{x_i : z_i = j\}$. Conditioning on the memberships, the distributions of $\{(\theta_j, S_j)\}_{j=1}^k$ are mutually independent. Thus, we have

$$R_{\text{Bayes}}(w, L; \Theta) \geq \sum_{j=1}^k \inf_{\hat{\theta}_j} \mathbb{E}_{\theta_j \sim w_j} [L(\hat{\theta}_j(S_j), \theta_j)] \geq \sum_{j=1}^k \mathbb{E} \left[\inf_{\hat{\theta}_j} \mathbb{E}_{\theta_j \sim w_j} [L(\hat{\theta}_j(S_j), \theta_j)] | n_j \right] \quad (57)$$

where w_j is the prior distribution $\mathcal{N}(D_{e_j}; (1 + \rho^2)I_{d \times d})$ and n_j is the cardinality of S_j . We focus on the inner term on the right-hand side, namely $\inf_{\hat{\theta}_j} \mathbb{E}_{\theta_j \sim w_j} [L(\hat{\theta}_j(S_j), \theta_j)] | n_j$, and find that it is the Bayes risk of Gaussian mean estimation with n_j i.i.d. samples, with the true parameter θ_j satisfying a Gaussian prior w_j . This Bayes risk can be easily lower bounded by the techniques that we develop in this paper.

Lemma 21 *Suppose that the standard deviation of normal perturbation $\rho \leq 1$ and $n_j \geq 1$. For a universal constant c , the Bayes risk is lower bounded by*

$$R_{\text{Bayes}}(w_j, n_j) := \inf_{\hat{\theta}_j} \mathbb{E}_{\theta_j \sim w_j} [L(\hat{\theta}_j(S_j), \theta_j)] | n_j \geq \frac{cd}{\theta_j}.$$

Proof [Proof of Lemma 21]

We denote the distribution of instances in S_j by P_{θ_j} and let \mathcal{P} be the set of such distributions. Since the support of w_j is \mathbb{R}^d , we start by defining a prior whose support is an Euclidean ball of radius $\Gamma := \sqrt{2d}$. Let \bar{w} be the truncated prior satisfying:

$$\bar{w}(x) = \begin{cases} w_j(x)/c_1 & \text{if } \|x - D_{e_j}\|_2 \leq \Gamma \\ 0 & \text{otherwise.} \end{cases}$$

The normalization factor c_1 is equal to the total mass of w in the ball $\{x : \|x - D_{e_j}\|_2 \leq \Gamma\}$. It is straightforward to verify that the radius Γ is sufficiently large so that c_1 is lower bounded by a universal constant. The prior \bar{w} can be viewed as restricting the original prior in a finite radius. According to Remark 11, we may lower bound the Bayes risk by

$$R_{\text{Bayes}}(w_j, n_j) \geq c_1 \cdot R_{\text{Bayes}}(\bar{w}, n_j).$$

Thus, it suffices to lower bound the second term on the right-hand side.

We follow the similar steps of Example 1 to establish the lower bound. We start by upper bounding the terms $\sup_{\theta \in \mathcal{A}} \bar{w}(B_\Gamma(\theta, L))$ and the chi-squared informativity $I_{\chi^2}(\bar{w}; \mathcal{P})$. Using definition of the multivariate normal distribution, it is easy to see that

$$\sup_{\theta \in \mathcal{A}} \bar{w}(B_\Gamma(\theta, L)) = \bar{w}(B_\Gamma(D_{e_j}, L)) \leq \frac{V(\sqrt{L})}{c_1(2\pi(1 + \rho^2))^{d/2}}$$

where $V(\sqrt{t})$ represents the volume of the Euclidean ball of radius \sqrt{t} . Thus, there is a universal constant c_2 such that $\sup_{a \in A} \bar{w}(B_t(a, L)) \leq (c_2 \sqrt{t}/\Gamma)^d$. On the other hand, we follow the same steps of Example 1 to upper bound the chi-square informativity. Note that our setup has n_j i.i.d. observations, but in Example 1 there is only one observation. In this generalized setup, the chi-square distance $\chi^2(P_{\theta_0} \| P_{\theta'})$ is equal to $\exp(n_j \|\theta - \theta'\|_2^2 / \sigma^2) - 1$. Plugging this formula into the argument of Example 1, we obtain the upper bound $I_{\chi^2}(\bar{w}, \mathcal{P}) \leq (3e\Gamma \sqrt{n_j/d})^d - 1$.

Let I_{pr}^* be the obtained informativity upper bound. If we choose $t = cd/n_j$ for a sufficiently small constant $c > 0$, then we have $\sup_{a \in A} \bar{w}(B_t(a, L)) < \frac{1}{4}(1 + I_{\text{pr}}^*)^{-1}$. Corollary 12 then gives $R_{\text{Bayes}}(\bar{w}, n_j) \geq cd/n_j$. ■

Combining inequality (57) and Lemma 21, we have

$$R_{\text{Bayes}}(w, L; \Theta) \geq \sum_{j=1}^k \frac{cdk}{2n} \mathbb{P}(n_j \leq 2n/k).$$

Recall that every n_j satisfies a binomial distribution $B(n, 1/k)$, which has median $\lfloor n/k \rfloor$ or $\lceil n/k \rceil$, thus the probability $\mathbb{P}(n_j \leq 2n/k)$ will be at least $1/2$. It implies that the Bayes risk is lower bounded by $\Omega(dk^2/n)$. Putting pieces together, we have the following lower bound on the minimax risk.

Proposition 22 *Assume that the standard deviation of normal perturbation $\rho \leq 1$, then for some universal constant c the minimax risk of smoothed analysis is lower bounded by $R_{\text{minimax}} \geq c \frac{dk^2}{n}$.*

Comparing proposition 20 and proposition 22, we find that both the upper bound and the lower bound are tight. More precisely, under the assumptions of proposition 20, the minimax risk of smoothed analysis is precisely on the order of dk^2/n .

7. Bayes Risk Lower Bounds for Sparse Linear Regression

Linear regression is a canonical problem in machine learning and statistics. For a fixed design matrix $X \in \mathbb{R}^{n \times d}$ and an unknown parameter $\theta \in \mathbb{R}^d$, the learner observes a noise-corrupted response vector $y = X\theta + \varepsilon$, where ε satisfies an isotropic normal distribution $N(0, \sigma^2 I_{d \times d})$. The goal is to take the response vector as input and find an estimator $\hat{\theta} \in \mathbb{R}^d$ for the true parameter θ . The risk is measured either by the estimation error $I_{\text{est}}(\hat{\theta}, \hat{\theta}) := \|\hat{\theta} - \theta\|_2^2$, or by the prediction error $I_{\text{pre}}(\hat{\theta}, \hat{\theta}) := \|X\hat{\theta} - X\theta\|_2^2$. Both errors will be studied in this section.

For high-dimensional linear regression, the dimension d can be much greater than the sample size n . In order to prevent over-fitting, one needs to impose structural assumptions on the true parameter, for example, assuming that the number of non-zero entries in vector θ is at most k ($k \ll d$). Formally, we use $\mathbb{B}_0(k)$ to represent the set of k -sparse vectors in \mathbb{R}^d , and assume that $\theta \in \mathbb{B}_0(k)$. Under this setting, we want to compute an estimator $\hat{\theta} \in \mathbb{R}^d$ to minimize the estimation error or the prediction error. Note that the estimator $\hat{\theta}$ does not need to be k -sparse. Hence, our theoretical framework includes *improper learners* which are allowed to output non-sparse estimates whenever they achieve small risks.

The minimax risks of sparse linear regression have been well-studied. Under the same problem setting, Raskutti et al. (2011) proved information theoretic lower bounds on both the estimation error and the prediction error. Certain lower bounds have also been proved under the computation tractability constraint Zhang et al. (2014), or proved for the family of regularized M-estimators Zhang et al. (2015). All these lower bounds handle the worst-case scenario — given an arbitrary estimator, they prove the existence of a parameter θ that attains the lower bound. This setting might be too pessimistic in practice. The goal of this section is to study the Bayes risk of sparse linear regression under a natural prior, whose construction is described in the next subsection.

7.1 Prior Definition and Assumptions

We define a prior over k -sparse d -dimensional vectors for the true parameter $\theta \in \mathbb{R}^d$, referred to as distribution w , as follows:

1. Uniformly sample a subset of k indices from the integer set $\{1, 2, \dots, d\}$, naming this subset by K .
2. For every index $i \in K$, the coordinate θ_i is generated by sampling from the normal distribution $N(0, \tau^2)$. For any $i \notin K$, define $\theta_i := 0$.

Given an index set K , we use θ_K as a shorthand notation to denote the coordinates of the vector $\theta \in \mathbb{R}^d$ whose indices belong to the set K . Similarly, we use θ_{-K} to denote the subvector whose indices are not in K . Then the second step of the above generative process can be rephrased as generating $\theta_K \sim N(0, \tau^2 I_{k \times k})$ and defining $\theta_{-K} = 0$. It is clear that the sampled θ belongs to the k -sparse ℓ_0 -ball $\mathbb{B}_0(k) := \{\theta \in \mathbb{R}^d : \|\theta\|_0 \leq k\}$.

One may consider variants of the prior defined above. For example, one can assume that the number of non-zero entries of the vector θ is not exactly equal to k , but random sampled from a Poisson distribution with mean k . One may also redefine the prior of non-zero entries to be a non-Gaussian distribution. However, these variants don't add essential technical challenge to the analysis, thus we focus on the prior w as a concrete example for illustrating the general idea.

We make an additional assumption on the design matrix X that is important for characterizing the minimax risk (see, e.g. Raskutti et al., 2011), and in this section, we study their effects on the Bayes risk. Specifically, the design matrix X satisfies the *sparse eigenvalue conditions* with parameter (κ_u, κ_ℓ) if:

$$\kappa_\ell \|\beta\|_2 \leq \frac{\|X\beta\|_2}{\sqrt{n}} \leq \kappa_u \|\beta\|_2 \quad \text{for any } (2k)\text{-sparse vector } \beta \in \mathbb{R}^d. \quad (58)$$

Here, both κ_u and κ_ℓ are positive constants. As a concrete example, if entries of the matrix X are i.i.d. sampled from a normal distribution, then the matrix is called a *Gaussian random design*. This type of matrices have been extensively studied for sparse linear regression (Candes et al., 2006; Guédon et al., 2008), and proved to satisfy condition (58) with $\kappa_u/\kappa_\ell = \mathcal{O}(1)$ (Raskutti et al., 2010). For the rest of this section, we assume that the design matrix X satisfies the condition (58).

7.2 Bayes Risk Lower Bounds

For sparse linear regression, we denote the parameter space and action space by $\Theta = \mathbb{B}_0(k)$ and $\mathcal{A} = \mathbb{R}^d$, respectively. We present a Bayes risk lower bound with respect to the prior distribution defined in Section 7.1, then demonstrate its consequences.

Theorem 23 *Assume that the design matrix X satisfies the sparse eigenvalue condition (58), and that $d > k^3$. There are universal constants $c', c'' > 0$ such that for any $\tau > 0$, we have Bayes risk lower bounds: $R_{\text{Bayes}}(w, L_{\text{est}}; \Theta) \geq c' T(\tau)$ and $R_{\text{Bayes}}(w, L_{\text{pre}}; \Theta) \geq c'' \kappa_u^2 T(\tau)$, where $T(\tau)$ is a term defined by*

$$T(\tau) := k\tau^2 \max \left\{ \frac{1}{1 + \kappa_u^2 \sigma^2 \tau^2 / \sigma^2}, \exp \left(-\frac{4\kappa_u^2 n}{\sigma^2} \left[\tau^2 - \frac{\sigma^2 \log(d/k)}{16\kappa_u^2 n} \right]_+ \right) \right\}. \quad (59)$$

The proof of Theorem 23 follows the general strategy that we sketched in earlier sections: first, we bound the mutual informativity using the techniques described in Section 5, then we upper bound the probability $\sup_{a \in \mathcal{A}} w(B_t(a, L))$ for a specific scalar $t > 0$. Combining the two upper bounds with Corollary 12 establishes the theorem. See Appendix E for the proof. We make a few important remarks of this result in the below.

Estimation versus prediction By Theorem 23, the lower bounds on the estimator error and the prediction error differ by a factor κ_u^2 . As a consequence, if we multiply a constant to the design matrix, then the term κ_u^2 will also be scaled. If the scalar is very small, then the lower bound on the prediction error will be close to zero, but the lower on the estimation error won't. These are the right scaling for both risks. Indeed, when the design matrix converges to an all-zero matrix, the true parameters will be hard to identify, but the constant estimator $\hat{\theta} \equiv 0$ will be able to achieve a small prediction error.

Comparison with minimax risk lower bounds It is worth comparing Theorem 23 with the well-studied minimax risk lower bound. Under the sparse eigenvalue condition (58), Raskutti et al. (2011) proved the follow minimax risk lower bound:

$$\inf_{\hat{\theta}} \max_{\theta \in \mathbb{B}_0(k)} \mathbb{E}[L_{\text{est}}(\hat{\theta}, \hat{\theta})] \geq c' \frac{\sigma^2 k \log(d/k)}{\kappa_u^2 n} \quad \text{and} \quad \inf_{\hat{\theta}} \max_{\theta \in \mathbb{B}_0(k)} \mathbb{E}[L_{\text{pre}}(\hat{\theta}, \hat{\theta})] \geq c'' \frac{\kappa_u^2 \sigma^2 k \log(d/k)}{\kappa_u^2 n}, \quad (60)$$

where c' and c'' are universal constants. These bounds are matched by Theorem 23. In particular, if we assume $d > k^3$ and consider the prior distribution with variance:

$$\tau^2 = \begin{pmatrix} \tau_u^2 \\ \tau_s^2 \end{pmatrix} := \begin{pmatrix} \sigma^2 \log(d/k) \\ 16\kappa_u^2 n \end{pmatrix}, \quad (61)$$

then expression (59) implies $T(\tau) = k\tau^2$, and as a consequence, we have

$$R_{\text{Bayes}}(w, L_{\text{est}}; \Theta) \geq c' \frac{\sigma^2 k \log(d/k)}{\kappa_u^2 n} \quad \text{and} \quad R_{\text{Bayes}}(w, L_{\text{pre}}; \Theta) \geq c'' \frac{\kappa_u^2 \sigma^2 k \log(d/k)}{\kappa_u^2 n}, \quad (62)$$

where c' and c'' are universal constants. The minimax risk lower bounds (60) and the Bayes risk lower bounds (62) thus match by a universal constant factor. Therefore, using our

technique, we can directly obtain this classical minimax result on sparse linear regression. It is worth noting that the lower bounds of Raskutti et al. (2011) were proved by constructing a uniform prior over a discrete packing set over the parameter space. The existence of the proper packing set was proved in a non-constructive, worst-case fashion, which might be too pessimistic in practice. In contrast, our lower bound was established for a realistic and flexible prior which admits a simple closed-form definition and allows for different levels of variance. The theorem also shows that the prior w with the variance level (61) is in fact a *least favorable prior* for sparse linear regression.

Bayes risk on the spectrum of priors Besides the least-favorable setting (61), let us consider the Bayes risk under other choices of the parameter τ^2 . When $\tau^2 < \tau_u^2$, Theorem 23 implies

$$R_{\text{Bayes}}(w, L_{\text{est}}; \Theta) \geq c' k\tau^2 \quad \text{and} \quad R_{\text{Bayes}}(w, L_{\text{pre}}; \Theta) \geq c'' \kappa_u^2 k\tau^2. \quad (63)$$

When $\tau^2 \rightarrow +\infty$, Theorem 23 implies

$$R_{\text{Bayes}}(w, L_{\text{est}}; \Theta) \geq c' \frac{k\sigma^2}{\kappa_u^2 n} \quad \text{and} \quad R_{\text{Bayes}}(w, L_{\text{pre}}; \Theta) \geq c'' \frac{\kappa_u^2 k\sigma^2}{\kappa_u^2 n}. \quad (64)$$

In both cases, the Bayes risk lower bounds can be significantly smaller than the minimax risk. We argue that these lower bounds are essentially tight under specific assumptions. That is, when taking the prior information into account, we can indeed achieve better rates than the minimax rate.

First, notice that the upper bound:

$$\mathbb{E}_{\theta \sim w}[L_{\text{est}}(\hat{\theta}, \hat{\theta})] \leq k\tau^2 \quad \text{and} \quad \mathbb{E}_{\theta \sim w}[L_{\text{pre}}(\hat{\theta}, \hat{\theta})] \leq \kappa_u^2 k\tau^2.$$

can always be achieved using the constant estimator $\hat{\theta} \equiv 0$. It means that for the case of $\tau^2 < \tau_u^2$, the lower bounds (63) are tight under the assumption $\kappa_u/\kappa_\ell = \mathcal{O}(1)$.

For the case of $\tau^2 \rightarrow +\infty$, we consider the ℓ_0 -norm constrained estimator:

$$\hat{\theta} := \arg \inf_{\beta \in \mathbb{B}_0(k)} \|X\beta - y\|_2^2. \quad (65)$$

Whenever $\kappa_u/\kappa_\ell = \mathcal{O}(1)$, Raskutti et al. (2011) showed that the estimator (65) achieves an error bound $\|\hat{\theta} - \theta\|_2^2 \leq c \frac{k \log(d)}{\kappa_u^2 n}$ with high probability for a constant $c > 0$. Suppose that $\tau^2 = C \frac{k \log(d)}{n}$ with a scaling factor $C > c$. For any $i \in K$, the expectation of θ_i^2 is equal to τ^2 , so that the probability of $\theta_i^2 \leq c \frac{k \log(d)}{n}$ is bounded by $\mathcal{O}(c/C)$. It means that by choosing a large enough C (specifically, choosing $C \gg ck$), the lower bound $\theta_i^2 > c \frac{k \log(d)}{n}$ will hold for every $i \in K$ with a probability close to 1. Combining this fact with the bound $\|\hat{\theta} - \theta\|_2^2 \leq c \frac{k \log(d)}{n}$, we find that the support of $\hat{\theta}$ must agree with K , so that the estimator must satisfy:

$$\hat{\theta}_K = \arg \inf_{\beta \in \mathbb{R}^k} \|X_K \beta - y\|_2^2 \quad \text{and} \quad \hat{\theta}_{-K} = 0,$$

where X_K is a submatrix of X consisting of columns indexed by K . In other words, the vector $\hat{\theta}_K$ is the least-square estimator for a k -dimensional linear regression problem. For estimators taking this form, both the estimation error and the prediction error are known to match the lower bound (64) with high probability.

8. Conclusions

In this paper, we presented lower bounds for the Bayes risk in abstract decision-theoretic problems. Our bounds are quite general and only require upper bounds on $\sup_{a \in \mathcal{A}} w(B_t(a, L))$ and the f -informativity $I_f(w, \mathcal{P})$ for their application. Because of the generality, the bounds are not always tight however. For example, the bounds involve $\sup_{a \in \mathcal{A}} w(B_t(a, L))$ and this quantity becomes large when the prior w has a spike. In such situations, our main Bayes risk lower bound in Theorem 9 will not be tight. In specific examples, this looseness can be remedied by adhoc fixes such as the one described in Remark 11. Obtaining tight lower bounds for the Bayes risk in the generality considered in this paper is a challenging open problem.

Appendix A. Proofs and Additional Results for Section 3 on Bayes Risk Lower Bound for Zero-one Loss

A.1 Proof of Lemma 1

Recall the expression (13) of $\phi_f(a, b)$. We first fix b and show that $g(a) : a \mapsto \phi_f(a, b)$ is a non-increasing for $a \in [0, b]$. There is nothing to prove if $b = 0$ so let us assume that $b > 0$. We will consider the cases $0 < b < 1$ and $b = 1$ separately. For $0 < b < 1$, note that for every $a \in (0, b]$, we have,

$$g'_L(a) = f'_L\left(\frac{a}{b}\right) - f'_R\left(\frac{1-a}{1-b}\right),$$

where g'_L and f'_L represent left derivatives and f'_R represents right derivative (note that f'_L and f'_R exist because of the convexity of f). Because $\frac{a}{b} \leq \frac{1-a}{1-b}$ for every $0 \leq a \leq b$ and f is convex, we see that

$$g'_L(a) \leq f'_R\left(\frac{a}{b}\right) - f'_R\left(\frac{1-a}{1-b}\right) \leq 0$$

for every $a \in (0, b]$ which implies that $g(a)$ is non-increasing on $[0, b]$.

When $b = 1$, we have $g'_L(a) = f'_L(a) - f'(\infty)$ which is always ≤ 0 because f is convex (note that $f'(\infty) = \lim_{x \uparrow \infty} f(x)/x = \lim_{x \uparrow \infty} (f(x) - f(1))/(x - 1)$).

The convexity and continuity of g follow from the convexity of f and the expression for ϕ_f .

Next, we fix a and show that $h(b) : b \mapsto \phi_f(a, b)$ is non-decreasing for $b \in [a, 1]$. For every $b \in [a, 1)$, we have,

$$h'_R(b) = f\left(\frac{a}{b}\right) - \frac{a}{b}f'_L\left(\frac{a}{b}\right) - f\left(\frac{1-a}{1-b}\right) + \frac{1-a}{1-b}f'_R\left(\frac{1-a}{1-b}\right), \quad (66)$$

where h'_R represents the right derivative of h . By the convexity of f ,

$$f\left(\frac{a}{b}\right) - f\left(\frac{1-a}{1-b}\right) \geq f'_R\left(\frac{1-a}{1-b}\right) \left(\frac{a}{b} - \frac{1-a}{1-b}\right). \quad (67)$$

Combining (66) with (67), we obtain that,

$$h'_R(b) \geq \frac{a}{b} \left(f'_R\left(\frac{1-a}{1-b}\right) - f'_L\left(\frac{a}{b}\right) \right) \geq \frac{a}{b} \left(f'_L\left(\frac{1-a}{1-b}\right) - f'_L\left(\frac{a}{b}\right) \right) \geq 0,$$

where the last inequality is because that $\frac{a}{b} \leq \frac{1-a}{1-b}$ for every $0 \leq a \leq b$ and f is convex. The non-negativity of $h'_R(b)$ implies that $h(b)$ is non-decreasing on $[a, 1]$.

A.2 A Variant of Fano's Inequality from Braun and Pokutta (2014)

One of the main results in Braun and Pokutta (2014) (Proposition 2.2) establishes the following variant of Fano's inequality. Consider the setting of Lemma 3. In particular, recall the quantities R^0 and $R^0_{\mathcal{Q}}$ from (21) and also the sets $\mathcal{B}(a)$, $a \in \mathcal{A}$ from (16). (Braun and Pokutta, 2014, Proposition 2.2) proved the following: for any decision rule \mathfrak{D} ,

$$R^0 \geq \frac{-I(w, \mathcal{P}) - H(R^0)}{\log[(1 - w_{\min})/w_{\max}]}, \quad (68)$$

where $H(x) := -x \log x - (1-x) \log(1-x)$, $w_{\min} := \inf_{a \in \mathcal{A}} w(B(a))$ and $w_{\max} := \sup_{a \in \mathcal{A}} w(B(a))$.

Below we provide a proof of this inequality using Lemma 3. The proof given in Braun and Pokutta (2014) is quite different proof. Using (20) from Lemma 3 with $f(x) = x \log x$, we have for any decision rule

$$\int_{\Theta} D_f(P_\theta \| Q) w(d\theta) \geq R^3 \log \frac{R^3}{R_0^3} + (1 - R^3) \log \frac{1 - R^3}{1 - R_0^3}.$$

We can rewrite this as

$$\int_{\Theta} D_f(P_\theta \| Q) w(d\theta) \geq -H(R^3) - R^3 \log R_0^3 - (1 - R^3) \log(1 - R_0^3) \quad (69)$$

where $H(x) := -x \log x - (1-x) \log(1-x)$. Since L in Lemma 3 is zero-one valued,

$$R_0^3 = 1 - \mathbb{E}_Q w(B(\mathfrak{q}(X))) \quad (70)$$

where \mathbb{E}_Q denotes expectation taken under $X \sim Q$ and $B(\mathfrak{q}(X))$ is defined in (16). As a result, we have

$$1 - \max_{a \in \mathcal{A}} w(B(a)) \leq R_0^3 \leq 1 - \min_{a \in \mathcal{A}} w(B(a)). \quad (71)$$

Using the bounds in (71) on the right hand side of (69), we deduce

$$\int_{\Theta} D_f(P_\theta \| Q) w(d\theta) \geq -H(R^3) - R^3 \log(1 - w_{\min}) - (1 - R^3) \log w_{\max}.$$

where $w_{\min} := \inf_{a \in \mathcal{A}} w(B(a))$ and $w_{\max} := \sup_{a \in \mathcal{A}} w(B(a))$ for notational simplicity. Taking the infimum on the left hand side above over all probability measures Q , we obtain

$$I(w, \mathcal{P}) \geq -H(R^3) - R^3 \log(1 - w_{\min}) - (1 - R^3) \log(w_{\max}).$$

Provided $w_{\min} + w_{\max} < 1$, one can rewrite the above inequality as (68). This completes the proof of (68).

A.3 Proof of Corollary 7

1. **Proof of inequality (26):** Applying Theorem 2 with $f(x) = x^2 - 1$, we obtain

$$I_{\chi^2}(w, \mathcal{P}) \geq \frac{(R_0 - R)^2}{R_0(1 - R_0)}$$

Because $R \leq R_0$, we can invert the above to obtain (26).

2. **Proof of inequality (27):** Theorem 2 with $f(x) = |x - 1|/2$ gives

$$I_{TV}(w, \mathcal{P}) \geq \frac{R_0}{2} \left| \frac{R}{R_0} - 1 \right| + \frac{1 - R_0}{2} \left| \frac{1 - R}{1 - R_0} - 1 \right| = R_0 - R,$$

where the last equality uses the fact that $R \leq R_0$. Inverting the above inequality, we obtain (27).

3. **Proof of inequality (28):** Theorem 2 with $f(x) = f_{1/2}(x) = 1 - \sqrt{x}$ gives

$$I_{f_{1/2}}(w, \mathcal{P}) \geq 1 - \sqrt{RR_0} - \sqrt{(1 - R)(1 - R_0)}. \quad (72)$$

Assume that P_θ has density p_θ with respect to a common dominating measure μ . We shall show below that

$$I_{f_{1/2}}(w, \mathcal{P}) = 1 - \sqrt{\int_{\mathcal{X}} u^2 d\mu} \quad \text{where } u := \int_{\Theta} \sqrt{p_\theta} w(d\theta). \quad (73)$$

To see this, fix a probability measure Q that has a density q with respect to μ . We can then write

$$\int_{\Theta} D_{f_{1/2}}(P_\theta \| Q) w(d\theta) = 1 - \int_{\mathcal{X}} \sqrt{q} \left(\int_{\Theta} \sqrt{p_\theta} w(d\theta) \right) d\mu = 1 - \int_{\mathcal{X}} \sqrt{q u^2} d\mu$$

It follows then from the Cauchy-Schwarz inequality that

$$\int_{\Theta} D_{f_{1/2}}(P_\theta \| Q) w(d\theta) = 1 - \int_{\mathcal{X}} \sqrt{q u^2} d\mu \geq 1 - \sqrt{\int_{\mathcal{X}} u^2 d\mu},$$

with equality holding when q is proportional to u^2 . This proves (73). We now see that

$$\int_{\mathcal{X}} u^2 d\mu = \int_{\Theta} \int_{\Theta} \int_{\mathcal{X}} \sqrt{p_\theta} \sqrt{p_{\theta'}} d\mu w(d\theta) w(d\theta') = 1 - \frac{1}{2} h^2 \quad (74)$$

where h^2 is defined as

$$h^2 = \int_{\Theta} \int_{\Theta} H^2(P_\theta \| P_{\theta'}) w(d\theta) w(d\theta'). \quad (75)$$

This, together with (72) and (73), gives the inequality

$$\sqrt{RR_0} + \sqrt{(1 - R)(1 - R_0)} \geq \sqrt{1 - \frac{h^2}{2}} \quad (76)$$

Now under the assumption $h^2 \leq 2R_0$, the right hand side of the inequality (76) lies between $\sqrt{1 - R_0}$ and 1. On the other hand, it can be checked that, as a function in R , the left hand side of (76) is strictly increasing from $\sqrt{1 - R_0}$ (at $R = 0$) to 1 at $(R = R_0)$. Therefore, from (76), we know that $R \geq \hat{R}$ where $\hat{R} \in [0, R_0]$ is the solution to the equation obtained by replacing the inequality (76) with an equality. One can solve this equation and obtain two solutions. One of two solutions can be discarded by the fact that $R \leq R_0$. The other solution is given by:

$$\hat{R} = R_0 - (2R_0 - 1) \frac{h^2}{2} - \sqrt{R_0(1 - R_0) \sqrt{h^2(2 - h^2)}}$$

and thus we have $R \geq \hat{R}$ which proves inequality (28).

We note that the lower bound on R in (28) only holds under the condition $h^2 \leq 2R_0$. When $h^2 > 2R_0$, inequality (28) holds for every $R \in [0, R_{Q^*}]$ and thus cannot provide a non-trivial lower bound on R . As an example, when $\Theta = \mathcal{A} = \{1, \dots, N\}$, $L(\theta, a) = \mathbb{I}\{\theta \neq a\}$ and w is the uniform prior on Θ , it is easy to see that $R_0 = 1 - (1/N)$ and

$$h^2 = \frac{1}{N^2} \sum_{\theta \neq \theta'} H^2(P_\theta \| P_{\theta'}) \leq 2 \frac{N(N-1)}{N^2} = 2R_{Q^*}. \quad (77)$$

Inequality (28) therefore is equivalent to

$$R \geq 1 - \frac{1}{N} - \frac{N-2h^2}{N} - \frac{\sqrt{N-1}}{N} \sqrt{h^2(2-h^2)}.$$

This recovers the result in Example II.6 in Guntuboyina (2011b).

A.4 Derivations of Le Cam's Inequality (Two Hypotheses) and Assouad's Lemma and other Results from Corollary 7

To demonstrate the application of Corollary 7, we apply it to derive the two hypotheses version of Le Cam's inequality (with total variation distance) and Assouad's lemma (see Theorem 2.12 in (Tsybakov, 2010)).

The simplest version of the Le Cam's inequality, the so-called two-point argument, is an easy corollary of (27). Indeed, applying (27) with $\Theta = \mathcal{A} = \{\theta_0, \theta_1\}$, $L(\theta, a) = \mathbb{I}\{\theta \neq a\}$ and $w\{0\} = w\{1\} = 1/2$ (and note that $R_0 = 1/2$), we obtain that for any distribution Q on \mathcal{X} ,

$$\frac{1}{2} (\|P_{\theta_0} - Q\|_{TV} + \|P_{\theta_1} - Q\|_{TV}) \geq I_{TV}(w, \mathcal{P}) \geq 1/2 - R.$$

Taking $Q = (P_{\theta_0} + P_{\theta_1})/2$, we obtain Le Cam's inequality:

$$R_{\min} \geq \frac{1}{2} (1 - \|P_{\theta_0} - P_{\theta_1}\|_{TV}). \quad (78)$$

The more involved Le Cam's inequality considers $\Theta = \mathcal{A} = \Theta_0 \cup \Theta_1$ for two disjoint subsets Θ_0 and Θ_1 and loss function $L(\theta, a) = \mathbb{I}\{\theta \in \Theta_1, a \in \Theta_2\} + \mathbb{I}\{\theta \in \Theta_2, a \in \Theta_1\}$. The inequality states that for every pair of probability measures w_0 and w_1 concentrated on Θ_0 and Θ_1 respectively,

$$R_{\min} \geq \frac{1}{2} (1 - \|m_0 - m_1\|_{TV}) \quad (79)$$

where m_0 and m_1 are marginal densities given by $m_\tau(x) = \int p_\theta(x) w_\tau(d\theta)$ for $\tau = 0, 1$. To prove (79), consider the prior $w = (w_0 + w_1)/2$. Under this prior, the problem is easily converted to the previous binary testing problem. In particular, the data generating process under the prior w can be viewed as first sampling $\tau \sim \text{Uniform}\{0, 1\}$ and then $X \sim m_\tau$. The decision $a \in \mathcal{A}$ can be converted into the binary decision $\hat{\tau} = \mathbb{I}\{a \in \Theta_1\}$. The loss function is $L(\tau, \hat{\tau}) = \mathbb{I}\{\tau \neq \hat{\tau}\}$. The Bayes risk under the prior w can be re-written as,

$$R_{\text{Bayes}}(w, L; \Theta) = \frac{1}{2} \inf_{\tau} \sum_{\tau=0,1} \int_{\mathcal{X}} \mathbb{I}(\tau \neq \hat{\tau}(x)) m_\tau(x) \mu(dx), \quad (80)$$

which has the same form as the Bayes risk in the earlier binary testing problem. Applying the same argument as for proving (78), we obtain the lower bound on the Bayes risk in (80), $R_{\text{Bayes}}(w, L; \Theta) \geq \frac{1}{2} (1 - \|m_0 - m_1\|_{TV})$, which further implies (79).

Another classical minimax inequality involving the total variation distance is Assouad's inequality (Assouad, 1983) which states that if $\Theta = \mathcal{A} = \{0, 1\}^d$ and the loss function L is defined by the Hamming distance, i.e., $L(\theta, a) = \sum_{i=1}^d \mathbb{I}\{\theta_i \neq a_i\}$, then

$$R_{\min} \geq \frac{d}{2} \min_{L(\theta, \theta')=1} (1 - \|P_\theta - P_{\theta'}\|_{TV}). \quad (81)$$

This inequality is also a consequence of (27): let w be the uniform probability measure on Θ and $L_1(\theta, a) = \mathbb{I}\{\theta_1 \neq a_1\}$. Under w , the marginal distribution of the first coordinate is $w_1\{0\} = w_1\{1\} = 1/2$. Let $m_\tau(x) := \sum_{\theta: \theta_1=\tau} p_\theta(x)/2^{d-1}$ for $\tau \in \{0, 1\}$ be the corresponding marginal density of X and let $Q(x) = \frac{1}{2} (m_0(x) + m_1(x))$. Applying the same argument as for proving (78), we obtain that the minimax risk for the zero-one valued loss function $L_1(\theta, a)$ is bounded below by $\frac{1}{2} (1 - \|m_0 - m_1\|_{TV}) \geq \frac{1}{2} \min_{L(\theta, \theta')=1} (1 - \|P_\theta - P_{\theta'}\|_{TV})$. Repeating this argument for $L_i(\theta, a) := \mathbb{I}\{\theta_i \neq a_i\}$ for $i = 2, \dots, d$ and adding up the resulting bounds, we obtain (81).

By using Le Cam's inequality (see, e.g., Lemma 2.3 in (Tsybakov, 2010)) which states that:

$$\|P_\theta - P_{\theta'}\|_{TV} \leq \sqrt{H^2(P_\theta \| P_{\theta'}) \left(1 - \frac{1}{4} H^2(P_\theta \| P_{\theta'})\right)},$$

the inequality in (81) further implies the Hellinger distance version of Assouad's inequality in the book Tsybakov (2010, Theorem 2.12), i.e.,

$$R_{\min} \geq \frac{d}{2} \min_{L(\theta, \theta')=1} \left\{ 1 - \sqrt{H^2(P_\theta \| P_{\theta'}) \left(1 - \frac{1}{4} H^2(P_\theta \| P_{\theta'})\right)} \right\}. \quad (82)$$

A.5 Comparison of the Bounds for Different Divergences

We provide some qualitative comparisons of Bayes risk lower bounds given by Theorem 2 for different power divergences. In particular, let us consider the discrete setting where $\Theta = \mathcal{A} = \{\theta_1, \dots, \theta_N\}$, $L(\theta, a) = \mathbb{I}\{\theta \neq a\}$, and w is the discrete uniform. Note that in such a "multiple testing problem" setup, R_0 is equal to $1 - (1/N)$. We take N sufficiently large so that R_0 is close to 1. To establish minimax lower bounds, a typical approach is to reduce the estimation problem to a multiple hypotheses testing problem in the aforementioned setup, then try to prove that the Bayes risk $R \geq c > 0$ (see Section 2.2. in Tsybakov (2010)). Without loss of generality, we take $c = 1/2$ and we shall see how the three inequalities (25), (26) and (28) work to establish $R \geq 1/2$.

Let us start with (25) corresponding to KL divergence, which is equivalent to the classical Fano's inequality (3) in the discrete setting. To establish $R \geq 1/2$, the following condition should hold:

$$I(w, \mathcal{P}) \leq \frac{1}{2} \log \left(\frac{N}{4} \right). \quad (83)$$

We remark that $I(w, \mathcal{P})$ is at most $\log N$ even if every the pairwise KL divergence $D(P_\theta \| P_{\theta'})$ equals ∞ for $i \neq j$. This fact will be clear from the inequality (47) from Section 5 (let $M = N$

and $Q_j = P_{\theta_j}$ for $1 \leq j \leq M$). The upper bound on $I(w, \mathcal{P})$ in (47) further provides a sufficient condition to verify (83).

Now we turn to (26) corresponding to the chi-squared divergence. Since $R_0 = 1 - (1/N)$, inequality (26) implies a sufficient condition for $R \geq 1/2$:

$$I_{\chi^2}(w, \mathcal{P}) \leq \frac{N^2}{N-1} \left(\frac{1}{2} - \frac{1}{N} \right)^2. \quad (84)$$

When N is large, the above condition is equivalent to $I_{\chi^2}(w, \mathcal{P}) \leq N/4$. Note that the maximum possible value of $I_{\chi^2}(w, \mathcal{P})$ in this discrete setting is $N-1$ (even when $\chi^2(P_{\theta_i} \| P_{\theta_j}) = \infty$ for every $i \neq j$) and this follows from our upper bounds on f -informativity for a class of power divergences in (50) (see Section 5).

The conditions (83) and (84) don't imply each other. The chi-squared divergence is always greater than the KL divergence (see Lemma 2.7 in Tsybakov (2010)), but the upper bound required by (84) is also weaker than that required by (83). For both divergences, constructing more hypotheses (i.e., choosing $N > 2$) is often helpful for showing $R \geq 1/2$.

For the Hellinger distance (inequality (28)), we claim that it gives no more useful bounds than those obtained by a simple two point argument. To see this, since $R_0 = 1 - (1/N)$, inequality (28) implies

$$R \geq 1 - \frac{1}{N} - \frac{N-2}{2} \frac{h^2}{N} - \frac{\sqrt{N-1}}{2} \sqrt{h^2(2-h^2)}$$

where $h^2 = \sum_{i,j} H^2(P_{\theta_i} \| P_{\theta_j})/N^2$. When N is large, the above inequality reduces to effectively $R \geq 1 - (h^2/2)$. Therefore a sufficient condition for $R \geq 1/2$ is $h^2 \leq 1$, which is equivalent to,

$$\frac{1}{N(N-1)/2} \sum_{i < j} H^2(P_{\theta_i} \| P_{\theta_j}) \leq \frac{N}{N-1}.$$

When N is large, the above displayed condition implies the existence of $i < j$ for which $H^2(P_{\theta_i} \| P_{\theta_j}) \leq 1$. Let \tilde{w} denote the prior $\tilde{w}^i = \tilde{w}^j = 1/2$. It is easy to see that the Bayes risk for \tilde{w} equals $R_{\text{Bayes}}(\tilde{w}) = \frac{1}{2} (1 - \|P_{\theta_i} - P_{\theta_j}\|_{TV})$. By Le Cam's inequality (see Lemma 2.3 in Tsybakov (2010)), we have,

$$R_{\text{Bayes}}(\tilde{w}) \geq \frac{1}{2} \left(1 - H(P_{\theta_i} \| P_{\theta_j}) \sqrt{1 - \frac{H^2(P_{\theta_i} \| P_{\theta_j})}{4}} \right)$$

Since $H(P_{\theta_i} \| P_{\theta_j}) \leq 1$, it is easy to verify from the above that $R_{\text{Bayes}}(\tilde{w}) \geq 1/8$. Therefore in this discrete setting, if inequality (28) implies $R_{\text{Bayes}}(\tilde{w}) \geq 1/2$, then there is a much simpler two point prior \tilde{w} for which $R_{\text{Bayes}}(\tilde{w}) \geq 1/8$. It shows that for Hellinger distance, considering $N > 2$ hypotheses is not more useful than using a pair of hypotheses. The reason is that the Hellinger informativity can be written as an expression involving pairwise Hellinger distances. In particular, it can be seen from the proof of inequality (28) that

$$I_{H^{1/2}}(w, \mathcal{P}) = 1 - \left(1 - \frac{1}{2N^2} \sum_{i,j} H^2(P_{\theta_i} \| P_{\theta_j}) \right)^{1/2}.$$

In contrast, the mutual information, $I(w, \mathcal{P})$, cannot be written in terms of $D(P_{\theta_i} \| P_{\theta_j})$ for $i \neq j$ (recall that $I(w, \mathcal{P})$ is always at most $\log N$ even when $D(P_{\theta_i} \| P_{\theta_j}) = \infty$ for all $i \neq j$). The same holds for $I_{\chi^2}(w, \mathcal{P})$ as well (which is always at most $N-1$ even if $\chi^2(P_{\theta_i} \| P_{\theta_j}) = \infty$ for all $i \neq j$).

If the eventual goal of obtaining Bayes risk lower bounds is to obtain lower bounds up to multiplicative constants on the minimax risk, then the bound in (28) gives no more useful bounds than those obtained by the simple two point argument. In this sense, inequality (28) induced by Hellinger distance is not as useful as inequalities (25) and (26). In fact, the Hellinger distance is seldom used in lower bounding minimax risk involving many hypotheses (for example, none of the minimax rates in the examples of Tsybakov (2010) involving multiple hypotheses testing are established via Hellinger distance).

Appendix B. Proofs and Additional Results for Section 5 on Upper Bounds on f -informativity

B.1 Proof of Lemma 15

Let $\phi(t) \equiv t^r$ with $\phi'(t) = r t^{r-1}$ and $\phi''(t) = r(r-1)t^{r-2}$ and $\varphi(t) = t^{1/r}$ with $\varphi'(t) = \frac{1}{r} t^{(1-r)/r}$. Then

$$f(w) = \varphi \left(\int_T \phi(u(t)) \mu(dt) \right).$$

To prove the concavity of $f(w)$, considering the scalar function

$$h(s) = \varphi \left(\int_T \phi(u(t) + sv(t)) \mu(dt) \right), \quad (85)$$

for arbitrary $u, v \in L^r_{\mu}(T)$. We notice that concavity of f is equivalent to concavity at zero for all functions of the form h , and we therefore only have to show that $h''(0) \leq 0$. Let $g(s) = \int_T \phi(u(t) + sv(t)) \mu(dt)$,

$$\begin{aligned} h'(s) &= \varphi'(g(s)) \int_T \phi'(u(t) + sv(t)) v(t) \mu(dt) \\ h''(s) &= \varphi''(g(s)) \left(\int_T \phi'(u(t) + sv(t)) v(t) \mu(dt) \right)^2 \\ &\quad + \varphi'(g(s)) \int_T \phi''(u(t) + sv(t)) v^2(t) \mu(dt) \end{aligned}$$

By plugging in the definitions of $\phi(t)$, $\varphi(t)$, $g(s)$ and setting $s = 0$, we have

$$h''(0) = \frac{1-r}{f(w)} \left(\left(\int_T (f'(u))^{1-r} \int_T u(t)^{r-1} v(t) \mu(dt) \right)^2 - f(w)^{2-r} \int_T u(t)^{r-2} v^2(t) \mu(dt) \right)$$

Applying the Cauchy-Schwarz inequality

$$\left(\int_T a(t) b(t) \mu(dt) \right)^2 \leq \left(\int_T a(t)^2 \mu(dt) \right) \left(\int_T b(t)^2 \mu(dt) \right)$$

with $a(t) = \left(\frac{f(u)}{u(t)} \right)^{-r/r}$ and $b(t) = v(t) \left(\frac{f(u)}{u(t)} \right)^{1-r/r}$ and noticing that $r < 1$, we have $h''(0) \leq 0$, which completes the proof.

B.2 Example Demonstrating the Effectiveness of Theorem 14

In this example, we show the tightness of the upper bound in (49) in terms of chi-squared divergence ($\alpha = 2$). In particular, let the distribution P be the n -fold product of $N(0, 1)$ and Q_ξ be the n -fold product of $N(\xi, 1)$ where $\xi \sim N(0, 1)$. It is straightforward to show that the marginal distribution \bar{Q} is a n -dimensional Gaussian distribution with mean $\mathbf{0}$ and covariance matrix $I_n + \mathbf{1}_n \mathbf{1}_n^T$, where $\mathbf{1}_n$ denotes the n -dimensional all one vector and I_n the $n \times n$ identity matrix.

Since $\chi^2(P\|Q_\xi) = \exp(n\xi^2) - 1$, the right hand side of (49) equals to $\sqrt{2n+1} - 1$. The term $\chi^2(P\|\bar{Q})$ on the left hand side of (49) is difficult to evaluate. However, we can lower bound $\chi^2(P\|\bar{Q})$ using the following standard inequality $\exp(D(P\|\bar{Q})) - 1 \leq \chi^2(P\|\bar{Q})$ (see Lemma 2.7 in Tsybakov (2010)). By the closed-form expression for KL divergence between two multivariate Gaussian distributions, we have $D(P\|\bar{Q}) = \frac{1}{2}(\log(n+1) - n/(n+1))$ and thus

$$e^{-1/2}\sqrt{n+1} - 1 \leq \exp(D(P\|\bar{Q})) - 1 \leq \chi^2(P\|\bar{Q})$$

As we can see, the upper bound $\sqrt{2n+1} - 1$ in (49) is quite tight and $\chi^2(P\|\bar{Q})$ is on the order of \sqrt{n} .

B.3 Proof of Corollary 17

Fix $0 < \delta \leq A^{-1/2}$. Partition the entire parameter space Θ into small hypercubes each with side length δ . For each such hypercube S and let π_S denote the probability measure w conditioned to be in S i.e., $\pi_S(C) := w(C)/w(S)$ for measurable set $C \subseteq S$.

For every decision rule $\mathfrak{d}(X)$, clearly

$$\int_{\Theta} \mathbb{E}_{\Theta} L(\theta, \mathfrak{d}(X)) w(d\theta) = \sum_S w(S) \int_S \mathbb{E}_{\Theta} L(\theta, \mathfrak{d}(X)) d\pi_S(\theta)$$

where the sum above is over all hypercubes S in the partition. This implies therefore that

$$R_{\text{Bayes}}(w, L; \Theta) \geq \sum_S w(S) R_{\text{Bayes}}(\pi_S, L; S).$$

The proof will therefore be completed if we show that

$$R_{\text{Bayes}}(\pi_S, L; S) \geq \frac{1}{2} e^{-2pA\delta^2} \delta^{2p} V^{-p/d} \int_S \left(\frac{1}{r_\delta(\bar{\theta})} \right)^{p/d} \pi_S(d\theta) \quad (86)$$

for every fixed hypercube S . So let us fix S and, for notational simplicity, let $\pi := \pi_S$. We will use (39) to prove a lower bound on $R_{\text{Bayes}}(\pi_S, L; S)$. Note first that

$$\begin{aligned} \inf_Q \int_S D(P_\theta\|Q)\pi(d\theta) &\leq \int_S \int_S D(P_\theta\|P_{\theta'})\pi(d\theta)\pi(d\theta') \\ &\leq A \max_{\theta \in S, \theta' \in S} \|\theta - \theta'\|_2^2 \leq Ad\delta^2 =: I_f^{\text{up}}. \end{aligned} \quad (87)$$

Also, letting f_w^{\max} and f_w^{\min} be the maximum and minimum values of f_w in S , we have

$$\sup_{a \in S} \pi(B_L(a, L)) \leq \frac{f_w^{\max}}{w(S)} \text{Vol}(B_L(a, L)) \leq \frac{f_w^{\max} V_\ell^d / p}{f_w^{\min} \delta^d}.$$

Let $\tilde{\theta}$ be an arbitrary point in the set S . Since S has diameter $\sqrt{d}\delta$, the set $\{\theta : \|\theta - \tilde{\theta}\|_2 \leq \sqrt{d}\delta\}$ contains S . We obtain from the definition of $r_\delta(\theta)$ that $f_w^{\max} / f_w^{\min} \leq r_\delta(\tilde{\theta})$ so that

$$\sup_{a \in S} \pi(B_L(a, L)) \leq r_\delta(\tilde{\theta}) V \delta^{-d/p}.$$

Thus, by (87), the choice

$$t = e^{-2pA\delta^2} \delta^{2p} \left(\frac{1}{8V r_\delta(\tilde{\theta})} \right)^{p/d},$$

leads to $\sup_{a \in S} \pi(B_L(a, L)) < \frac{1}{4} e^{-2I_f^{\text{up}}}$. Employing (39), we deduce

$$R_{\text{Bayes}}(\pi, L; S) \geq \frac{1}{2} e^{-2pA\delta^2} \delta^{2p} \left(\frac{1}{8V r_\delta(\tilde{\theta})} \right)^{p/d} \geq \frac{1}{2} e^{-2p} \delta^{2p} \left(\frac{1}{8V r_\delta(\tilde{\theta})} \right)^{p/d}$$

where we used the fact that $\delta^2 \leq 1/A$. Because $\tilde{\theta} \in S$ is arbitrary, we can write

$$\begin{aligned} R_{\text{Bayes}}(\pi, L; S) &\geq \frac{1}{2} e^{-2p} \delta^{2p} (8V)^{-p/d} \sup_{\tilde{\theta} \in S} \left(\frac{1}{r_\delta(\tilde{\theta})} \right)^{p/d} \\ &\geq \frac{1}{2} e^{-2p} \delta^{2p} (8V)^{-p/d} \int_S \left(\frac{1}{r_\delta(\theta)} \right)^{p/d} \pi(d\theta). \end{aligned}$$

This proves (86).

Appendix C. More Examples on Bayes Risk Lower Bounds

In this section, we provide more examples on the applications of derived Bayes risk lower bound in Theorem 9 and Corollary 12. For the clarity of the presentation, in each example, we will first present the Bayes risk lower bound and then provide the proof.

C.1 Generalized Linear Model

Fix $d \geq 1$ and let $\Theta = \mathcal{A} = \mathbb{R}^d$ with $L(\theta, a) = \|\theta - a\|_2^2$ for a fixed $p > 0$. Also fix $n \geq 1$ and an $n \times d$ matrix X whose rows are written as x_1^T, \dots, x_n^T . As in the last example, λ_{\max} denotes the maximum eigenvalue of $X^T X/n$.

For $\theta \in \Theta$, let P_θ denote the joint distribution of independent random variables Y_1, \dots, Y_n where Y_i has the density

$$\exp \left[\frac{y\beta_i - b(\beta_i)}{a(\phi)} + c(y, \phi) \right] \quad \text{for } y \in \mathbb{R} \quad (88)$$

with $\beta_i = x_i^T \theta$ for $i = 1, \dots, n$. The parameter ϕ is taken to be a constant and the functions $a(\cdot), c(\cdot, \cdot)$ and $b(\cdot)$ are assumed to be known. We assume the existence of a constant $K > 0$ such that $b''(\beta) \leq K$ for all β where $b''(\cdot)$ is the second derivative of $b(\cdot)$. This assumption indeed holds for many generalized linear models (e.g., binomial, Gaussian) and we will discuss the case (i.e., Poisson) where this assumption fails at the end of this example.

Let w denote the Gaussian prior with mean zero and covariance matrix $\tau^2 I_d$. Using Corollary 17, we can prove that

$$R_{\text{Bayes}}(w, L; \Theta) \geq C \left[d \min \left(\frac{a(\phi)}{nK}, \tau^2 \right) \right]^{1/p/2} \quad (89)$$

for a constant C that depends only on p . Let us illustrate this lower bound by considering a simple case of $p = 2$. We note that the term $\frac{a(\phi)}{nK}$ is the well-known minimax risk of generalized linear model under the squared loss. The parameter τ characterizes the strength of the prior information. In fact, since $\tau^2 I$ is the variance of the Gaussian prior distribution, a small value of τ provides strong prior information that each θ_j should be concentrated around 0. When τ is large, i.e., with less prior information, the lower bound of the Bayes risk in (89) is the same as the minimax risk up to a constant factor. On the other hand, when τ is small, i.e., with strong prior information, the lower bound of the Bayes risk becomes $d\tau^2$, which is smaller than the minimax risk.

The proof of (89) will involve Corollary 17 for which we need to determine A, V and $r_\delta(\theta)$. As before, it is easy to check that $V = \text{Vol}(B)$. To determine A , fix a pair θ_1, θ_2 and, letting $\beta_i^{(j)} = x_i^T \theta_j$ for $j = 1, 2$ and $i = 1, \dots, n$, observe that

$$D(P_{\theta_1} \| P_{\theta_2}) = \frac{1}{a(\phi)} \sum_{i=1}^n \left(b(\beta_i^{(1)}) (\beta_i^{(1)} - \beta_i^{(2)}) - (b(\beta_i^{(1)}) - b(\beta_i^{(2)})) \right)$$

By the second order Taylor expansion of $b(\beta_i^{(2)})$ at the point $\beta_i^{(1)}$, we obtain

$$D(P_{\theta_1} \| P_{\theta_2}) = \frac{1}{a(\phi)} \sum_{i=1}^n \frac{b''(\tilde{\beta}_i)}{2} (\beta_i^{(1)} - \beta_i^{(2)})^2$$

where $\tilde{\beta}_i$ lies between $\min(\beta_i^{(1)}, \beta_i^{(2)})$ and $\max(\beta_i^{(1)}, \beta_i^{(2)})$. Now because of our assumption that $b''(\cdot)$ is bounded from above by K , we get

$$\begin{aligned} D(P_{\theta_1} \| P_{\theta_2}) &\leq \frac{K}{2a(\phi)} \|\beta^{(1)} - \beta^{(2)}\|_2^2 = \frac{K}{2a(\phi)} (\theta_1 - \theta_2)^T X^T X (\theta_1 - \theta_2) \\ &\leq \frac{nK\lambda_{\max}}{2a(\phi)} \|\theta_1 - \theta_2\|_2^2. \end{aligned}$$

We can thus take $A = nK\lambda_{\max}/(2a(\phi))$ in Corollary 17. Next we control $r_\delta(\theta)$. For given θ and δ ,

$$r_\delta(\theta) = \sup \left\{ \exp \left(-\frac{1}{2\tau^2} (\|\theta_1\|_2^2 - \|\theta_2\|_2^2) \right) : \|\theta_1 - \theta_2\|_2 \leq \sqrt{d}\delta \right\}.$$

For θ_1, θ_2 with $\|\theta_1 - \theta_2\|_2 \leq \sqrt{d}\delta$, $i = 1, 2$, we have

$$\begin{aligned} \|\theta_1\|_2^2 - \|\theta_2\|_2^2 &= \|\theta_1 - \theta_2\|_2^2 + 2\theta_1^T (\theta_1 - \theta_2) - \|\theta_2 - \theta_1\|_2^2 - 2\theta_2^T (\theta_2 - \theta_1) \\ &\leq \|\theta_1 - \theta_2\|_2^2 - \|\theta_2 - \theta_1\|_2^2 + 2\|\theta_1\|_2 (\|\theta_1 - \theta_2\|_2 + \|\theta_2 - \theta_1\|_2) \\ &\leq d\delta^2 + 4\sqrt{d}\delta \|\theta\|_2. \end{aligned}$$

As a result $r_\delta(\theta)^{-p/d} \geq \exp(-p\delta^2/(2\tau^2)) \exp(-2p\delta \|\theta\|_2 / (\tau^2 \sqrt{d}))$ and hence

$$\begin{aligned} \int_{\Theta} \left(\frac{1}{r_\delta(\theta)} \right)^{p/d} w(d\theta) &\geq \exp \left(-\frac{p\delta^2}{2\tau^2} \right) \int_{\Theta} \exp \left(-\frac{2p\delta \|\theta\|_2}{\tau \sqrt{d}} \right) w(d\theta) \\ &\geq \exp \left(-\frac{p\delta^2}{2\tau^2} - \frac{4p\delta}{\tau} \right) \int_{\Theta} \mathbb{I} \{ \|\theta\|_2 < 2\tau\sqrt{d} \} w(d\theta). \end{aligned}$$

By Chebyshev's inequality, we have

$$\int_{\Theta} \mathbb{I} \{ \|\theta\|_2 \geq 2\tau\sqrt{d} \} w(d\theta) \leq \frac{1}{4\tau^2 d} \int_{\Theta} \|\theta\|_2^2 w(d\theta) = \frac{1}{4} \quad (90)$$

Consequently,

$$\int_{\Theta} \left(\frac{1}{r_\delta(\theta)} \right)^{p/d} w(d\theta) \geq \frac{3}{4} \exp \left(-\left(\frac{p\delta^2}{2\tau^2} + \frac{4p\delta}{\tau} \right) \right). \quad (91)$$

Corollary 17 therefore gives

$$R_{\text{Bayes}}(w, L; \Theta) \geq \frac{3}{8} e^{-2p} (8V)^{-p/d} \delta^p \exp \left(-\frac{p\delta^2}{2\tau^2} - \frac{4p\delta}{\tau} \right) \quad \text{whenever } \delta^2 \leq 1/4.$$

We make the choice

$$\delta^2 := \min(1/4, \tau^2) = \min \left(\frac{2a(\phi)}{nK\lambda_{\max}}, \tau^2 \right)$$

which implies that the exponential term in the right hand side of (91) is bounded from below by $\exp(-9p/2)$. We thus have

$$R_{\text{Bayes}}(w, L; \Theta) \geq \frac{3}{8} e^{-13p/2} (8V)^{-p/d} \left[\min \left(\frac{2a(\phi)}{nK\lambda_{\max}}, \tau^2 \right) \right]^{1/p/2}.$$

The inequality (89) now follows because $V^{1/d} \geq d^{-1/2}$.

The assumption that $b''(\beta) \leq K$ which was used for the proof of (89) holds under some widely used densities of Y_i in (88). For Gaussian distribution in (88), we have $b(\beta) = \frac{\beta^2}{2}$ so that $b''(\beta) = 1$ for $\beta \in \mathbb{R}$. For binomial distribution, $b(\beta) = \log(1 + \exp(\beta))$ and $b''(\beta) = \frac{\exp(\beta)}{(1 + \exp(\beta))^2} \leq \frac{1}{4}$ for all $\beta \in \mathbb{R}$. However, for Poisson distribution, $b(\beta) = \exp(\beta)$ and thus $b''(\beta) = \exp(\beta)$ is unbounded on \mathbb{R} . To address this issue, we restrict the prior to the subset $\Theta = \{\theta \in \Theta : \|\theta\|_2 \leq 2\tau\sqrt{d}\}$ and define the re-scaled prior distribution π on $\tilde{\Theta}$ as $\pi(S) = w(S)/w(\tilde{\Theta})$ for any measurable set $S \subseteq \tilde{\Theta}$. Let $B = \max_{i=1, \dots, n} \|x_i\|_2$. For any $\beta = x_i^T \theta$ for some $i = 1, \dots, n$ and $\theta \in \tilde{\Theta}$, we have $b''(\beta) \leq \exp(2\tau\sqrt{d}B) := K$. We note that such a restriction of the parameter space will not affect the order of the Bayes risk lower bound. In particular, since now $b''(\beta) \leq K$ when $\theta \in \tilde{\Theta}$, applying the same argument, we obtain the lower bound on $R_{\text{Bayes}}(\pi, L; \tilde{\Theta})$. By (90), we have $w(\tilde{\Theta}) \geq 3/4$ and the lower bound on $R_{\text{Bayes}}(w, L; \Theta)$ can be easily established by noticing that $R_{\text{Bayes}}(w, L; \Theta) \geq w(\tilde{\Theta}) R_{\text{Bayes}}(\pi, L; \tilde{\Theta}) \geq \frac{3}{4} R_{\text{Bayes}}(\pi, L; \tilde{\Theta})$.

C.2 Spiked Covariance Model

Fix $\Theta = \mathcal{A} = B$ where B is the unit Euclidean closed ball of radius one and let $L_t(\theta, a) := \|\theta - a\|_F^2$ for a fixed $p > 0$. Also fix $n \geq d/2$. For $\theta \in \Theta$, let P_θ denote the joint distribution of independent and identically distributed observations X_1, \dots, X_n satisfying the Gaussian distribution with zero mean and covariance matrix $\Sigma_\theta := I_d + \theta\theta^T$. This is the problem of estimating the principal component for a rank-one spiked covariance model. Let w denote the uniform distribution on B . We shall prove that

$$R_{\text{Bayes}}(w, L; \Theta) \geq C \left[\min \left(\frac{1}{2}, \frac{d}{n} \right) \right]^{p/2} \quad (92)$$

where C only depends on p .

The proof is based on the application of (32) with $f(x) = x^2 - 1$, i.e., on inequality (40). For this, we need to bound the term $\sup_{a \in \mathcal{A}} w(B_t(a, L))$ and the f -informativity corresponding to the chi-squared divergence. It is easy to see that $\sup_{a \in \mathcal{A}} w(B_t(a, L)) \leq t^{d/p}$.

For the f -informativity, we will use the bound (51) with $\alpha = 2$ which requires bounding $M_{\chi^2}(\epsilon, \Theta)$. According to (Guntuboyina, 2011a, Theorem 4.6.1), for two Gaussian distributions with mean zero and covariance matrices Σ_1 and Σ_2 such that $2\Sigma_1^{-1} - \Sigma_2^{-1}$ is positive definite and $\|\Sigma_1 - \Sigma_2\|_F^2 \leq \frac{1}{2}\lambda_{\min}(\Sigma_2)$, we have

$$\chi^2(N_d(0, \Sigma_1) \| N_d(0, \Sigma_2)) \leq \exp \left(\frac{\|\Sigma_1 - \Sigma_2\|_F^2}{\lambda_{\min}(\Sigma_2)^2} \right) - 1. \quad (93)$$

Here $\|\cdot\|_F$ denotes the Frobenius norm defined as $\|A\|_F^2 := \sum_{i,j} a_{ij}^2$ where $A = (a_{ij})$ and λ_{\min} denotes the smallest eigenvalue.

Using this result, we get that for $\theta_1, \theta_2 \in \Theta$ (note that $\lambda_{\min}(\Sigma_\theta) = 1$ for all θ),

$$\chi^2(P_{\theta_1} \| P_{\theta_2}) \leq \exp(n \|\Sigma_{\theta_1} - \Sigma_{\theta_2}\|_F^2) - 1, \quad (94)$$

provided

$$2\Sigma_{\theta_1}^{-1} - \Sigma_{\theta_2}^{-1} \text{ is positive definite and } \|\Sigma_{\theta_1} - \Sigma_{\theta_2}\|_F^2 \leq 1/2. \quad (95)$$

In the sequel, whenever we employ (94), the conditions (95) hold. But, for ease of presentation, instead of verifying (95) for every application of (94), we will simply assume (94) and verify the necessary conditions at the end of the proof. Assuming (94), we see that $\chi^2(P_{\theta_1} \| P_{\theta_2}) \leq \epsilon^2$ provided $\|\Sigma_{\theta_1} - \Sigma_{\theta_2}\|_F^2 \leq \log(1 + \epsilon^2)/n$. Now for $\theta_1, \theta_2 \in \Theta$

$$\begin{aligned} \|\Sigma_{\theta_1} - \Sigma_{\theta_2}\|_F^2 &= \|\theta_1\theta_1^T - \theta_2\theta_2^T\|_F^2 = \|\theta_1\theta_1^T - \theta_1\theta_2^T + \theta_1\theta_2^T - \theta_2\theta_2^T\|_F^2 \\ &\leq 2(\|\theta_1\|_2^2 + \|\theta_2\|_2^2) \|\theta_1 - \theta_2\|_2^2 \leq 4\|\theta_1 - \theta_2\|_2^2. \end{aligned}$$

It follows therefore that the ϵ^2 -covering number in the chi-squared divergence can be bounded from above by the $\sqrt{\log(1 + \epsilon^2)}/(2\sqrt{n})$ -covering number of B under the usual Euclidean norm. Consequently

$$M_{\chi^2}(\epsilon, \Theta) \leq \left(\frac{36n}{\log(1 + \epsilon^2)} \right)^{d/2} \text{ provided } \log(1 + \epsilon^2) \leq 4n.$$

We now set ϵ to satisfy $\log(1 + \epsilon^2) = \min(n/2, d)$ so that Corollary 16 gives

$$\begin{aligned} I_{\chi^2}(w, \mathcal{P}) &\leq M_{\chi^2}(\epsilon)(1 + \epsilon^2) - 1 \\ &\leq \exp \left(\min \left(\frac{n}{2}, d \right) \right) \left[36 \max \left(2, \frac{n}{d} \right) \right]^{d/2} - 1 =: I_f^{\text{up}}. \end{aligned}$$

It follows that $\sup_{a \in \mathcal{A}} w(B_t(a, L)) < \frac{1}{4}(1 + I_f^{\text{up}})^{-1}$ provided $t = (4(1 + I_f^{\text{up}}))^{-p/d}$. Inequality (40) then proves

$$R_{\text{Bayes}}(w, L; \Theta) \geq \frac{1}{2} \left(4(1 + I_f^{\text{up}}) \right)^{-p/d} \geq \frac{1}{2} (24\epsilon)^{-p} \left[\min \left(\frac{1}{2}, \frac{d}{n} \right) \right]^{p/2}$$

which implies (92).

It remains to justify the conditions (95) when we used (94). It should be clear that for this, we only need to verify (95) when

$$\|\Sigma_{\theta_1} - \Sigma_{\theta_2}\|_F^2 \leq \frac{\log(1 + \epsilon^2)}{n} = \min \left(\frac{1}{2}, \frac{d}{n} \right). \quad (96)$$

We only need to check that $2\Sigma_{\theta_1}^{-1} - \Sigma_{\theta_2}^{-1}$ is positive definite under the above condition. For this, observe that by Weyl's inequality,

$$\lambda_{\min} \left(2\Sigma_{\theta_1}^{-1} - \Sigma_{\theta_2}^{-1} \right) \geq \lambda_{\min} \left(2\Sigma_{\theta_1}^{-1} \right) - \lambda_{\max} \left(\Sigma_{\theta_2}^{-1} \right) = \frac{2}{1 + \|\theta_1\|_2^2} - 1 \geq 0.$$

This implies that $2\Sigma_{\theta_1}^{-1} - \Sigma_{\theta_2}^{-1}$ is positive semi-definite and $\|\theta_1\|_2 = 1$ is a necessary condition for $\lambda_{\min} \left(2\Sigma_{\theta_1}^{-1} - \Sigma_{\theta_2}^{-1} \right) = 0$. Under the condition that $\|\theta_1\|_2 = 1$, by Sherman-Morrison formula,

$$2\Sigma_{\theta_2}^{-1} - \Sigma_{\theta_1}^{-1} = I_d - \theta_1\theta_1^T + \frac{\theta_2\theta_2^T}{1 + \theta_2^T\theta_2}.$$

It is then easy to check that $\lambda_{\min} \left(2\Sigma_{\theta_1}^{-1} - \Sigma_{\theta_2}^{-1} \right) = 0$ only if θ_2 is orthogonal to θ_1 . However, when $\|\theta_1\|_2 = 1$ and θ_2 is orthogonal to θ_1 , $\|\Sigma_{\theta_1} - \Sigma_{\theta_2}\|_F^2 = \|\theta_1\|_2^2 + \|\theta_2\|_2^2 > 1$, which contradicts (96). Therefore $2\Sigma_{\theta_1}^{-1} - \Sigma_{\theta_2}^{-1}$ is positive definite and this completes the proof of (92).

C.3 Gaussian Model with General Loss

In this example, we consider Gaussian location model with continuous prior with a bounded Lebesgue density and general loss functions. Here, we do not specify the form of the prior and loss. We only present this example to illustrate applications of Theorem 9 and Corollary 12. Our main bound is inequality (97). This bound however might be suboptimal for specific priors w because we do not use knowledge about the specific form of w . However, when the specific form of w is available, the argument can often be easily modified to improve inequality (97). We provide examples of this at the end of this subsection.

C.3.1 GAUSSIAN MODEL WITH SQUARED LOSS

Fix $d \geq 1$. Suppose $\Theta = \mathcal{A} = \mathbb{R}^d$ and let $L(\theta; a) := \|\theta - a\|_2^2$ where $\|\cdot\|_2$ is the usual Euclidean norm on \mathbb{R}^d . For each $\theta \in \mathbb{R}^d$, let P_θ denote the Gaussian distribution with mean θ and covariance matrix $\sigma^2 I_d$ ($\sigma^2 > 0$ is a constant). For every prior w on \mathbb{R}^d with a Lebesgue density bounded by $W > 0$, we have

$$R_{\text{Bayes}}(w; L; \Theta) \gtrsim \frac{d\sigma^4 W^{-2/d}}{(\sigma^2 + V)^2} \quad (97)$$

where

$$V := \min_{s \in \mathbb{R}^d} \int_{\Theta} \frac{1}{d} \sum_{i=1}^d (\theta_i - s_i)^2 w(d\theta). \quad (98)$$

To prove (97), we shall apply (32) with $f(x) = x \log x$, i.e., we apply (39). The resulting f -informativity (a.k.a mutual information) can be bounded in the following way. Because $I(w; \mathcal{P}) \leq \int D(P_\theta \| Q) w(d\theta)$ for every Q . In particular, we take Q to be the Gaussian distribution with mean t and covariance matrix $(\sigma^2 + V)I_d$, where $t = \operatorname{argmin}_{s \in \mathbb{R}^d} \int_{\Theta} \frac{1}{d} \sum_{i=1}^d (\theta_i - s_i)^2 w(d\theta)$, i.e., $t_i = \int_{\Theta} \theta_i w(d\theta)$ is ‘‘center’’ of the prior. Then, we obtain

$$I(w; \mathcal{P}) \leq \int_{\Theta} D(N(\theta, \sigma^2 I_d) \| N(t, (\sigma^2 + V)I_d)) w(d\theta).$$

Using the standard formula for the KL divergence between two Gaussians, we deduce that

$$I(w; \mathcal{P}) \leq \frac{1}{2} \int_{\Theta} \left[\frac{\sum_{i=1}^d ((\theta_i - t_i)^2 - V)}{\sigma^2 + V} + d \log \frac{\sigma^2 + V}{\sigma^2} \right] w(d\theta)$$

which by (98) implies that

$$I(w; \mathcal{P}) \leq \frac{d}{2} \log \frac{\sigma^2 + V}{\sigma^2}. \quad (99)$$

Let J_f^w denote the right hand side above. To apply (39), we also need an upper bound on $\sup_{a \in \mathcal{A}} w(B_1(a, L))$. Because of the assumption that the Lebesgue density of w is bounded from above by W , we get

$$\sup_{a \in \mathcal{A}} w(B_1(a, L)) \leq W r^{d/2} \operatorname{Vol}(B) \quad (100)$$

where B is the Euclidean ball with unit radius. Thus the choice

$$t = cW^{-2/d} \operatorname{Vol}(B)^{-2/d} \frac{\sigma^4}{(\sigma^2 + V)^2},$$

for a small enough universal positive constant c , ensures $\sup_{a \in \mathcal{A}} w\{B_1(a)\} < \frac{1}{4} e^{-2J_f^w}$ (recall that J_f^w is the right hand side of (99)). Consequently, inequality (39) implies that $R_{\text{Bayes}} \geq t/2$. The proof of (97) is now completed using the standard fact: $\operatorname{Vol}(B)^{1/d} \asymp d^{-1/2}$.

However, since the form of the prior w is unspecified in this example, the simple upper bound on $\sup_{a \in \mathcal{A}} w(B_1(a, L))$ in (100) could be loose. But this can be easily fixed when

the concrete form of the prior is available. For example, for a spiked model with a large W (see an example of mixture prior in Remark 11 in the main text), the lower bound in (97) could be sub-optimal but can be easily tightened using the proposed chaining technique in Remark 11 in the main text. For another example, let w be the uniform prior on the hyper-rectangle $H = [-\epsilon, \epsilon] \times [-1, 1]^{d-1}$ for some very small ϵ . Here inequality (100) is equivalent to

$$\sup_{a \in \mathcal{A}} w(B_1(a, L)) \leq W r^{d/2} \operatorname{Vol}(B).$$

When $\epsilon \rightarrow 0$, we have $W \rightarrow \infty$ so that the upper bound is fairly loose. However, since H is the support of w , we can also use the following upper bound:

$$\sup_{a \in \mathcal{A}} w(B_1(a, L)) \leq W r^{d/2} \operatorname{Vol}(B \cap H).$$

When $\epsilon \rightarrow 0$, we have $W \rightarrow \infty$ but $\operatorname{Vol}(B \cap H) \rightarrow 0$. In particular, the product limit $\lim_{\epsilon \rightarrow 0} W \operatorname{Vol}(B \cap H) \rightarrow 0$ is finite. It converges to the maximum value of $w(B_1(a, L))$ where w is restricted in a $(d-1)$ -dimensional subspace of \mathbb{R}^d . Once we replace inequality (100) by the above upper bound, the associated Bayes risk lower bound will be tight.

C.3.2 GAUSSIAN MODEL WITH GENERAL LOSS

Consider the same setup as in the previous example but now allow the loss function to be $L(\theta, a) = \|\theta - a\|^2$ for an arbitrary norm $\|\cdot\|$ (not necessarily the Euclidean norm) on \mathbb{R}^d . In this case, we obtain the following Bayes risk lower bound:

$$R_{\text{Bayes}}(w; L; \Theta) \gtrsim \frac{\sigma^4 W^{-2/d}}{(\sigma^2 + V)^2} \frac{d^2}{(\mathbb{E}\|Z\|_*)^2}. \quad (101)$$

where Z is a standard Gaussian vector and $\|\cdot\|_*$ is the dual norm corresponding to $\|\cdot\|$ defined by $\|x\|_* := \sup\{x \cdot y : \|y\| \leq 1\}$. The quantities W and V are as defined in the previous example.

The proof of (101) is largely similar to that of (97). We use (39) along with (99) for controlling $I(w; \mathcal{P})$. To control $\sup_{a \in \mathcal{A}} w(B_1(a, L))$, we again use the fact that the Lebesgue density of w is bounded from above by W to obtain

$$\sup_{a \in \mathcal{A}} w(B_1(a, L)) \leq W \operatorname{Vol} \left\{ \theta \in \mathbb{R}^d : \|\theta\| < \sqrt{t} \right\}. \quad (102)$$

To deal with the volume term above, we use Urysohn’s inequality to obtain an upper bound in terms of the volume of the unit Euclidean unit ball B . The original reference for Urysohn’s inequality is Urysohn (1924) but it has been recently used in a statistical context by Ma and Wu (2015). Urysohn’s inequality gives

$$\left(\frac{\operatorname{Vol} \{ \theta \in \mathbb{R}^d : \|\theta\| < \sqrt{t} \}}{\operatorname{Vol}(B)} \right)^{\frac{1}{d}} \leq \frac{\sqrt{t}}{\sqrt{d}} \mathbb{E}\|Z\|_* \quad \text{with } Z \sim N(0, I_d). \quad (103)$$

Inequalities (102) and (103) together give

$$\sup_{a \in \mathcal{A}} w(B_1(a, L)) \leq W r^{d/2} \operatorname{Vol}(B) \left(\frac{\mathbb{E}\|Z\|_*}{\sqrt{d}} \right)^d.$$

The choice

$$t = c \text{Vol}(B)^{-2/d} \frac{W^{-2/d} \sigma^4}{(\sigma^2 + V)^2 (\mathbb{E}\|Z\|_*)^2} d$$

for a small enough universal positive constant c ensures $\sup_{a \in A} w\{B_t(a)\} < \frac{1}{4} e^{-2I_r}$ (I_r^{up} is the right hand side of (99)). The proof of (101) is then completed by noting that $\text{Vol}(B)^{1/d} \asymp d^{-1/2}$.

Appendix D. Proof of Lemma 19 in Section 6

Consider the i -th instance $x_i \in \mathbb{R}^d$ sampled from $N(\theta_{z_i}; I_{d \times d})$, where z_i is the membership. Note that for any $j \in [k] \setminus \{z_i\}$, the distance between θ_{z_i} and θ_j is lower bounded by D . We have

$$\|x_i - \theta_j\|_2^2 - \|x_i - \theta_{z_i}\|_2^2 = \|\theta_j - \theta_{z_i}\|_2^2 - 2\langle \theta_j - \theta_{z_i}, x_i - \theta_{z_i} \rangle. \quad (104)$$

The random variable $\langle \theta_j - \theta_{z_i}, x_i - \theta_{z_i} \rangle$ satisfies distribution $N(0; \|\theta_j - \theta_{z_i}\|_2^2)$. Let Φ be the CDF of the standard normal distribution. Then with probability $\Phi(\frac{\|\theta_j - \theta_{z_i}\|_2 - 1}{2})$, we have

$$\langle \theta_j - \theta_{z_i}, x_i - \theta_{z_i} \rangle \leq \|\theta_j - \theta_{z_i}\|_2 \cdot \frac{\|\theta_j - \theta_{z_i}\|_2 - 1}{2}. \quad (105)$$

Combining (104) and (105), we have

$$\|x_i - \theta_j\|_2^2 - \|x_i - \theta_{z_i}\|_2^2 \geq \|\theta_j - \theta_{z_i}\|_2. \quad (106)$$

On the other hand, the triangular inequality implies

$$\|x_i - \theta_j\|_2 + \|x_i - \theta_{z_i}\|_2 \leq 2\|x_i - \theta_{z_i}\|_2 + \|\theta_j - \theta_{z_i}\|_2. \quad (107)$$

The random variable $\|x_i - \theta_{z_i}\|_2^2$ satisfies a chi-square distribution with d degrees of freedom. It is upper bounded by βd with probability at least $1 - \exp(-\frac{d}{2}(1 - \beta + \log \beta))$ for any $\beta > 1$ (Dasgupta and Gupta, 2003). Putting (106) and (107) together, we have

$$\|x_i - \theta_j\|_2 - \|x_i - \theta_{z_i}\|_2 = \frac{\|x_i - \theta_j\|_2^2 - \|x_i - \theta_{z_i}\|_2^2}{\|x_i - \theta_j\|_2 + \|x_i - \theta_{z_i}\|_2} \geq \frac{\|\theta_j - \theta_{z_i}\|_2}{2\|\theta_j - \theta_{z_i}\|_2 + \sqrt{\beta d}} \geq \frac{3}{6 + \sqrt{\beta d}}$$

with probability at least $\Phi(\frac{D-1}{2}) - \exp(-\frac{d}{2}(1 - \beta + \log \beta))$. By choosing $D = c\sqrt{\log(nk/\delta)}$ and $\beta = c\log(nk/\delta)/d$ for a sufficiently large constant c , this probability is lower bounded by $1 - \delta/(nk)$. Applying union bound, the inequality holds for any (i, j) pair with probability at least $1 - \delta$.

Appendix E. Proof of Theorem 23 in Section 7

We start with a simplified case where the random index set K is given to the estimator. Knowing this information makes the problem easier, and makes the Bayes risk lower. In addition, it reduces the d -dimensional regression problem to a k -dimensional problem where a closed-form of the Bayes risk can be derived, which establishes the following lower bound:

Claim 1 For any $\tau > 0$, the Bayes risk is lower bounded by:

$$R_{\text{Bayes}}(w, L_{\text{est}}; \Theta) \geq \frac{1}{1 + \kappa_n^2 \tau^2 n / \sigma^2} \cdot k \tau^2, \quad \text{and} \quad R_{\text{Bayes}}(w, L_{\text{pre}}; \Theta) \geq \frac{1}{1 + \kappa_n^2 \tau^2 n / \sigma^2} \cdot \kappa_n^2 k \tau^2.$$

See Section E.1 for the proof.

For the rest of this proof, we establish stronger lower bounds using the fact that the index set K is unknown. It is easy to verify that for any random variable X sampled from $N(0, 1)$, the probability of $|X| \geq 1/2$ is greater than $1/2$. Consider a subset of the parameter space Θ :

$$\bar{\Theta} := \left\{ \theta \in \Theta : \|\theta\|_2^2 \leq 2k\tau^2 \text{ and } \sum_{i=1}^d \mathbb{1}[\theta_i] \geq \tau/2 \geq k/2 \right\}. \quad (108)$$

For a random vector θ sampled from the prior distribution w , the quantity $\|\theta\|_2^2/\tau^2$ satisfies a chi-square distribution with k degrees of freedom. For any $k \geq 1$, the event $\|\theta\|_2^2 \leq 2k\tau^2$ happens with probability at least 0.84. Given an index set K , for any $i \in K$ the random variable $\mathbb{1}[\theta_i] \geq \tau/2$ satisfies the Bernoulli distribution with parameter greater than $1/2$, so that the event $\sum_{i=1}^d \mathbb{1}[\theta_i] \geq \tau/2$ happens with probability at least $1/2$. Combining these two lower bounds and applying union bound, we obtain $w(\bar{\Theta}) \geq 1/2 - (1 - 0.84) > 1/4$. As a consequence, if we define a distribution \bar{w} over the subset $\bar{\Theta}$ by $\bar{w}(A) := w(A \cap \bar{\Theta})/w(\bar{\Theta})$, then Remark 11 implies that

$$R_{\text{Bayes}}(w, L; \Theta) \geq w(\bar{\Theta}) \cdot R_{\text{Bayes}}(\bar{w}, L; \bar{\Theta}) \geq \frac{1}{4} R_{\text{Bayes}}(\bar{w}, L; \bar{\Theta}). \quad (109)$$

Hence it suffices to focus on the Bayes risk for the marginal prior \bar{w} .

Let the action space $\mathcal{A} := \mathbb{R}^d$ and let the loss function be either the estimation error L_{est} or the prediction error L_{pre} . In order to lower bound the Bayes risk, it suffices to bound the chi-square informativity $I_{\chi^2}(\bar{w}, \mathcal{P})$ and the quantity $\sup_{a \in \mathcal{A}} \bar{w}(B_t(a, L))$, then applying Corollary 12. We begin with an upper bound on the chi-square informativity.

Claim 2 For any $\tau > 0$, the chi-square informativity is bounded by:

$$I_{\chi^2}(\bar{w}, \mathcal{P}) + 1 \leq \exp(2\kappa_n^2 \tau^2 k n / \sigma^2) \quad (110)$$

See Section E.2 for the proof.

Next, we upper bound the quantity $\sup_{a \in \mathcal{A}} \bar{w}(B_t(a, L))$. We begin by claiming a property of all Euclidean balls of small enough radius.

Claim 3 For any point $a \in \mathbb{R}^d$, let $B(a, r)$ be the Euclidean ball of radius r centering at a . If $r \leq \frac{1}{8}\sqrt{k}\tau$, then there is a universal constant $c > 0$ such that

$$\sup_{a \in \mathcal{A}} \bar{w}(B(a, r)) \leq \frac{c^k}{(d/k^2)^{k/4}} \left(\frac{\tau}{\sqrt{k}\tau} \right)^k.$$

See Section E.3 for the proof.

Lower bound on estimation error For the estimation error, we obtain by Claim 3 that for any $t \leq \frac{1}{64}k\tau^2$, the following upper bound holds:

$$\sup_{a \in \mathcal{A}} \bar{w}(B_t(a, L_{\text{est}})) = \sup_{a \in \mathcal{A}} \bar{w}(B(a, \sqrt{t})) \leq \frac{c^k}{(d/k^2)^{k/4}} \left(\frac{\sqrt{t}}{\sqrt{k\tau}} \right)^k. \quad (111)$$

Combining Claim 3 with inequality (111), and applying inequality (40) in Corollary 12, we obtain the lower bound:

$$R_{\text{Bayes}}(\bar{w}, L_{\text{est}}; \Theta) \geq \frac{1}{2} \sup \left\{ 0 < t \leq \frac{k\tau^2}{64} : \left(\frac{\sqrt{t}}{\sqrt{k\tau}} \right)^k \leq \frac{(d/k^2)^{k/4}}{c^k} \cdot \frac{1}{4} \exp(-2\kappa_n^2 \tau^2 kn / \sigma^2) \right\}.$$

The right-hand side is lower bounded by any scalar t satisfying:

$$t \leq \frac{1}{64} k\tau^2 \quad \text{and} \quad \frac{\sqrt{t}}{\sqrt{k\tau}} \leq \frac{(d/k^2)^{1/4}}{c} \cdot \frac{1}{4^{1/k}} \exp(-2\kappa_n^2 \tau^2 n / \sigma^2)$$

It implies that for some universal constant $c' > 0$, we have:

$$\begin{aligned} R_{\text{Bayes}}(\bar{w}, L_{\text{est}}; \Theta) &\geq c' k\tau^2 \min \left\{ 1, \exp\left(\frac{1}{2} \log(d/k^2) - 4\kappa_n^2 \tau^2 n / \sigma^2\right) \right\} \\ &= c' k\tau^2 \exp \left(\min \left\{ 0, \frac{1}{2} \log(d/k^2) - \frac{4\kappa_n^2 \tau^2 n}{\sigma^2} \right\} \right) \\ &= c' k\tau^2 \exp \left(-\frac{4\kappa_n^2 n}{\sigma^2} \left[\tau^2 - \frac{\sigma^2 \log(d/k^2)}{8\kappa_n^2 n} \right]_+ \right) \\ &\geq c' k\tau^2 \exp \left(-\frac{4\kappa_n^2 n}{\sigma^2} \left[\tau^2 - \frac{\sigma^2 \log(d/k)}{16\kappa_n^2 n} \right]_+ \right), \end{aligned} \quad (112)$$

where the last inequality uses the assumption $d > k^3$ and its implication $\log(d/k^2) > \frac{1}{2} \log(d/k)$.

Combining inequality (112) with Claim 1 yields the lower bound:

$$R_{\text{Bayes}}(w, L_{\text{est}}; \Theta) \geq c' k\tau^2 \max \left\{ \frac{1}{1 + \kappa_n^2 \tau^2 n / \sigma^2}, \exp \left(-\frac{4\kappa_n^2 n}{\sigma^2} \left[\tau^2 - \frac{\sigma^2 \log(d/k)}{16\kappa_n^2 n} \right]_+ \right) \right\},$$

which completes the proof.

Lower bound on prediction error For the prediction error, we consider an arbitrary vector $a \in \mathbb{R}^d$ and an arbitrary scalar t satisfying $\sqrt{t} \leq \frac{n}{16} \sqrt{k\tau}$. Let θ' be the vector in Θ which minimizes the term $\frac{1}{n} \|X(a - \theta')\|_2^2$. If the inequality $\frac{1}{n} \|X(a - \theta')\|_2^2 > t$ is true, then we have

$$\sup_{a \in \mathcal{A}} \bar{w}(B_t(a, L_{\text{pre}})) = 0. \quad (113)$$

Otherwise, we assume that $\frac{1}{n} \|X(a - \theta')\|_2^2 \leq t$. Then for any vector $\theta \in \Theta$ satisfying $\frac{1}{n} \|X(\theta - a)\|_2^2 \leq t$, we have the upper bound

$$\frac{1}{n} \|X(\theta - \theta')\|_2^2 \leq (n^{-1/2} \|X(\theta - a)\|_2 + n^{-1/2} \|X(a - \theta')\|_2)^2 \leq (\sqrt{t} + \sqrt{t})^2 \leq 4t.$$

It means that $B_t(a, L_{\text{pre}}) \subseteq B_{4t}(\theta', L_{\text{pre}})$. Since the vector θ' is k -sparse, the sparse eigenvalue condition implies that for any vector $\theta \in \Theta$, if $L_{\text{pre}}(\theta, \theta') \leq 4t$, then $\|\theta - \theta'\|_2 \leq \frac{2\sqrt{t}}{\kappa_\ell}$, so that $B_{4t}(\theta', L_{\text{pre}}) \subseteq B(\theta', \frac{2\sqrt{t}}{\kappa_\ell})$. Using Claim 3, we have

$$\sup_{a \in \mathcal{A}} \bar{w}(B_t(a, L_{\text{pre}})) \leq \sup_{a \in \mathcal{A}} \bar{w}(B(\theta', \frac{2\sqrt{t}}{\kappa_\ell})) \leq \sup_{a \in \mathcal{A}} \bar{w}(B(a, L_{\text{est}})) \leq \frac{c^k}{(d/k^2)^{k/4}} \left(\frac{2\sqrt{t}}{\kappa_\ell \sqrt{k\tau}} \right)^k. \quad (114)$$

Combining equation (113) and inequality (114) we obtain

$$\sup_{a \in \mathcal{A}} \bar{w}(B_t(a, L_{\text{pre}})) \leq \frac{c^k}{(d/k^2)^{k/4}} \left(\frac{2\sqrt{t}}{\kappa_\ell \sqrt{k\tau}} \right)^k \quad \text{for any } \sqrt{t} \leq \frac{\kappa_\ell}{16} \sqrt{k\tau}. \quad (115)$$

Comparing inequalities (111) and (115), we find that they differ by a factor of $(2/\kappa_\ell)^k$. Thus, following the same steps for deriving Inequality (112), we can find a universal constant $c'' > 0$ such that:

$$R_{\text{Bayes}}(\bar{w}, L_{\text{pre}}; \Theta) \geq c'' \kappa_\ell^2 k\tau^2 \exp \left(-\frac{4\kappa_n^2 n}{\sigma^2} \left[\tau^2 - \frac{\sigma^2 \log(d/k)}{16\kappa_n^2 n} \right]_+ \right) \quad (116)$$

Combining inequality (116) with Claim 1 yields:

$$R_{\text{Bayes}}(w, L_{\text{pre}}; \Theta) \geq c'' \kappa_\ell^2 k\tau^2 \max \left\{ \frac{1}{1 + \kappa_n^2 \tau^2 n / \sigma^2}, \exp \left(-\frac{4\kappa_n^2 n}{\sigma^2} \left[\tau^2 - \frac{\sigma^2 \log(d/k)}{16\kappa_n^2 n} \right]_+ \right) \right\},$$

which completes the proof.

E.1 Proof of Claim 1

The Bayes risk of the original problem is lower bounded by that of the following simplified problem: estimating θ when the index set K is known, and without loss of generality, we assume that $K = [k]$. For this case, let X' be the submatrix consisting of the first k columns of matrix X , and let θ' be the subvectors consisting of the first k coordinate of vectors θ . Given the response vector y , the posterior distribution of θ' is equal to

$$p(\theta' | y) \propto p(\theta) p(y | \theta) = N(\theta'; 0, \tau^{-2} I) N(y; X\theta', \sigma^2 I) \propto N(\theta'; \Sigma^{-1}(X')^\top y, \sigma^2 \Sigma^{-1}),$$

where $\Sigma := (X')^\top X' + \frac{\sigma^2}{\tau^2} I$ is a shorthand notation. As a consequence, the Bayes estimator $\hat{\theta}$ is given by $\hat{\theta}_K = \Sigma^{-1}(X')^\top y$ and $\hat{\theta}_{-K} = 0$. The Bayes risk on the estimation error is lower bounded by:

$$R_{\text{Bayes}}(w, L_{\text{est}}; \Theta) = \mathbb{E}[\|\Sigma^{-1}(X')^\top y - \theta'\|_2^2] = \sigma^2 \text{tr}(\Sigma^{-1}) \geq \frac{\sigma^2}{\kappa_n^2 \tau^2 n + \sigma^2} \cdot k\tau^2,$$

where the last inequality uses the sparse eigenvalue condition — it guarantees that all eigenvalues of the matrix Σ are less than or equal to $n\kappa_n^2 + \sigma^2/\tau^2$.

The Bayes estimator for minimizing the prediction error is also given by $\hat{\theta}_K = \Sigma^{-1}(X')^\top y$ and $\hat{\theta}_{-K} = 0$. Thus, the Bayes risk is lower bounded by:

$$\begin{aligned} R_{\text{Bayes}}(w, L_{\text{pre}}; \Theta) &= \frac{1}{n} \mathbb{E} \left[\|X'(\Sigma^{-1}(X')^\top y - \theta')\|_2^2 \right] = \frac{\sigma^2}{n} \text{tr}(X' \Sigma^{-1}(X')^\top) \\ &\geq \frac{\sigma^2}{k_1^2 \tau^2 n + \sigma^2} \cdot k_1^2 k \tau^2, \end{aligned}$$

where the last inequality uses the sparse eigenvalue condition — it guarantees that all eigenvalues of the matrix $X' \Sigma^{-1}(X')^\top$ are greater than or equal to $\frac{nk_1^2}{nk_1^2 + \sigma^2} \tau^2$.

E.2 Proof of Claim 2

Corollary 16 shows that the chi-square informativity can be bounded using the covering number $M_{\chi^2}(\epsilon, \Theta)$. Consider the zero vector $\theta_0 := 0$ and an arbitrary vector $\theta \in \Theta$. Their response vectors are generated from $P_{\theta_0} := N(0, \sigma^2 I)$ and $P_\theta := N(X\theta, \sigma^2 I)$, so that the chi-square divergence between P_{θ_0} and P_θ is equal to $\chi^2(P_{\theta_0}, P_\theta) = \exp(\|X\theta\|_2^2 / \sigma^2) - 1$. By the sparse eigenvalue condition and the fact that $\|\theta\|_2^2 \leq 2k\tau^2$, we have

$$\chi^2(P_{\theta_0}, P_\theta) \leq \exp(\kappa_n^2 \|\theta\|_2^2 / \sigma^2) - 1 \leq \exp(2\kappa_n^2 \tau^2 kn / \sigma^2) - 1.$$

It means that if we choose $\epsilon^2 = \exp(2\kappa_n^2 \tau^2 kn / \sigma^2) - 1$, then $M_{\chi^2}(\epsilon, \Theta) = 1$, so that the chi-square informativity is bounded by

$$I_{\chi^2}(\bar{w}, \mathcal{P}) + 1 \leq (1 + \epsilon^2) M_{\chi^2}(\epsilon, \Theta) = \exp(2\kappa_n^2 \tau^2 kn / \sigma^2). \quad (117)$$

E.3 Proof of Claim 3

Consider an arbitrary vector $a \in \mathbb{R}^d$, and let I_a be the set of indices defined by:

$$I_a = \{i \in [d] : |a_i| \geq \tau/4\}.$$

If $|I_a| > 2k$, then for any $\theta \in \bar{\Theta}$, there are at least $k+1$ coordinates such that $\theta_i = 0$ but $|a_i| \geq \tau/4$. It means that $\|a - \theta\|_2 > \frac{1}{4}\sqrt{k}\tau$. Since $r \leq \frac{1}{8}\sqrt{k}\tau$, we have $\bar{w}(B(a, r)) = 0$.

Otherwise, we assume that $|I_a| \leq 2k$. Given an index set K , let w_K and \bar{w}_K be the conditional version of the prior distribution w and \bar{w} , conditioning on the fact that the k -sparse index set is K . Recall that for any θ in the support of \bar{w}_K , there are at least $k/2$ coordinates such that $|\theta_i| \geq \tau/2$. If $|I_a \cap K| < k/4$, then there are at least $k/4$ coordinates such that $|\theta_i| \geq \tau/2$ but $|a_i| < \tau/4$. It means that $\|a - \theta\|_2 > \frac{3}{8}\sqrt{k}\tau$ for any θ in the support of \bar{w}_K , and as a consequence, we have $\bar{w}_K(B(a, r)) = 0$.

Thus, a necessary condition for $\bar{w}_K(B(a, r)) > 0$ to hold is $|I_a \cap K| \geq k/4$. Given $|I_a| \leq 2k$, the number of index set K satisfying this constraint is bounded by $\binom{2k}{k/4} \binom{d-k/4}{3k/4}$. To prove this bound, notice that every set K satisfying $|I_a \cap K| \geq k/4$ can be generated by the following two-step procedure: first, generate $k/4$ element from I_a ; second, generate the remaining $3k/4$ elements from the remaining $d - k/4$ integers of $\{1, \dots, d\}$. There are totally $\binom{2k}{k/4} \binom{d-k/4}{3k/4}$ ways of generating the set. We note that the same K can have multiple ways to generate, so that the above combinatorial number is a strict upper bound on the number of sets.

For any set K satisfying the above constraint, we have:

$$\bar{w}_K(B(a, r)) \leq 4w_K(B(a, r)) \leq 4w_K(B(0, r)), \quad (118)$$

where the last equation holds because w_K represents an isotropic normal distribution in \mathbb{R}^k , so that the maximum probability is achieved by centering at the origin. The right-hand side of inequality (118) the probability a k -dimension normal random variable $X \sim N(0, \tau^2 I_{k \times k})$ satisfying $\|X\|_2 \leq r$. As we showed in the proof of Lemma 21, this probability is bounded by $(\frac{c\tau}{\sqrt{k}\tau})^k$ for a universal constant $c > 0$. Putting pieces together, we have

$$\sup_{a \in A} \bar{w}(B(a, r)) \leq \frac{\binom{2k}{k/4} \binom{d-k/4}{3k/4}^k}{\binom{d}{k}} \cdot 4 \left(\frac{c\tau}{\sqrt{k}\tau} \right)^k.$$

By the definition of the combinatorial numbers, we have:

$$\begin{aligned} \frac{\binom{2k}{k/4} \binom{d-k/4}{3k/4}^k}{\binom{d}{k}} &= \binom{2k}{k/4} \frac{k!(d-k/4)!}{(3k/4)! d!} \leq \binom{2k}{k/4} \frac{k!}{(3k/4)!} \frac{1}{d^{k/4}} \\ &\leq \frac{(2k)^{k/2}}{d^{k/4}} = \left(\frac{d}{4k^2} \right)^{-k/4}. \end{aligned}$$

Combining the two upper bounds above completes the proof.

Abstract

We consider the emphatic temporal-difference (TD) algorithm, ETD(λ), for learning the value functions of stationary policies in a discounted, finite state and action Markov decision process. The ETD(λ) algorithm was recently proposed by Sutton, Mahmood, and White (2016) to solve a long-standing divergence problem of the standard TD algorithm when it is applied to off-policy training, where data from an exploratory policy are used to evaluate other policies of interest. The almost sure convergence of ETD(λ) has been proved in our recent work under general off-policy training conditions, but for a narrow range of diminishing stepsize. In this paper we present convergence results for constrained versions of ETD(λ) with constant stepsize and with diminishing stepsize from a broad range. Our results characterize the asymptotic behavior of the trajectory of iterates produced by those algorithms, and are derived by combining key properties of ETD(λ) with powerful convergence theorems from the weak convergence methods in stochastic approximation theory. For the case of constant stepsize, in addition to analyzing the behavior of the algorithms in the limit as the stepsize parameter approaches zero, we also analyze their behavior for a fixed stepsize and bound the deviations of their averaged iterates from the desired solution. These results are obtained by exploiting the weak Feller property of the Markov chains associated with the algorithms, and by using ergodic theorems for weak Feller Markov chains, in conjunction with the convergence results we get from the weak convergence methods. Besides ETD(λ), our analysis also applies to the off-policy TD(λ) algorithm, when the divergence issue is avoided by setting λ sufficiently large. It yields, for that case, new results on the asymptotic convergence properties of constrained off-policy TD(λ) with constant or slowly diminishing stepsize.

Keywords: Markov decision processes, approximate policy evaluation, reinforcement learning, temporal-difference methods, importance sampling, stochastic approximation, convergence

1. Introduction

We consider discounted finite state and action Markov decision processes (MDPs) and the problem of learning an approximate value function for a given policy from *off-policy* data, that is, from data due to a different policy. The first policy is called the *target policy* and the second the *behavior policy*. The case of *on-policy* learning, where the target and behavior policies are the same, has been well-studied and widely applied (see e.g.,

Sutton, 1988; Tsitsiklis and Van Roy, 1997; and the books Bertsekas and Tsitsiklis, 1996; Sutton and Barto, 1998). Off-policy learning provides additional flexibilities and is useful in many contexts. For example, one may want to avoid executing the target policy before estimating the potential risk for safety concerns, or one may want to learn value functions for many target policies in parallel from one exploratory behavior. These require off-policy learning. In addition, insofar as value functions (with respect to different reward/cost assignments) reflect statistical properties of future outcomes, off-policy learning can be used by an autonomous agent to build an experience-based internal model of the world in artificial intelligence applications (Sutton, 2009). Algorithms for off-policy learning are thus not only useful as model-free computational methods for solving MDPs, but can also potentially be a step toward the goal of making autonomous agents capable of learning over a long life-time, facing a sequence of diverse tasks.

In this paper we focus on a new off-policy learning algorithm proposed recently by Sutton, Mahmood, and White (2016): the emphatic temporal-difference (TD) learning algorithm, or ETD(λ). The algorithm is similar to the standard TD(λ) algorithm with linear function approximation (Sutton, 1988), but uses a novel scheme to resolve a long-standing divergence problem in TD(λ) when applied to off-policy data. Regarding the divergence problem, while TD(λ) was proved to converge for the on-policy case (Tsitsiklis and Van Roy, 1997), it was known quite early that the algorithm can diverge in other cases (Baird, 1995; Tsitsiklis and Van Roy, 1997).¹ The difficulty is intrinsic to sampling states according to an arbitrary distribution. Since then alternative algorithms without convergence issues have been sought for off-policy learning. In particular, in the off-policy LSTD(λ) algorithm (Bertsekas and Yu, 2009; Yu, 2012), which is an extension of the on-policy least-squares version of TD(λ) proposed by Bradtke and Barto (1996) and Boyan (1999), with higher computational complexity than TD(λ), the linear equation associated with TD(λ) is estimated from data and then solved.² In the gradient-TD algorithms (Sutton et al., 2008, 2009; Maei, 2011) and the proximal gradient-TD algorithms (Liu et al., 2009; Mahadevan and Liu, 2012; see also Mahadevan et al., 2014; Liu et al., 2015), the difficulty in TD(λ) is overcome by reformulating the approximate policy evaluation problem TD(λ) attempts to solve as optimization problems and then tackle them with optimization techniques. (See the surveys Geist and Scherrer, 2014 and Dann et al., 2014 for other algorithm examples.)

Compared to the algorithms just mentioned, ETD(λ) is closer to the standard TD(λ) algorithm and addresses the issue in TD(λ) more directly. It introduces a novel weighting scheme to re-weight the states when forming the eligibility traces in TD(λ), so that the weights reflect the occupation frequencies of the target policy rather than the behavior policy. An important result of this weighting scheme is that under natural conditions on the function approximation architecture, the average dynamics of ETD(λ) can be described by an affine function involving a negative definite matrix (Sutton et al., 2016; Yu, 2015a),³

1. For related discussions, see also Bertsekas and Tsitsiklis (1996); Sutton and Barto (1998); and Sutton et al. (2016).
2. An efficient algorithm for solving the estimated equations is the one given by Yao and Liu (2008) based on the line search method. It can also be applied to finding approximate solutions under additional penalty terms suggested by Pires and Szepesvári (2012).
3. Sutton et al. (2016) work with the negation of the matrix that we associate with ETD(λ) in this paper. The negative definiteness property we discuss here corresponds to the positive definiteness property discussed in their work.

which provides a desired stability property, similar to the case of convergent on-policy TD algorithms.

The almost sure convergence of ETD(λ), under general off-policy training conditions, has been shown in our recent work (Yu, 2015a) for diminishing stepsize. That result, however, requires the stepsize to diminish at the rate of $O(1/t)$, with t being the time index of the iterate sequence. This range of stepsize is too narrow for applications. In practice, algorithms tend to make progress too slowly if the stepsize becomes too small, and the environment may be non-stationary, so it is often preferred to use a much larger stepsize or constant stepsize.

The purpose of this paper is to provide an analysis of ETD(λ) for a broad range of stepsizes. Specifically, we consider constant stepsize and stepsize that can decrease at a rate much slower than $O(1/t)$. We will maintain general off-policy training conditions, without placing restrictions on the behavior policy. However, we will consider constrained versions of ETD(λ), which constrain the iterates to be in a bounded set, and a mode of convergence that is weaker than almost sure convergence. Constraining the ETD(λ) iterates is not only needed in analysis, but also a means to control the variances of the iterates, which is important in practice since off-policy learning algorithms generally have high variances. Almost sure convergence is no longer guaranteed for algorithms using large stepsizes; hence we analyze their behavior with respect to a weaker convergence mode.

We study a simple, basic version of constrained ETD(λ) and several variations of it, some of which are biased but can mitigate the variance issue better. To give an overview of our results, we shall refer to the first algorithm as the unbiased algorithm, and its biased variations as the biased variants. Two groups of results will be given to characterize the asymptotic behavior of the trajectory of iterates produced by these algorithms. The first group of results are derived by combining key properties of ETD(λ) with powerful convergence theorems from the weak convergence methods in stochastic approximation theory. The results show (roughly speaking) that:

- (i) In the case of diminishing stepsize, under mild conditions, the trajectory of iterates produced by the unbiased algorithm eventually spends nearly all its time in an arbitrarily small neighborhood of the desired solution, with an arbitrarily high probability (Theorem 4); and the trajectory produced by the biased algorithms has a similar behavior, when the algorithmic parameters are set to make the biases sufficiently small (Theorem 6). These results entail the convergence in mean to the desired solution for the unbiased algorithm (Corollary 2), and the convergence in probability to some vicinity of the desired solution for the biased variants.

- (ii) In the case of constant stepsize, imagine that we run the algorithms for all stepsizes; then conclusions similar to those in (i) hold in the limit as the stepsize parameter approaches zero (Theorems 5 and 7). In particular, a smaller stepsize parameter results in an increasingly longer segment of the trajectory to spend, with an increasing probability, nearly all its time in some neighborhood of the desired solution. The size of the neighborhood can be made arbitrarily small as the stepsize parameter approaches zero and, in the case of the biased variants, also as their biases are reduced.

The next group of results are for the constant-stepsize case and complement the results in (ii) by focusing on the asymptotic behavior of the algorithms for a fixed stepsize. Among others, they show (roughly speaking) that:

- (iii) For any given stepsize parameter, asymptotically, the expected maximal deviation of multiple consecutive averaged iterates from the desired solution can be bounded in terms of the masses that the invariant probability measures of certain associated Markov chains assign to a small neighborhood of the desired solution. Those probability masses approach one when the stepsize parameter approaches zero and, in the case of the biased variants, also when their biases are sufficiently small (Theorems 8 and 9).

- (iv) For a perturbed version of the unbiased algorithm and its biased variants, the maximal deviation of averaged iterates from the desired solution, under a given stepsize parameter, can be bounded almost surely in terms of those probability masses mentioned in (iii), for each initial condition (Theorems 10 and 11).

To derive the first group of results, we use powerful convergence theorems from the weak convergence methods in stochastic approximation theory (Kushner and Clark, 1978; Kushner and Schwartz, 1984; Kushner and Yin, 2003). This theory builds on the ordinary differential equation (ODE) based proof method, treats the trajectory of iterates as a whole, and studies its asymptotic behavior through the continuous-time processes corresponding to left-shifted and interpolated iterates. The probability distributions of these continuous-time interpolated processes are analyzed (as probability measures on a function space) by the weak convergence methods, leading to a characterization of their limiting distributions, from which asymptotic properties of the trajectory of iterates can be obtained.

Most of our efforts in the first part of our analysis are to prove that the constrained ETD(λ) algorithms satisfy the conditions required by the general convergence theorems just mentioned. We prove this by using key properties of ETD(λ) iterates, most importantly, the ergodicity and uniform integrability properties of the trace iterates, and the convergence of certain averaged processes which, intuitively speaking, describe the averaged dynamics of ETD(λ). Some of these properties were established earlier in our work (2015a) when analyzing the almost sure convergence of ETD(λ). Building upon that work, we prove the remaining properties needed in the analysis.

To derive the second group of results, we exploit the fact that in the case of constant stepsize, the iterates together with other random variables involved in the algorithms form weak Feller Markov chains, and such Markov chains have nice ergodicity properties. We use ergodic theorems for weak Feller Markov chains (Meyn, 1989; Meyn and Tweedie, 2009), together with the properties of ETD(λ) iterates and the convergence results we get from the weak convergence methods, in this second part of our analysis.

Besides ETD(λ), the analysis we give in the paper also applies to off-policy TD(λ), when the divergence issue mentioned earlier is avoided by setting λ sufficiently close to 1. The reason is that in that case the off-policy TD(λ) iterates have the same properties as the ones used in our analysis of ETD(λ) and therefore, the same conclusions hold for constrained versions of off-policy TD(λ), regarding their asymptotic convergence properties for constant or slowly diminishing stepsize (these results are new, to our knowledge). Similarly, our analysis also applies directly to the ETD(λ, β) algorithm, a variation of ETD(λ) recently proposed by Hallak et al. (2016).

Regarding practical performance of the algorithms, the biased ETD variant algorithms are much more robust than the unbiased algorithm despite the latter's superior asymptotic convergence properties. (This is not a surprise, for the biased algorithms are in fact defined

by using a well-known robustifying approach from stochastic approximation theory.) Their behavior is demonstrated by experiments in (Mahmood et al., 2015; Yu, 2016). In particular, the report (Yu, 2016) is our companion note for this paper and includes several simulation results to illustrate some of the theorems we give here regarding the behavior of multiple consecutive iterates of the biased algorithms.

The paper is organized as follows. In Section 2 we provide the background for the ETD(λ) algorithm. In Section 3 we present our convergence results on constrained ETD(λ) and several variants of it, and we give the proofs in Section 4. We conclude the paper in Section 5 with a brief discussion on direct applications of our convergence results to the off-policy TD(λ) algorithm and the ETD(λ, β) algorithm, as well as to ETD(λ) under relaxed conditions, followed by a discussion on several open issues. In Appendix A we include the key properties of the ETD(λ) trace iterates that are used in the analysis.

2. Preliminaries

In this section we describe the policy evaluation problem in the off-policy case, the ETD(λ) algorithm and its constrained version. We also review the results from our prior work (2015a) that are needed in this paper.

2.1 Off-policy Policy Evaluation

Let $\mathcal{S} = \{1, \dots, N\}$ be a finite set of states, and let \mathcal{A} be a finite set of actions. Without loss of generality we assume that for all states, every action in \mathcal{A} can be applied. If $a \in \mathcal{A}$ is applied at state $s \in \mathcal{S}$, the system moves to state s' with probability $p(s' | s, a)$ and yields a random reward with mean $r(s, a, s')$ and bounded variance, according to a probability distribution $q(\cdot | s, a, s')$. These are the parameters of the MDP model we consider; they are unknown to the learning algorithms to be introduced.

A *stationary policy* is a time-invariant decision rule that specifies the probability of taking an action at each state. When actions are taken according to such a policy, the states and actions (S_t, A_t) at times $t \geq 0$ form a (time-homogeneous) Markov chain on the space $\mathcal{S} \times \mathcal{A}$, with the marginal state process $\{S_t\}$ being also a Markov chain.

Let π and π^o be two given stationary policies, with $\pi(a | s)$ and $\pi^o(a | s)$ denoting the probability of taking action a at state s under π and π^o , respectively. While the system evolves under the policy π^o , generating a stream of state transitions and rewards, we wish to use these observations to evaluate the performance of the policy π , with respect to a discounted reward criterion, the definition of which will be given shortly. Here π is the target policy and π^o the behavior policy. It is allowed that $\pi^o \neq \pi$ (the off-policy case), provided that at each state, all actions taken by π can also be taken by π^o (cf. Assumption 1(ii) below).

Let $\gamma(s) \in [0, 1]$, $s \in \mathcal{S}$, be state-dependent discount factors, with $\gamma(s) < 1$ for at least one state. We measure the performance of π in terms of the expected discounted total rewards attained under π as follows: for each state $s \in \mathcal{S}$,

$$v_\pi(s) := \mathbb{E}^\pi \left[R_0 + \sum_{t=1}^{\infty} \gamma(S_1) \gamma(S_2) \cdots \gamma(S_t) \cdot R_t \mid S_0 = s \right], \quad (1)$$

where R_t is the random reward received at time t , and \mathbb{E}^π denotes expectation with respect to the probability distribution of the states, actions and rewards, (S_t, A_t, R_t) , $t \geq 0$, generated under the policy π . The function v_π on \mathcal{S} is called the *value function* of π . The special case of γ being a constant less than 1 corresponds to the γ -discounted reward criterion: $v_\pi(s) = \mathbb{E}^\pi [\sum_{j=0}^{\infty} \gamma^j R_t \mid S_0 = s]$. In the general case, by letting γ depend on the state, the formulation is able to also cover certain undiscounted total reward MDPs with termination;⁴ however, for v_π to be well-defined (i.e., to have the right-hand side of Equation 1 well-defined for each state), a condition on the target policy is needed, which is stated below and will be assumed throughout the paper.

Let P_π denote the transition matrix of the Markov chain on \mathcal{S} induced by π . Let Γ denote the $N \times N$ diagonal matrix with diagonal entries $\gamma(s)$, $s \in \mathcal{S}$.

Assumption 1 (conditions on the target and behavior policies)

- (i) *The target policy π is such that $(I - P_\pi \Gamma)^{-1}$ exists.*
- (ii) *The behavior policy π^o induces an irreducible Markov chain on \mathcal{S} , and moreover, for all $(s, a) \in \mathcal{S} \times \mathcal{A}$, $\pi^o(a | s) > 0$ if $\pi(a | s) > 0$.*

Under Assumption 1(i), the value function v_π in (1) is well-defined, and furthermore, v_π satisfies uniquely the Bellman equation⁵

$$v_\pi = r_\pi + P_\pi \Gamma v_\pi, \quad \text{i.e.,} \quad v_\pi = (I - P_\pi \Gamma)^{-1} r_\pi,$$

where r_π is the expected one-stage reward function under π (i.e., $r_\pi(s) = \mathbb{E}^\pi [R_0 \mid S_0 = s]$ for $s \in \mathcal{S}$).

2.2 The ETD(λ) Algorithm

Like the standard TD(λ) algorithm (Sutton, 1988; Tsitsiklis and Van Roy, 1997), the ETD(λ) algorithm (Sutton et al., 2016) approximates the value function v_π by a function of the form $v(s) = \phi(s)^\top \theta$, $s \in \mathcal{S}$, using a parameter vector $\theta \in \mathbb{R}^n$ and n -dimensional feature representations $\phi(s)$ for the states. (Here $\phi(s)$ is a column vector and $^\top$ stands for transpose.) In matrix notation, denote by Φ the $N \times n$ matrix with $\phi(s)$, $s \in \mathcal{S}$, as its rows. Then the columns of Φ span the subspace of approximate value functions, and the approximation problem is to find in that subspace a function $v = \Phi \theta \approx v_\pi$.

We focus on a general form of the ETD(λ) algorithm, which uses state-dependent λ values specified by a function $\lambda : \mathcal{S} \rightarrow [0, 1]$. Inputs to the algorithm are the states, actions and rewards, $\{(S_t, A_t, R_t)\}$, generated under the behavior policy π^o , where R_t is the random reward received upon the transition from state S_t to S_{t+1} with action A_t . The algorithm can access the following functions, in addition to the features $\phi(s)$:

4. We may view $v_\pi(s)$ as the expected (undiscounted) total rewards attained under π starting from the state s and up to a random termination time $\tau \geq 1$ that depends on the states in a Markovian way. In particular, if at time $t \geq 1$, the state is s and termination has not occurred yet, the probability of $\tau = t$ (terminating at time t) is $1 - \gamma(s)$. Then $v_\pi(s)$ can be equivalently written as $v_\pi(s) = \mathbb{E}^\pi [\sum_{j=0}^{\tau-1} R_t \mid S_0 = s]$.
5. One can verify this Bellman equation directly. It also follows from the standard MDP theory, as by definition v_π here can be related to a value function in a discounted MDP where the discount factors depend on state transitions, similar to discounted semi-Markov decision processes (see e.g., Puterman, 1994).

- (i) the state-dependent discount factor $\gamma(s)$ that defines v_π , as described earlier;
- (ii) $\lambda : \mathcal{S} \rightarrow [0, 1]$, which determines the single or multi-step Bellman equation for the algorithm (cf. the subsequent Equations 6-7 and Footnote 7);
- (iii) $\rho : \mathcal{S} \times \mathcal{A} \rightarrow \mathbb{R}_+$ given by $\rho(s, a) = \pi(a | s) / \pi^o(a | s)$ (with $0/0 = 0$), which gives the likelihood ratios for action probabilities that can be used to compensate for sampling states and actions according to the behavior policy π^o instead of the target policy π ;
- (iv) $i : \mathcal{S} \rightarrow \mathbb{R}_+$, which gives the algorithm additional flexibility to weight states according to the degree of “interest” indicated by $i(s)$.

The algorithm also uses a sequence $\alpha_t > 0, t \geq 0$, as stepsize parameters. We shall consider only deterministic $\{\alpha_t\}$.

To simplify notation, let

$$\rho_t = \rho(S_t, A_t), \quad \gamma_t = \gamma(S_t), \quad \lambda_t = \lambda(S_t).$$

ETD(λ) calculates recursively $\theta_t \in \mathbb{R}^n$, $t \geq 0$, according to

$$\theta_{t+1} = \theta_t + \alpha_t e_t \cdot \rho_t (R_t + \gamma_{t+1} \phi(S_{t+1})^\top \theta_t - \phi(S_t)^\top \theta_t), \quad (2)$$

where $e_t \in \mathbb{R}^n$, called the “eligibility trace,” is calculated together with two nonnegative scalar iterates (F_t, M_t) according to⁶

$$F_t = \gamma_t \rho_{t-1} F_{t-1} + i(S_t), \quad (3)$$

$$M_t = \lambda_t i(S_t) + (1 - \lambda_t) F_t, \quad (4)$$

$$e_t = \lambda_t \gamma_t \rho_{t-1} e_{t-1} + M_t \phi(S_t). \quad (5)$$

For $t = 0$, (e_0, F_0, θ_0) are given as an initial condition of the algorithm.

We recognize that the iteration (2) has the same form as TD(λ), but the trace e_t is calculated differently, involving an “emphasis” weight M_t on the state S_t , which itself evolves along with the iterate F_t , called the “follow-on” trace. If M_t is always set to 1 regardless of F_t and $i(\cdot)$, then the iteration (2) reduces to the off-policy TD(λ) algorithm in the case where γ and λ are constants.

2.3 Associated Bellman Equations and Approximation and Convergence Properties of ETD(λ)

Let Λ denote the diagonal matrix with diagonal entries $\lambda(s), s \in \mathcal{S}$. Associated with ETD(λ) is a generalized multistep Bellman equation of which v_π is the unique solution (Sutton, 1995):⁷

$$v = r_{\pi, \gamma}^\lambda + P_{\pi, \gamma}^\lambda v. \quad (6)$$

6. The definition (5) we use here differs slightly from the original definition of e_t used by Sutton et al. (2016), but the two are equivalent and (5) appears to be more convenient for our analysis.

7. For the details of this Bellman equation, we refer the readers to the early work (Sutton, 1995; Sutton and Barto, 1998) and the recent work (Sutton et al., 2016). We remark that similar to the standard one-step Bellman equation, which is a recursive relation that expresses v_π in terms of the expected one-stage reward and the expected total future rewards given by v_π itself, one can use the strong Markov property to derive other recursive relations satisfied by v_π , in which the expected one-stage reward is replaced by the expected rewards attained by π up to some random stopping time. This gives rise to a general class of Bellman equations, of which (6) is one example. Earlier works on using such equations in TD

Here $P_{\pi, \gamma}^\lambda$ is an $N \times N$ substochastic matrix, $r_{\pi, \gamma}^\lambda \in \mathbb{R}^N$ is a vector of expected discounted total rewards attained by π up to some random time depending on the function λ , and they can be expressed in terms of P_π and τ_π as

$$P_{\pi, \gamma}^\lambda = I - (I - P_\pi \Gamma \Lambda)^{-1} (I - P_\pi \Gamma), \quad r_{\pi, \gamma}^\lambda = (I - P_\pi \Gamma \Lambda)^{-1} \tau_\pi. \quad (7)$$

ETD(λ) aims to solve a projected version of the Bellman equation (6) (Sutton et al., 2016), which takes the following forms in the space of approximate value functions and in the space of the θ -parameters, respectively:

$$v = \Pi (r_{\pi, \gamma}^\lambda + P_{\pi, \gamma}^\lambda v), \quad v \in \text{column-space}(\Phi), \quad \iff \quad C\theta + b = 0, \quad \theta \in \mathbb{R}^n. \quad (8)$$

Here Π is a projection onto the approximation subspace with respect to a weighted Euclidean norm or seminorm, under a condition on the approximation architecture that will be explained shortly. The weights that define this norm also define the diagonal entries M_{ss} , $s \in \mathcal{S}$, of a diagonal matrix \bar{M} , which are given by

$$\text{diag}(\bar{M}) = d_{\pi^o, i}^\top (I - P_{\pi, \gamma}^\lambda)^{-1}, \quad \text{with } d_{\pi^o, i} \in \mathbb{R}^N, \quad d_{\pi^o, i}(s) = d_{\pi^o}(s) \cdot i(s), \quad s \in \mathcal{S}, \quad (9)$$

where $d_{\pi^o}(s) > 0$ denotes the steady state probability of state s for the behavior policy π^o , under Assumption 1(ii). For the corresponding linear equation in the θ -space in (8),

$$C = -\Phi^\top \bar{M} (I - P_{\pi, \gamma}^\lambda) \Phi, \quad b = \Phi^\top \bar{M} r_{\pi, \gamma}^\lambda. \quad (10)$$

From the expression (9) of the diagonal matrix \bar{M} , the most important difference between the earlier TD algorithms and ETD(λ) can be seen. For on-policy TD(λ), in stead of (9), the target matrix \bar{M} is determined by the steady state probabilities of the states under the target policy π under an ergodicity assumption (Tsitisklis and Van Roy, 1997), and for off-policy TD(λ), it is determined by the steady state probabilities $d_{\pi^o}(s)$ under the behavior policy π^o . Here, due to the emphatic weighting scheme (3)-(5), the diagonals of \bar{M} given by (9) reflect the occupation frequencies (with respect to $P_{\pi, \gamma}^\lambda$) of the target policy rather than the behavior policy.

Let $\|\cdot\|$ denote the (unweighted) Euclidean norm. The matrix C is said to be *negative definite* if there exists $c > 0$ such that $\theta^\top C \theta \leq -c \|\theta\|^2$ for all $\theta \in \mathbb{R}^n$; and *negative semidefinite* if in the preceding inequality $c = 0$. A salient property of ETD(λ) is that the matrix C is always negative semidefinite (Sutton et al., 2016), and under natural and mild conditions, C is negative definite. This is proved in our work (2015a) and summarized below.

Call those states s with $M_{ss} > 0$ *emphatized states* (define this set of states to be empty if \bar{M} given by Equation 9 is ill-defined, a case we will not encounter).

Assumption 2 (condition on the approximation architecture)

The set of feature vectors of *emphatized states*, $\{\phi(s) \mid s \in \mathcal{S}, M_{ss} > 0\}$, contains n linearly independent vectors.

Learning include the paper (Sutton, 1995) and Chap. 5.3 of the book (Bertsekas and Tsitsiklis, 1996). Recently, Ueno et al. (2011) considered an even broader class of Bellman equations using the concept of estimating equations from statistics, and Yu and Bertsekas (2012) focused on a special class of generalized Bellman equations and discussed their potential advantages from an approximation viewpoint. But an in-depth study of the application of such equations is still lacking currently. Because generalized Bellman equations offer flexible ways to address the bias vs. variance problem in learning the value functions of a policy, they are especially important and deserve further study, in our opinion.

Theorem 1 (Yu, 2015a, Prop. C.2) *Under Assumption 1, the matrix C is negative definite if and only if Assumption 2 holds.*

Assumption 2, which implies the linear independence of the columns of Φ , is satisfied in particular if the set of feature vectors, $\{\phi(s) \mid s \in \mathcal{S}, i(s) > 0\}$, contains n linearly independent vectors, since states with positive interest $i(s)$ are among the emphasized states.⁸ So this assumption can be easily satisfied in reinforcement learning without model knowledge.⁹

In view of Theorem 1, under Assumptions 1-2, the equation $C\theta + b = 0$ has a unique solution θ^* ; equivalently, $\Phi\theta^*$ is the unique solution to the projected Bellman equation (7):

$$\Phi\theta^* = \Pi(v_{\pi,\gamma}^\lambda + P_{\pi,\gamma}^\lambda \Phi\theta^*),$$

where Π is a well-defined projection operator that projects a vector in \mathbb{R}^N onto the approximation subspace with respect to the seminorm on \mathbb{R}^N given by

$$\sqrt{\sum_{s \in \mathcal{S}} \bar{M}_{ss} \cdot v(s)^2}, \quad \forall v \in \mathbb{R}^N$$

(which is a norm if $\bar{M}_{ss} > 0$ for all $s \in \mathcal{S}$). The relation between the approximate value function $v = \Phi\theta^*$ and the desired value function v_π , in particular, the approximation error, can be characterized by using the oblique projection viewpoint (Scherrer, 2010) for projected Bellman equations.¹⁰

The almost sure convergence of ETD(λ) to θ^* is proved in (Yu, 2015a, Theorem 2.2) under Assumptions 1 and 2, for diminishing stepsize satisfying $\alpha_t = O(1/t)$ and $\frac{\alpha_t - \alpha_{t+1}}{\alpha_t} = O(1/t)$. Despite this convergence guarantee, the stepsize range is too narrow for applications, as we discussed in the introduction. In this paper we will focus on constrained ETD(λ) algorithms that restrict the θ -iterates in a bounded set, but can operate with much larger stepsizes and also suffer less from the issue of high variance in off-policy learning. We will analyze their behavior under Assumptions 1 and 2, although our analysis extends to the case without Assumption 2 (see the discussion in Section 5.1).

8. This follows from the definition (9) of the diagonals \bar{M}_{ss} . Since $(I - P_{\pi,\gamma}^\lambda)^{-1} = I + \sum_{k=1}^{\infty} (P_{\pi,\gamma}^\lambda)^k \geq I$, we have $\text{diag}(M) = d_{\pi,\gamma}^{-1}(I - P_{\pi,\gamma}^\lambda)^{-1} \geq d_{\pi,\gamma}^{-1}$. Hence $i(s) > 0$ implies $\bar{M}_{ss} \geq d_{\pi,\gamma}^{-1} \cdot i(s) > 0$.

9. There is another way to verify Assumption 2 without calculating M . Suppose ETD(λ) starts from a state S_0 with $i(S_0) > 0$. Then it can be shown that if $S_t = s$ and $M_t > 0$, we must have $M_{ss} > 0$. This means that as soon as we find among states S_t with emphasis weights $M_t > 0$ n states that have linearly independent feature vectors, we can be sure that Assumption 2 is satisfied.

10. Briefly speaking, Scherrer (2010) showed that the solutions of projected Bellman equations are oblique projections of v_π on the approximation subspace. An oblique projection is defined by two nonorthogonal subspaces of equal dimensions and is the projection onto the first subspace orthogonally to the second (Saad, 2003). In the special case of ETD(λ), the first of these two subspaces is the approximation subspace $\{v \in \mathbb{R}^N \mid v = \Phi\theta \text{ for some } \theta \in \mathbb{R}^n\}$, and the second is the image of the approximation subspace under the linear transformation $(I - P_{\pi,\gamma}^\lambda)^\top M$. Essentially it is the angle between the two subspaces that determines the approximation bias $\Phi\theta^* - \Pi v_\pi$ in the worst case, for a worst-case choice of $r_{\pi,\gamma}^\lambda$. (For details, see also Yu and Bertsekas 2012, Sec. 2.2.) Recently, for the case of constant λ, i and γ , Hallak et al. (2016) derived bounds on the approximation bias that are based on contraction arguments and are comparable to the bound for on-policy TD(λ) (Tsitiklis and Van Roy, 1997). These bounds lie above the bounds given by the oblique projection view (cf. Yu and Bertsekas, 2010; Yu and Bertsekas, 2012, Sec. 2.2); however, they are expressed in terms of λ and γ , so they give us explicit numbers instead of analytical expressions to bound the approximation bias.

2.4 Constrained ETD(λ), Averaged Processes and Mean ODE

We consider first a constrained version of ETD(λ) that simply scales the θ -iterates, if necessary, to keep them bounded:

$$\theta_{t+1} = \Pi_B(\theta_t + \alpha_t \tilde{e}_t \cdot \rho_t (R_t + \gamma_{t+1} \phi(S_{t+1})^\top \theta_t - \phi(S_t)^\top \theta_t)), \quad (11)$$

where Π_B is the Euclidean projection onto a closed ball $B \subset \mathbb{R}^n$ at the origin with radius r_B : $B = \{\theta \in \mathbb{R}^n \mid \|\theta\| \leq r_B\}$. Under Assumptions 1 and 2, when the radius r_B is sufficiently large (greater than the threshold given in Lemma 1 below), from any given initial (e_0, F_0, θ_0) , the algorithm (11) converges almost surely to θ^* , for diminishing stepsize $\alpha_t = O(1/t)$ (Yu, 2015a, Theorem 4.1).

Our interest in this paper is to apply (11) with a much larger range of stepsizes, in particular, constant stepsize or stepsize that diminishes much more slowly than $O(1/t)$. In Sections 3 and 4, we will analyze the algorithm (11) and its two variants for such stepsizes. To prepare for the analysis, in the rest of this section, we review several results from our prior work (2015a) that will be needed.

First, we discuss about the ‘‘mean ODE’’ that we wish to associate with (11). It is the projected ODE

$$\dot{x} = \bar{h}(x) + z, \quad z \in -\mathcal{N}_B(x), \quad (12)$$

where the function \bar{h} is the left-hand side of the equation $Cx + b = 0$ we want to solve:

$$\bar{h}(x) = Cx + b; \quad (13)$$

$\mathcal{N}_B(x)$ is the normal cone of B at x (i.e., $\mathcal{N}_B(x) = \{0\}$ for x in the interior of B and $\mathcal{N}_B(x) = \{ax \mid a \geq 0\}$ for x on the boundary of B); and z is the boundary reflection term that cancels out the component of $\bar{h}(x)$ in $\mathcal{N}_B(x)$ (i.e., $z = -y$ where y is the projection of $\bar{h}(x)$ on $\mathcal{N}_B(x)$), and it is the ‘‘minimal force’’ needed to keep the solution $x(\cdot)$ of (12) in B (Kushner and Yin, 2003, Chap. 4.3).

The negative definiteness of the matrix C ensures that when the radius of B is sufficiently large, the boundary reflection term is zero for all $x \in B$ and the projected ODE (12) has no stationary points other than θ^* (see Yu 2015a, Sec. 4.1 for a simple proof):

Lemma 1 *Let $c > 0$ be such that $x^\top Cx \leq -c|x|^2$ for all $x \in \mathbb{R}^n$. Suppose B has a radius $r_B > |b|/c$. Then θ^* lies in the interior of B ; a solution $x(\tau), \tau \in [0, \infty)$, to the projected ODE (12) for an initial condition $x(0) \in B$ coincides with the unique solution to $\dot{x} = \bar{h}(x)$, with the boundary reflection term being $z(\cdot) \equiv 0$; and the only solution $x(\tau), \tau \in (-\infty, +\infty)$, of (12) in B is $x(\cdot) \equiv \theta^*$.*

Informally speaking, suppose we have proved that (12) is the mean ODE for the algorithm (11) under stepsizes of our interest. Then applying powerful convergence theorems from stochastic approximation theory (Kushner and Yin, 2003), we can assert that the iterates θ_t will eventually ‘‘follow closely’’ a solution of the mean ODE. This together with the solution property of the mean ODE given in Lemma 1 will then give us a characterization of the asymptotic behavior of the algorithm (11) for a constraint set B with sufficiently large radius.

Several properties of the ETD(λ) iterates will be important in proving that (12) is indeed the mean ODE for (11) and reflects its average dynamics. We now discuss two such properties (other key properties will be given in Appendix A). They concern the ergodicity of the Markov chain $\{(S_t, A_t, e_t, F_t)\}$ on the joint space of states, actions and traces, and the convergence of certain averaged sequences associated with the algorithm (11). They will also be useful in analyzing variants of (11).

Let $Z_t = (S_t, A_t, e_t, F_t)$, $t \geq 0$. It was shown in (Yu, 2015a) that under Assumption 1, $\{Z_t\}$ is a weak Feller Markov chain¹¹ on the infinite state space $S \times \mathcal{A} \times \mathbb{R}^{r+1}$ and is ergodic. Specifically, on a metric space, a sequence of probability measures $\{\mu_t\}$ is said to *converge weakly* to a probability measure μ if for any bounded continuous function f , $\int f d\mu_t \rightarrow \int f d\mu$ as $t \rightarrow \infty$ (Dudley, 2002, Chap. 9.3). We are interested in the weak convergence of the occupation probability measures of the process $\{Z_t\}$, where for each initial condition $Z_0 = z$, the *occupation probability measures* $\mu_{z,t}$, $t \geq 0$, are defined by $\mu_{z,t}(D) = \frac{1}{t+1} \sum_{k=0}^t \mathbb{1}(Z_k \in D)$ for any Borel subset D of $S \times \mathcal{A} \times \mathbb{R}^{r+1}$, with $\mathbb{1}(\cdot)$ denoting the indicator function.

Theorem 2 (ergodicity of $\{Z_t\}$; Yu, 2015a, Theorem 3.2) *Under Assumption 1, the Markov chain $\{Z_t\}$ has a unique invariant probability measure ζ , and for each initial condition $Z_0 = z$, the sequence $\{\mu_{z,t}\}$ of occupation probability measures converges weakly to ζ , almost surely.*

Let \mathbb{E}_ζ denote expectation with respect to the stationary process $\{Z_t\}$ with ζ as its initial distribution. By the definition of weak convergence, the weak convergence of $\{\mu_{z,t}\}$ given in Theorem 2 implies that for each given initial condition of Z_0 , the averages $\frac{1}{t} \sum_{k=0}^{t-1} f(Z_k)$ converge almost surely to $\mathbb{E}_\zeta\{f(Z_0)\}$ for any bounded continuous function f .¹² To study the average dynamics of the algorithm (11), however, we need to also consider unbounded functions. In particular, the function related to both (11) and the unconstrained ETD(λ) is $h : \mathbb{R}^n \times \Xi \rightarrow \mathbb{R}^n$,

$$h(\theta, \xi) = e \cdot \rho(s, a) (r(s, a, s') + \gamma(s') \phi(s')^\top \theta - \phi(s)^\top \theta), \quad (14)$$

where

$$\xi = (e, F, s, a, s') \in \Xi := \mathbb{R}^{n+1} \times S \times \mathcal{A} \times S.$$

Writing ξ_t for the traces and transition at time t : $\xi_t = (e_t, F_t, S_t, A_t, S_{t+1})$, we can express the recursion (11) equivalently as

$$\theta_{t+1} = \Pi_B(\theta_t + \alpha_t h(\theta_t, \xi_t) + \alpha_t e_t \cdot \tilde{\omega}_{t+1}), \quad (15)$$

where $\tilde{\omega}_{t+1} = \rho_t(R_t - r(S_t, A_t, S_{t+1}))$ is the noise part of the observed reward.

The convergence to $h(\theta)$ of the averaged sequence $\frac{1}{t} \sum_{k=0}^{t-1} h(\theta, \xi_k)$, with θ held fixed and t going to infinity, will be needed to prove that (12) is the mean ODE of (11). Since

11. See Section 4.3.1 or the book by Meyn and Tweedie (2009, Chap. 6) for the definition and properties of weak Feller Markov chains.

12. With the usual discrete topology for the finite space $S \times \mathcal{A}$ and the usual topology for the Euclidean space \mathbb{R}^{n+1} , the space $S \times \mathcal{A} \times \mathbb{R}^{n+1}$ equipped with the product topology is metrizable. A continuous function $f(s, a, e, F)$ on this space is a function that is continuous in (e, F) for each $(s, a) \in S \times \mathcal{A}$.

$\bar{h}(\theta) = C\theta + b$, this convergence for each fixed θ can be identified with the convergence of the matrix and vector iterates calculated by ELSTD(λ)—the least-squares version of ETD(λ)—to approximate the left-hand side of the equation $C\theta + b = 0$. It was proved in our work (2015a) as a special case of the convergence of averaged sequences for a larger set of functions including $h(\theta, \cdot)$. Since this general result will be needed in analyzing variants of (11), we give its formulation here.

Throughout the rest of the paper, we let $\|\cdot\|$ denote the infinity norm of a Euclidean space, and we use this notation for both vectors and matrices (viewed as vectors). For \mathbb{R}^m -valued random variables X_t , we say $\{X_t\}$ converges to a random variable X in mean if $\mathbb{E}\|X_t - X\| \rightarrow 0$ as $t \rightarrow \infty$.

Consider a vector-valued function $g : \Xi \rightarrow \mathbb{R}^m$ such that with $\xi = (e, F, s, a, s')$, $g(\xi)$ is Lipschitz continuous in (e, F) uniformly in (s, a, s') . That is, there exists a finite constant L_g such that for any $(e, F)_t, (\hat{e}, \hat{F}) \in \mathbb{R}^{r+1}$,

$$\|g(e, F, s, a, s') - g(\hat{e}, \hat{F}, s, a, s')\| \leq L_g \|(e, F) - (\hat{e}, \hat{F})\|, \quad \forall (s, a, s') \in S \times \mathcal{A} \times S. \quad (16)$$

For each $\theta \in \mathbb{R}^n$, the function $h(\theta, \cdot)$ in (14) is a special case of g . The convergence of the averaged sequence $\frac{1}{t} \sum_{k=0}^{t-1} g(\xi_k)$ is given in the theorem below; the part on convergence in mean will be used frequently later in this paper. The convergence of $\frac{1}{t} \sum_{k=0}^{t-1} h(\theta, \xi_k)$ then follows as a special case.

Theorem 3 (convergence of averaged sequences; Yu, 2015a, Theorems 3.1-3.3)

Let g be a vector-valued function satisfying the Lipschitz condition (16). Then under Assumption 1, $\mathbb{E}_\zeta[\|g(\xi_0)\|] < \infty$ and for any given initial $(e_0, F_0) \in \mathbb{R}^{r+1}$, as $t \rightarrow \infty$, $\frac{1}{t} \sum_{k=0}^{t-1} g(\xi_k)$ converges to $\bar{g} = \mathbb{E}_\zeta[g(\xi_0)]$ in mean and almost surely.

Corollary 1 (Yu, 2015a, Theorem 2.1) *Under Assumption 1, for the functions \bar{h}, h given in (13), (14) respectively, the following hold: For each $\theta \in \mathbb{R}^n$, $\mathbb{E}_\zeta[\|h(\theta, \xi_0)\|] < \infty$ and $\bar{h}(\theta) = \mathbb{E}_\zeta[h(\theta, \xi_0)]$; and for any given initial $(e_0, F_0) \in \mathbb{R}^{r+1}$, as $t \rightarrow \infty$, $\frac{1}{t} \sum_{k=0}^{t-1} h(\theta, \xi_k)$ converges to $\bar{h}(\theta)$ in mean and almost surely.*

3. Convergence Results for Constrained ETD(λ)

In this section we present the convergence properties of the constrained ETD(λ) algorithm (11) and several variants of it, for constant stepsize and for stepsize that diminishes slowly. We will explain briefly how the results are obtained, leaving the detailed analyses to Section 4. The first set of results about the algorithm (11) will be given first in Section 3.1, followed by similar results in Section 3.2 for two variant algorithms that have biases but can mitigate the variance issue in off-policy learning better. These results are obtained through applying two general convergence theorems from (Kushner and Yin, 2003), which concern weak convergence of stochastic approximation algorithms for diminishing and constant stepsize. Finally, the constant-stepsize case will be analyzed further in Section 3.3, in order to refine some results of Sections 3.1-3.2 so that the asymptotic behavior of the algorithms for a fixed stepsize can be characterized explicitly. In that subsection, besides the three algorithms just mentioned, we will also discuss another variant algorithm with perturbation.

Regarding notation, recall that $\mathbb{1}(\cdot)$ is the indicator function, $|\cdot|$ stands for the usual (unweighted) Euclidean norm and $\|\cdot\|$ the infinity norm for \mathbb{R}^m . We denote by $N_\delta(D)$ the δ -neighborhood of a set $D \subset \mathbb{R}^m$: $N_\delta(D) = \{x \in \mathbb{R}^m \mid \inf_{y \in D} |x - y| \leq \delta\}$, and we write $N_\delta(\theta^*)$ for the δ -neighborhood of θ^* . For the iteration index t , the notation $t \in [k_1, k_2]$ or $t \in [k_1, k_2]$ will be used to mean that the range of t is the set of integers in the interval $[k_1, k_2]$ or $[k_1, k_2)$. More definitions and notation will be introduced later where they are needed.

3.1 Main Results

We consider first the algorithm (11) for diminishing stepsize. Let the stepsize change slowly in the following sense.

Assumption 3 (condition on diminishing stepsize) *The (deterministic) nonnegative sequence $\{\alpha_t\}$ satisfies that $\sum_{t \geq 0} \alpha_t = \infty$, $\alpha_t \rightarrow 0$ as $t \rightarrow \infty$, and for some sequence of integers $m_t \rightarrow \infty$,*

$$\lim_{t \rightarrow \infty} \sup_{0 \leq j \leq m_t} \left| \frac{\alpha_{t+j} - 1}{\alpha_t} \right| = 0. \quad (17)$$

The condition (17) is the condition A.8.2.8 in (Kushner and Yin, 2003, Chap. 8) and allows stepsizes much larger than $O(1/t)$. We can have $\alpha_t = O(t^{-\beta})$, $\beta \in (0, 1]$, and even larger stepsizes are possible. For example, partition the time interval $[0, \infty)$ into increasingly longer intervals $I_k, k \geq 0$, and set α_t to be constant within each interval I_k . Then the condition (17) can be fulfilled by letting the constants for each I_k decrease as $O(k^{-\beta})$, $\beta \in (0, 1]$.

We now state the convergence result. For any $T > 0$, let $m(k, T) = \min\{t \geq k \mid \sum_{j=k}^t \alpha_j > T\}$. If we draw a continuous timeline and put each iteration of the algorithm at a specific moment, with the stepsize α_j being the length of time between iterations j and $j+1$, then $m(k, T)$ is the latest iteration before time T has elapsed since the k -th iteration. If $\alpha_t = O(t^{-\beta})$, $\beta \in (0, 1]$, for example, then for fixed T , there are $O(k^\beta)$ iterates between the k -th and $m(k, T)$ -th iteration.

Recall that Assumption 1, Assumption 2, and Lemma 1 are given in Sections 2.1, 2.3, and 2.4, respectively.

Theorem 4 (convergence of constrained ETD with diminishing stepsize)

Suppose Assumptions 1-2 hold and the radius of B exceeds the threshold given in Lemma 1. Let $\{\theta_t\}$ be generated by the algorithm (11) with stepsize $\{\alpha_t\}$ satisfying Assumption 3, from any given initial condition (ϵ_0, F_0) . Then there exists a sequence $T_k \rightarrow \infty$ such that for any $\delta > 0$,

$$\limsup_{k \rightarrow \infty} \mathbf{P} \left(\theta_t \notin N_\delta(\theta^*), \text{ some } t \in [k, m(k, T_k)] \right) = 0.$$

This theorem implies $\theta_t \rightarrow \theta^*$ in probability. Since $\{\theta_t\}$ is bounded, by (Dudley, 2002, Theorem 10.3.6), θ_t must also converge to θ^* in mean:

Corollary 2 (convergence in mean) *In the setting of Theorem 4, $\mathbb{E}[\|\theta_t - \theta^*\|] \rightarrow 0$ as $t \rightarrow \infty$.*

Another important note is that the conclusion of Theorem 4 is much stronger than that $\theta_t \rightarrow \theta^*$ in probability. Here as $k \rightarrow \infty$, we consider an increasingly longer segment $[k, m(k, T_k)]$ of iterates, and are able to conclude that the probability of that *entire segment* being inside an arbitrarily small neighborhood of θ^* approaches 1. This is the power of the weak convergence methods (Kushner and Clark, 1978; Kushner and Shwartz, 1984; Kushner and Yin, 2003), by which our conclusion is obtained.

In the case of constant stepsize, we consider all the trajectories that can be produced by the algorithm (11) using some constant stepsize, and we ask what the properties of these trajectories are in the limit as the stepsize parameter approaches 0. Here there is a common timeline used in relating trajectories generated with different stepsizes (and it comes from the ODE-based analysis): we imagine again a continuous timeline, along which we put the iterations at moments that are evenly separated in time by α , if the stepsize parameter is α . The scalars T, T_α in the theorem below represent amounts of time with respect to this continuous timeline.

Theorem 5 (convergence of constrained ETD with constant stepsize)

Suppose Assumptions 1-2 hold and the radius of B exceeds the threshold given in Lemma 1. For each $\alpha > 0$, let $\{\theta_t^\alpha\}$ be generated by the algorithm (11) with constant stepsize α , from any given initial condition (ϵ_0, F_0) . Let $\{k_\alpha \mid \alpha > 0\}$ be any sequence of nonnegative integers that are nondecreasing as $\alpha \rightarrow 0$. Then the following hold:

- (i) For any $\delta > 0$,
- $$\lim_{T \rightarrow \infty} \lim_{\alpha \rightarrow 0} \frac{1}{T/\alpha} \sum_{t=k_\alpha}^{k_\alpha + \lceil T/\alpha \rceil} \mathbb{1}(\theta_t^\alpha \in N_\delta(\theta^*)) = 1 \quad \text{in probability.}$$
- (ii) Let $\alpha k_\alpha \rightarrow \infty$ as $\alpha \rightarrow 0$. Then there exists a sequence $\{T_\alpha \mid \alpha > 0\}$ with $T_\alpha \rightarrow \infty$ as $\alpha \rightarrow 0$, such that for any $\delta > 0$,
- $$\limsup_{\alpha \rightarrow 0} \mathbf{P} \left(\theta_t^\alpha \notin N_\delta(\theta^*), \text{ some } t \in [k_\alpha, k_\alpha + T_\alpha/\alpha] \right) = 0.$$

Part (ii) above is similar to Theorem 4. Here as $\alpha \rightarrow 0$, an increasingly longer segment $[k_\alpha, k_\alpha + T_\alpha/\alpha]$ of the tail of the trajectory $\{\theta_t^\alpha\}$ is considered, and it is concluded that the probability of that *entire segment* being inside an arbitrarily small neighborhood of θ^* approaches 1. Part (i) above, roughly speaking, says that as α diminishes, within the segment $[k_\alpha, k_\alpha + T/\alpha]$, the fraction of iterates θ_t^α that lie in a small δ -neighborhood of θ^* approaches 1 for sufficiently large T .

We give the proofs of Theorems 4-5 in Section 4.1. As mentioned earlier, most of our efforts will be to use the properties of ETD iterates to show that the conditions of two general convergence theorems from stochastic approximation theory (Kushner and Yin, 2003, Theorems 8.2.2, 8.2.3) are satisfied by the algorithm (11). After that we can specialize the conclusions of those theorems to obtain Theorems 4-5. Specifically, after furnishing their conditions, applying (Kushner and Yin, 2003, Theorems 8.2.2, 8.2.3) will give us directly the desired conclusions in Theorems 4-5 with $N_\delta(L_B)$ in place of $N_\delta(\theta^*)$, where $N_\delta(L_B)$ is the δ -neighborhood of the *limit set* L_B for the projected ODE (12). This limit set is defined as follows:

$$L_B := \bigcap_{\tau > 0} \overline{\bigcup_{x(0) \in B} \{x(\tau), \tau \geq \tau\}}$$

where $x(\tau)$ is a solution of the projected ODE (12) with initial condition $x(0)$, the union is over all the solutions with initial $x(0) \in B$, and D for a set D denotes taking the closure of D . It can be shown that $L_B = \{\theta^*\}$ under our assumptions, so Theorems 4-5 will then follow as special cases of (Kushner and Yin, 2003, Theorems 8.2.2, 8.2.3).

Remark 1 (on weak convergence methods) The theorems from the book (Kushner and Yin, 2003) which we will apply are based on the weak convergence methods. While it is beyond the scope of this paper to explain these powerful methods, let us mention here a few basic facts about them to elucidate the origin of the convergence theorems we gave above. In the Framework of (Kushner and Yin, 2003), one studies a trajectory of iterates produced by an algorithm by working with continuous-time processes that are piecewise constant or linear interpolations of the iterates. (Often one also left-shifts a trajectory of iterates to bring the “asymptotic part” of the trajectory closer to the origin of the continuous time axis.) In the case of our problem, for example, for diminishing stepsize, these continuous-time processes are $x^k(\tau)$, $\tau \in [0, \infty)$, indexed by $k \geq 0$, where for each k , x^k is a piecewise constant interpolation of θ_{k+t} , $t \geq 0$, given by $x^k(\tau) = \theta_k$ for $\tau \in [0, \alpha_k)$ and $x^k(\tau) = \theta_{k+t}$ for $\tau \in [\sum_{m=0}^{t-1} \alpha_{k+m}, \sum_{m=0}^t \alpha_{k+m})$, $t \geq 1$. Similarly, for constant stepsize, the continuous-time processes involved are $x^\alpha(\tau)$, $\tau \in [0, \infty)$, indexed by $\alpha > 0$, and for each α , x^α is a piecewise constant interpolation of $\theta_{k+\alpha t}$, $t \geq 0$, given by $x^\alpha(\tau) = \theta_{k+\alpha t}$ for $\tau \in [t\alpha, (t+1)\alpha)$. The behavior of the sequence $\{x^k\}$ or $\{x^\alpha\}$ as $k \rightarrow \infty$ or $\alpha \rightarrow 0$, tells us the asymptotic properties of the algorithm as the number of iterations grows to infinity or as the stepsize parameter approaches 0. With the weak convergence methods, one considers the probability distributions of the continuous-time processes in such sequences, and analyze the convergence of these probability distributions and their limiting distributions along any subsequences. Here each continuous-time process takes values in a space of vector-valued functions on $[0, \infty)$ or $(-\infty, \infty)$ that are right-continuous and have left-hand limits, and this function space equipped with an appropriate metric, known as the Skorohod metric, is a complete separable metric space (Kushner and Yin, 2003, p. 238-240). On this space, one analyzes the weak convergence of the probability distributions of the continuous-time processes. Under certain conditions on the algorithm, the general conclusions from (Kushner and Yin, 2003, Theorems 8.2.2, 8.2.3) are that any subsequence of these probability distributions contains a further subsequence which is convergent, and that all the limiting probability distributions must assign the full measure 1 to the set of solutions of the mean ODE associated with the algorithm. This general weak convergence property then yields various conclusions about the asymptotic behavior of the algorithm and its relation with the mean ODE solutions. When further combined with the solution properties of the mean ODE, it leads to specific results such as the theorems we give in this section. ■

3.2 Two Variants of Constrained ETTD(λ) with Biases

We now consider two simple variants of (11). They constrain the ETTD iterates even more, at a price of introducing biases in this process, so that unlike (11), they can no longer get to θ^* arbitrarily closely. Instead they aim at a small neighborhood of θ^* , the size of which depends on how they modify the ETTD iterates. On the other hand, because the trace iterates $\{(e_t, F_t)\}$ can have unbounded variances and are also naturally unbounded in

common off-policy situations (see discussions in Yu, 2012, Prop. 3.1 and Footnote 3, p. 3320-3322 and Yu, 2015a, Remark A.1, p. 23), these variant algorithms have the advantage that they make the θ -iterates more robust against the drastic changes that can occur to the trace iterates. Indeed our definition of the variant algorithms below follows a well-known approach to “robustifying” algorithms in stochastic approximation theory (see discussions in Kushner and Yin, 2003, p. 23 and p. 141).

The two variant algorithms are defined as follows. For each $K > 0$, let $\psi_K : \mathbb{R}^n \rightarrow \mathbb{R}^n$ be a bounded Lipschitz continuous function such that

$$\|\psi_K(x)\| \leq \|x\| \quad \forall x \in \mathbb{R}^n, \quad \text{and} \quad \psi_K(x) = x \quad \text{if } \|x\| \leq K. \quad (18)$$

(For instance, let $\psi_K(x) = \pi x/|x|$ if $|x| \geq \bar{r}$ and $\psi_K(x) = x$ otherwise, for $\bar{r} = \sqrt{\pi}K$; or let $\psi_K(x)$ be the result of truncating each component of x to be within $[-K, K]$.) For the first variant of the algorithm (11), we replace e_t in (11) by $\psi_K(e_t)$:

$$\theta_{t+1} = \Pi_B \left(\theta_t + \alpha_t \psi_K(e_t) \cdot \rho_t (R_t + \gamma_{t+1} \phi(S_{t+1})^\top \theta_t - \phi(S_t)^\top \theta_t) \right). \quad (19)$$

For the second variant, we apply ψ_K to bound the entire increment in (11) before it is multiplied by the stepsize α_t and added to θ_t :

$$\theta_{t+1} = \Pi_B \left(\theta_t + \alpha_t \psi_K(Y_t) \right), \quad \text{where } Y_t = e_t \cdot \rho_t (R_t + \gamma_{t+1} \phi(S_{t+1})^\top \theta_t - \phi(S_t)^\top \theta_t). \quad (20)$$

As will be proved later, these two algorithms are associated with mean ODEs of the form,

$$\dot{x} = \bar{h}_K(x) + z, \quad z \in -N_B(x), \quad (21)$$

where $\bar{h}_K : \mathbb{R}^n \rightarrow \mathbb{R}^n$ is determined by each algorithm and deviates from the function $h(x) = Cx + b$ due to the alterations introduced by ψ_K . This ODE is similar to the projected ODE (12), except that since \bar{h}_K is an approximation of \bar{h} , θ^* is no longer a stable or stationary point for the mean ODE (21). The two variant algorithms thus have a bias in their θ -iterates, and the bias can be made smaller by choosing a larger K . This is reflected in the two convergence theorems given below. They are similar to the previous two theorems for the algorithm (11), except that now given a desired small neighborhood of θ^* , a sufficiently large K needs to be used in order for the θ -iterates to reach that neighborhood of θ^* and exhibit properties similar to those shown in the previous case.

Theorem 6 (constrained ETTD variants with diminishing stepsize)

In the setting of Theorem 4, let $\{\theta_t\}$ be generated instead by the algorithm (19) or (20), with a bounded Lipschitz continuous function ψ_K satisfying (18), and with stepsize $\{\alpha_t\}$ satisfying Assumption 3. Then for each $\delta > 0$, there exists $K_\delta > 0$ such that if $K \geq K_\delta$, then it holds for some sequence $T_k \rightarrow \infty$ that

$$\limsup_{k \rightarrow \infty} \mathbf{P} \left(\theta_t \notin N_\delta(\theta^*), \text{ some } t \in [k, m(k, T_k)] \right) = 0.$$

Theorem 7 (constrained ETTD variants with constant stepsize)

In the setting of Theorem 5, let $\{\theta_t\}$ be generated instead by the algorithm (19) or (20), with a bounded Lipschitz continuous function ψ_K satisfying (18) and with constant stepsize $\alpha > 0$. Let $\{K_\alpha | \alpha > 0\}$ be any sequence of nonnegative integers that are nondecreasing as $\alpha \rightarrow 0$. Then for each $\delta > 0$, there exists $K_\delta > 0$ such that the following hold if $K \geq K_\delta$:

- (i)
$$\lim_{T \rightarrow \infty} \lim_{\alpha \rightarrow 0} \frac{1}{T/\alpha} \sum_{t=k_\alpha}^{k_\alpha + \lceil T/\alpha \rceil} \mathbb{1}(\theta_t^\alpha \in N_\delta(\theta^*)) = 1 \quad \text{in probability.}$$
- (ii) Let $\alpha k_\alpha \rightarrow \infty$ as $\alpha \rightarrow 0$. Then there exists a sequence $\{T_\alpha \mid \alpha > 0\}$ with $T_\alpha \rightarrow \infty$ as $\alpha \rightarrow 0$, such that
- $$\limsup_{\alpha \rightarrow 0} \mathbf{P} \left(\theta_t^\alpha \notin N_\delta(\theta^*), \text{ some } t \in [k_\alpha, k_\alpha + T_\alpha/\alpha] \right) = 0.$$

We give the proofs of the above two theorems in Section 4.2. Because the proofs are similar for the two variant algorithms, we include in this paper only the proofs for the first variant—the proofs for the second variant can be found in the arXiv version of this paper (Yu, 2015b).

The proof arguments are largely the same as those that we will use first in Section 4.1 to prove Theorems 4-5 for the algorithm (11). Indeed, for all the three algorithms, the main proof step is the same, which is to apply the general conclusions of (Kushner and Yin, 2003, Theorems 8.2.2, 8.2.3) to establish the connection between the iterates of an algorithm and the solutions of an associated mean ODE, and this step does not concern what the solutions of the ODE are actually. (For the two variant algorithms, verifying that the conditions of Theorems 8.2.2, 8.2.3 in Kushner and Yin, 2003 are met is, in fact, easier because various functions involved in the analysis become bounded due to the use of the bounded function ψ_K .) For the two variant algorithms, the result of this step is that the same conclusions given in Theorems 4-5 hold with $N_\delta(L_B)$ in place of $N_\delta(\theta^*)$, where L_B is the limit set of the projected mean ODE (21) associated with each variant algorithm. To attain Theorems 6-7, we then combine this with the fact that by choosing K sufficiently large, one can make the limit set $L_B \subset N_\delta(\theta^*)$ for an arbitrarily small δ .

3.3 More about the Constant-stepsize Case

For the constant-stepsize case, the results given in Theorems 5 and 7 bear similarities to their counterparts for the diminishing stepsize case given in Theorems 4 and 6. However, they characterize the behavior of the iterates in the limit as the stepsize parameter approaches 0, and deal with only a finite segment of the iterates for each stepsize (although in their part (ii) both the segment's length $T_\alpha/\alpha \rightarrow \infty$ and its starting position $k_\alpha \rightarrow \infty$ as $\alpha \rightarrow 0$). So unlike in the diminishing stepsize case, these results do not tell us explicitly about the behavior of θ_t^α for a fixed stepsize α as we take t to infinity.

The purpose of the present subsection is to analyze further the case of a fixed stepsize just mentioned. We observe that for a fixed stepsize α , the iterates θ_t^α together with $Z_t = (S_t, A_t, \epsilon_t, F_t)$ form a weak Feller Markov chain $\{(Z_t, \theta_t^\alpha)\}$ (see Lemma 4, Section 4.3.1). Thus we can apply several ergodic theorems for weak Feller Markov chains (Meyn, 1989; Meyn and Tweedie, 2009) to analyze the constant-stepsize case and combine the implications from these theorems with the results we obtained previously using the weak convergence methods from stochastic approximation theory.

We now present our results using this approach. Let \mathcal{M}_α denote the set of invariant probability measures of the Markov chain $\{(Z_t, \theta_t^\alpha)\}$. This set depends on the particular

algorithm used to generate the θ -iterates, but we shall use the notation \mathcal{M}_α for all the algorithms we discuss here, for notational simplicity. We know that $\{Z_t\}$ has a unique invariant probability measure (Theorem 2, Section 2.4), but it need not be so for the Markov chain $\{(Z_t, \theta_t^\alpha)\}$ when $\{\theta_t^\alpha\}$ is generated by the algorithm (11) or its two variants. The set \mathcal{M}_α can therefore have multiple elements (it is nonempty; see Prop. 6, Section 4.3.2). We denote by \mathcal{M}_α the set that consists of the marginal of μ on B (the space of the θ 's), for all the invariant probability measures $\mu \in \mathcal{M}_\alpha$.

As in the previous analysis, we are interested in the behavior of multiple consecutive θ -iterates. In order to characterize that, we consider for each $m \geq 1$, the Markov chain

$$\left\{ ((Z_t, \theta_t^\alpha), (Z_{t+1}, \theta_{t+1}^\alpha), \dots, (Z_{t+m-1}, \theta_{t+m-1}^\alpha)) \right\}_{t \geq 0}$$

(i.e., each state now consists of m consecutive states of the chain $\{(Z_t, \theta_t^\alpha)\}$). We shall refer to this chain as the *m-step version* of $\{(Z_t, \theta_t^\alpha)\}$. Similar to \mathcal{M}_α , denote by \mathcal{M}_α^m the set of invariant probability measures of the m -step version of $\{(Z_t, \theta_t^\alpha)\}$, and correspondingly define \mathcal{M}_α^m to be the set of marginals of μ on B^m for all $\mu \in \mathcal{M}_\alpha^m$. The set \mathcal{M}_α^m is, of course, determined by \mathcal{M}_α , since each invariant probability measure in \mathcal{M}_α^m is just the m -dimensional distribution of a stationary Markov chain $\{(Z_t, \theta_t^\alpha)\}$.

Our first result, given in Theorem 8 below, says that for the algorithm (11), as the stepsize α approaches zero, the invariant probability measures in \mathcal{M}_α^m will concentrate their masses on an arbitrarily small neighborhood of $(\theta^*, \dots, \theta^*)$ (m copies of θ^*). Moreover, for a fixed stepsize, as the number of iterations grows to infinity, the expected maximal deviation of the m consecutive averaged iterates from θ^* can be bounded in terms of the masses those invariant probability measures assign to the vicinities of $(\theta^*, \dots, \theta^*)$. Here by averaged iterates, we mean

$$\bar{\theta}_t^\alpha = \frac{1}{t} \sum_{k=0}^{t-1} \theta_k^\alpha, \quad \forall t \geq 1, \quad (22)$$

and we shall refer to $\{\bar{\theta}_t^\alpha\}$ as the *averaged sequence* corresponding to $\{\theta_t^\alpha\}$. This iterative averaging is also known as ‘‘Polyak-averaging’’ when it is applied to accelerate the convergence of the θ -iterates (see Polyak and Juditsky, 1992; Kushner and Yin, 2003, Chap. 10; and the references therein). This is not the role of the averaging operation here, however. The purpose here is to bring to bear the ergodic theorems for weak Feller Markov chains, in particular, the weak convergence of certain averaged probability measures or occupation probability measures to the invariant probability measures of the m -step version of $\{(Z_t, \theta_t^\alpha)\}$. (For the details see Section 4.3, where the proofs of the results of this subsection will be given.) It can also be seen that for a sequence $\{\beta_t\}$ with $\beta_t \in [0, 1], \beta_t \rightarrow 0$ as $t \rightarrow \infty$, if we drop a fraction β_t of the terms in (22) when averaging the θ 's at each time t , the resulting differences in the averaged iterates $\bar{\theta}_t^\alpha$ are asymptotically negligible. Therefore, although our results below will be stated for (22), they apply to a variety of averaging schemes.

Recall that $N_\delta(\theta^*)$ denotes the closed δ -neighborhood of θ^* . In what follows, $N'_\delta(\theta^*)$ denotes the open δ -neighborhood of θ^* , i.e., the open ball around θ^* with radius δ . We write $[N_\delta(\theta^*)]^m$ or $[N'_\delta(\theta^*)]^m$ for the Cartesian product of m copies of $N_\delta(\theta^*)$ or $N'_\delta(\theta^*)$. Recall also that r_B is the radius of the constraint set B .

Theorem 8 *In the setting of Theorem 5, let $\{\theta_t^c\}$ be generated by the algorithm (11) with constant stepsize $\alpha > 0$, and let $\{\theta_t^c\}$ be the corresponding averaged sequence. Then the following hold for any $\delta > 0$ and $m \geq 1$:*

- (i) $\liminf_{\alpha \rightarrow 0} \inf_{\mu \in \mathcal{M}_{\alpha}^m} \mu([N_{\delta}(\theta^*)]^m) = 1$, and more strongly, with $m_{\alpha} = \lfloor \frac{m}{\alpha} \rfloor$,
- $$\liminf_{\alpha \rightarrow 0} \inf_{\mu \in \mathcal{M}_{m_{\alpha}}^m} \mu([N_{\delta}(\theta^*)]^{m_{\alpha}}) = 1.$$
- (ii) *For each stepsize α and any initial condition of (e_0, F_0, θ_0^c) ,*

$$\limsup_{k \rightarrow \infty} \mathbb{E} \left[\sup_{k \leq k < k+m} |\bar{\theta}_k^c - \theta^*| \right] \leq \delta \kappa_{\alpha, m} + 2r_B (1 - \kappa_{\alpha, m}),$$

where $\kappa_{\alpha, m} = \inf_{\mu \in \mathcal{M}_{\alpha}^m} \mu([N'_{\delta}(\theta^*)]^m)$.

Note that in part (ii) above, $\kappa_{\alpha, m} \rightarrow 1$ as $\alpha \rightarrow 0$ by part (i). Note also that for $m = 1$, the conclusions from the preceding theorem take the simplest form:

$$\liminf_{\alpha \rightarrow 0} \inf_{\mu \in \mathcal{M}_{\alpha}} \mu(N_{\delta}(\theta^*)) = 1,$$

$$\limsup_{t \rightarrow \infty} \mathbb{E} [|\bar{\theta}_t^c - \theta^*|] \leq \delta \kappa_{\alpha} + 2r_B (1 - \kappa_{\alpha}), \quad \text{for } \kappa_{\alpha} = \inf_{\mu \in \mathcal{M}_{\alpha}} \mu(N'_{\delta}(\theta^*)).$$

The conclusions for $m > 1$ are, however, much stronger. They also suggest that in practice, instead of simply choosing the last iterate of the algorithm as its final output at the end of its run, one can base that choice on the behavior of multiple consecutive $\bar{\theta}_k^c$ during the run.

For the two variant algorithms (19) and (20), we have a similar result given in Theorem 9 below. Here the neighborhood of $(\theta^*, \dots, \theta^*)$ around which the masses of the invariant probability measures are concentrated, depends not only on the stepsize α but also on the biases of these algorithms. The proofs of Theorems 8-9 are given in Section 4.3.2.

Theorem 9 *In the setting of Theorem 5, let $\{\theta_t^c\}$ be generated instead by the algorithm (19) or (20), with constant stepsize $\alpha > 0$ and with a bounded Lipschitz continuous function ψ_K satisfying (18). Let $\{\theta_t^c\}$ be the corresponding averaged sequence. Then the following hold:*

- (i) *For any given $\delta > 0$, there exists $K_{\delta} > 0$ such that for all $K \geq K_{\delta}$,*
- $$\liminf_{\alpha \rightarrow 0} \inf_{\mu \in \mathcal{M}_{\alpha}^m} \mu([N_{\delta}(\theta^*)]^m) = 1, \quad \forall m \geq 1,$$
- and more strongly, with $m_{\alpha} = \lfloor \frac{m}{\alpha} \rfloor$,
- $$\liminf_{\alpha \rightarrow 0} \inf_{\mu \in \mathcal{M}_{m_{\alpha}}^m} \mu([N_{\delta}(\theta^*)]^{m_{\alpha}}) = 1, \quad \forall m \geq 1.$$

- (ii) *Regardless of the choice of K , given any $\delta > 0$, $m \geq 1$ and stepsize α , for each initial condition of (e_0, F_0, θ_0^c) ,*

$$\limsup_{k \rightarrow \infty} \mathbb{E} \left[\sup_{k \leq k < k+m} |\bar{\theta}_k^c - \theta^*| \right] \leq \delta \kappa_{\alpha, m} + 2r_B (1 - \kappa_{\alpha, m}),$$

where $\kappa_{\alpha, m} = \inf_{\mu \in \mathcal{M}_{\alpha}^m} \mu([N'_{\delta}(\theta^*)]^m)$.

Finally, we consider a simple modification of the preceding algorithms, for which the conclusions of Theorems 8(ii) and 9(ii) can be strengthened. This is our motivation for introducing the modification, but we shall postpone the discussion till Remark 2 at the end of this subsection.

For any of the algorithms (11), (19) or (20), if the original recursion under a constant stepsize α can be written as

$$\theta_{t+1}^c = \Pi_B(\theta_t^c + \alpha Y_t^c),$$

we now modify this recursion formula by adding a perturbation term $\alpha \Delta_{\theta_t^c}$ as follows. Let

$$\theta_{t+1}^c = \Pi_B(\theta_t^c + \alpha Y_t^c + \alpha \Delta_{\theta_t^c}^c), \quad (23)$$

where for each $\alpha > 0$, $\Delta_{\theta_t^c}^c, t \geq 0$, are \mathbb{R}^n -valued random variables such that¹³

- (i) they are independent of each other and also independent of the process $\{Z_t\}$;
- (ii) they are identically distributed with zero mean and finite variance, where the variance can be bounded uniformly for all α ; and

- (iii) they have a positive continuous density function with respect to the Lebesgue measure. Below we refer to (23) as the perturbed version of the algorithm (11), (19) or (20).

Theorem 10 *In the setting of Theorem 5, let $\{\theta_t^c\}$ be generated instead by the perturbed version (23) of the algorithm (11) for a constant stepsize $\alpha > 0$, and let $\{\bar{\theta}_t^c\}$ be the corresponding averaged sequence. Then the conclusions of Theorems 5 and 8 hold. Furthermore, let the stepsize α be given. Then the Markov chain $\{(Z_t, \bar{\theta}_t^c)\}$ has a unique invariant probability measure $\bar{\mu}_{\alpha}$, and for any $\delta > 0$, $m \geq 1$ and initial condition of (e_0, F_0, θ_0^c) , almost surely,*

$$\liminf_{t \rightarrow \infty} \frac{1}{t} \sum_{k=0}^{t-1} \mathbb{1} \left(\sup_{k \leq j < k+m} |\theta_j^c - \theta^*| < \delta \right) \geq \bar{\mu}_{\alpha}^{(m)}([N'_{\delta}(\theta^*)]^m)$$

and

$$\limsup_{t \rightarrow \infty} |\bar{\theta}_t^c - \theta^*| \leq \delta \kappa_{\alpha} + 2r_B (1 - \kappa_{\alpha}), \quad \text{with } \kappa_{\alpha} = \bar{\mu}_{\alpha}(N'_{\delta}(\theta^*)),$$

where $\bar{\mu}_{\alpha}^{(m)}$ is the unique element in $\mathcal{M}_{\alpha}^{(m)}$, and $\bar{\mu}_{\alpha}$ is the marginal of $\bar{\mu}_{\alpha}$ on B .

Theorem 11 *In the setting of Theorem 5, let $\{\theta_t^c\}$ be generated instead by the perturbed version (23) of the algorithm (19) or (20), with a constant stepsize $\alpha > 0$ and with a bounded Lipschitz continuous function ψ_K satisfying (18). Let $\{\bar{\theta}_t^c\}$ be the corresponding averaged sequence. Then the conclusions of Theorems 7 and 9 hold. Furthermore, for any given stepsize α , the conclusions of the second part of Theorem 10 also hold.*

Note that in the second part of Theorem 10, both $\bar{\mu}_{\alpha}^{(m)}([N'_{\delta}(\theta^*)]^m)$ and κ_{α} approach 1 as $\alpha \rightarrow 0$, since by the first part of the theorem, the conclusions of Theorem 8 hold. For the second part of Theorem 11, the same is true provided that K is sufficiently large (so that $N_{\delta}(LB) \subset N_{\delta}(\theta^*)$ where LB is the limit set of the ODE associated with the algorithm),

13. We adopt these conditions for simplicity. They are not the weakest possible for our purpose, and our proof techniques can be applied to other types of perturbations as well. For related discussions, see Remark 2 at the end of this section, as well as Remark 3 and the discussion before Prop. 8 in Section 4.3.3.

and this can be seen from the conclusions of Theorem 9(i), which holds for the perturbed version (23) of the two variant algorithms, as the first part of Theorem 11 says. The proofs of Theorems 10-11 are given in Section 4.3.3.

Remark 2 (on the role of perturbation) At first sight it may seem counter-productive to add noise to the θ -iterates in the algorithm (23). Our motivation for such random perturbations of the θ -iterates is that this can ensure that the Markov chain $\{(Z_t, \theta_t^*)\}$ has a unique invariant probability measure (see Prop. 9, Section 4.3.3). The uniqueness allows us to invoke a result of Meyn (1989) on the convergence of the occupation probability measures of a weak Feller Markov chain, so that we can bound the deviation of the averaged iterates from θ^* not only in an expected sense as before, but also for almost all sample paths under each initial condition, as in the second part of Theorems 10-11. For the unperturbed algorithms, we can only prove such pathwise bounds on $\limsup_{t \rightarrow \infty} \|\bar{\theta}_t^* - \theta^*\|$ for a subset of the initial conditions of (Z_0, θ_0^*) . A more detailed discussion of this is given in Remark 3 at the end of Section 4.3.3, after the proofs of the preceding theorems.

Regarding other effects of the perturbation, intuitively, larger noise terms may help the Markov chain “mix” faster, but they can also result in less probability mass $\bar{\mu}_\alpha(N_\delta^*(\theta^*))$ around θ^* than in the case without perturbation. What is a suitable amount of noise to add to achieve a desired balance? We do not yet have an answer. It seems reasonable to us to let the magnitude of the variance of the perturbation terms $\Delta_{\theta,t}^\alpha$ be approximately $\alpha^{2\epsilon}$ for some $\epsilon \in (0, 1]$, so that a typical perturbation $\alpha \Delta_{\theta,t}^\alpha$ is at a smaller scale relative to the “signal part” αY_t^α in an iteration. Further investigation is needed. ■

4. Proofs for Section 3

We now prove the theorems given in the preceding section. We shall use KY as an abbreviation for the book (Kushner and Yin, 2003), which we will refer to frequently below.

4.1 Proofs for Theorems 4 and 5

In this subsection we prove Theorems 4 and 5 (Section 3.1) on convergence properties of the constrained ETD(λ) algorithm (11). We will apply two theorems from (KY), Theorems 8.2.2 and 8.2.3, which concern weak convergence of stochastic approximation algorithms for constant and diminishing stepsize, respectively. This requires us to show that the conditions of those theorems are satisfied by our algorithm. The major conditions concern the uniform integrability, tightness, and convergence in mean of certain sequences of random variables involved in the algorithm. Our proofs will rely on many properties of the ETD iterates that we have established in (2015a) when analyzing the almost sure convergence of the algorithm.

4.1.1 CONDITIONS TO VERIFY

We need some definitions and notation, before describing the conditions required. For some index set \mathcal{K} , let $\{X_k\}_{k \in \mathcal{K}}$ be a set of random variables taking values in a metric space \mathbf{X} (in our context \mathbf{X} will be \mathbb{R}^m or Ξ). The set $\{X_k\}_{k \in \mathcal{K}}$ is said to be *tight* or *bounded in probability*, if there exists for each $\delta > 0$ a compact set $D_\delta \subset \mathbf{X}$ such that

$$\inf_{k \in \mathcal{K}} \mathbf{P}(X_k \in D_\delta) \geq 1 - \delta.$$

For \mathbb{R}^m -valued X_k , the set $\{X_k\}_{k \in \mathcal{K}}$ is said to be *uniformly integrable* (u.i.) if

$$\lim_{a \rightarrow \infty} \sup_{k \in \mathcal{K}} \mathbb{E}[\|X_k\| \mathbb{1}(\|X_k\| \geq a)] = 0.$$

To analyze the constrained ETD(λ) algorithm (11), which is given by

$$\theta_{t+1} = \Pi_B(\theta_t + \alpha_t Y_t), \quad \text{where } Y_t := e_t \cdot \rho_t (R_t + \gamma_{t+1} \phi(S_{t+1})^\top \theta_t - \phi(S_t)^\top \theta_t),$$

let E_t denote expectation conditioned on \mathcal{F}_t , the sigma-algebra generated by $\theta_m, \xi_m, m \leq t$, where we recall $\xi_m = (\epsilon_m, F_m, S_m, A_m, S_{m+1})$ and its space $\mathbb{R}^{m+1} \times \mathcal{S} \times \mathcal{A} \times \mathcal{S}$ is denoted by Ξ . By writing $Y_t = E_t[Y_t] + (Y_t - E_t[Y_t])$, we have the equivalent form of (11) given in (15):

$$\theta_{t+1} = \Pi_B(\theta_t + \alpha_t h(\theta_t, \xi_t) + \alpha_t e_t \cdot \tilde{\omega}_{t+1}).$$

In other words, $h(\theta_t, \xi_t) = E_t[Y_t]$ and $e_t \cdot \tilde{\omega}_{t+1} = Y_t - E_t[Y_t]$, a noise term that satisfies $E_t[e_t \cdot \tilde{\omega}_{t+1}] = 0$.

This algorithm belongs to the class of stochastic approximation algorithms with “exogenous noises” studied in the book (KY) – the term “exogenous noises” reflects the fact that the evolution of $\{\xi_t\}$ is not driven by the θ -iterates. Theorems 4 and 5 will follow as special cases from Theorems 8.2.3 and 8.2.2 of (KY, Chap. 8), respectively, if we can show that the algorithm (11) satisfies the following conditions.

Conditions for the case of diminishing stepsize:

- (i) The sequence $\{Y_t\} = \{h(\theta_t, \xi_t) + e_t \cdot \tilde{\omega}_{t+1}\}$ is u.i. (This corresponds to the condition A.8.2.1 in KY.)
- (ii) The function $h(\theta, \xi)$ is continuous in θ uniformly in $\xi \in D$, for each compact set $D \subset \Xi$. (This corresponds to the condition A.8.2.3 in KY.)
- (iii) The sequence $\{\xi_t\}$ is tight. (This corresponds to the condition A.8.2.4 in KY.)
- (iv) The sequence $\{h(\theta_t, \xi_t)\}$ is u.i., and so is $\{h(\theta, \xi_t)\}$ for each fixed $\theta \in B$. (This corresponds to the condition A.8.2.5 in KY.)
- (v) There is a continuous function $\bar{h}(\cdot)$ such that for each $\theta \in B$ and each compact set $D \subset \Xi$,

$$\lim_{k \rightarrow \infty, t \rightarrow \infty} \frac{1}{k} \sum_{m=t}^{t+k-1} E_t [h(\theta, \xi_m) - \bar{h}(\theta)] \mathbb{1}(\xi_t \in D) = 0 \quad \text{in mean,}$$

where k and t are taken to ∞ in any way possible. In other words, if we denote the average on the left-hand side by $\bar{X}_{k,t}$, then the requirement “ $\lim_{k \rightarrow \infty, t \rightarrow \infty} \bar{X}_{k,t} = 0$ in mean” means that along any subsequences $k_j \rightarrow \infty, t_j \rightarrow \infty$, we must have $\lim_{j \rightarrow \infty} E[\|\bar{X}_{k_j, t_j}\|] = 0$. (This condition corresponds to the condition A.8.2.7 in KY.)

For the case of constant stepsize, we consider the iterates that could be generated by the algorithm for all stepsizes. To distinguish between the iterates associated with different stepsizes, in the conditions below, the superscript α is attached to the variables involved in the algorithm with stepsize α , and similarly, the conditional expectation E_t is denoted by E_t^α instead.

Conditions for the case of constant stepsize:

In addition to the condition (ii) above (which corresponds to the condition A.8.1.6 in KY for the case of constant stepsize), the following conditions are required.

- (i') The set $\{Y_t^\alpha \mid t \geq 0, \alpha > 0\} := \{h(\theta_t^\alpha, \xi_t^\alpha) + e_t^\alpha \cdot \tilde{\omega}_{t+1}^\alpha \mid t \geq 0, \alpha > 0\}$ is u.i. (This corresponds to the condition A.8.1.1 in KY.)
- (iii') The set $\{\xi_t^\alpha \mid t \geq 0, \alpha > 0\}$ is tight. (This corresponds to the condition A.8.1.7 in KY.)
- (iv') The set $\{h(\theta_t^\alpha, \xi_t^\alpha) \mid t \geq 0, \alpha > 0\}$ is u.i., in addition to the uniform integrability of $\{h(\theta_t, \xi_t^\alpha) \mid t \geq 0, \alpha > 0\}$ for each $\theta \in B$. (This corresponds to the condition A.8.1.8 in KY.)
- (v') There is a continuous function $\bar{h}(\cdot)$ such that for each $\theta \in B$ and each compact set $D \subset \Xi$,

$$\lim_{k \rightarrow \infty, t \rightarrow \infty, \alpha \rightarrow 0} \frac{1}{k} \sum_{m=d}^{t+k-1} \mathbb{E}_t^\alpha [h(\theta, \xi_m^\alpha) - \bar{h}(\theta)] \mathbb{1}(\xi_t^\alpha \in D) = 0 \quad \text{in mean,}$$

where α is taken to 0 and k, t are taken to ∞ in any way possible. (This condition corresponds to the condition A.8.1.9 in KY, and it is in fact stronger than the latter condition but is satisfied by our algorithms as we will show.)

The preceding conditions allow ξ_t^α and θ_t^α to be generated under different initial conditions for different α . While we will need this generality later in Section 4.3, here we will focus on a common initial condition for all stepsizes, for simplicity. Then, the preceding conditions for the constant-stepsize case are essentially the same as those for the diminishing stepsize case, because except for the θ -iterates, all the other variables (such as ξ_t and $\tilde{\omega}_t$) involved in the algorithm have identical probability distributions for all stepsizes α and are not affected by the θ -iterates. For this reason, in the proofs below, except for the θ -iterates, we simply omit the superscript α for other variables in the case of constant stepsize, and to verify the two sets of conditions above, we shall treat the case of diminishing stepsize and the case of constant stepsize simultaneously.

As mentioned in Section 2.4, these conditions are to ensure that the projected ODE (12), $\dot{x} = \bar{h}(x) + z, z \in -N_B(x)$, is the mean ODE for the algorithm (11) and reflects its average dynamics. Among the proofs for these conditions given next, the proof for the convergence in mean condition (v) and (v') will be the most involved.

4.1.2 PROOFS

The condition (ii) is clearly satisfied. In what follows, we prove that the rest of the conditions are satisfied as well. We start with the tightness conditions (iii) and (iii'), as they are immediately implied by a property of the trace iterates we already know. We then tackle the uniform integrability conditions (i), (i'), (iv) and (iv'), before we address the convergence in mean required in (v) and (v'). The proofs build upon several key properties of the ETD iterates we have established in (2015a) and recounted in Section 2.4 and Appendix A.

First, we show that the tightness conditions (iii) and (iii') are satisfied. This is implied by the following property of traces: $\sup_{t \geq 0} \mathbb{E}[\|(e_t, F_t)\|] < \infty$ for any given initial condition (e_0, F_0) (see Prop. 11, Appendix A).

Proposition 1 *Under Assumption 1, for each given initial $(e_0, F_0) \in \mathbb{R}^{n+1}$, $\{(e_t, F_t)\}$ is tight and hence $\{\xi_t\}$ is tight.*

Proof By Prop. 11, $c := \sup_{t \geq 0} \mathbb{E}[\|(e_t, F_t)\|] < \infty$. Then, by the Markov inequality, for $a > 0$, $\sup_{t \geq 0} \mathbf{P}[\|(e_t, F_t)\| \geq a] \leq c/a \rightarrow 0$ as $a \rightarrow \infty$. This implies that $\{(e_t, F_t)\}$ is tight. Since the space $\mathcal{S} \times \mathcal{A} \times \mathcal{S}$ is finite and $\xi_t = (e_t, F_t, S_t, A_t, S_{t+1})$, $\{\xi_t\}$ is also tight. ■

We now handle the uniform integrability conditions (i), (i'), (iv) and (iv'). The uniform integrability of the trace sequence $\{e_t\}$, as we will prove, is important here.

Proposition 2 *Under Assumption 1, for each given initial $(e_0, F_0) \in \mathbb{R}^{n+1}$, the following sets of random variables are u.i.:*

- (i) $\{e_t\}$;
- (ii) $\{h(\theta, \xi_t)\}$ for each fixed $\theta \in B$;
- (iii) $\{h(\theta_t, \xi_t)\}$ in the case of diminishing stepsize; and $\{h(\theta_t^\alpha, \xi_t) \mid t \geq 0, \alpha > 0\}$ in the case of constant stepsize;
- (iv) $\{h(\theta_t, \xi_t) + e_t \tilde{\omega}_{t+1}\}$ in the case of diminishing stepsize; and $\{h(\theta_t^\alpha, \xi_t) + e_t \tilde{\omega}_{t+1} \mid t \geq 0, \alpha > 0\}$ in the case of constant stepsize.

The proof of Prop. 2 will use facts about u.i. sequences of random variables given in the lemma below. This lemma basically follows from the definition of uniform integrability. We therefore omit its proof, which can be found in the arXiv version of this paper (Yu, 2015b).

Lemma 2 *Let $X_k, Y_k, k \in \mathcal{K}$ (some index set) be real-valued random variables with X_k and Y_k defined on a common probability space for each k .*

- (i) *If $\{X_k\}_{k \in \mathcal{K}}, \{Y_k\}_{k \in \mathcal{K}}$ are u.i., then $\{X_k + Y_k\}_{k \in \mathcal{K}}$ is u.i.*
- (ii) *If $\{X_k\}_{k \in \mathcal{K}}$ is u.i. and for all k , $|Y_k| \leq |X_k|$ a.s., then $\{Y_k\}_{k \in \mathcal{K}}$ is u.i.*
- (iii) *If $\{X_k\}_{k \in \mathcal{K}}, \{Y_k\}_{k \in \mathcal{K}}$ are u.i. and for some $c \geq 0$, $\mathbb{E}[\|Y_k\| \mid X_k] \leq c$ a.s. for all k , then $\{X_k Y_k\}_{k \in \mathcal{K}}$ is u.i.*

We now proceed to prove Prop. 2. The proof will involve auxiliary variables, which we call truncated traces. They are defined similarly to the trace iterates (e_t, F_t) , but instead of depending on all the past states and actions, they only depend on a certain number of the most recent states and actions. Specifically, for each integer $K \geq 1$, we define truncated traces $(\tilde{e}_{t,K}, \tilde{F}_{t,K})$ as follows:

$$(\tilde{e}_{t,K}, \tilde{F}_{t,K}) = (e_t, F_t) \quad \text{for } t \leq K,$$

and for $t \geq K + 1$, with the shorthand $\beta_t := \rho_{t-1} \gamma^t \lambda_t$,

$$\tilde{F}_{t,K} = \sum_{k=d-K}^t i(S_k) \cdot (\rho_k \gamma_{k+1} \cdots \rho_{t-1} \gamma^t), \quad (24)$$

$$\tilde{M}_{t,K} = \lambda_t i(S_t) + (1 - \lambda_t) \tilde{F}_{t,K}, \quad (25)$$

$$\tilde{e}_{t,K} = \sum_{k=d-K}^t \tilde{M}_{k,K} \cdot \phi(S_k) \cdot (\beta_{k+1} \cdots \beta_t). \quad (26)$$

Note that when $t \geq 2K + 1$, the traces $(\tilde{e}_{t,K}, \tilde{F}_{t,K})$ no longer depend on the initial (e_0, F_0) ; being functions of the states and actions between time $t - 2K$ and t only, they lie in a bounded set determined by K , since the state and action spaces are finite. For $t = 0, \dots, 2K$, $(\tilde{e}_{t,K}, \tilde{F}_{t,K})$ also lie in a bounded set, which is determined by K and the initial (e_0, F_0) . We will use these bounded truncated traces to approximate the original traces $\{(e_t, F_t)\}$ in the analysis.

An important approximation property, given in Prop. 13 (Appendix A), is that for each K and any initial (e_0, F_0) from a given bounded set E ,

$$\sup_{t \geq 0} \mathbb{E} \left[\left\| (e_t, F_t) - (\tilde{e}_{t,K}, \tilde{F}_{t,K}) \right\| \right] \leq L_K,$$

where L_K is a finite constant that depends on K and E and decreases monotonically to 0 as K increases:

$$L_K \downarrow 0 \quad \text{as } K \rightarrow \infty.$$

We will use this property in the following analysis.

Proof of Prop. 2 First, we prove $\{e_t\}$ is u.i. We then use this to show the uniform integrability of the other sets required in parts (ii)-(iv).

(i) To prove $\{e_t\}$ is u.i., we shall exploit its relation with the truncated traces, $\tilde{e}_{t,K}$, $t \geq 0$ for integers $K \geq 1$. Note that since the state and action spaces are finite, the truncated traces $\{\tilde{e}_{t,K}\}$ lie in a bounded set (this set depends on K and the initial (e_0, F_0)), so there exists a constant a_K such that $\|\tilde{e}_{t,K}\| \leq a_K$ for all t . This fact will greatly simplify the analysis. Let us first fix K and consider $a \geq a_K$. Denote $\bar{a} = a - a_K \geq 0$. Then

$$\begin{aligned} \mathbb{E} \|e_t\| \mathbb{1}(\|e_t\| \geq a) &\leq \mathbb{E} \|e_t\| \mathbb{1}(\|e_t - \tilde{e}_{t,K}\| \geq \bar{a}) \\ &\leq \mathbb{E} \|e_t - \tilde{e}_{t,K}\| \mathbb{1}(\|e_t - \tilde{e}_{t,K}\| \geq \bar{a}) + \mathbb{E} \|\tilde{e}_{t,K}\| \mathbb{1}(\|e_t - \tilde{e}_{t,K}\| \geq \bar{a}) \\ &\leq \mathbb{E} \|e_t - \tilde{e}_{t,K}\| \mathbb{1}(\|e_t - \tilde{e}_{t,K}\| \geq \bar{a}) + a_K \mathbb{1}(\|e_t - \tilde{e}_{t,K}\| \geq \bar{a}). \end{aligned} \quad (27)$$

For the second term on the right-hand side, we can bound its expectation by

$$\mathbb{E} [a_K \mathbb{1}(\|e_t - \tilde{e}_{t,K}\| \geq \bar{a})] = a_K \mathbf{P}(\|e_t - \tilde{e}_{t,K}\| \geq \bar{a}) \leq a_K \cdot L_K / \bar{a}, \quad \forall t, \quad (28)$$

where in the last inequality L_K is a constant that depends on K (and the initial (e_0, F_0)) and has the property that $L_K \downarrow 0$ as $K \rightarrow \infty$, and this inequality is derived by bounding the Markov inequality $\mathbf{P}(\|e_t - \tilde{e}_{t,K}\| \geq \bar{a}) \leq \mathbb{E} \|e_t - \tilde{e}_{t,K}\| / \bar{a}$ with Prop. 13, which bounds $\sup_{t \geq 0} \mathbb{E} \|e_t - \tilde{e}_{t,K}\|$ by L_K . Similarly, for the first term on the right-hand side of (27), using Prop. 13, we can bound its expectation by L_K :

$$\mathbb{E} [\|e_t - \tilde{e}_{t,K}\| \mathbb{1}(\|e_t - \tilde{e}_{t,K}\| \geq \bar{a})] \leq \mathbb{E} \|e_t - \tilde{e}_{t,K}\| \leq L_K, \quad \forall t. \quad (29)$$

From (27)-(29) it follows that

$$\sup_{t \geq 0} \mathbb{E} [\|e_t\| \mathbb{1}(\|e_t\| \geq a)] \leq L_K + a_K \cdot L_K / (a - a_K),$$

so for fixed K , by taking $a \rightarrow \infty$, we obtain

$$\limsup_{a \rightarrow \infty} \sup_{t \geq 0} \mathbb{E} [\|e_t\| \mathbb{1}(\|e_t\| \geq a)] \leq L_K.$$

Since $L_K \downarrow 0$ as $K \rightarrow \infty$ (Prop. 13), this implies $\lim_{a \rightarrow \infty} \sup_{t \geq 0} \mathbb{E} [\|e_t\| \mathbb{1}(\|e_t\| \geq a)] = 0$, which proves the uniform integrability of $\{e_t\}$.

(ii) We now prove for each θ , $\{h(\theta, \xi_t)\}$ is u.i. Since the state and action spaces are finite and θ is given, using the expression of $h(\theta, \xi_t)$, we can bound it as $\|h(\theta, \xi_t)\| \leq L \|e_t\|$ for some constant L . As just proved, $\{e_t\}$ is u.i. (equivalently $\{\|e_t\|\}$ is u.i.) and thus $\{L \|e_t\|\}$ is u.i., so by Lemma 2(ii), $\{h(\theta, \xi_t)\}$ is u.i. (since this is by definition equivalent to $\{\|h(\theta, \xi_t)\|\}$ being u.i., which is true by Lemma 2(ii)).

(iii) The uniform integrability of $\{h(\theta_t, \xi_t)\}$ in the case of diminishing stepsize or $\{h(\theta_t^\alpha, \xi_t)\}$ $t \geq 0, \alpha > 0$ in the case of constant stepsize follows from the same argument given for (ii) above, because θ_t or θ_t^α for all $t \geq 0$ and $\alpha > 0$ lie in the bounded set B by the definition of the constrained ETD(λ) algorithm.

(iv) Consider first the case of diminishing stepsize. We prove that $\{h(\theta_t, \xi_t) + e_t \tilde{\omega}_{t+1}\}$ is u.i. (recall $\tilde{\omega}_{t+1} = \rho_t (R_t - r(S_t, A_t, S_{t+1}))$ is the noise part of the observed reward). Since we already showed that $\{h(\theta_t, \xi_t)\}$ is u.i., by Lemma 2(i), it is sufficient to prove that $\{e_t \tilde{\omega}_{t+1}\}$ is u.i. Now $\{e_t\}$ is u.i. by part (i). Since the random rewards R_t in our model have bounded variances, the noise variables $\tilde{\omega}_{t+1}, t \geq 0$, also have bounded variances. This implies that $\{\tilde{\omega}_{t+1}\}$ is u.i. (Billingsley, 1968, p. 32) and that $\mathbb{E}[\|\tilde{\omega}_{t+1}\| | e_t] < c$ for some constant c (independent of t). It then follows from Lemma 2(iii) that $\{e_t \tilde{\omega}_{t+1}\}$ is u.i., and hence $\{h(\theta_t, \xi_t) + e_t \tilde{\omega}_{t+1}\}$ is u.i.

Similarly, in the case of constant stepsize, it follows from Lemma 2(i) that the set $\{h(\theta^\alpha, \xi_t) + e_t \tilde{\omega}_{t+1} | t \geq 0, \alpha > 0\}$ is u.i., because $\{h(\theta^\alpha, \xi_t) | t \geq 0, \alpha > 0\}$ is u.i. by part (iii) proved earlier and $\{e_t \tilde{\omega}_{t+1}\}$ is u.i. as we just proved. ■

Finally, we handle the conditions (v) and (v') stated in Section 4.1.1. The two conditions are the same condition in the case here, because they concern each fixed θ , whereas $\{\xi_t\}$ is not affected by the stepsize and the θ -iterates. So we can focus just on the condition (v) in presenting the proof, for notational simplicity. For the algorithm (11), the continuous function \bar{h} required in the condition is the function $\bar{h}(\theta) = C\theta + b$ associated with the desired mean ODE (12). We now prove the required convergence in mean by using the properties of trace iterates and the convergence results given in Theorem 3 and Corollary 1 (Section 2.4).

Proposition 3 *Let Assumption 1 hold. For each $\theta \in B$ and each compact set $D \subset \Xi$,*

$$\lim_{k \rightarrow \infty} \frac{1}{k} \sum_{m=i}^{i+k-1} \mathbb{E}_t [h(\theta, \xi_m) - \bar{h}(\theta)] \mathbb{1}(\xi_t \in D) = 0 \quad \text{in mean.}$$

Proof Denote $X_{k,t} = \frac{1}{k} \sum_{m=t}^{t+k-1} (h(\theta, \xi_m) - \bar{h}(\theta)) \mathbb{1}(\xi_t \in D)$. Since $\mathbb{E}[\|X_{k,t}\|] \leq \mathbb{E}[\|X_{k,t}\|]$, to prove $\lim_{k,t} \mathbb{E}[\|X_{k,t}\|] = 0$ (here and in what follows we simply write " k, t " under a limit symbol for " $k \rightarrow \infty, t \rightarrow \infty$ "), it is sufficient to prove $\lim_{k,t} \mathbb{E}[\|X_{k,t}\|] = 0$, that is, to prove

$$\lim_{k,t} \frac{1}{k} \sum_{m=i}^{i+k-1} (h(\theta, \xi_m) - \bar{h}(\theta)) \mathbb{1}(\xi_t \in D) = 0 \quad \text{in mean.} \quad (30)$$

Furthermore, since $\limsup_{k,t} \mathbb{E}[\|X_{k,t}\| \mathbb{1}(\xi_t \in D)]$ is upper-bounded by

$$\sum_{(s,a,s') \in \mathcal{S} \times \mathcal{A} \times \mathcal{S}} \limsup_{k,t} \mathbb{E}[\|X_{k,t}\| \mathbb{1}(\xi_t \in D, (S_t, A_t, S_{t+1}) = (s, a, s'))],$$

it is sufficient in the proof to consider only those compact sets D of the form $D = E \times \{(s, a, s')\}$, for each compact set $E \subset \mathbb{R}^{n+1}$ and each $(s, a, s') \in \mathcal{S} \times \mathcal{A} \times \mathcal{S}$. Henceforth, let us fix a compact set E together with a triplet (s, a, s') as the set D under consideration, and for this set D , we proceed to prove (30).

To show (30), what we need to show is that for two arbitrary subsequences of integers $k_j \rightarrow \infty, t_j \rightarrow \infty$,

$$\lim_{j \rightarrow \infty} \frac{1}{k_j} \sum_{m=t_j}^{t_j+k_j-1} (h(\theta, \xi_m) - \bar{h}(\theta)) \mathbb{1}(\xi_{t_j} \in D) = 0 \quad \text{in mean.} \quad (31)$$

To this end, we first define auxiliary trace variables to decompose each difference term $h(\theta, \xi_m) - \bar{h}(\theta)$ into two difference terms as follows:

- (a) Fix a point $(\bar{e}, \bar{F}) \in E$.
- (b) For each $j \geq 1$, define a sequence of trace pairs, $(\bar{e}_m^j, \bar{F}_m^j)$, $m \geq t_j$, by using the same recursion (3)-(5) that defines the traces $\{e_t, F_t\}$, based on the same trajectory $\{(S_t, A_t)\}$, but starting at time $m = t_j$ with the initial $(\bar{e}_{t_j}^j, \bar{F}_{t_j}^j) = (\bar{e}, \bar{F})$.

Denote $\xi_m^j = (e_m^j, F_m^j, S_m, A_m, S_{m+1})$ for $m \geq t_j$; it differs from ξ_m only in the two trace components. Next, for each m , we write $h(\theta, \xi_m) - h(\theta) = (h(\theta, \xi_m^j) - h(\theta)) + (h(\theta, \xi_m) - h(\theta, \xi_m^j))$ and correspondingly, we write

$$\frac{1}{k_j} \sum_{m=t_j}^{t_j+k_j-1} (h(\theta, \xi_m) - \bar{h}(\theta)) = \frac{1}{k_j} \sum_{m=t_j}^{t_j+k_j-1} (h(\theta, \xi_m^j) - \bar{h}(\theta)) + \frac{1}{k_j} \sum_{m=t_j}^{t_j+k_j-1} (h(\theta, \xi_m) - h(\theta, \xi_m^j)).$$

We see that for (31) to hold, it is sufficient that

$$\lim_{j \rightarrow \infty} \frac{1}{k_j} \sum_{m=t_j}^{t_j+k_j-1} (h(\theta, \xi_m^j) - \bar{h}(\theta)) \mathbb{1}(\xi_{t_j} \in D) = 0 \quad \text{in mean,} \quad (32)$$

and

$$\lim_{j \rightarrow \infty} \frac{1}{k_j} \sum_{m=t_j}^{t_j+k_j-1} (h(\theta, \xi_m) - h(\theta, \xi_m^j)) \mathbb{1}(\xi_{t_j} \in D) = 0 \quad \text{in mean.} \quad (33)$$

Let us now prove these two statements.

Proof of (32): Since the set $D = E \times \{(s, a, s')\}$ and $\mathbb{1}(\xi_{t_j} \in D) \leq \mathbb{1}((S_{t_j}, A_{t_j}, S_{t_j+1}) = (s, a, s'))$, we can remove ξ_{t_j} from consideration and show instead

$$\lim_{j \rightarrow \infty} \frac{1}{k_j} \sum_{m=t_j}^{t_j+k_j-1} (h(\theta, \xi_m^j) - \bar{h}(\theta)) \mathbb{1}((S_{t_j}, A_{t_j}, S_{t_j+1}) = (s, a, s')) = 0 \quad \text{in mean,} \quad (34)$$

which will imply (32). By definition ξ_m^j , $m \geq t_j$, are generated from the initial trace pairs (\bar{e}, \bar{F}) and initial transition $(S_{t_j}, A_{t_j}, S_{t_j+1})$ at time $m = t_j$. So if $(S_{t_j}, A_{t_j}, S_{t_j+1}) = (s, a, s')$, then conditioned on this transition at t_j , the sequence $\{\xi_m^j, m \geq t_j\}$ has the same probability distribution as a sequence $\hat{\xi}_m, m \geq 0$, where $\hat{\xi}_m = (\hat{e}_m, \hat{F}_m, \hat{S}_m, \hat{A}_m, \hat{S}_{m+1})$ is generated from the initial condition $\hat{\xi}_0 = (\bar{e}, \bar{F}, s, a, s')$ by the same recursion (3)-(5) and a trajectory $\{(S_m, A_m)\}$ of states and actions under the behavior policy. This shows that

$$\begin{aligned} & \mathbb{E} \left[\left\| \frac{1}{k_j} \sum_{m=t_j}^{t_j+k_j-1} (h(\theta, \xi_m^j) - \bar{h}(\theta)) \mathbb{1}((S_{t_j}, A_{t_j}, S_{t_j+1}) = (s, a, s')) \right\| \right] \\ & \leq \mathbb{E} \left[\left\| \frac{1}{k_j} \sum_{m=0}^{k_j-1} (h(\theta, \hat{\xi}_m) - \bar{h}(\theta)) \right\| \right], \end{aligned}$$

from which we see that the convergence in mean stated by (34) holds if we have

$$\lim_{k \rightarrow \infty} \frac{1}{k} \sum_{m=0}^{k-1} (h(\theta, \hat{\xi}_m) - \bar{h}(\theta)) = 0 \quad \text{in mean.} \quad (35)$$

Now since for each θ , the function $h(\theta, \cdot)$ is Lipschitz continuous in e uniformly in the other arguments, (35) holds by Theorem 3 and its implication Corollary 1 (Section 2.4). Consequently, (34) holds, and this implies (32).

Proof of (33): Using the expression of h and the finiteness of the state and action spaces, we can bound the difference $h(\theta, \xi_m) - h(\theta, \xi_m^j)$ by

$$\|h(\theta, \xi_m) - h(\theta, \xi_m^j)\| \leq c \cdot \|e_m - e_m^j\|$$

for some constant c (independent of m, j). Let us show

$$\lim_{j \rightarrow \infty} \frac{1}{k_j} \sum_{m=t_j}^{t_j+k_j-1} \|e_m - e_m^j\| \mathbb{1}(\xi_{t_j} \in D) = 0 \quad \text{in mean,} \quad (36)$$

which will imply (33).

To prove (36), similarly to the preceding proof, we first decompose each difference term $e_m - e_m^j$ in (36) into several difference terms, by using truncated traces $\{\tilde{e}_{m,K}, \tilde{F}_{m,K}\}$ and $\{\tilde{e}_{m,K}^j, \tilde{F}_{m,K}^j \mid m \geq t_j\}$, $j \geq 1, K \geq 1$, which we now introduce. Specifically, for each $K \geq 1$, $\{\tilde{e}_{m,K}, \tilde{F}_{m,K}\}$ are defined by (24)-(26). For each $j \geq 1$ and $K \geq 1$, the truncated traces $\{\tilde{e}_{m,K}^j, \tilde{F}_{m,K}^j \mid m \geq t_j\}$ are also defined by (24)-(26), except that the initial time is set to be t_j (instead of 0) and for $m \leq t_j + K$, $(\tilde{e}_{m,K}^j, \tilde{F}_{m,K}^j)$ is set to be $(\tilde{e}_{m,K}^j, \tilde{F}_{m,K}^j)$ (instead of (e_m, F_m)).

Let us fix K for now. We bound the difference $e_m - e_m^j$ by the sum of three difference terms as

$$\|e_m - e_m^j\| \leq \|e_m - \tilde{e}_{m,K}\| + \|\tilde{e}_{m,K} - \tilde{e}_{m,K}^j\| + \|\tilde{e}_{m,K} - \tilde{e}_{m,K}^j\|, \quad (37)$$

and correspondingly, we consider the following three sequences of variables, as j tends to ∞ :

$$\frac{1}{k_j} \sum_{m=t_j}^{t_j+k_j-1} \|e_m - \tilde{e}_{m,K}\| \mathbb{1}(\xi_{t_j} \in D), \quad \frac{1}{k_j} \sum_{m=t_j}^{t_j+k_j-1} \|e_m^j - \tilde{e}_{m,K}^j\|, \quad (38)$$

and

$$\frac{1}{k_j} \sum_{m=t_j}^{t_j+k_j-1} \|\tilde{e}_{m,K} - \tilde{e}_{m,K}^j\| \mathbb{1}(\xi_{t_j} \in D). \quad (39)$$

In what follows, we will bound their expected values as $j \rightarrow \infty$ and then take $K \rightarrow \infty$; this will lead to (36).

The analyses for the two sequences in (38) are similar. Recall $D = E \times \{(s, a, s')\}$, so $\xi_{t_j} \in D$ implies $(e_{t_j}, F_{t_j}) \in E$. Since the set E is bounded, if $(e_{t_j}, F_{t_j}) \in E$, then we can use Prop. 13 (Appendix A) to bound the expectation of $\|e_m - \tilde{e}_{m,K}\|$ for $m \geq t_j$ conditioned on \mathcal{F}_{t_j} , and this gives us the bound

$$\sup_{m \geq t_j} \mathbb{E}_{t_j} [\|e_m - \tilde{e}_{m,K}\|] \mathbb{1}(\xi_{t_j} \in D) \leq L_K$$

where L_K is a constant that depends on K and the set E , and has the property that $L_K \downarrow 0$ as $K \rightarrow \infty$. From this bound, we obtain

$$\mathbb{E} \left[\frac{1}{k_j} \sum_{m=t_j}^{t_j+k_j-1} \|e_m - \tilde{e}_{m,K}\| \mathbb{1}(\xi_{t_j} \in D) \right] \leq L_K, \quad \forall j \geq 1. \quad (40)$$

Similarly, for the second sequence in (38), by Prop. 13 we have

$$\mathbb{E} \left[\frac{1}{k_j} \sum_{m=t_j}^{t_j+k_j-1} \|e_m^j - \tilde{e}_{m,K}^j\| \right] \leq L_K, \quad \forall j \geq 1, \quad (41)$$

where L_K is some constant that can be chosen to be the same constant in (40) (because the point (\tilde{e}, \tilde{F}) , which is the initial trace pair for (e_m^j, F_m^j) at time $m = t_j$, lies in E).

Consider now the sequence in (39). As discussed after the definition (24)-(26) of truncated traces, because of truncation, these traces lie in a bounded set determined by K and the set in which the initial trace pair lies. Therefore, there exists a finite constant c_K which depends on K and E , such that for all $m \geq t_j$,

$$\|\tilde{e}_{m,K}^j\| \leq c_K, \quad \text{and} \quad \|\tilde{e}_{m,K}\| \leq c_K \text{ if } (e_{t_j}, F_{t_j}) \in E.$$

Also by their definition, once m is sufficiently large, the truncated traces do not depend on the initial trace pairs; in particular,

$$\tilde{e}_{m,K}^j = \tilde{e}_{m,K}, \quad \forall m \geq t_j + 2K + 1.$$

From these two arguments it follows that

$$\mathbb{E} \left[\frac{1}{k_j} \sum_{m=t_j}^{t_j+k_j-1} \|\tilde{e}_{m,K} - \tilde{e}_{m,K}^j\| \mathbb{1}(\xi_{t_j} \in D) \right] \leq \frac{(2K+1) \cdot 2c_K}{k_j} \rightarrow 0 \text{ as } j \rightarrow \infty. \quad (42)$$

Finally, combining (40)-(42) with (37), we obtain

$$\begin{aligned} & \limsup_{j \rightarrow \infty} \mathbb{E} \left[\frac{1}{k_j} \sum_{m=t_j}^{t_j+k_j-1} \|e_m - e_m^j\| \mathbb{1}(\xi_{t_j} \in D) \right] \\ & \leq \limsup_{j \rightarrow \infty} \mathbb{E} \left[\frac{1}{k_j} \sum_{m=t_j}^{t_j+k_j-1} \|e_m - \tilde{e}_{m,K}\| \mathbb{1}(\xi_{t_j} \in D) \right] + \limsup_{j \rightarrow \infty} \mathbb{E} \left[\frac{1}{k_j} \sum_{m=t_j}^{t_j+k_j-1} \|e_m^j - \tilde{e}_{m,K}^j\| \right] \\ & \quad + \lim_{j \rightarrow \infty} \mathbb{E} \left[\frac{1}{k_j} \sum_{m=t_j}^{t_j+k_j-1} \|\tilde{e}_{m,K} - \tilde{e}_{m,K}^j\| \mathbb{1}(\xi_{t_j} \in D) \right] \\ & \leq 2L_K. \end{aligned}$$

Since $L_K \downarrow 0$ as $K \rightarrow \infty$ (Prop. 13, Appendix A), by taking $K \rightarrow \infty$, we obtain

$$\lim_{j \rightarrow \infty} \mathbb{E} \left[\frac{1}{k_j} \sum_{m=t_j}^{t_j+k_j-1} \|e_m - e_m^j\| \mathbb{1}(\xi_{t_j} \in D) \right] = 0.$$

This proves (36), which implies (33). \blacksquare

With Props. 1-3, we have furnished all the conditions required in order to apply (KY, Theorems 8.2.2, 8.2.3) to the constrained ETD algorithm (11), so we can now specialize the conclusions of these two theorems to our problem. In particular, they tell us that the projected ODE (12) is the mean ODE for (11), and furthermore, by (KY, Theorem 8.2.3) (respectively, KY, Theorem 8.2.2), the conclusions of Theorem 4 (respectively, Theorem 5) hold with $N_\delta(L_B)$ in place of $N_\delta(\theta^*)$, where $N_\delta(L_B)$ is the δ -neighborhood of the limit set L_B for the projected ODE (12). Recall that this limit set is given by

$$L_B = \bigcap_{\tau > 0} \overline{\cup_{x(0) \in B} \{x(\tau), \tau \geq \bar{\tau}\}}$$

where $x(\tau)$ is a solution of the projected ODE (12) with initial condition $x(0)$, the union is over all the solutions with initial $x(0) \in B$, and \bar{D} for a set D denotes the closure of D .

Now when the matrix C is negative definite (as implied by Assumptions 1-2) and when the radius of B exceeds the threshold given in Lemma 1, by the latter lemma, the solutions $x(\tau), \tau \in [0, \infty)$, of the ODE (12) coincide with the solutions of $\dot{x} = \bar{h}(x) = Cx + b$ for all initial $x(0) \in B$. Then from the negative definiteness of C (Theorem 1, Section 2.3), it follows that as $\tau \rightarrow \infty$, $x(\tau) \rightarrow \theta^*$ uniformly in the initial condition, and consequently, $L_B = \{\theta^*\}$.¹⁴ Thus $N_\delta(L_B) = N_\delta(\theta^*)$ and we obtain Theorems 4 and 5.

¹⁴The details for this statement are as follows. Since \bar{h} is bounded on B and the boundary reflection term $z(\cdot) \equiv 0$ under our assumptions (Lemma 1, Section 2.4), a solution $x(\cdot)$ of (12) is Lipschitz continuous on $[0, \infty)$. We calculate $V(\tau)$ for the Lyapunov function $V(\tau) = |x(\tau) - \theta^*|^2$. By the negative definiteness of the matrix C , for some $c > 0$, $x^T C x \leq -c|x|^2$ for all $x \in \mathbb{R}^n$. Then, since $\bar{h}(x) = Cx + b = C(x - \theta^*)$, we have $\dot{V}(\tau) = 2 \langle x(\tau) - \theta^*, \bar{h}(x(\tau)) \rangle \leq -2c|x(\tau) - \theta^*|^2$, and hence for any $\delta > 0$, there exists $\epsilon > 0$ such that $\dot{V}(\tau) \leq -\epsilon$ if $V(\tau) = |x(\tau) - \theta^*|^2 \geq \delta^2$. This together with the continuity of the solution $x(\cdot)$ implies that for any $x(0) \in B$, within time $\bar{\tau} = r_B^2/\epsilon$, the trajectory $x(\tau)$ must reach $N_\delta(\theta^*)$ and stay in that set thereafter. By the definition of the limit set and the arbitrariness of δ , this implies $L_B = \{\theta^*\}$.

4.2 Proofs for Theorems 6 and 7

In this subsection we prove the part of Theorems 6-7 for the first variant of the constrained ETD(λ) algorithm given in (19), Section 3.2. The proof for the second variant algorithm (20) is similar and can be found in the arXiv version of this paper (Yu, 2015b). Like in the previous subsection, we will apply (KY, Theorems 8.2.2, 8.2.3) and show that the required conditions are met. Using the properties of the mean ODE of the variant algorithm, we will then specialize the conclusions of those theorems to obtain the desired results.

Consider the first variant algorithm (19):

$$\theta_{t+1} = \Pi_B \left(\theta_t + \alpha_t \psi_K(e_t) \cdot \rho_t (R_t + \gamma_{t+1} \phi(S_{t+1})^\top \theta_t - \phi(S_t)^\top \theta_t) \right).$$

We define a function $h_K : \mathbb{R}^n \times \Xi \rightarrow \mathbb{R}^n$ by

$$h_K(\theta, \xi) = \psi_K(e) \cdot \rho(s, a) (\tau(s, a, s') + \gamma(s') \phi(s')^\top \theta - \phi(s)^\top \theta), \quad \text{for } \xi = (e, F, s, a, s'), \quad (43)$$

and write (19) equivalently as

$$\theta_{t+1} = \Pi_B \left(\theta_t + \alpha_t h_K(\theta_t, \xi_t) + \alpha_t \psi_K(e_t) \cdot \tilde{\omega}_{t+1} \right)$$

with $\tilde{\omega}_{t+1} = \rho_t (R_t - \tau(S_t, A_t, S_{t+1}))$ as before. Note that $\mathbb{E}_t[\psi_K(e) \tilde{\omega}_{t+1}] = 0$, and the algorithm is similar to the algorithm (11)—equivalently (15)—except that we have h_K and $\psi_K(e_t)$ in place of h and e_t , respectively.

We note two properties of the function h_K . They follow from direct calculations and will be useful in our analysis shortly:

- (a) Using the Lipschitz continuity of the function ψ_K (cf. Equation 18, Section 3.2), we have that for each $\theta \in \mathbb{R}^n$, there exists a finite $c > 0$ such that with $\xi = (e, F, s, a, s')$ and $\xi' = (e', F', s, a, s')$,

$$\|h_K(\theta, \xi) - h_K(\theta, \xi')\| \leq c \|e - e'\|, \quad \forall (s, a, s') \in \mathcal{S} \times \mathcal{A} \times \mathcal{S}. \quad (44)$$

Thus $h_K(\theta, \cdot)$ is Lipschitz continuous in (e, F) uniformly in (s, a, s') .

- (b) Since the set B is bounded, we can bound the difference $h_K(\theta, \xi) - h(\theta, \xi)$ for all θ in B as follows. For some finite constant $c > 0$,

$$\|h_K(\theta, \xi) - h(\theta, \xi)\| \leq c \|\psi_K(e) - e\| \leq 2c \|e\| \cdot \mathbb{1}(\|e\| \geq K), \quad \forall \theta \in B, \quad (45)$$

where the last inequality follows from the property (18) of ψ_K :

$$\|\psi_K(x)\| \leq \|x\| \quad \forall x \in \mathbb{R}^n, \quad \text{and} \quad \psi_K(x) = x \quad \text{if } \|x\| \leq K.$$

We now apply (KY, Theorems 8.2.2, 8.2.3) to obtain the desired conclusions in Theorems 6-7 for the algorithm (19). This requires us to show that the conditions (i)-(v) and (i')-(v') given in Section 4.1.1 are still satisfied when we replace e_t by $\psi_K(e_t)$ and h by h_K . The uniform integrability conditions (i), (i'), (iv) and (iv') require the following sets to be u.i.: $\{h_K(\theta_t, \xi_t) + \psi_K(e_t) \cdot \tilde{\omega}_{t+1}\}$ and $\{h_K(\theta_t^c, \xi_t) + \psi_K(e_t) \cdot \tilde{\omega}_{t+1} \mid t \geq 0, \alpha > 0\}$, $\{h_K(\theta_t, \xi_t)\}$ and $\{h_K(\theta_t^c, \xi_t) \mid t \geq 0, \alpha > 0\}$, and $\{h_K(\theta, \xi)\}$ for each θ . These conditions are evidently

satisfied, in view of the boundedness of the functions ψ_K and $h_K(\theta, \cdot)$ for each θ , the boundedness of the θ -iterates due to constraints, and the finite variances of $\{\tilde{\omega}_t\}$. The condition (ii) on the continuity of $h_K(\cdot, \xi)$ uniformly in $\xi \in D$, for each compact set $D \subset \Xi$, is also clearly satisfied, whereas the condition (iii) (equivalently (iii')) on the tightness of $\{\xi_t\}$ was already verified earlier in Prop. 1 (Section 4.1.2).

What remains is the condition (v) (which is equivalent to (v')), for the same reason as discussed immediately before Prop. 3, Section 4.1.2). It requires the existence of a continuous function $h_K : \mathbb{R}^n \rightarrow \mathbb{R}^n$ such that for each $\theta \in B$ and each compact set $D \subset \Xi$,

$$\lim_{k \rightarrow \infty, t \rightarrow \infty} \frac{1}{k} \sum_{m=t}^{t+k-1} \mathbb{E}_t[h_K(\theta, \xi_m) - \bar{h}_K(\theta)] \mathbb{1}(\xi \in D) = 0 \quad \text{in mean.} \quad (46)$$

If this condition is satisfied as well, then the mean ODE for the algorithm (19) is given by

$$\dot{x} = \bar{h}_K(x) + z, \quad z \in -\mathcal{N}_B(x). \quad (47)$$

To furnish the condition (v), we first identify the function $\bar{h}_K(\theta)$ to be $\mathbb{E}_\zeta[h_K(\theta, \xi_0)]$, the expectation of $h_K(\theta, \xi_0)$ under the stationary distribution of the process $\{Z_t\}$ with the invariant probability measure ζ as its initial distribution. We relate the functions $h_K, K > 0$, to \bar{h} in the proposition below, and we will use it to characterize the bias of the algorithm (19) later.

Proposition 4 *Let Assumption 1 hold. Consider the setting of the algorithm (19), and for each $\theta \in \mathbb{R}^n$, let $\bar{h}_K(\theta) = \mathbb{E}_\zeta[h_K(\theta, \xi_0)]$. Then the function \bar{h}_K is Lipschitz continuous on \mathbb{R}^n , and*

$$\sup_{\theta \in B} \|\bar{h}_K(\theta) - \bar{h}(\theta)\| \rightarrow 0 \quad \text{as } K \rightarrow \infty. \quad (48)$$

Proof For each θ , the function $h_K(\theta, \cdot)$ is by definition bounded. Under Assumption 1, the Markov chain $\{(S_t, A_t, e_t, F_t)\}$ has a unique invariant probability measure ζ (Theorem 2, Section 2.4). Therefore, $h_K(\theta)$ is well-defined and finite. Let $c_1 = \sup_{e \in \mathbb{R}^n} \|\psi_K(e)\| < \infty$ (since ψ_K is bounded). For any θ, θ', ξ , using the definition of h_K , a direct calculation shows that for some $c_2 > 0$, $\|h_K(\theta, \xi) - h_K(\theta', \xi)\| \leq c_1 c_2 \|\theta - \theta'\|$ for all $\xi \in \Xi$, from which it follows that

$$\|\bar{h}_K(\theta) - \bar{h}_K(\theta')\| \leq \mathbb{E}_\zeta[\|h_K(\theta, \xi_0) - h_K(\theta', \xi_0)\|] \leq c_1 c_2 \|\theta - \theta'\|.$$

This shows that \bar{h}_K is Lipschitz continuous. We now prove (48). Since $\bar{h}_K(\theta) = \mathbb{E}_\zeta[h_K(\theta, \xi_0)]$ by definition and $h(\theta) = \mathbb{E}_\zeta[h(\theta, \xi_0)]$ by Corollary 1 (Section 2.4), it is sufficient to prove the following statement, which entails (48):

$$\sup_{\theta \in B} \mathbb{E}_\zeta[\|h_K(\theta, \xi_0) - h(\theta, \xi_0)\|] \rightarrow 0 \quad \text{as } K \rightarrow \infty. \quad (49)$$

By (45), for some constant $c > 0$,

$$\|h_K(\theta, \xi_0) - h(\theta, \xi_0)\| \leq 2c \|e_0\| \cdot \mathbb{1}(\|e_0\| \geq K), \quad \forall \theta \in B,$$

and therefore,

$$\sup_{\theta \in B} \mathbb{E}_\zeta \left[\left| \langle h_K(\theta, \xi_0) - h(\theta, \xi_0) \rangle \right| \right] \leq 2c \mathbb{E}_\zeta \left[\|\epsilon_0\| \cdot \mathbb{1}(\|\epsilon_0\| \geq K) \right].$$

By Theorem 3 (Section 2.4), $\mathbb{E}_\zeta \|\epsilon_0\| < \infty$ and hence $\mathbb{E}_\zeta \|\epsilon_0\| \cdot \mathbb{1}(\|\epsilon_0\| \geq K) \rightarrow 0$ as $K \rightarrow \infty$. Together with the preceding inequality, this implies (49), which in turn implies (48). \blacksquare

We now show that the convergence in mean required in (46) is satisfied.

Proposition 5 *Under Assumption 1, the conclusion of Prop. 3 (Section 4.1.2) holds in the setting of the algorithm (19), with the functions h_K and \bar{h}_K in place of h and \bar{h} , respectively.*

Proof The same arguments given in the proof of Prop. 3 apply here, with the functions h_K, \bar{h}_K in place of h, \bar{h} , respectively. Only two details are worth noting here. The proof relies on the Lipschitz continuity property of h_K given in (44). As mentioned earlier, this property implies that for each θ , with $\xi = (e, F, s, a, s')$, $h_K(\theta, \xi)$ is Lipschitz continuous in (e, F) uniformly in (s, a, s') , so we can apply Theorem 3 to conclude that (35) and hence (32) hold in this case (for h_K, \bar{h}_K instead of h, \bar{h}). The property (44) also allows us to obtain (33) in this case, by exactly the same proof given earlier. \blacksquare

Thus we have furnished all the conditions required by (KY, Theorems 8.2.2, 8.2.3). As in the case of the algorithm (11), by these two theorems, the assertions of Theorems 4-5 hold for the variant algorithm (19) with $N_\delta(L_B)$ in place of $N_\delta(\theta^*)$, where L_B is the limit set of the projected mean ODE associated with (19):

$$\dot{x} = \bar{h}_K(x) + z, \quad z \in -\mathcal{N}_B(x).$$

To finish the proof for Theorems 6-7, it is now sufficient to show that for any given $\delta > 0$, we can choose a number K_δ large enough so that $L_B \subset N_\delta(\theta^*)$ for all $K \geq K_\delta$. We prove this below, using Prop. 4. Note that the set L_B reflects the bias of the constrained algorithm (19), so what we are showing now is that this bias decreases as K increases.

Lemma 3 *Let Assumptions 1-2 hold, and let the radius of the set B exceed the threshold given in Lemma 1. Then for all K sufficiently large, given any initial condition $x(0) \in B$, a solution to the projected ODE (47) coincides with the unique solution to $\dot{x} = \bar{h}_K(x)$, with the boundary reflection term being $z(\cdot) \equiv 0$. Given $\delta > 0$, there exists K_δ such that for $K \geq K_\delta$, the limit set L_B of (47) satisfies $L_B \subset N_\delta(\theta^*)$.*

Proof Under Assumptions 1-2, the matrix C is negative definite (Theorem 1, Section 2.3), and when the radius of the set B exceeds the threshold given in Lemma 1, there exists a constant $\epsilon > 0$ such that for all boundary points x of B , $\langle x, \bar{h}(x) \rangle < -\epsilon$. At such points x , the normal cone $\mathcal{N}_B(x) = \{ax \mid a \geq 0\}$, and

$$\langle x, \bar{h}_K(x) \rangle = \langle x, \bar{h}(x) \rangle + \langle x, \bar{h}_K(x) - \bar{h}(x) \rangle < -\epsilon + \langle x, \bar{h}_K(x) - \bar{h}(x) \rangle.$$

By (48) in Prop. 4, $\langle x, \bar{h}_K(x) - \bar{h}(x) \rangle \rightarrow 0$ uniformly on B as $K \rightarrow \infty$. Thus when K is sufficiently large, at all boundary points x of B , $\langle x, \bar{h}_K(x) \rangle < 0$; i.e., $\bar{h}_K(x)$ points inside B

and the boundary reflection term $z = 0$. It then follows that for such K , given an initial condition $x(0) \in B$, a solution to (47) coincides with the unique solution to $\dot{x} = \bar{h}_K(x)$, where the uniqueness is ensured by the Lipschitz continuity of \bar{h}_K proved in Prop. 4 (cf. Borkar, 2008, Chap. 11.2).

To prove the second statement concerning the limit set of the projected ODE, let K be large enough so that the conclusion of the first part holds. Let $x(\tau), \tau \in [0, \infty)$, be the solution of (47) for a given initial $x(0) \in B$. Since \bar{h}_K is bounded on B , $x(\cdot)$ is Lipschitz continuous on $[0, \infty)$. Let $V(\tau) = |x(\tau) - \theta^*|^2$, and we calculate $\dot{V}(\tau)$. Since for all x , $\bar{h}_K(x) = Cx + b = C(x - \theta^*)$ and $x^\top Cx \leq -c|x|^2$ for some $c > 0$ by the negative definiteness of C , a direct calculation shows that

$$\begin{aligned} \dot{V}(\tau) &= 2 \langle x(\tau) - \theta^*, \bar{h}_K(x(\tau)) \rangle \\ &= 2 \langle x(\tau) - \theta^*, \bar{h}(x(\tau)) \rangle + 2 \langle x(\tau) - \theta^*, \bar{h}_K(x(\tau)) - \bar{h}(x(\tau)) \rangle \\ &\leq -2c|x(\tau) - \theta^*|^2 + 2|x(\tau) - \theta^*| \cdot |\bar{h}_K(x(\tau)) - \bar{h}(x(\tau))|. \end{aligned}$$

By (48) in Prop. 4, $\sup_{x \in B} |\bar{h}_K(x) - \bar{h}(x)| \rightarrow 0$ as $K \rightarrow \infty$. It then follows that for any $\delta > 0$, there exist $\epsilon > 0$ and $K_\delta > 0$ such that for all $K \geq K_\delta$, $\dot{V}(\tau) \leq -\epsilon$ if $V(\tau) = |x(\tau) - \theta^*|^2 \geq \delta^2$. This together with the continuity of the solution $x(\cdot)$ shows that for any $x(0) \in B$, within time $\bar{\tau} = r_B^2/\epsilon$ (where r_B is the radius of B), the trajectory $x(\tau)$ must reach $N_\delta(\theta^*)$ and stay in that set thereafter. Consequently, for all $K \geq K_\delta$, the limit set $L_B = \bigcap_{\tau \geq 0} \bigcup_{x(0) \in B} \{x(\tau), \tau \geq \bar{\tau}\} \subset N_\delta(\theta^*)$. \blacksquare

This completes the proofs of Theorems 6 and 7 for the first variant algorithm (19).

4.3 Further Analysis of the Constant-stepsize Case

We now consider again the case of constant stepsize, and prove Theorems 8-11 given in Section 3.3. The proofs will be based on combining the results we obtained earlier by using stochastic approximation theory, with the ergodic theorems of weak Feller Markov chains. As before the proofs will also rely on the key properties of the ETD iterates.

4.3.1 WEAK FELLER MARKOV CHAINS

We shall focus on Markov chains on complete separable metric spaces. For such a Markov chain $\{X_t\}$ with state space \mathbf{X} , let $P(\cdot, \cdot)$ denote its transition kernel, that is, $P : \mathbf{X} \times \mathcal{B}(\mathbf{X}) \rightarrow [0, 1]$,

$$P(x, D) = \mathbf{P}_x(X_1 \in D), \quad \forall x \in \mathbf{X}, D \in \mathcal{B}(\mathbf{X}),$$

where $\mathcal{B}(\mathbf{X})$ denotes the Borel sigma-algebra on \mathbf{X} , and \mathbf{P}_x denotes the probability distribution of $\{X_t\}$ conditioned on $X_0 = x$. Multiple-step transition kernels will also be needed. For $t \geq 1$, the t -step transition kernel $P^{(t)}(\cdot, \cdot) : \mathbf{X} \times \mathcal{B}(\mathbf{X}) \rightarrow [0, 1]$ is given by

$$P^{(t)}(x, D) = \mathbf{P}_x(X_t \in D), \quad \forall x \in \mathbf{X}, D \in \mathcal{B}(\mathbf{X}),$$

and for $t = 0$, P^0 is defined as $P^0(x, \cdot) = \delta_x$, the Dirac measure that assigns probability 1 to the point x , for each $x \in \mathbf{X}$. Define averaged probability measures $\bar{P}_k(x, \cdot)$ for $k \geq 1$ and

$x \in \mathbf{X}$, as

$$\bar{P}_k(x, \cdot) = \frac{1}{k} \sum_{t=0}^{k-1} P^t(x, \cdot).$$

The Markov chain $\{X_t\}$ has the *weak Feller* property if for every bounded continuous function f on \mathbf{X} ,

$$Pf(x) := \int f(y)P(x, dy) = \mathbb{E}[f(X_1) \mid X_0 = x]$$

is a continuous function of x (Meyn and Tweedie, 2009, Prop. 6.1.1). Weak Feller Markov chains have nice properties. In our analysis, we will use in particular several properties relating to the invariant probability measures of these chains and convergence of certain probability measures to the invariant probability measures.

Recall that if μ and μ_t , $t \geq 0$, are probability measures on \mathbf{X} , $\{\mu_t\}$ is said to converge weakly to μ if $\int f d\mu_t \rightarrow \int f d\mu$ for every bounded continuous function f on \mathbf{X} . For $\{\mu_t\}$ that is not necessarily convergent, we shall call the limiting probability measure of any of its convergent subsequence, in the sense of weak convergence, a *weak limit* of $\{\mu_t\}$. For an (arbitrary) index set \mathcal{K} , a set of probability measures $\{\mu_k\}_{k \in \mathcal{K}}$ on \mathbf{X} is said to be *tight* if for every $\delta > 0$, there exists a compact set $D_\delta \subset \mathbf{X}$ such that $\mu_k(D_\delta) \geq 1 - \delta$ for all $k \in \mathcal{K}$. An important fact is that on a complete separable metric space, any tight sequence of probability measures has a further subsequence that converges weakly to some probability measure (Dudley, 2002, Theorem 11.5.4).

For weak Feller Markov chains, their averaged probability measures $\{\bar{P}_k(x, \cdot)\}_{k \geq 1}$ are known to have the following property; see e.g., the proof of Lemma 4.1 in (Meyn, 1989). It will be needed in our proofs of Theorems 8-9.

Lemma 4 *Let $\{X_t\}$ be a weak Feller Markov chain with transition kernel $P(\cdot, \cdot)$ on a metric space \mathbf{X} . For each $x \in \mathbf{X}$, any weak limit of $\{\bar{P}_k(x, \cdot)\}_{k \geq 1}$ is an invariant probability measure of $\{X_t\}$.*

Recall that the occupation probability measures of $\{X_t\}$, denoted $\{\mu_{x,t}\}$ for each initial condition $x \in \mathbf{X}$, are defined as follows:

$$\mu_{x,t}(D) := \frac{1}{t} \sum_{k=0}^{t-1} \mathbb{1}(X_k \in D), \quad \forall D \in \mathcal{B}(\mathbf{X}),$$

where the chain $\{X_t\}$ starts from $X_0 = x$, and each $\mu_{x,t}$ is a random variable taking values in the space of probability measures on \mathbf{X} . Let “ $\mathbf{P}_{x\text{-a.s.}}$ ” stand for “almost surely with respect to \mathbf{P}_x ”. The next lemma concerns the convergence of occupation probability measures of a weak Feller Markov chain. It is a result of Meyn (1989) and will be needed in our proofs of Theorems 10-11.

Lemma 5 (Meyn, 1989, Prop. 4.2) *Let $\{X_t\}$ be a weak Feller Markov chain with transition kernel $P(\cdot, \cdot)$ on a complete separable metric space \mathbf{X} . Suppose that*

- (i) $\{X_t\}$ has a unique invariant probability measure μ ;
- (ii) for each compact set $E \subset \mathbf{X}$, the set $\{\bar{P}_k(x, \cdot) \mid x \in E, k \geq 1\}$ is tight; and

- (iii) for all initial conditions $x \in \mathbf{X}$, there exists a sequence of compact sets $E_k \uparrow \mathbf{X}$ (that is $E_k \subset E_{k+1}$ for all k and $\cup_k E_k = \mathbf{X}$) such that

$$\lim_{k \rightarrow \infty} \liminf_{t \rightarrow \infty} \mu_{x,t}(E_k) = 1, \quad \mathbf{P}_{x\text{-a.s.}}$$

Then, for each initial condition $x \in \mathbf{X}$, the sequence $\{\mu_{x,t}\}$ of occupation probability measures converges weakly to μ , \mathbf{P}_x -almost surely.

The condition (iii) above is equivalent to that the sequence $\{\mu_{x,t}\}$ of occupation probability measures is almost surely tight for each initial condition.

4.3.2 PROOFS OF THEOREMS 8 AND 9

In this subsection we prove Theorem 8 for the algorithm (11) and Theorem 9 for its two variants (19) and (20). We also show that the conclusions of Theorems 8-9 hold for the perturbed version (23) of these algorithms as well. The proof arguments are largely the same for all the algorithms we consider here. So except where noted otherwise, it will be taken for granted through out this subsection that $\{\theta_t^\alpha\}$ is generated by either of the six algorithms just mentioned for a constant stepsize $\alpha > 0$.

We start with some preliminary analysis given in the next two lemmas. Recall $Z_t = (S_t, A_t, e_t, F_t)$ and $\{Z_t\}$ is a weak Feller Markov chain on $\mathcal{Z} := S \times \mathcal{A} \times \mathbb{R}^{n+1}$ (Yu, 2015a, Sec. 3.1), and its evolution is not affected by the θ -iterates. We consider the Markov chain $\{(Z_t, \theta_t^\alpha)\}$ on the state space $\mathcal{Z} \times B$ (note that this is a complete separable metric space). This chain also has the weak Feller property:

Lemma 6 *Let Assumption 1(ii) hold. The process $\{(Z_t, \theta_t^\alpha)\}$ is a weak Feller Markov chain.*

The proof of the preceding lemma is a straightforward verification using the definition of the weak Feller property. It is included in the arXiv version of this paper (Yu, 2015b) but omitted here due to space limit.

In order to study the behavior of multiple consecutive θ -iterates, we consider for $m \geq 1$, the m -step version of $\{(Z_t, \theta_t^\alpha)\}$, that is, the Markov chain $\{X_t\}$ on $(\mathcal{Z} \times B)^m$ where each state X_t consists of m consecutive states of the original chain $\{(Z_t, \theta_t^\alpha)\}$:

$$X_t = ((Z_t, \theta_t^\alpha), \dots, (Z_{t+m-1}, \theta_{t+m-1}^\alpha)).$$

Similarly to Lemma 6, it is straightforward to show that the m -step version of a weak Feller Markov chain is a weak Feller chain as well. Thus the m -step version of $\{(Z_t, \theta_t^\alpha)\}$ is also a weak Feller Markov chain, and we can apply the ergodic theorems for weak Feller Markov chains to analyze it. In particular, in this subsection we will use Lemma 4 to prove Theorems 8-9; in the next subsection we will also use Lemma 5.

In analyzing the m -step version of $\{(Z_t, \theta_t^\alpha)\}$, sometimes it will be more convenient for us to take as its initial condition the condition of just (Z_0, θ_0^α) —instead of $(Z_0, \theta_0^\alpha), \dots, (Z_{m-1}^\alpha, \theta_{m-1}^\alpha)$ —and to work with the following objects that are essentially equivalent to the averaged probability measures $\{P_k(x, \cdot)\}$ and the occupation probability measures $\{\mu_{x,t}\}$ defined earlier for a general Markov chain $\{X_t\}$. Specifically, with $\{X_t\}$ denoting the m -step

version of $\{(Z_t, \theta_t^z)\}$, for each $(z, \theta) \in \mathcal{Z} \times B$, we define probability measures $\tilde{P}_{(z, \theta)}^{(m, k)}$, $k \geq 1$, on the space $\mathbf{X} = (\mathcal{Z} \times B)^m$, by

$$\tilde{P}_{(z, \theta)}^{(m, k)}(D) := \frac{1}{k} \sum_{t=0}^{k-1} \mathbf{P}_{(z, \theta)}(X_t \in D), \quad \forall D \in \mathcal{B}(\mathbf{X}). \quad (50)$$

Similarly, we define occupation probability measures $\{\mu_{(z, \theta), t}^{(m)}\}$ for each $(z, \theta) \in \mathcal{Z} \times B$ by

$$\mu_{(z, \theta), t}^{(m)}(D) := \frac{1}{t} \sum_{k=0}^{t-1} \mathbb{1}(X_k \in D), \quad \forall D \in \mathcal{B}(\mathbf{X}), \quad (51)$$

where the initial $(Z_0, \theta_0^z) = (z, \theta)$. Compared with the definitions of $\{\tilde{P}_k(x, \cdot)\}$ and $\{\mu_{x, t}\}$ for $\{X_t\}$, apparently, all the previous conclusions given in Section 4.3.1 for $\{\tilde{P}_k(x, \cdot)\}$ and $\{\mu_{x, t}\}$ hold for $\{\tilde{P}_{(z, \theta)}^{(m, k)}\}$ and $\{\mu_{(z, \theta), t}^{(m)}\}$ as well; therefore we can use the objects $\{\tilde{P}_{(z, \theta)}^{(m, k)}\}$ and $\{\mu_{(z, \theta), t}^{(m)}\}$, and $\{\mu_{x, t}\}$, interchangeably in our analysis.

Lemma 7 *Let Assumption 1 hold. For $m \geq 1$, let $\{X_t\}$ be the m -step version of $\{(Z_t, \theta_t^z)\}$ on $\mathbf{X} = (\mathcal{Z} \times B)^m$, with transition kernel $P(\cdot, \cdot)$. Then $\{X_t\}$ satisfies the conditions (ii)-(iii) of Lemma 5.*

Proof To show that the condition (ii) of Lemma 5 is satisfied, fix a compact set $E \subset \mathbf{X}$ and let us first show that the set $\{P^t(x, \cdot) \mid x \in E, t \geq 0\}$ is tight. Since the set B is compact and the state and action spaces are finite, of concern here is just the tightness of the marginals of these probability measures on the space of the trace components $(e_t, F_t, \dots, e_{t+m-1}, F_{t+m-1})$ of the state X_t . By Prop. 11 (Appendix A), for all initial conditions of (e_0, F_0) in a given bounded subset of \mathbb{R}^{n+1} , $\sup_{t \geq 0} \mathbb{E}[\|(e_t, F_t)\|] \leq L$ for a constant L (that depends on the subset). So for the set E , applying the Markov inequality together with the union bound, we have that there exists a constant $L > 0$ such that for all $x \in E$ and $a > 0$, $\mathbf{P}_x(\sup_{k \leq t < k+m} \|(e_k, F_k)\| \geq a) \leq mL/a$ for all $k \geq 0$. Now for any given $\delta > 0$, let a be large enough so that $mL/a < \delta$ and let D_a be the closed ball in \mathbb{R}^{n+1} centered at the origin with radius a . Then for the compact set $D = (S \times A \times D_a \times B)^m$, we have $\mathbf{P}^k(x, D) = \mathbf{P}_x(\sup_{k \leq t < k+m} \|(e_t, F_t)\| \leq a) \geq 1 - \delta$ for all $x \in E$ and all $k \geq 0$. This shows that the set $\{P^t(x, \cdot) \mid x \in E, t \geq 0\}$ is tight. Consequently, the averages of the probability measures in this set must also form a tight set; in particular, the set $\{P_k(x, \cdot) \mid x \in E, k \geq 1\}$ must be tight. Hence $\{X_t\}$ satisfies the condition (ii) of Lemma 5.

Consider now the condition (iii) of Lemma 5. For positive integers k , let E_k in that condition be the compact set $(S \times A \times D_k \times B)^m$, where D_k is the closed ball of radius k in \mathbb{R}^{n+1} centered at the origin. We wish to show that for each initial condition $x \in \mathbf{X}$,

$$\lim_{k \rightarrow \infty} \liminf_{t \rightarrow \infty} \mu_{x, t}(E_k) = 1, \quad \mathbf{P}_{x-a.s.} \quad (52)$$

Since the θ_t -iterates do not affect the evolution of Z_t , they can be neglected in the proof. It is sufficient to consider instead the m -step version of $\{Z_t\}$ and show that for the compact sets $\tilde{E}_k = (S \times A \times D_k)^m$, it holds for any initial condition $z \in \mathcal{Z}$ of Z_0 that

where $\{\hat{\mu}_{z, t}^{(m)}\}$ are the occupation probability measures of the m -step version of $\{Z_t\}$, defined analogously to (51) with (Z_t, \dots, Z_{t+m-1}) in place of X_t .

To prove (52), consider $\{Z_t\}$ first and its occupation probability measures $\{\mu_{z, t}\}$ for each initial condition $Z_0 = z \in \mathcal{Z}$. By Theorem 2 (Section 2.4), \mathbf{P}_z -almost surely, $\{\mu_{z, t}\}$ converges weakly to ζ (the unique invariant probability measure of $\{Z_t\}$). So by (Dudley, 2002, Theorem 11.1.1), for the open set $\tilde{D}_k = S \times A \times D_k^c$, where D_k^c denotes the interior of D_k (i.e., D_k^c is the open ball with radius k), almost surely,

$$\liminf_{t \rightarrow \infty} \hat{\mu}_{z, t}(\tilde{D}_k) \geq \zeta(\tilde{D}_k), \quad \text{and hence} \quad \lim_{k \rightarrow \infty} \liminf_{t \rightarrow \infty} \hat{\mu}_{z, t}(\tilde{D}_k) = 1. \quad (53)$$

Now for the m -step version of $\{Z_t\}$, with $[\tilde{D}_k]^m$ denoting the Cartesian product of m copies of \tilde{D}_k , we have

$$\hat{\mu}_{z, t}^{(m)}([\tilde{D}_k]^m) := \frac{1}{t} \sum_{j=0}^{t-1} \mathbb{1}(Z_{j+j'} \in \tilde{D}_k), \quad 0 \leq j' < m) \geq 1 - \sum_{j'=0}^{m-1} \frac{1}{t} \sum_{j=0}^{t-1} \mathbb{1}(Z_{j+j'} \notin \tilde{D}_k). \quad (54)$$

For each $j' < m$, by the definition of $\hat{\mu}_{z, t}$, we have $\limsup_{t \rightarrow \infty} \frac{1}{t} \sum_{j=0}^{t-1} \mathbb{1}(Z_{j+j'} \notin \tilde{D}_k) = \limsup_{t \rightarrow \infty} \hat{\mu}_{z, t}(\tilde{D}_k^c)$, where \tilde{D}_k^c denotes the complement of \tilde{D}_k in $S \times A \times \mathbb{R}^{n+1}$. By (53), $\lim_{k \rightarrow \infty} \limsup_{t \rightarrow \infty} \hat{\mu}_{z, t}(\tilde{D}_k^c) = 0$ almost surely. Hence for each $j' < m$, we have $\lim_{k \rightarrow \infty} \limsup_{t \rightarrow \infty} \frac{1}{t} \sum_{j=0}^{t-1} \mathbb{1}(Z_{j+j'} \notin \tilde{D}_k) = 0$ almost surely. We then obtain from (54), by taking the limits as $t \rightarrow \infty$ and $k \rightarrow \infty$, that

$$\liminf_{k \rightarrow \infty} \liminf_{t \rightarrow \infty} \hat{\mu}_{z, t}^{(m)}([\tilde{D}_k]^m) \geq 1 - \sum_{j'=0}^{m-1} \limsup_{k \rightarrow \infty} \limsup_{t \rightarrow \infty} \frac{1}{t} \sum_{j=0}^{t-1} \mathbb{1}(Z_{j+j'} \notin \tilde{D}_k) = 1$$

almost surely. The desired equality (52) then follows, since $[\tilde{D}_k]^m \subset \tilde{E}_k$. \blacksquare

Recall that \mathcal{M}_a^m is the set of invariant probability measures of the m -step version of $\{(Z_t, \theta_t^z)\}$. By Lemma 7 the latter Markov chain satisfies the condition (ii) of Lemma 5, and this implies that the set $\{\tilde{P}_{(z, \theta)}^{(m, k)}\}_{k \geq 1}$ is tight for each initial condition $(Z_0, \theta_0^z) = (z, \theta)$. Recall that any subsequence of a tight sequence has a further convergent subsequence (Dudley, 2002, Theorem 11.5.4). For $\{\tilde{P}_{(z, \theta)}^{(m, k)}\}_{k \geq 1}$, all the weak limits (i.e., the limits of its convergent subsequences) must be invariant probability measures in \mathcal{M}_a^m , by the property of weak Feller Markov chains given in Lemma 4:

Proposition 6 *Under Assumption 1, consider the m -step version of $\{(Z_t, \theta_t^z)\}$ for $m \geq 1$. For each $(z, \theta) \in \mathcal{Z} \times B$, the sequence $\{\tilde{P}_{(z, \theta)}^{(m, k)}\}_{k \geq 1}$ of probability measures is tight, and any weak limit of this sequence is an invariant probability measure of the m -step version of $\{(Z_t, \theta_t^z)\}$. (Thus $\mathcal{M}_a^m \neq \emptyset$.)*

We are now ready to prove Theorems 8-9. The idea is to use the conclusions on the θ_t -iterates that we can obtain by applying (KY, Theorem 8.2.2), to infer the concentration of the mass around a small neighborhood of $(\theta^*, \dots, \theta^*)$ (m copies of θ^*) for the marginals

of all the invariant probability measures in the set \mathcal{M}_α^m , when α is sufficiently small. This can then be combined with Prop. 6 above to prove the desired conclusions on the θ -iterates for a given stepsize.

Recall that \mathcal{M}_α is the set of invariant probability measures of $\{(Z_t, \theta_t^\alpha)\}$. Recall also that \mathcal{M}_α^m denotes the set of marginals of the invariant probability measures in \mathcal{M}_α^m , on the space of the θ 's.

Proposition 7 *In the setting of Theorem 5, for each $\alpha > 0$, let $\{\theta_t^\alpha\}$ be generated instead by the algorithm (11) or its perturbed version (23), with constant stepsize α and under the condition that the initial (Z_0, θ_0^α) is distributed according to some invariant probability measure in \mathcal{M}_α . Then the conclusions of Theorem 5 continue to hold.*

Proof The proof arguments are the same as those for Theorem 5 given in Section 4.1. We only need to show that the conditions (ii) and (i')-(v') given in Section 4.1.1 for applying (KY, Theorem 8.2.2) are still satisfied under our present assumptions.

For the algorithm (11), the only difference from the previous assumptions in Theorem 5 is that here for each stepsize α , the initial (Z_0, θ_0^α) has a distribution $\mu_\alpha \in \mathcal{M}_\alpha$. The condition (ii) does not depend on such initial conditions, so it continues to hold. For the other conditions, note that since $\{Z_t\}$ has a unique invariant probability measure ζ (Theorem 2), regardless of the choice of μ_α , for all α , $\{Z_t\}$ is stationary and has the same distribution. Then the tightness condition (iii') trivially holds because as $\{\xi_t\}$ is also stationary and unaffected by the stepsize, each ξ_t^α in (iii') has the same distribution. Similarly, since $\{e_t\}$ is stationary and unaffected by the stepsize, and each e_t has the same distribution with the mean of $\|e_t\|$ given by $\mathbb{E}_\zeta[\|e_t\|] < \infty$ (Theorem 3), we obtain that $\{e_t\}$ is u.i. From this the uniform integrability required in the conditions (i') and (iv') follows as a consequence, as shown in the proof of Prop. 2(ii)-(iv). Lastly, the convergence in mean condition (v') continues to hold (by the same proof given for Prop. 3). This is because $\{\xi_t\}$ has the same distribution regardless of the stepsize, and because the condition (v') is for each compact set D and concerns tails of a trajectory starting at instants t with $\xi_t \in D$, which renders any initial condition on Z_0 ineffective. Thus all the required conditions are met, and we obtain the same conclusions on the θ -iterates as given in Theorem 5.

For the perturbed version (23) of the algorithm (11), the only difference to (11) under the present assumptions is the perturbation variables $\Delta_{\theta_t^\alpha}^m$ involved in each iteration. But by definition these variables have conditional zero mean: $\mathbb{E}_{\xi_t^\alpha}[\Delta_{\theta_t^\alpha}^m] = 0$, so the only condition in which they appear is the uniform integrability condition (i'): $\{Y_t^\alpha \mid t \geq 0, \alpha > 0\}$ is u.i., where Y_t^α is now given by $Y_t^\alpha = h(\theta_t^\alpha, \xi_t) + e_t \cdot \tilde{\omega}_{t+1} + \Delta_{\theta_t^\alpha}^m$. By definition $\Delta_{\theta_t^\alpha}^m$ for all α and t have bounded variance, and hence $\{\Delta_{\theta_t^\alpha}^m\}$ is u.i. (Billingsley, 1968, p. 32). The set $h(\theta_t^\alpha, \xi_t) + e_t \cdot \tilde{\omega}_{t+1} \mid t \geq 0, \alpha > 0\}$ is u.i., which follows from the u.i. of $\{e_t\}$, as we just verified in the case of the algorithm (11). Therefore, by Lemma 2(i), $\{Y_t^\alpha \mid t \geq 0, \alpha > 0\}$ is u.i. and the condition (i') is satisfied. Since the perturbed version (23) meets all the required conditions, and shares with (11) the same mean ODE, the same conclusions given in Theorem 5 hold for this algorithm as well. ■

We now prove Theorem 8 for the algorithm (11). We prove its part (i) and part (ii) separately, as the arguments are different. Our proofs below also apply to the perturbed

version (23) of the algorithm (11), and together with the preceding proposition, they establish the first part of Theorem 10 (which says that the conclusions of both Theorem 5 and Theorem 8 hold for the perturbed algorithm).

Proof of Theorem 8(i) Proof by contradiction. Consider the statement of Theorem 8(i):

$$\forall \delta > 0, \quad \liminf_{\alpha \rightarrow 0} \inf_{\mu \in \mathcal{M}_{\alpha}^{m_\alpha}} \mu([N_\delta(\theta^*)]^{m_\alpha}) = 1, \quad \text{where } m_\alpha = \lceil \frac{m}{\alpha} \rceil.$$

Suppose it is not true. Then there exist $\delta, \epsilon > 0$, $m \geq 1$, a sequence $\alpha_k \rightarrow 0$, and a sequence $\mu_{\alpha_k} \in \mathcal{M}_{\alpha_k}^{m_{\alpha_k}}$, where $m_{\alpha_k} = m_{\alpha_k}$, such that

$$\mu_{\alpha_k}([N_\delta(\theta^*)]^{m_{\alpha_k}}) \leq 1 - \epsilon, \quad \forall k \geq 0. \quad (55)$$

Each μ_{α_k} corresponds to an invariant probability measure of $\{(Z_t, \theta_t^{\alpha_k})\}$ in \mathcal{M}_{α_k} , which we denote by $\hat{\mu}_{\alpha_k}$. For each $k \geq 0$, generate the iterates $\{\theta_t^{\alpha_k}\}$ using $\hat{\mu}_{\alpha_k}$ as the initial distribution of $(Z_0, \theta_0^{\alpha_k})$. For other values of α , generate the iterates $\{\theta_t^\alpha\}$ using some $\hat{\mu}_\alpha \in \mathcal{M}_\alpha$ as the initial distribution of (Z_0, θ_0^α) . By Prop. 7, the conclusions of Theorem 5 hold:

$$\limsup_{\alpha \rightarrow 0} \mathbf{P}\left(\theta_t^\alpha \notin N_\delta(\theta^*), \text{ some } t \in [k_\alpha, k_\alpha + T_\alpha/\alpha]\right) = 0,$$

where $T_\alpha \rightarrow \infty$ as $\alpha \rightarrow 0$, and this implies for the given m ,

$$\limsup_{\alpha \rightarrow 0} \mathbf{P}\left(\theta_t^\alpha \notin N_\delta(\theta^*), \text{ some } t \in [k_\alpha, k_\alpha + \lceil \frac{m}{\alpha} \rceil]\right) = 0. \quad (56)$$

But for each $\alpha > 0$, the process $\{(Z_t, \theta_t^\alpha)\}$ with the initial distribution $\hat{\mu}_\alpha$ is stationary, so the probability in the left-hand side of (56) is just $1 - \mu_\alpha([N_\delta(\theta^*)]^{m_\alpha})$, for the marginal probability measure $\mu_\alpha \in \mathcal{M}_{\alpha}^{m_\alpha}$ that corresponds to the invariant probability measure $\hat{\mu}_\alpha$. Therefore, by (56), $\liminf_{\alpha \rightarrow 0} \mu_\alpha([N_\delta(\theta^*)]^{m_\alpha}) = 1$. On the other hand, by (55), $\liminf_{\alpha \rightarrow 0} \mu_{\alpha_k}([N_\delta(\theta^*)]^{m_{\alpha_k}}) \leq \liminf_{k \rightarrow \infty} \mu_{\alpha_k}([N_\delta(\theta^*)]^{m_{\alpha_k}}) < 1$, a contradiction. Thus the statement of Theorem 8(i) recaptured at the beginning of this proof must hold.

This also proves the other statement of Theorem 8(i), $\liminf_{\alpha \rightarrow 0} \inf_{\mu \in \mathcal{M}_\alpha^m} \mu([N_\delta(\theta^*)]^{m_\alpha}) = 1$, because for $\alpha < 1$, by the correspondences between those invariant probability measures in \mathcal{M}_α^m and those in $\mathcal{M}_{\alpha}^{m_\alpha}$, $\inf_{\mu \in \mathcal{M}_\alpha^m} \mu([N_\delta(\theta^*)]^{m_\alpha}) \geq \inf_{\mu \in \mathcal{M}_\alpha^{m_\alpha}} \mu([N_\delta(\theta^*)]^{m_\alpha})$. This completes the proof. ■

Proof of Theorem 8(ii) We suppress the superscript α of θ_t^α in the proof. The statement is trivially true if $\delta \geq 2r_B$, so consider the case $\delta < 2r_B$. Let $(z, \theta) \in Z \times B$ be the initial condition of (Z_0, θ_0) . By convexity of the Euclidean norm, $|\theta_t - \theta^*| \leq \frac{t}{\alpha} \sum_{j=0}^{t-1} |\theta_j - \theta^*|$, and therefore, for all $k \geq 1$,

$$\sup_{k \leq t < k+m} |\bar{\theta}_t - \theta^*| \leq \frac{1}{k} \sum_{j=0}^{k-1} \sup_{j \leq t < j+m} |\theta_t - \theta^*|, \quad (57)$$

and

$$\mathbb{E} \left[\sup_{k \leq t < k+m} |\bar{\theta}_t - \theta^*| \right] \leq \frac{1}{k} \sum_{j=0}^{k-1} \mathbb{E} \left[\sup_{j \leq t < j+m} |\theta_t - \theta^*| \right]. \quad (58)$$

With $N'_\delta(\theta^*)$ denoting the open δ -neighborhood of θ^* , we have

$$\begin{aligned}
& \frac{1}{k} \sum_{j=0}^{k-1} \mathbb{E} \left[\sup_{j \leq t < j+m} |\theta_t - \theta^*| \right] \\
& \leq \frac{1}{k} \sum_{j=0}^{k-1} \mathbb{E} \left[\left(\sup_{j \leq t < j+m} |\theta_t - \theta^*| \cdot \mathbb{1}(\theta_t \in N'_\delta(\theta^*), j \leq t < j+m) \right) \right. \\
& \quad \left. + \frac{1}{k} \sum_{j=0}^{k-1} \mathbb{E} \left[\left(\sup_{j \leq t < j+m} |\theta_t - \theta^*| \right) \cdot \mathbb{1}(\theta_t \notin N'_\delta(\theta^*), \text{some } t \in [j, j+m]) \right) \right] \\
& \leq \delta \cdot \bar{P}_{(z, \theta)}^{(m, k)}(D_\delta) + 2r_B \cdot (1 - \bar{P}_{(z, \theta)}^{(m, k)}(D_\delta)), \tag{59}
\end{aligned}$$

where $D_\delta = \{(z^1, \theta^1, \dots, z^m, \theta^m) \in (\mathcal{Z} \times B)^m \mid \sup_{1 \leq i \leq m} |\theta^i - \theta^*| < \delta\}$, and the second inequality follows from the definition (50) of the averaged probability measure $\bar{P}_{(z, \theta)}^{(m, k)}$.

By Prop. 6, $\{\bar{P}_{(z, \theta)}^{(m, k)}\}_{k \geq 1}$ is tight and all its weak limits are in \mathcal{M}_α^m , the set of invariant probability measure of the m -step version of $\{(Z_t, \theta_t)\}$. There is also the fact that on a metric space, if a sequence of probability measures μ_k converges to some probability measure μ weakly, then $\liminf_{k \rightarrow \infty} \mu_k(D) \geq \mu(D)$ for any open set D (Dudley, 2002, Theorem 11.1.1). From these two arguments we have that for the set D_δ , which is open with respect to the topology on $(\mathcal{Z} \times B)^m$,

$$\liminf_{k \rightarrow \infty} \bar{P}_{(z, \theta)}^{(m, k)}(D_\delta) \geq \inf_{\mu \in \mathcal{M}_\alpha^m} \mu(D_\delta) = \inf_{\mu \in \mathcal{M}_\alpha^m} \mu([N'_\delta(\theta^*)]^m) =: \kappa_{\alpha, m}. \tag{60}$$

Combining the three inequalities (58)-(60), and using also the relation $\delta < 2r_B$, we obtain

$$\limsup_{k \rightarrow \infty} \mathbb{E} \left[\sup_{k \leq t < k+m} |\bar{\theta}_t - \theta^*| \right] \leq \delta \kappa_{\alpha, m} + 2r_B(1 - \kappa_{\alpha, m}).$$

This complete the proof. \blacksquare

We prove Theorem 9 in exactly the same way as we proved Theorem 8, so we omit the details and only outline the proof here. First, for the variant algorithms (19) and (20) as well as their perturbed version (23), we consider fixed K and ψ_K . Similar to Prop. 7, we show that if for each stepsize α , the initial (Z_0, θ_0^α) is distributed according to some invariant probability measure in \mathcal{M}_α , then the algorithms continue to satisfy the conditions given in Section 4.1.1, so we can apply (KY, Theorem 8.2.2) to assert that the conclusions of Theorem 5 continue to hold with $N_\delta(\theta^*)$ replaced by the limit set $N_\delta(L_B)$ of the mean ODE associated with each algorithm. (Recall Theorem 7 is also obtained in this way.) Subsequently, with $N_\delta(L_B)$ in place of $N_\delta(\theta^*)$ again, and with K and ψ_K still held fixed, we use the same proof for Theorem 8(i) to obtain that for any $\delta > 0$ and $m \geq 1$,

$$\liminf_{\alpha \rightarrow 0} \inf_{\mu \in \mathcal{M}_{m\alpha}^m} \mu([N_\delta(L_B)]^{m\alpha}) = 1, \quad \text{where } m_\alpha = \lceil \frac{m}{\alpha} \rceil.$$

Finally, we combine this with the fact that given any $\delta > 0$, the limit set $N_\delta(L_B) \subset N_\delta(\theta^*)$ for all K sufficiently large (see Lemma 3 in Section 4.2, which holds for (19) and (20), as well as their perturbed version (23) since the latter has the same mean ODE as the original algorithm). Theorem 9(i) then follows: given $\delta > 0$, for all K sufficiently large,

$$\liminf_{\alpha \rightarrow 0} \inf_{\mu \in \mathcal{M}_{m\alpha}^m} \mu([N_\delta(\theta^*)]^{m\alpha}) = 1.$$

The proof for Theorem 9(ii) is exactly the same as that for Theorem 8(ii) given earlier. In particular, this proof relies solely on the weak Feller property of the Markov chain $\{(Z_t, \theta_t^*)\}$ and the convergence property of the averaged probability measures of the m -step version of $\{(Z_t, \theta_t^*)\}$, all of which have shown to hold for the algorithms (19) and (20) and their perturbed version (23) in this subsection.

The preceding arguments also show that the first part of Theorem 11 holds; that is, the conclusions of Theorem 7 and Theorem 9 hold for the perturbed version (23) of the algorithm (19) or (20) as well.

4.3.3 PROOFS OF THEOREMS 10 AND 11

In this subsection we establish completely Theorems 10 and 11 regarding the perturbed version (23) of the algorithms (11), (19) and (20). We have already proved the first part of both of these theorems in the previous subsection. Below we tackle their second part, which, as we recall, is stronger than the corresponding part of Theorems 8 and 9 in that for a fixed stepsize α , the deviation of the averaged iterates $\{\bar{\theta}_t^*\}$ from θ^* in the limit as $t \rightarrow \infty$ is now characterized not in an expected sense but for almost all sample paths.

To simplify the presentation, except where noted otherwise, it will be taken for granted throughout this subsection that $\{\theta_t^*\}$ is generated by the perturbed version (23) of any of the three algorithms (11), (19) and (20). Recall that when updating θ_t^* to θ_{t+1}^* , the perturbed algorithm (23) adds the perturbation term $\alpha \Delta_{\theta, t}$ to the iterate before the projection Π_B , where $\Delta_{\theta, t} \geq 0$, are assumed to be i.i.d. \mathbb{R}^m -valued random variables that have zero mean and bounded variances and have a positive continuous density function with respect to the Lebesgue measure. (Here and in what follows, we omit the superscript α of the noise terms $\Delta_{\theta, t}$ since we deal with a fixed stepsize α in this part of the analysis.) As mentioned in Section 3.3, these conditions are not as weak as possible. Indeed, the purpose of the perturbation is to make the invariant probability measure of $\{(Z_t, \theta_t^*)\}$ unique so that we can invoke the ergodic theorem for weak Feller Markov chains given in Lemma 5, Section 4.3.1. Therefore, any conditions that can guarantee the uniqueness of the invariant probability measure can be used. In the present paper, for simplicity, we focus on the conditions we assumed earlier on $\Delta_{\theta, t}$, and prove the uniqueness just mentioned under these conditions, although our proof arguments can be useful for weaker conditions as well.

Proposition 8 *Under Assumption 1, $\{(Z_t, \theta_t^*)\}$ has a unique invariant probability measure.*

The next two lemmas are the intermediate steps to prove Prop. 8. We need the notion of a stochastic kernel, of which the transition kernel of a Markov chain is one example. For two topological spaces \mathbf{X} and \mathbf{Y} , a function $Q: \mathcal{B}(\mathbf{X}) \times \mathbf{Y} \rightarrow [0, 1]$ is a (Borel measurable) stochastic kernel on \mathbf{X} given \mathbf{Y} , if for each $y \in \mathbf{Y}$, $Q(\cdot | y)$ is a probability measure

on $\mathcal{B}(\mathbf{X})$ and for each $D \in \mathcal{B}(\mathbf{X})$, $Q(D | y)$ is a Borel measurable function on \mathbf{Y} . For the algorithms we consider, the iteration that generates $(Z_{t+1}, \theta_{t+1}^\alpha)$ from (Z_t, θ_t^α) can be equivalently described in terms of stochastic kernels. In particular, the transition from Z_t to Z_{t+1} is described by the transition kernel of the Markov chain $\{Z_t\}$, and the probability distribution of θ_{t+1}^α given θ_t^α and $\xi_t = (e_t, F_t, S_t, A_t, S_{t+1})$ is described by another stochastic kernel, which will be our focus in the analysis below.

Lemma 8 *Let Assumption 1(ii) hold. Let $Q(d\theta' | \xi, \theta)$ be the stochastic kernel (on B given $\Xi \times B$) that describes the probability distribution of θ_{t+1}^α given $\xi_t = \xi, \theta_t^\alpha = \theta$. Then for each bounded set $E \subset \Xi$, there exist $\beta \in (0, 1]$ and a probability measure Q_1 on B such that*

$$Q(d\theta' | \xi, \theta) \geq \beta Q_1(d\theta'), \quad \forall \xi \in E, \theta \in B. \quad (61)$$

Proof We consider only the case where $\{\theta_t^\alpha\}$ is generated by the perturbed version of the algorithm (11); the proof for the perturbed version of the two other algorithms (19) and (20) follows exactly the same arguments. In the proof below we use the notation that for a scalar c and a set $D \subset \mathbb{R}^n$, the set $cD = \{cx | x \in D\}$.

By the definitions of the algorithms (11) and (23), for $\xi = (e, F, s, a, s') \in \Xi$ and $\theta \in B$, we can express $Q(\cdot | \xi, \theta)$ as

$$Q(D | \xi, \theta) = \int \mathbb{1}(\Pi_B(\theta + \alpha f(\xi, \theta, r) + \alpha \Delta) \in D) p(d\Delta) q(dr | s, a, s'), \quad \forall D \in \mathcal{B}(B), \quad (62)$$

where $f(\xi, \theta, r) = e \cdot \rho(s, a)(r + \gamma(s')) \phi(s')^\top \theta - \phi(s)^\top \theta$, and $p(\cdot)$ is the common distribution of the perturbation variables $\Delta \theta_t$. Let $\bar{r} > 0$ be large enough so that for some $c > 0$, $q([- \bar{r}, \bar{r}] | \bar{s}, \bar{a}, \bar{s}') \geq c$ for all $(\bar{s}, \bar{a}, \bar{s}') \in \mathcal{S} \times \mathcal{A} \times \mathcal{S}$. Let E be an arbitrary bounded subset of Ξ . For all $\xi \in E$, $\theta \in B$ and $r \in [- \bar{r}, \bar{r}]$, since E and B are bounded, $g(\xi, \theta, r) := (\theta + \alpha f(\xi, \theta, r))/\alpha$ lies in a compact subset of \mathbb{R}^n , which we denote by D . Let $\epsilon \in (0, r_B/\alpha]$ and let D_ϵ be the ϵ -neighborhood of D . By our assumption on the perturbation variables involved in the algorithm (23), $p(\cdot)$ has a positive continuous density function with respect to the Lebesgue measure $\ell(\cdot)$. Therefore, there exists some $c' > 0$ such that for any Borel subset D of the compact set $-D_\epsilon := \{-x | x \in D_\epsilon\}$, $p(D) \geq c' \ell(D)$.

Now consider an arbitrary $\xi \in E$, $\theta \in B$, and $r \in [- \bar{r}, \bar{r}]$. We have $y := g(\xi, \theta, r) \in D$. Let $B_\epsilon(-y)$ be the ϵ -neighborhood of $-y$, and let B_ϵ denote the closed ball in \mathbb{R}^n centered at the origin with radius ϵ . If $\Delta \in B_\epsilon(-y)$, then $\theta + \alpha f(\xi, \theta, r) + \alpha \Delta = \alpha y + \alpha \Delta \in \alpha B_\epsilon \subset B$ (since $\alpha \epsilon \leq r_B$). Therefore, for any $D \in \mathcal{B}(B)$,

$$\begin{aligned} \int \mathbb{1}(\Pi_B(\theta + \alpha f(\xi, \theta, r) + \alpha \Delta) \in D) p(d\Delta) &\geq \int_{B_\epsilon(-y)} \mathbb{1}(\alpha y + \alpha \Delta \in D) p(d\Delta) \\ &\geq c' \int_{B_\epsilon(-y)} \mathbb{1}(\alpha y + \alpha \Delta \in D) \ell(d\Delta) \\ &= c' \ell(\tfrac{1}{\alpha} D \cap B_\epsilon), \end{aligned} \quad (63)$$

where in the second inequality we used the fact that $B_\epsilon(-y) \subset -D_\epsilon$ and restricted to $B(-D_\epsilon)$, $p(d\Delta) \geq c' \ell(d\Delta)$, as discussed earlier.

To finish the proof, define the probability measure Q_1 on B by $Q_1(D) = \ell(\frac{1}{\alpha} D \cap B_\epsilon)/\ell(B_\epsilon)$ for all $D \in \mathcal{B}(B)$. Then for all $\xi \in E$ and $\theta \in B$, using (62) and (63) and our choice of \bar{r} , we have

$$Q(D | \xi, \theta) \geq \int_{[- \bar{r}, \bar{r}]} c' \ell(B_\epsilon) \cdot Q_1(D) q(dr | s, a, s') \geq c \cdot c' \ell(B_\epsilon) \cdot Q_1(D), \quad D \in \mathcal{B}(B),$$

and the desired inequality (61) then follows by letting $\beta = cc' \ell(B_\epsilon) > 0$ (we must have $\beta \leq 1$ since we can choose $D = B$ in the inequality above). \blacksquare

We will use the preceding result in the proof of the next lemma.

Lemma 9 *Let Assumption 1 hold. Let $\{\mu_{x,t}\}$ be the sequence of occupation probability measures of $\{(Z_t, \theta_t^\alpha)\}$ for each initial condition $x \in \mathcal{Z} \times B$. Suppose that for some $x = (z, \theta) \in \mathcal{Z} \times B$ and $\mu \in \mathcal{M}_\alpha$, $\{\mu_{x,t}\}$ converges weakly to μ , \mathbf{P}_x -almost surely. Then for each $\theta' \in B$ and $x' = (z', \theta')$, $\{\mu_{x',t}\}$ also converges weakly to μ , $\mathbf{P}_{x'}$ -almost surely.*

Proof We use a coupling argument to prove the statement. In the proof, we suppress the superscript α of θ_t^α . Let $\{X_t\}$ denote the process $\{(Z_t, \theta_t)\}$ with initial condition $x = (z, \theta)$, and let $\{X'_t\}$ denote the process $\{(Z_t, \theta_t)\}$ with initial condition $x' = (z', \theta')$, for an arbitrary $\theta' \in B$. In what follows, we first define a sequence

$$\{(Z_t, \tilde{\theta}_t, \hat{\theta}_t)\} \quad \text{with } (Z_0, \tilde{\theta}_0, \hat{\theta}_0) = (z, \theta, \theta'),$$

in such a way that the two marginal processes $\{(Z_t, \tilde{\theta}_t)\}$ and $\{(Z_t, \hat{\theta}_t)\}$ have the same probability distributions as $\{X_t\}$ and $\{X'_t\}$, respectively. We then relate the occupation probability measures $\{\mu_{x,t}\}$, $\{\mu_{x',t}\}$ to those of the marginal processes, $\{\tilde{\mu}_{x,t}\}$, $\{\hat{\mu}_{x',t}\}$, which are defined as

$$\tilde{\mu}_{x,t}(D) = \frac{1}{t} \sum_{k=0}^{t-1} \mathbb{1}((Z_k, \tilde{\theta}_k) \in D), \quad \hat{\mu}_{x',t}(D) = \frac{1}{t} \sum_{k=0}^{t-1} \mathbb{1}((Z_k, \hat{\theta}_k) \in D), \quad \forall D \in \mathcal{B}(\mathcal{Z} \times B).$$

We now define $\{(Z_t, \tilde{\theta}_t, \hat{\theta}_t)\}$. First, let $\{Z_t\}$ be generated as before with $Z_0 = z$. Denote $\xi_t = (e_t, F_t, S_t, A_t, S_{t+1})$ as before, and let Q be the stochastic kernel that describes the evolution of θ_{t+1} given (ξ_t, θ_t) . By Lemma 7, the occupation probability measures of $\{Z_t\}$ is almost surely tight for each initial condition. This implies the existence of a compact set $\bar{E} \subset \mathbb{R}^{n+1}$ such that for the compact set $E = \bar{E} \times \mathcal{S} \times \mathcal{A} \times \mathcal{S} \subset \Xi$, the sequence $\{\xi_t\}$ visits E infinitely often with probability one. For this set E , by Lemma 8, there exist some $\beta \in (0, 1]$ and probability measure Q_1 on B such that $Q(\cdot | \xi, \tilde{\theta}) \geq \beta Q_1(\cdot)$ for all $\xi \in E$ and $\tilde{\theta} \in B$. Therefore, on $E \times B$, we can write $Q(\cdot | \xi, \tilde{\theta})$ as the convex combination of Q_1 and another stochastic kernel Q_0 as follows:

$$Q(\cdot | \xi, \tilde{\theta}) = \beta Q_1(\cdot) + (1 - \beta) Q_0(\cdot | \xi, \tilde{\theta}), \quad \forall \xi \in E, \tilde{\theta} \in B, \quad (64)$$

where $Q_0(\cdot | \xi, \tilde{\theta}) = [Q(\cdot | \xi, \tilde{\theta}) - \beta Q_1(\cdot)] / (1 - \beta)$ and Q_0 is a stochastic kernel on B given $E \times B$.

Next, independently of $\{Z_t\}$, generate a sequence $\{Y_t\}_{t \geq 1}$ of i.i.d., $\{0, 1\}$ -valued random variables such that $Y_t = 1$ with probability β and $Y_t = 0$ with probability $1 - \beta$. Set $Y_0 = 0$. Let

$$t_Y = \min\{t \geq 1 \mid Y_t = 1, \xi_{t-1} \in E\}.$$

Then $t_Y < \infty$ with probability one. (Since $\{\xi_t\}$ visits E infinitely often and the process $\{Y_t\}$ is independent of $\{\xi_t\}$, this follows easily from applying the Borel-Cantelli lemma to $\{(\xi_{t_k}, Y_{t_k+1})\}_{k \geq 1}$, where t_k is when the k -th visit to E by $\{\xi_t\}$ occurs.)

Now for each $t \geq 0$, let us define the pair $(\tilde{\theta}_{t+1}, \tilde{\theta}'_{t+1})$ according to the following rule, based on the values of $(\xi_0, \tilde{\theta}_0, \tilde{\theta}'_0), \dots, (\xi_t, \tilde{\theta}_t, \tilde{\theta}'_t)$ and (Y_0, \dots, Y_{t+1}) :

- (i) In the case $t < t_Y$ and $\xi_t \notin E$, generate $\tilde{\theta}_{t+1}$ and $\tilde{\theta}'_{t+1}$ according to $Q(\cdot \mid \xi_t, \tilde{\theta}_t)$ and $Q(\cdot \mid \xi_t, \tilde{\theta}'_t)$ respectively.
- (ii) In the case $t < t_Y$ and $\xi_t \in E$, if $Y_{t+1} = 0$, generate $\tilde{\theta}_{t+1}$ and $\tilde{\theta}'_{t+1}$ according to $Q_0(\cdot \mid \xi_t, \tilde{\theta}_t)$ and $Q_0(\cdot \mid \xi_t, \tilde{\theta}'_t)$ respectively; if $Y_{t+1} = 1$, generate $\tilde{\theta}_{t+1}$ according to $Q_1(\cdot)$ and let $\tilde{\theta}'_{t+1} = \tilde{\theta}_{t+1}$.
- (iii) In the case $t \geq t_Y$, generate $\tilde{\theta}_{t+1}$ according to $Q(\cdot \mid \xi_t, \tilde{\theta}_t)$ and let $\tilde{\theta}'_{t+1} = \tilde{\theta}_{t+1}$.

In view of (64), it can be verified directly by induction on t that the marginal process $\{(Z_t, \tilde{\theta}_t)\}$ (resp. $\{(Z_t, \tilde{\theta}'_t)\}$) in the preceding construction has the same probability distribution as $\{X_t\}$ (resp. $\{X'_t\}$). This implies that $\{\mu_{x,t}\}$ (resp. $\{\mu_{x',t}\}$) converges weakly to μ with probability one if and only if $\{\tilde{\mu}_{x,t}\}$ (resp. $\{\tilde{\mu}_{x',t}\}$) converges weakly to μ with probability one. On the other hand, by construction $\tilde{\theta}_t = \tilde{\theta}'_t$ for $t \geq t_Y$, where $t_Y < \infty$ with probability one, so except on a null set, $\{\tilde{\mu}_{x,t}\}$ and $\{\tilde{\mu}_{x',t}\}$ have the same weak limits. Combining these two arguments with the assumption that $\{\mu_{x,t}\}$ converges weakly to μ with probability one, it follows that the three sequences $\{\mu_{x,t}\}$, $\{\mu_{x',t}\}$, and $\{\tilde{\mu}_{x',t}\}$ must all converge weakly to μ with probability one. ■

Proof of Prop. 8 We suppress the superscript α of θ_t^α in the proof. Let $\{X_t\} = \{(Z_t, \theta_t)\}$. By Prop. 6, the set \mathcal{M}_α of invariant probability measures of $\{X_t\}$ is nonempty. Recall also that since the evolution of $\{Z_t\}$ is not affected by the θ -iterates, the marginal of any $\mu \in \mathcal{M}_\alpha$ on the space \mathcal{Z} must equal ζ , the unique invariant probability measure of $\{Z_t\}$ (Theorem 2).

Suppose $\{X_t\}$ has multiple invariant probability measures; i.e., there exist $\mu, \mu' \in \mathcal{M}_\alpha$ with $\mu \neq \mu'$. Then by (Dudley, 2002, Theorem 11.3.2) there exists a bounded continuous function f on $\mathcal{Z} \times B$ such that

$$\int f d\mu \neq \int f d\mu'. \quad (65)$$

On the other hand, since μ is an invariant probability measure of $\{X_t\}$, applying a strong law of large numbers for stationary processes (Doob, 1953, Chap. X, Theorem 2.1; see also Meyn and Tweedie, 2009, Lemma 17.1.1 and Theorem 17.1.2) to the stationary Markov chain $\{X_t\}$ with initial distribution μ , we have that there exist a set $D_1 \subset \mathcal{Z} \times B$ with $\mu(D_1) = 1$ and a measurable function g_f on $\mathcal{Z} \times B$ such that

- (i) for each $x \in D_1$, with the initial condition $X_0 = x$, $\lim_{t \rightarrow \infty} \frac{1}{t} \sum_{k=0}^{t-1} f(X_k) = g_f(x)$, $\mathbf{P}_{x^{\text{-a.s.}}}$;
- (ii) $\mathbb{E}_\mu[g_f(X_0)] = \mathbb{E}_\mu[f(X_0)]$ (i.e., $\int g_f d\mu = \int f d\mu$).

The same is true for the invariant probability measure μ' : there exist a set $D_2 \subset \mathcal{Z} \times B$ with $\mu'(D_2) = 1$ and a measurable function $g'_f(x)$ such that

- (i) for each $x \in D_2$, with the initial condition $X_0 = x$, $\lim_{t \rightarrow \infty} \frac{1}{t} \sum_{k=0}^{t-1} f(X_k) = g'_f(x)$, $\mathbf{P}_{x^{\text{-a.s.}}}$;
- (ii) $\mathbb{E}_{\mu'}[g'_f(X_0)] = \mathbb{E}_{\mu'}[f(X_0)]$ (i.e., $\int g'_f d\mu' = \int f d\mu'$).

Also, since $\{X_t\}$ is a weak Feller Markov chain (Lemma 6), by (Meyn, 1989, Prop. 4.1), for a set of initial conditions x with μ -measure 1, the occupation probability measures $\{\mu_{x,t}\}$ of $\{X_t\}$ converge weakly, $\mathbf{P}_{x^{\text{-almost surely}}}$, to some (nonrandom) $\tilde{\mu}_x \in \mathcal{M}_\alpha$ that depends on the initial x . The same is true for μ' . So by excluding from D_1 a μ -null set and from D_2 a μ' -null set if necessary, we can assume that the sets D_1, D_2 above also satisfy that for each $x \in D_1 \cup D_2$, the occupation probability measures $\{\mu_{x,t}\}$ converge weakly to an invariant probability measure $\tilde{\mu}_x$ almost surely. Then since $\frac{1}{t} \sum_{k=0}^{t-1} f(X_k)$ is the same as $\int f d\mu_{x,t}$ for $X_0 = x$, we have, by the weak convergence of $\{\mu_{x,t}\}$ just discussed, that

$$g_f(x) = \int f d\tilde{\mu}_x \quad \text{for each } x \in D_1, \quad g'_f(x) = \int f d\tilde{\mu}_x \quad \text{for each } x \in D_2. \quad (66)$$

Certainly we must have $g_f(x) = g'_f(x)$ on $D_1 \cap D_2$. We now relate the values of these two functions at points that share the same z -component. In particular, let $\text{proj}(D_1)$ denote the projection of D_1 on \mathcal{Z} : $\text{proj}(D_1) = \{z \in \mathcal{Z} \mid \exists \theta \text{ with } (z, \theta) \in D_1\}$, and let $D_{1,z}$ be the vertical section of D_1 at z : $D_{1,z} = \{\theta \mid (z, \theta) \in D_1\}$. Define $\text{proj}(D_2)$ and $D_{2,z}$ similarly. If $x = (z, \theta) \in D_1 \cup D_2$ and $x' = (z, \theta') \in D_1 \cup D_2$, then in view of Lemma 9 and the weak convergence of $\{\mu_{x,t}\}$ and $\{\mu_{x',t}\}$, we must have $\tilde{\mu}_x = \tilde{\mu}_{x'}$. Consequently, by (66), for each $z \in \text{proj}(D_1)$, $g_f(z, \cdot)$ is constant on $D_{1,z}$; for each $z \in \text{proj}(D_2)$, $g'_f(z, \cdot)$ is constant on $D_{2,z}$; and for each $z \in \text{proj}(D_1) \cap \text{proj}(D_2)$, the constants that $g_f(z, \cdot)$, $g'_f(z, \cdot)$ take on $D_{1,z}, D_{2,z}$, respectively, are the same.

We now show $\int f d\mu = \int f d\mu'$ to contradict (65) and finish the proof. Since $\mu(D_1) = \mu'(D_2) = 1$ and by Theorem 2 (Section 2.4) μ, μ' have the same marginal distribution on \mathcal{Z} , which is ζ , there exists a Borel set $E \subset \text{proj}(D_1) \cap \text{proj}(D_2)$ with $\zeta(E) = 1$. Consider the sets $(E \times B) \cap D_1$ and $(E \times B) \cap D_2$, which have μ -measure 1 and μ' -measure 1, respectively. By (Dudley, 2002, Prop. 10.2.8), we can decompose μ, μ' into the marginal ζ on \mathcal{Z} and the conditional distributions $\mu(d\theta \mid z), \mu'(d\theta \mid z)$ for $z \in E$. Then

$$1 = \mu((E \times B) \cap D_1) = \int_E \mu(d\theta \mid z) \zeta(dz), \quad 1 = \mu'((E \times B) \cap D_2) = \int_E \int_{D_{2,z}} \mu'(d\theta \mid z) \zeta(dz),$$

where the equality for the iterated integral in each relation follows from (Dudley, 2002, Theorem 10.2.1(ii)). These relations imply that for some set $E_0 \subset E$ with $\zeta(E_0) = 0$,

$$\int_{D_{1,z}} \mu(d\theta \mid z) = \int_{D_{2,z}} \mu'(d\theta \mid z) = 1, \quad \forall z \in E \setminus E_0. \quad (67)$$

We now calculate $\int g_f d\mu$ and $\int g'_f d\mu'$. We have

$$\int g_f d\mu = \int_{(E \times B) \cap D_1} g_f d\mu = \int_E \int_{D_{1,z}} g_f(z, \theta) \mu(d\theta \mid z) \zeta(dz), \quad (68)$$

$$\int g'_f d\mu' = \int_{(E \times B) \cap D_2} g'_f d\mu' = \int_E \int_{D_{2,z}} g'_f(z, \theta) \mu'(d\theta \mid z) \zeta(dz), \quad (69)$$

where the equality for the iterated integral in each relation also follows from (Dudley, 2002, Theorem 10.2.1(ii)). As discussed earlier, for each $z \in E \subset \text{proj}(D_1) \cap \text{proj}(D_2)$, the two constant functions, $g_f(z, \cdot)$ on $D_{1,z}$ and $g_f(z, \cdot)$ on $D_{2,z}$, have the same value. Using this together with (67), we conclude that

$$\int_{D_{1,z}} g_f(z, \theta) \mu(d\theta | z) = \int_{D_{2,z}} g_f(z, \theta) \mu'(d\theta | z), \quad \forall z \in E \setminus E_0. \quad (70)$$

Since $\zeta(E_0) = 0$, we obtain from (68)-(70) that $\int g_f d\mu = \int g_f' d\mu'$. But $\int g_f d\mu = \int f d\mu$ and $\int g_f' d\mu' = \int f' d\mu'$ (as we obtained at the beginning of the proof), so $\int f d\mu = \int f' d\mu'$, a contradiction to (65). This proves that $\{X_t\}$ must have a unique invariant probability measure. ■

Proposition 8 implies that for every $m \geq 1$, the m -step version of $\{(Z_t, \theta_t^*)\}$ has a unique invariant probability measure. This together with Lemma 7 (Section 4.3.2) furnishes the conditions (A1)-(A3) of (Meyn, 1989, Prop. 4.2) for weak Feller Markov chains (these conditions are the conditions (i)-(iii) of our Lemma 5). We can therefore apply the conclusions of (Meyn, 1989, Prop. 4.2) (see Lemma 5 in our Section 4.3.1) to the m -step version of $\{(Z_t, \theta_t^*)\}$ here, and the result is the following proposition:

Proposition 9 *Under Assumption 1, for each $m \geq 1$, the m -step version of $\{(Z_t, \theta_t^*)\}$ has a unique invariant probability measure $\mu^{(m)}$, and the occupation probability measures $\mu_{(z,\theta),t}^{(m)}$, $t \geq 1$, as defined by (51), converge weakly to $\mu^{(m)}$ almost surely, for each initial condition $(z, \theta) \in \mathcal{Z} \times B$ of (Z_0, θ_0^*) .*

With Prop. 9 we can proceed to prove the second part of Theorems 10 and 11. Given that we have already established their first part in the previous subsection, the arguments for their second part are the same for both theorems and are given below. The proof is similar to that for Theorem 8(ii) in Section 4.3.2, except that here, instead of working with the averaged probability measures $\{P_{(z,\theta)}^{(m,k)}\}$, Prop. 9 allows us to work with the occupation probability measures.

Proof of the second part of both Theorem 10 and Theorem 11 We suppress the superscript α of θ_α^* in the proof. By Prop. 9, $\{(Z_t, \theta_t)\}$ has a unique invariant probability measure μ_α , and its m -step version has a corresponding unique invariant probability measure $\mu_\alpha^{(m)}$. We prove first the statement that for each initial condition $(z, \theta) \in \mathcal{Z} \times B$, almost surely,

$$\liminf_{t \rightarrow \infty} \frac{1}{t} \sum_{k=0}^{t-1} \mathbb{1} \left(\sup_{k \leq j < k+m} |\theta_j - \theta^*| < \delta \right) \geq \mu_\alpha^{(m)}([N_\delta^*(\theta^*)]^m), \quad (71)$$

where $\bar{\mu}_\alpha^{(m)}$ is the unique element in $\bar{\mathcal{M}}_\alpha^m$, and $N_\delta^*(\theta^*)$ is the open δ -neighborhood of θ^* . For each t , by the definition (51) of the occupation probability measure $\mu_{(z,\theta),t}^{(m)}$, the average in the left-hand side above is the same as $\mu_{(z,\theta),t}^{(m)}(D_\delta)$, where $D_\delta = \{z^1, \theta^1, \dots, z^m, \theta^m\} \in (\mathcal{Z} \times B)^m \mid \sup_{1 \leq j \leq m} |\theta^j - \theta^*| < \delta\}$. By Prop. 9, $\mathbf{P}_{(z,\theta)}$ -almost surely, $\{\mu_{(z,\theta),t}^{(m)}\}$ converges

weakly to $\mu_\alpha^{(m)}$, and therefore, except on a null set of sample paths, we have by (Dudley, 2002, Theorem 11.1.1) that for the open set D_δ ,

$$\liminf_{t \rightarrow \infty} \mu_{(z,\theta),t}^{(m)}(D_\delta) \geq \mu_\alpha^{(m)}(D_\delta) = \bar{\mu}_\alpha^{(m)}([N_\delta^*(\theta^*)]^m).$$

This proves (71).

We now prove the statement that for each initial condition $(z, \theta) \in \mathcal{Z} \times B$, almost surely,

$$\limsup_{t \rightarrow \infty} |\bar{\theta}_t - \theta^*| \leq \delta \kappa_\alpha + 2r_B (1 - \kappa_\alpha), \quad \text{where } \kappa_\alpha = \bar{\mu}_\alpha(N_\delta^*(\theta^*)), \quad (72)$$

and $\bar{\mu}_\alpha$ is the marginal of μ_α on B . The statement is trivially true if $\delta \geq 2r_B$, so consider the case $\delta < 2r_B$. Fix an initial condition $(z, \theta) \in \mathcal{Z} \times B$ for (Z_0, θ_0) , and let $\{\mu_{(z,\theta),t}\}$ be the corresponding occupation probability measures of $\{(Z_t, \theta_t)\}$. For the averaged sequence $\{\bar{\theta}_t\}$, by convexity of the norm $|\cdot|$,

$$|\bar{\theta}_t - \theta^*| \leq \frac{1}{t} \sum_{k=0}^{t-1} |\theta_k - \theta^*|. \quad (73)$$

We have

$$\begin{aligned} \frac{1}{t} \sum_{k=0}^{t-1} |\theta_k - \theta^*| &\leq \frac{1}{t} \sum_{k=0}^{t-1} |\theta_k - \theta^*| \cdot \mathbb{1}(\theta_k \in N_\delta^*(\theta^*)) + \frac{1}{t} \sum_{k=0}^{t-1} |\theta_k - \theta^*| \cdot \mathbb{1}(\theta_k \notin N_\delta^*(\theta^*)) \\ &\leq \delta \cdot \mu_{(z,\theta),t}(D_\delta) + 2r_B \cdot (1 - \mu_{(z,\theta),t}(D_\delta)), \end{aligned} \quad (74)$$

where $D_\delta = \{z^1, \theta^1\} \in \mathcal{Z} \times B \mid |\theta^1 - \theta^*| < \delta\}$. By Prop. 9, $\mathbf{P}_{(z,\theta)}$ -almost surely, $\{\mu_{(z,\theta),t}\}$ converges weakly to μ_α . Therefore, except on a null set of sample paths, we have by (Dudley, 2002, Theorem 11.1.1) that for the open set D_δ ,

$$\liminf_{t \rightarrow \infty} \mu_{(z,\theta),t}(D_\delta) \geq \mu_\alpha(D_\delta) = \bar{\mu}_\alpha(N_\delta^*(\theta^*)). \quad (75)$$

Combining the three inequalities (73)-(75), and using also the relation $\delta < 2r_B$, we obtain that (72) holds almost surely for each initial condition $(z, \theta) \in \mathcal{Z} \times B$. ■

Remark 3 (on the role of perturbation again) As mentioned before Prop. 8, our purpose of perturbing the constrained ETD algorithms is to guarantee that the Markov chain $\{(Z_t, \theta_t^*)\}$ has a unique invariant probability measure. Without the perturbation, this cannot be ensured, so we cannot apply the ergodic theorem given in Lemma 5 to exploit the convergence of occupation probability measures, as we did in the preceding proof, even though $\{(Z_t, \theta_t^*)\}$ satisfies the remaining two conditions required by that ergodic theorem (cf. Lemma 7, Section 4.3.2).

In connection with this discussion, let us clarify a point. We know that the occupation probability measures of $\{Z_t\}$ converge weakly to its unique invariant probability measure ζ almost surely for each initial condition of Z_0 (Theorem 2). But this fact alone cannot rule out the possibility that $\{(Z_t, \theta_t^*)\}$ has multiple invariant probability measures and that its occupation probability measures do not converge for some initial condition (z, θ) .

Finally, another property of weak Feller Markov chains and its implication for our problem are worth noting here. By (Meyn, 1989, Prop. 4.1), for a weak Feller Markov chain $\{X_t\}$, provided that an invariant probability measure μ exists, we have that for a set of initial conditions x with μ -measure 1, the occupation probability measures $\{\mu_{x,t}\}$ converge weakly, \mathbf{P}_x -almost surely, to an invariant probability measure μ_x that depends on the initial condition. Thus, for the unperturbed algorithms (11), (19) and (20), despite the possibility of $\{(Z_t, \theta_t^\alpha)\}$ having multiple invariant probability measures, the preceding proof can be applied to those initial conditions from which the occupation probability measures converge almost surely. In particular, this argument leads to the following conclusion. In the case of the algorithm (11), (19) or (20), under the same conditions as in Theorem 8 or 9, it holds for any invariant probability measure μ of $\{(Z_t, \theta_t^\alpha)\}$ that for each initial condition (z, θ) from some set of initial conditions with μ -measure 1,

$$\limsup_{t \rightarrow \infty} |\bar{\theta}_t^\alpha - \theta^*| \leq \delta \kappa_\alpha + 2r_B(1 - \kappa_\alpha) \quad \mathbf{P}_{(z, \theta)\text{-a.s.}},$$

where $\kappa_\alpha = \inf_{\mu \in \bar{\mathcal{M}}_\alpha} \mu(N_\delta^c(\theta^*))$. The limitation of this result, however, is that the set of initial conditions involved is unknown and can be small. ■

5. Discussion

In this section we discuss direct applications of our convergence results to ETD(λ) under relaxed conditions and to two other algorithms, the off-policy TD(λ) algorithm and the ETD(λ, β) algorithm (Hallak et al., 2016). We then discuss several open issues to conclude the paper.

5.1 The Case without Assumption 2

Let Assumption 1 hold. Recall from Section 2.3 that ETD(λ) aims to solve the equation $C\theta + b = 0$, where

$$b = \Phi^\top \bar{M} r_{\pi, \gamma}^\lambda, \quad C = -\Phi^\top G \Phi \quad \text{with} \quad G = \bar{M}(I - P_{\pi, \gamma}^\lambda).$$

In this paper we have focused on the case where Assumption 2 holds and C is negative definite (Theorem 1, Section 2.3). If Assumption 2 does not hold, then either there are less than n emphasized states (i.e., states s with $M_{ss} > 0$), or the feature vectors of emphasized states are not rich enough to contain n linearly independent vectors. In either case the function approximation capacity is not fully utilized. It is hence desirable to fulfill Assumption 2 by adding more states with positive interest weights $i(s)$ or by enriching the feature representation.

Nevertheless, suppose Assumption 2 does not hold (in which case C is negative semidefinite as shown by Sutton et al., 2016). This essentially has no effects on the convergence properties of the constrained or unconstrained ETD(λ) algorithms, because of the emphatic weighting scheme (3)-(5), as we explain now.

Let there be at least one state s with interest weight $i(s) > 0$ (the case is vacuous otherwise). Partition the state space into the set of emphasized states and the set of non-emphasized states:

$$\mathcal{J}_1 = \{s \in S \mid \bar{M}_{ss} > 0\}, \quad \mathcal{J}_0 = \{s \in S \mid \bar{M}_{ss} = 0\}.$$

Corresponding to the partition, by rearranging the indices of states if necessary, we can write

$$\Phi = \begin{bmatrix} \Phi_1 \\ \Phi_0 \end{bmatrix}, \quad r_{\pi, \gamma}^\lambda = \begin{bmatrix} r_1 \\ r_0 \end{bmatrix}, \quad \bar{M} = \begin{bmatrix} \bar{M} & 0_{|\mathcal{J}_1| \times |\mathcal{J}_0|} \\ 0_{|\mathcal{J}_0| \times |\mathcal{J}_1|} & 0_{|\mathcal{J}_0| \times |\mathcal{J}_0|} \end{bmatrix},$$

where $0_{m \times m'}$ denotes an $m \times m'$ zero matrix, \bar{M} is a diagonal matrix with \bar{M}_{ss} , $s \in \mathcal{J}_1$, as its diagonals. Let \hat{Q} be the sub-matrix of $P_{\pi, \gamma}^\lambda$ that consists of the entries whose row/column indices are in \mathcal{J}_1 . For the equation $C\theta + b = 0$, clearly $b = \Phi_1^\top \bar{M} r_1$. Consider now the matrix C . It is shown in the proof of Prop. C.2 in (Yu, 2015a) that G has a block-diagonal structure with respect to the partition $\{\mathcal{J}_1, \mathcal{J}_0\}$,

$$G = \begin{bmatrix} \hat{G} & 0_{|\mathcal{J}_1| \times |\mathcal{J}_0|} \\ 0_{|\mathcal{J}_0| \times |\mathcal{J}_1|} & 0_{|\mathcal{J}_0| \times |\mathcal{J}_0|} \end{bmatrix},$$

where the block corresponding to \mathcal{J}_0 is a zero matrix as shown above, and the block \hat{G} corresponding to \mathcal{J}_1 is a positive definite matrix given by

$$\hat{G} = \hat{M}(I - \hat{Q}), \quad (76)$$

and \hat{M} can be expressed explicitly as

$$\text{diag}(\hat{M}) = d_{\pi, i}^\top (I - \hat{Q})^{-1}, \quad d_{\pi, i}^\top \in \mathbb{R}^{|\mathcal{J}_1|}, \quad d_{\pi, i}^\top(s) = d_{\pi^o}(s) \cdot i(s), \quad s \in \mathcal{J}_1. \quad (77)$$

Thus the matrix C has a special structure:

Theorem 12 (structure of the matrix C ; Yu, 2015a, Appendix C.2, p. 41-44) *Let Assumption 1 hold, and let $i(s) > 0$ for at least one state $s \in S$. Then*

$$C = -\Phi_1^\top \hat{G} \Phi_1, \quad \text{where } \hat{G} = \hat{M}(I - \hat{Q}) \text{ is positive definite.}$$

Let $\text{range}(A)$ denote the range space of a matrix A . By the positive definiteness of the matrix \hat{G} given in the preceding theorem, the negative semidefinite matrix C possesses the following properties (we omit the straightforward proof):

Proposition 10 *Let Assumption 1 hold, and let $i(s) > 0$ for at least one state $s \in S$. Then the matrix C satisfies that*

- (i) $\text{range}(C) = \text{range}(C^\top) = \text{span}\{\phi(s) \mid s \in \mathcal{J}_1\}$; and
- (ii) there exists $c > 0$ such that for all $x \in \text{span}\{\phi(s) \mid s \in \mathcal{J}_1\}$, $x^\top C x \leq -c \|x\|^2$.

Two observations then follow immediately:

- (i) Since $b = \Phi_1^\top \bar{M} r_1 \in \text{span}\{\phi(s) \mid s \in \mathcal{J}_1\}$, Prop. 10(i) shows that the equation $C\theta + b = 0$ admits a solution, and a unique one in $\text{span}\{\phi(s) \mid s \in \mathcal{J}_1\}$, which we denote by θ^* .¹⁵

15. From the structures of G , $P_{\pi, \gamma}^\lambda$, \hat{Q} and \hat{M} shown in (Yu, 2015a, Appendix C.2, p. 41-44), which give rise to (76)-(77), we also have the following facts. The approximate value function $v = \Phi_1 \theta^*$ for the emphasized states \mathcal{J}_1 is the unique solution of the projected Bellman equation $v = \Pi(r_1 + Qv)$, where Π is the projection onto the column space of Φ_1 with respect to the weighted Euclidean norm on $\mathbb{R}^{|\mathcal{J}_1|}$ defined by the weights \bar{M}_{ss} , $s \in \mathcal{J}_1$ (the diagonals of \bar{M}). The equation $v = r_1 + Qv$ is indeed a generalized Bellman equation for the emphasized states only, and has $v_{\pi}(s)$, $s \in \mathcal{J}_1$, as its unique solution. Then for the emphasized states, the relation between the approximate value function $\Phi_1 \theta^*$ and v_{π} on \mathcal{J}_1 , in particular the approximation error, can again be characterized using the oblique projection viewpoint (Scherer, 2010), similar to the case with Assumption 2 discussed in Section 2.3.

(ii) Prop. 10(ii) shows that C acts like a negative definite matrix on the space of feature vectors, $\text{span}\{\phi(s)|s \in \mathcal{J}_1\}$, that the ETD(λ) algorithms naturally operate on.¹⁶

We remark that for an arbitrary negative semidefinite matrix C , neither of these conclusions holds. They hold here as direct consequences of the positive definiteness of the matrix \tilde{G} that underlies C , and this positive definiteness property is due to the emphatic weighting scheme (3)-(5) employed by ETD(λ).

Now let us discuss the behavior of the constrained ETD(λ) algorithms starting from some state S_0 of interest (i.e., $i(S_0) > 0$), in the absence of Assumption 2. Recall that earlier we did not need Assumption 2 when applying the two general convergence theorems from (Kushner and Yin, 2003), and we used the negative definiteness of C implied by this assumption only near the end of our proofs to get the solution properties of the mean ODE associated with each algorithm. In the absence of Assumption 2, for the unperturbed algorithms (11), (19) and (20), we can simply restrict attention to the subspace $\text{span}\{\phi(s)|s \in \mathcal{J}_1\}$ and use the property in Prop. 10(ii) in lieu of negative definiteness. After all, the θ -iterates of these algorithms always lie in the span of the feature vectors if the initial $\theta_0, e_0 \in \text{span}\{\phi(s)|s \in \mathcal{J}_1\}$ and in the case of the two biased algorithms (19) and (20), if the function $\psi_K(x)$ does not change the direction of x . On the subspace $\text{span}\{\phi(s)|s \in \mathcal{J}_1\}$, in view of Prop. 10(ii), the function $\theta - \theta^{*12}$ serves again as a Lyapunov function for analyzing the ODE solutions in exactly the same way as before. Thus, in the absence of Assumption 2, for the algorithms (11), (19) and (20) that set θ_0, e_0 and ψ_K as just described, and for $rB > |b|/c$ where c is as in Prop. 10(ii), the conclusions of Theorems 4-9 in Section 3 continue to hold with $N_\delta(\theta^*)$ or $N'_\delta(\theta^*)$ replaced by $N_\delta(\theta^*) \cap \text{span}\{\phi(s)|s \in \mathcal{J}_1\}$ or $N'_\delta(\theta^*) \cap \text{span}\{\phi(s)|s \in \mathcal{J}_1\}$.

The same is true for the almost sure convergence of the unconstrained ETD(λ) algorithm (2) under diminishing stepsize: with $i(S_0) > 0$ and $\theta_0, e_0 \in \text{span}\{\phi(s)|s \in \mathcal{J}_1\}$, the conclusion of (Yu, 2015a, Theorem 2.2) continues to hold in the absence of Assumption 2; that is, for $\alpha_t = O(1/t)$ with $\frac{\alpha_t}{\alpha_{t-1}} = O(1/t)$, $\theta_t \xrightarrow{\text{a.s.}} \theta^*$.

It can be seen now that without Assumption 2, complications can only arise through initializing the algorithms outside the desired subspace. We discussed such situations in the arXiv version of this paper (Yu, 2015b, Sec. 5.1), but we shall omit them here in part because it does not seem natural to initialize θ_0, e_0 with a component perpendicular to $\text{span}\{\phi(s)|s \in \mathcal{J}_1\}$ in the first place.

As a final note, in the absence of Assumption 2, any solution $\bar{\theta}$ of $C\bar{\theta} + b = 0$ gives *the same approximate value function for emphasized states*, but the approximate values $\Phi_{\bar{\theta}}\bar{\theta}$ for non-emphasized states in \mathcal{J}_0 are *different* for different solutions $\bar{\theta}$. Thus one needs to be cautious in using the approximate values $\Phi_{\bar{\theta}}\bar{\theta}$. They correspond to different extrapolations from the approximate values $\Phi_{\theta^*}\theta^*$ for the emphasized states, whereas $\Phi_{\bar{\theta}}\bar{\theta}$ is not defined to take into account approximation errors for those states in \mathcal{J}_0 , although its approximation error for emphasized states can be well characterized (cf. Footnote 15).

16. Start ETD(λ) from a state S_0 with $i(S_0) > 0$. It can be verified that the emphatic weighting scheme dictates that if $S_t \in \mathcal{J}_0$, then the emphasis weight M_t for that state must be zero. Consequently, e_t is a linear combination of the features of the emphasized states and the initial e_0 . So when $e_0 \in \text{span}\{\phi(s)|s \in \mathcal{J}_1\}$, $e_t \in \text{span}\{\phi(s)|s \in \mathcal{J}_1\}$ always, and if in addition $\theta_0 \in \text{span}\{\phi(s)|s \in \mathcal{J}_1\}$, then $\theta_t \in \text{span}\{\phi(s)|s \in \mathcal{J}_1\}$ always. This is very similar to the case of TD(λ) with possibly linearly dependent features discussed in (Tsitisklis and Van Roy, 1997).

5.2 Off-policy TD(λ) and ETD(λ, β)

Applying TD(λ) to off-policy learning by using importance sampling techniques was first proposed in (Precup et al., 2000, 2001), and the focus there was on episodic data. The analysis we gave in this paper applies directly to the (non-episodic) off-policy TD(λ) algorithm studied in (Bertsekas and Yu, 2009; Yu, 2012; Dann et al., 2014), when its divergence issue is avoided by setting λ sufficiently large. Specifically, we consider constant $\gamma \in [0, 1)$ and constant $\lambda \in [0, 1]$, and an infinitely long trajectory generated by the behavior policy as before. The algorithm is the same as TD(λ) except for incorporating the importance sampling weight p_t :¹⁷

$$\theta_{t+1} = \theta_t + \alpha_t e_t \cdot p_t (R_t + \gamma \phi(S_{t+1})^\top \theta_t - \phi(S_t)^\top \theta_t),$$

where

$$e_t = \lambda \gamma^{t-1} e_{t-1} + \phi(S_t).$$

The constrained versions of the algorithm are defined similarly to those for ETD(λ).

Under Assumption 1(ii), the associated projected Bellman equation is the same as that for on-policy TD(λ) (Tsitisklis and Van Roy, 1997) except that the projection norm is the weighted Euclidean norm with weights given by the steady state probabilities $d_{\pi^o}(s)$, $s \in \mathcal{S}$. Assuming Φ has full column rank, the corresponding equation in the θ -space, $C\theta + b = 0$, has the desired property that the matrix C is negative definite, if λ is sufficiently large (in particular if $\lambda = 1$) (Bertsekas and Yu, 2009). For that case, the conclusions given in this paper for constrained ETD(λ) all hold for the corresponding versions of off-policy TD(λ). (Similarly, for the case of C being negative semidefinite due to Φ having rank less than n , the discussion given in the previous subsection for ETD(λ) also applies.) The reason is that besides the property of C , the other properties of the iterates that we used in our analysis, which are given in Section 2 and Appendix A, all hold for off-policy TD(λ). In fact, some of these properties were first derived for off-policy LSTD(λ) and TD(λ) in (Yu, 2012) and extended later in (Yu, 2015a) to ETD(λ).

For the same reason, the convergence analyses we gave in (2015a) and this paper for ETD also apply to a variation of the ETD algorithm, ETD(λ, β), proposed recently by Hallak et al. (2016), when the parameter β is set in an appropriate range.

5.3 Open Issues

A major difficulty in applying off-policy TD learning, especially with $\lambda > 0$, is the high variances of the iterates. For ETD(λ), off-policy TD(λ) and their least-squares versions, because of the growing variances of products of the importance sampling weights $p_t p_{t+1} \dots$ along a trajectory, and because of the amplifying effects these weights can have on the traces, the variances of the traces iterates can grow unboundedly with time, severely affecting the behavior of the algorithms in practice. (The problem of growing variances when applying

17. It is not necessary to multiply the term $\phi(S_t)^\top \theta_t$ by p_t , and that version of the algorithm was the one given in (Bertsekas and Yu, 2009; Yu, 2012). The experimental results in (Dann et al., 2014) suggest to us that each version can have less variance than the other in some occasions, however. As far as convergence analysis is concerned, the two versions are essentially the same and the analyses given in (Yu, 2012, 2015a) and this paper indeed apply simultaneously to both versions of the algorithm.

importance sampling to simulate Markov systems was also known earlier and discussed in prior works; see e.g., Glynn and Iglehart, 1989; Randhawa and Juneja, 2004.) The two biased constrained algorithms discussed in this paper were motivated by the need to mitigate the variance problem, and their robust behavior has been observed in our experiments (Mahmood et al., 2015; Yu, 2016). However, beyond simply constraining the iterates, more variance reduction techniques are needed, such as control variates (Randhawa and Juneja, 2004; Ahamed et al., 2006) and weighted importance sampling (Precup et al., 2000, 2001; Mahmood et al., 2014; Mahmood and Sutton, 2015). To overcome the variance problem in off-policy learning, further research is required.

Regarding convergence analysis of ETD(λ), the results we gave in (2015a) and this paper concern only the convergence properties and not the rates of convergence. For on-policy TD(λ) and LSTD(λ), convergence rate analyses are available (Konda, 2002, Chap. 6). Such analyses in the off-policy case will give us better understanding of the asymptotic behavior of the off-policy algorithms. Finally, besides asymptotic behavior of the algorithms, their finite-time or finite-sample properties (such as those considered by Munos and Szepesvári, 2008; Antos et al., 2008; Lazaric et al., 2012; Liu et al., 2015), and their large deviations properties are also worth studying.

Acknowledgments

Appendix A. Key Properties of Trace Iterates

In this appendix we list four key properties of trace iterates $\{(e_t, F_t)\}$ generated by the ETD(λ) algorithm. Three of them were derived in (Yu, 2015a, Appendix A), and used in the convergence analysis of ETD(λ) in both (Yu, 2015a) and the present paper.

As discussed in Section 3.2, $\{(e_t, F_t)\}$ can have unbounded variances and is naturally unbounded in common off-policy situations. However, as the proposition below shows, $\{(e_t, F_t)\}$ is bounded in a stochastic sense.

Proposition 11 *Under Assumption 1, given a bounded set $E \subset \mathbb{R}^{n+1}$, there exists a constant $L < \infty$ such that if the initial $(e_0, F_0) \in E$, then $\sup_{t \geq 0} \mathbb{E}[\|(e_t, F_t)\|] < L$.*

The preceding proposition is the same as (Yu, 2015a, Prop. A.1) except that the conclusion is for all the initial (e_0, F_0) from the set E , instead of a fixed initial (e_0, F_0) . By making explicit the dependence of the constant L on the initial (e_0, F_0) , the same proof of (Yu, 2015a, Prop. A.1) (which is a relatively straightforward calculation) applies to the preceding proposition.

We note that Prop. 11 does not imply the *uniform integrability* of $\{(e_t, F_t)\}$ —this stronger property does hold for the trace iterates, as we proved in Prop. 2(i), Section 4.1.2. (The latter and its proof focus on $\{e_t\}$ only, but the same argument applies to $\{(e_t, F_t)\}$.)

The next proposition concerns the change in the trace iterates due to the change in its initial condition. It is the same as (Yu, 2015a, Prop. A.2); its proof is more involved than the proofs of the two other properties of the trace iterates and uses, among others, a theorem for nonnegative random processes (Neveu, 1975). We did not use this proposition directly in the analysis of the present paper, but it is important in establishing that the Markov chain $\{Z_t\}$ has a unique invariant probability measure (Theorem 2, Section 2.4), which the results of the present paper rely on. In addition, it is helpful for understanding the behavior of the trace iterates.

Let (\hat{e}_t, \hat{F}_t) , $t \geq 1$, be defined by the same recursion (3)-(5) that defines (e_t, F_t) , using the same state and action random variables $\{(S_t, A_t)\}$, but with a different initial condition (\hat{e}_0, \hat{F}_0) . We write a zero vector in any Euclidean space as $\mathbf{0}$.

Proposition 12 *Under Assumption 1, for any two given initial conditions (e_0, F_0) and (\hat{e}_0, \hat{F}_0) ,*

$$F_t - \hat{F}_t \xrightarrow{a.s.} \mathbf{0}, \quad e_t - \hat{e}_t \xrightarrow{a.s.} \mathbf{0}.$$

The third proposition below concerns approximating the trace iterates (e_t, F_t) by truncated traces that depend on a fixed number of the most recent states and actions only. First, let us express the traces (e_t, F_t) , by using their definitions (cf. Equations 3-5), as

$$F_t = F_0 \cdot (\rho_0 \gamma_1 \cdots \rho_{t-1} \gamma_t) + \sum_{k=1}^t i(S_k) \cdot (\rho_k \gamma_{k+1} \cdots \rho_{t-1} \gamma_t), \quad (78)$$

$$e_t = e_0 \cdot (\beta_1 \cdots \beta_t) + \sum_{k=1}^t M_k \cdot \phi(S_k) \cdot (\beta_{k+1} \cdots \beta_t), \quad (79)$$

where $\beta_k = \rho_{k-1} \gamma_k \lambda_k$ and

$$M_k = \lambda_k i(S_k) + (1 - \lambda_k) F_k.$$

For each integer $K \geq 1$, the truncated traces $(\tilde{e}_{t,K}, \tilde{F}_{t,K})$ are defined by limiting the summations in (78)-(79) to be over $K+1$ terms only as follows:

$$(\tilde{e}_{t,K}, \tilde{F}_{t,K}) = (e_t, F_t) \quad \text{for } t \leq K,$$

and for $t \geq K+1$,

$$\tilde{F}_{t,K} = \sum_{k=t-K}^t i(S_k) \cdot (\rho_k \gamma_{k+1} \cdots \rho_{t-1} \gamma_t), \quad (80)$$

$$\tilde{M}_{t,K} = \lambda_t i(S_t) + (1 - \lambda_t) \tilde{F}_{t,K}, \quad (81)$$

$$\tilde{e}_{t,K} = \sum_{k=t-K}^t \tilde{M}_{k,K} \cdot \phi(S_k) \cdot (\beta_{k+1} \cdots \beta_t). \quad (82)$$

We have the following approximation property for truncated traces, in which the notation “ $L_K \downarrow 0$ ” means that L_K decreases monotonically to 0 as $K \rightarrow \infty$.

Proposition 13 *Let Assumption 1 hold. Given a bounded set $E \subset \mathbb{R}^{n+1}$, there exist constants $L_K, K \geq 1$, with $L_K \downarrow 0$ as $K \rightarrow \infty$, such that if the initial $(e_0, F_0) \in E$, then*

$$\sup_{t \geq 0} E \left[\left\| (e_t, F_t) - (\bar{e}_{t,K}, \bar{F}_{t,K}) \right\| \right] \leq L_K.$$

The preceding proposition is the same as (Yu, 2015a, Prop. A.3(i)), except that the initial (e_0, F_0) can be from a bounded set E instead of being fixed. The proof given in (Yu, 2015a) applies here as well, similar to the case of Prop. 11. This proposition about truncated traces was used in (Yu, 2015a) to obtain the convergence in mean given in Theorem 3 (Section 2.4) and allowed us to work with simple finite-space Markov chains, instead of working with the infinite-space Markov chain $\{Z_t\}$ directly, in that proof. In the present paper, it has expedited our proofs of Props. 2-3 (Section 4.1.2) regarding the uniform integrability and convergence in mean conditions for constrained ETD(λ).

Finally, the uniform integrability of $\{(e_t, F_t)\}$ (proved in Prop. 2(i) in this paper, as already mentioned) is important both for convergence analysis and for understanding the behavior of the trace iterates.

Abstract

RLScore is a Python open source module for kernel based machine learning. The library provides implementations of several regularized least-squares (RLS) type of learners. RLS methods for regression and classification, ranking, greedy feature selection, multi-task and zero-shot learning, and unsupervised classification are included. Matrix algebra based computational short-cuts are used to ensure efficiency of both training and cross-validation.

A simple API and extensive tutorials allow for easy use of RLScore.

Keywords: cross-validation, feature selection, kernel methods, Kronecker product kernel, pair-input learning, python, regularized least-squares

1. Introduction

RLScore implements learning algorithms based on minimizing the regularized risk functional

$$\operatorname{argmin}_{f \in \mathcal{H}} R(f) + \lambda \|f\|^2,$$

where f is the learned predictor, \mathcal{H} a reproducing kernel Hilbert space of functions, $R(f)$ the empirical risk, $\|f\|^2$ the regularizer, and $\lambda > 0$ a regularization parameter.

Regularized least-squares¹ (RLS) is the classical method resulting from the choice $R(f) = \sum_{i=1}^n (f(\mathbf{x}_i) - y_i)^2$. The method admits a closed form solution, leading to efficient algorithms for leave-one-out cross-validation (LOO), multi-target learning, and fast selection of regularization parameter (Rifkin and Lippert, 2007). For example, the LOO predictions can be obtained essentially for free as the sideproduct of computations needed for training the method once. Previously, these methods have been implemented in libraries such as GURLS (Tacchetti et al., 2013) and Python scikit-learn (Pedregosa et al., 2011).

In the recent years, research in RLS methods has led to the development of a large variety of new efficient algorithms, that analogously to the classical RLS methods offer unique computational benefits both for training and model selection. These include leave-pair-out and leave-group-out cross-validation, methods for feature selection, ranking and unsupervised classification, as well as pair-input learning methods with applications to interaction prediction, cold start recommendations and zero-shot learning. RLScore is a Python module that provides a simple high-level interface to a library of highly optimized implementations of these methods.

1. aka kernel ridge regression, least-squares support vector machine

2. Implemented Algorithms

RLScore implements a large variety of fast holdout and CV algorithms. A fast leave-group-out (LGO) CV (Pahikkala et al., 2012b), where folds containing multiple instances are left out, is provided, complementing the classical fast RLS LOO algorithm (also included) (Rifkin and Lippert, 2007). The approach allows implementing fast K-fold CV, and more importantly, implementing CV for non i.i.d. data with natural group structure. Typical examples include leave-query-out CV for learning to rank, leave-sentence-out or leave-document out CV in text mining, leave-image-out CV for object recognition etc. Further, a leave-pair-out (LPO) algorithm (Pahikkala et al., 2009), that corresponds to leaving each combination of two instances (or a subset of these) from the data out in turn, is provided. LPO can be used to compute an almost unbiased estimate of area under ROC curve (Airola et al., 2011) and its generalization, the pairwise ranking accuracy.

RankRLS method implements efficient algorithms for both minimizing pairwise ranking losses and computing cross-validation estimates for ranking. The method has been shown to be highly competitive compared to ranking support vector machines (Pahikkala et al., 2009). Unsupervised variants of RLS classification inspired by the maximum margin clustering approach have also been developed (Pahikkala et al., 2012a).

Greedy RLS extends the basic RLS to learning sparse linear models in linear time, combining fast update formulas for feature addition and LOO with a greedy search (Naula et al., 2014). The computational short cuts allow scaling the approach to genome wide studies with hundreds of thousands of features. The method produced the winning submission of sub-challenge 3 of 2014 Broad-DREAM Gene Essentiality Prediction Challenge due to its ability to select a minimal accurate subset of features for multi-task learning problems.

RLS methods allow also fast learning from pair-input data. Applications include protein-protein and drug-target interaction prediction (Pahikkala et al., 2015), forecasting winners of two-player games, collaborative filtering, learning to rank for information retrieval etc. When making predictions for new pairs unseen in training set, the setting has natural applications in transfer and zero-shot learning. In the kernel methods framework this can be expressed as a learning problem where objects from two domains have their own kernel functions, and their joint kernel is the Kronecker product kernel. Efficient training and cross-validation algorithms for this setting have been recently derived (see e.g. Pahikkala et al. 2013; Stock et al. 2016).

3. Software Package

RLScore is implemented as a Python module that depends on NumPy (van der Walt et al., 2011) for basic data structures and linear algebra, SciPy (Jones et al., 2001-) for sparse matrices and optimization methods, and Cython (Behnel et al., 2011) for implementing low-level routines in C-language. The aim of the software is to provide high quality implementations of algorithms developed by the authors that combine efficient training with automated performance evaluation and model selection methods.

RLScore implements a modular design, where data representation, learning algorithms, and prediction are separated from each other where possible. The most basic kernel-based learning methods operate on a singular value decomposition of the data produced by an

adapter object. The hypothesis space used depends on the adapter, choices include both linear and kernel feature spaces, as well as Nyström type of reduced-set approximation. After training, the adapter creates a suitable type of linear or kernel predictor. The predictor object can be used or saved to disk independently of the algorithm used to train it.

The API design has been influenced by common Python data analysis environments such as NumPy, SciPy and scikit-learn, making it easy to combine RLScore with existing data analysis pipelines. The most fundamental classes in RLScore are learner objects in module `rlscore.learner`. At initialization, a learner is trained, and function `predict` is used for prediction. The predictor object can also be directly accessed and used independently of the learner. The majority of the learners also implement fast holdout and cross-validation functions, and support kernels, and fast multi-target learning. Unit tests are used to verify the implementations. Extensive tutorials describe how RLScore can be used to solve different types of problems. Listing 1 presents a simple demonstration of the interface.

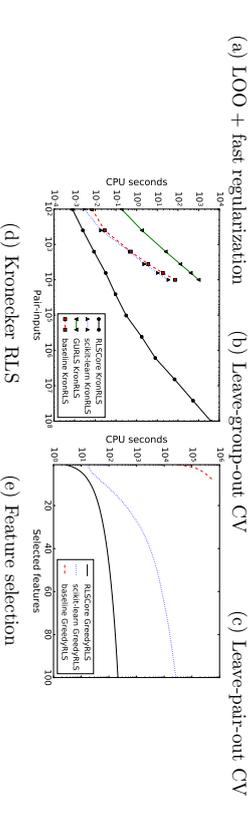

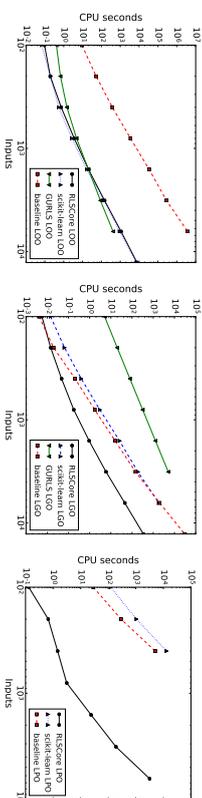

Listing 1: feature selection with greedy RLS algorithm

```
import numpy as np
from rlscore.learner import GreedyRLS
from scipy.stats import kendalltau

#regression problem with 3 important features
X = np.random.randn(100, 20)
y = X[:, 0] + X[:, 2] - X[:, 5] + 0.1*np.random.randn(100)
#select 3 features with greedy RLS
rls = GreedyRLS(X[:50], y[:50], regparam=1, subsetsize=3)
#Did we select the right features?
print(rls.selected)
#Compute test set predictions
p = rls.predict(X[50:])
print(kendalltau(y[50:], p))
```

4. Benchmarks

Here we demonstrate the advantages of RLScore solvers on five benchmark tasks. Each of the considered tasks can be expressed either as a single or a sequence of RLS problems with closed form solutions. The *baseline* method solves each resulting system $(\mathbf{K} + \lambda \mathbf{D})\mathbf{A} = \mathbf{Y}$ or $(\mathbf{X}^T \mathbf{X} + \lambda \mathbf{I})\mathbf{W} = \mathbf{X}^T \mathbf{Y}$ with Python `numpy.linalg.solve` that calls the LAPACK `gesv` routine. Further we compare to two existing RLS solvers implemented in Python `scikit-learn` (version 0.18) (Pedregosa et al., 2011) and the MATLAB GURLS package (Tacheteli et al., 2013). The RLScore algorithms produce exactly the same results as the compared methods, but make use of a number of computational short-cuts resulting in substantial increases in efficiency. GURLS results were not included for LPO and feature selection as the runtimes were impractically long. Benchmark codes for comparing RLScore and scikit-learn RLS implementations are included in the RLScore code repository.

- (a) Leave-one-out CV and regularization parameter selection (parameter grid $\{2^{-15}, \dots, 2^{15}\}$, linear kernel, equal number of instances and features). Both scikit-learn and GURLS also implement fast LOO and regularization.
- (b) Leave-group-out CV, 10 instances per fold, Gaussian kernel, 500 features.
- (c) Leave-pair-out CV, Gaussian kernel, 500 features.
- (d) Kronecker product kernel $\mathbf{K} \otimes \mathbf{G}$ is a popular choice in pair-input learning. **KronRLS** allows learning with the kernel without explicitly forming the pairwise kernel matrix. We generate two kernel matrices of size $n \times n$, the label vector \mathbf{Y} contains n^2 entries, one label for each pair. Baseline explicitly constructs the $n^2 \times n^2$ -sized kernel matrix.
- (e) Learning sparse models. We consider greedy forward selection, where on each iteration one selects the feature whose addition provides the lowest RLS LOO error. **GreedyRLS** implements this procedure in linear time, with scikit-learn we use the fast LOO algorithm, baseline is a pure wrapper implementation. Data matrix \mathbf{X} contains 10000 instances and 1000 features, and the number of outputs in \mathbf{Y} is 10.

RLScore scales to orders of magnitude larger problem sizes than the baselines on all but the LOO experiment. With the exception of LOO, none of the considered fast algorithms are available in other software implementations. RLScore contains also a large variety of other methods, with new ones being added with each release.

Acknowledgments

We would like to acknowledge the support from the Academy of Finland (grants 134020 and 289903) and the co-authors who participated in developing the implemented algorithms.

Abstract

Structured prediction models have been found to learn effectively from a few large examples—sometimes even just one. Despite empirical evidence, canonical learning theory cannot guarantee generalization in this setting because the error bounds decrease as a function of the number of examples. We therefore propose new PAC-Bayesian generalization bounds for structured prediction that decrease as a function of both the number of examples and the size of each example. Our analysis hinges on the stability of joint inference and the smoothness of the data distribution. We apply our bounds to several common learning scenarios, including max-margin and soft-max training of Markov random fields. Under certain conditions, the resulting error bounds can be far more optimistic than previous results and can even guarantee generalization from a single large example.

Keywords: structured prediction, learning theory, PAC-Bayes, generalization bounds

1. Introduction

Many important applications of machine learning require making multiple interdependent predictions whose dependence relationships form a graph. In some cases, the number of inputs and outputs can be enormous. For instance, in natural language processing, a document may contain thousands of words to be assigned a part-of-speech tag; in computer vision, a digital image may contain millions of pixels to be segmented; and in social network analysis, a relational graph may contain millions of users to be categorized. Obtaining fully annotated examples can be time-consuming and expensive, due to the number of variables. It is therefore common to train a structured predictor on far fewer examples than are used in the unstructured setting. In the extreme (yet not atypical) case, the training set consists of a single example, with large internal structure. A central question in statistical learning theory is *generalization*; that is, whether the expected error at test time will be reasonably close to the empirical error measured during training. Canonical learning-theoretic results for structured prediction (e.g., Taskar et al., 2004; Bartlett et al., 2005; McAllester, 2007) only guarantee generalization when the number of training examples is high. Yet, this pessimism contradicts a wealth of experimental results (e.g., Taskar et al., 2002; Tsochantzidis et al., 2005), which indicate that training on a few large examples is sufficient. In this work,

we address the question of when generalization is possible in this setting. We derive new generalization bounds for structured prediction that are far more optimistic than previous results. When sufficient conditions hold, our bounds guarantee generalization from a few large examples—even just one.

The intuition behind our analysis is motivated by a common practice known alternately as *templating* or *parameter-tying*. At a high level, templating shares parameters across substructures (e.g., nodes, edges, etc.) with identical local structure. (Templating is explained in detail in Section 2.2.2.) Originally proposed for relational learning as a way of dealing with non-uniformly-structured examples, templating has an additional benefit in that it effectively limits the complexity of the hypothesis class by reducing the number of parameters to be learned. Each instance of a substructure within an example acts as a kind of “micro example” of a template. Since each example may contain many micro examples, it is plausible that generalization could occur from even a single example.

Part of the difficulty when formalizing this intuition is that the micro examples are interdependent. Like all statistical arguments, generalization bounds must show that the empirical error concentrates around the expected error, and analyzing the concentration of functions of dependent random variables is nontrivial. Moreover, inference in a structured predictor is typically formulated as a global optimization over all outputs simultaneously. Due to model-induced dependencies, changes to one input may affect many of the outputs, which affects the loss differently than in binary or multiclass prediction. Thus, this problem cannot be viewed as simply learning from interdependent data, which has been studied extensively (e.g., Usumier et al., 2006; Mohri and Rostamizadeh, 2010; Ralaivola et al., 2010).

We therefore have two obstacles: the dependence in the data distribution and the dependence induced by the predictor. We characterize the former dependence using concepts from measure concentration theory (Kontorovich and Ramanan, 2008), and we view the latter dependence through the lens of algorithmic *stability*. Unlike previous literature (e.g., Bousquet and Elisseeff, 2002), we are not interested in the stability of the learning algorithm; rather, we examine the stability of inference (more specifically, a functional of the predictions) with respect to perturbations of the input. In prior work (London et al., 2013, 2014), we used the term *collective stability* to describe the stability of the predictions, guaranteeing collective stability for predictors whose inference objectives are strongly convex. In this work, we propose a form of stability that generalizes collective stability by analyzing the loss function directly. Our new definition accommodates a broader range of loss functions and predictors, and eliminates our previous reliance on strong convexity. Moreover, we support functions that are *locally* stable over some subset of their domain, and random functions that are stable with high probability.

This probabilistic notion of stability lends itself nicely to the *PAC-Bayes* framework, in which prediction proceeds by drawing a random hypothesis from a distribution on the hypothesis class. For this and other technical reasons, we use PAC-Bayesian analysis to derive our generalization bounds. When certain conditions are met by the distributions on the data and hypothesis class, our bounds can be as tight as $\tilde{O}(1/\sqrt{mn})$, where m is the number of examples, and n is the size of each example. Note that this expression decreases as either m or n increase. This rate is much tighter than previous results, which only

guarantee $\tilde{O}(1/\sqrt{m})$. From our bounds, we conclude that it is indeed possible to generalize from a few large examples—potentially even just one.

1.1 Related Work

One of the earliest explorations of generalization in structured prediction is by Collins (2001), who developed risk bounds for language parsers using various classical tools, such as the Vapnik-Chervonenkis dimension and margin theory. In Taskar et al.’s (2004) landmark paper on max-margin Markov networks, the authors use covering numbers to derive risk bounds for their proposed class of models. Bartlett et al. (2005) improved this result using PAC-Bayesian analysis.¹ McAllester (2007; 2011) provided a comprehensive PAC-Bayesian study of various structured losses and learning algorithms. Recently, Hazan et al. (2013) proposed a PAC-Bayes bound with a form often attributed to Catoni (2007), which can be minimized directly using gradient descent. Gigante et al. (2013) used PAC-Bayesian analysis to derive risk bounds for the kernel regression approach to structured prediction. In a similar vein as the above literature, yet taking a significantly different approach, Bradley and Gnestrin (2012) derived finite sample complexity bounds for learning conditional random fields using the composite likelihood estimator.

All of the above works have approached the problem from the traditional viewpoint, that the generalization error should decrease proportionally to the number of examples. In a previous publication (London et al., 2013), we proposed the first bounds that decrease with both the number of examples and the size of each example (given suitably weak dependence within each example). We later refined these results using PAC-Bayesian analysis (London et al., 2014). Our current work builds upon this foundation to derive similarly optimistic generalization bounds, while accommodating a broader range of loss functions and hypothesis classes.

From a certain perspective, our work fits into a large body of literature on learning from various types of interdependent data. Most of this is devoted to “unstructured” prediction. Usui et al. (2006) and Ralavola et al. (2010) used concepts from graph coloring to analyze generalization in learning problems that induce a dependency graph, such as bipartite ranking. In this case, the training data contains dependencies, but prediction is localized to each input-output pair. Similarly, Mohri and Rostamizadeh (2009, 2010) derived risk bounds for ϕ -mixing and β -mixing temporal data, using an “independent blocking” technique due to Yu (1994). The hypotheses they consider predict each time step independently, which makes independent blocking possible. Since we are interested in hypotheses (and loss functions) that perform joint inference, which may not decompose over the outputs, we cannot employ techniques such as graph coloring and independent blocking.

A related area of research is learning to forecast time series data. In this setting, the goal is to predict the next (or, some future) value in the series, given a moving window of previous observations. The generalization error of time series forecasting has been studied extensively by McDonald et al. (e.g., 2012) in the β -mixing regime. Similarly, Alquier and Wintenburger (2012) derived oracle inequalities for ϕ -mixing conditions.

¹ PAC-Bayesian analysis is often accredited to McAllester (1998, 1999), and has been refined by a number of authors (e.g., Herbrich and Graepel, 2001; Langford and Shawe-Taylor, 2002; Seeger, 2002; Ambrožek and Catoni, 2006; Catoni, 2007; Germain et al., 2009; Lever et al., 2010; Seldin et al., 2012).

The idea of learning from one example is related to the “one-network” learning paradigm, in which data is generated by a (possibly infinite) random field, with certain labels observed for training. The underlying model is estimated from the partially observed network, and the learned model is used to predict the missing labels, typically with some form of joint inference. Xiang and Neville (2011) examined maximum likelihood and pseudo-likelihood estimation in this setting, proving that are asymptotically consistent. Note that this is a *transductive* setting, in that the network data is fixed (i.e., realized), so the learned hypothesis is not expected to generalize to other network data. In contrast, we analyze *inductive* learning, wherein the model is applied to future draws from a distribution over network data.

Connections between stability and generalization have been explored in various forms. Bousquet and Elisseeff (2002) proposed the stability of a learning algorithm as a tool for analyzing generalization error. Wainwright (2006) analyzed the stability of marginal probabilities in variational inference, identifying the relationship between stability and strong convexity (similar to our work in London et al., 2013, 2014). He used this result to show that an *inconsistent* estimator, which uses approximate inference during training, can asymptotically yield lower regret (relative to the optimal Bayes least squares estimator) than using the *true* model with approximate inference. Honorio (2011) showed that the Bayes error rate of various graphical models is related to the stability of their log-likelihood functions with respect to changes in the model parameters.

1.2 Our Contributions

Our primary contribution is a new PAC-Bayesian analysis of structured prediction, producing generalization bounds that decrease when either the number of examples, m , or the size of each example, n , increase. Under suitable conditions, our bounds can be as tight as $\tilde{O}(1/\sqrt{mn})$. Our results apply to any composition of loss function and hypothesis class that satisfies our local stability conditions, which includes a broad range of modeling regimes used in practice. We also propose a novel view of PAC-Bayesian “derandomization,” based on the principle of stability, which provides a general proof technique for converting a generalization bound for a randomized structured predictor into a bound for a deterministic structured predictor.

As part of our analysis, we derive a new bound on the moment-generating function of a locally stable functional. The tightness of this bound (hence, our generalization bounds) hinges on a measure of the aggregate dependence between the random variables within each example. Our bounds are meaningful when the dependence is sub-logarithmic in the number of variables. We provide two examples of stochastic processes for which this condition holds. These results, and their implications for measure concentration, are of independent interest.

We apply our PAC-Bayes bounds to several common learning scenarios, including *margin* and *soft-margin* training of (conditional) Markov random fields. To demonstrate the benefit of local stability analysis, we also consider a specific generative process that induces unbounded stability in certain predictors, given certain inputs. These examples suggest several factors to be considered when modeling structured data, in order to obtain the best generalization rate: (1) templating is crucial; (2) the norm of the parameters contributes to the stability of inference, and should be controlled via regularization; and (3) limiting

local interactions in the model can improve stability, hence, generalization. All of these considerations can be summarized by the classic tension between representational power and overfitting, applied to the structured setting. Most importantly, these examples confirm that generalization from limited training examples is indeed possible for many structured prediction techniques used in practice.

1.3 Organization

The remainder of this paper is organized as follows. Section 2 introduces the notation used throughout the paper and reviews some background in structured prediction, templated Markov random fields, generalization error and PAC-Bayesian analysis. In Section 3, we propose general properties that characterize the local stability of a generic functional (e.g., the composition of a loss function and hypothesis). In Section 4, we introduce the statistical quantities and inequalities used in our analysis, as well as some examples of “nice” dependence conditions. Section 5 presents our main results: new PAC-Bayes bounds for structured prediction. We also propose a general proof technique for derandomizing the bounds using stability. In Section 6, we apply our bounds to a number of common learning scenarios. Specifically, we examine learning templated Markov random fields in the max-margin and soft-max frameworks, under various assumptions about the data distribution. Section 7 concludes our study with a discussion of the results and their implications for practitioners of structured prediction.

2. Preliminaries

This section introduces the notation and background used in this paper. We begin with notational conventions. We then formally define structured prediction and review some background on templated Markov random fields, a general class of probabilistic graphical models commonly used in structured prediction. Finally, we review the concept of generalization and discuss the PAC-Bayes framework, which we use to state our main results.

2.1 Notational Conventions

Let $\mathcal{X} \subseteq \mathbb{R}^k$ denote a domain of observations, and let \mathcal{Y} denote a finite set of discrete labels. Let $\mathcal{Z} \triangleq \mathcal{X} \times \mathcal{Y}$ denote the cross product of the two, representing input-output pairs.

Let $\mathbf{Z} \triangleq (Z_i)_{i=1}^n$ denote a set of n random variables, with joint distribution \mathbb{D} on a sample space \mathcal{Z}^n . We denote *realizations* of \mathbf{Z} by $\mathbf{z} \in \mathcal{Z}^n$. We use $\Pr_{\mathbf{Z} \sim \mathbb{D}}\{\cdot\}$ to denote the probability of an event over realizations of \mathbf{Z} , distributed according to \mathbb{D} . Similarly, we use $\mathbb{E}_{\mathbf{Z} \sim \mathbb{D}}[\cdot]$ to specify an expectation over \mathbf{Z} . When it is clear from context which variable(s) and distribution the probability (or expectation) is taken over, we may omit the subscript notation. We will occasionally employ the shorthand $\mathbb{D}(\mathcal{S})$ to denote the measure of a subset $\mathcal{S} \subseteq \mathcal{Z}^n$ under \mathbb{D} ; i.e., $\mathbb{D}(\mathcal{S}) = \Pr_{\mathbf{Z} \sim \mathbb{D}}\{\mathbf{Z} \in \mathcal{S}\}$. With a slight abuse of notation, which should be clear from context, we also use $\mathbb{D}(\mathbf{Z}_{i,j} | E)$ to denote the distribution of some subset of the variables, (Z_i, \dots, Z_j) , conditioned on an event, E .

For a graph $G \triangleq (\mathcal{V}, \mathcal{E})$, with nodes \mathcal{V} and edges \mathcal{E} , we use $|G| \triangleq |\mathcal{V}| + |\mathcal{E}|$ to denote the total number of nodes and edges in G .

2.2 Structured Prediction

At its core, *structured prediction* (sometimes referred to as *structured output prediction* or *structured learning*) is about learning concepts that have a natural internal structure. In the framework we consider, each example of a concept contains n interdependent random variables, $\mathbf{Z} \triangleq (Z_i)_{i=1}^n$, with joint distribution \mathbb{D} . Each $Z_i \triangleq (X_i, Y_i)$ is an input-output pair, taking values in $\mathcal{Z} = \mathcal{X} \times \mathcal{Y}$.² Each example is associated with an implicit dependency graph, $G \triangleq (\mathcal{V}, \mathcal{E})$, where $\mathcal{V} \triangleq \{1, \dots, n\}$ indexes \mathbf{Z} , and \mathcal{E} captures the dependencies in \mathbf{Z} . Unless otherwise stated, assume that the edge structure is given *a priori*. The edge structure may be obvious from context, or may be inferred beforehand. To simplify our analysis, we assume that each example uses the same structure.

The prediction task is to infer $\mathbf{Y} \triangleq (Y_i)_{i=1}^n$, conditioned on $\mathbf{X} \triangleq (X_i)_{i=1}^n$. A *hypothesis*, h , maps \mathcal{X}^n to \mathcal{Y}^n , using some internal parametric representation that incorporates the structure of the problem (an example of which is given in Section 2.2.1). We are interested in hypotheses that perform joint reasoning over all variables simultaneously. We therefore assume that computing $h(\mathbf{X})$ implicitly involves a global optimization that does not decompose over the outputs, due to dependencies.

2.2.1 MARKOV RANDOM FIELDS

To better understand structured prediction, it will help to consider a specific hypothesis class. One popular class is that of *Markov random fields* (MRFs), a broad family of undirected graphical models that generalizes many models used in practice, such as relational Markov networks (Taskar et al., 2002), conditional random fields (Lafferty et al., 2001), and Markov logic networks (Richardson and Domingos, 2006). In this section, we review some background on MRFs.

Recall that each example is associated with a dependency graph, $G \triangleq (\mathcal{V}, \mathcal{E})$. We assume that the edge set is undirected. This does not limit the applicability of our analysis, since there exists a straight-forward conversion from directed models (Koller and Friedman, 2009). The parameters of an MRF are organized according to the *cliques* (i.e., complete subgraphs), \mathcal{C} , contained in G . For each clique, $c \in \mathcal{C}$, we associate a real-valued *potential* function, $\theta_c(\mathbf{y} | \mathbf{x}; \mathbf{w})$, parameterized by a vector of weights, $\mathbf{w} \in \mathbb{R}^d$, for some $d \geq 1$. This function indicates the score for \mathbf{Y}_c being in state \mathbf{y}_c , conditioned on the observation $\mathbf{X} = \mathbf{x}$. The potentials define a log-linear conditional probability distribution,

$$p(\mathbf{Y} = \mathbf{y} | \mathbf{X} = \mathbf{x}; \mathbf{w}) \triangleq \exp \left(\sum_{c \in \mathcal{C}} \theta_c(\mathbf{y} | \mathbf{x}; \mathbf{w}) - \Phi(\mathbf{x}; \mathbf{w}) \right),$$

where

$$\Phi(\mathbf{x}; \mathbf{w}) \triangleq \ln \sum_{\mathbf{y} \in \mathcal{Y}^n} \exp \left(\sum_{c \in \mathcal{C}} \theta_c(\mathbf{y} | \mathbf{x}; \mathbf{w}) \right)$$

is a normalizing function known as the *log-partition*.

For convenience, we represent the label space, \mathcal{Y} , by the set of $|\mathcal{Y}|$ standard basis (i.e., “one-hot”) vectors, $\mathbf{e}_1, \dots, \mathbf{e}_{|\mathcal{Y}|}$. Thus, the joint state of a clique, c , is represented by a

2. To minimize bookkeeping, we have assumed a one-to-one correspondence between input and output variables, and that the Z_i variables have identical domains, but these assumptions can be relaxed.

vector, $\mathbf{y}_c = \bigotimes_{i \in \mathcal{C}} y_i$, of length $|\mathcal{C}| \triangleq |\mathcal{Y}|^{|\mathcal{C}|}$. With a slight abuse of notation, we overload the potential functions so that $\theta_c(\mathbf{x}; \mathbf{w}) \in \mathbb{R}^{|\mathcal{C}|}$ denotes a vector of potentials, and

$$\theta_c(\mathbf{y} | \mathbf{x}; \mathbf{w}) = \theta_c(\mathbf{x}; \mathbf{w}) \cdot \mathbf{y}_c.$$

Thus, with

$$\theta(\mathbf{x}; \mathbf{w}) \triangleq (\theta_c(\mathbf{x}; \mathbf{w}))_{c \in \mathcal{C}} \quad \text{and} \quad \hat{\mathbf{y}} \triangleq (\hat{y}_c)_{c \in \mathcal{C}},$$

we have that

$$\sum_{c \in \mathcal{C}} \theta_c(\mathbf{y} | \mathbf{x}; \mathbf{w}) = \theta(\mathbf{x}; \mathbf{w}) \cdot \hat{\mathbf{y}}.$$

We refer to $\hat{\mathbf{y}}$ as the *full* representation of \mathbf{y} .

The canonical inference problems for MRFs are *maximum a posteriori* (MAP) inference, which computes the mode of the distribution,

$$\arg \max_{\mathbf{y} \in \mathcal{Y}^n} p(\mathbf{Y} = \mathbf{y} | \mathbf{X} = \mathbf{x}; \mathbf{w}),$$

and *marginal* inference, which computes the marginal distribution of a subset of the variables. In general, both tasks are intractable—MAP inference is NP-hard and marginal inference is $\#\text{-P-hard}$ (Roth, 1996)—though there are some useful special cases for which inference is tractable, and many approximation algorithms for the general case. In this work, we assume that an efficient (approximate) inference algorithm is given.

2.2.2 TEMPLATING

An important property of the above construction is that the same vector of weights, \mathbf{w} , is used to parameterize all of the potential functions. One could imagine that \mathbf{w} contains a unique subvector, \mathbf{w}_c , for every clique. However, one could also bin the cliques by a set of *templates*—such as singletons (nodes), pairs (edges) or triangles (hyperedges)—then use the same weights for each template. This technique is alternatively referred to as *templating* or *parameter-typing*.

With templating, one can define general inductive rules to reason about datasets of arbitrary size and structure. Because of this flexibility, templating is used in many *relational* models, such as relational Markov networks (Taskar et al., 2002), relational dependency networks (Neville and Jensen, 2004), and Markov logic networks (Richardson and Domingos, 2006).

A templated model implicitly assumes that all *groundings* (i.e., instances) of a template should be modeled identically, meaning location within the graph is irrelevant. A non-templated model is location-aware and therefore has higher representational power. However, without templating, the dimensionality of \mathbf{w} scales with the number of cliques; whereas, with templating, the dimensionality of \mathbf{w} is constant. Thus, we find the classic tension between representational power and overfitting. To mitigate overfitting, one must restrict model complexity. Yet, too little expressivity will hamper predictive performance. This consideration is critical to the application of our generalization bounds.

In practice, templated models typically consist of unary and pairwise templates. We refer to these as pairwise models. Higher-order templates (i.e., cliques of three or more)

can capture certain inductive rules that pairwise models cannot. For example, for a binary relation r , the transitive closure $r(A, B) \wedge r(B, C) \implies r(A, C)$ requires triadic templates. Rules like this are sometimes used for link prediction and entity resolution. Of course, this additional expressivity comes at a cost, as will become apparent later.

2.2.3 DEFINING THE POTENTIAL FUNCTIONS

In many applications of MRFs, the potentials are defined as multilinear functions of $(\mathbf{w}, \mathbf{x}, \mathbf{y})$. For example, assuming each node i has local observations $x_i \in \mathcal{X}$ and label $y_i \in \mathcal{Y}$, we can define a vector of local *features*,

$$f_i(\mathbf{x}, \mathbf{y}) \triangleq x_i \otimes y_i,$$

using the Kronecker product (since y_i is a standard basis vector). Similarly, for each edge $\{i, j\} \in \mathcal{E}$, let

$$f_{ij}(\mathbf{x}, \mathbf{y}) \triangleq \frac{1}{2} \begin{bmatrix} x_i \\ x_j \end{bmatrix} \otimes (y_i \otimes y_j).$$

Here, we have defined the edge features using a concatenation of the local observations, though this need not be the case. In general, the edge features can be arbitrary functions of the observations, such as kernels or similarity functions. Or, we could eschew the observations altogether and just use $y_i \otimes y_j$, which is typical in practice.

The potential functions are then defined as weighted feature functions. For the following, we will assume that the weights are templated, as described in Section 2.2.2. For each node, we associate a set of singleton weights, $\mathbf{w}_s \in \mathbb{R}^{d_s}$, and for each edge, a set of pairwise weights, $\mathbf{w}_p \in \mathbb{R}^{d_p}$, where d_s and d_p denote the respective lengths of the node and edge features. Then,

$$\theta_i(\mathbf{y} | \mathbf{x}; \mathbf{w}) \triangleq \mathbf{w}_s \cdot f_i(\mathbf{x}, \mathbf{y}) \quad \text{and} \quad \theta_{ij}(\mathbf{y} | \mathbf{x}; \mathbf{w}) \triangleq \mathbf{w}_p \cdot f_{ij}(\mathbf{x}, \mathbf{y});$$

and, with

$$\mathbf{w} \triangleq \begin{bmatrix} \mathbf{w}_s \\ \mathbf{w}_p \end{bmatrix} \quad \text{and} \quad \mathbf{f}(\mathbf{x}, \mathbf{y}) \triangleq \begin{bmatrix} \sum_{i \in \mathcal{V}} f_i(\mathbf{x}, \mathbf{y}) \\ \sum_{\{i, j\} \in \mathcal{E}} f_{ij}(\mathbf{x}, \mathbf{y}) \end{bmatrix},$$

we have that

$$\theta(\mathbf{x}; \mathbf{w}) \cdot \hat{\mathbf{y}} = \mathbf{w} \cdot \mathbf{f}(\mathbf{x}, \mathbf{y}).$$

In Section 6, we apply our generalization bounds to the above construction of a templated MRF, consisting of singleton and pairwise linear potentials (with or without edge features).

2.3 Learning and Generalization

Given a set of m training examples, $\hat{\mathbf{Z}} \triangleq (\mathbf{Z}^{(i)})_{i=1}^m$, drawn independently and identically from \mathbb{D} , the goal of learning is to produce a hypothesis from a specified class, denoted $\mathcal{H} \subseteq \{h : \mathcal{X}^n \rightarrow \mathcal{Y}^n\}$. We do not assume that the data is generated according to some target concept in \mathcal{H} , so \mathcal{H} may be misspecified.

Hypotheses are evaluated using a *loss function* of the form $L : \mathcal{H} \times \mathcal{X}^n \rightarrow \mathbb{R}_+$, which may have access to the internal representation of the hypothesis. For a given loss function,

L , let $\bar{L}(h) \triangleq \mathbb{E}_{\mathbf{Z} \sim \mathbb{D}}[L(h, \mathbf{Z})]$ denote the expected loss over realizations of an example. This quantity, known as the *risk*, corresponds to the error h will incur on future predictions. Let

$$\hat{L}(h, \hat{\mathbf{Z}}) \triangleq \frac{1}{m} \sum_{l=1}^m L(h, \mathbf{Z}^{(l)})$$

denote the average loss on the training set, $\hat{\mathbf{Z}}$. Most learning algorithms minimize (an upper bound on) $\hat{L}(h, \hat{\mathbf{Z}})$, since it is an *empirical* estimate of the risk.

The goal of our analysis is to upper-bound the difference of the expected and empirical risks, $\bar{L}(h) - \hat{L}(h, \hat{\mathbf{Z}})$ —which we refer to as the *generalization error*³—thereby yielding an upper bound on the risk. As is typically done in generalization analysis, we show that, with high probability over draws of a training set, the generalization error is upper-bounded by a function of certain properties of the domain, hypothesis class and learning algorithm, which decreases as the (effective) size of the training set increases. Note that small generalization error does not necessarily imply small risk, since the empirical risk may be large. Nonetheless, small generalization error implies that the empirical risk will be a good estimate of the risk, thus motivating empirical risk minimization.

2.3.1 PAC-BAYES

PAC-Bayes is a framework for analyzing the risk of a randomized predictor. One begins by fixing a *prior* distribution, \mathbb{P} , on the hypothesis space, \mathcal{H} . Then, given some training data, one constructs a *posterior* distribution, \mathbb{Q} , the parameters of which are typically learned from the training data. For example, when \mathcal{H} is a subset of Euclidean space, a common PAC-Bayesian construction is a standard multivariate Gaussian prior with an isotropic Gaussian posterior, centered at the learned hypothesis. To make a prediction on an input, \mathbf{x} , one draws a hypothesis, $h \in \mathcal{H}$, according to \mathbb{Q} , then computes $h(\mathbf{x})$.

Since prediction is randomized, the risk quantities are defined over draws of h , which we denote by

$$\hat{L}(\mathbb{Q}, \hat{\mathbf{Z}}) \triangleq \mathbb{E}_{h \sim \mathbb{Q}}[\hat{L}(h, \hat{\mathbf{Z}})] \quad \text{and} \quad \bar{L}(\mathbb{Q}) \triangleq \mathbb{E}_{h \sim \mathbb{Q}}[\bar{L}(h)].$$

The goal of PAC-Bayesian analysis is to upper-bound some measure of discrepancy between these quantities. The discrepancy is sometimes defined as the KL divergence between error rates, or the squared difference. In this work, we upper-bound the difference, $\bar{L}(\mathbb{Q}) - \hat{L}(\mathbb{Q}, \hat{\mathbf{Z}})$, which is the PAC-Bayesian analog of the generalization error.

3. Stability

A key component of our analysis is the *stability* of the loss function. In this section, we introduce some definitions of stability and relate them to other forms found in the literature. Broadly speaking, stability ensures that changes to the input result in proportional changes in the output. In structured prediction, where inference is typically a global optimization over many interdependent variables, changing any single observation may affect many of the inferred values. The structured loss functions we consider *implicitly* require some form

³ Our definition of generalization error differs from some literature, in which the term is used to refer to the expected loss.

of joint inference; therefore, their stability is nontrivial. In this chapter, we introduce some definitions of stability and relate them to other forms found in the literature.

The following definitions will make use of the *Hamming distance*. For vectors $\mathbf{z}, \mathbf{z}' \in \mathcal{Z}^n$, denote their Hamming distance by

$$D_H(\mathbf{z}, \mathbf{z}') \triangleq \sum_{i=1}^n \mathbf{1}\{z_i \neq z'_i\}.$$

3.1 Uniform and Local Stability

Throughout this section, let $\mathcal{F} \triangleq \{\varphi : \mathcal{Z}^n \rightarrow \mathbb{R}\}$ denote an arbitrary class of functionals; e.g., \mathcal{F} could be a structured loss function composed with a class of hypotheses. The definitions in this section describe notions of stability that hold either *uniformly* over the domain of \mathcal{F} (for each $\varphi \in \mathcal{F}$), or *locally* over some subset of the domain (for some subset of \mathcal{F}).

Definition 1. We say that a function $\varphi \in \mathcal{F}$ is *β -uniformly stable* if, for any inputs $\mathbf{z}, \mathbf{z}' \in \mathcal{Z}^n$,

$$|\varphi(\mathbf{z}) - \varphi(\mathbf{z}')| \leq \beta D_H(\mathbf{z}, \mathbf{z}'). \quad (1)$$

Similarly, the class \mathcal{F} is *β -uniformly stable* if every $\varphi \in \mathcal{F}$ is β -uniformly stable.

Equation 1 means that the change in the output should be proportional to the Hamming distance between the inputs. Put differently, a uniformly stable function is Lipschitz under the Hamming norm.

Uniform stability over the entire domain can be a strong requirement. Sometimes, stability only holds for a certain subset of inputs, such as points contained in a Euclidean ball of a certain radius. We refer to the set of inputs for which stability holds as the “good” set; all other inputs are “bad.” The precise meaning of good and bad depends on the hypothesis class. Given some delineation of good and bad, we obtain the following localized notion of stability.

Definition 2. For a subset $\mathcal{B}_Z \subseteq \mathcal{Z}^n$, we say that a function $\varphi \in \mathcal{F}$ is *(β, \mathcal{B}_Z) -locally stable* if Equation 1 holds for all $\mathbf{z}, \mathbf{z}' \notin \mathcal{B}_Z$. The class \mathcal{F} is *(β, \mathcal{B}_Z) -locally stable* if every $\varphi \in \mathcal{F}$ is (β, \mathcal{B}_Z) -locally stable.

Definition 2 has an alternate probabilistic interpretation. If \mathbb{D} is a distribution on \mathcal{Z}^n , then Equation 1 holds with some probability over draws of $\mathbf{z}, \mathbf{z}' \sim \mathbb{D}$. If the bad set \mathcal{B}_Z has measure $\mathbb{D}(\mathcal{B}_Z) \leq \nu$, then (β, \mathcal{B}_Z) -local stability is similar to, though slightly weaker than, the *strongly difference-bounded* property proposed by Kutin (2002). If φ is strongly difference-bounded, then Equation 1 must hold for any $\mathbf{z} \notin \mathcal{B}_Z$ and $\mathbf{z}' \in \mathcal{Z}^n$ (which could be in \mathcal{B}_Z). All functions that are strongly difference-bounded are locally stable, but the converse is not true.

The notion of probabilistic stability can be extended to distributions on the function class. For any stability parameter β (and bad inputs \mathcal{B}_Z), the function class is partitioned into functions that satisfy Equation 1, and those that do not. Therefore, for any distribution \mathbb{Q} on \mathcal{F} , uniform (or local) stability holds with some probability over draws of $\varphi \sim \mathbb{Q}$. This idea motivates the following definition.

Definition 3. Fix some $\beta \geq 0$ and $\mathcal{B}_Z \subseteq \mathcal{Z}^n$, and let $\mathcal{B}_F \subseteq \mathcal{F}$ denote the subset of functions that are not (β, \mathcal{B}_Z) -locally stable. We say that a distribution \mathbb{Q} on \mathcal{F} is $(\beta, \mathcal{B}_Z, \eta)$ -locally stable if $\mathbb{Q}(\mathcal{B}_F) \leq \eta$.

Note the taxonomical relationship between these definitions. Definition 1 is the strongest condition, since it implies Definitions 2 and 3. Clearly, if \mathcal{F} is β -uniformly stable, then it is (β, \emptyset) -locally and $(\beta, \emptyset, 0)$ -locally stable. Definition 2 extends Definition 1 by accommodating broader domains. Definition 3 extends this even further, by accommodating classes in which only some functions satisfy local stability.

Definition 3 is particularly interesting in the PAC-Bayes framework, in which a predictor is selected at random according to a (learned) posterior distribution. With prior knowledge of the hypothesis class (and data distribution), a posterior can be constructed so as to place low mass on predictors that do not satisfy uniform or local stability. As we show in Section 6, this technique lets us relax certain restrictions on the hypothesis class.

Stability measures the change in the output relative to the change in the inputs. A related property is that the change in the output is bounded—i.e., the function has bounded range.

Definition 4. We say that $\varphi \in \mathcal{F}$ is α -uniformly range-bounded if, for any $\mathbf{z}, \mathbf{z}' \in \mathcal{Z}^n$,

$$|\varphi(\mathbf{z}) - \varphi(\mathbf{z}')| \leq \alpha.$$

Range-boundedness is implied by stability, but the range constant, α , may be smaller than the upper bound implied by stability. Our analysis uses range-boundedness as a fall-back property when “good” stability does not hold.

3.2 Connections to Other Notions of Stability

In the learning theory literature, the word “stability” has traditionally been associated with a learning algorithm, rather than an inference algorithm. A learning algorithm is said to be stable with respect to a loss function if the loss of a learned hypothesis varies by a bounded amount upon replacing (or deleting) examples from the training set. This property has been used to derive generalization bounds (e.g., Bousquet and Elisseeff, 2002), similar to the way we use stability of inference. The key idea is that stability enables concentration of measure, which is central to generalization. That said, learning stability is distinct from inference stability, and neither property implies the other. Indeed, a learning algorithm might return hypotheses with drastically different losses for slightly different training sets, even if each hypothesis, composed with the loss function, is uniformly stable. Likewise, a stable learning algorithm might produce hypotheses with unstable loss.

Our definition of stability should also be contrasted with *sensitivity analysis*. Since the terms are often used interchangeably, we distinguish the two as follows: stability measures the amount of change induced in the *output* of a function upon perturbing its input within a certain range, and sensitivity analysis measures the amount of perturbation one can apply to the *input* such that its output remains within a certain range. By these definitions, one is the dual of the other. In the context of probabilistic inference, sensitivity analysis has been used to determine the maximum amount one can perturb the model parameters (or evidence) such that the likelihood of a query stays within a given tolerance, or such that

the most likely assignment does not change (Chan and Darwiche, 2005, 2006). Stability measures *how much* the likelihood or most likely assignment changes.

Our first generalization bounds for structured prediction (London et al., 2013) crucially relied on a property we referred to as *uniform collective stability*. A class of vector-valued functions, $\mathcal{G} \triangleq \{g : \mathcal{Z}^n \rightarrow \mathbb{R}^N\}$, has β -uniform collective stability if, for any $g \in \mathcal{G}$, and any $\mathbf{z}, \mathbf{z}' \in \mathcal{Z}^n$,

$$\|g(\mathbf{z}) - g(\mathbf{z}')\|_1 \leq \beta D_{\text{H}}(\mathbf{z}, \mathbf{z}').$$

We later relaxed this requirement to various non-uniform definitions of collective stability (London et al., 2014). Because collective stability implicitly involves the maximizing argument of a high-dimensional global optimization (i.e., a vector of predictions), we restricted our previous analyses to predictors with strongly convex inference objectives. Strong convexity let us bound the collective stability of a predictor; hence, the stability of its *output* composed with an *admissible*⁴ loss function. Our new definitions involve the output of a *functional* (i.e., a scalar-valued function of multiple inputs), which essentially means that we are interested in the stability of the loss, instead of the collective stability of the predictions. In our new analysis, the loss function has access to the model and may use it for inference. However, the loss function may not require the same inference used for prediction. (For example, the losses considered in Section 6 use the maximum of the inference objective instead of the maximizing argument.) This framework lets us analyze a broad range of structured losses, without requiring strongly convex inference. Further, it can be shown that any predictor with “good” collective stability (such as one with a strongly convex inference objective), composed with an admissible loss function, satisfies our new definitions of stability. Therefore, our new definitions are strictly more general than collective stability.

4. Statistical Tools

Reasoning about the concentration of functions of dependent random variables requires sophisticated statistical machinery. In this section, we review some supporting definitions and introduce a quantity to summarize the amount of dependence in the data distribution. We use this quantity in a new moment-generating function inequality for locally stable functions of dependent random variables. We then provide some example conditions under which dependence is suitably bounded, thereby supporting improved generalization bounds.

4.1 Quantifying Dependence

For probability measures \mathbb{P} and \mathbb{Q} on a σ -algebra (i.e., event space) Σ , the *total variation distance* is

$$\|\mathbb{P} - \mathbb{Q}\|_{\text{TV}} \triangleq \sup_{A \in \Sigma} |\mathbb{P}(A) - \mathbb{Q}(A)|.$$

As a special case, when the sample space, Ω , is finite,

$$\|\mathbb{P} - \mathbb{Q}\|_{\text{TV}} = \frac{1}{2} \sum_{\omega \in \Omega} |\mathbb{P}(\omega) - \mathbb{Q}(\omega)|.$$

4. See (London et al., 2013, 2014) for a precise definition of loss admissibility.

Let π be a permutation of $[n] \triangleq \{1, \dots, n\}$, where $\pi(i)$ denotes the i^{th} element in the sequence and $\pi(i : j)$ denotes a subsequence of elements i through j . Used to index variables $\mathbf{Z} \triangleq (Z_i)_{i=1}^n$, denote by $Z_{\pi(i)}$ the i^{th} variable in the permutation and $\mathbf{Z}_{\pi(i:j)}$ the subsequence $(Z_{\pi(i)}, \dots, Z_{\pi(j)})$.

Definition 5. We say that a sequence of permutations, $\boldsymbol{\pi} \triangleq (\pi_i)_{i=1}^n$, is a *filtration* if, for $i = 1, \dots, n-1$,

$$\pi_i(1 : i) = \pi_{i+1}(1 : i).$$

Let $\Pi(n)$ denote the set of all filtrations for a given n .

The following data structure quantifies the dependence between subsets of variables defined by a filtration.

Definition 6. Let $\mathbf{Z} \triangleq (Z_i)_{i=1}^n$ denote random variables with joint distribution \mathbb{D} on \mathcal{Z}^n . Fix a filtration, $\boldsymbol{\pi} \in \Pi(n)$, and a set of inputs, $\mathcal{B}_Z \subseteq \mathcal{Z}^n$. Let $\bar{\mathcal{B}}$ denote the event $\mathbf{Z} \notin \mathcal{B}_Z$. For $i \in [n]$, let $\mathcal{Z}_{\boldsymbol{\pi}, \bar{\mathcal{B}}}^i$ denote the subset of \mathcal{Z}^i such that, for every $\mathbf{z} \in \mathcal{Z}_{\boldsymbol{\pi}, \bar{\mathcal{B}}}^i$, $\mathbf{Z}_{\pi_i(1:i)} = \mathbf{z}$ is consistent with $\bar{\mathcal{B}}$. With a slight abuse of notation, for $\mathbf{z} \in \mathcal{Z}_{\boldsymbol{\pi}, \bar{\mathcal{B}}}^{i-1}$, let $\mathcal{Z}_{\boldsymbol{\pi}, \bar{\mathcal{B}}}^i(\mathbf{z})$ denote the subset of \mathcal{Z} such that, for any $z \in \mathcal{Z}_{\boldsymbol{\pi}, \bar{\mathcal{B}}}^i(\mathbf{z})$, $\mathbf{Z}_{\pi_i(1:i)} = (\mathbf{z}, z)$ is consistent with $\bar{\mathcal{B}}$. Then, for $i \in [n]$, $j > i$, $\mathbf{z} \in \mathcal{Z}_{\boldsymbol{\pi}, \bar{\mathcal{B}}}^{i-1}$ and $z, z' \in \mathcal{Z}_{\boldsymbol{\pi}, \bar{\mathcal{B}}}^i(\mathbf{z})$, we define the *ϑ -mixing coefficients*⁵ as

$$\vartheta_{ij}^{\boldsymbol{\pi}}(\mathbf{z}, z, z') \triangleq \|\mathbb{D}(\mathbf{Z}_{\pi_i(j:n)} | \bar{\mathcal{B}}, \mathbf{Z}_{\pi_i(1:i)} = (\mathbf{z}, z)) - \mathbb{D}(\mathbf{Z}_{\pi_i(j:n)} | \bar{\mathcal{B}}, \mathbf{Z}_{\pi_i(1:i)} = (\mathbf{z}, z'))\|_{\text{TV}}.$$

We use these to define the upper-triangular *dependence matrix*, $\boldsymbol{\Gamma}_{\boldsymbol{\pi}} \in \mathbb{R}^{n \times n}$, with entries

$$\gamma_{ij}^{\boldsymbol{\pi}} \triangleq \begin{cases} 1 & \text{for } i = j, \\ \sup_{\mathbf{z} \in \mathcal{Z}_{\boldsymbol{\pi}, \bar{\mathcal{B}}}^{i-1}, z, z' \in \mathcal{Z}_{\boldsymbol{\pi}, \bar{\mathcal{B}}}^i(\mathbf{z})} \vartheta_{ij}^{\boldsymbol{\pi}}(\mathbf{z}, z, z') & \text{for } i < j, \\ 0 & \text{for } i > j. \end{cases}$$

When $\mathcal{B}_Z = \emptyset$, we simply omit the subscript notation.

Each ϑ -mixing coefficient measures the influence of some variable, $Z_{\pi_i(i)}$, on some subset, $\mathbf{Z}_{\pi_i(j:n)}$, given some assignment to the variables, $\mathbf{Z}_{\pi_i(1:i-1)}$, that preceded $Z_{\pi_i(i)}$ in the filtration; $\gamma_{ij}^{\boldsymbol{\pi}}$ measures the maximal influence of $Z_{\pi_i(i)}$ conditioned on any assignment to $\mathbf{Z}_{\pi_i(1:i-1)}$. Thus, to summarize the amount of dependence in the data distribution, we use the induced matrix infinity norm of $\boldsymbol{\Gamma}_{\boldsymbol{\pi}}$, denoted

$$\|\boldsymbol{\Gamma}_{\boldsymbol{\pi}}\|_{\infty} \triangleq \max_{i \in [n]} \sum_{j=1}^n |\gamma_{ij}^{\boldsymbol{\pi}}|,$$

which effectively measures the maximal aggregate influence of any single variable, given the filtration. Observe that, if (Z_1, \dots, Z_n) are mutually independent, then $\boldsymbol{\Gamma}_{\boldsymbol{\pi}}^{\boldsymbol{\pi}}$ is the identity matrix and $\|\boldsymbol{\Gamma}_{\boldsymbol{\pi}}\|_{\infty} = 1$. At the other extreme, if (Z_1, \dots, Z_n) are deterministically dependent, then the top row of $\boldsymbol{\Gamma}_{\boldsymbol{\pi}}^{\boldsymbol{\pi}}$ is $\mathbf{1}$, so $\|\boldsymbol{\Gamma}_{\boldsymbol{\pi}}\|_{\infty} = n$.

⁵ The ϑ -mixing coefficients were introduced by Kontorovich and Ramanan (2008) as *η -mixing* and are related to the *maximal coupling coefficients* used by Chazottes et al. (2007).

Viewed through the lens of stability, $\|\boldsymbol{\Gamma}_{\boldsymbol{\pi}}\|_{\infty}$ can be interpreted as measuring the stability of the data distribution. From this perspective, distributions with strong, long-range dependencies (when $\|\boldsymbol{\Gamma}_{\boldsymbol{\pi}}\|_{\infty}$ is big) are unstable, whereas distributions with weak, local dependence (when $\|\boldsymbol{\Gamma}_{\boldsymbol{\pi}}\|_{\infty}$ is small) are stable. Intuitively, the same can be said for inference in MRFs; potentials that emphasize interactions between adjacent variables create long-range dependencies, which causes instability, whereas potentials that emphasize local signal make adjacent variables more independent, which promotes stability. Thus, dependence and stability are two sides of the same coin.

The filtration used to define $\boldsymbol{\Gamma}_{\boldsymbol{\pi}}^{\boldsymbol{\pi}}$ can have a strong impact on $\|\boldsymbol{\Gamma}_{\boldsymbol{\pi}}\|_{\infty}$. Since we do not assume that \mathbf{Z} corresponds to a temporal process, there may not be an obvious ordering of the variables. However, the types of stochastic processes we are interested in are typically endowed with a topology. If the topology is a graph, the filtration can be determined by traversing the graph. For instance, for a Markov tree process, Kontorovich (2012) ordered the variables via a breadth-first traversal from the root; for an Ising model on a lattice, Chazottes et al. (2007) ordered the variables with a spiraling traversal from the origin. (Both of these examples used a static permutation of the variables, not a filtration.) If the filtration is determined by graph traversal, the ϑ -mixing coefficients can be viewed as measuring the strength of dependence as a function of graph distance. Viewed as such, $\|\boldsymbol{\Gamma}_{\boldsymbol{\pi}}\|_{\infty}$ effectively captures the slowest decay of dependence along any traversal from a given set of traversals.

The aforementioned works (Kontorovich, 2012; Chazottes et al., 2007) showed that, for Markov trees and grids, under suitable contraction or temperature regimes, $\|\boldsymbol{\Gamma}_{\boldsymbol{\pi}}\|_{\infty}$ is bounded independently of n (i.e., $\|\boldsymbol{\Gamma}_{\boldsymbol{\pi}}\|_{\infty} = \mathcal{O}(1)$). By exploiting filtrations, we can show that the same holds for Markov random fields of any bounded-degree structure, provided the distribution exhibits suitable mixing. We discuss these conditions in Section 4.3.

4.2 A Moment-Generating Function Inequality for Local Stability

With the supporting definitions in mind, we now present a new moment-generating function inequality for locally stable functions of dependent random variables. The proof is provided in Appendix A.3.

Proposition 1. Let $\mathbf{Z} \triangleq (Z_i)_{i=1}^n$ denote random variables with joint distribution \mathbb{D} on \mathcal{Z}^n . Fix a set of “bad” inputs, $\mathcal{B}_Z \subseteq \mathcal{Z}^n$, and let $\bar{\mathcal{B}}$ denote the event $\mathbf{Z} \notin \mathcal{B}_Z$. Let $\varphi : \mathcal{Z}^n \rightarrow \mathbb{R}$ denote a measurable function with (β, \mathcal{B}_Z) -local stability. Then, for any $\tau \in \mathbb{R}$ and filtration $\boldsymbol{\pi} \in \Pi(n)$,

$$\mathbb{E}_{\mathbf{Z} \sim \mathbb{D}} \left[e^{\tau(\varphi(\mathbf{Z}) - \mathbb{E}[\varphi(\mathbf{Z}) | \bar{\mathcal{B}}])} | \bar{\mathcal{B}} \right] \leq \exp \left(\frac{\tau^2}{8} n \beta^2 \|\boldsymbol{\Gamma}_{\boldsymbol{\pi}}\|_{\infty}^2 \right).$$

This bound yields a novel concentration inequality for uniformly stable functions of dependent random variables, which we discuss in Appendix A.4. Though we will not use this corollary in our analysis, it may be of independent interest.

Proposition 1 builds on work by Samson (2000), Chazottes et al. (2007) and Kontorovich and Ramanan (2008). Our analysis differs from theirs in that we accommodate functions that are not uniformly stable. In this respect, our analysis is similar to that of Kutin (2002) and Vu (2002), though these works assume independence between variables. Because we

allow interdependence—as well as other technical challenges, related to our definitions of local stability—we do not use the same proof techniques as the aforementioned works.

4.3 Bounded Dependence Conditions

The infinity norm of the dependency matrix has a trivial upper bound, $\|\mathbf{\Gamma}_{\mathcal{F}}^{\pi}\|_{\infty} \leq n$. However, we are interested in bounds that are sub-logarithmic in (or, even better, independent of) n . In this section, we describe some general settings in which $\|\mathbf{\Gamma}_{\mathcal{F}}^{\pi}\|_{\infty}$ has a nontrivial upper bound.

For the remainder of this section, let $\mathbf{Z} \triangleq (Z_i)_{i=1}^n$ denote random variables with joint distribution \mathbb{D} on \mathcal{Z}^n . Assume that \mathbb{D} is associated with a graph, $G \triangleq (\mathcal{V}, \mathcal{E})$, where $\mathcal{V} \triangleq [n]$ indexes \mathbf{Z} .

We use the following notion of distance-based dependence. For simplicity of exposition, we assume that $\mathcal{B}_{\mathbf{Z}} = \emptyset$, so we can omit \mathcal{B} from the following notation.

Definition 7. For any two subsets, $\mathcal{S}, \mathcal{T} \subseteq \mathcal{V}$, we define their graph distance, $D_G(\mathcal{S}, \mathcal{T})$, as the length of the shortest path from any node in \mathcal{S} to any node in \mathcal{T} . We then define the distance-based ϑ -mixing coefficients as

$$\vartheta(k) \triangleq \sup_{\substack{\mathcal{S} \subseteq \mathcal{V}, i \in \mathcal{S} \\ \mathcal{T} \subseteq \mathcal{V} \setminus \mathcal{S}; D_G(i, \mathcal{T}) \geq k \\ z \in \mathcal{Z}^{|\mathcal{S}|-1}, z, z' \in \mathcal{Z}}} \left| \mathbb{D}(\mathbf{Z}_{\mathcal{T}} | \mathbf{Z}_{\mathcal{S}} = \mathbf{z}, Z_i = z) - \mathbb{D}(\mathbf{Z}_{\mathcal{T}} | \mathbf{Z}_{\mathcal{S}} = \mathbf{z}, Z_i = z') \right|_{\mathcal{V}^{\mathcal{T}}},$$

where $\vartheta(0) \triangleq 1$.

The distance-based ϑ -mixing coefficients upper-bound the maximum influence exerted by any subset of the variables on any other subset that is separated by graph distance at least k . The sequence $(\vartheta(0), \vartheta(1), \vartheta(2), \dots)$ roughly measures how dependence decays with graph distance. Note that $\vartheta(k)$ uniformly upper-bounds $\vartheta_{i_j}^{\pi}$ when $D_G(\pi_i(i), \pi_i(j) : n) \geq k$. Therefore, for each upper-triangular entry of $\mathbf{\Gamma}^{\pi}$, we have that

$$\gamma_{i_j}^{\pi} \leq \vartheta(D_G(\pi_i(i), \pi_i(j) : n)).$$

Using the distance-based ϑ -mixing coefficients, we now show that, for certain Markov random fields, it is possible to upper-bound $\|\mathbf{\Gamma}_{\mathcal{F}}^{\pi}\|_{\infty}$ independently of n .

Proposition 2. Suppose \mathbb{D} is defined by an MRF, such that its graph, G , has maximum degree Δ_G . For any positive constant $\epsilon > 0$, if \mathbb{D} admits a distance-based ϑ -mixing sequence such that, for all $k \geq 1$, $\vartheta(k) \leq (\Delta_G + \epsilon)^{-k}$, then there exists a filtration π such that

$$\|\mathbf{\Gamma}^{\pi}\|_{\infty} \leq 1 + \Delta_G/\epsilon.$$

The proof is provided in Appendix A.5.

Uniformly geometric distance-based ϑ -mixing may seem like a restrictive condition. However, our analysis is overly pessimistic, in that it ignores the structure of the MRF beyond simply the maximum degree of the graph. Further, it does not take advantage of the actual conditional independencies present in the distribution. Nevertheless, there is a natural interpretation of the above conditions that follows from considering the mixing coefficients at distance 1: for the immediate neighbors of a node—i.e., its Markov blanket—its

ϑ -mixing coefficient must be less than $1/\Delta_G$. This loosely means that the combination of all incoming influence must be less than 1, implying that there is sufficiently strong influence from local observations.

Another important setting is when the graph is a chain. Chain-structured stochastic processes (usually temporal) under various mixing assumptions have been well-studied (see Bradley, 2005 for a comprehensive survey). It can be shown that any contracting Markov chain has $\|\mathbf{\Gamma}^{\pi}\|_{\infty} = O(1)$ (Kontorovich, 2012). Here, we provide an alternate condition, using distance-based ϑ -mixing, under which the dependency matrix of a Markov chain has suitably low norm. The key property of a chain graph is that the number of nodes at distance k from any starting node is constant. We can therefore relax the assumption of geometric decay used in the previous result.

Proposition 3. Suppose \mathbb{D} is an undirected Markov chain (i.e., chain-structured MRF) of length n . For any constants $\epsilon > 0$ and $p \geq 1$, if \mathbb{D} admits a distance-based ϑ -mixing sequence such that, for all $k \geq 1$, $\vartheta(k) \leq \epsilon k^{-p}$, then there exists a filtration, π , such that

$$\|\mathbf{\Gamma}^{\pi}\|_{\infty} \leq \begin{cases} 1 + \epsilon(1 + \ln(n-1)) & \text{if } p = 1, \\ 1 + \epsilon\zeta(p) & \text{if } p > 1, \end{cases}$$

where $\zeta(p) \triangleq \sum_{j=1}^{\infty} j^{-p}$ is the Riemann zeta function.

The proof is provided in Appendix A.6.

For $p > 1$, the Riemann function converges to a constant. For example, $\zeta(2) = \pi^2/6 \approx 1.645$. However, even $p = 1$ yields a sufficiently low growth rate. In the following section, we prove generalization bounds of the form $O(\|\mathbf{\Gamma}^{\pi}\|_{\infty}/\sqrt{mn})$, which still converges if $\|\mathbf{\Gamma}^{\pi}\|_{\infty} = O(\ln n)$, albeit at a slower rate.

5. PAC-Bayes Bounds

We now present some new PAC-Bayes generalization bounds using the stability definitions from Section 3. The first theorem is stated for a given stability parameter, β . We then generalize this result to hold for all β simultaneously, meaning β can depend on the posterior. We conclude this section with a general technique for derandomizing the bounds based on stability.

It will help to begin with a high-level sketch of the analysis, which we specialize to various settings in Sections 5.1 and 5.2. It will help to view the composition of the loss function, L , and the hypothesis class \mathcal{H} , as a family of functions, $L \circ \mathcal{H} = \{L(h, \cdot) : h \in \mathcal{H}\}$. If \mathbb{Q} is a distribution on \mathcal{H} , it is also a distribution on $L \circ \mathcal{H}$. Each member of $L \circ \mathcal{H}$ is a random function, determined by the draw of $h \sim \mathbb{Q}$. Further, when $L(h, \cdot)$ is composed with a training set $\tilde{\mathbf{Z}} \sim \mathbb{D}^m$ in $\hat{L}(h, \cdot)$, the generalization error, $\bar{L}(h) - \hat{L}(h, \tilde{\mathbf{Z}})$, becomes a centered random variable. Part of our analysis involves bounding the moment-generating function of this random variable, and to do so requires the notions of stability from Section 3. The stability of $L(h, \cdot)$ is determined by h , so the “bad” members of $L \circ \mathcal{H}$ are in fact the “bad” hypotheses (for the given loss function).

Let $\mathbf{Z} \triangleq (\mathbf{Z}^{(j)})_{j=1}^m$ denote a training set of m structured examples, distributed according to \mathbb{D}^m . Fix some $\beta \geq 0$ and a set of bad inputs $\mathcal{B}_{\mathbf{Z}}$, with measure $\nu \triangleq \mathbb{D}(\mathcal{B}_{\mathbf{Z}})$. Implicitly, the

pair (β, \mathcal{B}_Z) fixes a set of hypotheses $\mathcal{B}_H \subseteq \mathcal{H}$ for which $L(h, \cdot)$ does not satisfy Equation 1 with $\beta \triangleq \beta/n$ and \mathcal{B}_Z . For the time being, \mathcal{B}_H is independent of \mathcal{Q} . Fix a prior \mathbb{P} and posterior \mathcal{Q} on \mathcal{H} . (We will later consider all posteriors.) We define a convenience function,

$$\tilde{\phi}(h, \hat{\mathbf{Z}}) \triangleq \begin{cases} \mathbb{E}_{\mathbf{Z} \sim \mathbb{D}} [L(h, \mathbf{Z}) | \bar{\mathcal{B}}] - \hat{L}(h, \hat{\mathbf{Z}}) & \text{if } h \notin \mathcal{B}_H, \\ 0 & \text{otherwise,} \end{cases}$$

where $\bar{\mathcal{B}}$ denotes the event $\mathbf{Z} \notin \mathcal{B}_Z$. First, for any uniformly bounded random variable, with $|X| \leq b$, and some event, \bar{E} ,

$$\mathbb{E}[X] = \mathbb{E}[X \mathbb{1}\{\bar{E}\}] + \mathbb{E}[X \mathbb{1}\{\bar{E}^c\}] \leq b \mathbb{P}_{\mathbb{P}}\{\bar{E}\} + \mathbb{E}[X \mathbb{1}\{\bar{E}^c\}].$$

We use this identity to show that, if $L \circ \mathcal{H}$ is α -uniformly range-bounded, and \mathcal{Q} is $(\beta/n, \mathcal{B}_Z, \eta)$ -locally stable, then

$$\bar{L}(\mathcal{Q}) - \hat{L}(\mathcal{Q}, \hat{\mathbf{Z}}) \leq \alpha\eta + \alpha\nu + \mathbb{E}_{h \sim \mathcal{Q}} [\tilde{\phi}(h, \hat{\mathbf{Z}})].$$

To bound the $\mathbb{E}_{h \sim \mathcal{Q}} [\tilde{\phi}(h, \hat{\mathbf{Z}})]$, we use Donsker and Varadhan's (1975) *change of measure* inequality.

Lemma 1. For any measurable function $\varphi : \Omega \rightarrow \mathbb{R}$, and any two distributions, \mathbb{P} and \mathcal{Q} , on Ω ,

$$\mathbb{E}_{\omega \sim \mathbb{P}} [\varphi(\omega)] \leq D_{\text{kl}}(\mathbb{P} \parallel \mathcal{Q}) + \ln \mathbb{E}_{\omega \sim \mathcal{Q}} [e^{\varphi(\omega)}].$$

(McAllester (2003) provides a straightforward proof.) Using Lemma 1, for any free parameter $u \geq 0$, we have that

$$\mathbb{E}_{h \sim \mathcal{Q}} [\tilde{\phi}(h, \hat{\mathbf{Z}})] \leq \frac{1}{u} \left(D_{\text{kl}}(\mathcal{Q} \parallel \mathbb{P}) + \ln \mathbb{E}_{h \sim \mathbb{P}} [e^{u\tilde{\phi}(h, \hat{\mathbf{Z}})}] \right).$$

Combining the above inequalities yields

$$\bar{L}(\mathcal{Q}) - \hat{L}(\mathcal{Q}, \hat{\mathbf{Z}}) \leq \alpha\eta + \alpha\nu + \frac{1}{u} \left(D_{\text{kl}}(\mathcal{Q} \parallel \mathbb{P}) + \ln \mathbb{E}_{h \sim \mathbb{P}} [e^{u\tilde{\phi}(h, \hat{\mathbf{Z}})}] \right).$$

The remainder of the analysis concerns how to bound $\mathbb{E}_{h \sim \mathbb{P}} [e^{u\tilde{\phi}(h, \hat{\mathbf{Z}})}]$ and how to optimize u . For the first task, we combine Markov's inequality with the moment-generating function bound from Section 4.2. Optimizing u takes some care, since we would like the bounds to hold simultaneously for all posteriors. We therefore adopt a discretization technique (Seldin et al., 2012) that approximately optimizes the bound for all posteriors. We use a similar technique to obtain bounds that hold for all β .

5.1 Fixed Stability Bounds

In the following theorem, we derive a new PAC-Bayes bound for posteriors with local stability, with β fixed. Fixing β means that the set of “bad” hypotheses is determined by the characteristics of the hypothesis class independently of the posterior.

Theorem 1. Fix $m \geq 1$, $n \geq 1$, $\pi \in \Pi(\eta)$, $\delta \in (0, 1)$, $\alpha \geq 0$ and $\beta \geq 0$. Fix a distribution, \mathbb{D} , on \mathcal{Z}^n . Fix a set of bad inputs, \mathcal{B}_Z , with $\nu \triangleq \mathbb{D}(\mathcal{B}_Z)$. Let $\Gamma_{\frac{\pi}{\beta}}$ denote the dependency matrix induced by \mathbb{D} , π and \mathcal{B}_Z . Fix a prior, \mathbb{P} , on a hypothesis class, \mathcal{H} . Fix a loss function, L , such that $L \circ \mathcal{H}$ is α -uniformly range-bounded. Then, with probability at least $1 - \delta - mv$ over realizations of a training set, $\mathbf{Z} \triangleq (\mathbf{Z}^{(l)})_{l=1}^m$, drawn according to \mathbb{D}^n , the following hold: 1) for all $l \in [m]$, $\mathbf{Z}^{(l)} \notin \mathcal{B}_Z$; 2) for all $\eta \in [0, 1]$ and posteriors \mathcal{Q} with $(\beta/n, \mathcal{B}_Z, \eta)$ -local stability,

$$\bar{L}(\mathcal{Q}) \leq \hat{L}(\mathcal{Q}, \hat{\mathbf{Z}}) + \alpha(\eta + \nu) + 2\beta \|\Gamma_{\frac{\pi}{\beta}}\|_{\infty} \sqrt{\frac{D_{\text{kl}}(\mathcal{Q} \parallel \mathbb{P}) + \ln \frac{2}{\delta}}{2mn}}. \quad (2)$$

To interpret the bound, suppose $\alpha = O(1)$, $\beta = O(1)$, and that the data distribution is weakly dependent, with $\|\Gamma_{\frac{\pi}{\beta}}\|_{\infty} = O(1)$. We would then have that the generalization error decreases at a rate of $O(\eta + \nu + (mn)^{-1/2})$. Since η is a function of the posterior, we can reasonably assume that $\eta = O((mn)^{-1/2})$. (Section 6 provides examples of this.) However, while ν may be proportional to n , it is unreasonable to believe that ν will decrease with m , since \mathbb{D} is almost certainly agnostic to the number of training examples. Thus, Theorem 1 is interesting when either ν is negligible, or when m is a small constant.

It can be shown that any hypothesis class with *collective* stability, composed with a suitable loss function, satisfies the conditions of the bound. Thus, Theorem 1 is strictly more general than our prior PAC-Bayes bounds (London et al., 2014). Moreover, Theorem 1 easily applies to compositions with uniform stability, since $\mathcal{Q}(\mathcal{B}_H) = 0$ for all posteriors. This insight yields the following corollary.

Corollary 1. Suppose $L \circ \mathcal{H}$ is (β/n) -uniformly stable. Then, with probability at least $1 - \delta$ over realizations of \mathbf{Z} , for all \mathcal{Q} ,

$$\bar{L}(\mathcal{Q}) \leq \hat{L}(\mathcal{Q}, \hat{\mathbf{Z}}) + 2\beta \|\Gamma_{\frac{\pi}{\beta}}\|_{\infty} \sqrt{\frac{D_{\text{kl}}(\mathcal{Q} \parallel \mathbb{P}) + \ln \frac{2}{\delta}}{2mn}}. \quad (3)$$

As we show in Section 6.1.2, Corollary 1 is useful when the hypothesis class and instance space are uniformly bounded. Even when this property does not hold, we obtain an identical bound for all posteriors with $(\beta/n, \emptyset, 0)$ -local stability, meaning the support of the posterior is (β/n) -uniformly stable. However, this condition is less useful, since it is assumed that the posterior construction puts nonzero density on a learned hypothesis, which may not satisfy uniform stability for a fixed β .

It is worth noting that, if the hypothesis class does not use joint inference—for example, if a global prediction, $h(\mathbf{X})$, is in fact a set of independent, local predictions, $(h(X_1), \dots, h(X_n))$ —and the loss function decomposes over the labels, then uniform stability is trivially satisfied. In this case, Corollary 1 produces a PAC-Bayes bound for learning traditional predictors from interdependent data. If we further have that (Z_1, \dots, Z_n) are independent and identically distributed (i.i.d.)—for instance, if they represent “micro examples” drawn independently from some target distribution—then Corollary 1 reduces to standard PAC-Bayes bounds for learning from i.i.d. data (e.g., McAllester, 1999).

We now prove Theorem 1.

Proof (Theorem 1) We begin by defining two convenience functions,

$$\phi(h, \hat{\mathbf{Z}}) \triangleq \bar{L}(h) - \hat{L}(h, \hat{\mathbf{Z}}) \quad (4)$$

$$\text{and } \tilde{\phi}(h, \hat{\mathbf{Z}}) \triangleq \begin{cases} \mathbb{E}_{\mathbf{Z} \sim \mathbb{D}} [L(h, \mathbf{Z}) | \bar{\mathcal{B}}] - \hat{L}(h, \hat{\mathbf{Z}}) & \text{if } h \notin \mathcal{B}_{\mathcal{H}}, \\ 0 & \text{otherwise,} \end{cases} \quad (5)$$

If $L \circ \mathcal{H}$ is α -uniformly range-bounded (Definition 4), then, for any $h \in \mathcal{H}$,

$$\begin{aligned} \phi(h, \hat{\mathbf{Z}}) &= \frac{1}{m} \sum_{l=1}^m \bar{L}(h) - L(h, \mathbf{Z}^{(l)}) \\ &\leq \frac{1}{m} \sum_{l=1}^m \sup_{\mathbf{z} \in \mathcal{Z}^m} |L(h, \mathbf{z}) - L(h, \mathbf{Z}^{(l)})| \\ &\leq \frac{1}{m} \sum_{l=1}^m \alpha = \alpha. \end{aligned} \quad (6)$$

It follows that

$$\begin{aligned} \phi(h, \hat{\mathbf{Z}}) &= \mathbb{E}_{\mathbf{Z} \sim \mathbb{D}} [L(h, \mathbf{Z}) - \hat{L}(h, \hat{\mathbf{Z}})] \\ &= \mathbb{E}_{\mathbf{Z} \sim \mathbb{D}} \left[\left(L(h, \mathbf{Z}) - \hat{L}(h, \hat{\mathbf{Z}}) \right) \mathbb{1}\{\mathbf{Z} \notin \mathcal{B}_{\mathcal{Z}}\} \right] + \mathbb{E}_{\mathbf{Z} \sim \mathbb{D}} \left[\left(L(h, \mathbf{Z}) - \hat{L}(h, \hat{\mathbf{Z}}) \right) \mathbb{1}\{\mathbf{Z} \in \mathcal{B}_{\mathcal{Z}}\} \right] \\ &\leq \mathbb{E}_{\mathbf{Z} \sim \mathbb{D}} \left[\left(L(h, \mathbf{Z}) - \hat{L}(h, \hat{\mathbf{Z}}) \right) \mathbb{1}\{\mathbf{Z} \notin \mathcal{B}_{\mathcal{Z}}\} \right] + \alpha \mathbb{E}_{\mathbf{Z} \sim \mathbb{D}} [\mathbb{1}\{\mathbf{Z} \in \mathcal{B}_{\mathcal{Z}}\}] \\ &\leq \mathbb{E}_{\mathbf{Z} \sim \mathbb{D}} \left[\left(L(h, \mathbf{Z}) - \hat{L}(h, \hat{\mathbf{Z}}) \right) \mathbb{1}\{\mathbf{Z} \notin \mathcal{B}_{\mathcal{Z}}\} \right] + \alpha \nu \\ &= \Pr_{\mathbf{Z} \sim \mathbb{D}} \{ \mathbf{Z} \notin \mathcal{B}_{\mathcal{Z}} \} \left(\mathbb{E}_{\mathbf{Z} \sim \mathbb{D}} [L(h, \mathbf{Z}) | \bar{\mathcal{B}}] - \hat{L}(h, \hat{\mathbf{Z}}) \right) + \alpha \nu \\ &\leq \mathbb{E}_{\mathbf{Z} \sim \mathbb{D}} [L(h, \mathbf{Z}) | \bar{\mathcal{B}}] - \hat{L}(h, \hat{\mathbf{Z}}) + \alpha \nu. \end{aligned} \quad (7)$$

Moreover, for any posterior \mathbb{Q} with $(\beta/\eta, \mathcal{B}_{\mathcal{Z}} \cdot \eta)$ -local stability,

$$\begin{aligned} \bar{L}(\mathbb{Q}) - \hat{L}(\mathbb{Q}, \hat{\mathbf{Z}}) &= \mathbb{E}_{h \sim \mathbb{Q}} [\phi(h, \hat{\mathbf{Z}})] \\ &= \mathbb{E}_{h \sim \mathbb{Q}} [\phi(h, \hat{\mathbf{Z}}) \mathbb{1}\{h \in \mathcal{B}_{\mathcal{H}}\}] + \mathbb{E}_{h \sim \mathbb{Q}} [\phi(h, \hat{\mathbf{Z}}) \mathbb{1}\{h \notin \mathcal{B}_{\mathcal{H}}\}] \\ &\leq \alpha \mathbb{E}_{h \sim \mathbb{Q}} [\mathbb{1}\{h \in \mathcal{B}_{\mathcal{H}}\}] + \mathbb{E}_{h \sim \mathbb{Q}} [\phi(h, \hat{\mathbf{Z}}) \mathbb{1}\{h \notin \mathcal{B}_{\mathcal{H}}\}] \\ &\leq \alpha \eta + \mathbb{E}_{h \sim \mathbb{Q}} [\phi(h, \hat{\mathbf{Z}}) \mathbb{1}\{h \notin \mathcal{B}_{\mathcal{H}}\}] \\ &\leq \alpha \eta + \alpha \nu + \mathbb{E}_{h \sim \mathbb{Q}} [\tilde{\phi}(h, \hat{\mathbf{Z}})]. \end{aligned} \quad (8)$$

Then, for any $u \in \mathbb{R}$, using Lemma 1, we have that

$$\begin{aligned} \bar{L}(\mathbb{Q}) - \hat{L}(\mathbb{Q}, \hat{\mathbf{Z}}) &\leq \alpha \eta + \alpha \nu + \frac{1}{u} \mathbb{E}_{h \sim \mathbb{Q}} [u \tilde{\phi}(h, \hat{\mathbf{Z}})] \\ &\leq \alpha \eta + \alpha \nu + \frac{1}{u} \left(D_{\text{KL}}(\mathbb{Q} \| \mathbb{P}) + \ln \mathbb{E}_{h \sim \mathbb{P}} [e^{u \tilde{\phi}(h, \hat{\mathbf{Z}})}] \right). \end{aligned} \quad (9)$$

Since u cannot depend on (η, \mathbb{Q}) , we define it in terms of fixed quantities. For $j = 0, 1, 2, \dots$, let $\delta_j \triangleq \delta 2^{-(j+1)}$, let

$$u_j \triangleq 2^j \sqrt{\frac{8mn \ln \frac{2}{\delta}}{\beta^2 \|\mathbf{T}_{\bar{\mathcal{B}}}\|^2}}, \quad (10)$$

and define an event,

$$E_j \triangleq \mathbb{1} \left\{ \mathbb{E}_{h \sim \mathbb{P}} [e^{u_j \tilde{\phi}(h, \hat{\mathbf{Z}})}] \geq \frac{1}{\delta_j} \exp \left(\frac{u_j^2 \beta^2 \|\mathbf{T}_{\bar{\mathcal{B}}}\|^2}{8mn} \right) \right\}. \quad (11)$$

Note that u_j and E_j are independent of (η, \mathbb{Q}) , since β (hence, $\mathcal{B}_{\mathcal{H}}$) is fixed. Let $E \triangleq \bigcup_{j=0}^{\infty} E_j$ denote the event that any E_j occurs. We also define an event

$$B \triangleq \bigcup_{l=1}^m \mathbb{1} \{ \mathbf{Z}^{(l)} \in \mathcal{B}_{\mathcal{Z}} \}, \quad (12)$$

which indicates that at least one of the training examples is ‘‘bad.’’ Using the law of total probability and the union bound, we then have that

$$\begin{aligned} \Pr_{\mathbf{Z} \sim \mathbb{D}^m} \{ B \cup E \} &= \Pr_{\mathbf{Z} \sim \mathbb{D}^m} \{ B \} + \Pr_{\mathbf{Z} \sim \mathbb{D}^m} \{ E \cap \neg B \} \\ &\leq \Pr_{\mathbf{Z} \sim \mathbb{D}^m} \{ B \} + \Pr_{\mathbf{Z} \sim \mathbb{D}^m} \{ E | \neg B \} \\ &\leq \sum_{l=1}^m \Pr_{\mathbf{Z}^{(l)} \sim \mathbb{D}} \{ \mathbf{Z}^{(l)} \in \mathcal{B}_{\mathcal{Z}} \} + \sum_{j=0}^{\infty} \Pr_{\mathbf{Z} \sim \mathbb{D}^m} \{ E_j | \neg B \} \\ &\leq m\nu + \sum_{j=0}^{\infty} \Pr_{\mathbf{Z} \sim \mathbb{D}^m} \{ E_j | \neg B \}. \end{aligned} \quad (13)$$

The last inequality follows from the definition of ν . Then, using Markov’s inequality, and rearranging the expectations, we have that

$$\Pr_{\mathbf{Z} \sim \mathbb{D}^m} \{ E_j | \neg B \} \leq \delta_j \exp \left(-\frac{u_j^2 \beta^2 \|\mathbf{T}_{\bar{\mathcal{B}}}\|^2}{8mn} \right) \mathbb{E}_{h \sim \mathbb{P}} \mathbb{E}_{\mathbf{Z} \sim \mathbb{D}^m} [e^{u_j \tilde{\phi}(h, \hat{\mathbf{Z}})} | \neg B]. \quad (14)$$

Let

$$\varphi(h, \mathbf{Z}) \triangleq \begin{cases} \frac{1}{m} (\mathbb{E}_{\mathbf{Z} \sim \mathbb{D}} [L(h, \mathbf{Z}) | \bar{\mathcal{B}}] - L(h, \mathbf{Z})) & \text{if } h \notin \mathcal{B}_{\mathcal{H}}, \\ 0 & \text{otherwise,} \end{cases} \quad (15)$$

and note that $\tilde{\varphi}(h, \mathbf{Z}) = \sum_{l=1}^m \varphi(h, \mathbf{Z}^{(l)})$. Then, since $\mathbf{Z}^{(1)}, \dots, \mathbf{Z}^{(m)}$ are independent and identically distributed, we can write the inner expectation over \mathbf{Z} as

$$\begin{aligned} \mathbb{E}_{\mathbf{Z} \sim \mathbb{D}^m} \left[e^{u_j \tilde{\varphi}(h, \mathbf{Z})} \mid \neg B \right] &= \prod_{l=1}^m \mathbb{E}_{\mathbf{Z}^{(l)} \sim \mathbb{D}} \left[e^{u_j \varphi(h, \mathbf{Z}^{(l)})} \mid \neg B \right] \\ &= \prod_{l=1}^m \mathbb{E}_{\mathbf{Z}^{(l)} \sim \mathbb{D}} \left[e^{u_j \varphi(h, \mathbf{Z}^{(l)})} \mid \mathbf{Z}^{(l)} \notin \mathcal{B}_{\mathcal{Z}} \right] \\ &= \prod_{l=1}^m \mathbb{E}_{\mathbf{Z}^{(l)} \sim \mathbb{D}} \left[e^{u_j \varphi(h, \mathbf{Z}^{(l)})} \mid \overline{\mathcal{B}} \right]. \end{aligned} \quad (16)$$

By construction, $\varphi(h, \cdot)$ outputs zero whenever $h \in \mathcal{B}_{\mathcal{H}}$. In these cases, $\varphi(h, \cdot)$ trivially satisfies uniform stability, which implies local stability. Further, if \mathbb{Q} is $(\beta/n, \mathcal{B}_{\mathcal{Z}}, \eta)$ -locally stable, then every $L(h, \cdot) : h \notin \mathcal{B}_{\mathcal{H}}$ is $(\beta/n, \mathcal{B}_{\mathcal{Z}})$ -locally stable, and it is easily verified that $\varphi(h, \cdot) : h \notin \mathcal{B}_{\mathcal{H}}$ is $(\beta/(mn), \mathcal{B}_{\mathcal{Z}})$ -locally stable. Thus, $\varphi(h, \cdot) : h \in \mathcal{H}$ is $(\beta/(mn), \mathcal{B}_{\mathcal{Z}})$ -locally stable. Since $\mathbb{E}_{\mathbf{Z} \sim \mathbb{D}}[\varphi(h, \mathbf{Z}) \mid \overline{\mathcal{B}}] = 0$, we therefore apply Proposition 1 and have, for all $h \in \mathcal{H}$,

$$\mathbb{E}_{\mathbf{Z}^{(l)} \sim \mathbb{D}} \left[e^{u_j \varphi(h, \mathbf{Z}^{(l)})} \mid \overline{\mathcal{B}} \right] \leq \exp \left(\frac{u_j^2 \beta^2 \|\Gamma_{\overline{\mathcal{B}}}^{\mathbb{T}}\|_{\infty}^2}{8m^2 n} \right). \quad (17)$$

Combining Equations 14, 16 and 17, we have that

$$\begin{aligned} \Pr_{\mathbf{Z} \sim \mathbb{D}^m} \{ E_j \mid \neg B \} &\leq \delta_j \exp \left(-\frac{u_j^2 \beta^2 \|\Gamma_{\overline{\mathcal{B}}}^{\mathbb{T}}\|_{\infty}^2}{8mn} \right) \mathbb{E}_{h \sim \mathbb{P}} \left[\prod_{l=1}^m \mathbb{E}_{\mathbf{Z}^{(l)} \sim \mathbb{D}} \left[e^{u_j \varphi(h, \mathbf{Z}^{(l)})} \mid \overline{\mathcal{B}} \right] \right] \\ &\leq \delta_j \exp \left(-\frac{u_j^2 \beta^2 \|\Gamma_{\overline{\mathcal{B}}}^{\mathbb{T}}\|_{\infty}^2}{8mn} \right) \mathbb{E}_{h \sim \mathbb{P}} \left[\prod_{l=1}^m \exp \left(\frac{u_j^2 \beta^2 \|\Gamma_{\overline{\mathcal{B}}}^{\mathbb{T}}\|_{\infty}^2}{8m^2 n} \right) \right] \\ &= \delta_j \exp \left(-\frac{u_j^2 \beta^2 \|\Gamma_{\overline{\mathcal{B}}}^{\mathbb{T}}\|_{\infty}^2}{8mn} \right) \exp \left(\frac{u_j^2 \beta^2 \|\Gamma_{\overline{\mathcal{B}}}^{\mathbb{T}}\|_{\infty}^2}{8mn} \right) = \delta_j. \end{aligned} \quad (18)$$

Then, combining Equations 13 and 18, and using the geometric series identity, we have that

$$\Pr_{\mathbf{Z} \sim \mathbb{D}^m} \{ B \cup E \} \leq m\nu + \sum_{j=0}^{\infty} \delta_j = m\nu + \delta \sum_{j=0}^{\infty} 2^{-(j+1)} = m\nu + \delta.$$

Thus, with probability at least $1 - \delta - m\nu$ over realizations of $\tilde{\mathbf{Z}}$, every $l \in [m]$ satisfies $\mathbf{Z}^{(l)} \notin \mathcal{B}_{\mathcal{Z}}$, and every u_j satisfies

$$\mathbb{E}_{h \sim \mathbb{P}} \left[e^{u_j \tilde{\varphi}(h, \mathbf{Z})} \right] \leq \frac{1}{\delta_j} \exp \left(\frac{u_j^2 \beta^2 \|\Gamma_{\overline{\mathcal{B}}}^{\mathbb{T}}\|_{\infty}^2}{8mn} \right). \quad (19)$$

We now show how to select j for any particular posterior \mathbb{Q} . Let

$$j^* \triangleq \left\lfloor \frac{1}{2 \ln 2} \ln \left(\frac{D_{\text{kl}}(\mathbb{Q} \parallel \mathbb{P})}{\ln(2/\delta)} + 1 \right) \right\rfloor, \quad (20)$$

and note that $j^* \geq 0$. For all $v \in \mathbb{R}$, we have that $v - 1 \leq \lfloor v \rfloor \leq v$, and $2^{\ln v} = v^{\ln 2}$. We apply these identities to Equation 20 to show that

$$\frac{1}{2} \sqrt{\frac{D_{\text{kl}}(\mathbb{Q} \parallel \mathbb{P})}{\ln(2/\delta)} + 1} \leq 2^{j^*} \leq \sqrt{\frac{D_{\text{kl}}(\mathbb{Q} \parallel \mathbb{P})}{\ln(2/\delta)} + 1},$$

$$\sqrt{\frac{2mn \left(D_{\text{kl}}(\mathbb{Q} \parallel \mathbb{P}) + \ln \frac{2}{\delta} \right)}{\beta^2 \|\Gamma_{\overline{\mathcal{B}}}^{\mathbb{T}}\|_{\infty}^2}} \leq u_{j^*} \leq \sqrt{\frac{8mn \left(D_{\text{kl}}(\mathbb{Q} \parallel \mathbb{P}) + \ln \frac{2}{\delta} \right)}{\beta^2 \|\Gamma_{\overline{\mathcal{B}}}^{\mathbb{T}}\|_{\infty}^2}}. \quad (21)$$

implying

Further, by definition of δ_{j^*} ,

$$\begin{aligned} D_{\text{kl}}(\mathbb{Q} \parallel \mathbb{P}) + \ln \frac{1}{\delta_{j^*}} &= D_{\text{kl}}(\mathbb{Q} \parallel \mathbb{P}) + \ln \frac{2}{\delta} + j^* \ln 2 \\ &\leq D_{\text{kl}}(\mathbb{Q} \parallel \mathbb{P}) + \ln \frac{2}{\delta} + \frac{\ln 2}{2 \ln 2} \ln \left(\frac{D_{\text{kl}}(\mathbb{Q} \parallel \mathbb{P})}{\ln(2/\delta)} + 1 \right) \\ &= D_{\text{kl}}(\mathbb{Q} \parallel \mathbb{P}) + \ln \frac{2}{\delta} + \frac{1}{2} \ln \left(D_{\text{kl}}(\mathbb{Q} \parallel \mathbb{P}) + \ln \frac{2}{\delta} \right) - \frac{1}{2} \ln \ln \frac{2}{\delta} \\ &\leq D_{\text{kl}}(\mathbb{Q} \parallel \mathbb{P}) + \ln \frac{2}{\delta} + \frac{1}{2} \left(D_{\text{kl}}(\mathbb{Q} \parallel \mathbb{P}) + \ln \frac{2}{\delta} \right). \end{aligned} \quad (22)$$

The last inequality uses the identity $v - \ln \ln(2/\delta) \leq v + 1 \leq e^v$, for all $v \in \mathbb{R}$ and $\delta \in (0, 1)$. It can be shown that this bound is approximately optimal, in that it is at most twice what it would be for a fixed posterior.

Putting it all together, we now have that, with probability at least $1 - \delta - m\nu$, the approximately optimal (u_{j^*}, δ_{j^*}) for any posterior \mathbb{Q} satisfies

$$\begin{aligned} \tilde{L}(\mathbb{Q}) - \hat{L}(\mathbb{Q}, \tilde{\mathbf{Z}}) &\leq \alpha(\eta + \nu) + \frac{1}{u_{j^*}} \left(D_{\text{kl}}(\mathbb{Q} \parallel \mathbb{P}) + \ln \mathbb{E}_{h \sim \mathbb{P}} \left[e^{u_{j^*} \tilde{\varphi}(h, \tilde{\mathbf{Z}})} \right] \right) \\ &\leq \alpha(\eta + \nu) + \frac{1}{u_{j^*}} \left(D_{\text{kl}}(\mathbb{Q} \parallel \mathbb{P}) + \ln \frac{1}{\delta_{j^*}} + \frac{u_{j^*}^2 \beta^2 \|\Gamma_{\overline{\mathcal{B}}}^{\mathbb{T}}\|_{\infty}^2}{8mn} \right) \\ &\leq \alpha(\eta + \nu) + \frac{3 \left(D_{\text{kl}}(\mathbb{Q} \parallel \mathbb{P}) + \ln \frac{2}{\delta} \right)}{2u_{j^*}} + \frac{u_{j^*} \beta^2 \|\Gamma_{\overline{\mathcal{B}}}^{\mathbb{T}}\|_{\infty}^2}{8mn} \\ &\leq \alpha(\eta + \nu) + 2\beta \|\Gamma_{\overline{\mathcal{B}}}^{\mathbb{T}}\|_{\infty} \sqrt{\frac{D_{\text{kl}}(\mathbb{Q} \parallel \mathbb{P}) + \ln \frac{2}{\delta}}{2mn}}. \end{aligned}$$

The first inequality substitutes u_{j^*} into Equation 9; the second uses Equation 19; the third is from Equation 22; and the last uses the lower and upper bounds from Equation 21. ■

5.2 Posterior-Dependent Stability

In Theorem 1, we required β to be fixed *a priori*, meaning we required the user to pre-specify a desired stability. In this section, we prove bounds that hold for all $\beta \geq 1$ simultaneously,

meaning the value of β can depend on the learned posterior. (The requirement of nonnegativity is not restrictive, since stability with $\beta \leq 1$ implies stability with $\beta = 1$.)

Theorem 2. Fix $m \geq 1$, $n \geq 1$, $\boldsymbol{\pi} \in \Pi(n)$, $\delta \in (0, 1)$ and $\alpha \geq 0$. Fix a distribution, \mathbb{D} , on \mathcal{Z}^n . Fix a set of bad inputs, \mathcal{B}_Z , with $\nu \triangleq \mathbb{D}(\mathcal{B}_Z)$. Let $\mathbf{I}_{\frac{\boldsymbol{\pi}}{m}}$ denote the dependency matrix induced by \mathbb{D} , $\boldsymbol{\pi}$ and \mathcal{B}_Z . Fix a prior, \mathbb{P} , on a hypothesis class, \mathcal{H} . Fix a loss function, L , such that $L \circ \mathcal{H}$ is α -uniformly range-bounded. Then, with probability at least $1 - \delta - m\nu$ over realizations of $\hat{\mathbf{Z}} \triangleq (\mathbf{Z}^{(l)})_{l=1}^m$, drawn according to \mathbb{D}^m , the following hold: 1) for all $l \in [m]$, $\mathbf{Z}^{(l)} \notin \mathcal{B}_Z$; 2) for all $\beta \geq 1$, $\eta \in [0, 1]$ and posteriors \mathbb{Q} with $(\beta/n, \mathcal{B}_Z, \eta)$ -local stability,

$$\bar{L}(\mathbb{Q}) \leq \hat{L}(\mathbb{Q}, \hat{\mathbf{Z}}) + \alpha(\eta + \nu) + 4\beta \left\| \mathbf{I}_{\frac{\boldsymbol{\pi}}{m}} \right\|_{\infty} \sqrt{\frac{D_{\text{KL}}(\mathbb{Q} \parallel \mathbb{P}) + \ln \frac{4}{\delta} + \ln \beta}{2mn}}. \quad (23)$$

The proof is similar to that of Theorem 1, so we defer it to Appendix B.1.

Theorem 2 immediately yields the following corollary by taking $\mathcal{B}_Z \triangleq \emptyset$.

Corollary 2. With probability at least $1 - \delta$ over realizations of $\hat{\mathbf{Z}}$, for all $\beta \geq 1$, $\eta \in [0, 1]$ and \mathbb{Q} with $(\beta/n, \emptyset, \eta)$ -local stability,

$$\bar{L}(\mathbb{Q}) \leq \hat{L}(\mathbb{Q}, \hat{\mathbf{Z}}) + \alpha\eta + 4\beta \left\| \mathbf{I}_{\boldsymbol{\pi}} \right\|_{\infty} \sqrt{\frac{D_{\text{KL}}(\mathbb{Q} \parallel \mathbb{P}) + \ln \frac{4}{\delta} + \ln \beta}{2mn}}. \quad (24)$$

In Section 6, we apply this corollary to unbounded hypothesis classes, with bounded instance spaces. Corollary 2 trivially implies a bound for posteriors with $(\beta/n, \emptyset, 0)$ -local stability, such as those with bounded support on an unbounded hypothesis class, where β may depend on a learned model.

5.3 Derandomizing the Loss using Stability

PAC-Bayes bounds are stated in terms of a randomized predictor. Yet, in practice, one is usually interested in the loss of a learned, deterministic predictor. Given a properly constructed posterior distribution, it is possible to convert a PAC-Bayes bound to a generalization bound for the learned hypothesis. There are various ways to go about this for unstructured hypotheses; however, many of these methods fail for structured predictors, since the output is not simply a scalar, but a high-dimensional vector. In this section, we present a generic technique for derandomizing PAC-Bayes bounds for structured prediction based on the idea of stability. An attractive feature of this technique is that it obviates margin-based arguments, which often require a free-parameter for the margin.

We first define a specialized notion of local stability that measures the difference in loss induced by perturbing a given hypothesis. For the following, we view the posterior \mathbb{Q} as a function that, given a hypothesis $h \in \mathcal{H}$, returns a distribution \mathbb{Q}_h on \mathcal{H} .

Definition 8. Fix a hypothesis class, \mathcal{H} , a set of inputs, $\mathcal{B}_Z \subseteq \mathcal{Z}^n$, a loss function, L , and a posterior, \mathbb{Q} . We say that the pair (L, \mathbb{Q}) has $(\lambda, \mathcal{B}_Z, \eta)$ -local stability if, for any $h \in \mathcal{H}$ and $\mathbf{z} \notin \mathcal{B}_Z$, there exists a set $\mathcal{B}_{\mathcal{H}}(h, \mathbf{z}) \subseteq \mathcal{H}$ such that $\mathbb{Q}_h(\mathcal{B}_{\mathcal{H}}(h, \mathbf{z})) \leq \eta$ and, for all $h' \notin \mathcal{B}_{\mathcal{H}}(h, \mathbf{z})$,

$$|L(h, \mathbf{z}) - L(h', \mathbf{z})| \leq \lambda. \quad (25)$$

This form of stability is a slightly weaker condition than the previous definitions, in that each input, (h, \mathbf{z}) , has its own “bad” set, $\mathcal{B}_{\mathcal{H}}(h, \mathbf{z})$. This distinction means that “badness” is relative, whereas, in Definitions 2 and 3, it is absolute.

Proposition 4. Fix a hypothesis class, \mathcal{H} , a set of inputs, $\mathcal{B}_Z \subseteq \mathcal{Z}^n$, with $\nu \triangleq \mathbb{D}(\mathcal{B}_Z)$, and a loss function, L , such that, for any $\mathbf{z} \in \mathcal{Z}^n$, $L(\cdot, \mathbf{z})$ is α -uniformly range-bounded. Let \mathbb{Q} denote a posterior function on \mathcal{H} . If (L, \mathbb{Q}) has $(\lambda, \mathcal{B}_Z, \eta)$ -local stability, then, for all $h \in \mathcal{H}$,

$$|\bar{L}(h) - \bar{L}(\mathbb{Q}_h)| \leq \alpha(\eta + \nu) + \lambda, \quad (26)$$

and, for all $\hat{\mathbf{z}} \triangleq (\mathbf{z}^{(l)})_{l=1}^m$ such that, $\forall l \in [m]$, $\mathbf{z}^{(l)} \notin \mathcal{B}_Z$,

$$|\hat{L}(h, \hat{\mathbf{z}}) - \hat{L}(\mathbb{Q}_h, \hat{\mathbf{z}})| \leq \alpha\eta + \lambda. \quad (27)$$

Proof Define a convenience function

$$\varphi(h, h', \mathbf{z}) \triangleq |L(h, \mathbf{z}) - L(h', \mathbf{z})|.$$

For any $\mathbf{z} \notin \mathcal{B}_Z$, using the range-boundedness and stability assumptions, we have that

$$\begin{aligned} & \mathbb{E}_{h' \sim \mathbb{Q}_h} [\varphi(h, h', \mathbf{z})] \\ &= \mathbb{E}_{h' \sim \mathbb{Q}_h} [\varphi(h, h', \mathbf{z}) \mathbb{1}\{h' \in \mathcal{B}_{\mathcal{H}}(h, \mathbf{z})\}] + \mathbb{E}_{h' \sim \mathbb{Q}_h} [\varphi(h, h', \mathbf{z}) \mathbb{1}\{h' \notin \mathcal{B}_{\mathcal{H}}(h, \mathbf{z})\}] \\ &\leq \alpha\eta + \lambda. \end{aligned}$$

Therefore, if $\forall l \in [m]$, $\mathbf{z}^{(l)} \notin \mathcal{B}_Z$, by linearity of expectation and the triangle inequality,

$$\begin{aligned} |\hat{L}(h, \hat{\mathbf{z}}) - \hat{L}(\mathbb{Q}_h, \hat{\mathbf{z}})| &= \left| \frac{1}{m} \sum_{l=1}^m \mathbb{E}_{\mathbf{z}^{(l)} \sim \mathbb{Q}_h} [L(h, \mathbf{z}^{(l)}) - L(h', \mathbf{z}^{(l)})] \right| \\ &\leq \frac{1}{m} \sum_{l=1}^m \mathbb{E}_{h' \sim \mathbb{Q}_h} [\varphi(h, h', \mathbf{z}^{(l)})] \\ &\leq \alpha\eta + \lambda. \end{aligned}$$

thus proving Equation 27. Furthermore,

$$\begin{aligned} |\bar{L}(h) - \bar{L}(\mathbb{Q}_h)| &= \left| \mathbb{E}_{\mathbf{z} \sim \mathbb{D}} \mathbb{E}_{h' \sim \mathbb{Q}_h} [L(h, \mathbf{Z}) - L(h', \mathbf{Z})] \right| \\ &\leq \mathbb{E}_{\mathbf{z} \sim \mathbb{D}} \mathbb{E}_{h' \sim \mathbb{Q}_h} [\varphi(h, h', \mathbf{Z})] \\ &= \mathbb{E}_{\mathbf{z} \sim \mathbb{D}} \mathbb{E}_{h' \sim \mathbb{Q}_h} [\varphi(h, h', \mathbf{Z}) \mathbb{1}\{\mathbf{Z} \in \mathcal{B}_Z\}] + \mathbb{E}_{\mathbf{z} \sim \mathbb{D}} \mathbb{E}_{h' \sim \mathbb{Q}_h} [\varphi(h, h', \mathbf{Z}) \mathbb{1}\{\mathbf{Z} \notin \mathcal{B}_Z\}] \\ &\leq \alpha\nu + \alpha\eta + \lambda, \end{aligned}$$

which proves Equation 26. \blacksquare

Proposition 4 can easily be combined with the PAC-Bayes bounds from the previous sections to obtain derandomized generalization bounds. We analyze some examples in Section 6.

5.3.1 NORMED VECTOR SPACES

When the hypothesis class is a normed vector space (as is the case in all of the examples in Section 6), Definition 8 can be decomposed into properties of the loss function and posterior separately.

Definition 9. Fix a hypothesis class, \mathcal{H} , equipped with a norm, $\|\cdot\|$. Fix a set of inputs, $\mathcal{B}_Z \subseteq \mathcal{Z}^n$. We say that a loss function, L , has (λ, \mathcal{B}_Z) -local hypothesis stability if, for all $h, h' \in \mathcal{H}$ and $\mathbf{z} \notin \mathcal{B}_Z$,

$$|L(h, \mathbf{z}) - L(h', \mathbf{z})| \leq \lambda \|h - h'\|.$$

Definition 10. Fix a hypothesis class, \mathcal{H} , equipped with a norm, $\|\cdot\|$. We say that a posterior, \mathbb{Q} , has (β, η) -local hypothesis stability if, for any $h \in \mathcal{H}$, there exists a set $\mathcal{B}_H(h) \subseteq \mathcal{H}$ such that $\mathbb{Q}_h(\mathcal{B}_H(h)) \leq \eta$ and, for all $h' \notin \mathcal{B}_H(h)$, $\|h - h'\| \leq \beta$.

When both of these properties hold, we have the following.

Proposition 5. Fix a hypothesis class, \mathcal{H} , equipped with a norm, $\|\cdot\|$. Fix a set of inputs, $\mathcal{B}_Z \subseteq \mathcal{Z}^n$. If a loss function, L , has (λ, \mathcal{B}_Z) -local hypothesis stability, and a posterior, \mathbb{Q} , has (β, η) -local hypothesis stability, then (L, \mathbb{Q}) has $(\lambda\beta, \mathcal{B}_Z, \eta)$ -local stability.

The proof is provided in Appendix B.2.

6. Example Applications

To illustrate how various learning algorithms and modeling decisions affect the generalization error, we now apply our PAC-Bayes bounds to the class of pairwise MRFs with templated, linear potentials (described in Section 2.2.3). We derive generalization bounds for two popular training regimes, *max-margin* and *soft-max* learning, under various assumptions about the instance space and feature functions. The bounds in this section are stated in terms of a deterministic predictor, meaning we use the PAC-Bayes framework as an analytic tool only. That said, one could easily adapt our analysis to obtain bounds for a randomized predictor by skipping the derandomization step.

6.1 Max-Margin Learning

For classification tasks, the goal is to output the labeling that is closest to the true labeling, by some measure of closeness. This is usually measured by the *Hamming loss*,

$$L_H(h, \mathbf{x}, \mathbf{y}) \triangleq \frac{1}{n} D_H(\mathbf{y}, h(\mathbf{x})).$$

The Hamming loss can be considered the structured equivalent of the θ -1 loss. Unfortunately, the Hamming loss is not convex, making it difficult to minimize directly. Thus, many learning algorithms minimize a convex upper bound.

One such method is *max-margin* learning. Max-margin learning aims to find the “simplest” model that scores the correct outputs higher than all incorrect outputs by a specified margin. Though typically formulated as a quadratic program, the learning objective can also be stated as minimizing a *hinge loss*, with model regularization.

Structured predictors learned with a max-margin objective are alternatively referred to as *max-margin Markov networks* (Taskar et al., 2004) or *StructSVM* (Tschantzaris et al., 2005), depending on the form of the hinge loss. In this section, we consider the former formulation, defining the structured hinge loss as

$$L_h(h, \mathbf{x}, \mathbf{y}) \triangleq \frac{1}{n} \left(\max_{\mathbf{y}' \in \mathcal{Y}^n} D_H(\mathbf{y}, \mathbf{y}') + h(\mathbf{x}, \mathbf{y}') - h(\mathbf{x}, \mathbf{y}) \right), \quad (28)$$

where

$$h(\mathbf{x}, \mathbf{y}) \triangleq \boldsymbol{\theta}(\mathbf{x}; \mathbf{w}) \cdot \hat{\mathbf{y}} \quad (29)$$

is the unnormalized log-likelihood. The Hamming distance, $D_H(\mathbf{y}, \mathbf{y}')$, implies that the margin, $h(\mathbf{x}, \mathbf{y}) - h(\mathbf{x}, \mathbf{y}')$, should scale linearly with the distance between \mathbf{y} and \mathbf{y}' .

In theory, the structured hinge loss can be defined with any distance function; though, in practice, the Hamming distance is commonly used. One attractive property of the Hamming distance is that, when

$$h(\mathbf{x}) \triangleq \arg \max_{\mathbf{y} \in \mathcal{Y}^n} h(\mathbf{x}, \mathbf{y}) = \arg \max_{\mathbf{y} \in \mathcal{Y}^n} p(\mathbf{Y} = \mathbf{y} \mid \mathbf{X} = \mathbf{x}; \mathbf{w}) \quad (30)$$

(i.e., MAP inference), the hinge loss upper-bounds the Hamming loss. Another benefit is that it decomposes along the unary cliques. Indeed, with $\delta(\mathbf{y}) \triangleq \begin{bmatrix} 1-\mathbf{y} \\ \mathbf{0} \end{bmatrix}$ (i.e., one minus the unary clique states, then zero-padded to be the same length as $\hat{\mathbf{y}}$), observe that $D_H(\mathbf{y}, \mathbf{y}') = \delta(\mathbf{y}) \cdot \hat{\mathbf{y}}'$. This identity yields a convenient equivalence:

$$L_h(h, \mathbf{x}, \mathbf{y}) = \frac{1}{n} \left(\max_{\mathbf{y}' \in \mathcal{Y}^n} (\boldsymbol{\theta}(\mathbf{x}; \mathbf{w}) + \delta(\mathbf{y})) \cdot \hat{\mathbf{y}}' - \boldsymbol{\theta}(\mathbf{x}; \mathbf{w}) \cdot \hat{\mathbf{y}} \right).$$

The term $\boldsymbol{\theta}(\mathbf{x}; \mathbf{w}) \cdot \hat{\mathbf{y}}$ is constant with respect to \mathbf{y}' , and is thus irrelevant to the maximization. Therefore, letting

$$\hat{\boldsymbol{\theta}}(\mathbf{x}, \mathbf{y}; \mathbf{w}) \triangleq \boldsymbol{\theta}(\mathbf{x}; \mathbf{w}) + \delta(\mathbf{y}), \quad (31)$$

computing the hinge loss is equivalent to performing *loss-augmented* MAP inference with $\hat{\boldsymbol{\theta}}(\mathbf{x}, \mathbf{y}; \mathbf{w})$. Provided inference can be computed efficiently with the given class of models, so too can the hinge loss.⁶

6.1.1 STRUCTURED RAMP LOSS

Applying our generalization bounds requires a uniformly range-bounded loss function. Since the hinge loss is not uniformly range-bounded for certain hypothesis classes, we therefore introduce the structured *ramp loss*:

$$L_r(h, \mathbf{x}, \mathbf{y}) \triangleq \frac{1}{n} \left(\max_{\mathbf{y}' \in \mathcal{Y}^n} D_H(\mathbf{y}, \mathbf{y}') + h(\mathbf{x}, \mathbf{y}') - \max_{\mathbf{y}'' \in \mathcal{Y}^n} h(\mathbf{x}, \mathbf{y}'') \right),$$

where $h(\mathbf{x}, \mathbf{y})$ is defined in Equation 29. The ramp loss is 1-uniformly range-bounded. Further, when $h(\mathbf{x})$ performs MAP inference (Equation 30),

$$L_H(h, \mathbf{x}, \mathbf{y}) \leq L_r(h, \mathbf{x}, \mathbf{y}) \leq L_H(h, \mathbf{x}, \mathbf{y}). \quad (32)$$

6. The results in this section are easily extended to approximate MAP inference algorithms, such as linear programming relaxations. The bounds are the same, but the semantics of the loss functions change, since approximate MAP solutions might be fractional.

Thus, we can analyze the generalization properties of the ramp loss to obtain bounds for the difference of the expected Hanning loss and empirical hinge loss. To distinguish quantities of different loss functions, we will use a subscript notation: e.g., \bar{L}_π is the expected Hanning loss, and \hat{L}_h is the empirical hinge loss.

Using the templated, linear potentials defined in Section 2.2.3, we obtain two technical lemmas for the structured ramp loss. Proofs are provided in Appendices C.1 and C.2.

Lemma 2. Fix any $p, q \geq 1$ such that $1/p + 1/q = 1$. Fix a graph, $G \triangleq (\mathcal{V}, \mathcal{E})$, with maximum degree Δ_G . Assume that $\sup_{x \in \mathcal{X}} \|x\|_p \leq R$. Then, for any MRF h with weights \mathbf{w} , and any $\mathbf{z}, \mathbf{z}' \in \mathcal{Z}^n$, where $\mathbf{z} = (\mathbf{x}, \mathbf{y})$ and $\mathbf{z}' = (\mathbf{x}', \mathbf{y}')$,

$$|L_r(h, \mathbf{z}) - L_r(h, \mathbf{z}')| \leq \frac{1}{n} \left((2\Delta_G + 4)R \|\mathbf{w}\|_q + 1 \right) D_h(\mathbf{z}, \mathbf{z}'). \quad (33)$$

Further, if the model does not use edge observations (i.e., $f_{ij}(\mathbf{x}, \mathbf{y}) \triangleq y_i \otimes y_j$), then

$$|L_r(h, \mathbf{z}) - L_r(h, \mathbf{z}')| \leq \frac{1}{n} \left(4R \|\mathbf{w}\|_q + 1 \right) D_h(\mathbf{z}, \mathbf{z}'). \quad (34)$$

Lemma 3. Fix any $p, q \geq 1$ such that $1/p + 1/q = 1$. Fix a graph, $G \triangleq (\mathcal{V}, \mathcal{E})$. Assume that $\sup_{x \in \mathcal{X}} \|x\|_p \leq R$. Then, for any example $\mathbf{z} \in \mathcal{Z}^n$, and any two MRFs, h, h' with weights \mathbf{w}, \mathbf{w}' ,

$$|L_r(h, \mathbf{z}) - L_r(h', \mathbf{z})| \leq \frac{2 \|G\|_R}{n} \|\mathbf{w} - \mathbf{w}'\|_q.$$

Lemma 3 implies that L_r has $(2 \|G\|_R/n, \emptyset)$ -local hypothesis stability.

6.1.2 GENERALIZATION BOUNDS FOR MAX-MARGIN LEARNING

We now apply our PAC-Bayes bounds to the class of max-margin Markov networks that perform MAP inference, with the templated, linear potentials defined in Section 2.2.3. We denote this class by \mathcal{H}_{M3N} . As a warm-up, we first assume that both the observations and weights are uniformly bounded by the 2-norm unit ball. By Lemma 2, this means that the ramp loss satisfies uniform stability, meaning we can apply Corollary 1.

Example 1. Fix any $m \geq 1$, $n \geq 1$, $\pi \in \Pi(n)$ and $\delta \in (0, 1)$. Fix a graph, $G \triangleq (\mathcal{V}, \mathcal{E})$, with maximum degree Δ_G . Assume that $\sup_{x \in \mathcal{X}} \|x\|_2 \leq 1$. Then, with probability at least $1 - \delta$ over realizations of $\hat{\mathbf{Z}} \triangleq (\mathbf{Z}^{(i)})_{i=1}^m$, for all $h \in \mathcal{H}_{\text{M3N}}$ with $\|\mathbf{w}\|_2 \leq 1$,

$$\bar{L}_\pi(h) \leq \hat{L}_h(h, \hat{\mathbf{Z}}) + \frac{4}{mn} + (4\Delta_G + 10) \|\Gamma^\pi\|_\infty \sqrt{\frac{d \ln(2m |G|) + \ln \frac{4}{\delta}}{2mn}}.$$

The proof is given in Appendix C.3. Note that, with the bounded degree assumption, $|G| \leq n\Delta_G = O(n)$.

We now relax the assumption that the hypothesis class is bounded. One approach is to apply a covering argument directly to Example 1. However, it is interesting to see how other prior/posterior constructions behave. Of particular interest are Gaussian constructions, which correspond to 2-norm regularization. Since the support of a Gaussian is unbounded, this construction requires a non-uniform notion of stability. The following example illustrates how to use posterior-dependent, local stability.

Example 2. Fix any $m \geq 1$, $n \geq 1$, $\pi \in \Pi(n)$ and $\delta \in (0, 1)$. Fix a graph, $G \triangleq (\mathcal{V}, \mathcal{E})$, with maximum degree Δ_G . Assume that $\sup_{x \in \mathcal{X}} \|x\|_2 \leq 1$. Then, with probability at least $1 - \delta$ over realizations of $\hat{\mathbf{Z}} \triangleq (\mathbf{Z}^{(i)})_{i=1}^m$, for all $h \in \mathcal{H}_{\text{M3N}}$,

$$\bar{L}_\pi(h) \leq \hat{L}_h(h, \hat{\mathbf{Z}}) + \frac{7}{mn} + 4\beta_h \|\Gamma^\pi\|_\infty \sqrt{\frac{\frac{1}{2} \|\mathbf{w}\|_2^2 + \frac{d}{2} \ln(2d(m |G|)^2 \ln(2dm)) + \ln \frac{4\beta_h}{\delta}}{2mn}},$$

where

$$\beta_h \triangleq (2\Delta_G + 4) \left(\|\mathbf{w}\|_2 + \frac{1}{m |G|} \right) + 1.$$

Example 2 is only slightly worse than Example 1, incurring a $O(\ln \ln(mn))$ term for the Gaussian construction. Both bounds guarantee generalization when either m or n is large.

The proof of Example 2 uses a concentration inequality for vectors of Gaussian random variables, the proof of which is given Appendix C.4.

Lemma 4. Let $\mathbf{X} \triangleq (X_i)_{i=1}^d$ be independent Gaussian random variables, with mean vector $\boldsymbol{\mu} \triangleq (\mu_1, \dots, \mu_d)$ and variance σ^2 . Then, for any $p \geq 1$ and $\epsilon > 0$,

$$\Pr \left\{ \|\mathbf{X} - \boldsymbol{\mu}\|_p \geq \epsilon \right\} \leq 2d \exp \left(-\frac{\epsilon^2}{2\sigma^2 q^{2/p}} \right).$$

For $p = 2$ and small σ^2 , this bound can be significantly sharper than Chebyshev's inequality.

Proof (Example 2) Define the prior, \mathbb{P} , as a standard multivariate Gaussian, with zero mean and unit variance. More precisely, let

$$p(h) \triangleq (2\pi)^{-d/2} e^{-\frac{1}{2} \|\mathbf{w}\|_2^2}$$

denote the density of \mathbb{P} . Given a (learned) hypothesis, h , we construct the posterior, \mathbb{Q}_h , as an isotropic Gaussian, centered at \mathbf{w} , with variance

$$\sigma^2 \triangleq (2d(m |G|)^2 \ln(2dm))^{-1}$$

in all dimensions. Its density is

$$q_h(h) \triangleq (2\pi\sigma^2)^{-d/2} e^{-\frac{1}{2\sigma^2} \|\mathbf{w}' - \mathbf{w}\|_2^2}.$$

Note that the support of both distributions is \mathbb{R}^d , which is unbounded.

Our proof technique involves four steps. First, we upper-bound the KL divergence between \mathbb{Q}_h and \mathbb{P} . Then, we identify a β_h and η such that \mathbb{Q}_h is $(\beta_h/n, \emptyset, \eta)$ -locally stable. Combining the first two steps with Corollary 2 yields a PAC-Bayes bound for the randomized predictor. The final step is to derandomize this bound using Proposition 4.

The KL divergence between Gaussians is well known. Thus, it is easily verified that

$$\begin{aligned} D_{\text{KL}}(\mathbb{Q}_h \| \mathbb{P}) &= \frac{1}{2} \left[d(\sigma^2 - 1) + \|\mathbf{w}\|_2^2 - d \ln \sigma^2 \right] \\ &= \frac{1}{2} \left[d \left(\frac{1}{2d(m |G|)^2 \ln(2dm)} - 1 \right) + \|\mathbf{w}\|_2^2 + d \ln(2d(m |G|)^2 \ln(2dm)) \right] \\ &\leq \frac{1}{2} \left[\|\mathbf{w}\|_2^2 + d \ln(2d(m |G|)^2 \ln(2dm)) \right]. \end{aligned}$$

The inequality follows from the fact that $\sigma^2 \leq 1$ for all $d \geq 1$, $m \geq 1$ and $n \geq 1$ (implying $|G| \geq 1$).

To determine the local stability of \mathbb{Q}_h , for any $h \in \mathcal{H}_{\text{M3N}}$, we define a ‘‘bad’’ set of hypotheses,

$$\mathcal{B}_{\mathcal{H}_{\text{M3N}}}(h) \triangleq \left\{ h' \in \mathcal{H}_{\text{M3N}} : \|\mathbf{w}' - \mathbf{w}\|_2 \geq \frac{1}{m|G|} \right\}.$$

Using Lemma 4,

$$\begin{aligned} \mathbb{Q}_h(\mathcal{B}_{\mathcal{H}_{\text{M3N}}}(h)) &= \Pr_{h' \sim \mathbb{Q}_h} \left\{ \|\mathbf{w}' - \mathbf{w}\|_2 \geq \frac{1}{m|G|} \right\} \\ &\leq 2d \exp \left(-\frac{2d(m|G|)^2 \ln(2dmn)}{2d(m|G|)^2} \right) \\ &= \frac{1}{mn}. \end{aligned} \quad (35)$$

Further, for every $h' \notin \mathcal{B}_{\mathcal{H}_{\text{M3N}}}(h)$,

$$\|\mathbf{w}'\|_2 - \|\mathbf{w}\|_2 \leq \|\mathbf{w}' - \mathbf{w}\|_2 \leq \frac{1}{m|G|}.$$

When combined with Lemma 2, with $R = 1$, we have that

$$\begin{aligned} |L_{\mathcal{R}}(h, \mathbf{z}) - L_{\mathcal{R}}(h', \mathbf{z}')| &\leq \frac{1}{n} ((2\Delta_G + 4) \|\mathbf{w}'\|_2 + 1) D_{\text{H}}(\mathbf{z}, \mathbf{z}') \\ &\leq \frac{1}{n} \left((2\Delta_G + 4) \left(\|\mathbf{w}\|_2 + \frac{1}{m|G|} \right) + 1 \right) D_{\text{H}}(\mathbf{z}, \mathbf{z}') \\ &= \frac{\beta_h}{n} D_{\text{H}}(\mathbf{z}, \mathbf{z}'). \end{aligned}$$

Thus, every \mathbb{Q}_h is $(\beta_h/n, \theta, 1/(mn))$ -locally stable.

Having established an upper bound on the KL divergence and local stability of all posteriors, we can now apply one of our PAC-Bayes bounds. Since the definition of β_h depends on the posterior via \mathbf{w} , we must use a bound from Section 5.2. In this case, there are no ‘‘bad’’ inputs, since the observations are bounded in the unit ball, so we can invoke Corollary 2. Recalling that the ramp loss is 1-uniformly difference bounded, we then have that, with probability at least $1 - \delta$, every $\mathbb{Q}_h : h \in \mathcal{H}_{\text{M3N}}$ satisfies

$$\begin{aligned} \bar{L}_{\mathcal{R}}(\mathbb{Q}_h) &\leq \hat{L}_{\mathcal{R}}(\mathbb{Q}_h, \hat{\mathbf{Z}}) + \frac{1}{mn} \\ &\quad + 4\beta_h \|\Gamma^\pi\|_\infty \sqrt{\frac{\frac{1}{2} \|\mathbf{w}\|_2^2 + \frac{d}{2} \ln(2d(m|G|)^2 \ln(2dmn)) + \ln \frac{4\beta_h}{\delta}}{2mn}}. \end{aligned} \quad (36)$$

We now derandomize the loss terms in Equation 36. Observe that \mathcal{H}_{M3N} is a normed vector space, since it consists of weight vectors in \mathbb{R}^d . In this case, we will use the 2-norm. By Equation 35, it is clear that \mathbb{Q} has $(1/(m|G|), 1/(mn))$ -local hypothesis stability (Definition 10), since every $h \in \mathcal{H}_{\text{M3N}}$ results in the same probability bound. Further, by Lemma 3, with $R = 1$,

$$|L_{\mathcal{R}}(h, \mathbf{z}) - L_{\mathcal{R}}(h', \mathbf{z})| \leq \frac{2|G|}{n} \|\mathbf{w} - \mathbf{w}'\|_2, \quad (37)$$

meaning $L_{\mathcal{R}}$ has $(2|G|/n, \theta)$ -local hypothesis stability (Definition 9). Therefore, by Proposition 5, $(L_{\mathcal{R}}, \mathbb{Q})$ has $(2/(mn), \theta, 1/(mn))$ -local stability. It then follows, via Proposition 4 and Equation 32, that

$$\bar{L}_{\text{H}}(h) \leq \bar{L}_{\mathcal{R}}(h) \leq \bar{L}_{\mathcal{R}}(\mathbb{Q}_h) + \frac{3}{mn}, \quad (38)$$

and

$$\hat{L}_{\mathcal{R}}(\mathbb{Q}_h, \hat{\mathbf{Z}}) \leq \hat{L}_{\mathcal{R}}(h, \hat{\mathbf{Z}}) + \frac{3}{mn} \leq \hat{L}_{\text{H}}(h, \hat{\mathbf{Z}}) + \frac{3}{mn}. \quad (39)$$

Combining Equations 36, 38 and 39 completes the proof. \blacksquare

6.2 Soft-Max Learning

A drawback of max-margin learning is that the learning objective is not differentiable everywhere, due to the hinge loss. Thus, researchers (Gimpel and Smith, 2010; Hazan and Urtasun, 2010) have proposed a smooth alternative, based on the *soft-max* function. This form of learning has been popularized for learning conditional random fields (CRFs).

The soft-max loss, for a given temperature parameter, $\epsilon \in [0, 1]$, is defined as

$$L_{\text{SM}}(h, \mathbf{x}, \mathbf{y}) \triangleq \frac{1}{n} (\Phi_\epsilon(\mathbf{x}, \mathbf{y}; \mathbf{w}) - h(\mathbf{x}, \mathbf{y})), \quad (40)$$

where $h(\mathbf{x}, \mathbf{y})$ is the unnormalized log-likelihood (Equation 29) and

$$\begin{aligned} \Phi_\epsilon(\mathbf{x}, \mathbf{y}; \mathbf{w}) &\triangleq \epsilon \ln \sum_{\mathbf{y}' \in \mathcal{Y}^n} \exp \left(\frac{1}{\epsilon} (D_{\text{H}}(\mathbf{y}, \mathbf{y}') + h(\mathbf{x}, \mathbf{y}')) \right) \\ &= \epsilon \ln \sum_{\mathbf{y}' \in \mathcal{Y}^n} \exp \left(\frac{1}{\epsilon} \hat{\theta}(\mathbf{x}, \mathbf{y}; \mathbf{w}) \cdot \mathbf{y}' \right). \end{aligned} \quad (41)$$

is the soft-max function. We purposefully overload the notation of the log-partition function due to its relationship to the soft-max. Observe that, for $\epsilon = 1$, the soft-max becomes the log-partition of the distribution induced by the loss-augmented potentials, and Equation 40 is the corresponding negative log-likelihood, scaled by $1/n$. Further, as $\epsilon \rightarrow 0$, the soft-max approaches the max operator and Equation 40 becomes the hinge loss (Equation 28).

The latter equivalence can be illustrated by convex conjugacy. This requires some additional notation. Let $\mu \in [0, 1]^{|Y|+|E|+|Y|^2}$ denote a vector of marginal probabilities for all cliques and clique states. Let \mathcal{M} denote the set of all consistent marginal vectors, often called the *marginal polytope*. For every $\mu \in \mathcal{M}$, there is a corresponding distribution, p_μ , such that $\mu_c \cdot \mathbf{y}_c = p_\mu(\mathbf{Y}_c = \mathbf{y}_c)$ for every clique, $c \in \mathcal{C}$, and clique state, \mathbf{y}_c . Let $\Phi^*(\mu)$ denote the *convex conjugate* of the log-partition, which, for $\mu \in \mathcal{M}$, is equal to the negative entropy of p_μ .⁷ With these definitions, the soft-max, like the log-partition, has the following variational form:

$$\begin{aligned} \Phi_\epsilon(\mathbf{x}, \mathbf{y}; \mathbf{w}) &= \max_{\mu \in \mathcal{M}} \hat{\theta}(\mathbf{x}, \mathbf{y}; \mathbf{w}) \cdot \mu - \epsilon \Phi^*(\mu) \\ &= \max_{\mu \in \mathcal{M}} (\hat{\theta}(\mathbf{x}, \mathbf{y}; \mathbf{w}) + \delta(\mathbf{y})) \cdot \mu - \epsilon \Phi^*(\mu). \end{aligned} \quad (42)$$

⁷ We omit some details of the conjugate function for simplicity of exposition. See Wainwright and Jordan (2008) for a precise definition.

This maximization is equivalent to marginal inference with loss-augmented potentials.⁸ Let μ_u denote the marginals of the unary cliques, and observe that

$$\delta(\mathbf{y}) \cdot \boldsymbol{\mu} = \frac{1}{2} \|\mathbf{y} - \boldsymbol{\mu}_u\|_1 \triangleq D_1(\mathbf{y}, \boldsymbol{\mu}). \quad (43)$$

With a slight abuse of notation, we define an alternate scoring function for marginals:

$$h_\epsilon(\mathbf{x}, \boldsymbol{\mu}) \triangleq \boldsymbol{\theta}(\mathbf{x}; \mathbf{w}) \cdot \boldsymbol{\mu} - \epsilon \Phi^*(\boldsymbol{\mu}). \quad (44)$$

Note that each full labeling, $\hat{\mathbf{y}}$, corresponds to a vertex of the marginal polytope, so $\hat{\mathbf{y}} \in \mathcal{M}$. Further, $h_\epsilon(\mathbf{x}, \hat{\mathbf{y}}) = h(\mathbf{x}, \mathbf{y})$, since $\Phi^*(\hat{\mathbf{y}}) = 0$. Thus, combining Equations 42 to 44, we have that the soft-max loss (Equation 40) is equivalent to

$$L_{sm}(h, \mathbf{x}, \mathbf{y}) = \frac{1}{n} \left(\max_{\boldsymbol{\mu} \in \mathcal{M}} D_1(\mathbf{y}, \boldsymbol{\mu}) + h_\epsilon(\mathbf{x}, \boldsymbol{\mu}) - h_\epsilon(\mathbf{x}, \hat{\mathbf{y}}) \right),$$

which resembles a smoothed hinge loss for $\epsilon \in (0, 1)$.

Like the regular hinge loss, $L_{sm}(h, \mathbf{x}, \mathbf{y})$ is not uniformly range-bounded for certain hypothesis classes, so it cannot be used with our PAC-Bayes bounds. However, we can use the ramp loss, with a slight modification:

$$L_{sr}(h, \mathbf{x}, \mathbf{y}) \triangleq \frac{1}{n} \left(\max_{\boldsymbol{\mu} \in \mathcal{M}} D_1(\mathbf{y}, \boldsymbol{\mu}) + h_\epsilon(\mathbf{x}, \boldsymbol{\mu}) - \max_{\boldsymbol{\mu}' \in \mathcal{M}} h_\epsilon(\mathbf{x}, \boldsymbol{\mu}') \right).$$

We have essentially just replaced the maxes over \mathcal{Z}^n with maxes over \mathcal{M} and used Equation 44 instead of Equation 29. We refer to this loss as the *soft ramp loss*. The stability properties of the regular ramp loss over to the soft ramp loss; it is straightforward to show that Lemmas 2 and 3 hold when $L_r(h, \mathbf{x}, \mathbf{y})$ is replaced with $L_{sr}(h, \mathbf{x}, \mathbf{y})$.⁹ The distance function, $D_1(\mathbf{y}, \boldsymbol{\mu})$, has a probabilistic interpretation:

$$D_1(\mathbf{y}, \boldsymbol{\mu}) = \sum_{i=1}^n 1 - p_{\boldsymbol{\mu}}(Y_i = y_i | \mathbf{X} = \mathbf{x}).$$

This identity motivates another loss function: with

$$h_\epsilon(\mathbf{x}) \triangleq \arg \max_{\boldsymbol{\mu} \in \mathcal{M}} h_\epsilon(\mathbf{x}, \boldsymbol{\mu}),$$

let

$$L_1(h, \mathbf{x}, \mathbf{y}) \triangleq \frac{1}{n} D_1(\mathbf{y}, h_\epsilon(\mathbf{x})) = \frac{1}{n} \sum_{i=1}^n 1 - p(Y_i = y_i | \mathbf{X} = \mathbf{x}; \mathbf{w}).$$

Note that

$$L_1(h, \mathbf{x}, \mathbf{y}) \leq L_{sr}(h, \mathbf{x}, \mathbf{y}) \leq L_{sm}(h, \mathbf{x}, \mathbf{y}).$$

⁸ Since marginal inference is often intractable, exact inference could be replaced with a tractable surrogate, such as the Bethe approximation.

⁹ The additional $\epsilon \Phi^*(\cdot)$ term in Equation 44 is canceled out in Equations 55, 56, 58 and 59.

Marginal inference, $h_\epsilon(\mathbf{x})$, can be decoded by selecting the labels with the highest marginal probabilities. This technique is sometimes referred to as *posterior decoding*. Conveniently, because the marginals sum to one, it can be shown that the Hamming loss of the posterior decoding is at most twice L_1 .

In the following example, we consider the class of soft-max CRFs, \mathcal{H}_{car} . For historical reasons, these models typically do not use edge observations, which is a common modeling decision in, e.g., sequence models. We therefore assume that the edge features are simply $f_{ij}(\mathbf{x}, \mathbf{y}) \triangleq y_i \otimes y_j$.

Example 3. Fix any $m \geq 1$, $n \geq 1$, $\boldsymbol{\pi} \in \Pi(n)$, $\delta \in (0, 1)$ and $G \triangleq (\mathcal{V}, \mathcal{E})$. Assume that $\sup_{x \in \mathcal{X}} \|x\|_2 \leq 1$. Then, with probability at least $1 - \delta$ over realizations of $\mathbf{Z} \triangleq (\mathbf{Z}^{(i)})_{i=1}^m$, for all $h \in \mathcal{H}_{\text{car}}$,

$$\bar{L}_1(h) \leq \hat{L}_{sm}(h, \mathbf{Z}) + \frac{T}{mn} + 4\beta_n \|\Gamma^\boldsymbol{\pi}\|_\infty \sqrt{\frac{\frac{1}{2} \|\mathbf{w}\|_2^2 + \frac{d}{2} \ln(2d(m|G|)^2 \ln(2dmn)) + \ln \frac{4\beta_n}{\delta}}{2mn}},$$

where

$$\beta_n \triangleq 4 \left(\|\mathbf{w}\|_2 + \frac{1}{m|G|} \right) + 1.$$

We omit the proof, since it is almost identical to Example 2. The key difference worth noting is that, since the model does not use edge observations, the graph's maximum degree does not appear in β_n .

6.3 Possibly Unbounded Domains

Until now, we have assumed that the observations are uniformly bounded in the unit ball. This assumption is common in the literature, but it does not quite match what happens in practice. Typically, one will rescale each dimension of the input space using the minimum and maximum values found in the training data. While this procedure guarantees a bound on the observations at training time, the bound may not hold at test time when one rescales by the limits estimated from the training set. This outcome would violate the preconditions of the stability guarantees used to prove the previous examples.

Now, suppose we knew that the observations were bounded with high probability. In the following example, we construct a hypothetical data distribution under which this assumption holds. We combine this with Theorem 2 to derive a variant of Example 2.

Example 4. Fix any $m \geq 1$, $n \geq 1$, $\boldsymbol{\pi} \in \Pi(n)$, $\delta \in (0, 1)$ and $G \triangleq (\mathcal{V}, \mathcal{E})$. Suppose the data generating process, \mathbb{D} , is defined as follows. For each $y \in \mathcal{Y}$, assume there is an associated isotropic Gaussian over $\mathcal{X} \subseteq \mathbb{R}^k$, with mean $\mu_y \in \mathcal{X} : \|\mu_y\|_2 \leq 1$ and variance $\sigma_y^2 \leq (2k \ln(2km^2))^{-1}$. First, \mathbf{Y} is sampled according to some arbitrary distribution, conditioned on G . Then, for each $i \in [n]$, conditioned on $Y_i = y_i$, a vector of observations, $x_i \in \mathcal{X}$, is sampled according to $(\mu_{y_i}, \sigma_{y_i}^2)$.

Note that, conditioned on the labels, (y_1, \dots, y_n) , the observations, (x_1, \dots, x_n) , are mutually independent. It therefore does not make sense to model edge observations, so we use $f_{ij}(\mathbf{x}, \mathbf{y}) \triangleq y_i \otimes y_j$. For the following, we abuse our previous notation and let \mathcal{H}_{max} denote the class of max-margin Markov networks that use these edge features.

Let $\mathcal{B}_Z \triangleq \{\exists i : \|X_i\|_2 \geq 2\}$ denote a set of “bad” inputs, and let $\Gamma_{\frac{\beta_h}{m}}$ denote the dependency matrix induced by \mathbb{D} , $\boldsymbol{\pi}$ and \mathcal{B}_Z . Then, with probability at least $1 - \delta - m/n$ over realizations of $\hat{\mathbf{Z}} \triangleq (\mathbf{Z}^{(i)})_{i=1}^m$, for all $h \in \mathcal{H}_{M,3N}$,

$$\bar{T}_n(h) \leq \hat{I}_n(h, \hat{\mathbf{Z}}) + \frac{11}{mn} + \frac{2}{n} + 4\beta_h \sqrt{\frac{\frac{1}{2} \|\mathbf{w}\|_2^2 + \frac{d}{2} \ln(2d(m|G|)^2 \ln(2dmn)) + \ln \frac{4\beta_h}{\delta}}{2mn}},$$

where

$$\beta_h \triangleq 8 \left(\|\mathbf{w}\|_2 + \frac{1}{m|G|} \right) + 1.$$

The proof is provided in Appendix C.5.

Note that the dominating term is $2/n$, meaning the bound is meaningful for large n and small m . This rate follows intuition, since one should not expect η to depend on the number of training examples; moreover, the probability of drawing a “bad” example should increase proportionally to the number of independent draws.

7. Discussion

We have proposed new PAC-Bayes bounds for structured prediction that can decrease with both the number of examples, m , and the size of each example, n , thus proving that generalization is indeed possible from a few large examples. Under suitable conditions, our bounds can be as tight as $\tilde{O}(1/\sqrt{mn})$. The bounds reveal the connection between generalization and the stability of a structured loss function, as well as the role of dependence in the generating distribution. The stability conditions used in this work generalize our previous work, thereby accommodating a broader range of structured loss functions, including max-margin and soft-max learning. We also provide bounds on the norm of the dependency matrix, which is a result that may be useful outside of this context.

The examples in Section 6 identify several take-aways for practitioners. Primarily, they indicate the importance of templating (or, parameter-tying). Observe that all of the bounds depend on d , the number of parameters¹⁰, via a term that is $\tilde{O}(d/n)$. Clearly, if d scales linearly with n , the number of nodes, then this term is bounded away from zero as $n \rightarrow \infty$. Consequently, one cannot hope to generalize from one example. Though we do not prove this formally, the intuition is fairly simple: if there is a different \mathbf{w}_i for each node i , and \mathbf{w}_{ij} for each edge $\{i, j\}$, then one example provides exactly one “micro example” from which one can estimate $\{\mathbf{w}_i\}_{i \in \mathcal{V}}$ and $\{\mathbf{w}_{ij}\}_{i, j \in \mathcal{E}}$. In this setting, our bounds become $\tilde{O}(1/\sqrt{mn})$, which is no better (and no worse) than previous bounds. Thus, templating is crucial to achieving the fast generalization rate.¹¹

Another observation is that Examples 2 to 4 depend on the norm of the weight vector, \mathbf{w} . Specifically, we used the 2-norm, for its relationship to Gaussian priors; though, one could substitute any norm, due to the equivalence of norms in finite dimension. Dependence

10. We believe that this dependence is unavoidable when derandomizing PAC-Bayes bounds for structured prediction. Evidence to support this conjecture is given by McAllester’s (2007) bound, which depends on the number of templates, and the number of parameters is roughly linear in the number of templates.

11. It may be possible to achieve a fast rate without templating if one imposes a sparsity assumption on the optimal weight vector, but it seems likely that the sparsity would depend on n .

on the norm of the weights is a standard feature of most generalization bounds. This term is commonly interpreted as a measure of hypothesis complexity. Weight regularization during training controls the norm of the weights, thereby effectively limiting the complexity of the learned model.

We also find that the structure of the model influences the bounds via Δ_G , the maximum degree of the graph, and $|G|$, the total number of nodes and edges. (Since the bounds are sub-logarithmic in G , and $\frac{1}{n} \ln |G| \leq \frac{2}{n} \ln n$, one could reasonably argue that Δ_G is the only important structural term.) It is important to note that the edges in the model need not necessarily correspond to concrete relationships in the data. For example, there are many ways to define the “influential” neighbors of a user in a social network, though the user may be connected to nearly everyone in the network; the adjacencies one models may be a subset of the true adjacencies. Therefore, Δ_G and $|G|$ are quantities that one can control; they become part of the trade-off between representational power and overfitting. In light of this trade-off, recall that the stability term, β_h , partially depends on whether one conditions on the observations in the edge features; as shown in Examples 3 and 4, β_h can be reduced to $\tilde{O}(\|\mathbf{w}\|_2)$ if one does not. On the other hand, if observations are modeled in the edge features, and $\Delta_G = O(\sqrt{n})$, then the bounds become $\tilde{O}(1/\sqrt{m})$. Thus, under this modeling assumption, controlling the maximum degree is critical.

Our improved generalization rate critically relies on the dependency matrix, $\Gamma_{\frac{\beta_h}{m}}$, having low infinity norm. If this condition does not hold—for instance, suppose every variable has some non-negligible dependence on every other variable, and $\|\Gamma_{\frac{\beta_h}{m}}\|_\infty = O(n)$ —then our bounds are no more optimistic than previous results and may in fact be slightly looser than some. However, if the dependence is sub-logarithmic, i.e., $\|\Gamma_{\frac{\beta_h}{m}}\|_\infty = O(\ln n)$, then our bounds are much more optimistic. In Section 4.3, we examined two settings in which this assumption holds; these settings can be characterized by the following conditions: strong local signal, bounded interactions (i.e., degree), and dependence that decays with graph distance. Since the data distribution is determined by nature, it is not a variable one can control. There may be situations in which the mixing coefficients can be estimated from data, as done by McDonald et al. (2011) for β -mixing time series. We leave this as a question for future research. Identifying weaker sufficient dependence conditions is also of interest.

There are several ways in which our analysis can be refined and extended. In Lemma 2, which we use to establish the stability of the ramp loss, we used a rather coarse application of Hölder’s inequality to isolate the influence of the weights. This technique ignores the relative magnitudes of the node and edge weights. Indeed, it may be the case that the edge weights are significantly lower than the node weights. A finer analysis of the weights could improve Equation 33 and might yield new insights for weight regularization. One could also abstract the desirable properties of the potential functions to accommodate a broader class than the linear potentials used in our examples. Finally, we conjecture that our bounds could be tightened by adapting Germain et al.’s (2009) analysis to bound $\phi^2(h, \hat{\mathbf{Z}}) \triangleq (\bar{I}(h) - \hat{I}(h, \hat{\mathbf{Z}}))^2$ instead of $\phi(h, \hat{\mathbf{Z}}) \triangleq \bar{I}(\mathbb{Q}) - \hat{I}(\mathbb{Q}, \hat{\mathbf{Z}})$. The primary challenge would be bounding the moment-generating function, $\mathbb{E}_{\mathbf{Z} \sim \mathbb{D}^m} [e^{u \phi^2(h, \hat{\mathbf{Z}})}]$, since our martingale-based method would not work. If successful, this analysis could yield bounds that tighten when the empirical loss is small.

Appendix A. Proofs from Section 4

This appendix contains the deferred proofs from Section 6. We begin with some supplemental background in measure concentration. We then prove Proposition 1, and derive a concentration inequality implied by the result. We conclude with the proofs of Propositions 2 and 3.

A.1 The Method of Bounded Differences

Our proof of Proposition 1 follows McDiarmid’s *method of bounded differences* (McDiarmid, 1989), which uses a construction known as a *Doob martingale difference sequence*. Let $\varphi : \mathcal{Z}^n \rightarrow \mathbb{R}$ denote a measurable function. Let $\mathbf{Z} \triangleq (Z_i)_{i=1}^n$ denote a set of random variables with joint distribution \mathbb{D} , and let $\mu \triangleq \mathbb{E}[\varphi(\mathbf{Z})]$ denote the mean of φ . For $i \in [n]$, let

$$V_i \triangleq \mathbb{E}[\varphi(\mathbf{Z}) \mid \mathbf{Z}_{1:i}] - \mathbb{E}[\varphi(\mathbf{Z}) \mid \mathbf{Z}_{1:i-1}],$$

$$\sum_{i=1}^n V_i = \varphi(\mathbf{Z}) - \mu.$$

where $V_i \triangleq \mathbb{E}[\varphi(\mathbf{Z}) \mid \mathbf{Z}_i] - \mu$. The sequence (V_1, \dots, V_n) has the convenient property that

Therefore, using the law of total expectation, we have that, for any $\tau \in \mathbb{R}$,

$$\begin{aligned} \mathbb{E} \left[e^{\tau(\varphi(\mathbf{Z}) - \mu)} \right] &= \mathbb{E} \left[\prod_{i=1}^n e^{\tau V_i} \right] \\ &= \mathbb{E} \left[\left(\prod_{i=1}^{n-1} e^{\tau V_i} \right) \mathbb{E} \left[e^{\tau V_n} \mid \mathbf{Z}_{1:n-1} \right] \right] \\ &\leq \mathbb{E} \left[\prod_{i=1}^{n-1} e^{\tau V_i} \right] \sup_{\mathbf{z} \in \mathcal{Z}^{n-1}} \mathbb{E} \left[e^{\tau V_n} \mid \mathbf{Z}_{1:n-1} = \mathbf{z} \right] \\ &\vdots \\ &\leq \prod_{i=1}^n \sup_{\mathbf{z} \in \mathcal{Z}^{i-1}} \mathbb{E} \left[e^{\tau V_i} \mid \mathbf{Z}_{1:i-1} = \mathbf{z} \right]. \end{aligned} \quad (45)$$

Note that the order in which we condition on variables is arbitrary, and does not necessarily need to correspond to any spatio-temporal process. The important property is that the

sequence of σ -algebras generated by the conditioned variables are *nested* (McDiarmid (1998) called this a *filter*), which is guaranteed by the construction of (V_1, \dots, V_n) .

One can then use Hoeffding’s lemma (Hoeffding, 1963) to bound each term in the above product.

Lemma 5. *If ξ is a random variable, such that $\mathbb{E}[\xi] = 0$ and $a \leq \xi \leq b$ almost surely, then for any $\tau \in \mathbb{R}$,*

$$\mathbb{E} \left[e^{\tau \xi} \right] \leq \exp \left(\frac{\tau^2 (b-a)^2}{8} \right).$$

Clearly, $\mathbb{E}[V_i \mid \mathbf{Z}_{1:i-1}] = 0$. Thus, if, for all $i \in [n]$, there exists a value $c_i \geq 0$ such that

$$\sup_{\mathbf{z} \in \mathcal{Z}^{i-1}} \sup_{z \in \mathcal{Z}} (V_i - \inf_{z \in \mathcal{Z}} V_i) = \sup_{\mathbf{z} \in \mathcal{Z}^{i-1}} \mathbb{E}[\varphi(\mathbf{Z}) \mid \mathbf{Z}_{1:i} = (\mathbf{z}, z)] - \mathbb{E}[\varphi(\mathbf{Z}) \mid \mathbf{Z}_{1:i} = (\mathbf{z}, z')] \leq c_i,$$

then

$$\mathbb{E} \left[e^{\tau(\varphi(\mathbf{Z}) - \mu)} \right] \leq \prod_{i=1}^n \exp \left(\frac{\tau^2 c_i^2}{8} \right) = \exp \left(\frac{\tau^2}{8} \sum_{i=1}^n c_i^2 \right).$$

When Z_1, \dots, Z_n are mutually independent, and φ has β -uniformly stability, upper-bounding c_i is straightforward: it becomes complicated when we relax the independence assumption, or when φ is not uniformly stable. The following section addresses the former challenge.

A.2 Coupling

To analyze interdependent random variables, we use a theoretical construction known as *coupling*. For random variables Z_1 and Z_2 , with respective distributions \mathbb{D}_1 and \mathbb{D}_2 over a common sample space \mathcal{Z} , a coupling is any joint distribution \mathbb{D} over $\mathcal{Z} \times \mathcal{Z}$ such that the marginal distributions, $\mathbb{D}(Z_1)$ and $\mathbb{D}(Z_2)$, are equal to $\mathbb{D}_1(Z_1)$ and $\mathbb{D}_2(Z_2)$ respectively.

Using a construction due to Fiebig (1993), one can create a coupling of two sequences of random variables, such that the probability that any two corresponding variables are different is upper-bounded by the θ -mixing coefficients in Definition 6. The following is an adaptation of this result (due to Samson, 2000) for continuous domains.

Lemma 6. *Let $\mathbf{Z}^{(1)} \triangleq (Z_i^{(1)})_{i=1}^n$ and $\mathbf{Z}^{(2)} \triangleq (Z_i^{(2)})_{i=1}^n$ be random variables with respective distributions \mathbb{D}_1 and \mathbb{D}_2 over a sample space \mathcal{Z}^n . Then there exists a coupling \mathbb{D} , with marginal distributions $\mathbb{D}(\mathbf{Z}^{(1)}) = \mathbb{D}_1(\mathbf{Z}^{(1)})$ and $\mathbb{D}(\mathbf{Z}^{(2)}) = \mathbb{D}_2(\mathbf{Z}^{(2)})$, such that, for any $i \in [n]$,*

$$\Pr_{(\mathbf{Z}^{(1)}, \mathbf{Z}^{(2)}) \sim \mathbb{D}} \left\{ Z_i^{(1)} \neq Z_i^{(2)} \right\} \leq \left\| \mathbb{D}_1(\mathbf{Z}_{1:n}^{(1)}) - \mathbb{D}_2(\mathbf{Z}_{1:n}^{(2)}) \right\|_{TV},$$

where $\Pr_{(\mathbf{Z}^{(1)}, \mathbf{Z}^{(2)}) \sim \mathbb{D}} \{ Z_i^{(1)} \neq Z_i^{(2)} \}$ denotes the marginal probability that $Z_i^{(1)} \neq Z_i^{(2)}$ under \mathbb{D} .

Note that the requirement of strictly positive densities is not restrictive, since one can always construct a positive density from a simply nonnegative one. We defer to Samson (2000) for details.

We are now equipped with the tools to prove Proposition 1.

A.3 Proof of Proposition 1

Conditioned on $\bar{\mathbf{B}}$, every realization of \mathbf{Z} is in the “good” set. We define a Doob martingale difference sequence, using the filtration π :

$$V_i^\pi \triangleq \mathbb{E}[\varphi(\mathbf{Z}) | \bar{\mathbf{B}}, \mathbf{Z}_{\pi_i(1:i)}] - \mathbb{E}[\varphi(\mathbf{Z}) | \bar{\mathbf{B}}, \mathbf{Z}_{\pi_i(1:i-1)}],$$

where $V_1^\pi \triangleq \mathbb{E}[\varphi(\mathbf{Z}) | \bar{\mathbf{B}}, \mathbf{Z}_{\pi_1(1)}] - \mathbb{E}[\varphi(\mathbf{Z}) | \bar{\mathbf{B}}]$. Note that $\mathbb{E}[V_i^\pi | \bar{\mathbf{B}}] = 0$ and, for $\mathbf{Z} \notin \mathcal{B}_Z$,

$$\sum_{i=1}^n V_i^\pi = \varphi(\mathbf{Z}) - \mathbb{E}[\varphi(\mathbf{Z}) | \bar{\mathbf{B}}].$$

We therefore have, via Equation 45, that

$$\mathbb{E} \left[e^{\tau(\varphi(\mathbf{Z}) - \mathbb{E}[\varphi(\mathbf{Z}) | \bar{\mathbf{B}}])} | \bar{\mathbf{B}} \right] \leq \prod_{i=1}^n \sup_{\mathbf{z} \in \mathcal{Z}_{\pi_i}^{i-1}} \mathbb{E} \left[e^{\tau V_i^\pi} | \bar{\mathbf{B}}, \mathbf{Z}_{\pi_i(1:i-1)} = \mathbf{z} \right],$$

where the supremum over $\mathcal{Z}_{\pi_i}^{i-1}$ comes from the fact that the expectations are conditioned on $\bar{\mathbf{B}}$. Recall that each permutation in π has the same prefix, thus preserving the order of conditioned variables, and ensuring that the sequence of σ -algebras is nested.

What remains is to show that, for all $i \in [n]$,

$$\begin{aligned} & \sup_{\mathbf{z} \in \mathcal{Z}_{\pi_i}^{i-1}} \sup_{\mathbf{z}' \in \mathcal{Z}_{\pi_i}^i} (V_i^\pi) - \inf_{\mathbf{z}' \in \mathcal{Z}_{\pi_i}^i} (V_i^\pi) \\ &= \sup_{\mathbf{z} \in \mathcal{Z}_{\pi_i}^{i-1}} \mathbb{E}[\varphi(\mathbf{Z}) | \bar{\mathbf{B}}, \mathbf{Z}_{\pi_i(1:i)} = (\mathbf{z}, \mathbf{z})] - \mathbb{E}[\varphi(\mathbf{Z}) | \bar{\mathbf{B}}, \mathbf{Z}_{\pi_i(1:i)} = (\mathbf{z}, \mathbf{z}')] \end{aligned} \quad (46)$$

is bounded, so as to apply Lemma 5. (Again, the suprema over $\mathcal{Z}_{\pi_i}^i(\mathbf{z})$ stem from conditioning on $\bar{\mathbf{B}}$.) To do so, we will use the coupling construction from Lemma 6. Fix any $\mathbf{z} \in \mathcal{Z}_{\pi_i}^{i-1}$ and $\mathbf{z}', \mathbf{z}' \in \mathcal{Z}_{\pi_i}^i(\mathbf{z})$, and let $N \triangleq n - i$. Define random variables $\xi^{(1)} \triangleq (\xi_j^{(1)})_{j=1}^N$ and $\xi^{(2)} \triangleq (\xi_j^{(2)})_{j=1}^N$, with coupling distribution $\hat{\mathbb{D}}$ such that

$$\begin{aligned} \hat{\mathbb{D}}(\xi^{(1)}) &\triangleq \mathbb{D}(\mathbf{Z}_{\pi_i(i+1:n)} | \bar{\mathbf{B}}, \mathbf{Z}_{\pi_i(1:i)} = (\mathbf{z}, \mathbf{z})) \\ \text{and } \hat{\mathbb{D}}(\xi^{(2)}) &\triangleq \mathbb{D}(\mathbf{Z}_{\pi_i(i+1:n)} | \bar{\mathbf{B}}, \mathbf{Z}_{\pi_i(1:i)} = (\mathbf{z}, \mathbf{z}')). \end{aligned} \quad (47)$$

In other words, the marginal distributions of $\xi^{(1)}$ and $\xi^{(2)}$ are equal to the conditional distributions of $\mathbf{Z}_{\pi_i(i+1:n)}$ given $\bar{\mathbf{B}}$ and, respectively, $\mathbf{Z}_{\pi_i(1:i)} = (\mathbf{z}, \mathbf{z})$ or $\mathbf{Z}_{\pi_i(1:i)} = (\mathbf{z}, \mathbf{z}')$. Note that we have renumbered the coupled variables according to π_i . This does not affect the distribution, but it does affect how we later apply Lemma 6. Denote by π_i^{-1} the inverse of π_i (i.e., $\pi_i^{-1}(\pi_i(1:n)) = [n]$), and let

$$\psi(\mathbf{z}) = \varphi(\mathbf{z}_{\pi_i^{-1}(1:n)}).$$

Put simply, ψ inverts the permutation applied to its input, so as to ensure $\psi(\mathbf{z}_{\pi_i(1:n)}) = \varphi(\mathbf{z})$. For convenience, let

$$\Delta\psi \triangleq \psi(\mathbf{z}, \mathbf{z}, \xi^{(1)}) - \psi(\mathbf{z}, \mathbf{z}', \xi^{(2)})$$

denote the difference. Using these definitions, we have the following equivalence:

$$\mathbb{E}[\varphi(\mathbf{Z}) | \bar{\mathbf{B}}, \mathbf{Z}_{\pi_i(1:i)} = (\mathbf{z}, \mathbf{z})] - \mathbb{E}[\varphi(\mathbf{Z}) | \bar{\mathbf{B}}, \mathbf{Z}_{\pi_i(1:i)} = (\mathbf{z}, \mathbf{z}')] = \mathbb{E}[\psi(\mathbf{z}, \mathbf{z}, \xi^{(1)}) - \psi(\mathbf{z}, \mathbf{z}', \xi^{(2)})].$$

Because the expectations are conditioned on $\bar{\mathbf{B}}$, both realizations, $(\mathbf{z}, \mathbf{z}, \xi^{(1)})$ and $(\mathbf{z}, \mathbf{z}', \xi^{(2)})$, are “good,” in the sense that Equation 1 holds. We therefore have that

$$\begin{aligned} & \mathbb{E}[\psi(\mathbf{z}, \mathbf{z}, \xi^{(1)}) - \psi(\mathbf{z}, \mathbf{z}', \xi^{(2)})] \leq \beta \mathbb{E} \left[D_{\text{H}}((\mathbf{z}, \mathbf{z}, \xi^{(1)}), (\mathbf{z}, \mathbf{z}', \xi^{(2)})) \right] \\ & \leq \beta \left(1 + \mathbb{E} \left[\sum_{j=1}^N \mathbb{1}\{\xi_j^{(1)} \neq \xi_j^{(2)}\} \right] \right) \\ & = \beta \left(1 + \sum_{j=1}^N \Pr_{(\mathbf{z}^{(1)}, \mathbf{z}^{(2)}) \sim \hat{\mathbb{D}}} \left\{ \xi_j^{(1)} \neq \xi_j^{(2)} \right\} \right). \end{aligned}$$

In the second inequality, we assumed that $\mathbf{z} \neq \mathbf{z}'$. Recall from Lemma 6 and Definition 6 that

$$\begin{aligned} & 1 + \sum_{j=1}^N \Pr_{(\mathbf{z}^{(1)}, \mathbf{z}^{(2)}) \sim \hat{\mathbb{D}}} \left\{ \xi_j^{(1)} \neq \xi_j^{(2)} \right\} \\ & \leq 1 + \sum_{j=i+1}^n \|\mathbb{D}(\mathbf{Z}_{\pi_i(j:n)} | \bar{\mathbf{B}}, \mathbf{Z}_{\pi_i(1:i)} = (\mathbf{z}, \mathbf{z})) - \mathbb{D}(\mathbf{Z}_{\pi_i(j:n)} | \bar{\mathbf{B}}, \mathbf{Z}_{\pi_i(1:i)} = (\mathbf{z}, \mathbf{z}'))\|_{\text{TV}} \\ & = 1 + \sum_{j=i+1}^n \vartheta_{ij}^\pi(\mathbf{z}, \mathbf{z}, \mathbf{z}') \\ & \leq 1 + \sum_{j=i+1}^n \gamma_{ij}^\pi = \sum_{j=i}^n \gamma_{ij}^\pi. \end{aligned}$$

The above inequalities hold uniformly for all $\mathbf{z} \in \mathcal{Z}_{\pi_i}^{i-1}$ and $\mathbf{z}, \mathbf{z}' \in \mathcal{Z}_{\pi_i}^i(\mathbf{z})$; thus,

$$\sup_{\mathbf{z} \in \mathcal{Z}_{\pi_i}^{i-1}} \sup_{\mathbf{z}' \in \mathcal{Z}_{\pi_i}^i(\mathbf{z})} (V_i^\pi) - \inf_{\mathbf{z}' \in \mathcal{Z}_{\pi_i}^i(\mathbf{z})} (V_i^\pi) \leq \beta \sum_{j=i}^n \gamma_{ij}^\pi.$$

Then, since we have identified a uniform upper bound for Equation 46, we apply Lemma 5 and obtain

$$\begin{aligned} & \mathbb{E} \left[e^{\tau(\varphi(\mathbf{Z}) - \mathbb{E}[\varphi(\mathbf{Z}) | \bar{\mathbf{B}}])} | \bar{\mathbf{B}} \right] \leq \exp \left(\frac{\tau^2}{8} \sum_{i=1}^n \left(\beta \sum_{j=i}^n \gamma_{ij}^\pi \right)^2 \right) \\ & \leq \exp \left(\frac{\tau^2}{8} n \beta^2 \max_{i \in [n]} \left(\sum_{j=i}^n \gamma_{ij}^\pi \right)^2 \right) \\ & = \exp \left(\frac{\tau^2}{8} n \beta^2 \|\Gamma_{\bar{\mathbf{B}}}^\pi\|_\infty^2 \right), \end{aligned}$$

which completes the proof.

A.4 A New Concentration Inequality

Proposition 1, implies the following concentration inequality, which may be of independent interest.

Corollary 3. *Let $\mathbf{Z} \triangleq (Z_i)_{i=1}^n$ denote random variables with joint distribution \mathbb{D} on \mathcal{Z}^n , and let $\varphi : \mathcal{Z}^n \rightarrow \mathbb{R}$ denote a measurable function. If φ is β -uniformly stable, then, for any $\epsilon > 0$ and $\boldsymbol{\pi} \in \Pi(n)$,*

$$\Pr\{\varphi(\mathbf{Z}) - \mathbb{E}[\varphi(\mathbf{Z})] \geq \epsilon\} \leq \exp\left(\frac{-2\epsilon^2}{n\beta^2 \|\boldsymbol{\Gamma}^\boldsymbol{\pi}\|_\infty^2}\right).$$

Proof First, note that, for any $\tau \in \mathbb{R}$,

$$\Pr\{\varphi(\mathbf{Z}) - \mathbb{E}[\varphi(\mathbf{Z})] \geq \epsilon\} = \Pr\left\{e^{\tau(\varphi(\mathbf{Z}) - \mathbb{E}[\varphi(\mathbf{Z})])} \geq e^{\tau\epsilon}\right\},$$

due to the monotonicity of exponentiation. We then apply Markov's inequality and obtain

$$\Pr\left\{e^{\tau(\varphi(\mathbf{Z}) - \mathbb{E}[\varphi(\mathbf{Z})])} \geq e^{\tau\epsilon}\right\} \leq \frac{1}{e^{\tau\epsilon}} \mathbb{E}\left[e^{\tau(\varphi(\mathbf{Z}) - \mathbb{E}[\varphi(\mathbf{Z})])}\right].$$

Since φ has β -uniform stability, we can apply Proposition 1 by taking $\mathcal{B}\mathcal{Z} \triangleq \emptyset$. Thus,

$$\Pr\left\{e^{\tau(\varphi(\mathbf{Z}) - \mathbb{E}[\varphi(\mathbf{Z})])} \geq e^{\tau\epsilon}\right\} \leq \frac{1}{e^{\tau\epsilon}} \exp\left(\frac{\tau^2}{8} n \beta^2 \|\boldsymbol{\Gamma}^\boldsymbol{\pi}\|_\infty^2\right).$$

Optimizing with respect to τ , we take $\tau \triangleq \frac{4\epsilon}{n\beta^2 \|\boldsymbol{\Gamma}^\boldsymbol{\pi}\|_\infty^2}$ to complete the proof. \blacksquare

Corollary 3 extends some current state-of-the-art results (e.g., Kontorovich and Razmanan, 2008, Theorem 1.1) by supporting filtrations of the mixing coefficients. Further, when Z_1, \dots, Z_n are mutually independent (i.e., $\|\boldsymbol{\Gamma}^\boldsymbol{\pi}\|_\infty = 1$), we recover McDiarmid's inequality.

A.5 Proof of Proposition 2

We construct the filtration $\boldsymbol{\pi}$ recursively. We initialize π_1 using a breadth-first traversal of the graph, starting from any node. Then, for $i = 2, \dots, n$, we set $\pi_i(1 : i-1) \triangleq \pi_{i-1}(1 : i-1)$, and determine $\pi_i(i : n)$ using a breadth-first traversal over the induced subgraph of $\pi_{i-1}(i : n)$, starting from $\pi_{i-1}(i-1)$. This ensures that nodes closer to $\pi_i(i)$ appear earlier in the permutation, so that the higher mixing coefficients are not incurred for all $j = i+1, \dots, n$.

The degree of any node in this induced subgraph is at most the maximum degree of the whole graph, Δ_G , so the number of nodes at distance k from node $\pi_i(i)$ is at most Δ_G^k . Hence, the number of subsets, $\pi_i(j : n) : j > i$, at distance k from $\pi_i(i)$ is at most Δ_G^k . Therefore,

$$\sum_{j=i}^n \gamma_{ij}^\boldsymbol{\pi} \leq \sum_{k=0}^{\infty} \Delta_G^k \theta(k) \leq \sum_{k=0}^{\infty} \left(\frac{\Delta_G}{\Delta_G + \epsilon}\right)^k.$$

Since $\Delta_G/(\Delta_G + \epsilon) < 1$ for $\epsilon > 0$, this geometric series converges to

$$\frac{1}{1 - \Delta_G/(\Delta_G + \epsilon)} = 1 + \Delta_G/\epsilon,$$

which completes the proof.

A.6 Proof of Proposition 3

For a chain graph, we define each permutation uniformly as $\pi_i \triangleq [n]$. Each upper-triangular entry of $\boldsymbol{\Gamma}^\boldsymbol{\pi}$ then satisfies $\gamma_{ij}^\boldsymbol{\pi} \leq \theta(j-i)$. The number of unconditioned variables at distance $k = j-i$ is exactly one. Thus, for any row i ,

$$\sum_{j=i}^n \gamma_{ij}^\boldsymbol{\pi} \leq 1 + \sum_{k=1}^{n-i} \theta(k) \leq 1 + \epsilon \sum_{k=1}^{n-i} k^{-p}.$$

For $p = 1$, $(k^{-p})_{k=1}^{\infty}$ is a Harmonic series. Thus, the partial sum, $\sum_{k=1}^{n-i} k^{-p}$, is the $(n-i)$ th Harmonic number, which is upper-bounded by $\ln(n-i) + 1$, and maximized at row $i = 1$. For $p > 1$,

$$1 + \epsilon \sum_{k=1}^{n-i} k^{-p} \leq 1 + \epsilon \sum_{k=1}^{\infty} k^{-p} = 1 + \zeta(p),$$

by definition.

Appendix B. Proofs from Section 5

This appendix contains the deferred proofs from Section 5.

B.1 Proof of Theorem 2

For $i = 0, 1, 2, \dots$, let $\beta_i \triangleq 2^{i+1}$. Since Equation 2 falls with probability $\delta + m\nu$, we could simply invoke Theorem 1 for each β_i with $\delta_i \triangleq \beta_i^{-1}(\delta + m\nu)$. This approach would introduce an additional $O(\ln(m\nu)^{-1})$ term in the numerator of Equation 23. We therefore choose instead to cover β and u simultaneously. Accordingly, for $j = 0, 1, 2, \dots$, let

$$u_j \triangleq 2^j \sqrt{\frac{8mn \ln \frac{2\beta_j}{\delta}}{\beta_j^2 \|\boldsymbol{\Gamma}^\beta\|_\infty^2}}.$$

Each β_j defines a set of ‘‘bad’’ hypotheses, $\mathcal{B}_j^{u_j}$, which we use in Equation 5 to define a function $\tilde{\phi}_j$. Let $\tilde{\phi}_j \triangleq \delta \beta_j^{-1} 2^{-U+1}$, and define an event

$$E_{ij} \triangleq \mathbf{1} \left\{ \mathbb{E}_{h \sim \mathcal{D}^p} \left[e^{u_j \tilde{\phi}_j(h; \mathbf{Z})} \right] \geq \frac{1}{\delta_{ij}} \exp\left(\frac{u_j^2 \beta_j^2 \|\boldsymbol{\Gamma}^\beta\|_\infty^2}{8mn}\right) \right\}.$$

Note that none of the above depend on $(\beta, \eta, \mathcal{Q})$. Using the event B defined in Equation 12, we have, via Proposition 1, that

$$\Pr_{\mathcal{Z} \sim \mathcal{D}^m} \{E_{ij} | \neg B\} \leq \delta_{ij} \exp\left(-\frac{u_j^2 \beta_j^2 \|\boldsymbol{\Gamma}^\beta\|_\infty^2}{8mn}\right) \mathbb{E}_{h \sim \mathcal{D}^p} \mathbb{E}_{\mathcal{Z} \sim \mathcal{D}^m} \left[e^{u_j \tilde{\phi}_j(h; \mathbf{Z})} | \neg B \right] \leq \delta_{ij}.$$

Then, using the same reasoning as Equation 13, with $E \triangleq \bigcup_{j=0}^{\infty} E_{ij}$,

$$\begin{aligned} \Pr_{\mathbf{Z} \sim \mathbb{D}^{nm}} \{B \cup E\} &\leq m\nu + \sum_{i=0}^{\infty} \sum_{j=0}^{\infty} \Pr_{\mathbf{Z} \sim \mathbb{D}^{nm}} \{E_{ij} | \neg B\} \\ &\leq m\nu + \sum_{i=0}^{\infty} \sum_{j=0}^{\infty} \delta_{ij} \\ &= m\nu + \delta \sum_{i=0}^{\infty} \beta_i^{-1} \sum_{j=0}^{\infty} 2^{-(j+1)} \\ &= m\nu + \delta \sum_{i=0}^{\infty} 2^{-(i+1)} \sum_{j=0}^{\infty} 2^{-(j+1)} \\ &= m\nu + \delta. \end{aligned}$$

Therefore, with probability at least $1 - \delta - m\nu$, every $l \in [m]$ satisfies $\mathbf{Z}^{(l)} \notin \mathcal{B}_{\mathbf{Z}}$, and every (i, j) satisfies

$$\mathbb{E}_{h \sim \mathbb{P}} \left[e^{u_{ij} \tilde{\phi}_i(h; \mathbf{z})} \right] \leq \frac{1}{\delta_{ij}} \exp \left(\frac{u_{ij}^2 \beta_i^2 \|\Gamma_{\mathbb{F}}\|_{\infty}^2}{8mn} \right). \quad (48)$$

Observe that $(\beta/n, \mathcal{B}_{\mathbf{Z}}, \eta)$ -local stability implies $(\beta_i/n, \mathcal{B}_{\mathbf{Z}}, \eta)$ -local stability for all $\beta_j \geq \beta$. Therefore, for any particular $(\beta, \eta, \mathbb{Q})$ such that \mathbb{Q} is $(\beta/n, \mathcal{B}_{\mathbf{Z}}, \eta)$ -locally stable, we select $i^* \triangleq \lfloor (\ln 2)^{-1} \ln \beta \rfloor$. This ensures that $\beta \leq \beta_{i^*}$, so \mathbb{Q} also satisfies $(\beta_{i^*}/n, \mathcal{B}_{\mathbf{Z}}, \eta)$ -local stability. Then, letting

$$j^* \triangleq \left\lfloor \frac{1}{2 \ln 2} \ln \left(\frac{D_{\text{kl}}(\mathbb{Q} \|\mathbb{P})}{\ln(2\beta_{i^*}/\delta)} + 1 \right) \right\rfloor,$$

we have that

$$\frac{1}{2} \sqrt{\frac{8mn \left(D_{\text{kl}}(\mathbb{Q} \|\mathbb{P}) + \ln \frac{2\beta_{i^*}}{\delta} \right)}{\beta_{i^*}^2 \|\Gamma_{\mathbb{F}}\|_{\infty}^2}} \leq u_{i^*, j^*} \leq \sqrt{\frac{8mn \left(D_{\text{kl}}(\mathbb{Q} \|\mathbb{P}) + \ln \frac{2\beta_{i^*}}{\delta} \right)}{\beta_{i^*}^2 \|\Gamma_{\mathbb{F}}\|_{\infty}^2}}. \quad (49)$$

Moreover,

$$\begin{aligned} D_{\text{kl}}(\mathbb{Q} \|\mathbb{P}) + \ln \frac{1}{\delta_{i^*, j^*}} &\leq D_{\text{kl}}(\mathbb{Q} \|\mathbb{P}) + \ln \frac{2\beta_{i^*}}{\delta} + \frac{1}{2} \ln \left(\frac{D_{\text{kl}}(\mathbb{Q} \|\mathbb{P})}{\ln(2\beta_{i^*}/\delta)} + 1 \right) \\ &\leq D_{\text{kl}}(\mathbb{Q} \|\mathbb{P}) + \ln \frac{2\beta_{i^*}}{\delta} + \frac{1}{2} \left(D_{\text{kl}}(\mathbb{Q} \|\mathbb{P}) + \ln \frac{2\beta_{i^*}}{\delta} \right). \end{aligned} \quad (50)$$

Thus, with probability at least $1 - \delta - m\nu$,

$$\begin{aligned} \bar{L}(\mathbb{Q}) - \hat{L}(\mathbb{Q}; \hat{\mathbf{Z}}) &\leq \alpha(\eta + \nu) + \frac{1}{u_{i^*, j^*}} \left(D_{\text{kl}}(\mathbb{Q} \|\mathbb{P}) + \ln \mathbb{E}_{h \sim \mathbb{P}} \left[e^{u_{i^*, j^*} \tilde{\phi}_{i^*}(h; \hat{\mathbf{z}})} \right] \right) \\ &\leq \alpha(\eta + \nu) + \frac{1}{u_{i^*, j^*}} \left(D_{\text{kl}}(\mathbb{Q} \|\mathbb{P}) + \ln \frac{1}{\delta_{i^*, j^*}} + \frac{u_{i^*, j^*}^2 \beta_{i^*}^2 \|\Gamma_{\mathbb{F}}\|_{\infty}^2}{8mn} \right) \\ &\leq \alpha(\eta + \nu) + \frac{3 \left(D_{\text{kl}}(\mathbb{Q} \|\mathbb{P}) + \ln \frac{2\beta_{i^*}}{\delta} \right)}{2u_{i^*, j^*}} + \frac{8mn}{8mn} \\ &\leq \alpha(\eta + \nu) + 2\beta_{i^*} \sqrt{\frac{D_{\text{kl}}(\mathbb{Q} \|\mathbb{P}) + \ln \frac{2\beta_{i^*}}{\delta}}{2mn}}. \end{aligned}$$

The first inequality uses Equation 9; the second uses Equation 48; the third and fourth use Equations 49 and 50. Noting that $\beta_{i^*} \leq 2\beta$ completes the proof.

B.2 Proof of Proposition 5

Fix any $h \in \mathcal{H}$ and $\mathbf{z} \notin \mathcal{B}_{\mathbf{Z}}$. By Definition 10, there exists a set $\mathcal{B}_{\mathcal{H}}(h)$ with measure $\mathbb{Q}_h(\mathcal{B}_{\mathcal{H}}(h)) \leq \eta$. For any $\mathbf{z} \notin \mathcal{B}_{\mathbf{Z}}$, let $\mathcal{B}_{\mathcal{H}}(h, \mathbf{z}) \triangleq \mathcal{B}_{\mathcal{H}}(h)$, and note that $\mathbb{Q}_h(\mathcal{B}_{\mathcal{H}}(h, \mathbf{z})) \leq \eta$ as well. Further, for any $h' \notin \mathcal{B}_{\mathcal{H}}(h, \mathbf{z})$, $\|h - h'\| \leq \beta$. Thus, by Definition 9,

$$\|L(h, \mathbf{z}) - L(h', \mathbf{z})\| \leq \lambda \|h - h'\| \leq \lambda \beta,$$

which completes the proof.

Appendix C. Proofs from Section 6

This appendix contains the deferred proofs from Section 6. Certain proofs require the following technical lemmas, which apply to the linear feature functions defined in Section 2.2.3.

Lemma 7. Fix a graph, $G \triangleq (V, \mathcal{E})$, with maximum degree Δ_G . Suppose \mathcal{X} is uniformly bounded by the p -norm ball with radius R ; i.e., $\sup_{\mathbf{x} \in \mathcal{X}} \|\mathbf{x}\|_p \leq R$. Then, for any $\mathbf{x}, \mathbf{x}' \in \mathcal{X}^n$ and $\mathbf{y} \in \mathcal{Y}^n$,

$$\|\mathbf{f}(\mathbf{x}, \mathbf{y}) - \mathbf{f}(\mathbf{x}', \mathbf{y})\|_p \leq (\Delta_G + 2)RD_{\mathcal{H}}(\mathbf{x}, \mathbf{x}'). \quad (51)$$

Further, if the model does not use edge observations (i.e., $f_{ij}(\mathbf{x}, \mathbf{y}) \triangleq y_i \otimes y_j$), then

$$\|\mathbf{f}(\mathbf{x}, \mathbf{y}) - \mathbf{f}(\mathbf{x}', \mathbf{y})\|_p \leq 2RD_{\mathcal{H}}(\mathbf{x}, \mathbf{x}'). \quad (52)$$

Proof We start by considering a pair, $\mathbf{x}, \mathbf{x}' \in \mathcal{X}^n : D_{\mathcal{H}}(\mathbf{x}, \mathbf{x}') = 1$, that differ at a single coordinate, corresponding to a node i . This means that the aggregate features differ at one local feature, and any edge involving i . Thus, using the triangle inequality, we have that

$$\begin{aligned} \|\mathbf{f}(\mathbf{x}, \mathbf{y}) - \mathbf{f}(\mathbf{x}', \mathbf{y})\|_p &= \left\| \left[\begin{array}{c} f_i(\mathbf{x}, \mathbf{y}) - f_i(\mathbf{x}', \mathbf{y}) \\ \sum_{j:(i,j) \in \mathcal{E}} f_{ij}(\mathbf{x}, \mathbf{y}) - f_{ij}(\mathbf{x}', \mathbf{y}) \end{array} \right] \right\|_p \\ &\leq \|f_i(\mathbf{x}, \mathbf{y}) - f_i(\mathbf{x}', \mathbf{y})\|_p + \sum_{j:(i,j) \in \mathcal{E}} \|f_{ij}(\mathbf{x}, \mathbf{y}) - f_{ij}(\mathbf{x}', \mathbf{y})\|_p. \end{aligned} \quad (53)$$

Note that the second term disappears when the model does not use edge observations.

Recall that the features are defined using a Kronecker product. For any vectors \mathbf{u}, \mathbf{v} , $\|\mathbf{u} \otimes \mathbf{v}\|_p = \|\mathbf{u}\|_p \|\mathbf{v}\|_p$. Using this identity, and the fact that each $g \in \mathcal{Y}$ has $\|g\|_1 = 1$, we have that

$$\begin{aligned} \|f_i(\mathbf{x}, \mathbf{y}) - f_i(\mathbf{x}', \mathbf{y})\|_p &= \|(x_i - x'_i) \otimes y_i\|_p \\ &= \|x_i - x'_i\|_p \|y_i\|_p \\ &\leq \left(\|x_i\|_p + \|x'_i\|_p \right) \times 1 \\ &\leq 2R, \end{aligned}$$

and

$$\begin{aligned} \|f_{ij}(\mathbf{x}, \mathbf{y}) - f_{ij}(\mathbf{x}', \mathbf{y})\|_p &= \left\| \frac{1}{2} \begin{bmatrix} x_i \\ x_j \end{bmatrix} - \begin{bmatrix} x'_i \\ x'_j \end{bmatrix} \right\|_p \otimes (y_i \otimes y_j) \Big\|_p \\ &= \frac{1}{2} \|x_i - x'_i\|_p \|y_i\|_p \|y_j\|_p \\ &\leq \frac{1}{2} \left(\|x_i\|_p + \|x'_i\|_p \right) \times 1 \times 1 \\ &\leq R. \end{aligned}$$

Combining these inequalities with Equation 53, and using the fact that i participates in at most Δ_G edges, we have that

$$\|\mathbf{f}(\mathbf{x}, \mathbf{y}) - \mathbf{f}(\mathbf{x}', \mathbf{y})\|_p \leq 2R + \sum_{j:\{i,j\} \in \mathcal{E}} R \leq (2 + \Delta_G)R.$$

For no edge observations, the righthand side is simply $2R$. Thus, since the bounds hold for any single coordinate perturbation, Equations 51 and 52 follow from the triangle inequality. ■

Lemma 8. For a graph, $G \triangleq (\mathcal{V}, \mathcal{E})$, and recall that $|G| \triangleq |\mathcal{V}| + |\mathcal{E}|$. Suppose \mathcal{X} is uniformly bounded by the p -norm ball with radius R ; i.e., $\sup_{\mathbf{x} \in \mathcal{X}} \|\mathbf{x}\|_p \leq R$. Then, for all $\mathbf{x} \in \mathcal{X}^n$ and $\mathbf{y} \in \mathcal{Y}^n$,

$$\|\mathbf{f}(\mathbf{x}, \mathbf{y})\|_p \leq |G| R.$$

Proof Invoking the triangle inequality, we have that

$$\begin{aligned} \|\mathbf{f}(\mathbf{x}, \mathbf{y})\|_p &= \left\| \left[\sum_{i \in \mathcal{V}} f_i(\mathbf{x}, \mathbf{y}) \right] \right\|_p \\ &\leq \sum_{i \in \mathcal{V}} \|f_i(\mathbf{x}, \mathbf{y})\|_p + \sum_{\{i,j\} \in \mathcal{E}} \|f_{ij}(\mathbf{x}, \mathbf{y})\|_p \\ &= \sum_{i \in \mathcal{V}} \|x_i \otimes y_i\|_p + \sum_{\{i,j\} \in \mathcal{E}} \left\| \frac{1}{2} \begin{bmatrix} x_i \\ x_j \end{bmatrix} \otimes (y_i \otimes y_j) \right\|_p \\ &= \sum_{i \in \mathcal{V}} \|x_i\|_p \|y_i\|_p + \sum_{\{i,j\} \in \mathcal{E}} \frac{1}{2} \left\| \begin{bmatrix} x_i \\ x_j \end{bmatrix} \right\|_p \|y_i\|_p \|y_j\|_p \\ &\leq \sum_{i \in \mathcal{V}} \|x_i\|_p \|y_i\|_p + \sum_{\{i,j\} \in \mathcal{E}} \frac{1}{2} \left(\|x_i\|_p + \|x_j\|_p \right) \|y_i\|_p \|y_j\|_p \\ &\leq \sum_{i \in \mathcal{V}} R \times 1 + \sum_{\{i,j\} \in \mathcal{E}} \frac{1}{2} (R + R) \times 1 \times 1 \\ &= (|\mathcal{V}| + |\mathcal{E}|)R = |G|R, \end{aligned}$$

which completes the proof. ■

Note that Lemmas 7 and 8 hold when discrete labels are replaced with marginals, since each clique's marginals sum to one. This adaptation enables the proof of Example 3.

C.1 Proof of Lemma 2

To simplify notation, let:

$$\begin{aligned} \mathbf{y}_1 &\triangleq \arg \max_{\mathbf{u} \in \mathcal{Y}^n} D_H(\mathbf{y}, \mathbf{u}) + h(\mathbf{x}, \mathbf{u}); & \mathbf{y}_2 &\triangleq \arg \max_{\mathbf{u} \in \mathcal{Y}^n} h(\mathbf{x}, \mathbf{u}); \\ \mathbf{y}'_1 &\triangleq \arg \max_{\mathbf{u} \in \mathcal{Y}^n} D_H(\mathbf{y}', \mathbf{u}) + h(\mathbf{x}', \mathbf{u}); & \mathbf{y}'_2 &\triangleq \arg \max_{\mathbf{u} \in \mathcal{Y}^n} h(\mathbf{x}', \mathbf{u}). \end{aligned}$$

Using this notation, we have that

$$\begin{aligned} n |L_n(h, \mathbf{z}) - L_n(h, \mathbf{z}')| &= |D_H(\mathbf{y}, \mathbf{y}_1) + h(\mathbf{x}, \mathbf{y}_1) - h(\mathbf{x}, \mathbf{y}_2) - (D_H(\mathbf{y}', \mathbf{y}'_1) + h(\mathbf{x}', \mathbf{y}'_1) - h(\mathbf{x}', \mathbf{y}'_2))| \\ &\leq |D_H(\mathbf{y}, \mathbf{y}_1) + h(\mathbf{x}, \mathbf{y}_1) - (D_H(\mathbf{y}', \mathbf{y}'_1) + h(\mathbf{x}', \mathbf{y}'_1))| + |h(\mathbf{x}, \mathbf{y}_2) - h(\mathbf{x}', \mathbf{y}'_2)|. \end{aligned} \quad (54)$$

using the triangle inequality.

Focusing on the second absolute difference, we can assume, without loss of generality, that $h(\mathbf{x}, \mathbf{y}_2) \geq h(\mathbf{x}', \mathbf{y}'_2)$, meaning

$$\begin{aligned} |h(\mathbf{x}, \mathbf{y}_2) - h(\mathbf{x}', \mathbf{y}'_2)| &= h(\mathbf{x}, \mathbf{y}_2) - h(\mathbf{x}', \mathbf{y}'_2) \\ &\leq h(\mathbf{x}, \mathbf{y}_2) - h(\mathbf{x}', \mathbf{y}_2) \\ &= \mathbf{w} \cdot (\mathbf{f}(\mathbf{x}, \mathbf{y}_2) - \mathbf{f}(\mathbf{x}', \mathbf{y}_2)) \\ &\leq \|\mathbf{w}\|_q \|\mathbf{f}(\mathbf{x}, \mathbf{y}_2) - \mathbf{f}(\mathbf{x}', \mathbf{y}_2)\|_p \\ &\leq \|\mathbf{w}\|_q (\Delta_G + 2)R D_H(\mathbf{x}, \mathbf{x}'). \end{aligned} \quad (55)$$

The first inequality uses the optimality of \mathbf{y}'_2 , implying $-h(\mathbf{x}', \mathbf{y}'_2) \leq -h(\mathbf{x}', \mathbf{y}_2)$; the second inequality uses Hölder's inequality; the third inequality uses Lemma 7 (Equation 51). Note that we obtain the same upper bound if we assume that $h(\mathbf{x}, \mathbf{y}_2) \leq h(\mathbf{x}', \mathbf{y}'_2)$, since we can reverse the terms inside the absolute value and proceed with \mathbf{y}'_2 instead of \mathbf{y}_2 .

We now return to the first absolute difference. To reduce clutter, it will help to use the loss-augmented potentials, $\tilde{\theta}(\mathbf{x}, \mathbf{y}; \mathbf{w})$, from Equation 31. Recall that $\delta(\mathbf{y})$ denotes the loss augmentation vector for \mathbf{y} . We then have that

$$|(D_{\mathbb{H}}(\mathbf{y}, \mathbf{y}_1) + h(\mathbf{x}, \mathbf{y}_1)) - (D_{\mathbb{H}}(\mathbf{y}', \mathbf{y}'_1) + h(\mathbf{x}', \mathbf{y}'_1))| = |\tilde{\theta}(\mathbf{x}, \mathbf{y}; \mathbf{w}) \cdot \hat{\mathbf{y}}_1 - \tilde{\theta}(\mathbf{x}', \mathbf{y}'; \mathbf{w}) \cdot \hat{\mathbf{y}}'_1|.$$

If we assume (without loss of generality) that $\tilde{\theta}(\mathbf{x}, \mathbf{y}; \mathbf{w}) \cdot \hat{\mathbf{y}}_1 \geq \tilde{\theta}(\mathbf{x}', \mathbf{y}'; \mathbf{w}) \cdot \hat{\mathbf{y}}'_1$, then

$$\begin{aligned} |\tilde{\theta}(\mathbf{x}, \mathbf{y}; \mathbf{w}) \cdot \hat{\mathbf{y}}_1 - \tilde{\theta}(\mathbf{x}', \mathbf{y}'; \mathbf{w}) \cdot \hat{\mathbf{y}}'_1| &= \tilde{\theta}(\mathbf{x}, \mathbf{y}; \mathbf{w}) \cdot \hat{\mathbf{y}}_1 - \tilde{\theta}(\mathbf{x}', \mathbf{y}'; \mathbf{w}) \cdot \hat{\mathbf{y}}'_1 \\ &\leq \tilde{\theta}(\mathbf{x}, \mathbf{y}; \mathbf{w}) \cdot \hat{\mathbf{y}}_1 - \tilde{\theta}(\mathbf{x}', \mathbf{y}'; \mathbf{w}) \cdot \hat{\mathbf{y}}_1 \\ &= (\tilde{\theta}(\mathbf{x}; \mathbf{w}) + \delta(\mathbf{y}) - \tilde{\theta}(\mathbf{x}'; \mathbf{w}) - \delta(\mathbf{y}')) \cdot \hat{\mathbf{y}}_1 \\ &= \mathbf{w} \cdot (\mathbf{f}(\mathbf{x}, \mathbf{y}_1) - \mathbf{f}(\mathbf{x}', \mathbf{y}'_1)) + (\delta(\mathbf{y}) - \delta(\mathbf{y}')) \cdot \hat{\mathbf{y}}_1 \\ &\leq \|\mathbf{w}\|_q (\Delta_G + 2)R D_{\mathbb{H}}(\mathbf{x}, \mathbf{x}') + (\delta(\mathbf{y}) - \delta(\mathbf{y}')) \cdot \hat{\mathbf{y}}_1 \\ &\leq \|\mathbf{w}\|_q (\Delta_G + 2)R D_{\mathbb{H}}(\mathbf{x}, \mathbf{x}') + D_{\mathbb{H}}(\mathbf{y}, \mathbf{y}'). \end{aligned} \quad (56)$$

The first inequality uses the optimality of \mathbf{y}'_1 ; the second inequality uses Hölder's inequality and Lemma 7 again; the last inequality uses the fact that

$$(\delta(\mathbf{y}) - \delta(\mathbf{y}')) \cdot \hat{\mathbf{y}}_1 = D_{\mathbb{H}}(\mathbf{y}, \mathbf{y}_1) - D_{\mathbb{H}}(\mathbf{y}', \mathbf{y}'_1) \leq D_{\mathbb{H}}(\mathbf{y}, \mathbf{y}').$$

The upper bound in Equation 56 also holds when $\tilde{\theta}(\mathbf{x}', \mathbf{y}'; \mathbf{w}) \cdot \hat{\mathbf{y}}'_1 \geq \tilde{\theta}(\mathbf{x}, \mathbf{y}; \mathbf{w}) \cdot \hat{\mathbf{y}}_1$.

Combining Equations 55 to 57, we then have that

$$\begin{aligned} n |L_{\mathcal{I}}(h, \mathbf{z}) - L_{\mathcal{I}}(h, \mathbf{z}')| &\leq 2(\Delta_G + 2)R \|\mathbf{w}\|_q D_{\mathbb{H}}(\mathbf{x}, \mathbf{x}') + D_{\mathbb{H}}(\mathbf{y}, \mathbf{y}') \\ &\leq 2(\Delta_G + 2)R \|\mathbf{w}\|_q D_{\mathbb{H}}(\mathbf{z}, \mathbf{z}') + D_{\mathbb{H}}(\mathbf{z}, \mathbf{z}'). \end{aligned}$$

Dividing both sides by n yields Equation 33. To obtain Equation 34, we use Lemma 7's Equation 52 in Equations 55 and 56, which reduces the term $(\Delta_G + 2)$ to just 2.

C.2 Proof of Lemma 3

The proof proceeds similarly to that of Lemma 2. Let

$$\begin{aligned} \mathbf{y}_1 &\triangleq \arg \max_{\mathbf{u} \in \mathcal{Y}^n} D_{\mathbb{H}}(\mathbf{y}, \mathbf{u}) + h(\mathbf{x}, \mathbf{u}); & \mathbf{y}_2 &\triangleq \arg \max_{\mathbf{u} \in \mathcal{Y}^n} h(\mathbf{x}, \mathbf{u}); \\ \mathbf{y}'_1 &\triangleq \arg \max_{\mathbf{u} \in \mathcal{Y}^n} D_{\mathbb{H}}(\mathbf{y}, \mathbf{u}) + h'(\mathbf{x}, \mathbf{u}); & \mathbf{y}'_2 &\triangleq \arg \max_{\mathbf{u} \in \mathcal{Y}^n} h'(\mathbf{x}, \mathbf{u}). \end{aligned}$$

Using this notation, we have that

$$\begin{aligned} n |L_{\mathcal{I}}(h, \mathbf{z}) - L_{\mathcal{I}}(h', \mathbf{z})| &\leq |(D_{\mathbb{H}}(\mathbf{y}, \mathbf{y}_1) + h(\mathbf{x}, \mathbf{y}_1)) - (D_{\mathbb{H}}(\mathbf{y}, \mathbf{y}'_1) + h'(\mathbf{x}, \mathbf{y}'_1))|, \quad (57) \end{aligned}$$

via the triangle inequality. Assuming $h(\mathbf{x}, \mathbf{y}_2) \geq h'(\mathbf{x}, \mathbf{y}'_2)$, we have that

$$\begin{aligned} |h(\mathbf{x}, \mathbf{y}_2) - h'(\mathbf{x}, \mathbf{y}'_2)| &= h(\mathbf{x}, \mathbf{y}_2) - h'(\mathbf{x}, \mathbf{y}'_2) \\ &\leq h(\mathbf{x}, \mathbf{y}_2) - h'(\mathbf{x}, \mathbf{y}_2) \\ &= (\mathbf{w} - \mathbf{w}') \cdot \mathbf{f}(\mathbf{x}, \mathbf{y}_2) \\ &\leq \|\mathbf{w} - \mathbf{w}'\|_q \|\mathbf{f}(\mathbf{x}, \mathbf{y}_2)\|_p \\ &\leq \|\mathbf{w} - \mathbf{w}'\|_q |G| R, \end{aligned} \quad (58)$$

via Lemma 8. Further, using the loss-augmented potentials, and assuming $\tilde{\theta}(\mathbf{x}, \mathbf{y}; \mathbf{w}) \cdot \hat{\mathbf{y}}_1 \geq \tilde{\theta}(\mathbf{x}, \mathbf{y}'; \mathbf{w}') \cdot \hat{\mathbf{y}}'_1$, we have that

$$\begin{aligned} |(D_{\mathbb{H}}(\mathbf{y}, \mathbf{y}_1) + h(\mathbf{x}, \mathbf{y}_1)) - (D_{\mathbb{H}}(\mathbf{y}, \mathbf{y}'_1) + h'(\mathbf{x}, \mathbf{y}'_1))| &= \tilde{\theta}(\mathbf{x}, \mathbf{y}; \mathbf{w}) \cdot \hat{\mathbf{y}}_1 - \tilde{\theta}(\mathbf{x}, \mathbf{y}'; \mathbf{w}') \cdot \hat{\mathbf{y}}'_1 \\ &\leq \tilde{\theta}(\mathbf{x}, \mathbf{y}; \mathbf{w}) \cdot \hat{\mathbf{y}}_1 - \tilde{\theta}(\mathbf{x}, \mathbf{y}'; \mathbf{w}') \cdot \hat{\mathbf{y}}_1 \\ &= (\tilde{\theta}(\mathbf{x}; \mathbf{w}) + \delta(\mathbf{y}) - \tilde{\theta}(\mathbf{x}'; \mathbf{w}') - \delta(\mathbf{y}')) \cdot \hat{\mathbf{y}}_1 \\ &= (\mathbf{w} - \mathbf{w}') \cdot \mathbf{f}(\mathbf{x}, \mathbf{y}_1) \\ &\leq \|\mathbf{w} - \mathbf{w}'\|_q \|\mathbf{f}(\mathbf{x}, \mathbf{y}_1)\|_p \\ &\leq \|\mathbf{w} - \mathbf{w}'\|_q |G| R. \end{aligned} \quad (59)$$

Combining the inequalities and dividing by n completes the proof.

C.3 Proof of Example 1

Since the weights are uniformly bounded, we define the prior, \mathbb{P} , as a uniform distribution on the d -dimensional unit ball. Given a (learned) hypothesis, h , with weights \mathbf{w} , we construct a posterior, \mathbb{Q}_h , as a uniform distribution on a d -dimensional ball with radius ϵ , centered at \mathbf{w} , and clipped at the boundary of the unit ball; i.e., its support is $\{\mathbf{w}' \in \mathbb{R}^d : \|\mathbf{w}' - \mathbf{w}\|_2 \leq \epsilon, \|\mathbf{w}'\|_2 \leq 1\}$. We let $\epsilon \triangleq (m|G|)^{-1}$, meaning the radius of the ball should decrease as the size of the training set increases.

For a uniform distribution, \mathbb{U} , with *support* $\text{supp}(\mathbb{U}) \subseteq \mathcal{H}$, we denote its *volume* by

$$\text{vol}(\mathbb{U}) \triangleq \int_{\mathcal{H}} \mathbb{1}\{h \in \text{supp}(\mathbb{U})\} dh.$$

The probability density function of \mathbb{U} is the inverse of its volume. The volume of \mathbb{P} is the volume of a unit ball, which is proportional to 1. Similarly, the volume of \mathbb{Q}_h is at least the volume of a d -dimensional ball with radius $\epsilon/2$ (due to the intersection with the unit ball), which is proportional to $(\epsilon/2)^d$.¹² Therefore, using p and q_h to denote their respective

¹² We withhold the precise definitions for simplicity of exposition. It will suffice to recognize their relative proportions, since the withheld constant depends only on d , and is thereby canceled out in the KL divergence.

densities, we have that

$$\begin{aligned} D_{\text{KL}}(\mathbb{Q}_h \|\mathbb{P}) &= \int_{\mathcal{H}} q_h(t') \ln \frac{q_h(t')}{p(t')} dt' \\ &= \int_{\mathcal{H}} q_h(t') \ln \frac{\text{vol}(\mathbb{P})}{\text{vol}(\mathbb{Q}_h)} dt' \\ &\leq \int_{\mathcal{H}} q_h(t') \ln(2/\epsilon)^d dt' \\ &= d \ln(2m |G|). \end{aligned}$$

By assumption, every allowable hypothesis has a weight vector \mathbf{w} with $\|\mathbf{w}\|_2 \leq 1$. We also assume that $\sup_{x \in \mathcal{X}} \|x\|_2 \leq 1$. Therefore, with $R = 1$ and $\beta \triangleq (2\Delta_G + 4) + 1$, Lemma 2 immediately proves that $L_r \circ \{h \in \mathcal{H}_{\text{KNS}} : \|\mathbf{w}\|_2 \leq 1\}$ is (β/n) -uniformly stable. Invoking Corollary 1, we then have that, with probability at least $1 - \delta$, every $\mathbb{Q}_h : \|\mathbf{w}\|_2 \leq 1$ satisfies

$$\bar{I}_r(\mathbb{Q}_h) \leq \hat{L}_r(\mathbb{Q}_h, \hat{\mathcal{Z}}) + 2((2\Delta_G + 4) + 1) \|\mathbf{r}^\top\|_\infty \sqrt{\frac{d \ln(2m |G|) + \ln \frac{2}{\delta}}{2mn}}. \quad (60)$$

By construction, every $h' \sim \mathbb{Q}_h$ satisfies $\|\mathbf{w}' - \mathbf{w}\|_2 \leq (m |G|)^{-1}$, so \mathbb{Q} has $(1/(m |G|), 0)$ -local hypothesis stability. As demonstrated in Equation 37, L_r has $(2 |G|/n, \emptyset)$ -local hypothesis stability. Thus, via Proposition 5, (L_r, \mathbb{Q}) has $(2/(mn), \emptyset, 0)$ -local stability. Then, via Proposition 4 and Equation 32, we have that

$$\bar{I}_n(h) \leq \bar{I}_r(h) \leq \bar{I}_r(\mathbb{Q}_h) + \frac{2}{mn}, \quad (61)$$

and

$$\hat{L}_r(\mathbb{Q}_h, \hat{\mathcal{Z}}) \leq \hat{L}_r(h, \hat{\mathcal{Z}}) + \frac{2}{mn} \leq \hat{L}_n(h, \hat{\mathcal{Z}}) + \frac{2}{mn}. \quad (62)$$

Combining Equations 60 to 62 completes the proof.

C.4 Proof of Lemma 4

We begin with a fundamental property of the normal distribution, which is used to prove the concentration inequality.

Fact 1. *If X is a Gaussian random variable, with mean μ and variance σ^2 , then, for any $\epsilon > 0$,*

$$\Pr\{|X - \mu| \geq \epsilon\} \leq 2 \exp\left(-\frac{\epsilon^2}{2\sigma^2}\right). \quad (63)$$

Observe that, if $\|\mathbf{X} - \boldsymbol{\mu}\|_p \geq \epsilon$, then there must exist at least one coordinate $i \in [d]$ such that $|X_i - \mu_i| \geq \epsilon/d^{1/p}$; otherwise, we would have

$$\|\mathbf{X} - \boldsymbol{\mu}\|_p = \left(\sum_{i=1}^d |X_i - \mu_i|^p\right)^{1/p} < \left(d \left(\frac{\epsilon}{d^{1/p}}\right)^p\right)^{1/p} = \epsilon.$$

We therefore have that

$$\begin{aligned} \Pr\left\{\|\mathbf{X} - \boldsymbol{\mu}\|_p \geq \epsilon\right\} &\leq \Pr\left\{\exists i : |X_i - \mu_i| \geq \frac{\epsilon}{d^{1/p}}\right\} \\ &\leq \sum_{i=1}^d \Pr\left\{|X_i - \mu_i| \geq \frac{\epsilon}{d^{1/p}}\right\} \\ &\leq \sum_{i=1}^d 2 \exp\left(-\frac{\epsilon^2}{2\sigma^2 d^{2/p}}\right). \end{aligned}$$

The second inequality uses the union bound; the last uses Fact 1. Summing over $i = 1, \dots, d$ completes the proof.

C.5 Proof of Example 4

We first show that $\mathbb{D}(\mathcal{B}_{\mathcal{Z}}) \leq 1/n$. Then, the rest of the proof is a simple modification of the previous analyses.

Observe that, for any x and μ_y ,

$$\|x\|_2 - 1 \leq \|x\|_2 - \|\mu_y\|_2 \leq \|x - \mu_y\|_2.$$

So, if $\|x\|_2 \geq 2$, then $\|x - \mu_y\|_2 \geq 1$. Therefore, using the union bound, and Lemma 4, we can upper-bound the measure of $\mathcal{B}_{\mathcal{Z}}$ as follows:

$$\begin{aligned} \mathbb{D}(\mathcal{B}_{\mathcal{Z}}) &= \Pr_{\mathcal{Z} \sim \mathbb{D}}\{\exists i : \|X_i\|_2 \geq 2\} \\ &\leq \sup_{\mathbf{y} \in \mathcal{Y}^n} \Pr_{\mathbf{X} \sim \mathbb{D}}\{\exists i : \|X_i\|_2 \geq 2 \mid \mathbf{Y} = \mathbf{y}\} \\ &= \sup_{\mathbf{y} \in \mathcal{Y}^n} \sum_{i=1}^n \Pr_{\mathbf{X} \sim \mathbb{D}}\{\|X_i\|_2 \geq 2 \mid Y_i = y_i\} \\ &\leq \sup_{\mathbf{y} \in \mathcal{Y}^n} \sum_{i=1}^n \Pr_{X_i \sim \mathbb{D}}\{\|X_i - \mu_{y_i}\|_2 \geq 1 \mid Y_i = y_i\} \\ &\leq \sup_{\mathbf{y} \in \mathcal{Y}^n} \sum_{i=1}^n 2k \exp\left(-\frac{1}{2k\sigma_{g_i}^2}\right) \\ &\leq \sum_{i=1}^n 2k \exp\left(-\frac{2k \ln(2kn^2)}{2k}\right) = \frac{1}{n}. \end{aligned}$$

Conditioned on $\mathbf{Z} \notin \mathcal{B}_{\mathcal{Z}}$, we have that Lemmas 7 and 8 hold for $R = 2$; hence, so do Lemmas 2 and 3. With \mathbb{P}, \mathbb{Q}_h and $\mathcal{B}_{\mathcal{H}_{\text{KNS}}}(h)$ constructed identically to Example 2, this means that \mathbb{Q}_h is $(\beta_h/n, \mathcal{B}_{\mathcal{Z}}, 1/(mn))$ -locally stable. Further, L_r has $(4 |G|/n, \mathcal{B}_{\mathcal{Z}})$ -local hypothesis stability; and \mathbb{Q} has $(1/(m |G|), 1/(mn))$ -local hypothesis stability; by Proposition 5, this means that (L_r, \mathbb{Q}) has $(4/(mn), \mathcal{B}_{\mathcal{Z}}, 1/(mn))$ -local stability. Thus, invoking Theorem 2 and Proposition 4, with $\nu = 1/n$, we have that, with probability at least $1 - \delta - m/n$, all

$l \in [m]$ satisfy $\mathbf{Z}^{(l)} \notin \mathcal{B}_z$, and all $h \in \mathcal{H}_{\text{MN}}$ satisfy

$$\begin{aligned} \bar{L}_r(h) &\leq \hat{L}_r(\mathbb{Q}_h) + \frac{5}{mn} + \frac{1}{n} \\ &\leq \hat{L}_r(\mathbb{Q}_h, \hat{\mathbf{Z}}) + \frac{6}{mn} + \frac{2}{n} \\ &\quad + 4\beta_h \|\Gamma_{\mathbb{P}}\|_{\infty} \sqrt{\frac{\frac{1}{2} \|\mathbf{w}\|_2^2 + \frac{d}{2} \ln(2d(m|G|)^2 \ln(2dmm)) + \ln \frac{4\beta_h}{\delta}}{2mn}}. \end{aligned}$$

Further, since none of the training examples in the sample are “bad,” we also have that

$$\hat{L}_r(\mathbb{Q}_h, \hat{\mathbf{Z}}) \leq \hat{L}_r(h, \hat{\mathbf{Z}}) + \frac{5}{mn} \leq \hat{L}_h(h, \hat{\mathbf{Z}}) + \frac{5}{mn}.$$

Combining these inequalities completes the proof.

Abstract

We consider loss functions for multiclass prediction problems. We show when a multiclass loss can be expressed as a “proper composite loss”, which is the composition of a proper loss and a link function. We extend existing results for binary losses to multiclass losses. We subsume results on “classification calibration” by relating it to properness. We determine the stationarity condition, Bregman representation, order-sensitivity, and quasi-convexity of multiclass proper losses. We then characterise the existence and uniqueness of the composite representation for multiclass losses. We show how the composite representation is related to other core properties of a loss: mixability, admissibility and (strong) convexity of multiclass losses which we characterise in terms of the Hessian of the Bayes risk. We show that the simple integral representation for binary proper losses can not be extended to multiclass losses but offer concrete guidance regarding how to design different loss functions. The conclusion drawn from these results is that the proper composite representation is a natural and convenient tool for the design of multiclass loss functions.

Keywords: Proper losses, Multiclass losses, Link Functions, Convexity and quasi-convexity of losses, Margin losses, Classification calibration, Parametrisations and representations of loss functions, Admissibility, Mixability, Minimality, Superprediction set

1. Introduction

Machine learning is done for a purpose. The performance of a machine learning solution is judged by means of a loss function. Different choices of loss function will lead to different solutions. The theory of binary losses (i.e. losses suitable for binary prediction problems) is well understood. This paper extends that understanding to multiclass losses and aids the choice of a suitable loss function by exploring the parametrisations available and the implications of different choices. It does so by systematically exploring a decomposition of a multiclass loss into two components, one which affects the statistical performance, and one which affects the computational optimisation of models.

The problem setting is where one is given a bag $\{(x_i, y_i)\}_i$ of pairs of points x_i and their accompanying labels $y_i \in [n] := \{1, \dots, n\}$, drawn from a finite set of size n . The task can

be either predict a label for an unseen instance, or predict the probability that a label takes on a particular value. These two problems are called multiclass *classification* and *probability estimation* respectively.

Proper composite losses are the composition of a *proper loss* and an *invertible link* (both defined formally below). This representation makes the understanding of multiclass losses easier because, crucially, it separates two distinct concerns: the statistical and the computational. The statistical properties are controlled by the proper loss, while the link function is essentially just a parametrisation. Choice of a suitable link can help—for example, a nonconvex proper loss can be made convex (and thus more amenable to numerical optimisation) by choice of the appropriate link. For prediction purposes it is desirable to use an *admissible* loss (one where every possible prediction is uniquely optimal for some underlying distribution). It turns out that every proper composite loss is admissible; in fact proper composite losses satisfy a stronger adequacy property than admissibility.

We characterise when a multiclass loss has a proper composite representation and when such representations are unique. We consider integral representations (whereby the proper component can be expressed as a weighted combination of elementary proper losses). We show the surprising result that there is a fundamental difference between $n = 2$ and $n > 2$ in terms of the simplicity of the parametrisation of the class of elementary proper losses. It has been known for some time that proper losses are characterised by their conditional Bayes risks (or entropy functions). It has already been shown how important properties of a loss that control the performance of certain learning tasks can be expressed directly in terms of the Bayes risk. In this paper we extend results due to Reid and Williamson (2010) (for $n = 2$) to general n and characterise the convexity of a proper loss in terms of the associated Bayes risk.

We also illuminate the connection between classification and probability estimation by characterising the relationship between the crucial property that a loss should have for each of these: *classification calibrated* (which we first generalise to make sense in the more general setting we consider) and *properness*. We explain the relationship between these two concepts, which captures the idea behind the probing reduction from classification to class probability estimation.

We also show how the results of the paper can provide tools to help with the design of multiclass losses, putting this on firmer ground than in the past.

1.1 Previous Work

With some exceptions, existing work on multiclass loss functions attempts to work directly with $\ell: \mathcal{Y} \rightarrow \mathbb{R}^n$. As we shall show this conflates two separate concerns—the design of the *statistical* properties of the loss, those that affect statistical performance, with the aspects that affect the computational properties that control the ease with which empirical averages of the loss are minimized. The proper composite representation is not new—in hindsight the observation of Grünwald and Dawid (2004) that every loss induces a proper scoring rule is tantamount to the proper composite representation. Furthermore, its components (link functions and proper losses) have a long history. The novelty of the present work is to systematically use these two components as a canonical parametrisation of loss functions. Key differences between the present paper and previous work are tabulated in Table 1.

Attribute	Previous Work	Present Paper	Ref.
Structure and Semantics	None—just a function, possibly convex in parameters	Clear separation of concerns and meaning for λ and W . Gives meaning to predictions v as transformed probabilities.	Fig. 1
Classification versus probability estimation	Little insight in the multiclass case; confer recent works such as (Reid and Williamson, 2010, 2011; Narasimhan and Agarwal, 2013; Menon and Williamson, 2014) for the binary case	Clear connection via a characterisation relating classification calibrated, prediction calibrated and proper losses	§3
Effect of choice of loss function on performance	Margin based. Only a sufficient condition and only for statistical batch setting. Mixes up statistical fundamentals (\mathcal{L}) with parametrization (Ψ). Strong convexity for speed of convergence in online setting; cf. (Abemethy et al., 2009).	Mixability and Stochastic Mixability. Characterisation in online setting. Both online worst-case and statistical batch settings. Parametrisation Ψ automatically ignored.	§6.1
Admissibility	Not considered explicitly. Ensured however by assuming ℓ is convex.	All proper composite losses admissible. All continuous Bayes losses have a proper composite representation.	§6.2
Quasi-convexity and Minimality	Guaranteed by assuming ℓ is convex.	Quasi-convexity guaranteed for all continuous proper losses; minimality for all continuous proper composite losses.	§6.4
Convexifiability	No principled way to convexify a loss; can make convex surrogate approximations.	All continuous proper losses convexifiable (using the canonical link).	§6.4
Design principles and parameterisation	No guidance; choose ℓ or margin function ϕ , in which case symmetry imposed.	Principled: general asymmetric losses possible; parametrise via (Δ, Ψ) ; separation of concerns.	§8.3
Connections to divergences	Many to one for margin losses in binary case. (Nguyen et al., 2009)	Explicit 1:1 correspondence for binary and multiclass case (Reid and Williamson, 2011; García and Williamson, 2012).	§9

Table 1: Comparison of present paper to previous works on loss functions.

Proper losses are the natural losses to use for probability estimation. They have been studied in detail when $n = 2$ (the “binary case”) where there is a nice integral representation (Bijia et al., 2005; Gneiting and Raftery, 2007; Reid and Williamson, 2011), and characterization (Reid and Williamson, 2010) when differentiable. The proper composite representation for binary losses has proved very illuminating in the study of bipartite ranking problems (Menon and Williamson,

2014). Classification calibrated losses are an analog of proper losses for the problem of classification (Bartlett et al., 2006). The relationship between classification calibration and properness was determined by Reid and Williamson (2010) for $n = 2$. Most of these results have had no multiclass analogue until now. Whilst there is much work on classification problems, it is now widely understood that there are often advantages in being able to predict probabilities, rather than just labels (Bennett, 2003; Cohen and Goldszmidt, 2004).

The theory of loss functions makes it clear how one ideally chooses a loss—one takes account of one’s utility concerning various incorrect predictions (Kiefer, 1987), (Berger, 1985, Section 2.4). The practice rarely involves such a step, primarily, we conjecture, because there is no adequate understanding of the way one can parametrise losses effectively, especially in the multiclass case. There is little guidance in the literature concerning how to choose a loss function; typically heuristic arguments are used for the choice—confer e.g. (Ighodaro et al., 1982; Nayak and Naik, 1989). An early approach to multiclass losses is simply reduction to binary (Allwein et al., 2001; Beygelzimer et al., 2007; Crammer and Singer, 2001; Dietterich and Bakiri, 1995; Zadrozny and Elkan, 2002). Related approaches are pairwise coupling or Bradley-Terry models (Hastie and Tibshirani, 1998; Wu and Weng, 2004; Huang et al., 2006) where certain relationships are assumed to hold between the pairwise probabilities and the multivariate probability of interest.

The design of losses for multiclass prediction has received recent attention (Zhang, 2004; Hill and Doucet, 2007; Tewari and Bartlett, 2007; Liu, 2007; Santos-Rodríguez et al., 2009; Zou et al., 2008; Zhang et al., 2009) although none of these papers developed the connection to proper losses, and most restrict consideration to margin losses (which imply certain symmetry conditions). Zou et al (2005) proposed a multiclass generalisation of “admissible losses” (their name for classification calibration) for multiclass margin classification. Liu (2007) considered several multiclass generalisations of hinge loss (suitable for multiclass SVMs) and showed some of them were and others were not Fisher consistent, and when they were not it was shown how the training algorithm could be modified to make the losses behave consistently. Shi et al. (2010) have investigated the relationship between classification calibration of multiclass losses and losses for structure prediction, and have proposed an extension of classification calibration which they call parametric consistency, which attempts to take account of the function class used (classification calibration is, like all the results in this paper, concerned with behaviour *per point*, in practice one typically optimises over restricted classes of functions). Multiclass losses have also been considered in the development of multiclass boosting (e.g. Zhu et al., 2009; Mukherjee and Schapire, 2013; Wu and Lange, 2010).

1.2 Outline

The rest of the paper is organised as follows. In §2 we set up the problem formally and state some purely mathematical results we will need; §3 we relate properness, classification calibration, and the notion used by Tewari and Bartlett (2007) which we rename “prediction calibrated”; §4 we provide a novel characterization of multiclass properness; §5 we study composite proper losses (the composition of a proper loss with an invertible link) and characterise when a given loss has such a representation and when the representation is unique; §6 we develop a number of interesting implications of the representation and the characterisation results in terms of

mixability (§6.1), admissibility (§6.2) and convexity (§6.4), where we give a complete characterisation of the (strong) convexity of composite multiclass proper losses in terms of the Bayes risk; §7: we present a (somewhat surprising) negative result concerning the integral representation of proper multiclass losses; §8: we outline how the above results can aid in the design of proper losses, especially by use of a (new) multiclass extension of the ‘‘canonical link’’; finally, §9 summarises the key contributions and outlines some future directions.

2. Formal Setup

Suppose \mathcal{X} is some set and $\mathcal{Y} = [n] = \{1, \dots, n\}$ is a set of labels. (Throughout the paper n is an integer greater than or equal to 2.) We suppose we are given data $S = \{(x_i, y_i)\}_{y_i \in [n]}$ such that $y_i \in \mathcal{Y}$ is the label corresponding to $x_i \in \mathcal{X}$. These data follow a joint distribution $\mathbb{P}_{\mathcal{X}, \mathcal{Y}}$ on $\mathcal{X} \times [n]$. We denote by $\mathbb{E}_{\mathcal{X}, \mathcal{Y}}$ and $\mathbb{E}_{\mathcal{Y}, \mathcal{X}}$ respectively, the expectation and the conditional expectation with respect to $\mathbb{P}_{\mathcal{X}, \mathcal{Y}}$. Given a new observation x we want to predict the probability $p_i := \mathbb{P}(Y = i | X = x)$ of x belonging to class i , for $i \in [n]$. *Multiclass classification* requires the learner to predict the most likely class of x ; that is to find $\hat{y} \in \arg \max_{i \in [n]} p_i$.

A loss measures the quality of prediction. Let $\Delta^n := \{(p_1, \dots, p_n) : \sum_{i \in [n]} p_i = 1, \text{ and } 0 \leq p_i \leq 1, \forall i \in [n]\}$ denote the *n-simplex*. For multiclass probability estimation, $\ell: \Delta^n \rightarrow \mathbb{R}_+^n$. The *partial losses* ℓ_i are the components of $\ell(q) = (\ell_1(q), \dots, \ell_n(q))'$ and $\ell_i(q)$ is the loss incurred by predicting $q \in \Delta^n$ when $y = i$. A commonly used loss for probability estimation is the *log loss* ℓ^{\log} defined by $\ell_i^{\log}(q) := -\log q_i$ for $i \in [n]$. Other examples of multiclass losses we will refer to in this paper include the *square loss* $\ell^{\text{sq}}(q) := \sum_{j \in [n]} (\|j - q_j\|)^2$, the *absolute loss* $\ell_i^{\text{abs}}(q) := \sum_{j \in [n]} \|[i - j] - q_j\|$ and the *0-1 loss* $\ell_i^{01}(q) := \mathbb{1}_{\{j \in \arg \max_{j \in [n]} q_j\}}$. Here, $\mathbb{1}\{P\}$ denotes the function that is 1 when P is true and 0 otherwise.

Throughout the paper, A' denotes transpose of the matrix or vector A , except when applied to a real-valued function where it denotes derivative. We denote matrix multiplication of compatible matrices A and B by $A \cdot B$, so the inner product of two vectors $x, y \in \mathbb{R}^n$ is $x' \cdot y$. The *conditional risk* L associated with a loss ℓ is the function

$$L: \Delta^n \times \Delta^n \ni (p, q) \mapsto L(p, q) = \mathbb{E}_{Y \sim p} \ell_Y(q) = p' \cdot \ell(q) \in \mathbb{R}_{++},$$

where $Y \sim p$ means Y is drawn according to a multinomial distribution with parameter $p \in \Delta^n$. In a typical learning problem one will construct an estimate $q: \mathcal{X} \rightarrow \Delta^n$. The *full risk* is $\mathbb{L}(q) = \mathbb{E}_{\mathcal{X}, \mathcal{Y}} \mathbb{E}_{\mathcal{Y}, \mathcal{X}} \ell_Y(q(X))$. Minimizing $\mathbb{L}(q)$ over $q: \mathcal{X} \rightarrow \Delta^n$ is equivalent to minimizing $L(p(x), q(x))$ over $q(x) \in \Delta^n$ for all $x \in \mathcal{X}$ where $p(x) = (p_1(x), \dots, p_n(x))'$, and $p_i(x) = \mathbb{P}(Y = i | X = x)$. Thus it suffices to only consider the conditional risk; confer (Reid and Williamson, 2011).

If one is interested in estimating probabilities ($\ell: \Delta^n \rightarrow \mathbb{R}_+^n$) it is natural to require the associated conditional risk is minimised when estimating the true underlying probability. Such a loss is called *proper* (formally: if $L(p, p) \leq L(p, q)$, $\forall p, q \in \Delta^n$). It is *strictly proper* if the inequality is strict when $p \neq q$ (so it is uniquely minimised by predicting the correct probability). The *conditional Bayes risk* is defined by

$$\underline{L}: \Delta^n \ni p \mapsto \inf_{q \in \Delta^n} L(p, q).$$

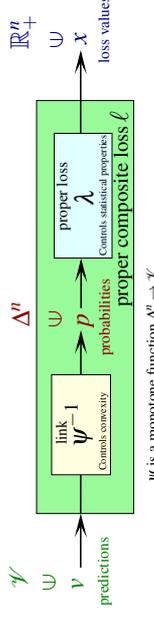

Figure 1: The idea of a proper composite loss.

This function is always concave (Gneiting and Raftery, 2007). If ℓ is proper, then $L(p) = L(p, p) = p' \cdot \ell(p)$. Strictly proper losses induce *Fisher consistent* estimators of probabilities: if ℓ is strictly proper, $p = \arg \min_q L(p, q)$. By considering when the derivatives $\frac{\partial}{\partial q_i} L(p, q)$ are zero it is straight-forward to show that, of the example losses introduced above, the log loss, square loss, and 0-1 loss are proper, while absolute loss is not. Furthermore, both log loss and square loss are strictly proper while 0-1 loss is proper but not strictly proper. Using the fact that, for proper losses, the Bayes risk $\underline{L}(p) = L(p, p)$ we see that $\underline{L}^{\log}(p) = -\sum_{i \in [n]} p_i \log p_i$ (i.e., Shannon entropy); $\underline{L}^{\text{sq}}(p) = 1 - \sum_{i \in [n]} p_i^2$; and $\underline{L}^{01}(p) = \min_i \{1 - p_i\}$.

The losses above are defined on the simplex Δ^n since the argument (a predictor) represents a probability vector. However it is sometimes desirable to use another set \mathcal{Y} of predictors. For example if one wishes to use linear predictors, their natural range is \mathbb{R}^n . One can consider losses $\ell: \mathcal{Y} \rightarrow \mathbb{R}_+^n$. Suppose there exists an invertible function $\psi: \Delta^n \rightarrow \mathcal{Y}$. Then ℓ can be written as a composition of a loss λ defined on the simplex with ψ^{-1} . That is, $\ell(v) = \lambda \psi(v) := \lambda(\psi^{-1}(v))$. Such a function $\lambda \psi$ is a *composite loss*. If λ is proper, we say ℓ is a *proper composite loss*, with *associated proper loss* λ and *link* ψ ; see Figure 1. Many commonly used multiclass losses are composite losses, even though they are not often expressed as such; see the example in §8.4.

Throughout the paper, ℓ is a general loss defined on \mathcal{Y} , where \mathcal{Y} may equal Δ^n , and λ is always a loss defined on Δ^n , which may be proper. For such a loss $\lambda: \Delta^n \rightarrow \mathbb{R}_+^n$, its corresponding conditional risk is denoted $\Lambda(p, q)$ and its conditional Bayes risk is $\underline{\Lambda}(p)$.

In order to differentiate the losses we project the n -simplex into a subset of \mathbb{R}^{n-1} . Let

$$\tilde{\Delta}^n := \left\{ (p_1, \dots, p_{n-1})' : p_i \geq 0, \forall i \in [n], \sum_{i=1}^{n-1} p_i \leq 1 \right\}$$

denote the ‘‘bottom’’ of the n -simplex. We denote by

$$\Pi_{\Delta}: \Delta^n \ni p = (p_1, \dots, p_n)' \mapsto \tilde{p} = (p_1, \dots, p_{n-1})' \in \tilde{\Delta}^n,$$

the projection of the Δ^n , and

$$\Pi_{\tilde{\Delta}}^{-1}: \tilde{\Delta}^n \ni \tilde{p} = (\tilde{p}_1, \dots, \tilde{p}_{n-1})' \mapsto p = (p_1, \dots, p_{n-1}, 1 - \sum_{i=1}^{n-1} \tilde{p}_i)' \in \Delta^n$$

its inverse. For convenience, we will often use $\tilde{n} := n - 1$ to denote the dimension of the set $\tilde{\Delta}^n$.

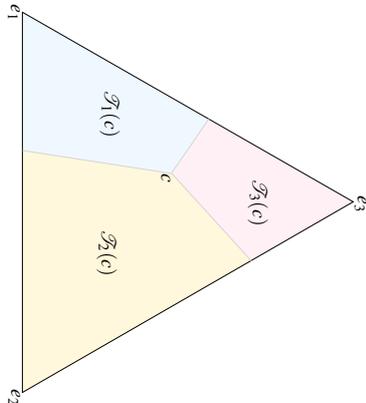

Figure 2: A partitioning of the 3-simplex by regions $\mathcal{F}_i(c)$, $i = 1, 2, 3$, where $c = (.35, .2, .45)$ as viewed from the direction $(1, 1, 1)$.

We use the following notation. The k th unit vector e_k is the n vector with all components zero except the k th which is 1. The n -vector $\mathbb{1}_n := (1, \dots, 1)^\top$. The (relative) interior of the simplex is $\hat{\Delta}^n := \{p_1, \dots, p_n\}$; $\Sigma_{i \in [n]} p_i = 1$, and $0 < p_i < 1$, $\forall i \in [n]$ and the boundary is $\partial \hat{\Delta}^n := \Delta^n \setminus \hat{\Delta}^n$. We also adopt notation from [Magnus and Neudecker \(1999\)](#). For the reader's convenience we list the essential notations and conventions in [Appendix A](#).

3. Relating Properness to Classification Calibration

Properness is an attractive property of a loss for the task of class probability estimation. However if one is merely interested in *classifying* (predicting $\hat{y} \in [n]$ given $x \in \mathcal{X}$) then it is stronger than one needs. In this section we relate *classification calibration* (the analog of properness for classification problems) to properness.

Suppose $c \in \hat{\Delta}^n$. We cover Δ^n with n subsets each representing one class:

$$\mathcal{F}_i(c) := \{p \in \Delta^n : \forall j \neq i \ p_i c_j \geq p_j c_i\}, \quad i \in [n].$$

Observe that for $i \neq j$, the sets $\mathcal{F}_i(c) := \{p \in \Delta^n : p_i c_j = p_j c_i\}$ are subsets of dimension $n-2$ through c and all e_k such that $k \neq i$ and $k \neq j$. These subsets partition \mathbb{R}^n into two parts. The set $\mathcal{F}_{ij}(c)$ is the intersection of Δ^n and the subspaces delimited by the precedent $(n-2)$ -subspace and in the same side as e_i . An example of this partition is shown graphically in [Figure 2](#). We will make use of the following properties of $\mathcal{F}_i(c)$.

Lemma 1 Suppose $c \in \hat{\Delta}^n$, $i \in [n]$. Then the following hold:

1. For all $p \in \Delta^n$, there exists i such that $p \in \mathcal{F}_i(c)$.
2. Suppose $p \in \Delta^n$. $\mathcal{F}_i(c) \cap \mathcal{F}_j(c) \subseteq \{p \in \Delta^n : p_i c_j = p_j c_i\}$, a subset of a subspace of dimension $n-2$.

3. Suppose $p \in \Delta^n$. If $p \in \cap_{i=1}^n \mathcal{F}_i(c)$ then $p = c$.
4. For all $p, q \in \Delta^n$, $p \neq q$, there exists $c \in \hat{\Delta}^n$, and $i \in [n]$ such that $p \in \mathcal{F}_i(c)$ and $q \notin \mathcal{F}_i(c)$.

The proof is deferred to [Appendix B.1](#).

Classification calibrated losses have been developed and studied under some different definitions and names ([Zhang, 2004](#); [Bartlett et al., 2006](#)). Below we generalise the notion of c -calibration which was proposed for $n = 2$ by [Reid and Williamson \(2010\)](#) and developed by [Scott \(2011, 2012\)](#) as a generalisation of the notion of classification calibration of [Bartlett et al. \(2006\)](#); confer also [Steinwart \(2007\)](#).

Definition 2 Suppose $\ell : \Delta^n \rightarrow \mathbb{R}_+^n$ is a loss and $c \in \hat{\Delta}^n$. We say ℓ is *c -calibrated at $p \in \Delta^n$* if for all $i \in [n]$ such that $p \notin \mathcal{F}_i(c)$ then $\forall q \in \mathcal{F}_i(c)$, $\underline{L}(p) < \underline{L}(p, q)$. We say that ℓ is *c -calibrated* if $\forall p \in \Delta^n$, ℓ is c -calibrated at p .

[Definition 2](#) means that if the probability vector q one predicts doesn't belong to the same subset (i.e. doesn't predict the same class) as the real probability vector p , then the loss might be larger than $\underline{L}(p)$.

Classification calibration in the sense used by [Bartlett et al. \(2006\)](#) corresponds to $\frac{1}{2}$ -calibrated losses when $n = 2$. If $c_{\text{mid}} := (\frac{1}{2}, \dots, \frac{1}{2})^\top$, c_{mid} -calibration induces Fisher-consistent estimates in the case of classification. Furthermore " ℓ is c_{mid} -calibrated and for all $i \in [n]$, and ℓ_i is continuous and bounded below" is equivalent to " ℓ is infinite sample consistent" as defined by [Zhang \(2004\)](#). This is because if ℓ is continuous and $\mathcal{F}_i(c)$ is closed, then $\forall q \in \mathcal{F}_i(c)$, $\underline{L}(p) < \underline{L}(p, q)$ if and only if $\underline{L}(p) < \inf_{q \in \mathcal{F}_i(c)} \underline{L}(p, q)$.

The following result generalises the correspondence between binary classification calibration and properness ([Reid and Williamson, 2010](#), [Theorem 16](#)) to multiclass losses ($n > 2$).

Proposition 3 A continuous loss $\ell : \Delta^n \rightarrow \mathbb{R}_+^n$ is strictly proper if and only if it is c -calibrated for all $c \in \hat{\Delta}^n$.

Proof (\Rightarrow) Suppose that ℓ is strictly proper. Then for all $c \in \hat{\Delta}^n$, for all $i \in [n]$ such that $p \notin \mathcal{F}_i(c)$ and for all $q \in \mathcal{F}_i(c)$ then $p \neq q$ and thus $\underline{L}(p) < \underline{L}(p, q)$ since ℓ is strictly proper.

(\Leftarrow) Suppose that ℓ is c -calibrated for all $c \in \hat{\Delta}^n$. Suppose $p, q \in \Delta^n$ and $p \neq q$. By [Lemma 1](#) (part 4) one can partition p and q into two different classes; there exists $c \in \hat{\Delta}^n$ and $i \in [n]$ such that $q \in \mathcal{F}_i(c)$ and $p \notin \mathcal{F}_i(c)$. Hence $\underline{L}(p) < \underline{L}(p, q)$ since ℓ is c -calibrated. Since ℓ is continuous and Δ^n is closed, the infimum in the definition of $\underline{L}(p)$ is attained. Since $\underline{L}(p) < \underline{L}(p, q)$ for all $q \neq p$, we conclude $\underline{L}(p) = \underline{L}(p, p)$. Thus ℓ is strictly proper. ■

In particular, a continuous strictly proper loss is c_{mid} -calibrated. Thus for any estimator \hat{q}_n of the conditional probability vector one constructs by minimizing the empirical average of a continuous strictly proper loss, one can build an estimator of the label (corresponding to the largest probability of \hat{q}_n) which is Fisher consistent for the problem of classification.

In the binary case, ℓ is classification calibrated if and only if the following implication holds ([Bartlett et al., 2006](#)):

$$\left(\underline{L}(f_n) \rightarrow \min_g \underline{L}(g) \right) \Rightarrow \left(\mathbb{P}_{\mathcal{X}, \mathcal{Y}}^{\mathbb{P}_{\mathcal{X}, \mathcal{Y}}}(\mathcal{Y} \neq f_n(\mathcal{X})) \rightarrow \min_g \mathbb{P}_{\mathcal{X}, \mathcal{Y}}^{\mathbb{P}_{\mathcal{X}, \mathcal{Y}}}(\mathcal{Y} \neq g(\mathcal{X})) \right). \quad (1)$$

Tewari and Bartlett (2007) have characterised when (1) holds in the multiclass case. Since there is no reason to assume the equivalence between classification calibration and (1) still holds for $n > 2$, we give different names for these two notions. We use *classification calibration* for the notion (Definition 2) linked to Fisher consistency and use *prediction calibrated* (defined below) for the notion of Tewari and Bartlett (equivalent to (1)).

Definition 4 Suppose $\ell: \mathcal{Y} \rightarrow \mathbb{R}_+^n$ is a loss. Let $\mathcal{G}_\ell := \text{co}(\{\ell(v) : v \in \mathcal{Y}\})$, the convex hull of the image of \mathcal{Y} . ℓ is said to be *prediction calibrated* if there exists a prediction function $\text{pred}: \mathbb{R}^n \rightarrow [n]$ such that

$$\forall p \in \Delta^n: \inf_{z \in \mathcal{G}_\ell: p_{\text{pred}(z)} \leq \max_{i \in [n]} p_i} p' \cdot z > \inf_{z \in \mathcal{G}_\ell} p' \cdot z = \underline{L}(p).$$

Suppose that $\ell: \Delta^n \rightarrow \mathbb{R}_+^n$ is such that ℓ is prediction calibrated and $\text{pred}(\ell(p)) \in \arg \max_i p_i$. Then ℓ is c_{mid} -calibrated almost everywhere.

By introducing a *reference link* Ψ (which corresponds to the actual link ψ if ℓ is a proper composite loss $\ell = \lambda \circ \Psi^{-1}$) we now show how the pred function can be canonically expressed in terms of $\arg \max_i p_i$.

Proposition 5 Suppose $\ell: \mathcal{Y} \rightarrow \mathbb{R}_+^n$ is a loss. Let $\tilde{\Psi}: \Delta^n \rightarrow \mathcal{Y}$ satisfy $\tilde{\Psi}(p) \in \arg \min_{v \in \mathcal{Y}} L(p, v)$ and $\lambda = \ell \circ \tilde{\Psi}$. Then λ is proper. If ℓ is prediction calibrated then $\text{pred}(\lambda(p)) \in \arg \max_{i \in [n]} p_i$.

Proof We show first that λ is proper. Let $p \in \Delta^n$. Then

$$\Lambda(p, p) = L(p, \tilde{\Psi}(p)) = L(p, \arg \min_v L(p, v)) = \min_v L(p, v) \leq \min_{q \in \Delta^n} \Lambda(p, q).$$

Thus λ is proper and $\underline{L}(p) = \Lambda(p)$. We now assume that ℓ is prediction calibrated. Suppose that $\text{pred}(z = \lambda(p)) \notin \arg \max_i p_i$. Then $p_{\text{pred}(\lambda(p))} < \max_i p_i$, thus $p' \cdot z = \Lambda(p, p) > \underline{L}(p) = \Lambda(p)$ which contradicts the properness of λ . ■

4. Characterizing Properness

We now present some simple (but new) consequences of properness in the multiclass case (Proposition 6). We also build some connections between the properness of multiclass losses and the properness of binary losses that can be derived from them via a restriction of the multiclass loss to a line connecting two points in the n -simplex (Proposition 7). Finally, we show that multiclass proper losses are effectively characterised by their Bayes risks (Proposition 8) and the continuity of losses is intimately tied to the differentiability of their Bayes risks (Proposition 9). An important implication of these last results is that we are able to study the class of multiclass proper losses by focusing our attention on concave functions defined over probabilities.

To state our propositions we need to introduce monotone functions, directional derivatives, and superdifferentials (cf. (Hiriart-Urruty and Lemaréchal, 2001)). We say $f: C \subset \mathbb{R}^n \rightarrow \mathbb{R}^n$ is *monotone* (resp. *strictly monotone*) on C when for all x and y in C ,

$$(f(x) - f(y))' \cdot (x - y) \geq 0 \quad \text{resp.} \quad (f(x) - f(y))' \cdot (x - y) > 0; \quad (2)$$

confer (Hiriart-Urruty and Lemaréchal, 2001; Rockafellar and Wets, 2004). If a function $f: \mathbb{R}^n \rightarrow \mathbb{R}$ is concave then $\lim_{t \downarrow 0} \frac{f(x+td) - f(x)}{t}$ exists, and is called the *directional derivative* of f at x in the direction d and is denoted $Df(x, d)$. By analogy with the usual definition of subdifferential for convex functions, we introduce the *superdifferential* $\partial f(x)$ for concave f at x is

$$\begin{aligned} \partial f(x) &:= \{s \in \mathbb{R}^n : s' \cdot y \geq Df(x, y), \forall y \in \mathbb{R}^n\} \\ &= \{s \in \mathbb{R}^n : f(y) \leq f(x) + s' \cdot (y - x), \forall y \in \mathbb{R}^n\}. \end{aligned}$$

Similarly, a vector $s \in \partial f(x)$ is called a *supergradient* of f at x .

Proposition 6 Suppose $\ell: \Delta^n \rightarrow \mathbb{R}_+^n$ is a loss. If ℓ is proper, then $-\ell$ is monotone on Δ^n . Furthermore, if ℓ is strictly proper then it is also invertible.

Proof For all $p, q \in \Delta^n$, $(\ell(p) - \ell(q))' \cdot (p - q) = p' \cdot \ell(p) - q' \cdot \ell(p) + q' \cdot \ell(q) - p' \cdot \ell(q) \leq 0$ since $p' \cdot \ell(p) \leq p' \cdot \ell(q)$. For the strictly proper case, we just have to check that ℓ is injective. By way of contradiction assume ℓ is not invertible. Then there exists $p \neq q$ such that $\ell(p) = \ell(q)$, which means $L(p, p) = L(p, q)$, contradicting the supposed strict properness of ℓ . ■

The following proposition presents several characterisations of multiclass properness. It shows how the characterisation of properness in the general (not necessarily differentiable) multiclass case can be reduced to the binary case. We also show this is equivalent to testing the properness condition for the loss on all possible line segments joining two distributions within the simplex. This latter characterisation can be viewed as a statement connecting ‘‘order sensitivity’’ and properness: the true class probability minimizes the risk and if the prediction moves away from the true class probability in a line then the risk increases. This property appears convenient for optimisation purposes: if one reaches a local minimum in the second argument of the risk and the loss is strictly proper then it is a global minimum. If the loss is proper, such a local minimum is a global minimum or a constant in an open set. But observe that typically one is minimising the full risk $\mathbb{L}(q(\cdot))$ over functions $q: \mathcal{X} \rightarrow \Delta^n$. We note that order sensitivity of ℓ does *not* imply this optimisation problem is well behaved; one needs convexity of $q \mapsto L(p, q)$ for all $p \in \Delta^n$ to ensure convexity of the functional optimisation problem; we characterise when that holds in section 6.4.

Proposition 7 Suppose $\ell: \Delta^n \rightarrow \mathbb{R}_+^n$ is a loss. We define the binary loss

$$\tilde{\ell}^{p,q}: [0, 1] \ni \eta \mapsto \begin{pmatrix} \tilde{\ell}_1^{p,q}(\eta) \\ -\tilde{\ell}_2^{p,q}(\eta) \end{pmatrix} = \begin{pmatrix} q' \cdot \ell(p + \eta(q - p)) \\ p' \cdot \ell(p + \eta(q - p)) \end{pmatrix}.$$

The following statements are equivalent:

1. ℓ is proper;
2. $\tilde{\ell}^{p,q}$ is proper for all $p, q \in \Delta^n$;
3. $\forall p, q \in \Delta^n, \forall 0 \leq h_1 \leq h_2, L(p, p + h_1(q - p)) \leq L(p, p + h_2(q - p))$; and

4. *there exists a concave function $f : \Delta^n \rightarrow \mathbb{R}$ and $\forall q \in \Delta^n$, there exists a supergradient $A(q) \in \partial f(q)$ such that $\forall p, q \in \Delta^n$, $p' \cdot \ell(q) = L(p, q) = f(q) + (p - q)' \cdot A(q)$.*

The proof is deferred to Appendix B.3.

Characterisation (2) shows that in order to check if a loss is proper one need only check the properness in each line. One could use the easy characterization of properness for differentiable binary losses ($\ell : [0, 1] \rightarrow \mathbb{R}_+^2$ is proper if and only if $\forall \eta \in [0, 1]$, $\frac{\ell(\eta)}{1-\eta} = \frac{\ell(\eta)}{\eta} \geq 0$, (Reid and Williamson, 2010)). However this needs to be checked for all lines defined by $p, q \in \partial \Delta^n$. The above result can also be seen as a generalisation of a result by Lambert (2010) who proved that properness is equivalent to the fact that the further your prediction is from reality, the larger the loss (hence the name “order sensitivity”); also confer the results on monotonicity due to Nau (1983). His result relied upon on the total order of \mathbb{R} . In the multiclass case, there does not exist such a total order. Yet, as the above result shows, one can compare two predictions if they are in the same line as the true real class probability.

Characterisation (4) is a restatement of the well known Bregman representation of proper losses: Cid-Suñer and Figueras-Vidal (2001) presented the differentiable case, and Gneiting and Raftery (2007, Theorem 3.2) the general case. This last property gives us the form of the proper losses associated with a given Bayes risk. Suppose $\underline{L} : \Delta^n \rightarrow \mathbb{R}_+$ is concave. The proper losses whose Bayes risk is equal to \underline{L} are

$$\ell : \Delta^n \ni q \mapsto \left(\underline{L}(q) + (e_i - q)' \cdot A(q) \right)_{i=1}^n \in \mathbb{R}_+^n, \forall A(q) \in \partial \underline{L}(q). \quad (3)$$

This result suggests that some information is lost by representing a proper loss via its Bayes risk (when the last is not differentiable). The next proposition elucidates this by showing that proper losses which have the same Bayes risk are equal almost everywhere.

Proposition 8 *Two proper losses $\ell^1, \ell^2 : \Delta^n \rightarrow \mathbb{R}_+^n$ have the same conditional Bayes risk function \underline{L} if and only if $\ell^1 = \ell^2$ almost everywhere. If \underline{L} is differentiable, $\ell^1 = \ell^2$ everywhere.*

Proof A concave function is differentiable almost everywhere (Hiriart-Urruty and Lemaréchal, 2001, theorem 4.2.3). Thus (3) proves that two proper losses ℓ^1 and ℓ^2 which have the same Bayes risk are equal almost everywhere. Suppose now that two proper losses are equal almost everywhere. Then their associated Bayes risks \underline{L}^1 and \underline{L}^2 are equal almost everywhere and continuous (since they are concave). If there exists p such that $\underline{L}^1(p) \neq \underline{L}^2(p)$, then since \underline{L}^1 and \underline{L}^2 are continuous, there exists $\varepsilon > 0$ such that $\forall q \in B(p, \varepsilon) \cap \Delta^n$, $\underline{L}^1(q) \neq \underline{L}^2(q)$, where $B(p, \varepsilon)$ is a ball of radius ε centred at p . Yet this contradicts the fact that \underline{L}^1 and \underline{L}^2 are equal almost everywhere. Hence the Bayes risks are equal everywhere. ■

While the previous proposition shows that losses are closely related to their Bayes risks the next proposition also shows how the continuity of a loss is related to the differentiability of its Bayes risk.

Proposition 9 *Suppose $\ell : \Delta^n \rightarrow \mathbb{R}_+^n$ is a proper loss. Then ℓ is continuous in Δ^n if and only if \underline{L} is differentiable on Δ^n ; ℓ is continuous at $p \in \Delta^n$ if and only if \underline{L} is differentiable at $p \in \Delta^n$.*

The proof of this result can be found in Appendix B.2. This type of relationship is further explored in Section 6.4 where the convexity of a composite loss is related to properties of its Bayes risk.

5. The Proper Composite Representation: Uniqueness and Existence

Many natural predictors have a range other than the simplex (for example those induced by linear functions). It is thus sometimes convenient to define a loss on some set \mathcal{Y} rather than Δ^n ; confer (Reid and Williamson, 2010). The link function explicates the result of Grünwald and Dawid (2004) that every decision problem induces a decision problem expressed in terms of proper losses; (see van Erven et al., 2011, section 6, for further explanation).

Traditionally (McCullagh and Nelder, 1989) links are defined only for binary problems (where one is using univariate probabilities). However there is scattered (but seemingly un-systematic) work on multivariate links (Glonek and McCullagh, 1995; Glonek, 1996), primarily from the perspective of probabilistic modelling (as opposed to the design of loss functions). Sometimes multivariate links are constructed from univariate links (Molenberghs and Lesaffre, 1999).

Composite losses (see the definition in §2) are a way of constructing losses on sets other than Δ^n : given a proper loss $\lambda : \Delta^n \rightarrow \mathbb{R}_+$ and an invertible link $\psi : \Delta^n \rightarrow \mathcal{Y}$, one defines $\lambda \circ \psi : \mathcal{Y} \rightarrow \mathbb{R}_+$ as $\lambda \circ \psi^{-1}$. We now consider the question: given a loss $\ell : \mathcal{Y} \rightarrow \mathbb{R}_+$, when does ℓ have a proper composite representation (whereby ℓ can be written as $\ell = \lambda \circ \psi^{-1}$), and is this representation unique? We first consider the binary case. Here the prediction space $\mathcal{Y} \subseteq \mathbb{R}$ is assumed to be either an interval or the entire real line.

5.1 The Binary Case

Our first result shows that if you can write a binary loss as a proper composite loss, the proper loss defined on the simplex is unique. Furthermore, as soon as the loss is not constant the link function is also unique. If the loss is constant on an interval, then you can choose any value of the link function on this interval which keeps the link function continuous and invertible and still obtain a composite proper loss. The proof can be found in Appendix B.4. As is common in the literature, we write the binary labels as $\{-1, +1\}$ and so the partial losses are ℓ_{-1} and ℓ_{+1} .

Proposition 10 *Suppose $\ell = \lambda \circ \psi^{-1} : \mathcal{Y} \rightarrow \mathbb{R}_+^2$ is a proper composite loss and that the proper loss λ is differentiable and the link function ψ is differentiable and invertible. Then the proper loss λ is unique. Furthermore ψ is unique if $\forall v_1, v_2 \in \mathcal{Y}$, $\exists v \in [v_1, v_2]$, $\ell_1(v) \neq 0$ or $\ell_{-1}(v) \neq 0$. If there exists $v_1, v_2 \in \mathcal{Y}$ such that $\ell_1(v) = \ell_{-1}(v) = 0 \forall v \in [v_1, v_2]$, one can choose any $\psi|_{[v_1, v_2]}$ such that ψ is differentiable, invertible and continuous in $[v_1, v_2]$ and obtain $\ell = \lambda \circ \psi^{-1}$, and ψ is uniquely defined where ℓ is invertible.*

We now determine necessary and sufficient conditions for a binary loss to be expressed as a proper composite loss. Once again, the proof is deferred to Section B.5.

Proposition 11 *Suppose $\ell : \mathcal{Y} \rightarrow \mathbb{R}_+^2$ is a differentiable binary loss such that $\forall v \in \mathcal{Y}$, $\ell_{-1}(v) \neq 0$ or $\ell_1(v) \neq 0$. Then ℓ can be expressed as a proper composite loss if and only if the following three conditions hold:*

1. ℓ_1 is decreasing (increasing);
2. ℓ_{-1} is increasing (decreasing); and
3. $f: \mathcal{Y} \ni v \mapsto \frac{\ell_1(v)}{\ell_{-1}(v)}$ is strictly increasing (decreasing) and continuous.

Observe that the last condition is always satisfied if both ℓ_1 and ℓ_{-1} are convex.

5.2 Binary Margin Losses

Suppose $\varphi: \mathbb{R} \rightarrow \mathbb{R}_+$ is a function. The loss $\ell_\varphi: \mathcal{Y} \ni v \mapsto (\ell_{-1}(v), \ell_1(v))' = (\varphi(-v), \varphi(v))' \in \mathbb{R}_+^2$ is called a binary *margin loss*. Binary margin losses are often used for classification problems. We will now show how the previous proposition applies to them.

Corollary 12 Suppose $\varphi: \mathbb{R} \rightarrow \mathbb{R}_+$ is differentiable and $\forall v \in \mathbb{R}, \varphi'(v) \neq 0$ or $\varphi'(-v) \neq 0$. Then ℓ_φ can be expressed as a proper composite loss if and only if $f: \mathbb{R} \ni v \mapsto -\frac{\varphi'(v)}{\varphi'(-v)}$ is strictly monotonic continuous and φ is monotonic.

If φ is convex or concave then f defined above is monotonic. However not all binary margin losses are composite proper losses. One can even build a smooth margin loss which cannot be expressed as a proper composite loss. Consider $\varphi(x) = \frac{1 - \arctan(\frac{x-1}{x})}{x}$. Then $f(v) = \frac{\varphi'(v)}{\varphi'(-v)} = \frac{2-2x+2}{x^2-2x+2}$ which is not invertible. This loss is illustrated in Figure 5, after some additional concepts are introduced.

5.3 The Multiclass Case

Uniqueness of the composite representation remains straightforward in the multiclass case.

Proposition 13 Suppose a loss $\ell: \mathcal{Y} \rightarrow \mathbb{R}_+^n$ has two proper composite representations $\ell = \lambda \circ \psi^{-1} = \mu \circ \phi^{-1}$ where λ and μ are proper losses with corresponding Bayes risks Δ and \underline{M} respectively, and ψ and ϕ are continuous invertible link-functions. Then $\lambda = \mu$ almost everywhere where.

If ℓ is continuous and has a composite representation, then the proper loss (in the decomposition) is unique ($\lambda = \mu$ everywhere).

If ℓ is invertible and has a composite representation, then the representation is unique.

Proof $\Delta(p) = \inf_q p' \cdot \lambda(q) = \inf_q p' \cdot \ell(\psi(q)) = \inf_v L(p, v)$ (since ψ is invertible)
 $= \inf_v L(p, v) = \inf_v L(p, \phi(q)) = \underline{M}(p)$.

Then λ and μ are two proper losses which have the same Bayes risk, so these two losses are equal almost everywhere.

If moreover ℓ is continuous, $\lambda = \ell \circ \psi$ and $\mu = \ell \circ \phi$ are continuous. So $\lambda = \mu$ everywhere. If moreover ℓ is invertible, $\psi = \lambda \circ \ell^{-1}$ and $\phi = \mu \circ \ell^{-1}$. So ψ and ϕ are also equal almost everywhere and as they are continuous, they are equal everywhere. So $\lambda = \ell \circ \psi = \ell \circ \phi = \mu$. ■

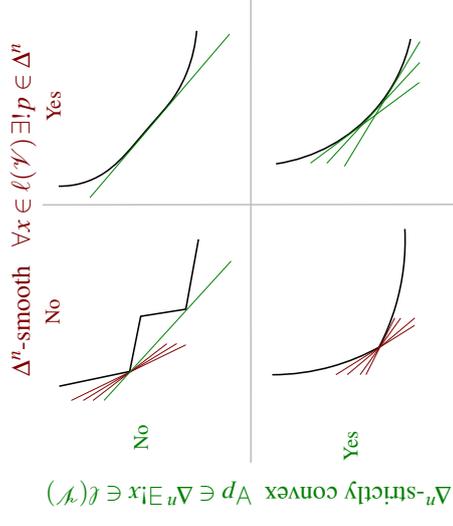

Figure 3: Illustration of Δ^n -smoothness and Δ^n -strict convexity. The hyperplanes witness the possession or non-possession of the respective properties.

Characterising the existence of a composite representation is more complex in the multiclass case. We need to introduce some definitions: We make use of a set of *hyperplanes* for $p \in \Delta^n$ and $\beta \in \mathbb{R}$,

$$h_p^\beta := \{x \in \mathbb{R}^n; x' \cdot p = \beta\}.$$

A hyperplane h_p^β *supports* a set A at $x \in A$ when $x \in h_p^\beta$ and for all $a \in A$, $a' \cdot p \geq \beta$ or for all $a \in A$, $a' \cdot p \leq \beta$. Given a loss $\ell: \mathcal{Y} \rightarrow \mathbb{R}_+^n$, the *loss image* $\ell(\mathcal{Y}) := \{\ell(v); v \in \mathcal{Y}\}$.

Definition 14 Let $\mathfrak{S}(p, x) := \{\ell(\mathcal{Y}) \text{ is supported by } h_p^\beta \text{ at } x \text{ for some } \beta \in \mathbb{R}\}$.

1. A loss image $\ell(\mathcal{Y})$ is Δ^n -strictly convex if for all $p \in \Delta^n$ there exists a unique $x \in \ell(\mathcal{Y})$ such that $\mathfrak{S}(p, x)$.
2. A loss image $\ell(\mathcal{Y})$ is Δ^n -smooth if for all $x \in \ell(\mathcal{Y})$ there exists a unique $p \in \Delta^n$ such that $\mathfrak{S}(p, x)$.

This definition is illustrated in Figure 3. Dropping the uniqueness requirement in these definitions would drastically change things: since we will require ℓ is continuous, $\ell(\mathcal{Y})$ is always closed. Since by assumption $\ell(\mathcal{Y}) \subset [0, \infty)^n$ every such loss satisfies the weakened version of Δ^n -strict convexity: for all $p \in \Delta^n$ there exists $x \in \ell(\mathcal{Y})$ such that $\mathfrak{S}(p, x)$. The weakened version of Δ^n -smoothness requires that for all $x \in \ell(\mathcal{Y})$ there exists $p \in \Delta^n$ such that $\mathfrak{S}(p, x)$ is

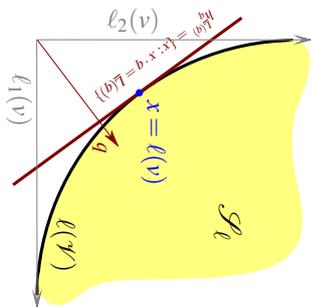

Figure 4: Illustration of geometry of loss functions. The locus of the vector valued loss ℓ is plotted as v varies over \mathcal{Y} . The superprediction set \mathcal{S}_ℓ is the region to the “north-east” of the loss image $\ell(\mathcal{Y})$. The hyperplane $h_q^{\ell(v)}$ has normal vector q and offset $\underline{L}(q)$. It supports \mathcal{S}_ℓ at the point $x = \ell(v)$ indicating the Bayes risk is achieved at v for the true probability q .

a convexity-like requirement. (Confer the following result (Schneider, 1993, Theorem 1.3.3): *Suppose A is closed set such that $A \neq \emptyset$ and through each boundary point of A there is a support plane to A ; then A is convex*)

The name “ Δ^n -strictly convex” is justified by the observation that replacing Δ^n by $B_{\mathbb{R}^n}$ (the ℓ_1^n unit ball) gives a natural definition of strict convexity of a general set in \mathbb{R}^n . We also observe that both Δ^n -strict convexity and Δ^n -smoothness are closely related to the curvature of the Bayes risk \underline{L} by way of the fact that the support function of the set $\ell(\mathcal{Y})$ (restricted to Δ^n) is the Bayes risk; confer (Williamson, 2014). Specifically, Δ^n -strict convexity is equivalent to the Hessian $H\underline{L}(p)$ being non-singular for all $p \in \Delta^n$ while Δ^n -smoothness is implied whenever $\underline{L}(p)$ is continuously differentiable.

Suppose $A, B \subset \mathbb{R}^n$. Then the *Minkowski sum* $A + B := \{a + b : a \in A, b \in B\}$.

Definition 15 Given a loss $\ell : \mathcal{Y} \rightarrow \mathbb{R}_+^n$, we denote by

$$\mathcal{S}_\ell := \ell(\mathcal{Y}) + [0, \infty)^n = \{x \in \mathbb{R}_+^n : \exists v \in \mathcal{Y}, \forall i \in [n], x_i \geq \ell_i(v)\}$$

the *superprediction set* of ℓ (Kahnishkan and Vyugin, 2008).

One can characterise the existence of proper composite representations in terms of properties the superprediction set. We start with an old result; confer (Dawid, 2007).

Proposition 16 Every continuous proper loss has a convex superprediction set.

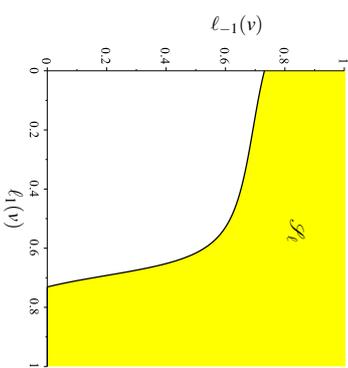

Figure 5: Superprediction set of a binary margin loss which is not a composite proper loss. See text following Corollary 12.

Proof Suppose ℓ is proper but \mathcal{S}_ℓ is not convex. Then there exists $x_0 \in \ell(\Delta^n)$ such that $\ell(\Delta^n)$ is not supported at x_0 by any hyperplane h_p with normal vector $p \in \Delta^n$. Let $q_0 \in \Delta^n$ be such that $\ell(q_0) = x_0$. Then there is a hyperplane h_{q_0} (with normal q_0) that supports $\ell(\Delta^n)$ at some $x_1 \neq x_0$. Thus $q_0^\top \ell(q)$ is minimised at q_1 and not minimised at q_0 and thus ℓ is can not be proper—a contradiction. ■

The geometry of continuous proper losses is illustrated (for $n = 2$) in Figure 4. The superprediction set of the margin loss discussed following Corollary 12 is not convex as can be seen in Figure 5.

Continuous proper losses are quasiconvex, canonically so, as the following result shows.

Proposition 17 Suppose $\ell : \Delta^n \rightarrow \mathbb{R}_+^n$ is a continuous proper loss. Then its superprediction set \mathcal{S}_ℓ is convex and, for all $p \in \Delta^n$, the function $f_p(q) := L(p, q) := p \cdot \ell(q)$ is quasi-convex. Conversely, suppose $f_p(q) := p \cdot \ell(q)$ is quasi-convex in q for all $p \in \Delta^n$. Then there is a unique convex set S such that $\mathcal{S}_\ell = S$ and ℓ is necessarily proper.

The proof is in Appendix B.6. Some (but not all) proper losses are in addition convex; this is studied in more detail in Section 6.4 below.

Working with \mathcal{S}_ℓ is problematic for characterising the existence of strictly proper composite representations (essentially because while for a strictly proper loss ℓ , $\ell(\Delta^n)$ is Δ^n -strictly convex, \mathcal{S}_ℓ is not strictly convex (because of the flat spots at the extremes—bounded losses have superprediction sets with flats parallel to the axes by construction)¹. We will thus characterise proper and strictly proper composite representations in terms of properties of $\ell(\mathcal{Y})$ rather than \mathcal{S}_ℓ .

¹ It turns out that by starting with the superprediction set, and defining the loss in terms of the (super-) gradient of the (concave) support function of the superprediction set, these difficulties can be avoided (Williamson, 2014).

Proposition 18 Suppose $\ell: \mathcal{Y} \rightarrow \mathbb{R}_+^n$ is a continuous loss. ℓ has a proper composite representation if and only if $\ell(\mathcal{Y})$ is Δ^n -smooth. Additionally, ℓ is strictly proper composite if and only if $\ell(\mathcal{Y})$ is also Δ^n -strictly convex.

The proof is in Section B.7.

6. Implications: Mixability, Admissibility, Minimality and Convexity

We now consider some of the implications that the proper composite representation has for several previously studied properties of loss functions.

6.1 Mixability

Mixability is a fundamental property of a loss function in the study of “prediction with expert advice.” In this setting learning takes place in fixed number of sequential rounds. Each round a learner is presented with predictions some finite number of experts. The learner then makes a prediction and the outcome for that round is revealed. The learner’s and experts’ predictions are assessed using some predefined loss function and the aim of the learner is to incur a total loss not much worse than the best expert – *i.e.*, the one with the smallest total loss. The difference between the learner’s total loss and that of the best expert is known as the *regret*. In his seminal work, [Vovk \(1995\)](#) showed that no matter how the experts behave, there exists a strategy for the learner (called the “aggregating algorithm”) that guarantees a regret bounded by $\frac{\ln K}{\eta}$ where K is the number of experts and η is a positive number called the *mixability constant* (defined below) that only depends on the loss. Losses for which this constant is defined are called *mixable*. Furthermore, this constant *characterises* when such a constant regret bound is possible. That is, if a loss is not mixable then there is no strategy the learner can use to guarantee a constant regret bound.

Formally, mixability of a loss ℓ is defined in terms of the convexity of a transformation of the loss’s superprediction set \mathcal{S}_ℓ (see Definition 15). We say that for $\eta > 0$ the η -*exponentiated superprediction set* is the image of $\mathcal{S}_\ell \subset \mathbb{R}^n$ under the mapping $E_\eta: \mathbb{R}^n \rightarrow \mathbb{R}_+^n$ defined by $E_\eta(x) := (e^{-\eta x_i})_{i=1}^n$. A loss ℓ is said to be η -*mixable* if its η -exponentiated superprediction set is convex. The *mixability* of ℓ is the smallest value of η for which ℓ is η -mixable. For further details, the reader is referred to papers by [Vovk \(1995\)](#), [Kalmishkan and Vyugin \(2008\)](#); [Vovk and Zhdanov \(2009\)](#).

Recently, [van Erven et al. \(2012b\)](#)² have shown that the mixability of a loss is related to the curvature of the loss’s Bayes risk relative to the curvature of the Bayes risk for log loss. The main result here builds on some of the insights from that work and shows that mixable losses (under mild conditions) always have proper composite representations.

For $\alpha \in (0, 1)$ we write $\tilde{\alpha} := 1 - \alpha$. For $x, y \in \mathbb{R}^n$, $x \leq y \Leftrightarrow (x_i \leq y_i, \forall i \in [n])$. We now give a necessary condition for mixability.

2. An extension of this notion of mixability can be related to a natural convex duality ([Reid et al., 2015](#)).

Lemma 19 Suppose $\ell: \mathcal{Y} \rightarrow \mathbb{R}_+^n$, $x_0 = \ell(v_0)$, $x_1 = \ell(v_1)$ with $x_0 \neq x_1$. For $\alpha \in (0, 1)$, define $x_\alpha := \tilde{\alpha}x_0 + \alpha x_1$ and $v_\alpha = \tilde{\alpha}v_0 + \alpha v_1$. If for some α

$$x_\alpha \leq \ell(v_\alpha) \quad (4)$$

then ℓ is not mixable.

Proof Pick some $\eta > 0$. Let $f_\eta(a) = e^{-\eta a}$ for $a \in \mathbb{R}$ so that for $x \in \mathbb{R}^n$ we have $E_\eta(x) = (f_\eta(x_i))_{i=1}^n$. Observe that the function f_η is strictly monotone decreasing ($a < b \Rightarrow f_\eta(a) > f_\eta(b)$) and strictly convex ($\tilde{\alpha}f_\eta(a) + \alpha f_\eta(b) > f_\eta(\tilde{\alpha}a + \alpha b)$). For $i \in [n]$ set $x_{0,i} = \ell_i(v_0)$ and $x_{1,i} = \ell_i(v_1)$. By assumption, we have

$$\tilde{\alpha}x_{0,i} + \alpha x_{1,i} \leq \ell_i(\tilde{\alpha}v_0 + \alpha v_1), \quad \forall i \in [n],$$

which by strict monotonicity

$$\Rightarrow f_\eta(\tilde{\alpha}x_{0,i} + \alpha x_{1,i}) \geq f_\eta(\ell_i(\tilde{\alpha}v_0 + \alpha v_1)), \quad \forall i \in [n],$$

and hence by strict convexity

$$\begin{aligned} &\Rightarrow \tilde{\alpha}f_\eta(x_{0,i}) + \alpha f_\eta(x_{1,i}) > f_\eta(\ell_i(\tilde{\alpha}v_0 + \alpha v_1)), \quad \forall i \in [n] \\ &\Leftrightarrow \tilde{\alpha}E_\eta(\ell(v_0)) + \alpha E_\eta(\ell(v_1)) > E_\eta(\ell(\tilde{\alpha}v_0 + \alpha v_1)) \end{aligned}$$

and thus ℓ is not mixable since we have witnessed the non-convexity of the η -exponentiated superprediction set for ℓ . ■

[van Erven et al. \(2012b\)](#) showed that (under some mild conditions) a proper loss λ and the composite loss λ^ψ obtained via the reference link $\tilde{\psi}$ (see Proposition 5) share the same mixability constant. We now show that mixable losses always have strictly proper composite representations.

Proposition 20 Suppose $\ell: \mathcal{Y} \rightarrow \mathbb{R}_+^n$ is a Δ^n -smooth continuous loss. If ℓ is mixable then ℓ has a strictly proper composite representation.

Proof We prove the contrapositive. Lack of a strictly proper composite representation is equivalent then to $\ell(\mathcal{Y})$ being not Δ^n -strictly convex. Suppose then that $\ell(\mathcal{Y})$ is indeed not Δ^n -strictly convex. There are two possibilities to consider:

1. There exists $p \in \Delta^n$ such that there is no $x \in \ell(\mathcal{Y})$ such that $\ell(\mathcal{Y})$ is supported by h_p^β at x for some $\beta \in \mathbb{R}$; or
2. There exists $p \in \Delta^n$ such that there exists $v_0, v_1 \in \mathcal{Y}$, $v_0 \neq v_1$, $x_0 = \ell(v_0)$, $x_1 = \ell(v_1)$, $\exists \beta \in \mathbb{R}$, h_p^β supports $\ell(\mathcal{Y})$ at x_1 and x_2 .

Since $\ell(\mathcal{Y}) \subset [0, \infty)^n$ and ℓ is continuous (and hence $\ell(\mathcal{Y})$ is closed), for all $p \in \Delta^n$ there always exists $x \in \ell(\mathcal{Y})$ such that h_p^β supports $\ell(\mathcal{Y})$ at x . Thus under the hypothesis, case 2 must always hold. Then by continuity of ℓ and the definition of a supporting hyperplane, there exists $\alpha \in (0, 1)$ such that (4) holds and so ℓ is not mixable. ■

6.2 Admissibility

The above results are strongly related to the classical notion of admissibility (Ferguson, 1967; Chernoff and Moses, 1986; Kiefer, 1987), which is particularly simple in our situation. We adapt the terminology of Ferguson (1967) to be consistent with elsewhere in the present paper:

Definition 21 Suppose $\ell : \mathcal{Y} \rightarrow \mathbb{R}_+^n$ is a loss. A prediction $v_1 \in \mathcal{Y}$ is better than $v_2 \in \mathcal{Y}$ if $\ell(v_1) \leq \ell(v_2)$ and for some $i \in [n]$, $\ell_i(v_1) < \ell_i(v_2)$. A prediction v_1 is **equivalent** to v_2 if $\ell(v_1) = \ell(v_2)$. A prediction $v \in \mathcal{Y}$ is **admissible** if there is no prediction better than v . If a prediction $v \in \mathcal{Y}$ is the Bayes-optimal for some distribution p , that is for all $v \in \mathcal{Y}$ there exists $p \in \Delta^n$ such that $v \in \arg\min_{v \in \mathcal{Y}} p' \cdot \ell(v)$, then we say v is **strongly admissible**.

Ferguson (1967, Theorem 1, page 60) states the following (which we present for invertible losses, so that $\ell(v_1) = \ell(v_2) \Rightarrow v_1 = v_2$).

Proposition 22 Suppose $\ell : \mathcal{Y} \rightarrow \mathbb{R}_+^n$ is invertible and $p \in \Delta^n$. If $v \in \mathcal{Y}$ is the unique prediction such that $L(p, v) = L(p)$, then v is admissible.

Proposition 18 then implies the following.

Corollary 23 Suppose $\ell : \mathcal{Y} \rightarrow \mathbb{R}_+^n$ is continuous and invertible. If ℓ has a strictly proper composite representation then all $v \in \mathcal{Y}$ are admissible and strongly admissible.

Proof If ℓ has a strictly proper composite representation, then $\ell(\mathcal{Y})$ is Δ^n -strictly convex and thus for all $p \in \Delta^n$ there exists a unique $x \in \ell(\mathcal{Y})$ such that $h_p^{L(p)}$ supports $\ell(\mathcal{Y})$ at x . Thus by Proposition 22, v such that $\ell(v) = x$ is an admissible prediction. Furthermore, since $\ell(\mathcal{Y})$ is Δ^n -smooth, this previous argument actually holds for all $v \in \mathcal{Y}$ and thus ℓ is admissible. Furthermore, it follows directly from the definition of Δ^n -smoothness that all v are strongly admissible. ■

Proposition 24 If $\ell : \mathcal{Y} \rightarrow \mathbb{R}_+^n$ is continuous and has a proper composite representation then every prediction is admissible.

Proof We will prove the contrapositive: Suppose a continuous loss $\ell : \mathcal{Y} \rightarrow \mathbb{R}_+^n$ is such that there exist $x_0, x_1 \in \ell(\mathcal{Y})$ with x_1 better than x_0 . Then ℓ can not have a proper composite representation. Observe that “ x_1 is better than x_0 ” is equivalent to

$$\begin{aligned} \forall i \in [n], \quad \ell_i'(x_0 - x_1) &\geq 0 \\ \exists i \in [n], \quad \ell_i'(x_0 - x_1) &> 0. \end{aligned}$$

Consider two mutually exclusive and exhaustive cases:

1. $\ell_i'(x_0 - x_1) > 0, \forall i \in [n]$. Then for all $p \in \Delta^n$, $p' \cdot (x_0 - x_1) > 0 \Rightarrow p' \cdot x_0 > p' \cdot x_1$ and thus $\ell(\mathcal{Y})$ can not be supported at x_0 by h_p^β for any $p \in \Delta^n$ and thus $\ell(\mathcal{Y})$ is not Δ^n -smooth.
2. Alternatively suppose

$$\ell_i'(x_0 - x_1) \begin{cases} = 0, & i \in I \subset [n] \\ > 0, & i \in [n] \setminus I \end{cases}$$
 with $1 \leq |I| < n$. Consider the two mutually exclusive subcases over $p \in \Delta^n$:

- (a) $p_i > 0$ for some $i \in [n] \setminus I$. Then $p' \cdot (x_0 - x_1) > 0$ and $\ell(\mathcal{Y})$ can not be supported at x_0 by h_p^β for any $\beta \in \mathbb{R}$.
- (b) $p_i = 0$ for all $i \in [n] \setminus I$. Then $p' \cdot (x_0 - x_1) = 0$ in which case $\ell(\mathcal{Y})$ is supported by h_p^β for some β at both x_0 and x_1 .

In either of these subcases, the Δ^n -smoothness condition is violated.

Thus in both cases we have shown $\ell(\mathcal{Y})$ can not be Δ^n -smooth and by Proposition 18 can not have a proper composite representation. ■

As can be seen in Figure 6, there can be no hope of a converse: mere admissibility of every prediction $x \in \ell(\mathcal{Y})$ can not imply that ℓ has a proper composite representation.

However strong admissibility of every prediction implies $\ell(\mathcal{Y})$ is Δ^n -smooth and so if ℓ is continuous, strong admissibility of every prediction implies (via Proposition 18) that ℓ has a proper composite representation.

The relationship between strict convexity of \mathcal{S}_ℓ and admissibility is not new (Brown, 1981); but the connection with our characterisation of composite proper losses is new.

We conclude that if ℓ is continuous and invertible and we desire that all predictions are admissible, then it suffices to only consider losses with a proper composite representation. Continuous invertible losses that do not have a proper composite representation are “redundant” in the sense that there are guaranteed to exist predictions that are not Bayes optimal for any true distribution.

6.3 Minimality

We say a loss $\ell : \mathcal{Y} \rightarrow \mathbb{R}_+^n$ is **minimax** if its conditional risk $L(p, v) = p' \cdot \ell(v)$ satisfies

$$\max_{p \in \Delta^n} \min_{v \in \mathcal{Y}} L(p, v) = \min_{v \in \mathcal{Y}} \max_{p \in \Delta^n} L(p, v). \quad (5)$$

Minimality of proper losses has been studied in a very general setting by Grünwald and Dawid (2004) who showed the connection between robust Bayes procedures and maximum entropy; confer classical results presented, for example, by Ferguson (1967). In this brief subsection we point out some simple implications of our earlier results. Setting $\mathcal{Y} = \Delta^n$, observe that for all proper losses $\lambda : \Delta^n \rightarrow \mathbb{R}_+^n$, $p \mapsto \Lambda(p, q) = p' \cdot \lambda(q)$ is linear for all $q \in \Delta^n$, and if λ is also continuous, by Proposition 17 $q \mapsto \Lambda(p, q)$ is quasi-convex for all $p \in \Delta^n$. It thus follows from the minimax theorem of Sion (1958) that all continuous proper losses satisfy

$$\max_{p \in \Delta^n} \min_{q \in \Delta^n} \Lambda(p, q) = \min_{q \in \Delta^n} \max_{p \in \Delta^n} \Lambda(p, q) \quad (6)$$

and are thus minimax.

Suppose $\ell = \lambda \circ \psi^{-1} : \mathcal{Y} \rightarrow \mathbb{R}_+^n$ is a proper composite loss, with conditional risk $L(p, v) = \Lambda(p, \psi^{-1}(v))$. Since ψ^{-1} is invertible,

$$\max_{p \in \Delta^n} \min_{v \in \mathcal{Y}} L(p, v) = \max_{p \in \Delta^n} \min_{q \in \Delta^n} \Lambda(p, q), \quad (7)$$

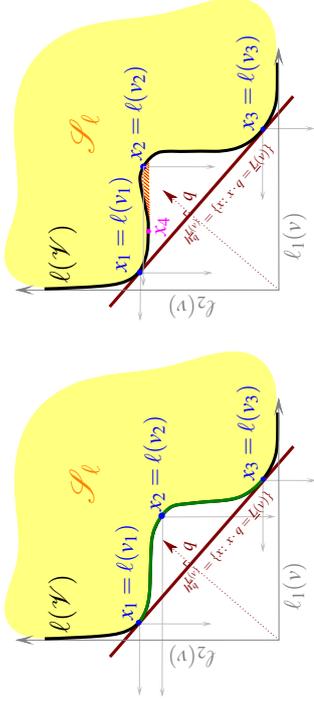

Figure 6: *Left:* Illustration of a continuous loss ℓ (which can be presumed invertible) with a non-convex superprediction set. For true probability q , v_1 and v_2 both are Bayes optimal since $q \cdot \ell(v_1) = q \cdot \ell(v_2) = \underline{\ell}(v)$; thus $h_{\underline{\ell}(v)}^{\Delta^N} = h_{\underline{\ell}(v_2)}^{\Delta^N}$ supports $\ell(\mathcal{Y})$ at both x_1 and x_3 . The point x_2 is never a member of a supporting hyperplane of $\ell(\mathcal{Y})$ and is thus never the Bayes optimal prediction for any q and so not strongly admissible. The green line indicates the set of predictions that are not strongly admissible—they will never be Bayes optimal for any $q \in \Delta^N$. Such predictions are, however, admissible, as can be seen by the grey translated negative orthants centred at x_1 , x_2 and x_3 (each orthant does not contain any other predictions “better than” them). All the other predictions whose image lies in the black line are both admissible and strongly admissible. The loss image $\ell(\mathcal{Y})$ is not Δ^N -smooth because there exist no $p \in \Delta^N$ that supports $\ell(\mathcal{Y})$ at x_2 . Hence by Proposition 18, ℓ can not have a proper composite representation. *Right:* Similar to the figure on the left, except there are now some predictions, such as x_2 , which are not admissible: x_4 is *better than* x_2 as can be seen since x_4 is contained in the interior of the shifted negative orthant centred at x_2 . Note in this case the boundary of the super-prediction set \mathcal{S}_ℓ does not equal $\ell(\mathcal{Y})$ (see the part of \mathcal{S}_ℓ cross-hatched in red). This loss can not have a proper composite representation by Proposition 24.

where by the relationship between q and v , $\arg \min_{v \in \mathcal{Y}} L(p, v) = \psi \left(\arg \min_{q \in \Delta^N} \Lambda(p, q) \right)$. Similarly,

$$\min_{v \in \mathcal{Y}} \max_{p \in \Delta^N} L(p, v) = \min_{q \in \Delta^N} \max_{p \in \Delta^N} \Lambda(p, q). \quad (8)$$

Since λ is proper, Λ satisfies (6) which combined with (7) and (8) proves the following.

Proposition 25 *Every continuous proper composite loss is minimax.*

Note that this alone does not imply that all continuous proper composite losses are quasi-convex, which would follow if ψ mapped convex sets to convex sets; however this can not be true in

general in \mathbb{R}^n because convexity preserving mappings must be affine (Webster, 1994, Theorem 7.3.7); confer (Meyer and Kay, 1973). Recall Proposition 17 showed the quasi-convexity of all proper losses.

Proposition 25 means that the use of the classical minimax theorem by Abernethy et al. (2009) in order to prove their main result for *convex* losses can be foregone; their result also holds for arbitrary continuous proper composite losses.

6.4 Convexity

In order to computationally optimise models with respect to a loss function it is convenient if the loss is convex. In this subsection we develop conditions for the convexity of multiclass composite proper losses. We assume throughout this section that the loss and link are twice differentiable. We start by proving some identities for their first and second derivatives.

6.4.1 TECHNICAL PRELIMINARIES

Suppose $\ell = \lambda \circ \psi^{-1}$ is composed of the proper loss $\lambda: \Delta^n \rightarrow \mathbb{R}_+^+$ and the inverse of the link $\psi: \Delta^n \rightarrow \mathcal{Y}$. In order to simplify the calculation of derivatives for the function $\ell: \mathcal{Y} \rightarrow \mathbb{R}_+^+$ we will assume the set \mathcal{Y} is a flat, $(n-1)$ -dimensional, convex subset of \mathbb{R}_+^+ . We do so since if \mathcal{Y} were some arbitrary manifold the extra definitions required to make sense of convexity (e.g., in terms of geodesics) and derivatives on manifolds would obscure the gist of the results below. Furthermore, little is lost either practically or theoretically by assuming a simple \mathcal{Y} . In practice, predictions are usually vectors in \mathbb{R}_+^+ , and in theory one could always choose a parametrisation of \mathcal{Y} in terms of some simpler space \mathcal{U} and redefine the link via composition with that parametrisation. Alternatively, since links must be invertible, a composite loss could be defined by a choice of loss and choice of *inverse link* $\psi^{-1}: \mathcal{Y} \rightarrow \Delta^n$ for a \mathcal{Y} assumed to be flat, etc.

Recalling the convention that $\bar{n} := n-1$, let $v \in \mathcal{Y}$ fixed but arbitrary with corresponding $\bar{p} = \psi^{-1}(v)$ where $\bar{\psi}(\bar{p}) := \psi(\bar{p}_1, \dots, \bar{p}_{\bar{n}}, p_n)$ with $p_n := \sum_{i=1}^{\bar{n}} \bar{p}_i$ is the induced function from $\bar{\Delta}^{\bar{n}}$ to \mathcal{Y} . By the chain rule and the inverse function theorem, the derivatives for each of the partial losses ℓ_i satisfy

$$D\ell_i(v) = D[\lambda_i(\bar{\psi}^{-1}(v))] = D\lambda_i(\bar{p}) \cdot [D\bar{\psi}(\bar{p})]^{-1}. \quad (9)$$

We use e_i^j to denote the i th n -dimensional unit vector, $e_i^i = (0, \dots, 0, 1, 0, \dots, 0)^T$ when $i \in [n]$, and define $e_i^i = 0_n$ when $i > n$. We can now write $D\lambda_i(\bar{p})$ in terms of the $n \times \bar{n}$ matrix $D\bar{\lambda}(\bar{p})$ using $D\lambda_i(\bar{p}) = (e_i^i)^T \cdot D\lambda(\bar{p}) = (D\bar{\lambda}(\bar{p})^T \cdot D\lambda_n(\bar{p}))^T$, where $\bar{\lambda}(\bar{p}) = (\lambda_1(\bar{p}), \dots, \lambda_{\bar{n}}(\bar{p}))^T$, and so

$$D\lambda_i(\bar{p}) = (e_i^i)^T \cdot D\lambda(\bar{p}) = (e_i^i)^T \cdot \begin{pmatrix} D\bar{\lambda}(\bar{p}) \\ D\lambda_n(\bar{p}) \end{pmatrix}. \quad (10)$$

Furthermore, since λ is proper, Lemma 6 of (van Erven et al., 2012b) means we can use the relationship between a proper loss and its projected Bayes risk $\bar{L} := \underline{L} \circ \Pi_{\Delta}^{-1}$ to write

$$D\bar{\lambda}(\bar{p}) = W(\bar{p}) \cdot H\bar{L}(\bar{p}) \quad (11)$$

$$D\lambda_n(\bar{p}) = y(\bar{p})^T \cdot D\bar{\lambda}(\bar{p}) \quad (12)$$

where $W(\tilde{\beta}) := I_n - \mathbb{1}_n \cdot \tilde{p}'$ and where $\gamma(\tilde{\beta}) := -\tilde{\beta}'/p_n(\tilde{\beta})$ and $p_n(\tilde{\beta}) := 1 - \sum_{i \in [n]} p_i$. Thus, combining (10–12) we have for all $i \in [n]$

$$\begin{aligned} D\lambda_i(\tilde{\beta}) &= (e_i^i)' \cdot W(\tilde{\beta}) \cdot H\tilde{L}(\tilde{\beta}) \\ &= ((e_i^i)' - (e_i^i)' \cdot \mathbb{1}_n \cdot \tilde{p}') \cdot H\tilde{L}(\tilde{\beta}) \\ &= (e_i^i - \tilde{p})' \cdot H\tilde{L}(\tilde{\beta}) \end{aligned} \quad (13)$$

and

$$\begin{aligned} D\lambda_n(\tilde{\beta}) &= \gamma(\tilde{\beta})' \cdot W(\tilde{\beta}) \cdot H\tilde{L}(\tilde{\beta}) \\ &= \frac{-1}{p_n(\tilde{\beta})} \tilde{p}' \cdot (I_n - \mathbb{1}_n \cdot \tilde{p}') \cdot H\tilde{L}(\tilde{\beta}) \\ &= \frac{-1}{p_n(\tilde{\beta})} (\tilde{p}' - (1 - p_n(\tilde{\beta}))\tilde{p}') \cdot H\tilde{L}(\tilde{\beta}) \\ &= -\tilde{p}' \cdot H\tilde{L}(\tilde{\beta}). \end{aligned} \quad (14)$$

Finally, noting that by definition $e_i^i = 0$, (14) and (13) can be merged and combined with (9) to obtain the following proposition.

Proposition 26 For all $i \in [n]$, $\tilde{p} \in \tilde{\Delta}^n$ (the relative interior of $\tilde{\Delta}^n$), and $v = \tilde{\psi}(\tilde{\beta})$,

$$D\ell_i(v) = -(e_i^i - \tilde{p})' \cdot \kappa(\tilde{\beta}) \quad (15)$$

where

$$\kappa(\tilde{\beta}) := -H\tilde{L}(\tilde{\beta}) \cdot [D\tilde{\psi}(\tilde{\beta})]^{-1}. \quad (16)$$

Using the definition of the Hessian $H\ell_i = D([D\ell_i]')$ and the product rule (31) gives

$$\begin{aligned} D[D\ell_i(v)] &= D_{v,i} \left[\underbrace{[D\tilde{\psi}(\tilde{\beta})]^{-1}}_{f(\tilde{\beta})} \cdot \underbrace{H\tilde{L}(\tilde{\beta}) \cdot (e_i^i - \tilde{p})}_{\kappa(\tilde{\beta})} \right] \\ &= \left((e_i^i - \tilde{p})' \otimes I_n \right) \cdot D_{v,i} [f(\tilde{\beta})] + (I_1 \otimes f(\tilde{\beta})) \cdot D(e_i^i - \tilde{\psi}^{-1}(v)) \\ &= \left((e_i^i - \tilde{p})' \otimes I_n \right) \cdot D_{v,i} \left[H\tilde{L}(\tilde{\beta}) \cdot [D\tilde{\psi}(\tilde{\beta})]^{-1} \right] - \left([D\tilde{\psi}(\tilde{\beta})]^{-1} \right)' \cdot H\tilde{L}(\tilde{\beta}) \cdot [D\tilde{\psi}(\tilde{\beta})]^{-1}, \end{aligned}$$

where $D_{v,i}$ is used to indicate that the derivative is with respect to v even when the terms inside the derivative are expressed using $\tilde{\beta}$. We have now established the following proposition.

Proposition 27 For all $i \in [n]$, $\tilde{p} \in \tilde{\Delta}^n$, and $v = \tilde{\psi}(\tilde{\beta})$,

$$H\ell_i(v) = -\left((e_i^i - \tilde{p})' \otimes I_n \right) \cdot D[\kappa(\tilde{\psi}^{-1}(v))] + (\kappa(\tilde{\beta})) \cdot [D\tilde{\psi}(\tilde{\beta})]^{-1},$$

where $\kappa(\tilde{\beta})$ is defined in (16).

The product $\kappa(\tilde{\beta}) := -H\tilde{L}(\tilde{\beta}) [D\tilde{\psi}(\tilde{\beta})]^{-1}$ that appears in both propositions above can be interpreted as the curvature of the Bayes risk function L relative to the rate of change of the link function $\tilde{\psi}$. When the link function is the identity $\tilde{\psi}(\tilde{\beta}) = \tilde{\beta}$ (i.e. when we have a proper loss directly) the expressions for the derivative and Hessian of each ℓ_i simplify to

$$\begin{aligned} D\ell_i(\tilde{\beta}) &= (e_i^i - \tilde{p})' \cdot H\tilde{L}(\tilde{\beta}) \\ H\ell_i(\tilde{\beta}) &= \left((e_i^i - \tilde{p})' \otimes I_n \right) \cdot D[H\tilde{L}(\tilde{\beta})] - H\tilde{L}(\tilde{\beta})'. \end{aligned} \quad (17) \quad (18)$$

The form of κ as the product of $H\tilde{L}$ and $D\tilde{\psi}$ suggests another simplification.

Definition 28 The canonical link function for a loss λ with Bayes risk \underline{L} is defined via

$$\tilde{\psi}_\lambda(\tilde{\beta}) := -D\underline{L}(\tilde{\beta})'. \quad (19)$$

We will show in section 8.1 that (19) is indeed guaranteed to be a legitimate link. The term κ simplifies to $\kappa(\tilde{\beta}) = I_n$ since $D\tilde{\psi}(\tilde{\beta}) = -D(D\underline{L}(\tilde{\beta})') = -H\underline{L}(\tilde{\beta})$. For this choice of link function, the first and second derivatives become considerably simpler.

Proposition 29 If $\lambda: \Delta^n \rightarrow \mathbb{R}_+^n$ is a proper loss and $\tilde{\psi}_\lambda$ is its associated canonical link then, for all $i \in [n]$, $\tilde{p} \in \tilde{\Delta}^n$, and $v = \tilde{\psi}_\lambda(\tilde{\beta})$, the composite loss $\ell = \lambda \circ \tilde{\psi}$ satisfies

$$\begin{aligned} D\ell_i(v) &= (e_i^i - \tilde{p}) \\ H\ell_i(v) &= [H\underline{L}(\tilde{\beta})]^{-1}. \end{aligned} \quad (20) \quad (21)$$

The simplified form of the Hessian above is established by noting that since $\kappa(\tilde{\beta}) = I_n$ we have $D[\kappa(\tilde{\psi}^{-1}(v))] = 0$ for all $v \in \mathcal{Y}$ in Proposition 27.

The above propositions hold for any number of classes n . It is instructive (both here and later in the paper) to examine the binary case where $n = 2$. In this case, Proposition 26 and Proposition 27 reduce to

$$\ell_1'(v) = -(1 - \tilde{p})\kappa(\tilde{\beta}) \quad ; \quad \ell_2'(v) = \tilde{p}\kappa(\tilde{\beta}) \quad (22)$$

$$\ell_1''(v) = \frac{-(1 - \tilde{p})\kappa(\tilde{\beta}) + \kappa(\tilde{\beta})}{\tilde{\psi}'(\tilde{\beta})} \quad (23)$$

$$\ell_2''(v) = \frac{\tilde{p}\kappa(\tilde{\beta}) + \kappa(\tilde{\beta})}{\tilde{\psi}'(\tilde{\beta})} \quad (24)$$

where $\kappa(\tilde{\beta}) = -\frac{\underline{L}''(\tilde{\beta})}{\tilde{\psi}'(\tilde{\beta})} \geq 0$ and so $\frac{d}{dv} \kappa(\tilde{\psi}^{-1}(v)) = \frac{\kappa'(\tilde{\beta})}{\tilde{\psi}'(\tilde{\beta})}$.

6.4.2 CONDITIONS FOR CONVEXITY OF MULTICLASS COMPOSITE PROPER LOSSES

We will now consider when multiclass proper losses are convex, and give a characterisation in terms of the corresponding Bayes risk which as we have seen is the natural way to parametrise a loss. The results below are the multiclass generalisation of the characterisation of convexity of binary composite losses (Reid and Williamson, 2010). In fact we obtain more general results

even in the binary case because here we consider *strongly* convex losses. We will also show how any non-convex proper loss can be made convex by suitable choice of a link function (the canonical link)³.

For a convex set $C \subseteq \mathbb{R}^n$, a loss $\ell: C \rightarrow \mathbb{R}_+^n$ is said to be *convex* if for all $p \in \Delta^n$, the map $C \ni v \mapsto L(p, v) = p' \cdot \ell(v)$ is convex. That is, a loss is convex if, under any distribution p over outcomes $i \in [n]$, the expected loss $\mathbb{E}_{p \sim p}[\ell_i(v)]$ is convex in v . It is easy to see that ℓ is convex if and only if $\ell_i: C \rightarrow \mathbb{R}_+$ is convex for all $i \in [n]$. (The ‘‘if’’ part follows since a sum of convex functions is convex; the ‘‘only if’’ follows by considering $p = e_i$, for $i \in [n]$.)

Definition 30 Suppose $C \subseteq \mathbb{R}^n$ is convex. A function $f: C \rightarrow \mathbb{R}$ is **strongly convex on C with modulus $c \geq 0$** if for all $x, x_0 \in C$, $\forall \alpha \in (0, 1)$,

$$f(\alpha x + (1 - \alpha)x_0) \leq \alpha f(x) + (1 - \alpha)f(x_0) - \frac{1}{2}c\alpha(1 - \alpha)\|x - x_0\|^2.$$

When $c = 0$ in the above definition, f is convex. The function f is strongly convex on C with modulus c if and only if $x \mapsto f(x) - \frac{c}{2}\|x\|^2$ is convex on C (Hiriart-Urruty and Lemaréchal, 2001, page 73). Therefore, the maps $v \mapsto \ell_i(v)$ are c -strongly convex if and only if $\text{H}\ell_i(v) \succeq cI_n$. By applying Proposition 27 we obtain the following characterisation of the c -strong convexity of the loss ℓ .

Proposition 31 A proper composite loss $\ell = \lambda \circ \psi^{-1}$ is strongly convex with modulus $c \geq 0$ if and only if for all $\tilde{p} \in \tilde{\Delta}^n$ and for all $i \in [n]$

$$\left((e_i^{\tilde{p}} - \tilde{p}) \otimes I_n \right) \cdot \text{D} \left(\kappa(\tilde{\psi}^{-1}(v)) \right) \preceq \kappa(\tilde{p}) \cdot [\text{D}\tilde{\psi}(\tilde{p})]^{-1} - cI_n. \quad (25)$$

We now consider the implications of Proposition 31 in two special cases: in the multiclass case with canonical link, and in the binary case with the identity link.

Recall that the canonical link $\tilde{\psi}$ is chosen so that $\tilde{\psi}(\tilde{p}) = -\text{D}\tilde{L}(\tilde{p})'$. This simplifies $\kappa(\tilde{p})$ to the identity matrix I_n so $\text{D}\kappa(\tilde{p}) = 0$. In this case the above proposition reduces to the following corollary.

Corollary 32 If $\ell = \lambda \circ \psi^{-1}$ is defined so that $\tilde{\psi} = -\text{D}\tilde{L}$ then each map $v \mapsto \ell_i(v)$ is c -strongly convex if and only if $[-\text{H}\tilde{L}(\tilde{p})]^{-1} \succeq cI_n$, or equivalently $-\text{H}\tilde{L}(\tilde{p}) \preceq \frac{1}{c}I_n$.

An immediate consequence of this result is obtained by observing that the definiteness constraint is always met when $c = 0$ since \tilde{L} is always a concave function. Thus, using a canonical link guarantees a proper composite loss is convex.

There is an upper definiteness condition analogous to that for strong convexity that has implications for rates of convergence in numerical optimisation. Boyd and Vandenberghe (2004, §9.1.2) show that if a twice differentiable function $f: \mathcal{B} \rightarrow \mathbb{R}$ satisfies

$$MI \succeq \text{H}f(x) \succeq mI$$

³ There are problems associated with the domain of definition of such link functions than need to be dealt with (Kamalanarayanan et al., 2015).

for all $x \in \mathcal{B} \subset \mathbb{R}^n$ then the value $\frac{M}{m}$ is an upper bound on the *condition number* of $\text{H}f$, that is, the ratio of maximum to minimum eigenvalue of $\text{H}f$. This value measures the eccentricity of the sublevel sets of f and controls the rate at which optima of f are approached.

Applying this result to the Hessian of a composite loss ℓ with a canonical link shows that the condition number bound is controlled by the Hessian of the Bayes risk of ℓ . Specifically, if the condition number is to be no more than M/m then $\frac{M}{m} \succeq -\text{H}\tilde{L}(\tilde{p}) \succeq \frac{1}{m}$ for all \tilde{p} . In the case that $M = m$ and the condition number is 1, the only Hessian that satisfies these conditions is $\text{H}\tilde{L}(\tilde{p}) = -I_n$ which is easily shown to be the Bayes risk for square loss. Thus, square loss is the only canonical composite loss for which a condition number of 1 is possible.

In the binary case, when $n = 2$, (23) and (24) and the positivity of $\tilde{\psi}'$ simplify (25) to the two conditions:

$$\left. \begin{aligned} (1 - \tilde{p})\kappa'(\tilde{p}) &\leq \kappa(\tilde{p}) - c\tilde{\psi}'(\tilde{p}) \\ -\tilde{p}\kappa'(\tilde{p}) &\leq \kappa(\tilde{p}) - c\tilde{\psi}'(\tilde{p}) \end{aligned} \right\}, \quad \forall \tilde{p} \in (0, 1).$$

Further assuming that $\tilde{\psi}$ is the identity link ($\tilde{\psi}(v) = v$) and letting $w(\tilde{p}) := -\tilde{L}''(\tilde{p})$ gives

$$\left. \begin{aligned} w'(\tilde{p}) &\leq \frac{1}{1-\tilde{p}}(w(\tilde{p}) - c) \\ w'(\tilde{p}) &\geq \frac{1}{\tilde{p}}(w(\tilde{p}) - c) \end{aligned} \right\}, \quad \forall \tilde{p} \in (0, 1) \\ \Leftrightarrow -\frac{1}{\tilde{p}} &\leq \frac{w'(\tilde{p})}{w(\tilde{p}) - c} \leq \frac{1}{1-\tilde{p}}, \quad \forall \tilde{p} \in (0, 1). \quad (26)$$

The last equivalence is achieved by dividing through by $w(\tilde{p}) - c$ which must necessarily be positive since if it were not the final pair of inequalities would imply $-\frac{1}{\tilde{p}} \geq \frac{1}{1-\tilde{p}}$, a contradiction given that $\tilde{p} \in [0, 1]$. Note that (26) reduces to (Reid and Williamson, 2010, Corollary 26) for $c = 0$.

Observe that if $g(\tilde{p}) := \log(w(\tilde{p}) - c)$ then $g'(\tilde{p}) = \frac{w'(\tilde{p})}{w(\tilde{p}) - c}$ is the middle term in (26). This allows a simplification of the inequality. Specifically, if we assume $w(\frac{1}{2}) = 1$ then

$$\left. \begin{aligned} -\frac{1}{\tilde{p}} &\leq g'(\tilde{p}) \leq \frac{1}{1-\tilde{p}}, \quad \forall \tilde{p} \in (0, 1) \\ \Rightarrow \int_{\frac{1}{2}}^q \frac{1}{\tilde{p}} d\tilde{p} &\leq \int_{\frac{1}{2}}^q g'(\tilde{p}) d\tilde{p} \leq \int_{\frac{1}{2}}^q \frac{1}{1-\tilde{p}} d\tilde{p}, \quad \forall q \in (0, 1) \\ \Leftrightarrow -\log(q) - \log(2) &\leq g(q) - \log(1 - c) \\ &\leq -\log(2) - \log(1 - q), \quad \forall q \in (0, 1) \\ \Leftrightarrow \frac{1}{2q} &\leq e^{g(q) - \log(1 - c)} \leq \frac{1}{2(1 - q)}, \quad \forall q \in (0, 1) \end{aligned} \right\} \quad (27)$$

which gives the following proposition purely in terms of $w(\tilde{p})$, rather than $w(\tilde{p})$ and its derivative.

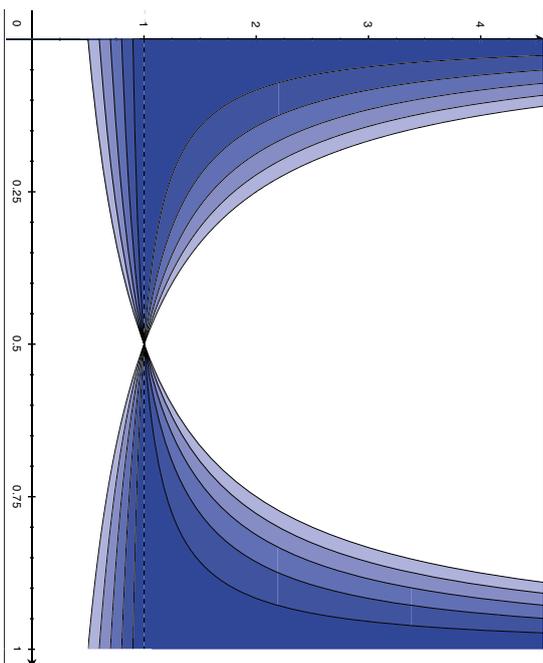

Figure 7: Graph of $w(\bar{p}) = -\underline{\ell}''(\bar{p})$ as a function of \bar{p} necessary for a suitably normalised binary proper loss to be strongly convex with modulus $c \in \{0, \frac{1}{5}, \frac{2}{5}, \frac{3}{5}, \frac{4}{5}, 1\}$. The regions R_c are nested by subsethood so that $R_0 \supset R_{1/5} \supset R_{2/5} \supset R_{3/5} \supset R_{4/5} \supset R_1$, where R_1 is simply the dotted line (containing only the function $w(c) = 1$, $\forall c \in [0, 1]$, which is the weight function corresponding to squared loss). The palest shaded region corresponds to R_0 , the allowable range of $w(c)$ necessary for the corresponding proper loss to be convex, and the darkest corresponds to $R_{4/5}$.

Proposition 33 Let $w(\bar{p}) = -\underline{\ell}''(\bar{p})$ and assume $w(1/2) = 1$. A proper binary loss $\ell: \Delta^2 \rightarrow \mathbb{R}_+^2$ is strongly convex with modulus $c \in [0, 1]$ only if

$$\frac{1}{2\bar{p}} \leq \frac{w(\bar{p}) - c}{1 - c} \leq \frac{1}{2(1 - \bar{p})}, \quad \forall \bar{p} \in (0, 1), \quad (28)$$

where \leq denotes \leq for $\bar{p} \geq \frac{1}{2}$ and denotes \geq for $\bar{p} \leq \frac{1}{2}$.

When $c = 0$ (corresponding to ℓ being convex) this is equivalent to an expression by Reid and Williamson (2010, Equation 31), where it was incorrectly claimed this condition was also sufficient. Inequation 28 is illustrated in Figure 7.

The above proposition only gives a necessary condition for strong convexity. (In addition to w belonging to the specified region, $w(\bar{p})$ also needs to be suitably controlled). A sufficient condition is useful for designing strongly convex proper losses. Observe that if

$$w(\bar{p}) = \exp\left(\int_{1/2}^{\bar{p}} u(t)dt + K\right) + c$$

where $u: [0, 1] \rightarrow \mathbb{R}$ and $K, c \in \mathbb{R}$, then $\frac{\partial}{\partial \bar{p}} \log(w(\bar{p}) - c) = u(\bar{p})$. We require $w(1/2) = 1$ and so $\exp\left(\int_{1/2}^{1/2} u(t)dt + K\right) + c = 1$ and so $e^K = 1 - c$ and

$$w(\bar{p}) = (1 - c) \exp\left(\int_{1/2}^{\bar{p}} u(t)dt\right) + c \quad (29)$$

satisfies (26) if

$$-\frac{1}{\bar{p}} \leq u(\bar{p}) \leq \frac{1}{1 - \bar{p}}, \quad \forall \bar{p} \in (0, 1), \quad (30)$$

and hence the loss with weight function w is strongly convex with modulus c . Thus by choosing u to satisfy (30) and constructing w via (29) one can design strongly convex proper binary losses.

One can ask whether equation (25) can be simplified in the $n > 2$ case by using a matrix version of the logarithmic derivative trick in a manner similar to that used above when $n = 2$. Such a result does exist (Horn and Johnson, 1991, Section 6.6, 19) but it requires that $(\underline{H}\underline{\ell}(\bar{p}))^{-1}$ and $D(\underline{H}\underline{\ell}(\bar{p}))$ commute for all $\bar{p} \in \bar{\Delta}^n$, which is not generally the case.

7. Integral Representations of Proper Losses

Binary proper losses have an attractive integral representation that provides substantial insight and is a useful tool for both designing losses and understanding the implications of different choices of loss. Specifically, there exists a family of “extremal” loss functions (cost-weighted generalisations of the 0-1 loss) parametrised by $c \in [0, 1]$ and defined for all $\eta \in [0, 1]$ by $\underline{\ell}_{-1}(\eta) := c\|\eta \geq c\|$ and $\underline{\ell}_1 := (1 - c)\|\eta < c\|$. As shown by Buja et al. (2005) and Reid and Williamson (2011), given these extremal functions, any proper binary loss ℓ can be expressed as the weighted integral

$$\ell = \int_0^1 \rho^* w(c) dc + \text{constant}$$

with “weight function” $w(c) = -\underline{\ell}''(c)$. This representation is a special case of a representation from Choquet theory (Phelps, 2001; Simon, 2011) which characterises when every point in some set can be expressed as a weighted combination of the “extremal points” of the set. Although there is such a representation when $n > 2$, the difficulty is that the set of extremal points is much larger and this rules out the existence of a nice small set of “primitive” proper losses when $n > 2$, and consequently rules out an easy-to-work-with weight function parameterizing all possible multiclass losses in a manner analogous to the binary case. The rest of this section makes this statement precise.

A convex cone \mathcal{K} is a set of points closed under positive linear combinations. That is, $\mathcal{K} = \alpha\mathcal{K} + \beta\mathcal{K}$ for any $\alpha, \beta \geq 0$. A point $f \in \mathcal{K}$ is extremal if $f = \frac{1}{2}(g + h)$ for $g, h \in \mathcal{K}$

implies $\exists \alpha \in \mathbb{R}_+$ such that $g = \alpha f$. That is, f cannot be represented as a non-trivial combination of other points in \mathcal{X} . The set of extremal points for \mathcal{X} will be denoted $\text{ex } \mathcal{X}$. Suppose U is a bounded closed convex set in \mathbb{R}^d , and $\mathcal{X}_b(U)$ is the set of convex functions on U bounded by 1, then $\mathcal{X}_b(U)$ is compact with respect to the topology of uniform convergence. Bronshtein (1978, Theorem 2.2) showed that the extremal points of the convex cone $\mathcal{X}(U) = \{\alpha f + \beta g : f, g \in \mathcal{X}_b(U), \alpha, \beta \geq 0\}$ are dense (w.r.t. the topology of uniform convergence) in $\mathcal{X}(U)$ when $d > 1$. This means for any function $f \in \mathcal{X}(U)$ there is a sequence of functions (g^i) such that for all i $g^i \in \text{ex } \mathcal{X}(U)$ and $\lim_{i \rightarrow \infty} \|f - g^i\|_\infty = 0$, where $\|f\|_\infty := \sup_{u \in U} |f(u)|$. We use this result to show that the set of extremal Bayes risks is dense in the set of Bayes risks when $n > 2$.

In order to simplify our analysis, we restrict attention to fair proper losses. A loss is *fair* if each partial loss is zero on its corresponding vertex of the simplex ($\ell_i(e_i) = 0, \forall i \in [n]$). A proper loss is *fair* if and only if its Bayes risk is zero at each vertex of the simplex (in this case the Bayes risk is also called fair). One does not lose generality by studying fair proper losses since any proper loss is a sum of a fair proper loss and a constant vector.

The set of fair proper losses defined on Δ^n form a closed convex cone, denoted \mathcal{L}_n . The set of concave functions which are zero on all the vertices of the simplex Δ^n is denoted \mathcal{F}_n and is also a closed convex cone.

Proposition 34 *Suppose $n > 2$. Then for any fair proper loss $\ell \in \mathcal{L}_n$ there exists a sequence (ℓ^i) of extremal fair proper losses $(\ell^i \in \text{ex } \mathcal{L}_n)$ which converges almost everywhere to ℓ .*

The implication of this proposition is that the set of extremal multiclass proper losses is very large. Some intuition can be gleaned from Figure 8 from which it is apparent that there is a qualitative difference between the complexity of the set of extremal concave functions in one dimension (corresponding to $n = 2$) and higher dimensions ($n > 2$). The proof of Proposition 34 requires the following lemma which relies upon the correspondence between a proper loss and its Bayes risk (Proposition 8) and the fact that two continuous functions equal almost everywhere are equal everywhere.

Lemma 35 *If $\ell \in \text{ex } \mathcal{L}_n$ then its corresponding Bayes risk \underline{L} is extremal in \mathcal{F}_n . Conversely, if $\underline{L} \in \text{ex } \mathcal{F}_n$ then all the proper losses ℓ with Bayes risk equal to \underline{L} are extremal in \mathcal{L}_n .*

Proof We suppose that $\ell \in \text{ex } \mathcal{L}_n$ and denote its Bayes risk by $\underline{L}(p) = p' \cdot \ell(p)$. Let $\underline{F}, \underline{G} \in \mathcal{F}_n$ so that $\underline{L} = \frac{1}{2}(\underline{F} + \underline{G})$. Suppose f and g are proper losses whose Bayes risks are respectively equal to \underline{F} and \underline{G} , then $\forall p \in \Delta^n$ and almost everywhere in q (more precisely where $\underline{L}, \underline{F}$ and \underline{G} are differentiable), $\underline{L}(p, q) = \frac{1}{2}(\underline{G}(p, q) + \underline{F}(p, q))$. Then $\ell = \frac{1}{2}(g + f)$ almost everywhere, so there exists α such as $g = \alpha \ell$ almost everywhere, hence $\underline{G} = \alpha \underline{L}$ almost everywhere and then everywhere by continuity. So \underline{L} is extremal in \mathcal{F}_n .

Now suppose that the concave function \underline{L} is extremal and let ℓ be a proper loss whose Bayes risk is \underline{L} . Then $\underline{L}(p, q) = p' \cdot \ell(q) = \underline{L}(q) + (p - q)' \cdot A(q)$ where $A(q) \in \partial \underline{L}(q)$. Suppose that there exist $f, g \in \mathcal{L}_n$ so that $\ell = \frac{1}{2}(f + g)$ almost everywhere, and have associated Bayes risks \underline{F} and \underline{G} , respectively. Then $\underline{L}(p) = p' \cdot \ell(p) = p' \cdot \frac{1}{2}(f(p) + g(p)) = \frac{1}{2}(\underline{F} + \underline{G})$ almost everywhere so $\underline{L} = \frac{1}{2}(\underline{F} + \underline{G})$ everywhere by continuity. Since \underline{L} is extremal we must have $\underline{F} = \alpha \underline{L}$ and so $f = \alpha \ell$ where \underline{L} is differentiable (and so almost everywhere). Thus ℓ is extremal in \mathcal{L}_n . ■

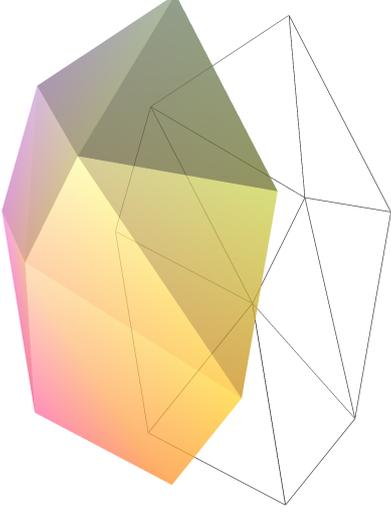

Figure 8: Complexity of extremal concave functions in two dimensions (corresponds to $n = 3$). The figure shows the graph of an extremal concave function in two dimensions. The lines below indicate where the slope changes. The pattern of these lines can be made arbitrarily complex. This illustrates the fact (Proposition 34) that the set of extremal concave functions is very large.

We also need a correspondence between the uniform convergence of a sequence of Bayes risk functions and the convergence of their associated proper losses.

Lemma 36 *Suppose $\underline{L}, \underline{L}^i \in \mathcal{F}_n$ for $i \in \mathbb{N}$ and suppose ℓ and $\ell^i, i \in \mathbb{N}$ are associated proper losses. Then (\underline{L}^i) converges uniformly to \underline{L} if and only if (ℓ^i) converges almost everywhere to ℓ .*

Proof We require two facts from convex analysis: confer (Hiriart-Urruty and Lemaréchal, 2001, Theorems B.3.1.4 and D.6.2.7). If a sequence (f^i) of convex functions f^i converges pointwise to f then: 1) the sequence converges uniformly on any compact domain; and 2) $\forall \varepsilon > 0, \partial f^i(x) \subset \partial f(x) + \mathcal{B}(0, \varepsilon)$ for i large enough. Then the reverse implication of the lemma is a direct consequence of the first result and the forward implication is obtained by considering the set $\{x : \forall n, \underline{L}^i$ and \underline{L} are differentiable at $x\}$ which is of measure 1. ■

Proof (Proposition 34) When $n > 2$ the simplex Δ^n is isomorphic to a subset of \mathbb{R}^d for $d > 1$. Since \mathcal{F}_n is a convex cone associated with the set of bounded concave functions (i.e., the fair Bayes risks), (Bronshtein, 1978, Theorem 2.2) guarantees (with an appropriate change from concavity to convexity) that $\text{ex } \mathcal{F}_n$ is dense in \mathcal{F}_n w.r.t. the topology of uniform convergence. Therefore, if $\ell \in \mathcal{L}_n$ there exists a sequence (f^i) with $f^i \in \text{ex } \mathcal{F}_n$ which converges uniformly to the Bayes risk \underline{L} of ℓ and so by Lemma 36 there is a corresponding sequence (ℓ^i) of fair proper

losses that converges almost everywhere to ℓ . Lemma 35 guarantees that each ℓ^i is extremal in \mathcal{L}_ρ since each $\ell^i \in \text{ex } \mathcal{F}_n$, and so we have shown there exists a sequence (θ^j) with $\theta^j \in \text{ex } \mathcal{L}_\rho$ which converges to an ℓ which was arbitrary. ■

8. Tools for Designing Losses

In this section we show how the results developed above could be used to design losses for particular purposes. There is no question about how this should be done “in principle” (Berger, 1985, Section 2.4). And even when not made explicit at the outset, *all* inference ultimately has an *implicit* loss function that captures what matters to the end user, even if the original purpose was to merely “gather information”, simply because in the end the “information” is acted upon (DeGroot, 1962). Until now, the lack of convenient and canonical parametrisations of multi-class loss functions has made the comparison of different loss functions, and their tuning for specific applications, difficult.

In subsection 8.1, we show how to construct a parametric family of valid link functions from a finite number of “base” links by effectively taking their convex combination. By composing each link with a fixed proper loss, this immediately allows for the specification of a family of losses with a fixed Bayes risk. This construction enables the creation of losses with a range of optimisation characteristics (ϵ , g , convexity, robustness) but a common statistical basis (ℓ, ϵ) , the same Bayes risk.

In subsection 8.2 we show how it is possible to build losses by building them up from constraints on their Bayes risk curves on the edges of the simplex. This allows a loss to be constructed by effectively specifying its behaviour on pairs of outcomes. We show how this observation can be used to create piecewise linear, proper losses for cost-sensitive misclassification.

Finally (subsection 8.3) we observe how link functions are in fact themselves very similar to loss functions, and (subsection 8.4) we present some examples of proper composite losses from the literature (where they were not expressed in the proper composite parametrisation)

8.1 Families of Losses with Fixed Bayes Risk

The theory developed above suggests that each choice of proper loss λ and link function ψ results in an overall loss function with properties (ϵ , g , convexity) that depend entirely on their relationship to each other. Given these two “knobs” for parameterising a loss function, we can begin to ask what kind of practical trade-offs are involved when selecting a composite loss as a surrogate loss for a particular problem.

We now propose a simple scheme for constructing families of losses with the same Bayes risk. This is achieved by fixing a choice of proper loss λ and creating a parameterised family (described below) of link functions ψ_α for parameters $\alpha \in A$. Since the Bayes risk is entirely determined by λ any composite loss $\lambda \circ \psi_\alpha^{-1}$ for $\alpha \in A$ will have Bayes risk $\underline{L}(\rho) = \rho^* \cdot \lambda(\rho)$. Thus, we are able to examine the effect different choices of composite loss can have on a problem *without changing the essential underlying problem*.⁴

4. Of course, this argument only holds in a point-wise analysis. That is, where choices for estimates $\hat{\mu}(\delta)$ can be made independently. Once a restricted hypothesis class for the functions ρ is introduced the choice of link can

In order to construct a parametric family of links we first choose some set of inverse link functions $\mathcal{F} = \{\psi_1^{-1}, \dots, \psi_B^{-1}\}$ with a common domain, that is, $\psi_b^{-1}: \mathcal{Y} \rightarrow \Delta^n$ for a convex n and \mathcal{Y} . This collection will be called the *basis set* of link functions. We then take the convex hull of \mathcal{F} to form a set of inverse link functions Ψ^{-1} . Each $\psi^{-1} \in \Psi^{-1}$ is then identified with the unique $\alpha \in A = \Delta^B$ such that $\sum_{b=1}^B \alpha_b \psi_b^{-1} = \psi^{-1}$. For this construction to be valid, it is necessary to show that every such $\psi^{-1} \in \Psi^{-1}$ is indeed an inverse link function, that is, it is invertible.

The following proposition shows that it suffices to assume that all of the basis functions are *strictly monotone* (see Equation 2).

Proposition 37 *Every function ψ^{-1} in the set $\Psi^{-1} = \text{co}(\mathcal{F})$ is invertible whenever each basis function in \mathcal{F} is strictly monotone.*

This result is a consequence of: 1) strict monotonicity being preserved under convex combination; and 2) strict monotonicity implies invertibility. The first claim is established by considering strictly monotone f and g and some $\alpha \in [0, 1]$ and noting that if $h = \alpha f + (1 - \alpha)g$ then $h(u) - h(v) = \alpha(f(u) - f(v)) + (1 - \alpha)(g(u) - g(v))$. A strictly monotone function f that is not invertible is impossible since if we have $(f(u) - f(v))(u - v) > 0$ for all u, v then a $u \neq v$ such that $f(u) = f(v)$ would lead to a contradiction.

Strictly monotone basis functions are easily obtained via canonical links for strictly proper losses. By definition, a canonical link satisfies $\psi = -D_{\underline{L}}$ for some Bayes risk function. Strict properness guarantees \underline{L} is strictly concave (van Erven et al., 2012b, Lemma 1). Kachurovskii’s theorem (Hiriart-Urruty and Lemaréchal, 2001, Theorem 4.1.4) states that the derivative of a function is (strictly) monotone if and only if the function is (strictly) convex. Since $f(f^{-1}(u)) = f(f^{-1}(v))(f^{-1}(u) - f^{-1}(v)) = (u - v)(f^{-1}(u) - f^{-1}(v))$ we see that strictly monotone functions have strictly monotone inverses and we have established the following proposition.

Proposition 38 *If λ is a strictly proper loss then its canonical link $\psi_\lambda = -D_{\underline{L}}$ has a strictly monotone inverse.*

This result means that a set of basis links can be defined via a choice of strictly concave Bayes risk functions. As an example, the class of Fisher-consistent margin losses proposed by Zou et al. (2008) provides a flexible starting point for designing sets of link functions as described above. They give explicit formulae for the inverse link for a composite loss defined by a choice of convex function $\phi: \mathbb{R} \rightarrow \mathbb{R}$. Specifically, if the loss for predicting $v \in \mathcal{Y} = \{v \in \mathbb{R}^n: \sum_i v_i = 0\}$ is given by $\ell(v) = \phi(v)$ then its inverse link is $\psi_\phi^{-1}(v) = \frac{1}{\sum_{i=1}^n \phi(v_i)}$ where $Z_\phi(v)$ normalises the vector to lie in Δ^n . Each choice of strictly convex ϕ gives a valid inverse link which can be used as a basis function.

8.2 Piecewise Linear Multiclass Losses

We now build a family of conditional Bayes risks. Suppose we are given $\frac{n(n-1)}{2}$ concave functions $\{\underline{L}^{i,j}: \Delta^2 \rightarrow \mathbb{R}\}_{1 \leq i < j \leq n}$ on Δ^2 , and we want to build a concave function \underline{L} on Δ^n affect the minimal achievable risk. The interaction between the hypothesis class and the loss function is complex (van Erven et al., 2015).

which is equal to one of the given functions on each edge of the simplex ($\forall 1 \leq i_1 < i_2 \leq n$, $\underline{L}(0, \dots, 0, p_{i_1}, 0, \dots, 0, p_{i_2}, 0, \dots, 0) = \underline{L}^{i_1, i_2}(p_{i_1}, p_{i_2})$). This is equivalent to choosing a binary loss function, knowing that the observation is in the class i_1 or i_2 . The result below gives one possible construction. (There exists an infinite number of solutions—one can simply add any concave function equal to zero in each edge).

Lemma 39 Suppose we have a family of concave functions $\{\underline{L}^{i_1, i_2} : \Delta^2 \rightarrow \mathbb{R}\}_{1 \leq i_1 < i_2 \leq n}$, then

$$\underline{L} : \Delta^n \ni p \mapsto \underline{L}((p_1, \dots, p_n)) = \sum_{1 \leq i_1 < i_2 \leq n} (p_{i_1} + p_{i_2}) \underline{L}^{i_1, i_2} \left(\left(\frac{p_{i_1}}{p_{i_1} + p_{i_2}}, \frac{p_{i_2}}{p_{i_1} + p_{i_2}} \right) \right)$$

is concave and $\forall 1 \leq i_1 < i_2 \leq n$, $\underline{L}((0, \dots, 0, p_{i_1}, 0, \dots, 0, p_{i_2}, 0, \dots, 0)) = \underline{L}^{i_1, i_2}((p_{i_1}, p_{i_2}))$.

Proof In order to show that \underline{L} is concave it suffices to show that for $g : \Delta^2 \rightarrow \mathbb{R}$ concave, $f : p \in \Delta^n \rightarrow f(p) = (p_1 + p_2)g\left(\frac{p_1}{p_1 + p_2}, \frac{p_2}{p_1 + p_2}\right)$ is concave, since a sum of concave functions is concave.

Let $\gamma \in [0, 1]$, $p, q \in \Delta^n$. Since g is concave, $\forall \alpha \in [0, 1]$, $\forall p, q \in \Delta^2$, $g\left(\frac{\alpha}{\alpha + (1-\alpha)}p + \frac{1-\alpha}{\alpha + (1-\alpha)}q\right) \geq \alpha g\left(\frac{p}{\alpha + (1-\alpha)}\right) + (1-\alpha)g\left(\frac{q}{\alpha + (1-\alpha)}\right)$. Then with $\alpha = \frac{\gamma(p_1 + p_2)}{\gamma(p_1 + p_2) + (1-\gamma)(q_1 + q_2)}$, we get $f(\gamma p + (1-\gamma)q) \geq \gamma f(p) + (1-\gamma)f(q)$.

Moreover, $\underline{L}((0, \dots, 0, p_{i_1}, 0, \dots, 0, p_{i_2}, 0, \dots, 0)) = \sum_{i_1, i_2} \underline{L}^{i_1, i_2}((p_{i_1} \times 0 + p_{i_2} \times 0))$

$+ (p_{i_1} + p_{i_2}) \underline{L}^{i_1, i_2} \left(\left(\frac{p_{i_1}}{p_{i_1} + p_{i_2}}, \frac{p_{i_2}}{p_{i_1} + p_{i_2}} \right) \right) = \underline{L}^{i_1, i_2}((p_{i_1}, p_{i_2}))$, ($p \in \Delta^n$, so $p_{i_1} + p_{i_2} = 1$).

Using this family of Bayes risks, one can build a family of proper losses. ■

Lemma 40 Suppose we have a family of binary proper losses $\ell^{i_1, i_2} : \Delta^2 \rightarrow \mathbb{R}^+$. Then

$$\ell : \Delta^n \ni p \mapsto \ell(p) = \left(\sum_{j=1}^{j-1} \ell^{i, j} \left(\frac{p_i}{p_i + p_j} \right) + \sum_{i=j+1}^n \ell^{i, j} \left(\frac{p_j}{p_i + p_j} \right) \right)_{j=1}^n \in \mathbb{R}^+$$

is a proper n -class loss such that

$$\ell_i((0, \dots, 0, p_{i_1}, 0, \dots, 0, p_{i_2}, 0, \dots, 0)) = \begin{cases} \ell^{i_1, i_2}(p_{i_1}) & i = i_1 \\ \ell^{i_1, i_2}(p_{i_2}) & i = i_2 \\ 0 & \text{otherwise} \end{cases}$$

Proof Use the correspondence between Bayes risk and proper losses and Lemma 39. ■

Observe that it is much easier to work at first with the Bayes risk and then using the correspondence between Bayes risks and proper losses.

We have already seen (Section 7) that it is not possible to parametrise all extremal concave functions in a tractable manner. However, for the sake of offering a range of knobs to the designer to design losses, it could often suffice to use a subset of extremal losses. These will all have polyhedral forms. A convex polytope is a compact convex intersection of a finite set of half-spaces and is therefore the convex hull of its vertices. Let $\{a_i\}$ be a finite family of affine functions defined on Δ^n . Now define the convex polyhedral function f by $f(x) := \max_i a_i(x)$. The set $K := \{P_i = \{x \in \Delta^n : f(x) = a_i(x)\}\}$ is a covering of Δ^n by polytopes. Bronshtein (1978, Theorem 2.1) shows that for f , P_i and K so defined, f is extremal if the following two conditions

are satisfied: 1) for all polytopes P_i in K and for every face F of P_i , $F \cap \Delta^n \neq \emptyset$ implies F has a vertex in Δ^n ; 2) every vertex of P_i in Δ^n belongs to n distinct polytopes of K . The set of all such f is dense in $\mathcal{K}(U)$.

Using this result it is straightforward to exhibit some sets of extremal fair Bayes risks $\{\underline{L}_c(p) : c \in \Delta^n\}$. Two examples are when

$$\underline{L}_c(p) = \sum_{i=1}^n \frac{p_i}{c_i} \prod_{j \neq i} \mathbb{1}_{\left\{ \frac{p_j}{c_j} \leq \frac{p_i}{c_i} \right\}}$$

or

$$\underline{L}_c(p) = \bigwedge_{i \in [n]} \frac{1-p_i}{c_i}.$$

Any convex combination of either of these families will be the Bayes risk of a proper fair multiclass loss. Thus the convex combination of the elementary losses induced by such $\underline{L}_c(p)$ will also be proper fair multiclass losses.

8.3 Parametrisation of Composite Losses

A composite loss $\ell = \lambda \circ \psi^{-1} : \mathcal{Y} \rightarrow \mathbb{R}^+$ is directly parametrised by the proper loss $\lambda : \Delta^n \rightarrow \mathbb{R}^+$ and the invertible link $\psi : \Delta^n \rightarrow \mathbb{R}^n$. However we have seen (Section 4) that proper losses λ are more nicely parametrised by their concave conditional Bayes risk $\Delta : \Delta^n \rightarrow \mathbb{R}$, which being scalar valued, are simpler objects to work with than λ . Although not every invertible function ψ can be written as the gradient of an analogous convex function $\Psi : \Delta^n \rightarrow \mathbb{R}$, by Kachurovskii's theorem (see Section 8.1) if for some $\Psi : \Delta^n \rightarrow \mathbb{R}$, $\psi = D\Psi$, then ψ is monotone (resp. strictly monotone) if and only if Ψ is convex (resp. strictly convex). A link ψ is a gradient if and only if $D\psi$ is symmetric (so that $H\Psi$ is symmetric) as a Hessian needs to be.

Thus if one were willing to restrict oneself to links such that $D\psi$ is symmetric, then a composite loss ℓ can be parametrised by (Δ, Ψ) , which are concave (resp. strictly convex) functions from Δ^n to \mathbb{R} . The parametrisation of ψ via Ψ allows the specification of the canonical link as that satisfying $\Psi = -\Delta$.

8.4 Examples from Related Work

In this subsection we look at some existing candidate multiclass losses from the perspective of proper composite representations. Not all such losses as the generalisation of hinge loss are so representable, a prominent example being those introduced by Crammer and Singer (2001).

Zou et al. (2008) presented multi-category losses of the form $\ell_j(f) = \phi_j(f_j)$ for f such that $\sum_j f_j = 0$ and $\phi_j(0) < 0$ and $\phi_j''(t) \geq 0$ so that we have Fisher consistency and the inverse link is $\frac{1/\phi_j(f_j)}{\sum_j 1/\phi_j(f_j)}$. As their examples of this class show, it is not always possible to write the link in closed form, even if the inverse link can be (e.g., logit loss $\phi(t) = \log(1+e^t)$).

The coherence functions of Zhang et al. (2009) are a separate class of surrogate functions that emphasise the margin of a prediction:

$$\ell_\zeta(v) = T \log \left[1 + \sum_{i \neq j} \exp(T^{-1}(1 + v_i - v_j)) \right].$$

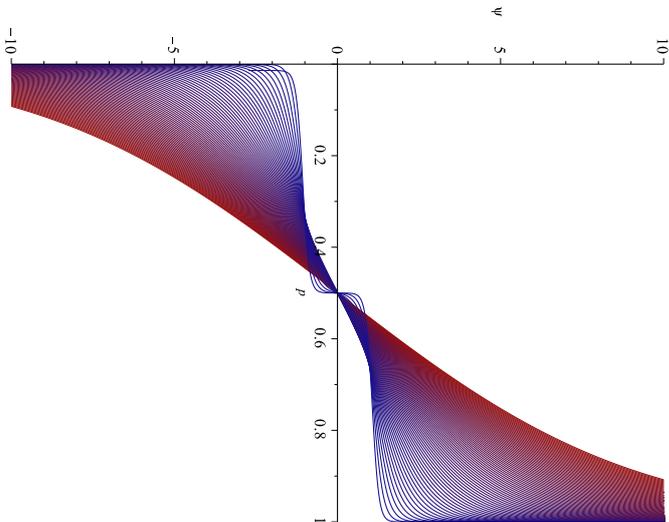

Figure 9: Illustration of the link function in the proper composite representation of the binary coherence loss for $T \in [0.1, 4]$. Blue corresponds to $T = 0.1$ and red to $T = 4$, with there being 80 equal increments of T plotted.

We will illustrate some aspects of the present paper with reference to this parametrised family of losses. For ease of calculation, we consider only $n = 2$ below, but the conclusions we draw below hold for $n > 2$ also. In the binary case, this corresponds to a parametric family of margin losses with margin function

$$\phi_T(z) := T \log \left(1 + \exp \left(\frac{1-z}{T} \right) \right),$$

and thus $\phi_T'(z) = \frac{e^{(1-z)/T}}{1+e^{(1-z)/T}}$ and one can check that $g_T(v) := -\frac{\phi_T'(v)}{\phi_T'(1-v)}$ is strictly monotone continuous and ϕ_T is monotone for all $T > 0$ and thus by Corollary 12 there is a strictly proper composite representation. Identifying $\ell_{-1}(v)$ with $\phi(-v)$ and $\ell_1(v)$ with $\phi(v)$ we can find for a

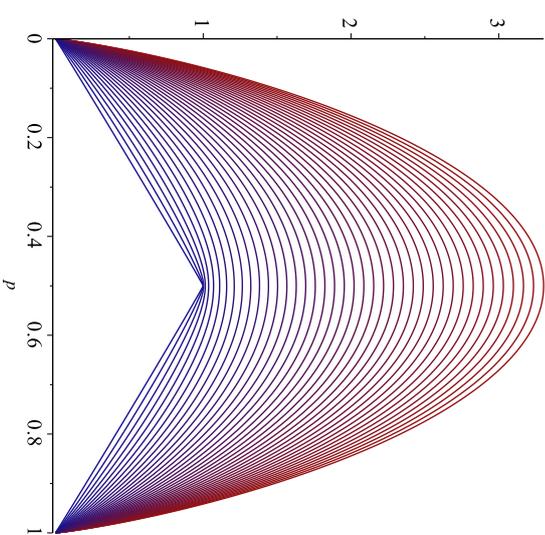

Figure 10: Illustration of the conditional Bayes risk corresponding to the binary coherence loss for $T \in [0.02, 4]$ with blue corresponding to $T = 0.02$ and red to $T = 4$.

given p the v that minimises $L(p, v)$ by solving

$$\frac{\partial}{\partial v} L(p, v) = (1-p)\phi_T'(-v) + p\phi_T'(v) = 0$$

and obtain $\frac{1-p}{p} = -g_T(v)$. Solving this for v (using Maple) we find the link function component of the proper composite representation:

$$\psi_T(p) = T \left(\ln \left(\frac{1}{2(1-p)} \left(2pe^{T^{-1}} - e^{T^{-1}} + \sqrt{4e^{2T^{-1}}p^2 - 4pe^{2T^{-1}} - 4p^2 + e^{2T^{-1}} + 4p} \right) \right) \right).$$

This is illustrated in Figure 9. Zou et al (2008, Theorem 1) effectively compute ψ_T^{-1} for general n . One can determine the proper component as

$$L_T(p) = p\phi_T(\psi_T(p)) + (1-p)\phi_T(-\psi_T(p))$$

which is plotted in Figure 10. One can glean further insight by considering the corresponding weight function $w_T^*(p) := -L_T''(p)$, which is plotted in Figure 11.

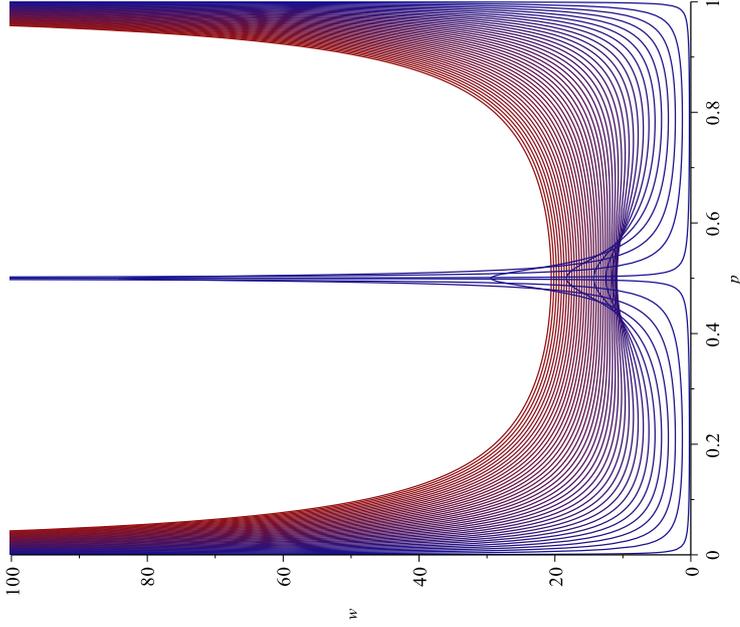

Figure 11: Weight function of the proper loss component of the proper composite representation of the binary coherence loss for $T \in [0.02, 4]$, where blue corresponds to $T = 0.02$ and red to $T = 4$.

The weight function view makes it clear how the proper component of the loss approaches 0-1 loss as $T \rightarrow 0$. (The weight function for 0/1 loss is $w(c) = \delta(c - \frac{1}{2})$; note the convergence in Figure 11 is not uniform, given the behaviour at 0 and 1.) Observe too that as well as the proper loss varying with T , the associated link also varies (in a complex way—see Figure 9). Thus not only is one varying the statistical properties of the loss (in a substantial way—when T is small, the weight is centered near $p = \frac{1}{2}$, whereas for large T , a series expansion of $w_T(p)$ shows that $w_T(p) \approx T \left(\frac{1}{p} + \frac{1}{1-p} \right) + 4$. An alternative to this class of losses, would be to fix a link, and then

vary the proper component. For a given model or hypothesis class \mathcal{F} this has the advantage that the effective hypothesis class $\{\psi^{-1} \circ f : f \in \mathcal{F}\}$ remains fixed, and only the (proper) loss varies. The (Δ, Ψ) parametrisation of section 8.3 offers a convenient way to do this.

9. Conclusions

We have systematically studied multiclass composite losses. The results of the paper (summarised below) show that this is an attractive parametrisation of multiclass losses. If one desires all predictions be strongly admissible, then there is nothing lost in using the proper composite representation. Since the link is only a reparametrisation, this means one still has the relationship between losses and divergences as described by [García-García and Williamson \(2012\)](#).

The proper composite representation leads to a desirable separation of concerns, where the inferential properties of the loss (such as its mixability) are governed by the proper loss, and the convexity (necessary for numerical optimisation) is controlled by the link function. It thus seems to be *the* best way to parametrise loss functions.

The key technical contributions of the paper are as follows.

- Relationship between prediction calibration and classification calibration, showing that the latter can be seen as a “pointwise” version of the former (Section 3);
- Characterisation of multiclass proper losses in terms of their binary restrictions (Proposition 7);
- Every (multiclass) proper loss is quasi-convex (Proposition 17);
- Characterisation of which binary margin losses have a proper composite representation (Corollary 12);
- Characterisation of when a multiclass loss has a proper composite representation and when the representation is unique (Section 5.3);
- Relationship between the proper composite representation, mixability and admissibility (Sections 6.1 and 6.2);
- Necessary conditions for strong convexity of multiclass proper losses in terms of their corresponding Bayes risks (Proposition 31);
- Canonical links always convexify proper losses, and outline how this can help in the design of losses (Proposition 32);
- The attractive (simply parametrised) integral representation for binary proper losses can *not* be extended to the multiclass case (Section 7);

These results suggest that in order to design losses for multiclass prediction problems it is helpful to use the composite representation, and design the proper part via the Bayes risk as suggested for the binary case by [Bajja et al. \(2005\)](#). The link function can be tuned to control the optimisation properties of the loss. Merely requiring the loss to be convex confounds two separate aspects of

a loss: the *shape* of $\ell(\gamma)$ which controls the predictive performance, and the *parameterization* of $\ell(\gamma)$ which affects the numerical optimisation of a loss.

There remain open questions. Perhaps the most practically important is the interaction between the loss and restricted hypothesis classes: typically one does not optimise conditionally, one optimises the full expected risk with respect to a restricted function class $\mathcal{F} \subset \mathcal{G}^{\mathcal{X}}$. The question of how knowledge of \mathcal{F} should influence the design of a loss remains open; some initial work along these lines is the notion of ‘‘stochastic mixability’’ (van Erven et al., 2012a, 2015).

Acknowledgments

The research reported here was performed whilst Elodie Vernet was a student at ENS Cachan and visiting ANU and NICTA, and was supported by the Australian Research Council and NICTA, which was funded by the Australian government through the ICT centre of excellence program. An earlier version of some of these results appeared in NIPS2011 and ICML2012. The work benefited from discussions with Jake Abernethy, Tim van Erven, Rafael Frongillo, and Dario García-García, and comments from the referees who we thank. Thanks also to Harish Guruprasad for identifying a flaw in an earlier proof of quasi-convexity of proper losses.

Appendix A. Matrix Calculus

If $A = [a_{ij}]$ is an $n \times m$ matrix, $\text{vec} A$ is the vector of columns of A stacked on top of each other. The *Kronecker product* of an $m \times n$ matrix A with a $p \times q$ matrix B is the $mp \times nq$ matrix

$$A \otimes B := \begin{pmatrix} A_{1,1}B & \cdots & A_{1,m}B \\ \vdots & \ddots & \vdots \\ A_{m,1}B & \cdots & A_{m,m}B \end{pmatrix}.$$

We use the following properties of Kronecker products (Magnus and Neudecker, 1999, Chapter 2): $(A \otimes B)(C \otimes D) = (AC \otimes BD)$ for all appropriately sized A, B, C, D , and $I_n \otimes A = A$.

If $f : \mathbb{R}^n \rightarrow \mathbb{R}^m$ is differentiable at c then the *partial derivative* of f with respect to the j th coordinate at c is denoted $D_j f(c)$. The $m \times n$ matrix of partial derivatives of f is the *Jacobian* of f and denoted

$$(Df(c))_{ij} := D_j f(c) \quad \text{for } i \in [m], j \in [n].$$

If F is a matrix valued function $Df(X) := Df(\text{vec} X)$ where $f(X) := \text{vec} F(X)$.

We will require the *product rule* for matrix valued functions (Vetter, 1970; Fackler, 2005): Suppose $f : \mathbb{R}^n \rightarrow \mathbb{R}^{m \times p}$, $g : \mathbb{R}^n \rightarrow \mathbb{R}^{p \times q}$ so that $(f \times g) : \mathbb{R}^n \rightarrow \mathbb{R}^{m \times q}$. Then

$$D(f \times g)(x) = (g(x)' \otimes I_m) \cdot Df(x) + (I_q \otimes f(x)) \cdot Dg(x). \quad (31)$$

The *Hessian* at $x \in \mathcal{X} \subseteq \mathbb{R}^n$ of a real-valued function $f : \mathcal{X} \rightarrow \mathbb{R}$ is the $n \times n$ real, symmetric matrix of second derivatives at x

$$(Hf(x))_{jk} := D_{kj} f(x) = \frac{\partial^2 f}{\partial x_j \partial x_k}.$$

Note that the derivative D_{kj} is in row j , column k . It is easy to establish that the Jacobian of the transpose of the Jacobian of f is the Hessian of f . That is,

$$Hf(x) = D((Df(x))) \quad (32)$$

(Magnus and Neudecker, 1999, Chapter 10). If $\mathcal{X} \subset \mathbb{R}^n$ and $f : \mathcal{X} \rightarrow \mathbb{R}^m$ is a vector-valued function, then the Hessian of f at $x \in \mathcal{X}$ is the $mm \times n$ matrix that consists of the Hessians of the functions f_i stacked vertically:

$$Hf(x) := \begin{pmatrix} Hf_1(x) \\ \vdots \\ Hf_m(x) \end{pmatrix}.$$

Appendix B. Deferred Proofs

This appendix contains proofs of results in the main text that, due to their length or technicality, are better presented outside the flow of the main text.

B.1 Proof of Lemma 1

1. We prove this by contradiction. Suppose $p \in \Delta^n$ such that for all $i \in [n]$, $p \notin \mathcal{F}(c)$. Then

$$p \notin \mathcal{F}_1(c) \Rightarrow \exists j_2 \neq j_1 \text{ such that } \frac{p_{j_2}}{c_{j_1}} < \frac{p_{j_1}}{c_{j_2}}$$

$$p \notin \mathcal{F}_2(c) \Rightarrow \exists j_3 \neq j_2 \text{ such that } \frac{p_{j_3}}{c_{j_2}} < \frac{p_{j_2}}{c_{j_3}}$$

and hence by repeating this argument

$$p \notin \mathcal{F}_n(c) \Rightarrow \exists j_{n+1} \neq j_n \text{ such that } \frac{p_{j_{n+1}}}{c_{j_n}} < \frac{p_{j_n}}{c_{j_{n+1}}}.$$

Thus we have $n+1$ indices j_1, \dots, j_{n+1} belonging to $[n]$ and therefore one is repeated (jk and $\frac{p_k}{c_k} < \frac{p_k}{c_k}$ which is a contradiction).

2. Obvious.

3. If $p \in \cap_{i=1}^n \mathcal{F}_i(c)$, then for all $j \in [n]$, $c_j = \sum_i p_i c_i = \sum_i p_i c_i = p_j$. Thus $p = c$.

4. We prove this by contradiction. Suppose $p \neq q$ such that for all c if $p \in \mathcal{F}(c)$ then $q \in \mathcal{F}(c)$. Observe that $\forall j \in [n]$, $p \in \mathcal{F}_j(p)$, and so $q \in \cap_{j=1}^n \mathcal{F}_j(q)$, and hence $q = p$, a contradiction.

B.2 Proof of Proposition 9

Observe that

$$\partial \underline{L}(p) = \{(s', 0)' + \alpha \mathbb{1}, s \in \partial \underline{L}(p), \alpha \in \mathbb{R}\}. \quad (33)$$

Indeed $(\tilde{q} - \tilde{p})' \cdot s = (q - p)' \cdot ((s', 0)' + \alpha \mathbb{1})$.

(\Rightarrow) We first assume that L is differentiable at p . We use the following result (Hiriart-Urruty and Lemaréchal, 2001, page 203): *If f is a convex function, then $\forall \varepsilon > 0, \exists \delta > 0, \exists \tilde{\delta} > 0, y \in \mathcal{B}(x, \delta) \Rightarrow \partial f(y) \subset \partial f(x) + \mathcal{B}(0, \varepsilon)$.*

Assume $\varepsilon > 0$, then since \underline{L} is differentiable at \tilde{p} , $\exists \tilde{\delta} > 0$, such that

$$\forall \tilde{q} \in \mathcal{B}(\tilde{p}, \tilde{\delta}), \forall A(\tilde{q}) \in \partial \underline{L}(\tilde{q}), \|A(\tilde{q}) - D\underline{L}(\tilde{p})\| \leq \varepsilon. \quad (34)$$

Then there exists δ such that $q \in \mathcal{B}(p, \delta)$ implies $\tilde{p} \in \mathcal{B}(\tilde{p}, \tilde{\delta})$. Thus using (3) and (34), $\forall i \in [n]$, $\forall q \in \mathcal{B}(p, \delta)$, for $\alpha_1, \alpha_2 \in \mathbb{R}$,

$$\begin{aligned} \ell_i(q) - \ell_i(p) &= \underline{L}(q) + (e_i - q)' \cdot ((A(\tilde{q})', 0)' + \alpha_1 \mathbb{1}) - \\ &\quad (\underline{L}(p) + (e_i - p)' \cdot ((D\underline{L}(\tilde{p})', 0)' + \alpha_2 \mathbb{1})), \\ &= \underline{L}(q) - \underline{L}(p) + (\tilde{e}_i - \tilde{q})' \cdot A(\tilde{q}) - (\tilde{e}_i - \tilde{p})' \cdot D\underline{L}(\tilde{p}) + \gamma, \quad \forall A(\tilde{q}) \in \partial \underline{L}(\tilde{q}), \end{aligned}$$

where $A(\tilde{q}) \in \partial \underline{L}(\tilde{q})$, and

$$\begin{aligned} \gamma &= -(e_i - q)' \cdot \alpha_1 \mathbb{1} + (e_i - p)' \cdot \alpha_2 \mathbb{1} = -\alpha_1 + \alpha_1 q' \cdot \mathbb{1} + \alpha_2 - \alpha_2 p' \cdot \mathbb{1} \\ &= -\alpha_1 + \alpha_1 + \alpha_2 - \alpha_2 = 0 \end{aligned}$$

and so

$$\ell_i(q) - \ell_i(p) = \underline{L}(q) - \underline{L}(p) + (\tilde{e}_i - \tilde{q})' \cdot (A(\tilde{q}) - D\underline{L}(\tilde{p})) + (\tilde{p} - \tilde{q})' \cdot D\underline{L}(\tilde{p}).$$

By continuity of \underline{L} , $\|\underline{L}(q) - \underline{L}(p)\| < \varepsilon$ for small enough δ . Furthermore by (34), $\|A(\tilde{q}) - D\underline{L}(\tilde{p})\| \leq 0$ and $\|\tilde{p} - \tilde{q}\| \leq \varepsilon$. Hence $\|\ell_i(q) - \ell_i(p)\| \leq \varepsilon + \varepsilon + \delta$ which can be made arbitrarily small by suitable choice of ε . Thus ℓ_i is continuous for all $i \in [n]$ and so ℓ is continuous.

(\Rightarrow) Assume that \underline{L} is not differentiable at $p \in \Delta^n$. Thus there exists two different supergradients at p : $A(\tilde{p})$ and $B(\tilde{p})$. Assume that one of these supergradients, $A(\tilde{p})$, is the one associated to the loss ℓ in the sense that for all $i \in [n]$ $\ell_i(p) = \underline{L}(p) + (\tilde{e}_i - \tilde{p})' \cdot A(\tilde{p})$.

Suppose that $\forall i \in [n]$,

$$(e_i - p)' \cdot ((A(\tilde{p})', 0)' + \alpha_1 \mathbb{1}) \leq (e_i - p)' \cdot ((B(\tilde{p})', 0)' + \alpha_2 \mathbb{1}), \quad \alpha_1, \alpha_2 \in \mathbb{R}. \quad (35)$$

Thus

$$\begin{aligned} \sum_{i \in [n]} q_i (e_i - p)' \cdot ((A(\tilde{p})', 0)' + \alpha_1 \mathbb{1}) &\leq \sum_{i \in [n]} q_i (e_i - p)' \cdot ((B(\tilde{p})', 0)' + \alpha_2 \mathbb{1}), \quad \forall q \in \Delta^n, \alpha_1, \alpha_2 \in \mathbb{R} \\ \Leftrightarrow (q - p)' \cdot ((A(\tilde{p})', 0)' + \alpha_1 \mathbb{1}) &\leq (q - p)' \cdot ((B(\tilde{p})', 0)' + \alpha_2 \mathbb{1}), \quad \forall q \in \Delta^n, \alpha_1, \alpha_2 \in \mathbb{R} \\ \Leftrightarrow (\tilde{q} - \tilde{p})' \cdot A(\tilde{p}) &\leq (\tilde{q} - \tilde{p})' \cdot B(\tilde{p}), \quad \forall \tilde{q} \in \tilde{\Delta}^n. \end{aligned} \quad (36)$$

Since $p \in \Delta^n$ we can choose \tilde{q}_1 and $\tilde{q}_2 \in \tilde{\Delta}^n$ such that $\tilde{q}_1 - \tilde{p} = \tilde{p} - \tilde{q}_2$ and so the only way (36) can hold is if

$$(\tilde{q} - \tilde{p})' \cdot A(\tilde{p}) = (\tilde{q} - \tilde{p})' \cdot B(\tilde{p}).$$

Since $p \in \Delta^n$ is arbitrary, we obtain that $A(\tilde{p}) = B(\tilde{p})$, a contradiction and so (35) must be false. Thus there exists $i \in [n]$ such that

$$(e_i - p)' \cdot ((A(\tilde{p})', 0)' + \alpha_1 \mathbb{1}) > (e_i - p)' \cdot ((B(\tilde{p})', 0)' + \alpha_2 \mathbb{1}), \quad \alpha_1, \alpha_2 \in \mathbb{R}.$$

Thus

$$\exists i \in [n], (\tilde{e}_i - \tilde{p})' \cdot A(\tilde{p}) > (\tilde{e}_i - \tilde{p})' \cdot B(\tilde{p}). \quad (37)$$

Let $p_\eta := p + \eta(e_i - p)$ and denote by $C(\tilde{p}_\eta)$ the supergradient associated with ℓ at p_η (that is, $\ell_i(p_\eta) = \underline{L}(p_\eta) + (\tilde{e}_i - \tilde{p}_\eta)' \cdot C(\tilde{p}_\eta)$). By definition of the supergradient,

$$\underline{L}(p_\eta) \leq \underline{L}(p) + (\tilde{p}_\eta - \tilde{p})' \cdot B(\tilde{p}) \quad \text{and} \quad \underline{L}(p) \leq \underline{L}(p_\eta) + (\tilde{p} - \tilde{p}_\eta)' \cdot C(\tilde{p}_\eta).$$

Thus

$$\begin{aligned} \underline{L}(p_\eta) &\leq \underline{L}(p_\eta) + C(\tilde{p}_\eta)' \cdot (\tilde{p} - \tilde{p}_\eta) + B(\tilde{p})' \cdot (\tilde{p}_\eta - \tilde{p}) \\ \Rightarrow C(p_\eta)' \cdot (\tilde{p}_\eta - \tilde{p})' &\leq B(\tilde{p})' \cdot (\tilde{p}_\eta - \tilde{p})'. \end{aligned}$$

But by definition of p_η , $\tilde{p}_\eta - \tilde{p} = \tilde{p} + \eta(\tilde{e}_i - \tilde{p}) - \tilde{p} = \eta(\tilde{e}_i - \tilde{p})$. Thus for $\eta > 0$,

$$C(\tilde{p}_\eta)' \cdot (\tilde{e}_i - \tilde{p}) \leq B(\tilde{p})' \cdot (\tilde{p} - \tilde{e}_i). \quad (38)$$

and so

$$\text{Now } \ell_i(p_\eta) = \underline{L}(p_\eta) + (\tilde{e}_i - \tilde{p}_\eta)' \cdot C(\tilde{p}_\eta), \text{ Hence (38) implies}$$

$$\ell_i(p_\eta) \leq \underline{L}(p_\eta) + (\tilde{e}_i - \tilde{p})' \cdot B(\tilde{p}).$$

However $\lim_{\eta \searrow 0} p_\eta = p$ and by continuity of \underline{L} ,

$$\begin{aligned} \lim_{\eta \searrow 0} \underline{L}(p_\eta) + (\tilde{e}_i - \tilde{p})' \cdot B(\tilde{p}) &= \underline{L}(p) + (\tilde{e}_i - \tilde{p})' \cdot B(\tilde{p}) \\ &< \underline{L}(p) + (\tilde{e}_i - \tilde{p})' \cdot A(\tilde{p}) \\ &= \ell_i(p) \text{ by (37)}. \end{aligned}$$

Thus $\lim_{\eta \searrow 0} \ell_i(p_\eta) < \ell_i(p)$ and so ℓ_i is not continuous at p and thus ℓ is not continuous at p .

B.3 Proof of Proposition 7

The proof shows the equivalence of statements 1 and 2 and, separately the equivalence of 1 and 3 and 1 and 4.

1 \Rightarrow 2: Suppose that ℓ is proper and $p, q \in \partial \Delta^n$. Let $\tilde{L}^{p,q}$ denote the conditional risk associated with $\tilde{\ell}^{p,q}$. Then

$$\begin{aligned} \tilde{L}^{p,q}(\eta, \tilde{\eta}) &= (\eta q + (1 - \eta)p)' \cdot \ell(p + \eta(q - p)) = \underline{L}(p + \eta(q - p), p + \tilde{\eta}(q - p)) \\ &\geq \underline{L}(p + \eta(q - p), p + \eta(q - p)) = \tilde{L}^{p,q}(\eta, \eta). \end{aligned}$$

Hence $\tilde{\ell}^{p,q}$ is proper.

1 \Leftarrow 2: Suppose that $\tilde{p}^{p,q}$ is proper $\forall p, q \in \partial \Delta^n$. Suppose $p, q \in \Delta^n$. Then there exists \tilde{p} and $\tilde{q} \in \partial \Delta^n$ such that $p = \tilde{p} + \eta(\tilde{q} - \tilde{p})$ and $q = \tilde{p} + \hat{\eta}(\tilde{q} - \tilde{p})$, where $\eta, \hat{\eta} \in [0, 1]$ (the line passing through p and q cuts $\partial \Delta^n$ at \tilde{p} and \tilde{q} ; see Figure 12). Then

$$L(p, q) = \tilde{L}^{\tilde{p}, \tilde{q}}(\eta, \hat{\eta}) \geq \tilde{L}^{\tilde{p}, \tilde{q}}(\eta, \eta) = L(p, p).$$

Hence ℓ is proper.

One can easily prove that 3 \Rightarrow 1 by taking $h_1 = 0$.

For 3 \Leftarrow 1 we use a result of Lambert (2010, Proposition 1), which tells us a binary probability estimation loss ℓ_b is proper

if and only if $\forall \eta \leq \eta_1 \leq \eta_2$ or $\eta \geq \eta_2, L_b(\eta, \eta_1) \leq L_b(\eta, \eta_2)$ (the assumptions on the statistic are checked in the binary case with the statistic function $\Gamma: \Delta^2 \ni p \mapsto \mathbb{E}(p) \in [0, 1]$). We also know that if ℓ is proper then $\forall p, q \in \partial \Delta^n$, $\tilde{p}^{p,q}$ (introduced in Proposition 7) is proper. We assume that ℓ is proper, $\forall p, q \in \Delta^n$, $\forall 0 \leq h_1 \leq h_2$, we introduce the projections $\tilde{p}, \tilde{q} \in \partial \Delta^n$ of p and q , then there exists η and μ such that $p = \tilde{p} + \eta(\tilde{q} - \tilde{p})$ and $q = \tilde{p} + \mu(\tilde{q} - \tilde{p})$. We denote $\eta_1 = \eta + h_1(\mu - \eta)$ and $\eta_2 = \eta + h_2(\mu - \eta)$. Then the result of Lambert applied to $\tilde{p}^{p,q}$ gives us $L(p, p + h_1(q - p)) \leq L(p, p + h_2(q - p))$. One can adapt the proof in the case of strict properness.

1 \Rightarrow 4: If ℓ is proper, $p^i \cdot \ell(q) = q^i \cdot \ell(q) + (p - q)^i \cdot \ell(q) = \underline{L}(q) + (p - q)^i \cdot \ell(q)$. Thus $\forall q \in \Delta^n$ there exists $A(q)$ such as $L(p, q) = \underline{L}(q) + (p - q)^i \cdot A(q)$. Since ℓ is proper, $\forall p \in \Delta^n$, $0 \leq L(p, p) - L(p, q) = \underline{L}(q) - \underline{L}(p) + (p - q)^i \cdot A(q)$. Then $A(q)$ is a supergradient of $\underline{L} = f$ (which is concave) at q , and $p^i \cdot \ell(q) = f(q) + (p - q)^i \cdot A(q)$.

4 \Rightarrow 1: If there exists a function f concave and $\forall q \in \Delta^n$, there exists a supergradient $A(q) \in \partial f(q)$ such that $\forall p, q \in \Delta^n$, $p^i \cdot \ell(q) = f(q) + (p - q)^i \cdot A(q)$. Then, $L(p, p) - L(p, q) = f(p) - f(q) + (p - q)^i \cdot A(q) \geq 0$. Hence ℓ is proper.

B.4 Proof of Proposition 10

The proposition is a direct consequence of the characterization of differentiable binary proper losses (Reid and Williamson, 2010). A differentiable binary loss λ is proper if and only if $\frac{-\lambda'_1(\eta)}{1-\eta} = \frac{\lambda'_1(\eta)}{\eta} \geq 0, \forall \eta \in (0, 1)$.

Suppose the loss ℓ can be expressed as a proper composite loss: $\ell = \lambda \circ \psi^{-1}$ and so $\lambda = \ell \circ \psi$. Therefore for $y \in \{-1, 1\}$, $\lambda'_1(\eta) = \psi^i(\eta) \ell'_1(\psi(\eta))$. Then λ is proper and thus

$$\frac{-\lambda'_1(\eta)}{1-\eta} = \frac{\lambda'_1(\eta)}{\eta}, \quad \forall \eta \in (0, 1) \quad (39)$$

$$\Leftrightarrow \frac{\psi^i(\psi^{-1}(v))}{1-\psi^{-1}(v)} \ell'_1(v) = \frac{\psi^i(\psi^{-1}(v))}{\psi^{-1}(v)} \ell'_{-1}(v), \quad \forall v \in \mathcal{Y}$$

$$\Leftrightarrow \psi^i(\psi^{-1}(v)) = 0 \text{ or } \ell'_{-1}(v) = \ell'_1(v) = 0 \text{ or } \psi^{-1}(v) = \frac{\ell'_{-1}(v)}{\ell'_1(v)}, \quad \forall v \in \mathcal{Y}. \quad (40)$$

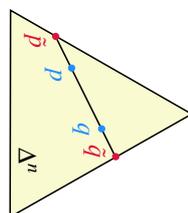

Figure 12: Illustration of proof of Proposition 7.

Since ψ is differentiable and invertible, ψ' cannot equal zero on an interval. By continuity, ψ^{-1} is uniquely defined on an interval I when $\forall v_1, v_2 \in I, \exists v \in [v_1, v_2], \ell'_1(v) \neq 0$ or $\ell'_{-1}(v) \neq 0$. If $I = \mathcal{Y}$ then ψ is unique and thus $\lambda = \ell \circ \psi$ is unique.

If $\ell'_1(v) = \ell'_{-1}(v) = 0, \forall v \in [v_1, v_2]$ then one can choose any $\psi|_{[v_1, v_2]}$ which is differentiable, invertible and such that ψ is continuous in v_1 and v_2 and as ℓ_1 and ℓ_{-1} are constant on $[v_1, v_2]$, $\lambda(\eta) = \ell(\psi(\eta))$ does not depend on ψ and so in any case λ is unique.

B.5 Proof of Proposition 11

The loss λ is proper if and only if (39) and $-\lambda'_1(\eta) \geq 0$ and $\lambda'_{-1}(\eta) \geq 0$. This is equivalent to there exists an invertible ψ such that (40) holds and

$$-\psi^i(\psi^{-1}(v)) \ell'_1(v) \geq 0 \text{ and } \psi^i(\psi^{-1}(v)) \ell'_{-1}(v) \geq 0, \quad \forall v \in \mathcal{Y}. \quad (41)$$

(\Rightarrow) Suppose ℓ has a composite representation with ψ strictly increasing and thus $\psi'(v) > 0$ for all $v \in \mathcal{Y}$ and thus $-\ell'_1(v) \geq 0$ and $\ell'_{-1}(v) \geq 0$. Hence ℓ_1 is decreasing and ℓ_{-1} is increasing. By hypothesis, $\ell'_{-1}(v) \neq 0$ or $\ell'_1(v) \neq 0$. Furthermore $\psi'(v)$ can not equal zero except at isolated points. Thus (40) implies $\psi^{-1}(v) = \frac{\ell'_{-1}(v)}{\ell'_1(v) - \ell'_1(v)}$ and thus f is strictly increasing. (If instead ψ was strictly decreasing, we can run the same argument to conclude ℓ_1 is increasing, ℓ_{-1} is decreasing and f is strictly decreasing.)

(\Leftarrow) Suppose ℓ_1 is decreasing, ℓ_{-1} is increasing and f is strictly increasing. By setting $\psi^{-1}(v) = \frac{1}{1-f(v)}$, ψ^{-1} is invertible and (41) holds. The other case is analogous.

B.6 Proof of Proposition 17

Fix an arbitrary $p \in \Delta^n$. The function f_p is quasi-convex if its α sublevel sets

$$F_p^\alpha := \{q \in \Delta^n : p^i \ell(q) \leq \alpha\}$$

are convex for all $\alpha \in \mathbb{R}$ (Greenberg and Pierskalla, 1971). Fix an arbitrary $\alpha > \underline{L}(p)$, and thus $F_p^\alpha \neq \emptyset$. Let

$$Q_p^\alpha := \{x \in \mathbb{R}^n : p^i x \leq \alpha\}$$

so $F_p^\alpha = \{q \in \Delta^n : \ell(q) \in Q_p^\alpha\}$. Denote by

$$H_p^\beta := \{x : x^i \cdot q = \beta\}$$

the hyperplane in direction $q \in \Delta^n$ with offset $\beta \in \mathbb{R}$ and by

$$H_p^\beta := \{x : x^i \cdot q \geq \beta\}$$

the corresponding half-space. Since ℓ is proper, \mathcal{S}_ℓ is supported at $x = \ell(q)$ by the hyperplane $H_q^{\underline{L}(q)}$ and furthermore since \mathcal{S}_ℓ is convex, $\mathcal{S}_\ell = \bigcap_{q \in \Delta^n} H_q^{\underline{L}(q)}$.

Let

$$V_p^\alpha := \bigcap_{x \in (\Delta^n) \cap Q_p^\alpha} H_x^{\ell^{-1}(x)} = \bigcap_{q \in F_p^\alpha} H_q^{\underline{L}(q)}$$

Observe that

$$\inf\{\beta : h_{\beta}^{\Delta} \cap \ell(\mathcal{Y}) \neq \emptyset\} = \inf\{p' \cdot \ell(v) : h_{p'}^{\Delta, \ell(v)} \cap \ell(\mathcal{Y}) \neq \emptyset, v \in \mathcal{Y}\}.$$

Thus $p' \cdot \lambda(p) = p' \cdot (\ell \circ \psi)(p) = \inf_{v \in \mathcal{Y}} p' \cdot \ell(v)$. By Δ^x -smoothness of $\ell(\mathcal{Y})$, for all $v \in \mathcal{Y}$ there exists a unique $p \in \Delta^n$ such that $\psi(p) = v$ and thus ψ is invertible. Hence $p' \cdot \lambda(p) = \inf_{q \in \Delta^n} p' \cdot \lambda(q)$ and thus λ is proper. Since $\ell(\mathcal{Y})$ is Δ^n -strictly convex there exists a unique point where $h_{\beta}^{\Delta(p)}$ supports $\ell(\mathcal{Y})$. Hence λ is strictly proper and we have shown that ℓ has a strictly proper composite representation.

Strictly proper composite $\ell \Rightarrow \Delta^x$ -strictly convex: Suppose ℓ has a strictly proper composite representation $\ell(v) = \lambda(\psi^{-1}(v))$. Pick $p \in \Delta^n$. By assumption, there exists $v \in \mathcal{Y}$ such that $\psi^{-1}(v) = p$. Since λ is strictly proper, there is a unique $q \in \Delta^n$ which minimises $q \mapsto p' \cdot \lambda(q)$. By invertibility of ψ , there thus exists a unique $v \in \mathcal{Y}$ that minimises $v \mapsto p' \cdot \ell(v)$ and so there is a unique x at which h_{β}^{Δ} supports $\ell(\mathcal{Y})$ for some $\beta \in \mathbb{R}$. Thus $\ell(\mathcal{Y})$ is Δ^n -strictly convex.

Now pick an arbitrary $v \in \mathcal{Y}$ which induces an arbitrary $x = \ell(v) \in \ell(\mathcal{Y})$. Let $p = \psi^{-1}(v)$. Then $h_{\beta}^{\Delta(p)}$ supports $\ell(\mathcal{Y})$ at x since λ is proper. Suppose there was another $q \neq p, q \in \Delta^n$ such that $h_{\beta}^{\Delta(q)}$ supports $\ell(\mathcal{Y})$ at x . But that would require that $v = \psi(q)$ which is impossible since $v = \psi(p)$ and ψ is invertible. Thus p is unique and $\ell(\mathcal{Y})$ is Δ^n -smooth.

Abstract

Identification of latent variables that govern a problem and the relationships among them, given measurements in the observed world, are important for causal discovery. This identification can be accomplished by analyzing the constraints imposed by the latents in the measurements. We introduce the concept of *pairwise cluster comparison* (PCC) to identify causal relationships from clusters of data points and provide a two-stage algorithm called *learning PCC* (LPCC) that learns a latent variable model (LVM) using PCC. First, LPCC learns exogenous latents and latent colliders, as well as their observed descendants, by using pairwise comparisons between data clusters in the measurement space that may explain latent causes. Since in this first stage LPCC cannot distinguish endogenous latent non-colliders from their exogenous ancestors, a second stage is needed to extract the former, with their observed children, from the latter. If the true graph has no serial connections, LPCC returns the true graph, and if the true graph has a serial connection, LPCC returns a pattern of the true graph. LPCC's most important advantage is that it is not limited to linear or latent-tree models and makes only mild assumptions about the distribution. The paper is divided in two parts: Part I (this paper) provides the necessary preliminaries, theoretical foundation to PCC, and an overview of LPCC; Part II formally introduces the LPCC algorithm and experimentally evaluates its merit in different synthetic and real domains. The code for the LPCC algorithm and data sets used in the experiments reported in Part II are available *online*.

Keywords: causal discovery, clustering, learning latent variable model, multiple indicator model, pure measurement model

1. Introduction

Latent (unmeasured, hidden, unrecorded) variables, as opposed to observed (measured, manifest, recorded) variables, cannot usually be observed directly in a domain but only inferred from other observed variables or indicators (Spirites, 2013). Concepts such as “quality of life,” “economic stability,” “gravitational fields,” and “psychological stress”

play a key role in scientific theories and models, and yet such entities are latent (Klee, 1997).

Sometimes, latent variables correspond to aspects of physical reality that could, in principle, be measured but may not be for practical reasons, for example, “quarks”. In this situation, the term hidden variables is commonly used, reflecting the fact that the variables are “really there”, but hidden. On the other hand, latent variables may not be physically real but instead correspond to abstract concepts such as “psychological stress” or “mental states”. The terms hypothetical variables or hypothetical constructs may be used in these situations.

Latent variable models (LVMs) represent latent variables and the causal relationships among them to explain observed variables that have been measured in the domain. These models are common and essential in diverse areas, such as in economics, social sciences, psychology, natural language processing, and machine learning. Thus, they have recently become the focus of an increasing number of studies. LVMs reduce dimensionality by aggregating (many) observed variables into a few latent variables, each of which represents a “concept” explaining some aspects of the domain that can be interpreted from the data. Latent variable modeling is a century-old enterprise in statistics. It originated with the work of Spearman (1904), who developed factor analytic models for continuous variables in the context of intelligence testing.

Learning an LVM exploits values of the measured variables as manifested in the data to make an inference about the causal relationships among the latent variables and to predict the value of these variables. Statistical methods for learning an LVM, such as factor analysis, are most commonly used to reveal the existence and influence of latent variables. Although these methods effectively reduce dimensionality and may fit the data reasonably well, the resulting models might not have any correspondence to real causal mechanisms (Silva et al., 2006). On the other hand, the focus of learning Bayesian networks (BNs) is on causal relations among observed variables, whereas the detection of latent variables and the interrelations among themselves and with the observed variables has received little attention. Learning an LVM using Inductive Causation* (IC*) (Pearl, 2000; Pearl and Verma, 1991) and Fast Causal Inference (FCI) (Spirites et al., 2000) returns partial ancestral graphs, which indicate for each link whether it is a (potential) manifestation of a hidden common cause for the two linked variables. The structural EM algorithm (Friedman, 1998) learns a structure using a fixed set of previously given latents. By searching for “structural signatures” of latents, the FindHidden algorithm (Elidan et al., 2000) detects substructures that suggest the presence of latents in the form of dense subnetworks. Elidan and Friedman (2001) give a fast algorithm for determining the cardinality – the number of possible states – of latent variables introduced this way. However, Silva et al. (2006) suspected that FindHidden cannot always find a pure measurement sub-model,¹ which is a flaw in causal analysis. Also, the recovery of latent trees of binary and Gaussian variables has been suggested (Pearl, 2000). Hierarchical latent class (HLC) models, which are rooted trees where the leaf nodes are observed while all other nodes are latent, were proposed for the clustering of categorical data (Zhang, 2004). Two greedy algorithms are suggested (Harmeling

¹A pure measurement model contains all graph variables and all and only edges directed from latent variables to observed variables, where each observed variable has only one latent parent and no observed parent.

and Williams, 2011) to expedite learning of both the structure of a binary HLC and the cardinalities of the latents. The BIN-G algorithm determines both the structure of the tree and the cardinality of the latent variables in a bottom-up fashion. The BIN-A algorithm first determines the tree structure using agglomerative hierarchical clustering and then determines the cardinality of the latent variables in the same manner as the BIN-G algorithm. Latent-tree models are also used to speed approximate inference in BNs trading the approximation accuracy with inferential complexity (Wang et al., 2008).

Models in which multiple latents may have multiple indicators (observed children), also known as multiple indicator models (MIMs) (Bartholomew et al., 2002; Spirites, 2013), are a very important subclass of structural equation models (SEM), which are widely used, together with BNs, in applied and social sciences to analyze causal relations (Pearl, 2000; Shimizu et al., 2011). For these models, and others that are not tree-constrained, most of the mentioned algorithms may lead to unsatisfactory results. This is one of the most difficult problems in machine learning and statistics since, in general, a joint distribution can be generated by an infinite number of different LVMs. However, an algorithm that fills the gap between learning latent-tree models and learning MIMs is BuildPureClusters (BPC; Silva et al., 2006). BPC searches for the set (an equivalence class) of MIMs that best matches the set of vanishing tetrad differences (Scheines et al., 1995), but is limited to linear models (Spirites, 2013).

In this study, we make another attempt in this direction and target the goal of Silva et al. (2006), but concentrate on the discrete case, rather than on the continuous case dealt with BPC. Towards this mission, we borrow ideas and principles of clustering and unsupervised learning. Interestingly, the same difficulty in learning MIMs is also faced in the domain of unsupervised learning that confronts similar questions such as: (1) How many clusters are there in the observed data? and (2) Which classes do the clusters really represent? Due to this similarity, our study suggests linking the two domains – learning a causal graphical model with latent variables and clustering analysis. We propose a concept and an algorithm that combine learning causal graphical models with clustering. According to the *pairwise cluster comparison* (PCC) concept, we compare pairwise clusters of data points representing instantiations of the observed variables to identify those pairs of clusters that exhibit major changes in the observed variables due to changes in their ancestor latent variables. Changes in a latent variable that are manifested in changes in the observed variables reveal this latent variable and its causal paths of influence in the domain. Using the *learning PCC* (LPCC) algorithm, we learn an LVM. We identify PCCs and use them to learn latent variables – exogenous and endogenous (the latter may be either colliders or non-colliders) – and their causal interrelationships as well as their children (latent variables and observed variables) and causal paths from latent variables to observed variables.

This paper is the first of two parts that introduce, describe, and evaluate LPCC. In this paper (Part I), we provide its foundations and theoretical infrastructure, from preliminaries to a broad overview of the PCC concept and LPCC algorithm. In the second paper (Part II), we formally introduce the two-stage LPCC algorithm, which implements the PCC concept, and evaluate LPCC, in comparison to state-of-the-art algorithms, using simulated and real-world data sets. The outline of the two papers is as follows:

Part I:

- **Section 2: Preliminaries to LVM learning** describes the assumptions of our approach and basic definitions of essential concepts of graphical models and SEM;
- **Section 3: Preliminaries to LPCC** formalizes our ideas and builds the theoretical basis for LPCC;
- **Section 4: Overview of LPCC** starts with an illustrative example and a broad description of the LPCC algorithm and then describes each step of LPCC in detail;
- **Section 5: Discussion and future research** summarizes and discusses the contribution of LPCC and suggests several new avenues of research;

• **Appendix A** provides proofs to all propositions, lemmas, and theorems for which the proof is either too detailed, lengthy, or impedes the flow of reading. All other proofs are given in the body of the paper;

• **Appendix B** sets a method to calculate a threshold in support of Section 4.4; and

• **Appendix C** supplies a detailed list of assumptions LPCC makes and the meaning of their violation.

Part II:

• **Section 2: The LPCC algorithm** introduces and formally describes a two-stage algorithm that implements the PCC concept;

• **Section 3: LPCC evaluation** evaluates LPCC, in comparison to state-of-the-art algorithms, using simulated and real-world data sets;

• **Section 4: Related works** compares LPCC to state-of-the-art LVM learning algorithms;

• **Section 5: Discussion** summarizes the theoretical advantages (from Part I) and the practical benefits (from this part) of using LPCC;

• **Appendix A** brings assumptions, definitions, propositions, and theorems from Part I that are essential to Part II;

• **Appendix B** supplies additional results for the experiments with the simulated data sets; and

• **Appendix C** provides PCC analysis for two example databases.

2. Preliminaries to LVM learning

The goal of our study is to reconstruct an LVM from i.i.d. data sampled from the observed variables in an unknown model. To accomplish this, we propose learning from pairwise cluster comparison using LPCC. First, we present the assumptions that LPCC makes and the constraints it applies on LVM and compare them to those required by other state-of-the-art methods.

Assumption 1 *The underlying model is a Bayesian network, $BN = \langle G, \Theta \rangle$, encoding a discrete joint probability distribution P for a set of random variables $V = LUO$, where $G = \langle V, E \rangle$ is a directed acyclic graph (DAG) whose nodes V correspond to latents L and observed variables O , and E is the set of edges between nodes in G . Θ is the set of parameters, i.e., the conditional probabilities of variables in V given their parents.*

Assumption 2 *No observed variable in O is an ancestor of any latent variable in L . This property is called the measurement assumption (Spirtes et al., 2000).*

Before we present additional assumptions about the learned LVM, we need Definitions 1–4 (following Silva et al., 2006), which are specific to LVM:

Definition 1 *A model satisfying Assumptions 1 and 2 is a latent variable model.*

Definition 2 *Given an LVM G with a variable set V , the subgraph containing all variables in V and all and only those edges directed into variables in O is called the measurement model of G .*

Definition 3 *Given an LVM G , the subgraph containing all and only G 's latent nodes and their respective edges is called the structural model of G .*

When each model variable is a linear function of its parents in the graph plus an additive error term of positive finite variance, the latent variable model is linear; this is also known as SEM. Great interest has been shown in linear LVMs and their applications in social science, econometrics, and psychometrics (Bollen, 1989), as well as in their learning (Silva et al., 2006). The motivation to use linear models usually comes from social and related sciences. For example,² researchers give subjects a questionnaire with questions like: "On a scale of 1 to 5, how much do you agree with the statement: 'I feel sad every day'." The answer is measured by an observed variable, and the linearity of the influence of an unknown cause (say depression in this case) on the answer (value) to the question is assumed. By using other questions, which researchers assume also measure depression, they expect to discover a latent depression variable that is a parent of several observed variables (each measuring a question), together indicating depression. It is common to require several questions/observed variables for the identification of each latent variable and to consider the information revealed through only a single question as noise, which cannot guarantee the identification of the latent. Researchers expect that other questions will be clustered by another latent variable that measures another aspect in the domain, and thus

²P. Spirtes, private communication.

questions of one cluster will be independent of questions of another cluster conditioned on the latent variables. They also attribute unconditional independence that is detected between observed variables of different clusters to errors in the learning algorithm.

Adding the linearity assumption to Assumptions 1 and 2 allows for the transformation of Definition 1 into that of a linear LVM. Since assuming linearity means linearity is assumed in the measurement model, a key to learning a linear LVM is learning the measurement model and only then the structural model. In learning the measurement model of MIM, the linearity assumption entails constraints on the covariance matrix of the observed variables and thereby eliminates learning co-variants (dependencies) between pairs of observed variables that "should" not be connected in the learned model (Silva et al., 2006; Spirtes, 2013). If, however, the linearity assumption does not hold, the algorithms suggested in Silva et al. (2006) may not find a model and would output a "can't tell" answer, which is, nevertheless, a better result than learning an incorrect model.

In this study, we dispense with the linearity assumption and apply the above concepts to learn not necessarily linear MIMs or latent-tree models. Our suggested algorithm, LPCC, is not limited by the linearity assumption and learns a model as long as it is MIM. In addition, we are interested in discrete LVMs.

Another important definition we need is:

Definition 4 *A pure measurement model is a measurement model in which each observed variable has only one latent parent and no observed parent.*

Assumption 3 *The measurement model of G is pure.*

As a principled way of testing conditional independence among latents, Silva et al. (2006) focus on MIMs, which are pure measurement models. Practically, these models have a smaller equivalence class of the latent structure than that of non-pure models and thus are easier to unambiguously learn. Consider, for example, that we are interested in learning the topic of a document (e.g., the first page in a newspaper) from anchor word (key phrase) distributions and that this document may cover several topics (e.g., politics, sports, and finance). Simplification of this topic modeling problem, following the representation of a topic using a latent variable in LVM, can be achieved by assuming and learning a pure measurement model representing a pure topic model for which each specific document covers only a single topic, which is reasonable in some cases, such as a sports or financial newspaper.

LPCC does not assume that the true measurement model is linear (which is a parametric assumption that, e.g., BPC makes), but rather assumes that the model is pure (a structural assumption). When the true causal model is pure, LPCC will identify it correctly (or find its pattern that represents the equivalence class of the true graph). When it is not pure, LPCC – similarly to BPC (Silva et al., 2006) – will learn a pure sub-model of the true model using two indicators for each latent (compared to three indicators per latent that are required by BPC). Part II of this paper presents several examples of real-world problems from different domains for which LPCC learns a pure (sometimes sub-) model, never less accurately than other methods.

That is, LPCC assumes that:

Assumption 4 *The true model G is MIM, in which each latent has at least two observed children and may have latent parents.*

Causal structure discovery – learning the number of latent variables in the model, their interconnections and connections to the observed variables, as well as the interconnections among the observed variables – is very difficult and thus requires making some assumptions about the problem. Particularly, MIMs, in which multiple observed variables are assumed to be affected by latent variables and perhaps by each other (Spirites, 2013), are reasonable models but have attracted scant attention in the machine-learning community. As Silva et al. (2006) pointed out, factor analysis, principal component analysis, and regression analysis adapted to learning LVMs are well understood but have not been proven, under any general assumptions, to learn the true causal LVM, calling for better learning methods. By assuming that the true model manifests local influence of each latent variable on at least a small number of observed variables, Silva et al. (2006) showed that learning the complete Markov equivalence class of MIM is feasible. Similar to Silva et al. (2006), we assume that the true model is MIM; thus, this is where we place our focus on learning. Note also that based on Assumptions 3 and 4, the observed variables in G are d-separated, given the latents.

3. Preliminaries to LPCC

Figure 1 sketches a range of MIMs, which all exhibit pure measurement models, from basic to more complex models. Compared to G1, which is a basic MIM of two unconnected latents, G2 shows a structural model that is characterized by a latent collider. Note that such an LVM cannot be learned by latent-tree algorithms such as in Zhang (2004). G3 and G4 demonstrate serial and diverging structural models, respectively, that together with G2 cover the three basic structural models. G5 and G6 manifest more complex structural models comprising a latent collider and a combination of serial and diverging connections. As the structural model becomes more complicated, the learning task becomes more challenging; hence, G1–G6 present a spectrum of such challenges to an LVM learning algorithm.³

In Section 3.1, we build the infrastructure to pairwise cluster comparison that relies on understanding the influence of the exogenous latent variables on the observed variables in the LVM. This influence is divided into major and minor effects that are introduced and explained in Section 3.2. In Section 3.3, we link this structural influence to data clustering and introduce the pairwise cluster comparison concept for learning an LVM.

3.1 The influence of exogenous latents on observed variables is fundamental to learning an LVM

We distinguish between observed (O) and latent (L) variables and between exogenous (EX) and endogenous (EN) variables. EX have zero in-degree, are autonomous, and unaffected

³In Part II of the paper, we compare LPCC with BPC and exploratory factor analysis using these six LVMs. Since BPC requires three indicators per latent to identify a latent, we determined from the beginning three indicators per latent for all true models to recover. Nevertheless, in Part II, we evaluate the learning algorithms for increasing numbers of indicators.

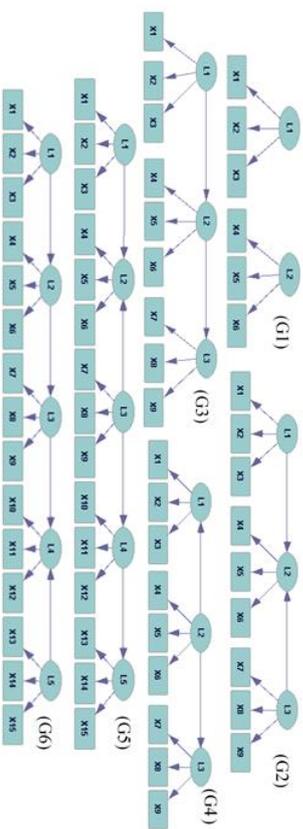

Figure 1: Example LVMs that are all MIMs. Each is based on a pure measurement model and a structural model of different complexity, posing a different challenge to a learning algorithm.

by the values of the other variables (e.g., L1 in all graphs but G4 in Figure 1), whereas EN are all non-exogenous variables in G (e.g., L2 in all graphs but G1 and G4, and X1 in all graphs in Figure 1). We identify three types of variables: (1) Exogenous latents, $EX \subset (L \cap NC)$ [all exogenous variables are latent non-colliders (NC)]; (2) Endogenous latents, $EL \subset (L \cap EN)$, which are divided into latent colliders $CCEL$ (e.g., L2 in G2 and G5; note that all latent colliders are endogenous) and latent non-colliders (in serial and diverging connections) $SEL \cap NC$ (e.g., L3 in G3, G4, and G6), thus $NC = (EX \cup S)$; and (3) Observed variables, $O \subset EN$, which are always endogenous and childless, that are divided into children of exogenous latents $OEX \subset O$ (e.g., X1 and X9 in G2), children of latent colliders $OCC \subset O$ (e.g., X4, X5, and X6 in G2), and children of endogenous latent non-colliders $OSEL \subset O$ (e.g., X4, X5, and X6 in G3). We denote value configurations of EX, EN (when we do not know whether the endogenous variables are latent or observed), EL, C, NC (when we do not know whether the non-collider variables are exogenous or endogenous), S, O, OEX, OC, and OS by $ex, en, el, c, nc, s, o, oex, oc,$ and os , respectively.

Since the underlying model is a BN, the joint probability over V , which is represented by the BN, is factored according to the local Markov assumption for G . That is, any variable in V is independent of its non-descendants in G conditioned on its parents in G :

$$P(\mathbf{V}) = \prod_{V_i \in V} P(V_i | \mathbf{Pa}_i) \quad (1)$$

where \mathbf{Pa}_i are the parents of V_i . It can be factorized under our assumptions as:

$$P(\mathbf{V}) = P(\mathbf{EX}, \mathbf{C}, \mathbf{S}, \mathbf{OEX}, \mathbf{OC}, \mathbf{OS}) = \prod_{EX_i \in \mathbf{EX}} P(EX_i) \prod_{C_j \in \mathbf{C}} P(C_j | \mathbf{Pa}_j) \prod_{S_t \in \mathbf{S}} P(S_t | Pa_t) \prod_{OEX_m \in \mathbf{OEX}} P(OEX_m | EX_m) \prod_{OC_k \in \mathbf{OC}} P(OC_k | C_k) \prod_{OS_v \in \mathbf{OS}} P(OS_v | S_v) \quad (2)$$

where \mathbf{Pa}_j are the latent parents of the latent collider C_j , Pa_t is the latent parent of the latent non-collider S_t (in other words, $\mathbf{Pa}_j, Pa_t \subset \mathbf{NC}$), $C_k \in \mathbf{C}$ and $S_v \in \mathbf{S}$ are the latent collider and latent non-collider parents of observed variables OC_k and OS_v , respectively, and $EX_m \in \mathbf{EX}$ is the exogenous latent parent of observed variable OEX_m .

In this paper, we claim and demonstrate that the influence of exogenous (latent) variables on observed variables is fundamental to learning an LVM and introduce LPCC that identifies and exploits this influence to learn an MIM. In this section, we prove that changes in values of the observed variables are due to changes in values of the exogenous variables and thus the identification of the former indicates the existence of the latter. To do that, we analyze the propagation of influence along paths connecting both variables, remembering that the paths may contain latent colliders and latent non-colliders. First, however, we should analyze paths among the latents and only then paths ending in their sinks (i.e., the observed variables). To prove that all changes in the graph, and specifically those measured in the observed variables, are the result of changes in the exogenous latent variables, we will need to first provide some definitions (following Spirtes et al., 2000; Pearl, 1988, 2000) of paths and some assumptions about the possible paths between latents in the structural model.

Definition 5 A path between two nodes V_1 and V_n in a graph \mathbf{G} is a sequence of nodes $\{V_1, \dots, V_n\}$, such that V_i and V_{i+1} are adjacent in \mathbf{G} , $1 \leq i < n$, i.e., $\{V_i, V_{i+1}\} \in \mathbf{E}$.

Note that a unique set of edges is associated with each given path. Paths are assumed to be simple by definition; in other words, no node appears in a path more than once, and an empty path consists of a single node.

Definition 6 A collider on a path $\{V_1, \dots, V_n\}$ is a node V_i , $1 < i < n$, such that V_{i-1} and V_{i+1} are parents of V_i .

Definition 7 A directed path T_{V_n} from V_1 to V_n in a graph \mathbf{G} is a path between these two nodes, such that for every pair of consecutive nodes V_i and V_{i+1} , $1 \leq i < n$ on the path, there is an edge from V_i into V_{i+1} in \mathbf{E} . V_1 is the source, and V_n is the sink of the path. A directed path has no colliders.

While BPC (Silva et al., 2006) needs to make a parametric assumption about the linearity of the model, LPCC makes assumptions about the model structure (Assumption 3 above and Assumption 5 below). This is also the approach of latent-tree algorithms (Zhang, 2004; Harmeling and Williams, 2011; Wang et al., 2008) that restrict the learned structure to a tree (note that LPCC is not limited to a tree because it allows latent variables

to be colliders). This shows a tradeoff between the structural and parametric assumptions that an algorithm for learning an LVM usually has to make; the fewer parametric assumptions the algorithm makes, the more structural assumptions it has to make and vice versa.

Assumption 5 A latent collider does not have any latent descendants (and thus cannot be a parent of another latent collider).

To distinguish between latent colliders and latent non-colliders, their observed children, and their connectivity patterns to their exogenous variables, we use Lemma 1. Latent colliders and their observed children are connected to several exogenous variables via several directed paths, whereas latent non-colliders and their observed children are connected only to a single exogenous variable via a single directed path. Use of these different connectivity patterns – from exogenous latents through endogenous latents (both colliders and non-colliders) to observed variables – simplifies (2) and the analysis of the influence of latents on observed variables.

Lemma 1

1. Each latent non-collider NC_t has only one exogenous latent ancestor EX_{NC_t} , and there is only one directed path T_{NC_t} from EX_{NC_t} (source) to NC_t (sink). (Note that we use the notation NC_t , rather than S_t , since the lemma applies to both exogenous and endogenous latent non-colliders.)
2. Each latent collider C_j is connected to a set of exogenous latent ancestors \mathbf{EX}_{C_j} via a set of directed paths T_{C_j} from \mathbf{EX}_{C_j} (sources) to C_j (sink).

Lemma 1 allows us to separate the influence of all exogenous variables to separate paths of influence, each from exogenous to observed variables. Proposition 1 quantifies the propagation of this influence along the paths through the joint probability distribution.

Proposition 1 The joint probability over \mathbf{V} due to value assignment \mathbf{ex} to exogenous set \mathbf{EX} is determined only by this assignment and the BN conditional probabilities.

Proof The first product in (2) for assignment \mathbf{ex} is of \mathbf{ex} 's priors. In the other five products, the probabilities are of endogenous latents or observed variables conditioned on their parents, which, based on Lemma 1, are either on the directed paths from \mathbf{EX} to the latents/observed variables or exogenous themselves. Either way, any assignment of endogenous latents or observed variables is a result of the assignment \mathbf{ex} to \mathbf{EX} that is mediated to the endogenous latents/observed variables by the BN probabilities:

$$P(\mathbf{V} | \mathbf{EX} = \mathbf{ex}) = P(\mathbf{EX}, \mathbf{C}, \mathbf{S}, \mathbf{OEX}, \mathbf{OC}, \mathbf{OS} | \mathbf{EX} = \mathbf{ex}) = \prod_{EX_i \in \mathbf{EX}} P(EX_i = ex_i) \prod_{C_j \in \mathbf{C}} P(C_j = c_j | \mathbf{Pa}_j = \mathbf{pa}_j) \prod_{S_t \in \mathbf{S}} P(S_t = nc_t | Pa_t = pa_t) \prod_{OEX_m \in \mathbf{OEX}} P(OEX_m = oe_{x_m} | EX_m = ex_m) \prod_{OC_k \in \mathbf{OC}} P(OC_k = oc_k | C_k = c_k) \prod_{OS_v \in \mathbf{OS}} P(OS_v = os_v | S_v = s_v) \quad (3)$$

where

- ex_i and ex_m are the values of EX_i and EX_m (the latter is the parent of the m th observed child of the exogenous latents), respectively, in the assignment \mathbf{ex} to EX ;
- $\mathbf{pa}_{-j}^{ex_{C_j}}$ is the configuration of C_j 's parents due to configuration \mathbf{ex}_{C_j} of C_j 's exogenous ancestors in \mathbf{ex} ;
- $pa_i^{ex_{S_i}}$ is the value of S_i 's parent due to the value ex_{S_i} of S_i 's exogenous ancestor in \mathbf{ex} ;
- $c_k^{ex_{C_k}}$ is the value of OC_k 's collider parent due to the configuration \mathbf{ex}_{C_k} of C_k 's exogenous ancestors in \mathbf{ex} ; and
- $s_v^{ex_{S_v}}$ is the value of OS_v 's non-collider parent due to the value ex_{S_v} of S_v 's exogenous ancestor in \mathbf{ex} .

Proposition 1 along with Lemma 1 are a key in our analysis because they show paths of hierarchical influence of latents on observed variables – from exogenous latents through endogenous latents (both colliders and non-colliders) to observed variables. Recognition and use of these paths of influence guides LPCC in learning LVMs.

To formalize our ideas, we introduce several concepts in Section 3.2. First, we define local influence on a single EN of its direct parents. Second, we use local influences and the BNMarkov property to generalize the influence of EX on EN . Third, exploiting the connectivity between the exogenous ancestors and their endogenous descendants, as described by Lemma 1, we focus on the influence of a specific (partial) set of exogenous variables on the values of their endogenous descendants. Analysis of the influence of all configurations \mathbf{exs} on all \mathbf{ens} and that of the configurations of specific exogenous ancestors in these \mathbf{exs} on their endogenous descendants enable learning the structure and parameters of the model and causal discovery. Finally, in Section 3.3, we show how these concepts can be exploited to learn an LVM from data clustering.

3.2 Major and minor effects and values

So far, we have analyzed the structural influences (path of hierarchies) of the latents on the observed variables. In this section, we complement this analysis with the parametric influences, which we divide into major and minor effects.

Definition 8 A local effect on an endogenous variable EN is the influence of a configuration of EN 's direct latent parents on any of EN 's values.

1. A major local effect is the largest local effect on EN_i , and it is identified by the maximal conditional probability of a specific value en_i of EN_i given a configuration \mathbf{pa}_i of EN_i 's latent parents \mathbf{Pa}_i , which is $MAE_{EN_i}(\mathbf{pa}_i) = \max_{en_i} P(EN_i = en_i | \mathbf{Pa}_i = \mathbf{pa}_i)$.
2. A minor local effect is any non-major local effect on EN_i , and it is identified by a conditional probability of any other value of EN_i given \mathbf{pa}_i , that is smaller than $MAE_{EN_i}(\mathbf{pa}_i)$. The minor local effect set, $MIESE_{EN_i}(\mathbf{pa}_i)$, comprises all such probabilities.

3. A major local value is the en_i corresponding to $MAE_{EN_i}(\mathbf{pa}_i)$, i.e., the most probable value of EN_i due to \mathbf{pa}_i , $MAV_{EN_i}(\mathbf{pa}_i) = \operatorname{argmax}_{en_i} P(EN_i = en_i | \mathbf{Pa}_i = \mathbf{pa}_i)$.
4. A minor local value is an en_i corresponding to a minor local effect, and $MIVSE_{EN_i}(\mathbf{pa}_i)$ is the set of all minor values that correspond to $MIESE_{EN_i}(\mathbf{pa}_i)$.

When EN_i is an observed variable or an endogenous latent non-collider, and thus has only a single parent Pa_i , the configuration \mathbf{pa}_i is actually the value pa_i of Pa_i .

So far, we have listed our assumptions about the structure of the model. Following is a parametric assumption:

Assumption 6 For every endogenous variable EN_i in G and every configuration \mathbf{pa}'_i of EN_i 's parents \mathbf{Pa}_i , there exists a certain value en'_i of EN_i , such that $P(EN_i = en'_i | \mathbf{Pa}_i = \mathbf{pa}'_i) > P(EN_i = en''_i | \mathbf{Pa}_i = \mathbf{pa}'_i)$ for every other value en''_i of EN_i . This assumption is related to the most probable explanation of a hypothesis given the data (Pearl, 1988).

Note that in the case that Assumption 6 is violated, in other words, if more than one value of EN_i gets the maximum probability value given a configuration of parents, LPCC still learns a model because the implementation will randomly choose a value that maximizes the probability as the most probable. However, the correctness of the algorithm is guaranteed only if all assumptions are valid; in other words, given the assumptions are valid, all causal claims made by the output graph are correct.

Proposition 2 The major local value $MAV_{EN_i}(\mathbf{pa}'_i)$ of an endogenous variable EN_i given a certain configuration of its parents \mathbf{pa}'_i is also certain.

Proof Assumption 6 guarantees that given a certain configuration \mathbf{pa}'_i of \mathbf{Pa}_i , there exists a certain value en'_i of EN_i , such that $P(EN_i = en'_i | \mathbf{Pa}_i = \mathbf{pa}'_i) > P(EN_i = en''_i | \mathbf{Pa}_i = \mathbf{pa}'_i)$ for every other value en''_i of EN_i . From the definition of a major local value, $MAV_{EN_i}(\mathbf{pa}'_i) = en'_i$. ■

We need one additional assumption about the model parameters that reflects parent-child influence in the causal model. Specifically, to identify parent-child relations, LPCC needs for each observed variable or endogenous latent non-collider to get different MAVs for different values of their latent parent. Similarly, LPCC needs a collider to get different values for each of its parents in at least two parent configurations in which this parent changes, whereas the other parents do not.

Assumption 7 First, for every EN_i that is an observed variable or an endogenous latent non-collider and for every two values pa'_i and pa''_i of Pa_i , $MAV_{EN_i}(pa'_i) \neq MAV_{EN_i}(pa''_i)$. Second, for every C_j that is a latent collider and for every $Pa_j \in \mathbf{Pa}_j$, there are at least two configurations \mathbf{pa}'_j and \mathbf{pa}''_j of \mathbf{Pa}_j in which only the value of Pa_j is different and $MAV_{C_j}(\mathbf{pa}'_j) \neq MAV_{C_j}(\mathbf{pa}''_j)$.

By aggregation over all local influences, we can now generalize these concepts through the BN parameters and Markov property from local influences on specific endogenous variables to influence on all endogenous variables in the graph.

Definition 9 An effect on EN is the influence of a configuration \mathbf{ex} of EX on EN . The effect is measured by a value configuration \mathbf{en} of EN due to \mathbf{ex} . A major effect (MAE) is the largest effect of \mathbf{ex} on EN and a minor effect (MIE) is any non-MAE effect of \mathbf{ex} on EN . Also, a major value configuration (MAV) is the configuration \mathbf{en} of EN corresponding to MAE (i.e., the most probable \mathbf{en} due to \mathbf{ex}), and a minor value configuration is a configuration \mathbf{en} corresponding to any MIE.

[Note the difference between a major effect, MAE, and a major local effect, MAE_{EN_j} , and between a major value configuration, MAV, and a major local value, MAV_{EN_j} (and similarly for the “minors”).]

Based on the proof of Proposition 1, we can quantify the effect of \mathbf{ex} on EN . For example, a major effect of \mathbf{ex} on EN can be factorized according to the product of major local effects on EN (weighted by the product of priors, $P(EX_j = ex_j)$):

$$\begin{aligned} MAE(\mathbf{ex}) &= \prod_{EX_i \in \mathbf{EX}} P(EX_i = ex_i) \prod_{C_j \in \mathbf{C}} MAE_{C_j}(\mathbf{pa}_j^{\mathbf{ex}_{C_j}}) \prod_{S_t \in \mathbf{S}} MAE_{S_t}(pa_t^{\mathbf{ex}_{S_t}}) \\ &= \prod_{OEX_m \in \mathbf{OEX}} MAE_{OEX_m}(ex_m) \prod_{OC_k \in \mathbf{OC}} MAE_{OC_k}(c_k^{\mathbf{ex}_{C_k}}) \prod_{OS_v \in \mathbf{OS}} MAE_{OS_v}(s_v^{\mathbf{ex}_{S_v}}) \\ &= \prod_{EX_i \in \mathbf{EX}} P(EX_i = ex_i) \prod_{C_j \in \mathbf{C}} \max_{c_j'} P(C_j = c_j' | \mathbf{pa}_j = \mathbf{pa}_j) \prod_{S_t \in \mathbf{S}} \max_{s_t'} P(S_t = s_t' | pa_t = pa_t) \\ &= \prod_{OEX_m \in \mathbf{OEX}} \max_{oc_k'} P(OEX_m = oc_k' | EX_m = ex_m) \prod_{OC_k \in \mathbf{OC}} \max_{oc_k'} P(OC_k = oc_k' | C_k = c_k) \\ &= \prod_{OS_v \in \mathbf{OS}} \max_{os_v'} P(OS_v = os_v' | S_v = s_v^{\mathbf{ex}_{S_v}}). \end{aligned} \quad (4)$$

A configuration \mathbf{en} of EN in which each variable in EN takes on the major local value is major or a MAV. Any effect in which at least one EN takes on a minor local effect is minor, and any configuration in which at least one EN takes on a minor local value is minor. We denote the set of all minor effects for \mathbf{ex} with $MIES(\mathbf{ex})$ (with correspondence to $MIES_{EN_j}$) and the set of all minor configurations with $MIVS(\mathbf{ex})$ (with correspondence to $MIVS_{EN_j}$).

Motivated by Lemma 1 and Proposition 1, we are interested in representing the influence on a subset of the endogenous variables of the subset of the exogenous variables that impact these endogenous variables. This partial representation of MAE will enable LPCC to recover the relationships between exogenous ancestors and only the descendants that are affected by these exogenous variables. To achieve this, we first extend the concept of effect to the concept of partial effect of specific exogenous variables and then quantify it. Later, we shall formalize all of this in Lemma 2.

Definition 10 A partial effect on a subset of endogenous variables $\mathbf{EN}' \subseteq \mathbf{EN}$ is the influence of a configuration \mathbf{ex} of \mathbf{EN}' 's exogenous ancestors $\mathbf{EX} \subseteq \mathbf{EX}$ on \mathbf{EN}' . We define a partial major effect $MAE_{\mathbf{EN}'}(\mathbf{ex})$ as the largest partial effect of \mathbf{ex} on \mathbf{EN}' and a partial minor effect $MIE_{\mathbf{EN}'}(\mathbf{ex})$ as any non- $MAE_{\mathbf{EN}'}(\mathbf{ex})$ partial effect of \mathbf{ex} on \mathbf{EN}' . A partial major value configuration $MAV_{\mathbf{EN}'}(\mathbf{ex})$ is the \mathbf{en}' of \mathbf{EN}' corresponding to $MAE_{\mathbf{EN}'}(\mathbf{ex})$; in other words, the most probable \mathbf{en}' due to \mathbf{ex} , and a partial minor value configuration is an \mathbf{en}' corresponding to any $MIE_{\mathbf{EN}'}(\mathbf{ex})$.

We are interested in representing the influence of exogenous variables on their observed descendants and all the variables in the directed paths connecting them. To do this, we separately analyze the (partial) effect of each exogenous variable on each observed variable for which the exogenous is its ancestor and all the latent variables along the path connecting these two. We distinguish between two cases (both are represented in Lemma 1): (1) Observed descendants in \mathbf{OEX} and \mathbf{OS} that are, respectively, children of exogenous latents and children of latent non-colliders that are linked to their exogenous ancestors, each via a single directed path; and (2) Observed descendants in \mathbf{OC} that are children of latent colliders and linked to their exogenous ancestors via a set of directed paths through their latent collider parents. Thus, we are interested in:

1. The partial effect of a value of exogenous ancestor EX_{NC_v} to non-collider NC_v on any configuration of the set of variables $\{TS_{NC_v} \setminus EX_{NC_v}, ON_{C_v}\}$, where ON_{C_v} is an observed child of latent non-collider NC_v , and TS_{NC_v} is the set of variables in the directed path (recall Definition 7) T_{NC_v} from EX_{NC_v} to NC_v . The corresponding $MAE_{\{TS_{NC_v} \setminus EX_{NC_v}, ON_{C_v}\}}(ex_{NC_v})$ and $MAV_{\{TS_{NC_v} \setminus EX_{NC_v}, ON_{C_v}\}}(ex_{NC_v})$ are partial major effect and partial major value configuration, respectively. For example, we may be interested in the partial effect of a value of $EX_{NC_v} = EX_{L5} = L3$ in $G5$ (Figure 1) on $\{TS_{NC_v} \setminus EX_{NC_v}, ON_{C_v}\} = \{TS_{L5} \setminus L3, X13\} = \{L4, L5, X13\}$. Note that we use here the notation NC_v since we are interested in both exogenous and endogenous latent non-colliders. When we are interested in the partial effect on an observed variable in \mathbf{OEX} , its exogenous ancestor (which is also its direct parent) is also the latent non-collider, NC_v , and the effect is not measured on any other variable but this observed variable. This is *Case 1*, which is analyzed below;

2. The partial effect of a configuration of exogenous variables \mathbf{EX}_{C_k} to collider C_k on any configuration of the set of variables $\{TS_{C_k} \setminus \mathbf{EX}_{C_k}, OC_k\}$, where OC_k is an observed child of latent collider C_k ,⁴ and TS_{C_k} is the set of variables in the set of directed paths \mathbf{T}_{C_k} from \mathbf{EX}_{C_k} to C_k . The corresponding $MAE_{\{TS_{C_k} \setminus \mathbf{EX}_{C_k}, OC_k\}}(\mathbf{ex}_{C_k})$ and $MAV_{\{TS_{C_k} \setminus \mathbf{EX}_{C_k}, OC_k\}}(\mathbf{ex}_{C_k})$ are partial major effect and partial major value configuration, respectively. For example, we may be interested in the partial effect of a configuration of $\mathbf{EX}_{C_k} = \mathbf{EX}_{L4} = \{L1, L5\}$ in $G6$ (Figure 1) on $\{TS_{C_k} \setminus \mathbf{EX}_{C_k}, OC_k\} = \{\{L1, L2, L3, L4\} \setminus \{L1, L5\}, X11\} = \{L2, L3, L4, X11\}$. This is *Case 2*, which is analyzed below.

⁴Throughout the paper, we use a child index also for its parent, e.g., OC_k 's parent is C_k , although generally, we use the index j for a collider, such as C_j .

Following, we provide detailed descriptions for these partial effects and partial values for observed children of latent non-colliders (Case 1) and observed children of latent colliders (Case 2) and formalize their properties in Propositions 3–7 to set the stage for Lemma 2.

Case 1: Observed children of latent non-colliders

If the latent non-collider NC_v is exogenous, $NC_v = EX_v$ and $ONC_v = OEX_v$, then, $\{TS_{NC_v} \setminus EX_{NC_v}, ONC_v\} = OEX_v$. Thus, the partial effect is simply the local effect, and the partial major effect is the major local effect $MAEOEX_v(ex_v)$. If the latent non-collider NC_v is endogenous, then $NC_v = S_v$ and $ONC_v = OS_v$. Then, all variables in $\{TS_{NC_v} \setminus EX_{NC_v}, OS_v\}$ are d-separated by EX_{NC_v} from $EX \setminus EX_{NC_v}$. For example, [L4, L5, X13] in G5 (Figure 1) are d-separated by L3 from L2 and its children. Thus, the effect of ex on the joint probability distribution (3) can be factored to the: a) joint probability over $EX = ex$; b) conditional probabilities of the influenced variables along a specific directed path that ends at OS_v on $EX_{NC_v} = ex_{NC_v}$ (note that the value ex_{NC_v} for all $S_i \in TS_{NC_v}$ is the same because $EX_{NC_v} = EX_v$ is the same exogenous ancestor of all latent non-colliders on the path to S_v); and c) conditional probabilities of all the remaining variables in the graph on $EX = ex$:

$$\begin{aligned} P(V|EX = ex) &= P(EX = ex)P(TS_{NC_v} \setminus EX_{NC_v}, OS_v | EX_{NC_v} = ex_{NC_v}) \\ P(V \setminus \{TS_{NC_v} \setminus EX_{NC_v}, OS_v\} | EX = ex) & \end{aligned} \quad (5)$$

in which the second factor corresponds to the partial effect of $EX_{NC_v} = ex_{NC_v}$ on $TS_{NC_v} \setminus EX_{NC_v}$ (the latent non-colliders on the path from EX_{NC_v} to S_v) and S_v 's observed child, OS_v , and the third factor corresponds to the influence of $EX = ex$ on all the other (latent and observed) variables in the graph. We can write the second factor describing the partial effect of the value ex_{NC_v} on the values of the variables $TS_{NC_v} \setminus EX_{NC_v}$ in the directed path from EX_{NC_v} to OS_v (including) as:

$$\begin{aligned} P(TS_{NC_v} \setminus EX_{NC_v}, OS_v | EX_{NC_v} = ex_{NC_v}) &= \\ \prod_{S_i \in \{TS_{NC_v} \setminus EX_{NC_v}\}} P(S_i = s_i | P_{a_i} = pa_i^{ex_{NC_v}}) P(OS_v = os_v | S_v = s_v^{ex_{NC_v}}) & \end{aligned} \quad (6)$$

The partial major effect in (4) for this directed path can be written as (note again that $ex_{NC_v} = ex_{S_v}$):

$$\begin{aligned} MAE_{TS_{NC_v} \setminus EX_{NC_v}, OS_v}(ex_{NC_v}) &= MAE_{TS_{NC_v} \setminus EX_{NC_v}}(ex_{NC_v}) \cdot MAE_{OS_v}(s_v^{ex_{NC_v}}) = \\ \prod_{S_i \in \{TS_{NC_v} \setminus EX_{NC_v}\}} MAE_{S_i}(pa_i^{ex_{NC_v}}) \cdot MAE_{OS_v}(s_v^{ex_{NC_v}}) & \end{aligned} \quad (7)$$

Proposition 3 The MAV $\{TS_{NC_v} \setminus EX_{NC_v}, ONC_v\}(ex_{NC_v})$ corresponding to

$MAE_{TS_{NC_v} \setminus EX_{NC_v}, ONC_v}(ex_{NC_v})$ is a certain value configuration for each certain value ex_{NC_v} .

(Note that here we use the notation NC_v rather than S_v since the proposition applies to both exogenous and endogenous latent non-colliders.)

Proposition 4 All corresponding values in $MAV_{TS_{NC_v} \setminus EX_{NC_v}, ONC_v}(ex'_{NC_v})$ and $MAV_{TS_{NC_v} \setminus EX_{NC_v}, ONC_v}(ex''_{NC_v})$ for two values ex'_{NC_v} and ex''_{NC_v} of EX_{NC_v} are different.

(Here also we use the notation NC_v , since the proposition applies to both exogenous and endogenous latent non-colliders.)

So far, we have analyzed the impact of an exogenous variable on a latent non-collider by ‘‘propagating’’ the exogenous (source) impact along the path to the latent non-collider (sink). Propositions 3 and 4, respectively, guarantee that a certain value of the exogenous variable is responsible for a certain value of the latent non-collider and different values of the exogenous are echoed through different values of the latent non-collider. Proposition 4 is based on the correspondence between changes in values of a latent non-collider and changes in values of its parent; a correspondence that is guaranteed by Assumption 7 (first part). Propositions 3 and 4, respectively, ensure the existence and uniqueness of the value a latent non-collider gets under the influence of an exogenous ancestor: one (Proposition 3) and only one (Proposition 4) value of the latent non-collider changes with a change in the value of the exogenous. We formalize this in the following Proposition 5.

Proposition 5 EX_{NC_v} changes values (i.e., has two values ex'_{NC_v} and ex''_{NC_v}) if and only if NC_v changes values in the two corresponding major value configurations:

$$MAV_{TS_{NC_v} \setminus EX_{NC_v}, ONC_v}(ex'_{NC_v}) \text{ and } MAV_{TS_{NC_v} \setminus EX_{NC_v}, ONC_v}(ex''_{NC_v}).$$

Case 2: Observed children of latent colliders

In the case of an observed variable OC_k that is a child of a latent collider C_k , all variables in $\{TS_{C_k} \setminus EX_{C_k}, OC_k\}$ are d-separated by EX_{C_k} from $EX \setminus EX_{C_k}$. Thus, the effect of ex on the joint probability distribution (3) can be factored (similarly to Case 1) to the: a) joint probability over $EX = ex$; b) conditional probabilities of the influenced variables along all directed paths that end at OC_k on $EX_{C_k} = ex_{C_k}$ (note that all variables along each directed path T_{C_k} are influenced by the same ex_{C_k}); and c) conditional probabilities of all the remaining variables in the graph on $EX = ex$:

$$\begin{aligned} P(V|EX = ex) &= P(EX = ex)P(TS_{C_k} \setminus EX_{C_k}, OC_k | EX_{C_k} = ex_{C_k}) \\ P(V \setminus \{TS_{C_k} \setminus EX_{C_k}, OC_k\} | EX = ex) & \end{aligned} \quad (8)$$

in which the second factor corresponds to the partial effect on $\{TS_{C_k} \setminus EX_{C_k}, OC_k\}$ of EX_{C_k} and the third factor corresponds to the partial effect on all variables other than $\{TS_{C_k} \setminus EX_{C_k}, OC_k\}$. We can decompose the second factor into a product of: a) a product over all directed paths into C_k of a product of partial effects over all variables (excluding C_k) in such a path; b) the partial effect on C_k ; and c) the partial effect on its child OC_k :

$$\begin{aligned} P(TS_{C_k} \setminus EX_{C_k}, OC_k | EX_{C_k} = ex_{C_k}) &= \\ \prod_{T_{C_k} \in \{TS_{C_k} \setminus EX_{C_k}\}} \prod_{S_i \in T_{C_k}} P(S_i = s_i | P_{a_i} = pa_i^{ex_{C_k}}) P(C_k = c_k | P_{a_k} = pa_k^{ex_{C_k}}) P(OC_k = oc_k | C_k = c_k^{ex_{C_k}}), & \end{aligned} \quad (9)$$

This factor can be rewritten as:

$$P(\mathbf{TS}_{C_k} \setminus \mathbf{EX}_{C_k}, \mathbf{OC}_k | \mathbf{EX}_{C_k} = \mathbf{ex}_{C_k}) = \prod_{\mathbf{TS}_{C_k} \in \mathbf{TS}_{C_k}} P(\{\mathbf{TS}_{C_k} \setminus \mathbf{EX}_{C_k}, C_k\} | \mathbf{EX}_{C_k} = \mathbf{ex}_{C_k}) P(C_k = c_k | \mathbf{pa}_k = \mathbf{pa}_k) P(\mathbf{OC}_k = oc_k | C_k = c_k, \mathbf{ex}_{C_k}). \quad (10)$$

It reflects the partial effects of a configuration \mathbf{ex}_{C_k} on the values of the variables in $\{\mathbf{TS}_{C_k} \setminus \mathbf{EX}_{C_k}\}$ and the values C_k and \mathbf{OC}_k get, and thus the partial major effect of the second factor can be represented as:

$$MAE_{(\mathbf{TS}_{C_k} \setminus \mathbf{EX}_{C_k}, \mathbf{OC}_k)}(\mathbf{ex}_{C_k}) = \prod_{\mathbf{TS}_{C_k} \in \mathbf{TS}_{C_k}} MAE_{(\mathbf{TS}_{C_k} \setminus \mathbf{EX}_{C_k}, C_k)}(\mathbf{ex}_{C_k}) MAE_{C_k}(\mathbf{pa}_k) MAE_{\mathbf{OC}_k}(c_k, \mathbf{ex}_{C_k}). \quad (11)$$

Proposition 6 The $MAE_{(\mathbf{TS}_{C_k} \setminus \mathbf{EX}_{C_k}, \mathbf{OC}_k)}(\mathbf{ex}_{C_k})$ corresponding to $MAE_{(\mathbf{TS}_{C_k} \setminus \mathbf{EX}_{C_k}, \mathbf{OC}_k)}(\mathbf{ex}_{C_k})$ is a certain value configuration for each certain value configuration \mathbf{ex}_{C_k} .

We wish to apply the same mechanism as in Case 1 to analyze the impact of more than a single exogenous ancestor on a latent collider, but here the impact is propagated toward the collider along more than a single path. To accomplish this, the following Proposition 7 analyzes the effect on a collider of each of its exogenous ancestors by considering the effect of such an exogenous on the corresponding collider's parent (using Proposition 5, similar to Case 1 for a latent non-collider) and then the effect of this parent on the collider itself (using the second part of Assumption 7).

Proposition 7 For every exogenous ancestor $EX_{C_k} \in \mathbf{EX}_{C_k}$ of a latent collider C_k , there are at least two configurations \mathbf{ex}'_{C_k} and \mathbf{ex}''_{C_k} of \mathbf{EX}_{C_k} in which only EX_{C_k} changes values when C_k changes values in the two corresponding major value configurations $MAV_{(\mathbf{TS}_{C_k} \setminus \mathbf{EX}_{C_k}, \mathbf{OC}_k)}(\mathbf{ex}'_{C_k})$ and $MAV_{(\mathbf{TS}_{C_k} \setminus \mathbf{EX}_{C_k}, \mathbf{OC}_k)}(\mathbf{ex}''_{C_k})$.

Lemma 2

1. A latent non-collider NC_v and its observed child ONC_v , both descendants of an exogenous variable EX_{NC_v} , change their values in any two major configurations if and only if EX_{NC_v} has changed its value in the corresponding two configurations of \mathbf{EX} .
2. A latent collider C_k and its observed child OC_k , both descendants of a set of exogenous variables \mathbf{EX}_{C_k} , change their values in any two major configurations only if at least one of the exogenous variables in \mathbf{EX}_{C_k} has changed its value in the corresponding two configurations of \mathbf{EX} .

3.3 PCC by clustering observational data

Practically, we use observational data that were generated from an unknown LVM and measured over the observed variables. Proposition 1 showed us that each configuration

of observed variables (which is part of a configuration of the endogenous variables) and their joint probability is a result of the assignment of a configuration \mathbf{ex} to the exogenous variables \mathbf{EX} . Therefore, we define:

Definition 11 An observed value configuration, observed major value configuration, and observed minor value configuration due to \mathbf{ex} are the parts in \mathbf{en} , MAV , and a minor value configuration, respectively, that correspond to the observed variables.

The following two propositions formalize the relationships between the observed major value configurations and the set of possible \mathbf{ex} .

Proposition 8 There is only a single observed major value configuration to each exogenous configuration \mathbf{ex} of \mathbf{EX} .

Proof Based on Lemma 2, different observed major value configurations can be obtained if and only if there is more than a single exogenous configuration \mathbf{ex} of \mathbf{EX} . Thus, an exogenous configuration \mathbf{ex} can only lead to a single observed major value configuration. ■

Proposition 9 There are different observed major value configurations to different exogenous configurations \mathbf{ex} .

Proof Assume for the sake of contradiction that two different value configurations \mathbf{ex}_1 and \mathbf{ex}_2 led to the same observed major value configuration. Because the two configurations are different, there is at least one exogenous variable EX' that has different values in \mathbf{ex}_1 and \mathbf{ex}_2 . Since based on Assumption 4, EX' has at least two observed children, then, based on Assumption 7, each of these children has different values in the two observed major value configurations due to the different value of EX' in \mathbf{ex}_1 and \mathbf{ex}_2 . This is contrary to our assumption that there is only one observed major value configuration. ■

Due to the probabilistic nature of \mathbf{BN} , each observed value configuration due to \mathbf{ex} may be represented by several data points. Clustering these data points may produce several clusters for each \mathbf{ex} and each cluster corresponds to another observed value configuration. Based on Propositions 8 and 9, one and only one of the clusters corresponds to each of the observed major value configurations, whereas the other clusters correspond to observed minor value configurations. We distinguish between these clusters using Definition 12.

Definition 12 The single cluster that corresponds to the observed major value configuration, and thus also represents the major effect $MAE(\mathbf{ex})$ due to configuration \mathbf{ex} of \mathbf{EX} , is the major cluster for \mathbf{ex} , and all the clusters that correspond to the observed minor value configurations due to minor effects in $MIES(\mathbf{ex})$ are minor clusters.

To resolve between different types of minor effects/clusters, we make two definitions.

Definition 13 A k -order minor effect is a minor effect in which exactly k endogenous variables in \mathbf{EN} correspond to minor local effects. An \mathbf{en} corresponding to a k -order minor effect is a k -order minor value configuration.

Definition 14 *Minor clusters that correspond to k -order minor effects are k -order minor clusters.*

Based on Proposition 9 and Definition 12, the set of all major clusters (corresponding to all observed major value configurations) reflects the effect of all possible **ex**s, and thus the number of major clusters is expected to be equal to the number of **EX** configurations. Therefore, the identification of all major clusters is a key to the discovery of exogenous variables and their causal interrelations. For this purpose, we introduce the concept of *pairwise cluster comparison* (PCC); PCC measures the differences between two clusters; each represents the response of LVM to another **ex**.

Definition 15 *Pairwise cluster comparison is a procedure by which pairs of clusters are compared, for example through a comparison of their centroids. The result of PCC between a pair of cluster centroids of dimension $|\mathbf{O}|$, where \mathbf{O} is the set of observed variables, can be represented by a binary vector of size $|\mathbf{O}|$ in which each element is 1 or 0 depending, respectively, on whether or not there is a difference between the corresponding elements in the compared centroids.*

When PCC is between clusters that represent observed major value configurations (i.e., PCC between major clusters), an element of 1 identifies an observed variable that has changed its value between the compared clusters due to a change in **ex**. Thus, the 1s in a major–major PCC provide evidence of causal relationships between **EX** and **O**. Practically, LPCC always identifies all observed variables that are represented by 1s together in all PCCs as the observed descendants of the same exogenous variable (Section 4.1). However, due to the probabilistic nature of BN and the existence of endogenous latents (mediating the connections from **EX** to **O**), some of the clusters are k -order minor clusters (in different orders), representing k -order minor configurations/effects. Minor clusters are more difficult to identify than major clusters because the latter reflect the major effects of **EX** on **EN** and, therefore, are considerably more populated by data points than the former. Nevertheless, minor clusters are important in causal discovery by LPCC even though a major–minor PCC cannot tell the effect of **EX** on **EN** because an observed variable in two compared (major and minor) clusters should not necessarily change its value as a result of a change in **ex**. Their importance is because a major cluster, which is a zero-order minor value configuration and thus has zero minor values, cannot indicate (when compared with another major cluster) the existence of minor values. On the contrary, PCC between major and minor clusters shows (through the number of 1s) the number of minor values represented in the minor cluster, and this is exploited by LPCC for identifying the endogenous latents and interrelations among them (Section 4.4). That is, PCC is the source to identify causal relationships in the unknown LVM; major–major PCCs are used for identifying the exogenous variables and their descendants; and major–minor PCCs are used for identifying the endogenous latents, their interrelations, and their observed children.

4. Overview of the LPCC concept⁵

Let us demonstrate the relations between clustering results and learning an LVM using LPCC through an example. G1 in Figure 1 shows a model having two exogenous variables,

⁵Preliminary versions of the PCC concept and LPCC algorithm are given in Asbeh and Lerner (2012).

L1 and L2, each having three children X1, X2, X3 and X4, X5, X6, respectively. ⁶ For the example, let us assume that all variables are binary,⁷ i.e., L1 and L2 have four possible **ex**s (L1L2 = 00, 01, 10, 11). First, we generated a synthetic data set of 1,000 patterns from G1 over the six observed variables. We used a uniform distribution over L1 and L2 and set the probabilities of an observed child, $X_i, i = 1, \dots, 6$, given its latent parent, $L_k, k = 1, 2$ (only if L_k is a direct parent of X_i , e.g., L1 and X1), to be $P(X_i = v | L_k = v) = 0.8, v = 0, 1$. Second, using the self-organizing map (SOM) (Kohonen, 1997), we clustered the data set and found 16 clusters, of which four were major (see Section 4.3 for details on how to identify major clusters). This meets our expectation of four major clusters corresponding to the four possible **ex**s. These clusters are presented in Table 1a by their centroids, which are the most prevalent patterns in the clusters, and in Table 1b by their PCCs. For example, PCC1,2, comparing clusters C1 and C2, shows that when moving from C1 to C2, only the values corresponding to variables X1, X2, and X3 have been changed (i.e., $\delta X_1 = \delta X_2 = \delta X_3 = 1$ in Table 1b). Lemma 2 guarantees that the three variables are descendants of the same **EX** that changed its value between two **ex**s represented by C1 and C2. PCC1,4, PCC2,3, and PCC3,4 reinforce this conclusion. Indeed, we know from the true graph, G1, that this **EX** is latent L1. A similar conclusion can be deduced about X4, X5, and X6 as descendants of an exogenous latent, which we know, based on the true graph, is L2.

Centroid	X1	X2	X3	X4	X5	X6
C1	0	0	1	1	1	1
C2	1	1	1	1	1	1
C3	0	0	0	0	0	0
C4	1	1	1	0	0	0

PCC	δX_1	δX_2	δX_3	δX_4	δX_5	δX_6
PCC1,2	1	1	1	0	0	0
PCC1,3	0	0	0	1	1	1
PCC1,4	1	1	1	1	1	1
PCC2,3	1	1	1	1	1	1
PCC2,4	0	0	0	1	1	1
PCC3,4	1	1	1	1	0	0

Table 1: (a) Centroids of major clusters for G1 and (b) PCCs between these major clusters

LPCC is fed by data that is sampled from the observed variables in the unknown model. LPCC clusters the data using SOM (although any other clustering algorithm is good as well) and selects an initial set of major clusters (Section 4.3). Then, LPCC learns LVM in two stages. In the first stage, LPCC first identifies exogenous latent variables and latent colliders (without distinguishing them yet) and their corresponding observed descendants (Section 4.1) before distinguishing them (Section 4.2). LPCC iteratively improves the selection of the major clusters (Section 4.3), and the entire stage is repeated until convergence. In the second stage, LPCC identifies endogenous latent non-colliders with their children. Because this stage cannot distinguish from the outset between latent non-colliders and their latent ancestors, LPCC also needs to apply a mechanism to split these two types of latent variables from each other and to find the links between them after the split (Section 4.4). A flowchart of the LPCC algorithm is given in Figure 2.

⁶We remind that we determined three indicators per latent in all true models we demonstrate their learning (Figure 1) because BPC requires three indicators per latent to identify that latent; which makes the experimental evaluation we did in Part II of the paper fair.

⁷This is only for demonstration purposes. Part II of the paper shows evaluation results also for ternary latent variables and observed variables of different dimensions.

4.1 Identification of exogenous latent variables and latent colliders and their descendants

Table 1b shows that $PCC1,2$ (and $PCC3,4$) provides evidence that $X1, X2$, and $X3$ may be descendants of the same exogenous latent ($L1$, as we know) that has changed its value between the two exs represented by $C1$ and $C2$ (and $C3$ and $C4$). Relying only on one PCC may be inadequate when concluding that these variables are descendants of the same exogenous latent because there may be other exogenous latents that have changed their values too. Table 1b shows that $PCC2,3$ (and $PCC1,4$) provides the same evidence about $X1, X2$, and $X3$. But, $PCC2,3$ and $PCC1,4$ also show that the values corresponding to $X4, X5$, and $X6$ have been changed together too, whereas these values did not change in $PCC1,2$ and $PCC3,4$. Does this mean that $X4, X5$, and $X6$ are also descendants of the same latent ancestor of $X1, X2$, and $X3$? If we combine the two pieces of evidence provided by, e.g., $PCC1,2$ and $PCC2,3$, we can answer this question with a “no”. This is because $X4, X5$, and $X6$ changed their values only in $PCC2,3$ but not in $PCC1,2$, and thus they cannot be descendants of $L1$. This insight strengthens the evidence that $X1, X2$, and $X3$ are the only descendants of $L1$. A similar analysis using $PCC1,3$ and $PCC2,4$ will identify that $X4, X5$, and $X6$ are descendants of another latent variable ($L2$, as we know). Therefore, we define:

Definition 16 A maximal set of observed (MSO) variables is the set of variables that always changes its values together in each major-major PCC in which at least one of the variables changes value.

That is, there is a particular interest in identifying the MSOs that always change their values together in each major-major PCC in which at least one of the variables changes value. For example, $X1$ (Table 1) changes its value in $PCC1,2, PCC1,4, PCC2,3$, and $PCC3,4$ and always together with $X2$ and $X3$ (and vice versa). Thus $\{X1, X2, X3\}$ (and similarly $\{X4, X5, X6\}$) is an MSO. Each MSO includes descendants of the same exogenous latent variable L , and after considering all PCCs, LPCC identifies an MSO for each exogenous latent variable.

Based on any identified MSO, LPCC introduces to the learned graph a new latent variable L together with all the observed variables that are included in this MSO as its children. At this stage, LPCC cannot yet distinguish between exogenous latents and latent colliders since the main goal at this stage is to identify latent variables. For now, LPCC focuses on the identification of the relations between the latents and the observed variables, but not on the identification of the interrelations between the latents. The latter task that is needed for distinguishing the latent colliders from the exogenous latents is performed in a further step (Section 4.2). Note, however, that the identification of endogenous latent non-colliders needs a different analysis that is based on major-minor PCCs and not on major-major PCCs, and thus it is described separately in Section 4.4.

The following Theorem 1 helps us formalize this identification step. For this theorem, we also need Definition 17 of equivalence relation/classes from set theory and Lemma 3, which is important by itself and for better understanding of LPCC, but also for proving Theorem 1.

Definition 17 A given binary relation (i.e., between two elements) \sim on a set A is said to be an equivalence relation if and only if it is reflexive ($a \sim a$), symmetric (if $a \sim b$ then $b \sim a$), and

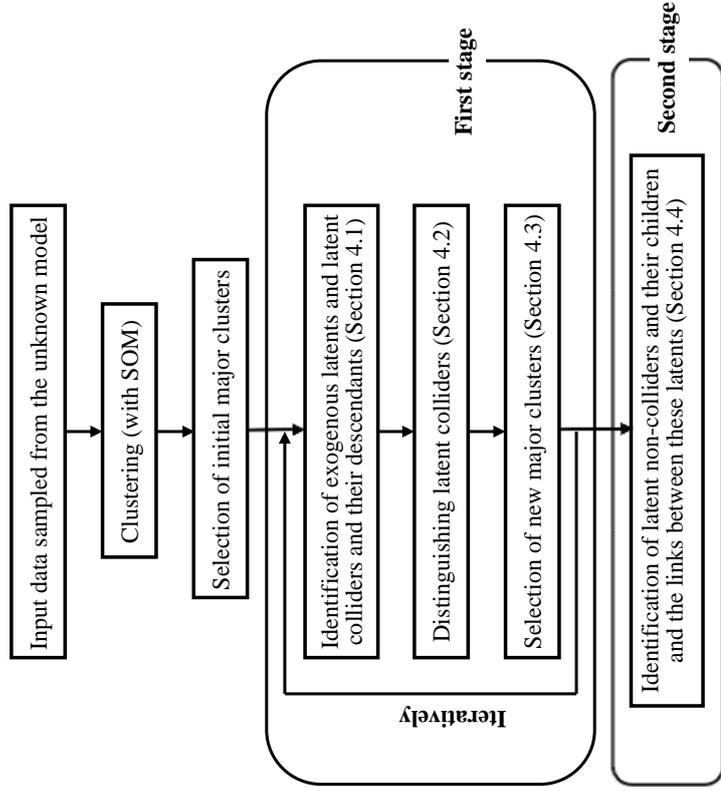

Figure 2: An overview of the LPCC algorithm.

transitive (if $a \sim b$ and $b \sim c$) for all a, b , and c in A . The equivalence class of a under \sim , denoted $[a]$, is defined as: $[a] = \{b \in A \mid b \sim a\}$ (Erderton, 1977).

Note that every two equivalence classes are either equal or disjoint. Therefore, the set of all equivalence classes of A forms a partition of A : every element of A belongs to one and only one equivalence class. It follows from the properties of an equivalence relation that: $a \sim b$ if and only if $|a| = |b|$. The following Lemma 3 is important since it shows that each **MSO** is an equivalence class, and thus **MSOs** corresponding to the learned latents are disjoint. At this stage, LPCC learns a set of at least two observed variables corresponding to a specific **MSO** for each latent where none of the observed variables is shared with other **MSOs** for other latents; in other words, a pure measurement model.

Lemma 3 *The relation “always changes together with” on the set O of all observed variables, such as “variable $O_j \in O$ always changes together with variable $O_j \in O$ in each PCC in which either O_i or O_j has changed” is an equivalence relation. Each equivalence class for this relation comprises an **MSO**.*

Proof All three conditions that are required for a binary relation to become equivalence are met:

1. O_j always changes with O_j (trivial).
2. If O_i always changes with O_j , then O_j always changes with O_i .
3. If O_j always changes with O_j , and O_j always changes with O_k , then O_i always changes with O_k .

Thus, the set of observed variables in a model can be represented by a set of equivalence classes for this relation, where each equivalence class includes all the variables that have the same equivalence relation, such as an **MSO**. ■

Theorem 1 *Variables of a particular **MSO** are children of a particular exogenous latent variable **EX** or its latent non-collider descendant or children of a particular latent collider **C**.*

Note that Theorem 1 guarantees that each of multiple latent variables (either an exogenous or any of its non-collider descendants or a collider) is identified by its own **MSO**, regardless of the latent cardinality.

4.2 Distinguishing latent collider variables

After identifying the exogenous latents and latent colliders together (Section 4.1), we need now to separate them. To demonstrate our concept for distinguishing latent colliders, we use graph G2 in Figure 1, which shows two exogenous latent variables, L1 and L3, that collide in one endogenous latent variable, L2. We assume that all latent variables are binary,⁸ and each has three binary observed children X1, X2, and X3 (L1), X4, X5, and X6

⁸See footnote 7.

(L2), and X7, X8, and X9 (L3). Having two exogenous binary variables, we expect to find four major clusters in the data generated from G2. Each cluster will correspond to one of the four possible **ex**s (L1L3= 00, 01, 10, 11). In this case, as for G1 that was analyzed in the introduction to Section 4, we expect the values of X1, X2, and X3 to change together in all the PCCs following a change in the value of L1, and the values of X7, X8, and X9 to change together in all the PCCs following a change in the value of L3. However, the values of X4, X5, and X6 will change together with those of X1, X2, and X3 in part of the PCCs and together with those of X7, X8, and X9 in the remaining PCCs, but always together in all of the PCCs. This will be evidence that X4, X5, and X6 are descendants of the same latent variable (L2, as we know), which is a collider of L1 and L3.

So far, LPCC learned latent variables but could not distinguish between exogenous latents and latent colliders (learning latent non-colliders will be described in Section 4.4). To learn that an already learned latent variable L is a collider for a set of other already learned (exogenous) latent ancestor variables **LACEX**, LPCC requires that: (1) The values of the children of L will change with the values of descendants of different latent variables in **LA** in different parts of major-major PCCs; and (2) The values of the children of L will not change in any PCC unless the values of descendants of at least one of the variables in **LA** change. This insures that L does not change independently of latents in **LA** that are L 's ancestors. We formalize this identification step in Theorem 2:

Theorem 2 *A latent variable L is a collider of a set of latent ancestors **LACEX** only if:*

1. *The values of the children of L change in different parts of some major-major PCCs each time with the values of descendants of another latent ancestor in **LA**; and*
2. *The values of the children of L do not change in any PCC unless the values of descendants of at least one of the variables in **LA** change too.*

4.3 Strategy for choosing major clusters

In this problem of unsupervised identification of latent variables given only observational data, LPCC has to deal with a lack of prior information regarding the distribution of each latent variable. Therefore, in its first iteration, LPCC assumes a uniform distribution over the latents and selects the major clusters based only on cluster size, which is the number of patterns clustered by the cluster. Clusters that are larger than the average cluster size are selected as majors. However, this initial selection may generate false negative errors (i.e., deciding a major cluster is minor). This may happen when a latent variable L has a skewed distribution over its values due to a low probability of L to take on any of its rare values. Then, the value configuration **ex** for which $L=v$, where v is a rare value, will be represented only by small clusters that could not be chosen as majors, although at least one of them should be major in representing v .

In addition, the initial selection may perform a false positive error (i.e., deciding a minor cluster is major), e.g., as a result of a very weak influence of L on any of its children (observed variables) X_i . In the discrete case, this weak influence can be represented as (almost) equal conditional probabilities of an observed variable to take on two different values $v_1 \neq v_2$ given the same value v of its latent parent, $P(X_i=v_1 \mid L=v) \cong P(X_i=v_2 \mid L=v)$. This may lead to splitting a data cluster that represents a configuration in which $L=v$ into

two clusters with almost the same size, and, when enough samples exist in both clusters, accepting both as major clusters instead of only one. For example, consider $G1$ in Figure 1, where all the variables are binary. Suppose that $P(X_2 = 0 | L1 = 0) = 0.6$ and $P(X_2 = 1 | L1 = 0) = 0.4$. This may split the cluster representing the configuration $L1L2=00$ into two clusters; in the first cluster $X_2 = 0$ and in the second cluster $X_2 = 1$. Due to the similar probabilities, both clusters may have approximately the same size, and if enough samples exist for $L1L2=00$ these two clusters may be larger than the average cluster size. Therefore, both may be accepted as major clusters in the initial selection. Recall that each ex should be represented by a single major cluster, which is the cluster that reflects the major effect of ex on the observed variables. In the example, only the cluster in which $X_2 = 0$ should be a major cluster, but due to the similar probabilities a false positive error could occur by also accepting the cluster in which $X_2 = 1$ as major.

To avoid these possible errors due to skewed data and circumstances that undermine identifiability, LPCC decides on major clusters iteratively. After learning a graph based on the initial selection of major clusters based on their sizes, it becomes possible to learn the cardinalities of the latent variables and consequently to find all possible exs (Section 4.1). Then, for each ex , we can select the most probable cluster given the data and use it as an update to the major cluster that represents this ex . Using an EM-style procedure (Dempster et al., 1977), the set of major clusters can be updated iteratively and probabilistically and augment LPCC to learn more accurate graphs (see Section 2.1 in Part II for more details). This process can be repeated until convergence to a final graph (Figure 2). Since the final graph depends on the initial graph, the iterative approach cannot guarantee finding the optimal model, but only improving the initial graph.

4.4 Identification of latent non-collider variables

So far (Section 4.1), based on major-major PCCs, all the endogenous latent non-colliders that are descendants of an exogenous variable EX were temporarily combined with EX , and all the observed children of these latent non-colliders were temporarily combined with the direct children of EX . Thus, to identify latent non-colliders, LPCC needs to split them from their previously learned ancestor together with their observed children. We suggest that this identification stage be based on major-minor PCCs (recall that latent colliders were already identified separately, as described in Section 4.2).

To exemplify this need, let us observe $G3$ in Figure 1, which shows a serial connection of three latent variables $L1$, $L2$, and $L3$. Assume each of the latents is binary and has three binary observed children. $L1$ is the only EX with two possible exs ($L1=0, 1$), and $L2$ and $L3$ are NCs; $L2$ is a child of $L1$ and a parent of $L3$. We synthetically generated a random data set of 1,000 patterns from $G3$ over the nine observed variables. We set the probabilities of: 1) $L1$ uniformly; 2) an observed child X_i , $i = 1, \dots, 9$, given its latent parent L_k , $k = 1, 2, 3$ (only if L_k is a direct parent of X_i , e.g., $L1$ and $X1$), as $P(X_i = v | L_k = v) = 0.8, v = 0, 1$; and 3) an endogenous latent L_j , $j = 2, 3$, given its latent parent L_k , $k = 1, 2$ (only if L_k is a direct parent of L_j , e.g., $L1$ and $L2$), as $P(L_j = v | L_k = v) = 0.8, v = 0, 1$. Table 2 presents the seventeen largest clusters using their centroids and sizes, from which $C1$ and $C2$ were selected as major clusters (initially, $C1-C6$ were selected, because they are larger than the average cluster size of 21, but then the iterative strategy described in Section 4.3 left only $C1$ and $C2$ as

major clusters). This meets our expectation of two major clusters corresponding to the two possible exs of $L1$. However, because all the elements in $PCC1,2$ are 1s (compare $C1$ and $C2$ in Table 2), the nine observed variables establish a single MSO and by Theorem 1 are considered descendants of the same exogenous variable. That is, the model $G0$ learned in the first phase of LPCC has only one exogenous latent variable (i.e., $L1$), and all of the nine observed descendants are learned as its direct children, which is contrary to $G3$. Since $L2$ and $L3$, which are latent non-colliders that are descendants of $L1$ in $G3$, were combined in $G0$ with $L1$, LPCC should split them from $L1$ along with their observed children in order to learn the true graph.

Thus, in the second phase, LPCC tests the assumption that $G0$ is true. If the assumption is rejected, LPCC infers that an exogenous latent EX has latent non-collider descendants, which were temporarily joined to EX in the first phase, and hence splits them from EX . To be able to reject the assumption about the correctness of $G0$, and thereby identify a possible split of an exogenous latent EX , we first define a first-order minor cluster (1-MC).

Centroid	X1	X2	X3	X4	X5	X6	X7	X8	X9	size
$C1$	1	1	1	1	1	1	1	1	1	49
$C2$	0	0	0	0	0	0	0	0	0	47
$C3$	1	1	1	1	1	1	1	1	0	28
$C4$	0	0	0	0	0	0	0	1	0	24
$C5$	0	1	0	0	0	0	0	0	0	22
$C6$	1	1	1	1	1	1	0	0	0	22
$C7$	0	0	1	0	0	0	0	0	0	21
$C8$	0	0	0	1	1	1	1	1	1	19
$C9$	0	0	0	0	0	0	1	1	1	18
$C10$	1	1	1	0	0	0	0	0	0	16
$C11$	0	0	0	1	0	0	0	0	0	14
$C12$	0	0	0	0	0	0	1	0	0	14
$C13$	1	0	1	1	1	1	1	1	1	14
$C14$	1	1	1	0	1	1	1	1	1	14
$C15$	1	0	0	0	0	0	0	0	0	13
$C16$	1	1	1	1	1	1	0	1	1	12
$C17$	0	0	0	0	0	1	0	0	0	12

Table 2: The seventeen largest clusters for $G3$ represented by their centroids and sizes

A 1-MC is a cluster that corresponds to a 1-order minor value configuration (Definitions 13 and 14), which exists when exactly one endogenous variable in EN (either latent or observed) has a minor local value (Definition 13) as a response to a value $ex \in ex$ that $EX \in EX$ has obtained. By analyzing, for each exogenous EX , PCCs between 1-MCs and the major clusters that identified EX , LPCC reveals the existence of the latent non-colliders that were previously combined with EX (Section 4.1). Following that, LPCC splits these non-colliders from EX . We will show that if only one observed variable changes in such PCCs (e.g., $X9$ in $PCC1,3$ in Table 3; $C1$ is major and $C3$ is 1-MC) as a response to ex , then the minor value in the 1-MC is of an observed descendant of EX . And, if two or more observed variables change in such PCCs (e.g., $X7-X9$ in $PCC1,6$ in Table 4; $C1$ is major and $C6$ is 1-MC) as a response to ex , then the minor value in the 1-MC is due to a minor value of a

latent non-collider descendant of EX . Thus, PCCs between 1-MCs and major clusters that show a change in the values of two or more observed variables provide evidence of the existence of an NC that should be split from its exogenous ancestor. Following, we describe how LPCC finds the set of 1-MCs. Then, we elaborate why and how the analysis of the PCCs between 1-MCs and major clusters is used to identify and split latent non-colliders from their exogenous ancestor.

PCC	$\delta X1$	$\delta X2$	$\delta X3$	$\delta X4$	$\delta X5$	$\delta X6$	$\delta X7$	$\delta X8$	$\delta X9$
$PCC1,3$	0	0	0	0	0	0	0	0	1
$PCC2,3$	1	1	1	1	1	1	1	1	0

Table 3: PCCs for $C3$ with $C1$ and $C2$ (Table 2) in learning $G3$

PCC	$\delta X1$	$\delta X2$	$\delta X3$	$\delta X4$	$\delta X5$	$\delta X6$	$\delta X7$	$\delta X8$	$\delta X9$
$PCC1,6$	0	0	0	0	0	0	1	1	1
$PCC2,6$	1	1	1	1	1	1	0	0	0
$PCC1,8$	1	1	1	0	0	0	0	0	0
$PCC2,8$	0	0	0	1	1	1	1	1	1
$PCC1,9$	1	1	1	1	1	1	0	0	0
$PCC2,9$	0	0	0	0	0	0	1	1	1
$PCC1,10$	0	0	0	1	1	1	1	1	1
$PCC2,10$	1	1	1	0	0	0	0	0	0

Table 4: All 25-PCCs for $G3$

To find the set of 1-MCs, LPCC first calculates a threshold on the maximal size of 2-order minor clusters (2-MCs). This threshold represents the maximal size of a minor cluster that corresponds to a 2-order minor value configuration, i.e., a minor cluster that represents exactly two endogenous variables in EN that have minor values (Definition 13). This threshold is an approximation for the maximal probability of having minor values as a response to any ex in exactly two descendants of EX , where all other descendants of EX in EN have major values. This approximation is derived from the product of the maximal minor local effects (Definition B.1 in Appendix B) of two observed descendants of EX and the maximal major local effects (Definition B.1) of the other observed descendants in EN (Appendix B). Thus, the sizes of all 1-MCs lie between the maximal size of a 2-MC (i.e., the threshold) and the minimal size of a major cluster (note that a major cluster is also a zero-order minor cluster corresponding to a zero-order minor value configuration). For example, based on the analysis above, $C2$ is the minimal major cluster in learning $G3$, and all the fifteen clusters (Table 2) that are smaller than $C2$ and larger than the threshold (calculated as 11), i.e., $C3$ - $C17$, are 1-MCs. Note that this procedure is separately applied to each $EX \in EX$. That is, for each EX , there is a different set of 1-MCs, each representing a single minor value of a descendant of EX and used to identify this descendant, whereas the other descendants of EX have major values.

Recall that every 1-MC corresponds to a 1-order minor value configuration that is due to exactly a single minor value of either an observed variable O or a latent non-collider NC , where both O and NC are descendants of EX in EN . The main difference between

these two cases is that in the former, the minor value in O is reflected only in this value, whereas in the latter, the minor value in NC may affect the values of all descendant latents of NC together with those of all the direct children (observed variables) of NC and its descendant latents. A minor value in O is identified based on the probability of this value conditioned on a certain value of O 's direct parent that is smaller than the maximal probability achieved for another value of O (i.e., the major value) conditioned on the same value of O 's direct parent. This happens for each value of the direct parent and does not require a change in EX to happen. From definition, a minor value in O in a 1-order minor value configuration can only happen when all EX 's descendants, except O , obtain major values. Although the mechanism of obtaining a minor value in a latent descendant NC of EX is similar to that in O , the impact of such a minor value is not locally restricted to NC , as for O , but it simultaneously affects all the descendants (latent and observed) of NC , which again, from definition, obtain major values.

We are only interested in the second case of minor values of NC , because their identification helps split this NC from its ancestor EX to which it was initially combined (Section 4.1). Since the observed variables in both cases are among EX 's descendants, which were already used to identify EX , it is a challenge to distinguish between them. Following, we analyze 1-MCs to identify these two cases and concentrate on the second case.

Case 1: A minor value of an observed variable

When comparing, for a specific EX , two centroids – one of a major cluster and the other of a 1-MC that corresponds to an observed minor value configuration (Definition 11) in which an observed variable O , which is a descendant of EX , has a minor value – we can observe that when:

1. EX changes values between two ex s that correspond to the compared clusters, all observed descendants of EX , except O , change values together, and when
2. EX does not change values between two ex s that correspond to the compared clusters, the only observed descendant of EX that changes value is O .

Thus, a PCC – between the centroid of such 1-MC and a centroid of any of the major clusters – that shows the same value for all but one (i.e., O) of the observed descendants of EX (i.e., either 1 if EX changes values in the corresponding ex s or 0 if it does not) identifies a minor value in O . For example, in Table 3, $PCC1,3$ and $PCC2,3$ of $C3$, which is a 1-MC, with the two major clusters $C1$ and $C2$ (Table 2) show the set of observed variables $X1$ - $X8$ that either do or do not change values together, whereas the single observed variable $X9$ acts contrarily. This is evidence that $C3$ is a 1-MC due to exactly a single minor value of an observed variable descendant ($X9$) of $L1$ in $G3$. Such an analysis helps LPCC ignore, on the one hand, observed descendants of $L1$ that cannot reflect minor values in $L1$'s latent (non-collider) descendants, and focus, on the other hand, on the latent descendants that should be split from $L1$, as part of Case 2.

Case 2: A minor value of a latent non-collider

The minor value of a latent non-collider NC , which is a descendant of EX , can be reflected only via the values of its observed descendants in an observed minor value configuration that is represented by a certain 1-MC. By definition, all of these observed descendants

have major values in this 1-order minor configuration since only NC has a minor value in this configuration. The major value of each of these observed descendants is certain given the minor value of NC (Proposition 2) and different from the certain major value it would have if NC had a major value (Assumption 7) instead of its minor value.

When comparing for a specific EX , two centroids – one of a major cluster and the other of a 1-MC that corresponds to an observed minor value configuration in which a latent non-collider NC , which is a descendant of EX , has a minor value – we can observe that when:

1. EX changes values between two exs that correspond to the compared clusters, all observed descendants of EX , but not observed descendants of NC , change values together, and when
2. EX does not change values between two exs that correspond to the compared clusters, the only observed descendants of EX that change values are those of NC .

Thus, a PCC – between the centroid of such 1-MC and a centroid of any of the major clusters – that shows two sets of two or more observed variables, each set having a different value, identifies a minor value in NC . The first set in such a PCC comprises the descendants of NC (with a value of 0 if EX changes values in the corresponding exs or 1 if it does not), and the second set comprises all other observed variables that are descendants of EX , but not NC (with a value of 1 if EX changes values in the corresponding exs or 0 if it does not). For example, $PCC1,6$ and $PCC2,6$ (Table 4) of $C6$, which is a 1-MC, with the two major clusters $C1$ and $C2$ (Table 2), show two sets of observed variables for $G3$. The first set consists of $X1-X6$ and the second of $X7-X9$. This is evidence that $C6$ is a 1-MC due to a minor value of a latent non-collider descendant of $L1$, and $L1$ should be split into two latents (each is responsible for one of the two sets). One latent (which we know is $L3$) is a parent of $X7$, $X8$, and $X9$, and the other latent is a parent of $X1-X6$ (which we will show is also split to $L1$ and $L2$, each with its three children).

Distinguishing between Case 1 and Case 2 gives us an instrument to identify latent non-colliders. We are interested in PCCs between 1-MCs and major clusters that show two sets of two or more elements corresponding to the observed variables. Variables in each set have the same value, which is different than that of the other set. Following, we infer that each set is of a different latent than the one that was expected to be sole. We denote such PCC by 2S-PCC (i.e., PCC of “two sets”) and the corresponding 1-MC by 2S-MC (Definition 18). Thus, to identify a latent non-collider that was combined to an exogenous latent EX , we consider only the 2S-PCCs; these PCCs are the result of comparing all the 2S-MCs among the 1-MCs for EX with the major clusters that revealed EX . Table 4 represents all 2S-PCCs for $G3$.

Definition 18 2S-PCC is PCC between 1-MC and a major cluster that shows two sets of two or more elements corresponding to the observed variables. Elements in each set have the same value, which is different than that of the other set. Accordingly, this 1-MC is defined as 2S-MC.

The following Theorem 3 helps formalize this identification step, but to prove this theorem, we first need Lemma 4. Recall that the challenge here is to identify a latent non-collider NC that is a descendant of an exogenous latent EX , but was wrongly combined with this exogenous ancestor. To face this challenge, we need to find a circumstance in which EX and NC are involved that is different than that which led to the inability to distinguish between them. NC could not be distinguished from EX when we analyzed major value configurations. But, although a major value configuration is the most probable configuration (Definition 9), minor value configurations are possible too – according to the probability tables of the latents, each given its direct parent – albeit less likely. A minor value configuration in which only NC takes a minor value (i.e., a first-order minor value configuration) is exactly what we need.⁹ This is because all NC 's latent ancestors, in the first-order minor value configuration, take the same major values they took in the major value configuration and thus influence their descendants the same. But, the minor value NC takes influences its (latent and observed) descendants differently than the major value NC took in the major value configuration. This influence is revealed in the different values the observed children of NC and its descendants take compared to the values they took when NC had a major value. Since the two value configurations are represented in two corresponding clusters – a major cluster and a 2S-MC for NC – the signature of NC can uniquely be detected by comparing the two clusters using 2S-PCC.¹⁰

Lemma 4 shows that it is possible to identify NC because: 1) Even when EX leads to major values in all NC 's ancestors (and in most cases also in NC), NC can still take a minor value; and 2) even when EX changes values, leading all NC 's ancestors to change values as well, NC can still keep the same (minor) value. Thereby, minor value configurations for NC demonstrate its autonomy, enabling its identification and its split from EX .

Lemma 4 Let a latent non-collider NC be a descendant of an exogenous latent variable EX . 2S-PCC is a PCC between a “two-set” first-order minor cluster 2S-MC due to a minor value in NC and a major cluster that identified EX . ex' and ex'' are two value configurations of EX that correspond to the compared clusters by 2S-PCC. When:

1. EX does not change values between ex' and ex'' , all the elements in 2S-PCC corresponding to the observed descendants of the latent ancestors of NC (including EX) show no change (i.e., are 0), whereas the elements corresponding to the observed descendants of NC show a change (i.e., are 1), and when
2. EX changes values between ex' and ex'' , all the elements in 2S-PCC corresponding to the observed descendants of the latent ancestors of NC (including EX) show a change (i.e., are 1), whereas the elements corresponding to the observed descendants of NC show no change (i.e., are 0).

⁹All other first-order minor value configurations (due to other latent variables, which are also EX 's descendants) or k -order minor value configurations (Definition 13) due to EX are irrelevant to the identification of NC , although the former – as will be shown in Theorem 3 – play a role in determining the direct observed children of NC among its observed descendants.

¹⁰Any 2S-PCC, which is detected for EX , will point to the NC that corresponds to the 2S-MC that is compared by this 2S-PCC.

Before moving to Theorem 3, let us illustrate the two cases discussed in Lemma 4 for G3. The “EX does not change values between \mathbf{ex} and \mathbf{ex}'' ” case can be demonstrated, for example, when comparing C1 and C6 (Table 2). In response to $EX(L1)=1$, NC’s (L3) parent (L2) takes a major value of 1 in both the value configurations of the latent variables in response to $\mathbf{ex}' = \mathbf{ex}''$.¹¹ Also, L3 takes a major value of 1 in the configuration that is represented by C1, which is one of the two major clusters. But L3, in response to the same configuration of its latent ancestors (L1 and L2), takes a minor value of 0 in the value configuration that is represented by the 2S-MC C6. By comparing C1 and C6, the corresponding 2S-PCC (i.e., $PCC1,6$; see Table 4) shows two sets of elements: the first of 0s that correspond to the observed variables X1–X6, which do not change values between the clusters, and the second of 1s that correspond to X7–X9, which do change values between the clusters. This is the evidence we are looking for that is needed to identify L3.

The “EX changes values between \mathbf{ex}' and \mathbf{ex}'' ” case can be demonstrated, for example, when comparing C1 and C9 (Table 2). In response to $EX(L1)=1$ and $EX(L1)=0$, NC’s (L3) parent (L2) takes a major value of 1 in response to L1=1 and a major value of 0 in response to L1=0. In the first instance, L3 takes a major value of 1 to create the major configuration that is represented by C1, and in the second instance, L3 takes a minor value of 1 in the value configuration that is represented by the 2S-MC C9 (and although the first value is major and second is minor, they are both 1). By comparing C1 and C9, the corresponding 2S-PCC shows two sets of elements, the first of 1s that correspond to the observed variables X1–X6, which changed values between the clusters, and the second of 0s that correspond to X7–X9, which did not change values between the clusters. This is additional support of the existence of L3. However, relying only on part of the 2S-PCCs may be inadequate to conclude on all possible splits. For example, $PCC1,8$ and $PCC2,8$ (Table 4) show that X1–X3 and X4–X9 are children of different latents, but do not suggest the split of X7–X9 as $PCC1,6$ and $PCC2,6$ do. Therefore, similarly to the MSO concept that was introduced for major-major PCCs to identify exogenous latents, it is necessary to introduce also for 2S-PCCs a maximal set of observed variables (2S-MSO) that always change their values together in all 2S-PCCs. We define:

Definition 19 A 2S-MSO is the maximal set of observed variables that always change their values together in all 2S-PCCs.

For example, X1 in Table 4 changes its value in $PCC2,6$, $PCC1,8$, $PCC1,9$, and $PCC2,10$ and always together with X2 and X3 (and the other way around). Thus, {X1, X2, X3} and similarly {X4, X5, X6} and {X7, X8, X9} are 2S-MSOs. Each 2S-MSO includes children of the same latent non-collider, which is a descendant of EX, or EX itself. After computing all 2S-PCCs for EX, LPCC detects 2S-MSOs for all these latent variables and thereby identifies all possible splits for EX. Note that compared to MSO (Section 4.1), which is identified in major-major PCCs to reveal exogenous latents, 2S-MSO is identified in PCCs between 2S-MCs and major clusters to reveal splits of latent non-colliders from the exogenous latent that was previously learned using these major clusters.

¹¹Note that the values the three latents take in the two-value configurations can only be inferred from the values their children (X1–X3 for L1, X4–X6 for L2, and X7–X9 for L3) take.

Theorem 3 Variables of a particular 2S-MSO are children of an exogenous latent variable EX or any of its descendant latent non-colliders NC.

After splitting the latent non-collider descendants from their exogenous latent ancestors EX, we need to identify the links between these latents. To identify these links, LPCC exploits the following Proposition 10 and Theorem 4. We will see that in the case of a serial connection, LPCC learns the undirected links among the latents, and in the case of a diverging connection, LPCC learns the directed links among the latents. That is, LPCC learns a pattern over the structural model of G, which represents a Markov equivalence class of models among the latents. In the special case where G has no serial connection, LPCC learns the true graph.

Proposition 10 In 2S-PCCs in which only the observed children of a single latent change, the latent is

1. EX or its leaf latent non-collider descendant, if the connection is serial; or
2. EX’s leaf latent non-collider descendant, if the connection is diverging.

Proof We already showed that at least a single 2S-PCC exists in the serial connection case in which only the observed children of EX change (Theorem 3). In addition, in the proof of Theorem 3 (Part II), we already showed that for any NC that is a latent non-collider descendant of EX, NC’s observed children change values in some 2S-PCCs with observed children of a latent non-collider descendant of NC and in the other 2S-PCCs with observed children of a latent non-collider ancestor of NC, but never alone. A special case in the proof of Theorem 3 is when NC is a leaf. Then, at least a single 2S-PCC exists in which only the children of NC change. ■

We will exemplify Proposition 10 using G3. Table 4 shows all the 2S-PCCs for G3 from which we can identify three 2S-MSOs: {X1, X2, X3}, {X4, X5, X6}, and {X7, X8, X9}. If we consider only 2S-PCCs due to C1 (the first major cluster), {X1, X2, X3} change alone in $PCC1,8$, and {X7, X8, X9} change alone in $PCC1,6$. By Proposition 10, these two 2S-MSOs are observed children of an exogenous latent variable EX and its leaf latent non-collider descendant. From knowing G3, we know that these two latents are L1 and L3. Note that if more than a single leaf of EX exists (i.e., in the case of a diverging connection emerging from EX), then for each such leaf, there is a 2S-PCC in which only the observed children of this leaf change alone. This will help LPCC to identify a diverging connection and determine EX as the source in all paths leading to the leaves (sinks). As a result, LPCC could identify the correct direction of the links among the latents.

Proposition 10 guarantees that if the connection is serial, we find the source (EX) and sink of the path between them (but not who is who). To identify the directionality between any two latent non-collider variables on the path between the source and sink, we will need more. To motivate the need, suppose that when learning G3, we already identified L1 as EX and L3 as EX’s leaf descendant (Proposition 10), and now we have to split L2 from L1 using the two major clusters, C1 and C2 (Table 2), which revealed L1, and identify the directionality among these three latent variables. Lemma 4 (first part) guarantees that the

observed children of a latent non-collider $NC1$, which is a child of another non-collider $NC2$ (both are descendants of EX), will change in all 2S-PCCs with the observed children of $NC2$ except in a single additional 2S-PCC due to a minor value of $NC1$. That is, $NC1$ is identified as a direct child of $NC2$ if the observed children of $NC1$ change in all 2S-PCCs (due to a specific major cluster and when EX does not change value), in which the children of $NC2$ change plus an additional 2S-PCC in which they change without the children of $NC2$.¹² In our case, this means that the observed children of $L3$, which is a child of $L2$, will change values in all 2S-PCCs in which the observed children of $L2$ change values, and also in an additional 2S-PCC, which is due to a minor value in $L3$. Indeed, $PCC1,10$ (Table 4), due to $C1$, shows that when EX does not change values and the observed children of $L3$, $\{X7,X8,X9\}$, change values, the observed children of $L2$, $\{X4,X5,X6\}$, also change values. In addition, $PCC1,6$, which is the result of comparing $C1$ and 2-MC $C6$ due to a minor value of $L3$, shows that $\{X7,X8,X9\}$ change values without $\{X4,X5,X6\}$ once. $PCC2,8$ and $PCC2,9$ demonstrate the same, when using major cluster $C2$ instead of $C1$ (and $C9$ is the 2-MC that reveals the minor value of $L3$). This provides an indication that $L3$ is a child of $L2$.

But, Proposition 10 cannot guarantee distinguishing between EX and its leaf latent non-collider descendant (hereby a “leaf”); hence, what if we mistakenly identified them? In the $G3$ example, this means we identified $L3$ as EX and $L1$ as EX 's leaf. Lemma 4 demonstrates an interplay between EX and NC (and all of its descendants) as presented in 2S-PCCs due to a minor value in NC ; when one of them changes, the other does not and vice versa. Because the leaf is one of NC 's descendants, Lemma 4 guarantees that the observed children of the leaf do not change if and only if EX changes value. That is, by the second part of Lemma 4, if EX changes, then the observed children of the leaf do not change. Thus, if we find 2S-PCCs that show that the observed children of the leaf do not change, then we have evidence that EX changed. This guarantees that the observed children of a latent non-collider $NC2$ (or EX itself), which is a parent of another non-collider $NC1$, will change in all 2S-PCCs with the observed children of $NC1$, except in a single additional 2S-PCC due to a minor value of $NC2$ (or if $NC2$ is EX). In our case, this means that the observed children of $L1$, which is $L2$'s parent, will change values in all 2S-PCCs in which the observed children of $L2$ change values, and also in an additional 2S-PCC. Indeed, $PCC1,9$ (Table 4), due to $C1$, shows that when the leaf does not change value and the observed children of $L1$, $\{X1,X2,X3\}$, change values, the observed children of $L2$, $\{X4,X5,X6\}$, also change values. In addition, $PCC1,8$ shows that $\{X1,X2,X3\}$ change values without $\{X4,X5,X6\}$ once. $PCC2,6$ and $PCC2,10$ demonstrate the same when using major cluster $C2$ instead of $C1$. This provides an indication that $L1$ is a child of $L2$, which is the opposite direction between the two in $G3$. That is, the interplay between EX and its leaf lets LPCC identify the directionality between latent non-colliders on the path between

¹²Note that Lemma 4 makes a clear distinction between NC 's ancestors (and their observed children) and NC 's descendants (and their observed children), when NC gets a minor value. That is, all NC 's ancestors follow EX (and change values or not with it) and all NC 's descendants follow its change of value. This change of NC “breaks” the influence of EX on the latents on the path emerging from EX and “starts” NC 's own influence on its latent descendants. And this is what is so important in finding the traces of minor values of endogenous latents through 2S-PCCs, that these traces identify the existence of the latents. Particularly, when EX does not change values and all its descendants get major values, the observed children of $NC1$ and $NC2$ will change together, and it is only a minor value that $NC1$ gets that can make a 2S-PCC in which $NC1$'s observed children change without those of $NC2$, and thereby indicate that $NC1$ is $NC2$'s child.

EX and the leaf, and in both directions. This means that LPCC can identify only the undirected links between the latents in the serial case.

In the diverging case, the children of EX never change alone, and every latent that its children change alone in some 2S-PCC is a leaf (Proposition 10). Therefore, by performing an analysis as for the serial case using 2S-PCCs in which the observed children of the leaf do not change for each leaf of the branches of the diverging connection, LPCC can identify the links among the latents in opposite directions on each branch. We formalize this by Theorem 4.

Theorem 4 *A latent non-collider $NC1$ is a direct child of another latent non-collider $NC2$ (both on the same path emerging in EX) only if:*

- *In all 2S-PCCs for which EX does not change, the observed children of $NC1$ always change with those of $NC2$ and also in a single 2S-PCC without the children of $NC2$; and*
- *In all 2S-PCCs for which a latent non-collider leaf descendant of EX does not change, the observed children of $NC2$ always change with those of $NC1$ and also in a single 2S-PCC without the children of $NC1$.*

LPCC uses Theorem 4 to identify the links between the split latents. In the serial connection, there are only two latents with observed children that change alone in some 2S-PCCs, that is, EX and its leaf latent non-collider descendant. However, LPCC cannot distinguish between them and thus finds all the links between these two latents as undirected. In the diverging connection, the observed children of EX never change alone (Proposition 10); thus, every latent with children that change alone in some 2S-PCCs can only be a leaf. Thereby, LPCC can identify the directed links among the latents repeatedly on each of the paths from EX to each of the leaves (Theorem 4). Still, LPCC needs to distinguish between the serial and diverging connections. In the case where the observed children of three or more latents change alone in some 2S-PCC, it is clear that it is a diverging connection. Then, LPCC treats these latents as leaves and returns directed paths from EX to each such leaf. However, in the case in which LPCC identifies that the observed children of exactly two latents change alone in some 2S-PCCs, it applies the analysis proposed in Theorem 4 to each of the latents. If it obtains the same path with opposite directions, then LPCC considers it as a serial connection and returns the undirected path; otherwise, it considers it as a diverging connection and returns the two directed paths from EX .

5. Discussion and Future Research

We introduced the PCC concept and LPCC algorithm for learning LVMs:

1. LPCC combines learning graphical models with data clustering by using the PCC concept to analyze clustering results of discrete variables for learning LVMs;
2. LPCC learns MIM, which is a large subclass of SEM. In MIM, multiple latent variables may have multiple indicators (observed children), and no observed variable may be an ancestor of any latent variable;

3. LPCC is not limited to latent-tree models, which are only a subclass of MIM, and does not make special assumptions, such as linearity, about the distribution;
 4. LPCC assumes that the measurement model of the true graph is pure, but, if the true graph is not pure, LPCC learns a pure sub-model of the true model, if one exists. LPCC's only assumption about the structural model is that a latent collider does not have any latent descendants (a detailed list of assumptions LPCC makes is given in Appendix O);
 5. LPCC is a two-stage algorithm. First, LPCC learns the exogenous latents and the latent colliders, as well as their observed descendants, by utilizing pairwise comparisons between data clusters in the measurement space that may explain latent causes. Second, LPCC learns the endogenous latent non-colliders and their children by splitting these latents from their previously learned latent ancestors;
 6. LPCC learns an equivalence class of the structural model of the true graph; and
 7. LPCC is formally expressed as an algorithm and evaluated using synthetic and real-world databases in Part II of the paper.
- A number of open problems invite further research including:
1. Extending LPCC to identify observed variables that are effects of other observed variables;
 2. Providing a formal analysis for the conditions of model identification and its sensitivity to parameterization. Learning by LPCC that an observed variable O is a descendant of a latent variable L depends on two factors. The first factor is the "graph distance", which means that the more edges that separate O from L , the less likely O would be grouped with other observed variables, descendants of L . The second factor is the conditional probabilities of an observed variable given its latent parent, which means that the stronger the probabilities are, the more likely the link will be identified by LPCC. Although the iterative strategy for choosing the major clusters (Section 4.3) improves the identification of observed children with weak associations with their latent parents, the final graph still depends on the initial graph. That is, the iterative approach alone cannot guarantee finding the optimal model. Future analysis should take into account both factors;
 3. Analyzing LPCC complexity. Future research should dive into this topic and decompose LPCC complexity to those of clustering, identification of major-major PCCs, and identification of major-minor PCCs. Assume a set $V = (\text{LUO})$ with a variable maximal cardinality, $k = \max(|V_i|)$, a number of exogenous variables, $|\text{EX}|$, and a number of major value configurations (major clusters), $|\text{ex}| = k^{|\text{EX}|}$. A preliminary analysis shows that LPCC complexity in identifying major-major PCCs is $O(k^{2|\text{EX}|})$. To compute the LPCC's complexity in identifying major-minor PCCs, we first have to identify 1-MC minor clusters (values), with complexity of $O((|V| - |\text{EX}|)k^{|\text{EX}|}(k - 1))$ due to $(k - 1)$ minor values for each of $k^{|\text{EX}|}$ parent configurations of $(|V| - |\text{EX}|)$ endogenous variables. Then, the complexity in identifying major-minor

PCCs is $O((|V| - |\text{EX}|)k^{2|\text{EX}|}(k - 1))$, and the total complexity in computing PCCs is $O((|V| - |\text{EX}|)k^{2|\text{EX}|})$, which is exponential in $|\text{EX}|$, but in most problems $|\text{EX}| \ll |V|$. However, a more elaborated analysis that also includes the complexity of clustering is desired.

4. Exploring the impact of clustering – as is manifested by the clustering algorithm and its parameters – on the LPCC results. In Part II, we show a problem in which the data structure is hierarchical, and a clustering algorithm that is more sophisticated than SOM, which is suggested in Section 4, is needed to preprocess the data used to learn an LVM that is meaningful to the domain. Exploring the requirements on clustering and any guidelines about the best approach to take for clustering is a direction of further research; and
5. Suggesting ways to use the graphical model to cluster data points. Although we have established and exploited a link between cluster analysis and learning an LVM, in this work, we only studied learning (reconstructing) the graphical model by analyzing clusters of observational data. Another very interesting line of future research is in the opposite direction, extending previous studies such as that in Zhang (2004). Because MIM models learned by LPCC are richer than HLC models (which are only a subset of MIM), such a line of research may enable accurate clustering of observational data generated by a model also having collider nodes.

Acknowledgments

Appendix A. Proofs of propositions, lemmas, and theorems

In this appendix, we give proofs of propositions, lemmas, and theorems for which the proof is too detailed, lengthy, or impedes the flow of reading. All other proofs are given in the body of the paper.

Lemma 1

1. Each latent non-collider NC_t has only one exogenous latent ancestor EX_{NC_t} , and there is only one directed path T_{NC_t} from EX_{NC_t} (source) to NC_t (sink). (Note that we use the notation NC_t , rather than S_t , since the Lemma applies to both exogenous and endogenous latent non-colliders.)
2. Each latent collider C_j is connected to a set of exogenous latent ancestors EX_{C_j} via a set of directed paths T_{C_j} from EX_{C_j} (sources) to C_j (sink).

Proof

1. If the latent non-collider is exogenous, $NC_t = EX_t$, then $EX_{NC_t} = EX_t$, and T_{NC_t} is the empty path consisting of EX_t . For example, $EX_{L3} = L3$ and $T_{L3} = L3$ in G2 and G5 in Figure 1. If, however, the latent non-collider is endogenous, $NC_t = S_t$, and we assume by contradiction that it has more than one exogenous latent ancestor and thus more than one directed path from each exogenous ancestor to S_t (and according to Assumption 5, none of the paths passes through a collider) that collide at S_t , then S_t is a collider. This is contrary to the assumption that NC_t is a non-collider. That is, EX_{S_t} is the only exogenous latent ancestor of S_t , and T_{S_t} is the only directed path from EX_{S_t} through S_t 's parent Pa_t to S_t . For example, $EX_{L5} = L3$ and $T_{L5} = \{L3, L4, L5\}$ in G5 (Figure 1).

[Note that if S_t has no endogenous latent non-collider ancestors, then $Pa_t = EX_{S_t}$, and T_{S_t} equals the ordered sequence $\{EX_{S_t}, S_t\}$, e.g., $EX_{L4} = L3$ and $T_{L4} = \{L3, L4\}$ in G5 (Figure 1).]

2. Under Assumption 5, any parent Pa_j of latent collider C_j could be either a latent non-collider or an exogenous latent; in other words, $Pa_j \subset (NC \cup EX)$. If Pa_j is a latent non-collider, then it is on the directed path T_{C_j} from EX_{C_j} to C_j ; and if Pa_j is an exogenous latent EX_{C_j} , then it is the source of a directed path T_{C_j} (or more than a single directed path) to C_j . $EX_{C_j} = \cup EX_{C_j}$ is the set of exogenous ancestors of C_j , and $T_{C_j} = \cup T_{C_j}$ is the set of directed paths from EX_{C_j} to C_j . For example, $EX_{L4} = \{L1, L5\}$ and $T_{L4} = \{\{L1, L2, L3, L4\}, \{L5, L4\}\}$ in G6 (Figure 1). ■

Proposition 3 The $MAV_{(TS_{NC_v} \setminus EX_{NC_v}, ONC_v)}(ex_{NC_v})$ corresponding to $MAE_{(TS_{NC_v} \setminus EX_{NC_v}, ONC_v)}(ex_{NC_v})$ is a certain value configuration for each certain value ex_{NC_v} .

(Note that here we use the notation NC_v rather than S_v since the proposition applies to both exogenous and endogenous latent non-colliders.)

Proof If the latent non-collider NC_v is exogenous, $NC_v = EX_v$ and $ONC_v = OEX_v$, then $\{TS_{NC_v} \setminus EX_{NC_v}, OEX_v\} = OEX_v$ and the partial major value is the local major value $MAV_{OEX_v}(ex_v)$, which by Proposition 2 is certain for a certain value ex_v .

If the latent non-collider NC_v is endogenous, $NC_v = S_v$ and $ONC_v = OS_v$, then we consider $\{TS_{S_v} \setminus EX_{S_v}, OS_v\}$, which is a set of ordered variables along the directed path T_{S_v} that ends in OS_v . The remainder of the proof is by induction:

Basis: Based on Proposition 2, $MAV_{S_1}(ex_{S_1})$, where S_1 is the first variable in $\{TS_{S_v} \setminus EX_{S_v}, OS_v\}$ and a direct child of EX_{S_v} , given a certain value ex_{S_1} , is also certain.

Step: If the major value of the i th variable, S_i , in the subset $\{TS_{S_v} \setminus EX_{S_v}, OS_v\}$, i.e., $MAV_{S_i}(pa_{S_i}^{ex_{S_i}})$, is certain for a certain value $pa_{S_i}^{ex_{S_i}}$, then the major value of the $(i+1)$ th variable, S_{i+1} , in the subset (which is S_i 's child), i.e., $MAV_{S_{i+1}}(pa_{S_{i+1}}^{ex_{S_i}})$, is by Proposition 2 certain too for a certain value $pa_{S_{i+1}}^{ex_{S_i}}$ (which is $MAV_{S_i}(pa_{S_i}^{ex_{S_i}})$). ■

Proposition 4 All corresponding values in $MAV_{(TS_{NC_v} \setminus EX_{NC_v}, ONC_v)}(ex'_{NC_v})$ and $MAV_{(TS_{NC_v} \setminus EX_{NC_v}, ONC_v)}(ex''_{NC_v})$ for two values ex'_{NC_v} and ex''_{NC_v} of EX_{NC_v} are different.

(Here also we use the notation NC_v , since the proposition applies to both exogenous and endogenous latent non-colliders.)

Proof If the latent non-collider NC_v is exogenous, $NC_v = EX_v$ and $ONC_v = OEX_v$, then $\{TS_{NC_v} \setminus EX_{NC_v}, OEX_v\} = OEX_v$, and, by Assumption 7, the corresponding $MAV_{OEX_v}(ex'_v)$ and $MAV_{OEX_v}(ex''_v)$ are different for two values ex'_v and ex''_v .

If the latent non-collider NC_v is endogenous, $NC_v = S_v$ and $ONC_v = OS_v$, then we consider $\{TS_{S_v} \setminus EX_{S_v}, OS_v\}$, which is a set of ordered variables along the directed path T_{S_v} that ends in OS_v . The remainder of the proof is by induction:

Basis: The major local values $MAV_{S_1}(ex'_{S_1})$ and $MAV_{S_1}(ex''_{S_1})$ of the first variable, S_1 , in $\{TS_{S_v} \setminus EX_{S_v}, OS_v\}$ (which is also a direct child of EX_{S_v}) and two values ex'_{S_1} and ex''_{S_1} of EX_{S_v} are different based on Assumption 7.

Step: If the major local values of the i th variable, S_i , in $\{TS_{S_v} \setminus EX_{S_v}, OS_v\}$ and two values ex'_i and ex''_i of EX_{S_v} , i.e., $MAV_{S_i}(ex'_i)$ and $MAV_{S_i}(ex''_i)$, are different, then the major local values of S_{i+1} (S_i 's child), and the two values $MAV_{S_i}(ex'_i)$ and $MAV_{S_i}(ex''_i)$, i.e., $MAV_{S_{i+1}}(pa_{S_{i+1}}^{ex'_i}) = MAV_{S_{i+1}}(MAV_{S_i}(ex'_i))$ and $MAV_{S_{i+1}}(pa_{S_{i+1}}^{ex''_i}) = MAV_{S_{i+1}}(MAV_{S_i}(ex''_i))$ are different too based on Assumption 7. ■

Proposition 5 EX_{NC_v} changes values (i.e., has two values ex'_{NC_v} and ex''_{NC_v}) if and only if NC_v changes values in the two corresponding major value configurations: $MAV_{(TS_{NC_v} \setminus EX_{NC_v}, ONC_v)}(ex'_{NC_v})$ and $MAV_{(TS_{NC_v} \setminus EX_{NC_v}, ONC_v)}(ex''_{NC_v})$.

Proof (“if”) Proposition 3 guarantees that NC_v has a certain value in $MAV_{(TS_{NC_v} \setminus EX_{NC_v}, ONC_v)}(ex_{NC_v})$ for a certain value ex_{NC_v} of EX_{NC_v} . Thus, if NC_v has

different values in two $MAV_{\{TS_{C_q} \setminus EX_{N_{C_q}}, ON_{C_q}\}}(ex_{N_{C_q}})$, then $EX_{N_{C_q}}$ should also have two corresponding values, say $ex'_{N_{C_q}}$ and $ex''_{N_{C_q}}$.

(“only if”) Proposition 4 guarantees that N_{C_q} will have different values in $MAV_{\{TS_{N_{C_q}} \setminus EX_{N_{C_q}}, ON_{C_q}\}}(ex'_{N_{C_q}})$ and $MAV_{\{TS_{N_{C_q}} \setminus EX_{N_{C_q}}, ON_{C_q}\}}(ex''_{N_{C_q}})$ for two values $ex'_{N_{C_q}}$ and $ex''_{N_{C_q}}$ of $EX_{N_{C_q}}$. Thus, if N_{C_q} has only a certain value in two

$MAV_{\{TS_{N_{C_q}} \setminus EX_{N_{C_q}}, ON_{C_q}\}}(ex_{N_{C_q}})$ then $EX_{N_{C_q}}$ should have also a certain value in the corresponding two $ex_{N_{C_q}}$. ■

Proposition 6 The $MAV_{\{TS_{C_q} \setminus EX_{C_q}, OC_k\}}(ex_{C_q})$ corresponding to $MAE_{\{TS_{C_q} \setminus EX_{C_q}, OC_k\}}(ex_{C_q})$ is a certain value configuration for each certain value configuration ex_{C_q} .

Proof $\{TS_{C_q} \setminus EX_{C_q}, OC_k\}$ comprises sets of variables $\{TS_{C_q} \setminus EX_{C_q}, OC_k\}$ along all directed paths through C_k that end at OC_k . We will divide each such set into to three subsets $\{TS_{C_q} \setminus EX_{C_q}, C_k\}$, C_k , and OC_k and consider a value configuration for ex_{C_q} for each subset separately. First, since no latent collider can be a child of a latent collider (Assumption 5), a value configuration for the subset $\{TS_{C_q} \setminus EX_{C_q}, C_k\}$ is considered to be identical to a value configuration for $\{TS_{N_{C_q}} \setminus EX_{N_{C_q}}\}$, and thus according to Proposition 3, is a certain value configuration for a certain value ex_{C_q} . Because $MAV_{\{TS_{C_q} \setminus EX_{C_q}, C_k\}}(ex_{C_q})$ is a certain value configuration for a certain ex_{C_q} for each directed path TS_{C_q} that is included in TS_{C_q} , the product of these value configurations, which corresponds to the product of $MAE_{\{TS_{C_q} \setminus EX_{C_q}, C_k\}}(ex_{C_q})$ in (11), is also certain. Second, since C_k 's parents $\mathbf{Pa}_k \subset \bigcup_{TS_{C_q} \in TS_{C_q}} \{TS_{C_q} \setminus EX_{C_q}, C_k\}$, $\mathbf{pa}_k^{ex_{C_q}}$ are certain value configurations. Thus, based on Proposition 2, $MAV_{C_q}(\mathbf{pa}_k^{ex_{C_q}})$ is also a certain value and similarly $MAV_{OC_k}(C_k^{ex_{C_q}})$ is certain, where $C_k^{ex_{C_q}} = MAV_{C_q}(\mathbf{pa}_k^{ex_{C_q}})$. Therefore, all variables in $\{TS_{C_q} \setminus EX_{C_q}, OC_k\}$ are certain in the major configuration for a certain value configuration ex_{C_q} . ■

Proposition 7 For every exogenous ancestor $EX_{C_q} \in \mathbf{EX}_{C_q}$ of a latent collider C_k , there are at least two configurations ex'_{C_q} and ex''_{C_q} of \mathbf{EX}_{C_q} in which only EX_{C_q} changes values when C_k changes values in the two corresponding major value configurations $MAV_{\{TS_{C_q} \setminus EX_{C_q}, OC_k\}}(ex'_{C_q})$ and $MAV_{\{TS_{C_q} \setminus EX_{C_q}, OC_k\}}(ex''_{C_q})$.

Proof We divide the proof into two parts. In the first part, we prove that for each exogenous ancestor of a latent collider, there are at least two MAVs in which only the collider's parent on the path from the exogenous to the collider (of all collider's parents) changes values together with the exogenous. We are aided in this part of the proof by Proposition 5 after considering the collider's parent as a latent non-collider. In the second part, using Assumption 7, we show that each such collider's parent changes values together with the collider in the same two MAVs in which the parent changes values together with the exogenous. Thereby, we prove that for each exogenous ancestor of a latent collider, there are at least two MAVs in which the collider changes values only with this exogenous ancestor.

For the first part, Proposition 5 guarantees that any exogenous ancestor EX_{C_q} of a parent $Pa_k \in \mathbf{Pa}_k$ of collider C_k (and thus $EX_{Pa_k} = EX_{C_q}$ and Pa_k is also a latent non-collider) changes its value if and only if Pa_k changes its value in two value configurations $MAV_{\{TS_{Pa_k} \setminus EX_{Pa_k}, OP_{Pa_k}\}}(ex_{Pa_k}')$. By the opposite of Proposition 5, any exogenous ancestor $EX_{C_q}^*$ of a parent $Pa_k^* \in \mathbf{Pa}_k \setminus Pa_k$ of C_k is certain if and only if Pa_k^* is certain in two value configurations $MAV_{\{TS_{Pa_k^*} \setminus EX_{Pa_k^*}, OP_{Pa_k^*}\}}(ex_{Pa_k^*}')$.

For the second part, we know by Assumption 7 (second part) that for every C_k that is a latent collider and for every $Pa_k \in \mathbf{Pa}_k$, there are at least two configurations \mathbf{pa}_k' and \mathbf{pa}_k'' of \mathbf{Pa}_k in which only the value of Pa_k is different and $MAV_{C_q}(\mathbf{pa}_k') \neq MAV_{C_q}(\mathbf{pa}_k'')$. That is, the collider (which is the only variable in MAV_{C_q}) changes values together with each of its parents in at least two parents' configurations.

Combining the two parts, we have proven that a collider changes values following a change in the value of each of its parents in at least two configurations of the parents, when the change of values of this parent is due to a change of values of its exogenous ancestor in two exogenous configurations. This means that the collider changes values with each of its exogenous ancestors in at least two exogenous configurations. That is, for two configurations ex'_{C_q} and ex''_{C_q} of \mathbf{EX}_{C_q} in which only EX_{C_q} changes values, there are at least two configurations \mathbf{pa}_k' and \mathbf{pa}_k'' of \mathbf{Pa}_k in which $Pa_k \in \mathbf{Pa}_k$ changes values in $MAV_{\{TS_{C_q} \setminus EX_{C_q}, OC_k\}}(ex'_{C_q})$ and $MAV_{\{TS_{C_q} \setminus EX_{C_q}, OC_k\}}(ex''_{C_q})$ with EX_{C_q} . Since these values of Pa_k in \mathbf{pa}_k' and \mathbf{pa}_k'' also change with values of C_k , C_k changes values with EX_{C_q} in ex'_{C_q} and ex''_{C_q} . Therefore, there are at least two configurations ex'_{C_q} and ex''_{C_q} of \mathbf{EX}_{C_q} in which only EX_{C_q} has changed values when C_k changes values in the two corresponding major value configurations $MAV_{\{TS_{C_q} \setminus EX_{C_q}, OC_k\}}(ex'_{C_q})$ and $MAV_{\{TS_{C_q} \setminus EX_{C_q}, OC_k\}}(ex''_{C_q})$. ■

Lemma 2

1. A latent non-collider N_{C_q} and its observed child ON_{C_q} , both descendants of an exogenous variable $EX_{N_{C_q}}$, change their values in any two major configurations if and only if $EX_{N_{C_q}}$ has changed its value in the corresponding two configurations of \mathbf{EX} .
2. A latent collider C_k and its observed child OC_k , both descendants of a set of exogenous variables \mathbf{EX}_{C_q} , change their values in any two major configurations only if at least one of the exogenous variables in \mathbf{EX}_{C_q} has changed its value in the corresponding two configurations of \mathbf{EX} .

Proof

1. First (“only if”), by Proposition 3, the major value configuration of a latent non-collider N_{C_q} and its observed child ON_{C_q} , both of which are descendants of an exogenous variable $EX_{N_{C_q}}$, are certain for any certain $ex_{N_{C_q}}$. That is, if N_{C_q} and ON_{C_q} changed their values in any two major configurations, it is only because $EX_{N_{C_q}}$ has changed its value in the corresponding two configurations of \mathbf{EX} . Second (“if”), by Proposition 4, the major value configurations of N_{C_q} and ON_{C_q} are changed if $EX_{N_{C_q}}$ has changed its value between two configurations of \mathbf{EX} .

2. By Proposition 6, the major value configuration of a collider C_k and its observed child OC_k , both of which are descendants of a set of exogenous variables EX_{C_k} , are certain for a certain ex_{C_k} . That is, if C_k and OC_k changed their values in any two major configurations, it is only because at least one of the variables in EX_{C_k} also changed its value in the corresponding two configurations of EX . ■

Theorem 1 *Variables of a particular MSO are children of a particular exogenous latent variable EX or its latent non-collider descendant or children of a particular latent collider C .*

Proof The proof is divided into two separate cases. In the first case, we show that the children of a particular exogenous latent variable or its non-collider descendant belong to the same **MSO**, and in the second case, we show that the children of a particular collider latent belong to the same **MSO**.

Case 1: MSO of observed children of an exogenous latent or its latent non-collider descendants

Let ONC_i ¹³ (in $OEX \cup OS$) be a set of observed variables that are children of an exogenous variable EX_i and any of its latent non-collider descendants (if they exist), and let OC_i be a set of observed variables that are children of latent colliders where each has EX_i as an exogenous ancestor with other exogenous variables. Note that OC_i may be empty, if EX_i does not have any collider descendants, but ONC_i is never empty because it includes at least OEX_i (Assumption 4). Because no observed child can be included in both OC_i and ONC_i , these sets are disjoint. Their union, $OV_i = ONC_i \cup OC_i$, includes all the observed variables that are affected by EX_i and thus should change their values when EX_i changes.

- First, by Lemma 2 (first part), any subset of variables in ONC_i (and thus also ONC_i itself, which is a maximal set) always changes together in all PCCs that correspond to a change in EX_i and never change together in any other PCC. These variables belong to the same **MSO** that represents EX_i .
- Second, let subset $OC_{i,j}$ of OC_i contain all variables that (1) have a shared exogenous ancestor EX_j (besides EX_i) and (2) change their values together in at least one PCC, which corresponds to a change only in the value of EX_j . By Lemma 2, the other variables in OV_i that are not descendants of EX_j do not change in that PCC. Thus, variables in $OC_{i,j}$ do not belong to the same **MSO** for which variables in ONC_i belong.

Consequently, variables in ONC_i will change together only in all PCCs that correspond to a change in EX_i , and therefore, will establish a maximal set of the variables $MSO_i = ONC_i$ that corresponds to all and only observed variables that are children of exogenous variable EX_i and its latent non-collider descendants.

¹³So far, observed variables had their own indices and their parents/ancestors also had these indices. In Theorem 1, the index is associated with the exogenous variable (Case 1) and the collider latent (Case 2), since these are the central subjects of interest here.

Case 2: MSO of observed children of a latent collider

In this case, it is important to note that different colliders and their children are affected by different sets of exogenous variables. Thus, we assume:

Assumption 8 *Latent colliders do not share exactly the same sets of exogenous ancestors.*

(In case Assumption 8 is violated, for example, if several latent colliders share exactly the same set of exogenous ancestors, LPCC does not identify the latent colliders as separate and learns one collider as the parent of all children of the latent colliders. Nevertheless, we believe this assumption is very realistic.)

Let OC_j be the set of the observed variables that are children of latent collider C_j that is a descendant of a set of exogenous variables EX_{C_j} . By Lemma 2, any variable in OC_j should not change in any PCC unless at least one of its exogenous ancestors changes. The sets of variables that should change together with variables in OC_j if any of the exogenous variables in EX_{C_j} change is represented by:

$$OV = \bigcup_{EX_i \in EX_{C_j}} OV_i = \bigcup_{EX_i \in EX_{C_j}} (ONC_i \cup OC_i) = \bigcup_{EX_i \in EX_{C_j}} (ONC_i \cup \{OC_i \setminus OC_j\}) \cup OC_j \quad (12)$$

where the union is over all exogenous ancestors EX_i of C_j . We separate the proof to include three sets of observed variables: 1) OC_j , which are children of C_j ; 2) ONC_i , which are children of an exogenous variable EX_i and any of its latent non-collider descendants; and 3) $\{OC_i \setminus OC_j\}$, which are children of latent colliders, other than C_j , that are descendants of EX_i .

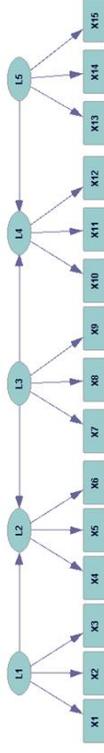

Figure 3: IVM with two latent colliders.

For example, for latent collider $C_j = L2$ in Figure 3, $EX_{L_2} = \{L1, L3\}$, $OC_{L_2} = \{X4, X5, X6\}$, $ONC_{L_1} = \{X1, X2, X3\}$, $ONC_{L_3} = \{X7, X8, X9\}$, and $\{OC_{L_4} \setminus OC_{L_2}\} = \{X10, X11, X12\}$.

Following, we analyze the three subsets of OV , specifically, OC_j , ONC_i , and $\{OC_i \setminus OC_j\}$, and show that only variables in OC_j (or any subset of OC_j) will always change together, whereas other variables in OV will not. We analyze the subsets ONC_i and $\{OC_i \setminus OC_j\}$ for each exogenous $EX_i \in EX_{C_j}$; thus, the analysis is also correct for their union (12).

- **OC_j**: By Lemma 2 (second part), any subset of variables in OC_j always changes together in all PCCs that correspond to a change in at least one exogenous variable in EX_{C_j} . In addition, none of the variables in OC_j has an exogenous ancestor that is not in EX_{C_j} ; therefore, no variable in OC_j ever changes in any PCC that corresponds to an exogenous variable that is not in EX_{C_j} . These variables belong to the same **MSO** that represents C_j .

- ONC_i : We previously showed in Case 1 that each ONC_i forms an MSO that corresponds to a single EX_i , and this is the only exogenous ancestor for ONC_i . By Lemma 3, an MSO is an equivalence class; therefore, no other variable in a subset of OV (including OC_j) can be added to ONC_i , and it will remain an MSO . Similarly, no subset of variables in ONC_i can be added to any subset of OV to obtain an MSO .

• $\{\text{OC}_i, \text{OC}_j\}$: Any subset of $\text{OC}_i \setminus \text{OC}_j$ does not change together with any subset of OC_j because (Assumption 8) for each variable OC_j in $\text{OC}_i \setminus \text{OC}_j$, there is an exogenous ancestor EX_j that is not an ancestor of variables in OC_i . Thus, by Proposition 7, OC_j changes its value in a PCC that corresponds to a change only in the value of EX_j , whereas the variables in OC_i , which are not descendants of EX_j , do not change in that PCC.

Consequently, all and only variables in OC_i (maximal subset of OC_i) compose MSO_i that changes together in all PCCs that correspond to a change in EX_{C_i} . ■

Theorem 2 *A latent variable L is a collider of a set of latent ancestors LACEX only if:*

1. *The values of the children of L change in different parts of some major–minor PCCs each time with the values of descendants of another latent ancestor in LA ; and*
2. *The values of the children of L do not change in any PCC unless the values of descendants of at least one of the variables in LA change too.*

Proof Recall that by this point (Section 4.1), latent variables that have already been learned are either exogenous or colliders. Thus, first, we show that a latent variable L that satisfies (2) has to be a collider for a set of latent ancestors LACEX by assuming by contradiction that L is not a collider but an exogenous variable. If L is an exogenous variable, then there exists at least a single major–minor PCC $_L$ that corresponds to two ex s in which only L changes its value. Thus, in PCC $_L$, only the values of descendants of L change, whereas descendants of other variables in any sub-set LACEX do not change. This is in contrast to (2).

Second, we show that if L satisfies (1), then LA is the set of L 's exogenous ancestors that collide in L . Let ONC_i (in $\text{OEX} \cup \text{OS}$) be the set of observed variables that are children of $\text{LA}_i \in \text{LA}$ or children of its latent non-collider descendants. Let OC_i be the set of children of latent colliders where each has LA_i as its ancestor with other exogenous variables in LA or not. $\text{OV}_i = \text{ONC}_i \cup \text{OC}_i$ includes all the observed variables that are affected by LA_i and thus may change their values when LA_i changes values. In addition, let OC_L be the set of children of L . We need to show that if L satisfies (1), then $\text{OC}_L \subset \text{OC}_i$ for each $\text{LA}_i \in \text{LA}$. Since LA_i is an ancestor of L , (1) ensures that there exists a PCC in which only the values of descendants of LA_i , including OC_L change, whereas the values of descendants of other variables in $\text{LA} \setminus \text{LA}_i$ do not change. Thus, $\text{OC}_L \subset \text{OV}_i$. However, none of the children in OC_L belongs to ONC_i ; otherwise, it would have already been identified (Theorem 1) as a descendant of LA_i . Thus, $\text{OC}_L \subset \text{OC}_i$. ■

Lemma 4 *Let a latent non-collider NC be a descendant of an exogenous latent variable EX . 2S-PCC is PCC between a “two-set” first-order minor cluster 2S-MC due to a minor value in NC and a major cluster that identified EX . ex' and ex'' are two value configurations of EX that correspond to the compared clusters by 2S-PCC. When:*

1. *EX does not change values between ex' and ex'' , all the elements in 2S-PCC corresponding to the observed descendants of the latent ancestors of NC (including EX) show no change (i.e., are 0), whereas the elements corresponding to the observed descendants of NC show a change (i.e., are 1), and when*
2. *EX changes values between ex' and ex'' , all the elements in 2S-PCC corresponding to the observed descendants of the latent ancestors of NC (including EX) show a change (i.e., are 1), whereas the elements corresponding to the observed descendants of NC show no change (i.e., are 0).*

Proof 2S-MC represents a 1-order minor configuration of EN in which only NC has a minor value, and all the other variables in EN have major values. Thus, when

- EX does not change values between ex' and ex'' (i.e., $\text{ex}' = \text{ex}''$), then
 1. the major value configuration of the latent ancestors of NC is the same for both ex s (Proposition 3), and for each such latent, each of its observed children has the same major local value (Proposition 2) for both ex s. Thus, all the observed children of the latent ancestors of NC do not change values in both clusters, and all the corresponding elements in 2S-PCC are 0; and
 2. NC may take either a major or minor value in response to $\text{ex}' (= \text{ex}'')$, depending on the probabilities of NC to take any of its values conditioned on the values NC 's direct parent takes. The result of the first case is a major cluster (NC and both its ancestors and descendants have major values) and that of the second case is 1-MC. Since all NC 's ancestors and descendants have major values, whereas NC has a minor value, this 1-MC is 2S-MC by definition. Using these two clusters, LPCC creates 2S-PCC. Since NC d-separates its descendants (both latents and observed) from its ancestors, the values of NC 's descendants are determined only by NC in a way similar to that which we used to prove Proposition 3. Since we are concerned with the case in which NC takes different values for ex' and ex'' , its descendants too have different values in the two corresponding configurations, and following Assumption 7, all of their observed children have different values in the corresponding observed configurations and clusters. Therefore, these children change their values between the clusters, as represented by 1s in the 2S-PCC.

- EX changes values between ex' and ex'' , then
 1. by Proposition 4, all the latent ancestors of NC have different values for ex' and ex'' , and by Assumption 7, all the observed children of these latents have

different values for \mathbf{ex}' and \mathbf{ex}'' . Thus, in any 2S-PCC between two clusters corresponding to \mathbf{ex}' and \mathbf{ex}'' , all the elements that correspond to the observed children of the latent ancestors of NC (including EX) show a change (i.e., are 1); and

2. NC does not change values between \mathbf{ex}' and \mathbf{ex}'' because if it did, then by Proposition 4, all of its latent descendants have different values for \mathbf{ex}' and \mathbf{ex}'' , and by Assumption 7, all of their observed children have different values in the two corresponding observed configurations. And following, in any 2S-PCC between two clusters corresponding to \mathbf{ex}' and \mathbf{ex}'' , all the elements that correspond to NC and its descendants would show a change (i.e., are 1). But, since as we already showed that all the observed children of the ancestors of NC are equal to 1 in these 2S-PCCs, it is contrary to the definition of a 2S-PCC that needs two sets of two or more elements of different values. Thus, NC cannot change values between \mathbf{ex}' and \mathbf{ex}'' . Following and by Proposition 3, all the latent descendants of NC have certain values for this certain value of NC in both configurations, and by Proposition 2, all the observed children of these latents have certain values in the corresponding observed configurations. Thus, all the elements in 2S-PCC that correspond to the observed children of NC and its descendants do not show a change (i.e., are 0).

Note that the proof implicitly assumes that NC is on a serial connection emerging from EX . In a diverging connection, all the latent variables that are on the paths other than the one that includes NC can be considered with NC 's ancestors because both the latents on the other paths and NC 's ancestors are d-separated (for these 2S-PCCs) by NC from its descendants. Thus, the analysis proposed above for a serial connection generalizes also to the diverging connection. ■

Theorem 3 *Variables of a particular 2S-MSO are children of an exogenous latent variable EX or any of its descendant latent non-colliders NC.*

Proof 1. Variables of 2S-MSO that are children of EX

We need, first, to prove that the children of EX always change values together and second, that no other observed child of another latent can always change value with them. First, Lemma 4 guarantees that the observed children of EX always change values together since a value change of EX between two \mathbf{exs} corresponds to the compared clusters in all 2S-PCCs of 2S-MCs with the major clusters for EX . The remainder of the proof is divided into two cases: 1) a serial connection and 2) a diverging connection. In case 1, there exists at least a single 2S-PCC in which only the observed children of EX change. This 2S-PCC is between a major cluster for EX and 2S-MC due to a minor value of the direct latent non-collider

child NC^{14} of EX (e.g., L2 is the direct latent non-collider child of L1 in G3).¹⁵ Thus, only the elements in 2S-PCC that correspond to the observed children of EX show a change and are equal to 1 (e.g., PCC2.10 in Table 4), which guarantees that the observed children of EX establish a 2S-MSO.

In case 2, the same analysis proposed in case 1 is repeated for each of the direct latent non-collider children of EX in each of the paths that emerges from EX . Let us use the same notation NC for each such direct child in each path in turn. In this case, not only do the observed children of EX change each time EX changes, but also the observed descendants of the other direct latent non-collider children of EX (in all paths except that which includes NC) change with EX . This shows that the observed children of EX change which in observed descendants of the direct latent non-collider children of EX (all but the descendants of NC), but never together with all of them (as at each time, another NC is excluded). This guarantees that the observed children of EX establish a 2S-MSO.

II. Variables of 2S-MSO that are children of EX's descendant NC

In a serial connection, we identify three possible situations in which either NC , its latent descendant, or its latent ancestor takes a minor value. In each of these situations, no other latent or observed variable can take a minor value because we focus the analysis on 2S-MC through the evaluation of 2S-PCC between this minor cluster and a major cluster for EX . For each of the three situations, EX may change its value or not, so we have to consider six cases:

1. 2S-MC is due to a minor value of any of NC 's latent non-collider descendants, $NC1$, and EX does not change value between two \mathbf{exs} that correspond to the compared clusters. Then, by Lemma 4 (first part), all of $NC1$'s observed descendants do change values, but all the observed children of $NC1$'s latent ancestors, including those of NC , do not change values.
2. 2S-MC is due to a minor value of any of NC 's latent non-collider descendants, $NC1$, and EX changes value between two \mathbf{exs} that correspond to the compared clusters. Then, by Lemma 4 (second part), all of $NC1$'s observed descendants do not change values, but all the observed children of $NC1$'s latent ancestors, including those of NC , change values.
3. 2S-MC is due to a minor value of NC , and EX does not change value between two \mathbf{exs} that correspond to the compared clusters. Then, by Lemma 4 (first part), all of NC 's

¹⁴A) We focus on the latent non-collider NC that is the direct child of EX since only a minor value that NC takes can d-separate EX and its observed children from NC 's observed children and the observed children of the remaining latent non-colliders, and partition the elements in the corresponding 2S-PCC into two sets in which the first consists of the observed children of EX and the second consists of the observed children of all EX 's latent descendants. B) In our circumstances, where at least a single latent non-collider has been combined with EX , the existence of such a latent variable is guaranteed. C) It is also guaranteed that the 1-MC due to the minor value of the direct latent child of EX is 2S-MC because it cannot be due to an observed variable (see Case 2 above).

¹⁵We assume that all possible 1-MCs, including the one corresponding to a minor value of the direct latent non-collider child NC of EX , are found. Practically, if we err in estimating the threshold on the maximal 2-MC (as described above and in Appendix B), we may miss this 1-MC, but this is an identification issue that does not affect the correctness of the theorem.

observed descendants do change values, but all the observed children of its ancestors do not.

4. 2S-MC is due to a minor value of NC , and EX changes value between two exs that correspond to the compared clusters. Then, by Lemma 4 (second part), all of NC 's observed descendants do not change values, but all the observed children of its ancestors do.
5. 2S-MC is due to a minor value of NC 's latent non-collider ancestor, $NC1$, and EX does not change value between two exs that correspond to the compared clusters. Then, by Lemma 4 (first part), all the observed children of $NC1$ and of its latent descendants, including those of NC , change values.
6. 2S-MC is due to a minor value of NC 's latent non-collider ancestor, $NC1$, and EX changes value between two exs that correspond to the compared clusters. Then, by Lemma 4 (second part), all the observed children of $NC1$ and of its latent descendants, including those of NC , do not change values.

That is, in all six cases, NC 's observed children change values together; in some 2S-PCCs they change values with observed children of a latent non-collider ancestor of NC and in some other 2S-PCCs with observed children of a latent non-collider descendant of NC . Thus, not only will the set of all the observed children of NC always change values together, but also no observed child of any of NC 's latent non-collider ancestors or descendants can be part of this set. This means that the set of observed children of NC is a maximal set of variables that always change together, i.e., **2S-MSO**.

Note that if NC does not have a latent non-collider descendant or ancestor, then Cases 1 and 2 and Cases 5 and 6, respectively, do not exist. In the special case where NC is a leaf (i.e., does not have a latent descendant), Case 3 guarantees that there exists at least a single 2S-PCC in which only the observed children of NC change.

In a diverging connection, all the latent variables that are on paths other than the one that includes NC can be considered with NC 's ancestors because NC d-separates them all from its descendants. Thus, the same analysis proposed in the serial case also holds in the diverging case. ■

Theorem 4 A latent non-collider $NC1$ is a direct child of another latent non-collider $NC2$ (both on the same path emerging in EX) only if:

- In all 2S-PCCs for which EX does not change, the observed children of $NC1$ always change with those of $NC2$ and also in a single 2S-PCC without the children of $NC2$; and
- In all 2S-PCCs for which a latent non-collider leaf descendant of EX does not change, the observed children of $NC2$ always change with those of $NC1$ and also in a single 2S-PCC without the children of $NC1$.

Proof Let $NC1$ and $NC2$ be latent non-collider descendants of EX (both on the same path emerging from EX), and $NC1$ be a direct child of $NC2$. A 2S-PCC may result from a 2S-MC

due to a minor value in: 1) a latent ancestor of $NC1$ (including $NC2$ itself), 2) $NC1$, or 3) a latent descendant of $NC1$. In the first type of such 2S-PCC (for which EX does not change), Lemma 4 (first part) guarantees that the children of $NC1$ and $NC2$ change together in (1) and do not change at all in (3), whereas in (2) only the observed children of $NC1$ change. Thus, the children of $NC1$ always change with the children of $NC2$, and in addition also in a single 2S-PCC in which the children of $NC2$ do not change.

In the second type of such 2S-PCC for which the observed children of the leaf latent non-collider descendant of EX do not change, Lemma 4 (second part) guarantees that EX changes value, and the children of $NC1$ and $NC2$ do not change at all in (1) and change together in (3), whereas in (2) only the observed children of $NC2$ change. Thus, the children of $NC2$ always change with the children of $NC1$, and in addition also in a single 2S-PCC in which the children of $NC1$ do not change. The same analysis is true for both a serial and diverging connection. ■

Appendix B. Setting a threshold for the maximal size of 2-order minor clusters (Section 4.4)

In this appendix, we describe the calculation of a 2-order minor cluster threshold (2MCT) on the maximal size of 2-order minor clusters (2-MCs) that were introduced in Section 4.4.

This threshold represents the maximal size of a minor cluster that corresponds to a 2-order minor value configuration (Definition 13), i.e., a minor cluster that represents exactly two endogenous variables in EN that have minor values. This threshold is separately calculated to each $EX_i \in EX$, when all endogenous variables in EN , except the two mentioned, have major values. This threshold is an approximation for the maximal probability of having minor values as a response to any ex in exactly two descendants of EX , where all other descendants of EX and the other exogenous variables in EX have major values. This approximation is derived from the product of the maximal minor local effects (Definition B.1) of two observed descendants of EX_i , the maximal major local effects (Definition B.1) of the other observed descendants of EX_i , the maximal major local effects of the descendants of the other exogenous variables in EX , and the maximal prior of all exogenous variables in EX . We define:

Definition B.1 A maximal major local effect on an observed child O_j of a latent parent Pa_i is the maximal major effect on O_j over all values pa_i' of Pa_i , such that $MaxMAE_i = \max_{pa_i'} MAE_i(pa_i')$. Similarly, a maximal minor local effect is the maximal minor effect over all values pa_i' of Pa_i , such that $MaxMIE_i = \max_{pa_i'} MIE_i(pa_i')$.

First, we find $MaxMAE_i$ and $MaxMIE_i$, which are the sorted vectors of $MaxMAE_i$ and $MaxMIE_i$ (Definition B.1) of all $O_j \in Ch_i$ (observed descendants of EX_i), respectively. These vectors include the maximal major local effects and the maximal minor local effects on the observed descendants of EX_i sorted from the highest to the lowest. Note that EX_i replaces the actual direct parent of an observed variable for calculating the maximal major and minor effects since the direct parent has not been identified and split yet from EX_i at this stage.

Using these maximal major and minor effects and their sorted vectors for EX_i , we can calculate the approximation of the threshold. First, the maximal probability of exactly two minor values among the descendants of EX_i can be approximated by:

$$\prod_{t=1}^2 \text{MaxMIEV}_i(t).$$

Second, the maximal probability of the other descendants of EX_i to have major values can be approximated by:

$$\prod_{t=1}^{|\text{Ch}_i|-2} \text{MaxMAEV}_i(t).$$

Third, the maximal probability of the other descendants of the other exogenous variables to have major values can be approximated by:

$$\prod_{EX_j \in \text{EX} \setminus \{EX_i, \text{Ch}_i\}} \text{MaxMAE}_t.$$

Fourth, the maximal prior of all the exogenous variables is represented by:

$$\prod_{EX_k \in \text{EX}} \text{max}_{ex'_k} P(EX_j = ex'_k).$$

Then, the threshold for the maximal size of 2-order minor clusters (measured by the number of patterns in such a cluster) for EX_i can be approximated by the product of all the above approximations multiplied by the data size N :

$$2MCT_i = N \prod_{t=1}^2 \text{MaxMIEV}_i(t) \prod_{t=1}^{|\text{Ch}_i|-2} \text{MaxMAEV}_i(t) \prod_{EX_j \in \text{EX} \setminus \{EX_i, \text{Ch}_i\}} \text{MaxMAE}_t \prod_{EX_k \in \text{EX}} \text{max}_{ex'_k} P(EX_j = ex'_k).$$

Appendix C. Assumptions LPCC makes and the meaning of their violation

Assumption	Essential?	If violated
Assumption 1 The underlying model is a Bayesian network, $\text{BN} = \langle G, \Theta \rangle$, encoding a discrete joint probability distribution P for a set of random variables $V = \text{LUO}$, where $G = \langle V, E \rangle$ is a directed acyclic graph (DAG) whose nodes V correspond to latents L and observed variables O , and E is the set of edges between nodes in G . Θ is the set of parameters, i.e., the conditional probabilities of variables in V given their parents. Assumption 2 No observed variable in O is an ancestor of any latent variable in L (the <i>measurement assumption</i> , Spirtes et al., 2000). Assumption 3 The measurement model of G is pure.	Yes [made also in similar algorithms, e.g., that of Silva et al. (2006) for continuous joint probability distributions].	If neither was investigated theoretically nor studied experimentally what LPCC returns, if the underlying model is not a BN (i.e., there are cycles in G), no latent variables exist in the domain, or an observed variable is an ancestor of a latent variable.
Assumption 4 The true model G is MIM, in which each latent has at least two observed children and may have latent parents.	No (only needed for the correctness of the learned model).	When the true causal model is pure, LPCC will identify it correctly (or find its pattern). However, when it is not pure, LPCC – similarly to BPC (Silva et al., 2006) – will learn a pure sub-model of the true model using two indicators for each latent (compared to three indicators per latent that are required by BPC). If a latent has only one observed child, LPCC will not identify this latent.
Assumption 5 A latent collider does not have any latent descendants (and thus cannot be a parent of another latent collider).	Yes [made also by Silva et al. (2006), which requires three indicators per latent].	If this assumption is violated, and a latent collider has latent descendants, but none of them is a collider, LPCC does not identify the latent descendants as separate and join them, along with their observed children, to the learned ancestor latent collider. The case in which this assumption is violated, and at least one of the latent descendants of the collider is a latent collider itself, needs further investigation.
Assumption 6 For every endogenous variable EN_i in G and every configuration pa'_i of EN_i 's parents Pa_i , there exists a certain value en'_i of EN_i , such that $P(EN_i = en'_i \text{Pa}_i = \text{pa}'_i) > P(EN_i = en'_i \text{Pa}_i = \text{pa}'_i)$ for every other value en''_i of EN_i . This assumption is related to the most probable explanation of a hypothesis given the data (Pearl, 1988).	No (only needed for the correctness of the learned model).	If more than one value of EN_i gets the maximal probability value given a configuration of parents, LPCC still learns a model because the implementation will randomly choose one of the values that maximize the probability as the most probable. However, the correctness of the algorithm will not be guaranteed.
Assumption 7 First, for every EN_i that is an observed variable or an endogenous latent non-collider and for every two values pa'_i and pa''_i of Pa_i , $\text{MAVEN}_i(\text{pa}'_i) \neq \text{MAVEN}_i(\text{pa}''_i)$. Second, for every C_j that is a latent collider and for every $\text{Pa}_j \in \text{Pa}_j$, there are at least two configurations pa'_j and pa''_j of Pa_j in which only the value of Pa_j is different and $\text{MAV}_{C_j}(\text{pa}'_j) \neq \text{MAV}_{C_j}(\text{pa}''_j)$.	Not essential but very reasonable.	Regarding the second part of the assumption first: if this assumption is violated, and a collider has the same major value for any value of one of its parents (while the values of the other parents are the same), then its correlation to this parent should be very weak, which challenges the existence of their connection in the domain, and of course, the ability of any learning algorithm to identify this connection. Although the first part of the assumption may be considered similarly (based on a parent-child correlation), it also invites further investigation.
Assumption 8 Latent colliders do not share exactly the same sets of exogenous ancestors.	Not essential but very reasonable.	If this assumption is violated, and several latent colliders share exactly the same set of exogenous ancestors, LPCC does not identify the latent colliders as separate and learns a single collider as the parent of all children of the latent colliders.

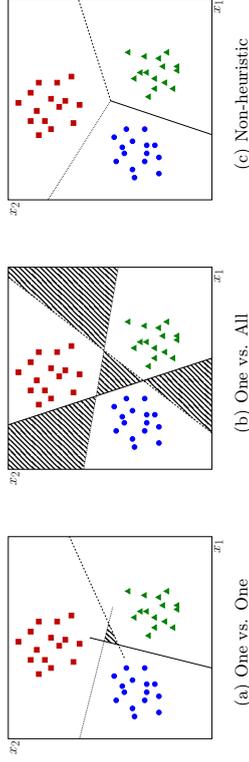

Figure 1: Illustration of ambiguity regions for common heuristic multiclass SVMs. In the shaded regions *ties* occur for which no classification rule has been explicitly trained. Figure (c) corresponds to an SVM where all classes are considered simultaneously, which eliminates any possible ties. Figures inspired by Statnikov et al. (2011).

Abstract

Traditional extensions of the binary support vector machine (SVM) to multiclass problems are either heuristics or require solving a large dual optimization problem. Here, a generalized multiclass SVM is proposed called GenSVM. In this method classification boundaries for a K -class problem are constructed in a $(K - 1)$ -dimensional space using a simplex encoding. Additionally, several different weightings of the misclassification errors are incorporated in the loss function, such that it generalizes three existing multiclass SVMs through a single optimization problem. An iterative majorization algorithm is derived that solves the optimization problem without the need of a dual formulation. This algorithm has the advantage that it can use warm starts during cross validation and during a grid search, which significantly speeds up the training phase. Rigorous numerical experiments compare linear GenSVM with seven existing multiclass SVMs on both small and large data sets. These comparisons show that the proposed method is competitive with existing methods in both predictive accuracy and training time, and that it significantly outperforms several existing methods on these criteria.

Keywords: support vector machines, SVM, multiclass classification, iterative majorization, MM algorithm, classifier comparison

1. Introduction

For binary classification, the support vector machine has shown to be very successful (Cortes and Vapnik, 1995). The SVM efficiently constructs linear or nonlinear classification boundaries and is able to yield a sparse solution through the so-called support vectors, that is, through those observations that are either not perfectly classified or are on the classification boundary. In addition, by regularizing the loss function the overfitting of the training data set is curbed. Due to its desirable characteristics several attempts have been made to extend the SVM to classification problems where the number of classes K is larger than two. Overall, these extensions differ considerably in the approach taken to include multiple classes. Three types of approaches for multiclass SVMs (MSVMs) can be distinguished.

First, there are heuristic approaches that use the binary SVM as an underlying classifier and decompose the K -class problem into multiple binary problems. The most commonly used heuristic is the one-vs-one (OvO) method where decision boundaries are constructed

between each pair of classes (Kreßel, 1999). OvO requires solving $K(K - 1)$ binary SVM problems, which can be substantial if the number of classes is large. An advantage of OvO is that the problems to be solved are smaller in size. On the other hand, the one-vs-all (OvA) heuristic constructs K classification boundaries, one separating each class from all the other classes (Vapnik, 1998). Although OvA requires fewer binary SVMs to be estimated, the complete data set is used for each classifier, which can create a high computational burden. Another heuristic approach is the directed acyclic graph (DAG) SVM proposed by Platt et al. (2000). DAGSVM is similar to the OvO approach except that the class prediction is done by successively voting away unlikely classes until only one remains. One problem with the OvO and OvA methods is that there are regions of the space for which class predictions are ambiguous, as illustrated in Figures 1a and 1b.

In practice, heuristic methods such as the OvO and OvA approaches are used more often than other multiclass SVM implementations. One of the reasons for this is that there are several software packages that efficiently solve the binary SVM, such as LibSVM (Chang and Lin, 2011). This package implements a variation of the sequential minimal optimization algorithm of Platt (1999). Implementations of other multiclass SVMs in high-level (statistical) programming languages are lacking, which reduces their use in practice.

The second type of extension of the binary SVM use error correcting codes. In these methods the problem is decomposed into multiple binary classification problems based on a constructed coding matrix that determines the grouping of the classes in a specific binary subproblem (Dietterich and Bakiri, 1995; Allwein et al., 2001; Crammer and Singer, 2002b). Error correcting code SVMs can thus be seen as a generalization of OvO and OvA. In Dietterich and Bakiri (1995) and Allwein et al. (2001), a coding matrix is constructed that determines which class instances are paired against each other for each binary SVM. Both approaches require that the coding matrix is determined beforehand. However, it is a priori

1. An exception to this is the method of Lee et al. (2004), for which an R implementation exists. See <http://www.stat.osu.edu/~ykLee/software.html>.

unclear how such a coding matrix should be chosen. In fact, as Crammer and Singer (2002b) show, finding the optimal coding matrix is an NP-complete problem.

The third type of approaches are those that optimize one loss function to estimate all class boundaries simultaneously, the so-called single machine approaches (Rifkin and Klautau, 2004). In the literature, such methods have been proposed by, among others, Weston and Watkins (1998), Bredeisen and Bennett (1999), Crammer and Singer (2002a), Lee et al. (2004), and Gherneur and Monfrini (2011). The method of Weston and Watkins (1998) yields a fairly large quadratic problem with a large number of slack variables; that is, $K - 1$ slack variables for each observation. The method of Crammer and Singer (2002a) reduces this number of slack variables by only penalizing the largest misclassification error. In addition, their method does not include a bias term in the decision boundaries, which is advantageous for solving the dual problem. Interestingly, this approach does not reduce parsimoniously to the binary SVM for $K = 2$. The method of Lee et al. (2004) uses a sum-to-zero constraint on the decision functions to reduce the dimensionality of the problem. This constraint effectively means that the solution of the multiclass SVM lies in a $(K - 1)$ -dimensional subspace of the full K dimensions considered. The size of the margins is reduced according to the number of classes, such that asymptotic convergence is obtained to the Bayes optimal decision boundary when the regularization term is ignored (Rifkin and Klautau, 2004). Finally, the method of Gherneur and Monfrini (2011) is a quadratic extension of the method developed by Lee et al. (2004). This extension keeps the sum-to-zero constraint on the decision functions, drops the nonnegativity constraint on the slack variables, and adds a quadratic function of the slack variables to the loss function. This means that at the optimum the slack variables are only positive on average, which differs from common SVM formulations.

The existing approaches to multiclass SVMs suffer from several problems. All current single machine multiclass extensions of the binary SVM rely on solving a potentially large dual optimization problem. This can be disadvantageous when a solution has to be found in a small amount of time, since iteratively improving the dual solution does not guarantee that the primal solution is improved as well. Thus, stopping early can lead to poor predictive performance. In addition, the dual of such single machine approaches should be solvable quickly in order to compete with existing heuristic approaches.

Almost all single machine approaches rely on misclassifications of the observed class with each of the other classes. By simply summing these misclassification errors (as in Lee et al., 2004) observations with multiple errors contribute more than those with a single misclassification do. Consequently, observations with multiple misclassifications have a stronger influence on the solution than those with a single misclassification, which is not a desirable property for a multiclass SVM, as it overemphasizes objects that are misclassified with respect to multiple classes. Here, it is argued that there is no reason to penalize certain misclassification regions more than others.

Single machine approaches are preferred for their ability to capture the multiclass classification problem in a single model. A parallel can be drawn here with multinomial regression and logistic regression. In this case, multinomial regression reduces exactly to the binary logistic regression method when $K = 2$, both techniques are single machine approaches, and many of the properties of logistic regression extend to multinomial regression. Therefore,

it can be considered natural to use a single machine approach for the multiclass SVM that reduces parsimoniously to the binary SVM when $K = 2$.

The idea of casting the multiclass SVM problem to $K - 1$ dimensions is appealing, since it reduces the dimensionality of the problem and is also present in other multiclass classification methods such as multinomial regression and linear discriminant analysis. However, the sum-to-zero constraint employed by Lee et al. (2004) creates an additional burden on the dual optimization problem (Dogan et al., 2011). Therefore, it would be desirable to cast the problem to $K - 1$ dimensions in another manner. Below a simplex encoding will be introduced to achieve this goal. The simplex encoding for multiclass SVMs has been proposed earlier by Hill and Doucet (2007) and Mroueh et al. (2012), although the method outlined below differs from these two approaches. Note that the simplex coding approach by Mroueh et al. (2012) was shown to be equivalent to that of Lee et al. (2004) by Avila Pires et al. (2013). An advantage of the simplex encoding is that in contrast to methods such as O^*O and O^*A , there are no regions of ambiguity in the prediction space (see Figure 1c). In addition, the low dimensional projection also has advantages for understanding the method, since it allows for a geometric interpretation. The geometric interpretation of existing single machine multiclass SVMs is often difficult since most are based on a dual optimization approach with little attention for a primal problem based on hinge errors.

A new flexible and general multiclass SVM is proposed, called GenSVM. This method uses the simplex encoding to formulate the multiclass SVM problem as a single optimization problem that reduces to the binary SVM when $K = 2$. By using a flexible hinge function and an ℓ_p norm of the errors the GenSVM loss function incorporates three existing multiclass SVMs that use the sum of the hinge errors, and extends these methods. In the linear version of GenSVM, $K - 1$ linear combinations of the features are estimated next to the bias terms. In the nonlinear version, kernels can be used in a similar manner as can be done for binary SVMs. The resulting GenSVM loss function is convex in the parameters to be estimated. For this loss function an iterative majorization (IM) algorithm will be derived with guaranteed descent to the global minimum. By solving the optimization problem in the primal it is possible to use warm starts during a hyperparameter grid search or during cross validation, which makes the resulting algorithm very competitive in total training time, even for large data sets.

To evaluate its performance, GenSVM is compared to seven of the multiclass SVMs described above on several small data sets and one large data set. The smaller data sets are used to assess the classification accuracy of GenSVM, whereas the large data set is used to verify feasibility of GenSVM for large data sets. Due to the computational cost of these rigorous experiments only comparisons of linear multiclass SVMs are performed, and experiments on nonlinear MSVMs are considered outside the scope of this paper. Existing comparisons of multiclass SVMs in the literature do not determine any statistically significant differences in performance between classifiers, and resort to tables of accuracy rates for the comparisons (for instance Hsu and Lin, 2002). Using suggestions from the benchmark literature predictive performance and training time of all classifiers is compared using performance profiles and rank tests. The rank tests are used to uncover statistically significant differences between classifiers.

This paper is organized as follows. Section 2 introduces the novel generalized multiclass SVM. In Section 3, features of the iterative majorization theory are reviewed and a number

of useful properties are highlighted. Section 4 derives the IM algorithm for GenSVM, and presents pseudocode for the algorithm. Extensions of GenSVM to nonlinear classification boundaries are discussed in Section 5. A numerical comparison of GenSVM with existing multiclass SVMs on empirical data sets is done in Section 6. Section 7 concludes the paper.

2. GenSVM

Before introducing GenSVM formally, consider a small illustrative example of a hypothetical data set of $n = 90$ objects with $K = 3$ classes and $m = 2$ attributes. Figure 2a shows the data set in the space of these two attributes x_1 and x_2 , with different classes denoted by different symbols. Figure 2b shows the $(K - 1)$ -dimensional simplex encoding of the data after an additional RBF kernel transformation has been applied and the mapping has been optimized to minimize misclassification errors. In this figure, the triangle shown in the center corresponds to a regular K -simplex in $K - 1$ dimensions, and the solid lines perpendicular to the faces of this simplex are the decision boundaries. This $(K - 1)$ -dimensional space will be referred to as the *simplex space* throughout this paper. The mapping from the input space to this simplex space is optimized by minimizing the misclassification errors, which are calculated by measuring the distance of an object to the decision boundaries in the simplex space. Prediction of a class label is also done in this simplex space, by finding the nearest simplex vertex for the object. Figure 2c illustrates the decision boundaries in the original space of the input attributes x_1 and x_2 . In Figures 2b and 2c, the support vectors can be identified as the objects that lie on or beyond the dashed margin lines of their associated class. Note that the use of the simplex encoding ensures that for every point in the predictor space a class is predicted, hence no ambiguity regions can exist in the GenSVM solution.

The misclassification errors are formally defined as follows. Let $\mathbf{x}_i \in \mathbb{R}^m$ be an object vector corresponding to m attributes, and let y_i denote the class label of object i with $y_i \in \{1, \dots, K\}$, for $i \in \{1, \dots, n\}$. Furthermore, let $\mathbf{W} \in \mathbb{R}^{m \times (K-1)}$ be a weight matrix, and define a translation vector $\mathbf{t} \in \mathbb{R}^{K-1}$ for the bias terms. Then, object i is represented in the $(K - 1)$ -dimensional simplex space by $\mathbf{s}'_i = \mathbf{x}'_i \mathbf{W} + \mathbf{t}$. Note that here the *linear* version of GenSVM is described, the nonlinear version is described in Section 5.

To obtain the misclassification error of an object, the corresponding simplex space vector \mathbf{s}'_i is projected on each of the decision boundaries that separate the true class of an object from another class. For the errors to be proportional with the distance to the decision boundaries, a regular K -simplex in \mathbb{R}^{K-1} is used with distance 1 between each pair of vertices. Let \mathbf{U}_K be the $K \times (K - 1)$ coordinate matrix of this simplex, where a row \mathbf{u}_k of \mathbf{U}_K gives the coordinates of a single vertex k . Then, it follows that with $k \in \{1, \dots, K\}$ and $l \in \{1, \dots, K - 1\}$ the elements of \mathbf{U}_K are given by

$$u_{kl} = \begin{cases} -\frac{1}{\sqrt{2(l^2+l)}} & \text{if } k \leq l \\ \frac{l}{\sqrt{2(l^2+l)}} & \text{if } k = l + 1 \\ 0 & \text{if } k > l + 1. \end{cases} \quad (1)$$

See Appendix A for a derivation of this expression. Figure 3 shows an illustration of how the misclassification errors are computed for a single object. Consider object A with true class

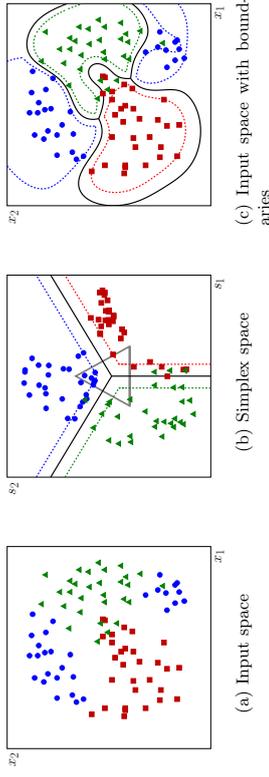

Figure 2: Illustration of GenSVM for a 2D data set with $K = 3$ classes. In (a) the original data is shown, with different symbols denoting different classes. Figure (b) shows the mapping of the data to the $(K - 1)$ -dimensional simplex space, after an additional RBF kernel mapping has been applied and the optimal solution has been determined. The decision boundaries in this space are fixed as the perpendicular bisectors of the faces of the simplex, which is shown as the gray triangle. Figure (c) shows the resulting boundaries mapped back to the original input space, as can be seen by comparing with (a). In Figures (b) and (c) the dashed lines show the margins of the SVM solution.

$y_A = 2$. It is clear that object A is misclassified as it is not located in the shaded area that has vertex \mathbf{u}_2 as the nearest vertex. The boundaries of the shaded area are given by the perpendicular bisectors of the edges of the simplex between vertices \mathbf{u}_2 and \mathbf{u}_1 and between vertices \mathbf{u}_2 and \mathbf{u}_3 , and form the decision boundaries for class 2. The error for object A is computed by determining the distance from the object to each of these decision boundaries. Let $q_A^{(21)}$ and $q_A^{(23)}$ denote these distances to the class boundaries, which are obtained by projecting $\mathbf{s}'_A = \mathbf{x}'_A \mathbf{W} + \mathbf{t}$ on $\mathbf{u}_2 - \mathbf{u}_1$ and $\mathbf{u}_2 - \mathbf{u}_3$ respectively, as illustrated in the figure. Generalizing this reasoning, scalars $q_i^{(kj)}$ can be defined to measure the projection distance of object i onto the boundary between class k and j in the simplex space, as

$$q_i^{(kj)} = (\mathbf{x}'_i \mathbf{W} + \mathbf{t}')(\mathbf{u}_k - \mathbf{u}_j). \quad (2)$$

It is required that the GenSVM loss function is both general and flexible, such that it can easily be tuned for the specific data set at hand. To achieve this, a loss function is constructed with a number of different weightings, each with a specific effect on the object distances $q_i^{(kj)}$. In the proposed loss function, flexibility is added through the use of the Huber hinge function instead of the absolute hinge function, and by using the ℓ_p norm of the hinge errors instead of the sum. The motivation for these choices follows.

As is customary for SVMs a hinge loss is used to ensure that instances that do not cross their class margin will yield zero error. Here, the flexible and continuous Huber hinge loss

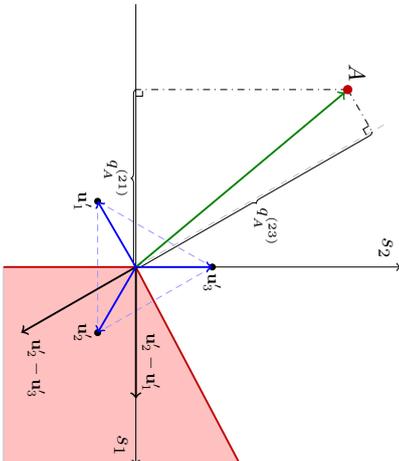

Figure 3: Graphical illustration of the calculation of distances $q_i^{(y_A j)}$ for an object A with $y_A = 2$ and $K = 3$. The figure shows the situation in the $(K - 1)$ -dimensional space. The distance $q_A^{(21)}$ is calculated by projecting $s'_A = X'_A \mathbf{W} + \mathbf{t}'$ on $\mathbf{u}_2 - \mathbf{u}_1$, and the distance $q_A^{(23)}$ is found by projecting s'_A on $\mathbf{u}_2 - \mathbf{u}_3$. The boundary between the class 1 and class 3 regions has been omitted for clarity, but lies along \mathbf{u}_2 .

is used (after the Huber error in robust statistics, see Huber, 1964), which is defined as

$$h(q) = \begin{cases} 1 - q - \frac{\kappa + 1}{2} & \text{if } q \leq -\kappa \\ \frac{1}{2(\kappa + 1)}(1 - q)^2 & \text{if } q \in (-\kappa, 1] \\ 0 & \text{if } q > 1, \end{cases} \quad (3)$$

with $\kappa > -1$. The Huber hinge loss has been independently introduced in Chapelle (2007), Rosset and Zhu (2007), and Groenen et al. (2008). This hinge error is zero when an instance is classified correctly with respect to its class margin. However, in contrast to the absolute hinge error, it is continuous due to a quadratic region in the interval $(-\kappa, 1]$. This quadratic region allows for a softer weighting of objects close to the decision boundary. Additionally, the smoothness of the Huber hinge error is a desirable property for the iterative majorization algorithm derived in Section 4.1. Note that the Huber hinge error approaches the absolute hinge for $\kappa \downarrow -1$, and the quadratic hinge for $\kappa \rightarrow \infty$.

The Huber hinge error is applied to each of the distances $q_i^{(y_A j)}$, for $j \neq y_i$. Thus, no error is counted when the object is correctly classified. For each of the objects, errors with respect to the other classes are summed using an ℓ_p norm to obtain the total object error

$$\left(\sum_{\substack{j=1 \\ j \neq y_i}}^K h^p \left(q_i^{(y_A j)} \right) \right)^{1/p}$$

The ℓ_p norm is added to provide a form of regularization on Huber weighted errors for instances that are misclassified with respect to multiple classes. As argued in the Introduction, simply summing misclassification errors can lead to overemphasizing of instances with multiple misclassification errors. By adding an ℓ_p norm of the hinge errors the influence of such instances on the loss function can be tuned. With the addition of the ℓ_p norm on the hinge errors it is possible to illustrate how GenSVM generalizes existing methods. For instance, with $p = 1$ and $\kappa \downarrow -1$, the loss function solves the same problem as the method of Lee et al. (2004). Next, for $p = 2$ and $\kappa \downarrow -1$ it resembles that of Guenieur and Monfimi (2011). Finally, for $p = \infty$ and $\kappa \downarrow -1$ the ℓ_p norm reduces to the max norm of the hinge errors, which corresponds to the method of Crammer and Singer (2002a). Note that in each case the value of κ can additionally be varied to include an even broader family of loss functions.

To illustrate the effects of p and κ on the total object error, refer to Figure 4. In Figures 4a and 4b, the value of p is set to $p = 1$ and $p = 2$ respectively, while maintaining the absolute hinge error using $\kappa = -0.95$. A reference point is plotted at a fixed position in the area of the simplex space where there is a nonzero error with respect to two classes. It can be seen from this reference point that the value of the combined error is higher when $p = 1$. With $p = 2$ the combined error at the reference point approximates the Euclidean distance to the margin, when $\kappa \downarrow -1$. Figures 4a, 4c, and 4d show the effect of varying κ . It can be seen that the error near the margin becomes more quadratic with increasing κ . In fact, as κ increases the error approaches the squared Euclidean distance to the margin, which can be used to obtain a quadratic hinge multiclass SVM. Both of these effects will become stronger when the number of classes increases, as increasingly more objects will have errors with respect to more than one class.

Next, let $\rho_i \geq 0$ denote optional object weights, which are introduced to allow flexibility in the way individual objects contribute to the total loss function. With these individual weights it is possible to correct for different group sizes, or to give additional weights to misclassifications of certain classes. When correcting for group sizes, the weights can be chosen as

$$\rho_i = \frac{n}{n_k K}, \quad i \in G_k, \quad (4)$$

where $G_k = \{i : y_i = k\}$ is the set of objects belonging to class k , and $n_k = |G_k|$. The complete GenSVM loss function combining all n objects can now be formulated as

$$L_{\text{MSVM}}(\mathbf{W}, \mathbf{t}) = \frac{1}{n} \sum_{k=1}^K \sum_{i \in G_k} \rho_i \left(\sum_{j \neq k} h^p \left(q_i^{(k j)} \right) \right)^{1/p} + \lambda \text{tr } \mathbf{W}' \mathbf{W}, \quad (5)$$

where $\lambda \text{tr } \mathbf{W}' \mathbf{W}$ is the penalty term to avoid overfitting, and $\lambda > 0$ is the regularization parameter. Note that for the case where $K = 2$, the above loss function reduces to the loss function for binary SVM given in Groenen et al. (2008), with Huber hinge errors.

The outline of a proof for the convexity of the loss function in (5) is given. First, note that the distances $q_i^{(k j)}$ in the loss function are affine in \mathbf{W} and \mathbf{t} . Hence, if the loss function is convex in $q_i^{(k j)}$ it is convex in \mathbf{W} and \mathbf{t} as well. Second, the Huber hinge function is trivially convex in $q_i^{(k j)}$, since each separate piece of the function is convex, and the Huber

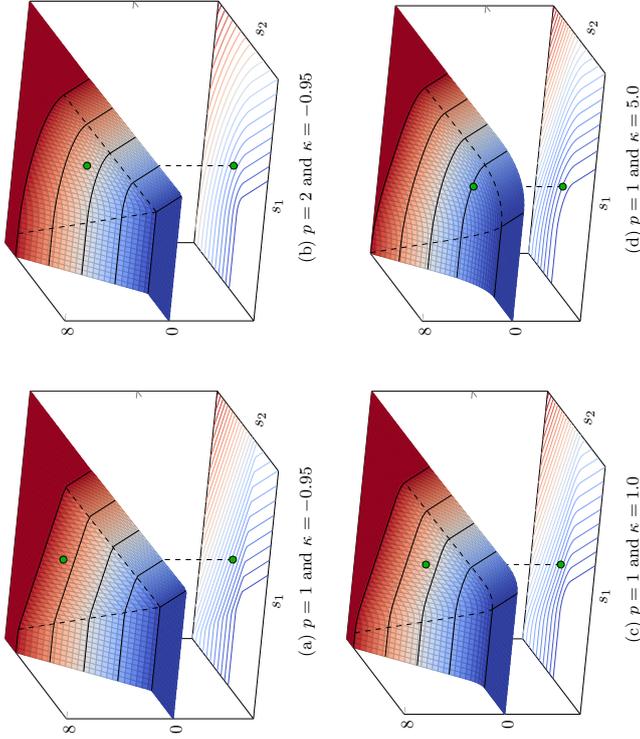

Figure 4: Illustration of the ℓ_p norm of the Huber weighted errors. Comparing figures (a) and (b) shows the effect of the ℓ_p norm. With $p = 1$ objects that have errors w.r.t. both classes are penalized more strongly than those with only one error, whereas with $p = 2$ this is not the case. Figures (a), (c), and (d) compare the effect of the κ parameter, with $p = 1$. This shows that with a large value of κ , the errors close to the boundary are weighted quadratically. Note that s_1 and s_2 indicate the dimensions of the simplex space.

hinge is continuous. Third, the ℓ_p norm is a convex function by the Minkowski inequality, and it is monotonically increasing by definition. Thus, it follows that the ℓ_p norm of the Huber weighted instance errors is convex (see for instance Rockafellar, 1997). Next, since it is required that the weights ρ_i are non-negative, the sum in the first term of (5) is a convex combination. Finally, the penalty term can also be shown to be convex, since $\text{tr } \mathbf{W}^* \mathbf{W}$ is the square of the Frobenius norm of \mathbf{W} , and it is required that $\lambda > 0$. Thus, it holds that the loss function in (5) is convex in \mathbf{W} and \mathbf{t} .

Predicting class labels in GenSVM can be done as follows. Let $(\mathbf{W}^*, \mathbf{t}^*)$ denote the parameters that minimize the loss function. Predicting the class label of an unseen sample \mathbf{x}'_{n+1} can then be done by first mapping it to the simplex space, using the optimal projection: $\mathbf{s}'_{n+1} = \mathbf{x}'_{n+1} \mathbf{W}^* + \mathbf{t}^*$. The predicted class label is then simply the label corresponding to

the nearest simplex vertex as measured by the squared Euclidean norm, or

$$\hat{y}_{n+1} = \arg \min_k \|\mathbf{s}'_{n+1} - \mathbf{u}'_k\|^2, \quad \text{for } k = 1, \dots, K. \quad (6)$$

3. Iterative Majorization

To minimize the loss function given in (5), an iterative majorization (IM) algorithm will be derived. Iterative majorization was first described by Weiszfeld (1937), however the first application of the algorithm in the context of a line search comes from Ortega and Rheinboldt (1970, p. 253–255). During the late 1970s, the method was independently developed by De Leeuw (1977) as part of the SMACOF algorithm for multidimensional scaling, and by Voss and Eckhardt (1980) as a general minimization method. For the reader unfamiliar with the iterative majorization algorithm a more detailed description has been included in Appendix B and further examples can be found in for instance Hunter and Lange (2004).

The asymptotic convergence rate of the IM algorithm is linear, which is less than that of the Newton-Raphson algorithm (De Leeuw, 1994). However, the largest improvements in the loss function will occur in the first few steps of the iterative majorization algorithm, where the asymptotic linear rate does not apply (Havel, 1991). This property will become very useful for GenSVM as it allows for a quick approximation to the exact SVM solution in few iterations.

There is no straightforward technique for deriving the majorization function for any given function. However, in the next section the derivation of the majorization function for the GenSVM loss function is presented using an “outside-in” approach. In this approach, each function that constitutes the loss function is majorized separately and the majorization functions are combined. Two properties of majorization functions that are useful for this derivation are now formally defined. In these expressions, \bar{x} is a supporting point, as defined in Appendix B.

P1. Let $f_1 : \mathcal{Y} \rightarrow \mathcal{Z}$, $f_2 : \mathcal{X} \rightarrow \mathcal{Y}$, and define $f = f_1 \circ f_2 : \mathcal{X} \rightarrow \mathcal{Z}$, such that for $x \in \mathcal{X}$, $f(x) = f_1(f_2(x))$. If $g_1 : \mathcal{Y} \times \mathcal{Y} \rightarrow \mathcal{Z}$ is a majorization function of f_1 , then $g : \mathcal{X} \times \mathcal{X} \rightarrow \mathcal{Z}$ defined as $g = g_1 \circ f_2$ is a majorization function of f . Thus for $x, \bar{x} \in \mathcal{X}$ it holds that $g(x, \bar{x}) = g_1(f_2(x), f_2(\bar{x}))$ is a majorization function of $f(x)$ at \bar{x} .

P2. Let $f_i : \mathcal{X} \rightarrow \mathcal{Z}$ and define $f : \mathcal{X} \rightarrow \mathcal{Z}$ such that $f(x) = \sum_i a_i f_i(x)$ for $x \in \mathcal{X}$, with $a_i \geq 0$ for all i . If $g_i : \mathcal{X} \times \mathcal{X} \rightarrow \mathcal{Z}$ is a majorization function for f_i at a point $\bar{x} \in \mathcal{X}$, then $g : \mathcal{X} \times \mathcal{X} \rightarrow \mathcal{Z}$ given by $g(x, \bar{x}) = \sum_i a_i g_i(x, \bar{x})$ is a majorization function of f .

Proofs of these properties are omitted, as they follow directly from the requirements for a majorization function given in Appendix B. The first property allows for the use of the “outside-in” approach to majorization, as will be illustrated in the next section.

4. GenSVM Optimization and Implementation

In this section, a quadratic majorization function for GenSVM will be derived. Although it is possible to derive a majorization algorithm for general values of the ℓ_p norm parameter,²

² For a majorization algorithm of the ℓ_p norm with $p \geq 2$, see Groenen et al. (1999).

the following derivation will restrict this value to the interval $p \in [1, 2]$ since this simplifies the derivation and avoids the issue that quadratic majorization can become slow for $p > 2$. Pseudocode for the derived algorithm will be presented, as well as an analysis of the computational complexity of the algorithm. Finally, an important remark on the use of warm starts in the algorithm is given.

4.1 Majorization Derivation

To shorten the notation, define

$$\begin{aligned} \mathbf{V} &= [\mathbf{t} \ \mathbf{W}]^T, \\ \mathbf{z}'_i &= [1 \ \mathbf{x}'_i], \\ \delta_{kj} &= \mathbf{u}_k - \mathbf{u}_j, \end{aligned}$$

such that $q_i^{(kj)} = \mathbf{z}'_i \mathbf{V} \delta_{kj}$. With this notation it becomes sufficient to optimize the loss function with respect to \mathbf{V} . Formulated in this manner (5) becomes

$$L_{\text{MSVM}}(\mathbf{V}) = \frac{1}{n} \sum_{k=1}^K \sum_{i \in G_k} \rho_i \left(\sum_{j \neq k} h^p(q_i^{(kj)}) \right)^{1/p} + \lambda \text{tr} \mathbf{V}' \mathbf{J} \mathbf{V}, \quad (7)$$

where \mathbf{J} is an $m+1$ diagonal matrix with $J_{i,i} = 1$ for $i > 1$ and zero elsewhere. To derive a majorization function for this expression the ‘‘outside-in’’ approach will be used, together with the properties of majorization functions. In what follows, variables with a bar denote supporting points for the IM algorithm. The goal of the derivation is to find a quadratic majorization function in \mathbf{V} such that

$$L_{\text{MSVM}}(\mathbf{V}) \leq \text{tr} \mathbf{V}' \mathbf{Z}' \mathbf{A} \mathbf{Z}' \mathbf{V} - 2 \text{tr} \mathbf{V}' \mathbf{Z}' \mathbf{B} + C, \quad (8)$$

where \mathbf{A} , \mathbf{B} , and C are coefficients of the majorization depending on $\bar{\mathbf{V}}$. The matrix \mathbf{Z} is simply the $n \times (m+1)$ matrix with rows \mathbf{z}'_i .

Property P2 above means that the summation over instances in the loss function can be ignored for now. Moreover, the regularization term is quadratic in \mathbf{V} , and thus requires no majorization. The outermost function for which a majorization function has to be found is thus the ℓ_p norm of the Huber hinge errors. Hence it is possible to consider the function $f(\mathbf{x}) = \|\mathbf{x}\|_p$ for majorization. A majorization function for $f(\mathbf{x})$ can be constructed, but a discontinuity in the derivative at $\mathbf{x} = \mathbf{0}$ will remain (Tatsui and Morikawa, 2012).

To avoid the discontinuity in the derivative of the ℓ_p norm, the following inequality is needed (Hardy et al., 1934, eq. 2.10.3)

$$\left(\sum_{j \neq k} h^p(q_i^{(kj)}) \right)^{1/p} \leq \sum_{j \neq k} h(q_i^{(kj)}).$$

This inequality can be used as a majorization function only if equality holds at the supporting point

$$\left(\sum_{j \neq k} h^p(\bar{q}_i^{(kj)}) \right)^{1/p} = \sum_{j \neq k} h(\bar{q}_i^{(kj)}).$$

It is not difficult to see that this only holds if at most one of the $h(\bar{q}_i^{(kj)})$ errors is nonzero for $j \neq k$. Thus an indicator variable ε_i is introduced which is 1 if at most one of these errors is nonzero, and 0 otherwise. Then it follows that

$$\begin{aligned} L_{\text{MSVM}}(\mathbf{V}) &\leq \frac{1}{n} \sum_{k=1}^K \sum_{i \in G_k} \rho_i \left[\varepsilon_i \sum_{j \neq k} h(q_i^{(kj)}) + (1 - \varepsilon_i) \left(\sum_{j \neq k} h^p(q_i^{(kj)}) \right)^{1/p} \right] \\ &\quad + \lambda \text{tr} \mathbf{V}' \mathbf{J} \mathbf{V}. \end{aligned} \quad (9)$$

Now, the next function for which a majorization needs to be found is $f_1(x) = x^{1/p}$. From the inequality $a^\alpha b^\beta \leq \alpha a + \beta b$, with $\alpha + \beta = 1$ (Hardy et al., 1934, Theorem 37), a linear majorization inequality can be constructed for this function by substituting $a = x$, $b = \bar{x}$, $\alpha = 1/p$ and $\beta = 1 - 1/p$ (Groenen and Heiser, 1996). This yields

$$f_1(x) = x^{1/p} \leq \frac{1}{p} \bar{x}^{1/p-1} x + \left(1 - \frac{1}{p}\right) \bar{x}^{1/p} = g_1(x; \bar{x}).$$

Applying this majorization and using property P1 gives

$$\begin{aligned} \left(\sum_{j \neq k} h^p(q_i^{(kj)}) \right)^{1/p} &\leq \frac{1}{p} \left(\sum_{j \neq k} h^p(\bar{q}_i^{(kj)}) \right)^{1/p-1} \left(\sum_{j \neq k} h^p(q_i^{(kj)}) \right) \\ &\quad + \left(1 - \frac{1}{p}\right) \left(\sum_{j \neq k} h^p(\bar{q}_i^{(kj)}) \right)^{1/p}. \end{aligned}$$

Plugging this into (9) and collecting terms yields

$$\begin{aligned} L_{\text{MSVM}}(\mathbf{V}) &\leq \frac{1}{n} \sum_{k=1}^K \sum_{i \in G_k} \rho_i \left[\varepsilon_i \sum_{j \neq k} h(q_i^{(kj)}) + (1 - \varepsilon_i) \omega_i \sum_{j \neq k} h^p(q_i^{(kj)}) \right] \\ &\quad + \Gamma^{(1)} + \lambda \text{tr} \mathbf{V}' \mathbf{J} \mathbf{V}, \end{aligned} \quad (10)$$

with

$$\omega_i = \frac{1}{p} \left(\sum_{j \neq k} h^p(\bar{q}_i^{(kj)}) \right)^{1/p-1}.$$

The constant $\Gamma^{(1)}$ contains all terms that only depend on previous errors $\bar{q}_i^{(kj)}$. The next majorization step by the ‘‘outside-in’’ approach is to find a quadratic majorization function for $f_2(x) = h^p(x)$, of the form

$$f_2(x) = h^p(x) \leq a(\bar{x}, p)x^2 - 2b(\bar{x}, p)x + c(\bar{x}, p) = g_2(x; \bar{x}).$$

Since this derivation is mostly an algebraic exercise it has been moved to Appendix C. In the remainder of this derivation, $a_{i,jk}^{(p)}$ will be used to abbreviate $a(\bar{q}_i^{(kj)}, p)$, with similar

abbreviations for b and c . Using these majorizations and making the dependence on \mathbf{V} explicit by substituting $q_i^{(kj)} = \mathbf{z}_i^t \mathbf{V} \boldsymbol{\delta}_{kj}$ gives

$$\begin{aligned} L_{\text{MSVM}}(\mathbf{V}) &\leq \frac{1}{n} \sum_{k=1}^K \sum_{i \in G_k} \rho_i \varepsilon_i \sum_{j \neq k} \left[a_{ijk}^{(1)} \mathbf{z}_i^t \mathbf{V} \boldsymbol{\delta}_{kj} \boldsymbol{\delta}_{kj}' \mathbf{V}' \mathbf{z}_i - 2b_{ijk}^{(1)} \mathbf{z}_i^t \mathbf{V} \boldsymbol{\delta}_{kj} \right] \\ &\quad + \frac{1}{n} \sum_{k=1}^K \sum_{i \in G_k} \rho_i (1 - \varepsilon_i) \omega_i \sum_{j \neq k} \left[a_{ijk}^{(p)} \mathbf{z}_i^t \mathbf{V} \boldsymbol{\delta}_{kj} \boldsymbol{\delta}_{kj}' \mathbf{V}' \mathbf{z}_i - 2b_{ijk}^{(p)} \mathbf{z}_i^t \mathbf{V} \boldsymbol{\delta}_{kj} \right] \\ &\quad + \Gamma^{(2)} + \lambda \text{tr } \mathbf{V}' \mathbf{J} \mathbf{V}, \end{aligned} \quad (14)$$

where $\Gamma^{(2)}$ again contains all constant terms. Due to dependence on the matrix $\boldsymbol{\delta}_{ij} \boldsymbol{\delta}_{kj}'$, the above majorization function is not yet in the desired quadratic form of (8). However, since the maximum eigenvalue of $\boldsymbol{\delta}_{ij} \boldsymbol{\delta}_{kj}'$ is 1 by definition of the simplex coordinates, it follows that the matrix $\boldsymbol{\delta}_{ij} \boldsymbol{\delta}_{kj}' - \mathbf{I}$ is negative semidefinite. Hence, it can be shown that the inequality $\mathbf{z}_i^t (\mathbf{V} - \bar{\mathbf{V}}) (\boldsymbol{\delta}_{ij} \boldsymbol{\delta}_{kj}' - \mathbf{I}) (\mathbf{V} - \bar{\mathbf{V}})' \mathbf{z}_i \leq 0$ holds (Bijleveld and De Leeuw, 1991, Theorem 4). Rewriting this gives the majorization inequality

$$\mathbf{z}_i^t \mathbf{V} \boldsymbol{\delta}_{ij} \boldsymbol{\delta}_{kj}' \mathbf{V}' \mathbf{z}_i \leq \mathbf{z}_i^t \mathbf{V} \mathbf{V}' \mathbf{z}_i - 2\mathbf{z}_i^t \mathbf{V} (\mathbf{I} - \boldsymbol{\delta}_{ij} \boldsymbol{\delta}_{kj}') \bar{\mathbf{V}} \mathbf{z}_i + \mathbf{z}_i^t \bar{\mathbf{V}} (\mathbf{I} - \boldsymbol{\delta}_{ij} \boldsymbol{\delta}_{kj}') \bar{\mathbf{V}}' \mathbf{z}_i.$$

With this inequality the majorization inequality becomes

$$\begin{aligned} L_{\text{MSVM}}(\mathbf{V}) &\leq \frac{1}{n} \sum_{k=1}^K \sum_{i \in G_k} \rho_i \mathbf{z}_i^t \mathbf{V} (\mathbf{V}' - 2\bar{\mathbf{V}}') \mathbf{z}_i \sum_{j \neq k} \left[\varepsilon_i a_{ijk}^{(1)} + (1 - \varepsilon_i) \omega_i a_{ijk}^{(p)} \right] \\ &\quad - \frac{2}{n} \sum_{k=1}^K \sum_{i \in G_k} \rho_i \mathbf{z}_i^t \mathbf{V} \sum_{j \neq k} \left[\varepsilon_i \left(b_{ijk}^{(1)} - a_{ijk}^{(1)} \bar{q}_i^{(kj)} \right) \right. \\ &\quad \left. + (1 - \varepsilon_i) \omega_i \left(b_{ijk}^{(p)} - a_{ijk}^{(p)} \bar{q}_i^{(kj)} \right) \right] \boldsymbol{\delta}_{kj} \\ &\quad + \Gamma^{(3)} + \lambda \text{tr } \mathbf{V}' \mathbf{J} \mathbf{V}, \end{aligned} \quad (11)$$

where $\bar{q}_i^{(kj)} = \mathbf{z}_i^t \bar{\mathbf{V}} \boldsymbol{\delta}_{kj}$. This majorization function is quadratic in \mathbf{V} and can thus be used in the IM algorithm. To derive the first-order condition used in the update step of the IM algorithm (step 2 in Appendix B), matrix notation for the above expression is introduced. Let \mathbf{A} be an $n \times n$ diagonal matrix with elements α_i , and let \mathbf{B} be an $n \times (K - 1)$ matrix with rows $\boldsymbol{\beta}_i$, where

$$\alpha_i = \frac{1}{n} \sum_{j \neq k} \left[\varepsilon_i a_{ijk}^{(1)} + (1 - \varepsilon_i) \omega_i a_{ijk}^{(p)} \right], \quad (12)$$

$$\boldsymbol{\beta}_i = \frac{1}{n} \sum_{j \neq k} \left[\varepsilon_i \left(b_{ijk}^{(1)} - a_{ijk}^{(1)} \bar{q}_i^{(kj)} \right) + (1 - \varepsilon_i) \omega_i \left(b_{ijk}^{(p)} - a_{ijk}^{(p)} \bar{q}_i^{(kj)} \right) \right] \boldsymbol{\delta}_{kj}. \quad (13)$$

Then the majorization function of $L_{\text{MSVM}}(\mathbf{V})$ given in (11) can be written as

$$\begin{aligned} L_{\text{MSVM}}(\mathbf{V}) &\leq \text{tr} (\mathbf{V} - 2\bar{\mathbf{V}})' \mathbf{Z}' \mathbf{A} \mathbf{Z} \mathbf{V} - 2 \text{tr } \mathbf{B}' \mathbf{Z} \mathbf{V} + \Gamma^{(3)} + \lambda \text{tr } \mathbf{V}' \mathbf{J} \mathbf{V} \\ &= \text{tr } \mathbf{V}' (\mathbf{Z}' \mathbf{A} \mathbf{Z} + \lambda \mathbf{J}) \mathbf{V} - 2 \text{tr} (\bar{\mathbf{V}}' \mathbf{Z}' \mathbf{A} + \mathbf{B}') \mathbf{Z} \mathbf{V} + \Gamma^{(3)}. \end{aligned}$$

This majorization function has the desired functional form described in (8). Differentiation with respect to \mathbf{V} and equating to zero yields the linear system

$$(\mathbf{Z}' \mathbf{A} \mathbf{Z} + \lambda \mathbf{J}) \mathbf{V} = \mathbf{Z}' \mathbf{A} \bar{\mathbf{Z}} + \mathbf{Z}' \mathbf{B}. \quad (14)$$

The update \mathbf{V}^+ that solves this system can then be calculated efficiently by Gaussian elimination.

4.2 Algorithm Implementation and Complexity

Pseudocode for GenSVM is given in Algorithm 1. As can be seen, the algorithm simply updates all instance weights at each iteration, starting by determining the indicator variable ε_i . In practice, some calculations can be done efficiently for all instances by using matrix algebra. When step doubling (see Appendix B) is applied in the majorization algorithm, line 25 is replaced by $\mathbf{V} \leftarrow 2\mathbf{V}^+ - \bar{\mathbf{V}}$. In the implementation step doubling is applied after a burn-in of 50 iterations. The implementation used in the experiments described in Section 6 is written in C, using the ATLAS (Whaley and Dongarra, 1998) and LAPACK (Anderson et al., 1999) libraries. The source code for this C library is available under the open source GNU GPL license, through an online repository. A thorough description of the implementation is available in the package documentation.

The complexity of a single iteration of the IM algorithm is $O(n(m+1)^2)$ assuming that $n > m > K$. As noted earlier, the convergence rate of the general IM algorithm is linear. Computational complexity of standard SVM solvers that solve the dual problem through decomposition methods lies between $O(n^2)$ and $O(n^3)$ depending on the value of λ (Boftou and Lin, 2007). An efficient algorithm for the method of Crammer and Singer (2002a) developed by Keerthi et al. (2008) has a complexity of $O(n\bar{m}K)$ per iteration, where $\bar{m} \leq m$ is the average number of nonzero features per training instance. In the methods of Lee et al. (2004) and Weston and Watkins (1998), a quadratic programming problem with $n(K-1)$ dual variables needs to be solved, which is typically done using a standard solver. An analysis of the exact convergence of GenSVM, including the expected number of iterations needed to achieve convergence at a factor ϵ , is outside the scope of the current work and a subject for further research.

4.3 Smart Initialization

When training machine learning algorithms to determine the optimal hyperparameters, it is common to use cross validation (CV). With GenSVM it is possible to initialize the matrix $\bar{\mathbf{V}}$ such that the final result of a fold is used as the initial value for \mathbf{V}_0 for the next fold. This same technique can be used when searching for the optimal hyperparameter configuration in a grid search, by initializing the weight matrix with the outcome of the previous configuration. Such warm-start initialization greatly reduces the time needed to perform cross validation with GenSVM. It is important to note here that using warm starts is not easily possible with dual optimization approaches. Therefore, the ability to use warm starts can be seen as an advantage of solving the GenSVM optimization problem in the primal.

Algorithm 1: GenSVM Algorithm

```

Input:  $\mathbf{X}, \mathbf{y}, \rho, \beta, \kappa, \lambda, \epsilon$ 
Output:  $\mathbf{V}$ 
1  $K \leftarrow \max(\mathbf{Y})$ 
2  $t \leftarrow 1$ 
3  $\mathbf{Z} \leftarrow [\mathbf{1} \ \mathbf{X}]$ 
4 Let  $\bar{\mathbf{V}} \leftarrow \mathbf{V}_0$ 
5 Generate  $\mathbf{J}$  and  $\mathbf{U}_K$ 
6  $L_t = L_{\text{MSVM}}(\bar{\mathbf{V}})$ 
7  $L_{t-1} = (1 + 2\epsilon)L_t$ 
8 while  $(L_{t-1} - L_t)/L_t > \epsilon$  do
9   for  $i \leftarrow 1$  to  $n$  do
10    Compute  $\bar{q}_i^{(g,j)} = \mathbf{z}_i^T \bar{\mathbf{V}} \mathbf{g}_{g,j}$  for all  $j \neq g_i$ 
11    Compute  $h(\frac{\bar{q}_i^{(g,j)}}{q_i^{(g,j)}}$ ) for all  $j \neq g_i$  by (3)
12    if  $\epsilon_i = 1$  then
13      Compute  $q_{i,g_i}^{(1)}$  and  $b_{i,g_i}^{(1)}$  for all  $j \neq g_i$  according to Table 4 in Appendix C
14    else
15      Compute  $\omega_i$  following (10)
16      Compute  $q_{i,g_i}^{(p)}$  and  $b_{i,g_i}^{(p)}$  for all  $j \neq g_i$  according to Table 4 in Appendix C
17    end
18    Compute  $\alpha_i$  by (12)
19    Compute  $\beta_i$  by (13)
20  end
21  Construct  $\mathbf{A}$  from  $\alpha_i$ 
22  Construct  $\mathbf{B}$  from  $\beta_i$ 
23  Find  $\mathbf{V}^+$  that solves (14)
24   $\bar{\mathbf{V}} \leftarrow \mathbf{V}^+$ 
25   $\mathbf{V} \leftarrow \mathbf{V}^+$ 
26   $L_{t-1} \leftarrow L_t$ 
27   $L_t \leftarrow L_{\text{MSVM}}(\bar{\mathbf{V}})$ 
28   $t \leftarrow t + 1$ 
29 end

```

5. Nonlinearity

One possible method to include nonlinearity in a classifier is through the use of spline transformations (see for instance Hastie et al., 2009). With spline transformations each attribute vector \mathbf{x}_j is transformed to a spline basis \mathbf{N}_j , for $j = 1, \dots, m$. The transformed input matrix $\mathbf{N} = [\mathbf{N}_1, \dots, \mathbf{N}_m]$ is then of size $n \times l$, where l depends on the degree of the spline transformation and the number of interior knots chosen. An application of spline transformations to the binary SVM can be found in Groenen et al. (2007).

A more common way to include nonlinearity in machine learning methods is through the use of the kernel trick, attributed to Aizerman et al. (1964). With the kernel trick, the dot product of two instance vectors in the dual optimization problem is replaced by the dot product of the same vectors in a high dimensional feature space. Since no dot products appear in the primal formulation of GenSVM, a different method is used here.

By applying a preprocessing step on the kernel matrix, nonlinearity can be included using the same algorithm as the one presented for the linear case. Furthermore, predicting class labels requires a postprocessing step on the obtained matrix \mathbf{V}^* . A full derivation is given in Appendix D.

6. Experiments

To assess the performance of the proposed GenSVM classifier, a simulation study was done comparing GenSVM with seven existing multiclass SVMs on 13 small data sets. These experiments are used to precisely measure predictive accuracy and total training time using performance profiles and rank plots. To verify the feasibility of GenSVM for large data sets an additional simulation study is done. The results of this study are presented separately in Section 6.4. Due to the large number of data sets and methods involved, experiments were only done for the linear kernel. Experiments on nonlinear multiclass SVMs would require even more training time than for linear MSVMs and is considered outside the scope of this paper.

6.1 Setup

Implementations of the heuristic multiclass SVMs (OVO, OvA, and DAG) were included through LibSVM (v. 3.16, Chang and Lin, 2011). LibSVM is a popular library for binary SVMs with packages for many programming languages, it is written in C++ and implements a variation of the SMO algorithm of Platt (1999). The OvO and DAG methods are implemented in this package, and a C implementation of OvA using LibSVM was created for these experiments.³ For the single-machine approaches the MSVMpack package was used (v. 1.3, Laner and Guenieur, 2011), which is written in C. This package implements the methods of Weston and Watkins (W&W, 1998), Crammer and Singer (CKS, 2002a), Lee et al. (LLW, 2004), and Guenieur and Monfimi (MSVM², 2011). Finally, to verify if implementation differences are relevant for algorithm performance the LibLinear (Fan et al., 2008) implementation of the method by Crammer and Singer (2002a) is also included (denoted LL CKS). This implementation uses the optimization algorithm by Keerthi et al. (2008).

To compare the classification methods properly, it is desirable to remove any bias that could occur when using cross validation (Cawley and Talbot, 2010). Therefore, *nested* cross validation is used (Stone, 1974), as illustrated in Figure 5. In nested CV, a data set is randomly split in a number of *chunks*. Each of these chunks is kept apart from the remaining chunks once, while the remaining chunks are combined to form a single data set. A grid search is then applied to this combined data set to find the optimal hyperparameters with which to predict the test chunk. This process is then repeated for each of the chunks. The predictions of the test chunk will be unbiased since it was not included in the grid search. For this reason, it is argued that this approach is preferred over approaches that simply report maximum accuracy rates obtained during the grid search.

3. The LibSVM code used for DAGSVM is the same code as was used in Hsu and Lin (2002) and is available at <http://www.csie.ntu.edu.tw/~cjlin1/libsvmtools>.

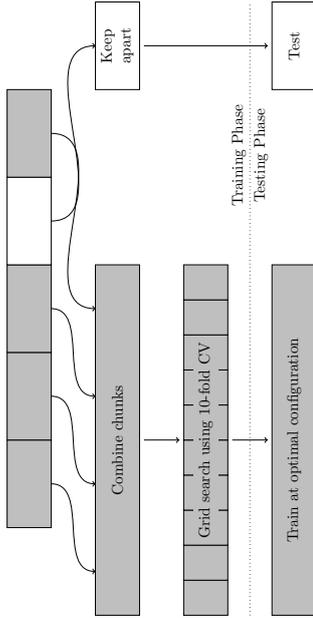

Figure 5: An illustration of nested cross validation. A data set is initially split in five *chunks*. Each chunk is kept apart once, while a grid search using 10-fold CV is applied to the combined data from the remaining 4 chunks. The optimal parameters obtained there are then used to train the model one last time, and predict the chunk that was kept apart.

For the experiments 13 data sets were selected from the UCI repository (Bache and Lichman, 2013). The selected data sets and their relevant statistics are shown in Table 1. All attributes were rescaled to the interval $[-1, 1]$. The **image segmentation** and **vowel1** data sets have a predetermined train and test set, and were therefore not used in the nested CV procedure. Instead, a grid search was done on the provided training set for each classifier, and the provided test set was predicted at the optimal hyperparameters obtained. For the data sets without a predetermined train/test split, nested CV was used with 5 initial chunks. Hence, $5 \cdot 11 + 2 = 57$ pairs of independent train and test data sets are obtained.

While running the grid search, it is desirable to remove any fluctuations that may result in an unfair comparison. Therefore, it was ensured that all methods had the same CV split of the training data for the same hyperparameter configuration (specifically, the value of the regularization parameter). In practice, it can occur that a specific CV split is advantageous for one classifier but not for others (either in time or performance). Thus, ideally the grid search would be repeated a number of times with different CV splits, to remove this variation. However, due to the size of the grid search this is considered to be infeasible. Finally, it should be noted here that during the grid search 10-fold cross validation was applied in a non-stratified manner, that is, without resampling of small classes.

The following settings were used in the numerical experiments. The regularization parameter was varied on a grid with $\lambda \in \{2^{-18}, 2^{-16}, \dots, 2^{18}\}$. For GenSVM the grid search was extended with the parameters $\kappa \in \{-0.9, 0.5, 5.0\}$ and $p \in \{1.0, 1.5, 2.0\}$. The stopping parameter for the GenSVM majorization algorithm was set at $\epsilon = 10^{-6}$ during the grid search in the training phase and at $\epsilon = 10^{-8}$ for the final model in the testing phase. In addition, two different weight specifications were used for GenSVM: the unit weights with $\theta_i = 1, \forall i$, as well as the group-size correction weights introduced in (4). Thus, the grid search consists of 342 configurations for GenSVM, and 19 configurations

Data set	Instances (n)	Features (m)	Classes (K)	min n_k	max n_k
breast tissue	106	9	6	14	22
iris	150	4	3	50	50

Table 1: Data set summary statistics. Data sets with an asterisk have a predetermined test data set. For these data sets, the number of training instances is denoted for the train and test data sets respectively. The final two columns denote the size of the smallest and the largest class, respectively.

for the other methods. Since nested CV is used for most data sets, it is required to run 10-fold cross validation on a total of 28158 hyperparameter configurations. To enhance the reproducibility of these experiments, the exact predictions made by each classifier for each configuration were stored in a text file.

To run all computations in a reasonable amount of time, the computations were performed on the Dutch National LIISA Compute Cluster. A master-worker program was developed using the message passing interface in Python (Dalcin et al., 2005). This allows for efficient use of multiple nodes by successively sending out tasks to worker threads from a single master thread. Since the total training time of a classifier is also of interest, it was ensured that all computations were done on the exact same core type.⁴ Furthermore, training time was measured from within the C programs, to ensure that only the time needed for the cross validation routine was measured. The total computation time needed to obtain the presented results was about 152 days, using the LIISA Cluster this was done in five and a half wall-clock time.

During the training phase it showed that several of the single machine methods implemented through MSVMpack did not converge to an optimal solution within reasonable amount of time.⁵ Instead of limiting the maximum number of iterations of the method, MSVMpack was modified to stop after a maximum of 2 hours of training time per configuration. This results in 12 minutes of training time per cross validation fold. The solution found after this amount of training time was used for prediction during cross validation.

4. The specific type of core used is the Intel Xeon E5-2650 v2, with 16 threads at a clock speed of 2.6 GHz. At most 14 threads were used simultaneously, reserving one for the master thread and one for system processes.

5. The default MSVMpack settings were used with a chunk size of 4 for all methods.

Whenever training was stopped prematurely, this was recorded.⁶ Of the 57 training sets, 24 configurations had prematurely stopped training in one or more CV splits for the LLW method, versus 19 for W&W, 9 for MSVM², and 2 for C&S (MSVMpack). For the LibSVM methods, 13 optimal configurations for OvA reached the default maximum number of iterations in one or more CV folds, versus 9 for DAGSVM, and 3 for OvO. No early stopping was needed for GensVM or for LL C&S.

Determining the optimal hyperparameters requires a performance measure on the obtained predictions. For binary classifiers it is common to use either the hitrate or the area under the ROC curve as a measure of classifier performance. The hitrate only measures the percentage of correct predictions of a classifier and has the well known problem that no correction is made for group sizes. For instance, if 90% of the observations of a test set belong to one class, a classifier that always predicts this class has a high hitrate, regardless of its discriminatory power. Therefore, the adjusted Rand index (ARI) is used here as a performance measure (Hubert and Arabie, 1985). The ARI corrects for chance and can therefore more accurately measure discriminatory power of a classifier than the hitrate can. Using the ARI for evaluating supervised learning algorithms has previously been proposed by Santos and Embrechts (2009).

The optimal parameter configurations for each method on each data set were chosen such that the maximum predictive performance was obtained as measured with the ARI. If multiple configurations obtained the highest performance during the grid search, the configuration with the smallest training time was chosen. The results on the training data show that during cross validation GensVM achieved the highest classification accuracy on 41 out of 57 data sets, compared to 15 and 12 for DAG and OvO, respectively. However, these are results on the training data sets and therefore can contain considerable bias. To accurately assess the out-of-sample prediction accuracy the optimal hyperparameter configurations were determined for each of the 57 training sets, and the test sets were predicted with these parameters. To remove any variations due to random starts, building the classifier and predicting the test set was repeated 5 times for each classifier.

Below the simulation results on the small data sets will be evaluated using performance profiles and rank tests. Performance profiles offer a visual representation of classifier performance, while rank tests allow for identification of statistically significant differences between classifiers. For the sake of completeness tables of performance scores and computation times for each method on each data set are provided in Appendix E. To promote reproducibility of the empirical results, all the code used for the classifier comparisons and all the obtained results will be released through an online repository.

6.2 Performance Profiles

One way to get insight in the performance of different classification methods is through *performance profiles* (Dolan and Moré, 2002). A performance profile shows the empirical cumulative distribution function of a classifier on a performance metric.

6. For the classifiers implemented through LibSVM very long training times were only observed for the OvA method, however due to the nature of this method it is not trivial to stop the calculations after a certain amount of time. This behavior was observed in about 1% of all configurations tested on all data sets, and is therefore considered negligible. Also, for the LibSVM methods it was recorded whenever the maximum number of iterations was reached.

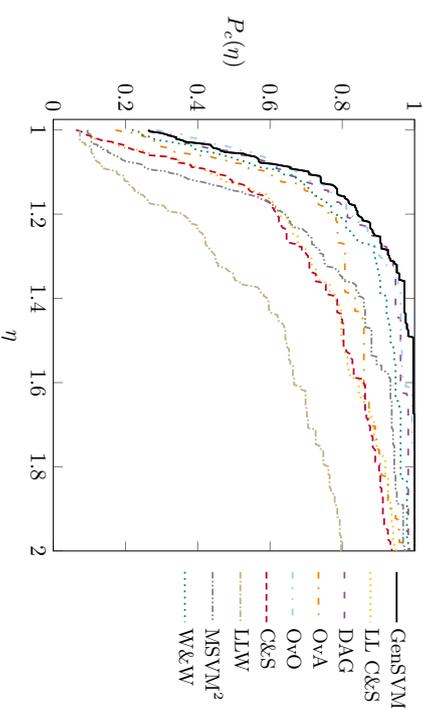

Figure 6: Performance profiles for classification accuracy created from all repetitions of the test set predictions. The methods OvA, C&S, LL C&S, MSVM², W&W, and LLW will always have a smaller probability of being within a factor η of the maximum performance than the GensVM, OvO, or DAG methods.

Let \mathcal{D} denote the set of data sets, and \mathcal{C} denote the set of classifiers. Further, let $p_{d,c}$ denote the performance of classifier $c \in \mathcal{C}$ on data set $d \in \mathcal{D}$ as measured by the ARI. Now define the performance ratio $v_{d,c}$ as the ratio between the best performance on data set d and the performance of classifier c on data set d , that is

$$v_{d,c} = \frac{\max\{p_{d,c} : c \in \mathcal{C}\}}{p_{d,c}}.$$

Thus the performance ratio is 1 for the best performing classifier on a data set and increases for classifiers with a lower performance. Then, the performance profile for classifier c is given by the function

$$P_c(\eta) = \frac{1}{N_D} |\{d \in \mathcal{D} : v_{d,c} \leq \eta\}|,$$

where $N_D = |\mathcal{D}|$ denotes the number of data sets. Thus, the performance profile estimates the probability that classifier c has a performance ratio below η . Note that $P_c(1)$ denotes the empirical probability that a classifier achieves the highest performance on a given data set.

Figure 6 shows the performance profile for classification accuracy. Estimates of $P_c(1)$ from Figure 6 show that there is a 28.42% probability that OvO achieves the optimal performance, versus 26.32% for both GensVM and DAGSVM. Note that this includes cases where each of these methods achieves the best performance. Figure 6 also shows that although there is a small difference in the probabilities of GensVM, OvO, and DAG within

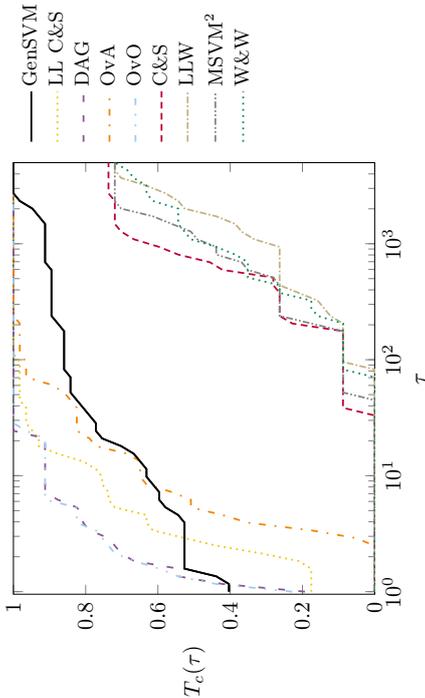

Figure 7: Performance profiles for training time. GenSVM has a priori about 40% chance of requiring the smallest time to perform the grid search on a given method. The methods implemented through MSVMpack always have a lower chance of being within a factor τ of the smallest training time than any of the other methods.

a factor of 1.08 of the best predictive performance, for $\eta \geq 1.08$ GenSVM almost always has the highest probability. It can also be concluded that since the performance profiles of the MSVMpack implementation and the LibLinear implementation of the method of Crammer and Singer (2002a) nearly always overlap, implementation differences have a negligible effect on the classification performance of this method. Finally, the figure shows that OVA and the methods of Lee et al. (2004), Crammer and Singer (2002a), Weston and Watkins (1998), and Guermeur and Monfrini (2011) always have a smaller probability of being within a given factor of the optimal performance than GenSVM, OVO, or DAG do.

Similarly, a performance profile can be constructed for the training time necessary to do the grid search. Let $t_{d,c}$ denote the total training time for classifier c on data set d . Next, define the performance ratio for time as

$$w_{d,c} = \frac{t_{d,c}}{\min\{t_{d,c} : c \in \mathcal{C}\}}.$$

Note that here the classifier with the smallest training time has preference. Therefore, comparison of classifier computation time is done with the lowest computation time achieved on a given data set d . Again, the ratio is 1 when the lowest training time is reached, and it increases for higher computation time. Hence, the performance profile for time is defined

$$T_c(\tau) = \frac{1}{N_D} |\{d \in \mathcal{D} : w_{d,c} \leq \tau\}|.$$

The performance profile for time estimates the probability that a classifier c has a time ratio below τ . Again, $T_c(1)$ denotes the fraction of data sets where classifier c achieved the smallest training time among all classifiers.

Figure 7 shows the performance profile for the time needed to do the grid search. Since large differences in training time were observed, a logarithmic scale is used for the horizontal axis. This performance profile clearly shows that all MSVMpack methods suffer from long computation times. The fastest methods are GenSVM, OVO, and DAG, followed by the LibLinear implementation of C&S. From the value of $T_c(1)$ it is found that GenSVM has the highest probability of being the fastest method for the total grid search, with a probability of 40.35%, versus 22.81% for OVO, 19.30% for DAG, and 17.54% for LibLinear C&S. The other methods never achieve the smallest grid search time. It is important to note here that the grid search for GenSVM is 18 times larger than that of the other methods. These results illustrate the incredible advantage GenSVM has over other methods by using warm starts in the grid search.

In addition to the performance profile, the average computation time per hyperparameter configuration was also examined. Here, GenSVM has an average training time of 0.97 seconds per configuration, versus 20.56 seconds for LibLinear C&S, 24.84 seconds for OVO, and 25.03 seconds for DAGSVM. This is a considerable difference, which can be explained again by the use of warm starts in GenSVM (see Section 4.3). When the total computation time per data set is averaged, it is found that GenSVM takes on average 331 seconds per data set, LibLinear C&S 391 seconds, OVO 472 seconds, and DAG 476 seconds. The difference between DAGSVM and OVO can be attributed to the prediction strategy used by DAGSVM. Thus it can be concluded that on average GenSVM is the fastest method during the grid search, despite the fact it has 18 times more hyperparameters to consider than the other methods.

6.3 Rank Tests

Following suggestions from Demšar (2006), ranks are used to investigate significant differences between classifiers. The benefit of using ranks instead of actual performance metrics is that ranks have meaning when averaged across different data sets, whereas average performance metrics do not. Ranks are calculated for the performance as measured by the ARI, the total training time needed to do the grid search, and the average time per hyperparameter configuration. When ties occur fractional ranks are used.

Figure 8 shows the average ranks for both classification performance and total and average training time for all classifiers. From Figure 8a it can be seen that GenSVM is in second place in terms of overall classification performance measured by the ARI. Only OVO has higher performance than GenSVM *on average*. Similarly, Figure 8b shows the average ranks for the total training time. Here, GenSVM is on average the fourth fastest method for the complete grid search. When looking at the rank plot for the average training time per hyperparameter configuration, it is clear that the warm starts used during training in GenSVM are very useful as it ranks as the fastest method on this metric, as shown in Figure 8c.

As Demšar (2006) suggests, the Friedman rank test can be used to find significant differences between classifiers (Friedman, 1937, 1940). If τ_{ed} denotes the fractional rank of

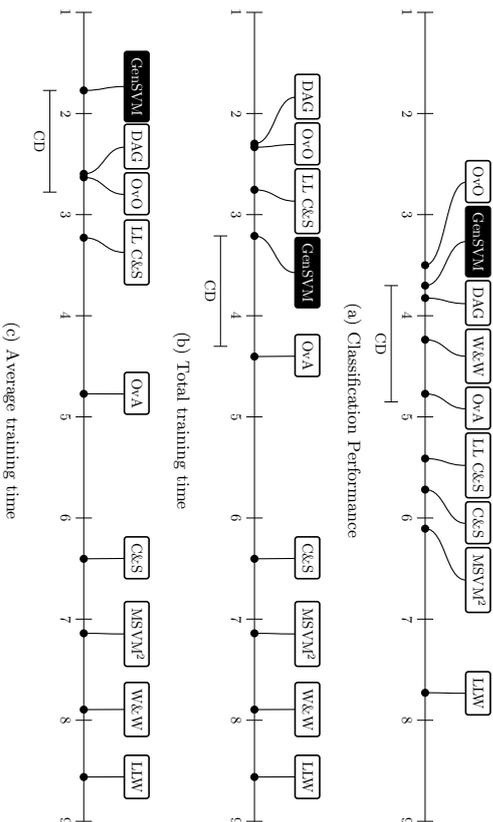

Figure 8. Figure (a) shows the average ranks for performance, (b) shows the average ranks for the total computation time needed for the grid search, and (c) shows the ranks for the average time per hyperparameter configuration. It can be seen that GenSVM obtains the second overall rank in predictive performance, fourth overall rank in total training time, and first overall rank in average training time. In all figures, CD shows the critical difference of Holm’s procedure. Classifiers beyond this CD differ significantly from GenSVM at the 5% significance level.

classifier c on data set d , then with N_C classifiers and N_D data sets the Friedman statistic is given by

$$\chi_F^2 = \frac{12N_D}{N_C(N_C + 1)} \left[\sum_c R_c^2 - \frac{N_C(N_C + 1)^2}{4} \right]. \quad (15)$$

Here, $R_c = 1/N_D \sum_d r_{cd}$ denotes the average rank of classifier c . This test statistic is distributed following the χ^2 distribution with $N_C - 1$ degrees of freedom. As Demsar (2006) notes, Iman and Davenport (1980) showed that the Friedman statistic is undesirably conservative and the F -statistic is to be used instead, which is given by

$$F_F = \frac{(N_D - 1)\chi_F^2}{N_D(N_C - 1) - \chi_F^2},$$

and is distributed following the F -distribution with $N_C - 1$ and $(N_C - 1)(N_D - 1)$ degrees of freedom. Under the null hypothesis of either test there is no significant difference in the performance of any of the algorithms.

When performing the Friedman test, it is found that with the ranks for classifier performance $\chi_F^2 = 116.3$ ($p < 10^{-16}$), and $F_F = 19.2$ ($p = 10^{-16}$). Hence, with both tests the

null hypothesis of equal classification accuracy can be rejected. Similarly, for training time the test statistics are $\chi_F^2 = 384.8$ ($p < 10^{-16}$) and $F_F = 302.4$ ($p \approx 10^{-16}$). Therefore, the null hypothesis of equal training time can also be rejected. When significant differences are found through the Friedman test, Demsar (2006) suggests to use Holm’s step-down procedure as a post-hoc test, to find which classifiers differ significantly from a chosen reference classifier (Holm, 1979). Here, GenSVM is used as a reference classifier, since comparing GenSVM with existing methods is the main focus of these experiments.

Holm’s procedure is based on testing whether the z -statistic comparing classifier i with classifier j is significant, while adjusting for the familywise error rate. Following Demsar (2006), this z -statistic is given by

$$z = (R_{\text{GenSVM}} - R_i) \sqrt{\frac{6N_D}{N_C(N_C + 1)}}, \quad (16)$$

where R_{GenSVM} is the average rank of GenSVM and R_i the average rank of another classifier, for $i = 1, \dots, N_C - 1$. Subsequently, the p -values computed from this statistic are sorted in increasing order, as $p_1 < p_2 < \dots < p_{N_C - 1}$. Then, the null hypothesis of equal classification accuracy can be rejected if $p_i < \alpha / (N_C - i)$. If for some i the null hypothesis cannot be rejected, all subsequent tests will also fail. By inverting this procedure, a critical difference (CD) can be computed that indicates the minimal difference between the reference classifier and the next best classifier.⁷ These critical differences are also illustrated in the rank plots in Figure 8.

Using Holm’s procedure, it is found that for predictive performance GenSVM significantly outperforms the method of Lee et al. (2004) ($p < 10^{-14}$), the method of Gernemur and Montfrini (2011) ($p = 10^{-6}$), the MSVMpack implementation of Grammer and Singer (2002a) ($p = 4 \cdot 10^{-5}$), and the Liblinear implementation of the same method ($p = 0.0004$) at the 5% significance level. Note that since this last method is included twice these test results are conservative. In terms of total training time, GenSVM is significantly faster than all methods implemented through MSVMpack (C&S, W&W, MSVM², and LLW) and OVA at the 5% significance level. Recall that the hyperparameter grid for GenSVM is 18 times larger than that of the other methods. When looking at average training time per hyperparameter configuration, GenSVM is significantly faster than all methods except OVO and DAG, at the 1% significance level.

6.4 Large Data sets

The above results focus on the predictive performance of GenSVM as compared to other multiclass SVM methods. To assess the practicality of GenSVM for large data sets additional simulations were done on three more data sets. The covtype data set ($n = 581016$, $m = 54$, $K = 7$) and the kddcup99 data set ($n = 494021$, $m = 116$, $K = 23$) were selected from the UCI repository (Bache and Lichman, 2013).⁸ Additionally, the *cars* data set ($n = 100968$, $m = 338$, $K = 8$) was retrieved from the Keel repository (Alcalá et al.,

7. This is done by taking the smallest value of $\alpha / (N_C - i)$ for which the null hypothesis is rejected, looking up the corresponding z -statistic, and inverting (16).

8. For kddcup99 the 10% training data set and the corrected test data set are used here, both available through the UCI repository.

2010). For large data sets the LibLinear package (Fan et al., 2008) is often used, so the SVM methods from this package were added to the list of alternative methods.⁹

LibLinear includes five different SVM implementations: a coordinate descent algorithm for the ℓ_2 -regularized ℓ_1 -loss and ℓ_2 -loss dual problems (Hsieh et al., 2008), a coordinate descent algorithm for the ℓ_1 -regularized ℓ_2 -loss SVM (Yuan et al., 2010; Fan et al., 2008), a Newton method for the primal ℓ_2 -regularized ℓ_2 -loss SVM problem (Lin et al., 2008), and finally a sequential dual method for the multiclass SVM by Crammer and Singer (2002a) introduced by Keerthi et al. (2008). This last method was again included to facilitate a comparison between the implementations of LibLinear and MSVMpack. Note that with the exception of this last method all methods in LibLinear are binary SVMs that implement the one-vs-all strategy.

With the different variants of the linear multiclass SVMs included in LibLinear, a total of 13 methods were considered for these large data sets. Since training of the hyperparameters for each method leads to a high computational burden the nested CV procedure was replaced by a grid search using ten-fold CV on a training set of 80% of the data, followed by out-of-sample prediction on the remaining 20% using the final model. The `kddcup99` data set comes with a separate test data set of 292302 instances, so this was used for the out-of-sample predictions. The grid search on the training set used the same hyperparameter configurations as for the small data sets above, with 342 configurations for GenSVM and 19

9. Yet another interesting SVM approach to multiclass classification is the Pegasos method by Shalev-Shwartz et al. (2011). However, the LibLinear package includes five different approaches to SVM, including a fast solver for the method by Crammer and Singer (2002a), which makes it more convenient to include in the list of methods. Moreover, according to the LibLinear documentation (Fan et al., 2008): “LibLinear is competitive or even faster than state of the art linear classifiers such as Pegasos (Shalev-Shwartz et al., 2011) and SVM^{part} (Joachims, 2006)”.

Table 3: Overview of training time for each of the large data sets. The average training time per hyperparameter configuration is also shown. All values are reported in seconds. For LibSVM the full grid search could never be completed, and results are averaged only over the finished configurations.

configurations for the other methods. The only difference was that for GenSVM $\epsilon = 10^{-9}$ was used when training the final model. To accelerate the GenSVM computations, support for sparse matrices was added.

Due to the large data set sizes, many methods had trouble converging within a reasonable amount of time. Therefore, total computation time was limited to five hours per hyperparameter configuration per method, both during CV and when training the final model. Where possible this limitation was included in the main optimization routine of each method, such that training was stopped when convergence was reached or when more than five hours had passed. Additionally, for all methods the CV procedure was stopped prematurely if more than five hours had passed after completion of a fold. In this case, cross validation performance is only measured for the folds that were completed. These computations were again performed on the Dutch National LISA Compute Cluster.

Table 2 shows the out-of-sample predictive performance of the different MSVMs on the large data sets. It can be seen that GenSVM is the best performing method on the `fars` data set and the second best method on the `covtype` data set, just after LL C&S. The LibSVM methods outperform the other methods on the `kddcup99` data set, with DAGSVM having the highest performance. No results are available for LibSVM for the `covtype` data set because convergence could not be reached within the five hour time limit during the test phase.

Results on the computation time are reported in Table 3. The ℓ_2 -regularized ℓ_2 -loss method by Lin et al. (2008) is clearly the fastest method. However, for the `covtype` data set GenSVM total training time is competitive with some of the other LibLinear methods, and outperforms these methods in terms of average training time. For the `fars` data set the

average training time of GenSVM is also competitive with some of the LibLinear methods, most notably the method by Crammer and Singer (2002a). The MSVMpack methods seem to be infeasible for such large data sets, as computations were stopped by the five hour time limit for almost all hyperparameter configurations. Early stopping was also needed for the LibLinear implementation of C&S on the `covtype` and `fars` data sets, and for the LibSVM methods on all data sets. For GenSVM, early stopping was only needed for the `kddcup99` data set, which explains the high total computation time there. Especially on these large data sets the advantage of using warm starts in GenSVM is visible: training time was less than 30 seconds in 30% of hyperparameters on `fars`, 23% on `covtype`, and 11% on `kddcup99`.

7. Discussion

A generalized multiclass support vector machine has been introduced, called GenSVM. The method is general in the sense that it subsumes three multiclass SVMs proposed in the literature and it is flexible due to several different weighting options. The simplex encoding of the multiclass classification problem used in GenSVM is intuitive and has an elegant geometrical interpretation. An iterative majorization algorithm has been derived to minimize the convex GenSVM loss function in the primal. This primal optimization approach has computational advantages due to the possibility to use warm starts, and because it can be easily understood. The ability to use warm starts contributes to small training time during cross validation in a grid search, and allows GenSVM to perform competitively on large data sets.

Rigorous computational tests of linear multiclass SVMs on small data sets show that GenSVM significantly outperforms three existing multiclass SVMs (four implementations) on predictive performance at the 5% significance level. On this metric, GenSVM is the second-best performing method overall and the best method among single-machine multiclass SVMs, although the difference with the method of Weston and Watkins (1998) could not be shown to be statistically significant. GenSVM outperforms five other methods on total training time and has the smallest total training time when averaged over all data sets, despite the fact that its grid of hyperparameters is 18 times larger than that of other methods. Due to the possibility of warm starts it also has the smallest average training time per hyperparameter and significantly outperforms all but two alternative methods in this regard at the 1% significance level. For the large data sets, it was found that GenSVM still achieves high classification accuracy and that total training time remains manageable due to the warm starts. In practice, the number of hyperparameters could be reduced if smaller training time is desired. Since GenSVM outperforms existing methods on a number of data sets and achieves fast training time it is a worthwhile addition to the collection of methods available to the practitioner.

In the comparison tests MSVMpack (Lauer and Guerneur, 2011) was used to access four single machine multiclass SVMs proposed in the literature. A big advantage of using this library is that it allows for a single straightforward C implementation, which greatly reduces the programming effort needed for the comparisons. However, as is noted in the MSVMpack documentation, slight differences exist between MSVMpack and method-specific implementations. For instance, on small data sets MSVMpack can be slower, due to working set

selection and shrinking procedures in other implementations. However, classification performance is comparable between MSVMpack and method-specific implementations, as was verified by adding the LibLinear implementation of the method of Crammer and Singer (2002a) to the list of alternative methods. Thus, we argue that the results for predictive accuracy presented above are accurate regardless of implementation, but small differences can exist for training time when other implementations for single machine MSVMs are used.

Another interesting conclusion that can be drawn from the experimental results is that the one-vs-all method never performs as good as one-vs-one, DAGSVM, or GenSVM. In fact, the profile plot in Figure 6 shows that OvA always has a smaller probability of obtaining the best classification performance as either of these three methods. These results are also reflected in the classification accuracy of the LibLinear methods on the large data set. In the literature, the paper by Rifkin and Klantau (2004) is often cited as evidence that OvA performs well (see for instance Keerthi et al., 2008). However, the simulation results in this paper suggest that OvA is in fact inferior to OvO, DAG, and GenSVM.

This paper was focused on linear multiclass SVMs. An obvious extension is to incorporate nonlinear multiclass SVMs through kernels. Due to the large number of data sets and the long training time the numerical experiments were limited to linear multiclass SVM. Nonlinear classification through kernels can be achieved by linear methods through a preprocessing step of an eigendecomposition on the kernel matrix, which is a process of the order $O(n^3)$. In this case, GenSVM will benefit from precomputing kernels before starting the grid search, or using a larger stopping criterion in the IM algorithm by increasing ϵ in Algorithm 1. In addition, approximations can be done by using rank approximated kernel matrices, such as the Nystrom method proposed by Williams and Seeger (2001). Such enhancements are considered topics for further research.

Finally, the potential of using GenSVM in an online setting is recognized. Since the solution can be found quickly when a warm-start is used, GenSVM may be useful in situations where new instances have to be predicted at a certain moment, and the true class label arrives later. Then, re-estimating the GenSVM solution can be done as soon as the true class label of an object arrives, and a previously known solution can be used as a warm start. It is expected that in this scenario only a few iterations of the IM algorithm are needed to arrive at a new optimal solution. This, too, is considered a subject for further research.

Acknowledgments

The computational experiments of this work were performed on the Dutch National LISA Compute Cluster, and supported by the Dutch National Science Foundation (NWO). The authors thank SURFsara (www.surfsara.nl) for the support in using the LISA cluster.

Appendix A. Simplex Coordinates

The simplex used in the formulation of the GenSVM loss function is a regular K -simplex in \mathbb{R}^{K-1} with distance 1 between each pair of vertices, which is centered at the origin. Since these requirements alone do not uniquely define the simplex coordinates in general, it will

be chosen such that at least one of the vertices lies on an axis. The 2-simplex in \mathbb{R}^1 is uniquely defined with the coordinates $-\frac{1}{2}$ and $+\frac{1}{2}$. Using these requirements, it is possible to define a recursive formula for \mathbf{U}_K , the simplex coordinate matrix of the K -simplex in \mathbb{R}^{K-1} as

$$\mathbf{U}_K = \begin{bmatrix} \mathbf{U}_{K-1} & \mathbf{1}t \\ \mathbf{0}' & s \end{bmatrix}, \quad \text{with} \quad \mathbf{U}_2 = \begin{bmatrix} -\frac{1}{2} \\ \frac{1}{2} \end{bmatrix}.$$

Note that the matrix \mathbf{U}_K has K rows and $K-1$ columns. Since the simplex is centered at zero it holds that the elements in each column sum to 0, implying that $s = -(K-1)t$. Denote by \mathbf{u}_i' the i -th row of \mathbf{U}_K and by $\tilde{\mathbf{u}}_i'$ the i -th row of \mathbf{U}_{K-1} , then it follows from the edge length requirement that

$$\|\mathbf{u}_i' - \mathbf{u}_K'\|^2 = \|\tilde{\mathbf{u}}_i' - \mathbf{0}' + t - s\|^2 = \|\tilde{\mathbf{u}}_i'\|^2 + (t-s)^2 = 1, \quad \forall i \neq K.$$

From the requirement of equal distance from each vertex to the origin it follows that

$$\begin{aligned} \|\mathbf{u}_i'\|^2 &= \|\mathbf{u}_K'\|^2, \\ \|\tilde{\mathbf{u}}_i'\|^2 + t^2 &= s^2, \quad \forall i \neq K. \end{aligned}$$

Combining these two expressions yields the equation $2s^2 - 2st - 1 = 0$. Substituting $s = -(K-1)t$ and choosing $s > 0$ and $t < 0$ gives

$$t = \frac{-1}{\sqrt{2K(K-1)}}, \quad s = \frac{K-1}{\sqrt{2K(K-1)}}.$$

Note that using $K=2$ in these expressions gives $t = -\frac{1}{2}$ and $s = \frac{1}{2}$, as expected. The recursive relationship defined above then reveals that the first $K-1$ elements in column $K-1$ of the matrix are equal to t , and the K -th element in column $K-1$ is equal to s . This can then be generalized for an element u_{kl} in row k and column l of \mathbf{U}_K , yielding the expression given in (1).

Appendix B. Details of Iterative Majorization

In this section a brief introduction to iterative majorization is given, following the description of Voss and Eckhardt (1980). The section concludes with a note on step doubling, a common technique to speed up quadratic majorization algorithms.

Given a continuous function $f: \mathcal{X} \rightarrow \mathbb{R}$ with $\mathcal{X} \subseteq \mathbb{R}^d$, construct a *majorization function* $g(x, \bar{x})$ such that

$$\begin{aligned} f(\bar{x}) &= g(\bar{x}, \bar{x}), \\ f(x) &\leq g(x, \bar{x}) \quad \text{for all } x \in \mathcal{X}, \end{aligned}$$

with $\bar{x} \in \mathcal{X}$ a so-called *supporting point*. In general, the majorization function is constructed such that its minimum can easily be found, for instance by choosing it to be quadratic in x . If $f(x)$ is differentiable at the supporting point, the above conditions imply $\nabla f(\bar{x}) = \nabla g(\bar{x}, \bar{x})$. The following procedure can now be used to find a stationary point of $f(x)$,

1. Let $\bar{x} = x_0$, with x_0 a random starting point.

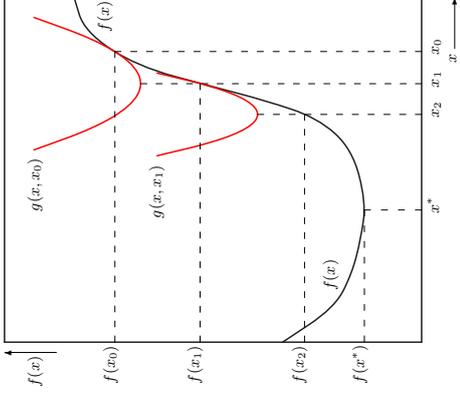

Figure 9: One-dimensional graphical illustration of the iterative majorization algorithm, adapted from De Leeuw (1988). The minimum of a majorization function $g(x, x_r)$ provides the supporting point for the next majorization function $g(x, x_{r+1})$. The sequence of supporting points $\{x_r\}$ converges towards the stationary point x^* if $f(x)$ is bounded from below, as is the case here.

2. Minimize $g(x, \bar{x})$ with respect to x , such that $x^+ = \arg \min g(x, \bar{x})$.
3. If $f(\bar{x}) - f(x^+) < \epsilon f(x^+)$ stop, otherwise let $\bar{x} = x^+$ and go to step 2.

In this algorithm ϵ is a small constant. Note that $f(x)$ must be bounded from below on \mathcal{X} for the algorithm to converge. In fact, the following *sandwich inequality* can be derived (De Leeuw, 1993)

$$f(x^+) \leq g(x^+, \bar{x}) \leq g(\bar{x}, \bar{x}) = f(\bar{x}).$$

This inequality shows that if $f(x)$ is bounded from below the iterative majorization algorithm achieves global convergence to a stationary point of the function (Voss and Eckhardt, 1980). The iterative majorization algorithm is illustrated in Figure 9, where the majorization functions are shown as a quadratic function. As can be seen from the illustration, the sequence of supporting points $\{x_r\}$ converges to the stationary point x^* of the function $f(x)$. In practical situations, this convergence is to a local minimum of $f(x)$.

For quadratic majorization the number of iterations can often be reduced by using a technique known as *step doubling* (De Leeuw and Heiser, 1980). Step doubling reduces the number of iterations by using $\bar{x} = x_{r+1} = 2x^+ - x_r$ as the next supporting point in Step 3 of the algorithm, instead of $\bar{x} = x_{r+1} = x^+$. Intuitively, step doubling can be understood as stepping over the minimum of the majorization function to the point lying directly

“opposite” the supporting point \bar{x} (see also Figure 9). Note that the guaranteed descent of the IM algorithm still holds when using step doubling, since $f(2x^+ - \bar{x}) \leq g(2x^+ - \bar{x}; \bar{x}) = g(\bar{x}; \bar{x}) = f(\bar{x})$. In practice, step doubling reduces the number of iterations by half. A caveat of using step doubling is that the distance to the stationary point can be increased if the initial point is far from this point. Therefore, in practical applications, a burn-in should be used before step doubling is applied.

Appendix C. Huber Hinge Majorization

In this appendix, the majorization function will be derived of the Huber hinge error raised to the power p . Thus, a quadratic function $g(x, \bar{x}) = ax^2 - 2bx + c$ is required, which is a majorization function of

$$f(x) = h^p(x) = \begin{cases} (1-x-\frac{\kappa+1}{2})^p & \text{if } x \leq -\kappa \\ \frac{1}{(2(\kappa+1))^p}(1-x)^{2p} & \text{if } x \in (-\kappa, 1] \\ 0 & \text{if } x > 1, \end{cases}$$

with $p \in [1, 2]$. Each piece of $f(x)$ provides a possible region for the supporting point \bar{x} . These regions will be treated separately, starting with $\bar{x} \in (-\kappa, 1]$.

Since the majorization function must touch $f(x)$ at the supporting point, we can solve $f(\bar{x}) = g(\bar{x}; \bar{x})$ and $f'(\bar{x}) = g'(\bar{x}; \bar{x})$ for b and c to find

$$b = a\bar{x} + \frac{p}{1-\bar{x}} \left(\frac{1-\bar{x}}{\sqrt{2(\kappa+1)}} \right)^{2p}, \quad (17)$$

$$c = a\bar{x}^2 + \left(1 + \frac{2p\bar{x}}{1-\bar{x}} \right) \left(\frac{1-\bar{x}}{\sqrt{2(\kappa+1)}} \right)^{2p}, \quad (18)$$

whenever $\bar{x} \in (-\kappa, 1]$. Note that since $p \in [1, 2]$ the function $f(x)$ can become proportional to a fourth power on the interval $x \in (-\kappa, 1]$. The upper bound of the second derivative of $f(x)$ on this interval is reached at $x = -\kappa$. Equating $f''(-\kappa)$ to $g''(-\kappa; \bar{x}) = 2a$ and solving for a yields

$$a = \frac{1}{4}p(2p-1) \left(\frac{\kappa+1}{2} \right)^{p-2}. \quad (19)$$

Figure 10a shows an illustration of the majorization function when $\bar{x} \in (-\kappa, 1]$.

For the interval $\bar{x} \leq -\kappa$ the following expressions are found for b and c using similar reasoning as above

$$b = a\bar{x} + \frac{1}{2}p \left(1 - \bar{x} - \frac{\kappa+1}{2} \right)^{p-1}, \quad (20)$$

$$c = a\bar{x}^2 + p\bar{x} \left(1 - \bar{x} - \frac{\kappa+1}{2} \right)^{p-1} + \left(1 - \bar{x} - \frac{\kappa+1}{2} \right)^p. \quad (21)$$

To obtain the largest possible majorization step it is desired that the minimum of the majorization function is located at $x \geq 1$, such that $g(x_{min}, \bar{x}) = 0$. This requirement yields

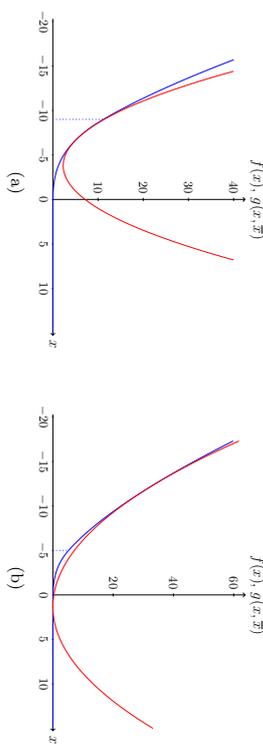

Figure 10: Graphical illustration of the majorization of the function $f(x) = h^p(x)$. Figure (a) shows the case where $\bar{x} \in (-\kappa, 1]$, whereas (b) shows the case where $\bar{x} \leq (p + \kappa - 1)/(p - 2)$. In both cases $p = 1.5$. It can be seen that in (b) the minimum of the majorization function lies at $x > 1$, such that the largest possible majorization step is obtained.

$c = b^2/a$, which gives

$$a = \frac{1}{4}p^2 \left(1 - \bar{x} - \frac{\kappa+1}{2} \right)^{p-2}. \quad (22)$$

Note however that due to the requirement that $f(x) \leq g(x; \bar{x})$ for all $x \in \mathbb{R}$, this majorization is not valid for all values of \bar{x} . Solving the requirement for the minimum of the majorization function, $g(x_{min}, \bar{x}) = 0$ for \bar{x} yields

$$\bar{x} \leq \frac{p + \kappa - 1}{p - 2}.$$

Thus, if \bar{x} satisfies this condition, (22) can be used for a , whereas for cases where $\bar{x} \in ((p + \kappa - 1)/(p - 2), -\kappa]$, the value of a given in (19) can be used. Figure 10b shows an illustration of the case where $\bar{x} \leq (p + \kappa - 1)/(p - 2)$.

Next, a majorization function for the interval $\bar{x} > 1$ is needed. Since it has been derived that for the interval $\bar{x} \leq (p + \kappa - 1)/(p - 2)$ the minimum of the majorization function lies at $x \geq 1$, symmetry arguments can be used to derive the majorization function for $\bar{x} > 1$, and ensure that it is also tangent at $x = (p\bar{x} + \kappa - 1)/(p - 2)$. This yields the coefficients

$$a = \frac{1}{4}p^2 \left(\frac{p}{p-2} \left(1 - \bar{x} - \frac{\kappa+1}{2} \right) \right)^{p-2}, \quad (23)$$

$$b = a \left(\frac{p\bar{x} + \kappa - 1}{p - 2} \right) + \frac{1}{2}p \left(\frac{p}{p-2} \left(1 - \bar{x} - \frac{\kappa+1}{2} \right) \right)^{p-1}, \quad (24)$$

$$c = a \left(\frac{p\bar{x} + \kappa - 1}{p - 2} \right)^2 + p \left(\frac{p\bar{x} + \kappa - 1}{p - 2} \right) \left(\frac{p}{p-2} \left(1 - \bar{x} - \frac{\kappa+1}{2} \right) \right)^{p-1} + \left(\frac{p}{p-2} \left(1 - \bar{x} - \frac{\kappa+1}{2} \right) \right)^p. \quad (25)$$

Region	a	b	c
$\bar{x} \leq \frac{p+\kappa-1}{p-2}$	(22)	(20)	(21)
$\bar{x} \in \left(\frac{p+\kappa-1}{p-2}, -\kappa \right]$	(19)	(20)	(21)
$\bar{x} \in (-\kappa, 1]$	(19)	(17)	(18)
$\bar{x} > 1, p \neq 2$	(23)	(24)	(25)
$\bar{x} > 1, p = 2$	(19)	$a\bar{x}$	$a\bar{x}^2$

Table 4: Overview of quadratic majorization coefficients for different pieces of $h^p(x)$, depending on \bar{x} .

Finally, observe that some of the above coefficients are invalid if $p = 2$. However, since the upper bound on the interval $\bar{x} \in (-\kappa, 1]$ given in (19) is still valid if $p = 2$, it is possible to do a separate derivation with this value for a to find for $\bar{x} > 1$, $b = a\bar{x}$ and $c = a\bar{x}^2$. For the other regions the previously derived coefficients still hold. Table 4 gives an overview of the various coefficients depending on the location of \bar{x} .

Appendix D. Kernels in GenSVM

To include kernels in GenSVM a preprocessing step is needed on the kernel matrix, and a preprocessing step is needed on the obtained parameters before doing class prediction. Let $k : \mathbb{R}^m \times \mathbb{R}^m \rightarrow \mathbb{R}^+$ denote a positive definite kernel satisfying Mercer's theorem, and let \mathcal{H}_k denote the corresponding reproducing kernel Hilbert space. Furthermore, define a feature mapping $\phi : \mathbb{R}^m \rightarrow \mathcal{H}_k$ as $\phi(\mathbf{x}) = k(\mathbf{x}, \cdot)$, such that by the reproducing property of k it holds that $k(\mathbf{x}_i, \mathbf{x}_j) = \langle \phi(\mathbf{x}_i), \phi(\mathbf{x}_j) \rangle_{\mathcal{H}_k}$.

Using this, the kernel matrix \mathbf{K} is defined as the $n \times n$ matrix with elements $k(\mathbf{x}_i, \mathbf{x}_j)$ on the i -th row and j -th column. Thus, if Φ denotes the $n \times l$ matrix with rows $\phi(\mathbf{x}_i)$ for $i = 1, \dots, n$ and $l \in [1, \infty]$, then $\mathbf{K} = \Phi\Phi'$. Note that it depends on the chosen kernel whether Φ is finite dimensional. However, the rank of Φ can still be determined through \mathbf{K} , since $r = \text{rank}(\Phi) = \text{rank}(\mathbf{K}) \leq \min(n, l)$.

Now, let the reduced singular value decomposition of Φ be given by

$$\Phi = \mathbf{P}\Sigma\mathbf{Q}',$$

where \mathbf{P} is $n \times r$, Σ is $r \times r$, and \mathbf{Q} is $l \times r$. Note that here, $\mathbf{P}'\mathbf{P} = \mathbf{I}_r$, $\mathbf{Q}'\mathbf{Q} = \mathbf{I}_r$, and Σ is diagonal. Under the mapping $\mathbf{X} \rightarrow \Phi$ it follows that the simplex space vectors become

$$\begin{aligned} \mathbf{S} &= \Phi\mathbf{W} + \mathbf{1}\mathbf{t}' \\ &= \mathbf{P}\Sigma\mathbf{Q}'\mathbf{W} + \mathbf{1}\mathbf{t}' \\ &= \mathbf{M}\mathbf{Q}'\mathbf{W} + \mathbf{1}\mathbf{t}'. \end{aligned}$$

Here \mathbf{W} is $l \times (K-1)$ to correspond to the dimensions of Φ , and the $n \times r$ matrix $\mathbf{M} = \mathbf{P}\Sigma$ has been introduced. In general \mathbf{W} cannot be determined, since l might be infinite. This problem can be solved as follows. Decompose \mathbf{W} in two parts, $\mathbf{W} = \mathbf{W}_1 + \mathbf{W}_2$, where \mathbf{W}_1 is in the linear space of \mathbf{Q} and \mathbf{W}_2 is orthogonal to that space, thus

$$\begin{aligned} \mathbf{W}_1 &= \mathbf{Q}\mathbf{Q}'\mathbf{W}, \\ \mathbf{W}_2 &= (\mathbf{I}_l - \mathbf{Q}\mathbf{Q}')\mathbf{W}. \end{aligned}$$

Then it follows that

$$\begin{aligned} \mathbf{S} &= \mathbf{M}\mathbf{Q}'\mathbf{W} + \mathbf{1}\mathbf{t}' \\ &= \mathbf{M}\mathbf{Q}'(\mathbf{W}_1 + \mathbf{W}_2) + \mathbf{1}\mathbf{t}' \\ &= \mathbf{M}\mathbf{Q}'\mathbf{W}_1 + (\mathbf{I}_l - \mathbf{Q}\mathbf{Q}')\mathbf{W} + \mathbf{1}\mathbf{t}' \\ &= \mathbf{M}\mathbf{Q}'\mathbf{W}_1 + \mathbf{M}(\mathbf{Q}' - \mathbf{Q}'\mathbf{Q}\mathbf{Q}')\mathbf{W} + \mathbf{1}\mathbf{t}' \\ &= \mathbf{M}\mathbf{Q}'\mathbf{W}_1 + \mathbf{M}(\mathbf{Q}' - \mathbf{Q}')\mathbf{W} + \mathbf{1}\mathbf{t}' \\ &= \mathbf{M}\mathbf{Q}'\mathbf{W}_1 + \mathbf{1}\mathbf{t}', \end{aligned}$$

where it has been used that $\mathbf{Q}'\mathbf{Q} = \mathbf{I}_r$. If the penalty term of the GenSVM loss function is considered, it is found that

$$P_\lambda(\mathbf{W}) = \lambda \text{tr } \mathbf{W}'\mathbf{W} = \lambda \text{tr } \mathbf{W}'_1\mathbf{W}_1 + \lambda \text{tr } \mathbf{W}'_2\mathbf{W}_2,$$

since

$$\begin{aligned} \mathbf{W}'_1\mathbf{W}_2 &= \mathbf{W}'\mathbf{Q}\mathbf{Q}'(\mathbf{I}_l - \mathbf{Q}\mathbf{Q}')\mathbf{W} \\ &= \mathbf{W}'\mathbf{Q}\mathbf{Q}'\mathbf{W} - \mathbf{W}'\mathbf{Q}\mathbf{Q}'\mathbf{W} \\ &= \mathbf{O}. \end{aligned}$$

Here again it has been used that $\mathbf{Q}'\mathbf{Q} = \mathbf{I}_r$, and \mathbf{O} is defined as a $(K-1) \times (K-1)$ dimensional matrix of zeroes. Note that the penalty term depends on \mathbf{W}_2 whereas the simplex vectors \mathbf{S} do not. Therefore, at the optimal solution it is required that \mathbf{W}_2 is zero, to minimize the loss function.

Since \mathbf{W}_1 is still $l \times (K-1)$ dimensional with l possibly infinite, consider the substitution $\mathbf{W}_1 = \mathbf{Q}\Omega$, with Ω an $r \times (K-1)$ matrix. The penalty term in terms of Ω then becomes

$$P_\lambda(\mathbf{W}_1) = \lambda \text{tr } \mathbf{W}'_1\mathbf{W}_1 = \lambda \text{tr } \Omega'\mathbf{Q}'\mathbf{Q}\Omega = \lambda \text{tr } \Omega'\Omega = P_\lambda(\Omega).$$

Note also that

$$\begin{aligned} \mathbf{S} &= \mathbf{M}\mathbf{Q}'\mathbf{W}_1 + \mathbf{1}\mathbf{t}' \\ &= \mathbf{M}\mathbf{Q}'\mathbf{Q}\Omega + \mathbf{1}\mathbf{t}' \\ &= \mathbf{M}\Omega + \mathbf{1}\mathbf{t}'. \end{aligned}$$

The question remains on how to determine the matrices \mathbf{P} and Σ , given that the matrix Φ cannot be determined explicitly. These matrices can be determined by the eigendecomposition of \mathbf{K} , where $\mathbf{K} = \mathbf{P}\Sigma^2\mathbf{P}'$. In the case where $r < n$, Σ^2 contains only the first r

eigenvalues of \mathbf{K} , and \mathbf{P} the corresponding r columns. Hence, if \mathbf{K} is not of full rank, a dimensionality reduction is achieved in Ω . The complexity of finding the eigendecomposition of the kernel matrix is $O(n^3)$.

Since the distances $q_i^{(k)}$ in the GenSVM loss function can be written as $q_i^{(k)} = \mathbf{s}_i' \delta_{k_j}$ it follows that the errors can again be calculated in this formulation. Finally, to predict the simplex space vectors of a test set \mathbf{X}_2 the following is used. Let Φ_2 denote the feature space mapping of \mathbf{X}_2 , then

$$\begin{aligned} \mathbf{S}_2 &= \Phi_2 \mathbf{W}_1 + \mathbf{1}t' \\ &= \Phi_2 \mathbf{Q} \mathbf{Q} + \mathbf{1}t' \\ &= \Phi_2 \mathbf{Q} \mathbf{Q} \mathbf{P}' \mathbf{P} \Sigma^{-1} \Omega + \mathbf{1}t' \\ &= \Phi_2 \Phi' \mathbf{P}' \Sigma^{-1} \Omega + \mathbf{1}t' \\ &= \mathbf{K}_2 \mathbf{P} \Sigma^{-1} \Omega + \mathbf{1}t' \\ &= \mathbf{K}_2 \mathbf{M} \Sigma^{-2} \Omega + \mathbf{1}t', \end{aligned}$$

where $\mathbf{K}_2 = \Phi_2 \Phi'$ is the kernel matrix between the test set and the training set, and it was used that $\Sigma \mathbf{P}' \mathbf{P} \Sigma^{-1} = \mathbf{I}_r$, and $\Phi' = \mathbf{Q} \Sigma \mathbf{P}'$ by definition.

With the above expressions for \mathbf{S} and $F_\lambda(\Omega)$, it is possible to derive the majorization function of the loss function for the nonlinear case. The first order conditions can then again be determined, which yields the following system

$$\begin{pmatrix} \mathbf{1}' \\ \mathbf{M}' \end{pmatrix} \mathbf{A} \begin{bmatrix} \mathbf{1} & \mathbf{M} \\ \mathbf{0} & \mathbf{I}_r \end{bmatrix} \begin{bmatrix} t \\ \Omega \end{bmatrix} = \begin{bmatrix} \mathbf{1}' \\ \mathbf{M}' \end{pmatrix} \mathbf{A} \begin{bmatrix} \mathbf{1} & \mathbf{M} \\ \Omega & \end{bmatrix} + \begin{bmatrix} \mathbf{1}' \\ \mathbf{M}' \end{bmatrix} \mathbf{B}. \quad (26)$$

This system is analogous to the system solved in linear GenSVM. In fact, it can be shown that by writing $\mathbf{Z} = [\mathbf{1} \ \mathbf{M}]$ and $\mathbf{V} = [t' \ \Omega]'$, this system is equivalent to (14). This property is very useful for the implementation of GenSVM, since nonlinearity can be included by simply adding a preprocessing and postprocessing step to the existing GenSVM algorithm.

Appendix E. Additional Simulation Results

Tables 5 and 6 respectively show the predictive accuracy rates and ARI scores on each data set averaged over each of the 5 test folds. For readability all scores are rounded to four decimal digits, however identifying the classifier with the highest score was done on the full precision scores. As can be seen, the choice of performance metric has an effect on which classification method has the highest classification performance. Regardless of the performance metric the tables show that MSVM² and W&W never achieve the maximum classification performance on a data set. Note that conclusions drawn from tables of performance scores are quite limited and the results presented in Section 6 provide more insight into the performance of the various classifiers.

Table 7 shows the computation time averaged over the five nested CV folds for each data set and each method. In the grid search GenSVM considered 342 hyperparameter configurations versus 19 configurations for the other methods. Despite this difference GenSVM outperformed the other methods on five data sets, DAG outperformed other methods on four data sets, OvO on two, and LibLinear C&S was fastest on the remaining two data

sets. To illustrate the effect of the larger grid search in GenSVM on the computation time, Table 8 shows the average computation time per hyperparameter configuration. This table shows that GenSVM is faster than other methods on nine out of thirteen data sets, which illustrates the influence of warm starts in the GenSVM grid search.

Editor: Kevin Murphy

Abstract

Government surveys of business establishments receive a large volume of submissions where a small subset contain errors. Analysts need a fast-computing algorithm to flag this subset due to a short time window between collection and reporting. We offer a computationally-scalable optimization method based on non-parametric mixtures of hierarchical Dirichlet processes that allows discovery of multiple industry-indexed local partitions linked to a set of global cluster centers. Outliers are nominated as those clusters containing few observations. We extend an existing approach with a new “merge” step that reduces sensitivity to hyperparameter settings. Survey data are typically acquired under an informative sampling design where the probability of inclusion depends on the surveyed response such that the distribution for the observed sample is different from the population. We extend the derivation of a penalized objective function to use a pseudo-posterior that incorporates sampling weights that “undo” the informative design. We provide a simulation study to demonstrate that our approach produces unbiased estimation for the outlying cluster under informative sampling. The method is applied for outlier nomination for the Current Employment Statistics survey conducted by the Bureau of Labor Statistics.

1. Introduction

1.1 Outlier Detection and Informative Sampling

The U.S. Bureau of Labor Statistics (BLS) administers the Current Employment Statistics (CES) survey to over 350000 non-farm, public and private business establishments across the U.S. on a monthly basis, receiving approximately 270000 submitted responses in each month. Estimated total employment is published for local, state and national geographies in the U.S., as well as for domains defined by establishment size and industry categories within each geography. The BLS conducts a quality check to discover and correct establishment submission errors, particularly among those establishments whose entries are influential in the overall published domain-level estimates. Of the 270000 submissions, approximately 100000 – 150000 of those include employment changes from the prior to the current submission month. The CES maintains a short lag time of approximately 7 days between receipt of establishment submissions at the end of a month and subsequent publication of employment estimates for that month, such that investigations of submission data quality must be done quickly. The relatively large number of submissions with non-zero changes in employment levels, coupled with the rapid publication schedule, require use of quick-executing, automated data analysis tools that output a relatively small, outlying set of the submissions for further investigation and correction by BLS analysts.

The CES survey utilizes a stratified sampling design with strata constructed by combinations of state, broad industry grouping, and employment size (divided into 8 categories). Business establishments are sampled by their unique unemployment insurance (UI) tax identification numbers, which may contain a cluster of multiple individual sites. If a business establishment is selected for inclusion at the UI level, all of the associated sites in that cluster are also included. Stratum-indexed inclusion probabilities are set to be proportional to average employment size for member establishments of that stratum, which is

done because larger establishments compose a higher percentage of the published employment statistics. The correlation between establishment employment levels and inclusion probabilities induces informativeness into the sampling design, meaning that the probabilities of inclusion are correlated with the response variable of interest. The distribution for the resulting observed sample will be different from that for the population (because the sample emphasizes relatively larger establishments), such that inference made (e.g. about outliers) with the former distribution will be biased for the latter.

1.2 Methodologies for Outlier Detection

The Dirichlet process (DP) (Blackwell and MacQueen 1973) and more generally, species sampling formulations (Ishwaran and James 2003), induce a prior over partitions due to their almost surely discrete construction. Convolving a discrete distribution under a DP prior with a continuous likelihood in a mixture formulation is increasingly used for outlier detection (Quintana and Iglesias 2003), where one supposes that each observation is realized from one of multiple generation processes (Shotwell and Slate 2011). Each cluster collects an ellipse cloud of observations that are centered on the cluster mean.

In this article, we improve and extend sequential, penalized partition (clustering) algorithms of Kulis and Jordan (2011); Broderick et al. (2012), that each approximately estimate a maximum a posteriori (MAP) partition and associated cluster centers or means, to account for data acquired under an informative sampling design under which the distribution for the observed sample is different from that for the population (Bonny et al. 2012). We incorporate first order sampling weights into our model for partitions that “undo” the sampling design so that our application nominates outliers with respect to the population generating (mixture) distribution. The algorithm of Kulis and Jordan (2011) is of a class of approaches (see also Wang and Dunson 2011; Shotwell and Slate 2011) that each produce

an approximation for the MAP from a mixture of DPs posterior distribution (where the (unknown) mixing measure over the parameters that define the data likelihood is drawn from a DP).

We follow Kulis and Jordan (2011) and straightforwardly extend our formulation from a DP prior imposed on the mixing distribution to a hierarchical Dirichlet process (HDP) prior (Teh et al. 2006), which allows our estimation of a distinct “local” partition (set of clusters) for each subset of establishments in the CES binned to one of $J = 24$ industry groupings. The local clusters of the industry-indexed partitions may share cluster centers (means) from a global clustering partition. The hierarchical construction of local clusters that draw from or share global cluster means permits the estimation of a dependence structure among the local partitions and encourages a parsimonious discovery of global clusters as compared to running separate global clustering models on each industry group. We refer to this model as hierarchical clustering.

We apply our (sampling-weighted) global and hierarchical clustering models, derived from the MAP approximations, for the nomination of outliers based on identification of the subset of clusters that together collect relatively few observations (with “few” defined heuristically). Quintana and Iglesias (2003) implement a mixture of DPs, for the purpose of outlier detection, where a partition is sampled at each step of an MCMC under an algorithm that minimizes a loss function. The loss function penalizes the size of the partition (or total number of clusters discovered), which will tend to assign most observations into relatively few clusters, while only a small number of observations will lie outside these clusters, a useful feature for outlier detection. We extend small variance asymptotic result of Broderick et al. (2012) for our global and hierarchical clustering formulations to produce objective functions that penalize the number of estimated clusters. We further devise a new “merge” step among all pairs of discovered clusters in each iteration of our estimation algorithms.

Both the penalized likelihood and the merge step encourage parsimony in the number of clusters discovered.

We next derive our sampling-weighted global and hierarchical clustering algorithms in Section 2, followed by a simulation study that demonstrates the importance of correcting estimation for an informative sampling design for outlier detection in Section 3. The simulation study also demonstrates the efficacy of outlier detection performance for the sampling-weighted hierarchical formulation estimated on synthetic data generated in a nested fashion that is similar to the structure of CES survey data. We apply the sampling-weighted hierarchical algorithm to discover local, by-industry partitions and to nominate observations for outliers for our CES survey application in Section 4. We conclude the paper with a discussion in Section 5.

2. Estimation of Partitions from Asymptotic Non-parametric Mixtures

We begin by specifying a Dirichlet process mixtures of Gaussians model to which we apply small variance asymptotics to derive a penalized K – means optimization expression and an associated fast-computing estimation algorithm. We include the sampling weights in our mixture formulation that asymptotically corrects for an informative sampling design (Savitsky and Toth 2015). We continue and extend this MAP approximation approach to a hierarchical Dirichlet process mixtures of Gaussians model to achieve a hard, point estimate sampling-weighted hierarchical clustering algorithm that permits specification of a set of local, industry indexed, clusters linked to a common set of global clusters.

We implement both algorithms we present, below, in the `growClusters` package for **R** (R Core Team 2014), which is written in C++ for fast computation and available from the authors on request.

2.1 Asymptotic Sampling-weighted Mixtures of Dirichlet Processes

We specify a probability model for a mixture of K_{\max} allowed components to introduce Bayesian estimation of partitions of observations into clusters and the associated cluster centers. The mixtures of DPs will be achieved in the limit of this probability model as K_{\max} increases to infinity.

$$\alpha x_1^1 \mathbf{x}_i | s_i, \mathbf{M} = (\boldsymbol{\mu}_1, \dots, \boldsymbol{\mu}_{K_{\max}})', \sigma^2, \tilde{w}_i \stackrel{\text{iid}}{\sim} \mathcal{N}_d(\boldsymbol{\mu}_{s_i}, \sigma^2 \mathbb{I}_d)^{w_i} \quad (1a)$$

$$s_i | \boldsymbol{\tau} \stackrel{\text{iid}}{\sim} \mathcal{M}(1, \tau_1, \dots, \tau_{K_{\max}}) \quad (1b)$$

$$\boldsymbol{\mu}_p | G_0 \stackrel{\text{iid}}{\sim} G_0 := \mathcal{N}_d(\mathbf{0}, \rho^2 \mathbb{I}_d) \quad (1c)$$

$$\tau_1, \dots, \tau_{K_{\max}} \sim \mathcal{D}(\alpha/K_{\max}, \dots, \alpha/K_{\max}), \quad (1d)$$

for $i = 1, \dots, n$ sample establishments and $p = 1, \dots, K_{\max}$ allowable clusters. Each cluster candidate, p , indexes a unique value for the associated cluster center, $\boldsymbol{\mu}_p$. The set of cluster assignments of observations together compose a partition of observations, where partitions are indexed by $\mathbf{s} = (s_1, \dots, s_n)$, for $s_i \in \{1, \dots, K\}$. The prior distributions for the cluster centers and assignments induce a random distribution prior, G , for drawing a mean value for each \mathbf{x}_i for $i = 1, \dots, n$, by sampling unique values in the support of G from G_0 and assigning the mean value (that we interpret as a cluster) for each observation by drawing from the set of unique values with probabilities, $\boldsymbol{\tau}$, which are, in turn, randomly drawn from a Dirichlet distribution. As $K_{\max} \uparrow \infty$ in Equation 1d, such that number of possible clusters are countably infinite, this construction converges to a (non-parametric) mixture of Dirichlet processes (Neal 2000). We also note that α influences the number of clusters discovered. For any given K_{\max} : larger values for α will produce draws for $\boldsymbol{\tau}$ that assign larger probabilities to more of the $p \in \{1, \dots, K_{\max}\}$ clusters, such that it is highly influential in the determination of the number of discovered clusters, $K < K_{\max}$.

The likelihood contribution for each observation, $i \in \{1, \dots, n\}$, in Equation 1a is uplifted by a sampling weight, $\tilde{w}_i = n \times w_i / \sum_{i=1}^n w_i$ for $w_i \propto 1/\pi_i$, constructed to be inversely proportional to the known inclusion probability in the sample. This formulation for the sampling weight assigns importance for that observation likelihood based on the amount of information in the finite population represented by that observation. The weights sum to the sample size, n , so that an observation with a low inclusion probability in the sample will have a weight greater than 1, meaning that it “represents” more than a single unit in a re-balanced sample. The weighting serves to “undo” the sampling design by re-balancing the information in the observed sample to approximate that in the population. The sum of the weights directly impacts the estimation of posterior uncertainty such that the summation to n expresses the asymptotic amount of information in the observed sample. This construction is known as a “pseudo” likelihood because the distribution for the population is approximated by weighting each observation back to the population. Savitsky and Toth (2015) provide three conditions that define a class of sampling designs under which the pseudo posterior (defined from the pseudo likelihood) is guaranteed to contract in L_1 on the unknown true generating distribution, P_0 . The first condition states that the inclusion probability, π_i , for each unit in the finite population, $i \in \{1, \dots, N\}$, must be strictly greater than 0. This condition ensures that no portion of the population may be systematically excluded from the sample. The second condition on the sampling design requires the second order inclusion dependence for any two units, $i, j \in \{1, \dots, N\}$, be globally bounded from above by a constant; for example, a two-stage design in which units within selected clusters are sampled without replacement is within this class to the extent that the number of population units within each cluster asymptotically increases. The third condition requires the sampling fraction, n/N , to converge to a constant as the population size limits to infinity.

Samples may be drawn from the joint posterior distribution under Equation 1 using Markov chain Monte Carlo (MCMC), though the computation will not scale well with increasing sample size as a partition is formed through sequential assignments of observations to clusters (including to possibly new, unpopulated clusters) on each MCMC iteration. We, instead, derive an optimization expression that allows for scalable approximation of the single MAP partition by taking the limit of the joint posterior distribution as the likelihood variance, $\sigma^2 \downarrow 0$.

We marginalize out τ from the joint prior, $f(\mathbf{s}, \boldsymbol{\tau} | \boldsymbol{\alpha}) = f(\mathbf{s} | \boldsymbol{\tau}) f(\boldsymbol{\tau} | \boldsymbol{\alpha})$, by using the Pólya urn scheme of Blackwell and MacQueen (1973), which produces,

$$f(s_1, \dots, s_n | \boldsymbol{\alpha}) = \alpha^K \frac{\Gamma(\alpha + 1)}{\Gamma(\alpha + n)} \prod_{p=1}^K (n_p - 1)!,$$

where $n_p = \sum_{i=1}^n \mathbf{1}(s_i = p)$ is the number of observations (e.g. establishments) assigned to cluster, p and K denotes the number of estimated clusters. We generally follow Broderick et al. (2012) and derive our optimization expression from the joint pseudo posterior distribution,

$$\begin{aligned} f(\mathbf{s}, \mathbf{M} | \mathbf{X}, \tilde{\mathbf{w}}) \propto f(\mathbf{X}, \mathbf{s}, \mathbf{M} | \tilde{\mathbf{w}}) &= \prod_{p=1}^K \prod_{i: s_i=p} \mathcal{N}_d(\mathbf{x}_i | \boldsymbol{\mu}_p, \sigma^2 \mathbb{I}_d)^{\tilde{w}_i} \\ &= \alpha^K \frac{\Gamma(\alpha + 1)}{\Gamma(\alpha + n)} \prod_{p=1}^K (n_p - 1)! \\ &\quad \prod_{p=1}^K \mathcal{N}_d(\boldsymbol{\mu}_p | \mathbf{0}, \rho^2 \mathbb{I}_d). \end{aligned} \quad (2)$$

Broderick et al. (2012) point out that if one limits $\sigma^2 \downarrow 0$ in Equation 2, each observation will be allocated to its own cluster since the prior allows a countably infinite number of clusters. To avoid this degenerate outcome, define a constant λ and set $\alpha = \exp(-\lambda / (2\sigma^2))$, which

produces $\alpha \downarrow 0$ as $\sigma^2 \downarrow 0$. This functional form for α achieves the result and avoids the degenerate outcome, where the λ hyperparameter controls the size of the partition as $\sigma^2 \downarrow 0$. Commonly-used approaches that also specify an approximate MAP of a mixture of DPs also restrict α ; Shotwell and Slate (2011) fix the value for α and Wang and Dunson (2011) restrict the values of α to a discrete grid. Plugging in this expression for α into Equation 2, and taking -1 times the logarithm of both sides results in,

$$\begin{aligned} -\log f(\mathbf{X}, \mathbf{s}, \mathbf{M}, \tilde{\mathbf{w}}) &= \sum_{p=1}^K \sum_{i: s_i=p} \left[\mathcal{O}(\log \sigma^2) + \frac{\tilde{w}_i}{2\sigma^2} \|\mathbf{x}_i - \boldsymbol{\mu}_p\|^2 \right] \\ &\quad + K \frac{\lambda}{2\sigma^2} + \mathcal{O}(1) \end{aligned} \quad (3)$$

where the expression in the first line derives from the log-kernel of a multivariate Gaussian distribution and $f(\sigma^2) = \mathcal{O}(h(\sigma^2))$ denotes that there exist constants, $c_1, c_2 > 0$, such that $|f(\sigma^2)| \leq c_1 |h(\sigma^2)|$, for $\sigma^2 < c_2$. Multiplying both sides of Equation 3 by $2\sigma^2$ and taking the limit as $\sigma^2 \downarrow 0$ results in the asymptotically equivalent sampling-weighted global clustering optimization problem,

$$\underset{\mathbf{K}, \mathbf{s}, \mathbf{M}}{\operatorname{argmin}} \sum_{p=1}^K \sum_{i: s_i=p} \tilde{w}_i \|\mathbf{x}_i - \boldsymbol{\mu}_p\|^2 + K\lambda, \quad (4)$$

whose solution is a MAP approximation for the sample-adjusted mixtures of DPs of Equation 1. We minimize a sampling-weighted distance in Equation 4, which will approximate a MAP partition and associated cluster centers with respect to the distribution for the *population*, which is our interest, rather than that for the realized sample.

Although we derive the sampling-weighted approximate MAP by letting the variance around a partition, σ^2 , limit to 0, this constructive derivation offers no comment on whether

the distribution over the space of partitions for a particular data set expresses a low or high variance. Our purpose is to extract a hard, point estimate that computationally scales to a large number of multivariate observations (that we employ for the purpose of nominating outliers). To the extent that computational considerations allow, one would obtain richer inference on both an asymptotically exact MAP of the marginal distribution over the space of partitions and an associated measure of uncertainty by using the fully Bayesian nonparametric mixture model.

Shotwell and Slate (2011) note that employing a MAP approximation (which selects the partition assigned the largest approximated value for the posterior mass) implicitly uses a 0 – 1 loss function. While other choices for the loss function may produce useful results, we prefer use of the MAP approximation as we would expect concentration of the estimated joint posterior distribution from the model of Equation 1 around the MAP due to the large sample sizes for our CES application.

2.2 Sampling-weighted Global Clustering Algorithm

We specify an estimation algorithm for MAP approximation, below, which is guaranteed to converge to a local optimum, since each step reduces (or doesn't increase) the objective function of Equation 4 and there are only a finite number of possible partitions. The algorithm operates, sequentially, on the observations and specifies successive assignment and cluster center estimation steps.

We introduce a new merge step, that tests all unique cluster pairs for merging and conducts a merge of any pair of clusters if such reduces the objective function, which reduces the sensitivity of the estimated partition to the specified values of the penalty parameter.

The observations are each weighted using the sampling weights in the computations of distances to cluster centers and the computation of cluster centers. Observations with higher weights contribute relatively more information to the computation of cluster centers. We demonstrate in the simulation study to follow that this procedure produces nearly unbiased population estimates for cluster centers, conditioned on the generation of the finite population from disjoint clusters. Since lower-weighted observations (less representative of the population from which they were drawn) contribute relatively less to the objective function, the weighting will also impact the number of clustered discovered and assignment of the multivariate observations to those clusters.

The algorithm for estimating a MAP partition and associated cluster centers is specified with,

1. **Input:** $n \times d$ data matrix, \mathbf{X} ; $n \times 1$ vector of sampling weights, \vec{w} , for observed units and cluster penalty parameter, λ .
2. **Output:** $K \times d$ matrix of cluster centers, $\mathbf{M} = (\mu_1, \dots, \mu_K)'$, and $n \times 1$ vector of cluster assignments, \mathbf{s} , where $s_i \in \{1, \dots, K\}$ for units, $i = 1, \dots, n$.
3. **Initializer:** $s_i = 1, \forall i$. $d \times 1$ cluster center, $\mu_1 = \sum_{i=1}^n (\mathbf{x}_i \vec{w}_i) / \sum_{i=1}^n \vec{w}_i$.
4. Repeat the following steps until convergence (when the decrease in energy is below

$$e \leftarrow \sum_{p=1}^K \sum_{i \in \{i: s_i=p\}} w_i \|\mathbf{x}_i - \mu_p\|^2 + \lambda K$$

a set threshold).

5. **Assign units to clusters for each unit, $i = 1, \dots, n$:**
 - (a) Compute distance, $d_{ip} = \vec{w}_i \|\mathbf{x}_i - \mu_p\|^2$ for $p = 1, \dots, K$.
 - (b) If $\min_p d_{ip} > \lambda$, create new cluster to which unit i is assigned; $K \leftarrow K + 1$, $s_i \leftarrow K$, $\mu_K \leftarrow \mathbf{x}_i$; else $s_i \leftarrow \operatorname{argmin}_p d_{ip}$.
6. **Re-compute centers for clusters, $p = 1, \dots, K$:** Let $\mathbf{S}_p = \{i : s_i = p\}$ and $\mu_p = \sum_{i \in \mathbf{S}_p} (\mathbf{x}_i \vec{w}_i) / \sum_{i \in \mathbf{S}_p} \vec{w}_i$.

7. Assess merge of unique cluster pairs, $(p \in (1, \dots, K), p' \in (1, \dots, K))$:

- (a) Perform test merge of each pair of clusters:
- (b) Set matrix of cluster centers for virtual step, $\mathbf{M}^* = \mathbf{M}$.
- (c) Compose index set of observations assigned to clusters p' or p ; $\mathbf{S}_p^* = \{i : s_i = p \text{ or } s_i = p'\}$.
- (d) Compute (weighted average) merged cluster centers, $\mu_p^* = \left(\sum_{i \in \mathbf{S}_p^*} \mathbf{x}_i \tilde{w}_i \right) / \sum_{i \in \mathbf{S}_p^*} \tilde{w}_i$ and set rows p and p' of \mathbf{M}^* equal to this value.
- (e) Compute energy under the tested move, $e^* \leftarrow \sum_{p=1}^K \sum_{i \in \mathbf{S}_p^*} \tilde{w}_i \|\mathbf{x}_i - \mu_p^*\|^2 + \lambda(K-1)$. If $e^* < e$, execute a merge of p and p' :
- (f) Re-assign units linked to p' to p , $\mathbf{s}_{i:s_i=p'} \leftarrow p$.
- (g) Re-set cluster labels, p in \mathbf{s} to be contiguous after removing p' , such that $p \leftarrow p-1, \forall p > p'$, leaving $s_i \in (1, \dots, K-1)$. Delete row, p' , from \mathbf{M}^* and set $\mathbf{M} \leftarrow \mathbf{M}^*$.

2.3 Asymptotic Sampling-weighted Mixtures of Hierarchical Dirichlet

Processes

The CES survey is administered to establishments across a diverse group of industries that comprise the U.S. economy. CES survey analysts examine month-over-month reporting changes in the average employment and production worker variables within each of 24 NAICS industry categories (outlined in Section 4 that analyzes a data set of CES responses). The by-industry focus reflects the experience that both reporting patterns and establishment processes tend to express more similarity within than between industries. Yet, there are also commonalities in the reporting processes and types of reporting errors committed among the establishments due to overlapping skill sets of reporting analysts, similarities in organization structures, as well as the use of a single BLS-suggested reporting process.

So we want to perform separate estimations of partitions within each industry group, but allow those partitions to express similarities or dependencies across industries. We next

use the result of Kulis and Jordan (2011) that generalizes the approximate MAP algorithm obtained from mixtures of Dirichlet processes to mixtures of hierarchical Dirichlet processes. The hierarchical Dirichlet process (HDP) of Teh et al. (2006) specifies a DP partition for each industry that we refer to as a local (to industry) partition or clustering. These local partitions draw their cluster center values from a set of ‘‘global’’ clusters, such that local clusters may be connected across industry partitions by their sharing of common global cluster centers (from a single global partition) in a hierarchical manner.

We next specify a hierarchical mixture model that will converge to a sampling-weighted mixtures of HDPs in the limit of the *allowable* maximum number of global and local clusters as a generalization of our earlier DP specification,

$$\mathbf{x}_i^{d \times 1} | s_i^j, \mathbf{M} = (\mu_1, \dots, \mu_{K_{\max}}), \sigma^2, \tilde{w}_i \stackrel{\text{ind}}{\sim} \mathcal{N}_d(\mu_{s_i^j}, \sigma^2 \mathbb{I}_d), \quad i = 1, \dots, n_j \quad (5a)$$

$$v_c^j | \tau \stackrel{\text{iid}}{\sim} \mathcal{M}(1, \tau_1, \dots, \tau_{K_{\max}}), \quad c = 1, \dots, L_{\max} \quad (5b)$$

$$z_i^j | \pi^j \stackrel{\text{iid}}{\sim} \mathcal{M}(1, \pi_1^j, \dots, \pi_{L_{\max}}^j) \quad (5c)$$

$$s_i^j = v_{z_i^j}^j \quad (5d)$$

$$\mu_p | G_0 \stackrel{\text{iid}}{\sim} G_0 := \mathcal{N}_d(\mathbf{0}, \rho^2 \mathbb{I}_d) \quad (5e)$$

$$\tau_1, \dots, \tau_{K_{\max}} \sim \mathcal{D}(\alpha / K_{\max}, \dots, \alpha / K_{\max}) \quad (5f)$$

$$\pi_1^j, \dots, \pi_{L_{\max}}^j \sim \mathcal{D}(\gamma / L_{\max}, \dots, \gamma / L_{\max}), \quad (5g)$$

for each industry partition, $j = 1, \dots, (J = 24)$, where K_{\max} denotes the allowable number of global clusters and L_{\max} denotes the maximum allowable number of local clusters over all J partitions. An $n_j \times d$ data matrix, \mathbf{X}^j , includes the $d \times 1$ responses, (\mathbf{x}_i^j) , for establishments in industry, j . The $L_{\max} \times 1$ vector, \mathbf{v}^j , indexes the global cluster assignment for each local cluster, $c \in (1, \dots, L)$ for industry, j . The $n_j \times 1$ vector, \mathbf{z}^j , assigns each individual establishment, $i \in (1, \dots, n_j)$, to a local cluster, $c \in 1, \dots, L_{\max}$. So, z_i^j indexes

the local cluster assignment for establishment, i , in industry, j and v_i^j indexes the global assignment for all of the establishments assigned to local cluster, c , in industry, j . We may chain together the local cluster assignment for observation, i , and the global cluster assignment for the local cluster containing i to produce the $n_j \times 1$ index, s^j , that holds the global cluster assignment for each establishment in industry, j . The vectors of probabilities for local cluster assignments of establishments, $(\pi^j)_{j=1,\dots,J}$ and for global cluster assignments of local clusters, τ , are random probability vectors drawn from Dirichlet distributions. As before, Equation 5 converges to a sampling-weighted mixture of HDDPs in the limit to infinity of K_{\max} and L_{\max} (Teh et al. 2006).

We achieve the following optimization algorithm by following a similar asymptotic derivation in the limit of $\sigma^2 \downarrow 0$, as earlier,

$$\arg \min_{K, S, M} \sum_{p=1}^K \sum_{j=1}^J \sum_{i: s_i^j=p} \bar{w}_i^j \|\mathbf{x}_i^j - \boldsymbol{\mu}_p\|^2 + K\lambda_K + L\lambda_L, \quad (6)$$

where $L = \sum_{j=1}^J L_j$ denotes the total number of estimated local clusters and L_j denotes the number local clusters estimated for data set, $j = 1, \dots, J$. As before, K denotes the number of estimated global clusters.

2.4 Sampling-weighted Hierarchical Clustering Algorithm

We sketch a summary overview of the MAP approximation algorithm derived from sampling-weighted mixtures of HDDPs. A more detailed, step-by-step, enumeration of the algorithm is offered in Appendix A. As with the sampling-weighted global clustering estimation, the algorithm will return a $K \times d$ matrix of global cluster centers, \mathbf{M} , and a vector for each industry, s^j , $j \in (1, \dots, J)$, that holds the global cluster assignments, $s_i^j \in (1, \dots, K)$, for the set of n_j observations in industry, j . Each vector s^j conveys additional information

about the local partitions of the hierarchical clustering. The estimation algorithm allows a distinct number of local clusters, L_j , to be discovered for each industry. The number of unique global cluster values, $p \in (1, \dots, K)$, that are assigned across all the establishments in industry j defines the structure - number of local clusters and establishments assigned to each cluster - of the local partition for that industry.

The algorithm contains an assignment step to directly assign each establishment, i , in industry, j , to a global cluster, as with the mixtures of DPs algorithm. For a new global and local cluster to be created, however, the minimum distance to the global cluster centers must be greater than the sum of local and global cluster penalty parameters, $\lambda_L + \lambda_K$. An observation is assigned to a global cluster by first assigning it to a local cluster that is, in turn, next assigned to that global cluster. A new local cluster will be created if an observation in an industry is assigned to a global cluster, p , that is not currently assigned to any local cluster for that industry. It is typical for only a subset of the K global clusters to be used in each local partition across the J industries. To the extent that the industry partitions share global clusters, then $K < \sum_{j=1}^J L_j$, and there will be a dependence among those partitions.

A second assignment step performs assignments to global clusters for *groups* of establishments in industry, j , who are assigned to the same local cluster, c . All of the establishments in local cluster, c , in industry, j , may have their assignments changed from global cluster, p , to global cluster, p' . This group assignment of establishments to global clusters contrasts with only changing global cluster assignments for establishments on an individual basis. This is a feature of the HDP and helps mitigate order dependence in the estimation of the MAP approximation. We specify a new “shed” step (that is not included in the algorithm of Knulis and Jordan (2011)) to remove any previously defined

global clusters that may not be linked to any local clusters across the J industries after this second assignment step of local-to-global clusters.

We continue to employ a merge step that tests each unique pair of global clusters for merging. We find in runs performed on synthetic data that the merge step helps reduce (but does not eliminate) the sensitivity (in number of clusters formed) to specifications of (λ_K, λ_L) . The number of merges increase under lower values for these penalty parameters. If global cluster, p' , is merged into p and deleted, then so are the local clusters, \mathbf{c} , assigned to p' across the J industries and establishments that were previously assigned to each $c \in \mathbf{c}$ are now re-assigned to existing local clusters linked to global cluster, p .

3. Simulation Study

We conduct a two-part Monte Carlo simulation study that assesses the effectiveness to detect an outlying cluster with respect to the population from an informative sample, where an outlying cluster is defined to contain a small percentage of the total number of establishments. Both parts of the simulation study generate a synthetic finite ‘‘population’’ from which repeated samples are drawn under a sampling design where the probabilities of selecting each establishment are a function of their response values, such that we produce informative samples. The informative samples are presented to the partition estimation models. The first part of the simulation study compares the accuracy of outlier detection under inclusion of sampling weights, used to correct for informativeness, versus excluding the sampling weights (where both employ the global (hard) clustering model using the estimation algorithm specified in Section 2.2. The sampling weights are set to a vector of 1’s in the case that excludes sampling weights). The second part of the simulation study compares the outlier estimation performance between the sampling-weighted global clustering model, on the one hand, and the sampling-weighted hierarchical clustering model,

on the other hand, for data generated from local partitions that share global cluster centers. We first devise an approach to select the penalty parameters for our estimation models, which determine the number of clusters discovered, that we will need for our two-part study.

3.1 Selection of Penalty Parameters

It is difficult to find a principled way to specify the penalty parameter, λ , for the global clustering model or (λ_L, λ_K) , for the hierarchical clustering model. Their specification is critical because these penalty parameters determine the number of discovered clusters. Relatively larger values estimate fewer clusters. Both cross-validation and randomly separating the data into distinct training and test sets (in the case the analyst possesses a sufficient number of observations) tends towards assignment of each observation to its own cluster by selecting nearly 0 values for the penalty parameters as poor fit overwhelms the penalty.

We demonstrate this tendency with a simulation study using the sampling-weighted hierarchical clustering model. We generate a population with $J = 3$ data sets, each of size $N_j = 15000$, with the local partition structure in each data set composed of $L_j = 5$, $j = 1, \dots, J$ clusters randomly selecting from $K = 7$ global cluster centers. Establishments are randomly assigned to the $L_j = 5$ local clusters for each data set under a skewed distribution of $(0.6, 0.25, 0.1, 0.025, 0.025)$ to roughly mimic the structure we find in the CES data set analysed in Section 4. Data observations are generated from a multivariate Gaussian,

$$\mathbf{x}_i^j \stackrel{\text{i.i.d.}}{\sim} \mathcal{N}_d \left(\boldsymbol{\mu}_j, \sigma_j^2 \mathbb{I}_d \right),$$

centered on the local cluster mean of each observation and σ is set equal to 1.5 times the average over the $J = 3$ data sets, $N_j = 15000$ establishments and $d = 15$ dimensions of the assignment-weighted centers, $\mathbf{M}_{s,1:d}$, the mean values of \mathbf{X}_j .

We next take a sample of $n_j = 2250$ from each of the $J = 3$ data sets under a fixed sample size, proportional-to-size design where inclusion probabilities are set to be proportional to the variances of the $(d = 15) \times 1$, $\{\mathbf{x}_i\}$, inducing informativeness. The taking of an informative sample addresses the class of data in which we are interested and mimics our motivating GES data application. Observations are next randomly allocated into two sets of equal size; one used to train the model and the other to evaluate the resultant energy. The training sample is presented to the sampling-weighted hierarchical clustering model. Figure 1 displays the sampling-weighted hierarchical objective function (energy) values, evaluated on the test set, over a grid of global and local cluster penalty parameters. We observe that the energy doesn't reach a balanced optimum, but decreases along with values of the penalty parameters. The rate of decrease declines for these synthetic data, possibly suggesting the identification of an "elbow" for selecting penalty parameters, though there is little-to-no sensitivity in the values for the global penalty parameter, λ_K , which prevents precise identification of a value. The rate of decrease in energy on the GES data does not decline, however. We see a similar result under 10-fold cross-validation.

As an alternative, we employ penalty parameter selection statistics that combine measures of cohesion within clusters and separation between clusters to select the number of clusters. We devise a sampling-weighted version of the Calinski Harabasz (C) criterion, which is based on within cluster sum-of-squares (WSS) and between clusters sum-of-

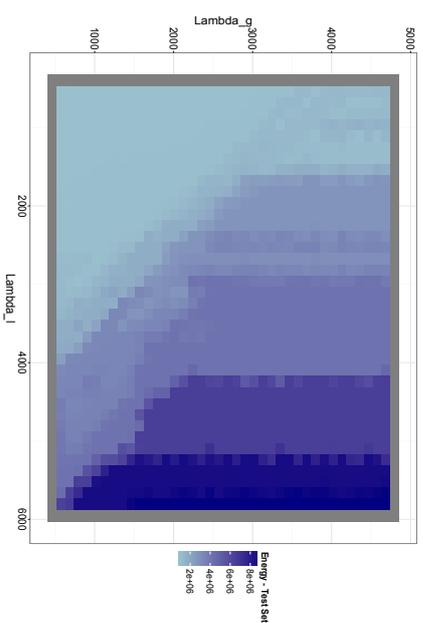

Figure 1: Heat map of (energy) values under the sampling-weighted hierarchical clustering model over grid of global and local cluster penalty parameters. The vertical axis represents the global cluster penalty, λ_K , and the horizontal axis, the local cluster penalty, λ_L . The energy is measured from assignment to a test set not used for training the model. The darker colors represent higher energy (optimization function) values.

squares ($BGSS$),

$$WGSS = \sum_{p=1}^K \sum_{i: s_i^k = k} \tilde{w}_i \|\mathbf{x}_i - \boldsymbol{\mu}_p\|^2$$

$$BGSS = \sum_{p=1}^K n_p \|\boldsymbol{\mu}_p - \boldsymbol{\mu}^G\|^2,$$

where $\mathbf{s}^v = (\mathbf{s}^1, \dots, \mathbf{s}^v)'$ stacks the set of J_i $\{\mathbf{s}^j\}$ into a vector, which retains information on the local partitions (based on the co-clustering relationships). The weighted total number of establishments linked to each cluster, $p \in (1, \dots, K)$ is denoted by $n_p = \sum_{i: s_i = p} \tilde{w}_i$ and $\boldsymbol{\mu}^G = \frac{\sum_{i=1}^n \tilde{w}_i \mathbf{x}_i}{\sum_{i=1}^n \tilde{w}_i}$. The C criterion is then formed as, $C = \frac{n-K}{K-1} \frac{WGSS}{BGSS}$, where K is determined by the number of unique values in \mathbf{s}^v , which is equal to the number of rows in the $K \times d$, $\mathbf{M} = (\boldsymbol{\mu}'_1, \dots, \boldsymbol{\mu}'_K)$ (and d denotes the dimension of each observation, \mathbf{x}_i). Larger values for C are preferred.

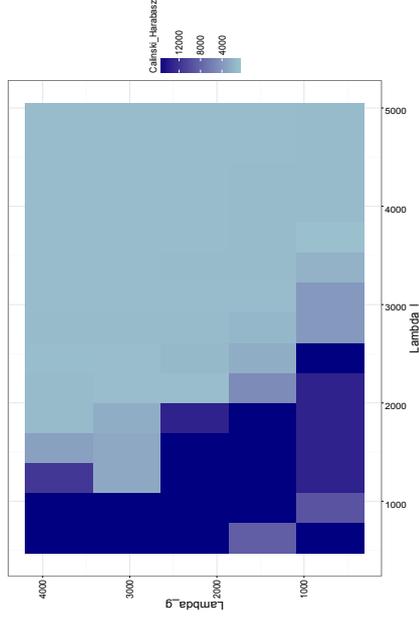

Figure 2: Heat map of Calinski Harabasz (C) index values under the mixtures of HDP model over grid of global and local cluster penalty parameters. The vertical axis represents the global cluster penalty, λ_K , and the horizontal axis, the local cluster penalty, λ_L . The darker colors represent higher C values. Global and local cluster penalty parameters with higher C values are preferred.

Our proposed procedure estimates a clustering on the sampled data over a grid of (local, global) penalty parameter values, where we compute the C statistic for each (λ_L, λ_K) in the grid, selecting that clustering which maximizes the C statistic. (Our `growclusters` package uses the farthest-first algorithm to convert user-specified minimum and maximum number of global and local clusters to the associated penalty parameters. The farthest first is a rough heuristic, so we are conservative in the specified range of $1 \geq \lambda_K \leq 30$, $1 \geq \lambda_L \leq 20$). We perform estimation using the sampling-weighted hierarchical clustering algorithm over a 5×15 grid of global and local clustering penalty parameters, respectively; on the full sample of $n_j = 2250$ for the $J = 3$ data sets. Figure 2 suggests selection of penalty parameters from the upper left-quadrant of the grid. We chose the values of $(\lambda_L = 1232, \lambda_K = 2254)$ that maximized the C index for our sampling-weighted hierarchical clustering model. Figure 3 presents the resulting estimated distribution of the n_j (informative sample) observations within clusters of each local partition (that index the $J = 3$ datasets), where the support of each local distribution indicates to which global cluster center each local cluster is linked. We note that the correct number ($K = 7$) of global clusters and local clusters ($L_j = 5$) is returned and that the skewed distribution of establishments within each local partition mimics that of the population (which is estimated from our informative sample). We use the Rand statistic $\in (0, 1)$, which measures the concordance of pairwise clustering assignments, to compare the true partition assigned in the the population versus the estimated partition, where the latter is estimated from the observed informative sample, rather than the population, itself. The computed Rand value is 1, indicating perfect agreement between the true and estimated partitions in their pairwise clustering assignments. (See Shotwell (2013) for a discussion of alternative statistics, including the Rand, for comparing the similarity of two partitions).

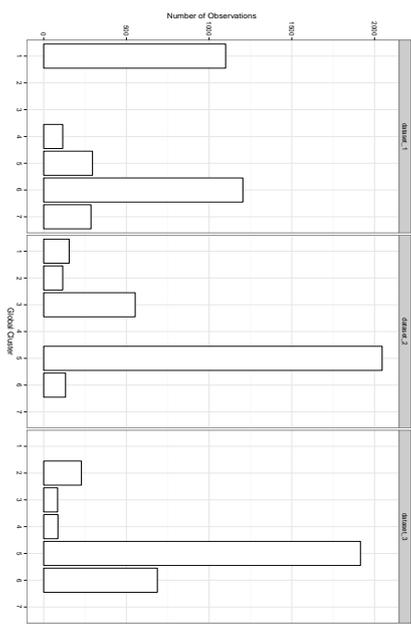

Figure 3: Estimated distribution of establishments in $J = 3$ local cluster partitions. The support of each distribution indicates the global cluster to which each local cluster is linked.

We additionally compute a sampling-weighted version of the silhouette index, $h_i = \frac{a_i - b_i}{\max(a_i, b_i)}$, where a_i is the average distance to observations co-clustered with i and b_i is the average distance to other observations in the nearest cluster to that holding i . The total index, $h^K = \frac{\sum_{i=1}^n w_i h_i}{\sum_{i=1}^n w_i}$, $\in (0, 1)$ and, like the C index, prefers partitions where the clusters are compact and well-separated. These two indices select the same penalty parameter values from the grid of values evaluated on both the simulation and CES data. We prefer our sampling-weighted C since the computation is more scalable to a large number of observations. The C index was used to select the penalty parameters for all implementations of the mixtures of DPs and HDDPs models.

Lastly, our procedure for selecting (λ_L, λ_K) by evaluating the Calinski Harabasz statistic over a grid generally selects the same clustering under inclusion or exclusion of the merge move on synthetic datasets. Figure 4 examines the numbers of merges that take place on

each run on the grid of penalty parameter values in the case we include the merge step, and reveals that the number of merges increases at relatively low values of the penalty parameters. In this case, and in others we tested on synthetic data, the merges took place outside of the range of nearly optimum penalty parameter values, though one may imagine the possibility of merges taking place in this range on a real dataset. There would be a reduction in the sensitivity for the number of clusters estimated to the values of the penalty parameter, which may have the effect of increasing the sub-space of nearly optimal penalty parameters (that produce the same clustering results). While we recommend and employ our selection procedure for penalty parameters in our simulations and application to follow, further simulations (not shown) demonstrate that inclusion of the merge step produces estimated clusters that are consistently closer to the truth as compared to excluding the merge step when the penalty parameters are specified by a heuristic procedure, like the farthest first algorithm employed in Kulis and Jordan (2011).

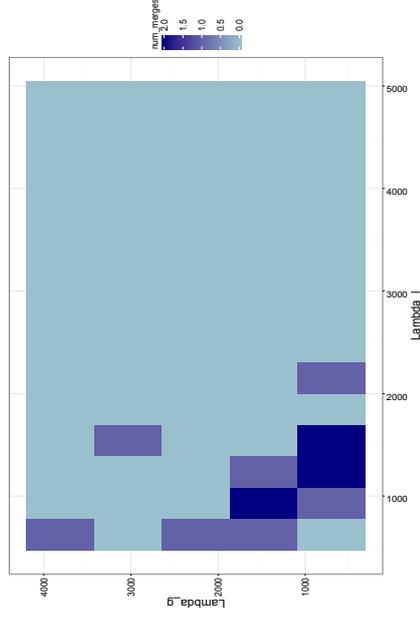

Figure 4: Heat map of the number of merges that took place under the mixtures of HDP estimation model over grid of global and local cluster penalty parameters. The vertical axis represents the global cluster penalty, λ_K , and the horizontal axis, the local cluster penalty, λ_L . The darker colors represent higher number of merges.

Our selection procedure that computes the Calinski Harabasz statistic over a range of global and local cluster penalty parameters defined on a grid and selects that clustering which produces the maximum value of this statistic will be used for every estimation run of the global and hierarchical clustering algorithms in the sequel.

3.2 Outlier Estimation Under Informative Sampling

Our next simulation study compares the outlier detection power when accounting for, versus ignoring, the informativeness in the observed sample by generating data under a simple, non-hierarchical global partition. We construct a set of $K = 5$ global cluster centers, each of dimensions, $d = 15$. Each cluster center expresses a distinct pattern over the $d = 15$ dimensions,

$$\stackrel{(d=15) \times 1}{\boldsymbol{\mu}_1} = (1, 1.5, 2.0, \dots, 7.5, 8)$$

$$\boldsymbol{\mu}_2 = (8, 7.5, \dots, 1)$$

$$\boldsymbol{\mu}_3 = (1, \dots, 7, 8, 7, \dots, 1)$$

$\boldsymbol{\mu}_4 =$ Sampling from $(1, \dots, 8)$ under equal probability with replacement, $d = 15$ times

$\boldsymbol{\mu}_5 =$ Sampling from $(-2, \dots, 6)$ under equal probability with replacement, $d = 15$ times,

to generate $\mathbf{M} = (\boldsymbol{\mu}_1, \dots, \boldsymbol{\mu}_5)'$. Without loss of generality, the last cluster, $\boldsymbol{\mu}_5$, is defined as the outlier cluster and includes negative values, though there is overlap with the support of the other four clusters for values > 0 . We create the $(N = 25000) \times 1$ cluster assignment vector, \mathbf{s} , by randomly assigning establishments in the (finite) population to clusters (with equal probabilities) such that the first 4 clusters are assigned equal numbers of observations, while the last (outlying) cluster (with mean $\boldsymbol{\mu}_5$ is assigned 150 observations, according with our earlier definition of an outlying cluster as having relatively few assigned observations).

We then generate our $N \times d$ matrix of population response values, \mathbf{X} , from the multivariate Gaussian distribution,

$$\stackrel{d \times 1}{\mathbf{x}_i} \stackrel{\text{i.i.d.}}{\sim} \mathcal{N}_d(\boldsymbol{\mu}_s, \sigma^2 \mathbb{I}_d),$$

where the standard deviation, σ , is set equal to 1.5 times the average over the $N = 25000$ establishments and $d = 15$ dimensions of the assignment-weighted matrix, $\mathbf{M}_{\mathbf{s},1:d}$, the mean values of \mathbf{X} . We may think of this process for generating a finite population as taking a census of all establishments in the population. Establishments who report values in any of the first 4 clusters are drawn from the true population generating distribution, while those establishments who report values from cluster 5 commit errors such that the reported values are from a different (shifted) distribution that generates the population of errors. Our inferential interest is to uncover outlying values with respect to the population, rather than the sample, as an observation may not be outlying relative to the sample, but may relative to the population (or vice versa).

We assign the population establishments, evenly, to one of $H = 10$ strata, so there are $N_h = 2500$ establishments assigned to each stratum. Our sampling design employs simple random sampling of establishments within each of the H strata. The sample size taken from each stratum is set proportionally to the average of the by-establishment variances of the $(d = 15) \times 1$, $\{\mathbf{x}_i\}$ for establishments, $i = 1, \dots, N_h$, assigned to each stratum, $h = 1, \dots, H$. Each generated sample produces the by-stratum sample sizes, $\mathbf{n} = (45, 90, 136, 181, 227, 272, 318, 363, 409, 459)$, ordered according to variance quantile, from left-to-right, for a total sample size of $n = \sum_{h=1}^H n_h = 2500$. This sampling design assigns higher probabilities to larger variance strata (and all establishments in each stratum have an equal probability of selection), which is often done, in practice, because there is expected to be more information in these strata.

The population of establishments are assigned to clusters based on the mean values of \mathbf{x}_i , not the associated variances (as the variances in each cluster are roughly equal). We conversely use the variance of each \mathbf{x}_i rather than the mean, in order to construct our sampling design with the goal to produce sampling inclusion probabilities that are nearly independent from the probabilities of assignment to the population clusters. So our model formulation doesn't (inadvertently) parameterize the sampling design, which is the most general set-up.

We generate a population and subsequently draw $B = 100$ samples under our informative single stage, stratified sampling design with inclusion probabilities of each stratum proportional to the average of the variances of member establishment response values (across the $d = 15$ dimensions), as described above. We run our sampling-weighted global clustering algorithm on each sample under two alternative configurations: 1. excluding the sampling weights, so that we do not correct for the informative sampling design; 2. including the sampling weights, such that we estimate outliers and cluster centers with respect to the clustering parameters for the population, asymptotically, conditioned on the generation of the finite population from disjoint clusters. We include two methods as comparators; firstly, we utilize the model-based clustering (MBC) algorithm of Fraley and Raftery (2002) that defines a finite mixture of Gaussians model of similar form as our (penalized) mixtures of DPs construction. Fraley and Raftery (2002) employ the EM algorithm to solve their mixture model (initialized by a hierarchical agglomeration algorithm) and select the number of clusters, K , using the Bayesian information criterion (BIC); secondly, we include the trimmed K-means method of Fritz et al. (2012), which intends to robustify the K-means algorithm by removing outlying data points that may induce mis-estimation of the partition. The authors note that these outlying points may be used to nominate outliers. Both implementations exclude employment of sampling weights to correct for informative

sampling. We also considered to include the algorithm of Shotwell and Slate (2011), but it did not computationally scale to the size of data we contemplate for our CES application.

The left-hand set of box plots in Figure 5 displays the distributions (within 95% confidence intervals under repeated sampling) of the true positive rate for identifying outlying observations, constructed as the number of true outliers discovered divided by the total number of true outliers, estimated on each Monte Carlo iteration for our three comparator models. The right-hand set of box plots display the false positive rate, which we define as the number of false discoveries divided by the total number of observations nominated as outliers. The inclusion of false positives permits assessment of the efficiency to detect outliers. Each set of box plots compares estimation under the global clustering algorithm *including* sampling weights, on the one hand, to a version of the global clustering algorithm, the MBC, and trimmed K-means, on the other hand, that all *exclude* the sampling weights. Outliers were detected in each simulation iteration, $b = 1, \dots, B$, based on selecting those clusters whose total observations (among the selected clusters) cumulatively summed to less than $C = 1.1$ times the total number of true outliers in the informative sample, which is how we would select outlying clusters on a real dataset where we don't know the truth. (We experimented with different values of $C \in [1, 1.5]$ and realized the same comparative results, as presented below).

Figure 5 reveals that failure to account for the informative sampling design induces a deterioration in outlier detection accuracy.

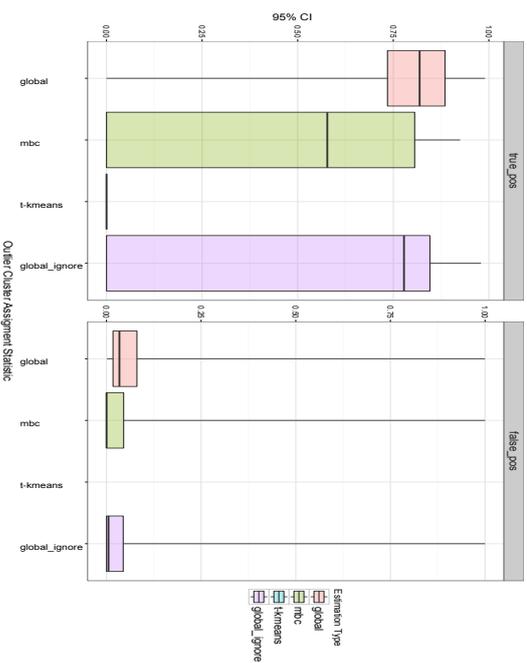

Figure 5: Accuracy of outlier detection under informative sampling. The left-hand plot panel presents the distributions of the true positive rates, and the right-hand panel presents the distribution for the false positive rates, both within 95% confidence intervals estimated from $B = 100$ Monte Carlo draws of informative samples. Each sample is of size, $n = 2500$, from a population of size, $N = 25000$, with a population cluster of outliers of size, $N_5 = 250$. The left-hand box plot within each plot panel is estimated from the sampling-weighted global clustering algorithm that accounts for the informative sampling design by including sampling weights, while the middle two box plots represent the model-based clustering (MBC) and trimmed K-means algorithms, respectively, that ignore the informative sampling design as does the right-hand box plot that represents the global clustering algorithm without inclusion of sampling weights.

Figure 6 presents the distribution over the number of discovered clusters for each of

the three comparator models: 1. global clustering model, *including* sampling weights; 2. MBC, *excluding* sampling weights; 3. Trimmed K-means, *excluding* sampling weights; 4. global clustering model, *excluding* sampling weights. The dashed line at $K = 5$ clusters is the correct generating value. While the the models excluding the sampling weights (except for the trimmed K-means) estimate a higher number of clusters, such is not the primary reason for their reduced outlier detection accuracy, as we observe from Figure 5 that the false positive rates are slightly lower for these two models compared to the model that includes the sampling weights. The reduced accuracy is primarily driven by biased estimation of the $d \times 1$ cluster centers, $\{\mu_{p_j}\}_{j=1,\dots,K}$, (relative to the population), whose estimation is performed together with assignment to clusters in a single iteration of the algorithm. We examine this bias in the next simulation study.

The trimmed K-means does relatively well in capturing the number of true clusters, absent the outlying cluster. The trimming is not isolating these points as outliers, however, but collapsing them into a larger cluster; hence, the trimmed k-means does not nominate any outliers.

3.3 Comparison of Outlier Estimation between Hierarchical and Global Clustering under Informative Sampling

We now generate a set of local partitions hierarchically linked to a collection of global cluster centers. We generate $J = 8$ local populations, $(\mathbf{X}^j)_{j=1,\dots,J}$, each of size $N_j = 25000$, and associated local partitions, $(\mathbf{s}^j)_{j=1,\dots,J}$, where each local partition contains, $L_j = 2$ clusters, including one that is composed of 150 outliers. The set of J local partitions randomly select their local cluster centers from the same $K = 5$ global cluster centers that we earlier introduced, which induces a dependence structure among the set of local partitions. We conduct $B = 100$ Monte Carlo draws, where we take an informative sample within each of the $J = 8$ datasets on each draw, using the same stratified sampling informative design, described above. Estimation is conducted on the set of J informative samples produced in each draw using both the sampling-weighted global clustering algorithm and the hierarchical clustering algorithm outlined in Section 2.4. Our goal is to uncover the global cluster center for the outlier cluster and the set of observations in each local dataset that are assigned to the outlier cluster. We concatenate the set of informative samples generated over the J datasets when conducting estimation using the global clustering algorithm because our primary interest is in outlier detection, rather than inference on the local partitions. (The performance of the global clustering algorithm relative to the hierarchical clustering algorithm is worse than shown in the case we separately estimate a global clustering on each dataset).

Figure 7 is of the same format as Figure 5, with two panels displaying distributions over true positive and false positive rates, respectively, for our choice of models. The set of five box plots compare the following models: 1. hierarchical clustering model, including the sampling weights to both estimate global partitions linked to a global partition and control for informative sampling; 2. global clustering model, including sampling weights to

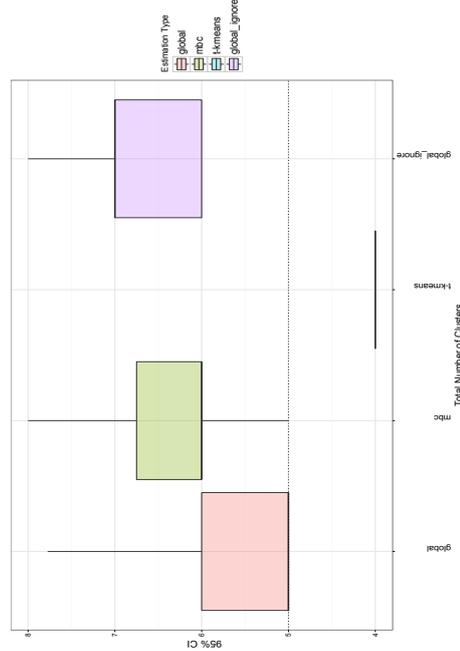

Figure 6: Comparison of distributions for number of estimated clusters, K , between the global clustering model including the sampling weights in the left-hand box plot, to the MBC in the middle box plot and the global clustering model in the right-hand box plot, where both exclude the sampling weights.

control for informative sampling; 3. model-based clustering, excluding sampling weights; 4. trimmed K-means robust clustering, excluding sampling weights; 5. global clustering model, excluding sampling weights. Results for the hierarchical clustering model, shown in the left-hand box plot of each panel, outperforms the global clustering model, where both include sampling weights, because the hierarchical model additionally estimates the dependent set of local clusters. The hierarchical clustering algorithm appears to do a better job of borrowing estimation information among the $J = 8$ local partitions.

Figure 8 presents distributions for each dimension, $d = 1, \dots, 15$, of the outlier cluster center, μ_5 , under four of the five comparison models (excluding the trimmed K-means) in the same order as displayed in Figure 7. The sampling-weighted hierarchical clustering model produces perfectly *unbiased* estimates for the population values of the global outlier cluster center, while the other 3 models (excluding the trimmed K-means) induce bias in proportion to their outlier detection performances. Unbiased estimation of the outlier cluster center as compared to the other clusters is important to detect an outlying cluster because the cluster centers encode the degree of separation of the outlying cluster(s) from the others. We see that the true positive detection rates across the methods shown in Figure 7 are roughly proportional to the levels of bias estimated in the dimensions of the outlying cluster center displayed in Figure 8. Since the trimmed K-means does not nominate any outliers, we cannot compute a outlying cluster center under this method.

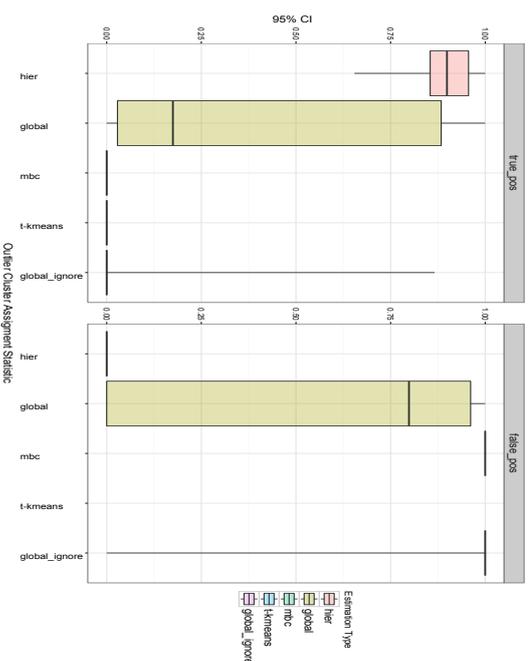

Figure 7: Accuracy of outlier detection under informative sampling for global vs hierarchical clustering model: The left-hand panel presents the distributions of the true positive rate, and the right-hand panel presents the distributions for the false positive rate, both within 95% confidence intervals estimated from $B = 100$ Monte Carlo draws of informative samples from each of $J = 8$ local populations. Each sample is of size, $n_j = 2500$, $j = 1, \dots, 8$, from a population of size, $N_j = 25000$, with a cluster of outliers of size, $N_{j,5} = 125$. The box plots represent the following models, from left-to-right: 1. hierarchical clustering model, including the sampling weights to both estimate global partitions linked to a global partition and control for informative sampling; 2. global clustering model, including sampling weights to control for informative sampling; 3. model-based clustering excluding sampling weights; 4. trimmed K-means, excluding sampling weights; 5. global clustering model excluding sampling weights.

We also examined the effect of excluding the merge move for the hierarchical clustering algorithm in this simulation study. While excluding the merge move induced an over-estimation of the the number of clusters (6 instead of the true 5), the outlier detection accuracy wasn't notably impacted, likely because employment of the C algorithm for selection of the number of local and global clustering penalty parameters protected against a large magnitude misestimation of the number of global and local clusters. We find a larger discrepancy between employment or not of the merge move for a *single* run of the clustering algorithm where the penalty parameters are set in an ad hoc fashion (e.g., through use of the farthest-first algorithm as in Kulis and Jordan (2011), a procedure that we do not recommend).

4. Application

We apply our hierarchical clustering algorithm to a data set of one month changes in CES survey responses for estimation of industry-indexed (local) partitions that may express a dependence structure across industries by potentially sharing global clusters. Outliers are nominated by selecting all establishment observations in any local cluster that holds a small percentage of observations (e.g. < 1%). Our CES survey application focuses on the set of 108017 establishments whose reported employment statistics differ between November and December, 2009 as a typical illustration. We are interested to flag those establishments whose responses express unusually large changes in employment statistics between November to December, relative to their November employment levels. So we normalize the observed statistics to,

$$\delta_{ijt} = \frac{x_{ijt}}{x_{ij(t-1)}}, j = 1, \dots, d \tag{7}$$

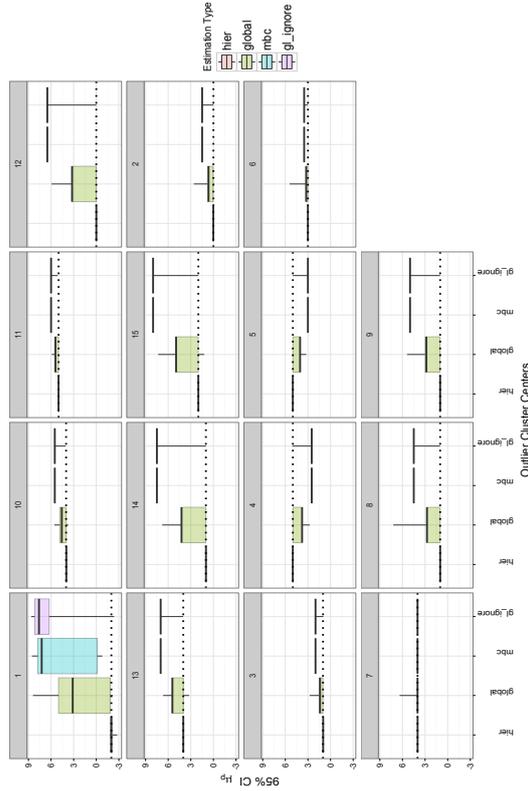

Figure 8: Comparison of estimation bias for each of $d = 15$ dimensions of the outlier global cluster mean, μ_5 , estimated from $J = 8$ local partitions under the following models, from left-to-right: 1. hierarchical clustering model, including the sampling weights to both estimate global partitions linked to a global partition and control for informative sampling; 2. global clustering model, including sampling weights to control for informative sampling; 3. model-based clustering, excluding sampling weights; 4. global clustering model, excluding sampling weights. The dashed line in each panel is the true value the center for each dimension, $d = 1, \dots, 15$

which has support on the positive real line that we, in turn, cluster. The distribution of δ_{jt} is highly right-skewed for all dimensions, $j \in \{1, \dots, d\}$, so we use a logarithm transform of the statistic to perform clustering in order to conform to the mixtures of Gaussians assumptions in Equation 5a. Alternatively, we could replace the squared Euclidean distance in Equation 6 with the Bregman divergence (which is uniquely specified for exponential family distributions) and replace the mixtures of Gaussian distributions with Exponential distributions, as suggested by Jiang et al. (2012) (which produces the same results on these data).

We focus on four employment variables of particular importance to CES (that also express high response rates): 1. “ae”, which is the total employment for each reporting establishment; 2. “pw”, which is production worker employment for each establishment; 3. “npr”, which is the total payroll dollars expended for employees of each establishment; 4. “nhr”, which is the average weekly hours worked for each establishment. So the dimension of our CES survey application is $d = 4$.

We select penalty parameters from the range, $(9 \leq \lambda_L \leq 829, 17 \leq \lambda_K \leq 187)$, on a 15×20 grid, using the Calinski Harabasz and silhouette statistics, which both choose $(\lambda_L = 19, \lambda_K = 145)$ from this grid. The selected penalty parameters did not change when including or excluding the merge step. Nevertheless, the number of clusters estimated without inclusion of the merge step was $K = 10$, while $K = 9$ was estimated when including the merge step. The resulting inference on the nomination of outliers, however, was unchanged so that we prefer the parsimonious model (in terms of number of clusters selected). The selected penalty parameters and resulting estimated clustering also did not change when we employed a finer grid. Results from inclusion of the merge step are presented in Table 1, where we discover $K = 9$ global clusters shared among the $J = 23$ local partitions, and each local partition holds between $L_j = 2 - 9$ clusters. Each column of Table 1 presents

the results for one of the $K = 9$ global clusters, from left-to-right in descending order of the number of establishments assigned to each global cluster. The first four rows (labeled “ae_ratio”, “pw_ratio”, “npr_ratio”, “nhr_ratio”) present the estimated global cluster centers, μ_{g_i} , for change ratio in ae, pw, npr, and nhr respectively, after reversing the logarithm transform. The fourth through final rows present the by-industry, local partitions, s_i^j , and their links to the global cluster centers. Scanning each of the columns, we see that all of the $K = 9$ global clusters are shared among the local partitions, indicating a high degree of dependence among them.

The fifth row (labeled “ae_avg”) averages the total employment, ae, over all establishments in all industries linked to the associated global cluster as reported for the month of November. The second column from the right represents a cluster whose centers indicate unusually large increases in reported employment and payroll from November-to-December. The establishments linked to this cluster are of generally small-sized, with an average of 20 reported employees in November. Establishments with a relatively small number of employees will receive high sampling weights due to their low inclusion probabilities, such that their high magnitude shifts in reported employment levels may be influential in the estimation of the sampling-weighted total employment estimates for November and December. It might, however, be expected that the retail (and associated wholesale) hiring might dramatically increase in anticipation of holiday shopping. So we would nominate the remaining 470 establishments linked to this global cluster as outliers for further analysis investigation by the BLS. Previous analysis conducted within the BLS suggests that smaller establishments generally tend to commit submission errors at a higher rate. The result excluding the merge step splits this cluster into two in a manner that doesn’t change inference about outlier nominations.

The smallest-size (right-most) cluster has a mean of 0.01 in the monthly change ratio for the variable “npr”, indicating an unusually large magnitude decrease in the number of employees (and payroll dollars) reported from November-to-December. This cluster contains 113 relatively large-sized establishments with an average of 278 reported employees in November. The moderate-to-large size of establishments in this cluster will tend to receive smaller sampling weights, however, (because they have higher sample inclusion probabilities), and so are less influential. So BLS would generally place a lower priority for investigation on this cluster than the previous discussed. The small number of establishments in this cluster, coupled with the large magnitude decreases in reported employment variables, however, would likely prompt an investigation of the submissions for all establishments in this cluster. The two Retail industries show 17 establishments in this cluster of establishments expressing a large decrease in employment. The seasonal hiring in this industry, mentioned above, may suggest to place an especially high priority on investigation of these establishments.

5. Discussion

The BLS seeks to maintain a short lead time for the CES survey between receipt of monthly establishment responses and publication of estimates. Retaining estimation quality requires investigation of establishment responses for errors, which may prove influential in published estimates (by region and industry, for example). BLS analysts, therefore, require an automated, fast-computing tool that nominates as outliers for further investigation a small subset of the over 100000 establishments whose responses reflect month-over-month changes in employment levels.

We have extended the MAP approximation algorithm of Kulis and Jordan (2011) and Broderick et al. (2012) for estimation of partitions among a set of observations to appli-

cations where the observations were acquired under an informative sampling design. We replace the usual likelihood in estimation of the joint posterior over partitions and associated cluster centers with a pseudo-likelihood that incorporates the first order sampling weights that serve to undo the sampling design. The resulting estimated parameters of the approximate MAP objective function are asymptotically unbiased with respect to the population, conditioned on the generation of the finite population from disjoint clusters. Our simulation study demonstrated that failure to correct for informative sampling reduces the outlier detection accuracy by inducing biased estimation of the cluster centers.

Our use of sampling-weighted partition estimation algorithms focuses on outlier detection, so we incorporated a new merge step, which may increase robustness against estimation of local optima and encourage discovery of clusters containing large numbers of observations, which may be a feature for outlier detection where we nominate as outliers those observations in clusters containing relatively few observations. We additionally constructed the sampling-weighted C statistic that our simulation study demonstrated was very effective for selection of the local and global cluster penalty parameters, (λ_L, λ_G) , that together determine the numbers of local and global clusters.

The sampling-weighted hierarchical clustering algorithm permitted our estimation of industry-indexed local clusters, which fits well into the BLS view that industry groupings tend to collect establishments with similar employment patterns and reporting processes. We saw that all of the estimated $K = 9$ global clusters for percentage change in employment from November to December, 2009 were shared among the local by-industry clusters, which served to both sharpen estimation of the local partitions and global cluster centers and to discover small global clusters of potentially outlying observations.

Appendix A. Hierarchical Clustering Algorithm

Loop over algorithm blocks, A.2 and A.3 until convergence.

Algorithm A.1: INITIALIZE LOCAL AND GLOBAL CLUSTER OBJECTS

Input: Set of $n_j \times d$ data matrices, $\{\mathbf{X}^j\}_{j=1,\dots,J}$, where each holds $1 \times d$ observations for n_j units in local dataset, j . Set of $n_j \times 1$ vectors, $\{\mathbf{w}^j\}$ of sampling weights for n_j units in local dataset, j . λ_L , local cluster penalty parameter. λ_K , global cluster penalty parameter.

Output: $K \times d$, $\mathbf{M} = (\mu_1, \dots, \mu_K)$, a matrix of $1 \times d$ global cluster centers for $p = 1, \dots, K$ global clusters. A set of $n_j \times 1$ vectors, $\{s^j\}_{j=1,\dots,J}$, where $s^j \in \{1, 2, \dots, K\}$, linking units in each dataset, \mathbf{X}^j , to a global cluster, $p \in \{1, \dots, K\}$. The number of unique values in s^j , denoted by L_j , specifies the local partition structure for dataset, \mathbf{X}^j .

- 1 **Initialize:** Initialize number of global clusters, $K = 1$.
- 2 **for** $j \leftarrow 1$ **to** J **do**
 - 3 $L_j \times 1$, v^j records link of each local cluster, $c \in \{1, \dots, L_j\}$, to global cluster, $p \in \{1, \dots, K\}$. Initialize $L_j = 1$ and $v_{L_j}^j = 1$.
 - 4 $n_j \times 1$, \mathbf{z}^j , records link of each unit, i , in dataset, j , to a local cluster, $c \in \{1, \dots, L_j\}$. Initialize $z_i^j = 1$, $\forall i$.
 - 5 $n_j \times 1$, \mathbf{s}^j records link of each unit, i , in dataset, j to a global cluster, $p \in \{1, \dots, K\}$. Initialize $s_i^j \leftarrow v_{z_i^j}^j$, $\forall i$.
- 6 Set $d \times 1$ cluster center, $\mu_1 \leftarrow \left(\sum_{j=1}^J \sum_{i=1}^{n_j} \tilde{w}_i^j \mathbf{x}_i^j \right) / \left(\sum_{j=1}^J \sum_{i=1}^{n_j} \tilde{w}_i^j \right)$.
- 7 Compute energy,

$$e \leftarrow \sum_{p=1}^K \sum_{j=1}^J \sum_{i \in \{i: s_i^j = p\}} \tilde{w}_i^j \left\| \mathbf{X}_i^j - \mu_p \right\|^2 + \lambda_K K + \lambda_L L$$
, where $L = \sum_{j=1}^J L_j$.

45

Algorithm A.2: BUILD LOCAL AND GLOBAL CLUSTERS

1 Assignment of units to global clusters.

- 2 **for** $j \leftarrow 1$ **to** J **and** $i \leftarrow 1$ **to** n_j **do**
 - 3 Compute distance metric, $d_{ijp} = \tilde{w}_i^j \left\| \mathbf{X}_{i,1:d}^j - \mu_p \right\|^2$ for $p = 1, \dots, K$.
 - 4 For those global clusters, p , not linked to any local cluster in j , $\{p : v_p^j \neq p, \forall c \in \{1, \dots, L_j\}\}$,
 - 5 $d_{ijp} \leftarrow d_{ijp} + \lambda_L$ (since must add local cluster if assign i to p).
 - 6 **if** $\min_p d_{ijp} > \lambda_L + \lambda_K$ **then**
 - 7 Create new local cluster linked to new global cluster.
 - 8 $L_j \leftarrow L_j + 1$, $z_i^j = L_j$
 - 9 $K \leftarrow K + 1$, $\mu_K \leftarrow \mathbf{X}_i^j$, $v_{L_j}^j \leftarrow K$
 - 10 **else**
 - 11 Let $\hat{p} \leftarrow \operatorname{argmin}_p d_{ijp}$.
 - 12 **if** $v_i^j = \hat{p}$ for some $c \in \{1, \dots, L_j\}$ **then**
 - 13 | Assign unit i in j to local cluster c , $z_i^j \leftarrow c$ and $v_c^j = \hat{p}$.
 - 14 **else**
 - 15 | Create new local cluster for unit i and link to global cluster, \hat{p} .
 - 16 | $L_j \leftarrow L_j + 1$ and $z_i^j = L_j$ and $v_{L_j}^j = \hat{p}$.

17 Re-assignment of (all units in) local clusters to global clusters.

- 18 **for** local partitions, $j \leftarrow 1$ **to** J **and** local cluster, $c \leftarrow 1$ **to** L_j **do**
 - 19 Let $\mathbf{z}_c^j = \{i : \mathbf{z}^j = c\}$ and $1 \times d$, $\mu_{jc} = \left(\sum_{i \in \mathbf{z}_c^j} \tilde{w}_i^j \mathbf{x}_i^j \right) / \left(\sum_{i \in \mathbf{z}_c^j} \tilde{w}_i^j \right)$.
 - 20 Compute sum of local-to-global cluster distances:

$$d_{jcp} = \sum_{i \in \mathbf{z}_c^j} \tilde{w}_i^j \left\| \mathbf{X}_i^j - \mu_p \right\|^2$$
, for $p = 1, \dots, K$.
 - 21 **if** $\min_p d_{jcp} > \lambda_K + \sum_{i \in \mathbf{z}_c^j} \tilde{w}_i^j \left\| \mathbf{X}_i^j - \mu_{jc} \right\|^2$ **then**
 - 22 | Set $K \leftarrow K + 1$, $v_c^j = K$, and $\mu_K = \mu_{jc}$
 - 23 **else** $v_c^j \leftarrow \operatorname{argmin}_p d_{jcp}$
- 25 **Shed global clusters no longer assigned to any local clusters.**
- 26 **for** $p \leftarrow 1$ **to** K **global clusters do**
 - 27 **if** $v^j \neq p$, $\forall j \in \{1, \dots, J\}$ **then**
 - 28 | Recode global cluster labels in v^j such that $p' \leftarrow p - 1$, $\forall p' > p$
 - 29 Set $K \leftarrow K - 1$
 - 30 Delete cluster center for p , $\mathbf{M} \leftarrow \mathbf{M}_{-p,1:d}$.
 - 31 **for** local partitions, $j \leftarrow 1$ **to** J **and** units, $i \leftarrow 1$ **to** n_j **do**
 - 32 | $s_i^j \leftarrow v_{z_i^j}^j$.
- 33 **Re-compute global cluster centers**
- 34 **for** $p \leftarrow 1$ **to** K **global clusters do**
 - 35 **for** $j \leftarrow 1$ **to** J **datasets do**
 - 36 | Compute units in j assigned to global cluster p , $\mathbf{S}_{jp} = \{i : s_i^j = p\}$;
 - 37 | Compute $\mu_p = \left(\sum_{j=1}^J \sum_{i \in \mathbf{S}_{jp}} \mathbf{x}_i^j \tilde{w}_i^j \right) / \sum_{j=1}^J \sum_{i \in \mathbf{S}_{jp}} \tilde{w}_i^j$.

46

Algorithm A.3: MERGE GLOBAL CLUSTERS

```

1  Compute energy of current state,  $e \leftarrow \sum_{p=1}^K \sum_{j=1}^J \sum_{i \in (i: s_i^j = p)} \tilde{w}_i^j \left\| \mathbf{x}_i^j - \boldsymbol{\mu}_p \right\|^2 + \lambda_K K + \lambda_L L$ 
2  for  $p \leftarrow 2$  to  $K$  and  $p' \leftarrow 1$  to  $(p-1)$  do
3      Perform test merge for each pair of global clusters.
4      Set matrix of cluster centers for virtual step,  $\mathbf{M}^* \leftarrow \mathbf{M}$ .
5      for local partitions,  $j \leftarrow 1$  to  $J$  do
6          Let  $\mathbf{S}_{j,p'}^* = \{i : s_i^j = p'\}$ 
7          if  $|\mathbf{S}_{j,p'}^*| > 0$  then
8              [ There are some units in  $\mathbf{s}^j$  assigned to global cluster,  $p'$ , Re-assign units linked
9                  to  $p$  to  $p$ .  $\mathbf{S}_{j,p}^* = \{i : s_i^j = p \text{ or } s_i^j = p'\}$  ]
10             Compute merged cluster centers,  $\boldsymbol{\mu}_{p'}^* = \left( \sum_{j=1}^J \sum_{i \in \mathbf{S}_{j,p}^*} \mathbf{x}_i^j \tilde{w}_i^j \right) / \sum_{j=1}^J \sum_{i \in \mathbf{S}_{j,p}^*} \tilde{w}_i^j$ 
11             Set  $\mathbf{M}_{p',1:d}^* \leftarrow \mathbf{M}_{p,1:d}^*$ 
12             Compute number of local clusters shed if merge global cluster,  $(p', p)$ .
13             for local partitions,  $j \leftarrow 1$  to  $J$  do
14                 [ Local clusters linked to  $p', p$ :  $\mathbf{c}_{j,p'} = \{c : \mathbf{v}^j = p'\}$  and  $\mathbf{c}_{j,p} = \{c : \mathbf{v}^j = p\}$ ,
15                      $L_{j,p'} = |\mathbf{c}_{j,p'}|$  and  $L_{j,p} = |\mathbf{c}_{j,p}|$  ]
16             Reduced number of local clusters,  $L^* = L - \sum_{j=1}^J L_{j,p}$ , and global clusters,  $K^* \leftarrow K - 1$ .
17             Compute energy under the test merge,
18              $e^* \leftarrow \sum_{p=1}^K \sum_{j=1}^J \sum_{i \in \mathbf{S}_{j,p}^*} \tilde{w}_i^j \left\| \mathbf{x}_i^j - \boldsymbol{\mu}_{p'}^* \right\|^2 + \lambda_K K^* + \lambda_L L^*$ 
19             if  $e^* < e$  then
20                 Execute merge of global clusters,  $p$  and  $p'$ 
21                 for local partitions,  $j \leftarrow 1$  to  $J$  do
22                     if  $L_{j,p'} > 0$  then
23                         [ Cluster  $p'$  is linked to local partition,  $j$ .
24                             if  $L_{j,p} = 0$  then  $\mathbf{v}_{\mathbf{c}_{j,p'}}^j \leftarrow p$ 
25                             else
26                                 [ Reassign local clusters linked to  $p'$  to  $p$ .
27                                      $\mathbf{z}_{\mathbf{c}_{p'}^j}^j = \{i : \mathbf{z}^j \in \mathbf{c}_{j,p'}\}$  and  $\mathbf{z}_{\mathbf{c}_{p'}^j}^j \leftarrow \mathbf{c}_{j,p}$ .
28                                     Remove now empty local clusters linked to  $p'$ ,  $\mathbf{v}^j \leftarrow \mathbf{v}_{-\mathbf{c}_{p'}^j}^j$ .
29                                     Recode  $\mathbf{z}^j$  local cluster assignments so labels are contiguous by setting
30                                          $c \leftarrow c - 1, \forall c > \mathbf{c}_{j,p'}$ .
31                                     Recode global cluster labels in  $\mathbf{v}^j$  such that  $p \leftarrow p - 1, \forall p > p'$  ]
32                                 Remove global cluster center for  $p'$ .
33                                  $\mathbf{M}^* \leftarrow \mathbf{M}_{-p',1:d}^*$ 
34                                 for units,  $i \leftarrow 1$  to  $n_j$  do
35                                     [  $s_i^j \leftarrow \mathbf{v}_{z_i^j}^j$  ]
36                                  $\mathbf{M} \leftarrow \mathbf{M}^*$

Abstract

Approximate Newton methods are standard optimization tools which aim to maintain the benefits of Newton's method, such as a fast rate of convergence, while alleviating its drawbacks, such as computationally expensive calculation or estimation of the inverse Hessian. In this work we investigate approximate Newton methods for policy optimization in Markov decision processes (MDPs). We first analyse the structure of the Hessian of the total expected reward, which is a standard objective function for MDPs. We show that, like the gradient, the Hessian exhibits useful structure in the context of MDPs and we use this analysis to motivate two Gauss-Newton methods for MDPs. Like the Gauss-Newton method for non-linear least squares, these methods drop certain terms in the Hessian. The approximate Hessians possess desirable properties, such as negative definiteness, and we demonstrate several important performance guarantees including guaranteed ascent directions, invariance to affine transformation of the parameter space and convergence guarantees. We finally provide a unifying perspective of key policy search algorithms, demonstrating that our second Gauss-Newton algorithm is closely related to both the EM algorithm and natural gradient ascent applied to MDPs, but performs significantly better in practice on a range of challenging domains.

Keywords: Markov decision processes, reinforcement learning, Newton method, function approximation

1. Introduction

Markov decision processes (MDPs) are the standard model for optimal control in a fully observable environment (Bertsekas, 2010). Strong empirical results have been obtained in numerous challenging real-world optimal control problems using the MDP framework. This includes problems of non-linear control (Stengel, 1993; Li and Todorov, 2004; Todorov and

Tassa, 2009; Deisenroth and Rasmussen, 2011; Rawlik et al., 2012; Spall and Cristion, 1998; Levine and Koltun, 2013b; Schulman et al., 2015; Heess et al., 2015; Lillicrap et al., 2016), robotic applications (Kober and Peters, 2011; Kohl and Stone, 2004; Vlassis et al., 2009), biological movement systems (Li, 2006), traffic management (Richter et al., 2007; Srinivasan et al., 2006), helicopter flight control (Abbeel et al., 2007), elevator scheduling (Crites and Barto, 1995) and numerous games, including chess (Veness et al., 2009), go (Silver et al., 2016; Gelly and Silver, 2008), backgammon (Tesauro, 1994) and Atari 2600 video games (Mnih et al., 2015; Schulman et al., 2015).

It is well known that the global optimum of a MDP with finite state and action sets can be obtained through methods based on dynamic programming, such as value iteration (Bellman, 1957) and policy iteration (Howard, 1960). However, these techniques are known to suffer from the curse of dimensionality, which makes them infeasible for many real-world problems of interest. As a result, most research in the reinforcement learning and control theory literature has focused on obtaining approximate or locally optimal solutions. There exists a broad spectrum of such techniques, including approximate dynamic programming methods (Bertsekas, 2010; Mnih et al., 2015), tree search methods (Russell and Norvig, 2009; Kocsis and Szepesvári, 2006; Browne et al., 2012; Silver et al., 2016), local trajectory-optimization techniques, such as differential dynamic programming (Jacobson and Mayne, 1970) and iLQG (Li and Todorov, 2006), and policy search methods (Williams, 1992; Baxter and Bartlett, 2001; Sutton et al., 2000; Marbach and Tsitsiklis, 2001; Kakade, 2002; Kober and Peters, 2011; Levine and Koltun, 2013b; Silver et al., 2014; Schulman et al., 2015; Heess et al., 2015; Lillicrap et al., 2016).

The focus of this paper is on policy search methods, which are a family of algorithms that have proven extremely popular in recent years, and which have numerous desirable properties that make them attractive in practice. Policy search algorithms are typically specialized applications of techniques from numerical optimization (Nocedal and Wright, 2006; Dempster et al., 1977). As such, the controller is given a differentiable parameterisation and an objective function is defined in terms of this parameterisation. Local information about the objective function, such as the gradient, is then used to update the parameters of the controller in an incremental manner until the algorithm converges to a local optimum of the objective function. There are several benefits to such an approach: the smooth updates of the control parameters endow these algorithms with very general convergence guarantees; as performance is improved at each iteration (or at least on average in stochastic policy search methods) these algorithms have good anytime performance properties; it is not necessary to approximate the value function, which is typically a difficult function to approximate—instant it is only necessary to approximate a low-dimensional projection of the value function, an observation which has led to the emergence of so called *actor-critic* methods (Konda and Tsitsiklis, 2003, 1999; Bhatnagar et al., 2008, 2009); policy search methods are easily extendable to models for optimal control in a partially observable environment, such as the Finite State Controllers (Meuleau et al., 1999; Toussaint et al., 2006).

In (stochastic) gradient ascent (Williams, 1992; Baxter and Bartlett, 2001; Sutton et al., 2000) the control parameters are updated by moving in the direction of the gradient of an objective function. While gradient ascent has enjoyed some success, it suffers from serious issues that can hinder its performance: specifically, it is not scale invariant (Nocedal and

Wright, 2006) and the search direction is often poorly-scaled, i.e., the variation of the objective function differs dramatically along the different components of the gradient. Poor scaling of the gradient leads to a poor rate of convergence (Noceval and Wright, 2006). It also makes the construction of a good step size sequence a difficult problem, which is an important issue in stochastic methods.¹ Poor scaling is a well known problem with gradient ascent and alternative numerical optimization techniques have been considered in the policy search literature. Two approaches that have proven to be particularly popular are expectation maximization (Dempster et al., 1977) and natural gradient ascent (Amari, 1997, 1998; Amari et al., 1992), which have both been successfully applied to various challenging MDPs (see the works of Dayan and Hinton (1997); Kober and Peters (2009); Toussaint et al. (2011); Levine and Kolthun (2013a) and Kakade (2002); Bagnell and Schneider (2003) respectively).

An avenue of research that has received less attention is the application of Newton’s method to Markov decision processes. Although such an extension of the *GPOMDP* algorithm is provided in the work of Baxter and Bartlett (2001), they give no empirical results in either that article or the accompanying paper of empirical comparisons (Baxter et al., 2001). There has since been only a limited amount of research into using the second order information contained in the Hessian during the parameter update. To the best of our knowledge only two attempts have been made: in the work of Schraudolph et al. (2006) an on-line estimate of a Hessian-vector product is used to adapt the step size sequence in an on-line manner; in the work of Ngo et al. (2011), Bayesian policy gradient methods (Ghahramanah and Engel, 2007) are extended to Newton’s method. There are several reasons for this lack of interest. Firstly, in many problems the construction and inversion of the Hessian is too computationally expensive to be feasible. Additionally, the objective function of a MDP is typically not concave, and so the Hessian is not guaranteed to be negative-definite. As a result, the search direction of Newton’s method may not be an ascent direction, and hence a parameter update could actually lower the objective. Additionally, the variance of sample-based estimators of the Hessian will be larger than that of estimators of the gradient. This is an important point because the variance of gradient estimates can be a problematic issue and various methods, such as baselines (Weaver and Tao, 2001; Greensmith et al., 2004), exist to reduce the variance.

Many of these problems are not particular to Markov decision processes, but are general longstanding issues that plague Newton’s method. Various methods have been developed in the optimization literature to alleviate these issues, while also maintaining desirable properties of Newton’s method. For instance, quasi-Newton methods were designed to efficiently mimic Newton’s method using only evaluations of the gradient obtained during previous iterations of the algorithm. These methods have low computational costs, a super-linear rate of convergence and have proven to be extremely effective in practice. See the work of Nocedal and Wright (2006) for an introduction to quasi-Newton methods. Alternatively, the well-known Gauss-Newton method is a popular approach that aims to efficiently mimic Newton’s method. The Gauss-Newton method is particular to non-linear least squares objective functions, for which the Hessian has a particular structure. Due to this structure there exist certain terms in the Hessian that can be used as a useful proxy for the Hessian

itself, with the resulting algorithm having various desirable properties. For instance, the preconditioning matrix used in the Gauss-Newton method is guaranteed to be positive-semidefinite, so that the non-linear least squares objective is guaranteed not to increase for a sufficiently small step size.

While a straightforward application of quasi-Newton methods will not typically be possible for MDPs,² in this paper we consider whether an analogue to the Gauss-Newton method exists, so that the benefits of such methods can be applied to MDPs. The specific contributions are as follows:

- In Section 3, we present an analysis of the Hessian of the total expected reward, which is a standard objective function for MDPs. Our starting point is a derivation of the Hessian for the total expected reward (Theorem 3) and we analyse the behavior of individual terms of the Hessian to provide insight into constructing efficient approximate Newton methods for policy optimization. In particular, we provide conditions under which certain terms become negligible near local optima.

- Motivated by this analysis, in Section 4 we provide two Gauss-Newton type methods for policy optimization in MDPs. These methods retain certain terms of our Hessian decomposition in the preconditioner in a gradient-based policy search algorithm. The first method discards terms which are difficult to approximate and which, for appropriately selected classes of controller, will become negligible near local optima. The second method further discards an additional term which is not guaranteed to be negative semi-definite. We provide an analysis of our Gauss-Newton methods and give several important performance guarantees for the second Gauss-Newton method: We demonstrate that the preconditioning matrix is negative-semidefinite when the controller is log-concave in the control parameters (detailing some widely used controllers for which this condition holds) guaranteeing that the search direction is an ascent direction; We show that the method is invariant to affine transformations of the parameter space and thus does not suffer the significant drawback of gradient ascent. We provide a convergence analysis, demonstrating linear convergence to local optima, in terms of the step size of the update.

Our methods apply to finite and continuous state and action sets. For simplicity of exposition we have presented results for the finite case to avoid measurability considerations. Some of our experiments have continuous state and action sets. Similarly our method is suitable for unknown transition dynamics, but can also be trivially used in a model-based approach with a known or estimated dynamics model.

- In Section 5 we present a unifying perspective for several policy search methods. In particular we relate the search direction of our second Gauss-Newton algorithm to that of expectation maximization (which provides new insights into the latter algorithm when used for policy search), and we also discuss its relationship to the natural gradient algorithm.

2. In quasi-Newton methods, to ensure an increase in the objective function, it is necessary to satisfy the secant condition (Nocedal and Wright, 2006). This condition is satisfied when the objective is concave/convex or the strong Wolfe conditions are met during a line search. For this reason, stochastic applications of quasi-Newton methods has been restricted to convex/concave objective functions (Schraudolph et al., 2007).

1. This is because line search techniques lose much of their desirability in stochastic numerical optimization algorithms, due to variance in the evaluations.

- In Section 6 we present experiments demonstrating state-of-the-art performance on challenging domains including Tetris and robotic arm applications.

2. Preliminaries and Background

In Section 2.1 we introduce Markov decision processes, along with some standard terminology relating to these models that will be required throughout the paper. In Section 2.2 we introduce policy search methods and provide an overview of the literature.

2.1 Markov Decision Processes

In a Markov decision process an *agent*, or *controller*, sequentially interacts with an environment by selecting actions (based on the current state of the environment) after which the system transitions to a new state (often in a stochastic manner) and the agent receives a scalar reward (dependent upon the selected action and the state of the environment). The optimality of an agent’s behavior is measured in terms of the total (discounted) reward the agent can expect to receive, so that optimal control is obtained when this quantity is maximized.

Formally a MDP is described by the tuple $(\mathcal{S}, \mathcal{A}, D, P, R)$, in which \mathcal{S} and \mathcal{A} are sets, known respectively as the state and action space, D is the initial state distribution, which is a distribution over the state space, P encodes the transition dynamics using a set of conditional distributions over the state space, $\{P(\cdot|s, a)\}_{(s, a) \in \mathcal{S} \times \mathcal{A}}$, and $R : \mathcal{S} \times \mathcal{A} \rightarrow [0, R_{\max}]$ is the (possibly stochastic³) reward function, which is assumed to be bounded and non-negative.⁴ We use the notation s_t and a_t to denote the random variable of the state and action of the t^{th} time step, $t \in \mathbb{N}$, respectively. The state at the initial time step is determined by the initial state distribution, $s_1 \sim D(\cdot)$. At any given time step, $t \in \mathbb{N}$, and given the state of the environment, the agent selects an action, $a_t \sim \pi(\cdot|s_t)$, according to the *policy* π . The next state is determined according to the transition dynamics, $s_{t+1} \sim P(\cdot|a_t, s_t)$. At each time step the agent receives a scalar reward, which is determined by the reward function.

In this paper we consider the total expected reward, which is a standard objective function in the reinforcement learning literature (Bertsekas, 2010). We shall consider the infinite horizon discounted reward framework. In this framework there is a discount factor, $\gamma \in [0, 1)$, and the objective function takes the form,

$$U(\pi) := \sum_{t=1}^{\infty} \mathbb{E}_{s_t, a_t \sim p_t} \left[\gamma^{t-1} R(s_t, a_t); \pi \right]. \quad (1)$$

3. For notational convenience we shall consider a deterministic reward function in this paper. The extension to the case of a stochastic reward function can be done by considering the expectation over the reward function where appropriate.
4. Given either an episodic finite horizon or a discounted infinite horizon MDP in which the reward function is bounded but not necessarily non-negative, one can construct an auxiliary MDP that has a bounded non-negative reward function and has the same optimal policies as the original MDP. This can be achieved, for example, by setting the reward function of the auxiliary MDP as $R_{\text{auxiliary}}(s, a) = R(s, a) - \min_{(s, a) \in \mathcal{S} \times \mathcal{A}} R(s, a)$, which only requires knowledge of the lower bound of the reward function in the original MDP. The same is not true, however, of absorbing state MDPs with a discount factor of 1.

We use the semi-colon to identify parameters of the distribution, rather than conditioning variables. The distribution of s_t and a_t , which we denote by p_t , is given by the marginal at time t of the joint distribution over $(s_{1:t}, a_{1:t})$, with $s_{1:t} = (s_1, s_2, \dots, s_t)$, $a_{1:t} = (a_1, a_2, \dots, a_t)$, which is given by,

$$p(s_{1:t}, a_{1:t}; \pi) := \pi(a_t|s_t) \left\{ \prod_{\tau=1}^{t-1} P(s_{\tau+1}|s_{\tau}, a_{\tau}) \times \pi(a_{\tau}|s_{\tau}) \right\} D(s_1). \quad (2)$$

We use the notation $\xi_t := (s_1, a_1, s_2, a_2, \dots, s_t, a_t)$ to denote trajectories through the state-action space of length, $t \in \mathbb{N}$. We use ξ to denote trajectories that are of infinite length, and use Ξ to denote the space of all such trajectories. Given a trajectory, $\xi \in \Xi$, we use the notation $\bar{R}(\xi)$ to denote the total discounted reward of the trajectory, so that $\bar{R}(\xi) = \sum_{t=1}^{\infty} \gamma^{t-1} R(s_t, a_t)$. Similarly, we use the notation $p(\xi; \pi)$ to denote the probability of generating the trajectory ξ under the policy π .

We now introduce several functions that are of central importance. The state value function w.r.t. policy π is defined as the total expected future reward given the current state,

$$V_{\pi}(s) := \sum_{s_1, a_1 \sim p_1}^{\infty} \left[\gamma^{t-1} R(s_t, a_t) \mid s_1 = s; \pi \right].$$

It can be seen that, $U(\pi) = \mathbb{E}_{s \sim D} [V_{\pi}(s)]$. The state value function can also be written as the solution of the following fixed-point equation, $V_{\pi}(s) = \mathbb{E}_{a \sim \pi(\cdot|s)} \left[R(s, a) + \gamma \mathbb{E}_{s' \sim P(\cdot|s, a)} [V_{\pi}(s')] \right]$, which is known as the Bellman equation (Bertsekas, 2010). The state-action value function w.r.t. policy π is given by,

$$Q_{\pi}(s, a) := R(s, a) + \gamma \mathbb{E}_{s' \sim P(\cdot|s, a)} [V_{\pi}(s')], \quad (3)$$

and gives the value of performing an action, in a given state, and then following the policy. Note that, $V_{\pi}(s) = \sum_{a \in \mathcal{A}} \pi(a|s) Q_{\pi}(s, a)$. Finally, the advantage function, $A_{\pi}(s, a) := Q_{\pi}(s, a) - V_{\pi}(s)$, gives the relative advantage of an action in relation to the other actions available in that state. It can be seen that, $\sum_{a \in \mathcal{A}} \pi(a|s) A_{\pi}(s, a) = 0$, for each $s \in \mathcal{S}$.

2.2 Policy Search Methods

In policy search methods the policy is given some differentiable parametric form, denoted $\pi(a|s; \mathbf{w})$, with policy parameters, $\mathbf{w} \in \mathcal{W} \subset \mathbb{R}^n$, $n \in \mathbb{N}$. (We also use the notation, $\pi_{\mathbf{w}}(a|s) \equiv \pi(a|s; \mathbf{w})$, where appropriate.) Local information, such as the gradient of the objective function, is then used to update the policy in an incremental manner until the algorithm converges to a local optimum of the objective function. We overload notation and write the objective function directly in terms of the parameter vector, i.e.,

$$U(\mathbf{w}) := U(\pi_{\mathbf{w}}), \quad \forall \mathbf{w} \in \mathcal{W}, \quad (4)$$

while the trajectory distribution is written in the form $p(a_{1:t}, s_{1:t}; \mathbf{w}) = p(a_{1:t}, s_{1:t}; \pi_{\mathbf{w}})$. Similarly, $V(s; \mathbf{w})$, $Q(s, a; \mathbf{w})$ and $A(s, a; \mathbf{w})$ denote respectively the state value function,

state-action value function and the advantage function in terms of the parameter vector \mathbf{w} . We introduce the function,

$$p_\gamma(s, a; \mathbf{w}) := \sum_{t=1}^{\infty} \gamma^{t-1} p_t(s_t = s, a_t = a; \mathbf{w}). \quad (5)$$

Note that $\sum_{(s,a) \in \mathcal{S} \times \mathcal{A}} p_\gamma(s, a; \mathbf{w}) = (1 - \gamma)^{-1}$. Additionally, the objective function can be written in the form $U(\mathbf{w}) = \sum_{(s,a) \in \mathcal{S} \times \mathcal{A}} p_\gamma(s, a; \mathbf{w}) R(s, a)$.

We shall consider two forms of policy search algorithm in this paper: gradient-based optimization methods and methods based on iteratively optimizing a lower-bound on the objective function. In gradient-based methods the update of the policy parameters takes the form,

$$\mathbf{w}^{\text{new}} = \mathbf{w} + \alpha \mathcal{M}(\mathbf{w}) \frac{\partial}{\partial \mathbf{w}} U(\mathbf{w}), \quad (6)$$

where $\alpha \in \mathbb{R}^+$ is a step size parameter and $\mathcal{M}(\mathbf{w})$ is some preconditioning matrix that possibly depends on $\mathbf{w} \in \mathcal{W}$. If U is smooth, $\mathcal{M}(\mathbf{w})$ is positive-definite and α is sufficiently small then such an update will increase the total expected reward. If the preconditioning matrix is always positive-definite, the step size sequence is appropriately selected and U is Lipschitz, which is the case when $\|\frac{\partial}{\partial \mathbf{w}} \log \pi(a|s; \mathbf{w})\|_2$ is uniformly bounded by $M \in \mathbb{R}$ for all $\mathbf{w} \in \mathcal{W}$ and $(a, s) \in \mathcal{A} \times \mathcal{S}$, then iteratively updating the policy parameters according to (6) will result in the policy parameters converging to a local optimum of U . This generic gradient-based policy search algorithm is given in Algorithm 1. Gradient-based methods vary in the form of the preconditioning matrix used in the parameter update. The choice of the preconditioning matrix determines various aspects of the resulting algorithm, such as the computational complexity; the rate at which the algorithm converges to a local optimum and invariance properties of the parameter update. Typically the gradient, $\frac{\partial}{\partial \mathbf{w}} U(\mathbf{w})$, and the preconditioner, $\mathcal{M}(\mathbf{w})$, will not be known exactly and must be approximated by collecting data from the system. In the context of reinforcement learning, the expectation maximization (EM) algorithm searches for the optimal policy by iteratively optimizing a lower bound on the objective function. While EM does not have an update of the form given in (6) we shall see in Section 5.2 that the algorithm is closely related to such an update. We now review specific policy search methods.

2.2.1 GRADIENT ASCENT

Gradient ascent corresponds to the choice $\mathcal{M}(\mathbf{w}) = I_n$, where I_n denotes the $n \times n$ identity matrix, so that the parameter update takes the form:

Policy search update using gradient ascent

$$\mathbf{w}^{\text{new}} = \mathbf{w} + \alpha \frac{\partial}{\partial \mathbf{w}} U(\mathbf{w}). \quad (7)$$

The gradient, $\frac{\partial}{\partial \mathbf{w}} U(\mathbf{w})$, can be written in a relatively simple form using the following theorem:

<p>Algorithm 1: Generic gradient-based policy search algorithm</p> <p>Input: Initial vector of policy parameters, $\mathbf{w}_0 \in \mathcal{W}$, and a step size sequence, $(\alpha_k)_{k=0}^{\infty}$ with $\alpha_k \in \mathbb{R}^+$ for $k \in \mathbb{N}$.</p> <p>Set iteration counter, $k \leftarrow 0$.</p> <p>repeat</p> <p> Either calculate or estimate the gradient of the objective, $\frac{\partial}{\partial \mathbf{w}} U(\mathbf{w}) _{\mathbf{w}=\mathbf{w}_k}$, and the preconditioner, $\mathcal{M}(\mathbf{w}_k)$, at the current point in the parameter space.</p> <p> Update policy parameters, $\mathbf{w}_{k+1} = \mathbf{w}_k + \alpha_k \mathcal{M}(\mathbf{w}_k) \frac{\partial}{\partial \mathbf{w}} U(\mathbf{w}) _{\mathbf{w}=\mathbf{w}_k}$.</p> <p> Update iteration counter, $k \leftarrow k + 1$.</p> <p>until Convergence of the policy parameters;</p> <p>return \mathbf{w}_k</p>

Theorem 1 (Policy Gradient Theorem (Sutton et al., 2000)). *Suppose we are given a Markov decision process with objective (1) and Markovian trajectory distribution (2). For any given parameter vector, $\mathbf{w} \in \mathcal{W}$, the gradient of (4) takes the form,*

$$\frac{\partial}{\partial \mathbf{w}} U(\mathbf{w}) = \sum_{s \in \mathcal{S}} \sum_{a \in \mathcal{A}} p_\gamma(s, a; \mathbf{w}) Q(s, a; \mathbf{w}) \frac{\partial}{\partial \mathbf{w}} \log \pi(a|s; \mathbf{w}). \quad (8)$$

Proof. This is a well-known result that can be found in Sutton et al. (2000). A derivation of (8) is provided in Section A.1 in the Appendix. \square

It is not possible to calculate the gradient exactly for many real-world MDPs of interest. For instance, in discrete domains the size of the state-action space may be too large for enumeration over these sets to be feasible. Alternatively, in continuous domains the presence of non-linearities in the transition dynamics makes the calculation of the occupancy marginals an intractable problem. Additionally, it can be the case that P and R are unknown in practice. In such cases it can be preferable to directly estimate the gradient using samples obtained from the environment, rather than building a model of the MDP. Various techniques have been proposed in the literature to estimate the gradient, including the method of finite-differences (Kiefer and Wolfowitz, 1952; Kohl and Stone, 2004; Tadrake and Zhang, 2005), simultaneous perturbation methods (Spall, 1992; Spall and Criston, 1998; Srinivasan et al., 2006) and likelihood-ratio methods (Glynn, 1986, 1990; Williams, 1992; Baxter and Bartlett, 2001; Konda and Tsitsiklis, 2003, 1999; Sutton et al., 2000; Bhatnagar et al., 2009; Kober and Peters, 2011). Likelihood-ratio methods, which originated in the statistics literature and were later applied to MDPs, are now the prominent method for estimating the gradient. There are numerous such methods in the literature, including Monte-Carlo methods (Williams, 1992; Baxter and Bartlett, 2001) and actor-critic methods (Konda and Tsitsiklis, 2003, 1999; Sutton et al., 2000; Bhatnagar et al., 2009; Kober and Peters, 2011). Gradient ascent is known to perform poorly on objective functions that are poorly-scaled, that is, if changes to some parameters produce much larger variations to the function than changes in other parameters. In this case gradient ascent zig-zags along the ridges of the

objective in the parameter space (see e.g., the work of Nocedal and Wright, 2006). It can be difficult to gauge an appropriate scale for the steps sizes in poorly-scaled problems and the robustness of optimization algorithms to poor scaling is of significant practical importance.

2.2.2 NATURAL GRADIENT ASCENT

Natural gradient ascent techniques originated in the neural network and blind source separation literature (Amari, 1997, 1998; Amari et al., 1996, 1992), and were introduced into the policy search literature in the work of Kakade (2002). To address the issue of poor scaling, natural gradient methods take the perspective that the parameter space should be viewed with a manifold structure in which the distance between two points on the manifold captures the discrepancy between the distribution over trajectories parameterized by the two corresponding parameter vectors. In natural gradient ascent $\mathcal{M}(\mathbf{w}) = G^{-1}(\mathbf{w})$ in (6), with $G(\mathbf{w})$ a suitable metric tensor for the manifold, so that the parameter update takes the form:

Policy search update using natural gradient ascent

$$\mathbf{w}^{\text{new}} = \mathbf{w} + \alpha G^{-1}(\mathbf{w}) \frac{\partial}{\partial \mathbf{w}} U(\mathbf{w}). \quad (9)$$

In the case of Markov decision processes a standard choice for $G(\mathbf{w})$ is the Fisher information matrix of the policy distribution, averaged over the state distribution, which takes the form,

$$G(\mathbf{w}) = \sum_{s \in \mathcal{S}} \sum_{a \in \mathcal{A}} p_\gamma(s, a; \mathbf{w}) \frac{\partial}{\partial \mathbf{w}} \log \pi(a|s; \mathbf{w}) \frac{\partial^\top}{\partial \mathbf{w}} \log \pi(a|s; \mathbf{w}). \quad (10)$$

It was shown in the work of Bagnell and Schneider (2003) that (10) corresponds to the Fisher information matrix of the distribution over trajectories in the state-action space, given π . The use of the Fisher information matrix can be viewed as imposing a local norm on the parameter space which is derived from a second order approximation to the KL-divergence between induced trajectory distributions (Coolen et al., 2005). For brevity we refer to this choice of $G(\mathbf{w})$ as *the* natural gradient algorithm. When the policy distribution satisfies the Fisher regularity conditions (see Lehmann and Casella, 1998, Lemma 5.3) there is an alternate, equivalent, form of the Fisher information matrix given by,

$$G(\mathbf{w}) = - \sum_{s \in \mathcal{S}} \sum_{a \in \mathcal{A}} p_\gamma(s, a; \mathbf{w}) \frac{\partial^2}{\partial \mathbf{w}^2} \log \pi(a|s; \mathbf{w}). \quad (11)$$

Equation (11) can be derived by differentiating the identity, $\sum_{a \in \mathcal{A}} \pi(a|s; \mathbf{w}) \frac{\partial}{\partial w_i} \log \pi(a|s; \mathbf{w}) = \sum_{a \in \mathcal{A}} \frac{\partial}{\partial w_i} \pi(a|s; \mathbf{w}) = 0$, with respect to w_j , and taking expectation over $s \in \mathcal{S}$. Other metric tensors have also been considered in the policy search literature, such as in the work of Morimura et al. (2008).

There are several desirable properties of the natural gradient approach: the Fisher information matrix is always positive-semidefinite, regardless of the policy parameterisation;

the search direction is invariant to the parameterisation of the policy, (Bagnell and Schneider, 2003; Peters and Schaal, 2008). Additionally, the natural gradient update direction can be obtained by regressing the state-action value function, or the advantage function, using a compatible function approximator (Sutton et al., 2000), and minimizing a square loss weighted by the (discounted) trajectory distribution (Kakade, 2002). Furthermore, natural gradient ascent has been shown to perform well in some difficult MDP environments, including Tetris (Kakade, 2002) and several challenging robotics problems (Peters and Schaal, 2008). However, theoretically, the rate of convergence of natural gradient ascent is the same as gradient ascent, i.e., linear, although, it has been noted to be substantially faster in practice.

2.2.3 EXPECTATION MAXIMIZATION

An alternative optimization procedure that has been the focus of much research in the planning and reinforcement learning communities is the EM-algorithm (Dayan and Hinton, 1997; Toussaint et al., 2006, 2011; Kober and Peters, 2009, 2011; Hoffman et al., 2009; Furmston and Barber, 2009, 2010; Levine and Koltun, 2013a). The EM-algorithm is a powerful optimization technique popular in the statistics and machine learning community (see e.g., the works of Dempster et al., 1977; Little and Rubin, 2002; Neal and Hinton, 1999) that has been successfully applied to a large number of problems. See the work of Barber (2012) for a general overview of some of the applications of the algorithm in the machine learning literature. Among the strengths of the algorithm are its guarantee of increasing the objective function at each iteration, its often simple update equations, and its generalization to highly intractable models through variational Bayes approximations (Saul et al., 1996).

Given the advantages of the EM-algorithm it is natural to extend the algorithm to the MDP framework. Several derivations of the EM-algorithm for MDPs exist (Kober and Peters, 2011; Toussaint et al., 2011). For reference, we state the lower-bound upon which the algorithm is based in the following theorem. The proof is based on an application of Jensen's inequality and can be found in the work of Kober and Peters (2011).

Theorem 2. *Suppose we are given a Markov decision process with objective (1) and Markovian trajectory distribution (2). Given any distribution, q , over the space of trajectories, Ξ , then the following bound holds,*

$$\log U(\mathbf{w}) \geq H(q(\xi)) + \mathbb{E}_{\xi \sim q(\cdot)} \left[\log(p(\xi; \mathbf{w}) \bar{R}(\xi)) \right], \quad \forall \mathbf{w} \in \mathcal{W}. \quad (12)$$

The distribution, q , in Theorem 2 is often referred to as the variational distribution. An EM-algorithm is obtained through coordinate-wise optimization of (12) with respect to the variational distribution (the E-step) and the policy parameters (the M-step). In the E-step the lower-bound is optimized when $q(\xi) \propto p(\xi; \mathbf{w}') \bar{R}(\xi)$, in which \mathbf{w}' are the current policy parameters. In the M-step the lower-bound is optimized with respect to \mathbf{w} , which, given $q(\xi) \propto p(\xi; \mathbf{w}') \bar{R}(\xi)$ and the Markovian structure of $\log p(\xi; \mathbf{w})$, is equivalent to optimizing the function,

$$\mathcal{Q}(\mathbf{w}, \mathbf{w}') = \sum_{(s, a) \in \mathcal{S} \times \mathcal{A}} p_\gamma(s, a; \mathbf{w}') Q(s, a; \mathbf{w}') \log \pi(a|s; \mathbf{w}), \quad (13)$$

with respect to the first parameter, \mathbf{w} . The E-step and M-step are iterated in this manner until the policy parameters converge to a local optimum of the objective function.

Alternative bound optimisation techniques exist in the policy search literature. For instance, the trust region policy optimisation algorithm (Schulman et al., 2015) is based on a generalisation of a lower-bound of the total expected reward given in the work of Kakade and Langford (2002). While the lower-bound is intractable in large-scale MDPs, the introduction of several heuristics enables the authors to obtain strong empirical results in both non-linear control problems and Atari games.

3. The Hessian of the Total Expected Discounted Return

In this section we provide an analysis of the Hessian of the total expected reward of a MDP. This analysis will then be used in Section 4 to propose Gauss-Newton type methods for MDPs. In Section 3.1 we provide a novel representation of the Hessian of the total expected reward, in Section 3.2 we detail the definiteness properties of certain terms in the Hessian and in Section 3.3 we analyse the behaviour of individual terms of the Hessian in the vicinity of a local optimum.

3.1 The Policy Hessian Theorem

There is a standard expansion of the Hessian of the total expected reward in the policy search literature (Baxter and Bartlett, 2001; Kakade, 2001, 2002) that, as with the gradient, takes a relatively simple form. This is summarized in the following result.

Theorem 3 (Policy Hessian Theorem). *Suppose we are given a Markov decision process with objective (1) and Markovian trajectory distribution (2). For any given parameter vector, $\mathbf{w} \in \mathcal{W}$, the Hessian of (4) takes the form,*

$$\mathcal{H}(\mathbf{w}) = \mathcal{H}_1(\mathbf{w}) + \mathcal{H}_2(\mathbf{w}) + \mathcal{H}_{12}(\mathbf{w}) + \mathcal{H}_{12}^\top(\mathbf{w}), \quad (14)$$

in which the matrices $\mathcal{H}_1(\mathbf{w})$, $\mathcal{H}_2(\mathbf{w})$ and $\mathcal{H}_{12}(\mathbf{w})$ can be written in the form,

$$\mathcal{H}_1(\mathbf{w}) := \sum_{s \in \mathcal{S}} \sum_{a \in \mathcal{A}} p_\gamma(s, a; \mathbf{w}) Q(s, a; \mathbf{w}) \frac{\partial}{\partial \mathbf{w}} \log \pi(a|s; \mathbf{w}) \frac{\partial^\top}{\partial \mathbf{w}} \log \pi(a|s; \mathbf{w}), \quad (15)$$

$$\mathcal{H}_2(\mathbf{w}) := \sum_{s \in \mathcal{S}} \sum_{a \in \mathcal{A}} p_\gamma(s, a; \mathbf{w}) Q(s, a; \mathbf{w}) \frac{\partial^2}{\partial \mathbf{w}^2} \log \pi(a|s; \mathbf{w}), \quad (16)$$

$$\mathcal{H}_{12}(\mathbf{w}) := \sum_{s \in \mathcal{S}} \sum_{a \in \mathcal{A}} p_\gamma(s, a; \mathbf{w}) \frac{\partial}{\partial \mathbf{w}} \log \pi(a|s; \mathbf{w}) \frac{\partial^\top}{\partial \mathbf{w}} Q(s, a; \mathbf{w}). \quad (17)$$

Proof. A derivation for a sample-based estimator of the Hessian can be found in Baxter and Bartlett (2001). For ease of reference a derivation of (14) is provided in Section A.1 in the Appendix. \square

We remark that $\mathcal{H}_1(\mathbf{w})$ and $\mathcal{H}_2(\mathbf{w})$ are relatively simple to estimate, in the same manner as estimating the policy gradient. The term $\mathcal{H}_{12}(\mathbf{w})$ is more difficult to estimate since it

contains terms involving the gradient, $\frac{\partial^\top}{\partial \mathbf{w}} Q(s, a; \mathbf{w})$, resulting in a double sum over state-actions.

Below we will present a novel form for the Hessian of the total expected reward, with attention given to the term $\mathcal{H}_1(\mathbf{w}) + \mathcal{H}_2(\mathbf{w})$ in (14), which will require the following notion of a parameterisation with constant curvature.

Definition 1. *A policy parameterisation is said to have constant curvature with respect to the action space, if for each $(s, a) \in \mathcal{S} \times \mathcal{A}$ the Hessian of the log-policy, $\frac{\partial^2}{\partial \mathbf{w}^2} \log \pi(a|s; \mathbf{w})$, does not depend upon the action, i.e.,*

$$\frac{\partial^2}{\partial \mathbf{w}^2} \log \pi(a|s; \mathbf{w}) = \frac{\partial^2}{\partial \mathbf{w}^2} \log \pi(a'|s; \mathbf{w}), \quad \forall a, a' \in \mathcal{A}.$$

A common class of policy which satisfies the property of Definition 1 is, $\pi(a|s; \mathbf{w}) \propto \exp(\mathbf{w}^\top \phi(a, s))$, in which $\phi(a, s)$ is a vector of features that depends on the state-action pair, $(a, s) \in \mathcal{A} \times \mathcal{S}$. Under this parameterisation,

$$\frac{\partial^2}{\partial \mathbf{w}^2} \log \pi(a|s; \mathbf{w}) = -\text{COV}_{a' \sim \pi(\cdot|s; \mathbf{w})}(\phi(a', s), \phi(a', s)),$$

which does not depend on, $a \in \mathcal{A}$. In the case when the action space is continuous, then the policy parameterisation $\pi(a|s; \mathbf{w}; \Sigma) \propto \exp(-\frac{1}{2}(a - \mathbf{w}^\top \phi(s))^\top \Sigma^{-1}(a - \mathbf{w}^\top \phi(s)))$, in which $\phi : \mathcal{S} \rightarrow \mathbb{R}^n$ is a given feature map, satisfies the properties of Definition 1 with respect to the mean parameters, $\mathbf{w} \in \mathcal{W}$.

We now present a novel decomposition of the Hessian for Markov decision processes.

Theorem 4. *Suppose we are given a Markov decision process with objective (1) and Markovian trajectory distribution (2). For any given parameter vector, $\mathbf{w} \in \mathcal{W}$, the Hessian of (4) takes the form,*

$$\mathcal{H}(\mathbf{w}) = \mathcal{A}_1(\mathbf{w}) + \mathcal{A}_2(\mathbf{w}) + \mathcal{H}_{12}(\mathbf{w}) + \mathcal{H}_{12}^\top(\mathbf{w}), \quad (18)$$

with,

$$\mathcal{A}_1(\mathbf{w}) := \sum_{(s, a) \in \mathcal{S} \times \mathcal{A}} p_\gamma(s, a; \mathbf{w}) A(s, a; \mathbf{w}) \frac{\partial}{\partial \mathbf{w}} \log \pi(a|s; \mathbf{w}) \frac{\partial^\top}{\partial \mathbf{w}} \log \pi(a|s; \mathbf{w}),$$

$$\mathcal{A}_2(\mathbf{w}) := \sum_{(s, a) \in \mathcal{S} \times \mathcal{A}} p_\gamma(s, a; \mathbf{w}) A(s, a; \mathbf{w}) \frac{\partial^2}{\partial \mathbf{w}^2} \log \pi(a|s; \mathbf{w}).$$

When the policy parameterization has constant curvature with respect to the action space, then the Hessian takes the form,

$$\mathcal{H}(\mathbf{w}) = \mathcal{A}_1(\mathbf{w}) + \mathcal{H}_{12}(\mathbf{w}) + \mathcal{H}_{12}^\top(\mathbf{w}). \quad (19)$$

Proof. See Section A.2 in the Appendix. \square

We now present an analysis of the terms of the policy Hessian, simplifying the expansion and demonstrating conditions under which certain terms disappear. The analysis will be used to motivate our Gauss-Newton methods in Section 4.

3.2 Analysis of the Policy Hessian

An interesting comparison can be made between the expansions (14) and (18, 19) in terms of the definiteness properties of the component matrices. As the state-action value function is non-negative over the entire state-action space, it can be seen that $\mathcal{H}_1(\mathbf{w})$ is positive-semidefinite for all $\mathbf{w} \in \mathcal{W}$. Similarly, it can be shown that under certain common policy parameterisations $\mathcal{H}_2(\mathbf{w})$ is negative-semidefinite over the entire parameter space. This is summarized in the following theorem.

Theorem 5. *The matrix $\mathcal{H}_2(\mathbf{w})$ is negative-semidefinite for all $\mathbf{w} \in \mathcal{W}$ if: 1) the policy is log-concave with respect to the policy parameters; or 2) the policy parameterisation has constant curvature with respect to the action space.*

Proof. See Section A.3 in the Appendix. \square

It can be seen, therefore, that when the policy parameterisation satisfies the properties of Theorem 5 the expansion (14) gives $\mathcal{H}(\mathbf{w})$ in terms of a positive-semidefinite term, $\mathcal{H}_1(\mathbf{w})$, a negative-semidefinite term, $\mathcal{H}_2(\mathbf{w})$, and a remainder term, $\mathcal{H}_{12}(\mathbf{w}) + \mathcal{H}_{12}^\top(\mathbf{w})$. In Section 3.3 we shall show that this remainder term becomes negligible around a local optimum when given a sufficiently rich policy parameterisation, in a sense that we introduce in Definition 2. In contrast to the state-action value function, the advantage function takes both positive and negative values over the state-action space. As a result, the matrices $\mathcal{A}_1(\mathbf{w})$ and $\mathcal{A}_2(\mathbf{w})$ in (18, 19) can be indefinite over parts of the parameter space.

3.3 Analysis in Vicinity of a Local Optimum

In this section we consider the term $\mathcal{H}_{12}(\mathbf{w}) + \mathcal{H}_{12}^\top(\mathbf{w})$, which is both difficult to estimate and not guaranteed to be negative definite. In particular, we shall consider the conditions under which this term becomes either negligible or vanishes completely at a local optimum. We start by noting that,

$$\begin{aligned} \mathcal{H}_{12}(\mathbf{w}) &= \sum_{(s,a) \in \mathcal{S} \times \mathcal{A}} p_\gamma(s,a;\mathbf{w}) \frac{\partial}{\partial \mathbf{w}} \log \pi(a|s;\mathbf{w}) \frac{\partial^\top}{\partial \mathbf{w}} \left(R(s,a) + \gamma \sum_{s'} p(s'|a,s) V(s';\mathbf{w}) \right), \\ &= \gamma \sum_{(s,a) \in \mathcal{S} \times \mathcal{A}} p_\gamma(s,a;\mathbf{w}) \frac{\partial}{\partial \mathbf{w}} \log \pi(a|s;\mathbf{w}) \sum_{s'} p(s'|a,s) \frac{\partial^\top}{\partial \mathbf{w}} V(s';\mathbf{w}). \end{aligned} \quad (20)$$

Our approach is to obtain a bound of, $\frac{\partial}{\partial w_i} V(s;\mathbf{w})|_{\mathbf{w}=\mathbf{w}^*}$, for all $s' \in \mathcal{S}$ and $i \in \{1, \dots, n\}$, when $\mathbf{w}^* \in \mathcal{W}$, is a local optimum of (4). Given such a bound it is then possible to obtain a bound on the term, $\mathcal{H}_{12}(\mathbf{w}) + \mathcal{H}_{12}^\top(\mathbf{w})$, at a local optimum. In the limit the bound gives conditions under which, $\frac{\partial}{\partial \mathbf{w}} V(s';\mathbf{w}) = \mathbf{0}$, for all $s' \in \mathcal{S}$, at a local optimum, thus giving sufficient conditions under which the term, $\mathcal{H}_{12}(\mathbf{w}) + \mathcal{H}_{12}^\top(\mathbf{w})$, vanishes at a local optimum. We start by introducing the notion of a ϵ -value-consistent policy class, with $\epsilon \in \mathbb{R}$, $\epsilon \geq 0$.

Definition 2. *Given $\epsilon \in \mathbb{R}$, with $\epsilon \geq 0$, then a policy parameterisation is said to be ϵ -value-consistent w.r.t. a Markov decision process if whenever $\frac{\partial}{\partial w_i} V(\hat{s};\mathbf{w}) \neq 0$ for some $\hat{s} \in \mathcal{S}$, $\mathbf{w} \in \mathcal{W}$ and $i \in \{1, \dots, n\}$, then $\forall s \in \mathcal{S}$ it holds that either,*

$$\text{sign} \left(\frac{\partial}{\partial w_i} V(s;\mathbf{w}) \right) = \text{sign} \left(\frac{\partial}{\partial w_i} V(\hat{s};\mathbf{w}) \right), \quad (21)$$

or

$$\left| \frac{\partial}{\partial w_i} V(s;\mathbf{w}) \right| \leq \epsilon. \quad (22)$$

Furthermore, for any state, $s \in \mathcal{S}$, for which, $\frac{\partial}{\partial w_i} V(s;\mathbf{w}) = 0$, it also holds that $\frac{\partial}{\partial w_i} \pi(a|s;\mathbf{w}) = 0$, $\forall a \in \mathcal{A}$. A policy parameterisation is said to be value-consistent if it is θ -value-consistent.

This property of a policy class captures the notion that when maximally improving the value in one state, then the amount that the value of another state can decrease is bounded. When a policy class is value-consistent, then changing a parameter to maximally improve the value in one state, does not worsen the value in another state. i.e., when a policy class is value-consistent, there is no trade-off between improving the value in different states.

Example. To illustrate the concept of a value-consistent policy parameterisation we now consider two simple maze navigation MDPs, one with a value-consistent policy parameterisation, and one with a policy parameterisation that is not value-consistent. The two MDPs are displayed in Figure 1. Walls of the maze are solid lines, while the dotted lines indicate state boundaries and are passable. The agent starts, with equal probability, in one of the states marked with an ‘S’. The agent receives a positive reward for reaching the goal state, which is marked with a ‘G’, and is then reset to one of the start states. All other state-action pairs return a reward of zero. The discount factor in both MDPs is 0.95. There are four possible actions (up, down, left, right) in each state, and the optimal policy is to move, with probability one, in the direction indicated by the arrow. We define the mapping, $o : \mathcal{S} \rightarrow \{0, 1\}^4$, which indicates the presence of a wall on each of the four state boundaries. We use the notation, $\mathcal{O} := \{o(s)|s \in \mathcal{S}\}$. We consider the policy parameterisation, $\pi(a|s;\mathbf{w}) \propto \exp(\mathbf{w}^\top \phi(a,s))$, in which, $\phi : \mathcal{A} \times \mathcal{S} \rightarrow \mathbb{R}^{3|\mathcal{O}|}$, is a feature map. We consider the feature map,

$$\phi(a,s) = \begin{cases} \mathbf{0} & \text{if } a = \text{up}, \\ \mathbf{e}_{i(o)+3j(s)} & \text{otherwise,} \end{cases}$$

in which, $i : \mathcal{A} \setminus \{\text{up}\} \rightarrow \{1, 2, 3\}$, is an index function over the actions, $\mathcal{A} \setminus \{\text{up}\}$, and $j : \mathcal{S} \rightarrow \{0, 1, \dots, |\mathcal{O}| - 1\}$, is an index function over the aliased states, i.e., $j(s) = j(s)$ iff $o(s) = o(s')$. We use the notation, $\mathbf{e}_i \in \mathbb{R}^{3|\mathcal{O}|}$, $i \in \{1, \dots, 3|\mathcal{O}|\}$, to denote the i^{th} standard basis vector. Perceptual aliasing (Whitehead, 1992) occurs in both MDPs under this policy parameterisation, with states 2, 3 & 4 aliased in the hallway problem, and states 4, 5 & 6 aliased in McCallum’s grid. In the hallway problem all of the aliased states have the same optimal action, and the value of these states all increase/decrease in unison. Hence, it can be seen that the policy parameterisation is value-consistent for the hallway problem. In McCallum’s grid, however, the optimal action for states 4 & 6 is to move upwards, while in state 5 it is to move downwards. In this example increasing the probability of moving downwards in state 5 will also increase the probability of moving downwards in states 4 & 6. There is a point, therefore, at which increasing the probability of moving downwards in state 5 will decrease the value of states 4 & 6. Thus this policy parameterisation is not value-consistent for McCallum’s grid. Numerical inspection of the parameter space indicates that this policy parameterisation is ϵ -value-consistent, with $\epsilon \approx 0.2$.

We now show that tabular policies—i.e., policies such that, for each state $s \in \mathcal{S}$, the conditional distribution $\pi(a|s;\mathbf{w}_s)$ is parameterized by a separate parameter vector $\mathbf{w}_s \in \mathbb{R}^{n_s}$ for some $n_s \in \mathbb{N}$ —are value-consistent, regardless of the given Markov decision process.

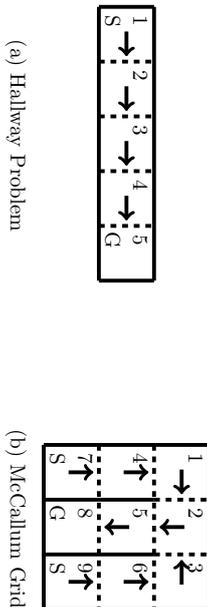

Figure 1: (a) The hallway problem. Under the feature map, ϕ , states 2, 3 and 4 map to the same feature, and the optimal policy is identical on these states. (b) McCallum’s grid. Under the feature map, ϕ , states 4, 5 and 6 map to the same feature, but now the optimal policy differs among these states.

Theorem 6. *Suppose that a given Markov decision process has a tabular policy parameterisation, then the policy parameterisation is value-consistent.*

Proof. See Section A.4 in the Appendix. \square

We now show that given an ϵ -value-consistent policy parameterisation and a local optimum, $\mathbf{w}^* \in \mathcal{W}$, the terms, $\frac{\partial}{\partial w_i} V(s; \mathbf{w}) \big|_{\mathbf{w}=\mathbf{w}^*}$, are bounded in magnitude by ϵ_i for all $s' \in \mathcal{S}$ and $i \in \{1, \dots, n\}$.

Theorem 7. *Suppose that $\mathbf{w}^* \in \mathcal{W}$ is a local optimum of the differentiable objective function, $U(\mathbf{w}) = \mathbb{E}_{s \sim p(\cdot)} [V(s; \mathbf{w})]$. Suppose that the Markov chain induced by \mathbf{w}^* is ergodic. Suppose that the policy parameterisation is ϵ -value-consistent, $\epsilon \in \mathbb{R}$, $\epsilon \geq 0$, w.r.t. the given Markov decision process. Then*

$$\left| \frac{\partial}{\partial w_i} V(s; \mathbf{w}) \bigg|_{\mathbf{w}=\mathbf{w}^*} \right| \leq \epsilon, \quad \forall s \in \mathcal{S}. \quad (23)$$

Proof. See Appendix A.5 \square

If a policy parameterisation is ϵ -value-consistent and the parameterisation satisfies the bound, $\left| \frac{\partial}{\partial w} \log \pi(a|s; \mathbf{w}) \right| \leq M$, $M \in \mathbb{R}$, for all $(s, a) \in \mathcal{S} \times \mathcal{A}$ and $\mathbf{w} \in \mathcal{W}$, then it follows from Theorem 7 that the terms of the matrix, $\mathcal{H}_{12}(\mathbf{w}^*) + \mathcal{H}_{12}^\top(\mathbf{w}^*)$, are bounded by $2e\gamma M/(1 - \gamma)$. A further corollary of Theorem 7 is that when a policy class is value-consistent the term, $\mathcal{H}_{12}(\mathbf{w}) + \mathcal{H}_{12}^\top(\mathbf{w})$, vanishes near local optima. Furthermore, when we have the additional condition that the gradient of the state value function is continuous in \mathbf{w} (at $\mathbf{w} = \mathbf{w}^*$) then $\mathcal{H}_{12}(\mathbf{w}) + \mathcal{H}_{12}^\top(\mathbf{w}) \rightarrow \mathbf{0}$ as $\mathbf{w} \rightarrow \mathbf{w}^*$. This condition will be satisfied if, for example, the policy is continuously differentiable w.r.t. the policy parameters.

Example (continued). Returning to the MDPs given in Figure 1, we now empirically observe the behaviour of the term $\mathcal{H}_{12}(\mathbf{w}) + \mathcal{H}_{12}^\top(\mathbf{w})$ as the policy approaches a local optimum of the objective function. Figure 2 gives the magnitude of $\mathcal{H}_{12}(\mathbf{w}) + \mathcal{H}_{12}^\top(\mathbf{w})$, in terms of the spectral norm, in relation to the distance from the local optimum. In correspondence with

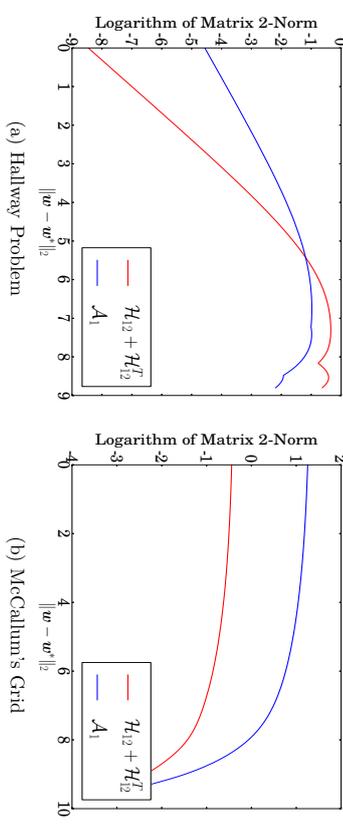

Figure 2: Graphical illustration of the logarithm of the spectral norm of $\mathcal{H}_{12}(\mathbf{w}) + \mathcal{H}_{12}^\top(\mathbf{w})$ and $\mathcal{A}_1(\mathbf{w})$ in terms of $\|\mathbf{w} - \mathbf{w}^*\|_2$ for the hallway problem (a) and McCallum’s grid (b). For the given policy parameterisation, $\mathcal{H}(\mathbf{w}) = \mathcal{A}_1(\mathbf{w}) + \mathcal{H}_{12}(\mathbf{w}) + \mathcal{H}_{12}^\top(\mathbf{w})$, so the plot displays the two components of the Hessian as the policy converges to a local optimum. As expected, in the hallway problem, $\mathcal{H}_{12}(\mathbf{w}) + \mathcal{H}_{12}^\top(\mathbf{w}) \rightarrow \mathbf{0}$ as $\mathbf{w} \rightarrow \mathbf{w}^*$. Conversely, in McCallum’s grid, $\mathcal{H}_{12}(\mathbf{w}) + \mathcal{H}_{12}^\top(\mathbf{w}) \not\rightarrow \mathbf{0}$ as $\mathbf{w} \rightarrow \mathbf{w}^*$, but the term, $\mathcal{H}_{12}(\mathbf{w}) + \mathcal{H}_{12}^\top(\mathbf{w})$, is still dominated by, $\mathcal{A}_1(\mathbf{w})$, in the vicinity of a local optima. In this example the magnitude of $\mathcal{A}_1(\mathbf{w})$ is roughly five times greater than that of $\mathcal{H}_{12}(\mathbf{w}) + \mathcal{H}_{12}^\top(\mathbf{w})$ when $\|\mathbf{w} - \mathbf{w}^*\|_2 \approx 0.0045$.

the theory, $\mathcal{H}_{12}(\mathbf{w}) + \mathcal{H}_{12}^\top(\mathbf{w}) \rightarrow \mathbf{0}$ as $\mathbf{w} \rightarrow \mathbf{w}^*$ in the hallway problem, while this is not the case in McCallum’s grid. This simple example illustrates the fact that if the feature representation is well chosen, in the sense that it is value-consistent, the term $\mathcal{H}_{12}(\mathbf{w}) + \mathcal{H}_{12}^\top(\mathbf{w})$ vanishes in the vicinity of a local optimum.

4. Gauss-Newton Methods for Markov Decision Processes

In this section we propose several Gauss-Newton type methods for MDPs, motivated by the analysis of Section 3. The algorithms are outlined in Section 4.1, and key performance analysis is provided in Section 4.2.

4.1 The Gauss-Newton Methods

The first Gauss-Newton method we propose drops the Hessian terms which are difficult to estimate, but are expected to be negligible in the vicinity of local optima. Specifically, it was shown in Section 3.3 that if the policy parameterisation is value-consistent with a given MDP, then $\mathcal{H}_{12}(\mathbf{w}) + \mathcal{H}_{12}^\top(\mathbf{w}) \rightarrow \mathbf{0}$ as \mathbf{w} converges towards a local optimum of the objective function. In such cases $\mathcal{A}_1(\mathbf{w}) + \mathcal{A}_2(\mathbf{w})$, as defined in Theorem 4, will be a good approximation to the Hessian in the vicinity of a local optimum. For this reason, the

first Gauss-Newton method that we propose for MDPs is to precondition the gradient with $\mathcal{M}(\mathbf{w}) = -(\mathcal{A}_1(\mathbf{w}) + \mathcal{A}_2(\mathbf{w}))^{-1}$ in (6), so that the update is of the form:

Policy search update using the first Gauss-Newton method

$$\mathbf{w}^{\text{new}} = \mathbf{w} - \alpha(\mathcal{A}_1(\mathbf{w}) + \mathcal{A}_2(\mathbf{w}))^{-1} \frac{\partial}{\partial \mathbf{w}} U(\mathbf{w}). \quad (24)$$

When the policy parameterisation has constant curvature with respect to the action space $\mathcal{A}_2(\mathbf{w}) = 0$ it is sufficient to calculate just $\mathcal{A}_1^{-1}(\mathbf{w})$.

The second Gauss-Newton method we propose removes further terms from the Hessian which are not guaranteed to be negative-semidefinite. As was seen in Section 3.1, when the policy parameterisation satisfies the properties of Theorem 5 then $\mathcal{H}_2(\mathbf{w})$ is negative-semidefinite over the entire parameter space.⁵ Recall that in (6) it is necessary that $\mathcal{M}(\mathbf{w})$ is positive-definite (in Newton’s method this corresponds to requiring the Hessian to be negative-definite) to ensure an increase of the objective function. That $\mathcal{H}_2(\mathbf{w})$ is negative-semidefinite over the entire parameter space is therefore a highly desirable property of a preconditioning matrix, and for this reason the second Gauss-Newton method that we propose for MDPs is to precondition the gradient with $\mathcal{M}(\mathbf{w}) = -\mathcal{H}_2^{-1}(\mathbf{w})$ in (6), so that the update is of the form:

Policy search update using the second Gauss-Newton method

$$\mathbf{w}^{\text{new}} = \mathbf{w} - \alpha \mathcal{H}_2^{-1}(\mathbf{w}) \frac{\partial}{\partial \mathbf{w}} U(\mathbf{w}). \quad (25)$$

We shall see that the second Gauss-Newton method has important performance guarantees including: a guaranteed ascent direction; linear convergence to a local optimum under a step size which does not depend upon unknown quantities; invariance to affine transformations of the parameter space; and efficient estimation procedures for the preconditioning matrix. We will also show in Section 5 that the second Gauss-Newton method is closely related to both the EM and natural gradient algorithms.

We shall also consider a diagonal form of the approximation for both forms of Gauss-Newton methods. Denoting the diagonal matrix formed from the diagonal elements of $\mathcal{A}_1(\mathbf{w}) + \mathcal{A}_2(\mathbf{w})$ and $\mathcal{H}_2(\mathbf{w})$ by $\mathcal{D}_{\mathcal{A}_1 + \mathcal{A}_2}(\mathbf{w})$ and $\mathcal{D}_{\mathcal{H}_2}(\mathbf{w})$, respectively, then we shall consider the methods that use $\mathcal{M}(\mathbf{w}) = -\mathcal{D}_{\mathcal{A}_1 + \mathcal{A}_2}^{-1}(\mathbf{w})$ and $\mathcal{M}(\mathbf{w}) = -\mathcal{D}_{\mathcal{H}_2}^{-1}(\mathbf{w})$ in (6). We call these methods the diagonal first and second Gauss-Newton methods, respectively. This

5. That the preconditioning matrix is negative-semidefinite and not negative-definite is a standard problem with many optimisation techniques that require the inversion of a preconditioning matrix. This includes natural gradient ascent when the Fisher information matrix is used to precondition the gradient (Thomas, 2014). Various approaches can be taken with regard to this problem: Add a ridge term to the preconditioning matrix; Minimize $\|\mathcal{H}_2(\mathbf{w})\mathbf{p} + \frac{\partial}{\partial \mathbf{w}} U(\mathbf{w})\|^2$ with respect to \mathbf{p} by gradient descent, and use \mathbf{p} as the search direction; Precondition the gradient with the pseudoinverse $-\mathcal{H}_2^{\dagger}(\mathbf{w})$.

diagonalization amounts to performing the approximate Newton methods on each parameter independently, but simultaneously.

4.1.1 ESTIMATION OF THE PRECONDITIONERS AND THE GAUSS-NEWTON UPDATE DIRECTION

It is possible to extend typical techniques used to estimate the policy gradient to estimate the preconditioner for the Gauss-Newton method, by including either the Hessian of the log-policy, the outer product of the derivative of the log-policy, or the respective diagonal terms. As an example, in Section B.1 of the Appendix we detail the extension of the recurrent state formulation of gradient evaluation in the average reward framework (Williams, 1992) to the second Gauss-Newton method. We use this extension in the Tetris experiment that we consider in Section 6. Given n_s sampled state-action pairs, the complexity of this extension scales as $\mathcal{O}(n_s n^2)$ for the second Gauss-Newton method, while it scales as $\mathcal{O}(n_s n)$ for the diagonal version of the algorithm. We provide more details of situations in which the inversion of the preconditioning matrices can be performed more efficiently in Section B.2 of the Appendix.

4.2 Performance Guarantees and Analysis

4.2.1 ASCENT DIRECTIONS

In general the objective (4) is not concave, which means that the Hessian will not be negative-definite over the entire parameter space. In such cases Newton’s method can actually lower the objective and this is an undesirable aspect of Newton’s method. We now consider ascent directions for the Gauss-Newton methods, and in particular demonstrate that the proposed second Gauss-Newton method guarantees an ascent direction in typical settings.

Ascent directions for the first Gauss-Newton method: As mentioned previously, the matrix $\mathcal{A}_1(\mathbf{w}) + \mathcal{A}_2(\mathbf{w})$ will typically be indefinite, and so a straightforward application of the first Gauss-Newton method will not necessarily result in an increase in the objective function. There are, however, standard correction techniques that one could consider to ensure that an increase in the objective function is obtained, such as adding a ridge term to the preconditioning matrix. A survey of such correction techniques can be found in Boyd and Vandenberghe (2004).

Ascent directions for the second Gauss-Newton method: It was seen in Theorem 5 that $\mathcal{H}_2(\mathbf{w})$ will be negative-semidefinite over the entire parameter space if either the policy is log-concave with respect to the policy parameters, or the policy has constant curvature with respect to the action space. It follows that in such cases an increase of the objective function will be obtained when using the second Gauss-Newton method with a sufficiently small step-size. Additionally, the diagonal terms of a negative-semidefinite matrix are non-positive, so that $\mathcal{D}_{\mathcal{H}_2}(\mathbf{w})$ is negative-semidefinite whenever $\mathcal{H}_2(\mathbf{w})$ is negative-semidefinite, and thus similar performance guarantees exist for the diagonal version of the second Gauss-Newton algorithm.

To motivate this result we now briefly consider some widely used policies that are either log-concave or blockwise log-concave. Firstly, consider the linear softmax policy parameterisation, $\pi(a|s; \mathbf{w}) \propto \exp \mathbf{w}^T \phi(a, s)$, in which $\phi(a, s) \in \mathbb{R}^n$ is a feature vector. This

policy is widely used in discrete systems and is log-concave in \mathbf{w} , which can be seen from the fact that $\log \pi(a|s; \mathbf{w})$ is the sum of a linear term and a negative log-sum-exp term, both of which are concave (Boyd and Vandenberghe, 2004). In systems with a continuous state-action space a common choice of controller is $\pi(a|s; K, \Sigma) = \mathcal{N}(a|K\phi(s), \Sigma)$, in which $\phi(s) \in \mathbb{R}^n$ is a feature vector. This controller is not jointly log-concave in K and Σ , but it is blockwise log-concave in K and Σ^{-1} . In terms of K the log-policy is quadratic and the coefficient matrix of the quadratic term is negative-semidefinite. In terms of Σ^{-1} the log-policy consists of a linear term and a log-determinant term, both of which are concave.

4.2.2 AFFINE INVARIANCE

An undesirable aspect of gradient ascent is that its performance is dependent on the choice of basis used to represent the parameter space. An important and desirable property of Newton’s method is that it is invariant to non-singular affine transformations of the parameter space (Boyd and Vandenberghe, 2004). The proposed approximate Newton methods have various invariance properties, and these properties are summarized in the following theorem.

Theorem 8. *The first and second Gauss-Newton methods are invariant to (non-singular) affine transformations of the parameter space. The diagonal versions of these algorithms are invariant to (non-singular) rescalings of the parameter space.*

Proof. See Section A.6 in the Appendix. \square

4.2.3 CONVERGENCE ANALYSIS

We now provide a local convergence analysis of the Gauss-Newton framework. We shall focus on the full Gauss-Newton methods, with the analysis of the diagonal Gauss-Newton method following similarly. Additionally, we shall focus on the case in which a constant step size is considered throughout, which is denoted by $\alpha \in \mathbb{R}^+$. We say that an algorithm converges linearly to a limit L at a rate $r \in (0, 1)$ if $\lim_{k \rightarrow \infty} \frac{|l(\mathbf{w}_{k+1}) - L|}{|l(\mathbf{w}_k) - L|} = r$. If $r = 0$ then the algorithm converges super-linearly. We denote the parameter update function of the first and second Gauss-Newton methods by G_1 and G_2 , respectively, so that $G_1(\mathbf{w}) = \mathbf{w} - \alpha(\mathcal{A}_1(\mathbf{w}) + \mathcal{A}_2(\mathbf{w}))^{-1} \frac{\partial}{\partial \mathbf{w}} U(\mathbf{w})$ and $G_2(\mathbf{w}) = \mathbf{w} - \alpha \mathcal{H}_2^{-1}(\mathbf{w}) \frac{\partial}{\partial \mathbf{w}} U(\mathbf{w})$. Given a matrix, $A \in L(\mathbb{R}^n)$ we denote the spectral radius of A by $\rho(A) = \max_i |\lambda_i|$, where $\{\lambda_i\}_{i=1}^n$ are the eigenvalues of A . Throughout this section we shall use $\nabla G(\mathbf{w}^*)$ to denote $\frac{\partial}{\partial \mathbf{w}} G(\mathbf{w})|_{\mathbf{w}=\mathbf{w}^*}$.

Theorem 9 (Convergence analysis for the first Gauss-Newton method). *Suppose that $\mathbf{w}^* \in \mathcal{W}$ is such that $\frac{\partial}{\partial \mathbf{w}} U(\mathbf{w})|_{\mathbf{w}=\mathbf{w}^*} = \mathbf{0}$ and $\mathcal{A}_1(\mathbf{w}^*) + \mathcal{A}_2(\mathbf{w}^*)$ is invertible, then G_1 is Fréchet differentiable at \mathbf{w}^* and $\nabla G_1(\mathbf{w}^*)$ takes the form,*

$$\nabla G_1(\mathbf{w}^*) = I - \alpha(\mathcal{A}_1(\mathbf{w}^*) + \mathcal{A}_2(\mathbf{w}^*))^{-1} \mathcal{H}(\mathbf{w}^*). \quad (26)$$

If $\mathcal{H}(\mathbf{w}^)$ and $\mathcal{A}_1(\mathbf{w}^*) + \mathcal{A}_2(\mathbf{w}^*)$ are negative-definite, and the step size is in the range,*

$$\alpha \in (0, 2/\rho((\mathcal{A}_1(\mathbf{w}^*) + \mathcal{A}_2(\mathbf{w}^*))^{-1} \mathcal{H}(\mathbf{w}^*))) \quad (27)$$

then \mathbf{w}^ is a point of attraction of the first Gauss-Newton method, the convergence is at least linear and the rate is given by $\rho(\nabla G_1(\mathbf{w}^*)) < 1$. When the policy parameterisation is*

value-consistent with respect to the given Markov decision process, then (26) simplifies to,

$$\nabla G_1(\mathbf{w}^*) = (1 - \alpha)I, \quad (28)$$

and whenever $\alpha \in (0, 2)$ then \mathbf{w}^ is a point of attraction of the first Gauss-Newton method, and the convergence to \mathbf{w}^* is linear if $\alpha \neq 1$ with a rate given by $\rho(\nabla G_1(\mathbf{w}^*)) < 1$, and convergence is super-linear when $\alpha = 1$.*

Proof. See Section A.7 in the Appendix. \square

Theorem 10 (Convergence analysis for the second Gauss-Newton method). *Suppose that $\mathbf{w}^* \in \mathcal{W}$ is such that $\frac{\partial}{\partial \mathbf{w}} U(\mathbf{w})|_{\mathbf{w}=\mathbf{w}^*} = \mathbf{0}$ and $\mathcal{H}_2(\mathbf{w}^*)$ is invertible, then G_2 is Fréchet differentiable at \mathbf{w}^* and $\nabla G_2(\mathbf{w}^*)$ takes the form,*

$$\nabla G_2(\mathbf{w}^*) = I - \alpha \mathcal{H}_2^{-1}(\mathbf{w}^*) \mathcal{H}(\mathbf{w}^*). \quad (29)$$

If $\mathcal{H}(\mathbf{w}^)$ is negative-definite and the step size is in the range,*

$$\alpha \in (0, 2/\rho(\mathcal{H}_2^{-1}(\mathbf{w}^*) \mathcal{H}(\mathbf{w}^*))) \quad (30)$$

then \mathbf{w}^ is a point of attraction of the second Gauss-Newton method, convergence to \mathbf{w}^* is at least linear and the rate is given by $\rho(\nabla G_2(\mathbf{w}^*)) < 1$. Furthermore, $\alpha \in (0, 2)$ implies condition (30). When the policy parameterisation is value-consistent with respect to the given Markov decision process, then (29) simplifies to,*

$$\nabla G_2(\mathbf{w}^*) = I - \alpha \mathcal{H}_2^{-1}(\mathbf{w}^*) \mathcal{A}_1(\mathbf{w}^*). \quad (31)$$

Proof. See Section A.7 in the Appendix. \square

The conditions of Theorem 10 look analogous to those of Theorem 9, but they differ in important ways: in Theorem 10 it is not necessary to assume that the preconditioning matrix is negative-definite and the sets in (27) will not be known in practice, whereas the condition $\alpha \in (0, 2)$ in Theorem 10 is more practical, i.e., for the second Gauss-Newton method convergence is guaranteed for a constant step size which is easily selected and does not depend upon unknown quantities.

It will be seen in Section 5.2 that the second Gauss-Newton method has a close relationship to the EM-algorithm. For this reason we postpone additional discussion about the rate of convergence of the second Gauss-Newton method until then.

5. Relation to Existing Policy Search Methods

In this section we consider the relationship between the second Gauss-Newton method and existing policy search methods. In Section 5.1 we examine its relation to natural gradient ascent and in Section 5.2 to the EM-algorithm.

5.1 Natural Gradient Ascent and the Second Gauss-Newton Method

Comparing the form of the Fisher information matrix given in (11) with \mathcal{H}_2 (16) it can be seen that there is a close relationship between natural gradient ascent and the second Gauss-Newton method: in \mathcal{H}_2 there is an additional weighting of the integrand from the state-action value function. Hence, \mathcal{H}_2 incorporates information about the reward structure of the objective function that is not present in the Fisher information matrix.

We now consider how this additional weighting affects the search direction for natural gradient ascent and the Gauss-Newton approach. Given a norm on the parameter space, $\|\cdot\|$, the steepest ascent direction at $\mathbf{w} \in \mathcal{W}$ with respect to that norm is given by,

$$\hat{\mathbf{p}} = \operatorname{argsup}_{\{\mathbf{p} \mid \|\mathbf{p}\|=1\}} \lim_{\alpha \rightarrow 0} \frac{U(\mathbf{w} + \alpha \mathbf{p}) - U(\mathbf{w})}{\alpha}.$$

Natural gradient ascent is obtained by considering the (local) norm $\|\cdot\|_{G(\mathbf{w})}$ given by $\|\mathbf{w} - \mathbf{w}'\|_{G(\mathbf{w})}^2 := (\mathbf{w} - \mathbf{w}')^\top G(\mathbf{w})(\mathbf{w} - \mathbf{w}')$, with $G(\mathbf{w})$ as in (10). The natural gradient method allows less movement in the directions that have high norm which, as can be seen from the form of (10), are those directions that induce large changes to the policy over the parts of the state-action space that are likely to be visited under the current policy parameters. More movement is allowed in directions that either induce a small change in the policy, or induce large changes to the policy, but only in parts of the state-action space that are unlikely to be visited under the current policy parameters. In a similar manner the second Gauss-Newton method can be obtained by considering the (local) norm $\|\cdot\|_{\mathcal{H}_2(\mathbf{w})}$, given by $\|\mathbf{w} - \mathbf{w}'\|_{\mathcal{H}_2(\mathbf{w})}^2 := -(\mathbf{w} - \mathbf{w}')^\top \mathcal{H}_2(\mathbf{w})(\mathbf{w} - \mathbf{w}')$ so that each term in (11) is additionally weighted by the state-action value function, $Q(s, a; \mathbf{w})$. Thus, the directions which have high norm are those in which the policy is rapidly changing in state-action pairs that are not only likely to be visited under the current policy, but also have high value. Thus the second Gauss-Newton method updates the parameters more conservatively if the behaviour in high value states is affected. Conversely, directions which induce a change only in state-action pairs of low value have low norm, and larger increments can be made in those directions.

5.2 Expectation Maximization and the Second Gauss-Newton Method

It has previously been noted (Kober and Peters, 2011) that the parameter update of gradient ascent and the EM-algorithm can be related through the function Q defined in (13). In particular, the gradient (8) evaluated at \mathbf{w}_k can be written in terms of Q as follows,

$$\frac{\partial}{\partial \mathbf{w}} U(\mathbf{w})|_{\mathbf{w}=\mathbf{w}_k} = \frac{\partial}{\partial \mathbf{w}} Q(\mathbf{w}, \mathbf{w}_k)|_{\mathbf{w}=\mathbf{w}_k},$$

while the parameter update of the EM-algorithm is given by $\mathbf{w}_{k+1} = \operatorname{argmax}_{\mathbf{w} \in \mathcal{W}} Q(\mathbf{w}, \mathbf{w}_k)$. In other words, gradient ascent moves in the direction that most rapidly increases Q with respect to the first variable, while the EM-algorithm maximizes Q with respect to the first variable. While this relationship is true, it is also quite a negative result. It states that in situations in which it is not possible to explicitly maximize Q with respect to its first variable, then the alternative, in terms of the EM-algorithm, is a generalized EM-algorithm, which is equivalent to gradient ascent. Given that the EM-algorithm is typically used to

overcome the negative aspects of gradient ascent, this is an undesirable alternative. It is possible to find the optimum of (13) numerically, but this is also undesirable as it results in a double-loop algorithm that could be computationally expensive. Finally, this result provides no insight into the behaviour of the EM-algorithm, in terms of the direction of its parameter update, when the maximization over \mathbf{w} in (13) can be performed explicitly.

We now demonstrate that the step-direction of the EM-algorithm has an underlying relationship with the second of our proposed Gauss-Newton methods. In particular, we show that under suitable regularity conditions the direction of the EM-update, $\mathbf{w}_{k+1} - \mathbf{w}_k$, is the same, up to first order, as the direction of the second Gauss-Newton method.

Theorem 11. *Suppose we are given a Markov decision process with objective (1) and Markovian trajectory distribution (2). Consider the parameter update (M-step) of expectation maximization at the k^{th} iteration of the algorithm, i.e., $\mathbf{w}_{k+1} = \operatorname{argmax}_{\mathbf{w} \in \mathcal{W}} Q(\mathbf{w}, \mathbf{w}_k)$. Provided that $Q(\mathbf{w}, \mathbf{w}_k)$ is twice continuously differentiable in the first parameter we have that,*

$$\mathbf{w}_{k+1} - \mathbf{w}_k = -\mathcal{H}_2^{-1}(\mathbf{w}_k) \frac{\partial}{\partial \mathbf{w}} U(\mathbf{w})|_{\mathbf{w}=\mathbf{w}_k} + \mathcal{O}(\|\mathbf{w}_{k+1} - \mathbf{w}_k\|^2). \quad (32)$$

Additionally, in the case where the log-policy is quadratic the relation to the approximate Newton method is exact, i.e., the second term on the r.h.s. of (32) is zero.

Proof. See Section A.8 in the Appendix. \square

Given a sequence of parameter vectors, $(\mathbf{w}_k)_{k=1}^\infty$, generated through an application of the EM-algorithm, then $\lim_{k \rightarrow \infty} \|\mathbf{w}_{k+1} - \mathbf{w}_k\| = 0$. This means that the rate of convergence of the EM-algorithm will be the same as that of the second Gauss-Newton method when considering a constant step size of one. We formalize this intuition and provide the convergence properties of the EM-algorithm when applied to Markov decision processes in the following theorem. This is, to our knowledge, the first formal derivation of the convergence properties for this application of the EM-algorithm.

Theorem 12. *Suppose that the sequence, $(\mathbf{w}_k)_{k \in \mathbb{N}}$, is generated by an application of the EM-algorithm, where the sequence converges to \mathbf{w}^* . Denote the update operation of the EM-algorithm by G_{EM} , so that $\mathbf{w}_{k+1} = G_{\text{EM}}(\mathbf{w}_k)$. Using $\nabla G_{\text{EM}}(\mathbf{w}^*)$ to denote $\frac{\partial}{\partial \mathbf{w}} G_{\text{EM}}(\mathbf{w})|_{\mathbf{w}=\mathbf{w}^*}$, then,*

$$\nabla G_{\text{EM}}(\mathbf{w}^*) = I - \mathcal{H}_2^{-1}(\mathbf{w}^*) \mathcal{H}(\mathbf{w}^*).$$

When the policy parameterisation is value-consistent with respect to the given Markov decision process this simplifies to $\nabla G_{\text{EM}}(\mathbf{w}^) = I - \mathcal{H}_2^{-1}(\mathbf{w}^*) \mathcal{A}_1(\mathbf{w}^*)$. When the Hessian, $\mathcal{H}(\mathbf{w}^*)$, is negative-definite then $\rho(\nabla G_{\text{EM}}(\mathbf{w}^*)) < 1$ and \mathbf{w}^* is a local point of attraction for the EM-algorithm.*

Proof. See Section A.9 in the Appendix. \square

6. Experiments

In this section we provide an empirical evaluation of the Gauss-Newton methods on a variety of domains. We summarize the experimental results here. For reproducibility, more details can be found in Appendix C.

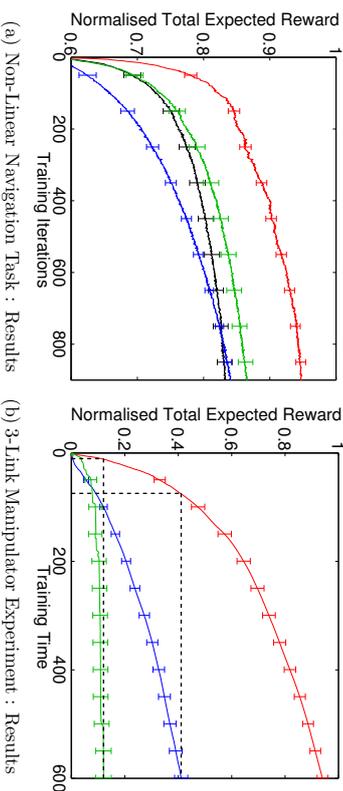

Figure 3: (a) Results from the non-linear navigation task, with the results for gradient ascent (black), expectation maximization (blue), natural gradient ascent (green) and the second Gauss-Newton method (red). (b) Normalized total expected reward plotted against training time (in seconds) for the 3-link rigid manipulator. The plot shows the results expectation maximization (blue), the second Gauss-Newton method (red) and natural gradient ascent (green).

6.1 Non-Linear Navigation Experiment

The first domain that we consider is the synthetic two-dimensional non-linear MDP considered in the work of Vlassis et al. (2009). In this experiment we consider gradient ascent, natural gradient ascent, expectation maximisation and the second Gauss-Newton method. Details of the domain and the experiment settings are given in Section C.1. The experiment was repeated 100 times and the results of the experiment are given in Figure 3a, which gives the mean and standard error of the results. The step size sequences of gradient ascent, natural gradient ascent and the Gauss-Newton method were all tuned for performance and the results shown were obtained from the best step size sequence for each algorithm.

6.2 N-link Rigid Manipulator Experiment

The N-link rigid robot arm manipulator is a standard continuous model, consisting of an end effector connected to an N-linked rigid body (Khali, 2001). A typical continuous control problem for such systems is to apply appropriate torque forces to the joints of the manipulator so as to move the end effector into a desired position. More details on the settings of the domain used in this experiment can be found in Section C.2. We consider a policy of the form,

$$\pi(a|s; \mathbf{w}) = \mathcal{N}(a|Ks + \mathbf{m}, \sigma^2 I), \quad (33)$$

with $\mathbf{w} = (K, \mathbf{m}, \sigma)$ and $s \in \mathbb{R}^{n_s}$, $a \in \mathbb{R}^{n_a}$, for some $n_s, n_a \in \mathbb{N}$. We consider a 3-link rigid manipulator, which results in a parameter space with 22 dimensions.

In this experiment we compare gradient ascent, natural gradient ascent, expectation maximization and the second Gauss-Newton method. The step size sequences of gradient ascent, natural gradient ascent and the Gauss-Newton method were all tuned for performance. Details of the experiment settings and the procedure used to tune the step size sequences are described in Section C.2. We repeated the experiment 100 times, each time with a different random initialisation of the system. The final results, obtained using the best step size sequence for each algorithm, are given in Figure 3b. We omit the result of gradient ascent as we were unable to obtain any meaningful results for this domain with this algorithm. In this experiment the maximal value of the objective function varied dramatically depending on the random initialization of the system. To account for this variation the results from each run of the experiment are normalized by the maximal value achieved between the algorithms in that run. This means that the results displayed are the percentages of reward received in comparison to the best results among the algorithms considered in the experiment. The second Gauss-Newton method significantly outperforms all of the comparison algorithms. In the experiment the Gauss-Newton method only took around 50 seconds to obtain the same performance as 300 seconds of training with expectation maximization. Furthermore expectation maximization was only able to obtain 40% of the performance of the Gauss-Newton method, while natural gradient ascent was only able to obtain around 15% of the performance. The step direction of expectation maximization is very similar to the search direction of the second Gauss-Newton method in this problem. In fact, given that the log-policy is quadratic in the mean parameters, they are the same for the mean parameters. The difference in performance between the Gauss-Newton method and expectation maximization is largely explained by the tuning of the step size in the Gauss-Newton method, compared to the constant step size of 1.0 in expectation maximization.

6.3 Tetris Experiment

In this experiment we consider the Tetris domain, which is a popular computer game designed by Alexey Pajitnov in 1985. Firstly, we compare the performance of the full and diagonal second Gauss-Newton methods to other policy search methods. We model the policy using a linear softmax parameterisation. We used the same set of features as used in the works of Bertsekas and Ioffe (1996) & Kakade (2002). Under this parameterisation it is not possible to obtain the explicit maximum over \mathbf{w} in (13), so a straightforward application of the EM-algorithm is not possible in this problem. We therefore compare the diagonal and full versions of the second Gauss-Newton method with steepest and natural gradient ascent. Due to computational costs we consider a 10×10 board in this experiment, which results in a state space with roughly 7×2^{100} states (Bertsekas and Ioffe, 1996). We ran 100 repetitions of the experiment, each consisting of 100 training iterations, and the mean and standard error of the results are given in Figure 4a. It can be seen that the full Gauss-Newton method outperforms all of the other methods, while the performance of the diagonal Gauss-Newton method is comparable to natural gradient ascent.

We also ran several training runs of the full approximate Newton method on the full-sized 20×10 board and were able to obtain a score in the region of 14,000 completed lines, which was obtained after roughly 40 training iterations. An approximate dynamic programming based method has previously been applied to the Tetris domain in the work of Bertsekas and

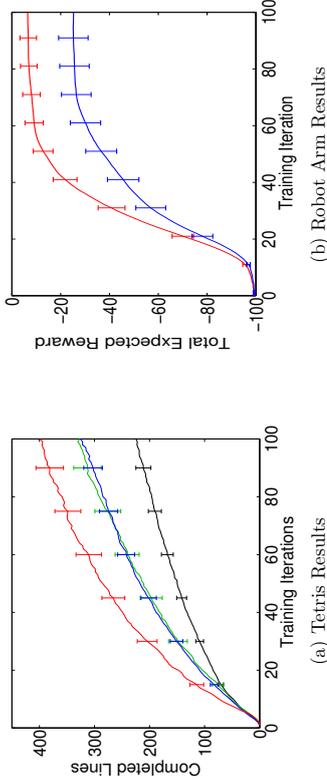

Figure 4: (a) Results from the Tetris experiment, with results for gradient ascent (black), natural gradient ascent (green), the diagonal Gauss-Newton method (blue) and the Gauss-Newton method (red). (b) Results from the robot arm experiment, with results for the second Gauss-Newton method (red) and the EM-algorithm (blue).

Ioffe (1996). The same set of features were used and a score of roughly 4,500 completed lines was obtained after around 6 training iterations, after which the solution then deteriorated. More recently a modified policy iteration approach (Gabillon et al., 2013) was able to obtain significantly better performance in the game of Tetris, completing approximately 51 million lines in a 20×10 board. However, these results were obtained through an entirely different set of features, and analysis of the results in the work of (Gabillon et al., 2013) indicates that this difference in features makes a substantial difference in performance. On a 10×10 board using the same features as in the work of Bertsekas and Ioffe (1996) the approach was able to complete approximately 500 lines on average.

6.4 Robot Arm Experiment

In the final experiment we consider a robotic arm application. We use the Simulation Lab (Schaal, 2006) environment, which provides a physically realistic engine of a Barrett WAMTM robot arm. We consider the ball-in-a-cup domain (Kober and Peters, 2009), which is a challenging motor skill problem that is based on the traditional children’s game. In this domain a small cup is attached to the end effector of the robot arm. A ball is attached to the cup through a piece of string. At the beginning of the task the robot arm is stationary and the ball is hanging below the cup in a stationary position. The aim of the task is for the robot arm to learn an appropriate set of joint movements to first swing the ball above the cup and then to catch the ball in the cup when the ball is in its downward trajectory. More details of the domain and the experiment settings are provided in Section C.4.

In this experiment we compare gradient ascent, natural gradient ascent, expectation maximization, the first Gauss-Newton method and the second Gauss-Newton method. We

repeated the experiment 50 times and the results are given in Figure 4b. We were unable to successfully learn to catch the ball in the cup using either gradient ascent, natural gradient ascent or the first Gauss-Newton method. For this reason the results for these algorithms are omitted. It can be seen that the second Gauss-Newton method significantly outperforms the EM-algorithm in this domain. Out of the 50 runs of the experiment, the second Gauss-Newton method was successfully able to learn to catch the ball in the cup 45 times. The EM-algorithm successfully learnt the task 36 times. We note that in this experiment the policy took the form, $\pi(a; \mathbf{w}) = \mathcal{N}(a | \boldsymbol{\mu}, (L L^*)^{-1})$, with, $\mathbf{w} = (\boldsymbol{\mu}, L)$. (More details of the policy parameterisation can be found in Section C.4.) A fixed step size of 1.0 was used in the second Gauss-Newton method, which means that, as the log-policy is quadratic in $\boldsymbol{\mu}$, the update of $\boldsymbol{\mu}$ in the second Gauss-Newton method and the EM-algorithm were the same. The difference in performance can therefore be attributed to the difference in the updates of L between the two algorithms.

7. Conclusions

Approximate Newton methods, such as quasi-Newton methods and the Gauss-Newton method, are standard optimization techniques. These methods aim to maintain the benefits of Newton’s method, while alleviating its shortcomings. In this paper we have considered approximate Newton methods in the context of policy optimization in MDPs. The first contribution of this paper was to provide a novel analysis of the Hessian of the total expected reward, which is a standard objective function for policy optimization. This included providing a novel form for the Hessian, as well as detailing the positive/negative semidefiniteness properties of certain terms in the Hessian. Furthermore, we have shown that when the policy parameterisation is sufficiently rich, in the sense that it is ϵ -value-consistent with an appropriately small value of ϵ , then the remaining terms in the Hessian become negligible in the vicinity of a local optimum. Motivated by this analysis we introduced two Gauss-Newton Methods for MDPs. Like the Gauss-Newton method for non-linear least squares, these methods involve approximating the Hessian by ignoring certain terms in the Hessian. The approximate Hessians possess desirable properties, such as negative-semidefiniteness, and we demonstrated several important performance guarantees including guaranteed ascent directions, invariance to affine transformation of the parameter space, and convergence guarantees. We also demonstrated our second Gauss-Newton algorithm is closely related to both the EM-algorithm and natural gradient ascent applied to MDPs, providing novel insights into both of these algorithms. We have compared the proposed Gauss-Newton methods with other techniques in the policy search literature over a range of challenging domains, including Tetris and a robotic arm application. We found that the second Gauss-Newton method performed significantly better than other methods in all of the domains that we considered.

We have provided a convergence analysis of the two proposed Gauss-Newton methods for the setting in which the gradient and the preconditioning matrices can be calculated exactly. An interesting piece of future work is to extend this analysis to the stochastic setting, in which these quantities are estimated from samples of the MDP, either through a Monte-Carlo approach or in a stochastic approximation framework.

Acknowledgements

We would like to thank Peter Dayan, David Silver, Nicolas Heess for helpful discussions on this work and Gerhard Neumann and Christian Daniel for their assistance in the robot arm experiment. We also thank the anonymous reviewers for their suggested improvements. Appendix A. Proofs

A.1 Proofs of Theorems 1 and 3

We begin with an auxiliary Lemma.

Lemma 1. *Suppose we are given a Markov decision process with objective (1) and Markovian trajectory distribution (2). For any given parameter vector, $\mathbf{w} \in \mathcal{W}$, the following identities hold,*

$$\frac{\partial}{\partial \mathbf{w}} V(s; \mathbf{w}) = \sum_{t=1}^{\infty} \sum_{s_t \in \mathcal{S}} \sum_{a_t \in \mathcal{A}} \gamma^{t-1} p(s_t, a_t | s_1 = s; \mathbf{w}) Q(s_t, a_t; \mathbf{w}) \frac{\partial}{\partial \mathbf{w}} \log \pi(a_t | s_t; \mathbf{w}) \quad (34)$$

$$\frac{\partial}{\partial \mathbf{w}} Q(s, a; \mathbf{w}) = \sum_{t=2}^{\infty} \sum_{s_t \in \mathcal{S}} \sum_{a_t \in \mathcal{A}} \gamma^{t-1} p(s_t, a_t | s_1 = s, a_1 = a; \mathbf{w}) Q(s_t, a_t; \mathbf{w}) \frac{\partial}{\partial \mathbf{w}} \log \pi(a_t | s_t; \mathbf{w}). \quad (35)$$

Proof. We start by writing the state value function in the form

$$V(s; \mathbf{w}) = \sum_{t=1}^{\infty} \sum_{s_{1:t}} \sum_{a_{1:t}} \gamma^{t-1} p(s_{1:t}, a_{1:t} | s_1 = s; \mathbf{w}) R(s_t, a_t), \quad (36)$$

so that,

$$\frac{\partial}{\partial \mathbf{w}} V(s; \mathbf{w}) = \sum_{t=1}^{\infty} \sum_{s_{1:t}} \sum_{a_{1:t}} \gamma^{t-1} p(s_{1:t}, a_{1:t} | s_1 = s; \mathbf{w}) \frac{\partial}{\partial \mathbf{w}} \log p(s_{1:t}, a_{1:t} | s_1 = s; \mathbf{w}) R(s_t, a_t).$$

Using the fact that

$$\frac{\partial}{\partial \mathbf{w}} \log p(s_{1:t}, a_{1:t} | s_1 = s; \mathbf{w}) = \sum_{\tau=1}^t \frac{\partial}{\partial \mathbf{w}} \log \pi(a_{\tau} | s_{\tau}; \mathbf{w}), \quad (37)$$

we have that,

$$\begin{aligned} \frac{\partial}{\partial \mathbf{w}} V(s; \mathbf{w}) &= \sum_{t=1}^{\infty} \sum_{s_t, a_t} \sum_{\tau=1}^t \sum_{s_{1:\tau}, a_{1:\tau}} \gamma^{t-1} p(s_{\tau}, a_{\tau}, s_t, a_t | s_1 = s; \mathbf{w}) \frac{\partial}{\partial \mathbf{w}} \log \pi(a_{\tau} | s_{\tau}; \mathbf{w}) R(s_t, a_t) \\ &= \sum_{\tau=1}^{\infty} \sum_{s_{\tau}, a_{\tau}} \gamma^{\tau-1} p(s_{\tau}, a_{\tau} | s_1 = s; \mathbf{w}) \frac{\partial}{\partial \mathbf{w}} \log \pi(a_{\tau} | s_{\tau}; \mathbf{w}) \sum_{t=\tau}^{\infty} \sum_{s_{t:\tau}, a_{t:\tau}} \gamma^{t-\tau} p(s_t, a_t | s_{\tau}, a_{\tau}; \mathbf{w}) R(s_t, a_t) \\ &= \sum_{\tau=1}^{\infty} \sum_{s_{\tau}, a_{\tau}} \gamma^{\tau-1} p(s_{\tau}, a_{\tau} | s_1 = s; \mathbf{w}) \frac{\partial}{\partial \mathbf{w}} \log \pi(a_{\tau} | s_{\tau}; \mathbf{w}) Q(s_{\tau}, a_{\tau}; \mathbf{w}). \end{aligned} \quad (38)$$

where in the second line we swapped the order of summation and the third line follows from the definition (3). Identity (35) now follows by applying (3):

$$\begin{aligned} \frac{\partial}{\partial \mathbf{w}} Q(s, a; \mathbf{w}) &= \gamma \sum_{s'} P(s'|s, a) \frac{\partial}{\partial \mathbf{w}} V(s'; \mathbf{w}) \\ &= \gamma \sum_{s'} P(s'|s, a) \sum_{t=2}^{\infty} \sum_{s_t \in \mathcal{S}} \sum_{a_t \in \mathcal{A}} \gamma^{t-2} p(s_t, a_t | s_2 = s'; \mathbf{w}) \frac{\partial}{\partial \mathbf{w}} \log \pi(a_t | s_t; \mathbf{w}) Q(s_t, a_t; \mathbf{w}) \\ &= \sum_{t=2}^{\infty} \sum_{s_t \in \mathcal{S}} \sum_{a_t \in \mathcal{A}} \gamma^{t-1} p(s_t, a_t | s_1 = s, a_1 = a; \mathbf{w}) Q(s_t, a_t; \mathbf{w}) \frac{\partial}{\partial \mathbf{w}} \log \pi(a_t | s_t; \mathbf{w}). \end{aligned}$$

□

Theorem 1. *Proof.* Theorem 1 follows immediately from Lemma 1 by taking the expectation over s_1 w.r.t. the start state distribution p_1 and using the definition (5) of the discounted trajectory distribution. □

Theorem 3. *Proof.* Starting from $U(\mathbf{w}) = \sum_{t=1}^{\infty} \sum_{s_{1:t}, a_{1:t}} \gamma^{t-1} p(s_{1:t}, a_{1:t}; \mathbf{w}) R(s_t, a_t)$, the Hessian of (4) takes the form

$$\begin{aligned} \frac{\partial^2}{\partial \mathbf{w}^2} U(\mathbf{w}) &= \sum_{t=1}^{\infty} \sum_{s_{1:t}, a_{1:t}} \gamma^{t-1} p(s_{1:t}, a_{1:t}; \mathbf{w}) \frac{\partial^2}{\partial \mathbf{w}^2} \log p(s_{1:t}, a_{1:t}; \mathbf{w}) R(s_t, a_t) \\ &\quad + \sum_{t=1}^{\infty} \sum_{s_{1:t}, a_{1:t}} \gamma^{t-1} p(s_{1:t}, a_{1:t}; \mathbf{w}) \frac{\partial}{\partial \mathbf{w}} \log p(s_{1:t}, a_{1:t}; \mathbf{w}) \frac{\partial^{\top}}{\partial \mathbf{w}} \log p(s_{1:t}, a_{1:t}; \mathbf{w}) R(s_t, a_t). \end{aligned} \quad (39)$$

Using the fact that $\frac{\partial^2}{\partial \mathbf{w}^2} \log p(s_{1:t}, a_{1:t} | s_1 = s; \mathbf{w}) = \sum_{\tau=1}^t \frac{\partial^2}{\partial \mathbf{w}^2} \log \pi(a_{\tau} | s_{\tau}; \mathbf{w})$ we will show that the first term in (39) is equal to $\mathcal{H}_2(\mathbf{w})$ as defined in (16):

$$\begin{aligned} &\sum_{t=1}^{\infty} \sum_{s_{1:t}, a_{1:t}} \gamma^{t-1} p(s_{1:t}, a_{1:t}; \mathbf{w}) \frac{\partial^2}{\partial \mathbf{w}^2} \log p(s_{1:t}, a_{1:t}; \mathbf{w}) R(s_t, a_t) \\ &= \sum_{t=1}^{\infty} \sum_{s_{1:t}, a_{1:t}} \gamma^{t-1} p(s_{1:t}, a_{1:t}; \mathbf{w}) \sum_{\tau=1}^t \frac{\partial^2}{\partial \mathbf{w}^2} \log \pi(a_{\tau} | s_{\tau}; \mathbf{w}) R(s_t, a_t) \\ &= \sum_{\tau=1}^{\infty} \gamma^{\tau-1} \sum_{s_{\tau}, a_{\tau}} p(s_{\tau}, a_{\tau}; \mathbf{w}) \frac{\partial^2}{\partial \mathbf{w}^2} \log \pi(a_{\tau} | s_{\tau}; \mathbf{w}) \sum_{t=\tau}^{\infty} \gamma^{t-\tau} \sum_{s_t, a_t} p(s_t, a_t | s_{\tau}, a_{\tau}; \mathbf{w}) R(s_t, a_t) \\ &= \sum_{\tau=1}^{\infty} \gamma^{\tau-1} \sum_{s_{\tau}, a_{\tau}} p(s_{\tau}, a_{\tau}; \mathbf{w}) \frac{\partial^2}{\partial \mathbf{w}^2} \log \pi(a_{\tau} | s_{\tau}; \mathbf{w}) Q(s_{\tau}, a_{\tau}; \mathbf{w}). \end{aligned}$$

$$= \mathcal{H}_2(\mathbf{w})$$

where in the third line we swapped the order of summation.

Using (37) we can write the second term in (39) as,

$$\begin{aligned} &\sum_{t=1}^{\infty} \sum_{s_{1:t}, a_{1:t}} \gamma^{t-1} p(s_{1:t}, a_{1:t}; \mathbf{w}) \frac{\partial}{\partial \mathbf{w}} \log p(s_{1:t}, a_{1:t}; \mathbf{w}) \frac{\partial^{\top}}{\partial \mathbf{w}} \log p(s_t, a_t; \mathbf{w}) R(s_t, a_t) \\ &= \sum_{t=1}^{\infty} \sum_{\tau=1}^t \sum_{s_{1:t}, a_{1:t}} \gamma^{t-1} p(s_{1:t}, a_{1:t}; \mathbf{w}) \frac{\partial}{\partial \mathbf{w}} \log \pi(a_{\tau} | s_{\tau}; \mathbf{w}) \frac{\partial^{\top}}{\partial \mathbf{w}} \log \pi(a_{\tau} | s_{\tau}; \mathbf{w}) R(s_t, a_t) \\ &\quad + \sum_{t=1}^{\infty} \sum_{\substack{\tau_1 \neq \tau_2 \\ \tau_1, \tau_2=1}}^t \sum_{s_{1:t}, a_{1:t}} \gamma^{t-1} p(s_{1:t}, a_{1:t}; \mathbf{w}) \frac{\partial}{\partial \mathbf{w}} \log \pi(a_{\tau_1} | s_{\tau_1}; \mathbf{w}) \frac{\partial^{\top}}{\partial \mathbf{w}} \log \pi(a_{\tau_2} | s_{\tau_2}; \mathbf{w}) R(s_t, a_t). \end{aligned} \quad (40)$$

By swapping the order of summation and following analogous calculations to those above, it can be shown that the first term in (40) is equal to $\mathcal{H}_1(\mathbf{w})$ as defined in (15). It remains to show that the second term in (40) is given by $\mathcal{H}_{12}(\mathbf{w}) + \mathcal{H}_{12}^{\top}(\mathbf{w})$, with $\mathcal{H}_{12}(\mathbf{w})$ as given in (17). Splitting the second term in (40) into two terms,

$$\begin{aligned} &\sum_{t=1}^{\infty} \sum_{\substack{\tau_1, \tau_2=1 \\ \tau_1 \neq \tau_2}}^t \sum_{s_{1:t}, a_{1:t}} \gamma^{t-1} p(s_{1:t}, a_{1:t}; \mathbf{w}) \frac{\partial}{\partial \mathbf{w}} \log \pi(a_{\tau_1} | s_{\tau_1}; \mathbf{w}) \frac{\partial^{\top}}{\partial \mathbf{w}} \log \pi(a_{\tau_2} | s_{\tau_2}; \mathbf{w}) R(s_t, a_t) \\ &= \sum_{t=1}^{\infty} \sum_{\tau_2=1}^t \sum_{\tau_1=1}^{\tau_2-1} \sum_{s_{1:t}, a_{1:t}} \gamma^{t-1} p(s_{1:t}, a_{1:t}; \mathbf{w}) \frac{\partial}{\partial \mathbf{w}} \log \pi(a_{\tau_1} | s_{\tau_1}; \mathbf{w}) \frac{\partial^{\top}}{\partial \mathbf{w}} \log \pi(a_{\tau_2} | s_{\tau_2}; \mathbf{w}) R(s_t, a_t) \\ &\quad + \sum_{t=1}^{\infty} \sum_{\tau_1=1}^t \sum_{\tau_2=1}^{\tau_1-1} \sum_{s_{1:t}, a_{1:t}} \gamma^{t-1} p(s_{1:t}, a_{1:t}; \mathbf{w}) \frac{\partial}{\partial \mathbf{w}} \log \pi(a_{\tau_1} | s_{\tau_1}; \mathbf{w}) \frac{\partial^{\top}}{\partial \mathbf{w}} \log \pi(a_{\tau_2} | s_{\tau_2}; \mathbf{w}) R(s_t, a_t), \end{aligned} \quad (41)$$

we will show that the first term is equal to $\mathcal{H}_{12}(\mathbf{w})$. Given this, it immediately follows that the second term is equal to $\mathcal{H}_{12}^{\top}(\mathbf{w})$. Using the Markov property of the transition dynamics and the policy it follows that the first term in (41) is given by,

$$\begin{aligned} &\sum_{t=1}^{\infty} \sum_{\tau_2=1}^t \sum_{\tau_1=1}^{\tau_2-1} \sum_{s_{1:t}, a_{1:t}} \gamma^{\tau_1-1} p(s_{\tau_1}, a_{\tau_1}; \mathbf{w}) \frac{\partial}{\partial \mathbf{w}} \log \pi(a_{\tau_1} | s_{\tau_1}; \mathbf{w}) \\ &\quad \times \sum_{s_{\tau_2}, a_{\tau_2}} \gamma^{\tau_2-\tau_1} p(s_{\tau_2}, a_{\tau_2} | s_{\tau_1}, a_{\tau_1}; \mathbf{w}) \frac{\partial^{\top}}{\partial \mathbf{w}} \log \pi(a_{\tau_2} | s_{\tau_2}; \mathbf{w}) \sum_{s_t, a_t} \gamma^{t-\tau_2} p(s_t, a_t | s_{\tau_2}, a_{\tau_2}; \mathbf{w}) R(s_t, a_t). \end{aligned}$$

Rearranging the summation over t , τ_1 and τ_2 this can be rewritten in the form,

$$\begin{aligned} & \sum_{\tau_1=1}^{\infty} \sum_{s_{\tau_1}, a_{\tau_1}} \gamma^{\tau_1-1} p(s_{\tau_1}, a_{\tau_1}; \mathbf{w}) \frac{\partial}{\partial \mathbf{w}} \log \pi(a_{\tau_1} | s_{\tau_1}; \mathbf{w}) \\ & \times \left\{ \sum_{\tau_2=\tau_1+1}^{\infty} \sum_{s_{\tau_2}, a_{\tau_2}} \gamma^{\tau_2-\tau_1} p(s_{\tau_2}, a_{\tau_2} | s_{\tau_1}, a_{\tau_1}; \mathbf{w}) \frac{\partial^{\top}}{\partial \mathbf{w}} \log \pi(a_{\tau_2} | s_{\tau_2}; \mathbf{w}) \right. \\ & \left. \sum_{t=\tau_2}^{\infty} \sum_{s_t, a_t} \gamma^{t-\tau_2} p(s_t, a_t | s_{\tau_2}, a_{\tau_2}; \mathbf{w}) R(s_t, a_t) \right\} \\ & = \sum_{\tau_1=1}^{\infty} \sum_{s_{\tau_1}, a_{\tau_1}} \gamma^{\tau_1-1} p(s_{\tau_1}, a_{\tau_1}; \mathbf{w}) \frac{\partial}{\partial \mathbf{w}} \log \pi(a_{\tau_1} | s_{\tau_1}; \mathbf{w}) \\ & \times \sum_{\tau_2=\tau_1+1}^{\infty} \sum_{s_{\tau_2}, a_{\tau_2}} \gamma^{\tau_2-\tau_1} p(s_{\tau_2}, a_{\tau_2} | s_{\tau_1}, a_{\tau_1}; \mathbf{w}) \frac{\partial^{\top}}{\partial \mathbf{w}} \log \pi(a_{\tau_2} | s_{\tau_2}; \mathbf{w}) Q(s_{\tau_2}, a_{\tau_2}; \mathbf{w}) \\ & = \sum_{\tau_1=1}^{\infty} \sum_{s_{\tau_1}, a_{\tau_1}} \gamma^{\tau_1-1} p(s_{\tau_1}, a_{\tau_1}; \mathbf{w}) \frac{\partial}{\partial \mathbf{w}} \log \pi(a_{\tau_1} | s_{\tau_1}; \mathbf{w}) \frac{\partial^{\top}}{\partial \mathbf{w}} Q(s_{\tau_1}, a_{\tau_1}; \mathbf{w}) \\ & = \mathcal{H}_{12}(\mathbf{w}) \end{aligned}$$

Where the penultimate line follows from (35). This completes the proof. \square

A.2 Proof of Theorem 4

Recalling that the state-action value function takes the form, $Q(s, a; \mathbf{w}) = V(s; \mathbf{w}) + A(s, a; \mathbf{w})$, the matrices $\mathcal{H}_1(\mathbf{w})$ and $\mathcal{H}_2(\mathbf{w})$ can be written in the following forms,

$$\mathcal{H}_1(\mathbf{w}) = \mathcal{A}_1(\mathbf{w}) + \mathcal{V}_1(\mathbf{w}), \quad \mathcal{H}_2(\mathbf{w}) = \mathcal{A}_2(\mathbf{w}) + \mathcal{V}_2(\mathbf{w}), \quad (42)$$

where,

$$\begin{aligned} \mathcal{A}_1(\mathbf{w}) &= \sum_{(s,a) \in \mathcal{S} \times \mathcal{A}} p_{\gamma}(s, a; \mathbf{w}) A(s, a; \mathbf{w}) \frac{\partial}{\partial \mathbf{w}} \log \pi(a | s; \mathbf{w}) \frac{\partial^{\top}}{\partial \mathbf{w}} \log \pi(a | s; \mathbf{w}) \\ \mathcal{A}_2(\mathbf{w}) &= \sum_{(s,a) \in \mathcal{S} \times \mathcal{A}} p_{\gamma}(s, a; \mathbf{w}) A(s, a; \mathbf{w}) \frac{\partial^2}{\partial \mathbf{w}^2} \log \pi(a | s; \mathbf{w}) \\ \mathcal{V}_1(\mathbf{w}) &= \sum_{(s,a) \in \mathcal{S} \times \mathcal{A}} p_{\gamma}(s, a; \mathbf{w}) V(s, a; \mathbf{w}) \frac{\partial}{\partial \mathbf{w}} \log \pi(a | s; \mathbf{w}) \frac{\partial^{\top}}{\partial \mathbf{w}} \log \pi(a | s; \mathbf{w}) \\ \mathcal{V}_2(\mathbf{w}) &= \sum_{(s,a) \in \mathcal{S} \times \mathcal{A}} p_{\gamma}(s, a; \mathbf{w}) V(s, a; \mathbf{w}) \frac{\partial^2}{\partial \mathbf{w}^2} \log \pi(a | s; \mathbf{w}). \end{aligned}$$

We begin with the following auxiliary lemmas.

Lemma 2. *Suppose we are given a Markov decision process with objective (1) and Markovian trajectory distribution (2). Provided that the policy satisfies the Fisher regularity conditions, then for any given parameter vector, $\mathbf{w} \in \mathcal{W}$, the matrices $\mathcal{V}_1(\mathbf{w})$ and $\mathcal{V}_2(\mathbf{w})$ satisfy the following relation $\mathcal{V}_1(\mathbf{w}) = -\mathcal{V}_2(\mathbf{w})$.*

Proof. As the policy satisfies the Fisher regularity conditions, then for any state, $s \in \mathcal{S}$, the following relation holds

$$\sum_{a \in \mathcal{A}} \pi(a | s; \mathbf{w}) \frac{\partial}{\partial \mathbf{w}} \log \pi(a | s; \mathbf{w}) \frac{\partial^{\top}}{\partial \mathbf{w}} \log \pi(a | s; \mathbf{w}) = - \sum_{a \in \mathcal{A}} \pi(a | s; \mathbf{w}) \frac{\partial^2}{\partial \mathbf{w}^2} \log \pi(a | s; \mathbf{w}).$$

This means that $\mathcal{V}_1(\mathbf{w})$ can be written in the form

$$\begin{aligned} \mathcal{V}_1(\mathbf{w}) &= \sum_{s \in \mathcal{S}} p_{\gamma}(s; \mathbf{w}) V(s; \mathbf{w}) \sum_{a \in \mathcal{A}} \pi(a | s; \mathbf{w}) \frac{\partial}{\partial \mathbf{w}} \log \pi(a | s; \mathbf{w}) \frac{\partial^{\top}}{\partial \mathbf{w}} \log \pi(a | s; \mathbf{w}), \\ &= - \sum_{s \in \mathcal{S}} p_{\gamma}(s; \mathbf{w}) V(s; \mathbf{w}) \sum_{a \in \mathcal{A}} \pi(a | s; \mathbf{w}) \frac{\partial^2}{\partial \mathbf{w}^2} \log \pi(a | s; \mathbf{w}) = -\mathcal{V}_2(\mathbf{w}), \end{aligned}$$

which completes the proof. \square

Lemma 3. *Suppose we are given a Markov decision process with objective (1) and Markovian trajectory distribution (2). If the policy parameterisation has constant curvature with respect to the action space, then $\mathcal{A}_2(\mathbf{w}) = \mathbf{0}$.*

Proof. When a policy parameterisation has constant curvature with respect to the action space, then we use, $\mathcal{H}_{\pi}(s, \mathbf{w})$, to denote $\frac{\partial^2}{\partial \mathbf{w}^2} \log \pi(a | s; \mathbf{w})$, for each $a \in \mathcal{A}$. Recalling Definition 2, the matrix $\mathcal{A}_2(\mathbf{w})$ takes the form,

$$\begin{aligned} \mathcal{A}_2(\mathbf{w}) &= \sum_{(s,a) \in \mathcal{S} \times \mathcal{A}} p_{\gamma}(s, a; \mathbf{w}) A(s, a; \mathbf{w}) \frac{\partial^2}{\partial \mathbf{w}^2} \log \pi(a | s; \mathbf{w}), \\ &= \sum_{s \in \mathcal{S}} p_{\gamma}(s; \mathbf{w}) \mathcal{H}_{\pi}(s, \mathbf{w}) \sum_{a \in \mathcal{A}} \pi(a | s; \mathbf{w}) A(s, a; \mathbf{w}). \end{aligned}$$

The relation $\mathcal{A}_2(\mathbf{w}) = \mathbf{0}$ follows because $\sum_{a \in \mathcal{A}} \pi(a | s; \mathbf{w}) A(s, a; \mathbf{w}) = 0$, for all $s \in \mathcal{S}$. \square

Lemmas 2 & 3, along with the relation (42), directly imply the result of Theorem 4.

A.3 Proof of Theorem 5 and Definiteness Results

Theorem 5. *Proof.* The first result follows from the fact that when the policy is log-concave with respect to the policy parameters, then $\mathcal{H}_2(\mathbf{w})$ is a non-negative mixture of negative-definite matrices, which again is negative-definite (Boyd and Vandenberghe, 2004).

The second result follows because when the policy parameterisation has constant curvature with respect to the action space, then by Lemma 3 in Section A.2 $\mathcal{A}_2(\mathbf{w}) = \mathbf{0}$, so that $\mathcal{H}_2(\mathbf{w}) = \mathcal{A}_2(\mathbf{w}) + \mathcal{V}_2(\mathbf{w}) = \mathcal{V}_2(\mathbf{w}) = -\mathcal{V}_1(\mathbf{w})$, with

$$\begin{aligned} \mathcal{V}_1(\mathbf{w}) &= \sum_{(s,a) \in \mathcal{S} \times \mathcal{A}} p_{\gamma}(s, a; \mathbf{w}) V(s, a; \mathbf{w}) \frac{\partial}{\partial \mathbf{w}} \log \pi(a | s; \mathbf{w}) \frac{\partial^{\top}}{\partial \mathbf{w}} \log \pi(a | s; \mathbf{w}) \\ \mathcal{V}_2(\mathbf{w}) &= \sum_{(s,a) \in \mathcal{S} \times \mathcal{A}} p_{\gamma}(s, a; \mathbf{w}) V(s, a; \mathbf{w}) \frac{\partial^2}{\partial \mathbf{w}^2} \log \pi(a | s; \mathbf{w}). \end{aligned}$$

The result now follows because $-\mathcal{V}_1(\mathbf{w})$ is negative-semidefinite for all $\mathbf{w} \in \mathcal{W}$. \square

Lemma 4. For any $\mathbf{w} \in \mathcal{W}$ the matrix $\mathcal{H}_{11}(\mathbf{w}) = \mathcal{H}_1(\mathbf{w}) + \mathcal{H}_{12}(\mathbf{w}) + \mathcal{H}_{12}^\top(\mathbf{w})$ is positive-semidefinite.

Proof. This follows immediately from the form of $\mathcal{H}_1(\mathbf{w}) + \mathcal{H}_{12}(\mathbf{w}) + \mathcal{H}_{12}^\top(\mathbf{w})$ given by (40) in Theorem 3, which is positive-semidefinite since the reward function is assumed to be non-negative. \square

A.4 Proof of Theorem 6

We first prove an auxiliary lemma about the gradient of the state value function in the case of a tabular policy. As we are considering a tabular policy we have a separate parameter vector \mathbf{w}_s for each state $s \in \mathcal{S}$. We denote the parameter vector of the entire policy by \mathbf{w} , in which this is given by the concatenation of the parameter vectors of the different states. The dimension of \mathbf{w} is given by $n = \sum_{s \in \mathcal{S}} n_s$. In order to show that tabular policies are value-consistent we start by relating the gradient of $V(\hat{s}; \mathbf{w})$ to the gradient of $V(\bar{s}; \mathbf{w})$, where the gradient is taken with respect to the policy parameters of state \bar{s} , while the policy parameters of the remaining states are held fixed.

Lemma 5. Suppose we are given a Markov decision process with a tabular policy such that $V(s; \mathbf{w})$ is differentiable for each $s \in \mathcal{S}$. Given $\bar{s}, \hat{s} \in \mathcal{S}$, such that $\bar{s} \neq \hat{s}$, then we have that

$$\frac{\partial}{\partial \mathbf{w}_{\bar{s}}} V(\hat{s}; \mathbf{w}) = p_{\text{hit}}(\hat{s} \rightarrow \bar{s}) \frac{\partial}{\partial \mathbf{w}_{\bar{s}}} V(\bar{s}; \mathbf{w}), \quad (43)$$

where the notation $\frac{\partial}{\partial \mathbf{w}_{\bar{s}}} V(\hat{s}; \mathbf{w})$ is used to denote the gradient of the state value function w.r.t. the policy parameter of state \bar{s} , with the policy parameters of all other states considered fixed. The term $p_{\text{hit}}(\hat{s} \rightarrow \bar{s})$ in (43) is given by

$$p_{\text{hit}}(\hat{s} \rightarrow \bar{s}) = \sum_{t=2}^{\infty} \gamma^{t-1} p(s_t = \bar{s} | s_1 = \hat{s}, s_\tau \neq \bar{s}, \tau = 1, \dots, t-1; \mathbf{w}).$$

Furthermore, when Markov chain induced by the policy parameters is ergodic then $p_{\text{hit}} > 0$.

Proof. Given the equality $V(s; \mathbf{w}) = \sum_{a \in \mathcal{A}} \pi(a|s; \mathbf{w}) Q(s, a; \mathbf{w})$, we have that

$$\frac{\partial}{\partial \mathbf{w}_{\bar{s}}} V(\hat{s}; \mathbf{w}) = \sum_{a \in \mathcal{A}} \left(\frac{\partial}{\partial \mathbf{w}_{\bar{s}}} \pi(a|\hat{s}; \mathbf{w}) Q(\hat{s}, a; \mathbf{w}) + \pi(a|\hat{s}; \mathbf{w}) \frac{\partial}{\partial \mathbf{w}_{\bar{s}}} Q(\hat{s}, a; \mathbf{w}) \right).$$

As the policy is tabular and $\hat{s} \neq \bar{s}$ we have that $\frac{\partial}{\partial \mathbf{w}_{\bar{s}}} \pi(a|\hat{s}; \mathbf{w}) = 0$, so that this simplifies to

$$\frac{\partial}{\partial \mathbf{w}_{\bar{s}}} V(\hat{s}; \mathbf{w}) = \sum_{a \in \mathcal{A}} \pi(a|\hat{s}; \mathbf{w}) \frac{\partial}{\partial \mathbf{w}_{\bar{s}}} Q(\hat{s}, a; \mathbf{w}).$$

Using the fact that $Q(s, a; \mathbf{w}) = R(s, a) + \gamma \sum_{s' \in \mathcal{S}} p(s'|s; a) V(s'; \mathbf{w})$, we have

$$\begin{aligned} \frac{\partial}{\partial \mathbf{w}_{\bar{s}}} V(\hat{s}; \mathbf{w}) &= \gamma \sum_{s' \in \mathcal{S}} p(s'|\hat{s}; \mathbf{w}) \frac{\partial}{\partial \mathbf{w}_{\bar{s}}} V(s'; \mathbf{w}) \\ &= \gamma p(\bar{s}|\hat{s}; \mathbf{w}) \frac{\partial}{\partial \mathbf{w}_{\bar{s}}} V(\bar{s}; \mathbf{w}) + \gamma \sum_{\substack{s' \in \mathcal{S} \\ s' \neq \bar{s}}} p(s'|\hat{s}; \mathbf{w}) \frac{\partial}{\partial \mathbf{w}_{\bar{s}}} V(s'; \mathbf{w}). \end{aligned} \quad (44)$$

Applying equation (44) recursively gives

$$\begin{aligned} \frac{\partial}{\partial \mathbf{w}_{\bar{s}}} V(\hat{s}; \mathbf{w}) &= \sum_{t=2}^{\infty} \gamma^{t-1} p(s_t = \bar{s} | s_1 = \hat{s}, s_\tau \neq \bar{s}, \tau = 1, \dots, t-1; \mathbf{w}) \frac{\partial}{\partial \mathbf{w}_{\bar{s}}} V(\bar{s}; \mathbf{w}) \\ &= p_{\text{hit}}(\hat{s} \rightarrow \bar{s}) \frac{\partial}{\partial \mathbf{w}_{\bar{s}}} V(\bar{s}; \mathbf{w}), \end{aligned} \quad (45)$$

which completes the proof. The probability, $p(s_t = \bar{s} | s_1 = \hat{s}, s_\tau \neq \bar{s}, \tau = 1, \dots, t-1; \mathbf{w})$, is equivalent to the probability that the first hitting time (of hitting state \bar{s} when starting in state \hat{s}) is equal to t . The strict inequality, $p_{\text{hit}}(\hat{s} \rightarrow \bar{s}) > 0$, follows from the ergodicity of the Markov chain induced by \mathbf{w} . \square

We are now ready to prove Theorem 6.

Theorem 6. *Proof.* Suppose that there exists $i \in \{1, \dots, n\}$, $\mathbf{w} \in \mathcal{W}$ and $\hat{s} \in \mathcal{S}$ such that $\frac{\partial}{\partial w_i} V(\hat{s}; \mathbf{w}) \neq 0$, for some $\hat{s} \in \mathcal{S}$. As the policy parameterisation is tabular, then the i^{th} component of \mathbf{w} corresponds to a policy parameter for a particular state, $\bar{s} \in \mathcal{S}$. From Lemma 5 it follows that

$$\frac{\partial}{\partial w_i} V(s; \mathbf{w}) = p_{\text{hit}}(s \rightarrow \bar{s}) \frac{\partial}{\partial w_i} V(\bar{s}; \mathbf{w}),$$

for all $s \in \mathcal{S}$. It follows that for states, $s \in \mathcal{S}$, for which $p_{\text{hit}}(s \rightarrow \bar{s}) > 0$ that we have

$$\text{sign} \left(\frac{\partial}{\partial w_i} V(s; \mathbf{w}) \right) = \text{sign} \left(\frac{\partial}{\partial w_i} V(\bar{s}; \mathbf{w}) \right),$$

while in states for which $p_{\text{hit}}(s \rightarrow \bar{s}) = 0$ we have $\text{sign} \left(\frac{\partial}{\partial w_i} V(s; \mathbf{w}) \right) = 0$.

It remains to show that for states in which $p_{\text{hit}}(s \rightarrow \bar{s}) = 0$ that $\text{sign} \left(\frac{\partial}{\partial w_i} \pi(a|s; \mathbf{w}) \right) = 0$, $\forall a \in \mathcal{A}$. This property follows immediately from the fact that the policy parameterisation is tabular and $p_{\text{hit}}(\bar{s} \rightarrow \bar{s}) \neq 0$. \square

A.5 Proof of Theorem 7

Lemma 6. Given a Markov decision process and a policy parameterisation that is ϵ -value-consistent, if there exists $i \in \{1, \dots, n\}$ and $\hat{s} \in \mathcal{S}$ such that,

$$\left| \frac{\partial}{\partial w_i} V(\hat{s}; \mathbf{w}) \Big|_{\mathbf{w}=\mathbf{w}^*} \right| > \epsilon, \quad (46)$$

then for each $s \in \mathcal{S}$,

$$\text{sign} \left(\frac{\partial}{\partial w_i} V(s; \mathbf{w}) \right) = \text{sign} \left(\frac{\partial}{\partial w_i} V(\hat{s}; \mathbf{w}) \right).$$

Proof. In order to obtain a contradiction suppose that there exists $s \in \mathcal{S}$ such that,

$$\text{sign} \left(\frac{\partial}{\partial w_i} V(s; \mathbf{w}) \right) \neq \text{sign} \left(\frac{\partial}{\partial w_i} V(\hat{s}; \mathbf{w}) \right). \quad (47)$$

By definition 2 it follows that for all $s' \in S$,

$$\text{sign} \left(\frac{\partial}{\partial u_i} V(s'; \mathbf{w}) \right) = \text{sign} \left(\frac{\partial}{\partial u_i} V(s; \mathbf{w}) \right), \quad (48)$$

or

$$\left| \frac{\partial}{\partial u_i} V(s'; \mathbf{w}) \right| \leq \epsilon. \quad (49)$$

From (47) it follows that,

$$\left| \frac{\partial}{\partial u_i} V(\hat{s}; \mathbf{w}) \right| \leq \epsilon. \quad (50)$$

This is a contradiction of (46), which completes the proof. \square

Theorem 7. Proof. In order to obtain a contradiction suppose that there exists $i \in \{1, \dots, n\}$ and $\hat{s} \in S$ such that,

$$\left| \frac{\partial}{\partial u_i} V(\hat{s}; \mathbf{w}) \Big|_{\mathbf{w}=\mathbf{w}^*} \right| > \epsilon. \quad (51)$$

We suppose that $\frac{\partial}{\partial u_i} V(\hat{s}; \mathbf{w}) \Big|_{\mathbf{w}=\mathbf{w}^*} > \epsilon$ (an identical argument can be used for the case $\frac{\partial}{\partial u_i} V(\hat{s}; \mathbf{w}) \Big|_{\mathbf{w}=\mathbf{w}^*} < -\epsilon$). As the policy parameterisation is ϵ -value-consistent it follows from lemma 6 that, for each $s \in S$,

$$\frac{\partial}{\partial u_i} V(s; \mathbf{w}) \Big|_{\mathbf{w}=\mathbf{w}^*} \geq 0. \quad (52)$$

In order to obtain a contradiction we will show that there is no $s \in S$ for which (52) holds with equality. Given this property a contradiction is obtained because it follows that

$$\frac{\partial}{\partial u_i} U(\mathbf{w}) \Big|_{\mathbf{w}=\mathbf{w}^*} = \mathbb{E}_{p_i(s)} \left[\frac{\partial}{\partial u_i} V(s; \mathbf{w}) \Big|_{\mathbf{w}=\mathbf{w}^*} \right] > 0,$$

contradicting the fact that \mathbf{w}^* is a local optimum of the objective function. Introducing the notation

$$\begin{aligned} S_{=} &= \{s \in S \mid \frac{\partial}{\partial u_i} V(s; \mathbf{w}) \Big|_{\mathbf{w}=\mathbf{w}^*} = 0\}, \\ S_{>} &= \{s \in S \mid \frac{\partial}{\partial u_i} V(s; \mathbf{w}) \Big|_{\mathbf{w}=\mathbf{w}^*} > 0\}, \end{aligned}$$

we wish to show that $S_{=} = \emptyset$. In particular, for a contradiction, suppose that $S_{=} \neq \emptyset$. This means, given the ergodicity of the Markov chain induced by \mathbf{w}^* and the fact that $S_{>} \neq \emptyset$, that there exists $s \in S_{=}$ and $s' \in S_{>}$ such that $p(s'|s; \mathbf{w}^*) = \sum_{a \in \mathcal{A}} p(s'|s, a) \pi(a|s; \mathbf{w}^*) > 0$. We now consider the form of $\frac{\partial}{\partial u_i} V(s; \mathbf{w}) \Big|_{\mathbf{w}=\mathbf{w}^*}$. In particular, we have

$$\begin{aligned} \frac{\partial}{\partial u_i} V(s; \mathbf{w}) &= \sum_{a \in \mathcal{A}} \frac{\partial}{\partial u_i} \pi(a|s; \mathbf{w}) \left(R(a, s) + \gamma \sum_{s_{\text{next}} \in S} p(s_{\text{next}}|s, a) V(s_{\text{next}}; \mathbf{w}) \right) \\ &+ \gamma \sum_{a \in \mathcal{A}} \pi(a|s; \mathbf{w}) \sum_{s_{\text{next}} \in S} p(s_{\text{next}}|s, a) \frac{\partial}{\partial u_i} V(s_{\text{next}}; \mathbf{w}). \end{aligned}$$

As $s \in S_{=}$, we have by value consistency that $\frac{\partial}{\partial u_i} \pi(a|s; \mathbf{w}) \Big|_{\mathbf{w}=\mathbf{w}^*} = 0$. This means that

$$\frac{\partial}{\partial u_i} V(s; \mathbf{w}) \Big|_{\mathbf{w}=\mathbf{w}^*} = \gamma \sum_{a \in \mathcal{A}} \pi(a|s; \mathbf{w}) \sum_{s_{\text{next}} \in S} p(s_{\text{next}}|s, a) \frac{\partial}{\partial u_i} V(s_{\text{next}}; \mathbf{w}) \Big|_{\mathbf{w}=\mathbf{w}^*} > 0.$$

The inequality follows from the fact that $p(s'|s; \mathbf{w}^*) > 0$, for some $s' \in S_{>}$. This is a contradiction of the fact that $s \in S_{=}$, so it follows that $S_{=} = \emptyset$ and for all $s \in S$ we have $\frac{\partial}{\partial u_i} V(s; \mathbf{w}) \Big|_{\mathbf{w}=\mathbf{w}^*} > 0$, which completes the proof. \square

A.6 Proof of Theorem 8

Theorem 8. Proof. A optimisation method is said to affine invariant if, given any objective function (for which the optimisation technique is applicable), $f: \mathcal{W} \rightarrow \mathbb{R}$, and non-singular affine mapping, $T \in \mathbb{R}^{n \times n}$, the update of the objective $f(\mathbf{w}) = f(T\mathbf{w})$ is related to the update of the original objective through the same affine mapping, i.e., $\mathbf{v} + \Delta \mathbf{v}_{\text{step}} = T(\mathbf{w} + \Delta \mathbf{w}_{\text{step}})$, in which $\mathbf{v} = T\mathbf{w}$ and $\Delta \mathbf{v}_{\text{step}}$ and $\Delta \mathbf{w}_{\text{step}}$ denote the respective steps in the parameter space.

We shall consider the second Gauss-Newton method, with the result for the diagonal approximate Newton method following similarly. Given a non-singular affine transformation, $T \in \mathbb{R}^{n \times n}$, define the objective, $\tilde{U}(\mathbf{w}) = U(T\mathbf{w}) = U(\mathbf{v})$, with $\mathbf{v} = T\mathbf{w}$, and denote the approximate Hessian of $\tilde{U}(\mathbf{w})$ by $\tilde{\mathcal{H}}_2(\mathbf{w})$. Given $\mathbf{w} \in \mathcal{W}$, then it is sufficient to show that,

$$T\mathbf{w}_{\text{new}} = T \left(\mathbf{w} - \alpha \tilde{\mathcal{H}}_2^{-1}(\mathbf{w}) \frac{\partial}{\partial \mathbf{w}} \tilde{U}(\mathbf{w}) \right) = \mathbf{v} - \alpha \mathcal{H}_2^{-1}(\mathbf{v}) \frac{\partial}{\partial \mathbf{v}} U(\mathbf{v}) = \mathbf{v}_{\text{new}}, \quad \forall \alpha \in \mathbb{R}^+.$$

Following calculations analogous to those in Section A.1 it can be shown that,

$$\begin{aligned} \frac{\partial}{\partial \mathbf{w}} \tilde{U}(\mathbf{w}) &= \sum_{s, a} p_\gamma(s, a; T\mathbf{w}) Q(s, a; T\mathbf{w}) \frac{\partial}{\partial \mathbf{w}} \log p(a|s; T\mathbf{w}), \\ \tilde{\mathcal{H}}_2(\mathbf{w}) &= \sum_{s, a} p_\gamma(s, a; T\mathbf{w}) Q(s, a; T\mathbf{w}) \frac{\partial^2}{\partial \mathbf{w}^2} \log p(a|s; T\mathbf{w}). \end{aligned}$$

Using the relations

$$\begin{aligned} \frac{\partial}{\partial \mathbf{w}} \log \pi(a|s; T\mathbf{w}) &= T^{-\top} \frac{\partial}{\partial \mathbf{v}} \log \pi(a|s; \mathbf{v}), \\ \frac{\partial^2}{\partial \mathbf{w}^2} \log \pi(a|s; T\mathbf{w}) &= T^{-\top} \frac{\partial^2}{\partial \mathbf{v}^2} \log \pi(a|s; \mathbf{v}) T, \end{aligned}$$

it follows that

$$\begin{aligned} \frac{\partial}{\partial \mathbf{w}} \tilde{U}(\mathbf{w}) &= T^{-\top} \frac{\partial}{\partial \mathbf{v}} U(\mathbf{v}), \\ \tilde{\mathcal{H}}_2(\mathbf{w}) &= T^{-\top} \mathcal{H}_2(\mathbf{v}) T. \end{aligned}$$

From this we have, for any $\alpha \in \mathbb{R}^+$, that

$$T\mathbf{w}_{\text{new}} = T \left(\mathbf{w} - \alpha \tilde{\mathcal{H}}_2^{-1}(\mathbf{w}) \frac{\partial}{\partial \mathbf{w}} \tilde{U}(\mathbf{w}) \right) = \mathbf{v} - \alpha \mathcal{H}_2^{-1}(\mathbf{v}) \frac{\partial}{\partial \mathbf{v}} U(\mathbf{v}) = \mathbf{v}_{\text{new}}, \quad \forall \alpha \in \mathbb{R}^+.$$

which completes the proof. \square

A.7 Proofs of Theorems 9 and 10

We begin by stating a well-known tool for analysis of convergence of iterative optimization methods. Given an iterative optimization method, defined through a mapping $G: \mathcal{W} \rightarrow \mathbb{R}^n$, where $\mathcal{W} \subseteq \mathbb{R}^n$, the local convergence at a point $\mathbf{w}^* \in \mathcal{W}$ is determined by the spectral radius of the Jacobian of G at \mathbf{w}^* , $\nabla G(\mathbf{w}^*)$. This is formalized through the well-known Ostrowski's Theorem, a formal proof of which can be found in the work of Ortega and Rheinboldt (1970).

Lemma 7 (Ostrowski's Theorem). *Suppose that we have a mapping $G: \mathcal{W} \rightarrow \mathbb{R}^n$, where $\mathcal{W} \subseteq \mathbb{R}^n$, such that $\mathbf{w}^* \in \text{int}(\mathcal{W})$ is a fixed-point of G and, furthermore, G is Fréchet differentiable at \mathbf{w}^* . If the spectral radius of $\nabla G(\mathbf{w}^*)$ satisfies $\rho(\nabla G(\mathbf{w}^*)) < 1$, then \mathbf{w}^* is a point of attraction of G . Furthermore, if $\rho(\nabla G(\mathbf{w}^*)) > 0$, then the convergence towards \mathbf{w}^* is linear and the rate is given by $\rho(\nabla G(\mathbf{w}^*))$.*

We now prove Theorems 9 and 10.

Theorem 9 (Convergence analysis for the first Gauss-Newton method). *Proof.* A formal proof that G_1 is Fréchet differentiable can be found in Section 10.2.1 of Ortega and Rheinboldt (1970). We now demonstrate the form of $\nabla G_1(\mathbf{w}^*)$. For simplicity we shall assume that $(\mathcal{A}_1(\mathbf{w}^*) + \mathcal{A}_2(\mathbf{w}^*))^{-1}$ is differentiable. This is not a necessary condition, and a proof that does not make this assumption can be found in Section 10.2.1 of Ortega and Rheinboldt (1970). We have that,

$$G_1(\mathbf{w}) = \mathbf{w} - \alpha(\mathcal{A}_1(\mathbf{w}) + \mathcal{A}_2(\mathbf{w}))^{-1} \frac{\partial^\top}{\partial \mathbf{w}} U(\mathbf{w}),$$

so that $\nabla G_1(\mathbf{w})$ is given by

$$\nabla G_1(\mathbf{w}) = I - \alpha \frac{\partial}{\partial \mathbf{w}} (\mathcal{A}_1(\mathbf{w}) + \mathcal{A}_2(\mathbf{w}))^{-1} \frac{\partial^\top}{\partial \mathbf{w}} U(\mathbf{w}) - \alpha (\mathcal{A}_1(\mathbf{w}) + \mathcal{A}_2(\mathbf{w}))^{-1} \frac{\partial^2}{\partial \mathbf{w}^2} U(\mathbf{w}).$$

The fact that $\frac{\partial^2}{\partial \mathbf{w}^2} U(\mathbf{w})|_{\mathbf{w}=\mathbf{w}^*} = \mathbf{0}$ means that

$$\nabla G_1(\mathbf{w}^*) = I - \alpha(\mathcal{A}_1(\mathbf{w}^*) + \mathcal{A}_2(\mathbf{w}^*))^{-1} \mathcal{H}(\mathbf{w}^*).$$

As $\mathcal{H}(\mathbf{w}^*)$ and $\mathcal{A}_1(\mathbf{w}^*) + \mathcal{A}_2(\mathbf{w}^*)$ are negative-definite, it follows that the eigenvalues of $(\mathcal{A}_1(\mathbf{w}^*) + \mathcal{A}_2(\mathbf{w}^*))^{-1} \mathcal{H}(\mathbf{w}^*)$ are positive. Hence,

$$\rho(\nabla G_1(\mathbf{w}^*)) = \max\{|1 - \alpha\lambda_{\min}|, |1 - \alpha\lambda_{\max}|\}, \quad (53)$$

with λ_{\min} and λ_{\max} respectively denoting the minimal and maximal eigenvalues of $(\mathcal{A}_1(\mathbf{w}^*) + \mathcal{A}_2(\mathbf{w}^*))^{-1} \mathcal{H}(\mathbf{w}^*)$. Hence, $\rho(\nabla G_1(\mathbf{w}^*)) < 1$ provided that $\alpha \in (0, 2\lambda_{\max}^{-1})$, or, written in terms of the spectral radius, $\alpha \in (0, 2/\rho(\mathcal{A}_1(\mathbf{w}^*) + \mathcal{A}_2(\mathbf{w}^*))^{-1} \mathcal{H}(\mathbf{w}^*))$.

When the policy parameterisation is value-consistent with respect to the given MDP, then from Theorem 7 $\mathcal{H}_{12}(\mathbf{w}^*) + \mathcal{H}_{22}(\mathbf{w}^*) = \mathbf{0}$, so that $\mathcal{H}(\mathbf{w}^*) = \mathcal{A}_1(\mathbf{w}^*) + \mathcal{A}_2(\mathbf{w}^*)$. It then follows that $\nabla G_1(\mathbf{w}^*) = (1 - \alpha)I$. Convergence for this case follows in the same manner. \square

Theorem 10 (Convergence analysis for the second Gauss-Newton method). *Proof.* The formulas (29) and (31) follow as in the proof of Theorem 9. Using the same approach as in Theorem 9, it can be shown that $\rho(\nabla G_2(\mathbf{w}^*)) < 1$ provided that, $\alpha \in (0, 2/\rho(\mathcal{H}_2(\mathbf{w}^*)^{-1} \mathcal{H}(\mathbf{w}^*)))$. As $\mathcal{H}(\mathbf{w}^*)$ and $\mathcal{H}_2(\mathbf{w}^*)$ are negative-definite the eigenvalues of $\mathcal{H}_2(\mathbf{w}^*)^{-1} \mathcal{H}(\mathbf{w}^*)$ are positive. Furthermore, as $\mathcal{H}(\mathbf{w}^*) = \mathcal{H}_{11}(\mathbf{w}^*) + \mathcal{H}_2(\mathbf{w}^*)$, and, by Lemma 4, $\mathcal{H}_{11}(\mathbf{w}^*)$ is positive-semidefinite, it follows that the eigenvalues of $\mathcal{H}_2(\mathbf{w}^*)^{-1} \mathcal{H}(\mathbf{w}^*)$ all lie in the range $(0, 1]$. This means that $\alpha \in (0, 2)$ is sufficient to ensure that $\rho(\nabla G_2(\mathbf{w}^*)) < 1$. \square

A.8 Proof of Theorem 11

Theorem 11. *Proof.* We use the notation $\nabla^{10} \mathcal{Q}(\mathbf{w}_j, \mathbf{w}_k)$ to denote the derivative with respect to the first variable of \mathcal{Q} , evaluated at $(\mathbf{w}_j, \mathbf{w}_k)$, and similarly $\nabla^{20} \mathcal{Q}(\mathbf{w}_j, \mathbf{w}_k)$ for the second derivative and $\nabla^{01} \mathcal{Q}(\mathbf{w}_j, \mathbf{w}_k)$ for the derivative with respect to the second variable etc. The idea of the proof is simple and consists of performing a Taylor expansion of $\nabla^{10} \mathcal{Q}(\mathbf{w}, \mathbf{w}_k)$. As \mathcal{Q} is assumed to be twice continuously differentiable in the first component this Taylor expansion is possible and gives

$$\nabla^{10} \mathcal{Q}(\mathbf{w}_{k+1}, \mathbf{w}_k) = \nabla^{10} \mathcal{Q}(\mathbf{w}_k, \mathbf{w}_k) + \nabla^{20} \mathcal{Q}(\mathbf{w}_k, \mathbf{w}_k)(\mathbf{w}_{k+1} - \mathbf{w}_k) + \mathcal{O}(\|\mathbf{w}_{k+1} - \mathbf{w}_k\|^2). \quad (54)$$

As $\mathbf{w}_{k+1} = \text{argmax}_{\mathbf{w} \in \mathcal{W}} \mathcal{Q}(\mathbf{w}, \mathbf{w}_k)$ it follows that $\nabla^{10} \mathcal{Q}(\mathbf{w}_{k+1}, \mathbf{w}_k) = 0$. This means that, upon ignoring higher order terms in $\mathbf{w}_{k+1} - \mathbf{w}_k$, the Taylor expansion (54) can be rewritten into the form

$$\mathbf{w}_{k+1} - \mathbf{w}_k = -\nabla^{20} \mathcal{Q}(\mathbf{w}_k, \mathbf{w}_k)^{-1} \nabla^{10} \mathcal{Q}(\mathbf{w}_k, \mathbf{w}_k). \quad (55)$$

The proof is completed by observing that

$$\nabla^{10} \mathcal{Q}(\mathbf{w}_k, \mathbf{w}_k) = \frac{\partial}{\partial \mathbf{w}} U(\mathbf{w})|_{\mathbf{w}=\mathbf{w}_k}, \quad \nabla^{20} \mathcal{Q}(\mathbf{w}_k, \mathbf{w}_k) = \mathcal{H}_2(\mathbf{w}_k).$$

The second statement follows because in the case where the log-policy is quadratic the higher order terms in the Taylor expansion vanish. \square

A.9 Proof of Theorem 12

Theorem 12. *Proof.* In the EM-algorithm the update of the policy parameters takes the form

$$G_{\text{EM}}(\mathbf{w}_k) = \text{argmax}_{\mathbf{w} \in \mathcal{W}} \mathcal{Q}(\mathbf{w}, \mathbf{w}_k),$$

where the function $\mathcal{Q}(\mathbf{w}, \mathbf{w}')$ is given by

$$\mathcal{Q}(\mathbf{w}, \mathbf{w}') = \sum_{(s, \theta) \in S \times \Lambda} p_\gamma(s, \theta; \mathbf{w}') Q(s, \theta; \mathbf{w}') \left[\log \pi(\theta|s; \mathbf{w}') \right].$$

Note that \mathcal{Q} is a two parameter function, where the first parameter occurs inside the bracket, while the second parameter occurs outside the bracket. Also note that $\mathcal{Q}(\mathbf{w}, \mathbf{w}')$ satisfies

the following identities

$$\begin{aligned}\nabla^{10}\mathcal{Q}(\mathbf{w}, \mathbf{w}') &= \sum_{(s,a) \in \mathcal{S} \times \mathcal{A}} p_\gamma(s, a; \mathbf{w}') Q(s, a; \mathbf{w}') \left[\frac{\partial}{\partial \mathbf{w}} \log \pi(a|s; \mathbf{w}') \right], \\ \nabla^{20}\mathcal{Q}(\mathbf{w}, \mathbf{w}') &= \sum_{(s,a) \in \mathcal{S} \times \mathcal{A}} p_\gamma(s, a; \mathbf{w}') Q(s, a; \mathbf{w}') \left[\frac{\partial^2}{\partial \mathbf{w}^2} \log \pi(a|s; \mathbf{w}') \right], \\ \nabla^{11}\mathcal{Q}(\mathbf{w}, \mathbf{w}') &= \sum_{(s,a) \in \mathcal{S} \times \mathcal{A}} \frac{\partial}{\partial \mathbf{w}'} \left(p_\gamma(s, a; \mathbf{w}') Q(s, a; \mathbf{w}') \right) \frac{\partial^T}{\partial \mathbf{w}} \log \pi(a|s; \mathbf{w}').\end{aligned}$$

Here we have used the notation ∇^{ij} to denote the i^{th} derivative with respect to the first parameter and the j^{th} derivative with respect to the second parameter. Note that when we set $\mathbf{w} = \mathbf{w}'$ in the first two of these terms we have $\nabla^{10}\mathcal{Q}(\mathbf{w}, \mathbf{w}) = \frac{\partial}{\partial \mathbf{w}} U(\mathbf{w})$, $\nabla^{20}\mathcal{Q}(\mathbf{w}, \mathbf{w}) = \mathcal{H}_2(\mathbf{w})$. A key identity that we need for the proof is that $\nabla^{11}\mathcal{Q}(\mathbf{w}, \mathbf{w}) = \mathcal{H}_1(\mathbf{w}) + \mathcal{H}_{12}(\mathbf{w}) + \mathcal{H}_{12}^\top(\mathbf{w})$. This follows from the observation that $\frac{\partial}{\partial \mathbf{w}} U(\mathbf{w}) = \nabla^{10}\mathcal{Q}(\mathbf{w}, \mathbf{w})$, so that

$$\frac{\partial^2}{\partial \mathbf{w}^2} U(\mathbf{w}) = \frac{\partial}{\partial \mathbf{w}} \left(\nabla^{10}\mathcal{Q}(\mathbf{w}, \mathbf{w}) \right) = \nabla^{20}\mathcal{Q}(\mathbf{w}, \mathbf{w}) + \nabla^{11}\mathcal{Q}(\mathbf{w}, \mathbf{w}),$$

so that

$$\begin{aligned}\mathcal{H}_1(\mathbf{w}) + \mathcal{H}_{12}(\mathbf{w}) + \mathcal{H}_{12}^\top(\mathbf{w}) &= \mathcal{H}(\mathbf{w}) - \mathcal{H}_2(\mathbf{w}) = \nabla^{20}\mathcal{Q}(\mathbf{w}, \mathbf{w}) + \nabla^{11}\mathcal{Q}(\mathbf{w}, \mathbf{w}) - \nabla^{20}\mathcal{Q}(\mathbf{w}, \mathbf{w}), \\ &= \nabla^{11}\mathcal{Q}(\mathbf{w}, \mathbf{w}),\end{aligned}$$

as claimed.

Now, to calculate the matrix $\nabla^{GEM}(\mathbf{w}^*)$ we perform a Taylor series expansion of $\nabla^{10}\mathcal{Q}(\mathbf{w}, \mathbf{w}')$ in both parameters around the point $(\mathbf{w}^*, \mathbf{w}^*)$, and evaluated at $(\mathbf{w}_{k+1}, \mathbf{w}_k)$, which gives

$$\begin{aligned}\nabla^{10}\mathcal{Q}(\mathbf{w}_{k+1}, \mathbf{w}_k) &= \nabla^{10}\mathcal{Q}(\mathbf{w}^*, \mathbf{w}^*) + \nabla^{20}\mathcal{Q}(\mathbf{w}^*, \mathbf{w}^*)(\mathbf{w}_{k+1} - \mathbf{w}^*) \\ &\quad + \nabla^{11}\mathcal{Q}(\mathbf{w}^*, \mathbf{w}^*)(\mathbf{w}_k - \mathbf{w}^*) + \dots\end{aligned}$$

As \mathbf{w}^* is a local optimum of $U(\mathbf{w})$ we have that $\nabla^{10}\mathcal{Q}(\mathbf{w}^*, \mathbf{w}^*) = \mathbf{0}$. Furthermore, as the sequence $\{\mathbf{w}_k\}_{k \in \mathbb{N}}$ was generated by the EM-algorithm, we have, for each $k \in \mathbb{N}$, that $\mathbf{w}_{k+1} = \text{argmax}_{\mathbf{w} \in \mathcal{V}} \mathcal{Q}(\mathbf{w}, \mathbf{w}_k)$, which implies that $\nabla^{10}\mathcal{Q}(\mathbf{w}_{k+1}, \mathbf{w}_k) = \mathbf{0}$. Finally, as $\nabla^{20}\mathcal{Q}(\mathbf{w}^*, \mathbf{w}^*) = \mathcal{H}_2(\mathbf{w}^*)$ and $\nabla^{11}\mathcal{Q}(\mathbf{w}^*, \mathbf{w}^*) = \mathcal{H}_1(\mathbf{w}^*)$ we have

$$\mathbf{0} = \mathcal{H}_2(\mathbf{w}^*)(\mathbf{w}_{k+1} - \mathbf{w}^*) + (\mathcal{H}_1(\mathbf{w}^*) + \mathcal{H}_{12}(\mathbf{w}^*) + \mathcal{H}_{12}^\top(\mathbf{w}^*))(\mathbf{w}_k - \mathbf{w}^*) + \dots$$

Using the fact that $\mathbf{w}_{k+1} = GEM(\mathbf{w}_k)$ and $\mathbf{w}^* = GEM(\mathbf{w}^*)$, taking the limit $k \rightarrow \infty$ gives

$$\mathbf{0} = \mathcal{H}_2(\mathbf{w}^*) \nabla^{GEM}(\mathbf{w}^*) + \mathcal{H}_1(\mathbf{w}^*) + \mathcal{H}_{12}(\mathbf{w}^*) + \mathcal{H}_{12}^\top(\mathbf{w}^*),$$

so that

$$\nabla^{GEM}(\mathbf{w}^*) = -\mathcal{H}_2^{-1}(\mathbf{w}^*)(\mathcal{H}_1(\mathbf{w}^*) + \mathcal{H}_{12}(\mathbf{w}^*) + \mathcal{H}_{12}^\top(\mathbf{w}^*)) = I - \mathcal{H}_2^{-1}(\mathbf{w}^*)\mathcal{H}(\mathbf{w}^*).$$

In the case where the policy parameterisation value-consistent with respect to the given MDP then we have $\mathcal{H}_{12}(\mathbf{w}^*) + \mathcal{H}_{12}(\mathbf{w}^*)^\top = \mathbf{0}$, so that $\nabla^{GEM}(\mathbf{w}^*) = I - \mathcal{H}_2^{-1}(\mathbf{w}^*)\mathcal{A}_1(\mathbf{w}^*)$. The rest of the proof follows from the result in Theorem 10 when considering $\alpha = 1$. \square

Appendix B. Further Details for Estimation of Preconditioners and the Gauss-Newton Update Direction

B.1 Recurrent State Search Direction Evaluation for Second Gauss-Newton Method

In the work of Williams (1992) a sampling algorithm was provided for estimating the gradient of an infinite horizon MDP with average rewards. This algorithm makes use of a recurrent state, which we denote by \mathbf{s}^* . In Algorithm 2 we detail a straightforward extension of this algorithm to the estimation the approximate Hessian, $\mathcal{H}_2(\mathbf{w})$, in this MDP framework. The analogous algorithm for the estimation of the diagonal matrix, $\mathcal{D}_2(\mathbf{w})$, follows similarly. In Algorithm 2 we make use of an *eligibility trace* for both the gradient and the approximate Hessian, which we denote by Φ^1 and Φ^2 respectively. The estimates (up to a positive scalar) of the gradient and the approximate Hessian are denoted by Δ^1 and Δ^2 respectively.

B.2 Inversion of Preconditioning Matrices

A computational bottleneck of Newton's method is the inversion of the Hessian matrix, which scales with $\mathcal{O}(n^3)$. In a standard application of Newton's method this inversion is performed during each iteration, and in large parameter systems this becomes prohibitively costly. We now consider the inversion of the preconditioning matrix in proposed Gauss-Newton methods.

Firstly, in the diagonal forms of the Gauss-Newton methods the preconditioning matrix is diagonal, so that the inversion of this matrix is trivial and scales linearly in the number of parameters. In general the preconditioning matrix of the full Gauss-Newton methods will have no form of sparsity, and so no computational savings will be possible when inverting the preconditioning matrix. There is, however, a source of sparsity that allows for the efficient inversion of \mathcal{H}_2 in certain cases of interest. In particular, any product structure (with respect to the control parameters) in the model of the agent's behaviour will lead to sparsity in \mathcal{H}_2 . For example, in partially observable Markov decision processes in which the behaviour of the agent is modeled through a finite state controller (Meuleau et al., 1999) there are three functions that are to be optimized, the initial belief distribution, the belief transition dynamics and the policy. In this case the dynamics of the system are given by,

$$p(\mathbf{s}' | \mathbf{s}, \mathbf{o}', \mathbf{b}' | \mathbf{s}, \mathbf{o}, \mathbf{b}, \mathbf{a}; \mathbf{v}, \mathbf{w}) = p(\mathbf{s}' | \mathbf{s}, \mathbf{o}) p(\mathbf{o}' | \mathbf{s}, \mathbf{o}; \mathbf{v}) \pi(\mathbf{a}' | \mathbf{b}', \mathbf{o}'; \mathbf{w}),$$

in which $\mathbf{o} \in \mathcal{O}$ is an observation from a finite observation space, \mathcal{O} , and $\mathbf{b} \in \mathcal{B}$ is the belief state from a finite belief space, \mathcal{B} . The initial belief is given by the initial belief distribution, $p(\mathbf{b} | \mathbf{o}; \mathbf{u})$. The parameters to be optimized in this system are \mathbf{u} , \mathbf{v} and \mathbf{w} . It can be seen that in this system $\mathcal{H}_2(\mathbf{u}, \mathbf{v}, \mathbf{w})$ is block-diagonal (across the parameters \mathbf{u} , \mathbf{v} and \mathbf{w}) and the matrix inversion can be performed more efficiently by inverting each of the block matrices individually. By contrast, the Hessian $\mathcal{H}(\mathbf{u}, \mathbf{v}, \mathbf{w})$ does not exhibit any such sparsity properties.

<p>Algorithm 2: Recurrent state sampling algorithm to estimate the search direction of the second Gauss-Newton method. Appendix C. Experiments

C.1 Non-Linear Navigation Experiment

The state-space of the problem is two-dimensional, $\mathbf{s} = (s^1, s^2)$, in which s^1 is the agent's position and s^2 is the agent's velocity. The control is one-dimensional and the dynamics of

the system is given as follows,

$$\begin{aligned} s_{t+1}^1 &= s_t^1 + \frac{1}{1 + e^{-u_t}} - 0.5 + \kappa, \\ s_{t+1}^2 &= s_t^2 - 0.1 s_{t+1}^1 + \kappa, \end{aligned}$$

with κ a zero-mean Gaussian random variable with standard deviation $\sigma_\kappa = 0.02$. The agent starts in the state $\mathbf{s} = (0, 1)$, with the addition of Gaussian noise with standard deviation 0.001, and the objective is for the agent to reach the target state, $\mathbf{s}_{\text{target}} = (0, 0)$. We use the same policy as in Vlassis et al. (2009), which is given by $a_t = (\mathbf{w} + \boldsymbol{\epsilon}_t)^\top \mathbf{s}_t$, with control parameters, \mathbf{w} , and $\boldsymbol{\epsilon}_t \sim \mathcal{N}(\boldsymbol{\epsilon}; \mathbf{0}, \sigma_\epsilon^2 I)$. The objective function is non-trivial for $\mathbf{w} \in [0, 60] \times [-8, 0]$. In the experiment the initial control parameters were sampled from the region $\mathbf{w}_0 \in [0, 60] \times [-8, 0]$. In all algorithms 50 trajectories were sampled during each training iteration and used to estimate the search direction. We consider a finite planning horizon, $H = 80$.

C.2 N -link Rigid Manipulator Experiment

The state of the system is given by $\mathbf{q}, \dot{\mathbf{q}}, \ddot{\mathbf{q}} \in \mathbb{R}^N$, where $\mathbf{q}, \dot{\mathbf{q}}$ and $\ddot{\mathbf{q}}$ denote the angles, velocities and accelerations of the joints respectively, while the control variables are the torques applied to the joints $\boldsymbol{\tau} \in \mathbb{R}^N$. The nonlinear state equations of the system are given by (Spong et al., 2005),

$$M(\mathbf{q})\ddot{\mathbf{q}} + C(\dot{\mathbf{q}}, \mathbf{q})\dot{\mathbf{q}} + \mathbf{g}(\mathbf{q}) = \boldsymbol{\tau}, \quad (56)$$

where $M(\mathbf{q})$ is the inertia matrix, $C(\dot{\mathbf{q}}, \mathbf{q})$ denotes the Coriolis and centripetal forces and $\mathbf{g}(\mathbf{q})$ is the gravitational force. While this system is highly nonlinear it is possible to define an appropriate control function $\hat{\boldsymbol{\tau}}(\mathbf{q}, \dot{\mathbf{q}})$ that results in linear dynamics in a different state-action space. This technique is known as feedback linearisation (Khalil, 2001), and in the case of an N -link rigid manipulator recasts the torque action space into the acceleration action space. This means that the state of the system is now given by \mathbf{q} and $\ddot{\mathbf{q}}$, while the control is $\mathbf{a} = \ddot{\mathbf{q}}$. Ordinarily in such problems the reward would be a function of the generalized co-ordinates of the end effector, which results in a non-trivial reward function in terms of $\mathbf{q}, \dot{\mathbf{q}}$ and $\ddot{\mathbf{q}}$. This can be accounted for by modelling the reward function as a mixture of Gaussians (Hoffman et al., 2009), but for simplicity we consider the simpler problem where the reward is a function of $\mathbf{q}, \dot{\mathbf{q}}$ and $\ddot{\mathbf{q}}$ directly.

We consider the finite horizon undiscounted problem in this section, so that the gradient of the objective function takes the form

$$\frac{\partial}{\partial \mathbf{w}} U(\mathbf{w}) = \int \int ds da \frac{\partial}{\partial \mathbf{w}} \log \pi(a | s; \mathbf{w}) \sum_{t=1}^H p_t(s, a; \mathbf{w}) Q(s, a, t; \mathbf{w}),$$

with the preconditioning matrices of natural gradient ascent and the Gauss-Newton methods taking analogous forms. It can be shown that for the policy parameterisation given in (33) the derivative of $\log \pi(a | s; \mathbf{w})$ is quadratic in (s, a) , for all $(s, a) \in \mathcal{S} \times \mathcal{A}$. This means that to calculate the search directions of gradient ascent, natural gradient ascent, expectation maximization and the Gauss-Newton methods it is sufficient to calculate the

first two moments of $p_t(s, a; \mathbf{w})Q(s, a, t; \mathbf{w})$ w.r.t. (s, a) , for each $t \in \{1, \dots, H\}$. These calculations can be done using the methods presented in the work of Furnston (2012).

For all algorithms that required the specification of a step size we ran the experiment over a collection of step size sequences and use the optimal step size sequence in the final experiment. In both steepest gradient ascent and natural gradient ascent we considered the following fixed step sizes: 0.001, 0.01, 0.1, 1, 10, 20, 30, 100 and 250. We were unable to obtain any reasonable results with steepest gradient ascent with any of these fixed step sizes, for which reason the results are omitted. In natural gradient ascent we found 30 to be the best step size of those considered. In the Gauss-Newton method we considered the following fixed step sizes: 10, 20, 30, 100 and 250 and found that the fixed step size of 30 gave consistently good results without overstepping in the parameter space. The smaller step sizes obtained better results than expectation maximization, but less than the fixed step size of 30. The larger step sizes often found superior results, but would sometimes overstep in the parameter space. For these reasons we used the fixed step size of 30 in the final experiment.

C.3 Tetris Experiment

In Tetris there exists a board, which is typically a 20×10 grid, which is empty at the beginning of a game. During each stage of the game a four block piece, called a tetrozoid, appears at the top of the board and begins to fall down the board. While the tetrozoid is moving the player is allowed to rotate the tetrozoid and to move it left or right. The tetrozoid stops moving once it reaches either the bottom of the board or a previously positioned tetrozoid. In this manner the board begins to fill up with tetrozoid pieces. There are seven different variations of tetrozoid, as shown in Figure 5a. When a horizontal line of the board is completely filled with (pieces of) tetrozoids the line is removed from the board and the player receives a score of one. The game terminates when the player is not able to fully place a tetrozoid on the board due to insufficient space remaining on the board. An example configuration of the board during a game of Tetris is given in Figure 5b. More details on the game of Tetris can be found in the work of Falvey (2003). As in other applications of Tetris in the reinforcement learning literature (Kakade, 2002; Bertsekas and Ioffe, 1996) we consider a simplified version of the game in which the current tetrozoid remains above the board until the player decides upon a desired rotation and column position for the tetrozoid.

We use the same procedure to evaluate the search direction for all the algorithms in the experiment. Irrespective of the policy, a game of Tetris is guaranteed to terminate after a finite number of turns (Bertsekas and Ioffe, 1996). We therefore model each game as an absorbing state MDP. The reward at each time step is equal to the number of lines deleted. We use a recurrent state approach (Williams, 1992) to estimate the gradient, using the empty board as a recurrent state. (Since a new game starts with an empty board this state is recurrent.⁶) We use analogous versions of this recurrent state approach for natural gradient ascent, the diagonal Gauss-Newton method and the full Gauss-Newton

6. This is actually an approximation because it does not take into account that the state is given by the configuration of the board and the current piece, so this particular ‘recurrent state’ ignores the current piece. Empirically we found that this approximation gave better results, presumably due to reduced variance in the estimands, and there is no reason to believe that it is unfairly biasing the comparison between the various parametric policy search methods.

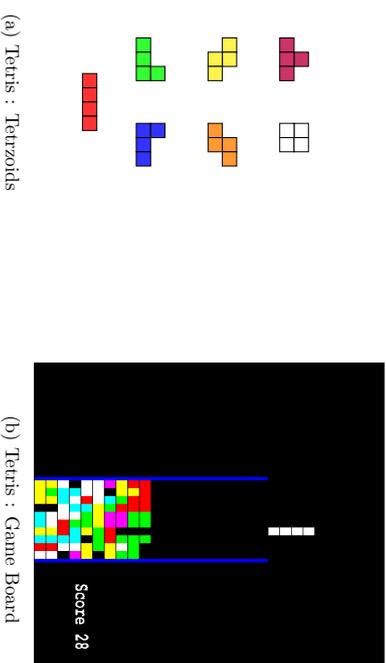

Figure 5: A graphical illustration of the game of tetris with (a) the collection of possible pieces, or tetrozoids, of which there are seven (b) a possible configuration of the board, which in this example is of height 20 and width 10.

method. As in the work of Kakade (2002), we use the sample trajectories obtained during the gradient evaluation to estimate the Fisher information matrix. During each training iteration an approximation of the search direction is obtained by sampling 1000 games, using the current policy to sample the games. It is computationally very expensive to perform experiments on the Tetris domain. When performing the experiment we found that it would be prohibitively expensive to perform an extensive sweep over different step size sequences for all of the different algorithms. For this reason we decided to implement a simple line search in this domain. Given the current approximate search direction we use the following basic line search method to obtain a step size: For every step size in a given finite set of step sizes sample a set number of games and then return the step size with the maximal score over these games. In practice, in order to reduce the susceptibility to random noise, we used the same simulator seed for each possible step size in the set. In this line search procedure we sampled 1000 games for each of the possible step sizes. We use the same set of step sizes

$$\{0.1, 0.5, 1.0, 2.0, 4.0, 8.0, 16.0, 32.0, 64.0, 128.0\}.$$

in all of the different training algorithms in the experiment. To reduce the amount of noise in the results we use the same set of simulator seeds in the search direction evaluation for each of the algorithms considered in the experiment. In particular, we generate a $n_{\text{experiments}} \times n_{\text{iterations}}$ matrix of simulator seeds, with $n_{\text{experiments}}$ the number of repetitions of the experiment and $n_{\text{iterations}}$ the number of training iterations in each experiment. We use this one matrix of simulator seeds in all of the different training algorithms, with the element in the j^{th} column and i^{th} row corresponding to the simulator seed of the j^{th} training iteration of the i^{th} experiment. In a similar manner, the set of simulator seeds we use for the line search procedure is the same for all of the different training algorithms. Finally, to

make the line search consistent among all of the different training algorithms we normalize the search direction and use the resulting unit vector in the line search procedure.

C.4 Robot Arm Experiment

The domain in the robot arm experiment is episodic, with each episode 20 seconds in length. The state of the domain is given by the angles and velocities of the seven joints in the robot arm, along with the Cartesian coordinates of the ball. The action is given by the joint accelerations of the robot arm. We denote the position of the cup and the ball by $(x_c, y_c, z_c) \in \mathbb{R}^3$ and $(x_b, y_b, z_b) \in \mathbb{R}^3$ respectively. The reward function is given by,

$$r(x_c, y_c, x_b, y_b, t) = \begin{cases} -20((x_c - x_b)^2 + (y_c - y_b)^2) & \text{if } t = t_c, \\ 0 & \text{if } t \neq t_c, \end{cases}$$

in which t_c is the moment the ball crosses the z -plane (level with the cup) in a downward direction. If no such t_c exists then the reward of the episode is given by -100 .

We use the motor primitive framework (Jipspeert et al., 2002, 2003; Schaal et al., 2007; Kober and Peters, 2011) in this domain, applying a separate motor primitive to each dimension of the action space. Each motor primitive consists of a parametrized curve that models the desired action sequence (for the respective dimension of the action space) through the course of the episode. Given this collection of motor primitives the control engine within the simulator tries to follow the desired action sequence as closely as possible while also satisfying the constraints on the system, such as the physical constraints on the torques that can safely be applied without damaging the robot arm. As in the work of Kober and Peters (2011) we use dynamic motor primitives, using 10 shape parameters for each of the individual motor primitives. The robot arm has 7 joints, so that there are 70 motor primitive parameters in total. We optimize the parameters of the motor primitives by considering the MDP induced by this motor primitive framework. The action space corresponds to the space of possible motor primitives, so that $\mathcal{A} = \mathbb{R}^{70}$. There is no state space in this MDP and the planning horizon is 1, so that this MDP is effectively a bandit problem. The reward of an action is equal to the total reward of the episode induced by the motor primitive. We consider a policy of the form,

$$\pi(a; \mathbf{w}) = \mathcal{N}(a | \boldsymbol{\mu}, (LL^*)^{-1}),$$

with $\mathbf{w} = (\boldsymbol{\mu}, L)$, $\boldsymbol{\mu}$ the mean of the Gaussian and LL^* the Cholesky decomposition of the precision matrix. We consider a diagonal precision matrix, which results in a total of 140 policy parameters.

In this experiment we compare gradient ascent, natural gradient ascent, expectation maximization, the first Gauss-Newton method and the second Gauss-Newton method. As the planning horizon is of length 1 it follows that $\mathcal{H}_{12}(\mathbf{w}) = \mathbf{0}$, $\forall \mathbf{w} \in \mathcal{W}$, so that the first Gauss-Newton method coincides with Newton's method for this MDP. The policy is block-wise log-concave in $\boldsymbol{\mu}$ and L , but not jointly log-concave in $\boldsymbol{\mu}$ and L . As a result we construct block diagonal forms of the preconditioning matrices for the first and second Gauss-Newton methods, with a separate block for $\boldsymbol{\mu}$ and L . Additionally, since the planning horizon is of length 1 it is possible to calculate the Fisher information exactly in this domain. For gradient ascent and natural gradient ascent we considered several different step size sequences. Each

sequence considered had a constant step size throughout, and the sequences differed in the size of this step size. We considered step sizes of length 1, 0.1, 0.01 and 0.001. For both Gauss-Newton methods we considered a fixed step size of one throughout training (i.e., no tuning of the step size sequence was performed for either the first or the second Gauss-Newton methods). As in the work of Kober and Peters (2009) the initial value of $\boldsymbol{\mu}$ is set so that the trajectory of the robot arm mimics that of a given human demonstration. The diagonal elements of the precision matrix are initialized to 0.01. During each training iteration we sampled 15 actions from the policy and used the episodes generated from these samples to estimate the search direction. To deal with this low number of samples we used the 'effective' sample size up to 150. Finally, we used the reward/fitness shaping approach of Wierstra et al. (2014) in all the algorithms considered, using the same shaping function as in Wierstra et al. (2014). In each run of the experiment we performed 100 updates of the policy parameters.

Abstract

Predicting breast cancer risk has long been a goal of medical research in the pursuit of precision medicine. The goal of this study is to develop novel penalized methods to improve breast cancer risk prediction by leveraging structure information in electronic health

records. We conducted a retrospective case-control study, garnering 49 mammography descriptors and 77 high-frequency/low-penetrance single-nucleotide polymorphisms (SNPs) from an existing personalized medicine data repository. Structured mammography reports and breast imaging features have long been part of a standard electronic health record (EHR), and genetic markers likely will be in the near future. Lasso and its variants are widely used approaches to integrated learning and feature selection, and our methodological contribution is to incorporate the dependence structure among the features into these approaches. More specifically, we propose a new methodology by combining group penalty and l^p ($1 \leq p \leq 2$) fusion penalty to improve breast cancer risk prediction, taking into account structure information in mammography descriptors and SNPs. We demonstrate that our method provides benefits that are both statistically significant and potentially significant to people's lives.

Keywords: structure information, breast cancer risk prediction, mammography descriptors, genetic variants, personalized medicine

1. Introduction

Breast cancer is the most common non-skin malignancy affecting women, with approximately 1.67 million cases diagnosed annually worldwide (Ferlay et al., 2013). If an individual's risk of breast cancer could be predicted, then screening, prevention, and treatment strategies could be targeted toward those women to maximize survival benefit and minimize harm. Risk prediction models are important tools to improve breast cancer care by leveraging multi-dimensional electronic health data. Traditional breast cancer risk prediction models use demographic risk factors to estimate breast cancer risk, but they demonstrate only limited discriminatory power. In clinical practice, mammography is the most common breast cancer screening test, and the only imaging modality supported by randomized trials demonstrating reduction in mortality rate. However, its effectiveness is not universally accepted (Freedman et al., 2004). Recent advances in genome-wide association studies (GWAS) have revitalized the quest for genetic variants (single-nucleotide polymorphisms—SNPs) in risk prediction. However, the optimism of these studies has been tempered by disappointment and caution (Gail, 2008, 2009; Wacholder et al., 2010).

Although many breast cancer risk prediction models have been developed, current applications of these models are inadequate in the following respects: (1) due to the rare occurrence of breast cancer, many seemingly 'large' studies have small effective sample size to adequately model a large number of variables; (2) even for large studies, investigators often fail to systematically model risk factor interactions to avoid overly complicated models which are hard to interpret; and (3) they do not take available structure information into consideration. For example, there are five descriptors for mass margins in mammogram: circumscribed, microlobulated, obscured, indistinct, and spiculated, with an order of increasing probability of malignancy. However, few models utilize this structure information (group structure and dependence structure) to improve predictive performance. The quest for novel breast cancer risk prediction models is motivated to address these shortcomings.

In this paper, we propose to develop novel penalized methods to improve breast cancer risk prediction by incorporating unique structure information embedded in electronic health record data. Regularization is a common technique used in regression and classification problems. The lasso (Tibshirani, 1996) is one of the most popular penalized method and

Table 2: The 77 SNPs identified to be associated with breast cancer

2.1.3 GENETIC VARIANTS

We decided to focus on high-frequency/low-penetrance SNPs that affect breast cancer risk as opposed to low frequency SNPs with high penetrance or intermediate penetrance. We consolidated a list of 77 common genetic variants (Table 2) which were identified by recent large-scale GWAS studies or used to generate published predictive models (Liu et al., 2014). The list included 41 SNPs identified by COGS through a meta-analysis of 9 GWAS studies (Michailidou et al., 2013). Recently, a similar set of 77 breast cancer-associated SNPs is also studied for risk prediction (Mavaddat et al., 2015).

2.2 Logistic Regression

Assume that we have independent and identical distributed subjects $\{(x_i, y_i)\}_{i=1}^n$, where the explanatory variable $X \in \mathcal{R}^d$ and the binary response variable $Y \in \{-1, 1\}$. Note that the conditional probability $\eta(x) = \mathbb{P}(Y = 1|X = x)$ plays an important role in the classification problem. Denote $x_i = (x_{i1}, \dots, x_{id})^T$, and linear logistic regression model is defined by

$$\log \frac{\eta(x_i)}{1 - \eta(x_i)} = x_i^T \beta, \quad i = 1, \dots, n,$$

where $\beta = (\beta_1, \dots, \beta_d)^T$ is the slope parameter. And the logistic regression estimator $\hat{\beta}$ is given by the minimizer of the negative log-likelihood function

$$L(\beta) = \frac{1}{n} \sum_{i=1}^n \log(1 + \exp(-y_i \cdot x_i^T \beta)). \quad (1)$$

With $\hat{\beta}$, we then estimate the conditional probability $\eta(x_i)$ by

$$\hat{\eta}(x_i) = \frac{\exp(x_i^T \hat{\beta})}{1 + \exp(x_i^T \hat{\beta})} = \frac{1}{1 + \exp(-x_i^T \hat{\beta})}.$$

Then we should predict $y_i = 1$ if $\hat{\eta}(x_i) \geq 0.5$ and $y_i = -1$ if $\hat{\eta}(x_i) < 0.5$.

2.3 Group Penalty and ℓ^p Fusion Penalty

Note that there exist natural group structure and dependence structure in mammography features (Figure 1), which allows us to include the structure information into our risk prediction models directly. For genetic variants, group structures also exist (Liu et al., 2012, 2013). In this paper, we apply hierarchical clustering to cluster the 77 SNPs based on their dissimilarity matrix obtained by computing Spearman's correlation or Hamming distance among them. More details are provided in Section 2.5.

Suppose that d features are divided into G groups with d_g the number of features in group g . Define $\beta_g \in \mathbb{R}^{d_g}$ to be the corresponding coefficient vector in group g . The group lasso logistic regression (Meier et al., 2008) is defined as the following optimization problem

$$\min_{\beta \in \mathbb{R}^d} \left\{ L(\beta) + \lambda_1 \sum_{g=1}^G \sqrt{d_g} \|\beta_g\|_2 \right\},$$

where $L(\beta)$ is defined by (1) and $\lambda_1 \geq 0$ is the tuning parameter. It includes lasso as a special case with $G = d$.

The fact that there exist dependence structure within each mammography feature group and each SNP group encourages us to propose the following novel method by combining group lasso logistic regression and ℓ^{p^*} fusion penalty.

$$\min_{\beta \in \mathbb{R}^d} \left\{ L(\beta) + \sum_{g=1}^G \left(\lambda_1 \sqrt{d_g} \|\beta_g\|_2 + \lambda_2 \|D_g \beta_g\|_{p^*} \right) \right\}, \quad (2)$$

where D_g is a $(d_g - 1) \times d_g$ sparse matrix with only $D[i, j] = 1$ and $D[i, i+1] = -1$, $\lambda_2 \geq 0$ is the tuning parameter, and $1 \leq p \leq 2$ is the shrinkage parameter.

Moreover, if the within-group dependence structures are different for groups $\{1, \dots, G_1\}$ and $\{G_1 + 1, \dots, G\}$, we can split the ℓ^{p^*} fusion penalty into two parts as

$$\min_{\beta \in \mathbb{R}^d} \left\{ L(\beta) + \lambda_1 \sum_{g=1}^G \sqrt{d_g} \|\beta_g\|_2 + \lambda_2 \left(\sum_{g=1}^{G_1} \|D_g \beta_g\|_{p_1}^{p_1} + \sum_{g=G_1+1}^G \|D_g \beta_g\|_{p_2}^{p_2} \right) \right\}, \quad (3)$$

where $1 \leq p_1, p_2 \leq 2$ are selected based on cross validation.

The novelty of our method compared to previous works is three-fold: First, it includes within-group fusion penalty in the model and makes the coefficients of features in the same group close to each other, which reflects the dependence structure of features and improves the risk prediction; Second, in breast cancer risk prediction, we find that the dependence structures are different for mammography features and SNPs, which are actually two different views of the same data. And the utilization of method (3) will improve the predictive performance further; At last, we find that genetic variants improve risk prediction on mammography features, which provides some insight regarding personalized breast cancer diagnosis.

2.4 Computational Algorithms

Many algorithms have been proposed in the literatures to solve the logistic regression with fused lasso regularization (Lin, 2015; Yu et al., 2015). In this subsection we adopt the fast iterative shrinkage thresholding algorithm (Beck and Teboulle, 2009) to solve (2) as

$$\beta^{k+1} = \arg \min_{\beta \in \mathbb{R}^d} L(\beta^k) + \langle \beta - \beta^k, \nabla L(\beta^k) \rangle + \frac{\tau}{2} \|\beta - \beta^k\|_2^2 + \sum_{g=1}^G \left(\lambda_1 \sqrt{d_g} \|\beta_g\|_2 + \lambda_2 \|D_g \beta_g\|_{p^*} \right)$$

with $\beta = (\beta_1, \dots, \beta_d)^T$ and $\tau > 0$ the Lipschitz constant of $L(\cdot)$.

And the iteration step is equivalent to solving

$$\min_{\beta \in \mathbb{R}^d} \left\{ \frac{1}{2} \|\beta - (\beta^k - \frac{1}{\tau} \nabla L(\beta^k))\|_2^2 + \sum_{g=1}^G \left(\frac{\lambda_1 \sqrt{d_g}}{\tau} \|\beta_g\|_2 + \frac{\lambda_2}{\tau} \|D_g \beta_g\|_{p^*} \right) \right\}. \quad (4)$$

Therefore, it suffices to solve the following optimization problem within each group

$$\min_{\beta_g \in \mathbb{R}^{d_g}} \left\{ \frac{1}{2} \|\beta_g - z\|_2^2 + \rho_1 \|\beta_g\|_2 + \rho_2 \|D_g \beta_g\|_{p^*} \right\}, \quad (5)$$

where $z = \beta_g^k - \frac{1}{\tau} \nabla L(\beta_g^k)$, $\rho_1 = \frac{\lambda_1 \sqrt{d_g}}{\tau}$ and $\rho_2 = \frac{\lambda_2}{\tau}$.

The proximity operator (Polson et al., 2015) of a function f is defined as

$$P_f(z) = \arg \min_t \left\{ \frac{1}{2} \|t - z\|^2 + \lambda f(t) \right\}.$$

- For $f(t) = |t|$ and $z \in \mathbb{R}$, $P_f(z) := S_1(z, \lambda) = \text{sign}(z) \max\{|z| - \lambda, 0\}$, which is also called soft threshold operator.
- For $f(t) = |t|^p$ with $1 < p \leq 2$ and $z \in \mathbb{R}$, $P_f(z) := S_p(z, \lambda) = \text{sign}(z) \xi$, where ξ is the unique nonnegative solution to $\xi + p \lambda \xi^{p-1} = |z|$. In particular, we have $S_2(z, \lambda) = \frac{z + \sqrt{z^2 + 8\lambda^2}}{2\sqrt{2}}$, $S_{3/2}(z, \lambda) = z + 9\lambda^2 \text{sign}(z) (1 - \sqrt{1 + 16|z|/(9\lambda^2)})/8$ and $S_{4/3}(z, \lambda) = z + \frac{4\lambda}{3\sqrt{3}} ((\chi - z)^{1/3} - (\chi + z)^{1/3})$ with $\chi = \sqrt{z^2 + 256\lambda^3/729}$.
- For $f(t) = \|t\|_2$ and $z \in \mathbb{R}^d$, $P_f(z) := S_{2,1}(z, \lambda) = \max\{1 - \frac{\lambda}{\|z\|_2}, 0\} * z$.

With the help of these proximity operators and Bregman splitting algorithm (Ye and Xie, 2011), we can solve (5) by iteratively solving the following procedures:

$$\begin{cases} \beta_g^{k+1} = \arg \min_{\beta_g} \frac{1}{2} \|\beta_g - z\|_2^2 + \langle u^k, \beta_g - a^k \rangle + \langle v^k, D_g \beta_g - b^k \rangle \\ \quad + \frac{\mu}{2} \|\beta_g - a^k\|_2^2 + \frac{\mu}{2} \|D_g \beta_g - b^k\|_2^2 \\ a^{k+1} = \arg \min_{a} \rho_1 \|a\|_2 + \langle u^k, \beta^{k+1} - a \rangle + \frac{\mu}{2} \|\beta^{k+1} - a\|_2^2 \\ b^{k+1} = \arg \min_b \rho_2 \|b\|_{p^*} + \langle v^k, D_g \beta^{k+1} - b \rangle + \frac{\mu}{2} \|D_g \beta^{k+1} - b\|_2^2 \\ u^{k+1} = u^k + \mu (\beta^{k+1} - a^{k+1}) \\ v^{k+1} = v^k + \mu (D_g \beta^{k+1} - b^{k+1}) \end{cases}$$

where μ acts like a step size in this algorithm.

Remark 1 The minimization over β , a and b can all be solved in closed form.

- $\beta^{k+1} = [\mu + 1]I + \mu D_g^T D_g]^{-1} [z + \mu(a^k - u^k/\mu) + \mu D_g^T (b^k - v^k/\mu)]$
- $a^{k+1} = S_{2,1}(\beta^{k+1} + u^k/\mu, \rho_1/\mu)$
- $b^{k+1} = S_{p^*}(\beta^{k+1} + v^k/\mu, \rho_2/\mu)$

Note that $(\mu + 1)I + \mu D_g^T D_g$ is a triagonal positive definite matrix.

Remark 2 For $p = 1$, we can solve (5) more efficiently by the algorithm proposed in Zhou et al. (2012) based on the fact

$$P_{\|\cdot\|_2 + \|D_g(\cdot)\|_1} = P_{\|\cdot\|_2} \circ P_{\|D_g(\cdot)\|_1}.$$

However, we cannot show this equation for $1 < p \leq 2$.

Remark 3 For $p = 2$, since $\|\cdot\|_2^2$ is Lipschitz continuous, we can rewrite (4) as

$$\min_{\beta \in \mathbb{R}^d} \left\{ \frac{1}{2} \left\| \beta - \left(\beta^k - \frac{1}{\bar{\tau}} (\nabla L(\beta^k) + 2\lambda_2 \sum_{g=1}^G D_g^T D_g \beta^k) \right) \right\|_2^2 + \sum_{g=1}^G \frac{\lambda_1 \sqrt{d_g}}{\bar{\tau}} \|\beta_g\|_2 \right\},$$

where $\bar{\tau}$ is the Lipschitz constant of $L(\beta) + \lambda_2 \sum_{g=1}^G \|D_g \beta_g\|_2^2$. Then we can solve it efficiently via the proximity operator of $\|\cdot\|_2$.

2.5 Study Design and Statistical Analysis

We apply the ℓ^p fused group lasso logistic regression algorithm to the Marshfield breast cancer data set. There are 11 groups for 49 mammography features (Figure 1). For SNPs, we compute the Hamming distances (Wang et al., 2015) of 77 SNPs to get the dissimilarity matrix and then apply hierarchical clustering to obtain 10 groups.

We built three prediction models based on different sets of risk factors: the Mammo model developed by using mammography features only, the SNP77 model developed by using 77 SNPs only, and the Combined model developed by using both mammography features and 77 SNPs. We furthermore apply five methods for each model: logistic regression (LR), lasso in logistic regression (LR+Lasso), ℓ^p fused lasso logistic regression (LR+fusedLasso), group lasso logistic regression (LR+groupLasso), and ℓ^p fused group lasso logistic regression (LR+Structure).

The ℓ^p fused group lasso logistic regression method has several parameters. For the tuning parameters λ_1 and λ_2 , we let them vary among a given set of values, and the shrinkage parameter p (or p_1 and p_2) among $\{1, 4/3, 3/2, 2\}$. Each combination of these parameters is evaluated using stratified 5-fold cross-validation, and AUC (the area under the receiver operating characteristic (ROC) curve) is used as the performance measure. All 738 samples are randomly partitioned into five equal sized folds with approximately equal proportions of cases and controls. In each iteration (totally five iterations), four folds are used as training set and the rest one as validation set to compute AUC. And the parameters with the best average AUC are selected. At last we repeat this process ten times and report the average AUC. We obtain p-value by performing two-tailed two-sample t-test when we compare AUCs.

3. Experimental Results

In this section, we demonstrate the performance of the ℓ^p fused group lasso logistic regression method from three aspects: the significant improvement of AUCs by considering the structure information, the predictive performance under different p (or p_1 and p_2), and the detected important mammography features and SNPs.

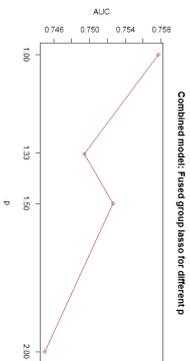

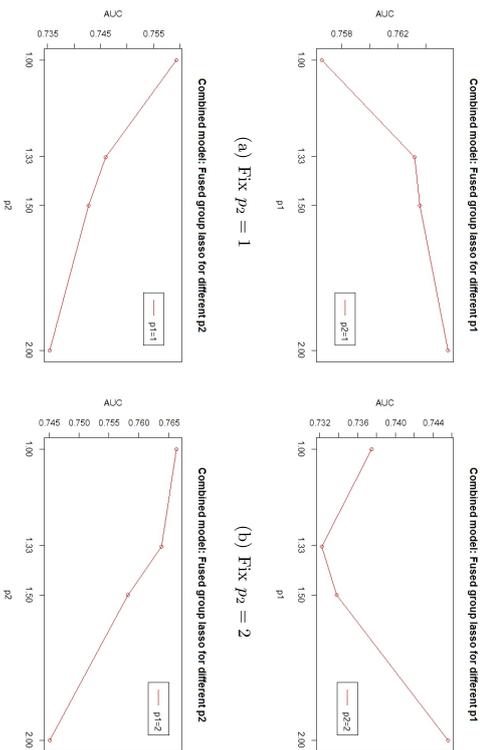

3.1 Performance of Fused Group Lasso

The result is summarized in Table 3.

Models/Methods	LR	Lasso	fusedLasso	groupLasso	Structure	p-value
Mammo	0.700	0.710	0.710	0.716	0.723	< 0.001
SNP77	0.590	0.598	0.676	0.614	0.684	< 0.001
Combined	0.697	0.721	0.754	0.727	0.766	< 0.001

Table 3: Predictive performance of three prediction models by using five different methods. The p-values represent the differences between AUCs of LR and LR+Structure.

- 1) The fifth column describes the predictive performance of the three prediction models by considering structure information in the logistic regression method. We find that the predictive performance of the three prediction models has been improved respectively, compared to those described in the first column. For each prediction model, the difference of the predictive performance is significant between LR+Structure and LR (p-value < 0.001), which demonstrates that breast cancer prediction models utilizing structure information can improve risk prediction significantly. We also find that mammography descriptors demonstrate a significantly higher predictive performance than 77 SNPs in terms of AUC (0.723 vs. 0.684, p-value < 0.001). The Combined model demonstrates significant improvement of the prediction performance, compared to the Mammo model (0.766 vs. 0.723, p-value < 0.001).
- 2) The first column describes the predictive performance of the three prediction models by using the logistic regression method. Mammography descriptors demonstrate a significantly higher predictive performance than 77 SNPs in terms of AUC (0.700 vs. 0.590, p-value < 0.001). We find that the difference of predictive performance between the Combined model and the Mammo model is negligible (0.697 vs. 0.700, p-value=0.277).
- 3) The second column describes the predictive performance of the three prediction models by using lasso in the logistic regression method. The predictive performance of the three prediction models has been improved, compared to those without lasso (using logistic regression method only). Mammography descriptors still demonstrate a significantly higher predictive performance than 77 SNPs in terms of AUC (0.710 vs. 0.598, p-value < 0.001). However, the Combined model demonstrates modest improvement of prediction performance, compared to the Mammo model (0.721 vs. 0.710, p-value=0.0057).
- 4) The third and fourth columns describe the predictive performance of the three prediction models by considering group structure or dependence structure in the logistic regression method. For the SNP77 model, fused lasso demonstrates a significantly higher performance than group lasso in terms of AUC (0.676 vs. 0.614, p-value < 0.001). For the Mammo model, group lasso plays a more important role than fused lasso (0.716 vs. 0.710, p-value=0.0073). Moreover, both fused lasso and group lasso demonstrate improved prediction performance compared to lasso.

Figure 2: The AUCs under different values of p by using method (2).Figure 3: The AUCs under different values of p_1 and p_2 by using method (3).

3.2 Performance under Different Values of p

Figure 2 and Figure 3 describe the the pattern of predictive performance for p' fused group lasso logistic regression over the shrinkage parameter p (or p_1 and p_2) in terms of AUC.

1) The Combined model demonstrates a higher predictive performance for $p = 1$ compared to $p = 2$ in terms of AUC (0.757 vs. 0.745, p-value < 0.001), see Figure 2.

2) Figure 3 describes the prediction performance of method (3) under different values of p_1 for mammography descriptors and p_2 for 77 SNPs.

FAN, WU, YUAN, PAGE, LIU, ONG, PEISSIG, AND BURNSIDE

- Fix $p_2 = 1$ or $p_2 = 2$, the fused group lasso with $p_1 = 2$ demonstrates higher predictive performance compared to $p_1 = 1$, see Figure 3(a) and 3(b).
- Fix $p_1 = 1$ or $p_1 = 2$, the predictive performance of the fused group lasso logistic regression decreases as p_2 increases, see Figure 3(c) and 3(d).
- The fused group lasso logistic regression with $p_1 = 2$ and $p_2 = 1$ demonstrates higher predictive performance than $p_1 = p_2 = 1$ (0.766 vs. 0.757, p-value=0.0053) and $p_1 = p_2 = 2$ (0.766 vs. 0.745, p-value < 0.001).

3.3 Important Features Detected by Fused Group Lasso

To take into account both group and dependence structure information in mammography features and SNPs, two penalty terms (group penalty and fusion penalty) are introduced into the logistic regression model. The idea of group penalty is to force the coefficients of features in the same group to be all zero or nonzero in order to achieve the goal of selecting features within a group simultaneously. The idea of fusion penalty is to shrink the successive difference of coefficients of features in the same group in order to take advantage of the dependence structure information. Applying fusion penalty with $p = 1$ tends to result in zero successive difference of coefficients, while $p = 2$ tends to small but nonzero successive difference of coefficients.

From a feature selection point of view, we can get the order of feature groups selected by fused group lasso via choosing the tuning parameters appropriately. We list below the feature groups selected from high to low in terms of predictive performance.

- 1) For mammography descriptors, the following features are predictive of malignancy (from most to least): ‘‘Mass Size’’, ‘‘Mass Margins’’, ‘‘Mass Shape’’, ‘‘Architectural Distortion’’ and ‘‘Mass Palpability’’, consistent with the literature (BI-RADS, 2014).
- 2) For 77 SNPs, three groups are selected in order, see Table 4.

Feature Group	SNPs
Group 1	rs2016394, rs1432679, rs13281615, rs4666451 rs981782, rs1292011, rs1436904, rs527616
Group 2	rs11249433, rs13387042, rs4973768, rs10069690 rs7904519, rs8051542, rs3760982
Group 3	rs2981579, rs2981582

Table 4: SNP groups selected by fused group lasso.

Remark 4 It verifies that ‘‘Mass size’’, ‘‘Mass Margins’’ and ‘‘Mass Shape’’ are the most important mammography descriptors in breast cancer diagnosis. These results are consistent with previous studies about comparing the importance of mammography features and SNPs in breast cancer risk prediction (Wu et al., 2013, 2014).

4. Discussion and Conclusions

This study demonstrates that models utilizing the novel combination of clinically relevant structure and ℓ^p fused group lasso logistic regression can improve breast cancer risk prediction significantly. Our study also shows that both mammography features and SNPs contribute to this improvement.

The structure information of the mammography features is derived from the BI-RADS lexicon, which is used widely in breast imaging practice. Thus, our model would likely be generalizable to other practices. On the other hand, we extracted the structure information of SNPs by computing Hamming distances (Wang et al., 2015). This method may not perform as well in small sample sizes, which may affect our results perhaps making our predictive performance results conservative.

Our methods for SNPs may not take advantage of biological knowledge that currently exists. For example, it may be possible to utilize the biological information available in HapMap (which encodes linkage disequilibrium) to more accurately emulate the patterns or dependence structure of SNPs, as in (Liu et al., 2012). Furthermore, we realize that taking into account more complicated structure information such as graph or tree structure (Sun and Wang, 2012) may further improve predictive performance of risk prediction models. We leave these promising directions for future work.

In conclusion, our results demonstrate that including structure information in the computational methods we test improves breast cancer risk prediction. Our models use diverse breast cancer risk factors including demographics, genetics, and imaging and leverage structure found in a standardized lexicon that is universally captured in electronic health records (EHRs) throughout the US. This information will increasingly be combined in complex ways. Merging imaging features, clinical notes and genetic data with models that accurately predict disease risk has the potential to provide powerful knowledge to practicing physicians.

Abstract

We demonstrate that, in the classical non-stochastic regret minimization problem with d decisions, gains and losses to be respectively maximized or minimized are fundamentally different. Indeed, by considering the additional sparsity assumption (at each stage, at most s decisions incur a nonzero outcome), we derive optimal regret bounds of different orders. Specifically, with gains, we obtain an optimal regret guarantee after T stages of order $\sqrt{T \log s}$, so the classical dependency in the dimension is replaced by the sparsity size.

With losses, we provide matching upper and lower bounds of order $\sqrt{T s \log(d)/d}$, which is decreasing in d . Eventually, we also study the bandit setting, and obtain an upper bound of order $\sqrt{T s \log(d/s)}$ when outcomes are losses. This bound is proven to be optimal up to the logarithmic factor $\sqrt{\log(d/s)}$.

Keywords: regret minimization, bandit, sparsity

1. Introduction

We consider the classical problem of regret minimization (Hannan, 1957) that has been well developed during the last decade (Cesa-Bianchi and Lugosi, 2006; Rakhlin and Tewari, 2008; Bubeck, 2011; Shalev-Shwartz, 2011; Hazan, 2012; Bubeck and Cesa-Bianchi, 2012). We recall that in this sequential decision problem, a decision maker (or agent, player, algorithm, strategy, policy, depending on the context) chooses at each stage a decision in a finite set (that we write as $[d] := \{1, \dots, d\}$) and obtains as an *outcome* a real number in $[0, 1]$. We specifically chose the word *outcome*, as opposed to *gain* or *loss*, as our results show that there exists a fundamental discrepancy between these two concepts.

The criterion used to evaluate the policy of the decision maker is the *regret*, i.e., the difference between the cumulative performance of the best stationary policy (that always picks a given action $i \in [d]$) and the cumulative performance of the policy of the decision maker.

We focus here on the *non-stochastic* framework, where no assumption (apart from boundedness) is made on the sequence of possible outcomes. In particular, they are not i.i.d. and we can even assume, as usual, that they depend on the past choices of the decision maker. This broad setup, sometimes referred to as *individual sequences* (since a policy must be good against *any* sequence of possible outcomes) incorporates prediction with expert advice (Cesa-Bianchi and Lugosi, 2006), data with time-evolving laws, etc. Perhaps the most fundamental results in this setup are the upper bound of order $\sqrt{T \log d}$ achieved by the Exponential Weight Algorithm (Littlestone and Warmuth, 1994; Vovk, 1990; Cesa-Bianchi, 1997; Auer et al., 2002) and the asymptotic lower bound of the same order (Cesa-Bianchi et al., 1997). This general bound is the same whether outcomes are gains in $[0, 1]$ (in which case, the objective is to maximize the cumulative sum of gains) or losses in $[0, 1]$ (where the decision maker aims at minimizing the cumulative sum). Indeed, a loss ℓ can easily be turned into gain g by defining $g := 1 - \ell$, the regret being invariant under this transformation.

This idea does not apply anymore with structural assumption. For instance, consider the framework where the outcomes are limited to *s-sparse vectors*, i.e. vectors that have at most s nonzero coordinates. The coordinates which are nonzero may change arbitrarily over time. In this framework, the aforementioned transformation does not preserve the sparsity assumption. Indeed, if (ℓ_1, \dots, ℓ_d) is a s -sparse loss vector, the corresponding gain vector $(1 - \ell_1, \dots, 1 - \ell_d)$ may even have full support. Consequently, results for loss vectors do not apply directly to sparse gains, and vice versa. It turns out that both setups are fundamentally different.

The sparsity assumption is actually quite natural in learning and have also received some attention in online learning (Gerchinovitz, 2013; Carpenter and Munos, 2012; Abbasi-Yadkori et al., 2012; Djolonga et al., 2013). In the case of gains, it reflects the fact that the problem has some hidden structure and that many options are irrelevant. For instance, in the canonical click-through-rate example, a website displays an ad and gets rewarded if the user clicks on it; we can safely assume that there are only a small number of ads on which a user would click.

The sparse scenario can also be seen through the scope of prediction with experts. Given a finite set of expert, we call the *winner of a stage* the expert with the highest revenue (or the smallest loss); ties are broken arbitrarily. And the objective would be to win as many stages as possible. The s -sparse setting would represent the case where s experts are designated as winners (or, non-loser) at each stage.

In the case of losses, the sparsity assumption is motivated by situations where rare failures might happen at each stage, and the decision maker wants to avoid them. For instance, in network routing problems, it could be assumed that only a small number of paths would lose packets as a result of a single, rare, server failure. Or a learner could have access to a finite number of classification algorithms that perform ideally most of the time; unfortunately, some of them makes mistakes on some examples and the learner would like to prevent that. The general setup is therefore a number of algorithms/experts/actions that mostly perform well (i.e., find the correct path, classify correctly, optimize correctly some target function, etc.); however, at each time instance, there are rare mistakes/accidents and the objective would be to find the action/algorithm that has the smallest number (or probability in the stochastic case) of failures.

1.1 Summary of Results

We investigate regret minimization scenarios both when outcomes are gains on the one hand, and losses on the other hand. We recall that our objectives are to prove that they are fundamentally different by exhibiting rates of convergence of different order.

When outcomes are gains, we construct an algorithm based on the Online Mirror Descent family (Shalev-Shwartz, 2007, 2011; Bubeck, 2011). By choosing a regularizer based on the ℓ^p norm, and then tuning the parameter p as a function of s , we get in Theorem 2 a regret bound of order $\sqrt{T \log s}$, which has the interesting property of being independent of the number of decisions d . This bound is trivially optimal, up to the constant.

If outcomes are losses instead of gains, although the previous analysis remains valid, a much better bound can be obtained. We build upon a regret bound for the Exponential Weight Algorithm (Littlestone and Warmuth, 1994; Freund and Schapire, 1997) and we manage to get in Theorem 4 a regret bound of order $\sqrt{T s \log \frac{d}{d}}$, which is *decreasing* in d , for a given s . A nontrivial matching lower bound is established in Theorem 6.

Both of these algorithms need to be tuned as a function of s . In Theorem 9 and Theorem 10, we construct algorithms which essentially achieve the same regret bounds without prior knowledge of s , by adapting over time to the sparsity level of past outcome vectors, using an adapted version of the doubling trick.

Finally, we investigate the bandit setting, where the only feedback available to the decision maker is the outcome of his decisions (and, not the outcome of all possible decisions). In the case of losses we obtain in Theorem 11 an upper bound of order $\sqrt{T s \log(d/s)}$, using the Greedy Online Mirror Descent family of algorithms (Audibert and Bubeck, 2009; Audibert et al., 2013; Bubeck, 2011). This bound is proven to be optimal up to a logarithmic factor, as Theorem 13 establishes a lower bound of order $\sqrt{T} s$.

The rates of convergence achieved by our algorithms are summarized in Figure 1.

1.2 General Model and Notation

We recall the classical non-stochastic regret minimization problem. At each time instance $t \geq 1$, the decision maker chooses a decision d_t in the finite set $[d] = \{1, \dots, d\}$, possibly at random, according to $x_t \in \Delta_d$, where

$$\Delta_d = \left\{ x = (x^{(1)}, \dots, x^{(d)}) \in \mathbb{R}_+^d \mid \sum_{i=1}^d x^{(i)} = 1 \right\}$$

is the set of probability distributions over $[d]$. Nature then reveals an outcome vector $\omega_t \in [0, 1]^d$ and the decision maker receives $\omega_t^{(d_t)} \in [0, 1]$. As outcomes are bounded, we can easily replace $\omega_t^{(d_t)}$ by its expectation that we denote by $\langle \omega_t, x_t \rangle$. Indeed, Hoeffding-Azuma concentration inequality will imply that all the results we will state in expectation hold with high probability.

Given a time horizon $T \geq 1$, the objective of the decision maker is to minimize his regret, whose definition depends on whether outcomes are *gains* or *losses*. In the case of gains (resp. losses), the notation ω_t is then changed to g_t (resp. ℓ_t) and the regret is:

$$R_T = \max_{i \in [d]} \sum_{t=1}^T g_t^{(i)} - \sum_{t=1}^T \langle g_t, x_t \rangle \quad (\text{resp. } R_T = \sum_{t=1}^T \langle \ell_t, x_t \rangle - \min_{k \in [d]} \sum_{t=1}^T \ell_t^{(k)}).$$

In both cases, the well-known Exponential Weight Algorithm guarantees a bound on the regret of order $\sqrt{T \log d}$. Moreover, this bound cannot be improved in general as it matches a lower bound.

We shall consider an additional structural assumption on the outcomes, namely that ω_t is s -sparse in the sense that $\|\omega_t\|_0 \leq s$, i.e., the number of nonzero components of ω_t is less than s , where s is a fixed known parameter. The set of components which are nonzero is not fixed nor known, and may change arbitrarily over time.

We aim at proving that it is then possible to drastically improve the previously mentioned guarantee of order $\sqrt{T \log d}$ and that losses and gains are two fundamentally different settings with minimax regrets of different orders.

2. When Outcomes are Gains to be Maximized

2.1 Online Mirror Descent Algorithms

We quickly present the general Online Mirror Descent algorithm (Shalev-Shwartz, 2011; Bubeck, 2011; Bubeck and Cesa-Bianchi, 2012; Kwon and Mertikopoulos, 2014) and state the regret bound it incurs; it will be used as a key element in Theorem 2.

A convex function $h : \mathbb{R}^d \rightarrow \mathbb{R} \cup \{+\infty\}$ is called a *regularizer* on Δ_d if h is strictly convex and continuous on its domain Δ_h , and $h(x) = +\infty$ outside Δ_h . Denote $\delta_h = \max_{\Delta_d} h - \min_{\Delta_h} h$ and $h^* : \mathbb{R}^d \rightarrow \mathbb{R}^d$ the Legendre-Fenchel transform of h :

$$h^*(y) = \sup_{x \in \mathbb{R}^d} \{ \langle y, x \rangle - h(x) \}, \quad y \in \mathbb{R}^d,$$

which is differentiable since h is strictly convex. For all $y \in \mathbb{R}^d$, it holds that $\nabla h^*(y) \in \Delta_d$. Let $\eta \in \mathbb{R}$ be a parameter to be tuned. The Online Mirror Descent Algorithm associated with the regularizer h and parameter η is defined by:

$$x_t = \nabla h^* \left(\eta \sum_{k=1}^{t-1} \omega_k \right), \quad t \geq 1,$$

where $\omega_t \in [0, 1]^d$ denote the vector of outcomes and x_t the probability distribution chosen at stage t . The specific choice $h(x) = \sum_{i=1}^d x^{(i)} \log x^{(i)}$ for $x = (x^{(1)}, \dots, x^{(d)}) \in \Delta_d$ (and

$h(x) = +\infty$ otherwise) gives the celebrated Exponential Weight Algorithm, which can be written explicitly, component by component:

$$x_t^{(i)} = \frac{\exp\left(\eta \sum_{k=1}^{t-1} \omega_k^{(i)}\right)}{\sum_{j=1}^d \exp\left(\eta \sum_{k=1}^{t-1} \omega_k^{(j)}\right)}, \quad t \geq 1, i \in [d].$$

The following general regret guarantee for strongly convex regularizers is expressed in terms of the dual norm $\|\cdot\|_*$ of $\|\cdot\|$. Similar statements have appeared in e.g. (Shalev-Shwartz, 2011, Theorem 2.21), (Bubeck and Cesa-Bianchi, 2012, Theorem 5.6) and (Kwon and Mertikopoulos, 2014, Theorem 5.1).

Theorem 1 *Let $K > 0$ and assume h to be K -strongly convex with respect to a norm $\|\cdot\|$. Then, for any sequence of outcome vectors $(\omega_t)_{t \geq 1}$ in \mathbb{R}^d , the Online Mirror Descent strategy associated with h and η (with $\eta > 0$ in cases of gains and $\eta < 0$ in cases of losses) guarantees, for $T \geq 1$, the following regret bound:*

$$R_T \leq \frac{\delta_h}{|\eta|} + \frac{|\eta|}{2K} \sum_{t=1}^T \|\omega_t\|_*^2.$$

2.2 Upper Bound on the Regret

We first assume $s \geq 2$. Let $p \in (1, 2]$ and define the following regularizer:

$$h_p(x) = \begin{cases} \frac{1}{2} \|x\|_p^2 & \text{if } x \in \Delta_d \\ +\infty & \text{otherwise.} \end{cases}$$

One can easily check that h_p is indeed a regularizer on Δ_d and that $\delta_{h_p} \leq 1/2$. Moreover, it is $(p-1)$ -strongly convex with respect to $\|\cdot\|_p$: see (Bubeck, 2011, Lemma 5.7) or (Kakade et al., 2012, Lemma 9).

We can now state our first result, the general upper bound on regret when outcomes are s -sparse gains.

Theorem 2 *Let $\eta > 0$ and $s \geq 3$. Against all sequences of s -sparse gain vectors g_t , i.e., $g_t \in [0, 1]^d$ and $\|g_t\|_0 \leq s$, the Online Mirror Descent algorithm associated with regularizer h_p and parameter η guarantees:*

$$R_T \leq \frac{1}{2\eta} + \frac{\eta T s^2/q}{2(p-1)},$$

where $1/p + 1/q = 1$. In particular, the choices $\eta = \sqrt{(p-1)/Ts^2/q}$ and $p = 1 + (2 \log s - 1)^{-1}$ give:

$$R_T \leq \sqrt{2eT} \log s.$$

Proof h_p being $(p-1)$ -strongly convex with respect to $\|\cdot\|_p$, and $\|\cdot\|_q$ being the dual norm of $\|\cdot\|_p$, Theorem 1 gives:

$$R_T \leq \frac{\delta_{h_p}}{\eta} + \frac{\eta}{2(p-1)} \sum_{t=1}^T \|g_t\|_q^2.$$

For each $t \geq 1$, the norm of g_t can be bounded as follows:

$$\|g_t\|_q^2 = \left(\sum_{i=1}^d |g_t^{(i)}| \right)^{2/q} \leq \left(\sum_{s \text{ terms}} |g_t^{(i)}|^q \right)^{2/q} \leq s^{2/q},$$

which yields

$$R_T \leq \frac{1}{2\eta} + \frac{\eta T s^{2/q}}{2(p-1)}.$$

We can now balance both terms by choosing $\eta = \sqrt{(p-1)/(T s^{2/q})}$ and get:

$$R_T \leq \sqrt{\frac{T s^{2/q}}{p-1}}.$$

Finally, since $s \geq 3$, we have $2 \log s > 1$ and we set $p = 1 + (2 \log s - 1)^{-1} \in (1, 2]$, which gives:

$$\frac{1}{q} = 1 - \frac{1}{p} = \frac{p-1}{p} = \frac{(2 \log s - 1)^{-1}}{1 + (2 \log s - 1)^{-1}} = \frac{1}{2 \log s},$$

and thus:

$$R_T \leq \sqrt{\frac{T s^{2/q}}{p-1}} = \sqrt{2T \log s e^{2 \log s/q}} = \sqrt{2eT} \log s. \quad \blacksquare$$

We emphasize the fact that we obtain, up to a multiplicative constant, the exact same rate as when the decision maker only has a set of s decisions.

Theorem 2 was restricted to $s \geq 3$ to simplify the analysis. In the cases $s = 1, 2$, we can easily derive a bound of respectively \sqrt{T} and $\sqrt{2T}$ using the same regularizer with $p = 2$.

2.3 Matching Lower Bound

For $s \in [d]$ and $T \geq 1$, we denote $v_T^{g,s,d}$ the minimax regret of the T -stage decision problem with outcome vectors restricted to s -sparse gains:

$$v_T^{g,s,d} = \min_{\text{strat.}} \max_{(g_t)_t} R_T$$

where the minimum is taken over all possible policies of the decision maker, and the maximum over all sequences of s -sparse gains vectors.

To establish a lower bound in the present setting, we can assume that only the s first coordinates of g_t may be positive (for all $t \geq 1$) and that the decision maker is aware of that. Therefore he has no interest in assigning positive probabilities to any decision but the first s ones. Indeed, for any mixed action x_t , the decision maker can construct alternative mixed action $x'_t = (x_t^{(1)}, \dots, x_t^{(s)}, 0, \dots, 0)$ which obviously give a higher payoff:

$$\langle g_t, x_t \rangle \leq \langle g_t, x'_t \rangle$$

and therefore a lower regret:

$$\max_{t \in [d]} \sum_{t=1}^T g_t^{(t)} - \sum_{t=1}^T \langle g_t, x_t^* \rangle \leq \max_{t \in [d]} \sum_{t=1}^T g_t^{(t)} - \sum_{t=1}^T \langle g_t, x_t \rangle.$$

Therefore, we can restrict the strategies of the decision maker to those which assign positive probability to the s first components only. That setup, which is simpler for the decision maker than the original one, is obviously equivalent to the basic regret minimization problem with only s decisions. Therefore, the classical lower bound (Cesa-Bianchi et al., 1997, Theorem 3.2.3) holds and we obtain the following:

Theorem 3

$$\liminf_{s \rightarrow +\infty} \liminf_{T \rightarrow +\infty} \frac{v_T^{g^*, d}}{\sqrt{T} \log s} \geq \frac{\sqrt{2}}{2}.$$

The same lower bound, up to the multiplicative constant actually holds non asymptotically, see (Cesa-Bianchi and Lugosi, 2006, Theorem 3.6).

An immediate consequence of Theorem 3 is that the regret bound derived in Theorem 2 is asymptotically minimax optimal, up to a multiplicative constant.

3. When Outcomes are Losses to be Minimized

3.1 Upper Bound on the Regret

We now consider the case of losses, and the regularizer shall no longer depend on s (as with gains), as we will always use the Exponential Weight Algorithm. Instead, it is the parameter η that will be tuned as a function of s .

Theorem 4 *Let $s \geq 1$. For any sequence of s -sparse loss vectors $(\ell_t)_{t \geq 1}$, i.e., $\ell_t \in [0, 1]^d$ and $\|\ell_t\|_0 \leq s$, the Exponential Weight Algorithm with parameter $-\eta$ where*

$$\eta := \log \left(1 + \sqrt{2d \log d / sT} \right) > 0$$

guarantees, for $T \geq 1$:

$$R_T \leq \sqrt{\frac{2sT \log d}{d}} + \log d.$$

We build upon the following regret bound for losses which is written in terms of the performance of the best action. It is often called *improvement for small losses*: see e.g. (Littstone and Warmuth, 1994) or (Cesa-Bianchi and Lugosi, 2006, Theorem 2.4).

Theorem 5 *Let $\eta > 0$. For any sequence of loss vectors $(\ell_t)_{t \geq 1}$ in $[0, 1]^d$, the Exponential Weight Algorithm with parameter $-\eta$ guarantees, for all $T \geq 1$:*

$$R_T \leq \frac{\log d}{1 - e^{-\eta}} + \left(\frac{\eta}{1 - e^{-\eta}} - 1 \right) L_T^*,$$

where $L_T^* = \min_{t \in [d]} \sum_{t=1}^T \ell_t^{(t)}$ is the loss of the best stationary decision.

Proof Let $T \geq 1$ and $L_T^* = \min_{t \in [d]} \sum_{t=1}^T \ell_t^{(t)}$ be the loss of the best stationary policy. First note that since the loss vectors ℓ_t are s -sparse, we have $s \geq \sum_{t=1}^d \ell_t^{(t)}$. By summing over $1 \leq t \leq T$:

$$sT \geq \sum_{t=1}^T \sum_{t=1}^d \ell_t^{(t)} = \sum_{t=1}^d \left(\sum_{t=1}^T \ell_t^{(t)} \right) \geq d \left(\min_{t \in [d]} \sum_{t=1}^T \ell_t^{(t)} \right) = dL_T^*,$$

and therefore, we have $L_T^* \leq Ts/d$.

Then, by using the inequality $\eta \leq (e^\eta - e^{-\eta})/2$, the bound from Theorem 5 becomes:

$$R_T \leq \frac{\log d}{1 - e^{-\eta}} + \left(\frac{e^\eta - e^{-\eta}}{2(1 - e^{-\eta})} - 1 \right) L_T^*.$$

The factor of L_T^* in the second term can be transformed as follows:

$$\frac{e^\eta - e^{-\eta}}{2(1 - e^{-\eta})} - 1 = \frac{(1 + e^{-\eta})(e^\eta - e^{-\eta})}{2(1 - e^{-2\eta})} - 1 = \frac{(1 + e^{-\eta})e^\eta}{2} - 1 = \frac{e^\eta - 1}{2},$$

and therefore the bound on the regret becomes:

$$R_T \leq \frac{\log d}{1 - e^{-\eta}} + \frac{e^\eta - 1}{2} L_T^* \leq \frac{\log d}{1 - e^{-\eta}} + \frac{(e^\eta - 1)Ts}{2d},$$

where we have been able to use the upper-bound on L_T^* since $\frac{e^\eta - 1}{2} \geq 0$. Along with the choice $\eta = \log(1 + \sqrt{2d \log d / Ts})$ and standard computations, this yields:

$$R_T \leq \sqrt{\frac{2Ts \log d}{d}} + \log d. \quad \blacksquare$$

Interestingly, the bound from Theorem 4 shows that $\sqrt{2sT \log d / d}$, the dominating term of the regret bound, is *decreasing* when the number of decisions d increases. This is due to the sparsity assumptions (as the regret increases with s , the maximal number of decision with positive losses). Indeed, when s is fixed and d increases, more and more decisions are optimal at each stage, a proportion $1 - s/d$ to be precise. As a consequence, it becomes *easier* to find an optimal decisions when d increases. However, this intuition will turn out not to be valid in the bandit framework.

On the other hand, if the proportion s/d of positive losses remains constant then the regret bound achieved is of the same order as in the usual case.

3.2 Matching Lower Bound

When outcomes are losses, the argument from Section 2.3 does not allow to derive a lower bound. Indeed, if we assume that only the first s coordinates of the loss vectors ℓ_t can be positive, and that the decision maker knows it, then he just has to take at each stage the decision $d_t = d$ which incurs a loss of 0. As a consequence, he trivially has a regret

$R_T = 0$. Choosing at random, but once and for all, a fixed subset of s coordinates does not provide any interesting lower bound either. Instead, the key idea of the following result is to choose at random and at each stage the s coordinates associated with positive losses. And we therefore use the following classical probabilistic argument. Assume that we have found a probability distribution on $(\ell_t)_t$ such that the expected regret can be bounded from below by a quantity which does not depend on the strategy of the decision maker. This would imply that for any algorithm, there exists a sequence of $(\ell_t)_t$ such that the regret is greater than the same quantity.

In the following statement, $v_T^{s,d}$ stands for the minimax regret in the case where outcomes are losses.

Theorem 6 For all $s \geq 1$,

$$\liminf_{d \rightarrow +\infty} \liminf_{T \rightarrow +\infty} \frac{v_T^{s,d}}{\sqrt{T^s \log d}} \geq \frac{\sqrt{2}}{2}.$$

The main consequences of this theorem are that the algorithm described in Theorem 4 is asymptotically minimax optimal (up to a multiplicative constant) and that gains and losses are fundamentally different from the point of view of regret minimization.

Proof We define the sequence of i.i.d. loss vectors ℓ_t ($t \geq 1$) as follows. First, we draw a set $I_t \subset [d]$ of cardinality s uniformly among the $\binom{d}{s}$ possibilities. Then, if $i \in I_t$ set $\ell_t^{(i)} = 1$ with probability $1/2$ and $\ell_t^{(i)} = 0$ with probability $1/2$, independently for each component. If $i \notin I_t$, we set $\ell_t^{(i)} = 0$.

As a consequence, we always have that ℓ_t is s -sparse. Moreover, for each $t \geq 1$ and each coordinate $i \in [d]$, $\ell_t^{(i)}$ satisfies:

$$\mathbb{P}[\ell_t^{(i)} = 1] = \frac{s}{2d} \quad \text{and} \quad \mathbb{P}[\ell_t^{(i)} = 0] = 1 - \frac{s}{2d},$$

thus $\mathbb{E}[\ell_t^{(i)}] = s/2d$. Therefore we obtain that for any algorithm $(x_t)_{t \geq 1}$, $\mathbb{E}[\langle \ell_t, x_t \rangle] = s/2d$. This yields that

$$\begin{aligned} \mathbb{E} \left[\frac{R_T}{\sqrt{T}} \right] &= \mathbb{E} \left[\frac{1}{\sqrt{T}} \left(\sum_{t=1}^T \langle \ell_t, x_t \rangle - \min_{i \in [d]} \sum_{t=1}^T \ell_t^{(i)} \right) \right] \\ &= \mathbb{E} \left[\frac{\max_{i \in [d]} \frac{1}{\sqrt{T}} \sum_{t=1}^T (s - \ell_t^{(i)})}{\sqrt{T}} \right] \\ &= \mathbb{E} \left[\frac{\max_{i \in [d]} \frac{1}{\sqrt{T}} \sum_{t=1}^T X_t^{(i)}}{\sqrt{T}} \right], \end{aligned}$$

where $t \geq 1$, we have defined the random vector X_t by $X_t^{(i)} = s/2d - \ell_t^{(i)}$ for all $i \in [d]$. For $t \geq 1$, the X_t are i.i.d. zero-mean random vectors with values in $[-1, 1]^d$. We can therefore apply the comparison Lemma 8 to get:

$$\liminf_{T \rightarrow +\infty} \mathbb{E} \left[\frac{R_T}{\sqrt{T}} \right] = \liminf_{T \rightarrow +\infty} \mathbb{E} \left[\max_{i \in [d]} \frac{1}{\sqrt{T}} \sum_{t=1}^T X_t^{(i)} \right] \geq \mathbb{E} \left[\max_{i \in [d]} Z^{(i)} \right],$$

where $Z \sim \mathcal{N}(0, \Sigma)$ with $\Sigma = (\text{cov}(X_1^{(i)}, X_1^{(j)}))_{i,j}$.

We now make appeal to Slepian's lemma, recalled in Proposition 7 below. Therefore, we introduce the Gaussian vector $W \sim \mathcal{N}(0, \tilde{\Sigma})$ where

$$\tilde{\Sigma} = \text{diag} \left(\text{Var } X_1^{(1)}, \dots, \text{Var } X_1^{(1)} \right).$$

As a consequence, the first two hypotheses of Proposition 7 follow from the definitions of Z and W . Let $i \neq j$, then

$$\mathbb{E} \left[Z^{(i)} Z^{(j)} \right] = \text{cov}(Z^{(i)}, Z^{(j)}) = \text{cov}(\ell_1^{(i)}, \ell_1^{(j)}) = \mathbb{E} \left[\ell_1^{(i)} \ell_1^{(j)} \right] - \mathbb{E} \left[\ell_1^{(i)} \right] \mathbb{E} \left[\ell_1^{(j)} \right].$$

By definition of ℓ_1 , $\ell_1^{(i)} \ell_1^{(j)} = 1$ if and only if $\ell_1^{(i)} = \ell_1^{(j)} = 1$ and $\ell_1^{(i)} \ell_1^{(j)} = 0$ otherwise. Therefore, using the random subset I_1 that appears in the definition of ℓ_1 :

$$\begin{aligned} \mathbb{E} \left[Z^{(i)} Z^{(j)} \right] &= \mathbb{P} \left[\ell_1^{(i)} = \ell_1^{(j)} = 1 \right] - \left(\frac{s}{2d} \right)^2 \\ &= \mathbb{P} \left[\ell_1^{(i)} = \ell_1^{(j)} = 1 \mid \{i, j\} \subset I_1 \right] \mathbb{P} \left[\{i, j\} \subset I_1 \right] - \left(\frac{s}{2d} \right)^2 \\ &= \frac{1}{4} \cdot \frac{\binom{d-2}{s-2}}{\binom{d}{s}} - \left(\frac{s}{2d} \right)^2 \\ &= \frac{1}{4} \left(\frac{s(s-1)}{d(d-1)} - \frac{s^2}{d^2} \right) \leq 0, \end{aligned}$$

and since $\mathbb{E} \left[W^{(i)} W^{(j)} \right] = 0$ by independence, the third hypothesis of Slepian's lemma is also satisfied. It yields that, for all $\theta \in \mathbb{R}$:

$$\begin{aligned} \mathbb{P} \left[\max_{i \in [d]} Z^{(i)} \leq \theta \right] &= \mathbb{P} \left[Z^{(1)} \leq \theta, \dots, Z^{(d)} \leq \theta \right] \\ &\leq \mathbb{P} \left[W^{(1)} \leq \theta, \dots, W^{(d)} \leq \theta \right] = \mathbb{P} \left[\max_{i \in [d]} W^{(i)} \leq \theta \right]. \end{aligned}$$

This inequality between two cumulative distribution functions implies the reverse inequality on expectations:

$$\mathbb{E} \left[\max_{i \in [d]} Z^{(i)} \right] \geq \mathbb{E} \left[\max_{i \in [d]} W^{(i)} \right].$$

The components of the Gaussian vector W being independent, and of same variance $\text{Var } \ell_1^{(1)}$, we have

$$\mathbb{E} \left[\max_{i \in [d]} W^{(i)} \right] = \kappa_d \sqrt{\text{Var } \ell_1^{(1)}} = \kappa_d \sqrt{\frac{s}{2d} \left(1 - \frac{s}{2d} \right)} \geq \kappa_d \sqrt{\frac{s}{4d}},$$

where κ_d is the expectation of the maximum of d Gaussian variables. Combining everything gives:

$$\liminf_{T \rightarrow +\infty} \frac{v_T^{s,d}}{\sqrt{T}} \geq \liminf_{T \rightarrow +\infty} \mathbb{E} \left[\frac{R_T}{\sqrt{T}} \right] \geq \mathbb{E} \left[\max_{i \in [d]} Z^{(i)} \right] \geq \mathbb{E} \left[\max_{i \in [d]} W^{(i)} \right] \geq \kappa_d \sqrt{\frac{s}{4d}}.$$

And for large d , since κ_d is equivalent to $\sqrt{2 \log d}$ (see e.g. Galambos, 1978),

$$\liminf_{d \rightarrow +\infty} \liminf_{T \rightarrow +\infty} \frac{\kappa_{T, \kappa, d}^{\kappa, \kappa, d}}{\sqrt{T \frac{\kappa}{d} \log d}} \geq \sqrt{2}.$$

■

Proposition 7 (Slepian (1962)) *Let $Z = (Z^{(1)}, \dots, Z^{(d)})$ and $W = (W^{(1)}, \dots, W^{(d)})$ be Gaussian random vectors in \mathbb{R}^d satisfying:*

$$(i) \mathbb{E}[Z] = \mathbb{E}[W] = 0;$$

$$(ii) \mathbb{E}[Z^{(i)}]^2 = \mathbb{E}[W^{(i)}]^2 \text{ for } i \in [d];$$

$$(iii) \mathbb{E}[Z^{(i)}Z^{(j)}] \leq \mathbb{E}[W^{(i)}W^{(j)}] \text{ for } i \neq j \in [d].$$

Then, for all real numbers $\theta_1, \dots, \theta_d$, we have:

$$\mathbb{P}\left[Z^{(1)} \leq \theta_1, \dots, Z^{(d)} \leq \theta_d\right] \leq \mathbb{P}\left[W^{(1)} \leq \theta_1, \dots, W^{(d)} \leq \theta_d\right].$$

The following lemma is an extension of e.g. (Cesa-Bianchi and Lugosi, 2006, Lemma A.11) to random vectors with correlated components.

Lemma 8 (Comparison lemma) *For $t \geq 1$, let $(X_t)_{t \geq 1}$ be i.i.d. zero-mean random vectors in $[-1, 1]^d$, Σ be the covariance matrix of X_t and $Z \sim \mathcal{N}(0, \Sigma)$. Then,*

$$\liminf_{T \rightarrow +\infty} \mathbb{E}\left[\max_{i \in [d]} \frac{1}{\sqrt{T}} \sum_{t=1}^T X_t^{(i)}\right] \geq \mathbb{E}\left[\max_{i \in [d]} Z^{(i)}\right].$$

Proof Denote

$$Y_T = \max_{i \in [d]} \frac{1}{\sqrt{T}} \sum_{t=1}^T X_t^{(i)}.$$

Let $A \leq 0$ and consider the function $\phi_A : \mathbb{R} \rightarrow \mathbb{R}$ defined by $\phi_A(x) = \max(x, A)$.

$$\begin{aligned} \mathbb{E}[Y_T] &= \mathbb{E}[Y_T \cdot \mathbb{1}_{\{Y_T \geq A\}}] + \mathbb{E}[Y_T \cdot \mathbb{1}_{\{Y_T < A\}}] \\ &= \mathbb{E}[\phi_A(Y_T) \cdot \mathbb{1}_{\{Y_T \geq A\}}] + \mathbb{E}[Y_T \cdot \mathbb{1}_{\{Y_T < A\}}] \\ &= \mathbb{E}[\phi_A(Y_T)] - \mathbb{E}[\phi_A(Y_T) \cdot \mathbb{1}_{\{Y_T < A\}}] + \mathbb{E}[Y_T \cdot \mathbb{1}_{\{Y_T < A\}}] \\ &= \mathbb{E}[\phi_A(Y_T)] - \mathbb{E}[(A - Y_T) \cdot \mathbb{1}_{\{A - Y_T > 0\}}]. \end{aligned}$$

Let us estimate the second term. Denote $Z_T = (A - Y_T) \cdot \mathbb{1}_{\{A - Y_T > 0\}}$. We clearly have, for all $u > 0$, $\mathbb{P}[Z_T > u] = \mathbb{P}[A - Y_T > u]$. And Z_T being nonnegative, we can write:

$$\begin{aligned} 0 &\leq \mathbb{E}[(A - Y_T) \cdot \mathbb{1}_{\{A - Y_T > 0\}}] = \mathbb{E}[Z_T] \\ &= \int_0^{+\infty} \mathbb{P}[Z_T > u] \, du \\ &= \int_0^{+\infty} \mathbb{P}[A - Y_T > u] \, du \\ &= \int_{-A}^{+\infty} \mathbb{P}[Y_T < -u] \, du \\ &= \int_{-A}^{+\infty} \mathbb{P}\left[\max_{i \in [d]} \frac{1}{\sqrt{T}} \sum_{t=1}^T X_t^{(i)} < u\right] \, du \\ &\leq \int_{-A}^{+\infty} \mathbb{P}\left[\sum_{t=1}^T X_t^{(1)} < u\sqrt{T}\right] \, du. \end{aligned}$$

For $u > 0$, using Hoeffding's inequality together with the assumptions $\mathbb{E}[X_t^{(1)}] = 0$ and $X_t^{(1)} \in [-1, 1]$, we can bound the last integrand:

$$\mathbb{P}\left[\sum_{t=1}^T X_t^{(1)} < u\sqrt{T}\right] \leq e^{-u^2/2},$$

Which gives:

$$0 \leq \mathbb{E}[(A - Y_T) \cdot \mathbb{1}_{\{A - Y_T > 0\}}] \leq \int_{-A}^{+\infty} e^{-u^2/2} \, du \leq \frac{e^{-A^2/2}}{-A}.$$

Therefore:

$$\mathbb{E}[Y_T] \geq \mathbb{E}[\phi_A(Y_T)] + \frac{e^{-A^2/2}}{A}.$$

We now take the liminf on both sides as $t \rightarrow +\infty$. The left-hand side is the quantity that appears in the statement. We now focus on the second term of the right-hand side. The central limit theorem gives the following convergence in distribution:

$$\frac{1}{\sqrt{T}} \sum_{t=1}^T X_t \xrightarrow[T \rightarrow +\infty]{\mathcal{L}} X.$$

The application $(x^{(1)}, \dots, x^{(d)}) \mapsto \max_{i \in [d]} x^{(i)}$ being continuous, we can apply the continuous mapping theorem:

$$Y_T = \max_{i \in [d]} \frac{1}{\sqrt{T}} \sum_{t=1}^T X_t^{(i)} \xrightarrow[T \rightarrow +\infty]{\mathcal{L}} \max_{i \in [d]} X^{(i)}.$$

This convergence in distribution allows the use of the portmanteau lemma: ϕ_A being lower semi-continuous and bounded from below, we have:

$$\liminf_{t \rightarrow +\infty} \mathbb{E}[\phi_A(Y_T)] \geq \mathbb{E} \left[\phi_A \left(\max_{i \in [d]} X^{(i)} \right) \right],$$

and thus:

$$\liminf_{t \rightarrow +\infty} \mathbb{E}[Y_T] \geq \mathbb{E} \left[\phi_A \left(\max_{i \in [d]} X^{(i)} \right) \right] + \frac{e^{-A^2/2}}{A}.$$

We would now like to take the limit as $A \rightarrow -\infty$. By definition of ϕ_A , for $A \leq 0$, we have the following domination:

$$\left| \phi_A \left(\max_{i \in [d]} X^{(i)} \right) \right| \leq \left| \max_{i \in [d]} X^{(i)} \right| \leq \max_{i \in [d]} |X^{(i)}| \leq \sum_{i=1}^d |X^{(i)}|,$$

where each $X^{(i)}$ is L^1 since it is a normal random variable. We can therefore apply the dominated convergence theorem as $A \rightarrow -\infty$:

$$\mathbb{E} \left[\phi_A \left(\max_{i \in [d]} X^{(i)} \right) \right] \xrightarrow{A \rightarrow -\infty} \mathbb{E} \left[\max_{i \in [d]} X^{(i)} \right],$$

and eventually, we get the stated result: \blacksquare

$$\liminf_{t \rightarrow +\infty} \mathbb{E}[Y_T] \geq \mathbb{E} \left[\max_{i \in [d]} X^{(i)} \right].$$

4. When the Sparsity Level s is Unknown

We no longer assume in this section that the decision maker have the knowledge of the sparsity level s . We modify our algorithms to be adaptive over the sparsity level of the observed gain/loss vectors. The algorithms are proved to essentially achieve the same regret bounds as in the case where s is known. The constructions follow the same ideas behind the classical doubling trick. However, the latter cannot be directly applied here: the usual doubling trick involves time intervals whose lengths are always the same, whereas we here need to make the lengths on the sparsity levels of the payoff vectors.

Specifically, let $T \geq 1$ be the number of rounds and s^* the highest sparsity level of the gain/loss vectors chosen by Nature up to time T . In the following, we construct algorithms which achieve regret bounds of order $\sqrt{T \log s^*}$ and $\sqrt{T s^* \log d}$ for gains and losses respectively, without prior knowledge of s^* .

4.1 For Losses

Let $(\ell_t)_{t \geq 1}$ be the sequence of loss vectors in $[0, 1]^d$ chosen by Nature, and $T \geq 1$ the number of rounds. We denote $s^* = \max_{1 \leq t \leq T} \|\ell_t\|_0$ the higher sparsity level of the loss vectors up

to time T . The goal is to construct an algorithm which achieves a regret bound of order $\sqrt{T s^* \log d}$ without any prior knowledge about the sparsity level of the loss vectors.

The time instances $\{1, \dots, T\}$ will be divided into several time intervals. On each of those, the previous loss vectors will be left aside, and a new instance of the Exponential Weight Algorithm with a specific parameter will be run. Let $M = \lceil \log_2 s^* \rceil$ and $\tau(0) = 0$. Then, for $1 \leq m < M$ we define

$$\tau(m) = \min \{1 \leq t \leq T \mid \|\ell_t\|_0 > 2^m\} \quad \text{and} \quad \tau(M) = T.$$

In other words, $\tau(m)$ is the first time instance at which the sparsity level of the loss vector exceeds 2^m . $(\tau(m))_{1 \leq m \leq M}$ is thus a nondecreasing sequence. We can then define the time intervals $I(m)$ as follows. For $1 \leq m \leq M$, let

$$I(m) = \begin{cases} \{\tau(m-1) + 1, \dots, \tau(m)\} & \text{if } \tau(m-1) < \tau(m) \\ \emptyset & \text{if } \tau(m-1) = \tau(m). \end{cases}$$

The sets $(I(m))_{1 \leq m \leq M}$ clearly form a partition of $\{1, \dots, T\}$ (some of the intervals may be empty). For $1 \leq t \leq T$, we define $m_t = \min \{m \geq 1 \mid \tau(m) \geq t\}$ which implies $t \in I(m_t)$. In other words, m_t is the index of the only interval t belongs to.

Let $C > 0$ be a constant to be chosen later and for $1 \leq m \leq M$, let

$$\eta(m) = \log \left(1 + C \sqrt{\frac{d \log d}{2^m T}} \right)$$

be the parameter of the Exponential Weight Algorithm to be used on interval $I(m)$. In this section, h will be entropic regularizer on the simplex $h(x) = \sum_{i=1}^d x^{(i)} \log x^{(i)}$, so that $y \mapsto \nabla h^*(y)$ is the *logit map* used in the Exponential Weight Algorithm. We can then define the played actions to be:

$$x_t = \nabla h^* \left(-\eta(m_t) \sum_{\substack{t' < t \\ t' \in I(m_t)}} \ell_{t'} \right), \quad t = 1, \dots, T.$$

Theorem 9 *The above algorithm with $C = 2^{3/4}(\sqrt{2} + 1)^{1/2}$ guarantees*

$$R_T \leq 4 \sqrt{\frac{T s^* \log d}{d}} + \frac{\lceil \log s^* \rceil \log d}{2} + 5 s^* \sqrt{\frac{\log d}{dT}}.$$

Proof Let $1 \leq m \leq M$. On time interval $I(m)$, the Exponential Weight Algorithm is run with parameter $\eta(m)$ against loss vectors in $[0, 1]^d$. Therefore, the following regret bound

Algorithm 1: For losses in full information without prior knowledge about sparsity
input: $T \geq 1$, $d \geq 1$ integers, and $C > 0$.

```

 $\eta \leftarrow \log(1 + C\sqrt{d\log d/2T});$ 
 $m \leftarrow 1;$ 
for  $i \leftarrow 1$  to  $d$  do
   $w^{(i)} \leftarrow 1/d;$ 
end
for  $t \leftarrow 1$  to  $T$  do
  draw and play decision  $i$  with probability  $w^{(i)}/\sum_{j=1}^d w^{(j)}$ ;
  observe loss vector  $\ell_t$ ;
  if  $\|\ell_t\|_0 \leq 2^m$  then
    for  $i \leftarrow 1$  to  $d$  do
       $w^{(i)} \leftarrow w^{(i)}e^{-\eta\ell_t^{(i)}};$ 
    end
  else
     $m \leftarrow \lceil \log_2 \|\ell_t\|_0 \rceil;$ 
     $\eta \leftarrow \log(1 + C\sqrt{d\log d/2^m T});$ 
    for  $i \leftarrow 1$  to  $d$  do
       $w^{(i)} \leftarrow 1/d;$ 
    end
  end
end

```

derived in the proof of Theorem 4 applies:

$$\begin{aligned}
R(m) &:= \sum_{t \in I(m)} \langle \ell_t, x_t \rangle - \min_{i \in [d]} \sum_{t \in I(m)} \ell_t^{(i)} \\
&\leq \frac{\log d}{1 - e^{-\eta(m)}} + \frac{e^{\eta(m)} - 1}{2} \min_{i \in [d]} \sum_{t \in I(m)} \ell_t^{(i)} \\
&= \frac{1}{C} \sqrt{2^m T \log d} + \frac{\log d}{C} + \frac{C}{2} \sqrt{\frac{d \log d}{2^m T}} \cdot \min_{i \in [d]} \sum_{t \in I(m)} \ell_t^{(i)}.
\end{aligned}$$

We now bound the ‘‘best loss’’ quantity from above, using the fact that ℓ_t is 2^m -sparse for $t \in I(m) \setminus \{\tau(m)\}$ and that $\ell_{\tau(m)}$ is s^* -sparse:

$$\begin{aligned}
\sum_{i=1}^d \sum_{t \in I(m)} \ell_t^{(i)} &= \sum_{t \in I(m)} \sum_{i=1}^d \ell_t^{(i)} = \sum_{t \in I(m)} \sum_{i=1}^d \rho_t^{(i)} + \sum_{i=1}^d \rho_{\tau(m)}^{(i)} \\
&\leq (\tau(m) - \tau(m-1))2^m + s^*,
\end{aligned}$$

which implies:

$$\min_{i \in [d]} \sum_{t \in I(m)} \ell_t^{(i)} \leq \frac{(\tau(m) - \tau(m-1))2^m + s^*}{d}.$$

Therefore, the regret on interval $I(m)$, which we will denote $R(m)$, is bounded by:

$$\begin{aligned}
R(m) &:= \sum_{t \in I(m)} \langle \ell_t, x_t \rangle - \min_{i \in [d]} \sum_{t \in I(m)} \ell_t^{(i)} \\
&\leq \frac{1}{C} \sqrt{\frac{2^m T \log d}{d}} + \frac{\log d}{C} + \frac{C}{2} \sqrt{\frac{2^m \log d}{dT}} (\tau(m) - \tau(m-1)) + \frac{C}{2} \sqrt{\frac{\log d}{2^m d T}} s^* \\
&\leq \frac{1}{C} \sqrt{\frac{2^m T \log d}{d}} + \frac{\log d}{C} + \frac{C}{2} \sqrt{\frac{2s^* \log d}{dT}} (\tau(m) - \tau(m-1)) + \frac{C}{2} \sqrt{\frac{\log d}{2^m d T}} s^*,
\end{aligned}$$

where we used $2^m \leq 2^M \leq 2^{\lceil \log_2 s^* \rceil} \leq 2^{\log_2 s^* + 1} = 2s^*$ for the third term of the last line.

We now turn the whole regret R_T from 1 to T . Since $(I(m))_{1 \leq m \leq M}$ is a partition of $\{1, \dots, T\}$, we obtain

$$\begin{aligned}
R_T &= \sum_{t=1}^T \langle \ell_t, x_t \rangle - \min_{i \in [d]} \sum_{t=1}^T \ell_t^{(i)} \\
&\leq \sum_{m=1}^M \sum_{t \in I(m)} \langle \ell_t, x_t \rangle - \sum_{m=1}^M \min_{i \in [d]} \sum_{t \in I(m)} \ell_t^{(i)} \\
&= \sum_{m=1}^M R(m) \\
&\leq \frac{1}{C} \sqrt{\frac{T \log d}{d}} \sum_{m=1}^M \sqrt{2^m} + C \sqrt{\frac{s^* T \log d}{2d}} + \frac{M \log d}{C} + \frac{C}{2} \sqrt{\frac{\log d}{dT}} s^* \sum_{m=1}^M 2^{-m/2}.
\end{aligned}$$

The sum in the first term above can be bounded as follows

$$\sum_{m=1}^M \sqrt{2^m} \leq \sum_{m=1}^M \sqrt{2^m} = \sqrt{2} \frac{\sqrt{2^M} - 1}{\sqrt{2} - 1} \leq \sqrt{2} \frac{\sqrt{2} \sqrt{2^M} - 1}{\sqrt{2} - 1} = 2 \frac{\sqrt{s^*} - 1}{\sqrt{2} - 1} = 2(\sqrt{2} + 1)\sqrt{s^*},$$

whereas the sum in the last term can be bounded by $\sqrt{2} + 1$. Eventually, the choice $C = 2^{3/4}(\sqrt{2} + 1)^{1/2}$ gives:

$$R_T \leq 2^{5/4}(\sqrt{2} + 1)^{1/2} \sqrt{\frac{T s^* \log d}{d}} + \frac{\lceil \log s^* \rceil \log d}{2^{3/4}(\sqrt{2} + 1)^{1/2}} + 2^{1/4}(\sqrt{2} + 1)^{3/2} s^* \sqrt{\frac{\log d}{dT}},$$

and the statement follows from numerical computation of the constant factors. \blacksquare

4.2 For Gains

The construction is similar to the case of losses, but the time intervals are slightly different. Let $(g_t)_{t \geq 1}$ be the sequence of gain vectors in $[0, 1]^d$ chosen by Nature. We assume $s^* \geq 2$ and set $M = \lceil \log_2 \log_2 s^* \rceil$ and $\tau(0) = 0$. For $1 \leq m \leq M$ we define

$$\tau(m) = \min\{1 \leq t \leq T \mid \|g_t\|_0 > 2^{2^m}\} \quad \text{and} \quad \tau(M) = T.$$

We now define the time intervals $I(m)$. For $1 \leq m \leq M$,

$$I(m) = \begin{cases} \{\tau(m-1) + 1, \dots, \tau(m)\} & \text{if } \tau(m-1) < \tau(m) \\ \emptyset & \text{if } \tau(m-1) = \tau(m). \end{cases}$$

Therefore, for $1 \leq m \leq M$ and $t < \tau(m)$, we have $\|g_t\|_0 \leq 2^{2^m}$. For $1 \leq t \leq T$, we denote $m_t = \min\{m \geq 1 \mid \tau(m) \geq t\}$. Let $C > 0$ be a constant to be chosen later and for $1 \leq m \leq M$, let

$$\begin{aligned} p(m) &= 1 + \frac{1}{\log 2 \cdot 2^{m+1} - 1}, \\ q(m) &= \left(1 - \frac{1}{p(m)}\right)^{-1}, \\ \eta(m) &= C \sqrt{\frac{p(m) - 1}{T 2^{2^{m+1}/q(m)}}}. \end{aligned}$$

As in Section 2.2, for $p \in (1, 2]$, we denote h_p the regularizer on the simplex defined by:

$$h_p(x) = \begin{cases} \frac{1}{2} \|x\|_p^2 & \text{if } x \in \Delta_d \\ +\infty & \text{otherwise.} \end{cases}$$

The algorithm is then defined by:

$$x_t = \nabla h_{p(m_t)}^* \left(\eta(m_t) \sum_{\substack{t' < t \\ t' \in I(m_t)}} g_{t'} \right), \quad t = 1, \dots, T.$$

Algorithm 2: For gains in full information without prior knowledge about sparsity.

input: $T \geq 1$, $d \geq 1$ integers, and $C > 0$.

$p \leftarrow 1 + (4 \log 2 - 1)^{-1}$;

$q \leftarrow (1 - 1/p)^{-1}$;

$\eta \leftarrow C \sqrt{(p-1)/2^{4/q} T}$;

$m \leftarrow 1$;

$y \leftarrow (0, \dots, 0) \in \mathbb{R}^d$;

for $t \leftarrow 1$ **to** T **do**

draw and play decision $i \sim \nabla h_p^*(\eta \cdot y)$;

observe gain vector g_t ;

if $\|g_t\|_0 \leq 2^{2^m}$ **then**

| $y \leftarrow y + g_t$;

else

| $m \leftarrow \lceil \log_2 \log_2 \|g_t\|_0 \rceil$;

| $p \leftarrow 1 + (\log 2 \cdot 2^{m+1} - 1)^{-1}$;

| $q \leftarrow (1 - 1/p)^{-1}$;

| $\eta \leftarrow C \sqrt{(p-1)/2^{2^{m+1}/q} T}$;

| $y \leftarrow (0, \dots, 0)$;

end

end

Theorem 10 *The above algorithm with $C = (e\sqrt{2}(\sqrt{2} + 1))^{1/2}$ guarantees*

$$R_T \leq 7\sqrt{T} \log s^* + \frac{4s^*}{\sqrt{T}}.$$

Proof Let $1 \leq m \leq M$. On time interval $I(m)$, the algorithm boils down to an Online Mirror Descent algorithm with regularizer $h_{p(m)}$ and parameter $\eta(m)$. Therefore, using Theorem 1, the regret on this interval is bounded as follows.

$$\begin{aligned} R(m) &:= \max_{t \in I(m)} \sum_{t' \in I(m)} g_{t'} - \sum_{t \in I(m)} \langle g_t, x_t \rangle \\ &\leq \frac{1}{2\eta(m)} + \frac{\eta(m)}{2(p(m) - 1)} \sum_{t \in I(m)} \|g_t\|_{q(m)}^2 \\ &= \frac{1}{2\eta(m)} + \frac{\eta(m)}{2(p(m) - 1)} \left(\sum_{\substack{t \in I(m) \\ t < \tau(m)}} \|g_t\|_{q(m)}^2 + \|g_{\tau(m)}\|_{q(m)}^2 \right). \end{aligned}$$

g_t being 2^{2^m} -sparse for $t < \tau(m)$ and $g_{\tau(m)}$ being s^* -sparse, the $q(m)$ -norms can therefore be bounded from above as follows:

$$\|g_t\|_{q(m)}^2 \leq 2^{2^{m+1}/q(m)} \quad \text{and} \quad \|g_{\tau(m)}\|_{q(m)}^2 \leq (s^*)^{2/q(m)}.$$

The bound on $R(m)$ then becomes

$$\begin{aligned} R(m) &\leq \frac{1}{2\eta(m)} + \frac{\eta(m)(\tau(m) - \tau(m-1))2^{2^{m+1}/q(m)}}{2(p(m)-1)} + \frac{\eta(m)(s^*)^{2/q(m)}}{2(p(m)-1)} \\ &= \frac{1}{2C} \sqrt{T} e(\log 2 \cdot 2^{m+1} - 1) + \frac{C}{2} \sqrt{\frac{e(\log 2 \cdot 2^{m+1} - 1)}{T}} (\tau(m) - \tau(m-1)) \\ &\quad + \frac{C}{2} (s^*)^{1/(\log 2 \cdot 2^m)} \sqrt{\frac{e(\log 2 \cdot 2^{m+1} - 1)}{T}} \\ &\leq \frac{1}{2C} \sqrt{T} e \log 2 \cdot 2^{m+1} + C \sqrt{\frac{e \log s^*}{T}} (\tau(m) - \tau(m-1)) \\ &\quad + \frac{C}{2} s^* \sqrt{\frac{e \log 2 \cdot 2^{m+1}}{T}}, \end{aligned}$$

where for the second term of the last expression we used:

$$\begin{aligned} \log 2 \cdot 2^{m+1} - 1 &\leq \log 2 \cdot 2^{M+1} = \log 2 \cdot \exp(\log 2 (\lceil \log 2 \log_2 s^* \rceil + 1)) \\ &\leq \log 2 \cdot \exp(\log 2 (\log_2 \log_2 s^* + 2)) \\ &= \log 2 \cdot e^{2 \log 2} \exp(\log 2 \cdot \log_2 \log_2 s^*) \\ &= 4 \log 2 \cdot \exp(\log \log_2 s^*) \\ &= 4 \log 2 \cdot \log_2 s^* \\ &= 4 \log s^*. \end{aligned}$$

Then, the whole regret R_T is bounded by the sum of the regrets on each interval:

$$\begin{aligned} R_T &\leq \sum_{m=1}^M R(m) \leq \frac{1}{2C} \sqrt{T} e \log 2 \sum_{m=1}^M \sqrt{2^{m+1}} + C \sqrt{\frac{e \log s^*}{T}} \sum_{m=1}^M (\tau(m) - \tau(m-1)) \\ &\quad + \frac{C s^*}{2} \sqrt{\frac{e \log 2}{T}} \sum_{m=1}^M 2^{-(m+1)/2}. \end{aligned}$$

The second sum is equal to T and the third sum is bounded from above by $(\sqrt{2} + 1)/\sqrt{2}$. Let us bound the first sum from above:

$$\begin{aligned} \sqrt{\log 2} \sum_{m=1}^M \sqrt{2^{m+1}} &= 2 \sqrt{\log 2} \frac{2^{M/2} - 1}{\sqrt{2} - 1} \\ &\leq 2(\sqrt{2} + 1) \sqrt{\log 2} \cdot \exp\left(\frac{\log 2}{2} (\log_2 \log_2 s^* + 1)\right) \\ &= 2(\sqrt{2} + 1) \sqrt{\log 2} \cdot \sqrt{2} e^{\log \log_2 s^*} \\ &= 2\sqrt{2}(\sqrt{2} + 1) \sqrt{\log 2 \log_2 s^*} \\ &= 2\sqrt{2}(\sqrt{2} + 1) \sqrt{\log s^*}. \end{aligned}$$

Therefore,

$$R_T \leq \frac{\sqrt{2}(\sqrt{2} + 1)}{C} \sqrt{T} e \log s^* + C \sqrt{T} e \log s^* + \frac{C(\sqrt{2} + 1)s^*}{2} \sqrt{\frac{e \log 2}{2T}}.$$

Choosing $C = (e\sqrt{2}(\sqrt{2} + 1))^{1/2}$ balances the first two term and gives:

$$\begin{aligned} R_T &\leq 2(e\sqrt{2}(\sqrt{2} + 1))^{1/2} \sqrt{T} \log s^* + 2^{-5/4} e \sqrt{\log 2} (\sqrt{2} + 1)^{3/2} \frac{s^*}{\sqrt{T}} \\ &\leq \tau \sqrt{T} \log s^* + \frac{4s^*}{\sqrt{T}}. \end{aligned}$$

■

5. The Bandit Setting

We now turn to the bandit framework—see for instance (Bubeck and Cesa-Bianchi, 2012) for a recent survey. Recall that the minimax regret (Audibert and Bubeck, 2009) in the basic bandit framework (without sparsity) is of order \sqrt{Td} . In the case of losses, we manage to take advantage of the sparsity assumption and obtain in Theorem 11 an upper bound of order $\sqrt{T s \log \frac{d}{s}}$, and a lower bound of order $\sqrt{T s}$ in Theorem 13. This establishes the order of the minimax regret up to a logarithmic factor. In the case of gains, the argument from Section 2.3 can be adapted to get a lower bound of order \sqrt{sT} ; but the upper bound techniques from losses do not seem to work: this difficulty is discussed below in Remark 12.

For simplicity, we shall assume that the sequence of outcome vectors $(\omega_t)_{t \geq 1}$ is chosen before stage 1 by the environment, which is called *oblivious* in that case. We refer to (Bubeck and Cesa-Bianchi, 2012, Section 3) for a detailed discussion on the difference between oblivious and non-oblivious opponent, and between regret and pseudo-regret.

As before, at stage t , the decision maker chooses $x_t \in \Delta_d$ and draws decision $d_t \in [d]$ according to x_t . The main difference with the previous framework is that the decision maker only observes his own outcome $\omega_t^{d_t}$ before choosing the next decision d_{t+1} .

5.1 Upper Bounds on the Regret with Sparse Losses

We shall focus in this section on s -sparse losses. The algorithm we consider belongs to the family of Greedy Online Mirror Descent. We follow (Bubeck and Cesa-Bianchi, 2012, Section 5) and refer to it for the detailed and rigorous construction. Let $F_q(x)$ be the Legendre function associated with the potential $\psi(x) = (-x)^{-q}$ ($q > 1$), i.e.,

$$F_q(x) = -\frac{q}{q-1} \sum_{i=1}^d (x^i)^{1-1/q}.$$

The algorithm, which depends on a parameter $\eta > 0$ to be fixed later, is defined as follows. Set $x_1 = (\frac{1}{d}, \dots, \frac{1}{d}) \in \Delta_d$. For all $t \geq 1$, we define the estimator $\hat{\ell}_t$ of ℓ_t as usual:

$$\hat{\ell}_t^{(i)} = \mathbb{1}_{\{d_t=i\}} \frac{\ell_t^{(i)}}{x_t^{(i)}}, \quad i \in [d],$$

which is then used to compute

$$z_{t+1} = \nabla F_q^* (\nabla F_q(x_t) - \eta \hat{\ell}_t) \quad \text{and} \quad x_{t+1} = \arg \min_{x \in \Delta_d} D_{F_q}(x, z_{t+1}),$$

where $D_{F_q} : \mathcal{D} \times \mathcal{D} \rightarrow \mathbb{R}$ is the Bregman divergence associated with F_q :

$$D_{F_q}(x', x) = F_q(x') - F_q(x) - \langle \nabla F_q(x), x' - x \rangle.$$

Theorem 11 *Let $\eta > 0$ and $q > 1$. For any sequence of s -sparse loss vectors, the above strategy with parameter η guarantees, for $T \geq 1$:*

$$R_T \leq q \left(\frac{d^{1/q}}{\eta(q-1)} + \frac{\eta T s^{1-1/q}}{2} \right).$$

In particular, if $d/s \geq e^2$, the choices

$$\eta = \sqrt{\frac{2d^{1/q}}{(q-1)T s^{1-1/q}}} \quad \text{and} \quad q = \log(d/s)$$

yield the following regret bound:

$$R_T \leq 2\sqrt{e} \sqrt{Ts \log \frac{d}{s}}.$$

Proof The general regret bound for Greedy Online Mirror Descent (Bubeck and Cesa-Bianchi, 2012, Theorem 5.10) gives:

$$R_T \leq \frac{\max_{x \in \Delta_d} F(x) - F(x_1)}{\eta} + \frac{\eta}{2} \sum_{t=1}^T \sum_{i=1}^d \mathbb{E} \left[\frac{(\hat{\ell}_t^{(i)})^2}{(\psi^{-1})(x_t^{(i)})} \right],$$

with $(\psi^{-1})(x) = (q x^{1+1/q})^{-1}$. Let us bound the first term.

$$\frac{1}{\eta} \max_{x \in \Delta_d} F(x) - F(x_1) \leq \frac{1}{\eta} \frac{q}{q-1} \left(0 + d(1/d)^{1-1/q} \right) = \frac{qd^{1/q}}{\eta(q-1)}.$$

We turn to the second term. Let $1 \leq t \leq T$.

$$\begin{aligned} \sum_{i=1}^d \mathbb{E} \left[\frac{(\hat{\ell}_t^{(i)})^2}{(\psi^{-1})(x_t^{(i)})} \right] &= q \sum_{i=1}^d \mathbb{E} \left[\frac{(\hat{\ell}_t^{(i)})^2 (x_t^{(i)})^{1+1/q}}{(x_t^{(i)})^2} \right] \\ &= q \sum_{i=1}^d \mathbb{E} \left[\mathbb{1}_{\{d_t=i\}} \left[\frac{(\hat{\ell}_t^{(i)})^2 (x_t^{(i)})^{1+1/q}}{(x_t^{(i)})^2} \right] \right] \\ &= q \sum_{i=1}^d \mathbb{E} \left[\frac{(\hat{\ell}_t^{(i)})^2 (x_k^{(i)})^{1/q}}{(x_k^{(i)})^2} \right] \\ &= q \mathbb{E} \left[\sum_{[s \text{ terms}]_s} \frac{(\hat{\ell}_t^{(i)})^2 (x_t^{(i)})^{1/q}}{(x_t^{(i)})^2} \right] \\ &\leq qs(1/s)^{1/q} = qs^{1-1/q}, \end{aligned}$$

where we used the assumption that ℓ_t has at most s nonzero components, and the fact that $x_t \in \Delta_d$. The first regret bound is thus proven. By choosing $\eta = \sqrt{\frac{2s^{1-1/q}}{(q-1)Td^{1/q}}}$, we balance both terms and get:

$$R_T \leq 2q \sqrt{\frac{Td^{1/q}s^{1-1/q}}{2(q-1)}} = \sqrt{2q} \sqrt{Ts \left(\frac{d}{s} \right)^{1/q} \left(\frac{q}{q-1} \right)}.$$

If $d/s \geq e^2$ and $q = \log(d/s)$, then $q/(q-1) \leq 2$ and finally:

$$R_T \leq 2\sqrt{e} \sqrt{Ts \log \frac{d}{s}}. \quad \blacksquare$$

Remark 12 *The previous analysis cannot be carried in the case of gains because the bound from (Bubeck and Cesa-Bianchi, 2012, Theorem 5.10) that we use above only holds for nonnegative losses (and its proof strongly relies on this assumption). We are unaware of techniques which could provide a similar bound in the case of nonnegative gains.*

5.2 Matching Lower Bound

The following theorem establishes that the bound from Theorem 11 is optimal up to a logarithmic factor. We denote $\hat{v}_T^{s,d}$ the minimax regret in the bandit setting with losses.

Theorem 13 *For all $d \geq 2$, $s \in [d]$ and $T \geq d^2/4s$, the following lower bound holds:*

$$\hat{v}_T^{s,d} \geq \frac{1}{32} \sqrt{Ts}.$$

The intuition behind the proof is the following. Let us consider the case where $s = 1$ and assume that ℓ_t is a unit vector $e_{i_t} = (\mathbb{1}\{j = i_t\})_j$ where $\mathbb{P}(i_t = i) \simeq (1 + \varepsilon)/d$ for all $i \in [d]$, except one fixed coordinate i^* where $\mathbb{P}(i_t = i^*) \simeq 1/d - \varepsilon$.

Since $1/d$ goes to 0 as d increases, the Kullback-Leibler divergence between two Bernoulli of parameters $(1 + \varepsilon)/d$ and $1/d - \varepsilon$ is of order $d\varepsilon^2$. As a consequence, it would require approximately $1/d\varepsilon^2$ samples to distinguish between the two. The standard argument that one of the coordinates has not been chosen more than T/d times, yields that one should take $1/d\varepsilon^2 \simeq T/d$ so that the regret is of order $T\varepsilon$. This provides a lower bound of order \sqrt{T} . Similar arguments with $s > 1$ give a lower bound of order \sqrt{sT} .

We emphasize that one cannot simply assume that the s components with positive losses are chosen at the beginning once for all, and apply standard lower bound techniques. Indeed, with this additional information, the decision maker just has to choose, at each stage, a decision associated with a zero loss. His regret would then be uniformly bounded (or even possibly equal to zero).

5.3 Proof of Theorem 13

Let $d \geq 1$, $1 \leq s \leq d$, $T \geq 1$, and $\varepsilon \in (0, s/2d)$. Denote $\mathfrak{P}_s([d])$ the set of subsets of $[d]$ of cardinality s , δ_{ij} the Kronecker symbol, and $B(1, p)$ the Bernoulli distribution of parameter $p \in [0, 1]$. If P, Q are two probability distributions on the same set, $D(P \| Q)$ will denote the relative entropy of P and Q .

5.3.1 RANDOM s -SPARSE LOSS VECTORS ℓ_t AND ℓ_t^j

For $t \geq 1$, define the random s -sparse loss vectors $(\ell_t)_{t \geq 1}$ as follows. Draw Z uniformly from $[d]$. We will denote $\mathbb{P}_s[\cdot] = \mathbb{P}[\cdot | Z = i]$ and $\mathbb{E}_s[\cdot] = \mathbb{E}[\cdot | Z = i]$. Knowing $Z = i$, the random vectors ℓ_t are i.i.d and defined as follows. Draw I_t uniformly from $\mathfrak{P}_s([d])$. If $j \in I_t$, define $\ell_t^{(j)}$ such that:

$$\mathbb{P}_s[\ell_t^{(j)} = 1] = 1 - \mathbb{P}_s[\ell_t^{(j)} = 0] = \frac{1}{2} - \frac{\varepsilon d}{s} \delta_{ij}.$$

If $j \notin I_t$, set $\ell_t^{(j)} = 0$. Therefore, one can check that for each component $j \in [d]$ and all $t \geq 1$,

$$\mathbb{E}_s[\ell_t^{(j)}] = \frac{s}{2d} - \varepsilon \delta_{ij}.$$

For $t \geq 1$, define the i.i.d. random s -sparse loss vectors $(\ell_t^j)_{t \geq 1}$ as follows. Draw I_t uniformly from $\mathfrak{P}_s([d])$. Then if $j \in I_t$, set $(\ell_t^j)^{(i)}$ such that:

$$\mathbb{P}[(\ell_t^j)^{(i)} = 1] = \mathbb{P}[(\ell_t^j)^{(j)} = 0] = 1/2.$$

And if $j \notin I_t$, set $(\ell_t^j)^{(i)} = 0$. Therefore, one can check that for each component $j \in [d]$ and all $t \geq 1$,

$$\mathbb{E}[(\ell_t^j)^{(i)}] = \frac{s}{2d}.$$

By construction, ℓ_t and ℓ_t^j are indeed random s -sparse loss vectors.

5.3.2 A DETERMINISTIC STRATEGY σ FOR THE PLAYER

We assume given a deterministic strategy $\sigma = (\sigma_t)_{t \geq 1}$ for the player:

$$\sigma_t : ([d] \times [0, 1])^{t-1} \rightarrow [d].$$

Therefore,

$$d_t = \sigma_t(d_1, \omega_1^{(d_1)}, \dots, d_{t-1}, \omega_{t-1}^{(d_{t-1})}),$$

where d_t denotes the decision chosen by the strategy at stage t and ω_t the outcome vector of stage t . But since d_t is determined by previous decisions and outcomes, we can consider that σ_t only depends on the received outcomes:

$$\sigma_t : [0, 1]^{t-1} \rightarrow [d],$$

$$d_t = \sigma_t(\omega_1^{(d_1)}, \dots, \omega_{t-1}^{(d_{t-1})}).$$

We define d_t and d_t^j to be the (random) decisions played by deterministic strategy σ against the random loss vectors $(\ell_t)_{t \geq 1}$ and $(\ell_t^j)_{t \geq 1}$ respectively:

$$\begin{aligned} d_t &= \sigma_t(\ell_1^{(d_1)}, \dots, \ell_{t-1}^{(d_{t-1})}), \\ d_t^j &= \sigma_t((\ell_1^j)^{(d_1)}, \dots, (\ell_{t-1}^j)^{(d_{t-1})}). \end{aligned}$$

For $t \geq 1$ and $i \in [d]$, define $A_t^{(i)}$ to be the set of sequences of outcomes in $\{0, 1\}$ of the first $t-1$ stages for which strategy σ plays decision i at stage t :

$$A_t^{(i)} = \left\{ (u_1, \dots, u_{t-1}) \in \{0, 1\}^{t-1} \mid \sigma_t(u_1, \dots, u_{t-1}) = i \right\},$$

and $B_t^{(i)}$ the complement:

$$B_t^{(i)} = \{0, 1\}^{t-1} \setminus A_t^{(i)}.$$

Note that for a given $t \geq 1$, $(A_t^{(i)})_{i \in [d]}$ is a partition of $\{0, 1\}^{t-1}$ (with possibly some empty sets).

For $i \in [d]$, define $\tau_i(T)$ (resp. $\tau_i^j(T)$) to be the number of times decision i is played by strategy σ against loss vectors $(\ell_t)_{t \geq 1}$ (resp. against $(\ell_t^j)_{t \geq 1}$) between stages 1 and T :

$$\tau_i(T) = \sum_{t=1}^T \mathbb{1}_{\{d_t=i\}} \quad \text{and} \quad \tau_i^j(T) = \sum_{t=1}^T \mathbb{1}_{\{d_t^j=i\}}.$$

5.3.3 THE PROBABILITY DISTRIBUTIONS \mathbb{Q} AND \mathbb{Q}_i ($i \in [d]$) ON BINARY SEQUENCES

We consider binary sequences $\vec{u} = (u_1, \dots, u_T) \in \{0, 1\}^T$. We define \mathbb{Q} and \mathbb{Q}_i ($i \in [d]$) to be probability distributions on $\{0, 1\}^T$ as follows:

$$\begin{aligned} \mathbb{Q}_i[\vec{u}] &= \mathbb{P}_i \left[\ell_1^{(d_1)} = u_1, \dots, \ell_T^{(d_T)} = u_T \right], \\ \mathbb{Q}[\vec{u}] &= \mathbb{P} \left[(\ell_1^j)^{(d_1)} = u_1, \dots, (\ell_T^j)^{(d_T)} = u_T \right]. \end{aligned}$$

Fix $(u_1, \dots, u_{t-1}) \in \{0, 1\}^t$. The applications

$$u_t \mapsto \mathbb{Q}[u_t | u_1, \dots, u_{t-1}] \quad \text{and} \quad u_t \mapsto \mathbb{Q}_i[u_t | u_1, \dots, u_{t-1}],$$

are probability distributions on $\{0, 1\}$, which we now aim at identifying. The first one is Bernoulli of parameter $s/2d$. Indeed,

$$\begin{aligned} \mathbb{Q}[1 | u_1, \dots, u_{t-1}] &= \mathbb{P} \left[(\ell_t^j)^{(d_t)} = 1 \mid (\ell_1^j)^{(d_1)} = u_1, \dots, (\ell_{t-1}^j)^{(d_{t-1})} = u_{t-1} \right] \\ &= \mathbb{P} \left[(\ell_t^j)^{(d_t)} = 1 \right] \\ &= \mathbb{P} [d_t \in I_t] \mathbb{P} \left[(\ell_t^j)^{(d_t)} = 1 \mid d_t \in I_t \right] \\ &= \frac{s}{d} \times \frac{1}{2} \\ &= \frac{s}{2d}. \end{aligned}$$

where we used the independence of the random vectors $(\ell_t^i)_{i \geq 1}$ for the second inequality. We now turn to the second distribution, which depends on (u_1, \dots, u_{t-1}) . If $(u_1, \dots, u_{t-1}) \in A_t^{(i)}$, it is a Bernoulli of parameter $s/2d - \varepsilon$:

$$\begin{aligned} \mathbb{Q}_i[1 | u_1, \dots, u_{t-1}] &= \mathbb{P}_i \left[\ell_t^{(d_t)} = 1 \mid \ell_1^{(d_1)} = u_1, \dots, \ell_{t-1}^{(d_{t-1})} = u_{t-1} \right] \\ &= \mathbb{P}_i \left[\ell_t^{(i)} = 1 \mid \ell_1^{(d_1)} = u_1, \dots, \ell_{t-1}^{(d_{t-1})} = u_{t-1} \right] \\ &= \mathbb{P}_i \left[\ell_t^{(i)} = 1 \right] \\ &= \mathbb{P}_i [i \in I_t] \mathbb{P}_i \left[\ell_t^{(i)} = 1 \mid i \in I_t \right] \\ &= \frac{s}{d} \times \left(\frac{1}{2} - \frac{\varepsilon d}{s} \right) \\ &= \frac{s}{2d} - \varepsilon. \end{aligned}$$

where for the third inequality, we used the assumption that the random vectors $(\ell_t)_{t \geq 1}$ are independent under \mathbb{P}_i , i.e. knowing $Z = i$. On the other hand, if $(u_1, \dots, u_{t-1}) \in B_t^{(i)}$, we can prove similarly that the distribution is a Bernoulli of parameter $s/2d$.

5.3.4 COMPUTATION THE RELATIVE ENTROPY OF \mathbb{Q}_i AND \mathbb{Q}

We apply iteratively the chain rule to the relative entropy of $\mathbb{Q}[\vec{u}]$ and $\mathbb{Q}_i[\vec{u}]$. Using the short-hand $\mathbb{D}_i[\cdot] := D(\mathbb{Q}[\cdot] \parallel \mathbb{Q}_i[\cdot])$,

$$\begin{aligned} D(\mathbb{Q}[\vec{u}] \parallel \mathbb{Q}_i[\vec{u}]) &= \mathbb{D}_i[\vec{u}] \\ &= \mathbb{D}_i[u_1] + \mathbb{D}_i[u_2, \dots, u_T \mid u_1] \\ &= \mathbb{D}_i[u_1] + \mathbb{D}_i[u_2 \mid u_1] + \mathbb{D}_i[u_3, \dots, u_T \mid u_1, u_2] \\ &= \sum_{t=1}^T \mathbb{D}_i[u_t \mid u_1, \dots, u_{t-1}]. \end{aligned}$$

We now use the definition of the conditional relative entropy, and make the previously discussed Bernoulli distributions appear. For $1 \leq t \leq T$,

$$\begin{aligned} \mathbb{D}_i[u_t \mid u_1, \dots, u_{t-1}] &= \sum_{u_1, \dots, u_{t-1}} \mathbb{Q}[u_1, \dots, u_{t-1}] \\ &\quad \times \sum_{u_t} \mathbb{Q}[u_t \mid u_1, \dots, u_{t-1}] \log \frac{\mathbb{Q}[u_t \mid u_1, \dots, u_{t-1}]}{\mathbb{Q}_i[u_t \mid u_1, \dots, u_{t-1}]} \\ &= \frac{1}{2^{t-1}} \sum_{u_1, \dots, u_{t-1}} \sum_{u_t} \mathbb{Q}[u_t \mid u_1, \dots, u_{t-1}] \log \frac{\mathbb{Q}[u_t \mid u_1, \dots, u_{t-1}]}{\mathbb{Q}_i[u_t \mid u_1, \dots, u_{t-1}]} \\ &= \frac{1}{2^{t-1}} \sum_{(u_1, \dots, u_{t-1}) \in A_t^{(i)}} D\left(B\left(1, \frac{s}{2d}\right) \parallel B\left(1, \frac{s}{2d} - \varepsilon\right)\right) \\ &\quad + \frac{1}{2^{t-1}} \sum_{(u_1, \dots, u_{t-1}) \in B_t^{(i)}} D\left(B\left(1, \frac{s}{2d}\right) \parallel B\left(1, \frac{s}{2d}\right)\right) \\ &= \frac{1}{2^{t-1}} \sum_{(u_1, \dots, u_{t-1}) \in A_t^{(i)}} \mathbb{B}\left(\frac{s}{2d}, \varepsilon\right), \end{aligned}$$

where we used the short-hand $\mathbb{B}\left(\frac{s}{2d}, \varepsilon\right) := D\left(B\left(1, \frac{s}{2d}\right) \parallel B\left(1, \frac{s}{2d} - \varepsilon\right)\right)$. Eventually:

$$D(\mathbb{Q}[\vec{u}] \parallel \mathbb{Q}_i[\vec{u}]) = \mathbb{B}\left(\frac{s}{2d}, \varepsilon\right) \sum_{t=1}^T \frac{|A_t^{(i)}|}{2^{t-1}}.$$

5.3.5 UPPER BOUND ON $\frac{1}{d} \sum_{i=1}^d \mathbb{E}_i[\tau_i(T)]$ USING PINSKER'S INEQUALITY

In this step, we will make use of Pinsker's inequality to make the relative entropy appear.

Proposition 14 (Pinsker's inequality) *Let X be a finite set, and P, Q probability distributions on X . Then,*

$$\frac{1}{2} \sum_{x \in X} |P(x) - Q(x)| \leq \sqrt{\frac{1}{2} D(P \parallel Q)}.$$

Immediate consequence:

$$\sum_{\substack{x \in X \\ P(x) > Q(x)}} (P(x) - Q(x)) \leq \sqrt{\frac{1}{2} D(P \parallel Q)}.$$

Let $i \in [d]$. If $(u_1, \dots, u_T) \in \{0, 1\}^T$ is given, since the decisions d_t and d'_t are determined by the previous losses $\ell_t^{(d_t)}$ and $(\ell'_t)^{(d'_t)}$ respectively, we have in particular:

$$\mathbb{E}_i \left[\tau_i(T) \mid \ell_1^{(d_1)} = u_1, \dots, \ell_T^{(d_T)} = u_T \right] = \mathbb{E} \left[\tau'_i(T) \mid (\ell'_t)^{(d'_t)} = u_1, \dots, (\ell'_T)^{(d'_T)} = u_T \right].$$

Therefore,

$$\begin{aligned}
\mathbb{E}_t[\tau_t(T)] - \mathbb{E}[\tau_t'(T)] &= \sum_{\vec{u}} \mathbb{Q}_t[\vec{u}] \cdot \mathbb{E}_t[\tau_t(T) \mid \forall t, \ell_t^{(d)} = u_t] \\
&\quad - \sum_{\vec{u}} \mathbb{Q}[\vec{u}] \cdot \mathbb{E}[\tau_t'(T) \mid \forall t, (\ell_t^i)^{d_t} = u_t] \\
&= \sum_{\vec{u}} (\mathbb{Q}_t[\vec{u}] - \mathbb{Q}[\vec{u}]) \mathbb{E}_t[\tau_t(T) \mid \forall t, \ell_t^{(d)} = u_t] \\
&\leq \sum_{\mathbb{Q}_t[\vec{u}] > \mathbb{Q}[\vec{u}]} (\mathbb{Q}_t[\vec{u}] - \mathbb{Q}[\vec{u}]) \mathbb{E}_t[\tau_t(T) \mid \forall t, \ell_t^{(d)} = u_t] \\
&\leq T \sum_{\vec{u}} \frac{(\mathbb{Q}_t[\vec{u}] - \mathbb{Q}[\vec{u}])}{\mathbb{Q}_t[\vec{u}] > \mathbb{Q}[\vec{u}]} \\
&\leq T \sqrt{\frac{1}{2} D(\mathbb{Q}[\vec{u}] \parallel \mathbb{Q}_t[\vec{u}])} \\
&= T \sqrt{\frac{\mathbb{B}(s/2d, \varepsilon)}{2} \left[\sum_{t=1}^T \frac{|A_t^{(i)}|}{2^{t-1}} \right]},
\end{aligned}$$

where we used Pinsker's inequality in the fifth line. Moreover, we have:

$$\frac{1}{d} \sum_{i=1}^d \mathbb{E}[\tau_t'(T)] = \frac{1}{d} \mathbb{E} \left[\sum_{t=1}^T \sum_{i=1}^d \mathbb{1}_{\{d_t=i\}} \right] = \frac{1}{d} \mathbb{E} \left[\sum_{i=1}^T \mathbb{1} \right] = \frac{T}{d}.$$

Combining this with the previous inequality gives:

$$\begin{aligned}
\frac{1}{d} \sum_{i=1}^d \mathbb{E}_t[\tau_t(T)] &\leq \frac{1}{d} \sum_{i=1}^d \mathbb{E}[\tau_t'(T)] + T \sqrt{\frac{\mathbb{B}(s/2d, \varepsilon)}{2} \frac{1}{d} \sum_{i=1}^d \left[\sum_{t=1}^T \frac{|A_t^{(i)}|}{2^{t-1}} \right]} \\
&\leq \frac{T}{d} + T \sqrt{\frac{\mathbb{B}(s/2d, \varepsilon)}{2} \sqrt{\frac{1}{d} \sum_{t=1}^T \sum_{i=1}^d \frac{|A_t^{(i)}|}{2^{t-1}}}} \\
&= \frac{T}{d} + T \sqrt{\frac{\mathbb{B}(s/2d, \varepsilon)}{2} \frac{1}{d} \sum_{t=1}^T \frac{|\{0, 1\}^{t-1}|}{2^{t-1}}} \\
&= \frac{T}{d} + T \sqrt{\frac{\mathbb{B}(s/2d, \varepsilon)}{2} \sqrt{\frac{T}{T}}} \\
&= \frac{T}{d} + T^{3/2} \sqrt{\frac{\mathbb{B}(s/2d, \varepsilon)}{2d}}.
\end{aligned}$$

where we used Jensen for the second inequality, and for the third line, we remembered that $(A_t^{(i)})_{i \in [d]}$ is a partition of $\{0, 1\}^{t-1}$.

5.3.6 AN UPPER BOUND ON $\mathbb{B}(s/2d, \varepsilon)$ FOR SMALL ENOUGH ε

We first write $\mathbb{B}(s/2d, \varepsilon)$ explicitly.

$$\begin{aligned}
\mathbb{B}\left(\frac{s}{2d}, \varepsilon\right) &= D(B(1, s/2d) \parallel B(1, s/2d - \varepsilon)) \\
&= \frac{s}{2d} \log \frac{s/2d}{s/2d - \varepsilon} + \left(1 - \frac{s}{2d}\right) \log \frac{1 - s/2d}{1 - s/2d + \varepsilon} \\
&= -\frac{s}{2d} \log \left(1 - \frac{2d\varepsilon}{s}\right) + \left(\frac{s}{2d} - 1\right) \log \left(1 + \frac{\varepsilon}{1 - m/2d}\right).
\end{aligned}$$

We now bound the two logarithms from above using respectively the two following easy inequalities:

$$\begin{aligned}
-\log(1-x) &\leq x + x^2, \quad \text{for } x \in [0, 1/2] \\
-\log(1+x) &\leq -x + x^2, \quad \text{for } x \geq 0.
\end{aligned}$$

This gives:

$$\begin{aligned}
\mathbb{B}\left(\frac{s}{2d}, \varepsilon\right) &\leq \frac{s}{2d} \left(\frac{2d\varepsilon}{s} + \frac{4d^2\varepsilon^2}{s^2}\right) + \left(1 - \frac{s}{2d}\right) \left(-\frac{\varepsilon}{1 - s/2d} + \frac{\varepsilon^2}{(1 - s/2d)^2}\right) \\
&= \frac{4d^2\varepsilon^2}{s(2d-s)},
\end{aligned}$$

which holds for $2d\varepsilon/s \leq 1/2$, in other words, for $\varepsilon \leq s/4d$.

5.3.7 LOWER BOUND ON THE EXPECTATION OF THE REGRET OF σ AGAINST ℓ_t

We can now bound from below the expected regret incurred when playing σ against loss vectors $(\ell_t)_{t \geq 1}$. For $\varepsilon \leq s/4d$,

$$\begin{aligned}
R_T &= \mathbb{E} \left[\sum_{t=1}^T \ell_t^{(d_t)} - \min_{j \in [d]} \sum_{t=1}^T \ell_t^{(j)} \right] \\
&= \frac{1}{d} \sum_{t=1}^d \mathbb{E}_i \left[\sum_{t=1}^T \ell_t^{(d_t)} - \min_{j \in [d]} \sum_{t=1}^T \ell_t^{(j)} \right] \\
&\geq \frac{1}{d} \sum_{t=1}^d \left(\mathbb{E}_i \left[\sum_{t=1}^T \ell_t^{(d_t)} \right] - \min_{j \in [d]} \sum_{t=1}^T \mathbb{E}_i \left[\ell_t^{(j)} \right] \right) \\
&= \frac{1}{d} \sum_{t=1}^d \left(\mathbb{E}_i \left[\sum_{t=1}^T \ell_t^{(d_t)} \mid d_t \right] - T \min_{j \in [d]} \left(\frac{s}{2d} - \varepsilon \delta_{ij} \right) \right) \\
&= \frac{1}{d} \sum_{t=1}^d \left(\mathbb{E}_i \left[\sum_{t=1}^T \left(\frac{s}{2d} - \varepsilon \delta_{id_t} \right) \right] - T \left(\frac{s}{2d} - \varepsilon \right) \right) \\
&= \sum_{t=1}^d \varepsilon (T - \mathbb{E}_i [\tau_i(T)]) \\
&= \varepsilon \left(T - \frac{1}{d} \sum_i \mathbb{E}_i [\tau_i(T)] \right).
\end{aligned}$$

We now use the upper bound derived in Section 5.3.5.

$$\begin{aligned}
R_T &\geq \varepsilon \left(T - \frac{T}{d} - T^{3/2} \sqrt{\frac{\mathbb{B}(s/2d, \varepsilon)}{2d}} \right) \\
&\geq \varepsilon \left(T - \frac{T}{d} - T^{3/2} \varepsilon \sqrt{\frac{2d}{s(2d-s)}} \right) \\
&\geq \varepsilon \left(T - \frac{T}{d} - 2T^{3/2} \varepsilon \frac{1}{\sqrt{s}} \right),
\end{aligned}$$

where in the penultimate, we used the upper bound on $\mathbb{B}(s/2d, \varepsilon)$ that we established above, and in the last line, the fact that $s \leq d$. Let $C > 0$ and we choose $\varepsilon = C\sqrt{s}/T$. Then, for $\varepsilon \leq s/4d$,

$$\begin{aligned}
R_T &\geq \varepsilon T \left(1 - \frac{1}{d} - 2\varepsilon \sqrt{\frac{T}{s}} \right) \\
&= C\sqrt{sT} \left(1 - \frac{1}{d} \right) - 2\sqrt{sT}C^2 \\
&\geq \sqrt{sT} \left(\frac{C}{2} - 2C^2 \right),
\end{aligned}$$

where in the last line, we used the assumption $d \geq 2$. The choice $C = 1/8$ give:

$$R_T \geq \frac{1}{32} \sqrt{sT},$$

which holds for $\varepsilon = C\sqrt{s/T} \leq s/4d$ i.e. for $T \geq d^2/4s$.

The above inequality does not depend on σ . As it is a classic that a randomized strategy is equivalent to some random choice of deterministic strategies, this lower bound holds for any strategy of the player. In other words, for $T \geq d^2/4s$,

$$v_T^{\ell, s, d} \geq \frac{1}{32} \sqrt{sT}. \quad \blacksquare$$

5.4 Discussion

If the outcomes are not losses but gains, then there is an important discrepancy between the upper and lower bounds we obtain. Indeed, obtaining small losses regret bound as in the first displayed equation of the proof of Theorem 11 is still open. An idea for circumventing this issue would be to enforce exploration by perturbing x_t into $(1-\gamma)x_t + \gamma\mathcal{U}$ where \mathcal{U} is the uniform distribution over $[d]$, but usual computations show that the only obtainable upper bounds are of order of \sqrt{dT} . The aforementioned techniques used to bound the regret from below with losses would also work with gains, which would give a lower bound of order \sqrt{sT} . Therefore, finding the optimal dependency in the dimension and/or the sparsity level is still an open question in that specific case. We tend to believe that the upper bound could be improved: imagine the case $s = 1$, the restriction on the payoff vectors is huge, and we think that this could be taken advantage of. This would imply that there is no discrepancy between gains and losses, unlike the full information setting, which would be an interesting fact.

Abstract

In this paper we generalize the framework of the Feasible Descent Method (FDM) to a Randomized (R-FDM) and a Randomized Coordinate-wise Feasible Descent Method (RC-FDM) framework. We show that many machine learning algorithms, including the famous SDCA algorithm for optimizing the SVM dual problem, or the stochastic coordinate descent method for the LASSO problem, fits into the framework of RC-FDM. We prove linear convergence for both R-FDM and RC-FDM under the weak strong convexity assumption. Moreover, we show that the duality gap converges linearly for RC-FDM, which implies that the duality gap also converges linearly for SDCA applied to the SVM dual problem.

Keywords: feasible descent method, stochastic methods, iteration complexity, convergence theory, weak strong convexity

1. Introduction

In this paper we are interested in the following optimization problem

$$\min_{x \in X} f(x), \quad (1)$$

where the function f is smooth and convex, and $X \subseteq \mathbb{R}^n$ is a convex set. The Feasible Descent Method (FDM) (Luo and Tseng 1993; Necoara 2015; Wang and Lin 2014) is any algorithm, which produces a sequence of points $\{x_k\}_{k=0}^{\infty}$, where there exist constants $\beta \geq 0$, $\zeta > 0$ and $\omega_k \geq \bar{\omega} > 0$, such that for every iteration k , the following conditions are satisfied:

$$\begin{aligned} x_{k+1} &= \mathbf{Proj}_X(x_k - \omega_k \nabla f(x_k) + z_k), & (2) \\ \|z_k\| &\leq \beta \|x_k - x_{k+1}\|, & (3) \\ f(x_{k+1}) &\leq f(x_k) - \zeta \|x_k - x_{k+1}\|^2, & (4) \end{aligned}$$

where $\mathbf{Proj}_X(y) := \arg \min_{x \in X} \|x - y\|$ is the projection of y onto X .

As was shown in Luo and Tseng (1993), many first order algorithms, including steepest descent, the gradient projection algorithm, the extra gradient method, the proximal minimization algorithm and the cyclic coordinate descent method, fit into the framework of FDM. However, randomized first order algorithms are becoming increasingly popular in the optimization and machine learning literature, and the following question naturally arises:

“Can the framework of FDM be extended to a randomized setting?”

In this paper we give an affirmative answer to this question: we show that, indeed, a randomized version of FDM can be formulated and we will show that, for example, the inexact gradient projection algorithm (when the gradient is corrupted with random noise) or the stochastic coordinate descent method, fit into this new framework.

1.1 Assumptions and Notations

In this section we state the assumptions and introduce the notation that will be used in this paper. In particular, throughout this paper we will assume that f satisfies weak strong convexity, and that the gradient of f is Lipschitz.

Now we formalize the first assumption, which is that the function f enjoys weak strong convexity. Henceforth, we use \mathbb{R}_{++}^n to denote the set of vectors in \mathbb{R}^n , with (strictly) positive components, and we denote the i -th component of the vector x by $x^{(i)}$.

Assumption 1. We assume that there exists a positive vector $w \in \mathbb{R}_{++}^n$ such that the function $f(x)$ satisfies the weak strong convexity property on the set X , which is defined as

$$f(x) - f(\bar{x}) \geq \kappa_f \|x - \bar{x}\|_W^2, \quad \forall x \in X, \quad (5)$$

where $\kappa_f > 0$, $W = \mathbf{diag}(w)$, $\|x\|_W^2 = \sum_{i=1}^n w_i (x^{(i)})^2$, $f^* = \min_{x \in X} f(x)$, and

$$\bar{x} := \arg \min_{y \in X: f(y)=f^*} \|x - y\|_W. \quad (6)$$

Let us remark that, if f is smooth and has a Lipschitz continuous gradient, then Assumption 1 is weaker than the strong convexity assumption or the global error bound property, Necoara (2015). We now provide a few examples of functions that are used in machine learning, which are weakly strongly convex, but are not strongly convex.

1. In particular, let $x \in \mathbb{R}^n$ and let $c \in \mathbb{R}$. We have

$$\mathbf{shrink}_c(x) = \text{sign}(x) \max\{|x| - c, 0\}, \quad \text{and} \quad f(x) = \frac{1}{2} \|\mathbf{shrink}_c(x)\|_2^2,$$

where the shrinkage function is applied component-wise to vector x . Note that f is not strongly convex because $f(x) = 0$ for $x \in [-c, c]$ (which is the minimizer set). On the other hand, $f(x) = \frac{1}{2} \|x + c\|_2^2$ for $x \leq -c$ and $f(x) = \frac{1}{2} \|x - c\|_2^2$ for $x \geq c$. Thus, $f(x)$ is weakly strongly convex. See also Zhang and Yin (2013).

2. Another illustrative example of function which is weakly strongly convex but not strongly convex is $f(x) = \frac{1}{2} \|Ax - b\|^2$ with $A \in \mathbb{R}^{m \times n}$ such that $m < n$. If x^* is some optimal solution then $x^* + t$ is also optimal iff $t \in \text{null}(A)$. One can easily show that κ_f is related to the smallest non-negative singular value of matrix $A^T A$.

The second assumption we make regards the smoothness of f , and is defined precisely as follows.

Assumption 2. We assume that $f(x)$ has a coordinate-wise Lipschitz continuous gradient with constants L_i , i.e. $\forall x \in X$ and $\forall \delta \in \mathbb{R} : x + \delta e_i \in X$ the following inequality holds

$$|\nabla_i f(x) - \nabla_i f(x + \delta e_i)| \leq L_i |\delta|, \quad (7)$$

where e_i denotes the i -th column of the identity matrix $I \in \mathbb{R}^{n \times n}$.

As was shown in Richtárik and Takáč (2014), Assumption 2 implies that the function $f(x)$ has a Lipschitz continuous gradient with Lipschitz constant $L_f^W > 0$ with respect to the norm $\|\cdot\|_W$, i.e. $\forall x, y \in X$ we have

$$\|\nabla f(x) - \nabla f(y)\|_W^* \leq L_f^W \|x - y\|_W, \quad (8)$$

where $\|x\|_W^* = \sqrt{\sum_{i=1}^n \frac{1}{w_i} (x^{(i)})^2}$ is the dual norm to $\|\cdot\|_W$. Moreover, Richtárik and Takáč (2014) also showed that $L_f^W \leq \sum_{i=1}^n \frac{L_i}{w_i}$.

We define the projection operator onto the set X , with respect to the norm $\|\cdot\|_W$, as follows

$$\text{Proj}_X^W(x) = \arg \min_{y \in X} \|x - y\|_W^2 = \arg \min_{y \in X} \sum_{i=1}^n w_i (x^{(i)} - y^{(i)})^2. \quad (9)$$

1.2 Applications

In this section we discuss several problems that arise in the optimization and machine learning literature, which fit into the FDM framework that we analyze in this paper. We also provide details showing that, for each problem, the objective function satisfies the assumptions in Section 1.1. (A discussion regarding the value of the weak strong convexity parameter κ_f will be given in Section 4.)

The dual of SVM. Consider the classical linear SVM problem. The goal is, given n training points (a_i, y_i) , where $a_i \in \mathbb{R}^d$ are the features for point i and $y_i \in \{-1, +1\}$ is its label, find $w \in \mathbb{R}^d$ such that the regularized empirical loss function is minimized, i.e., solve the following optimization problem

$$\min_{w \in \mathbb{R}^d} \{\mathbf{P}(w) := \frac{1}{n} \sum_{i=1}^n \ell_i(w^T a_i) + \frac{\lambda}{2} \|w\|^2\}, \quad (10)$$

where $\lambda > 0$ is a regularization parameter, and, in the case of SVM, the function $\ell_i(w^T a_i) = \max\{0, 1 - y_i w^T a_i\}$ is the hinge loss. Clearly, the objective function (10) is not smooth. However, one can formulate the dual problem (Hsieh et al. 2008; Shalev-Shwartz and Zhang 2013; Takáč et al. 2013)

$$\min_{x \in \mathbb{R}^n, 0 \leq x^{(i)} \leq 1} \{f(x) := \frac{1}{2\lambda n^2} x^T Q x - \frac{1}{n} \mathbf{1}^T x\}, \quad (11)$$

where $Q_{i,j} = y_i y_j \langle a_i, a_j \rangle$, and $\mathbf{1}$ denotes the vector of all ones, which is smooth. The linear SVM problem (10) can now be solved via the dual problem (11). Note that (11) is

of the form (1), so our new FDM framework can be used to solve this important machine learning problem.

Lasso problem and least squares problem. Consider the following optimization problem

$$\min_{x \in \mathbb{R}^n} g(x) + \lambda \|x\|_1, \quad (12)$$

where $\lambda \geq 0$ and $g(x)$ is a smooth function with the special structure: $g(x) = h(Ax) + q^T x$, where $A \in \mathbb{R}^{m \times n}$ is some data matrix, $q \in \mathbb{R}^m$ is some vector and h is a strongly convex function. It is a simple exercise to show that, if we double the dimension of x to $[x^+, x^-]$, we can replace the term $\lambda \|x\|_1$ in (12) with $\lambda \mathbf{1}^T x^+ + \lambda \mathbf{1}^T x^-$ and impose the constraints $x^+, x^- \geq 0$. Then the Lasso problem (12) can be reformulated as a smooth optimization problem with simple box constraints.

ℓ_2 **regularized empirical loss minimization.** Many machine learning problems have the following structure (Chang et al. (2008))

$$\min_{x \in \mathbb{R}^n} f(x) = \frac{1}{n} \sum_{i=1}^n \ell_i(a_i^T x) + \frac{\lambda}{2} x^T x, \quad (13)$$

where $\lambda > 0$ is a regularization parameter and ℓ_i is a loss function. Because we assume that f must be smooth, the following commonly used loss functions fit our assumptions: the logistic loss function $\ell_i(a_i^T x) = \log(1 + \exp(-y_i a_i^T x))$; the squared loss function $\ell_i(a_i^T x) = (y_i - a_i^T x)^2$ and the squared hinge loss function $\ell_i(a_i^T x) = (\max\{0, 1 - y_i a_i^T x\})^2$. Hence, any machine learning problem of the form (13) (used with any of the mentioned loss functions) fits our randomized FDM framework.

1.3 Related work

Liu and Tseng (1993) are among the first to establish asymptotic linear convergence for a non-strongly convex problem under the local error bound property. They consider a class of feasible descent methods, which includes, for example, the cyclic coordinate descent method. The error bound measures how close the current solution is to the optimal solution set, with respect to the projected gradient. Recently, Wang and Lin (2014) proved that the feasible descent method enjoys a linear convergence rate (from the beginning, rather than only locally) under the global error bound property. Considering the class of smooth constrained optimization problems with the global error bound property, Necoara and Clipci (2016); Necoara and Nedelcu (2014a) showed a linear convergence rate for the parallel version of the stochastic coordinate descent method. Liu and Wright (2015) analyzed the asynchronous stochastic coordinate descent method (SCDM) under the weak strong convexity assumption. Very recently, Necoara (2015) showed that, if the objective function is smooth, then the class of problems with the global error bound property is a subset of the class of problems with the weak strong convexity property.

1.4 Contributions

In this section we list the most important contributions of this paper (not in order of their significance):

- **Randomized and Randomized Coordinate Feasible Descent Methods.** We extend the well known framework of Feasible Descent Methods (FDM) (Luo and Tseng 1993) to randomized and randomized coordinate FDM and show that the SCDM algorithm fits into our new proposed framework.

- **Linear Convergence Rate.** We show that any stochastic or deterministic algorithm, which fits our Randomized FDM (R-FDM) or Randomized Coordinate-FDM (RC-FDM) framework and satisfies our previously stated assumptions, converges linearly in expectation.

- **Linear Convergence of the Duality Gap for SDCA for SVM.** As a consequence of our analysis, we show that when SDCA is applied to the dual of the SVM problem, the duality gap converges linearly. Previously, linear convergence of the duality gap was only proven in case when the matrix Q in (11) is positive definite (Shalev-Shwartz and Zhang 2013; Takáč et al. 2015). However, our new linear convergence result holds, even when Q is singular.

- **Inexact Randomized Coordinate Descent.** By the nature of the FDM framework, *inexact* first order methods belong to the class of FDMs, (where inexact methods are methods that incorporate some kind of inexact information, for example, via inexact gradients, or via inexact updates). Our new randomized coordinate FDM framework includes inexact randomized coordinate descent methods. Therefore, another contribution of this work is that it provides a linear convergence rate for e.g. randomized coordinate descent with *inexact* computations of (partial) gradient, which was analyzed in various settings. (See, for example, Devolder et al. 2014; Bonettini 2011; Tappenden et al. 2016; Hua and Yamashita 2012; Necoara and Nedelcu 2014b.)

- **Flexibility and wide applicability.** Our randomized- and randomized coordinate-FDM framework is extremely *flexible*. It is a general framework that not only covers and unifies many existing algorithms, but any algorithm that fits our framework is also covered by the FDM convergence guarantees. Moreover, as demonstrated in Section 1.2, a very wide range of optimization and machine learning problems can be written in the form (1), and subsequently, they can be solved via the new FDM framework. Problems include the dual of SVM, the LASSO problem, and any ℓ_2 -regularized empirical loss functions where the loss function is smooth and separable. All such problems appear very frequently in the machine learning literature.

- **Parallel methods.** The RC-FDM framework is sufficiently general so as to include parallel randomized coordinate descent methods.

1.5 Paper Outline

In Section 2 we derive the Randomized (R-FDM) and the Randomized Coordinate (RC-FDM) Feasible Descent Methods. In Section 3 we derive the convergence rate for any method which fits into the R-FDM or RC-FDM framework and we compare our results with those in Liu and Wright (2015) for SCDM. In Section 4 we briefly review the global error bound property and using the result in Necoara (2015) we compare our convergence

results with Wang and Lin (2014). In Section 5 we show that the duality gap converges linearly for SDCA applied to the dual of the SVM problem, and in Section 6 we present a brief summary.

2. Randomized and Randomized Coordinate Feasible Descent Method

The framework of Feasible Descent Methods (FDM) broadly covers many algorithms that use first-order information (Luo and Tseng 1993) including gradient descent, cyclic coordinate descent and also the inexact gradient descent algorithm. We generalize the classical FDM framework to a randomized setting, which we call the Randomized Feasible Descent Method (R-FDM). Algorithms that use randomization have become extremely popular over the past few years, and the success, reliability, scalability, applicability and efficiency of such random algorithms is well documented. To the best of our knowledge this is the first time such a unifying R-FDM framework has been proposed and that a global linear convergence rate has been established under Assumptions 1 and 2. Further, we also show that the popular minibatch stochastic coordinate descent/ascent method, fits into the R-FDM framework.

Definition 3 (Randomized Feasible Descent Method (R-FDM)). *A sequence $\{x_k\}_{k=0}^{\infty}$ is generated by R-FDM if there exist $\beta \geq 0$, $\zeta > 0$ and $\{\omega_k\}_{k=0}^{\infty}$ with $\min_k \omega_k \geq \bar{\omega} > 0$ such that for every iteration k , the following conditions are satisfied,*

$$x_{k+1} = \mathbf{Proj}_X(x_k - \omega_k W^{-1}(\nabla f(x_k) - z_k)), \quad (14)$$

$$\mathbf{E}[\|z_k\|_W^2] \leq \beta^2 \mathbf{E}[\|x_k - x_{k+1}\|_W^2], \quad (15)$$

$$\mathbf{E}[f(x_{k+1})] \leq f(x_k) - \zeta \mathbf{E}[\|x_k - x_{k+1}\|_W^2], \quad (16)$$

where z_k is some random vector, which satisfies the Markov property, conditioned on x_k .

We will now compare the new Randomized FDM framework (Definition 3) with the original FDM ((2)–(4)), where, for simplicity of exposition, we will take $\|\cdot\|_W \equiv \|\cdot\|_2$ (i.e., $W = I$). Notice that the first step of R-FDM (14) is the same as the first step of FDM (2); it is a projected (gradient) descent type step. Note the role that z_k plays in (14); it captures any error/inexactness/noise in the update step, and it is clear to see that if $z_k = 0$ for all k , (i.e., no inexactness) then (14) is the same update as in a projected gradient descent method. Next, (15) gives an upper bound for $\|z_k\|_W^2$, which shows that, in order to guarantee convergence, the noise in (14) cannot be arbitrarily large, which intuitively makes sense. Finally, (16) guarantees that there is a reduction in the objective value, in expectation, after each iteration. The key difference between FDM and R-FDM is that for FDM, (3) and (4) hold deterministically (with a deterministic vector z_k), whereas for R-FDM (3) and (4) only need to hold *in expectation*. That is, for R-FDM, conditions (3) and (4) are replaced by conditions (15) and (16), where z_k is a random vector. Notice that (15) and (16) are weaker conditions than (3) and (4). That is, for FDM, (3) and (4) must hold at every iteration (i.e., they are deterministic), whereas for the R-FDM framework, the conditions (15) and (16) are equivalent to (3) and (4) holding *only on average*. The R-FDM framework is *extremely general*. It encapsulates algorithms that involve a (possibly noisy) projection step, has small enough noise *on average* and decreases the objective function *on average*, as the iterations progress.

Remark 4. We will see later (in the proof of convergence of R-FDM) that (15) can be related to the existence of constant $\eta > 0$ such that $\mathbf{E}[\|z_k\|_W^2] \leq \eta (f(x_k) - \mathbf{E}[f(x_{k+1})])^2$.

We will now demonstrate that (see Theorem 7), under an additional mild assumption, if the set $X = \mathbb{R}^n$, then SCDM (captured in Algorithm 1 with Option I.) is equivalent to R-FDM. We also remark that there is a need to modify R-FDM so that the stochastic coordinate descent method can be analyzed even when $X \neq \mathbb{R}^n$. However, first we describe SCDM and make the following assumption in order to establish the equivalence of SCDM with $X = \mathbb{R}^n$ and R-FDM.

Algorithm 1 Stochastic Coordinate Descent Method (SCDM)

- 1: **Input:** $f(x), \{\omega_k\}_{k=0}^{\infty}$: diagonal matrix $W \succ 0, x_0$.
 - 2: **Input:** $X = X_1 \times \dots \times X_n$, where $X_i = [a, b]$ with $-\infty \leq a < b \leq +\infty$
 - 3: **while** $k \geq 0$: **do**
 - 4: choose $i \in \{1, 2, \dots, n\}$ uniformly at random
 - 5: set $x_{k+1} = x_k$
 - 6: Option I: $x_{k+1} = \arg \min_{x^{(i)} \in X_i} f(x_k^{(1)}, x_k^{(2)}, \dots, x_k^{(i-1)}, x_k^{(i)}, x_k^{(i+1)}, \dots, x_k^{(n)})^T$
 - 7: Option II: $x_{k+1} = \text{Proj}_X^W(x_k - \omega_k W^{-1} \nabla_i f(x_k) e_i)$
 - 8: **end while**
-

Remark 5. For simplicity of exposition, Algorithm 1 is the serial form of SCDM, although a minibatch version of SCDM does exist. We will see in Definition 9 that our RC-FDM framework is flexible and general, because it also works in the parallel/minibatch case.

Assumption 6. The function f is coordinate-wise strongly convex with respect to the norm $\|\cdot\|_W$ with parameter $\gamma > 0$, if, for any $x \in X$ and any $i \in \{1, 2, \dots, n\}$ we have

$$f(x^{(1)}, \dots, x^{(i-1)}, \zeta, x^{(i+1)}, \dots, x^{(n)}) - f(x) + \nabla_i f(x)(x^{(i)} - \zeta) \geq \gamma \omega_i |\zeta - x^{(i)}|^2. \quad (17)$$

Note that Assumption 6 does not imply strong convexity of the function f . For example, (17) is satisfied for the Lasso problem or for the SVM dual problem whenever $\forall i: \|a_i\| > 0$, and neither of those problems is strongly convex.

Theorem 7. Let Assumptions 1, 2 and 6 hold. If $X = \mathbb{R}^n$ then the Stochastic Coordinate Descent Method (SCDM) (Algorithm 1 with Option I.) is equivalent to R-FDM with the parameters $\beta^2 = 2[(L_f^W)^2 + 1] + (n-1)r^2$, $\zeta = \gamma$ and $\omega_k = 1$, where $r^2 = \max_{\frac{L_f^2}{\omega_i^2}}$.

Let us comment that, if importance sampling is incorporated into SCDM, the convergence rate in Theorem 7 can be slightly improved, as the parameter r can be made to be $r^2 = \frac{1}{n} \sum_i \frac{L_i^2}{\omega_i^2}$, i.e., ‘average’ rather than ‘max’. However, it is typical to consider the case $\omega_i = L_i$ so that $r^2 = 1$ in Theorem 7 regardless.

The following remark compares the result of the above theorem with the cyclic rule.

Remark 8. It was shown in Luo and Tseng (1993) that for the cyclic coordinate descent method (which is not randomized and hence Equation 14-16 hold deterministically) we have

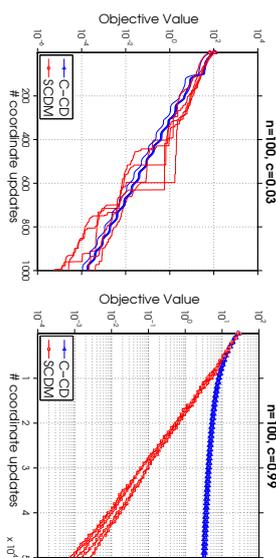

Figure 1: Number of coordinate updates v.s. objective gap for two methods.

$\omega_k^{\text{cyclic}} = 1$, $\zeta^{\text{cyclic}} = \gamma$ and $(\beta^{\text{cyclic}})^2 = (1 + \sqrt{n})L_f^W)^2 = 1 + 2\sqrt{n}L_f^W + n(L_f^W)^2$. For simplicity, let us assume that $W = \text{diag}(L_1, L_2, \dots, L_n)$. Then $r^2 = 1$ and $L_f^W \in [1, n]$. For the cyclic coordinate descent method and SCDM, ω_k and ζ are the same. However, if we consider the worst case (when $L_f^W = n$) we have that $\beta^2 \sim \mathcal{O}(n^2)$, whereas $(\beta^{\text{cyclic}})^2 \sim \mathcal{O}(n^3)$. Also note that one iteration of cyclic coordinate descent requires n coordinate updates, whereas SCDM updates just one coordinate, and therefore each iteration of SCDM is n times cheaper. In the other extreme, when $L_f^W = 1$ we have that both $\beta^2 \sim (\beta^{\text{cyclic}})^2 \sim \mathcal{O}(n)$, but again we recall that one iteration of SCDM is n times cheaper.

We present two experiments to support the discussion above. We apply both the cyclic coordinate descent method and SCDM to the problem

$$\min_{x \in \mathbb{R}^n} f(x) = x^T A x,$$

where the matrix $A \in \mathbb{R}^{n \times n}$ has ones on the diagonal and constant c elsewhere, Sun and Ye (2016). The optimal solution to this problem is $x = 0$. For the first experiment we set $n = 100$ and $c = 0.03$ ($L_f^W = 3.97 \approx 1$), and in the second experiment we keep n unchanged and set $c = 0.99$ ($L_f^W = 99.01 \approx n$). For each method we randomly select five starting points. From Figure 1, it is easy to see that when c is large (i.e., $L_f^W \approx n$) SCDM performs much better than cyclic coordinate descent. On the other hand, there is not such an obvious difference between the two methods when c is small. Thus, the difference in performance between the two methods depends upon the parameter L_f^W . Moreover, the case where c is small is more friendly for both methods, since they require far fewer coordinate updates to reach optimality, compared with the large c case. These results highlight and support Remark 8, regarding the theoretical gap between two methods.

It turns out that if $X \neq \mathbb{R}^n$ then SCDM does not fit the R-FDM framework because $\nabla_i f(x_k)$ cannot be bounded by $\|x_k - x_{k+1}\|_W$, as is shown in the proof of Theorem 7. Thus, there is a need to modify R-FDM such that the SCDM algorithm can be analyzed for bounded problems.

The natural modification to R-FDM, which would allow SCDM to fit the R-FDM framework is the following: at each iteration k we require that in (14), only a subset of coordinates of the vector x_k are updated. This can be achieved by the following method.

Definition 9. [Randomized Coordinate Feasible Descent Method (RC-FDM)] Let $X = X_1 \times \dots \times X_n$, where X_i are intervals. A sequence $\{x_k\}_{k=0}^{\infty}$ is generated by RC-FDM if there exists $\beta \geq 0$, $\zeta > 0$ and $\{\omega_k\}_{k=0}^{\infty}$ with $\min_k \omega_k \geq \bar{\omega} > 0$ such that for every iteration k , the following are satisfied

$$x_{k+1} = \mathbf{Proj}_X^W(x_k - \omega_k W^{-1}(\nabla f(x_k) - z_k)_{\mathcal{I}}), \quad (18)$$

$$(\|(z_k)_{\mathcal{I}}\|_W^*)^2 \leq \beta^2 \|x_k - x_{k+1}\|_W^2, \quad (19)$$

$$f(x_{k+1}) \leq f(x_k) - \zeta \|x_k - x_{k+1}\|_W^2, \quad (20)$$

where \mathcal{I} is a set of coordinates that are selected uniformly at random from the set $\{1, 2, \dots, n\}$ with $|\mathcal{I}| = \tau$, where $1 \leq \tau \leq n$, $x_{\mathcal{I}}$ is a vector whose elements $j \notin \mathcal{I}$ are set to 0 and z_k is some fixed vector at iteration k .

Now, we show that even if $X \neq \mathbb{R}^n$, SCDM fits the RC-FDM. Theorem 10 holds if Option I. is used in Algorithm 1 and Theorem 11 holds if Option II. is used.

Theorem 10. Let Assumptions 1, 2 and 6 hold. Let $\tau = 1$ for simplicity, if $X = X_1 \times \dots \times X_n$, where X_i are intervals then the Stochastic Coordinate Descent Method in Algorithm 1 with Option I. is RC-FDM with $\beta^2 = 2[(L_f^W)^2 + 1]$, $\zeta = \gamma$, and $\omega_k = 1$.

Theorem 11. Let Assumptions 1, 2 and 6 hold. Let $\tau = 1$ for simplicity, if $X = X_1 \times \dots \times X_n$, where X_i are intervals then the Stochastic Coordinate Descent Method in Algorithm 1 with Option II. is RC-FDM with $z_k = 0$, $\zeta = \gamma$, $\beta = 0$, $\omega_k = 1$, and $W = \text{diag}(L_1, L_2, \dots, L_n)$.

3. Convergence Analysis

Necoara (2015) proved a linear convergence rate for FDM under Assumptions 1 and 2. The following theorem shows that a linear convergence rate can also be established for R-FDM.

Theorem 12 (Linear Convergence of R-FDM). Let Assumptions 1 and 2 hold. If the sequence $\{x_k\}_{k=0}^{\infty}$ is produced by R-FDM, i.e. (14)-(16) are satisfied, then

$$\mathbf{E}[f(x_k) - f^*] \leq \left(\frac{c}{1+c}\right)^k (f(x_0) - f^*), \quad (21)$$

where

$$c = \frac{2}{\kappa_f \zeta} \left((L_f^W + \frac{1}{\bar{\omega}})^2 + \beta^2 \right). \quad (22)$$

The next theorem establishes a linear convergence rate for RC-FDM.

Theorem 13 (Linear Convergence of RC-FDM). Let $X = X_1 \times \dots \times X_n$, where X_i are intervals. Further, let Assumptions 1 and 2 hold, and let the sequence $\{x_k\}_{k=0}^{\infty}$ be produced by RC-FDM, i.e. (18)-(20) are satisfied. Then, for $z_k \neq 0$, there exists $c \in (0, 1)$ such that, for all k ,

$$\mathbf{E}[f(x_k) - f^*] \leq (1-c)^k (f(x_0) - f^*). \quad (23)$$

Moreover, if for all k we have $z_k \equiv 0$, and $\frac{L_i}{\omega_k} \geq \max_i \frac{L_i}{\omega_k}$, then $c = \frac{2\bar{\omega}\tau}{n(2\bar{\omega}+1)}$ with

$$\mathbf{E}[f(x_k) - f^*] \leq (1-c)^k \left(f(x_0) - f^* + \frac{\tau}{2\bar{\omega}} \|x_0 - \bar{x}_0\|_W^2 \right). \quad (24)$$

3.1 Comparison with the Results in Related Literature

In Theorem 13 we established a linear rate of convergence for RC-FDM for any z_k . We will now compare our result with the one presented in Liu and Wright (2015) for the projected coordinate gradient descent algorithm, and also with the result presented in Necoara (2015) for deterministic FDM. For this comparison we will assume that $\tau = 1$ (i.e., for serial RC-FDM), because the first paper only considers a serial algorithm, and for ease of comparison with the results in the second paper. (However, RC-FDM works for general $1 \leq \tau \leq n$.)

The projected coordinate gradient descent algorithm (Liu and Wright 2015) fits the RC-FDM framework. We also note that the result in Liu and Wright (2015) only holds for $z_k = 0$, so our result is more general. Further, even though the paper Liu and Wright (2015) considers an asynchronous implementation, where the update computed at iteration k is based on gradient information at a point up to ν iterations old, if $\nu = 0$ then their method fits into the RC-FDM framework. One of the benefits of our work is that more general norms can be used. So, for simplicity, and to match with the work in Liu and Wright (2015), let us assume that $L_i = 1$ for all i and we also choose $w_i = 1$ for all i . (This is the case e.g. for the SVM dual problem). The geometric rate in (24) in our work is then $1 - \frac{\kappa_f}{n(\kappa_f + \frac{1}{\bar{\omega}})}$ and from Theorem 4.1 in Liu and Wright (2015) for $\nu = 0$ we obtain that the geometric rate is $1 - \frac{\kappa_f}{n(\kappa_f + L_{\max})}$, where $L_{\max} \geq 1$ is such that

$$\|\nabla f(x) - \nabla f(x + \delta e_i)\|_{\infty} \leq L_{\max} |\delta|$$

holds $\forall x \in \mathbb{R}^n$, $\delta \in \mathbb{R}$ and $i \in \{1, 2, \dots, n\}$. Hence, in this case our convergence results are better because $\frac{1}{2} \leq 1 \leq L_{\max}$.

In Necoara (2015) the author provided a linear convergence rate for deterministic FDM. It is shown in Theorem 3.2 in Necoara (2015) that the coefficient of the linear rate is $1 - \frac{\zeta}{\zeta + \bar{\rho}}$ where $\bar{\rho} = \frac{1}{\kappa_f} (L_f + \frac{1}{\bar{\omega}} + \beta)^2$ whereas, in Theorem 13 of this work, from (21) we see that the coefficient is the same but with a different ρ . To be precise, in our case we have $\bar{\rho} = \frac{2}{\kappa_f} \left((L_f^W + \frac{1}{\bar{\omega}})^2 + \beta^2 \right)$. Our result can be better or worse than that in Necoara (2015), depending on the values of L_f^W , $\bar{\omega}$ and β , but our results holds for R-FDM, which is broader than FDM.

4. Global Error Bound Property

In this section we describe a class of problems that satisfies the Global Error Bound (GEB) property. We show that this implies the weak strong convexity property and we compare the convergence rate obtained in this paper with several results in the current literature derived for problems obeying the GEB. We begin by defining the projected gradient.

Definition 14 (Projected Gradient). For any $x \in \mathbb{R}^n$ let us define the projected gradient as follows,

$$\nabla^+ f(x) := x - \mathbf{Proj}_X^W(x - \nabla f(x)). \quad (25)$$

Note that projected gradient is zero at x if and only if x is an optimal solution of (1). Also, we will employ the projected gradient to define an error bound, which measures the distance between x and the optimal solution. Now, we are ready to define a global error bound as follows.

Definition 15 (Definition 6 in Wang and Lin 2014). *An optimization problem admits a global error bound if there is a constant $\eta_f \geq 0$ such that*

$$\|x - \bar{x}\| \leq \eta_f \|\nabla^+ f(x)\|_W^*, \quad \forall x \in X, \quad (26)$$

where \bar{x} and $\nabla^+ f(x)$ are defined in (6) and (25), respectively. A relaxed condition called the global error bound from the beginning is if the above inequality holds only for $x \in X$ such that $f(x) - f(\bar{x}) \leq M$, where M is a constant, and usually we have that $M = f(x_0) - f^*$.

Let us consider a special instance of (1) when X is a polyhedral set, i.e.

$$X = \{x \in \mathbb{R}^n : Bx \leq c\}, \quad (27)$$

and the function f has the following structure

$$f(x) = h(Ax) + q^T x, \quad (28)$$

where $B \in \mathbb{R}^{k \times n}$, $A \in \mathbb{R}^{d \times n}$, h is a σ_h strongly convex function and f satisfies Assumption 2. We also assume that there exists an optimal solution and hence the optimal solution set X^* is assumed to be non-empty, Wang and Lin (2014). It is easy to observe that if f is strongly convex, then (5) is trivially satisfied. Just recently, Necora (2015) showed that if (26) is satisfied, then (5) is satisfied with

$$\kappa_f = \frac{L_f^W}{2\eta_f^2}. \quad (29)$$

For problem (28) it was discussed in Wang and Lin (2014) that

$$\eta_f = \theta^2 (1 + L_f^W) \left(\frac{1 + 2\|\nabla h(A\bar{x})\|^2}{\sigma_h} + 4M \right) + 2\theta \|\nabla f(\bar{x})\|, \quad (30)$$

where θ is a constant from the Hoffman bound (Hoffman 1952; Li 1993; Robinson 1973) defined as follows

$$\theta := \sup_{u,v} \left\{ \begin{array}{l} \left\| \begin{pmatrix} u \\ v \end{pmatrix} \right\| \\ \left\| B^T u + \begin{pmatrix} A \\ q^T \end{pmatrix} v \right\| = 1, u \geq 0 \end{array} \right\} \quad \text{and the corresponding rows of } B, A \text{ to } u, v \text{'s} \\ \left. \begin{array}{l} \text{non-zero elements are linearly independent.} \end{array} \right\}. \quad (31)$$

Note that the constant θ can be very large; we will discuss this in Section 5.

Necora (2015) derived that, for problem (28), the weak strong convexity property (5) holds with

$$\kappa_f = \frac{\sigma_h}{2\theta^2}. \quad (32)$$

Note that κ_f given in (32) is $\mathcal{O}(\theta^{-2})$ whereas κ_f obtained from (29) is of the order θ^{-4} . Therefore we will compare our results using the latter estimates of κ_f .

5.1 Comparison with the Results in Related Literature

In Theorem 8 in Wang and Lin (2014), under the global error bound property, it is proven that FDM converges at a linear rate: $f(x_{k+1}) - f^* \leq (1 - \frac{1}{1+\zeta})(f(x_k) - f^*)$, with¹

$$\begin{aligned} \bar{c} &= \frac{1}{\zeta} (L_f^W + \frac{1}{\omega} + \beta)(1 + \eta_f(\frac{1}{\omega} + \beta)) = \frac{1}{\zeta} (L_f^W + \frac{1}{\omega} + \beta)(1 + \theta^2 \frac{1 + L_f^W}{\omega} (\frac{1}{\omega} + \beta)) \\ &\sim \mathcal{O} \left(\frac{\theta^2}{\zeta \sigma_h} (1 + L_f^W) (\frac{1}{\omega} + \beta)(L_f^W + \frac{1}{\omega} + \beta) \right). \end{aligned}$$

From Theorem 12 in this work, we have linear convergence of RC-FDM with the coefficient

$$c = \frac{2}{\kappa_f \zeta} \left((L_f^W + \frac{1}{\omega})^2 + \beta^2 \right) \stackrel{(32)}{=} \frac{4\theta^2}{\sigma_h \zeta} \left((L_f^W + \frac{1}{\omega})^2 + \beta^2 \right).$$

These coefficients are very similar, but FDM Wang and Lin (2014) covers only cyclic coordinate descent and not a randomized coordinate descent method (which is covered by Theorem 12).

5. Linear Convergence Rate of SDCA for Dual of SVM

In this section we show that the SDCA algorithm (which is SCDM applied to Equation 11) achieves a linear convergence rate for the duality gap. This improves upon the result obtained in Shalev-Shwartz and Zhang (2013); Takáč et al. (2015); Takáč et al. (2013), where only a sublinear rate was derived.

Assume, for simplicity, that in problem (10) for all $i \in \{1, 2, \dots, n\}$ it holds that $\|a_i\| \leq 1$. Then, from Takáč et al. (2015); Takáč et al. (2013), we have that for any $x \in \mathbb{R}^n$, $s \in [0, 1]$ and the function f defined in (11),

$$f(x) - f^* \geq sG(x) - s^2 \frac{\sigma^2}{2\lambda}, \quad (33)$$

where f^* denotes the optimal value of (11), $A = [a_1, a_2, \dots, a_n]$, $\sigma^2 = \frac{1}{n} \|X\| \in [\frac{1}{n}, 1]$ and $G(x)$ is the duality gap at the point x , which is defined as $G(x) := P(\frac{1}{\lambda n} Ax) + f(x)$.

We remark that SDCA for problem (11) is equivalent to RC-FDM, where the constants in (18)-(20) are: $z_k = 0$, $\beta^2 = 0$, $w_i = L_i = \frac{1}{\lambda n^2} \|a_i\|^2$, and $\omega_k = 1$. Hence, if we choose $x_0 = \mathbf{0}$ then from Theorem 13 we have that $\mathbf{E}[f(x_k) - f^*] \leq (1 - c)^k (f(\mathbf{0}) - f^* + \|x^*\|_2^2)$ with $c = \frac{2\kappa_f}{n(2\kappa_f + 1)}$.

Now, we see that rearranging (33) gives

$$G(x) \stackrel{(33)}{\leq} s \frac{\sigma^2}{2\lambda} + \frac{1}{s} (f(x) - f^*). \quad (34)$$

If we want to achieve $G(x) \leq \epsilon$ it is sufficient to choose both terms on right hand side of (34) to be $\leq \frac{\epsilon}{2}$. Hence, we can set $s = \min\{1, \frac{\epsilon}{2}\}$. All we have to do now is to choose k such that $f(x_k) - f^* \leq s \frac{\epsilon}{2}$. In the following theorem we establish linear convergence of the duality gap $G(x)$ for the SDCA algorithm.

1. In Wang and Lin (2014) it is shown that, in special cases (e.g. $X = \mathbb{R}^n$), (30) is $\eta_f = \theta^{2+L_f^W/\sigma_h}$.

Theorem 16. Let $s = \min\{1, \frac{1}{c}\sigma^2\}$ and let K be such that

$$K \geq n \left(1 + \frac{1}{2\kappa_f}\right) \log \frac{2(f(\mathbf{0}) - f^* + \|x^*\|_L^2)}{s\epsilon}.$$

Then if the SDCA algorithm is applied to problem (11) to produce $\{x_k\}_{k=0}^\infty$, then $\forall k \geq K$ we have that $\mathbf{E}[G(x_k)] \leq \epsilon$.

Let us now comment on the size of the parameter $\kappa_f \stackrel{(32)}{=} \frac{\sigma_f}{2\theta^2}$. In our case, X is the polyhedral set (27) defined by $B = (-I_n, I_n)^T$, and $c = (\mathbf{0}^T, \mathbf{1}^T)^T$, where $I_n \in \mathbb{R}^{n \times n}$ is the identity matrix. Because of this structure (31) simplifies to

$$\theta := \sup_{u, v} \left\{ \left\| \begin{pmatrix} u \\ v \end{pmatrix} \right\| \left\| \begin{pmatrix} I_n u + \begin{pmatrix} A \\ q \end{pmatrix}^T v \end{pmatrix} \right\| = 1 \right. \\ \left. \text{and the corresponding rows of } I_n, A \text{ to } u, v \text{'s} \right. \\ \left. \text{non-zero elements are linearly independent.} \right\}. \quad (35)$$

To show that θ can be very large, let us assume that two rows of the matrix A are highly correlated (in this case rows corresponds to features). We denote these two rows by A_1 and A_2 , and let us assume that $A_1 = A_2 + \delta e_1$. Then we can chose $v = (-\frac{1}{\delta}, \frac{1}{\delta}, 0, \dots, 0)^T$ and $u = \mathbf{0}$. This particular choice is feasible in optimization problem (35) and hence is imposing a lower-bound on θ : $\theta \geq \frac{\sqrt{2}}{|\delta|}$. Clearly, for small δ , this shows that θ can be arbitrarily large.

6. Summary

In this paper we have extended the framework of the feasible descent method FDM to a randomized, and a randomized coordinate, FDM framework. We have shown that many problems in the machine learning literature fit our problem structure, and subsequently, any algorithm that fits our FDM framework can be used to successfully solve them. We have proven a linear convergence rate (under the weak strong convexity assumption) for both methods, and we have shown that the convergence rates are similar to the deterministic/non-randomized FDM. We also showed that for the cyclic coordinate descent method, the coefficients in FDM are worse than, or similar to, the stochastic coordinate descent method (and hence the theory tells us that they converge at roughly the same speed), but each iteration of the stochastic coordinate descent method is n -times cheaper. We concluded the paper with a result showing that, for the SDCA algorithm applied to the dual of the linear SVM, the duality gap converges linearly.

Appendix A. Proof of Theorem 7

Let us define an auxiliary vector \tilde{x} such that

$$\tilde{x}^{(i)} = \arg \min_{x^{(i)} \in X_i} f((x_k^{(1)}, x_k^{(2)}, \dots, x_k^{(i-1)}, x_k^{(i)}, x_k^{(i+1)}, \dots, x_k^{(n)})^T). \quad (36)$$

Then we can see that if coordinate i is chosen during iteration k in Algorithm 1 then

$$x_{k+1}^{(i)} = \begin{cases} x_k^{(j)}, & \text{if } j \neq i, \\ \tilde{x}^{(i)}, & \text{otherwise.} \end{cases} \quad (37)$$

If coordinate i is chosen during iteration k , then the optimality conditions for Step 6 of Algorithm 1, give us that

$$x_{k+1}^{(i)} = \mathbf{Proj}_{X_i}^W \left(x_{k+1}^{(i)} - \frac{1}{w_i} \nabla_i f(x_{k+1}) \right). \quad (38)$$

Moreover, by (37), for $j \neq i$ we have that $x_k^{(j)} = x_{k+1}^{(j)}$ which is possible only if $z_k^{(j)} = \nabla_j f(x_k)$.

Note that x_{k+1} is a random variable, which depends on i and x_k only. Therefore, we can define a random z_k such that the i -th coordinate is

$$z_k^{(i)} = \nabla_i f(x_k) - \nabla_i f((x_k^{(1)}, x_k^{(2)}, \dots, x_k^{(i-1)}, \tilde{x}^{(i)}, x_k^{(i+1)}, \dots, x_k^{(n)})^T) + w_i(x_k^{(i)} - \tilde{x}^{(i)}) \quad (39)$$

and the j -th coordinate (for $j \neq i$) is defined as $z_k^{(j)} = \nabla_j f(x_k)$. It is easy to verify that for z_k defined above, condition (14) holds. Now, we will compute $\mathbf{E}[\|z_k\|_W^2]$. We have that if the i -th coordinate is chosen then

$$\begin{aligned} & \frac{1}{w_i} (z_k^{(i)})^2 \\ &= \frac{1}{w_i} \left(\nabla_i f(x_k) - \nabla_i f((x_k^{(1)}, x_k^{(2)}, \dots, x_k^{(i-1)}, \tilde{x}^{(i)}, x_k^{(i+1)}, \dots, x_k^{(n)})^T) + w_i(x_k^{(i)} - \tilde{x}^{(i)}) \right)^2 \\ &\leq \frac{2}{w_i} \left(\nabla_i f(x_k) - \nabla_i f((x_k^{(1)}, x_k^{(2)}, \dots, x_k^{(i-1)}, \tilde{x}^{(i)}, x_k^{(i+1)}, \dots, x_k^{(n)})^T) \right)^2 + 2w_i(x_k^{(i)} - \tilde{x}^{(i)})^2 \\ &\leq 2 \left(\|\nabla_i f(x_k) - \nabla_i f((x_k^{(1)}, x_k^{(2)}, \dots, x_k^{(i-1)}, \tilde{x}^{(i)}, x_k^{(i+1)}, \dots, x_k^{(n)})^T)\|_W \right)^2 + 2w_i(x_k^{(i)} - \tilde{x}^{(i)})^2 \\ &\stackrel{(8)}{\leq} 2(L_f^W \|x_k - (x_k^{(1)}, x_k^{(2)}, \dots, x_k^{(i-1)}, \tilde{x}^{(i)}, x_k^{(i+1)}, \dots, x_k^{(n)})^T\|_W)^2 + 2w_i(x_k^{(i)} - \tilde{x}^{(i)})^2 \\ &= 2(L_f^W)^2 w_i (x_k^{(i)} - \tilde{x}^{(i)})^2 + 2w_i(x_k^{(i)} - \tilde{x}^{(i)})^2 = 2[(L_f^W)^2 + 1]w_i(x_k^{(i)} - \tilde{x}^{(i)})^2, \end{aligned} \quad (40)$$

otherwise

$$\frac{1}{w_i} (z_k^{(i)})^2 = \frac{1}{w_i} (\nabla_i f(x_k))^2.$$

Hence, we obtain that

$$\mathbf{E}[\|z_k\|_W^2] \stackrel{(40)}{\leq} \sum_{i=1}^n \frac{1}{n} 2[(L_f^W)^2 + 1]w_i(x_k^{(i)} - \tilde{x}^{(i)})^2 + \frac{n-1}{n} \sum_{i=1}^n \frac{1}{w_i} (\nabla_i f(x_k))^2. \quad (41)$$

From the optimality condition of Step 6 of Algorithm 1, and the fact that $X_i = \mathbb{R}$, we know that for all i the following holds,

$$\nabla_i f(x_k^{(1)}, \dots, x_k^{(i-1)}, \bar{x}^{(i)}, x_k^{(i+1)}, \dots, x_k^{(n)}) = 0. \quad (42)$$

Therefore $\forall i$ we have

$$\begin{aligned} \frac{1}{w_i} (\nabla_i f(x_k))^2 &= \frac{1}{w_i} (\nabla_i f(x_k) - \nabla_i f(x_k^{(1)}, \dots, x_k^{(i-1)}, \bar{x}^{(i)}, x_k^{(i+1)}, \dots, x_k^{(n)}))^2 \\ &\stackrel{(7)}{\leq} \frac{1}{w_i} L_f^2 (\bar{x}^{(i)} - x_k^{(i)})^2 = \frac{1}{w_i^2} L_f^2 w_i (\bar{x}^{(i)} - x_k^{(i)})^2. \end{aligned}$$

If we denote by $r^2 = \max_i \frac{L_f^2}{w_i^2}$, then we obtain from (41)

$$\begin{aligned} \mathbf{E}[|z_k|_{W^*}^2] &\stackrel{(40)}{\leq} \sum_{i=1}^n \left[\frac{1}{n} 2(L_f^W)^2 + 1 \right] + \frac{n-1}{n} r^2 \sum_{i=1}^n w_i (x_k^{(i)} - \bar{x}^{(i)})^2 \\ &= \left[\frac{1}{n} 2(L_f^W)^2 + 1 \right] + \frac{n-1}{n} r^2 \sum_{i=1}^n w_i (x_k^{(i)} - \bar{x}^{(i)})^2 \\ &= (2[(L_f^W)^2 + 1] + (n-1)r^2) \frac{1}{n} \sum_{i=1}^n w_i (x_k^{(i)} - \bar{x}^{(i)})^2 \\ &= (2[(L_f^W)^2 + 1] + (n-1)r^2) \mathbf{E}[\|x_k - x_{k+1}\|_W^2] \end{aligned}$$

and we can conclude that (15) holds with $\beta^2 = 2[(L_f^W)^2 + 1] + (n-1)r^2$.

Now, it remains to show (16). From (36) we know that

$$\nabla_i f(x_k^{(1)}, x_k^{(2)}, \dots, x_k^{(i-1)}, \bar{x}^{(i)}, x_k^{(i+1)}, \dots, x_k^{(n)})^T (\bar{x}^{(i)} - x_k^{(i)}) \leq 0. \quad (43)$$

Therefore, from (17) with $\xi = x_k^{(i)}$ and $x = (x_k^{(1)}, \dots, x_k^{(i-1)}, \bar{x}^{(i)}, x_k^{(i+1)}, \dots, x_k^{(n)})^T \stackrel{(37)}{=} x_{k+1}$, we have that

$$f(x_k) - f(x_{k+1}) \geq \gamma w_i |x_k^{(i)} - x_{k+1}^{(i)}|^2 + \nabla_i f(x_{k+1})(x_k^{(i)} - x_{k+1}^{(i)}) \geq \gamma w_i |x_k^{(i)} - x_{k+1}^{(i)}|^2. \quad (44)$$

Therefore

$$f(x_k) - f(x_{k+1}) \stackrel{(44)}{\geq} \gamma w_i |x_k^{(i)} - x_{k+1}^{(i)}|^2 = \gamma \|x_k - x_{k+1}\|_W^2.$$

and by taking expectation on both sides of the above, (16) follows with $\zeta = \gamma$.

Appendix B. Proof of Theorem 10

The proof is very similar to the proof of Theorem 7. Let us define an auxiliary vector \bar{x} in the same way as in (36). Then we can see that if coordinate i is chosen during iteration k in Algorithm 1 then (37) holds, and the optimality conditions for Step 6 of Algorithm 1 imply that (38) holds.

Note that x_{k+1} is a random variable which depends on i and x_k only. Therefore, we can define z_k such that i -th coordinate is given by (39). It is easy to verify that for z_k defined in (39), the condition (18) holds. Now, let us compute $(\|z_k\|_{W^*})^2$. We have that

$$(\|z_k\|_{W^*})^2 = \frac{1}{w_i} (z_k^{(i)})^2 \stackrel{(40)}{\leq} 2(L_f^W)^2 + 1 + w_i (x_k^{(i)} - \bar{x}^{(i)})^2 \stackrel{(37)}{=} 2[(L_f^W)^2 + 1] \|x_k^{(i)} - x_{k+1}^{(i)}\|_W^2.$$

Therefore, we conclude that (19) holds with $\beta^2 = 2[(L_f^W)^2 + 1]$.

Now, it remains to show (20). Again from (36) we know that (43) holds. Therefore from (17) with $\xi = x_k^{(i)}$ and $x = (x_k^{(1)}, \dots, x_k^{(i-1)}, \bar{x}^{(i)}, x_k^{(i+1)}, \dots, x_k^{(n)})^T \stackrel{(37)}{=} x_{k+1}$ we have (44). Therefore $f(x_k) - f(x_{k+1}) \geq \gamma w_i |x_k^{(i)} - x_{k+1}^{(i)}|^2 = \gamma \|x_k - x_{k+1}\|_W^2$, so (20) holds with $\zeta = \gamma$.

Appendix C. Proof of Theorem 12

This proof is based on the proof of Theorem 3.2 in Neocora (2015). We can write the optimality conditions for x_{k+1} from (14) and using the definition of a projection given in (9). We have that $\forall x \in X$, the following inequality holds

$$\langle W(x_{k+1} - x_k + \omega_k W^{-1}(\nabla f(x_k) - z_k)), x - x_{k+1} \rangle \geq 0. \quad (45)$$

Now, using the convexity of f we obtain that

$$\begin{aligned} f(x_{k+1}) - f^* &= f(x_{k+1}) - f(\bar{x}_{k+1}) \leq \langle \nabla f(x_{k+1}), x_{k+1} - \bar{x}_{k+1} \rangle \\ &= \langle \nabla f(x_{k+1}) - \nabla f(x_k) + \nabla f(x_k), x_{k+1} - \bar{x}_{k+1} \rangle. \end{aligned} \quad (46)$$

Plugging $x = \bar{x}_{k+1}$ into (45) we obtain

$$\left\langle \frac{1}{\omega_k} W(x_{k+1} - x_k) - z_k, \bar{x}_{k+1} - x_{k+1} \right\rangle \geq \langle \nabla f(x_k), x_{k+1} - \bar{x}_{k+1} \rangle. \quad (47)$$

Plugging this into (46) gives us that

$$\begin{aligned} f(x_{k+1}) - f(\bar{x}_{k+1}) &\stackrel{(46), (47)}{\leq} \left\langle \nabla f(x_{k+1}) - \nabla f(x_k) - \frac{1}{\omega_k} W(x_{k+1} - x_k) + z_k, x_{k+1} - \bar{x}_{k+1} \right\rangle \\ &\stackrel{CS}{\leq} \|\nabla f(x_{k+1}) - \nabla f(x_k)\|_W^* \|x_{k+1} - \bar{x}_{k+1}\|_W \\ &\quad + \left\langle -\frac{1}{\omega_k} W(x_{k+1} - x_k) + z_k, x_{k+1} - \bar{x}_{k+1} \right\rangle \\ &\stackrel{(8)}{\leq} L_f^W \|x_{k+1} - x_k\|_W \|x_{k+1} - \bar{x}_{k+1}\|_W \\ &\quad + \left\langle -\frac{1}{\omega_k} W(x_{k+1} - x_k), x_{k+1} - \bar{x}_{k+1} \right\rangle + \langle z_k, x_{k+1} - \bar{x}_{k+1} \rangle \\ &\stackrel{CS}{\leq} L_f^W \|x_{k+1} - x_k\|_W \|x_{k+1} - \bar{x}_{k+1}\|_W \\ &= \left(L_f^W + \frac{1}{\omega_k} \right) \|x_{k+1} - x_k\|_W + \|z_k\|_W^* \|x_{k+1} - \bar{x}_{k+1}\|_W \\ &\stackrel{(5)}{\leq} \left(L_f^W + \frac{1}{\omega_k} \right) \|x_{k+1} - x_k\|_W + \|z_k\|_W^* \sqrt{\frac{1}{\kappa_f} (f(x_{k+1}) - f(\bar{x}_{k+1}))}. \end{aligned} \quad (48)$$

Therefore, we can conclude that

$$f(x_{k+1}) - f^* \stackrel{(48)}{\leq} \frac{1}{\kappa_f} \left((L_f^W + \frac{1}{\omega}) \|x_{k+1} - x_k\|_W + \|z_k\|_W^* \right)^2. \quad (49)$$

Taking the expectation of (49) with respect to the random vector z_k , we obtain

$$\begin{aligned} \mathbf{E}[f(x_{k+1}) - f(\bar{x}_{k+1})] &\stackrel{(49)}{\leq} \frac{1}{\kappa_f} \mathbf{E} \left[\left((L_f^W + \frac{1}{\omega}) \|x_{k+1} - x_k\|_W + \|z_k\|_W^* \right)^2 \right] \\ &\leq \frac{2}{\kappa_f} \left((L_f^W + \frac{1}{\omega})^2 \mathbf{E}[\|x_{k+1} - x_k\|_W^2] + \mathbf{E}[\|z_k\|_W^*]^2 \right) \\ &\stackrel{(15)}{\leq} \frac{2}{\kappa_f} \left((L_f^W + \frac{1}{\omega})^2 + \beta^2 \right) \mathbf{E}[\|x_k - x_{k+1}\|_W^2] \\ &\stackrel{(16)}{\leq} \frac{2}{\kappa_f} \left((L_f^W + \frac{1}{\omega})^2 + \beta^2 \right) \frac{1}{\zeta} (f(x_k) - \mathbf{E}[f(x_{k+1})]) \\ &= \underbrace{\frac{2}{\kappa_f} \left((L_f^W + \frac{1}{\omega})^2 + \beta^2 \right) \frac{1}{\zeta}}_c (f(x_k) - f(\bar{x}_k)) \\ &\quad + \mathbf{E}[f(\bar{x}_{k+1})] - \mathbf{E}[f(x_{k+1})]. \end{aligned} \quad (50)$$

Finally, from (50) we obtain that

$$\mathbf{E}[f(x_{k+1}) - f^*] = \mathbf{E}[f(x_{k+1}) - f(\bar{x}_{k+1})] \leq \frac{c}{1+c} (f(x_k) - f(\bar{x}_{k+1})) = \frac{c}{1+c} (f(x_k) - f^*),$$

and the result follows.

Appendix D. Proof of Theorem 13 if $z_k = 0$

Let us define an auxiliary vector \tilde{x} such that

$$\tilde{x}^{(j)} = \mathbf{Proj}_X^W(x_k - \omega_k W^{-1}(\nabla f(x_k) - z_k)_{[j]}). \quad (51)$$

Then we can see that if coordinates \mathcal{I} is chosen during iteration k in Algorithm 1 then

$$x_{k+1}^{(j)} = \begin{cases} x_k^{(j)}, & \text{if } j \notin \mathcal{I}, \\ \tilde{x}^{(j)}, & \text{otherwise.} \end{cases} \quad (52)$$

Therefore, let us estimate the expected value of f at a random point x_{k+1} , where the expectation is taken with respect to the selection of coordinates \mathcal{I} at iteration k . Let

$h \in \mathbb{R}^n$. Then if $\frac{1}{\omega_k} \geq \max_i \frac{L_i}{\omega_i}$ we have

$$\begin{aligned} \mathbf{E}[f(x_k + h_{[T]})] &\stackrel{(7)}{\leq} f(x_k) + \mathbf{E} \left[\langle \nabla f(x_k), h_{[T]} \rangle + \frac{L_T}{2\omega_T} \|h_{[T]}\|_W^2 \right] \\ &\leq f(x_k) + \mathbf{E} \left[\langle \nabla f(x_k), h_{[T]} \rangle + \frac{1}{2\omega_k} \|h_{[T]}\|_W^2 \right] \\ &\stackrel{(52)}{=} f(x_k) + \frac{T}{n} \left(\langle \nabla f(x_k), h \rangle + \frac{1}{2\omega_k} \|h\|_W^2 \right) \\ &= \frac{n-T}{n} f(x_k) + \frac{T}{n} \underbrace{\left(f(x_k) + \langle \nabla f(x_k) - z_k, h \rangle + \frac{1}{2\omega_k} \|h\|_W^2 + \langle z_k, h \rangle \right)}_{\mathcal{H}(h; x_k, z_k)}. \end{aligned} \quad (53)$$

Now, observe that

$$\begin{aligned} \tilde{x} &= x_k + \arg \min_{h: x+x_k \in X} \mathcal{H}(h; x_k, z_k) \\ &= x_k + \arg \min_{h \in \mathbb{R}^n} \{ \mathcal{H}(h; x_k, z_k) + \Phi_X(x + x_k) \} =: x_k + \hat{h}, \end{aligned} \quad (54)$$

where $\Phi_X(x)$ is the indicator function for the set X , i.e.

$$\Phi_X(x) = \begin{cases} 0, & \text{if } x \in X, \\ +\infty, & \text{otherwise.} \end{cases} \quad (55)$$

From the first order optimality conditions of (54) we have

$$\nabla f(x_k) - z_k + \frac{1}{\omega_k} W\hat{h} + s = 0, \quad (56)$$

where $s \in \partial\Phi(x_k + \hat{h})$. We can define a composite gradient mapping Lu and Xiao (2013); Nesterov (2013); Tappenden et al. (2015) as

$$g := -\frac{1}{\omega_k} W\hat{h}. \quad (57)$$

Therefore, we can observe that

$$-\nabla f(x_k) + z_k + g \stackrel{(56)}{\in} \partial\Phi(x_k + \hat{h}). \quad (58)$$

It is also easy to show that

$$\|\hat{h}\|_W^2 = \|\omega_k W^{-1}g\|_W^2 = \omega_k^2 (\|g\|_W^*)^2 \quad (59)$$

and

$$\langle g, \hat{h} \rangle = -\frac{1}{\omega_k} \|\hat{h}\|_W^2 \stackrel{(59)}{=} -\omega_k (\|g\|_W^*)^2. \quad (60)$$

Finally note that for any $y \in X$ we have

$$\begin{aligned} \|x_k + \hat{h} - y\|_W^2 &= \|x_k - y\|_W^2 + 2\omega_k \langle g, y - x_k \rangle + \|\hat{h}\|_W^2 \\ &\stackrel{(59)}{=} \|x_k - y\|_W^2 + 2\omega_k \langle g, y - x_k \rangle + \omega_k^2 (\|g\|_W^*)^2. \end{aligned} \quad (61)$$

Now, we are ready to bound $\mathcal{H}(h; x_k, z_k) + \Phi(x + h)$ for $h = \hat{h}$. We have

$$\begin{aligned} &\mathcal{H}(\hat{h}; x_k, z_k) + \Phi(x_k + \hat{h}) \\ &= f(x_k) + \langle \nabla f(x_k) - z_k, \hat{h} \rangle + \frac{1}{2\omega_k} \|\hat{h}\|_W^2 + \Phi(x_k + \hat{h}) \\ &\stackrel{(58)}{\leq} f(y) + \langle \nabla f(x_k), x_k - y \rangle + \langle \nabla f(x_k) - z_k, \hat{h} \rangle + \frac{1}{2\omega_k} \|\hat{h}\|_W^2 \\ &\quad + \Phi(y) + \langle -\nabla f(x_k) + z_k + g, x_k + \hat{h} - y \rangle \\ &= f(y) + \Phi(y) + \frac{1}{2\omega_k} \|\hat{h}\|_W^2 + \langle g, x_k - y \rangle + \langle z_k, x_k - y \rangle + \langle g, \hat{h} \rangle \\ &\stackrel{(60), (59)}{=} f(y) + \Phi(y) + \frac{1}{2} \omega_k (\|g\|_W^*)^2 + \langle g, x_k - y \rangle + \langle z_k, x_k - y \rangle - \omega_k (\|g\|_W^*)^2 \\ &= f(y) + \Phi(y) - \frac{1}{2} \omega_k (\|g\|_W^*)^2 + \langle g, x_k - y \rangle + \langle z_k, x_k - y \rangle \\ &\stackrel{(61)}{=} f(y) + \Phi(y) - \frac{1}{2\omega_k} \left(\|x_k + \hat{h} - y\|_W^2 - \|x_k - y\|_W^2 \right) + \langle z_k, x_k - y \rangle \\ &\stackrel{(32), (63)}{=} f(y) + \Phi(y) - \frac{1}{2\omega_k} \frac{n}{\tau} \left(\mathbf{E} \|x_{k+1} - y\|_W^2 - \|x_k - y\|_W^2 \right) + \langle z_k, x_k - y \rangle, \end{aligned}$$

where in the last step, we use

$$n \mathbf{E} \|x_{k+1} - y\|_W^2 = \tau \|x_k + \hat{h} - y\|_W^2 + (n - \tau) \|x_k - y\|_W^2.$$

Now, from (53) we conclude that $\forall y$ we have

$$\begin{aligned} \mathbf{E}[f(x_{k+1})] &\leq \frac{n - \tau}{n} f(x_k) + \frac{\tau}{n} \left(f(y) + \Phi(y) - \frac{n}{2\omega_k \tau} \mathbf{E} \|x_{k+1} - y\|_W^2 \right) \\ &\quad + \frac{n}{2\omega_k \tau} \|x_k - y\|_W^2 + \langle z_k, x_k + \hat{h} - y \rangle, \end{aligned}$$

which can be equivalently written as

$$\begin{aligned} \mathbf{E} \left[f(x_{k+1}) + \frac{1}{2\omega_k} \|x_{k+1} - y\|_W^2 \right] &\leq f(x_k) + \frac{1}{2\omega_k} \|x_k - y\|_W^2 \\ &\quad - \frac{\tau}{n} (f(x_k) - f(y) - \Phi(y)) + \frac{\tau}{n} \langle z_k, x_k + \hat{h} - y \rangle. \end{aligned}$$

If we choose $y = \bar{x}_k$ then the latter inequality reads as follows

$$\begin{aligned} \mathbf{E} \left[f(x_{k+1}) + \frac{1}{2\omega_k} \|x_{k+1} - \bar{x}_k\|_W^2 \right] &\leq f(x_k) + \frac{1}{2\omega_k} \|x_k - \bar{x}_k\|_W^2 \\ &\quad - \frac{\tau}{n} (f(x_k) - f^*) + \frac{\tau}{n} \langle z_k, x_k + \hat{h} - \bar{x}_k \rangle. \end{aligned}$$

From the definition of \bar{x} we obtain that $\|x_{k+1} - \bar{x}_{k+1}\|_W \leq \|x_{k+1} - \bar{x}_k\|_W$ and therefore

$$\begin{aligned} \mathbf{E} \left[f(x_{k+1}) - f^* + \frac{1}{2\omega_k} \|x_{k+1} - \bar{x}_{k+1}\|_W^2 \right] &\leq (1 - \frac{\tau}{n}) (f(x_k) - f^*) \\ &\quad + \frac{1}{2\omega_k} \|x_k - \bar{x}_k\|_W^2 + \frac{\tau}{n} \langle z_k, x_k + \hat{h} - \bar{x}_k \rangle. \end{aligned}$$

Let us assume that $\forall k : z_k = 0$. Then let us define $c = \frac{2\tau\omega^2}{n(2\delta+1)} \in (0, 1)$,

$$\mathbf{E} \left[f(x_{k+1}) - f^* + \frac{1}{2\omega_k} \|x_{k+1} - \bar{x}_{k+1}\|_W^2 \right] \leq (1 - c) \left(f(x_k) - f^* + \frac{1}{2\omega_k} \|x_k - \bar{x}_k\|_W^2 \right). \quad (62)$$

Therefore,

$$\begin{aligned} \mathbf{E}[f(x_k) - f^*] &\leq \mathbf{E} \left[f(x_k) - f^* + \frac{1}{2\omega_k} \|x_k - \bar{x}_k\|_W^2 \right] \\ &\stackrel{(62)}{\leq} (1 - c)^k \left(f(x_0) - f^* + \frac{1}{2\omega_0} \|x_0 - \bar{x}_0\|_W^2 \right). \end{aligned}$$

Appendix E. Proof of Theorem 13 if $z_k \neq 0$

The proof follows similar arguments to the proof of Theorem 13 when $z_k = 0$. Let us define an auxiliary vector \tilde{x} in the same way as in (51). Then we can see that if coordinates \mathcal{I} is chosen during iteration k in Algorithm 1 then (52) holds. Therefore, let us estimate the expected value of f at a random point x_{k+1} , where the expectation is taken with respect to the selection of coordinate i at iteration k . Let $h \in \mathbb{R}^n$. Then if $\frac{1}{\omega_k} \geq \max_{i \in \mathcal{I}_k} \frac{L_i}{\omega_i}$ we have that (53) holds. Now, observe that

$$\begin{aligned} \tilde{x} &= x_k + \arg \min_{h: x_k + h \in X} \mathcal{H}(h; x_k, z_k) \\ &= x_k + \arg \min_{h \in \mathbb{R}^n} \{ \mathcal{H}(h; x_k, z_k) + \Phi_X(h + x_k) \} =: x_k + \hat{h}, \end{aligned} \quad (63)$$

where $\Phi_X(x)$ is indicator function for set X , (55). Now, we have

$$\begin{aligned} \mathcal{H}(\hat{h}; x_k, z_k) &= \min_{h \in \mathbb{R}^n} \left\{ f(x_k) + \langle \nabla f(x_k) - z_k, h \rangle + \frac{1}{2\omega_k} \|h\|_W^2 + \Phi_X(h + x_k) \right\} \\ &= \min_{y \in \mathbb{R}^n} \left\{ f(x_k) + \langle \nabla f(x_k) - z_k, y - x_k \rangle + \frac{1}{2\omega_k} \|y - x_k\|_W^2 + \Phi_X(y) \right\} \\ &\leq \min_{\lambda \in [0, 1]} \left\{ f(\lambda \bar{x}_k + (1 - \lambda)x_k) + \langle -z_k, \lambda(\bar{x}_k - x_k) \rangle \right. \\ &\quad \left. + \frac{1}{2\omega_k} \|\lambda(\bar{x}_k - x_k)\|_W^2 + \Phi_X(\lambda(\bar{x}_k - x_k) + x_k) \right\} \\ &\leq \min_{\lambda \in [0, 1]} \left\{ \lambda f(x_k) + (1 - \lambda)f(x_k) + \lambda \|z_k\|_W^* \|\bar{x}_k - x_k\|_W + \frac{\lambda^2}{2\omega_k} \|\bar{x}_k - x_k\|_W^2 \right\}. \end{aligned}$$

Note that from (52) and (63) we have

$$\|\hat{h}\|_W^2 = \sum_{i=1}^n \|\hat{h}_i\|_i^2 = \frac{n}{\tau} \mathbf{E} \|x_{k+1} - x_k\|_W^2 \stackrel{(20)}{\leq} \frac{n}{\zeta \tau} \mathbf{E}[f(x_k) - f(x_{k+1})]. \quad (64)$$

Therefore, we conclude that

$$\begin{aligned} \mathbf{E}[f(x_{k+1}) - f^*] &\stackrel{(53), (19)}{\leq} \min_{\lambda \in [0,1]} \left\{ f(x_k) - f^* + \frac{\tau}{n} \left(\lambda (f(\bar{x}_k) - f(x_k)) + \lambda \|z_k\|_{W^*}^* \|\bar{x}_k - x_k\|_W \right) \right. \\ &\quad \left. + \frac{\lambda^2}{2\omega_k} \|\bar{x}_k - x_k\|_W^2 + \|z_k\|_W^2 \|\hat{h}\|_W \right\} \\ &\stackrel{(5)}{\leq} \min_{\lambda \in [0,1]} \left\{ f(x_k) - f^* + \frac{\tau}{n} \left(-\lambda (f(x_k) - f^*) + \lambda \|z_k\|_{W^*}^* \|\bar{x}_k - x_k\|_W \right) \right. \\ &\quad \left. + \frac{\lambda^2}{2\omega_k \kappa_f} (f(x_k) - f^*) + \|z_k\|_W \|\hat{h}\|_W \right\}. \end{aligned} \quad (65)$$

Now, let us denote by $\xi_k = f(x_k) - f^*$. Notice that

$$\left(\|z_k\|_{W^*}^* \right)^2 = \sum_{i=1}^n \left(\|z_k\|_{W^*}^* \right)^2 \stackrel{(19), (20)}{\leq} \frac{\beta^2}{n \zeta} (\xi_k - \mathbf{E}[\xi_{k+1}]) \quad (65)$$

where the expectation is with respect to the random choice i during the k -th iteration. Therefore we have

$$\begin{aligned} \mathbf{E}[\xi_{k+1}] &\leq \min_{\lambda \in [0,1]} \left\{ \xi_k + \frac{\tau}{n} \left(-\lambda \xi_k + \lambda \|z_k\|_{W^*}^* \|\bar{x}_k - x_k\|_W + \frac{\lambda^2}{2\omega_k \kappa_f} \xi_k + \|z_k\|_{W^*}^* \|\hat{h}\|_W \right) \right\} \\ &\stackrel{(65), (64)}{\leq} \min_{\lambda \in [0,1]} \left\{ \xi_k + \frac{\tau}{n} \left(-\lambda \xi_k + \lambda \|z_k\|_{W^*}^* \|\bar{x}_k - x_k\|_W \right) \right. \\ &\quad \left. + \frac{\lambda^2}{2\omega_k \kappa_f} \xi_k + \frac{n\beta}{\zeta \sqrt{\tau}} (\xi_k - \mathbf{E}[\xi_{k+1}]) \right\} \end{aligned}$$

which is equivalent to

$$\begin{aligned} \left(1 + \frac{\sqrt{\tau}\beta}{\zeta}\right) \mathbf{E}[\xi_{k+1}] &\leq \left(1 + \frac{\sqrt{\tau}\beta}{\zeta}\right) \xi_k + \min_{\lambda \in [0,1]} \left\{ -\frac{\tau}{n} \lambda \xi_k + \frac{\tau}{n} \lambda \|z_k\|_{W^*}^* \|\bar{x}_k - x_k\|_W + \frac{\tau}{n} \frac{\lambda^2}{2\omega_k \kappa_f} \xi_k \right\} \\ &\stackrel{(65), (5)}{\leq} \left(1 + \frac{\sqrt{\tau}\beta}{\zeta}\right) \xi_k + \min_{\lambda \in [0,1]} \left\{ -\frac{\tau}{n} \lambda \xi_k + \frac{\tau}{n} \lambda \sqrt{n \frac{\beta^2}{\zeta} (\xi_k - \mathbf{E}[\xi_{k+1}])} \sqrt{\frac{1}{\kappa_f^2} \xi_k + \frac{\tau}{n} \frac{\lambda^2}{2\omega_k \kappa_f} \xi_k} \right\}. \end{aligned}$$

Using the fact that $\forall a, b \in \mathbb{R}_+$, we have $\sqrt{ab} \leq \frac{1}{2}a + \frac{1}{2}b$ we obtain that

$$\begin{aligned} &\left(1 + \frac{\sqrt{\tau}\beta}{\zeta}\right) \mathbf{E}[\xi_{k+1}] \\ &\leq \left(1 + \frac{\sqrt{\tau}\beta}{\zeta}\right) \xi_k + \min_{\lambda \in [0,1]} \left\{ -\frac{\tau}{n} \lambda \xi_k + \sqrt{\frac{\beta^2}{\zeta} (\xi_k - \mathbf{E}[\xi_{k+1}])} \sqrt{\frac{\lambda^2}{n \kappa_f^2} \xi_k + \frac{\tau}{n} \frac{\lambda^2}{2\omega_k \kappa_f} \xi_k} \right\} \\ &\leq \left(1 + \frac{\sqrt{\tau}\beta}{\zeta}\right) \xi_k + \min_{\lambda \in [0,1]} \left\{ -\frac{\tau}{n} \lambda \xi_k + \frac{\beta^2}{2\zeta} (\xi_k - \mathbf{E}[\xi_{k+1}]) + \frac{1}{2} \frac{\lambda^2}{n \kappa_f} \xi_k + \frac{\tau}{n} \frac{\lambda^2}{2\omega_k \kappa_f} \xi_k \right\}. \end{aligned}$$

Therefore, we obtain

$$\left(1 + \frac{\sqrt{\tau}\beta}{\zeta} + \frac{\beta^2}{2\zeta}\right) \mathbf{E}[\xi_{k+1}] \leq \left(1 + \frac{\sqrt{\tau}\beta}{\zeta} + \frac{\beta^2}{2\zeta}\right) \xi_k + \frac{\tau}{n\omega_k \kappa_f} \min_{\lambda \in [0,1]} \left\{ -\lambda \omega_k \kappa_f + \frac{\tau}{2} (1 + \omega\tau) \right\} \xi_k. \quad (66)$$

The optimal λ^* that minimizes the above expression is

$$\lambda^* = \min \left\{ 1, \frac{\omega_k \kappa_f}{\omega\tau + 1} \right\}.$$

Consider now two cases:

- $\lambda^* < 1$. In this case

$$-\lambda^* \omega_k \kappa_f + \frac{(\lambda^*)^2}{2} (1 + \omega\tau) = -\frac{1}{2} \frac{(\omega_k \kappa_f)^2}{\omega\tau + 1}.$$

Combining this with (66) gives

$$\left(1 + \frac{\sqrt{\tau}\beta}{\zeta} + \frac{\beta^2}{2\zeta}\right) \mathbf{E}[\xi_{k+1}] \leq \left(1 + \frac{\sqrt{\tau}\beta}{\zeta} + \frac{\beta^2}{2\zeta} - \frac{1}{2n} \frac{\omega_k \kappa_f}{\omega\tau + 1}\right) \xi_k,$$

which is equivalent to

$$\mathbf{E}[\xi_{k+1}] \leq \left(1 - \frac{1}{2n} \frac{2\omega_k \kappa_f \zeta}{(\omega\tau + 1)(2\zeta + 2\beta\sqrt{\tau} + \beta)}\right) \xi_k.$$

- $\lambda^* = 1$. In this case $\frac{\omega_k \kappa_f}{\omega\tau + 1} \geq 1$ and hence

$$-\lambda^* \omega_k \kappa_f + \frac{(\lambda^*)^2}{2} (1 + \omega\tau) = -\omega_k \kappa_f + \frac{1}{2} (1 + \omega\tau) \leq -\omega_k \kappa_f + \frac{1}{2} \omega_k \kappa_f = -\frac{1}{2} \omega_k \kappa_f.$$

Therefore, from (66) we can conclude that

$$\mathbf{E}[\xi_{k+1}] \leq \left(1 - \frac{\zeta\tau}{n(2\zeta + 2\beta\sqrt{\tau} + 1 + \beta^2)}\right) \xi_k.$$

Abstract

We introduce a novel scheme for choosing the regularization parameter in high-dimensional linear regression with Lasso. This scheme, inspired by Lepski's method for bandwidth selection in non-parametric regression, is equipped with both optimal finite-sample guarantees and a fast algorithm. In particular, for any design matrix such that the Lasso has low sup-norm error under an "oracle choice" of the regularization parameter, we show that our method matches the oracle performance up to a small constant factor, and show that it can be implemented by performing simple tests along a single Lasso path. By applying the Lasso to simulated and real data, we find that our novel scheme can be faster and more accurate than standard schemes such as Cross-Validation.

Keywords: Lasso, regularization parameter, tuning parameter, high-dimensional regression, oracle inequalities

1. Introduction

Regularized estimators—among them the Lasso (Tibshirani, 1996), the Square-Root and the Scaled Lasso (Antoniadis, 2010; Belloni et al., 2011; Städler et al., 2010; Sun and Zhang, 2012), as well as estimators based on nonconvex penalties such as MCP (Zhang, 2010) and SCAD (Fan and Li, 2001)—all hinge on finding a "suitable" choice of tuning parameters. There are many possible methods for solving this so-called calibration problem, but for high-dimensional regression problems, there is not a single method that is computationally tractable and for which the non-asymptotic theory is well understood.

The focus of this paper is the calibration of the Lasso for sparse linear regression, where the tuning parameter needs to be adjusted to both the noise distribution and the

design matrix (van de Geer and Lederer, 2013; Hebiri and Lederer, 2013; Dalalyan et al., 2014). Calibration schemes for this setting are typically based on Cross-Validation (CV) or BIC-type criteria. However, CV-based procedures can be computationally intensive and are currently lacking in non-asymptotic theory for high-dimensional problems. BIC-type criteria, on the other hand, are computationally simpler but also lacking in non-asymptotic guarantees. Another approach is to replace the Lasso with Square-Root Lasso or TREX (Lederer and Müller, 2015); however, Square-Root Lasso still contains a tuning parameter that needs to be calibrated to certain aspects of the model, and the theory for TREX is currently fragmentary. For these reasons and given the extensive use of the Lasso in practice, understanding the calibration of Lasso is important.

In this paper, we introduce a new scheme for calibrating the Lasso in the supremum norm (ℓ_∞)-loss, which we refer to as *Adaptive Validation for ℓ_∞* (AV_∞). This method is based on tests that are inspired by Lepski's method for non-parametric regression (Lepski, 1990; Lepski et al., 1997); see also Chichignoud and Lederer (2014). In contrast to current schemes for the Lasso, our method is equipped with both optimal theoretical guarantees and a fast computational routine.

The remainder of this paper is organized as follows. In Section 2, we introduce the AV_∞ method. Our main theoretical results show that this method enjoys finite sample guarantees for the calibration of Lasso with respect to sup-norm loss (Theorem 3) and variable selection (Remark 4). In addition, we provide a simple and fast algorithm (Algorithm 1). In Section 3, we illustrate these features with applications to simulated data and to biological data. We conclude with a discussion in Section 4.

Notation: The indicator of events is denoted by $\mathbb{1}\{\cdot\} \in \{0, 1\}$, the cardinality of sets by $|\cdot|$, the sup-norm or maximum norm of vectors in \mathbb{R}^p vectors by $\|\cdot\|_\infty$, the number of non-zero entries by $\|\cdot\|_0$, the ℓ_1 - and ℓ_2 -norms by $\|\cdot\|_1$ and $\|\cdot\|_2$, respectively, and $[p] := \{1, \dots, p\}$. For given vector $\beta \in \mathbb{R}^p$ and subset A of $[p]$, $\beta_A \in \mathbb{R}^{|A|}$ and $\beta_{A^c} \in \mathbb{R}^{|A^c|}$ denote the components in A and in its complement A^c , respectively.

2. Background and Methodology

In this section, we introduce some background and then move onto a description of the AV_∞ method.

2.1 Framework

We study the calibration of the Lasso tuning parameter in high-dimensional linear regression models that can contain many predictors and allow for the possibility of correlated and heavy-tailed noise. More specifically, we assume that the data (Y, X) with outcome $Y \in \mathbb{R}^n$ and design matrix $X \in \mathbb{R}^{n \times p}$ is distributed according to a linear regression model

$$Y = X\beta^* + \varepsilon, \tag{Model}$$

where $\beta^* \in \mathbb{R}^p$ is the regression vector and $\varepsilon \in \mathbb{R}^n$ is a random noise vector. Our framework allows for p larger than n and requires that the noise variables ε satisfy only the second moment condition

$$\max_{i \in \{1, \dots, n\}} \mathbb{E}[\varepsilon_i^2] < \infty. \tag{1}$$

* Corresponding author. Postal address: Department of Statistics at University of Washington, Box 354322, Seattle, WA 98195

A standard approach for estimating β^* in such a model is by computing the l_1 -regularized least-squares estimate, known as the Lasso, and given by

$$\hat{\beta}_\lambda \in \underset{\beta \in \mathbb{R}^p}{\operatorname{arg\,min}} \left\{ \frac{\|Y - X\beta\|_2^2}{n} + \lambda \|\beta\|_1 \right\}. \quad (\text{Lasso})$$

Note that this equation actually defines a family of estimators indexed by the tuning parameter $\lambda > 0$, which determines the level of regularization.

Intuitively, the optimal choice of λ is dictated by a trade-off between bias and some form of variance control. Bias is induced by the shrinkage effect of the l_1 -regularizer, which acts even on non-zero coordinates of the regression vector. Thus, the bias grows as λ is increased. On the other hand, l_1 -regularization is useful in canceling out fluctuations in the score function, which for the linear regression model is given by $X^\top \varepsilon/n$. Thus, an optimal choice of λ is the smallest one that is large enough to control these fluctuations.

A large body of theoretical work (e.g., van de Geer and Bühlmann (2009); Büchel et al. (2009); Bühlmann and van de Geer (2011); Negahban et al. (2012)) has shown that an appropriate formalization of this intuition is based on the event

$$\mathcal{T}_\lambda := \left\{ \frac{\|X^\top \varepsilon\|_\infty}{n} \leq \frac{\lambda}{4} \right\}. \quad (2)$$

When this event holds, then as long as the design matrix X is “well-behaved”, it is possible to obtain bounds on the sup-norm error of the Lasso estimate. There are various ways of characterizing well-behaved design matrices; of most relevance for sup-norm error control are mutual incoherence conditions (Bunea, 2008; Lounici, 2008) as well as ℓ_∞ -restricted eigenvalues (Ye and Zhang, 2010). See van de Geer and Bühlmann (2009) and Section 2.3 for further discussion of these design conditions.

In order to bring sharp focus to the calibration problem, rather than focusing on any particular design condition, it is useful to instead work under the generic assumption that the Lasso sup-norm error is controlled under the event \mathcal{T}_λ defined in equation (2). More formally, we state:

Assumption 1 ($\ell_\infty(C)$) *There is a numerical constant C such that conditional on \mathcal{T}_λ , the Lasso ℓ_∞ -error is upper bounded as $\|\hat{\beta}_\lambda - \beta^*\|_\infty \leq C\lambda$.*

As mentioned above, there are many conditions on the design matrix X under which Assumption $\ell_\infty(C)$ is valid, and we consider a number of them in the sequel.

With this set-up in place, we can now focus specifically on how to choose the regularization parameter. Since we can handle only finitely many tuning parameters in practice, we restrict ourselves to the selection of a tuning parameter among a finite but arbitrarily large number of choices. It is easy to see that $\lambda_{\max} := 2\|X^\top Y\|_\infty/n$ is the smallest tuning parameter for which $\hat{\beta}_\lambda$ equals zero. Accordingly, for a given positive integer $N \in \mathbb{N}$, let us form the grid

$$0 < \lambda_1 < \dots < \lambda_N = \lambda_{\max},$$

denoted by $\Lambda := \{\lambda_1, \dots, \lambda_N\}$ for short. Assumption $\ell_\infty(C)$ guarantees that the sup-norm error is proportional to λ whenever the event \mathcal{T}_λ holds; consequently, for a given probability

of error $\delta \in (0, 1)$, it is natural to choose the smallest λ for which event \mathcal{T}_λ holds with probability at least $1 - \delta$, assuming that it is finite. This criterion can be formalized as follows:

Definition 1 (Oracle tuning parameter) *For any constant $\delta \in (0, 1)$, the oracle tuning parameter is given by*

$$\lambda_\delta^* := \arg \min_{\lambda \in \Lambda} \{\mathbb{P}(\mathcal{T}_\lambda) \geq 1 - \delta\}. \quad (3)$$

Note that by construction, if we solve the Lasso using the oracle choice λ_δ^* , and if the design matrix X fulfills Assumption $\ell_\infty(C)$, then the resulting estimate satisfies the bound $\|\hat{\beta}_{\lambda_\delta^*} - \beta^*\|_\infty \leq C\lambda_\delta^*$ with probability at least $1 - \delta$. Unfortunately, the oracle choice is inaccessible to us, since we cannot compute the probability of the event \mathcal{T}_λ based on the observed data. However, as we now describe, we can mimic this performance, up to a factor of three, using a simple data-dependent procedure.

2.2 Adaptive Calibration Scheme

Let us now describe a data-dependent scheme for choosing the regularization parameter, referred to as Adaptive Calibration for ℓ_∞ (AV_∞):

Definition 2 (AV_∞) *Under Assumption $\ell_\infty(C)$ and for a given constant $\bar{C} \geq C$, Adaptive Calibration for ℓ_∞ (AV_∞) selects the tuning parameter*

$$\hat{\lambda} := \min \left\{ \lambda \in \Lambda \mid \max_{\substack{X, X' \in \Lambda \\ X, X' \geq \lambda}} \left[\frac{\|\hat{\beta}_X - \hat{\beta}_{X'}\|_\infty}{\lambda + \lambda'} - \bar{C} \right] \leq 0 \right\}. \quad (4)$$

The definition is based on tests for sup-norm differences of Lasso estimates with different tuning parameters. We stress that Definition 2 requires neither prior knowledge about the regression vector nor about the noise.

The tests in Definition 2 can be formulated in terms of the binary random variables

$$\hat{\tau}_{\lambda_j} := \prod_{k=j}^N \mathbb{1} \left\{ \frac{\|\hat{\beta}_{\lambda_j} - \hat{\beta}_{\lambda_k}\|_\infty}{\lambda_j + \lambda_k} - \bar{C} \leq 0 \right\} \quad \text{for } j \in [N],$$

from the AV_∞ tuning parameter $\hat{\lambda}$ can be computed as follows:

Data: $\hat{\beta}_{\lambda_1}, \dots, \hat{\beta}_{\lambda_N}, \bar{C}$
Result: $\hat{\lambda} \in \Lambda$

Set initial index: $j \leftarrow N$

while $\hat{\tau}_{\lambda_{j-1}} \neq 0$ **and** $j > 1$ **do**
 | Update index: $j \leftarrow j - 1$
end

Set output: $\hat{\lambda} \leftarrow \lambda_j$

Algorithm 1: Algorithm for AV_∞ in Definition 2.

This algorithm can be readily implemented and only requires the computation of one Lasso solution path. In strong contrast, k -fold Cross-Validation requires the computation of k solution paths. Consequently, the Lasso with AV_∞ can be computed about k times faster than Lasso with k -fold Cross-Validation.

The following result guarantees that the Lasso with AV_∞ method achieves the sup-norm error up to a constant pre-factor:

Theorem 3 (Optimality of AV_∞) *Suppose that condition $\ell_\infty(C)$ holds and the AV_∞ method is implemented with parameter $\bar{C} \geq C$. Then for any $\delta \in (0, 1)$, the AV_∞ output pair $(\hat{\lambda}, \hat{\beta}_\lambda)$ given by the rule (4) satisfies the bounds*

$$\hat{\lambda} \leq \lambda_\delta^* \quad \text{and} \quad \|\hat{\beta}_\lambda - \beta^*\|_\infty \leq 3\bar{C}\lambda_\delta^* \quad (5)$$

with probability at least $1 - \delta$.

Remark 4 (Relevance for estimation and variable selection) *The ℓ_∞ -bound from equation (5) directly implies that the AV_∞ scheme is adaptively optimal for the estimation of the regression vector β^* in ℓ_∞ -loss. As another important feature, Theorem 3 entails strong variable selection guarantees. First, the ℓ_∞ -bound implies that AV_∞ recovers all non-zero entries of the regression vector β^* that are larger than $3\bar{C}\lambda_\delta^*$ in absolute value. Additionally, by virtue of the bound $\hat{\lambda} \leq \lambda_\delta^*$, thresholding $\hat{\beta}_\lambda$ by $3\bar{C}\hat{\lambda}$ leads to exact support recovery if all non-zero entries of β^* are larger than $6\bar{C}\lambda_\delta^*$ in absolute value. In strong contrast, standard calibration schemes are not equipped with comparable variable selection guarantees, and there is no theoretically sound guidance for how to threshold standard schemes.*

We prove Theorem 3 in Appendix A; here let us make a few remarks about its consequences. First, if we knew the oracle value λ_δ^* defined in equation (3), then under Assumption $\ell_\infty(C)$, the Lasso estimate $\hat{\beta}$ would satisfy the ℓ_∞ -bound $\|\hat{\beta} - \beta^*\|_\infty \leq C\lambda_\delta^*$. Consequently, when the AV_∞ method is implemented with parameter C , then its sup-norm error is optimal up to a factor of three. For standard calibration schemes, among them Cross-Validation, no comparable guarantees are available in the literature. In fact, we are not aware of any finite sample guarantees for standard calibration schemes.

We point out that Theorem 3—in contrast to asymptotic results or results with unspecified constants—provides explicit guarantees for arbitrary sample sizes. Moreover, Theorem 3 does not presume prior knowledge about the regression vector or the noise distribution and allows, in particular, for correlated, heavy-tailed noise. From the perspective of theoretical sharpness, the best choice for \bar{C} is $\bar{C} = C$. However, Theorem 3 shows that it also suffices to know an upper bound for C . We provide more details on choices of C and \bar{C} below.

We finally observe that the specific choice of the grid enters Theorem 3 only via the oracle. Indeed, for any choice of the grid, Theorem 3 ensures that $\hat{\lambda}$ performs as well as the oracle tuning parameter λ_δ^* , which is the “best” tuning parameter on the grid.

2.3 Conditions on the Design Matrix for ℓ_∞ -guarantees

Let us now describe some conditions on the design matrix X that are sufficient for Assumption $\ell_\infty(C)$. We stress that these are conditions to ensure that the Lasso satisfies

ℓ_∞ -bounds; importantly, our method itself does not impose any additional restrictions. We defer all proofs of the results stated here to Appendix B and, for simplicity, we assume in the following that the sample covariance $\hat{\Sigma} := X^\top X/n$ has been normalized such that $\hat{\Sigma}_{jj} = 1$ for all $j \in [p]$.

The significance of the event \mathcal{T}_λ lies in the following implication: when \mathcal{T}_λ holds, then it can be shown (e.g., Bickel et al. (2009); Bühlmann and van de Geer (2011); Negahban et al. (2012)) that the Lasso error $\hat{\Delta} := \hat{\beta}_\lambda - \beta^*$ must belong to the cone

$$\mathcal{C}(S) := \{\Delta \in \mathbb{R}^p \mid \|\Delta_{S^c}\|_1 \leq 2\|\Delta_S\|_1\}, \quad (6)$$

where S denotes the support of β^* , and S^c its complement. Accordingly, all known conditions involve controlling the behavior of the sample covariance matrix $\hat{\Sigma}$ for vectors lying within this cone.

The most directly stated sufficient condition is based on lower bounding the ℓ_∞ -restricted eigenvalue: there exists some $\gamma > 0$ such that

$$\|\hat{\Sigma}\Delta\|_\infty \geq \gamma\|\Delta\|_\infty \quad \text{for all } \Delta \in \mathcal{C}(S). \quad (7)$$

See van de Geer and Bühlmann (2009) for an overview of various conditions for the Lasso, and their relations. Based on (7), we prove in Appendix B.1 the following result:

Lemma 5 (ℓ_∞ -restricted eigenvalue) *Suppose that $\hat{\Sigma}$ satisfies the γ -RE condition (7) and that \mathcal{T}_λ holds. Then Assumption $\ell_\infty(C)$ is valid with $C = \frac{5}{4\gamma}$.*

Although this result is cleanly stated, the RE condition cannot be verified in practice, since it involves the unknown support set S . Accordingly, let us now state some sufficient and verifiable conditions for obtaining bounds on the restricted eigenvalues, and hence for verifying Assumption $\ell_\infty(C)$.

For a given integer $\tilde{s} \in [2, p]$ and scalar $\nu > 0$, let us say that the sample covariance $\hat{\Sigma}$ is diagonally dominant with parameters (\tilde{s}, ν) if

$$\max_{\substack{T \subset [p] \\ |T| = \tilde{s}}} \sum_{k \in T} |\hat{\Sigma}_{jk}| < \nu \quad \text{for all } j \in [p]. \quad (8)$$

In the context of this definition, the reader should recall that we have assumed that $\hat{\Sigma}_{jj} = 1$ for all $j \in [p]$. Note that this condition can be verified in polynomial-time, since the subset T achieving the maximum in row j can be obtained simply by sorting the entries $\{|\hat{\Sigma}_{jk}|, k \in [p] \setminus j\}$. The significance of this condition lies in the following result:

Lemma 6 (Diagonal dominance of order \tilde{s}) *Suppose that $\tilde{s} \geq 9|S|$ and $\hat{\Sigma}$ is \tilde{s} -order diagonally dominant with parameter $\nu \in [0, 1)$. Then under the event \mathcal{T}_λ , Assumption $\ell_\infty(C)$ is valid with $C = \frac{5}{4(1-\nu)}$.*

See Appendix B.2 for the proof.

It is worth noting that the diagonal dominance condition is weaker than the pairwise incoherence conditions that have been used in past work on sup-norm error (Lounici, 2008). The pairwise incoherence of the sample covariance is given by $\rho(\hat{\Sigma}) = \max_{j \neq k} |\hat{\Sigma}_{jk}|$. If the pairwise incoherence satisfies the bound $\rho(\hat{\Sigma}) \leq \nu/\tilde{s}$, then it follows that $\hat{\Sigma}$ is diagonally dominant with parameters (\tilde{s}, ν) .

By combining Lemma 6 with Theorem 3, we obtain the following corollary:

Corollary 7 Suppose that $\tilde{s} \geq 9|S|$ and $\tilde{\Sigma}$ is \tilde{s} -order diagonally dominant with parameter $\nu \in [0, 1)$. Then for any $\delta \in (0, 1)$, the AV_∞ method with $C = \frac{5}{4(1-\nu)}$ returns an estimate $\hat{\beta}_\lambda$ such that

$$\|\hat{\beta}_\lambda - \beta^*\|_\infty \leq \frac{15}{4(1-\nu)} \lambda_s^* \quad (9)$$

with probability at least $1 - \delta$.

Another sufficient condition for the sup-norm optimality of AV_∞ is a design compatibility condition due to van de Geer (2007). For each index $j \in [p]$, suppose that we define the deterministic vector

$$\eta^j \in \arg \min_{\substack{\beta \in \mathbb{R}^p \\ \beta_j = -1}} \left\{ \frac{\|X\beta\|_2^2}{n} + \sqrt{\frac{\log(p)}{n}} \|\beta\|_1 \right\}.$$

Note that this optimization problem defining the vector regression of the j th column of the design matrix on the set of all other columns, where we have imposed an l_1 -penalty with weight $\sqrt{\frac{\log(p)}{n}}$. We can then derive the following sup-norm bound for the Lasso.

Lemma 8 (Lasso bound under compatibility) Assume that X fulfills the compatibility condition

$$\min_{\|\beta^s\|_1 \leq 3\|\beta^s\|_1} \left\{ \frac{\sqrt{|S|} \|X\beta\|_2}{\sqrt{n} \|\beta^s\|_1} \right\} \geq t \quad (\text{Compatibility})$$

for a constant $t > 0$. Additionally, assume that

$$\sup_{j \in [p]} \frac{|S|}{t^2 \|\eta^j\|_1} \leq \frac{1}{\log n} \sqrt{\frac{n}{\log p}}.$$

Then under the event \mathcal{F}_λ , Assumption $\ell_\infty(C)$ is valid with

$$C := \left(\frac{3}{4} + \frac{1}{\log(n)} \right) \max_{j \in [p]} \frac{\|\eta^j\|_2 / n + \sqrt{\log(p)/n} \|\eta^j\|_1^{-j/2}}{\|\eta^j\|_1}.$$

This bound is a consequence of results in (van de Geer, 2014); the proof is deferred to Section B.3. We are now ready to state the optimality of AV_∞ with respect to this bound.

Corollary 9 (Optimality of AV_∞) Assume that the assumptions in Lemma 8 are met. Then for any constant $\delta > 0$, the following bound for Lasso AV_∞ with $\bar{C} = C$, and C as above, holds with probability at least $1 - \delta$:

$$\|\hat{\beta}_\lambda - \beta^*\|_\infty \leq 3C\lambda_s^* \quad (10)$$

This result demonstrates the optimality of AV_∞ for sup-norm loss under the compatibility condition.

Remark 10 (Constant \bar{C} in practice) The optimal choice is $\bar{C} = C$ in view of our theoretical results. The constant C (or an upper bound of it) can be readily computed, because it depends only on X (cf. Lemma 8) or on X and an upper bound on s (cf. Lemma 6). However, we propose the universal choice $C = 0.75$ for all practical purposes. Note that accurate support recovery and ℓ_∞ -estimation is possible only if the design is near orthogonal. A direct computation yields the bound $\|\beta_\lambda - \beta^*\|_\infty \leq C\lambda$ with $C = 0.75$ for orthogonal design. Letting $\alpha \rightarrow \infty$ in Theorem 1 due to Lounici (2008) yields the same bound with $C \approx 0.75$ for near orthogonal designs. This provides strong theoretical support for the choice $\bar{C} = 0.75$. The empirical evidence in Section 3 indicates that a further calibration is indeed not necessary.

3. Simulations

In this section, we perform experiments on both simulated and real data to demonstrate the practical performance of AV_∞ .

3.1 Simulated Data

We simulate data from linear regression models as in equation (Model) with $n = 200$ observations and $p \in \{300, 900\}$ parameters. More specifically, we sample each row of the design matrix $X \in \mathbb{R}^{n \times p}$ from a p -dimensional normal distribution with mean 0 and covariance matrix $(1 - \kappa)I + \kappa\mathbb{1}$, where I is the identity matrix, $\mathbb{1} := (1, \dots, 1)^T (1, \dots, 1)$ is the matrix of ones, and $\kappa \in \{0, 0.2, 0.4\}$ is the magnitude of the mutual correlations. For the entries of the noise $\varepsilon \in \mathbb{R}^n$, we take the one-dimensional normal distribution with mean 0 and variance 1. The entries of β^* are first set to 0 except for 6 uniformly at random chosen entries that are each set to 1 or -1 with equal probability. The entire vector β^* is then rescaled such that the signal-to-noise ratio $\|X\beta^*\|_2^2/n$ is equal to 5. We finally consider a grid of 100 tuning parameters $\lambda := \{\lambda_{\max}/1.3^0, \lambda_{\max}/1.3^1, \dots, \lambda_{\max}/1.3^{99}\}$ with $\lambda_{\max} := 2\|X^T Y\|_\infty/n$. We run 100 experiments for each set of parameters and report the corresponding means (thick, colored bars) and standard deviations (thin, black lines). All computations are conducted with the software R (R Core Team, 2013) and the glmnet package (Friedman et al., 2010). While we restrict the presentation to the parameter settings described, we found similar results over a wide range of settings.

We compare the sup-norm and variable selection performance of the following three procedures:

- Oracle: Lasso with the tuning parameter that minimizes the ℓ_∞ loss (this tuning parameter is unknown in practice);
- AV_∞ : Lasso with AV_∞ and $\bar{C} = 0.75$;
- Cross-Validation: Lasso with 10-fold Cross-Validation.

Our choice $\bar{C} = 0.75$ is motivated by a theorem due to Lounici (2008) in the regime $\alpha \rightarrow \infty$; see Remark 10 for details.

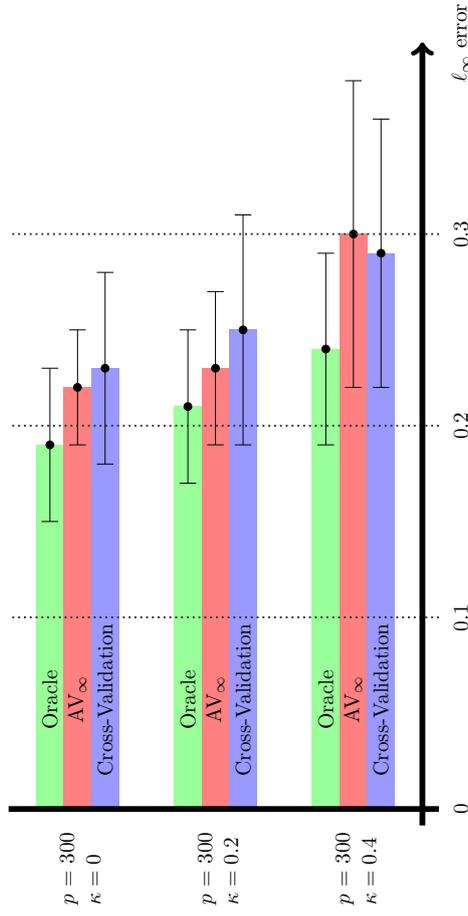

Figure 1: Sup-norm error $\|\hat{\beta}_\lambda - \beta^*\|_\infty$ of the Lasso with three different calibration schemes for the tuning parameter λ . Depicted are the results for three simulation settings that differ in the correlation level κ . The simulation settings and the calibration schemes are specified in the body of the text.

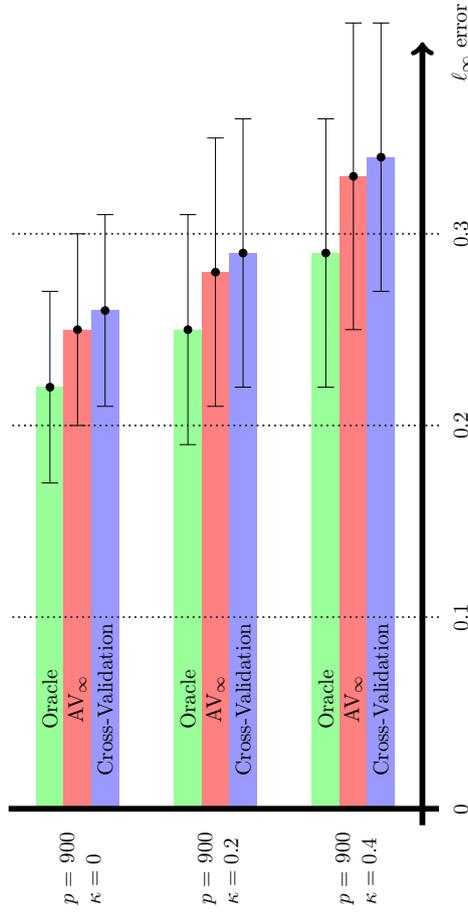

Figure 2: Sup-norm error $\|\hat{\beta}_\lambda - \beta^*\|_\infty$ of the Lasso with three different calibration schemes for the tuning parameter λ . Depicted are the results for three simulation settings that differ in the correlation level κ . The simulation settings and the calibration schemes are specified in the body of the text.

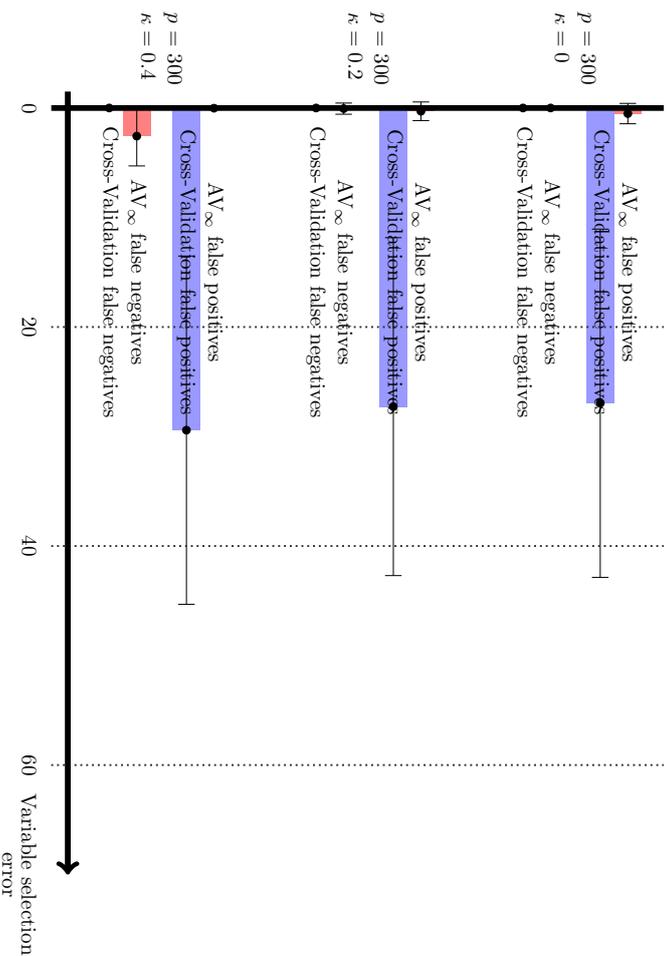

Figure 3: Number of false positives $\{|j : \beta_j^* = 0, (\hat{\beta}_\lambda)_j \neq 0\}$ and false negatives $\{|j : \beta_j^* \neq 0, (\hat{\beta}_\lambda)_j = 0\}$ of the Lasso with AV_∞ and Cross-Validation as calibration schemes for the tuning parameter λ . For AV_∞ , the safe threshold described after Theorem 3 is applied. The simulations settings correspond to those in Figure 1.

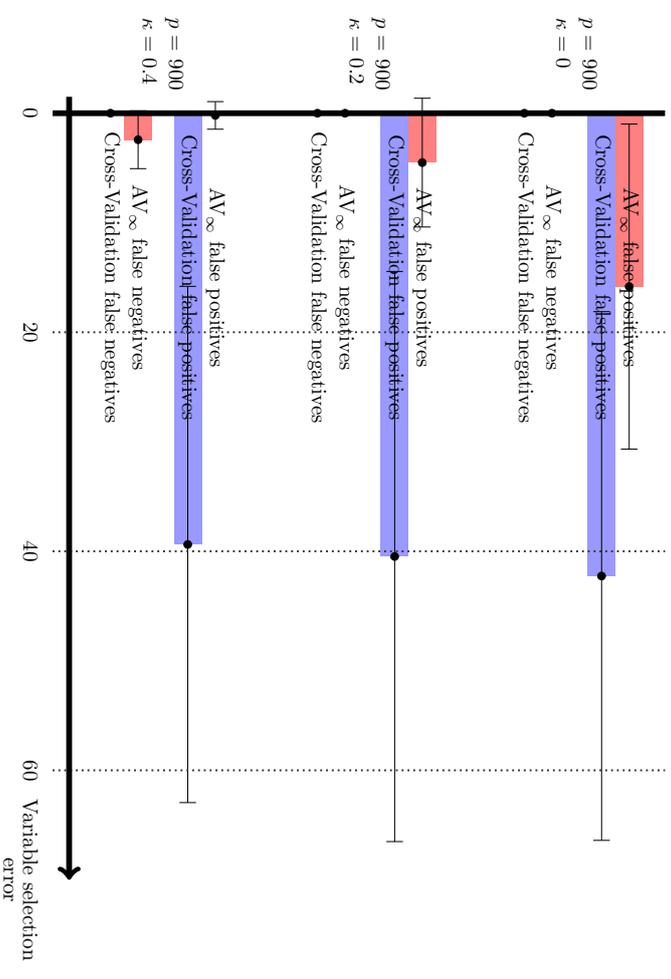

Figure 4: Number of false positives $\{|j : \beta_j^* = 0, (\hat{\beta}_\lambda)_j \neq 0\}$ and false negatives $\{|j : \beta_j^* \neq 0, (\hat{\beta}_\lambda)_j = 0\}$ of the Lasso with AV_∞ and Cross-Validation as calibration schemes for the tuning parameter λ . For AV_∞ , the safe threshold described after Theorem 3 is applied. The simulations settings correspond to those in Figure 2.

Sup-norm error: In Figures 1 and 2, we compare the ℓ_∞ error of the four procedures. We observe that AV_∞ outperforms Cross-Validation for most settings under consideration. We also mention that the same conclusions can be drawn if the normal distribution for the noise is replaced by other, possibly heavy-tailed distributions (for conciseness, we do not show the outputs).

Variable selection: In Figures 3 and 4, we compare the variable selection performance of AV_∞ and Cross-Validation. More specifically, we compare the number of false positives $\{|j : \beta_j^* = 0, (\hat{\beta}_\lambda)_j \neq 0\}$ and the number of false negatives $\{|j : \beta_j^* \neq 0, (\hat{\beta}_\lambda)_j = 0\}$. In contrast to Cross-Validation, AV_∞ allows for a safe threshold of size $3C\hat{\lambda}$ (recall the discussion after Theorem 3). Therefore, we report the results of Lasso with AV_∞ and an additional threshold of size $3C\hat{\lambda}$ applied to each component (that is, we consider the vector with entries $(\hat{\beta}_\lambda)_j \mathbb{1}\{|\hat{\beta}_\lambda|_j \geq 3C\hat{\lambda}\}$), and we report the results of Lasso with Cross-Validation (without threshold). We observe that, as compared to Cross-Validation, AV_∞ with subsequent thresholding can lead to a considerably smaller number of false positives, while keeping the number of false negatives on a low level. Note that one could perform a similar thresholding of the Cross-Validation solution, but unlike for AV_∞ , there is no theory to guide the choice of the threshold. This problem also applies to other standard calibration schemes.

Computational complexity: Cross-Validation with 10 folds requires the computation 10 Lasso paths, while AV_∞ requires the computation of only one Lasso path - or even less. AV_∞ is therefore about 10 times more efficient than 10-fold Cross-Validation.

Let us conclude with remarks on the scope of the simulations. First, many methods have been proposed for tuning the regularization parameter in the Lasso, including Cross-Validation, BIC and AIC-type criteria, Stability Selection (Meinshausen and Bühlmann, 2010), LinSelect (Baraud et al., 2014; Giraud et al., 2012), permutation approaches (Sabourin et al., 2015), and many more. On top of that, there are many modifications and extensions of the Lasso itself, including BoLasso (Bach, 2008), Square-Root/Scaled Lasso (Antoniadis, 2010; Belloni et al., 2011; Städler et al., 2010; Sun and Zhang, 2012), SCAD (Fan and Li, 2001), MCP (Zhang, 2010), and others. Detailed comparisons among the selection schemes and the methods can be found in the cited papers. We also refer to Leeb and Pötscher (2008) for theoretical insights about limitations of the methods.

In our simulations, we instead focus on the Lasso and, since we are not aware of guarantees similar to ours for any selection scheme, we compare to the most popular and most extensively studied selection scheme, Cross-Validation. This comparison shows that, beyond its theoretical properties and the easy and efficient implementation, AV_∞ is also a competitor in numerical experiments.

3.2 Riboflavin Production in *B. subtilis*

We now consider variable selection for a data set that describes the production of riboflavin (vitamin B₂) in *B. subtilis* (*Bacillus subtilis*), see (Bühlmann et al., 2014). The data set comprises the expressions of $p = 4088$ genes and the corresponding riboflavin production rates for $n = 71$ strains of *B. subtilis*. We apply AV_∞ and then impose the threshold $3C\hat{\lambda}$.

The resulting genes and the corresponding parameter values are given in the first column of Table 1. We see that these results commensurate with the results from previous

AV_∞	Stability Selection	B-TREX
YXLD_at -0.405	YXLD_at	YXLD_at
YOAB_at -0.420	YOAB_at	YOAB_at
YEBC_at -0.146	LYSC_at	YXLE_at
ARGF_at -0.313		
XHLB_at 0.278		

Table 1: Variable selection results for the riboflavin data set. The first column depicts the genes and the corresponding parameter values yielded by AV_∞ . The second and third column depict the genes returned by approaches based on Stability Selection and TREX.

approaches based on Stability Selection (Bühlmann et al., 2014) and TREX (Lederer and Müller, 2015), which are given in the third and fourth column.

4. Conclusions

We have introduced a novel method for sup-norm calibration, known as AV_∞ , that is equipped with finite sample guarantees for estimation in ℓ_∞ -loss and for variable selection. Moreover, we have shown that AV_∞ allows for simple and fast implementations. These properties make AV_∞ a competitive algorithm, as standard methods such as Cross-Validation are computationally more demanding and lack non-asymptotic guarantees.

In order to bring sharp focus to the issue, we have focused this paper exclusively on the calibration of the Lasso. However, we suspect that the methods and techniques developed here could be more generally applicable, for instance to problems with nonconvex penalties (e.g., SCAD, MCP). In particular, the paper (Loh and Wainwright, 2014) provides guarantees for ℓ_∞ -recovery using such nonconvex methods, which could be combined with our results. Another interesting direction for future work is the use of our methods for more general decomposable penalty functions (Negahban et al., 2012), including the nuclear norm that is often used in matrix estimation.

We also stress that our goals are ℓ_∞ -estimation and variable selection, which are feasible only under strict conditions on the design matrix. Other objectives, including prediction and ℓ_2 -estimation, can typically be achieved under less stringent conditions. However, the corresponding oracle inequalities contain quantities (such as the sparsity level) that are typically unknown in practice. Adaptations of our method to objectives beyond the ones considered here thus need further investigation. We refer to (Chételet et al., 2014) for ideas in this direction. However, there might be no approach that is uniformly optimal for all objectives, see also the papers (Yang, 2005; Zhao and Yu, 2006).

Finally, as pointed out by one of the reviewers, another field for further study is model misspecification. It would be interesting to see how robust the Lasso with the AV_∞ scheme is with respect to, for example, non-linearities in the model.

Acknowledgements

We thank Sara van de Geer and Sébastien Loustau for the inspiring discussions. We also thank the reviewers for the careful reading of the manuscript and the insightful comments. Appendix A. Proof of Theorem 1

Define the event $\mathcal{T}_\delta^* := \left\{ \frac{\|\mathbf{X}^\top \varepsilon\|_\infty}{n} \leq \frac{\lambda_\delta^*}{4} \right\}$ and note that $\mathbb{P}[\mathcal{T}_\delta^*] \geq 1 - \delta$ by our definition of the oracle tuning parameter in (3). Thus, it suffices to show that the two bounds hold conditioned on the event \mathcal{T}_δ^* .

Bound on $\hat{\lambda}$: To show that $\hat{\lambda} \leq \lambda_\delta^*$, we proceed by proof by contradiction. If $\hat{\lambda} > \lambda_\delta^*$, then the definition of the AV $_\infty$ method implies that there must exist two tuning parameters $\lambda', \lambda'' \geq \lambda_\delta^*$ such that

$$\|\hat{\beta}_{\lambda'} - \hat{\beta}_{\lambda''}\|_\infty > \bar{C}(\lambda' + \lambda''). \quad (11)$$

However, since \mathcal{T}_λ and $\mathcal{T}_{\lambda''}$ are both subsets of \mathcal{T}_δ^* , Assumption $\ell_\infty(C)$ implies that we must have the simultaneous inequalities $\|\hat{\beta}_{\lambda'} - \beta^*\|_\infty \leq C\lambda'$ and $\|\hat{\beta}_{\lambda''} - \beta^*\|_\infty \leq C\lambda''$. Combined with the triangle inequality, we find that

$$\|\hat{\beta}_{\lambda'} - \hat{\beta}_{\lambda''}\|_\infty \leq \|\hat{\beta}_{\lambda'} - \beta^*\|_\infty + \|\beta^* - \hat{\beta}_{\lambda''}\|_\infty \leq C(\lambda' + \lambda'').$$

Since $\bar{C} \geq C$, this upper bound contradicts our earlier conclusion (11) and, therefore, yields the desired claim.

Bound on the sup-norm error: On the event \mathcal{T}_δ^* , we have $\hat{\lambda} \leq \lambda_\delta^*$ and so the AV $_\infty$ definition implies that

$$\|\hat{\beta}_{\hat{\lambda}} - \hat{\beta}_{\lambda_\delta^*}\|_\infty \leq \bar{C}(\hat{\lambda} + \lambda_\delta^*) \leq 2\bar{C}\lambda_\delta^*.$$

Combined with the triangle inequality, we find that

$$\|\hat{\beta}_{\hat{\lambda}} - \beta^*\|_\infty \leq \|\hat{\beta}_{\hat{\lambda}} - \hat{\beta}_{\lambda_\delta^*}\|_\infty + \|\hat{\beta}_{\lambda_\delta^*} - \beta^*\|_\infty \leq 2\bar{C}\lambda_\delta^* + \|\hat{\beta}_{\lambda_\delta^*} - \beta^*\|_\infty.$$

Finally, under \mathcal{T}_δ^* and $\bar{C} \geq C$, Assumption $\ell_\infty(C)$ implies that $\|\hat{\beta}_{\lambda_\delta^*} - \beta^*\|_\infty \leq C\lambda_\delta^* \leq \bar{C}\lambda_\delta^*$, and combining the pieces completes the proof. \blacksquare

Appendix B. Remaining Proofs for Section 2

In this appendix, we provide the proofs of Lemmas 5, 6, and 8.

B.1 Proof of Lemma 5

By the first-order stationarity conditions for an optimum, the Lasso solution $\hat{\beta}_\lambda$ must satisfy the stationary condition $\frac{1}{n}\mathbf{X}^\top(\mathbf{X}\hat{\beta}_\lambda - Y) + \lambda\hat{z} = 0$, where $\hat{z} \in \mathbb{R}^p$ belongs to the sub-differential of the ℓ_1 -norm at $\hat{\beta}_\lambda$. Since $Y = \mathbf{X}\beta^* + \varepsilon$, we find that

$$\hat{\Sigma}(\hat{\beta}_\lambda - \beta^*) = -\lambda\hat{z} + \frac{\mathbf{X}^\top \varepsilon}{n}.$$

Taking the ℓ_∞ -norm of both sides and applying the triangle inequality yields

$$\|\hat{\Sigma}(\hat{\beta}_\lambda - \beta^*)\|_\infty \leq \lambda\|\hat{z}\|_\infty + \left\| \frac{\mathbf{X}^\top \varepsilon}{n} \right\|_\infty \leq \lambda + \frac{\lambda}{4} = \frac{5}{4}\lambda.$$

using the bound from event \mathcal{T}_λ , and the fact that $\|\hat{z}\|_\infty \leq 1$, by definition of the ℓ_1 -sub-differential. As noted previously, under the event \mathcal{T}_λ , the error vector $\Delta = \hat{\beta}_\lambda - \beta^*$ belongs to the cone $\mathcal{C}(S)$ in (6), so that the γ -RE condition can be applied so as to obtain the lower bound $\|\hat{\Sigma}(\hat{\beta}_\lambda - \beta^*)\|_\infty \geq \gamma\|\hat{\beta}_\lambda - \beta^*\|_\infty$. Combining the pieces concludes the proof. \blacksquare

B.2 Proof of Lemma 6

Since $\Delta \in \mathcal{C}(S)$, we have

$$\|\Delta\|_2^2 \leq 9\|\Delta_S\|_2^2 \leq 9|S|\|\Delta_S\|_2^2 \leq 9|S|\|\Delta\|_1\|\Delta\|_\infty,$$

which implies $\|\Delta\|_1 \leq 9|S|\|\Delta\|_\infty$. In view of Lemma 5, it thus suffices to prove the lower bound

$$\|\hat{\Sigma}\Delta\|_\infty \geq (1 - \nu)\|\Delta\|_\infty \quad \text{for all } \Delta \in A := \mathbb{B}_1(9|S|) \cap \mathbb{B}_\infty(1), \quad (12)$$

where we set $\mathbb{B}_d(r) := \{\beta \in \mathbb{R}^p : \|\beta\|_d \leq r\}$ for $d \in [0, \infty]$ and $r \geq 0$. We claim that

$$\underbrace{\mathbb{B}_1(9|S|) \cap \mathbb{B}_\infty(1)}_A \subseteq 2 \operatorname{cl} \operatorname{conv} \underbrace{\{\mathbb{B}_0(9|S|) \cap \mathbb{B}_\infty(1)\}}_B, \quad (13)$$

where $\operatorname{cl} \operatorname{conv}$ denotes the closed convex hull. Taking this as given for the moment, let us use it to prove the desired claim. We have

$$\begin{aligned} \max_{\Delta \in A} \frac{\|\hat{\Sigma} - I\Delta\|_\infty}{\|\Delta\|_\infty} &= \max_{\Delta \in A/2} \frac{\|\hat{\Sigma} - I\Delta\|_\infty}{\|\Delta\|_\infty} \leq \max_{\Delta \in B} \frac{\|\hat{\Sigma} - I\Delta\|_\infty}{\|\Delta\|_\infty} \leq \max_{j \in [p]} \max_{\substack{T=[9|S|] \\ T \subseteq [p]^j}} \sum_{k \in T} |\hat{\Sigma}_{jk}| \leq \nu \end{aligned} \quad (14)$$

using the diagonal dominance (8). Combined with the triangle inequality, the lower bound (12) follows.

It remains to prove the inclusion (13). Since both A and B are closed and convex, it suffices to prove that $\phi_A(\theta) \leq \phi_B(\theta)$ for all $\theta \in \mathbb{R}^p$, where $\phi_A(\theta) := \sup_{z \in A} \langle z, \theta \rangle$ and $\phi_B(\theta) := \sup_{z \in B} \langle z, \theta \rangle$ are the support functions. For a given vector $\theta \in \mathbb{R}^p$, let T be the

subset indexing its top $9|S|$ values in absolute value. By construction, we are guaranteed to have the bound $9|S|\|\theta_{T^c}\|_\infty \leq \|\theta_T\|_1$, and consequently

$$\begin{aligned} \sup_{z \in A} \langle (z_T, \theta_T) + (z_{T^c}, \theta_{T^c}) \rangle \phi_A(\theta) &\leq \sup_{z \in A} (\|z_T\|_\infty \|\theta_T\|_1 + \|z_{T^c}\|_1 \|\theta_{T^c}\|_\infty) \\ &\leq \|\theta_T\|_1 + 9|S| \|\theta_{T^c}\|_\infty \\ &\leq 2\|\theta_T\|_1. \end{aligned}$$

On the other hand, for this same subset T , we have $\phi_B(\theta) \geq \sup_{z \in B} \langle z_T, \theta_T \rangle = 2\|\theta_T\|_1$, which completes the proof. \blacksquare

B.3 Proof of Lemma 8

In order to prove Lemma 8, we use a somewhat simplified version of a recent result due to van de Geer (2014). So as to simplify notation, we first define the norms $\|a\|_j := |a_j|$ and $\|a\|_{-j} := \sum_{i \neq j} |a_i|$ for any vector a . We then have:

Lemma 11 (van de Geer (2014), Lemma 2.1) *Given any tuning parameter $\lambda > 0$, it holds that*

$$\|\hat{\beta}_\lambda - \beta^*\|_j \leq D_j \left(\frac{\|X^T \varepsilon\|_\infty}{n} + \frac{\sqrt{\log(p)} \|\hat{\beta}_\lambda - \beta^*\|_{-j}}{2\sqrt{n} \|\gamma^j\|_1} + \frac{\lambda}{2} \right)$$

where for each $j \in [p]$,

$$D_j := \frac{\|\gamma^j\|_1}{\|X\gamma^j\|_2^2/n + \sqrt{\log(p)/n} \|\gamma^j\|_{-j}/2}.$$

This result provides a specific bound for each coordinate of Lasso. Lemma 8 can then readily be proven using this result together with Theorem 6.1 from Bühlmann and van de Geer (2011). \blacksquare

Appendix C. Strong Correlations

In this paper, we assume that the correlations in design matrix are small, which is needed for precise ℓ_∞ -estimation and variable selection. In the interest of completeness, however, we add here two simulations where the correlations are large. Overall, we use the same settings as described in the main part of the paper, but we set $\kappa = 0.9$. The results are summarized in Figure 5 (note that the x-scale in the upper part of the figure is different from the scales of the corresponding plots in the main part of the paper). We find that AV_∞ misses about half of the pertinent variables but has almost no false positives. Cross-Validation, on the other hand, has less false negatives but selects many irrelevant variables. As expected, none of the methods, including the oracle, provide accurate ℓ_∞ -estimation.

Abstract

The class of linkage-based algorithms is perhaps the most popular class of hierarchical algorithms. We identify two properties of hierarchical algorithms, and prove that linkage-based algorithms are the only ones that satisfy both of these properties. Our characterization clearly delineates the difference between linkage-based algorithms and other hierarchical methods. We formulate an intuitive notion of locality of a hierarchical algorithm that distinguishes between linkage-based and “global” hierarchical algorithms like bisecting k -means, and prove that popular divisive hierarchical algorithms produce clusterings that cannot be produced by any linkage-based algorithm.

1. Introduction

Clustering is a fundamental and immensely useful task, with many important applications. There are many clustering algorithms, and these algorithms often produce different results on the same data. Faced with a concrete clustering task, a user needs to choose an appropriate algorithm. Currently, such decisions are often made in a very ad hoc, if not completely random, manner. Users are aware of the costs involved in employing different clustering algorithms, such as running times, memory requirements, and software purchasing costs. However, there is very little understanding of the differences in the outcomes that these algorithms may produce.

It has been proposed to address this challenge by identifying significant properties that distinguish between different clustering paradigms (see, for example, Ackerman et al. (2010b) and Fisher and Van Ness (1971)). By focusing on the input-output behaviour of algorithms, these properties shed light on essential differences between them (Ackerman et al. (2010b, 2012)). Users could then choose desirable properties based on domain expertise, and select an algorithm that satisfies these properties.

In this paper, we focus hierarchical algorithms, a prominent class of clustering algorithms. These algorithms output dendrograms, which the user can then traverse to obtain the desired clustering. Dendrograms provide a convenient method for exploring multiple

clusterings of the data. Notably, for some applications the dendrogram itself, not any clustering found in it, is the desired final outcome. One such application is found in the field of phylogeny, which aims to reconstruct the tree of life.

One popular class of hierarchical algorithms is linkage-based algorithms. These algorithms start with singleton clusters, and repeatedly merge pairs of clusters until a dendrogram is formed. This class includes commonly-used algorithms such as single-linkage, average-linkage, complete-linkage, and Ward’s method.

In this paper, we provide a property-based characterization of hierarchical linkage-based algorithms. We identify two properties of hierarchical algorithms that are satisfied by all linkage-based algorithms, and prove that at the same time no algorithm that is not linkage-based can satisfy both of these properties.

The popularity of linkage-based algorithms leads to a common misconception that linkage-based algorithms are synonymous with hierarchical algorithms. We show that even when the internal workings of algorithms are ignored, and the focus is placed solely on their input-output behaviour, there are natural hierarchical algorithms that are not linkage-based. We define a large class of divisive algorithms that includes the popular bisecting k -means algorithm, and show that no linkage-based algorithm can simulate the input-output behaviour of any algorithm in this class.

2. Previous Work

Our work falls within the larger framework of studying properties of clustering algorithms. Several authors study such properties from an axiomatic perspective. For instance, Wright (1973) proposes axioms of clustering functions in a weighted setting, where every domain element is assigned a positive real weight, and its weight may be distributed among multiple clusters. A recent, and influential, paper in this line of work is Kleinberg’s impossibility result (Kleinberg (2003)), where he proposes three axioms of partitional clustering functions and proves that no clustering function can simultaneously satisfy these properties.

Properties have been used to study different aspects of clustering. Ackerman and Ben-David (2008) consider properties satisfied by clustering quality measures, showing that properties analogous to Kleinberg’s axioms are consistent in this setting. Meila (2005) studies properties of criteria for comparing clusterings, functions that map pairs of clusterings to real numbers, and identifies properties that are sufficient to uniquely identify several such criteria. Puzicha et al. (2000) explore properties of clustering objective functions. They propose a few natural properties of clustering objective functions, and then focus on objective functions that arise by requiring functions to decompose into additive form.

Most relevant to our work are previous results distinguishing linkage-based algorithms based on their properties. Most of these results are concerned with the single-linkage algorithm. In the hierarchical clustering setting, Jardine and Sibson (1971) and Carlsson and Mémoli (2010) formulate a collection of properties that define single linkage.

Zadeh and Ben-David (2009) characterize single linkage in the partitional setting where instead of constructing a dendrogram, clusters are merged until a given number of clusters remain. Finally, Ackerman et al. (2010a) characterize linkage-based algorithms in the same partitional setting in terms of a few natural properties. These results enable a comparison

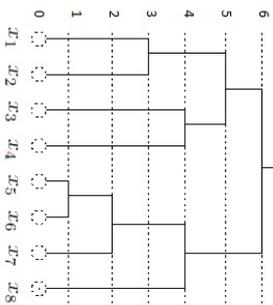

Figure 1: A dendrogram of domain set $\{x_1, \dots, x_8\}$. The horizontal lines represent levels and every leaf is associated with an element of the domain.

of the input-output behaviour of (a partitional variant of) linkage-based algorithms with other partitional algorithms.

In this paper, we characterize hierarchical linkage-based algorithms, which map data sets to dendrograms. Our characterization is independent of any stopping criterion. It enables the comparison of linkage-based algorithms to other hierarchical algorithms, and clearly delineates the differences between the input/output behaviour of linkage-based algorithms and other hierarchical methods.

3. Definitions

A *distance function* is a symmetric function $d : X \times X \rightarrow \mathbb{R}^+$, such that $d(x, x) = 0$ for all $x \in X$. The data sets that we consider are pairs (X, d) , where X is some finite domain set and d is a distance function over X . We say that a distance function d over X *extends* distance function d' over $X' \subseteq X$, denoted $d' \subseteq d$, if $d'(x, y) = d(x, y)$ for all $x, y \in X'$. Two distance functions d over X and d' over X' *agree* on a data set Y if $Y \subseteq X$, $Y \subseteq X'$, and $d(x, y) = d'(x, y)$ for all $x, y \in Y$.

A *k-clustering* $C = \{C_1, C_2, \dots, C_k\}$ of a data set X is a partition of X into k non-empty disjoint subsets of X (so, $\cup_i C_i = X$). A *clustering* of X is a k -clustering of X for some $1 \leq k \leq |X|$. For a clustering C , let $|C|$ denote the number of clusters in C . For $x, y \in X$ and clustering C of X , we write $x \sim_C y$ if x and y belong to the same cluster in C and $x \not\sim_C y$, otherwise.

Given a rooted tree T where the edges are oriented away from the root, let $V(T)$ denote the set of vertices in T , and $E(T)$ denote the set of edges in T . We use the standard interpretation of the terms leaf, descendant, parent, and child.

A dendrogram over a data set X is a binary rooted tree where the leaves correspond to elements of X . In addition, every node is assigned a level, using a level function (η); leaves are placed at level 0, parents have higher levels than their children, and no level is empty. See Figure 1 for an illustration. Formally,

Definition 1 (dendrogram) A dendrogram over (X, d) is a triple (T, M, η) where T is a binary rooted tree, $M : \text{leaves}(T) \rightarrow X$ is a bijection, and $\eta : V(T) \rightarrow \{0, \dots, h\}$ is onto (for some $h \in \mathbb{Z}^+ \cup \{0\}$) such that

1. For every leaf node $x \in V(T)$, $\eta(x) = 0$.
2. If $(x, y) \in E(T)$, then $\eta(x) > \eta(y)$.

Given a dendrogram $\mathcal{D} = (T, M, \eta)$ of X , we define a mapping from nodes to clusters $C : V(T) \rightarrow 2^X$ by $C(x) = \{M(y) \mid y \text{ is a leaf and a descendant of } x\}$. If $C(x) = A$, then we write $v(A) = x$. We think of $v(A)$ as the vertex (or node) in the tree that represents cluster A .

We say that $A \subseteq X$ is a cluster in \mathcal{D} if there exists a node $x \in V(T)$ so that $C(x) = A$. We say that a clustering $C = \{C_1, \dots, C_k\}$ of $X' \subseteq X$ is in \mathcal{D} if C_i is in \mathcal{D} for all $1 \leq i \leq k$. Note that a dendrogram may contain clusterings that do not partition the entire domain, and $\forall i \neq j$, $v(C_i)$ is not a descendant of $v(C_j)$, since $C_i \cap C_j = \emptyset$.

Definition 2 (sub-dendrogram) A sub-dendrogram of (T, M, η) rooted at $x \in V(T)$ is a dendrogram (T', M', η') where

1. T' is the subtree of T rooted at x ,
2. For every $y \in \text{leaves}(T')$, $M'(y) = M(y)$, and
3. For all $y, z \in V(T')$, $\eta'(y) < \eta'(z)$ if and only if $\eta(y) < \eta(z)$.

Definition 3 (Isomorphisms) A few notions of isomorphisms of structures are relevant to our discussion.

1. We say that (X, d) and (X', d') are isomorphic domains, denoted $(X, d) \cong_X (X', d')$, if there exists a bijection $\phi : X \rightarrow X'$ so that $d(x, y) = d'(\phi(x), \phi(y))$ for all $x, y \in X$.
2. We say that two clusterings (or partitions) C of some domain (X, d) and C' of some domain (X', d') are isomorphic clusterings, denoted $(C, d) \cong_C (C', d')$, if there exists a domain isomorphism $\phi : X \rightarrow X'$ so that $x \sim_C y$ if and only if $\phi(x) \sim_{C'} \phi(y)$.
3. We say that (T_1, η_1) and (T_2, η_2) are isomorphic trees, denoted $(T_1, \eta_1) \cong_T (T_2, \eta_2)$, if there exists a bijection $H : V(T_1) \rightarrow V(T_2)$ so that

- (a) for all $x, y \in V(T_1)$, $(x, y) \in E(T_1)$ if and only if $(H(x), H(y)) \in E(T_2)$, and
- (b) for all $x \in V(T_1)$, $\eta_1(x) = \eta_2(H(x))$.

4. We say that $\mathcal{D}_1 = (T_1, M_1, \eta_1)$ of (X, d) and $\mathcal{D}_2 = (T_2, M_2, \eta_2)$ of (X', d') are isomorphic dendrograms, denoted $\mathcal{D}_1 \cong_{\mathcal{D}} \mathcal{D}_2$, if there exists a domain isomorphism $\phi : X \rightarrow X'$ and a tree isomorphism $H : (T_1, \eta_1) \rightarrow (T_2, \eta_2)$ so that for all $x \in \text{leaves}(T_1)$, $\phi(M_1(x)) = M_2(H(x))$.

4. Hierarchical and Linkage-Based Algorithms

In the hierarchical clustering setting, linkage-based algorithms are hierarchical algorithms that can be simulated by repeatedly merging close clusters. In this section, we formally define hierarchical algorithms and linkage-based hierarchical algorithms.

4.1 Hierarchical Algorithms

In addition to outputting a dendrogram, we require that hierarchical clustering functions satisfy a few natural properties.

Definition 4 (Hierarchical clustering function) *A hierarchical clustering function F is a function that takes as input a pair (X, d) and outputs a dendrogram (T, M, η) . We require such a function, F , to satisfy the following:*

1. Representation Independence: *Whenever $(X, d) \cong_X (X', d')$, then $F(X, d) \cong_D F(X', d')$.*
2. Scale Invariance: *For any domain set X and any pair of distance functions d, d' over X , if there exists $c \in \mathbb{R}^+$ such that $d(a, b) = c \cdot d'(a, b)$ for all $a, b \in X$, then $F(X, d) = F(X, d')$.*
3. Richness: *For all data sets $\{(X_1, d_1), \dots, (X_k, d_k)\}$ where $X_i \cap X_j = \emptyset$ for all $i \neq j$, there exists a distance function \hat{d} over $\bigcup_{i=1}^k X_i$ that extends each of the d_i 's (for $i \leq k$), so that the clustering $\{X_1, \dots, X_k\}$ is in $F(\bigcup_{i=1}^k X_i, \hat{d})$.*

The last condition, richness, requires that by manipulating between-cluster distances every clustering can be produced by the algorithm. Intuitively, if we place the clusters sufficiently far apart, then the resulting clustering should be in the dendrogram.

In this work, we focus on distinguishing linkage-based algorithms from other hierarchical algorithms.

4.2 Linkage-Based Algorithms

The class of linkage-base algorithms includes some of the most popular hierarchical algorithms, such as single-linkage, average-linkage, complete-linkage, and Ward's method.

Every linkage-based algorithm has a linkage function that can be used to determine which clusters to merge at every step of the algorithm.

Definition 5 (Linkage Function) *A linkage function is a function*

$$\ell : \{(X_1, X_2, d) \mid d \text{ over } X_1 \cup X_2\} \rightarrow \mathbb{R}^+$$

such that,

1. ℓ is representation independent: *For all (X_1, X_2) and (X'_1, X'_2) , if $(\{X_1, X_2\}, d) \cong_C (\{X'_1, X'_2\}, d')$ then $\ell(X_1, X_2, d) = \ell(X'_1, X'_2, d')$.*
2. ℓ is monotonic: *For all (X_1, X_2, d) if d' is a distance function over $X_1 \cup X_2$ such that for all $x \sim_{\{X_1, X_2\}} y$, $d(x, y) = d'(x, y)$ and for all $x \not\sim_{\{X_1, X_2\}} y$, $d(x, y) \leq d'(x, y)$ then $\ell(X_1, X_2, d) \geq \ell(X_1, X_2, d')$.*

As in our characterization of partitional linkage-based algorithms, we assume that a linkage function has a countable range. Say, the set of non-negative algebraic real numbers. The following are the linkage-functions of some of the most popular linkage-based algorithms,

- **Single-linkage:** $\ell(A, B, d) = \min_{a \in A, b \in B} d(a, b)$
- **Average-linkage:** $\ell(A, B, d) = \sum_{a \in A, b \in B} d(a, b) / (|A| \cdot |B|)$
- **Complete-linkage:** $\ell(A, B, d) = \max_{a \in A, b \in B} d(a, b)$

For a dendrogram \mathcal{D} and clusters A and B in \mathcal{D} , if there exists x so that $\text{parent}(v(A)) = \text{parent}(v(B)) = x$, then let $\text{parent}(A, B) = x$, otherwise $\text{parent}(A, B) = \emptyset$.

We now define hierarchical linkage-based functions.

Definition 6 (Linkage-Based Function) *A hierarchical clustering function F is linkage-based if there exists a linkage function ℓ so that for all (X, d) , $F(X, d) = (T, M, \eta)$ where $\eta(\text{parent}(A, B)) = m$ if and only if $\ell(A, B)$ is minimal in $\{\ell(S, T) : S \cap T = \emptyset, \eta(S) < m, \eta(T) < m, \eta(\text{parent}(S)) \geq m, \eta(\text{parent}(T)) \geq m\}$.*

Note that the above definition implies that there exists a linkage function that can be used to simulate the output of F . We start by assigning every element of the domain to a leaf node. We then use the linkage function to identify the closest pair of nodes (with respect to the clusters that they represent), and repeatedly merge the closest pairs of nodes that do yet have parents, until only one such node remains.

4.3 Locality

We introduce a new property of hierarchical algorithms. Locality states that if we select a clustering from a dendrogram (a union of disjoint clusters that appear in the dendrogram), and run the hierarchical algorithm on the data underlying this clustering, we obtain a result that is consistent with the original dendrogram.

Definition 7 (Locality) *A hierarchical function F is local if for all X, d , and $X' \subseteq X$, whenever clustering $C = \{C_1, C_2, \dots, C_k\}$ of X' is in $F(X, d) = (T, M, \eta)$, then for all $1 \leq i \leq k$*

1. *Cluster C_i is in $F(X', d|_{X'}) = (T', M', \eta')$, and the sub-dendrogram of $F(X, d)$ rooted at $v(C_i)$ is also a sub-dendrogram of $F(X', d|_{X'})$ rooted at $v(C_i)$.*
2. *For all $x, y \in X'$, $\eta'(x) < \eta'(y)$ if and only if $\eta(x) < \eta(y)$.*

Locality is often a desirable property. Consider for example the field of phylogenetics, which aims to reconstruct the tree of life. If an algorithm clusters phylogenetic data correctly, then if we cluster any subset of the data, we should get results that are consistent with the original dendrogram.

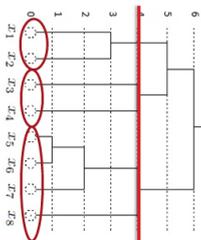

Figure 2: An example of an A-cut.

4.4 Outer Consistency

Clustering aims to group similar elements and separate dissimilar ones. These two requirements are often contradictory and algorithms vary in how they resolve this contradiction. Kleinberg (2003) proposed a formalization of these requirements in his “consistency” axiom for partitional clustering algorithms. Consistency requires that if within-cluster distances are decreased, and between-cluster distances are increased, then the output of a clustering function does not change.

Since then it was found that while many natural clustering functions fail consistency, most satisfy a relaxation, which requires that the output of an algorithm is not changed by increasing between-cluster distances (Ackerman et al. (2010b)). Given successfully clustered data, if points that are already assigned to different clusters are drawn even further apart, then it is natural to expect that, when clustering the resulting new data set, such points will not share the same cluster. Here we propose a variation of this requirement for the hierarchical clustering setting.

Given a dendrogram produced by a hierarchical algorithm, we select a clustering C from a dendrogram and pull apart the clusters in C (thus making the clustering C more pronounced). If we then run the algorithm on the resulting data, we can expect that the clustering C will occur in the new dendrogram. Outer consistency is a relaxation of the above property, making this requirement only on a subset of clusterings.

For a cluster A in a dendrogram \mathcal{D} , the A-cut of \mathcal{D} is a clustering in \mathcal{D} represented by nodes on the same level as $v(A)$ or directly below $v(A)$. For convenience, if node u is the root of the dendrogram, then assume its parent has infinite level, $\eta(\text{parent}(u)) = \infty$. Formally,

Definition 8 (A-cut) *Given a cluster A in a dendrogram $\mathcal{D} = (T, M, \eta)$, the A-cut of \mathcal{D} is $\text{cut}_A(\mathcal{D}) = \{C(u) \mid u \in V(T), \eta(\text{parent}(u)) > \eta(v(A)) \text{ and } \eta(u) \leq \eta(v(A))\}$.*

Note that for any cluster A in \mathcal{D} of (X, d) , the A-cut is a clustering of X , and A is one of the clusters in that clustering.

For example, consider the diagram in Figure 2. Let $A = \{x_3, x_4\}$. The horizontal line on level 4 of the dendrogram represents the intuitive notion of a cut. To obtain the corresponding clustering, we select all clusters represented by nodes on the line, and for

the remaining clusters, we choose clusters represented by nodes that lay directly below the horizontal cut. In this example, clusters $\{x_3, x_4\}$ and $\{x_5, x_6, x_7, x_8\}$ are represented by nodes directly on the line, and $\{x_1, x_2\}$ is a cluster represented by a node directly below the marked horizontal line.

Recall that a distance function d over X is (C, d) -outer-consistent if $d(x, y) = d(x, y)$ whenever $x \sim_C y$, and $d'(x, y) \geq d(x, y)$ whenever $x \not\sim_C y$.

Definition 9 (Outer-Consistency) *A hierarchical function F is outer consistent if for all (X, d) and any cluster A in $F(X, d)$, if d' is $(\text{cut}_A(F(X, d)), d)$ -outer-consistent then $\text{cut}_A(F(X, d)) = \text{cut}_A(F(X, d'))$.*

5. Main Result

The following is our characterization of linkage-based hierarchical algorithms.

Theorem 10 *A hierarchical function F is linkage-based if and only if F is outer consistent and local.*

We prove the result in the following subsections (one for each direction of the iff). In the last part of this section, we demonstrate the necessity of both properties.

5.1 All Local, Outer-Consistent Hierarchical Functions are Linkage-Based

Lemma 11 *If a hierarchical function F is outer-consistent and local, then F is linkage-based.*

We show that there exists a linkage function ℓ so that when ℓ is used in Definition 6 then for all (X, d) the output is $F(X, d)$. Due to the representation independence of F , one can assume w.l.o.g. that the domain sets over which F is defined are (finite) subsets of the set of natural numbers, \mathbb{N} .

Definition 12 (The (pseudo-) partial ordering $<_F$) *We consider triples of the form (A, B, d) , where $A \cap B = \emptyset$ and d is a distance function over $A \cup B$. Two triples, (A, B, d) and (A', B', d') are equivalent, denoted $(A, B, d) \cong (A', B', d')$ if they are isomorphic as clusterings, namely, if $\{(A, B), d\} \cong_C \{(A', B'), d'\}$.*

$<_F$ is a binary relation over equivalence classes of such triples, indicating that F merges a pair of clusters earlier than another pair of clusters. Formally, denoting \cong -equivalence classes by square brackets, we define it by: $[(A, B, d)] <_F [(A', B', d')]$ if

1. At most two sets in $\{A, B, A', B'\}$ are equal and no set is a strict subset of another.
2. The distance functions d and d' agree on $(A \cup B) \cap (A' \cup B')$.
3. There exists a distance function d^* over $X = A \cup B \cup A' \cup B'$ so that $F(X, d^*) = (T, M, \eta)$ such that
 - (a) d^* extends both d and d' ,

- (b) There exist $(x, y), (x, z) \in E(T)$ such that $C(x) = A \cup B$, $C(y) = A$, and $C(z) = B$
- (c) For all $D \in \{A', B'\}$, either $D \subseteq A \cup B$, or $D \in \text{cut}_{A \cup B} F(X, d^*)$.
- (d) $\eta(v(A')) < \eta(v(A \cup B))$ and $\eta(v(B')) < \eta(v(A \cup B))$.

Since we define hierarchical algorithms to be representation independent, we can just discuss triples, instead of their equivalence classes. For the sake of simplifying notation, we will omit the square brackets in the following discussion.

In the following lemma we show that if $(A, B, d) <_F (A', B', d')$, then $A' \cup B'$ cannot have a lower level than $A \cup B$.

Lemma 13 *Given a local and outer-consistent hierarchical function F , whenever*

- $(A_1, B_1, d_1) <_F (A_2, B_2, d_2)$, there is no data set (X, d) such that $A_1, B_1, A_2, B_2 \subseteq X$ and $\eta(v(A_2 \cup B_2)) \leq \eta(v(A_1 \cup B_1))$, where $F(X, d) = (T, M, \eta)$.

Proof By way of contradiction, assume that such (X, d) exists. Let $X' = A_1 \cup B_1 \cup A_2 \cup B_2$. Since $(A_1, B_1, d_1) <_F (A_2, B_2, d_2)$, there exists d' that satisfies the conditions of Definition 12.

Consider $F(X', d|X')$. By locality, the sub-dendrogram rooted at $v(A_1 \cup B_1)$ contains the same nodes in both $F(X', d|X')$ and $F(X, d)$, and similarly for the sub-dendrogram rooted at $v(A_2 \cup B_2)$. In addition, the relative level of nodes in these subtrees is the same.

Construct a distance function d^* over X' that is both $(\{A_1 \cup B_1, A_2 \cup B_2\}, d|X')$ -outer consistent and $(\{A_1 \cup B_2, A_2, B_2\}, d')$ -outer consistent as follows:

- $d^*(x, y) = \max(d(x, y), d'(x, y))$ whenever $x \in A_1 \cup B_1$ and $y \in A_2 \cup B_2$
- $d^*(x, y) = d_1(x, y)$ whenever $x, y \in A \cup B$
- $d^*(x, y) = d_2(x, y)$ whenever $x, y \in A' \cup B'$

Note that $\{A_1 \cup B_1, A_2 \cup B_2\}$ is an $(A_1 \cup B_1)$ -cut of $F(X', d|X')$. Therefore, by outer-consistency, $\text{cut}_{A_1 \cup B_1}(F(X', d^*)) = \{A_2 \cup B_2, A_1 \cup B_1\}$.

Since d' satisfies the conditions in Definition 12, $\text{cut}_{A_1 \cup B_1} F(X, d') = \{A_1 \cup B_1, A_2, B_2\}$. By outer-consistency we get that $\text{cut}_{A_1 \cup B_1}(F(X', d^*)) = \{A_2 \cup B_2, A_1, B_1\}$. Since these sets are all non-empty, this is a contradiction. ■

We now define equivalence with respect to $<_F$.

Definition 14 $[(\cong_F)]$ (A, B, d) and (A', B', d') are *F-equivalent*, denoted $[(A, B, d)] \cong_F [(A', B', d')]$, if either they are isomorphic as clusterings, $(\{A, B\}, d) \cong_C (\{A', B'\}, d')$ or

1. At most two sets in $\{A, B, A', B'\}$ are equal and no set is a strict subset of another.
2. The distance functions d and d' agree on $(A \cup B) \cap (A' \cup B')$.
3. There exists a distance function d^* over $X = A \cup B \cup A' \cup B'$ so that $F(A \cup B \cup A' \cup B', d^*) = (T, \eta)$ where
 - (a) d^* extends both d and d' ,

- (b) There exist $(x, y), (x, z) \in E(T)$ such that $C(x) = A \cup B$, and $C(y) = A$, and $C(z) = B$,
- (c) There exist $(x', y'), (x', z') \in E(T)$ such that $C(x') = A' \cup B'$, and $C(y') = A'$, and $C(z') = B'$, and
- (d) $\eta(x) = \eta(x')$

(A, B, d) is comparable with (C, D, d') if they are $<_F$ comparable or $(A, B, d) \cong_F (C, D, d')$.

Whenever two triples are F -equivalent, then they have the same $<_F$ or \cong_F relationship with all other triples.

Lemma 15 *Given a local, outer-consistent hierarchical function F , if $(A, B, d_1) \cong_F (C, D, d_2)$, then for any (E, F, d_3) , if (E, F, d_3) is comparable with both (A, B, d_1) and (C, D, d_2) then*

- if $(A, B, d_1) \cong_F (E, F, d_3)$ then $(C, D, d_2) \cong_F (E, F, d_3)$
- if $(A, B, d_1) <_F (E, F, d_3)$ then $(C, D, d_2) <_F (E, F, d_3)$

Proof Let $X = A \cup B \cup C \cup D \cup E \cup F$. By richness (condition 3 of Definition 4), there exists a distance function d that extends d_i for $i \in \{1, 2, 3\}$ so that $\{A \cup B, C \cup D, E \cup F\}$ is a clustering in $F(X, d)$. Assume that (E, F, d_3) is comparable with both (A, B, d_1) and (C, D, d_2) . By way of contradiction, assume that $(A, B, d_1) \cong_F (E, F, d_3)$ and $(C, D, d_2) <_F (E, F, d_3)$. Then by locality, in $F(X, d)$, $\eta(v(A \cup B)) = \eta(v(E \cup F))$.

Observe that by locality, since $(C, D, d_1) <_F (E, F, d_3)$, then $\eta(v(C \cup D)) < \eta(v(E \cup F))$ in $F(X, d)$. Therefore (again by locality) $\eta(v(A \cup B)) \neq \eta(v(C \cup D))$ in any data set that extends d_1 and d_2 , contradicting that $(A, B, d_1) \cong_F (C, D, d_2)$. ■

Note that $<_F$ is not transitive. In particular, if $(A, B, d_1) <_F (C, D, d_2)$ and $(C, D, d_2) <_F (E, F, d_3)$, it may be that (A, B, d_1) and (E, F, d_3) are incomparable. To show that $<_F$ can be extended to a partial ordering, we first prove the following ‘‘anti-cycle’’ property.

Lemma 16 *Given a hierarchical function F that is local and outer-consistent, there exists no finite sequence $(A_1, B_1, d_1) <_F \dots <_F (A_n, B_n, d_n) <_F (A_1, B_1, d_1)$.*

Proof Without loss of generality, assume that such a sequence exists. By richness, there exists a distance function d that extends each of the d_i where $\{A_1 \cup B_1, A_1 \cup B_2, \dots, A_n \cup B_n\}$ is a clustering in $F(\bigcup_i A_i \cup B_i, d) = (T, M, \eta)$.

Let i_0 be so that $\eta(v(A_{i_0} \cup B_{i_0})) \leq \eta(v(A_j \cup B_j))$ for all $j \neq i_0$. By the circular structure with respect to $<_F$, there exists j_0 so that $(A_{j_0}, B_{j_0}, d_{j_0}) <_F (A_{i_0}, B_{i_0}, d_{i_0})$. This contradicts Lemma 13. ■

We make use of the following general result.

Lemma 17 *For any cycle-free, anti-symmetric relation $P(\cdot, \cdot)$ over a finite or countable domain D there exists an embedding h into \mathbb{R}^+ so that for all $x, y \in D$, if $P(x, y)$ then $h(x) < h(y)$.*

Proof First we convert the relation P into a partial order by defining $a < b$ whenever there exists a sequence x_1, \dots, x_k so that $P(a, x_1), P(x_2, x_3), \dots, P(x_k, b)$. This is a partial ordering because P is antisymmetric and cycle-free. To map the partial order to the positive reals, we first enumerate the elements, which can be done because the domain is countable. The first element is then mapped to any value, $\phi(x_1)$. By induction, we assume that the first n elements are mapped in an order preserving manner. Let x_{r_1}, \dots, x_{r_k} be all the members of $\{x_1, \dots, x_n\}$ that are below x_{n+1} in the partial order. Let $r_1 = \max\{\phi(x_{r_1}), \dots, \phi(x_{r_k})\}$, and similarly let r_2 be the minimum among the images of all the members of $\{x_1, \dots, x_k\}$ that are above x_{n+1} in the partial order. Finally, let $\phi(x_{n+1})$ be any real number between r_1 and r_2 . It is easy to see that now ϕ maps $\{x_1, \dots, x_n, x_{n+1}\}$ in a way that respects the partial order. ■

Finally, we define our linkage function by embedding the \cong_F -equivalence classes into the positive real numbers in an order preserving way, as implied by applying Lemma 17 to $<_F$. Namely, $\ell_F : \{[A, B, d]\} : A \subseteq \mathbb{N}, B \subseteq \mathbb{N}, A \cap B = \emptyset$ and d is a distance function over $A \cup B \rightarrow \mathbb{R}^+$ so that $[A, B, d] <_F [A', B', d']$ implies $\ell_F([A, B, d]) < \ell_F([A', B', d'])$.

Lemma 18 *The function ℓ_F is a linkage function for any hierarchical function F that satisfies locality and outer-consistency.*

Proof Since ℓ_F is defined on \cong_F -equivalence classes, representation independence of hierarchical functions implies that ℓ_F satisfies condition 1 of Definition 5. The function ℓ_F satisfies condition 2 of Definition 5 by Lemma 19, whose proof follows. ■

Lemma 19 *Consider d_1 over $X_1 \cup X_2$ and d_2 that is $(\{X_1, X_2\}, d_1)$ -outer-consistent, then $(X_1, X_2, d_2) \not\prec_F (X_1, X_2, d_1)$, whenever F is local and outer-consistent.*

Proof Assume that there exist such d_1 and d_2 where $(X_1, X_2, d_2) <_F (X_1, X_2, d_1)$. Let d_3 over $X_1 \cup X_2$ be a distance function such that d_3 is $(\{X_1, X_2\}, d_1)$ -outer-consistent and d_2 is $(\{X_1, X_2\}, d_3)$ -outer-consistent. In particular, d_3 can be constructed as follows:

- $d_3(x, y) = \frac{d_1(x, y) + d_2(x, y)}{2}$ whenever $x \in X_1$ and $y \in X_2$
- $d_3(x, y) = d_1(x, y)$ whenever $x, y \in X_1$ or $x, y \in X_2$

Set $(X_1, X_2', d_2) \cong_F (X_1, X_2, d_2)$ and $(X_1'', X_2'', d_3) \cong_F (X_1, X_2, d_3)$.

Let $X = X_1 \cup X_2 \cup X_1' \cup X_2' \cup X_1'' \cup X_2''$. By richness, there exists a distance function d^* that extends d_i for all $1 \leq i \leq 3$ so that $\{X_1 \cup X_2, X_1' \cup X_2', X_1'' \cup X_2''\}$ is a clustering in $F(X, d^*)$.

Let $F(X, d^*) = (T, M, \eta)$. Since $(X_1', X_2', d_2) <_F (X_1, X_2, d_1)$, by locality and outer-consistency, we get that $\eta(v(X_1' \cup X_2')) < \eta(v(X_1 \cup X_2))$. We consider the level $(\eta$ value) of $v(X_1' \cup X_2')$ with respect to the levels of $v(X_1' \cup X_2')$ and $v(X_1 \cup X_2)$ in $F(X, d^*)$.

We now consider a few cases.

Case 1: $\eta(v(X_1' \cup X_2')) \leq \eta(v(X_1' \cup X_2'))$. Then there exists an outer-consistent change moving X_1 and X_2 further away from each other until $(X_1, X_2, d_1) = (X_1'', X_2'', d_3)$. Let d be the distance function that extends d_1 and d_2 which shows that $(X_1', X_2', d_2) <_F (X_1, X_2, d_1)$.

$cut_{X_1' \cup X_2'} F(X_1 \cup X_2 \cup X_1' \cup X_2', d) = \{X_1' \cup X_2', X_1, X_2\}$. We can apply outer consistency on $\{X_1' \cup X_2', X_1, X_2\}$ and move X_1 and X_2 away from each other until $\{X_1, X_2\}$ is isomorphic to $\{X_1'', X_2''\}$. By outer consistency, this modification should not affect the $(X_1 \cup X_2)$ -cut. Applying locality, we have two isomorphic data sets that produce different dendrograms, one in which the further pair $(\{X_1', X_2'\}$ with distance function d_2) is not below the medium pair $(\{X_1'', X_2''\}$ with distance function d_3), and the other in which the medium pair is above the furthest pair.

Case 2: $\eta(v(X_1'' \cup X_2'')) \geq \eta(v(X_1 \cup X_2))$. Since X_2'' is isomorphic to X_2 for all $i \in \{1, 2\}$, $\eta(v(X_2)) = \eta(v(X_2''))$ for all $i \in \{1, 2\}$. This gives us that in this case, $cut_{X_1 \cup X_2} F(X_1 \cup X_2 \cup X_1'' \cup X_2'') = \{X_1 \cup X_2, X_1'', X_2''\}$. We can therefore apply outer consistency and separate X_1'' and X_2'' until $\{X_1'', X_2''\}$ is isomorphic to $\{X_1' \cup X_2'\}$. So this gives us two isomorphic data sets, one in which the further pair is not below the closest pair, and the other in which the further pair is below the closest pair.

Case 3: $\eta(X_1 \cup X_2) < \eta(X_1'' \cup X_2'') < \eta(X_1' \cup X_2')$. Notice that $cut_{X_1' \cup X_2'} F(X_1 \cup X_2 \cup X_1' \cup X_2', d^*) = \{X_1' \cup X_2', X_1, X_2\}$. So outer-consistency applies when we increase the distance between X_1 and X_2 until $\{X_1, X_2\}$ is isomorphic to $\{X_1' \cup X_2'\}$. This gives us two isomorphic sets, one in which the medium pair is below the further pair, and another in which the medium pair is above the furthest pair. ■

The following Lemma concludes the proof that every local, outer-consistent hierarchical algorithm is linkage-based.

Lemma 20 *Given any hierarchical function F that satisfies locality and outer-consistency, let ℓ_F be the linkage function defined above. Let L_{ℓ_F} denote the linkage-based algorithm that ℓ_F defines. Then L_{ℓ_F} agrees with F on every input data set.*

Proof Let (X, d) be any data set. We prove that at every level s , the nodes at level s in $F(X, d)$ represent the same clusters as the nodes at level s in $L_{\ell_F}(X, d)$. In both $F(X, d) = (T, M, \eta)$ and $L_{\ell_F}(X, d) = (T', M', \eta')$, level 0 consists of $|X|$ nodes each representing a unique elements of X .

Assume the result holds below level k . We show that pairs of nodes that do not have parents below level k have minimal ℓ_F value only if they are merged at level k in $F(X, d)$. Consider $F(X, d)$ at level k . Since the dendrogram has no empty levels, let $x \in V(T)$ where $\eta(x) = k$. Let x_1 and x_2 be the children of x in $F(X, d)$. Since $\eta(x_1), \eta(x_2) < k$, these nodes also appear in $L_{\ell_F}(X, d)$ below level k , and neither node has a parent below level k .

If x is the only node in $F(X, d)$ above level $k - 1$, then it must also occur in $L_{\ell_F}(X, d)$. Otherwise, there exists a node $y_1 \in V(T)$, $y_1 \notin \{x_1, x_2\}$ so that $\eta(y_1) < k$ and $\eta(\text{parent}(y_1)) \geq k$. Let $X' = \mathcal{C}(x) \cup \mathcal{C}(y_1)$. By locality, $cut_{\mathcal{C}(x)} F(X', d|X') = \{\mathcal{C}(x), \mathcal{C}(y_1)\}$, y_1 is below x , and x_1 and x_2 are the children of x . Therefore, $(\mathcal{C}(x_1), \mathcal{C}(x_2), d) <_F (\mathcal{C}(x_1), \mathcal{C}(y_1), d)$ and $\ell_F(\mathcal{C}(x_1), \mathcal{C}(x_2), d) < \ell_F(\mathcal{C}(x_1), \mathcal{C}(y_1), d)$.

Assume that there exists $y_2 \in V(T)$, $y_2 \notin \{x_1, x_2, y_1\}$ so that $\eta(y_2) < k$ and $\eta(\text{parent}(y_2)) \geq k$. If $\text{parent}(y_2) = \text{parent}(y_2)$ and $\eta(\text{parent}(y_1)) = k$, then $(\mathcal{C}(x_1), \mathcal{C}(x_2), d) \cong_F (\mathcal{C}(y_1), \mathcal{C}(y_2), d)$ and so $\ell_F(\mathcal{C}(x_1), \mathcal{C}(x_2), d) = \ell_F(\mathcal{C}(y_1), \mathcal{C}(y_2), d)$.

Otherwise, let $X' = C(x) \cup C(y_1) \cup C(y_2)$. By richness, there exists a distance function d^* that extends $d(C(x))$ and $d(C(y_1) \cup C(y_2))$, so that $\{C(x), C(y_1) \cup C(y_2)\}$ is in $F(X', d^*)$. Note that by locality, the node $v(C(y_1) \cup C(y_2))$ has children $v(C(y_1))$ and $v(C(y_2))$ in $F(X', d^*)$. We can separate $C(x)$ from $C(y_1) \cup C(y_2)$ in both $F(X', d^*)$ and $F(X', d|X')$ until both are equal. Then by outer-consistency, $\text{cut}_{C(x)} F(X', d|X') = \{C(x), C(y_1), C(y_2)\}$ and by locality y_1 and y_2 are below x . Therefore, $(C(x_1), C(x_2), d) <_F (C(y_1), C(y_2), d)$ and so $\ell_F(C(x_1), C(x_2), d) < \ell_F(C(y_1), C(y_2), d)$. ■

5.2 All Linkage-Based Functions are Local and Outer-Consistent

Lemma 21 *Every linkage-based hierarchical clustering function is local.*

Proof Let $C = \{C_1, C_2, \dots, C_k\}$ be a clustering in $F(X, d) = (T, M, \eta)$. Let $X' = \cup_i C_i$. For all $X_1, X_2 \in X'$, $\ell(X_1, X_2, d) = \ell(X_1, X_2, d|X')$. Therefore, for all $1 \leq i \leq k$, the sub-dendrogram rooted at $v(C_i)$ in $F(X, d)$ also appears in $F(X, d')$, with the same relative levels. ■

Lemma 22 *Every linkage-based hierarchical clustering function is outer-consistent.*

Proof Let $C = \{C_1, C_2, \dots, C_k\}$ be a C_i -cut in $F(X, d)$ for some $1 \leq i \leq k$. Let d' be (C, d) -outer-consistent. Then for all $1 \leq i \leq k$, and all $X_1, X_2 \subseteq C_i$, $\ell(X_1, X_2, d) = \ell(X_1, X_2, d')$, while for all $X_1 \subseteq C_i, X_2 \subseteq C_j$, for any $i \neq j$, $\ell(X_1, X_2, d) \leq \ell(X_1, X_2, d')$ by monotonicity. Therefore, for all $1 \leq j \leq k$, the sub-dendrogram rooted at $v(C_j)$ in $F(X, d)$ also appears in $F(X, d')$. All nodes added after these sub-dendrograms are at a higher level than the level of $v(C_i)$. And since the C_i -cut is represented by nodes that occur on levels no higher than the level of $v(C_i)$, the C_i -cut in $F(X, d')$ is the same as the C_i -cut in $F(X, d)$. ■

5.3 Necessity of Both Properties

We now show that both the locality and outer-consistency properties are necessary for defining linkage-based algorithms. Neither property individually is sufficient for defining this family of algorithms. Our results above showing that all linkage-based algorithms are both local and outer-consistent already imply that a clustering function that satisfies one, but not both, of these requirements is not linkage-based. It remains to show that neither of these two properties implies the other. We do so by demonstrating the existence of a hierarchical function that satisfies locality but not outer-consistency, and one that satisfies outer-consistency but not locality.

Consider a hierarchical clustering function F that applies average-linkage on data sets with an even number of elements, and single-linkage on data sets consisting of an odd number of elements. Since both average-linkage and single-linkage are linkage-based algorithms, they are both outer-consistent. It follows that F is outer-consistent. However, this hierarchical clustering function fails locality, as it is easy to construct a data set with an even number of

elements where average-linkage detects an odd-sized cluster, for which single-linkage would produce a different dendrogram.

Now, consider the following function

$$\ell(X_1, X_2, d) = \frac{1}{\max_{x \in X_1, y \in X_2} d(x, y)}.$$

The function ℓ is not a linkage-function since it fails the monotonicity condition. The function ℓ also does not conform with the intended meaning of a linkage-function. For instance, $\ell(X_1, X_2, d)$ is smaller than $\ell(X'_1, X'_2, d')$ when *all* the distances between X_1 and X_2 are (arbitrarily) larger than any distance between X'_1 and X'_2 . If we then consider the hierarchical clustering function F that results by utilizing ℓ in a greedy fashion to construct a dendrogram (by repeatedly merging the closest clusters according to ℓ), then the function F is local by the same argument as the proof of Lemma 21. We now demonstrate that F is not outer-consistent. Consider a data set (X, d) such that for some $A \subset X$, the A -cut of $F(X, d)$ is a clustering with at least 3 clusters where every cluster consists of at least 2 elements. Then if we move two clusters sufficiently far away from each other and all other data, they will be merged by the algorithm before any of the other clusters are formed, and so the A -cut on the resulting data changes following an outer-consistent change. As such, F is not outer-consistent.

6. Divisive Algorithms

Our formalism provides a precise sense in which linkage-based algorithms make only local considerations, while many divisive algorithms inevitably take more global considerations into account. This fundamental distinction between these paradigms can be used to help select a suitable hierarchical algorithm for specific applications.

This distinction also implies that many divisive algorithms cannot be simulated by any linkage-based algorithm, showing that the class of hierarchical algorithms is strictly richer than the class of linkage-based algorithm (even when focusing only on the input-output behaviour of algorithms).

A 2-clustering function \mathcal{F} maps a data set (X, d) to a 2-partition of X . An \mathcal{F} -Divisive algorithm is a divisive algorithm that uses a 2-clustering function \mathcal{F} to decide how to split nodes. Formally,

Definition 23 (\mathcal{F} -Divisive) *A hierarchical clustering function is \mathcal{F} -Divisive with respect to a 2-clustering function \mathcal{F} , if for all (X, d) , $\mathcal{F}(X, d) = (T, M, \eta)$ such that for all $x \in V(T)/\text{leaves}(T)$ with children x_1 and x_2 , $\mathcal{F}(C(x)) = \{C(x_1), C(x_2)\}$.*

Note that Definition 23 does not place restrictions on the level function. This allows for some flexibility in the levels. Intuitively, it doesn't force an order on splitting nodes.

The following property represents clustering functions that utilize contextual information found in the remainder of the data set when partitioning a subset of the domain.

Definition 24 (Context sensitive) \mathcal{F} is context-sensitive if there exist x, y, z, w and distance functions d and d' , where d' extends d , such that $\mathcal{F}(\{x, y, z\}, d) = \{\{x\}, \{y, z\}\}$ and $\mathcal{F}(\{x, y, z, w\}, d') = \{\{x, y\}, \{z, w\}\}$.

Many 2-clustering functions, including k -means, min-sum, and min-diameter are context-sensitive (see Corollary 29, below). Natural divisive algorithms, such as bisecting k -means (k -means-Divisive), rely on context-sensitive 2-clustering functions.

Whenever a 2-clustering algorithm is context-sensitive, then the \mathcal{F} -divisive function is not local.

Theorem 25 *If \mathcal{F} is context-sensitive then the \mathcal{F} -divisive function is not local.*

Proof

Since \mathcal{F} is context-sensitive, there exists a distance functions $d \subset d'$ so that $\{x\}$ and $\{y, z\}$ are the children of the root in $\mathcal{F}(\{x, y, z\}, d)$, while in $\mathcal{F}(\{x, y, z, w\}, d')$, $\{x, y\}$ and $\{z, w\}$ are the children of the root and z and w are the children of $\{z, w\}$. Therefore, $\{\{x, y\}, \{z\}\}$ is clustering in $\mathcal{F}(\{x, y, z, w\}, d)$. But cluster $\{x, y\}$ is not in $\mathcal{F}(\{x, y, z\}, d)$, so the clustering $\{\{x, y\}, \{z\}\}$ is not in $\mathcal{F}(\{x, y, z\}, d)$, and so \mathcal{F} -divisive is not local. ■

Applying Theorem 10, we get:

Corollary 26 *If \mathcal{F} is context-sensitive, then the \mathcal{F} -divisive function is not linkage-based.*

We say that two hierarchical algorithms disagree if they may output dendrograms with different clusterings. Formally,

Definition 27 *Two hierarchical functions F_0 and F_1 disagree if there exists a data set (X, d) and a clustering C of X so that C is in $F_0(X, d)$ but not in $F_1(X, d)$, for some $i \in \{0, 1\}$.*

Theorem 28 *If \mathcal{F} is context-sensitive, then the \mathcal{F} -divisive function disagrees with every linkage-based function.*

Proof Let L be any linkage-based function. Since \mathcal{F} is context-sensitive, there exists distance functions $d \subset d'$ so that $\mathcal{F}(\{x, y, z\}, d) = \{\{x\}, \{y, z\}\}$ and $\mathcal{F}(\{x, y, z, w\}, d') = \{\{x, y\}, \{z, w\}\}$.

Assume that L and \mathcal{F} -divisive produce the same output on $(\{x, y, z, w\}, d')$. Therefore, since $\{\{x, y\}, \{z\}\}$ is a clustering in \mathcal{F} -divisive($\{x, y, z, w\}, d'$), it is also a clustering in $L(\{x, y, z, w\}, d')$. Since L is linkage-based, by Theorem 10, L is local. Therefore, $\{\{x, y\}, \{z\}\}$ is a clustering in $L(\{x, y, z\}, d)$. But it is not a clustering in \mathcal{F} -divisive($\{x, y, z\}, d$). ■

Corollary 29 *The divisive algorithms that are based on the following 2-clustering functions disagree with every linkage-based function: k -means, min-sum, min-diameter.*

Proof Set $x = 1$, $y = 3$, $z = 4$, and $w = 6$ to show that these 2-clustering functions are context-sensitive. The result follows by Theorem 28. ■

7. Conclusions

In this paper, we provide the first property-based characterization of hierarchical linkage-based clustering. Our characterization shows the existence of hierarchical methods that cannot be simulated by any linkage-based method, revealing inherent input-output differences between agglomeration and divisive hierarchical algorithms.

This work falls in the larger framework of property-based analysis of clustering algorithms, which aims to provide a better understanding of these techniques as well as aid users in the crucial task of algorithm selection. It is important to note that our characterization is not intended to demonstrate the superiority of linkage-based methods over other hierarchical techniques, but rather to enable users to make informed trade-offs when choosing algorithms. In particular, properties investigated in previous work should also be considered, while future work will continue to investigate important properties with the ultimate goal of providing users with a property-based taxonomy of popular clustering methods that would enable selecting suitable methods for a wide range of applications.

Abstract

It is important for causal discovery to identify any latent variables that govern a problem and the relationships among them, given measurements in the observed world. In Part I of this paper, we were interested in learning a discrete latent variable model (LVM) and introduced the concept of *pairwise cluster comparison* (PCC) to identify causal relationships from clusters of data points and an overview of a two-stage algorithm for *learning PCC* (LPCC). First, LPCC learns exogenous latent variables and latent colliders, as well as their observed descendants, by using pairwise comparisons between data clusters in the measurement space that may explain latent causes. Second, LPCC identifies endogenous latent non-colliders with their observed children. In Part I, we showed that if the true graph has no serial connections, then LPCC returns the true graph, and if the true graph has a serial connection, then LPCC returns a pattern of the true graph. In this paper (Part II), we formally introduce the LPCC algorithm that implements the PCC concept. In addition, we thoroughly evaluate LPCC using simulated and real-world data sets in comparison to state-of-the-art algorithms. Besides using three real-world data sets, which have already been tested in learning an LVM, we also evaluate the algorithms using data sets that represent two original problems. The first problem is identifying young drivers' involvement in road accidents, and the second is identifying cellular subpopulations of the immune system from mass cytometry. The results of our evaluation show that LPCC improves in accuracy with the sample size, can learn large LVMs, and is accurate in learning compared to state-of-the-art algorithms. The code for the LPCC algorithm and data sets used in the experiments reported here are available online.

Keywords: learning latent variable models, graphical models, clustering, pure measurement model

1. Introduction

We began Part I by describing the task of learning a latent variable model (LVM). We dispensed with the linearity assumption (for a child given its parents) and concentrated on the discrete case. In addition, we did not limit our analysis to learning latent-tree mod-

els and focused on multiple indicator models (MIMs) that are a very important subclass of structural equation models (SEM) – models that are widely used in applied and social sciences to analyze causal relations. By borrowing ideas from unsupervised learning, we could introduce the notion of pairwise cluster comparison (PCC). PCC compares pairwise clusters of data points representing instantiations of the observed variables to identify those pairs of clusters that exhibit changes in the observed variables due to changes in their ancestor latent variables. Changes in a latent variable that are manifested in changes in its descendant observed variables reveal this latent variable and its causal paths of influence in the domain. Learning PCC (LPCC) was introduced as a tool to transform data clusters into knowledge about latent variables – their number, types, cardinalities, and interrelations among themselves and with the observed variables – that is needed to learn an LVM.

Part I provided preliminaries and the theoretical support of LPCC. Several definitions and theorems that were already introduced also play an important role in Part II. To ease reading Part II, on the one hand, and to supply the necessary theoretical background, on the other hand, we have summarized these definitions, propositions, and theorems from Part I here in Appendix A. Following is a brief summary of the PCC concept and LPCC algorithm; the full details appear in Part I.

First in the LPCC algorithm is clustering of data that are sampled from the observed variables in the unknown model. Clustering in the current implementation is based on the self-organizing map (SOM) algorithm (Kohonen, 1997), although any other clustering algorithm that does not need a preliminary determination of the number of clusters may be suitable.¹ Second, LPCC selects an initial set of major clusters (Section 4.3 of Part I; Definition 12 in Appendix A²). Third, LPCC learns an LVM in two stages. In the first stage (Section 4.1 of Part I), LPCC analyzes PCCs³ (Definition 15) between two major clusters to find maximal sets of observed (**MSO** by Definition 16) variables that always change together. By Theorem 1, variables of a particular **MSO** are children of a particular exogenous latent variable or its latent non-collider descendant or children of a particular latent collider. This stage allows the identification of exogenous latent variables and latent colliders together and their corresponding observed descendants. Then (Section 4.2 of Part I), LPCC distinguishes the latent colliders from the exogenous latent variables using Theorem 2. To complete this stage, LPCC iteratively improves the selection of the major clusters (Section 4.3 of Part I), and the entire stage is repeated until convergence. In the second stage, LPCC identifies endogenous latent non-colliders with their children (Section 4.4 of Part I). Because distinguishing endogenous latent non-colliders from their exogenous ancestors could not be performed using major-major PCCs, in this stage LPCC needs to apply a mechanism to split these two types of latent variables from each other and then direct them using comparison of major clusters to (a special type of) minor clusters (2S-MC; Definition 14) that correspond to 2-order minor effects (Definition 13). For this task, LPCC

¹See for example Section 3.6, where we replaced SOM with hierarchical clustering.

²The definitions and theorems that are mentioned here are borrowed from Part I and are summarized in Appendix A.

³PCC is a procedure by which pairs of clusters are compared through a comparison of their centroids, and the result can be represented by a binary vector in which each element is 1 or 0 depending, respectively, on whether or not there is a difference between the corresponding elements in the compared clusters.

analyzes 2S-PCCs (Definition 18), which are PCCs between major and minor clusters that show two sets (this is the source of “2S” in the name 2S-PCC) of two or more elements in the PCC, and identifies 2S-MSOs (Definition 19), which are maximal sets of observed variables that always change their values together in all 2S-PCCs. Different 2S-MSOs due to an exogenous latent variable represent latent non-colliders that are descendants of this exogenous variable; hence, LPCC can distinguish between the two types of variables by analyzing 2S-MSOs (Theorem 3). To direct the edges between latent non-colliders on a path emerging in an exogenous latent, LPCC checks changes of several 2S-PCCs with respect to changes of the latent non-colliders’ exogenous ancestor. Theorem 4 guarantees that LPCC finds all diverging connections and represents all serial connections using a pattern of the true graph, which completes learning the LVM. A flowchart of the LPCC algorithm is given in Figure 1.

A main section of Part II is a formal description of the two-stage LPCC algorithm, which is founded on the PCC concept. Part II also provides an experimental evaluation of LPCC, in comparison to state-of-the-art algorithms, using simulated data sets (Section 3.1) and real-world data sets (Sections 3.2–3.6). The outline of the paper is as follows:

- **Section 2: The LPCC algorithm** introduces and formally describes a two-stage algorithm that implements the PCC concept;
- **Section 3: LPCC evaluation** evaluates LPCC, in comparison to state-of-the-art algorithms, using simulated data sets (Section 3.1) and real-world data sets (Sections 3.2–3.6);
- **Section 4: Related works** compares LPCC to state-of-the-art LVM learning algorithms;
- **Section 5: Discussion** summarizes the theoretical advantages (from Part I) and the practical benefits (from this part) of using LPCC;
- **Appendix A** provides essential assumptions, definitions, propositions, and theorems from Part I;
- **Appendix B** supplies additional results for the experiments with the simulated data sets (Section 3.1); and
- **Appendix C** provides PCC analysis for two example databases.

2. The LPCC algorithm

We introduced a two-stage algorithm, LPCC, that implements the PCC concept (Part I). The algorithm gets a data set \mathbf{D} over the observed variables \mathbf{O} and learns an LVM. In the first stage, LPCC learns the exogenous variables and the latent colliders as well as their descendants using the LEXC algorithm (Section 2.1). In the second stage, LPCC augments the graph learned by LEXC by learning the endogenous latent non-colliders and their children using the LNC algorithm (Section 2.2).

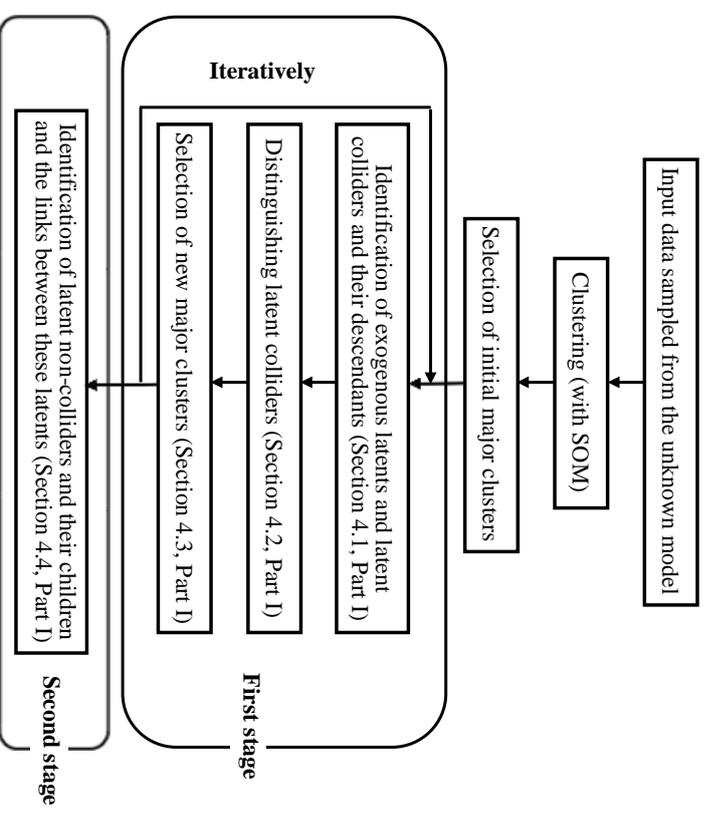

Figure 1: An overview of the LPCC algorithm as described in Part I.

2.1 Learning exogenous and latent colliders (LEXC)

LEXC (Algorithm 1) adapts an iterative approach and learns the initial graph in six steps. The first step is clustering \mathbf{D} using the self-organizing map (SOM) (Kohonen, 1997). We chose SOM because it does not require prior knowledge about the expected number of clusters, which is essential when targeting uncertainty in the number of latent variables in the model, but any other clustering algorithm that preserves this property can replace SOM. The result of the first step is a cluster set \mathbf{c} in which each cluster c is represented by its centroid.

In the second step, LEXC performs an initial selection of the major clusters set (Definition 12 in Appendix A), where a cluster in \mathbf{c} whose size (measured by the number of clustered patterns) is larger than the average cluster size in \mathbf{c} is selected as a major cluster (Section 4.3 of Part I). $\mathbf{MC} = \{\mathbf{MC}_j\}_{j=1}^n$ is a matrix that holds information about the major clusters, where each matrix row represents a centroid of one of the n major clusters (see, e.g., Table 2 in Part I).

In the third step, LEXC creates a matrix that represents all PCCs (Definition 15), derived from \mathbf{MC} . This matrix is $\mathbf{PCCM} = \{\mathbf{PCC}_{ij}\}_{i=1, j>1}^{n,n}$ where \mathbf{PCC}_{ij} is a Boolean vector representing the result of PCC between major clusters c_i and c_j having centroids \mathbf{MC}_i and \mathbf{MC}_j in \mathbf{MC} , respectively (see, e.g., Table 4 in Part I). The k -th element of \mathbf{PCC}_{ij} represents by “1” a change in value, if one exists, in the observed variable $O_k \in \mathbf{O}$ when comparing \mathbf{MC}_i and \mathbf{MC}_j (for example, Table 4 in Part I shows a change in element 7, corresponding to X_7 , of $\mathbf{PCC}_{2,9}$ between C2 and C9). We use the notation $\mathbf{PCC}_{ij} \rightarrow \delta O_k$ if the value of O_k has been changed and $\mathbf{PCC}_{ij} \rightarrow \neg\delta O_k$ otherwise.

In the fourth step, LEXC identifies exogenous latents and their descendants (Theorem 1) using a matrix \mathbf{MSOS} that holds all \mathbf{MSOs} (Definition 16) that always change their corresponding values together in all major-major PCCs in \mathbf{PCCM} . For each identified \mathbf{MSO}_i , LEXC adds a latent L_i to \mathbf{G} and to a latent set \mathbf{L} and also edges from L_i to each observed variable $O \in \mathbf{MSO}_i$. The observed children of latent $L_i \in \mathbf{L}$ in \mathbf{G} are \mathbf{Ch}_i .

In the fifth step, LEXC identifies in two phases, each corresponding to one condition in Theorem 2, the latent variables that are collider nodes in the graph along with their latent ancestors. In the first phase, LEXC considers for each latent variable $L_i \in \mathbf{L}$, a set of potential ancestors from the other latents in \mathbf{L} . We call them potential ancestors because another condition should be fulfilled in the second phase to turn them into actual ancestors. To simplify the notation, we represent the latent as an object and the set of potential ancestors as a field of this object, called \mathbf{PAS} (for potential ancestor set). For example, $L_i.\mathbf{PAS}$ represents that LEXC identifies a potential ancestor set \mathbf{PAS} to latent L_i . In addition, we use the notation $\mathbf{PCC}_{fg} \rightarrow \delta L_i$ if all of the variables in \mathbf{Ch}_i change their values in $\mathbf{PCC}_{fg} \in \mathbf{PCCM}$ and $\mathbf{PCC}_{fg} \rightarrow \neg\delta L_i$ otherwise. In the first phase of the fifth step, LEXC checks for each $L_j \in \mathbf{L}$ whether there exists a vector $\mathbf{PCC}_{fg} \in \mathbf{PCCM}$ in which L_j changes value together with $L_j \in \mathbf{L}$, but not with $L_k \in \mathbf{L}, \forall k \neq i, j$, and if so, it adds L_j to $L_i.\mathbf{PAS}$. At the end of this phase, the set $L_i.\mathbf{PAS}$ contains all of the latents in \mathbf{L} that change values with L_i in \mathbf{PCCM} . Still, this is not enough to decide that L_j is a collider of the variables in $L_i.\mathbf{PAS}$. An additional condition must be fulfilled, which is that L_j should never have changed in any $\mathbf{PCC}_{fg} \in \mathbf{PCCM}$ unless at least one of the variables in $L_i.\mathbf{PAS}$ has also changed in this \mathbf{PCC}_{fg} (Section 4.2 of Part I). The second phase of the fifth step checks this condition, and

Algorithm 1 LEXC

```

if fulfilled, it adds an edge from each variable in L_i , **PAS** to L_j to complete the identification of L_j as a collider.

In the sixth and last step, and to deal with possible false positive and false negative errors (Section 4.3 of Part I), LEXC searches for a new set of major clusters **NMC** based on the already learned graph and all the clusters that initially were identified by SOM. First, LEXC learns for each latent $L_i \in \mathbf{L}$ its cardinality, which is the number of different value configurations of L_i corresponding to all value configurations of \mathbf{Ch}_i in \mathbf{D} . Each such value configuration of observed children is due to a value l_i of L_i , and we denote it by $l_i \rightarrow \mathbf{ch}_i$. Then, LEXC finds the set of all possible **exs** (all possible configurations of all exogenous latents in \mathbf{L} , $L_i \in \mathbf{L} \cap \mathbf{EX}$). For each **ex**, LEXC finds the most probable cluster, $c^* = \mathit{argmax}_{c \in \mathbf{C}} P(c|\mathbf{ex})$, where the posterior probability $P(c|\mathbf{ex})$ for each $c \in \mathbf{C}$ is approximated by the ratio between c 's size and the size of \mathbf{D} . Thus, the cluster for which the values corresponding to the children of $L_i \in \mathbf{L} \cap \mathbf{EX}$, $l_i \rightarrow \mathbf{ch}_i$, are most probable due to l_i in **ex** is selected as the most probable to represent this **ex**. Each such cluster is added to **NMC**. If **NMC=MC**, **NMC** cannot improve the graph, and thus LEXC stops and returns the learned graph \mathbf{G} . Otherwise, LEXC reinitializes **MC** to be **NMC** and relearns a new graph.

2.2 Learning latent non-colliders (LNC)

Using the data set \mathbf{D} , LNC has to split the set of latent variables \mathbf{L} in graph \mathbf{G} , which was learned by LEXC, into exogenous latents and latent non-colliders. First, LNC (Algorithm 2) adds $|\mathbf{L}|$ elements to the end of each vector in \mathbf{D} and creates an incomplete data set **IND**. For a vector in **IND** for which values of the observed children for a specific latent $L_i \in \mathbf{L}$ take major values, the value of the latent can be reconstructed exactly, $l_i \rightarrow \mathbf{ch}_i$; however, when not all observed children take major values, this value of the latent cannot be reconstructed, and this is the reason why **IND** is incomplete. Second, using the EM algorithm (Lauritzen, 1995; Dempster et al., 1977) and **IND**, LNC learns (Section 4.4 of Part I) \mathbf{G} 's parameters and uses them to compute a threshold (Appendix B in Part I) on the maximal size of 2-MCs. This threshold is needed to find 1-order minor clusters (1-MCs; Definition 14). Note that after learning the parameters, the graph turns into a model, \mathbf{M}_0 . Third, for each exogenous latent $EX_i \in \mathbf{L} \cap \mathbf{EX}$ in turn, LNC tests if EX_i should be split (Section 4.4 of Part I). For this test, LNC needs first to find the set of 1-MCs for EX_i , and to compute all the PCCs between these clusters and the major clusters for EX_i . We denote the set of these PCCs by **PCCS**. Then, LNC finds all the PCCs in **PCCS** that are **2S-PCC** (Definition 18); these will be used to identify all possible **2S-MSOs** (Definition 19) and thus all possible latent non-collider descendants that should be split from EX_i (Theorem 3).

After identifying the latent non-colliders' descendants of EX_i and splitting them from EX_i , LNC finds the links between these latents (Section 4.4 of Part I). LNC first finds the set L' of all latents whose children change alone in some 2S-PCCs. These are the candidates to be EX_i or its leaves (Proposition 10). Then, for each $L \in L'$, LNC finds the 2S-PCCs in **2S-PCC** in which the observed children of L' do not change and are due to comparisons with the same major cluster. This set is denoted by **2S-PCC'**. Then, for every two latent non-collider descendants that were split from EX_i , LNC checks if there is a directed link

between them using Theorem 4. Note that, we assume by default that L is a leaf, so LNC does not need to redirect the links in the diverging connection case. After finding all the possible directed paths, LNC identifies if the connection is serial (in case $|\mathbf{L}'|$ is exactly two) and if so it makes the links on this path undirected; otherwise, the path is directed as part of a diverging connection. Finally, LNC returns a pattern \mathbf{G} , which represents a Markov equivalence class of the true graph.

Algorithm 2 LNC

```

1: Input: Data set  $\mathbf{D}$  over the observed variables  $\mathbf{O}$  and the graph  $\mathbf{G}$  learned by LEXC
2: Output: The final learned LVM  $\mathbf{G}$ 
3: Initialize: IND =  $\mathbf{0}$ , PCCS =  $\phi$ , 2S-PCC =  $\phi$ , 2S-MSOS =  $\phi$ , 2S-PCC' =  $\phi$ 
4: Create IND (see text)
5: Learn  $\mathbf{G}$ 's parameters using the EM algorithm to obtain an LVM,  $\mathbf{M}_0$ 
6: For each latent  $EX_i \in \mathbf{L}$ 
7:   Identify and split the latent non-collider descendants of  $EX_i$ 
8:   Find the set of 1-MCs according to  $\mathbf{M}_0$ 
9:   PCCS  $\leftarrow$  compute all PCCs between the 1-MCs and the major clusters for  $EX_i$ 
10:  2S-PCC  $\leftarrow$  find all 2S-PCCs in PCCS
11:  2S-MSOS  $\leftarrow$  find all possible 2S-MSOs using 2S-PCC
12:  For each 2S-MSO $_j \in \mathbf{2S-MSOS}$ 
13:    Add a latent non-collider  $NC_j$  to  $EX_i$ ,  $\mathbf{L}$ , and  $\mathbf{G}$ 
14:    For each observed variable  $O \in \mathbf{2S-MSO}_j$ 
15:      Split  $O$  from the children of  $EX_i$  and add an edge  $NC_j \rightarrow O$  to  $\mathbf{G}$ 
16:    Identify the links between the new latent non-colliders that were split from  $EX_i$ 
17:     $\mathbf{L}' \leftarrow$  all latents that were split (including  $EX_i$ ) and whose observed children change alone
    in some 2S-PCC
18:    For each  $L' \in \mathbf{L}'$  % assume by default  $L'$  is a leaf and apply Theorem 4
19:      2S-PCC'  $\leftarrow$  all 2S-PCCs in 2S-PCC in which the observed children of  $L'$  do not change
20:      For each two latent non-colliders  $NC_j, NC_k$ ,  $k \neq j$  that were split from  $EX_i$ :
21:        If
22:          1) the observed children of  $NC_k$  always change with those of  $NC_j$  in 2S-PCC'; and
23:          2) the observed children of  $NC_j$  change  $t$  times and the observed children of  $NC_k$ 
           change  $t+1$  times in 2S-PCC'
24:          Then add a directed edge from  $NC_k$  to  $NC_j$  to  $\mathbf{G}$ 
25:        % Identify if the connection is serial, and if so make the links in the path undirected
26:        If  $|\mathbf{L}'|=2$ 
27:          If there are two paths with the same latents but opposite directions, then make the edges
           between the latents undirected.
28:        Return  $\mathbf{G}$ 

```

3. LPCC Evaluation

We implemented the LPCC algorithm in Matlab, except for the SOM algorithm that was implemented using the SOM Toolbox (Vesanto et al., 2000). We evaluated LPCC using simulated data sets (Section 3.1) and five real-world data sets: data from the political action survey (Section 3.2), Holzinger and Swineford's data (Section 3.3), the HIV test data (Section 3.4), data of young driver (YD) involvement in road accidents (Section 3.5), and

a mass cytometry data set of the immune system (Section 3.6). In the case of the real-world data sets, we did not have an objective measure for evaluation; thus, we compared the LPCC output to hypothesized, theoretical models from the literature and to the outputs of four state-of-the-art learning algorithms. The first algorithm is FCI (Spirtes et al., 2000), and because we noticed (see below) for the political action survey and Holzinger and Swineford’s data sets that FCI is not suitable for learning MIM models, we did not use it for the other data sets. The second algorithm is for learning HLC models (Zhang, 2004), and since the theoretical models for all but the HIV data set are not latent-tree models, we used this algorithm only for the HIV data set. The third algorithm is exploratory factor analysis (EFA). Because the theoretical models for the political action survey and Holzinger and Swineford’s data set were already tested by confirmatory factor analysis [Joreskog, 2004; Arbuckle, 1997, p. 375]; and [Joreskog and Sorbom, 1989, p. 247]], we completed the examination of EFA also to the YD and mass cytometry data sets. The fourth algorithm, which is actually two algorithms, BuildPureClusters (BPC) and BuildSinglePureClusters (BSPC) of Silva (2005), is especially suitable for MIM models. BPC is Silva’s (2005) main algorithm; hence, we used it in all the evaluations. BPC assumes that the observed variables are continuous and normally distributed, whereas BSPC is a variant of BPC for discrete observed variables. We ran BPC using its implementation in the Tetrad IV package, which can take discrete data (as in all the data sets in this evaluation), as input and treat them as continuous.⁴ BPC learns LVM by testing Tetrad constraints at a given significance level (α). We used Wishart’s Tetrad test (Silva, 2005; Spirtes et al., 2000; Wishart, 1928), applying three significance levels of 0.01, 0.05 (Tetrad’s default), and 0.1. For the simulated data sets, we compared LPCC to EFA and BPC.

3.1 Evaluation using simulated data sets

We used Tetrad IV to construct the graphs G1, G2, G3, and G4 of Figure 2, once with binary and once with ternary variables. The priors on the exogenous latents were always distributed uniformly. We compared performances for three parameterization levels that differ by the conditional probabilities, $p_j=0.7, 0.75,$ and 0.8 , between a latent L_k and each of its children EN_i . For all graphs in the binary case, except L2 in G2, $P(EN_i = v | L_k = v) = p_j, v = 0$ or 1 . For all graphs in the ternary case, except L2 in G2, $P(EN_i = v | L_k = v) = p_j, P(EN_i \neq v | L_k = v) = (1 - p_j)/2, v = 0, 1,$ or 2 . Concerning L2 in G2, $P(L_2 = 0 | L_1, L_3 = 0, 0, 1, 1, 0) = P(L_2 = 1 | L_1, L_3 = 1) = p_j$ in the binary case and $P(L_2 = v | \max\{L_1, L_3\} = v) = p_j$ and $P(L_2 \neq v | \max\{L_1, L_3\} = v) = (1 - p_j)/2$ in the ternary case. Each such scheme imposes a different “parametric complexity” on the model and thereby affects the task of learning the latent model and the causal relations. That is, using $p_j=0.7$ poses a larger challenge to learning than $p_j=0.75$, which poses a larger challenge than $p_j=0.8$. For example for G3 and the binary case, the correlations between any latent and any of its children for the parametric settings $p_j=0.7, 0.75,$ and 0.8 are $0.4, 0.5,$

⁴Although all our data sets are discrete and BSPC is the suggested algorithm in Silva (2005) for discrete data, BSPC is neither published nor implemented in Tetrad IV, and is only mentioned in a complementary chapter in Silva (2005) as a variant of BPC suitable for discrete data. Since no concrete algorithm is suggested for BSPC, we used BPC as described above. However, for the political action survey, we could use the results for BSPC that are provided in Silva (2005). The Tetrad package is available at <http://www.phil.cmu.edu/projects/tetrad>.

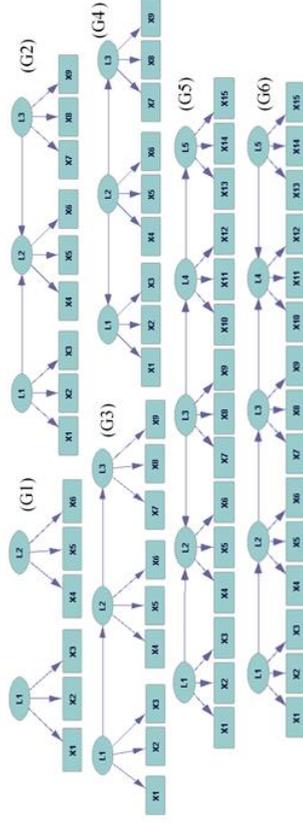

Figure 2: Example LVMs that are all MIMs. Each is based on a pure measurement model and a structural model of different complexity, posing a different challenge to a learning algorithm.

and 0.6 , respectively. Note that correlation of 0.4 is relatively low, providing a great challenge to the learning algorithms, and trying to learn an LVM for lower correlation values yields poor results by all algorithms.⁵ Tetrad IV was also used to draw data sets of 125, 250, 500, 750, 1000, and 2,000 samples for each test. Overall, we evaluated the LPCC algorithm using 144 synthetic data sets for four graphs (G1–G4), two types of variables, three parameterization levels, and six data set sizes.

In addition, we evaluated LPCC using the two large graphs in Figure 2, G5 and G6, which combine all types of links between the latents, such as serial, converging, and diverging. Each graph has five latents with three observed children each. Tetrad IV was used to draw data sets of 250, 500, 1000, and 2,000 samples, where all variables are binary and for two parametric settings $p_j=0.75$ and 0.8 . In all cases, we report on the structural hamming distance (SHD) (Tsamardinos et al., 2006) as a performance measure for learning the LVM structure. SHD is a global structural measure that accounts for all the possible learning errors: addition and deletion of an undirected edge, and addition, removal, and reversal of edge orientation.

Figures 3–5 show learning curves for SHD (the lower value is the better one) and increasing sample sizes for LPCC, BPC, and EFA. Figures 3 and 4 show SHD performance in learning G1–G4 with binary variables and ternary variables, respectively, and for two parametric settings, $p_j=0.7$ and 0.8 . Figure 5 shows performance in learning G5 and G6 with binary variables for two parametric settings $p_j=0.75$ and 0.8 (for $p_j=0.7$ the algorithms performed poorly and thus their results are excluded here). In addition, in Appendix B, we compare LPCC with BPC (Section B.1) and with EFA (Section B.2) in learning G1–G4 with binary and ternary variables for three parametric settings, $p_j=0.7, 0.75,$ and 0.8 . The graphs demonstrate the LPCC sensitivity to the parametric complexity – the

⁵For example, a common practice in EFA is that a correlation (loading) of at least 0.4 is needed in order to add a link between a latent variable and an observed variable.

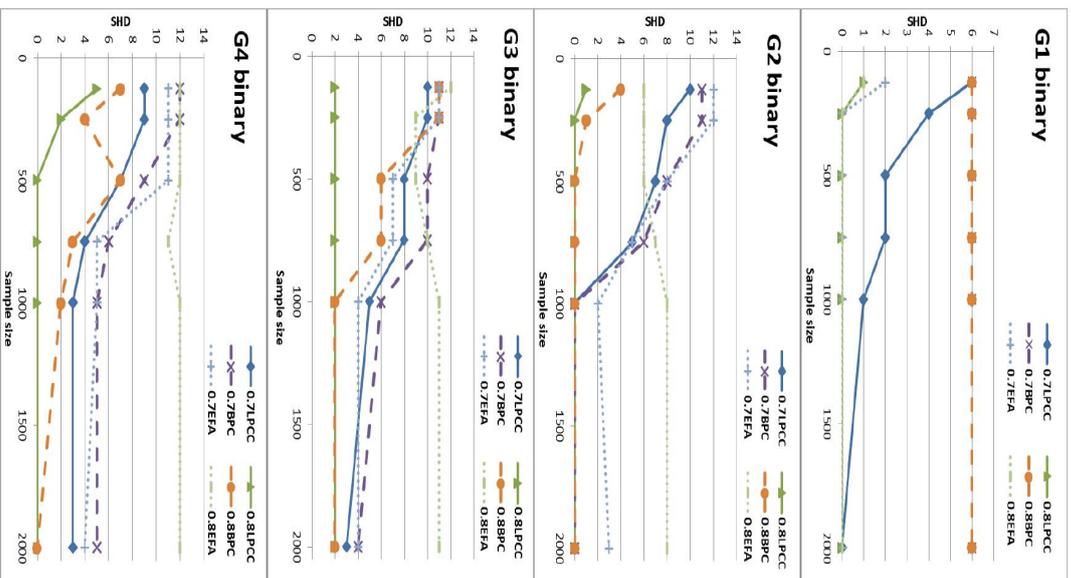

Figure 3: SHD learning curves of LPCC compared to those of BPC and EFA for G1–G4 of Figure 2 with binary variables, two parameterization levels, and increasing sample sizes. The lines of LPCC and EFA for a parametrization of 0.8 coincide for G1.

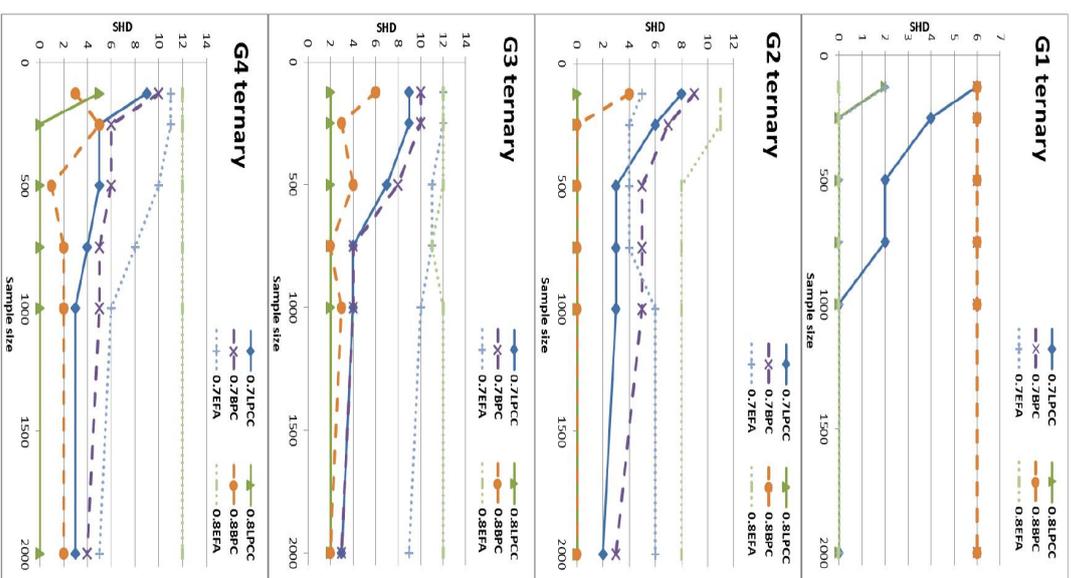

Figure 4: SHD learning curves of LPCC compared with those of BPC and EFA for G1–G4 of Figure 2 with ternary variables, two parameterization levels, and increasing sample sizes. The line of LPCC for a parametrization of 0.7 coincides with that of EFA for a parametrization of 0.7 for G1.

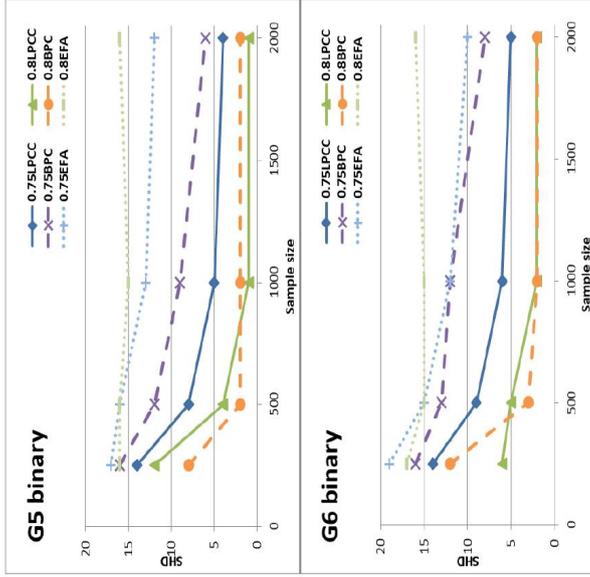

Figure 5: SHD learning curves of LPCC compared to those of BPC and EFA for G5 and G6 of Figure 2 with binary variables, two parameterization levels, and increasing sample sizes.

lower the complexity is, the faster learning is and the sooner the error vanishes – and the LPCC good asymptotic behavior, demonstrating accuracy improvement with the sample size. Generally, Figures 3–5 (and those in Appendix B) show superiority of LPCC over BPC and EFA; LPCC demonstrates higher accuracies (smaller errors) and a better asymptotic behavior than BPC and EFA.

Specifically in regard to EFA, the algorithm – contrary to what is expected from a learning algorithm (see LPCC and BPC) – fails as the experiment conditions improve and the learning task becomes easier (e.g., larger parameterization levels and/or data samples as in the graphs for G4 with binary variables and G2 with ternary variables). Larger parameterization levels increase the chances of EFA to learn links between latent variables and observed variables – some of them are not between a latent and its real child – to compensate for the algorithm’s inability to identify links among latents (as EFA assumes latents are uncorrelated). The increase in the sample size helps increase the confidence of EFA in learning these erroneous links (see the graphs for G2, G5, and G6 with binary variables). As Figures 3–5, together with the more detailed Figures 19 and 20 in Appendix B, demonstrate, EFA is inferior to LPCC for all parameterization levels and sample sizes

and all graphs but G1. Independent latent variables, as manifested in G1, is the ultimate prerequisite for a successful application of EFA, and indeed, EFA shows competitive (and sometimes, for small sample sizes, even slightly improved) performance to LPCC in learning G1.

Unlike LPCC, BPC is not suitable for learning models such as G1, where the latents are independent and each has fewer than four observed children. This is because BPC requires the variables in a Tetrad constraint to all be mutually dependent, where in the case of G1, there are at most three mutually dependent variables, so no Tetrad constraint can be tested, and no graph is learned (SHD=6 for missing all the six edges in G1). However, it is reasonable to assume that a practitioner would naturally analyze the data before trying BPC, and if they recognize that not all observed variables are correlated (e.g., X1 and X4 for G1), then they will not use BPC. As Figures 3–5, together with the more detailed Figures 17 and 18 in Appendix B, demonstrate, for most graphs, parameterization levels, and sample sizes (except for some cases with small sample sizes), LPCC is superior to BPC.

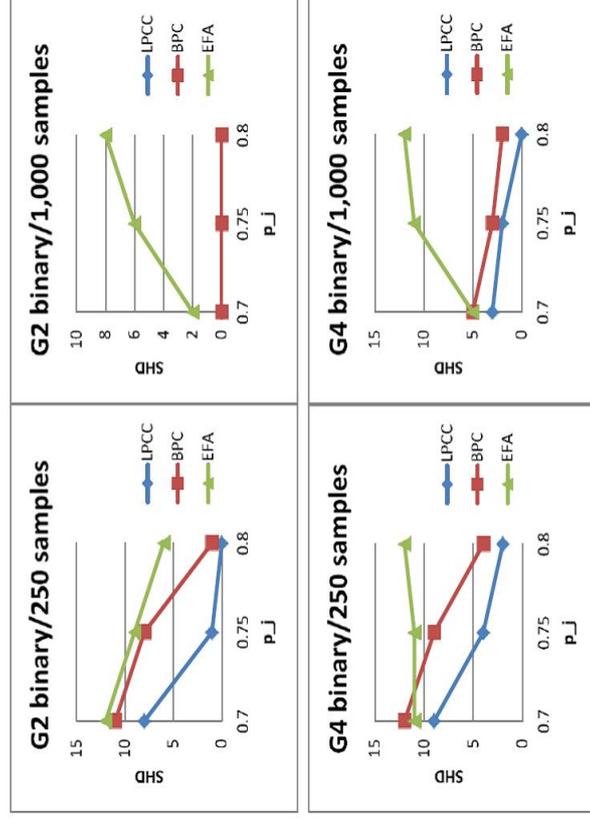

Figure 6: SHD of the LPCC, BPC, and EFA algorithms for increasing parameterization levels for four combinations of learned graphs (G2 and G4) and sample sizes (250 and 1,000 samples). Note that for G2/1,000 samples, both LPCC and BPC learn the structure perfectly for any parameterization level.

Another view of these results is manifested in Figure 6 that shows SHD values for the LPCC, BPC, and EFA algorithms for increasing parametrization levels for four combinations of learned graphs and sample sizes. Figure 6 shows that both LPCC and BPC improve performance, as expected, with increased levels of latent-observed variable correlation (ρ_j): LPCC never falls behind BPC, and its advantage over BPC is especially vivid for a small sample size. EFA, besides falling behind LPCC and BPC, also demonstrates worsening of performance with increasing the parametrization level, especially for large sample sizes, for the reasons provided above.

Finally, we expand the evaluation by examining the algorithms when the number of indicators a latent has increases. Figure 7 shows the SHD values of the LPCC, BPC, and EFA algorithms for increasing numbers of binary indicators per latent variable in G2, a parametrization level (ρ_j) of 0.75, and four sample sizes. The figure exhibits clear superiority of LPCC over BPC and EFA for almost all numbers of indicators and sample sizes. While LPCC hardly worsens its performance with the increase of complexity (number of indicators a latent has), both BPC and EFA are affected by this increase. Also worth mentioning is the difficulty these two latter algorithms have in learning an LVM for which latent variables have exactly two indicators, regardless of the sample size.

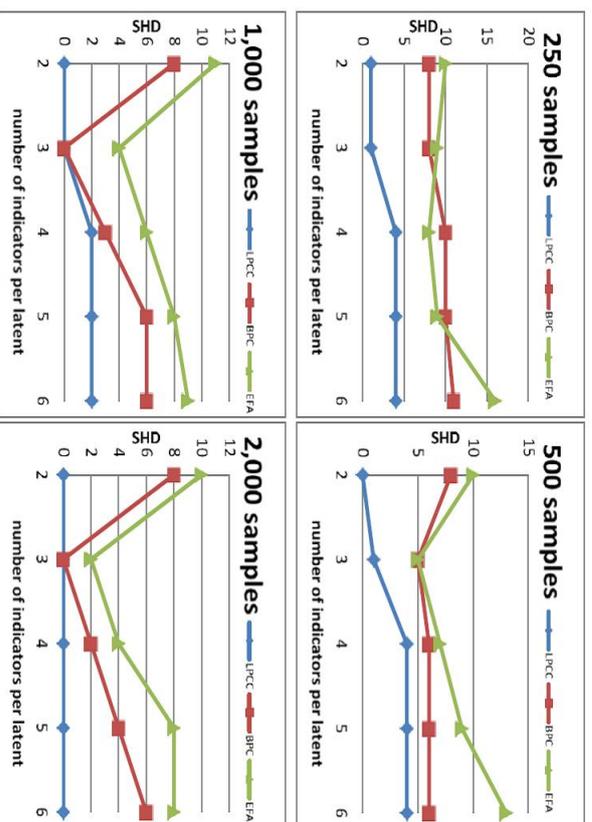

Figure 7: SHD values of the LPCC, BPC, and EFA algorithms for increasing numbers of binary indicators a latent variable has in G2, $\rho_j = 0.75$, and four sample sizes.

To understand the differences among the three algorithms in more detail, we analyze the errors they make. For example, when using 1,000 samples (the reference is the bottom-left graph in Figure 7). When the number of indicators a latent has is less than 4, LPCC learns the LVM perfectly, and when this number is greater, LPCC errs twice in missing an edge from a latent to one of its indicators. BPC cannot learn an LVM using two indicators per latent, and thus it misses all eight edges in G2 and returns an empty graph. It successfully learns the LVM when each latent has exactly three indicators, but then fails to direct the edges among the latent variables and misses at least a single edge between a latent and an indicator when the latent variables have more than three indicators each. For two indicators per latent, EFA detects only two factors and fails to connect them. It connects one factor to six indicators and the second factor to five indicators, and thereby errs in learning seven extra edges from latent variables to observed variables, missing two edges from the missing latent variable to two observed variables, and missing the two edges among the latent variables, which accounts for eleven errors in total. For three indicators per latent, EFA detects three indicators for two of the latents and five indicators for the other and misses the edges among the latents, which accounts for four errors in total. For four to six indicators per latent, EFA learns more extra edges between the latent and observed variables, together with missing the edges among the latents. This experiment vividly demonstrates the advantage of LPCC over BPC and EFA in that not only does LPCC detect edges between latent and observed variables more accurately, but it also detects latent-latent connections in all scenarios, which is impressive especially when the sample size is small and/or the number of indicators a latent has is large.

3.2 The political action survey data

We evaluated LPCC using a simplified political action survey data set over the following six variables (Joreskog, 2004):

- NOSAY: “People like me have no say in what the government does.”
- VOTING: “Voting is the only way that people like me can have any say about how the government runs things.”
- COMPLEX: “Sometimes politics and government seem so complicated that a person like me cannot really understand what is going on.”
- NOCARE: “I don’t think that public officials care much about what people like me think.”
- TOUCH: “Generally speaking, those we elect to Congress in Washington lose touch with people pretty quickly.”
- INTEREST: “Parties are only interested in people’s votes, but not in their opinions.”

These six variables represent the operational definition of political efficacy and correspond to questions to which the respondents have to give their degree of agreement on a discrete ordinal scale of four values. This data set is available as part of the LISREL software for latent variable analysis and contains the responses to these questions from a

sample of 1,076 United States respondents. A model consisting of two latents that correspond to a previously established theoretical trait of Efficacy and Responsiveness based on Joreskog (2004) is given in Figure 8a. VOTING is discarded by Joreskog for this particular data based on the argument that the question for VOTING is not clearly phrased.

Similar to the theoretical model, LPCC finds two latents (Figure 8b): One corresponds to NOSAY and VOTING and the other corresponds to NOCARE, TOUCH, and INTEREST (a detailed description of the PCC analysis that led to these results is in Appendix C). Compared with the theoretical model, LPCC misses the edge between Efficacy and NOCARE and the bidirectional edge between the latents. Both edges are not supposed to be discovered by LPCC or BSPC/BPC; the former because the algorithms learn a pure measurement model in which each observed variable has only one latent parent and the latter because no cycles are assumed. Nevertheless, compared with the theoretical model, LPCC makes no use of prior knowledge.

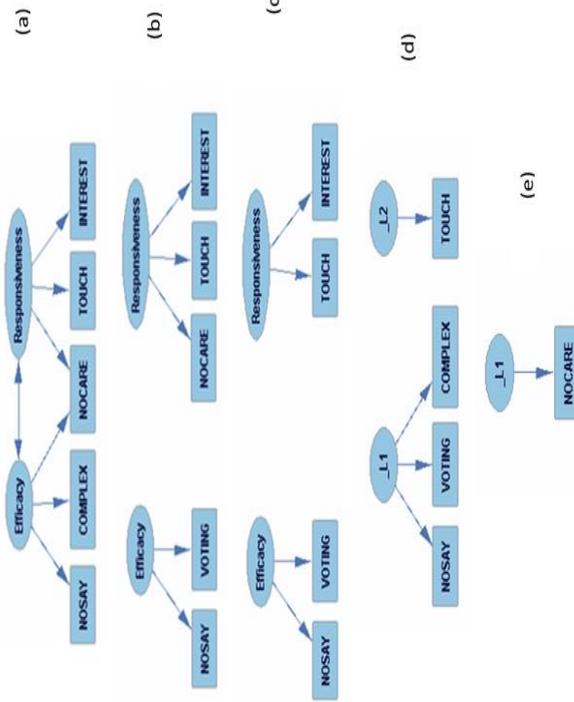

Figure 8: The political action survey: (a) A theoretical model (Joreskog, 2004) and five outputs of (b) LPCC, (c) BSPC, (d) BPC for $\alpha=0.01$ and 0.05, and (e) BPC for $\alpha=0.1$.

BSPC output (Figure 8c) is very similar to LPCC output, except for NOCARE, which was not identified by BSPC as a measure of Responsiveness, making the output obtained by LPCC closer to the theoretical model than that of BSPC. In addition, both algorithms

identify VOTING as a child of Efficacy (at the expense of COMPLEX), and thereby challenge the decision made in Joreskog (2004) to discard VOTING from the model. The outputs of the BPC algorithm (Figure 8d) for both $\alpha=0.01$ and $\alpha=0.05$ are poorer than those of LPCC and BSPC. BPC finds two latents. The first latent corresponds to NOSAY, VOTING, and COMPLEX with partial resemblance to the theoretical model (identifying NOSAY and COMPLEX as indicators of this latent) and partial resemblance to the outputs of LPCC and BPC (identifying NOSAY and VOTING as indicators of the latent). However, the second latent found by BPC corresponds only to TOUCH and misses INTEREST (identified in the theoretical model and by LPCC and BSPC as an indicator of Responsiveness) and NOCARE (that is identified in the theoretical model and by LPCC as an indicator of Responsiveness). The output of the BPC algorithm using $\alpha=0.1$ (Figure 8e) gives very little information about the problem as it finds only one latent that corresponds only to NOCARE. These last two figures show the sensitivity of BPC to the significance level, which is a parameter whose value should be determined beforehand. Note that the success of the LPCC and BSPC algorithms emphasizes the importance of such algorithms in learning discrete problems.

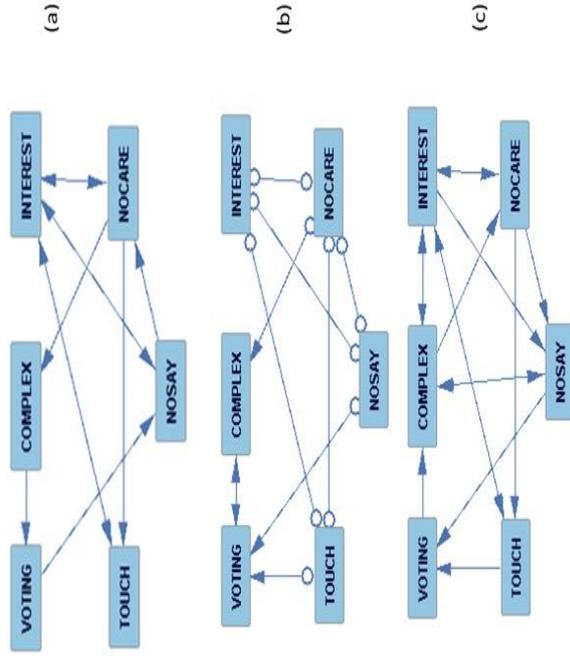

Figure 9: FCI outputs for the political action survey data set and significance levels of (a) 0.01, (b) 0.05, and (c) 0.1.

The outputs of the FCI algorithm using any of the above significance levels are not sufficient (Figure 9). For example, the FCI outputs that were learned using $\alpha=0.01$ (Figure 9a) and 0.05 (Figure 9b) show that NOSAY and INTEREST potentially have a latent common cause. However, these two variables are indicators of different latents in the theoretical model. These results are understandable because unlike LPCC, BPC, and BSPC, FCI is not suitable for learning MIM models such as the political action survey.

3.3 Holzinger and Swineford’s data

Holzinger and Swineford (1939) collected data from 26 psychological tests administered to 145 seventh- and eighth-grade children in the Grant-White School in Chicago, Illinois. In this evaluation, we use a subset of this data over only six variables representing the scores in six intelligence tests. The variables are: scores on a visual perception test (VisPerc), scores on a cube test (Cubes), scores on a lozenge test (Lozenges), scores on a paragraph comprehension test (ParComp), scores on a sentence completion test (SenComp), and scores on a word meaning test (WordMean). There are two hypothesized intelligence factors, which are spatial ability and verbal ability factors. The first three variables measure spatial ability and the latter three variables measure verbal ability. A confirmatory factor model that fits this data well was extracted from the Amos manual (Arbuckle 1997, p. 375; Joreskog and Sorbom 1989, p. 247) and is shown in Figure 10a.

We ran LPCC using a dichotomous (binary) presentation of the continuous data. For each variable, scores that were above the average score were recorded as 2, and scores below the average score were recorded as 1. Despite the small size of the data set and the loss of information due to the discretization process, LPCC found two latents (Figure 10b). The first latent corresponds to VisPerc and Lozenges, and the other latent corresponds to ParComp, SenComp, and WordMean (a detailed description of the PCC analysis is in Appendix C). Our model matches the theoretical model, except for missing one link between Spatial and Cubes (and the link between the latents that the model is not supposed to identify).

The outputs of the BPC algorithm using $\alpha=0.01$ and 0.05 (Figure 10c) were not good compared to the theoretical model and LPCC output. In both cases, BPC found only a single latent variable that corresponds to only four of the six indicators, specifically, VisPerc, Lozenges, Cubes, and WordMean. Notice that WordMean and the other three variables belong to two different latent variables in the theoretical model. However, for a significance level of 0.1 , BPC output (Figure 10d) is the closest of all models to the theoretical model. These results show the sensitivity of BPC to the significance level, which is a parameter that does not have a predetermined value. LPCC does not have this disadvantage. Note that the superiority of BPC for a significance level of 0.1 for Holzinger and Swineford’s data set is in contrast to the model inferiority for other significance levels (Figure 10e) and for the political action survey data set with any significance level.

The output of the FCI algorithm using a significance level of 0.01 or 0.05 (Figure 11a) indicates that ParComp, SenComp, and WordMean potentially have a latent common cause. In addition, Lozenges potentially has a latent common cause with VisPerc and with Cubes, but there is no link between VisPerc and Cubes. For α of 0.1 , the output of the FCI algorithm (Figure 11b) indicates that ParComp, SenComp, and WordMean potentially

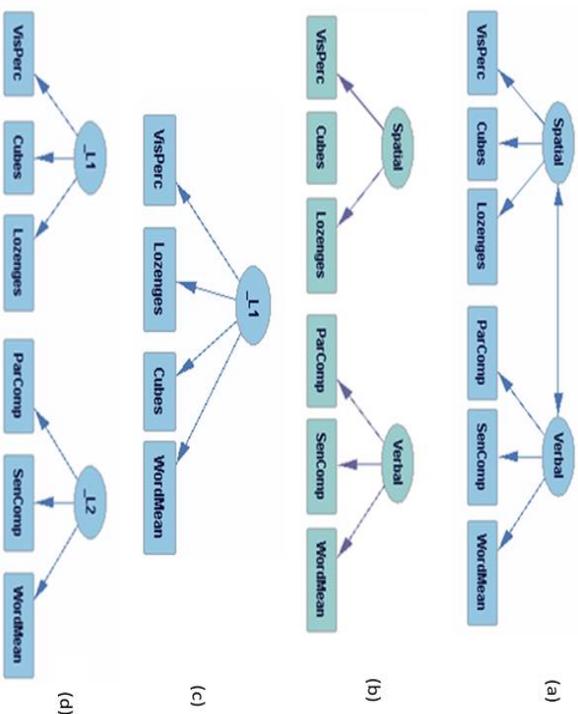

Figure 10: (a) A theoretical model for Holzinger and Swineford’s data set based on a confirmatory factor model that fits this data well and the outputs of (b) LPCC, (c) BPC for $\alpha=0.01$ and 0.05 , and (d) BPC for $\alpha=0.1$.

have a latent common cause, and Lozenges, VisPerc, and Cubes potentially have another latent common cause. This model matches the theoretical model (Figure 11a) except for the bidirectional edge between the latents.

3.4 The HIV test data

We also evaluated LPCC using the HIV test data (Zhang, 2004). This data set consists of results for 428 subjects of four diagnostic tests for the human immunodeficiency virus (HIV): “radioimmunoassay of antigen ag121” (A); “radioimmunoassay of HIV p24” (B); “radioimmunoassay of HIV gp120” (C); and “enzyme-linked immunosorbent assay” (D). A negative result is represented by 0 and a positive result by 1. LPCC learned a model identical to that in Zhang (2004) (Figure 12), where X1 and X2 are both binary latent variables. However, unlike the algorithm in Zhang (2004) that aims at learning tree-latent models like the one required for the HIV data, LPCC is not limited to latent-tree models. BPC returned an empty model for any conventional α .

of traffic offenses for the first six months after obtaining a driving license. YDs in the two databases were grouped according to the following classes:

DB1:

Accident and no offense: All YDs who had at least one accident and committed at least one offense in the three-month period after ADP (the “period”). There were 345 such drivers; hence, this number defined a group size.

Offense but no accident: 345 drivers who committed at least one offense, but had no accidents in the period.

Accident but no offense: 345 drivers who had at least one accident, but committed no offense in the period.

No accident and no offense: 345 drivers who did not have any accidents or commit any offenses in the period.

In total, there are 1,380 observations (YDs) for DB1.

DB2:

Accident and offense: All YDs who had at least one accident and committed at least one offense in the period (similar to this class in DB1).

No accident and no offense: 345 drivers who did not have any accidents or commit any offenses in the period (similar to this class in DB1).

In total, there are 690 observations (YDs) for DB2.

All observations in both databases are represented by thirteen observed variables that a previous study indicated as relevant to the explanation of YD involvement in road accidents and offenses (Lerner, 2012; Lerner and Meyer, 2012). In addition, we used four observed variables that indicate if YDs or their parents were involved in a road accident or an offense. A detailed description of all seventeen observed variables is given in Table 1.

We ran LPCC on DB1 and DB2 and compared its results to those of EFA and BPC. We ran BPC using a significance level (alpha) of 0.05 (Tetrad’s default). Exploratory factor analysis was applied in two phases. First, principal component analysis (PCA) was used for factor extraction, where the Kaiser criterion (Kaiser, 1960) was used for determining the number of factors. Any factor with an associated eigenvalue less than 1.0 was dropped because this value is equal to the information accounted for by an average single observed variable. Second, the factor model was rotated using varimax, which is an orthogonal rotation method of the factor axes to maximize the variance of the squared loadings of a factor on all the variables. Factor loadings, also called component loadings in PCA, are the correlation coefficients between the variables and factors, indicating how strongly the latter influence the former. Analogous to Pearson’s correlation coefficient, the squared factor loading is the percent of variance in that indicator variable explained by the factor. The varimax rotation method has the effect of differentiating the original variables by the extracted factors. Each factor tends to have either large or small loadings of any particular variable. A varimax solution yields results that make it as easy as possible to identify each variable with a single factor (with the highest loading on the variable). In confirmatory factor analysis (CFA), loadings should be 0.7 or above to confirm that independent variables identified a priori are represented by a particular factor, using the rationale that the

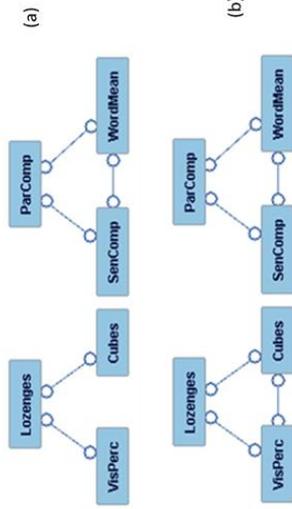

Figure 11: FCI outputs for Holzinger and Swineford’s data set and significance levels of (a) 0.01 and (b) 0.1.

3.5 Explanation of young drivers’ involvement in road accidents using LPCC

We produced two databases (DB1 and DB2) from a main database that includes all young drivers (between the ages of 18 and 24 years) who received their private-car driving licenses in Israel between 2002 and 2008. The main database includes more than 600,000 drivers and their parents who were involved in more than 600,000 road accidents and committed more than 2,000,000 traffic offenses in this period. We were interested in explaining young driver (YD) involvement in road accidents and offenses using LPCC and the databases. By “explaining”, we mean that we wanted to find the factors among all variables representing a driver, car, accident, offenses, and so forth and the interrelations that could explain YD involvement in road accidents and offenses. These factors could also contribute to prediction of YD involvement in road accidents and offenses with the highest accuracy. We concentrated on the first three months after the accompanied driving phase (ADP), which is a three-month driving phase in which a YD is accompanied by an experienced driver. We concentrated on the three months after ADP because: (1) this is the first solo experience of YDs, and it is when they commit most of their traffic offenses or are involved in most of their road accidents; and (2) we only had detailed monthly records

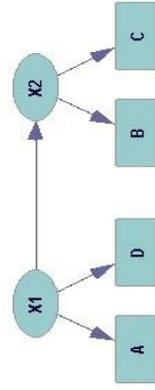

Figure 12: Model learned for HIV using LPCC.

0.7 level corresponds to about half of the variance in the indicator being explained by the factor. However, the 0.7 standard is high, and real-world data may not meet this criterion, which is why some researchers, including us in this study (particularly for exploratory purposes such as this case), use a lower level, where 0.4 is the common practice (Marly, 1994). In addition, we adapted Occam's razor parsimony principle (to explain the variance with the fewest possible factors) and required the variance explained criterion to be above 50%.

Number	Variable	Variable short name	Variable values
1	Age	gil	1 (17-18), 2 (19-20), 3 (21-22), 4 (23-24)
2	Gender	Min	1 (male), 2 (female)
3	Medical limitations	lim	1 (no), 2 (yes)
4	Father is allowed to drive	MurF	1 (yes), 2 (no)
5	Mother is allowed to drive	MurM	1 (yes), 2 (no)
6	Has a motorcycle license	of	1 (no), 2 (yes)

Table 1: Seventeen observed variables in DB1 and DB2

Results for DB1:

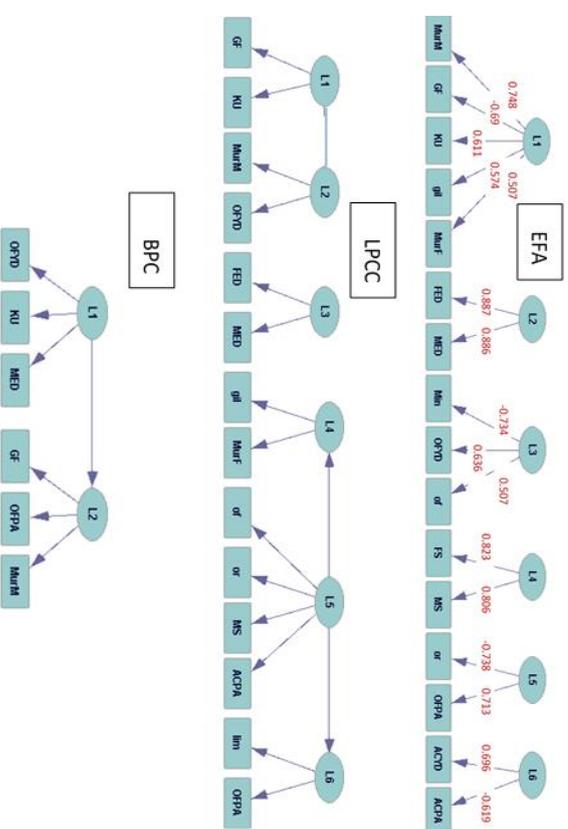

Figure 13: LVMs learned by EFA, LPCC, and BPC for DB1. Numbers for EFA represent the factor loadings, where plus and minus signs indicate positive and negative correlation, respectively.

Both LPCC and EFA found six latent variables (Figure 13). L1 in EFA is a parent of five observed variables, where each describes another aspect of the demographic or socioeconomic state of the YD or his/her family. The variables (see Table 1) *father is allowed to drive* (MurF), *mother is allowed to drive* (MurM), *age* (gil), and *ethnic group* (KU) are positively associated, whereas the variable *socioeconomic index* (GF) is negatively associated with L1. Based on the values of these variables, we can identify groups in the YDs' population, such as a group of YDs that are not Jewish, their parents are not allowed to drive, and their age and their socioeconomic status are low. L1 is not connected by EFA to other latent variables that relate to YD involvement in road accidents or offenses; thus, it does not contribute much to this study. However, L1 and L2 as learned by LPCC relate the socioeconomic state of the YD family (GF and KU are children of L1) with YD offenses (OFYD

⁶The Or Yarok (i.e., "green light" in Hebrew) kit includes documentation and accessories, such as CDs, with instructions, movies, and advice regarding safe driving. Granting the kit before licensure was found (Lerner, 2012) helpful in reducing young drivers' involvement in road accidents.

is a child of L2), thus LPCC links the socioeconomic state of YD with its involvement in traffic offenses. For example, according to LPCC, a YD who is not Jewish, with a low socioeconomic index, and whose mother is not allowed to drive is more likely to be involved in traffic offenses.

Latents L2 in EFA and L3 in LPCC describe the educational status of the YDs' parents and indicate a similar tendency between the parents' educational levels. However, both EFA and LPCC analyses do not link the educational status of the YD family to involvement in road accidents and traffic offenses.

L3 in EFA shows a negative relationship between a YD's gender (Min) or having a motorcycle license (of) and his/her tendency to commit road offenses. Male drivers tend to commit more traffic offenses than female drivers, and drivers who have a motorcycle license tend to commit more traffic offenses than drivers who do not have such a license. L4 in EFA shows the marital status of the YD parents, and not surprisingly, it indicates that the father's and mother's marital status is correlated. L5 in EFA shows that the parents of YDs who did not receive the "Or Yarok kit" tend to commit more traffic offenses. That is, the introduction of the kit in the family seems to also reduce involvement in road offenses of family members other than the YD. L6 in EFA shows a negative relationship between YD involvement in road accidents and the involvement of their parents in accidents. One explanation for this negative relationship could be that in a family in which one member was involved in an accident, other members tend to be more careful and thus decrease their involvement in accidents. Due to the independency assumption (between the factors) in EFA, L3, L4, L5, and L6 are not related, and EFA is not able to holistically represent relations among variables representing demographic and socioeconomic characteristics and road accidents and offenses of YDs and their parents.

LPCC describes involvements in road accidents and offenses in a more comprehensive way using a structure that is based on three latents with a diverging link from L5 to L4 and L6. L5 shows a relationship among the variables *motorcycle license*, *received "Or Yarok kit"*, *mother's marital status*, and *parents' involvement in accidents*. For example, it was found that there is a relation between receiving the "Or Yarok kit" and decreasing values of parents' involvement in accidents. However, we note that the variable parents' involvement in accidents is sparse in DB1, making its relationship with the other variables via L5 quite arguable. An interesting relationship found in the LPCC results is between parents' accidents (child of L5) and parents' offenses (child of L6). This relationship was missed by EFA since each variable in EFA is a child of a different latent that is independent of the other latent (due to EFA's orthogonality assumption).

BPC finds only two latents compared to six latents that are found by LPCC and EFA. A possible explanation for the low number of latents identified by BPC is that BPC requires that a latent have at least three observed children to be identified, whereas LPCC requires only two (see latents L1–L4 and L6 in the LPCC model, each having two observed children). L1 and L2 as learned by BPC relate the demographic-socioeconomic state of the YD family (KU and GF) with YD offenses, as the LPCC model did, but the two latents in the BPC model mix the indicators. It is more reasonable to believe that if L1 is a parent of L2 as BPC identified, then offenses of YDs (OFYD) should be a child of L2 and not of L1, and GF should be a child of L1 and not of L2 since socioeconomic status is expected to affect violent road behavior and not the opposite. BPC also relates OFYD with offenses

of their parents (OFFA), a relation that seems reasonable and is not identified by EFA and LPCC. However, the identification of OFYD as L1's child and OFFA as L2's child implies that it is the YD offenses that affect the offenses of their parents and not the opposite, as may be expected. Another relation that is identified only by BPC is between the mother's education level (MED) and both YDs' and their parents' offenses.

Results for DB2:

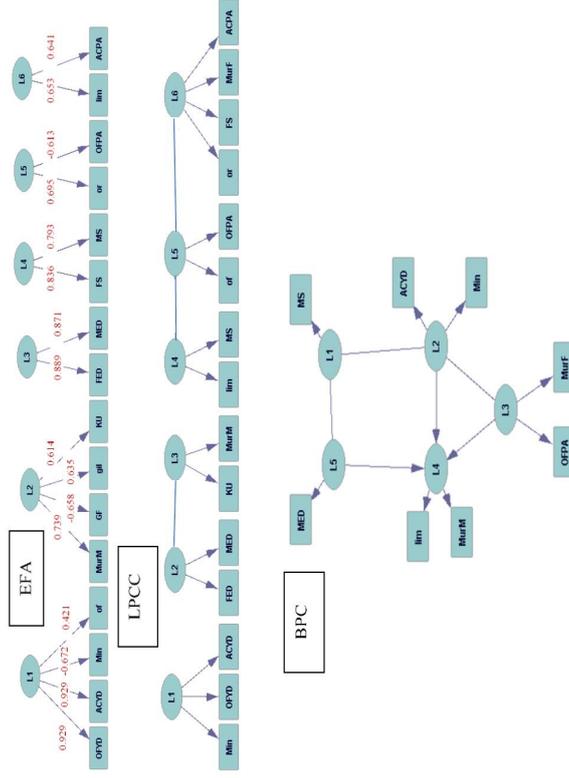

Figure 14: LVMs learned by EFA, LPCC, and BPC for DB2. Numbers for EFA represent the factor loadings, where plus and minus signs indicate positive and negative correlations, respectively.

Again, both the EFA and LPCC algorithms found six latent variables (Figure 14). L1 in EFA is interesting and very important because it links YD involvement in accidents and offenses with gender and motorcycle license. The loading coefficients show that male YDs, especially those who have a motorcycle license, are involved more in both accidents and offenses (in both cases with loadings of 0.929). L1 in LPCC shows a similar relation between gender and a YD's involvement in accidents and offenses, but without a relation to having a motorcycle license. Also in the EFA results, this last relation is quite weak, with a boundary loading value of 0.421, whereas the threshold for connecting an observed variable to a latent factor is 0.4 (which is a common practice in EFA). The relation found

ers between these cellular subpopulations. This observation is demonstrated clearly in the results obtained by BPC, EFA, and LPCC in Figures 15a, 15b, and 16a, respectively. LPCC and EFA managed to learn models with eight latents each and BPC a model with one latent, but none of the three latent variable models seems to be biologically meaningful, as judged by biological experts.

However, LPCC has an advantage over the other two algorithms because to advance learning an LVM, LPCC clusters the input data in its first stage. We exploit this advantage by improving clustering of the input to consider the domain specific properties. This act of clustering – that is natural to LPCC – coincides with the conventional clustering-based analysis of CyTOF data, which is mandatory to this domain because the data shows a hierarchical structure (as outlined below). Therefore, instead of using SOM, we initialized LPCC based on the clustering results obtained by Citrus (Bruggner et al., 2014). Citrus applies hierarchical clustering to the cell events; however, instead of cutting the hierarchy at an arbitrary height to identify the clusters, it uses a minimum cluster size threshold (we used a 1% threshold of the observations, i.e., 8,000 observations), for which only clusters larger than this threshold are selected. By selecting automatically and based on the data only large enough clusters, we preserve the requirement of LPCC of not determining the number of clusters arbitrarily and facilitate the avoidance of noisy clusters. In addition, we performed another purification procedure by selecting only clusters for which the ratio of the cluster marker entropy to the distribution marker entropy is smaller than a threshold.

Following this cluster purification procedure, LPCC found a five-latent variable model that is represented in Figure 16b. L1 is a parent of five markers that represent T cells (except for CD457 that may be expressed also by other leukocytes, and CD62L that is an activation marker that also can be expressed by T cells). L2 partially represents monocytes by having the markers CD11b and CD86 as its children; however, this representation is not perfect since it wrongly connects CD34, which is a phenotypic marker of stem cells. Thus, L2 may be representing monocytes that are antigen-representing cells excluding CD34. L3 and L4 are linked by a directed edge from L3 into L4 and together represent macrophage cells. Although both latents represent the same population of cells, LPCC correctly splits it into two latent variables since the children of L3 are expressed only by macrophages, but the children of L4 may also be expressed by monocytes, which are the macrophages' precursor. L5 is a parent of three markers that represent B cells together with another marker, IA-IE, which is an activation marker that can also be expressed by B cells. Still, the model learned by LPCC represents only sixteen of the 37 markers in this experiment. This may be explained by the high level of overlap and number of shared markers among the different subpopulations. Despite that, these results are encouraging and demonstrate a significant improvement compared to previous results obtained by BPC, EFA, and LPCC before cluster purification.

Analysis of cell sub-populations in the immune system naturally lends itself to the use of clustering methodologies, as immunologists traditionally resort to the classification of cells as belonging to cellular subpopulations. Cell subpopulations are usually defined by the stable expression of markers on said cells. Yet, not all markers capture protein expression that is stably expressed, and the expression of some proteins may be noisy or plastic,

⁷The cellular markers we use are well known in immunology (Janeway et al., 2001), and thus their description is avoided here for clarity of the demonstration.

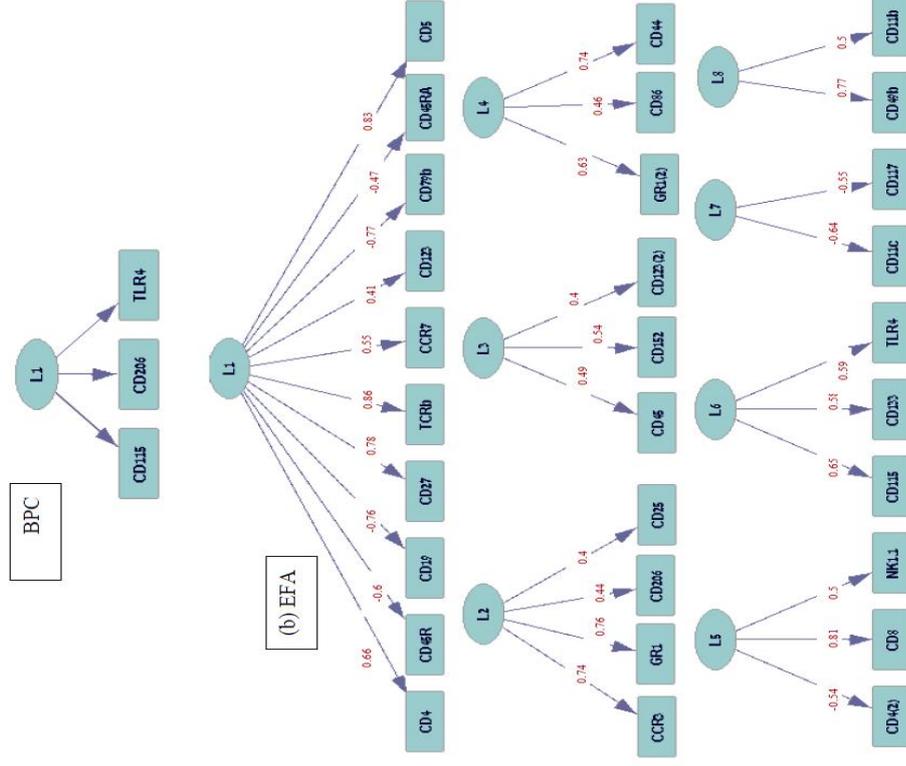

Figure 15: LVMs learned by (a) BPC and (b) EFA. Numbers for EFA represent the factor loadings, where plus and minus signs indicate positive and negative correlation, respectively.

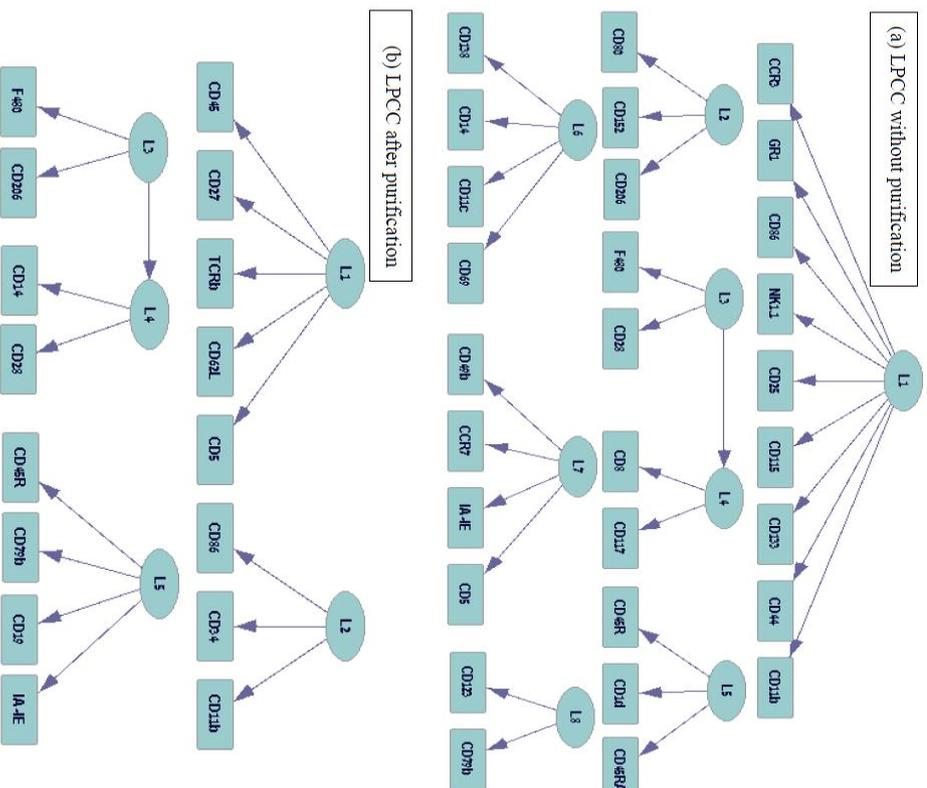

Figure 16: LVMs learned by LPCC (a) before and (b) after a purification procedure.

varying over time and conditions. With this in mind, clustering and noise filtration – two pre-processing steps of LPCC – provide great benefit in this context, yielding improved results. Specifically, the pre-processing step of clustering the data prior to LPCC provides an advantage as it compartmentalizes marker relationships to the context in which they matter, whereas the noise filtering step focuses the analysis to those markers whose relationship with one another may be meaningful.

4. Related Works

The traditional framework for discovering latent variables is factor analysis and its variants (e.g., see Bartholomew et al., 2002). This is, by far, the most common method used in several applied sciences (Glymour, 2002). However, a limitation of factor analysis is its level of subjectivity stemming from the many methodological decisions a researcher must make to complete an analysis, where the results of this analysis largely depend on the quality of these decisions (Henson and Roberts, 2006). Moreover, factor analysis and its variants provide only a limited ability in causal explanation (see Silva, 2005, and our evaluation section). Therefore, in this section, we will focus on related work in the framework of learning causal graphical models beyond the variants of factor analysis.

The main goal of heuristic methods such as those of Elidan et al. (2000) is the reduction of the number of parameters in a BN. The idea is to reduce the variance of the resulting density estimator, achieving better probabilistic predictions. For probabilistic modeling, the results described by Elidan et al. are a convincing demonstration of the suitability of their approach, which is intuitively sound. However, such heuristic methods provide neither formal interpretation of what the resulting structure is, nor explicit assumptions on how such latents should interact with the observed variables. Further, such heuristic methods do not provide an analysis of possible equivalence classes, and consequently, there is no search algorithm that can account for equivalence classes. Therefore, for a causality discovery under the assumption that multiple observed variables have hidden common causes, such as in MIM that is widely used in applied sciences, the results described by Elidan et al. are unsatisfying.

Unlike other algorithms (Pearl, 2000; Zhang, 2004; Harmeling and Williams, 2011; Wang et al., 2008), LPCC is suitable for learning MIM models and not just latent-tree models. This LPCC quality is shared by BPC (Silva et al., 2006). Both LPCC and BIN-A (Harmeling and Williams, 2011) apply clustering as a preprocessing step to learn latent models. But, LPCC applies clustering to the data points, whereas BIN-A clusters the variables using agglomerative hierarchical clustering, which is suitable to learn HLC models, as in Zhang (2004). LPCC provides a consistent and substantive analysis of data-point clustering using the PCC concept, and can learn all types of links between the latents; thus, unlike BIN-A, it is not limited to binary latent trees.

FCL (Spirites et al., 2000) is not comparable to LPCC in learning MIM models as illustrated for the political action survey and the Holzinger and Swinford databases (Sections 3.2 and 3.3). Compared to BPC and FCL, LPCC does not rely on statistical tests and pre-setting of a significance level for learning LVM.

Contrary to BPC, LPCC concentrates on the discrete case and dispenses with the linearity assumption. However, LPCC assumes that the measurement model is pure; still a

weaker assumption than the one latent-tree models make. Unlike LPCC, BPC is not suitable for learning models such as G1 in Figure 2, where the latents are independent and each has fewer than four observed children. This is because BPC requires the variables in a Tetrad constraint to all be mutually dependent, where in the case of G1, there are at most three mutually dependent variables, so no Tetrad constraint can be tested and no graph is learned (Section 3.1). In addition, BPC is not suitable for learning models such as the HIV model (Section 3.4), where each latent has only two indicators and BPC requires three indicators for a latent to be identified. This also explains the poor results of BPC on the YD databases compared to the LPCC results (Section 3.5).

When the attributes are categorical, cluster analysis is sometimes called latent class analysis (LCA) (Lazarsfeld and Henry, 1968; Goodman, 1974; Bartholomew and Knott, 1999), where data are assumed to be generated by a latent class model (LCM). An LCM consists of a class variable (latent) that represents the clusters to be identified and a number of other variables that represent attributes (observed variables) of objects.⁸ LCMs assume local independence; in other words, the observed variables are conditionally independent given the latent variable. A serious problem with the use of LCA, known as local dependence, is that the local independence assumption is often violated. To relax this strong assumption, Zhang (2004) proposed a richer, tree-structured latent variable model, specifically, the HLC model. The network structure is a rooted tree, and the leaves of the tree are the observed variables. HLC models were chosen for two reasons. First, the class of HLC models is significantly larger than the class of LCMs and can accommodate local dependence. Second, inference in an HLC model takes time that is linear in the model size (because it is a tree), which makes it computationally feasible to run EM. However, MIM models learned by LPCC are richer than HLC models that are only a subset of MIMs. Thus, LPCC may contribute to clustering analysis of data generated by richer models, while keeping the advantage of accommodating local dependence.

5. Discussion

In Part I, we introduced the PCC concept and LPCC algorithm for learning LVMs. We showed that LPCC: 1) Is not limited to latent-tree models, and does not make a linearity assumption about the distribution; 2) Learns MIMs; 3) Learns a MIM with no assumptions about the number of latent variables and their interrelations (except the assumption that a latent collider does not have any latent descendants; Assumption 5) and which observed variables are the children of which latents; and 4) Learns an equivalence class of the structural model of the true graph.

In Part II, we formally introduced the LPCC two-stage algorithm. First, LPCC learns the exogenous latents and the latent colliders, as well as their observed descendants, by utilizing pairwise comparisons between data clusters in the measurement space that may explain latent causes. Second, LPCC learns the endogenous latent non-colliders and their children by splitting these latents from their previously learned latent ancestors.

Using simulated and real-world data sets, we showed in Part II that LPCC improves accuracy with the sample size, can learn large LVMs, and has consistently good results

⁸This model has the same graphical structure as the naive-Bayes classifier, but because it is trained in an unsupervised manner (clustering), we refer to it as an LCM.

compared to models that are expert-based or learned by state-of-the-art algorithms. Using LPCC to identify possible causes of young drivers' involvement in road accidents, we found interesting relations among latent and observed variables and can provide illuminating insights into this important problem. Using LPCC to identify cell subpopulations in the immune system, we offer an LVM that makes sense to expert biologists in describing this challenging system. A criticism of LPCC may be its reliance on performing preliminary clustering to the data. Changes in the data used for clustering may affect the LPCC output. Yet, our experience shows that even if the clustering results change for different data samples drawn from the distribution, the same major and 1-order minor clusters are usually identified. In addition, as the biological example (Section 3.6) illustrates, when a structure is inherent to the data, clustering of the data first yields high benefit in learning an LVM later and improves results. Structured real-life problems are prevalent in many disciplines (Vazquez et al., 2004); hence, being a clustering-based LVM learning mechanism gives LPCC an advantage more than a disadvantage.

Finally, a number of open problems that invite further research were provided in the discussion of Part I.

Acknowledgments

Special thanks to the *Israel National Road Safety Authority* and *Ran Naor Foundation for the Advancement of Road Safety Research* for supporting the research to explain young drivers' involvement in road accidents (Section 3.5) and to Shai Shen-Orr, Elina Starostevsky, and Tania Dubovik from the Department of Immunology at the Technion for providing the mass-cytometry data set and helping in the evaluation of the results of its analysis (Section 3.6). The authors also thank the two anonymous reviewers for their comments and suggestions that helped improve the paper and the special issue editors: Isabelle Guyon and Alexander Statnikov. Nuaman Asbeh thanks the *Planning and Budgeting Committee* (PBC) of the *Israel Council for Higher Education* for its support through a scholarship for distinguished Ph.D. students.

Appendix A. Important assumptions, definitions, propositions, and theorems from Part I (numbers are taken from Part I)

Assumption 5 *A latent collider does not have any latent descendants (and thus cannot be a parent of another latent collider).*

Definition 12 *The single cluster that corresponds to the observed major value configuration, and thus also represents the major effect MAE (ex) due to configuration ex of EX, is the major cluster for ex, and all the clusters that correspond to the observed minor value configurations due to minor effects in MIES (ex) are minor clusters.*

Definition 13 *A k-order minor effect is a minor effect in which exactly k endogenous variables in EN correspond to minor local effects. An en corresponding to a k-order minor effect is a k-order minor value configuration.*

Definition 14 Minor clusters that correspond to k -order minor effects are k -order minor clusters.

Definition 15 Pairwise cluster comparison is a procedure by which pairs of clusters are compared, for example through a comparison of their centroids. The result of PCC between a pair of cluster centroids of dimension $|\mathbf{O}|$, where \mathbf{O} is the set of observed variables, can be represented by a binary vector of size $|\mathbf{O}|$ in which each element is 1 or 0 depending, respectively, on whether or not there is a difference between the corresponding elements in the compared centroids.

Definition 16 A maximal set of observed (MSO) variables is the set of variables that always changes its values together in each major-major PCC in which at least one of the variables changes value.

Definition 18 2S-PCC is PCC between 1-MC and a major cluster that shows two sets of two or more elements corresponding to the observed variables. Elements in each set have the same value, which is different than that of the other set. Accordingly, this 1-MC is defined as 2S-MC.

Definition 19 A 2S-MSO is the maximal set of observed variables that always change their values together in all 2S-PCCs.

Proposition 10 In 2S-PCCs in which only the observed children of a single latent change, the latent is

1. EX or its leaf latent non-collider descendant, if the connection is serial; or
2. EX's leaf latent non-collider descendant, if the connection is diverging.

Theorem 1 Variables of a particular MSO are children of a particular exogenous latent variable EX or its latent non-collider descendant or children of a particular latent collider C.

Theorem 2 A latent variable L is a collider of a set of latent ancestors LACEX only if:

1. The values of the children of L change in different parts of some major-major PCCs each time with the values of descendants of another latent ancestor in LA; and
2. The values of the children of L do not change in any PCC unless the values of descendants of at least one of the variables in LA change too.

Theorem 3 Variables of a particular 2S-MSO are children of an exogenous latent variable EX or any of its descendant latent non-colliders NC.

Theorem 4 A latent non-collider NC1 is a direct child of another latent non-collider NC2 (both on the same path emerging in EX) only if:

- In all 2S-PCCs for which EX does not change, the observed children of NC1 always change with those of NC2 and also in a single 2S-PCC without the children of NC2; and
- In all 2S-PCCs for which EX does not change, the observed children of NC1 always change, the observed children of NC2 always change with those of NC1 and also in a single 2S-PCC without the children of NC1.

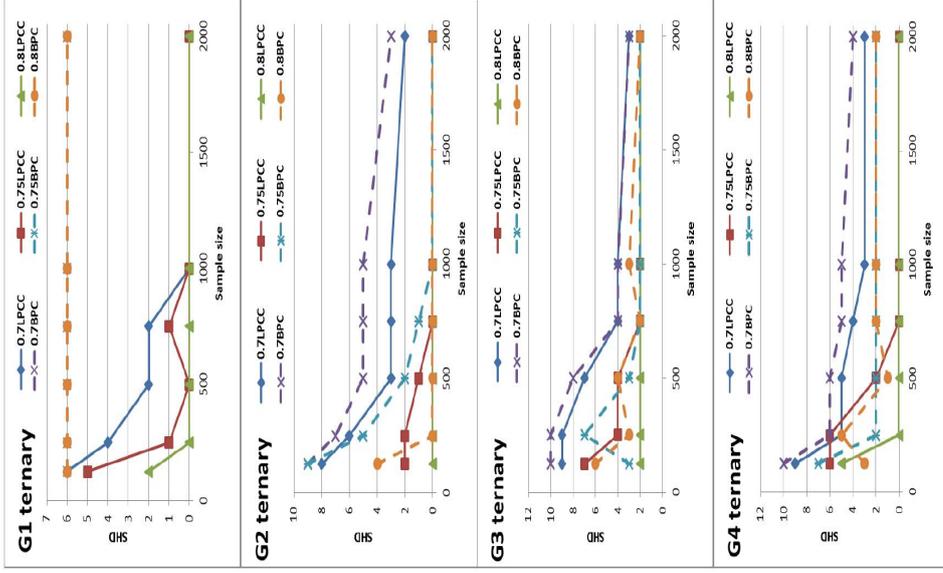

Figure 18: SHD learning curves of LPCC compared with those of BPC for G1–G4 of Figure 2 with ternary variables, three parameterization levels, and increasing sample sizes.

B.2 LPCC compared to EFA

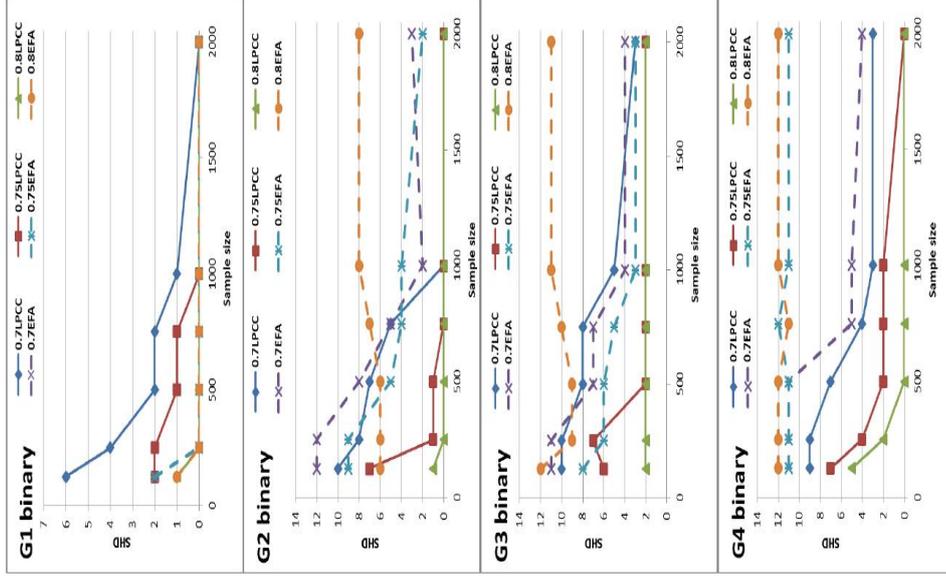

Figure 19: SHD learning curves of LPCC compared with those of EFA for G1–G4 of Figure 2 with binary variables, three parameterization levels, and increasing sample sizes. The lines of LPCC and EFA for a parametrization of 0.8 coincide for G1.

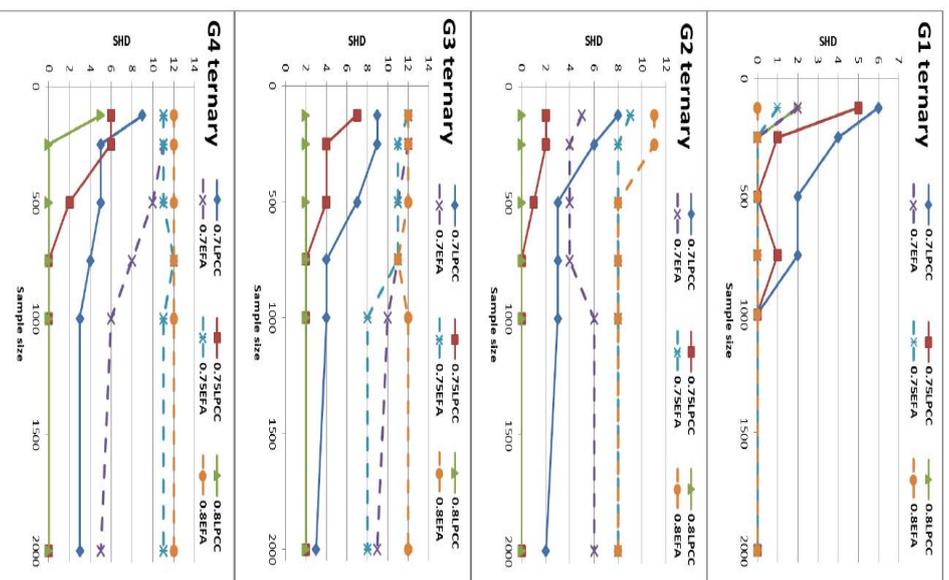

Figure 20: SHD learning curves of LPCC compared with those of EFA for G1–G4 of Figure 2 with ternary variables, three parameterization levels, and increasing sample sizes. The line of LPCC for a parameterization of 0.8 coincides with that of EFA for a parameterization of 0.7 for G1.

Appendix C. PCC analysis for two example databases

C.1 Results for the political action survey data (Section 3.2)

We applied clustering analysis to the political action survey data using SOM having 250 unit map size (similar results were obtained for SOMs having 125 and 500 unit map sizes). U-matrix visualization⁹ of the SOM result is given in Figure 21. As presented in Table 2, nine clusters were found, and since four clusters are larger than the average cluster size of 45, only four of the nine clusters are major. Table 3 shows PCCs between these four major clusters. Note that NOSAY and VOTING always change together in all PCCs in which either of them changes, and this is also the case for NOCARE, TOUCH, and INTEREST. Therefore, LPCC found two latents (Figure 8 b): One (Efficacy) corresponds to NOSAY and VOTING and the other (Responsiveness) corresponds to NOCARE, TOUCH, and INTEREST.

Centroid	NOSAY	VOTING	COMPLEX	NOCARE	TOUCH	INTEREST
C1(86)	3	3	2	3	3	3
C2(60)	2	2	2	2	2	2
C3(57)	3	3	2	2	2	2
C4(49)	3	3	3	3	3	3
C5(39)	3	2	2	2	2	2
C6(31)	3	3	2	3	2	2
C7(31)	3	2	3	3	3	3
C8(28)	1	1	1	1	1	1
C9(27)	3	2	2	3	3	3

Table 2: Nine clusters are represented by their centroids for the political action survey data. Cluster sizes are in parentheses. The first four clusters are major.

PCC	δ NOSAY	δ VOTING	δ COMPLEX	δ NOCARE	δ TOUCH	δ INTEREST
PCC1,2	1	1	0	1	1	1
PCC1,3	0	0	0	1	1	1
PCC1,4	0	0	1	0	0	0
PCC2,3	1	1	0	0	0	0
PCC2,4	1	1	1	1	1	1
PCC3,4	0	0	1	1	1	1

Table 3: PCCs between the four major clusters for the political action survey data.

⁹The U-matrix is a widely used visualization of SOM. It computes (for each unit in the SOM) the mean of the distance measures between neighbors. By plotting this data on a 2D map using a color scheme, we can visualize a landscape with walls (red areas) and valleys (blue areas). The walls separate different clusters; they represent extreme distances between neighboring units, whereas patterns mapped to units in the same valley are similar and belong to the same cluster (Ultsch et al., 1993).

C.2 Results for Holzinger and Swineford's data (Section 3.3)

We applied clustering analysis to the European Values Survey (Holzinger and Swineford's) data set using SOM having a 100 map size. Fifteen clusters were found (Table 4), and since the average cluster size is 7.4, four clusters are major. Based on major-major PCCs (Table 5), one learned latent (Spatial) corresponds to VisPerc and Lozenges (that always change together in all PCCs in which either of them changes) and the other latent (Verbal) corresponds to ParComp, SenComp, and WordMean (Figure 10). It is interesting to see that in half of the PCCs in which VisPerc and Lozenges change together, Cubes also changes. If Cubes would have changed in all PCCs in which VisPerc and Lozenges change together, then it would be found as Spatial's child, and the learned model would be exactly the theoretical model (Figure 10a). This did not happen, probably because the PCCs in which Cubes did not change with VisPerc and Lozenges relate to relatively small clusters.

Centroid	VisPerc	Cubes	Lozenges	ParComp	SenComp	WordMean
C1(19)	1	1	1	1	1	1
C2(18)	2	2	2	2	2	2
C3(9)	1	2	1	1	1	1
C4(8)	2	2	2	1	1	1
C5(7)	1	1	1	1	1	2
C6(7)	2	1	2	1	1	1
C7(7)	1	1	2	1	1	1
C8(6)	2	1	2	2	2	2
C9(6)	2	1	1	1	1	1
C10(5)	2	1	1	2	2	2
C11(5)	1	2	2	2	2	2
C12(4)	1	2	2	2	1	2
C13(4)	2	2	1	2	2	2
C14(3)	1	1	1	2	2	2
C15(3)	2	1	1	1	2	2

Table 4: Fifteen clusters are represented by their centroids for Holzinger and Swineford's data. Cluster sizes are in parentheses. The first four clusters are major.

PCC	$\delta VisPerc$	$\delta Cubes$	$\delta Lozenges$	$\delta ParComp$	$\delta SenComp$	$\delta WordMean$
PCC1,2	1	1	1	1	1	1
PCC1,3	0	1	0	0	0	0
PCC1,4	1	1	1	0	0	0
PCC2,3	1	0	1	1	1	1
PCC2,4	0	0	0	1	1	1
PCC3,4	1	0	1	0	0	0

Table 5: PCCs between the four major clusters for Holzinger and Swineford's data.

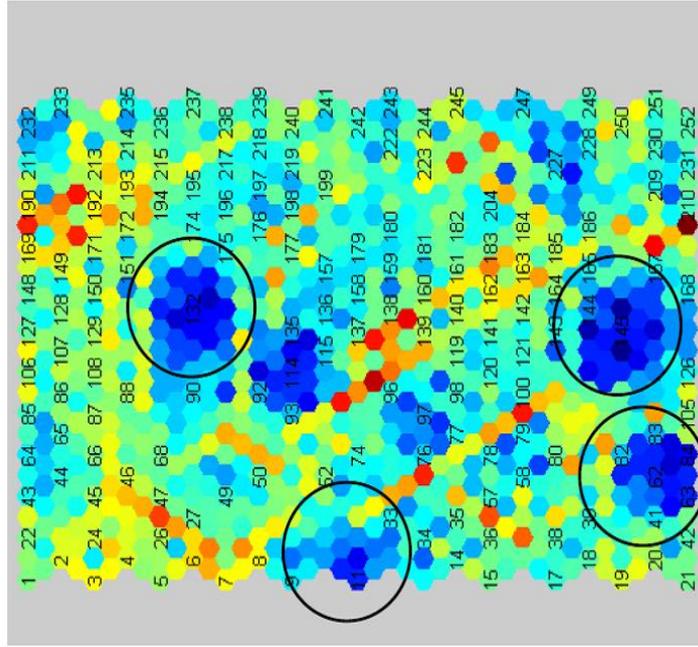

Figure 21: U-matrix visualization of a 250 unit map size SOM (numbers on the map represent the SOM units) obtained for the political action survey data. Vectors that were mapped to the same map unit belong to the same valley (blue area) and the same cluster. Of the nine clusters that were found (Table 2), four are major (circled) and the remaining are minor.

Abstract

Complex chronic diseases (e.g., autism, lupus, and Parkinson's) are remarkably heterogeneous across individuals. This heterogeneity makes treatment difficult for caregivers because they cannot accurately predict the way in which the disease will progress in order to guide treatment decisions. Therefore, tools that help to predict the trajectory of these complex chronic diseases can help to improve the quality of health care. To build such tools, we can leverage clinical markers that are collected at baseline when a patient first presents and *longitudinally* over time during follow-up visits. Because complex chronic diseases are typically systemic, the longitudinal markers often track disease progression in multiple organ systems. In this paper, our goal is to predict a function of time that models the future trajectory of a single target clinical marker tracking a disease process of interest. We want to make these predictions using the histories of many related clinical markers as input. Our proposed solution tackles several key challenges. First, we can easily handle irregularly and sparsely sampled markers, which are standard in clinical data. Second, the number of parameters and the computational complexity of learning our model grows linearly in the number of marker types included in the model. This makes our approach applicable to diseases where many different markers are recorded over time. Finally, our model accounts for latent factors influencing disease expression, whereas standard regression models rely on observed features alone to explain variability. Moreover, our approach can be applied dynamically in continuous-time and updates its predictions as soon as any new data is available. We apply our approach to the problem of predicting lung disease trajectories in scleroderma, a complex autoimmune disease. We show that our model improves over state-of-the-art baselines in predictive accuracy and we provide a qualitative analysis of our model's output. Finally, the variability of disease presentation in scleroderma makes clinical trial recruitment challenging. We show that a prognostic tool that integrates multiple types of routinely collected longitudinal data can be used to identify individuals at greatest risk of rapid progression and to target trial recruitment.

Keywords: gaussian processes, conditional random fields, prediction of functional targets, latent variable models, disease trajectories, precision medicine

1. Introduction

In complex chronic diseases (CCD) such as autism, lupus, and Parkinson's, the way the disease manifests may vary greatly across individuals. This makes treatment challenging

because caregivers cannot easily predict an individual's future trajectory to guide therapy decisions. For example, in scleroderma, an autoimmune disorder, lung disease is a common cause of morbidity and mortality (Varga et al., 2012), but there are no known biomarkers or precise algorithms for stratifying individuals into groups based on similar lung disease course. A tool that can provide accurate forecasts of disease progression can help clinicians to tailor treatments to each patient based on their most likely course.

To monitor disease progression, clinicians collect many clinical markers both at baseline when an individual first visits the clinic and *longitudinally* during routine follow-up visits. Many CCDs are systemic, and so the markers are designed to monitor the disease's impact across many organ systems. In scleroderma, individuals may be affected across six organ systems—the lungs, heart, skin, gastrointestinal tract, kidneys, and vasculature—to varying extents (Varga et al., 2012). Example clinical markers include PFVC (percent of predicted forced vital capacity), which is used to measure lung damage severity; TSS (total skin score), which is used to measure skin disease activity; and, PDLCO (percent of carbon monoxide diffused by the lung), used to measure vasculature health.

Our goal is to predict a function of time that models the future trajectory of a single target clinical marker tracking a disease process of interest. We want to make these predictions by leveraging baseline information and additional time-dependent clinical markers (henceforth referred to as auxiliary markers) as they are collected. This is the focal challenge of personalized medicine: integrative analysis of heterogeneous data from an individual's medical history to improve care (Collins and Varmus, 2015). So far, efforts in integrative analysis have focused on combining inferences from molecular data modalities (Rosenbloom et al., 2013). Our focus in this paper is on leveraging routinely recorded information from the electronic health record—both static and time-dependent—to make precise estimates of an individual's disease course.

A key challenge in this setting is that these data are collected during routine clinical visits and therefore they are sparse and irregularly sampled. Predicting an individual's future disease is commonly framed as a regression problem where the target clinical marker at a specific time in the future is modeled as a function of observed input features alone. These features are computed by generating summaries from the observed data (e.g., the last PFVC value or the trend in the PFVC over the last six months). However, training conditional models is less straightforward from data where varying numbers of repeated measurements are sampled per patient and across different markers. In this setting, others have focused on dynamical prediction (e.g., Rizopoulos and Ghosh, 2011; Proust-Lima et al., 2014) by fitting parametric models to the longitudinal data and using the resulting model parameters as features for prediction. But existing formulations do not scale to high-dimensional problems with many auxiliary markers.

Another key challenge in predicting disease trajectories in CCDs is that differences in trajectories across individuals may be largely due to factors that are not yet known. For example, different disease pathways or biological mechanisms (e.g., genetic mutations or autoimmune markers) may be driving different subtypes of the disease (Lewis et al., 2005; Lötvald et al., 2011; Doshi-Velez et al., 2014; Saria and Goldenberg, 2015), each associated with distinct disease trajectories (Schulam et al., 2015). But, in many diseases, our knowledge of these pathways is, at best, limited. In this setting, Schulam et al. (2015) use a latent variable model to infer subtypes—subgroups with similar trajectories—using

repeated measurements of clinical marker data in the electronic health record. Schulam and Saria (2015) extend these ideas and introduce a transfer learning framework for predicting individual-specific disease trajectories that accounts for subtypes and other latent factors causing heterogeneity in disease expression. These works, however, focus on modeling single marker trajectories. We build on Schulam and Saria (2015) in this paper.

1.1 Contributions

In this paper, we describe a scalable framework for predicting a target marker trajectory (i.e. a continuous-time function) that allows us to use multiple longitudinal clinical marker histories as inputs. Our approach makes it easy to handle irregular sampling patterns across markers. Because we use a discriminative training criterion that conditions on marker histories instead of jointly modeling them, the framework is not as sensitive to misspecified dependencies across marker types. Moreover, the number of parameters and computational complexity scales linearly with the number of markers, which makes it possible to apply our approach in high-dimensional settings where many different marker types are available. Finally, our approach aligns with the dynamical nature of clinical medicine; it can be used to make predictions using continuously growing marker histories. We apply our approach to the problem of predicting lung disease trajectories in scleroderma, a complex autoimmune disease. We show that our model improves over state-of-the-art baselines in predictive accuracy and we provide a qualitative analysis of our model’s output. Moreover, we demonstrate the clinical utility of our model by measuring performance on early detection of individuals who develop aggressive lung disease.

2. Related Work

Most predictive models used in medicine are cross-sectional—they use features from data measured up until the current time to predict a clinical marker or outcome at a fixed point in the future. As an example, consider the mortality prediction model by Lee et al. (2003), where logistic regression is used to integrate features into a prediction about the probability of death within 30 days for a given patient. To predict the outcome at multiple time points, it is common to fit separate models (e.g., Wang et al. 2012; Zhou et al. 2011). These models are trained to use features extracted from a fixed-size window, rather than a dynamically growing history. Moreover, they tackle heterogeneity in a limited way—any differences across individuals must be explained by observed features alone.

A common approach to dynamical prediction of trajectories is to use Markov models such as order- p autoregressive models (AR- p), HMMs, state space models, and dynamic Bayesian networks (e.g. Hassan and Nath 2005; Quinn et al. 2009; Murphy 2002). While such models naturally make dynamic predictions using the full history by forward-filtering, they typically assume discrete, regularly-spaced observation times.

To model an individual’s disease trajectory using sparse and irregularly sampled clinical markers, we draw heavily from ideas in the functional data analysis (FDA) literature (see e.g., Ramsay 2006). In FDA, sequences of measurements are assumed to be samples from an underlying continuous function. A common first-step in FDA is to project the irregular observations on to a functional basis, such as B-splines, and then analyze the time series in coefficient space. However, coefficient estimates can have high variance when a time series

has too few observations, which is common in clinical data. James and Sugar (2003) address this issue by modeling the parameters of individual trajectories as random variables with a low-rank parameterization of the mean and covariance. This work is closely related to ours, and the idea of sharing statistical strength across trajectories through a structured prior over individual-specific parameters is used broadly throughout trajectory analysis to account for sparsity. Gaussian processes (GPs) are also commonly used in FDA: they offer flexible nonparametric models of trajectories but can also help to counteract sparsity by sharing kernel hyperparameters across individuals—see Roberts et al. (2013) for a recent review of GPs applied to time series data. Recent work by Liu and Hauskrecht (2014) combines the advantages of Markov models (e.g. AR processes and state space models) and Gaussian processes to make predictions of clinical laboratory test results. To account for variability in collections of functions, a number of authors have proposed variants of GPs that account for variability in the mean function (e.g. Lázaro-Gredilla et al. 2012; Shi et al. 2012) and the covariance function (e.g. Shi et al. 2005). Another related line of work in the FDA literature is function-to-function regression (e.g., Oliva et al. 2015). In most approaches to function-to-function regression (FFR) the input and output are defined on fixed domains. In contrast, our problem requires updated predictions as the clinical history continues to grow; both the input and output domains are therefore constantly changing.

Most related to our work is that by Rizopoulos (2011), where the focus is on making dynamical predictions about a time-to-event outcome (e.g. time until death) using all previously observed values of a longitudinally recorded marker. As more data is collected, they dynamically update posterior distributions over individual-specific longitudinal model parameters (as is done in FDA), which serve as time-varying features for the time-to-event prediction. Proust-Lima et al. (2014) tackles the same task but uses a mixture of trajectories to model longitudinal data. As more observations are collected, the posterior over a set of classes is updated, each of which has a distinct set of time-to-event model parameters. These are both state-of-the-art models for the task of dynamical disease trajectory prediction; we will revisit them in our experimental section where we use the approaches as baselines. To scale these models to multivariate time series, however, requires careful specification of the joint model across different markers, which can be challenging in high-dimensional settings (e.g., Dürichen et al. 2015) and may be difficult to scale. For example, Rizopoulos and Ghosh (2011) use a random effects model with a full covariance matrix to describe dependencies across markers, which scales quadratically in the number of marker types (as opposed to linearly as is the case for C-LTM). Because C-LTM is discriminatively trained (we optimize the likelihood of future target trajectories given target and auxiliary marker histories), it is less sensitive to misspecification of the dependencies across markers.

3. Coupled Latent Trajectory Model

Our goal is to predict a *continuous function* modeling the future trajectory of a *target clinical marker* (e.g. PFVC) that tracks disease progression in a specific organ. To make our predictions, we will use a collection of baseline (i.e. static) markers measured when an individual first visits the clinic, the previously observed values of the target marker, and the previously observed values of a collection of *auxiliary clinical markers* tracking related organ systems. See Figure 6a-d for example applications. In these figures, the posterior

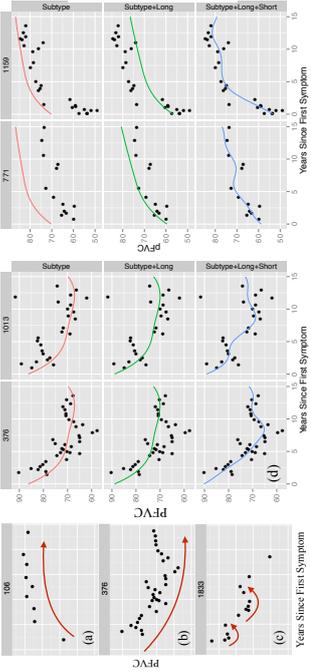

Figure 1: Plots (a-c) show example marker trajectories. Plot (d) shows four individuals with adjustments to a population and subpopulation fit (row 1). Row 2 makes an individual-specific long-term adjustment. Row 3 makes individual-specific short-term adjustments. To simplify, we only show mean functions; posterior uncertainty intervals are omitted.

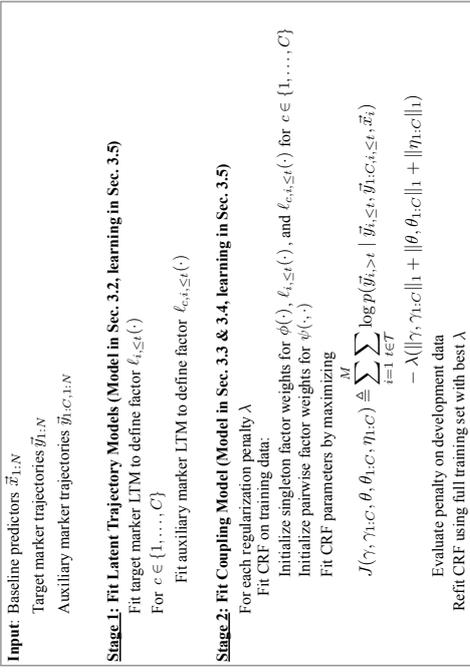

Figure 2: Two-stage procedure for fitting the Coupled Latent Trajectory Model (C-LTM).

distribution over the PFVC values (blue and green shaded regions) are conditioned upon baseline markers (e.g. gender and race), the observed PFVC values (black points), and auxiliary marker histories (e.g. TSS). We learn our model from a database of clinical histories of individuals, which are comprised of the individuals' baseline information and irregularly sampled trajectories of both the target and auxiliary markers. Formally, our

model will estimate the following conditional distribution (notation is described in the subsequent paragraph):

$$\mathcal{D}(i, t) \triangleq p(\mathbf{y}_i(\cdot) \mid \vec{y}_{i \leq t}, \vec{y}_{1:C,i \leq t}, \vec{x}_i). \quad (1)$$

Notation. For an individual i , we denote each target marker observation using y_{ij} and its measurement time using t_{ij} where $j \in \{1, \dots, N_i\}$. We use $\vec{y}_i \in \mathbb{R}^{N_i}$ and $\vec{t}_i \in \mathbb{R}^{N_i}$ to denote all of individual i 's marker values and measurement times respectively. We assume that the target marker observations are noisy observations of a latent continuous-time function (the trajectory), which we denote using $\mathbf{y}_i(\cdot)$. Each individual has baseline (static) information collected into a vector, which we denote using \vec{x}_i . We use C to denote the number of auxiliary marker types, N_{ci} to denote the number of observations of the c^{th} type, and use y_{cij} and t_{cij} to denote individual i 's j^{th} measurement of marker type c . We use $\vec{y}_{ci} \in \mathbb{R}^{N_{ci}}$ and $\vec{t}_{ci} \in \mathbb{R}^{N_{ci}}$ to denote the vector containing all of individual i 's c^{th} marker values and times respectively. We will also frequently need to refer to the vector of marker values observed up until a time t , which we denote using $\vec{y}_{i \leq t}$ ($\vec{y}_{ci \leq t}$ for auxiliary markers). Similarly, for markers observed after a time t , we use $\vec{y}_{i > t}$ ($\vec{y}_{ci > t}$ for auxiliary markers). The term $\vec{y}_{1:C,i \leq t}$ refers to all auxiliary markers measured on individual i up until time t .

At a high-level, we will model Eq. 1 by first assuming that each clinical marker trajectory (both target and auxiliary) can be d-separated (rendered conditionally independent) of all other marker types given a marker type-specific latent variable. We denote these latent variables using z_i for the target marker and z_{ci} for auxiliary marker c , and will describe them further later in this section. Under this assumption, we can write Eq. 1 as

$$\begin{aligned} \mathcal{D}(i, t) &= \sum_{z_i} p(\mathbf{y}(\cdot) \mid z_i, \vec{y}_{i \leq t}, \vec{x}_i) p(z_i \mid \vec{y}_{i \leq t}, \vec{y}_{1:C,i \leq t}, \vec{x}_i) \\ &\propto \sum_{z_i} p(\mathbf{y}(\cdot) \mid z_i, \vec{y}_{i \leq t}, \vec{x}_i) p(\vec{y}_{i \leq t} \mid z_i, \vec{x}_i) p(z_i \mid \vec{y}_{1:C,i \leq t}, \vec{x}_i) \\ &\propto \sum_{z_i} p(\mathbf{y}(\cdot) \mid z_i, \vec{y}_{i \leq t}, \vec{x}_i) \underbrace{p(\vec{y}_{i \leq t} \mid z_i, \vec{x}_i)}_{\text{LTM predictive, Section 3.2.2, Eq. 24}} \sum_{z_{1:C,i}} \underbrace{p(z_i, z_{1:C,i} \mid \vec{x}_i)}_{\text{Coupling Model, Section 3.3, Eq. 25}} \prod_{c=1}^C \underbrace{p(\vec{y}_{ci \leq t} \mid z_{ci}, \vec{x}_i)}_{\text{LTM likelihood, Section 3.2.1, Eq. 16}} \end{aligned} \quad (2)$$

We will learn this parameterization of $\mathcal{D}(i, t)$ in two stages. The models for the target and each of the auxiliary markers are learned independently during the first stage; using these, the LTM predictive and likelihood terms can be computed in Eq. 2. We treat the target and auxiliary markers as instances of the Latent Trajectory Model (LTM), which we review in Section 3.2. We emphasize, however, that any other generative model can be used if better suited to the domain. The coupling model is learned in the second stage, and is described in Section 3.3. We refer to the model created by combining these components as the Coupled Latent Trajectory Model (C-LTM), which we describe in Section 3.4. An overview of the procedure used to fit the C-LTM is shown in Figure 2.

3.1 Preliminaries

The Latent Trajectory Model (LTM) uses B-splines to model longitudinal trajectories, and our coupling model uses a conditional random field (CRF). We briefly introduce these two concepts, and point to resources where the interested reader can find additional details.

3.1.1 B-SPLINES

A common approach to fitting nonlinear functions of time while maintaining a linear dependence on model parameters is to use a basis expansion. Such an expansion defines some non-linear function $f(t)$ as a linear combination of other functions $\phi_1(t), \dots, \phi_d(t)$:

$$y = f(t | \beta) = \sum_{i=1}^d \beta_i \phi_i(t) = \Phi^\top(t) \bar{\beta}, \quad (3)$$

where ϕ_1, \dots, ϕ_d act as bases in some vector space of nonlinear functions and $\Phi(t) \in \mathbb{R}^d$ is the vector containing the values of the p basis functions evaluated at time t . The benefit of this formulation is that the function f is linear in the model parameters β , making it relatively easy to fit complex models. B-splines are a particular family of basis functions that we can use to parameterize nonlinear functions. Others include polynomial bases and radial basis functions. However, there are two advantages to using B-splines. First, each basis function is non-zero only over a compact interval of the real line, which improves statistical stability and also allows for computational speed ups that take advantage of sparse basis matrices (Gelman et al., 2014). This is in contrast to polynomials, where each basis takes non-zero values globally. The second advantage is that the family of functions parameterized by B-splines are not infinitely differentiable (in contrast to radial basis functions) and therefore not smooth (Gelman et al., 2014). This bias is often helpful in modeling functions from the real-world that arise from non-smooth processes. Because B-splines are linear in their parameters, we can use the well-developed machinery of linear regression for learning. See Ch. 20 in Gelman et al. (2014) or Ch. 5 in Friedman et al. (2001) for further details.

Penalized B-splines. In practice, the parameters of a B-spline model are fit using a penalized least squares criterion. The penalty is typically introduced in order to control the smoothness of the fit. For data \tilde{y} measured at times \tilde{t} with corresponding basis matrix $\Phi(\tilde{t}) = [\Phi(t_1), \dots, \Phi(t_n)]^\top$, we minimize the following objective:

$$J(\bar{\beta}) = \|\tilde{y} - \Phi(\tilde{t})\bar{\beta}\|_2^2 + \rho \bar{\beta}^\top \Omega \bar{\beta}, \quad (4)$$

where Ω is a first-order differences matrix as described by Eilers and Marx (1996). The penalized objective is still quadratic in $\bar{\beta}$ and so can be easily minimized.

3.1.2 CONDITIONAL RANDOM FIELDS

Conditional random fields (CRFs) provide a framework for modeling and learning the joint distribution of a collection of random variables conditioned on some set of observations (see e.g., Murphy 2012). The parameterization is identical to that of Markov random fields (MRF), but the factors that define the distribution can be functions of the observations (this allows the distribution to vary depending on the values of the observations). For some

output y , input x and parameters θ , the conditional probability is defined to be:

$$p(y | x, \theta) = \frac{1}{Z(x, \theta)} \prod_c \psi_c(y_c | x, \theta), \quad Z(x, \theta) \triangleq \sum_y \prod_c \psi_c(y_c | x, \theta), \quad (5)$$

where $\psi_c(y_c | x, \theta)$ is a non-negative factor that can be interpreted as scoring the configuration of the subset of variables y_c given the observations x and parameters θ . The term $Z(x, \theta)$ is called the *partition function* and ensures that the distribution is normalized. When we can write

$$\log \psi_c(y_c | x, \theta) = \theta_c^\top f_c(y_c, x) \iff \psi_c(y_c | x, \theta) = \exp \left\{ \theta_c^\top f_c(y_c, x) \right\}, \quad (6)$$

where f_c extracts some vector of features from the observations x and the target y_c , then we say that the CRF is a log-linear model. Log-linear models have a number of desirable properties, the most relevant to this work being the ease with which we can differentiate the log-likelihood with respect to model parameters. To compute the derivative with respect to θ_c (the parameters corresponding to the c^{th} factor) we have:

$$\frac{\partial \log p(y | x, \theta)}{\partial \theta_c} = f_c(y_c, x) - \frac{\partial \log Z(x, \theta)}{\partial \theta_c}. \quad (7)$$

To compute the partial derivative in the second term on the RHS, first note that

$$\begin{aligned} \frac{\partial Z(x, \theta)}{\partial \theta_c} &= \sum_{y'} \left(\prod_{d \neq c} \psi_d(y'_d | x, \theta_d) \right) \frac{\partial \psi_c(y'_c | x, \theta_c)}{\partial \theta_c} \\ &= \sum_{y'} \left(\prod_{d \neq c} \psi_d(y'_d | x, \theta_d) \right) \psi_c(y'_c | x, \theta_c) f_c(y'_c, x). \end{aligned} \quad (8) \quad (9)$$

This implies that the partial derivative of $\log Z(x, \theta)$ is simply:

$$\frac{\partial \log Z(x, \theta)}{\partial \theta_c} = \frac{1}{Z(x, \theta)} \frac{\partial Z(x, \theta)}{\partial \theta_c} = \mathbb{E}_y [f_c(y_c, x) | x] \quad (10)$$

This means that the gradient of the log-likelihood with respect to a set of parameters θ_c is the difference between the observed features $f_c(y_c, x)$ and their expectation under the current set of parameters θ . To learn the weights, we can apply gradient-based algorithms to optimize the likelihood of a set of observed training input-output pairs. In addition, a regularizer is often added to the objective to discourage complexity or induce sparsity. We will use these ideas in the derivation of our learning algorithm. See Ch. 19 in Murphy (2012) for further details.

3.2 Latent Trajectory Model

The Latent Trajectory Model (LTM) is a probabilistic model introduced by Schulam and Saria (2015) for obtaining individualized predictions of a clinical marker trajectory in populations with diverse disease expression. LTM posits that the measured markers are

to occur. The OU kernel is ideal for modeling such deviations as it is both mean-reverting and draws from the corresponding stochastic process are only first-order continuous, which eliminates long-range dependencies between deviations (Rasmussen and Williams, 2006). Applications in other domains may require different kernel structures motivated by properties of transient deviations in the trajectories.

Accounting for treatments. Several interventions are common in scleroderma, but none have been proven to significantly alter the long-term course of the disease. For example, steroids are commonly administered, but there have been no randomized controlled trials confirming its effects on patients with scleroderma-related lung disease—see, for example, Ch. 35 in Varga et al. (2012). Immunosuppressants are also commonly used to treat scleroderma-related lung disease, but the proven effects are modest and have only been demonstrated over the course of one year (Tashkin et al., 2006). We assume that these types of transient interventions are well-modeled by the individual-specific short-term component, and so we do not explicitly model the treatment effects of steroids or immunosuppressants in our data. Others have developed methods for estimating treatment effects from observational time series (e.g., Chib and Hamilton 2002; Kleinberg and Hirpsak 2011; Brodersen et al. 2015). More recently, see Xu et al. (2016) for an application using functional data. Treatment effects can be incorporated within the trajectory likelihood in diseases where treatments are suspected to alter long term trajectory. We leave this more general case as a direction for future work.

Missing data mechanism. The LTM assumes observations of the trajectory are missing at random (MAR). This implies that we can use maximum likelihood estimation without needing to incorporate additional information about the sampling model; see Appendix B. When the data are missing not at random, assumptions about the missing data mechanism should be explicated and incorporated within the individual marker models.

In summary, the latent, individual-specific factors in the model (z_i , \bar{b}_i , and f_i from Eq. 11B, 11C, and 11D respectively) each contribute to describe the observed trajectory at different granularities. These are all treated as random variables and marginalized out during learning to avoid overfitting. When making predictions, we can use an individual’s observed data to compute posterior distributions over these latent factors, which allows us to tailor predictions.

3.2.1 LTM LIKELIHOOD

Given parameters $\Theta = \{\Lambda, \pi_{1:G}, \bar{\beta}_{1:G}, \Sigma_b, a, \ell, \sigma^2\}$, we can compute the observed-data likelihood of a given clinical marker trajectory by marginalizing z_i , \bar{b}_i and f_i out of the joint distribution defined by our model:

$$p(\bar{y}_i | \bar{x}_i; \Theta) = \sum_{z_i=1}^G \underbrace{p(z_i | \Theta)}_{\text{Multinomial prior}} \int_{\mathbb{R}^{d_\ell}} \underbrace{p(\bar{b}_i | \Theta)}_{\text{Normal prior}} \int_{\mathbb{R}^{N_i}} \underbrace{p(f_i | \Theta)}_{\text{GP prior}} p(\bar{y}_i | z_i, \bar{b}_i, f_i, \bar{x}_i; \Theta) df_i d\bar{b}_i \quad (13)$$

$$= \sum_{z_i=1}^G \pi_{z_i} \mathcal{N}(\bar{y}_i | \Phi_p(\bar{t}_i) \Lambda \bar{x}_i + \Phi_z(\bar{t}_i) \bar{\beta}_{z_i}, K(\bar{t}_i, \bar{t}_i)). \quad (14)$$

Moving from Eq. 13 to Eq. 14, we evaluate the innermost integral using the fact that the GP prior over f_i is conjugate to Eq. 11 yielding a new multivariate normal (Rasmussen and Williams, 2006). To evaluate the next integral in Eq. 13, we again have that the normal prior over \bar{b}_i is conjugate to the multivariate normal obtained by marginalizing over f_i , which gives us the multivariate normal shown in Eq. 14 where the covariance function is defined as

$$K(t_1, t_2) = \Phi_\ell(t_1)^\top \Sigma_b \Phi_\ell(t_2) + \text{Kou}(t_1, t_2) + \sigma^2 \mathbb{1}(t_1 = t_2). \quad (15)$$

We see that the observed-data likelihood for individual i is defined by a mixture of multivariate normals where each subtype is associated with a class in the mixture. The mixing probabilities are defined by the multinomial over subtypes. The mean of the multivariate normal is defined by the population and subpopulation models, and the covariance is defined by the individual long-term and short-term components of the model. To obtain the LTM likelihood needed in Eq. 2, we will condition Eq. 14 on subtype z_i . This gives us the following expression:

$$p(\bar{y}_i | z_i, \bar{x}_i) \triangleq \mathcal{N}\left(\bar{y}_i | \Phi_p(\bar{t}_i) \Lambda \bar{x}_i + \Phi_z(\bar{t}_i) \bar{\beta}_{z_i}, K(\bar{t}_i, \bar{t}_i)\right). \quad (16)$$

3.2.2 LTM PREDICTIVE

As presented, the LTM can be easily applied to the task of disease activity trajectory prediction. Note that the LTM provides a posterior distribution over the trajectory using baseline markers and measurements of the target marker (e.g. PFVC) as they are recorded. It does not incorporate information from other time-varying markers such as TSS and PDLCO. Suppose we have estimates of the model parameters $\Theta = \{\Lambda, \pi_{1:G}, \bar{\beta}_{1:G}, \Sigma_b, a, \ell, \sigma^2\}$, then we can predict an individual’s future course by computing the posterior predictive distribution $p(\bar{y}_{i>t} | \bar{y}_{i \leq t}, \bar{x}_i)$, where $\bar{y}_{i>t}$ denotes marker values after time t and $\bar{y}_{i \leq t}$ denotes marker values observed prior to time t . To compute the expected marker value at time t_i^* , we evaluate the following expression:

$$\hat{y}(t_i^*) = \sum_{z_i=1}^G \int_{\mathbb{R}^{d_\ell}} \int_{\mathbb{R}^{N_i}} \underbrace{\mathbb{E}[y_i^* | z_i, \bar{b}_i, f_i]}_{\text{prediction given latent vars.}} p\left(z_i, \bar{b}_i, f_i | \bar{y}_{i \leq t}, x_{0:t}, \Theta\right) df_i d\bar{b}_i \quad (17)$$

$$= \mathbb{E}_{z_i, \bar{b}_i, f_i}^* \left[\Phi_p(t_i^*)^\top \Lambda \bar{x}_i + \Phi_z(t_i^*)^\top \bar{\beta}_{z_i} + \Phi_\ell(t_i^*)^\top \bar{b}_i + f_i(t_i^*) \right] \quad (18)$$

$$= \underbrace{\Phi_p(t_i^*)^\top \Lambda \bar{x}_i}_{\text{pop. prediction}} + \underbrace{\Phi_z(t_i^*)^\top \mathbb{E}_{z_i}^*[\bar{\beta}_{z_i}]}_{\text{subpop. prediction}} + \underbrace{\Phi_\ell(t_i^*)^\top \mathbb{E}_{\bar{b}_i}^*[\bar{b}_i]}_{\text{ind. long prediction}} + \underbrace{\mathbb{E}_{f_i}^*[f_i(t_i^*)]}_{\text{ind. short prediction}}, \quad (19)$$

where E^* denotes an expectation conditioned on $\bar{y}_{i \leq t}, x_i, \Theta$. We see that the prediction takes a natural form: we compute the value of the individual’s disease activity trajectory at the future time point by replacing the latent factors with their posterior expectations. Computing the population prediction is straightforward as all quantities are observed. To compute the subpopulation prediction, we need to compute the marginal posterior over z_i ,

then we can write $\mathcal{D}(i, t)$ (Eq. 1) as

$$\mathcal{D}(i, t) = \sum_{z_i} p(\mathbf{Y}(\cdot) | z_i, \bar{y}_i \leq t, \bar{x}_i) p(z_i | \mathcal{H}(i, t)). \quad (29)$$

Intuitively, we see that the predictive distribution under C-LTM is simply a weighted combination of the subtype-specific predictive distributions under LTM (Eq. 24). Moreover, the distribution $p(z_i | \mathcal{H}(i, t))$ is the marginal distribution over z_i in a conditional random field with structure similar to the coupling model (Eq. 25) but augmented with additional singleton factors defined by the LTM likelihood functions given the marker trajectory histories. The LTM likelihood factors in Eq. 27 are added into the model unchanged, but additional parameters $\{\gamma, \gamma_{1:C}\}$ can be included to reweight those terms (a similar idea is used in Raina et al. (2003)).¹ The factor graph for this conditional random field is shown in Figure 4. Note that the weight $p(z_i | \mathcal{H}(i, t))$ can be efficiently computed in time linear in the number of auxiliary markers using the junction tree algorithm.

The C-LTM offers a number of advantages for predictive modeling of disease trajectories in domains where many other related marker trajectories are available. First, it allows irregularly and sparsely sampled trajectories to be neatly summarized using modularized, single-marker generative models. These can capture important latent factors and account for marker-specific measurement models and noise processes. Second, we can discriminatively use auxiliary marker trajectory histories when modeling Eq. 1 instead of specifying a joint generative model, which sidesteps the challenges associated with correctly specifying dependencies between many different marker types. Finally, the model can be used in continuous time and it dynamically updates predictions as new observations arrive.

3.5 Learning the C-LTM

We have described two components of our approach: the Latent Trajectory Model (LTM) and the coupling model. When these components are combined as shown in Section 3.4, then we obtain the C-LTM. The C-LTM has two conceptually distinct sets of parameters. The first set are those belonging to the individually trained LTMs for each marker type. To learn these, we can use the EM algorithm described in Schulam and Sarria (2015). To learn the parameters for the C-LTM, we keep the single-marker model parameters fixed (e.g. those learned for the LTM), and use a standard gradient-based CRF learning algorithm (as described in Section 3.1.2) to optimize the penalized log-likelihood of example trajectory predictions. For completeness, we provide additional details for both stages in Appendix A.

3.5.1 SCALABILITY

The EM algorithm used to learn the parameters of the LTM poses no serious challenges to scalability. The primary computational burden lies in the E-step wherein sufficient statistics from all individuals are computed and collected. This is linear in the number of patient records being analyzed, but since the inference required to compute the sufficient statistics can be performed independently for each individual given the current parameter estimates, the E-step can be easily parallelized to offset slow learning due to large numbers

of patient records. For any given individual, the E-step is dominated by the inversion of the $N_i \times N_i$ covariance matrix. We do not expect this to be problematic, however, because clinical markers in chronic diseases are observed at a maximum rate of 12 times per year. Moreover, such diseases occur over periods on the order of tens of years. Therefore, the number of measurements will be at most on the order of 100-200.

Learning the parameters of the CRF requires a sweep through all $M|T|$ training instances in order to compute and aggregate the gradient at each iteration. The primary computational burden is computing the expected values of the features (Eq. 42), however, the tree-structured graphical model shown in Figure 4 allows the junction tree algorithm to run in time linear in the number of auxiliary markers. On a standard laptop, we are able to train the model on 772 patients (5,458 PFVC measurements) in 10-20 minutes.

Online inference for predicting a given individual’s future trajectory is also computationally straightforward. The key quantities are (1) the weights $p(z_i | \mathcal{H}(i, t))$ in Eq. 29, which are easily computed using the junction tree algorithm in time linear in the number of auxiliary markers, and (2) the subtype-specific predictive densities $p(\mathbf{Y}(\cdot) | z_i, \bar{y}_i \leq t, \bar{x}_i)$, which have the same computational complexity as the E-step in the LTM learning algorithm.

4. Experiments

We demonstrate our approach by building a tool for predicting lung disease trajectories for individuals with scleroderma. Lung disease is currently the leading cause of death among scleroderma patients, and is notoriously difficult to treat due to the lack of accurate predictors of decline and tremendous variability across individual trajectories (Allanore et al., 2015). Clinicians use percent of predicted forced vital capacity (PFVC) to track lung severity, which is expected to drop as the disease progresses. In addition, they collect demographic information and other clinical marker values that measure the impact of disease on the different organ systems involved in scleroderma.

Data description. We train and validate our model using data from the Johns Hopkins Scleroderma Center patient registry, one of largest collections of clinical scleroderma data in the world. Demographic information is collected during the patient’s first visit to the clinic. PFVC and other clinical markers are collected during routine visits thereafter. To select individuals from the registry, we used the following criteria. First, we include individuals who were seen at the clinic within two years of their earliest scleroderma-related symptom² (1,186 individuals). Second, we exclude all individuals with fewer than two PFVC measurements after first being seen by the clinic (398 individuals). Finally, we exclude individuals who received a lung transplant (16 individuals) because their natural trajectory is altered by the intervention. Transplants are rare so removing patients with transplants should not introduce significant bias. As mentioned earlier, there are no other known course-altering therapies for scleroderma.

Our final data set contains 772 individuals and a total of 5,458 PFVC measurements tracking individuals over a period of 20 years. The first, second, and third quartiles of the total number of PFVC measurements for an individual are 3, 5, and 9 respectively. The maximum number of PFVC measurements for one individual is 63. The first, second, and third quartiles of the measurement times are 1 year, 2.8 years, and 5.9 years. The first,

¹ When using a penalty, we can center the weights at 1 so that the default behavior is to leave the likelihood factors unchanged as in Eq. 27

² Date of first symptom is established during the first encounter by both the patient and clinician.

second, and third quartiles of elapsed time between measurements are 0.4 years, 0.7 years, and 1.10 years. The minimum and maximum elapsed time is 0.002 years and 16.4 years respectively.

The baseline demographic information includes gender and African American race, both of which have been shown to be associated with disease severity in scleroderma (Allanore et al., 2015). Antibody data are also collected at baseline, but since these are only available for a small subset of individuals, we do not include that data here. For time-dependent predictors, we include 5 auxiliary clinical markers. Three of the auxiliary markers are similar to PFVC in that they are continuous-valued test results used to measure the health of organ systems. We include: percent of predicted forced expiratory volume in one second (PFEV1), which measures the force with which air is expelled from the lungs; percent of predicted diffusing capacity (PDLCO), which measures the efficiency of oxygen diffusion from the lungs to the bloodstream; and total skin score (TSS), which is a cumulative measure of the thickness of the skin at various points on the body. In addition, we include 2 severity scores—clinical Likert-scaled judgements of organ damage severity: Raynaud’s phenomenon (RP) severity score, which measures the severity of damage to the extremities by issues related to the vasculature, and GI severity score that measures the severity of damage to the GI tract. For the interested reader, a more detailed discussion of these markers and their relationship to the disease can be found in Varga et al. (2012).

Experimental setup. For the 4 continuous-valued clinical markers (PFVC, PFEV1, PDLCO, TSS) we use the LTM and for the 2 severity scores (GI and RP) we use a simpler model that we will describe later. For the population model, we use constant functions (i.e. the basis expansion $\Phi_p(t)$ contains an intercept term whose coefficient is determined by baseline covariates). For the subpopulation B-splines, we set boundary knots at 0 and 25 years (the maximum observation time in our data set is 23 years), use two interior knots that divide the time period from 0-25 years into three equally spaced chunks, and use quadratics as the piecewise components. For the individual-specific long-term basis Φ_t , we use the same basis as the population model (constant functions).

We divide our data into 10 folds and use log-likelihood on the first fold for tuning hyperparameters. For PFVC, we select $G = 9$ subtypes using BIC. For the kernel hyperparameters $\Theta_1 = \{\Sigma_b, \alpha, \ell, \sigma^2\}$ we set $\Sigma_b \in \mathbb{R}$ to be 16.0, which corresponds to the variance of individual-specific intercepts. We set $\alpha = 6$, $\ell = 2$, and $\sigma^2 = 1$ using a grid search over values chosen using domain knowledge. Qualitatively, these make sense; we expect transient deviations to last around 2 years and to change PFVC by around ± 6 units. Finally, we penalize the expected log-likelihood with respect to $\beta_{1,G}$ as in Eq. 4 and set the weight $\rho = 0.01$, which was chosen based on the clinical interpretability of the learned subtype trajectories. The remaining 9 folds were used for our cross-validation experiments. The parameters of each trajectory model are estimated independently for each fold (e.g. the B-spline coefficients of the subtype trajectories). For the severity scores, which are Likert-scaled and not continuous, we use a simple naive Bayes generative model wherein the latent “class” is an indicator of whether the individual ever reaches a high severity level (a cutoff in the severity scale determined by clinical collaborators). Severity score observations are treated as iid draws from a class-specific multinomial distribution (i.e. the likelihood for these auxiliary markers is a multinomial distribution over severity scores). Finally, we estimate the parameters of the C-LTM by maximizing the objective in Eq. 33 augmented

with an $L1$ regularizer. We optimize the objective using the Orthant-Wise Limited-memory Quasi-Newton (OWL-QN) algorithm (Andrew and Gao, 2007). To generate training examples for the C-LTM, we use times $\mathcal{T} = \{1, 2, 4\}$ (the first three quintiles of observation times in our data) to fit three different models. We choose time points earlier in the disease course because this is when it is most valuable to leverage all available information. In our cross-validated experimental results below, we estimate the penalty of the $L1$ regularization term in each fold by splitting a portion of the training data into a development set. We sweep the penalty from 1.0×10^{-7} to 1.0×10^{-1} and choose based on development set performance.

Baselines. As a first baseline, we fit a regression model using static predictors only (features in \vec{x}_i). This is to compare against typical approaches in clinical prediction which rely only on observed features to predict disease progression (e.g. Khanna et al. 2011). The regression function is as follows, where $\Phi(t)$ is a B-spline basis:

$$\hat{y}(t) \mid \vec{x}_i = \Phi(t)^\top \left(\vec{\beta}_0 + \sum_{\sigma_{ij}} \vec{x}_{i,j} \vec{\beta}_j + \sum_{\sigma_{ij}, \sigma_{ik}} \vec{x}_{i,j} \vec{x}_{i,k} \vec{\beta}_{ij} \right). \quad (30)$$

The following baselines reflect state-of-the-art approaches for dynamical prediction. The focus for each of these models, as discussed in the related work section, is on dynamical prediction of single marker trajectories using the marker history and static measurements collected during the first visit. The second baseline, like Rizopoulos (2011) and Shi et al. (2012), defines a single mean function parameterized in the same way as the first baseline and models individual-specific variations using a GP with the same kernel as in Equation 15 (using hyper-parameters as above). The third baseline is a mixture of B-splines, which models subpopulations that can express different trajectory shapes (as in Proust-Lima et al. (2014)).³ Finally, we use the LTM (no coupling to auxiliary markers) as a baseline. All B-spline bases used in these baseline models are parameterized in the same way as the C-LTM (described above).

Evaluation. Prediction accuracy for all models is measured using the absolute error between the predicted and a smoothed version of the individual’s observed trajectory. We make predictions after one, two, and four years of follow-up, which are summarized using averages computed in the second year of follow-up ($t \in \{1, 2\}$), in the third and fourth year of follow-up ($t \in \{2, 4\}$), fifth to eighth year of follow-up ($t \in \{4, 8\}$), and beyond the eighth year of follow-up ($t \in \{8, 25\}$)⁴. Mean absolute errors (MAE) and standard errors are estimated using 9-fold CV⁵ at the level of individuals (i.e. all of an individual’s data is held-out). Significance tests are computed against baselines using a paired t-test with point-wise predictions aggregated across folds.

4.1 Results

In this section, we present four sets of results. The first two are qualitative, and demonstrate the advantages of the C-LTM over the baseline models using examples. In the first

3. For the B-spline mixture, we use the subtypes discovered by LTM as the mixture classes. Without accounting for individual-specific variability explicitly, we have found that fitting a B-spline mixture using EM recovers poor classes that do not capture important trajectory shapes in the data. For additional details, see Section 3 in the supplement of Schulam and Saria (2015).
4. After the eighth year, data becomes too sparse to further divide this time span.
5. Recall that the first of 10 folds is used for hyperparameter estimates.

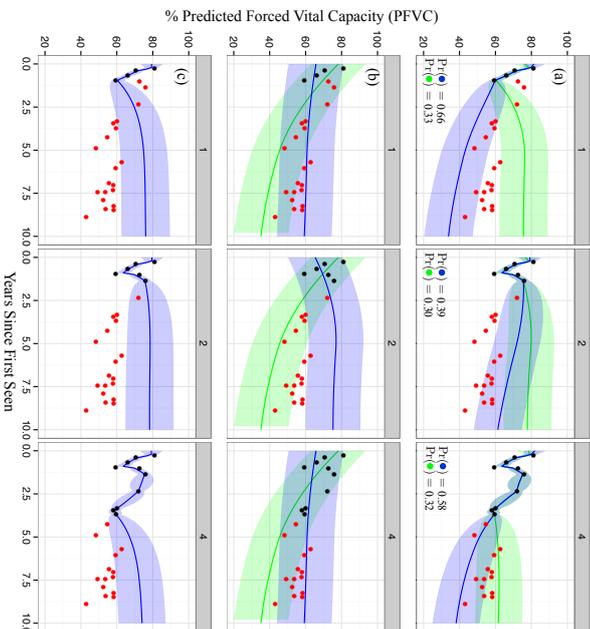

Figure 5: Examples of predictions made using 1, 2, and 4 years of data (moving across columns from left to right). Plot (a) shows dynamic predictions using C-LTM. Red markers are unobserved. Blue shows the trajectory predicted using the most likely subtype, and green shows the second most likely. Plot (b) shows dynamic predictions for the B-spline mixture baseline. Plot (c) shows the same for the B-spline + GP baseline.

qualitative analysis, we compare predictions made by C-LTM to those made by the B-spline mixture and the B-spline + GP. In the second qualitative analysis, we compare the C-LTM inferences with those from the LTM, which is a state-of-the-art single-marker model. The second two results are quantitative. The first compares predictive accuracies between the baseline models and the C-LTM. The second investigates clinical utility by using each model to predict a severity score that we use to detect individuals with aggressive lung disease.

4.1.1 VISUAL COMPARISON TO BASELINES

As an illustrative example to compare C-LTM with baselines, in Figures 5a, 5b, and 5c we show the dynamic predictions made using the C-LTM, the B-spline mixture, and the B-spline + GP baselines on a sample patient.⁶ For each model, we show 95% posterior

⁶ This patient was selected as an exemplar for the types of errors commonly made by the baseline models.

intervals for the future trajectory. For the C-LTM and B-spline mixture, the most likely subtype is shown in blue and the second most likely is in green. The B-spline mixture (Figure 5b) cannot explain individual-specific sources of variation (e.g. short-term deviations from the mixture mean) and so over-reacts to the slight rise in PFVC seen in the last two observed (black) measurements in the second panel (year 2). The B-spline + GP (Figure 5c) cannot capture long-term differences in trajectory means (e.g. due to subtypes) and so pulls back to the population mean over time even after four years of data suggest a declining trajectory. On the other hand, at year 1 the C-LTM (Figure 5a) maintains the hypothesis that the individual may decline or return to stability (correctly putting most weight on the former). After 2 years of data, the temporary recovery seems to have caused confidence in the declining trajectory to fall (going from 66% to 39%), but the top-weighted hypothesis is still correct. After 4 years of data, the model again becomes confident in the declining trajectory. Clinically, this robustness to short-term changes is important. After having seen the recovery between years 1 and 2, a clinician may become less immediately concerned with the individual's future lung disease, possibly delaying immunotherapy until a rapid decline becomes more evident. Note that the B-spline mixture, on the other hand, over-reacts to the recovery and predicts that the individual will continue to recover.

4.1.2 ANALYSIS OF EXAMPLE INFERENCES

In Figure 6a-d, we show the C-LTM's target and auxiliary marker inferences for four different patients. For the target marker (PFVC) and auxiliary markers (TSS, PDLCO, and PFEV1), we show the most likely (blue) and second most likely (green) subtype and their corresponding trajectories. For the RP and GI severity score markers, we show the most likely severity class (high versus low). The dashed lines indicate the threshold at which high and low are determined based on judgements by our clinical collaborators. For PFVC, PFEV1, and PDLCO lower values indicate more severe progression. For TSS, higher values indicate severe progression. In Figures 6e-h, we show the predictions made by LTM to visually compare against predictions made using the baseline markers and PFVC history only (i.e. that do not leverage information from auxiliary markers).

In Figure 6a, we see a 55-year-old woman who presents with mildly impaired lung function (approximately 65 PFVC), but seems to recover over the course of the first year to reach a PFVC above 75 (considered by clinicians to be relatively healthy). Using this information alone, one may suspect that she will not have future lung issues. Indeed, this is what LTM predicts as shown in Figure 6e. By examining her auxiliary markers, however, we see that the picture is less clear. In particular, PFEV1 (a clinical marker closely related to PFVC) both decreases and increases over that period. C-LTM infers a mildly declining trajectory for PFEV1. In addition, PDLCO is also noisy and overall low, which suggests that the blood is not efficiently absorbing oxygen. This can happen for a number of reasons, but active lung disease is one of them. Finally, we see that her initial skin score is quite high and C-LTM projects it to stay high for the next few years, which is associated with active lung disease. We see that C-LTM has successfully incorporated inferences about the future trends of the auxiliary markers and correctly predicts that this woman's PFVC will decline after this initial improvement.

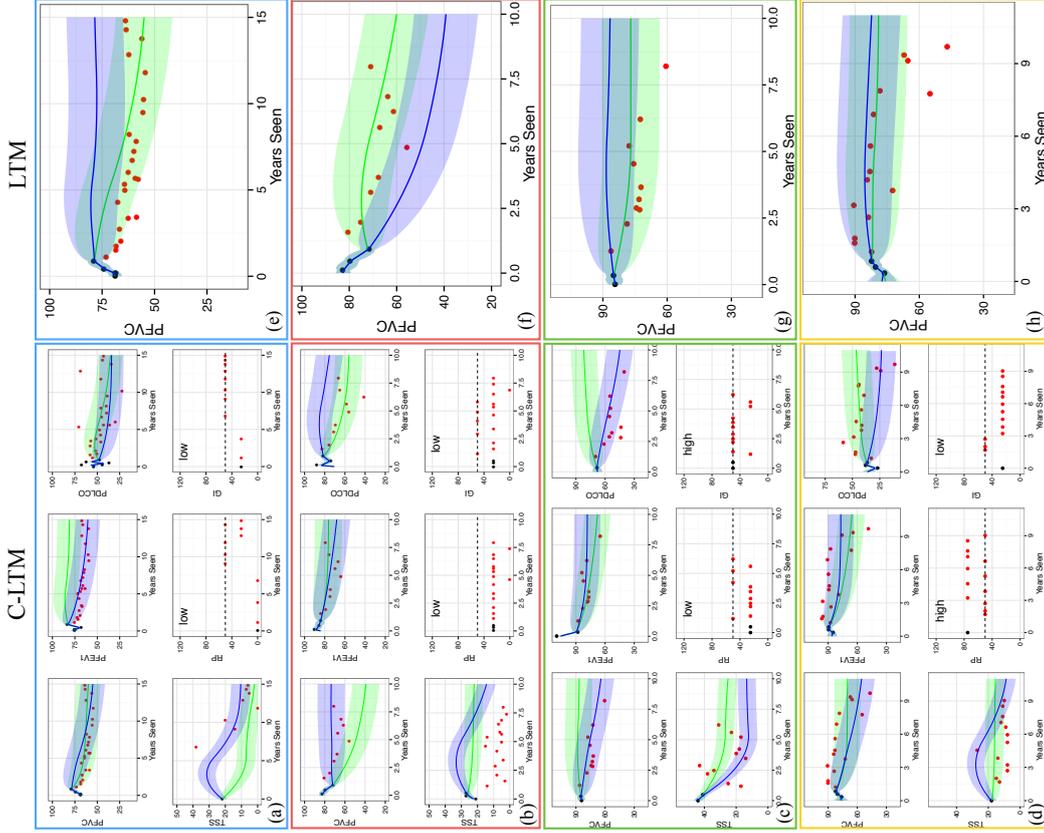

Figure 6: The predicted PFVC trajectory and the auxiliary markers are shown for two different patients. Red markers are unobserved. For the auxiliary markers TSS, PFEV1, and PDLCO we show the most likely (blue) and second most likely (green) subtype and their corresponding trajectories. For the RP and GI severity scores, we show the most likely severity class (high versus low). The dashed lines indicate the threshold at which high and low are determined clinically.

In Figure 6b, we see a 75 year-old white woman who presents with healthy lung function (approximately 85 PFVC), but is consistently declining over the course of the first year by nearly 15 PFVC. A clinical rule of thumb is that a drop in 10 PFVC over the course of a year warrants close monitoring for active lung disease. We see that LTM extrapolates this initial trend and predicts that this individual will continue to decline rapidly (Figure 6f). Just as in the previous example, however, the auxiliary markers paint a more complete picture of this individual. In the first few PFEV1 observations, we see that this decline is not quite as pronounced and the progression is predicted to be more mild. In PDLCO we see that oxygen is absorbed into the blood at healthy levels and also predicted to remain stable (although incorrectly in this case). Finally, C-LTM predicts that the RP and GI severity scores will remain low, which also supports the prediction that this woman will stabilize. Note that in this example C-LTM overestimates the course of PDLCO and TSS. Although the model still makes the correct prediction for PFVC in spite of this mistake, it highlights that the performance of our approach may be further improved with better auxiliary marker inferences. As research in systems biology yields new insights into modeling specific measurements more precisely, the modular architecture of C-LTM makes it possible to improve overall performance by incorporating improved versions of the target or auxiliary marker models.

In Figure 6c, we see a 76 year-old white woman that presents with healthy lung function (just under 90 PFVC), which also appears to be stable given the subsequent test result taken later that same year. The LTM predicts that this individual's most likely course is to remain stable. From the PFEV1 trajectory, however, we see that there was a large initial loss in PFEV1, which, together with the unusually high skin score (TSS) suggests that this woman's disease is active. The activity in the other organ systems allows the C-LTM to offset the stability seen in the first two PFVC measurements and correctly predict the consistently declining lung trajectory.

Finally, in Figure 6d, we see a 67 year-old African American man with mildly impaired lung function early in the disease course (around 75 PFVC) that seems to recover over the next one or two years to a healthier 85 PFVC. In Figure 6h, we see that the LTM predicts that a stable trajectory thereafter is likely. By considering other organ systems, however, we see that this man's blood-oxygen diffusion is severely limited early in the disease course (nearly 25% of the predicted DLCO). Moreover, we see that the this individual's Raynaud's phenomenon severity score is high early on and correctly predicted to remain that way. The low PDLCO and high RP severity score point to active vasculature disease, which is hypothesized to cause late deterioration in lung function. We see that C-LTM correctly uses this evidence to predict an accurate disease trajectory.

4.1.3 PREDICTIVE ACCURACY

In Table 1, we report performance of the C-LTM, LTM, and the three other baseline models. First, we note that the C-LTM statistically significantly outperforms the B-spline with baseline features for all predictions. This baseline makes static predictions using baseline information only, and cannot adapt to an individual as new data becomes available. Moreover, after an initial amount of data has been collected on an individual, C-LTM statistically significantly outperforms all other models. This is not surprising. When compared to the

Table 1: Mean absolute error of PFVC predictions for the B-spline with baseline features, the B-spline + GP, LTM, and C-LTM. Bold numbers indicate best performance across baseline models and proposed model. ★ indicates statistically significant improvement against the B-spline model with baseline features only using a paired t-test ($\alpha = 0.05$). ◆ indicates statistical significance compared against the B-spline + GP. ◆ indicates statistical significance compared against the B-spline mixture. ♠ indicates statistical significance compared against LTM.

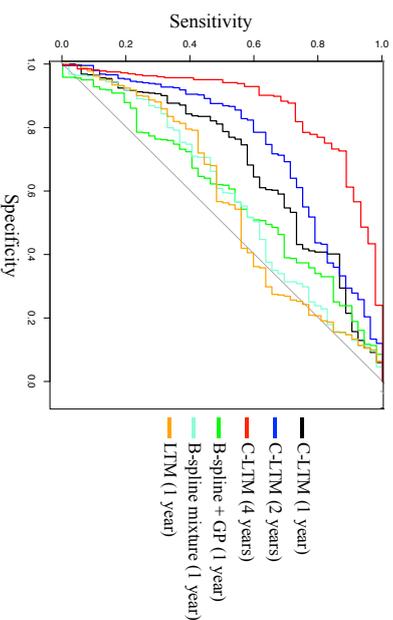

LTM, we see that C-LTM benefits from leveraging information from auxiliary markers. As more information is collected, both models are able to the individual and provide comparable predictions. The B-spline mixture is not able to personalize beyond capturing long-term trends across subpopulations, so we see that it becomes less competitive compared to both C-LTM and LTM as more data are collected. Finally, the B-spline + GP cannot capture long-term trends specific to subpopulations (as we saw in Section 4.1.1), and so we see that it does poorly when making predictions.

4.1.4 CLINICAL UTILITY

One may naturally wonder whether the observed improvements in MAE reported above translate to practical benefits in the clinic. In the examples shown in Figure 6, we have walked through cases where the model makes predictions that would seem unlikely if we were to consider PFVC alone. This suggests that the model can augment expert clinical judgement and may serve to protect against incorrect extrapolations. In this section, we further elaborate upon this intuition by studying clinical utility quantitatively. In particular, we compare how well the B-spline + GP, B-spline mixture, LTM, and C-LTM are able to detect individuals who will have rapidly declining lung function. It is notoriously difficult to predict which scleroderma patients will rapidly decline using only information from early in the disease course. In addition to improving prognoses, more accurate detection of rapidly declining lung function can help to improve the recruitment for clinical trials evaluating drugs for scleroderma-related lung disease. If we include many individuals in a study who

Model / Years of Data	1	2	4
B-spline + GP	0.59	0.63	0.74
B-spline mixture	0.58	0.63	0.76
LTM	0.57	0.71	0.84
C-LTM	0.68	0.75	0.87

(a) AUCs for detecting declining individuals.

(b) ROCs comparing B-spline + GP at 1 year, B-spline mixture at 1 year, LTM at 1 year, and C-LTM at years 1, 2, and 4.

Figure 7: Declining individual detection results.

are predicted to have active lung disease but do not, the results of the study are blurred because both arms of the trial may include many individuals without active lung disease.

To test how well these different models can detect individuals that will experience rapidly declining lung function, we use the predictions of future PFVC measurements to produce a score. The score is defined to be the difference between the individual's first PFVC measurement and the minimum predicted value in the future—this will be higher for individuals on whom a model predicts deteriorating lung function and lower for those predicted to be stable. To label an individual as declining, we require that they (1) have at least one observation within the first year of being seen by the clinic, (2) have 3 years between their first and last measurements, (3) have at least 4 PFVC measurements, and (4) have an initial PFVC measurement that is 20 PFVC higher than their last measurement. Requirements (2) and (3) are to ensure that the trajectory can be reliably annotated as declining or not. For each model, we make predictions at years 1, 2, and 4 and compute the score described above for each individual. We then compute the AUC for each model at each year. Table 7a displays the results of this experiment. We see that C-LTM achieves higher AUC at all years than the baseline models. Figure 7b displays the ROCs for the B-spline + GP (green), B-spline mixture (cyan), LTM (orange), and the proposed model (black) at year 1

and also includes the ROCs for the proposed model at years 2 (blue) and 4 (red) to visualize how performance improves as more data is added. Clinically, an AUC of 0.87 for predicting individuals with lung decline after—on average—four years of data is high and has not been shown previously.

5. Discussion

The goal of personalized (also called precision) medicine is to develop tools that help to tailor prognoses to the characteristics and unique medical history of the individual. In this paper, we describe an approach to personalized prognosis that uses an integrative analysis of multiple clinical marker histories from the individuals' medical records. Our approach combines single-marker latent variable models (the LTM) with a CRF coupling model to make more accurate predictions about the future trajectory of a target clinical marker.

The coupled model (C-LTM) has several advantages. First, the marker-specific LTMs account for marker trajectory shapes using components at the population, subpopulation, individual long-term, and individual short-term levels, which simultaneously allows for heterogeneity across and within individuals, and enables statistical strength to be shared across observations at different “resolutions” of the data. Within an individual marker model, the population and subpopulation components are learned offline, while estimates of the individual-specific parameters are refined over the course of the disease as data accrues for that individual. Second, our coupling model allows us to condition both the target and auxiliary marker histories to make predictions about the future target marker trajectory. We therefore use the marker-specific latent variable models to neatly summarize and extract information from the irregularly sampled and sparse, while simultaneously sidestepping the issue of jointly modeling both the target and auxiliary markers. The conditional formulation is less sensitive to misspecified dependencies between different marker types and can also be easily scaled to diseases with a large number of auxiliary markers. Finally, our model aligns with clinical practice; predictions are dynamically updated in continuous time as new marker observations are measured. We also note that our description of the method and the experimental results focus on predicting the trajectory of a single clinical marker, but multiple latent factor regression models can be easily fit so that many markers can be simultaneously predicted. Using this extension, we only need to maintain different CRF parameters; the latent variable models are shared since they are fit independently as a precursor to learning the CRF.

There are several shortcomings of the proposed approach that are promising directions for future research. First, the model implicitly assumes that the data generating process is noninformative (i.e. missing data is missing at random (Little and Rubin, 2014)). This is appropriate for clinical markers that are routinely collected, but additional machinery would be required to model markers whose missingness is informative. For example, in some cases, additional measurements may be made due to clinical suspicion caused by factors that are not clearly documented in the health record. Researchers have begun to explore more complex missing-data mechanisms for disease trajectory modeling (e.g., Lange et al. 2015; Coley et al. 2016), and it will be important to incorporate these ideas into the framework discussed here to integrate the full set of markers measured during a clinical visit. Another shortcoming is our focus on discrete latent factors of the auxiliary marker trajectories. Continuous-valued

latent factors may also be useful, but would make learning and inference in the latent factor CRF more challenging.

There are also several other immediate opportunities for improving the model. Auxiliary markers are integrated via separate marker-specific generative models. While we incorporated two different types of models—trajectory and maximum-severity based—both of which were data driven, existing and new clinical knowledge should be brought to bear to improve these models, which we expect will improve predictions of the target trajectories. Further, in this work, we focused on modeling the dependency of the target subtype on the auxiliary markers. In addition, estimates of the individual-specific long-term and short-term components may also benefit from conditioning on the auxiliary markers. Finally, the parameters for the pairwise potentials learned in our model may serve as a means for generating hypotheses about the co-evolution of organ-specific trajectories.

The ideas proposed here also open up other longer-term directions for future work. The proposed model does not account for the effects of treatment on an individual's long-term trajectory. In many chronic conditions, as is the case for scleroderma, drugs only provide short-term relief (accounted for in our model by the individual-specific adjustments). However, if treatments that alter long-term course are available and commonly prescribed, then these should be included within the model as an additional component that influences the trajectory. Learning these treatment effects from noisy electronic health record data (e.g., Xu et al. 2016) present an exciting and challenging direction for future work.

We have demonstrated our model by developing a prognostic tool for predicting lung disease trajectories in patients with scleroderma, an autoimmune disease. We showed that the proposed model makes more accurate predictions than state-of-the-art approaches. Accurate tools for prognosis can allow clinicians and patients to more actively manage their disease. While we have focused model development and evaluation on scleroderma, this work is broadly applicable to other complex diseases (Craig, 2008), many of which track disease activity using clinical scales of severity. The proposed model is most directly applicable to CCDs where heterogeneity in disease presentation is common. Examples of such diseases include lupus, multiple sclerosis, inflammatory bowel disease (IBD), chronic obstructive pulmonary disease (COPD), and asthma. Extensions of the proposed ideas, and the model, to these diseases offer an opportunity to address important open challenges in precision medicine.

Acknowledgments

We would like to thank Drs. Laura Hummers, Fredrick Wigley and Robert Wise who have provided extensive clinical guidance as well as the data set with which this study was conducted. We would also like to thank Dr. Colin Ligon for his generous support in chart reviewing patients; many of the key ideas in our work were motivated by these chart reviews. Finally, we would like to thank Zachary Barnes who helped deploy a previous iteration of this model as a tool in the clinic and shadowed clinicians while it was in use. Our work has benefited from the lessons he learned when observing the clinicians use this tool.

Appendix A. Learning the C-LTM: Details

In this section, we provide additional details on the learning algorithm for the C-LTM. Recall that this consists of two stages: (1) independently fitting the single-marker models (the LTM in our case), and (2) fitting the parameters of the coupling model. We describe both stages below.

A.1 Learning the LTM

To learn the parameters of the single-marker model $\Theta = \{\Lambda, \pi_{1:G}, \bar{\beta}_{1:G}, \Sigma_b, a, \ell, \sigma^2\}$, we maximize the observed-data log-likelihood of a training sample of M retrospectively observed trajectories (i.e. the probability of all individual's marker values \bar{y}_i given measurement times \bar{t}_i and features \bar{x}_i). Using the expression for the observed-data likelihood in Eq. 14, we have that the observed-data log-likelihood for all individuals in a training sample is

$$\mathcal{L}(\Theta) = \sum_{i=1}^M \log \left[\sum_{z_i=1}^G \pi_{z_i} \mathcal{N} \left(\bar{y}_i \mid \Phi_b(\bar{t}_i) \Lambda \bar{x}_i + \Phi_z(\bar{t}_i) \bar{\beta}_{z_i}, K(\bar{t}_i, \bar{t}_i) \right) \right]. \quad (31)$$

To maximize the observed-data log-likelihood with respect to Θ , we partition the parameters into two subsets. The first subset, $\Theta_1 = \{\Sigma_b, \alpha, \ell, \sigma^2\}$, contains values that parameterize the covariance function shown in Equation 15. As is often done when designing the kernel of a Gaussian process, we use a combination of domain knowledge to choose candidate values and model selection using observed-data log-likelihood as a criterion for choosing among candidates (Rasmussen and Williams, 2006). The second subset, $\Theta_2 = \{\Lambda, \pi_{1:G}, \bar{\beta}_{1:G}\}$, contains values that parameterize the mean of the multivariate normal distribution in Equation 14. We learn these parameters using expectation maximization (EM) to find a local maximum of the observed-data log-likelihood in Equation 31 (Dempster et al., 1977).

Expectation step. All parameters related to \bar{b}_i and \bar{f}_i are limited to the covariance kernel and are not optimized using EM. We therefore only need to consider the subtype indicators z_i as unobserved in the expectation step. Because z_i is discrete, its posterior is computed by normalizing the joint probability of z_i and \bar{y}_i . Let $\pi_{z_i}^*$ denote the posterior probability that individual i has subtype $g \in \{1, \dots, G\}$, then we have

$$\pi_{z_i}^* \propto \pi_g \mathcal{N} \left(\bar{y}_i \mid \Phi_b(\bar{t}_i) \Lambda \bar{x}_i + \Phi_z(\bar{t}_i) \bar{\beta}_g, K(\bar{t}_i, \bar{t}_i) \right). \quad (32)$$

Maximization step. In the maximization step, we optimize the marginal probability of the soft assignments under the multinomial model with respect to $\pi_{1:G}$. This amounts to collecting total “soft counts” computed in Eq. 32 for each subtype and renormalizing. To optimize the expected complete-data log-likelihood with respect to Λ and $\bar{\beta}_{1:G}$, we note that the mean of the multivariate normal for each individual is a linear function of these parameters. Holding Λ fixed, we can therefore solve for $\bar{\beta}_{1:G}$ in closed form and vice versa. We use a block coordinate ascent approach, alternating between solving for Λ and $\bar{\beta}_{1:G}$ until convergence. To control the smoothness of the subtypes we penalize the log-likelihood with respect to the subtype parameters $\bar{\beta}_{1:G}$ as in Eq. 4. Because the penalized expected complete-data log-likelihood is concave with respect to all parameters in Θ_2 , each maximization step is guaranteed to converge. The exact computations required to maximize the expected log-likelihood can be found in Schulam and Saria (2015) and its supplement.

A.2 Learning the Coupling Model

To learn the parameters of the latent-factor CRF regression, we directly maximize the conditional probability of future target markers given previously observed target markers, previously observed auxiliary markers, and static baseline covariates on a collection of examples extracted from retrospective data. Suppose we are given records containing the target marker, auxiliary markers, and baseline covariates for M individuals. We choose a collection of times \mathcal{T} that will be used to create training examples of history-future pairs. For example, we may choose $\mathcal{T} = \{1, 2\}$ because early management decisions are made using prognoses at years 1 and 2. We emphasize, however, that the model is *not* restricted to making predictions at years 1 and 2; it can make predictions at arbitrary times. The times \mathcal{T} are simply used to create training instances. We also note that it is possible to train specialized models for different time periods. For example, we may train one model for making predictions in the first 2 years and another for beyond 4 years. Given the M records and times \mathcal{T} , we define the objective:

$$J(\gamma, \gamma_{1:C}, \theta, \theta_{1:C}, \eta_{1:C}) = \sum_{i=1}^M \sum_{t \in \mathcal{T}} \log p(\bar{y}_{i,t} > \ell \mid \mathcal{H}(i, t)) \quad (33)$$

$$= \sum_{i=1}^M \sum_{t \in \mathcal{T}} \log \left(\sum_{z_i} \underbrace{p(\bar{y}_{i,t} > \ell \mid z_i)}_{(A)} \underbrace{p(z_i \mid \mathcal{H}(i, t))}_{(B)} \right), \quad (34)$$

where (A) is the subtype-specific multivariate normal likelihood in Eq. 14 and (B) is the conditional distribution over z_i shown in Eq. 28. To learn the parameters, we maximize this objective with respect to $\gamma, \gamma_{1:C}, \theta, \theta_{1:C}$, and $\eta_{1:C}$ using gradient-based methods (e.g. L-BFGS). In our experiments, we optimize a regularized version of the objective, but for simplicity this section discusses the computations required to compute the gradient of Eq. 33 only. Consider a single summand of Eq. 33

$$\log p(\bar{y}_{i,t} > \ell \mid \mathcal{H}(i, t)) = \log \left(\sum_{z_i} p(\bar{y}_{i,t} > \ell \mid z_i) p(z_i \mid \mathcal{H}(i, t)) \right). \quad (35)$$

To reiterate, the parameters of the density $p(\bar{y}_{i,t} > \ell \mid z_i)$ are assumed to have been learned in a separate step (e.g. using the EM algorithm presented above), and so we are only concerned with estimating the parameters of the singleton and pairwise factors in the CRF:

$$\gamma, \gamma_{1:C}, \theta, \theta_{1:C}, \eta_{1:C}.$$

Gradient of the objective. We derive the gradient for a single summand of the objective (Eq. 33), which are combined additively to form the full gradient used at each iteration. Although our model is log-linear over all latent variables z_i and $z_{1:C,i}$, Eq. 35 is not linear in the parameters because the random field does not directly estimate the conditional distribution over the future target clinical markers, but instead estimates the weights assigned to each configuration of the latent variables. We therefore have that the partial derivative of Eq. 35 with respect to any parameter θ_k is:

$$\frac{\partial \log p(\bar{y}_{i,t} > \ell \mid \mathcal{H}(i, t))}{\partial \theta_k} = \frac{\left(\sum_{z_i} p(\bar{y}_{i,t} > \ell \mid z_i) \frac{\partial p(z_i \mid \mathcal{H}(i, t))}{\partial \theta_k} \right)}{p(\bar{y}_{i,t} > \ell \mid \mathcal{H}(i, t))}. \quad (36)$$

To complete the expression for the partial derivative, we need to compute the partial derivative of the probability of a given target marker latent variable z with respect to the parameter θ_k . We have that:

$$\frac{\partial p(z | \mathcal{H}(i, t))}{\partial \theta_k} = \frac{\partial}{\partial \theta_k} \frac{Z'_{i,t}(z)}{Z_{i,t}} = \frac{1}{Z_{i,t}} \frac{\partial Z'_{i,t}(z)}{\partial \theta_k} + Z'_{i,t}(z) \frac{\partial Z_{i,t}^{-1}}{\partial \theta_k}. \quad (37)$$

We can now leverage identities from the theory of log-linear models to continue with the derivation. In particular, recall that log-linear models are in the exponential family of distributions. As a consequence, we can consider the parameters $\gamma, \gamma_{1:C}, \theta, \theta_{1:C}, \eta_{1:C}$ as the *natural parameters* of the distribution. The corresponding *sufficient statistics* are therefore the factors in the log-linear model:

$$\begin{aligned} T(z, z_{1:C}, \vec{x}_i) &= [l_{i,\leq t}(z), l_{1,i,\leq t}(z_1), \dots, l_{C,i,\leq t}(z_C), \\ & f_1^\top(z, \vec{x}_i), f_1^\top(z_1, \vec{x}_i), \dots, f_C^\top(z_C, \vec{x}_i), \\ & g_1^\top(z, z_1), \dots, g_C^\top(z, z_C)]^\top. \end{aligned} \quad (38) \quad (39)$$

An important property of exponential families is that the gradient of the log-normalizing-constant with respect to the natural parameters is simply the expected value of the sufficient statistics computed using the current value of the natural parameters. Note that both $Z'_{i,t}(z)$ and $Z_{i,t}$ are normalizing constants of exponential family distributions. In the case of $Z'_{i,t}$ this is trivial to see because it is the normalizing constant of our log-linear model. In the case of $Z_{i,t}(z)$ we see that it is the normalizing constant of a log-linear model over the auxiliary marker latent variables $z_{1:C}$ given *both* z and the clinical history $\mathcal{H}(i, t)$. We therefore have:

$$\begin{aligned} \frac{\partial \log Z'_{i,t}(z)}{\partial \theta_k} &= \mathbb{E}_{z_{1:C}} [T(z, z_{1:C}, \vec{x}_i)_k | z, \mathcal{H}(i, t)] \\ &\implies \frac{\partial Z'_{i,t}(z)}{\partial \theta_k} = Z'_{i,t}(z) \mathbb{E}_{z_{1:C}} [T(z, z_{1:C}, \vec{x}_i)_k | z, \mathcal{H}(i, t)], \quad (40) \\ \frac{\partial \log Z_{i,t}}{\partial \theta_k} &= \mathbb{E}_{z, z_{1:C}} [T(z, z_{1:C}, \vec{x}_i)_k | \mathcal{H}(i, t)] \\ &\implies \frac{\partial Z_{i,t}^{-1}}{\partial \theta_k} = -\frac{1}{Z_{i,t}} \mathbb{E}_{z, z_{1:C}} [T(z, z_{1:C}, \vec{x}_i)_k | \mathcal{H}(i, t)], \quad (41) \end{aligned}$$

where we have used $T(z, z_{1:C}, \vec{x}_i)_k$ to denote the feature (or sufficient statistic) corresponding to the parameter θ_k . By plugging these partial derivatives back into Eq. 37, we have

$$\begin{aligned} \frac{\partial}{\partial \theta_k} \frac{Z'_{i,t}(z)}{Z_{i,t}} &= \frac{Z'_{i,t}(z)}{Z_{i,t}} (\mathbb{E}_\Theta [T(z, z_{1:C}, \vec{x}_i)_k | z, \mathcal{H}(i, t)] - \mathbb{E}_\Theta [T(z, z_{1:C}, \vec{x}_i)_k | \mathcal{H}(i, t)]) \\ &= p(z | \mathcal{H}(i, t)) (\mathbb{E}_\Theta [T(z, z_{1:C}, \vec{x}_i)_k | z, \mathcal{H}(i, t)] - \mathbb{E}_\Theta [T(z, z_{1:C}, \vec{x}_i)_k | \mathcal{H}(i, t)]). \end{aligned} \quad (42) \quad (43)$$

In words, we see that the partial derivative with respect to a parameter θ_k is the expected value of its corresponding feature given that we have observed the target marker latent variable z and clinical history $\mathcal{H}(i, t)$ minus the expected value of the feature given only the

clinical history $\mathcal{H}(i, t)$. The difference is then weighted by the probability of observing the target marker latent variable given the clinical history. By plugging this expression back into Eq. 36, we arrive at the final expression for the partial derivative of a single summand with respect to θ_k :

$$\begin{aligned} \frac{\partial \log p(\vec{y}_{k,>t} | \mathcal{H}(i, t))}{\partial \theta_k} &= \sum_z \frac{p(\vec{y}_{k,>t} | z) p(z | \mathcal{H}(i, t))}{p(\vec{y}_{k,>t} | \mathcal{H}(i, t))} (\mathbb{E}_\Theta [T(z, z_{1:C}, \vec{x}_i)_k | z, \mathcal{H}(i, t)] - \mathbb{E}_\Theta [T(z, z_{1:C}, \vec{x}_i)_k | \mathcal{H}(i, t)]) \\ &= \sum_z p(z | \vec{y}_{k,>t}, \mathcal{H}(i, t)) (\mathbb{E}_\Theta [T(z, z_{1:C}, \vec{x}_i)_k | z, \mathcal{H}(i, t)] - \mathbb{E}_\Theta [T(z, z_{1:C}, \vec{x}_i)_k | \mathcal{H}(i, t)]). \end{aligned} \quad (44) \quad (45)$$

The partial derivative has a nice interpretation. Each summand has similar structure to the partial derivative of $p(z | \mathcal{H}(i, t))$ (Eq. 42), but the weight conditioned on only the clinical history has been replaced with a weight conditioned on both the clinical history *and* the future target marker trajectory. The partial derivatives of the summands of the objective in Eq. 33 are added together to obtain the partial derivative with respect to the objective. These partial derivatives are combined to form a gradient, which is easily plugged into existing first-order optimization routines. Optionally, the objective can be augmented with a regularizer to restrict the complexity of the model or to encourage a sparse solution to the learning problem. This concludes our discussion of the learning algorithm.

Appendix B. Missing Data for Continuous-Time Trajectories

Trajectories in continuous-time can be thought of as random *functions* $F(\cdot)$ (Gaussian processes are an example of a family of distributions over random functions). Although the function specifies infinitely many values, to learn continuous-time models we maximize the probability of a finite set of observations (or a penalized version of this objective). In *observational* health care data, we need to be careful that we do not bias our likelihood-based learners by unduly ignoring the dependence between the finite set of times at which we observe the trajectory and the trajectory's values at those times. For example, if the trajectory is more likely to be sampled when its value is low, then our model will learn that trajectories with high values are less likely than they actually are.

The aim of this section is to posit a set of assumptions about continuous trajectory observation times that are (1) substantively reasonable, and (2) justify the use of standard likelihood-based learning. At a high-level, we assume that trajectory observation times are functions of the previous observation times and the values of the trajectory sampled at those times. These assumptions are more formally encoded in the graphical model shown in Figure 8, which expresses dependencies for an individual with three trajectory observations. In the figure, $F(\cdot)$ denotes the full trajectory, $\{T_1, T_2, T_3\}$ are random variables denoting the times at which the trajectory is sampled, and $\{Y_1^*, Y_2^*, Y_3^*\}$ are the observed data. The conditional probability distribution of any Y_t^* given the trajectory and associated observation time is simply:

$$p(Y_t^* = y_t^* | T_t = t_i, F = f) = \mathbb{I}(f(t_i) = y_t^*). \quad (46)$$

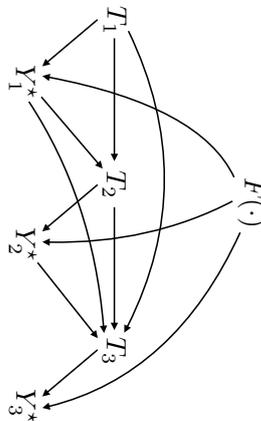

Figure 8: Example missing data mechanism in continuous-time.

These assumptions are reasonable in many healthcare settings. For example, in an ICU where a patient is constantly under supervision, we can reasonably assume that clinical marker measurements are made at times that depend on the previous observations (e.g. the individual is thought to be at risk and so measurements are taken more frequently) and on previous observation times (e.g. a measurement has not been recorded in a while, so we should collect a new one). In the outpatient setting, an individual with a particular disease that is being actively managed by a physician will have follow-up visits scheduled either routinely or more frequently if the physician is especially concerned. On the other hand, modeling the progression of a disease such as the flu using information from a general practitioner’s office may not satisfy our assumption because individual’s with less severe manifestations are less likely to visit.

Conditioned on these assumptions about the dependencies between the trajectory, observation times, and observed values, we want to justify likelihood-based learning. Suppose we have a trajectory model with parameters Θ that allows us to compute the probability of any finite set of trajectory values. For example, we can compute $p_{\Theta}(F(t_1) = y_1^*, F(t_2) = y_2^*, F(t_3) = y_3^*)$. The observed data, however, are the observation times and sampled values: $\{T_{1:n}, Y_{1:n}^*\}$. Proper likelihood-based learning requires that we maximize:

$$p(T_{1:n} = t_{1:n}, Y_{1:n}^* = y_{1:n}^*). \quad (47)$$

However, this expression is determined by both the observation time mechanism and the trajectory model. Our goal is to show that this can be factored into two terms: one that depends on the observed data and the observation time mechanism parameters, and the other that depends on the sampled trajectory values and the trajectory model parameters Θ . To do this, we first see that Equation 47 can be written as

$$\int p(F = f)p(T_{1:n} = t_{1:n}, Y_{1:n}^* = y_{1:n}^* | F = f)dF. \quad (48)$$

The integrand in Equation 48 can be now be factored further to obtain

$$p(F = f) \prod_{i=1}^n p(T_i = t_i | \mathcal{H}_i)p(Y_i^* = y_i^* | T_i = t_i, F = f), \quad (49)$$

where \mathcal{H}_i is defined to be the previous $i - 1$ observation times and sampled trajectory values. Note that the first term in the product of Equation 49 can be pulled out of the integral, allowing us to write Equation 48 as

$$\left[\prod_{i=1}^n p(T_i = t_i | \mathcal{H}_i) \right] \left[\int p(F = f) \prod_{i=1}^n p(Y_i^* = y_i^* | T_i = t_i, F = f)dF \right]. \quad (50)$$

The left-hand factor above depends only on the observation time mechanism and the observed data. Moreover, the right-hand factor depends only on the trajectory model and the sampled trajectory values, which we now show:

$$\begin{aligned} \int p(F = f) \prod_{i=1}^n p(Y_i^* = y_i^* | T_i = t_i, F = f)dF \\ &= \int p(F = f) \prod_{i=1}^n \mathbb{I}(f(t_i) = y_i^*)dF \\ &= \int p(F = f) \mathbb{I}(f(t_1) = y_1^*, \dots, f(t_n) = y_n^*)dF \\ &= p_{\Theta}(f(t_1) = y_1^*, \dots, f(t_n) = y_n^*). \end{aligned} \quad (51)$$

We therefore see that, given our observation time mechanism assumptions, maximizing the likelihood of the sampled trajectory values under our trajectory model is equivalent to maximizing the “proper” likelihood in Equation 47 with respect to the model parameters Θ . This result aligns with Theorems 7.1 and 8.1 found in Rubin’s original paper on missing data (Rubin, 1976).

Abstract

Predicting breast cancer risk has long been a goal of medical research in the pursuit of precision medicine. The goal of this study is to develop novel penalized methods to improve breast cancer risk prediction by leveraging structure information in electronic health

records. We conducted a retrospective case-control study, garnering 49 mammography descriptors and 77 high-frequency/low-penetrance single-nucleotide polymorphisms (SNPs) from an existing personalized medicine data repository. Structured mammography reports and breast imaging features have long been part of a standard electronic health record (EHR), and genetic markers likely will be in the near future. Lasso and its variants are widely used approaches to integrated learning and feature selection, and our methodological contribution is to incorporate the dependence structure among the features into these approaches. More specifically, we propose a new methodology by combining group penalty and l^p ($1 \leq p \leq 2$) fusion penalty to improve breast cancer risk prediction, taking into account structure information in mammography descriptors and SNPs. We demonstrate that our method provides benefits that are both statistically significant and potentially significant to people's lives.

Keywords: structure information, breast cancer risk prediction, mammography descriptors, genetic variants, personalized medicine

1. Introduction

Breast cancer is the most common non-skin malignancy affecting women, with approximately 1.67 million cases diagnosed annually worldwide (Ferlay et al., 2013). If an individual's risk of breast cancer could be predicted, then screening, prevention, and treatment strategies could be targeted toward those women to maximize survival benefit and minimize harm. Risk prediction models are important tools to improve breast cancer care by leveraging multi-dimensional electronic health data. Traditional breast cancer risk prediction models use demographic risk factors to estimate breast cancer risk, but they demonstrate only limited discriminatory power. In clinical practice, mammography is the most common breast cancer screening test, and the only imaging modality supported by randomized trials demonstrating reduction in mortality rate. However, its effectiveness is not universally accepted (Freedman et al., 2004). Recent advances in genome-wide association studies (GWAS) have revitalized the quest for genetic variants (single-nucleotide polymorphisms—SNPs) in risk prediction. However, the optimism of these studies has been tempered by disappointment and caution (Gail, 2008, 2009; Wacholder et al., 2010).

Although many breast cancer risk prediction models have been developed, current applications of these models are inadequate in the following respects: (1) due to the rare occurrence of breast cancer, many seemingly 'large' studies have small effective sample size to adequately model a large number of variables; (2) even for large studies, investigators often fail to systematically model risk factor interactions to avoid overly complicated models which are hard to interpret; and (3) they do not take available structure information into consideration. For example, there are five descriptors for mass margins in mammogram: circumscribed, microlobulated, obscured, indistinct, and spiculated, with an order of increasing probability of malignancy. However, few models utilize this structure information (group structure and dependence structure) to improve predictive performance. The quest for novel breast cancer risk prediction models is motivated to address these shortcomings.

In this paper, we propose to develop novel penalized methods to improve breast cancer risk prediction by incorporating unique structure information embedded in electronic health record data. Regularization is a common technique used in regression and classification problems. The lasso (Tibshirani, 1996) is one of the most popular penalized method and

Table 2: The 77 SNPs identified to be associated with breast cancer

2.1.3 GENETIC VARIANTS

We decided to focus on high-frequency/low-penetrance SNPs that affect breast cancer risk as opposed to low frequency SNPs with high penetrance or intermediate penetrance. We consolidated a list of 77 common genetic variants (Table 2) which were identified by recent large-scale GWAS studies or used to generate published predictive models (Liu et al., 2014). The list included 41 SNPs identified by COGS through a meta-analysis of 9 GWAS studies (Michailidou et al., 2013). Recently, a similar set of 77 breast cancer-associated SNPs is also studied for risk prediction (Mavaddat et al., 2015).

2.2 Logistic Regression

Assume that we have independent and identical distributed subjects $\{(x_i, y_i)\}_{i=1}^n$, where the explanatory variable $X \in \mathcal{R}^d$ and the binary response variable $Y \in \{-1, 1\}$. Note that the conditional probability $\eta(x) = \mathbb{P}(Y = 1|X = x)$ plays an important role in the classification problem. Denote $x_i = (x_{i1}, \dots, x_{id})^T$, and linear logistic regression model is defined by

$$\log \frac{\eta(x_i)}{1 - \eta(x_i)} = x_i^T \beta, \quad i = 1, \dots, n,$$

where $\beta = (\beta_1, \dots, \beta_d)^T$ is the slope parameter. And the logistic regression estimator $\hat{\beta}$ is given by the minimizer of the negative log-likelihood function

$$L(\beta) = \frac{1}{n} \sum_{i=1}^n \log(1 + \exp(-y_i \cdot x_i^T \beta)). \quad (1)$$

With $\hat{\beta}$, we then estimate the conditional probability $\eta(x_i)$ by

$$\hat{\eta}(x_i) = \frac{\exp(x_i^T \hat{\beta})}{1 + \exp(x_i^T \hat{\beta})} = \frac{1}{1 + \exp(-x_i^T \hat{\beta})}.$$

Then we should predict $y_i = 1$ if $\hat{\eta}(x_i) \geq 0.5$ and $y_i = -1$ if $\hat{\eta}(x_i) < 0.5$.

2.3 Group Penalty and ℓ^p Fusion Penalty

Note that there exist natural group structure and dependence structure in mammography features (Figure 1), which allows us to include the structure information into our risk prediction models directly. For genetic variants, group structures also exist (Liu et al., 2012, 2013). In this paper, we apply hierarchical clustering to cluster the 77 SNPs based on their dissimilarity matrix obtained by computing Spearman's correlation or Hamming distance among them. More details are provided in Section 2.5.

Suppose that d features are divided into G groups with d_g the number of features in group g . Define $\beta_g \in \mathbb{R}^{d_g}$ to be the corresponding coefficient vector in group g . The group lasso logistic regression (Meier et al., 2008) is defined as the following optimization problem

$$\min_{\beta \in \mathbb{R}^d} \left\{ L(\beta) + \lambda_1 \sum_{g=1}^G \sqrt{d_g} \|\beta_g\|_2 \right\},$$

where $L(\beta)$ is defined by (1) and $\lambda_1 \geq 0$ is the tuning parameter. It includes lasso as a special case with $G = d$.

The fact that there exist dependence structure within each mammography feature group and each SNP group encourages us to propose the following novel method by combining group lasso logistic regression and ℓ^{p_1} fusion penalty.

$$\min_{\beta \in \mathbb{R}^d} \left\{ L(\beta) + \sum_{g=1}^G \left(\lambda_1 \sqrt{d_g} \|\beta_g\|_2 + \lambda_2 \|D_g \beta_g\|_{p_2} \right) \right\}, \quad (2)$$

where D_g is a $(d_g - 1) \times d_g$ sparse matrix with only $D[i, j] = 1$ and $D[i, i+1] = -1$, $\lambda_2 \geq 0$ is the tuning parameter, and $1 \leq p \leq 2$ is the shrinkage parameter.

Moreover, if the within-group dependence structures are different for groups $\{1, \dots, G_1\}$ and $\{G_1 + 1, \dots, G\}$, we can split the ℓ^{p_1} fusion penalty into two parts as

$$\min_{\beta \in \mathbb{R}^d} \left\{ L(\beta) + \lambda_1 \sum_{g=1}^G \sqrt{d_g} \|\beta_g\|_2 + \lambda_2 \left(\sum_{g=1}^{G_1} \|D_g \beta_g\|_{p_1} + \sum_{g=G_1+1}^G \|D_g \beta_g\|_{p_2} \right) \right\}, \quad (3)$$

where $1 \leq p_1, p_2 \leq 2$ are selected based on cross validation.

The novelty of our method compared to previous works is three-fold: First, it includes within-group fusion penalty in the model and makes the coefficients of features in the same group close to each other, which reflects the dependence structure of features and improves the risk prediction; Second, in breast cancer risk prediction, we find that the dependence structures are different for mammography features and SNPs, which are actually two different views of the same data. And the utilization of method (3) will improve the predictive performance further; At last, we find that genetic variants improve risk prediction on mammography features, which provides some insight regarding personalized breast cancer diagnosis.

2.4 Computational Algorithms

Many algorithms have been proposed in the literatures to solve the logistic regression with fused lasso regularization (Lin, 2015; Yu et al., 2015). In this subsection we adopt the fast iterative shrinkage thresholding algorithm (Beck and Teboulle, 2009) to solve (2) as

$$\beta^{k+1} = \arg \min_{\beta \in \mathbb{R}^d} L(\beta^k) + \langle \beta - \beta^k, \nabla L(\beta^k) \rangle + \frac{\tau}{2} \|\beta - \beta^k\|_2^2 + \sum_{g=1}^G \left(\lambda_1 \sqrt{d_g} \|\beta_g\|_2 + \lambda_2 \|D_g \beta_g\|_{p_2} \right)$$

with $\beta = (\beta_1, \dots, \beta_d)^T$ and $\tau > 0$ the Lipschitz constant of $L(\cdot)$.

And the iteration step is equivalent to solving

$$\min_{\beta \in \mathbb{R}^d} \left\{ \frac{1}{2} \|\beta - (\beta^k - \frac{1}{\tau} \nabla L(\beta^k))\|_2^2 + \sum_{g=1}^G \left(\frac{\lambda_1 \sqrt{d_g}}{\tau} \|\beta_g\|_2 + \frac{\lambda_2}{\tau} \|D_g \beta_g\|_{p_2} \right) \right\}. \quad (4)$$

Therefore, it suffices to solve the following optimization problem within each group

$$\min_{\beta_g \in \mathbb{R}^{d_g}} \left\{ \frac{1}{2} \|\beta_g - z\|_2^2 + \rho_1 \|\beta_g\|_2 + \rho_2 \|D_g \beta_g\|_{p_2} \right\}, \quad (5)$$

where $z = \beta_g^k - \frac{1}{\tau} \nabla L(\beta_g^k)$, $\rho_1 = \frac{\lambda_1 \sqrt{d_g}}{\tau}$ and $\rho_2 = \frac{\lambda_2}{\tau}$.

The proximity operator (Polson et al., 2015) of a function f is defined as

$$P_f(z) = \arg \min_t \left\{ \frac{1}{2} \|t - z\|^2 + \lambda f(t) \right\}.$$

- For $f(t) = |t|$ and $z \in \mathbb{R}$, $P_f(z) := S_1(z, \lambda) = \text{sign}(z) \max\{|z| - \lambda, 0\}$, which is also called soft threshold operator.
- For $f(t) = |t|^p$ with $1 < p \leq 2$ and $z \in \mathbb{R}$, $P_f(z) := S_p(z, \lambda) = \text{sign}(z) \xi$, where ξ is the unique nonnegative solution to $\xi + p \lambda \xi^{p-1} = |z|$. In particular, we have $S_2(z, \lambda) = \frac{z + \sqrt{z^2 + 8\lambda^2}}{2\sqrt{2}}$, $S_{3/2}(z, \lambda) = z + 9\lambda^2 \text{sign}(z) (1 - \sqrt{1 + 16|z|/(9\lambda^2)})/8$ and $S_{4/3}(z, \lambda) = z + \frac{4\lambda}{3\sqrt{3}} ((\chi - z)^{1/3} - (\chi + z)^{1/3})$ with $\chi = \sqrt{z^2 + 256\lambda^3/729}$.
- For $f(t) = \|t\|_2$ and $z \in \mathbb{R}^d$, $P_f(z) := S_{2,1}(z, \lambda) = \max\{1 - \frac{\lambda}{\|z\|_2}, 0\} * z$.

With the help of these proximity operators and Bregman splitting algorithm (Ye and Xie, 2011), we can solve (5) by iteratively solving the following procedures:

$$\begin{cases} \beta_g^{k+1} = \arg \min_{\beta_g} \frac{1}{2} \|\beta_g - z\|_2^2 + \langle u^k, \beta_g - a^k \rangle + \langle v^k, D_g \beta_g - b^k \rangle \\ \quad + \frac{\mu}{2} \|\beta_g - a^k\|_2^2 + \frac{\mu}{2} \|D_g \beta_g - b^k\|_2^2 \\ a^{k+1} = \arg \min_{a} \rho_1 \|a\|_2 + \langle u^k, \beta^{k+1} - a \rangle + \frac{\mu}{2} \|\beta^{k+1} - a\|_2^2 \\ b^{k+1} = \arg \min_b \rho_2 \|b\|_{p_2} + \langle v^k, D_g \beta^{k+1} - b \rangle + \frac{\mu}{2} \|D_g \beta^{k+1} - b\|_2^2 \\ u^{k+1} = u^k + \mu (\beta^{k+1} - a^{k+1}) \\ v^{k+1} = v^k + \mu (D_g \beta^{k+1} - b^{k+1}) \end{cases}$$

where μ acts like a step size in this algorithm.

Remark 1 The minimization over β , a and b can all be solved in closed form.

- $\beta^{k+1} = [(\mu + 1)I + \mu D_g^T D_g]^{-1} [z + \mu(a^k - u^k/\mu) + \mu D_g^T (b^k - v^k/\mu)]$
- $a^{k+1} = S_{2,1}(\beta^{k+1} + u^k/\mu, \rho_1/\mu)$
- $b^{k+1} = S_{p_2}(\beta^{k+1} + v^k/\mu, \rho_2/\mu)$

Note that $(\mu + 1)I + \mu D_g^T D_g$ is a triagonal positive definite matrix.

Remark 2 For $p = 1$, we can solve (5) more efficiently by the algorithm proposed in Zhou et al. (2012) based on the fact

$$P_{\|\cdot\|_2 + \|D_g(\cdot)\|_1} = P_{\|\cdot\|_2} \circ P_{\|D_g(\cdot)\|_1}.$$

However, we cannot show this equation for $1 < p \leq 2$.

Remark 3 For $p = 2$, since $\|\cdot\|_2^2$ is Lipschitz continuous, we can rewrite (4) as

$$\min_{\beta \in \mathbb{R}^d} \left\{ \frac{1}{2} \left\| \beta - \left(\beta^k - \frac{1}{\bar{\tau}} (\nabla L(\beta^k) + 2\lambda_2 \sum_{g=1}^G D_g^T D_g \beta^k) \right) \right\|_2^2 + \sum_{g=1}^G \frac{\lambda_1 \sqrt{d_g}}{\bar{\tau}} \|\beta_g\|_2 \right\},$$

where $\bar{\tau}$ is the Lipschitz constant of $L(\beta) + \lambda_2 \sum_{g=1}^G \|D_g \beta_g\|_2^2$. Then we can solve it efficiently via the proximity operator of $\|\cdot\|_2$.

2.5 Study Design and Statistical Analysis

We apply the ℓ^p fused group lasso logistic regression algorithm to the Marshfield breast cancer data set. There are 11 groups for 49 mammography features (Figure 1). For SNPs, we compute the Hamming distances (Wang et al., 2015) of 77 SNPs to get the dissimilarity matrix and then apply hierarchical clustering to obtain 10 groups.

We built three prediction models based on different sets of risk factors: the Mammo model developed by using mammography features only, the SNP77 model developed by using 77 SNPs only, and the Combined model developed by using both mammography features and 77 SNPs. We furthermore apply five methods for each model: logistic regression (LR), lasso in logistic regression (LR+Lasso), ℓ^p fused lasso logistic regression (LR+fusedLasso), group lasso logistic regression (LR+groupLasso), and ℓ^p fused group lasso logistic regression (LR+Structure).

The ℓ^p fused group lasso logistic regression method has several parameters. For the tuning parameters λ_1 and λ_2 , we let them vary among a given set of values, and the shrinkage parameter p (or p_1 and p_2) among $\{1, 4/3, 3/2, 2\}$. Each combination of these parameters is evaluated using stratified 5-fold cross-validation, and AUC (the area under the receiver operating characteristic (ROC) curve) is used as the performance measure. All 738 samples are randomly partitioned into five equal sized folds with approximately equal proportions of cases and controls. In each iteration (totally five iterations), four folds are used as training set and the rest one as validation set to compute AUC. And the parameters with the best average AUC are selected. At last we repeat this process ten times and report the average AUC. We obtain p-value by performing two-tailed two-sample t-test when we compare AUCs.

3. Experimental Results

In this section, we demonstrate the performance of the ℓ^p fused group lasso logistic regression method from three aspects: the significant improvement of AUCs by considering the structure information, the predictive performance under different p (or p_1 and p_2), and the detected important mammography features and SNPs.

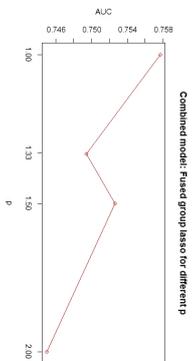

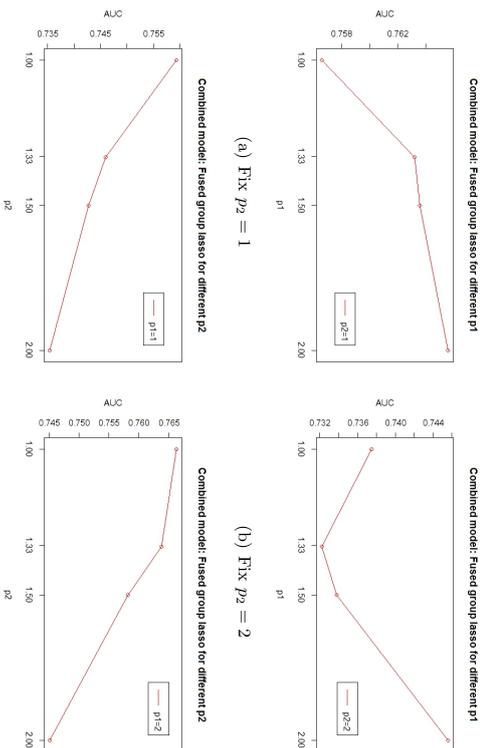

3.1 Performance of Fused Group Lasso

The result is summarized in Table 3.

Models/Methods	LR	Lasso	fusedLasso	groupLasso	Structure	p-value
Mammo	0.700	0.710	0.710	0.716	0.723	< 0.001
SNP77	0.590	0.598	0.676	0.614	0.684	< 0.001
Combined	0.697	0.721	0.754	0.727	0.766	< 0.001

Table 3: Predictive performance of three prediction models by using five different methods. The p-values represent the differences between AUCs of LR and LR+Structure.

- 1) The fifth column describes the predictive performance of the three prediction models by considering structure information in the logistic regression method. We find that the predictive performance of the three prediction models has been improved respectively, compared to those described in the first column. For each prediction model, the difference of the predictive performance is significant between LR+Structure and LR (p-value < 0.001), which demonstrates that breast cancer prediction models utilizing structure information can improve risk prediction significantly. We also find that mammography descriptors demonstrate a significantly higher predictive performance than 77 SNPs in terms of AUC (0.723 vs. 0.684, p-value < 0.001). The Combined model demonstrates significant improvement of the prediction performance, compared to the Mammo model (0.766 vs. 0.723, p-value < 0.001).
- 2) The first column describes the predictive performance of the three prediction models by using the logistic regression method. Mammography descriptors demonstrate a significantly higher predictive performance than 77 SNPs in terms of AUC (0.700 vs. 0.590, p-value < 0.001). We find that the difference of predictive performance between the Combined model and the Mammo model is negligible (0.697 vs. 0.700, p-value=0.277).
- 3) The second column describes the predictive performance of the three prediction models by using lasso in the logistic regression method. The predictive performance of the three prediction models has been improved, compared to those without lasso (using logistic regression method only). Mammography descriptors still demonstrate a significantly higher predictive performance than 77 SNPs in terms of AUC (0.710 vs. 0.598, p-value < 0.001). However, the Combined model demonstrates modest improvement of prediction performance, compared to the Mammo model (0.721 vs. 0.710, p-value=0.0057).
- 4) The third and fourth columns describe the predictive performance of the three prediction models by considering group structure or dependence structure in the logistic regression method. For the SNP77 model, fused lasso demonstrates a significantly higher performance than group lasso in terms of AUC (0.676 vs. 0.614, p-value < 0.001). For the Mammo model, group lasso plays a more important role than fused lasso (0.716 vs. 0.710, p-value=0.0073). Moreover, both fused lasso and group lasso demonstrate improved prediction performance compared to lasso.

Figure 2: The AUCs under different values of p by using method (2).Figure 3: The AUCs under different values of p_1 and p_2 by using method (3).

3.2 Performance under Different Values of p

Figure 2 and Figure 3 describe the the pattern of predictive performance for p' fused group lasso logistic regression over the shrinkage parameter p (or p_1 and p_2) in terms of AUC.

- 1) The Combined model demonstrates a higher predictive performance for $p = 1$ compared to $p = 2$ in terms of AUC (0.757 vs. 0.745, p -value < 0.001), see Figure 2.
- 2) Figure 3 describes the prediction performance of method (3) under different values of p_1 for mammography descriptors and p_2 for 77 SNPs.

FAN, WU, YUAN, PAGE, LIU, ONG, PEISSIG, AND BURNSIDE

- Fix $p_2 = 1$ or $p_2 = 2$, the fused group lasso with $p_1 = 2$ demonstrates higher predictive performance compared to $p_1 = 1$, see Figure 3(a) and 3(b).
- Fix $p_1 = 1$ or $p_1 = 2$, the predictive performance of the fused group lasso logistic regression decreases as p_2 increases, see Figure 3(c) and 3(d).
- The fused group lasso logistic regression with $p_1 = 2$ and $p_2 = 1$ demonstrates higher predictive performance than $p_1 = p_2 = 1$ (0.766 vs. 0.757, p -value=0.0053) and $p_1 = p_2 = 2$ (0.766 vs. 0.745, p -value < 0.001).

3.3 Important Features Detected by Fused Group Lasso

To take into account both group and dependence structure information in mammography features and SNPs, two penalty terms (group penalty and fusion penalty) are introduced into the logistic regression model. The idea of group penalty is to force the coefficients of features in the same group to be all zero or nonzero in order to achieve the goal of selecting features within a group simultaneously. The idea of fusion penalty is to shrink the successive difference of coefficients of features in the same group in order to take advantage of the dependence structure information. Applying fusion penalty with $p = 1$ tends to result in zero successive difference of coefficients, while $p = 2$ tends to small but nonzero successive difference of coefficients.

From a feature selection point of view, we can get the order of feature groups selected by fused group lasso via choosing the tuning parameters appropriately. We list below the feature groups selected from high to low in terms of predictive performance.

- 1) For mammography descriptors, the following features are predictive of malignancy (from most to least): ‘‘Mass Size’’, ‘‘Mass Margins’’, ‘‘Mass Shape’’, ‘‘Architectural Distortion’’ and ‘‘Mass Palpability’’, consistent with the literature (BI-RADS, 2014).
- 2) For 77 SNPs, three groups are selected in order, see Table 4.

Feature Group	SNPs
Group 1	rs2016394, rs1432679, rs13281615, rs4666451 rs981782, rs1292011, rs1436904, rs527616
Group 2	rs11249433, rs13387042, rs4973768, rs10069690 rs7904519, rs8051542, rs3760982
Group 3	rs2981579, rs2981582

Table 4: SNP groups selected by fused group lasso.

Remark 4 It verifies that ‘‘Mass size’’, ‘‘Mass Margins’’ and ‘‘Mass Shape’’ are the most important mammography descriptors in breast cancer diagnosis. These results are consistent with previous studies about comparing the importance of mammography features and SNPs in breast cancer risk prediction (Wu et al., 2013, 2014).

4. Discussion and Conclusions

This study demonstrates that models utilizing the novel combination of clinically relevant structure and ℓ^p fused group lasso logistic regression can improve breast cancer risk prediction significantly. Our study also shows that both mammography features and SNPs contribute to this improvement.

The structure information of the mammography features is derived from the BI-RADS lexicon, which is used widely in breast imaging practice. Thus, our model would likely be generalizable to other practices. On the other hand, we extracted the structure information of SNPs by computing Hamming distances (Wang et al., 2015). This method may not perform as well in small sample sizes, which may affect our results perhaps making our predictive performance results conservative.

Our methods for SNPs may not take advantage of biological knowledge that currently exists. For example, it may be possible to utilize the biological information available in HapMap (which encodes linkage disequilibrium) to more accurately emulate the patterns or dependence structure of SNPs, as in (Liu et al., 2012). Furthermore, we realize that taking into account more complicated structure information such as graph or tree structure (Sun and Wang, 2012) may further improve predictive performance of risk prediction models. We leave these promising directions for future work.

In conclusion, our results demonstrate that including structure information in the computational methods we test improves breast cancer risk prediction. Our models use diverse breast cancer risk factors including demographics, genetics, and imaging and leverage structure found in a standardized lexicon that is universally captured in electronic health records (EHRs) throughout the US. This information will increasingly be combined in complex ways. Merging imaging features, clinical notes and genetic data with models that accurately predict disease risk has the potential to provide powerful knowledge to practicing physicians.

Abstract

Comparing with the standard L_2 -norm support vector machine (SVM), the L_1 -norm SVM enjoys the nice property of simultaneously performing classification and feature selection. In this paper, we investigate the statistical performance of L_1 -norm SVM in ultra-high dimension, where the number of features p grows at an exponential rate of the sample size n . Different from existing theory for SVM which has been mainly focused on the generalization error rates and empirical risk, we study the asymptotic behavior of the coefficients of L_1 -norm SVM. Our analysis reveals that the estimated L_1 -norm SVM coefficients achieve near oracle rate, that is, with high probability, the L_2 error bound of the estimated L_1 -norm SVM coefficients is of order $O_p(\sqrt{q \log p/n})$, where q is the number of features with nonzero coefficients. Furthermore, we show that if the L_1 -norm SVM is used as an initial value for a recently proposed algorithm for solving non-convex penalized SVM (Zhang et al., 2016b), then in two iterative steps it is guaranteed to produce an estimator that possesses the oracle property in ultra-high dimension, which in particular implies that with probability approaching one the zero coefficients are estimated as exactly zero. Simulation studies demonstrate the fine performance of L_1 -norm SVM as a sparse classifier and its effectiveness to be utilized to solve non-convex penalized SVM problems in high dimension.

Keywords: feature selection, L_1 -norm SVM; non-convex penalty, oracle property, error bound, support vector machine, ultra-high dimension

1. Introduction

Support vector machine (SVM), originally introduced by Boser et al. (1992) and Vapnik (1995) and subsequently investigated by many others, is a popular and highly powerful technique for classification and has a solid mathematical foundation in statistical learning. In modern applications, we often face the challenge of classification at the presence of a very large number of redundant features. For example, in genomics it is of fundamental importance to build a classifier using a small number of genes from thousands of candidate genes for the purpose of disease diagnosis and drug discovery; in spam email classification,

it is desirable to build an accurate classifier using a relatively small number of words from a dictionary that contains a huge number of different words. For such applications, the standard L_2 -norm SVM suffers from some potential drawbacks. First, L_2 -norm SVM does not automatically build in dimension reduction and hence usually does not yield an interpretable sparse decision rule. Second, the generalization performance of L_2 -norm SVM can deteriorate by including many redundant features (e.g., Zhu et al., 2004).

The standard L_2 -norm SVM has the well known *hinge loss*+ L_2 *norm penalty* formulation. An effective way to perform simultaneous variable selection and classification using SVM is to replace the L_2 -norm penalty with the L_1 -norm penalty, which results in the L_1 -norm SVM. See the earlier work of Bradley and Mangasarian (1998) and Song et al. (2002). Important advancement on the methodology and theory of L_1 -norm SVM has been obtained in recent years, for example, Zhu et al. (2004) proposed a path-following algorithm and effectively demonstrated the advantages of L_1 -norm SVM in high-dimensional sparse scenario; Tarigan and van de Geer (2004) investigated the adaptivity of SVMs with L_1 penalty and derived its adaptive rates; Tarigan, Van De Geer, et al. (2006) obtained an oracle inequality involving both model complexity and margin for L_1 -norm SVM; Wang and Shen (2007) extended L_1 -norm SVM to multi-class classification problems; Zou (2007) proposed to use adaptive L_1 penalty with the SVM; and Wegkamp and Yuan (2011) considered L_1 -norm SVM with a built-in reject option.

The existing theory in the literature on SVM has been largely focused on the analysis of generalization error rate and empirical risk, see Greenshtein et al. (2006), Wang and Shen (2007), Van de Geer (2008), among others. These results neither contain nor directly imply the transparent error bound of the estimated coefficients of L_1 -norm SVM studied in this paper. Our work makes a significant departure from most of the existing literature and is motivated by the recent growing interest of understanding the statistical properties of the estimated SVM coefficients (also referred to as the weight vector). For a linear binary SVM, the decision function is a hyperplane that separates two classes. The coefficients of SVM describe this hyperplane which directly predicts which class a new observation point belongs to. Moreover, the magnitudes of the SVM coefficients provide critical information on the importance of the features and can be used for feature ranking (Chang and Lin, 2008; Guyon et al., 2002). Koo et al. (2008) derived a novel Bahadur type representation of the coefficients of the L_2 -norm SVM and established the asymptotic normality of the estimated coefficients when the number of features p is fixed. Park et al. (2012) studied the oracle properties of SCAD-penalized SVM coefficients, also for the fixed p case. The aforementioned worked has only considered small, fixed number of features. More recently, Zhang et al. (2016b) proposed a systemic framework for non-convex penalized SVM regarding variable selection consistency and oracle property in high dimension. Zhang et al. (2016a) investigated a consistent information criterion for tuning parameter selection for support vector machine in the diverging model space. Both of these two papers directly assume an appropriate initial value exists in the high-dimensional setting.

In this paper, we study the asymptotic behavior of the estimated L_1 -norm SVM coefficients and derive that the error bound is of near-oracle rate $O(\sqrt{q \log p/n})$, where q is the number of features with nonzero coefficients, n is the sample size, and the number of candidate features p can be of exponential order of n (i.e., the ultra-high dimensional case). Furthermore, in Section 4 we show that this sharp error bound helps greatly extend the

applicability of the recent algorithm and theory of high-dimensional non-convex-penalized SVM (Zhang et al., 2016b) by providing a statistically valid and computationally convenient initial value. The use of non-convex penalty function aims to further reduce the bias associated with the L_1 penalty and accurately identify the set of relevant features for classification. However, the presence of non-convex penalty results in computational complexity. Zhang et al. (2016b) proposed an algorithm and showed that given an appropriate initial value, in two iterative steps the algorithm is guaranteed to produce an estimator that possesses the oracle property in the ultra-high dimension and consequently with probability approaching one the zero coefficients are estimated as exactly zero. However, the availability of a qualified initial estimator is itself a challenging issue in high dimension. Zhang et al. (2016b) provided an initial estimator that would satisfy the requirement when $p = o(\sqrt{n})$. Our result shows that the L_1 -norm SVM can be a valid initial estimator under general conditions when p grows at an exponential rate of n , which completes the algorithm and theory of Zhang et al. (2016b).

The rest of the paper is organized as follows. In Section 2, we introduce the basics and computation of the L_1 -norm penalized support vector machine. Section 3 derives the near-oracle error bound for the estimated L_1 -norm SVM coefficients in the ultra-high dimension. Section 4 investigates the application of the result in Section 3 for non-convex penalized SVM in the ultra-high dimension. Section 5 demonstrates through Monte Carlo experiments the effectiveness of L_1 -norm SVM coefficients both as a sparse classifier and as an initial value for the non-convex penalized SVM algorithm. Technical proofs and additional notes are given in the appendices.

2. L_1 -norm support vector machine

We consider the classical binary classification problem. Let $\{Y_i, \mathbf{X}_i\}_{i=1}^n$ be a random sample from an unknown distribution $P(\mathbf{X}, Y)$. The response variable (class label) $Y_i \in \{1, -1\}$ has the marginal distribution: $P(Y_i = 1) = \pi_+$ and $P(Y_i = -1) = \pi_-$, where $\pi_+, \pi_- > 0$ and $\pi_+ + \pi_- = 1$. We write $\mathbf{X}_i = (X_{i0}, X_{i1}, \dots, X_{ip})^T = (X_{i0}, (\mathbf{X}_i^-)^T)^T$, where $X_{i0} = 1$ corresponds to the intercept term. Let f and g be the conditional density functions of \mathbf{X}_+ - given $Y_i = 1$ and \mathbf{X}_- given $Y_i = -1$, respectively. Moreover, in this paper we use the following notation for vector norms: for $\mathbf{x} = (x_1, \dots, x_k)^T \in \mathbb{R}^k$ and a positive integer m , we define $\|\mathbf{x}\|_m = \left(\sum_{i=1}^k |x_i|^m\right)^{1/m}$, $\|\mathbf{x}\|_\infty = \max\{|x_1|, \dots, |x_k|\}$ and $\|\mathbf{x}\|_0 = \sum_{i=1}^k I(x_i \neq 0)$.

The standard linear SVM can be expressed as the following regularization problem

$$\min_{\boldsymbol{\beta}} n^{-1} \sum_{i=1}^n (1 - Y_i \mathbf{X}_i^T \boldsymbol{\beta})_+ + \lambda \|\boldsymbol{\beta}_-\|_2^2, \quad (1)$$

where $(1 - u)_+ = \max\{1 - u, 0\}$ is often called the hinge loss function, λ is a tuning parameter and $\boldsymbol{\beta} = (\beta_0, (\boldsymbol{\beta}_-)^T)^T$ with $\boldsymbol{\beta}_- = (\beta_1, \beta_2, \dots, \beta_p)^T$. Generally for a given vector \mathbf{e} , we use \mathbf{e}_- to denote the subvector with the first entry of \mathbf{e} omitted. Actually, optimization problem in (1) is known as the primal problem of the SVM, which can be efficiently solved by quadratic programming algorithms.

The L_1 -norm SVM replaces the L_2 penalty in (1) by the L_1 penalty. That is, we consider the objective function

$$l_n(\boldsymbol{\beta}, \lambda) = n^{-1} \sum_{i=1}^n (1 - Y_i \mathbf{X}_i^T \boldsymbol{\beta})_+ + \lambda \|\boldsymbol{\beta}_-\|_1, \quad (2)$$

and define

$$\widehat{\boldsymbol{\beta}}(\lambda) = \arg \min_{\boldsymbol{\beta}} l_n(\boldsymbol{\beta}, \lambda). \quad (3)$$

For a given data point X_i , it is classified into class + (corresponding to $\widehat{Y}_i = 1$) if $\mathbf{X}_i^T \widehat{\boldsymbol{\beta}}(\lambda) > 0$ and into class - (corresponding to $\widehat{Y}_i = -1$) if $\mathbf{X}_i^T \widehat{\boldsymbol{\beta}}(\lambda) < 0$.

By introducing the slack variables, we can transform our optimization problem (3) as a linear programming problem (Zhu et al., 2004)

$$\begin{aligned} \min_{\xi, \zeta, \boldsymbol{\beta}} & \left(\frac{1}{n} \sum_{i=1}^n \xi_i + \lambda \sum_{j=1}^p \zeta_j \right) \\ \text{subject to} & \xi_i \geq 0, \quad i = 1, 2, \dots, n, \\ & \xi_i \geq 1 - Y_i \mathbf{X}_i^T \boldsymbol{\beta}, \quad i = 1, 2, \dots, n, \\ & \zeta_j \geq \beta_j, \zeta_j \geq -\beta_j, \quad j = 1, 2, \dots, p. \end{aligned} \quad (4)$$

Several R packages are available to solve such a standard linear programming problem, such as `lpSolve` and `linprog`.

3. An error bound of L_1 -norm SVM in ultra-high dimension

In this section, we will describe the near-oracle error bound for the estimated L_1 -norm SVM coefficients under the ultra-high dimensional setting. The choice of the tuning parameter λ will be studied to achieve this error bound.

3.1 Preliminaries

The key result of the paper is an error bound of $\|\widehat{\boldsymbol{\beta}}(\lambda) - \boldsymbol{\beta}^*\|_2$, where $\boldsymbol{\beta}^*$ is the minimizer of the population version of the hinge loss function, that is,

$$\boldsymbol{\beta}^* = \arg \min_{\boldsymbol{\beta}} L(\boldsymbol{\beta}), \quad (5)$$

where $L(\boldsymbol{\beta}) = E(1 - Y \mathbf{X}^T \boldsymbol{\beta})_+$. Lin (2002) suggested that there is a close connection between the minimizer of the population hinge loss function and the Bayes rule. The definition of $\boldsymbol{\beta}^*$ above is also used in Koo et al. (2008) and Park et al. (2012), both of which only considered the fixed p case. We are interested in the error bound of $\|\widehat{\boldsymbol{\beta}}(\lambda) - \boldsymbol{\beta}^*\|_2$ when $p \gg n$. In the ultra-high dimensional settings, it is often reasonable to assume that $\boldsymbol{\beta}^* = (\beta_0^*, \beta_1^*, \dots, \beta_p^*)^T$ is sparse in the sense that most of its components are exactly zero. We define the index set of active features as $T = \{1 \leq j \leq p : \beta_j^* \neq 0\}$. We denote the cardinality of T by $|T| = q$. To incorporate the intercept term, we also define $T_+ = T \cup \{0\}$.

Next, we introduce the gradient vector and Hessian matrix of the population hinge loss function $L(\beta)$. We define

$$S(\beta) = -E(I(1 - Y\mathbf{X}^T\beta \geq 0)Y\mathbf{X}) \quad (6)$$

as the $(p+1)$ -dimensional gradient vector and

$$H(\beta) = E(\delta(1 - Y\mathbf{X}^T\beta)\mathbf{X}\mathbf{X}^T) \quad (7)$$

as the $(p+1) \times (p+1)$ -dimensional Hessian matrix where $I(\cdot)$ is the indicator function and $\delta(\cdot)$ is the Dirac delta function. Section 6.1 in Koo et al. (2008) has explained more details and theoretical properties of $S(\beta)$ and $H(\beta)$ under certain conditions.

Throughout the paper, we assume the following regularity condition.

(A1) The densities f and g are continuous with common support $\mathcal{S} \subset \mathbb{R}^p$ and have finite second moments. In addition, there exists a constant $M > 0$ such that $|X_j| \leq M$, $j \in \{1, \dots, p\}$.

REMARK 1. Condition (A1) ensures that $H(\beta)$ is well defined and continuous in β . The bound of \mathbf{X}_- can be relaxed with further technical complexity. More details can be found in Park et al. (2012) and Koo et al. (2008).

3.2 The choice of the tuning parameter λ and a fact about $\hat{\beta}$

The estimated L_1 -norm SVM parameter $\hat{\beta}(\lambda)$ defined in (3) depends on the tuning parameter λ . We will first show that a universal choice

$$\lambda = c\sqrt{2A(\alpha)\log p/n}, \quad (8)$$

where c is some given constant, α is a small probability and $A(\alpha) > 0$ is a constant such that $4p^{-\frac{A(\alpha)}{M^2}+1} \leq \alpha$, can provide theoretical guarantee on the good performance of $\hat{\beta}(\lambda)$.

The above choice of λ is motivated by a principle in the setting of penalized least squares regression (Bickel et al., 2009), which advocates to choose the penalty level λ to dominate the subgradient of the loss function evaluated at the true value. Intuitively, the subgradient evaluated at β^* summarizes the estimation noise. See also the application of the same principle to choose the penalty level for quantile regression (Belloni and Chernozhukov, 2011; Wang, 2013). Another more technical motivation of this principle comes from the KKT condition in convex optimization theory. Let $\hat{\beta}$ be the oracle estimator (formally defined in Section 4) that minimizes the sample hinge loss function when the index set T is known in advance. Define the subgradient function

$$\hat{S}(\beta) = -n^{-1} \sum_{i=1}^n I(1 - Y_i \mathbf{X}_i^T \beta \geq 0) Y_i \mathbf{X}_i.$$

Then it follows from the argument as in Theorem 3.1 of Zhang et al. (2016b) that under some weak regularity conditions $\|\hat{S}(\beta)\|_\infty \leq \lambda$ with probability approaching one. It follows from Koo et al. (2008) that the oracle estimator $\hat{\beta}$ provides a consistent and asymptotically normal estimate of β^* .

Hence, in the ideal case where the population parameter β^* is known, an intuitive choice of λ is to set its value to be larger than the supremum norm of $S(\beta^*)$ with large probability, that is

$$P(\lambda \geq c\|\hat{S}(\beta^*)\|_\infty) \geq 1 - \alpha, \quad (9)$$

where $c > 1$ is some given constant and α is a small probability. Lemma 1 below shows that the choice of λ given in (8) satisfies this requirement.

Lemma 1 Assume that condition (A1) is satisfied. Suppose $\lambda = c\sqrt{2A(\alpha)\log p/n}$, we have

$$P(\lambda \geq c\|\hat{S}(\beta^*)\|_\infty) \geq 1 - \alpha$$

with α being a given small probability defined earlier in this section.

The proof of Lemma 1 is given in the Appendix A. The crux of the proof is to bound the tail probability of $\sum_{i=1}^n I(1 - Y_i \mathbf{X}_i^T \beta^* \geq 0) Y_i \mathbf{X}_i$ by applying Hoeffding's inequality and the union bound. Later in this section, we will show that this choice of λ warrants near-oracle rate performance of $\hat{\beta}(\lambda)$. Let $\mathbf{h} = \beta^* - \hat{\beta}(\lambda)$. We state below an interesting fact about \mathbf{h} .

Lemma 2 For $\lambda \geq c\|\hat{S}(\beta^*)\|_\infty$ and $\bar{C} = \frac{c-1}{c+1}$, we have

$$\mathbf{h} \in \Delta_{\bar{C}},$$

where

$$\Delta_{\bar{C}} = \{\gamma \in \mathbf{R}^{p+1} : \|\gamma_{T_+}\|_1 \geq \bar{C}\|\gamma_{T_+^c}\|_1, \text{ where } T_+ = T \cup \{0\}, T \subset \{1, 2, \dots, p\} \text{ and } |T| \leq q\},$$

with T_+^c denoting the complement of T_+ , and γ_{T_+} denoting the $(p+1)$ -dimensional vector that has the same coordinates as γ on T_+ and zero coordinates on T_+^c .

We call $\Delta_{\bar{C}}$ the restricted set. The proof of Lemma 2 is also given in Appendix A.

3.3 Regularity conditions

Let $\mathcal{X} = (\mathbf{X}_1, \mathbf{X}_2, \dots, \mathbf{X}_n)^T$ denote the feature design matrix. We define restricted eigenvalues as follows

$$\lambda_{\max} = \max_{\mathbf{d} \in \mathbb{R}^{p+1}; \|\mathbf{d}\|_0 \leq 2(q+1)} \frac{\mathbf{d}^T \mathcal{X}^T \lambda \mathbf{d}}{\eta \|\mathbf{d}\|_2^2} \quad (10)$$

and

$$\lambda_{\min}(H(\beta^*); q) = \min_{\mathbf{d} \in \Delta_{\bar{C}}} \frac{\mathbf{d}^T H(\beta^*) \mathbf{d}}{\|\mathbf{d}\|_2^2}. \quad (11)$$

These are similar to the sparse eigenvalue notion in Bickel, Ritov, and Tsybakov (2009) and Meinshausen and Yu (2009) for analyzing sparse least squares regression, see also Cai, Wang, and Xu (2010).

In addition to condition (A1) introduced in Section 2, we require the following regularity conditions for the main theory of this paper.

(A2) $q = O(n^{c_1})$ for some $0 \leq c_1 < 1/2$.

(A3) There exists a constant M_1 such that $\lambda_{\max} \leq M_1$ almost surely.

(A4) $\lambda_{\min}(H(\boldsymbol{\beta}^*); q) \geq M_2$, for some constant $M_2 > 0$.

(A5) $n^{(1-\alpha_2)/2} \min_{j \in \mathcal{I}} |\beta_j^*| \geq M_3$ for some constants $M_3 > 0$ and $2c_1 < \alpha_2 \leq 1$.

(A6) Denote the conditional density of $\mathbf{X}^T \boldsymbol{\beta}^*$ given $Y = +1$ and $Y = -1$ as f^* and g^* , respectively. It is assumed that f^* is uniformly bounded away from 0 and ∞ in a neighborhood of 1 and g^* is uniformly bounded away from 0 and ∞ in a neighborhood of -1 .

REMARK 2. Conditions (A2) and (A5) are very common in high dimensional literature. Basically, condition (A2) states that the number of nonzero variables cannot diverge at a rate larger than \sqrt{n} . Condition (A5) controls the decay rate of true parameter $\boldsymbol{\beta}^*$. Condition (A3) is not restrictive, see the relevant discussions in Meinshausen and Yu (2009). Condition (A4) requires the smallest restricted eigenvalue has a lower bound. This would be satisfied if $H(\boldsymbol{\beta}^*)$ is positive definite. We provide a thorough discussion of this condition in Appendix B, including an example that demonstrates the validity of this condition. Condition (A6) warrants that there is sufficient information around the non-differentiable point of the hinge loss, similarly to Condition (C3) in Wang, Wu, and Li (2012) for quantile regression.

3.4 An error bound of $\widehat{\beta}(\lambda)$ in ultra-high dimension

Before stating the main theorem, we first present an important lemma, which has to do with the empirical process behavior of the hinge loss function.

Lemma 3 Assume that conditions (A1)-(A3) are satisfied. For $\mathbf{h} \in \mathbb{R}^{p+1}$, let

$$\begin{aligned} B(\mathbf{h}) &= \frac{1}{n} \left| \sum_{i=1}^n (1 - Y_i \mathbf{X}_i^T \boldsymbol{\beta}^* + Y_i \mathbf{X}_i^T \mathbf{h})_+ - \sum_{i=1}^n (1 - Y_i \mathbf{X}_i^T \boldsymbol{\beta}^*)_+ \right. \\ &\quad \left. - E \left(\sum_{i=1}^n (1 - Y_i \mathbf{X}_i^T \boldsymbol{\beta}^* + Y_i \mathbf{X}_i^T \mathbf{h})_+ - \sum_{i=1}^n (1 - Y_i \mathbf{X}_i^T \boldsymbol{\beta}^*)_+ \right) \right|. \end{aligned}$$

Assume $p > n$, then for all n sufficiently large

$$P \left(\sup_{\|\mathbf{h}\|_0 \leq q+1, \|\mathbf{h}\|_2 \neq 0} \frac{B(\mathbf{h})}{\|\mathbf{h}\|_2} \geq (1 + 2C_1 \sqrt{M_1}) \sqrt{\frac{2q \log p}{n}} \right) \leq 2p^{-2q(C_1^2-1)},$$

where $C_1 > 1$ is a constant.

Lemma 3 guarantees that $n^{-1} (\sum_{i=1}^n (1 - Y_i \mathbf{X}_i^T \boldsymbol{\beta}^* + Y_i \mathbf{X}_i^T \mathbf{h})_+ - \sum_{i=1}^n (1 - Y_i \mathbf{X}_i^T \boldsymbol{\beta}^*)_+)$ is close to its expected value with high probability. This provides an important tool to handle the non-smoothness of the hinge loss function in proving the main theory, which is stated below.

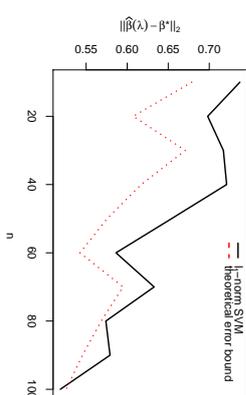

Figure 1: L_2 -norm estimation error comparison

Theorem 4 Suppose that conditions (A1)-(A6) hold, then the estimated L_1 -norm SVM coefficients vector $\widehat{\beta}(\lambda)$ satisfies

$$\|\widehat{\beta}(\lambda) - \boldsymbol{\beta}^*\|_2 \leq \sqrt{1 + \frac{1}{C}} \left(\frac{2\lambda \sqrt{q+1}}{M_2} + \frac{2C}{M_2} \sqrt{\frac{2q \log p}{n}} \left(\frac{5}{4} + \frac{1}{C} \right) \right)$$

with probability at least $1 - 2p^{-2q(C_1^2-1)}$, where C is a constant, C_1 is given in Lemma 3 and \widehat{C} is defined in Lemma 2.

From this theorem, we can easily capture the near-oracle property for l_1 penalized SVM estimator, such that with high probability,

$$\|\widehat{\beta}(\lambda) - \boldsymbol{\beta}^*\|_2 = O_p \left(\sqrt{\frac{q \log p}{n}} \right)$$

when $\lambda = c\sqrt{2A(\alpha) \log p/n}$. Actually, in the inequality of Theorem 4, the first term satisfies $\frac{\lambda \sqrt{q}}{M_2} = \frac{2}{M_2} \sqrt{\frac{2A(\alpha) q \log p}{n}}$ and it is also trivial to have the second term of the same order. Hence the near-oracle property of $\widehat{\beta}(\lambda)$ will hold given λ above.

To numerically evaluate the above error bound of the L_1 -norm SVM, we consider the simulation setting in Model 4 of Section 5.1. We choose $p = 0.1 * n^2$, $q = \lfloor n^{1/3} \rfloor$ and $\boldsymbol{\beta}^* = ((1.1, \dots, 1.1)_q, 0, \dots, 0)^T$, which allows p and q to vary with sample size n . Figure 1 depicts the average of $\|\widehat{\beta}(\lambda) - \boldsymbol{\beta}^*\|_2$ across 200 simulation runs for different values of n for L_1 -norm SVM and compares the curve with the theoretical error bound $(\sqrt{\frac{q \log p}{n}})$. We observe that these two curves display similar decreasing pattern and approach each other as n gets larger.

4. Application to non-convex penalized SVM in ultra-high dimension

In this section, we will step further to discuss the advantage of non-convex penalized SVM in ultra-high dimension. Similarly, the oracle property of non-convex penalized SVM coefficients will be investigated.

4.1 Why non-convex penalty?

Recently, several authors studied non-convex penalized SVM for simultaneous variable selection and classification, see Zhang et al. (2006), Becker et al. (2011), Park et al. (2012) and Zhang et al. (2016b). The idea is to replace the L_2 norm in standard SVM (1) by a non-convex penalty term in the form $\sum_{j=1}^p p_\lambda(|\beta_j|)$, where $p_\lambda(\cdot)$ is a symmetric penalty function with tuning parameter λ . Two commonly used non-convex penalty functions are the SCAD penalty and the MCP penalty. The SCAD penalty (Fan and Li, 2001) is defined by

$$p_\lambda(|\beta|) = \lambda|\beta|I(0 \leq |\beta| < \lambda) + \frac{a\lambda|\beta| - (\beta^2 + \lambda^2)/2}{a-1}I(\lambda \leq |\beta| \leq a\lambda) + \frac{(a+1)\lambda^2}{2}I(|\beta| > a\lambda)$$

for some $a > 2$. The MCP (Zhang, 2010) is defined by

$$p_\lambda(|\beta|) = \lambda(|\beta| - \frac{\beta^2}{2a\lambda})I(0 \leq |\beta| < a\lambda) + \frac{a\lambda^2}{2}I(|\beta| \geq a\lambda)$$

for some $a > 1$.

The motivation of using non-convex penalty function is to further reduce the bias resulted from L_1 penalty and accurately identify the set of relevant features \mathcal{T} . The use of non-convex penalty function was introduced in the setting of penalized least squares regression (Fan and Li, 2001; Zhang, 2010). These authors observed that L_1 penalized least squares regression requires stringent conditions, often not satisfied in real data analysis, to achieve variable selection consistency. The use of non-convex penalty function alleviates the bias caused by L_1 penalty which overpenalizes large coefficients, and leads to the so called *oracle property*. That is, under regularity conditions the resulted non-convex penalized estimator is able to estimate zero coefficients as exactly zero with probability approaching one, and estimate the nonzero coefficients as efficiently as if the set of relevant features is known in advance.

4.2 Oracle property in ultra-high dimension

The oracle property of non-convex penalized SVM coefficients is investigated by Park et al. (2012) for the case of fixed number of features and more recently by Zhang et al. (2016b) for the large p case. The oracle estimator of β^* is defined as

$$\tilde{\beta} = \arg \min_{\beta, \beta_{\mathcal{T}_+} = 0} \tilde{l}_n(\beta), \quad (12)$$

where $\tilde{l}_n(\beta) = n^{-1} \sum_{i=1}^n (1 - Y_i \mathbf{X}_i^T \beta)_+$ is the sample hinge loss function and $\beta_{\mathcal{T}_+}$ denotes the vector containing the components of β with indices in \mathcal{T}_+ and others to be zero.

To solve the non-convex penalized SVM, we choose to use the local linear approximation (LLA) algorithm. The LLA algorithm starts with an initial value $\beta^{(0)}$. At each step t , we update the β to be $\beta^{(t)}$ by solving

$$\min_{\beta} \left\{ n^{-1} \sum_{i=1}^n (1 - Y_i \mathbf{X}_i^T \beta)_+ + \sum_{j=1}^p p_\lambda^{(\epsilon-1)}(|\beta_j|) \right\}, \quad (13)$$

where $p_\lambda^{(\cdot)}$ denotes the derivative of the penalty function $p_\lambda(\cdot)$. Specifically, we have $p_\lambda^{(0)} = p_\lambda^{(0+)} = \lambda$.

Zhang et al. (2016b) showed that if an appropriate initial estimator exists, then under quite general regularity conditions, the LLA algorithm can identify the oracle estimator with probability approaching one in just two iterative steps (see their Theorem 3.4). This result provides a systematic framework for non-convex penalized SVM in high dimension. However it relies on the availability of a qualified initial value $\tilde{\beta}^{(0)} = (\tilde{\beta}_0^{(0)}, \tilde{\beta}_1^{(0)}, \dots, \tilde{\beta}_p^{(0)})^T$ that satisfies

$$P(|\tilde{\beta}_j^{(0)} - \beta_j^*| > \lambda, \text{ for some } 1 \leq j \leq p) \rightarrow 0 \text{ as } n \rightarrow \infty. \quad (14)$$

Yet the availability of such an appropriate initial value is itself a challenging problem in ultra-high dimension. Zhang et al. (2016b) showed that such an initial estimator is guaranteed when $p = o(\sqrt{n})$. The error bound we derived on L_1 -norm SVM ensures that a qualified initial value is indeed available under general conditions in ultra-high dimension and hence greatly extends the applicability of the result of Zhang et al. (2016b). In the following we restate Theorem 3.4 of Zhang et al. (2016b) for the ultra-high dimensional case.

Theorem 5 Assume $\tilde{\beta}(\lambda)$ is the solution to the L_1 -norm SVM with tuning parameter $\lambda = c\sqrt{2A(\alpha)} \log p/n$ defined above. Suppose that conditions (A1)-(A6) hold, then we have $P(|\tilde{\beta}_j(\lambda) - \beta_j^*| > \lambda, \text{ for some } 1 \leq j \leq p) \rightarrow 0$ as $n \rightarrow \infty$. Furthermore, the LLA algorithm initiated by $\tilde{\beta}(\lambda)$ finds the oracle estimator in two iterations with probability tending to 1, i.e., $P(\tilde{\beta}^{(nc)}(\lambda) = \tilde{\beta})$, where $\tilde{\beta}^{(nc)}(\lambda)$ is the solution for non-convex penalized SVM with given λ .

5. Simulation experiments

In this section, we will investigate the finite sample performance of the L_1 -norm SVM. We will also study its application to non-convex penalized SVM in high dimension.

5.1 Monte Carlo results for L_1 -norm SVM

We generate random data from each of the following four models.

- Model 1: $Pr(Y = 1) = Pr(Y = -1) = 0.5$, $\mathbf{X}_- | (Y = 1) \sim MN(\boldsymbol{\mu}, \boldsymbol{\Sigma})$, $\mathbf{X}_- | (Y = -1) \sim MN(-\boldsymbol{\mu}, \boldsymbol{\Sigma})$, $q = 5$, $\boldsymbol{\mu} = (0.1, 0.2, 0.3, 0.4, 0.5, 0, \dots, 0)^T \in \mathbb{R}^p$, $\boldsymbol{\Sigma} = (\sigma_{ij})$ with diagonal entries equal to 1, nonzero entries $\sigma_{ij} = -0.2$ for $1 \leq i \neq j \leq q$ and other entries equal to 0. The Bayes rule is $\text{sign}(1.39X_1 + 1.47X_2 + 1.56X_3 + 1.65X_4 + 1.74X_5)$ with Bayes error 6.3%.

- **Model 2:** $Pr(Y = 1) = Pr(Y = -1) = 0.5$, $\mathbf{X}_-(Y = 1) \sim MN(\boldsymbol{\mu}, \boldsymbol{\Sigma})$, $\mathbf{X}_-(Y = -1) \sim MN(-\boldsymbol{\mu}, \boldsymbol{\Sigma})$, $q = 5$, $\boldsymbol{\mu} = (0.1, 0.2, 0.3, 0.4, 0.5, 0, \dots, 0)^T \in \mathbb{R}^p$, $\boldsymbol{\Sigma} = (\sigma_{ij})$ with $\sigma_{ij} = -0.4^{|i-j|}$ for $1 \leq i, j \leq q$ and other entries equal to 0. The Bayes rule is $\text{sign}(3.09X_1 + 4.45X_2 + 5.06X_3 + 4.77X_4 + 3.58X_5)$ with Bayes error 0.6%.
- **Model 3:** model stays the same as Model 2, but $\boldsymbol{\Sigma} = (\sigma_{ij})$ with nonzero elements $\sigma_{ij} = -0.4^{|i-j|}$ for $1 \leq i, j \leq q$ and $\sigma_{ij} = 0.4^{|i-j|}$ for $q < i, j \leq p$. The Bayes rule is still $\text{sign}(3.09X_1 + 4.45X_2 + 5.06X_3 + 4.77X_4 + 3.58X_5)$ with Bayes error 0.6%.
- **Model 4:** $\mathbf{X}_- \sim MN(\mathbf{0}_p, \boldsymbol{\Sigma})$, $\boldsymbol{\Sigma} = (\sigma_{ij})$ with nonzero elements $\sigma_{ij} = 0.4^{|i-j|}$ for $1 \leq i, j \leq p$, $Pr(Y = 1|\mathbf{X}_-) = \Phi(\mathbf{X}_-^T \boldsymbol{\beta}^*)$, where $\Phi(\cdot)$ is the cumulative density function of the standard normal distribution, $\boldsymbol{\beta}_*^* = (1.1, 1.1, 1.1, 1.1, 0, \dots, 0)^T$ and $q = 4$. The Bayes rule is $\text{sign}(1.1X_1 + 1.1X_2 + 1.1X_3 + 1.1X_4)$ with Bayes error 10.4%.

Model 1 and Model 4 are identical to the ones in Zhang et al. (2016b). In particular, Model 1 focuses on a standard linear discriminate analysis setting. On the other hand, Model 4 is a typical probit regression case. Models 2 and 3 are designed with autoregressive covariance as correlation decaying off-diagonal-wise. We consider sample size $n = 100$ with $p = 1000$ and 1500, and $n = 200$ with $p = 1500$ and 2000. Similarly as in Cai, Liu, and Luo (2011), we use an independent tuning data set of size $2n$ to tune our λ by minimizing the prediction error using five-fold cross validation. The tuning range spans from 2^{-6} to 2 as equally-spaced sequence with 100 elements. For each simulation scenario, we conduct 200 runs. Then we generate an independent test data set of size n to report the estimated test error.

We evaluate the performance of L_1 -norm SVM by its testing misclassification error rate, estimator error and variable selection ability. In particular, we measure the estimation accuracy by two criteria: the L_2 estimation error $\|\hat{\boldsymbol{\beta}}(\lambda) - \boldsymbol{\beta}^*\|_2$ where Appendix B provides details on the calculation of $\boldsymbol{\beta}^*$ and the absolute value of the sample correlation between $\mathbf{X}^T \hat{\boldsymbol{\beta}}(\lambda)$ and $\mathbf{X}^T \boldsymbol{\beta}^*$. The absolute value of the sample correlation (AAC) is also used as accuracy measure in Cook et al. (2007). To summarize, we will report

- **Test error:** the misclassification error rate.
- L_2 **error:** $\|\hat{\boldsymbol{\beta}}(\lambda) - \boldsymbol{\beta}^*\|_2$.
- **AAC:** Absolute absolute correlation $\text{corr}(\mathbf{X}^T \hat{\boldsymbol{\beta}}(\lambda), \mathbf{X}^T \boldsymbol{\beta}^*)$.
- **Signal:** the average of number of nonzero regression coefficients $\hat{\beta}_i \neq 0$ with $i = 1, 2, 3, 4, 5$ for Model 1-3 and with $i = 1, 2, 3, 4$ for Model 4. This measures the ability of L_1 -norm SVM selecting relevant features.
- **Noise:** the average of number of nonzero regression coefficients $\hat{\beta}_i(\lambda) \neq 0$ with $i \notin \{1, 2, 3, 4, 5\}$ for Model 1-3 and with $i \notin \{1, 2, 3, 4\}$ for Model 4. This measures the ability of L_1 -norm SVM not selecting noise features.

Table 1 summarizes the simulation results for all four models. The numbers in the parentheses are the corresponding standard errors based on 200 replications. Overall, the L_1 -norm SVM performs satisfactorily for classification with relatively low error rates in all

Table 1: Simulation results for L_1 -norm SVMs

Model	n	p	Test error	L_2 error	AAC	Signal	Noise
Model 1	100	1000	0.17(0.06)	0.53(0.14)	0.89(0.03)	4.84(0.41)	38.20(5.50)
	100	1500	0.19(0.05)	0.59(0.14)	0.89(0.03)	4.75(0.47)	40.27(5.41)
	200	1500	0.10(0.003)	0.27(0.07)	0.96(0.02)	5.00(0.07)	19.80(4.12)
Model 2	100	2000	0.10(0.02)	0.27(0.06)	0.96(0.02)	5.00(0.00)	23.61(4.80)
	100	1000	0.06(0.04)	0.34(0.12)	0.95(0.02)	4.88(0.35)	21.25(4.22)
	100	1500	0.07(0.04)	0.39(0.12)	0.95(0.02)	4.79(0.41)	28.80(4.61)
Model 3	100	1500	0.02(0.01)	0.21(0.07)	0.97(0.01)	4.99(0.10)	5.41(2.25)
	200	2000	0.02(0.02)	0.22(0.07)	0.97(0.01)	4.99(0.10)	6.88(2.50)
	100	1000	0.06(0.05)	0.36(0.14)	0.95(0.02)	4.8(0.40)	19.93(3.87)
Model 4	100	1500	0.06(0.04)	0.37(0.13)	0.95(0.02)	4.83(0.40)	27.55(4.85)
	200	1500	0.02(0.02)	0.22(0.07)	0.97(0.02)	5.00(0.07)	5.18(2.19)
	200	2000	0.02(0.02)	0.20(0.08)	0.97(0.02)	5.00(0.07)	6.72(2.67)
Model 4	100	1000	0.16(0.04)	0.52(0.13)	0.94(0.03)	3.88(0.33)	12.87(3.65)
	100	1500	0.17(0.05)	0.55(0.14)	0.93(0.03)	3.81(0.42)	12.09(3.56)
	200	1500	0.13(0.03)	0.33(0.09)	0.97(0.01)	4.00(0.00)	11.12(3.53)
200	2000	0.15(0.03)	0.43(0.07)	0.94(0.02)	4.00(0.00)	48.34(7.71)	

the models. Actually, the error rates are all quite close to the Bayes errors. It is also successful in eliminating most of the irrelevant features. The performance improves with increased sample size. In terms of estimation accuracy, the L_2 error decreases as p decreases and n increases, which echoes the result in main theorem. We observe that AAC is greater than 0.9 in most cases, implying that the direction of $\hat{\boldsymbol{\beta}}(\lambda)$ matches that of the Bayes rule.

It is worth noting that the earlier literature have already performed thorough numerical analysis to compare the performance of L_1 -norm SVM with L_2 -norm SVM and logistic regression. For example, Zhu et al. (2004) observes that the performance of L_1 -norm SVM and L_2 -norm SVM is similar when there is no redundant features; however, the performance of L_2 -norm SVM can be adversely affected by the presence of redundant features. Rocha et al. (2009) numerically compared L_1 -norm SVM with logistic regression classifier and discovered that they are comparable but their relative finite-sample advantage depends on the sample size and design. See similar observation in Zou (2007), Zhang et al. (2016b), among others. Although L_1 -norm SVM can outperform regular L_2 -norm SVM when there are many redundant features, it shares the drawback of L_1 penalized least squares regression that it overpenalizes large coefficients and tends to have larger false positives (including more noise features) comparing with the non-convex penalized SVM, which will be investigated in Section 5.2.

5.2 Monte Carlo results for non-convex penalized SVM

In this subsection, we consider the same four models as in Section 5.1. Instead of the L_1 -norm SVM, we use it as the initial value for the non-convex penalized SVM algorithm proposed in Zhang et al. (2016b). We consider two popular choices of non-convex penalty

functions: SCAD penalty (with $a = 3.7$) and MCP penalty (with $a = 3$). As suggested in Zhang et al. (2016b), we used the recently developed high-dimensional BIC criterion to choose the tuning parameter for non-convex penalized SVMs. More specifically, the SVM-extended BIC is defined as

$$SVMIC_\gamma(T) = \sum_{i=1}^n 2\xi_i + \log(n)/|T| + 2\gamma \binom{p}{|T|}, \quad 0 \leq \gamma \leq 1,$$

where in practice we can set $\gamma = 0.5$ as suggested by Chen and Chen (2008) and choose the λ that minimizes the above $SVMIC_\gamma$ for non-convex penalized SVM.

Table 2: Simulation results for SCAD penalized SVM

Model	n	p	Test error	L_2 error	AAC	Signal	Noise
Model 1	100	1000	0.10(0.05)	0.25(0.17)	0.95(0.04)	4.88(0.38)	4.92(5.82)
	100	1500	0.12(0.06)	0.35(0.20)	0.93(0.05)	4.84(0.53)	9.31(8.89)

	200	1500	0.03(0.03)	0.19(0.10)	0.96(0.03)	4.91(0.29)	2.77(3.53)
	200	2000	0.02(0.01)	0.15(0.06)	0.98(0.02)	5.00(0.07)	1.40(1.81)
Model 3	100	1000	0.05(0.04)	0.30(0.16)	0.94(0.04)	4.53(0.58)	0.58(0.84)
	100	1500	0.04(0.04)	0.24(0.15)	0.95(0.04)	4.75(0.46)	1.08(1.15)
	200	1500	0.02(0.01)	0.14(0.06)	0.98(0.01)	4.99(0.10)	1.30(1.53)
	200	2000	0.02(0.01)	0.15(0.06)	0.98(0.02)	5.00(0.00)	1.32(1.83)
Model 4	100	1000	0.15(0.05)	0.51(0.20)	0.94(0.04)	3.50(0.59)	7.54(5.20)
	100	1500	0.17(0.05)	0.61(0.18)	0.93(0.04)	3.57(0.71)	8.86(6.37)
	200	1500	0.12(0.03)	0.19(0.10)	0.99(0.01)	3.98(0.14)	3.19(2.45)
	200	2000	0.14(0.03)	0.39(0.19)	0.97(0.03)	3.69(0.51)	0.95(1.07)

Tables 2 and 3 summarize the simulation results for SCAD and MCP penalty functions, respectively. We observe that the SCAD-penalized SVM and MCP-penalized MCP have similar performance, both demonstrating a clear advantage of selecting the relevant features and excluding irrelevant ones over L_1 -norm SVM. The Noise size decreases dramatically to less than 3 as the sample size gets larger. The Signal size is almost 5 when $n = 200$ for Model 1-3 and 4 for Model 4, implying the success of selecting the exact true model. We also observe that non-convex penalized SVM has uniformly smaller L_2 error and larger AAC than L_1 -norm SVM. This resonates with the observation in the literature that eliminating irrelevant features enhances classification performance. The Monte Carlo study confirms the effectiveness of the algorithm of Zhang et al. (2016b) for feature selection for SVM in high dimension when using L_1 -norm SVM as an initial value.

6. Conclusion and discussion

We investigate the statistical properties of L_1 -norm SVM coefficients in ultra-high dimension. We proved that L_1 -norm SVM coefficients achieve a near-oracle rate of estimation error. To deal with the non-smoothness of the hinge loss function, we employ empirical processes techniques to derive the theory. Furthermore, we showed that under some general regularity conditions, the L_1 -norm SVM provides an appropriate initial value for the recent algorithm developed by Zhang et al. (2016b) for non-convex penalized SVM in high dimension. Combined with the theory in that paper, we extended the applicability and validity of their result to the ultra-high dimension.

Our work is motivated by the importance of identifying individual features for SVM in analyzing high-dimensional data, which frequently arise in genomics and many other fields. We not only closed a theoretical gap on the estimation error bound on L_1 -SVM when $p \gg n$, but also verified that (Section 4) this leads to consistently identifying important features when combined with a two-step iterative algorithm in the ultra-high dimensional setting. Hence, we have guarantee for both algorithm convergence and theoretical performance. We believe such results are of direct interest to JMLR readers given the popularity of SVM in practice. Our work has substantial difference from the existing work in the literature. The existing theory on SVM has been largely focused on the analysis of generalization error rate and empirical risk. These results neither contain nor directly imply the transparent error bound of the estimated coefficients of L_1 -norm SVM studied in this paper. Furthermore, the techniques used in the paper for deriving the L_2 error bound when $p \gg n$ are completely different from those used in $p < n$ setting. Although our approach for deriving the L_2 -error bound is inspired by the recent work in the literature for Lasso. There is substantial

new technical challenge to deal with the nonsmooth Hinge loss function and requires more delicate application of empirical process techniques. Also, unlike Lasso, we do not require Gaussian or sub-Gaussian conditions in the technical derivation.

Acknowledgments

Appendix A: Technical Proofs

Proof of Lemma 1. By the union bound, we have

$$\begin{aligned} P(c\sqrt{2A(\alpha)}\log p/n \leq c\|\widehat{S}(\boldsymbol{\beta}^*)\|_\infty) \\ \leq \sum_{j=0}^p P\left(\sqrt{2A(\alpha)}\log p/n \leq n^{-1}\sum_{i=1}^n I(1 - Y_i \mathbf{X}_i^T \boldsymbol{\beta}^* \geq 0) Y_i X_{ij}\right). \end{aligned}$$

Notice that we have $S(\boldsymbol{\beta}^*) = 0$ because of minimizer $\boldsymbol{\beta}^*$ and the definition of gradient vector. Then, for each i and j , $E(Y_i X_{ij} I(1 - Y_i \mathbf{X}_i^T \boldsymbol{\beta}^* \geq 0)) = 0$, by Hoeffding's inequality,

$$\begin{aligned} P\left(\sqrt{2A(\alpha)}\log p/n \leq n^{-1}\sum_{i=1}^n I(1 - Y_i \mathbf{X}_i^T \boldsymbol{\beta}^* \geq 0) Y_i X_{ij}\right) \\ \leq 2\exp\left(-\frac{4A(\alpha)n\log p}{4n\Delta T^2}\right) = 2p^{-\frac{A(\alpha)}{\Delta T^2}}. \end{aligned}$$

Therefore $P(c\sqrt{2A(\alpha)}\log p/n \leq c\|\widehat{S}(\boldsymbol{\beta}^*)\|_\infty) \leq (p+1) \cdot 2p^{-\frac{A(\alpha)}{\Delta T^2}} \leq \alpha$.

Proof of Lemma 2. Since $\widehat{\boldsymbol{\beta}}$ minimizes $l_n(\boldsymbol{\beta})$, we have

$$\begin{aligned} \frac{1}{n} \sum_{i=1}^n (1 - Y_i \mathbf{X}_i^T \widehat{\boldsymbol{\beta}}) + \lambda \|\widehat{\boldsymbol{\beta}}_-\|_1 &\leq \frac{1}{n} \sum_{i=1}^n (1 - Y_i \mathbf{X}_i^T \boldsymbol{\beta}^*) + \lambda \|\boldsymbol{\beta}^*\|_1, \\ \frac{1}{n} \sum_{i=1}^n (1 - Y_i \mathbf{X}_i^T \boldsymbol{\beta}^* + Y_i \mathbf{X}_i^T \mathbf{h}_+) - \frac{1}{n} \sum_{i=1}^n (1 - Y_i \mathbf{X}_i^T \boldsymbol{\beta}^*) &\leq \lambda \|\boldsymbol{\beta}^*\|_1 - \lambda \|\widehat{\boldsymbol{\beta}}_-\|_1. \end{aligned}$$

Recalling $T = \{1 \leq j \leq p : \beta_j^* \neq 0\}$ and $T_+ = T \cup \{0\}$, we have

$$\begin{aligned} \|\boldsymbol{\beta}^*\|_1 - \|\widehat{\boldsymbol{\beta}}_-\|_1 &\leq \|\boldsymbol{\beta}_{T_+}^*\|_1 - \|\widehat{\boldsymbol{\beta}}_-\|_1 \\ &\leq \|\mathbf{h}_{T_+}\|_1 - \|\mathbf{h}_{T_+^c}\|_1. \end{aligned}$$

This implies

$$\frac{1}{n} \sum_{i=1}^n (1 - Y_i \mathbf{X}_i^T \boldsymbol{\beta}^* + Y_i \mathbf{X}_i^T \mathbf{h}_+) - \frac{1}{n} \sum_{i=1}^n (1 - Y_i \mathbf{X}_i^T \boldsymbol{\beta}^*) \leq \lambda (\|\mathbf{h}_{T_+}\|_1 - \|\mathbf{h}_{T_+^c}\|_1). \quad (15)$$

Since the subdifferential of $l_n(\boldsymbol{\beta})$ at the point of $\boldsymbol{\beta}^*$ is $\widehat{S}(\boldsymbol{\beta}^*)$ and recall the assumption $\lambda \geq c\|\widehat{S}(\boldsymbol{\beta}^*)\|_\infty$, we have

$$\begin{aligned} &\frac{1}{n} \sum_{i=1}^n (1 - Y_i \mathbf{X}_i^T \boldsymbol{\beta}^* + Y_i \mathbf{X}_i^T \mathbf{h}_+) - \frac{1}{n} \sum_{i=1}^n (1 - Y_i \mathbf{X}_i^T \boldsymbol{\beta}^*) \\ &\geq \widehat{S}^T(\boldsymbol{\beta}^*) \mathbf{h} \\ &\geq -\|\mathbf{h}\|_1 \cdot \|\widehat{S}(\boldsymbol{\beta}^*)\|_\infty \\ &\geq -\frac{\lambda}{c} (\|\mathbf{h}_{T_+}\|_1 + \|\mathbf{h}_{T_+^c}\|_1). \end{aligned}$$

Hence, we have

$$\begin{aligned} \lambda (\|\mathbf{h}_{T_+}\|_1 - \|\mathbf{h}_{T_+^c}\|_1) &\geq -\frac{\lambda}{c} (\|\mathbf{h}_{T_+}\|_1 + \|\mathbf{h}_{T_+^c}\|_1), \\ \|\mathbf{h}_{T_+}\|_1 &\geq C \|\mathbf{h}_{T_+^c}\|_1, \end{aligned}$$

where $C = \frac{c-1}{c+1}$. We have thus proved that $\mathbf{h} \in \Delta_C$.

Proof of Lemma 3. We first consider a fixed $\mathbf{h} \in \mathbb{R}^{p+1}$ such that $\|\mathbf{h}\|_0 \leq q+1$ and $\|\mathbf{h}\|_2 \neq 0$. Note that the Hinge loss function is Lipschitz continuous and we have

$$\frac{|(1 - Y_i \mathbf{X}_i^T \boldsymbol{\beta}^* + Y_i \mathbf{X}_i^T \mathbf{h}_+) - (1 - Y_i \mathbf{X}_i^T \boldsymbol{\beta}^*)|}{\|\mathbf{h}\|_2} \leq \frac{|\mathbf{X}_i^T \mathbf{h}|}{\|\mathbf{h}\|_2}.$$

By Hoeffding's inequality, we have $\forall t > 0$,

$$P\left(\frac{B(\mathbf{h})}{\|\mathbf{h}\|_2} \geq \frac{t}{\sqrt{n}} |\mathcal{X}\| \right) \leq 2 \exp\left(-\frac{2nt^2}{4\|\mathcal{X}\mathbf{h}\|_2^2/\|\mathbf{h}\|_2^2}\right).$$

Hence by assumption (A3),

$$P\left(\frac{B(\mathbf{h})}{\|\mathbf{h}\|} \geq \frac{t}{\sqrt{n}} |\mathcal{X}\| \right) \leq 2 \exp\left(-\frac{t^2}{2\lambda_{\max}^2}\right) \leq 2 \exp\left(-\frac{t^2}{2M_1^2}\right).$$

Let $t = C\sqrt{2q\log p}$, where C is an arbitrary given positive constant. Then

$$P\left(\frac{B(\mathbf{h})}{\|\mathbf{h}\|} \geq C\sqrt{\frac{2q\log p}{n}}\right) \leq 2 \exp\left(-\frac{C^2 q \log p}{M_1^2}\right) \leq 2p^{-C^2 q/M_1} \leq 2p^{-C^2(q+1)/(2M_1)}.$$

Next we will derive an upper bound for $\sup_{\|\mathbf{h}\|_0 \leq q+1, \|\mathbf{h}\|_2 \neq 0} \frac{B(\mathbf{h})}{\|\mathbf{h}\|}$. We consider covering $\{\mathbf{h} \in \mathbb{R}^{p+1}, \|\mathbf{h}\|_0 \leq q+1\}$ with ϵ -balls such that for any \mathbf{h}_1 and \mathbf{h}_2 in the same ball we have $\left|\frac{\|\mathbf{h}_1\|}{\|\mathbf{h}_2\|} - \frac{\|\mathbf{h}_2\|}{\|\mathbf{h}_1\|}\right| \leq \epsilon$, where ϵ is a small positive number. The number of ϵ -balls that is required to cover a k -dimensional unit ball is bounded by $(3/\epsilon)^k$, see for example Rogers (1963) and Bourgain and Milman (1987). Since \mathbf{h} is a $(p+1)$ -dimensional vector with at most $q+1$ nonzero coordinates and $\mathbf{h}/\|\mathbf{h}\|_2$ has unit length in L_2 norm, the covering number we require is at most $(3p/\epsilon)^{q+1}$. Let N denote such an ϵ -net. By the union bound,

$$P\left(\sup_{\mathbf{h} \in N} \frac{B(\mathbf{h})}{\|\mathbf{h}\|} \geq C\sqrt{\frac{2q\log p}{n}}\right) \leq 2 \left(\frac{3p}{\epsilon}\right)^{q+1} p^{-C^2(q+1)/(2M_1)} = 2 \left(\frac{3}{\epsilon}\right)^{q+1} p^{-C^2/(2M_1)},$$

for any given positive constant C . Furthermore, for any $\mathbf{h}_1, \mathbf{h}_2 \in \mathbb{R}^{p+1}$ such that $\|\mathbf{h}_1\|_0 \leq q+1$, $\|\mathbf{h}_2\|_0 \leq q+1$, $\|\mathbf{h}_1\|_2 \neq 0$ and $\|\mathbf{h}_2\|_2 \neq 0$, we have

$$\begin{aligned} \left| \frac{B(\mathbf{h}_1)}{\|\mathbf{h}_1\|_2} - \frac{B(\mathbf{h}_2)}{\|\mathbf{h}_2\|_2} \right| &\leq \frac{2}{n} \|\mathcal{X}(\mathbf{h}_1/\|\mathbf{h}_1\|_2 - \mathbf{h}_2/\|\mathbf{h}_2\|_2)\|_1 \\ &\leq \frac{2}{\sqrt{n}} \|\mathcal{X}(\mathbf{h}_1/\|\mathbf{h}_1\|_2 - \mathbf{h}_2/\|\mathbf{h}_2\|_2)\|_2 \\ &\leq 2\sqrt{M_1}\epsilon. \end{aligned}$$

Therefore,

$$\sup_{\|\mathbf{h}_1\|_0 \leq q+1, \|\mathbf{h}_1\|_2 \neq 0} \frac{B(\mathbf{h})}{\|\mathbf{h}\|} \leq \sup_{\mathbf{h} \in \mathcal{N}} \frac{B(\mathbf{h})}{\|\mathbf{h}\|} + 2\sqrt{M_1}\epsilon.$$

Let $\epsilon = \sqrt{\frac{2q \log p}{2M_1 n}}$, we have

$$\begin{aligned} P \left(\sup_{\|\mathbf{h}_1\|_0 \leq q+1, \|\mathbf{h}_1\|_2 \neq 0} \frac{B(\mathbf{h})}{\|\mathbf{h}\|} \geq C \sqrt{\frac{2q \log p}{n}} \right) \\ &\leq P \left(\sup_{\mathbf{h} \in \mathcal{N}} \frac{B(\mathbf{h})}{\|\mathbf{h}\|} \geq (C-1) \sqrt{\frac{2q \log p}{n}} \right) \\ &\leq 2(2M_1 n)^{\frac{q+1}{2}} (3p)^{-(C-1)^2/(2M_1)} (q+1) \\ &\leq 2(\sqrt{2M_1 n} 3p)^{1-(C-1)^2/(2M_1)} (q+1). \end{aligned}$$

Since $p > n$, take $C = 1 + 2C_1\sqrt{M_1}$ for some $C_1 > 1$, then for all n sufficiently large,

$$P \left(\sup_{\|\mathbf{h}_1\|_0 \leq q+1, \|\mathbf{h}_1\|_2 \neq 0} \frac{B(\mathbf{h})}{\|\mathbf{h}\|} \geq (1 + 2C_1\sqrt{M_1}) \sqrt{\frac{2q \log p}{n}} \right) \leq 2p^{-2q(C_1^2-1)}.$$

Lemma 6 For any $x \in \mathbb{R}^n$,

$$\|x\|_2 - \frac{\|x\|_1}{\sqrt{n}} \leq \frac{\sqrt{n}}{4} \left(\max_{1 \leq i \leq n} |x_i| - \min_{1 \leq i \leq n} |x_i| \right).$$

Proof. This proof was given in Cai, Wang, and Xu (2010). We include it here for completeness and easy reference. It is obvious that the result holds when $|x_1| = |x_2| = \dots = |x_n|$. Without loss of generality, we now assume that $x_1 \geq x_2 \geq \dots \geq x_n \geq 0$ and not all x_i are equal. Let

$$f(x) = \|x\|_2 - \frac{\|x\|_1}{\sqrt{n}}.$$

Note that for any $i \in \{2, 3, \dots, n-1\}$

$$\frac{\partial f}{\partial x_i} = \frac{x_i}{\|x\|_2} - \frac{1}{\sqrt{n}}.$$

This implies that when $x_i \leq \frac{\|x\|_2}{\sqrt{n}}$, $f(x)$ is decreasing w.r.t x_i ; otherwise $f(x)$ is increasing w.r.t x_i . Hence, if we fix x_1 and x_n , when $f(x)$ achieves its maximum, x must be of the form that $x_1 = x_2 = \dots = x_k$ and $x_{k+1} = \dots = x_n$ for some $1 \leq k \leq n$. Now,

$$f(x) = \sqrt{k(x_1^2 - x_n^2) + nx_n^2} - \frac{k}{\sqrt{n}}(x_1 - x_n) - \sqrt{nx_n}.$$

Treat this as a function of k for $k \in (0, n)$.

$$g(x) = \sqrt{k(x_1^2 - x_n^2) + nx_n^2} - \frac{k}{\sqrt{n}}(x_1 - x_n) - \sqrt{nx_n}.$$

By taking the derivatives, it is easy to see that

$$\begin{aligned} g(k) &\leq g \left(n \frac{(\frac{x_1+x_n}{2})^2 - x_n^2}{x_1^2 - x_n^2} \right) \\ &= \sqrt{n}(x_1 - x_n) \left(\frac{1}{2} - \frac{x_1 + 3x_n}{4(x_1 + x_n)} \right). \end{aligned}$$

Since $\frac{1}{2} - \frac{x_1+3x_n}{4(x_1+x_n)} \geq \frac{1}{4}$, we have

$$\|x\|_2 \leq \frac{\|x\|_1}{\sqrt{n}} + \frac{\sqrt{n}}{4}(x_1 - x_n).$$

We can also see that the above inequality becomes an equality if and only if $x_{k+1} = \dots = x_n = 0$ and $k = \frac{n}{4}$.

Proof of Theorem 4. Let $\mathbf{h} = \boldsymbol{\beta}^* - \hat{\boldsymbol{\beta}}$, then it follows from Lemma 2 that $\mathbf{h} \in \Delta_{\mathcal{C}}$. Assume without loss of generality that $|h_0| \geq |h_1| \geq \dots \geq |h_p|$. Create a partition of $\{0, 1, 2, \dots, p\}$ as

$$S_0 = \{0, 1, 2, \dots, q\}, S_1 = \{q+1, q+2, \dots, 2q+1\}, S_2 = \{2q+2, 2q+3, \dots, 3q+2\}, \dots$$

where S_i , $i = 1, 2, \dots$, has cardinality $q+1$, except the last set which may have cardinality smaller than $q+1$. This partition leads to the following decomposition

$$\begin{aligned} &\frac{1}{n} \sum_{i=1}^n (1 - Y_i \mathbf{X}_i^T \boldsymbol{\beta}^* + Y_i \mathbf{X}_i^T \mathbf{h})_+ - \frac{1}{n} \sum_{i=1}^n (1 - Y_i \mathbf{X}_i^T \boldsymbol{\beta}^*)_+ \\ &= \frac{1}{n} \sum_{i=1}^n (1 - Y_i \mathbf{X}_i^T \boldsymbol{\beta}^* + Y_i \mathbf{X}_i^T \sum_{k \geq 0} \mathbf{h}_{S_k})_+ - \frac{1}{n} \sum_{i=1}^n (1 - Y_i \mathbf{X}_i^T \boldsymbol{\beta}^*)_+ \\ &= \sum_{j \geq 1} \frac{1}{n} \left(\sum_{i=1}^n (1 - Y_i \mathbf{X}_i^T \boldsymbol{\beta}^* + Y_i \mathbf{X}_i^T \sum_{k=0}^j \mathbf{h}_{S_k})_+ - \sum_{i=1}^n (1 - Y_i \mathbf{X}_i^T \boldsymbol{\beta}^* + Y_i \mathbf{X}_i^T \sum_{k=0}^{j-1} \mathbf{h}_{S_k})_+ \right) \\ &\quad + \frac{1}{n} \left(\sum_{i=1}^n (1 - Y_i \mathbf{X}_i^T \boldsymbol{\beta}^* + Y_i \mathbf{X}_i^T \mathbf{h}_{S_0})_+ - \sum_{i=1}^n (1 - Y_i \mathbf{X}_i^T \boldsymbol{\beta}^*)_+ \right), \end{aligned} \quad (16)$$

where the first equation follows from the definition of \mathbf{h}_{S_k} , $k \geq 0$; the second equation holds by observing that the intermediate terms cancel out each other. The purpose of the above decomposition is to obtain more accurate probability bounds by appealing to Lemma 3. This is made possible by noting that the j th term in the sum of the above decomposition has the increment indexed by \mathbf{h}_{S_j} , which has at most $q+1$ nonzero coordinates. Lemma 3 implies that uniformly for $j = 1, 2, \dots$, with probability at least $1 - 2p^{-2q}(C_1^2 - 1)$,

$$\begin{aligned} & \frac{1}{n} \left(\sum_{i=1}^n (1 - Y_i \mathbf{X}_i^T \boldsymbol{\beta}^* + Y_i \mathbf{X}_i^T \sum_{k=0}^j \mathbf{h}_{S_k})_+ - \sum_{i=1}^n (1 - Y_i \mathbf{X}_i^T \boldsymbol{\beta}^* + Y_i \mathbf{X}_i^T \sum_{k=0}^{j-1} \mathbf{h}_{S_k})_+ \right) \\ & \geq \frac{1}{n} E \left(\sum_{i=1}^n (1 - Y_i \mathbf{X}_i^T \boldsymbol{\beta}^* + Y_i \mathbf{X}_i^T \sum_{k=0}^j \mathbf{h}_{S_k})_+ - \sum_{i=1}^n (1 - Y_i \mathbf{X}_i^T \boldsymbol{\beta}^* + Y_i \mathbf{X}_i^T \sum_{k=0}^{j-1} \mathbf{h}_{S_k})_+ \right) \\ & \quad - C \sqrt{\frac{2q \log p}{n}} \|\mathbf{h}_{S_j}\|_2, \end{aligned}$$

where $C = 1 + 2C_1 \sqrt{M_T}$. Hence by (16), with probability at least $1 - 2p^{-2q}(C_1^2 - 1)$,

$$\frac{1}{n} \left(\sum_{i=1}^n (1 - Y_i \mathbf{X}_i^T \boldsymbol{\beta}^* + Y_i \mathbf{X}_i^T \mathbf{h})_+ - \sum_{i=1}^n (1 - Y_i \mathbf{X}_i^T \boldsymbol{\beta}^*)_+ \right) \geq M(\mathbf{h}) - C \sqrt{\frac{2q \log p}{n}} \sum_{j \geq 0} \|\mathbf{h}_{S_j}\|_2 \quad (17)$$

where $M(\mathbf{h}) = \frac{1}{n} E(\sum_{i=1}^n (1 - Y_i \mathbf{X}_i^T \boldsymbol{\beta}^* + Y_i \mathbf{X}_i^T \mathbf{h})_+ - \sum_{i=1}^n (1 - Y_i \mathbf{X}_i^T \boldsymbol{\beta}^*)_+)$.

It is straightforward to show that $\|\mathbf{h}_{S_0}\|_1 \geq \|\mathbf{h}_{T^c}\|_1 \geq C \|\mathbf{h}_{T^c}\|_2 \geq C \|\mathbf{h}_{S_0}\|_1$. By Lemma 6, we have

$$\begin{aligned} \sum_{j \geq 1} \|\mathbf{h}_{S_j}\|_2 & \leq \sum_{j \geq 1} \frac{\|\mathbf{h}_{S_j}\|_1}{\sqrt{q+1}} + \frac{\sqrt{q+1}}{4} |h_q| \\ & \leq \frac{\|\mathbf{h}_{S_0^c}\|_1}{\sqrt{q+1}} + \frac{\|\mathbf{h}_{S_0}\|_1}{4\sqrt{q+1}} \\ & \leq \left(\frac{1}{\sqrt{q+1}C} + \frac{1}{4\sqrt{q+1}} \right) \|\mathbf{h}_{S_0}\|_1 \\ & \leq \left(\frac{1}{4} + \frac{1}{C} \right) \|\mathbf{h}_{S_0}\|_2. \end{aligned} \quad (18)$$

By the definition of \mathbf{h} , (15), (17) and (18), we have

$$\begin{aligned} M(\mathbf{h}) & \leq \lambda (\|\mathbf{h}_{T^c}\|_1 - \|\mathbf{h}_{T^c}\|_1) + \left(\frac{1}{4} + \frac{1}{C} \right) C \sqrt{\frac{2q \log p}{n}} \|\mathbf{h}_{S_0}\|_2 + C \sqrt{\frac{2q \log p}{n}} \|\mathbf{h}_{S_0}\|_2 \\ & \leq \lambda \sqrt{q+1} \|\mathbf{h}_{S_0}\|_2 + C \sqrt{\frac{2q \log p}{n}} \left(\frac{5}{4} + \frac{1}{C} \right) \|\mathbf{h}_{S_0}\|_2. \end{aligned} \quad (19)$$

Condition (A4) imply that

$$M(\mathbf{h}) = \frac{1}{2} \mathbf{h}^T H(\boldsymbol{\beta}^*) \mathbf{h} + o(\|\mathbf{h}\|_2^2) \geq \frac{1}{2} M_2 \|\mathbf{h}\|_2^2 + o(\|\mathbf{h}\|_2^2). \quad (20)$$

Combining (19) and (20), we have

$$\frac{1}{2} M_2 \|\mathbf{h}\|_2^2 + o(\|\mathbf{h}\|_2^2) \leq \lambda \sqrt{q+1} \|\mathbf{h}_{S_0}\|_2 + C \sqrt{\frac{2q \log p}{n}} \left(\frac{5}{4} + \frac{1}{C} \right) \|\mathbf{h}_{S_0}\|_2.$$

Note that $\|\mathbf{h}\|_2^2 = \|\mathbf{h}_{S_0}\|_2^2 + \sum_{j \geq 1} \|\mathbf{h}_{S_j}\|_2^2 \geq \|\mathbf{h}_{S_0}\|_2^2$, and

$$\sum_{j \geq 1} \|\mathbf{h}_{S_j}\|_2^2 \leq |h_q| \sum_{j \geq 1} \|\mathbf{h}_{S_j}\|_1 \leq \frac{1}{C} |h_q| \|\mathbf{h}_{S_0}\|_1 \leq \frac{1}{C} \|\mathbf{h}_{S_0}\|_2^2.$$

So $\|\mathbf{h}\|_2^2 \leq (1 + \frac{1}{C}) \|\mathbf{h}_{S_0}\|_2^2$. This implies $o(\|\mathbf{h}\|_2^2) = o(\|\mathbf{h}_{S_0}\|_2^2)$. To wrap up, we have

$$\|\mathbf{h}_{S_0}\|_2 + o(\|\mathbf{h}_{S_0}\|_2) \leq \frac{2\lambda \sqrt{q+1}}{M_2} + \frac{2C}{M_2} \sqrt{\frac{2q \log p}{n}} \left(\frac{5}{4} + \frac{1}{C} \right).$$

Hence,

$$\|\mathbf{h}\|_2 + o(\|\mathbf{h}\|_2) \leq \sqrt{1 + \frac{1}{C}} \left(\frac{2\lambda \sqrt{q+1}}{M_2} + \frac{2C}{M_2} \sqrt{\frac{2q \log p}{n}} \left(\frac{5}{4} + \frac{1}{C} \right) \right).$$

We therefore have

$$\|\hat{\boldsymbol{\beta}} - \boldsymbol{\beta}^*\|_2 \leq \sqrt{1 + \frac{1}{C}} \left(\frac{2\lambda \sqrt{q+1}}{M_2} + \frac{2C}{M_2} \sqrt{\frac{2q \log p}{n}} \left(\frac{5}{4} + \frac{1}{C} \right) \right)$$

with probability at least $1 - 2p^{-2q}(C_1^2 - 1)$.

Proof of Theorem 5. It follows by combining the result of Theorem 3.3 with that of Theorem 4 in of Zhang et al. (2016b).

Appendix B: Discussions of Condition (A4)

We note that Condition (A4) is satisfied if the smallest eigenvalues of $H(\boldsymbol{\beta}^*)$ has a positive lower bound. In the following, we provide a set of sufficient conditions to guarantee the positive definiteness of $H(\boldsymbol{\beta}^*)$.

(A1*) For some $1 \leq k \leq p$,

$$\int_S I(X_k \geq V_k^-) X_k g(\mathbf{X}) d\mathbf{X} < \int_S I(X_k \leq U_k^+) X_k f(\mathbf{X}) d\mathbf{X}$$

or

$$\int_S I(X_k \leq V_k^+) X_k g(\mathbf{X}) d\mathbf{X} > \int_S I(X_k \geq U_k^-) X_k f(\mathbf{X}) d\mathbf{X}$$

Here U_k^+ , V_k^+ $\in [-\infty, +\infty]$ are upper bounds such that $\int_S I(X_k \leq U_k^+) f(\mathbf{X}) d\mathbf{X} = \min(1, \frac{\pi_k^+}{\pi_k^-})$ and $\int_S I(X_k \leq V_k^+) g(\mathbf{X}) d\mathbf{X} = \min(1, \frac{\pi_k^+}{\pi_k^-})$. Similarly, lower bounds U_k^- , $V_k^- \in [-\infty, +\infty]$ and are defined as $\int_S I(X_k \geq U_k^-) f(\mathbf{X}) d\mathbf{X} = \min(1, \frac{\pi_k^-}{\pi_k^+})$ and $\int_S I(X_k \geq V_k^-) g(\mathbf{X}) d\mathbf{X} = \min(1, \frac{\pi_k^-}{\pi_k^+})$.

(A2*) For an orthogonal transformation A_j that maps $\frac{\beta^*}{\|\beta^*\|_2}$ to the j -th unit vector \mathbf{e}_j for some $j \in \{1, 2, 3, \dots, p\}$, there exists rectangles

$$D^+ = \{x \in M^+ : l_i \leq (A_j x)_i \leq v_i \text{ with } l_i < v_i \text{ for } i \neq j\}$$

and

$$D^- = \{x \in M^- : l_i \leq (A_j x)_i \leq v_i \text{ with } l_i < v_i \text{ for } i \neq j\}$$

such that $f(x) \geq B_1 > 0$ on D^+ , and $g(x) \geq B_2 > 0$ on D^- , where $M^+ = \{x \in \mathbf{R}^p : x^T \beta^+ + \beta_0^+ = 1\}$ and $M^- = \{x \in \mathbf{R}^p : x^T \beta^+ + \beta_0^+ = -1\}$.

Also with some technical modification, Condition (A1) in our paper can be further relaxed to

(A3*) The densities f and g are continuous with common support $\mathcal{S} \subset \mathbb{R}^p$ and have finite second moments.

As an interesting side result, Lemma 5 in Koo et al. (2008) showed that Condition (A4) holds under (A1*)-(A3*). Although their paper's results on the Bahadur representation of L_1 -norm SVM coefficients are restricted to the classical fixed p case, a careful examination of the derivation showed that this particular lemma holds irrespective of the dimension of p .

In the following, we demonstrate that Conditions (A1*)-(A3*) hold in a nontrivial example where we have two multivariate normal distributions in \mathcal{R}^p . The marginal distribution of Y is given by $\pi_+ = \pi_- = 1/2$. Let f and g be the density functions of \mathbf{X}_- given $Y = 1$ and -1 , respectively. Here, we assume f and g are multivariate normal densities with different mean vectors $\boldsymbol{\mu}$ and $\boldsymbol{\nu}$ and a common covariance matrix $\boldsymbol{\Sigma}$. This setup was also considered in Koo et al. (2008) but we will provide more details to show condition (A4) is satisfied in our high-dimensional settings. In particular, we will provide some details for deriving the analytic forms of β^* and $H(\beta^*)$, which complements the results in Koo et al. (2008).

For normal density functions f and g , it is straightforward to check Condition (A3*) is satisfied. While $U_k^+ = V_k^+ = +\infty$ and $U_k^- = V_k^- = -\infty$, Condition (A1*) also holds. Since D^+ and D^- are bounded rectangles in \mathbb{R}^p , the normal densities f and g are always bounded away from zero on D^+ and D^- . Thus (A2*) is satisfied. Denote the density and cumulative distribution function of standard normal distribution $N(0, 1)$ as ϕ and Φ , respectively. Then we have $S(\beta^*) = 0$, where $S(\cdot)$ is defined in (6), that is

$$E_f(I(1 - \mathbf{X}^T \beta^* \geq 0)) = E_g(I(1 + \mathbf{X}^T \beta^* \geq 0)) \quad (21)$$

and

$$E_f(I(1 - \mathbf{X}^T \beta^* \geq 0) \mathbf{X}_-) = E_g(I(1 + \mathbf{X}^T \beta^* \geq 0) \mathbf{X}_-) \quad (22)$$

For left hand of equation (21), we have $\mathbf{X}^T \beta^* \sim N(\boldsymbol{\mu}^T \beta^*, \beta^{*T} \boldsymbol{\Sigma} \beta^*)$, thus

$$E_f(I(1 - \mathbf{X}^T \beta^* \geq 0)) = P_f(1 - \beta_0^+ - \mathbf{X}^T \beta^* \geq 0) = \Phi(c_f), \quad (23)$$

where $c_f = \frac{1 - \beta_0^+ - \boldsymbol{\mu}^T \beta^*}{\|\boldsymbol{\Sigma}^{1/2} \beta^*\|_2}$. Similarly, $E_g(I(1 + \mathbf{X}^T \beta^* \geq 0)) = \Phi(c_g)$, where $c_g = \frac{1 + \beta_0^+ + \boldsymbol{\nu}^T \beta^*}{\|\boldsymbol{\Sigma}^{1/2} \beta^*\|_2}$.

To obtain an analytic expression of $E_f(I(1 - \mathbf{X}^T \beta^* \geq 0))$, we consider an orthogonal matrix \mathbf{P} that satisfies $\frac{\mathbf{P} \boldsymbol{\Sigma}^{1/2} \beta^*}{\|\boldsymbol{\Sigma}^{1/2} \beta^*\|_2} = (1, 0, 0, \dots, 0)^T$. Such a matrix \mathbf{P} can always be constructed. Actually, let $\mathbf{P} = (\mathbf{P}_1, \mathbf{P}_2, \dots, \mathbf{P}_p)^T$ and $\mathbf{P}_1 = \frac{\boldsymbol{\Sigma}^{1/2} \beta^*}{\|\boldsymbol{\Sigma}^{1/2} \beta^*\|_2}$. By using Gram-Schmidt process, we can generate other orthogonal vectors \mathbf{P}_i based on \mathbf{P}_1 with $i = 2, 3, \dots, p$. Since $\mathbf{P} \boldsymbol{\Sigma}^{-1/2} (\mathbf{X}_- - \boldsymbol{\mu}) = \mathbf{Z}$, a standard multivariate normal random vector, we have $I - \mathbf{X}^T \beta^* = c_f \|\boldsymbol{\Sigma}^{1/2} \beta^*\|_2 - \mathbf{Z}^T \mathbf{P} \boldsymbol{\Sigma}^{1/2} \beta^*$. Thus

$$\begin{aligned} E_f(I(1 - \mathbf{X}^T \beta^* \geq 0) \mathbf{X}_-) &= E_\phi(I(c_f - Z_1 \geq 0)(\boldsymbol{\Sigma}^{1/2} \mathbf{P}^T \mathbf{Z} + \boldsymbol{\mu})) \\ &= E_\phi(I(c_f - Z_1 \geq 0) \boldsymbol{\mu}) + E_\phi(I(c_f - Z_1 \geq 0) \boldsymbol{\Sigma}^{1/2} \mathbf{P}^T \mathbf{Z}). \end{aligned}$$

where ϕ is the joint probability density function of a p -dimensional standard multivariate normal distribution. We will compute the above expectation componentwise. Let $\boldsymbol{\Sigma}^{1/2} = \Lambda = (\Lambda_1, \Lambda_2, \dots, \Lambda_p)^T$. For $k = 1, \dots, p$, we have

$$E_f(I(1 - \mathbf{X}^T \beta^* \geq 0) X_k) = \mu_k \Phi(c_f) + E_\phi(I(c_f - Z_1 \geq 0) \Lambda_k^T \sum_{i=1}^p P_i Z_i)$$

where, since Z_2, \dots, Z_p have mean zero and are independent of Z_1 ,

$$\begin{aligned} E_\phi(I(c_f - Z_1 \geq 0) \Lambda_k^T \sum_{i=1}^p (P_i Z_i)) &= E_\phi(I(c_f - Z_1 \geq 0) \Lambda_k^T P_1 Z_1) \\ &= \Lambda_k^T \frac{\boldsymbol{\Sigma}^{1/2} \beta^*}{\|\boldsymbol{\Sigma}^{1/2} \beta^*\|_2} E_\phi(I(c_f - Z_1 \geq 0) Z_1) \\ &= \Lambda_k^T \frac{\boldsymbol{\Sigma}^{1/2} \beta^*}{\|\boldsymbol{\Sigma}^{1/2} \beta^*\|_2} \int_{-\infty}^{+\infty} I(c_f - x \geq 0) x \phi(x) dx \\ &= \Lambda_k^T \frac{\boldsymbol{\Sigma}^{1/2} \beta^*}{\|\boldsymbol{\Sigma}^{1/2} \beta^*\|_2} \int_{-\infty}^{c_f} x \phi(x) dx \end{aligned}$$

Since $x\phi(x)$ is an odd function and $\phi(x)$ is symmetric, we have

$$\int_{-\infty}^{c_f} x \phi(x) dx = \int_{-\infty}^{c_f} x \phi(x) dx = -\frac{1}{\sqrt{2\pi}} \int_{c_f^2}^{+\infty} \frac{1}{2} \exp(-\frac{z}{2}) dz = -\phi(c_f).$$

Therefore, for $k = 1, \dots, p$, $E_f(I(1 - \mathbf{X}^T \beta^* \geq 0) X_k) = \mu_k \Phi(c_f) - \Lambda_k^T \frac{\boldsymbol{\Sigma}^{1/2} \beta^*}{\|\boldsymbol{\Sigma}^{1/2} \beta^*\|_2} \phi(c_f)$. Hence

$$E_f(I(1 - \mathbf{X}^T \beta^* \geq 0) \mathbf{X}_-) = \boldsymbol{\mu} \Phi(c_f) - \phi(c_f) \boldsymbol{\Sigma}^{1/2} \mathbf{P}_1.$$

Similarly,

$$E_g(I(1 + \mathbf{X}^T \beta^* \geq 0) \mathbf{X}_-) = \boldsymbol{\nu} \Phi(c_g) + \phi(c_g) \boldsymbol{\Sigma}^{1/2} \mathbf{P}_1$$

Then, we have

$$\Phi(c_f) = \Phi(c_g) \quad (24)$$

and

$$\mu\Phi(c_f) - \phi(c_f)\Sigma^{1/2}\mathbf{P}_1 = \nu\Phi(c_g) + \phi(c_g)\Sigma^{1/2}\mathbf{P}_1 \quad (25)$$

From (24), we have $\tilde{c} = c_f = c_g$, which implies

$$\beta_-^T(\mu + \nu) = -2\beta_0^* \quad (26)$$

From (25),

$$\frac{\beta_-^*}{\|\Sigma^{1/2}\beta_-^*\|_2} = \frac{\Phi(\tilde{c})}{2\phi(\tilde{c})}\Sigma^{-1}(\mu - \nu) \quad (27)$$

Let $d_\Sigma(\mu, \nu) = ((\mu - \nu)^T \Sigma^{-1} (\mu - \nu))^{1/2}$ be the Mahalanobis distance between μ and ν and $R(x) = \frac{\phi(x)}{\Phi(x)}$. As $\Sigma^{1/2} \frac{\beta_-^*}{\|\Sigma^{1/2}\beta_-^*\|_2}$ has l_2 norm equal to 1, we have $\|\frac{\Phi(\tilde{c})}{2\phi(\tilde{c})}\Sigma^{-1/2}(\mu - \nu)\|_2 = 1$,

i.e., $R(\tilde{c}) = \frac{d_\Sigma(\mu, \nu)}{2}$. $R(x)$ is a monotonically decreasing function, thus we have $\tilde{c} = R^{-1}\left(\frac{d_\Sigma(\mu, \nu)}{2}\right)$. Meanwhile, $\tilde{c} = c_f = \frac{1 - \beta_0^* - \mu^T \beta_-^*}{\|\Sigma^{1/2}\beta_-^*\|_2}$, we can solve the problem based on (26) and (27),

$$\beta_0^* = -\frac{(\mu - \nu)^T \Sigma^{-1} (\mu + \nu)}{2\tilde{c}d_\Sigma(\mu, \nu) + d_\Sigma^2(\mu, \nu)} \quad (28)$$

From (25),

$$\beta_-^* = \frac{2\Sigma^{-1}(\mu - \nu)}{2\tilde{c}d_\Sigma(\mu, \nu) + d_\Sigma^2(\mu, \nu)} \quad (29)$$

By plugging (28) and (29) into (7), we can calculate $H(\beta^*)$ as

$$H(\beta^*) = \frac{\phi(\tilde{c})}{4}(2\tilde{c} + d_\Sigma(\mu, \nu)) \begin{pmatrix} 2 & (\mu + \nu)^T \\ \mu + \nu & H_{22}(\beta^*) \end{pmatrix} \quad (30)$$

where

$$H_{22}(\beta^*) = \mu\mu^T + \nu\nu^T + 2\Sigma + 2 \left(\left(\frac{\tilde{c}}{d_\Sigma(\mu, \nu)} \right)^2 + \frac{\tilde{c}}{d_\Sigma(\mu, \nu)} - \frac{1}{d_\Sigma^2(\mu, \nu)} \right) (\mu - \nu)(\mu - \nu)^T$$

As we have obtained the analytic form of $H(\beta^*)$, we consider Model 1 in Section 5.1 as an example. In Model 1, $q = 5$, $\mu = (0.1, 0.2, 0.3, 0.4, 0.5, 0, \dots, 0)^T$ and $\nu = (-0.1, -0.2, -0.3, -0.4, -0.5, 0, \dots, 0)^T \in \mathbb{R}^p$ and $\pi^+ = \pi^- = 1/2$. The covariance matrix $\Sigma = (\sigma_{ij})$ consists of nonzero entries $\sigma_{ij} = -0.2$ for $1 \leq i \neq j \leq q$ and other entries equal to 0. From (28) and (29), we have $\beta^* = (0, 1.39, 1.47, 1.56, 1.65, 1.74, 0, \dots, 0)^T$. Based on (30), we derived $H(\beta^*)$ and numerically validated its positive-definiteness.

Abstract

Conditional random fields maximize the log-likelihood of training labels given the training data, e.g., objects given images. In many cases the training labels are structures that consist of a set of variables and the computational complexity for estimating their likelihood is exponential in the number of the variables. Learning algorithms relax this computational burden using approximate inference that is nested as a sub-procedure. In this paper we describe the objective function for nested learning and inference in conditional random fields. The devised objective maximizes the log-beliefs — probability distributions over subsets of training variables that agree on their marginal probabilities. This objective is concave and consists of two types of variables that are related to the learning and inference tasks respectively. Importantly, we afterwards show how to blend the learning and inference procedure and effectively get to the identical optimum much faster. The proposed algorithm currently achieves the state-of-the-art in various computer vision applications.

1. Introduction

Learning and inference of structured models drives much of the research in machine learning applications, from computer vision and natural language processing to computational biology. Examples include object detection (e.g., by Felzenszwalb et al. (2010)), parsing (e.g., by Koo et al. (2010)), or protein design (e.g., by Sontag et al. (2008)). The inference problem in these cases involves assessing the likelihood of labelings, whether outlined objects, parse trees, or molecular structures. The learning procedure searches for the parameters that maximize the likelihood of the training set.

Conditional random fields (CRFs) form an effective framework for maximizing the log-likelihood of training labels in structured models. Learning the parameters of these models

can be computationally expensive since the label space of real-world problems is usually exponential in the size of its variables.

When the label structure corresponds to a tree, exactly inferring the likelihood of the training labels can be done in time, linear in the number of variables using sum-product belief propagation as a subroutine. We refer to this approach as nested learning and inference. In contrast, when the label structure corresponds to a general graph, we cannot infer the likelihood exactly. However nested learning and inference can still be applied using approximate inference algorithms such as convex sum-product belief propagation (Wainwright et al., 2005; Heskes, 2006; Meltzer et al., 2009; Hazan and Shashua, 2010). Nevertheless, the approximate inference algorithms might be computationally expensive to be used as a nested subroutine of the learning algorithm.

In this article we suggest to interleave optimization of learning parameters with optimization of inference parameters. We call this approach blending learning and inference in CRFs. For this end we propose an optimization program that maximizes log-beliefs, i.e., probability distributions over subsets of training variables that agree on their marginal probabilities. These beliefs are elements of the local polytope (Wainwright and Jordan, 2008). The log-beliefs objective is concave and consists of two types of variables that are related to the learning and inference tasks respectively. We are able to blend the learning and inference procedures by alternating maximizations over the inference and learning variables. With blending we reach the nested learning-inference optimum much faster.

We also define loss-adjusted beliefs to integrate prior knowledge about the desired inference as well as a parameter that controls the smoothness of the beliefs. In the past and partly due to its efficiency, the presented machine learning algorithm was shown to improve the state-of-the-art in various computer vision tasks, including 2D scene understanding (Yao et al., 2012), 3D scene understanding (Lin et al., 2013), shape reconstruction (Salzmann and Urtasun, 2012), indoor scene understanding (Schwing et al., 2012a; Schwing and Urtasun, 2012), depth estimation (Yamaguchi et al., 2012), flow estimation (Yamaguchi et al., 2013) and visual-language understanding (Fidler et al., 2013). This manuscript extends our previous work (Hazan and Urtasun, 2010) to high order setting while simplifying its theory and proofs. The code is publicly available on <http://www.alexander-schwing.de/projects/GeneralStructuredPrediction/LatentVariables.php>.

The reminder of the paper is organized as follows. In Section 3 we review the parameter learning setting of CRFs that maximize the log-likelihood of training labels given corresponding data instances. We also present the nested learning and inference approach as well as approximate inference algorithms of belief propagation and its convex variants. In Section 4 we describe the objective function for nested learning and inference that maximize the log-beliefs. We then describe a blending algorithm to optimize this objective and describe its convergence properties using convex duality. Next we present loss-adjusted beliefs and the appropriate modifications for blending in Section 5, drawing connections to blending in the structured SVMs setting suggested by Meshi et al. (2010). We then demonstrate the effectiveness of our approach in Section 6. We conclude by describing the generality of our approach, relating blending and convexity to the penalty method.

2. Related work

Learning log-beliefs extends the CRFs framework that maximizes the log-likelihood of conditional Gibbs distributions (cf. Lafferty et al. (2001); Lebon and Lafferty (2002)). Gibbs distributions, also known as Markov random fields, are probability distributions that are defined on a product space using potential functions over subsets of variables. Gibbs probability models often consider exponentially many possible assignments for these variables. In this case, approximate inference methods are used in a black box manner to estimate the gradient and the objective of CRFs, resulting in the nested learning-inference algorithm illustrated in Figure 1. Nested learning-inference algorithms are successfully dealing with real-world problems, e.g.: (Levin and Weiss, 2006) in computer vision, (Yanover et al., 2007) in computational biology and (Sutton and McCallum, 2009) in language processing to name a few.

The current work extends and simplifies our previous work (Hazan and Urtasun, 2010). We simplify the learning objective while formulating it as the maximization of log-beliefs, which are pseudo-marginal probabilities of the Gibbs distribution. We extend the learning procedure while considering pseudo-marginals of Gibbs distributions on any subset of its variables. In the last couple of years, the presented machine learning algorithm was shown to improve the state-of-the-art in various computer vision tasks: Considering outdoor scene understanding (Yao et al., 2012), each (super)pixel is represented by a variable of the Gibbs model and its possible assignments correspond to discrete semantic label, e.g., person, car, tree and so on. Our learning algorithm estimates the parameters that maximize the probability of the training data per variable (i.e., pixel and its observed object) and subsets of variables (e.g., neighborhood of pixels and their observed objects). Considering indoor scene understanding (Schwing et al., 2012a; Schwing and Urtasun, 2012; Lin et al., 2013) each wall or a 3D object in the room is represented by a subset of variables and our learning algorithm estimates the position of these objects while maximizing likelihood of these subsets within the training data. In depth estimation and optimal flow (Yamaguchi et al., 2012, 2013) the variables of the Gibbs models are either continuous or discrete. The continuous variables correspond to the possible hyperplanes that either explain the depth or the optical flow of the super pixels in the training images. The discrete variables maintain consistency between adjacent super pixels. Our learning algorithm estimates the probable hyperplanes and their spatial relations in the training data.

Our approach suggests to blend the inference and learning steps and reach the same optimum as nested approaches while being at least an order of magnitude faster. Blending helps the algorithm to avoid computationally expensive inference algorithms when learning parameters w that are far from optimal. Similar observations have been made in the context of coordinate descent by Tappen et al. (2013). Other approaches for blending CRFs appear are developed by Donke (2011). Lemma 3 describes how to infer non-consistent beliefs. These beliefs are different from the beliefs that are usually derived during the runtime of approximate inference algorithms. The theoretical characterization of the optimal points for the learning-inference procedures are described by Wainwright (2006); Wainwright et al. (2003).

Meshi et al. (2010) describe blending learning and inference in the context of structured SVMs, which are constructed to minimize the loss between the predicted labels and the

observed ones (cf. Taskar et al., 2004; Tschantz et al., 2004; Collins, 2002)). The ideas of blending learning and inference in structured SVMs also appear in (Taskar et al., 2005; Anguelov et al., 2005). In contrast, our work focuses on blending learning and inference when maximizing log-probabilities. Nevertheless, our loss-adjusted beliefs may describe a probabilistic alternative to blended learning in structured-SVMs. When setting the counting numbers $c_r = 0$, we effectively work with zero-one probabilities (i.e., max-beliefs) thus we recover the algorithm of Meshi et al. (2010).

3. Background

Log-likelihood learning in structured models involves data instances $x \in \mathcal{X}$ and their labels $y \in \mathcal{Y}$. The structure is incorporated into the labels which may refer to sequences, grids, or other high-dimensional objects. For every data instance x , its possible labels are described by a set of feature functions $\phi_k : \mathcal{X} \times \mathcal{Y} \rightarrow \mathbb{R}$, $k \in \{1, \dots, K\}$. A linear combination of the K features is used to score the different labels $y \in \mathcal{Y}$ using the parameters $w \in \mathbb{R}^K$. Formally we obtain the score $\theta(y; x, w)$ of a label via

$$\theta(y; x, w) = \sum_k w_k \phi_k(x, y).$$

The real valued score is mapped to the probability scale via the Gibbs distribution:

$$p(y|x; w) \propto \exp(\theta(y; x, w)). \quad (1)$$

Within the CRF framework, the goal is to learn the parameters of the potential functions to maximize the conditional likelihood of the training data $(x, y) \in \mathcal{S}$:

$$\max_w \sum_{(x,y) \in \mathcal{S}} \log p(y|x; w) - \frac{C}{2} \|w\|_2^2. \quad (2)$$

The regularization term is sometimes considered as a Gaussian prior over the parameters w . The regularized likelihood of CRFs is a concave and smooth function and its optimal parameters may be attained by gradient ascent. The gradient measures the disagreements between the inferred distribution over labels and the groundtruth training labels, i.e.,

$$\frac{\partial \log p(y|x; w)}{\partial w_k} = \sum_{g \in \mathcal{Y}} p(g|x; w) \phi_k(x, g) - \phi_k(x, y). \quad (3)$$

The computational complexity of CRFs is governed by inference, which amounts to evaluating the probability $p(g|x; w)$ for computing the objective and the gradient.

We consider cases in which the labels $y \in \mathcal{Y}$ are n -tuples, i.e., $y = (y_1, \dots, y_n)$, and hence the configuration space is exponential in n . The features describe relations between subsets of elements $r \subset \{1, \dots, n\}$, also called regions or factors. We denote by \mathcal{R}_k the regions required to compute the feature $\phi_k(x, y)$. Importantly, the features are functions of their regions labels $y_r \subset \{y_1, \dots, y_n\}$, i.e.,

$$\phi_k(x, y_1, \dots, y_n) = \sum_{r \in \mathcal{R}_k} \phi_{k,r}(x, y_r). \quad (4)$$

Thus the features define hypergraphs whose nodes represent the n labels indexes, and the regions $\mathcal{R} = \cup_k \mathcal{R}_k$ correspond to its hyperedges. A convenient way to represent a hypergraph is by its region graph. A region graph is a directed graph whose nodes represent the regions and its direct edges correspond to the inclusion relation, i.e., a directed edge from node r to s is possible only if $s \subset r$. We adopt the terminology where the sets $P(r)$ and $C(r)$ represent all nodes that are parents and children of the node r , respectively.

The Hammersley-Clifford theorem (e.g., Lauritzen (1996)) asserts that the Gibbs distributions $p(\hat{y}|x; w)$ defined in Equation (1) correspond to a Markov random field (MRF) whose statistical independencies are described by the joint hypergraph. These independencies are determined by the Markov property: two nodes in the graph are conditionally independent when they are separated by observed nodes. Aji and McEliece (2001) show that whenever the region graph is bipartite and has no cycles, the Markov property provides a low dimensional representation of the Gibbs distribution using its marginal probabilities $p(\hat{y}_r|x; w) = \sum_{\hat{y}_{\setminus r}} p(\hat{y}|x; w)$, namely

$$p(\hat{y}|x; w) = \prod_{r \in \mathcal{R}} p(\hat{y}_r|x; w)^{1-|P(r)|}. \quad (5)$$

In such cases the inference step, i.e., estimating the probabilities $p(\hat{y}|x; w)$ can be performed efficiently using message-passing algorithms. When the region graph has no cycles it is bipartite, therefore it has two types of regions: outer regions, i.e., regions that are not contained by other regions, and inner regions. To differentiate between those regions we denote outer regions by α and inner regions by i . In this case, one can use the belief propagation algorithm to efficiently infer the marginal probabilities without performing exponentially many operations:

Algorithm 1 Sum-product belief propagation

Set $\mathcal{K}_r = \{k : r \in \mathcal{R}_k\}$. For every (x, y) , we set $\theta_r(\hat{y}_r) = \sum_{k \in \mathcal{K}_r} w_k \phi_{k,r}(x, \hat{y}_r)$.

Repeat until convergence:

$$\mu_{\alpha \rightarrow i}(y_i) = \log \left(\sum_{y_\alpha \setminus y_i} \exp \left((\theta_\alpha(y_\alpha) + \sum_{j \in C(\alpha) \setminus i} \lambda_{j \rightarrow \alpha}(y_j)) \right) \right)$$

$$\lambda_{i \rightarrow \alpha}(y_i) = \theta_i(y_i) + \sum_{\beta \in P(i) \setminus \alpha} \mu_{\beta \rightarrow i}(y_i)$$

Output:

$$b_i(y_i) \propto \exp \left(\theta_i(y_i) + \sum_{\alpha \in P(i)} \mu_{\alpha \rightarrow i}(y_i) \right)$$

$$b_\alpha(y_\alpha) \propto \left(\theta_\alpha(y_\alpha) + \sum_{i \in C(\alpha)} \lambda_{i \rightarrow \alpha}(y_i) \right)$$

The marginal probabilities $p(\hat{y}_r|x; w)$ appear as the beliefs $b_r(\hat{y}_r)$. In general, when the region graph has cycles, the belief propagation algorithm is no longer guaranteed to output the marginal probabilities. Nevertheless, when it converges it provides beliefs that agree on their marginal probabilities, namely $\sum_{y_\alpha \setminus y_i} b_\alpha(y_\alpha) = b_i(y_i)$. In some cases the belief propagation algorithm infers beliefs $b_r(\hat{y}_r)$ which approximate well the marginal probabilities, while in other cases it produces non-accurate results or might even fail to converge. A possi-

ble explanation for this behavior comes from the fact that the belief propagation algorithm iterates the stationary points of a non-convex objective called the Bethe free energy (Yedidia et al., 2005). Recently, in an extensive effort to derive converging belief propagation type algorithms, the non-convex Bethe free energy was replaced by convex free energies while introducing nonnegative counting numbers c_r that replace the Bethe coefficients. Consequently, the belief propagation algorithm was replaced by block coordinate descent over the dual program (Heskes, 2006; Meltzer et al., 2009; Hazan and Shashua, 2008). These dual block coordinate descent algorithms belong to the family of the norm-product belief propagation algorithms:

Algorithm 2 Norm-Product Belief Propagation

Set $\hat{c}_i = c_i + \sum_{\alpha \in P(i)} c_\alpha$. Repeat until convergence:

$$\mu_{\alpha \rightarrow i}(y_i) = c_\alpha \log \left(\sum_{y_\alpha \setminus y_i} \exp \left((\theta_\alpha(y_\alpha) + \sum_{j \in C(\alpha) \setminus i} \lambda_{j \rightarrow \alpha}(y_j)) / c_\alpha \right) \right)$$

$$\lambda_{i \rightarrow \alpha}(y_i) = \frac{c_i}{c_i} \left(\theta_i(y_i) + \sum_{\beta \in P(i)} \mu_{\beta \rightarrow i}(y_i) \right) - \mu_{\alpha \rightarrow i}(y_i)$$

Output:

$$b_i(y_i) \propto \exp \left(\theta_i(y_i) + \sum_{\alpha \in P(i)} \mu_{\alpha \rightarrow i}(y_i) \right)^{1/c_i}$$

$$b_\alpha(y_\alpha) \propto \exp \left(\theta_\alpha(y_\alpha) + \sum_{i \in C(\alpha)} \lambda_{i \rightarrow \alpha}(y_i) \right)^{1/c_\alpha}$$

The norm-product algorithm, illustrated in Algorithm 2, reduces to belief propagation when setting its coefficients to $c_r = 1 - |P(r)|$, namely, the Bethe counting numbers. We refer the interested reader to (Wainwright and Jordan, 2008) for more details.

The norm-product algorithm iterates over the fixed point solutions for the variational problem

$$\arg \max_{b \in L(\mathcal{C})} \sum_{r \in \mathcal{R}} b_r(y_r) \theta_r(y_r) + \sum_r c_r H(b_r). \quad (6)$$

The set $L(\mathcal{C})$ is known as the local polytope, and contains probability distributions $b_r(y_r)$ that agree on their overlapping variables, i.e.,

$$L(\mathcal{C}) = \left\{ b_r(y_r) : b_r(y_r) \geq 0, \sum_{y_r} b_r(y_r) = 1, \forall p \in P(r) \sum_{y_p \setminus y_r} b_p(y_p) = b_r(y_r) \right\}. \quad (7)$$

Throughout this work we refer to elements in the local polytope as beliefs.

The variational program given in Equation (6) is concave whenever $c_r \geq 0$. The norm-product algorithm given in Algorithm 2 performs block coordinate descent on its dual program. Therefore it is guaranteed to converge to beliefs that agree on their marginal probabilities. Typically its inferred beliefs approximate the marginal probabilities as well as the belief propagation approximations (Meshi et al., 2009). Thus in its various forms it is used as the inference step when learning the parameters of CRFs. Such nested loop algorithms for performing learning and inference are presented in Figure 1. Unfortunately, iteratively executing the norm-product algorithm as an inference procedure to compute

Learning with nested inference for CRFs

1. Set $\theta_r(y_r; x, w) = \sum_{k \in K_r} w_k \phi_{k,r}(x, y_r)$. Repeat until convergence:
2. Inference: For every $(x, y) \in S$:

$$b^* = \arg \max_{b(\cdot|x) \in L(G)} \sum_{r \in \mathcal{R}} \sum_{y_r \in \mathcal{Y}_r} b_r(y_r|x) \theta_r(y_r; x, w) + \sum_{r \in \mathcal{R}} H(b_r).$$

3. Learning:

$$w_k \leftarrow w_k - \eta \left(\sum_{(x,y) \in S} \sum_{r \in \mathcal{R}} \left(\sum_{y_r} b_r^*(y_r|x) \phi_{k,r}(x, y_r) - \phi_{k,r}(x, y_r) \right) + C w_k \right).$$

Figure 1: Nested (unblended) inference in learning. The inference step is performed in every iteration. The learning step improves the parameters till learning is attained. η is typically referred as the learning rate and may be set as $1/\sqrt{t}$, where t is the iteration index. The abbreviation $b \in L(G)$ describes conditional beliefs $b(\cdot|x)$ for every $x \in S$. Each of these conditional beliefs is in the local polytope, as defined in Equation (7).

the gradient is computationally demanding and this method has not been used widely (see Section 2 for more details). In the following we explore duality to provide the means to blend the learning and inference tasks efficiently.

4. Blending learning and inference

Log-likelihood of Gibbs distributions, as defined in Equation (1) with potentials $\theta(y; x, w)$ that are linear functions of their parameters w , results in a concave program. When using nested (unblended) inference, the learning algorithm executes a concave program for inferring beliefs about its marginal probabilities that are required for computing its gradient. Our main result explicitly defines the concave program whose optimal solutions are the limit points of the nested learning and inference algorithm that is shown in Figure 1. Using this characterization we are able to derive an algorithm that blends the learning and inference steps. Consequently it is orders of magnitude faster than the nested algorithm that uses inference as a black-box algorithm. Since our blended algorithm optimizes a concave program, it is guaranteed to reach the same optimum as the nested algorithm.

Theorem 1 *The limit points of the nested inference and learning algorithm in Figure 1 are described by the optimal points of the following concave program maximizing log-beliefs:*

$$\begin{aligned} & \max_{w, \lambda} \sum_{(x,y) \in S} \sum_{r \in \mathcal{R}} \log b_r(y_r|x; w, \lambda) - \frac{C}{2} \|w\|^2 \\ \text{s.t. } & b_r(y_r|x; w, \lambda) \propto \exp \left(\theta_r(y_r; x, w) + \sum_{c \in C(r)} \lambda_{c \rightarrow r}(y_c; x) - \sum_{p \in P(r)} \lambda_{r \rightarrow p}(y_r; x) \right) \end{aligned}$$

Proof The theorem replaces maximization over $b \in L(G)$ with maximization over λ . Decoupling the maximizations takes the form $\max_w \sum_{(x,y) \in S} \left(\max_{\lambda} \left\{ \sum_{r \in \mathcal{R}} \log b_r(y_r|x; w, \lambda) \right\} \right)$. In the following we show how to derive the result from Lagrange optimality conditions (KKT):

$$\begin{aligned} \lambda^* &= \arg \max_{\lambda} \sum_{r \in \mathcal{R}} \log b_r(y_r|x; w, \lambda) \\ b^* &= \arg \max_{b \in L(G)} \sum_{r \in \mathcal{R}} \sum_{y_r \in \mathcal{Y}_r} b_r(y_r|x) \theta_r(y_r; x, w) + \sum_{r \in \mathcal{R}} H(b_r) \\ &\implies b_r^*(y_r|x) \propto \exp \left(\theta_r(y_r; x, w) + \sum_{c \in C(r)} \lambda_{c \rightarrow r}^*(y_c; x) - \sum_{p \in P(r)} \lambda_{r \rightarrow p}^*(y_r; x) \right) \end{aligned} \quad (8)$$

Using the above Lagrange optimality conditions, the theorem follows since the inference nested within the learning algorithm applies gradient ascent to the following program:

$$\max_w \sum_{(x,y) \in S} \left(\max_{\lambda} \left\{ \sum_{r \in \mathcal{R}} \log b_r(y_r|x; w, \lambda) \right\} - \frac{C}{2} \|w\|^2 \right) = \max_w \sum_{(x,y) \in S} \sum_{r \in \mathcal{R}} \log b_r^*(y_r|x) - \frac{C}{2} \|w\|^2.$$

Equation (8) states the Lagrange optimality conditions for maximum-likelihood maximum-entropy type duality. Consider the constrained inference algorithm in Figure (1) and the Lagrange multipliers $\lambda_{r \rightarrow p}(y_r; x, w)$ for the marginalization constraints $\sum_{y_r} b_r(y_r|x) = b_r(y_r|x)$. Its corresponding Lagrangian is $L(b, \lambda) = \sum_{r, y_r} b_r(y_r|x) \theta_r(y_r; x, w, \lambda) + \sum_r H(b_r)$ where $\theta_r(y_r; x, w, \lambda) = \theta_r(y_r; x, w) + \sum_{c \in C(r)} \lambda_{c \rightarrow r}(y_c; x) - \sum_{p \in P(r)} \lambda_{r \rightarrow p}(y_r; x)$. Its dual function is $q(\lambda) = \max_b L(b, \lambda)$ while $b_r(y_r|x)$ are subject to probability constraints. Conjugate duality between the entropy function and the log-partition function (cf. Wainwright and Jordan (2008)) implies that $q(\lambda) = \sum_r \log \left(\sum_{y_r} \exp(\theta_r(y_r; x, w, \lambda)) \right)$. Since strong duality between the entropy and the log-partition function holds, its Lagrange optimality conditions imply

$$\lambda^* = \arg \min_{\lambda} \sum_{r \in \mathcal{R}} \log \left(\sum_{y_r} \exp(\theta_r(y_r; x, w, \lambda)) \right).$$

The theorem then follows since $\sum_{r \in \mathcal{R}} \sum_{p \in P(r)} \lambda_{r \rightarrow p}(y_r; x) - \sum_{r \in \mathcal{R}} \sum_{c \in C(r)} \lambda_{c \rightarrow r}(y_c; x) \equiv 0$ therefore $\sum_r \log b_r^*(y_r|x) = -q(\lambda^*)$ and the Lagrange optimality conditions in Equation (8) hold. Thus $b_r^*(y_r|x)$ can be replaced by its re-parameterization $\frac{1}{Z_r} \exp(\theta_r(y_r; x, w, \lambda^*))$, with $Z_r = \sum_{y_r} \exp(\theta_r(y_r; x, w, \lambda^*))$. ■

The maximum log-beliefs program describes the variational landscape of nested inference in learning. Thus it can be used to measure the step-size η in Figure 1. For example, the Armijo rule that determines the step size according to the variational neighborhood results in a faster convergence per iteration than using a fixed learning rate.

The nested learning and inference algorithm performs a complete inference step before performing a single learning step. The inference step derives beliefs that agree on their marginal probabilities. In this work we use the maximum log-beliefs concave program to blend the learning and inference steps. Specifically, we use block coordinate ascent steps

to blend learning (optimization w.r.t. w) with incomplete inference steps (optimization w.r.t. λ) that derive beliefs $b_r(y_r|x; w, \lambda)$ that not necessarily agree on their marginal probabilities, i.e., $\sum_{y_p \in \mathcal{Y}_p} b_p(y_p|x; w, \lambda) = b_r(y_r|x; w, \lambda)$. Such an approach is computationally favorable since it does not require to perform a complete inference step for initial learning parameters. Concavity ensures that blending reaches the maximum log-beliefs optimum thus it guarantees to derive consistent beliefs upon convergence.

Performing block coordinate descent on the maximum log-beliefs program in Theorem 1 requires minimizing a block of variables while holding the rest fixed. We begin by describing how to infer the optimal set of variables $\lambda_{r \rightarrow p}(y_r; x)$ that are related to a region and its parents in the graphical model.

Lemma 2 Blended inference: *Consider the program given in Theorem 1. For a given region r , the optimal inference parameters $\lambda_{r \rightarrow p}^*(y_r; x)$, for every $p \in P(r)$, $y_r \in \mathcal{Y}_r$, $x \in \mathcal{S}$, when fixing all other λ takes the following form:*

$$\begin{aligned} \mu_{p \rightarrow r}(y_p; x) &= \log \left(\sum_{y_p \in \mathcal{Y}_p} \exp(\theta_p(y_p; x; w) + \sum_{c \in C(p) \setminus r} \lambda_{c \rightarrow p}(y_c; x) - \sum_{p' \in P(p)} \lambda_{p \rightarrow p'}(y_{p'}; x)) \right) \\ \lambda_{r \rightarrow p}^*(y_r; x) &= \frac{\theta_r(y_r; x; w) + \sum_{c \in C(r)} \lambda_{c \rightarrow r}(y_c; x) + \sum_{p' \in P(r)} \mu_{p' \rightarrow r}(y_{p'}; x)}{1 + |P(r)|} - \mu_{p \rightarrow r}(y_p; x) \end{aligned}$$

Proof The maximum log-beliefs program in Theorem 1 is smooth, concave and unconstrained as a function of λ , therefore the optimum is achieved when the gradient vanishes. Setting

$$\theta_r(y_r; x; w, \lambda) = \theta_r(y_r; x; w) + \sum_{c \in C(r)} \lambda_{c \rightarrow r}(y_c; x) - \sum_{p \in P(r)} \lambda_{r \rightarrow p}(y_p; x) \quad (9)$$

and $b_r(y_p|x; w, \lambda) \propto \exp(\theta_r(y_p|x; w, \lambda))$, the gradient with respect to $\lambda_{r \rightarrow p}(y_p; x)$ takes the form

$$\frac{\partial \sum_{(x, y), r} \log b_r(y_r|x; w, \lambda)}{\partial \lambda_{r \rightarrow p}(y_r; x)} = \sum_{y_p \in \mathcal{Y}_p} b_p(y_p|x; w, \lambda) - b_r(y_r|x; w, \lambda).$$

The optimal dual variables are those for which the gradient vanishes, i.e., the corresponding beliefs agree on their marginal probabilities. When setting $\mu_{p \rightarrow r}(y_r; x)$ as above, the marginalization of $b_p(y_p|x; w, \lambda)$ satisfies

$$\sum_{y_p \in \mathcal{Y}_p} b_p(y_p|x; w, \lambda) \propto \exp(\mu_{p \rightarrow r}(y_r; x) + \lambda_{r \rightarrow p}(y_r; x)).$$

Therefore, by taking the logarithm, the gradient vanishes whenever the beliefs numerators agree up to an additive constant:

$$\sum_{y_p \in \mathcal{Y}_p} b_p(y_p|x; w, \lambda^*) - b_r(y_r|x; w, \lambda^*) = 0 \iff \mu_{p \rightarrow r}(y_r; x) + \lambda_{r \rightarrow p}^*(y_r; x) = \theta_r(y_r; x; w, \lambda^*).$$

The right hand side of the condition almost characterizes completely the optimal variables $\lambda_{r \rightarrow p}^*(y_r; x)$ by $\lambda_{r \rightarrow p}^*(y_r; x) = \theta_r(y_r; x; w, \lambda^*) - \mu_{p \rightarrow r}(y_r; x)$. Unfortunately, $\theta_r(y_r; x; w, \lambda^*)$ depends on $\sum_{p \in P(r)} \lambda_{r \rightarrow p}^*(y_r; x)$ thus it cannot serve as an update rule in its current form.

To complete the proof we require to replace $\sum_{p \in P(r)} \lambda_{r \rightarrow p}^*(y_r; x)$ with another quantity that does not depend on $\lambda_{r \rightarrow p}^*(y_r; x)$ for every $p \in P(r)$ and $y_r \in \mathcal{Y}_r$.

To isolate this quantity we sum both sides of the equality $\mu_{p \rightarrow r}(y_r; x) + \lambda_{r \rightarrow p}^*(y_r; x) = \theta_r(y_r; x; w, \lambda^*)$ with respect to $p \in P(r)$, thus we are able to obtain

$$(1 + |P(r)|) \sum_{p \in P(r)} \lambda_{r \rightarrow p}^*(y_r; x) = |P(r)|(\theta_r(y_r; x; w) + \sum_{c \in C(r)} \lambda_{c \rightarrow r}(y_c; x)) - \sum_{p \in P(r)} \mu_{p \rightarrow r}(y_r; x)$$

Plugging it into the above equation results in the desired block dual ascent update rule. ■

One can verify that since the program is not strictly concave in λ , the optimal solutions can be achieved for every additive shift of $\lambda_{r \rightarrow p}(y_r; x)$. The above lemma describes an analytic solution for the optimal $\lambda_{r \rightarrow p}(y_r; x)$, that are computed in the block coordinate steps of the algorithm. In practice, block coordinate descent with analytic steps provides a significant speedup over conventional gradient methods and can be parallelized and distributed easily, as shown by Schwing et al. (2011).

A learning step updates the weights w so as to maximize the log-beliefs. When using blended inference, the beliefs are not required to agree on their marginal probabilities. However, they are governed by the concave program in Theorem 1. Its concavity guarantees that these beliefs agree on their marginals at the optimum.

Lemma 3 Blended learning: *Consider the program given in Theorem 1. The gradient of its objective function with respect to w_k takes the form:*

$$\sum_{(x, y) \in \mathcal{S}} \sum_{r \in \mathcal{R}_k} \sum_{\hat{y}_r \in \mathcal{Y}_r} b_r(\hat{y}_r|x; w, \lambda) \phi_{k,r}(x, \hat{y}_r) - \phi_{k,r}(x, y_r) + C w_k.$$

Proof We let

$$\log b_r(y_r|x; w, \lambda) = \theta_r(y_r; x; w, \lambda) - \log \left(\sum_{\hat{y}_r} \exp(\theta_r(\hat{y}_r; x; w, \lambda)) \right).$$

The theorem follows by noting that $\theta_r(y_r; x; w) = \sum_{k \in \mathcal{K}_r} w_k \phi_{k,r}(x, y_r)$, recalling the definition of $\theta_r(y_r; x; w, \lambda)$ in Equation (9) and that $b_r(\hat{y}_r|x; w, \lambda)$ which is defined in Theorem 1 is the gradient of its log-partition function, i.e., $\log \left(\sum_{\hat{y}_r} \exp(\theta_r(\hat{y}_r; x; w, \lambda)) \right)$. ■

The computational complexity of the gradient depends on the structure of the features, especially the number of regions and their labels. Our framework prefers features with small regions and reasonable number of labels. Another computational issue relates to the step size η for increasing the objective along the gradient of w_k . In general, the gradient updates verify that the chosen step size η reduces the objective. Theoretically, we can use the fact that the gradient is Lipschitz continuous to predetermine a step size that guarantees ascent. In practice it gives worse performance than searching for a step size depending on the gradient and the objective at any given point.

Lemmas 2 and 3 describe the inference and learning steps for maximizing the log-beliefs maximization in Theorem 1. Since the program is concave, the order of the maximization steps is not important, and as long as all inference and learning parameters are optimized the maximal value is attained. For example, one can maximize the inference variables λ till

Blending learning and inference

1. Set $\theta_r(\hat{y}_r; x, w) = \sum_{k \in K_r} w_k \phi_{k,r}(x, \hat{y}_r)$. Repeat until convergence:
2. For every $(x, y) \in \mathcal{S}$, $r \in \mathcal{R}$, $\hat{y}_r \in \mathcal{Y}_r$, $p \in P(r)$:

$$H_{p \rightarrow r}(\hat{y}_r; x) = \log \left(\sum_{\hat{y}_p \in \mathcal{Y}_p} \exp(\theta_r(\hat{y}_p; x, w)) + \sum_{c \in C(p)} \lambda_{c \rightarrow p}(\hat{y}_c; x) - \sum_{p' \in P(p)} \lambda_{p \rightarrow p'}(\hat{y}_p; x) \right)$$

$$\lambda_{r \rightarrow p}(\hat{y}_r; x) = \frac{\theta_r(\hat{y}_r; x, w) + \sum_{c \in C(r)} \lambda_{c \rightarrow r}(\hat{y}_c; x) + \sum_{p' \in P(r)} H_{p' \rightarrow r}(\hat{y}_p; x)}{1 + |P(r)|} - |H_{p \rightarrow r}(\hat{y}_r; x)|$$
3. Set $b_r(\hat{y}_r|x; w, \lambda) \propto \exp(\theta_r(\hat{y}_r; x, w) + \sum_{c \in C(r)} \lambda_{c \rightarrow r}(\hat{y}_c; x) - \sum_{p \in P(r)} \lambda_{r \rightarrow p}(\hat{y}_r; x))$.

$$w_k \leftarrow w_k - \eta \left(\sum_{(x,y) \in \mathcal{S}} \sum_{r \in \mathcal{R}_k} \sum_{\hat{y}_r \in \mathcal{Y}_r} \left(\sum_{p \in P(r)} b_r(\hat{y}_p|x; w, \lambda) \phi_{k,r}(x, \hat{y}_p) - \phi_{k,r}(x, \hat{y}_r) \right) + C w_k \right).$$

Figure 2: The inference step is described in Lemma 2 and the learning step is described in Lemma 3. The step size η is set to guarantee convergence (e.g., corresponding to the Lipschitz constant or the Armijo rule.) Concavity of the program in Theorem 1 ensures that the blending converges to consistent inferred beliefs, see Theorem 4.

they do not change before optimizing the learning parameters w . We refer to this approach in Figure 1 as nested inference within learning since it performs the approximate inference heuristic described in Section 3 as a black-box solver. Nested learning and inference is computationally unfavorable in general as it requires to infer λ till convergence for every gradient step for learning w . Since concavity ensures that the maximization does not depend on the order of the maximizing steps, it also provides a principled way to blend the learning and inference steps. Particularly, it may learn the w parameters using inferred beliefs $b_r(\hat{y}_r|x; w, \lambda) \propto \exp(\theta_r(\hat{y}_r; x, w, \lambda))$ that do not agree on their marginal probabilities. For this purpose our algorithm infers the parametrized beliefs *differently* than the (outer) beliefs that are computed by the nested learning algorithm in Figure 1. This blending property is important in practice, since shortly upon initialization, where the given parameters w are far from the optimum, it is not advisable to spend time on computing consistent beliefs. Figure 2 summarizes the inference-learning blending algorithm.

The block coordinate descent algorithm is guaranteed to converge, as it monotonically increases the log-beliefs in Theorem 1, which are upper bounded by its dual. Moreover, the values that are generated by the algorithm converge to the program's optimal value (see Theorem 4 for exact statement). It is not immediately clear that the algorithm converges to its optimal value since the program is not strictly concave. Consequently, the sequence of variables $\lambda_{r \rightarrow p}(\hat{y}_r; x)$ generated by the algorithm is not guaranteed to be bounded. As a trivial example, adding an arbitrary constant to the variables, $\lambda_{r \rightarrow p}(\hat{y}_r; x) + c$, does not

change the objective value, hence the algorithm can generate a monotonically decreasing unbounded sequences. Convergence to the optimum holds by convex duality:

Theorem 4 *The learning-inference blending algorithm in Figure 2 for log-beliefs maximization is guaranteed to converge. Moreover, the value of its objective is guaranteed to converge to the global maximum, and its sequence of beliefs are guaranteed to converge to consistent beliefs that are the unique solution of the dual program*

$$\min_{z_{b_r}} \sum_{(x,y) \in \mathcal{S}} \frac{1}{2C} \|z\|^2 - \sum_{r \in \mathcal{R}} H(b_r)$$

$$\text{subject to } b_r(\hat{y}_r|x) \geq 0, \quad \sum_{p \in P(r)} b_r(\hat{y}_p|x) = 1, \quad b_r(\hat{y}_r|x) = \sum_{\hat{y}_p \in \mathcal{Y}_p} b_p(\hat{y}_p|x)$$

$$z_k = \sum_{(x,y) \in \mathcal{S}} \sum_{r \in \mathcal{R}_k} \left(\sum_{\hat{y}_p} b_r(\hat{y}_p|x) \phi_{k,r}(x, \hat{y}_p) - \phi_{k,r}(x, \hat{y}_r) \right)$$

Proof The update rules in Figure 2 iteratively apply the block coordinate ascent rules in Lemmas 2 and 3 thus monotonically increase the primal objective in Theorem 1. This program is concave thus it is bounded by its dual program, therefore the value of its objective is guaranteed to converge. To derive the dual program we construct the Lagrangian

$$L(w, \lambda, b) = -\frac{C}{2} \|w\|^2 + \sum_k w_k \left(\sum_{(x,y) \in \mathcal{S}} \sum_{r \in \mathcal{R}_k} \phi_{k,r}(x, \hat{y}_r) \right) - \sum_{(x,y) \in \mathcal{S}} \log \left(\sum_{\hat{y}_p} \exp(\theta_r(\hat{y}_p; x)) + \sum_{c \in C(r)} \lambda_{c \rightarrow r}(\hat{y}_c; x) - \sum_{p \in P(r)} \lambda_{r \rightarrow p}(\hat{y}_r; x) \right) + \sum_{(x,y) \in \mathcal{S}} \sum_{\hat{y}_p} b_r(\hat{y}_p|x) \left(\theta_r(\hat{y}_p; x) - \sum_k w_k \phi_{k,r}(x, \hat{y}_p) \right).$$

The variables $b_r(\hat{y}_r|x)$ are the Lagrange multipliers for the equality constraints $\theta_r(\hat{y}_r; x) = \sum_k w_k \phi_{k,r}(x, \hat{y}_r)$. The dual program takes the form $q(b) = \max_{w, \lambda} L(w, \lambda, b)$. Setting z_k as above, since the $\|\cdot\|^2$ is the conjugate dual of $\|\cdot\|^2$, the maximization over w takes the form $\max_w \left\{ -\frac{C}{2} \|w\|^2 - \sum_k w_k z_k \right\} = \frac{1}{2C} \|z\|^2$. To complete the derivation of the dual, the maximization over λ , for every (x, y) takes the form $\max_{\lambda} \left\{ \sum_{r, \hat{y}_p} b_r(\hat{y}_p|x) (\theta_r(\hat{y}_p; x) - \sum_{p' \in P(r)} \lambda_{c \rightarrow r}(\hat{y}_c; x) + \sum_{p \in P(r)} \lambda_{r \rightarrow p}(\hat{y}_r; x)) \right\}$. This is the conjugate dual of the log-partition function, which is known to be the entropy function $H(b_r)$. The mixing of the messages between the different regions results in the marginalization constraints in the dual program. An alternative proof for the conjugate duality between the re-parametrized log-partitions and entropies subject to marginalization constraints appears in the more generalized setting of Theorem 5.

Finally, since the dual is strictly convex subject to linear marginalization constraints and the linear moment constraints the convergence properties are a consequence of Tseng and Bertsekas (1987). ■

The convergence of the block coordinate ascent depends on the step size η , which requires to increase the log-beliefs. This can be done by the Armijo rule, or by using the fact that

the function z_k^2 is strongly convex (e.g., Tseng and Bertsekas (1987)) and its gradient is Lipschitz continuous (e.g., Nesterov (2004)). In practice, Theorem 4 describes how to measure the convergence of the algorithm. Specifically, it may be derived from the primal objective value, the dual objective value or the beliefs themselves, as all these quantities converge. Unfortunately, the variables λ might not converge, but if they do converge, their convergence point is optimal.

5. Blending learning and loss adjusted inference

Loss adjusted inference emerges from Support Vector Machines (SVMs) where a loss function indicates preferences between different labels. In the following we consider nonnegative loss functions $\ell_r(\hat{y}_r, \hat{y}_r) \geq 0$ over subsets of variables, while $\ell_r(\hat{y}_r, \hat{y}_r) = 0$. We suggest to augment our learned beliefs with loss adjusted probability models. Given a training example (x, y) , we define the loss adjusted belief model to be

$$b_r(\hat{y}_r|x; w, \lambda) \propto \exp\left(\ell_r(\hat{y}_r, \hat{y}_r) + \theta_r(\hat{y}_r; x, w, \lambda)\right).$$

Note that these beliefs should be conditioned over x as well as the vector $\ell_r(\cdot, \hat{y}_r)$. However, to simplify the notation, we leave this conditioning implicit. The intuition for using the loss as a prior and for deriving loss adjusted beliefs is based on encouraging to learn parameters that decrease probabilities over labels with higher loss with respect to the training labels. The likelihood approach aims at maximizing the beliefs $b_r(\hat{y}_r|x; w, \lambda)$. Since the beliefs are probability distributions, it equivalently aims at minimizing the log-beliefs of all other assignments, namely, $b_r(\hat{y}_r|x; w, \lambda)$ for every $\hat{y}_r \neq y_r$. Since the loss $\ell_r(\hat{y}_r, \hat{y}_r)$ is a nonnegative function it implies that loss-adjusted maximum-likelihood learns parameters that better reduce scores of non-observed training labels, namely $\theta_r(\hat{y}_r; x, w, \lambda)$ for any $\hat{y}_r \neq y_r$. The algorithms for maximizing loss adjusted beliefs follow the derivations presented in Section 4, while replacing $\theta_r(\hat{y}_r; x, w, \lambda)$ with $\theta_r(\hat{y}_r; x, w, \lambda) + \ell_r(\hat{y}_r, \hat{y}_r)$. Letting $z = (x, y)$ we introduce $\theta_r(\hat{y}_r; z, w, \lambda) = \theta_r(\hat{y}_r; x, w, \lambda) + \ell_r(\hat{y}_r, \hat{y}_r)$.

The norm-product approach for inference may use counting numbers c_r to control the peakedness of the beliefs, namely

$$b_r(\hat{y}_r|x; w, \lambda, c) \propto \exp\left(\frac{\theta_r(\hat{y}_r; x, w, \lambda) + \ell_r(\hat{y}_r, \hat{y}_r)}{c_r}\right). \quad (10)$$

As $c_r \rightarrow 0$ this distribution approaches a zero-one probability around the most likely structure, i.e., the desired loss adjusted prediction. Thus the following program blends learning with loss adjusted inference, as well as structured predictions (cf. Meshi et al. (2010)):

Theorem 5 Consider the loss adjusted beliefs given in Equation (10) and their maximum likelihood concave program:

$$\max_{w, \lambda} \sum_{z \in \mathcal{S}} \sum_{r \in \mathcal{R}} c_r \cdot \log b_r(\hat{y}_r|x; w, \lambda, c) - \frac{C}{2} \|w\|^2.$$

Set $\hat{\theta}_r(\hat{y}_r; z, w) = \theta_r(\hat{y}_r; x, w) + \ell_r(\hat{y}_r, \hat{y}_r)$. Then, blending the following loss adjusted learning and inference update rules is guaranteed to converge to the programs optimal value for any

$c_r > 0$.

$$\mu_{p \rightarrow r}(\hat{y}_r; x) = c_p \log \left(\sum_{\hat{y}_p, \hat{y}_r} \exp \left((\hat{\theta}_p(\hat{y}_p; z, w) + \sum_{c \in \mathcal{C}(p)} \lambda_{c \rightarrow p}(y_c; x) - \sum_{p' \in \mathcal{P}(p)} \lambda_{p \rightarrow p'}(\hat{y}_{p'}, x)) / c_p \right) \right)$$

$$\lambda_{r \rightarrow p}(\hat{y}_r; x) = \frac{c_r \left(\hat{\theta}_r(\hat{y}_r; z, w) + \sum_{c \in \mathcal{C}(r)} \lambda_{c \rightarrow r}(y_c; x) + \sum_{p' \in \mathcal{P}(r)} \mu_{p' \rightarrow r}(\hat{y}_{p'}, x) \right)}{c_r + \sum_{p \in \mathcal{P}(r)} c_p} - \mu_{p \rightarrow r}(\hat{y}_r; x)$$

$$w_k \leftarrow w_k - \eta \left(\sum_{(x, y) \in \mathcal{S}} \sum_{r \in \mathcal{R}_k} \left(\sum_{\hat{y}_r \in \mathcal{Y}_r} b_r(\hat{y}_r|x; w, \lambda, c) \phi_{k,r}(x, \hat{y}_r) - \phi_{k,r}(x, y_r) \right) + C w_k \right).$$

Moreover, the beliefs converge to consistent beliefs that are the unique solution of the dual program

$$\max_{b_r, u} \sum_{(x, y) \in \mathcal{S}} \left(c_r H(b_r) + \sum_{\hat{y}_r} b_r(\hat{y}_r|x) \ell_r(\hat{y}_r, \hat{y}_r) \right) - \frac{1}{2C} \|u\|^2,$$

subject to $u_k = \sum_{(x, y) \in \mathcal{S}} \sum_{r \in \mathcal{R}_k} b_r(\hat{y}_r|x) \phi_{k,r}(x, \hat{y}_r) - \phi_{k,r}(x, y_r)$, $b_r(\hat{y}_r|x) \geq 0$, $\sum_{\hat{y}_r} b_r(\hat{y}_r|x) = 1$ and $b_r(\hat{y}_r|x) = \sum_{\hat{y}_p \setminus \hat{y}_r} b_p(\hat{y}_p|x)$.

Proof The update rule for w follows from Lemma 3 and the update rule for λ follows from Lemma 2. Since the program is unconstrained, the optimal λ is attained when the gradient vanishes, or equivalently $\sum_{\hat{y}_p, \hat{y}_r} b_p(\hat{y}_p|x; w, \lambda) = b_r(\hat{y}_r|x; w, \lambda)$, while $b_r(\cdot)$ are the reparametrized beliefs. When setting $\mu_{p \rightarrow r}(\hat{y}_r; x)$ as above, the marginalization of $b_p(\hat{y}_p|x; w, \lambda)$ satisfy $\sum_{\hat{y}_p \setminus \hat{y}_r} b_p(\hat{y}_p|x; w, \lambda) \propto \exp\left(\left(\mu_{p \rightarrow r}(\hat{y}_r; x) + \lambda_{r \rightarrow p}(\hat{y}_r; x)\right) / c_p\right)$. Therefore, by taking the logarithm, the gradient vanishes whenever the beliefs numerators agree

$$\frac{\mu_{p \rightarrow r}(\hat{y}_r; x) + \lambda_{r \rightarrow p}(\hat{y}_r; x)}{c_p} = \frac{\theta_r(\hat{y}_r; z, w) + \sum_{c \in \mathcal{C}(r)} \lambda_{c \rightarrow r}(y_c; x) - \sum_{p \in \mathcal{P}(r)} \lambda_{r \rightarrow p}(\hat{y}_r; x)}{c_r}$$

Multiplying both sides by $c_r c_p$ and summing both sides with respect to $p' \in \mathcal{P}(r)$ we are able to isolate $\sum_{p' \in \mathcal{P}(r)} \lambda_{r \rightarrow p'}(\hat{y}_r; x)$. Plugging it into the above equation results in the desired inference update rule, i.e., $\lambda_{r \rightarrow p}(\hat{y}_r; x)$ for which the partial derivatives vanish.

To prove the duality theorem we show that the primal program is the dual of its dual program using its Lagrangian. For every $r, \hat{y}_r, p \in \mathcal{P}(r)$ we introduce the Lagrange multipliers $\lambda_{r \rightarrow p}(\hat{y}_r; x)$ for the marginalization constraints $b_r(\hat{y}_r|x) = \sum_{\hat{y}_p \setminus \hat{y}_r} b_p(\hat{y}_p|x)$. We also introduce the Lagrange multipliers u_k for the constraints $u_k = \sum_{(x, y) \in \mathcal{S}} \sum_{r \in \mathcal{R}_k} b_r(\hat{y}_r|x) \phi_{k,r}(x, \hat{y}_r) - \phi_{k,r}(x, y_r)$. We let Δ_r refer to the probability simplex constraining the beliefs $b_r(\hat{y}_r|x)$. Then the primal program takes the form $p(\lambda, w) = \max_{b_r \in \Delta_r} L(b, u, \lambda, w)$ which decomposes to $\sum_{z, r} c_r \max_{b_r \in \Delta_r} \{H(b_r) + \sum_{\hat{y}_r} b_r(\hat{y}_r|x) (\ell_r(\hat{y}_r, \hat{y}_r) + \theta_r(\hat{y}_r; x, w, \lambda)) / c_r\} + w^\top d + \max_{u_k} \{w^\top u - \frac{C}{2} \|u\|^2\}$, where d_k are the empirical moments $d_k = \sum_{(x, y) \in \mathcal{S}} \phi_{k,r}(x, y_r)$. Thus the primal is the sum of conjugate dual functions. The primal is then derived since the log-partition function is the conjugate dual of the entropy function and the conjugate dual of $\frac{C}{2} \|u\|^2$ is $\frac{C}{2} \|w\|^2$. The form in the theorem is obtained since $\ell_r(\hat{y}_r, \hat{y}_r) = 0$ and $\sum_r \sum_{p \in \mathcal{P}(r)} \lambda_{r \rightarrow p}(\hat{y}_r; x) - \sum_r \sum_{c \in \mathcal{C}(r)} \lambda_{c \rightarrow r}(y_c; x) \equiv 0$. Finally, the convergence properties are a consequence of Tseng and Bertsekas (1987) similarly to Theorem 4. ■

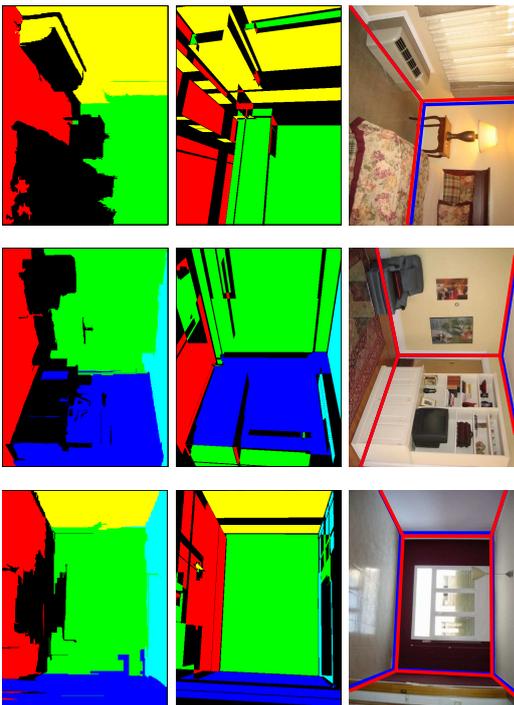

Figure 3: The top row shows three indoor scenes from the layout dataset (Hedau et al., 2009). Orientation maps (Lee et al., 2009) and geometric context (Holm et al., 2007) features for the respective images are illustrated in the center and bottom row respectively.

Note that the log-beliefs are balanced by c_r , to compensate for their exponent peakedness. This balancing makes the objective well defined at $c_r = 0$ as the limit of $c_r \rightarrow 0$. In this case the program is non-smooth and one needs to consider the sub gradient in the form of max-beliefs. However, this setting was already developed, although in the different context of structured-SVMs using dual losses, and we refer the interested reader to Meshi et al. (2010) for more details.

6. Experiments

The effectiveness of the discussed framework was recently illustrated by employing this algorithm as the learning engine for various computer vision tasks: scene understanding (Yao et al. (2012)), Lin et al. (2013)), shape reconstruction (Salzman and Urtasun (2012)) indoor scene understanding (Schwing et al. (2012a); Schwing and Urtasun (2012)), depth estimation (Yamaguchi et al. (2012)), flow estimation (Yamaguchi et al. (2013)) and visual-language understanding (Fidler et al. (2013)). The code is publicly available on <http://www.alexander-schwing.de/projectGeneralStructuredPredictionLatentVariables.php>.

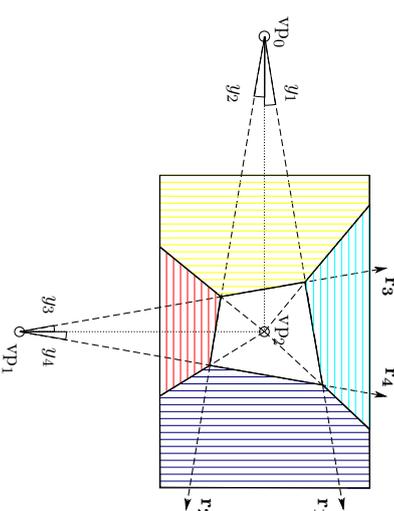

Figure 4: Ray parameterization of the layout given detected vanishing points. A state of a discretized variable y_i gives rise to a particular ray r_i originating from a detected vanishing point. Four rays are sufficient to define a room layout, i.e., the location of the walls.

In the following we demonstrate the various properties of blending learning and inference. For this purpose we elaborate more carefully on a 3D scene understanding application (Schwing et al., 2012a) evaluated on the well known layout dataset (Hedau et al., 2009) containing 314 indoor images. Given a single image similar to the ones illustrated in the top row of Figure 3, we aim at estimating the location of the left, front and right walls as well as ceiling and floor. Formulating this task as a pixelwise semantic segmentation application permits a large number of configurations that are physically not plausible. We therefore constrain the space of configurations by parametrizing the application using three dominant vanishing points as illustrated in Figure 4. The random variables y_1, \dots, y_4 correspond to discretized angles of rays, each one originating from a detected vanishing point. Such a parametrization in terms of rays permits only physically plausible configurations and assumes the world to be Manhattan like, i.e., the observed room is aligned according to the three dominant directions.

To obtain the dominant directions we employ the vanishing point detector of Hedau et al. (2009). Due to the involved randomness it failed in our case on 9 training images and was successful on all 105 test instances. For image x and a given layout hypothesis $y = (y_1, \dots, y_4)$ we compute a 55-dimensional feature vector $\phi(x; y)$ which is constructed based on geometric context (Holm et al., 2007) and orientation maps (Lee et al., 2009) illustrated in the middle and bottom row of Figure 3 respectively.

More specifically, for each of the five hypothesized wall areas (note that the back wall is never observed) obtained from projecting the predicted layout y into the image, we count how frequently geometric context estimates the five different wall labels plus an additional clutter label within each hypothesized wall. This gives rise to a $5 \cdot 6 = 30$ dimensional

feature vector. Similarly for orientation map evidence we count how many of the five possible labels fell onto each of the five hypothesized wall areas, resulting in a $5 \cdot 5 = 25$ dimensional vector. Combining both image evidences we hence obtain a feature vector ϕ having a total of $K = 55$ entries, each being represented by a graphical model having nodes $\mathcal{R}_k, k \in \{1, \dots, K\}$.

Note that a vanilla implementation of these color counting features results in potentials of order four for the front wall, and of order three for all other walls. High-order potentials increase the complexity of learning and inference, therefore, the exact decomposition of these high-order potentials into pairwise terms using ‘integral geometry’ Schwing et al. (2012a) is important for tractability.

In our experiments we learn and infer with the same counting numbers. For example, when we learn log-beliefs by setting the counting numbers to 1, we also infer with log-beliefs at test time, namely setting the counting numbers to 1. Figure 5 demonstrates the tradeoffs of learning with various counting numbers. This experiment also compares to blending of structured-SVMs of Meshi et al. (2010) when setting the counting numbers to 0.

In Figure 6 we illustrate the optimized cost function, i.e., the surrogate training loss over wall clock time. We observe that our discussed blended learning approach (‘Ours’) converges quickly, i.e., in less than 50 seconds, to a zero primal dual gap. In contrast it takes the standard learning approach (‘Standard 20’), which performs 20 message passing iterations, more than 600 seconds to converge to the same solution. Hence blended learning is more than 10 times faster on this example. Next we investigate whether a standard message passing approach with 20 iterations is overly pessimistic for this dataset. To this end we use 10 message passing iterations and refer to the obtained result as ‘Standard 10’. Investigating Figure 6 more carefully we observe that 10 message passing iterations are not sufficient to close the duality gap, i.e., the approach does never converge to the same solution.

These plots validate our theoretical results. However, often we are interested in the resulting test set error. Therefore we compare learning which uses the proposed blending approach with the standard technique using the test set performance in Figure 7. More specifically, in Figure 7(a) we illustrate the test set performance of blending with all counting numbers equal to one (‘Blending (1)’) and compare it to the test set performance of blending with all counting numbers equal to zero (‘Blending (0)’) derived by Meshi et al.

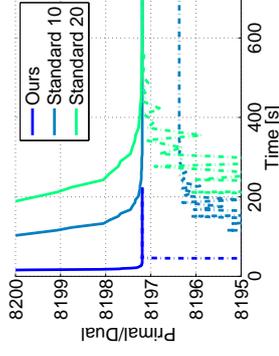

Figure 6: Primal surrogate loss (dashed) and its dual (solid) over wall clock time measured in seconds for blended learning, the standard approach with 10 iterations, and the standard approach with 20 iterations.

(2010), the test set performance of convex learning with 20 message passing iterations with both counting numbers equal to zero (cf. Meshi et al. (2010)) and one, i.e., ‘Standard 20 (0)’ and ‘Standard 20 (1)’ respectively. We observe that the test set accuracy drops significantly faster which is expected since we are able to update the parameter vector more frequently. Similar to the aforementioned surrogate training loss result we observe a performance improvement of more than one order of magnitude, i.e., we obtain accurate test set results more than 10 times faster.

In a next experiment we evaluate the importance of the loss function. The results are illustrated in Figure 7(b). We observe the loss to be important for the case where the counting numbers equal zero. We are able to obtain a performance similar to loss-included setting if the counting numbers are equal to one. However algorithms which do not use a loss function while having counting numbers equal to zero got stuck prematurely and are hence not even visible in Figure 7(b), where the scale was adjusted to fit the other plots.

Next we observe the behavior if we reduce the number of iterations for standard learning from 20 down to 2. Recall, from the surrogate training loss results that the primal-dual gap will not reach zero in this setting. The test set errors are illustrated in Figure 7(c). We observe that the standard method is approaching the blending technique. This indicates that a primal-dual gap is not necessarily important for good generalization performance.

In Figure 7(d) we illustrate that blending offers a wide range of possibilities. Indeed, we are not restricted to performing only a single message passing iteration before updating the parameter vector. Rather any arbitrary scheduling is possible. As illustrated in the results we observe slightly faster convergence when updating the messages twice as frequently as the parameter vector, i.e., we perform two rounds of message passing updates before updating the parameters of the model. This is expected since the distribution is more accurate while message passing updates are quick in this setup. We refer the interested reader to (Schwing et al., 2012a) for additional results exploring counting numbers other than zero and one.

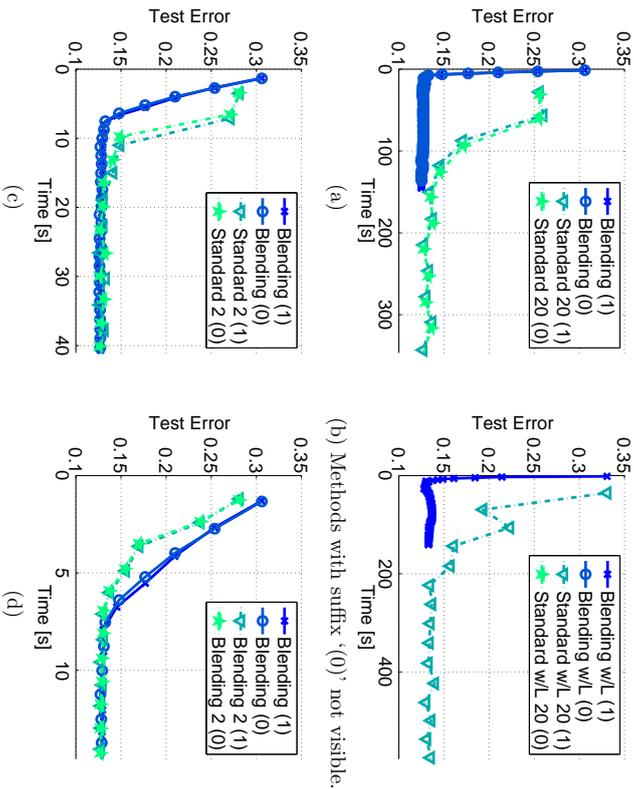

Figure 7: A comparison of the test set error over training time for different parameter settings. In (a) we compare standard learning with blended learning when including a loss function. In (b) we provide the comparison when not using a loss function. Note that using MAP estimation without loss got stuck at a high error. The results in (c) demonstrate the effects when reducing the iterations of the standard learning method, while (d) illustrates the flexibility offered by blending where we use two message passing iterations before updating the parameters.

7. Conclusion and Discussion

In this paper we describe the objective function for nested learning and inference in CRFs, for which approximate inference algorithms are used as a sub-procedure. The devised objective maximizes the log-likelihoods — probability distributions over subsets of variables that agree on their marginal probabilities. This objective is concave and consists of two types of variables that are related to the learning and inference tasks respectively. Therefore, we are able to blend the learning and inference procedures and effectively get to the optimum much faster than nested learning and inference approach, which uses inference algorithms as black-box solvers. We show the computational advantage for using blended algorithms over nested ones. We also provide an efficient C++ implementation with a Matlab wrapper.

This work extends Hazan and Urtasun (2010) while simplifying its theoretical and practical concepts. Specifically, we introduce the learning program as maximizing log-likelihoods, explain the relations between nested and blended learning-inference and derives a blending algorithm for general graphs. This work is extended to latent variables (Schwing et al. (2012b)) and deep learning (Chen* et al. (2015); Schwing and Urtasun (2015)). The effectiveness of the discussed framework was recently illustrated by employing this algorithm as the learning engine for various computer vision tasks: 2D scene understanding (Yao et al. (2012)), 3D scene understanding (Lin et al. (2013)), shape reconstruction (Salzman and Urtasun (2012)) indoor scene understanding (Schwing et al. (2012a); Schwing and Urtasun (2012)), depth estimation (Yamaguchi et al. (2012)), flow estimation (Yamaguchi et al. (2013)) and visual-language understanding (Fidler et al. (2013)). We believe it is interesting to show in the future if this algorithm provides state-of-the-art performance in domains other than computer vision, or whether the statistics in computer vision are used by this approach in a special manner.

The computational complexity of our algorithm depends on norm-products over the labels of regions. Therefore, efficient techniques over large regions in inference can be applied as sub-procedure in our algorithm, e.g., Kohli et al. (2009); Batra et al. (2010); Tatlow et al. (2010, 2011); Tatlow and Zemel (2012).

In our framework, we can enforce the moment matching constraints through general concave functions. These function translate to a regularization in the primal. For computational efficiency we choose the square function but we did not investigate the different moment matching and regularization functions. Moreover, we enforce the marginalization constraints through indicator functions, in order to obtain closed-form solution in the primal block coordinate descent. However, we have shown that using the penalty method we can enforce the marginalization constraints with different convex functions. Further explorations of structured prediction with squared penalties appears in work by Mochi et al. (2015). We leave the affect of general convex functions on moment matching and regularization, as well as marginalization constraints and efficient message-passing to future research.

Interestingly, our approach confirms that the parameters of graph based structured predictors can be efficiently learned in many real-life problems. This validates the intuition behind the theoretical results of Wainwright et al. (2003); Wainwright (2006) which asserts that whenever learning and inference occur together one can use pseudo moment matching for learning the parameters. This concept was put forward in the general framework of learning to reason by Khadon and Roth (1997) and we leave for future research to find different frameworks which have similar learning-prediction robustness.

8. Extensions: regularizations and the penalty method

Duality theory turned out to be very effective in machine learning as it provides a principled way to decompose the different ingredients of the primal objective through its Lagrange multipliers. The dual decomposition in turn provides the means to efficiently estimate the different ingredients while maintaining their consistency using the dual objective.

When dealing with convex programs one usually needs to consider the set of primal feasible solutions while constructing the dual function. We find it simpler to describe

the primal program using extended real-valued convex functions, which are functions that can take on the value of infinity. By using extended real-valued functions we can ignore their domains, i.e., points for which a function attains the value other than infinity, thus simplifying the derivations. The dual programs of extended real valued convex functions $g(\mu)$ are conveniently formulated in terms of their conjugate dual

$$g^*(z) = \max_{\mu} \left\{ \mu^{\top} z - g(\mu) \right\}.$$

Throughout this work we use the following duality theorem, known as the Fenchel duality (cf. Fenchel (1951); Rockafellar (1970); Bertsekas et al. (2003)):

Theorem 6 *Let $f(\cdot), h_1(\cdot), h_2(\cdot)$ be extended real-valued, continuous and convex functions.*

The following are primal and dual programs:

$$\begin{aligned} \min_{\lambda, w} \quad & \sum_{(x,y) \in S_T \times \mathcal{R}} f(\theta_r(\cdot; x, w, \lambda) + \ell_r(\cdot, \hat{y}_r)) + \sum_k h_1(w_k) + \sum_{(x,y), r, \hat{y}_r, p \in P(r)} h_2(\lambda_{r \rightarrow p}(\hat{y}_r; x)) \\ \max_{b_r} \quad & \sum_{(x,y) \in S_T \times \mathcal{R}} \left(-f^*(b_r) + \sum_{\hat{y}_r} b_r(\hat{y}_r | x) \ell_r(\hat{y}_r, \hat{y}_r) \right) \\ & - \sum_k h_1^* \left(\sum_{(x,y), r} \left(\sum_{\hat{y}_r} b_r(\hat{y}_r) \phi_{k,r}(x, \hat{y}_r) - \phi_{k,r}(x, y_r) \right) \right) \\ & - \sum_{(x,y), r, \hat{y}_r, p} h_2^* \left(\sum_{\hat{y}_p, \hat{y}_r} b_p(\hat{y}_p | x) - b_r(\hat{y}_r | x) \right) \end{aligned}$$

Proof The proof goes along the lines of Theorem 5. The dual program takes the form

$$\begin{aligned} \sum_{(x,y) \in S_T \times \mathcal{R}} \left(-f^*(b_r) + \sum_{\hat{y}_r} b_r(\hat{y}_r | x) \ell_r(\hat{y}_r, \hat{y}_r) \right) - \sum_k h_1^*(u_k) - \sum_{(x,y), r, \hat{y}_r, p} h_2^*(\delta_{r \rightarrow p}(\hat{y}_r; x)) \\ \text{s.t.} \quad u_k = \sum_{(x,y), r} \left(\sum_{\hat{y}_r} b_r(\hat{y}_r | x) \phi_{k,r}(x, \hat{y}_r) - \phi_{k,r}(x, y_r) \right) \\ \delta_{r \rightarrow p}(\hat{y}_r; x) = \sum_{\hat{y}_p, \hat{y}_r} b_p(\hat{y}_p | x) - b_r(\hat{y}_r | x) \end{aligned}$$

Constructing its Lagrangian with the Lagrange multipliers $w_k, \lambda_{r \rightarrow p}(\hat{y}_r; x)$, we obtain the primal program $p(w, \lambda) = \max_{b_r, u, \lambda} L(b_r, \lambda, w)$ which decomposes to $\sum_{(x,y), r} \max_{b_r} \{ -f^*(b_r) + \sum_{\hat{y}_r} b_r(\hat{y}_r | x) (\ell_r(\hat{y}_r, \hat{y}_r) - \theta_r(\hat{y}_r; x, w, \lambda)) \} + \sum_{(x,y), r, \hat{y}_r, p} \max_{\delta_{r \rightarrow p}} \{ \delta_{r \rightarrow p}(\hat{y}_r) - h_2^*(\delta_{r \rightarrow p}(\hat{y}_r)) \} + w^{\top} e + \sum_k \max_{u_k} \{ u_k u_k - h_1^*(u_k) \}$, where $e_k = \sum_{(x,y), r} \phi_{k,r}(x, y_r)$. The result then follows since the conjugate dual of $f^*(\cdot), h_1^*(\cdot), h_2^*(\cdot)$ are $f(\cdot), h_1(\cdot), h_2(\cdot)$ respectively. ■

The above formulation describes a dual program with a selection rule $f^*(\cdot)$, a penalty function for learning moment matchings $h_1^*(\cdot)$ and a penalty function $h_2^*(\cdot)$ for fitting the marginalization constraints. Although these penalty functions are conceptually different — $h_1^*(\cdot)$ relates to learning the parameters w and $h_2^*(\cdot)$ relates to inferring the marginal probabilities — they have the same variational interpretation.

The primal program translates the dual penalty functions $h_1^*(\cdot), h_2^*(\cdot)$ to regularization functions $h_1(\cdot), h_2(\cdot)$. Whenever the primal functions are smooth we can use the chain rule to derive the primal program gradients:

$$\begin{aligned} \frac{\partial}{\partial w_k} & : \sum_{(x,y) \in S_T \times \mathcal{R}} \left(\sum_{r \in \mathcal{R}} \left(\sum_{\hat{y}_r} \frac{\partial f(\theta_r(\cdot; z, w, \lambda))}{\partial \theta_r(\hat{y}_r; z, w, \lambda)} \phi_{k,r}(x, \hat{y}_r) - \phi_{k,r}(x, y_r) \right) + \nabla h_k(w_k) \right) \\ \frac{\partial}{\partial \lambda_{r \rightarrow p}(\hat{y}_r; x)} & : \sum_{\hat{y}_p, \hat{y}_r} \left(\frac{\partial f(\theta_r(\cdot; z, w, \lambda))}{\partial \theta_p(\hat{y}_p; z, w, \lambda)} - \frac{\partial f(\theta_r(\cdot; z, w, \lambda))}{\partial \theta_r(\hat{y}_r; z, w, \lambda)} + \nabla h_2(\lambda_{r \rightarrow p}(\hat{y}_r; x)) \right) \end{aligned}$$

The above generalizes the learning-inference blending algorithm for general functions $f(\cdot)$ and regularizations $h_1(\cdot), h_2(\cdot)$. The power of setting $f(\cdot)$ to be the log-partition function is that its derivatives are beliefs therefore we obtain an intuitive probabilistic interpretation. The parameters derivatives result in moment matching constraints

$$\sum_{(x,y) \in S_T \times \mathcal{R}} \left(\sum_{\hat{y}_r} \left(\sum_{r \in \mathcal{R}} \frac{\partial f(\theta_r(\cdot; z, w, \lambda))}{\partial \theta_r(\hat{y}_r; z, w, \lambda)} \phi_{k,r}(x, \hat{y}_r) - \phi_{k,r}(x, y_r) \right) \right).$$

The re-parametrization derivatives with respect to the messages $\lambda_{r \rightarrow p}(\hat{y}_r; x)$ are then marginalization constraints

$$\sum_{\hat{y}_p, \hat{y}_r} \left(\frac{\partial f(\theta_p(\cdot; z, w, \lambda))}{\partial \theta_p(\hat{y}_p; z, w, \lambda)} - \frac{\partial f(\theta_r(\cdot; z, w, \lambda))}{\partial \theta_r(\hat{y}_r; z, w, \lambda)} \right)$$

Moreover, whenever $h_2(\cdot) \equiv 0$, we are able to derive closed-form update rules.

Editor: Jeff Bilmes

Frey, 2007) to active set selection for non-parametric learning (Rasmussen, 2004), to viral marketing (Kenpe et al., 2003), and data subset selection for the purpose of training complex models (Lin and Bilmes, 2011). Many such problems can be reduced to the problem of *maximizing a submodular set function* subject to cardinality or other feasibility constraints such as matroid, or knapsack constraints (Krause and Gomes, 2010; Krause and Golovin, 2012; Lee et al., 2009a).

Submodular functions exhibit a natural diminishing returns property common in many well known objectives: the marginal benefit of any given element decreases as we select more and more elements. Functions such as entropy or maximum weighted coverage are typical examples of functions with diminishing returns. As a result, submodular function optimization has numerous applications in machine learning and social networks: viral marketing (Kenpe et al., 2003; Babaei et al., 2013; Mirzasoileiman et al., 2012), information gathering (Krause and Guestrin, 2011), document summarization (Lin and Bilmes, 2011), and active learning (Golovin and Krause, 2011; Guillory and Bilmes, 2011).

Although maximizing a submodular function is NP-hard in general, a seminal result of Nemhauser et al. (1978) states that a simple greedy algorithm produces solutions competitive with the optimal (intractable) solution (Nemhauser and Wolsey, 1978; Feige, 1998). However, such greedy algorithms or their accelerated variants (Minoux, 1978; Badanidiyuru and Vondrák, 2014; Mirzasoileiman et al., 2015a) do not scale well when the dataset is massive. As data volumes in modern applications increase faster than the ability of individual computers to process them, we need to look at ways to adapt our computations using parallelism.

MapReduce (Dean and Ghemawat, 2008) is arguably one of the most successful programming models for reliable and efficient parallel computing. It works by distributing the data to independent machines: *map* tasks redistribute the data for appropriate parallel processing and the output then gets sorted and processed in parallel by *reduce* tasks.

To perform submodular optimization in MapReduce, we need to design suitable parallel algorithms. The greedy algorithms that work well for centralized submodular optimization do not translate easily to parallel environments. The algorithms are inherently sequential in nature, since the marginal gain from adding each element is dependent on the elements picked in previous iterations. This mismatch makes it inefficient to apply classical algorithms directly to parallel setups.

In this paper, we develop a distributed procedure for maximizing submodular functions, that can be easily implemented in MapReduce. Our strategy is to partition the data (e.g., randomly) and process it in parallel. In particular:

- We present a simple, parallel protocol, called GREDI for distributed submodular maximization subject to cardinality constraints. It requires minimal communication, and can be easily implemented in MapReduce style parallel computation models.
- We show that under some natural conditions, for large datasets the quality of the obtained solution is provably competitive with the best centralized solution.
- We discuss extensions of our approach to obtain approximation algorithms for (not-necessarily monotone) submodular maximization subject to more general types of constraints, including matroid and knapsack constraints.

Abstract

Many large-scale machine learning problems—clustering, non-parametric learning, kernel machines, etc.—require selecting a small yet representative subset from a large dataset. Such problems can often be reduced to maximizing a submodular set function subject to various constraints. Classical approaches to submodular optimization require centralized access to the full dataset, which is impractical for truly large-scale problems. In this paper, we consider the problem of submodular function maximization in a distributed fashion. We develop a simple, two-stage protocol GREDI, that is easily implemented using MapReduce style computations. We theoretically analyze our approach, and show that under certain natural conditions, performance close to the centralized approach can be achieved. We begin with monotone submodular maximization subject to a cardinality constraint, and then extend this approach to obtain approximation guarantees for (not necessarily monotone) submodular maximization subject to more general constraints including matroid or knapsack constraints. In our extensive experiments, we demonstrate the effectiveness of our approach on several applications, including sparse Gaussian process inference and exemplar based clustering on tens of millions of examples using Hadoop.

Keywords: distributed computing, submodular functions, approximation algorithms, greedy algorithms, map-reduce

1. Introduction

Numerous machine learning tasks require selecting representative subsets of manageable size out of large datasets. Examples range from exemplar based clustering (Dueck and

- We implement our approach for exemplar based clustering and active set selection in Hadoop, and show how our approach allows to scale exemplar based clustering and sparse Gaussian process inference to datasets containing tens of millions of points.
- We extensively evaluate our algorithm on several machine learning problems, including exemplar based clustering, active set selection and finding cuts in graphs, and show that our approach leads to parallel solutions that are very competitive with those obtained via centralized methods (98% in exemplar based clustering, 97% in active set selection, 90% in finding cuts).

This paper is organized as follows. We begin in Section 2 by discussing background and related work. In Section 3, we formalize the distributed submodular maximization problem under cardinality constraints, and introduce example applications as well as naive approaches toward solving the problem. We subsequently present our GREEDY algorithm in Section 4, and prove its approximation guarantees. We then consider maximizing a submodular function subject to more general constraints in Section 5. We also present computational experiments on very large datasets in Section 6, showing that in addition to its provable approximation guarantees, our algorithm provides results close to the centralized greedy algorithm. We conclude in Section 7.

2. Background and Related Work

2.1 Distributed Data Analysis and MapReduce

Due to the rapid increase in dataset sizes, and the relatively slow advances in sequential processing capabilities of modern CPUs, parallel computing paradigms have received much interest. Inhabiting a sweet spot of resiliency, expressivity and programming ease, the MapReduce style computing model (Dean and Ghemawat, 2008) has emerged as prominent foundation for large scale machine learning and data mining algorithms (Chu et al., 2007; Ekamayake et al., 2008). A MapReduce job takes the input data as a set of $< key; value >$ pairs. Each job consists of three stages: the *map* stage, the *shuffle* stage, and the *reduce* stage. The map stage, partitions the data randomly across a number of machines by associating each element with a *key* and produce a set of $< key; value >$ pairs. Then, in the shuffle stage, the value associated with all of the elements with the same key gets merged and sent to the same machine. Each reducer then processes the values associated with the same key and outputs a set of new $< key; value >$ pairs with the same key. The reducers' output could be an input to another MapReduce job, and a program in MapReduce paradigm can consist of multiple rounds of map and reduce stages (Karloff et al., 2010).

2.2 Centralized and Streaming Submodular Maximization

The problem of centralized maximization of submodular functions has received much interest, starting with the seminal work of Nemhauser et al. (1978). Recent work has focused on providing approximation guarantees for more complex constraints (for a more detailed account, see the recent survey by Krause and Golovin, 2012). Golovin et al. (2010) consider an algorithm for online distributed submodular maximization with an application to sensor selection. However, their approach requires k stages of communication, which is unrealistic

for large k in a MapReduce style model. Krause and Gomes (2010) consider the problem of submodular maximization in a streaming model; however, their approach makes strong assumptions about the way the data stream is generated and is not applicable to the general distributed setting. Recently, Badanidiyuru et al. (2014) provide a single pass streaming algorithm for cardinality-constrained submodular maximization with $1/2 - \epsilon$ approximation guarantee to the optimum solution that makes no assumptions on the data stream.

There has also been new improvements in the running time of the standard greedy solution for solving SET-COVER (a special case of submodular maximization) when the data is large and disk resident (Cornode et al., 2010). More generally, Badanidiyuru and Vondrak (2014) and Mirzasoileman et al. (2015a) improve the running time of the greedy algorithm for maximizing a monotone submodular function by reducing the number of oracle calls to the objective function. Very recently, Mirzasoileman et al. (2016) provided a fast algorithm for maximizing non-monotone submodular functions under general constraints. In a similar spirit, Wei et al. (2014) propose a multi-stage framework for submodular maximization. In order to reduce the memory and computation cost, they apply an approximate greedy procedure to maximize surrogate (proxy) submodular functions instead of optimizing the target function at each stage. The above approaches are sequential in nature and it is not clear how to parallelize them. However, they can be naturally integrated into our distributed framework to achieve further acceleration.

2.3 Scaling Up: Distributed Algorithms

Recent work has focused on specific instances of submodular optimization in distributed settings. Such scenarios often occur in large-scale graph mining problems where the data itself is too large to be stored on one machine. In particular, Chierichetti et al. (2010) address the MAX-COVER problem and provide a $(1 - 1/e - \epsilon)$ approximation to the centralized algorithm at the cost of passing over the dataset many times. Their result is further improved by Brelloch et al. (2011). Lattanzi et al. (2011) address more general graph problems by introducing the idea of filtering, namely, reducing the size of the input in a distributed fashion so that the resulting, much smaller, problem instance can be solved on a single machine. This idea is, in spirit, similar to our distributed method GREEDY. In contrast, we provide a more general framework, and characterize settings where performance competitive with the centralized setting can be obtained. The present version is a significant extension of our previous conference paper (Mirzasoileman et al., 2013), providing theoretical guarantees for both monotone and non-monotone submodular maximization problems subject to more general types of constraints, including matroid and knapsack constraints (described in Section 5), and additional empirical results (Section 6). Parallel to our efforts (Mirzasoileman et al., 2013), Kumar et al. (2013) has taken the approach of adapting the sequential greedy algorithm to distributed settings. However, their method requires knowledge of the ratio between the largest and smallest marginal gains of the elements, and generally requires a non-constant (logarithmic) number of rounds. We provide empirical comparisons in Section 6.4.

Figure 1: Cluster exemplars (left column) discovered by our distributed algorithm Greedy described in Section 4 applied to the Tiny Images dataset (Torralba et al., 2008), and a set of representatives from each cluster.

3. Submodular Maximization

In this section, we first review submodular functions and how to greedily maximize them. We then describe the *distributed submodular maximization* problem, the focus of this paper. Finally, we discuss two naive approaches towards solving this problem.

3.1 Greedy Submodular Maximization

Suppose that we have a large dataset of images, e.g., the set of all images on the Web or an online image hosting website such as Flickr, and we wish to retrieve a subset of images that best represents the visual appearance of the dataset. Collectively, these images can be considered as *exemplars* that *summarize* the visual categories of the dataset as shown in Fig. 1.

One way to approach this problem is to formalize it as the *k-medoid* problem. Given a set $V = \{e_1, e_2, \dots, e_n\}$ of images (called ground set) associated with a (not necessarily symmetric) dissimilarity function, we seek to select a subset $S \subseteq V$ of at most k exemplars or cluster centers, and then assign each image in the dataset to its least dissimilar exemplar. If an element $e \in V$ is assigned to exemplar $v \in S$, then the cost associated with e is the dissimilarity between e and v . The goal of the *k-medoid* problem is to choose exemplars that minimize the sum of dissimilarities between every data point $e \in V$ and its assigned cluster center.

Solving the *k-medoid* problem optimally is NP-hard, however, as we discuss in Section 3.4, we can transform this problem, and many other summarization tasks, to the problem of maximizing a monotone submodular function subject to a cardinality constraint

$$\max_{S \subseteq V} f(S) \quad \text{s.t.} \quad |S| \leq k. \quad (1)$$

Submodular functions are set functions which satisfy the following natural diminishing returns property.

Definition 1 (c.f., Nemhauser et al. (1978)) A set function $f : 2^V \rightarrow \mathbb{R}$ is submodular, if for every $A \subseteq B \subseteq V$ and $e \in V \setminus B$

$$f(A \cup \{e\}) - f(A) \geq f(B \cup \{e\}) - f(B).$$

Furthermore, f is called monotone iff for all $A \subseteq B \subseteq V$ it holds that $f(A) \leq f(B)$.

We will generally additionally require that f is nonnegative, i.e., $f(A) \geq 0$ for all sets A . Problem (1) is NP-hard for many classes of submodular functions (Feige, 1998). A fundamental result by Nemhauser et al. (1978) establishes that a simple greedy algorithm that starts with the empty set and iteratively augments the current solution with an element of maximum incremental value

$$v^* = \arg \max_{v \in V \setminus A} f(A \cup \{v\}), \quad (2)$$

continuing until k elements have been selected, is guaranteed to provide a constant factor approximation.

Theorem 2 (Nemhauser et al., 1978) For any non-negative and monotone submodular function f , the greedy heuristic always produces a solution $A^{\text{gc}}[k]$ of size k that achieves at least a constant factor $(1 - 1/e)$ of the optimal solution.

$$f(A^{\text{gc}}[k]) \geq (1 - 1/e) \max_{|A| \leq k} f(A).$$

This result can be easily extended to $f(A^{\text{gc}}[l]) \geq (1 - e^{-l/k}) \max_{|A| \leq k} f(A)$, where l and k are two positive integers (see, Krause and Golovin, 2012).

3.2 Distributed Submodular Maximization

In many today’s applications where the size of the ground set $|V| = n$ is very large and cannot be stored on a single computer, running the standard greedy algorithm or its variants (e.g., lazy evaluations, Minoux, 1978; Leskovec et al., 2007; Mirzasoileiman et al., 2015a) in a centralized manner is infeasible. Hence, we seek a solution that is suitable for large-scale parallel computation. The greedy method described above is in general difficult to parallelize, since it is inherently sequential: at each step, only the object with the highest marginal gain is chosen and every subsequent step depends on the preceding ones.

Concretely, we consider the setting where the ground set V is very large and cannot be handled on a single machine, thus must be distributed among a set of m machines. While there are several approaches towards parallel computation, in this paper we consider the following model that can be naturally implemented in MapReduce. The computation proceeds in a sequence of rounds. In each round, the dataset is distributed to m machines. Each machine i carries out computations independently in parallel on its local data. After all machines finish, they synchronize by exchanging a limited amount of data (of size polynomial in k and m , but independent of n). Hence, any distributed algorithm in this model must specify: 1) how to distribute V among the m machines, 2) which algorithm should run on each machine, and 3) how to communicate and merge the resulting solutions.

In particular, the distributed submodular maximization problem requires the specification of the above steps in order to implement an approach for submodular maximization. More precisely, given a monotone submodular function f , a cardinality constraint k , and a number of machines m , we wish to produce a solution $A^{\text{d}}[m, k]$ of size k such that $f(A^{\text{d}}[m, k])$ is competitive with the optimal centralized solution $\max_{|A| \leq k, A \subseteq V} f(A)$.

3.3 Naive Approaches Towards Distributed Submodular Maximization

One way to solve problem (1) in a distributed fashion is as follows. The dataset is first partitioned (randomly, or using some other strategy) onto the m machines, with V_i representing the data allocated to machine i . We then proceed in k rounds. In each round, all machines—in parallel—compute the marginal gains of all elements in their sets V_i . Next, they communicate their candidate to a central processor, who identifies the globally best element, which is in turn communicated to the m machines. This element is then taken into account for computing the marginal gains and selecting the next elements. This algorithm (up to decisions on how break ties) implements exactly the centralized greedy algorithm, and hence provides the same approximation guarantees on the quality of the solution. Unfortunately, this approach requires synchronization after each of the k rounds. In many applications, k is quite large (e.g., tens of thousands), rendering this approach impractical for MapReduce style computations.

An alternative approach for large k would be to greedily select k/m elements independently on each machine (without synchronization), and then merge them to obtain a solution of size k . This approach that requires only two rounds (as opposed to k), is much more communication efficient, and can be easily implemented using a single MapReduce stage. Unfortunately, many machines may select redundant elements, and thus the merged solution may suffer from diminishing returns. It is not hard to construct examples for which this approach produces solutions that are a factor $\Omega(m)$ worse than the centralized solution.

In Section 4, we introduce an alternative protocol GREEDY, which requires little communication, while at the same time yielding a solution competitive with the centralized one, under certain natural additional assumptions.

3.4 Applications of Distributed Submodular Maximization

In this part, we discuss two concrete problem instances, with their corresponding submodular objective functions f , where the size of the datasets often requires a distributed solution for the underlying submodular maximization.

3.4.1 LARGE-SCALE NONPARAMETRIC LEARNING

Nonparametric learning (i.e., learning of models whose complexity may depend on the dataset size n) are notoriously hard to scale to large datasets. A concrete instance of this problem arises from training Gaussian processes or performing MAP inference in Determinantal Point Processes, as considered below. Similar challenges arise in many related learning methods, such as training kernel machines, when attempting to scale them to large data sets.

Active Set Selection in Sparse Gaussian Processes (GPs). Formally a GP is a joint probability distribution over a (possibly infinite) set of random variables \mathbf{X}_V , indexed by the ground set V , such that every (finite) subset \mathbf{X}_S for $S = \{e_1, \dots, e_s\}$ is distributed according to a multivariate normal distribution. More precisely, we have

$$P(\mathbf{X}_S = \mathbf{x}_S) = \mathcal{N}(\mathbf{X}_S; \mu_S, \Sigma_S),$$

where $\mu = (\mu_{e_1}, \dots, \mu_{e_s})$ and $\Sigma_S = [\kappa_{e_i, e_j}]$ are prior mean and covariance matrix, respectively. The covariance matrix is parameterized via a positive definite kernel $\mathcal{K}(\cdot, \cdot)$. As a

concrete example, when elements of the ground set V are embedded in a Euclidean space, a commonly used kernel in practice is the squared exponential kernel defined as follows:

$$\mathcal{K}(e_i, e_j) = \exp(-\|e_i - e_j\|_2^2 / \theta^2).$$

Gaussian processes are commonly used as priors for nonparametric regression. In GP regression, each data point $e \in V$ is considered a random variable. Upon observations $\mathbf{Y}_A = \mathbf{X}_A + \mathbf{n}_A$ (where \mathbf{n}_A is a vector of independent Gaussian noise with variance σ^2), the predictive distribution of a new data point $e \in V$ is a normal distribution $P(\mathbf{X}_e | \mathbf{Y}_A) = \mathcal{N}(\mu_{e|A}, \Sigma_{e|A}^2)$, where mean $\mu_{e|A}$ and variance $\Sigma_{e|A}^2$ are given by

$$\mu_{e|A} = \mu_e + \Sigma_{e,A}(\Sigma_{A,A} + \sigma^2 \mathbf{I})^{-1}(\mathbf{X}_A - \mu_A), \quad (3)$$

$$\Sigma_{e|A}^2 = \sigma_e^2 - \Sigma_{e,A}(\Sigma_{A,A} + \sigma^2 \mathbf{I})^{-1}\Sigma_{A,e}. \quad (4)$$

Evaluating (3) and (4) is computationally expensive as it requires solving a linear system of $|A|$ variables. Instead, most efficient approaches for making predictions in GPs rely on choosing a small—so called *active*—set of data points. For instance, in the Informative Vector Machine (IVM) one seeks a set S such that the *information gain*, defined as

$$f(S) = I(\mathbf{Y}_S; \mathbf{X}_V) = H(\mathbf{X}_V) - H(\mathbf{X}_V | \mathbf{Y}_S) = \frac{1}{2} \log \det(\mathbf{I} + \sigma^{-2} \Sigma_S)$$

is maximized. It can be shown that this choice of f is monotone submodular (Krause and Guestrin, 2005a). For medium-scale problems, the standard greedy algorithms provide good solutions. For massive data however, we need to resort to distributed algorithms. In Section 6, we will show how GREEDY can choose near-optimal subsets out of a dataset of 45 million vectors.

Inference for Determinantal Point Processes. A very similar problem arises when performing inference in Determinantal Point Processes (DPPs). DPPs (Macchi, 1975) are distributions over subsets with a preference for diversity, i.e., there is a higher probability associated with sets containing dissimilar elements. Formally, a point process \mathcal{P} on a set of items $V = \{1, 2, \dots, N\}$ is a probability measure on 2^V (the set of all subsets of V). \mathcal{P} is called *determinantal point process* if for every $S \subseteq V$ we have:

$$\mathcal{P}(S) \propto \det(K_S),$$

where K is a positive semidefinite kernel matrix, and $K_S \equiv [\kappa_{i,j}]_{i,j \in S}$ is the restriction of K to the entries indexed by elements of S (we adopt that $\det(K_\emptyset) = 1$). The normalization constant can be computed explicitly from the following equation

$$\sum_S \det(K_S) = \det(\mathbf{I} + K),$$

where \mathbf{I} is the $N \times N$ identity matrix. Intuitively, the kernel matrix determines which items are similar and therefore less likely to appear together.

In order to find the most diverse and informative subset of size k , we need to find $\arg \max_{|S| \leq k} \det(K_S)$ which is NP-hard, as the total number of possible subsets is exponential (Ko et al., 1995). However, the objective function is log-submodular, i.e. $f(S) = \log \det(K_S)$ is a submodular function (Kulesza, 2012). Hence, MAP inference in large DPPs is another potential application of distributed submodular maximization.

3.4.2 LARGE-SCALE EXEMPLAR BASED CLUSTERING

Suppose we wish to select a set of exemplars, that best represent a massive dataset. One approach for finding such exemplars is solving the k -medoid problem (Kaufman and Rousseeuw, 2009), which aims to minimize the sum of pairwise dissimilarities between exemplars and elements of the dataset. More precisely, let us assume that for the dataset V we are given a nonnegative function $l : V \times V \rightarrow \mathbb{R}$ (not necessarily assumed symmetric, nor obeying the triangle inequality) such that $l(\cdot, \cdot)$ encodes dissimilarity between elements of the underlying set V . Then, the cost function for the k -medoid problem is:

$$L(S) = \frac{1}{|V|} \sum_{v \in V} \min_{e \in S} l(e, v). \quad (5)$$

Finding the subset

$$S^* = \arg \min_{|S|=k} L(S)$$

of cardinality at most k that minimizes the cost function (5) is NP-hard. However, by introducing an auxiliary element e_0 , a.k.a. phantom exemplar, we can turn L into a monotone submodular function (Krause and Gomes, 2010)

$$f(S) = L(\{e_0\}) - L(S \cup \{e_0\}). \quad (6)$$

In words, f measures the decrease in the loss associated with the set S versus the loss associated with just the auxiliary element. We begin with a phantom exemplar and try to find the active set that together with the phantom exemplar reduces the value of our loss function more than any other set. Technically, any point e_0 that satisfies the following condition can be used as a phantom exemplar:

$$\max_{v' \in V} l(v, v') \leq l(v, e_0), \quad \forall v \in V \setminus S.$$

This condition ensures that once the distance between any $v \in V \setminus S$ and e_0 is greater than the maximum distance between elements in the dataset, then $L(S \cup \{e_0\}) = L(S)$. As a result, maximizing f (a monotone submodular function) is equivalent to minimizing the cost function L . This problem becomes especially computationally challenging when we have a large dataset and we wish to extract a manageable-size set of exemplars, further motivating our distributed approach.

3.4.3 OTHER EXAMPLES

Numerous other real world problems in machine learning can be modeled as maximizing a monotone submodular function subject to appropriate constraints (e.g., cardinality, matroid, knapsack). To name a few, specific applications that have been considered range from efficient content discovery for web crawlers and multi topic blog-watch (Chierichetti et al., 2010), over document summarization (Lin and Bilmes, 2011) and speech data subset selection (Wei et al., 2013), to outbreak detection in social networks (Leskovec et al., 2007), online advertising and network routing (De Vries and Vohra, 2003), revenue maximization in social networks (Hartline et al., 2008), and inferring network of influence (Gomez Rodriguez et al., 2010). In all such examples, the size of the dataset (e.g., number of webpages,

size of the corpus, number of blogs in the blogosphere, number of nodes in social networks) is massive, thus GREEDI offers a scalable approach, in contrast to the standard greedy algorithm, for such problems.

4. The GREEDI Approach for Distributed Submodular Maximization

In this section we present our main results. We first provide our distributed solution GREEDI for maximizing submodular functions under cardinality constraints. We then show how we can make use of the geometry of data inherent in many practical settings in order to obtain strong data-dependent bounds on the performance of our distributed algorithm.

4.1 An Intractable, yet Communication Efficient Approach

Before we introduce GREEDI, we first consider an intractable, but communication-efficient two-round parallel protocol to illustrate the ideas. This approach, shown in Algorithm 1, first distributes the ground set V to m machines. Each machine then finds the *optimal* solution, i.e., a set of cardinality at most k , that maximizes the value of f in each partition. These solutions are then merged, and the optimal subset of cardinality k is found in the combined set. We denote this distributed solution by $f(A^d[m, k])$.

As the optimum centralized solution $A^c[k]$ achieves the maximum value of the submodular function, it is clear that $f(A^c[k]) \geq f(A^d[m, k])$. For the special case of selecting a single element $k = 1$, we have $f(A^c[1]) = f(A^d[m, 1])$. Furthermore, for *modular* functions f (i.e., those for which f and $-f$ are both submodular), it is easy to see that the distributed scheme in fact returns the optimal centralized solution as well. In general, however, there can be a gap between the distributed and the centralized solution. Nonetheless, as the following theorem shows, this gap cannot be more than $1/\min(m, k)$. Furthermore, this result is tight.

Theorem 3 *Let f be a monotone submodular function and let $k > 0$. Then, $f(A^d[m, k]) \geq \frac{1}{\min(m, k)} f(A^c[k])$. In contrast, for any value of m and k , there is a monotone submodular function f such that $f(A^c[k]) = \min(m, k) \cdot f(A^d[m, k])$.*

The proof of all the theorems can be found in the appendix. The above theorem fully characterizes the performance of Algorithm 1 in terms of the best centralized solution. In practice, we cannot run Algorithm 1, since there is no efficient way to identify the optimum subset $A^c[k]$ in set V , unless P=NP. In the following, we introduce an efficient distributed approximation – GREEDI. We will further show, that under some additional assumptions, much stronger guarantees can be obtained.

4.2 Our GREEDI Approximation

Our efficient distributed method GREEDI is shown in Algorithm 2. It parallels the intractable Algorithm 1, but replaces the selection of optimal subsets, i.e., $A^c[k]$, by greedy solutions $A_g^c[k]$. Due to the approximate nature of the greedy algorithm, we allow it to pick sets slightly larger than k . More precisely, GREEDI is a two-round algorithm that takes the ground set V , the number of partitions m , and the cardinality constraint k . It first distributes the ground set over m machines. Then each machine separately runs the

Algorithm 1 Inefficient Distributed Submodular Maximization

Input: Set V , #of partitions m , constraints k .

Output: Set $A^d[m, k]$.

- 1: Partition V into m sets V_1, V_2, \dots, V_m .
 - 2: In each partition V_i find the optimum set $A_i^c[k]$ of cardinality k .
 - 3: Merge the resulting sets: $B = \cup_{i=1}^m A_i^c[k]$.
 - 4: Find the optimum set of cardinality k in B . Output this solution $A^d[m, k]$.
-

Algorithm 2 Greedy Distributed Submodular Maximization (GREEDI)

Input: Set V , #of partitions m , constraints κ .

Output: Set $A^{sd}[m, \kappa]$.

- 1: Partition V into m sets V_1, V_2, \dots, V_m (arbitrarily or at random).
 - 2: Run the standard greedy algorithm on each set V_i to find a solution $A_i^{gc}[\kappa]$.
 - 3: Find $A_{\max}^{gc}[\kappa] = \arg \max_A \{F(A) : A \in \{A_i^{gc}[\kappa], \dots, A_m^{gc}[\kappa]\}\}$
 - 4: Merge the resulting sets: $B = \cup_{i=1}^m A_i^{gc}[\kappa]$.
 - 5: Run the standard greedy algorithm on B to find a solution $A_B^{gc}[\kappa]$.
 - 6: Return $A^{sd}[m, \kappa] = \arg \max_A \{F(A) : A \in \{A_{\max}^{gc}[\kappa], A_B^{gc}[\kappa]\}\}$.
-

standard greedy algorithm by sequentially finding an element $e \in V_i$ that maximizes the discrete derivative (2). Each machine i -in parallel-continues adding elements to the set $A_i^{gc}[\cdot]$ until it reaches κ elements. We define $A_{\max}^{gc}[\kappa]$ to be the set with the maximum value among $\{A_1^{gc}[\kappa], A_2^{gc}[\kappa], \dots, A_m^{gc}[\kappa]\}$. Then the solutions are merged, i.e., $B = \cup_{i=1}^m A_i^{gc}[\kappa]$, and another round of greedy selection is performed over B until κ elements are selected. We denote this solution by $A_B^{gc}[\kappa]$. The final distributed solution with parameters m and κ , denoted by $A^{sd}[m, \kappa]$, is the set with a higher value between $A_{\max}^{gc}[\kappa]$ and $A_B^{gc}[\kappa]$ (c.f., Figure 2 shows GREEDI schematically). The following result parallels Theorem 3.

Theorem 4 Let f be a monotone submodular function and $\kappa \geq k$. Then

$$f(A^{sd}[m, \kappa]) \geq \frac{(1 - e^{-\kappa/k})}{\min(m, k)} f(A^c[k]).$$

For the special case of $\kappa = k$ the result of 4 simplifies to $f(A^{sd}[m, \kappa]) \geq \frac{(1-1/e)}{\min(m, k)} f(A^c[k])$. Moreover, it is straightforward to generalize GREEDI to multiple rounds (i.e., more than two) for very large datasets.

In light of Theorem 3, one can expect that in general it is impossible to eliminate the dependency of the distributed solution on $\min(k, m)$ ¹. However, as we show in the sequel, in many practical settings, the ground set V exhibits rich geometrical structure that can be used to obtain stronger guarantees.

1. It has been very recently shown by Mirzasoleiman et al. (2015b) that the tightest dependency is $\Theta(\sqrt{\min(m, k)})$.

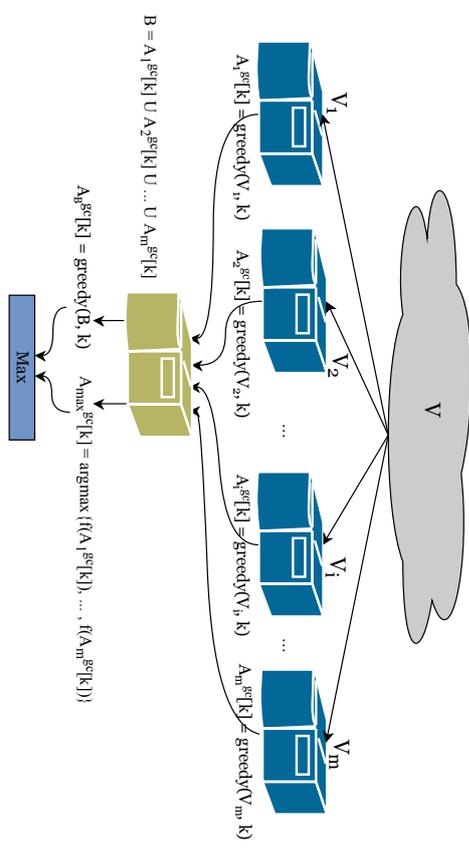

Figure 2: Illustration of our two-round algorithm GREEDI

4.3 Performance on Datasets with Geometric Structure

In practice, we can hope to do much better than the worst case bounds shown previously, by exploiting underlying structure often present in real data and important set functions. In this part, we assume that a metric $d : V \times V \rightarrow \mathbb{R}$ exists on the data elements, and analyze performance of the algorithm on functions that vary slowly with changes in the input. We refer to these as *Lipschitz functions*:

Definition 5 Let $\lambda > 0$. A set function $f : 2^V \rightarrow \mathbb{R}$ is λ -Lipschitz w.r.t. metric d on V , if for any integer k , any equal sized sets $S = \{e_1, e_2, \dots, e_k\} \subseteq V$ and $S' = \{e'_1, e'_2, \dots, e'_k\} \subseteq V$ and any matching of elements: $M = \{(e_1, e'_1), (e_2, e'_2), \dots, (e_k, e'_k)\}$, the difference between $f(S)$ and $f(S')$ is bounded by:

$$|f(S) - f(S')| \leq \lambda \sum_i d(e_i, e'_i). \quad (7)$$

We can show that the objective functions from both examples in Section 3.4 are λ -Lipschitz for suitable kernels/distance functions:

Proposition 6 Suppose that the covariance matrix of a Gaussian process is parametrized via a positive definite kernel $\mathcal{K} : V \times V \rightarrow \mathbb{R}$ which is Lipschitz continuous with respect to metric $d : V \times V \rightarrow \mathbb{R}$ with constant \mathcal{L} , i.e., for any triple of points $x_1, x_2, x_3 \in V$, we have $|\mathcal{K}(x_1, x_3) - \mathcal{K}(x_2, x_3)| \leq \mathcal{L}d(x_1, x_2)$. Then, the mutual information $I(\mathbf{Y}; S; \mathbf{X}) = \frac{1}{2} \log \det(\mathbf{I} + \mathbf{K})$ for the Gaussian process is λ -Lipschitz with $\lambda = \mathcal{L}k^3$, where k is the number of elements in the selected subset S .

Proposition 7 Let $d : V \times V \rightarrow \mathbb{R}$ be a metric on the elements of the dataset. Furthermore, let $l : V \times V \rightarrow \mathbb{R}$ encode the dissimilarity between elements of the underlying set V . Then for $l = d^\alpha$, $\alpha \geq 1$ the loss function $L(S) = \frac{1}{|V|} \sum_{e \in V} \min_{e' \in S} l(e, e')$ (and hence also the corresponding submodular utility function f) is λ -Lipschitz with $\lambda = \alpha R^{\alpha-1}$, where R is the diameter of the ball encompassing elements of the dataset in the metric space. In particular, for the k -medoid problem, which minimizes the loss function over all clusters with respect to $l = d$, we have $\lambda = 1$, and for the k -means problem, which minimizes the loss function over all clusters with respect to $l = d^2$, we have $\lambda = 2R$.

Beyond Lipschitz-continuity, many practical instances of submodular maximization can be expected to satisfy a natural density condition. Concretely, whenever we consider a representative set (i.e., optimal solution to the submodular maximization problem), we expect that any of its constituent elements has potential candidates for replacement in the ground set. For example, in our exemplar-based clustering application, we expect that cluster centers are not isolated points, but have many almost equally representative points close by. Formally, for any element $v \in V$, we define its α -neighborhood as the set of elements in V within distance α from v (i.e., α -close to v):

$$N_\alpha(v) = \{w : d(v, w) \leq \alpha\}.$$

By λ -Lipschitz-continuity, it must hold that if we replace element v in set S by an α -close element v' (i.e., $v' \in N_\alpha(v)$) to get a new set S' of equal size, it must hold that $|f(S') - f(S)| \leq \alpha\lambda$.

As described earlier, our algorithm GREEDI partitions V into sets V_1, V_2, \dots, V_m for parallel processing. If in addition we assume that elements are assigned uniformly at random to different machines, α -neighborhoods are sufficiently dense, and the submodular function is Lipschitz continuous, then GREEDI is guaranteed to produce a solution close to the centralized one. More formally, we have the following theorem.

Theorem 8 Under the conditions that 1) elements are assigned uniformly at random to m machines, 2) for each $e_i \in A^c[k]$ we have $|N_\alpha(e_i)| \geq km \log(k/\delta^{1/m})$, and 3) f is λ -Lipschitz continuous, then with probability at least $(1 - \delta)$ the following holds:

$$f(A^{gd}[m, \kappa]) \geq (1 - e^{-\kappa/k})(f(A^c[k]) - \lambda\alpha k).$$

Note that once the above conditions are satisfied for small values of α (meaning that there is a high density of data points within a small distance from each element of the optimal solution) then the distributed solution will be close to the optimal centralized one. In particular if we let $\alpha \rightarrow 0$, the distributed solution is guaranteed to be within a $1 - e^{-\kappa/k}$ factor from the optimal centralized solution. This situation naturally corresponds to very large datasets. In the following, we discuss more thoroughly this important scenario.

4.4 Performance Guarantees for Very Large Datasets

Suppose that our dataset is a finite sample V drawn i.i.d. from an underlying infinite set \mathcal{V} , according to some (unknown) probability distribution. Let $A^c[k]$ be an optimal solution in the infinite set, i.e., $A^c[k] = \arg \max_{S \subseteq \mathcal{V}} f(S)$, such that around each $e_i \in A^c[k]$, there is

a neighborhood of radius at least α^* where the probability density is at least β at all points (for some constants α^* and β). This implies that the solution consists of elements coming from reasonably dense and therefore representative regions of the dataset.

Let us suppose $g : \mathbb{R} \rightarrow \mathbb{R}$ is the growth function of the metric: $g(\alpha)$ is defined to be the volume of a ball of radius α centered at a point in the metric space. This means, for $e_i \in A^c[k]$ the probability of a random element being in $N_\alpha(e_i)$ is at least $\beta g(\alpha)$ and the expected number of α neighbors of e_i is at least $E[|N_\alpha(e_i)|] = n\beta g(\alpha)$. As a concrete example, Euclidean metrics of dimension D have $g(\alpha) = O(\alpha^D)$. Note that for simplicity we are assuming the metric to be homogeneous, so that the growth function is the same at every point. For heterogeneous spaces, we require g to have a uniform lower bound on the growth function at every point.

In these circumstances, the following theorem guarantees that if the dataset V is sufficiently large and f is λ -Lipschitz, then GREEDI produces a solution close to the centralized one.

Theorem 9 For $n \geq \frac{8km \log(k/\delta^{1/m})}{\beta g(\frac{\varepsilon}{\lambda k})}$, where $\frac{\varepsilon}{\lambda k} \leq \alpha^*$, if the algorithm GREEDI assigns elements uniformly randomly to m processors, then with probability at least $(1 - \delta)$,

$$f(A^{gd}[m, \kappa]) \geq (1 - e^{-\kappa/k})(f(A^c[k]) - \varepsilon).$$

The above theorem shows that for very large datasets, GREEDI provides a solution that is within a $1 - e^{-\kappa/k}$ factor of the optimal centralized solution. This result is based on the fact that for sufficiently large datasets, there is a suitably dense neighborhood around each member of the optimal solution. Thus, if the elements of the dataset are partitioned uniformly randomly to m processors, at least one partition contains a set $A_i^c[k]$ such that its elements are very close to the elements of the optimal centralized solution and provides a constant factor approximation of the optimal centralized solution.

4.5 Handling Decomposable Functions

So far, we have assumed that the objective function f is given to us as a black box, which we can evaluate for any given set S independently of the dataset V . In many settings, however, the objective f depends itself on the entire dataset. In such a setting, we cannot use GREEDI as presented above, since we cannot evaluate f on the individual machines without access to the full set V . Fortunately, many such functions have a simple structure which we call *decomposable*. More precisely, we call a submodular function f *decomposable* if it can be written as a sum of submodular functions as follows (Krause and Gomes, 2010):

$$f(S) = \frac{1}{|V|} \sum_{i \in V} f_i(S)$$

In other words, there is separate submodular function associated with every data point $i \in V$. We require that each f_i can be evaluated without access to the full set V . Note that the exemplar based clustering application we discussed in Section 3.4 is an instance of this framework, among many others. Let us define the evaluation of f restricted to $D \subseteq V$ as

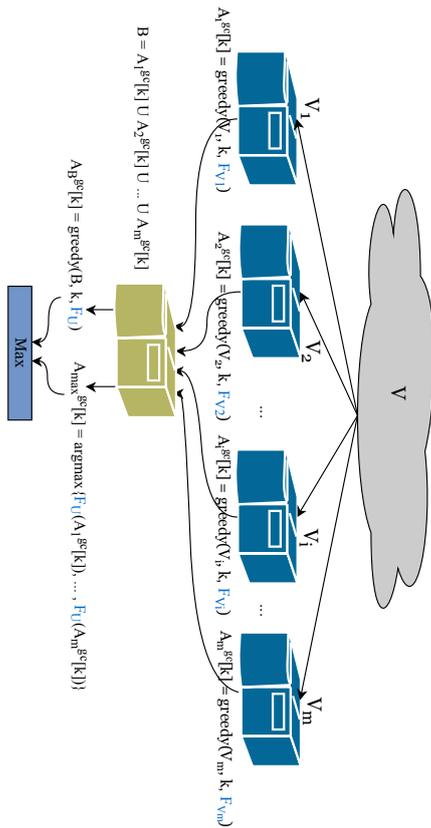

Figure 3: Illustration of our two-round algorithm GREEDI for decomposable functions

follows:

$$f_D(S) = \frac{1}{|D|} \sum_{i \in D} f_i(S)$$

In the remaining of this section, we show that assigning each element of the dataset randomly to a machine and running GREEDI will provide a solution that is with high probability close to the optimum solution. For this, let us assume that f_i 's are bounded, and without loss of generality $0 \leq f_i(S) \leq 1$ for $1 \leq i \leq |V|, S \subseteq V$. Similar to Section 4.3 we assume that GREEDI performs the partition by assigning elements uniformly at random to the machines. These machines then each greedily optimize f_i . The second stage of GREEDI optimizes f_U , where $U \subseteq V$ is chosen uniformly at random with size $|n/m|$.

Then, we can show the following result. First, for any fixed ϵ, m, k , let us define n_0 to be the smallest integer such that for $n \geq n_0$ we have $\ln(n)/n \leq \epsilon^2/(mk)$.

Theorem 10 For $n \geq \max(n_0, m \log(\delta/4m)/\epsilon^2)$, $\epsilon < 1/4$, and under the assumptions of Theorem 9, we have, with probability at least $1 - \delta$,

$$f(A^{gr}[m, \kappa]) \geq (1 - e^{-n/m}) (f(A^c[k]) - 2\epsilon).$$

The above result demonstrates why GREEDI performs well on decomposable submodular functions with massive data even when they are evaluated locally on each machine. We will report our experimental results on exemplar-based clustering in the next section.

4.6 Performance of GREEDI on Random Partitions Without Geometric Structure

Very recently, Barbosa et al. (2015) and Mirrokni and Zadimoghaddam (2015) proved that under random partitioning of the data among m machines, the expected utility of GREEDI will be only a constant factor away from the optimum.

Theorem 11 (Barbosa et al. (2015); Mirrokni and Zadimoghaddam (2015)) *If elements are assigned uniformly at random to the machines, and $\kappa = k$, GREEDI gives a constant factor approximation guarantee (in the average case) to the optimum centralized solution².*

$$\mathbb{E}[f(A^{gr}[m, k])] \geq \frac{1-1/e}{2} f(A^c[k]).$$

These results show that random partitioning of the data is sufficient to guarantee that GREEDI provides a constant factor approximation, irrespective of m and k , and without the requirement of any geometric structure. On the other hand, if geometric structure is present, the bounds from the previous sections can provide sharper approximation guarantees.

5. (Non-Monotone) Submodular Functions with General Constraints

In this section we show how GREEDI can be extended to handle 1) more general constraints, and 2) non-monotone submodular functions. More precisely, we consider the following optimization setting

$$\begin{aligned} & \text{Maximize } f(S) \\ & \text{Subject to } S \in \zeta. \end{aligned}$$

Here, we assume that the feasible solutions should be members of the constraint set $\zeta \subseteq 2^V$. The function $f(\cdot)$ is submodular but may not be monotone. By overloading the notation we denote the set that achieves the above constrained optimization problem by $A^c[\zeta]$. Throughout this section we assume that the constraint set ζ is hereditary, meaning that if $A \in \zeta$ then for any $B \subseteq A$ we also require that $B \in \zeta$. Cardinality constraints are obviously hereditary, so are all the examples we mention below.

5.1 Matroid Constraints

A matroid \mathcal{M} is a pair (V, \mathcal{I}) where V is a finite set (called the ground set) and $\mathcal{I} \subseteq 2^V$ is a family of subsets of V (called the independent sets) satisfying the following two properties:

- *Hereditary property:* $A \subseteq B \subseteq V$ and $B \in \mathcal{I}$ implies that $A \in \mathcal{I}$, i.e. every subset of an independent set is independent.
- *Augmentation property:* If $A, B \in \mathcal{I}$ and $|B| > |A|$, there is an element $e \in B \setminus A$ such that $A \cup \{e\} \in \mathcal{I}$.

2. In fact, Mirrokni and Zadimoghaddam (2015) proved a 0.27-approximation guarantee which is slightly worse than $(1 - 1/e)/2$.

Maximizing a submodular function subject to matroid constraints has found several applications in machine learning and data mining, ranging from content aggregation on the web (Abbassi et al., 2013) to viral marketing (Narayanan and Nanavati, 2012) and online advertising (Streeter et al., 2009).

One way to approximately maximize a monotone submodular function $f(S)$ subject to the constraint that each S is independent, i.e., $S \in \mathcal{I}$, is to use a generalization of the greedy algorithm. This algorithm, which starts with an empty set and in each iteration picks the feasible element with maximum benefit until there is no more element e such that $S \cup \{e\} \in \mathcal{I}$, is guaranteed to provide a $\frac{1}{2}$ -approximation of the optimal solution (Fisher et al., 1978). Recently, this bound has been improved to $(1 - 1/e)$ using the continuous greedy algorithm (Calinescu et al., 2011). For non-negative and non-monotone submodular functions with matroid constraints, the best known result is a 0.325-approximation based on simulated annealing (Gharan and Vondrák, 2011).

Curvature: For a submodular function f , the total curvature of f with respect to a set S is defined as:

$$c = 1 - \min_{j \in V} \frac{f(j|S \setminus j)}{f(j)}.$$

Intuitively, the notion of curvature determines how far away f is from being modular. In other words, it measures how much the marginal gain of an element w.r.t. set S can decrease as a function of S . In general, $c \in [0, 1]$, and for additive (modular) functions, $c = 0$, i.e., the marginal values are independent of S . In this case, the greedy algorithm returns the optimal solution to $\max\{f(S) : S \in \mathcal{I}\}$. In general, the greedy algorithm gives a $\frac{1}{1+c}$ -approximation to maximizing a non-decreasing submodular function with curvature c subject to a matroid constraint (Conforti and Cornuéjols, 1984). In case of the uniform matroid $\mathcal{I} = \{S : |S| \leq k\}$, the approximation factor is $(1 - e^{-c})/c$.

Intersection of Matroids: A more general case is when we have p matroids $\mathcal{M}_1 = (V, \mathcal{I}_1), \mathcal{M}_2 = (V, \mathcal{I}_2), \dots, \mathcal{M}_p = (V, \mathcal{I}_p)$ on the same ground set V , and we want to maximize the submodular function f on the intersection of p matroids. That is, $\mathcal{I} = \bigcap_i \mathcal{I}_i$ consists of all subsets of V that are independent in all p matroids. This constraint arises, e.g., when optimizing over rankings (which can be modeled as intersections of two partition matroids). Another recent application considered is finding the influential set of users in viral marketing when multiple products need to be advertised and each user can tolerate only a small number of recommendations (Du et al., 2013). For p matroid constraints, the $\frac{1}{p+1}$ -approximation provided by the greedy algorithm (Fisher et al., 1978) has been improved to a $(\frac{1}{p} - \epsilon)$ -approximation for $p \geq 2$ by Lee et al. (2009b). For the non-monotone case, a $1/(p + 2 + 1/p + \epsilon)$ -approximation based on local search is also given by Lee et al. (2009b).

p -systems: p -independence systems generalize constraints given by the intersection of p matroids. Given an independence family \mathcal{I} and a set $V' \subseteq V$, let $S(V')$ denote the set of maximal independent sets of \mathcal{I} included in V' , i.e., $S(V') = \{A \in \mathcal{I} \mid \forall e \in V' \setminus A : A \cup \{e\} \notin \mathcal{I}\}$. Then we call (V, \mathcal{I}) a p -system if for all nonempty $V' \subseteq V$ we have

$$\max_{A \in S(V')} |A| \leq p \cdot \min_{A \in S(V')} |A|.$$

Similar to p matroid constraints, the greedy algorithm provides a $\frac{1}{p+1}$ -approximation guarantee for maximizing a monotone submodular function subject to a p -systems constraint (Fisher et al., 1978). For the non-monotone case, Gupta et al. (2010) provided a $p/((p + 1)(3p + 3))$ -approximation can be achieved by combining an algorithm of Gupta et al. (2010) with the result for unconstrained submodular maximization of Buchbinder et al. (2012). This result has been recently tightened to $p/((p + 1)(2p + 1))$ by Mirzasoleiman et al. (2016).

5.2 Knapsack Constraints

In many applications, including feature and variable selection in probabilistic models (Krause and Guestrin, 2005a) and document summarization (Lin and Bilmes, 2011), elements $e \in V$ have non-uniform costs $c(e) > 0$, and we wish to find a collection of elements S that maximize f subject to the constraint that the total cost of elements in S does not exceed a given budget \mathcal{R} , i.e.

$$\max_S f(S) \text{ s.t. } \sum_{v \in S} c(v) \leq \mathcal{R}.$$

Since the simple greedy algorithm ignores cost while iteratively adding elements with maximum marginal gains according (see Eq. 2) until $|S| \leq \mathcal{R}$, it can perform arbitrary poorly. However, it has been shown that taking the maximum over the solution returned by the greedy algorithm that works according to Eq. 2 and the solution returned by the modified greedy algorithm that optimizes the cost-benefit ratio

$$v^* = \arg \max_{\substack{e \in V \setminus S \\ c(e) \leq \mathcal{R} - c(S)}} \frac{f(S \cup \{e\}) - f(S)}{c(v)},$$

provides a $(1 - 1/\sqrt{\epsilon})$ -approximation of the optimal solution (Krause and Guestrin, 2005b). Furthermore, a more computationally expensive algorithm which starts with all feasible solutions of cardinality 3 and augments them using the cost-benefit greedy algorithm to find the set with maximum value of the objective function provides a $(1 - 1/\epsilon)$ -approximation (Sviridenko, 2004). For maximizing non-monotone submodular functions subject to knapsack constraints, a $(1/5 - \epsilon)$ -approximation algorithm based on local search was given by Lee et al. (2009a).

Multiple Knapsack Constraints: In some applications such as procurement auctions (Garg et al., 2001), video-on-demand systems and e-commerce (Kulik et al., 2009), we have a d -dimensional budget vector \mathcal{R} and a set of element $e \in V$ where each element is associated with a d -dimensional cost vector. In this setting, we seek a subset of elements $S \subseteq V$ with a total cost of at most \mathcal{R} that maximizes a non-decreasing submodular function f . Kulik et al. (2009) proposed a two-phase algorithm that provides a $(1 - 1/e - \epsilon)$ -approximation for the problem by first guessing a constant number of elements of highest value, and then taking the value residual problem with respect to the guessed subset. For the non-monotone case, Lee et al. (2009a) provided a $(1/5 - \epsilon)$ -approximation based on local search.

p -system and d knapsack constraints: A more general type of constraint that has recently found interesting applications in viral marketing (Du et al., 2013) and personalized data summarization Mirzasoleiman et al. (2016) which can be cast by combining a

Constraint	monotone submodular functions	Approximation (τ)	non-monotone submodular functions
Cardinality	$1 - 1/e$ (Fisher et al., 1978)	0.325 (Gharan and Vondrák, 2011)	
1 matroid	$1 - 1/e$ (Ghahesou et al., 2011)	0.325 (Gharan and Vondrák, 2011)	
p matroid	$1/p - \epsilon$ (Lee et al., 2009b)	$1/(p + 2 + 1/p + \epsilon)$ (Lee et al., 2009b)	
1 knapsack	$1 - 1/e$ (Sviridenko, 2004)	$1/5 - \epsilon$ (Lee et al., 2009a)	
d knapsack	$1 - 1/e - \epsilon$ (Kuhlé et al., 2009)	$1/5 - \epsilon$ (Lee et al., 2009a)	
p -system	$1/(p + 1)$ (Fisher et al., 1978)	$p/((p + 1)(2p + 1))$ (Mirzasoleiman et al., 2016)	
p -system + d knapsack	$1/(p + 2d + 1)$ (Bardandiyuru and Vondrák, 2014)	$(1 + \epsilon)/(p + 1)(2p + 2d + 1)/p$ (Mirzasoleiman et al., 2016)	

Table 1: Approximation guarantees (τ) for monotone and non-monotone submodular maximization under different constraints.

p -system with d knapsack constraints. For maximizing a monotone submodular function Bardandiyuru and Vondrák (2014) proposed a modified version of the greedy algorithm that guarantees a $1/(p + 2d + 1)$ -approximation. By combining this algorithm with the one proposed in (Gupta et al., 2010), Mirzasoleiman et al. (2016) provided a fast algorithm for maximizing a non-monotone submodular function subject to a p -system and d knapsack constraints with $(1 + \epsilon)/(p + 1)(2p + 2d + 1)/p$ -approximation.

Table 1 summarizes the approximation guarantees for monotone and non-monotone submodular maximization under different constraints.

5.3 GREEDI APPROXIMATION GUARANTEE UNDER MORE GENERAL CONSTRAINTS

Assume that we have a set of constraints $\zeta \subseteq 2^V$ that is hereditary. Further assume we have access to a "black box" algorithm X that gives us a constraint factor approximation guarantee for maximizing a non-negative (but not necessarily monotone) submodular function f subject to ζ , i.e.

$$X : (f, \zeta) \rightarrow A^X \in \zeta \text{ s.t. } f(A^X[\zeta]) \geq \tau \max_{A \in \zeta} f(A). \quad (8)$$

We can modify GREEDI to use any such approximation algorithm as a black box, and provide theoretical guarantees about the solution. In order to process a large dataset, it first distributes the ground set over m machines. Then instead of greedily selecting elements, each machine i -in parallel—separately runs the black box algorithm X on its local data in order to produce a feasible set $A_i^X[\zeta]$ meeting the constraints ζ . We denote by $A_{\max}^{\text{loc}}[\zeta]$ the set with maximum value among $A_i^X[\zeta]$. Next, the solutions are merged: $B = \cup_{i=1}^m A_i^X[\zeta]$, and the black box algorithm is applied one more time to set B to produce a solution $A_B^{\text{loc}}[\zeta]$. Then, the distributed solution for parameter m and constraints ζ , $A^{Xd}[m, \zeta]$, is the best among $A_{\max}^{\text{loc}}[\zeta]$ and $A_B^{\text{loc}}[\zeta]$. This procedure is given in more detail in Algorithm 3.

The following result generalizes Theorem 4 for maximizing a submodular function subject to more general constraints.

Algorithm 3 GREEDI under General Constraints

Input: Set V , #of partitions m , constraints ζ , submodular function f .

Output: Set $A^{Xd}[m, \zeta]$.

- 1: Partition V into m sets V_1, V_2, \dots, V_m .
- 2: In parallel: Run the approximation algorithm X on each set V_i to find a solution $A_i^X[\zeta]$.
- 3: Find $A_{\max}^{\text{loc}}[\zeta] = \arg \max_A \{f(A) \mid A \in \{A_1^X[\zeta], \dots, A_m^X[\zeta]\}\}$.
- 4: Merge the resulting sets: $B = \cup_{i=1}^m A_i^X[\zeta]$.
- 5: Run the approximation algorithm X on B to find a solution $A_B^{\text{loc}}[\zeta]$.
- 6: Return $A^{Xd}[m, \zeta] = \arg \max\{A_{\max}^{\text{loc}}[\zeta], A_B^{\text{loc}}[\zeta]\}$.

Theorem 12 *Let f be a non-negative submodular function and X be a black box algorithm that provides a τ -approximation guarantee for submodular maximization subject to a set of hereditary constraints ζ . Then*

$$f(A^{Xd}[m, \zeta]) \geq \frac{\tau}{\min(m, \rho([\zeta]))} f(A^c[\zeta]),$$

where $f(A^c[\zeta])$ is the optimum centralized solution, and $\rho([\zeta]) = \max_{A \in \zeta} |A|$.

Specifically, for submodular maximization subject to the matroid constraint \mathcal{M} , we have $\rho(A \in \mathcal{I}) = r_{\mathcal{M}}$ where $r_{\mathcal{M}}$ is the rank of the matroid (i.e., the maximum size of any independent set in the system). For submodular maximization subject to the knapsack constraint \mathcal{R} , we can bound $\rho([\zeta] \leq \mathcal{R})$ by $\lceil \mathcal{R} / \min_{v \in \mathcal{V}} c(v) \rceil$ (i.e. the capacity of the knapsack divided by the smallest weight of any element).

Performance on Datasets with Geometric Structure. When the submodular function $f(\cdot)$ and the constraint set ζ have more structure, then we can provide much better approximation guarantees. Assuming the elements of V are embedded in metric space with distance $d : V \times V \rightarrow \mathbb{R}^+$, we say that ζ is *locally replaceable* with respect to a set $S \subseteq V$ with parameter $\alpha > 0$ if

$$\forall S' \subseteq V \text{ s.t. } |S'| = |S| \text{ and } d_{\infty}(S, S') \leq \alpha \Rightarrow S' \in \zeta.$$

Here, we define the distance d_{∞} between two sets S and S' of the same size k as follows. Let M be the set of all possible matchings between S and S' , i.e.,

$$M = \{((e_1, e'_1), \dots, (e_k, e'_k)) \text{ s.t. } e_i \in S \text{ and } e'_i \in S' \text{ for } 1 \leq i \leq k\}.$$

Then $d_{\infty}(S, S') = \min_M \max_i d(e_i, e'_i)$. We require locality only with respect to $A^c[\zeta]$ to ensure that the optimum solution can be well approximated. What the locally replaceable property requires is that as elements of $A^c[\zeta]$ get replaced by nearby elements, the resulting set is also a feasible solution. Combining this property with λ -Lipschitzness will provide us with the following theorem.

Theorem 13 *Under the conditions that 1) elements are assigned uniformly at random to m machines, 2) for each $e_i \in A^c[\zeta]$ we have $|\mathcal{N}_{\alpha}(e_i)| \geq \rho([\zeta])m \log(\rho([\zeta])/\delta^{1/m})$, 3) $f(\cdot)$ is*

λ -Lipschitz, and 4) ζ is locally replaceable with respect to $A^c[\zeta]$ with parameter α , then with probability at least $(1 - \delta)$,

$$f(A^{Xd}[m, \zeta]) \geq \tau(f(A^c[\zeta]) - \lambda\alpha\rho(\zeta)).$$

The above result generalizes Theorem 8 for maximizing non-negative submodular functions subject to different constraints.

Performance Guarantee for Very Large Datasets. Similarly, we can generalize Theorem 9 for maximizing non-negative submodular functions subject to more general constraints. Suppose that our dataset is a finite sample V drawn i.i.d. from an underlying infinite set \mathcal{V} , according to some (unknown) probability distribution. Let $A^c[\zeta]$ be an optimal solution in the infinite set, i.e., $A^c[\zeta] = \arg \max_{S \subseteq \mathcal{V}} f(S)$, such that around each $e_i \in A^c[\zeta]$, there is a neighborhood of radius at least α^* where the probability density is at least β at all points (for some constants α^* and β). Recall that $g: \mathbb{R} \rightarrow \mathbb{R}$ is the growth function where $g(\alpha)$ measures the volume of a ball of radius α centered at a point in the metric space.

Theorem 14 For $n \geq \frac{8\rho(\zeta)m \log(\rho(\zeta)/\delta^{1/m})}{\beta g(\frac{\epsilon}{\lambda\rho(\zeta)})}$, where $\frac{\epsilon}{\lambda\rho(\zeta)} \leq \alpha^*$, if GREEDI assigns elements uniformly at random to m processors and under the conditions that f is λ -Lipschitz, and ζ is locally replaceable with respect to $A^c[\zeta]$ with parameter α^* , then with probability at least $(1 - \delta)$, we have

$$f(A^{Xd}[m, \zeta]) \geq \tau(f(A^c[\zeta]) - \epsilon).$$

Performance Guarantee for Decomposable Functions. For the case of decomposable functions described in Section 4.5, the following generalization of Theorem 10 holds for maximizing a non-negative submodular function subject to more general constraints. Let us define n_0 to be the smallest integer such that for $n \geq n_0$ we have $\ln(n)/n \leq \epsilon^2/(m \cdot \rho(\zeta))$.

Theorem 15 For $n \geq \max(n_0, m \log(\delta/4m)/\epsilon^2)$, $\epsilon < 1/4$, and under the assumptions of Theorem 14, we have, with probability at least $1 - \delta$,

$$f(A^{Xd}[m, \zeta]) \geq \tau(f(A^c[\zeta]) - 2\epsilon).$$

6. Experiments

In our experimental evaluation we wish to address the following questions: 1) how well does GREEDI perform compared to the centralized solution, 2) how good is the performance of GREEDI when using decomposable objective functions (see Section 4.5), and finally 3) how well does GREEDI scale in the context of massive datasets. To this end, we run GREEDI on three scenarios: exemplar based clustering, active set selection in GPs and finding the maximum cuts in graphs.

We compare the performance of our GREEDI method to the following naive approaches:

- *random/random*: in the first round each machine simply outputs k randomly chosen elements from its local data points and in the second round k out of the merged mk elements, are again randomly chosen as the final output.

- *random/greedy*: each machine outputs k randomly chosen elements from its local data points, then the standard greedy algorithm is run over mk elements to find a solution of size k .

- *greedy/merge*: in the first round k/m elements are chosen greedily from each machine and in the second round they are merged to output a solution of size k .

- *greedy/max*: in the first round each machine greedily finds a solution of size k and in the second round the solution with the maximum value is reported.

For GREEDI, we let each of the m machines select a set of size αk , and select a final solution of size k among the union of the m solutions (i.e., among αkm elements). We present the performance of GREEDI for different parameters $\alpha > 0$. For datasets where we are able to find the centralized solution, we report the ratio of $f(A_{\text{dist}}[k])/f(A^c[k])$, where $A_{\text{dist}}[k]$ is the distributed solution (in particular $A^{\text{gd}}[m, \alpha k, k] = A_{\text{dist}}[k]$ for GREEDI).

6.1 Exemplar Based Clustering

Our exemplar based clustering experiment involves GREEDI applied to the clustering utility $f(S)$ (see Sec. 3.4) with $d(x, x') = \|x - x'\|^2$. We performed our experiments on a set of 10,000 *Tiny Images* (Torralba et al., 2008). Each 32 by 32 RGB pixel image was represented by a 3,072 dimensional vector. We subtracted from each vector the mean value, normalized it to unit norm, and used the origin as the auxiliary exemplar. Fig. 4a compares the performance of our approach to the benchmarks with the number of exemplars set to $k = 50$, and varying number of partitions m . It can be seen that GREEDI significantly outperforms the benchmarks and provides a solution that is very close to the centralized one. Interestingly, even for very small $\alpha = \kappa/k < 1$, GREEDI performs very well. Since the exemplar based clustering utility function is decomposable, we repeated the experiment for the more realistic case where the function evaluation in each machine was restricted to the local elements of the dataset in that particular machine (rather than the entire dataset). Fig 4b shows similar qualitative behavior for decomposable objective functions.

Large scale experiments with Hadoop. As our first large scale experiment, we applied GREEDI to the whole dataset of 80,000,000 *Tiny Images* (Torralba et al., 2008) in order to select a set of 64 exemplars. Our experimental infrastructure was a cluster of 10 quad-core machines running Hadoop with the number of reducers set to $m = 8000$. Hereby, each machine carried out a set of reduce tasks in sequence. We first partitioned the images uniformly at random to reducers. Each reducer separately performed the lazy greedy algorithm on its own set of 10,000 images ($\approx 123\text{MB}$) to extract 64 images with the highest marginal gains w.r.t. the local elements of the dataset in that particular partition. We then merged the results and performed another round of lazy greedy selection on the merged results to extract the final 64 exemplars. Function evaluation in the second stage was performed w.r.t. a randomly selected subset of 10,000 images from the entire dataset. The maximum running time per reduce task was 2.5 hours. As Fig. 5a shows, GREEDI highly outperforms the other distributed benchmarks and can scale well to very large datasets. Fig. 5b shows a set of cluster exemplars discovered by GREEDI where Fig. 5c and Fig. 5d show 100 nearest images to exemplars 26 and 63 (shown with red borders) in Fig. 5b.

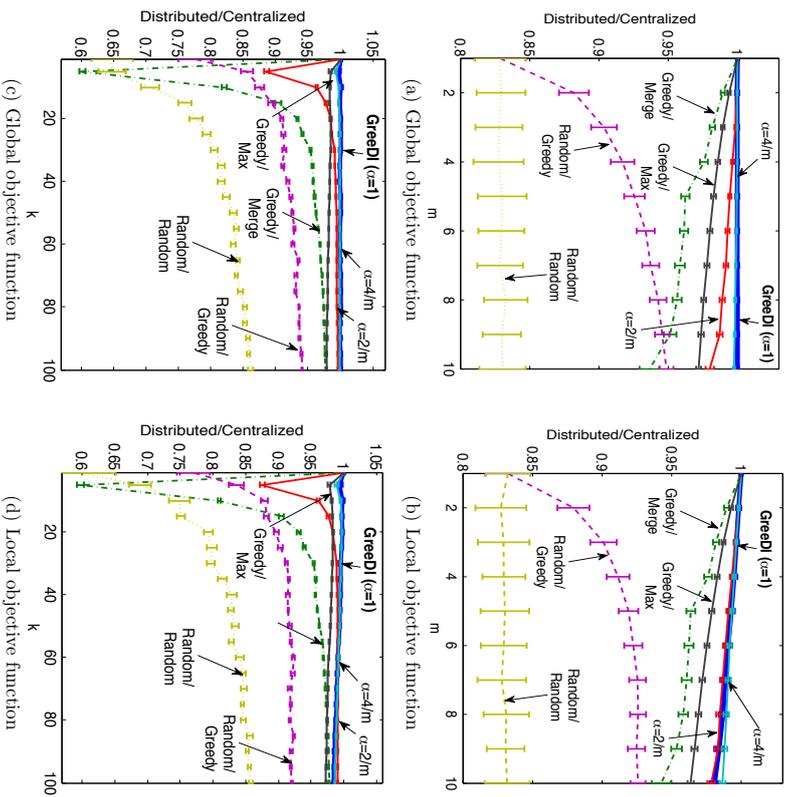

Figure 4: Performance of GREEDI compared to the other benchmarks. a) and b) show the mean and standard deviation of the ratio of distributed vs. centralized solution for global and local objective functions with budget $k = 50$ and varying the number m of partitions. c) and d) show the same ratio for global and local objective functions for $m = 5$ partitions and varying budget k , for a set of 10,000 *Tiny Images*.

6.2 Active Set Selection

Our active set selection experiment involves GREEDI applied to the information gain $f(S)$ (see Sec. 3.4) with Gaussian kernel, $h = 0.75$ and $\sigma = 1$. We used the *Parkinsons Telemor-toring* dataset (Tsanas et al., 2010) consisting of 5,875 bio-medical voice measurements with 22 attributes from people with early-stage Parkinson’s disease. We normalized the vectors to zero mean and unit norm. Fig. 6b compares the performance GREEDI to the

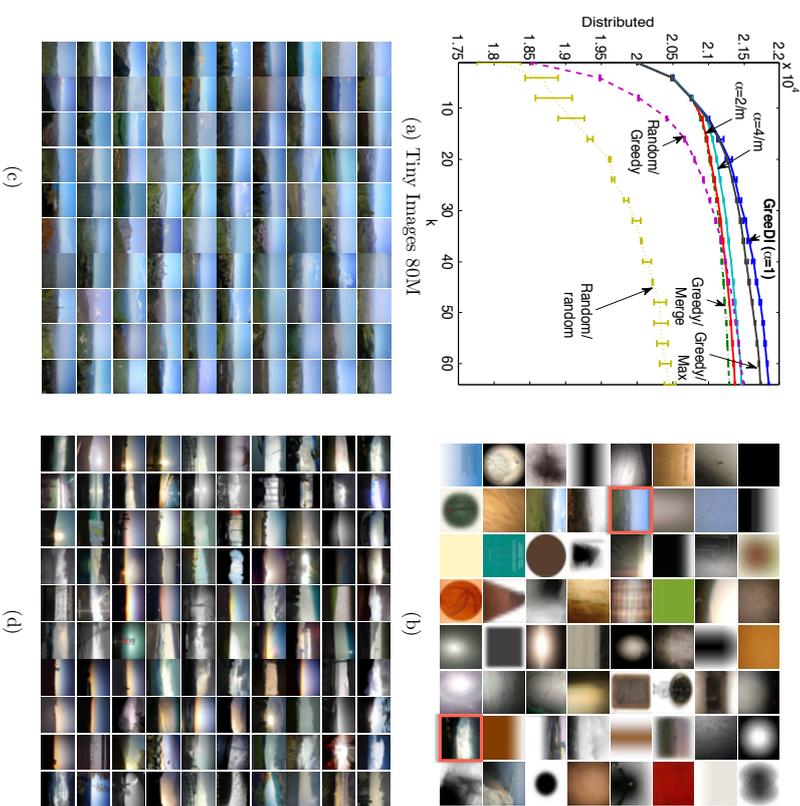

Figure 5: Performance of GREEDI compared to the other benchmarks. a) shows the distributed solution with $m = 8000$ and varying k for local objective functions on the whole dataset of 80,000,000 *Tiny Images*. b) shows a set of cluster exemplars discovered by GREEDI, and each column in c) shows 100 images nearest to exemplars 26 and d) shows 100 images nearest to exemplars 63 in b).

benchmarks with fixed $k = 50$ and varying number of partitions m . Similarly, Fig 6a shows the results for fixed $m = 10$ and varying k . We find that GREEDI significantly outperforms the benchmarks.

Large scale experiments with Hadoop. Our second large scale experiment consists of 45,811,888 user visits from the Featured Tab of the Today Module on Yahoo! Front Page (web, 2012). For each visit, both the user and each of the candidate articles are associated with a feature vector of dimension 6. Here, we used the normalized user features. Our experimental setup was a cluster of 8 quad-core machines running Spark with the number

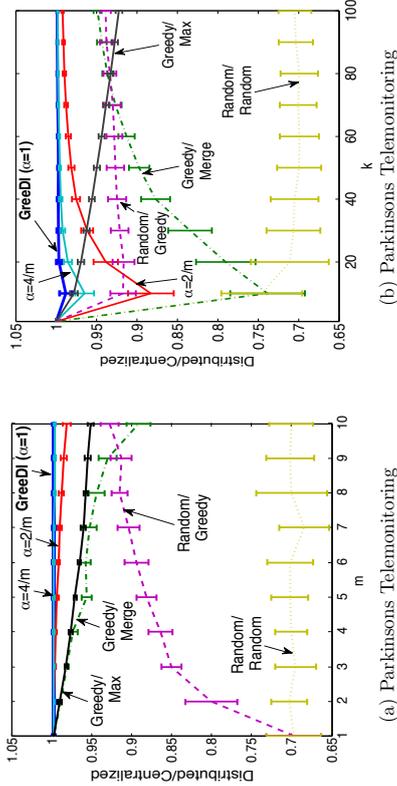

Figure 6: Performance of GREEDI compared to the other benchmarks. a) shows the ratio of distributed vs. centralized solution with $k = 50$ and varying m for *Parkinson's Telemonitoring*. b) shows the same ratio with $m = 10$ and varying k on the same dataset.

of reducers set to $m = 32$. Each reducer performed the lazy greedy algorithm on its own set of $\approx 1,431,621$ vectors ($\approx 34\text{MB}$) in order to extract 256 elements with the highest marginal gains w.r.t the local elements of the dataset in that particular partition. We then merged the results and performed another round of lazy greedy selection on the merged results to extract the final active set of size 256. The maximum running time per reduce task was 12 minutes for selecting 128 elements and 48 minutes for selecting 256 elements. Fig. 7 shows the performance of GREEDI compared to the benchmarks. We note again that GREEDI significantly outperforms the other distributed benchmarks and can scale well to very large datasets.

Performance Comparison. Fig. 8 shows the speedup of GREEDI compared to the centralized greedy benchmark for different values of k and varying number of partitions m . As Fig. 8a shows, for small values of m , the speedup is almost linear in the number of machines. However, for large values of m the running time of the second stage of GREEDI increases and ultimately dominates the whole running time. Hence, we do not observe a linear speedup anymore. This effect can be observed in Fig. 8b. For larger values of k , the speedup is higher on fewer machines, but decreases more quickly by increasing m , as the second stage takes longer to complete.

6.3 Non-Monotone Submodular Function (Finding Maximum Cuts)

We also applied GREEDI to the problem of finding maximum cuts in graphs. In our setting we used a *Facebook-like social network* (Opsahl and Panzarasa, 2009). This dataset includes the users that have sent or received at least one message in an online student community at University of California, Irvine and consists of 1,899 users and 20,296 directed ties. Fig. 9a and 9b show the performance of GREEDI applied to the cut function on graphs. We evaluated the objective function locally on each partition. Thus, the links

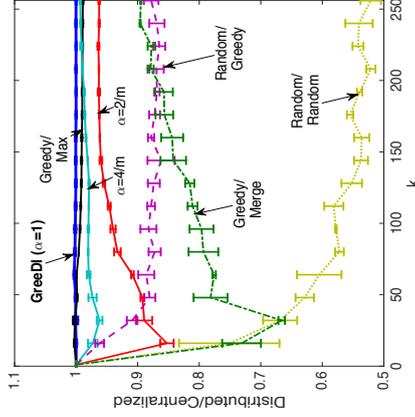

Figure 7: Performance of GREEDI with $m = 32$ and varying budget k compared to the other benchmarks on *Yahoo! Webscope data*.

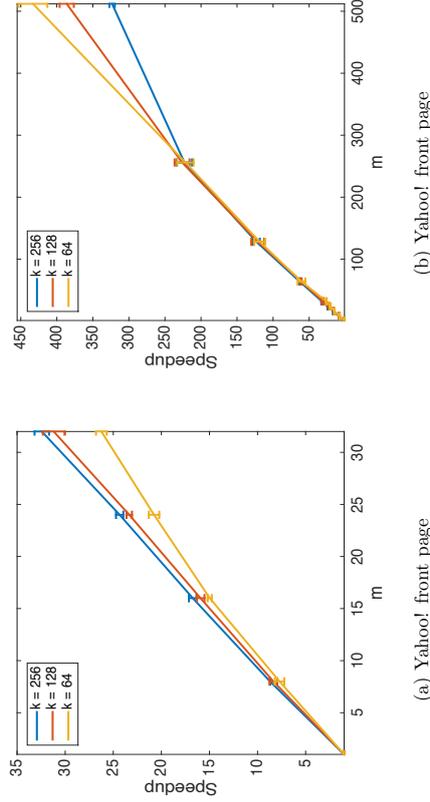

Figure 8: Running time of GREEDI compared to the centralized greedy algorithm. a) shows the ratio of centralized vs. distributed solution with $k = 64, 128, 256$ and up to $m = 32$ machines for *Yahoo Webscope data*. b) shows the same ratio with $k = 64, 128, 256$ and up to $m = 512$ machines on the same dataset. Both experiments are performed on a cluster of 8 quad core machines.

between the partitions are disconnected. Since the problem of finding the maximum cut in a graph is non-monotone submodular, we applied the RandomGreedy algorithm proposed by Buchbinder et al. (2014) to find the near optimal solution in each partition.

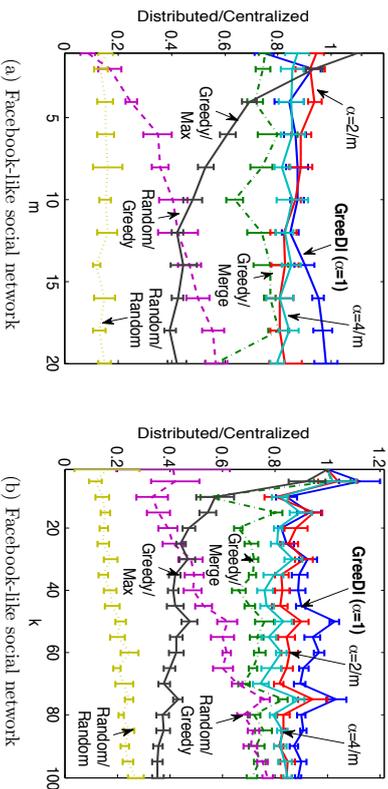

Figure 9: Performance of GREEDI compared to the other benchmarks. a) shows the mean and standard deviation of the ratio of distributed to centralized solution for budget $k = 20$ with varying number of machines m and b) shows the same ratio for varying budget k with $m = 10$ on *Facebook-like social network*.

Although the cut function does not decompose additively over individual data points, perhaps surprisingly, GREEDI still performs very well, and significantly outperforms the benchmarks. This suggests that our approach is quite robust, and may be more generally applicable.

6.4 Comparison with Greedy Scaling.

Kumar et al. (2013) recently proposed an alternative approach—GREEDYSCALING—for parallel maximization of submodular functions. GREEDYSCALING is a randomized algorithm that carries out a number (typically less than k) rounds of MapReduce computations. We applied GREEDI to the submodular coverage problem in which given a collection V of sets, we would like to pick at most k sets from V in order to maximize the size of their union. We compared the performance of our GREEDI algorithm to the reported performance of GREEDYSCALING on the same datasets, namely *Accidents* (Gauts et al., 2003) and *Kosarak* (Bodon, 2012). As Fig 10a and 10b shows, GREEDI outperforms GREEDYSCALING on the *Accidents* dataset and its performance is comparable to that of GREEDYSCALING in the *Kosarak* dataset.

7. Conclusion

We have developed an efficient distributed protocol GREEDI, for constrained submodular maximization. We have theoretically analyzed the performance of our method and showed that under certain natural conditions it performs very close to the centralized (albeit impractical in massive datasets) solution. We have also demonstrated the effectiveness of our approach through extensive experiments, including active set selection in GPs on a dataset

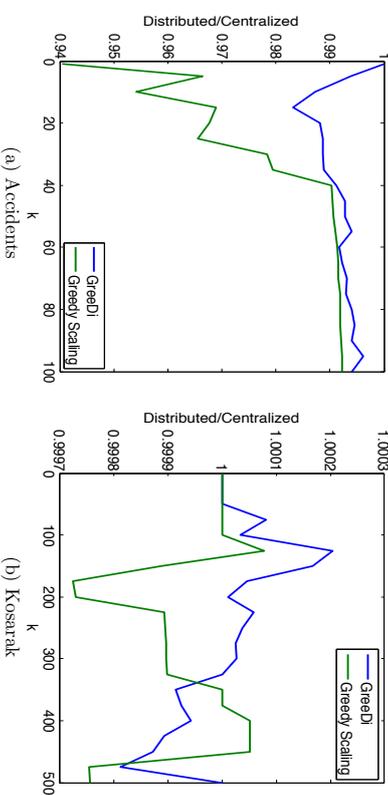

Figure 10: Performance of GREEDI compared to the GreedyScaling algorithm of Kumar et al. (2013) (as reported in their paper). a) shows the ratio of distributed to centralized solution on *Accidents* dataset with 340,183 elements and b) shows the same ratio for *Kosarak* dataset with 990,002 elements. The results are reported for varying budget k and varying number of machines $m = n/\mu$ where $\mu = O(kn^\delta \log n)$ and n is the size of the dataset. The results are reported for $\delta = 1/2$. Note that the results presented by Kumar et al. (2013) indicate that GreedyScaling generally requires a substantially larger number of MapReduce rounds compared to GREEDI.

of 45 million examples, and exemplar based summarization of a collection of 80 million images using Hadoop. We believe our results provide an important step towards solving submodular optimization problems in very large scale, real applications.

Appendix A. Proofs

This section presents the complete proofs of theorems presented in the article.

A.1 Proof of Theorem 3

⇒ direction:

The proof easily follows from the following lemmas.

Lemma 16 $\max_i f(A_i^c[k]) \geq \frac{1}{m} f(A^c[k])$.

Proof Let B_i be the elements in V_i that are contained in the optimal solution, $B_i = A_i^c[k] \cap V_i$. Then we have:

$$f(A^c[k]) = f(B_1 \cup \dots \cup B_m) = f(B_1) + f(B_2|B_1) + \dots + f(B_m|B_{m-1}, \dots, B_1).$$

Using submodularity of f , for each $i \in \{1 \dots m\}$, we have

$$f(B_i|B_{i-1} \dots B_1) \leq f(B_i),$$

and thus,

$$f(A^c[k]) \leq f(B_1) + \dots + f(B_m).$$

Since, $f(A_i^c[k]) \geq f(B_i)$, we have

$$f(A^c[k]) \leq f(A_1^c[k]) + \dots + f(A_m^c[k]).$$

Therefore,

$$f(A^c[k]) \leq m \max_i f(A_i^c[k]).$$

Lemma 17 $\max_i f(A_i^c[k]) \geq \frac{1}{k} f(A^c[k])$.

Proof Let $f(A^c[k]) = f(\{u_1, \dots, u_k\})$. Using submodularity of f , we have

$$f(A^c[k]) \leq \sum_{i=1}^k f(u_i).$$

Thus, $f(A^c[k]) \leq k f(u^*)$ where $u^* = \arg \max_i f(u_i)$. Suppose that the element with highest marginal gain (i.e., u^*) is in V_j . Then the maximum value of f on V_j would be greater or equal to the marginal gain of u^* , i.e., $f(A_j^c[k]) \geq f(u^*)$ and since $f(\max_i f(A_i^c[k])) \geq f(A_j^c[k])$, we can conclude that

$$f(\max_i f(A_i^c[k])) \geq f(u^*) \geq \frac{1}{k} f(A^c[k]).$$

Since $f(A^d[m, k]) \geq \max_i f(A_i^c[k])$; from Lemma 16 and 17 we have

$$f(A^d[m, k]) \geq \frac{1}{\min(m, k)} f(A^c[k]).$$

⇐ direction:

Let us consider a set of unbiased and independent Bernoulli random variables $X_{i,j}$ for $i \in \{1, \dots, m\}$ and $j \in \{1, \dots, k\}$, i.e., $\Pr(X_{i,j} = 1) = \Pr(X_{i,j} = 0) = 1/2$ and $(X_{i,j} \perp X_{i',j'})$ if $i \neq i'$ or $j \neq j'$. Let us also define $Y_i = (X_{i,1}, \dots, X_{i,k})$ for $i \in \{1, \dots, m\}$. Now assume that $V_i = \{X_{i,1}, \dots, X_{i,k}, Y_i\}$, $V = \bigcup_{i=1}^m V_i$ and $f(S) = H(S)$, where H is the entropy of the subset S of random variables. Note that H is a monotone submodular function. It is easy to see that $A_i^c[k] = \{X_{i,1}, \dots, X_{i,k}\}$ or $A_i^c[k] = Y_i$ as in both cases $H(A_i^c[k]) = k$. If we assume $A_i^c[k] = \{X_{i,1}, \dots, X_{i,k}\}$, then $B = \{X_{i,j} | 1 \leq i \leq m, 1 \leq j \leq k\}$. Hence, by selecting at most k elements from B , we have $H(A^d[m, k]) = k$. On the other hand, the set of k elements that maximizes the entropy is $\{Y_1, \dots, Y_m\}$. Note that $H(Y_i) = k$ and $Y_i \perp Y_j$ for $i \neq j$. Hence, $H(A^c) = k \cdot m$ if $m \geq k$ or otherwise $H(A^c[k]) = k^2$.

A.2 Proof of Theorem 4

Let us first mention a slight generalization over the performance of the standard greedy algorithm. It follows easily from the argument in (Nemhauser et al., 1978).

Lemma 18 *Let f be a non-negative submodular function, and let $A^{gc}[q]$ of cardinality q be the greedy selected set by the standard greedy algorithm. Then,*

$$f(A^{gc}[q]) \geq \left(1 - e^{-\frac{q}{k}}\right) f(A^c[k]).$$

By Lemma 18 we know that

$$f(A_i^{gc}[k]) \geq (1 - \exp(-\kappa/k)) f(A_i^c[k]).$$

Now, let us define

$$B^{gc} = \bigcup_{i=1}^m A_i^{gc}[k],$$

$$A_{\max}^{gc}[k] = \max_i f(A_i^{gc}[k]),$$

$$\bar{A}[k] = \arg \max_{S \subseteq B^{gc}, |S| \leq \kappa} f(S).$$

Then by using Lemma 18 again, we obtain

$$\begin{aligned} f(A^{gd}[m, \kappa]) &\geq \max \{ f(A_{\max}^{gc}[k]), (1 - \exp(-\kappa/\kappa)) f(\bar{A}[k]) \} \\ &\geq \frac{(1 - \exp(-\kappa/k))}{\min(m, k)} f(A^c[k]). \end{aligned}$$

A.3 Proof of Proposition 6

Let K be a positive definite kernel matrix defined in section 3.4.1. If we replace a point $e_i \in S$ with another point $e'_i \in V \setminus S$, the corresponding row and column i in the modified kernel matrix K' will be changed. W.l.o.g assume that we replace the first element $e_1 \in S$ with another element $e'_1 \in V \setminus S$, i.e., $\Delta K = K' - K$ has the following form with non-zero entries only on the first row and first column,

$$\Delta K \equiv K' - K \leq \begin{pmatrix} a_1 & a_2 & \dots & a_k \\ a_2 & 0 & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ a_k & 0 & \dots & 0 \end{pmatrix}.$$

Note that kernel is Lipschitz continuous with constant \mathcal{L} , hence we have $|a_i| \leq \mathcal{L}d(e_1, e'_1)$ for $1 \leq i \leq k$. Then the absolute value of the change in the objective function would be

$$\begin{aligned}
 |f(S) - f(S')| &= \left| \frac{1}{2} \log \det(\mathbf{I} + K') - \frac{1}{2} \log \det(\mathbf{I} + K) \right| \\
 &= \frac{1}{2} \left| \log \frac{\det(\mathbf{I} + K')}{\det(\mathbf{I} + K)} \right| \\
 &= \frac{1}{2} \left| \log \frac{\det(\mathbf{I} + K + \Delta K)}{\det(\mathbf{I} + K)} \right| \\
 &= \frac{1}{2} \left| \log[\det(\mathbf{I} + K + \Delta K) \cdot \det(\mathbf{I} + K)^{-1}] \right| \\
 &= \frac{1}{2} \left| \log \det(\mathbf{I} + \Delta K(\mathbf{I} + K)^{-1}) \right|. \tag{9}
 \end{aligned}$$

Note that since K is positive-definite, $\mathbf{I} + K$ is an invertible matrix. Furthermore, since ΔK and K are symmetric matrices they both have k real eigenvalues. Therefore, $(\mathbf{I} + K)^{-1}$ has k eigenvalues $\lambda_i = \frac{1}{1 + \lambda_i} \leq 1$, for $1 \leq i \leq k$, where $\lambda_1' \cdots \lambda_k'$ are (non-negative) eigenvalues of kernel matrix K .

Now, we bound the maximum eigenvalues of ΔK and $\Delta K(\mathbf{I} + K)^{-1}$ respectively. Consider vectors $x, x' \in \mathbb{R}^n$, such that $\|x\|_2 = \|x'\|_2 = 1$. We have,

$$\begin{aligned}
 |x^T \Delta K x'| &= \begin{pmatrix} x_1 \\ x_2 \\ \vdots \\ x_k \end{pmatrix}^T \begin{pmatrix} a_1 & a_2 & \cdots & a_k \\ a_2 & 0 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ a_k & 0 & \cdots & 0 \end{pmatrix} \begin{pmatrix} x'_1 \\ x'_2 \\ \vdots \\ x'_k \end{pmatrix} \\
 &= \begin{pmatrix} x_1 & x_2 & \cdots & x_k \\ x_2 & 0 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ x_k & 0 & \cdots & 0 \end{pmatrix}^T \begin{pmatrix} \sum_{i=1}^k a_i x_i x'_i \\ a_2 x'_1 \\ \vdots \\ a_k x'_1 \end{pmatrix} \\
 &= |x_1| \sum_{i=1}^k a_i x_i^2 + x'_1 \sum_{i=2}^k a_i x_i \\
 &= |x_1| \cdot \left| \sum_{i=1}^k a_i x_i^2 \right| + |x'_1| \cdot \left| \sum_{i=2}^k a_i x_i \right| \\
 &= |x_1| \cdot \sum_{i=1}^k |a_i x_i^2| + |x'_1| \cdot \sum_{i=2}^k |a_i x_i| \\
 &\leq 2k\mathcal{L}d(e_1, e'_1), \tag{10}
 \end{aligned}$$

where we used the following facts to derive the last inequality: 1) the Lipschitz continuity of the kernel gives us an upperbound on the values of $|a_i|$, i.e., $|a_i| \leq \mathcal{L}d(e_1, e'_1)$ for $1 \leq i \leq k$; and 2) since $\|x\|_2 = \|x'\|_2 = 1$, the absolute value of the elements in vectors x and x' cannot

be greater than 1, i.e., $|x_i| \leq 1, |x'_i| \leq 1$, for $1 \leq i \leq k$. Therefore,

$$\lambda_{\max}(\Delta K) = \max_{x: \|x\|_2=1} |x^T \Delta K x| \leq 2k\mathcal{L}d(e_1, e'_1).$$

Now, let $v_1, \dots, v_k \in \mathbb{R}^n$ be the k eigenvectors of matrix $(\mathbf{I} + K)^{-1}$. Note that $\{v_1, \dots, v_k\}$ is an orthonormal system and thus for any $x \in \mathbb{R}^n$ we can write it as $x = \sum_{i=1}^k c_i v_i$ and we have $\|x\|_2^2 = \sum_{i=1}^k c_i^2$. In order to bound the largest eigenvalue of $\Delta K(\mathbf{I} + K)$, we write

$$\begin{aligned}
 |x^T \Delta K (\mathbf{I} + K)^{-1} x| &= \left| x^T \Delta K (\mathbf{I} + K)^{-1} \sum_{i=1}^k c_i v_i \right| \\
 &= \left| x^T \Delta K \sum_{i=1}^k \lambda_i c_i v_i \right| \\
 &= \left| \sum_{j=1}^k c_j v_j^T \Delta K \left(\sum_{i=1}^k \lambda_i c_i v_i \right) \right| \\
 &= \sum_{i,j=1}^k \lambda_i c_i v_i^T \Delta K v_j \\
 &\stackrel{(a)}{\leq} 2k\mathcal{L}d(e_1, e'_1) \sum_{i,j=1}^k |c_i| |c_j| \\
 &= 2k\mathcal{L}d(e_1, e'_1) \left(\sum_{i=1}^k |c_i| \right)^2,
 \end{aligned}$$

where in (a) we used Eq. 10 and the fact that $\lambda_i \leq 1$ for $1 \leq i \leq k$. Using Cauchy-Schwarz inequality

$$\left(\sum_{i=1}^k |c_i| \right)^2 \leq k \sum_{i=1}^k |c_i|^2$$

and the assumption $\|x\|_2 = 1$, we conclude

$$\begin{aligned}
 |x^T \Delta K (\mathbf{I} + K)^{-1} x| &\leq 2k^2 \mathcal{L}d(e_1, e'_1) \sum_{i=1}^k |c_i|^2 \\
 &\leq 2k^2 \|x\|_2^2 \mathcal{L}d(e_1, e'_1) \\
 &\leq 2k^2 \mathcal{L}d(e_1, e'_1).
 \end{aligned}$$

Therefore,

$$\lambda_{\max}(\Delta K(\mathbf{I} + K)^{-1}) = \max_{x: \|x\|_2=1} |x^T \Delta K (\mathbf{I} + K)^{-1} x| \leq 2k^2 \mathcal{L}d(e_1, e'_1). \tag{11}$$

Finally, we can write the determinant of a matrix as the product of its eigenvalues, i.e.

$$\det(\mathbf{I} + \Delta K(\mathbf{I} + K)^{-1}) \leq (1 + 2k^2 \mathcal{L}d(e_1, e'_1))^k. \quad (12)$$

By substituting Eq. 11 and Eq. 12 into Eq. 9 we obtain

$$\begin{aligned} |f(S) - f(S')| &\leq \frac{1}{2} \left| \log(1 + 2k^2 \mathcal{L}d(e_1, e'_1))^k \right| \\ &\leq \frac{k}{2} \left| \log(1 + 2k^2 \mathcal{L}d(e_1, e'_1)) \right| \\ &\leq k^3 \mathcal{L}d(e_1, e'_1), \end{aligned}$$

where in the last inequality we used $\log(1+x) \leq x$, for $x \geq 0$.

Replacing all the k points in set S with another set S' of the same size, we get

$$|f(S) - f(S')| \leq k^3 \mathcal{L} \sum_{i=1}^k d(e_i, e'_i).$$

Hence, the differential entropy of the Gaussian process is λ -Lipschitz with $\lambda = \mathcal{L}k^3$.

A.4 Proof of Proposition 7

Assume we have a set S of k exemplars, i.e., $S_0 = \{e_1, \dots, e_k\}$, and each element of the dataset $v \in V$ is assigned to its closest exemplar. Now, if we replace set S with another set S' of the same size, the loss associated with every element $v \in V$ may be changed. W.l.o.g, assume we swap one exemplar at a time, i.e., in step i , $1 \leq i \leq k$, we have $S_i = \{e_1, \dots, e'_i, e_{i+1}, \dots, e_k\}$. Swapping the i^{th} exemplar $e_i \in S_{i-1}$ with another element $e'_i \in S'$, 4 cases may happen: 1) element v was not assigned to e_i before and doesn't get assigned to e'_i , 2) element v was assigned to e_i before and gets assigned to e'_i , 3) element v was not assigned to e_i before and gets assigned to e'_i , 4) element v was assigned to e_i before and gets assigned to another exemplar $e_x \in S_i \setminus \{e'_i\}$. For any element $v \in V$, we look into the four cases and show that in each case

$$|l(e'_i, v) - l(e_i, v)| \leq d(e_i, e'_i) \alpha R^{\alpha-1}.$$

- Case 1: In this case, element v was assigned to another exemplar $e_x \in S_i \setminus e_i$ and the assignment doesn't change. Therefore, there is no change in the value of the loss function.
- Case 2: In this case, element v was assigned to e_i before and gets assigned to e'_i . let $a = d(e_i, v)$ and $b = d(e'_i, v)$. Then we can write

$$\begin{aligned} |l(e'_i, v) - l(e_i, v)| &= |a^\alpha - b^\alpha| \\ &= |(a-b)(a^{\alpha-1} + a^{\alpha-2}b + \dots + ab^{\alpha-2} + b^{\alpha-1})| \\ &\leq d(e_i, e'_i) \alpha R^{\alpha-1}, \end{aligned} \quad (13)$$

where in the last step we used triangle inequality $|d(e_i, v) - d(e_i, v)| \leq d(e_i, e'_i)$ and the fact that data points are in a ball of diameter R in the metric space.

- Case 3: In this case, v was assigned to another exemplar $e_x \in S_{i-1} \setminus \{e_i\}$ and gets assigned to e'_i , which implies that $|l(e'_i, v) - l(e_x, v)| \leq |l(e_i, v) - l(e'_i, v)|$, since otherwise e would have been assigned to e_i before.

- Case 4: In the last case, element v was assigned to e_i before and gets assigned to another exemplar $e_x \in S_i \setminus \{e'_i\}$. Thus, we have $|l(e_x, v) - l(e_i, v)| \leq |l(e'_i, v) - l(e_i, v)|$ since otherwise v would have been assigned to e_x before. Hence, in all four cases the following inequality holds:

$$\left| \min_{e \in S_{i-1}} l(e, v) - \min_{e \in S_i} l(e, v) \right| \leq |l(e'_i, v) - l(e_i, v)| \leq d(e_i, e'_i) \alpha R^{\alpha-1}.$$

By using Eq. 13 and averaging over all elements $v \in V$, we have

$$\begin{aligned} |L(S_{i-1}) - L(S_i)| &= \frac{1}{|V|} \sum_{v \in V} \left| \min_{e \in S_{i-1}} l(e, v) - \min_{e \in S_i} l(e, v) \right| \\ &\leq \alpha R^{\alpha-1} d(e_i, e'_i). \end{aligned}$$

Thus, for any point e_0 that satisfies

$$\max_{v \in V} l(v, v') \leq l(v, e_0), \quad \forall v \in V \setminus S,$$

we have $L(\{e_0 \cup S\}) = L(\{S\})$ and thus

$$\begin{aligned} |f(S_{i-1}) - f(S_i)| &= |L(\{e_0\}) - L(\{e_0 \cup S_{i-1}\}) - L(\{e_0\}) + L(\{e_0 \cup S_i\})| \\ &\leq \alpha R^{\alpha-1} d(e_i, e'_i). \end{aligned}$$

Now, if we replace all the k points in set S with another set S' of the same size, we get

$$\begin{aligned} |f(S) - f(S')| &= \left| \sum_{i=1}^k f(S_{i-1}) - f(S_i) \right| \\ &= \sum_{i=1}^k |f(S_{i-1}) - f(S_i)| \\ &\leq \alpha R^{\alpha-1} \sum_{i=1}^k d(e_i, e'_i). \end{aligned}$$

Therefore, for $l = d^\alpha$, the loss function is λ -Lipschitz with $\lambda = \alpha R^{\alpha-1}$.

A.5 Proof of Theorem 8

In the following, we say that sets S and S' are γ -close if $|f(S) - f(S')| \leq \gamma$. First, we need the following lemma.

Lemma 19 *If for each $e_i \in A_i^c[k]$, $|N_\alpha(e_i)| \geq km \log(k/\delta^{1/m})$, and if V is partitioned into sets V_1, V_2, \dots, V_m , where each element is randomly assigned to one set with equal probabilities, then there is at least one partition with a subset $A_i^c[k]$ such that $|f(A_i^c[k]) - f(A_i^c[k])| \leq \lambda \alpha k$ with probability at least $(1 - \delta)$.*

Proof By the hypothesis, the α neighborhood of each element in $A^c[k]$ contains at least $km \log(k/\delta^{1/m})$ elements. For each $e_i \in A^c[k]$, let us take a set of $m \log(k/\delta^{1/m})$ elements from its α -neighborhood. These sets can be constructed to be mutually disjoint, since each α -neighborhood contains $m \log(k/\delta^{1/m})$ elements. We wish to show that at least one of the m partitions of V contains elements from α -neighborhoods of each element.

Each of the $m \log(k/\delta^{1/m})$ elements goes into a particular V_j with a probability $1/m$. The probability that a particular V_j does not contain an element α -close to $e_i \in A^c[k]$ is $\delta^{1/m}$. The probability that V_j does not contain elements α -close to one or more of the k elements is at most $\delta^{1/m}$ (by union bound). The probability that each V_1, V_2, \dots, V_m does not contain elements from the α -neighborhood of one or more of the k elements is at most δ . Thus, with high probability of at least $(1 - \delta)$, at least one of V_1, V_2, \dots, V_m contains an $A^c[k]$ that is $\lambda\alpha k$ -close to $A^c[k]$. ■

By lemma 19, for some V_{i_0} $|f(A^c[k]) - f(A_{i_0}^c[k])| \leq \lambda\alpha k$ with the given probability. Furthermore, $f(A_{i_0}^c[k]) \geq (1 - e^{-\alpha/k})f(A^c[k])$ by Lemma 18. Therefore, the result follows using arguments analogous to the proof of Theorem 4.

A.6 Proof of Theorem 9

The following lemma says that in a sample drawn from distribution over an infinite dataset, a sufficiently large sample size guarantees a dense neighborhood near each element of $A^c[k]$ when the elements are from representative regions of the data.

Lemma 20 *A number of elements: $n \geq \frac{Sk m \log(k/\delta^{1/m})}{\beta g(\alpha)}$, where $\alpha \leq \alpha^*$, suffices to have at least $4km \log(k/\delta^{1/m})$ elements in the α -neighborhood of each $e_i \in A^c[k]$ with probability at least $(1 - \delta)$, for small values of δ .*

Proof The expected number of α -neighbors of an $e_i \in A^c[k]$ is $E[|N_\alpha(e_i)|] \geq Sk m \log(k/\delta^{1/m})$. We now show that in a random set of samples, at least a half of this number of neighbors is realized with high probability near each element of $A^c[k]$.

This follows from a Chernoff bound:

$$\Pr[|N_\alpha(e_i)| \leq 4km \log(k/\delta^{1/m})] \leq e^{-km \log(k/\delta^{1/m})} \leq (\delta^{1/m}/k)^{km}.$$

Therefore, the probability that some $e_i \in A^c[k]$ does not have a suitable sized neighborhood is at most $k(\delta^{1/m}/k)^{km}$. For $\delta \leq 1/k$, $k\delta^{km} \leq \delta^m$. Therefore, with probability at least $(1 - \delta)$, the α -neighborhood of each element $e_i \in A^c[k]$ contains at least $4km \log(1/\delta)$ elements. ■

Lemma 21 *For $n \geq \frac{Sk m \log(k/\delta^{1/m})}{\beta g(\frac{\delta}{k})}$, where $\frac{\delta}{k} \leq \alpha^*$, if V is partitioned into sets V_1, V_2, \dots, V_m , where each element is randomly assigned to one set with equal probabilities, then for sufficiently small values of δ , there is at least one partition with a subset $A^c[k]$ such that $|f(A^c[k]) - f(A_{i_0}^c[k])| \leq \varepsilon$ with probability at least $(1 - \delta)$.*

Proof Follows directly by combining Lemma 20 and Lemma 19. The probability that some element does not have a sufficiently dense $\varepsilon/\lambda k$ -neighborhood with $km \log(2k/\delta^{1/m})$ elements is at most $(\delta/2)$ for sufficiently small δ , and the probability that some partition does not contain elements from the one or more of the dense neighborhoods is at most $(\delta/2)$. Therefore, the result holds with probability at least $(1 - \delta)$. ■

By Lemma 21, there is at least one V_j such that $|f(A^c[k]) - f(A_{j_0}^c[k])| \leq \varepsilon$ with the given probability. And $f(A_{j_0}^c[k]) \geq (1 - e^{-\alpha/k})f(A^c[k])$ using Lemma 18. The result follows using arguments analogous to the proof of Theorem 4.

A.7 Proof of Theorem 10

Note that each machine has on the average n/m elements. Let us define Π_i the event that $n_i/2m < |V_i^c| < 2n_i/m$. Then based on the Chernoff bound we know that $\Pr(\neg\Pi_i) \leq 2\exp(-n_i/8m)$. Let us also define $\xi_i(S)$ the event that $|f_{V_i}(S) - f(S)| < \varepsilon$, for some fixed $\varepsilon < 1$ and a fixed set S with $|S| \leq k$. Note that $\xi_i(S)$ denotes the event that the empirical mean is close to the true mean. Based on the Hoeffding inequality (without replacement) we have $\Pr(\neq \xi_i S) \leq 2\exp(-2n\varepsilon^2/m)$. Hence,

$$\Pr(\xi(S) \wedge \Pi_i) \geq 1 - 2\exp(-2n\varepsilon^2/m) - 2\exp(-n/8m).$$

Let ξ_i be an event that $|f_{V_i}(S) - f(S)| < \varepsilon$, for any S such that $|S| \leq k$. Note that there are at most n^k sets of size at most k . Hence,

$$\Pr(\xi_i \wedge \Pi_i) \geq 1 - 2n^k \exp(-2n\varepsilon^2/m) - \exp(-n/8m). \quad (14)$$

As a result, for $\varepsilon < 1/4$ we have

$$\Pr(\xi_i \wedge \Pi_i) \geq 1 - 4n^k \exp(-2n\varepsilon^2/m).$$

Since there are m machines, by the union bound we can conclude that

$$\Pr(\xi(S) \wedge \Pi_i \text{ on all machines}) \geq 1 - 4mn^k \exp(-2n\varepsilon^2/m).$$

The above calculation implies that we need to choose $\delta \geq 4mn^k \exp(-2n\varepsilon^2/m)$. Let n_0 be chosen in a way that for any $n \geq n_0$ we have $\ln(n)/n \leq \varepsilon^2/(mk)$. Then, we need to choose n as follows:

$$n = \max\left(n_0, \frac{m \log(\delta/4m)}{\varepsilon^2}\right).$$

Hence for the above choice of n , there is at least one V_i such that $|f(A^c[k]) - f(A_{i_0}^c[k])| \leq \varepsilon$ with probability $1 - \delta$. Hence the solution is ε away from the optimum solution with probability $1 - \delta$. Now if we confine the evaluation of $f(A_{i_0}^c)$ to data point only in machine i then under the assumption of Theorem 9 we lose another ε . Formally, the result at this point simply follows by combining Theorem 4 and Theorem 9.

A.8 Proof of Theorem 12

The proof is similar to the proof of Theorem 3 and Theorem 4 and follows from the following lemmas.

Lemma 22 $\max_i f(A_i^c[\zeta]) \geq \frac{1}{m} f(A^c[\zeta])$.

Proof Let B_i be the elements in V_i that are contained in the optimal solution, $B_i = A^c[\zeta] \cap V_i$. Since $A^c[\zeta] \in \zeta$ and ζ is a set of hereditary constraints, we must have $B_i \in \zeta$ as well. Using submodularity of f and by the same argument as in the proof of Lemma 16, we have

$$\begin{aligned} f(A^c[\zeta]) &= f(B_1 \cup \dots \cup B_m) = f(B_1) + f(B_2|B_1) + \dots + f(B_m|B_{m-1}, \dots, B_1) \\ &\leq f(B_1) + \dots + f(B_m). \end{aligned}$$

Since $f(A_i^c[\zeta]) \geq f(B_i)$ we get

$$f(A^c[\zeta]) \leq f(A_1^c[\zeta]) + \dots + f(A_m^c[\zeta]) \leq m \max_i f(A_i^c[\zeta]).$$

■

Lemma 23 $\max_i f(A_i^c[\zeta]) \geq \frac{1}{k} f(A^c[\zeta])$.

Proof The proof follows the outline of the proof of Lemma 17. Let $f(A^c[\zeta]) = f(\{u_1, \dots, u_{\rho(\zeta)}\})$. Since $A^c[\zeta] \in \zeta$ and ζ is a set of hereditary constraints, we have $u_i \in \zeta$. Using submodularity of f , we have

$$f(A^c[\zeta]) \leq \sum_{i=1}^{\rho(\zeta)} f(u_i) \leq \rho(\zeta) f(u^*),$$

where $u^* = \arg \max_i f(u_i)$. Suppose that $u^* \in V_j$, we get

$$f(\max_i f(A_i^c[\zeta])) \geq f(A_j^c[\zeta]) \geq f(u^*) \geq \frac{1}{\rho(\zeta)} f(A^c[\zeta]).$$

Since $f(A^d[m, \rho(\zeta)]) \geq \max_i f(A_i^c[\zeta])$; from Lemma 23 and 22 we have

$$f(A^d[m, \rho(\zeta)]) \geq \frac{1}{\min(m, \rho(\zeta))} f(A^c[\zeta]).$$

For the black box algorithm X with a τ -approximation guarantee, we have

$$f(A_i^X[\zeta]) \geq \tau f(A_i^c[\zeta]).$$

Now, we generalize the definitions used in the proof of Theorem 4

$$\begin{aligned} B^{\text{gc}} &= \cup_{i=1}^m A_i^{\text{gc}}[\zeta], \\ A_{\max}^{\text{gc}}[\zeta] &= \max_i f(A_i^{\text{gc}}[\zeta]), \\ \bar{A}[\zeta] &= \arg \max_{S \subseteq B^{\text{gc}} \& |S| \leq \rho(\zeta)} f(S). \end{aligned}$$

Then using Eq. 15 again, we obtain

$$\begin{aligned} f(A^d[m, \zeta]) &\geq \max \{f(A_{\max}^{\text{gc}}[\zeta]), \tau f(\bar{A}[\zeta])\} \\ &\geq \frac{\tau}{\min(m, \rho(\zeta))} f(A^c[\zeta]). \end{aligned}$$

Note that since we do not use monotonicity of the submodular function in any of the proofs, the results hold in general for constrained maximization of any non-negative submodular function.

A.9 Proof of Theorem 13

Lemma 24 If for each $e_i \in A^X[\zeta]$, $|N_\alpha(e_i)| \geq \rho(\zeta) m \log(\rho(\zeta)/\delta^{1/m})$, and if V is partitioned into sets V_1, V_2, \dots, V_m , where each element is randomly assigned to one set with equal probabilities, then there is at least one partition with a subset $A_i^X[\zeta] \in \zeta$ such that $|f(A^c[\zeta]) - f(A_i^X[\zeta])| \leq \lambda \alpha \rho(\zeta)$ with probability at least $(1 - \delta)$.

The proof is similar to the proof of Lemma 19 by taking disjoint sets of size $m \log(\rho(\zeta)/\delta^{1/m})$ in an α -neighborhood of each $e_i \in A^X[\zeta]$ and showing that with high probability, at least one of the m partitions of V contains elements from α -neighborhoods of each element in the optimal solution. Note that now the size of the optimal solution is at most $\rho(\zeta)$. Since ζ is locally replaceable with parameter α , as elements of $A^c[\zeta]$ gets replaced by nearby elements in their α -neighborhood, the resulting set is also a feasible solution.

By Lemma 24, for some V_i , $|f(A^c[\zeta]) - f(A_i^X[\zeta])| \leq \lambda \alpha \rho(\zeta)$ with the given probability. On the other hand, for the black box algorithm X , we have $f(A_i^X[\zeta]) \geq \tau f(A_i^c[\zeta])$. Therefore, the result follows using arguments analogous to the proof of Theorem 12.

A.10 Proof of Theorem 14

We use the following Lemmas to show that in a sample drawn from a distribution over an infinite dataset, a sufficiently large sample size guarantees a dense neighborhood near each element of the optimal solution.

Lemma 25 A number of elements: $n \geq \frac{8\rho(\zeta)m \log(\rho(\zeta)/\delta^{1/m})}{\beta g(\alpha)}$, where $\alpha \leq \alpha^*$, suffices to have at least $4\rho(\zeta)m \log(\rho(\zeta)/\delta^{1/m})$ elements in the α -neighborhood of each $e_i \in A^c[\zeta]$ with probability at least $(1 - \delta)$, for small values of δ .

Lemma 26 For $n \geq \frac{8\rho(\zeta)m \log(\rho(\zeta)/\delta^{1/m})}{\beta g(\frac{\varepsilon}{\lambda \rho(\zeta)})}$, where $\frac{\varepsilon}{\lambda \rho(\zeta)} \leq \alpha^*$, if V is partitioned into sets V_1, V_2, \dots, V_m , where each element is randomly assigned to one set with equal probabilities, then for sufficiently small values of δ , there is at least one partition with a subset $A_i^c[\zeta]$ such that $|f(A^c[\zeta]) - f(A_i^c[\zeta])| \leq \varepsilon$ with probability at least $(1 - \delta)$.

The proofs follows the same arguments as in the proof of Lemma 20 and 21. Recall that, by assumption ζ is locally replaceable with parameter α . Hence, for $\varepsilon \leq \alpha \lambda \rho(\zeta)$, any set ε -close to the optimal solution is also a feasible solution.

By Lemma 26, there is at least one V_i such that $|f(A_i^c(\zeta)) - f(A_i^c(\zeta))| \leq \epsilon$ with the given probability. Furthermore, for the black box algorithm X , we have $f(A_i^{opt}(\zeta)) \geq \tau f(A_i^c(\zeta))$. Thus the result follows using arguments analogous to the proof of Theorem 12.

A.11 Proof of Theorem 15

Again the proof follows the same line of reasoning as the proof of Theorem 10, except that for a constraint set ζ with $\rho(\zeta) = \max_{S \subseteq \zeta} |S|$, there are at most $n^{\rho(\zeta)}$ feasible solutions. Using the same definitions for Π_i and ξ_i as in the proof of Theorem 10, instead of Eq. 14 we get

$$\Pr(\xi_i \wedge \Pi_i) \geq 1 - 2n^{\rho(\zeta)} (\exp(-2n\epsilon^2/m) - \exp(-n/8m)).$$

As a result, for $\epsilon < 1/4$ and using union bound we conclude that

$$\Pr((\xi_i \wedge \Pi_i) \text{ on all machines}) \geq 1 - 4mn^{\rho(\zeta)} \exp(-2n\epsilon^2/m),$$

which implies that we need to choose $\delta \geq 4mn^{\rho(\zeta)} \exp(-2n\epsilon^2/m)$. Now if n_0 be chosen in a way that for any $n \geq n_0$ we have $\ln(n)/n \leq \epsilon^2/(mb)$, we get $n \geq \max(n_0, m \log(\delta/4m)/\epsilon^2)$.

Bearing in mind that ζ is locally replaceable, there is at least one V_i such that the solution $A_i^c(\zeta)$ is feasible and ϵ away from the optimum solution with probability $1 - \delta$. Now under the assumption of Theorem 14, if we evaluate $f(A_i^c)$ only on machine i , then we lose another ϵ . Now by combining Theorem 12 and Theorem 14 we get the desired result.

Abstract

The PAC-Bayesian approach is a powerful set of techniques to derive non-asymptotic risk bounds for random estimators. The corresponding optimal distribution of estimators, usually called the Gibbs posterior, is unfortunately often intractable. One may sample from it using Markov chain Monte Carlo, but this is usually too slow for big datasets. We consider instead variational approximations of the Gibbs posterior, which are fast to compute. We undertake a general study of the properties of such approximations. Our main finding is that such a variational approximation has often the same rate of convergence as the original PAC-Bayesian procedure it approximates. In addition, we show that, when the risk function is convex, a variational approximation can be obtained in polynomial time using a convex solver. We give finite sample oracle inequalities for the corresponding estimator. We specialize our results to several learning tasks (classification, ranking, matrix completion), discuss how to implement a variational approximation in each case, and illustrate the good properties of said approximation on real datasets.

1. Introduction

A Gibbs posterior, also known as a PAC-Bayesian or pseudo-posterior, is a probability distribution for random estimators of the form:

$$\hat{\rho}_\lambda(d\theta) = \frac{\exp[-\lambda r_n(\theta)]}{\int \exp[-\lambda r_n] d\pi} \pi(d\theta).$$

More precise definitions will follow, but for now, θ may be interpreted as a parameter (in a finite or infinite-dimensional space), $r_n(\theta)$ as an empirical measure of risk (e.g. prediction error), and $\pi(d\theta)$ a prior distribution.

We will follow in this paper the PAC (Probably Approximately Correct)-Bayesian approach, which originates from machine learning (Shawe-Taylor and Williamson, 1997;

McAllester, 1998; Catoni, 2004); see Catoni (2007) for an exhaustive study, and Jiang and Tamer (2008); Yang (2004); Zhang (2006); Dalalyan and Tsybakov (2008) for related perspectives (such as the aggregation of estimators in the last three papers). There, $\hat{\rho}_\lambda$ appears as the probability distribution that minimizes the upper bound of an oracle inequality on the risk of *random* estimators. The PAC-Bayesian approach offers sharp theoretical guarantees on the properties of such estimators, without assuming a particular model for the data generating process.

The Gibbs posterior has also appeared in other places, and under different motivations: in Econometrics, as a way to avoid direct maximization in moment estimation (Chernozhuikov and Hong, 2003); and in Bayesian decision theory, as a way to define a Bayesian posterior distribution when no likelihood has been specified (Bissiri et al., 2013). Another well-known connection, although less directly useful (for Statistics), is with thermodynamics, where r_n is interpreted as an energy function, and λ as the inverse of a temperature.

Whatever the perspective, estimators derived from Gibbs posteriors usually show excellent performance in diverse tasks, such as classification, regression, ranking, and so on, yet their actual implementation is still far from routine. The usual recommendation (Dalalyan and Tsybakov, 2012; Alquier and Bian, 2013; Guedj and Alquier, 2013) is to sample from a Gibbs posterior using MCMC (Markov chain Monte Carlo, see e.g. Green et al., 2015); but constructing an efficient MCMC sampler is often difficult, and even efficient implementations are often too slow for practical uses when the dataset is very large.

In this paper, we consider instead VB (Variational Bayes) approximations, which have been initially developed to provide fast approximations of ‘true’ posterior distributions (i.e. Bayesian posterior distributions for a given model); see Jordan et al. (1999); MacKay (2002) and Chap. 10 in Bishop (2006).

Our main results are as follows: when PAC-Bayes bounds are available - mainly, when a strong concentration inequality holds - replacing the Gibbs posterior by a variational approximation does not affect the rate of convergence to the best possible prediction, on the condition that the Kullback-Leibler divergence between the posterior and the approximation is itself properly controlled. Furthermore, for convex risks we show that one can obtain polynomial time algorithms based on optimal convex solvers.

We also provide empirical bounds, which may be computed from the data to ascertain the actual performance of estimators obtained by variational approximation. All the results gives strong incentives, we believe, to recommend Variational Bayes as the default approach to approximate Gibbs posteriors. We also provide a R package¹, written in C++ to compute a Gaussian variational approximation in the case of the hinge risk.

The rest of the paper is organized as follows. In Section 2, we present the notations and assumptions. In Section 3, we introduce variational approximations and the corresponding algorithms. The main results are provided in a general form in Section 4: in Subsection 4.1, we give results under the assumption that a Hoeffding type inequality holds (slow rates) and

1. PACVB package: <https://cran.r-project.org/web/packages/PACVB/index.html>

in Subsection 4.2, we give results under the assumption that a Bernstein type inequality holds (fast rates). Note that for the sake of brevity, we will refer to these settings as ‘‘Hoeffding assumption’’ and ‘‘Bernstein assumption’’ even though this terminology is non-standard. We then apply these results in various settings: classification (Section 5), convex classification (Section 6), ranking (Section 7), and matrix completion (Section 8). In each case, we show how to specialise the general results of Section 4 to the considered application, in order to obtain the properties of the VB approximation, and we also discuss its numerical implementation. All the proofs are collected in the Appendix.

2. PAC-Bayesian framework

We observe a sample $(X_1, Y_1), \dots, (X_n, Y_n)$, taking values in $\mathcal{X} \times \mathcal{Y}$, where the pairs (X_i, Y_i) have the same distribution P . We will assume explicitly that the (X_i, Y_i) 's are independent in several of our specialised results, but we do not make this assumption at this stage, as some of our general results, and more generally the PAC-Bayesian theory, may be extended to dependent observations; see e.g. Alquier and Li (2012). The label set \mathcal{Y} is always a subset of \mathbb{R} . A set of predictors is chosen by the statistician: $\{f_\theta : \mathcal{X} \rightarrow \mathbb{R}, \theta \in \Theta\}$. For example, in linear regression, we may have: $f_\theta(x) = \langle \theta, x \rangle$, the inner product of $\mathcal{X} = \mathbb{R}^d$, while in classification, one may have $f_\theta(x) = \mathbb{1}_{\langle \theta, x \rangle > 0} \in \{0, 1\}$.

We assume we have at our disposal a risk function $R(\theta)$; typically $R(\theta)$ is a measure of the prediction error. We set $\bar{R} = R(\bar{\theta})$, where $\bar{\theta} \in \arg \min R$; i.e. \bar{f}_θ is an optimal predictor. We also assume that the risk function $R(\theta)$ has an empirical counterpart $r_n(\theta)$, and set $\bar{r}_n = r_n(\bar{\theta})$. Often, R and r_n are based on a loss function $\ell : \mathbb{R}^2 \rightarrow \mathbb{R}$; i.e. $R(\theta) = \mathbb{E}[\ell(Y, f_\theta(X))]$ and $\bar{r}_n(\theta) = \frac{1}{n} \sum_{i=1}^n \ell(Y_i, f_\theta(X_i))$. (In this paper, the symbol \mathbb{E} will always denote the expectation with respect to the (unknown) law P of the (X_i, Y_i) 's.) There are situations however (e.g. ranking), where R and r_n have a different form.

We define a prior probability measure $\pi(\cdot)$ on the set Θ (equipped with the standard σ -algebra for the considered context), and we let $\mathcal{M}_+^1(\Theta)$ denote the set of all probability measures on Θ .

Definition 2.1 We define, for any $\lambda > 0$, the pseudo-posterior $\hat{\rho}_\lambda$ by

$$\hat{\rho}_\lambda(\theta) = \frac{\exp[-\lambda r_n(\theta)]}{\int \exp[-\lambda r_n] d\pi} \pi(d\theta).$$

The pseudo-posterior $\hat{\rho}_\lambda$ (also known as the Gibbs posterior, Catoni (2004, 2007), or the exponentially weighted aggregate, Dalalyan and Tsybakov (2008)) plays a central role in the PAC-Bayesian approach. It is obtained as the distribution that minimizes the upper bound of a certain oracle inequality applied to *random* estimators. Practical estimators (predictors) may be derived from the pseudo-posterior, by e.g. taking the expectation, or sampling from it. Of course, when $\exp[-\lambda r_n(\theta)]$ may be interpreted as the likelihood of a

certain model, $\hat{\rho}_\lambda$ becomes a Bayesian posterior distribution, but we will not restrict our attention to this particular case.

The following ‘theoretical’ counterpart of $\hat{\rho}_\lambda$ will prove useful to state results.

Definition 2.2 We define, for any $\lambda > 0$, π_λ as

$$\pi_\lambda(\theta) = \frac{\exp[-\lambda R(\theta)]}{\int \exp[-\lambda R] d\pi} \pi(d\theta).$$

We will derive PAC-Bayesian bounds on predictions obtained by variational approximations of $\hat{\rho}_\lambda$ under two types of assumptions: a Hoeffding-type assumption, from which we may deduce slow rates of convergence (Subsection 4.1), and a Bernstein-type assumption, from which we may obtain fast rates of convergence (Subsection 4.2).

Definition 2.3 We say that a Hoeffding assumption is satisfied for prior π when there is a function f and an interval $I \subset \mathbb{R}_+^*$ such that, for any $\lambda \in I$, for any $\theta \in \Theta$,

$$\left. \begin{aligned} \pi(\mathbb{E} \exp \{\lambda [R(\theta) - r_n(\theta)]\}) \\ \pi(\mathbb{E} \exp \{\lambda [r_n(\theta) - R(\theta)]\}) \end{aligned} \right\} \leq \exp [f(\lambda, n)]. \quad (1)$$

Inequality (1) can be interpreted as an integrated version (with respect to π) of Hoeffding's inequality, for which $f(\lambda, n) \asymp \lambda^2/n$. In many cases the loss will be bounded uniformly over θ ; then Hoeffding's inequality will directly imply (1). The expectation with respect to π in (1) allows us to treat some cases where the loss is not upper bounded by specifying a prior with sufficiently light tails.

Definition 2.4 We say that a Bernstein assumption is satisfied for prior π when there is a function g and an interval $I \subset \mathbb{R}_+^*$ such that, for any $\lambda \in I$, for any $\theta \in \Theta$,

$$\left. \begin{aligned} \pi(\mathbb{E} \exp \{\lambda [R(\theta) - \bar{R}] - \lambda [r_n(\theta) - \bar{r}_n]\}) \\ \pi(\mathbb{E} \exp \{\lambda [r_n(\theta) - \bar{r}_n] - \lambda [R(\theta) - \bar{R}]\}) \end{aligned} \right\} \leq \pi(\exp [g(\lambda, n) |R(\theta) - \bar{R}|]). \quad (2)$$

This assumption is satisfied for example by sums of i.i.d. sub-exponential random variables, see Subsection 2.4 p. 27 in Boucheron et al. (2013), when a margin assumption on the function $R(\cdot)$ is satisfied (Tsybakov, 2004). This is discussed in Section 4.2. Again, extensions beyond the i.i.d. case are possible, see e.g. Wintenberger (2010) for a survey and new results. In all these examples, the important feature of the function g that we will use to derive rates of convergence is the fact that there is a constant $c > 0$ such that when $\lambda = cn$, $g(\lambda, n) = g(cn, n) \lesssim n$.

As mentioned previously, we will often consider $r_n(\theta) = \frac{1}{n} \sum_{i=1}^n \ell(Y_i, f_\theta(X_i))$, however, the previous assumptions can also be satisfied when $r_n(\theta)$ is a U-statistic, using Hoeffding's decomposition of U-statistics combined with the corresponding inequality for sums of independent variables (Hoeffding, 1948). This idea comes from Cl emenceon et al. (2008) and we will use it in our ranking application.

Remark 2.1 We could consider more generally inequalities of the form

$$\frac{\pi(\mathbb{E} \exp \{\lambda[R(\theta) - \bar{R}] - \lambda[r_n(\theta) - \bar{r}_n]\})}{\pi(\mathbb{E} \exp \{\lambda[r_n(\theta) - \bar{r}_n] - \lambda[R(\theta) - \bar{R}]\})} \leq \pi(\exp [g(\lambda, n)[R(\theta) - \bar{R}]^\kappa])$$

that allow using the more general form of the margin assumption of Mammen and Tsybakov (1999); Tsybakov (2004). PAC-Bayes bounds in this context are provided by Catoni (2007). However, the techniques involved would require many pages to be described so we decided to focus on the cases $\kappa = 0$ and $\kappa = 1$ to keep the exposition simple.

3. Numerical approximations of the pseudo-posterior

3.1 Monte Carlo

As already explained in the introduction, the usual approach to approximate $\hat{\rho}_\lambda$ is MCMC (Markov chain Monte Carlo) sampling. Ridgway et al. (2014) proposed tempering SMC (Sequential Monte Carlo, e.g. Del Moral et al. (2006)) as an alternative to MCMC to sample from Gibbs posteriors: one samples sequentially from $\hat{\rho}_\lambda$, with $0 = \lambda_0 < \dots < \lambda_T = \lambda$ where λ is the desired temperature. One advantage of this approach is that it makes it possible to contemplate different values of λ , and choose one by e.g. cross-validation. Another advantage is that such an algorithm requires little tuning; see Appendix B for more details on the implementation of tempering SMC. We will use tempering SMC as our gold standard in our numerical studies.

SMC and related Monte Carlo algorithms tend to be too slow for practical use in situations where the sample size is large, the dimension of Θ is large, or f_θ is expensive to compute. This motivates the use of fast, deterministic approximations, such as Variational Bayes, which we describe in the next section.

3.2 Variational Bayes

Various versions of VB (Variational Bayes) have appeared in the literature, but the main idea is as follows. We define a family $\mathcal{F} \subset \mathcal{M}_+^1(\Theta)$ of probability distributions that are considered as tractable. Then, we define the VB-approximation of $\hat{\rho}_\lambda$: $\hat{\rho}_\lambda$.

Definition 3.1 Let

$$\tilde{\rho}_\lambda = \arg \min_{\rho \in \mathcal{F}} \mathcal{K}(\rho, \hat{\rho}_\lambda),$$

where $\mathcal{K}(\rho, \hat{\rho}_\lambda)$ denotes the KL (Kullback-Leibler) divergence of $\hat{\rho}_\lambda$ relative to ρ : $\mathcal{K}(m, \mu) = \int \log \frac{d\mu}{d\mu} dm$ if $m \ll \mu$ (i.e. μ dominates m), $\mathcal{K}(m, \mu) = +\infty$ otherwise.

The difficulty is to find a family \mathcal{F} (a) which is large enough, so that $\tilde{\rho}_\lambda$ may be close to $\hat{\rho}_\lambda$, and (b) such that computing $\tilde{\rho}_\lambda$ is feasible. Moreover, even when there are algorithms for $\tilde{\rho}_\lambda$ that are efficient in practice, we may, depending on the problem at hand, have more

or less strong guarantees on the quality of the optimization. For example, while in Section 6 we consider a setting where an exact upper bound for the optimization error is available, in Section 8 this is no longer the case.

We now review two types of families popular in the VB literature.

- Mean field VB: for a certain decomposition $\Theta = \Theta_1 \times \dots \times \Theta_d$, \mathcal{F} is the set of product probability measures

$$\mathcal{F}^{\text{MF}} = \left\{ \rho \in \mathcal{M}_+^1(\Theta) : \rho(d\theta) = \prod_{i=1}^d \rho_i(d\theta_i), \forall i \in \{1, \dots, d\}, \rho_i \in \mathcal{M}_+^1(\Theta_i) \right\}. \quad (3)$$

The infimum of the KL divergence $\mathcal{K}(\rho, \hat{\rho}_\lambda)$, relative to $\rho = \prod_i \rho_i$ satisfies the following fixed point condition (Parisi, 1988; Bishop, 2006, Chap. 10):

$$\forall j \in \{1, \dots, d\} \quad \rho_j(d\theta_j) \propto \exp \left(\int \{-\lambda r_n(\theta) + \log \pi(\theta)\} \prod_{i \neq j} \rho_i(d\theta_i) \right) \pi(d\theta_j). \quad (4)$$

This leads to a natural algorithm where we update successively every ρ_j until stabilization.

- Parametric family:

$$\mathcal{F}^{\text{P}} = \{\rho \in \mathcal{M}_+^1(\Theta) : \rho(d\theta) = f(\theta; m) d\theta, m \in M\};$$

and M is finite-dimensional; say \mathcal{F}^{P} is the family of Gaussian distributions (of dimension d). In this case, several methods may be used to compute the infimum. As above, one may use fixed-point iteration, provided an equation similar to (4) is available. Alternatively, one may directly maximize $\int \log[\exp\{-\lambda r_n(\theta)\} \frac{d\pi}{d\theta}(\theta)] \rho(d\theta)$ with respect to parameter m , using numerical optimization routines. This approach was used for instance in Hoffman et al. (2013) with combination of some stochastic gradient descent to perform inference on a latent Dirichlet allocation model. See also e.g. Khan (2014); Khan et al. (2013) for efficient algorithms for Gaussian variational approximation.

In what follows (Subsections 4.1 and 4.2) we provide tight bounds for the prediction risk of $\tilde{\rho}_\lambda$. This leads to the identification of a condition on \mathcal{F} such that the risk of $\tilde{\rho}_\lambda$ is not worse than the risk of $\hat{\rho}_\lambda$. We will make this condition explicit in various examples, using either mean field VB or parametric approximations.

Remark 3.1 An useful identity, obtained by direct calculations, is: for any $\rho \ll \pi$,

$$\log \int \exp[-\lambda r_n(\theta)] \pi(d\theta) = -\lambda \int r_n(\theta) \rho(d\theta) - \mathcal{K}(\rho, \pi) + \mathcal{K}(\rho, \hat{\rho}_\lambda). \quad (5)$$

Since the left hand side does not depend on ρ , one sees that $\bar{\rho}_\lambda$, which minimizes $\mathcal{K}(\rho, \hat{\rho}_\lambda)$ over \mathcal{F} , is also the minimizer of:

$$\bar{\rho}_\lambda = \arg \min_{\rho \in \mathcal{F}} \left\{ \int \tau_n(\theta) \rho(d\theta) + \frac{1}{\lambda} \mathcal{K}(\rho, \pi) \right\}$$

This equation will appear frequently in the sequel in the form of an empirical upper bound.

4. General results

This section gives our general results, under either a Hoeffding Assumption (Definition 2.3) or a Bernstein Assumption (Definition 2.4), on risks bounds for the variational approximation, and how it relates to risks bounds for Gibbs posteriors. These results will be specialised to several learning problems in the following sections.

4.1 Bounds under the Hoeffding assumption

4.1.1 EMPIRICAL BOUNDS

Theorem 4.1 *Under the Hoeffding assumption (Definition 2.3), for any $\varepsilon > 0$, with probability at least $1 - \varepsilon$ we have simultaneously for any $\rho \in \mathcal{M}_+^1(\Theta)$,*

$$\int R d\rho \leq \int \tau_n d\rho + \frac{f(\lambda, n) + \mathcal{K}(\rho, \pi) + \log\left(\frac{2}{\varepsilon}\right)}{\lambda}.$$

This result is a simple variant of a result in Catoni (2007) but for the sake of completeness, its proof is given in Appendix A. It gives us an upper bound on the risk of both the pseudo-posterior (take $\rho = \hat{\rho}_\lambda$) and its variational approximation (take $\rho = \bar{\rho}_\lambda$). These bounds may be computed from the data, and therefore provide a simple way to evaluate the performance of the corresponding procedure, in the spirit of the first PAC-Bayesian inequalities (Shawe-Taylor and Williamson, 1997; McAlester, 1998, 1999). However, these bounds do not provide the rate of convergence of these estimators. For this reason, we also provide oracle-type inequalities.

4.1.2 ORACLE-TYPE INEQUALITIES

Another way to use PAC-Bayesian bounds is to compare $\int R d\hat{\rho}_\lambda$ to the best possible risk, thus linking this approach to oracle inequalities. This is the point of view developed in Catoni (2004, 2007); Dalalyan and Tsybakov (2008).

Theorem 4.2 *Assume that the Hoeffding assumption is satisfied (Definition 2.3). For any $\varepsilon > 0$, with probability at least $1 - \varepsilon$ we have simultaneously*

$$\int R d\hat{\rho}_\lambda \leq \mathcal{B}_\lambda(\mathcal{M}_+^1(\Theta)) := \inf_{\rho \in \mathcal{M}_+^1(\Theta)} \left\{ \int R d\rho + 2 \frac{f(\lambda, n) + \mathcal{K}(\rho, \pi) + \log\left(\frac{2}{\varepsilon}\right)}{\lambda} \right\}$$

7

and

$$\int R d\bar{\rho}_\lambda \leq \mathcal{B}_\lambda(\mathcal{F}) := \inf_{\rho \in \mathcal{F}} \left\{ \int R d\rho + 2 \frac{f(\lambda, n) + \mathcal{K}(\rho, \pi) + \log\left(\frac{2}{\varepsilon}\right)}{\lambda} \right\}.$$

Moreover,

$$\mathcal{B}_\lambda(\mathcal{F}) = \mathcal{B}_\lambda(\mathcal{M}_+^1(\Theta)) + \frac{2}{\lambda} \inf_{\rho \in \mathcal{F}} \mathcal{K}(\rho, \pi_\lambda^2)$$

where we remind that π_λ is defined in Definition 2.2.

In this way, we are able to compare $\int R d\hat{\rho}_\lambda$ to the best possible aggregation procedure in $\mathcal{M}_+^1(\Theta)$ and $\int R d\bar{\rho}_\lambda$ to the best aggregation procedure in \mathcal{F} . More importantly, we are able to obtain explicit expressions for the right-hand side of these inequalities in various models, and thus to obtain rates of convergence. This will be done in the remaining sections. This leads to the second interest of this result: if there is a $\lambda = \lambda(n)$ that leads to $\mathcal{B}_\lambda(\mathcal{M}_+^1(\Theta)) \leq \bar{R} + s_n$ with $s_n \rightarrow 0$ for the pseudo-posterior $\hat{\rho}_\lambda$, then we only have to prove that there is a $\rho \in \mathcal{F}$ such that $\mathcal{K}(\rho, \pi_\lambda)/\lambda \leq c s_n$ for some constant $c > 0$ to ensure that the VB approximation $\bar{\rho}_\lambda$ also reaches the rate s_n .

We will see in the following sections several examples where the approximation does not deteriorate the rate of convergence. But first let us show the equivalent oracle inequality under the Bernstein assumption.

4.2 Bounds under the Bernstein assumption

In this context the empirical bound on the risk would depend on the minimal achievable risk $\bar{\tau}_n$ and cannot be computed explicitly. We give the oracle inequality for both the Gibbs posterior and its VB approximation in the following theorem.

Theorem 4.3 *Assume that the Bernstein assumption is satisfied (Definition 2.4). Assume that $\lambda \in I$ satisfies $\lambda - g(\lambda, n) > 0$. Then for any $\varepsilon > 0$, with probability at least $1 - \varepsilon$ we have simultaneously:*

$$\begin{aligned} \int R d\hat{\rho}_\lambda - \bar{R} &\leq \bar{\mathcal{B}}_\lambda(\mathcal{M}_+^1(\Theta)), \\ \int R d\bar{\rho}_\lambda - \bar{R} &\leq \bar{\mathcal{B}}_\lambda(\mathcal{F}), \end{aligned}$$

where, for either $\mathcal{A} = \mathcal{M}_+^1(\Theta)$ or $\mathcal{A} = \mathcal{F}$,

$$\bar{\mathcal{B}}_\lambda(\mathcal{A}) = \frac{1}{\lambda - g(\lambda, n)} \inf_{\rho \in \mathcal{A}} \left\{ [\lambda + g(\lambda, n)] \int (R - \bar{R}) d\rho + 2\mathcal{K}(\rho, \pi) + 2\log\left(\frac{2}{\varepsilon}\right) \right\}.$$

In addition,

$$\bar{\mathcal{B}}_\lambda(\mathcal{F}) = \bar{\mathcal{B}}_\lambda(\mathcal{M}_+^1(\Theta)) + \frac{2}{\lambda - g(\lambda, n)} \inf_{\rho \in \mathcal{F}} \mathcal{K}\left(\rho, \pi_{\frac{\lambda + g(\lambda, n)}{2}}\right).$$

8

The main difference with Theorem 4.2 is that the function $R(\cdot)$ is replaced by $R(\cdot) - \bar{R}$. This is well known way to obtain better rates of convergence.

5. Application to classification

5.1 Preliminaries

In all this section, we assume that $\mathcal{Y} = \{0, 1\}$ and we consider linear classification: $\Theta = \mathcal{X} = \mathbb{R}^d$, $f_\theta(x) = \mathbf{1}_{\{\theta \cdot x\} > 0}$. We put $r_n(\theta) = \frac{1}{n} \sum_{i=1}^n \mathbf{1}_{\{f_\theta(X_i) \neq Y_i\}}$, $R(\theta) = \mathbb{P}(Y \neq f_\theta(X))$ and assume that the $\{(X_i, Y_i)\}_{i=1}^n$ are i.i.d. In this setting, it is well-known that the Hoeffding assumption always holds. We state as a reminder the following lemma.

Lemma 1 *Hoeffding assumption (1) is satisfied with $f(\lambda, n) = \lambda^2/(2n)$, $\lambda \in \mathbb{R}_+$.*

The proof is given in Appendix A for the sake of completeness.

It is also possible to prove that Bernstein assumption (2) holds in the case where the so-called margin assumption of Mammen and Tsybakov is satisfied. This condition we use was introduced by Tsybakov (2004) in a classification setting, based on a related definition in Mammen and Tsybakov (1999).

Lemma 2 *Assume that Mammen and Tsybakov's margin assumption is satisfied: i.e. there is a constant C such that*

$$\mathbb{E}[(\mathbf{1}_{f_\theta(X) \neq Y} - \mathbf{1}_{f_\theta(X) \neq Y})^2] \leq C[R(\theta) - \bar{R}].$$

Then Bernstein assumption (2) is satisfied with $g(\lambda, n) = \frac{C\lambda^2}{2n-\lambda}$.

Remark 5.1 *We refer the reader to Tsybakov (2004) for a proof that*

$$\mathbb{P}(0 < \langle \bar{\theta}, X \rangle \mid \leq t) \leq C't$$

for some constant $C' > 0$ implies the margin assumption. In words, when X is not likely to be in the region $\langle \bar{\theta}, X \rangle \simeq 0$, where points are hard to classify, then the problem becomes easier and the classification rate can be improved.

We propose in this context a Gaussian prior: $\pi = \mathcal{N}_d(0, \theta^2 I_d)$, and we consider a VB approach based on Gaussian families. The corresponding optimization problem is not convex, but remains feasible as we explain below.

5.2 Three sets of Variational Gaussian approximations

Consider the three following Gaussian families

$$\begin{aligned} \mathcal{F}_1 &= \left\{ \Phi_{\mathbf{m}, \sigma^2}, \mathbf{m} \in \mathbb{R}^d, \sigma^2 \in \mathbb{R}_+^* \right\}, \\ \mathcal{F}_2 &= \left\{ \Phi_{\mathbf{m}, \sigma^2}, \mathbf{m} \in \mathbb{R}^d, \sigma^2 \in (\mathbb{R}_+^*)^d \right\} \text{ (mean field approximation),} \\ \mathcal{F}_3 &= \left\{ \Phi_{\mathbf{m}, \Sigma}, \mathbf{m} \in \mathbb{R}^d, \Sigma \in \mathcal{S}^{d \times d} \right\} \text{ (full covariance approximation),} \end{aligned}$$

where $\Phi_{\mathbf{m}, \sigma^2}$ is Gaussian distribution $\mathcal{N}_d(\mathbf{m}, \sigma^2 I_d)$, $\Phi_{\mathbf{m}, \Sigma}$ is $\mathcal{N}_d(\mathbf{m}, \text{diag}(\sigma^2))$, and $\Phi_{\mathbf{m}, \Sigma}$ is $\mathcal{N}_d(\mathbf{m}, \Sigma)$. Obviously, $\mathcal{F}_1 \subset \mathcal{F}_2 \subset \mathcal{F}_3 \subset \mathcal{M}_+^d(\Theta)$, and

$$\mathcal{B}_\lambda(\mathcal{M}_+^d(\Theta)) \leq \mathcal{B}_\lambda(\mathcal{F}_3) \leq \mathcal{B}_\lambda(\mathcal{F}_2) \leq \mathcal{B}_\lambda(\mathcal{F}_1). \quad (6)$$

Note that, for the sake of simplicity, we will use the following classical notations in the rest of the paper: $\varphi(\cdot)$ is the density of $\mathcal{N}(0, 1)$ w.r.t. the Lebesgue measure, and $\Phi(\cdot)$ the corresponding c.d.f. The rest of Section 5 is organized as follows. In Subsection 5.3, we calculate explicitly $\mathcal{B}_\lambda(\mathcal{F}_2)$ and $\mathcal{B}_\lambda(\mathcal{F}_1)$. Thanks to (6) this also gives an upper bound on $\mathcal{B}_\lambda(\mathcal{F}_3)$ and proves the validity of the three types of Gaussian approximations. Then, we give details on algorithms to compute the variational approximation based on \mathcal{F}_2 and \mathcal{F}_3 , and provide a numerical illustration on real data.

5.3 Theoretical analysis

We start with the empirical bound for \mathcal{F}_2 (and \mathcal{F}_1 as a consequence), which is a direct corollary of Theorem 4.1.

Corollary 5.1 *For any $\varepsilon > 0$, with probability at least $1 - \varepsilon$ we have, for any $\mathbf{m} \in \mathbb{R}^d$, $\sigma^2 \in (\mathbb{R}_+^*)^d$,*

$$\int \text{Rd}\Phi_{\mathbf{m}, \sigma^2} \leq \int r_n \text{d}\Phi_{\mathbf{m}, \sigma^2} + \frac{\lambda}{2n} + \frac{\frac{1}{2} \sum_{i=1}^d \left[\log \left(\frac{\theta^2}{\sigma_i^2} \right) + \frac{\sigma_i^2}{\theta^2} \right] + \frac{\|\mathbf{m}\|^2}{2\theta^2} - \frac{d}{2} + \log \left(\frac{1}{\varepsilon} \right)}{\lambda}.$$

We now want to apply Theorem 4.2 in this context. In order to do so, we introduce an additional assumption.

Definition 5.1 *We say that Assumption A1 is satisfied when there is a constant $c > 0$ such that, for any $(\theta, \theta') \in \Theta^2$ with $\|\theta\| = \|\theta'\| = 1$, $\mathbb{P}\langle X, \theta \rangle \langle X, \theta' \rangle < 0 \leq c\|\theta - \theta'\|$.*

This is not a strong assumption. It is satisfied when X has an isotropic distribution, and more generally when $X/\|X\|$ has a bounded density on the unit sphere². The intuition

² If the density of $X/\|X\|$ with respect to the uniform measure on the unit sphere is upper bounded by B then $\mathbb{P}\langle X, \theta \rangle \langle X, \theta' \rangle < 0 \leq \frac{B}{2\pi} \arccos(\theta, \theta') \leq \frac{B}{2\pi} \sqrt{5-5\langle \theta, \theta' \rangle} \leq \frac{B}{2\pi} \sqrt{\frac{5}{2}} \|\theta - \theta'\|$.

beyond A1 is that for a “typical” X , a very small change in θ will only induce a change in $\text{sign}(X; \theta)$ with a small probability. When it is not satisfied, two parameters θ and θ' very close to each other can lead to very different predictions, and thus, whatever the accuracy of an approximation of θ , it might still lead to poor predictions.

Corollary 5.2 *Assume that the VB approximation is done on either \mathcal{F}_1 , \mathcal{F}_2 or \mathcal{F}_3 . Take $\lambda = \sqrt{nd}$ and $\vartheta = \frac{1}{\sqrt{n}}$. Under Assumption A1, for any $\varepsilon > 0$, with probability at least $1 - \varepsilon$ we have simultaneously*

$$\int \text{Rd}\hat{\rho}_\lambda \left\{ \leq \bar{R} + \sqrt{\frac{d}{n}} \log(4ne) + \frac{c}{\sqrt{n}} + \frac{1}{4n} \sqrt{\frac{d}{n}} + \frac{2 \log(\frac{\varepsilon}{2})}{\sqrt{nd}} \right\}.$$

See the appendix for a proof. Note also that the values $\lambda = \sqrt{nd}$ and $\vartheta = \frac{1}{\sqrt{n}}$ allow to derive this almost optimal rate of convergence, but are not necessarily the best choices in practice.

Remark 5.2 *Note that Assumption A1 is not necessary to obtain oracle inequalities on the risk integrated under $\hat{\rho}_\lambda$. We refer the reader to Chapter 1 in Catoni (2007) for such assumption-free bounds. However, it is clear that without this assumption the shape of $\hat{\rho}_\lambda$ and $\hat{\rho}_\lambda$ might be very different. Thus, it seems reasonable to require that A1 is satisfied for the approximation of $\hat{\rho}_\lambda$ by $\hat{\rho}_\lambda$ to make sense.*

We finally provide an application of Theorem 4.3. Under the additional constraint that the margin assumption is satisfied, we obtain a better rate.

Corollary 5.3 *Assume that the VB approximation is done on either \mathcal{F}_1 , \mathcal{F}_2 or \mathcal{F}_3 . Under Assumption A1 (Definition 5.1 page 10), and under Mammen and Tsybakov margin assumption, with $\lambda = \frac{2n}{C+2}$ and $\vartheta > 0$, for any $\varepsilon > 0$, with probability at least $1 - \varepsilon$,*

$$\int \text{Rd}\hat{\rho}_\lambda \left\{ \leq \bar{R} + \frac{(C+2)(C+1)}{2} \left\{ \frac{d \log \frac{n}{\vartheta}}{n} + \frac{d\vartheta}{n^2} + \frac{1}{\vartheta} - \frac{d}{\vartheta n} + \frac{2}{n} \log \frac{2}{\varepsilon} \right\} + \frac{\sqrt{d}2c(2C+1)}{n} \right\}.$$

It is possible to minimize the bound with respect to ϑ explicitly, this choice or any constant instead will lead to a rate in $d \log(n)/n$. Note that the rate d/n is minimax-optimal in this context. This is, for example, a consequence of more general results in Lecué (2007) under a general form of the margin assumption. See the Appendix for a proof.

5.4 Implementation and numerical results

For family \mathcal{F}_2 (mean field), the variational lower bound (5) equals

$$\mathcal{L}_{\lambda, \vartheta}(\mathbf{m}, \boldsymbol{\sigma}) = -\frac{\lambda}{n} \sum_{i=1}^n \Phi \left(-Y_i \frac{X_i \mathbf{m}}{\sqrt{X_i \text{diag}(\boldsymbol{\sigma}^2) X_i^T}} \right) - \frac{\mathbf{m}^T \mathbf{m}}{2\vartheta} + \frac{1}{2} \sum_{k=1}^d \left(\log \sigma_k^2 - \frac{\sigma_k^2}{\vartheta} \right),$$

11

while for family \mathcal{F}_3 (full covariance), it equals

$$\mathcal{L}_{\lambda, \vartheta}(\mathbf{m}, \Sigma) = -\frac{\lambda}{n} \sum_{i=1}^n \Phi \left(-Y_i \frac{X_i \mathbf{m}}{\sqrt{X_i \Sigma X_i^T}} \right) - \frac{\mathbf{m}^T \mathbf{m}}{2\vartheta} + \frac{1}{2} \left(\log |\Sigma| - \frac{1}{\vartheta} \text{tr} \Sigma \right).$$

Both functions are non-convex, but the multimodality of the latter may be more severe due to the larger dimension of \mathcal{F}_3 . To address this issue, we recommend using the reparametrization of Oppier and Archambeau (2009), which makes the dimension of the latter optimization problem $\mathcal{O}(n)$; see Khan (2014) for a related approach. In both cases, we found that deterministic annealing to be a good approach to optimize such non-convex functions. We refer to Appendix B for more details on deterministic annealing and on our particular implementation.

We now compare the numerical performance of the mean field and full covariance VB approximations to the Gibbs posterior (as approximated by SMC, see Section 3.1) for the classification of standard datasets; see Table 1. The datasets are all available in the UCI repository³ except for the DNA dataset which is part of the R package mlbench by Leisch and Dimitriadou (2010). When no split between the training sample is provided we split the data in half. The design matrices are centered and scaled before being used. For the Glass dataset we compare the “silicon” class against the other classes.

We also include results for a linear SVM (support vector machine) and a radial kernel SVM; the latter comparison is not entirely fair, since this is a non-linear classifier, while all the other classifiers are linear. Except for the Glass and DNA datasets, the full covariance VB approximation performs as well as or better than both SMC and SVM (while being much faster to compute, especially compared to SMC). Note that some high errors for the VB approximations can be due to the fact that the optimization of the objective is harder (we address this issue in next section).

Interestingly, VB outperforms SMC in certain cases. This might be due to the fact that a VB approximation tends to be more concentrated around the mode than the Gibbs posterior it approximates. Mean field VB does not perform so well on certain datasets (e.g. Indian). This may be due either to the approximation family being too small, or to the corresponding optimisation problem to be strongly multi-modal. We address this issue in next section.

6. Application to classification under convexified loss

Compared to the previous section, the advantage of convex classification is that the corresponding variational approximation will amount to minimizing a convex function. This

means that (a) the minimization problem will be easier to deal with; and (b) we will be able to compute a bound for the integrated risk after a given number of steps of the minimization procedure.

The setting is the same as in the previous section, except that for convenience we now take $\mathcal{Y} = \{-1, 1\}$, and the risk is based on the hinge loss,

$$r_n^H(\theta) = \frac{1}{n} \sum_{i=1}^n \max(0, 1 - Y_i(\theta, X_i)).$$

We will write R^H for the theoretical counterpart and \bar{R}^H for its minimum in θ . We keep the superscript H in order to allow comparison with the risk R under the 0-1 loss. We assume in this section that the X_i are uniformly bounded, that is, we have almost surely $\|X_i\|_\infty = \max_j |X_{i,j}| < c_x > 0$. Note that we do not require an assumption of the form (A1) to obtain the results of this section, as we rely directly on the Lipschitz continuity of the hinge risk.

6.1 Theoretical Results

Contrary to the previous section, the risk is not bounded in θ , and we must specify a prior distribution for the Hoeffding assumption to hold.

Lemma 3 *Under an independent Gaussian prior π such that each component is $N(0, \theta^2)$, and for $\lambda < \frac{1}{c_x} \sqrt{\frac{n}{2}}$ and with bounded design $|X_{i,j}| < c_x$, Hoeffding assumption (1) is satisfied with $f(\lambda, n) = \lambda^2 / (4n) - \frac{1}{2} \log \left(1 - \frac{\theta^2 \lambda^2 c_x^2}{2n} \right)$.*

The main impact of such a bound is that the prior variance cannot be taken too big relative to λ .

Corollary 6.1 *Assume that the VB approximation is done on either \mathcal{F}_1 , \mathcal{F}_2 or \mathcal{F}_3 . Take $\lambda = \frac{1}{c_x} \sqrt{\frac{n}{\theta^2}}$ and $\vartheta = \frac{1}{\sqrt{d}}$. For any $\varepsilon > 0$, with probability at least $1 - \varepsilon$ we have simultaneously*

$$\left. \int R^H d\hat{\rho}_\lambda \right\} \leq \bar{R}^H + \frac{c_x}{2} \sqrt{\frac{d}{n}} \log \frac{n}{d} + c_x \frac{d}{n} \sqrt{\frac{d}{n}} + \frac{1}{\sqrt{nd}} \left(\frac{2c_x^2 + 1}{2c_x} + 2c_x \log \frac{2}{\varepsilon} \right)$$

The oracle inequality in the above corollary enjoys the same rate of convergence as the equivalent result in the preceding section. In the following we link the two results.

Remark 6.1 *As stated in the beginning of the section we can use the estimator specified under the hinge loss to bound the excess risk of the 0-1 loss. We write R^* and R^{H*} the respective risk for their corresponding Bayes classifiers. From Zhang (2004) (section 3.3) we have the following inequality, linking the excess risk under the hinge loss and the 0-1 loss,*

$$R(\theta) - R^* \leq R^H(\theta) - R^{H*}$$

for every $\theta \in \mathbb{R}^p$. By integrating with respect to $\hat{\rho}^H$ (the VB approximation on any $\mathcal{F}_1, \mathcal{F}_2, \mathcal{F}_3$ of the Gibbs posterior for the hinge risk) and making use of Corollary 6.1 we have with high probability,

$$\hat{\rho}^H(R(\theta)) - R^* \leq \inf_{\theta \in \mathbb{R}^p} R^H(\theta) - R^{H*} + \mathcal{O} \left(\sqrt{\frac{d}{n}} \log \left(\frac{n}{d} \right) \right).$$

6.2 Numerical application

We have motivated the introduction of the hinge loss as a convex upper bound. In the sequel we show that the resulting VB approximation also leads to a convex optimization problem. This has the advantage of opening a range of possible optimization algorithms (Nesterov, 2004). In addition we are able to bound the error of the approximated measure after a fixed number of iterations (see Theorem 6.2).

Under the model \mathcal{F}_1 each individual risk is given by:

$$\rho_{\mathbf{m}, \sigma}(r_i(\theta)) = (1 - \Gamma_i \mathbf{m}) \Phi \left(\frac{1 - \Gamma_i \mathbf{m}}{\sigma \|\Gamma_i\|_2} \right) + \sigma \|\Gamma_i\|_2 \varphi \left(\frac{1 - \Gamma_i \mathbf{m}}{\sigma \|\Gamma_i\|_2} \right) := \Xi_i \left(\begin{pmatrix} \mathbf{m} \\ \sigma \end{pmatrix} \right),$$

writing $\Gamma_i := Y_i X_i$.

Hence the lower bound to be maximized is given by

$$\mathcal{L}(\mathbf{m}, \sigma) = -\frac{\lambda}{n} \left\{ \sum_{i=1}^n (1 - \Gamma_i \mathbf{m}) \Phi \left(\frac{1 - \Gamma_i \mathbf{m}}{\sigma \|\Gamma_i\|_2} \right) + \sum_{i=1}^n \sigma \|\Gamma_i\|_\varphi \left(\frac{1 - \Gamma_i \mathbf{m}}{\sigma \|\Gamma_i\|_2} \right) \right\} - \frac{\|\mathbf{m}\|_2^2}{2\theta} + \frac{d}{2} \left(\log \sigma^2 - \frac{\theta}{\sigma^2} \right).$$

It is easy to see that the function is convex in (\mathbf{m}, σ) , first note that the map

$$\Psi : \begin{pmatrix} x \\ y \end{pmatrix} \mapsto x \Phi \left(\frac{x}{y} \right) + y \varphi \left(\frac{x}{y} \right),$$

is convex and note that we can write $\Xi_i \left(\begin{pmatrix} \mathbf{m} \\ \sigma \end{pmatrix} \right) = \Psi \left(A \begin{pmatrix} x \\ y \end{pmatrix} + b \right)$ hence by composition of convex function with linear mappings we have the result. Similar reasoning could be held for the case \mathcal{F}_2 and \mathcal{F}_3 , where in later the parametrization should be done in \mathbb{C} such that $\Sigma = CC^*$. The bound is however not universally Lipschitz in σ , this impacts the optimization algorithms. In Theorem 6.2 we define a ball around the optimal value of the objective, containing the initial values. We denote it's radius by M . On this ball the objective is Lipschitz (with coefficient L) and optimal convex solvers can be used (e.g. Nesterov (2004) section 3.2.3).

On the class of function $\mathcal{F}_0 = \left\{ \Phi_{\mathbf{m}, \frac{1}{\sigma}}, \mathbf{m} \in \mathbb{R}^d \right\}$, for which our Oracle inequalities still hold we could get faster numerical algorithms. The objective function has Lipschitz continuous derivatives and we would get a rate of $\frac{L}{1+8L^2}$.

Other convex loss could be considered which could lead to convex optimization problems. For instance one could consider the exponential loss.

Theorem 6.2 *Assume that the VB approximation is based on either $\mathcal{F}_1, \mathcal{F}_2$ or \mathcal{F}_3 . Denote by $\tilde{\rho}_k(d\theta)$ the VB approximated measure after the k th iteration of an optimal convex solver using the hinge loss. Fix $M > 0$ large enough so that the optimal approximated mean and variance $\tilde{m}, \tilde{\Sigma}$ are at distance at most M from the initial value used by the solver. Take $\lambda = \sqrt{nd}$ and $\theta = \frac{1}{\lambda}$ then under the hypothesis of Corollary 6.1 with probability $1 - \epsilon$*

$$\int R^H d\tilde{\rho}_k \leq \bar{R}^H + \frac{LM}{\sqrt{1+k}} + \frac{c_x \sqrt{d}}{2} \log \frac{n}{d} + c_x \frac{d}{n} \sqrt{\frac{d}{n}} + \frac{1}{\sqrt{nd}} \left(\frac{2c_x^2 + 1}{2c_x} + 2c_x \log \frac{2}{\epsilon} \right)$$

where L is the Lipschitz coefficient on a ball of radius M defined above.

Note that this result is stronger and more practical than the previous ones: it ensures a certain error level (with fixed probability $1 - \epsilon$) for the k -th iterate of the optimization algorithm, for a known value of k . In contrast, previous results applied to the output of the optimizer "for k large enough".

We find that on average the misclassification error (Table 2) is lower than for the 0-1 loss where we have no guarantees that the maximum is attained.

Table 2: Comparison of misclassification rates (%). Misclassification rates for different datasets and for the proposed approximations of the Gibbs posterior. The hyperparameters are chosen by cross-validation. This is to be compared to Table 1. The variational Bayes approximation was computed using the R package we developed (see the introduction for a reference).

7. Application to ranking

7.1 Preliminaries

We now focus on the ranking problem. We follow Clémenton et al. (2008) for the definitions of the basic concepts: $\mathcal{Y} = \{0, 1\}$, $\Theta = \mathbb{R}^d$ and $f_\theta : \mathcal{X}^2 \rightarrow \{-1, +1\}$ for $\theta \in \Theta$; $f_\theta(x, x') = 1$ (resp. -1) means that x is more (resp. less) likely to correspond to label 1 than x' . The natural risk function is then

$$R(\theta) = \mathbb{P}[(Y_1 - Y_2)f_\theta(X_1, X_2) < 0]$$

and the empirical risk

$$r_n(\theta) = \frac{1}{n(n-1)} \sum_{1 \leq i \neq j \leq n} \mathbf{1}_{(Y_i - Y_j)f_\theta(X_i, X_j) < 0}.$$

Again, we recall classical results.

Lemma 4 *The Hoeffding-type assumption is satisfied with $f(\lambda, n) = \frac{\lambda^2}{2}$.*

The variant of the margin assumption adapted to ranking was established by Robbiano (2013) and Ridgway et al. (2014).

Lemma 5 *Assume the following margin assumption:*

$$\mathbb{E}[\mathbf{1}_{f_\theta(X_1, X_2)(Y_1 - Y_2) < 0} - \mathbf{1}_{f_\theta(X_1, X_2)(Y_1 - Y_2) < 0}]^2 \leq C[R(\theta) - \bar{R}].$$

Then Bernstein assumption (2) is satisfied with $g(\lambda, n) = \frac{C\lambda^2}{n-1-4\lambda}$.

We focus on linear classifiers, $f_\theta(x, x') = -1 + 2 \times \mathbf{1}_{\langle \theta, x \rangle > \langle \theta, x' \rangle}$. Like in the classification setting, $\langle x, \theta \rangle$ is interpreted as a score related to the probability that $Y = 1|X = x$. We consider a Gaussian prior

$$\pi(d\theta) = \prod_{i=1}^d \varphi(\theta_i; 0, \vartheta^2) d\theta_i$$

and the approximation families will be the same as in Section 5: $\mathcal{F}_1 = \{\Phi_{\mathbf{m}, \sigma^2}, \mathbf{m} \in \mathbb{R}^d, \sigma^2 \in \mathbb{R}_+^*\}$, $\mathcal{F}_2 = \{\Phi_{\mathbf{m}, \sigma^2}, \mathbf{m} \in \mathbb{R}^d, \sigma^2 \in (\mathbb{R}_+^*)^2\}$ and $\mathcal{F}_3 = \{\Phi_{\mathbf{m}, \Sigma}, \mathbf{m} \in \mathbb{R}^d, \Sigma \in \mathcal{S}^{d \times d}\}$.

7.2 Theoretical study

Here again, we start with the empirical bound.

Corollary 7.1 *For any $\varepsilon > 0$, with probability at least $1 - \varepsilon$ we have, for any $\mathbf{m} \in \mathbb{R}^d$, $\sigma^2 \in (\mathbb{R}_+^*)^d$,*

$$\int \text{Rd}\Phi_{\mathbf{m}, \sigma^2} \leq \int r_n d\Phi_{\mathbf{m}, \sigma^2} + \frac{\lambda}{n-1} + \frac{\frac{1}{2} \sum_{j=1}^d \left[\log \left(\frac{\vartheta^2}{\sigma_j^2} \right) + \frac{\sigma_j^2}{\vartheta^2} \right] + \frac{\|\mathbf{m}\|^2}{2\vartheta^2} - \frac{d}{2} + \log \left(\frac{1}{\varepsilon} \right)}{\lambda}.$$

In order to derive a theoretical bound, we introduce the following variant of Assumption A1.

Definition 7.1 *We say that Assumption A2 is satisfied when there is a constant $c > 0$ such that, for any $(\theta, \theta') \in \Theta^2$ with $\|\theta\| = \|\theta'\| = 1$, $\mathbb{P}(\langle X_1 - X_2, \theta \rangle \langle X_1 - X_2, \theta' \rangle < 0) \leq c\|\theta - \theta'\|$. Assumption A2 is just Assumption A1 applied to the distribution of $(X_1 - X_2)$. Intuitively, it means that two parameters close to each other rank X_1 and X_2 in the same way (with large probability).*

Corollary 7.2 *Use either \mathcal{F}_1 , \mathcal{F}_2 or \mathcal{F}_3 . Take $\lambda = \sqrt{\frac{d(n-1)}{2}}$ and $\vartheta = 1$. Under (A2), for any $\varepsilon > 0$, with probability at least $1 - \varepsilon$,*

$$\left. \int \text{Rd}\hat{\rho}_\lambda \right\} \leq \bar{R} + \sqrt{\frac{2d}{n-1}} \left(1 + \frac{1}{2} \log(2d(n-1)) \right) + \frac{c\sqrt{2}}{\sqrt{n-1}} + \frac{1}{(n-1)^{3/2}\sqrt{2d}} + \frac{2\sqrt{2}\log\left(\frac{2e}{\varepsilon}\right)}{\sqrt{(n-1)d}}.$$

Finally, under an additional margin assumption, we have:

Corollary 7.3 *Under Assumption A2 and the margin assumption of Lemma (5), for $\lambda = \frac{n-1}{C+5}$ and $\vartheta > 0$, for any $\varepsilon > 0$, with probability at least $1 - \varepsilon$,*

$$\left. \int \text{Rd}\hat{\rho}_\lambda \right\} \leq \bar{R} + \frac{(C+5)(C+1)}{2} \left\{ \frac{d \log \frac{n}{\vartheta}}{n-1} + \frac{d\theta}{n(n-1)} + \frac{1}{\vartheta} - \frac{d}{\vartheta n-1} + \frac{2}{n-1} \log \frac{2}{\varepsilon} \right\} + \frac{\sqrt{d}4c(C+1)}{n}.$$

It is possible to optimize the bound with respect to ϑ . The proof is similar to the ones of Corollaries 5.2, 5.3 and 7.2.

As in the case of classification, ranking under an AUC loss can be done by replacing the indicator function by the corresponding upper bound given by a hinge loss. In this case we can derive similar results as for the convexified classification in particular we can get a convex minimization problem and obtain result without requiring assumption (A2).

7.3 Algorithms and numerical results

As an illustration we focus here on family \mathcal{F}_2 (mean field). In this case the VB objective to maximize is given by:

$$\mathcal{L}(\mathbf{m}, \sigma^2) = -\frac{\lambda}{n_+ n_-} \sum_{i:Y_i=1, \vartheta:Y_i=0} \Phi \left(-\frac{\Gamma_{ij} \mathbf{m}}{\sqrt{\sum_{k=1}^d (\gamma_{ij}^k)^2 \sigma_k^2}} \right) - \frac{\|\mathbf{m}\|_2^2}{2\vartheta} + \frac{1}{2} \sum_{k=1}^d \left[\log \sigma_k^2 - \frac{\sigma_k^2}{\vartheta} \right], \quad (7)$$

where $\Gamma_{ij} = X_i - X_j$, $n_+ = \text{card}\{1 \leq i \leq n : Y_i = 1\}$, $n_- = n - n_+ = \text{card}\{1 \leq i \leq n : Y_i = 0\}$ and where $(\gamma_{ij}^k)_k$ are the elements of Γ .

This function is expensive to compute, as it involves $n_+ n_-$ terms, the computation of which is $\mathcal{O}(p)$.

We propose to use a stochastic gradient descent in the spirit of Hoffman et al. (2013). The model we consider is not in an exponential family, meaning we cannot use the trick developed by these authors. We propose instead to use a standard descent.

The idea is to replace the gradient by an unbiased version based on a batch of size B as described in Algorithm 4 in the Appendix. Robbins and Monro (1951) show that for a step-size $(\lambda_t)_t$ such that $\sum_t \lambda_t^2 < \infty$ and $\sum_t \lambda_t = \infty$ the algorithm converges to a local optimum.

In our case we propose to sample pairs of data with replacement and use the unbiased version of the derivative of the risk component. We use a simple gradient descent without any curvature information. One could also use recent research on stochastic quasi-Newton-Raphson (Byrd et al., 2014).

For illustration, we consider a small dataset (Pima), and a larger one (Adult). Both datasets are available in the UCI repository⁴. As for the previous experiment the data is scaled and centered. The latter is already quite challenging with $n_+ n_- = 193, 829, 520$ pairs to compare. In both cases with different size of batches convergence is obtained with a few iterations only and leads to acceptable bounds.

In Figure 1 we show the empirical bound on the AUC risk as a function of the iteration of the algorithm, for several batch sizes. The bound is taken for 95% probability, the batch sizes are taken to be $B = 1, 10, 20, 50$ for the Pima dataset, and 50 for the Adult dataset. The figure shows an additional feature of VB approximation in the context of

4. <https://archive.ics.uci.edu/ml/datasets.html>

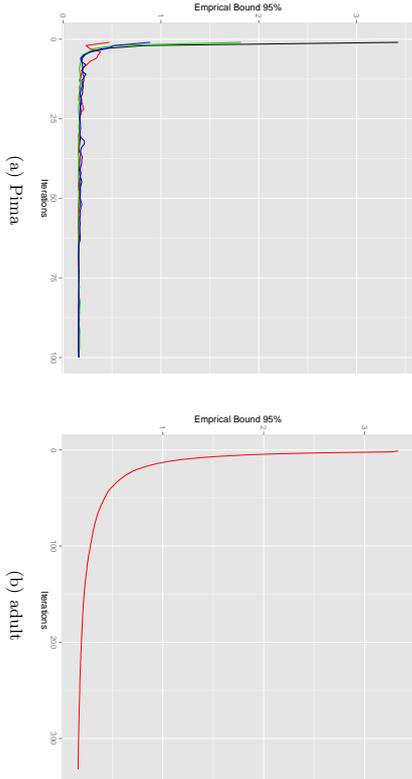

Figure 1: Error bound at each iteration, stochastic descent, Pima and Adult datasets.

Stochastic VB with fixed temperature $\lambda = 100$ for Pima and $\lambda = 1000$ for adult. The left panel shows several curves that correspond to different batch sizes; these curves are hard to distinguish. The right panel is for a batch size of 50. The adult dataset has $n = 32556$ observation and $n+n_- = 193829520$ possible pairs. The convergence is obtained in order of seconds. The bounds are the empirical bounds obtained in Corollary 7.1 for a probability of 95%.

Gibbs posterior: namely the possibility of computing the empirical upper bound given by Corollary 7.1. That is we can check the quality of the bound at each iteration of the algorithm, or for different values of the hyperparameters.

8. Application to matrix completion

The matrix completion problem has received increasing attention recently, partly due to spectacular theoretical results (Candes and Tao, 2010), and to challenging applications like the Netflix challenge (Bennett and Lanning, 2007). In the perspective of this paper, the specific interest of this application is twofold. First, this is a case where the family of approximations is not parametric, but rather of the form (3), i.e. the family of products of independent components. Then, there is no known theoretical result for the Gibbs estimator in the considered model, yet we can still directly bound the loss induced by the variational approximation.

We observe i.i.d. pairs $((X_i, Y_i))_{i=1}^n$ where $X_i \in \{1, \dots, m_1\} \times \{1, \dots, m_2\}$, and we assume that there is a $m_1 \times m_2$ -matrix M such that $Y_i = M_{X_i} + \varepsilon_i$ and the ε_i are centred. Assuming that X_i is uniform on $\{1, \dots, m_1\} \times \{1, \dots, m_2\}$, that $f_\theta(X_i) = \theta_{X_i}$, and taking the quadratic risk, $R(\theta) = \mathbb{E} [Y_i - \theta_{X_i}]^2$, we have that

$$R(\theta) - \bar{R} = \frac{1}{m_1 m_2} \|\theta - M\|_F^2$$

where $\|\cdot\|_F$ stands for the Frobenius norm.

A common way to parameterize the problem is

$$\Theta = \{\theta = UV^T, U \in \mathbb{R}^{m_1 \times K}, V \in \mathbb{R}^{m_2 \times K}\}$$

where K is large; e.g. $K = \min(m_1, m_2)$. Following Salakhutdinov and Mnih (2008), we define the following prior distribution: $U_{:,j} \sim \mathcal{N}(0, \gamma_j I)$, $V_{:,j} \sim \mathcal{N}(0, \gamma_j I)$ where the γ_j 's are i.i.d. from an inverse gamma distribution, $\gamma_j \sim \text{IG}(a, b)$.

Note that VB algorithms were used in this context by Lin and Teh (2007) (with a slightly simpler prior however: the γ_j 's are fixed rather than random). Since then, this prior and variants were used in several papers (e.g. Lawrence and Urtasun, 2009; Zhou et al., 2010). Until now, no theoretical results were proved to the best of our knowledge. Two papers prove minimax-optimal rates for slightly modified estimators (by truncation), for which efficient algorithms are unknown (Mai and Alquier, 2015; Suzuki, 2014). However, using Theorems 4.2 and 4.3 we are able to prove the following: if there is a PAC-Bayesian bound leading to a rate for $\hat{\rho}_\lambda$ in this context, then the same rate holds for $\hat{\rho}_\lambda$. In other words: if someone proves the conjecture that the Gibbs estimator is minimax-optimal (up to log terms) in this context, then the VB approximation will enjoy automatically the same property.

We propose the following approximation:

$$\mathcal{F} = \left\{ \rho(d(U, V)) = \prod_{i=1}^{m_1} u_i(dU_{:,i}) \prod_{j=1}^{m_2} v_j(dV_{:,j}) \right\}.$$

Theorem 8.1 *Assume that $M = UV^T$ with $|U_{i,k}|, |V_{j,k}| \leq C$. Assume that $\text{rank}(M) = r$ so that we can assume that $U_{:,r+1} = \dots = U_{:,K} = V_{:,r+1} = \dots = V_{:,K} = 0$ (note that the prior π does not depend on the knowledge of r through). Choose the prior distribution on the hyperparameters γ_j as inverse gamma $\text{Inv}^{-1}(a, b)$ with $b \leq 1/[2\beta(m_1 \vee m_2) \log(2K(m_1 \vee m_2))]$. Then there is a constant $C(a, C)$ such that, for any $\beta > 0$,*

$$\inf_{\rho \in \mathcal{F}} \mathcal{K}(\rho, \pi_\beta) \leq C(a, C) \left\{ r(m_1 + m_2) \log[\beta k(m_1 + m_2)K] + \frac{1}{\beta} \right\}.$$

See the Appendix for a proof.

For instance, in Theorem 4.3, in classification and ranking we had λ , $\lambda - g(\lambda, n)$ and $\lambda + g(\lambda, n)$ of order $\mathcal{O}(n)$. In this case we would have:

$$\frac{2}{\lambda - g(\lambda, n)} \inf_{\rho \in \mathcal{F}} \mathcal{K} \left(\rho, \pi_{\frac{\lambda + g(\lambda, n)}{2}} \right) = \mathcal{O} \left(\frac{\mathcal{C}(a, C)^r (m_1 + m_2) \log \left[\frac{nb(m_1 + m_2)K}{n} \right]}{n} \right),$$

and note that in this context it is known that the minimax rate is at least $r(m_1 + m_2)/n$ (Koltchinskii et al., 2011).

8.1 Algorithm

As already mentioned, the approximation family is not parametric in this case, but rather of type mean field. The corresponding VB algorithm amounts to iterating equation (4), which takes the following form in this particular case:

$$\begin{aligned} u_j(dU_{j,\cdot}) &\propto \exp \left\{ -\frac{\lambda}{n} \sum_i \mathbb{E}_{V_i U_{-j}} [(Y_{X_i} - (UV^T)_{X_i})^2] - \sum_{k=1}^K \mathbb{E}_{\gamma_j} \left[\frac{1}{2\gamma_k} U_{jk}^2 \right] \right\} \\ v_j(dV_{j,\cdot}) &\propto \exp \left\{ -\frac{\lambda}{n} \sum_i \mathbb{E}_{V_{-j} U} [(Y_{X_i} - (UV^T)_{X_i})^2] - \sum_{k=1}^K \mathbb{E}_{\gamma_j} \left[\frac{1}{2\gamma_k} V_{jk}^2 \right] \right\} \\ p(\gamma_k) &\propto \exp \left\{ -\frac{1}{2\gamma_k} \left(\sum_j \mathbb{E}_U U_{kj}^2 + \sum_i \mathbb{E}_V V_{ik}^2 \right) + (\alpha + 1) \log \frac{1}{\gamma_k} - \frac{\beta}{\gamma_k} \right\} \end{aligned}$$

where the expectations are taken with respect to the thus defined variational approximations. One recognises Gaussian distributions for the first two, and an inverse Gamma distribution for the third. We refer to Lim and Teh (2007) for more details on this algorithm and for a numerical illustration. However, we point out that in this case, while the algorithm seems to work well in practice, there is no theoretical guarantee that it will converge to the global minimum of the problem.

9. Discussion

We showed in several important scenarios that approximating a Gibbs posterior through VB (Variational Bayes) techniques does not deteriorate the rate of convergence of the corresponding procedure. We also described practical algorithms for fast computation of these VB approximations, and provided empirical bounds that may be computed from the data to evaluate the performance of the so-obtained VB-approximated procedure. We believe these results provide a strong incentive to recommend VB as the default approach to approximate Gibbs posteriors, in lieu of Monte Carlo methods. We also developed a R package⁵ for convexified losses (classification and bipartite ranking), applying the ideas of Section 6.

5. PACVB package: <https://cran.r-project.org/web/packages/PACVB/index.html>

We hope to extend our results to other applications beyond those discussed in this paper, such as regression. One technical difficulty with regression is that the risk function is not bounded, which makes our approach a bit less direct to apply. In many papers on PAC-Bayesian bounds for regression, the noise can be unbounded (usually, it is assumed to be sub-exponential), but one assumes that the predictors are bounded, see e.g. Alquier and Bian (2013). However, using the robust loss function of Audibert and Catoni, it is possible to relax this assumption (Audibert and Catoni, 2011; Catoni, 2012). This requires a more technical analysis, which we leave for further work.

Appendix A. Proofs

A.1 Preliminary remarks

Direct calculation yields, for any $\rho \ll \pi$ with $\int r_n d\rho < \infty$,

$$\mathcal{K}(\rho, \pi[r_n]) = \lambda \int r_n d\rho + \mathcal{K}(\rho, \pi) + \log \int \exp(-h) d\pi.$$

Two well known consequences are

$$\begin{aligned} \pi[h] &= \arg \min_{\rho \in \mathcal{M}_+^1(\mathfrak{e})} \left\{ \int h d\rho + \mathcal{K}(\rho, \pi) \right\}, \\ -\log \int \exp(-h) d\pi &= \min_{\rho \in \mathcal{M}_+^1(\mathfrak{e})} \left\{ \int h d\rho + \mathcal{K}(\rho, \pi) \right\}. \end{aligned}$$

We will use these inequalities many times in the followings. The most frequent application will be with $h(\theta) = \lambda r_n(\theta)$ (in this case $\pi[\lambda r_n] = \hat{\rho}_\lambda$) or $h(\theta) = \pm \lambda[r_n(\theta) - R(\theta)]$, the first case leads to

$$\mathcal{K}(\rho, \hat{\rho}_\lambda) = \lambda \int r_n d\rho + \mathcal{K}(\rho, \pi) + \log \int \exp(-\lambda r_n) d\pi, \quad (8)$$

$$\hat{\rho}_\lambda = \arg \min_{\rho \in \mathcal{M}_+^1(\mathfrak{e})} \left\{ \lambda \int r_n d\rho + \mathcal{K}(\rho, \pi) \right\}, \quad (9)$$

$$-\log \int \exp(-\lambda r_n) d\pi = \min_{\rho \in \mathcal{M}_+^1(\mathfrak{e})} \left\{ \lambda \int r_n d\rho + \mathcal{K}(\rho, \pi) \right\}. \quad (10)$$

We will use (8), (9) and (10) several times in this appendix.

A.2 Proof of the theorems in Subsection 4.1

Proof of Theorem 4.1. This proof follows the standard PAC-Bayesian approach (see Catoni (2007)). Apply Fubini's theorem to the first inequality of (1):

$$\mathbb{E} \int \exp \{ \lambda [R(\theta) - r_n(\theta)] - f(\lambda, n) \} \pi(d\theta) \leq 1$$

then apply the preliminary remark with $h(\theta) = \lambda[r_n(\theta) - R(\theta)]$:

$$\mathbb{E} \exp \left\{ \sup_{\rho \in \mathcal{M}_+^1(\Theta)} \int \lambda [R(\theta) - r_n(\theta)] \rho(d\theta) - \mathcal{K}(\rho, \pi) - f(\lambda, n) \right\} \leq 1.$$

Multiply both sides by ε and use $\mathbb{E}[\exp(U)] \geq \mathbb{P}(U > 0)$ for any U to obtain:

$$\mathbb{P} \left[\sup_{\rho \in \mathcal{M}_+^1(\Theta)} \int \lambda [R(\theta) - r_n(\theta)] \rho(d\theta) - \mathcal{K}(\rho, \pi) + \log(\varepsilon) > 0 \right] \leq \varepsilon.$$

Then consider the complementary event:

$$\mathbb{P} \left[\forall \rho \in \mathcal{M}_+^1(\Theta), \quad \lambda \int R d\rho \leq \lambda \int r_n d\rho + f(\lambda, n) + \mathcal{K}(\rho, \pi) + \log \left(\frac{1}{\varepsilon} \right) \right] \geq 1 - \varepsilon.$$

□

Proof of Theorem 4.2. Using the same calculations as above, we have, with probability at least $1 - \varepsilon$, simultaneously for all $\rho \in \mathcal{M}_+^1(\Theta)$,

$$\lambda \int R d\rho \leq \lambda \int r_n d\rho + f(\lambda, n) + \mathcal{K}(\rho, \pi) + \log \left(\frac{2}{\varepsilon} \right) \quad (11)$$

$$\lambda \int r_n d\rho \leq \lambda \int R d\rho + f(\lambda, n) + \mathcal{K}(\rho, \pi) + \log \left(\frac{2}{\varepsilon} \right). \quad (12)$$

We use (11) with $\rho = \hat{\rho}_\lambda$ and (9) to get

$$\lambda \int R d\hat{\rho}_\lambda \leq \inf_{\rho \in \mathcal{M}_+^1(\Theta)} \left\{ \lambda \int r_n d\rho + f(\lambda, n) + \mathcal{K}(\rho, \pi) + \log \left(\frac{2}{\varepsilon} \right) \right\}$$

and plugging (12) into the right-hand side, we obtain

$$\lambda \int R d\hat{\rho}_\lambda \leq \inf_{\rho \in \mathcal{M}_+^1(\Theta)} \left\{ \lambda \int R d\rho + 2f(\lambda, n) + 2\mathcal{K}(\rho, \pi) + 2 \log \left(\frac{2}{\varepsilon} \right) \right\}.$$

Now, we work with $\hat{\rho}_\lambda = \arg \min_{\rho \in \mathcal{F}} \mathcal{K}(\rho, \hat{\rho}_\lambda)$. Plugging (8) into (11) we get, for any ρ ,

$$\lambda \int R d\rho \leq f(\lambda, n) + \mathcal{K}(\rho, \hat{\rho}_\lambda) - \log \int \exp(-\lambda r_n) d\pi + \log \left(\frac{2}{\varepsilon} \right).$$

By definition of $\hat{\rho}_\lambda$, we have:

$$\lambda \int R d\hat{\rho}_\lambda \leq \inf_{\rho \in \mathcal{F}} \left\{ f(\lambda, n) + \mathcal{K}(\rho, \hat{\rho}_\lambda) - \log \int \exp(-\lambda r_n) d\pi + \log \left(\frac{2}{\varepsilon} \right) \right\}$$

and, using (8) again, we obtain:

$$\lambda \int R d\hat{\rho}_\lambda \leq \inf_{\rho \in \mathcal{F}} \left\{ \lambda \int r_n d\rho + f(\lambda, n) + \mathcal{K}(\rho, \pi) + \log \left(\frac{2}{\varepsilon} \right) \right\}.$$

We plug (12) into the right-hand side to obtain:

$$\lambda \int R d\hat{\rho}_\lambda \leq \inf_{\rho \in \mathcal{F}} \left\{ \lambda \int R d\rho + 2f(\lambda, n) + 2\mathcal{K}(\rho, \pi) + 2 \log \left(\frac{2}{\varepsilon} \right) \right\}.$$

This proves the second inequality of the theorem. In order to prove the claim

$$\mathcal{B}_\lambda(\mathcal{F}) = \mathcal{B}_\lambda(\mathcal{M}_+^1(\Theta)) + \frac{2}{\lambda} \inf_{\rho \in \mathcal{F}} \mathcal{K}(\rho, \pi_{\frac{\lambda}{2}}),$$

note that

$$\begin{aligned} \mathcal{B}_\lambda(\mathcal{F}) &= \inf_{\rho \in \mathcal{F}} \left\{ \int R d\rho + \frac{2f(\lambda, n)}{\lambda} + \frac{2\mathcal{K}(\rho, \pi)}{\lambda} + \frac{2 \log \left(\frac{2}{\varepsilon} \right)}{\lambda} \right\} \\ &= \inf_{\rho \in \mathcal{F}} \left\{ -\frac{2}{\lambda} \log \int \exp \left(-\frac{\lambda}{2} R \right) d\pi + \frac{2f(\lambda, n)}{\lambda} + \frac{2\mathcal{K}(\rho, \pi_{\frac{\lambda}{2}})}{\lambda} + \frac{2 \log \left(\frac{2}{\varepsilon} \right)}{\lambda} \right\} \\ &= -\frac{2}{\lambda} \log \int \exp \left(-\frac{\lambda}{2} R \right) d\pi + \frac{2f(\lambda, n)}{\lambda} + \frac{2 \log \left(\frac{2}{\varepsilon} \right)}{\lambda} + \frac{2}{\lambda} \inf_{\rho \in \mathcal{F}} \mathcal{K}(\rho, \pi_{\frac{\lambda}{2}}) \\ &= \mathcal{B}_\lambda(\mathcal{M}_+^1(\Theta)) + \frac{2}{\lambda} \inf_{\rho \in \mathcal{F}} \mathcal{K}(\rho, \pi_{\frac{\lambda}{2}}). \end{aligned}$$

This ends the proof. □

A.3 Proof of Theorem 4.3 (Subsection 4.2)

Proof of Theorem 4.3. As in the proof of Theorem 4.1, we apply Fubini, then (10) to the first inequality of (2) to obtain

$$\mathbb{E} \exp \left\{ \sup_{\rho} \int [\lambda [R(\theta) - \bar{R}] - \lambda [r_n(\theta) - \bar{\pi}_n] - g(\lambda, n)] [R(\theta) - \bar{R}] \rho(d\theta) - \mathcal{K}(\rho, \pi) \right\} \leq 1$$

and we multiply both sides by $\varepsilon/2$ to get

$$\mathbb{P} \left\{ \sup_{\rho} \left[\lambda - g(\lambda, n) \right] \left[\int R d\rho - \bar{R} \right] \geq \lambda \left[\int r_n d\rho - \bar{\pi}_n \right] + \mathcal{K}(\rho, \pi) + \log \left(\frac{2}{\varepsilon} \right) \right\} \leq \frac{\varepsilon}{2}. \quad (13)$$

We now consider the second inequality in (2):

$$\mathbb{E} \exp \left\{ \lambda [r_n(\theta) - \bar{\pi}_n] - \lambda [R(\theta) - \bar{R}] - g(\lambda, n) [R(\theta) - \bar{R}] \right\} \leq 1.$$

The same derivation leads to

$$\mathbb{P} \left\{ \sup_{\rho} \left[\lambda - g(\lambda, n) \right] \left[\int r_n d\rho - \bar{r}_n \right] \geq \lambda \left[\int R d\rho - \bar{R} \right] + \mathcal{K}(\rho, \pi) + \log \left(\frac{2}{\varepsilon} \right) \right\} \leq \frac{\varepsilon}{2}. \quad (14)$$

We combine (13) and (14) by a union bound argument, and we consider the complementary event: with probability at least $1 - \varepsilon$, simultaneously for all $\rho \in \mathcal{M}_+^1(\Theta)$,

$$\left| \lambda - g(\lambda, n) \right| \left[\int R d\rho - \bar{R} \right] \leq \lambda \left[\int r_n d\rho - \bar{r}_n \right] + \mathcal{K}(\rho, \pi) + \log \left(\frac{2}{\varepsilon} \right), \quad (15)$$

$$\lambda \left[\int r_n d\rho - \bar{r}_n \right] \leq \left[\lambda + g(\lambda, n) \right] \left[\int R d\rho - \bar{R} \right] + \mathcal{K}(\rho, \pi) + \log \left(\frac{2}{\varepsilon} \right). \quad (16)$$

We now derive consequences of these two inequalities (in other words, we focus on the event where these two inequalities are satisfied). Using (9) in (15) yields

$$\left| \lambda - g(\lambda, n) \right| \left[\int R d\hat{\rho}_\lambda - \bar{R} \right] \leq \inf_{\rho \in \mathcal{M}_+^1(\Theta)} \left\{ \lambda \left[\int r_n d\rho - \bar{r}_n \right] + \mathcal{K}(\rho, \pi) + \log \left(\frac{2}{\varepsilon} \right) \right\}.$$

We plug (16) into the right-hand side to obtain:

$$\begin{aligned} \left| \lambda - g(\lambda, n) \right| \left[\int R d\hat{\rho}_\lambda - \bar{R} \right] \\ \leq \inf_{\rho \in \mathcal{M}_+^1(\Theta)} \left\{ \left[\lambda + g(\lambda, n) \right] \left[\int R d\rho - \bar{R} \right] + 2\mathcal{K}(\rho, \pi) + 2 \log \left(\frac{2}{\varepsilon} \right) \right\}. \end{aligned}$$

Now, we work with $\hat{\rho}_\lambda$. Plugging (8) into (13) we get

$$\left| \lambda - g(\lambda, n) \right| \left[\int R d\rho - \bar{R} \right] \leq \mathcal{K}(\rho, \hat{\rho}_\lambda) - \log \int \exp[-\lambda(r_n - \bar{r}_n)] d\pi + \log \left(\frac{2}{\varepsilon} \right).$$

By definition of $\hat{\rho}_\lambda$, we have:

$$\begin{aligned} \left| \lambda - g(\lambda, n) \right| \left[\int R d\hat{\rho}_\lambda - \bar{R} \right] \\ \leq \inf_{\rho \in \mathcal{F}} \left\{ \mathcal{K}(\rho, \hat{\rho}_\lambda) - \log \int \exp[-\lambda(r_n - \bar{r}_n)] d\pi + \log \left(\frac{2}{\varepsilon} \right) \right\}. \end{aligned}$$

Then, apply (8) again to get:

$$\left| \lambda - g(\lambda, n) \right| \left[\int R d\hat{\rho}_\lambda - \bar{R} \right] \leq \inf_{\rho \in \mathcal{F}} \left\{ \lambda \int (r_n - \bar{r}_n) d\rho + \mathcal{K}(\rho, \pi) + \log \left(\frac{2}{\varepsilon} \right) \right\}.$$

Plug (16) into the right-hand side to get

$$\begin{aligned} \left| \lambda - g(\lambda, n) \right| \left[\int R d\hat{\rho}_\lambda - \bar{R} \right] \\ \leq \inf_{\rho \in \mathcal{F}} \left\{ \left[\lambda + g(\lambda, n) \right] \int (R - \bar{R}) d\rho + 2\mathcal{K}(\rho, \pi) + 2 \log \left(\frac{2}{\varepsilon} \right) \right\}. \end{aligned}$$

□

A.4 Proofs of Section 5

Proof of Lemma 1. Combine Theorem 2.1 p. 25 and Lemma 2.2 p. 27 in Boucheron et al. (2013). □

Proof of Lemma 2. Apply Theorem 2.10 in Boucheron et al. (2013), and plug the margin assumption. □

Proof of Corollary 5.2. We remind that thanks to (6) it is enough to prove the claim for \mathcal{F}_1 . We apply Theorem 4.2 to get:

$$\begin{aligned} \mathcal{B}_\lambda(\mathcal{F}_1) &= \inf_{(\mathbf{m}, \sigma^2)} \left\{ \int R d\Phi_{\mathbf{m}, \sigma^2} + \frac{\lambda}{n} + 2 \frac{\mathcal{K}(\Phi_{\mathbf{m}, \sigma^2}, \pi) + \log \left(\frac{2}{\varepsilon} \right)}{\lambda} \right\} \\ &= \inf_{(\mathbf{m}, \sigma^2)} \left\{ \int R d\Phi_{\mathbf{m}, \sigma^2} + \frac{\lambda}{n} + 2 \frac{d \left[\frac{1}{2} \log \left(\frac{\theta^2}{\sigma^2} \right) + \frac{\sigma^2}{2\theta^2} \right] + \frac{\|\mathbf{m}\|^2}{2\theta^2} - \frac{d}{2} + \log \left(\frac{2}{\varepsilon} \right)}{\lambda} \right\}. \end{aligned}$$

Note that the minimizer of $R, \bar{\theta}$, is not unique (because $f_\theta(x)$ does not depend on $\|\theta\|$) and we can chose it in such a way that $\|\bar{\theta}\| = 1$. Then

$$\begin{aligned} R(\theta) - \bar{R} &= \mathbb{E} \left[\mathbf{1}_{\langle \theta, X \rangle Y < 0} - \mathbf{1}_{\langle \bar{\theta}, X \rangle Y < 0} \right] \leq \mathbb{E} \left[\mathbf{1}_{\langle \theta, X \rangle \langle \bar{\theta}, X \rangle < 0} \right] \\ &= \mathbb{P} \left(\langle \theta, X \rangle \langle \bar{\theta}, X \rangle < 0 \right) \leq c \frac{\theta}{\|\theta\|} - \bar{\theta} \leq 2c \|\theta - \bar{\theta}\|. \end{aligned}$$

So:

$$\begin{aligned} \mathcal{B}_\lambda(\mathcal{F}_1) &\leq \bar{R} + \inf_{(\mathbf{m}, \sigma^2)} \left\{ 2c \int \|\theta - \bar{\theta}\| \Phi_{\mathbf{m}, \sigma^2}(d\theta) \right. \\ &\quad \left. + \frac{\lambda}{n} + 2 \frac{d \left[\frac{1}{2} \log \left(\frac{\theta^2}{\sigma^2} \right) + \frac{\sigma^2}{2\theta^2} \right] + \frac{\|\mathbf{m}\|^2}{2\theta^2} - \frac{d}{2} + \log \left(\frac{2}{\varepsilon} \right)}{\lambda} \right\}. \end{aligned}$$

We now restrict the infimum to distributions ν such that $\mathbf{m} = \bar{\theta}$:

$$\mathcal{B}(\mathcal{F}_1) \leq \bar{R} + \inf_{\sigma^2} \left\{ 2c \sqrt{d} \sigma + \frac{\lambda}{n} + \frac{d \log \left(\frac{\theta^2}{\sigma^2} \right) + \frac{d\sigma^2}{\theta^2} - d + 2 \log \left(\frac{2}{\varepsilon} \right)}{\lambda} \right\}.$$

We put $\sigma = \frac{1}{\lambda}$ and substitute $\frac{1}{\sqrt{d}}$ for ϑ to get

$$\mathcal{B}(\mathcal{F}_1) \leq \bar{R} + \frac{\lambda}{n} \frac{c\sqrt{d} + d \log(4\frac{\lambda^2}{d}) + r_n^2 + \frac{d^2}{4\lambda^2} + 2 \log\left(\frac{2}{\varepsilon}\right)}{\lambda}.$$

Substitute \sqrt{nd} for λ to get the desired result. \square

Proof of Corollary 5.3. We apply Theorem 4.3:

$$\begin{aligned} & \int (R - \bar{R}) d\bar{\rho}_\lambda \\ & \leq \inf_{\mathbf{m}, \sigma^2} \left\{ \frac{\lambda + g(\lambda, n)}{\lambda - g(\lambda, n)} \int (R - \bar{R}) d\Phi_{\mathbf{m}, \sigma^2} + \frac{1}{\lambda - g(\lambda, n)} \left(2\mathcal{K}(\Phi_{\mathbf{m}, \sigma^2}, \pi) + 2 \log\left(\frac{2}{\varepsilon}\right) \right) \right\} \end{aligned}$$

where $\lambda < \frac{2n}{c_{\mathcal{F}_1}}$. Computations similar to those in the proof of Corollary 5.2 lead to

$$\begin{aligned} \int R d\bar{\rho}_\lambda & \leq \bar{R} + \inf_{\mathbf{m}, \sigma^2} \left\{ \frac{\lambda + g(\lambda, n)}{2c} \frac{\lambda + g(\lambda, n)}{\lambda - g(\lambda, n)} \int \|\theta - \bar{\theta}\| \Phi_{\mathbf{m}, \sigma^2}(d\theta) \right. \\ & \quad \left. + 2 \frac{\frac{1}{2} \sum_{j=1}^d \left[\log\left(\frac{\vartheta^2}{\sigma^2}\right) + \frac{\sigma^2}{\vartheta^2} \right] + \frac{\|\mathbf{m}\|^2}{2\vartheta^2} - \frac{d}{2} + \log\left(\frac{2}{\varepsilon}\right)}{\lambda - g(\lambda, n)} \right\}. \end{aligned}$$

taking $\mathbf{m} = \bar{\theta}$ and $\lambda = \frac{2n}{c_{\mathcal{F}_2}}$, we get the result. \square

A.5 Proofs of Section 6

Proof of Lemma 3. For fixed θ we can upper bound the individual risk such that:

$$0 \leq \max(0, 1 - \langle \theta, X_i \rangle) \leq 1 + \langle \theta, X_i \rangle$$

such that we can apply Hoeffding's inequality conditionally on X_i and fixed θ .

We get,

$$\begin{aligned} \mathbb{E}[\exp(\lambda(R^H - r_n^H)) | X_1, \dots, X_n] & \leq \exp \left\{ \frac{\lambda^2}{8n^2} \sum_{i=1}^n (1 + \langle \theta, X_i \rangle)^2 \right\} \\ & \leq \exp \left\{ \frac{\lambda^2}{4n} + \frac{\lambda^2 c_x^2}{4n} \|\theta\|^2 \right\} \end{aligned}$$

where the last inequality stems from the fact that $(a + b)^2 \leq 2(a^2 + b^2)$ and the fact that we have supposed the X_i to be bounded. We can take the expectation of this term with

respect to the X_i 's and with respect to our Gaussian prior.

$$\begin{aligned} \pi \{ \mathbb{E}[\exp(\lambda(R^H - r_n^H))] \} & \leq \frac{\exp\left(\frac{\lambda^2}{4n}\right)}{(2\pi)^{\frac{d}{2}} \sqrt{\vartheta^2}} \int \exp\left(\frac{\lambda^2 c_x^2}{4n} \|\theta\|^2 - \frac{1}{2\vartheta^2} \|\theta\|^2\right) d\theta \\ & \leq \frac{\exp\left(\frac{\lambda^2}{4n}\right)}{(2\pi)^{\frac{d}{2}} \sqrt{\vartheta^2}} \int \exp\left(-\frac{1}{2} \left[\frac{1}{\vartheta^2} - \frac{\lambda^2 c_x^2}{2n} \right] \|\theta\|^2\right) d\theta \end{aligned}$$

The integral is a properly defined Gaussian integral under the hypothesis that $\frac{1}{\vartheta^2} - \frac{\lambda^2 c_x^2}{2n} > 0$ hence $\lambda < \frac{1}{c_x} \sqrt{\frac{2n}{d}}$. The integral is proportional to a Gaussian and we can directly write:

$$\pi \{ \mathbb{E}[\exp(\lambda(R^H - r_n^H))] \} \leq \frac{\exp\left(\frac{\lambda^2}{4n}\right)}{\sqrt{1 - \frac{\lambda^2 \lambda^2 c_x^2}{2n}}}$$

writing everything in the exponential gives the desired result. \square

Proof of Corollary 6.1. We apply Theorem 4.2 to get:

$$\begin{aligned} \mathcal{B}_\lambda(\mathcal{F}_1) & = \inf_{(\mathbf{m}, \sigma^2)} \left\{ \int R^H d\Phi_{\mathbf{m}, \sigma^2} + \frac{\lambda}{2n} - \frac{1}{\lambda} \log\left(1 - \frac{\vartheta^2 \lambda^2 c_x^2}{2n}\right) + 2 \frac{\mathcal{K}(\Phi_{\mathbf{m}, \sigma^2}, \pi) + \log\left(\frac{2}{\varepsilon}\right)}{\lambda} \right\} \\ & = \inf_{(\mathbf{m}, \sigma^2)} \left\{ \int R^H d\Phi_{\mathbf{m}, \sigma^2} + \frac{\lambda}{2n} - \frac{1}{\lambda} \log\left(1 - \frac{\vartheta \lambda^2 c_x^2}{2n}\right) \right. \\ & \quad \left. + 2 \frac{\frac{1}{2} \sum_{j=1}^d \left[\log\left(\frac{\vartheta^2}{\sigma^2}\right) + \frac{\sigma^2}{\vartheta^2} \right] + \frac{\|\mathbf{m}\|^2}{2\vartheta^2} - \frac{d}{2} + \log\left(\frac{2}{\varepsilon}\right)}{\lambda} \right\}. \end{aligned}$$

We use the fact that the hinge loss is Lipschitz and that the (X_i) are uniformly bounded $\|X\|_\infty \leq c_x$. We get $R^H(\theta) \leq R^H + c_x \sqrt{d} \|\theta - \bar{\theta}\|$ and restrict the infimum to distributions ν such that $m = \bar{\theta}$:

$$\mathcal{B}(\mathcal{F}_1) \leq \bar{R}^H + \inf_{\sigma^2} \left\{ c_x d \sigma^2 + \frac{\lambda}{2n} - \frac{1}{\lambda} \log\left(1 - \frac{\vartheta^2 \lambda^2 c_x^2}{2n}\right) + \frac{d \log\left(\frac{\vartheta^2}{\sigma^2}\right) + \frac{d\sigma^2}{\vartheta^2} + \frac{1}{\vartheta^2} - d + 2 \log\left(\frac{2}{\varepsilon}\right)}{\lambda} \right\}.$$

We specify $\sigma^2 = \frac{1}{\sqrt{dn}}$ and $\lambda = c_x \sqrt{\frac{2n}{d}}$ such that we get:

$$\mathcal{B}(\mathcal{F}_1) \leq \bar{R}^H + c_x \sqrt{\frac{d}{n}} + \frac{\sqrt{\vartheta^2}}{2c_x \sqrt{n}} - c_x \sqrt{\frac{\vartheta^2}{n}} \log\left(1 - \frac{1}{2}\right) + d \frac{c_x \vartheta}{\sqrt{n}} \log\left(\vartheta^2 \sqrt{nd}\right) + c_x \vartheta \frac{d}{\sqrt{nd}} + \frac{1}{\vartheta^2} - d + 2 \log\left(\frac{2}{\varepsilon}\right) \frac{1}{\sqrt{n}}.$$

To get the correct rate we take the prior variance to be $\vartheta^2 = \frac{1}{n}$ by replacing in the above equation we get the desired result.

□

Proof of Theorem 6.2. From Nesterov (2004) (th. 3.2.2) we have the following bound on the objective function minimized by VB, (the objective is not uniformly Lipschitz)

$$\rho^k(r_n^H) + \frac{1}{\lambda} \mathcal{K}(\rho^k, \pi) - \inf_{\rho \in \mathcal{F}_1} \left\{ \rho(r_n^H) + \frac{1}{\lambda} \mathcal{K}(\rho, \pi) \right\} \leq \frac{LM}{\sqrt{1+k}}. \quad (17)$$

We have from equation (11) specified for measures ρ^k probability $1 - \varepsilon$,

$$\lambda \int r_n^H d\rho^k \leq \lambda \int R^H d\rho^k + f(\lambda, n) + \mathcal{K}(\rho^k, \pi) + \log\left(\frac{1}{\varepsilon}\right)$$

Combining the two equations yields,

$$\int R^H d\rho^k \leq \frac{LM}{\sqrt{1+k}} + \frac{1}{\lambda} f(n, \lambda) + \inf_{\rho \in \mathcal{F}_1} \left\{ \rho(r_n^H) + \frac{1}{\lambda} \mathcal{K}(\rho, \pi) \right\} + \frac{1}{\lambda} \log \frac{1}{\varepsilon}$$

We can therefore write for any $\rho \in \mathcal{F}_1$,

$$\int R^H d\rho^k \leq \frac{LM}{\sqrt{1+k}} + \frac{1}{\lambda} f(n, \lambda) + \rho(r_n^H) + \frac{1}{\lambda} \mathcal{K}(\rho, \pi) + \frac{1}{\lambda} \log \frac{1}{\varepsilon}$$

Using equation (11) a second time we get with probability $1 - \varepsilon$

$$\int R^H d\rho^k \leq \frac{LM}{\sqrt{1+k}} + \frac{2}{\lambda} f(n, \lambda) + \rho(R^H) + \frac{2}{\lambda} \mathcal{K}(\rho, \pi) + \frac{2}{\lambda} \log \frac{2}{\varepsilon}$$

Because this is true for any $\rho \in \mathcal{F}_1$ in $1 - \varepsilon$ we can write the bound for the smallest measure in \mathcal{F}_1 .

$$\int R^H d\rho^k \leq \frac{LM}{\sqrt{1+k}} + \frac{2}{\lambda} f(n, \lambda) + \inf_{\rho \in \mathcal{F}_1} \left\{ \rho(R^H) + \frac{2}{\lambda} \mathcal{K}(\rho, \pi) \right\} + \frac{2}{\lambda} \log \frac{2}{\varepsilon}$$

By taking the Gaussian measure with variance $\frac{1}{n}$ and mean $\bar{\theta}$ in the infimum and taking $\lambda = \frac{1}{c_x} \sqrt{nd}$ and $\vartheta = \frac{1}{d}$, we can use the results of Corollary 6.1 to get the result. □

A.6 Proofs of Section 7

Proof of Lemma 4. The idea of the proof is to use Hoeffding's decomposition of U-statistics combined with Hoeffding's inequality for iid random variables. This was done in ranking by Clémengon et al. (2008), and later in Robbiano (2013); Ridgway et al. (2014) for ranking via aggregation and Bayesian statistics. The proof is as follows: we define

$$q_{i,j}^\theta = \mathbf{1}_{(Y_i - Y_j) f_\theta(X_i, X_j) < 0} - R(\theta)$$

so that

$$U_n := \frac{1}{n(n-1)} \sum_{i,j} q_{i,j}^\theta = r_n(\theta) - R(\theta).$$

From Hoeffding (1948) we have

$$U_n = \frac{1}{n!} \sum_{\pi} \frac{1}{\lfloor \frac{n}{2} \rfloor} \sum_{i=1}^{\lfloor \frac{n}{2} \rfloor} q_{\pi(i), \pi(i + \lfloor \frac{n}{2} \rfloor)}^\theta$$

where the sum is taken over all the permutations π of $\{1, \dots, n\}$. Jensen's inequality leads to

$$\begin{aligned} \mathbb{E} \exp[\lambda U_n] &= \mathbb{E} \exp \left[\lambda \frac{1}{n!} \sum_{\pi} \frac{1}{\lfloor \frac{n}{2} \rfloor} \sum_{i=1}^{\lfloor \frac{n}{2} \rfloor} q_{\pi(i), \pi(i + \lfloor \frac{n}{2} \rfloor)}^\theta \right] \\ &\leq \frac{1}{n!} \sum_{\pi} \mathbb{E} \exp \left[\frac{\lambda}{\lfloor \frac{n}{2} \rfloor} \sum_{i=1}^{\lfloor \frac{n}{2} \rfloor} q_{\pi(i), \pi(i + \lfloor \frac{n}{2} \rfloor)}^\theta \right]. \end{aligned}$$

We now use, for each of the terms in the sum we use the same argument as in the proof of Lemma 1 to get

$$\mathbb{E} \exp[\lambda U_n] \leq \frac{1}{n!} \sum_{\pi} \exp \left[\frac{\lambda^2}{2 \lfloor \frac{n}{2} \rfloor} \right] \leq \exp \left[\frac{\lambda^2}{n-1} \right]$$

(in the last step, we used $\lfloor \frac{n}{2} \rfloor \geq (n-1)/2$). We proceed in the same way to upper bound $\mathbb{E} \exp[-\lambda U_n]$. □

Proof of Lemma 5. As already done above, we use Bernstein inequality and Hoeffding decomposition. Fix θ . We define this time

$$q_{i,j}^\theta = \mathbf{1}_{\{(\theta, X_i - X_j)(Y_i - Y_j) < 0\}} - \mathbf{1}_{\{(\bar{\theta}, X_i - X_j)(Y_i - Y_j) < 0\}} - R(\theta) + \bar{R}$$

so that

$$U_n := r_n(\theta) - \bar{r}_n - R(\theta) + \bar{R} = \frac{1}{n(n-1)} \sum_{i \neq j} q_{i,j}^\theta.$$

Then,

$$U_n = \frac{1}{n!} \sum_{\pi} \frac{1}{\lfloor \frac{n}{2} \rfloor} \sum_{i=1}^{\lfloor \frac{n}{2} \rfloor} q_{\pi(i), \pi(i + \lfloor \frac{n}{2} \rfloor)}^\theta.$$

Jensen's inequality:

$$\begin{aligned} \mathbb{E} \exp[\lambda U_n] &= \mathbb{E} \exp \left[\lambda \frac{1}{n!} \sum_{\pi} \frac{1}{\lfloor \frac{n}{2} \rfloor} \sum_{i=1}^{\lfloor \frac{n}{2} \rfloor} q_{\pi^{(i)}, \pi^{(i+\lfloor \frac{n}{2} \rfloor)}^\theta} \right] \\ &\leq \frac{1}{n!} \sum_{\pi} \mathbb{E} \exp \left[\frac{\lambda}{\lfloor \frac{n}{2} \rfloor} \sum_{i=1}^{\lfloor \frac{n}{2} \rfloor} q_{\pi^{(i)}, \pi^{(i+\lfloor \frac{n}{2} \rfloor)}^\theta} \right]. \end{aligned}$$

Then, for each of the terms in the sum, use Bernstein's inequality:

$$\mathbb{E} \exp \left[\frac{\lambda}{\lfloor \frac{n}{2} \rfloor} \sum_{i=1}^{\lfloor \frac{n}{2} \rfloor} q_{\pi^{(i)}, \pi^{(i+\lfloor \frac{n}{2} \rfloor)}^\theta} \right] \leq \exp \left[\frac{\mathbb{E}((q_{\pi^{(1)}, \pi^{(1+\lfloor \frac{n}{2} \rfloor)}^\theta}^\theta)^2) \frac{\lambda^2}{\lfloor \frac{n}{2} \rfloor}}{2 \left(1 - 2 \frac{\lambda}{\lfloor \frac{n}{2} \rfloor}\right)} \right].$$

We use again $\lfloor \frac{n}{2} \rfloor \geq (n-1)/2$. Then, as the pairs (X_i, Y_i) are iid, we have $\mathbb{E}((q_{\pi^{(1)}, \pi^{(1+\lfloor \frac{n}{2} \rfloor)}^\theta}^\theta)^2) = \mathbb{E}((q_{1,2}^\theta)^2)$ and then $\mathbb{E}((q_{1,2}^\theta)^2) \leq C[R(\theta) - \bar{R}]$ thanks to the margin assumption. So

$$\mathbb{E} \exp \left[\frac{\lambda}{\lfloor \frac{n}{2} \rfloor} \sum_{i=1}^{\lfloor \frac{n}{2} \rfloor} q_{\pi^{(i)}, \pi^{(i+\lfloor \frac{n}{2} \rfloor)}^\theta} \right] \leq \exp \left[\frac{C[R(\theta) - \bar{R}] \frac{\lambda^2}{n-1}}{\left(1 - \frac{4\lambda}{n-1}\right)} \right].$$

This ends the proof of the proposition. \square

Proof of Corollary 7.2. The calculations are similar to the ones in the proof of Corollary 5.2 so we don't give the details. Note that when we reach

$$\mathcal{B}_\lambda(\mathcal{F}_1) \leq \bar{R} + \frac{2\lambda}{n-1} + \frac{c\sqrt{d} + d \log(2\lambda) + \frac{d}{4\lambda^2} + 2 \log \left(\frac{2e}{\varepsilon} \right)}{\lambda},$$

an approximate minimization with respect to λ leads to the choice $\lambda = \sqrt{\frac{d(n-1)}{2}}$. \square

A.7 Proofs of Section 8

Proof. First, note that, for any ρ ,

$$\begin{aligned} \mathcal{K}(\rho, \pi_\delta) &= \beta \int (R - \bar{R}) d\rho + \mathcal{K}(\rho, \pi) + \log \int \exp[-\beta(R - \bar{R})] d\pi \\ &\leq \beta \int (R - \bar{R}) d\rho + \mathcal{K}(\rho, \pi). \end{aligned}$$

Now, we define a subset of \mathcal{F} that will be used for the calculation of the bound. We define for $\delta > 0$ the probability distribution $\rho_{U,V,\delta}(d\theta)$ as π conditioned to $\theta = \mu^T$ with μ is

uniform on $\{V(i, \ell), |\mu_{i,\ell} - U_{i,\ell}| \leq \delta\}$ and ν is uniform on $\{V(i, \ell), |v_{i,\ell} - V_{j,\ell}| \leq \delta\}$. Note that

$$\begin{aligned} \int (R - \bar{R}) d\rho_{M,N,\delta} &= \int \mathbb{E}((\theta_X - M_X)^2) \rho_{U,V,\delta}(d\theta) \\ &\leq \int 3\mathbb{E}(((UV^T)_X - M_X)^2) \rho_{U,V,\delta}(d(\mu, \nu)) \\ &\quad + 3 \int \mathbb{E}(((UV^T)_X - (UV^T)_X)^2) \rho_{U,V,\delta}(d(\mu, \nu)) \\ &\quad + 3 \int \mathbb{E}(((\mu^T)_X - (U\nu^T)_X)^2) \rho_{U,V,\delta}(d(\mu, \nu)). \end{aligned}$$

By definition, the first term is 0. Moreover:

$$\begin{aligned} &\int \mathbb{E}(((UV^T)_X - (UV^T)_X)^2) \rho_{U,V,\delta}(d(\mu, \nu)) \\ &= \int \frac{1}{m_1 m_2} \sum_{i,j} \left[\sum_k U_{i,k} (v_{j,k} - V_{j,k}) \right]^2 \rho_{U,V,\delta}(d(\mu, \nu)) \\ &\leq \int \frac{1}{m_1 m_2} \sum_{i,j} \left[\sum_k U_{i,k}^2 \right] \left[\sum_k (v_{j,k} - V_{j,k})^2 \right] \rho_{U,V,\delta}(d(\mu, \nu)) \\ &\leq K r C^2 \delta^2. \end{aligned}$$

In the same way,

$$\begin{aligned} \int \mathbb{E}(((\mu^T)_X - (U\nu^T)_X)^2) \rho_{U,V,\delta}(d(\mu, \nu)) &\leq \int \|\mu - U\|_F^2 \|\nu\|_F^2 \rho_{U,V,\delta}(d(\mu, \nu)) \\ &\leq K r (C + \delta)^2 \delta^2. \end{aligned}$$

So:

$$\int (R - \bar{R}) d\rho_{M,N,\delta} \leq 2K r \delta^2 (C + \delta^2).$$

Now, let us consider the term $\mathcal{K}(\rho_{U,V,\delta}, \pi)$. An explicit calculation is possible but tedious. Instead, we might just introduce the set $G_\delta = \{\theta = \mu^T, \|\mu - U\|_F \leq \delta, \|\nu - V\|_F \leq \delta\}$ and note that $\mathcal{K}(\rho_{U,V,\delta}, \pi) \leq \log \frac{1}{\pi(G_\delta)}$. An upper bound for G_δ is calculated page 317-320 in Alquier (2014) and the result is given by (10) in this reference:

$$\begin{aligned} \mathcal{K}(\rho_{U,V,\delta}, \pi) &\leq 4\delta^2 + 2\|U\|_F^2 + 2\|V\|_F^2 + 2 \log(2) \\ &\quad + (m_1 + m_2) r \log \left(\frac{1}{\delta} \sqrt{\frac{3\pi(m_1 \vee m_2)K}{4}} \right) + 2K \log \left(\frac{\Gamma(a) 3^{a+1} \exp(2)}{b^{a+1} 2^a} \right) \end{aligned}$$

as soon as the restriction $b \leq \frac{\delta^2}{2m_1 K \log(2m_1 K)}, \frac{\delta^2}{2m_2 K \log(2m_2 K)}$ is satisfied. So we obtain:

$$\begin{aligned} \mathcal{K}(\rho_{U,V,\delta}, \pi_\beta) &\leq \beta^2 K r \delta^2 (C + \delta^2) + 4\delta^2 + 2\|U\|_F^2 + 2\|N\|_F^2 + 2\log(2) \\ &\quad + (m_1 + m_2)r \log\left(\frac{1}{\delta} \sqrt{\frac{3\pi(m_1 \vee m_2)K}{4}}\right) + 2K \log\left(\frac{\Gamma(a)3^{a+1} \exp(2)}{b^{a+1} 2^a}\right). \end{aligned}$$

Note that $\|U\|_F^2 \leq C^2 r m_1$, $\|V\|_F^2 \leq C^2 r m_2$ and $K \leq m_1 + m_2$ so it is clear that the choice $\delta = \sqrt{\frac{1}{\beta}}$ and $b \leq \frac{1}{2\beta(m_1 \vee m_2) \log(2K(m_1 \vee m_2))}$ leads to the existence of a constant $\mathcal{C}(a, C)$ such that

$$\mathcal{K}(\rho_{U,V,\delta}, \pi_\beta) \leq \mathcal{C}(a, C) \left\{ r(m_1 + m_2) \log[\beta h(m_1 + m_2)K] + \frac{1}{\beta} \right\}.$$

□

Appendix B. Implementation details

B.1 Sequential Monte Carlo

Tempering SMC approximates iteratively a sequence of distribution ρ_{λ_t} , with

$$\rho_{\lambda_t}(d\theta) = \frac{1}{Z_t} \exp(-\lambda_t r_n(\theta)) \pi(d\theta),$$

and temperature ladder $\lambda_0 = 0 < \dots < \lambda_T = \lambda$. The pseudo-code below is given for an adaptive sequence of temperatures.

Algorithm 1 Tempering SMC

Input N (number of particles), $\tau \in (0, 1)$ (ESS threshold), $\kappa > 0$ (random walk tuning parameter)

Init. Sample $\theta_0^i \sim \pi_\xi(\theta)$ for $i = 1$ to N , set $t \leftarrow 1$, $\lambda_0 = 0$, $Z_0 = 1$.

Loop a. Solve in λ_t the equation

$$\frac{\{\sum_{i=1}^N w_t(\theta_{t-1}^i)\}^2}{\sum_{i=1}^N \{w_t(\theta_{t-1}^i)\}^2} = \tau N, \quad w_t(\theta) = \exp[-(\lambda_t - \lambda_{t-1})r_n(\theta)] \quad (18)$$

using bisection search. If $\lambda_t \geq \lambda_T$, set $Z_T = Z_{t-1} \times \left\{ \frac{1}{N} \sum_{i=1}^N w_t(\theta_{t-1}^i) \right\}$, and stop.

b. Resample: for $i = 1$ to N , draw A_t^i in $1, \dots, N$ so that $\mathbb{P}(A_t^i = j) = w_t(\theta_{t-1}^j) / \sum_{k=1}^N w_t(\theta_{t-1}^k)$; see Algorithm 2 in the appendix.

c. Sample $\theta_t^i \sim M_t(\theta_{t-1}^{A_t^i}, d\theta)$ for $i = 1$ to N where M_t is a MCMC kernel that leaves invariant π_t ; see comments below.

d. Set $Z_t = Z_{t-1} \times \left\{ \frac{1}{N} \sum_{i=1}^N w_t(\theta_{t-1}^i) \right\}$.

The algorithm outputs a weighted sample (w_T^i, θ_T^i) approximately distributed as target posterior, and an unbiased estimator of the normalizing constant Z_{λ_T} .

Step **b.** of algorithm B.1 depends of a resampling algorithm. We choose to use Systematic resampling, see Algorithm 2.

Algorithm 2 Systematic resampling

Input: Normalised weights $W_i^t := w_i(\theta_{t-1}^i) / \sum_{k=1}^N w_k(\theta_{t-1}^i)$.

Output: indices $A^t \in \{1, \dots, N\}$, for $t = 1, \dots, N$.

- a. Sample $U \sim \mathcal{U}([0, 1])$.
- b. Compute cumulative weights as $C^n = \sum_{m=1}^n NW^m$.
- c. Set $s \leftarrow U$, $m \leftarrow 1$.
- d. **For** $n = 1 : N$

While $C^m < s$ **do** $m \leftarrow m + 1$.

$A^n \leftarrow m$, and $s \leftarrow s + 1$.

End For

For the MCMC step, we used a Gaussian random-walk Metropolis kernel, with a covariance matrix for the random step that is proportional to the empirical covariance matrix of the current set of simulations.

B.2 Optimizing the bound

A natural idea to find a global optimum of the objective is to try to solve a sequence of local optimization problems with increasing temperatures. For $\gamma = 0$ the problem can be solved exactly (as a KL divergence between two Gaussians). Then, for two consecutive temperatures, the corresponding solutions should be close enough.

This idea has been coined under several names. It has a long history in variational inference under the name ‘deterministic annealing’; see e.g. Yuille (2010) for an application to Markov random fields. In addition the intermediate results can be of interest in our case for selecting the temperature. One can compute the bound at almost no additional cost as a function of the current risk. In turns this can be used to monitor the bound.

Algorithm 3 Deterministic annealing

Input $(\lambda_t)_{t \in [0, T]}$ a sequence of temperature

Init. Set $m = 0$ and $\Sigma = \vartheta I_d$, the values minimizing KL-divergence for $\lambda = 0$

Loop $t=1, \dots, T$

- a. $m^{\lambda_t}, \Sigma^{\lambda_t} = \text{Minimize } \mathcal{L}^{\lambda_t}(m, \Sigma)$ using some local optimization routine with initial points $m^{\lambda_{t-1}}, \Sigma^{\lambda_{t-1}}$
- b. Break if the empirical bound increases.

End Loop

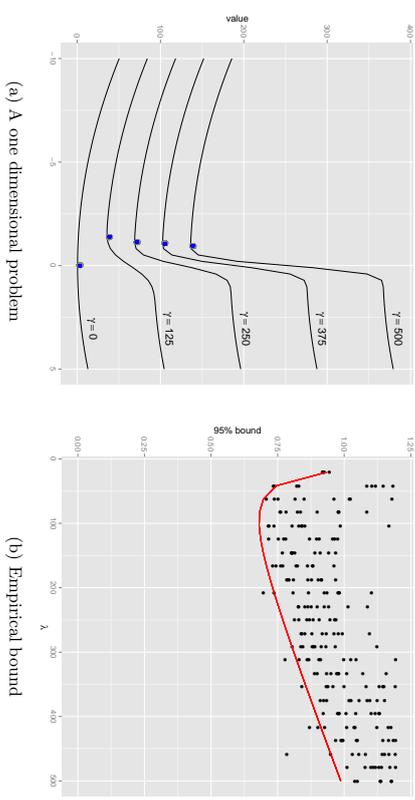

Figure 2: Deterministic annealing on a Pima Indians with one covariate and full model resp.

The right panel gives the empirical bound obtained for the DA method (in red). The dots are the results of direct global optimization based on L-BFGS algorithms (with starting values drawn from the prior). Each optimization problem is repeated 20 times.

We find that using a deterministic annealing algorithm with a limited amount of steps helps in finding a high enough optimum. On the left panel of Figure 2, we can see the one

dimensional case where the initial problem $\gamma = 0$ corresponds to a convex minimization problem and where the increasing temperature gradually complexifies the optimization problem. Figure 2 shows that the solution given by DA is in average lower than randomly initialized optimization.

Appendix C. Stochastic gradient descent

The stochastic gradient descent algorithm used in Section 7 is described as Algorithm 4.

Algorithm 4 Stochastic Gradient Descent

Input B a batch size, an unbiased estimator of the gradient $\tilde{\nabla}_B f$, $\eta \in (0, 1)$ and c

While \neg converged

a. $x_{t+1} = x_t - \lambda_t \tilde{\nabla}_B f(x_t)$

b. Update $\lambda_{t+1} = \frac{1}{(t+\phi)^\eta}$

End Loop

In all our experiments we take $c = 1$ and $\eta = 0.9$.
